This disorder is most commonly seen in the setting of immunosuppression due to systemic calcineurin inhibitors. *Courtesy Mark Kirchhof, MD, and Sheila Au, MD*.

URTICARIAL VASCULITIS	
Epidemiology	Favors middle-aged women
Characteristics of urticarial lesions	>24 hours in duration; painful & burning sensation as well as pruritus; residual purpura as they resolve
Sites of involvement	Often occur at pressure points
Concurrent angioedema	Up to 40% of patients
Extracutaneous manifestations (% of patients affected); more common in hypocomplementemic form*	Arthralgias (50%) – transient, migratory GI involvement (20%) – abdominal pain, nausea, vomiting, diarrhea Pulmonary obstructive disease (20%) Renal (5%–10%) – proteinuria, hematuria Ocular (unusual) – conjunctivitis, episcleritis, uveitis Other (unusual) – Raynaud phenomenon, livedo reticularis, splenomegaly, lymphadenopathy, idiopathic intracranial HTN, pericardial or muscle involvement
Associated disorders	Systemic lupus erythematosus Sjögren syndrome Serum sickness Cryoglobulinemia Infections – hepatitis B or C virus, Epstein–Barr virus Rarely, solar or cold urticaria, drugs, hypergammaglobulinemia
Laboratory evaluation	CBC with differential, platelet count; ESR, CRP; LFTs, BUN, creatinine Complement assays – C3, C4, CH50; if C4 low, C1q Urinalysis If indicated, pulmonary function tests, CXR Tests for associated disorders, e.g. ANA, anti-Ro Ab
Disease course	Average of 3 years
Treatment (primarily based upon small case series and case reports; see Table 24.10)	Antihistamines for associated pruritus NSAIDs – improvement in 50% of patients Colchicine, dapsone, hydroxychloroquine, methotrexate, plasmapheresis, omalizumab in normocomplementemic form Corticosteroids ± immunosuppressants†

*Higher incidence and greater severity in patients with hypocomplementemia.
†Especially for hypocomplementemic urticarial vasculitis.

eTable 18.1 Urticarial vasculitis. In a series of 132 patients, an elevated ESR (28%), hypocomplementemia (18%), and an ANA titer >1:160 (11%) were the more common abnormalities[e1]. Ab, antibodies; ANA, anti-nuclear antibodies; BUN, blood urea nitrogen; CRP, C-reactive protein; CXR, chest X-ray; ESR, erythrocyte sedimentation rate; GI, gastrointestinal; HTN, hypertension; LFTs, liver function tests; NSAIDs, nonsteroidal anti-inflammatory drugs; PFTs, pulmonary function tests.

19 Figurate Erythemas

Agustín España

Chapter Contents

Erythema Annulare Centrifugum 327
Erythema Marginatum 331
Erythema Migrans 333
Erythema Gyratum Repens 336

INTRODUCTION

Erythema represents a change in the color of the skin that is due to the dilation of blood vessels, especially those in the papillary and reticular dermis. The color, which is blanchable, can vary from pink to dark red to violaceous. Most erythemas last for days to months, but some may last only minutes (e.g. flushing). A very heterogeneous group of cutaneous disorders manifests as erythemas, ranging from palmar erythema of pregnancy to a diffuse scarlatiniform eruption. The erythemas discussed in this chapter all share a common feature – a figurate configuration.

In figurate erythemas, the lesions have an annular, arciform, or polycyclic appearance. While a wide range of cutaneous diseases can have an annular configuration (Table 19.1), there are four "classic" figurate erythemas: erythema annulare centrifugum, erythema marginatum, erythema migrans, and erythema gyratum repens.

ERYTHEMA ANNULARE CENTRIFUGUM

Synonyms: ■ Superficial or deep gyrate erythema ■ Erythema perstans ■ Palpable migrating (arciform) erythema

Key features

- Erythematous annular lesions that migrate centrifugally
- Superficial lesions can have the classic "trailing" white scale, while the deep gyrate erythemas have a more infiltrated border
- The disorder occurs more commonly in adults, and superficial lesions favor the thighs and hips
- Individual lesions usually last for several days to a few months
- Although often idiopathic in nature, it can be associated with infections (e.g. tinea pedis) and anecdotally with other disorders or exposures

Introduction

The term "erythema annulare centrifugum" (EAC) has come to encompass more than just annular erythematous plaques with trailing scale. One explanation for this is that once the other three major figurate erythemas (with specific etiologies; see below) and the disorders listed in Table 19.1 are excluded, EAC often becomes a "default" diagnosis. Unfortunately, this has led to some confusion, but until a specific "trigger" can be identified for each individual patient, this situation will persist. As a consequence, some authors have come to the conclusion that EAC, especially the deeper form, represents a clinical reaction pattern rather than a specific clinicopathologic entity[1]. Adding to the confusion is the school of thought in which the term EAC is reserved for only the superficial form.

History

In 1881, Colcott-Fox described persistent, ring-shaped lesions with pruritus, to which he gave the name "erythema gyratum perstans". The term "EAC" was introduced by Darier in 1916 while the name "erythema perstans" has been used by some authors to describe similar annular erythemas. It is now thought that all of these terms refer to clinical or pathologic variants of the entity now referred to as EAC[2]. However, Ackerman[3] preferred to call the two histologically different forms (superficial and deep) of EAC "superficial gyrate erythema" and "deep gyrate erythema", while Weyers et al.[4] believed that the superficial and deep forms of EAC were unrelated to one another and should not be referred to by the same name. These latter authors recommended that the term EAC be reserved for the superficial type, which in their opinion represented a specific clinicopathologic entity.

Epidemiology

Although EAC can appear in any age group, its peak incidence is in the fifth decade of life. There is no known sex difference. A rare autosomal dominantly inherited form of EAC, referred to as "familial annular erythema", has also been described[5].

Pathogenesis

It has been suggested that EAC, especially the superficial form with epidermal spongiosis histologically, represents a reaction pattern or "hypersensitivity" to one of many antigens[6]. EAC has been associated with infectious agents, particularly dermatophytes, but also with other fungi (e.g. *Candida*, *Penicillium* in blue cheese), viruses (e.g. poxvirus, EBV, varicella–zoster virus, HIV), bacteria (e.g. *Pseudomonas*, post-tonsillitis), parasites, and ectoparasites (e.g. *Phthirus pubis*). Less commonly, EAC has been linked to drugs (e.g. diuretics, nonsteroidal anti-inflammatory drugs, antimalarials, finasteride, amitriptyline, nivolumab, sorafenib, rituximab, pegylated interferon-α-2a plus ribavirin, ustekinumab [often as single case reports]), Crohn disease, pregnancy, autoimmune endocrinopathies, hypereosinophilic syndrome and, occasionally, neoplasms (e.g. lymphomas, leukemias, solid organ malignancies). The latter has been referred to as *p*araneoplastic *EAC e*ruption (PEACE)[7]. However, most of these associations are anecdotal, and, in the last group, Curth's postulates have not been consistently fulfilled (see Ch. 53). There are patients with EAC who noted resolution of their lesions after the diseases that presumably triggered the EAC were successfully treated. In one series, an associated disease was identified in only one-third of patients[8].

The peripheral migration of EAC lesions is thought to reflect localized production of proinflammatory cytokines and vasoactive peptides[9], but the precise mechanism is unknown.

Clinical Features

The initial lesions of EAC begin as firm pink papules that expand centrifugally and then develop central clearing. An individual lesion can enlarge to greater than 6 cm in diameter over a period of 1 to 2 weeks. If expansion of the annular plaque is not uniform, incomplete arcs appear, as do polycyclic lesions, or simply festooned bands. In the *superficial* form, the lesions are minimally elevated, and there is desquamation at the inner margin, i.e. trailing scale (Fig. 19.1A,B). The scale may not be present in all the lesions in a particular patient (Fig. 19.2A). There may be associated pruritus, especially in lesions that histologically show spongiosis.

DIFFERENTIAL DIAGNOSIS OF FIGURATE ERYTHEMA			
Disorders	**Clinical features**	**Histopathologic findings**	**Cross references**
Transient individual lesions (typically lasting <24 hours)			
Urticaria	Transient and recurrent wheals; pruritus	Dermal edema with sparse perivascular infiltrate of eosinophils and lymphocytes; occasionally neutrophils	Ch. 18
Urticaria multiforme (a variant of annular urticaria)	Annular and polycyclic wheals, often with central ecchymosis that should not be confused with necrosis; pruritus; edema of the face, hands, feet; absence of mucous membrane erosions or crusts; recent viral or bacterial infection	Indistinguishable from other forms of urticaria	
Serum sickness-like reaction	Annular and polycyclic wheals often have a purpuric component; acral edema; high fevers, arthralgias, lymphadenopathy; drug exposure (e.g. cefaclor, penicillins, minocycline)	Similar to urticaria; unlike serum sickness (e.g. due to equine- or rabbit-derived antithymocyte globulin), leukocytoclastic vasculitis is usually absent	
Erythema marginatum	Polycyclic erythematous eruption; antecedent group A streptococcal infection; additional manifestations of acute rheumatic fever, e.g. arthritis and carditis	Superficial perivascular infiltrate of neutrophils and lymphocytes; occasionally eosinophils	See text
Erythema marginatum-like lesions of hereditary angioedema	Transient polycyclic erythematous eruption; favors trunk; precedes or accompanies episodes of angioedema	Minimal to no inflammatory infiltrate	Ch. 18
African trypanosomiasis	Annular erythematous patches on the trunk associated with fever spikes	Perivascular lymphocytic infiltrate with many plasma cells; parasites are occasionally seen within the dermis	Ch. 83
Erythrokeratodermia variabilis et progressiva	Transient gyrate or circinate erythematous patches (usually fade/migrate within a few hours); also fixed figurate hyperkeratotic plaques; *GJB3, GJB4* > *GJA1* mutations	Scant perivascular lymphocytic infiltrate; dilated capillaries; psoriasiform acanthosis and mild hyperkeratosis (fixed plaques)	Ch. 57
Urticarial lesions lasting >24 hours			
Allergic urticarial eruption	Annular edematous plaques; favors trunk	Edema; superficial and deep lymphocytic infiltrate with eosinophils	
Wells syndrome	Edematous erythematous plaques, often annular or arcuate with a greenish color centrally; pruritus; peripheral eosinophilia	Diffuse infiltrate of eosinophils; flame figures	Ch. 26
Eosinophilic annular erythema	Recurrent annular edematous erythematous plaques; pruritus; some authors view as a subtype of Wells syndrome but peripheral eosinophilia is typically absent; originally described in children where overlap with eosinophilic form of annular erythema of infancy	Superficial and deep perivascular, periadnexal and interstitial lymphohistiocytic infiltrate with abundant eosinophils	
Annular erythema of infancy (including neutrophilic figurate erythema of infancy)	Recurrent annular erythematous plaques, usually lasting a few days; typically affects infants 3–11 months of age (see Fig. 19.4A); neutrophilic form can have purpura and vesicles and affect adults (see Fig. 19.4B)	Perivascular lymphocytes and eosinophils; sometimes a predominantly neutrophilic infiltrate	
Urticarial vasculitis	Urticarial plaques, often annular, that may have a purpuric or petechial component; pain, burning, and/or pruritus; systemic manifestations, especially in hypocomplementemic form	Leukocytoclastic vasculitis	Ch. 24
Erythema migrans	Erythema slowly migrates from site of tick bite; influenza-like syndrome; secondary distant lesions	Superficial and deep perivascular lymphohistiocytic infiltrate; eosinophils and plasma cells in some cases of erythema migrans; mucin and clusters of CD123+ plasmacytoid dendritic cells in LE tumidus; mucin in annular erythema of Sjögren syndrome	See text and Ch. 74
Erythema annulare centrifugum (deep)	Annular erythema with raised borders		See text
Lymphocytic infiltrate of Jessner	Annular erythematous plaques; favors face and upper trunk		Ch. 121
LE tumidus	Annular erythematous plaques; favors face, upper trunk > extensor forearms		Ch. 41
Annular erythema of Sjögren syndrome*	Annular erythematous plaques; favors face, arms, upper trunk; most common in Asian patients; anti-Ro antibodies		Ch. 45
Granulomatous lesions			
Granuloma annulare	Skin-colored to pink annular and arcuate plaques with borders composed of multiple papules; favors acral and extensor sites	Palisading granulomas with altered collagen and mucin	Ch. 93
Annular elastolytic giant cell granuloma	Pink annular plaques with atrophy and hypopigmentation centrally; favors sites of chronic sun exposure	Granulomatous infiltrate with elastophagocytosis by giant cells (border of lesion); absence of elastic fibers (center of lesion)	Ch. 93
Interstitial granulomatous dermatitis (IGD); interstitial granulomatous drug reaction (IGDR) (also referred to as reactive granulomatous dermatitis)	Annular erythematous plaques (or, in IGD, linear cords); favors axillae, groin, lateral trunk and legs; associated arthralgia/arthritis; IGDR is most often due to antihypertensive and lipid-lowering medications	Interstitial infiltrate of histiocytes with "rosetting" around collagen fibers and histiocytes surrounding single fibers of collagen; eosinophils may be present in IGDR	Ch. 93

Table 19.1 Differential diagnosis of figurate erythema.

DIFFERENTIAL DIAGNOSIS OF FIGURATE ERYTHEMA			
Disorders	**Clinical features**	**Histopathologic findings**	**Cross references**
Sarcoidosis	Red-brown annular plaques and papules; favors face; systemic manifestations	Sarcoidal granulomas ("naked tubercles")	Ch. 93
Borderline or tuberculoid leprosy	Annular plaques with raised erythematous borders and (in tuberculoid lesions) central hypopigmentation; asymmetric distribution; hypoesthesia, alopecia	Non-caseating granulomas with fragmentation of nerve fibers (tuberculoid leprosy); less well-defined granulomas (borderline leprosy)	Ch. 75
Papulosquamous lesions			
Erythema annulare centrifugum (superficial)	Annular lesions with trailing scale; favors thighs, hips and trunk	Superficial perivascular lymphocytes with focal spongiosis and parakeratosis; focal hemorrhage and exocytosis of lymphocytes in pityriasis rosea	See text
Erythema gyratum repens	Concentric erythematous rings with wood-grain appearance; erythema moves ~1 cm per day; associated with cancer		See text and Ch. 53
Pityriasis rosea	Herald patch on trunk; oval annular papules and plaques with central fine scaling and/or a collarette of trailing scale; Christmas-tree distribution on posterior trunk		Ch. 9
Pityriasis rubra pilaris	Appears as the primary "classic" lesions resolve; resembles erythema gyratum repens	Epithelial hyperplasia; alternating vertical and horizontal ortho- and parakeratosis; follicular plugging with shoulders of parakeratosis	See text and Ch. 9
Tinea corporis	Annular plaques with scale (exception: tinea incognito); pustules in border; concentric lesions in tinea imbricata; KOH-positive	Dermatophytes in the stratum corneum	Ch. 77
Lichen planus (LP), annular and actinic variants	Violaceous annular plaques; gray-brown to brown hyperpigmentation centrally; mucosal involvement; photodistribution in actinic LP	Hypergranulosis, band-like lymphocytic infiltrate at dermal–epidermal junction, necrotic keratinocytes	Ch. 11
Annular LE (subacute > discoid), *neonatal LE*, mothers of boys with chronic granulomatous disease	Photosensitivity; favors face (discoid), extensor upper extremities/upper trunk (SCLE), periorbital area (neonatal LE); anti-Ro antibodies (SCLE, neonatal LE); erythema gyratum atrophicans transiens neonatale is considered a variant of neonatal LE	Vacuolar interface dermatitis; variably dense periadnexal lymphohistiocytic inflammation with clusters of CD123+ plasmacytoid dendritic cells	Ch. 41
Seborrheic dermatitis	Erythematous annular plaques with scaling; favors face and central chest	Psoriasiform epithelial hyperplasia, spongiosis, perivascular lymphocytes	Ch. 13
Psoriasis	Annular scaly plaques with slow expansion	Psoriasiform epithelial hyperplasia, parakeratosis, diminished granular layer, elongated rete ridges, neutrophils migrating into epidermis	Ch. 8
Ichthyosis linearis circumflexa of Netherton syndrome	Serpiginous or circinate erythematous plaques bordered by double-edged scale; trichorrhexis invaginata; atopic diathesis, elevated serum IgE	Psoriasiform features with hyperkeratosis and a well-developed granular layer	Ch. 57
Lesions with absence or variable presence of scale			
Annular lichenoid dermatitis of youth	Red-brown annular patches or thin plaques with central hypopigmentation; favors groin and flanks; affects children and young adults	Lichenoid infiltrate; marked keratinocyte necrosis limited to the tips of rete ridges	Ch. 11
Erythema papulatum centrifugum	Usually a single, large annulus on the trunk whose border is 2–6 cm in width and composed of small erythematous papules, papulovesicles or crusted papules; favors Japanese men	Mononuclear infiltrate around eccrine ducts within the epidermis and dermis; spongiosis	
Secondary syphilis	Annular plaques with central hyperpigmentation; favors face; influenza-like symptoms; additional mucocutaneous manifestations; positive for RPR and FTA-ABS	Perivascular and interstitial infiltrate with plasma cells; also lichenoid or granulomatous infiltrate, exocytosis; bacilli can be identified by immunohistochemistry	Ch. 82
Mycosis fungoides	Annular erythematous or hypopigmented plaques, some with scale; admixed with classic lesions; often pruritic	Band-like infiltrate of lymphocytes in the papillary dermis with epidermotropism	Ch. 120
Neutrophilic sebaceous adenitis	Annular, indurated, erythematous plaques that favor the face and upper trunk of young adults; may be exacerbated by sun exposure	Focal necrosis of sebocytes; neutrophils within sebaceous glands; superficial and deep lymphocytic infiltrate	Ch. 25
Pustular lesions			
Pustular psoriasis (annular pattern)	Rapid expansion with erythematous borders studded with pustules	Subcorneal and spongiform pustules; neutrophils in the epidermis	Ch. 8
Sneddon–Wilkinson disease, IgA pemphigus	Pustules in a circinate pattern; peripheral expansion with central clearing; axillae, groin, inframammary areas	Subcorneal pustules; neutrophils in the epidermis; intercellular epidermal IgA deposition in IgA pemphigus	Chs. 8 & 29
Eosinophilic pustular folliculitis (Ofuji disease)	Grouped follicular pustules and papulopustules in an annular or serpiginous configuration; favors the face, trunk and arms	Infundibular eosinophilic pustules	Ch. 38

Table 19.1 Differential diagnosis of figurate erythema.

Continued

DIFFERENTIAL DIAGNOSIS OF FIGURATE ERYTHEMA			
Disorders	**Clinical features**	**Histopathologic findings**	**Cross references**
Erosive/vesiculobullous lesions			
Erythema multiforme (EM), Stevens–Johnson syndrome	Association with HSV and *Mycoplasma* vs drugs, respectively; target lesions more common in EM; mucosal involvement	Necrotic keratinocytes, vacuolar degeneration of the basal layer and variable inflammation	Ch. 20
Necrolytic migratory erythema	Erosion and crusting of advancing edge; periorificial involvement; glossitis; association with glucagonoma or liver/GI disorders (pseudoglucagonoma); constitutional symptoms	Pallor and edema of the upper epidermis; variable erosion	Ch. 53
Bullous pemphigoid, pemphigoid gestationis	Annular urticarial plaques; tense bullae; pruritus; peripheral eosinophilia	Subepidermal bullae with eosinophils > neutrophils; linear deposits of IgG and/or C3 in BMZ	Chs. 27 & 30
Linear IgA bullous dermatosis	Annular urticarial plaques; vesicles and bullae within border ("string of pearls"); pruritus	Subepidermal bullae with neutrophils > eosinophils; linear deposits of IgA in BMZ	Ch. 31
Epidermolysis bullosa simplex (especially generalized severe subtype [formerly Dowling–Meara subtype])	"Herpetiform" blisters in figurate array; episodic flares of migratory circinate erythema and blistering; *KRT5* or *KRT14* mutations	Intraepidermal split; eosinophilic inclusions within the keratinocytes	Ch. 32
Annular/cyclic epidermolytic ichthyosis	Migratory, annular or polycyclic, erythematous plaques with superficial blistering/peeling and scaling at the border; episodic flares; *KRT1* or *KRT10* mutations	Epidermolytic hyperkeratosis	Ch. 57
Purpuric lesions†			
Purpura annularis telangiectoides	"Cayenne pepper" petechiae and telangiectasias in annular configuration; favors trunk and legs	Capillary dilation and tight perivascular infiltrate of lymphocytes; extravasated erythrocytes; siderophages	Ch. 22
Acute hemorrhagic edema of infancy	Annular or targetoid, edematous, erythematous plaques that become purpuric; favors face, ears and extremities; febrile but non-toxic-appearing child <2 years of age	Leukocytoclastic vasculitis; perivascular IgA deposition in fewer than one-third of cases	Ch. 24
Perforating lesions‡			
Elastosis perforans serpiginosa	Peripheral edge composed of keratotic papules; favors neck and other flexural areas	Excess of degenerated elastic fibers in clumps in the superficial dermis with transepidermal elimination	Ch. 96

*Considered by some authors to be a form of SCLE.
†Purpura can also occur in urticarial vasculitis.
‡Giant variant of acquired perforating dermatosis can be annular.

Table 19.1 Differential diagnosis of figurate erythema. Key clinical features and histologic findings are provided. Disorders in *italics* favor children or childhood onset. Additional conditions that can present with figurate erythema include Kawasaki disease (may be erythema marginatum-like), hereditary periodic fever syndromes (especially *T*NF *r*eceptor-*a*ssociated *p*eriodic syndrome [TRAPS]; see Table 45.2), relapsing polychondritis, polymorphous light eruption, inflammatory vitiligo (including a papulosquamous variant), eosinophilic vasculitis, Sweet syndrome, neutrophilic eccrine hidradenitis, pyoderma vegetans (expanding pustular lesions), leukemia cutis, symmetric acral annular erythema, and porokeratosis. There is also an annular variant of acute generalized exanthematous pustulosis (e.g. due to terbinafine) and a generalized pustular figurate erythema associated with hydroxychloroquine. BMZ, basement membrane zone; FTA-ABS, fluorescent treponemal absorption; GI, gastrointestinal; LE, lupus erythematosus; RPR, rapid plasma reagin; SCLE, subacute cutaneous LE.

Occasionally, vesicles develop within the peripheral margin. In *deep* gyrate erythema, the advancing edges are obviously elevated (Fig. 19.1C) and there is usually no associated scale or pruritus.

As lesions resolve, there is no residual scarring, but postinflammatory hyperpigmentation can be seen and, on occasion, purpura. Although the lesions of EAC may be localized or generalized, they rarely, if ever, involve the palms, soles, scalp or mucous membranes. Individual lesions can persist for weeks to months, but associated systemic manifestations are uncommon. While new lesions can appear just as older ones resolve, there may be prolonged intervals of time between flares. Compared to the deep variant, the superficial form tends to recur more frequently but the individual lesions are often shorter-lived. The total duration of the disorder ranges from days to decades[2], and an unusual form of EAC has been described that recurs annually.

When EAC is due to an underlying disorder, flares of the former may correlate with recurrences of the latter. However, most patients with EAC do not have an identifiable underlying disorder, nor can the onset, fluctuations, or duration be related to a specific antigen.

Pathology

In *superficial* lesions of EAC, the findings are nonspecific, with mild spongiosis and microvesiculation plus associated focal parakeratosis, as well as a mild superficial perivascular lymphohistiocytic infiltrate. These histologic features correspond to the scale on the inner margin of the advancing erythematous arc. Characteristically, the inflammatory cells form a fairly tight aggregate around vessels, the so-called "coat sleeve" appearance (Fig. 19.1D). Rarely, eosinophils are found in the perivascular infiltrate. The advancing edge, which is slightly raised, may also show edema in the papillary dermis. The central area of clearing may contain dermal melanophages.

In *deep* lesions of EAC, the epidermis is usually unremarkable, and a mononuclear cell infiltrate with a sharply demarcated perivascular arrangement is present primarily within the mid and lower dermis. For this reason, the lesions are generally elevated and are more indurated than in the superficial form of EAC, and they do not have trailing scale.

Differential Diagnosis

EAC must be differentiated from other annular erythematous lesions (see Table 19.1)[10], particularly tinea corporis and annular psoriasis, when there is associated scale. Additional entities to consider include annular urticaria (Fig. 19.2B), allergic urticarial eruption, symmetric acral annular erythema, cutaneous lymphoid hyperplasia (pseudolymphoma), and lymphoma cutis. Patients with autoimmune disorders, including linear IgA bullous dermatosis, bullous pemphigoid, Sjögren

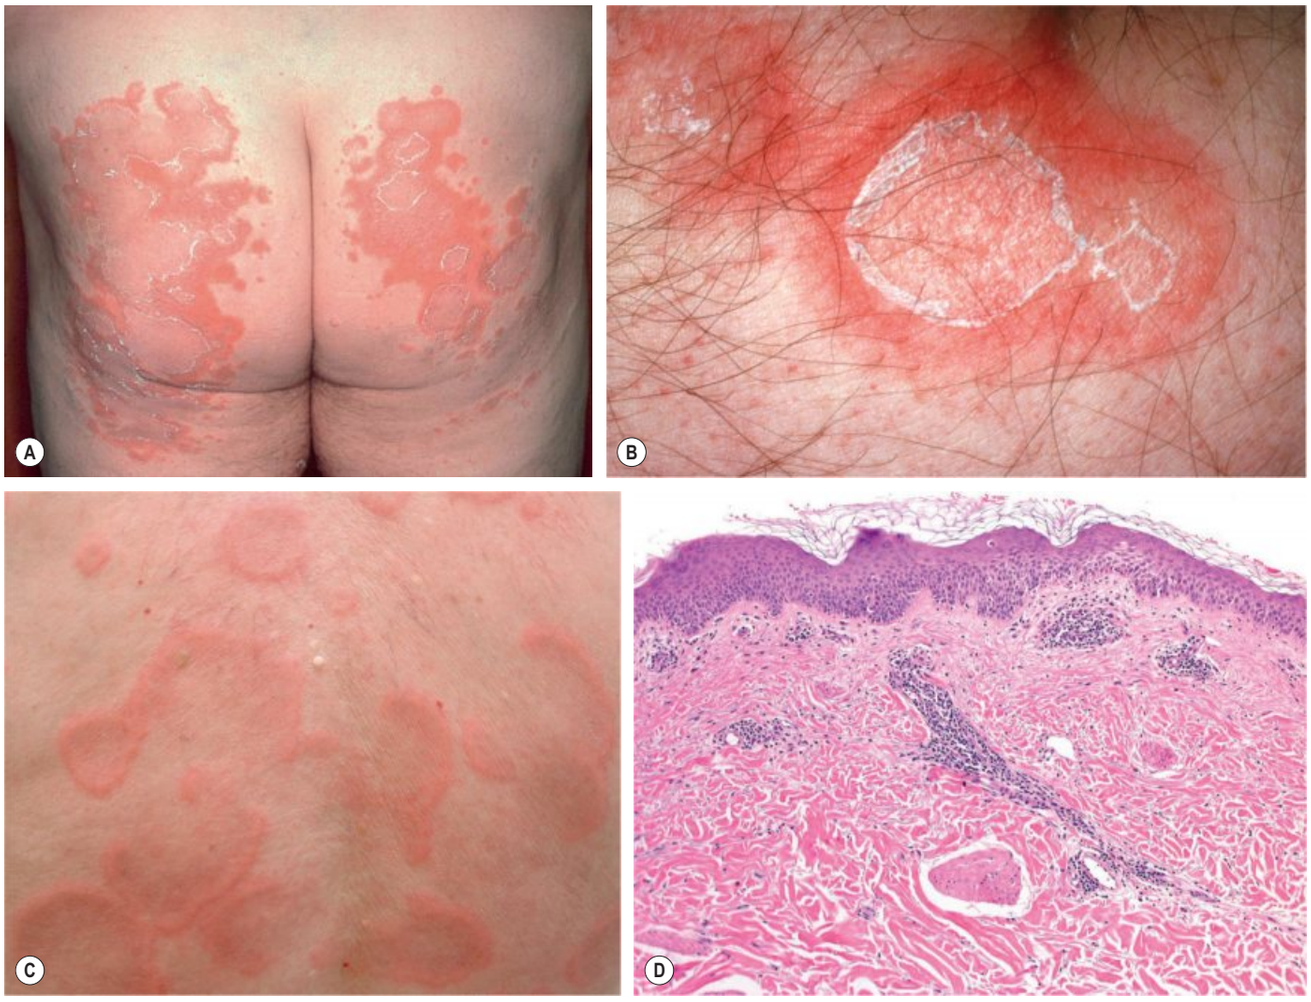

Fig. 19.1 Erythema annulare centrifugum. A, B Superficial form, with polycyclic plaque and delicate scale on the inner margin of the advancing edge (trailing scale). The scale is detached centrally. **C** Deep form, with obvious elevation of advancing edges and without trailing scale. **D** Photomicrograph of the superficial form with dermal perivascular lymphohistiocytic infiltrates; note the tight "coat sleeve"-like appearance of the infiltrate. *D, Courtesy Lorenzo Cerroni, MD.*

Fig. 19.2 A comparison of erythema annulare centrifugum and urticaria. The lesions in **A** have no scaling and may be confused with annular urticaria (**B**). However, individual lesions of urticaria are evanescent. Placement of an ink circle around a lesion, followed by longitudinal observation, allows this distinction.

syndrome, and lupus erythematosus (LE tumidus, subacute cutaneous LE, neonatal LE), can also have erythematous annular, arciform, and polycyclic lesions.

Treatment

If EAC is due to an underlying disorder, the skin lesions will usually resolve once the latter has been successfully treated. Topical corticosteroids applied to the advancing border of the lesions may be of benefit. Topical antipruritics and sedating antihistamines can be prescribed if there is associated pruritus. Even in the absence of an identifiable cause, some authors have advocated the empiric use of antibiotics (e.g. macrolides) or antifungal agents. Although systemic corticosteroids can induce a clinical remission, recurrences are common when the medication is discontinued. Based solely on case reports, the following have been reported as beneficial: topical tacrolimus, topical calcipotriene (calcipotriol), NB-UVB, oral metronidazole, apremilast, subcutaneous etanercept, and subcutaneous interferon-α. However, systemic therapies are seldom necessary.

ERYTHEMA MARGINATUM

Synonyms: ■ Erythema marginatum rheumaticum ■ Erythema annulare rheumaticum

Key features

- Migratory, annular and polycyclic, erythematous eruption
- Cutaneous manifestation of acute rheumatic fever
- Associated findings include carditis, migratory polyarthritis, Sydenham chorea, and subcutaneous nodules
- Seen more commonly in children than in adults

Introduction

Rheumatic fever (RF) is characterized by an abnormal immunologic response to a preceding infection with group A β-hemolytic streptococci and by the triad of fever, arthritis, and carditis. Cutaneous manifestations include erythema marginatum and subcutaneous nodules, but they are seen in a minority of patients. The diagnostic criteria of RF were recently revised in 2015 by the American Heart Association[11]: major criteria in low-risk populations are carditis or valvulitis (by echocardiography), polyarthritis, Sydenham chorea, erythema marginatum, and subcutaneous nodules. Minor criteria include fever, polyarthralgia, elevated acute phase reactants (ESR ≥60 mm, C-reactive protein ≥3 mg/dL), and prolonged PR interval on ECG. To establish the diagnosis of acute RF, two major or one major and two minor criteria must be accompanied by evidence of an antecedent group A streptococcal infection, e.g. a positive culture, an elevated or rising antistreptolysin O or anti-DNase B titer. In moderate- to high-risk populations, monoarticular arthritis is also considered a major criterion, with monoarthralgia and an ESR ≥30 mm representing additional minor criteria[11].

History

In 1831, Bright noted the presence of annular erythematous lesions in patients with RF. In 1889, Cheadle proposed the name "erythema marginatum rheumaticum"[12]. Carol and van Krieken first described the histopathologic findings in 1935. Two years later, Perry reported that rapid migration of the lesions was a characteristic finding[13]. In 1944, Jones established criteria for diagnosing RF[14].

Epidemiology

Attacks of acute RF are associated with antecedent group A β-hemolytic streptococcal infections of the pharynx. Approximately 3% of patients with untreated infections can develop acute RF. It is estimated that in high-income countries, i.e. low-risk populations, the incidence is 5 per 100 000, whereas in low-income countries, it ranges from 100 to 1000 per 100 000. Erythema marginatum is seen in less than 10% of patients with acute RF. The higher incidence of erythema marginatum in children (as compared to adults) reflects the predominance of RF during childhood; the peak age-related incidence is between 5 and 15 years[15].

Pathogenesis

The mechanisms that underlie erythema marginatum are unknown. Presumably, there is an abnormal humoral and cellular immune response to one or more antigens associated with group A β-hemolytic streptococci (e.g. M protein)[16]. Antigenic mimicry may play a role in that epitopes that cross-react with group A streptococcal antigens have been identified in human myosin, actin, tropomyosin, keratin, laminin, N-acetylglucosamine, and vimentin[17]. Specific characteristics of certain strains of group A β-hemolytic streptococci, such as higher M protein content and mucoid colony formation, may facilitate the development of acute RF[18]. Enhanced expression of genes that encode cysteine proteases (e.g. *Streptococcus pyogenes* exotoxin B [SpeB], immunoglobulin G degrading enzyme of *Str. pyogenes* [IdeS]) is thought to contribute to cardiotoxicity and virulence[19]. The role of host genetic factors is currently under investigation via genome-wide association studies[20].

Clinical Features

Following the initial episode of streptococcal pharyngitis, there is usually a latency period of 2–5 weeks before the development of the acute attack of RF. The lesions of *erythema marginatum* begin as erythematous macules that spread peripherally and become patches or plaques with no scale. Erythema marginatum can also have a polycyclic arrangement (Fig. 19.3). The lesions are usually asymptomatic, and, over a period of 12 hours, they can migrate from 2 to 12 mm; in areas of previous involvement, the skin may appear pale or lightly pigmented[15]. As with other erythemas, exposure to heat can accentuate lesions.

Fig. 19.3 Erythema marginatum. Polycyclic and evanescent annular lesions are seen on the trunk of this young patient.

The most common locations for erythema marginatum are the trunk, axillae and proximal extremities, with sparing of the face. New lesions usually last from a few hours to a few days and are often most noticeable during the afternoon. Recurrent crops can occur over a number of weeks. Erythema marginatum is associated primarily with the active phase of RF, and, in general, it is seen in conjunction with carditis. Of note, children less than 5 years of age appear to have a higher incidence of erythema marginatum as well as carditis and arthritis[21].

Subcutaneous nodules appear primarily over bony prominences, especially the wrists, elbows, knees and ankles, in patients with long-standing disease. The nodules are usually painless and are rare during the initial attack of RF. Similar nodules can be seen in patients with polyarticular juvenile idiopathic arthritis (see Ch. 45). In addition to the major and minor criteria (see above), patients may also have malaise, chest or abdominal pain, epistaxis, tachycardia and anemia, as well as a nonspecific urticarial eruption[18].

Pathology

An interstitial and perivascular infiltrate composed predominantly of neutrophils without vasculitis is observed. Occasionally, eosinophils are seen and in later stages, there can be extravasation of erythrocytes. Direct immunofluorescence microscopy for immunoglobulin and complement deposits is negative. These histologic findings are not unique to erythema marginatum, and overlapping features with the neutrophilic variant of annular erythema of infancy (neutrophilic figurate erythema of infancy) and the neutrophilic urticarial dermatosis seen in several autoinflammatory disorders may be observed.

Differential Diagnosis

The clinical differential diagnosis includes primarily annular urticaria (including urticaria multiforme) and annular erythema of infancy (Fig. 19.4A), as well as its variant neutrophilic figurate erythema of infancy[22]. Occasionally, neutrophilic figurate erythema is seen in adults and can be accompanied by vesicles and purpura (Fig. 19.4B). Less often, Still disease, hereditary periodic fever syndromes (particularly *T*NF *r*eceptor-*a*ssociated *p*eriodic *s*yndrome [TRAPS]; see Table 45.2), EAC, Kawasaki disease, and other entities listed in Table 19.1 need to be considered. Annular erythema with an appearance similar to erythema marginatum may precede or accompany episodes of hereditary angioedema[23] and is seen only occasionally in patients with cat scratch disease or psittacosis[24,25]. The angioedema-associated figurate erythema may be related to deposits of bradykinin within the dermis while the latter may reflect an overlap between erythema

Fig. 19.4 Annular erythema of infancy and neutrophilic figurate erythema. A Expanding annular urticarial plaques in a 6-month-old boy. Lesions are typically asymptomatic, expand slowly, and then resolve over a few days. New plaques may continue to appear for several months. **B** A neutrophilic variant occurs in both infants and adults and in the latter, there can be striking purpura within the lesions. *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Lorenzo Cerroni, MD.*

marginatum and EAC. In a patient receiving sorafenib, figurate lesions with associated scale-crust and hemorrhage developed and the name "erythema marginatum hemorrhagicum" was proposed, but clinically these lesions can easily be distinguished from erythema marginatum[26].

Treatment

There is no specific therapy for this dermatosis. In general, its clinical course is unaltered by treatment of the underlying acute RF; however, symptoms are usually mild and lesions resolve spontaneously.

ERYTHEMA MIGRANS

Synonyms: ■ Erythema chronicum migrans ■ Lyme borreliosis (early stage) ■ Lyme disease (early stage)

Key features

- Annular erythema develops at the site of the bite of a *Borrelia*-infected tick
- Several species of *Ixodes* ticks are infected with different genospecies of *Borrelia burgdorferi*
- Erythema migrans represents the initial cutaneous manifestation of Lyme disease and is seen in 60%–80% of patients diagnosed with the disease
- Multiple secondary lesions that may be smaller in size can occur as a result of spirochetemia or lymphatic spread

Introduction

Lyme disease (LD) is an infection due to *Borrelia burgdorferi* spirochetes that are transmitted by bites from several species of *Ixodes* ticks (e.g. *I. scapularis*, *I. pacificus*, *I. ricinus*; see Chs. 76 & 85). Erythema migrans represents the initial cutaneous manifestation.

History

The first report of an annular erythema developing after a tick bite was by Afzelius in 1909 and he coined the term "erythema migrans". Lipschütz then referred to these cutaneous lesions as "erythema chronicum migrans". In the US, Steere described an epidemic form of childhood arthritis preceded by erythema migrans in several communities in the vicinity of Lyme, Connecticut. In the 1980s, Burgdorfer isolated a new spirochete in lesions of erythema migrans and the organism was subsequently named *B. burgdorferi*[27].

Epidemiology

Although LD has a worldwide distribution, it is seen most commonly in the US (Northeast, mid-Atlantic, and Great Lakes regions) and in northern and eastern Europe. The competent hosts that serve as a reservoir for *Borrelia* include mice, chipmunks and birds, with deer playing a role in sustaining the life cycle[28]. In temperate regions, the peak incidence for LD is during the spring and the summer, and it occurs more commonly in those who spend time outdoors in or near fields and woods. Approximately 30 000 cases of Lyme disease are currently reported to the CDC each year, with 95% of confirmed cases coming from 14 states (www.cdc.gov/lyme/). Based upon recent US insurance claim data, an estimated 475 000 people were treated yearly for Lyme disease, but this number obviously includes noninfected individuals. In Europe, ~320 000 cases of LD are diagnosed each year, but the incidence varies depending upon the country[29,30]. Not all patients who have positive serologic tests for *B. burgdorferi* develop LD.

Pathogenesis

In mice, *B. burgdorferi* has been shown to usurp a tick salivary protein, Salp15, as a means of enhancing transmission[31]. By binding to the outer surface protein C (OspC) of *B. burgdorferi*, Salp15 provides protection against antibody-mediated killing. In addition, Salp15 inhibits adaptive immune responses against both *Borrelia* and tick antigens[32]. Of note, one of the proposed strategies for preventing LD is the development of anti-tick vaccines that utilize tick salivary proteins.

Once the *Borrelia* organisms have entered the body, spirochetal lipoproteins trigger an innate immune response, with cytokines being produced by macrophages[33]. In addition, a Th1 response is triggered and B cell responses facilitate the synthesis of antibodies against different antigens of *B. burgdorferi*. Spirochetemia is present in ~45% of patients at the time of their presentation with erythema migrans[34], and organisms can disseminate widely due to their ability to resist elimination by macrophages, evade complement, adhere to brain and epithelial cells, penetrate into the cytoplasm via intracellular junctions, and induce TNF production[35].

Even though the lesion expands centrifugally, *B. burgdorferi* organisms have been found both in the center and at the periphery of lesions

of erythema migrans. The persistence of the spirochete in the skin after the tick bite may be due to an absence of the production of interferon-γ and an ineffective immune response[33]. Also, different immune responses to the various genospecies of the *B. burgdorferi* sensu lato complex (*B. burgdorferi* sensu stricto, *B. afzelii, B. garinii*) may lead to different clinical presentations (e.g. borrelial lymphocytoma in Europe but not the US; see Ch. 74)[36]. More recently, an additional genospecies was identified in the upper midwestern US, *B. mayonii*, which may lead to a more severe clinical presentation due to an unusually high spirochetemia[37].

Clinical Features

LD is divided into three clinical stages: (1) early localized disease; (2) early disseminated disease; and (3) chronic disease (Table 19.2). Erythema migrans is an important clinical feature of early disease. Typically, 7–15 days (range, 3–30 days) after tick detachment, an erythematous, expanding, circular or annular plaque appears that may have a lighter-colored central area or a bull's-eye appearance (Fig. 19.5). The eventual diameter is usually at least 5 cm, and the center may become darker red to violaceous in color, crusted, or even vesicular. Lesions of primary erythema migrans favor the trunk, axilla, groin, and popliteal fossa. Untreated, the lesions usually last less than 6 weeks (median, 4 weeks). In 20%–25% of patients, multiple lesions can appear due to multiple tick bites or as a result of disseminated disease secondary to spirochetemia. Disseminated lesions tend to be smaller in size and less pronounced and usually appear days to weeks after the appearance of the primary erythema migrans (Fig. 19.6)[38].

Erythema migrans is seen in 60%–80% of patients diagnosed with LD. In the US, the systemic manifestations of this initial phase tend to be acute, with influenza-like symptoms, including fatigue, headache, arthralgia, myalgia and fever, as well as lymphadenopathy, conjunctivitis or hepatitis (see Table 19.2)[39]. In Europe, this initial clinical phase is usually less severe, and the lesions of erythema migrans tend to last longer. If untreated, ~60% of patients will go on to have monoarticular or oligoarticular arthritis (usually the knee) within weeks to months after the initial infection; ~10%, neurologic manifestations (most commonly facial nerve palsy); and ~5%, cardiac complications (usually varying degrees of atrioventricular block)[34]. For a discussion of borrelial lymphocytoma and acrodermatitis chronica atrophicans, see Chapter 74.

Depending upon the geographic region, *Ixodes* ticks can be co-infected with the following microbes (in addition to *B. burgdorferi*): *Babesia microti* (babesiosis)[40], *Anaplasma phagocytophilum* (anaplasmosis), *Borrelia miyamotoi*, or Powassan virus. Co-infections should be considered when patients with LD have prolonged or severe manifestations of infection, cytopenias, or an unusually high or persistent fever[28].

Pathology

The histologic features of erythema migrans are similar to those of a deep gyrate erythema (Fig. 19.7). While routine histology is often not specific, many specimens will show superficial and deep lymphoid infiltrates admixed with a few eosinophils and plasma cells. Immunohistochemical studies have shown a reduction in the number of Langerhans cells; in the dermis, the inflammatory infiltrate contains macrophages, $CD4^+$ T helper cells and $CD45RO^+$ memory T cells[41]. PCR analysis of tissue specimens can be performed to confirm the presence of *Borrelia* spirochetes within a lesion.

Differential Diagnosis

The 2022 revised CDC case definition for LD now includes three categories: "confirmed", "probable", and "suspected" (Table 19.3)[42]. These categories are based upon laboratory evidence and whether a person resides in a low-incidence versus high-incidence jurisdiction (state). Confirmatory laboratory evidence consists of one of the following: (1) isolation of *B. burgdorferi* sensu stricto or *B. mayonii* in culture; (2) detection of *B. burgdorferi* sensu stricto or *B. mayonii* in a clinical specimen by a *B. burgdorferi* group-specific nucleic acid amplification test (NAAT) assay; (3) detection of *B. burgdorferi* group-specific antigens by immunohistochemical assay on biopsy or autopsy tissues; or (4) positive serologic tests in a two-tier or equivalent format. The latter includes either: (1) the standard two-tier test (STTT) - a positive or equivocal first-tier screening assay, often an enzyme immunoassay (EIA) or immunofluorescence assay (IFA) for IgM, IgG or combination, followed by a concordant positive IgM or IgG immunoblot; or (2) modified two-tier test (MTTT) - positive or equivocal first-tier screen, followed by a different sequential positive or equivocal EIA in lieu of an immunoblot[42]. In 2019, the MTTT methodology was introduced in which an FDA-cleared second EIA (e.g. for VlsE1-IgG and pepC10-IgM) could be used in place of the Western immunoblot[44]. *Presumptive* laboratory evidence consists of a positive IgG immunoblot, interpreted by established criteria, without positive or equivocal first-tier screening.

Of note, the peak specific IgM response (usually directed against the 41 kDa flagellar antigen) occurs 3–6 weeks into the infection[35]. As a result, serologic testing has a low sensitivity, e.g. only 25%–40% of patients with erythema migrans during the acute phase (but without evidence of dissemination) have positive test results, with a slightly higher percentage in those with dissemination (~50%)[28]. During convalescence following antibiotic therapy, positive test results are still only observed in approximately half of those who did not have dissemination, presumably reflecting eradication of the spirochetes[28].

STAGES AND MAJOR ORGAN MANIFESTATIONS OF LYME DISEASE

Organ	Early localized disease	Early disseminated disease	Chronic disease
Skin	Erythema migrans		Acrodermatitis chronica atrophicans (Europe)
	Disseminated erythema migrans Borrelial lymphocytoma (Europe)		
Nervous system		Lymphocytic meningitis Cranial neuritis Bell palsy Radiculoneuropathy	Encephalopathy Encephalomyelitis Neuropathy
Musculoskeletal system		Arthralgia, arthritis Myositis	Chronic arthritis
Heart		Atrioventricular block Myopericarditis, pancarditis	
Lymphatic	Regional lymphadenopathy	Regional or generalized lymphadenopathy	
Other		Conjunctivitis, iritis Hepatitis Non-productive cough Microscopic hematuria or proteinuria	

Table 19.2 Stages and major organ manifestations of Lyme disease. Patients with erythema migrans may also have influenza-like symptoms, including fatigue, headache, myalgia, and fever. *Adapted from Müllegger RR. Dermatological manifestations of Lyme borreliosis. Eur J Dermatol. 2004;14:296–309.*

Fig. 19.5 Erythema migrans. A, B Annular erythema that spreads centrifugally; the peripheral erythematous border may or may not be sharply demarcated and is usually 1–2 cm in width. Concentric rings can form, leading to a bull's-eye appearance, but some lesions of EM have a more uniform color. Vesiculation centrally can also be seen (**B**). **C** The center may become violaceous in color. Patients may not report a history of a tick bite. *A, Courtesy Department of Dermatology, Medical University of Graz; C, Courtesy Dennis Cooper, MD.*

Fig. 19.6 Disseminated erythema migrans. Multiple pink circular and oval-shaped thin plaques with coalescence. Patients often have influenza-like symptoms. *Courtesy Ian W. Tattersall, MD, PhD.*

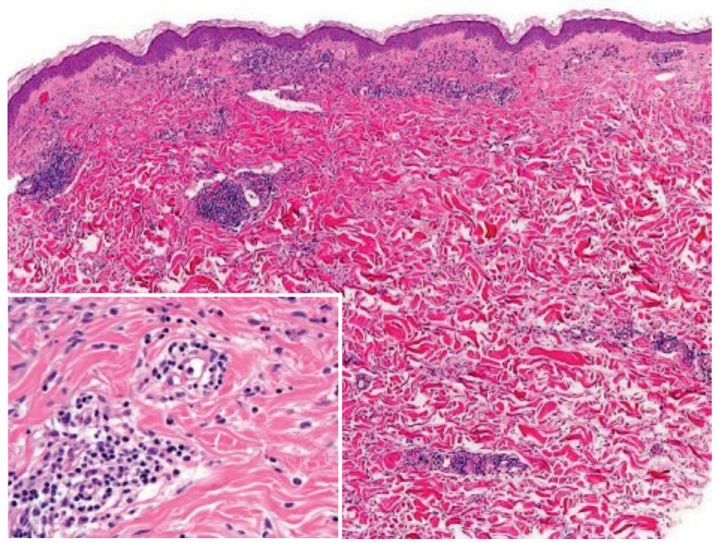

Fig. 19.7 Erythema migrans. A superficial and deep perivascular infiltrate is present within the dermis as well as a scattered interstitial pattern. The infiltrate is composed of lymphocytes and plasma cells (inset). *Courtesy Lorenzo Cerroni, MD.*

Although culture of tissue from the perimeter of erythema migrans lesions is essentially 100% specific and can distinguish live from dead organisms, it requires special agar (modified Barbour–Stoenner–Kelly medium) and prolonged observation, making it impractical in the standard clinical setting. As noted previously, detection of *B. burgdorferi* in skin biopsy specimens of erythema migrans via PCR is possible.

Erythema migrans must be distinguished from exaggerated local arthropod reactions (including to the tick bite), erysipelas, cellulitis, allergic contact dermatitis and non-pigmented fixed drug eruption, and less often, other entities outlined in Table 19.1. An erythema migrans-like skin lesion can be seen in southern tick-associated rash illness (STARI or Masters disease) which follows the bite of the lone star tick, *Amblyomma americanum* (see Ch. 85).

Treatment

Recommended antibiotic regimens are outlined in Table 19.4[43]. It is estimated that even in highly endemic areas, the risk of disease transmission from a recognized tick bite is low (1%–3%)[45]. This may be due to the observation that in general transmission from infected nymph ticks requires 36–48 hours of attachment and for adult ticks, ≥48 hours of attachment[28]. Therefore, routine treatment of tick bites with 2- to 3-week courses of antibiotics is not recommended. In patients from endemic areas (>20% of ticks infected) in whom the tick, identified as a nymphal or adult *I. scapularis*, has been attached for >36 hours and prophylaxis can be started within 72 hours of tick removal, a single 200 mg dose of doxycycline may decrease the risk of developing LD (from 3.2% in the placebo group to 0.4% in the treatment group in one study)[46].

ABRIDGED 2022 CDC LYME DISEASE SURVEILLANCE CASE DEFINITION
Definition of Erythema Migrans (EM)
A skin lesion that typically begins as a red macule or papule and expands over a period of days to weeks to form a large round lesion, often with partial central clearing. A single primary lesion must reach ≥5 cm in diameter. Secondary lesions also may occur. Annular erythematous lesions occurring within several hours of a tick bite represent hypersensitivity reactions and do not qualify as EM. EM may be accompanied by influenza-like symptoms (see text) and the diagnosis of EM must be made by a health care provider
Additional clinical criteria
• Recurrent, brief attacks of objective joint swelling in one or a few joints • Lymphocytic meningitis, cranial neuritis (particularly facial palsy [unilateral or bilateral]), radiculoneuropathy, or, rarely, encephalomyelitis • Acute onset of high-grade (2nd-degree or 3rd-degree) atrioventricular conduction defects that resolve in days to weeks and are sometimes associated with myocarditis
Laboratory criteria
• See text for details
Confirmed, probable, or suspect*
• High-incidence jurisdiction† - suspect if presumptive laboratory evidence • Low-incidence jurisdiction‡ - confirmed if confirmatory laboratory evidence and probable if presumptive laboratory evidence
*See website for details. †A jurisdiction with an average Lyme disease incidence of at least 10 confirmed cases/100 000 for the previous three reporting years [www.cdc.gov/lyme/stats/tables.html]. ‡A jurisdiction with an average Lyme disease incidence of <10 confirmed cases/100 000 for the previous three reporting years [www.cdc.gov/lyme/stats/tables.html].

ERYTHEMA GYRATUM REPENS

Synonym: ■ Gammel disease

Key features

- A figurate erythema that is migratory and composed of concentric rings with a wood-grain appearance
- It represents a paraneoplastic phenomenon and the most common underlying neoplasm is carcinoma of the lung
- The lesions may have associated pruritus and scale, and they characteristically exhibit rapid migration (up to 1 cm per day)
- The cutaneous lesions resolve when the neoplasm is successfully treated

Introduction

In the vast majority of patients, erythema gyratum repens (EGR) represents a paraneoplastic figurate erythema. In theory, the cutaneous lesions arise as a result of an immune reaction against tumor-associated antigens with the subsequent recognition of similar antigens in the skin.

History

EGR was first reported by Gammel in 1952, and his original description clearly identified its key clinical features.

TREATMENT OPTIONS FOR LYME DISEASE				
Manifestation	**Drug**	**Dose (pediatric dose*)**	**Duration (days)**	**Comments**
Erythema migrans	Doxycycline	100 mg (2 mg/kg) po BID	14 (range, 10–21)	• Not preferred in children <8 yrs of age†, or pregnant or lactating women • Good CNS penetration • Also treats human granulocytic anaplasmosis
	Amoxicillin	500 mg (16 mg/kg) po TID	14 (range, 14–21)	
	Cefuroxime axetil	500 mg (15 mg/kg) po BID	14 (range, 14–21)	
	Azithromycin^	500 mg (10 mg/kg) po daily	7 (range, 5–10)	
Manifestation	**Drugs**		**Duration (days)**	**Comments**
Meningitis	Ceftriaxone (IV), cefotaxime (IV)		14 (range, 10–28)	
Cranial nerve palsy (without meningitis)	Same drugs and dosing as for erythema migrans		14 (range, 14–21)	• May not affect outcome of facial palsy
Carditis	If symptomatic, initiate treatment with parenteral antibiotic (e.g. ceftriaxone) then based upon clinical response, finish course with oral agents		14 (range, 14–21)	• Advanced heart block may require a pacemaker
Arthritis	Same parenteral agents as for meningitis and same oral agents as for erythema migrans		28	• If persists or recurs, a second course of antibiotics
*The maximum pediatric dose is the adult dose. †The American Academy of Pediatrics considers use of doxycycline for ≤21 days to be acceptable in children <8 years of age. ^For patients intolerant of both doxycycline and β-lactam antibiotics.				

Table 19.4 Treatment options for Lyme disease[43]. A Jarisch–Herxheimer-like reaction with an increase in systemic symptoms and in the size or intensity of the inflammation of the erythema migrans lesion occurs in ~15% of patients within 24 hours after the initiation of antimicrobial therapy. If all three antibiotics for erythema migrans are contraindicated, then macrolides (e.g. clarithromycin, erythromycin, azithromycin) can be prescribed but the cure rates are ~80% rather than 90% with recommended antibiotics[28]. BID, twice daily; IV, intravenous; po, orally; TID, three times daily; yrs, years.

Epidemiology

EGR is a very rare disorder seen primarily in adults. Risk factors parallel those for the underlying neoplasms.

Pathogenesis

A leading hypothesis is that EGR represents an immune reaction in which there is a cross-reaction between tumor and cutaneous antigens[47]. In a few patients, direct immunofluorescence (DIF) has demonstrated deposits of IgG and C3 in the basement membrane zone (BMZ) of the skin, and, in isolated cases, similar deposits were seen in the associated neoplasm[48]. However, this could simply represent a nonspecific finding. Caux et al.[48] suggested that the tumor produces a modification in its basement membrane and this subsequently induces an immune response. Recognition of similar antigens in the BMZ of the skin then leads to the cutaneous eruption. The responsible antigen(s) is not known, but a curious finding is an accumulation of active Langerhans cells in the upper layers of the epidermis[49]. Recently, a link between glutamine metabolism within the skin and the distinct pattern of EGR lesions was proposed[50].

Clinical Features

Patients usually have multiple, annular or polycyclic, erythematous lesions that develop scale at their edges and advance at a rapid rate (up to 1 cm per day)[51]. This rate of peripheral spread is significantly faster than that of EAC. Lesions have a wood-grain or zebra-like pattern, due to the development of "rings within rings" (Fig. 19.8). In some patients, the eruption is also pruritic. Additional findings in patients with EGR include acquired ichthyosis, palmoplantar keratoderma, and peripheral eosinophilia.

In at least 70% of patients, EGR is associated with an underlying neoplasm, most commonly of the lung then breast, esophagus or stomach[52]. The cutaneous lesions usually develop between 1 year prior to 1 year after the diagnosis of the neoplasm. EGR may coincide with underlying pulmonary tuberculosis, and patients with other disorders (see below) can also develop EGR-like lesions. Occasionally, no underlying disorder or malignancy can be identified.

Fig. 19.9 Resolving pityriasis rubra pilaris. The lesions can resemble erythema gyratum repens. *Courtesy Irwin Braverman, MD.*

Pathology

The histopathologic findings are nonspecific and include hyperkeratosis, focal parakeratosis, moderate patchy spongiosis and a mild, perivascular lymphohistiocytic infiltrate. In some cases, variable numbers of eosinophils are seen in the dermis.

Differential Diagnosis

In addition to excluding the other types of figurate erythema, EGR-like lesions may be seen in patients with erythrokeratodermia variabilis et progressiva and resolving pityriasis rubra pilaris (Fig. 19.9) as well as autoimmune bullous diseases, in particular bullous pemphigoid (both paraneoplastic and classic) and epidermolysis bullosa acquisita[52,53]. Similar appearing lesions can occasionally be seen in mycosis fungoides, resolving psoriasis, hypersensitivity reactions to azathioprine, urticarial vasculitis, and autoimmune connective tissue diseases, primarily lupus erythematosus (subacute variant [also referred to as LE gyratus repens] or an associated neutrophilic dermatosis or small vessel vasculitis), and Sjögren syndrome. In certain regions of the world (e.g. maritime and mainland Southeast Asia), tinea imbricata would also be included in the differential diagnosis.

Treatment

EGR resolves when the associated neoplasm is successfully treated. There may be a return of cutaneous lesions in association with the development of metastases or local recurrences of the malignancy.

Erythema Multiforme 339
Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis 344

ERYTHEMA MULTIFORME

Synonym: ■ Erythema multiforme minor – erythema multiforme von Hebra

Key features

- A self-limited but potentially recurrent disease
- Abrupt onset of papular "target" lesions, with the vast majority of lesions appearing within 24 hours
- Two types of target lesions are recognized: (1) typical, with at least three different zones; and (2) atypical papular, with only two different zones and/or a poorly defined border
- Target lesions favor acrofacial sites
- Erythema multiforme minor: typical and/or occasionally atypical papular target lesions with little or no mucosal involvement and no systemic symptoms
- Erythema multiforme major: typical and/or occasionally atypical papular target lesions with severe mucosal involvement and systemic features
- A preceding herpes simplex virus (HSV) infection is the most common precipitating factor; occasionally, there are other preceding infections or, rarely, drug exposure
- Diagnosis of erythema multiforme requires clinicopathologic correlation and is not based solely on histologic findings
- Erythema multiforme does not carry the risk of progressing to toxic epidermal necrolysis

Introduction

Erythema multiforme (EM) is an acute, self-limited skin disease characterized by the abrupt onset of symmetric fixed red papules, some of which evolve into typical and/or occasionally "atypical" papular target lesions[1,2]. The eruption is often precipitated by an infection, particularly HSV. Two forms of EM are recognized – EM minor and EM major. Both are characterized by the same type of elementary lesions (targets), but are distinguished by the presence or absence of mucosal involvement and systemic symptoms (Table 20.1). In the vast majority of patients, EM can be distinguished clinically from Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) based upon the type of elementary skin lesions and their distribution[2,3].

History

EM was first described by the Austrian dermatologist Ferdinand von Hebra in 1860[4,5]. The disease he described was mild with a sudden onset of hundreds of red papules. By daily observation, von Hebra recognized that some of the original papules evolved into lesions with concentric zones of color change, which he termed "target" lesions. Some of the target lesions resembled a "herpes iris". However, von Hebra described neither a prodrome nor the presence of mucosal lesions. He recognized that the condition could be recurrent and mentioned a "typus annuus" which recurred every spring.

In 1950, Bernard Thomas further subdivided EM into EM minor and EM major[6]. Thomas considered von Hebra's disease to be EM minor, and severe mucosal necrosis with "EM-like" cutaneous lesions to be EM major. Since 1950, much confusion has developed regarding the definition of EM, in part because some authors, especially in the US, have stated that EM major includes SJS. However, recent investigations have clarified the situation by providing strong evidence that the term "EM minor" should be reserved for von Hebra's disease and the term "EM major" should be used for EM associated with mucosal lesions and systemic symptoms, but not for describing SJS, because SJS and EM major are distinct clinical disorders[2,3]. That said, because these are biologic processes, there can be patients where the distinction proves challenging.

Epidemiology

EM is predominantly observed in young adults and is very uncommon during childhood[3,7]. There is a slight male preponderance, but no racial predilection. The exact incidence rate of EM is not known.

Pathogenesis

Current understanding suggests that EM is most likely a mucocutaneous immune reaction that occurs in the setting of an infection in certain "predisposed" individuals. HSV is clearly the most commonly associated infectious agent, with *Mycoplasma pneumoniae* (which also may be associated with SJS), *Histoplasma capsulatum*, and parapoxvirus (orf) observed less frequently (Table 20.2)[8]. Histoplasmosis-associated EM may occur more often in patients with concomitant erythema nodosum. To date, evidence for EBV as a precipitating factor is inconclusive[7]. Rarely, EM has been associated with drugs or systemic disease (see Table 20.2). Consequently, the possibility of SJS, generalized bullous fixed drug eruption, polymorphous exanthematous drug eruption, or urticaria multiforme should be strongly considered if the presumed diagnosis is drug-induced EM[7,9]. Of note, several physical agents such as trauma, cold, and UV and orthovoltage irradiation have been described as triggers for outbreaks of EM related to infectious agents, drugs, or systemic disease.

To date, there is no clearly defined genetic predisposition for the development of EM. Several small studies of HLA alleles have found different associations: HLA-DQw3 (specifically the DQB1*301 split), DRw53, and Aw33[10,11]. These HLA associations differ from those reported for SJS and TEN (see below).

Herpes simplex virus and Mycoplasma pneumoniae

In the majority of children and adults with EM, the disease is precipitated by HSV types 1 and 2[12,13]. Preceding herpes labialis is noted in ~50% of patients with EM[12,13]. Herpes labialis may precede the onset of the cutaneous lesions, occur simultaneously, or be evident after the target lesions of EM have appeared. Most commonly, herpes labialis precedes target lesions of EM by 3–14 days. It is presumed that most cases in children and young adults are due to HSV type 1, but documented cases of HSV type 2 in adolescents and young adults have been reported[12,13].

Most of our current knowledge regarding EM is related to the study of HSV-associated EM. Not only are HSV-encoded proteins found within affected epidermis[12,13], but HSV DNA can be detected within the early red papules or the outer zone of target lesions in 80% of individuals with EM[5]. The presence of fragments of HSV DNA (most often comprised of sequences that encode its DNA polymerase) within the cutaneous lesions, as well as the expression of virally encoded antigens

COMPARISON OF ERYTHEMA MULTIFORME (EM) MINOR, EM MAJOR, STEVENS–JOHNSON SYNDROME (SJS), SJS/TOXIC EPIDERMAL NECROLYSIS (TEN) OVERLAP, AND TEN						
	Type of skin lesions	**Distribution**	**Mucosal involvement**	**Systemic symptoms**	**Progression to TEN**	**Precipitating factors**
EM minor (Fig. 20.1 & 20.2)	• Typical targets • ± *Papular* atypical targets	Extremities (especially elbows, knees, wrists, hands), face	Absent or mild	Absent	No	• Herpes simplex virus • Other infectious agents
EM major (Fig. 20.3)	• Typical targets • ± *Papular* atypical targets • Occasionally bullous lesions	Extremities, face	Severe	Usually present • Fever • Arthralgias	No	• Herpes simplex virus • *Mycoplasma pneumoniae* • Other infectious agents • Rarely, drugs
SJS (Fig. 20.7 & 20.14)	• Dusky and/or dusky red *macules* with epidermal detachment and erosions • *Macular* atypical targets • Bullous lesions • <10% BSA detachment	Isolated lesions Confluence (+) Trunk, face	Severe	Usually present • Fever • Lymphadenopathy • Hepatitis • Cytopenias	Possible	• Drugs • Occasionally, *Mycoplasma pneumoniae** • Rarely, immunizations
SJS/TEN overlap (Fig. 20.11)	• Similar to SJS • 10%–30% BSA detachment	Isolated lesions Confluence (++) Trunk, face, neck	Severe	• Same as SJS	Likely	• Drugs
TEN (Fig. 20.8 & 20.9)	• Similar to SJS • >30% BSA detachment	Confluence (+++) Isolated lesions rare Trunk, face, neck, elsewhere	Severe, with involvement of respiratory and gastrointestinal mucosa	• Same as SJS plus nephritis		• Drugs
*Occasionally, also subcorneal pustules.						

Table 20.1 Comparison of erythema multiforme (EM) minor, EM major, Stevens–Johnson syndrome (SJS), SJS/toxic epidermal necrolysis (TEN) overlap, and TEN. BSA, body surface area; TEN, toxic epidermal necrolysis.

PRECIPITATING FACTORS IN ERYTHEMA MULTIFORME	
Infections (~90% of cases)	
Viral	• **Herpes simplex virus (HSV-1, HSV-2)** • Parapoxvirus (orf) • Vaccinia (smallpox vaccine) • Varicella zoster virus (chickenpox) • Adenovirus • Epstein–Barr virus • Cytomegalovirus • Hepatitis B & C viruses • Coxsackievirus • Parvovirus B19 • Human immunodeficiency virus
Bacterial	• ***Mycoplasma pneumoniae**** • *Chlamydophila* (formerly *Chlamydia*) *psittaci* (ornithosis) • *Salmonella* spp. • *Mycobacterium tuberculosis*
Fungal	• *Histoplasma capsulatum* • Dermatophytes
Drugs (unusual)	
Primarily	• Nonsteroidal anti-inflammatory drugs • Sulfonamides • Anticonvulsants, most commonly aromatic • Other antibiotics, e.g. aminopenicillins • Allopurinol
Exposures (unusual)	
	• Poison ivy • Vaccines (e.g. diphtheria & tetanus, hepatitis B virus)
Systemic disease (unusual to rare)	
	• Lupus erythematosus† (Rowell syndrome) • Inflammatory bowel disease • Behçet disease†
*Also precipitating factor for Stevens–Johnson syndrome and *Mycoplasma*-induced rash and mucositis (MIRM)/reactive infectious mucocutaneous eruption (RIME). †May be a pattern of cutaneous lesions in the disease rather than a precipitating factor.	

Table 20.2 Precipitating factors in erythema multiforme. This is a *non-exhaustive* list based primarily on case reports and small series of cases. The most common causes are in **bold**.

on keratinocytes, may be interpreted as evidence for replicating HSV within affected skin sites[12–14]. However, replication must be at a low level, because usually HSV cannot be cultured from EM lesions.

The inflammation within cutaneous lesions is believed to be a part of an HSV-specific host response[13]. Individuals with HSV-associated EM have normal immunity to HSV, but may have difficulty clearing the virus from infected cells; within sites of cutaneous lesions, HSV DNA may persist for 3 months after a lesion has healed[14]. Development of cutaneous lesions is initiated by the expression of HSV DNA sequences within the skin, followed by the recruitment of virus-specific T helper type 1 (Th1) cells that produce interferon-γ in response to viral antigens within the skin[15]. An "autoimmune" response is then thought to result from the recruitment of T cells that respond to autoantigens released by lysed/apoptotic viral antigen-containing cells. More recently it was shown that the HSV DNA fragments described above are transported (by peripheral blood $CD34^+$ Langerhans cell precursors) to the sites where EM skin lesions will develop prior to each eruption[16].

While HSV is the predominant cause of EM, there are other associated infectious agents. In particular, a severe acro-mucosal presentation with mucositis, conjunctivitis, and targetoid or bullous skin eruptions can be seen in patients with *M. pneumoniae* infections, primarily community-acquired pneumonia (see below). This variant occurs most commonly in young boys and adolescents. *M. pneumoniae* has been cultured from the bullae in patients with EM-like skin reactions, suggesting an etiologic role[17]. However, this association could also be explained by autoimmune molecular mimicry, as in *M. pneumoniae*-related Guillain–Barré syndrome[18].

Clinical Features

Due to a certain degree of clinical similarity, EM minor, EM major, SJS and TEN have, until recently, all been considered to be part of a single disease spectrum. However, as discussed previously, there is now strong evidence to support the concept that EM is a disease distinct from SJS and TEN at several levels – clinical, prognostic, and etiologic. Clinical criteria allow the distinction of both forms of EM from SJS/TEN in the vast majority of patients[2,3]. These clinical criteria are as follows: (1) the type of elementary skin lesion; (2) the distribution of skin lesions (topography); (3) the presence or absence of overt mucosal lesions; and (4) the presence or absence of systemic symptoms (see Table 20.1).

Elementary skin lesions (Fig. 20.1)

The characteristic elementary skin lesion of EM is the *typical target lesion*. The latter measures <3 cm in diameter, has a regular round shape and a well-defined border, and consists of at least three distinct zones, e.g. two concentric rings of color change surrounding a central circular zone that has evidence of damage to the epidermis in the form of bulla formation or crust[2]. Frequently, this central circular zone has a dusky appearance and over time, the lesion may resemble a "bull's eye".

While early target lesions often have a central dusky zone and a red outer zone ("iris" lesion), they can evolve to three zones of color change. Each concentric ring within the target lesion most likely represents one of a sequence of events of the same ongoing pathologic process. This may explain why some patients have only a limited number of fully developed, typical targets amidst a number of target lesions that are not yet typical or fully evolved, while in others all the lesions are at the same stage of development, thus creating a monomorphic clinical appearance. Given the possibility that only a few typical target lesions may be present, a complete skin examination is essential.

In EM, elevated *atypical papular target lesions* can either accompany typical target lesions or constitute the primary cutaneous lesion. These particular lesions are defined as round, edematous, palpable, and reminiscent of EM, but with only two zones and/or a poorly defined border. They must be distinguished from the flat (macular) atypical targets that are seen in SJS or TEN, but not EM. These macular lesions are defined as round lesions that are also reminiscent of EM, but with only two zones and/or a poorly defined border, as well as being non-palpable (with the exception of a potential central vesicle or bulla).

Distribution of skin lesions (topography)

Although there is considerable variation from individual to individual, numerous lesions are usually present[7]. In general, lesions of EM develop preferentially on the extremities and the *face*; target lesions favor the *upper extremities*, as does the entire eruption of EM[7,14,19]. The dorsal aspects of the hands and the forearms are the most frequently involved sites, but the palms, neck, face, and trunk are common locations as well (Fig. 20.2)[19]. Involvement of the legs is seen less frequently. EM lesions may also appear within areas of sunburn[7]. In addition, lesions tend to be grouped, especially on the elbows or knees.[7]

The Koebner phenomenon may be observed, with target lesions appearing within areas of cutaneous injury such as scratches[7] (see Fig. 20.1F) or as erythema and swelling of the proximal nail folds at sites of chronic self-trauma. The injury must precede the onset of the EM eruption because the Koebner phenomenon does not occur once the EM lesions have appeared.

Mucosal lesions

Severe mucosal involvement is characteristic of EM major. Mucosal involvement is usually absent in EM minor, and, when present, lesions are few in number and mildly symptomatic[3,7,12,13,19]. The primary mucosal lesions of EM are vesiculobullous and rapidly develop into painful erosions that involve the buccal mucosa and lips (Fig. 20.3), and less commonly the ocular and genital mucosae. On the lips, the erosions rapidly become covered by painful crusts. Erosions of the anogenital mucosa are often large and polycyclic with a moist base.

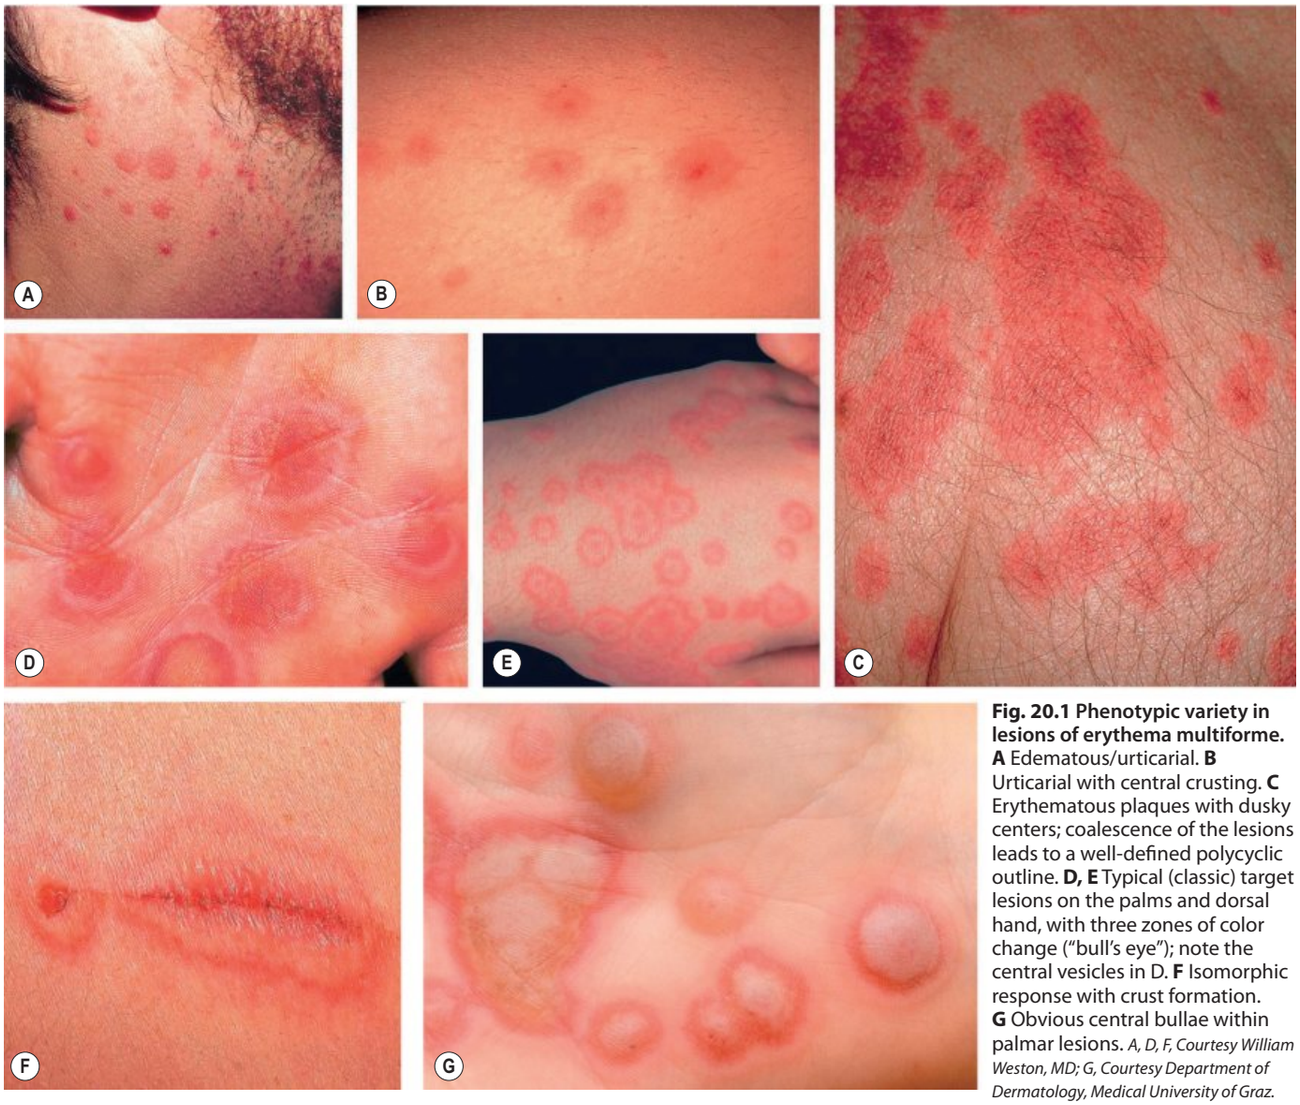

Fig. 20.1 Phenotypic variety in lesions of erythema multiforme. **A** Edematous/urticarial. **B** Urticarial with central crusting. **C** Erythematous plaques with dusky centers; coalescence of the lesions leads to a well-defined polycyclic outline. **D, E** Typical (classic) target lesions on the palms and dorsal hand, with three zones of color change ("bull's eye"); note the central vesicles in D. **F** Isomorphic response with crust formation. **G** Obvious central bullae within palmar lesions. *A, D, F, Courtesy William Weston, MD; G, Courtesy Department of Dermatology, Medical University of Graz.*

Fig. 20.2 Multiple lesions of erythema multiforme (EM) on the trunk. The dusky or crusted centers within the papules help to differentiate EM from a morbilliform drug eruption.

Fig. 20.3 Mucosal involvement in erythema multiforme major. A Typical target lesions are seen as well as serous crusting of the vermilion lips and eyelid margin. At the margin of the serous crusting of the lip, there are two zones of color with a polycyclic outline. **B** Erosions and hemorrhagic crusting of the lips in a child with the acro-mucosal variant associated with *Mycoplasma pneumoniae* infection, also referred to as MIRM (*Mycoplasma pneumoniae*-induced rash and mucositis) or RIME (reactive infectious mucocutaneous eruption). *B, Courtesy Julie V. Schaffer, MD.*

Systemic symptoms

Systemic symptoms are almost always present in EM major and absent or limited in EM minor. In EM major, the systemic symptoms that usually precede and accompany the skin lesions are fever and asthenia of varying degrees. Arthralgias with joint swelling have occasionally been described, as has pulmonary involvement resembling atypical pneumonia. Whether the latter is due to a pulmonary manifestation of EM versus an associated primary infection such as *Mycoplasma* pneumonia is unclear. Renal, hepatic, and hematologic abnormalities in the context of EM major are rare[20]. By integrating these four clinical criteria, a distinction can be made between EM minor, EM major, and SJS (see Table 20.1).

Natural history

In EM, almost all of the lesions appear within 24 hours and full development has occurred by 72 hours.[7,20] Pruritic or burning sensations within the lesions may be described. Individual lesions remain fixed at the same site for 7 days or longer[4,5,21].

For most individuals with EM, the episode lasts 2 weeks and heals without sequelae[7,20]; one possible rare exception is ocular damage in the setting of EM major, which may occur if adequate eye care is not promptly instituted. Occasionally, postinflammatory hyper- or hypopigmentation is seen. Patients with EM usually have an uncomplicated clinical course, although recurrences, in the case of HSV-associated EM, are quite common[7,20]. One recurrence each spring, as described by von Hebra, may occur[4]. Most individuals with recurrent HSV-associated EM have one or two episodes a year, with an exception being patients receiving immunosuppressive drugs[20,22,23]. The use of immunosuppressive agents such as oral corticosteroids may be associated with more frequent and longer episodes of EM[7,20]. These individuals may have five or six episodes per year or even almost continuous overlapping disease in which one attack has not completely resolved before another occurs. The incidence of secondary bacterial infections also increases in the setting of prolonged corticosteroid use[7,20]. Rarely, patients experience persistent EM with a months-long protracted course.

Pathology

EM is a clinicopathologic, not a purely histologic, diagnosis. Histologic findings are characteristic, but not specific, and are most useful for excluding entities in the differential diagnosis such as lupus erythematosus (LE) and vasculitis[7,20,22]. In EM, the keratinocyte is the target of the inflammatory insult, with apoptosis of individual or clusters of keratinocytes being the earliest pathologic finding (Fig. 20.4)[22]. As the process evolves, mild spongiosis and focal vacuolar degeneration of basal keratinocytes are observed. Superficial dermal edema and a perivascular infiltrate of lymphocytes with exocytosis into the epidermis are also seen.

Immunofluorescence findings are nonspecific[7]. Granular deposits of IgM and C3 around superficial blood vessels and focally at the dermal–epidermal junction have been described. Specific HSV antigens have been detected within keratinocytes by immunofluorescence, and HSV genomic DNA has been detected by PCR amplification of skin biopsy specimens[12,14].

Compared to SJS, the dermal inflammation component is more prominent in EM and the epidermal "necrolysis" component is more discrete[24]. Large areas of full-thickness epidermal necrosis are not seen in EM.

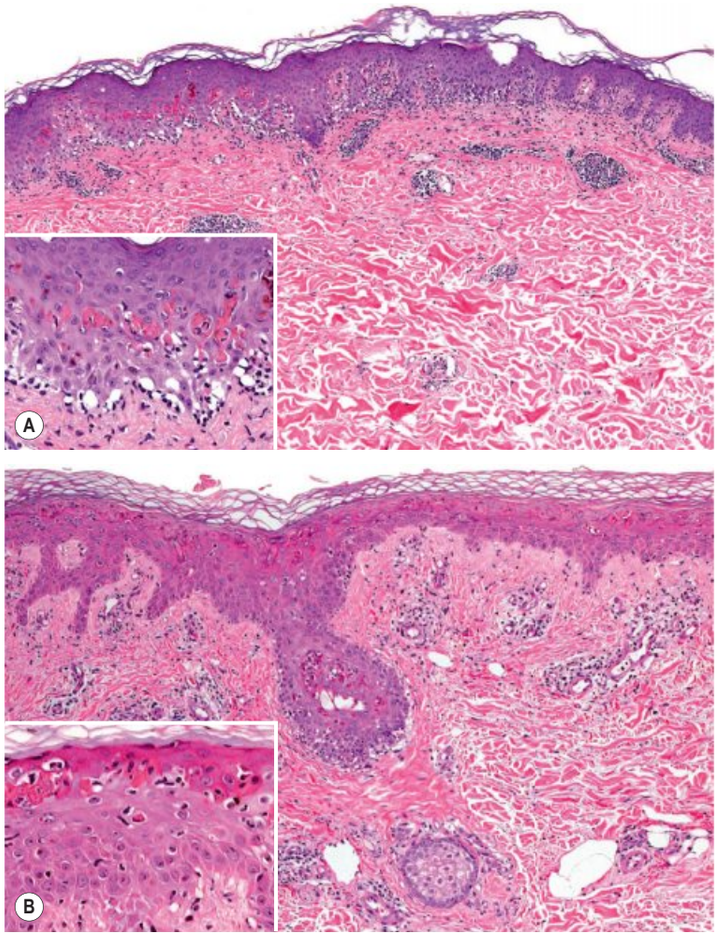

Fig. 20.4 Erythema multiforme – histopathologic features. A Early lesion – focal sites of apoptosis of keratinocytes with an interface dermatitis and vacuolar degeneration of the basal layer (inset). A perivascular lymphocytic infiltrate is also present. **B** Late lesion – more confluent necrosis of keratinocytes within the upper layers of the stratum spinosum (inset). The hair follicle still has evidence of an interface dermatitis. *Courtesy Lorenzo Cerroni, MD.*

Fig. 20.5 Acute annular urticaria (urticaria multiforme) in an infant misdiagnosed as erythema multiforme. These migratory, annular plaques are markedly edematous. Some of the lesions have an erythematous or dusky center while others have central clearing with two shades of peripheral rings. There are no crusts or blisters. The term "urticaria multiforme" has been used to describe these skin findings, which are often preceded by a viral or bacterial infection and accompanied by angioedema of the face, hands, and/or feet. *Courtesy Julie V. Schaffer, MD.*

COMPARISON OF URTICARIA AND ERYTHEMA MULTIFORME	
Urticaria	**Erythema multiforme**
Central zone is normal skin or transient duskiness*	Central zone is damaged skin (dusky, bullous, or crusted)
Individual lesions are transient, lasting <24 hours†	Individual lesions "fixed" for at least 7 days
New lesions appear daily	All lesions appear within first 72 hours
May be associated with swelling of face, hands, or feet (angioedema)	No edema

*May be referred to as urticaria multiforme.
†Can be documented by circling individual lesions with ink then observing over time.

Table 20.3 Comparison of urticaria and erythema multiforme.

Differential Diagnosis

Non-dermatologists often overdiagnose EM by labeling individuals with giant annular urticaria as having EM (Fig. 20.5)[9]. This is further highlighted by the term "urticaria multiforme", which represents a variant of urticaria that is often misdiagnosed as erythema multiforme or a serum sickness-like reaction in children[25]. This emphasizes the need to apply clinical criteria to distinguish EM from urticaria (Table 20.3)[7]. These include the presence of symmetrical fixed red papules or atypical papular target lesions, at least some of which evolve into typical target lesions. Particular attention should be given to the duration of individual lesions at a specific site and to epidermal damage in the center of the target lesions. EM papules are "fixed" at the same skin site for at least 7 days, whereas urticarial lesions last <24 hours at a particular site. The center of EM lesions demonstrates epithelial damage in the form of crusting or vesicles, whereas the center of giant urticaria is characterized by normal skin or erythema without epidermal damage. Administration of subcutaneous epinephrine (adrenaline) will clear urticaria within 20 minutes, but will not change EM lesions. Edema of the face, hands, and feet can be associated with urticaria, but is usually not observed in EM[7,9,20].

A number of other conditions can sometimes have "target-like" lesions and mimic EM, including fixed drug eruptions, Kawasaki disease, erythema annulare centrifugum, Sweet syndrome, and several forms of vasculitis[26]. A skin biopsy to exclude these entities is helpful. However, there is significant clinical and histologic overlap between EM and generalized bullous fixed drug eruption. The total number of lesions is helpful, especially when there are hundreds, but it is also important to try to determine the number of lesions present in the initial episode (i.e. fewer lesions in fixed drug eruption).

Recurrent EM during childhood may mimic polymorphous light eruption or juvenile spring eruption in that it may be sun-induced and develop with the first significant sun exposure in the spring[27]. In patients with systemic LE, occasional individual lesions can mimic true target lesions of EM, but other lesions characteristic of systemic LE are usually present[7]. That said, patients with Rowell syndrome may only have EM-like lesions as can children with Kawasaki disease. Early lesions of vasculitis, particularly urticarial vasculitis, may mimic target lesions of EM. Histologic examination assists in distinction; additional clues include an elevated ESR, autoantibodies, and low serum complement levels[7].

Whether *Mycoplasma pneumoniae*-induced rash and mucositis (MIRM) is a distinct disorder or within the spectrum of EM major or SJS remains a matter of debate (Table 20.4). More recently, as additional bacterial and viral triggers were identified, the term reactive infectious mucocutaneous eruption (RIME) was proposed[28].

Treatment

Therapeutic options include topical and systemic treatment of the acute eruption as well as prophylactic treatment of recurrent disease. Topical therapy includes topical antiseptics for eroded skin lesions and antiseptic/antihistamine rinses and local anesthetic solutions for oral lesions (see Ch. 72). Administration of topical ophthalmic preparations should be done in conjunction with an ophthalmologist.

There are no double-blind or open trials of systemic therapies for the acute episode of EM[7,20]. When a precipitating factor can be identified (e.g. HSV, *M. pneumoniae*), specific therapy should be instituted; in the case of HSV, this represents chronic suppressive antiviral therapy

KEY FEATURES OF *MYCOPLASMA PNEUMONIAE*-INDUCED RASH AND MUCOSITIS (MIRM)/ REACTIVE INFECTIOUS MUCOCUTANEOUS ERUPTION (RIME)

Children and adolescents >> adults
Prodromal symptoms (cough, malaise, fever) precede the eruptions by approximately one week
Predominance of mucosal involvement • Severe mucositis • Typically ≥2 mucosal sites (e.g. oral, ocular, anogenital, nasal) Absent or sparse polymorphic cutaneous involvement (<10% body surface area) • Typically vesiculobullous or atypical target lesions • Occasionally subcorneal pustules
For MIRM, clinical and/or laboratory evidence of *Mycoplasma pneumoniae* infection • PCR of pharyngeal swab • IgM and IgG serologies* For RIME, clinical and/or laboratory evidence of triggering infection, most often respiratory (see legend)
Often benign clinical course with excellent prognosis (<5% require intensive care but up to 10% may develop ocular sequelae) Supportive care and pain management similar to SJS with systemic antimicrobials if infectious trigger Systemic corticosteroids (e.g. 5–7 days of prednisone 1 mg/kg/day) – optional if severe†
*Serial measurements may be required to detect elevated IgM titers and are required to detect four-fold increase in IgG titers; enzyme-linked immunoabsorbent spot (ELISpot) assay of *Mycoplasma*-specific IgM antibody-secreting cells (ASCs) can improve diagnostic specificity and sensitivity. †Also case reports of etanercept, IVIg, and cyclosporine.

Table 20.4 Key features of *Mycoplasma pneumoniae*-induced rash and mucositis (MIRM)/reactive infectious mucocutaneous eruption (RIME). The terms MIRM then RIME were proposed to distinguish these infection-related eruptions from EM major and SJS/TEN. Prior to this distinction, patients were usually diagnosed as having incomplete, atypical or acro-mucosal SJS, *Mycoplasma*-associated EM major, *Mycoplasma*-associated SJS, Fuchs syndrome, or *Mycoplasma pneumoniae*-associated mucositis. Because other bacterial (e.g. *Chlamydophila pneumoniae*) and viral infections, especially respiratory (e.g. adenovirus, enteroviruses, human metapneumovirus, influenza B, parainfluenza virus type 2, rhinovirus, SARS-CoV-2), have been associated with similar mucocutaneous eruptions, this led to the term RIME. *Photographs: Courtesy Katherine G. Ligtenberg, MD, Jean L. Bolognia, MD, and Julie V. Schaffer, MD.*

(see below). As a rule, antiviral therapy has minimal impact if given after the appearance of the acute episode of EM. In most cases of EM, especially EM minor, symptomatic treatment will suffice. Oral antihistamines for 3 or 4 days may reduce the stinging and burning of the skin. In severe EM with functional impairment, early therapy with systemic corticosteroids (e.g. prednisone [0.5–1 mg/kg/day for 3–5 days] or pulse methylprednisolone [20 mg/kg/day for 3 days]) should be considered, despite the absence of controlled studies and the long-existing controversy regarding increasing the risk of infectious complications[29].

In individuals with HSV-associated EM with frequent recurrences, prophylaxis for at least 6 months with oral valacyclovir (500–1000 mg/day, with dose depending upon frequency of recurrences), famciclovir (250 mg twice daily), or acyclovir (10 mg/kg/day in divided doses) should be considered. A double-blind, placebo-controlled study in young adults with EM demonstrated the efficacy of acyclovir prophylaxis[23]. In addition to reducing the frequency of recurrences, occasionally the beneficial effect can continue even after the antiviral drug is discontinued. In non-responsive patients, the dose of the medication may be doubled, or a substitution made of the antiviral drug. However, as stated previously, treatment with acyclovir or valacyclovir after symptoms appear is ineffective[20]. Obviously, in those patients in whom EM is precipitated by factors other than reactivation of HSV, antivirals will be of no benefit.

In patients with recurrent EM that is resistant to prophylactic antiviral therapy, especially severe cases, several therapeutic approaches have been described; however, none have been validated by controlled trials and none have been consistently effective or free of side effects. Among these are: azathioprine (100 mg/day for several months), prednisone (0.5 mg/kg/day for several months), thalidomide, dapsone, cyclosporine, mycophenolate mofetil, and PUVA[20,30–33]. JAK inhibitors may be considered for persistent EM.

STEVENS–JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

Synonym: ■ Toxic epidermal necrolysis – Lyell syndrome

Key features

- Prodrome of upper respiratory tract symptoms, fever, and painful skin
- Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are two rare, potentially fatal, adverse cutaneous drug reactions of differing severity, characterized by mucocutaneous tenderness and erythema as well as extensive exfoliation
- SJS is characterized by <10% body surface area of epidermal detachment, SJS/TEN overlap by 10%–30%, and TEN by >30%
- The medications most frequently incriminated are allopurinol, nonsteroidal anti-inflammatory drugs, antibiotics, and aromatic anticonvulsants; TEN and SJS usually occur 7–21 days after initiation of the responsible drug
- The average mortality rate is 5% for SJS and 15%–25% for TEN; the mortality rates are often higher in the elderly and those with a very large surface area of epidermal detachment
- Exfoliation is due to extensive death of keratinocytes via apoptosis; the latter is mediated via the cytotoxic secretory protein granulysin and interaction of the death receptor–ligand pair Fas–FasL
- Optimal medical management of SJS and TEN requires early diagnosis, immediate discontinuation of the causative drug(s), and rapid initiation of supportive care
- Additional therapies include TNF inhibitors (e.g. etanercept), IVIg, cyclosporine, and pulse corticosteroids, but to date there is no consensus as to the most effective treatment

Introduction

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are rare, acute, and life-threatening mucocutaneous diseases that are nearly always drug-related. They are a consequence of extensive keratinocyte cell death that results in the separation of significant areas of skin at the dermal–epidermal junction, producing the appearance of scalded skin. This extensive cell death also results in mucous membrane detachment, and it contributes to the characteristic symptoms of SJS and TEN, which include: high fever, moderate to severe skin pain, anxiety, and asthenia. The disease runs an unpredictable course. An initially benign-appearing dermatosis can progress rapidly, and once overt skin detachment has occurred, it is difficult to determine when it will end. Several studies have addressed the clinical signs of SJS and TEN, and there is now a framework of diagnostic criteria. Mortality risk can be calculated by applying a severity-of-illness score specifically developed for predicting the clinical outcome of TEN (SCORTEN; see below).

As prognosis is correlated with the speed at which the culprit drug is identified and withdrawn, it is crucial to establish the correct clinical diagnosis rapidly, so the causal drug(s) can be discontinued and appropriate medical treatment begun as soon as possible. Although TEN, and especially SJS, were historically considered to be part of a spectrum of diseases that included EM major (all of which have clinically similar mucosal lesions), these disorders should now be distinguished, as their cause, management, and/or prognosis are usually distinct (see Table 20.1). SJS and TEN should also be distinguished from dermatoses such as staphylococcal scalded skin syndrome, generalized bullous fixed drug eruption, drug-induced linear IgA bullous dermatosis, toxic erythema of chemotherapy, and acute generalized exanthematous pustulosis, as their management and prognosis can vary significantly.

High-quality supportive treatment, ideally in intensive care units with modern equipment and trained nursing staff, is the current standard of care and can improve outcome. To date, one randomized prospective trial has been conducted with 96 patients in which etanercept was compared to prednisolone (see below). The lack of additional large prospective, controlled clinical studies can be explained in part by the low incidence of SJS and TEN as well as their life-threatening potential which make randomized clinical trials difficult to perform.

History

In 1922, two US physicians, Stevens and Johnson, described an acute mucocutaneous syndrome in two young boys. The condition was characterized by severe purulent conjunctivitis, severe stomatitis with extensive mucosal necrosis, and "EM-like" cutaneous lesions. It became known as Stevens–Johnson syndrome (SJS) and was recognized as a severe mucocutaneous disease with a prolonged course and occasional fatalities[2,3]. SJS was later designated as EM major by Bernard Thomas in 1950.[6] However, recent clinical investigations have made it clear that the term "EM major" should not be used to describe SJS as they are distinct disorders (see Table 20.1)[2,3].

In 1956, Alan Lyell described four patients with an eruption "resembling scalding of the skin objectively and subjectively", which he called "toxic epidermal necrolysis". "Toxic" referred to toxemia – circulation of a toxin – which was thought to be responsible for the constitutional symptoms and epidermal necrosis. Lyell coined the term "necrolysis" by combining the key clinical feature "epidermolysis" with the characteristic histopathologic feature "necrosis". He also described an attack on the mucous membranes as part of the syndrome, and noted that there was very little inflammation in the dermis, a feature that was later referred to as "dermal silence"[34]. This feature contrasted with the obvious inflammatory infiltrate of other blistering disorders such as EM, dermatitis herpetiformis, and bullous pemphigoid. TEN was considered at the time to be a cutaneous reaction pattern to multiple stimuli, including drugs (e.g. sulfonamides) and microbes (e.g. *Staphylococcus*)[35].

The description of a subgranular epidermal split in neonatal mice following exposure to phage group II *S. aureus*, the subsequent discovery of a new staphylococcal exotoxin called epidermolytic toxin, and the absence of overt keratinocyte necrosis led to the distinction between TEN and what would come to be known as "staphylococcal scalded skin syndrome" (SSSS; see Ch. 74)[36]. It should be noted here that one of Lyell's original patients actually represented SSSS, and although by that time he had already noted the histologic differences between TEN and SSSS, they were attributed to different degrees of injury.

As more patients with TEN were reported in the years following Lyell's treatise, it became clear that certain drugs such as sulfonamides, pyrazolones (e.g. phenylbutazone), barbiturates, and aromatic anticonvulsants were principally associated with TEN. At the same time, drugs were increasingly being incriminated as a cause of EM associated with severe stomatitis. Hence, EM epidermal type (as defined by Orfanos et al.[37] in the mid 1970s), SJS and TEN were, at the time, considered to be part of a continuous spectrum of cutaneous reactions. It was clear, however, that HSV was the major cause of EM, and that this virus was not associated with cases of TEN. In the late 1990s, the group of Jean-Claude Roujeau clarified this issue by providing clinical evidence that EM and SJS were clinically distinct disorders with different causes and prognoses[3]. Increasingly, SJS and TEN are considered to be two ends of a spectrum of severe epidermolytic adverse cutaneous drug reactions, differing by the extent of skin detachment (see Table 20.1).

Epidemiology

SJS and TEN are rare diseases that affect women more often than men. Certain patient groups have an increased risk of developing SJS/TEN, including those who metabolize drugs at a decreased rate (slow acetylator genotypes), are immunocompromised (e.g. HIV infection), are undergoing radiotherapy while concomitantly receiving anticonvulsants, or have specific human leukocyte antigen (HLA) alleles (Table 20.5; see Table 21.3). Examples of the latter are HLA-B*15:02 in Asians and East Indians who are exposed to carbamazepine and HLA-B*58:01 in Han Chinese exposed to allopurinol. Consequently, the FDA recently recommended genotyping of all Asians for the allele HLA-B*15:02 prior to the administration of carbamazepine. In Europe, ~5% of the patients with SJS/TEN are infected with HIV[43].

STEVENS–JOHNSON SYNDROME (SJS) AND TOXIC EPIDERMAL NECROLYSIS (TEN): EPIDEMIOLOGY AND RISK FACTORS	
Annual incidence	1.2–6 per million (SJS)
	0.4–1.2 per million (TEN)
Ratio women : men	1.5 : 1
Risk factors	Slow acetylator genotypes
	Immunosuppression (e.g. HIV infection, lymphoma)
	Concomitant administration of radiotherapy and aromatic anticonvulsants (most commonly, those with brain tumors)
	HLA-B*15:02 – Asians (in particular Han Chinese, Thai, Malaysian populations)† and East Indians exposed to carbamazepine
	HLA-B*15:02 – Taiwanese/lamotrigine
	HLA-B*15:02 – Han Chinese/phenytoin
	HLA-A*31:01 – Europeans/carbamazepine
	HLA-B*58:01 – Han Chinese/allopurinol

†The background prevalence of HLA-B*15:02 varies from 4% to 15% in affected populations but is extremely rare in Northern Europeans (<0.01%).

Table 20.5 Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN): epidemiology and risk factors. Table 21.3 contains additional HLA associations. *Data from refs 38–42.*

Death rates reported in large case series in which only supportive therapy was used are quite variable, and it is known that these rates are heavily dependent on factors such as patient age and extent of epidermal detachment. In the past, mortality rates were reported to be ~10% for SJS, 30% for SJS/TEN, and 50% for TEN[43,44], but these rates have decreased over the past few decades. A USA-based study that analyzed nationwide inpatient records from 2009 to 2012 reported a mean mortality of 5%, 19%, and 15% for SJS, SJS/TEN, and TEN, respectively[45]. The mortality risk is lower in children who have TEN.

Use of medications is reported in over 95% of patients with TEN. A strong association between drug ingestion and development of the cutaneous eruption is observed in 80% of cases. Other rare causes include infections and immunizations. The literature reflects a less clear relationship between drugs and SJS, as only 50% of reported SJS cases are attributed to drug exposure. This is certainly an underestimation, however, and most likely is due, in part, to the confusion that previously existed regarding the diagnostic distinction between SJS and EM, especially EM major.

More than 100 drugs have been identified to date as being associated with SJS/TEN. The most frequently implicated drugs are listed in Table 20.6 and consist primarily of allopurinol, antibiotics, nonsteroidal anti-inflammatory drugs, and aromatic anticonvulsants. Among the antibiotics, sulfonamides are the most strongly associated with SJS/TEN; other antimicrobials include aminopenicillins, quinolones, cephalosporins, and tetracyclines as well as antiretrovirals. In general, the risk of developing SJS/TEN is reported to be highest during the initial week(s) of therapy. For the aromatic anticonvulsants, the risk is greatest during the first two months of treatment[46]. Furthermore, drugs with long half-lives are more likely to cause drug reactions and a fatal outcome than those with short half-lives, even if they are chemically related[47].

Pathogenesis

To date, the precise sequence of molecular and cellular events that lead to the development of SJS/TEN is only partially understood. The proposed pathogenesis must take into account the rarity of the reaction and the involvement of specific types of drugs.

Compelling evidence suggests that SJS/TEN is associated with an impaired capacity to detoxify reactive intermediate drug metabolites. It is thought to be initiated by an immune response to an antigenic complex formed by the reaction of such metabolites with certain host

MEDICATIONS MOST FREQUENTLY ASSOCIATED WITH STEVENS–JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS
• Allopurinol
• Aminopenicillins
• Amithiozone (thioacetazone)*,†
• Antiretroviral drugs, especially NNRTIs (e.g. nevirapine, efavirenz, etravirine)
• Barbiturates
• Carbamazepine
• Cephalosporins
• Chlormezanone*,‡
• Immune checkpoint inhibitors (e.g. ipilimumab, nivolumab)¶
• Phenytoin anticonvulsants
• Lamotrigine (risk may be increased when co-administered with valproic acid)
• Phenylbutazone*,§
• Piroxicam and other NSAIDs (e.g. diclofenac)
• Quinolones
• Sulfonamide antibiotics, including sulfamethoxazole‖, sulfadiazine*,†
• Sulfasalazine
*Not available in the US.
†Antibacterial.
‡Sedative/hypnotic.
¶SJS/TEN-like eruptions may also occur with a delayed onset and favorable response to systemic corticosteroids.
§Nonsteroidal anti-inflammatory drug.
‖Usually in combination with trimethoprim.

Table 20.6 Medications most frequently associated with Stevens–Johnson syndrome and toxic epidermal necrolysis. NNRTIs, non-nucleoside reverse transcriptase inhibitors. For a complete updated list of drugs associated with SJS and TEN, refer to: Shear N. *Litt´s Drug Eruption and Reaction Manual*, 28th edn. London: CRC Press, 2022.

tissues[44,48–50]. Currently, three different concepts exist regarding how the neoantigenic drug–tissue complex is formed: (1) covalent binding of the drug to a cellular peptide (hapten/pro-hapten concept); (2) non-covalent, direct interaction of the drug with a specific MHC class I molecule or T cell receptor (p-i concept); and (3) presentation of an altered-self repertoire by direct drug–MHC I molecule interaction (altered peptide concept). Whereas the well-known hapten model is less likely to be HLA-restricted, the other two concepts favor specific HLA phenotypes. According to these models, drugs directly bind to specific HLA molecules and/or T cell receptors without being processed by an antigen-presenting cell. In the p-i concept, the mere pharmacologic interaction of certain drugs with immune receptors is sufficient to elicit a drug hypersensitivity reaction[51]. In contrast, more recent reports have shown that the drugs abacavir and carbamazepine modify the HLA-peptide repertoire resulting in enhanced presentation of self-peptides and autoimmune reactivity (altered peptide model)[52,53]. Of note, because of the increased risk of DRESS, patients are often screened for HLA-B*57:01 prior to receiving abacavir (see Table 21.3).

In line with the concept of HLA-restricted drug presentation are reports of specific drug-related HLA alleles as major susceptibility genes for the development of SJS and TEN (see Table 20.5)[38,39,54]. Notably, in Taiwan, HLA-B*15:02 screening prior to administration of carbamazepine decreased the risk of drug-induced SJS/TEN[55]. In addition to the alleles listed in Table 20.5, the HLA-DQB1*06:01 allele has been reported in a significantly disproportionate number of White patients with SJS *and* ocular complications, suggesting that this allele may confer an increased risk for this specific clinical phenotype[56].

Cytotoxic T cells expressing the skin-homing receptor, cutaneous lymphocyte-associated antigen (CLA), are seen early in the development of cutaneous lesions[57]. These are likely to be drug-specific cytotoxic T cells[58]. Important cytokines such as interleukin (IL)-6, TNF, interferon-γ, IL-18, and Fas ligand (FasL) are also present in the lesional epidermis and/or blister fluid of patients with TEN, and their actions could explain some of the constitutional symptoms of TEN as well as the frequently observed discrepancy between the extent of epidermal damage and the paucity of the inflammatory infiltrate[59,60]. Lastly, the typical interval between the onset of drug therapy and SJS/TEN is between 1 and 3 weeks, suggesting a period of sensitization and providing further support for the role of the immune system in disease pathogenesis. This period ("memory") is considerably shortened in patients who are unfortunately re-exposed to a drug that previously resulted in SJS or TEN.

The tissue damage described by pathologists as epidermal necrolysis is a reflection of massive keratinocyte cell death via apoptosis[61]. The apoptosis of individual keratinocytes is a hallmark of the early stages of SJS and TEN, and it is the first clear morphologic sign of specific tissue damage. The more classic histologic image of extensive epidermal "necrolysis" is, in fact, the aftermath of keratinocyte apoptosis. Indeed, the apoptotic state of cells is transient in nature, and it is followed by necrosis if the apoptotic cells are not rapidly phagocytosed. In SJS and TEN, within hours keratinocyte apoptosis becomes very abundant in lesional skin, thus rapidly overwhelming the phagocytic capacity of the affected skin. Over a period of hours to days, these apoptotic keratinocytes become necrotic and lose their cohesion to adjacent keratinocytes as well as the basement membrane. The entire epidermis then loses viability, creating the familiar histologic image of full-thickness epidermal necrolysis.

Fas ligand (FasL, CD95L), a member of the TNF family of cytokines, has the ability to induce apoptosis by binding to its specific cell surface receptor, the Fas (CD95, Apo-1) death receptor[62]. Such death receptors function as cell surface sensors that detect the presence of specific extracellular death signals and rapidly trigger cellular destruction by apoptosis (Fig. 20.6, pathway A). Notably, keratinocyte apoptosis within lesional skin of patients with TEN is associated with highly increased expression of keratinocyte FasL, together with conserved levels of keratinocyte Fas expression[59,62–64]. Overlaying cryostat sections of lesional skin with Fas-sensitive cells as targets has demonstrated that keratinocyte FasL is cytolytically active in TEN; cytolysis can be prevented by monoclonal antibodies that block the interaction of Fas and FasL.

Subsequently, the cytotoxic molecule granulysin was shown to play a role in the keratinocyte apoptosis observed in SJS/TEN (see Fig. 20.6D)[65]. High concentrations of granulysin, a secreted, cationic, cytolytic protein produced by cytotoxic T lymphocytes (CTLs), natural killer (NK) cells, and natural killer T (NKT) cells, were found in blister fluid from patients with SJS/TEN. Moreover, injection of recombinant granulysin into mouse skin induced epidermal necrolysis and an inflammatory cell infiltrate. More recently, it was demonstrated that necroptosis of keratinocytes (a form of programmed necrosis) can be triggered by the interaction of annexin A1 and formyl peptide receptor 1 (FPR1) and this may contribute to the pathogenesis of SJS/TEN (see Fig. 20.6C).[66] In SJS/TEN patients, data suggest that exposure to the causative drug induces annexin A1 secretion from monocytes. Annexin A1 in turn binds to FPR1 and induces FPR1 expression in keratinocytes, resulting in cell death via a necroptosis pathway. Lastly, the perforin/granzyme pathway can also induce keratinocyte apoptosis (see Fig. 20.6B). Following the binding of CTLs and NK cells to their target cells, they secrete granules containing perforin and granzyme B. Perforin allows granzyme B to transverse the cell membrane and activate the intrinsic apoptotic pathway[67]. Of interest, circulating levels of IL-15 appear to be associated with the severity and mortality rate of SJS/TEN[68].

In summary, the current model for the pathogenesis of SJS/TEN is as follows: upon exposure to certain types of drugs (see Table 20.6), an individual with particular predisposing factors (see Table 20.5) mounts a specific immune reaction to the drug or one of its metabolites. As a result of an interplay of cell types and cytokines that remains to be totally defined, there is a strong expression of the cytolytic molecule FasL on keratinocytes as well as secretion of granulysin from CTLs, NK cells and NKT cells and annexin A1 from monocytes. This leads to FasL-, granzyme B-, and granulysin-mediated apoptosis and/or annexin-dependent necroptosis of keratinocytes and subsequent epidermal necrosis and detachment (see Fig. 20.6).

Clinical Features

Initial symptoms of both TEN and SJS can be fever, stinging eyes, and pain upon swallowing, any of which can precede cutaneous manifestations by 1 to 3 days. Skin lesions tend to appear first on the trunk, spreading to the neck, face, and proximal upper extremities. The distal portions of the arms as well as the legs are relatively spared, but the palms and soles can be an early site of involvement. Erythema and erosions of the buccal, ocular, and genital mucosae are present in >90% of patients (Fig. 20.7). The epithelium of the respiratory tract is involved in 25% of patients with TEN, and gastrointestinal lesions

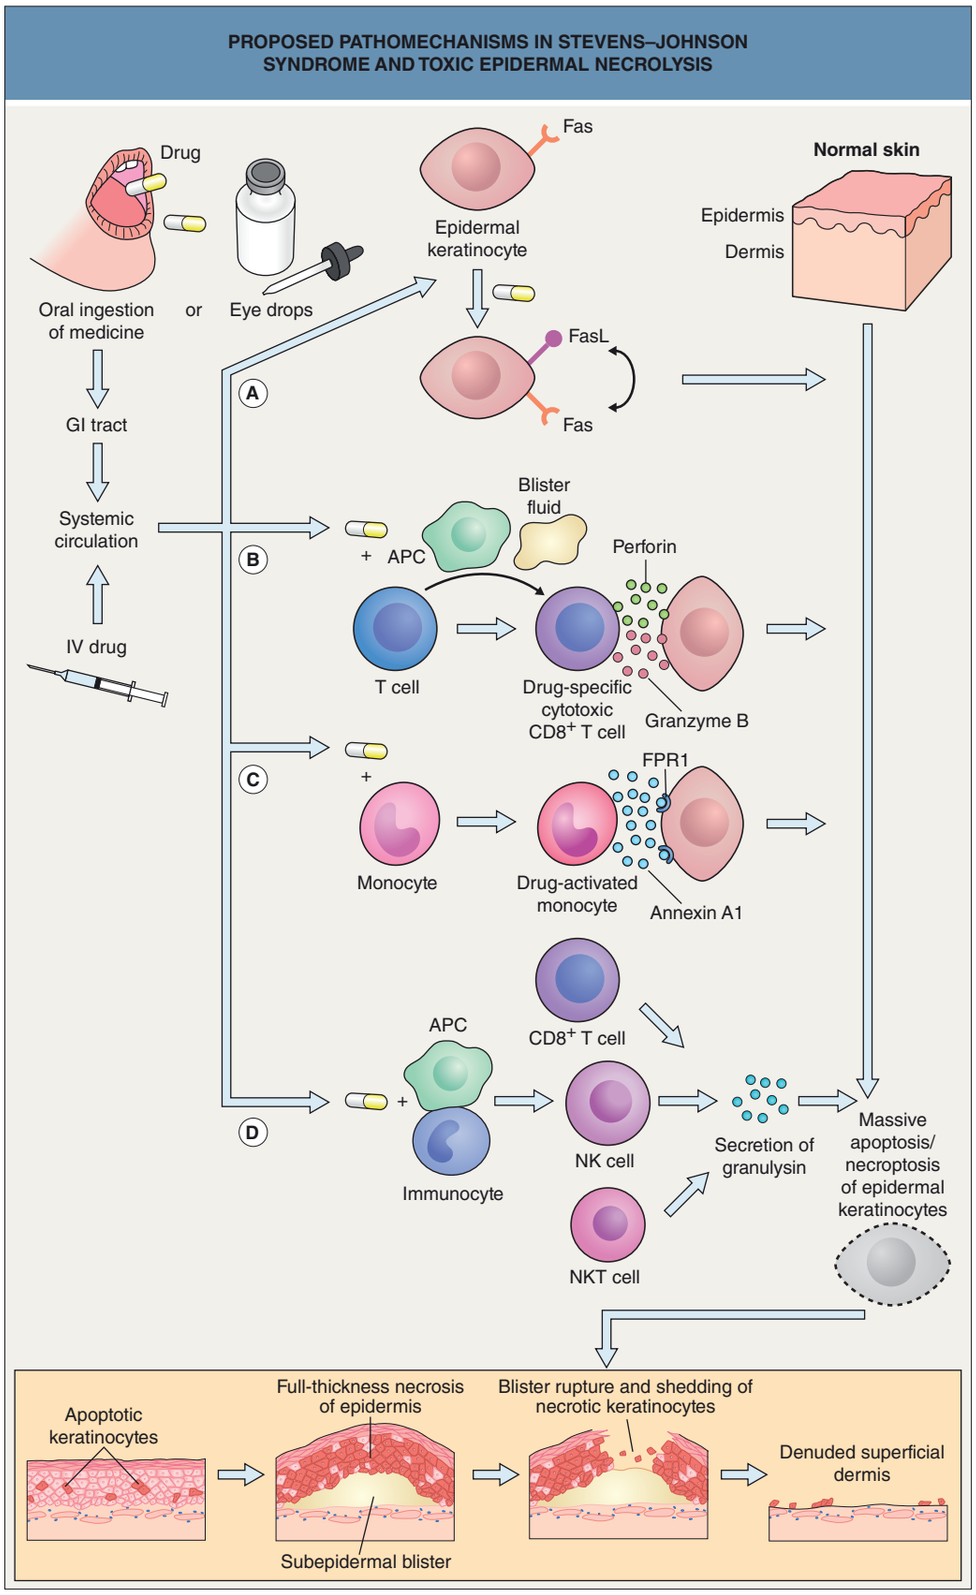

Fig. 20.6 Proposed pathomechanisms to explain apoptosis of epidermal keratinocytes in Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN). A number of medications can trigger widespread apoptosis of epidermal keratinocytes in individuals with SJS or TEN, leading to skin blistering and denudation. Several theories have been proposed for this condition: (**A**) the medication might induce upregulation of FasL by keratinocytes constitutively expressing Fas, leading to a death receptor-mediated apoptotic pathway; (**B**) the drug might interact with MHC class I-expressing cells and then drug-specific $CD8^+$ cytotoxic T cells accumulate within epidermal blisters, releasing perforin and granzyme B that kill keratinocytes; (**C**) drug-activated monocytes could secrete annexin A1, which induces necroptosis in keratinocytes via binding to formyl peptide receptor 1 (FPR1); and (**D**) the drug may also trigger the activation of $CD8^+$ T cells, NK cells and NKT cells to secrete granulysin, with keratinocyte death not requiring cell contact. IVIg contains antibodies against Fas that can block the binding of FasL to Fas. FPR1, formyl peptide receptor 1. *Adapted from Nickoloff BJ. Saving the skin from drug-induced detachment. Nat Med 2008;14:1311–13, with permission of Nature Publishing Group.*

(e.g. esophagitis, diarrhea) can also occur[69]. The skin lesions are usually tender, and mucosal erosions are very painful. Additional systemic manifestations include fever, lymphadenopathy, hepatitis, cytopenias, and cholestasis due to vanishing bile duct syndrome.

The morphology of the skin lesions has been studied in detail. First, lesions appear as erythematous, dusky red, or purpuric *macules* of irregular size and shape, and they have a tendency to coalesce (Fig. 20.8). At this stage, and in the presence of mucosal involvement and tenderness, the risk of rapid progression to SJS or TEN should be strongly suspected. In the absence of spontaneous epidermal detachment, a Nikolsky sign should be sought by exerting tangential mechanical pressure with a finger on several erythematous zones. This sign is considered positive if dermal–epidermal cleavage is induced. In some patients, the macular lesions observed at the onset can have a dusky center, giving them a target-like appearance. However, such lesions lack the three concentric rings characteristic of typical target lesions (as originally described by Hebra) and are not papular as in atypical target lesions of EM.

As the epidermal involvement progresses toward full-thickness necrosis, the dusky red macular lesions take on a characteristic gray hue. This process can be very rapid (hours), or take several days.

Fig. 20.7 Mucosal involvement in Stevens–Johnson syndrome. A Erythema and conjunctival erosions. **B** Erosions of the genital mucosa.

Fig. 20.8 Cutaneous features of toxic epidermal necrolysis (TEN). Characteristic dusky red color of the early macular eruption in TEN. Lesions with this color often progress to full-blown necrolytic lesions with dermal–epidermal detachment.

The necrotic epidermis then detaches from the underlying dermis, and fluid fills the space between the dermis and the epidermis, giving rise to bulla formation. The blisters have special features: they break easily (flaccid) and can be extended sideways by slight pressure of the thumb as more necrotic epidermis is displaced laterally (Asboe–Hansen sign). The skin resembles wet cigarette paper as it is pulled away by minimal trauma, often revealing large areas of raw and bleeding dermis, which is referred to as "scalding" (Fig. 20.9). These patients must therefore be handled with extreme care. Tense blisters are usually seen only on the palmoplantar surfaces, where the epidermis is thicker and, therefore, more resistant to mild trauma.

When evaluating such patients, the extent of necrolysis constitutes a major prognostic factor. The rules characteristically used to evaluate the surface area of thermal burns are appropriate for this purpose (see Ch. 88). Experience has shown that the extent of skin detachment is easily overestimated. Measurements should include detached and detachable epidermis (positive Nikolsky sign) but not purely erythematous areas (negative Nikolsky sign)[2]. The extent of skin detachment allows classification of the patient into one of three groups (Fig. 20.10; see Table 20.1):

- SJS: <10% of body surface area (BSA)
- SJS/TEN overlap (an intermediate category): 10%–30% of BSA (Fig. 20.11)
- TEN: >30% of BSA.

Mucosal erosions are present in >90% of patients (see above). Patients may describe photophobia and painful micturition.

It is also important to distinguish between SJS and EM, which are now considered to be different illnesses with different prognoses (see EM History)[3]. Their histologic features are similar and, therefore, not helpful in distinguishing between the two diseases. Differentiation is based primarily on clinical characteristics, especially the appearance of the target lesions and their distribution. To retain the diagnosis of EM, typical target lesions need to exist, whereas SJS should be considered if target lesions are atypical (see Table 20.1). Unfortunately, criteria for predicting which patients with SJS are likely to progress to TEN are currently unavailable. Recently, a case report form for SJS/TEN has been created by an NIH working group to help standardize the collection of patient information[70].

In TEN, factors correlated with poor outcome include increasing age and extent of epidermal detachment. In addition, the number of medications, elevation of serum urea, creatinine and glucose levels, neutropenia, lymphopenia, and thrombocytopenia have been statistically linked to poor outcome. Late withdrawal of the causative drug is also associated with a less favorable outcome. It has been estimated that prompt withdrawal of the offending drug reduces the risk of death by 30% per day[47]. SCORTEN is a severity-of-illness score for TEN, in which seven parameters with equal weight have been integrated to predict outcome (Table 20.7)[71]. However, one study suggested that it may underestimate mortality risk[73].

In 2019, a second mortality prediction model was introduced – the ABCD-10 score (*a*ge ≥50 years [1 point], serum *b*icarbonate level <20 mmol/l [1 point], active *c*ancer [2 points], *d*ialysis prior to admission [3 points], and epidermal detachment >*10%* body surface area [1 point]). Dialysis represented the strongest predictor of in-hospital mortality, but overall the predictability of the ABCD-10 score did not differ significantly from SCORTEN and needs further validation[72]. Recently, a cohort study involving 196 Asian patients suggested that SCORTEN was superior in predicting mortality rates when compared to ABCD-10[74].

On average, death occurs in every third patient with TEN, and it is mainly due to infections (*S. aureus* and *Pseudomonas aeruginosa*). Massive transepidermal fluid loss associated with electrolyte imbalance, inhibition of insulin secretion, insulin resistance, and onset of a hypercatabolic state can also be contributive factors. All these complications of TEN (that can also be observed in SJS) are best managed in intensive care units. They can unfortunately culminate in adult respiratory distress syndrome and multiple organ failure despite adequate supportive therapy.

Healing of areas of detached epidermis through re-epithelialization usually starts within days, and it is complete in most cases within 3 weeks. This process results from proliferation and migration of keratinocytes from "reservoir" sites, such as healthy epidermis surrounding denuded areas and hair follicles within the areas of detachment. Due to this conserved capacity for re-epithelialization, skin grafting is not required in SJS or TEN. Unfortunately, however, healing can be imperfect, and survivors may have both ocular (symblepharon, conjunctival synechiae, entropion, ingrowth of eyelashes) and cutaneous sequelae (scarring, dyspigmentation, eruptive melanocytic nevi), as well

Fig. 20.9 Clinical features of toxic epidermal necrolysis (TEN). A Detachment of large sheets of necrolytic epidermis (>30% body surface area), leading to extensive areas of denuded skin. A few intact bullae are still present. **B** Extensive symmetric hemorrhagic crusting of the face with areas of denudation. **C** Epidermal detachment of palmar skin. **D** Note the rolled and folded sheets of detached epidermis at the edge of denuded skin in addition to widespread erythema and intact bullae. *D, Courtesy Luis Requena, MD.*

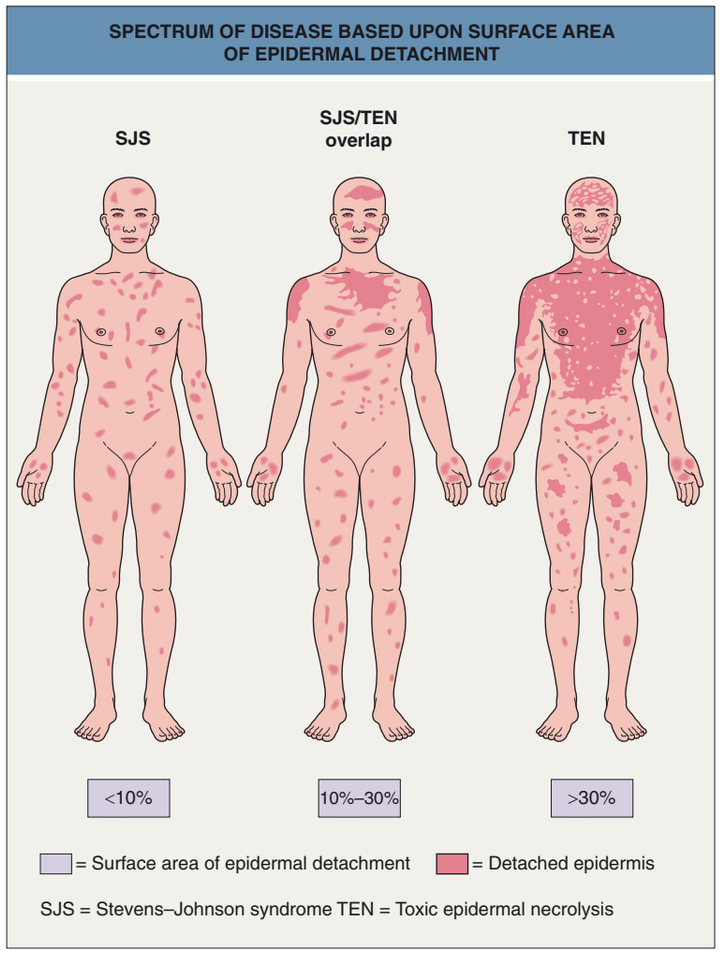

Fig. 20.10 Spectrum of disease based upon surface area of epidermal detachment.

as persistent erosions of the mucous membranes, urethral stenosis, phimosis, vaginal synechiae and stenosis with dyspareunia or hematocolpos, nail dystrophy, and diffuse hair loss (Fig. 20.12). These can often be minimized by optimizing skin care (see below), but, in TEN, up to 35% of survivors can have ocular symptoms ranging from sicca syndrome to blindness[44]. While amniotic membranes can be used acutely, scleral lenses (e.g. PROSE) assist in long-term care. Hypogeusia, dysphagia, progressive membranous glomerulonephritis, depression, and post-traumatic stress disorder represent additional sequelae.

Identification of the offending drug is an important and difficult task, but it should be among the first priorities. As noted previously, delayed withdrawal of the causative drug(s) is associated with increased mortality. Currently, there is no reliable *in vitro* test for the rapid identification of causative drugs. Patch testing shows weak sensitivity in SJS/TEN and is not appropriate for identification purposes; re-exposing the patient to the proposed causative drug is obviously not an acceptable option in severe drug reactions. The clinician, therefore, has to rely on previously reported associations and determine the probability (unlikely, possible, plausible, probable, very probable) for each medication based on the intrinsic ability of a particular drug to cause SJS/TEN (see Table 20.6 and reference therein) and extrinsic factors such as the initiation of a given medication with respect to the onset of SJS/TEN. SJS and TEN usually occur 7–21 days after initiation of the causative drug if it is the first exposure to the drug, but can occur within 2 days in the case of re-exposure to a drug that previously caused SJS or TEN. In general, the medication list of patients with SJS and TEN should be reduced to a strict minimum, appropriate substitutions made, and drugs with short half-lives favored. In an attempt to identify the culprit drug, ALDEN (algorithm of drug causality for epidermal necrolysis) and other causality assessment tools (CATs) have been developed which consider factors such as drug administration before and during disease progression, medication notoriety, and previous adverse reactions[75]. Unfortunately, available CATs, including ALDEN, have demonstrated poor reliability and validity[76].

Pathology

Histopathologic examination of lesional skin is a very useful tool for confirming the diagnosis of SJS and TEN, as the morphologic findings are distinct from those observed in SSSS (subcorneal blister with cleavage located in the granular layer of the epidermis) and acute generalized exanthematous pustulosis (AGEP; a neutrophil-rich infiltrate, superficial epidermal pustules and spongiosis, but no full-thickness epidermal necrolysis). Immediate analysis of frozen cryostat sections may be sufficient for this purpose.

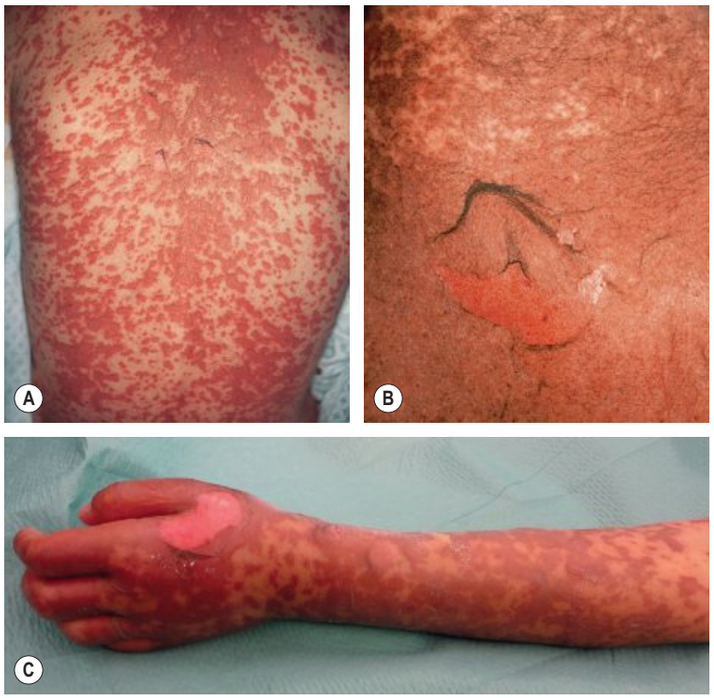

Fig. 20.11 Stevens–Johnson syndrome (SJS)/toxic epidermal necrolysis (TEN) overlap and early TEN. A In addition to mucosal involvement and numerous dusky lesions with flaccid bullae, there are areas of coalescence and multiple sites of epidermal detachment. Because the latter involved >10% body surface area, the patient was classified as having SJS/TEN overlap. **B** Close-up of epidermal detachment, the appearance of which has been likened to wet cigarette paper. **C** A child with early TEN due to diclofenac. There is coalescence of the dusky lesions as well as detached epidermis and denudation. *C, Courtesy Lisa Weibel, MD.*

SCORTEN	
Prognostic factors	**Points**
Age ≥40 years*	1
Heart rate ≥120 bpm	1
Cancer or hematologic malignancy*	1
BSA involved on day 1 >10%*	1
Serum urea level (>10 mmol/l)	1
Serum bicarbonate level (<20 mmol/l)*	1
Serum glucose level (>14 mmol/l)	1
SCORTEN	**Mortality rate (%)**
0–1	3.2
2	12.1
3	35.8
4	58.3
≥5	90

*Parameters also included in the ABCD-10 scoring system, but age ≥50 years, 2 points for active cancer, and 3 points for dialysis prior to admission. The predicted mortality rates varied from 2.3% (score = 0) to 84% (score = 6)[72].

Table 20.7 SCORTEN. A prognostic scoring system for patients with toxic epidermal necrolysis. The score is based upon seven prognostic factors. Some investigators also determine the red cell distribution width to hemoglobin ratio. BSA, body surface area. *Adapted from ref 71.*

Fig. 20.12 Sequelae of toxic epidermal necrolysis. A Symblepharon, erosion of lower lateral eyelid margin and sparse eyelashes; the patient also had entropion with an ingrowth of eyelashes and pebble-like scarring of facial skin. **B** Larger irregular areas of hypopigmented scarring. **C** Nail dystrophy consisting of longitudinal ridging and fissuring, fragility, and distal notching.

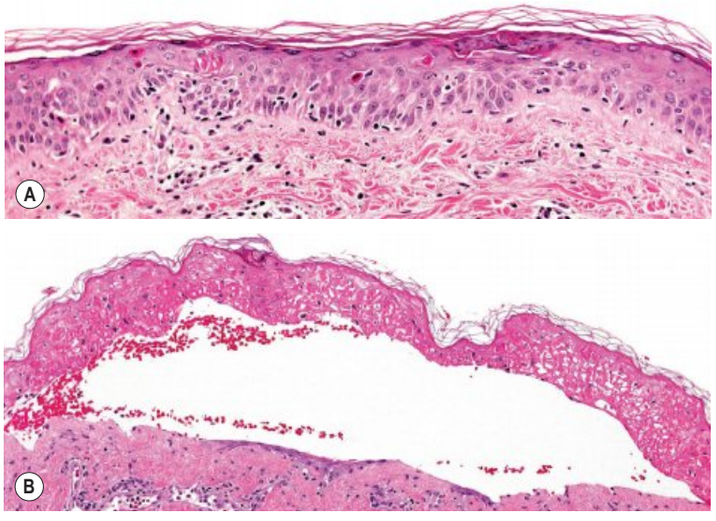

Fig. 20.13 Toxic epidermal necrolysis – histopathologic features. A Early lesions are characterized by apoptotic keratinocytes present individually and in clusters within the epidermis. Subtle vacuolar changes along the basal layer are accompanied by minimal inflammation, with scattered lymphocytes within the epidermis. **B** In later stages, a subepidermal blister with full-thickness necrosis of the overlying epidermis is seen. *Courtesy Lorenzo Cerroni, MD.*

In early lesions of SJS and TEN, apoptotic keratinocytes are observed scattered in the basal and immediate suprabasal layers of the epidermis (Fig. 20.13A). This is most likely the histologic correlate of the dusky to gray color that clinicians familiar with SJS/TEN consider as a warning sign of impending full-blown epidermal necrolysis and detachment. At later stages, lesional biopsy specimens show a subepidermal blister with overlying confluent necrosis of the entire epidermis and a sparse perivascular infiltrate composed primarily of lymphocytes (Fig. 20.13B). At an immunopathologic level, variable numbers of lymphocytes (usually $CD8^+$) and macrophages are observed within the epidermis, whereas lymphocytes in the papillary dermis are primarily $CD4^+$ cells[57].

DIFFERENTIAL DIAGNOSIS OF TOXIC EPIDERMAL NECROLYSIS	
Disease	**Clinical and histologic features**
Erythema multiforme and Stevens–Johnson syndrome	• See Table 20.1
Generalized bullous fixed drug eruption (see Ch. 21)	• When there are numerous mucocutaneous lesions • Timing post drug exposure differs • Microscopically, significant overlap
Acute generalized exanthematous pustulosis (AGEP; see Ch. 21)	• Numerous small, non-follicular pustules; can coalesce leading to large areas of exfoliation • Peripheral neutrophilia • *Microscopically, subcorneal pustules; no full-thickness epidermal necrosis*
Drug reaction with eosinophilia and systemic symptoms (DRESS; see Ch. 21)	• In addition to widespread erythema, vesiculobullae and pustules can develop • Facial edema; peripheral eosinophilia (most patients) • *Microscopically, changes are variable and sometimes nonspecific; necrosis usually absent; relatively dense dermal inflammatory infiltrate, often admixed with eosinophils*
Toxic erythema of chemotherapy (TEC; see Ch. 21)	• Exposure to particular chemotherapeutic or targeted agents • Symmetric dusky erythema, often involving skin folds, hands and feet and less often elbows and knees • Can be generalized but bullae less fragile • *Microscopically, usually minimal necrosis and presence of enlarged, atypical-appearing keratinocytes ("busulfan" cells)*
Drug-induced linear IgA bullous dermatosis (LABD), paraneoplastic pemphigus (PNP), bullous pemphigoid (see Chs. 29–31)	• Exposure to high-risk drugs, e.g. vancomycin for LABD • *Findings by routine histology and direct and indirect (PNP) immunofluorescence microscopy allow distinction*
Lupus erythematosus (Rowell syndrome; see Ch. 41)	• Usually resembles EM but can have TEN-like presentation • Appears *de novo* or as therapy tapered • Microscopically, significant overlap
Severe acute GVHD (stage/grade IV; see Ch. 52)	• Recipient of allogeneic hematopoietic stem cell transplant • Rare nowadays due to use of prophylactic GVHD therapies • Exposure to high-risk drugs for TEN and TEC is common • Microscopically, significant overlap
Staphylococcal scalded skin syndrome (SSSS; see Ch. 74)	• Children and occasionally adults • Split is more superficial so base is eroded epidermis not dermis • Perioral and periorbital accentuation with radial scale-crusts; no intraoral lesions • *Microscopically, subcorneal split with a normal underlying epidermis*
Invasive fungal dermatitis (see Ch. 34)	• Very-low-birth-weight newborns • Widespread erythema with erosions resembling a thermal burn • Usually due to candidal infection
Disseminated intravascular coagulation/purpura fulminans	• Bullae are hemorrhagic • Acral ischemia/necrosis • *Microscopically, fibrin thrombi within vessels in the dermis, with hemorrhage and minimal inflammation; necrosis of the epidermis, if present, is secondary to vascular occlusion*

Table 20.8 Differential diagnosis of toxic epidermal necrolysis. Distinctive histopathologic findings are in *italics*. In DRESS and AGEP, EM-like lesions can also be seen, including in the annular form of AGEP due to terbinafine.

Fig. 20.14 Early Stevens–Johnson syndrome. A In this child, there are individual erythematous lesions on the lower face, but coalescence on the cheeks. The two fresh bullae on the cheek are still intact. **B** This patient was originally diagnosed as a severe morbilliform drug eruption to penicillin, but then areas of epidermal detachment due to friction developed. *A, Courtesy Julie V. Schaffer, MD.*

Differential Diagnosis

The differential diagnosis of SJS consists primarily of EM (especially EM major), MIRM/RIME, autoimmune bullous diseases, and Kawasaki disease while the differential diagnosis for both SJS and TEN includes SSSS, drug-induced linear IgA bullous dermatosis (LABD), LE, generalized bullous fixed drug eruption, and the other entities outlined in Table 20.8. During the first 24–36 hours, SJS (as well as EM) may be diagnosed as a morbilliform drug reaction (Fig. 20.14).

Treatment

Optimal medical management of SJS and TEN requires early diagnosis, immediate discontinuation of the causative drug(s), and supportive care (Fig. 20.15).

Supportive care is similar to that performed for severe thermal burns, and it is aimed at limiting associated complications, which are the main cause of mortality. These include hypovolemia, electrolyte imbalance, renal insufficiency, and sepsis. Careful daily wound care, hydration, and nutritional support are essential and, preferably, done in an

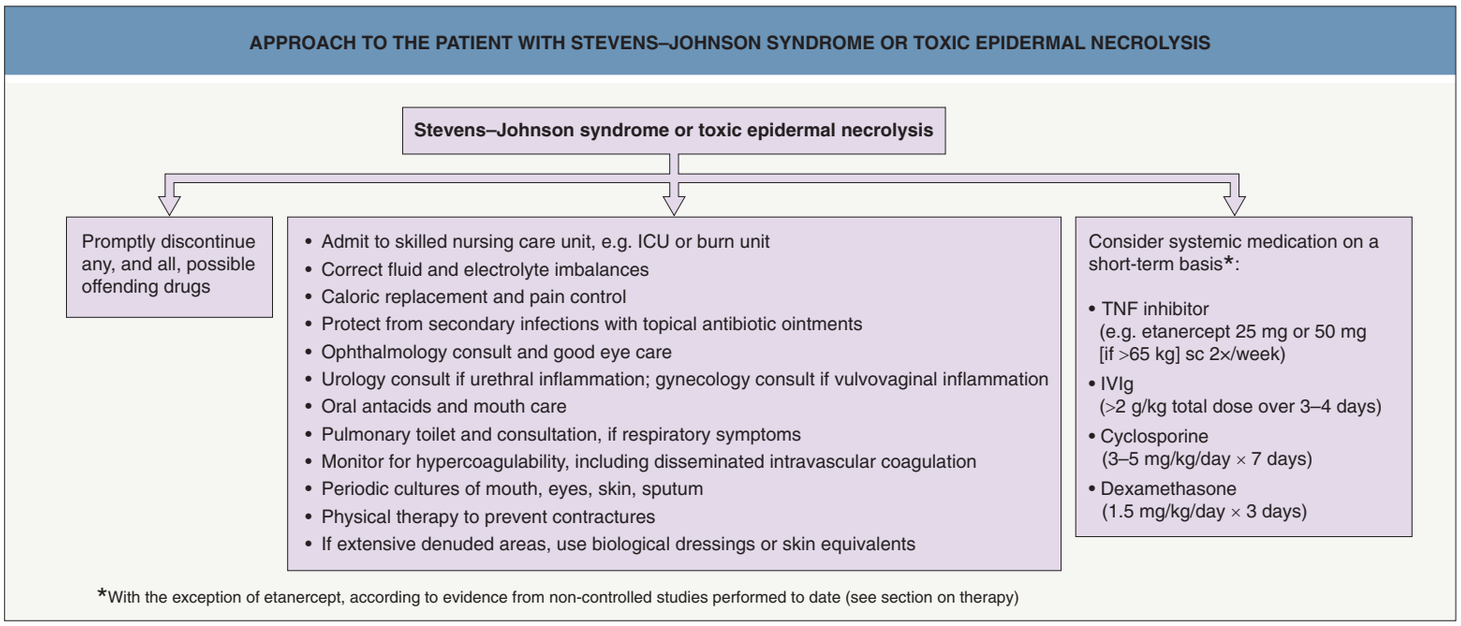

Fig. 20.15 Approach to the patient with Stevens–Johnson syndrome or toxic epidermal necrolysis. ICU, intensive care unit; sc, subcutaneous.

intensive care unit if there is epidermal detachment involving 10%–20% (or more) of BSA[77]. Use of a controlled pressure, thermoregulated bed and an aluminum survival sheet, instead of a regular bed and sheets, is recommended. All patient manipulations should be performed sterilely, and venous catheters should be placed, if possible, in a region of non-involved skin.

Wound care is best performed once daily with the help of, or in the presence of, a dermatologist. The patient should be manipulated as little as possible, as every movement is a potential cause of epidermal detachment. Cutaneous care should concentrate on the face, eyes, nose, mouth, ears, anogenital region, axillary folds, and interdigital spaces. Non-detached areas are kept dry and not manipulated. Detached areas, particularly on the back and pressure sites in contact with the bed, should be covered with Vaseline® gauze until re-epithelialization has occurred (see Ch. 145). For the face, serous and/or bloody crusts can be cleaned daily with isotonic sterile sodium chloride solution. An antibiotic ointment (e.g. mupirocin) or petrolatum ointment (if the patient is on systemic antibiotics) should be applied around orifices, e.g. ears, nose, mouth. Silicone dressings can be used to cover erosive denuded areas of skin. The silicone dressing does not need to be changed and can be left in place until re-epithelialization occurs, but its surface must be cleansed daily with isotonic sterile sodium chloride solution. Another option is to place a large non-adherent layered dressing (e.g. Exu-Dry™) over the patient and on the bed.

For the eyes, regular examination by an ophthalmologist is recommended. Eyelids should be gently cleansed daily with isotonic sterile sodium chloride solution, and an ophthalmic antibiotic ointment applied to the eyelids. In addition, antibiotic eyedrops should be administered three times a day to the cornea to reduce bacterial colonization, which can lead to scarring. Nostrils should be cleaned daily with a sterile cotton swab, moistened with isotonic sterile sodium chloride solution, and then the same procedure used to apply a little antibiotic (e.g. mupirocin) or petrolatum ointment. The mouth should be rinsed several times a day using a syringe with isotonic sterile sodium chloride solution, and then aspirated if the patient is unconscious. In the anogenital region and interdigital spaces, cutaneous care is performed daily by short applications of silver nitrate solution (0.5%) in the case of maceration, or simply sterile sodium chloride solution if there is no maceration.

In addition to supportive care, the most commonly employed systemic therapies have been TNF inhibitors, IVIg, cyclosporine, and corticosteroids. In a prospective, randomized, controlled trial involving 96 patients with SJS and TEN, etanercept was compared to intravenous prednisolone with the former resulting in shorter skin healing time (14 vs 19 days; $p = 0.01$) and less gastrointestinal hemorrhage[78]. However, to date, no additional large prospective, randomized, controlled clinical trials have been performed due in part to the low prevalence of these disorders. In general, therapy for severely affected patients with SJS has mirrored therapy for TEN, while those patients with milder non-progressive forms of SJS may receive only supportive care.

Although systemic corticosteroids have been a mainstay of therapy for decades, their use remains controversial[79]. A more recent study reported efficacy when the corticosteroids were administered acutely and over a short period of time as pulse therapy (intravenous dexamethasone 1.5 mg/kg for three consecutive days)[80]. In 2021, a network meta-analysis suggested that a combination of corticosteroids plus IVIg could reduce mortality in patients with SJS/TEN overlap and TEN[81]. Conflicting results have been observed with regard to the use of cyclosporine. A meta-analysis of 256 patients with SJS/TEN found significantly improved survival in patients treated with cyclosporine while a monocentric retrospective study of 174 patients did not see an advantage of cyclosporine over supportive care alone[82,83].

In 1998, IVIg was administered to a series of 10 patients, based upon the observation that IVIg contains antibodies that can block the binding of FasL to Fas (see Fig. 20.6A)[59]. High doses (0.75 g/kg/day for four consecutive days) were employed and blockage of the progression of epidermal detachment was observed[59]. Since then multiple published case series have been summarized in several meta-analyses[81,84–86]. While total doses of <2 g/kg may be insufficient for obtaining an optimal therapeutic effect[84], higher doses of IVIg (≥2 g/kg) correlated with an increased survival rate and lower mortality rate[85,87]. Relative contraindications for IVIg include a hypercoagulable state, IgA deficiency, and less so renal disease as the current products have less of an osmotic load.

In case reports and small uncontrolled series, several treatments have been reported as successful including cyclophosphamide (100–300 mg/day), plasmapheresis, and N-acetylcysteine (2 g/6 h)[88–90]. On the other hand, a controlled study using thalidomide was interrupted because of higher mortality in the thalidomide group compared with the placebo group[91].

Addressing the long-term complications of SJS/TEN clearly requires a multi-disciplinary approach.

eFig. 20.7 Toxic epidermal necrolysis – histopathologic features. Early lesions are characterized by apoptotic keratinocytes present individually and in clusters within the epidermis. Subtle vacuolar changes along the basal layer are accompanied by minimal inflammation, with scattered lymphocytes within the epidermis. *Courtesy Lorenzo Cerroni, MD.*

eFig. 20.8 Treatment of toxic epidermal necrolysis (TEN). Facial involvement of a patient with TEN (50% body surface area involvement) before (**A**) and 3 weeks after (**B**) treatment with IVIg (0.75 g/kg/day for 4 days).

eFig. 20.9 The Fas signaling pathway of apoptotic cell death. The death receptor Fas and its ligand FasL are transmembrane proteins. Fas signaling is triggered in the target cells by receptor tri(multi)-merization, induced upon contact with membrane-bound FasL from an adjacent cell. Subsequently, recruitment of intracellular signaling proteins FADD and pro-caspase-8 leads to autoactivation of the protease caspase-8 as well as apoptosis due to subsequent activation of downstream effector caspases (caspases-3, -6, -7), which cause cellular disintegration and death. Stimuli that induce apoptosis include cellular stress, growth factor withdrawal, DNA damage and cytokines.

21 Drug Reactions

Christina Bergqvist, Saskia Ingen-Housz-Oro and Olivier Chosidow

Key features

- The skin is one of the most common targets for adverse drug reactions
- To determine the cause of the eruption, a rigorous approach based on clinical characteristics, chronologic factors, and a literature search is required
- Exanthematous (morbilliform) eruptions and urticaria are the two most common forms of cutaneous drug reactions
- When an exanthematous eruption is associated with fever, lymphadenopathy, and/or edema of the face, drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS) should be considered and an evaluation for systemic involvement conducted
- Less common drug reactions include fixed, lichenoid, pustular, granulomatous, pseudolymphomatous, acneiform, bullous, photosensitivity, and vasculitic reactions, as well as Stevens–Johnson syndrome and toxic epidermal necrolysis
- Introduction of targeted therapies and immune checkpoint inhibitors to treat cancer has led to a wide range of cutaneous adverse reactions
- Early withdrawal of all potentially responsible drugs is essential, particularly in the case of severe cutaneous adverse reactions (SCARs)

INTRODUCTION

The skin is one of the most common sites for adverse drug reactions[1]. Although eruptions are usually observed in 0.1% to 1% of patients enrolled in pre-marketing trials of most systemic drugs, up to 5% of patients treated with antibiotics or aromatic anticonvulsants may develop a cutaneous eruption. Even higher incidences have been reported with newer targeted therapies and immune checkpoint inhibitors (ICIs) to treat cancer. In the mid 1990s, it was estimated that 1 of every 1000 hospitalized patients had a serious cutaneous drug reaction[1]. Introduction of the term SCARs (*s*evere *c*utaneous *a*dverse *r*eactions [to drugs]) reinforced the need for prompt identification followed by discontinuation of the most likely culprit drug(s) thereby decreasing both morbidity and mortality (Table 21.1)[2].

It may be tempting to consider most eruptive cutaneous drug reactions, especially the severe ones, as various presentations of a "hypersensitivity state". However, it is more precise to examine the specificity of the clinical, pathologic, and biologic patterns, thus allowing linkage of each type of adverse cutaneous reaction with a well-defined mechanism[3].

This chapter focuses on adverse cutaneous reactions due to systemically administered drugs. In addition, several specific types of cutaneous adverse reactions (CARs) are discussed in other chapters (Table 21.2).

SEVERE CUTANEOUS ADVERSE REACTIONS (SCARs)
Anaphylaxis
Anticoagulant-induced skin necrosis
Acute generalized exanthematous pustulosis (AGEP)
Drug rash with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS)
Generalized bullous fixed drug eruption
Stevens–Johnson syndrome and toxic epidermal necrolysis

Table 21.1 Severe cutaneous adverse reactions (SCARs). Trimethoprim-sulfamethoxazole-associated sudden conjunctivitis, lymphopenia, and rash combined with hemodynamic changes (SCoRCH) is a rare disorder.

EPIDEMIOLOGY

CARs to drugs occur in up to 8% of hospitalized patients[4]. In departments of dermatology, they represent 2% of consultations and ~5% of the admissions to an inpatient dermatology service. The incidence of fatalities due to drug reactions (systemic and cutaneous) among inpatients is between 0.1% and 0.3%[2]. There are multiple risk factors for developing an adverse drug reaction, including immunosuppression (e.g. HIV-infected individuals have a 10- to 50-fold greater risk of developing an exanthematous eruption to sulfamethoxazole) and specific HLA alleles (Table 21.3)[5].

Epidemiology of common CARs is still evolving. As a result, the incidence of drug reactions is difficult to establish precisely. Generally speaking, pre-marketing clinical trials, conducted before a new drug is licensed, include a limited number of patients, thus preventing a clear estimate of the true incidence. It is usually after several months or years of greater utilization that a more precise profile of the side effects of a newly released drug is established. Moreover, available information should be interpreted with caution, depending upon the method of data collection.

Table 21.3 Specific HLA alleles that increase the risk of cutaneous drug reactions. A number of HLA alleles also increase the risk of liver injury, including from penicillin derivatives. Highest relative risks are in **bold**. DRESS, drug reaction with eosinophilia and systemic symptoms; FDE, fixed drug eruption; NSAID, nonsteroidal anti-inflammatory drug; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

Reaction rates to commonly administered drugs have been confirmed by several prospective studies; however, the latter have been limited to inpatients[4]. In one series, adverse skin reactions occurred in 2.7% of 48 000 patients hospitalized over a 20-year period on a general internal medicine service; maculopapular exanthems (91.2%), urticaria (5.9%), and vasculitis (1.4%) were the reactions most commonly observed. The primary responsible drugs were penicillins, sulfonamides, and nonsteroidal anti-inflammatory drugs (NSAIDs).

Except for studies in hospitalized populations and those focusing on the most severe reactions, data regarding the incidence of cutaneous drug reactions in the general population are minimal, in part due to the absence of comprehensive post-marketing surveillance programs. In a retrospective cohort study from the Netherlands of 13 679 patients from general practices, the most frequently reported skin reactions to antimicrobials were due to trimethoprim–sulfamethoxazole (2.1% of users), fluoroquinolones (1.6%), and penicillins (1.1%).

PATHOGENESIS

Drug-induced skin reactions are mediated by either an immunologic or a non-immunologic mechanism (Table 21.4). In the former, drugs or their metabolites act as haptens, inducing a specific cell-mediated or humoral response. In the latter, some of the reactions are predictable given their relationship to the dose and/or the pharmacologic properties of the drug. However, the responsible pathophysiology may be difficult to identify simply on the basis of clinical appearance as the skin responds to a wide variety of stimuli through a limited number of morphologic reaction patterns. This may explain, at least in part, why the underlying mechanism of many cutaneous drug eruptions is still unknown.

Immunologically Mediated Drug Reactions

- *IgE-dependent drug reactions* (formerly type I, Gell–Coombs classification): urticaria, angioedema, and anaphylaxis.
- *Cytotoxic drug-induced reactions* (antibody against a fixed antigen; formerly type II): petechiae secondary to drug-induced thrombocytopenia.
- *Immune complex-dependent drug reactions* (formerly type III): vasculitis, serum sickness, and certain types of urticaria.
- *Delayed-type, cell-mediated drug reactions* (activation of $CD4^+$ and $CD8^+$ T cells; formerly type IV)[3]: exanthematous, fixed, and lichenoid drug eruptions, as well as Stevens–Johnson syndrome (SJS) and TEN. This group has been further subdivided into the following:
  - Th1 immune reaction (IVa): monocytes are preferentially recruited and activated by IFN-γ, leading to $CD8^+$ T cell activation and a proinflammatory response (TNF, IL-12)
  - Th2 immune reaction (IVb): eosinophils are preferentially recruited and activated in part by IL-4, -5, -13, and eotaxin, as in drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS), hereafter referred to as DRESS in the text

MECHANISMS OF CUTANEOUS DRUG-INDUCED REACTIONS	
Immunologic mechanism (unpredictable)	• IgE-dependent drug reactions • Cytotoxic drug-induced reactions • Immune complex-dependent drug reactions • Cell-mediated reactions
Non-immunologic mechanisms (sometimes predictable)	• Overdose • Pharmacologic side effects • Cumulative toxicity • Delayed toxicity • Drug–drug interactions • Alterations in metabolism • Exacerbation of disease
Idiosyncratic with a possible immunologic mechanism (unpredictable)	• DRESS/DIHS • SJS/TEN • Drug reactions in the setting of HIV infection • Drug-induced lupus erythematosus

Table 21.4 Mechanisms of cutaneous drug-induced reactions. DIHS, drug-induced hypersensitivity syndrome; DRESS, drug reaction with eosinophilia and systemic symptoms; HIV, human immunodeficiency virus; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

- Cytotoxic immune reaction (IVc): involves $CD4^+$ and $CD8^+$ T cells with release of perforin and granzyme B and/or Fas–FasL interactions, as in SJS/TEN (see Fig. 20.6)
- Neutrophil and T cell-based immune reaction (IVd): mediated via chemokines (e.g. CXCL8) and cytokines (e.g. GM-CSF), as in acute generalized exanthematous pustulosis (AGEP)

Several immunologic mechanisms have been proposed to explain SCARs including: (1) the *hapten/pro-hapten concept* – the drug or its metabolite covalently binds to an endogenous peptide and the resultant hapten is recognized by a highly restricted major histocompatibility complex (MHC); (2) the *pharmacoimmune reaction* ("p-i concept") – drugs induce formation of HLA–drug complexes that can directly activate T cell immune responses without the need for a specific peptide ligand[3]; and (3) *direct HLA–drug interactions* – certain drugs such as carbamazepine, abacavir, and sulfamethoxazole bind non-covalently within the peptide groove of a specific HLA and modify the antigen-binding cleft, thereby altering the endogenous peptide repertoire[6–9]. Interestingly, adoptive transfer of T cells expressing a public αβ T cell receptor to *HLA-B*15:02* transgenic mice receiving oral carbamazepine has been shown to induce a SCAR-like reaction[10].

Genetic factors

Specific HLA alleles have emerged as important genetic risk factors for SCARs, especially SJS/TEN and DRESS (see Table 21.3)[5,11,12]. Given the strong associations between HLA-B*15:02 and carbamazepine-triggered SJS/TEN in Asians and between HLA-B*57:01 and abacavir-triggered DRESS, pretreatment genetic testing is systematically performed in some countries in order to reduce the risk of SCARs. In patients with HLA-B*15:02 who are also carriers of CYP2C9*3 (portends intermediate or poor drug metabolizing phenotype), phenytoin should not be used as a therapeutic alternative to carbamazepine.

Non-immunologic Mechanisms (see Table 21.4)

Overdose

The clinical manifestations of a drug overdose are predictable and represent an exaggeration of the medication's pharmacologic actions. It may occur as a consequence of a prescribing error, deliberate or inadvertent excess by the patient, or altered absorption, metabolism, or excretion[13]. For example, overdose-related methotrexate toxicity can occur in patients with reduced renal function or in patients who erroneously take methotrexate daily instead of once weekly (Fig. 21.1).

Pharmacologic side effects

These reactions include undesirable or toxic effects that cannot be separated from the desired pharmacologic actions of the drug. An example would be alopecia and mucositis due to chemotherapeutic agents that target more rapidly dividing cells.

Cumulative toxicity

Prolonged exposure to a medication or its metabolites may lead to cumulative toxicity. For example, methotrexate can lead to hepatic fibrosis and accumulation of minocycline, hydroxychloroquine, amiodarone, or rarely levofloxacin within the skin can lead to cutaneous discoloration.

Delayed toxicity

This corresponds to a toxic, dose-dependent effect that occurs months to years after the discontinuation of a medication. Examples include squamous cell carcinomas and palmoplantar keratoses following exposure to arsenic and acute leukemia due to alkylating agents.

Drug–drug interactions

Interactions between two or more drugs administered simultaneously may occur at several different steps: (1) intestinal drug interactions; (2) displacement from binding proteins or receptor sites; (3) enzyme stimulation or inhibition; and (4) altered drug excretion (see Ch. 131). Examples of each include the interactions between tetracycline and calcium, methotrexate and sulfonamides, cyclosporine and azoles, and methotrexate and probenecid. A different scenario is a morbilliform eruption or TEN following the administration of both a common culprit drug (e.g. cephalosporin) and an immune checkpoint inhibitor (e.g. nivolumab) whereas re-exposure to just the immune checkpoint inhibitor does not lead to a CAR.

Alterations in metabolism

Drugs may induce cutaneous changes by their effects on the nutritional or metabolic status of the patient. Bexarotene may induce severe hypertriglyceridemia and eruptive xanthomas, while isoniazid may be associated with pellagra-like changes.

Exacerbation of disease

A variety of drugs can exacerbate pre-existing dermatologic diseases, such as androgens in patients with acne vulgaris, interferons in patients with sarcoidosis and psoriasis, or paradoxically TNF inhibitors in patients with psoriasis.

Photosensitivity

Systemically administered drugs in combination with light (ultraviolet or visible) may cause cutaneous photosensitivity, classically either phototoxicity (e.g. doxycycline, quinolones) or photoallergy (e.g. quinine, sulfonamide antibiotics). Topical medications may also lead to photosensitizing reactions (e.g. ketoprofen-induced photoallergic dermatitis). In addition, drugs can act as photocarcinogens, even after short use (e.g. voriconazole-induced squamous cell carcinomas). Oral medications may even induce systemic (e.g. hydralazine, minocycline) and cutaneous lupus erythematosus (e.g. terbinafine, hydrochlorothiazide).

Fig. 21.1 Methotrexate toxicity. Increased serum levels of methotrexate secondary to decreased renal excretion can lead to epidermal necrosis. **A** Large erosions and areas of epidermal necrosis with a shellac-like appearance in a patient with rheumatoid arthritis. **B** Epidermal necrosis limited to psoriatic plaques. *A, Courtesy Kalman Watsky, MD.*

Idiosyncratic With a Possible Immunologic Mechanism (see Table 21.4)

The pathophysiology of drug-induced skin reactions such as exanthematous drug eruptions, DRESS, AGEP and TEN, as well as the increased susceptibility of HIV-infected patients, may be partially explained by an interplay between a virus with its subsequent immune mechanisms and genetic predisposition.

DIAGNOSTIC FEATURES

Drug eruptions, both suspected and unsuspected, frequently lead to a dermatologic consultation, and it is often (although not always) possible to categorize a drug as having a high, medium, or low probability of being the culprit. A rigorous approach begins with an accurate description of the skin lesions and their distribution, in addition to associated signs and symptoms (Table 21.5). Data regarding all the drugs taken by the patient, including prescription, non-prescription/over-the-counter, and complementary or alternative treatments, as well as the dates of administration and doses need to be collected on a timeline[2]. The chronology of drug administration is of paramount importance (Table 21.6). The time between initiation of the drug and the onset of the skin eruption is a key element in identifying the culprit drug, as most immunologically mediated reactions occur 7 to 21 days after initiation of a new medication.

Evolution after drug withdrawal may be helpful, as common cutaneous eruptions (e.g. exanthematous) often clear when the suspected drug is discontinued. However, this assessment may prove difficult in the case of drugs with a long half-life or "persistent" drug reactions such as lichenoid and photoallergic eruptions, drug-induced pemphigus foliaceus and subacute cutaneous lupus erythematosus, or even SCARs, once the disease process has been definitively triggered.

The culprit drug should be withdrawn as soon as possible. The usual practice is to discontinue all other drugs that are non-essential. However, in some instances, it is necessary to weigh the risks versus the benefits of each drug and to determine if a similar-acting, but non-cross-reactive, drug is available as a substitute.

In the process of identifying the responsible drug, access to drug databases or drug agency websites is very helpful[5,6,14]. However, new or unusual drug reactions may not be identified. Moreover, the drug most frequently associated with adverse reactions may be innocent in a particular patient, and the physician dealing with a suspected drug reaction must remain open-minded.

RIGOROUS APPROACH TO DETERMINE THE CAUSE OF A DRUG ERUPTION	
Drug responsibility assessment	
Clinical characteristics	• Type of primary lesion (e.g. urticaria, erythematous papule, pustule, purpuric papule, vesicle, or bulla) • Distribution and number of lesions • Mucous membrane involvement, facial edema • Associated signs and symptoms: fever, pruritus, lymph node enlargement, visceral involvement
Chronological factors	• Document all drugs to which the patient has been exposed (including OTC and complementary) and the dates of administration • Date of eruption • Time interval between drug introduction (or reintroduction) and skin eruption • Response to removal of the suspected agent • Consider excipients (e.g. soybean oil) • Response to rechallenge*
Search of databases	• Bibliographic research (e.g. PubMed, Micromedex, Litt's Drug Eruption and Reaction Database) • MedWatch (fda.gov/medwatch) • Data collected by pharmaceutical companies • In the case of more recently released medications, extrapolation based on the class of drug and in particular the first drug released in the class
*Often inadvertent.	

Table 21.5 Rigorous approach to determine the cause of a drug eruption.
OTC, over-the-counter.

With the exception of assays for IgE antibodies, diagnostic or confirmatory assays to establish the responsible drug are not readily available. A number of *in vitro* tests have been designed, including the histamine release test, migration inhibition factor test, lymphocyte toxicity assay, lymphocyte transformation test, and basophil degranulation test[7]. However, their sensitivity and specificity have not been assessed in a reliable way with relevant controls. As a result, they are of limited value in the clinical setting.

Results of patch testing, in which drugs (usually with petrolatum or alcohol as the vehicle) are applied to the upper back for 48 hours, vary depending upon the responsible drug and the type of eruption[15] (Table 21.7). Prick and intradermal tests can be performed in patients with urticaria and angioedema, but they are contraindicated in SJS/TEN due to the risk of relapse. Of note, delayed reading of prick, intradermal, and patch tests is particularly important in the case of amoxicillin-induced morbilliform eruptions. Unfortunately, investigations involving series of patients with several different types of drug reactions have shown heterogeneous results. In general, these tests, when positive, may be helpful in preventing re-administration of the culprit drug, but with the exception of prick and intradermal tests in patients with urticaria and perhaps patch tests in a few disorders (see Table 21.7), their specificity and/or sensitivity are still controversial. Of note, delayed intradermal testing is increasingly being performed in patients with DRESS when there is uncertainty regarding the responsible drug and pretest probability is high.

Rechallenge carries the risk of inducing a more severe reaction, thus it is contraindicated after SCARs. In critical situations, rechallenge may be useful, e.g. a patient with active tuberculosis who develops a rash while receiving a cocktail of antituberculous drugs; a step-by-step reintroduction may be performed in specialized centers. However, the recurrence rate is not 100% with rechallenge and a negative result may give an erroneous sense of security.

CLINICAL FEATURES

Urticaria (see Ch. 18 for details)

Urticaria presents as transient, pruritic, erythematous, and edematous papules and plaques that may appear anywhere on the body. Lesions can vary significantly in size and number and may assume a figurate configuration (Fig. 21.2).

Although drugs are thought to be responsible for <10% of all cases of urticaria, they are more often associated with acute rather than chronic urticaria. Drug-induced urticaria may either occur immediately, i.e. less than one hour after drug intake (see below), or have a delayed appearance (late urticaria)[16]. Of note, patients with chronic urticaria should avoid acetylsalicylic acid (ASA; aspirin), as well as other NSAIDs, as they can lead to an exacerbation.

In IgE-mediated urticaria, lesions typically appear within minutes to less than an hour after drug administration, especially when there has been prior sensitization. Both immunologic assays, such as radioallergosorbent tests (RAST) that detect specific IgE antibodies, and skin tests (prick tests) are useful in confirming the diagnosis. Unfortunately, US commercial RAST panels only test for a limited number of drugs. Prick tests should be performed under appropriate medical supervision due to the risk of an anaphylactic reaction. Of note, in some series, only 10%–20% of patients who reported a history of penicillin allergy were truly allergic when assessed by skin testing.

Drugs that most frequently produce immunologically based urticaria are antibiotics, especially penicillins and cephalosporins, and less often, sulfonamides and minocycline. As the use of monoclonal antibodies for neoplastic and inflammatory diseases increases, so will cases of urticaria (and vasculitis; see below) due to these exogenous proteins (see Ch. 128).

In anaphylactoid reactions, which are not IgE-mediated but resemble anaphylaxis clinically, vasodilation results from the liberation of large amounts of histamine, bradykinin, and/or leukotrienes. Acetylsalicylic acid is the classic example of a drug that induces an anaphylactoid reaction and it does so via cyclooxygenase inhibition and subsequent accumulation of leukotrienes. The majority of urticarial reactions to radiocontrast media are also non-immunologic (Table 21.8), as are many, but not all, reactions to NSAIDs (e.g. ibuprofen, naproxen). Infusion of chemotherapy (e.g. taxanes) can also result in anaphylactoid reactions.

CHARACTERISTICS OF MAJOR DRUG-INDUCED ERUPTIONS				
Clinical presentation	**Percentage that are drug-induced (%)**	**Time interval**	**Mortality (%)**	**Selected responsible drugs**
Exanthematous (morbilliform) eruption	Child: 10–20 Adult: 50–70	4–14 days	0	Aminopenicillins Sulfonamides Cephalosporins Anticonvulsants (aromatic) Allopurinol Abacavir Nevirapine
Urticaria	<10	Minutes to hours	0	Penicillins Cephalosporins NSAIDs* Monoclonal antibodies Radiocontrast media*
Anaphylaxis	30	Minutes to hours	5	
Fixed drug eruption (FDE)	100	First exposure: 1–2 weeks Re-exposure: <48 hours, usually within 24 hours	0	Acetaminophen TMP-SMX NSAIDs Tetracyclines Pseudoephedrine†
Acute generalized exanthematous pustulosis (AGEP)	70–90	<4 days	1–2	β-Lactam antibiotics Macrolides Calcium channel blockers Clindamycin
Drug reaction with eosinophilia and systemic symptoms (DRESS)/ drug-induced hypersensitivity syndrome (DIHS)	70–90	15–40 days	5–10	Anticonvulsants (aromatic) Lamotrigine (especially in combination with valproate) Sulfonamides Abacavir Allopurinol Dapsone Minocycline Nevirapine Vancomycin
Stevens–Johnson syndrome (SJS)	70–90	7–21 days	5	Sulfonamides, β-lactam antibiotics Anticonvulsants (aromatic) Lamotrigine Allopurinol NSAIDs NNRTIs, e.g. nevirapine
Toxic epidermal necrolysis (TEN)			30	
*Often anaphylactoid reaction. †Non-pigmenting.				

Table 21.6 Characteristics of major drug-induced eruptions. See Chs. 18 and 20 for additional details. NNRTIs, non-nucleoside reverse transcriptase inhibitors; NSAIDs, nonsteroidal anti-inflammatory drugs; TMP-SMX, trimethoprim–sulfamethoxazole (co-trimoxazole).

CUTANEOUS DRUG ERUPTIONS – USE OF PATCH TESTING TO IDENTIFY THE RESPONSIBLE DRUG		
Type of cutaneous drug reaction	**% Patch test positivity***	**Comments**
Symmetrical drug-related intertriginous and flexural exanthema (SDRIFE)	50–80	Positive results most frequently observed with β-lactam antibiotics, clindamycin, erythromycin, pseudoephedrine, contrast agents > allopurinol, H1 blockers
Acute generalized exanthematous pustulosis (AGEP)	50–60	Positive results most frequently observed with β-lactam antibiotics and pristinamycin > carbimazole/metamizole, ciprofloxacin, clindamycin, diltiazem, metronidazole, morphine, NSAIDs, and pseudoephedrine
Fixed drug eruption	>40	*In situ* patch test recommended, i.e. at the site of a previous lesion
Drug reaction with eosinophilia and systemic symptoms (DRESS)	30–60	Should be performed at least 6 months after clinical resolution Positive results primarily observed with abacavir, β-lactam antibiotics, carbamazepine, proton pump inhibitors, and antituberculous drugs
Exanthematous (morbilliform) drug eruption	10–40	If patch test negative, prick tests can be discussed to increase positivity, depending upon disease severity
SJS/TEN	10–25	Reports of positive results with β-lactam antibiotics, carbamazepine, trimethoprim–sulfamethoxazole, and pseudoephedrine
*Range because results often depend upon particular drug.		

Table 21.7 Cutaneous drug eruptions – use of patch testing to identify the responsible drug. Patch tests are placed on the upper back for 48 hours and read at 3–7 days as with standard patch testing (see Ch. 14). Vehicles are usually petrolatum or alcohol and concentrations are either predetermined (commercially available products) or based upon literature review. SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

Fig. 21.2 Urticaria secondary to penicillin. Several of the lesions have a figurate appearance.

ADVERSE REACTIONS TO RADIOCONTRAST MEDIA
Iodinated
Immediate (<1 hour)
Urticaria (usually non-immunologic), angioedema
Anaphylactoid reaction
Delayed (1 hour to 1 week)
Exanthematous (morbilliform) eruption
Acute generalized exanthematous pustulosis (AGEP)
Symmetrical drug-related intertriginous and flexural exanthema (SDRIFE)
Iododerma (also >1 week)
DRESS/DIHS (iodinated > gadolinium)
Gadolinium
Urticaria, erythema (rare)
Anaphylactoid reactions, anaphylaxis (rare)
Nephrogenic systemic fibrosis (in the setting of renal insufficiency; see Ch. 43)

Table 21.8 Adverse reactions to radiocontrast media. DRESS/DIHS, drug reaction with eosinophilia and systemic symptoms/drug-induced hypersensitivity syndrome.

The most important step in the treatment of drug-induced urticaria is withdrawal of the causative agent. Treatment consists primarily of H1 antihistamines. Additional therapeutic options are discussed in Chapter 18 as is the differential diagnosis which includes the immune complex-mediated disorders urticarial vasculitis and serum sickness.

Angioedema (see Ch. 18 for details)

Angioedema is a consequence of transient edema of the deep dermal, subcutaneous, and submucosal tissues. It is associated with urticaria in 50% of cases and may be complicated by life-threatening anaphylaxis. Angioedema occurs in 1 to 2 per 1000 new users of angiotensin-converting enzyme (ACE) inhibitors and is due to an accumulation of bradykinin (see Fig. 18.6). The most severe cases of angioedema may start within a few minutes after drug administration. However, in the case of ACE inhibitor-induced angioedema, lesions may appear from 1 day to several years after starting the drug; most appear within the first year. Blacks and women are at increased risk for developing ACE inhibitor-induced angioedema.

The most common clinical presentation is an acute, asymmetric, pale or pink, subcutaneous swelling involving the face. Involvement of the oropharynx, larynx, and epiglottis can lead to impaired swallowing and stridor. Occasionally, there is edema of the intestinal wall with abdominal pain, nausea, vomiting, and diarrhea.

The major drugs implicated in angioedema, besides penicillins and ACE inhibitors, are NSAIDs, radiographic contrast media, and more recently, monoclonal antibodies (see Ch. 128). Although angiotensin II receptor antagonists do not increase levels of bradykinin, they are also associated with angioedema, albeit less frequently. It is important to note that drug-induced angioedema may actually represent an unmasking of another cause for angioedema, e.g. acquired C1 inhibitor deficiency due to autoimmune or lymphoproliferative disorders.

Anaphylaxis

Anaphylaxis consists of an acute life-threatening reaction that occurs within minutes of drug administration, usually parenteral. It occurs in about 1 per 5000 exposures to penicillin and combines skin signs (urticaria and/or angioedema) with systemic manifestations such as hypotension and tachycardia. Occasionally, there is hypotension in the absence of cutaneous lesions. In severe cases, the patient becomes unconscious as a result of cardiovascular shock. Prompt discontinuation of the culprit drug is mandatory, as is strict avoidance of the drug in the future. Subcutaneous epinephrine (adrenaline) is the primary treatment for life-threatening angioedema and anaphylaxis, along with careful monitoring. Systemic corticosteroids and H1 antihistamines are also beneficial. Of note, patients taking β-blockers may have a limited response to epinephrine.

The most frequently incriminated drugs are antibiotics, in particular the penicillins/aminopenicillins but also cephalosporins and quinolones, muscle relaxants, NSAIDs, and gadolinium-based contrast media[17]. Anaphylaxis can also be seen following exposure to latex (see Ch. 16) while anaphylactoid reactions are usually seen with NSAIDs and radiocontrast media (see Table 21.8).

Exanthematous Drug Eruptions

Synonyms: ■ Morbilliform drug eruption ■ Maculopapular drug eruption ■ Urticarial drug eruption

Exanthematous or morbilliform eruptions are the most common adverse drug reactions affecting the skin. They are often referred to as maculopapular drug eruptions or, in the case of non-dermatologists, "drug rashes".

The primary underlying pathomechanisms are most likely immunologic, complex, and cell-mediated. Several mechanisms have been proposed (see above) in which the drug or drug-peptide hapten presented by dendritic cells to T lymphocytes can either bind covalently or non-covalently to MHC molecules[9]. $CD4^+$ and $CD8^+$ T cells that strongly express perforin and granzyme are then recruited and their cytotoxic activity leads to death of keratinocytes.

Overall, most drug classes can induce an exanthematous eruption in ~1% of treated patients. Higher risk medications (>3% of treated patients) include aminopenicillins, allopurinol, sulfonamides, cephalosporins, and anticonvulsants (aromatic and lamotrigine). Certain viral infections are also known to increase the incidence of drug reactions. Depending upon the series, the frequency of aminopenicillin-induced exanthematous eruptions in patients with infectious mononucleosis ranges from 33% to 100% (see Ch. 80). One theory is that reactive drug metabolites disturb the balance between cytotoxic and regulatory immune responses, leading to a cytotoxic reaction that targets virally infected keratinocytes.

A morbilliform eruption classically begins 4 to 14 days after the initial drug administration, but appears earlier (less than 2 days) in the case of rechallenge[16]. Symmetrically distributed erythematous macules, papules, and/or urticarial lesions initially appear on the trunk and upper extremities; over time they can become confluent (Fig. 21.3A). Sometimes, the lesions on the distal lower extremities become petechial or purpuric (Fig. 21.3B). Mucous membranes are usually spared but pruritus and a low-grade fever are often present. There may also be annular plaques (Fig. 21.3C) or atypical "target" lesions, leading to a misdiagnosis of erythema multiforme. Once the culprit drug is discontinued, the eruption gradually resolves over one to two weeks, without complications and/or sequelae. However, for 1 to 3 days immediately following discontinuation of the responsible medication, an increase in extent and intensity may be observed.

Signs and symptoms that point to the possibility of a more severe drug-induced eruption (see Table 21.1) include skin pain, edema of the face, pustules, vesicles, purpuric macules, skin fragility (Nikolsky sign), mucous membrane involvement, and/or marked peripheral blood eosinophilia. Histologically, nonspecific findings are typically seen in morbilliform drug eruptions, i.e. a mild superficial perivascular and interstitial

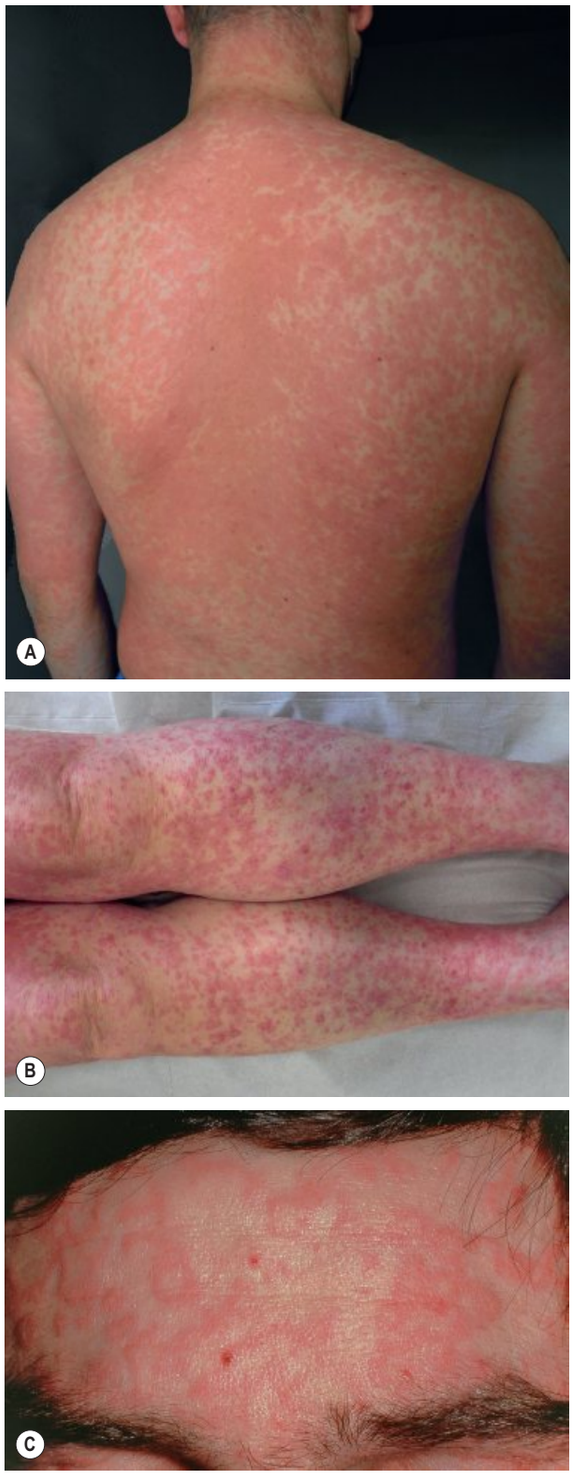

Fig. 21.3 Morbilliform (exanthematous) drug eruptions. A Erythematous papules and urticarial lesions with confluence on the midback induced by amoxicillin. **B** Due to dependency, lesions on the distal lower extremities can become petechial or purpuric. **C** Pink papules and annular lesions on the forehead due to phenobarbital. *A, B, Courtesy Laurence Valeyrie-Allanore, MD.*

lymphocytic infiltrate that may contain eosinophils (up to 70% of cases) in addition to interface changes.

The major entity in the differential diagnosis of a morbilliform drug eruption is a viral exanthem (e.g. Epstein–Barr virus [EBV], enterovirus, adenovirus, early HIV infection, human herpesvirus type 6 [HHV-6]; see Fig. 81.2). Peripheral blood eosinophilia and a polymorphous appearance point to a drug eruption, and in the absence of definitive evidence, drug eruptions are favored in adults whereas viral exanthems are favored in children. Occasionally, there is a viral infection that might enhance the risk of developing a drug eruption (see above)[9]. However, "idiopathic" exanthematous eruptions still remain a frequent occurence[18]. Toxic shock syndrome, scarlet fever, acute GVHD, Kawasaki disease, and SCARs should be excluded on the basis of associated clinical features (Fig. 21.4).

Treatment is supportive. Topical steroids may help to alleviate pruritus and reduce erythema. Discontinuing the culprit agent is the first therapeutic intervention. "Treating through", i.e. continuing the drug despite the cutaneous eruption, can be considered when there are no diagnostic criteria for a SCAR, the suspected drug is of paramount importance for the patient, and there is no satisfactory substitute drug. Desensitization may be considered in HIV-infected patients who require sulfonamides. Unfortunately, *in vitro* assays (see above) and patch testing (see Table 21.7) are of limited clinical utility.

RegiSCAR SCORING SYSTEM FOR DRESS			
Criteria	**No**	**Yes**	**Unknown/ unclassifiable**
Fever (≥38.5°C)	–1	0	–1
Lymphadenopathy (≥2 sites; >1 cm)	0	1	0
Circulating atypical lymphocytes	0	1	0
Peripheral hypereosinophilia	0		0
0.7–1.499 × 10^9/L - *or* - 10–19.9%*		1	
≥1.5 – 10^9/L - *or* - ≥20%*		2	
Skin involvement			
• Extent of cutaneous eruption >50% BSA	0	1	0
• Cutaneous eruption suggestive of DRESS†	–1	1	0
• Biopsy suggests DRESS	–1	0	0
Internal organs involved‡	0		0
One		1	
Two or more		2	
Resolution in ≥15 days	–1	0	–1
Laboratory results negative for at least three of the following (and none positive): (1) ANA; (2) blood cultures; (3) HAV/HBV/HCV serology; and (4) *Chlamydia* and *Mycoplasma* serology	0	1	0
Final score: <2, no case; 2–3, possible case; 4–5, probable case; >5, definite case			
*If leukocytes <4.0 × 10^9/L. †At least two of the following: edema, infiltration, purpura, scaling. ‡Liver, kidney, lung, muscle/heart, pancreas, or other organ and after exclusion of other explanations.			

Table 21.9 European Registry of Severe Cutaneous Adverse [Drug] Reactions (RegiSCAR) scoring system for DRESS (drug reaction with eosinophilia and systemic symptoms)[20]. This scoring system has been validated, but the resolution criterion is not helpful at the time of the initial diagnosis and the laboratory results criterion is in need of re-evaluation in the opinion of the editors. ANA, anti-nuclear antibody; BSA, body surface area; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus.

Drug Reaction With Eosinophilia and Systemic Symptoms (DRESS)

Synonyms: ■ Drug-induced hypersensitivity syndrome (DIHS) ■ Drug-induced delayed multi-organ hypersensitivity syndrome (DIDMOHS)

DRESS is an unusual, potentially life-threatening, multi-organ adverse drug reaction[2]. Its incidence has been estimated to be between 1 in 1000 and 1 in 10 000 exposures to drugs such as aromatic anticonvulsants (e.g. phenytoin, carbamazepine, phenobarbital) and sulfonamides[19]. Additional names for this syndrome have arisen in part because not all patients have peripheral blood eosinophilia[19,20]. To aid in the clinical diagnosis of this disorder, two accepted scoring systems have been proposed as outlined in Tables 21.9 and 21.10[21].

Although the precise pathogenesis of DRESS is still not fully understood, several underlying mechanisms have been proposed, including a specific alteration in the metabolism of particular drugs. For example, genetic polymorphisms that affect detoxification of anticonvulsants and sulfonamides have been identified in patients recovering from DRESS. For aromatic anticonvulsants, the inability to detoxify toxic arene oxide metabolites is probably a key factor and would provide an explanation for the cross-reactivity between phenytoin, carbamazepine, and phenobarbital which has been well documented, both *in vivo* and *in vitro*[22].

Distinct HLA alleles have been associated with a significantly increased risk of developing *drug-specific* DRESS in certain populations (see Table 21.3)[23–26]. In addition, IL-5 plays a role in the generation of eosinophilia and drug-specific T cells that are activated in the skin and internal organs serve to mediate the disorder.

Also implicated in the pathogenesis of DRESS is reactivation of human herpes viruses, primarily HHV-6 and HHV-7, but also CMV and EBV[27]. In patients with DRESS, transmission of HHV-6 to skin-infiltrating $CD4^+$ T cells (and subsequent replication) was found to require recruitment of HHV-6^+ peripheral monomyeloid cells to damaged skin[28]. A study of 40 patients with DRESS noted reactivation of EBV, HHV-6, or HHV-7 in 76% of patients; activated circulating $CD8^+$ T cells with cutaneous homing markers secreted large amounts of TNF and IFN-γ, especially in those with the most severe visceral involvement. In patients' EBV-transformed B cells, culprit drugs triggered the production of EBV.

Clinically, DRESS develops 2 to 8 weeks after drug initiation, i.e. later than most other immunologically mediated skin reactions. With re-exposure and perhaps depending upon the particular drug, there can be a shorter time to onset. Fever and a cutaneous eruption are the most

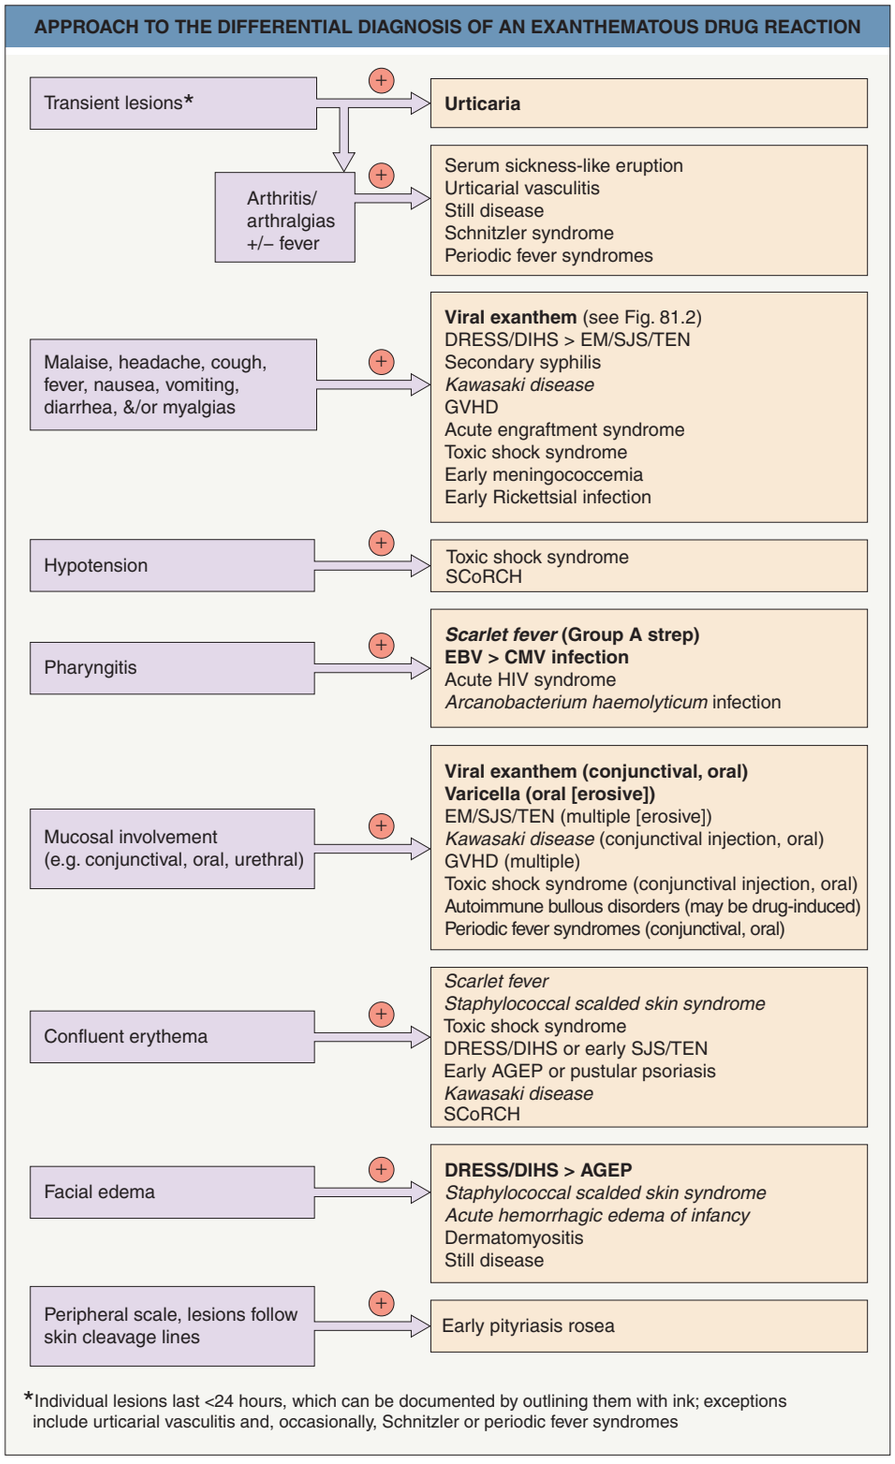

Fig. 21.4 Approach to the differential diagnosis of an exanthematous drug reaction. With a few exceptions (e.g. pityriasis rosea, drug-induced autoimmune bullous disorders), patients with these entities may be febrile. *Entities in italics occur primarily in children* and most common entities are in **bold**. Toxic shock syndrome can be staphylococcal or streptococcal (see Ch. 74). Drug-induced autoimmune bullous disorders: bullous pemphigoid or linear IgA bullous dermatosis > drug-induced pemphigus. Trimethoprim-sulfamethoxazole-associated sudden conjunctivitis, lymphopenia, and rash combined with hemodynamic changes (SCoRCH) is a rare disorder that presents with generalized sunburn-like erythema, fever, hypotension, and mild facial and acral edema as well as kidney and/or liver involvement; it can appear within a day if prior exposure and between 4 to 11 days if no prior exposure.

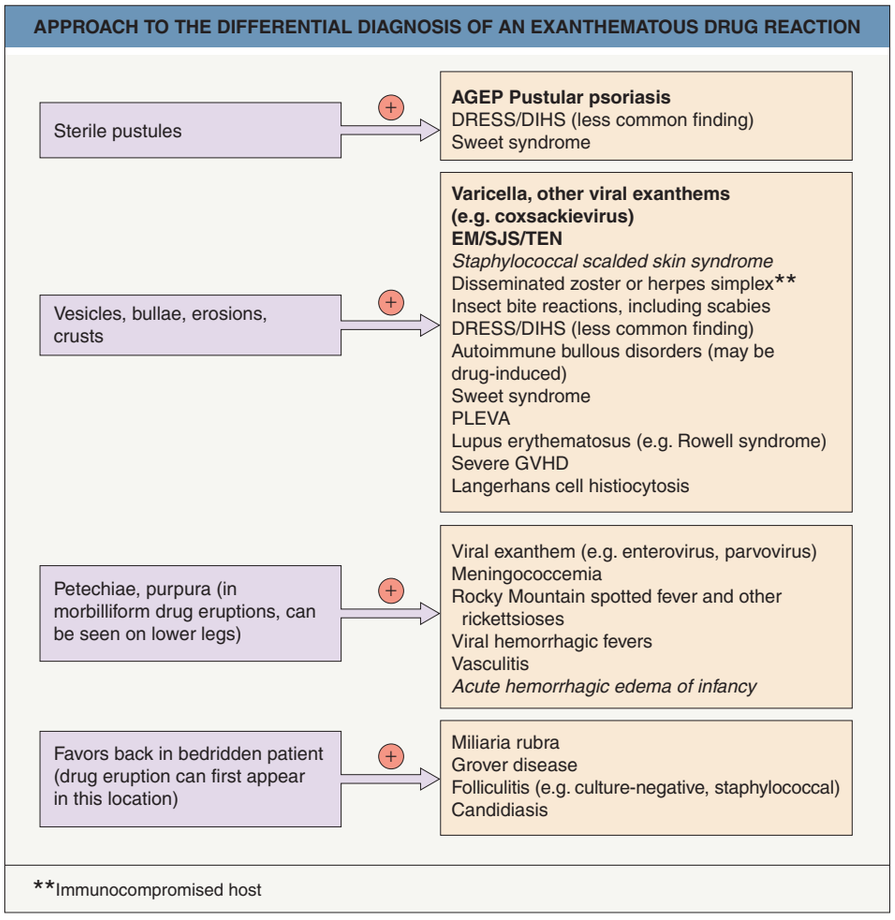

Fig. 21.4 Approach to the differential diagnosis of an exanthematous drug reaction. AGEP, acute generalized exanthematous pustulosis; CMV, cytomegalovirus; DIHS, drug-induced hypersensitivity syndrome; DRESS, drug reaction with eosinophilia and systemic symptoms; EBV, Epstein–Barr virus; EM, erythema multiforme; GVHD, graft-versus-host disease; PLEVA, pityriasis lichenoides et varioliformis acuta; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

J-SCAR DIAGNOSTIC CRITERIA FOR DRESS/DIHS
1. Maculopapular rash developing >3 weeks after starting therapy with a limited number of drugs
2. Prolonged clinical symptoms after discontinuation of the causative drug
3. Fever (>38°C)
4. Liver abnormalities (ALT >100 U/L)*
5. Leukocyte abnormalities (at least one present): (a) leukocytosis (>11 × 10^9/L); (b) atypical lymphocytes (>5%); and (c) eosinophilia (>1.5 × 10^9/L)
6. Lymphadenopathy
7. HHV-6 reactivation
*This can be replaced by other organ involvement (e.g. renal).

Table 21.10 Japanese Research Committee on Severe Cutaneous Adverse [Drug] Reactions (J-SCAR) diagnostic criteria for DRESS (drug reaction with eosinophilia and systemic symptoms)/DIHS (drug-induced hypersensitivity syndrome). Typical DIHS is defined as the presence of all 7 criteria, while atypical DIHS is defined as the presence of only the first 5 criteria.

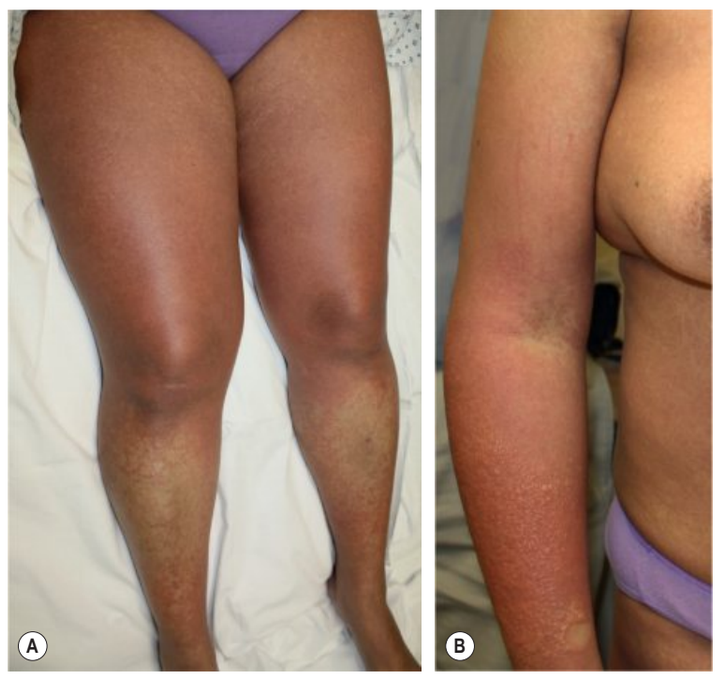

Fig. 21.5 Drug reaction with eosinophilia and systemic symptoms (DRESS) due to carbamazepine. A Exanthematous eruption with confluence on the thighs. **B** Edema and vesiculation on the forearm. *Courtesy Alicia Little, MD.*

common symptoms, seen in 85% and 75% of patients, respectively[21,29]. Cutaneous involvement usually begins as a morbilliform eruption (Fig. 21.5A), which later becomes edematous and oftentimes more extensive and sometimes erythrodermic. Less common manifestations include vesicles (Fig. 21.5B), follicular or non-follicular pustules (~20% of patients, overlapping with AGEP), and erythema multiforme-like or purpuric lesions. The face, upper trunk, and extremities are usually the initial sites of involvement. Edema of the face is a frequent finding and is a hallmark of DRESS whereas mucosal involvement, if present, is mild.

The major internal manifestations include lymphadenopathy and hepatitis (~80% of patients); rarely, the latter may become life-threatening (see Tables 21.9 and 21.10). Patients may also develop renal involvement (e.g. interstitial nephritis), myocarditis, interstitial pneumonitis, myositis, thyroiditis, and even infiltration of the brain by eosinophils. Of note, DRESS has overlap with and/or may progress to hemophagocytic lymphohistiocytosis. The cutaneous and visceral involvement may persist for several weeks or months after drug withdrawal, and additional sites of involvement (e.g. cardiac, thyroid) may develop weeks or months later, including following a taper of corticosteroids. Overall mortality due to DRESS ranges from 2% to 10%[21]. Possible predictors of more severe disease include a higher fever (>38.5°C), purpura, erythema multiforme-like lesions, and histologic features of severe dyskeratosis, interface dermatitis, and an intense lymphocytic infiltrate with atypical lymphocytes.

ASSESSMENT AND LONGITUDINAL EVALUATION OF PATIENTS WITH DRESS (DRUG REACTION WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS)
Basic laboratory screening during the acute phase with recommended repetitive tests *in italics**
• *CBC with differential, platelet count*, peripheral smear for atypical lymphocytes • *BUN, creatinine, urinalysis*, spot urine for protein : creatinine ratio† • *LFTs, creatine kinase (CK)*, lipase, CRP • *TSH, free T4* (repeat at 3 months, 1 year, and 2 years) • Fasting glucose (in anticipation of systemic corticosteroids)
Additional testing
• ECG, troponin T, baseline echocardiogram • Quantitative PCR for HHV-6, HHV-7, EBV, CMV • Wright stain of urine for eosinophilia (prior to instituting corticosteroids) • ANA, blood cultures (exclusion criteria in RegiSCAR scoring system) • If hemophagocytic lymphohistiocytosis suspected (see Ch. 91)‡: ferritin, triglycerides, LDH, BM examination
Further testing based upon laboratory abnormalities or signs and symptoms‡
• Liver – PT, PTT, albumin • Renal – albumin, renal ultrasound (if laboratory abnormalities) • Cardiac – ECG, troponin T, echocardiogram • Neurologic – brain MRI • Pulmonary – CXR, PFTs • Gastrointestinal – endoscopy • Pancreas – amylase, lipase, CT abdomen; rarely type I diabetes mellitus
*Testing is more frequent during the acute phase (e.g. twice weekly) with frequency also a reflection of disease severity. Longitudinal evaluation is recommended for at least one year. †Allows for immediate assessment for proteinuria. ‡Including during longitudinal evaluation.

Table 21.11 Assessment and longitudinal evaluation of patients with DRESS (drug reaction with eosinophilia and systemic symptoms). BM, bone marrow; BUN, blood urea nitrogen; CBC, complete blood count; CK, creatine kinase; CRP, C-reactive protein; LDH, lactic dehydrogenase; LFTs, liver function tests; PFT, pulmonary function test; PT, prothrombin time; PTT, partial thromboplastin time; TSH, thyroid stimulating hormone.

DRUGS ASSOCIATED WITH DRUG REACTION WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS (DRESS)	
Drug category	**Specific drugs**
Anticonvulsants	**Carbamazepine, lamotrigine*, phenobarbital, phenytoin**, oxcarbazepine, zonisamide > gabapentin, valproic acid
Antimicrobials	Amoxicillin, ampicillin, azithromycin, cefotaxime, **dapsone**, ethambutol, isoniazid, levofloxacin, linezolid, metronidazole, **minocycline**, piperacillin/tazobactam, pyrazinamide, quinine, rifampin, streptomycin, **sulfasalazine**, teicoplanin, **trimethoprim–sulfamethoxazole**, **vancomycin****
Antiretrovirals	**Abacavir**, **nevirapine**, zalcitabine
Analgesics/NSAIDS	Acetaminophen, celecoxib, diclofenac, ibuprofen
Antidepressants	Bupropion, fluoxetine
Antihypertensives	Amlodipine, captopril
Direct acting antivirals for hepatitis C	Boceprevir, telaprevir
Immune checkpoint inhibitors	Durvalumab, **ipilimumab**, nivolumab
Targeted therapies for cancer	Imatinib, sorafenib, **vemurafenib†**, vismodegib
Miscellaneous	**Allopurinol‡**, azathioprine, fluindione, hydroxychloroquine, lenalidomide, mexiletine, omeprazole, olanzapine, phenindione, ranitidine, strontium ranelate, ziprasidone; radiocontrast media
*Especially when coadministered with valproic acid. **Higher trough levels and re-exposure may be risk factors. †Increased risk after immune checkpoint inhibitor therapy and may have earlier onset. ‡Full doses in the setting of renal dysfunction a risk factor.	

Table 21.12 Drugs associated with drug reaction with eosinophilia and systemic symptoms (DRESS). Most commonly associated drugs are in **bold**. NSAIDs, nonsteroidal anti-inflammatory drugs.

Histologically, various inflammatory patterns can be seen, including eczematous, interface dermatitis, AGEP-like, and erythema multiforme-like. Prominent peripheral blood eosinophilia is common and is a very characteristic feature. It is often accompanied, and sometimes replaced, by mononucleosis-like atypical lymphocytosis. Elevation of hepatic enzymes can be a worrisome finding and requires serial evaluation. Thyroid and cardiac dysfunction (as detected by an ECG and echocardiogram) may develop as delayed complications and patients should therefore undergo longitudinal evaluation (Table 21.11).

The major entities in the differential diagnosis include other cutaneous drug eruptions, viral infections, hypereosinophilic syndrome, lymphoma (especially angioimmunoblastic T cell lymphoma), and pseudolymphoma (e.g. HIV-related $CD8^+$ cutaneous pseudolymphoma)[27]. Involvement of multiple internal organs differentiates DRESS from the more common morbilliform eruptions. In addition to the most common etiologies – the aromatic anticonvulsants (phenobarbital, carbamazepine, and phenytoin), lamotrigine (especially when coadministered with valproic acid), and sulfonamides – vancomycin, minocycline, allopurinol, and dapsone may also induce this syndrome, as well as drugs used to treat HIV infection (e.g. abacavir) and targeted therapies for cancer (e.g. vemurafenib; Table 21.12).

Early withdrawal of the culprit drug is mandatory, but this may not result in a rapid complete recovery. Although guidelines for the treatment of DRESS are still lacking, systemic corticosteroids (oral or intravenous) typically represent first-line therapy, at least in moderate-to-severe DRESS. Because relapse can occur when the dosage is reduced, a slow taper of corticosteroids over a period of 3 to 6 months is required[30]. In milder cases of DRESS, even in the setting of mild hepatitis, topical high-potency corticosteroids may be helpful and may lead to less viral reactivation[29]. In a recent trial of IVIg (without corticosteroids), there was an increased risk of complications, and little therapeutic benefit. There are also reports of successful treatment with cyclosporine or JAK inhibitors[30a,30b]. To date, antiviral strategies have only been proposed in case reports[31].

Fig. 21.6 Serum sickness due to antithymocyte globulin. The purpuric lesions are due to small vessel vasculitis in this patient with aplastic anemia. *Courtesy Jean L. Bolognia, MD.*

Serum Sickness-Like Eruption

This syndrome is more commonly observed in children and typically includes fever, arthralgias, arthritis, rash (urticarial, morbilliform), and lymphadenopathy[2]. It occurs 1 to 3 weeks after drug exposure. Unlike in "true" serum sickness due to non-human proteins (e.g. antithymocyte globulin, tositumomab, infliximab; Fig. 21.6), hypocomplementemia, circulating immune complexes, vasculitis, and renal disease are absent. This reaction occurs in approximately 1 in 2000 children given

cefaclor. Other drugs associated with serum sickness-like reactions are penicillins, NSAIDs, bupropion, phenytoin, sulfonamides, minocycline, and propranolol.

Vasculitis (see Ch. 24)

Drug-induced cutaneous small vessel vasculitis (CSVV) accounts for ~10% of all cases of CSVV and typically involves small vessels and in some patients medium-sized vessels. Drug-induced CSVV may be either a type II (cytotoxic) or a type III (immune complex) drug reaction.

Clinically, drug-induced CSVV usually presents as purpuric papules, primarily on the lower extremities. Urticaria-like lesions, hemorrhagic blisters, pustules, digital necrosis, and ulcers may also be seen. Systemic involvement is unusual, but suggestive symptoms are fever, myalgias, arthralgias, and/or headache. Internal manifestations include arthritis, nephritis, peripheral neuropathy, and gastrointestinal bleeding. Histopathologic examination demonstrates leukocytoclastic vasculitis.

Vasculitis usually develops 7 to 21 days after drug administration and within 3 days if a rechallenge. Systemic corticosteroids may benefit patients with systemic involvement; otherwise, discontinuing the culprit drug is usually sufficient. Additional management options are discussed in Chapter 24.

The primary medications associated with drug-induced CSVV include penicillins, NSAIDs (both oral and topical), sulfonamides, and cephalosporins; additional drugs are propylthiouracil, thiazide diuretics, furosemide, allopurinol, quinolones, levamisole, bortezomib, and systemic immunomodulators (e.g. granulocyte and granulocyte–macrophage colony-stimulating factors [G-CSF, GM-CSF], interferons, TNF inhibitors). ANCA-positive vasculitis with anti-myeloperoxidase antibodies has been associated with several drugs, including propylthiouracil, hydralazine, levamisole, and minocycline, and polyarteritis nodosa has been observed following hepatitis B vaccination[32] and in patients receiving minocycline.

Neutrophilic Drug Eruptions

Acute generalized exanthematous pustulosis

Synonyms: ■ Pustular drug eruption ■ Toxic pustuloderma

Acute generalized exanthematous pustulosis (AGEP) is an acute febrile drug eruption characterized by numerous small, primarily non-follicular, sterile pustules arising within large areas of edematous erythema. More than 90% of cases of AGEP are drug-induced. Occasionally, AGEP is due to other causes, e.g. enteroviral infection, exposure to mercury.

HLA-B5, -DR11, and -DQ3 have been found more frequently in patients with AGEP[33], and mutations in *IL36RN* may be a risk factor as well[34]. Prior sensitization (including contact sensitization) would explain the short interval (<4 days) between drug administration and the onset of the eruption, as this suggests an immunologic recall phenomenon. The percentage of positive patch tests to an incriminated drug is relatively high (50%–60%) (Fig. 21.7A)[15]. Blood neutrophilia and the accumulation of neutrophils within the lesions suggest the release of neutrophil-activating cytokines by drug-specific T lymphocytes (e.g. IL-3, IL-8, IL-17, G-CSF), but the precise underlying mechanisms of AGEP are still unknown.

Clinically, AGEP is characterized by a high fever, with skin lesions beginning on the face or in the major intertriginous zones (i.e. axillae and groin), followed by dissemination over a few hours. Numerous small (<5 mm), primarily non-follicular, sterile pustules arise within large areas of edematous erythema (Fig. 21.7B,C). There may be associated burning and/or pruritus. Lesions typically last from 1 to 2 weeks and are followed by superficial desquamation. In a series of 58 patients, systemic involvement was detected in a minority (17%) of patients, with the primary sites being the liver and kidneys followed by the lungs (acute respiratory distress)[34]. A validation score developed

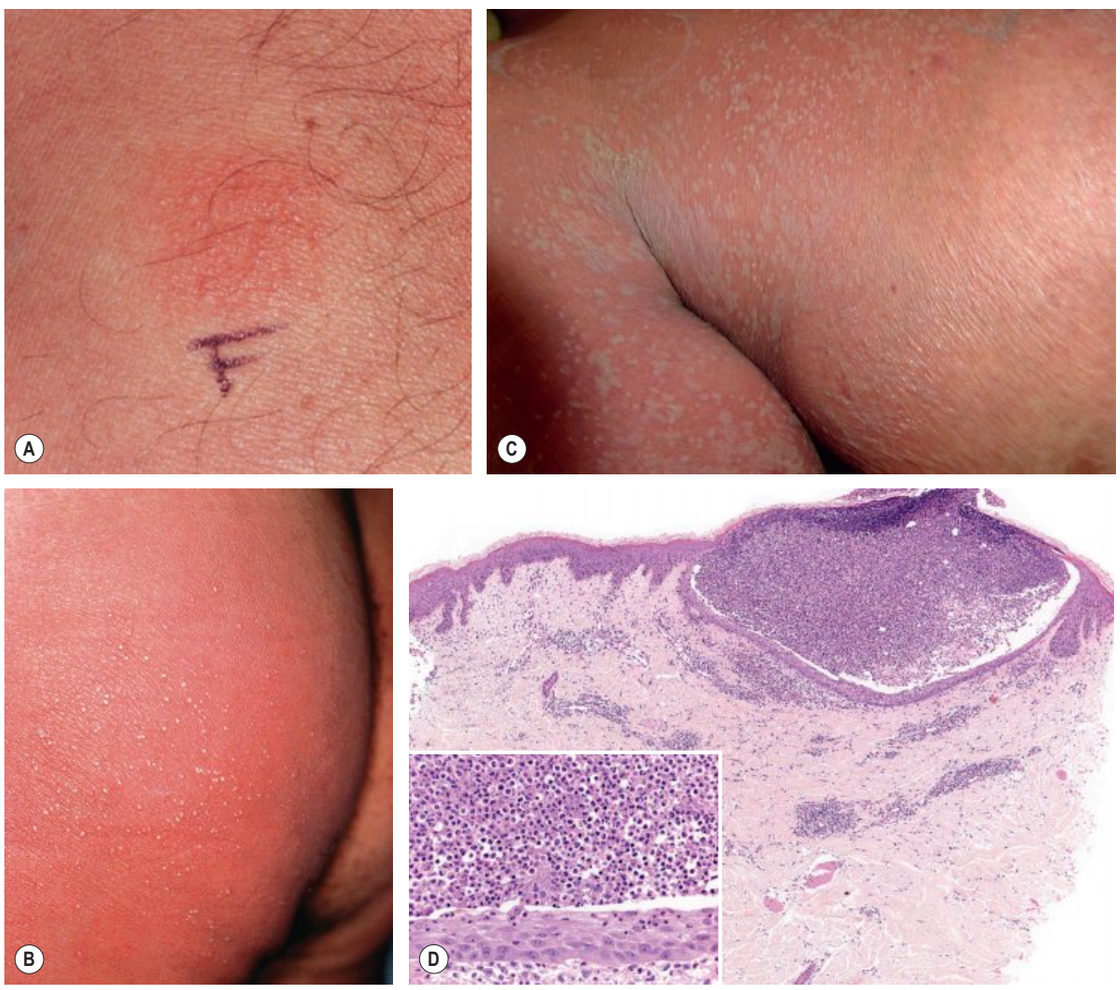

Fig. 21.7 Acute generalized exanthematous pustulosis (AGEP). **A** Positive patch test result 4 days following the application of 0.75% metronidazole in a patient with a previous pustular drug eruption to that medication. **B** Diffuse erythema of the buttock with multiple small sterile pustules due to a cephalosporin. **C** Numerous sterile pustules with superficial epidermal detachment in areas where the pustules have become confluent in a patient receiving amoxicillin. **D** Subcorneal pustule composed of neutrophils as well as scattered neutrophils within the epidermis (inset). *A, Courtesy Kalman Watsky, MD; C, Courtesy Laurence Valeyrie-Allanore, MD; D, Courtesy Lorenzo Cerroni, MD.*

AGEP – MOST COMMONLY ASSOCIATED MEDICATIONS	
• Acetaminophen • Antibiotics **Penicillins, aminopenicillins** Carbapenems **Cephalosporins** Chloramphenicol **Clindamycin** Gentamicin Isoniazid Macrolides Metronidazole **Pristinamycin** Quinolones **Sulfonamides** Tetracyclines Vancomycin	• Antimalarials, especially hydroxychloroquine • Antimycotics Amphotericin B Fluconazole Griseofulvin Itraconazole Ketoconazole Nystatin **Terbinafine** • Calcium channel blockers, especially **diltiazem** • Carbamazepine • Cetirizine • Herbal medicines • NSAIDs, including oxicam derivatives and COX-2 inhibitors • Proton pump inhibitors

Table 21.13 Acute generalized exanthematous pustulosis (AGEP) – most commonly associated medications. An annular variant can also occur, in particular with terbinafine and hydroxychloroquine, and the onset may be delayed. Common culprits are in **bold**.

by the EuroSCAR study group assists in categorizing cases as definite, probable, possible, or no AGEP[35].

Rarely, a localized variant of AGEP, referred to as acute localized exanthematous pustulosis (ALEP), occurs. There is involvement of a single site, most commonly the face, neck, or trunk, with ALEP most often due to b-lactam antibiotics. Fever and peripheral neutrophilia are associated findings.

Histologically, spongiform pustules are seen within the superficial layers of the epidermis (Fig. 21.7D). Edema of the papillary dermis and a perivascular mixed infiltrate with neutrophils and some eosinophils are usually present. A complete blood count typically reveals a marked leukocytosis with an elevated neutrophil count.

AGEP must be differentiated from acute pustular psoriasis of the von Zumbusch type; no personal history of psoriasis, rapid appearance, and recent drug exposure all favor AGEP. In severe forms of AGEP, the confluence of the pustules and subsequent superficial epidermal detachment may lead to confusion with TEN. However, the presence of subcorneal pustules in biopsy specimens allows one to distinguish between the two entities. In addition to facial edema, pustules may also be observed in DRESS, but the prolonged evolution, atypical lymphocytosis, marked hypereosinophilia, and common visceral involvement usually permit differentiation. That said, a true overlap drug reaction with features of both AGEP and DRESS may be observed[36].

Medications that most frequently induce AGEP include: (1) antibiotics, e.g. aminopenicillins, cephalosporins, clindamycin, and outside of the US, pristinamycin; and (2) calcium channel blockers, e.g. diltiazem. Additional associated drugs are listed in Table 21.13[37]. Withdrawal of the responsible drug is the major therapeutic intervention, in conjunction with topical corticosteroids and antipyretics.

Sweet syndrome (acute febrile neutrophilic dermatosis) (see Ch. 25)

Drug-induced Sweet syndrome is increasingly being recognized, but still remains a relatively unusual condition[38]. Sweet syndrome is characterized by fever, peripheral blood neutrophilia, and painful erythematous plaques that favor the face and upper extremities and contain dense neutrophilic dermal infiltrates. Neutrophilic infiltrates can be seen elsewhere, including the muscles and lung. In drug-induced Sweet syndrome, the lesions usually develop about a week after initial drug administration and neutrophilia is often absent. The latter finding most likely reflects the fact that drug-induced Sweet syndrome is frequently due to granulocyte growth factors used to reverse chemotherapy-induced neutropenia.

The list of drugs associated with drug-induced Sweet syndrome continues to expand. It includes granulocyte growth factors (G-CSF, GM-CSF, pegfilgrastim), all-*trans*-retinoic acid, other antineoplastic medications (e.g. bortezomib, FLT3 inhibitors, immune checkpoint inhibitors, imatinib, decitabine, azacitidine), antibiotics (e.g. trimethoprim–sulfamethoxazole, minocycline, quinolones), abacavir, azathioprine, furosemide, hydralazine, interferon-α, and NSAIDs[38]. Following withdrawal of the responsible drug, the fever abates in 1 to 3 days and the lesions disappear within 3 to 30 days. Systemic corticosteroids may be required in severe cases. Of note, when these medications are used to treat Sweet syndrome-associated disorders or treatment-associated neutropenia, timing of the eruption and degree of control of the underlying disorder need to be considered when determining underlying etiology.

Fig. 21.8 Iododerma. Edematous erythematous vesiculopustules on the buttocks with central crusts.

Halogenoderma

Bromoderma, fluoroderma, and iododerma are rare dermatoses that develop following exposure to bromides, fluorides, iodides, and iodine-containing compounds. The latter two groups are used as radiation protectants, in combination therapy for hyperthyroidism, and as expectorants (saturated solution of potassium iodide; SSKI). Systemic exposure to iodine-containing contrast media, irrigation of wounds with povidone-iodine, ingestion of iodide-containing supplements, and the use of amiodarone are additional causes of iododerma. One important risk factor for the development of these reactions is acute or chronic renal failure.

Halogens classically induce acneiform eruptions and pustules, but granulomatous or vegetative plaques, ulcers, and even bullae can be seen (Fig. 21.8). Although cutaneous lesions often appear after long-term exposure, they can appear in as quickly as a few days. Histologically, accumulation of neutrophils within the dermis is seen and exocytosis of neutrophils into the epidermis can lead to intraepidermal abscesses. In longer-standing lesions, papillomatosis develops. Histologic evaluation and measurement of blood levels of iodine and bromide aid in establishing the diagnosis. Halogenodermas may persist for weeks after drug withdrawal because of the slow elimination rate of iodides and bromides. Topical and systemic corticosteroids, in addition to diuretics, may hasten resolution, and, in severe cases, cyclosporine may be administered.

Other Neutrophilic Eruptions

Neutrophilic eccrine hidradenitis (NEH) is characterized by erythematous, often painful papules and plaques due to neutrophilic infiltrates around and within eccrine glands (Fig. 21.9). Common sites of involvement include the face, upper trunk, and dorsal aspect of the hands. NEH is most frequently seen 7–14 days after initiating chemotherapy, in particular cytarabine plus an anthracycline (e.g. idarubicin, mitoxantrone) for acute myelogenous leukemia; additional culprit drugs include bleomycin, imatinib, and G-CSF (see Ch. 39). Facial pustular neutrophilic eruption can be seen following SARS-CoV-2 vaccine administration.

Symmetrical Drug-Related Intertriginous and Flexural Exanthema (SDRIFE)

In SDRIFE, sharply demarcated, symmetrical areas of erythema develop in the anogenital region following exposure to a systemically administered drug, most commonly amoxicillin or another β-lactam antibiotic. Often based upon case reports, it has also been associated with other antimicrobials, radiocontrast media, and H2 blockers as well as the

Fig. 21.9 Neutrophilic eccrine hidradenitis. Erythematous plaques on the leg, which may be confused with Sweet syndrome. *Courtesy Laurence Valeyrie-Allanore, MD and Jean Revuz, MD.*

SYMMETRICAL DRUG-RELATED INTERTRIGINOUS AND FLEXURAL EXANTHEMA (SDRIFE) – CLINICAL CRITERIA AND REPORTED CULPRIT DRUGS	
Clinical criteria	
• Exposure to a *systemically* administered drug*, occurring with either the initial or a repeated dose (excluding contact allergens) • Sharply demarcated erythema of the gluteal/perianal area and/or V-shaped erythema of the inguinal/perigenital area • Involvement of at least one other intertriginous site/flexural fold • Symmetry of affected areas • Absence of systemic symptoms and signs	
Reported culprit drugs and vaccines	
Antimicrobials	HCTZ/telmisartan
Azoles	IVIg
β-Lactams	Mitomycin
Clindamycin	NSAIDs (e.g. celecoxib)
Macrolides	Oxycodone
Metronidazole	Progestin/estrogen vaginal ring
Terbinafine	Proton pump inhibitors
Tetracyclines	**Radiocontrast media**
Valacyclovir	Risperidone
Acetaminophen	Tacrolimus
Allopurinol	Traditional Chinese medicine
EGFR inhibitors (e.g. cetuximab, gefitinib)	TNF inhibitors
Everolimus	Zoledronic acid
H2 blockers (e.g. cimetidine, famotidine)	SARS-CoV-2 vaccine
*Not a chemotherapeutic agent so as to not confuse with toxic erythema of chemotherapy.	

Table 21.14 Symmetrical drug-related intertriginous and flexural exanthema (SDRIFE) – clinical criteria and reported culprit drugs. This entity is also referred to as drug-induced intertrigo, flexural drug eruption, and baboon syndrome. The latter term is also used to describe a form of systemic contact dermatitis. More common culprit drugs are in **bold**. *Adapted from Häusermann P, Harr TH, Bircher AJ. Baboon syndrome resulting from systemic drugs: is there strife between SDRIFE and allergic contact dermatitis syndrome? Contact Derm 2004;51:297–310.*

medications listed in Table 21.14. Typically, there is involvement of at least one other flexural site. Confusion arises because some patients with systemic contact dermatitis may have erythema of the buttocks and upper inner thighs, with both the latter clinical presentation – as well as SDRIFE – sometimes referred to as baboon syndrome. The differential diagnosis also includes fixed drug eruption and toxic erythema of chemotherapy, but the history of chemotherapy administration 2–4 weeks earlier permits distinction.

Bullous Eruptions

Fixed drug eruption

In fixed drug eruption (FDE), lesions develop from a few days to two weeks after the initial exposure. With subsequent exposures, they usually appear within 24 hours. However, because the first episode is often undiagnosed or underdiagnosed, a brief time interval is most commonly observed. Clinically, one or a few round to oval, sharply demarcated, erythematous to dusky violet plaques are seen (Fig. 21.10A,B). Associated edema varies and vesiculobullae may develop centrally (bullous FDE), followed by erosions due to epidermal detachment (Fig. 21.10B–E).

Lesions can appear anywhere on the body, as well as the mucous membranes (Fig. 21.10F), with common sites being the lips, face, hands, feet, and genitalia. Over several days, the lesions fade and often, but not always, leave residual postinflammatory brown pigmentation (Fig. 21.10G,H). Upon readministration of the causative drug, lesions recur in exactly the same sites. With each subsequent recurrence, additional sites of involvement may appear or the number of lesions may remain constant. The presence of numerous lesions, involving more than two or three anatomical sites, is referred to as generalized bullous FDE (GBFDE; see Fig. 21.10D,E), and it may be difficult to distinguish from TEN (especially when the oral mucosa is also involved), but an asymmetric distribution pattern and large skip areas point to GBFDE. GBFDE occurs more commonly in older patients, and prognosis correlates with the extent of skin detachment[39].

A non-pigmenting variant of FDE, characterized by large erythematous edematous plaques, has also been described. It occurs primarily after administration of pseudoephedrine, but has been observed with other drugs, e.g. NSAIDs, acetaminophen, tetrahydrozoline (eye drops). Linear FDE is a rare variant that may be confused with linear lichen planus. The proposed pathogenic events in FDE are depicted in Fig. 11.3.

Histopathology reveals a lichenoid infiltrate composed of lymphocytes admixed with eosinophils, and sometimes neutrophils. There are usually scattered necrotic keratinocytes in the epidermis (Fig. 21.11A) or rarely extensive epidermal necrosis that is indistinguishable from SJS/TEN (Fig. 21.11B); deeper extension of the infiltrate and more prominent melanin incontinence point to FDE. Dermal melanophages are often the only histologic finding in non-inflammatory lesions.

The drugs most frequently associated with FDE include antibiotics (sulfonamides, tetracyclines > β-lactams, fluoroquinolones, macrolides), NSAIDs, acetaminophen, aspirin, barbiturates, dapsone, proton pump inhibitors, and azole antifungal drugs[40]. In some patients, the responsible drug can be readministered without inducing an exacerbation, and there may be a refractory period after the occurrence of a fixed eruption. Provocation via patch testing in a previously *involved* site may be useful in determining the responsible drug (as long as not performed during the refractory period; see Table 21.7).

If there is a single lesion, the differential diagnosis includes a spider or arthropod bite reaction whereas when there are multiple lesions, it includes erythema multiforme and TEN. Genital and periungual lesions may be misdiagnosed as a recurrent HSV infection or paronychia, respectively.

Linear IgA bullous dermatosis

Linear IgA bullous dermatosis (LABD) is an autoantibody-mediated subepidermal blistering disease that may be drug-induced. Tense vesicles and bullae appear 24 hours to 15 days after the culprit medication is begun. The blisters often have an annular configuration, as in the idiopathic form of the disease (see Ch. 31), but there can also be a TEN-like clinical presentation, especially when due to vancomycin[41]. Histologic examination shows subepidermal bullae with neutrophils in the dermis. Direct immunofluorescence reveals linear deposition of IgA (+/– IgG, C3) within the basement membrane zone. Most patients lack circulating IgA autoantibodies. Resolution occurs within 2 to 5 weeks of discontinuation of the responsible medication. Vancomycin is the most common cause of drug-induced LABD; less often β-lactam antibiotics, captopril, NSAIDs, phenytoin, sulfonamide antibiotics, amiodarone, furosemide, lithium, rifampin, and G-CSF are the inciting drugs (see Table 31.5)[41]. The origin of the drug exposure may initially be obscure as in vancomycin-loaded bone cement spacers.

Fig. 21.10 Fixed drug eruptions. A An oval, well-demarcated red–brown plaque with a more erythematous border. **B** Multiple round violet-colored lesions with central bullae. **C** Erosive lesion of the penis due to epidermal detachment; this clinical presentation is sometimes misdiagnosed as recurrent HSV infection. **D, E** Generalized bullous FDE with involvement of the genitalia and intertriginous zones; erosions are seen following rupture of the bullae. Because of its more widespread distribution, this variant can be confused with TEN. **F** In the mouth, mucosal detachment leads to erosions. **G** As the inflammation resolves, the lesion acquires a brown hue. **H** Once inflammation is completely resolved, circular or oval areas of hyperpigmentation are commonly seen. Responsible drugs were phenolphthalein (**A**), acetaminophen (**B**), ciprofloxacin (**C**), naproxen (**D**), pseudoephedrine (**E**), allopurinol (**F**), metronidazole (**G**), and trimethoprim–sulfamethoxazole (**H**). *B, Courtesy Jeffrey P. Callen, MD, and Tyler Geers, MD; C, F, G, Courtesy Kalman Watsky, MD; D, Courtesy Sara Perkins, MD; E, Courtesy Edward W. Cowen, MD; H, Courtesy Mary Stone, MD.*

Drug-induced bullous pemphigoid

Drug-induced bullous pemphigoid (BP) may occur up to months after initial administration of a new medication. The clinical presentation is similar to the spontaneous form of this autoimmune disorder. Three major classes of inducers have been identified – diuretics (e.g. furosemide, spironolactone), neuroleptics (e.g. phenothiazine), and more recently, dipeptidyl peptidase 4 inhibitors ("gliptins") that function as hypoglycemic agents[42,43]. Anti-PD-1/PD-L1 antibodies have also been recognized as triggers of BP (see Ch. 30)[44]. The histologic and direct immunofluorescence findings are similar to those observed in BP, and the possibility of drug-induced disease should always be considered.

Drug-induced pemphigus vulgaris and pemphigus foliaceus are discussed in Chapter 29.

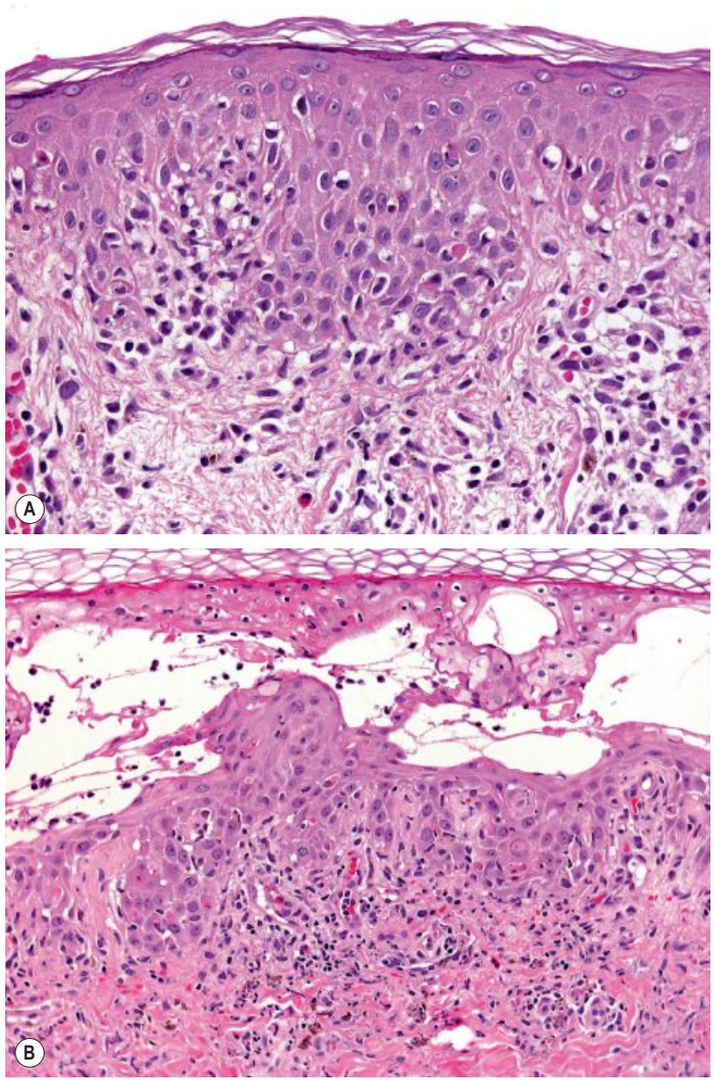

Fig. 21.11 Fixed drug eruptions – histopathologic features. A A few necrotic keratinocytes, mild vacuolar changes at the dermal–epidermal junction, papillary dermal edema, and melanophages can be seen as well as a mixed infiltrate with neutrophils and an occasional eosinophil. **B** Sometimes there is more extensive epidermal necrosis. *Courtesy Lorenzo Cerroni, MD.*

Stevens–Johnson syndrome and toxic epidermal necrolysis (see Ch. 20)

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are considered rare, life-threatening, drug-induced skin reactions within a clinical spectrum[45] and early detection is essential[2]. During the acute phase, the mean mortality rate is ~15% and depends upon body surface area involved as well as the level of supportive care[46,47].

These diseases are discussed in detail in Chapter 20.

Photosensitivity (see Ch. 87)

Cutaneous photosensitivity may be idiopathic, due to endogenous photosensitizers (e.g. porphyrins), or result from exogenous photosensitizers (e.g. medications). The combination of light (ultraviolet or visible) plus drug can lead to a range of cutaneous findings, but classically photosensitivity drug reactions are divided into two major types – phototoxic and photoallergic[48]. The former is more common than the latter.

Phototoxicity

Phototoxic drug reactions are usually predictable. They occur immediately after exposure to ultraviolet radiation (UVR) and are often dependent on the dose of the drug and/or UVR. There is a direct interaction of UVR with the drug (or its metabolite) within the skin such that an unstable singlet or triplet state is created, leading to the generation of reactive oxygen species. The latter are responsible for cellular damage.

Fig. 21.12 Phototoxic reaction in a patient receiving methotrexate. The erythema and bullae are obviously limited to sun-exposed sites and resemble an exaggerated sunburn. Patients on methotrexate can also experience a "sunburn-recall" phenomenon.

Fig. 21.13 Photolichenoid drug eruption due to hydrochlorothiazide. The lesions favored the extensor surfaces of the forearms.

Clinically, a phototoxic drug reaction usually resembles an exaggerated sunburn limited to sun-exposed sites (Fig. 21.12) and is often followed by postinflammatory hyperpigmentation. Histologically, necrotic keratinocytes are present as well as variable degrees of edema and vasodilation and a sparse lymphocytic infiltrate within the dermis.

Photo-onycholysis and pseudoporphyria are less common clinical presentations. In the former, the nail plate separates from the nail bed of several digits, with minimal nail bed changes. Fragility, erosions, and vesicles of the dorsal hands and face are observed in pseudoporphyria, but plasma porphyrins are normal (see Ch. 49).

The drugs most commonly responsible for phototoxic reactions contain ringed chemical structures and include doxycycline, quinolones, NSAIDs, thiazide diuretics, amiodarone, voriconazole, chlorpromazine, and vemurafenib[48] (see Table 87.5). Pseudoporphyria is most frequently linked to naproxen (see Table 49.5). For drugs with a short half-life, administration of the drug in the evening may decrease the risk below the clinical threshold for phototoxicity.

Photoallergy

Photoallergic drug reactions occur as a result of cell-mediated hypersensitivity to an allergen activated or produced by the effect of light on a drug (or its metabolite). UVR is required to convert the drug into an immunologically active compound (photoallergen) that induces the immune response. These reactions are idiosyncratic and can be maintained in the absence of excessive sun exposure.

Clinically, the lesions are pruritic and resemble eczema or lichen planus (Fig. 21.13); they are primarily in sun-exposed sites but may extend to

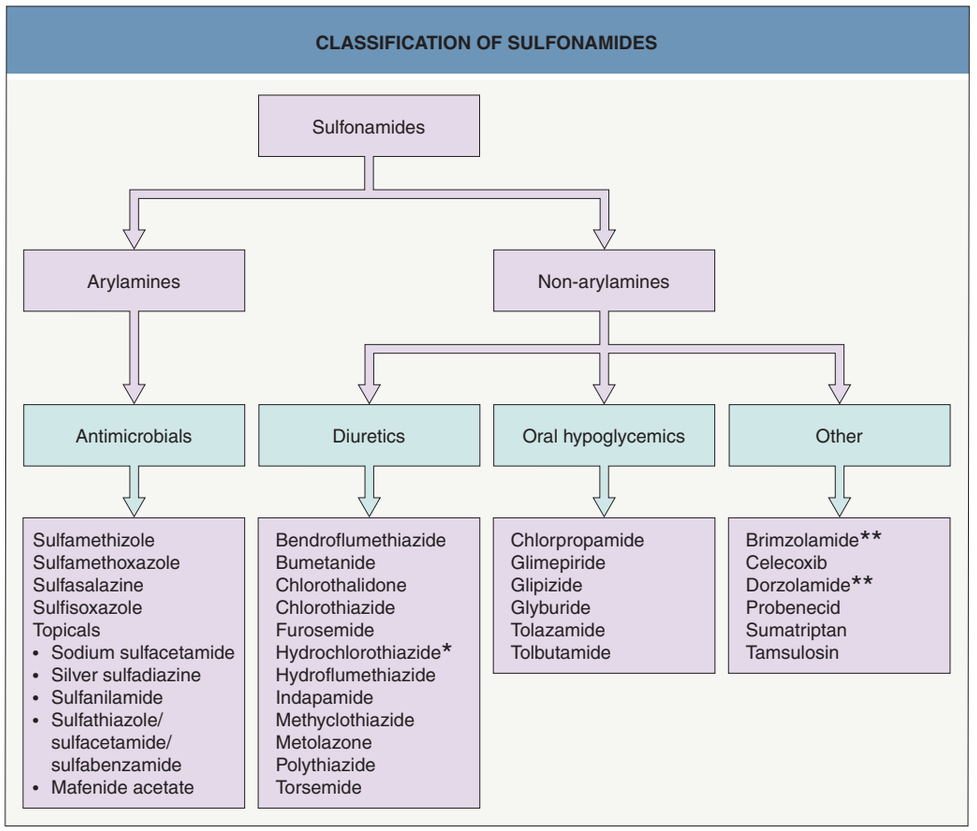

Fig. 21.14 Classification of sulfonamides. Approximately 10% of the patients with a history of a drug reaction to antimicrobial sulfonamides will also react to the non-arylamine sulfonamides. However, this is thought to be a reflection of a predisposition to allergic reactions rather than cross-reactivity. *Often combined with other antihypertensives, e.g. triamterene, angiotensin-converting enzyme inhibitors, β-blockers, angiotensin II receptor blockers. **Eyedrops.

non-sun-exposed areas. Chronic exposure to photoallergic drugs can, in an occasional patient, lead to extreme photosensitivity that persists for months to even years after the responsible drug is eliminated. These patients then fall within the spectrum of chronic actinic dermatitis (see Ch. 87). Photopatch testing can be useful in the clinical evaluation.

Classes of drugs commonly associated with photoallergic reactions include thiazide diuretics, sulfonamide antibiotics, sulfonylureas, and phenothiazines, all of which contain a sulfur moiety (Fig. 21.14). Additional medications that have been reported as photoallergens include quinine, quinidine, tricyclic antidepressants, griseofulvin, and both oral and topical NSAIDs. For example, topical ketoprofen is a frequent cause of photoallergic contact dermatitis.

In photoallergic reactions, drug withdrawal is recommended, given the risk of exacerbation even with relatively low-dose exposures to UVR and the risk of chronicity. Topical corticosteroids are a mainstay of therapy, along with physical barriers, reduced sun exposure, and broad-spectrum sunscreens.

Reactions to Anti-Neoplastic Agents – Chemotherapy, Targeted Therapy, and Immunotherapy

This group of medications can induce cutaneous reactions that range from benign to life-threatening[49], and their occurrence continues to rise as new antineoplastic agents are introduced.

Chemotherapy

Alopecia

One of the most common adverse reactions to chemotherapy is alopecia due to anagen effluvium in which there is an abrupt cessation of mitotic activity (Table 21.15)[50]. The alopecia involves primarily the scalp hairs, but other sites may be affected, such as the eyebrows and axillary and pubic regions. The hair loss is typically reversible, and the severity of alopecia depends primarily upon the specific drugs administered. However, drugs such as taxanes and busulfan can lead to irreversible diffuse thinning of scalp hair. Occasionally, patients with straight hair will develop curly hair when it regrows.

Scalp cooling during chemotherapy administration may diminish alopecia[51]. Possible mechanisms include local vasoconstriction of blood vessels, decreased follicle cell metabolic rate, reduced delivery of chemotherapy, and reduced cellular drug uptake. Cooling is begun 30 minutes prior to administration of chemotherapy and continued for at least 90 minutes following conclusion of the chemotherapy infusion. While scalp cooling is generally well tolerated, there are possible side effects including patient discomfort (feeling cold) and headache. In addition, it is to be avoided in patients with head and neck, CNS, or hematologic malignancies.

Stomatitis

Mucositis of the oral and gastrointestinal mucosae is a major, often dose-limiting, toxic effect of chemotherapy and it can be particularly severe when chemotherapy is combined with radiotherapy. Stomatitis occurs in over 40% of patients receiving chemotherapy and can be explained by:

- Direct drug-induced cytotoxic effects on the oral epithelial cells, which have a high mitotic index (Fig. 21.15).
- Indirect effects on the oral mucosa due to superimposed infections (e.g. *Candida*, herpes simplex virus) and/or hemorrhage, reflections of bone marrow suppression. These effects are typically observed at the therapeutic nadir of the white blood cell count. However, the prophylactic use of antivirals (e.g. acyclovir) and antifungals (e.g. fluconazole) as well as colony-stimulating factors (which reduce the duration of neutropenia) have decreased the impact of this second mechanism.

Dental evaluation and treatment prior to administering chemotherapy can reduce the risk of oral infections. Preventive measures include maintaining oral hygiene via the use of soft toothbrushes and rinsing with water and sodium bicarbonate. In addition to specific antimicrobial agents, topical anesthetics and anti-inflammatory agents may be helpful; in some patients, systemic analgesics are required. Occasionally, palifermin is prescribed, but its use can lead to white coating of the tongue and transient keratoses.

Additional reactions

Chemotherapeutic agents are also responsible for other mucocutaneous reactions such as ulcerations at sites of extravasation of intravenous

MUCOCUTANEOUS SIDE EFFECTS OF ANTINEOPLASTIC AGENTS	
Reactions	**Responsible drugs**
Alopecia, reversible	Alkylating agents: cyclophosphamide, ifosfamide, mechlorethamine (nitrogen mustard) Anthracyclines: daunorubicin, doxorubicin, idarubicin, mitoxantrone Endocrine therapy for breast cancer (pattern alopecia similar to androgenetic): tamoxifen, aromatase inhibitors (e.g. anastrozole, letrozole) Taxanes: paclitaxel, docetaxel Topoisomerase 1 inhibitors: topotecan, irinotecan Other: actinomycin D, busulfan, etoposide, gemcitabine, methotrexate, vincristine, vinblastine
Alopecia, irreversible	Busulfan, cyclophosphamide, thiotepa (conditioning regimens); docetaxel, paclitaxel
Mucositis	Anthracyclines (e.g. daunorubicin, doxorubicin), cyclophosphamide, etoposide, melphalan (high-dose), methotrexate (high-dose), taxanes, topotecan, continuous infusions of 5-FU, and prodrugs of 5-FU (e.g. capecitabine)
Extravasation reactions (e.g. chemical cellulitis, ulceration)	Anthracyclines, bendamustine, carmustine, 5-FU (irritant), mechlorethamine (vesicant), mitomycin C, vinblastine, vincristine, vinorelbine (vesicant)
Chemotherapy recall (tender sterile inflammatory nodules at sites of previous chemotherapy extravasation or administration)	Anthracyclines (e.g. doxorubicin, epirubicin), 5-FU, mitomycin C, paclitaxel
Hyperpigmentation (see Ch. 67)	Alkylating agents: bendamustine, busulfan, cisplatin, cyclophosphamide, mechlorethamine, melphalan Antimetabolites: capecitabine (5-FU prodrug), 5-FU, hydroxyurea, methotrexate Antitumor antibiotics: bleomycin, doxorubicin
Serpentine supravenous hyperpigmentation	Docetaxel, doxorubicin, 5-FU, fotemustine, vinorelbine; actinomycin D + vincristine, cisplatin + pemetrexed
Mucosal hyperpigmentation	Busulfan, cyclophosphamide, doxorubicin, 5-FU, hydroxyurea
Nail hyperpigmentation	Anthracyclines (e.g. daunorubicin, doxorubicin), bleomycin, cyclophosphamide, 5-FU, hydroxyurea, methotrexate
Onycholysis +/– subungual hemorrhage	Taxanes (e.g. paclitaxel, docetaxel [along with photosensitivity]); doxorubicin + cyclophosphamide
Radiation recall	Anthracyclines (e.g. daunorubicin, doxorubicin), capecitabine (5-FU prodrug), 5-FU, gemcitabine, taxanes > actinomycin D, dacarbazine, endocrine therapy (e.g. tamoxifen, letrozole), etoposide, hydroxyurea, melphalan, methotrexate, pemetrexed
Radiation enhancement	Doxorubicin, etoposide, 5-FU, gemcitabine, hydroxyurea, methotrexate, taxanes
Photosensitivity	5-FU and 5-FU prodrugs (e.g. capecitabine, tegafur), methotrexate, taxanes > dacarbazine, hydroxyurea, mitomycin C
Inflammation of "keratoses"	*Actinic keratoses*: 5-FU and 5-FU prodrugs (e.g. capecitabine), pentostatin, taxanes *Seborrheic keratoses*: cytarabine, taxanes *Disseminated superficial actinic porokeratosis:* 5-FU and 5-FU prodrugs, taxanes
Toxic erythema of chemotherapy: • Acral erythema (HFS) • Eccrine squamous syringometaplasia	 Anthracyclines, busulfan, clofarabine, cisplatin, cytarabine, fludarabine, 5-FU (prolonged infusions) and 5-FU prodrugs, methotrexate, taxanes (dorsal hands) Busulfan, carmustine, cyclophosphamide, cytarabine, taxanes
Neutrophilic eccrine hidradenitis	Anthracyclines, bleomycin, cyclophosphamide, cytarabine, topotecan
Ulcerations	Hydroxyurea (lower extremities), methotrexate (e.g. psoriatic plaques)
Nodulosis	Methotrexate (but usually in patients with rheumatoid arthritis)
Flushing	Asparaginase, high-dose BCNU, mithramycin
Periorbital edema	Pemetrexed (plus conjunctivitis and lower extremity edema)
Others:	*Acquired cutaneous adherence:* doxorubicin (plus ketoconazole*) *Dermatomyositis-like eruption:* hydroxyurea *Eccrine poromatosis*: polychemotherapy *Exanthematous eruption:* bleomycin, carboplatin, cladribine, cytarabine, doxorubicin, gemcitabine, methotrexate, paclitaxel, pemetrexed *Palmoplantar hyperkeratosis:* capecitabine, tegafur *Paraneoplastic pemphigus-like:* fludarabine *Pseudocellulitis and acute lipodermatosclerosis-like reaction:* gemcitabine *SJS/TEN:* bendamustine, bleomycin, busulfan, cyclophosphamide, docetaxel, doxorubicin, etoposide, methotrexate *Scleroderma-like reaction (especially extremities):* bleomycin, gemcitabine, pemetrexed, taxanes *SCLE:* taxanes, 5-FU and 5-FU prodrugs, doxorubicin + cyclophosphamide, gemcitabine *Urticaria:* asparaginase, bleomycin, chlorambucil, cyclophosphamide, daunorubicin *Vasculitis:* busulfan, cyclophosphamide, gemcitabine, hydroxyurea, levamisole, pemetrexed
*Rarely used nowadays.	

Table 21.15 Mucocutaneous side effects of antineoplastic agents. The mucocutaneous side effects of targeted therapies are reviewed in Table 21.16. Cutaneous squamous cell carcinomas are most commonly associated with fludarabine, hydroxyurea, and topical BCNU. Related side effects are shaded. 5-FU, 5-fluorouracil; HFS, hand–foot syndrome; SCLE, subacute cutaneous lupus erythematosus; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

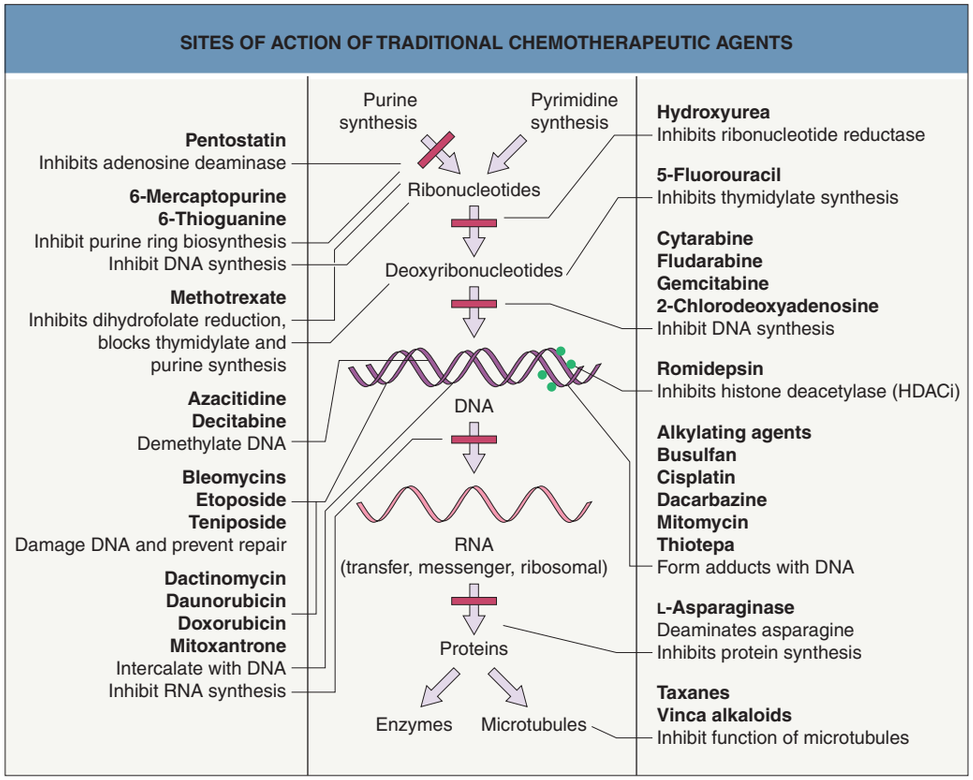

Fig. 21.15 Sites of action of chemotherapeutic agents. *Adapted with permission from Brunton L, Lazo J, Parker K (eds.). Goodman & Gilman's The Pharmacological Basis of Therapeutics, 11th edn. New York: McGraw-Hill Medical, 2005.*

medications; skin, oral, and nail hyperpigmentation (Fig. 21.16A); and acral erythema (Fig. 21.16C,D), also known as erythrodysesthesia. The frequency of extravasations has been markedly reduced by the use of "permanent" central venous catheters, whereas the incidence of acral erythema has increased in the setting of prolonged infusions of drugs and the chronic use of oral multi-kinase inhibitors (see below).

A variety of terms have been used to describe the cutaneous toxic effects of chemotherapy, e.g. "palmoplantar erythrodysesthesia", "hand–foot syndrome", "eccrine squamous syringometaplasia", "intertrigo eruption of chemotherapy", "malignant intertrigo", and "epidermal dysmaturation", creating some confusion. There is considerable overlap in the appearance of the symmetric erythematous to dusky patches which can develop edema, desquamation, and/or purpura (depending on the patient's platelet count), whether they favor acral sites, intertriginous zones, the scrotum, or the elbows and knees (Fig. 21.17). "Toxic erythema of chemotherapy" has been suggested as an encompassing term that allows simplification (Fig. 21.18). Treatment options include reduction of the chemotherapy dose, analgesia, topical medications (e.g. corticosteroids), high-dose vitamin D, low-dose acitretin for hyperkeratosis, and perhaps regional cooling as a preventive measure.

Additional reactions to chemotherapy include radiation recall or enhancement; photosensitivity (see Fig. 21.12); inflammation of pre-existing actinic or seborrheic keratoses (Fig. 21.16B); necrosis of plaques of psoriasis (see Fig. 21.1B) or mycosis fungoides; Raynaud phenomenon with digital necrosis (Fig. 21.16E); flagellate erythema or hyperpigmentation (Fig. 21.16F); and neutrophilic eccrine hidradenitis (see Fig. 21.9). Long-term administration of hydroxyurea is associated with the development of painful ulcerations of the malleolar region of the lower extremities as well as the development of cutaneous malignancies (see Fig. 105.20F). The ulcers may be difficult to heal unless the hydroxyurea is discontinued.

Targeted therapy

The use of targeted therapies that act on cell-surface receptors and intracellular signaling pathways is rapidly increasing[52]. Examples include specific inhibitors of VEGFR and EGFR and multi-kinase inhibitors that target the KIT receptor and mitogen-activated protein (MAP) kinase pathway (see Ch. 113). The side effects of targeted therapies and newer antineoplastic agents are outlined in Tables 21.16 and 21.17, respectively. Hand–foot skin reaction (HFSR), presenting with acral hyperkeratosis, erythema and occasionally blisters, is particularly prevalent with certain multi-kinase inhibitors (e.g. sorafenib, regorafenib). It can be treated with topical corticosteroids and keratolytics, avoidance of heat, trauma and irritants, and a drug holiday followed by dose reduction in severe cases.

Immunotherapy

As with targeted agents, the use of immunotherapies is expanding exponentially. ICIs are being used for common malignancies such as non-small-cell lung cancer as well as metastatic melanoma. The side effects of anti-CTLA-4 (e.g. ipilimumab), anti-PD-1 (e.g. nivolumab), and anti-PD-L1 (e.g. atezolizumab) antibodies are outlined in Table 21.18. The skin is the most common site for *i*mmune-*r*elated *a*dverse *e*vents (irAEs; Fig. 21.19) and often is the initial site, with an onset within six weeks. However, appearance of cutaneous side effects can be delayed and may even appear after discontinuation of the immunotherapy. Along with pruritus, morbilliform, psoriasiform, eczematous, and lichenoid dermatoses are most frequently observed and they are usually managed with topical therapies and continuation of immunotherapy (see Ch. 11). Less often, patients develop bullous pemphigoid or SCARs (e.g. SJS/TEN, DRESS). The appearance of irAEs, in particular vitiligo-like depigmentation in patients with melanoma, has been associated with improved tumor response rate and survival[53].

Drug-Induced Adverse Reactions Involving Hair and Mucosae

Hair

A considerable number of medications induce hair loss[51]. They affect the hair follicles via two major mechanisms: anagen effluvium (abrupt interruption of the active growth phase) and telogen effluvium (an increased number of hairs in the resting phase). In the former, hair loss occurs within 2 to 3 weeks of drug administration as with cytotoxic chemotherapy, whereas in telogen effluvium, there is usually a delay of 2 to 4 months. Clinically, both are diffuse non-scarring alopecias (see Ch. 69). The hair loss is usually reversible after discontinuation of the responsible agent. Diagnosis of drug-induced telogen effluvium can be difficult and requires observation of improvement after the suspected drug has been withdrawn. Table 21.19 lists a number of the drugs associated with alopecia, including β-blockers, lithium, retinoids, and heparin.

Fig. 21.16 Cutaneous side effects and complications of chemotherapeutic agents. A Horizontal melanonychia due to 5-fluorouracil. **B** Inflammation surrounding a seborrheic keratosis in a patient receiving paclitaxel. **C** Toxic erythema of chemotherapy (TEC) due to cytarabine, with obvious painful acral erythema involving the plantar surface. **D** TEC, also referred to as hand–foot syndrome when localized, due to capecitabine; diffuse glazed erythema and mild hyperkeratosis of palmoplantar skin. **E** Raynaud phenomenon and digital necrosis due to systemic bleomycin. **F** Multiple linear (flagellate) erythematous urticarial plaques in a patient receiving systemic bleomycin for Hodgkin lymphoma. **G** Chemical cellulitis due to extravasation of enfortumab vedotin (anti-Nectin-4 antibody attached to monomethyl auristatin, a cytotoxic microtubule inhibitor). *A–C, Courtesy Jean L. Bolognia, MD; D, F, Courtesy Kalman Watsky, MD; G, Courtesy Katherine Given, MD.*

Fig. 21.17 Toxic erythema of chemotherapy. Symmetric involvement of intertriginous zones and the scrotum. There is central desquamation and some of the lesions have a dusky color. The patient was receiving fludarabine plus intravenous busulfan. *Courtesy Leonard Kristal, MD.*

With regard to drug-induced hair growth, it is important to distinguish between hypertrichosis and hirsutism. The associated medications for both entities are discussed in Chapter 70.

Mucosal ulcerations

Stomatitis with erosions and ulcerations may occur either as part of a drug-induced mucocutaneous syndrome (e.g. FDE, SJS/TEN) or as a side effect of chemotherapy (see above & Table 21.15)[49]. In addition to cytotoxic drugs (e.g. methotrexate), several drug classes can cause oral ulcerations, including calcineurin inhibitors, anticholinergic bronchodilators, NSAIDs including acetylsalicylic acid, antihypertensives (e.g. β-blockers), antiretrovirals (e.g. protease inhibitors), bisphosphonates, platelet aggregation inhibitors, and vasodilators (e.g. nicorandil). Medications more commonly prescribed in the past such as metamizole, phenylbutazone, D-penicillamine, and gold salts can also produce oral ulcers. Additionally, allergic reactions to dental materials and exposure to metals such as mercuric chloride or copper sulfate may cause stomatitis. Irritation secondary to drugs excreted in the urine, such as foscarnet, can lead to penile ulceration.

Other Drug-Induced Cutaneous Reactions

Acneiform eruptions (including folliculitis)

Acneiform eruptions represent ~1% of drug-induced skin eruptions. Clinically, papules and/or pustules are seen primarily on the face and upper trunk, the same sites favored by acne; comedones are usually absent unless androgens are the cause. The interval between drug

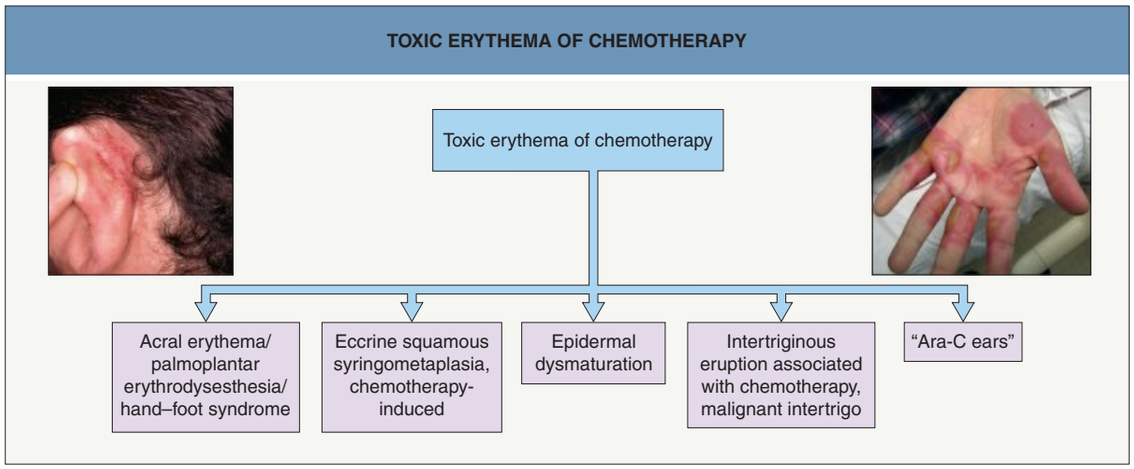

Fig. 21.18 Toxic erythema of chemotherapy. Use of a number of terms (especially those based on histologic findings), including palmoplantar erythrodysesthesia, eccrine squamous syringometaplasia and epidermal dysmaturation, has created some confusion for clinicians. There is considerable overlap in the appearance of the symmetric erythematous to dusky patches which can develop edema, erosions, desquamation or purpura, whether they favor acral sites, intertriginous zones, or the elbows and knees. "Toxic erythema of chemotherapy" has been suggested as an encompassing term that allows simplification. In addition, there is no need to implicate additional diagnoses when lesions are not limited to the hands and feet. Insets: Erythema of the ears due to cytarabine (cytosine arabinoside), sometimes referred to as "Ara-C ears"; the petechiae are due to thrombocytopenia. Dusky edematous plaques of the palm, some of which have developed sterile bullae. *Courtesy Jean L. Bolognia, MD and Boni Elewski, MD.*

MUCOCUTANEOUS SIDE EFFECTS OF SELECTED TARGETED THERAPIES

Drug	**Cetuximab[Ab] Necitumumab[Ab] Panitumumab[Ab] Amivantamab[bispecific Ab] Erlotinib[1st gen] Gefitinib[1st gen] Afatinib[2nd gen] Dacomitinib[2nd gen] Lapatinib[2nd gen] Neratinib[2nd gen] Osimertinib[3rd gen]**	**Dabrafenib Encorafenib Vemurafenib**	**Binimetinib Cobimetinib Selumetinib Trametinib**	**Pertuzumab Trastuzumab**	**Bosutinib Dasatinib Imatinib Nilotinib Ponatinib Avapritinib Ripretinib**	**Bevacizumab Ramucirumab Ranibizumab**

Other	**Genital eruption including scrotal > vulvar ulcers (cabozantinib, pazopanib, sorafenib, sunitinib), yellow skin discoloration (sunitinib), reversible hair depigmentation (sunitinib, pazopanib, cabozantinib),** acquired perforating dermatosis (sorafenib), angioedema (sorafenib), blue–gray macules (vandetanib), cutaneous vasculopathy (axitinib), eruptive nevi (sorafenib), facial edema (sunitinib, pazopanib), pyoderma gangrenosum, scalp pruritus (sorafenib), squamous proliferations (KAs, SCCs) (sorafenib), subungual splinter hemorrhages (sorafenib, sunitinib, pazopanib)	**Increased bleeding, petechiae and ecchymoses, palpable purpuric eruptions,** cutaneous staphylococcal infections, hair texture changes, nail changes (brittle nails, onycholysis), neutrophilic panniculitis	Bullous dermatitis, drug-induced lupus (SCLE, DLE), radiation enhancement, small vessel vasculitis, vitiligo	**Calcinosis cutis, calciphylaxis (associated hyperphosphatemia),** nail changes (onycholysis with or without subungual hemorrhage, onychomadesis), xerostomia	Lichenoid eruption, peripheral edema	Urticarial hypersensitivity reaction
Notes	HFSR is the most common	Petechiae, palpable purpuric eruptions, and folliculitis are most common Side effects are more common with ibrutinib	Alopecia (especially with endocrine therapy) and stomatitis are most common	Alopecia, stomatitis, and nail changes are most common	Uncommon	Exanthematous (morbilliform) eruptions are most common (particularly with alpelisib ~50%)

*Also referred to as papulopustular eruption; can be associated with secondary *Staphylococcus aureus* infection or *Demodex* infestation.
†May be bullous.
‡Topical β-blockers, such as timolol 0.5% gel twice daily under occlusion, may be effective in the treatment of pyogenic granuloma-like lesions.
¶(Pseudo)pyogenic granulomas may occur.

Table 21.16 Cutaneous side effects of selected targeted therapies. Entities in **bold** or shaded are more commonly observed. See following tables for the side effects of vismodegib and sonidegib (Table 108.10), mTOR and proteasome inhibitors (Table 21.17), and checkpoint inhibitors (Table 21.18). Brentuximab, alemtuzumab, and mogamulizumab are reviewed in Chapter 120; rituximab and other anti-tumor monoclonal antibodies are reviewed in Chapter 128. Monoclonal antibodies conjugated to cytotoxic agents (e.g. enfortumab vedotin, loncastuximab tesirine) are associated with a range of bullous reactions including toxic erythema of chemotherapy and SJS/TEN. Ab, antibody; AGEP, acute generalized exanthematous pustulosis; ALK, anaplastic lymphoma kinase; BTK, Bruton's tyrosine kinase; CDK, cyclin-dependent kinase; DLE, discoid lupus erythematosus; EGFR, epidermal growth factor receptor; EM, erythema multiforme; FGFR, fibroblast growth factor receptor; FLT3, FMS-related tyrosine kinase 3; gen, generation; HER2, receptor tyrosine-protein kinase erbB-2; HFSR, hand–foot skin reaction; HS, hidradenitis suppurativa; ICI, immune checkpoint inhibitor; KAs, keratoacanthomas; MEK, mitogen-activated protein kinase kinase; MET, mesenchymal epithelial transition factor; PI3K, phosphoinositide 3-kinase; PDGFR, platelet-derived growth factor receptor; PRP, pityriasis rubra pilaris; RAF, name derived from ability of 3611–MSV virus to induce "*ra*pidly growing *f*ibrosarcomas" in mice; RET, rearranged during transfection; SCARs, severe cutaneous adverse reactions; SCCs, squamous cell carcinomas; SCLE, subacute cutaneous lupus erythematosus; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis; VEGF, vascular endothelial growth factor; VEGFR, VEGF receptor. *Adapted from Robert C, et al. MUCOCUTANEOUS AND EXTRACUTANEOUS SIDE EFFECTS OF IMMUNE CHECKPOINT INHIBITORS
Mucocutaneous – most common*

• Eruptions (Fig. 21.20B,D)
  • morbilliform
  • lichenoid
  • psoriasiform
  • eczematous
• Pruritus
• Vitiligo-like depigmentation,including poliosis (Fig. 21.20C)†

Mucocutaneous – less common*
• Acute generalized exanthematous pustulosis, DRESS (including with radiation), erythema multiforme (minor and major), Stevens–Johnson syndrome, toxic epidermal necrolysis (Fig. 21.20A) • Bullous pemphigoid, pemphigus • Dermatomyositis, subacute cutaneous lupus erythematosus • Generalized lichen nitidus, lichen sclerosus, lichen planopilaris, PLEVA, PLC-like, lichen planus pemphigoides • Vogt–Koyanagi–Harada-like syndrome, alopecia areata, alopecia universalis • Sarcoidosis and sarcoidal lesions (including subcutaneous), granuloma annulare • Radiation sensitivity, photosensitivity • Atypical squamous proliferations, eruptive keratoacanthomas, and squamous cell carcinomas‡ • Eosinophilic fasciitis, morpheaform and sclerodermoid reactions • Erythema nodosum-like panniculitis • Acquired generalized lipodystrophy • Sjögren syndrome, vasculitis • Neutrophilic dermatoses, in particular Sweet syndrome • Oral ulcers, xerostomia, nail dystrophy (may occur with lichenoid or psoriasiform eruptions) • Acneiform eruption, papulopustular rosacea, Grover disease, urticaria
Extracutaneous
• Enteritis/colitis (diarrhea, nausea, vomiting), hepatitis • Adrenal insufficiency • Arthritis (primarily seronegative inflammatory arthritis) • Autoimmune thyroiditis (hypothyroidism ≫ hyperthyroidism) • Flare of existing autoimmune disorder (e.g. rheumatoid arthritis, systemic lupus) • Hypophysitis, hypopituitarism • Myocarditis • Nephritis, hyperkalemia • Neurotoxicity, including Guillain–Barré syndrome, PRES • Pancreatitis • Pneumonitis • Sarcoidosis (pulmonary, lymph nodes) • Type 1 diabetes, acute onset with severe hyperglycemia, ketoacidosis • Uveitis, episcleritis • Vasculitis
*More than one morphology may be seen in a patient. †May be intraoral, genital, or accentuated in sun-exposed sites. ‡May be driven by lichenoid inflammation.

Table 21.18 Mucocutaneous and extracutaneous side effects of immune checkpoint inhibitors. These include anti-CTLA-4 (e.g. ipilimumab, tremelimumab), anti-PD-1 (e.g. nivolumab, pembrolizumab, cemiplimab), and anti-PD-L1 (e.g. atezolizumab, avelumab, durvalumab) antibodies. Certain reactions are more commonly associated with anti-PD-1/PD-L1 antibodies (e.g. lichenoid eruption, bullous pemphigoid, psoriasiform eruption), and combination anti-CTLA-4/-PD-1 therapy is associated with increased frequency and severity of immune-related adverse events. Rarely, subcutaneous fat necrosis, circumoral plasmacytosis, and repigmentation of gray hair have been observed. DRESS, drug reaction with eosinophilia and systemic symptoms; PLEVA, pityriasis lichenoides et varioliformis acuta; PLC, pityriasis lichenoides chronica; PRES, posterior reversible encephalopathy syndrome.

exposure and the acneiform eruption depends on the responsible agent. Major drugs implicated in acneiform eruptions include corticosteroids, androgens, hydantoins, lithium, halogenides, and oral contraceptives (more often those that contain progestins with androgen-like effects) (see Table 36.1). Less commonly, JAK inhibitors, azathioprine, quinidine, and adrenocorticotropic hormone are the culprits.

DRUG-INDUCED ALOPECIA	

Telogen phase	• Amphetamines
	• **Anticoagulants:** heparin > warfarin
	• Anticonvulsants: carbamazepine, lamotrigine, phenytoin, valproic acid
	• Antidepressants: desipramine, fluoxetine, imipramine, maprotiline,
	• Antihypertensive agents:
	  • **β-Blockers:** acebutolol, propranolol, timolol
	  • ACE inhibitors: captopril, enalapril, ramipril
	  • Diuretics: spironolactone
	• Antimicrobials: fluconazole, gentamicin, isoniazid, terbinafine, thiamphenicol
	• Antithyroid drugs: carbimazole, thiouracils
	• Colchicine
	• **Interferons**
	• Lipid-lowering agents: cholestyramine, clofibrate
	• **Lithium**
	• NSAIDs: ibuprofen, indomethacin, naproxen, piroxicam
	• Oral contraceptives (discontinuation > initiation or change)
	• Endocrine therapies (e.g. **tamoxifen**, letrozole > anastrozole, goserelin, leuprolide)
	• **Retinoids** (acitretin > isotretinoin)
	• Others: allopurinol, bromocriptine, buspirone, cimetidine, L-dopa, pyridostigmine

Anagen phase	• Antineoplastic agents (see Tables 21.15 & 21.16) • Others: arsenic, bismuth, gold, thallium

Table 21.19 Drug-induced alopecia. The more commonly incriminated medications are in **bold**. ACE, angiotensin-converting enzyme.

With the introduction of EGFR and MEK inhibitors (Fig. 21.21A), there has been an increase in drug-induced follicular eruptions, inasmuch as papulopustular eruptions can occur in up to 80% of patients receiving these medications, in particular 1st and 2nd generation EGFR inhibitors (see Table 21.16). Lesions often appear within a few weeks of administration but may not develop until several months later. Areas rich in sebaceous glands, in particular the central face, scalp and trunk, are most commonly affected (Fig. 21.21B,C). Symptoms include stinging, pruritus, and pain. Although the initial pustules are sterile, secondary infection by *Staphylococcus aureus*, herpes simplex virus, and dermatophytes may occur as well as an increased density of *Demodex folliculorum*. Late-onset papulopustular acneiform eruptions that favor the lower extremities may appear months into therapy as can non-follicular purpuric papulopustular eruptions.

It has been suggested that papulopustular eruptions are a surrogate marker for efficacy of EGFR inhibitors as several studies have reported an association with increased overall response rate or survival. Of note, at the initiation of EGFR or MEK inhibitor therapy, some clinicians prescribe a prophylactic regimen consisting of oral doxycycline or minocycline plus low- to mid-potency topical corticosteroids[54]. Severe or recalcitrant papulopustular disease can be treated with higher potency topical corticosteroids, oral corticosteroids, or low-dose oral isotretinoin.

Anticoagulant-induced skin necrosis

Anticoagulant-induced skin necrosis is a rare, potentially life-threatening reaction induced by warfarin or heparin. *Warfarin-induced* necrosis typically begins 2 to 5 days after therapy is initiated and coincides with

Fig. 21.20 Spectrum of cutaneous reactions to immune checkpoint inhibitors (immune-*r*elated *a*dverse *e*vents). A SJS/TEN overlap due to ipilimumab. **B** Lichenoid dermatitis of the palms in a patient receiving pembrolizumab for metastatic colon cancer. **C** Vitiligo-like leukoderma in a patient with metastatic melanoma receiving nivolumab. **D** Widespread eruption of erythematous papules due to ipilimumab; many of the lesions are crusted. *A, Courtesy Marianna Freudzon, MD; B, Courtesy Jonathan Leventhal, MD. Fig. 21.21 Papulopustular (acneiform) reactions to epidermal growth factor receptor (EGFR) inhibitors. **A** EGFR signal transduction and sites of action of inhibitors. In addition to the tyrosine kinase inhibitors listed, there are drugs that block EGFR plus other targets such as ALK or VEGFR (e.g. vandetanib). **B** Numerous pustules on an erythematous base with coalescence on the central upper back. **C** Multiple follicular papulopustules, hyperpigmented scars, and a large multiloculated inflamed cyst on the cheek. gen, generation; P, phosphorylation; Tyr, tyrosine. *B, Courtesy Lauren Levy, MD, and Jonathan Leventhal, MD; C, Courtesy Kalman Watsky, MD.*

the expected early drop in protein C function (see Ch. 22). One in every 10 000 individuals who receives warfarin will develop this side effect, with middle-aged obese women and those with a hereditary deficiency of protein C being at highest risk.

Clinically, erythematous painful plaques evolve into hemorrhagic blisters and necrotic ulcers as a consequence of ischemic infarcts. The latter are due to occlusive thrombi within blood vessels of the skin and subcutaneous tissue[1]. The most common sites of involvement are areas with greater subcutaneous fat such as the breasts, thighs, abdomen, and buttocks. Therapy includes discontinuing warfarin and administering vitamin K, heparin (as the anticoagulant), and intravenous infusions of protein C concentrate. Warfarin necrosis should not be confused with anticoagulant-induced cholesterol emboli, which, despite the name "warfarin blue toe syndrome", is not restricted to this medication.

Heparin-induced cutaneous necrosis is due to antibodies that bind to complexes of heparin and platelet factor 4 and induce platelet aggregation and consumption (see Ch. 23). Platelet counts are usually depressed, but, unless the baseline platelet count is known, this may not be appreciated. In addition to relative thrombocytopenia, heparin can induce thrombosis and cutaneous necrosis, both at the site of injection and at distant sites (Fig. 21.22) as well as in internal organs (e.g. CNS). This is sometimes referred to as heparin-induced thrombocytopenia (HIT) syndrome. Discontinuation of the heparin and administration of anticoagulants, such as argatroban or bivalirudin, is recommended.

Granulomatous reactions

Granulomatous drug reactions can mimic interstitial granulomatous dermatitis and granuloma annulare and are discussed in Chapter 93. In addition, sarcoidal reactions have been seen in patients with hepatitis C viral infections who received interferon-α and ribavirin as well as immune checkpoint inhibitors.

Drug reactions in HIV infection

Patients with HIV infection are at increased risk for drug eruptions, especially when the $CD4^+$ count is between 100 and 400/mm^3 (see Ch. 78). As an example, the incidence of SJS/TEN in HIV-infected patients is 1/1000 per year (versus 1/1 000 000 per year in the general population). One possible explanation for this increased risk is a loss of skin-protective

Fig. 21.22 Heparin-induced thrombocytopenia (HIT) syndrome. **A** Ischemia and necrosis of the foot. **B** Petechiae due to thrombocytopenia and an irregular area of cutaneous necrosis due to thrombosis. *A, Courtesy Kalman Watsky, MD; B, Courtesy Jean L. Bolognia, MD.*

$CD4^+/CD25^+$ T regulatory cells in that HIV-infected patients were found to have an increased ratio of $CD8^+$:$CD4^+$ T cells within TEN lesions as well as a decreased number of skin-directed $CD4^+$ T cells[55].

The major culprit drugs include TMP-SMX, aminopenicillins, dapsone, abacavir, nevirapine, antituberculous drugs, and anticonvulsants. For example, up to 40% of HIV-infected patients may develop a "rash" during treatment with TMP-SMX. These adverse cutaneous reactions, especially when severe, necessitate discontinuation of the drug. In the case of mild reactions, "treating through", i.e. continuing the drug despite the cutaneous eruption, is possible and has been followed by the disappearance of the rash. Corticosteroids may lower the rate of reactions to sulfonamides in AIDS patients. Desensitization has been performed in these patients with varying results.

Drug-induced lupus erythematosus (LE)

A range of medications can induce systemic LE (SLE) and cutaneous LE, most commonly subacute cutaneous LE (SCLE) and occasionally discoid lupus erythematosus (DLE). In drug-induced SLE, patients may develop fever, malaise, polyarthritis, and serositis from drugs such as hydralazine, minocycline, and procainamide[56], but associated acute cutaneous LE is rare. Although symptoms typically appear at least one month after drug initiation and resolve days to weeks after discontinuation of the responsible medication, the skin lesions of SCLE are sometimes more persistent. Tables 41.2 and 41.10 review the drugs that have been reported to induce SLE and SCLE.

The pathogenesis of drug-induced SLE is not well understood, but one possibility is that reactive drug metabolites, interacting with nuclear histones, could act as haptens and activate the complement cascade. For example, procainamide-induced SLE occurs more frequently in patients who are slow acetylators as compared to rapid acetylators.

While drug-induced SLE is characterized by the presence of antihistone antibodies in up to 95% of cases, these antibodies are not specific and may be seen in patients with idiopathic SLE. Antibodies against double-stranded DNA are typically absent, with the exception of TNF inhibitor-induced SLE. The seroconversion from negativity to positivity for anti-nuclear antibodies alone is not sufficient to discontinue a particular medication, but if symptoms develop, the culprit drug should be withdrawn. However, the anti-nuclear antibodies may persist for 6 to 12 months.

In drug-induced SCLE, anti-SSA/Ro and anti-SSB/La antibodies are often present and the cutaneous and histologic findings are indistinguishable from those seen in the idiopathic form of the disease. It therefore behooves the clinician to carefully review all medications in patients with the diagnosis of SCLE, in particular terbinafine, thiazide diuretics, proton pump inhibitors, calcium channel blockers, and taxanes (see Table 41.2). Of note, patients receiving TNF inhibitors may develop cutaneous lesions of chronic (discoid), subacute, or acute cutaneous LE as well as anti-nuclear and anti-DNA antibodies.

Lymphomatoid drug reaction (see Ch. 121)

Synonyms: ■ Pseudolymphomatous drug reaction ■ Drug-induced cutaneous lymphoid hyperplasia

A lymphomatoid drug reaction has a benign biological behavior and does not satisfy the criteria for non-Hodgkin lymphoma[57]. Although this disorder was originally thought to represent a hypersensitivity reaction, current evidence indicates that the responsible drugs may depress immunologic functions and impair immunosurveillance, leading to an abnormal clonal or non-clonal proliferation of B cells or T cells.

Lymphomatoid drug reactions develop insidiously over a period of months or even years after initial administration of the culprit drug. Cutaneous lesions may be solitary or multiple, localized or generalized, and consist of erythematous to violet papules, plaques, or nodules. Numerous widespread tumors are rare as is an erythroderma simulating Sézary syndrome. There is often associated lymphadenopathy, but it may be the sole finding.

Histologically, a dense lymphocytic infiltrate is seen within the dermis that can mimic a T or B cell lymphoma. In some patients, the lymphocytic infiltrate is band-like, resembling mycosis fungoides, while in others there is a B cell pattern with reactive germinal centers.

Lesions resolve within weeks to months following withdrawal of the responsible medication. The majority of lymphomatoid drug reactions have been reported with anticonvulsants (phenytoin, phenobarbital, carbamazepine, lamotrigine), antipsychotics (e.g. chlorpromazine), and imatinib (see Table 121.1).

Pigmentary changes (see Ch. 67)

Drug-induced cutaneous hyperpigmentation may result from a variety of mechanisms, including: (1) enhanced melanin production; (2) deposition of drugs or their metabolites – sometimes complexed with melanin or iron and in some instances better described as discoloration; and (3) simply postinflammatory changes. The hyperpigmentation may be more pronounced in sun-exposed areas. The drugs most commonly implicated in cutaneous hyperpigmentation (or discoloration) include minocycline, antimalarials, amiodarone (Fig. 21.23), oral contraceptives, imipramine, chemotherapeutic agents, clofazimine, zidovudine, and less often fluoroquinolones. Exposure to heavy metals such as silver and gold as well as arsenic may also induce darkening of the skin, and bleomycin can lead to linear "flagellate" hyperpigmentation.

Hypopigmentation can occur with the chronic use of several topical medications, including retinoic acid and corticosteroids; depigmentation is associated primarily with the application of monobenzyl ether of hydroquinone and imiquimod or exposure to catechols, phenols, and quinones (i.e. contact or occupational leukoderma; see Ch. 66). Cutaneous hypopigmentation can result from oral tyrosine kinase inhibitors, in particular imatinib and cabozantinib.

A few drugs are capable of changing the color of hair. For example, chloroquine, imatinib, dasatinib, and sunitinib can lead to lightening or even depigmentation (see Table 21.16). Imatinib can also lead to darkening of the hair.

Drug-induced psoriasis

Drugs may be associated with a precipitation or exacerbation of psoriasis. The clinical manifestations of drug-induced psoriasis span the spectrum of psoriasis, from limited or generalized plaques to erythroderma and pustulosis of the palms and soles. Nail changes and scalp

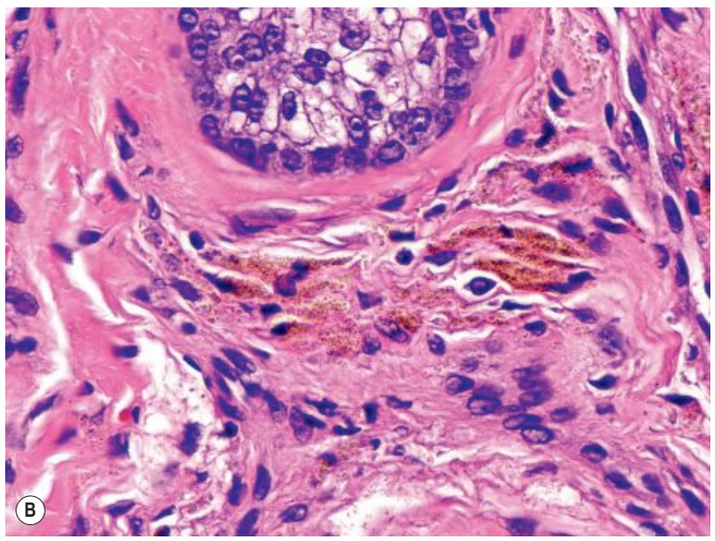

Fig. 21.23 Cutaneous discoloration due to amiodarone. A Gray–violet discoloration of the face. Note sparing of the lower eyelid. **B** Biopsy specimens demonstrate yellow–brown granules within dermal macrophages. *A, Courtesy Jean L. Bolognia, MD; B, Courtesy Luis Requena, MD.*

involvement may also be seen as well as plaques at the sites of injections (e.g. interferon). While a wide range of drugs have been implicated, those with the strongest causal relationship include lithium, β-blockers, NSAIDs (oral and topical), TNF inhibitors (especially infliximab), and interferons. Its association with additional medications (e.g. antimalarials, GM-CSF, potassium iodide) has been debated.

Lesions of drug-induced psoriasis usually regress within weeks to a few months of discontinuing the inciting drug. However, psoriasiform eruptions, including palmoplantar pustulosis, may be more persistent in patients receiving TNF inhibitors (see Ch. 128). The latter occur not just in individuals with psoriasis or rheumatoid arthritis, but also in patients being treated for other conditions, e.g. GVHD or inflammatory bowel disease, who have no personal or family history of psoriasis (Fig. 21.24). These eruptions may or may not follow a reduction in immunosuppression.

Histologic findings are similar to those in conventional psoriasis or pustular psoriasis. However, medications may induce more than one type of skin lesion, e.g. eczematous as well as psoriasiform in patients receiving TNF inhibitors, and this is reflected in the histologic findings.

The mainstay of treatment is recognition and discontinuation of the culprit drug when possible. If the psoriatic lesions fail to improve following discontinuation of the suspected drug, routine therapies for psoriasis are initiated. For mild TNF inhibitor-induced disease, a "treat through" approach can be considered, along with the addition of other anti-psoriatic treatments (e.g. methotrexate). In the case of moderate to severe TNF inhibitor-induced paradoxical psoriasis, switching to a different TNF inhibitor (moderate disease) or completely different class of immunomodulators ("biologics") is recommended.

Additional uncommon drug reactions

Examples of such drug reactions are outlined in Table 21.20.

Fig. 21.24 Psoriasiform eruption due to TNF inhibitor. Sterile pustulosis of the plantar surface developed in this patient with rheumatoid arthritis who had received infliximab for the previous 5 years. There was no reduction in immunosuppression prior to the onset of the psoriasiform eruption. *Courtesy Chris Bunick, MD.*

UNCOMMON ADVERSE MUCOCUTANEOUS DRUG REACTIONS	
Adverse reaction	**Drugs**
Bullous hemorrhagic dermatosis (intraepidermal hemorrhagic bullae at distant sites)	Enoxaparin Heparin
Eczematous drug reaction	Calcium channel blockers Intravenous immunoglobulins (including pompholyx) TNF inhibitors Ustekinumab, anti-IL-17 antibodies Immune checkpoint inhibitors EGFR inhibitors ACE inhibitors HMG-CoA reductase inhibitors (statins)*
Genital ulcers Scrotal Penile	 All-trans-retinoic acid†, anti-angiogenic multikinase inhibitors (e.g. cabozantinib, sunitinib) Foscarnet
Eosinophilic granulomatosis with polyangiitis	Montelukast Mesalazine
*Also xerosis. †Also oral ulcers.	

Table 21.20 Uncommon adverse mucocutaneous drug reactions. Drug-induced acanthosis nigricans is reviewed in Fig. 53.16. EGFR, epidermal growth factor; TNF, tumor necrosis factor.

Cutaneous Side Effects of Vaccines and Injected Medications

Vaccine-induced reactions

With the discontinuation of vaccinations for smallpox in the general population, the incidence of significant cutaneous side effects due to vaccines had markedly decreased. However, the introduction of lipid nanoparticle-encapsulated mRNA-based SARS-CoV-2 vaccines has led to a resurgence. Local inflammatory reactions consisting of erythema, swelling, and tenderness can be seen, as well as urticaria, angioedema, and anaphylaxis; in the past, the latter occurred primarily with live measles vaccines. Excessive limb swelling, mimicking cellulitis, has also been described, particularly with vaccines containing a pertussis component (Table 21.21). Lichenoid eruptions, erythema multiforme, and occasionally autoimmune reactions, e.g. polyarteritis nodosa, bullous pemphigoid, have been observed, with a wide range of reactions reported after the SARS-CoV-2 vaccine, from petechial exanthems to inflammatory reactions to hyaluronic acid soft tissue fillers. In addition, the commonly administered influenza vaccine has been associated with a serum sickness-like reaction, acute febrile neutrophilic dermatosis, and linear IgA bullous dermatosis.

REACTIONS LOCALIZED TO SITES OF INJECTIONS OF MEDICATIONS AND VACCINES	
Medication or vaccine	**Cutaneous reaction**
Medication	
Adalimumab*	Erythematous or urticarial plaques
Anakinra	Erythematous or urticarial plaques
Anti-sense oligonucleotides	Erythema accompanied by pruritus or pain, necrosis, ulceration
Bortezomib	Erythematous or urticarial plaque (Fig. 21.19), necrosis, spider-like or reticulated erythema
Corticosteroids	Deposits of drug (Fig. 125.8), dermal atrophy (Fig. 125.7 A), hypopigmentation (Fig. 125.7B), lipoatrophy, telangiectasias
Desensitization injections	Subcutaneous sarcoidosis
Enfuvirtide	Erythematous or morpheaform plaque
Etanercept*	Erythematous plaques (Fig. 128.8), eosinophilic cellulitis, vasculitis
Glatiramer acetate	Fibrosis, lipoatrophy, Nicolau syndrome†, panniculitis, vasospasm
GM-CSF*, G-CSF*	Pustular reaction, urticarial plaque (Fig. 128.3)
Heparin	Ecchymosis, erythematous plaques, necrosis, urticaria (see Ch. 23)
Hyaluronic acid, silicone	Granulomatous reaction (see Ch. 94), swelling
Interferon*	Development of plaque of psoriasis, lupus-like reaction, vasculopathy with necrosis
Interleukin-2	Granulomas, lobular panniculitis
Iron	Brown discoloration, hyperpigmentation
Low-molecular-weight, calcium-containing heparin	Calcinosis cutis
Meglumine antimoniate	Pruritic erythematous plaque, occasionally necrosis
Rituximab/hyaluronidase human	Erythematous plaque
SCI_g	Erythematous plaque
Vitamin B_{12}	Morpheaform plaque, pruritus
Vitamin K	Erythematous plaque, often annular (Fig. 21.25), morpheaform plaque (Texier disease)
Vaccine‡	
Aluminum-containing vaccine	Foreign body reaction, nodules
SARS-CoV-2 mRNA vaccine	Tender or pruritic erythematous plaque, either within one week or delayed (larger and primarily with Moderna vaccine); occasionally vesicular or multiple plaques
Thimerosal-containing vaccine	Allergic contact dermatitis

*Discussed in Chapter 128.
†Uncommon complication of intramuscular (and also intra-articular or subcutaneous) drug injection characterized by severe pain and erythematous–ecchymotic livedoid skin discoloration at the injection site leading to variable degrees of ischemic necrosis of the surrounding skin and deeper tissues.
‡Generalized reactions to vaccines can also occur, including anaphylaxis, Sweet syndrome, acute generalized exanthematous pustulosis, bullous pemphigoid, linear IgA bullous dermatosis, lichenoid eruptions, and erythema multiforme.

Table 21.21 Reactions localized to sites of injections of medications and vaccines (in addition to extravasation of those administered intravenously). See Table 21.22 and Table 89.4 for reactions to insulin and illicit drugs, respectively. Local injection site reactions consisting of an erythematous plaque and induration can be seen with systemic immunomodulators including ustekinumab, secukinumab, ixekizumab, risankizumab, and dupilumab. CSF, colony-stimulating factor; G, granulocyte; GM, granulocyte–macrophage; SCIg, subcutaneous immunoglobulin.

CUTANEOUS SIDE EFFECTS OF INSULIN INJECTIONS
Immediate hypersensitivity
Local reaction (erythema, pruritus)
Urticaria, angioedema
Anaphylaxis (rare)
Delayed hypersensitivity
Reaction at injection sites (erythema, induration)
Exanthematous (morbilliform) eruption (rare)
Acute generalized exanthematous pustulosis (AGEP) (rare)
Exfoliative dermatitis (rare)
Localized lipodystrophy
Lipoatrophy* (occurs less frequently with rapidly absorbed analogue insulins, e.g. insulin lispro)
Lipohypertrophy
Localized skin infections
Cellulitis and abscesses, most commonly due to *Staphylococcus aureus*
Granulomatous nodules, e.g. due to atypical mycobacteria
Ulcers
Localized acanthosis nigricans
Localized insulin-derived amyloidosis (subcutaneous amyloid mass)
*Rarely occurs at distant sites.

Table 21.22 Cutaneous side effects of insulin injections. Use of an insulin pump also carries the risk of scarring and allergic contact dermatitis to isobornyl acrylate in the adhesive.

Vaccination with BCG can lead to a benign, self-limited local reaction consisting of a plaque, pustule, or even ulcer (see Ch. 75). Occasionally, local abscess formation may follow vaccination of strongly reactive individuals, administration of a large amount of vaccine, or a deep injection. Delayed type hypersensitivity to a vaccine's aluminum adjuvant can appear weeks to months following vaccination, presenting as persistent erythema, a sterile abscess, or subcutaneous nodules.

Localized reactions to injected medications

In addition to the cutaneous reactions to vaccines discussed previously, Table 21.21 outlines cutaneous reactions that are localized to the sites of injections of medications and Table 21.22 reviews the side effects of insulin injections.

Treatment

A limited number of drug eruptions are life-threatening or lead to disabling sequelae. Management begins with the withdrawal of the suspect drug as soon as possible. Frequently, however, several drugs may be incriminated. As there is no clinical or laboratory test which permits identification of the culprit agent with certainty, the decision is usually made to discontinue all drugs that are non-essential as well as the "high-probability" drugs. Medications in the same chemical family are avoided as substitutions. Additional evaluation can be done, e.g. patch tests, prick, and intradermal tests, but results often return after decisions regarding drugs to discontinue have been made.

For mild drug eruptions, topical corticosteroids and oral antihistamines may be helpful. In the case of "acute skin failure" as in TEN, management must be undertaken in specialized intensive care units. Supportive interventions include warming of the environment, correction of electrolyte disturbances, high caloric supplementation, and prevention of sepsis[58].

The presumed immunologic etiology for drug eruptions has led to the use of systemic corticosteroids, immunosuppressive, and anticytokine therapies. There is minimal evidence for the usefulness of systemic corticosteroids, either as a preventive or as a therapeutic agent, in the most common forms of drug reactions (e.g. exanthematous) or SJS/TEN. However, topical or systemic corticosteroids represent the cornerstone of treatment for DRESS. In patients with mild exanthematous drug eruptions that occur during the treatment of a severe disease, it is sometimes possible to "treat through" the rash and continue the incriminated drug. That said, there is no agreement regarding this clinical approach and, in the case of severe reactions, resumption of the culprit drug, including chemically similar ones, is contraindicated. An allergy card and a detailed list of drugs to avoid *ad infinitum* should be given to the patient, with modifications made based upon additional testing (see above).

Fig. 21.25 Local reactions to vitamin K injections. A This patient was originally diagnosed as having erythema multiforme. **B** Large pink–violet plaque with areas of hemorrhage in an infant. *B, Courtesy Julie V. Schaffer, MD.*

Public health and drug policies should focus on the avoidance and prevention of SCARs at the population level. These measures include: (1) pharmacogenetic tests to identify patients at risk for SCARs in specific subpopulations (see Table 21.3); and (2) pharmacovigilance, which requires systematic reporting of culprit drugs to health authorities, pharmaceutical companies, and independent registries. Guidelines should be followed when prescribing drugs, especially allopurinol and trimethoprim–sulfamethoxazole[59], and both pharmaceutical companies and government agencies should avoid allowing look-alike and sound-alike drugs that could result in dispensing errors[60].

Additional figures and tables on Skin reactions to "drugs" received by at least 1000 patients, Drugs received by more than 1000 patients with no skin reactions (rates estimated to be ≤3 per 1000), Features that suggest a severe cutaneous adverse reaction (SCAR) to a drug, Frequency of clinical and laboratory features in drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS), Severity score of drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS), and Management of immune checkpoint inhibitor cutaneous side effects, available in our eBook (see inside front cover for access code).

Acknowledgments

The authors wish to thank Drs. Laurence Valeyrie-Allanore, Grace Obeid, and Jean Revuz for their valuable contributions to this chapter in the previous editions.

eFig. 21.2 Drug eruption chart. A Sample chart. This is a helpful working template for organizing all of the available patient information into one document for a patient with a suspected cutaneous adverse reaction (CAR). **Step 1:** Compile all of the recently consumed or administered drugs (including prescription, over-the-counter, and supplements) into the chart. **Step 2:** Review and list the pertinent laboratory information and physical findings at the bottom of the chart. **Step 3:** Exclude a **severe cutaneous adverse reaction** (SCAR) and categorize the type of CAR. **Step 4:** Based on time intervals and the most and least likely drugs to cause CAR (see Table 21.6), begin to formulate the most likely culprit drugs and recommend their discontinuation. In addition, discontinue unnecessary drugs. **Step 5:** Longitudinal evaluation of the patient is necessary to (1) exclude progression to a SCAR, (2) determine the response upon discontinuation of the culprit drug (noting that it might "get worse before it gets better"), and (3) provide supportive care to the patient. In this sample patient, the most likely culprit drugs are ceftazidime > ampicillin/sulbactam > vancomycin; however, the multi-vitamin, folate, famotidine, zolpidem, acetaminophen, ibuprofen, tramadol, Maalox®, and lorazepam (must taper off and not abruptly stop) were also discontinued. Note that the discontinuation of levofloxacin by the primary physicians was not necessary. **B** A blank template of the drug eruption chart. AST, aspartate aminotransferase; ALT, alanine aminotransferase; SC, subcutaneous; WBC, white blood cell count. *Courtesy Karynne O. Duncan, MD.*

SKIN REACTIONS TO "DRUGS" RECEIVED BY AT LEAST 1000 PATIENTS	
Drugs	**Reaction rate (per 1000 recipients)**
Ampicillin	52
Penicillin G	16
Cephalosporins	13
Packed red blood cells	8.1
Heparin	7.7
Nitrazepam	6.3
Barbiturates	4.7
Chlordiazepoxide	4.2
Diazepam	3.8
Propoxyphene	3.4
Guaifenesin	2.9
Furosemide	2.6
Phytonadione	0.9
Flurazepam	0.5
Chloral hydrate	0.2

eTable 21.1 Skin reactions to "drugs" received by at least 1000 patients. Arndt KA, Jick H. Rates of cutaneous reactions to drugs. *J Am Med Assoc*. 1976;235:918–923.

DRUGS RECEIVED BY MORE THAN 1000 PATIENTS WITH NO SKIN REACTIONS (RATES ESTIMATED TO BE ≤3 PER 1000)
• Potassium chloride • Milk of magnesia • Digoxin • Meperidine hydrochloride • Dioctyl sodium sulfosuccinate • Magnesium hydroxide • Aluminum hydroxide • Acetaminophen • Multivitamins • Bisacodyl • Diphenhydramine hydrochloride • Aspirin • Aminophylline • Prochlorperazine • Ferrous sulfate • Thiamine • Prednisone • Atropine • Codeine • Vitamin B complex and ascorbic acid • Pentazocine • Hydrochlorothiazide* • Phosphate enema • Castor oil • Tetracycline* • Morphine • Regular insulin • Warfarin • Spironolactone
*Notably phototoxic reactions were not included.

eTable 21.2 Drugs received by more than 1000 patients with no skin reactions (rates estimated to be ≤3 per 1000). Arndt KA, Jick H. Rates of cutaneous reactions to drugs. *J Am Med Assoc*. 1976;235:918–923.

FEATURES THAT SUGGEST A SEVERE CUTANEOUS ADVERSE REACTION (SCAR) TO A DRUG		
Cutaneous features	**Systemic features**	**Laboratory findings**
• Skin pain • Confluent erythema • Facial edema • Blisters or epidermal detachment • Mucosal erosions • Necrosis • Palpable purpura • Urticaria • Swelling of lips/tongue	• High fever • Lymphadenopathy • Arthralgia/arthritis • Shortness of breath, wheezing, stridor, hypotension • Other visceral involvement	• Marked eosinophilia • Lymphocytosis with atypical lymphocytes • Leukopenia • Abnormal liver or renal function tests • Thrombocytopenia • Neutrophilia

eTable 21.3 Features that suggest a severe cutaneous adverse reaction (SCAR) to a drug. *Adapted from Roujeau JC, Stern RS. Severe adverse cutaneous reactions to drugs. N Engl J Med 1994;331:1272–85.*

FREQUENCY OF CLINICAL AND LABORATORY FEATURES IN DRUG REACTION WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS (DRESS)/DRUG-INDUCED HYPERSENSITIVITY SYNDROME (DIHS)	
Clinical and laboratory features	**Percentage of patients**
Mucocutaneous	
Skin Extent of rash >50% BSA Maculopapular rash Facial edema Purpura Pustules	 45–80 60–100 40–85 10–30 15–30
Mucosae Mouth/throat/lips Eyes	50–60 50 10–15
Laboratory	
Eosinophilia	30–95
Atypical lymphocytes	30–65
Systemic	
Fever	70–100
Lymphadenopathy	30–90
Internal organ involvement 1 organ 2 or more organs	90 35–85 15–55
Liver	50–100
Kidney	5–55
Lung	5–35
Heart	≤15
Spleen	15
Pancreas	5

eTable 21.4 Frequency of clinical and laboratory features in drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS). BSA, body surface area.

SEVERITY SCORE OF DRUG REACTION WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS (DRESS)/DRUG-INDUCED HYPERSENSITIVITY SYNDROME (DIHS)		
Parameters	**Grade/extent**	**Score**
Fixed		
Age, years	≤40 / 41–74 / ≥75	–1 / 0 / 2
Duration of drug exposure after onset, days	0–6 / ≥7	0 / 1
Allopurinol exposure	Yes	1
Variable		
Pulsed prednisone	Yes	2
Skin involvement Erythema, % BSA Erosion, % BSA	 <70 / ≥70 / erythroderma <10 / 10–29 / ≥30	 0 / 1 / 2 0 / 1 / 3
Fever ≥38.5°C, duration in days	0 or 1 / 2–6 / ≥7	0 / 1 / 2
Appetite loss (≤70% of regular food intake), days	0–4 / ≥5	0 / 1
Renal dysfunction (creatinine, mg/dL)	<1 / 1–2 / ≥2.1 or HD	0 / 1 / 3
Liver dysfunction (ALT, IU/L)	<400 / 400–1000 / >1000	0 / 1 / 2
C-reactive protein (mg/dL)	≤2 / <2–<10 / ≥10–<15 / ≥15	–1 / 0 / 1 / 2

eTable 21.5 Severity score of drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS). Scores ≥4 were associated with the later development of cytomegalovirus (CMV) disease and complications and therefore early intervention with anti-CMV agents should be considered. ALT, alanine aminotransferase; BSA, body surface area; HD, hemodialysis. *Adapted from Mizukawa Y, et al. Drug-induced hypersensitivity syndrome/drug reaction with eosinophilia and systemic symptoms severity score: a useful tool for assessing disease severity and predicting fatal cytomegalovirus disease. J Am Acad Dermatol 2019;80:670–8.e672.*

MANAGEMENT OF IMMUNE CHECKPOINT INHIBITOR CUTANEOUS SIDE EFFECTS			
Inflammatory eruptions (morbilliform, lichenoid, eczematous and psoriasiform)			
Grade	***Clinical findings***	***Treatment recommendations***	***Immune checkpoint inhibitor management and preventive measures***
1	Symptoms without impact on QOL or controlled with "simple treatment" (topical regimen and/or oral antipruritic)	Simple treatment: Emollients, mild-to-moderate potency topical CS, oral antipruritics*	Continue ICI Avoid skin irritants Minimize sun exposure
2	Impact on QOL and requires intervention	Same as Grade 1 but higher potency CS Consider oral CS (e.g. prednisone 1 mg/kg tapered over at least 4 weeks) *Narrowband UVB, acitretin, apremilast*	Consider holding ICI and assess weekly until return to Grade 1
3	Fails to respond to Grade 2 treatment	Same as Grade 2 but consider higher dose of oral CS (e.g. (methyl)prednisolone 1–2 mg/kg) tapering over at least 4 weeks *Systemic immunomodulators depending upon type of eruption, e.g. anti-IL-4/-13 for eczematous, anti-IL-23 or -17 for psoriasiform*	Hold ICI & assess in conjunction with dermatologist when to resume
4	Severe, intolerable, fails to respond to Grade 2/3	Hospitalization & IV CS (e.g. methylprednisolone 1–2 mg/kg) with slow taper when the toxicity resolves	Same as Grade 3 Consider alternative therapy
Bullous eruptions (autoimmune bullous dermatoses and bullous drug reactions)			
Grade	***Clinical findings***	***Treatment recommendations***	***Immune checkpoint inhibitor management and preventive measures***
1	No symptoms, blisters covering <**10% BSA**, no erythema	Local care Consider other etiology	Continue ICI
2	Symptomatic blisters or erosions, impacting QOL **10%–30% BSA**	Local care & class I topical CS *Doxycycline +/– nicotinamide* Low threshold for oral CS (e.g. prednisone 0.5–1 mg/kg tapered over ≥4 weeks) *Dupilumab, methotrexate, omalizumab*	Hold ICI Evaluation for autoimmune bullous dermatosis & observe for progression to SCAR†
3	Blisters or erosions >**30% BSA** plus pain and ADLs impacted	Hospitalization & IV CS (e.g. methylprednisolone 1–2 mg/kg) with slow taper; if BP, consider rituximab or IVIg *Dupilumab, methotrexate, omalizumab*	Hold ICI & assess in conjunction with dermatologist regarding appropriateness of resuming
4	Blisters or erosions >**30% BSA** plus fluid or electrolyte abnormalities	Same as Grade 3	Permanently discontinue ICI
Severe cutaneous adverse reactions (including SJS/TEN, AGEP, and DRESS)			
Grade	***Clinical findings***	***Treatment recommendations***	***Immune checkpoint inhibitor management***
1	NA‡	Monitor closely for improvement or worsening	
2 DRESS	Morbilliform eruption **10%–30% BSA** plus systemic symptoms, lymphadenopathy, or facial swelling	Emollients, oral antihistamines, and moderate-to-high dose topical CS Consider oral CS (e.g. prednisone 0.5–1 mg/kg tapered over at least 12–24 weeks)	Consider holding ICI and assess every 3 days until return to Grade 1
3 SJS	Skin sloughing <**10% BSA** plus mucosal involvement	Hospitalization and IV CS (e.g. methylprednisolone 0.5–1 mg/kg initially then switch to oral and taper over at least 4 weeks) +/– *IVIG, cyclosporine or TNF inhibitor*	Hold ICI, consider alternative therapy
4 SJS/ TEN DRESS	Skin erythema & blistering/sloughing ≥**10% BSA** *or* concerning lab abnormalities	Hospitalization and IV CS (e.g. methylprednisolone 1–2 mg/kg), with taper when toxicity resolves to normal +/– IVIG or cyclosporine *or TNF inhibitor*	Permanently discontinue ICI

*Oral antipruritics include sedating and non-sedating antihistamines for mild itch; gabapentinoids, aprepitant, or dupilumab may be helpful for more severe itch.
†Includes Stevens–Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), drug reaction with eosinophilia and systemic symptoms (DRESS), and acute generalized exanthematous pustulosis (AGEP).
‡For SCARs, there is no Grade 1; if limited body surface area involvement with bullae or erosions, there should remain a high concern that this reaction will progress to Grade 3 or 4.

eTable 21.6 Management of immune checkpoint inhibitor cutaneous side effects. Additional skin-directed treatments in *italics* were not in guidelines; for Grade 2 bullous eruptions, skin "sloughing" was changed to "blisters or erosions" for consistency. ICI therapy is typically held until the rash is grade 1 or the prednisone dose ≤10 mg daily. ADL, activities of daily living; AGEP, acute generalized exanthematous pustulosis; BP, bullous pemphigoid; BSA, body surface area; CS, corticosteroids; DRESS, drug reaction with eosinophilia and systemic symptoms; ICI, immune checkpoint inhibitor; IV, intravenous; IVIg, intravenous immunoglobulin; NA, not available; QOL, quality of life; SCAR, severe cutaneous adverse reactions; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis; UVB, ultraviolet B. *Adapted from Brahmer JR, et al. Purpura: Mechanisms and Differential Diagnosis

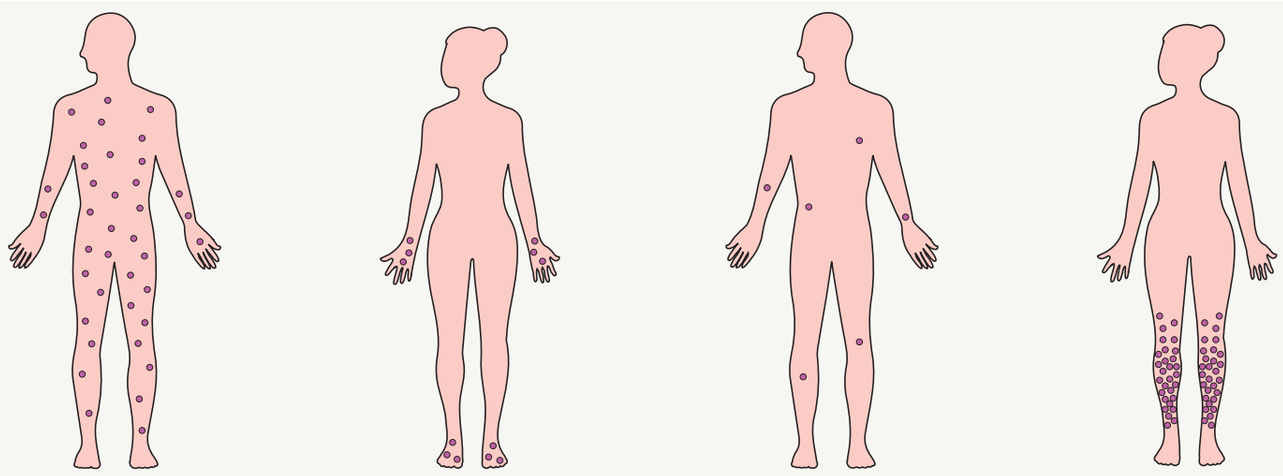
22

Warren W. Piette

INTRODUCTION



This chapter addresses the evaluation and classification of patients presenting with purpura, defined as visible hemorrhage within the skin or mucous membranes. The differential diagnosis presented in this chapter is directed toward syndromes of primary purpura, where the hemorrhage is an integral part of lesion formation, rather than hemorrhage secondary to causes such as trauma and scratching or hemorrhage into established lesions due to dependency (e.g. stasis dermatitis, eczema craquelé).

This chapter outlines a diagnostic approach based upon lesion number and distribution pattern, with a further focus on the morphology of the purpuric lesions. The initial goal is to identify the most plausible of three broad categories: simple hemorrhage (vascular breach), inflammatory hemorrhage (vessel-directed inflammation), or microvascular occlusion/ischemia. Assigning the patient to one of these three major categories facilitates a more directed, efficient, and accurate evaluation to prove or disprove the suspected pathomechanism and it serves to narrow the list of possible diagnoses.

Figure 22.1 illustrates this diagnostic approach based upon lesion number and distribution pattern. Interpretation of these clinical findings is then modified by lesional morphology, extracutaneous findings, and clinical context. For example, petechiae appearing in a generalized pattern requires exclusion of severe thrombocytopenia or perhaps thrombotic thrombocytopenic purpura, but they are most often due to a viral or drug eruption.

When *widespread*, purpuric lesions in a severely ill patient raise concern for serious drug eruptions (e.g. Stevens–Johnson syndrome) or some vasculitides whereas generalized retiform purpura in the setting of multi-organ disease suggests fulminant microvascular disease (e.g. catastrophic antiphospholipid syndrome) or sepsis-associated disseminated intravascular coagulation (DIC) with purpura fulminans. *Predominantly acral* lesions are divided into two subsets: (1) involvement of the ears and nose as well as the hands and feet, typically triggered by cold exposure; and (2) a more widespread distribution pattern with prominent involvement of the hands and feet, typically in the absence of cold exposure. A *pauci-random* distribution pattern is typical

APPROACH TO THE PATIENT WITH PURPURIC LESIONS BASED UPON NUMBER OF LESIONS AND DISTRIBUTION PATTERN

Multiple and generalized/widespread	Predominantly acral	Pauci-random	Multi-dependent
• Viral exanthem • Drug eruption • If only petechiae, severe thrombocytopenia • If retiform purpura & systemically ill patient, - Purpura fulminans - Sepsis/DIC - Catastrophic APLS - Fulminant ANCA-associated vasculitides	A) Multiple acral sites; typically cold-induced & retiform purpura due to vascular occlusion • Cryoglobulinemia, primarily type I • Rarely due to cryofibrinogens or cold agglutins B) Predominantly hands & feet • Viral exanthem, e.g. parvovirus • Erythema multiforme, including RIME/MIRM variant • Sepsis/DIC with hypotension; thromboses localized to vasoconstricted sites	• Usually <25 lesions • ANCA-associated vasculitides • Lymphomatoid papulosis • Occasionally, cutaneous PAN (more commonly pauci-dependent) • If favors areas with increased adipose tissue, - Warfarin-induced skin necrosis - Calciphylaxis	• 25–100 lesions • If macular & non-blanching, - Thrombocytopenia - Hypergammaglobulinemic purpura of Waldenström - Pigmented purpura - Occasionally, immune complex vasculitis* • If palpable & partially blanchable, - Immune complex vasculitis* - Occasionally, pigmented

*Presents similarly whether skin-limited or systemic, so clinical and laboratory evaluation of extracutaneous signs and symptoms required (see Ch. 24).

Fig. 22.1 Approach to the patient with purpuric lesions based upon number of lesions and distribution pattern. APLS, antiphospholipid antibody syndrome; DIC, disseminated intravascular coagulation; MIRM, *Mycoplasma*-induced rash and mucositis; RIME, reactive infectious mucocutaneous eruption; PAN, polyarteritis nodosa.

Fig. 22.2 Clinical examples of petechiae and purpura. A Round to oval petechiae, <3 mm in diameter. **B** Solar (actinic) purpura in sites of actinic damage plus trauma. **C** Palpable purpura due to cutaneous small vessel vasculitis (inflammation plus hemorrhage). **D** Non-inflammatory (bland) retiform purpura as well as hemorrhagic bullae in a patient with disseminated intravascular coagulation (DIC). *B, Courtesy Kalman Watsky, MD; D, Courtesy Judit Stenn, MD.*

of ANCA-associated vasculitides, various microvascular occlusive diseases, or lymphomatoid papulosis, and occasionally cutaneous polyarteritis nodosa (PAN). *Multi-dependent* patterns can result from severe thrombocytopenia but in the practice of dermatology is most commonly due to cutaneous small vessel vasculitis (see Ch. 24).

In 1989, the term *retiform purpura* was coined to describe a sign of certain vasculitic subsets, but nowadays it is generally used to denote a frequent marker of thrombotic or occlusive microvascular disease[1–3]. The morphologies of purpuric lesions are divided into two major subsets: (1) exclusively macular, whose shapes can be round, oval, irregular, or geometric; and (2) palpable and/or retiform. The macular group consists of petechiae (Fig. 22.2A, Table 22.1)[2], macular purpura (Table 22.2), and macular ecchymoses (Fig. 22.2B, Table 22.3). The palpable and/or retiform group consists of palpable purpura (Fig. 22.2C, Table 22.4), non-inflammatory retiform purpura (Fig. 22.2D; Table 22.5), and inflammatory retiform purpura (Table 22.6). In this chapter, lesions in the macular group are categorized on the basis of size and are defined as non-blanching and non-palpable; those in the palpable and/or retiform group can range in size from a few millimeters to several centimeters in diameter, may be palpable, and may partially blanch with pressure. The relevance of these morphologic subsets when sorting through the differential diagnosis is depicted in Figure 22.3.

Two major causes of purpura – microvascular occlusion syndromes and vasculitis – are discussed in Chapters 23 and 24[4]. Occlusion is important to recognize because it may mimic vasculitis but requires a very different approach to determine its etiology and appropriate therapy. The most typical presentation of microvascular occlusion syndromes is retiform purpura (see Table 22.5).

Livedo reticularis is a reflection of the physiologic anatomy of slow flow states. The three-dimensional structure and flow regulation of the dermal and subcutaneous vasculature give rise to the net-like pattern of livedo reticularis (see Fig. 106.1). The diameter of the almost-circular to polygonal individual units within the net-like grid varies from 2 cm or larger on the back to 5 mm or less on the palms or soles.

Retiform purpura morphology results from involvement of the same vessels that produce the livedo reticularis pattern. While the former was traditionally considered a component of livedo reticularis, the two should be distinguished based upon the presence or absence of purpura, hence the term "retiform purpura"[1,2]. Given the size of dermal vessels, the clot within the vessel is too small to be seen grossly. What is actually observed is hemorrhage around the dermal vessels, presumably due to ischemia with hemorrhage prior to complete occlusion of the vessel. A complete reticulate pattern is seen infrequently. Instead, the morphology of retiform purpura is composed of "puzzle pieces" of the livedo reticularis pattern. While some lesions have a branching appearance, very few, if any, are truly stellate, i.e. a central area of necrosis or hemorrhage with a radiating star-like pattern composed of straight lines.

Retiform lesions can be inflammatory or non-inflammatory, but the age of the lesion may blur this morphologic distinction, so in practice both groups of diagnoses need to be considered (see Tables 22.5 & 22.6). Inflammatory retiform purpura is accompanied by peripheral erythema, but the wound healing response can eventually lead to erythema and leukocytoclasis in lesions initiated by non-inflammatory occlusion (Fig. 22.4). As a corollary, vasculitis sometimes produces lesions that have minimal early erythema and lesions lose erythema during resolution.

Lastly, the retiform lesions of immune complex vasculitis are invariably sparse in number and are accompanied by many round purpuric lesions. In addition, these retiform lesions are typically more finely branched than either occlusive or ANCA-associated retiform purpura. However, when within confluent areas of purpura, they may have more intense branching hemorrhage or necrosis. Of note, vasculitic retiform lesions do not simply represent the crowding or collision of more classic round purpuric lesions, and they may occur with or without cutaneous arteritis.

The presence of a multi-dependent round and retiform pattern (many round/few retiform lesions) is seen most commonly with three types of immune complex vasculitis: (1) IgA-predominant; (2) autoimmune connective tissue disease-associated; and (3) mixed cryoglobulinemia. This pattern of round and retiform purpuric lesions may occasionally

DIFFERENTIAL DIAGNOSIS OF MACULAR PETECHIAE (≤4 MM IN DIAMETER)
Hemostatically relevant thrombocytopenia (<10 000–20 000/mm³)*
Major etiologies†

• Idiopathic thrombocytopenic purpura
• Thrombotic thrombocytopenic purpura
• Other acquired thrombocytopenias, including drug-related
  • Peripheral destruction (e.g. quinine, quinidine)
  • Drug-induced decreased production, idiosyncratic or dose-related (e.g. chemotherapy)
  • Bone marrow infiltration, fibrosis, or failure
• Disseminated intravascular coagulation (early sign)

Abnormal platelet function
Major etiologies†

• Congenital or hereditary platelet function defects
• Acquired platelet function defects
  • Aspirin, NSAIDs
  • Renal insufficiency
  • Monoclonal gammopathy (uncommon)
• Thrombocytosis secondary to myeloproliferative disorders (often >1 000 000/mm³)

Non-platelet etiologies
Major etiologies†

• Spiking elevations of intravascular venous pressure (Valsalva maneuver-like, e.g. repetitive vomiting, childbirth, paroxysmal coughing, seizure)
• Fixed increased pressure (e.g. stasis, ligatures) or intermittent pressure (e.g. blood pressure cuff – Rumpel–Leede sign)
• Trauma (often linear)
• Fat embolism syndrome
• Perifollicular (vitamin C deficiency)
• Mildly inflammatory conditions
  • Pigmented purpuric eruptions
  • Hypergammaglobulinemic purpura of Waldenström

*Platelets provide factors necessary for hemostasis of endothelial cell junctions. When counts fall below 10 000–20 000/mm³, inadequate platelet support leads to degradation of junction function, increased permeability, and hemorrhage³. †Partial list.

Table 22.1 Differential diagnosis of macular petechiae (≤4 mm in diameter). NSAIDs, nonsteroidal anti-inflammatory drugs.

DIFFERENTIAL DIAGNOSIS OF INTERMEDIATE MACULAR PURPURA (5–9 MM)
Major etiologies*
• Hypergammaglobulinemic purpura of Waldenström • Infection/inflammation in patients with thrombocytopenia • Rarely, minimally inflamed cutaneous small vessel vasculitis (usually dependent distribution)
*Partial list.

Table 22.2 Differential diagnosis of intermediate macular purpura (5–9 mm).

be seen in microscopic polyangiitis or granulomatous polyangiitis, but the lesions are fewer in number and more randomly distributed. The combination of many round/few retiform lesions is not seen with simple hemorrhage or microvascular occlusive disease.

THE TIME COURSE OF PURPURA

The three subsets of macular (non-palpable) purpura (see Tables 22.1–22.3) typically develop via simple hemorrhage, with extravasated red blood cells and minimal inflammation observed in biopsy specimens. These lesions simply evolve from initial hemorrhage to steady clearing of red blood cells and hemoglobin. Clinically this correlates with fading of lesions and, in larger lesions, transition of color from red–blue or purple to green, yellow, or brown before complete fading.

In syndromes of inflammatory hemorrhage, such as cutaneous small vessel vasculitis, as well as in microvascular occlusion, the evolution and

DIFFERENTIAL DIAGNOSIS OF MACULAR ECCHYMOSES (≥1 CM)
Procoagulant defect plus minor trauma
Major etiologies*
• Anticoagulant use • Hepatic insufficiency with poor procoagulant synthesis • Vitamin K deficiency • Disseminated intravascular coagulation (some)
Poor dermal support of vessels plus minor trauma
Major etiologies*
• Solar (actinic, senile) purpura • Corticosteroid therapy, topical or systemic • Vitamin C deficiency (scurvy) • Systemic amyloidosis (light chain-related, transthyretin-related; see Tables 47.1 & 47.2) • Ehlers–Danlos syndrome
Platelet disorders plus minor trauma
Major etiologies*
• Platelet function defects, including von Willebrand disease and those induced by medications and metabolic diseases • Acquired or congenital thrombocytopenia
Miscellaneous
• Papular purpuric gloves and socks syndrome
*Partial list.

Table 22.3 Differential diagnosis of macular ecchymoses (≥1 cm).

PALPABLE PURPURA: INFLAMMATORY PURPURA WITH PROMINENT EARLY ERYTHEMA
Leukocytoclastic vasculitis due to immune complex disease (see Fig. 24.1)
Small vessels only
• Idiopathic, infection- or drug-associated IgG or IgM complexes • Idiopathic IgA complexes (HSP), or IgA complexes associated with drugs or infection • Hypergammaglobulinemic purpura of Waldenström • Urticarial vasculitis: often minimally purpuric • Pustular vasculitis (e.g. bowel bypass syndrome)
Small- and medium-sized (macroscopic) vessels may be involved
• Mixed cryoglobulinemia • Rheumatic vasculitides (LE, RA, Sjögren syndrome)
Pauci-immune leukocytoclastic vasculitis (see Fig. 24.1)
ANCA-associated
• Granulomatosis with polyangiitis • Microscopic polyangiitis • Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome)
Other
• Erythema elevatum diutinum • Sweet syndrome (vasculitis unusual)
***Not* leukocytoclastic vasculitis**
Small vessels only
• Erythema multiforme • Pityriasis lichenoides et varioliformis acuta (PLEVA) • Pigmented purpuric eruptions • Hypergammaglobulinemic purpura of Waldenström (although some lesions have histologic evidence of leukocytoclastic vasculitis)
Classic target lesion – usually erythema multiforme, but can be small vessel vasculitis, especially IgA-associated

Table 22.4 Palpable purpura: inflammatory purpura with prominent early erythema. HSP, Henoch–Schönlein purpura; LE, lupus erythematosus; RA, rheumatoid arthritis.

DIFFERENTIAL DIAGNOSIS OF NON-INFLAMMATORY RETIFORM PURPURA
Occlusion primarily due to platelet-related thrombopathy
Major etiologies*
• Heparin-induced thrombocytopenia syndrome (HITS) • Thrombocytosis secondary to myeloproliferative disorders • Paroxysmal nocturnal hemoglobinuria • Thrombotic thrombocytopenic purpura (though platelet plugs form primarily in visceral vessels, and skin hemorrhage is due more often to thrombocytopenia)
Cold-related precipitation or agglutination
Major etiologies*
• Cryoglobulinemia, usually monoclonal (early lesions of mixed cryoglobulinemia are more often inflammatory and leukocytoclastic due to immune complex deposition) • Cryofibrinogenemia (though most cryofibrinogens are incidental findings in hospitalized patients) • Cold agglutinins (rarely cause occlusion; usually cause hemolysis or are asymptomatic)
Occlusion due to organisms growing in vessels
Major etiologies*
• Vessel-invasive fungi (e.g. *Mucor* spp., *Aspergillus* spp.; usually in immunocompromised patients) • Ecthyma gangrenosum (often *Pseudomonas* spp. or other Gram-negative bacilli proliferating in adventitia of subcutaneous arterioles) • Disseminated strongyloidiasis • Lucio phenomenon of Hansen disease • Rocky Mountain spotted fever, other rickettsial spotted fevers
Systemic alteration in control of coagulation
Major etiologies*

• Disseminated intravascular coagulation, often in the setting of sepsis
• Protein C- and S-related
  • Homozygous protein C or protein S deficiency (neonatal purpura fulminans)
  • Acquired protein C deficiency (some patients with sepsis-associated DIC)
  • Warfarin necrosis† (protein C dysfunction)
  • Postinfectious purpura fulminans (protein S dysfunction)
• Antiphospholipid antibody, lupus anticoagulant
• Levamisole-adulterated cocaine‡

Vascular coagulopathy
• Livedoid vasculopathy/atrophie blanche (may also have a systemic prothrombotic component) • Malignant atrophic papulosis/Degos disease (antiphospholipid antibody syndrome can mimic this disease) • Sneddon syndrome (can be related to antiphospholipid antibody syndrome) • Deficiency of adenosine deaminase 2 (ADA2)
Embolization or crystal deposition
Major etiologies*
• Cholesterol emboli • Oxalate crystal deposition (rare) • Marantic endocarditis, atrial myxoma, crystal globulins, hypereosinophilic syndrome (all rare)
Reticulocyte, red blood cell occlusion
• Sickle cell disease • Severe malaria (usually *Plasmodium falciparum*)
Miscellaneous
• Cutaneous calciphylaxis • Brown recluse (*Loxosceles*) spider bite reaction • Intravascular B cell lymphoma • Hydroxyurea (rare)
*Partial list. †Also referred to as Coumadin® necrosis. ‡Early lesions primarily thrombotic, but vasculitis can also occur; retiform purpura can be inflammatory.

Table 22.5 Differential diagnosis of non-inflammatory retiform purpura. DIC, disseminated intravascular coagulation; RBC, red blood cell; vWF, von Willebrand factor.

clearing of lesions is more complicated. This is outlined in Figure 22.4. Because of the different evolution of these two processes, it is possible for a biopsy specimen of a late lesion of vasculitis to resemble an early lesion of occlusion histologically. Conversely, a late lesion of occlusion with some resulting dermal necrosis may on histologic examination show features characteristic of leukocytoclastic vasculitis (LCV). This means that *both* the clinical morphology and the histopathology of a purpuric lesion must be interpreted within the context of the lesion's age and clinical setting.

HEMOSTASIS/COAGULATION

Primary hemostasis consists of adhesion, activation, and aggregation of platelets at the site of vascular injury. This leads to the formation of a platelet plug sufficient for routine minor injuries to the microvascular system. Platelets are also essential for maintaining the integrity of small blood vessels. There is molecular signaling crosstalk between megakaryocytes and endothelial cells, with platelets delivering megakaryocytic factors that are important for endothelial health.

Petechial hemorrhage due to severe thrombocytopenia (typically platelets <20 000/mcl) results from reduced delivery of these megakaryocyte/platelet factors to the endothelium, thereby impairing endothelial cell function and widening of the gaps between endothelial cells[5]. This probably also explains why platelet dysfunction does not typically result in petechial hemorrhage, since platelet number and factor delivery remain normal, but rather ecchymoses develop because platelet plugs fail to form at sites of injury.

When a platelet plug is inadequate due to the size of the vessel or the size of the injury, **secondary** hemostasis with clot formation is needed. Secondary hemostasis classically includes the intrinsic and extrinsic coagulation pathways that then converge into a common pathway, driving the formation of fibrin from fibrinogen via stepwise amplifications (Fig. 22.5)[6,7]. The *intrinsic* (contact activation) pathway is the longer of the two; it begins with factor XII activation, typically due to injury-related exposure of endothelial collagen. This pathway is assessed by the activated partial thromboplastin time (aPTT). The *extrinsic* pathway is triggered by tissue factor released from endothelial and other cells, which converts factor VII to factor VIIa, and then as the extrinsic pathway converges with the intrinsic pathway to form the common pathway, factor X is converted to factor Xa. The extrinsic pathway is monitored by the prothrombin time (PT).

Whereas insufficient clotting can lead to death via hemorrhage, inappropriate clotting produces thrombosis, embolus, and/or necrosis. Uncontrolled clotting with fibrinolysis can produce both thrombosis and hemorrhage, as in DIC. Ideally, a thrombus should form rapidly at sites of injury, but should not extend beyond where it is needed. Clotting factors that escape the local injury site must be prevented from triggering clotting at distant sites. As might be expected for a system that requires exquisite regulation to perform properly, the control of coagulation is multifaceted. Basal coagulation encompasses the constant low-level activation of some components of the procoagulant, natural anticoagulant, and fibrinolytic pathways, so that these systems are primed for a rapid response when needed. While Figure 22.5 appears complicated enough for a dermatologist, there are additional modifiers of coagulation including prekallikrein, C1 esterase inhibitor (see Fig. 18.6), factor XIII, and protein Z/protein Z-dependent protease inhibitor[6].

The initiation phase of clotting is down-regulated by *tissue factor pathway inhibitor* (TFPI) and *antithrombin III* (ATIII). TFPI and ATIII are bound to heparan sulfate molecules on the surface of endothelial cells (see Fig. 22.5). Their presence in close proximity to sites of desired clot formation allows them to capture activated clotting factors and prevent them from leaving the area. ATIII can neutralize thrombin as well as factors IXa, Xa, and XIIa; this process is greatly enhanced by heparan sulfate or heparin binding to ATIII.

The *thrombomodulin/protein C/protein S* system is the other major natural anticoagulant pathway. While both ATIII and protein C pathways

DIFFERENTIAL DIAGNOSIS OF INFLAMMATORY RETIFORM PURPURA
Vasculitis
Primarily dermal vessels
• IgA vasculitis
Dermal and subcutaneous vessels usually involved
• Mixed cryoglobulinemia • Rheumatic vasculitides (LE, RA) • Polyarteritis nodosa • Microscopic polyangiitis • Granulomatosis with polyangiitis • Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome)
Dermal vessel inflammation/occlusion/constriction
• Livedoid vasculopathy • Septic vasculitis • Chilblains (pernio) • Pyoderma gangrenosum

Table 22.6 Differential diagnosis of inflammatory retiform purpura. LE, lupus erythematosus; RA, rheumatoid arthritis.

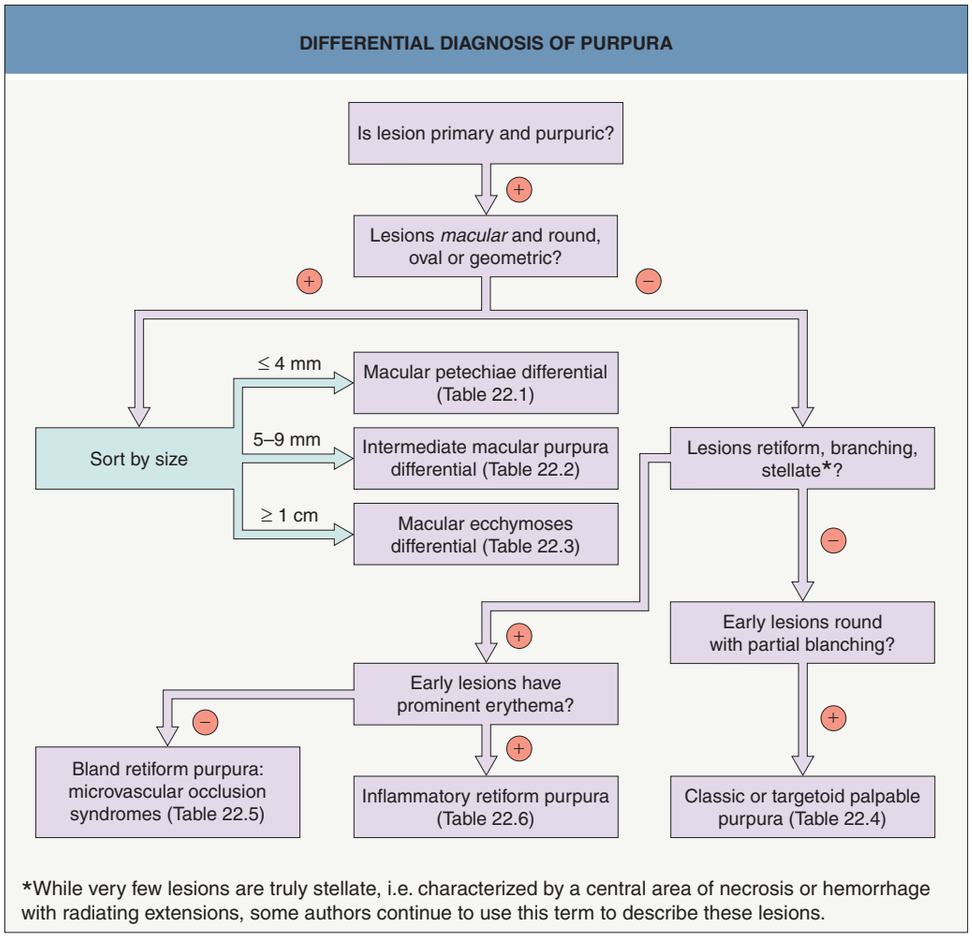


Fig. 22.3 Differential diagnosis of purpura. Morphology can be used as a primary sorting method, but combining morphology with an initial pattern approach as depicted in Figure 22.1 can improve accuracy. When discrepancies between the two arise, additional investigation is warranted.

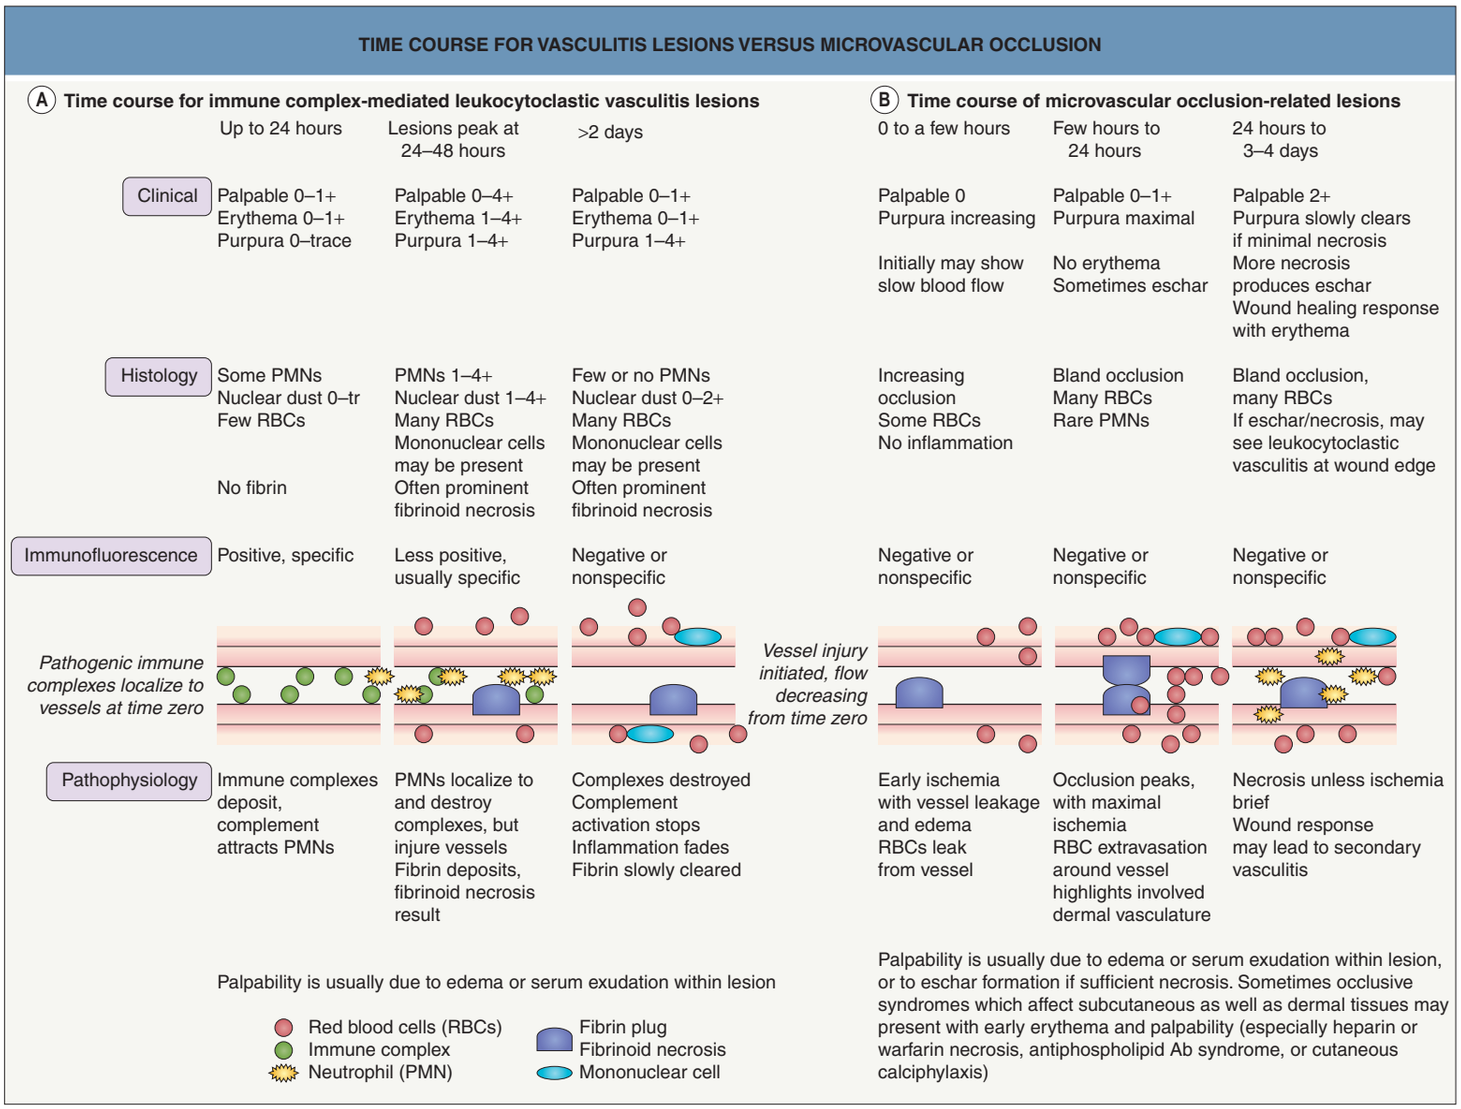

Fig. 22.4 Time course for skin lesions due to vasculitis versus microvascular occlusion. A Time course for lesions due to immune complex-mediated leukocytoclastic vasculitis. **B** Time course for lesions due to microvascular occlusion. Ab, antibody; tr, trace.

are important in large vessels, the protein C system seems to be critical for normal function of the microvasculature. Thrombin that escapes the clot site can bind to thrombomodulin on the endothelial cell surface. Once bound to thrombomodulin, thrombin no longer activates procoagulant factors, but instead avidly binds and activates protein C, a vitamin K-dependent anticoagulant protein (see Fig. 22.5). The anticoagulant function of activated protein C is enhanced by binding to a phospholipid surface, a high-density lipoprotein (HDL), and protein S (another vitamin K-dependent anticoagulant). This complex then inactivates factors Va and VIIIa. The factor V Leiden mutation is a single amino acid change at the site of cleavage by activated protein C, and this change renders it much more resistant to inactivation, thus explaining the associated prothrombotic state. In other patients, a polymorphism in the prothrombin gene, specifically 20210A within an untranslated region, increases the level of prothrombin and can lead to a prothrombotic state.

OVERLAP OF COAGULATION AND INFLAMMATORY VESSEL DISEASE

Hemostasis is one aspect of the host response to injury. It is clear that inflammatory injury can lead to fibrin deposition in vessels, as exemplified by fibrinoid necrosis in vasculitis (see Fig. 22.4). Both platelets and coagulation factors play an important role in vascular integrity, innate immunity, inflammatory responses, and wound healing[8,9]. For example, thrombin is a procoagulant factor, but it also acts to promote monocyte, fibroblast, and endothelial cell migration into an area of recent injury to begin removal of damaged tissue and initiate wound repair. Thrombin bound to thrombomodulin activates protein C, which in addition to its potent anticoagulant action also has important anti-inflammatory properties. In addition, a powerful angiogenesis inhibitor, angiostatin, is a cleavage product of plasminogen. Thromboinflammation is an expanding concept that recognizes the complex and vital integration of coagulation, inflammation, and wound healing pathways[8,9].

TESTS FOR COAGULATION

A thorough history (including family history) and physical examination are important in the proper selection and interpretation of tests measuring coagulation and anticoagulation parameters. A basic laboratory assessment of clotting includes a platelet count, PT, and aPTT (Table 22.7). Platelet function tests (e.g. bleeding time, ristocetin-induced platelet aggregation studies) are performed in settings suggesting platelet function defects unexplained by medications (e.g. aspirin, nonsteroidal anti-inflammatory drugs [NSAIDs]) or metabolic disorders such as renal failure. Another example would be the platelet dysfunction observed in Hermansky–Pudlak syndrome. Laboratory tests that are employed in the evaluation of thrombophilia/hypercoagulability are outlined in Table 105.9.

ANTIPLATELET AND ANTICOAGULANT AGENTS

Antiplatelet agents are used in specific clinical settings to reduce the risk of thrombosis. Medications that dermatologists are most likely

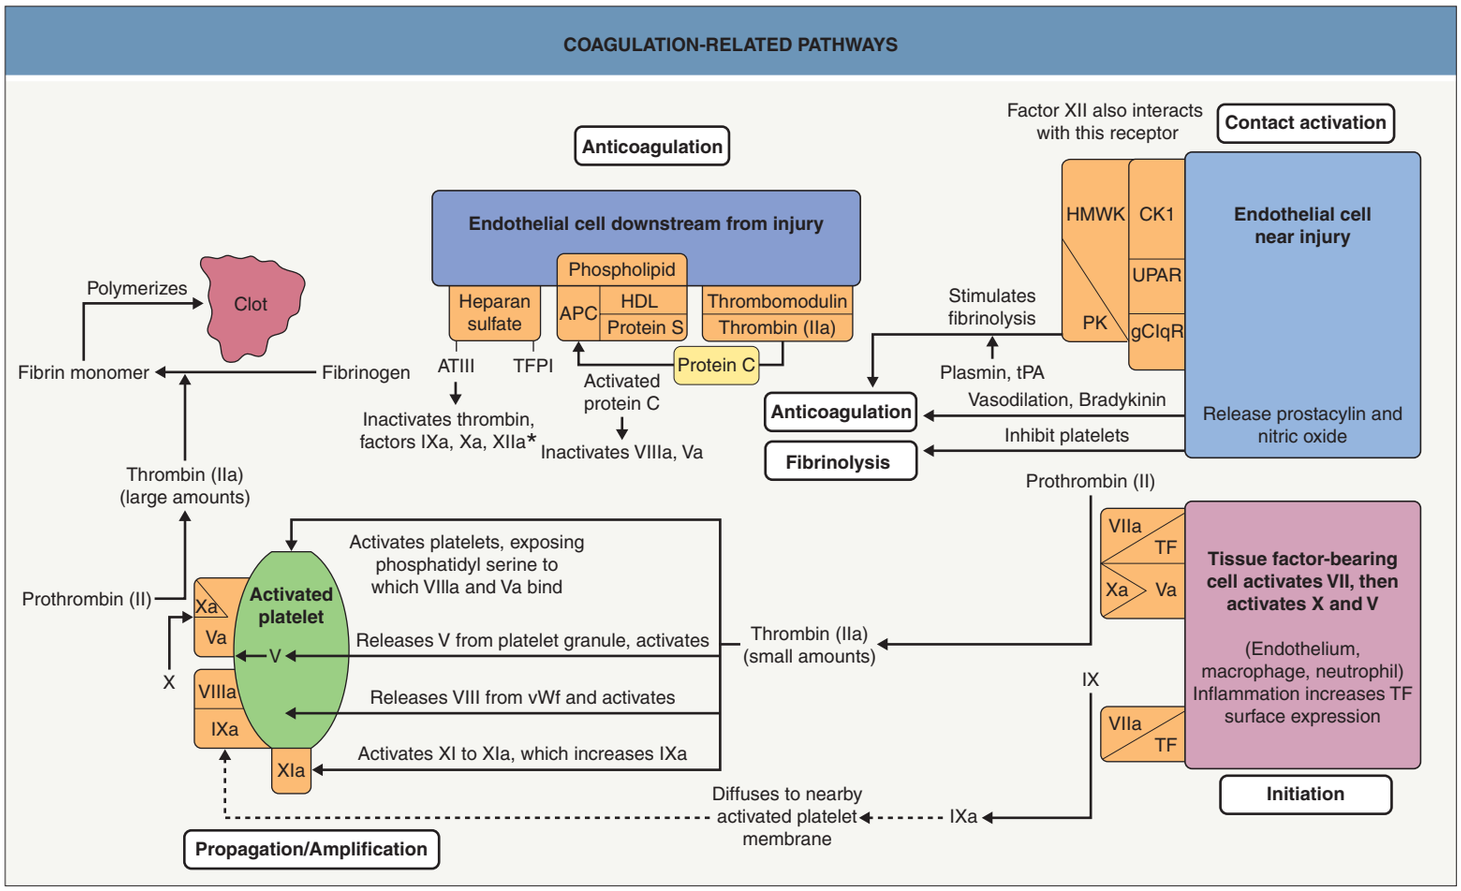

Fig. 22.5 Coagulation-related pathways. TFPI can inactivate factor Xa, and the TFPI–factor Xa complex can inhibit VIIa. *Enhanced by binding of heparin to ATIII. APC, activated protein C; ATIII, antithrombin III; CK1, cytokeratin 1; gC1qR, globular head of the C1q receptor; HDL, high-density lipoprotein; HMWK, high-molecular-weight kininogen; PK, prekallikrein; TF, tissue factor; TFPI, tissue factor pathway inhibitor; tPA, tissue plasminogen activator; UPAR, urokinase plasminogen activator receptor; vWF, von Willebrand factor.

INTERPRETATION OF PROTHROMBIN TIME (PT) AND ACTIVATED PARTIAL THROMBOPLASTIN TIME (APTT)	
Coagulation test results	**Most likely etiologies**
Normal PT, prolonged aPTT	Heparin administration Lupus anticoagulant* Acquired factor VIII inhibitor von Willebrand disease (defective platelet adhesion and functional deficiency of factor VIII) Significant deficiency of one of following: • Factor VIII, IX, XI, or XII • High-molecular-weight kininogen (HMWK) • Prekallikrein
Prolonged PT, normal aPTT	Factor VII deficiency Low-dose oral anticoagulant
Prolonged PT and prolonged aPTT	Deficiency or inhibitor of: • Fibrinogen • Prothrombin • Factor V or X Combined deficiency of multiple procoagulant factors: • Severe vitamin K deficiency • High-dose oral anticoagulant
*Other tests, such as the dilute Russell viper venom time, may help confirm the presence of lupus anticoagulant activity.	

Table 22.7 Interpretation of prothrombin time (PT) and activated partial thromboplastin time (aPTT). Repeating the test using a 1:1 mixture of the patient's plasma and normal plasma will usually normalize the time if there is a factor deficiency, but the time will remain prolonged if an inhibitor is present.

to use to treat microvascular involvement in livedoid vasculopathy or antiphospholipid antibody syndrome include acetosalicylic acid (ASA, aspirin; inhibits cyclooxygenase), dipyridamole or pentoxifylline (both increase cAMP), and clopidogrel (blocks ADP). *Anticoagulant* medications are listed by their mechanisms of action in Table 22.8[10–12], and their sites of interaction are illustrated in Figure 22.6. Unlike warfarin, dabigatran and direct oral anticoagulants (DOACs) that inhibit thrombin or factor Xa, respectively, do not require monitoring of the international normalized ratio (INR), i.e. prothrombin ratio[10]. Given their popularity, specific reversal agents became a priority and are now commercially available while others are in development (see Table 22.8)[11–14]. In addition to LWMH, DOACs are now being used more frequently for select syndromes with prominent microvascular cutaneous involvement such as livedoid vasculopathy.

SELECTED PURPURA SYNDROMES

Some syndromes that are not traditionally discussed in chapters on microvascular occlusion (Ch. 23) or vasculitis (Ch. 24) will be addressed here.

Pigmented Purpuric Dermatoses

Synonyms: ■ Pigmented purpuric eruptions ■ Capillaritis ■ Purpura pigmentosa chronica ■ Purpura simplex ■ Majocchi–Schamberg disease

Variants:
- ■ Schamberg disease: Schamberg purpura, progressive pigmentary dermatosis of Schamberg, purpura pigmentosa progressiva
- ■ Purpura annularis telangiectodes of Majocchi: Majocchi's disease
- ■ Pigmented purpuric lichenoid dermatitis of Gougerot and Blum
- ■ Eczematid-like purpura of Doucas and Kapetanakis: eczematoid purpura, itching purpura
- ■ Lichen aureus: lichen purpuricus

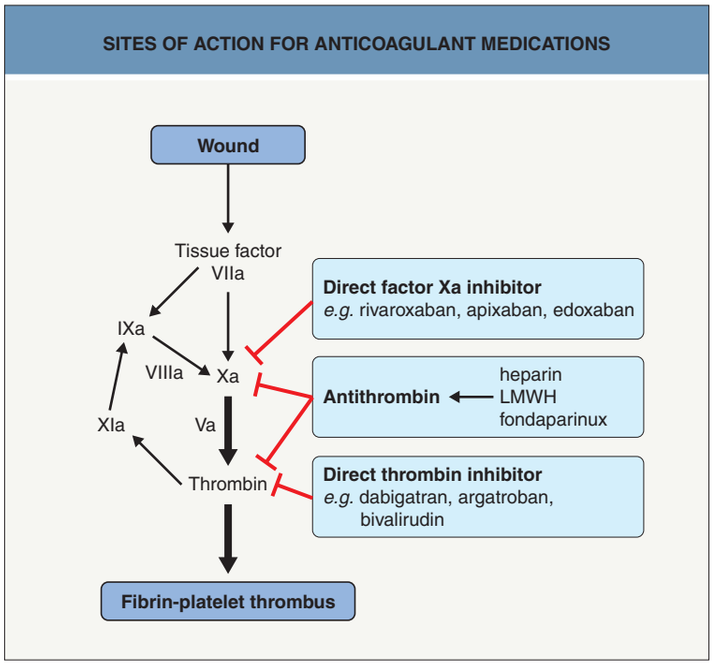

Fig. 22.6 Sites of action for anticoagulant medications. LMWH, low-molecular-weight heparin.

ANTICOAGULANTS		
Agent	**Route of administration**	**Reversal agent**
Interact with antithrombin to primarily inhibit factor IIa (thrombin) and/or factor Xa		
Unfractionated heparin	IV	Protamine sulfate
Enoxaparin (LMWH)	SC	Protamine sulfate (partial)
Dalteparin (LMWH)	SC	Protamine sulfate (partial)
Tinzaparin (LMWH)	SC or IV	Protamine sulfate (partial)
Fondaparinux (synthetic pentasaccharide)	SC	
Inhibit gamma carboxylation of vitamin K dependent factors: II, VII, IX, X, protein C, & protein S		
Warfarin	Oral	Vitamin K Urgent reversal: PCC, FPP, or recombinant factor VIIa
Direct thrombin inhibitor		
Dabigatran (NOAC*)	Oral	Idarucizumab
Argatroban	IV	Can be hemodialyzed
Bivalirudin (synthetic hirudin analogue)	IV	Can be hemodialyzed
Direct factor Xa inhibitor (DOAC)		
Rivaroxaban	Oral	Specific: Andexanet† Nonspecific: PCC
Apixaban	Oral	Specific: Andexanet† Nonspecific: PCC
Edoxaban	Oral	Nonspecific: PCC
Betrixaban	Oral	Nonspecific: PCC
Binds factor XI and XIa		
Abelacimab**	SC or IV	

*NOACs include DOACs plus dabigatran.
**Currently under investigation.
†Under evaluation for broader use.

Table 22.8 Anticoagulants. Ciraparantag is being evaluated as a possible reversal agent for heparin, LMWH, fondaparinux, and DOACs. DOAC, direct oral anticoagulant; FPP, fresh frozen plasma; IV, intravenous; LMWH, low-molecular-weight heparin; NOAC, novel oral anticoagulant or non-vitamin K oral anticoagulant; PCC, prothrombin complex concentrate; SC, subcutaneous.

Key features

- Clustered petechial hemorrhage
- Often a background of yellow–brown discoloration due to hemosiderin deposition
- The location and pattern depends on the particular variant

Introduction

Pigmented purpuric eruptions represent a group of diseases characterized by petechial hemorrhage thought to be secondary to capillaritis[15–18]. These diseases have no systemic findings, but they occasionally lead to a patient evaluation to exclude thrombocytopenia or vasculitis because of the purpuric (usually petechial) nature of the lesions and clinical misdiagnosis, especially of the rarer forms.

Pathogenesis

These diseases all result from minimal inflammation and hemorrhage of superficial papillary dermal vessels, usually capillaries. The reason for the inflammation is unknown.

Clinical features

The characteristics of the various forms of pigmented purpuric eruptions are outlined in Table 22.9 and illustrated in Figures 22.7 and 22.8. This disorder occurs in both children and adults[18].

Pathology

Histopathologic features include red cell extravasation, endothelial cell swelling, a perivascular lymphocytic infiltrate, and hemosiderin-containing macrophages (Fig. 22.9). The lichen aureus and Gougerot–Blum variants are characterized by a lichenoid infiltrate, and epidermal spongiosis with patchy parakeratosis is often observed in the latter as well as in eczematid-like purpura of Doucas and Kapetanakis. A rare granulomatous variant has also been described[17].

Differential diagnosis

The clinical picture is often sufficient for diagnosis, but a biopsy specimen may be required to distinguish the lichenoid variant from cutaneous small vessel vasculitis. Although usually on one extremity, angioma serpiginosum may occasionally be misdiagnosed as pigmented purpura. Lesions resembling capillaritis have been reported in patients with mycosis fungoides; allergic contact dermatitis (e.g. due to rubber or azo dyes); non-allergic reactions to topical medications (e.g. fluorouracil or eutectic mixture of local anesthetics [EMLA]); drug eruptions (e.g. carbromal, meprobamate, acetaminophen, infliximab, bezafibrate, glipizide, pseudoephedrine, NSAIDs, diuretics, creatine supplementation, medroxyprogesterone injections) based primarily on case reports; suction-induced purpura (e.g. cupping); rheumatoid arthritis; lupus erythematosus; hypergammaglobulinemic purpura of Waldenström; and perhaps due to diet (e.g. apple–cherry fruit spritzer)[16].

Pigmented purpuric eruptions on the legs must be differentiated from dermal hemorrhage secondary to venous hypertension, which presents with petechiae superimposed on diffuse hemosiderosis (Fig. 22.7B) rather than the discrete yellow–brown patches that characterize Schamberg disease. It also needs to be distinguished from exercise-induced vasculitis, also known as golfer's vasculitis, hiker's rash or ankle heat rash, which occurs with prolonged exercise in hot weather[19]. Histologically, findings in exercise-induced vasculitis range from urticarial vasculitis to frank LCV. Since exercise or prolonged standing may also induce recurrent macular vasculitis (see below), it is possible that there is some overlap between these two disorders.

Treatment

Topical corticosteroid therapy is occasionally helpful, especially in patients who report pruritus or have more evident erythema. Effective treatment of more extensive pigmented purpuric eruptions with narrowband UVB and PUVA has been described. Successful therapy with ascorbic acid (500 mg twice daily) plus rutoside (50 mg twice daily) has also been reported. While multiple treatments have been recommended, to date none have proven to be reproducibly effective.

TYPES OF PIGMENTED PURPURIC DERMATOSES			
Type	**Age/Sex**	**Morphology**	**Location**
Schamberg disease	• Most common form • Can occur in children • Peak frequency in middle-aged to older men	• Yellow–brown patches with an oval to irregular outline (Fig. 22.7A) • Pinpoint petechiae within patches – likened to "cayenne pepper" • Successive crops	• Favors lower legs • Can also involve thighs, buttocks, trunk, and arms
Purpura annularis telangiectodes of Majocchi	• Uncommon • Adolescents and young adults, especially women	• 1–3 cm annular plaques that may slowly expand • Punctate telangiectasias and petechiae within the border (Fig. 22.8A)	Trunk, proximal lower extremities

Pigmented purpuric lichenoid dermatitis of Gougerot and Blum	• Rare
	• Middle-aged to older men
		• Admixture of two types of lesions:
		  • Schamberg-like
		  • Purpuric red–brown lichenoid papules
		• Chronic
		• Occasionally pruritic
			On lower extremity, may be confused with cutaneous small vessel vasculitis

Eczematid-like purpura of Doucas and Kapetanakis	• Rare • Middle-aged to older men	• Scaly petechial or purpuric macules, papules, and patches (Fig. 22.8B) • Pruritic	Primarily lower extremities
Lichen aureus	• Rare	• Solitary patch • Color varies from golden to rust to purple–brown	Usually lower extremity, often over a perforator vein
Linear pigmented purpura	• Rare • Can occur in children and adolescents	• Linear array, usually unilateral (Fig. 22.8C) • Individual lesions similar in appearance to lichen aureus or Schamberg disease	Often a single extremity
Granulomatous pigmented purpura	• Very rare	• Brown patches with superimposed hemorrhagic papules*	Lower legs

*Histologically, hemorrhagic granulomatous inflammation in upper dermis.

Table 22.9 Types of pigmented purpuric dermatoses. Rarely, the first two types are familial.

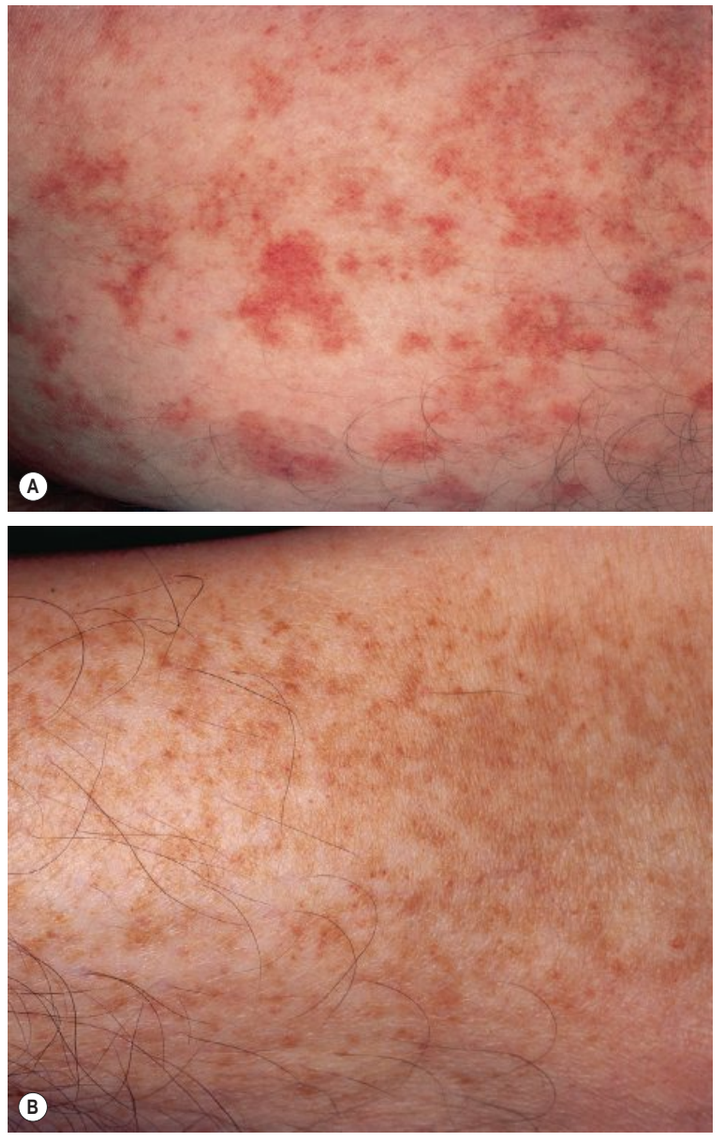

Fig. 22.7 Schamberg disease versus petechiae and hemosiderin secondary to venous hypertension. A Discrete yellow–brown and yellow–pink patches with superimposed petechiae in Schamberg disease. **B** Petechiae superimposed on more diffuse hemosiderin deposits in venous hypertension, referred to as "stasis purpura". *B, Courtesy Jean L. Bolognia, MD.*

Benign Hypergammaglobulinemic Purpura of Waldenström

Synonym: ▪ Recurrent macular vasculitis in hypergammaglobulinemia

Key features

- Usually affects women
- Recurrent crops of petechiae and larger purpuric macules on the lower extremities, which often burn or sting
- Patients typically have polyclonal hypergammaglobulinemia and may have elevated IgG or IgA rheumatoid factor (RF), but not necessarily IgM RF (the standard RF test)
- An autoimmune connective tissue disease develops in a subset of patients

Introduction

This syndrome was first described in 1943 by Waldenström, who reported three women with chronic relapsing purpura, hypergammaglobulinemia, an elevated ESR, and mild anemia. Hypergammaglobulinemic purpura of Waldenström is often associated with an autoimmune connective tissue disease (AI-CTD), especially Sjögren syndrome. In the most recent cutaneous vasculitis classification, this disorder has been renamed *recurrent macular vasculitis in hypergammaglobulinemia*[4].

Pathogenesis

Although associated with hypergammaglobulinemia, a strong argument can be made that a more specific feature of this condition is the presence of small circulating immune complexes, which often contain IgG or IgA rheumatoid factor (RF). Complexes of this size have also been identified in individuals with a clinical presentation that fits this syndrome but who lacked polyclonal hypergammaglobulinemia[20,21]. IgG and IgA RFs are highly soluble, which might explain the rapidity with which lesions appear and then resolve. The presence of monoclonal RF early on in the disease in some patients as well as the tendency of affected individuals to develop autoimmune and (less often) lymphoproliferative disorders supports the presence of a mild immune dysregulation syndrome.

Fig. 22.8 Less common forms of pigmented purpuric eruptions (capillaritis). **A** Purpura annularis telangiectodes of Majocchi characterized by annular plaques with cayenne pepper petechiae in the border. **B** Eczematid-like purpura that often presents with pruritus. **C** Linear pigmented purpuric dermatosis in which there is a linear array of yellow–brown macules and patches with superimposed petechiae and small, red–brown purpuric papules on the arm of a child. The eruption had been present for several months and was limited to this segment of skin. *B, Courtesy Kalman Watsky, MD; C, Courtesy Julie V. Schaffer, MD.*

Fig. 22.10 Hypergammaglobulinemic purpura of Waldenström. This young woman with Sjögren syndrome had recurrent crops of petechiae on her lower legs. Note the hemosiderin deposition at sites of older lesions. *Courtesy Julie V. Schaffer, MD.*

Clinical features

The purpura is often preceded by a slight itch, mild tingling or burning, and it may be aggravated by tight-fitting garments, prolonged standing, and heat. Macular hemorrhage (e.g. petechiae or larger purpuric macules) on the lower extremities represents the most common presentation, but the lesions may be fleeting (Fig. 22.10). Some patients have palpable purpura with histologic evidence of vasculitis (see below), which has led many authors to classify this entity as a subset of cutaneous small vessel vasculitis[22].

Recurrent macular vasculitis can be primary or secondary[22]. In younger patients it is usually primary, but over time some patients develop evidence of an AI-CTD, most frequently Sjögren syndrome and occasionally rheumatoid arthritis or lupus erythematosus. Much less often, a monoclonal gammopathy or very rarely, a lymphoma or multiple myeloma develops. Children with recurrent macular vasculitis frequently have an associated AI-CTD and it may also develop in patients with cystic fibrosis[23].

Laboratory evaluation typically reveals polyclonal hypergammaglobulinemia and an elevated ESR. Standard RF assays identify only IgM RF, so they will not detect the IgG and IgA RFs that are frequently found in this syndrome (although specific tests for IgG and IgA RF can be performed). Anti-SSA/Ro and -SSB/La antibodies are commonly present and may predict a higher likelihood of developing an associated AI-CTD.

Pathology

Simple hemorrhage is most frequently seen. Occasionally a mild perivascular lymphocytic infiltrate or rarely LCV may be present.

Differential diagnosis

The clinical picture is often characteristic. Some patients develop palpable purpura mimicking classic cutaneous small vessel vasculitis syndromes, but most patients present with recurring crops of burning or stinging macular hemorrhage. Exercise-induced vasculitis is also in the differential diagnosis[19].

Treatment

Some agents used to treat this syndrome, such as aspirin or support stockings, have also been reported to exacerbate the condition. Avoidance of precipitating factors such as alcohol and prolonged

standing may be helpful. In secondary cases, treatment is aimed at the underlying disease. When there is evidence of LCV histologically, treatment with colchicine or dapsone can be considered.

Gardner–Diamond Syndrome

Synonyms: ■ Psychogenic purpura ■ Autoerythrocyte sensitization

Key features

- Typically affects girls and young women with an underlying psychiatric illness and triggering stressors
- Painful, swollen ecchymoses occur spontaneously or at trauma sites

Introduction

In 1955, Gardner and Diamond described four women with an abnormal response to bruising characterized by the development of painful ecchymoses at sites of trauma followed by progressive erythema and edema.

Clinical features

This condition is seen almost exclusively in girls and young women, and in the majority of patients, it has been associated with psychiatric illnesses, especially depression[24,25]. Individuals report a sudden onset of painful, swollen bruises of variable size in any area of the body. Sometimes there are also prodromal symptoms. The lesions most commonly involve the extremities (lower > upper), usually resolve within a 2-week period, and typically recur. Original reports described appearance of these atypical purpuric lesions at sites of injection of a patient's own blood or other agents, hence the term autoerythrocyte sensitization. However, more recent reports have challenged the reproducibility of this finding.

Pathology

The histologic features of early lesions consist of edema, a minimal perivascular mononuclear infiltrate, and extravasated red blood cells in the upper dermis.

Differential diagnosis and treatment

Gardner–Diamond syndrome is a diagnosis of exclusion. Both child abuse and domestic abuse need to be considered[25]. Some clinicians view this disorder as a factitial disease, but proving a factitial origin is generally difficult. Gentle probing for an underlying, and potentially treatable, psychiatric condition may prove more productive than confronting the patient. Laboratory evaluation is generally unremarkable and histologic findings non-diagnostic. Patients may develop a lesion at the site of an intradermal injection of autologous washed erythrocytes. Some series report a high degree of success with psychological therapy, coupled with medications, most commonly selective serotonin reuptake inhibitors (SSRIs).

Paroxysmal Finger Hematoma

Synonyms: ■ Acute blue finger ■ Achenbach syndrome

Key features

- Recurrent acute episodes of painful ecchymoses on the palmar surface of one or more fingers

Clinical features

This idiopathic syndrome shares some similarities with Gardner–Diamond syndrome as it occurs primarily in females and may be preceded by prodromal symptoms such as pain, tingling, or itching. However, it has an older mean age of onset (48 years).

Recurrent painful ecchymoses develop on the palmar surface of the hand, primarily the fingers[26–28]. The right index finger is the most common site of involvement, and swelling may precede or accompany the ecchymoses. Evaluation is routinely negative, including Doppler ultrasonography, and is usually not indicated.

Differential diagnosis

Trauma, pernio, acrocyanosis, Raynaud phenomenon, and vascular insufficiency are often suspected, but the history, localization to the palmar surface, and time course aid in excluding these entities.

Treatment

While a variety of therapies have been tried, there is no specific successful treatment. The bleeding generally stops spontaneously, but pressure may be helpful. Typically, there is resolution within two weeks.

Onyalai

Onyalai is a Bantu name for a disease that often presents with hemorrhagic blisters in the mouth. It results from the consumption of sorghum grains contaminated with the fungus *Epicoccum sorghinum*. This fungus produces compounds which inhibit platelet aggregation and angiogenesis[29]. Onyalai may run a course indistinguishable from acute immune thrombocytopenic purpura (ITP). Literature regarding Onyalai is limited, treatment is unclear, and it appears to be less responsive to corticosteroids than is ITP.

Mondor Disease

Synonym: ■ Mondor syndrome of superficial thrombophlebitis

Key features

- Superficial thrombophlebitis affecting the anterolateral thoracoabdominal wall
- Pathogenic factors include trauma, surgical procedures, infections, and breast carcinoma
- Presents with the sudden onset of chest pain and subsequent appearance of a cord-like thrombosed vein

Introduction

Mondor disease is characterized by superficial thrombophlebitis of subcutaneous veins within the anterolateral thoracoabdominal wall, i.e. lateral thoracic, thoracoepigastric, and superior epigastric veins. Though previously reported by others, Henry Mondor provided a very detailed description of this condition in 1939[30]. A similar cord-like superficial thrombophlebitis can occur in other sites (e.g. the upper and lower extremities, abdomen, groin, penis).

Pathogenesis

Common pathogenic factors in chest wall thrombophlebitis include trauma, excessive physical activity, a surgical procedure on the breast, mastitis, a breast abscess, and pendulous breasts[30]. Up to 10% of patients with Mondor syndrome have an underlying breast carcinoma. Occasionally, the condition is associated with rheumatoid arthritis, filariasis, pregnancy, oral contraceptive use, intravenous drug use, intravenous catheters, a non-breast malignancy, or a hypercoagulable state (e.g. hereditary protein C deficiency, anti-cardiolipin antibodies).

Clinical features

A sudden onset of chest pain followed by the appearance of one or more visible or palpable cords (representing thrombophlebitic veins) typify this syndrome. Associated findings include tenderness, a sensation of tension, erythema, ecchymosis, pruritus, arthralgia, and rarely fever. Symptoms worsen on pulling the skin or elevating the breast and the ipsilateral upper extremity. The condition is usually unilateral and is three times more common in women than in men.

Pathology

A biopsy is rarely required. The process may involve arteries and lymphatic vessels as well as veins. Sclerosing endophlebitis with complete

or partial obliteration of the lumen by thrombus and inflammatory cells is typical. The time period between the onset of the condition and ultimate recanalization of the affected vessels varies from 2 weeks to more than 6 months.

Differential diagnosis

The clinical presentation is unique, and etiologic factors should be identified. Recurrent superficial thrombophlebitis (migratory thrombophlebitis) is frequently associated with an underlying malignancy (Trousseau syndrome; most often pancreatic or lung carcinoma), a hypercoagulable state (inherited or acquired), or an inflammatory condition (e.g. Behçet disease).

Treatment

The disease is usually benign and self-limited, except when associated with breast cancer. Aching pain typically ends within 10 days, but the cord often persists for weeks to months and may be tender. Local heat, rest of the arm, and breast support can improve symptoms. The rate of recurrence is ~5%.

INTRODUCTION

The differential diagnosis of microvascular syndromes involving the skin is extensive. It is critical to distinguish between inflammatory injury and *non-inflammatory occlusive injury* to vessels. The diagnosis of occlusive syndromes in the skin is greatly facilitated by recognizing the telltale lesions of retiform purpura or non-inflammatory (bland) necrosis.

Diseases that produce skin lesions secondary to microvascular occlusion have often been lumped with cutaneous vasculitic syndromes or discussed primarily as systemic diseases with little attention paid to cutaneous findings. While there is some overlap in the pathogenesis of deep venous thrombosis and pulmonary emboli and the pathogenesis of cutaneous microvascular occlusion syndromes, the two can differ substantially with respect to disease etiology and treatment.

The differential diagnosis for occlusive syndromes is best approached through major pathophysiologic categories (Table 23.1). These categories frequently have sufficiently distinctive clinical settings that a minimal history and physical examination plus laboratory findings quickly allows for an efficient sorting of the most likely diagnoses (Fig. 23.1). This is especially important in life-threatening situations when making timely decisions is crucial. A reasonable panel of initial laboratory tests is listed in Table 23.2.

It must be emphasized that some inflammatory syndromes capable of producing retiform purpura may occasionally present with lesions that have minimal inflammation (see Ch. 22). In particular, this may occur with the anti-neutrophil cytoplasmic antibody (ANCA)-positive syndromes of granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA), as well as ANCA-negative cutaneous polyarteritis nodosa.

Because treatment depends on pathogenesis (see Fig. 22.4), accurate diagnosis is critical prior to instituting appropriate therapy. The use of anti-inflammatory therapy for occlusive disease may not only be useless but actually harmful, and the same may be true for anticoagulant therapy in most vasculitides.

DISORDERS OF PLATELET-RELATED THROMBOPATHY

Heparin-Induced Thrombocytopenia (HIT) Syndrome

Key features

- Exposure to heparin, most often unfractionated
- Decreasing platelet counts (>50% of recent highest count) 5–10 days after heparin exposure
- Risk of arterial, venous, and microvascular occlusion
- Heparin-induced skin necrosis typically presents as retiform purpura or non-inflammatory necrosis
- Cutaneous lesions may arise locally at sites of heparin infusion/injection or at distant sites
- Detection of anti-platelet factor 4-heparin complex antibodies via ELISA has a very high negative predictive value (when absent) but low positive predictive value (when present)
- Non-necrotic hemorrhage and bullae are not signs of heparin-induced skin necrosis

Introduction

Heparin-induced thrombocytopenia (HIT) syndrome occurs in <0.1%–7% of adults exposed to heparin, with a third to half of these patients developing thrombosis[1,2]. Despite its rarity, it is an important iatrogenic cause of potential limb- and life-threatening disease.

HIT and heparin-induced skin necrosis were first recognized in the early 1970s. They may occur after subcutaneous or intravenous heparin administration, including the trace amounts injected to keep infusion lines open. Of note, the same pathogenic cascade may be activated without heparin exposure (see below) and HIT-like syndromes have also been described as vaccine-induced thrombotic thrombocytopenia (VITT).

Epidemiology

The risk of developing HIT is highest with unfractionated heparin, lower with low-molecular-weight heparin, and negligible with the synthetic pentasaccharide fondaparinux (see Table 22.8). Risk is higher following major surgery, especially orthopedic, coronary artery bypass grafting, or major arterial, as well as significant trauma. It is more frequently observed in women (but rare during pregnancy) and in individuals >50 years of age.

Pathogenesis

The innate immunity pathway in which binding of platelet factor 4 (PF4) to polyanions on the surface of bacteria leads to their phagocytosis can be compared to the pathologic pathway that underlies HIT. The latter involves the binding of PF4 to a polyanion, usually unfractionated heparin, to form ultralarge complexes (ULCs) consisting of multiple PF4 molecules bound to single heparin chains. This binding exposes an epitope on the quadrameric PF4 molecule, which then becomes the target of naturally occurring IgM antibodies[2] with subsequent complement activation and deposition of C3 on the ULCs. Presentation of these modified ULCs to splenic marginal B cells triggers synthesis of

DIFFERENTIAL DIAGNOSIS OF CUTANEOUS MICROVASCULAR OCCLUSION BASED ON PATHOPHYSIOLOGY
Platelet-related thrombopathy
• Heparin-induced thrombocytopenia syndrome • Thrombocytosis secondary to myeloproliferative neoplasms • Paroxysmal nocturnal hemoglobinuria • Primary thrombotic microangiopathies (TTP, STEC-HUS, CM-HUS)
Cold-related precipitation or agglutination
• Cryoglobulinemia (type I) • Cryofibrinogenemia • Cold agglutinins
Vessel-invasive organisms
• Ecthyma gangrenosum (primarily Gram-negative bacteria) • Opportunistic fungi (e.g. *Aspergillus* spp., *Rhizopus* spp.) • Disseminated strongyloidiasis • Lucio phenomenon of Hansen disease (leprosy) • *Rickettsia* spp.
Embolization
• Cholesterol embolus • Oxalate embolus • Atrial myxoma • Marantic endocarditis • Libman–Sacks endocarditis (lupus, often in association with antiphospholipid antibodies) • Infective endocarditis (acute, fungal) (rare)* • Crystalglobulin vasculopathy • Hypereosinophilic syndrome
Systemic coagulopathies
• Neonatal purpura fulminans • Warfarin† necrosis • Warfarin†-associated venous limb gangrene • Purpura fulminans of sepsis/disseminated intravascular coagulation • Postinfectious purpura fulminans • Antiphospholipid antibody/lupus anticoagulant syndrome
Vascular coagulopathies
• Sneddon syndrome/idiopathic livedo reticularis with CVAs • Livedoid vasculopathy • Hydroxyurea-associated vasculopathy • Interferon-induced vasculopathy • Benign and malignant atrophic papulosis/Degos disease • Levamisole/cocaine vasculopathy/vasculitis • Cutaneous calciphylaxis
Disorders of cell-related vascular occlusion
• Red blood cell occlusion • Intravascular cellular occlusion • Intravascular histiocytosis (occlusion with erythema but no purpura)
Miscellaneous/unknown mechanism
• *Loxosceles* (spider bites) • Large hematoma occlusion syndrome • SARS-CoV-2 infection
*Usually inflammatory. †Sometimes referred to by its trade name Coumadin®.

Table 23.1 Differential diagnosis of cutaneous microvascular occlusion based on pathophysiology. Entities are listed as they appear in the text. CM-HUS, complement-mediated hemolytic uremic syndrome; CVAs, cerebrovascular accidents; STEC-HUS, Shiga toxin-producing *E. coli* hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

pathogenic IgG antibodies which bind to PF4 complexed with glycosaminoglycans on platelets; this leads to platelet activation and aggregation. Other cells, especially monocytes, neutrophils, and endothelial cells, also interact with these complexes and enhance thrombosis[2].

Occasionally pathogenic antibodies persist after heparin cessation and anamnestic antibody responses can occur upon re-exposure to heparin. Since the antigen trigger is the exposed epitope on bound PF4, PF4 could potentially bind to endogenous polyanions with exposure of the same epitope. This would explain the rare instances of spontaneous or autoimmune HIT syndrome in the absence of heparin administration.

Clinical features

HIT usually occurs between days 5 and 10 of heparin therapy[1]. In patients exposed to heparin within the past 90–100 days, HIT may develop within hours after re-exposure. Occasionally, there is an anaphylactoid reaction within 30 minutes of a heparin bolus[1]. A delayed-onset form of heparin-induced skin necrosis has been described in which lesions can occur up to 3 weeks after exposure to heparin, including short chain variants[3,4]. Of note, heparin-dependent antibodies usually do not reappear if subsequent heparin use is *after* 100 days.

There are additional unusual clinical scenarios in which HIT can develop. In patients receiving *chronic* heparin, e.g. for renal dialysis, major surgery may trigger HIT within 5–10 days. Even in the absence of exposure to heparin, major surgery or bacterial infections can trigger a spontaneous or autoimmune HIT syndrome (see above).

Cutaneous lesions are usually tender, sharply demarcated, non-inflammatory, and purpuric or necrotic, often with a retiform morphology. Large necrotic areas with or without branching margins can also be seen. Lesions may occur at the site of subcutaneous injections (Fig. 23.2) or may develop at sites distant to the heparin infusion (see Fig. 21.22)[3,4]. Although consumption of platelets is part of this syndrome, absolute thrombocytopenia is often not present in patients with significant vascular occlusion. A decline in the platelet count of >50% from the most recent highest value prior to the administration of heparin (preferably from the day heparin is begun) should prompt consideration of HIT. All limbs and organs are at risk for vascular occlusion, including the CNS.

Heparin may also induce bullous hemorrhagic dermatosis that lacks necrosis (see Ch. 21). This adverse reaction is unrelated to HIT and is not associated with an increased risk of thrombosis[5].

Pathology

In HIT-associated thrombosis, there is non-inflammatory occlusion of blood vessels and ischemic necrosis. Microvascular as well as venous or arterial occlusion can be seen, both in the skin and internal organs.

Differential diagnosis

A recent history of heparin administration should prompt consideration of this diagnosis in any patient who develops retiform purpura or bland necrosis, whether or not the patient is thrombocytopenic. However, a decrease in the platelet count is a common incidental finding in patients who are ill and coincidently receiving heparin and so it can be unrelated to the development of this syndrome. Conversely, a normal platelet count does not exclude the diagnosis. Other cutaneous occlusion syndromes associated with thrombocytopenia include antiphospholipid antibody syndrome, purpura fulminans secondary to sepsis, and thrombotic thrombocytopenic purpura (although skin lesions due to microvascular occlusion are rare in the latter syndrome).

Detection of anti-PF4–heparin complex antibodies by ELISA has a 98%–99% negative predictive value but low positive predictive value[1]. While specialized testing can confirm the presence of anti-PF4–heparin complex antibodies, a clinical diagnosis is often needed before the results of this test are known. The 4Ts score based upon acute *t*hrombocytopenia, *t*iming of onset, *t*hrombosis, and absence of other causes of *t*hrombocytopenia is often used to estimate the likelihood of HIT syndrome. This score can be combined with functional assays (e.g. C-serotonin release assay, PF4-enhanced platelet activation assay) to greatly improve accuracy[6,7].

Treatment

Treatment requires cessation of heparin therapy and initiation of therapeutic anticoagulation. Argatroban and bivalirudin, direct thrombin inhibitors, are FDA-approved for the treatment of HIT and for patients with HIT undergoing cardiovascular procedures, respectively. Although not FDA-approved for these indications, subcutaneous fondaparinux is also effective. Whereas patients with HIT and thrombosis require therapeutic anticoagulation for at least three months, treatment duration for patients with only HIT has not been standardized.

Vitamin K antagonists (e.g. warfarin) are contraindicated during the acute phase because of an increased risk of developing venous limb gangrene secondary to decreased protein C levels[8]. Patients with delayed or spontaneous HIT should be anticoagulated with non-heparin agents (e.g. argatroban, bivalirudin). Based upon observational studies, direct oral anticoagulants (DOACs) may also be effective, although isolated cases of heparin necrosis-like skin lesions have been reported with rivaroxaban and apixaban[9]. For refractory and autoimmune HIT, IVIg and plasma exchange have been used[1,2].

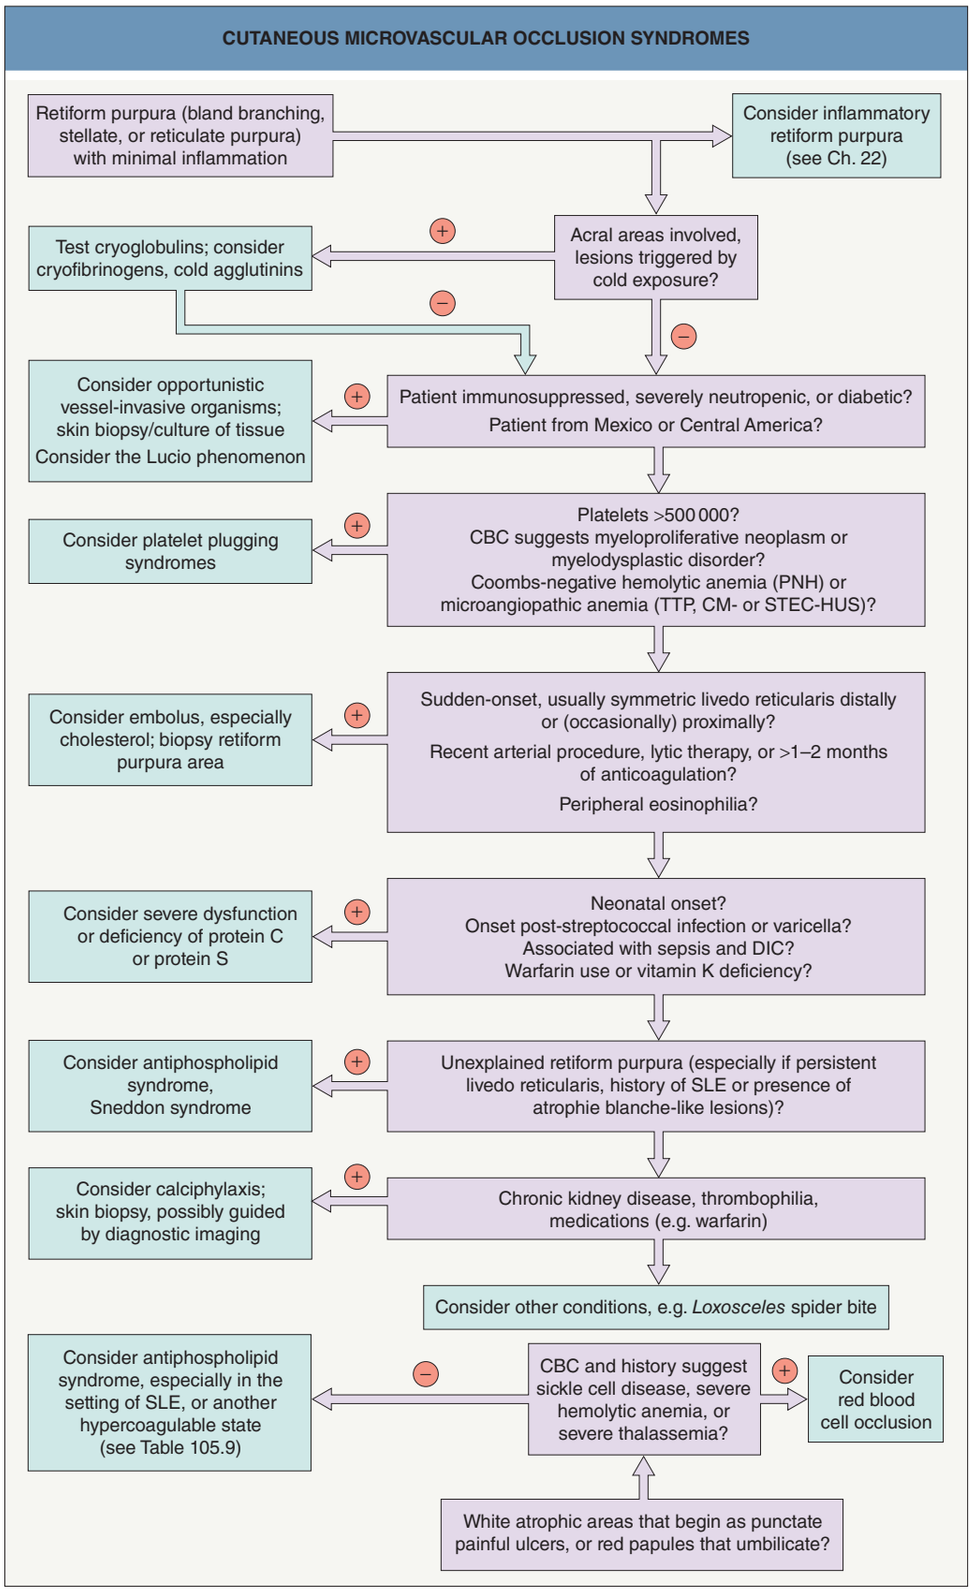

Fig. 23.1 Cutaneous microvascular occlusion syndromes. CM-HUS, complement-mediated hemolytic uremic syndrome; DIC, disseminated intravascular coagulation; PNH, paroxysmal nocturnal hemoglobinuria; SLE, systemic lupus erythematosus; STEC-HUS, Shiga toxin-producing *Escherichia coli* hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

Philadelphia Chromosome-Negative Myeloproliferative Neoplasms

Key features

- Philadelphia chromosome-negative myeloproliferative neoplasms include essential thrombocythemia (ET), polycythemia vera (PV), and primary myelofibrosis (PMF)
- 90% of patients have somatic phenotypic driver mutations in *JAK2* (V617F), *CALR*, or *MPL*
- Thrombosis, vascular events (e.g. stroke), and bleeding can occur in all three disorders

Introduction

Myeloproliferative neoplasms (MPNs) are clonal hematopoietic disorders whose manifestations depend on the type of stem cell affected, with some patients eventually developing myelodysplastic syndrome or acute myelogenous leukemia. The Philadelphia chromosome-negative MPNs (which exclude most chronic myelogenous leukemias) are clonal disorders driven by mutations in *JAK2*, *CALR*, or *MPL* in all but the 10% of patients who are "triple-negative". These genes encode a tyrosine kinase, calreticulin, and the thrombopoietin receptor, respectively. Many patients have additional non-driver mutations, typically involving epigenetic regulator genes (e.g. *TET2, DNMT3A*), chromatin

BASIC SCREENING TESTS FOR OCCLUSIVE SYNDROMES
Complete blood count with differential, platelet count, and blood smear

• Polycythemia or anemia, granulocytosis, thrombocytosis, poikilocytosis
  • May be sign of myeloproliferative neoplasms or myelodysplastic syndromes
• Evidence of red cell fragmentation (schistocytes) and microangiopathy, consider:
  • TTP–hemolytic uremic syndrome
  • Purpura fulminans with DIC, occasionally
  • Antiphospholipid antibody syndrome, occasionally
• Thrombocytopenia, consider:
  • Heparin-induced thrombocytopenia (HIT) syndrome
  • Purpura fulminans with DIC
  • TTP–hemolytic uremic syndrome
  • Antiphospholipid antibody syndrome, some patients
• Severe neutropenia
  • Immunocompromised; opportunistic infections very likely
• Eosinophilia
  • Cholesterol emboli
  • Hypereosinophilic syndrome (rare)

Partial thromboplastin time (PTT)
• Minimally prolonged in TTP–hemolytic uremic syndrome • Prolonged in purpura fulminans and DIC • Prolonged if lupus anticoagulant activity present and assay sensitive
Cryoglobulins (occasionally cryofibrinogen and cold agglutinins) when location and history suggest cold occlusion syndrome
Biopsy
• Confirms occlusion (e.g. due to thrombi) versus other mechanisms of vessel injury • May suggest cryoglobulin or cryofibrinogen precipitation • May diagnose calciphylaxis • May suggest cholesterol, oxalate, or crystalglobulin occlusion • Special stains for organisms in immunocompromised hosts, when appropriate
Basic hepatic and renal function screens
• Hepatic function can affect vitamin K-dependent factors and warfarin metabolism • Renal disease moves cutaneous calciphylaxis higher in the differential diagnosis, even though non-uremic calciphylaxis can occur
ANCA
• To evaluate for the uncommon non-inflammatory retiform purpura presentation of granulomatosis with polyangiitis (GPA) or microscopic polyangiitis (MPA) • ANCA may be available before permanent histologic sections

Table 23.2 Basic screening tests for occlusive syndromes. Elevated levels of fibrin degradation products, including D-dimers, are seen in purpura fulminans with DIC. TTP and hemolytic uremic syndrome are considered types of thrombotic microangiopathy. ANCA, anti-neutrophil cytoplasmic antibody; DIC, disseminated intravascular coagulation; TTP, thrombotic thrombocytopenic purpura.

regulator genes (e.g. *ASXL1*, *EZH2*), and splicing machinery genes (e.g. *SF3B1*), leading to variable disease expression[10].

Thrombosis, vascular events (e.g. stroke, pulmonary emboli), and hemorrhage are the most common causes of morbidity and mortality in PV and ET. The frequency of thrombosis is highest in PV, followed by PMF and ET, while bleeding complications are highest in PMF followed by ET and PV. The *JAK2* V617F, mutation is associated with an increased risk of thrombotic complications whereas *CALR* mutations have a lower risk.

Pathogenesis

In that thrombosis in ET has been attributed to platelet dysfunction/number and platelet-driven events appear important in patients with ET and other MPNs, these disorders are discussed under platelet-related thrombopathies. However, the degree of thrombocytosis does not correlate with thrombotic and vascular complications. For example, patients with ET and extreme thrombocytosis are at greater risk of bleeding than thrombosis[10].

Fig. 23.2 Heparin necrosis at site of subcutaneous heparin injection. Note branching or retiform pattern of intense hemorrhage and necrosis in the center of the lesion. *From Robson K, Piette W. Adv Dermatol 1999;15:153–82, used with permission.*

In both myeloproliferative and myelodysplastic disorders, platelets can function abnormally, leading to occlusion and/or hemorrhage. When the platelet count is $400–1000\times10^9$/L, thromboembolism is common, whereas both thrombosis and bleeding may occur with a platelet count of $1000–2000\times10^9$/L; bleeding predominates when the platelet count is $>2000\times10^9$/L[11]. Acquired von Willebrand syndrome may develop when the platelet count is $>1000\times10^9$/L, providing an explanation for the associated hemorrhage. When the platelet count is within the normal range in the setting of an MPD, the risk of thrombosis is uncertain.

Of the three most frequently associated genes (see Introduction), mutations in *MPL* and *CALR* occur more commonly in ET and PMF and only rarely in PV. A single mutation, *JAK2* V617F, is present in 90%–95% of PV patients and 50%–70% of those with ET and PMF. The *JAK2* mutations lead to activation of the JAK–STAT pathway (see Fig. 128.11)[10].

Epidemiology

Both PV and ET occur more often in women. They are uncommon before the age of 50 years, but the incidence increases almost exponentially after age 60 years.

Clinical features

Cutaneous lesions occur in ~20% of patients with ET, including purpura, hematomas, livedo reticularis and racemosa, erythromelalgia, Raynaud phenomenon, urticaria, cutaneous small vessel vasculitis, leg ulcers, gangrene, and recurrent superficial thrombophlebitis. An important subset of these cutaneous lesions is due to microvascular occlusion.

Erythromelalgia is a syndrome that can occur as a primary (idiopathic) or a secondary phenomenon (see Ch. 106). It is characterized by intense burning and paroxysmal bright erythema of the distal extremities. Most closely associated with ET, and less often with PV, erythromelalgia can occur with any myeloproliferative or myelodysplastic disorder if the platelet count is sufficiently elevated[12,13]. Because this form of secondary erythromelalgia is caused by platelet-mediated acral vasodilation, inflammation, and microvascular occlusion, patients can also develop discrete areas of purpura or necrosis, often retiform, as a unique manifestation. This version of erythromelalgia typically responds dramatically to aspirin administration, whereas idiopathic and other secondary forms generally show minimal or no benefit from aspirin.

Other clinical features of patients with MPNs depend on the diagnosis, e.g. PV patients may have a ruddy cyanosis and experience severe pruritus following exposure to warm water[14], while neutrophilic dermatoses (pyoderma gangrenosum, Sweet syndrome) have been reported with MPNs.

Pathology

Microvascular occlusion of dermal vessels or subcutaneous arterioles is found in biopsy specimens from retiform purpura or necrotic lesions.

Differential diagnosis

Useful findings which suggest an MPN include anemia or elevated hematocrit, an abnormal white blood cell count or differential, and an abnormal platelet count or platelet morphology. The differential diagnosis of reactive thrombocytosis, especially due to iron deficiency, post-splenectomy, infection or malignancy, must be considered when assessing the significance of an elevated platelet count.

Treatment

Low-risk patients with PV and ET may be treated with low-dose aspirin. Traditionally administered once daily, more recent data suggests 100 mg twice daily may be more beneficial[15]. In PV, control of the hematocrit is usually achieved via phlebotomy. In higher risk patients, options include cytoreductive therapy (typically hydroxyurea), pegylated interferon-α, or JAK inhibitors such as ruxolitinib[14,16]. Prompt and lasting relief of burning pain by low-dose aspirin is a characteristic finding in thrombocythemic ET while refractory pruritus in PV may respond to paroxetine (20 mg/day), interferon-α, UVB phototherapy, or ruxolitinib[14].

Paroxysmal Nocturnal Hemoglobinuria

Key features

- Coombs-negative intravascular and extravascular hemolytic anemia due to *PIG-A* mutations
- Cytopenias and thrombosis
- Cutaneous lesions are uncommon, but may be extensive

Introduction

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare hematopoietic stem cell disorder that is associated with an increased risk of thrombosis.

Pathogenesis

This disease is due to a somatic mutation in *PIG-A* (*p*hosphatidyl *i*nositol *g*lycan class *A*) in hematopoietic stem cells. This X-linked gene encodes a glycosylphosphatidylinositol (GPI)-anchored protein that is required for the cell membrane attachment of several important membrane proteins. Some of these proteins are responsible for protecting blood cells and platelets from complement-mediated injury.

The alternate complement pathway is part of the innate immune system, with chronic low-level activation of complement by a process termed C3 tickover. This results in C3 and C5 convertase amplification (involving Factors B and D) and formation of membrane attack complex (MAC) on the antigen. Normal red cells are protected from this attack by the presence of both CD55 (decay decelerating factor), which stabilizes these convertases, and CD59 (membrane inhibitor of reactive lysis), which inhibits MAC formation. These protective proteins are unable to anchor to cells lacking the GPI anchor protein[17]. The lack of protection leads to red cell lysis and activation of platelets.

The cause of venous thrombosis is multifactorial and is due in part to microparticle formation from platelets and other blood component membranes as well as depletion of nitric oxide related to hemolytic release of free hemoglobin.

Clinical features

This acquired clonal hematologic disorder classically presents with intravascular hemolysis, deficient hematopoiesis, and a thrombotic tendency. It may also occur in the setting of hematologic disorders such as aplastic anemia and myelodysplastic syndrome where it is often subclinical because of a limited number of mutated clones[17,18]. Thrombotic events are the most common cause of death, and venous thromboses (e.g. Budd–Chiari syndrome) are more common than arterial. Depletion of nitric oxide related to chronic hemolysis can lead to smooth muscle dystonia with dysphagia, abdominal pain, and erectile dysfunction[17]. There is also a six-fold increased risk of chronic kidney disease.

A variety of cutaneous findings have been reported in PNH, including hemorrhagic bullae, petechiae, leg ulcers, non-inflammatory retiform purpura, and a purpura fulminans-like presentation[19].

Pathology

Biopsy specimens reveal microvascular occlusion, typically fibrin thrombi. Detection of an absence or severe deficiency of GPI-anchored protein in ≥2 cell lineages (e.g. WBCs, RBCs) by flow cytometry of peripheral blood is diagnostic of PNH.

Differential diagnosis

The differential diagnosis of the various skin lesions that can occur in PNH is broad. The presence of hemolytic anemia plus pancytopenia should suggest the diagnosis.

Treatment

In the past, treatment was largely supportive, consisting of transfusions, iron and folic acid supplementation, and anticoagulation when needed. Nowadays, patients can receive life-long IV therapy with eculizumab or ravulizumab which inhibit the terminal phase of the complement cascade at the C5 stage and can reduce intravascular hemolysis and venous thrombosis[20]. Crovalimab, a C5 inhibitor which can be administered subcutaneously, has shown noninferiority to eculizumab; its prolonged half-life, as well as that of ravulizumab, is based upon SMART-Ig technology which allows prolonged recirculation. Because C5 inhibition does not prevent extravascular hemolysis[21], agents that inhibit C3 activation (e.g. pegcetacoplan) have been FDA approved for PNH or are in clinical trials (e.g. danicopan, iptacopan)[20,21].

Since complement inhibitors can increase the risk of meningococcemia via C5 inhibition, patients under 45 years of age should ideally receive the meningococcal vaccine at least 2 weeks before instituting therapy. However, patients still have a >1000-fold increased risk of *Neisseria* infections, leading to consideration of prophylactic chronic penicillin administration[20].

Primary Thrombotic Microangiopathy

Key features

- Thrombotic microangiopathy (TMA) is characterized by microangiopathic hemolytic anemia (RBC fragmentation with schistocyte formation) and thrombocytopenia
- The focus here will be the three primary TMAs: thrombotic thrombocytopenic purpura (TTP), Shiga toxin-producing *Escherichia coli* hemolytic uremic syndrome (STEC-HUS), and complement-mediated HUS (CM-HUS)
- Round, macular petechiae are seen in inherited or acquired ADAMTS13-related TMA (i.e. TTP), most likely due to simple hemorrhage
- Skin lesions are not observed in STEC-HUS while patients with CM-HUS occasionally develop distal necrosis or purpuric/necrotic lesions

Introduction

TMA is a syndrome characterized by microangiopathic hemolytic anemia and thrombocytopenia and it can be primary or secondary. The differential diagnosis can be challenging, especially since most of these syndromes evolve rapidly, leading to significant morbidity and mortality[22–24]. Within the larger spectrum of all TMAs, *primary* TMA includes three entities: TTP, HUS-STEC, and CM-HUS. The latter is also referred to as atypical HUS.

Pathogenesis

Hereditary TTP (Upshaw–Schulman syndrome) is due to biallelic mutations of *ADAMTS13*. Its protein product is an enzyme responsible for cleaving ultra-large multimers of von Willebrand factor (vWF). However, for 90% of patients, TTP is an acquired disorder that develops during adulthood and is immune-related with antibodies that reduce the function of ADAMTS to <10% of normal[25]. Complement activation is thought to contribute to acute TTP, with vWF multimers possibly acting as scaffolding to support alternative pathway activation. In acute TTP, complement activation has been associated with increased mortality[25].

HUS was initially recognized in association with *Shigella* dysentery, but can also be caused by Shiga toxin-producing enterohemorrhagic *E. coli*; STEC-HUS includes both etiologies. Historically, CM-HUS was referred

to as atypical HUS because of the absence of diarrhea. However, mutations that lead to complement dysfunction (e.g. increased complement activation due to deficiencies of alternate complement pathway inhibitory molecules) have been detected in at least 50% of patients with CM-HUS[25,26].

Clinical features

The complete syndrome of classic TTP is characterized by fever, petechiae, thrombocytopenia, microangiopathic hemolytic anemia (schistocytes or fragmented red cells prominent on peripheral smear), renal disease, and neurologic symptoms (most commonly headache and confusion). The macular petechiae usually reflect simple hemorrhage, but occasionally may be attributed to platelet plugging. While platelet occlusion occurs primarily in visceral organs, very few papers have addressed the histology of cutaneous lesions. Currently, the classic syndrome of TTP would be classified as within the spectrum of ADAMTS13 deficiency-mediated TMA, either inherited or acquired/immune[25].

The HUS syndromes may mimic the findings in TTP, but hemolysis and renal involvement predominate. STEC-HUS is typically associated with diarrhea in children, less so in adults, and is not associated with skin hemorrhage. The fatality rate in children is <3%, rising to 15%–30% in frail or elderly adults. Long-term sequelae are seen in a third of children and up to 50% of adults[26]. CM-HUS rarely leads to digital necrosis or scattered necrotic skin lesions[27].

Pathology

Microvascular occlusion of visceral terminal arterioles and capillaries is expected but is rare in the cutaneous microvasculature. Petechial (cutaneous) hemorrhage is most likely due to simple hemorrhage, but documentation is limited. In the rare lesions of CM-HUS, microvascular occlusion may be seen. Immunofluorescent staining of normal skin in patients with CM-HUS may be positive for MAC factors C5–9 in vessels, supporting but not confirming the diagnosis of CM-HUS[28].

Differential diagnosis

Traditionally, *primary* TMA requires exclusion of other causes of TMA, such as disseminated intravascular coagulation (DIC), sepsis, or other infections; pre-eclampsia, eclampsia, scleroderma renal crisis, or malignant hypertension; catastrophic antiphospholipid antibody syndrome; and HELLP syndrome of pregnancy (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelet count)[22–25]. Both toxic and immune drug-induced TTP-HUS also need to be excluded, e.g. cyclosporine, tacrolimus, VEGF inhibitors, gemcitabine, oxaliplatin, and quinine can trigger TMA[24]. In addition, an HUS-like syndrome that involves a VEGFR2 pathway can occur in infants with diacylglycerol kinase epsilon deficiency[24,29].

DIC is characterized by evidence of clot activation (prolonged prothrombin time [PT] and partial thromboplastin time [PTT]) as well as clot lysis (significant elevation of fibrin split products or D-dimers; marked decrease of plasma fibrinogen). Such findings are absent in the primary TMAs. A normal or minimally elevated PT plus profound thrombocytopenia strongly favors primary TMA over DIC.

Treatment

Since *TTP* is usually due to acquired antibodies to ADAMTS13, total plasma exchange represents first-line therapy, leading to a reduction in mortality of up to 90%. Corticosteroids are also helpful in reducing antibody production and in refractory cases, rituximab has been used. For patients with severe disease poorly responsive to plasma exchange, chronic relapsing disease, or congenital disease with absence of ADAMTS13, caplacizumab – a humanized anti-vWF antibody that interferes with platelet–vWF interactions – can reduce thromboembolic complications[25,30–32]. However, initial use of standard first-line therapy may lead to a more rapid response[33].

Treatment of hereditary TTP has traditionally been plasma infusions during flares and then routine prophylactic infusions in patients with frequent recurrences or serious complications[34]. In addition to caplacizumab, recombinant ADAMTS13 may represent a future therapy[34].

For *STEC-HUS*, treatment is primarily directed at eliminating the toxin-producing bacteria and providing supportive care. To restore more normal complement function, the C5 inhibitor eculizumab is currently first-line therapy for *CM-HUS*[35]. Selective C5aR1 blockade, which reduces C5a-induced platelet aggregation while preserving C5–9 formation and thus reducing the risk of serious infections from C5a inhibition (see above), may represent a future approach[36].

DISORDERS OF CRYOPRECIPITATION OR CRYOAGGLUTINATION

Key features

- Retiform purpura most often in an acral location
- Due to cryoglobulins and rarely cryofibrinogens or cold agglutinins
- Cold-induced cryoprecipitation and vascular occlusion most commonly associated with type I cryoglobulins
- In acute lesions, eosinophilic hyaline deposits occluding blood vessels may be present

Introduction

Cryoglobulins are immunoglobulins that are present in both serum and plasma and reversibly precipitate with cold exposure[37]. *Cryofibrinogens* are fibrinogens which precipitate in the cold, are consumed in clotting, and are therefore detectable only in plasma samples[38]. *Cold agglutinins* are antibodies which promote agglutination of red cells on exposure to cold, often leading to a brisk hemolytic anemia[39]. All three groups can cause occlusive syndromes in the skin that are triggered by cold exposure. While cryofibrinogens and cold agglutinins can be detected in many patients in association with a variety of illnesses, they are rarely the cause of cold-related occlusion syndromes directly due to cryoprecipitation or cryoagglutination.

Pathogenesis

Cryoglobulins cause disease via two mechanisms: occlusion (usually type I) or immune complex-mediated vasculitis (usually types II, III; see Table 24.6)[37]. Type I cryoglobulin is a monoclonal antibody, most often IgM, less often IgG, and rarely IgA. Because type I cryoglobulins are not part of an immune complex, they typically affect vessels via induction of hyperviscosity or precipitation in the cold. The possibility of secondary vasculitic changes in older occlusive lesions (see Fig. 22.4) needs to be considered in any reports of type 1 cryoglobulin-induced vasculitis[40].

Cryoglobulins change their configuration in the cold and become water-insoluble, but plasma proteins, pH, and salt concentrations (e.g. in renal glomeruli) can also induce conformational changes[37] as many of these proteins transform only at refrigerator temperatures, not at skin temperatures typically seen with cold exposure of acral areas. Simple occlusion with minimal early inflammation and often retiform purpura/necrosis develops when cryoproteins precipitate upon cold exposure. Intravascular deposits of type 1 cryoglobulins are subdivided into: (1) amorphous deposits – account for most cryo-occlusive syndromes; (2) gelatinous forms – lead to hyperviscosity; and (3) cryocrystals – rarest form with dense linear or herringbone-like arrays[41]. The presence of monoclonal immunoglobulins (IgG, IgM ≫ IgA, light chains), including type I cryoglobulins, points to an underlying plasma cell dyscrasia or lymphoproliferative disorder[37,42,43].

Cryofibrinogen precipitates are composed of fibrinogen, fibrin, fibronectin, and occasionally albumin, immunoglobulins, or other plasma proteins. *Cold agglutinins* bind to red cells in the cold, often triggering complement activation and red cell lysis. Because of their ability to bind multiple red blood cells, pentameric IgM antibodies more readily agglutinate these cells, leading to occlusion.

Epidemiology

The prevalence of cryofibrinogenemia varies from 2% to 9% in healthy individuals and from 8% to 13% in hospitalized patients[38]. Its female:male ratio is 1.4:1. Cryofibrinogenemia may be essential or secondary to a wide spectrum of disorders including infections, autoimmune diseases, and carcinomas. When a cryopathy has been suspected, cryofibrinogenemia was observed in 10%–50% of patients, although usually not in isolation.

Clinical features

The cardinal sign of cold occlusion, including that due to *cryoglobulinemia*, is purpuric or necrotic lesions, often retiform, at sites of cold exposure that are typically acral (Fig. 23.3). Other cutaneous findings include acral cyanosis, Raynaud phenomenon, and livedo reticularis.

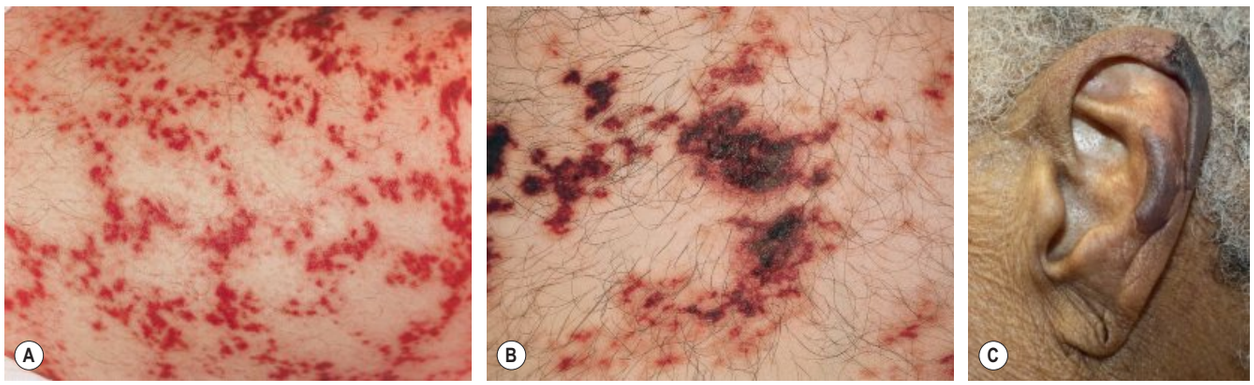

Fig. 23.3 Type I cryoglobulinemia in two patients with multiple myeloma (IgG type). A Retiform purpura of the lower extremity. **B** Areas of necrosis within the areas of retiform purpura. **C** Purpuric lesions of the antihelix and helix of the ear. *A,B, Courtesy Jean L. Bolognia, MD; C, Courtesy Jonathan Leventhal, MD.*

Although some reports describe cutaneous small vessel vasculitis in patients with type I cryoglobulins, it is likely that this finding is often a secondary leukocytoclastic vasculitis that occurs following occlusive necrosis or ulceration (see Fig. 22.4). Mixed (types II and III) cryoglobulins may cause occlusion if they are unstable at close to body temperature, but more frequently they induce lesions via immune complex mechanisms, with clustering of classic palpable purpura in dependent areas.

Because of the prevalence of *cryofibrinogenemia* (see above), clinical correlation is critical in judging the significance of its presence. Cutaneous findings are similar to those induced by cryoglobulins and include both venous and arterial occlusion.

Cold agglutinins are frequently asymptomatic incidental findings, as in *Mycoplasma* infections. When symptomatic, cold agglutinins lead to hemolysis post cold exposure, which can be severe[39,44]. Very rarely, cold exposure in patients with cold agglutinins can induce red cell agglutination, sludging, and vascular occlusion in cold-exposed sites[45]. Lesions may develop at infusion sites following administration of cold blood products. Although skin lesions due to vascular occlusion are unusual, in one study 90% of patients with primary cold agglutinin disease had symptoms, ranging from moderate acrocyanosis to severe Raynaud phenomenon precipitated by even slight cold exposure[44].

Pathology

In type I cryoglobulinemia, occlusion of small dermal vessels is a typical finding (Fig. 23.4). Types II and III cryoglobulinemia show features of an acute cutaneous small vessel vasculitis and are only rarely associated with intraluminal thrombi. Necrosis may be evident in older lesions of all types of cryoglobulinemia, along with secondary vasculitis. In patients with skin lesions due to vascular occlusion, deposits of cold agglutinins are seen as intravascular amorphous eosinophilic material admixed with red blood cells.

Differential diagnosis

The sudden onset of acral disease with cold exposure should suggest this group of disorders. Occasionally, syndromes of distal occlusion (e.g. cholesterol emboli, acral antiphospholipid antibody syndrome, sepsis with DIC and hypotension) may have a similar appearance, but without the history of cold exposure and usually with sparing of the nose and ears. Chilblains (pernio) must also be considered, but lesions are usually slow in onset and seldom progress to significant purpura or necrosis.

Treatment

Management of *cryoglobulin* occlusion is primarily directed at minimizing cold exposure and controlling the underlying plasma cell dyscrasia or lymphoproliferative disorder in order to reduce the titer of monoclonal cryoglobulin. Plasmapheresis or plasma exchange provides only short-term improvement. Patients with Waldenström macroglobulinemia and symptomatic hyperviscosity syndrome should not be treated with rituximab until the hyperviscosity is addressed, usually by plasmapheresis and other systemic therapy (e.g. ibrutinib)[46].

Treatment of *cryofibrinogenemia* also includes minimizing cold exposure. Beyond that, there is little evidence to guide treatment of cutaneous disease. Stanozolol, low-dose aspirin, corticosteroids, fibrinolytics, and immunosuppressives have been suggested, although a rationale for their use is not clear[38,47]. Anticoagulants are only recommended for patients with arterial or venous thrombosis. For secondary cryofibrinogenemia, therapy is aimed at the associated disease. Over time, some patients with "essential" cryofibrinogenemia may develop a lymphoma[47].

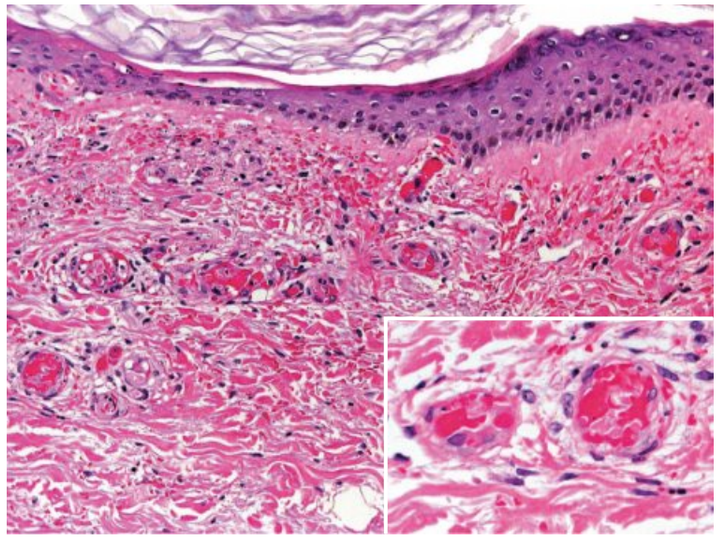

Fig. 23.4 Thrombotic vasculopathy due to type I cryoglobulinemia. In the dermis, there are eosinophilic thrombi within several blood vessels (inset) with hemorrhage and only a minimal inflammatory infiltrate. *Courtesy Lorenzo Cerroni, MD.*

In *cold agglutinin* disease, cold avoidance is recommended but often ineffective. When no secondary cause is identified (e.g. Epstein–Barr virus), most patients are assumed to have a low-grade lymphoproliferative disorder and are treated with rituximab therapy. Sutimlimab, a C1s inhibitor, can reduce hemolysis due to antibody-induced complement activation[44], but since it does not affect antibody levels, patients may still experience cold-related acral cyanosis and vascular occlusion.

DISORDERS OF OCCLUSION BY OPPORTUNISTIC ORGANISMS PROLIFERATING WITHIN VESSELS

Key features

- Retiform purpura or non-inflammatory necrosis
- Often associated with administration of immunosuppressive agents or severe neutropenia
- Poorly controlled diabetes mellitus is a risk factor for mucormycosis

Introduction/pathogenesis

These syndromes share the feature of vessel invasion by organisms (see Chs. 74 & 77), and usually occur in severely immunocompromised patients. All but disseminated strongyloidiasis can have organism growth within the endothelium or vascular wall. The immunocompromised

state is usually due to severe neutropenia and/or to the administration of multiple potent immunosuppressive agents, but may be due to chronic disease or malnutrition.

Clinical features/pathology

Ecthyma gangrenosum is the syndrome of occlusion by organisms (usually bacterial) proliferating in the adventitia of subcutaneous blood vessels. The classic organism is *Pseudomonas aeruginosa*, but ecthyma gangrenosum-like skin lesions have also been described with other organisms, including other *Pseudomonas* spp. (*P. cepacia, P. maltophilia), Serratia marcescens, Aeromonas hydrophila, Klebsiella pneumoniae, Vibrio vulnificus, Moraxella* spp., *Morganella morganii, Escherichia coli*, and *Staphylococcus aureus*; these lesions may also be due to fungal organisms, e.g. *Candida albicans, Mucor* spp., *Aspergillus fumigatus, Fusarium* spp., and *Neoscytalidium dimidiatum*[48,49].

Ecthyma gangrenosum begins as erythematous, painless macules, but typically progresses to purpuric or escharotic lesions which may be bullous or pustular, and frequently show retiform or branching features. There is extensive bacillary infiltration of the media, adventitia, and perivascular regions of blood vessels, typically with sparing of the lumen and intima. As the bacteria proliferate, gradual compression of the vessel wall narrows and then ultimately occludes the lumen of a subcutaneous arteriole that supplies an overlying cone of skin. This is followed by clot formation within many blood vessels in that skin zone. Immediate antibiotic therapy is crucial, although the prognosis is poor if the neutropenia persists, antimicrobial agents are ineffective, or the disease process is advanced. Of note, many authors include cutaneous lesions and histopathologic findings in this category which might more properly be classified as septic vasculitis due to bacteremia from Gram-negative rods, when sufficient neutrophils exist to provide a local response.

In severely immunocompromised patients, *vessel-invasive fungi* can result in necrotic lesions secondary to vessel invasion and thrombosis[48,49]. The most common opportunistic fungi in this group are *Aspergillus, Rhizopus*, *Mucor*, *Rhizomucor*, and *Lichtheimia* (formerly *Absidia*) spp. The latter four are causes of mucormycosis. In diabetic patients, mucormycosis may present in the central face with cutaneous necrosis, presumably originating from a sinus cavity infection. Opportunistic fungi that produce retiform purpura tend to proliferate and invade from within the lumen into the vessel wall and into vascular branches. Thrombus develops around the hyphal elements within the vessels and presumably also on the altered endothelium.

Disseminated strongyloidiasis can occur in patients infected with the human nematode *Strongyloides stercoralis*. Reticulated purpuric lesions, especially in the periumbilical region, have been described with dissemination, although such lesions are rare (see Ch. 83); their appearance has been likened to thumbprints (see Fig. 83.21). Histologically, the purpuric lesions demonstrate extravasated erythrocytes and larvae within capillaries and between collagen bundles. The mortality rate in disseminated disease is high.

Lucio phenomenon is common in Mexico and Central America, but rare in other areas. The associated thrombotic lesions are distinguished from erythema nodosum leprosum (an immune complex-mediated neutrophilic vasculitis with variable involvement of the panniculus) by an absence of fever, leukocytosis, and tenderness; a poor response to thalidomide; and restriction to patients with the diffuse non-nodular lepromatous form of Hansen disease. Some acute lesions present as retiform purpura, and these lesions frequently progress to chronic ulcers (see Fig. 75.10D)[50]. Extensive blanchable livedo reticularis of the extremities may also be present[51] and concomitant antiphospholipid antibody syndrome has been reported. Histologically, some cases have endothelial swelling and thrombus formation within dermal and some subcutaneous vessels whereas others show features of leukocytoclastic vasculitis in the superficial and mid-dermis with overlying epidermal necrosis.

Of the rickettsial infections (see Ch. 76), widespread cutaneous lesions with hemorrhage are most commonly observed in Rocky Mountain spotted fever. Initially, the eruption is not hemorrhagic, but by day 5, petechiae usually develop within lesions due to vascular hyperpermeability[52]. Progression of hemorrhage beyond 3–4 mm is typically associated with severe disease. Early petechial lesions may be comma-shaped or linear, reflecting hemorrhage following the microvasculature. Due to endothelial injury, DIC can develop later in the disease course, resulting in cutaneous necrosis that is often in a retiform pattern. Other spotted fevers that often have a hemorrhagic component are Brazilian spotted fever, boutonneuse fever, and Japanese spotted fever (see Ch. 76).

Differential diagnosis

The differential diagnosis includes other causes of non-inflammatory purpura due to cutaneous microvascular occlusion (see Table 23.1).

Treatment

Treatment is directed at mitigating the immunocompromised state where possible, and by selecting appropriate antimicrobial therapy based on identification of the invading organism. Ivermectin is the treatment of choice for disseminated strongyloidiasis.

DISORDERS OF OCCLUSION BY EMBOLI

Cholesterol Embolus

Key features

- Usually abrupt onset
- Livedo reticularis is usually much more prominent than retiform purpura
- Distal extremities, especially the legs, are the most likely site of cutaneous involvement

Introduction

Cholesterol embolus is primarily a disease of men 50 years of age or older. Common comorbidities include diabetes mellitus, hyperlipidemia, hypertension, tobacco use, and peripheral artery disease[28,53]. In autopsy studies, cholesterol embolism was observed in 15%–20% of patients older than 60 who had a history of atherosclerotic disease, and in up to 3% of unselected autopsies[53,54]. Given the relatively low frequency rate of the clinical diagnosis of cholesterol embolus, this figure suggests that cholesterol emboli are frequently undiagnosed or asymptomatic.

Pathogenesis

Since fragmentation of ulcerated atheromatous plaques is the cause of cholesterol emboli, affected patients usually have severe (but often unrecognized) atherosclerotic disease. Although spontaneous fragmentation of plaques can occur, there are three, possibly four, clinical settings known to prompt embolization. The first is *arterial or coronary catheterization*, which may disrupt a plaque, leading to emboli within hours to days of catheterization. The second is *acute thrombolytic therapy* given for myocardial infarction or stroke. Embolization may occur within hours to days of lytic therapy but a true causal relationship has been questioned. A third recently described trigger for cholesterol embolus is the *Heimlich maneuver*[55]. The fourth, *prolonged anticoagulation*, which typically occurs after 1 to 2 months of therapy, is also a matter of debate. Theoretically, anticoagulation slowly lyses the clot which may be reinforcing a friable plaque, leaving exposed areas of the plaque subject to the shear stress of arterial flow. This "warfarin blue toe syndrome" is not restricted to warfarin anticoagulation and should not be confused with warfarin necrosis[56]. Of note, ~20% of patients with cholesterol emboli have no known inciting event[54].

Clinical features

Clinical findings include fever, weight loss, myalgias, altered mental status, and a sudden onset of arterial hypertension. Transient ischemic attacks, strokes, renal failure, gastrointestinal ulcerations, and hemorrhagic pancreatitis may also occur. Patients with multisystem involvement can have significant morbidity and occasionally may die from embolic complications.

Cutaneous findings are reported in 35%–90% of patients with cholesterol embolization and they include: livedo reticularis (50%–75%), cyanosis/blue toes (30%–75%), ulceration (15%–40%), multiple sites of peripheral gangrene (0–35%), nodules (~10%), and purpura (~10%) (Fig. 23.5A–D)[57]. Because retiform purpura represents a purpuric accentuation of the livedo reticularis pattern, it may be described as livedo reticularis in some reports. Upper extremity lesions can appear if the plaque originated

Fig. 23.5 Cholesterol emboli. A Livedo reticularis is seen proximally on the thigh. **B** Both livedo reticularis and retiform purpura are seen distally. **C** Purpura of the digits. **D** Several irregularly shaped ulcers with eschars surrounded by retiform purpura on the thigh. **E** Histologically, intravascular clefts are seen which are due to dissolution of cholesterol crystals during fixation. *A,B,E, Courtesy Norbert Sepp, MD; D, Courtesy Kalman Watsky, MD.*

from the aortic arch. Rarely, cholesterol emboli occur more proximally (buttocks, thighs, flanks) and may mimic calciphylaxis or antiphospholipid antibody-related necrosis (Fig. 23.5D)[58]. Of note, an initial diagnosis of cholesterol emboli is made in only 35%–40% of patients[57].

Peripheral blood eosinophilia is observed in 15%–80% of recognized cases[57]. Other laboratory findings include decreased complement levels, leukocytosis, pyuria, eosinophiluria, elevations in the ESR, CRP, serum creatinine, BUN and amylase, and heme-positive urine or stool[57].

Pathology

A biopsy of the livedo reticularis is most informative when it consists of an elliptical incision centered on the blanched portion of the livedo reticularis and is deep enough to include fat (see Fig. 106.1). Areas of retiform purpura usually provide diagnostic findings in punch biopsy specimens and should be the first choice for biopsy when present.

Histologically, cholesterol emboli produce elongated clefts within lumina of small vessels (Fig. 23.5E), often in association with thrombi[53]. The clefts are created by dissolution of cholesterol crystals during the fixation process. The affected arteriole is usually at the dermal–subcutaneous junction. Neutrophils, eosinophils, and mononuclear cells may be seen in arterial walls within 24–48 hours in an experimentally produced cholesterol embolus, followed by multinucleated histiocytes within 3 to 6 days, and sometimes intimal fibrosis. Lesions of different ages may be found in the same patient, consistent with recurrent showers of emboli.

Differential diagnosis

The abrupt onset of distal livedo reticularis should prompt consideration of cholesterol or oxalate embolism. Retiform purpura, especially when it occurs distally in concert with more extensive distal livedo reticularis, is especially suggestive of this diagnosis. Acral cold occlusion syndromes (see above) need to be considered when distal lesions are present, as well as antiphospholipid antibody syndrome. Proximal cholesterol emboli mimicking calciphylaxis have been reported[58].

Treatment

Treatment is mainly supportive, unless surgical bypass or endovascular stent grafting can eliminate the source of embolism. Aspirin and other antiplatelet agents, HMG-CoA reductase inhibitors ("statins"), discontinuation of warfarin (per package insert), initiation of anticoagulation in patients with severe renal damage, systemic corticosteroids, iloprost, and hyperbaric oxygen have all been advocated as effective in occasional patients, but no therapeutic standard exists.

Oxalate Embolus

Introduction

Oxalate embolism is a rare event, usually occurring in association with primary hyperoxaluria. Three types of *primary* hyperoxaluria result from rare enzyme deficiencies in which there is increased hepatic production of oxalic acid[59]. This leads to hyperoxalemia and calcium oxalate deposition within tissues[59,60]. *Secondary* hyperoxaluria, and occasionally hyperoxalemia, usually reflects increased gut absorption of oxalate due to: (1) increased dietary intake of oxalate (e.g. rhubarb, spinach and green smoothies, almonds) or oxalate precursors (e.g. ascorbic acid, ethylene glycol, naftidrofuryl oxalate); (2) fat malabsorption leading to calcium binding by fatty acids in the gut and increased absorption of free oxalate; or (3) decreased intestinal oxalate degradation due to a change in gut microbiota[59].

Clinical features

Type 1 primary hyperoxaluria (oxalosis) is the most common and most severe form, usually presenting during childhood with recurrent urolithiasis. The kidney is the major site of oxalate deposition until progressive renal insufficiency develops, at which time clinical signs of deposition in other organs become evident. Therefore, oxalate embolus typically occurs after the development of renal failure. Death by the age

of 20 years is not unusual in patients with childhood onset. Types 2 and 3 primary hyperoxaluria are less severe and often do not present until adulthood[59].

Cutaneous findings in systemic oxalosis include acrocyanosis, Raynaud phenomenon, peripheral gangrene, acral cutaneous necrosis and infarcts, livedo reticularis, erythematous ulcerated nodules, miliary calcified deposits, and a cutaneous calciphylaxis-like presentation[60,61]. The calciphylaxis-like presentation can be misleading, not only because of lesional similarity, but also because both oxalate embolus and calciphylaxis typically occur in the setting of renal failure.

Pathology

Skin biopsy specimens demonstrate yellow–brown, birefringent crystals in a rectangular or radial pattern within and around vessels in the deep dermis and subcutaneous tissue. Crystals are yellow to golden-brown in routinely stained sections and birefringent under polarized light[61]. They also stain with alizarin red S at pH 7.0 but not at pH 4.2. Foreign body giant cells may be present. Although clinical lesions may mimic those of cutaneous calciphylaxis, calcium deposition in vessels is not a characteristic finding in cutaneous oxalate emboli.

Differential diagnosis

This disorder is most likely to be confused with cholesterol embolus or cutaneous calciphylaxis in a patient with renal failure, but the differential diagnosis includes other causes of retiform purpura and livedo reticularis. A history of renal calculi in a patient with sudden-onset livedo reticularis or retiform purpura suggests hyperoxaluria as a prime diagnostic possibility. Brawny, woody fibrosis of the distal upper and lower extremities, suggestive of nephrogenic systemic fibrosis, has also been described[60].

Treatment

In patients with primary hyperoxaluria without renal failure, therapeutic options include massive fluid intake and calcium oxalate crystallization inhibitors[59]. Oral pyridoxine may be helpful in type 1 oxalosis. Liver transplantation is the only "curative" treatment[59]. Renal transplantation is contraindicated without correction of the underlying abnormality, since the transplanted kidney will be damaged by continued oxalate deposition. Lumasiran, a small interfering RNA (siRNA), is approved for type 1 hyperoxaluria[59].

Other Embolus-Associated Syndromes

In addition to emboli from acute bacterial or fungal endocarditis (which are usually inflammatory in nature), cutaneous emboli or thrombi have been rarely described in patients with atrial myxomas, marantic endocarditis, crystalglobulins, and hypereosinophilic syndrome. Emboli from these disorders may produce retiform purpura, but cutaneous findings are diverse.

Atrial myxomas are rare, typically present between the third and sixth decades of life, and may be associated with symptoms or signs secondary to: (1) intracardiac obstruction – dyspnea, chest pain, syncope; (2) cytokine release by the tumor – fever, myalgias, arthralgias; and (3) extracardiac embolism – most often to the CNS but occasionally to skin[62]. Cutaneous findings of myxomatous emboli include acral papules (with claudication), purpuric, serpiginous or annular violaceous fingertip lesions, splinter hemorrhages, livedo reticularis, Raynaud phenomenon, toe necrosis, a red–violet malar flush, and distal petechiae[48,53,62]. Carney complex (NAME/LAMB syndromes) is associated with multiple, early-onset cardiac myxomas and may have other cutaneous findings such as lentigines and blue nevi, unrelated to the emboli. Treatment of atrial myxoma consists of surgical removal.

Marantic endocarditis results in focal deposits of fibrin and other blood elements on heart valves, similar to Libman–Sacks (antiphospholipid antibody-related) or acute rheumatic endocarditis[63]. Portions of these loose sterile deposits may occasionally embolize. Vegetations of *infective endocarditis* may also embolize. Emboli are more likely to occur with acute bacterial endocarditis, whereas cutaneous lesions in subacute bacterial endocarditis are more likely to result from immune complex disease, not embolization, despite frequent localization to hands.

Crystalglobulin vasculopathy is a rare syndrome of usually IgG or light chain paraproteins which spontaneously crystallize intravascularly. The crystalglobulinemia syndrome presents with rapidly progressive renal failure, polyarthropathy, peripheral neuropathy, cutaneous ulcerations, petechiae, and ecchymoses. Skin biopsies show intravascular crystalline deposits and thrombosis[53,64].

In the *hypereosinophilic syndrome*, an intracardiac mural thrombus can form, and thrombi in smaller vessels are not uncommon at autopsy in patients with this syndrome[53,65]. Clinical findings described to date include splinter hemorrhages, "non-blanching livedoid discoloration" (retiform purpura), digital gangrene, Raynaud phenomenon, and necrotic or blistering skin lesions, but some features may also be due to thrombosis or vasculitis related to the eosinophilia[7,53].

SYSTEMIC COAGULOPATHIES WITH CUTANEOUS MANIFESTATIONS

Disorders of the thrombomodulin, protein C, and protein S pathways may lead to fulminant microvascular occlusion syndromes. Antiphospholipid antibodies are also a major cause of microvascular occlusion, including the catastrophic antiphospholipid antibody syndrome. Many different pathways of antiphospholipid antibody-enhanced coagulation are known or suspected; some include interference with protein C or S function.

Protein C and S Disorders, Congenital and Acquired

Relevant associations:

- Neonatal purpura fulminans – congenital severe protein C or S deficiency
- Warfarin necrosis – acquired protein C dysfunction
- Purpura fulminans in children during recovery from streptococcal or varicella infections – severe acquired protein S dysfunction, probably antibody-mediated

Key feature

- Retiform, branching, or stellate purpura in one of the above clinical settings

Introduction

The term "purpura fulminans" was first used in the late 1800s to describe a syndrome of extensive purpura in severely ill patients, usually children, in the setting of an acute or convalescent infection. This term now includes at least three different syndromes (see below), including septic patients with widespread purpura of any type (petechiae, ecchymoses, palpable purpura, or retiform purpura). It would be more helpful to restrict the term *purpura fulminans* to the subset of patients (either neonatal or septic) with clinical features of DIC and occlusion, including retiform, branching, or necrotic purpura, and/or bland thrombi as the primary histologic finding.

Pathogenesis/clinical features

Despite some overlap in pathophysiology, the differential diagnosis for cutaneous microvascular occlusion is quite different from that of deep venous thrombosis (DVT) or pulmonary emboli (PE). With respect to skin, the protein C–protein S–thrombomodulin pathway is critically important (see Fig. 22.5).

Neonatal purpura fulminans

While severe congenital deficiency of antithrombin III may result in repeated DVT or PE, the only cutaneous finding is venous stasis ulcers from DVT-induced venous insufficiency. In contrast, homozygous (or compound heterozygous) deficiency or severe dysfunction of either protein C or protein S leads to neonatal purpura fulminans within a few hours to 5 days after birth, and it is fatal unless treated[66,67]. Clinically, non-inflammatory retiform purpura is seen until confluence results in large-scale cutaneous and limb necrosis (Fig. 23.6). Ultimately, there is visceral organ involvement. In addition, such infants are often born with cerebral thrombosis or retinal vessel occlusion with congenital blindness. Acquired neonatal purpura fulminans is most commonly due to group B streptococcal infections[67].

Fig. 23.6 Protein C deficiency in an infant. Large purpuric plaques, with development of bullae and necrotic ulcerations within those on the lower extremities. Note the retiform purpura surrounding the heel ulcer. *Courtesy Luis Requena, MD.*

Fig. 23.7 Warfarin (Coumadin®) necrosis. Striking areas of purpura and ischemia on the scrotum (**A**) and pannus (**B**). Note the branching outline of the purpura and central necrosis in the lesions on the abdomen. The differential diagnosis would include calciphylaxis (see Fig. 106.5). *A, Courtesy Kenneth Greer, MD; B, Courtesy Jean L. Bolognia, MD.*

For patients with congenital protein C deficiency, intravenous protein C concentrate or fresh frozen plasma (FFP) is used as initial therapy and then warfarin or low-molecular-weight heparin is begun, followed by tapering of factor replacement. Anticoagulation is continued for life. Liver transplantation is an option for restoring protein C activity[66,67]. Treatment of purpura fulminans due to congenital protein S deficiency is primarily replacement with FFP.

Warfarin necrosis

Warfarin therapy results in abnormal γ-carboxylation of the vitamin K-sensitive factors (II, VII, IX, X, protein C, protein S) by the liver; severe vitamin K deficiency results in a similar dysfunction. Of these factors, the two with the shortest half-life are factor VII and protein C. Factor VII is needed primarily to switch the idling coagulation system into progressive amplification of clotting, and there is considerable redundancy of the procoagulant cascade. In contrast, protein C is critical for preventing the distal spread of clot from the initial point of coagulant activation. In warfarin necrosis, the *pro*coagulant system takes significantly longer to reach its low-point equilibrium than does the protein C-dependent *anti*coagulant activity.

Warfarin necrosis usually develops within 2–5 days of warfarin initiation in the absence of heparin, and it is much more likely to occur if loading doses of warfarin are used[8,68,69]. This coincides with the expected early drop of protein C function. Reversal of warfarin necrosis via replacement with protein C concentrates and laboratory confirmation of very low functional levels of protein C in this setting support this pathomechanism. The incidence of warfarin necrosis is four times higher in women, with a peak incidence in the sixth and seventh decades of life. Although up to one-third of cases of warfarin necrosis may involve inherited partial deficiency of protein C, the disorder occurs more commonly in individuals without inherited defects in protein C. Late-onset warfarin necrosis, occurring up to 6 months after initiating therapy, has been attributed to poor compliance or inappropriate dosing, alterations in the synthetic function of the liver, or drug–drug interactions[69].

Affected sites usually overlie areas of abundant subcutaneous fat, such as the breast, hip, buttock, or thigh. Pain is often the presenting sign, followed by well-demarcated erythema, which rapidly becomes hemorrhagic and then necrotic (Fig. 23.7). Partial retiform or branching purpura typically can be seen within or at the margin of the cutaneous lesions. Biopsy specimens reveal bland (non-inflammatory) thrombosis of most of the dermal vessels[53]. Treatment consists of warfarin discontinuation and administration of vitamin K and heparin. Use of protein C replacement, if available, should also be strongly considered.

Warfarin-associated venous limb gangrene

Synonym: ■ Warfarin-induced venous limb ischemia/gangrene

Severe venous limb ischemia and gangrene is a catastrophic complication of warfarin therapy and there are two predisposing clinical settings – malignancy (often occult) and HIT syndrome (see above)[8]. In patients with a malignancy, there is platelet consumption and ongoing consumptive coagulopathy; administration of heparin leads to an increase in platelet counts while discontinuation of heparin leads to a decline. There is also evidence of persistent thrombin generation despite anticoagulation. Another characteristic finding is warfarin-associated supratherapeutic international normalized ratios (INRs).

Purpura fulminans with sepsis

Acquired purpura fulminans is most notably associated with meningococcal infection, perhaps due to the meningococcus' ability to bind directly to endothelial receptors via its type IV pili. However, it can also occur in association with sepsis from a variety of bacteria, including *S. aureus*, groups A and B β-hemolytic streptococci, *Streptococcus pneumoniae, Haemophilus influenzae*, and *H. aegyptius*[70,71]. In neonates, it is most often due to group B streptococcus.

In a septic patient with DIC, development of retiform purpura can be the first sign of microvascular thrombosis, possibly due to an inability of the protein C–thrombomodulin pathway to prevent propagation of clot[72]. Support for this hypothesis comes from a study in pediatric patients with purpura fulminans in whom early use of protein C correlated with improved survival[73]. However, in adults with septic shock, use of activated protein C did not confer survival benefit and increased the risk of bleeding[74]. While some authors support the use of protein C (as well as antithrombin) for sepsis with purpura fulminins[75], to date definitive studies in which native or activated protein C supplementation is administered to patients with new-onset retiform purpura in the setting of sepsis and DIC have not been done.

Purpura fulminans postinfection

While protein C abnormalities seem to correlate with acquired purpura fulminans in the setting of sepsis in both children and adults, a second clinical presentation has been recognized in children which occurs during the recovery period from group A streptococcal infections including scarlet fever, varicella–zoster, or rarely rubella or human herpesvirus 6 infection[76]. These patients acquire an antibody that can inhibit protein S function[76,77]. The development of postinfectious purpura fulminans ~7–10 days after the onset of the initial infection correlates with the production of infection-triggered antibodies. It is known that protein S requires phospholipid binding for full activity

and transient antibodies to phospholipids or coagulation proteins can develop in children with varicella–zoster viral infections. However, the presence of these antibodies is not predictive of thrombotic complications[77]. Because protein S is an important cofactor for tissue factor pathway inhibitor (which ordinarily acts to suppress tissue factor : factor VIIa-triggered coagulation; see Ch. 22), a reduction in its activity could enhance thrombosis via this mechanism[78].

Treatment of postinfectious purpura fulminans is challenging because there is no commercially available protein S concentrate and it is significantly more difficult to overcome antibody-mediated inhibition of protein S than to restore a deficiency of protein S. Therapeutic options include plasma exchange, plasmapheresis, or plasma replacement in combination with corticosteroids, low-molecular-weight heparin, and sometimes IVIg[76–79].

Antiphospholipid Antibody/Lupus Anticoagulant Syndrome

Key features

- Livedo reticularis, bland necrosis, retiform purpura, or atrophie blanche-like lesions are typical
- The definite diagnosis of antiphospholipid antibody syndrome requires at least one clinical and one laboratory criterion (Table 23.3)
- Pathogenicity of antibodies depends more on binding to certain proteins than to phospholipid binding alone

Introduction

The reagin test for syphilis developed by Wasserman in 1905 was the first antiphospholipid (aPL) antibody test[80]. Some of these antibodies were subsequently associated with thrombotic and obstetric syndromes. Despite their designation as aPL antibodies, it wasn't until the 1990s that co-binding of aPL antibodies to a protein was recognized as essential for pathogenicity[80].

Epidemiology

Antiphospholipid antibody syndrome (APS) is estimated to affect 0.3%–1% of the population[81]. In a 1000-patient cohort of individuals with APS, there was a strong female predominance (82%) and the mean age was 42 ± 14 years at study entry. Fifty-three percent of the patients had primary APS, 36% had APS secondary to systemic lupus erythematosus (SLE), and the remaining 11% had other associated diseases[82]. Thrombosis occurred in a third of patients, most commonly cerebrovascular accidents, transient ischemic attacks, DVTs, and PE. The most frequent obstetric and fetal complications were early pregnancy loss (~15% of pregnancies), premature birth (~50%), and intrauterine growth restriction (~25% of total live births). Mortality was ~10%, usually due to thrombosis (35%) or infection (30%).

Catastrophic APS (CAPS) occurred in 0.9% of this 1000-patient cohort and 55% of those affected died[82]. In a study of 500 patients with CAPS and thrombosis of multiple small vessels, the majority were female (70%), the mean age was 38 years, and the mortality was ~35%[83]. Autoimmune disease was present in 40%, primarily SLE (75%). Organs involved were kidneys (70%), lungs (60%), brain (55%), heart (50%), and skin (50%). Malignancy was a trigger primarily in older patients, whereas infection was a common trigger in younger patients. Lupus patients with CAPS were more likely to have severe cardiac and brain involvement, resulting in a higher mortality (50%).

Pathogenesis

The majority of, if not all, pathogenic aPL antibodies recognize cell surface proteins attached to plasma membrane phospholipids[81,84,85]. The three APS criteria antibody groups are: (1) IgM and IgG anti-β_2-glycoprotein I (β_2GPI) antibodies; (2) anti-cardiolipin (aCL) antibodies; and (3) lupus anticoagulant (LA) (see Table 23.3). The latter is most strongly associated with thrombosis and adverse pregnancy outcomes[85]. Antibodies against β_2GPI bind directly to this protein, which is not a phospholipid, and then may bind to phospholipids on cell membranes. β_2GPI is a unique five domain protein with anticoagulant, antiplatelet, and procoagulant actions (see Table 23.3). β_2GPI, along with C-reactive protein and thrombomodulin, are the only three proteins that have the dual capability of regulating the complement and coagulation systems both up and down depending on external stimuli[8].

Anticardiolipin antibodies are not pathogenic unless their binding is dependent on co-binding to a protein (usually β_2GPI). Likewise, LA is not pathogenic (prothrombotic) unless its binding is co-dependent on either β_2GPI or prothrombin[85]. Of note, pediatric patients with LA that targets prothrombin can rarely develop hypoprothrombinemia and present with bleeding rather than thrombosis. In addition, some forms of LA can punch holes in the annexin 5 shield, leading to phospholipid exposure and thrombosis vulnerability, including in placental vessels.

Different molecular mechanisms may underlie the obstetric versus thrombotic APS subsets[81,85]. Purified IgG from patients with obstetric, but not thrombotic, manifestations of APS were capable of inhibiting trophoblast invasion, while in thrombotic APS, neutrophils produced spontaneous neutrophil extracellular traps (NETs) which incorporated into thrombi[81,85]. Of note, aPL antibodies can also bind to β_2GPI receptors on platelets leading to platelet activation and aggregation, resulting in thrombocytopenia in roughly a third of patients with APS[85].

Vascular findings such as prominent and persistent livedo racemosa or reticularis are unlikely to be due solely to thrombotic mechanisms; they may be related in part to aPL antibodies binding to receptors on endothelial cells with inhibition of endothelial nitric oxide synthase. This would lead to impairment of nitric oxide production and release, inducing endothelial dysfunction and potentially endothelial cell proliferation and intimal hyperplasia[84,85].

Clinical features

APS is one of the more commonly acquired causes of hypercoagulability, presenting as thrombosis (arterial, venous, microvascular) and pregnancy morbidity (miscarriages, late intrauterine fetal demise, severe pre-eclampsia)[85]. Cutaneous findings associated with the APS are listed in Table 23.4. In one large study, the incidence of cutaneous findings were: livedo reticularis, 25%; leg ulcers, 6%; pseudovasculitic lesions, 4%; digital gangrene, 3%; cutaneous necrosis, 2%; and splinter hemorrhages, 0.7%[86] (Fig. 23.8). Cutaneous lesions may also develop indirectly, i.e. by embolization from heart valve vegetations (see embolus section).

ANTIPHOSPHOLIPID ANTIBODY SYNDROME: SAPPORO–SYDNEY CRITERIA

At least one clinical criterion and one laboratory criterion required*

Clinical criteria

1. Vascular thrombosis
   - One or more objectively confirmed episodes of arterial, venous, or small vessel thrombosis occurring in any tissue or organ
2. Pregnancy morbidity
   - One or more unexplained deaths of morphologically normal fetuses at or after the 10th week of gestation – *or* –
   - One or more premature births of morphologically normal neonates at or before the 34th week of gestation because of eclampsia, pre-eclampsia, or placental insufficiency – *or* –
   - Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation

Laboratory criteria – present on two or more occasions at least 12 weeks apart*

1. Anti-cardiolipin antibodies, IgG or IgM [>40 GPL or MPL – *or* – >99th percentile as measured by a standardized ELISA]
2. Lupus anticoagulant [detected according to the guidelines of the International Society on Thrombosis and Haemostasis]
3. Anti-β_2-glycoprotein I† antibodies, IgG or IgM [>99th percentile as measured by a standardized ELISA]

*Patients who do not meet these criteria may still have antiphospholipid antibody syndrome.
†β_2-glycoprotein I binds to ApoER2 receptor, affecting Factor XI effect on platelets and protein C activation, inhibits plasmin generation via direct binding to thrombin, impairs platelet aggregation, inhibits both activated protein C and the activation of protein C by thrombomodulin/thrombin complexes, and inhibits the anticoagulant effect of annexin V.

Table 23.3 Antiphospholipid antibody syndrome (APS): Sapporo–Sydney criteria. The criteria allow for standardization of patients enrolled in clinical studies. GPL, IgG phospholipid units; MPL, IgM phospholipid units. *Adapted from refs 52 and 54.*

CUTANEOUS FINDINGS IN PATIENTS WITH THE ANTIPHOSPHOLIPID ANTIBODY SYNDROME (APS)
• Livedo reticularis, with or without retiform purpura
• Cholesterol embolus-like proximal livedo reticularis with distal retiform purpura
• Acral livedo reticularis
• Sneddon syndrome
• Livedoid vasculopathy or Degos-like lesions
• Anetoderma-like lesions with microthrombosis
• Raynaud phenomenon
• Vasculitis-like lesions
• Pyoderma gangrenosum-like ulcers
• Nail fold ulceration
• Splinter hemorrhages
• Widespread cutaneous necrosis, typically as part of catastrophic APS
• Pseudo-Kaposi sarcoma (acroangiodermatitis)
• Superficial thrombophlebitis migrans

Table 23.4 Cutaneous findings in patients with the antiphospholipid antibody syndrome (APS).

Fig. 23.8 Antiphospholipid antibody syndrome. **A** Purpura and ischemia of the distal portion of the foot. The purpuric lesions have irregular borders (marked with ink). **B** Purpura and milder ischemia of the distal fingers. *A, Courtesy Jean L. Bolognia, MD.*

In addition to the skin, many other organ systems may be involved, with DVT/PE and CNS disease the most common extracutaneous manifestations. CAPS is uncommon and precipitating factors include infection (often younger patients), surgical procedures, drugs (e.g. sulfur-containing diuretics, captopril, oral contraceptives), discontinuation of anticoagulant therapy, and malignancy, especially in older individuals. These patients often present with multi-organ failure; the majority present with renal involvement as well as evidence of acute respiratory distress syndrome. In a series of 65 patients with CAPS and skin involvement, the cutaneous findings included livedo racemosa (45%), necrotic or ulcerated lesions (42%), splinter hemorrhages (29%), apparent distal inflammatory edema (hands, feet, face; 23%), and purpura (14%)[86a]. Complement activation appears to play a role in CAPS and up to 60% of patients with CAPS have germline mutations in complement regulatory genes[87].

Pathology and laboratory findings

As noted previously, LA is most strongly associated with thrombosis and adverse pregnancy outcomes[85]. Detection of LA activity requires a 3-step process: (1) screening assay, e.g. dilute Russell viper venom test, sensitive activated PTT – required because of heterogeneous nature of LA; (2) mixing 1–2 : 1 patient plasma : normal plasma – determines if factor deficiency (corrects prolonged clotting detected in screening assay) or the presence of an inhibitor; and (3) if no correction, determine if inhibitor is phospholipid-sensitive[85].

Tests for aCL and anti-β_2GPI antibodies depend on ELISA assays. In general, patients with triple positivity, i.e. all three antibody groups (see Table 23.3), are considered at highest risk for thrombosis. Additionally, some patients may fit an APS profile but be seronegative for criteria antibodies. The non-criteria antibody most strongly associated with the presence of LA and thrombosis is the anti-phosphatidylserine/prothrombin complex antibody. Of note, this antibody has been highly associated with skin-predominant polyarteritis nodosa, primarily in Japan[88]. In lupus patients, IgM aCL is not associated with thrombosis risk, but the non-criteria IgA aCL appears to be[85].

Histologic features of early lesions typically reveal non-inflammatory thrombosis of small dermal vessels; later lesions may show inflammation following necrosis or with wound healing. In CAPS, there can be arterial and venous occlusion as well as microvascular occlusion in multiple organs including the skin. Complement activation and NETosis can lead to inflammation of blood vessels.

Differential diagnosis

The differential diagnosis of APS includes many of the syndromes discussed in this chapter plus the diseases or syndromes associated with the cutaneous findings in Table 23.4. The presence of persistent or widespread livedo reticularis or livedo racemosa, especially in association with SLE, points to Sneddon syndrome or APS. Complement-mediated HUS (CM-HUS) and sepsis-associated purpura fulminans/DIC can mimic CAPS, but the latter does not typically result in prolonged PT/PTT or elevated fibrinolysis, as in DIC.

Treatment

Therapy for APS normally consists of heparin followed by a vitamin K antagonist to maintain an INR = 2.0–3.0[85,89]. In CAPS, treatment options include heparin, methylprednisolone, IVIg, plasmapheresis, and more recently C5 inhibitors (e.g. eculizumab)[85,90]. Rituximab, cyclophosphamide, and other immunosuppressive agents have been used for both refractory APS and for CAPS[85,91]. In general, direct-acting oral anticoagulants (DOACs) are not recommended[85,89]. Controversy surrounds the use of low-dose aspirin; while multiple lupus trials showed no benefit except for arterial thrombosis[85], it may have a role as preventive therapy in asymptomatic non-lupus patients with aPL antibodies. Hydroxychloroquine, HMG CoA reductase inhibitors ("statins"), and vitamin D replacement may be considered as adjunctive therapies.

DISORDERS OF VASCULAR COAGULOPATHIES WITH CUTANEOUS MANIFESTATIONS

Sneddon Syndrome

Synonym: ■ Idiopathic livedo reticularis with cerebrovascular accidents

Key features

- Usually affects young women
- Persistent livedo reticularis or livedo racemosa
- Labile hypertension
- Recurrent neurologic symptoms due to cerebrovascular disease

Introduction

This uncommon syndrome was first described in 1965[91]. An estimated four new cases of Sneddon syndrome occur per million inhabitants per year, with a prevalence of 0.26% in a hospital-based cohort of strokes from all causes[91].

SNEDDON SYNDROME AND CUTANEOUS/NEURAL MIMICS
Vasculopathies with livedo reticularis or racemosa plus cerebrovascular or CNS involvement
Sneddon syndrome • Idiopathic • Antiphospholipid (aPL) antibody-associated • NOTCH-3 pathway mutations • Adenosine deaminase 2 (ADA2) deficiency due to mutations in *ADA2*/*CECR1*
Primarily adult-onset
Systemic lupus erythematosus (may be associated with aPL antibodies)
Primarily pediatric-onset (selected)
Moya-moya angiopathy Alagille syndrome Susac syndrome (encephalopathy, retinal artery occlusion, hearing loss) Type I interferonopathies, including SAVI (STING-associated *v*asculopathy with onset in *i*nfancy; see Table 45.9) Majewski osteodysplastic primordial dwarfism type II Homocystinuria, hyperhomocysteinemia
Vasculopathies/vasculitis with livedo reticularis or racemosa or livedo-like macular hyperpigmentation, sometimes with peripheral neuropathy
Cryoglobulinemia, especially mixed Cutaneous predominant polyarteritis nodosa Lymphocytic thrombophilic arteritis/macular arteritis Livedoid vasculopathy Cold agglutinin disease

Table 23.5 Sneddon syndrome and cutaneous/neural mimics. CECR1, cat eye syndrome chromosome region, candidate 1; STING, *st*imulator of *in*terferon *g*enes. See references 91–98.

Pathogenesis

Sneddon syndrome is characterized by the association of persistent livedo reticularis or livedo racemosa with an increased risk of transient ischemic attacks (TIAs) and cerebrovascular accidents (CVAs). Underlying risk factors include aPL antibodies, mutations in the NOTCH3 signaling pathway, and adenosine deaminase 2 deficiency (Table 23.5)[91–95]. As in APS, vascular dysfunction of arterioles within the subcutis may drive the livedo reticularis or racemosa pattern, rather than thrombophilia.

Clinical features

Patients with Sneddon syndrome have persistent and usually widespread livedo reticularis or racemosa (see Fig. 106.2), labile systolic hypertension, and CNS disease. There is a strong female predominance (~80%) and the median age at diagnosis is ~40 years[91,92]. A history of fetal loss and Raynaud phenomenon are other recognized features[91]. Of note, the livedo reticularis or racemosa may precede neurologic symptoms by several years.

Neurologic complications tend to occur in three phases[91]: (1) headaches and vertigo (dizziness), which may precede the appearance of livedo reticularis; (2) recurrent TIAs and CVAs; and (3) cognitive decline and dementia. Seizures and chorea have also been reported, especially in aPL antibody-positive patients, as have ophthalmic complications including amaurosis fugax.

In one series of 53 patients, aPL antibody-negative patients were more likely to have CNS events (e.g. seizures, recurrent CVAs) and non-valvular cardiac defects (e.g. atrial septal defect), while aPL antibody-positive patients were more likely to have deep venous thromboses and positive ANAs (70% vs 20%)[92]; Libman–Sacks endocarditis was only seen in aPL antibody-positive patients. However, other studies have shown no differences in valvular disease, CVAs, or recurrent spontaneous abortions. One explanation is that in this series cardiovascular risk factors were much higher than in the normal population and this might have affected the rates of complications[92].

In addition to livedo reticularis or racemosa and Raynaud phenomenon, other occasionally reported cutaneous findings include acrocyanosis, angiomatosis, annular atrophic lichen planus, and peripheral gangrene[91].

Fig. 23.9 Livedo racemosa of the arms in a patient with the autosomal recessive disorder adenosine deaminase 2 deficiency. *Courtesy Edward Cowen, MD.*

Pathology

When standardized biopsies were performed (i.e. three biopsies from the center of livedo reticularis or racemosa rings that included subcutis; see Fig. 106.1), intimal proliferation with subtotal or total obliteration of the lumen of an arteriole or a small artery was found in 80% of cases. A single biopsy versus two biopsies showed the diagnostic features in 27% versus 50% of patients, respectively. These features could be observed only in a small minority of biopsies taken from the circular livedo segment[92]. Because similar biopsy findings were occasionally noted in control patients, these histologic findings are said to be supportive, but not diagnostic, of Sneddon syndrome[92].

In addition to frequently positive aPL antibodies, thrombocytopenia may be present. When the previously cited series of 53 patients was tested for thrombophilia, seven were positive – factor V Leiden mutation (3), protein S deficiency (2), protein C deficiency (1), and prothrombin mutation (1)[91,92].

Differential diagnosis

In addition to Sneddon syndrome, several other vasculopathies may present with persistent livedo reticularis/racemosa and CNS disease and whose onset is most often during infancy or childhood (see Table 23.5)[91–96]. Two disorders that may be on a continuum, cutaneous polyarteritis nodosa (cPAN) and lymphocytic thrombophilic arteritis (LTA), can have peripheral neuropathy plus livedo reticularis/racemosa (see Fig. 106.3)[97,98]. The latter may become hyperpigmented, but CNS involvement is not seen in either entity. Pediatric-onset livedo racemosa and stroke with or without PAN-like findings should prompt consideration of adenosine deaminase 2 deficiency (Fig. 23.9). While screening for the presence of aPL antibodies is important when evaluating patients with signs and symptoms of Sneddon syndrome, patients with cPAN may have anti-phosphatidylserine–prothrombin complex antibodies (see Ch. 24), which could lead to confusion with aPL-related Sneddon syndrome[88].

Treatment

Antiplatelet and antithrombotic agents, aspirin or clopidogrel and warfarin, respectively, are used for secondary stroke prophylaxis[91]. Patients with aPL antibodies are treated as those with primary APS (see above). In aPL antibody-negative patients, antiplatelet agents may be preferable due to a lower risk of bleeding and lack of clear evidence favoring antithrombotic agents. There are case reports of healing of ulcers following intravenous infusion of alprostadil, a synthetic analogue of prostaglandin E1.

Livedoid Vasculopathy

Synonyms: ■ Atrophie blanche ■ Livedo reticularis with summer ulceration ■ Segmental hyalinizing vasculitis ■ Livedoid vasculitis

Key features

- Favors the distal lower extremities, especially the ankles
- Female predominance
- Painful, punched-out ulcers
- White, round, or stellate scars with peripheral telangiectasias
- Livedo reticularis or racemosa in some patients

Introduction

Livedoid vasculopathy is an unusual disorder characterized by small, punctate, painful ulcers that sometimes cluster, are usually on the lower extremities near the ankles, and may be surrounded by reticulated erythema or hemorrhage[99,100]. Resolution classically results in small atrophic white macules with surrounding telangiectasias, referred to as atrophie blanche (see Fig. 105.7). Unfortunately, this term has also been used to describe similar lesions that can arise in the setting of venous insufficiency but are not preceded by small painful ulcerations, leading to variable analyses of etiologies and treatment outcomes.

Epidemiology

Based upon four retrospective series from different countries with a total of just over 200 patients[99–102], the ratio of women : men ranged from 2 : 1 to 5.2 : 1. Although most patients were middle-aged at disease onset, there was a wide range (6 to 67 years)[100]. In one study, flares were reported during the spring and summer in ~80% of patients, supporting previous reports of seasonal variation[102].

Pathogenesis

The precise pathogenesis of livedoid vasculopathy is not known, but it is thought to involve an alteration in endothelial function and/or in coagulation with formation of fibrin thrombi focally within superficial dermal blood vessels. A number of prothrombotic factors have been associated with this syndrome, including hyperhomocysteinemia, elevated lipoprotein (a), aPL antibodies, protein C and S abnormalities, factor V Leiden and prothrombin mutations, antithrombin III deficiency, sticky platelet syndrome, and excess plasminogen activator inhibitor (PAI-1; see Table 105.9)[99–102]. Because data from age-matched controls are frequently lacking and genetic polymorphisms for some of these thrombotic factors are relatively common (e.g. PAI-1), determination of their pathogenic role can be challenging.

Clinical features

Painful, persistent, and often punched-out ulcerations on the legs, especially over the malleoli and in women, should suggest this diagnosis (Fig. 23.10A), as should atrophic white scars with peripheral telangiectasias. Some patients, particularly those with prominent livedo surrounding these ulcers, may develop retiform or stellate purpura or ulcer extension.

In one study, peripheral neuropathy was documented in 10 of 20 evaluated patients, a finding which had been previously noted in the literature[100]. In all four retrospective series from different countries, a spectrum of associated prothrombotic laboratory findings were detected but they neither affected response to treatment nor predicted development of thrombotic complications such as venous thrombosis[99–102]. Of note, even in patients with DVTs/PE, routine screening for coagulation disorders may not be beneficial in directing therapy or predicting risk of recurrence[103].

Pathology

The characteristic histologic findings in livedoid vasculopathy are mild perivascular lymphocytic infiltrates and extravasated red cells surrounding superficial dermal vessels with hyalinized walls and luminal fibrin deposition[99–102] (Fig. 23.10B). Immunofluorescence findings are frequently positive (40%–100%), most often C3 and IgM deposits in blood vessel walls[102]. In a recent study of 62 patients, 95% had positive findings, usually for a combination of immunoreactants (C3 and IgM > IgA > IgG)[102a].

Differential diagnosis

Table 23.6 outlines other disorders that can present with painful, punched-out, vasculopathic ulcers, sometimes with surrounding livedo reticularis[104–110]. Porcelain white macules in the setting of venous insufficiency, but without antecedent punctate ulcerations, should be considered an unrelated entity.

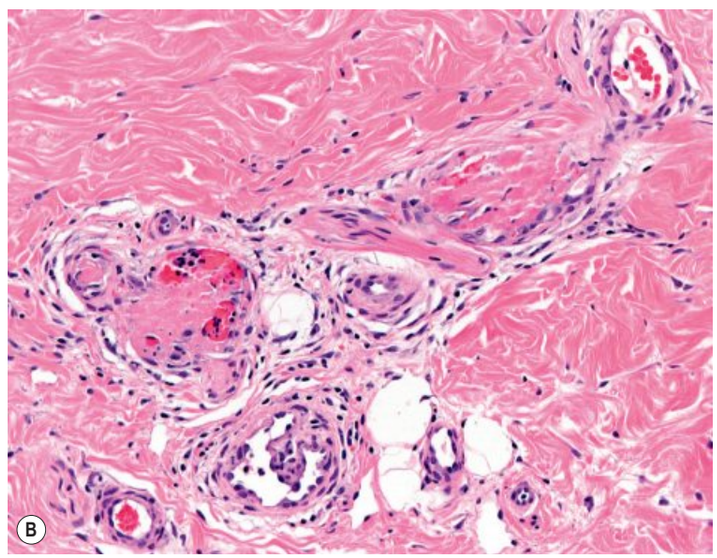

Fig. 23.10 Livedoid vasculopathy. A Punched-out ulcers are seen on the ankle as well as multiple stellate purpuric macules. **B** Thrombi are seen within two dermal blood vessels in addition to a mild perivascular lymphocytic infiltrate. *B, Courtesy Lorenzo Cerroni, MD.*

Treatment

In a systematic review of reported treatments for livedoid vasculopathy (n = 339 patients)[111], those best studied with good clinical outcomes were anticoagulants (e.g. DOACs, heparin)[99–101], pentoxifylline, antiplatelet agents (e.g. aspirin), anabolic steroids, and IVIg. However, there was insufficient evidence to recommend any one particular therapy[111]. Additional options include immunosuppressives (e.g. prednisone) and hyperbaric oxygen therapy. Given the risks of anticoagulation[100], some clinicians begin with the other treatments outlined above, alone or in combination, and then move to anticoagulants if disease control is not achieved. There are also case reports of the successful use of JAK inhibitors (e.g. tofacitinib) for refractory disease.

Hydroxyurea-Associated Vasculopathy

Patients with myeloproliferative disease and sickle cell disease can develop occlusion-related painful ulcerations, but hydroxyurea use in these disorders can occasionally increase the risk of painful ulcer development, usually in the perimalleolar region (see Fig. 105.20F)[112,113].

DISORDERS THAT MAY MIMIC LIVEDOID VASCULOPATHY
Antiphospholipid antibody syndrome
Atrophie blanche-like cutaneous polyarteritis nodosa
Autoimmune connective tissue diseases • SLE and rheumatoid arthritis (sometimes associated antiphospholipid antibodies) • Dermatomyositis vasculopathy, especially MDA-5 antibody-associated • Punctate ischemic ulcerations of systemic sclerosis
Degos disease
Hydroxyurea–associated ulcers
IgA-predominant cutaneous vasculitis
Interferonopathies (see Table 45.9)
Hypertensive (Martorell) ulcers
Non-infected ulcers of sickle cell disease

Table 23.6 Disorders that may mimic livedoid vasculopathy. These entities can present with painful, punched-out, ulcers and those in *italics* are discussed in the chapter. Porcelain white macules in the setting of venous insufficiency, but without antecedent punctate ulcerations, are an unrelated entity. SLE, systemic lupus erythematosus. *From references 104–110.*

Multiple papules and small plaques with porcelain white centers surrounded by an erythematous rim with telangiectasias in a patient with malignant atrophic papulosis. Similar-appearing lesion in a lupus patient with antiphospholipid antibody syndrome (inset). *Courtesy Edward Cowen, MD.*

Ulcers may resemble those of livedoid vasculopathy or they can be larger and more shallow[114]. The pathogenesis of these ulcers is unclear, but healing typically requires discontinuing the hydroxyurea. There is some evidence that ulceration is dependent on duration of treatment (≥1 year), daily dose (0.5–1 g), and cumulative dose (≥510 g)[53,113]. Histologically, vascular findings range from leukocytoclastic vasculitis to sometimes thrombotic occlusion[115]. Fibrosis, lymphocytic infiltration, and/or thickening of vessel walls may also be seen[53,112].

Interferon-Induced Vasculopathy/Cutaneous Necrosis

Atrophie blanche-like ulcers have been reported during interferon-α adjuvant therapy for melanoma[116]. In addition, a number of cutaneous findings have been reported at interferon-β injection sites, including microvascular occlusion and evidence of cutaneous necrosis or necrotic panniculitis clinically (see Fig. 128.1)[117,118]. While some blood vessels may have prominent perivascular inflammation, thromboses are typically noted in the deep dermis or fat, often without inflammation. Systemic thrombotic microangiopathy has also been reported[119].

Benign and Malignant Atrophic Papulosis

Synonyms: ■ Degos disease ■ Kohlmeier–Degos disease

Introduction

Described by Kohlmeier in 1941 and Degos in 1942 as malignant atrophic papulosis, this disorder typically occurs between the second and fourth decades of life and has a slight female predominance. In some patients, it may be familial.

Pathogenesis

There are two forms of atrophic papulosis – benign (skin-limited; BAP) and malignant (systemic; MAP). Risk factors or triggers of this small vessel vasculopathy include genetic predisposition (especially with the benign form), coagulation disorders, viral infections, and autoimmunity[118–121]. In addition to lymphocytic vasculitis and endothelial dysfunction, there is some evidence to support a role for dysregulated interferon-α and the C5–9 membrane attack complex in the underlying endothelial injury[122].

Clinical features

Atrophic papulosis is a rare vasculopathy that may affect only the skin (benign) versus other organs (malignant). The latter occurs more often, with the gastrointestinal tract (~70%) and CNS (~45%) the most commonly involved sites, and less often the lungs or eyes. In a recent systematic review (n = 347 patients), the mean age of onset was 34 years, 64% had systemic findings, and the mortality rate was 57% in the "malignant" form[118].

Cutaneous lesions are usually asymptomatic and begin as scattered crops of small erythematous papules (2–10 mm) on the trunk (~60%) or extremities (~60%)[118–120]. These evolve over 2 to 4 weeks, with the development of a central depression and ultimately a porcelain white scar (Fig. 23.11), often with a rim of telangiectasias and an appearance similar to atrophie blanche. Cutaneous findings typically precede systemic manifestations by 2 years, but this may range from 0 to 28 years[118]. Gastrointestinal lesions can lead to bowel perforation, and, along with CNS manifestations (e.g. CVAs), are the leading causes of death[118,120].

Pathology

Skin lesions are characterized histologically by a wedge-shaped area of ischemic dermis with a sparse perivascular lymphohistiocytic infiltrate at the edge of the ischemic area and an atrophic but slightly hyperkeratotic overlying epidermis. Edema and mucin deposition are found within the ischemic dermis, and in later stages sclerosis may be observed. The base of the lesion shows vascular damage with thrombosis, but examination of deeper tissue sections may be required for detection[123,124].

Differential diagnosis

It is important to consider other systemic diseases, especially SLE, dermatomyositis and APS, as possible causes of malignant atrophic papulosis-like lesions (Fig. 23.11, *inset*)[118,121]. Localized lesions can occur when due to interferon-α injections.

Treatment

Some studies recommend semi-annual evaluations for the first 7 years after diagnosis and then annually[120]. This is based on the observation that the likelihood of the benign variant increases to >95% after 7 years of skin-limited disease[120].

In the systematic review, surgery (especially bowel resection) was the most commonly reported intervention for MAP, but the therapeutic goal should be to prevent serious events requiring surgery[118]. Antiplatelet monotherapy was the most common pharmacologic treatment for BAP and MAP, with complete response rates of 42% and 20%, respectively. These results support an underlying coagulopathy. When antiplatelet agents were combined with other therapies, the complete response rate in BAP was similar to that achieved with antiplatelet monotherapy while the complete response rate in MAP was halved (9%). This suggests that antiplatelet monotherapy was more often prescribed for milder cases, whereas patients with more aggressive disease received multiple therapies that were unable to achieve complete resolution.

The C5 inhibitor eculizumab, which blocks vascular C5b-9 deposition, has also shown benefit in the treatment of MAP[118]. Complete and partial resolution of both variants has been reported with corticosteroids and other immunosuppressants, antimalarial drugs, and IVIg.

Levamisole-Adulterated Cocaine-Induced Vasculopathy/Vasculitis

Levamisole, an immunomodulatory and antiparasitic drug, is a frequent adulterant of illicit cocaine and it can induce a serious vasculopathy/vasculitis (see Ch. 89). In the US, levamisole is only approved for veterinary use.

Clinical features

A recent systematic review (n = 192 patients) found women to be more frequently affected (2 : 1), even though men are more likely to use the drug, suggesting a sex-based predisposition[124]. Median age at presentation was 44 years. The skin is frequently involved (95% of patients), typically with retiform purpura and necrotic lesions on the face, ears, and lower extremities more often than on the upper extremities or trunk (see Fig. 89.13)[124,125]. Approximately 20%–30% of patients have fever and arthralgias, with myalgias, acute renal failure, and pulmonary involvement in ~10% of patients.

Pathology and laboratory findings

Laboratory findings include leukopenia and/or neutropenia (40%–50% of patients), agranulocytosis (10%), ANCAs (95%), and both anti-myeloperoxidase and anti-proteinase antibodies in half of those with ANCAs; <5% of patients have only cANCA positivity. In addition, aPL antibodies are present in ~70% of patients and an ANA titer >1 : 80 in ~50%. Autoantibodies resolve after discontinuation of levamisole.

Histologically, both leukocytoclastic vasculitis (~50%) and thrombotic vasculopathy (~40%) can be seen. Sometimes there is an angiocentric neutrophil-rich infiltrate in the superficial and deep plexus[53]. Variation in the age of the thrombi, ranging from a fibrinous plug to organized fibrotic thrombi with focal recanalization, may be a clue to recurrent use of levamisole-adulterated cocaine. Direct immunofluorescence may show immune complexes and complement deposition in the vessel walls[53].

Differential diagnosis

The lesions of levamisole-induced vasculopathy tend to be more widespread than the acral lesions of cryoprotein-induced disorders. In the setting of sepsis and hypotension, purpura fulminans is a more likely diagnosis. Given the high incidence of ANCAs, aPL antibodies and ANAs, in concert with cytopenias, ANCA-associated vasculitides, systemic lupus, and APS need to be considered, especially in the presence of renal or pulmonary involvement. Since cANCA positivity is rare in this syndrome[124], its singular presence requires strong consideration of a primary ANCA-associated vasculitis. Of note, this syndrome is distinct from cocaine-induced vasculitis.

Treatment

In a review of 151 patients, 28 improved with drug cessation alone while 85 improved following additional interventions, most often prednisone at a median dose of 60 mg/day. Less often, cyclophosphamide, rituximab, methotrexate, thalidomide, and plasmapheresis are employed. Occasionally, surgery is required to remove necrotic tissue[124].

Calciphylaxis

Synonyms: ■ Calcific arteriolopathy ■ Calcific uremic arteriolopathy

The cutaneous manifestations of calciphylaxis are reviewed in Chapters 50 and 106. This section focuses on the mechanisms that underlie the associated thrombotic vasculopathy. While calcification in vessels or peri-eccrine areas within the subcutis is considered the gold standard for the diagnosis of cutaneous calciphylaxis, identical calcification has been demonstrated in normal skin in ~40% of patients with end-stage and chronic renal disease without calciphylaxis as well as in 18% of a small sample of control patients without renal disease undergoing elective surgery[126].

In one study, patients whose skin biopsies fulfilled the histologic criteria for calciphylaxis also had areas of thrombosis within vessels without evidence of calcification[127]. This raised the question of whether calcification is a driver of occlusion, an incidental factor, or a consequence of an underlying vascular dysfunction distinct from calcification (subcutaneous thrombotic vasculopathy). More recently, at least half of patients with uremic and non-uremic calciphylaxis were found to have lupus anticoagulant, offering an explanation for vascular dysfunction[128].

The elevated calcium × phosphate product, association of calciphylaxis with administration of vitamin D, and calciphylaxis in individuals without chronic kidney disease treated with teriparatide (PTH agonist for osteoporosis), suggests that calcium plays a triggering or synergistic role in this disease[129]. Vitamin K is thought, at least in part, to play a role in the pathogenesis of the vascular calcification. There are two forms of vitamin K: (1) K1 (phylloquinone), stored primarily in the liver, is an essential cofactor for synthesis of the procoagulant factors II, VII, IX, and X as well as the anticoagulant proteins C and S; and (2) K2 (metaquinone), stored primarily in vessels and bones, is essential for carboxylation of multiple inhibitors of vascular calcification, especially Gas6 (growth arrest-specific 6) and MGP (matrix Gla) proteins[130]. Chronic renal disease leads to depletion of vascular stores of vitamin K2, resulting in accelerated atherogenesis with arterial calcification and presumably increases the risk of cutaneous vessel calcification[130]. This may also explain why warfarin is associated with a greater risk of calciphylaxis, as warfarin or other vitamin K antagonists further interfere with impaired K2-dependent carboxylation of Gas6 and matrix Gla proteins.

DISORDERS OF CELL-RELATED VASCULAR OCCLUSION

Red Blood Cell (RBC) Vascular Occlusion: Sickle Cell Disease (SCD)

Introduction and pathogenesis

Cell-free hemoglobin, arginase-1, and RBC metabolites interfere with nitric oxide availability and contribute to vasculopathy in SCD[131]. Slow flow results in local hypoxemia, triggering further sickling, providing an explanation for lower extremity ulcerations[131]. In addition, cell-free hemoglobin and heme serve as danger signals, prime the innate immune system, and trigger a proinflammatory endothelial environment[131]. Adherent neutrophils often undergo NETosis which increases RBC entrapment as do activated platelets[131–133]. Damaged RBC-derived microparticles, which are found in large numbers in patients with SCD, also trigger a proinflammatory phenotype on endothelial cells[134]. Lastly, coagulation activation may play a role as inhibitors of thrombin or factor Xa improve microvascular stasis in a mouse model[135,136].

Clinical features

In SCD, the overall incidence of leg ulcers is 8%–10% and they most frequently develop during the second decade of life[137]. The incidence does vary widely by geographic location, from 1% in Saudi Arabia to 25% in the US to up to 75% in Jamaica. Ulcers may be triggered by trauma or edema, are frequently punched-out in appearance, and usually measure <10 cm^2 (see Fig. 105.20C)[137].

Treatment

Hydroxyurea reduces hemolysis and lowers exposure to phosphatidylserines on damaged RBC-derived microparticles, abolishing their proinflammatory properties[134]. There is a reduction in vaso-occlusive crises (VOCs) and presumably the risk of ulceration, but as noted previously hydroxyurea can independently cause ulcerations[137]. Additional potential therapies include L-glutamine (reduces oxidative stress), voxelotor (stabilizes oxygenated hemoglobin S)[133], and crizanlizumab (reduces VOCs via binding to P-selectin on endothelial cells and platelets)[133].

Allogeneic hematopoietic stem cell transplant can be effective in treating SCD, but only 15% of affected individuals have matched donors[133]. In the future, gene therapy may be an option. For example,

LentiGlobin™ for SCD (bb111) consists of a lentiviral vector with a modified β-globin gene that encodes an adult hemoglobin which sterically inhibits polymerization of hemoglobin S and can lead to prevention of severe VOCs[138]. Clinical trials are also underway utilizing CRISPR technology (see Fig. 3.13).

Red Blood Cell (RBC) Vascular Occlusion/Ischemia: Thalassemia

Approximately half of patients with severe β-thalassemia, particularly those in Southeast Asia, have hemoglobin E (HbE). Leg ulcers occur in ~20% patients with HbE β-thalassemia[139]. Ulcers are usually located on the medial or lateral malleoli and often follow minor trauma. They are thought to be due to tissue hypoxia, tend to become chronic, and are severely painful. RBC transfusions, zinc supplementation, and hydroxyurea, either alone or in combination with recombinant human erythropoietin, can accelerate healing. Hyperbaric oxygen and platelet-rich plasma may lead to improvement[139].

Red Blood Cell (RBC) Vascular Occlusion/ Ischemia: Other

Occasionally, other severe hemolytic anemias such as hereditary spherocytosis have been associated with leg ulcers[140]. Splenectomy, which reduces hemolysis and results in normalization of the reticulocyte count, may lead to ulcer resolution.

Intravascular Cellular Occlusion

Although chronic lymphocytic leukemia is the most common cause of a marked elevation of circulating atypical leukocytes, these cells are fragile and do not lead to vascular occlusion syndromes. Reduced perfusion of various organ systems may accompany high blast counts, nearly always of myelogenous origin. Cutaneous bland leukemic occlusion syndromes have not been reported, although repeated arterial occlusion from myeloblasts has been described (e.g. retinal artery, cerebral arteries)[141]. Leukemic vasculitis in the skin has been described[142], as has a case of T cell prolymphocytic leukemia with a cutaneous presentation that mimicked livedoid vasculopathy[143].

Intravascular lymphoma (B cell > T cell) is a very rare syndrome which is frequently diagnosed *post mortem*, usually because of vague clinical findings. CNS involvement is often the most severe clinical manifestation. Skin lesions are commonly observed (40% of patients) but nonspecific and include erythematous, sometimes painful plaques or nodules and macular or telangiectatic lesions[144]. The lower extremities are the most common location (often in association with edema), followed by the trunk. Occasionally, it may present as retiform purpura (Fig. 23.12). The histopathologic finding of intraluminal occlusion by atypical lymphocytes can be missed on initial interpretation (see Fig. 119.14).

Fig. 23.12 Intravascular B cell lymphoma. The clinical presentation in this patient was retiform purpura and necrosis with livedo reticularis. *Courtesy Lucinda Buescher, MD.*

Cutaneous intralymphatic histiocytosis is characterized by dilated lymphatic vessels filled with histiocytes, leading to overlying erythematous patches without purpura (see Fig. 121.6). This entity was previously referred to as cutaneous intravascular histiocytosis, until it was recognized that only lymphatic vessels are involved. It is often associated with chronic inflammation, rheumatoid arthritis, joint replacements, or metal implants[145].

DISORDERS OF OCCLUSION, MISCELLANEOUS

Loxosceles Spider Bites

Clinical and histologic features as well pathogenesis and treatment options are discussed in Chapter 85. At the site of the bite, edema, erythema, and a painful reddish blister develop that is surrounded by a cyanotic bluish discoloration with ischemic borders and then intensely erythematous halo. This results in a characteristic blue–white–red concentric pattern[146]. The cyanotic area can darken and enlarge over a few days, sometimes becoming geographic or retiform in appearance with central necrosis.

Systemic symptoms include fever, nausea, headache, shivering, weakness, myalgias, and arthralgias. Rarely, patients can develop hemolytic anemia, thrombocytopenia, disseminated intravascular coagulation, hemoglobinuria, myoglobinuria, acute renal failure, and gangrene[146].

Hematoma-Associated Retiform Purpura

Retiform purpura with necrosis, best explained by compression of subcutaneous arterioles by large trauma-induced hematomas, may rarely occur, including in patients with hemophilia[147].

SARS-CoV-2 Purpuric Syndromes

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is associated with a diminished type I interferon response during its early phase[148,149]. Resultant viral replication contributes significantly to septal capillary compromise within the lung as well as extrapulmonary pseudovirion dissemination with extrapulmonary vascular sequelae[148]. Spike glycoprotein and other viral capsid proteins localize to microvasculature expressing angiotensin-converting enzyme 2 (ACE2), the receptor utilized by spike glycoprotein[148]. The primary localizations of viral capsid/spike protein and its ACE2 receptor are the septal capillaries of the lung, deeper dermal and subcutaneous capillaries and venules of both diseased and normal-appearing skin, and the microvessels of the brain[148]. There is little evidence to support viral proliferation in tissues beyond the nasal epithelium and lung; evidence instead suggests that pseudovirions or spike proteins that disseminate from the lung and localize to sites of ACE2 receptors are important in disease expression. Differently modulated immune responses appear to correlate with observed patterns of vascular inflammation and coagulopathy.

Pernio/chilblains-like disease ("COVID toes")

Individuals with this disorder, more often children, are usually antibody- and PCR-negative for SARS-CoV-2, leading many authors to question whether there is a true association. Patients typically present with tender or pruritic red–purple papules on the toes > fingers which may blister or ulcerate[148,149]. Although the overall histologic features are similar to those of idiopathic pernio (see Ch. 88), a distinguishing feature is the presence of occlusion of some blood vessels within the reticular dermis. By immunostaining, there is increased MxA expression in the epidermis, eccrine coils, endothelia, T cells, and plasmacytoid dendritic cells, pointing to a robust type I interferon response[148,149].

One theory advanced in support of a true association is that a very brisk innate immune type I interferon response clears the virus quickly, without enough viral proliferation to trigger a humoral antibody response to SARS-CoV-2. This brisk response still allows vascular dissemination of pseudovirions (but not intact virus) which bind to ACE2 receptors, leading to a second wave of local type I interferon responses beyond the window of viral detection. However, this explanation is not universally accepted.

The relationship between pernio and interferon dysregulation is supported by the clinical findings in two inherited interferonopathies – familial chilblain lupus and Aicardi–Goutières syndrome (see Table 45.7)[149]. The theory that spike protein or RNA segments in

the absence of intact virions can trigger a type I interferon response is supported by reports of pernio-like lesions following SARS-CoV-2 vaccination[149]. A high density of eccrine glands on hands and feet might partially explain the favored location for this reaction.

Immune complex vasculitis and antiphospholipid antibodies

Skin-limited leukocytoclastic vasculitis (LCV), including one with mixed cryoglobulinemia, has been observed in patients with mild to moderately severe SARS-CoV-2 infection[148]. SARS-CoV-2-associated IgA LCV and IgA nephropathy have also been reported, as have IgA LCV and nephropathy following SARS-CoV-2 vaccination[150–152]. In skin-limited idiopathic IgA vasculitis, it is known that hypoglycosylated IgA becomes a target antigen for formation of immune complexes and for binding to renal mesangium[153]. Whether this is true of SARS-CoV-2-associated IgA vasculitis is not yet known.

Antiphospholipid antibodies have also been associated with SARS-CoV-2 infection. However, data suggest that most aPL antibodies are transient with many, if not all, instances likely representing a consequence of vascular injury rather than its cause[154,155].

Retiform thrombotic purpura

A hypercoagulable state and organ failure, particularly progressive acute respiratory distress syndrome (ARDS) and acute renal insufficiency, qualify as critical SARS-CoV-2 infection. In both affected and normal skin of patients with critical infections, there is evidence of complement activation in the ACE2-positive microvascular beds that have bound viral capsid protein (but not active viral replication)[148]. The mannan-binding lectin (MBL) pathway has been implicated as the driver of vascular damage that leads to thrombosis and coagulopathy, with possible augmentation by the alternate complement activation pathway. C5b-9 deposition and vascular injury are similar to that seen in CM-HUS. The MBL pathway is also implicated as an inducer of the overproduction of various cytokines (e.g. tumor necrosis factor, interleukin-6) by activated endothelium.

Histologically, there is a pauci-inflammatory thrombogenic vasculopathy affecting dermal capillaries and venules, and in half of the patients with retiform purpura, the arterioles and small arteries are also involved. This finding is associated with a higher risk of stroke and death. Degenerative endothelial cell changes with sloughing is more conspicuous in the deeper dermis and subcutaneous fat, along with secondary ischemic necrosis of eccrine coils[148].

SARS-CoV-2-related systemic coagulopathy

Malignancy-associated DIC frequently leads to bleeding with significant fibrinolysis while sepsis tends to suppress fibrinolysis and favor thrombosis, termed sepsis-induced coagulopathy (SIC)[156,157]. The coagulopathy of SARS-CoV-2 infection resembles SIC, but because it manifests in a distinct manner, the term COVID-19-associated coagulopathy (CAC) is often employed[156–158]. For example, a decreased platelet count and prolonged PT, hallmarks of SIC, are uncommon in the early phase of CAC. Symmetrical peripheral gangrene can occur due to microthromboses, and acute hepatic dysfunction (shock liver) appears to predispose to this complication[157].

Systemic thromboembolic events include PE, DVT, ischemic stroke, myocardial infarction, and systemic arterial embolism[159]. SARS-CoV-2 infection-associated DIC is an unusual but potentially lethal complication, reported in ~2% of hospitalized patients.

Vaccine-Induced Immune Thrombotic Thrombocytopenia (VITT)

Synonym: ■ Variant of thrombosis with thrombocytopenia syndrome (TTS)

Thrombosis with thrombocytopenia syndrome (TTS) has been used synonymously with vaccine-induced immune thrombotic thrombocytopenia, but TTS is more broadly applied to post-vaccination syndromes related to differing mechanisms[160,161]. VITT is specifically due to anti-platelet factor 4 (anti-PF4) antibodies that are induced primarily by adenoviral vector vaccines and, very rarely, SARS-CoV-2 mRNA vaccines. VITT strongly resembles spontaneous "heparin-induced" thrombocytopenia or classic HIT (see above). Unlike classic HIT, spontaneous HIT results from an anti-PF4 antibody that does not require co-binding to a long chain polyanion such as heparin and occurs in the absence of exposure to heparin.

The rate of this complication from SARS-CoV-2 viral vector vaccines is 3.83 per million doses versus 0.00855 per million with the mRNA vaccines, a 450-fold difference in frequency. The possibility exists that the rate in the mRNA vaccine group represents the background incidence of spontaneous HIT in the US. Compared to HIT, VITT appears to target a different antigenic site on PF4, which is shared with neutrophil activating peptide-2 (NAP2). NAP2 is one of the most abundant chemokines released from activated platelets and is known to be involved in the initiation and propagation of the immunothrombotic response[162].

Clinical features include cerebral venous (sinus) thrombosis (55%), PE (40%), extremity DVT (40%), and abdominal vein thrombosis (30%), with one sixth of the patients developing arterial thrombosis, mirroring the frequency seen in spontaneous HIT[160,161]. Characteristic laboratory findings include a moderate-to-severe thrombocytopenia and evidence of DIC with D-dimer elevation and hypofibrinogenemia.

eFig. 23.4 IgA vasculitis mimicking livedoid vasculopathy. This middle-aged women had a two-year history of small painful ulcers on her arms that healed with macular atrophy; biopsies two years apart showed classic findings of livedoid vasculopathy. Subsequently, she developed these lesions with a retiform pattern of ulceration and new-onset progressive sensory neuropathy and microscopic hematuria. Histologically, leukocytoclastic vasculitis with prominent IgA deposition was seen and low-dose dapsone led to clinical improvement. Hematuria was diagnosed as IgA mesangial glomerulopathy.

Pathogenesis 418
General Clinical Features 418
Pathology 419
Differential Diagnosis 421
Small Vessel Vasculitis 421
Predominantly Small and Medium-Sized Vessel Vasculitides 434
Predominantly Medium-Sized Vessel Vasculitis 444
Temporal Arteritis (Giant Cell Arteritis) 446
Diagnostic Approach to a Patient with Suspected Vasculitis 446

Key features

- The morphology of cutaneous lesions of vasculitis correlates with the size of the affected blood vessels, facilitating disease classification and diagnosis
- Cutaneous vasculitis can be a manifestation of a systemic vasculitis, a skin-limited or skin-predominant variant of a systemic vasculitis, or single-organ vasculitis with no detectable systemic involvement
- The diagnosis of cutaneous vasculitis requires careful clinicopathologic correlation and differentiation from mimickers, assessment for internal organ involvement and underlying disorders, and evaluation of features that point to a particular vasculitis subtype

INTRODUCTION

Vasculitis is defined as inflammation and destruction of blood vessels with resultant downstream ischemic tissue damage. Any organ system can be affected, and clinical manifestations correlate with the size of affected blood vessels, such that disorders are generally classified according to vessel size. Cutaneous vasculitis may represent: (1) a manifestation of a systemic vasculitis; (2) a skin-limited or skin-predominant variant of a systemic vasculitis; or (3) a single-organ vasculitis with no detectable systemic involvement[1].

Vasculitis can affect small, medium-sized, or large vessels of the arterial and/or venous systems (Table 24.1). Small vessels include arterioles, capillaries, and postcapillary venules, which are found in the superficial and mid dermis of the skin. Medium-sized vessels refer to the small arteries and veins that reside within the deep dermis or subcutis. Large vessels include the aorta and named arteries. Cutaneous involvement occurs almost exclusively with vasculitis of small and medium-sized vessels; therefore, the large vessel vasculitides are discussed only briefly or mentioned in Table 24.1.

Terminology

In this chapter, "*cutaneous vasculitis*" generally refers to vasculitis with any underlying etiology and affecting any sized vessel in which the clinical manifestations include, but are not necessarily limited to, the skin. *Cutaneous small vessel vasculitis* (CSVV), on the other hand, is a term defined as a single-organ, skin-limited type of vasculitis involving small blood vessels. *Leukocytoclastic vasculitis* (LCV) is a histopathologic term for vasculitis involving the small postcapillary venules of the dermis with neutrophilic inflammation. Patients whose cutaneous lesions have histologic findings of LCV may have skin-limited vasculitis, but this is not always the case; a careful and systematic evaluation is required to identify a particular vasculitis subtype and/or etiology. In summary, these three terms are not synonymous and should not be used interchangeably without appropriate clarification.

CLASSIFICATION

The 2012 revised International Chapel Hill Consensus Conference Nomenclature, which is based upon expert consensus, provides standardized terminology and disease definitions for the various types of vasculitis[2]. A 2018 dermatologic addendum to the Chapel Hill Nomenclature further classifies cutaneous vasculitides[1]. In addition, the Diagnostic and Classification Criteria in Vasculitis Study (DCVAS), a large, multinational observational study that utilized patient data, aims to develop and validate evidence-based diagnostic and classification criteria for use in practice and clinical trials. These data are the basis of revised ACR-EULAR classification criteria for large vessel vasculitis and ANCA-associated vasculitis[3].

Because a system based upon the *predominant* size of the involved blood vessels is conceptually useful and helps to predict the clinical presentation and corresponding histopathologic findings, this type of classification scheme will be employed in this chapter (see Table 24.1). Additional features that aid in classifying cutaneous vasculitis are systemic manifestations, direct immunofluorescence studies, and the presence or absence of pertinent laboratory findings, e.g. anti-neutrophil cytoplasmic antibodies (ANCAs) (see Fig. 24.16). Despite descriptions of distinct vasculitic syndromes, unique diagnostic criteria are often lacking and clinicopathologic correlation is always required.

EPIDEMIOLOGY

The annual population-based incidence of biopsy-proven LCV is ~45 per million. Of note, this figure includes various subtypes such as urticarial vasculitis, cryoglobulinemic vasculitis, and ANCA-associated vasculitis, any of which may demonstrate LCV histologically[4]. Cutaneous vasculitis occurs in all age groups (mean age in adults, 47 years; mean age in children, 7 years), has a slight female predominance[5,6], and is much more common in adults than in children. The most common type of vasculitis in children is IgA vasculitis (Henoch–Schönlein purpura).

PATHOGENESIS

Cutaneous small vessel vasculitis as well as other subtypes of small vessel vasculitis involving the skin are mediated by immune complexes that form in the presence of antigen excess. After their deposition within postcapillary venules, these complexes lead to complement-mediated chemotaxis of neutrophils (Fig. 24.1A). In ANCA-associated vasculitis, vessel wall damage is directly mediated by neutrophils rather than by immune complex deposition (Fig. 24.1B), hence the term "pauci-immune" vasculitis.

GENERAL CLINICAL FEATURES

The skin lesions of CSVV usually appear 7–10 days after the inciting event; rarely, drug-induced CSVV may appear within hours of administration of the responsible drug. In systemic vasculitis, systemic symptoms often precede the appearance of associated cutaneous lesions (average, 6 months), but the interval is variable and cutaneous findings can certainly be a presenting manifestation[5]. As noted, the cutaneous findings of vasculitis depend upon the predominant size of the vessels involved. CSVV typically presents with palpable or macular purpura,

CUTANEOUS VASCULITIS CLASSIFICATION SCHEME			
Caliber of the predominantly affected vessel	**Classification**	**Subclassification or etiologies**	**Morphology of cutaneous lesions**

Small	Small vessel vasculitis of the skin	• Cutaneous small vessel vasculitis (CSVV)
		• IgA vasculitis, including Henoch–Schönlein purpura
		• Acute hemorrhagic edema of infancy
		• Urticarial vasculitis
		• Erythema elevatum diutinum
		• Secondary causes of CSVV (see Table 24.4):
		  • Drug exposure
		  • Infections (septic vasculitis)
		  • AI-CTD
		  • Malignancies, most often hematologic
			• Palpable purpura (most common)
			• Petechiae
			• Macular purpura
			• Urticarial papules
			• Vesicles
			• Pustules
			• Targetoid papules and plaques
			• Round ulcers

Small and medium-sized ("mixed")	Cryoglobulinemic vasculitis (types II and III)	• Secondary to an underlying infection (e.g. HCV), AI-CTD, or lymphoplasmacytic disorder • Primary/idiopathic	• Petechiae • Palpable purpura • Livedo racemosa • Retiform purpura • Ulcers • Subcutaneous nodules • Digital necrosis
	ANCA-associated	• Granulomatosis with polyangiitis (formerly Wegener granulomatosis) • Microscopic polyangiitis • Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome) • Drug-induced	
	Secondary causes	• Infections • Inflammatory disorders (e.g., AI-CTD)	
Medium-sized	Polyarteritis nodosa (PAN)	• Classic (systemic) PAN • Cutaneous PAN (cutaneous arteritis)	• Livedo racemosa • Retiform purpura • Ulcers • Subcutaneous nodules • Digital necrosis
Large*	Temporal (giant cell) arteritis		• *Early* – erythematous or cyanotic skin, alopecia, purpura, tender nodules on frontotemporal scalp • *Late* – ulceration and/or gangrene of frontotemporal scalp or tongue
	Takayasu arteritis		• Erythematous subcutaneous nodules ± ulceration, pyoderma gangrenosum-like lesions on the extremities (lower > upper) • May have evidence of small and/or medium-sized vessel vasculitis
*Cutaneous manifestations are rare.			

Table 24.1 Cutaneous vasculitis classification scheme. In patients with Behçet disease, there can be involvement of small, medium-sized, and large vessels. AI-CTD, autoimmune connective tissue diseases; ANCA, anti-neutrophil cytoplasmic antibodies.

but urticarial papules, pustules, vesicles, petechiae, or targetoid lesions can be seen (Fig. 24.2 & 24.3). The lesions favor dependent sites, as well as areas under tight-fitting clothing, reflecting the influence of hydrostatic pressure and stasis on immune complex deposition. In general, the lesions are asymptomatic, but they may itch, burn, or sting.

In medium-sized vessel vasculitis, the affected blood vessels reside within the reticular dermis or subcutis. As a result, it typically presents with livedo racemosa, retiform purpura, ulcers, subcutaneous nodules, and/or digital necrosis. In general, the presence of larger ulcerations or necrosis suggests deeper arterial involvement. The combination of purpuric macules and papules plus features of medium-sized vessel disease points to a "mixed" pattern of vasculitis with involvement of both small and medium-sized vessels, as in cryoglobulinemic vasculitis and ANCA-associated vasculitis (see Table 24.1).

Common manifestations of systemic vasculitis include inflammatory arthritis as well as constitutional symptoms, such as fever, weight loss, and malaise. These common findings can be seen in virtually any type of systemic vasculitis, whereas other signs and symptoms (e.g. motor neuropathy, sinusitis) are more often associated with specific disease states. As in the skin, systemic manifestations tend to correlate with the size of the affected blood vessels; for example, glomerulonephritis is a manifestation of small vessel disease, while renal artery aneurysms and renovascular hypertension are features of medium-sized vessel vasculitis[6]. In a population-based study of 84 patients with biopsy-proven LCV, 39 patients (46%) had systemic manifestations, with renal involvement most commonly observed (17 of 39 patients)[4].

PATHOLOGY

Timing and appropriate sampling of the most likely involved vessels increase the diagnostic yield of a skin biopsy. Ideally, lesions should be biopsied for routine processing within the first 24 to 48 hours of appearance. When small vessel vasculitis is suspected, a biopsy specimen for direct immunofluorescence (DIF) should be obtained, as the presence of certain immunoglobulins (e.g. IgA) may suggest a particular diagnosis and prognosis. Biopsies for DIF should also be obtained from lesions of recent onset, ideally those that are only hours old. In general, punch biopsies are adequate for the diagnosis of small vessel vasculitis, while an incisional deep biopsy may be required to diagnose vasculitis of larger vessels.

In cutaneous vasculitis, the histologic findings vary depending upon the type and age of the sampled lesion in addition to the size of the affected vessel. The classic histopathologic features of CSVV are referred to as LCV and consist of transmural infiltration of the walls of small vessels (primarily postcapillary venules) by neutrophils undergoing karyorrhexis of their nuclei, as well as fibrinoid necrosis of the vessel walls (Fig. 24.4). Other findings include leukocytoclasia (degranulation and fragmentation of neutrophils, leading to the production of nuclear dust), extravasated erythrocytes, and signs of endothelial cell damage. However, lesions present for greater than 48 to 72 hours may have a predominantly mononuclear rather than neutrophilic infiltrate. In the case of palpable purpura, the most common clinical lesion of CSVV,

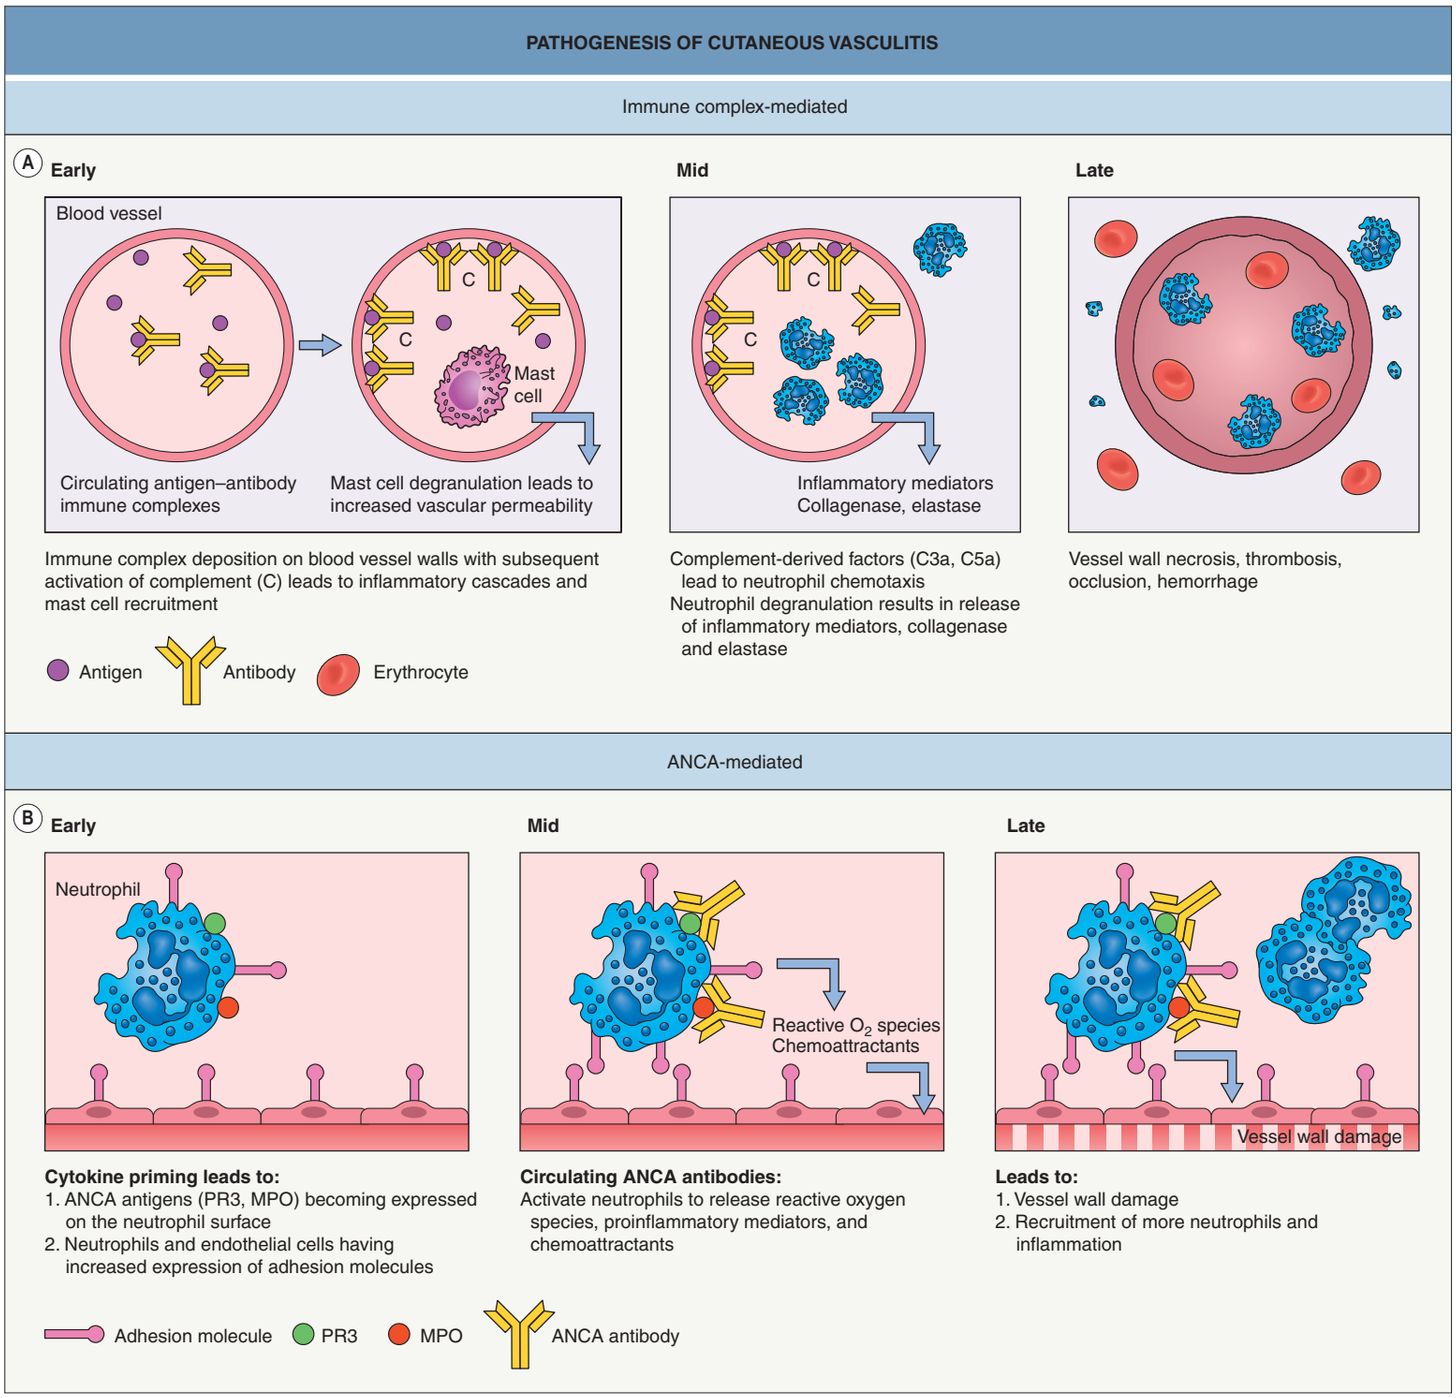

Fig. 24.1 Pathogenesis of cutaneous vasculitis – immune complex- versus anti-neutrophil cytoplasmic antibody (ANCA)-mediated. A In immune complex-mediated vasculitis, circulating antigens (e.g. infectious agents, medications, neoplasms) induce antibody formation. Binding of antibodies to circulating antigens creates immune complexes. Immune complex deposition within postcapillary venules activates complement and subsequently leads to an increase in adhesion molecule expression on the endothelium. Complement split products (C3a and C5a) induce mast cell degranulation and neutrophil chemotaxis. Mast cell degranulation leads to increased vascular dilation and permeability, enhancing immune complex deposition and leukocyte tethering to endothelium. Increased adhesion between inflammatory cells (especially neutrophils) and the endothelium is mediated by elevated expression of selectins (E-selectin, P-selectin) and members of the immunoglobulin superfamily (ICAM-1, VCAM-1, PECAM-1) on endothelial cells in concert with the upregulation of their corresponding ligands and receptors/adhesion molecules on leukocytes (e.g. P-selectin glycoprotein ligand-1, LFA-1, Mac-1) (see Ch. 102 for details). Neutrophils release proteolytic enzymes (such as collagenases and elastases) and free oxygen radicals that damage the vessel wall. In addition, formation of the membrane attack complex (C5–C9) on the endothelium leads to the activation of the clotting cascade and the release of cytokines and growth factors with ensuing thrombosis, inflammation, and angiogenesis. **B** In ANCA-mediated vasculitis, following primary activation by cytokines such as tumor necrosis factor (TNF), intracellular proteins from neutrophils (e.g., proteinase 3 [PR3], myeloperoxidase [MPO]) become expressed on the cell surface. After formation of ANCAs that recognize these antigens, binding of the autoantibodies to neutrophils leads to increased neutrophil adhesion to vessel walls and subsequent cellular activation. Neutrophils then release reactive oxygen species and other toxic mediators that result in vessel wall damage (see **A**). Because the vessel damage in ANCA-positive vasculitides is directly mediated by neutrophils rather than by immune complexes, they are referred to as "pauci-immune" vasculitides. Formation of ANCAs may be related to an impairment in neutrophil apoptosis which results in a prolonged opportunity for autoantibody development.

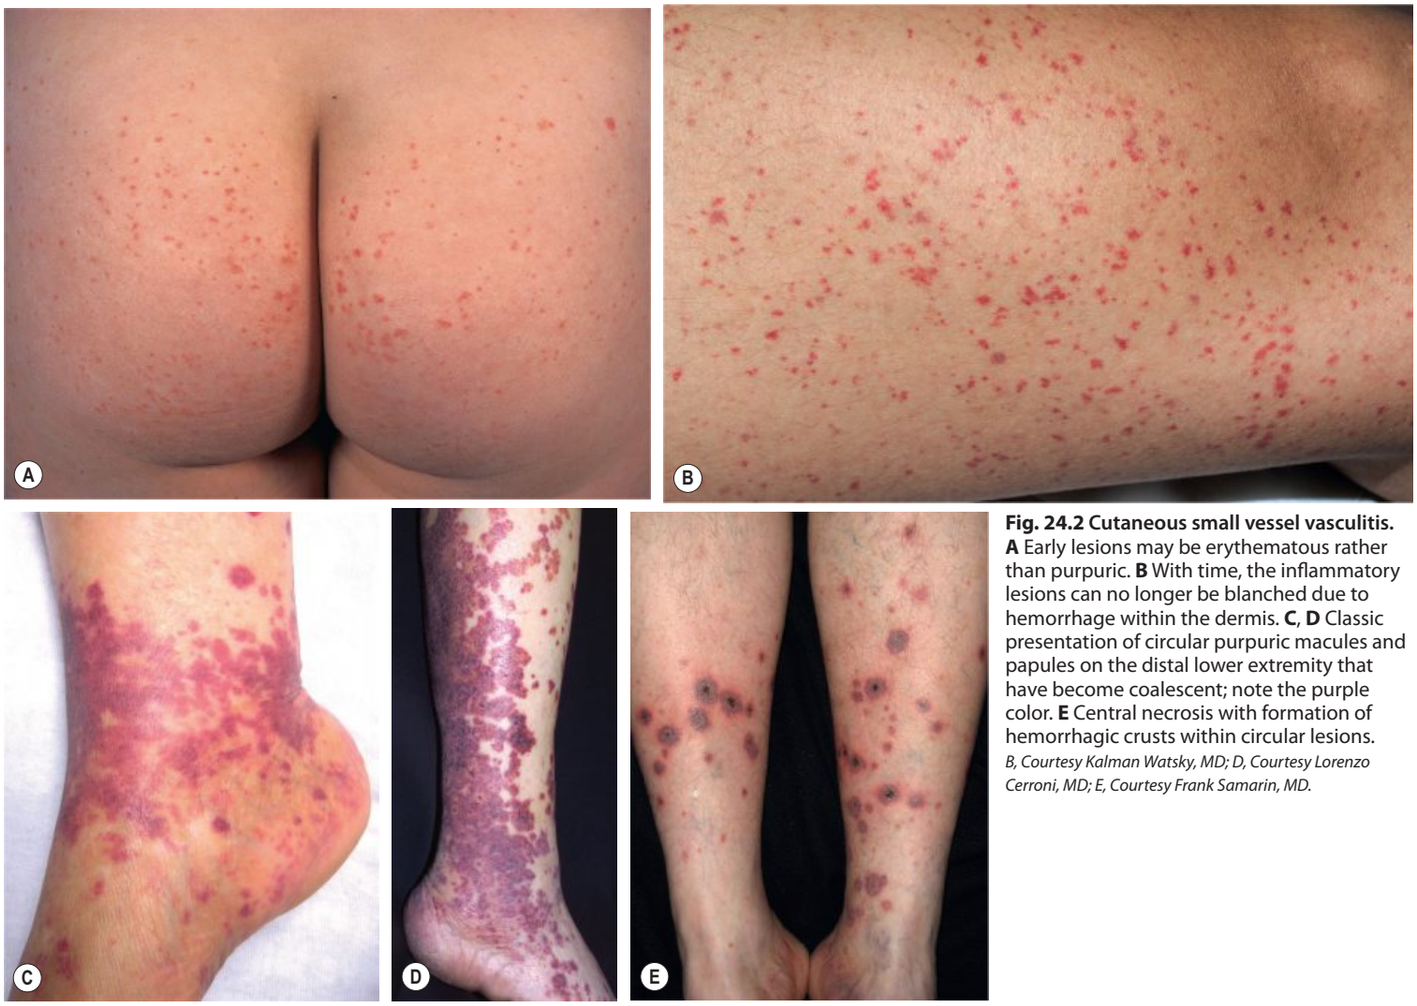

Fig. 24.2 Cutaneous small vessel vasculitis. **A** Early lesions may be erythematous rather than purpuric. **B** With time, the inflammatory lesions can no longer be blanched due to hemorrhage within the dermis. **C**, **D** Classic presentation of circular purpuric macules and papules on the distal lower extremity that have become coalescent; note the purple color. **E** Central necrosis with formation of hemorrhagic crusts within circular lesions. *B, Courtesy Kalman Watsky, MD; D, Courtesy Lorenzo Cerroni, MD; E, Courtesy Frank Samarin, MD.*

the small vessel involvement accounts for the small size of the lesions, the inflammatory response for the palpability and symptomatology (e.g. burning pain, pruritus), the red blood cell extravasation from damaged blood vessels for the non-blanching purpura, and the effect of gravity on immune complex deposition for the distribution of lesions on the lower legs and other dependent areas.

Some studies suggest that additional histologic findings may provide clues to the underlying etiology, e.g. eosinophils in drug-induced CSVV[7], thrombi in patients exposed to levamisole-tainted cocaine, and thrombi plus dense dermal inflammation in septic vasculitis. Involvement of deeper dermal vessels can alert the clinician to look for an underlying etiology rather than presuming the CSVV is idiopathic[8].

Vasculitis of medium-sized blood vessels is characterized by similar changes involving the vessels (e.g. small arteries) of the deep reticular dermis and subcutaneous fat. Neovascularization of the adventitia, in the form of small capillaries, is commonly seen in older lesions of medium-sized vessel vasculitis.

In ~80% of cases of small vessel vasculitis of the skin, DIF demonstrates deposition of C3, IgM, IgA, and/or IgG (generally in that order of frequency) in a granular pattern within the vessel walls[5]. Immunoglobulin deposition is highest (up to 100%) in skin lesions present for ≤48 hours[5]. On the other hand, in 30% of samples obtained 48–72 hours after lesion onset, the DIF will be negative for immunoglobulins, and only C3 will be detected in lesions present for >72 hours[5]. In patients with ANCA-associated vasculitis, the DIF of lesional skin is usually negative. After controlling for duration, it is preferable to biopsy more proximal lesions for DIF in order to avoid nonspecific vascular fluorescence that can occur at sites of increased hydrostatic pressure.

As stated previously, the term LCV is a histologic designation. Terms used to describe additional histologic forms of cutaneous vasculitis include "lymphocytic" and "granulomatous" (see below)[9]. Use of the term lymphocytic vasculitis requires clarification, as it does not represent a conventional type of vasculitis but rather a histologic finding seen in a number of non-vasculitic disorders such as pernio and pityriasis lichenoides et varioliformis acuta (Table 24.2).

DIFFERENTIAL DIAGNOSIS

Several disorders can present with skin lesions that resemble the various cutaneous manifestations of vasculitis; the most common entities in the differential diagnosis are listed in Table 24.3. Similarly, histologic findings of vasculitis may be seen in other conditions which are not types of primary vasculitis, including arthropod bites, neutrophilic dermatoses, and cutaneous ulceration. Careful clinicopathologic correlation is necessary to differentiate these vasculitis mimickers.

SMALL VESSEL VASCULITIS

Synonyms: ■ IgM/IgG immune complex vasculitis ■ Cutaneous leukocytoclastic vasculitis ■ Cutaneous leukocytoclastic angiitis ■ Hypersensitivity vasculitis ■ Cutaneous necrotizing venulitis

Key features

- A single-organ, skin-limited vasculitis involving small blood vessels
- Presents with palpable purpura, urticarial lesions, and/or hemorrhagic macules or vesicles; less common findings include targetoid lesions, pustules, and round ulcerations
- Lesions favor the lower extremities and other dependent areas or pressure points
- Histologically, there is leukocytoclastic vasculitis involving small vessels, primarily postcapillary venules
- Must be differentiated from vasculitis with extracutaneous involvement

Fig. 24.3 Clinical variants of cutaneous small vessel vasculitis. A Targetoid appearance that can resemble erythema multiforme. **B** Hemorrhagic vesicles in addition to palpable purpura. **C** Hemorrhagic crusts in an annular configuration. **D** Lesions involving the upper extremities. **E** Purpuric macules and papules with areas of confluence that resemble a purpuric morbilliform drug eruption. **F** Coalescence of palpable purpura as well as edema and an ulcer with a thick black eschar; petechiae are also present and in the instep resemble pinpricks. *B, Courtesy Kalman Watsky, MD; D, Courtesy Lindy Fox, MD, and Kanade Shinkai MD; E, Courtesy David A. LYMPHOCYTIC VASCULITIS

• Defined histologically as a perivascular lymphocytic dermal infiltrate with associated damage to the walls of small blood vessels; findings may range from extravasated RBCs and swelling or hyperplasia of endothelial cells to fibrin deposition and fibrinoid necrosis of the vessel wall
• Most commonly seen in:
  • **Pernio**
  • **Pityriasis lichenoides et varioliformis acuta (PLEVA)**
  • Rickettsial, viral infections
  • Autoimmune connective tissue diseases, e.g., lupus erythematosus, relapsing polychondritis
  • Behçet disease
  • Hypercoagulable disorders, e.g., Sneddon syndrome
  • Lymphocytic thrombophilic arteritis (macular arteritis)
  • Panniculitis, including lupus

Table 24.2 Lymphocytic vasculitis. This topic is one where there is ongoing debate. Most common entities in **bold**. Angiocentric infiltrates of atypical lymphocytes, sometimes with angiodestruction, may also be observed in some cutaneous lymphomas. RBC, red blood cell.

CLINICAL DIFFERENTIAL DIAGNOSIS OF CUTANEOUS VASCULITIS	
Clinical presentation	**Differential diagnosis**
Purpuric papules/plaques	Arthropod bites Morbilliform drug eruptions with hemorrhage in dependent sites Erythema multiforme Pityriasis lichenoides et varioliformis acuta Infectious emboli (septic vasculitis) due to bacteria (e.g., *Neisseria meningococcus* [acute meningococcemia]), rickettsiae, fungi (e.g., *Rhizopus*) Pigmented purpura (e.g. lichenoid capillaritis) Cellulitis
Purpuric macules/patches	**Hemorrhage** • Trauma • Solar (actinic) purpura* • Medication-related (i.e. aspirin, topical or systemic corticosteroids)* • Thrombocytopenia and platelet dysfunction • Coagulopathies* • Viral exanthems (e.g., enterovirus, parvovirus B19) • Scurvy • Primary systemic amyloidosis **Thromboses** • Thrombophilia/hypercoagulable state (e.g., antiphospholipid antibody; see Table 105.9) • Livedoid vasculopathy • Purpura fulminans (e.g., due to sepsis/DIC) • Heparin necrosis • Warfarin (Coumadin®) necrosis • Thrombotic microangiopathy • Paroxysmal nocturnal hemoglobinuria **Emboli** • Cholesterol • Cardiac (infective endocarditis ≫ myxomatous or marantic) • Fat • Air **Cold-related gelling** • Cryoglobulins (primarily type I) **Inflammation** • Pigmented purpura (capillaritis) • Hypergammaglobulinemic purpura of Waldenström (recurrent macular vasculitis in hypergammaglobulinemia) **Infection** • Lucio phenomenon (Hansen disease) • Strongyloidiasis
Urticarial lesions	Urticaria (including neutrophilic urticaria) Arthropod bites and papular urticaria Urticaria multiforme Serum sickness-like reaction Neutrophilic urticarial dermatosis Autoinflammatory diseases (e.g., periodic fevers; see Table 45.2) Still disease, including adult-onset Schnitzler syndrome Viral exanthems Kawasaki disease Sweet syndrome Urticarial phase of bullous pemphigoid
Ulcers ± atrophie blanche	Venous hypertension or peripheral arterial disease Pyoderma gangrenosum Livedoid vasculopathy Thrombophilia/hypercoagulable state (e.g., antiphospholipid antibodies; see Table 105.9) Calciphylaxis Infections (e.g., bacterial, mycobacterial, dimorphic or opportunistic fungal, protozoal) Hemoglobinopathies Factitial Halogenodermas Degos disease See Fig. 105.1 for additional entities
Nodules	Panniculitis Superficial migratory thrombophlebitis Dermal neoplasms Infections (e.g., bacterial, mycobacterial, dimorphic or opportunistic fungal)

CLINICAL DIFFERENTIAL DIAGNOSIS OF CUTANEOUS VASCULITIS	
Clinical presentation	**Differential diagnosis**
Digital gangrene	Arterial occlusive disease, including atherosclerosis Diabetes mellitus Thromboangiitis obliterans (Buerger disease) Systemic sclerosis Emboli (e.g., cholesterol, septic) Cryoglobulinemia (type I) > cryofibrinogenemia or cold agglutinin disease Thrombosis (e.g., antiphospholipid syndrome, purpura fulminans, myeloproliferative thrombocytosis) Calciphylaxis Hypereosinophilic syndrome Paraneoplastic acral vascular syndrome (e.g., with lung or ovarian carcinoma)
*Element of trauma.	

Table 24.3 Clinical differential diagnosis of cutaneous vasculitis. DIC, disseminated intravascular coagulation.

Introduction

CSVV is a type of single-organ, skin-limited vasculitis that involves primarily the dermal postcapillary venules and is characterized histologically by LCV. The dermatologic addendum to the Chapel Hill Consensus Conference Nomenclature proposes the term "IgM/IgG immune complex vasculitis" to further characterize this entity[1]. Because clinical manifestations of small vessel vasculitis of the skin (e.g. palpable purpura) and histologic findings of LCV may be seen in other disease entities (e.g. IgA vasculitis), systematic evaluation and consideration of other types of vasculitis involving small cutaneous vessels is necessary before establishing the diagnosis of CSVV (see Table 24.1). CSVV is often idiopathic in nature, but it may be secondary to an underlying cause such as an infection, medication, or autoimmune connective tissue disease (Table 24.4). Within the spectrum of small vessel vasculitis of the skin are several entities whose rather unique epidemiologic and clinical features warrant subclassification (see Table 24.1) and separate discussion (following sections).

Epidemiology

CSVV occurs in both sexes and at all ages[10], but it is more common in the adult population. It is estimated that ~10% of those affected are children. The annual population-based incidence of CSVV (excluding those with a distinct clinical subtype of small vessel vasculitis) is 21 cases per million[4].

Pathogenesis

CSVV is mediated by immune complex deposition (see Fig. 24.1A).

Clinical features

CSVV typically presents spontaneously, or after exposure to an inciting agent, with a crop of lesions consisting of non-blanching purpuric macules and papules, petechiae, urticarial lesions, or hemorrhagic vesicles ranging in size from 1 mm to several centimeters (see Fig. 24.2 & 24.3). Lesions often begin with erythema and then rapidly become purpuric; larger lesions arise via coalescence of papules. Occasionally, pustules, targetoid lesions, and round ulcerations are seen. CSVV favors dependent areas, as well as areas affected by trauma (Koebner phenomenon) or under tight-fitting clothing. Prolonged sitting or standing, as well as exercise, in particular walking or hiking in hot weather, can induce CSVV on the lower extremities. Although they may be asymptomatic, lesions can be associated with burning pain or pruritus and may be psychologically distressing. Residual postinflammatory hyperpigmentation can persist for months after the primary process resolves.

By definition, CSVV is skin-limited, or skin-predominant, so it is appropriate to apply this label to patients with small vessel vasculitis of the skin in whom there is no evidence of systemic vasculitis. That said, patients with CSVV commonly have low-grade constitutional symptoms and arthralgias which may accompany flares of skin vasculitis. Because of a lack of clarity regarding terminology and disease definitions in the literature, estimates of the prevalence of systemic symptoms in CSVV vary. Available data suggest that systemic symptoms occur in 5%–25% of patients with CSVV, with arthralgias and arthritis occurring most commonly (15%–65%), followed by genitourinary signs or symptoms (3%–7%), and gastrointestinal involvement (3%–5%)[11]. A population-based study demonstrated systemic symptoms in 11 of 38 patients (29%) with CSVV[4]. *In general, more overt signs or symptoms of systemic disease, such as marked constitutional symptoms, inflammatory arthritis, and gastrointestinal, renal, or neurologic involvement should increase the clinical suspicion for a systemic vasculitis*. In one study, the presence of paresthesias or fever were identified as risk factors for an associated systemic disease[12]. A stepwise approach to evaluation, guided by the presenting signs and symptoms, is recommended to help identify those patients with systemic manifestations of vasculitis or important underlying disorders (see Fig. 24.19)[13].

Approximately 90% of patients with CSVV will have spontaneous resolution of cutaneous lesions within several weeks or a few months, while another 10% will have chronic or recurrent disease at intervals of months to years[14]. In the latter group, the average duration of disease activity is reported to be ~24–28 months[4,5]. The presence of arthralgias or cryoglobulinemia and an absence of fever may portend chronicity[12]. An underlying cause for the CSVV, such as an autoimmune connective tissue disease or neoplasm, also affects prognosis.

Differential diagnosis

In addition to determining if the patient has a particular subtype of small vessel vasculitis (see Table 24.1) or has cutaneous vasculitis as a manifestation of a systemic vasculitic syndrome, causes of secondary cutaneous vasculitis also need to be considered (see Table 24.4; Fig. 24.5 & 24.6). Entities listed in Table 24.3, especially the first three categories, may mimic cutaneous vasculitis and need to be included in the clinical differential diagnosis.

Treatment

The initial intervention in CSVV consists of supportive care and elimination of potential triggers. The need for and choice of pharmacotherapy depends on the chronicity and severity of the cutaneous involvement and any potential underlying disease state. In cases of small vessel vasculitis of the skin where systemic involvement is identified, the choice of therapy must appropriately address those manifestations. Specific therapeutic options are outlined in Table 24.10.

CSVV often resolves without any specific treatment. Because it is usually self-limited as well as skin-limited, supportive measures (e.g. rest, leg elevation, compression) or symptomatic therapy (e.g. antihistamines, NSAIDs) may be sufficient.

Chronic (lasting >4 weeks) or severe cutaneous disease generally requires more aggressive systemic therapy. There is a dearth of high-quality data to guide management, but a number of agents, including colchicine, dapsone and azathioprine, appear to be effective for skin and joint manifestations in some patients and are usually well tolerated (see Table 24.10). A randomized trial is currently underway to assess the efficacy of these agents for skin-limited vasculitis[15].

Patients with severe, ulcerating, or progressive cutaneous disease who require rapid control of symptoms can be treated with a short course of high-dose oral corticosteroids (e.g. up to 1 mg/kg/day of prednisone). Because of adverse effects associated with long-term corticosteroid use, a taper over 4 to 6 weeks should be attempted. If the patient develops recurrent CSVV as the dosage is decreased, addition of a steroid-sparing agent is warranted. However, corticosteroids do not represent an appropriate long-term plan for chronic or recurrent CSVV. In addition to the oral medications listed previously, methotrexate (<25 mg weekly), mycophenolate mofetil, and rituximab have been reported to be useful in recalcitrant CSVV[16].

UNDERLYING CAUSES OF SECONDARY CUTANEOUS VASCULITIS

IgA Vasculitis (Henoch–Schönlein Purpura)

Synonyms: ■ Schönlein–Henoch purpura ■ Anaphylactoid purpura ■ Purpura rheumatica ■ Cutaneous small vessel vasculitis secondary to IgA immune complexes

Key features

- Most common form of vasculitis in children <10 years of age
- Frequently preceded by an upper respiratory tract infection
- Intermittent palpable purpura on the extremities with IgA-dominant immune deposits in the walls of small blood vessels
- Systemic involvement, in particular gastrointestinal, joint, and renal, is often observed, but IgA vasculitis may be skin-limited
- In adults (men > women), rarely associated with an underlying malignancy

Introduction

IgA vasculitis (IgAV), also referred to as Henoch–Schönlein purpura (HSP), is a type of vasculitis affecting small blood vessels in which vascular IgA deposition is a key diagnostic and pathophysiologic feature. This particular type of vasculitis occurs more commonly in children than in adults. The classic tetrad consists of palpable purpura, arthritis, abdominal pain, and hematuria. However, IgAV may be skin-limited or skin-predominant, with either no associated symptoms or mild arthralgias and/or constitutional symptoms.

Fig. 24.6 Cutaneous small vessel vasculitis associated with systemic disorders. The underlying diseases were Sjögren syndrome (**A**), rheumatoid arthritis (**B**), relapsing polychondritis with myelodysplasia (**C**), and endocarditis due to *Streptococcus mitis* (**D**). Note the Koebner phenomenon in **A** and rheumatoid nodules in **B**. Cutaneous vasculitis in association with relapsing polychondritis and myelodysplasia points to a likely diagnosis of VEXAS syndrome. *C, Courtesy Jean L. Bolognia, MD; D, Courtesy David A. Wetter, MD.*

Epidemiology

IgAV is the most common form of vasculitis in children, with an incidence of 30 to 270 cases per million children per year[17]. The average age of onset is 6 years, and 90% of cases occur in children <10 years of age[18,19]. In adults, the incidence of HSP is 8 to 18 cases per million[17], and the population-based incidence of biopsy-proven cutaneous IgA

vasculitis is 13 cases per million per year[4]. The disorder follows a seasonal pattern, with a peak occurrence during the winter. HSP has a slight male predominance in both children and adults.

Pathogenesis

IgAV frequently presents 1 to 2 weeks following an upper respiratory tract infection, especially in children. Although several studies have reported that 20%–50% of HSP patients have positive antistreptolysin O (ASO) titers[18], no causal role for group A β-hemolytic streptococci has been demonstrated. IgAV may be triggered by a medication or rarely it is a paraneoplastic phenomenon.

IgA (specifically IgA1) is thought to play a fundamental role in the pathogenesis of IgAV. IgA deposits in the postcapillary venules of the skin and mesangium and, less commonly, circulating IgA-containing immune complexes and increased serum levels of IgA have been demonstrated in patients with IgAV[19]. In a case series of over 400 patients with IgAV, increased serum IgA levels were found in ~30%[20]. Altered glycosylation of the hinge region of IgA1 may promote the formation of macromolecular complexes that lodge within the mesangium and activate the alternate complement pathway[18].

Certain genetic polymorphisms may predispose to more severe disease[21]. For example, HLA-B35 positivity may predispose to renal disease, while patients who do not have the ICAM-1 469 K/E variant have less severe gastrointestinal involvement[19].

Clinical features

IgAV classically presents with palpable purpura in association with arthritis, abdominal pain, and/or nephritis. Cutaneous lesions begin as erythematous macules or urticarial papules and evolve into palpable purpura ranging in size from pinpoint to several millimeters (Fig. 24.7). Urticaria, vesicles, bullae, targetoid lesions, and foci of necrosis can also be seen as well as lower extremity edema. Typically, lesions are symmetrically distributed on the lower extremities and buttocks but may also involve the trunk, upper extremities, and face. Individual lesions usually regress within 10 to 14 days, with resolution of cutaneous involvement over a period of several weeks to months. Recurrences of skin disease are observed in 5%–10% of patients[14].

Extracutaneous manifestations of IgAV are common. *Arthritis* occurs in up to 75% of patients with IgAV and most commonly affects the joints of the lower extremities (knees and ankles). *Gastrointestinal* involvement (50%–75% of patients) may precede the purpura and presents with colicky abdominal pain (65%), gastrointestinal bleeding (30%), and/or vomiting. Intussusception and bowel perforation are rare complications.

Renal involvement occurs in 40%–50% of patients and typically presents with microscopic hematuria (40%), often accompanied by proteinuria (25%). The appearance of cutaneous lesions generally precedes the development of nephritis. When it occurs, renal involvement usually appears within the first month of diagnosis (85%) and develops within six months in >95% of patients[22]. Therefore, close observation, with frequent urinalyses, is recommended during this time period[18]. In pediatric patients, risk factors for the development of nephritis include male sex, age >10 years at onset, severe gastrointestinal symptoms, arthritis/arthralgia, persistent or recurrent purpura, and several laboratory abnormalities (leukocytosis, thrombocytosis, elevated ASO titer, low C3)[23]. Depending upon the series, persistent renal disease has been observed in 8%–50% of patients[20], emphasizing the need for

Fig. 24.7 IgA vasculitis (Henoch–Schönlein purpura). A, B Early inflammatory lesions that are beginning to develop a hemorrhagic component. Sites of previous involvement on the shins are now dull pink patches. **C** More developed lesions with central necrosis. **D** Less common vesiculobullous variant. **E** Purpuric macules and papules of the buttocks with coalescence into a retiform configuration on the upper left; inflammatory retiform purpura can be seen in some forms of vasculitis, especially IgA vasculitis (see Table 22.6). **F** Accentuation of lesions at the sock lines due to increased pressure. *A, D, E, Courtesy David A. Wetter, MD; F, Courtesy Carlo Mainetti, MD.*

longitudinal monitoring until all abnormalities resolve. Fortunately, only 1%–3% of children develop long-term renal impairment[18]. Poor prognostic factors include renal failure at the time of onset, nephrotic syndrome, hypertension, and decreased factor XIII activity[5].

In young boys, *orchitis* is a rare manifestation of systemic disease. The *lung* is also a rare site of involvement, presenting as hemoptysis and/or pulmonary infiltrates due to diffuse alveolar hemorrhage[24].

Adult patients with IgAV present with clinical signs and symptoms similar to those in children. However, adults are more likely than children to: develop chronic renal insufficiency (up to 30%)[25]; have diarrhea and leukocytosis; require more aggressive therapy; and have a longer hospital stay[26]. Compared to younger adults, those >65 years of age are more likely to develop a 50% increase in serum creatinine and less likely to achieve clinical remission[27]. Lastly, adult patients with IgAV may have an underlying malignancy, most often cancer of a solid organ, in particular the lung[28]. Because 90% of the latter group are men, older male patients should be current with cancer screening guidelines and undergo symptom-based screening. However, there is no consensus regarding the recommended extent of the screening or the need for repeated screening.

Pathology

Histologically, LCV of the small dermal blood vessels is seen. In one series of adults with IgA vasculitis (age >40 years), an absence of dermal eosinophils was associated with an increased risk of renal involvement[29]. The presence of perivascular IgA deposition by DIF is the defining pathologic feature of IgAV (Fig. 24.8). Other immunoglobulins (C3, IgM, IgG) may be seen but are generally not as prominent as IgA and are considered nonspecific deposits. A few small studies have suggested that the presence of other findings, such as perivascular C3 or IgM deposits and papillary dermal edema, may be associated with an increased risk of renal involvement[30]. Of note, endothelial deposits of IgA are ~80% sensitive and specific for IgAV. Therefore, patients with signs and symptoms concerning for IgAV should be followed closely and treated appropriately for suspected systemic complications even if the DIF is negative for IgA[31].

Differential diagnosis

The clinical differential diagnosis includes any of the vasculitides involving small blood vessels (see Table 24.1), particularly CSVV, since the cutaneous findings in IgAV and CSVV can be indistinguishable. Several entities listed in Table 24.3, especially the first three categories, are also in the clinical differential diagnosis. Because vascular IgA deposition is not 100% sensitive or specific[32], the diagnosis of IgAV is supported by the presence of IgA in the appropriate clinical setting.

Treatment

As with other types of vasculitis, management of IgAV is dictated by the extent and severity of systemic and cutaneous manifestations. Because IgAV is generally self-limited, resolving over the course of weeks to months, treatment may be primarily supportive. For skin-limited IgAV, dapsone or colchicine may decrease the duration of cutaneous lesions and frequency of recurrences (see Table 24.10)[33]. Systemic corticosteroids are effective in treating associated arthritis and abdominal pain, as well as reducing the gastrointestinal complications and duration of skin lesions, but they do not prevent recurrences of purpura and are not suitable as a long-term therapy[34,35]. In adults, the following factors may predict relapsing disease: age >30 years, persistent purpura >1 month, abdominal pain, hematuria, an underlying systemic disorder, and absence of IgM on DIF[36].

In patients with renal involvement (e.g. microscopic hematuria, proteinuria), referral to a nephrologist is indicated. Corticosteroids have not been shown to be effective in preventing renal disease due to IgAV and are therefore not recommended. For example, a Cochrane review of interventions for preventing and treating IgAV nephritis found no difference in the risk of persistent kidney disease (up to 12 months following treatment) in children who received prednisone for 2–4 weeks at the time of presentation, as compared to placebo or supportive therapy[37]. In a randomized, double-blind, placebo-controlled trial involving 352 children with new-onset IgAV, early treatment with 14 days of prednisolone did not reduce the prevalence of proteinuria 12 months after disease onset[38]. For those who do develop evidence of IgAV nephritis, the treatment approach depends on disease severity and whether the patient is a child or adult. Individuals with limited evidence of renal involvement, mild proteinuria (<1 g/day), and normal serum creatinine warrant close monitoring and consideration for treatment with an angiotensin-converting enzyme inhibitor (ACEi) or angiotensin receptor blocker (ARB). Those with more significant proteinuria (≥1 g/day), elevated serum creatinine, or crescentic glomerulonephritis on kidney biopsy should initially receive, in addition to an ACEi or ARB, high-dose systemic corticosteroids. In sum, the current consensus is that corticosteroids do not prevent renal disease but should be used to treat severe nephritis[19].

Acute Hemorrhagic Edema of Infancy

Synonyms: ■ Acute hemorrhagic edema of childhood ■ Infantile acute hemorrhagic edema ■ Finkelstein disease ■ Seidlmayer syndrome ■ Finkelstein–Seidlmayer disease ■ Purpura en cocarde avec edema ■ Postinfectious cockade purpura

Key features

- Seen primarily in children between 4 and 24 months of age
- Annular, circular, or targetoid purpuric plaques on the face and extremities
- Tender, non-pitting edema of acral sites
- The child is well-appearing, and extracutaneous involvement is unusual
- Benign clinical course with spontaneous resolution within 1 to 3 weeks

Introduction

Acute hemorrhagic edema of infancy (AHEI) is an unusual form of small vessel vasculitis that usually affects children 4 to 24 months of age. Cutaneous lesions typically begin as plaques with variable degrees of hemorrhage and favor the head and extremities. They subsequently become edematous and targetoid in appearance. Previously considered a benign form of Henoch–Schönlein purpura (HSP), AHEI is now recognized as its own clinical entity.

Epidemiology

AHEI is a relatively rare disorder. It affects children <2 years of age, with ~70% of cases occurring in boys[39]. A seasonal variation is observed, with a peak incidence during the winter months.

Pathogenesis

Although the etiology of AHEI is unknown, up to 85% of patients have an associated infection, drug exposure, or immunization[40]. An infectious prodrome is observed in two-thirds of patients, most commonly a respiratory tract infection (80%), diarrheal illness (12%), or urinary tract infection (6%)[39]. There are multiple reported triggers, and they are listed in Table 24.5. As with other forms of small vessel vasculitis involving the skin, the pathogenesis of AHEI is thought to be due to immune complex deposition in response to an antigenic trigger.

TRIGGERS AND ASSOCIATIONS IN ACUTE HEMORRHAGIC EDEMA OF INFANCY AND URTICARIAL VASCULITIS	
Acute hemorrhagic edema of infancy – triggers	
Infections	
• Adenovirus	• Rotavirus
• Coxsackievirus	• Varicella zoster virus
• Cytomegalovirus	• *Campylobacter* spp.
• Epstein–Barr virus	• *Escherichia coli*
• Herpes simplex virus	• *Mycobacterium tuberculosis*
• Hepatitis A virus	• *Streptococcus* spp.
• Measles	
Medications	
• Acetaminophen	• Trimethoprim–sulfamethoxazole
• Penicillins	• NSAIDs
• Cephalosporins	
Urticarial vasculitis – associations	
Autoimmune connective tissue diseases (SLE, Sjögren syndrome)	
Serum sickness	
Cryoglobulinemia	
Infections	
• Hepatitis B virus	• Epstein–Barr virus
• Hepatitis C virus	• Lyme disease
	• SARS-CoV-2
Medications	
• Cimetidine	• Methotrexate
• Cocaine	• NSAIDs
• Diltiazem	• Potassium iodide
• Etanercept	• Procainamide
• Fluoxetine	• Procarbazine
• Infliximab	
Vaccines	
• Influenza (e.g. H1N1)	• SARS-CoV-2
Hematologic malignancies	
• Plasma cell dyscrasias (IgM, IgG, IgA)	
• Leukemias	
• Lymphomas	
• Castleman disease	
Solid organ malignancies – rare	
• Colon carcinoma	
• Renal cell carcinoma	

Table 24.5 Triggers and associations in acute hemorrhagic edema of infancy and urticarial vasculitis. NSAIDs, nonsteroidal anti-inflammatory drugs; SLE, systemic lupus erythematosus.

Clinical features

Children typically do not appear ill, although fever is present in ~45% of patients. The typical interval between the inciting event and the onset of disease is 1–2 weeks[41]. Cutaneous involvement presents abruptly with large erythematous patches or urticarial lesions that evolve into annular or targetoid purpuric plaques. The latter favor the cheeks, ears, and extremities (Fig. 24.9), but truncal involvement may also occur. Lesions may be asymptomatic, painful, or, less commonly, pruritic. Arcuate, polycyclic, scalloped, or rosette-shaped lesions and vesicobullae occur less commonly, as does healing with atrophic scars[41]. Tender, non-pitting edema of the face, ears, extremities (including the hands and feet), and scrotum is characteristic. Although mucosal and visceral involvement is unusual, oral petechiae, conjunctival injection, abdominal pain, arthralgias, glomerulonephritis, and intussusception (<1%) may occur[39,40,42]. The course is benign, with spontaneous and complete resolution without sequelae within 1 to 3 weeks. Although exacerbations may occur, once a remission has lasted 2 weeks, relapses as a rule are not observed[39].

Pathology

Leukocytoclastic vasculitis involving the capillaries and postcapillary venules of the upper and mid dermis is observed. Direct immunofluorescence reveals vascular deposition of a range of immunoreactants, including fibrinogen, C3, IgG, IgM, IgA, and IgE. IgA deposition is seen in ~10%–35% of cases[39].

Differential diagnosis

While AHEI was historically considered a variant of HSP, the distinct clinical presentation and infrequent presence of endothelial IgA deposits are distinguishing features. In young children with urticarial lesions and acrofacial edema, urticaria multiforme should be considered[43]. The differential diagnosis also includes erythema multiforme, urticaria, urticarial drug eruption, serum sickness-like reaction, Kawasaki disease, urticarial vasculitis, and Sweet syndrome. Given the significant cutaneous hemorrhage, trauma, acute meningococcemia, and purpura fulminans are sometimes considered. Routine laboratory tests are nonspecific, and the diagnosis is based on appropriate clinicopathologic correlation.

Treatment

Treatment is supportive (see Table 24.10). Antibiotics should be given to treat concurrent bacterial infections, if present. Antihistamines may be useful for symptomatic relief. Systemic corticosteroids have not been shown to alter the course of the disease, but they may be useful for ameliorating acute manifestations when severe[44].

Urticarial Vasculitis

Synonyms/Variants: ■ Normocomplementemic urticarial vasculitis ■ Hypocomplementemic urticarial vasculitis ■ Hypocomplementemic urticarial vasculitis syndrome ■ Anti-C1q vasculitis ■ McDuffie syndrome

Key features

- Recurrent urticarial lesions lasting >24 hours and resolving with bruise-like discoloration
- Two major subtypes: normocomplementemic and hypocomplementemic; low serum complement levels suggest systemic disease
- Clinical manifestations include constitutional symptoms, arthritis, and obstructive lung disease
- Associated with autoimmune connective tissue disease, especially systemic lupus erythematosus

Introduction

Urticarial vasculitis is a clinicopathologic entity consisting of persistent urticarial lesions that demonstrate the histopathologic features of LCV. Its association with autoimmune connective tissue disease and potential overlap with systemic lupus erythematosus (SLE) distinguish this disorder from typical CSVV. Although the relationship between urticarial vasculitis and neutrophilic urticaria is an area of debate, these and other related conditions (e.g. Still disease) may occur within a

Fig. 24.10 Urticarial vasculitis. A Urticarial papules and purpuric macules in a patient with hypocomplementemic urticarial vasculitis. **B** Arcuate, dull violet plaques of the lower extremities. *B, Courtesy David A. Wetter, MD.*

spectrum (see below). For this chapter, the definition of urticarial vasculitis is as follows: urticarial lesions that histopathologically demonstrate vasculitis, as defined by a *minimum of leukocytoclasia with vessel wall necrosis*, with or without fibrinoid deposits, perivascular inflammation, or red blood cell extravasation[45].

Epidemiology

The population-based incidence of urticarial vasculitis is 5 cases per million per year[4]. In patients with chronic urticaria in whom a strict definition of urticarial vasculitis (see above) is applied, the prevalence of urticarial vasculitis is said to be ~5%[45], although this is likely an overestimation. The peak incidence is during the fifth decade, and 60%–80% of patients with urticarial vasculitis are female. The hypocomplementemic form occurs almost exclusively in women[46]. Approximately 70%–80% of cases of urticarial vasculitis are normocomplementemic, and they follow a benign course with an average duration of 3 years.

Pathogenesis

The pathogenesis of urticarial vasculitis is similar to that of typical CSVV. In urticarial vasculitis, it is thought that complement activation triggers mast cell release of inflammatory mediators such as TNF that in turn increase the expression of ICAM on mast cells (important for eosinophil transmigration) and E-selectin on endothelial cells[45].

Although urticarial vasculitis is most often idiopathic, it can be associated with autoimmune connective tissue diseases (especially SLE and Sjögren syndrome), serum sickness, cryoglobulinemia, infections, medications, and hematologic malignancies (see Table 24.5).

Clinical features

Lesions of urticarial vasculitis consist of erythematous, indurated wheals (Fig. 24.10), with or without angioedema, that favor the trunk and proximal extremities. Urticarial vasculitis is distinguished from chronic urticaria by the persistence of individual lesions beyond 24 hours, burning pain rather than pruritus, and the presence of purpura and/or postinflammatory hyperpigmentation. Blanching of the skin via diascopy may reveal a central red–purple or brown macule, suggesting vasculitis. However, these features are not always present. Rarely, bullae, erythema multiforme-like lesions, livedo reticularis, Raynaud phenomenon, and laryngeal edema are clinical manifestations of urticarial vasculitis[45].

When evaluating patients with urticarial lesions that histologically demonstrate features of LCV, the most important prognostic feature is the presence or absence of hypocomplementemia. Patients with normal complement levels tend to have skin-limited disease and are perhaps best considered to have a subset of CSVV with hive-like lesions. Those with hypocomplementemia are much more likely to have systemic manifestations, including gastrointestinal, joint, or renal involvement, and to meet diagnostic criteria for SLE[47]. The hypocomplementemic urticarial vasculitis syndrome (HUVS) is typically a more severe syndrome defined by specific diagnostic criteria[45]:

- *Two major criteria*: (1) urticaria for 6 months; and (2) hypocomplementemia – *plus* –
- *Two or more minor criteria*: (1) vasculitis on skin biopsy; (2) arthralgia or arthritis; (3) uveitis or episcleritis; (4) glomerulonephritis; (5) recurrent abdominal pain; or (6) positive C1q precipitin test with a low C1q level.

Patients with hypocomplementemia who do not meet the criteria for HUVS are considered to have hypocomplementemic urticarial vasculitis but not HUVS.

Musculoskeletal involvement is the most common extracutaneous manifestation of urticarial vasculitis. Arthralgias of the hands, elbows, knees, ankles, and feet occur in half of all patients with urticarial vasculitis, but up to 50% of patients with HUVS have frank arthritis[45]. Up to 20% of patients with HUVS have *pulmonary* symptoms which can

resemble asthma or chronic obstructive pulmonary disease (COPD) and include cough, dyspnea, hemoptysis, laryngeal edema, and pleural effusions[14]. COPD is especially severe in smokers with urticarial vasculitis, and it is worse than would be expected due to smoking alone; therefore, patients should be told to avoid smoking. *Renal* involvement, manifesting as proteinuria or microscopic hematuria, occurs in up to 15% of patients with HUVS[45]. *Gastrointestinal* manifestations (abdominal pain, nausea, vomiting, diarrhea) occur in up to 30% of patients. Cardiac and central nervous system involvement are rare but reported. HUVS shares features with SLE, but distinctive clinical findings in HUVS include *ocular* inflammation (30%; conjunctivitis, episcleritis, iritis, uveitis), angioedema (50%), and COPD-like symptoms (20%)[45]. In a study of 57 patients with hypocomplementemic urticarial vasculitis, various systemic manifestations were observed, including ocular (56%), pulmonary (19%), gastrointestinal (18%), and renal (14%)[47].

In patients with urticarial vasculitis, the most common abnormal laboratory studies are an elevated ESR, low serum C3 and C4 levels, and a positive ANA. HUVS is usually marked by low serum complement levels (which may vary from non-detectable to normal, even during flares) plus the presence of anti-C1q precipitin and depressed C1q levels. Although up to a third of patients with SLE have circulating anti-C1q antibodies, and up to half of patients with HUVS have a positive ANA, patients with HUVS rarely have anti-dsDNA or anti-Sm antibodies[45].

Pathology

Histologically, urticarial vasculitis is defined as the presence of leukocytoclasia with vessel wall necrosis, with or without fibrinoid deposits, perivascular inflammation, or red blood cell extravasation[45]. In one series, an interstitial neutrophilic infiltrate was more commonly observed in patients with the hypocomplementemic form of urticarial vasculitis[46]. Eosinophils may also be noted. Although findings can be subtle and consist only of interstitial neutrophils or perivascular lymphocytes with extravasated erythrocytes (especially in older lesions), these findings alone do not fulfill the histologic criteria for the diagnosis of urticarial vasculitis.

By DIF, 70% of lesions demonstrate deposits of immunoglobulin, C3, or fibrinogen around blood vessels. A granular pattern of immunoreactants along the basement membrane zone occurs in ~80% of lesions and, when accompanied by hypocomplementemia, suggests the diagnosis of SLE. Basement membrane immunoreactants have also been associated with renal disease[45].

Differential diagnosis

The main entity in the differential diagnosis is urticaria (including delayed pressure urticaria, in which lesions can last longer than 24 hours). Urticarial vasculitis should also be distinguished from neutrophilic urticaria, which, although considered by some to be within the spectrum of urticarial vasculitis, is not associated with hypocomplementemia or autoimmune disease and is better thought of as a subset of urticaria that histologically demonstrates a neutrophilic infiltrate without vasculitis. The differential diagnosis also includes disorders that clinicopathologically present with urticarial lesions and an interstitial neutrophilic infiltrate (i.e. neutrophilic urticarial dermatosis)[48], including Schnitzler syndrome, adult-onset Still disease, and cryopyrin-associated periodic syndromes (see Ch. 45). Additional entities to consider are the urticarial phase of bullous pemphigoid, atypical erythema multiforme, urticaria multiforme[43], Sweet syndrome, tumid lupus erythematosus, SLE (see above), and rheumatoid neutrophilic dermatitis. For lesions of angioedema, the differential diagnosis includes acquired and inherited forms of angioedema (see Ch. 18).

Treatment

No randomized clinical trials have been performed to evaluate possible therapeutic options for urticarial vasculitis. Antihistamines may reduce the swelling and pain associated with cutaneous lesions but do not alter the course of the disease. Oral corticosteroids are effective, but the duration of use should be kept to a minimum (see Ch. 125). Indomethacin, dapsone (with or without pentoxifylline), colchicine, hydroxychloroquine, and mycophenolate mofetil have all been reported to be beneficial (see Table 24.10). Rituximab, omalizumab, anakinra, and canakinumab have been reported to improve recalcitrant hypocomplementemic urticarial vasculitis[49].

Erythema Elevatum Diutinum

Key features

- Symmetric, red–violet to red–brown papules and plaques
- Persistent lesions develop on extensor surfaces
- Fibrosing leukocytoclastic vasculitis

Introduction

Erythema elevatum diutinum (EED) is a rare, chronic dermatosis characterized by red–violet to red–brown papules, plaques, and nodules that favor extensor surfaces. Histopathologic features consist of LCV in early lesions, followed by fibrotic replacement of the dermis in older lesions.

Epidemiology

EED is rare, with descriptions of several hundred cases in the literature. The disease can develop at any age but is more common in middle-aged and older adults (ages 30–60 years). An earlier onset occurs more often in the setting of HIV infection[50]. The male-to-female ratio is approximately equal, and no racial predilection has been observed[51].

Pathogenesis

Although the etiology of EED is unknown, circulating immune complexes, with repeated deposition, associated inflammation and partial healing, are thought to represent the underlying pathogenesis[50]. Immune complex deposition results in complement activation, neutrophilic infiltration, and the release of destructive enzymes. The latter results in fibrin deposition in and around small dermal vessels during the later stages of the disease.

EED has been described in association with a number of systemic diseases, including infections, autoimmune diseases, and both benign and malignant hematologic disorders, especially IgA monoclonal gammopathy. Associated infections include β-hemolytic streptococci, HBV, HIV, tuberculosis, and syphilis[50]. Lesions identical to EED, both clinically and histologically, have been reproduced by the intradermal injection of streptococcal antigen into non-lesional skin of patients with EED[51]. In patients with HIV infection, EED may be due to either HIV-related antigen–antibody complexes directly damaging small blood vessels or HIV-induced immunosuppression allowing other infectious agents to serve as the antigenic stimulus.

Autoimmune or inflammatory conditions associated with EED include granulomatosis with polyangiitis (formerly Wegener granulomatosis), inflammatory bowel disease, celiac disease, relapsing polychondritis, SLE, and rheumatoid arthritis. In addition to plasma cell dyscrasias (especially IgA monoclonal gammopathy), associated hematologic disorders include myelodysplasia, myeloproliferative disorders, and hairy cell leukemia.

Clinical features

The typical cutaneous lesions of EED are violaceous, red–brown or yellowish papules, plaques, or nodules that are symmetrically distributed. They favor acral and periarticular sites, in particular the extensor surfaces of the elbows, knees, ankles, hands, and fingers (Fig. 24.11). Additional sites of involvement include the face, retroauricular area, trunk, axillae, buttocks, and genitalia[52]. Initially, the lesions are erythematous, but with time they become red–brown or violaceous in color as well as doughy or firm to palpation due to fibrosis.

In general, the lesions are asymptomatic, but they can be associated with a burning sensation or pruritus, especially early on[50]. Annular plaques with a raised border[52] and verrucous plaques on the soles[53] have also been described. Nodular lesions, primarily palmoplantar, that progress to form bulky masses are characteristic of EED in the setting of HIV infection[54]. Arthralgias may develop in underlying joints[51], but extracutaneous involvement, with the exception of ocular disease, is extremely rare. There have been reports of associated peripheral keratitis, nodular scleritis, panuveitis, and blindness[55,56]. The disease is chronic and has a relapsing and remitting course; the majority of cases resolve spontaneously over a period of 5 to 10 years, but the disease can last up to 40 years[51].

In patients presenting with EED, evaluation for an associated infection (e.g. streptococcal, viral hepatitis, HIV, syphilis), monoclonal

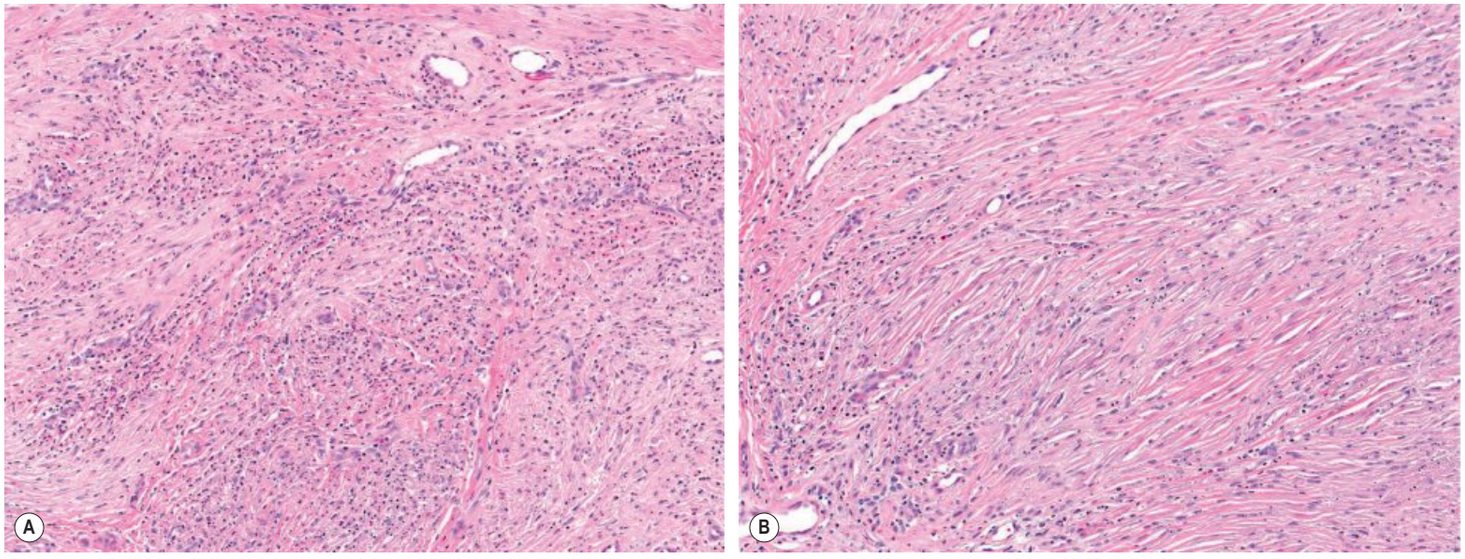

Fig. 24.12 Erythema elevatum diutinum – histopathologic features. A An early-stage lesion: dense neutrophilic infiltrates with focal leukocytoclastic vasculitis. **B** A late-stage lesion: a sparser inflammatory infiltrate and marked fibrosis. *Courtesy Lawrence E. Gibson, MD.*

gammopathy (serum immunofixation electrophoresis), or autoimmune disorder (see above) should be considered, based upon the clinical context.

Pathology

Early lesions of EED demonstrate the changes of LCV, with a neutrophilic infiltrate within the upper and mid dermis (Fig. 24.12A), admixed with some eosinophils. Involvement of the papillary and perifollicular adventitial dermis (without a grenz zone) is observed in more mature lesions[57]. The latter are also characterized by the presence of granulation tissue and perivascular, concentric, or storiform fibrosis plus mixed inflammation that is composed predominantly of neutrophils. In the late stage, capillary walls may have fibrinoid necrosis or fibrosis (Fig. 24.12B); vertically oriented capillaries can also be seen, and it may be difficult to discern the features of vasculitis. Intracellular lipidosis, previously termed "extracellular cholesterolosis", is a classic finding in late-stage lesions[58].

Differential diagnosis

The clinical differential diagnosis depends upon the stage of the lesion. For earlier lesions, one can consider neutrophilic dermatoses (e.g. Sweet syndrome, rheumatoid neutrophilic dermatitis) and palisaded neutrophilic and granulomatous dermatitis. Late-stage lesions may be confused primarily with tuberous xanthomas, granuloma annulare, rheumatoid nodules, fibroid nodules of *Borrelia*, and multicentric reticulohistiocytosis. Other granulomatous disorders (e.g. sarcoidosis, Hansen disease [leprosy], necrobiotic xanthogranuloma) are sometimes in the differential diagnosis, and for an isolated lesion, dermatofibroma or dermatofibrosarcoma protuberans (DFSP). Occasionally, lesions with a prominent vascular component, especially in an HIV-infected patient, might be mistaken for Kaposi sarcoma or bacillary angiomatosis.

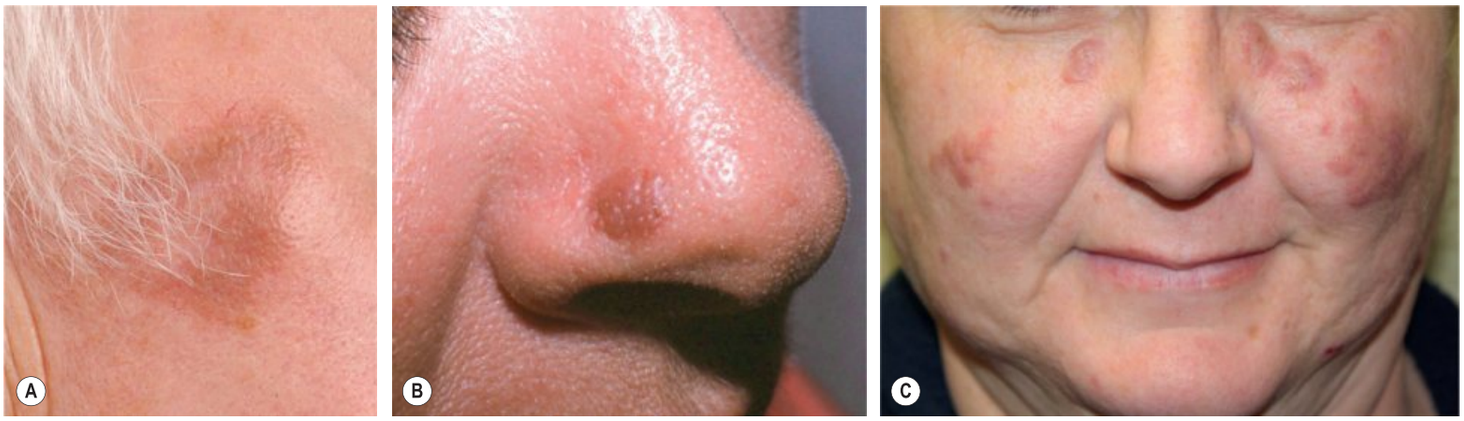

Fig. 24.13 Granuloma faciale. A Single light brown plaque of the lateral malar cheek. **B** Single red–brown papule of the nose. Clues to the diagnosis include prominent follicular openings and a lack of secondary changes such as scale. **C** Less commonly, patients present with multiple lesions. *A, Courtesy Department of Dermatology, Medical University of Graz; B, Courtesy Cloyce L. Stetson, MD; C, Courtesy Jeffrey P. Callen, MD.*

Histologically, the earliest lesions may share features with the neutrophilic dermatoses, but foci of LCV help to distinguish EED. Granuloma faciale may also be considered, but a predominance of eosinophils and plasma cells and the presence of a grenz zone are distinguishing features, as is the localization of lesions to the face. The differential diagnosis of later lesions includes tuberous xanthomas, fibrotic disorders or tumors (e.g. DFSP; see Chs. 98 & 116), and, occasionally, fibroid nodules of *Borrelia*, Kaposi sarcoma, and bacillary angiomatosis[50].

Treatment

Dapsone is the mainstay therapeutically[59], but relapses frequently occur upon discontinuation. If present, treatment of any associated infection or underlying systemic disorder is also recommended. Other therapies include NSAIDs, niacinamide, tetracyclines, chloroquine, colchicine, and plasmapheresis (see Table 24.10). Intralesional corticosteroids may be helpful for mild cases, but systemic corticosteroids are rarely indicated.

Granuloma Faciale

Key features

- Firm red–brown or violaceous plaques or nodules, often solitary and most commonly on the face
- Histologic features of small vessel vasculitis, with dense dermal infiltrates of neutrophils, lymphocytes and plasma cells, admixed with numerous eosinophils; the inflammation spares the upper papillary dermis (grenz zone), and fibrosis may be present

Introduction

Granuloma faciale is a chronic inflammatory dermatosis characterized by red–brown to violaceous plaques or nodules. The face is the most common site of involvement and lesions are more often solitary than multiple. Because histologic features of vasculitis are frequently present, the disease can be classified as a subtype of skin-limited vasculitis.

Epidemiology

Granuloma faciale occurs predominantly in middle-aged White men but has been observed in Black and Asian men as well as women.

Pathogenesis

While the precise pathogenesis remains unknown, granuloma faciale is thought to be a localized form of skin-limited small vessel vasculitis. Direct immunofluorescence (DIF) microscopy demonstrates granular deposition of IgG, IgA, IgM, and/or C3 in blood vessel walls, a nonspecific finding that suggests a role for immune complex-mediated vascular damage. Interferon-γ and increased IL-5 production have been implicated as potentially important disease mediators[60]. An increased ratio of IgG4-:IgG-bearing circulating plasma cells and/or relative increases of IgG4-positive plasma cells in skin lesions has been observed, but patients do not typically meet consensus criteria for IgG4-related disease[61].

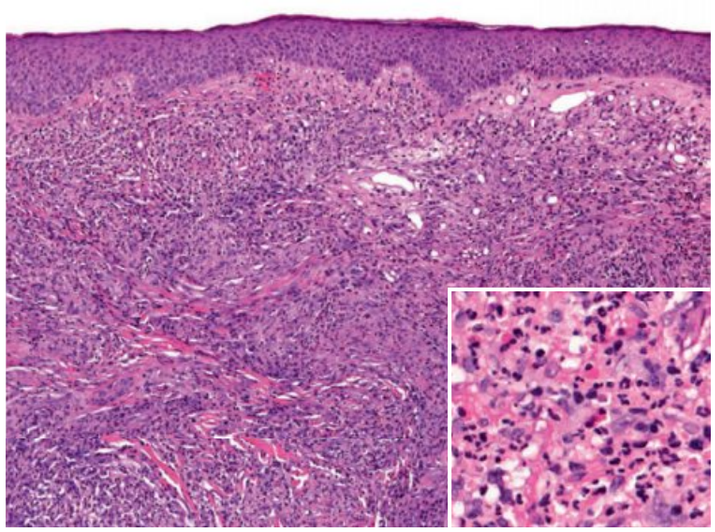

Fig. 24.14 Granuloma faciale – histopathologic features. Dense diffuse dermal inflammation with a grenz zone. Inset shows mixed infiltrate of lymphocytes, eosinophils, neutrophils, and plasma cells. *Courtesy Lorenzo Cerroni, MD.*

Clinical features

Granuloma faciale usually presents as a solitary, asymptomatic, red–brown or violaceous plaque on the face, with a predilection for the forehead, cheek, and preauricular area (Fig. 24.13A,B). Less often, multiple papules or plaques may be present (Fig. 24.13C); in one retrospective analysis of 66 patients, one-third had more than one lesion[62]. Uncommon locations for granuloma faciale include the ears, scalp, trunk, and extremities; in the previously cited study, 7% of patients had extrafacial involvement. The individual lesions tend to persist and only occasionally resolve spontaneously. Granuloma faciale has not been associated with systemic disease.

Pathology

In the dermis, there are perivascular and interstitial infiltrates of neutrophils, lymphocytes, and plasma cells, admixed with numerous eosinophils. Characteristically, the inflammation spares the upper papillary dermis, resulting in a "grenz zone" (Fig. 24.14). Features of leukocytoclastic vasculitis are most prominent early on, with older lesions tending to have fewer neutrophils and more eosinophils and plasma cells, as well as fibrosis. Because of the presence of eosinophils, IgG4-bearing plasma cells, and lamellar fibrosis, granuloma faciale can resemble IgG4-related disease histologically (see Table 26.2)[63].

Differential diagnosis

The clinical differential diagnosis of granuloma faciale includes cutaneous lymphoma, persistent arthropod bite reactions, angiolymphoid hyperplasia with eosinophilia, tumid lupus erythematosus, and

several granulomatous disorders (e.g. sarcoidosis, Hansen disease, granulomatous rosacea). The histopathology of granuloma faciale may have features in common with rheumatoid neutrophilic dermatitis, neutrophilic dermatosis associated with lupus erythematosus, epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia), or arthropod bite reaction. Granuloma faciale may also resemble erythema elevatum diutinum (EED), both clinically and histopathologically. However, EED presents as multiple red–brown papules, plaques, or nodules in a symmetric distribution on the extensor aspects of the extremities, with a predilection for skin that overlies joints. Fibrosis also tends to be more pronounced, and lipid-laden macrophages may be seen in EED, but not in granuloma faciale.

Treatment

Because of the facial location, treatment is often desired. Unfortunately, granuloma faciale is frequently resistant to therapy. Topical or intralesional corticosteroids (e.g. triamcinolone suspension 2.5–5 mg/ml) and topical calcineurin inhibitors (pimecrolimus, tacrolimus) are first-line therapeutic options. Prolonged therapy (e.g. 3–6 months) may be necessary for improvement. As with other recalcitrant dermatoses, there are several alternatives with reported efficacy, including topical and oral dapsone (50–150 mg daily), topical ruxolitinib, hydroxychloroquine, clofazimine (300 mg daily), topical PUVA, and TNF inhibitors[64].

Cryosurgery[65], electrosurgery, surgical excision, dermabrasion, and CO_2 or pulsed dye laser therapy may be effective, but each carries a risk of scarring given the depth of inflammation. In addition, recurrence after excision has been reported. Laser therapy targeting the prominent vascular component (e.g. 595 nm pulsed dye laser, 532 nm potassium titanyl phosphate laser) has led to improvement in a number of patients.

PREDOMINANTLY SMALL AND MEDIUM-SIZED VESSEL VASCULITIDES

Cryoglobulinemic Vasculitis

Synonyms: ■ Type II or III cryoglobulinemia ■ Mixed cryoglobulinemia ■ Cryoglobulinemic purpura ■ Essential cryoglobulinemic vasculitis

Key features

- Associated with mixed cryoglobulinemia (IgM and IgG), most commonly in the setting of hepatitis C virus (HCV) infection
- Palpable purpura, typically on the lower extremities
- Myalgias and arthralgias
- Peripheral neuropathy and glomerulonephritis

Introduction

Cryoglobulins are cold-precipitable immunoglobulins that can be divided into three subtypes, all of which have cutaneous manifestations (Table 24.6). Type I cryoglobulinemia, composed primarily of monoclonal IgM (and less frequently IgG > IgA), results in microvascular occlusion without vasculitis (see Ch. 23). In contrast, vasculitis is seen with type II and III cryoglobulins, also referred to as "mixed cryoglobulins," because they are composed of polyclonal IgGs – the autoantigens – and monoclonal or polyclonal IgMs, respectively. The IgM autoantibodies bind other antibodies and therefore have rheumatoid factor activity. Approximately 15% of patients with circulating mixed cryoglobulins present with symptoms due to cryoglobulinemic vasculitis[14]. Cryoglobulinemic vasculitis typically affects the skin, joints, peripheral nervous system, and kidneys.

Epidemiology

The frequency of mixed cryoglobulinemia varies according to geographic location; e.g. there is a higher prevalence in Southern Europe than in Northern Europe or North America[66]. In northwest Spain, the annual incidence was determined to be 4.8 cases per million. Geographic variations in the frequency of mixed cryoglobulinemia likely reflect differences in the prevalence of HCV infection. While 40%–60% of patients with HCV infection have cryoglobulinemia, overt cryoglobulinemic vasculitis develops in ~5%–30% of these individuals[67].

Pathogenesis

Mixed cryoglobulinemia occurs in the setting of specific infections, autoimmune connective tissue diseases, and hematologic malignancies[66] (see Table 24.6). When the association between HCV infection and mixed cryoglobulinemia was discovered in 1989, a cause for 80%–90% of "essential" cryoglobulinemia became apparent. Only 5% of cases are associated with HBV infection, and occasionally, HIV, EBV, cytomegalovirus, *Leishmania*, and *Treponema* spp. have been implicated[68]. In a minority of patients, mixed cryoglobulinemia has been associated with autoimmune connective tissue diseases, in particular Sjögren syndrome, SLE, and rheumatoid arthritis. Approximately 5% of the patients with mixed cryoglobulinemia have a lymphoproliferative disorder (e.g. B cell non-Hodgkin lymphoma, chronic lymphocytic leukemia, macroglobulinemia).

It is thought the underlying infectious, autoimmune, or lymphoproliferative disease causes B cell stimulation and proliferation, resulting in expansion of cryoglobulin-producing B cell clones. A significant percentage of lymphocytes in HCV-infected individuals possess a t(14;18) translocation that results in a rearrangement of *bcl-2*, whose protein product has an anti-apoptotic function; this can lead to B lymphocyte proliferation and may contribute to production of cryoglobulins. In HCV-infected patients who do not possess this *bcl-2* rearrangement, B cell activation and subsequent cryoglobulin and autoantibody production is believed to result from chronic immune stimulation by the virus[66]. For these reasons, patients with mixed cryglobulinemia are at increased risk of developing B cell non-Hodgkin lymphoma[69,70].

Cryoglobulinemic vasculitis occurs when immune complexes form from circulating cryoglobulins and deposit within the walls of small blood vessels. As with other forms of immune complex-mediated vasculitis, this immune complex deposition initiates complement activation and vascular inflammation. The presence of the hepatitis C virion (in association with IgM and IgG antibodies) within vessel walls raises the possibility that viral particles are a component of the cryoprecipitate[66].

CLASSIFICATION OF CRYOGLOBULINS				
Subtype	**Molecular composition**	**Associations**	**Pathophysiology**	**Clinical manifestations**
I	Monoclonal IgM > IgG*	Plasma cell dyscrasias, lymphoproliferative disorders	Vascular occlusion	Raynaud phenomenon, retiform purpura, gangrene, acrocyanosis
II†	Monoclonal IgM‡ (>IgG‡) against polyclonal IgG	HCV ≫ HBV, HIV; autoimmune connective tissue diseases (e.g. Sjögren syndrome); lymphoproliferative disorders (e.g. B cell non-Hodgkin lymphoma, CLL); subacute bacterial endocarditis	Vasculitis	Small and medium-sized vessel vasculitis: palpable purpura, livedo reticularis, retiform purpura, necrosis, and ulceration Arthralgias, peripheral neuropathy, glomerulonephritis
III†	Polyclonal IgM‡ against polyclonal IgG			

*Rarely IgA.
†Referred to as "mixed" cryoglobulins because either monoclonal or polyclonal immunoglobulins bind to polyclonal immunoglobulins.
‡Typically have rheumatoid factor activity (i.e. are directed against the Fc portion of IgG).

Table 24.6 Classification of cryoglobulins. See Chapter 23 for discussion of type I cryoglobulinemia. CLL, chronic lymphocytic leukemia; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus.

Clinical features

Cutaneous involvement occurs in nearly all patients with cryoglobulinemic vasculitis, most commonly manifesting as palpable purpura of the lower extremities (Fig. 24.15). Other cutaneous findings include livedo reticularis, retiform purpura, necrosis, and ulceration, reflecting a mixture of small and medium-sized vessel vasculitis. Skin lesions are not typically cold-induced, in contrast to the vascular occlusive lesions seen in type I cryoglobulinemia. The condition usually has a chronic course[71], but in those with HCV-associated disease, more effective direct-acting viral agents for treating HCV may be curative (see below).

Common extracutaneous findings at the time of presentation include weakness (80%), arthritis or arthralgias (70%), peripheral (typically sensory) neuropathy (60%), gastrointestinal disease or hepatitis (60%), and membranoproliferative glomerulonephritis (20%)[71]. The hepatitis reflects the underlying viral infection or an associated autoimmune hepatitis and is not a direct result of the cryoglobulinemia. Occasionally, patients have xerostomia or xerophthalmia, as seen in Sjögren syndrome.

The most commonly associated infections, autoimmune connective tissue diseases, and hematologic disorders are listed in the Pathogenesis section. B cell non-Hodgkin lymphoma is the most common associated malignancy. Rarely, solid tumors such as hepatocellular carcinoma and papillary thyroid carcinoma have been reported to have a relationship with cryoglobulinemic vasculitis.

Tests for circulating cryoglobulins are often falsely negative. Specimens should be drawn during a flare using collection tubes prewarmed to 37°C without anticoagulants. The specimen should be kept at 37°C and transported directly to the laboratory to prevent cryoprecipitation. If clinical suspicion remains high, negative tests should be repeated. By contrast, rheumatoid factor is frequently positive in patients with mixed cryoglobulinemia (~70% of patients), often at high levels. Patients typically have low serum complement levels, often with low or undetectable C4 levels; however, complement levels do not necessarily correlate with the severity of the disease[66]. HBV, HCV, and HIV serologies should be evaluated, followed by a determination of viral load if there is evidence of infection. Up to 15% of patients with mixed cryoglobulinemia have a monoclonal gammopathy as detected by serum protein electrophoresis and/or immunofixation electrophoresis[14].

Fig. 24.15 Cryoglobulinemic vasculitis. A Palpable purpura of the lower extremities. **B** Purpuric papules and retiform plaques with central necrosis and ulceration in a patient with type II cryoglobulinemia secondary to hepatitis C viral infection. These cutaneous manifestations reflect a "mixed" pattern of both small and medium-sized vessel vasculitis. The patient also had an elevated rheumatoid factor, decreased C4, and an IgM monoclonal gammopathy.
B, Courtesy David A. Wetter MD.

Pathology

Histologically, features of LCV are seen. DIF reveals granular deposits consisting predominantly of IgM and C3 in a vascular pattern in the papillary dermis[5].

Differential diagnosis

The differential diagnosis of cryoglobulinemic vasculitis includes all forms of vasculitis affecting small or medium-sized vessels (see Table 24.1). Cryoglobulinemic vasculitis can be differentiated from these disorders based upon the appropriate context and by the detection of circulating mixed cryoglobulins. Patients with Sjögren syndrome can also have arthralgias, arthritis, xerostomia/xerophthalmia, and the presence of rheumatoid factor and/or mixed cryoglobulins; however, they are typically SSA (Ro)/SSB (La)-positive, have distinct histopathologic findings in salivary gland biopsies, and less frequently are found to have hepatitis, glomerulonephritis, or hypocomplementemia[66].

Treatment

The treatment of mixed cryoglobulinemia should be directed at any underlying disease. In patients with mild manifestations of vasculitis, that may be sufficient. In general, those with moderate or severe disease should first receive immunosuppressive therapy until they have stabilized clinically, then therapy for the underlying condition can be initiated. All patients with HCV-associated mixed cryoglobulinemia should be treated with antiviral therapy (see Table 24.10). Direct-acting antiviral agents are significantly more effective and better tolerated than previous interferon-containing regimens. Observational studies suggest antiviral regimens are effective in attaining a sustained virologic response, as well as improving vasculitic symptoms among those with HCV-associated cryoglobulinemic vasculitis. In a study of 148 patients, >95% had a complete or partial clinical response, with a median follow-up of 15.3 months[72]. While rates of clinical improvement are high, correlating with sustained virologic response, clonal production of cryoglobulins persists in some patients, leading to relapses of vasculitis.

Patients with mild manifestations of cryoglobulinemic vasculitis (e.g. purpura, arthralgias, mild sensory neuropathy) may respond to agents such as colchicine or dapsone and/or symptomatic management with nonsteroidal anti-inflammatory drugs (NSAIDs) or gabapentin. Those with moderate to severe disease should receive high-dose systemic corticosteroids in combination with rituximab. Evidence from randomized trials and cohort studies demonstrate the efficacy and safety of this regimen compared to conventional therapy with systemic corticosteroids, either alone or in combination with cyclophosphamide[73,74]. In addition, plasma exchange should be considered in those with acute life-threatening disease, including pulmonary hemorrhage, rapidly progressive crescentic glomerulonephritis, and hyperviscosity syndrome. As expected, prognosis depends on the severity of organ involvement and the underlying disease[75]. In non-infectious mixed cryoglobulinemic vasculitis, predictors of early relapse include purpura, cutaneous necrosis, and articular involvement[76].

ANCA-Associated Vasculitides

Introduction

The ANCA-associated vasculitides (AAVs) are characterized by vasculitis of small to medium-sized vessels, the presence of ANCAs, and an overlapping spectrum of organ involvement, with each having distinguishing clinical and laboratory features. New ACR-EULAR classification criteria for these diseases have been proposed[3]. The three AAVs discussed here are granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA) (Table 24.7).

ANCAs are predominantly IgG autoantibodies directed against components of both primary granules of neutrophils and monocyte lysosomes, and they likely have an important role in the pathogenesis of AAVs via interactions with primed neutrophils and endothelial cells. By immunofluorescent staining, there are two vasculitis-relevant patterns: (1) cytoplasmic (c)-ANCAs – directed against the antigen proteinase

ANTI-NEUTROPHIL CYTOPLASMIC ANTIBODY (ANCA)-ASSOCIATED VASCULITIDES			
Disorder	**Cutaneous and oral findings**	**Extracutaneous manifestations**	**Histologic findings¶**

Granulomatosis with polyangiitis (GPA; formerly Wegener granulomatosis) [most often *c-ANCA/anti-PR3 antibody*]	• Purpuric macules and papules
	• Friable, papular gingivae ("strawberry gums"), oral ulcers
	• PNGD*
	• Subcutaneous nodules
	• Pyoderma gangrenosum-like ulcers
		• **Upper respiratory**:
		  • *bloody nasal discharge, nasal crusting, or sino-nasal congestion*
		  • *cartilaginous involvement (e.g. saddle nose)*
		  • *conductive or sensorineural hearing loss*
		  • *inflammation or consolidaton of nasal/paranasal sinuses on imaging*
		  • subglottic stenosis
		• **Pulmonary**: *nodules, mass, or cavitation*†
		• **Renal**: *pauci-immune glomerulonephritis*
		• **Ocular:** proptosis, scleritis
		• Less often neurologic, GI, and cardiac involvement
			• *Granulomatous inflammation*
			• Vasculitis of small ± medium-sized vessels

Microscopic polyangiitis (MPA) [most often p-ANCA/anti-MPO antibody]	• Purpuric macules and papules • Erythematous macules, urticarial or purpuric plaques • Livedo racemosa, ulcers, splinter hemorrhages	• **Renal**: *pauci-immune glomerulonephritis* • **Pulmonary**: capillaritis/hemorrhage, *lung fibrosis or interstitial lung disease* • **Neurologic**: mononeuritis multiplex • *Absence of sino-nasal symptoms or signs*; cardiac, GI, or ocular involvement	• Vasculitis of small ± medium-sized vessels • No granulomas

Eosinophilic granulomatosis with polyangiitis (EGPA; formerly Churg–Strauss syndrome‡) [most often ANCA-negative or p-ANCA/anti-MPO antibody]	• Purpuric macules and papules
	• PNGD*
	• Subcutaneous nodules
	• Urticarial plaques
	• Livedo racemosa, retiform purpura, ulcers
		• **Upper respiratory**: paranasal sinusitis†, allergic rhinitis§, *nasal polyps*§
		• **Pulmonary**:
		  • *obstructive airway disease* (asthma)§
		  • non-fixed infiltrate†
		• **Hematologic**: *peripheral eosinophilia (>10%)*, elevated IgE
		• **Neurologic**: *mononeuritis multiplex*
		• **Cardiac**: myo- or pericarditis
		• Less often renal, GI, and ocular involvement
			• *Extravascular eosinophils*
			• Granulomatous inflammation
			• Vasculitis of small ± medium-sized vessels

*Palisaded neutrophilic and granulomatous dermatitis, which typically presents with umbilicated, crusted papulonodules on extensor surfaces (e.g., elbows) or the face (especially in GPA).
†Evidence via computed tomography (CT).
‡Occasionally triggered by leukotriene inhibitors or omalizumab and/or rapid discontinuation of corticosteroid therapy (see text).
¶May be observed in biopsies of the skin, mucosa, respiratory tract, kidney, or nerve.
§Usually the initial manifestations.

Table 24.7 Anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitides (AAVs). See Fig. 24.16 for frequencies of specific ANCAs in each of these disorders. As in other forms of vasculitis, patients often have constitutional symptoms (e.g., fevers, malaise, weight loss), arthralgias, and arthritis. Features included in evidence-based classification criteria for each disorder are *italicized*; the 2022 American College of Rheumatology/European Alliance of Associations for Rheumatology classification criteria are weighted criteria which have been validated for use in research. GI, gastrointestinal; MPO, myeloperoxidase; PR3, proteinase 3.

3 (PR3); and (2) perinuclear (p)-ANCAs – directed against the antigen myeloperoxidase (MPO), with other antigens (e.g. lactoferrin, cathepsin G, elastase) serving as targets in the setting of nonspecific inflammation. ANCAs are useful diagnostically and for monitoring disease activity[77]. However, these autoantibodies are also found in patients receiving certain medications (e.g. propylthiouracil, hydralazine) and who have underlying chronic infections, rheumatologic or inflammatory disorders, and malignancies (see Table 40.6)[77].

In order to improve specificity with regard to AAVs, an indirect immunofluorescence (IIF) test should be used as a screening evaluation to detect perinuclear versus cytoplasmic staining, followed by an ELISA that specifically detects anti-PR3 and anti-MPO antibodies. However, up to 5% of serum samples are positive by ELISA only, so when there is a high index of suspicion for AAV, the ELISA should be performed even if the IIF screening test is negative. Because neither anti-PR3 ANCA nor anti-MPO ANCA is specific for a particular AAV and patients with AAV may be ANCA-negative, clinicopathologic correlation is required when evaluating a patient with suspected AAV (Fig. 24.16). Semi-quantitative analysis may allow for disease monitoring and response to treatment since the persistence of ANCAs following remission has been associated with disease relapse[78]. Furthermore, there is growing recognition that ANCA type (anti-PR3 versus anti-MPO) is perhaps more clinically and prognostically meaningful than is disease type (GPA versus MPA), such that experts and clinical trialists increasingly refer to AAV by ANCA type and stratify clinical trial enrollment accordingly.

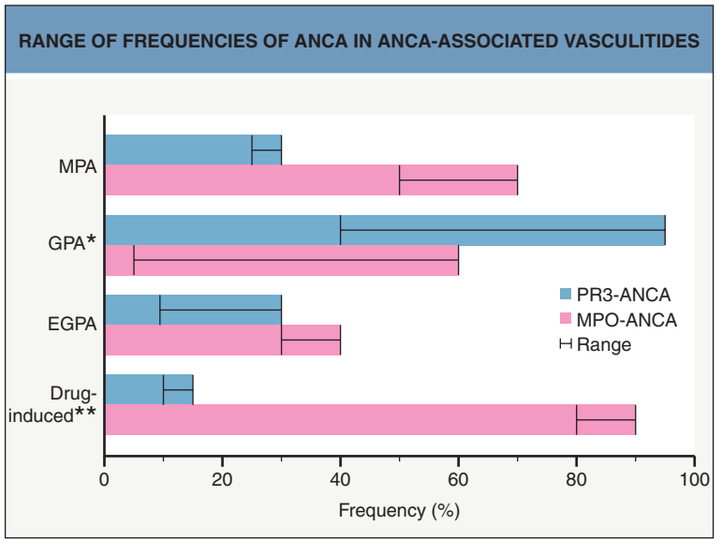

Fig. 24.16 Range of frequencies of ANCA in ANCA-associated vasculitides. Variability reflects differences in cohorts studied, disease extent and severity at time of assays, diagnostic criteria, and cutoff values of various ANCA assays. Negative ANCA testing does not exclude the presence of an ANCA-associated vasculitis, as overall frequencies for ANCA positivity are 90% (generalized GPA), 60% (limited GPA), 90% (MPA), and 50% (EGPA), respectively. *MPO-ANCAs are overrepresented in Chinese patients with GPA; 10% of non-Chinese patients with GPA have MPO-ANCAs[72]. **Examples include propylthiouracil, minocycline, hydralazine, and levamisole-tainted cocaine (see Tables 24.4 and 40.6). Note that other ANCA specificities may be detected in drug-induced vasculitis. ANCA, anti-neutrophil cytoplasmic antibody; EGPA, eosinophilic granulomatosis with polyangiitis; GPA, granulomatosis with polyangiitis; MPA, microscopic polyangiitis; MPO, myeloperoxidase; PR3, proteinase 3. *Adapted from Wiik AS, Rheum Dis Clin NA. 2010;36:479–89.*

Epidemiology

In a population-based study of biopsy-proven small vessel vasculitis of the skin, the annual incidence of an underlying AAV was 4 cases per million[4], i.e. ~10% of the patients had an AAV, emphasizing the importance of considering this group of disorders. Conversely, cutaneous manifestations are a common presenting feature of AAV, occurring in a third of patients[79].

Pathogenesis

The pathogenesis of AAV, depicted in Fig. 24.1B, is complex and includes genetic as well as environmental factors. Key elements include: autoreactive B-lymphocytes that produce ANCAs; abnormal T-regulatory function which allows persistent T cell activation, especially of Th17 cells; neutrophils that cause tissue damage via injury to vascular epithelium; and activation of the alternative complement pathway, namely C5a, and neutrophil extracellular traps (NETs) which drive vascular inflammation[80].

Natural history, clinical features, and treatment

The morbidity and mortality of AAVs are relatively high, stemming from associated end-organ damage as well as complications of immunosuppressive therapy[81]. Delay in diagnosis, renal impairment, propensity for relapse, the presence of ANCAs, and older age are risk factors for reduced survival. The three major AAVs are discussed in the following sections, including clinicopathologic features (see Table 24.7)[82], as well as treatment options (see Table 24.10).

Granulomatosis With Polyangiitis

Synonym: ▪ Wegener granulomatosis (historical)

Key features

- Necrotizing granulomatous inflammation of the upper and lower respiratory tracts
- Pauci-immune glomerulonephritis
- Systemic vasculitis that can involve the skin and oral mucosa
- c-ANCA and anti-PR3 antibodies most commonly detected

Introduction

Granulomatosis with polyangiitis (GPA) is classically described as the triad of granulomatous inflammation of the upper and lower respiratory tracts, systemic necrotizing vasculitis, and pauci-immune glomerulonephritis. Patients with GPA exist along a spectrum of severity, depending upon the number of organs involved and the degree of functional impairment. Those with organ- or life-threatening disease have a high mortality rate if left untreated, while patients without organ- or life-threatening GPA have primarily airway disease without constitutional symptoms or systemic vasculitis. The initial evaluation of patients with GPA should establish the extent of organ involvement, as evidence supports distinct treatment approaches based upon disease severity[81]. However, because this disorder can evolve over time, patients initially without organ- or life-threatening disease must still be closely monitored.

Epidemiology

The incidence of GPA varies widely by geographic region and is estimated to be 0.4 to 12 cases per million per year. The disease occurs most often in White individuals, with a peak age of onset of 45–65 years.

Pathogenesis

The pathophysiology of GPA is reflected in two clinicopathologic hallmarks of the disease – granuloma formation and small to medium-sized vessel vasculitis. Activity of alpha-1 antitrypsin, a proteinase inhibitor, has been found to be markedly reduced in patients with GPA[83], while ANCAs, environmental factors, and genetic polymorphisms (e.g. *PTPN22* 620W allele) all contribute to immune dysregulation.

Although the specific pathogenic roles of PR3 or anti-PR3 antibodies remain unclear, surface expression of PR3 on apoptotic and/or activated neutrophils may stimulate dendritic cell maturation and proinflammatory cytokine release by antigen-presenting cells, thereby favoring development of Th1-mediated granuloma formation (termed "*neutrophil priming*"). Expression of PR3 on the cell surface of neutrophils may impede phagocytosis by macrophages, thus prolonging the opportunity for autoantibody development. In turn, ANCAs binding to PR3 on neutrophils result in vessel damage (e.g. pauci-immune or nonimmune complex-mediated vasculitis; see Fig. 24.1B)[77,84]. Neutrophil priming may occur as a result of certain infections, such as *Staphylococcus aureus*. Of note, nasal carriage of *S. aureus* is associated with relapse of GPA, and treatment of nasal carriage with antibiotics improves outcomes.

Clinical features

Patients with GPA typically present with nonspecific symptoms such as fever, malaise, weight loss, arthralgias, and myalgias. In one-third of patients, mucocutaneous involvement is a presenting feature[79]. While the most common lesions are petechiae and purpuric macules and papules that may be painful, subcutaneous nodules, nonspecific rashes, and ulcerations that can resemble pyoderma gangrenosum may also be seen (Fig. 24.17). Papulonecrotic lesions are common and usually occur on extensor surfaces, particularly the elbows. They are sometimes referred to as Churg–Strauss nodules. Cutaneous involvement may be prognostically important, as it has been associated with an increased risk of severe systemic manifestations of GPA, including glomerulonephritis and alveolar hemorrhage[79].

The *upper or lower respiratory tracts* are involved in up to 90% of patients with GPA. Nasal, sinus, tracheal, and ear involvement represent the presenting complaints in >70% of patients. Suggestive symptoms and signs include recurrent epistaxis, mucosal ulcerations, nasal septal perforation, and saddle nose deformity. Patients with pulmonary involvement typically present with dyspnea, cough, hemoptysis, or pleuritis, and chest X-rays demonstrate irregular infiltrates or nodules. *Renal disease* is present in only 20% of patients at presentation, but ~75% of patients eventually develop glomerulonephritis[85]. Other organ systems commonly affected by necrotizing vasculitis in GPA include musculoskeletal (70%), ocular (30%–60%), neurologic (20%–50%), gastrointestinal (5%–10%), and cardiac (5%–40%).

Laboratory findings are consistent with an inflammatory process, including elevated acute phase reactants (ESR, C-reactive protein), anemia, and leukocytosis. The frequencies of ANCAs are depicted in Fig. 24.16 and vary depending upon disease activity and severity. Patients with GPA most frequently have circulating c-ANCAs and anti-PR3 antibodies. Those with renal involvement may have proteinuria, hematuria, or an active urine sediment with red blood cell casts, as well as progressive renal failure. Additional diagnostic testing that assists in assessing for systemic involvement and excluding alternative diagnoses is outlined in Table 24.8.

Pathology

The diagnosis of GPA should be confirmed or corroborated histologically whenever possible. In one large series of patients with GPA, skin biopsies were performed in only a minority (29%) of patients, but they were thought to be diagnostic of vasculitis in 82%[79]. Histologic findings may be nonspecific (e.g. perivascular lymphocytic infiltrates), or they may demonstrate LCV and/or granulomatous inflammation. Biopsies of the papulonecrotic lesions (Churg–Strauss nodules) show a palisading neutrophilic dermatitis with areas of granulomatous inflammation surrounding foci of basophilic necrobiosis, i.e. palisaded neutrophilic and granulomatous dermatitis (PNGD; see Ch. 93).

Differential diagnosis

The primary differential diagnosis for GPA includes the other AAVs, given the shared and overlapping features of these diseases. Additional disorders and their distinguishing features are outlined in Table 24.9.

Treatment

Treatment of GPA consists of an initial induction regimen followed by maintenance therapy, with the goal of inducing and maintaining a long-term, relapse-free remission. The standard therapy for patients with organ- or life-threatening disease (e.g. active glomerulonephritis, pulmonary hemorrhage) is systemic corticosteroids (e.g. 1 mg/kg/day of prednisone) in conjunction with either rituximab or cyclophosphamide (see Table 24.10). There is some practice variation regarding which of the two is chosen. The combination of corticosteroids and oral cyclophosphamide results in a complete remission in up to 75% of patients and a ~90% survival rate[85]. However, two seminal randomized trials demonstrated comparable efficacy for rituximab-based regimens[86,87]. Given the more favorable side-effect profile of rituximab, many authors now prefer this agent for initial therapy. With regard to corticosteroids, a reduced-dose, 4- to 6-month tapering regimen is recommended for

Fig. 24.17 Granulomatosis with polyangiitis. Wetter MD; E, Courtesy Jeffrey Gelhausen, MD and Nan Ring, MD.*

POSSIBLE ADDITIONAL DIAGNOSTIC TESTING FOR PATIENTS WITH SUSPECTED ANCA-ASSOCIATED VASCULITIDES								
	Chest X-ray and/or chest CT scan	**Electromyogram/ nerve conduction studies**	**Lung, nerve, or kidney biopsy**	**Upper respiratory tract or muscle biopsy**	**ECG, echocardiogram**	**CT scan of sinuses**	**Serum IgE level**	**Consider GI and ophthalmologic examination**
Granulomatosis with polyangiitis (GPA)	√	√	√*	√*	√	√		√
Microscopic polyangiitis (MPA)	√	√	√					
Eosinophilic granulomatosis with polyangiitis (EGPA)	√	√	√		√	√	√	√
*Depends upon signs and symptoms.								

Table 24.8 Possible additional diagnostic testing for patients with suspected ANCA-associated vasculitis. This is in addition to the general evaluation outlined in Fig. 24.19. ANCA, anti-neutrophil cytoplasmic antibody; CT, computed tomography; ECG, electrocardiogram; GI, gastrointestinal.

most patients; this is based upon randomized trial data demonstrating similar remission rates and fewer adverse events when compared to standard regimens[88,89]. Following induction of a remission, a maintenance regimen is initiated to try to prevent disease relapse. Although rituximab is generally favored for maintenance therapy[90], azathioprine, methotrexate, and mycophenolate mofetil may be reasonable alternatives depending on various patient-specific factors. Risk factors for relapse include PR3-ANCA positivity. The typical duration of maintenance therapy is 1 to 2 years.

Those *without* organ- or life-threatening disease as well as no renal dysfunction may receive weekly methotrexate (20–25 mg) as initial therapy and later as maintenance therapy, in combination with lower starting doses of corticosteroids (0.5 mg/kg/day prednisone equivalent). This regimen successfully induces a remission in most patients, but it is associated with a higher relapse rate[91]. Rituximab is also a reasonable option for these patients.

Recent work has led to a shift away from broader, more profound immunosuppression towards more targeted agents, resulting from improved understanding of disease pathophysiology. A phase III study evaluating the safety and efficacy of avacopan (an oral C5a inhibitor) as maintenance therapy found a higher sustained remission rate in the avacopan group than in the prednisone group, with similar rates of serious adverse events and approximately one-third the mean total dose of corticosteroids[92].

Additional alternative treatment regimens are summarized in Table 24.10.

Microscopic Polyangiitis

Synonym: ■ Microscopic polyarteritis

Key features

- Vasculitis of capillaries, venules, and medium-sized arteries
- Constitutional symptoms, crescentic necrotizing glomerulonephritis, and alveolar hemorrhage
- Purpura, livedo reticularis, and livedo racemosa
- p-ANCA and anti-MPO antibodies most commonly detected
- Absence of granuloma formation

KEY DISORDERS IN THE DIFFERENTIAL DIAGNOSIS OF ANCA-ASSOCIATED VASCULITIS AND THEIR DISTINGUISHING FEATURES		
ANCA-positive vasculitic syndrome	**Disorder in differential diagnosis**	**Distinguishing features of the disorder in the differential diagnosis**
Granulomatosis with polyangiitis (GPA)	Eosinophilic granulomatosis with polyangiitis	• Eosinophilia • Asthma • Lower incidence of severe renal disease
	Microscopic polyangiitis	• Absence of granulomatous inflammation
	NK/T cell lymphoma	• Destructive nasal midline lesion (see Table 45.3) • Characteristic histology
	Tuberculosis (lupus vulgaris), Hansen disease	• Destructive nasal midline lesion • Characteristic histologic features and laboratory findings
	Cocaine-induced destructive nasal midline lesion	• By ELISA, ANCAs are positive for both human neutrophil elastase and proteinase 3 • Neutropenia
	Goodpasture syndrome	• Kidney-bound or circulating anti-glomerular basement membrane antibodies
	SLE or rheumatoid vasculitis	• Distinct rheumatologic serologies • Develops in individuals with longstanding, poorly controlled disease
Microscopic polyangiitis (MPA)	Eosinophilic granulomatosis with polyangiitis	• Eosinophilia • Asthma and sinus disease • Increased incidence of cardiac involvement
	Granulomatosis with polyangiitis	• Granulomatous inflammation • Increased incidence of ocular and severe upper respiratory tract involvement
	Polyarteritis nodosa	• Absence of glomerulonephritis • Vasculitis of renal arteries with renovascular hypertension • Lower incidence of pulmonary involvement • ANCA-negative
	Goodpasture syndrome, SLE, rheumatoid vasculitis	• See above
Eosinophilic granulomatosis with polyangiitis (EGPA)	Microscopic polyangiitis	• No granulomatous inflammation • No history of asthma • No hypereosinophilia
	Granulomatosis with polyangiitis	• Increased incidence of glomerulonephritis • Lower incidence of cardiac or peripheral nerve involvement
	Hypereosinophilia, secondary	• Absence of vasculitic manifestations • Due to medications, parasitic infections, allergic disease, malignancy
	Hypereosinophilic syndrome	• Absence of vasculitic manifestations • Diagnosis of exclusion

Table 24.9 Key disorders in the differential diagnosis of ANCA-associated vasculitis and their distinguishing features. ANCAs, anti-neutrophil cytoplasmic antibodies; ELISA, enzyme-linked immunosorbent assay; SLE, systemic lupus erythematosus.

Introduction

Microscopic polyangiitis (MPA) is a systemic vasculitis involving small and medium-sized blood vessels that most commonly affects the skin, lungs, and kidneys. More than 90% of patients are ANCA-positive (most commonly p-ANCA and anti-MPO antibodies), but granulomatous inflammation is usually absent. Because the clinical features of MPA and GPA overlap considerably, it may at times be difficult to differentiate between these two entities. Given these similarities, most therapeutic trials of AAV include both patients with MPA and those with GPA or stratify enrollment by ANCA type (anti-MPO or anti-PR3 antibodies).

Epidemiology

The estimated annual incidence of MPA is 0.5 to 24 cases per million. The condition occurs most commonly in East Asia. The reported mean age of onset is 57 years, with a peak incidence between the ages of 65 and 75 years[93].

Pathogenesis

Similar to GPA, the etiology of MPA is largely attributed to the presence of autoreactive ANCAs, which form in the presence of proinflammatory cytokines and recognize exposed neutrophilic antigens. In MPA, ANCAs bind primarily to MPO, resulting in vascular damage. The precise role of predisposing genetic, environmental, and other factors is unknown[94] (see general Pathogenesis).

Clinical features

Most patients with MPA initially experience constitutional symptoms, such as fever, weight loss, arthralgias and myalgias, for months to years before other symptoms appear. Depending upon the series, 20%–70% of patients will have cutaneous involvement, most commonly petechiae and purpura (Fig. 24.18). Livedo reticularis and livedo racemosa are more often seen in MPA than in GPA or EGPA[79]. Other cutaneous findings may include a nonspecific rash, painful papules or nodules, and ulcers or gangrene[95]. Skin involvement is associated with higher rates of neurologic and musculoskeletal vasculitic manifestations but lower rates of renal and pulmonary complications[79].

Renal involvement occurs in nearly all patients with MPA (>90%); a pauci-immune, crescentic, necrotizing glomerulonephritis is the primary pathology, as in GPA. *Pulmonary* capillaritis (with dyspnea and pulmonary infiltrates) occurs in 30%–50% of patients and can result in diffuse alveolar hemorrhage (10%). Interstitial lung disease can also develop, occurring more often in MPA than in GPA[96]. *Neurologic* involvement is commonly observed and it usually presents as a peripheral neuropathy or mononeuritis multiplex in up to one-third of patients. Upper respiratory tract involvement occurs as well, but it is less common and less destructive than in GPA. The progressive clinical course of MPA typically leads to renal failure and/or pulmonary hemorrhage.

Anti-MPO antibodies (55%–65% of patients) are detected more often than anti-PR3 antibodies (20%–30%) (see Fig. 24.16). Uncommonly, patients may be ANCA-negative. Additional diagnostic testing for systemic involvement is outlined in Table 24.8, and Fig. 24.19 outlines an approach to the patient with suspected vasculitis.

Histologically, leukocytoclastic vasculitis was seen. **B** Petechiae and multiple purpuric macules with central necrosis on the plantar surface. *A, Courtesy David A. Wetter, MD; B, Courtesy Cara Whitney Hannon, MD and Robert Swerlick, MD.*

Pathology

The characteristic histologic findings include a segmental necrotizing vasculitis of small blood vessels (capillaries, venules, and arterioles) and, less often, a vasculitis of small and/or medium-sized arteries[79]. Granulomatous inflammation is absent.

Differential diagnosis

MPA frequently presents with petechiae and purpura and constitutional symptoms. If no additional internal organ involvement is evident at initial presentation, it may be difficult to distinguish MPA from CSVV or other types of vasculitis involving small blood vessels. The differential diagnosis includes the entities listed in Table 24.9.

Treatment

The treatment approach for MPA is the same as that for GPA, consisting of both an induction phase and a maintenance phase. As stated previously, because these two conditions are related, with overlapping features and outcomes, recent clinical trials have included patients with both diseases. To induce remission in patients with organ- or life-threatening disease such as active glomerulonephritis or pulmonary hemorrhage, corticosteroids (e.g. initial prednisone dose of 1 mg/kg/day) plus either rituximab (usually preferred) or cyclophosphamide are recommended (see Table 24.10)[86]. A reduced-dose, tapering regimen of corticosteroids should be employed, if possible. Maintenance therapy with rituximab should be initiated after remission has been achieved; alternatives include azathioprine, methotrexate, or mycophenolate mofetil[90]. Those *without* organ- or life-threatening disease may be treated with corticosteroids and weekly methotrexate or rituximab. The role of plasma exchange in the initial management of GPA and MPA is controversial[89].

Patients with MPA have a lower risk of relapse compared to those with GPA. In both disorders, the presence of anti-PR3 antibodies and persistent or rising ANCA titers are associated with an increased risk of relapse after remission.

Eosinophilic Granulomatosis With Polyangiitis

Synonyms: ■ Churg–Strauss syndrome ■ Churg–Strauss vasculitis ■ Allergic angiitis and granulomatosis

Key features

- Prodromal asthma and allergic rhinitis are followed by eosinophilic and vasculitic phases
- Peripheral eosinophilia and ANCA-positivity in half of patients (usually p-ANCA and anti-MPO antibodies)
- Cutaneous manifestations in ~50% of patients
- Most commonly pulmonary, neurologic, renal, and cardiac involvement
- Histologic features consist of eosinophils, extravascular granulomas, and vasculitis

Introduction

Eosinophilic granulomatosis with polyangiitis (EGPA), also referred to as Churg–Strauss syndrome, is characterized by vascular and extravascular granulomas, eosinophil-rich pulmonary infiltrates, and necrotizing vasculitis that involves small to medium-sized vessels within multiple organ systems. It is distinguished by an association with asthma and eosinophilia.

Epidemiology

Although the true incidence of EGPA is unknown due to uncertainties surrounding its diagnosis, it is thought to be the least common of the ANCA-associated vasculitides. EGPA has an estimated incidence ranging from 0.5 to 2.7 cases per million per year[97]. The mean age at diagnosis is 40 years, and it has no sex predominance. The incidence of EGPA in patients with asthma ranges from 35 to 65 per million per year.

AI-CTD, autoimmune connective tissue disease; ANA, anti-nuclear antibody; ANCA, anti-neutrophil cytoplasmic antibody; BMZ, basement membrane zone; BUN, blood urea nitrogen; CBC, complete blood count; CT, computerized tomography; DIF, direct immunofluorescence; ELISA, enzyme-linked immunosorbent assay; ENA, extractable nuclear antigen; ESR, erythrocyte sedimentation rate; H&E, hematoxylin and eosin; HIV, human immunodeficiency virus; Ig, immunoglobulin; IgAV, IgA vasculitis (Henoch–Schönlein purpura); SLE, systemic lupus erythematosus. *Adapted from Goeser MR, et al. Am J Clin Dermatol 2014;15:299–306.*

Pathogenesis

The onset of symptoms has been associated with various triggering factors, including vaccination, desensitization therapy, leukotriene inhibitors, omalizumab, and rapid discontinuation of corticosteroids. However, in some patients, this may more accurately represent an "unmasking" of the disease. T lymphocytes, eosinophils, and ANCAs all play a role in disease pathogenesis. Tissue infiltration and degranulation of eosinophils can lead to tissue injury, while T cells, both Th1 and Th2, are postulated to contribute to granuloma formation and allergic features, respectively. ANCA-dependent activation of neutrophils results in vasculitis (see Fig. 24.1B).

Two subsets of EGPA have been identified in which several risk genes (e.g. *HLA-DQ*) are associated with ANCA-positivity, while variants in *GPA33* and *IL5* are associated with ANCA-negative EGPA. The former group of patients is more likely to develop glomerulonephritis and neuropathy while the latter group more often has cardiomyopathy and pulmonary infiltrates.

Clinical features

The clinical presentation can be divided into three successive phases: (1) prodromal phase – symptoms of allergic rhinitis, nasal polyps, and asthma, which may persist for years; (2) eosinophilic phase – peripheral

eosinophilia and eosinophilic infiltration of internal organs, especially the lungs and gastrointestinal tract; and (3) vasculitic phase – systemic necrotizing vasculitis with granulomatous inflammation, which can occur several years to decades after the initial symptoms. Asthma, frequently severe, affects almost all patients and often precedes the onset of additional systemic manifestations by a decade or more[98]. Otitis media, allergic rhinitis, nasal polyposis, and sinusitis are also exceedingly common.

Cutaneous findings occur in 40%–75% of patients, typically during the third phase of the disease, but are the presenting sign in ~15% of patients[99]. Although petechiae and purpura are most often seen, a variety of nonspecific, non-vasculitic manifestations are also frequently observed. The latter include "rash", pruritus, and urticaria. Because these "allergic" skin findings occur more frequently in EGPA than in other types of ANCA-associated vasculitides, recognizing them as potentially consistent with EGPA in the right clinical setting is important[79]. Subcutaneous nodules, livedo racemosa, retiform purpura, and papulonecrotic lesions, particularly on the extensor surfaces (i.e. Churg–Strauss nodules, PNGD), may also be seen[100] (Fig. 24.20).

In addition to the respiratory tract, patients with EGPA often have neurologic and cardiac involvement, presenting as mononeuritis multiplex and cardiomyopathy, pericarditis, or an arrhythmia. Peripheral neuropathy affecting more than one site (mononeuritis multiplex) is seen in up to 75% of patients and may result in pain, numbness, or weakness[101]. Cardiac manifestations occur in up to half of patients, developing more often in those with higher peripheral blood eosinophil counts, and are the leading cause of death[102,103]. Necrotizing glomerulonephritis and pulmonary capillaritis resulting in diffuse alveolar hemorrhage occur less commonly than in the other AAVs. Musculoskeletal, gastrointestinal, and ocular involvement can also occur.

There are no specific laboratory findings, but peripheral eosinophilia (≥1500 cells/microL or ≥10% of the total leukocyte count) should prompt suspicion in the right clinical context. In addition, patients frequently have elevated serum IgE levels. ANCAs are present in roughly half of those with EGPA, with 75% of these antibodies p-ANCA and anti-MPO (see Fig. 24.16). ANCA positivity has been associated with a higher risk of vasculitic features, including peripheral neuropathy, glomerulonephritis, and histologic findings of vasculitis, as well as higher rates of disease relapse. On the other hand, cardiac involvement is more commonly observed in ANCA-negative patients[104].

Pathology

The histopathologic hallmarks are infiltrates of eosinophils, formation of extravascular granulomas, and necrotizing vasculitis of small to medium-sized vessels; both arteries and veins are affected. Biopsy specimens obtained from papulonecrotic lesions demonstrate a palisading dermatitis with eosinophil infiltration, granuloma formation, and eosinophilic necrobiosis.

Differential diagnosis

EGPA is suspected on the basis of its typical clinical findings of asthma, rhinosinusitis, and peripheral eosinophilia in addition to manifestations of vasculitis (e.g. cutaneous, neurologic, renal), biopsy findings of vasculitis, and/or ANCA positivity (if present). Due to the tendency

for this disease to evolve over time or to lack one or more of these features, diagnosis can be challenging and delayed. As with GPA and MPA, revised EULAR/ACR diagnostic criteria have been published[3,105].

The differential diagnosis of EGPA includes other vasculitides (see Table 24.9), other causes of secondary hypereosinophilia (e.g. parasitic infections), and hypereosinophilic syndrome (HES; see Ch. 26)[98], as well as chronic eosinophilic pneumonia and allergic bronchopulmonary aspergillosis.

Treatment

Systemic corticosteroids (usually 0.5–1 mg/kg/day prednisone equivalent) are the mainstay of therapy, and >90% of patients respond to treatment with corticosteroids alone. However, relapse is common, and patients with more severe internal organ involvement (e.g. cardiac, renal, gastrointestinal, CNS) generally require additional immunosuppressive therapy. In such patients, either cyclophosphamide or rituximab is typically added to the corticosteroid. The five-factors score (FFS), which is based on the presence or absence of various clinical factors associated with worse prognosis, can be used for risk stratification[106,107]. Guidelines recommend cyclophosphamide in those who have active cardiac involvement and in those who are ANCA-negative and have severe neurologic or gastrointestinal manifestations. Rituximab may be preferred in those with: ANCA positivity, active glomerulonephritis, prior cyclophosphamide treatment, or risk of gonadal toxicity. For patients with active, non-severe EGPA, corticosteroids combined with the anti-IL-5 monoclonal antibody mepolizumab are recommended. Alternative options for patients without organ-threatening disease include methotrexate or azathioprine plus corticosteroids[108].

Once remission has been achieved, corticosteroids should be tapered over ~12–18 months. However, many patients will need to continue low-dose corticosteroids (e.g. ≤10 mg/day prednisone) long-term. In addition, cyclophosphamide or rituximab can be replaced by less toxic immunosuppressive drugs such as azathioprine, methotrexate, or mycophenolate mofetil[108]. The data supporting azathioprine and other second- and third-line agents (e.g. methotrexate, leflunomide) for treatment of relapsed or refractory EGPA are limited (see Table 24.10)[103]. Of note, mepolizumab is FDA-approved for the treatment of EGPA based on a randomized trial in which increased rates of remission and reduced corticosteroid use were observed in patients with relapsing or refractory non-severe disease. Still, only about half of patients who received mepolizumab achieved remission[109]. Clinical trials of other anti-IL-5 drugs are ongoing.

PREDOMINANTLY MEDIUM-SIZED VESSEL VASCULITIS

Polyarteritis Nodosa

Synonyms: ■ Periarteritis nodosa ■ Panarteritis nodosa

Key features

- Segmental vasculitis of predominantly medium-sized arteries
- Both cutaneous and systemic (classic) forms
- Skin findings include livedo racemosa, subcutaneous nodules, retiform purpura, ulcerations, and peripheral gangrene
- Extracutaneous manifestations of the systemic variant include fever, arthralgias, myalgias, paresthesias, abdominal pain, orchitis, and renovascular hypertension
- The cutaneous variant has a chronic course and may be accompanied by mild systemic symptoms, primarily myalgias, arthralgias, and peripheral neuropathy

Introduction

Polyarteritis nodosa (PAN) is a multisystem vasculitis characterized by segmental necrotizing vasculitis involving predominantly medium-sized blood vessels. Some authors view cutaneous PAN as a "skin-predominant" variant, which typically follows a benign yet chronic course with relapses. Although these two entities are discussed together in this section, there is an alternative view that cutaneous PAN represents a distinct disorder (with occasional muscle or nerve involvement) rather than a skin-restricted variant of PAN[110]. Recently, the term *cutaneous arteritis* has been introduced as a synonym for cutaneous PAN.

Epidemiology

The incidence of classic PAN ranges from 4 to 16 cases per million, with a male:female ratio of 1.5:1. PAN can occur at any age but typically affects middle-aged adults (40–60 years). The true incidence of cutaneous PAN is unknown, but it may represent ~10% of all cases of PAN and is the most common form of PAN in children[111].

Pathogenesis

Although most cases of PAN are idiopathic, it may be associated with infections, inflammatory diseases (e.g. inflammatory bowel disease), malignancies (especially hairy cell leukemia), and medications. HBV infection is strongly linked to PAN, with prevalence depending on the regional frequency of HBV infection. Fortunately, widespread administration of the HBV vaccine has led to a significant reduction in HBV-associated PAN. Clinical features are the same as in idiopathic PAN, but disease onset generally occurs within six months of HBV infection and small studies suggest a higher risk of gastrointestinal, neurologic, and renal involvement[112]. Cutaneous PAN has been associated with other infections, particularly group A *Streptococcus* (especially in children), as well as long-term administration of minocycline[113].

A subset of children presenting with a PAN-like vasculitis have recessive loss-of-function mutations in *CECR1*, the gene encoding adenosine deaminase 2 (ADA2), suggesting a genetic susceptibility in some patients (see Ch. 45)[114,115]. Additionally, some adult patients with PAN have been diagnosed with the recently described autoinflammatory disorder VEXAS (vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic) syndrome[116].

Clinical features

Extracutaneous disease is the rule in classic PAN, and patients usually experience constitutional symptoms, such as weight loss and fever, as well as multi-organ involvement. Common symptoms include arthralgias, sensory and/or motor neuropathy (mononeuritis multiplex), myalgias (due to myopathy), and abdominal pain. Kidney involvement is common and occurs at the level of the interlobar renal arteries, resulting in renovascular hypertension and renal failure, but not glomerulonephritis. In male patients, orchitis frequently occurs, especially in association with HBV infection. Stroke, ischemic cardiomyopathy, and mesenteric ischemia with bowel infarction and perforation are rare, but devastating, complications of classic PAN; they result from thrombotic microangiopathy or vasculitic arterial occlusion. Gastrointestinal involvement heralds a poor prognosis, with a 1-year survival rate of <50%[112]. Classically, the lungs are spared.

In a series of 348 patients with *classic (systemic) PAN*, ~50% had cutaneous findings[111]. The lower legs are involved in the vast majority of patients. Common manifestations include tender erythematous nodules, livedo racemosa, inflammatory retiform purpura, and ulceration, findings indicative of medium-sized vessel vasculitis. Palpable purpura also occurs, indicating that there is vasculitis of small blood vessels and not just medium-sized vessels. Occasionally, atrophie blanche-like lesions are seen. Severe cutaneous complications of PAN include deep ulcerations and digital infarcts. Skin involvement in PAN is associated with joint disease and higher rates of relapse[111].

In systemic PAN, laboratory evaluation demonstrates nonspecific inflammation with leukocytosis, an elevated ESR, and thrombocytosis. Microscopic hematuria can be seen, but evidence of glomerulonephritis is absent. Microaneurysms of the renal, mesenteric, and/or celiac arteries detected by traditional, computed tomography (CT), or magnetic resonance (MR) angiography are highly suggestive of classic PAN.

Cutaneous PAN, a skin-predominant form of the disease, represents about 10% of PAN cases. The majority of patients present with patchy, focal livedo racemosa (so-called "starburst" livedo), and tender subcutaneous nodules on the lower legs (Fig. 24.21). Lesions appear less often on the arms and trunk. Ulcerations occur in up to half of patients[117] and may serve as a predictor for recurrences. Patients frequently report

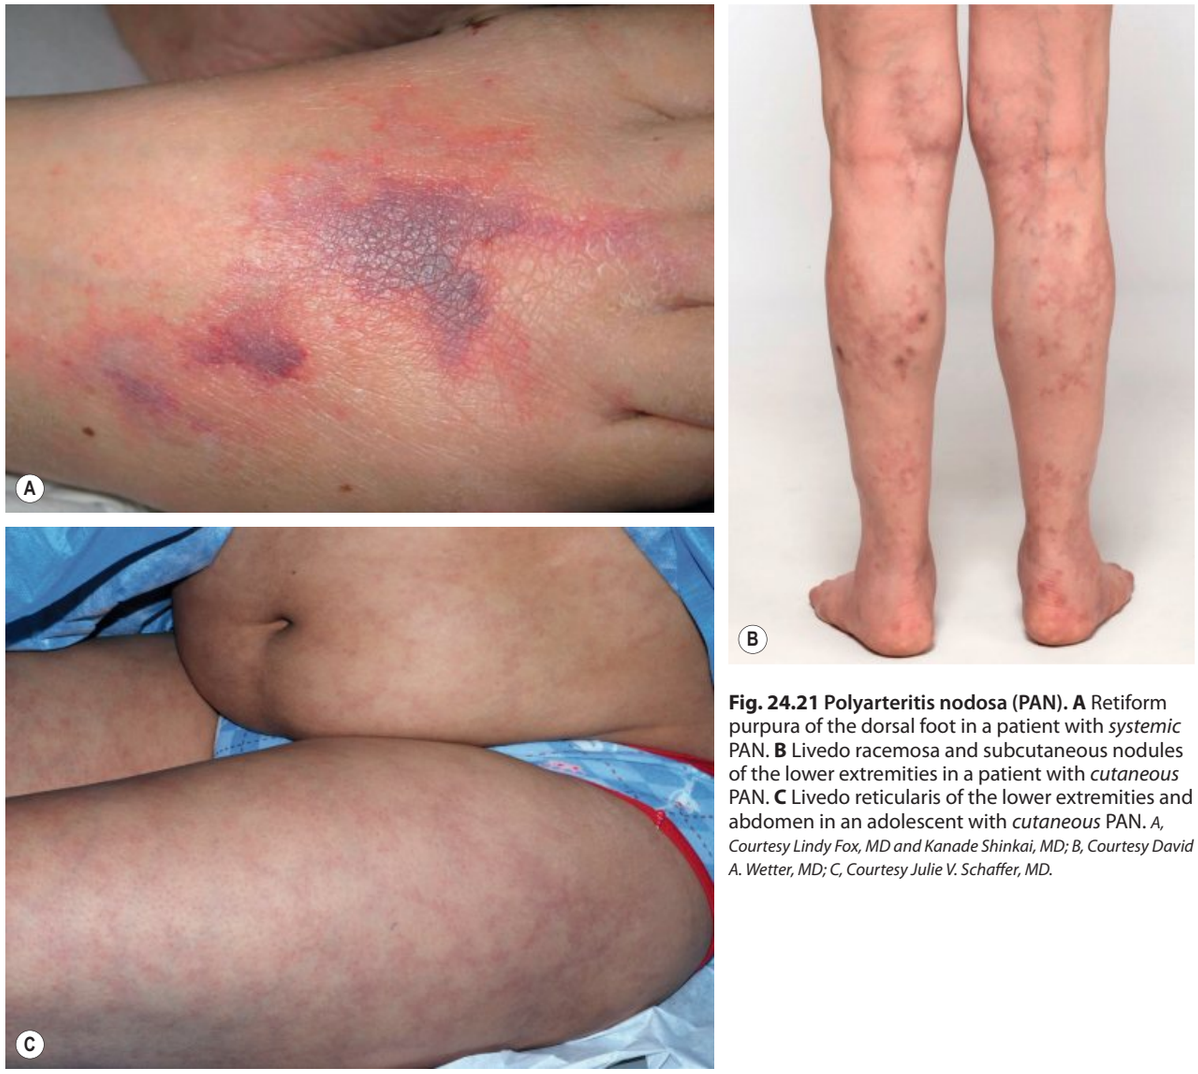

Fig. 24.21 Polyarteritis nodosa (PAN). A Retiform purpura of the dorsal foot in a patient with *systemic* PAN. **B** Livedo racemosa and subcutaneous nodules of the lower extremities in a patient with *cutaneous* PAN. **C** Livedo reticularis of the lower extremities and abdomen in an adolescent with *cutaneous* PAN. *A, Courtesy Lindy Fox, MD and Kanade Shinkai, MD; B, Courtesy David A. Wetter, MD; C, Courtesy Julie V. Schaffer, MD.*

mild systemic symptoms, consisting of fever, myalgias, arthralgias, and peripheral neuropathy localized to areas of skin involvement[118]. Although the latter can make differentiation of cutaneous versus systemic PAN more difficult, true cutaneous PAN should have neither prominent visceral manifestations nor muscle or nerve symptoms remote from skin lesions. In cutaneous PAN, a chronic, relapsing clinical course is typical[119], but progression to systemic PAN rarely, if ever, occurs. In two large series, only one patient was reported to have evolved from cutaneous to systemic PAN during the course of the disease[110,117].

While no diagnostic laboratory test for PAN exists, laboratory testing is helpful in determining the extent of organ involvement and narrowing the differential diagnosis. Measurement of serum creatinine and liver function tests as well as a urinalysis and HBV and HCV serologies should be performed. The presence of anti-PR3 or -MPO antibodies strongly argues in favor of an AAV and against a diagnosis of PAN.

Pathology

The histology of PAN is characterized by segmental necrotizing vasculitis of medium-sized muscular arteries (Fig. 24.22). Focal areas of involvement, with disruption of the elastic laminae, result in vessel wall weakening and necrosis, leading to aneurysmal dilation and/or stenosis. In the skin, affected medium-sized vessels are located within the deep dermis and subcutaneous fat[117], although overlying small blood vessels and nearby fat lobules may be secondarily involved. DIF, if performed, may show deposits of C3, IgM, and fibrin within or around vessel walls, but this is of uncertain significance.

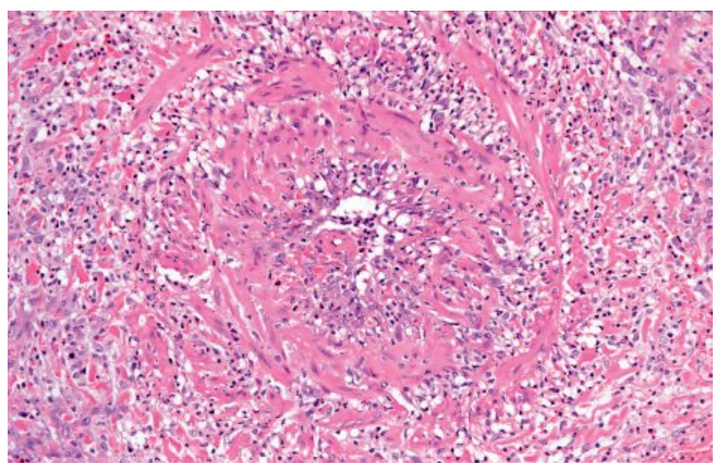

Fig. 24.22 Cutaneous polyarteritis nodosa (cutaneous arteritis) – histopathologic features. Vasculitis of a medium-sized vessel situated deep in the dermis. Neutrophils, neutrophilic debris, and fibrin within the arteriolar wall are seen. *Courtesy Lorenzo Cerroni, MD.*

Differential diagnosis

The diagnosis of PAN should be suspected based on characteristic symptoms, physical findings, and laboratory results. Biopsy of an involved organ (e.g. skin, muscle, nerve, kidney, testicle) to confirm

the presence of medium-sized vessel vasculitis should be performed whenever possible. Alternatively, detection of aneurysmal dilation and narrowing of renal and/or mesenteric vessels via angiography (conventional, CT, or MR) is often diagnostic.

The differential diagnosis of PAN is broad and includes cryoglobulinemic vasculitis, vasculitis secondary to autoimmune connective tissue disease (e.g. rheumatoid vasculitis), and AAV (see Table 24.9). In general, AAV can be distinguished from PAN by the presence of glomerulonephritis and pulmonary involvement in association with circulating ANCAs. There are several non-vasculitic diseases where aneurysmal dilations can be seen by angiography, including fibromuscular dysplasia, atherosclerosis, SLE, cholesterol emboli, Ehlers–Danlos syndrome, and emboli from infective endocarditis and left atrial myxoma.

The major entity in the differential diagnosis of cutaneous PAN is systemic PAN. A careful review of systems, angiography to assess involvement of visceral vessels, and diligent longitudinal evaluation are essential. Various panniculitides including erythema induratum (nodular vasculitis), calciphylaxis, cholesterol emboli, antiphospholipid syndrome, and other vasculopathies may have a similar presentation with livedo reticularis or racemosa, nodules, and ulcerations. Another entity to consider is lymphocytic thrombophilic arteritis (macular arteritis), which is characterized by livedo racemosa and reticulated hyperpigmentation on the lower extremities (see Fig. 106.3). Although histologic findings may be indistinguishable from cutaneous PAN, lymphocytic thrombophilic arteritis follows an indolent course and is rarely symptomatic. It may best be considered a forme fruste of cutaneous PAN and currently is not classified as an independent subtype of vasculitis[1].

When cutaneous lesions of PAN and livedo racemosa appear during childhood, the possibility of adenosine deaminase 2 (ADA2) deficiency should be considered; early-onset strokes are a serious manifestation of this disorder (see Table 45.7)[115]. A second autoinflammatory disorder, VEXAS syndrome (see above), is also in the differential diagnosis.

Treatment

Patients with mild *systemic PAN* should be treated with oral corticosteroids (e.g. 1 mg/kg/day of prednisone up to a maximum of 60–80 mg/day), tapered over 6 months. Approximately one-half of patients will achieve remission or cure with corticosteroids alone[106,120]. Azathioprine and methotrexate are commonly used steroid-sparing agents. Those with severe or refractory disease should receive corticosteroids plus cyclophosphamide for up to 12 months as initial therapy[106]. Treatment of HBV-associated PAN focuses first on eradication of the virus via antiviral agents[121]. Therapeutic alternatives are listed in Table 24.10.

Although it is often chronic and relapsing, *cutaneous PAN* follows a benign clinical course. Nevertheless, symptomatic disease generally warrants systemic therapy. Colchicine, dapsone, and azathioprine are commonly used and have favorable risk profiles[121a]. Case reports and expert opinion support a range of therapeutic alternatives as listed in Table 24.10. For mild disease, symptomatic relief may be achieved with NSAIDs alone.

TEMPORAL ARTERITIS (GIANT CELL ARTERITIS)

Rarely, cutaneous ulcers, primarily of the frontolateral scalp and tongue, can develop due to large vessel vasculitis (Fig. 24.23; see Table 24.1). Patients may have a history of headaches, jaw claudication, tenderness along the course of the temporal artery, and visual disturbances. They may also experience the muscle weakness associated with polymyalgia rheumatica. Cranial duplex ultrasound of the temporal artery is a non-invasive, but operator-dependent, option for initial diagnosis. In some centers, it has replaced temporal artery biopsy as the preferred initial diagnostic procedure. High-resolution MRI of cranial arteries is an alternative imaging modality with good sensitivity and specificity[122]. Plasma interleukin (IL)-6 levels may represent a marker of disease activity, and tocilizumab, an anti-IL-6 receptor antibody, is approved for the treatment of large vessel vasculitis[123]. High-dose corticosteroids are also employed as first-line therapy. In a phase 2 trial, mavrilimumab, an IgG4 monoclonal antibody which blocks GM-CSF signaling, demonstrated efficacy in maintaining clinical remission[123a].

DIAGNOSTIC APPROACH TO A PATIENT WITH SUSPECTED VASCULITIS

An approach to the patient with suspected cutaneous vasculitis is outlined in Figs. 24.19 and 24.24. Proper management includes clinicopathologic correlation and diagnosis, determination of any associated conditions, investigation for systemic involvement, and treatment.

History and Physical Examination

The clinician should assess the duration and acuity of symptoms and inquire about antecedent illnesses or exposures (e.g. medications). A history of autoimmune connective tissue disease or malignancy may be evident, but patients can present with cutaneous vasculitis as the initial sign of these diseases. The presence of systemic involvement (suggested by fever, weight loss, arthralgias, abdominal pain, paresthesias, cough, sinusitis, epistaxis, hematuria, or other focal symptoms) should be assessed via a thorough review of systems (see Fig. 24.19).

The cutaneous examination may be helpful in identifying the predominant vessel size affected (see Table 24.1 & Fig. 24.24). A complete head and neck, cardiopulmonary, abdominal, musculoskeletal, and neurologic examination should be performed in any patient in whom systemic vasculitis is suspected.

Laboratory Evaluation

A skin biopsy is necessary to assist in excluding entities that can mimic cutaneous vasculitis (see Table 24.3) and to identify the size of vessels involved. A fresh but well-developed lesion, e.g. one with both purpura and erythema, should be sampled in order to maximize the chance of obtaining characteristic histologic changes. If medium-sized vessel involvement is suspected, a deep punch, double-trephine ("telescoping") punch[124], or incisional biopsy that includes sufficient subcutaneous tissue should be performed. Biopsies obtained from nodules tend to have a higher diagnostic yield for medium-sized vessel vasculitis than those taken from an ulcer edge or livedo racemosa. Ulcers should be biopsied at their edge and include the peripheral rim of inflammation (if present), as incidental vasculitis can often be found underlying ulcers and is not a diagnostic finding. DIF should be routinely performed if immune complex-mediated small vessel vasculitis is suspected. Because immune complexes are degraded quickly by the inflammatory response, it is best performed on an early lesion.

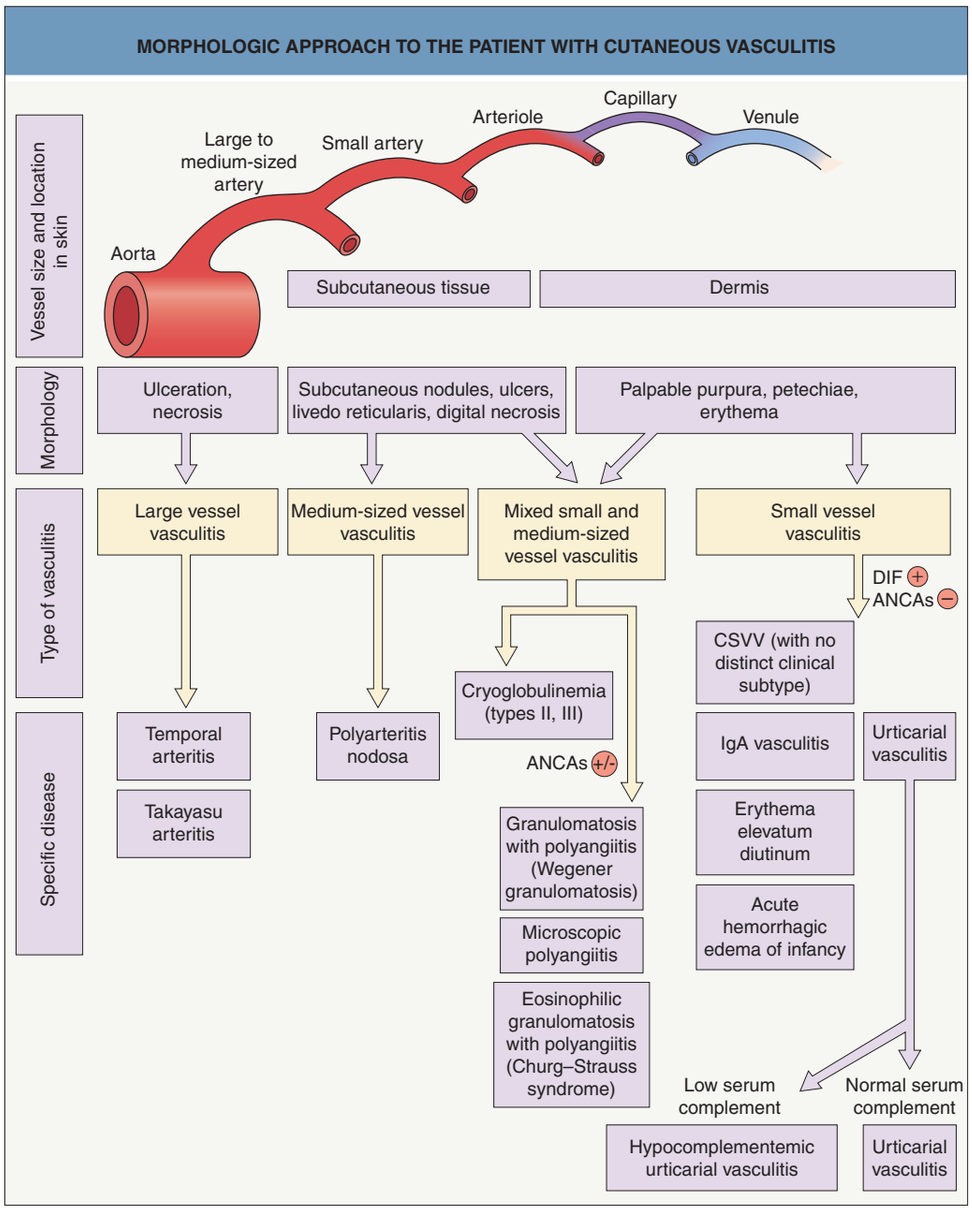

Fig. 24.24 Morphologic approach to the patient with suspected cutaneous vasculitis. ANCAs, anti-neutrophil cytoplasmic antibodies; CSVV, cutaneous small vessel vasculitis; DIF, direct immunofluorescence.

The laboratory evaluation of a patient with cutaneous vasculitis is outlined in Fig. 24.19. Basic testing should include a complete blood count, basic metabolic panel, and urinalysis. In straightforward initial episodes of small vessel vasculitis of the skin, in which the review of systems is negative, these studies may be all that are required. Additional tests can be performed in a stepwise fashion, based upon the suspected vasculitic syndrome or associated disease and as indicated by the patient's history, review of systems, and examination[13] (see Fig. 24.19 & Table 24.8). Laboratory tests to determine the extent of disease should be repeated with each subsequent episode of vasculitis. Tests for associated diseases are performed at baseline and only repeated if dictated by new information.

Treatment

The first step in the treatment of patients with cutaneous vasculitis is to determine whether the vasculitis is skin-limited or systemic as well as whether it is idiopathic or due to an associated disorder (e.g. autoimmune connective tissue disease) that must be addressed. Treatment is then based on the extent and severity of cutaneous and systemic involvement. Specific and detailed therapeutic approaches are discussed in conjunction with each disease and are outlined in Table 24.10. Along with an enhanced understanding of vasculitis pathogenesis has come a shift away from broad immunosuppression towards more targeted therapies[125].

Acknowledgment

The author wishes to thank David A. Wetter, MD, Jan Dutz, MD, Kanade Shinkai, MD, and Lindy P. Fox, MD, for their valuable contributions to this chapter in the previous editions.

INTRODUCTION

The neutrophilic dermatoses constitute a heterogeneous but linked spectrum of diseases[1], with significant overlapping histopathologic findings and similar pathogenic mechanisms and therapeutic approaches. They are often associated with underlying systemic diseases. Histologically, these disorders are characterized by perivascular and diffuse dermal or subcutaneous neutrophilic infiltrates without identifiable infectious agents (Fig. 25.1). The cutaneous manifestations vary, from urticarial plaques and vesiculopustules to nodules and ulcers. It is noteworthy that there may be several different types of clinical lesions in the same patient, simultaneously or sequentially. Cutaneous lesions may be localized or widespread, and in some patients, sterile neutrophilic infiltrates may occur in other organs including the lungs, eyes, joints, bones, heart, and kidneys. Peripheral neutrophilia may be present. Distinct entities have been defined by the nature of their clinical and histopathologic presentations as well as their associated diseases.

Patients with autoinflammatory disorders may develop neutrophilic dermatoses, from sterile pustules in DIRA (*d*eficiency of *I*L-1 *r*eceptor *a*ntagonist) to pyoderma gangrenosum in PAPA (*p*yogenic [sterile] *a*rthritis, *p*yoderma gangrenosum, and *a*cne) and PASH (*p*yoderma gangrenosum, *a*cne, and *s*uppurative *h*idradenitis) syndromes (see Tables 45.6 and 45.7). There is also overlap between neutrophilic dermatoses and neutrophilic urticaria (see Table 45.6).

NEUTROPHIL BIOLOGY

Granulocytes (neutrophils, eosinophils, and basophils) are cells essential to our defense against microbes as well as other inflammatory responses. The neutrophil is a terminally differentiated, non-dividing cell which is packed with granules whose contents kill and degrade target microorganisms. Recent advances in our understanding of neutrophil biology include the molecular and cellular mechanisms responsible for their production and release from the bone marrow (e.g. chemokine CXC receptor 4 [CXCR-4]; see Ch. 60); their recruitment, priming, and activation within inflamed tissues (Table 25.1); and the events resulting in their removal.

Granulocytes, including neutrophils, originate in the bone marrow from pluripotent cells where granulocyte colony-stimulating factor (G-CSF) plays a critical role in regulation of neutrophil development. To supply sufficient numbers of circulating cells, neutrophils are produced within the bone marrow at a prodigious baseline rate (>5–10 $\times$ 10^{10} neutrophils daily). The bone marrow also has the capacity to upregulate granulocyte production sharply in response to a number of stresses such as infection. Mature neutrophils appear to circulate in the peripheral bloodstream anywhere from 6 hours to up to 6 days before migrating into tissues; within such tissues the neutrophils survive for an additional 2 to 3 days. Senescent neutrophils, unlike platelets and erythrocytes, appear to be removed from the circulation following a return to the bone marrow where they undergo apoptosis.

Transcriptional profiling studies suggest that granulocytes arise via the selective expression of a subset of transcription factors (e.g. STAT3), granulocyte proteins (e.g. neutrophil elastase), and receptors (e.g. N-formyl-methionyl-leucyl-phenylalanine [fMLP]). Differentiation from pluripotent stem cells requires 7–10 days, and during this period, under the influence of cytokines, neutrophils acquire their characteristic appearance and granules (primary, secondary, and tertiary). The following stages of myeloid maturation are recognized: myeloblast, promyelocyte, myelocyte, metamyelocyte, band, and, finally, the segmented neutrophil. The progressive gain of differentiated characteristics is accompanied by a loss in the potential to proliferate, i.e. beyond the myelocyte stage, the cells are non-dividing. The intracellular granules acquired during maturation contain enzymes that mediate the oxidative and non-oxidative killing functions of the neutrophil[2]:

1. primary (azurophilic) granules – acquired at the promyelocyte stage and their contents include myeloperoxidase, lysozyme, neutrophil elastase, defensins, proteinase 3, cathepsin 3, and bactericidal/permeability-increasing protein
2. secondary granules – acquired at the transition to the myelocyte stage and their contents include lactoferrin, neutrophil collagenase, neutrophil gelatinase-associated lipocalin, and lysozyme
3. tertiary granules – acquired during later stages of neutrophil maturation and contain gelatinase B (matrix metalloproteinase 9) and leukolysin.

While much remains to be discovered about the pathophysiology of neutrophilic dermatoses, contributing factors include genetic predisposition, aberrant cell signaling and effector molecules, and ultimately abnormal neutrophil activity. Proinflammatory cytokines that play a key role in neutrophilic inflammation include IL-1β, TNF, and IL-17[2a]. The latter upregulates G-CSF activity, which is important for neutrophil differentiation and release, and it enhances production of IL-8. In addition to being a potent neutrophil chemoattractant, IL-8 has synergistic effects when combined with TNF. Under normal conditions, phagocytosis of neutrophils limits IL-23 secretion, and this in turn limits IL-17 activity[2b]. The response of neutrophilic dermatoses to inhibitors of IL-17, TNF, and IL-1 lends support to this proposed pathogenesis.

Inflammation

A critical role of inflammation is to deliver neutrophils and other leukocytes to a site of injury and then activate these cells to perform their function of protecting the host against infection. Neutrophils are among the first cells to arrive at sites of inflammation. Reasons for this include their abundance in the bloodstream and their rapid response to chemokines. When activated, neutrophils move at speeds up to 30 microns/min – the fastest cell in the body.

The motile responses of neutrophils to microbial infection include emigration out of the vasculature and movement toward the source of the inflammatory chemoattractant. This culminates in the phagocytic ingestion of opsonized microbes. In order to arrive at the site of infection, leukocytes must migrate out of the vasculature via margination, rolling, activation, and tight adhesion (see Ch. 102). They then move toward the site of injury or infection (see Table 25.1) and eventually undergo degranulation then apoptosis.

The price to be paid for the defensive potency of neutrophils for destroying microbes and necrotic tissues is that they can injure normal tissue. During activation and phagocytosis, neutrophils release products (e.g. lysosomal enzymes, reactive oxygen intermediates, products of arachidonic acid metabolism [prostaglandins and leukotrienes]) not just within

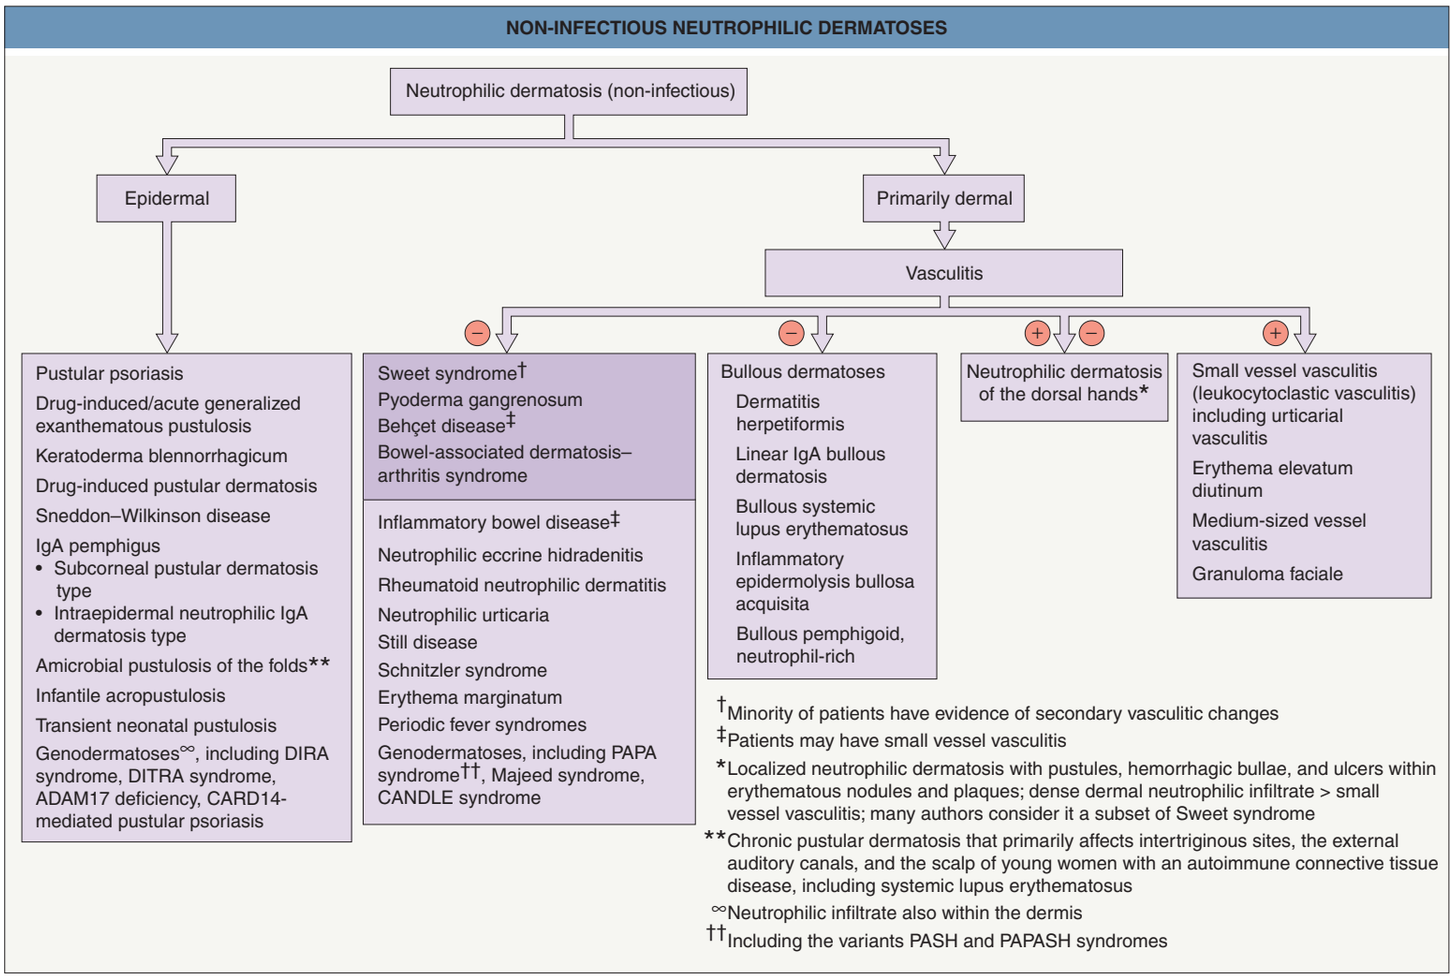

Fig. 25.1 Non-infectious neutrophilic dermatoses. Entities in the darker box are discussed in this chapter. CANDLE, chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature; DIRA, deficiency of the interleukin-1 receptor antagonist; DITRA, deficiency of the interleukin-36 receptor antagonist; PAPA, pyogenic arthritis, pyoderma gangrenosum, and acne; PAPASH, pyogenic arthritis, pyoderma gangrenosum, acne, and suppurative hidradenitis; PASH, pyoderma gangrenosum, acne, and suppurative hidradenitis.

the phagolysosome, but also into the extracellular space. Endothelial injury and tissue damage ensue, thus contributing to a number of acute and chronic diseases that affect the skin as well as other organs.

SWEET SYNDROME

Synonym: ■ Acute febrile neutrophilic dermatosis

Key features

- Constitutional signs and symptoms such as fever and malaise
- Clinically, erythematous plaques that are occasionally bullous
- Histologically, dense perivascular neutrophilic infiltrate, edema and, infrequently, bullae; leukocytoclasia with minimal to no evidence of vasculitis
- Associated conditions include infections, malignancies (especially acute myelogenous leukemia), inflammatory bowel disease, autoimmune disorders (e.g. systemic lupus erythematosus [SLE]), drugs, and pregnancy

History

The prototype of the neutrophilic dermatoses is Sweet syndrome. In 1964, Sweet[3] described eight middle-aged women who had an acute onset of fever and erythematous plaques associated with a nonspecific infection of the respiratory tract or gastrointestinal tract. Histologically, the skin lesions were characterized by a neutrophilic infiltrate. He named this constellation of findings "acute febrile neutrophilic dermatosis". In 1968, Whittle and colleagues reported a similar case and named it "Sweet's syndrome".

Epidemiology

Sweet syndrome is an uncommon disease, with a worldwide distribution and no obvious racial predilection, although the disorder appears to be more frequent in Japan. The average age of onset is 30–60 years, but infants, children, and the elderly may be affected; there is a female predominance of 4 to 1. At least half of patients have an identifiable associated disorder or trigger: 15%–30% have an internal malignancy (hematologic ≫ solid organ), ~25% a preceding infection, and ~10% exposure to a potentially causative drug (Table 25.2)[4–7]. While the epidemiologic statistics in part reflect associated underlying disorders including internal malignancies, inflammatory bowel disease, and autoimmune connective tissue diseases such as SLE[8], they do not completely explain the female predominance.

Pathogenesis

The pathogenesis of Sweet syndrome is poorly understood, but the association with underlying diseases suggests a hypersensitivity reaction. Local and systemic dysregulation of cytokine secretion, including inflammasome activation, has been observed. Implicated cytokines include IL-1, tumor necrosis factor (TNF), G-CSF,

NEUTROPHILS – THEIR RELATIONSHIP TO SITES OF INFLAMMATION
Intravascular adhesion, activation and migration
• Neutrophils are activated by chemoattractants (bacterial-derived and host-produced), ligands of selectins, immune complexes, and activated complement components to express β_2 integrins (e.g. LFA-1) that then adhere to ICAM-1 on endothelial cells (see Fig. 102.11) • Endothelial cells can be activated by thrombin, histamine, cytokines (e.g. IL-1β, TNF, IL-17), LPS/endotoxin, and immune complex–C1q aggregates to express adhesive molecules (e.g. P-selectin, E-selectin, ICAM-1, VCAM-1) • PSGL-1 and L-selectin on the neutrophil surface are critical for tethering of neutrophils to the vessel wall followed by rolling then firm adhesion via β_2 integrins (see above) • Diapedesis represents migration of cells through inter-endothelial spaces towards a chemical concentration gradient, i.e. towards a site of infection or injury
Migration within tissue
• Leukocytes adhere to matrix proteins and follow chemotactic gradients • In response to the binding of chemoattractants (e.g. fMLP, C5a, PAF, LTB_4), neutrophils change their shape and crawl by alternating the extrusion and retraction of frontal lamellipodia, where chemokine and phagocytic receptors are concentrated
Activation within tissue
• Upon arrival at the site of injury or infection, neutrophils become activated via several signaling pathways (e.g. MAPK/ERK, PKC, phospholipase A2, cytosolic $[Ca^{2+}]$) and surface receptors are expressed (e.g. Toll-like receptors, receptors for cytokines, opsonins) • Activation results in degranulation and secretion of lysosomal enzymes, activation of the oxidative burst, production of arachidonic acid metabolites, and secretion of cytokines
Phagocytosis
• Recognition and attachment of the particle to be ingested by the neutrophil is greatly enhanced by opsonization (coating by opsonins such as antibodies, complement or lectins), which targets it for phagocytosis • Binding of the particle to phagocytic neutrophil receptors initiates engulfment of the particle, which then fuses with a lysosomal granule, forming a phagolysosome
Degranulation
• Microbes are killed preferentially by oxygen-dependent, rather than oxygen-independent, mechanisms with formation of reactive oxygen intermediates • With discharge of the granule's contents into the phagolysosome, the neutrophil becomes degranulated • NETosis also occurs, representing the process of setting *n*eutrophil *e*xtracellular *t*raps; these traps are composed of histones and antimicrobial granular and cytoplasmic proteins • Neutrophils then rapidly undergo apoptosis and are ingested by macrophages

Table 25.1 Neutrophils – their relationship to sites of inflammation[2]. ERK, extracellular signal-regulated kinase; fMLP, N-formyl-methionyl-leucyl-phenylalanine (bacterial-derived formylated tripeptide); ICAM, intercellular adhesion molecule; IL, interleukin; LFA, lymphocyte function-associated antigen; LPS, lipopolysaccharide; LT, leukotriene; MAPK, mitogen-activated protein kinase; PAF, platelet-activating factor; PKC, phosphokinase C; PSGL-1, P-selectin glycoprotein ligand-1; TNF, tumor necrosis factor; VCAM, vascular cell adhesion molecule.

granulocyte–macrophage CSF (GM-CSF), and interferon-γ. A familial form of Sweet syndrome due to heterozygous mutations in *MEFV* (e.g. S242R) has been described[9]. Of note, this gain-of-function mutation in *MEFV* differs from those seen in familial Mediterranean fever. The term *pyrin-associated autoinflammatory disease* has been applied to these patients. As in PG and a murine model of neutrophilic dermatoses, the possibility that splice variants in *PTPN6* play a role in Sweet syndrome has been raised[10].

In hematologic malignancy-associated Sweet syndrome, the neutrophils in the cutaneous infiltrate and the malignant myeloid clone appear to share a clonal progenitor. This was observed when the skin lesions were present at the time of diagnosis as well as when they developed during treatment[11]. Thus, the inciting factors for malignancy-associated and familial Sweet syndrome likely differ from those of "classic" or drug-induced disease. However, downstream effectors presumably overlap with an end result of aberrant activation of neutrophils.

Clinical Features

The initial cutaneous lesions are tender, non-pruritic, erythematous plaques or papules, which may enlarge or coalesce to form plaques with an uneven mammillated surface (Fig. 25.2 & 25.3). Because of the pronounced associated edema, the lesions may have a pseudovesicular or pseudopustular appearance; however, some patients actually develop vesiculation, bullae, or pustules within their plaques. Occasionally, the plaques have a central yellowish discoloration creating a targetoid appearance. A facial erysipelas-like appearance has also been described as has a giant cellulitis-like variant. A relapsing localized variant can develop within areas of lymphedema or at sites of orthopedic implants[12]. The vesiculobullous variant, which is most frequently associated with acute myelogenous leukemia, can progress to ulceration resembling superficial pyoderma gangrenosum (PG). In this form, there may be a single lesion or multiple, asymmetrically distributed lesions.

The cutaneous eruption of Sweet syndrome favors the head, neck, and upper extremities (including the dorsal aspect of the hands), but can occur anywhere. In true malignancy-associated cases, the lesions tend to have a more widespread distribution. Papulonodules involving the lower legs may resemble erythema nodosum and although erythema nodosum has been reported in patients with Sweet syndrome, such nodules more likely represent a neutrophilic panniculitis. When isolated, the latter is often referred to as subcutaneous Sweet syndrome. A subset of patients, often with systemic involvement, can develop lesions that mimic necrotizing fasciitis, referred to as necrotizing neutrophilic dermatosis[13]; such lesions are also seen in patients with PG.

As with PG, specific lesions may be initiated by wounding injuries such as needle sticks, thermal burns, and surgical incisions. This phenomenon is known as pathergy. Oral lesions are uncommon, except in patients with hematologic disorders; initially they appear pseudopustular, and later ulcerate and appear as aphthae. The cutaneous eruption of Sweet syndrome usually resolves spontaneously within 5–12 weeks but recurs in up to 30% of patients.

An upper respiratory tract infection or flu-like illness frequently precedes the development of the syndrome. Fever occurs in 40%–80% of patients and can be intermittent. Extracutaneous involvement is also frequently seen (Fig. 25.4; Table 25.3).

Associated Diseases

These are summarized in Table 25.2 and should guide the history, including all medications, physical examination, and focused laboratory evaluation[4].

SWEET SYNDROME – ASSOCIATED DISORDERS AND TRIGGERS	
Infections	
• Viruses: **upper respiratory tract infections**, cytomegalovirus, hepatitis B virus, hepatitis C virus, HIV • Bacteria: *Yersinia*, streptococci • Mycobacteria: atypical mycobacteria, BCG vaccination, *M. tuberculosis*, *M. leprae* • Fungi: dimorphic, including sporotrichosis and coccidioidomycosis	
Malignancies	
• Hematologic (10%–20% of cases*), in particular **acute myelogenous leukemia** • **Myelodysplasia**, including VEXAS syndrome • Solid organ, predominantly the more common primary carcinomas	
Gastrointestinal disorders	
• **Inflammatory bowel disease: Crohn disease, ulcerative colitis**	
Drugs	
Most common	
• Colony stimulating factors (e.g. G-CSF, GM-CSF, pegfilgrastim)	• All-*trans*-retinoic acid (ATRA) > other retinoids
• Azathioprine	• Proteosome inhibitors (e.g. bortezomib)
Less common	
• Antibiotics (e.g. minocycline > TMP-SMX, quinolones)	• DNA hypomethylating drugs (e.g. decitabine, azacitidine)
• Hydralazine**	• FLT3 inhibitors
• NSAIDs (e.g. celecoxib)	• TNF inhibitors (e.g. adalimumab)
Uncommon (selected)	
• Abacavir	• BRAF inhibitors (e.g. vemurafenib)
• Furosemide	• Imatinib
• Immune checkpoint inhibitors (e.g. ipilimumab)	• Interferons
• Lenalidomide	• Oral contraceptives
• Propylthiouracil	• Vaccinations (e.g. BCG, pneumococcal)
Autoimmune disorders	
• Autoimmune connective tissue diseases (e.g. systemic lupus erythematosus [SLE]†, rheumatoid arthritis, dermatomyositis, relapsing polychondritis, Sjögren syndrome), autoimmune thyroid disease • Sarcoidosis • Behçet disease	
Immunodeficiencies	
• Anti-interferon-γ autoantibodies	
• Common variable immunodeficiency	
*Includes acute and chronic myelogenous leukemia, chronic lymphocytic leukemia, non-Hodgkin disease, Hodgkin disease, myeloma, and other myeloproliferative disorders. **Can simultaneously induce ANCA-positive vasculitis. †Some authors use the terms non-bullous neutrophilic LE or neutrophilic dermatosis in conjunction with LE rather than Sweet syndrome associated with SLE.	

Table 25.2 Sweet syndrome – associated disorders and triggers. The most common associations are in **bold**. BCG, bacillus Calmette–Guérin; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage CSF; HIV, human immunodeficiency virus; NSAIDs, nonsteroidal anti-inflammatory drugs; TMP-SMX, trimethoprim–sulfamethoxazole; TNF, tumor necrosis factor; VEXAS, vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic.

Fig. 25.2 Sweet syndrome. A Scattered edematous pink papules and plaques on the chest. **B** The edema can be quite marked as seen in these lesions on the upper back. *B, Courtesy Kalman Watsky, MD.*

Fig. 25.3 Sweet syndrome. A The periocular lesion demonstrates how some lesions can mimic cellulitis (pseudocellulitis). This patient also had neutrophilic esophageal ulcerations and subsequently developed colon cancer. **B** The plaques can have a pseudomammillated appearance due to the associated edema. **C** Hemorrhagic crusts may develop within the papules and plaques and in patients with acute leukemia and/or neutropenia, infectious etiologies are often the initial clinical diagnosis. *C, Courtesy Kalman Watsky, MD.*

Fig. 25.4 Sweet syndrome – ocular involvement. Obvious erythema and hemorrhage involving the sclera and conjunctiva. *Courtesy Kalman Watsky, MD.*

SYSTEMIC MANIFESTATIONS OF SWEET SYNDROME
Common (≥50%)
Fever Leukocytosis
Less common (20%–50%)
Arthralgias Arthritis: asymmetric, non-erosive, sterile, favors knees and wrists Myalgias Ocular involvement: conjunctivitis, episcleritis, limbal nodules, iridocyclitis
Uncommon
Neutrophilic alveolitis: cough, dyspnea and pleurisy; radiographic findings include interstitial infiltrates, nodules, pleural effusions Multifocal sterile osteomyelitis, a subtype of SAPHO (see Table 25.18) Renal involvement (e.g. mesangial glomerulonephritis): hematuria, proteinuria, renal insufficiency, acute renal failure
Unusual/rare
Acute myositis Hepatitis, pancreatitis, ileitis, colitis Aseptic meningitis, encephalitis, bilateral sensorineural hearing loss Other: aortitis, oral aphthae, pharyngitis, pharyngeal edema

Table 25.3 Systemic manifestations of Sweet syndrome[5,6]. SAPHO, synovitis, acne, pustulosis, hyperostosis and osteitis.

Pathology

The histopathologic features are contingent upon the type of cutaneous lesion sampled. The characteristic histologic presentation is a dense, diffuse dermal nodular and perivascular neutrophilic infiltrate without evidence of vasculitis (Fig. 25.5), although occasionally leukocytoclastic vasculitis (LCV) can be observed[14]. Leukocytoclasia with endothelial swelling, but without the fibrinoid necrosis that fulfills the criteria for LCV, is the usual finding. Occasionally, the dermal infiltrate may extend into the subcutis, creating a septal or, less frequently, a lobular panniculitis. Isolated neutrophilic panniculitis has been described.

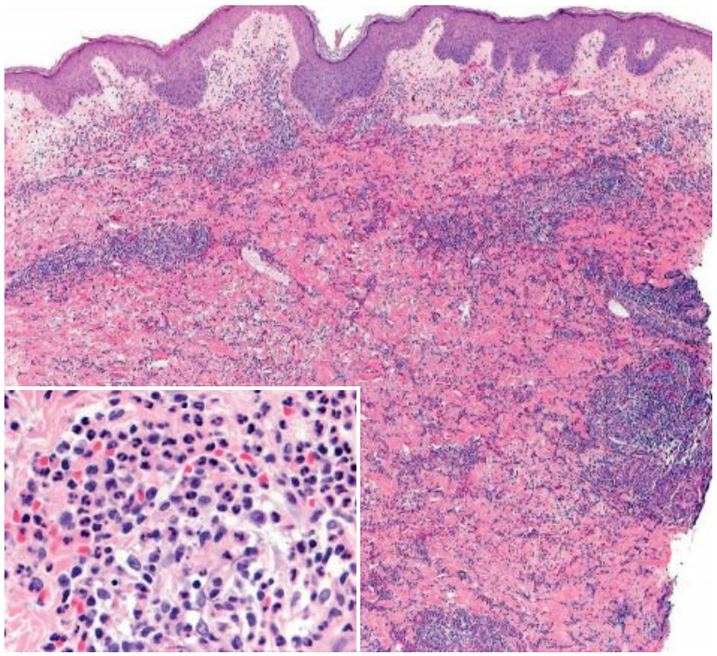

Fig. 25.5 Sweet syndrome – histopathologic features. Mild edema in the papillary dermis and a rather dense dermal infiltrate composed predominantly of neutrophils (inset). *Courtesy Lorenzo Cerroni, MD.*

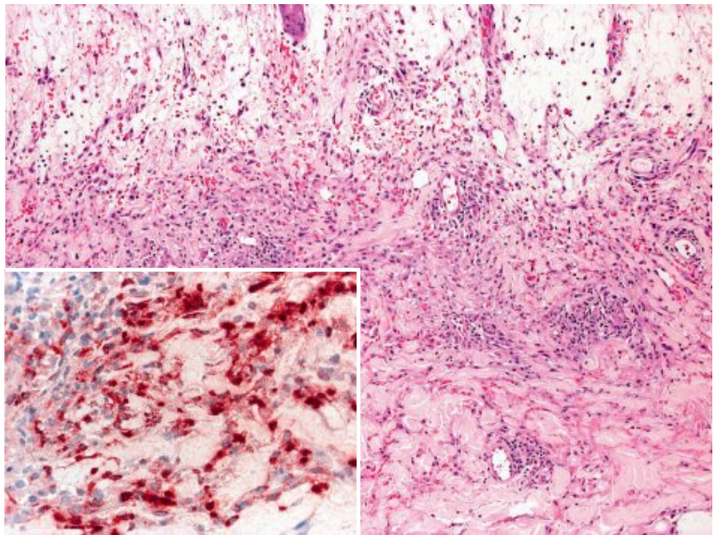

Fig. 25.6 Histiocytoid Sweet syndrome – histopathologic features. There is edema in the papillary dermis as well as a dermal infiltrate composed of histiocytoid cells admixed with neutrophils, a few eosinophils, and hemorrhage. The histiocytoid cells represent immature myeloid cells and therefore have stained positively for myeloperoxidase (inset). *Courtesy Lorenzo Cerroni, MD.*

In general, epidermal changes are not significant. However, neutrophils occasionally invade the epidermis, producing subcorneal pustules, and they may also infiltrate the adnexa. In the setting of significant edema, there can be epidermal spongiosis and sometimes reticular degeneration as well as intraepidermal and subepidermal vesiculation.

Three histologic variants of Sweet syndrome, histiocytoid, lymphocytic and eosinophilic, have been increasingly recognized. The histiocytoid variant is characterized by a dermal, and sometimes subcutaneous, infiltrate composed of histiocyte-like immature myeloid cells. These cells have myeloperoxidase activity (Fig. 25.6) and must be distinguished from those of leukemia cutis (bearing in mind that cells related to the malignant clone have been identified in some cases of histiocytoid Sweet syndrome associated with myelogenous leukemia). The lymphocytic variant is often associated with, and sometimes precedes, underlying myelodysplasia[15,16]. More recently, an eosinophilic variant has been described[17]. In a retrospective review, patients with the histiocytoid variant or subcutaneous involvement were more likely to have malignancy-associated disease[18].

CRITERIA FOR DIAGNOSIS OF SWEET SYNDROME
Major criteria
1. Abrupt onset of typical cutaneous lesions 2. Histopathology consistent with Sweet syndrome
Minor criteria
1. Preceded by one of the associated infections or vaccinations; accompanied by one of the associated malignancies or inflammatory disorders; associated with drug exposure or pregnancy 2. Presence of fever and constitutional signs and symptoms 3. Leukocytosis 4. Excellent response to systemic corticosteroids

Table 25.4 Criteria for diagnosis of Sweet syndrome. Both of the major and two minor criteria are needed for the diagnosis. *Reprinted with permission from Cutis. 1986;37:167–74. ©1986, Frontline Medical Communications Inc.*

Diagnosis and Differential Diagnosis

Although there are no specific diagnostic findings in this disease, a peripheral leukocytosis with neutrophilia and an elevated ESR and C-reactive protein (CRP) are frequently seen. In patients with an associated hematologic malignancy or myelodysplasia, there may be a high or low white cell count, lymphocytosis or lymphopenia, and thrombocytosis or thrombocytopenia. Although elevated serum levels of anti-neutrophil cytoplasmic antibody (ANCA) have been reported[19], in particular pANCA or an atypical ANCA, there is no strong evidence that it is a serologic marker for this disease.

In 1986, Su and Liu[20] proposed two major and four minor criteria for the diagnosis of Sweet syndrome, which have been widely accepted and are shown with minor revisions in Table 25.4. The differential diagnosis of the syndrome depends on the nature and age of the lesions and on the associated disorder (Table 25.5; see Fig. 25.1).

Patients with *neutrophilic dermatosis of the dorsal hands* develop tender, erythematous to violaceous plaques that may become bullous or ulcerative (Fig. 25.7)[21–23]. There is a spectrum of associated histologic features, from pustular vasculitis to those of PG or Sweet syndrome. Hence, some authors consider this to be a variant of Sweet syndrome.

In patients with hematologic malignancies, especially acute myelogenous leukemia, several neutrophilic dermatoses, e.g. Sweet syndrome, atypical (bullous) PG, and neutrophilic eccrine hidradenitis, can occur alone or in combination. The approach to such a patient is presented in Table 25.6.

In patients with rheumatoid arthritis, the possibility of rheumatoid neutrophilic dermatitis, including the uncommon annular variant, needs to be considered[24,25]. As noted in Table 25.5, Sweet syndrome can also mimic soft tissue infections, including cellulitis and necrotizing fasciitis[26,27]. This distinction can prove challenging, especially in immunocompromised hosts.

Treatment

When limited to the skin, Sweet syndrome is a benign condition which, if left untreated, may persist for weeks or months. Cutaneous lesions then involute spontaneously, rarely leaving scars. However, recurrences develop in ~30% of patients (with or without treatment) and occur even more often in those with hematologic disorders (~50%). Although the initial clinical presentation often suggests sepsis, antibiotics, in general, are ineffective. However, when the disease is associated with a recognized infection, treatment of the underlying infection may result in improvement.

The most effective therapy for Sweet syndrome is oral prednisone (0.5–1.0 mg/kg/day) for 2–6 weeks. There is prompt relief of not only the cutaneous, but also the extracutaneous, manifestations. In some patients, prolonged low-dose prednisone for an additional 2–3 months may be necessary to suppress recurrences. When the lesions are few and localized, topical superpotent or intralesional corticosteroids may prove helpful.

THE DIFFERENTIAL DIAGNOSIS OF SWEET SYNDROME
Inflammatory dermatoses
• *Pyoderma gangrenosum (bullous)* • *Neutrophilic dermatosis of the dorsal hands** • Neutrophilic eccrine hidradenitis • Rheumatoid neutrophilic dermatitis (dermatosis) • Palisaded neutrophilic and granulomatous dermatitis, especially early lesions • Other neutrophilic dermatoses (see Fig. 25.1) • Neutrophilic urticaria (e.g. Schnitzler syndrome) • Autoinflammatory diseases (see Tables 45.6 & 45.7) • Periodic fever syndromes (see Table 45.2) • Erythema multiforme • Urticarial vasculitis • Erythema elevatum diutinum • *Behçet disease* • *Bowel-associated dermatosis–arthritis syndrome* • Panniculitis, including erythema nodosum • Halogenoderma (iododerma or bromoderma) • Eosinophilic dermatoses (e.g. exaggerated arthropod bite reactions, Wells syndrome) • Autoimmune connective tissue diseases – acute, subacute, and neonatal lupus erythematosus • Interstitial granulomatous dermatitis
Infections
• Cellulitis, pyoderma, furunculosis • Septic vasculitis • Cryptococcosis† and dimorphic fungal infections • Mycobacterial infections
Neoplasms
• Leukemia cutis > lymphoma cutis
*Most authors consider this a variant of Sweet syndrome. †In cryptococcoid Sweet syndrome, the histopathologic findings can mimic cutaneous cryptococcosis.

Table 25.5 The differential diagnosis of Sweet syndrome[5,6]. Entities discussed in this chapter are in *italics*.

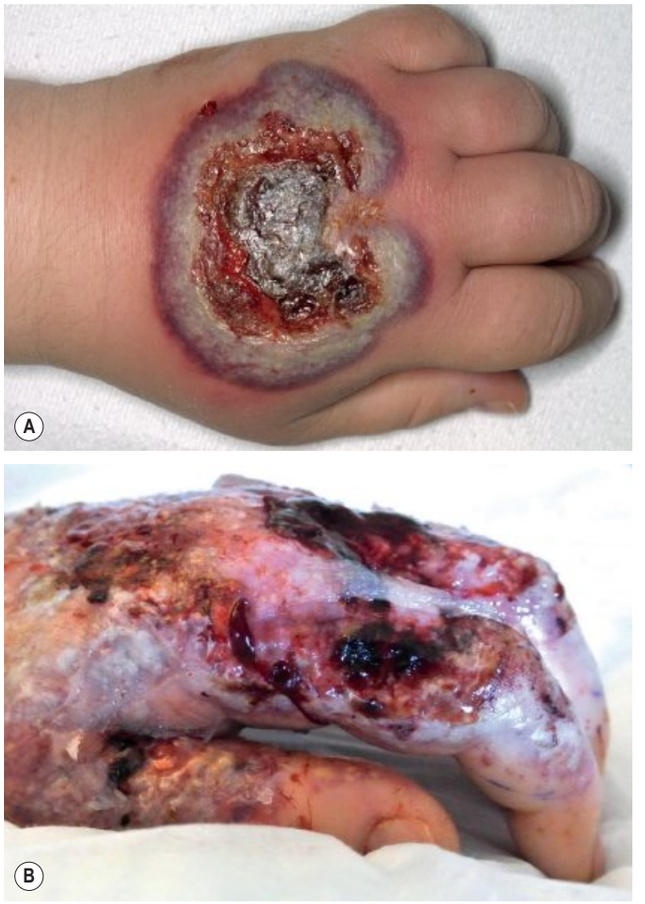

Fig. 25.7 Neutrophilic dermatosis of the dorsal hands. A Clinically and histologically, there is overlap with Sweet syndrome and bullous pyoderma gangrenosum. **B** More extensive necrotizing disease can be confused with an infectious process such as necrotizing cellulitis or necrotizing fasciitis.

NEUTROPHILIC DERMATOSES ASSOCIATED WITH HEMATOLOGIC MALIGNANCIES			
	Sweet syndrome	**Atypical (bullous) pyoderma gangrenosum**	**Neutrophilic eccrine hidradenitis**
Clinical manifestations			
• Cutaneous	Painful plaques and nodules with occasional blisters and pustules within lesions	Hemorrhagic bullae and superficial ulcerations	Erythematous edematous plaques and papules which may be painful, infrequent pustules
	Favors face, upper extremities and trunk	Favors face and upper extremities (especially dorsal hands)	Favors face, extremities, trunk
	Can recur (30%–50% of patients)	Can recur	Resolves spontaneously over ~2 weeks without scarring Can recur
• Systemic	Fever, arthralgia or arthritis Multiorgan involvement (Table 25.3) Neutrophilia Elevated ESR	Systemic features usually absent	Fever, neutropenia*
Histopathology	Papillary edema with dense dermal neutrophilic infiltrate Histiocytoid variant – histiocyte-like immature myeloid cells Lymphocytic variant – in the setting of myelodysplasia	Subepidermal hemorrhagic bullae Pustules with neutrophilic dermal infiltrate	Neutrophilic† infiltrate around and within eccrine glands, necrosis of eccrine epithelium, and sometimes eccrine squamous syringometaplasia
Associations	Infections, hematologic malignancies > solid tumors, IBD, autoimmune diseases, pregnancy, G-CSF, all-*trans*-retinoic acid (see Table 25.2)	Hematologic disorders, especially acute myelogenous leukemia, IgA monoclonal gammopathy and myelodysplasia, IBD, G-CSF	Leukemia with or without chemotherapy; post-chemotherapy for lymphoma and solid tumors; G-CSF; rarely infections
Primary treatment (in addition to treatment of underlying disease)	Systemic corticosteroids (0.5–1 mg/kg/day for 4–6 weeks), potassium iodide (900 mg/day), dapsone (100–200 mg/day), colchicine (1.0–1.5 mg/day or 1.2–1.8 mg/day‡) (see Table 25.11)	Systemic corticosteroids (see Table 25.11)	None (spontaneous resolution)
*Usually in setting of chemotherapy. †May be lymphocytic in setting of chemotherapy-induced neutropenia. ‡In the US, tablets are 0.6 mg; in other countries, tablets can be 0.5 mg.			

Table 25.6 Neutrophilic dermatoses associated with hematologic malignancies[6,18]. G-CSF, granulocyte colony-stimulating factor; IBD, inflammatory bowel disease.

The major alternative drugs are potassium iodide (900 mg/day; see Table 100.6), dapsone (100–200 mg/day), and colchicine (1–1.5 mg/day or 1.2–1.8 mg/day, depending upon dosage of commercially available tablets). They can also be used as corticosteroid-sparing agents. Nonsteroidal anti-inflammatory drugs (e.g. indomethacin, naproxen, sulindac), cyclosporine, thalidomide, lenalidomide, anakinra, methotrexate, and rituximab have also been reported to lead to improvement of Sweet syndrome. Evidence for any of these therapeutic regimens is based on case reports or small case series. Of note, while TNF inhibitors have been used to treat refractory Sweet syndrome, they can also be a cause of drug-induced Sweet syndrome.

PYODERMA GANGRENOSUM

Key features

- Four major clinical forms: ulcerative, bullous, pustular, and superficial granulomatous; additional variants include mucosal, peristomal, postsurgical, and necrotizing neutrophilic dermatosis
- Initial lesion is often a pustule on an erythematous or violaceous base, an erythematous nodule, or a bulla
- Characteristic lesion is an expanding ulcer with a necrotic undermined border; the base may be purulent or vegetative
- Histologically, a sterile dermal or adnexal abscess (without a vasculopathy) is seen in active, untreated, expanding lesions
- Associated illnesses include inflammatory bowel disease, arthritis, monoclonal gammopathies, and other hematologic disorders

Introduction

Pyoderma gangrenosum (PG) is an uncommon, chronic, recurrent, cutaneous ulcerative disease with a distinctive morphologic presentation. The laboratory and histopathologic findings can vary and therefore the diagnosis requires clinicopathologic correlation. This neutrophilic dermatosis is frequently associated with systemic disease[28–31].

History

In 1908, Brocq described a series of patients with skin ulcers he called "geometric phagedism". Two decades later, Brunsting, Goeckerman, and O'Leary coined the term "pyoderma gangrenosum" and advanced the theory that it had an infectious etiology (streptococci and staphylococci)[29].

Epidemiology

PG is a global disease. It can occur at any age but most commonly afflicts women between 20 and 50 years of age. Nearly half of the patients have an underlying systemic disease, most commonly inflammatory bowel disease, arthritis, or a hematologic disorder (e.g. IgA monoclonal gammopathy, acute myelogenous leukemia, myelodysplasia). Approximately 4% of cases of PG occur in infants and children. PG is also a cutaneous manifestation of several monogenic autoinflammatory diseases (see Tables 45.6 and 45.7).

Pathogenesis

Although the disease is idiopathic in 25%–50% of patients, an underlying immunologic abnormality is currently favored, given its frequent association with systemic diseases that have a suspected autoimmune pathogenesis. The association of PG with several autoinflammatory diseases points to aberrant activation of the innate immune system. In particular, enhanced activity of the IL-1 pathway is thought to play a role, as it does in several autoinflammatory disorders (see Fig. 4.2)[32]. In lesional skin biopsies, overexpression of IL-1α, IL-1β, and the IL-1 receptor as well as IL-8, IL-17, and TNF has been reported. Elevated serum levels of IL-1β have also been observed, and clinical improvement of PG following administration of the anti-IL-1β antibody canakinumab provides additional support for this proposed pathogenesis.

The adaptive immune system may also play a role as cytokines involved in the Th1/Th17 pathways (e.g. IL-23) and the JAK/STAT pathway have been implicated in the pathogenesis of PG. Pathergy is seen in 20%–30% of patients with PG and not only does this phenomenon lead to new cutaneous lesions but it can also aggravate them. Overexpression of IL-8 and IL-36 may contribute to this reaction to minor trauma.

Additional insights into the pathogenesis of PG should come from a better understanding of the monogenic primary immunodeficiencies and autoinflammatory disorders associated with PG (see below). As noted previously, based upon findings from a murine model of neutrophilic dermatoses, splice variants in *PTPN6* may play a role in PG as well as Sweet syndrome[10].

Clinical Features

Although the classic morphologic clinical presentation of PG is an ulcer, there are several variants (bullous, pustular, and superficial granulomatous/vegetative) which differ by their clinical presentation, location, and associated diseases (Table 25.7; Fig. 25.8 & 25.9)[28]. Cutaneous lesions are painful and most frequently occur on the lower extremities in patients with typical (classic) PG, especially the pretibial area (Fig. 25.10A,B,D), but they can occur anywhere (Fig. 25.10C,E), including

CLINICAL VARIANTS OF PYODERMA GANGRENOSUM
Vesiculobullous (also referred to as atypical or bullous PG)
• Lesions favor the face and upper extremities, especially the dorsal hands • Clinical appearance overlaps with the superficial bullous variant of Sweet syndrome (Fig. 25.8) • Occurs most commonly in the setting of acute myelogenous leukemia, myelodysplasia, IgA monoclonal gammopathy, and myeloproliferative disorders such as chronic myelogenous leukemia
Pustular
• Multiple, small, sterile pustules • Lesions usually regress without scarring, but can evolve into classic PG • Most commonly observed in patients with inflammatory bowel disease • Similar eruption may be seen in patients with Behçet disease or bowel-associated dermatosis–arthritis syndrome
Superficial granulomatous
• Localized, superficial vegetative or ulcerative lesion, which favors the trunk and usually follows trauma (e.g. surgery); may have verrucous border • Histologically, a superficial granulomatous response with a less intense neutrophilic infiltrate • Responds to less aggressive anti-inflammatory therapy • Controversy as to whether it is a variant of PG, a separate disorder, or related to granulomatosis with polyangiitis
Pyoderma/pyostomatitis vegetans
• Chronic, vegetative pyoderma of the labial and buccal mucosa (Fig. 25.9A) • May be associated with vegetative or ulcerative cutaneous PG (Fig. 25.9B) • Large verrucous plaques that may be studded with pustules • Seen in patients with inflammatory bowel disease

Table 25.7 Clinical variants of pyoderma gangrenosum (PG). Additional variants include peristomal, postsurgical/postoperative, and necrotizing neutrophilic dermatosis.

Fig. 25.8 Bullous pyoderma gangrenosum. This patient had ulcerative colitis.

Fig. 25.10 Pyoderma gangrenosum (PG) – clinical presentations. A, B Typical (classic) form in which the ulcer has an undermined and overhanging violet–gray edge as well as a surrounding violaceous border. **C** Grouped sterile pustular nodules. **D** Central ulceration surrounded by inflammatory papules and pustules. **E** Deeper ulcer with vegetative and pustular base. **F** Centrally, there is healing with cribriform (sievelike) scarring.

on mucous membranes and peristomal sites (Fig. 25.11A). A vulvovaginal variant has been observed in patients who have received rituximab.

The lesions of PG usually begin as a tender papulopustule (Fig. 25.12) with surrounding erythematous or violaceous induration, an erythematous nodule, or a bulla on a violaceous base; the papulopustule may be follicular. All these lesions then undergo necrosis leading to a central shallow or deep ulcer; loss of tissue can expose underlying tendons or muscles. When fully developed, the ulcer has a purulent base with an irregular, undermined and overhanging, gunmetal-colored border which extends centrifugally (see Fig. 25.10A,B). This border may have surrounding erythema. Re-epithelialization occurs from the margins and the ulcers heal with atrophic cribriform pigmented scars (Fig. 25.10F).

In PG, the number of ulcers can vary from one to over a dozen, and sometimes they coalesce (Fig. 25.11B). Although the ulcers are classically described as rapidly expanding, some are less inflammatory and expand more slowly. The latter may require less aggressive therapeutic interventions.

In patients with hematologic disorders or in drug-induced cases, the clinical course is often characterized by an acute onset of hemorrhagic or purulent bullous lesions, with a more widespread distribution that can include the upper extremities, particularly the dorsal hands, as well as the face. These lesions rapidly necrose and are often associated with fever and signs of toxicity. In those patients with associated inflammatory diseases, such as inflammatory bowel disease or arthritis, the more characteristic presentation is a chronic, slowly enlarging ulcer with excessive granulation tissue in its base and sometimes with evidence of spontaneous regression.

Clinical variants have been described based on the clinical presentation (see Table 25.7) or the location of the lesion (e.g. peristomal[33], mucosal including the genitalia) or the age of the afflicted[30]. While the clinical appearance of PG in children is similar to that in adults, the lesions more frequently involve the head and anogenital region[34]. As with Sweet syndrome, extracutaneous sterile neutrophilic infiltrates have been reported in the bones, lung, liver, pancreas, spleen, kidneys, and CNS of patients with PG[35].

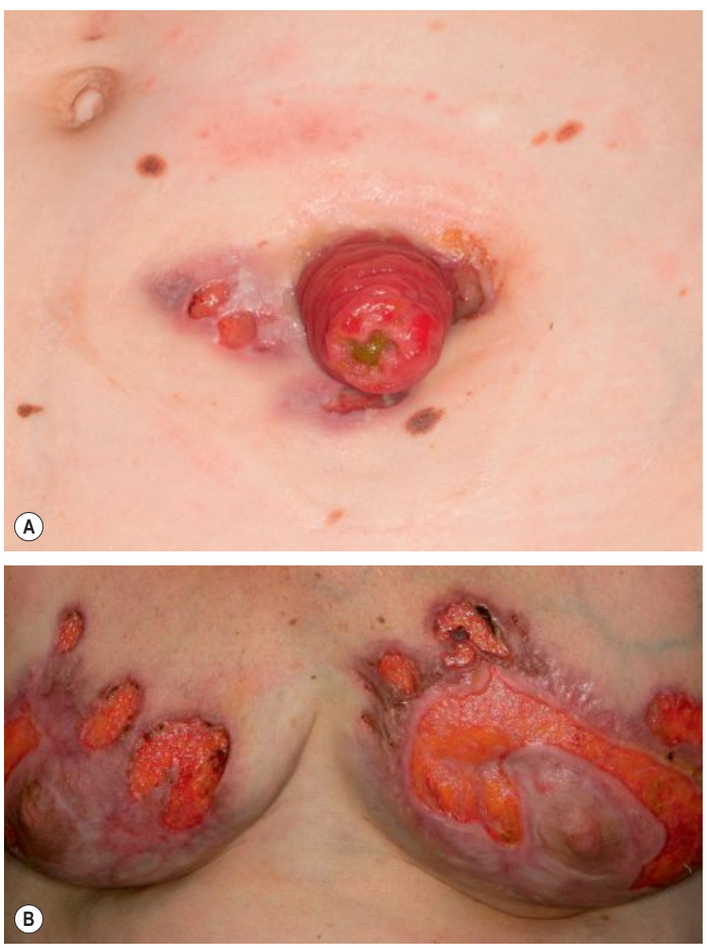

Fig. 25.11 Peristomal and postsurgical pyoderma gangrenosum (PG). **A** Several ulcers surround an ileostomy in a patient who had a total proctocolectomy performed because of refractory chronic ulcerative colitis. **B** Multiple ulcerations of the breasts following breast reduction. Because the original diagnosis postoperatively was soft tissue infection, multiple debridements had been performed and systemic antibiotics administered.

Associated Diseases

Between 50% and 70% of patients with PG have an antecedent, coincident, or subsequent associated disease or condition. The most common associations are inflammatory bowel disease (ulcerative colitis or Crohn disease [20%–30%]), arthritis (seronegative arthritis, spondylitis of inflammatory bowel disease or rheumatoid arthritis [20%]), and hematologic disease (in particular, acute > chronic myelogenous leukemia, myelodysplasia, hairy cell leukemia, and monoclonal gammopathy [15%–25%]). The monoclonal gammopathy is often composed of IgA.

Individuals with the autoinflammatory PAPA (*p*yogenic [sterile] *a*rthritis, *P*G and *a*cne) syndrome have been shown to have mutations in *PSTPIP1*, which encodes a CD2-binding protein, presumably leading to abnormal inflammatory responses (Fig. 25.13). PG-like lesions are also seen in patients with PASH and PAPASH syndromes (see Table 45.6), as well as in primary immunodeficiencies, e.g. leukocyte adhesion deficiency-1, common variable immunodeficiency due to *NFKB1* mutations (see Table 60.1).

Other neutrophilic dermatoses that have been reported in association with PG are subcorneal pustular dermatosis, Behçet disease, and Sweet syndrome.

Fig. 25.12 The earliest clinical lesion in pyoderma gangrenosum is a pustule with an inflammatory base. This patient had Crohn disease.

Fig. 25.13 Pyoderma gangrenosum in a patient with PAPA syndrome. Individuals with this monogenic autoinflammatory disorder have pyogenic sterile arthritis, pyoderma gangrenosum and acne. *Courtesy Maria Chanco Turner, MD.*

Pathology

The histopathology of PG can be nonspecific, especially when the disease is partially treated or minimally inflamed, and therefore be nondiagnostic. In early lesions, there is a neutrophilic vascular reaction, which can be folliculocentric. Neutrophilic infiltrates, often with leukocytoclasia, are seen in active, untreated, expanding lesions (Fig. 25.14). In fully developed ulcers, there is marked tissue necrosis with surrounding mononuclear cell infiltrates. In most patients with typical PG, chronic ulcers have fibrosing inflammation at the edge of the ulcer bed. Although biopsy specimens of PG may show nonspecific changes, histopathologic examination, often accompanied by tissue culture, assists in excluding other entities that can mimic PG[31].

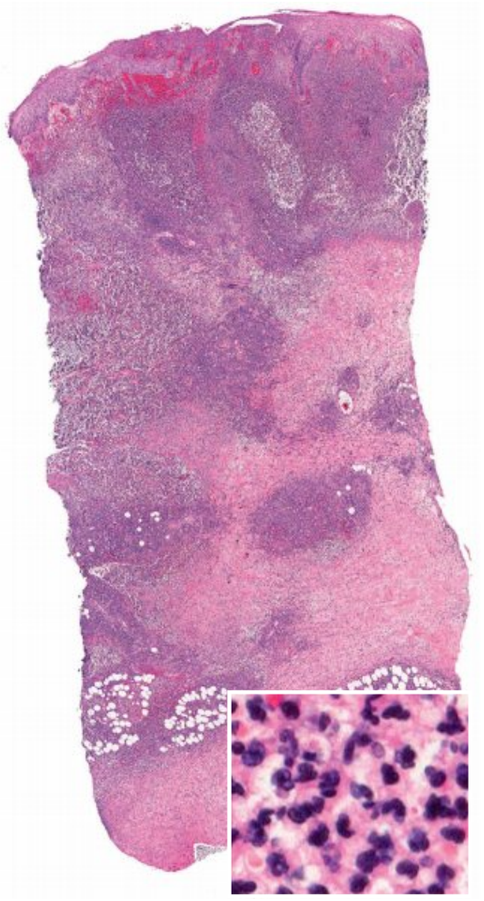

Fig. 25.14 Pyoderma gangrenosum. In expanding untreated lesions, a diffuse infiltrate of neutrophils (inset) is present at the edge of an ulceration. *Courtesy Lorenzo Cerroni, MD.*

Differential Diagnosis

Since there are no specific or diagnostic laboratory tests or histopathologic features and some of the associated conditions may not have declared themselves, the physician often needs to exclude other causes of cutaneous ulceration and search for a treatable associated disease. PG can be misdiagnosed: of 157 consecutive patients seen at one tertiary care medical center with a referral diagnosis of resistant ulcers due to PG, 15 (~10%) were found not to have PG[36]. To assist the clinician, three validated diagnostic schemes have been proposed (Table 25.8)[37]; all emphasize that no single criterion should be used in isolation. The evaluation of a patient with presumed PG is summarized in Table 25.9.

The differential diagnosis clearly depends on the evolutionary stage of the process – the initial inflammatory process characterized by erythematous papules, pustules, plaques, and nodules versus the later characteristic vegetative or ulcerative lesions (Table 25.10). Failure to establish the correct diagnosis can have serious consequences, including continued aggressive debridement and even amputation[38].

EVALUATION OF A PATIENT WITH PRESUMED PYODERMA GANGRENOSUM
• Thorough history and physical examination; review medications (e.g. rituximab), illicit drugs (e.g. cocaine) • Skin biopsy of *active* skin lesion with sufficient depth (panniculus) and sufficient tissue for special stains, culture, and/or PCR (bacterial, mycobacterial, fungal, viral, and occasionally parasitic). Possibility of future additional biopsies for immunofluorescence studies • Gastrointestinal tract studies – stool for occult blood and parasites, colonoscopy, biopsy, radiography, liver function tests, and if indicated, hepatitis evaluation • Hematologic studies – complete blood and platelet count, peripheral blood smear, and if indicated, bone marrow examination • Serologic studies – serum protein electrophoresis, immunofixation electrophoresis, anti-nuclear antibodies, anti-phospholipid antibodies, ANCA, VDRL • Chest X-ray and urinalysis

Table 25.9 Evaluation of a patient with presumed pyoderma gangrenosum[28–31]. ANCA, anti-neutrophil cytoplasmic antibodies.

THREE MAJOR PYODERMA GANGRENOSUM (PG) DIAGNOSTIC CRITERIA: SU CRITERIA, PARACELSUS SCORE, AND DELPHI CONSENSUS CRITERIA		
Su Criteria	**PARACELSUS Score**	**Delphi Consensus Criteria**
Diagnosis of PG requires both major criteria plus at least two minor criteria	*Highly likely PG requires score >10 points*	*Diagnosis of PG requires major criterion plus at least 4 of 8 minor criteria*
Major criteria	**Major criteria (3 points)**	**Major criterion**
• Rapid progression of a painful, necrolytic cutaneous ulcer with an irregular, violaceous, and undermined border • Other causes of cutaneous ulceration have been excluded	• Progressive course • Reddish-violaceous wound border • Absence of relevant differential diagnoses	• Biopsy with neutrophilic infiltrate
Minor criteria	**Minor criteria (2 points)**	**Minor criteria**
• History suggestive of pathergy or clinical finding of cribriform scarring • Systemic diseases associated with PG • Histopathological findings (sterile dermal neutrophilia, ± mixed inflammation, ± lymphocytic vasculitis) • Treatment response (rapid response to systemic steroid treatment)	• Amelioration due to immunosuppressant • Characteristically bizarre ulcer shape • Extreme pain >4 (VAS) **Additional criteria (1 point)** • Suppurative inflammation in histopathology • Undermined wound margins • Associated systemic disease	• Exclusion of infection on histology • Pathergy • PH of IBD or inflammatory arthritis • Papule, pustule, or vesicle that rapidly ulcerates • Peripheral erythema, undermining border, and tenderness at the site of ulceration • Multiple ulcerations (at least 1 occurring on an anterior lower leg) • Cribriform or wrinkled paper scars at healed ulcer sites • Decrease in ulcer size after immunosuppressive treatment

Table 25.8 Three major pyoderma gangrenosum (PG) diagnostic criteria: Su Criteria, PARACELSUS Score, and Delphi Consensus Criteria. These criteria are best applied to untreated disease, not disease partially treated by immunosuppressants. IBD, inflammatory bowel disease; PH, personal history; VAS, visual analogue scale for pain. *Adapted from Haag C, Hansen T, Hajar T, et al. Comparison of three diagnostic frameworks for pyoderma gangrenosum. J Invest Dermatol. 2021;141:59–63.*

DIFFERENTIAL DIAGNOSIS OF PYODERMA GANGRENOSUM
Early inflammatory non-ulcerative stage (papules, pustules, plaques, or nodules)
• Follicular infections (folliculitis, furuncle, carbuncle of bacterial, fungal, or viral origin) • Cellulitis or soft tissue infection (bacterial, mycobacterial, or fungal origin) • Insect bite reaction • Cutaneous T and B cell lymphomas • Halogenoderma (iododerma or bromoderma) • Panniculitides (inflammatory, infectious, metabolic, neoplastic) • Cutaneous polyarteritis nodosa • Sweet syndrome (see Table 25.5 for additional entities) • Behçet disease • Bowel-associated dermatosis–arthritis syndrome
Later ulcerative or vegetative stage
• Infections – streptococcal synergistic gangrene, ecthyma gangrenosum, atypical and typical mycobacterial infections, cutaneous lesions of the deep mycoses (e.g. blastomycosis, coccidioidomycosis, paracoccidioidomycosis, chromomycosis), cutaneous diphtheria, botryomycosis, gummatous treponemal ulcers • Parasitic infections – leishmaniasis, amebiasis, schistosomiasis • Vascular diseases – ulcerations due to venous hypertension, arterial insufficiency, non-septic emboli, hemoglobinopathies, thrombosis (secondary to hypercoagulability; see Ch. 105), or levamisole-induced vasculopathy/vasculitis • Vasculitis – cutaneous polyarteritis nodosa, microscopic polyangiitis, granulomatous vasculitides (granulomatosis with polyangiitis, eosinophilic granulomatosis with polyangiitis [Churg–Strauss syndrome], temporal arteritis), autoimmune connective tissue disease (systemic lupus erythematosus, rheumatoid arthritis), Behçet disease • Malignancy – squamous cell carcinoma, basal cell carcinoma, cutaneous T and B cell lymphoma • Miscellaneous – brown recluse spider bite, ulcerative necrobiosis lipoidica, pemphigus vegetans of the Hallopeau or Neumann type, blastomycosis-like pyoderma*, non-healing surgical wound, factitious ulcers, idiopathic granulomatous mastitis, ulcers in patients with primary immunodeficiencies (e.g. leukocyte adhesion deficiency-1; see Table 60.1)
*Growth of at least one pathogenic bacteria from culture of tissue.

Table 25.10 Differential diagnosis of pyoderma gangrenosum (PG)[28–31]. In a series of 95 patients misdiagnosed with PG, the most common etiologies were vascular (venous or arterial; 28), vasculitis (21), malignancy (16), infection (14), and drug-induced or exogenous tissue injury (13)[36].

Treatment

There is neither specific nor uniformly effective therapy for PG. The nature and intensity of the therapeutic approach depend on the number, size and depth of the lesions, the rate of expansion and appearance of new lesions, the associated disorder, the medical status of the patient, and the risk and patient tolerance of prolonged therapy. Prior to instituting treatment, evaluation for an associated disease is recommended and this assessment may be guided by the age of the patient[39].

The therapeutic goals are to reduce the inflammatory process of the wound, thereby promoting healing and reducing pain, and to control the contributing underlying disease (especially leukemias and inflammatory bowel disease), while producing the least adverse side effects. The standard medical treatment of PG is local or combined local and systemic corticosteroid therapy, with or without adjunctive systemic therapy; based upon an evidence-based review, cyclosporine is also considered first-line therapy[40].

When delivered in adequate dosage, systemic corticosteroids have generally been the most predictable and effective medication. Unfortunately, the more resistant lesions require more protracted therapy (>3 months) at a higher than desirable dosage, thus inviting adverse side effects. Such patients should be closely monitored and should receive supplemental calcium (1500 mg/day), vitamin D (800 IU/day) and, in most instances, bisphosphonates (see Ch. 125). Additional therapies, e.g. classic steroid-sparing agents, JAK, TNF and IL-12/23 inhibitors, are outlined in Table 25.11[41]. Once the inflammation is under control, gentle debridement of necrotic debris may be performed, but a test area, as with intralesional corticosteroids, allows for assessment of pathergy.

BEHÇET DISEASE

Key features

- A multisystem, polysymptomatic disease
- Diagnosis is based on International Study Group criteria of recurrent oral ulceration, recurrent genital ulceration, ocular abnormalities (e.g. uveitis, retinal vasculitis), and cutaneous lesions
- Cutaneous findings range from sterile papulopustules and palpable purpura to erythema nodosum-like lesions
- Histologically, a neutrophilic angiocentric infiltrate with leukocytoclastic (early) or lymphocytic (late) vasculitis is the characteristic finding

Introduction

Behçet disease is a multisystem, polysymptomatic disease with unpredictable exacerbations and remissions[42–45]. All organs of the body can be affected concomitantly or consecutively. As a result, all subspecialties can be involved in the care of these patients.

History

In the fifth century BCE, Hippocrates first described the symptomatology of this disease, and in 1936, Behçet reported a patient with eye disease and orogenital ulcers.

Epidemiology

Most patients are from regions along the ancient Silk Route, which stretched from the Korean peninsula and Japan to the Mediterranean Sea. Turkey has the highest prevalence, at 80 per 100 000. In Japan, it is 10 per 100 000; in the UK, 0.64 per 100 000; and in the US, 0.12 per 100 000[43]. In Japan and Korea, the incidence of Behçet disease is greater in women, but in Middle Eastern countries it is seen more frequently in men. The peak incidence is between 20 and 35 years of age. The familial form usually comprises 2%–5% of cases, except in the Middle East, where it represents 10%–15%.

Pathogenesis

Epidemiologic evidence suggests that genetic and environmental factors contribute to the development of this disease. More than 80% of Asian patients have the HLA-B51 allele, but it is present in only about 15% of White individuals from Western countries; thus, the allele appears to be an important risk factor for those who live along the Silk Route.

Earlier theories of pathogenesis entertained the possibility of an infectious etiology (viral or bacterial), but subsequent evidence failed to substantiate this hypothesis. Among the infectious agents investigated were HSV, hepatitis C virus, parvovirus B19, and streptococci[43]. These infections may potentially trigger an immunoregulatory defect in a genetically predisposed individual.

The pathomechanisms of Behçet disease involve vascular injuries and autoimmune responses. Circulating immune complexes and neutrophils appear to be responsible for the mucocutaneous lesions that are characterized histologically by a neutrophilic vascular reaction or even leukocytoclastic vasculitis. The neutrophils of Behçet disease produce an increased amount of superoxides and an excess of lysosomal enzymes, and they have enhanced chemotaxis, all of which lead to tissue injury. The elevated circulating levels of TNF, IL-1β, and IL-8 may result in activation of neutrophils and augmentation of cellular interactions between neutrophils and endothelial cells. Clonal expansion of autoreactive T cells that recognize a peptide derived from heat shock protein 60 has also been described. More recent genome-wide association studies found that single nucleotide polymorphisms in IL-10 and IL-23R regions were associated with the disease.

THERAPEUTIC LADDER FOR THE TREATMENT OF PYODERMA GANGRENOSUM		
Treatment	**Dose**	**Level of evidence**
Inflammatory disease		
Mild disease and/or adjunctive therapy		
Superpotent topical corticosteroids		1
Intralesional corticosteroids		2
Topical tacrolimus		1
Oral antibiotics (e.g. sulfonamides, minocycline)		2
Colchicine	0.5 or 0.6 mg po BID to TID*	3
Dapsone	50–150 mg po daily	2
Combination colchicine/dapsone		3
Other (e.g. oral potassium iodide, intralesional cyclosporine, topical timolol, topical cromolyn sodium, nicotine patch or cream)		3
More severe disease		
Prednisone/prednisolone	0.5–1.5 mg/kg/day	1
TNF inhibitors‡	Infliximab 5 mg/kg IV weeks 0, 2, and 6 then every 6-8 weeks; adalimumab 160 mg sc (initial dose) then 80 mg at week 2 and then 40 mg sc weekly or every other week; etanercept 25–50 mg sc twice a week	1 (infliximab§); 1 (adalimumab); 3 (etanercept)
Cyclosporine	2.5–5 mg/kg po daily	1
Tacrolimus	0.1–0.2 mg/kg po daily	3
Methylprednisolone	1 g daily for 3–5 days (IV pulse) for aggressive/recalcitrant disease¶¶	3
IL-12/23 antagonists	Ustekinumab 45–90 mg sc weeks 0 and 4, then every 8–12 weeks	3
Interleukin (IL)-1, IL-1R antagonists	Anakinra 100 mg sc daily then decrease; canakinumab 150 mg sc weeks 0, 2, 8 (depending on response)	2
Methotrexate¶	5–25 mg po, sc, or IM weekly	3
Azathioprine¶	50–150 mg po daily	3
Mycophenolate mofetil¶	1–1.5 g po twice daily	2
Thalidomide†	50–150 mg po nightly	2
IVIg	1–2 g/kg IV monthly (given over 2–5 consecutive days)	3
JAK inhibitors	Tofacitinib, 5 mg po BID or 11 mg XR po daily; ruxolitinib 5 mg then 10 mg po BID; baricitinib 2–4 mg po daily	3
Apremilast	30 mg po twice daily after initial escalation	3
IL-36R inhibitor	Spesolimab 900 mg IV; may repeat at one week	3
Granulocyte +/– monocyte apheresis, plasmapheresis		3
Total colectomy (severe chronic ulcerative colitis)**		3
Non-inflammatory disease (“cold”)		
Bio-occlusive dressings Compression, limb elevation		

*In the US, tablets are 0.6 mg; in other countries, tablets can be 0.5 mg.
†Especially in patients with Behçet disease.
‡Especially in patients with inflammatory bowel disease.
¶Often used in combination with other agents or as maintenance therapy.
§50%–70% response rate.
¶¶Followed by daily oral prednisone.
**PG can also occur post colectomy.

Table 25.11 Therapeutic ladder for the treatment of pyoderma gangrenosum[40,41,41a,41b]. Based upon case reports, anti-interleukin (IL)-23 and -17 antibodies have also been used. For severe disease associated with IgA monoclonal gammopathy, bortezomib, dexamethasone, ± cyclophosphamide. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

Clinical Features and Differential Diagnosis

Mucocutaneous involvement

Aphthous stomatitis, the major criterion, is frequently the first symptom of Behçet disease (65%–70% of patients), and it is almost always present during the course of the disease. The aphthosis may precede the other manifestations by many years, but a dramatic increase in severity often occurs in concert with the onset of other features. Oral ulcers begin as an erythematous papule, which develops a yellowish pseudomembrane and then forms a painful usually non-scarring ulcer (Fig. 25.15A,B); it heals over a period of weeks. The ulcers are indistinguishable from those that occur with complex aphthosis or inflammatory bowel disease and they must be differentiated from other causes of oral ulcers, e.g. pemphigus vulgaris, Marshall syndrome. The latter patients also have periodic fevers, pharyngitis, and cervical adenitis[46].

The genital aphthae involve primarily the scrotum and penis in men and the vulva in women. Compared to oral lesions, the anogenital

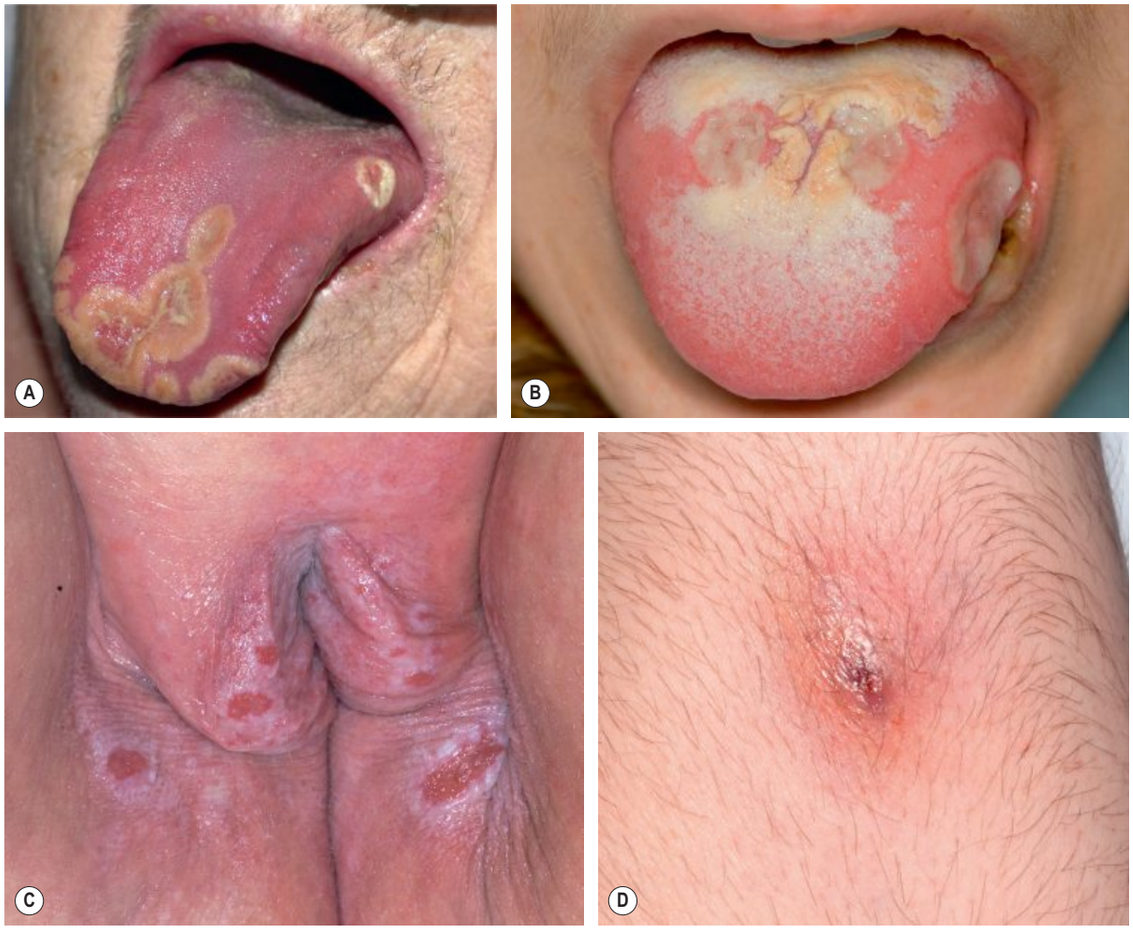

Fig. 25.15 Behçet disease – mucocutaneous lesions. A, B Oral aphthosis involving the tongue and lip; the ulcerations can be deep. These ulcers may be diagnosed as infectious (e.g. due to herpes simplex virus) or neoplastic rather than inflammatory. **C** Aphthae of the vulva and inguinal region. **D** Pathergy – a papulopustule appeared at the site of insertion of an intravenous catheter.

aphthae tend to be larger with irregular margins, but can vary in size (Fig. 25.15C); they are more painful. Distinction of genital lesions from lesions of HSV requires PCR, viral culture, or direct fluorescent antibody stain. Both immunobullous diseases (e.g. mucous membrane pemphigoid) and erosive lichen planus can also lead to oral and genital ulcerations.

Among the primary cutaneous lesions are acral and facial sterile vesiculopustules as well as pustular and/or purpuric papules[47]. Although the papulopustular lesions are usually not folliculocentric, they have nonetheless been described as acneiform, leading to some confusion (see Pathology below). The panniculitic erythema nodosum-like lesions favor women and appear on their legs and buttocks, and less often on the face and neck; they have to be differentiated from both superficial thrombophlebitis (which occurs in 30% of patients with Behçet disease) and erythema nodosum (which can develop in patients with Behçet disease). Pathergy also occurs (Fig. 25.15D), as in PG. Patients with features of both Behçet disease and relapsing polychondritis have been described and reported as MAGIC (*m*outh *a*nd *g*enital *u*lcers with *i*nflamed *c*artilage) syndrome (see Ch. 45)[48].

Patients with A20 haploinsufficiency, also referred to as familial Behçet-like autoinflammatory syndrome, can also have oral and genital ulcers as well as Sweet-like and erythema nodosum-like lesions and pustular eruptions (palmoplantar, folliculitis, pseudofolliculitis). This disorder is due to *TNFAIP3* mutations.

Systemic involvement

Systemic manifestations are summarized in Table 25.12 and distinctions between Behçet disease with bowel involvement and inflammatory bowel disease are outlined in Table 25.13.

Pathology

The histopathology of the cutaneous lesions is nonspecific. Vasculitic changes, which can involve all sizes of blood vessels within the dermis and subcutis, are probably secondary to the intense inflammation observed[49]. Both leukocytoclastic and lymphocytic vasculitis may be seen, and the affected vessels are sometimes occluded by fibrin thrombi.

The histologic features of the erythema nodosum-like lesions can vary from a neutrophilic lobular panniculitis to a septal and lobular panniculitis with a mixed inflammatory infiltrate, fat necrosis, and evidence of vasculitis.

Diagnosis

Since Behçet disease has no diagnostic test and is characterized by a complex constellation of signs and symptoms, various sets of clinical criteria have been created to assist in the diagnosis. Among the reported diagnostic criteria are those of the Japanese (1974), O'Duffy (1974), Zhang (1980), James (1986), and the International Study Group (ISG; 1990)[50]. The latter are presented in Table 25.14.

The development of the ISG criteria was based on the discriminating performance of various criteria-grouped combination sets, and the ISG criteria exhibited the highest sensitivity, specificity, and relative value. Controversy exists, however, about the failure of these criteria to require exclusion of inflammatory bowel disease.

Treatment

The management of the disease is difficult because of its variable course and the lack of sufficient double-blind studies. The therapeutic approach is a symptomatic one and is dictated by the nature of the mucocutaneous and visceral involvement. Because of the frequent vital organ involvement, e.g. the eye, and the tendency for the disease to recur, early and aggressive treatment is vital. CNS and large artery and vein involvement respond less favorably to therapy. There are multiple drugs available, both topical and systemic, that can be used as monotherapy or as combination therapy (Table 25.15)[51–53]. Evidence for many of the therapies is based on case-series data.

SYSTEMIC MANIFESTATIONS OF BEHÇET DISEASE
Ocular (leading cause of morbidity)[42–45]
• Occurs in 90% of patients; favors men, in whom it is more severe • Can be painful and may lead to blindness • Retinal vasculitis (more frequently associated with blindness) • Posterior uveitis (most characteristic ocular finding) • Anterior uveitis (Fig. 25.16), hypopyon • Secondary glaucoma, cataracts • Conjunctivitis, scleritis, keratitis, vitreous hemorrhage, optic neuritis
Joints
• Approximately 50% of patients develop arthritis • In majority (~80% of patients), duration of attacks is <2 months • Mono- or polyarthritic and non-erosive • Most commonly knees, wrists, and ankles
Gastrointestinal
• Abdominal pain and/or hemorrhage may be difficult to distinguish from IBD (see Table 25.13) • Ulcerations* develop within the small bowel (in particular the ileocecal region) as well as the transverse and ascending colon and esophagus; perforation can occur
Neurologic
• Usually appears later during the evolution of the disease • Associated with a poor prognosis • Acute meningo-encephalitis which may resolve spontaneously • Cranial nerve palsies • Brainstem lesions that can induce swallowing difficulties, laughter and crying • Pyramidal or extrapyramidal signs
Vascular
• Aneurysmal or occlusive arterial disease • Superficial or deep venous thrombosis
Cardiopulmonary
• Coronary arteritis, valvular disease, myocarditis • Recurrent ventricular arrhythmias • Pulmonary artery aneurysms
Renal
• Glomerulonephritis
*Resemble anogenital aphthae.

Table 25.12 Systemic manifestations of Behçet disease. IBD, inflammatory bowel disease.

BOWEL-ASSOCIATED DERMATOSIS–ARTHRITIS SYNDROME

Synonyms: ■ Bowel bypass syndrome ■ Bowel bypass syndrome without bowel bypass ■ Intestinal bypass arthritis–dermatitis syndrome

Key features

- Constitutional signs and symptoms are serum sickness-like
- Cutaneous lesions include erythematous and purpuric papules and vesiculopustules as well as nodular panniculitis
- Associated polyarthritis and tenosynovitis
- Histopathology includes dermal perivascular nodular neutrophilic infiltrates and edema as well as a lobular neutrophilic or septal panniculitis

Introduction

Bowel-associated dermatosis–arthritis syndrome (BADAS) is characterized by diarrhea with resultant malabsorption, arthritis, and skin lesions. It is seen in patients who have undergone intestinal bypass surgery, have blind loops of bowel following surgery, had biliopancreatic diversion, or have gastrointestinal disorders (Table 25.16)[54,55].

History

During the 1960s and 1970s, morbid obesity began to be treated surgically by jejunoileal bypass surgery and 20% of these patients developed a syndrome initially referred to as bowel bypass syndrome. In the 1980s, a similar syndrome was described in patients with inflammatory bowel disease or with blind loops of bowel after intestinal surgery[55].

Pathogenesis

In bowel-associated dermatosis–arthritis syndrome, there is usually bacterial overgrowth in a blind loop of bowel. It is postulated that resultant immune complexes containing bacterial antigens are then deposited within the skin and synovium[56]. The pathogenic role of bacteria in this syndrome is supported by the disappearance of the disease with antibiotic therapy or surgery.

Clinical Features

Bowel-associated dermatosis–arthritis syndrome is characterized clinically by constitutional flu-like symptoms, skin lesions[57], and a variety of systemic complications (see below). It can occur from 1 to 6 years after the responsible bowel surgery. Constitutional symptoms, which are usually present and may precede the cutaneous eruption, are similar to those of serum sickness, e.g. fever, chills, malaise, arthralgias and myalgias.

The characteristic skin lesions are erythematous macules which progress to papules and purpuric vesiculopustules within 48 hours and last for 2–4 weeks; they may recur at 4- to 6-week intervals. The lesions may be few or many (Fig. 25.17), and they favor the proximal extremities and trunk.

Recurrent, tender, erythematous subcutaneous nodules are also seen in these patients and may be associated with fever. They are due to either a nodular, non-suppurative, lobular neutrophilic panniculitis (involving both the trunk and extremities and healing with depressed scars) or erythema nodosum (generally involving only the lower extremities), two entities which differ clinically and histologically[58]. Among the more common non-cutaneous findings are tenosynovitis and non-destructive polyarthritis. Associated systemic complications include electrolyte imbalance from persistent diarrhea, hepatic dysfunction and failure, renal calculi composed of calcium oxalate, gallstones, zinc deficiency, vitamin A deficiency, beriberi, hyperuricemia, and emotional disturbances.

NEUTROPHILIC DERMATOSES ASSOCIATED WITH BOWEL DISORDERS				
		Behçet disease	**Bowel-associated dermatosis–arthritis syndrome**	**Inflammatory bowel disease**
Cutaneous lesions	Aphthosis	+ (oral and anogenital)	+ (oral)	+ (oral)
	Vesiculopustular dermatosis	+	+	+
	Sweet syndrome-like dermatosis	+	–	+
	Pyoderma gangrenosum	+	–	+
	Pyostomatitis vegetans	–	–	+
	Pyoderma vegetans	–	–	+
	Vasculitis	+	±	+ (including cutaneous polyarteritis)
	Superficial thrombophlebitis	+	–	+
	Erythema nodosum	+	+	+
	Neutrophilic lobular panniculitis	+	+	+
	Pathergy	+	–	+
Systemic signs and symptoms	Fever/flu-like syndrome	+	+	+ (fever)
	Ocular involvement	+	–	+ (iritis)
	Arthritis	+	+ (plus tenosynovitis)	+
	Neurologic involvement	+	–	–
Gastrointestinal pathology		Typical aphthae can occur in the esophagus and throughout the stomach and intestine and can produce severe, cramping pain; ulcerations similar in appearance to chronic ulcerative colitis	Blind loop of bowel	Ulcerations in Crohn disease are superficial or deep, linear, and segmental or diffuse and on biopsy reveal granulomatous disease

Table 25.13 Neutrophilic dermatoses associated with bowel disorders. Pyoderma vegetans is also referred to as pyodermatitis vegetans.

INTERNATIONAL STUDY GROUP CRITERIA FOR THE DIAGNOSIS OF BEHÇET DISEASE	
Major criterion	**Required features**
Recurrent oral ulceration	Aphthous (idiopathic) oral ulceration observed by physician or patient, recurring at least three times in a 12-month period
Plus any two of the following minor criteria:	
Recurrent genital ulceration	Aphthous genital ulceration or scarring, observed by physician or patient
Eye lesions	Anterior or posterior uveitis; cells in the vitreous by slit lamp examination; or retinal vasculitis observed by ophthalmologist
Cutaneous lesions	Erythema nodosum-like lesions observed by physician or patient; papulopustular lesions or pseudofolliculitis; or characteristic acneiform nodules observed by physician in postadolescent patient not on corticosteroids
Pathergy test*	Interpreted at 24–48 h by physician
*Pathergy test is performed on the flexor forearm by obliquely inserting a 20–22-gauge sterile hypodermic needle to a depth of 5 mm ± an intradermal injection of 0.1 ml of normal saline. A positive reaction is defined as the development of a papule or pustule.	

Table 25.14 International Study Group criteria for the diagnosis of Behçet disease[50]. *Adapted from International Study Group for Behçet's Disease. Criteria for diagnosis of Behçet's disease. Lancet. 1990;335:1078–80.*

Pathology

The characteristic lesions exhibit a perivascular, nodular neutrophilic infiltrate with nuclear dust and papillary and reticular dermal edema[57]. The infiltrate may be admixed with lymphocytes and histiocytes and may extend into the mid dermis and panniculus. A similar neutrophilic vascular pattern is seen in lesions of Sweet syndrome, Behçet disease, and the early phase of PG.

Differential Diagnosis

The papular eruption must be differentiated from that seen in urticarial vasculitis and erythema multiforme, whereas the pustular vasculitic lesions must be distinguished from other causes of small vessel vasculitis, disseminated gonococcemia (septic vasculitis), systemic candidiasis, subacute bacterial endocarditis, and Behçet disease. Pustular lesions may be misdiagnosed as folliculitis or arthropod bites (e.g. fire ants).

THERAPEUTIC LADDER FOR THE TREATMENT OF BEHÇET DISEASE		
Treatment	**Dose**	**Level of evidence**
Mucocutaneous disease		
Viscous lidocaine, topical sucralfate and other symptomatic treatments		3
Topical and inhalant corticosteroids		2
Tacrolimus (swish and spit)	1 mg in 0.5 liter of water; swish for 2 minutes BID	3
Intralesional corticosteroids		3
Colchicine	0.5–0.6 mg po thrice daily	1
Dapsone	50–150 mg po daily (or sulfapyridine equivalent)	1
Combination oral colchicine plus dapsone		3
Apremilast	30 mg po twice daily (oral ulcers)	1
Severe mucocutaneous disease		
Thalidomide	50–150 mg po nightly	1
Methotrexate	5–25 mg po, sc, or IM weekly	3
Prednisone, intermittent with taper	40–80 mg po daily usual starting dose	2
Interferon-α-2a	Variable dose (3–9× 10^6 IU sc 3× weekly)	1
TNF inhibitors	Infliximab 5 mg/kg IV at weeks 0, 2, and 6 then every 6–8 weeks; adalimumab 80 mg sc as initial dose then 40 mg sc weekly or every other week; etanercept 25–50 mg sc twice a week	1 (etanercept)
IL-12/23 inhibitors	Ustekinumab 45–90 mg sc week 0, week 4, and then once every 12 weeks	2
Systemic disease		
Prednisone	60–120 mg po daily usual starting dose (including split-dose), with taper to alternate days	2
Methylprednisolone acetate	40 mg IM 3× weekly	2
Azathioprine	50–150 mg po daily	1
Cyclophosphamide	Variable oral dose (50–200 mg daily) or IV pulse (500–1000 mg monthly then 500–1000 mg every 3 months)	3
Mycophenolate mofetil	1–1.5 g po twice daily	3
Cyclosporine	Variable doses (2–10 mg/kg po daily)	1
Tacrolimus	0.1–0.2 mg/kg po daily	2
IVIg	1–2 g/kg IV monthly (given over 2–5 consecutive days)	3
TNF inhibitors	See above for severe mucocutaneous disease	2
Interleukin(IL)-1, IL-1R antagonists	Anakinra, canakinumab (see Table 25.11)	3

Table 25.15 Therapeutic ladder for the treatment of Behçet disease[51–53]. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

CONDITIONS ASSOCIATED WITH BOWEL-ASSOCIATED DERMATOSIS–ARTHRITIS SYNDROME	
Surgical	**Medical**
• Gastric resection • Jejunoileal bypass • Blind loops of bowel following surgery • Biliopancreatic diversion	• Inflammatory bowel disease • Diverticulitis • Peptic ulcer disease • Cystic fibrosis

Table 25.16 Conditions associated with bowel-associated dermatosis–arthritis syndrome.

Treatment

Surgically, either revision of the bowel bypass or surgical resection of the blind loop of bowel is curative. Medically, systemic prednisone can produce significant symptomatic improvement of the cutaneous and rheumatologic manifestations, but it is not curative[55]. It is inadvisable to administer systemic corticosteroids as a long-term therapy. Antibiotics that have proven to be beneficial are listed in Table 25.17.

SYNOVITIS, ACNE, PUSTULOSIS, HYPEROSTOSIS, AND OSTEITIS (SAPHO) SYNDROME

Key features

- Presence of osteoarticular lesions, often in conjunction with an aseptic pustular dermatosis
- Usually a gradual onset of painful, multifocal osteoarticular lesions, especially of the anterior chest and axial skeleton
- The course of the osteoarticular lesions oscillates and is protracted, with gradual improvement that can be hastened by anti-inflammatory drugs

Introduction

SAPHO syndrome consists of a wide spectrum of aseptic neutrophilic dermatoses in association with aseptic osteoarticular lesions that have distinctive histologic and radiographic features[59,60]. Recognition of SAPHO syndrome is important so as to avoid misdirected therapies and unnecessary invasive procedures.

Fig. 25.17 Bowel-associated dermatosis–arthritis syndrome. A, B Papules and papulopustules can be erythematous or violaceous and purpuric. The number of lesions varies from a few to many.

THERAPEUTIC APPROACHES FOR BOWEL-ASSOCIATED DERMATOSIS–ARTHRITIS SYNDROME
Mild clinical expression
• Oral antibiotics to reduce bacterial overgrowth (4–8 weeks): tetracycline (500 mg 2–4 times daily), doxycycline (100 mg once to twice daily), minocycline (100 mg once to twice daily), clindamycin (600 mg daily), metronidazole (250–500 mg twice daily) • Aseptic neutrophilic inhibiting drugs (4–8 weeks): colchicine (0.6 mg thrice daily), dapsone (50–100 mg daily), thalidomide (50–200 mg daily)
Severe clinical expression
• Potent anti-inflammatory and immunomodulatory drugs (2–3 months): prednisone (40–60 mg daily then tapered), cyclosporine (200–300 mg daily), azathioprine (50–150 mg daily), mycophenolate mofetil (500 mg twice daily) • Surgical restoration of normal bowel anatomy • Possible role for TNF inhibitors (e.g. infliximab, adalimumab, etanercept)
Treatments based upon small case series and case reports.

Table 25.17 Therapeutic approaches for bowel-associated dermatosis–arthritis syndrome.

SAPHO SYNDROME
Osteoarticular manifestations (aseptic/sterile)
• Inflammatory synovitis • Arthrosteitis – inflammation of the osseous structures of a joint • Hyperostosis or osteitis, most often anterior chest wall (sternum, clavicles, ribs) and axial skeleton (spine*, pelvis) • Subtype: chronic recurrent multifocal osteomyelitis (CRMO) – frequent involvement of metaphyses of tubular bones and seen primarily in children
Associated cutaneous disorders
• **Palmoplantar pustulosis**, including TNF inhibitor-induced • Pustular psoriasis, including CARD14-mediated • Sneddon–Wilkinson disease (subcorneal pustular dermatosis) • Psoriasis • Follicular occlusion tetrad, in particular **acne conglobata** and hidradenitis suppurativa • **Acne fulminans** • Linear IgA bullous dermatosis • Behçet disease • Sweet syndrome • Pyoderma gangrenosum
Differential diagnosis (primarily genetic disorders)
• DIRA (deficiency of the interleukin-1 receptor antagonist) syndrome [*IL1RN* mutations] • PAPA (pyogenic [sterile] arthritis, pyoderma gangrenosum and acne) syndrome and its variant, PAPASH syndrome [*PSTPIP1* mutations] • Majeed syndrome (congenital dyserythropoietic anemia, CRMO, Sweet syndrome or cutaneous pustulosis [*LPIN2* mutations]) • Pyrin-associated autoinflammatory disease [*MEFV* mutations]
*Spondylitis or spondylodiscitis.

Table 25.18 SAPHO syndrome. SAPHO – synovitis, acne, pustulosis, hyperostosis and osteitis. Most common associated cutaneous disorders are in **bold**. PAPASH, *p*yogenic *a*rthritis, *p*yoderma gangrenosum, *a*cne, and *s*uppurative *h*idradenitis; TNF, tumor necrosis factor.

History

In 1972, chronic recurrent multifocal osteomyelitis was described as a rare chronic inflammatory musculoskeletal process in children and adults. Although cutaneous pustulosis and acne were reported in association with osteomyelitis and arthritis in the 1960s, it was not until 1987 that the acronym SAPHO (synovitis, *a*cne, *p*ustulosis, *h*yperostosis and *o*steitis) syndrome was coined to describe this clinicoradiologic entity that involves skin, bone, and joints.

Epidemiology

This is a rare and under-recognized syndrome that primarily affects children and young and middle-aged adults. It rarely presents after 60 years of age. There is no sex predilection, with the exception of a male predominance in those with acne. It has been observed most frequently in Japan, less often in Scandinavia, Germany and France, and infrequently in the US and Canada.

Pathogenesis

The pathogenesis of SAPHO appears to be multifactorial. Some hypothesize that it is the result of an autoimmune response triggered by low-virulence microorganisms and enhanced chemotaxis of neutrophils.

Clinical Features

The essential element is osteoarticular lesions, with pustular dermatoses noted in ~30% of children and ~85% of adults. The neutrophil is the "tie that binds" the clinical manifestations of this syndrome. Table 25.18 outlines the osteoarticular lesions of SAPHO. The affected bones are tender and the swollen joints are painful. Patients may be febrile with a leukocytosis and elevated ESR or CRP.

Bone scintigraphy demonstrates an increased uptake at involved sites[61]. MRI is very sensitive in assessing joint and tissue involvement and it helps in monitoring the disease. The osteoarticular involvement is intermittent with periodic exacerbations and remissions and there is no correlation with the activity of the associated sterile neutrophilic dermatosis. SAPHO is also associated with inflammatory bowel disease and is regarded as one of the seronegative spondyloarthropathies.

Pathology

Early in the process, medullary bone contains an inflammatory cellular infiltrate, consisting primarily of neutrophils, osteoclasts, and osteoblasts. Later on, cicatricial fibrosis surrounded by hypertrophic inactive bone is seen.

Differential Diagnosis

The differential diagnosis of the bone lesions includes classic bacterial osteomyelitis, primary bone tumors, metastases, and Langerhans cell histiocytosis. The possibility of a genetic syndrome with similar cutaneous and osseous manifestations also needs to be considered (see Table 25.18).

Treatment

Since precise knowledge of the pathogenesis of SAPHO syndrome is lacking, a variety of anti-inflammatory therapies have been tried. Although isotretinoin is used to treat associated severe acne, there are scattered case reports of isotretinoin-associated flares of SAPHO. Treatment options include NSAIDs and intra-articular corticosteroids for the arthritis; bisphosphonates for bone involvement; and systemic corticosteroids, other immunosuppressive medications (e.g. azathioprine, methotrexate), TNF antagonists (e.g. etanercept, adalimumab, infliximab), IL-1 antagonists (e.g. anakinra), and IL-12/23, IL-23, IL-17 or JAK inhibitors for both skin and bone disease. Of note, paradoxical induction of SAPHO was observed in a patient with inflammatory bowel disease treated with infliximab.

EROSIVE PUSTULAR DERMATOSIS

Synonym: ■ Erosive pustular dermatosis of the scalp

Key features

- Sterile pustules plus erosions and superficial ulcerations with keratotic crusts
- Most commonly develops within photodamaged atrophic skin of the midline scalp
- Can occur in other locations where the skin is atrophic or fragile, including sites of injury

History

In 1979, Pye et al.[62] described six elderly women with pustular and crusted lesions of the scalp that improved with potent topical corticosteroids.

Epidemiology

Erosive pustular dermatosis (EPD) occurs most commonly on the scalp of older adults with photodamaged skin. It has also been observed on the lower legs of individuals with venous insufficiency and at sites of injury, including in neonates.

Pathogenesis

It is unknown. The causes of erosive pustular dermatosis are not only limited to traumatic injuries but also include medications, comorbid conditions, and several dermatological procedures.

Significant cumulative photodamage in the setting of androgenetic alopecia and local mechanical trauma are risk factors, but how this leads to pustules and erosions is not known. Additional types of trauma include previous herpes zoster and thermal burns. There is a possible association with autoimmune disorders such as autoimmune thyroiditis.

Clinical Features

EPD is characterized by pustules, along with erosions and keratotic crusting, within atrophic or fragile skin. Tenderness is a common symptom and there may be associated pain or pruritus as well as drainage. The most common site of involvement is the photodamaged skin of the midline scalp in an elderly adult. Additional locations include the lower extremities in the setting of venous hypertension and at sites of injury, e.g. from thermal burns, surgical procedures, and skin graft placement. There have been a few reports of EPD in neonates following scalp injuries.

EPD can slowly progress and may eventually lead to scarring alopecia. Occasionally, there is secondary infection.

Pathology

The histopathologic findings are nonspecific. Regenerating epidermis in sun-damaged skin may show enlarged keratinocytes and should not be misinterpreted as actinic keratosis. Intraepidermal or subcorneal pustulation is usually observed.

Differential Diagnosis

The differential diagnosis for scalp lesions includes primarily hypertrophic actinic keratoses and squamous cell carcinomas. Additional entities to consider include folliculitis, pyoderma, cicatricial pemphigoid, EFGR inhibitor-induced pustular dermatosis and also, if at other sites, pustular psoriasis.

Treatment

In case series or case reports, topical therapies – corticosteroids (initially potent), calcineurin inhibitors, vitamin D analogues, dapsone – have been reported as successful treatments. Silicone gels or sheeting as well as photodynamic therapy (PDT) are additional therapeutic options. Topical and systemic antibiotics, including mupirocin and doxycycline, respectively, can also led to improvement. Severe EPD may benefit from oral retinoids, dapsone, or zinc sulfate. Supplementing medical therapy with mild debridement of the crusted areas via curettage may accelerate the response[63].

Chapter Contents

Eosinophil Biology 470
Tissue Effects and Innate Immunity 473
Eosinophil-Associated Dermatoses 473
Hypereosinophilic Syndromes 476

Key features

- Infiltration of eosinophils into the skin is not uncommon; therefore, clinicopathologic correlation is important to arrive at the correct clinical diagnosis
- Eosinophil-associated dermatoses include arthropod bite reactions and drug eruptions ("bugs and drugs"), atopic dermatitis, Wells syndrome, hypereosinophilic syndromes, autoimmune blistering diseases, and parasitic infections
- Activated eosinophils lose their morphologic integrity as they deposit toxic granule proteins and other inflammatory mediators in tissues; the absence of intact eosinophils may not be an accurate reflection of their relevance to a disease state
- In patients with persistent peripheral blood eosinophilia, as observed with hypereosinophilic syndromes, tissue infiltration and eosinophil-derived mediators may cause significant end-organ damage

EOSINOPHIL BIOLOGY

The eosinophil is a leukocyte ~10–16 microns in diameter that possesses a segmented (usually bi-lobed) nucleus. It is produced in the bone marrow and circulates transiently (8–18 hours) in the peripheral blood. Under normal conditions, circulating eosinophil counts range from 0 to 500 cells/mcl of human blood. Except for the bone marrow, gastrointestinal tract (distal to the esophagus), and lymphoid tissues (spleen, thymus, and lymph nodes), eosinophils are limited to diseased tissues.

In 1879, Paul Ehrlich named the "eosinophil" because of the intense staining of its distinctive cytoplasmic granules with the acidic dye, eosin. Ultrastructurally, eosinophils are characterized by membrane-bound, cytoplasmic granules that have an electron-dense core and less dense matrix (Fig. 26.1). The eosinophil produces multiple factors that make it a highly proinflammatory and pro-fibrotic leukocyte[1–3]. It also expresses a number of receptors on its cell surface that are important for activation[4,5], prolonged survival, and targeted migration into tissue compartments (see Fig. 26.1)[1–4,6].

Eosinophils are attracted into tissues by the coordinated actions of: (1) eosinophil activating cytokines (commonly referred to as "priming" cytokines); (2) tissue-released chemokines; and (3) endothelial adhesion molecules[7]. Eosinophils express receptors for granulocyte–macrophage colony-stimulating factor (GM-CSF), interleukin (IL)-3, and IL-5 which are important for bone marrow production, maturation, activation, and prolonged survival[1,3,8]. Several lines of investigation indicate that eosinophils are recruited to and activated within tissues by cytokines that largely come from a type 2 immune response (IL-33) or from Th2 cells (IL-4, IL-5, and IL-13). Natural killer cells also produce IL-5, and mast cell-derived cytokines contribute indirectly to eosinophil activation via induction of IL-5 and GM-CSF.

Eosinophils themselves elaborate important inflammatory and regulatory cytokines, including IL-1α, TGF-α and TGF-β_1, GM-CSF, IL-3, IL-5, IL-6, IL-8, TNF, and macrophage inflammatory protein 1α (CCL3; see Fig. 26.1). As a result, eosinophil activation also occurs in an autocrine manner. In cytotoxicity assays, eosinophils are maximally activated by GM-CSF, followed by IL-3, IL-5, TNF and IL-4, in order of potency[3,8]. Eosinophil numbers in the circulation and tissues is a function of balance of mediators that prolong survival versus those that induce apoptosis, like glucocorticoids. Glucocorticoids can counteract the prolonged survival induced by IL-3, IL-5 and GM-CSF, which may in part explain their therapeutic efficacy in most eosinophil-driven conditions. More recently, the surface receptors sialic acid-binding immunoglobulin-like lectins (Siglec) -8 and -10, which are expressed on eosinophils and mast cells, have been shown to mediate apoptosis[4].

Several members of the C-C chemokine gene superfamily are chemotactic for eosinophils, including the eotaxins 1, 2, and 3 (CCL11, CCL24, and CCL26). These chemokines signal primarily through C-C chemokine receptor (CCR)-3, which is highly expressed on eosinophils. In addition to their chemotactic properties, these chemokines also induce the release of reactive oxygen species. Eotaxins are produced by tissue resident cells positioning them as upstream mediators of cutaneous inflammation[9].

Eosinophils enter tissues by traversing blood vessels. Similar to other leukocytes, this transmigration involves adhering to endothelial adhesion molecules within the selectin and immunoglobulin supergene families[1,3]. In particular, eosinophils constitutively express very late antigen (VLA)-4, the ligand for vascular cell adhesion molecule (VCAM)-1; the latter is a cytokine-inducible endothelial adhesion molecule (see Fig. 102.11). After entering tissues, eosinophil activity is influenced by interactions between integrins on the eosinophil cell surface and both extracellular proteins (fibronectin, laminin, or collagen) and glycosaminoglycans (hyaluronic acid or chondroitin sulfate), which are induced under inflammatory conditions.

Granular Contents

Upon activation, eosinophils release their granular contents into the extracellular spaces by three mechanisms[1]: cytolytic degranulation, piecemeal degranulation, and regulated secretion. Cytolytic degranulation is characterized by organelle rupture, chromatolysis of nuclei with loss of morphologic integrity, and extensive deposition of eosinophil granules and granule products within tissue[1,3]; this process occurs in many inflammatory disorders, including atopic dermatitis, as well as in affected organs (including the skin) in patients with hypereosinophilic syndromes (HES).

Eosinophil major basic protein 1 (eMBP1), the constituent of the granules' crystalline cores (see Fig. 26.1), directly damages helminths and mammalian cells, exemplified by its ability to cause exfoliation of bronchial epithelial cells. In addition, eMBP1, but none of the other eosinophil granule proteins, induces basophil histamine release. Furthermore, eMBP1 stimulates neutrophils, leading to the release of superoxides and lysozyme. *Eosinophil cationic protein* (ECP or RNase3) and *eosinophil-derived neurotoxin* (EDN or RNase2) are members of the RNase family. ECP is a potent toxin for parasites through a different mechanism than eMBP1 and is more effective at killing certain helminths than eMBP1. EDN, as its name implies, is a neurotoxin and also has antiviral activity against RNA viruses.

Eosinophil peroxidase (EPO) kills numerous microorganisms in the presence of hydrogen peroxide (generated by eosinophils and other phagocytes) and halides. This combination of products also initiates mast cell secretion. Binding of EPO to microbes, including *Staphylococcus aureus*, greatly potentiates their killing by phagocytes. Similarly, EPO-coated tumor cells are spontaneously lysed by activated macrophages, and eMBP1 is also toxic to tumor cells. EPO and eMBP1 are potent platelet agonists that lead to release of 5-hydroxytryptamine (serotonin) and promote clotting.

In summary, the highly basic granule proteins released by activated eosinophils have evolved to not only protect us from parasitic helminths but also some bacteria and viruses, and they may in some settings possess anti-tumor properties.

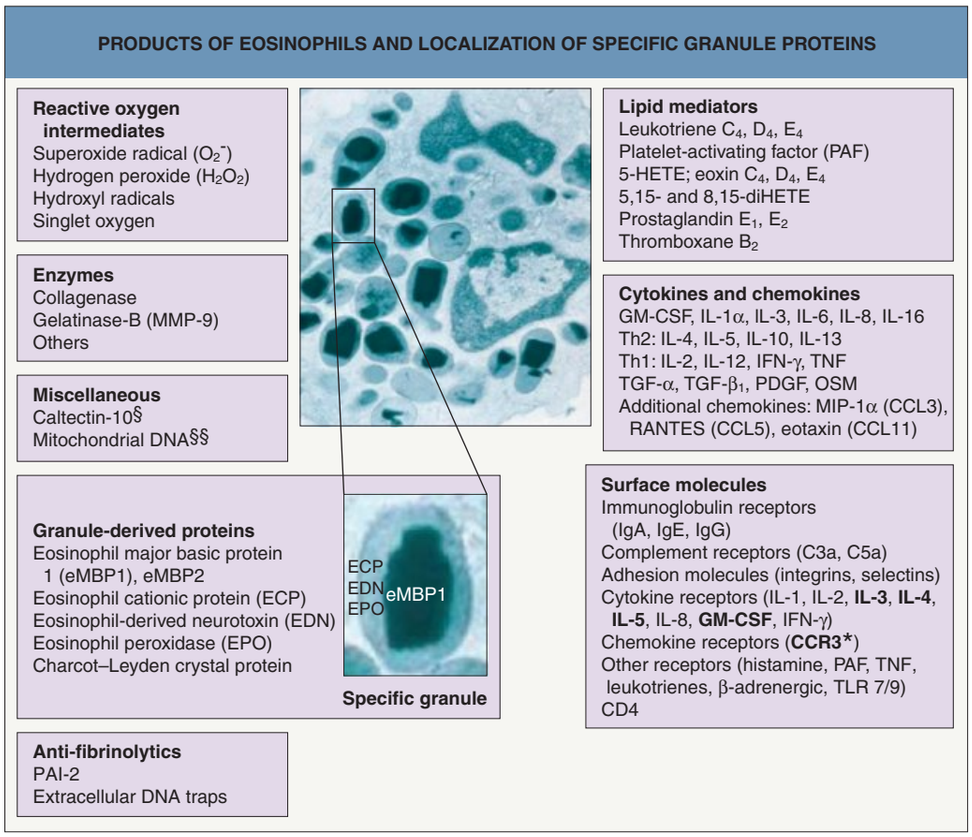

Fig. 26.1 Products of eosinophils and localization of specific granule proteins. The eosinophil produces myriad products that determine its role in inflammation. Specific granules contain major basic protein 1 and 2 (in the electron-dense core) and other toxic proteins (in the matrix). *Receptor for eotaxins and RANTES. §Charcot–Leyden crystal protein. §§Forms mitochondrial DNA traps with ECP and eMBP1. EOSINOPHIL-ASSOCIATED DERMATOSES	
Diagnosis	**Clinical clues**
Common entities	
Allergic contact dermatitis (Ch. 14)	History of exposure; suggestive distribution; positive patch test
Arthropod bite/sting reactions (Ch. 85)	Primarily involves exposed skin; mosquitoes, fleas, spiders, ticks, and mites; exaggerated reactions in patients with CLL
Atopic dermatitis (Ch. 12)	History of atopy; pruritus; flexural accentuation; lichenification
Drug eruptions (Ch. 21)	Drug history, especially new drugs within the previous 2 weeks or up to 6 weeks for DRESS/DIHS Histopathologically, eosinophils are present in ~50% of cutaneous drug reactions
Erythema toxicum neonatorum (Ch. 34)	Newborn with erythematous macules, papules and pustules, often with prominent erythematous flare
Parasitic infections, particularly helminths (Ch. 83)	Cysticercosis, dirofilariasis, larva migrans, gnathostomiasis, onchocerciasis, schistosomiasis, and others
Scabies (Ch. 84)	Marked nocturnal pruritus; web-space, umbilical and groin involvement; close physical contact
Urticaria (Ch. 18)	Pruritic, migratory, transient wheals; individual lesions last <24 hours
Less common entities	
Annular erythema of infancy[58] (Ch. 19)	Annular or serpiginous non-pruritic plaques in infants
Autoimmune bullous dermatoses (Chs. 29–32; see Table 29.4 for differential diagnosis of eosinophilic spongiosis)	Pemphigoid (particularly bullous pemphigoid, gestational pemphigoid) > pemphigus, linear IgA bullous dermatosis, dermatitis herpetiformis, epidermolysis bullosa acquisita
Eosinophilic dermatosis associated with hematological disorders (eosinophilic dermatosis of hematologic malignancy; Ch. 33)	Most common in patients with CLL, but reported in patients with other hematologic malignancies; severe insect bite reactions as well as insect bite-like reactions
Eosinophilic fasciitis (Shulman syndrome; Ch. 43)	Acute onset of symmetrical induration of skin and subcutaneous tissues of the limbs; peripheral blood eosinophilia
Eosinophilic granulomatosis with polyangiitis (EGPA; Ch. 24)	Palpable purpura and tender papulonodules; peripheral blood eosinophilia; pulmonary (e.g. asthma), neurologic (e.g. mononeuritis multiplex), and cardiac involvement; prominent IgG4 and IgE responses

Table 26.1 Eosinophil-associated dermatoses.

EOSINOPHIL-ASSOCIATED DERMATOSES	
Diagnosis	**Clinical clues**
Eosinophilic (pustular) folliculitis (Ch. 38)	*Immunosuppression, including HIV infection and post-transplant*:* severe pruritus and papules on the face and upper trunk
	Ofuji disease: chronic, recurrent follicular pustules in a seborrheic distribution with a tendency to form circinate plaques; most commonly observed in east Asia
	Pediatric: follicular pustules on the scalp of an infant
Eosinophilic, polymorphic, and pruritic eruption associated with radiotherapy (EPPER)[59]	Local and generalized pruritus; erythematous papules and sometimes vesicles
Eosinophilic vasculitis (histopathologic reaction pattern rather than specific dermatosis)[60]	Pruritic urticarial and purpuric papules, angioedema; juvenile temporal arteritis (see below)
Eosinophilic ulcer of the oral mucosa (Ch. 72)	Rapidly enlarging nodule that develops ulceration; tongue most common site
Epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia; Ch. 114)	Single or multiple nodules of the face, scalp, and/or ears
Granuloma faciale (Ch. 24)	Red-brown plaque(s), often with prominent follicular openings; lesions favor the face
Hypereosinophilic syndromes (HESs)	See text
Incontinentia pigmenti (Ch. 62)	Vesicles and bullae along the lines of Blaschko in neonate (stage I); peripheral blood eosinophilia
Juvenile temporal arteritis	Nodule in the temporal region in an older child or young adult due to eosinophilic vasculitis
Juvenile xanthogranuloma (Ch. 91)	Yellow to red–brown papules or nodules on the head and neck, upper trunk or proximal extremities; early lesions may have numerous eosinophils
Kimura disease (Ch. 114)	Subcutaneous masses and lymphadenopathy of the head and neck region; peripheral blood eosinophilia, increased serum IgE levels
Langerhans cell histiocytosis (especially eosinophilic granuloma; Ch. 91)	Disseminated pink and yellow–brown papules (often with crusts); intertriginous involvement; occasionally, nodules
Lymphoproliferative disorders of the skin, benign and malignant (Chs. 119–121)	Presentation varies depending upon specific type; variable number of eosinophils seen in entire spectrum of lymphoproliferative disorders and commonly observed in LyP and cutaneous ALCL
Cutaneous mastocytosis (Ch. 118)	Pink–tan to red–brown macules, papules and plaques that urticate with stroking (Darier sign)
Papuloerythroderma of Ofuji (see Ch. 10)	Most commonly in elderly men; widespread, pruritic, red–brown papules that may become more confluent with characteristic sparing of the skin folds ("deck-chair" sign); peripheral blood eosinophilia and elevated serum IgE level; can be associated with malignancies (especially CTCL), infections, or drugs
Polymorphic eruption of pregnancy (PEP; also referred to as pruritic urticarial papules and plaques of pregnancy [PUPPP]; Ch. 27)	Primigravida in third trimester; urticarial papules and plaques, especially in striae
Pruritic papular eruption of HIV disease[61] (Ch. 78)	Pruritic non-follicular papules in a symmetric distribution; HIV infection; may be an exaggerated reaction to arthropod antigens but without a recognized history of bites
Seabather's eruption (e.g. larvae of *Linuche unguiculata* and *Edwardsiella lineata*; Ch. 85)	Pruritic papules of skin covered by swimsuit; occurs after ocean swimming
Small vessel vasculitis (leukocytoclastic vasculitis; Ch. 24)	Palpable purpura that favors the lower extremities; eosinophils more commonly observed in drug-induced variant
Swimmer's itch or cercarial dermatitis (larvae of avian and mammalian schistosome species; Ch. 83)	Pruritic papules on uncovered skin; occurs after fresh-water swimming
Urticarial allergic eruption	Annular or gyrate urticarial plaques that persist >24 hours
Wells syndrome	See text
Less well-defined entities, with overlapping features	
Papular dermatitis (itchy red bump disease)	Markedly pruritic pink to red papules; may be associated with eczematous patches and/or dermographism; spongiotic dermatitis often seen histologically
Urticarial dermatitis	Very pruritic, urticarial and/or eczematous lesions involving the trunk and proximal extremities; favors the elderly (chronic eczematous eruption of aging) and may reflect immunosenescence; often requires UVB phototherapy, dapsone or systemic immunosuppressives (e.g. MTX, dupilumab) for control
Exudative discoid and lichenoid chronic dermatosis of Sulzberger and Garbe (oid-oid disease)[62]	Middle-aged men; pruritic lesions commonly involving genitals; progressive stages: discoid → exudative → lichenified; peripheral blood eosinophilia; possible variant of nummular dermatitis
Pachydermatous eosinophilic dermatitis[63]	South African Black teenage girls with generalized pruritic papules, hypertrophic genital lesions and peripheral blood eosinophilia; dapsone-responsive; possibly a variant of hypereosinophilic dermatitis of Nir–Westfried

*Hematopoietic stem cell or solid-organ.

Table 26.1 Eosinophil-associated dermatoses. *It should be emphasized that variable numbers of eosinophils may be encountered in a large number of inflammatory, neoplastic, and infectious skin disorders, in addition to those listed in this table.* ALCL, anaplastic large cell lymphoma; CLL, chronic lymphocytic leukemia; CTCL, cutaneous T cell lymphoma; DIHS, drug-induced hypersensitivity syndrome; DRESS, drug reaction with eosinophilia and systemic symptoms; LyP, lymphomatoid papulosis; MTX, methotrexate.

TISSUE EFFECTS AND INNATE IMMUNITY

The presence of eosinophils in healthy tissues such as the gastrointestinal tract suggests that they may also have a homeostatic function. In addition, eosinophil infiltration is associated with tissue remodeling and fibrosis. Although cytokines, including IL-5 and eotaxins, are known to mediate eosinophil development and survival, mechanisms underlying the basal regulation of eosinophils, including their circadian cycling, remained largely unknown until the identification of innate lymphoid cells (ILCs). Long-lived type 2 ILCs, also known as ILC2s, are resident in peripheral tissues and regulate basal eosinophilopoiesis and tissue eosinophil accumulation via constitutive and stimulated cytokine expression[10–12]. ILC2s secrete IL-5 constitutively and are induced to co-express IL-13 during type 2 inflammation, resulting in localized eotaxin production and eosinophil accumulation.

Studies of the interactions of skin ILCs with other cell types demonstrated that dermal ILCs interact selectively and strongly with mast cells[12,13]. Type 2 innate lymphocytes have been designated part of the "Th2 franchise", and a broad role for ILC2s is emerging for both eosinophils and metabolic homeostasis, e.g. in atopic dermatitis[10], in glucose metabolism within adipose tissue[14] and adipose tissue remodeling[15], and in allergic respiratory disease[16]. Interactions of eosinophils with nerves may in part explain pruritus and other neurophysiological changes (e.g. white dermographism) observed in eosinophil-infiltrated tissues[17,18].

Eosinophils may act as antigen-presenting cells for microbial (including staphylococcal superantigens), viral, and parasitic antigens, promoting T cell proliferation. They also play a role in the regulation of mast cell function. Activation of eosinophils via toll-like receptors (TLR) 7 and TLR9 affects several eosinophil functions, with the overall response influenced by a Th2-like cytokine milieu[19]. In addition, eosinophils can generate mitochondrial DNA traps that contain ECP and eMBP1 which have antimicrobial activity and can promote thrombosis. In summary, eosinophils participate in innate and acquired immunity[2] and their functional diversity has numerous ramifications for both homeostasis and disease pathogenesis[1].

EOSINOPHIL-ASSOCIATED DERMATOSES

"Eosinophil-associated dermatoses" encompass a wide range of diseases characterized by the presence of a few to many eosinophils and/or evidence of eosinophil degranulation in skin and/or mucous membranes. Disorders characteristically associated with eosinophil infiltration include arthropod bite reactions and ectoparasite infestations (see Chs. 84 & 85), drug eruptions (see Ch. 21), atopic dermatitis (see Ch. 12), helminth infections (see Ch. 83), and Wells syndrome (Fig. 26.2). However, there are a number of other skin diseases where tissue eosinophilia may be present, including bullous pemphigoid, urticaria, and eosinophilic granulomatosis with polyangiitis (EGPA; Churg–Strauss syndrome) (Table 26.1). In addition, tissue eosinophilia can be observed in a wide range of skin disorders, from inflammatory to infectious to neoplastic.

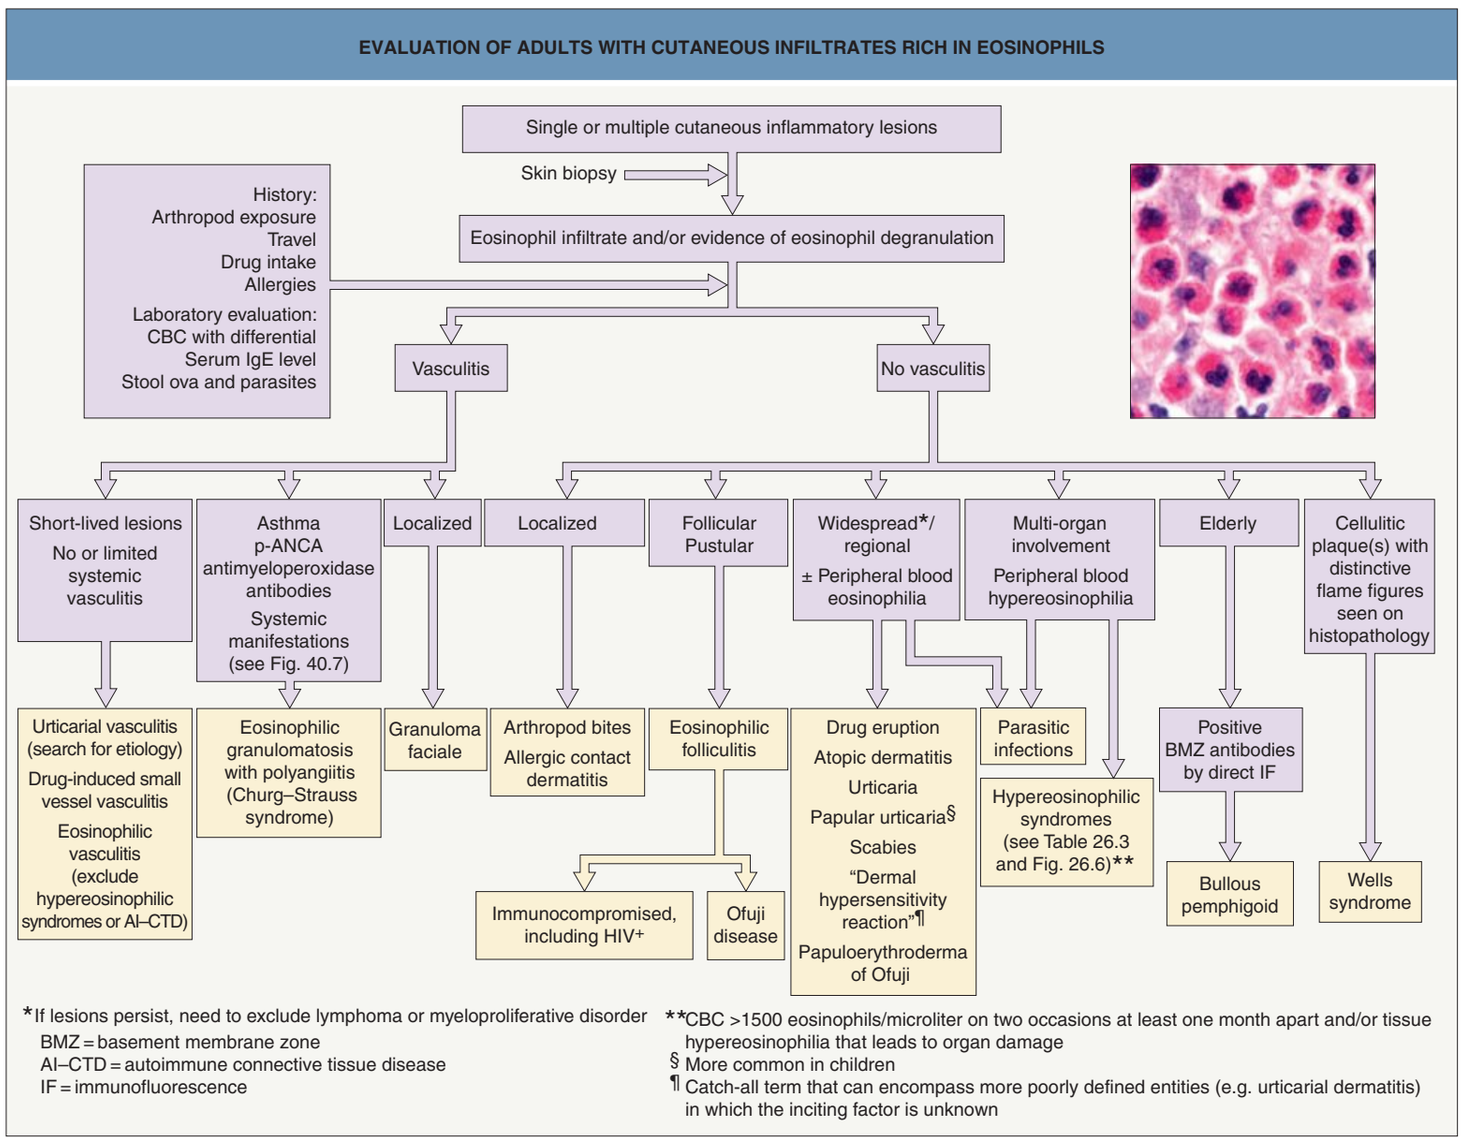

Fig. 26.2 Evaluation of adults with cutaneous infiltrates rich in eosinophils. These disorders are characterized histologically by eosinophil infiltration and/or eosinophil granule protein deposition. Peripheral blood eosinophilia occurs in some patients. Of note, systemic corticosteroids can significantly reduce the peripheral blood eosinophil count. *Photomicrograph, courtesy Lorenzo Cerroni, MD.*

More recently, it has been noted that mild to moderate peripheral eosinophilia (up to 35%–40%), along with tissue infiltration, is a key feature of IgG4-related disease (IgG4-RD[20]; Table 26.2)[20]. Initially described as a pancreatic disorder with increased serum IgG4 levels and numerous IgG4-positive plasma cells in affected tissues, the spectrum of IgG4-RD has been expanded to include any organ, including skin. Proposed cutaneous manifestations are granuloma faciale and lesions that resemble angiolymphoid hyperplasia with eosinophilia (see Table 26.2 & Ch. 24).

Wells Syndrome

Synonym: ■ Eosinophilic cellulitis

Key features

- The characteristic presentation is recurrent, painful and/or pruritic, edematous to indurated plaques
- Histologically, a diffuse dermal infiltrate composed of eosinophils and histiocytes is seen as are foci of amorphous/granular material, termed "flame figures", which reflect localized degranulation of eosinophils
- Flame figures are a characteristic but are not diagnostic feature, as they can be observed in a wide range of eosinophil-rich dermatoses
- Distinction between Wells syndrome as a specific entity and a reaction pattern occurring in the setting of another dermatosis may be difficult
- Dramatic improvement after administration of systemic corticosteroids

Introduction

Wells syndrome is a cutaneous disorder of unknown etiology characterized by one or more edematous (early) to indurated (late) plaques that resemble well-demarcated cellulitis. The classic histopathologic findings consist of a diffuse dermal infiltrate of eosinophils plus characteristic "flame figures".

History

Wells described the first patient in 1971 as "recurrent granulomatous dermatitis with eosinophilia". He later renamed the disease "eosinophilic cellulitis"[21]. Spigel and Winkelmann[22] proposed the eponym, Wells syndrome, in 1979.

Epidemiology

Over 100 cases of Wells syndrome have been reported to date, ranging from newborns to patients over 70 years of age.

Pathogenesis

The pathogenesis of Wells syndrome is unknown. Local hypersensitivity due to "triggers" has been proposed, including insect bites or stings, drugs, allergic contact dermatitis, an underlying malignancy, and infections (e.g. dermatophytes, viruses, *Toxocara canis*)[23,24]. Of note, peripheral lymphocytes isolated from patients with Wells syndrome were reported to have exaggerated responses to mosquito salivary gland extracts[25]. Activated eosinophils clearly play a major role in the pathophysiology of Wells syndrome and it is thought that Th2 cells, and IL-5 in particular, are responsible for eosinophil recruitment and activation in this disease[26].

Clinical features

In Wells syndrome, there are recurrent episodes of prodromal itching or burning, accompanied by markedly edematous plaques. The latter may have an annular or arcuate configuration[27], and vesicles and bullae can also be seen. Initially, the lesions are bright red, and then they fade to a pink–brown or slate-gray color (Fig. 26.3). The plaques may become indurated, and lesions usually resolve over 4 to 8 weeks. Less common clinical presentations include papules and hemorrhagic bullae. The extremities are most frequently affected, but involvement of the trunk can also be seen. The most common systemic complaint is malaise, with fever in less than a quarter of patients. Peripheral blood eosinophilia is common. Patients are often misdiagnosed as having erysipelas or acute cellulitis. Precipitating events, including arthropod bites and stings or vaccinations, have been described in a minority of patients[28].

Pathology

An interstitial dermal infiltrate of eosinophils, admixed with lymphocytes and histiocytes is seen (Fig. 26.4). The infiltrate is most prominent in the mid to deep dermis, with occasional involvement of the subcutaneous fat, fascia, and skeletal muscle. The superficial dermis may have massive papillary dermal edema to the point of subepidermal bulla formation. Intraepidermal vesiculation, with eosinophilic spongiosis, may also be present.

IgG4-RELATED DISEASE (IgG4-RD) AND CUTANEOUS DISORDERS THAT MAY HAVE INCREASED LESIONAL IgG4$^+$ PLASMA CELLS	
Characteristic findings (not present in all patients)	

• Clinical: swelling or mass(es) in one or more organ(s)/tissue(s)
• Blood: increased serum IgG4 level; increased serum IgE level; eosinophilia or hypereosinophilia
• Histopathology of affected organ(s)/tissue(s):
  • Dense infiltrates of lymphocytes and plasma cells
  • Fibrosis (typically storiform pattern)
  • IgG4$^+$ to IgG$^+$ plasma cells >40%; >10 IgG4$^+$ plasma cells/hpf
  • Eosinophil infiltrates
  • Obliterative phlebitis	

Affected organs/tissues and/or manifestations – emerging spectrum	
• Pancreas (autoimmune pancreatitis)	• Sclerosing cholangitis
• Lacrimal glands (bilateral)	• Salivary glands (often submandibular; bilateral; Mikulicz disease)
• Retroperitoneal fibrosis (previously viewed as idiopathic)	• Sinonasal eosinophilic angiocentric fibrosis
• Thyroid (Riedel thyroiditis, fibrous variant of Hashimoto thyroiditis)	• Aorta (aortitis, periaortitis)
• Orbit (pseudotumor, proptosis)	• Lung, pleura, pericardium, kidney (tubulointerstitial nephritis), prostate, stomach (lymphoplasmacytic gastritis), breast (sclerosing mastitis, pseudotumor)
Cutaneous disorders that may have increased lesional IgG4$^+$ plasma cells	
• Granuloma faciale	• Angiolymphoid hyperplasia with eosinophilia
• Kimura disease	• Rosai–Dorfman disease
• Cutaneous plasmacytosis	

Table 26.2 IgG4-related disease (IgG4-RD) and cutaneous disorders that may have increased lesional IgG4$^+$ plasma cells[64,65]. Corticosteroids represent the first-line treatment for systemic involvement, with anti-CD20 or anti-CD19 antibodies, Bruton tyrosine kinase inhibitors, and anti-SLAMF7 antibodies as potential additional therapies. hpf, high power field.

In addition to intact eosinophils, extracellular eosinophil granules are present in the dermis. The characteristic brightly eosinophilic flame figures consist of collagen fibers coated with eosinophil granule proteins[29] (Fig. 26.4, inset). Utilizing indirect immunofluorescence assays, extracellular eMBP1 from eosinophil granules has been localized to flame figures[30]. In addition, a palisade of histiocytes and a few multinucleated giant cells partially surround these flame figures. While flame figures are considered a hallmark of Wells syndrome, they are not a specific finding[31]. Flame figures can also be seen in other disorders in which degranulation of eosinophils occurs including arthropod bite and sting reactions, scabies, and less often, parasitic infections (e.g. onchocerciasis), bullous pemphigoid, pemphigus vegetans, and EGPA.

Fig. 26.3 Wells syndrome – clinical features. A Large edematous, erythematous plaque on the leg surrounded by several smaller plaques and nodules. This presentation may be misdiagnosed clinically as infectious cellulitis. **B** More mature dull pink nodules and plaques. *A, Courtesy Luis Requena, MD.*

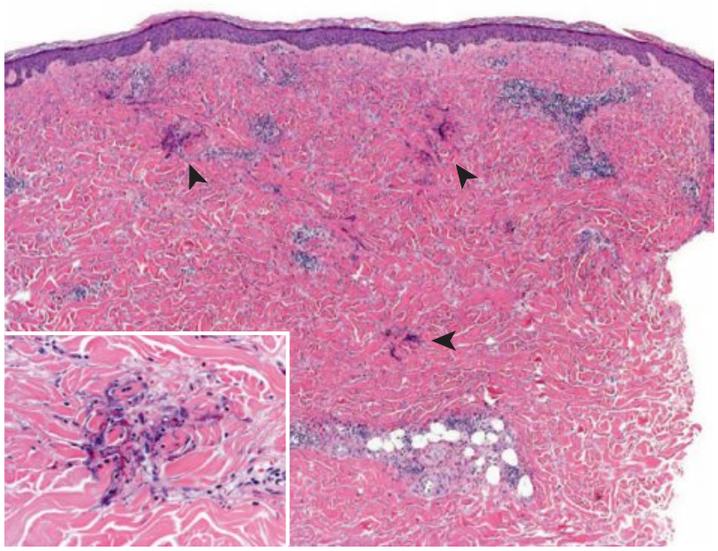

Fig. 26.4 Wells syndrome – histopathologic features. Perivascular and interstitial inflammatory infiltrates that contain eosinophils. There are several flame figures at sites of degranulated eosinophils (arrowheads; inset). *Courtesy Lorenzo Cerroni, MD.*

Differential diagnosis

Wells syndrome often has a striking clinicopathologic presentation[32]. Early on, bacterial cellulitis and erysipelas are the most common clinical mimics. The histopathologic findings of both erysipelas and bacterial cellulitis can also include significant edema, but neutrophils are the predominant inflammatory cell in these soft tissue infections. Other causes of pseudocellulitis, including exaggerated reactions to arthropod bites, should be considered (see Table 74.10).

Toxocara canis and other parasitic infections can present with clinical and pathologic findings resembling Wells syndrome. When a parasitic infection is suspected, laboratory evaluation including stool examinations, specific parasite serologies, and even PCR of stool may be necessary. Other disorders that may present with urticarial plaques due to infiltrates of eosinophils are listed in Table 26.1. Late (mature) lesions of Wells syndrome may clinically, but not histologically, resemble morphea.

Eosinophilic annular erythema (EAE) is also in the differential diagnosis, but this entity is considered by many to be a subset of Wells syndrome. EAE is a figurate erythema that presents with annular and polycyclic skin lesions due to dermal infiltrates of eosinophils. However, flame figures are uncommon. EAE has been observed in patients with a number of conditions including malignancy, autoimmune thyroid disease, borreliosis, chronic gastritis caused by *Helicobacter pylori* infection, diabetes mellitus, hepatitis C virus, chronic kidney disease, thymoma, and autoimmune pancreatitis[33].

Treatment

Initial therapy with prednisone 10–80 mg daily results in dramatic improvement within a few days in most patients[34]. Tapering the dose over one month is generally well tolerated. Flares or recurrence may be treated with additional courses of prednisone. Steroid-sparing medications, including minocycline, colchicine, antimalarials, dapsone,

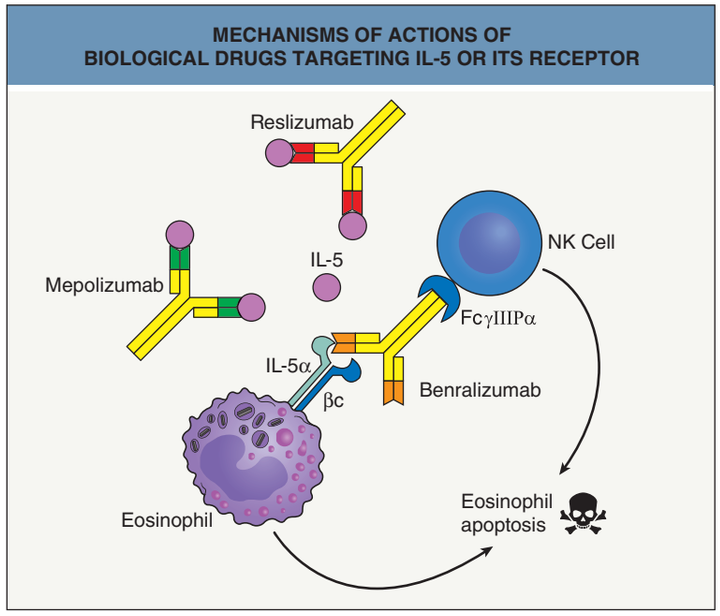

Fig. 26.5 Mechanisms of action of monoclonal antibodies that target IL-5 and IL-5Rα monoclonal antibodies. Anti-IL-5 antibodies inhibit its biological effects on eosinophils. Benralizumab interacts, via its Fab region, with the α subunit of the IL-5 receptor, thereby neutralizing IL-5 bioactivity. In addition, its Fc region binds to the FcγIIIRa on NK cells which induces apoptosis of eosinophils. See Ch. 138 for discussion of monoclonal antibodies that target the IL-4 receptor and IL-13. *From Pelaia C, Paolett G, Puggioni F, et al. Interlukin-5 in the pathophysiology of severe asthma. Front Physiol 2019;10:1514.*

griseofulvin, interferon-α and antihistamines, have limited evidence of efficacy. Recent reports suggest benefit with dupilumab, omalizumab (anti-IgE), mepolizumab (anti-IL-5), and benralizumab[35–37] (anti-α chain of IL-5R) (Fig. 26.5). For milder cases, potent topical corticosteroids may be sufficient[35–37].

HYPEREOSINOPHILIC SYNDROMES

Key features

- Mucocutaneous lesions occur in over 50% of patients with hypereosinophilic syndromes (HESs), most commonly presenting as pruritic erythematous papules or nodules, urticaria, angioedema, and/or mucosal ulcers
- Classification and treatment of HESs became more precise with discovery of the *FIP1L1-PDGFRA* fusion gene, whose protein product is a constitutively activated tyrosine kinase; additional chromosomal rearrangements have been identified that involve *PDGFRA*, *PDGFRB*, *FGFR1*, and *PCM1-JAK2* which encode platelet-derived growth factor receptor (PDGFR)-α, PDGFR-β, fibroblast growth factor receptor 1, and pericentriolar material 1/Janus kinase 2, respectively
- Based upon recently adopted terminology and classification criteria, primary (neoplastic) and secondary (reactive) forms of HES have been more clearly defined
- The *FIP1L1-PDGFRA* fusion gene and other genetic abnormalities (see above) are present in patients with primary (neoplastic) HES, which includes eosinophilic leukemia
- The lymphocytic (lymphoid) subtype of secondary (reactive) HES is characterized by a clonal proliferation of T cells with increased production of Th2 cytokines, particularly IL-5
- End-organ damage may occur from sustained tissue eosinophilia, including life-threatening endomyocardial fibrosis and/or thrombosis

Introduction

The term "hypereosinophilic syndrome" or "HES" was coined in the late 1960s to refer to a spectrum of eosinophil-associated diseases with common clinical features, including peripheral eosinophilia (>1500 cells/mcl) and internal organ involvement. In the 1990s, a subset of patients with HES was found to have a clonal proliferation of T cells, with increased production of IL-5. In 2003, it was discovered that some patients with the HES variant that responded to imatinib had a *FIP1L1-PDGFRA* fusion gene due to a chromosomal translocation[38]. Its protein product is a constitutively activated tyrosine kinase that is 100 times more sensitive to inhibition by imatinib than the BCR-ABL kinase present in chronic myelogenous leukemia (CML) patients. Since then, additional genetic abnormalities have been identified[8] and a number of HES variants have been described (Table 26.3)[39], leading to more tailored treatment recommendations (Fig. 26.6)[11,40].

History

The term "hypereosinophilic syndromes (HESs)" was first coined in 1968 with the diagnostic criteria initially proposed in 1975[41]. This was followed by the description of two major variants of HES – lymphocytic (LHES) and myeloproliferative (MHES). In 2011, experts from multiple disciplines came to a consensus regarding terminology and classification criteria during the Working Conference on Eosinophil Disorders and Syndromes[4,32,39]. The currently recognized clinical variants are outlined in Table 26.3[40]. Of note, the World Health Organization's definition of HES excludes myeloid variants associated with molecular abnormalities[42].

Epidemiology

Up to 25% of patients have associated HES (see Table 26.3), which has an equal sex distribution, while MHES (*FIP1L1-PDGFRA*- or other mutation-positive HES) has a striking male predominance (>90%). HES can affect all age groups, but the majority are adults. While individuals with the *FIP1L1-PDGFRA* fusion gene may be regarded as having chronic eosinophilic leukemia, there are rare patients who develop more aggressive disease with transformation to acute leukemia[8]. Patients with LHES are at risk for developing lymphoma.

Clinical Features

Patients present with signs and symptoms related to the organ systems affected by eosinophilic infiltrates. The most common mucocutaneous findings are pruritic erythematous macules, papules, plaques or nodules on the trunk and extremities or urticaria and angioedema[43,44]. Other cutaneous manifestations include erythema annulare centrifugum-like lesions, livedo reticularis, retiform purpura, and superficial thrombophlebitis, with the thrombotic entities occurring almost exclusively in primary HES.

Since eosinophils have been implicated as the primary cause of end-organ damage in all forms of HES, clinical improvement usually parallels a decrease in both blood and tissue eosinophilia[45]. However, the underlying pathogenesis of variants other than MHES and LHES still remains unclear[39]. Occasionally, patients with episodic angioedema with eosinophilia (Gleich syndrome) or the *n*odules, *e*osinophilia, *r*heumatism, *d*ermatitis and *s*welling (NERDS) syndrome may develop T cell clones and fulfill the diagnostic criteria for LHES (see Table 26.3). Therefore, as outlined in Figure 26.6, patients who cannot be classified as either MHES or LHES should continue to be monitored for cytogenetic abnormalities or T cell clonality[46,47].

Pathology

The histopathology of cutaneous lesions of HES is nonspecific and varies depending upon the type of skin lesion biopsied. Urticarial lesions have findings similar to ordinary urticaria, i.e. perivascular > interstitial infiltrates of lymphocytes, eosinophils, and occasional neutrophils. Biopsies from papules or plaques occasionally exhibit spongiosis in addition to the dermal infiltrate that usually contains at least a few eosinophils. Flame figures are occasionally present. When studied with immunohistochemical or immunofluorescence stains for specific eosinophil granule proteins, HES mucosal ulcers show extensive deposition of granule proteins in the absence of morphologically identifiable intact eosinophils. Thrombosis of dermal blood vessels has been observed in biopsy specimens from retiform purpura and necrotic skin lesions in HES patients.

Differential Diagnosis

The clinical and histopathologic differential diagnosis of HES includes other eosinophil-associated dermatoses (see Table 26.1), along with other dermatoses in which eosinophil degranulation occurs but infiltrates of intact eosinophils are not observed. The footprint of eosinophil participation is deposition of granular contents (e.g. eMBP1), which remain in the tissue while the cell itself is not morphologically identifiable, although parts of the eosinophil may be recognizable by electron microscopy. However, most other eosinophil-associated dermatoses will not be associated with peripheral blood hypereosinophilia of >1.5 cells × 10^9/L.

In contrast to Wells syndrome, patients with primary HES tend to be more systemically ill, with signs and symptoms of multi-organ involvement. Occasionally, dermal flame figures are seen in skin lesions of HES. EGPA can resemble HES clinically and is considered by some authors to be an HES-associated disease. Patients with EGPA have asthma as well as prominent IgG4 and IgE responses (see Ch. 24)[48]. While patients with EGPA have vasculitis of small and medium-sized vessels, vasculitis is an uncommon feature of HES. However, thromboembolic phenomena may produce lesions that mimic vasculitis (see Ch. 22).

Parasitic infections and infestations may closely resemble HES. A history of travel to endemic areas or a suggestive dietary history implicates helminthiasis. In such patients, serologic testing for anti-*Strongyloides* antibodies and three stool samples for ova and parasites should be obtained. A total serum IgE level >500 IU/ml is often seen in helminth infections. Inappropriate treatment of *Strongyloides stercoralis* with systemic corticosteroids or other immunosuppressives may result in severe sequelae, including death.

DIAGNOSTIC CRITERIA AND CLASSIFICATION OF HYPEREOSINOPHILIC SYNDROMES (HESs) AND OTHER ENTITIES WITH HYPEREOSINOPHILIA		
Three diagnostic criteria		
1. Peripheral blood hypereosinophilia – defined as >1.5 eosinophils × 10^9/L blood [>1500 eosinophils/mcl]* on two examinations at an interval of one month or greater† – and/or – Tissue hypereosinophilia defined by the following: • Percentage of eosinophils in bone marrow section exceeds 20% of all nucleated cells – and/or – • Pathologist is of the opinion that tissue infiltration by eosinophils is extensive – and/or – • Marked deposition of eosinophil granule proteins is found in the absence or presence of major tissue infiltration by eosinophils 2. Organ damage and/or dysfunction attributable to tissue hypereosinophilia 3. Exclusion of other disorders or conditions as major reason for organ damage		
Variants of HES (end-organ damage attributable to hypereosinophilia)		
Myeloid HES (MHES, neoplastic, primary) – 15%–20%	***Lymphocytic HES (LHES, secondary)***	***Overlap HES – eosinophilic disease restricted to a single organ – or – a defined eosinophilic syndrome that overlaps in clinical features with idiopathic HES***
• Underlying neoplasm of stem cells, myeloid cells, or eosinophils (WHO classification) • Eosinophils are considered (or shown) to be clonal‡ • Male predominance • In addition to typical skin lesions (see text), signs of cutaneous thromboses (e.g. retiform purpura) • Mucosal ulcers poor prognostic sign • Fever, weight loss, malaise, subendocardial fibrosis, restrictive cardiomyopathy, mitral or tricuspid valve insufficiency, hepatosplenomegaly, neutrophilia • Some patients have high serum tryptase and vitamin B_{12} levels, tissue fibrosis, splenomegaly, and bone marrow biopsies with increased numbers of $CD25^+$ atypical spindle-shaped mast cells¶	• Hypereosinophilia is thought to be cytokine-driven, due to clonal T cells§ producing Th2 cytokines (IL-5, -4, -13) • Skin is most commonly affected organ (severe pruritus, dermatitis, erythroderma, urticaria, angioedema) • Lymphadenopathy • Serum IgE and TARC (CCL17) levels are typically elevated (likely due to actions of IL-4, -13) • T cell clone often remains stable for years, but transformation to lymphoma can occur	• Episodic angioedema with eosinophilia (Gleich syndrome)‖ • *N*odules, *e*osinophilia, *r*heumatism, *d*ermatitis and swelling (NERDS) syndrome‖ • Eosinophilic granulomatosis with polyangiitis (EGPA) • Eosinophilia myalgia syndrome and toxic oil syndrome (both historic)
Associated HES (secondary, reactive)		***Overlap HES (eosinophilic disease restricted to an organ other than the skin)***
• HES in the setting of a known secondary cause • Hypereosinophilia cytokine-driven (IL-3, IL-5, GM-CSF), but not due to clonal T lymphocytes • Associated with underlying primary immunodeficiencies (e.g. Omenn syndrome, hyper IgE syndrome [*STAT3* or *DOCK8* mutations]), atopic diseases, helminth or other infections, drug hypersensitivity or other inflammatory disorders (e.g. chronic GVHD), hematologic or solid-organ malignancies • Systemic mastocytosis, including with an associated hematologic (non-mast cell lineage) neoplasm • Hypereosinophilia also seen in patients with cholesterol emboli, inflammatory bowel disease, and sarcoidosis		• Eosinophilic *gastrointestinal* diseases – eosinophilic esophagitis, gastroenteritis, colitis, pancreatitis, and hepatitis; eosinophilic ascites • Eosinophilic *pulmonary* diseases – eosinophilic asthma, bronchitis, pneumonia, pleuritis, rhinosinusitis (and nasal polyposis) • Eosinophilic *genitourinary* diseases – nephritis, cystitis, endometritis, myometritis • Other eosinophilic diseases – mastitis, myocarditis, synovitis, ocular disorders

*Eosinophilia is defined as 0.5–1.5 eosinophils × 10^9/L blood.
†In the case of evolving life-threatening end-organ damage, the diagnosis of HES can be made immediately to avoid delay in treatment.
‡*FIP1L1-PDGFRA* fusion gene (>80% of patients) and other rarer fusion genes or rearrangements involving *PDGFRB*, *FGFR1* or *PCM1-JAK2*, which encode platelet-derived growth factor receptor-β, fibroblast growth factor receptor-1, and pericentriolar material 1/Janus kinase 2, respectively; includes patients with eosinophilic leukemia, who may have other cytogenetic abnormalities. Point mutations in *JAK2* may also be seen.
¶In the WHO classification of mastocytosis, such patients (who have the *FIP1L1-PDGFRA* fusion gene) are designated as having systemic mastocytosis with associated clonal hematological non-mast cell-lineage disease (AHNMD).
§Some patients have phenotypically abnormal lymphocyte populations with unique surface phenotypes (e.g. $CD3^+CD4^-CD8^-$, $CD3^-CD4^+$).
‖May develop T cell clones.

Table 26.3 Diagnostic criteria and classification of hypereosinophilic syndromes (HESs) and other entities with hypereosinophilia. Two additional clinical variants are ***idiopathic*** and ***familial***[40]; the latter is rare and may have an autosomal dominant transmission pattern (with one case mapped to chromosome 5q where the IL-5 gene cluster resides) and it is sometimes asymptomatic[6]. *Data from references 52–55.*

In patients with HES and isolated urticarial plaques with or without angioedema, the differential diagnosis includes ordinary urticaria. In such patients, demonstration of internal organ involvement favors HES. In addition, HES with episodic angioedema may resemble hereditary or acquired angioedema clinically, but complement studies help to distinguish these entities (see Fig. 18.19). Furthermore, patients with hereditary angioedema often have a family history of the disease and rarely are their peripheral blood eosinophil counts as high as in HES.

Treatment

If patients do not present with life-threatening manifestations, high-dose corticosteroids (e.g. prednisone 1 mg/kg/day), if indicated, can be initiated after the evaluation is complete (see Fig. 26.6). Patients should be administered ivermectin if there has been exposure to *Strongyloides*.

If *FIP1L1-PDGFRA* or other genetic abnormalities involving *PDGFRA* or *PDGFRB* are present, imatinib therapy is warranted (see Fig. 26.6)[46,47]. As a tyrosine kinase inhibitor, imatinib prevents autophosphorylation of the fusion protein and phosphorylation of other substrates, resulting in termination of the signaling cascade that induces genes related to eosinophil proliferation and activation. Patients respond to varying doses of imatinib, depending upon an individual patient's sensitivity and ability of the given dosage to suppress the mutant clone. Imatinib doses ranging from 400 mg daily to 100 mg weekly or less have proven effective. However, maintenance therapy is required to avoid relapse. Because endomyocardial disease may worsen during the first several days of imatinib administration, serum levels of troponin and

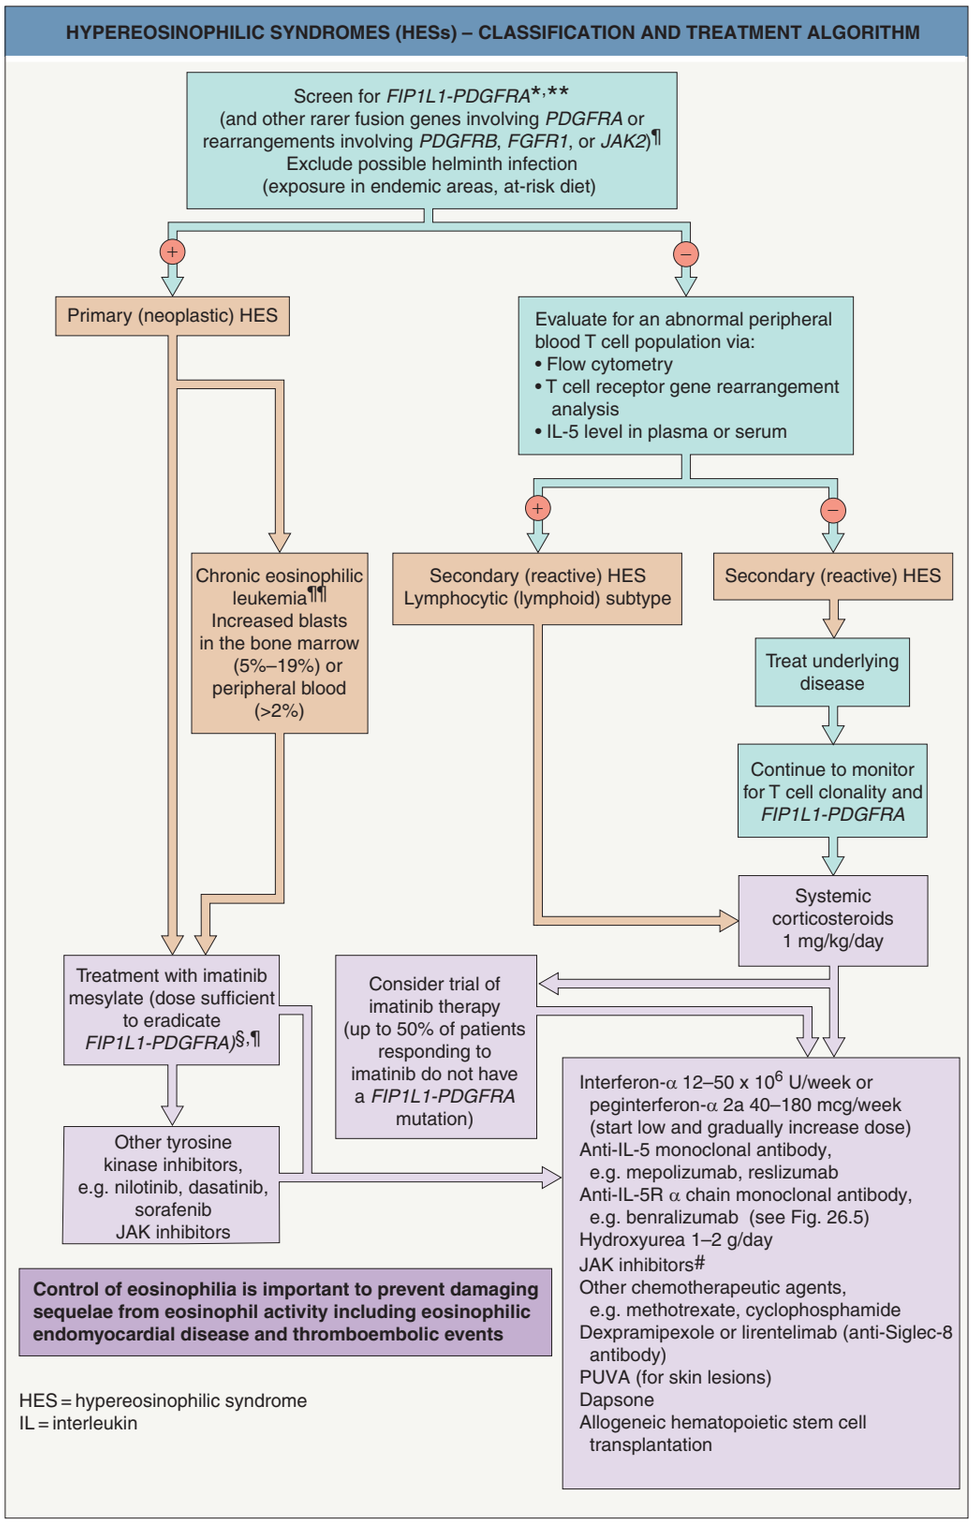

Fig. 26.6 Hypereosinophilic syndromes (HESs) – classification and treatment algorithm. *An 800 kb deletion on chromosome 4 produces a fusion gene composed of a portion of the *PDGFRA* (platelet-derived growth factor receptor α) gene that encodes its kinase domain linked to a previously uncharacterized gene that resembles *Fip1*, which encodes an essential component of the *Saccharomyces cerevisiae* polyadenylation machinery. The resultant product is a constitutively activated tyrosine kinase that is a target of the tyrosine kinase inhibitor, imatinib. Screening can be performed on a peripheral blood sample via reverse transcriptase-PCR or fluorescence *in situ* hybridization (FISH). **Bone marrow biopsy with cytogenetic studies should be done to exclude hematologic disorders that are accompanied by eosinophilia. Increased bone marrow mast cells and increased serum tryptase may be observed. ¶*PDGFRB*, *FGFR1*, and *JAK2* encode platelet-derived growth factor receptor-β, fibroblast growth factor receptor-1, and Janus kinase 2, respectively; patients with genetic abnormalities involving *PDGFRA* and *PDGFRB* typically respond to imatinib but not those involving *FGFR1*. Patients may become resistant due to new mutations (during blast crisis) or tandem mutations (during chronic phase). ¶¶May have other clonal cytogenetic and molecular genetic abnormalities; in the presence of eosinophilia, considered sufficient for diagnosis even in the absence of excess blasts. §Plus systemic corticosteroids if cardiac involvement. #Including those with *JAK2* mutations. *Data from refs 40,52–57.*

N-terminal pro-brain natriuretic peptide (NT-proBNP) should be monitored. Preemptive and concurrent treatment with corticosteroids is also recommended to maintain cardiac function. Other kinase inhibitors (nilotinib, dasatinib, and sorafenib) may also be useful in patients who do not respond to imatinib or become resistant as a consequence of mutations such as T674I in *FIP1L1-PDGFRA*[49].

Secondary HES is best managed by treating the underlying disease, once determined. When the underlying disease fails to respond to first-line therapies and the patient lacks *PDGFRA* or *PDGFRB* fusion genes, then corticosteroids are begun, usually prednisone at 1 mg/kg/day; ~70% of patients will respond, with the peripheral eosinophilia returning to normal levels. For patients who fail corticosteroid monotherapy or develop significant long-term side effects, there are several other therapeutic options (see Fig. 26.6). For example, patients with no detectable *FIP1L1-PDGFRA* fusion gene have achieved partial remission from imatinib, although the mechanism of response in these patients is unclear. Perhaps some patients had diagnostically occult *PDGFRA* or *PDGFRB* rearrangements[49]. Thus, imatinib represents a reasonable therapeutic option, given its relative safety.

Interferon (IFN)-α (12–50 × 10^6 U/week) has been beneficial in patients with both primary and secondary HES. Its mode of action is likely via myelosuppression but may include effects on Th2 helper cells by changing the cytokine milieu (including a decrease in IL-5 levels). For some patients, pegylated interferon (peginterferon-α 2a), administered weekly, is better tolerated. One concern regarding the use of IFN-α, based upon the findings of an *in vitro* study in which IFN-α acted as a growth factor for $CD3^-CD4^+$ cells, is probably minimized by concomitant corticosteroid therapy.

Two monoclonal antibodies against human IL-5 approved for the treatment of asthma, mepolizumab and reslizumab, and a monoclonal antibody directed against the alpha chain of the IL-5R, benralizumab, have been used to treat HES in clinical trials (see Fig. 26.5). Analyses of cytokine production by lymphocytes before and after treatment with mepolizumab showed a striking reduction in Th2 cytokine production (IL-13, IL-10) in addition to the expected IL-5 reduction[50]. In a randomized, double-blind, placebo-controlled trial involving *FIP1L1-PDGFRA*-negative patients who were already receiving prednisone (20–60 mg/day), administration of mepolizumab (750 mg IV every 4 weeks for 9 cycles) led to twice as many individuals (84% vs 43%) being successfully tapered to a stable prednisone dose of ≤10 mg/day[51].

The main treatment goals via single- or multiple-agent regimens are relief of symptoms and maintaining the peripheral eosinophil count in the range of $1–2 \times 10^9$/L blood or less[40]. HES patients also need to be routinely monitored for organ involvement, particularly cardiac disease, in addition to progression to lymphoma or leukemia. Patients who fail corticosteroid monotherapy have a worse prognosis.

Additional table on entities in which flame figures may be seen, available in our eBook (see inside front cover for access code).

INTRODUCTION AND BACKGROUND

For decades, the specific dermatoses of pregnancy represented a confusing group of overlapping entities, understood largely through anecdotes and case reports. However, more recent reviews have simplified and condensed the list of pregnancy-specific dermatoses (Table 27.1)[1–3]. For example, impetigo herpetiformis is now generally recognized as pustular psoriasis, perhaps induced by the relative hypocalcemia of pregnancy (see Ch. 8). Also, prurigo annularis, first reported in 1941 (without histology or laboratory information), and linear IgM disease of pregnancy (described in 1988) have not been subsequently reported yet are frequently perpetuated in reviews.

Much of the confusion can be dispelled by reviewing the original articles: Besnier (1904) first used the term "prurigo gestationis" to include all patients with pregnancy-related dermatoses, other than those with pemphigoid gestationis. Costello (1941) subsequently referred to these patients as "prurigo gestationis of Besnier" and estimated an incidence of 2% of all pregnancies. Bourne (1962) characterized a subset of patients with intensely pruritic papules or urticarial plaques that tended to appear during the later part of the third trimester, coining the term "toxaemic rash of pregnancy". Initial lesions typically developed within the abdominal striae of short women who experienced excessive weight gain during pregnancy. However, he offered no histopathologic or laboratory details.

Spangler et al. (also 1962) reported on a series of women with intensely pruritic, widely scattered, excoriated papules. Initial onset was during the second or third trimester and all patients suffered recurrences during subsequent gestations. The hallmarks of Spangler's cases were biochemical: elevated urinary human chorionic gonadotropin (HCG), decreased plasma hydrocortisone, and decreased serum half-life of hydrocortisone. Liver function tests and histopathology were not reported, and immunofluorescence (IF) was not yet available. Most notably, Spangler's papular dermatitis was associated with high fetal wastage, a finding now thoroughly discredited.

Nurse (1968) cited all of the above literature but ignored it, dividing patients with (non-pemphigoid gestationis) pregnancy eruptions into "early" and "late" forms. The late papular/urticarial form clearly overlapped with Bourne's "toxaemic rash of pregnancy", and has since been described as "pruritic urticarial papules and plaques of pregnancy" (PUPPP), "toxic erythema of pregnancy", and, most recently, "polymorphic eruption of pregnancy" (PEP). Nurse's "early-onset" patients and Spangler's "papular dermatitis" patients were undoubtedly drawn from the same clinical spectrum, and subsequently these entities were reclassified as forms of "prurigo of pregnancy" (see Table 27.1).

Pruritic folliculitis of pregnancy was added to the list of pregnancy-specific diseases in 1981, yet all six of the original patients were thought to have papular dermatitis clinically. They were classified as having a different entity based solely upon shared histologic features, that is, sterile folliculitis. In spite of their clinical similarity to the patients reported by Spangler, none had appropriate biochemical investigations. In 1998, an adaptation of the Holmes and Black classification scheme (1983)[2] was published[3] and listed pruritic folliculitis as a variant of prurigo of pregnancy (see Table 27.1).

Introduction of the term "atopic eruption of pregnancy (AEP)" represents the most recent revision to the classification of dermatoses of pregnancy[1]. Based upon an analysis of over 500 pregnant women with pruritus[1], significant overlap, both clinical and histologic, was noted amongst those patients with the diagnoses of prurigo of pregnancy, pruritic folliculitis of pregnancy, and eczema in pregnancy (~50% of the patients in this series)[4]. AEP was thought to be a useful diagnostic term that encompassed these three disorders and reminded the clinician that the eczema was more likely to be of new onset as opposed to a flare of previously diagnosed atopic dermatitis.

Because of the lack of primary lesions, intrahepatic cholestasis of pregnancy (ICP) had long been omitted from the list of pregnancy dermatoses. However, failure to appreciate ICP in a pregnant woman with widespread excoriations or even prurigo nodularis surely, in retrospect, accounts for some of the confusion in terminology. Furthermore, ICP is the most important diagnosis to exclude in a pregnant patient with pruritus, as it is associated with significant fetal risk (see below).

GESTATIONAL PEMPHIGOID

Synonyms: ■ Pemphigoid gestationis ■ Herpes gestationis

Key features

- Rare, pruritic, vesiculobullous eruption that develops during late pregnancy or the immediate postpartum period
- Linear C3 deposition along the basement membrane zone (BMZ) by direct IF
- IgG1 autoantibodies are directed against a transmembrane hemidesmosomal protein (BP180; BPAG2; collagen XVII)
- Increased risk of prematurity and small-for-gestational age neonates; the risk correlates with disease severity
- Commonly recurs in subsequent pregnancies

Introduction

Gestational pemphigoid is a rare, self-limited, autoimmune bullous disease. It is the most clearly characterized dermatosis of pregnancy and the only one that may also affect the skin of the newborn.

History

Milton first coined the term "herpes gestationis" in 1872 and Bulkley (1874) canonized the term "as embodying the clinical characters of the eruption and signifying at the same time the sex and state of the body in which it appears". Little additional insight was gained until IF techniques revealed complement deposition along the BMZ in 1973, a feature now accepted as essential for the diagnosis of gestational pemphigoid.

Epidemiology

The incidence of gestational pemphigoid has been estimated at 1:1700–1:50 000 pregnancies[5,6], correlating with the prevalence of

CLASSIFICATION OF THE DERMATOSES OF PREGNANCY

Atopic eruption of pregnancy (AEP)	Prurigo of pregnancy*,† Prurigo gestationis (Besnier) Early-onset prurigo of pregnancy (Nurse) Papular dermatitis of pregnancy (Spangler) Pruritic folliculitis of pregnancy* Linear IgM disease of pregnancy Eczema in pregnancy

*Former classification by Holmes & Black (1983)[2].
†Former classification by Shornick (1998)[3].

Table 27.1 Classification of the dermatoses of pregnancy[1]. The preferred terms are in bold.

HLA-DR3 and -DR4 in different populations. While occurring primarily during pregnancy and the immediate postpartum period, gestational pemphigoid has rarely developed in association with trophoblastic tumors (hydatidiform mole, choriocarcinoma). However, no case of a pemphigoid-like disease has been reported in men with choriocarcinoma, who have a biochemically similar yet entirely syngenic tumor; of note, the nuclear genome in placental tissue (and hence choriocarcinoma in women) is primarily paternal in origin. Patients with a history of gestational pemphigoid appear to be at increased risk for the development of Graves disease[7].

Pathogenesis

Historically, gestational pemphigoid was thought to be caused by an anti-BMZ "serum factor" (the "herpes gestationis [HG] factor") that induces C3 deposition along the dermal–epidermal junction. This factor is now known to be complement-fixing autoantibodies of the IgG1 subclass directed against a 180 kDa transmembrane hemidesmosomal protein (BP180; BPAG2; collagen XVII). As in patients with bullous pemphigoid (BP), it is the non-collagenous (NC) segment closest to the plasma membrane of the basal keratinocyte, NC16A, that constitutes the immunodominant region of BP180 (see Fig. 31.9). Circulating antibodies are almost exclusively directed against this domain, as demonstrated by ELISA and immunoblot studies of maternal or neonatal sera.

What initiates the production of autoantibody remains enigmatic. Because the antibodies also bind to amniotic basement membrane[8] (a structure derived from fetal ectoderm and antigenically similar to skin), attention has focused on immunogenetics and potential cross-reactivity between placental tissue and skin. Immunogenetic studies have revealed a marked increase in HLA antigens DR3 or DR4, and, curiously, nearly 50% of patients have the simultaneous presence of both. There is essentially a 100% incidence of anti-HLA antibodies in patients with a history of gestational pemphigoid[9]. Since the only source of disparate HLA antigens is typically the placenta (which is primarily of paternal origin), the universal finding of anti-HLA antibodies implies a high frequency of immunologic insult during gestation. Women with gestational pemphigoid also have increased expression of MHC class II antigens (DR, DP, DQ) within the villous stroma of their chorionic villi. It has therefore been proposed that gestational pemphigoid is a disease, initiated by the aberrant expression of MHC class II antigens (of paternal haplotype), that serves to initiate an allogeneic response to placental BMZ, which then cross-reacts with skin[10].

Fig. 27.1 Gestational pemphigoid. A Intact tense bullae arising within areas of edematous erythema as well as erosions due to ruptured bullae; lesions typically involve the umbilical region. **B** Confluent crusted erythematous plaques studded with small vesicles; umbilical involvement is again noted. Dusky urticarial lesions are also present on the thighs. *B, Courtesy Luis Requena, MD.*

Clinical Features

Gestational pemphigoid may develop during any trimester as well as immediately postpartum, but classically it presents during late pregnancy. There is an abrupt onset of cutaneous lesions on the trunk, in particular the abdomen and often within or immediately adjacent to the umbilicus (Fig. 27.1). Rapid progression to a generalized pemphigoid-like eruption then occurs, with pruritic urticarial papules and plaques, followed by clustered (herpetiform) vesicles or tense bullae on an erythematous base. The eruption may involve the entire body, sparing only the mucous membranes. While the clinical presentation and course may vary considerably, spontaneous improvement during late gestation is common. This is followed, however, by a flare at the time of delivery in 75% of patients. Such flares may be dramatic, with an explosive onset of blistering within hours.

Most disease activity spontaneously remits during the weeks to months following delivery, but there are isolated reports of a protracted course postpartum. Flares and/or recurrences in association with menstruation are common, and in 25%–50% of patients, they may also be induced by oral contraceptives (Table 27.2). Gestational pemphigoid may not develop during the patient's first pregnancy, but once established, it is quite likely to recur in subsequent pregnancies, usually with

DERMATOSES OF PREGNANCY – FETAL RISK, INVOLVEMENT OF NEWBORN SKIN, AND RISK OF RECURRENCE			
Dermatosis	**Fetal risk**	**Newborn skin involvement**	**Risk of recurrence**
Gestational pemphigoid	Increased risk of prematurity and small-for-gestational age neonates; risk correlates with disease severity	Mild and transient lesions of gestational pemphigoid in up to 10%	Commonly recurs ("skipped" pregnancies in only 5%–8% of women); recurrences induced by oral contraceptives in 25%–50%
Polymorphic eruption of pregnancy	None	None	Usually does not recur
Intrahepatic cholestasis of pregnancy	Increased risk of premature labor (20%–60%), intrapartal fetal distress (20%–30%), and stillbirths (1%–2%)	None	Recurrence in 45%–70% of subsequent pregnancies; may be triggered by oral contraceptives
Atopic eruption of pregnancy	None	None	Commonly recurs due to atopic diathesis

Table 27.2 Dermatoses of pregnancy – fetal risk, involvement of newborn skin, and risk of recurrence.

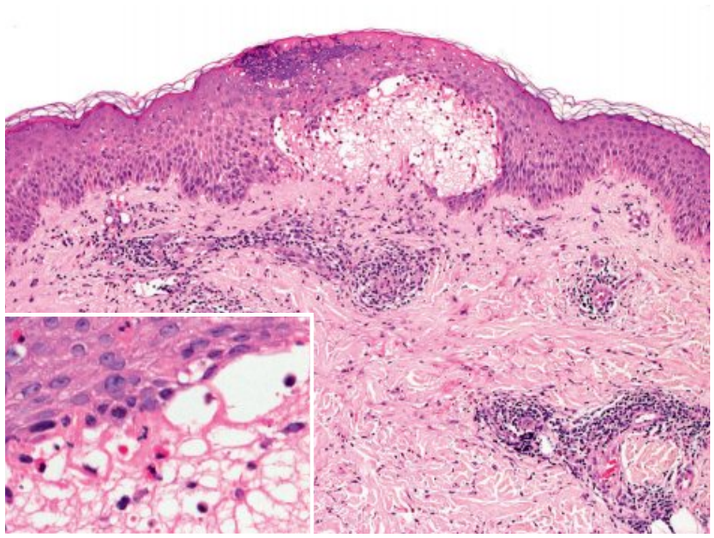

Fig. 27.2 Gestational pemphigoid – histopathologic features of an early lesion. an earlier onset and more severe course. "Skipped" pregnancies have been observed in 5%–8% of women.

Approximately 10% of newborns develop mild skin involvement due to passive transfer of maternal antibodies and this resolves spontaneously within days to weeks (see Ch. 34). There seems to be an increased risk of prematurity and small-for-gestational age neonates, presumably due to chronic placental insufficiency. More recently it was shown that this risk correlates with disease severity, i.e. occurrence of blistering and early onset, and not with the use of systemic corticosteroids[11].

Pathology

The classic histologic finding of a subepidermal vesicle is seen in the minority of patients. Instead, a nonspecific mixed cellular infiltrate containing a variable number of eosinophils is more common. The presence of eosinophils is the most constant histologic feature of gestational pemphigoid (Fig. 27.2).

The essential component for the diagnosis of gestational pemphigoid is a linear deposition of C3 along the BMZ of perilesional skin by direct IF microscopy (Fig. 27.3). This is observed in 100% of patients, and linear IgG deposition is seen in 30% of patients. When salt-split skin specimens are employed for *conventional* indirect IF, deposition of IgG along the bottom of the epidermal fragment is observed in 30% of patients. However, *complement-added* indirect IF reveals the circulating anti-BMZ IgG1 autoantibodies in essentially all patients. Determination of antibody titers via BP180-NC16A ELISA may be helpful in following disease activity and monitoring therapy.

An increased incidence of anti-thyroid antibodies has been documented, but clinically apparent thyroid dysfunction is uncommon[7]. Routine laboratory investigations are normal.

Differential Diagnosis

The most frequent considerations in the differential diagnosis are PEP and drug eruptions. PEP is a particularly challenging exclusion, given the difficulty of distinguishing PEP and urticarial lesions of gestational pemphigoid. Direct and indirect IF and, more recently, the BP180-NC16A ELISA are key to the differentiation and are especially relevant in helping the patient plan for future pregnancies.

Treatment

The primary goal in treating this self-limited disease is to relieve pruritus and suppress blister formation. In mild cases, the use of potent topical corticosteroids combined with emollients and systemic antihistamines may be adequate. However, systemic corticosteroids remain the cornerstone of therapy (Table 27.3). Most patients respond to 0.5 mg/kg of prednisolone daily; the dose is tapered as soon as blister formation is suppressed. The common flare associated with delivery usually requires a temporary increase in dosage. Those rare patients with refractory disease may benefit from plasmapheresis during pregnancy. Persistent disease after delivery is uncommon and is treated like BP.

Anecdotal alternatives to corticosteroids (dapsone, doxycycline, or minocycline ± nicotinamide, pyridoxine, cyclosporine) or adjuvants (methotrexate, cyclophosphamide, gold, IVIg) have been tried.

SPECIAL CONSIDERATIONS FOR CORTICOSTEROID AND ANTIHISTAMINE USE DURING PREGNANCY	
Corticosteroids	
Topical	• Recent large, population-based studies and a Cochrane review have *not* shown an increased risk of malformations, including oral cleft palate, or preterm delivery • Because fetal growth restriction has been reported with extensive use of potent corticosteroids (CS), particularly >300 g during the pregnancy, mild to moderate CS are recommended over potent CS • If potent CS are required, the treatment period should be limited in duration • Can add to risk of developing striae distensae
Systemic	• Prednisolone is the systemic corticosteroid of choice for dermatologic indications as it is largely inactivated in the placenta (mother : fetus = 10 : 1) • Use of the lowest effective corticosteroid dose is recommended • During the first trimester, particularly between weeks 8 and 11, a possible slightly increased risk of cleft lip/cleft palate has been debated, especially if high doses prescribed and for >10 days, but this was not substantiated by a recent large population-based case–control study • If use is long-term and extends late into gestation, fetal growth should be monitored and the risk of adrenal insufficiency in the newborn should be addressed
Antihistamines	
Systemic	• During the first trimester, the classic sedating agents (e.g. chlorpheniramine, diphenhydramine, clemastine, dimethindene) are preferred because of the preponderance of safety data • If a non-sedating agent is requested, loratadine is the first choice and cetirizine the second choice; both are considered safe throughout pregnancy

Table 27.3 Special considerations for corticosteroid and antihistamine use during pregnancy[30–33].

None of these medications, with the possible exception of cyclosporine and IVIg, are safe prior to term and thus should be avoided.

POLYMORPHIC ERUPTION OF PREGNANCY

Synonyms: ■ Pruritic urticarial papules and plaques of pregnancy (PUPPP) ■ Bourne's "toxaemic rash of pregnancy" ■ Nurse's "late-onset prurigo" of pregnancy ■ Toxic erythema of pregnancy

Key features

- Urticarial papules and plaques that usually first appear within striae distensae during the latter portion of the third trimester or immediately postpartum
- Development of polymorphous features (vesicles, erythema, target and eczematous lesions) with disease progression
- Most frequent in primiparous women
- Nonspecific histologic features, negative IF, and normal routine laboratory evaluation
- No maternal or fetal risks; usually does not recur

Introduction

Polymorphic eruption of pregnancy (PEP), formerly known as PUPPP, is a common gestational dermatosis. It is characterized by a typical clinical presentation, normal laboratory tests, and negative IF or ELISA.

History

The term PUPPP, introduced by Lawley et al.[12] in 1979, focuses on the initial clinical findings in this disorder but overlooks its later polymorphous features. In order to encompass the entire clinical spectrum, the term "polymorphic eruption of pregnancy" was introduced[3] and is now generally accepted.

Epidemiology

The incidence is ~1 in 160 deliveries[13]. It is seen predominantly in primiparous women and tends not to recur in subsequent pregnancies. There is neither an autoimmune diathesis nor an association with a specific HLA type.

Pathogenesis

The cause of PEP is unknown. Reference has been made to increased maternal weight gain and an increased frequency of multiple-gestation pregnancies[14,15]. It has therefore been suggested that rapid, late stretching of abdominal skin may lead to damage of connective tissue and elicitation of an allergic-type reaction, resulting in the initial appearance of the eruption within striae[16]. The lesions then become generalized as the inflammatory response develops cross-reactivity to collagen in otherwise normal-appearing skin. Immune tolerance during subsequent pregnancies might prevent recurrence. Additional theories include increased levels of progesterone in association with multiple gestations and peripheral chimerism (deposition of fetal DNA) that favors skin with increased vascularity and damaged collagen.

Clinical Features

Pruritic erythematous and edematous papules and plaques usually first appear within the abdominal striae, typically with periumbilical sparing (Fig. 27.4). Onset is most often during the latter part of the third trimester (85%) or in the immediate postpartum period (15%)[15]. The eruption typically spreads over a matter of days, but in general spares the face, palms, and soles. While pruritic urticarial papules are the initial lesions in almost all patients, approximately half will develop more polymorphic features as the disease evolves, including widespread erythema, target lesions, tiny vesicles, and eczematous plaques (Fig. 27.5). Irrespective of whether the eruption starts during pregnancy or postpartum, lesions resolve over an average of 4 weeks.

There are no maternal or fetal morbidities, and recurrences are unusual except for subsequent multiple-gestation pregnancies. To date, only a single possible case of newborn skin involvement has been described; however, the possibility of gestational pemphigoid was not excluded by IF studies[17]. Thus, it is generally agreed that neonatal skin is not affected by PEP.

Pathology

Skin biopsy specimens reveal nonspecific findings. Epidermal changes vary from modest spongiosis to acanthosis with hyperkeratosis and parakeratosis, depending upon the stage of the disease. The dermis shows a nonspecific perivascular lymphocytic infiltrate with a variable degree of dermal edema and a variable number of neutrophils and/or eosinophils. Early lesions may resemble arthropod bite reactions, with a deeper dermal infiltrate and an absence of epidermal changes (Fig. 27.6). The histologic correlate of microvesiculation is severe epidermal spongiosis and/or dermal edema. Direct IF reveals no relevant abnormalities and indirect IF is negative. Routine laboratory evaluation is normal.

Differential Diagnosis

Since lesions of PEP may show microvesiculation, contact dermatitis must be considered. Drug eruptions, urticaria, or viral exanthems may also be in the clinical differential diagnosis. The most important entity to exclude is urticarial gestational pemphigoid, whose lesions tend to appear earlier during gestation, have no association with abdominal striae and often involve the umbilicus, along with positive IF of perilesional skin.

Fig. 27.4 Polymorphic eruption of pregnancy. A, B On the abdomen, the edematous urticarial lesions favor the striae while sparing the umbilicus; note how skin phototype influences the color of the lesions. **C** Although there is periumbilical involvement, the umbilicus itself is spared and the edematous striae point to PEP.

Treatment

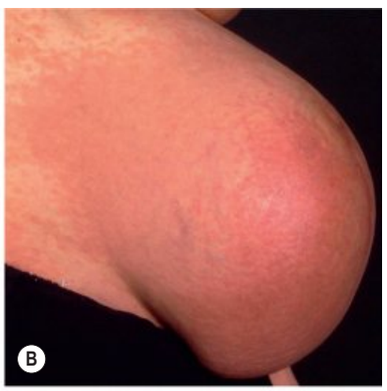
The majority of patients benefit from topical corticosteroids and oral antihistamines. More severe disease with a distressing degree of pruritus can be safely treated with a short course of systemic corticosteroids (see Table 27.3). Since the disease is self-limited and without serious sequelae, a conservative approach is justified.

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

Synonyms: ■ Cholestasis of pregnancy ■ Obstetric cholestasis ■ Cholestatic jaundice of pregnancy ■ Pruritus/prurigo gravidarum

Key features

- Pruritus without primary skin lesions with an onset during the third trimester
- Secondary changes correlate with disease duration and vary from subtle excoriations to severe prurigo nodularis
- Elevated total serum bile acid levels are diagnostic; histology is nonspecific and IF is negative
- Increased risk of prematurity, intrapartum fetal distress, and stillbirths
- Recurs in 45%–70% of subsequent pregnancies



Introduction

Intrahepatic cholestasis of pregnancy (ICP) is a rare form of genetically linked, hormone-dependent, reversible cholestasis. It typically presents late during pregnancy with dramatic pruritus. Although maternal prognosis is usually good (a small minority may develop steatorrhea and vitamin K deficiency), fetal risk is significant. As a result, ICP is the most important pruritic gestational condition to consider then promptly diagnose and treat in order to prevent fetal impairment.

History

ICP was first described in 1907 by Kehrer. In the past, much of the confusion arose from applying descriptive names such as "pruritus

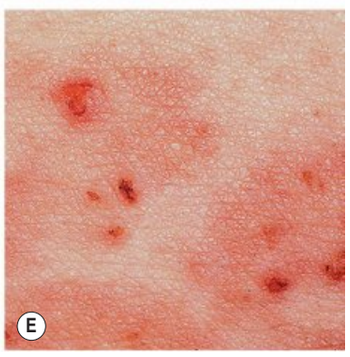


Fig. 27.5 Polymorphic eruption of pregnancy. The clinical spectrum includes: **A** urticarial papules and plaques, some of which demonstrate a steal phenomenon; **B** macular erythema, which can be widespread; **C** targetoid lesions; **D** tiny vesicles due to marked epidermal spongiosis or dermal edema; and **E** eczematous plaques, especially as lesions age.

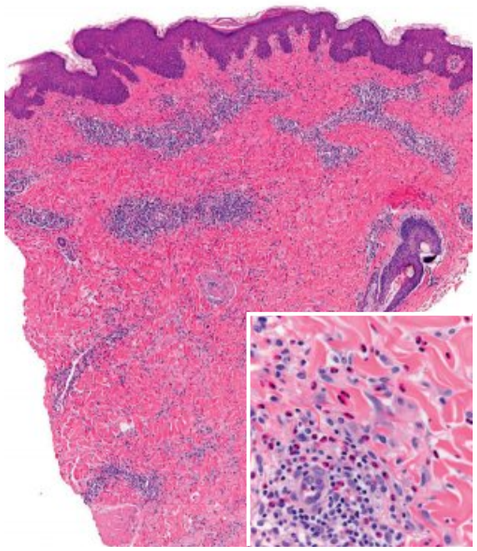

Fig. 27.6 Polymorphic eruption of pregnancy – histopathologic features. In this early lesion, a superficial and deep perivascular and interstitial lympho-histiocytic infiltrate is seen within the dermis. Numerous eosinophils are also present (inset).

gravidarum" for ICP without skin changes or "prurigo gravidarum" if skin lesions associated with scratching were present. While the first term was often combined with the mild unexplained pruritus that occurs in many women during pregnancy (most likely related to an atopic diathesis), the latter was confused with "prurigo of pregnancy" (see below). Because laboratory evaluation, including measurement of serum bile acid levels, was performed in only a minority of women, ICP was often missed.

Epidemiology

There are striking geographic and ethnic differences in the incidence of ICP. For example, it is most commonly observed in South America, with the highest incidence rates in Bolivia and Chile (9%–16%), particularly among Araucanian Indian women (~30%). In contrast, rates of 0.1% to 1.5% have been described in Europe and North America, with relative "hot spots" in Scandinavia and the Baltic states (1%–2%)[18]. Some of the variance is probably explained by different reporting criteria; however, endemic clustering and a positive family history in up to 50% of those affected point towards a genetic predisposition. A higher incidence of ICP is also seen in multiple-gestation pregnancies, which may be related to higher hormonal levels (e.g. estrogen) in these patients.

Pathogenesis

The key element is reduced excretion of bile acids, which leads to increased serum levels. This not only provokes severe pruritus in the mother, but also may have deleterious effects on the fetus. Toxic bile acids crossing the placenta can lead to acute fetal anoxia due to abnormal uterine contractility and vasoconstriction of chorionic veins as well as impaired fetal cardiomyocyte function[18]. One predisposing factor is mutations in genes (e.g. *ABCB4*, *ABCB11*, *ABCC2*) that encode bile transporter proteins[19,20]. While mild dysfunction of these canalicular transporters may not lead to clinical symptoms in non-pregnant individuals, when the transporters' capacity to secrete substrates is exceeded (as occurs in the setting of high levels of sex hormones during pregnancy), signs and symptoms of cholestasis can develop. Other contributing factors are the cholestatic effect of estrogen and progesterone metabolites, which peak late during pregnancy, and hepatitis C viral infection (see below). Furthermore, dietary factors such as selenium deficiency and increased intestinal permeability ("leaky gut") have been suggested as possible triggers.

Clinical Features

Patients typically present during their last trimester with a sudden onset of intense, generalized pruritus that often starts on the palms and soles. No primary skin lesions are seen, and secondary changes due to scratching vary from subtle excoriations early on to pronounced prurigo nodularis in those with pruritus of longer duration (Fig. 27.7).

Fig. 27.7 Intrahepatic cholestasis of pregnancy. Marked pruritus leads to secondary skin lesions that vary based on disease duration, from subtle linear excoriations and prurigo simplex early on (**A**) to pronounced prurigo nodularis when the pruritus is longstanding (**B**). *From Ambros-Rudolph CM, Glatz M, Trauner M, et al. The importance of serum bile acid level analysis and treatment with ursodeoxycholic acid in intrahepatic cholestasis of pregnancy: a case series from central Europe. Arch Dermatol 2007;143:757–62. © (2006) American Medical Association. All rights reserved.*

The extensor surfaces of the extremities, buttocks, and abdomen are usually most severely affected.

Although jaundice is often mentioned as a common finding in ICP, it actually occurs in only 10% of patients. Jaundice is usually a complication in those with the most severe and prolonged episodes of ICP. In such patients, concomitant extrahepatic cholestasis may be associated with steatorrhea and subsequent vitamin K deficiency, leading to an increased risk of intra- and postpartum hemorrhage.

Pruritus typically persists until delivery and then it resolves spontaneously within days. A protracted course is very unusual and should prompt one to exclude other liver diseases, especially primary biliary cirrhosis. Recurrence during subsequent pregnancies occurs in 45%–70% of patients, and recurrence with oral contraceptives is routine. No detectable abnormalities are generally present between gestations.

ICP is associated with significant fetal risk, in particular an increase in premature births (20%–60%), intrapartum fetal distress (20%–30%;

e.g. meconium staining of amniotic fluid, abnormal fetal heart rate), and fetal loss (1%–2%)[18]. Fetal risk correlates with the elevation in serum bile acid levels, especially when levels exceed 40 μmol/l[21]. Thus, prompt diagnosis and treatment is essential, as is close obstetric surveillance.

Pathology

Histologic findings in the skin and the liver are nonspecific and direct IF of perilesional skin is negative. The diagnosis is confirmed by an increase in total serum bile acid levels (>11 μmol/l in a pregnant woman; normal range in non-pregnant women, 0–6 μmol/l). Levels may range from 3 to 100 times normal. During pregnancy, alkaline phosphatase levels typically increase (placental origin) even in the absence of ICP, and γ-glutamyl transferase levels are usually lower than in the non-pregnant state. Serum levels of transaminases are usually elevated in those with ICP, but may be normal in 30% of patients[22]. In women with jaundice, conjugated (direct) bilirubin levels are increased and the prothrombin time may be prolonged. Hepatic ultrasonography generally is normal but may reveal gallstones in jaundiced patients, who are at increased risk for their development.

Differential Diagnosis

In the absence of primary lesions, the clinical differential diagnosis includes other causes of primary pruritus (see Ch. 6), including those that lead to cholestatic pruritus. Viral hepatitis is a common disorder and should be excluded by appropriate serologies. Of note, a history of hepatitis C viral infection is considered a risk factor for the development of ICP, and in one study, 20% of the women who were HCV RNA-positive developed ICP[23].

Treatment

Since fetal prognosis correlates with disease severity, the therapeutic goal is reduction of serum bile acid levels. This allows prolongation of the pregnancy and lessens both fetal risk and maternal symptoms. To date, the only successful agent has been oral ursodeoxycholic acid (UDCA)[18,22,24,25]. It is a naturally occurring, hydrophilic, non-toxic bile acid that has been used for a variety of cholestatic liver diseases. Although the exact mechanism of action in ICP is still not fully understood, there is evidence that UDCA corrects the maternal serum bile acid profile, decreases the passage of maternal bile acids to the fetoplacental unit, and improves the function of the bile acid transport system across the trophoblast. In a recent systematic review and individual participant data meta-analysis, prenatal UDCA was associated with a reduction in stillbirth in combination with preterm birth[26]. The authors concluded that UDCA should be prescribed, especially in women whose disease onset was before 37 gestational weeks and whose serum bile acid concentrations were ≥40 μmol/l.

UDCA is safe for mother and fetus, with its only side effect being mild diarrhea. Use of UDCA for ICP is off-label as it is only approved for primary biliary cirrhosis. The recommended oral dose is 15 mg/kg daily or, independent of body weight, 1 g daily. It should be started as early as possible and administered until delivery.

The use of S-adenosylmethionine, dexamethasone, epomediol, silymarin, phenobarbital or activated charcoal is not recommended as none have been shown to decrease fetal risk. Cholestyramine is contraindicated as it can further reduce vitamin K absorption and increase the risk of bleeding[25]. In jaundiced patients, the prothrombin time should be monitored, and intramuscular vitamin K administered as necessary. Close interdisciplinary collaboration with the obstetrician is essential and close monitoring of the fetus is recommended.

ATOPIC ERUPTION OF PREGNANCY

Synonyms: ■ Prurigo of pregnancy ■ Besnier's "prurigo gestationis" ■ Nurse's "early-onset prurigo" of pregnancy ■ Spangler's "papular dermatitis of pregnancy" ■ Pruritic folliculitis of pregnancy ■ Eczema in pregnancy

Key features

- Eczematous and/or papular skin lesions in a patient with an atopic diathesis in whom other specific dermatoses have been excluded
- Most common pruritic disorder during pregnancy
- Generally appears earlier than other pregnancy-related dermatoses (75% before the third trimester)
- Nonspecific histology; negative direct IF; elevated serum IgE levels in up to 70% of patients
- No maternal or fetal risks; commonly recurs in subsequent pregnancies

Introduction

Atopic eruption of pregnancy (AEP) is defined as either an *exacerbation* or the *first occurrence* of eczematous and/or papular skin changes during pregnancy in atopic individuals. As the majority of patients belong to the second group, the atopic link is often overlooked, leading to a number of different diagnoses, as evidenced by the many synonyms.

History

In retrospect, an association with atopy dates back to the first reports. When Besnier described the disorder "prurigo gestationis" in 1904, "prurigo" was the term dermatologists used for atopic dermatitis (Besnier was the first to note the association between atopic dermatitis, allergic rhinitis, and asthma). Nurse, in 1968, described accompanying eczematous features in most of the 31 patients in his "early-onset" prurigo group. In 1983, Holmes and Black were the first to suggest that "prurigo of pregnancy" could simply result from pregnancy-related pruritus in women with an atopic diathesis rather than being a distinct entity[3].

Epidemiology

AEP is by far the most common pruritic disorder in pregnant women and it tends to appear earlier than the other pregnancy-related dermatoses[1]. Its incidence is not known but may be as high as 1 in 5 to 1 in 20.

Pathogenesis

To prevent fetal rejection, a normal pregnancy is characterized by a lack of strong maternal cell-mediated immune function and reduced Th1 cytokine production (e.g. IL-12, interferon-γ) as well as a dominant humoral immune response with increased Th2 cytokine production (e.g. IL-4, IL-10). This natural switch towards a dominant Th2 response, which worsens the imbalance already present in most atopic patients, is thought to favor the development of AEP[1].

Clinical Features

In contrast to the other specific dermatoses of pregnancy, AEP appears earlier, often during the first trimester, with 75% of patients presenting before the third trimester. Approximately 20% of women experience an exacerbation of pre-existing atopic dermatitis, while the remaining 80% develop atopic skin changes for the first time during pregnancy. Two-thirds of patients present with eczematous lesions (Fig. 27.8), often involving "atopic sites" such as the face, neck, and flexural aspects of the extremities. One-third develop a papular eruption on the trunk and extremities, composed of either classic prurigo lesions or small erythematous papules (Fig. 27.9). Findings typically include xerosis (often marked) and other signs of the underlying atopic diathesis (see Ch. 12). Fetal and maternal prognoses are excellent and recurrences in subsequent pregnancies are common.

Pathology

Depending on the stage of the lesion, histologic features can vary. Epidermal changes include spongiosis, acanthosis, and erosions; the dermal infiltrate is composed of lymphocytes and usually admixed

eosinophils. If the histologic section includes a hair follicle, there may be sterile follicular inflammation. Direct IF is negative. Serum IgE levels may be elevated in up to 70% of patients, usually to a mild degree.

Differential Diagnosis

Of the specific pregnancy dermatoses, PEP and ICP are the ones that in particular need to be excluded. In AEP, the eruption starts significantly earlier during gestation and has no association with striae; serum bile acid levels are also normal. Furthermore, other pruritic dermatoses not specifically associated with pregnancy (e.g. scabies, viral exanthems, drug eruptions, contact dermatitis) must be considered.

Treatment

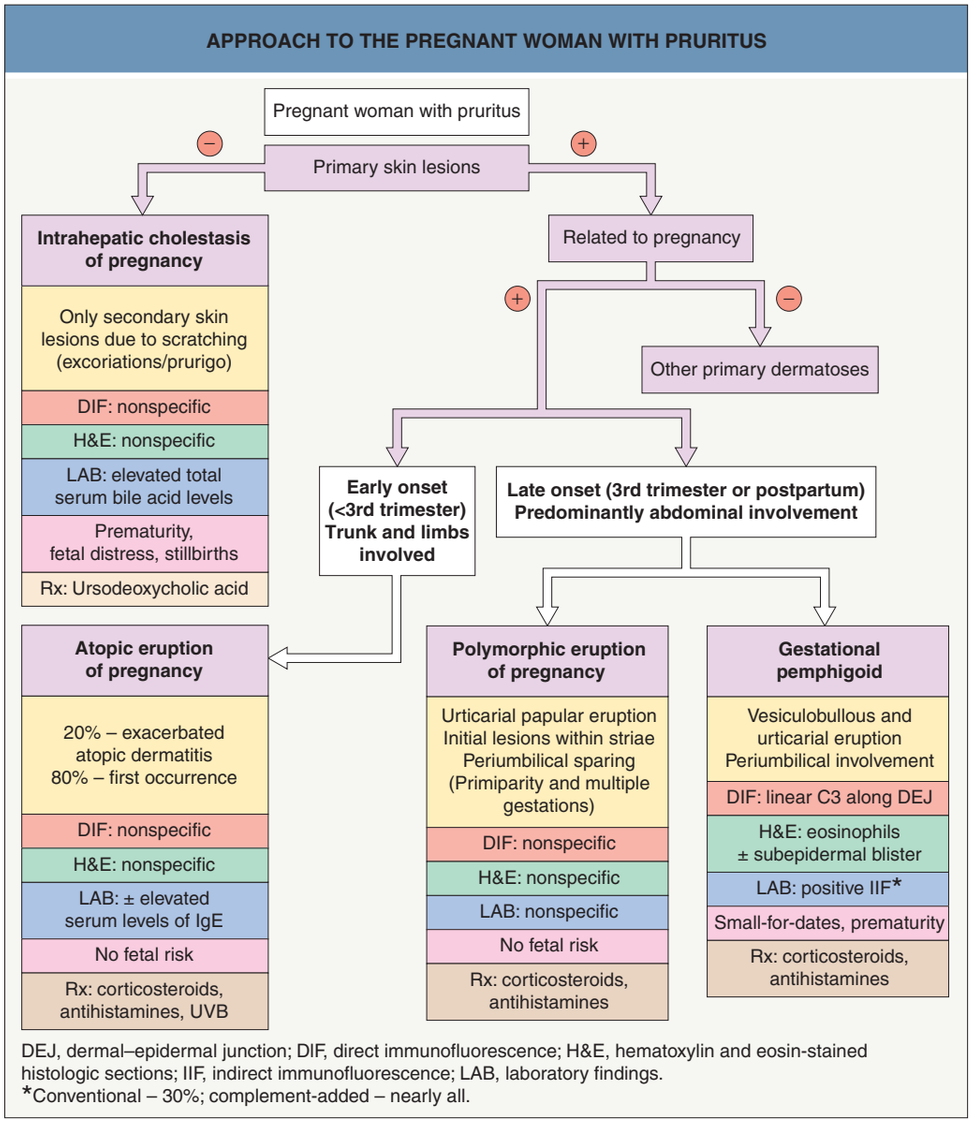
Cutaneous lesions respond rapidly to topical corticosteroids with or without systemic antihistamines. Topical tacrolimus may be used for sites such as face and intertriginous zones. Emollients, humectants, and topical antipruritic agents also play a role, as they do in non-pregnant patients with atopic dermatitis. Topical urea (10%), polidocanol, pramoxine, and menthol are considered safe during pregnancy. UVB irradiation is very helpful for severe disease. Secondary bacterial infection may require systemic antibiotics (e.g. penicillins, cephalosporins).

Fig. 27.8 Atopic eruption of pregnancy – eczematous lesions. The eczematous lesions often involve flexural areas and friction sites (**A,B**), as well as the breasts and abdomen (**B**). These changes are seen in approximately two-thirds of patients.

APPROACH TO THE PREGNANT WOMAN WITH PRURITUS

Pruritus is the major symptom in all four of the pregnancy-related dermatoses, but it may also be associated with coincidental dermatoses (e.g. scabies, urticaria, pityriasis rosea). A pregnant woman with severe pruritus and skin lesions requires urgent clinicopathologic assessment, given the possibility of associated fetal risks. Figure 27.10 is an algorithm that has proven helpful in distinguishing amongst the various pruritic dermatoses of pregnancy[1]. Primiparity and multiple gestations are significantly linked to PEP, while a history of identical skin findings in past pregnancies (recurrence) suggests ICP. An early presentation (75% before the third trimester) is typical for AEP, while the other disorders present late during pregnancy or postpartum. Abdominal location of skin lesions is characteristic of gestational pemphigoid and PEP, involvement of the trunk and extremities of AEP, and predominant involvement of the extremities of ICP. Pruritus as the sole presenting symptom followed by exclusively secondary cutaneous lesions due to scratching is only seen in ICP.

DERMATOSES INFLUENCED BY PREGNANCY



Pregnancy can have positive, as well as negative, effects on the status of pre-existing skin diseases[27]. Examples of pregnancy-influenced dermatoses are outlined in Table 27.4.

PHYSIOLOGIC CHANGES DURING PREGNANCY

Table 27.5 outlines many of the physiologic changes that have been associated with pregnancy. While some are very common, such as hyperpigmentation, others are more loosely associated, for example, nail changes. The majority of changes spontaneously regress following delivery[27].

Fig. 27.9 Atopic eruption of pregnancy – papular eruption. Scattered small erythematous papules (**A**) or excoriated prurigo lesions (**B**) favor the abdomen and extremities. These changes are seen in approximately one-third of patients. Note the absence of striae distensae.

DEJ, dermal–epidermal junction; DIF, direct immunofluorescence; H&E, hematoxylin and eosin-stained histologic sections; IIF, indirect immunofluorescence; LAB, laboratory findings.
*Conventional – 30%; complement-added – nearly all.

Fig. 27.10 Approach to the pregnant woman with pruritus[1]. Patients with refractory gestational pemphigoid may benefit from plasmapheresis during pregnancy. See Table 27.3 for special considerations regarding the use of corticosteroids (topical and oral) and antihistamines during pregnancy.

DERMATOSES INFLUENCED BY PREGNANCY	
Psoriasis	• Commonly improves during pregnancy, then flares within 6–12 weeks following delivery • Explanation: down-regulation of Th1 immune response during a normal pregnancy • May present as impetigo herpetiformis (generalized pustular psoriasis of pregnancy)
Atopic dermatitis Systemic lupus erythematosus Pemphigus vulgaris	• Usually worsens during pregnancy and then improves after delivery • Explanation: physiologic shift towards a strong Th2 immune response with an increase in Th2 cytokines (e.g. IL-4, IL-10)
Acne	• Can improve or flare; persistent acne often improves during pregnancy • The flares in women with acne gravidarum can be severe, in particular late in pregnancy due to hyperandrogenemia
Rosacea	• Often worsens during pregnancy, presumably due to immunologic, endocrine, and vascular changes • May present as rosacea fulminans
Melanocytic nevi	• With the exception of symmetric enlargement of nevi on the breasts and abdomen due to distention, changes in benign nevi are minimal; by dermoscopy, a symmetric peripheral rim of globules may be seen, which reverses after delivery • Nevi may darken during pregnancy, but those with worrisome features, clinically or by dermoscopy, should be biopsied

Table 27.4 Dermatoses influenced by pregnancy[27].

AUTOIMMUNE PROGESTERONE DERMATITIS

Although autoimmune progesterone dermatitis is not a specific dermatosis of pregnancy, it can first appear during pregnancy or postpartum[28]. Classically, there are recurrent cyclic flares of dermatitis that correspond to the luteal phase of the menstrual cycle, when progesterone levels increase. In addition to eczematous changes, lesions can vary from urticaria to papulovesicles to erythema multiforme-like. Some patients have primarily pruritus or oral erosions. At sites of intradermal injection of progesterone (e.g. 50 mg/ml), the vast majority of affected patients develop a cutaneous reaction characterized by urticaria (immediate [30 min]) and/or erythema and induration (delayed [24–48 h])[28]. Injections of saline and estrogen (e.g. estrone [1 mg/ml]) are often done concurrently, to serve as a control and to examine for

PHYSIOLOGIC CHANGES DURING PREGNANCY	
Pigmentary	
Hyperpigmentation (e.g. areolae, linea nigra; Fig. 27.11A) Melasma	• Hyperpigmentation (up to 90% of patients) and melasma (up to 70% of patients) are presumably of hormonal etiology • Melasma tends to persist postpartum in those with darker skin phototypes
Hair	
Hirsutism Postpartum telogen effluvium Postpartum androgenetic alopecia	• Some hirsutism is normal and typically regresses postpartum • Telogen effluvium may last up to 15 months • Postpartum patterned alopecia may or may not revert to normal
Nail	
Subungual hyperkeratosis Distal onycholysis Transverse grooving Brittleness	• There are no pathognomonic nail changes
Glandular	
Increased eccrine function (except palms) Increased sebaceous function Decreased apocrine function	• Eccrine sweating may increase (except on the palms) later in pregnancy and result in hyperhidrosis • The effect on apocrine function and sebaceous gland activity is incompletely understood
Connective tissue	
Striae distensae/gravidarum	• Develop in up to 90% of patients and often resolve • Both hormonal factors and physical stretching of the skin appear to be relevant in their development
Vascular	
Spider angiomas Palmar erythema (Fig. 27.11B) Non-pitting and pitting edema Varicosities Vasomotor instability Purpura Gingival hyperemia or hyperplasia Pyogenic granulomas (Fig. 27.11C) Hemorrhoids	• Vascular changes result from distention, instability, and new vessel formation • Clinically obvious changes are most pronounced during the third trimester and most changes regress spontaneously following delivery

Table 27.5 Physiologic changes during pregnancy[34]. *Adapted from Kroumpouzos G, Cohen LM. Dermatoses of pregnancy. J Am Acad Dermatol 2001;45:1–19.*

evidence of estrogen dermatitis[29], respectively. Both oral and intramuscular progesterone have been used as a challenge test in patients with delayed reactions. Treatment consists primarily of inhibiting ovulation via estrogen-containing preparations. Anecdotally, additional reported therapies include tamoxifen and danazol, each possibly suppressing ovulation via interaction with the hypothalamic–pituitary axis. Of note, some patients have had remissions during pregnancy.

Acknowledgment

The author and editors are grateful to Drs Heidi Bai and Jenny Murase for their help in creating the table of dermatologic drugs in pregnancy and lactation featured in the online version of this chapter.

Additional figures and table on An overview of the use of dermatologic drugs during pregnancy and lactation available in our eBook (see inside front cover for access code).

AN OVERVIEW OF THE USE OF DERMATOLOGIC DRUGS DURING PREGNANCY AND LACTATION	
Dermatologic Medication	**Pregnancy**
Acne & Hair – Topical	
Azelaic acid	No well-controlled studies in pregnant women. Embryo-fetal toxicity at 3–32× MRHD in animal studies. About 4% systemic absorption with topical application. **Limited use is safe** in pregnancy[e1].
Benzoyl peroxide	No well-controlled studies in pregnant women and no animal studies conducted. About 5% systemic absorption with topical application and metabolized to a food additive, benzoic acid. **Limited use is safe** in pregnancy[e2].
Salicylic acid	No well-controlled studies in pregnant women. Teratogenic in animal studies. Low systemic absorption with topical application. **Limited use is safe** in pregnancy. Avoid occlusive dressings[e1].
Adapalene	No well-controlled studies in pregnant women. Anophthalmia and agenesis of the optic chiasma reported in an infant whose mother used topical adapalene during pregnancy[e4]. Teratogenic and fetotoxic with oral use at 32× MRHD in animal studies. Low systemic absorption with topical application. **Limited use is likely safe if medically necessary** during pregnancy[e2].
Minoxidil	No well-controlled studies in pregnant women. Fetal hypertrichosis and congenital anomalies (brain, heart, and vascular malformations, caudal regression) reported in infants whose mothers used oral and topical minoxidil during pregnancy. No teratogenicity in animal studies. About 1.4% systemic absorption with topical application. Crosses lipid barriers. Brain and fetal concentrations may be higher than in plasma. **Limited use is likely safe if medically necessary** during pregnancy[e1].
Tretinoin	No well-controlled studies in pregnant women. Congenital malformations (holoprosencephaly, craniofacial defects, ear, eye, cardiac, and neural abnormalities, diaphragmatic hernia, limb defects, fetal growth restrictions) reported in infants whose mothers used topical tretinoin during the first trimester. Larger studies indicate no associated increased risk for congenital abnormalities (including retinoid embryopathy), live births, or miscarriages with topical application in the first trimester[e6]. Teratogenic (hydrocephaly, retinoid malformations) and fetotoxic (skeletal variations) in animal studies. Low systemic absorption after topical application. **Limited use is likely safe if medically necessary** during pregnancy[e2].
Tazarotene	Healthy deliveries have been reported with topical tazarotene use. Teratogenic (retinoid malformations, spina bifida, hydrocephaly, heart defects) and embryotoxic (reduced fetal body weight and skeletal ossification) in animal studies. Less than 6% systemic absorption with topical application[e7]. Highly bound to plasma (>99%). Placental transfer unlikely[e6]. **Contraindicated** in pregnancy; embryo-fetal toxicity warning.
Acne & Hair – Systemic	
Spironolactone	No reports of major malformations. Anti-androgenic effects (feminization of male fetus) and endocrine dysfunction in animal studies. Crosses the placenta. **Use with caution** in pregnancy due to male fetal feminization and hypospadias risk[e2].
Isotretinoin	Congenital defects (cleft palate, microphthalmia, small/absent external auditory canals, skull, cerebral and cerebellar malformations, hydrocephalus, microcephaly, cardiac defects, thymus and parathyroid gland abnormalities), low IQ score, premature birth, and spontaneous abortion have been reported. **Contraindicated** in pregnancy. If pregnancy occurs, discontinue isotretinoin immediately. Must register with iPLEDGE Program. Women of childbearing potential must be on two forms of contraception or abstinence one month before, during, and one month after therapy. Must have two negative pregnancy tests prior to initiation and one negative test monthly.
Finasteride	Abnormalities of the external genitalia of a male fetus have been shown in animal studies. Teratogenic effects may occur due to the ability of type II 5α-reductase inhibitors to inhibit the conversion of testosterone to dihydrotestosterone. **Contraindicated** in pregnancy.
Minoxidil	Fetal hypertrichosis and congenital anomalies (brain, heart, and vascular malformations, caudal regression) reported in infants whose mothers used oral and topical minoxidil during pregnancy. Neonatal hypertrichosis has been observed in animal studies. There are no well-controlled studies in pregnant women. **Use with caution** in pregnancy.
Anesthetics	
Lidocaine(& epinephrine [adrenaline])	No well-controlled studies in pregnant women. Most of the information comes from anesthetic use in obstetrics. No association with malformations with first trimester exposure in one study. No adverse effects in animal studies. Crosses the placenta within minutes. Fetus and infants are capable of metabolizing lidocaine[e6]. Addition of epinephrine may lead to placental vasoconstriction, fetal tachycardia, and low placental blood flow, but may be neglected with dosage used for dermatological interventions. Vasoconstriction prolongs anesthetic effects and reduces placental transfer of lidocaine. **Safe** in pregnancy as a local anesthetic[e2].
Antibiotics – Topical	
Bacitracin	No well-controlled studies in pregnant women or animal reproduction studies conducted. Poorly absorbed after topical application. **Safe** in pregnancy[e6].
Mupirocin	No well-controlled studies in pregnant women. Rapid metabolism and elimination suggests clinical levels will not reach fetus[e6]. No teratogenicity in animal studies. Less than 1% systemic absorption with topical application[e6]. **Safe** in pregnancy. Topical antibiotic of choice[e1].

eTable 27.1 An overview of the use of dermatologic drugs during pregnancy and lactation.

Lactation	Female Fertility	Male Fertility	Former FDA Category
Excretion into breast milk is not known. **Likely compatible** with breastfeeding[e1].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Excretion into breast milk not known. **Likely compatible** with breastfeeding[e2].	Limited safety data.	Limited safety data.	C
Excretion into breast milk not known. **Compatible** with breastfeeding[e3].	No adverse effects on fertility[e1].	No adverse effects on fertility[e1].	C
Excretion into breast milk not known. **Likely compatible** with breastfeeding.	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	C
Likely excreted in breast milk. Hypertrichosis was not evident in nursing infant[e5]. **Compatible** with breastfeeding[e2].	Decrease in conception rate at 1× and 5× MRHD with oral administration in animal studies.	Decrease in conception rate at 1× and 5× MRHD with oral administration in animal studies.	C
Likely excreted in breast milk in low amounts. **Likely compatible** with breastfeeding[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	C
Excreted into breast milk in low amounts[e2]. **Likely compatible** with breastfeeding. Should not be used on >20% body surface area[e2].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	X
Active metabolite, canrenone, excreted in breast milk in low amounts. No adverse effects reported with breastfeeding. Intense diuresis may suppress lactation. **Compatible** with breastfeeding[e3].	No adverse effects on fertility in animal studies.	Decreased testosterone may lead to gynecomastia, impotence, and reduced sperm motility at >100 mg/day. Decreased sperm concentration, but not fertility, in animal studies[e8].	C
Excreted in breast milk. Highly lipid soluble. Concentrations in breast milk would be significant. **Contraindicated** with breastfeeding[e3].	No adverse effects on fertility in animal studies.	No infertility reported. Increased sperm density and motility in one study[e8].	X
Excretion into breast milk is not known. **Not recommended** in women by the manufacturer.	No adverse effects on fertility in animal studies.	Male infertility and poor seminal quality have been reported and may be reversible upon discontinuation of finasteride.	X
Excretion in breast milk has been reported. **Not recommended** in nursing women by the manufacturer.	Decrease in conception rate at 1× and 5× MRHD with oral administration in animal studies.	Decrease in conception rate at 1× and 5× MRHD with oral administration in animal studies.	C
Excreted in breast milk in low amounts. **Compatible** with breastfeeding[e3].	Limited safety data.	Limited safety data.	B
Compatible with breastfeeding[e6].	Limited safety data.	Limited safety data.	C
Compatible with breastfeeding. Topical antibiotic of choice[e1].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B

AN OVERVIEW OF THE USE OF DERMATOLOGIC DRUGS DURING PREGNANCY AND LACTATION	
Dermatologic Medication	**Pregnancy**
Silver sulfadiazine	No well-controlled studies in pregnant women. Not teratogenic in animal studies. Extensive area application of silver sulfadiazine should be avoided in pregnant women with burns because absorption of sulfonamides can lead to kernicterus. **Use with caution** in late-term pregnancy due to kernicterus risk in burns.
Antibiotics – Systemic	
Cephalosporins	No adequate well-controlled studies in pregnant women. No associated congenital abnormalities with cephalexin, cefaclor, cefamandole, cefoperazone, cefotaxime, ceftibuten, and cefuroxime use in a large study. Four birth defects (3 cardiovascular defects) reported in infants with ceftriaxone exposure, but mothers had additional contributing factors. No adverse effects have been reported with second trimester or third trimester use[e6]. No teratogenicity or embryo-fetal toxicity in animal studies. **Safe** in pregnancy. Older cephalosporins preferred. Eliminated more quickly in pregnancy; may require dose adjustments[e2].
Clindamycin	No well-controlled studies in pregnant women during the first trimester. No associated congenital abnormalities when taken orally in the first trimester[e6]. No teratogenicity in animal studies. **Safe** in pregnancy. Second-line to beta-lactams due to potential for pseudomembranous colitis[e2].
Metronidazole	No well-controlled studies in pregnant women. No associations with congenital abnormalities were found in multiple studies, although one population-specific study found an association with cleft lip, cleft palate, and polysyndactyly[e6]. Crosses placental barrier and enters fetal circulation rapidly. No fetotoxicity in animal studies. Lower systemic absorption with topical administration. **Safe** in pregnancy[e2].
Penicillin	No well-controlled studies in pregnant women. No associations with congenital abnormalities were found in multiple studies. Rapidly enters fetal circulation. No adverse effects in animal studies. **Safe** in pregnancy[e6]. Antibiotic of choice[e1]. Eliminated more quickly in pregnancy, therefore, may need dose adjustment[e2].
Trimethoprim–sulfamethoxazole	No well-controlled studies in pregnant women. Associations with congenital malformation (neural tube defects, cardiovascular abnormalities, urinary tract defects, oral clefts, and club foot) in some, but not all studies. Trimethoprim interferes with folate metabolism. Teratogenic (cleft palate) and fetotoxic (fetal loss) at 6× RHD in animal studies. **Use with caution** in pregnancy due to potential adverse fetal effects. Avoid use near delivery due to potential risk for neonatal hyperbilirubinemia. Supplement with folic acid in first trimester to lower risk for neural tube defects[e2].
Dapsone	No well-controlled studies in pregnant women. No congenital anomalies reported with use. Measure G6PD levels before use to reduce risk for maternal anemia, neonatal hyperbilirubinemia, and hemolytic anemia. No teratogenicity in animal studies[e2]. **Use with caution** in pregnancy due to potential adverse fetal effects. Regarding infections for pregnancy, use recommended only for leprosy, malaria, and *P. carinii* infections during pregnancy[e6].
Ciprofloxacin	No associations with congenital abnormalities or musculoskeletal defects in multiple studies[e6]. No adverse effects in animal studies. Causes arthropathy in immature animals when administered directly. **Use with caution** in pregnancy due to potential adverse fetal effects. Use recommended only for complicated or resistant infections during pregnancy due to potential risk for cartilage damage[e2].
Doxycycline	No associations with congenital malformations with first trimester use[e2]. Discoloration of teeth (yellow–gray–brown) and bone growth inhibition reported in infants with exposure in second and third trimesters[e6]. Crosses placenta and found in fetal tissue. Embryo-fetal toxicity in animal studies. **Contraindicated** in the second and third trimesters due to potential for teeth discoloration, bone growth inhibition, and maternal hepatitis[e2].
Antifungals – Topical	
Clotrimazole	No adverse effects with topical use in pregnancy. No associations with congenital defects were found in multiple studies. Very minimal absorption with topical or intravaginal application[e6]. No adverse effects in animal studies. **Safe** in pregnancy. Topical antifungal of choice[e2].
Nystatin	No associations with congenital malformations[e6]. No animal reproduction studies conducted. Very minimal absorption with topical or vaginal application. **Safe** in pregnancy. Topical antifungal of choice for *Candida* infections[e1].
Ciclopirox	No well-controlled studies in pregnant women. No reports of congenital abnormalities after use. No teratogenicity in animal studies. About 1.3% absorbed after topical application[e6]. **Likely safe** in pregnancy[e2].
Terbinafine	No increased risk of major malformations or spontaneous abortions in topical or oral use in one study[e9]. No teratogenicity or embryo-fetal toxicity in animal studies. Less than 5% systemic absorption after topical application. **Limited use is likely safe if medically necessary** in pregnancy[e2].
Antifungals – Systemic	
Terbinafine	No increased risk of major malformations or spontaneous abortions in topical or oral use in one study[e9]. No teratogenicity or embryo-fetal toxicity in animal studies. Less than 5% systemic absorption after topical application. **Limited use is likely safe if medically necessary** in pregnancy[e2].

eTable 27.1 An overview of the use of dermatologic drugs during pregnancy and lactation.

Lactation	Female Fertility	Male Fertility	Former FDA Category
Sulfonamides are excreted into human milk and increases the possibility of kernicterus. **Use not recommended** with breastfeeding unless medically necessary.	Limited safety data.	Limited safety data.	B
Excreted in breast milk in low concentrations (<1%). **Compatible** with breastfeeding[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Excreted in breast milk. Bloody stools with negative stool cultures reported in a nursing infant whose mother was exposed to clindamycin; discontinued when clindamycin was stopped. **Compatible** with breastfeeding[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Excreted in breast milk. Diarrhea reported in a nursing infant whose mother was exposed to oral metronidazole[e6]. **Compatible** with breastfeeding[e1].	Limited safety data.	Infertility at high doses with oral administration in animal studies.	B
Excreted in breast milk in low levels. Diarrhea and rash reported in nursing infants[e1]. **Compatible** with breastfeeding[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Excreted in breast milk in low amounts. Potential risk for bilirubin displacement from albumin leading to kernicterus. Hemolytic reactions can occur in neonates without glucose-6-phosphate dehydrogenase (G6PD) deficiency as soon as 8 days after birth. **Compatible** with breastfeeding. **Use not recommended** in infants with G6PD deficiency, premature infants, or neonates with hyperbilirubinemia[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	C
Excreted in breast milk in substantial amounts. Hemolytic reaction reported in nursing infant. **Use not recommended** in infants with G6PD deficiency[e3].	No adverse effects reported by women. Reduced viable embryos and number of implantations at 127× MRHD in animal studies.	Reduced sperm motility at 15× MRHD in animal studies.	C
Excreted in human milk in low amounts. *Clostridium difficile* toxin reported in the stool of a nursing infant whose mother developed pseudomembranous colitis after taking ciprofloxacin[e6]. **Compatible** with breastfeeding. Monitor infant for diarrhea[e1].	No adverse effects on fertility in animal studies.	Decreased spermatogenesis and impaired fertility at 13× MRHD in animal studies[e6].	C
Excreted in breast milk in low amounts due to calcium chelation. Potential risk of tooth discoloration and bone growth inhibition in nursing infant, but unlikely in short-term use. **Compatible** with short-term use for breastfeeding. **Use not recommended** for longer than 3 weeks due to potential for infant dental staining[e3].	No adverse effects on fertility in animal studies.	*In vitro* study showed impaired sperm movement and decreased sperm viability. This was reversible after 20 minutes of doxycycline discontinuation[e8].	D
Compatible with breastfeeding. Topical antifungal of choice[e1].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Compatible with breastfeeding[e3].	Limited safety data.	Limited safety data.	C (vaginal: A)
Excretion into breast milk not known, but likely negligible[e6]. **Likely compatible** with breastfeeding[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Excreted in breast milk in low amounts. **Use not recommended** with breastfeeding unless medically necessary[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Excreted in breast milk in low amounts. **Use not recommended** with breastfeeding unless medically necessary.[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B

AN OVERVIEW OF THE USE OF DERMATOLOGIC DRUGS DURING PREGNANCY AND LACTATION	
Dermatologic Medication	**Pregnancy**
Griseofulvin	Two conjoined twins reported in infants with first trimester exposure[e6]. Teratogenic and embryotoxic at 4× MRHD in animal studies. Crosses placenta. **Contraindicated** in pregnancy. Effective contraception recommended in women of child-bearing potential due to griseofulvin interaction with estrogen-containing oral contraceptives, which may increase risk for unintended pregnancies.
Fluconazole	No well-controlled studies in pregnant women. Congenital anomalies (cleft palate, craniofacial and bone abnormalities, cardiovascular defects) reported in infants with first trimester exposure. Spontaneous abortions and birth defects were reported in larger studies, but no patterns have been identified[e6]. Teratogenic (cleft palate) and embryotoxic (supernumerary ribs, delayed ossifications) in animal studies. **Avoid** in pregnancy (especially 1st trimester) per manufacturer, unless treating severe or potentially life-threatening fungal infections. **Limited use likely safe** in low doses and in the short-term for vaginal candidiasis. Obtain fetal ultrasound with first trimester exposure[e2].
Ketoconazole	No well-controlled studies in pregnant women. Cardiovascular, skeletal, craniofacial, and neural defects reported in infants with first trimester exposure[e2]. No major birth defects observed with oral exposure in the first trimester in a large study[e6]. Serum testosterone is lowered at 800 mg/day and is absent at 1600 mg/day. Teratogenic and embryotoxic (syndactyly and oligodactyly) at 10× MRHD with oral use in animal studies. **Avoid** in pregnancy. **Limited use likely safe** only after the first trimester at low doses. Obtain fetal ultrasound with first trimester exposure[e2].
Itraconazole	No well-controlled studies in pregnant women. Cardiovascular, skeletal, craniofacial, and neural defects reported in infants with first trimester exposure[e2]. Teratogenic (skeletal defects, encephaloceles, macroglossia) and embryotoxic at 5–20× MRHD in animal studies. **Avoid** in pregnancy. **Limited use likely safe** only after the first trimester at low doses. Obtain fetal ultrasound with first trimester exposure[e2].
Immunomodulators – Topical	
Calcipotriene (calcipotriol)	No well-controlled studies in pregnant women. Calcium imbalance, skeletal and bone ossification abnormalities in animal studies. **Safe** in pregnancy with topical application of doses <100 g/week[e2].
Corticosteroids (hydrocortisone, triamcinolone, fluocinonide, clobetasol)	No well-controlled studies in pregnant women. No associations with malformations with topical corticosteroid use in large studies. Fetal growth restriction reported only with extensive use of potent topical corticosteroids in the third trimester and with extensive use (particularly >300 g)[e10]. Stria may form, especially with higher potency corticosteroids and occlusive dressings. Halogenation, especially fluorination, of corticosteroids determines risk profile due to its ability to pass through the placenta. Methylprednisolone aceponate is a potent topical corticosteroid used in Europe, but has limited side effects due to lack of halogenation. **Limited use is safe** in pregnancy. Mild-to-moderate potency corticosteroids are preferred over potent corticosteroids, but may use potent corticosteroids for a limited period of time[e2].
Tacrolimus	No well-controlled studies in pregnant women. Cardiac defects and dysfunction, neonatal hyperkalemia, renal dysfunction, premature birth, and low birth weight have been reported in infants with oral maternal administration during pregnancy[e6]. Teratogenic and embryotoxic (late resorptions, decreased live births, decreased weight and viability) with oral use and high maternal doses in animal studies. Crosses placenta. Poor systemic absorption with topical application. **Limited use is safe** with topical application in pregnancy[e2].
Pimecrolimus	No well-controlled studies in pregnant women. Embryo-fetal toxicity (skeletal variations) with oral use and high maternal doses in animal studies. Congenital anomalies, neonatal hyperkalemia, low birth weight, and premature delivery have been reported with oral maternal administration during pregnancy, though association was complicated by medically complex history. Poor systemic absorption with topical application due to large molecular size. **Limited use is safe** with topical application in pregnancy.
Crisaborole	No adequate and well-controlled studies in pregnant women. No teratogenicity with oral administration in animal studies. Systemic absorption after topical application[e1]. **Use with caution** due to limited safety data.
Immunomodulators – Systemic	
Prednisone	No well-controlled studies in pregnant women. Increased risk for orofacial clefts 4 weeks before conception and 12 weeks after conception, premature delivery, premature membrane rupture, intrauterine growth restriction, gestational diabetes, and maternal hypertensive disorders[e2]. Teratogenic (cleft palate) in animal studies. Barely crosses placental barrier (mother-to-child ratio 10:1). **Limited use is likely safe**. During first trimester, particularly between weeks 8 and 11, increased risk of cleft lip/cleft palate has been debated with high doses and for >10 days but could not be substantiated by recent large population-based case–control study[e11]. If use is long-term and extends late into gestation, fetal growth should be monitored and the risk of adrenal insufficiency in the newborn should be addressed.
Intravenous immunoglobulin	Healthy deliveries reported in mothers with pemphigus vulgaris and gestational pemphigoid. No animal studies conducted. Crosses placenta increasingly after 30 weeks of gestation. Hypertension and thrombosis may occur with immunoglobulins, especially in the setting of a hypercoagulable state due to pregnancy. **Use recommended** for active pemphigus and severe gestational pemphigoid during pregnancy.
Hydroxychloroquine	No associations with congenital, neurologic, or auditory abnormalities in studies. No similar risk of retinopathy in fetuses as seen with adults. **Use recommended** for active lupus during pregnancy. Reduces risk for cardiac neonatal lupus[e2].

eTable 27.1 An overview of the use of dermatologic drugs during pregnancy and lactation.

Lactation	Female Fertility	Male Fertility	Former FDA Category
Use not recommended with breastfeeding due to potential for tumorigenicity[e3].	Limited safety data.	Sperm abnormalities not detected in humans. Males should wait at least 6 months after therapy completion before fathering a child. Suppressed spermatogenesis in animal studies.	C (Microsize: X)
Excreted in breast milk. No adverse effects reported with use. **Compatible** with breastfeeding[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	C (low dose for vaginal candidiasis); D (all other)
Excreted in breast milk. **Likely compatible** with breastfeeding[e3].	Decreased pregnancy rates and ovulation at high doses in animal studies. Discontinue prior to conception planning[e1].	Decreased testosterone levels and oligospermia in one study[e8]. Discontinuation prior to conception planning[e1].	C
Excreted in breast milk. Itraconazole has the potential to concentrate in breast milk. No adverse effects reported with use. **Use not recommended** with breastfeeding[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	C
Vitamin D is a normal component of breast milk and excreted in low amounts. **Compatible** with breastfeeding. Limit doses to <10 000 IU/day due to potential for excess calcium in infant[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	C
Corticosteroids are normally present in breast milk. Iatrogenic hypertension reported in infant after high potency (class I) topical corticosteroid application to nipple. **Safe** with breastfeeding. **Use not recommended** on nipple area. Rinse off before using[e3].	Limited safety data.	Limited safety data.	C
Present in breast milk in low amounts. No adverse effects, increased infections, or developmental concerns reported in nursing infants. **Use with caution** due to limited safety data. **Use not recommended** on nipple area since oral consumption by the infant could be significant. Rinse off before using[e3].	No adverse effects on fertility in animal studies. Higher pre-implantation loss and adverse effects on estrous cycle in animal studies.	Reduced sperm function at high doses in animal studies[e1].	C
Present in breast milk in low amounts. **Use with caution** due to limited safety data. **Use not recommended** on nipple area since oral consumption by the infant could be significant. Rinse off before using[e3].	Adverse effects on estrus cycles and post-implantation loss at high oral doses in animal studies.	Reduced sperm function at high oral doses in animal studies.	C
Excretion in breast milk is not known. **Use with caution** due to limited safety data.	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	N/A
Systemic corticosteroids and metabolite prednisolone are excreted in breast milk. No adverse effects reported in nursing infants. High doses may cause temporary loss of milk supply. **Likely compatible** with breastfeeding. Delay breastfeeding until 3–4 hours after administration of high doses only (>1 g)[e3].	Limited safety data. Used in fertility treatments[e1].	Possible reversible decreased sperm count and motility. No need to discontinue while trying to conceive[e1].	C
Excreted in breast milk. **Compatible** with breastfeeding[e3].	Improved fertility in *in vitro* fertilization results[e2].	No adverse effects[e1].	C
Excreted in breast milk in low amounts. Eliminated slowly, which increases risk for toxicity. Observation of exposed breastfed infants over 1 year of age showed no adverse effects on growth, vision, or hearing. **Compatible** with breastfeeding[e3].	Limited safety data.	Limited safety data.	N/A

AN OVERVIEW OF THE USE OF DERMATOLOGIC DRUGS DURING PREGNANCY AND LACTATION	
Dermatologic Medication	**Pregnancy**
Azathioprine	No well-controlled studies in pregnant women. Sporadic anomalies (preaxial polydactyly, cardiac defects, neural defects), preterm delivery, pancytopenia, immunosuppression, and cytomegalovirus infection reported in infants exposed during pregnancy. Large upper lumbar myelomeningocele, bilateral dislocated hips, and talipes equinovarus reported in an infant whose father was on long-term therapy. Other studies have not found associations with congenital defects. No clear patterns have been established[e6]. Teratogenic (skeletal malformations and visceral abnormalities) in animal studies. **Use with caution** in pregnancy due to potential adverse fetal effects. Half the dose if mother is leukopenic in the third trimester to prevent infant leukopenia. Avoid intrauterine devices (IUDs) for contraception, as azathioprine interferes with the efficacy of IUDs[e2].
Mycophenolate mofetil	Fetal losses and congenital malformations (cleft lip and palate, hypertelorism, microphthalmos, colomba, micrognathia, external ear abnormalities, polydactyly, syndactyly, cardiac defects, esophageal atresia, spina bifida) reported in infants with first trimester exposure. Teratogenic and embryo-fetal toxic in animal studies. **Contraindicated** in pregnancy; embryo-fetal toxicity warning. Non-hormonal contraception recommended and avoid blood donation until 6 weeks after therapy completion. Blood products might be administered to pregnant woman[e2].
Rituximab	B cell lymphocytopenia in infants exposed during pregnancy, but returned to baseline in less than 6 months. Decreased lymphoid B cells in animal studies. No patterns of congenital anomalies identified in one study[e12]. Monoclonal antibodies are actively transferred across placenta in third trimester[e6]. **Contraindicated** in pregnancy. Effective contraception recommended during therapy and for 1 year after therapy completion[e2].
Omalizumab	No associations with major birth defects or miscarriage in infants with first trimester exposure. Women with poorly controlled asthma may have increased risk for prematurity, low birth weight, small for gestational age in neonate. No teratogenicity embryotoxicity in animal studies. Monoclonal antibodies are actively transferred across placenta in third trimester[e6]. **Use with caution** due to limited safety data.
Dupilumab	No associations with major birth defects or adverse outcomes identified with maternal exposure. Monoclonal antibodies are actively transferred across placenta in third trimester[e6]. Women with poorly controlled asthma may have increased risk of prematurity, low birth weight, and small for gestational age in neonate. No teratogenic effects, embryo-fetal toxicity, immunologic impairment in animal studies. **Use with caution** in pregnancy due to limited safety data.
Tralokinumab	No well-controlled studies in pregnant women. Monoclonal antibodies are actively transferred across placenta in third trimester. No teratogenic effects, embryofetal toxicity, immunologic impairment in animal studies. **Use with caution** due to limited safety data.
Psoriasis (also see eTable 8.1 for additional medications)	
Certolizumab	Negligible placental transfer. Risk for adverse effects (fetal loss, preterm delivery, low birth weight) are correlated to maternal disease activity rather than certolizumab. No adverse effects in animal studies. **Likely safe** in pregnancy. Preferred choice of biologic because pegylation of antibody prevents placental transfer[e1].
Etanercept	No significant difference in spontaneous abortions or congenital malformations in women with psoriasis exposed to biologics in one study[e13]. VACTERL syndrome (vertebral anomalies, cardiac anomalies, tracheoesophageal fistula, esophageal atresia, renal abnormalities, and limb anomalies) and spontaneous abortions reported in infants with first trimester exposure. However, no clear patterns have been established in multiple studies, and it is currently thought that there is no teratogenic risk[e1]. No teratogenic effects or embryo-fetal toxicity in animal studies. **Use recommended** for severe, recalcitrant disease during pregnancy. Preferred over other non-pegylated TNF inhibitors due to fusion protein makeup which allows etanercept to cross by simple diffusion in lower levels[e1]. Uncertain if routine use is recommended due to limited safety data. Avoid live vaccines in exposed infants for the first 6 months of life[e2].
Adalimumab	No significant difference in spontaneous abortions or congenital malformations in women with psoriasis exposed to biologics in one study[e13]. Lack of pattern of major birth defects was found in infants exposed during pregnancy from a registry of pregnant women with rheumatoid arthritis or Crohn disease. Spontaneous abortions and multiple healthy deliveries have been reported[e2]. No teratogenic effects or embryo-fetal toxicity in animal studies. Monoclonal antibodies are actively transferred across placenta in third trimester[e6]. **Use recommended** for severe, recalcitrant disease during pregnancy. Consider discontinuation after 30 weeks of gestation. Uncertain if routine use is recommended due to limited safety data. Avoid live vaccines in exposed infants for the first 6 months of life[e2].
Cyclosporine	No well-controlled studies in pregnant women. Low birth weight, premature birth, spontaneous abortions, and musculoskeletal hypoplasia reported in infants exposed in early pregnancy[e6]. No renal, neural, or immune effects observed when followed to early childhood. Most of the data are from transplant patients who take higher doses than dermatologic patients. Crosses placenta. Embryo-fetal toxicity (reduced fetal weight, skeletal growth delay) at maternally toxic doses, but no teratogenic effects in animal studies. **Use recommended** only for severe maternal disease[e2].
Apremilast	No associations with congenital defects or adverse outcomes in studies. Embryo-fetal toxicity (fetal loss and incomplete skeletal ossification) at higher than MRHD, but no teratogenicity in animal studies. **Use with caution** in pregnancy due to potential adverse fetal effects and limited safety data.
Methotrexate	Associated with spontaneous abortions, congenital malformations (skull anomalies, facial dysmorphisms, central nervous system abnormalities, limb abnormalities, cardiac anomalies), and intellectual impairment with first trimester exposure. Associated with intrauterine growth restriction and functional abnormalities with second and third trimester exposure. Potential risk in fetus with preconception exposure. No animal studies that meet current standards. Benzyl alcohol is a preservative in the formulation that can cross the placenta. **Contraindicated** in pregnancy for non-neoplastic diseases; embryo-fetal toxicity warning. Use effective contraception during and 6 months after final dose. If administered intramuscularly, use preservative-free formulations, when possible, to avoid benzyl alcohol toxicity.

eTable 27.1 An overview of the use of dermatologic drugs during pregnancy and lactation.

Lactation	Female Fertility	Male Fertility	Former FDA Category
Azathioprine and metabolites are excreted in breast milk at low levels and are undetectable in infant serum. Mild asymptomatic neutropenia in infants reported, however not seen in more recent cases. **Likely compatible** with breastfeeding due to more recent reports. Wait 4 hours after taking medication. Monitor infant blood count[e3].	Limited safety data.	No infertility cases reported in humans. Normal fertility and normal semen analysis in one study[e8]. Temporary depression in spermatogenesis and reduction in sperm count in animal studies.	D
Excreted in milk in animal studies. Potential risk for infection and lymphoma in nursing infants and affects neonatal development. No reported adverse effects in nursing infants. **Contraindicated** in breastfeeding[e3].	No adverse effect on fertility in animal studies.	No adverse effects on fertility in animal studies. Men should not donate semen during therapy and for 3 months after discontinuation.	D
Excreted in breast milk in low amounts. Healthy nursing infants reported with exposure. **Use not recommended** with breastfeeding. If mother chooses to breastfeed, monitor infant for infant B cell count[e3].	Limited safety data.	Limited safety data.	C
Excreted in human milk in very low amounts. Omalizumab is a large molecule and likely destroyed in infant's gastrointestinal tract. No associations with increased infections or infestations in nursing infants. **Use with caution** due to limited safety data.	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Known that maternal IgG present in human milk. Low expected systemic exposure in infant (large molecule and degraded in infant gastrointestinal tract). **Use with caution** due to limited safety data.	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	N/A
Known that maternal IgG present in human milk. Low expected systemic exposure in infant (large molecule and degraded in infant gastrointestinal tract). **Use with caution** due to limited safety data.	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	N/A
Excreted in breast milk in exceedingly low amounts. No adverse effects reported. **Likely compatible** with breastfeeding[e1].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	N/A
Excreted in breast milk in low amounts, and minimally absorbed by infant due to large molecular weight of etanercept. No adverse effects reported with use. **Likely compatible** with breastfeeding[e3].	No adverse effects on fertility[e1].	No adverse effects on fertility.[1]	B
Excreted in breast milk in low levels. Low expected systemic exposure in infants (adalimumab is a large molecule and is likely degraded in infant gastrointestinal tract). No adverse effects in nursing infants reported. **Likely compatible** with breastfeeding[e3].	No adverse effects on fertility[e1].	No adverse effect of TNF inhibitors on fertility[e8].	B
Excreted in breast milk. Mostly undetectable levels in infant serum. No reports of adverse effects on growth, development or kidney function in nursing infants. **Use not recommended** with breastfeeding. If mother chooses to breastfeed, monitor infant for toxicity (edema, tremor, hirsutism, hypertension, seizure, and infant plasma levels)[e3].	No adverse effects on fertility in animal studies.	No reported infertility cases. Normal semen parameters and testicular function in one human study. Depressed sperm count, fertility, and testosterone in animal studies[e8]. No need to discontinue while trying to conceive[e1].	C
Excreted in animal breast milk. **Use with caution** due to limited safety data.	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	C
Excreted in breast milk in low amounts. Potential risk for infant toxicity due to retention in neonatal gastrointestinal cells and ovarian cells. **Contraindicated** in breastfeeding[e3]. Avoid breastfeeding for at least 1 week after last dose.	Reported infertility and menstrual dysfunction during and after therapy cessation. **Discontinue** 3 months prior to planning pregnancy[e1].	Risk of oligospermia and sterility, reversible 3 months after discontinuation. **Discontinue** 3 months prior to planning pregnancy[e8].	X

AN OVERVIEW OF THE USE OF DERMATOLOGIC DRUGS DURING PREGNANCY AND LACTATION	
Dermatologic Medication	**Pregnancy**
Secukinumab	No significant difference in spontaneous abortions or congenital malformations in women with psoriasis exposed to biologics in one study[e13]. No clear patterns of congenital abnormalities or spontaneous abortions were identified in pregnant women with psoriasis, psoriatic arthritis, and ankylosing spondylitis in recent post-market surveillance data[e14]. No teratogenicity or embryo-fetal toxicity in animal studies. Monoclonal antibodies are actively transferred across placenta in third trimester[e6]. **Use with caution** due to limited safety data.
Ustekinumab	No significant difference in spontaneous abortions or congenital malformations in women with psoriasis exposed to biologics in one study[e13]. No adverse effects reported in 24 infants exposed during pregnancy[e15]. No teratogenicity, embryo-fetal toxicity or adverse developmental effects in animal studies. Monoclonal antibodies are actively transferred across placenta in third trimester[e6]. **Use with caution** due to limited safety data.
Ixekizumab	No significant difference in spontaneous abortions or congenital malformations in women with psoriasis exposed to biologics in one study[e13]. Neonatal deaths due to early delivery, trauma, or congenital defects at 19× MRHD in animal studies. Monoclonal antibodies are actively transferred across placenta in third trimester[e6]. **Use with caution** due to limited safety data.
Guselkumab	No significant difference in spontaneous abortions or congenital malformations in women with psoriasis exposed to biologics in one study[e13]. Neonatal deaths at 6× and 30× MRHD in animal studies. Monoclonal antibodies are actively transferred across placenta in third trimester[e6]. **Use with caution** due to limited safety data.
Antipruritic	
Diphenhydramine	Increased risk for cleft palate in 1 study, but no associations with teratogenicity in other large studies. No adverse effects in animal studies. **Safe** in pregnancy. First line antihistamine during pregnancy. First generation antihistamines preferred over second generation[e2]. Avoid use near delivery due to sedating effects on the infant.
Cetirizine	No well-controlled studies in pregnant women. No associations with teratogenicity in large studies. No teratogenicity in animal studies. **Safe** in pregnancy. Second choice of non-sedating antihistamine in pregnancy[e2]. First generation antihistamines preferred over second generation.
Loratadine	Associated with hypospadias in one study, but not others. No teratogenicity in animal studies. Best studied antihistamine with >5000 exposed pregnancies. **Safe** in pregnancy. First choice of non-sedating antihistamine[e2]. First generation antihistamines preferred over second generation.
Hydroxyzine	Hypotension, myoclonus and movement disorders, hypoxia, central nervous system depression, and urinary retention reported in infants exposed during second half of pregnancy. Associated with a slightly increased risk of congenital anomalies with first trimester use[e2]. Crosses placenta. **Use with caution** in pregnancy due to potential adverse fetal effects.
Antiviral	
Acyclovir	Birth defects approximated general population with first trimester exposure in one study. No teratogenicity in animal studies. **Safe** in pregnancy. Use recommended for herpes simplex virus (HSV) and varicella–zoster virus during pregnancy. Use for HSV prophylaxis at 36 weeks of gestation. First choice antiviral for herpes at 400 mg 3 times daily for 7–14 days[e2].
Lice & Scabies	
Permethrin	No adverse effects reported with use. No adverse fetal effects in animal studies. Less than 2% absorbed with topical application and rapid metabolism to inactive metabolites. **Safe** in pregnancy. Use recommended for scabies (first line during pregnancy) and lice (second line during pregnancy)[e2].
Ivermectin	No well-controlled studies in pregnant women. No adverse effects reported with use. Teratogenic (cleft palate) and embryo-fetal toxic (carpal flexure, decreased fetal weight) in higher than MRHD in some, but not all, animal studies. Behavioral development abnormalities were seen at all doses in animal studies. **Use recommended** for scabies if topical therapies are ineffective[e1].
Warts	
Imiquimod	No well-controlled studies in pregnant women. No teratogenicity reported in humans. Teratogenic (exencephaly, protruding tongue, low-set ears) and embryo-fetal toxic (increased resorption, decrease fetal weight, delay in skeletal ossification, bent limb bones) at maternally toxic doses. **Use with caution** due to potential adverse fetal effects[e2].

eTable 27.1 An overview of the use of dermatologic drugs during pregnancy and lactation. (M)RHD, (maximum) recommended human dose. **Green**: Use or limited use of drug is safe in pregnancy. **Peach:** Limited use is likely safe if medically necessary or is recommended for specific indications. **Blue:** Use with caution in pregnancy due to potential adverse fetal effects. **Red:** Use is contraindicated in pregnancy. **Yellow:** Use with caution in pregnancy due to limited safety data.

Lactation	Female Fertility	Male Fertility	Former FDA Category
Excretion in breast milk not known. Likely very low due to large molecule size and destruction in infant's gastrointestinal tract. **Use with caution** due to limited safety data.	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Undetectable or detectable at very low levels in breast milk. Likely destroyed in infant's gastrointestinal tract. **Use with caution** due to limited safety data.	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Excreted in animal breast milk. Likely very low due to large molecule size and destruction in infant's gastrointestinal tract. **Use with caution** due to limited safety data.	No adverse effects on reproductive organs or menstrual cycles in animal studies.	No adverse effects on reproductive organs or sperm in animal studies.	N/A
Excretion in breast milk is unknown. Likely very low due to large molecule size. Not excreted in animal breast milk. **Use with caution** due to limited safety data.	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	N/A
Excreted in breast milk. Short-term drowsiness and irritability reported in breastfed infants whose mothers were taking diphenhydramine, but no other adverse effects were found. **Likely compatible** with breastfeeding. Monitor infant for sedation. Second generation antihistamines preferred over first generation due to less-sedating effects[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Excreted in breast milk. **Compatible** with breastfeeding. Second generation antihistamines preferred over first generation due to less-sedating effects[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Loratadine and metabolite, descarboethoxyloratadine, excreted easily in breast milk. **Compatible** with breastfeeding. Second generation antihistamines preferred over first generation due to less-sedating effects[e3].	No adverse effects on fertility in animal studies.	Reported decrease in fertility, low sperm motility, and gynecomastia with chronic use. Reversible 3 months after discontinuation[e1].	B
Hydroxyzine metabolite, cetirizine, is excreted in breast milk. Seizures reported in breastfed infants. **Contraindicated** in breastfeeding.	Limited safety data.	Limited safety data.	C
Excreted in breast milk with oral administration. Topical application away from breast should pose negligible risk to infant. No adverse effects reported with use. **Compatible** with breastfeeding[e3].	No adverse effects on fertility in animal studies.	Reversible adverse effects on spermatogenesis in animal studies[e1].	B
No adverse effects in nursing infants over 2 months of age. **Compatible** with breastfeeding[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B
Poorly excreted in breast milk with oral administration. Neonatal toxicity in nursing animal studies, likely due to poorly developed blood–brain barriers in rats. **Compatible** with breastfeeding if topical therapies are ineffective[e3].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	C
Excretion in breast milk is not known. Not expected to cause adverse effects. **Likely compatible** with breastfeeding[e2].	No adverse effects on fertility in animal studies.	No adverse effects on fertility in animal studies.	B

Synonyms: ■ Bullous pemphigoid antigen 1: BP230; dystonin ■ Bullous pemphigoid antigen 2: BP180; type XVII collagen ■ Laminin 311: laminin 6 ■ Laminin 332: laminin 5; epiligrin; kalinin; nicein; GB3 antigen; BM600 ■ Laminin 511: laminin 10 ■ Type VII collagen: the epidermolysis bullosa acquisita antigen ■ Nidogen: entactin

Key features

- Basement membranes serve as: (1) a substrate for cell attachment; (2) a template for tissue repair; (3) a matrix for cell migration; (4) a foundation for an infrastructure that influences differentiation, morphogenesis, and apoptosis of epithelial cell layers; and (5) a permeability barrier for cells and macromolecules
- The ultrastructural subregions of the epidermal basement membrane are: (1) basal keratinocytes with their cytoskeletons, hemidesmosomal plaques, and plasma membranes; (2) the lamina lucida, an electron-lucent region containing anchoring filaments; (3) the lamina densa; and (4) the sublamina densa region of the papillary dermis
- In the "laminated" model of the epidermal basement membrane, keratin intermediate filaments within basal keratinocytes attach to hemidesmosomes at the basal plasma membranes. Anchoring filaments connect hemidesmosomes to the lamina densa. The lamina densa is tethered to the dermis by anchoring fibrils that begin and end on the underside of the lamina densa, forming ultrastructural loops that also serve as attachment sites for fibrillar proteins in the papillary dermis
- Acquired or inherited abnormalities in structural proteins within the epidermal basement membrane often result in a disease phenotype characterized by blister formation

INTRODUCTION

Basement membranes are specialized structures located between cells and their underlying stroma or between different cell types[1]. Basement membranes of various tissues differ ultrastructurally, biochemically, and functionally. All basement membranes contain an electron-dense, somewhat granular matrix of variable thickness called the lamina densa. Major components of the lamina densa include type IV collagen, laminins, and heparan sulfate proteoglycans. Other components of the lamina densa vary depending upon the tissue type.

Basement membranes serve a variety of functions that are manifest in a tissue-specific manner. Functions common to virtually all basement membranes include (1) substrates for cell attachment; (2) templates for tissue repair; (3) matrices for cell migration; (4) substrata that influence differentiation, morphogenesis, and apoptosis of epithelial cell layers; and (5) permeability barriers for cells and macromolecules. In the skin, the two major basement membrane complexes are found at the epidermal–dermal interface and around the dermal microvasculature. This chapter will deal largely with the epidermal basement membrane.

The epidermal basement membrane is a highly specialized structure that contains numerous tissue-specific elements (Table 28.1). The first characterization of this ultrastructural region in the skin was made via electron microscopy, which identified four distinct subregions of the epidermal basement membrane (Fig. 28.1). From superior to inferior, they are:

- basal keratinocytes with their cytoskeletons, hemidesmosomal plaques, and plasma membranes;
- the lamina lucida, an electron-lucent region that contains delicate anchoring filaments; the latter connect hemidesmosomes (HDs) in basal keratinocytes to the underlying lamina densa;
- the lamina densa; and
- the sublamina densa region that contains anchoring fibrils, anchoring plaques, and filamentous proteins of the papillary dermis.

These subregions of the epidermal basement membrane, readily identified in fixed skin samples by transmission electron microscopy, have served as a useful conceptual model of a highly complex adhesion unit that preserves the integrity of the skin (Fig. 28.2). Interestingly, specialized transmission electron microscopy studies of cryopreserved skin have suggested that the lamina lucida may actually represent an artifact of tissue dehydration[2]. Nonetheless, the classic laminated model of the epidermal basement membrane serves as a useful framework for understanding its structure, function, and impairment in disease.

ORIGIN OF THE EPIDERMAL BASEMENT MEMBRANE

The epidermal basement membrane is comprised of proteins derived from both keratinocytes of ectodermal origin and dermal fibroblasts of mesodermal origin. *Basal keratinocytes* produce hemidesmosomal components such as plectin, the epidermal isoform of bullous pemphigoid antigen 1 (BPAG1e), bullous pemphigoid antigen 2 (BPAG2; collagen XVII), and integrin subunits α_6 and β_4; they also contribute CD151 tetraspan, types IV and VII collagen, laminins 332 and 311, and heparan sulfate proteoglycans to the epidermal basement membrane. *Dermal fibroblasts* produce nidogen, types IV and VII collagen, and other proteins that are translocated to the plasma membranes of basal keratinocytes where they condense and are incorporated within the basement membrane. Integrins and other proteins within the plasma membrane of basal keratinocytes provide key localization and organizational cues that facilitate the incorporation of fibroblast-derived proteins into the basement membrane. The major proteins of the epidermal basement membrane are described below (Fig. 28.3).

BASAL KERATINOCYTES: HEMIDESMOSOME-ANCHORING FILAMENTS AND INTEGRINS

Plectin

Plectin is a 500 kDa, dumbbell-shaped, dimeric protein associated with the cytoplasmic plaque of HDs[3]. Like BPAG1, desmoplakin, periplakin, and envoplakin (see Ch. 29), plectin is a member of the plakin family. Plakins are large, multidomain cytolinkers that connect cytoskeletal networks to each other and to adhesive junctions such as desmosomes and HDs[4].

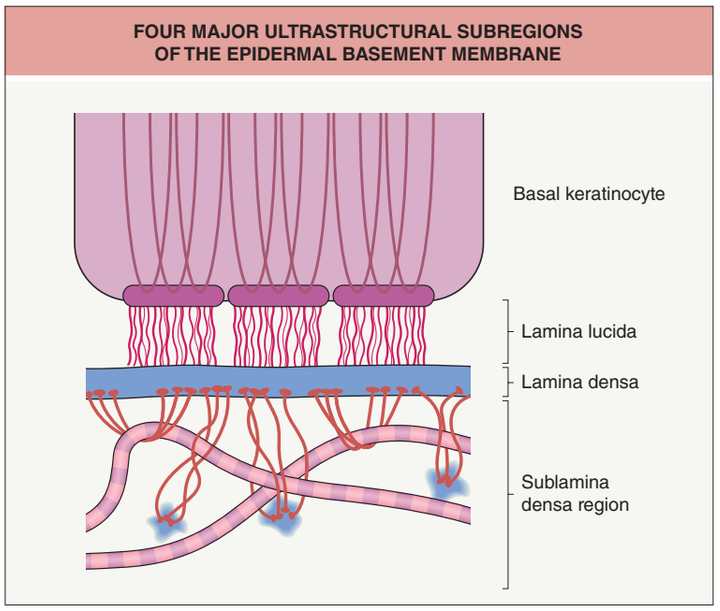

Fig. 28.1 Four major ultrastructural subregions of the epidermal basement membrane. The major ultrastructural subregions of the epidermal basement membrane consist of the following: (1) cytoskeleton, hemidesmosomal plaques, and plasma membranes of basal keratinocytes; (2) electron-lucent lamina lucida; (3) lamina densa; and (4) sublamina densa region of the papillary dermis.

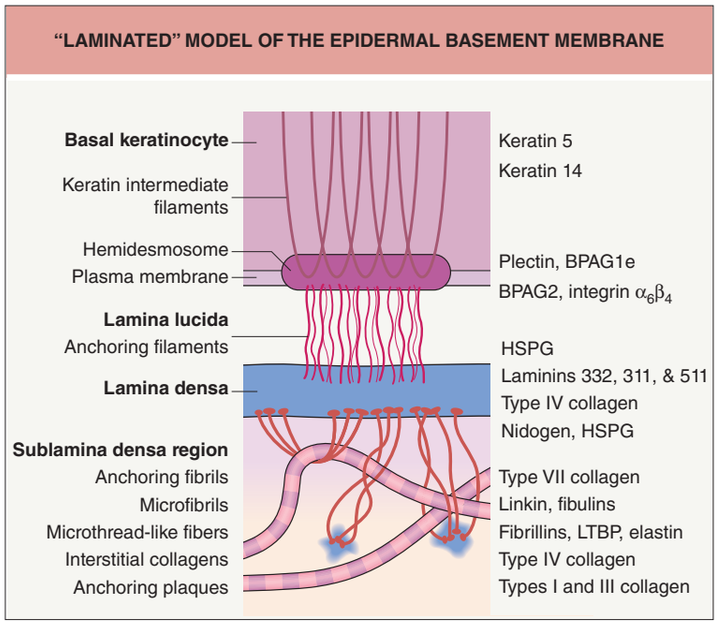

Fig. 28.2 "Laminated" model of the epidermal basement membrane. In the laminated model, keratin intermediate filaments attach to electron-dense hemidesmosomes on the basal plasma membranes of keratinocytes. Hemidesmosomes connect to the underlying lamina densa by small thread-like strands termed anchoring filaments. The lamina densa and the overlying epidermis are tethered to the papillary dermis by anchoring fibrils, a series of looping elements along the underside of the lamina densa that serve as attachment sites for fibrillar proteins in the papillary dermis. HSPG, heparan sulfate proteoglycans; LTBP, latent TGF-β-binding proteins.

The carboxy terminus of plectin binds keratin and vimentin intermediate filaments, whereas its amino terminus contains domains that bind the cytoplasmic tail of integrin subunit β_4, BPAG2, and actin. Mutations in the gene encoding plectin underlie forms of epidermolysis bullosa (EB) simplex that may be associated with muscular dystrophy or pyloric atresia (see Ch. 32). In mice, targeted inactivation of the gene encoding plectin impairs the cytoarchitecture of skin, muscle, and heart[5].

REPRESENTATIVE ADHESION PROTEINS IN THE EPIDERMAL BASEMENT MEMBRANE
Cytoskeleton of basal keratinocytes
• Keratin 5 • Keratin 14
Hemidesmosome-anchoring filament complexes
• Plectin • Bullous pemphigoid antigen 1e • Bullous pemphigoid antigen 2 (type XVII collagen) • Integrin subunit α_6 • Integrin subunit β_4 • Tetraspan CD151 • Laminin 332
Lamina densa
• Heparan sulfate proteoglycans (e.g. perlecan) • Laminin 332 (formerly laminin 5) • Laminin 311 (formerly laminin 6) • Laminin 511 (formerly laminin 10) • Nidogen • Type IV collagen
Sublamina densa region
• Type VII collagen • Type IV collagen • Elastin • Fibulins (glycoproteins found in microfibrillar bundles in the papillary dermis) • Fibrillins (large proteins that form an integral part of the microfibril structure) • Latent TGF-β-binding proteins • Linkin (main component of microthread-like fibers that comprise a delicate mesh-like network in the upper papillary dermis) • Type III collagen • Type I collagen

Table 28.1 Representative adhesion proteins in the epidermal basement membrane. TGF-β, transforming growth factor β.

Bullous Pemphigoid Antigen 1

Circulating autoantibodies from patients with bullous pemphigoid (BP) were used to define two autoantigens that reside in HDs of basal keratinocytes. The first of these autoantigens characterized, BPAG1e, is a 230 kDa plakin protein localized to the cytoplasmic plaque of HDs[6,7]. It has a central coiled-coil α-helical rod domain that contains a regular periodicity of acidic and basic amino acid residues. Studies showing that the periodicities of these residues are 180 degrees out of phase suggested that these proteins may self-aggregate by ionic interactions. The globular carboxy terminus of BPAG1e contains acidic and basic amino acids with a periodicity that promotes association with keratin intermediate filaments. The amino terminus of BPAG1e associates with the cytoplasmic domain of BPAG2, integrin subunit β_4, and ERBIN. The ERBIN protein interacts with the transmembrane tyrosine kinase receptor Erb-B2, thus serving as a potential link between HD biology and Erb-B2 signaling[4].

Consistent with the role that BPAG1e plays in cytoskeletal organization, BPAG1 knockout mice show signs of epithelial fragility in basal keratinocytes[8]. Unexpectedly, these mice also demonstrate neurologic impairment characterized by dystonia and ataxia, which results from concomitant inactivation of neuronal isoforms of BPAG1 (BPAG1n). The amino termini of BPAG1n differ from their epidermal counterpart in that BPAG1n contains actin- or microtubule-binding domains essential for maintaining the cytoarchitecture of neurons. Homozygous nonsense *BPAG1* mutations that affect only BPAG1e underlie a form of EB simplex[9].

Bullous Pemphigoid Antigen 2

BPAG2 (collagen XVII) is a transmembrane collagen associated with HD-anchoring filament complexes in basal keratinocytes[10]. The cytoplasmic amino terminus of BPAG2 consists of ~500 amino acid residues, with several potential phosphorylation sites within its central

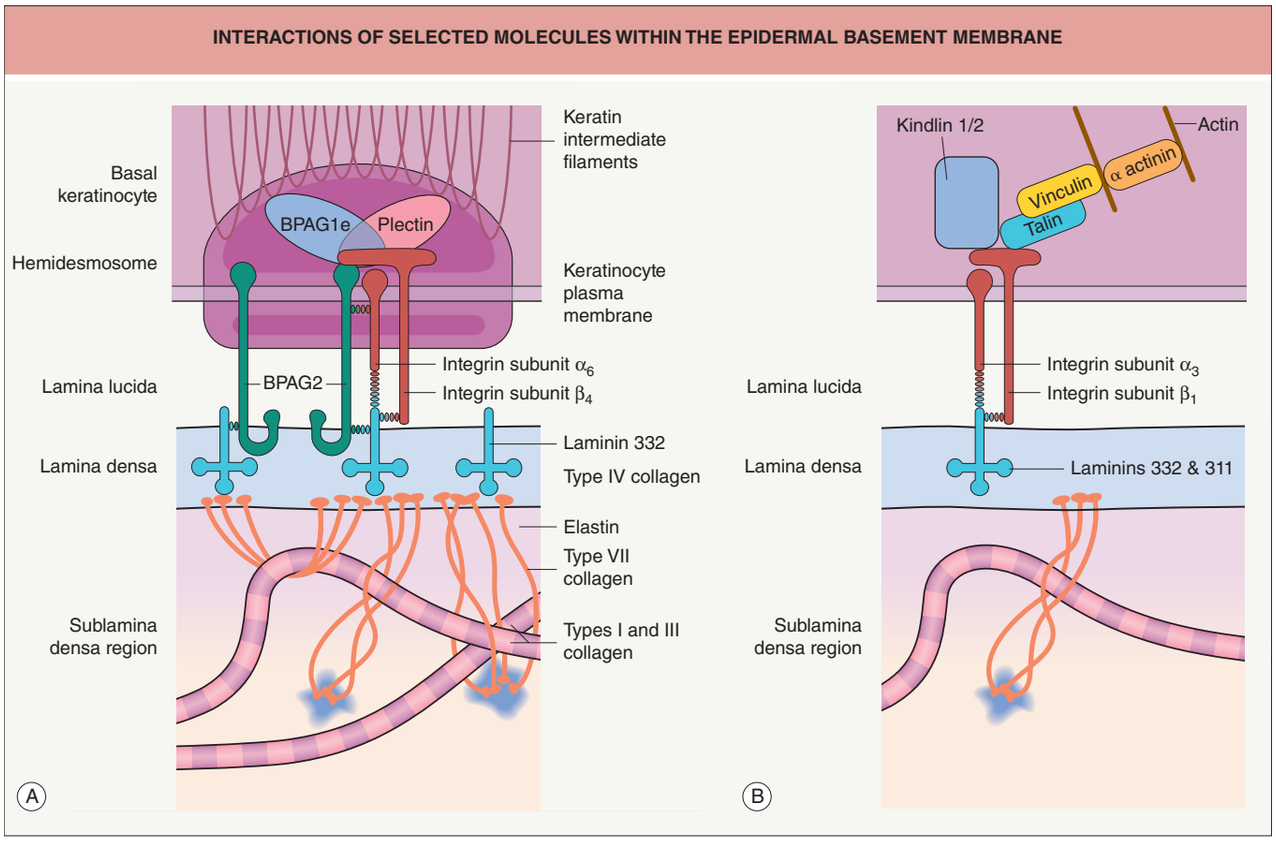

Fig. 28.3 Interactions of selected molecules within the epidermal basement membrane. A Important molecular interactions include: (1) plakin family members, BPAG1e and plectin, with keratin intermediate filaments; (2) plakin family members with BPAG2 and integrin $\alpha_6\beta_4$ (specifically, the large cytoplasmic domain of integrin subunit β_4); (3) the cytoplasmic domains of BPAG2 with integrin subunit β_4; (4) the extracellular domains of BPAG2 with integrin subunit α_6 and laminin 332; (5) integrin $\alpha_6\beta_4$ in hemidesmosomes with laminin 332 in the lamina densa; (6) laminin 332 with type VII collagen; (7) type VII collagen with type IV collagen, fibronectin, and type I collagen in the sublamina densa region. **B** In focal adhesion complexes, laminins 332 and 311 bind integrin $\alpha_3\beta_1$, which is associated with intracellular proteins such as kindlins, talin, vinculin, and, in turn, the actin microfilament network.

portion. The extracellular domain of BPAG2 contains 15 interrupted repeats that have multiple glycine-X-Y amino acid sequences; these are characteristic of collagen family proteins and therefore referred to as collagenous domains (coll 1–15; see Fig. 31.9). By rotary shadowing, the intracytoplasmic domain of BPAG2 appears as a globular head and the extracellular region as a central rod (coll 15) with a flexible tail (coll 1–14)[11]. Immunoelectron microscopy studies suggest that the coll 15 rod domain of BPAG2 inserts into the lamina densa and that its carboxy-terminal tail then loops back through the lamina densa into the lamina lucida (see Fig. 28.3)[12,13].

BPAG2 occurs in two forms[14]: (1) a 180 kDa full-length protein; and (2) a 120 kDa extracellular domain that is shed from plasma membranes of basal keratinocytes via proteolysis. Proteolytic processing of BPAG2 is mediated by "sheddases" of the *a d*isintegrin *a*nd *m*etalloproteinase (ADAM) family, in particular ADAM metallopeptidase domain 17 (ADAM17). Phosphorylation of BPAG2 by ecto-casein kinase 2 inhibits its proteolysis by ADAM17, a mechanism whereby the adhesion and motility of adjacent basal keratinocytes may be modulated[15].

In the epidermal basement membrane, the extracellular domain of BPAG2 is found as a homotrimer in which the collagenous domains form a cross-linked triple helix. The helix forms independently of amino acid sequences in the amino terminal portion of BPAG2 and is organized in a 5′ to 3′ orientation using the 16th *n*on-*c*ollagenous portion of the protein (NC16) as a nucleation site[16]. The cytoplasmic domain of BPAG2 associates with BPAG1e, integrin subunit β_4, and plectin[4]. The first extracellular segment of BPAG2 (NC16) contains 73 amino acid residues that bind integrin subunit α_6[17]. Immunogold electron microscopy studies have suggested that the carboxy-terminal portion of BPAG2 interacts with laminin 332 at the interface of these two proteins near the junction of the lamina lucida and the lamina densa (see Fig. 28.3)[12].

BPAG2 is targeted by autoantibodies from patients with BP, gestational pemphigoid, mucous membrane pemphigoid (MMP), and linear IgA bullous dermatosis (LABD)[18]. Autoantibodies from patients with BP, gestational pemphigoid, and LABD typically target the NC16A domain of BPAG2 (see Fig. 31.9). In contrast, the autoantibodies responsible for MMP tend to target the distal carboxy terminus of BPAG2, which extends deeper into the basement membrane, as well as NC16A. Patients with less severe subtypes of junctional EB often possess null mutations in the gene encoding BPAG2 (*COL17A1*) (Table 28.2). These individuals characteristically demonstrate a complete lack of BPAG2 in their epidermal basement membrane, along with a tendency for skin fragility, subepidermal blister formation, alopecia, dystrophic nails, and dental enamel hypoplasia[19]. Interestingly, *COL17A1* mutations resulting in deletion of the intracellular domain of BPAG2 that associates with BPAG1e, plectin, and integrin subunit β_4 result in a phenotype characterized by intraepidermal as well as junctional blister formation[20].

Integrins

Integrins are heterodimeric transmembrane receptors that promote cell–cell and cell–matrix interactions[21]. Ligand binding to integrin receptors modulates cell adhesion and growth, signal transduction, gene expression, and other fundamental biologic processes. All integrins are αβ-heterodimers. Numerous α- and β-subunits have been identified; several of these have alternatively spliced cytoplasmic domains (e.g. α_1, α_3, α_4, α_6, α_{11b}). Although some of the α-subunits can associate with more than one β-subunit, the number of heterodimers formed is limited.

Both α- and β-integrin subunits are glycoproteins with a single hydrophobic *transmembrane* domain and a *cytoplasmic* domain that is typically composed of ≤50 amino acid residues, although integrin subunit β_4 has a larger cytoplasmic domain of >1000 amino acid residues. Cytoplasmic domains of integrins typically interact with the actin cytoskeleton (see below) and other intracellular proteins. The

TARGETS COMMON TO AUTOIMMUNE AND INHERITED BLISTERING DISEASES			
Protein	**Structure**	**Autoimmune disease**	**Genetic disease**
BPAG1e	HD	BP	Recessive EB simplex
Type XVII collagen (BPAG2)	HD-anchoring filament complexes	BP, PG, MMP, linear IgA bullous dermatosis	Junctional EB (often milder)
Integrin subunit β_4	HD-anchoring filament complexes	Ocular MMP	Junctional EB with pyloric atresia
Laminin 332	Lamina lucida–lamina densa interface	Anti-epiligrin MMP	Junctional EB (often more severe)
Type VII collagen	Anchoring fibrils	EB acquisita Bullous eruption of SLE	Dystrophic EB (dominant and recessive)

Table 28.2 Targets common to autoimmune and inherited blistering diseases. BP, bullous pemphigoid; EB, epidermolysis bullosa; HD, hemidesmosome; MMP, mucous membrane (cicatricial) pemphigoid; PG, pemphigoid gestationis; SLE, systemic lupus erythematosus.

cytoplasmic domains and associations of integrin $\alpha_6\beta_4$ represent an exception to this model in that they are concentrated within HDs of epithelial cells[21].

The *extracellular* domains of integrin subunits associate to form heterodimers. The α- and β-subunits form a pocket that serves as a specific ligand-binding site, and switching either subunit can change ligand specificity. Particular integrin heterodimers can often bind to more than one ligand, and similarly, individual ligands are often recognized by more than one integrin. Integrins usually bind specific peptide sequences in a given group of adhesion molecules, such as the Arg-Gly-Asp (RGD) sequence in fibronectin and vitronectin. Integrin ligand binding is dependent on divalent cations (e.g. Ca^{2+}, Mg^{2+}, Mn^{2+}), and the cations can affect the affinity and the ligand specificity of the integrin.

Integrin-mediated cell–cell and cell–matrix adhesion triggers clustering of integrins and the assembly of signaling and adapter proteins at their cytoplasmic domains. This process creates an "outside in" signaling complex that conveys biochemical messages to different cellular compartments and links the integrin adhesion site to the actin cytoskeleton. In addition, an "inside out" signaling process fine-tunes affinity for extracellular ligands by altering the conformation of integrin ectodomains. Proteins that serve as major "inside out" integrin activators include talins and kindlins[22]. In basal keratinocytes, kindlin-1 and -2 and other proteins such as vinculin can form integrin-tethered macromolecular complexes termed *focal adhesions* through which the actin cytoskeleton connects to the extracellular matrix (see Fig. 28.3B).

Mutations in *FERMT1*, which encodes kindlin-1, are responsible for Kindler EB (Kindler syndrome), an autosomal recessive disease characterized by trauma-induced blistering, photosensitivity, poikiloderma, variable mucosal involvement, and increased risk of mucocutaneous squamous cell carcinoma (see Ch. 32)[23]. Lack of kindlin-1 in human keratinocytes results in defective signaling by Rho GTPases involved in remodeling the actin cytoskeleton and impaired adhesion due to reduced activity of the β_1 integrin subunit. Loss of kindlin-1 in mouse keratinocytes leads to decreased $\alpha_v\beta_6$ integrin-mediated transforming growth factor-β (TGF-β) activation and increased Wnt signaling, thereby stimulating cutaneous stem cell proliferation and contributing to skin cancer risk and cutaneous atrophy due to stem cell exhaustion[24].

Hemidesmosome-associated integrin $\alpha_6\beta_4$

The large cytoplasmic tail of integrin subunit β_4 contains sequences required for HD assembly; the membrane-proximal region directly associates with plectin, while the distal carboxy-terminal region binds BPAG2 (see Fig. 28.3)[21]. The proximal extracellular domain of integrin subunit α_6 binds the NC16A region of BPAG2[17]. Laminins 111 and 332 serve as the preferred ligands for this HD-integrin[25].

Patients harboring biallelic mutations in genes encoding either α_6 or β_4 integrin subunits develop junctional EB with pyloric atresia. They typically have subepithelial blistering of the oral and respiratory epithelia as well as the skin. Targeted deletions of genes encoding integrin subunits α_6 or β_4 in mice result in subepithelial blisters of the same tissues. The degeneration of basal keratinocytes observed in β_4-null mice suggests that this integrin subunit also plays a role in cell survival[26]. Transgenic mice carrying a targeted deletion of the cytoplasmic domain of integrin subunit β_4 have a proliferative defect of stratified and simple epithelia[27]. However, deletion of integrin subunit α_6 does not lead to developmental deficiencies in mouse epithelia.

Plasma membrane-associated integrins

Non-hemidesmosomal integrins expressed in basal keratinocytes include integrins $\alpha_2\beta_1$ and $\alpha_3\beta_1$. Both of these integrins are found along the lateral and apical aspects of these cells' plasma membranes, with additional basal localization for $\alpha_3\beta_1$[21]. Integrins bind the actin cytoskeleton and play a key role in cell–cell adhesion. Keratinocytes in culture utilize integrin $\alpha_3\beta_1$ to mediate initial adhesion to extracellular matrix via interaction with laminin 332.

Although integrin $\alpha_3\beta_1$ does not play a role in HD assembly, it provides key signals that regulate cytoskeletal assembly, function of integrin $\alpha_6\beta_1$, and the establishment and maintenance of basement membrane integrity[28]. Mice with targeted deletion of integrin subunit α_3 have disorganized basement membranes in the kidney as well as in the skin and exhibit mild blistering[29]. In these mice, the lamina densa appears normal beneath HDs but is missing (or sparse) between HDs. Homozygous mutations in the gene encoding the α_3 integrin subunit underlie a human disorder characterized by basement membrane disruption resulting in congenital nephrotic syndrome, interstitial lung disease, and a mild form of EB[30].

Tetraspan CD151

CD151 is a cell surface protein that belongs to the tetraspan superfamily, named for their four membrane-spanning domains. These proteins form "web-like" networks with other membrane proteins and regulate a variety of cellular processes. CD151, which is concentrated in HDs, associates with integrins $\alpha_6\beta_4$ in HDs and $\alpha_3\beta_1$ in the basolateral plasma membrane of basal keratinocytes.

In integrin subunit β_4-deficient keratinocytes, CD151 clusters with $\alpha_3\beta_1$ at the basal cell surface. Introduction of integrin subunit β_4 into the latter cells yields $\alpha_6\beta_4$ integrins that become incorporated into $\alpha_3\beta_1$–CD151 clusters, where they presumably induce the formation of HDs. Soon thereafter, the amount of $\alpha_3\beta_1$ integrins in such clusters diminishes, and CD151 becomes predominantly associated with $\alpha_6\beta_4$ integrins within HDs. CD151 is therefore considered to be a component of pre-HDs whose recruitment is regulated by integrin $\alpha_6\beta_4$. CD151 is also thought to provide a framework for the spatial organization of different HD components[31].

THE LAMINA DENSA

Laminins

Laminins are a family of heterotrimeric glycoproteins composed of at least 15 members in mammals[32]. Laminins consist of three subunits (α, β, and γ) that are joined and stabilized by interchain disulfide bonds and other associations (Fig. 28.4). Each laminin subunit is encoded by a different gene. To date, five α-, four β-, and three γ-subunits have been characterized[32]. Of note, the laminin α3 subunit gene (*LAMA3*) encodes two transcripts, α3A (short variant) and α3B (long variant).

Different laminin isoforms are created by the pairing of various α-, β-, and γ-subunits. In the current laminin nomenclature, each isoform's name reflects the numbers of its α-, β-, and γ-subunits (e.g. α3, β3, and γ2 in laminin 332, formerly termed laminin 5). Laminin isoforms are distributed in a tissue-specific manner, each having a variety of biologic functions. Laminins within basement membranes serve as ligands for overlying cell surface receptors (e.g. integrins), thereby providing key signals regarding the epithelial microenvironment.

The predominant laminins in epidermal basement membranes are 332 (α3β3γ2), 311 (α3β1γ1), and 511 (α5β1γ1). The overall structure of laminins is presented in Fig. 28.4 using laminin 111 (α1β1γ1), a primary component of dermal microvascular (but not epidermal)

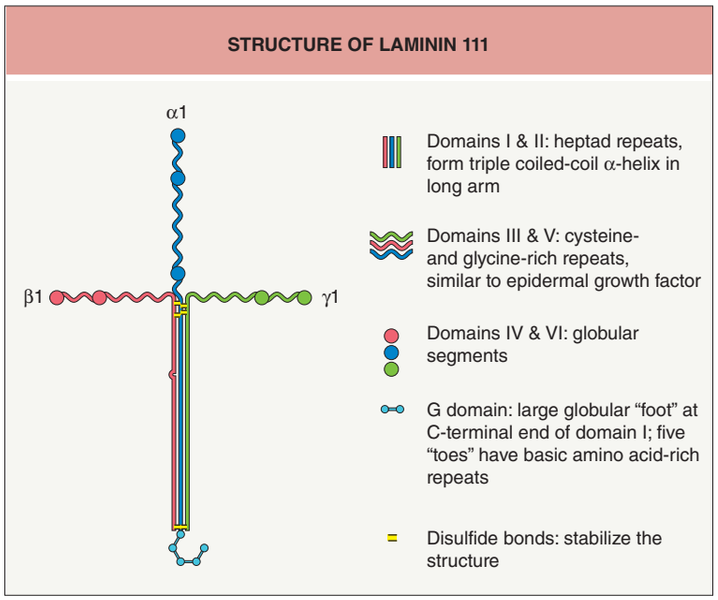

Fig. 28.4 Structure of laminin 111. Laminin 111 (laminin 1) serves as a prototype for the other laminin isoforms, which have similar structure and organization. Laminins consist of three subunits (α, β, γ), each encoded by a different gene and composed of six primary domains (domains I to VI).

basement membranes, as a prototype. The salient features of the laminin isoforms are summarized in Table 28.3[32–38].

The essential role that laminin 332 plays in the epidermal basement membrane is exemplified by inherited disruptions in the genes that encode its subunits (*LAMA3, LAMB3, LAMC2*), which lead to subtypes of junctional EB characterized by subepidermal blister formation and often early death in the more severe forms[19]. Moreover, patients with one form of mucous membrane pemphigoid (MMP) have IgG anti-basement membrane autoantibodies against laminin 332[39,40]. Passive transfer of rabbit anti-laminin 332 IgG to mice or patient IgG to grafts of human skin on immunodeficient mice elicit non-inflammatory subepithelial blisters with clinical, histologic, and immunopathologic features like those seen in patients with this form of MMP[41,42].

Type IV Collagen

Type IV collagen is a unique macromolecule that is specifically localized within basement membranes[1,43]. The structure of type IV collagen most closely resembles a procollagen, an intracellular form that retains globular domains at its amino and carboxy termini. Accordingly, type IV collagen links head-to-head rather than in parallel. Like all collagens, type IV collagen consists of three α-chain subunits; these subunits can be identical or genetically distinct but structurally related. To date, six type IV collagen α-chain subunits have been identified – polypeptides α_1(IV)–α_6(IV), with the corresponding genes *COL4A1–COL4A6*. The subunits of type IV collagen appear to be distributed in three major networks: (1) α_1 and α_2 in skin, smooth muscle, and glomerular basement membranes; (2) α_3, α_4, and α_5 in the glomerular basement membrane; and (3) α_5 and α_6 in skin and smooth muscle basement membranes.

Like all collagens, the α-chain subunits of type IV collagen associate to form a triple-helical structure[1]. The stability of this triple helix is dependent upon characteristic repeating glycine-X-Y amino acid sequences, accompanying residues rich in proline, and post-translational hydroxylation to hydroxyproline (see Ch. 95). The resulting triple helix has an extended, somewhat rigid conformation that is resistant to "ordinary" proteases (e.g. trypsin) and sensitive to specialized proteases (i.e. collagenases). Unlike classic fibrillar collagens, type IV collagen is not helical through its entire length. Short discontinuities in glycine-X-Y repeats within its α-subunits create non-helical domains that confer increased flexibility to this macromolecule as well as sites susceptible to damage by "ordinary" proteases.

The procollagen-like retained globular domains at the ends of type IV collagen are the 7S domain at the amino terminus and the smaller non-collagenous 1 (NC1) domain at its carboxy terminus[1]. The macromolecular structure of type IV collagen resembles a "hockey stick", where the blade of the stick corresponds to the amino-terminal 7S domain, the handle corresponds to the largely continuous triple-helical portion of the molecule, and the handle grip corresponds to the short globular NC1 domain at its carboxy terminus[1]. This model is particularly useful when one relates the lattice structure of type IV collagen matrices to an arrangement of hockey sticks created by: (1) the overlapping of four 7S blades to create a type IV collagen "spider" in which the handles are oriented at roughly right angles to each other; and (2) the subsequent polymerization of "spiders" at sites of their abutting carboxy termini (the handle grips/ends of the spiders' "legs") (Fig. 28.5). Such end-to-end, antiparallel interactions result in a two-dimensional type IV collagen lattice that serves as a key matrix within the lamina densa.

Defective type IV collagen underlies several diseases of basement membranes. For example, most patients with Alport syndrome (characterized by hematuria, progressive renal failure, sensorineural hearing loss, and occasionally ocular abnormalities) have mutations in *COL4A5* which encodes α_5(IV). In addition to this X-linked form of Alport syndrome, an autosomal recessive form is caused by mutations in *COL4A3* or *COL4A4*, and a rare autosomal dominant variant by mutations in *COL4A3*.

Goodpasture disease, a potentially lethal autoimmune disorder characterized by pulmonary hemorrhage and glomerulonephritis, is caused by anti-basement membrane antibodies directed against the NC1 domain of α_3(IV) and α_5(IV)[44]. Exposure of potentially pathogenic epitope(s) within α_3(IV) and/or α_5(IV) by infections or other events may represent an essential element in the development of this disease. Interestingly, antibodies against α_5(IV) ± α_6(IV) can cause a rare disorder characterized by subepidermal blisters and glomerulonephritis[45].

Fragments of type IV collagen α-chain subunits have important biologic activities. Canstatin, a basement membrane-derived fragment of α_2(IV), inhibits angiogenesis, lymphangiogenesis, and tumor growth[46]. Another example is tumstatin, a matrikine derived from the NC1 domain of α_3(IV) that possesses antiangiogenic and proapoptotic activities. Of note, peptides liberated by partial proteolysis of extracellular matrix macromolecules are termed matrikines[47].

Nidogen

Nidogen is a dumbbell-shaped 150 kDa glycoprotein localized to the lamina densa of basement membranes (see Fig. 28.5). Nidogen binds laminin isoforms containing the γ1-subunit (e.g., laminins 111, 311, 511; see Table 28.3) with high affinity. More specifically, the G3 domain at the carboxy terminus of nidogen binds the cysteine-rich, epidermal growth factor-like repeat in domain III of the γ1-subunit[34]. In addition, the G2 domain at the amino terminus of nidogen binds with high affinity to type IV collagen. Complexes of nidogen and laminin can also bind the core protein of heparan sulfate proteoglycans (HSPGs) such as perlecan as well as fibulins 1 and 2. Nidogen is therefore thought to stabilize various macromolecules within the lamina densa. Although traditionally nidogen has been postulated to link type IV collagen and laminin networks, more recent studies have found that perlecan (see below) may have a more important role in this connection[48] (see Fig. 28.5).

A second form of nidogen (nidogen 2) has ~45% identity with classic nidogen and is thought to link fibulins to HSPGs as well as to types I and IV collagen[49]. No autoimmune or inherited blistering diseases have been linked to nidogen, and mice engineered to lack nidogen 1 have no obvious abnormalities.

Heparan Sulfate Proteoglycans

Heparan sulfate proteoglycans (HSPGs) are a diverse group of macromolecules that are ubiquitous components of basement membranes. They are found within, immediately above, and just below the lamina densa of the epidermal basement membrane[1]. HSPGs consist of a central core protein that is lined with laterally emanating glycosaminoglycans in a so-called "bottle-brush" configuration (see Ch. 95)[1]. Different basement membranes contain HSPGs of various types and configurations. HSPGs interact with multiple components of the lamina densa and self-polymerize to contribute to the basement membrane matrix. The high sulfate content of HSPGs confers a negative charge to basement

FEATURES OF SELECTED LAMININS						
Laminin isoform (αβγ)*	**Previous numerical name†**	**Other names**	**Molecular weight, KDa**	**Processing, structure and assembly**	**Distribution**	**Interactions and functions**
111	1	EHS laminin, "classic" laminin	~800 (α: ~400; β: ~220; γ: ~210)	• Asymmetric cross: 3 short arms, 1 long arm (see Fig. 28.4) • Self-assembles into a network *in vitro*	• Dermal microvascular BMs • Little or none in epidermal BM	• Diverse biologic functions, largely mediated by interactions with integrin receptors
332	5	Epiligrin, kalinin, nicein, GB3 antigen, BM600	~410 (α: 200 for precursor/165 post processing; β: 140; γ: 155 for precursor/105 post processing)	• Cell-associated precursors of the α3- & γ2-subunits are processed following secretion • α3-subunit is truncated, lacks key N-terminal domains, and has a small G domain • β3-subunit is homolog of β1-subunit but does not undergo processing after secretion and has a truncated short arm • γ2-subunit's aa sequence has ~50% identity to that of the γ1-subunit, but the former's domains are truncated (I, II, III, IV, V) or absent (VI) • *Not* able to self-assemble into networks	• Found at interface of lamina lucida and lamina densa in epidermal BM • Produced and secreted by growing/migrating keratinocytes • Also in BMs of the trachea, gastrointestinal tract and amnion	• Attaches keratinocytes to the epidermal BM • γ2-subunit *lacks* domain that binds nidogen; instead, N-terminus of laminin 332 covalently associates with the branch points of the short arms of laminins 311 and 511, forming a complex that contains binding sites for nidogen (on γ1-subunit) and polymerization (on β_1-, β_2-, & γ_1-subunits) (see Fig. 28.5) • α3-subunit's G domain (positioned superiorly in epidermal BM) binds integrins $\alpha_6\beta_4$ (in HDs; see Fig. 28.3) and $\alpha_3\beta_1$ (in plasma membrane) • β3- or γ2-subunits of monomeric laminin 332 can bind the N-terminal NC1 domain of type VII collagen of anchoring fibrils (see Fig. 28.3) • Thereby links HD-anchoring filament complexes with underlying anchoring fibrils
311	6		~600 (α: 200 for precursor/165 post processing; β: ~220; γ: ~210)	• See above for processing and structure of α3-subunit	• As for laminin 332	• Joined with laminin 332 in a disulfide-bonded complex (see above) • Connected to type IV collagen and other molecules in the lamina densa via nidogen bound to the γ1-subunit (see Fig. 28.5)
511	10		~640–880 (α: 450 for precursor/210–380 post processing; β: ~220; γ: ~210)	• α5-subunit is thought to be processed	• BMs of many tissues	• Interacts with integrin $\alpha_3\beta_1$ and α-dystroglycan • Expressed in basement membranes of the interfollicular epidermis and dermal microvascular endothelial cells • Crucial for hair morphogenesis

*Each isoform's name reflects the numbers of its α-, β- and γ-subunits.
†Numbers reflect the order of the isoforms' discovery.

Table 28.3 Features of selected laminins[32–38]. aa, amino acid; BM, basement membrane; C-terminal, carboxy-terminal; EHS, Engelbreth–Holm–Swarm (a mouse tumor from which laminin 111 was initially isolated); G domain, globular segment at C-terminal end of domain I; HD, hemidesmosome; NC1, non-collagenous 1; N-terminal, amino-terminal.

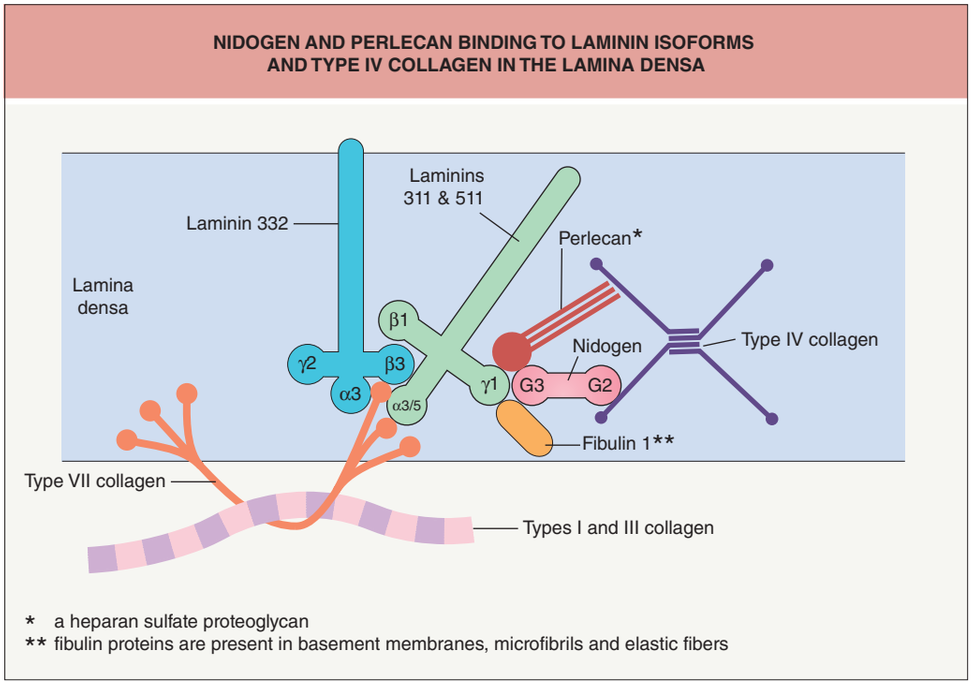

Fig. 28.5 Nidogen and perlecan binding to laminin isoforms and type IV collagen in the lamina densa. Nidogen binds both the γ-subunit of laminin 311 and type IV collagen, while nidogen–laminin complexes bind fibulins and heparan sulfate proteoglycan (HSPG) core proteins. Perlecan, an HSPG, is thought to have an important role in "spot welding" laminin and type IV collagen networks together. Laminin 332, which lacks the γ-domain required for nidogen binding, is stably bound to the basement membrane via a covalent association with the branch points of the short arms of laminin 311. A type IV collagen tetramer "spider" is created by the overlap of four amino terminal "hockey stick blade" domains. Such tetramers polymerize via their carboxy termini to create a macromolecular lattice within the lamina densa. Note that this figure is not drawn to scale.

membranes and thereby restricts their permeability. Perlecan is the best-characterized basement membrane HSPG and it is thought to "spot weld" laminin- and collagen IV-containing networks together (see Fig. 28.5)[48].

ANCHORING FIBRILS AND THE SUBLAMINA DENSA REGION

Type VII Collagen

Type VII collagen is restricted to the basement membrane of stratified squamous epithelia, where it localizes to the sublamina densa region[1]. It is the major component of anchoring fibrils and consists of three identical α-chains, each with a molecular weight of ~290 kDa[50]. Type VII collagen contains two non-collagenous domains: (1) the large, globular NC1 at its amino terminus; and (2) the smaller NC2 at its carboxy terminus (see Ch. 95).

The assembly of anchoring fibrils initiates when NC2 "tails" of individual type VII collagen molecules align in an antiparallel fashion and unite via disulfide bonds[1]. Once these tail-to-tail dimers form, the NC2 domain is proteolytically cleaved, leaving a long thread-like macromolecule characterized by a central rod with large globular NC1 domains at each end. Newly formed type VII collagen dimers then aggregate laterally with other dimers to form bundles resembling "wheat-stacks", which are termed anchoring fibrils (see Fig. 28.2). The globular NC1 domains in anchoring fibrils bind the lamina densa at one end, and the other end either loops back into the lamina densa or connects to electron-dense elements in the sublamina densa region termed anchoring plaques (see Fig. 28.2). Anchoring plaques are thought to represent portions of the lamina densa that have "dropped out" and fallen into the sublamina densa region as a consequence of basement membrane remodeling[51]. On a molecular level, specific subdomains within the NC1 domains of type VII collagen demonstrate affinity for type I fibrillar collagen in the dermis as well as type IV collagen in the lamina densa and anchoring plaques[52,53]. Type VII collagen also interacts with laminin 332, as outlined in Table 28.3[38]. The network of looping bands and tethers formed by anchoring fibrils connects the lamina densa with a series of fibrillar elements in the sublamina densa region.

The gene encoding type VII collagen, *COL7A1*, contains 118 exons but is compact due to its small introns. Mutations in *COL7A1* cause both dominant and recessive forms of dystrophic EB[54] (see Ch. 32). Patients with severe recessive dystrophic EB typically have mutations that lead to premature termination codons and nonsense-mediated mRNA decay, resulting in no detectable type VII collagen. Accordingly, these patients have no anchoring fibrils and manifest extreme skin fragility, mutilating scars, and an increased risk for cutaneous squamous cell carcinomas. Carriers of recessive dystrophic EB harbor only one mutant allele and produce sufficient amounts of type VII collagen from their normal allele to maintain basement membrane integrity and a normal skin phenotype. In contrast, patients with dominant dystrophic EB usually have a missense mutation in one *COL7A1* allele that creates a dominant-negative effect on protein derived from their other, normal *COL7A1* allele. Most dominant-negative *COL7A1* mutations result in glycine substitutions at critical points in the collagenous portion of type VII collagen. These abnormal proteins are incorporated (together with normal α-chains subunits) into type VII collagen trimers and disrupt their function. Consequently, patients with dominant dystrophic EB produce abnormal-appearing and/or reduced numbers of anchoring fibrils and demonstrate a blistering phenotype that is usually less severe than that seen in patients with recessive dystrophic EB.

EB acquisita (EBA) is an autoimmune subepidermal bullous disease in which blisters form in the sublamina densa region, usually as the result of mechanical trauma[55]. The antigen targeted in EBA is type VII collagen, and anti-type VII collagen IgG antibodies from most EBA patients bind four immunodominant epitopes within the NC1 domain of this protein[56,57]. Passive transfer of anti-type VII collagen IgG into mice can elicit lesions with clinical, histologic, and immunopathologic features like those in patients with EBA[58,59]. Of note, the bullous eruption of systemic lupus erythematosus (SLE), which tends to be more inflammatory, is caused by IgG autoantibodies directed against the same four immunodominant epitopes in type VII collagen that are recognized by autoantibodies from patients with EBA[57].

Microfibrils

Elastic fibers have two distinct components: (1) an amorphous component composed of the protein elastin; and (2) a microfibrillar component that has a regular diameter of 10–12 nm and consists primarily of fibrillins, which are associated with other proteins such as microfibril-associated glycoproteins, fibulins, and latent TGF-β-binding proteins (see Ch. 95). In the papillary dermis, microfibrillar elements insert vertically into the lamina densa and comprise what has classically been referred to as oxytalan fibers. At their inferior aspect, oxytalan fibers merge with microfibrillar elements oriented parallel to the skin's surface. These parallel microfibrillar elements contain an amorphous component, and they have been designated elaunin fibers. The network of oxytalan and elaunin fibers is contiguous with elastic fibers within the reticular dermis, which consist of microfibrillar elements associated with substantial amounts of elastin. The gradient of increasing amorphous component deeper in the dermis has been suggested to reflect maturation of elastic fibers in a top-down manner within the skin.

BASEMENT MEMBRANE REMODELING

The epidermal basement membrane is not only a physical barrier between the epidermis and the underlying dermis, but is also a dynamic structure that is constantly being remodeled. For example, the epidermal basement membrane is routinely penetrated by Langerhans cells trafficking into and out of the epidermis under normal physiologic conditions. Lymphocytes also cross the epidermal basement membrane in both inflammatory and neoplastic diseases. However, nonimmune and non-malignant cells rarely cross this ultrastructural barrier, with an absence of basement membranes in tumors correlating with malignancy and propensity for metastasis.

Metalloproteinases expressed by immune or malignant cells enable penetration of basement membranes. Such proteases also have important functions in remodeling epidermal and other basement membranes during morphogenesis, development, and other physiologic processes such as modification of mammary epithelia during pregnancy and lactation. In addition, metalloproteinases play a key role in alterations (e.g. thinning) of the epidermal basement membrane in aged and photoaged skin.

THE EPIDERMAL BASEMENT MEMBRANE IN BULLOUS DISEASES

Patients with acquired immunobullous diseases have autoantibodies directed against components of the epidermis (e.g. in pemphigus) or epidermal basement membrane (e.g. in various forms of pemphigoid). By utilizing autoantibodies from such patients, multiple autoantigens were identified thus demonstrating that individuals with a specific immunobullous disease have autoantibodies directed against a particular protein or proteins with important structural roles in the skin. Furthermore, the genes encoding these proteins often harbor mutations in patients with various forms of EB. Hence, either acquired or inherited alterations in key adhesion proteins in the skin result in disease phenotypes characterized by blister formation (see Table 28.2). The biology of the epidermal basement membrane in patients with autoimmune or inherited blistering diseases is briefly summarized below, and further details are provided in Chapters 30, 31, and 32.

Autoimmune Subepidermal Blistering Diseases

The autoantigens recognized in patients with subepidermal immunobullous diseases are outlined in Table 28.4. Once classified solely by their clinical and histologic features, these disorders are now also defined by their characteristic autoantigen–autoantibody pairings (Fig. 28.6). Profiling patients' autoantibodies to classify their bullous diseases has not only improved diagnostic accuracy but also increased recognition of the polymorphic nature of these conditions. For example, while EBA was once largely considered to be a diagnosis of exclusion for a rare, acquired skin fragility disorder, it is now recognized as a disease that may clinically resemble classic BP or mucous membrane pemphigoid (MMP) as well as dystrophic EB.

WELL-CHARACTERIZED SUBEPIDERMAL IMMUNOBULLOUS DISEASES			
Disease	**Antigen**	**Size (kDa)**	**Localization**
Bullous pemphigoid	BPAG1e	230	Intracytoplasmic plaque of hemidesmosomes
	BPAG2	180	Hemidesmosome-anchoring filament complexes
Pemphigoid gestationis	BPAG2	180	Hemidesmosome-anchoring filament complexes
Linear IgA bullous dermatosis	BPAG2	120→97	Hemidesmosome-anchoring filament complexes
Mucous membrane (cicatricial) pemphigoid	BPAG2	180	Hemidesmosome-anchoring filament complexes
Anti-epiligrin mucous membrane pemphigoid	Laminin 332	400–440	Lamina lucida–lamina densa interface
EB acquisita	Type VII collagen	290	Anchoring fibrils
Bullous eruption of systemic lupus erythematosus	Type VII collagen	290	Anchoring fibrils

Table 28.4 Well-characterized subepidermal immunobullous diseases. BPAG, bullous pemphigoid antigen; EB, epidermolysis bullosa.

LOCALIZATION OF AUTOANTIGENS IN SUBEPIDERMAL IMMUNOBULLOUS DISEASES AND MUTATED PROTEINS IN EPIDERMOLYSIS BULLOSA

Epidermal basement membrane	Autoantigens in immunobullous diseases	Mutated proteins in epidermolysis bullosa (EB)
Basal keratinocytes — Keratins 5 & 14		EB simplex
Lamina lucida — BPAG1e, plectin; BPAG2, integrin $\alpha_6\beta_4$	Bullous pemphigoid, pemphigoid gestationis LABD, mucous membrane pemphigoid	EB simplex, including subtypes with MD or PA Junctional EB, including subtype with PA
Lamina densa — Laminin 332	Anti-epiligrin mucous membrane pemphigoid	Junctional EB
Sublamina densa — Type VII collagen	Epidermolysis bullosa acquisita Bullous eruption of systemic lupus erythematosus	Dystrophic EB

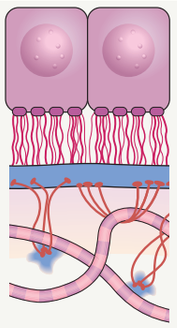

Fig. 28.6 Localization of autoantigens in immunobullous diseases and mutated proteins in epidermolysis bullosa. BPAG, bullous pemphigoid antigen; LABD, linear IgA bullous dermatosis; MD, muscular dystrophy; PA, pyloric atresia.

CLEAVAGE PLANE IN SALT-SPLIT SKIN AND USUAL SITES BOUND BY AUTOANTIBODIES IN INDIRECT IMMUNOFLUORESCENCE STUDIES

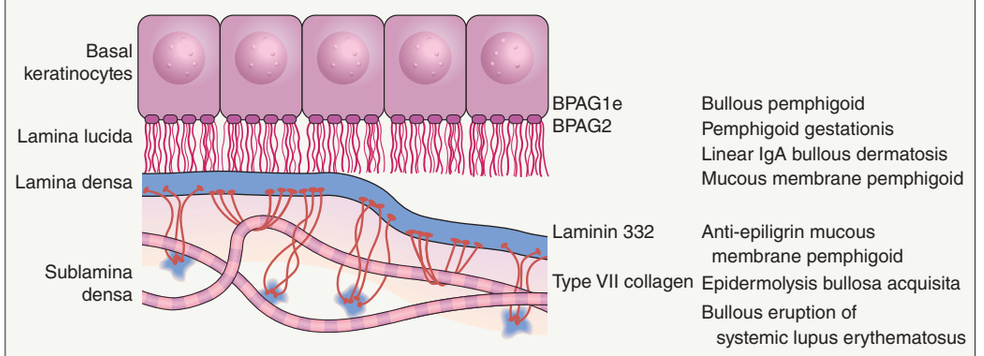

Fig. 28.7 Cleavage plane in salt-split skin and usual sites bound by autoantibodies in indirect immunofluorescence studies. The cleavage plane in 1 M NaCl salt-split skin is in the lower portion of the lamina lucida. Circulating autoantibodies from patients with various subepidermal immunobullous diseases bind to different sites, e.g. the epidermal versus dermal side of the split.

Advances in our understanding of the epidermal basement membrane and how it is targeted in various immunobullous diseases have also led to the development of immunopathologic techniques that have great clinical utility. One example of these techniques is the use of 1 M NaCl salt-split skin, cleaved within the lamina lucida, in immunofluorescence (IF) microscopy studies of patient sera and skin[60–62] (Fig. 28.7; Table 28.5). Indirect IF studies of salt-split skin first gained attention when it was shown that patients with an inflammatory form of EBA and those with classic BP could be distinguished by their IgG anti-basement membrane autoantibodies binding dermal and epidermal sides, respectively, of salt-split skin[60]. When it was found that IgG anti-basement membrane autoantibodies from patients with one form of MMP bound the dermal side of salt-split skin but showed no reactivity to type VII collagen, the search began for a previously unrecognized autoantigen, which was then identified as laminin 332 (epiligrin)[39,40].

For individuals who lack detectable circulating anti-basement membrane autoantibodies, the direct salt-split skin technique has been applied to studies of patient skin[61,62] (Table 28.5). In this technique, skin from a patient is split in the laboratory with 1 M NaCl then studied by direct IF microscopy to determine where immunoreactants localize *in situ*. For example, patients with EBA and anti-laminin-332 MMP have deposits of IgG that localize to the dermal side of salt-split skin. In contrast, patients with BP have deposits of IgG that localize to the epidermal (or both) side(s) of salt-split skin. The pattern of immunoreactant deposition as seen by direct IF microscopy can provide additional information, e.g. a u-serrated pattern distinguishes disorders in which type VII collagen is targeted from other subepidermal immunobullous diseases[63].

LOCALIZATION OF IMMUNOREACTANTS IN IMMUNOFLUORESCENCE MICROSCOPY STUDIES OF 1 M NaCl SALT-SPLIT SKIN		
Indirect immunofluorescence microscopy studies		
Disease	***Localization***	
Bullous pemphigoid	IgG characteristically epidermal; occasionally both sides with higher titer against the epidermal side	
Pemphigoid gestationis	IgG characteristically epidermal; occasionally both sides with higher titer against the epidermal side	
Linear IgA bullous dermatosis	IgA characteristically epidermal; rare patients with "IgA EBA" bind the dermal side	
MMP	IgG characteristically epidermal; occasionally both sides with higher titer against the epidermal side	
Anti-epiligrin MMP	IgG against dermal side of substrate	
EB acquisita	IgG against dermal side of substrate	
Anti-p200 pemphigoid (anti-laminin γ1 pemphigoid)	IgG against dermal side of substrate	
Anti-p105 pemphigoid	IgG against dermal side of substrate	
Direct immunofluorescence microscopy studies*		
Disease	***Localization of IgG***	***Localization of C3***
Bullous pemphigoid	Epidermal	Epidermal, dermal, or both
Pemphigoid gestationis	Epidermal	Epidermal, dermal, or both
Anti-epiligrin MMP	Dermal	Dermal
EB acquisita	Dermal	Dermal
*These studies utilize patient skin after it is split with 1 M NaCl.		

Table 28.5 Localization of immunoreactants in immunofluorescence microscopy studies of 1 M NaCl salt-split skin. EB, epidermolysis bullosa; MMP, mucous membrane (cicatricial) pemphigoid.

REPRESENTATIVE FORMS OF EPIDERMOLYSIS BULLOSA (EB)			
Disease	**Gene**	**Protein**	**Localization**
EB simplex	*KRT5*	Keratin 5	Intermediate filament cytoskeleton of basal keratinocytes
	KRT14	Keratin 14	Intermediate filament cytoskeleton of basal keratinocytes
EB simplex with muscular dystrophy	*PLEC*	Plectin	Intracytoplasmic plaque of hemidesmosomes
EB simplex, intermediate (former Ogna subtype)			
EB simplex with pyloric atresia			
Recessive EB simplex	*DST*	BPAG1	Intracytoplasmic plaque of hemidesmosomes
Junctional EB	*COL17A1*	BPAG2 (type XVII collagen)	Hemidesmosome-anchoring filament complexes
	ITGB4	β_4 integrin	Hemidesmosome-anchoring filament complexes
	LAMA3	Laminin 332, α3 subunit	Lamina lucida–lamina densa interface
	LAMB3	Laminin 332, β3 subunit	Lamina lucida–lamina densa interface
	LAMC2	Laminin 332, γ2 subunit	Lamina lucida–lamina densa interface
Junctional EB with pyloric atresia	*ITGA6*	α_6 integrin subunit	Hemidesmosome-anchoring filament complexes
	ITGB4	β_4 integrin subunit	Hemidesmosome-anchoring filament complexes
Dominant dystrophic EB	*COL7A1*	Type VII collagen	Anchoring fibrils
Recessive dystrophic EB			

Table 28.6 Representative forms of epidermolysis bullosa (EB). Homozygous mutations in the gene encoding the α3 integrin subunit can lead to congenital nephrotic syndrome, interstitial lung disease, and EB30. Additional forms of EB result from mutations in the genes encoding exophilin 5, kelch-like protein 24, CD151 antigen, and kindlin-1 (see Ch. 32). BPAG1, bullous pemphigoid antigen 1.

Inherited Subepidermal Blistering Diseases

The study of patients with various forms of EB has contributed to advances in our understanding of the epidermal basement membrane[64] (Table 28.6; see Fig. 28.6). Likewise, advances in cutaneous immunopathology facilitated the study of patients with EB. For example, because patients with EB simplex display cleavage within the cytoplasm of their basal keratinocytes, BPAG1e and type IV collagen localize to the dermal side of their blistered skin. In patients with various forms of junctional EB, BPAG1e localizes to the epidermal side of blistered skin, while type IV collagen remains attached to the dermis. Lastly, in patients with dystrophic EB, both BPAG1e and type IV collagen localize to the epidermal side of the cleavage plane, which sits within the sublamina densa region.

In addition to classifying patients with various forms of EB based upon mapping the plane of blister formation, studies of the immunoreactivity and ultrastructure of skin from EB patients have provided key insights regarding pathophysiology. For example, monoclonal antibodies against various subunits of laminin 332 generally fail to bind the skin of patients with severe junctional EB. Similarly, monoclonal antibodies against type VII collagen almost always fail to bind the skin of patients with severe recessive dystrophic EB.

SUMMARY

The basement membranes of various tissues differ in their ultrastructure, biochemical composition, and biological function. The epidermal basement membrane contains many highly specialized structures that are largely tissue-specific. Cell–matrix interactions between keratinocytes and the epidermal basement membrane provide key positional and environmental cues that directly modulate tissue morphogenesis, homeostasis, differentiation, wound healing, and acquisition of specialized functions.

29 Pemphigus

Masayuki Amagai

Synonyms: ■ Fogo selvagem: endemic pemphigus foliaceus; Brazilian pemphigus ■ Pemphigus erythematosus: Senear–Usher syndrome ■ IgA pemphigus: intercellular IgA dermatosis; intraepidermal neutrophilic IgA dermatosis; intercellular IgA vesiculopustular dermatosis ■ Paraneoplastic pemphigus: paraneoplastic autoimmune multi-organ syndrome

Key features

- Pemphigus is a group of autoimmune blistering diseases of the skin and mucous membranes that is characterized by:
  - histologically, intraepidermal blisters due to the loss of cell–cell adhesion of keratinocytes
  - immunopathologically, the finding of *in vivo* bound and circulating IgG autoantibodies directed against the cell surface of keratinocytes
- Pemphigus is divided into three major forms: pemphigus vulgaris, pemphigus foliaceus, and paraneoplastic pemphigus
- The functional inhibition of desmogleins, which play an important role in cell–cell adhesion of keratinocytes, by IgG autoantibodies results in blister formation
- Patients with pemphigus vulgaris and pemphigus foliaceus have IgG autoantibodies against desmoglein 3 and desmoglein 1, respectively, while patients with paraneoplastic pemphigus also have IgG autoantibodies against plakin molecules as well as a T cell-mediated autoimmune reaction that leads to an interface dermatitis
- IgA pemphigus is characterized by IgA, but not IgG, autoantibodies directed against keratinocyte cell surfaces and is divided into two major subtypes: intraepidermal neutrophilic (IEN) type and subcorneal pustular dermatosis (SPD) type
- Systemic corticosteroids are a mainstay of therapy in pemphigus vulgaris, given the rapidity of clinical response, but because of their potential side effects at effective doses, they are combined with steroid-sparing agents
- These additional therapies include immunosuppressive medications such as mycophenolate mofetil, high-dose IVIg (non-immunosuppressive), and anti-CD20 monoclonal antibodies
- Rituximab represents a first-line, FDA-approved therapeutic option for moderate-to-severe pemphigus and can also benefit patients who do not achieve clinical remission with systemic corticosteroids and/or other adjuvant immunosuppressive drugs

INTRODUCTION

The term pemphigus stems from the Greek *pemphix*, meaning blister or bubble, and it describes a group of chronic blistering skin diseases in which autoantibodies are directed against the cell surface of keratinocytes, resulting in the loss of cell–cell adhesion of keratinocytes through a process called acantholysis[1]. Pemphigus can be divided into three major forms: pemphigus vulgaris, pemphigus foliaceus, and paraneoplastic pemphigus (Table 29.1).

Pemphigus vulgaris and pemphigus foliaceus are the originally characterized, classic forms of pemphigus[2]. All patients with pemphigus vulgaris have mucosal membrane erosions, and more than half will also have cutaneous blisters and erosions. The blisters of pemphigus vulgaris develop within the deeper portion of the epidermis, just above the basal cell layer. Patients with pemphigus foliaceus only have cutaneous involvement without mucosal lesions, and the splits occur in the superficial portion of the epidermis, mostly at the granular layer. Pemphigus vegetans is a variant of pemphigus vulgaris, and pemphigus erythematosus and fogo selvagem represent localized and endemic variants of pemphigus foliaceus, respectively.

Paraneoplastic pemphigus is distinct from the classic forms of pemphigus[3], as it consists of both humoral and cellular autoimmune reactions. Patients with paraneoplastic pemphigus have a known or occult associated neoplasm, usually of lymphoid tissue. Painful, severe oral and conjunctival erosions are a prominent feature of paraneoplastic pemphigus.

HISTORY

The modern history of pemphigus began with the discovery by Beutner and Jordon in 1964 of circulating antibodies directed against the cell surface of keratinocytes in the sera of pemphigus vulgaris patients[4] (Fig. 29.1). This was followed by the finding of *in vivo* IgG deposition on the cell surface of keratinocytes in patients' skin. These discoveries formed the basis of our understanding of pemphigus as a tissue-specific autoimmune disease of the skin and mucous membranes. In the late 1970s and early 1980s, pemphigus autoantibodies were shown to be pathogenic, i.e. they could induce blister formation in skin organ-culture systems as well as by passive transfer of patients' IgG to neonatal mice[5]. In the mid and late 1980s, the target antigens of pemphigus were characterized by immunochemical methods, such as immunoprecipitation and immunoblotting[6]. In the early 1990s, the isolation of cDNA for pemphigus antigens demonstrated that pemphigus is an anti-cadherin autoimmune disease[7].

EPIDEMIOLOGY

The prevalence of pemphigus vulgaris and pemphigus foliaceus in men and women is approximately equal. The mean age of onset of disease is 50 to 60 years, although the range is broad and disease arising in the elderly and in children has been described. Pemphigus can be found all over the world. Although limited data are available regarding the incidence of pemphigus, in general, it ranges from 0.76 to 5 new cases per million per year, with a higher incidence observed in the Middle East, Southeast Europe, and India. However, the incidence is much higher (16 to 32 cases per million per year) in those of Jewish ancestry, particularly Ashkenazi Jews. Occasionally, this ancestry may not be readily apparent, as in the descendants of the *conversos* (Jews from the Iberian peninsula who were forced to convert to Catholicism), who currently reside in the southwestern USA and Latin America.

In most countries, pemphigus vulgaris is more common than pemphigus foliaceus; exceptions include Finland, Tunisia, and Brazil. For example, in Japan (incidence of pemphigus: 3.5 cases per million per year), the ratio of pemphigus vulgaris to pemphigus foliaceus is 2 : 1. In France (incidence: 1.7 cases per million per year), pemphigus vulgaris accounts for the majority of all cases (~75%), as it does in Bulgaria. In contrast, in Finland (incidence: much lower at 0.76 cases per million per year) and in Tunisia (incidence: 6.7 cases per million per year), pemphigus foliaceus is twice as common as pemphigus vulgaris. More interestingly, the female-to-male ratio in Tunisia is 4 : 1, and the incidence is higher in young women ages 25 to 34 years (15.5 cases per million per year). In addition to Brazil, Tunisia may have endemic foci of pemphigus foliaceus as may the Mt. Kilimanjaro area.

CLASSIFICATION OF PEMPHIGUS

• Pemphigus vulgaris
  • Pemphigus vegetans
• Pemphigus foliaceus
  • Pemphigus erythematosus: localized
  • Fogo selvagem: endemic
• Herpetiform pemphigus
• Drug-induced pemphigus*
• Paraneoplastic pemphigus
• IgA pemphigus

*ACE inhibitors (e.g. captopril), penicillamine > gold, pyritinol, antibiotics (especially β-lactams), immune checkpoint inhibitors (e.g. pembrolizumab), nifedipine, phenobarbital, piroxicam, propranolol, pyrazolone and topical imiquimod.

Table 29.1 Classification of pemphigus.

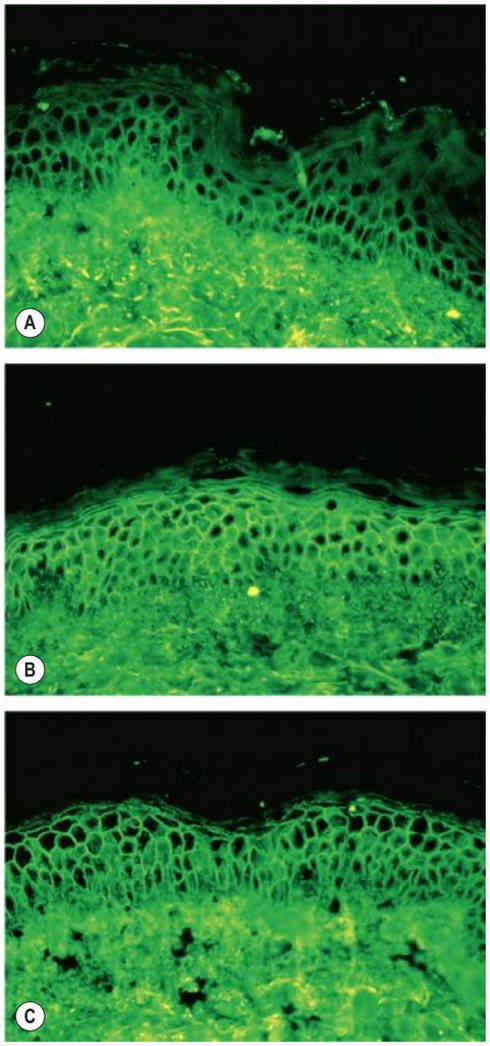

Fig. 29.1 Indirect immunofluorescence of pemphigus sera with normal human epidermis as a substrate. The hallmark of pemphigus is the finding of IgG autoantibodies directed against the cell surface of keratinocytes. **A** Pemphigus vulgaris sera containing anti-desmoglein 3 (anti-Dsg3) IgG alone stain predominantly the cell surfaces in the lower epidermis. **B** Pemphigus vulgaris sera containing both anti-Dsg3 IgG and anti-Dsg1 IgG stain the cell surfaces throughout the epidermis. **C** Pemphigus foliaceus sera, which contain only anti-Dsg1 IgG, stain the cell surfaces throughout the epidermis, but more intensely in the superficial layers.

Fogo Selvagem

Patients with fogo selvagem are clinically, histologically, and immunopathologically similar to patients with sporadic pemphigus foliaceus. However, fogo selvagem occurs in an endemic fashion in certain regions of Brazil and is thought to be caused by an environmental factor(s). Unlike sporadic pemphigus foliaceus, which is a disease of mostly middle-aged and older patients, fogo selvagem affects young adults and children of either sex or any race who are exposed to the local ecology in rural areas, and the incidence gradually decreases as the area is developed. The majority of patients live close to rivers and within the 10–15 km flying range of black flies (*Simulium* spp.), which may be the vector that precipitates the disease. There is also a high frequency of hematophagous insects (bedbugs and kissing bugs) in the homes of patients with fogo selvagem. Of note, a salivary protein from the sand fly *Lutzomyia longipalpis* was shown to induce cross-reactive antibodies to Dsg1[8].

Fogo selvagem frequently occurs in genetically related family members, although it is not contagious, and, to date, spread by blood products or body fluids has not been documented. In rural Brazil, the ratio of pemphigus foliaceus to pemphigus vulgaris is a remarkable 17:1. The prevalence in some rural areas of Brazil is as high as 3.4% of the population[9]. Furthermore, in these areas, more than 50% of normal individuals have anti-desmoglein 1 (anti-Dsg1) IgG autoantibodies, and it has been shown that the onset of the disease is preceded by a sustained antibody response consisting of non-pathogenic IgG1 and IgG4 antibodies. In certain genetically predisposed individuals, predominant IgG4 antibodies directed against the N-terminal extracellular EC1 and EC2 domains of Dsg1 are responsible for inducing disease (Fig. 29.2)[10]. Certainly, fogo selvagem provides a fascinating model for understanding the pathophysiologic and immunologic mechanisms involved in triggering an autoimmune response against skin components.

PATHOGENESIS

Pathogenic Autoantibodies in Pemphigus

The hallmark of pemphigus is the finding of IgG autoantibodies against the cell surface of keratinocytes (see Fig. 29.1)[4]. The pemphigus autoantibodies found in patients' sera play a primary pathogenic role in inducing the loss of cell adhesions between keratinocytes, and subsequent blister formation. Neonates of mothers with pemphigus vulgaris may have a transient disease caused by maternal IgG that crosses the placenta.[11] As maternal antibody is catabolized, the disease subsides. IgG fractions from patients can induce blister formation in the absence of complement or inflammatory cells in a skin organ-culture system[5]. Furthermore, passive transfer of patients' IgG to neonatal mice results in blisters in the mice with typical histologic findings[5]. Even monovalent Fab' fragments of IgG from patients with pemphigus foliaceus are sufficient to cause blisters in neonatal mice, indicating complement activation and surface cross-linking may not be essential in keratinocyte detachment[12].

Desmogleins as Pemphigus Antigens

Immunoelectron microscopy localized both pemphigus vulgaris and pemphigus foliaceus antigens to the desmosomes, the most prominent cell–cell adhesion junctions in stratified squamous epithelia[13]. Immunochemical characterization of pemphigus antigens by immunoprecipitation or immunoblotting with extracts from cultured keratinocytes or epidermis demonstrated that the pemphigus vulgaris and foliaceus antigens were 130 kDa and 160 kDa transmembrane glycoproteins, respectively (Table 29.2)[7,14]. By comparative immunochemical studies using anti-desmoglein 1 (Dsg1) monoclonal and polyclonal antibodies, the 160 kDa protein recognized by pemphigus foliaceus sera was subsequently shown to be identical to Dsg1. An 85 kDa plaque protein, plakoglobin, was co-immunoprecipitated with the 130 kDa and 160 kDa pemphigus antigens, demonstrating that plakoglobin forms a molecular complex with pemphigus vulgaris and foliaceus antigens[15].

Molecular cloning of cDNA encoding Dsg1 and pemphigus vulgaris antigens indicated that both molecules were members of the cadherin supergene family[7,16]. Thus, pemphigus was discovered to be an anti-cadherin autoimmune disease. The pemphigus vulgaris antigen was termed desmoglein 3 (Dsg3). The basic pathophysiology of pemphigus is as follows: autoantibodies inhibit the adhesive function of desmogleins and lead to the loss of the cell–cell adhesion of keratinocytes, resulting in blister formation.

Cadherins are a family of calcium-dependent cell–cell adhesion molecules that play an important role in the formation and maintenance of complex tissue integrity[17]. Based on sequence similarity, cadherins have two major subgroups: *classic* cadherins (e.g. E-, P-, N-cadherins) and *desmosomal* cadherins (desmogleins and desmocollins). All members of the cadherin family contain conserved repeated amino acid sequences (cadherin repeats) with calcium-binding motifs in their extracellular domains (see Fig. 29.2). When classic cadherins were introduced by gene transfection into non-adhesive mouse fibroblast L cells, the cells acquired strong cell adhesion activity mediated by a homophilic type of

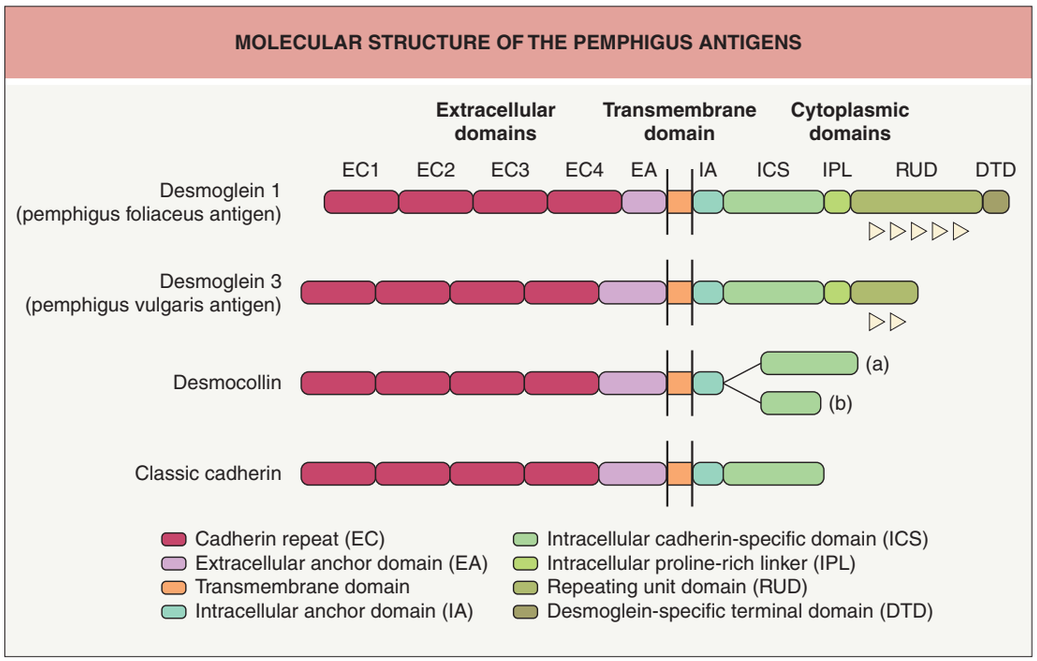

Fig. 29.2 Molecular structure of the pemphigus antigens. The extracellular (EC) region has four cadherin repeats, which have calcium-binding motifs. The intracellular cadherin-specific (ICS) domain is well conserved among cadherins and it is responsible for interactions with β-catenin or plakoglobin (see Fig. 29.3). Desmogleins have their own unique sequences (repeating unit domain [RUD]) of repeats of 29 ± 1 residues (arrowheads). Each desmocollin isotype has two products (a and b) derived from alternatively spliced transcripts of a single gene.

TARGET ANTIGENS IN PEMPHIGUS

Disease	Autoantibodies	Antigens	MW (kDa)
Pemphigus vulgaris			
Mucosal-dominant type	IgG	Desmoglein 3	130
Mucocutaneous type	IgG	Desmoglein 3	130
		Desmoglein 1	160
Pemphigus foliaceus	IgG	Desmoglein 1	160
Paraneoplastic pemphigus	IgG	Desmoglein 3	130
		Desmoglein 1	160
		Plectin*	500
		Epiplakin*	500
		Desmoplakin I*	250
		Desmoplakin II*	210
		BPAG1*	230
		Envoplakin*	210
		Periplakin*	190
		A2ML1	170
		Transglutaminase 1	90
Drug-induced pemphigus	IgG	Desmoglein 3	130
		Desmoglein 1	160
IgA pemphigus			
Subcorneal pustular dermatosis type	IgA	Desmocollin 1	110/100
Intraepidermal neutrophilic type	IgA	?	?
Pemphigus foliaceus type	IgA	Desmoglein 1	160
Pemphigus vulgaris type	IgA	Desmoglein 3	130
Pemphigus vegetans type	IgA	Desmoglein 3	130

*Members of plakin family.

Table 29.2 Target antigens in pemphigus. A minority of patients with classic pemphigus vulgaris and pemphigus foliaceus also have IgA autoantibodies and are classified as pemphigus vulgaris and pemphigus foliaceus. A2ML1, alpha-2-macroglobulin-like-1 protease inhibitor; BPAG1, bullous pemphigoid antigen 1.

interaction. Cadherins require their well-conserved cytoplasmic domains in order to associate with the plaque proteins, α-catenin, β-catenin and plakoglobin, which mediate and regulate binding to the cytoskeleton network (Fig. 29.3). As a consequence of these interactions, cadherins produce strong cellular adhesion and morphologic changes in the cells. Cadherin molecules form dimers as their functional unit, with the distal extracellular domain (EC1) of the cadherin from one cell binding to the same region of a second cadherin from an opposing cell[18].

Two major types of adhering junctions of epithelial cells are commonly distinguished: adherens junctions and desmosomes (see Fig. 29.3). The *adherens junction* anchors bundles of actin microfilaments and contains classic cadherins as its transmembrane components and α-catenin, β-catenin, and plakoglobin as its cytoplasmic components. In contrast, the *desmosome* anchors intermediate filaments like keratins and contains desmosomal cadherins as its transmembrane components and plakoglobin, plakophilin, and desmoplakin

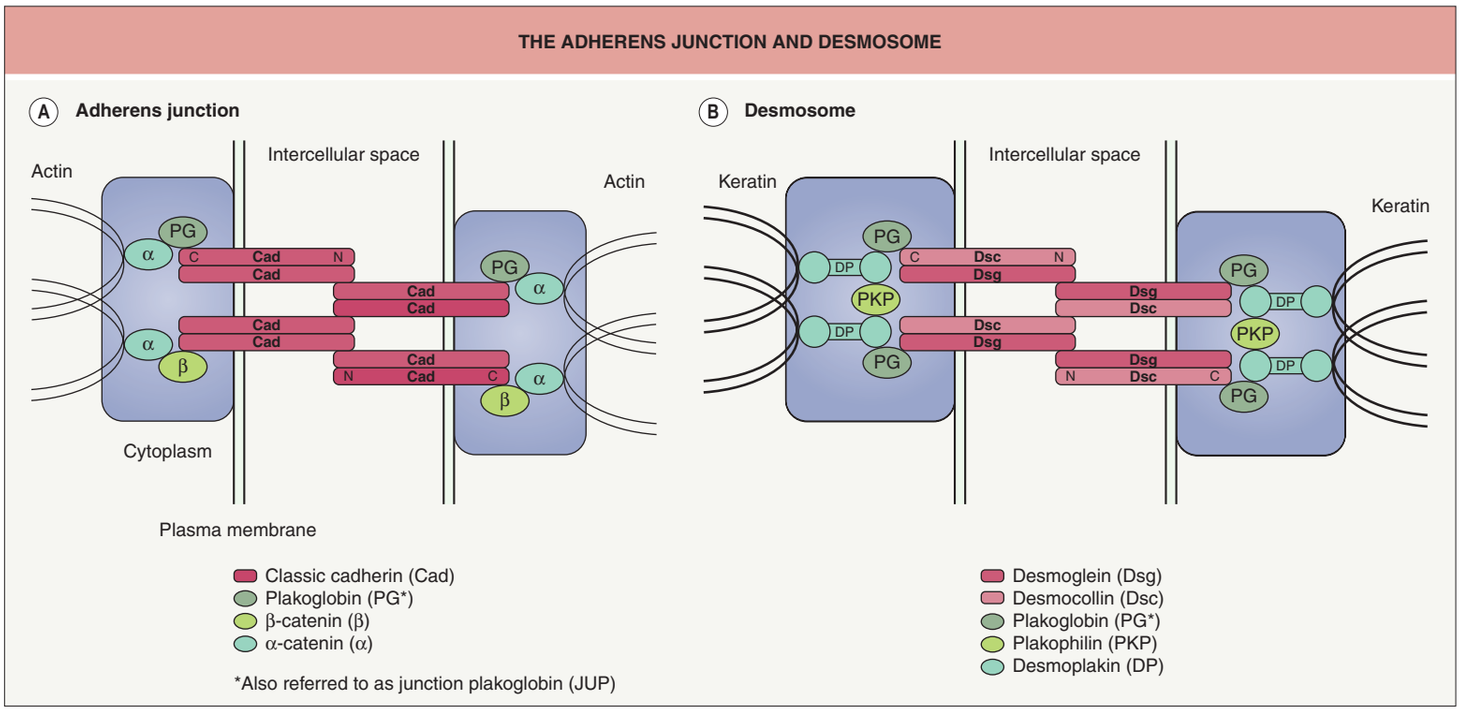

Fig. 29.3 The adherens junction and desmosome. A The adherens junction complex contains classic cadherins as transmembrane constituents and α-catenins, β-catenins, and plakoglobin as cytoplasmic constituents. A classic cadherin is directly coupled through its cytoplasmic tail to β-catenin or plakoglobin, which in turn is linked to α-catenin, which binds to actin. **B** The desmosome complex includes desmogleins and desmocollins as transmembrane constituents, and plakoglobin, plakophilin, and desmoplakin as cytoplasmic constituents. Desmogleins and desmocollins form heterodimers as a functional adhesive unit and associate with plakoglobin, which in turn binds to desmoplakin which links keratin to the membrane. C, carboxy terminus; N, amino terminus.

as its cytoplasmic components. In general, adherens junctions mediate quick but weak cellular adhesion, whereas desmosomes mediate slow but strong cellular adhesion.

Desmogleins have four cadherin repeats in their extracellular domain, as do classic cadherins (see Fig. 29.2). Desmogleins have four isoforms (Dsg1–4). Expression of Dsg1 and Dsg3 is basically restricted to stratified squamous epithelia, where blisters are formed in pemphigus, while Dsg2 is expressed in all desmosome-possessing tissues, including simple epithelia and myocardium. Dsg4 plays an important adhesive role primarily in hair follicles, and mutations in *DSG4* can lead to abnormal hair development (e.g. localized autosomal recessive hypotrichosis)[19].

Desmocollins are another group of transmembrane glycoproteins within desmosomes and they have three isoforms (Dsc1–3). Each isoform has two products derived from alternatively spliced mRNA of a single gene. Desmosomes always have desmoglein and desmocollin as a pair, with Dsg:Dsc heterodimers representing the fundamental adhesive unit of desmosomes and thus providing a structural framework for understanding desmosome assembly[20].

Plakoglobin and plakophilin, together with β-catenin, are members of the armadillo family of nuclear and junctional proteins, which are not only simple anchoring molecules but also dynamic regulators of cellular adhesion and proliferation. Desmoplakin is a dumbbell-shaped molecule composed of three domains: a central α-helical coiled-coil rod, flanked by globular carboxy- and amino-terminal domains that interact with intermediate filaments and armadillo family members, respectively (see Fig. 29.3). Desmoplakin has two products derived from alternatively spliced mRNA of a single gene: desmoplakin I (250 kDa) and II (210 kDa) (see Table 29.2). Desmoplakin, a member of the plakin family, plays an important role in the anchorage of the cytoskeleton to filament attachment sites on desmosomes.

Compelling evidence has accumulated that IgG autoantibodies against Dsg1 and Dsg3 are pathogenic and play a primary role in inducing the blister formation in pemphigus. Essentially, all patients with pemphigus have IgG autoantibodies against Dsg1 and/or Dsg3, depending on the subtype of pemphigus[21,22]. When anti-desmoglein IgG autoantibodies are removed from the sera of patients with pemphigus vulgaris, pemphigus foliaceus or paraneoplastic pemphigus (by immunoadsorption with recombinant desmoglein proteins), the sera are no longer pathogenic in inducing blister formation[23,24]. Furthermore, anti-desmoglein IgG autoantibodies that have been affinity-purified from pemphigus sera via desmoglein recombinant proteins can cause blisters when injected into neonatal mice[24,25]. Some pemphigus sera react with Dsg4 due to cross-reactivity of a subset of anti-Dsg1 IgG, although Dsg4/Dsg1-cross-reacting IgG has no demonstrable pathogenic effect[26]. IgG autoantibodies against non-desmoglein molecules, such as acetylcholine receptors or annexin-like molecules, have also been detected, but their pathogenic relevance in pemphigus remains to be determined.

Desmoglein Compensation Theory as Explanation for Localization of Blisters

The sites of blisters in pemphigus vulgaris and foliaceus are explained logically by the desmoglein compensation theory: Dsg1 and Dsg3 compensate for each other when they are coexpressed in the same cell (Fig. 29.4)[27,28]. While patients with pemphigus foliaceus have only anti-Dsg1 IgG autoantibodies, individuals with the mucosal-dominant type of pemphigus vulgaris have only anti-Dsg3 IgG autoantibodies. Those with the mucocutaneous type of pemphigus vulgaris have both anti-Dsg3 and anti-Dsg1 IgG autoantibodies. Of note, the intraepithelial expression pattern of Dsg1 and Dsg3 differs between the skin and mucous membranes. In the skin, Dsg1 is expressed throughout the epidermis, but more intensely in the superficial layers (see Fig. 29.1C), whereas Dsg3 is expressed in the lower portion of the epidermis, primarily in the basal and parabasal layers (see Fig. 29.1A). In contrast to the skin, Dsg1 and Dsg3 are expressed throughout the squamous layer of mucosa, but Dsg1 is expressed at a much lower level than Dsg3 (see Fig. 29.4B).

When sera contain only anti-Dsg1 IgG (which interferes with the function of Dsg1), blisters appear only in the superficial epidermis of the skin because that is the only area in which Dsg1 is present without coexpression of Dsg3. The splits occur between the second (SG2) and the third (SG3) layers of the stratum granulosum (SG) because IgG does not go beyond the tight junctions present between SG2 cells[29]. In the unaffected deep epidermis, the presence of Dsg3 compensates for the loss of function of Dsg1. Although the anti-Dsg1 IgG binds to mucosa, no blisters are formed, because of the coexpression of Dsg3.

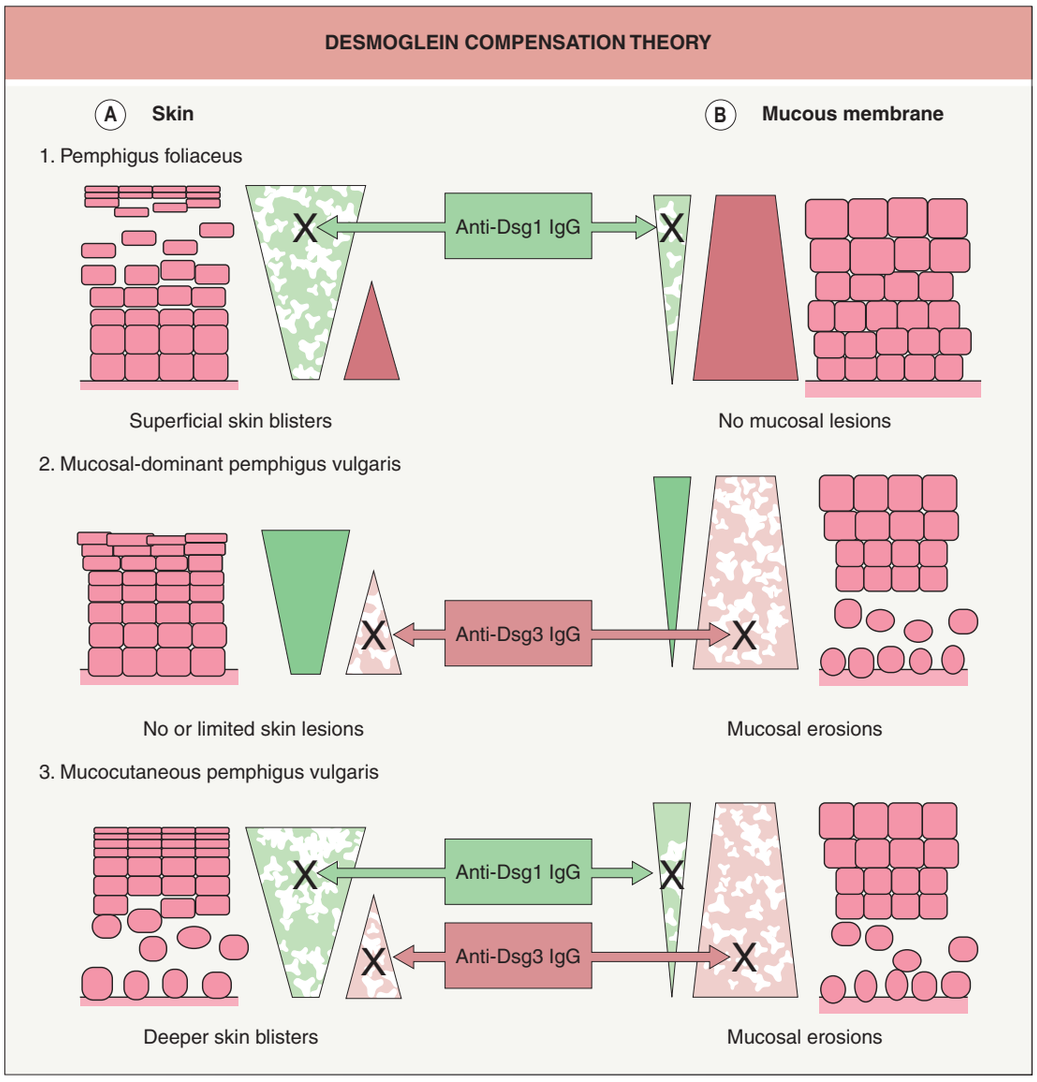

Fig. 29.4 Logical explanation for the localization of blister formation in classic pemphigus by desmoglein compensation theory. The colored triangles represent the distribution of desmoglein 1 (Dsg1, green) and desmoglein 3 (Dsg3, pink) in the skin (**A**) and mucous membranes (**B**). Pemphigus foliaceus sera contain only anti-Dsg1 IgG, which causes superficial blisters in the skin because Dsg3 functionally compensates for the impaired Dsg1 in the lower part of the epidermis (A1), whereas those antibodies do not cause blisters in the mucous membranes because cell–cell adhesion is mainly mediated by Dsg3 (B1). Sera containing only anti-Dsg3 IgG cause no or only limited blisters in the skin because Dsg1 compensates for the loss of Dsg3-mediated adhesion (A2); however, these sera induce separation in the mucous membranes, where the low expression of Dsg1 will not compensate for the loss of Dsg3-mediated adhesion (B2). When sera contain both anti-Dsg1 and anti-Dsg3 IgG, the function of both Dsgs is compromised and blisters occur in both the skin and mucous membranes (A3, B3). In neonatal skin, the situation is similar to that shown here for mucous membranes.

Thus, sera containing only anti-Dsg1 IgG cause superficial blisters in the skin without mucosal involvement, as is seen in patients with pemphigus foliaceus (see Fig. 29.4).

When sera contain only anti-Dsg3 IgG, they are inefficient in producing cutaneous blisters because coexpressed Dsg1 compensates for the impaired function of Dsg3, resulting in no, or only limited, skin lesions. However, in the mucous membranes, Dsg1 cannot compensate for the impaired Dsg3 function because of its low expression. Therefore, sera containing only anti-Dsg3 IgG cause oral erosions without apparent skin involvement, as is seen in patients with the mucosal-dominant type of pemphigus vulgaris (see Fig. 29.4).

When sera contain both anti-Dsg1 and anti-Dsg3 IgG, they interfere with the function of both Dsg1 and Dsg3, resulting in extensive blisters and erosions of the skin as well as the mucous membranes, as is seen in patients with the mucocutaneous type of pemphigus vulgaris. Possible explanations for why splits appear just above the basal layer, rather than the whole epithelium falling apart, include: (1) cell–cell adhesion in the basal and parabasal layers may be weaker than in other parts of the epithelium; and (2) autoantibodies, which penetrate from the dermis, might have better access to the lower part of the epithelia.

In pregnant women with pemphigus, autoantibodies cross the placenta and bind to the fetal epidermis. However, neonates develop blisters if the mother has pemphigus vulgaris, but very rarely if she has pemphigus foliaceus. This confusing observation is also explained by the desmoglein compensation theory[30]. The distribution of Dsg3 within neonatal epidermis is unlike that in adult epidermis; it is found on the surface of keratinocytes throughout the epidermis, which is similar to its distribution in mucous membranes (remember, neonatal skin is bathed in amniotic fluid). Therefore, pemphigus foliaceus sera containing only anti-Dsg1 IgG cannot efficiently induce blisters in neonatal skin.

As an extension of this compensation theory, exfoliative toxins, which are produced by *Staphylococcus aureus* and lead to bullous impetigo as well as staphylococcal scalded skin syndrome, specifically cleave Dsg1[31]. Inactivation of Dsg1 by this toxin induces superficial blisters in the epidermis that are clinically and histologically similar to those seen in pemphigus foliaceus.

In pemphigus, the disruption of cell–cell adhesion is currently thought to be mediated via the combined effects of direct inhibition by antibodies plus subsequent signal transduction induced by antibody binding[32]. The direct inhibition is mediated by steric hindrance, i.e. the binding of autoantibodies to desmogleins spatially interferes with the adhesive interaction of desmogleins between cells. This proposed pathogenesis is supported by the following observations: (1) in pemphigus vulgaris and foliaceus, dominant epitopes are localized to the functionally important N-terminal regions of desmogleins[25,33]; and (2) pathogenic anti-Dsg3 mouse or human monoclonal antibody, but *not* non-pathogenic monoclonal antibodies, recognizes the N-terminal adhesive surface of Dsg3 (see Fig. 29.3B)[33,34]. The phenotype of the *Dsg3* null mouse (whose *Dsg3* gene is genetically deleted) closely resembles that of human pemphigus vulgaris patients[35]. The role of signal transduction induced by antibody binding is supported by the *in vitro* observation that IgG from pemphigus vulgaris sera (when added to the media of cultured keratinocytes) causes a transient increase in intracellular calcium and/or inositol 1,4,5-triphosphate, activation of protein kinase C, or phosphorylation of Dsg3. Furthermore, with desmosomal disassembly, Dsg3 is internalized or endocytosed from the cell surface in association with keratin retraction[36].

Humoral and Cellular Autoimmunity in Paraneoplastic Pemphigus

Patients with paraneoplastic pemphigus develop characteristic IgG autoantibodies against multiple antigens[3], including Dsg3 and/or Dsg1[24], multiple members of the plakin family (plectin, epiplakin, desmoplakins I and II, bullous pemphigoid antigen 1, envoplakin, and periplakin), the protease inhibitor alpha-2-macroglobulin-like-1[37,38], and transglutaminase 1[38a] (see Table 29.2). Anti-desmoglein antibodies play a role in inducing the loss of cell adhesion of keratinocytes and initiate blister formation, while the pathophysiologic relevance of the anti-plakin autoantibodies is unclear, in that plakin molecules are intracellular and IgG cannot penetrate cell membranes. In addition to humoral autoimmunity, cell-mediated cytotoxicity is involved in the pathogenesis of paraneoplastic pemphigus, in which more severe and refractory oral erosions and stomatitis as well as more polymorphic skin eruptions are seen, in comparison with classic forms of pemphigus. It was demonstrated in mice that Dsg3-specific T cells not only help B cells produce anti-Dsg3 IgG (which causes acantholysis), but also directly infiltrate into the epidermis and induce an interface dermatitis[39]. Clarification of the exact roles of autoimmune T cells should provide valuable insights into the pathophysiology of paraneoplastic pemphigus.

Immunologic Mechanism of Pathogenic Autoantibody Production in Pemphigus

In contrast to the significant progress since the late 1980s in understanding the pathophysiologic mechanisms of blister formation in pemphigus, it is still unclear why patients with pemphigus begin to produce the pathogenic autoantibodies.

Pemphigus autoantibodies are composed of IgG isotypes, which may be produced after isotype switching, and they have a high affinity towards the antigen, which may be a result of affinity maturation of the antibodies. In addition, pemphigus sera recognize several distinct epitopes on desmogleins[40], and the presence of autoantibodies is associated with specific HLA class II alleles, including DRB1*0402, DRB1*1401, and DQB1*0302 in White individuals[41] and DRB1*14 and DQB1*0503 in Japanese. All of these features suggest that autoantibody production in pemphigus is T cell-dependent. More recently, T cells reactive against Dsg3 were shown to be present in peripheral blood from patients with pemphigus vulgaris as well as healthy individuals[42–44]. Certain peptides from Dsg3, predicted to fit into the DRB1*0402 pocket, were able to stimulate T cells from the pemphigus patients.

Another advance that will allow the study of T cells and B cells is the development of an active disease mouse model for pemphigus vulgaris[45]. This model is valuable not only for dissecting the cellular and molecular mechanisms involved in antibody production but also for developing novel therapeutic strategies.

CLINICAL FEATURES

Pemphigus Vulgaris

Essentially all patients with pemphigus vulgaris develop painful erosions of the oral mucosa. More than half of the patients also develop flaccid blisters and widespread cutaneous erosions. Pemphigus vulgaris is therefore divided into two subgroups: (1) the *mucosal-dominant* type with mucosal erosions but minimal skin involvement; and (2) the *mucocutaneous* type with extensive skin blisters and erosions in addition to mucosal involvement (see Fig. 29.4).

Mucous membrane lesions usually present as painful erosions (Fig. 29.5). Intact blisters are rare, probably because they are fragile and break easily. Although scattered or extensive erosions may be seen anywhere in the oral cavity, the most common sites are the buccal and palatine mucosae. The erosions are of different sizes with an irregular and ill-defined border, which, when extensive or painful, may result in decreased oral intake of food or liquids. The diagnosis of pemphigus vulgaris tends to be delayed in patients presenting with only oral involvement, as compared to patients with skin lesions.

The lesions may extend out onto the vermilion lip and lead to thick, fissured hemorrhagic crusts. Involvement of the throat produces hoarseness and difficulty in swallowing. The esophagus also may be involved and sloughing of its entire lining in the form of a cast has been reported. The conjunctivae, nasal mucosa, vagina, labia, penis and anus

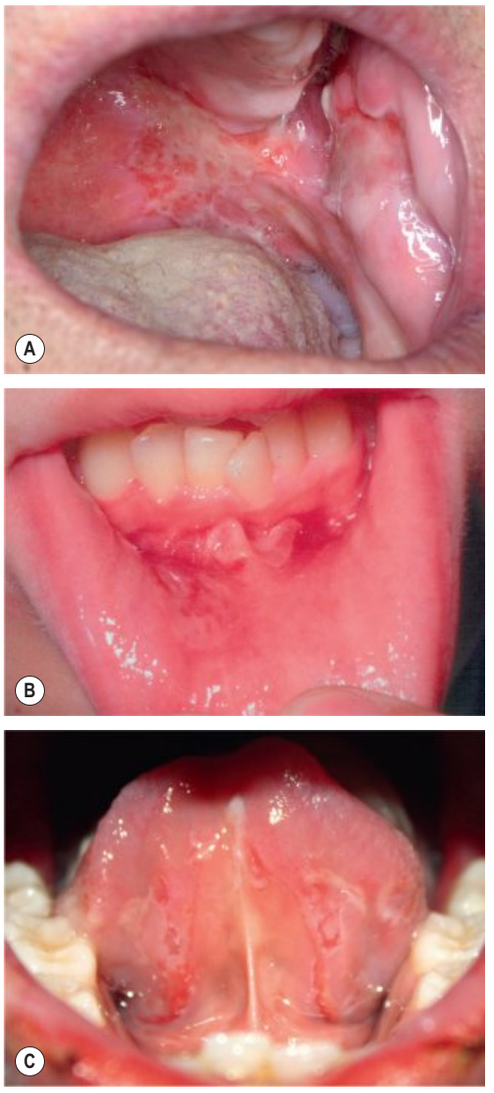

Fig. 29.5 Pemphigus vulgaris – oral involvement. Essentially all patients develop painful oral mucosal erosions. The most common sites are the buccal (**A**) and palatine mucosae, but lesions can also develop on the gingivae (**B**) and tongue (**C**). *A, Courtesy Lorenzo Cerroni, MD; B,C, Courtesy Jeffrey P. Callen, MD.*

can develop lesions as well. Cytology of vaginal cells may be misread as a malignancy when vaginal lesions are present.

The primary skin lesions of pemphigus vulgaris are flaccid, thin-walled, easily ruptured blisters (Fig. 29.6). They can appear anywhere on the skin surface and arise on either normal-appearing skin or erythematous bases. The fluid within the bullae is initially clear but may become hemorrhagic, turbid, or even seropurulent. The blisters are fragile and soon rupture to form painful erosions that ooze and bleed easily. These erosions often attain a large size and can become generalized. The erosions soon become partially covered with crusts that have little or no tendency to heal. Those lesions that do heal often leave hyperpigmented patches with no scarring. Associated pruritus is uncommon. Table 29.3 outlines more unusual clinical presentations of pemphigus vulgaris.

Because of an absence of cohesion within the epidermis, its upper layers easily move laterally with slight pressure or rubbing in patients with active disease (Nikolsky sign). The lack of cohesion of the skin may also be demonstrated with the "bulla-spread phenomenon" – gentle pressure on an intact bulla forces the fluid to spread under the skin away from the site of pressure (Asboe–Hansen sign, also referred to as the "indirect Nikolsky" or "Nikolsky II" sign). Without appropriate treatment, pemphigus vulgaris can be fatal because a large portion of the skin loses its epidermal barrier function, leading to the loss of body fluids or to secondary bacterial infections.

Pemphigus Vegetans

Pemphigus vegetans is a rare vegetative variant of pemphigus vulgaris, and it is thought to represent a reactive pattern of the skin to the autoimmune insult of pemphigus vulgaris.

Fig. 29.6 Pemphigus vulgaris – cutaneous involvement. A Flaccid blisters and an erosion due to rupture of a bulla. **B**, **C** Multiple erosions and hemorrhagic crusts of the back that can become extensive. Secondary bacterial infections are a potential complication. **D** A vegetative response can occasionally be seen in chronic recalcitrant lesions; the patient has a Cushingoid appearance due to use of chronic systemic corticosteroids. **E** The dyshidrosiform variant is uncommon. *A, D, Courtesy Luis Requena, MD; B, C, Courtesy Lorenzo Cerroni, MD; E, Courtesy Louis A. Fragola, Jr, MD.*

UNUSUAL CLINICAL PRESENTATIONS OF PEMPHIGUS VULGARIS
• Isolated crusted plaque on face or scalp
• Paronychia and/or onychomadesis
• Foot ulcers
• Dyshidrotic eczema or pompholyx
• Macroglossia
• Gingival hyperplasia

Table 29.3 Unusual clinical presentations of pemphigus vulgaris.

Pemphigus vegetans is characterized by flaccid blisters that become erosions and then form fungoid vegetations or papillomatous proliferations, especially in intertriginous areas and on the scalp or face (Fig. 29.7). Pustules rather than vesicles characterize early lesions, but these soon progress to vegetative plaques. The tongue may show cerebriform-like changes. Two subtypes are recognized: the severe Neumann type and the mild Hallopeau type. Occasionally, a vegetative response may also be seen in lesions of pemphigus vulgaris that tend to be resistant to therapy and remain for long periods of time in one location (see Fig. 29.6D).

Pemphigus Foliaceus

Patients with pemphigus foliaceus develop scaly, crusted cutaneous erosions, often on an erythematous base, but they do not have clinically apparent mucosal involvement even with widespread disease.

Fig. 29.7 Pemphigus vegetans. Large, thick, vegetating, papillomatous plaques arising in conjunction with erosions. Healed lesions have residual postinflammatory hyperpigmentation.

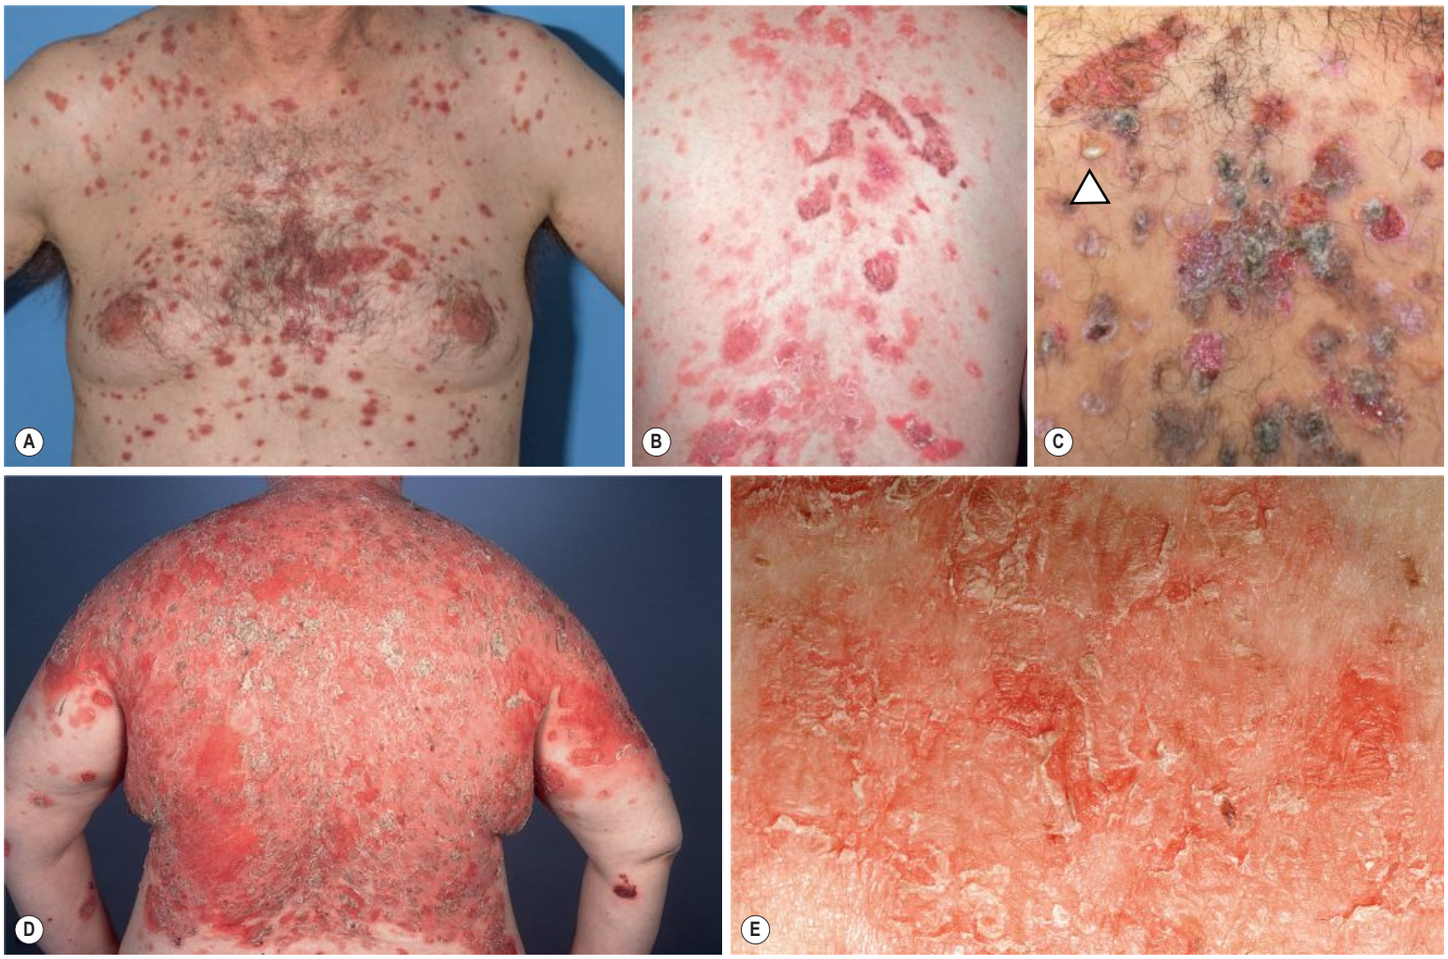

Fig. 29.8 Pemphigus foliaceus. A, B Multiple superficial erosions arising on an erythematous base on the trunk, a common site of involvement. Larger erosions as well as the characteristic scale-crusts are seen in **B**. **C** Thicker scale-crusts in addition to large erosions and one flaccid vesicle with seropurulent fluid where pus has settled in the lower half due to gravity similar to hypopyon ("half-half" blisters) (arrowhead). **D** As the disease progresses, the lesions become confluent, but because the vesicles are fragile and rupture easily, only erosions with scale-crust are observed. **E** The scales have been likened to cornflakes. *A, Courtesy Edward Cowen, MD; C, Courtesy Kalman Watsky, MD.*

The onset of disease is often subtle, with a few scattered crusted lesions that are transient and are frequently mistaken for impetigo. They are usually well demarcated and have a seborrheic distribution, i.e. they favor the face, scalp, and upper trunk (Fig. 29.8A–C). Because the vesicle is so superficial and fragile, often only the resultant crust and scale are seen (Fig. 29.8D, E). The disease may stay localized for years or it may rapidly progress, in some cases to generalized involvement and an exfoliative erythroderma (see Ch. 10). The Nikolsky sign is present. In contrast to the extensive oral lesions in pemphigus vulgaris, it is extremely rare, if ever, for patients with pemphigus foliaceus to develop mucosal involvement. Generally, patients with pemphigus foliaceus are not severely ill. However, they can experience burning and pain in association with the skin lesions.

Pemphigus Erythematosus (Senear–Usher Syndrome)

Pemphigus erythematosus is simply a localized variant of pemphigus foliaceus. Typical scaly and crusted lesions of pemphigus foliaceus appear in the malar region of the face (Fig. 29.9) and in other "seborrheic" areas. Originally, the term "pemphigus erythematosus" was introduced to describe patients with immunologic features of both lupus erythematosus (LE) and pemphigus, i.e. *in vivo* IgG and C3 deposition on cell surfaces of keratinocytes as well as the basement membrane zone, in addition to circulating anti-nuclear antibodies[46]. However, only a few patients have been reported to actually have the two diseases concurrently.

Herpetiform Pemphigus

Most patients with herpetiform pemphigus have a clinical variant of pemphigus foliaceus and the remainder may have a variant of pemphigus vulgaris. This disorder is characterized by: (1) erythematous urticarial plaques and tense vesicles that present in a herpetiform arrangement; (2) eosinophilic spongiosis and subcorneal pustules with minimal or no apparent acantholysis histologically; and (3) IgG autoantibodies directed against the cell surfaces of keratinocytes[47]. The target antigen is Dsg1 in most cases and Dsg3 in the remainder[48]. Some patients with herpetiform pemphigus will have features of pemphigus foliaceus or vulgaris during the course of their disease, and some patients will evolve into having pemphigus foliaceus or vulgaris. It is assumed that the pathogenic blister-inducing activity of the IgG autoantibodies

Fig. 29.9 Pemphigus erythematosus. Erythematous plaques with scale-crust and erosions on the nose and malar area of the face. *Courtesy Ronald P. Rapini, MD.*

in herpetiform pemphigus might be weaker than that seen in classic forms of pemphigus. Although often clinically less severe than pemphigus vulgaris, the course may be more chronic.

Drug-Induced Pemphigus

There are sporadic cases of pemphigus associated with the use of drugs, in particular penicillamine and captopril (see Table 29.1)[49]. In patients receiving penicillamine, pemphigus foliaceus is seen more commonly than pemphigus vulgaris, with a ratio of approximately 4:1. Although most patients with drug-induced pemphigus are shown to have autoantibodies against the same molecules involved in sporadic pemphigus, evidence suggests that some drugs may induce acantholysis without the production of antibodies. Both penicillamine and captopril contain sulfhydryl groups that are speculated to interact with the sulfhydryl groups in Dsg1 and Dsg3. This interaction may modify the antigenicity of the desmogleins, which may lead to autoantibody production, or their interaction may directly interfere with the adhesive function of the desmogleins. Imiquimod-induced pemphigus has also been reported as has a flare or recurrence of pemphigus due to immune checkpoint inhibitors. Most, but not all, patients with drug-induced pemphigus go into remission after the offending drug is discontinued.

Paraneoplastic Pemphigus

Paraneoplastic pemphigus is associated with underlying neoplasms, both malignant and benign. The most commonly associated neoplasms are non-Hodgkin lymphoma and chronic lymphocytic leukemia, followed by Castleman disease, malignant and benign thymomas, sarcomas, and Waldenström macroglobulinemia[3]. Non-Hodgkin lymphoma and chronic lymphocytic leukemia together account for two-thirds of patients. Castleman disease, a very rare lymphoproliferative disorder, is the third most commonly associated neoplasm in adults and the most commonly associated tumor in children and adolescents; its association with paraneoplastic pemphigus is strikingly disproportionate to its general occurrence. The absence of common tumors, such as adenocarcinomas of the breast or colon and squamous cell carcinomas, is notable.

The most constant clinical feature of paraneoplastic pemphigus is the presence of intractable stomatitis. Severe stomatitis is usually the earliest presenting sign and, after treatment, it is the one that persists and is extremely resistant to therapy. This stomatitis consists of erosions and ulcerations that affect all surfaces of the oropharynx and characteristically extend onto the vermilion lip (Fig. 29.10). Most patients also have a severe pseudomembranous conjunctivitis, which may progress to scarring and obliteration of the conjunctival fornices. Nasopharyngeal, esophageal, vaginal, labial, penile, and perianal lesions may also be seen.

Cutaneous findings are quite polymorphic and may present as erythematous macules, flaccid blisters and erosions resembling pemphigus vulgaris, tense blisters resembling bullous pemphigoid, erythema multiforme-like lesions, and lichenoid eruptions. The occurrence of blisters and erythema multiforme-like lesions on the palms and soles is often used to differentiate paraneoplastic pemphigus from pemphigus vulgaris, in which lesions on the palms and soles are unusual. In the chronic form of the disease, a lichenoid eruption may predominate over blistering lesions. Some patients with paraneoplastic pemphigus develop bronchiolitis obliterans, which can be fatal as a result of respiratory failure[50]. Although its pathophysiologic mechanism is still unclear, ectopic expression of epidermal antigens in the setting of squamous metaplasia is thought to render the lung a target organ[51]. Of note, a chest X-ray or CT scan obtained at the onset of bronchiolitis obliterans may be normal but pulmonary function tests will show small airway obstruction that does not reverse with bronchodilators.

Fig. 29.10 Paraneoplastic pemphigus. A The characteristic clinical feature is severe intractable stomatitis with multiple erosions; there may be a resemblance to erosive oral lichen planus. **B** The erosions, along with hemorrhagic crusts, can extend onto the vermilion lip and involve the nasal mucosa. **C** Papulosquamous lichenoid lesions, reflecting an interface dermatitis, can also be present. *A, Courtesy Luis Requena, MD; C, Courtesy Jennie Clarke, MD.*

IgA Pemphigus

IgA pemphigus represents a more recently characterized group of autoimmune intraepidermal blistering diseases presenting with a vesiculopustular eruption, neutrophilic infiltration of the skin, and *in vivo* bound and circulating IgA autoantibodies against the cell surface of keratinocytes; no IgG autoantibodies are present. IgA pemphigus usually occurs in middle-aged or elderly persons. Two distinct types of IgA pemphigus have been described: the *subcorneal pustular dermatosis type* and the *intraepidermal neutrophilic type*. Patients with both types of IgA pemphigus present with flaccid vesicles or pustules on either erythematous or normal skin (Fig. 29.11A). In both types, the pustules tend to coalesce to form an annular or circinate pattern with crusts in the center of the lesion (Fig. 29.11B), although a sunflower-like configuration of pustules is a characteristic sign of the intraepidermal neutrophilic type.

The most common sites of involvement are the axilla and groin, but lesions can also develop on the trunk and proximal extremities. Mucous membrane involvement is rare, and pruritus is often a significant symptom. In some patients, there is an underlying associated disorder such as IgA myeloma or ulcerative colitis. Because the subcorneal pustular dermatosis type of IgA pemphigus is clinically and

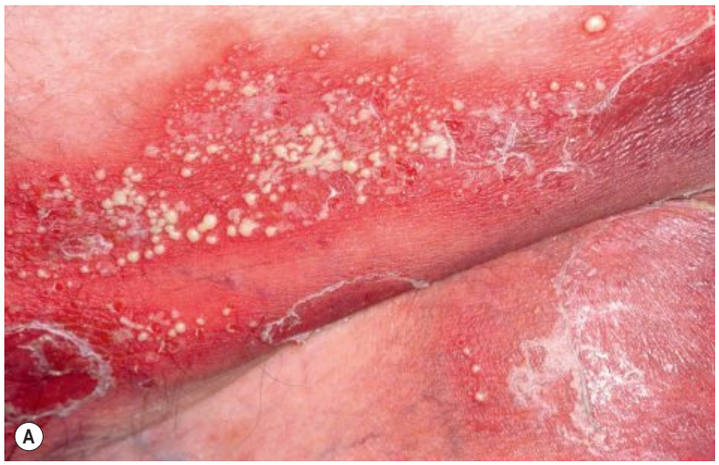

Fig. 29.11 IgA pemphigus – subcorneal pustular dermatosis (SPD) type. A Numerous superficial pustules arising within areas of erythema; these pustules rupture easily. The desquamation has a figurate configuration and overall there is a resemblance to pustular psoriasis. **B** Pustules tend to coalesce to form an annular or figurate pattern with crusts present centrally. Note the accumulation of the pustular component in the dependent portion of the vesiculopustule. *A, Courtesy Luis Requena, MD.*

histologically indistinguishable from classic subcorneal pustular dermatosis (Sneddon–Wilkinson disease; see Ch. 8), immunologic evaluation is essential to differentiate the two diseases.

IgA deposition on cell surfaces of epidermal keratinocytes is present in all cases, as shown by direct immunofluorescence (DIF) microscopy, and many patients have detectable circulating IgA autoantibodies, as shown by indirect immunofluorescence (IIF) microscopy. In the subcorneal pustular dermatosis type, IgA autoantibodies tend to react against upper epidermal surfaces, while in the intraepidermal neutrophilic type, IgA autoantibodies are found throughout the entire epidermis. The subclass of IgA autoantibodies is exclusively IgA1. IgA autoantibodies in the subcorneal pustular dermatosis type were shown to recognize desmocollin 1[52], while the autoimmune targets of the intraepidermal neutrophilic type remain to be identified. A subset of IgA pemphigus patients have IgA autoantibodies directed against Dsg1 or Dsg3, making the autoimmune targets of IgA pemphigus more heterogeneous. Besides the two major forms of IgA pemphigus, some authors include three additional forms of IgA pemphigus – IgA pemphigus foliaceus, IgA pemphigus vulgaris, and IgA pemphigus vegetans. The exact pathogenic role of IgA autoantibodies in inducing pustular formation in IgA pemphigus remains to be elucidated.

PATHOLOGY

For routine histology, it is best to perform biopsies of early lesions. If the vesicle or edematous papule is small enough, the entire lesion can be removed. Otherwise, the biopsy specimen should include the edge of a fresh vesicle or bulla plus the inflammatory rim (Fig. 29.12). Examination of perilesional, rather than lesional, skin is recommended for DIF in order to avoid negative staining due to secondary degeneration of target antigens and immunoreactants. In patients with only mucosal lesions, the biopsy specimen should consist of the active border of a denuded area, since intact blisters are rarely encountered. Cytologic examination (Tzanck smear) is useful for the rapid demonstration of acantholytic epidermal cells within the blister cavity. However, this bedside test merely represents a preliminary diagnostic tool and it should not supplant histologic examination. This is because acantholytic keratinocytes are occasionally seen in various non-acantholytic vesiculobullous or pustular diseases as a result of secondary acantholysis.

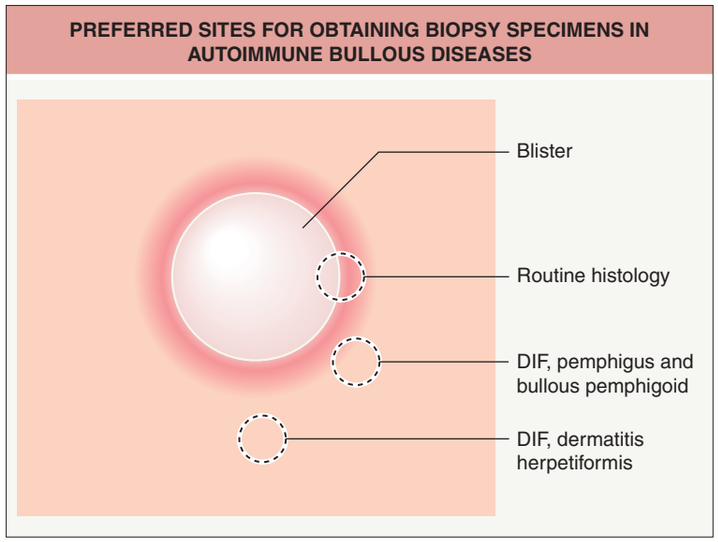

Fig. 29.12 Preferred sites for obtaining biopsy specimens in autoimmune bullous diseases. If the lesion is small enough, the entire vesicle can be removed for routine histology. If the lesions are not small, the edge of a fresh vesicle or bulla plus the inflammatory rim is recommended. For direct immunofluorescence (DIF) for various forms of pemphigus and bullous pemphigoid, perilesional skin is preferred, whereas nearby normal skin is recommended in dermatitis herpetiformis.

Pemphigus Vulgaris

The characteristic histologic finding in this form of pemphigus is intraepidermal blister formation due to a loss of cell–cell adhesion of keratinocytes (acantholysis) without keratinocyte necrosis (Fig. 29.13A). Whereas acantholysis usually occurs just above the basal cell layer (suprabasilar acantholysis), intraepithelial separation may occasionally be higher in the stratum spinosum. A few rounded-up (acantholytic) keratinocytes as well as clusters of epidermal cells are often seen within the blister cavity. Although the basal cells lose lateral desmosomal contact with their neighbors, they maintain their attachment to the basement membrane via *hemidesmosomes*, thus giving the appearance of a "row of tombstones" (Fig. 29.13B). The acantholytic process may involve hair follicles.

The dermal papillary outline is usually maintained and, frequently, the papillae protrude into the blister cavity. The blister cavity may contain a few inflammatory cells, notably eosinophils, and in the dermis there is a moderate perivascular mononuclear cell infiltrate with conspicuous eosinophils. In rare instances, the earliest histologic finding consists of eosinophilic spongiosis (Table 29.4), in which eosinophils infiltrate a spongiotic epidermis with little or no evidence of acantholysis.

In pemphigus vegetans, suprabasilar acantholysis is seen, in addition to considerable papillomatosis and acanthosis. Characteristically, there is an intense inflammatory cell infiltrate containing numerous eosinophils, and intraepidermal microabscesses of eosinophils are often seen.

Pemphigus Foliaceus

The histologic changes of pemphigus foliaceus, pemphigus erythematosus, and fogo selvagem are identical. Early blisters in pemphigus foliaceus have acantholysis in the upper epidermis, within or adjacent to the granular layer (Fig. 29.14). Because the blisters are superficial and fragile, it is often difficult to obtain an intact lesion for histologic examination. As a result, acantholysis is sometimes difficult to detect, but usually a few acantholytic keratinocytes can be found attached to the roof or floor of the blister. Of note, these cells are often almond- or spindle-shaped rather than round. When the blisters form within the granular layer, a "missing" horny layer with a few acantholytic keratinocytes

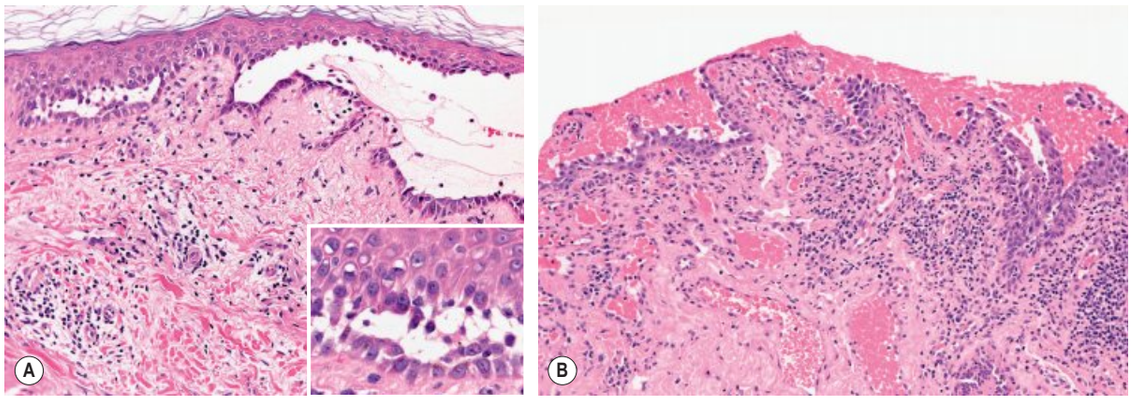

Fig. 29.13 Pemphigus vulgaris – histopathologic features. **A** Blisters in the skin show suprabasilar acantholysis with a few acantholytic cells in the blister cavity (inset). **B** Because blisters in the mouth rarely remain intact, the blister roof is often not seen in oral biopsy specimens. Nonetheless, the diagnosis can be made by the location of the split within the epithelium, the presence of acantholytic cells, and the "tombstones" appearance of the basal cells. *Courtesy Lorenzo Cerroni, MD.*

CAUSES OF EOSINOPHILIC SPONGIOSIS	
• Pemphigus vulgaris and its variants • Pemphigus foliaceus • Bullous pemphigoid and its variants • Pemphigoid gestationis (herpes gestationis) • Mucous membrane (cicatricial) pemphigoid • Linear IgA bullous dermatosis	• Arthropod-bite reactions, including scabies • Drug eruptions • Id reactions • Wells syndrome • Polymorphic eruption of pregnancy • Erythema toxicum neonatorum • Incontinentia pigmenti (first stage) • Atopic dermatitis • Contact dermatitis • Eosinophilic folliculitis • Mycosis fungoides • Prurigo pigmentosa • Still disease

Table 29.4 Causes of eosinophilic spongiosis.

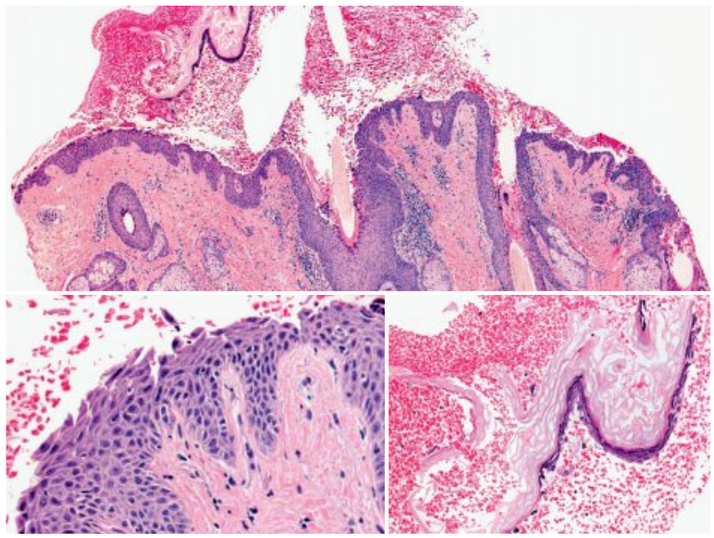

Fig. 29.14 Pemphigus foliaceus – histopathologic features. Because of the fragility of the blisters, the blister roof may become detached (right inset). The split is in the upper spinous layer of the epidermis and acantholytic cells are readily apparent (left inset). *Courtesy Lorenzo Cerroni, MD.*

may be the only histopathologic finding (the horny layer detaches as a consequence of superficial acantholysis). Although the deeper epidermis usually remains intact, secondary clefts may develop, leading to detachment of the epidermis in its midlevel, but rarely giving rise to limited areas of separation right above the basal layer.

These superficial blisters are histologically indistinguishable from those seen in staphylococcal scalded skin syndrome or bullous impetigo, because Dsg1 is targeted in both of these diseases[31]. Sometimes the blister cavity contains numerous acute inflammatory cells, particularly neutrophils. Eosinophilic spongiosis can be also seen in very early lesions of pemphigus foliaceus (see Table 29.4). The dermis shows a moderate number of inflammatory cells, among which eosinophils are often present.

Paraneoplastic Pemphigus

The histologic findings of cutaneous lesions in paraneoplastic pemphigus show considerable variability, reflecting the polymorphism seen clinically. The lesions show a unique combination of pemphigus vulgaris-like, erythema multiforme-like, and lichen planus-like histologic features, sometimes in the same specimen (Fig. 29.15). Intact cutaneous blisters demonstrate suprabasilar acantholysis and individual keratinocyte necrosis as well as lymphocytes within the epidermis. In addition, features of an interface dermatitis can be seen, including basal cell liquefactive degeneration or a dense band-like lymphocytic infiltrate in the upper dermis. Eosinophils are rare. Biopsy specimens of the severe ulcerative stomatitis usually yield only nonspecific changes of inflammation, but the perilesional oral epithelium should show suprabasilar acantholysis.

IgA Pemphigus

The characteristic histologic feature in IgA pemphigus is formation of an intraepidermal pustule or vesicle (Fig. 29.16). The contents of the pustules consist predominantly of neutrophils. Acantholysis is usually not seen. IgA pemphigus is divided into two subtypes depending on the

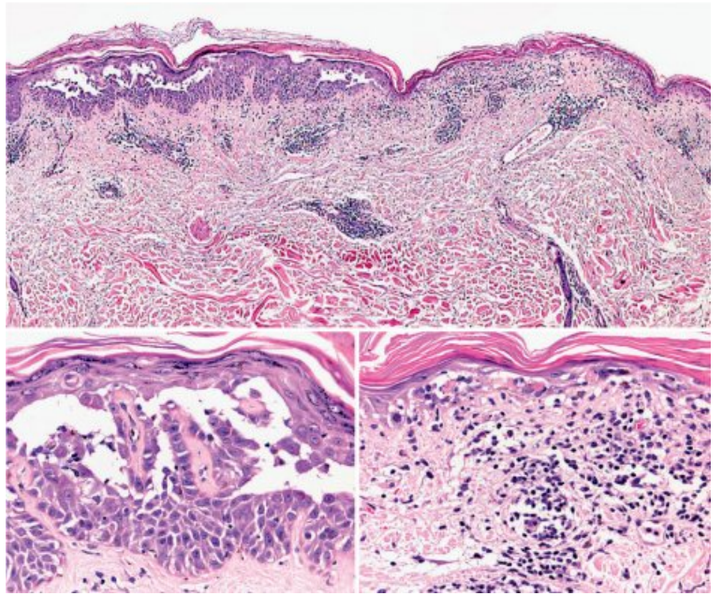

Fig. 29.15 Paraneoplastic pemphigus – histopathologic features. In the same biopsy specimen, there are areas of suprabasilar acantholysis (left inset) as well as an interface dermatitis with basal cell vacuolar change, necrotic keratinocytes, and lymphocytes within the epidermis (right inset). *Courtesy Lorenzo Cerroni, MD.*

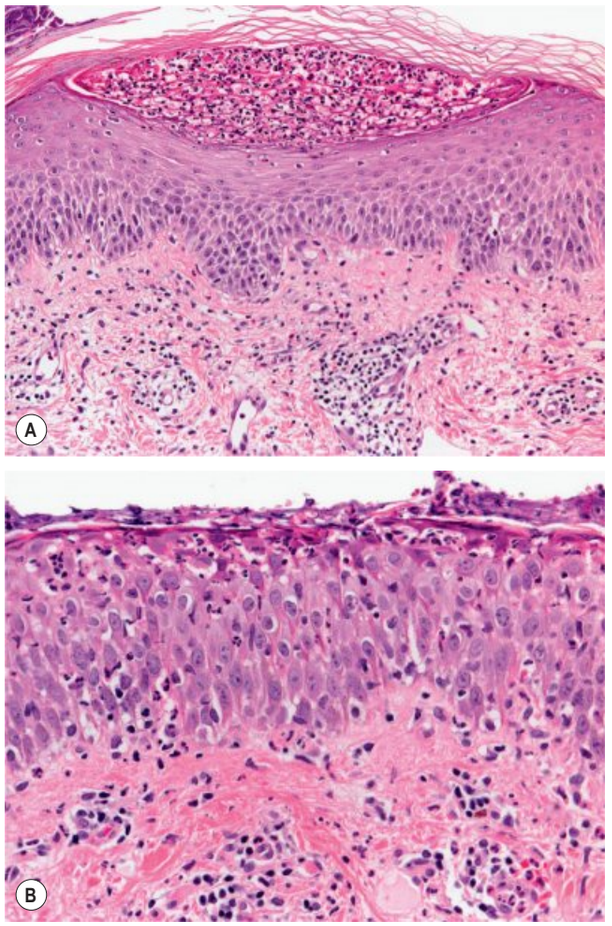

Fig. 29.16 IgA pemphigus – histopathologic features. Intraepidermal pustule with neutrophils present subcorneally in the subcorneal pustular dermatosis type (**A**), and within the entire epidermis in the intraepidermal neutrophilic type (**B**). *Courtesy Lorenzo Cerroni, MD.*

level of intraepidermal pustule; in the subcorneal pustular dermatosis type, pustules are located subcorneally in the upper epidermis, while in the intraepidermal neutrophilic type, suprabasilar pustules involving the lower or entire epidermis are present.

DIFFERENTIAL DIAGNOSIS

Demonstration of IgG (or IgA for IgA pemphigus) autoantibodies directed against the cell surface of keratinocytes is the gold standard for the diagnosis of pemphigus. By detection of these autoantibodies, pemphigus can be differentiated from other vesiculobullous or pustular diseases. Methods for demonstrating pemphigus autoantibodies include DIF, IIF, immunoprecipitation, immunoblotting, and enzyme-linked immunosorbent assay (ELISA).

DIF examines patients' skin or mucous membranes in order to demonstrate *in vivo* bound IgG deposition on the keratinocyte cell surfaces (Fig. 29.17A). The biopsy specimen should be taken from perilesional normal skin or mucous membrane (see Fig. 29.12). DIF is the most reliable and sensitive diagnostic test for all forms of pemphigus. However, on occasion, nonspecific cell surface staining may occur in other skin diseases, such as spongiotic dermatitis, burns, toxic epidermal necrolysis, systemic LE and lichen planus, or in patients with antibodies directed against blood groups A and B. If the DIF is negative, the diagnosis of pemphigus should be seriously questioned. IgG deposition is seen in up to 100% of patients with active pemphigus vulgaris and pemphigus foliaceus. IgM deposition is not found, but occasionally IgA deposition may also be seen. Complement (C3) deposition is not necessarily observed, probably because the dominant subclass of IgG is IgG4, which does not fix complement. The staining pattern of paraneoplastic pemphigus shows deposition of IgG and C3 on epidermal cell surfaces as well as variably along the basement membrane zone. In IgA pemphigus, IgA (but not IgG) deposition is detected on keratinocyte cell surfaces.

IIF examines patients' sera in order to demonstrate circulating IgG autoantibodies directed against epithelial cell surfaces (Fig. 29.17B). In order to optimize sensitivity, there are recommended substrates based upon the particular autoantibody (Table 29.5)[53]. Except for a few patients with early localized disease or those in remission, most patients with pemphigus have circulating anti-epithelial cell surface IgG as determined by IIF. Despite the different antigens involved in pemphigus vulgaris and foliaceus, the staining pattern obtained by DIF or IIF is similar, which makes it difficult to serologically distinguish the two diseases (compare Fig. 29.1B & C). Immunoprecipitation, immunoblotting, and ELISA can be used to demonstrate the target molecules of these autoantibodies.

Immunoprecipitation and immunoblotting detect the target antigens as protein bands of a particular molecular weight that have been separated by electrophoresis (see Ch. 30). Immunoblotting requires denaturation of the protein substrates, but immunoprecipitation does not. Therefore, immunoprecipitation is superior to immunoblotting in detecting antibodies that react with epitopes dependent on three-dimensional structure (conformational epitopes), while immunoblots detect antibodies that react with epitopes that are preserved even after denaturation (linear epitopes). However, an immunoblot is easier to perform because immunoprecipitation requires radioisotopes to label protein substrates.

ELISA is increasingly being used to detect antigen-specific autoantibodies for the diagnosis of pemphigus (Table 29.6)[21,22]. The patient's serum is tested on ELISA plates pre-coated with relevant recombinant proteins, e.g. Dsg1, Dsg3. Thus, specific antibodies directed against Dsg1 or Dsg3 can be detected. This assay has enabled investigators to serologically distinguish subtypes of pemphigus vulgaris and foliaceus. If a serum is positive against Dsg1 but negative against Dsg3, this suggests a diagnosis of pemphigus foliaceus. If negative against Dsg1 but positive against Dsg3, this suggests a diagnosis of the mucosal-dominant type of pemphigus vulgaris. If positive against both Dsg1 and Dsg3, this suggests a diagnosis of mucocutaneous type of pemphigus vulgaris (see Fig. 29.4). Furthermore, ELISA scores demonstrate parallel fluctuations with disease activity and are useful in monitoring disease activity, planning schedules for tapering corticosteroids, and predicting flares or relapses before there is clinical evidence. The *c*hemi*l*uminescent *e*nzyme *i*mmuno*a*ssay (CLEIA) is an even more sensitive and more rapid technique for detecting IgG autoantibodies in patients with pemphigus.

Differential Diagnosis of Pemphigus Vulgaris

Establishing the diagnosis in patients with only oral lesions is more difficult than in those with cutaneous blisters and erosions. The differential diagnosis of mucosal lesions of pemphigus vulgaris includes acute herpetic stomatitis, aphthous stomatitis, erythema multiforme major or Stevens–Johnson syndrome, lichen planus, systemic LE, and mucous membrane (cicatricial) pemphigoid. For cutaneous lesions of pemphigus vulgaris, the differential diagnosis includes other forms of pemphigus, bullous pemphigoid, linear IgA bullous dermatosis, erythema multiforme, Hailey–Hailey disease, and transient acantholytic dermatosis (Grover disease). The differential diagnosis of pemphigus vegetans is outlined in Table 29.7.

The demonstration of IgG autoantibodies against keratinocyte cell surfaces and anti-Dsg3 IgG, as mentioned above, will exclude these diseases (with the exception of drug-induced pemphigus vulgaris and paraneoplastic pemphigus). Fresh blisters of bullous pemphigoid are tense due to a subepidermal split. Hailey–Hailey disease has full-thickness acantholysis ("dilapidated brick wall") with epidermal hyperplasia and an impetiginized scale, and the acantholysis does not extend down follicles as it does in pemphigus. Transient acantholytic dermatosis exhibits only small foci of intraepidermal acantholysis in addition to dyskeratosis; the latter is not present in pemphigus.

Differential Diagnosis of Pemphigus Foliaceus

This differential includes other forms of pemphigus, bullous impetigo, subcorneal pustular dermatosis, subacute cutaneous LE, and seborrheic dermatitis. As discussed earlier for pemphigus vulgaris, the demonstration of IgG autoantibodies against epidermal cell surfaces is essential for separating these disorders from the pemphigus

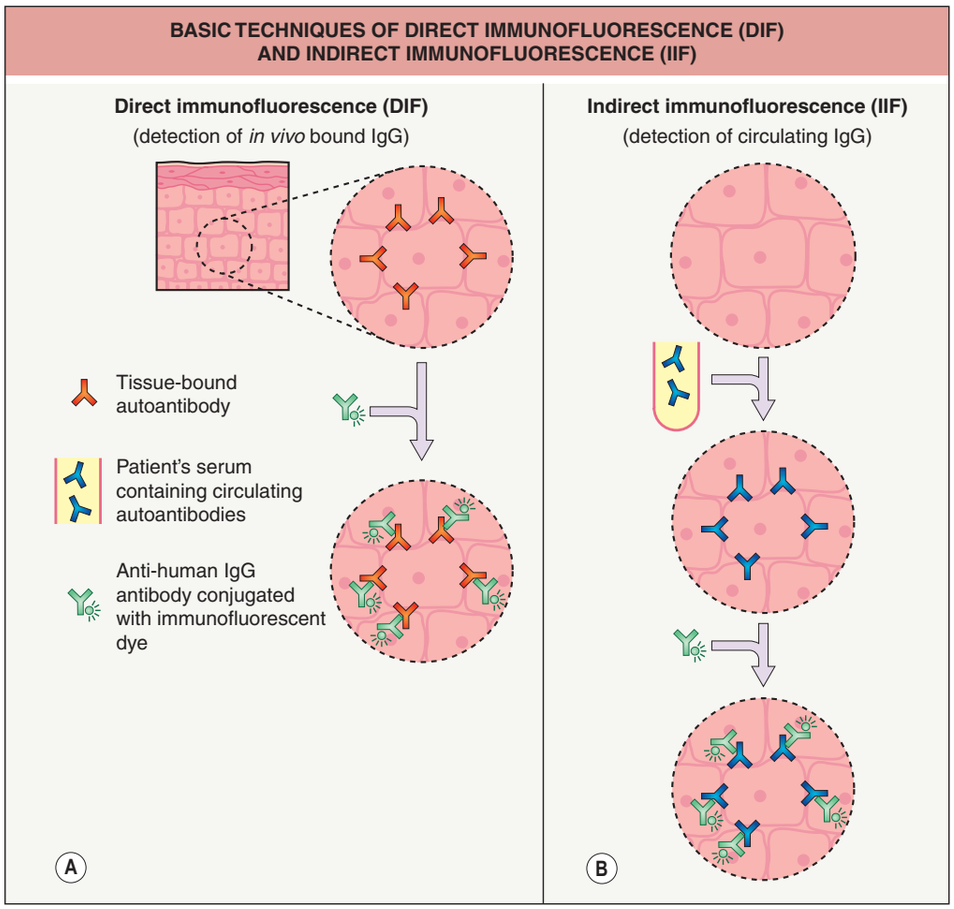

Fig. 29.17 Basic techniques of direct immunofluorescence (DIF) and indirect immunofluorescence (IIF). A DIF is performed on skin biopsy specimens in order to detect *in vivo* bound IgG. **B** IIF is performed utilizing patients' sera in order to detect circulating autoantibodies that bind epithelial antigens.

INDIRECT IMMUNOFLUORESCENCE (IIF) – RECOMMENDED SUBSTRATES	
Type of pemphigus	**Recommended substrates (autoantibodies)**
Pemphigus vulgaris	Monkey esophagus (anti-Dsg3)
Pemphigus foliaceus	Human skin or guinea pig esophagus (anti-Dsg1)
Paraneoplastic pemphigus	Monkey and guinea pig esophagus (anti-Dsg1, anti-Dsg3) Rat bladder (anti-plakin)
Bullous pemphigoid Linear IgA bullous dermatosis	Human skin, salt-split
Mucous membrane (cicatricial) pemphigoid	Human skin, salt-split; normal oral or genital mucosa or conjunctiva

Table 29.5 Indirect immunofluorescence (IIF) for pemphigus and bullous pemphigoid – recommended substrates.

ELISA TO DETECT IgG AUTOANTIBODIES IN AUTOIMMUNE BULLOUS DISEASES – AVAILABLE TARGET AUTOANTIGENS

family. A complete review of medications should be done to exclude the possibility of drug-induced pemphigus foliaceus. Because the lesions of pemphigus foliaceus may become secondarily infected, the finding of bacteria does not confirm a diagnosis of bullous impetigo. Likewise, a clinical flare or recalcitrant disease may represent a superimposed disorder, e.g. tinea corporis, especially in patients on systemic corticosteroids.

Differential Diagnosis of Paraneoplastic Pemphigus

This differential includes pemphigus vulgaris, mucous membrane pemphigoid, erythema multiforme or Stevens–Johnson syndrome, lichen planus, GVHD, persistent HSV infection, and other viral infections; stomatitis due to chemotherapy will be limited in duration (7–14 days) (Table 29.8). In two-thirds of patients with paraneoplastic pemphigus, it arises in the context of a known underlying neoplasm, usually a lymphoproliferative disorder, which may have been treated for years before the mucocutaneous lesions appear. In approximately one-third of patients, the underlying neoplasm is undiagnosed at the time the mucocutaneous disease develops. In these latter patients, examination for an occult neoplasm is required, and, given the most commonly associated ones (see earlier), a CT scan of the chest, abdomen, and pelvis should accompany a complete blood count, flow cytometry of peripheral blood, LDH, and serum protein and immunofixation electrophoreses. Severe intractable stomatitis that extends onto the vermilion lip is a key clinical feature in differentiating paraneoplastic pemphigus from

PEMPHIGUS VEGETANS – DIFFERENTIAL DIAGNOSIS	
Major entities	
Hailey–Hailey disease	Vegetative lesions also seen when Darier disease involves intertriginous zones; see Ch. 59
Pemphigoid vegetans	Especially in major body folds; see Fig. 30.6C
Blastomycosis-like pyoderma	Vegetating plaques due to inflammatory reaction to bacterial infection, most commonly *Staphylococcus aureus*; immunosuppression, systemic or local, a risk factor
Pyodermatitis–pyostomatitis vegetans	Form of pyoderma gangrenosum; see Ch. 25
Other entities	
Halogenoderma	
Infections Bacterial – granuloma inguinale, condylomata lata Fungal – dimorphic, chromomycosis Viral – condylomata acuminata, herpes simplex vegetans, chronic verrucous herpes zoster* Parasitic – amebic granuloma	
Buschke–Löwenstein tumors Extramammary Paget disease	
*Occurs in immunocompromised hosts.

THERAPEUTIC LADDER FOR PEMPHIGUS VULGARIS	
Standard treatment	
Oral prednisone	1 mg/kg/day as an initial dose (usually 60 mg/day) (1)
Rituximab	375 mg/m^2 once weekly for 4 weeks or 1 g initially then at two weeks; either regimen may need to be repeated every 3–6 months (1)
Aggressive treatment	
Immunosuppressive agents in combination with oral prednisone:	
Azathioprine	2–4 mg/kg/day (usually 100 to 300 mg/day) (1)
Mycophenolate mofetil	2–3 g/day (2)
Cyclophosphamide	1–3 mg/kg/day (usually 50 to 200 mg/day) (2)
Cyclosporine	3–5 mg/kg/day (2)*
Pulse methylprednisolone	1 g/day over a period of 2–3 hours for 3–5 consecutive days (2)
Methotrexate	7.5–20 mg/week (2)
Pulse cyclophosphamide	500–1000 mg/m^2 every 4 weeks (3)
Plasmapheresis	1–2 times per week, at the onset (2)
High-dose IVIg	400 mg/kg/day for 5 consecutive days (1); may need to be repeated monthly
Extracorporeal photopheresis	2 days per month (3)
Topical treatment	
• Topical corticosteroids (1), especially Class I to localized persistent sites	
• Topical antibiotics (2)	
• Topical immunomodulators (e.g. cyclosporine, tacrolimus) (3)	
Intralesional therapy	
• Corticosteroids (3)	
• Rituximab (5 mg/cm^2) (3)	
*In one trial, shown not to be of benefit when added to systemic corticosteroids.	

Table 29.9 Therapeutic ladder for pemphigus vulgaris. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

most cases of pemphigus vulgaris or mucous membrane pemphigoid. The gold standard for the diagnosis of paraneoplastic pemphigus is the demonstration of the characteristic combination of IgG autoantibodies – anti-plakin autoantibodies by immunoprecipitation, immunoblotting or ELISA and anti-desmoglein autoantibodies by ELISA (see Table 29.6).

Differential Diagnosis of IgA Pemphigus

The differential diagnosis includes subcorneal pustular dermatosis, pemphigus foliaceus, bullous impetigo, dermatitis herpetiformis, linear IgA bullous dermatosis, and pustular psoriasis. The clinical and histologic features of the SPD type of IgA pemphigus and classic subcorneal pustular dermatosis are indistinguishable. The demonstration of IgA autoantibodies is essential for separating these other disorders from IgA pemphigus.

TREATMENT

Pemphigus Vulgaris

Before the advent of systemic corticosteroids, pemphigus vulgaris was usually a fatal disease; most patients died within 2–5 years of the onset of the disease because large areas of the skin lost their epidermal barrier function, leading to the loss of body fluids or to secondary bacterial infections. Pemphigus foliaceus had a better prognosis, except for the occasional acute cases with generalized involvement. Because pemphigus is caused by pathogenic autoantibodies, therapy must be designed to reduce autoantibody production, not just to suppress local inflammation. The introduction of systemic corticosteroids and immunosuppressive agents has greatly improved the prognosis of pemphigus; however, the morbidity, and occasional mortality, is still significant due to complications of therapy. Systemic corticosteroids are the mainstay of therapy for pemphigus. Immunosuppressive agents are often used for their corticosteroid-sparing effect in order to reduce the side effects of the corticosteroids (Table 29.9), with the goal of therapy being to control the disease with the lowest possible dose of corticosteroids. High-dose IVIg, which is non-immunosuppressive, and anti-CD20 monoclonal antibodies have been recently added to the therapeutic armamentarium for pemphigus. Introduction of PDAI (pemphigus disease area index) and ABSIS (autoimmune bullous skin disorder intensity score) allow for more standardized assessment of disease extent and response to treatment[54].

Systemic corticosteroid therapy, usually in the form of oral prednisone, is standard treatment (see Ch. 125). Prednisone at 1 mg/kg/day (usually 60 mg/day) is a typical initial dosage. The therapeutic effects are clinically estimated by the number of new blisters per day and the rate of healing of new lesions, and the prednisone is then gradually tapered. Once clinical remission is obtained, changes in the titer of circulating autoantibodies, as determined by IIF or ELISA, are helpful in gauging the dose of prednisone[22]. If there is no response in 3–7 days, other options may be employed, as discussed below. Intravenous pulse therapy with 1 g/day methylprednisolone (over a period of 2–3 hours, with continuous cardiac monitoring) for 3–5 consecutive days is an alternative choice for severe cases.

In general, immunosuppressive agents, such as *azathioprine*, *mycophenolate mofetil* and *cyclophosphamide*, when combined with corticosteroids, may result in gaining early control of the disease and an increased percentage of clinical remissions[55–60]. For example, in patients with mild to moderate disease who received corticosteroids plus either placebo or mycophenolate mofetil in a prospective, randomized trial, the latter group showed faster and more durable responses[61]. Azathioprine is used at a dose of 2–4 mg/kg/day (usually 100–300 mg/day) and its major side effects are nausea and dose-dependent myelosuppression (see Ch. 130). Mycophenolate mofetil is used at a dose of 2–3 g/day and it has a similar action to azathioprine, with less myelosuppression but more gastrointestinal toxicity[58]. Cyclophosphamide is given at a dose of 1–3 mg/kg/day (usually 50–200 mg/day) orally or 500–1000 mg/m^2 every four weeks intravenously and its major side effects are hemorrhagic cystitis, sterility and leukopenia, with an increased risk of bladder carcinoma long-term; there is a movement away from lower doses of daily cyclophosphamide in an effort to possibly reduce the risk of bladder cancer. Chlorambucil, like cyclophosphamide, is an alkylating agent and although there is no bladder toxicity, side effects include myelosuppression and long-term an increased risk of developing leukemia.

If complete remission is achieved with the combined therapy, the dosage of the immunosuppressive drug is maintained while the prednisone is slowly tapered; when a dose of 5–10 mg/day is reached, careful taper then discontinuation of the immunosuppressive drug is attempted. In young patients, the potential increase in malignancies that might be associated with the use of these drugs must be taken into account. In some patients, especially those who are elderly with limited disease or those in whom corticosteroids are contraindicated, immunosuppressive agents alone may be used.

While *cyclosporine* (3–5 mg/kg/day) has been used as an immunosuppressive agent in some patients with pemphigus vulgaris, a randomized trial found that the addition of cyclosporine to corticosteroids did not offer a benefit. Also, *gold* is rarely utilized nowadays.

Plasmapheresis is useful for quickly reducing the titers of circulating autoantibodies and should be considered for severe pemphigus if the disease is unresponsive to a combination of prednisone and immunosuppressives[59]. Concomitant immunosuppression with corticosteroids and cyclophosphamide prevents a post-plasmapheresis rebound increase in the production of autoantibody.

High-dose IVIg is another option for resistant disease. IVIg is a blood product prepared from pooled plasma that has immunomodulatory effects when used in a high dose. It is thought to exert its effect via multiple modes of action, including modulation of expression and function of Fc receptors and the cytokine network; provision of anti-idiotypic antibodies; and modulation of dendritic cell, T cell, and B cell activation, differentiation, and effector functions[62]. A multicenter, randomized, placebo-controlled, double-blind trial demonstrated that high-dose IVIg is an effective and safe treatment for steroid-resistant pemphigus[63].

Rituximab is a potent B cell-depleting chimeric anti-CD20 monoclonal antibody that was first used to treat B cell malignancies, but increasingly is used for a variety of autoimmune diseases, including pemphigus. CD20 is a transmembrane glycoprotein specifically expressed on B cells (from the pre-B stage in the bone marrow to the activated and memory B stage in blood or secondary lymphoid organs), but its expression is lost upon plasma cell differentiation[64]. Rituximab seems not only to induce a depletion of CD20$^+$ B cells and a decline in IgG (including anti-desmoglein autoantibodies), but also decreases desmoglein-specific T cells[65]. When used as adjuvant therapy in non-randomized prospective studies, rituximab led to a complete remission in most of the patients with refractory pemphigus vulgaris and foliaceus[66–68]. A prospective, open-label, randomized trial demonstrated that as an adjuvant therapy rituximab led to a greater proportion of patients achieving complete remission off-therapy, compared with corticosteroid treatment alone[69]. The US FDA has approved rituximab for moderate-to-severe pemphigus and a consensus group has suggested that it be considered early in the course of disease rather than just for patients with recalcitrant disease[60]. The side effects of rituximab, including infusion reactions, reactivation of hepatitis B virus, and progressive multifocal leukoencephalopathy, are discussed in Chapter 128. Because rituximab is a chimeric biologic agent, patients may develop anti-drug antibodies and in theory a lower therapeutic response. As in primary cutaneous B cell lymphoma, there are reports of the use of intralesional injections of rituximab for refractory pemphigus vulgaris[70]. Humanized anti-CD20 antibodies, e.g. obinutuzumab, ofatumumab, may become alternative options for B cell depletion.

Desmoglein-specific immune suppression, via targeting T cells or B cells, would represent an ideal therapeutic strategy given that the target antigens and pathophysiological mechanisms of pemphigus have been well characterized. In 2020, the FDA granted DSG3-CAART, which targets Dsg3-specific B cells[71], orphan drug designation for the treatment of pemphigus vulgaris. Lastly, in a recent phase II trial, efgartigimod, an inhibitor of the neonatal Fc-receptor (FcRn) led to early disease control in 28 of 31 patients with either pemphigus vulgaris or pemphigus foliaceus[72].

Pemphigus Foliaceus

When pemphigus foliaceus is active and widespread, the treatment is, in general, similar to that for pemphigus vulgaris. In some patients, pemphigus foliaceus may be localized for many years; they do not necessarily have to be treated with systemic therapy, and superpotent topical corticosteroids may be sufficient to control the disease. Dapsone can also be used when neutrophils are dominant histologically.

Paraneoplastic Pemphigus

Patients with benign tumors, such as thymomas or localized Castleman disease, should have the tumor surgically excised. The majority of these patients will either improve substantially or clear completely. However, it may take 6–18 months to see complete resolution of lesions after excision of a benign neoplasm. In patients with malignant neoplasms, there is no consensus on a standard effective therapeutic regimen. Administration of tumor-specific chemotherapy or targeted therapy may result in complete resolution of the malignancy and a slow resolution of the skin lesions. Cutaneous lesions respond more rapidly to therapy, in contrast to the stomatitis, which is generally refractory to most forms of treatment. Overall, the prognosis of paraneoplastic pemphigus is poor due to its resistant nature to treatment.

IgA Pemphigus

Dapsone is the drug of choice for most patients with IgA pemphigus. A clinical response usually occurs within 24–48 hours. If dapsone is not well tolerated, sulfapyridine and acitretin are useful alternatives. Occasionally, those drugs are not effective, and low- to medium-dose prednisone may be considered, as well as photochemotherapy (PUVA) or colchicine.

BULLOUS PEMPHIGOID

Synonym: ■ Pemphigoid

Key features

- Bullous pemphigoid (BP) is the most common autoimmune subepidermal blistering disease, and its onset is often after 60 years of age
- It is usually a chronic disease, with spontaneous exacerbations and remissions, which may be accompanied by significant morbidity
- BP is associated with tissue-bound and circulating autoantibodies directed against BP antigen 180 (BP180, BPAG2, or type XVII collagen) and BP antigen 230 (BP230 or BPAG1e), components of junctional adhesion complexes called hemidesmosomes that promote dermal–epidermal cohesion
- The spectrum of clinical presentations is extremely broad. Characteristically, BP is an intensely pruritic eruption with widespread blister formation. In its early stages, or in variants of the disease, only eczematous or urticarial lesions (either localized or generalized) or just excoriations due to intense pruritus are present
- Diagnosis relies on immunopathologic examinations, particularly direct and indirect immunofluorescence (IF) microscopy as well as ELISA for anti-BP180/BP230 autoantibodies

Introduction

Bullous pemphigoid (BP) is the most common autoimmune subepidermal blistering disease. It typically presents in older adults as a generalized pruritic bullous eruption and is often associated with significant morbidity. The clinical presentation is quite polymorphic, particularly during the early stages of the disease or in atypical variants, in which full-blown bullous lesions may be absent. In these cases, establishing the diagnosis of BP requires a high degree of suspicion. The antigens targeted by patients' autoantibodies represent two components of hemidesmosomes, the junctional adhesion complexes found in skin and adjacent mucosae (see Fig. 28.3A).

History

In 1953 Lever recognized BP as a disorder distinct from the various types of "true" pemphigus based upon specific clinical and histopathologic features[1]. A decade later, Jordon, Beutner, and colleagues[2] demonstrated that BP patients had tissue-bound and circulating autoantibodies directed against the cutaneous basement membrane zone (BMZ), an observation that suggested that subepidermal dysadhesion was due to autoantibodies directed against structural components of the skin[2]. Further milestones in our understanding of BP included the immunochemical characterization of targeted proteins, the cloning of their genes, and the development of animal models of the disease[3–5].

Epidemiology

BP is typically a disease of older adults, with a mean age of presentation between 65 and 85 years. The annual incidence has been estimated to range from 5 to 45 new cases per million population per year. The incidence rate of BP appears to have significantly increased over the past two decades, most likely reflecting an aging population, better recognition of atypical variants, and a rise in drug-induced BP[6]. A relative risk for patients over 90 years of age appears to be ~300-fold higher than for those 60 years of age or younger. The disease also occurs in children, but rarely. Certain HLA class II alleles are more prevalent in patients with BP than in the general population[7]. In Caucasians, a significant association with the allele DQB1*0301 has been noted, while an increased frequency of the alleles DRB1*04, DRB1*1101, and DQB1*0302 has been observed in Japanese patients.

Pathogenesis

BP is an example of an immune-mediated disease that is associated with a humoral and cellular response directed against two well-characterized self-antigens: BP antigen 180 (BP180, also known as BPAG2 or type XVII collagen) and BP antigen 230 (BP230, also referred to as the epithelial isoform of BPAG1 [BPAG1e]) (Table 30.1)[3,4]. While the former is a transmembrane protein with a large collagenous extracellular domain, the latter is a cytoplasmic protein belonging to the plakin family (see Ch. 28). These two antigens are components of the hemidesmosomes, which are adhesion complexes promoting epithelial–stromal adhesion in stratified and other complex epithelia.

In vitro studies and *in vivo* animal models have demonstrated the pathogenic role of autoantibodies in BP. Furthermore, in gestational pemphigoid, a disease closely related to BP, the transplacental transfer of anti-BP180 autoantibodies from the mother to the neonate can result in a transient bullous eruption (see Ch. 34).

Humoral and cellular responses

Almost all patients with BP have circulating IgG autoantibodies that bind to BP180. Specifically, it is the non-collagenous NC16A domain, a region of BP180 located extracellularly but close to the transmembrane domain, that constitutes the immunodominant region (see Fig. 31.9)[8,9]. However, additional antigenic sites exist within both the extracellular and intracellular domains of BP180, and they are recognized by up to 70% of BP sera[8,9]. Patients with BP also exhibit significant autoreactivity to BP230, and BP230-reactive autoantibodies bind predominantly to the COOH-terminal region of this autoantigen[4,8,9]. The presence of several antigenic sites throughout BP180 and BP230 most likely results from the phenomenon known as "epitope spreading" (see below)[9]. This phenomenon may also account for the finding that patients' sera rarely contain autoantibodies targeting additional components of the BMZ.

Patients with BP develop an autoreactive T cell response to BP180 and BP230. Likely related to a dysfunction of regulatory T cells, it is crucial for stimulating B cells to produce autoantibodies[10,11]. The responsiveness of anti-BP180 autoreactive T cells is restricted by certain HLA class II alleles (e.g. HLA-DQB1*0301), which are prevalent in BP patients. These T lymphocytes, whose major relevant epitopes seem to be harbored within the NC16 domain, have a $CD4^+$ phenotype and produce both Th1 (e.g. interferon-γ) and Th2 cytokines (e.g. interleukin [IL]-4, IL-5, IL-13; see Ch. 4)[10,11]. Th2 and Th17 cytokines, which are particularly relevant to the pathophysiology of BP, predominate within lesional tissue and in patients' sera[10–13].

Upon binding of autoantibodies to their target antigens, subepidermal blister formation results from a cascade of events in which Fc

*Major target antigen; additional target antigens, which may be critical in the pathogenesis, have been identified in one-third of cases.
†Detectable in a subset of patients.
‡Binding to laminin 311 depends on the presence of cross-reactive autoantibodies directed against the α-chain of laminin 332 (laminin 5).
¶They constitute the most characteristic serologic marker for LABD. The 120 kDa LAD-1 antigen corresponds to the cleaved, shed extracellular domain of BP180/BPAG2. The 97 kDa LABD97 protein results from its further proteolytic degradation (see Fig. 31.9).
§Reactivity against the α_6 and β_4 subunits of the $\alpha_6\beta_4$ integrin have been described in subsets of patients with oral- and ocular-predominant MMP, respectively. The significance of these autoantibodies remains to be validated.

Table 30.1 Major autoantigens of subepidermal autoimmune-mediated blistering diseases. Not an exhaustive list. In the course of these diseases, it is possible to detect autoantibodies directed against additional antigens, the significance of which remains to be established. In certain cases, a so-called "intermolecular epitope spreading" phenomenon is thought to occur.

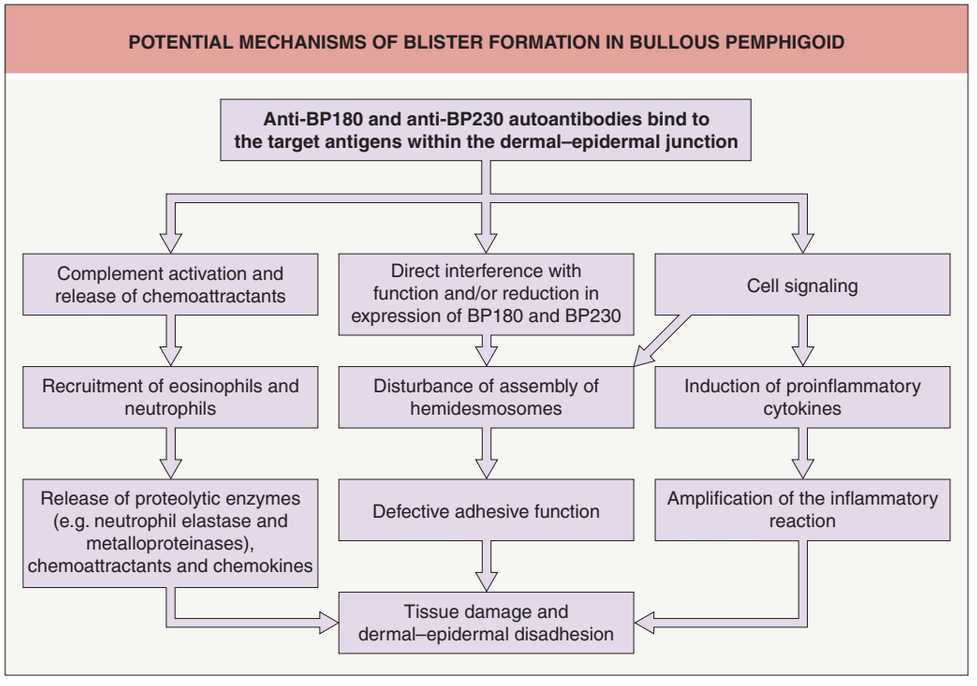

Fig. 30.1 Potential mechanisms of blister formation in bullous pemphigoid. IgG autoantibodies are classically involved in the pathogenesis, but more recently IgE autoantibodies have also been described. The latter may directly trigger the degranulation of FcεRI-expressing cells, such as eosinophils and mast cells.

receptor-mediated mechanisms are critical[5,11,14–18]. The latter involve activation of the complement cascade along with stimulation and recruitment of inflammatory cells including macrophages, neutrophils, mast cells, and eosinophils. These inflammatory cells contribute to tissue damage via liberation of various proteases (e.g. matrix metalloproteinase-9, neutrophil elastase, mast cell proteases), eosinophil toxic granules, and a variety of cytokines (e.g. IL-4, -5, -8, -13, -17, eotaxin). The latter serve to further amplify the inflammatory response[5,11–16] while the proteinases, together with reactive oxygen species, degrade various extracellular matrix proteins as well as BP180.[11–16] IgG anti-BP180 autoantibodies can also boost the inflammatory response by stimulating keratinocytes to express inflammatory cytokines (Fig. 30.1)[11]. Furthermore, IgG autoantibodies are able to directly impair dermal–epidermal adhesion without complement activation[11].

Finally, BP patients often have circulating IgE anti-BP180 autoantibodies which may bind to the epidermal BMZ. These IgE autoantibodies also seem able to form complexes with shed BP180 fragments, which are prominently detected in the dermis on the surface of mast cells and/or eosinophils expressing FcεRI. Hence, IgE autoantibodies most likely directly contribute to tissue damage by triggering the degranulation of these FcεRI-expressing cells[11,15,16].

Animal models have provided strong evidence that IgG autoantibodies against BP180 are pathogenic[5,11,14,17,18]. When passively transferred to neonatal mice (in which BP180 had been fully or partially humanized by genetic engineering), human autoantibodies against the NC16A domain were able to induce a blistering disorder that reproduced all the key features of BP[11,17]. In addition, passive transfer experiments in mice have indicated that IgE antibodies directed against BP180 contribute to skin inflammation[15]. The prevailing pathomechanism is that antibodies against the ectodomain of BP180 are critical for disease initiation, while the development of antibodies against BP230 represents a secondary event that contributes to tissue damage[9,11,18]. However, recent studies utilizing a mouse model demonstrated that anti-BP230 antibodies also had a direct pathogenic effect[19].

Clinical Features

Non-bullous pemphigoid

The cutaneous manifestations of BP can be extremely polymorphic (Figs. 30.2–30.6)[1,18,20–22]. In the prodromal, non-bullous phase of the disease, signs and symptoms are frequently nonspecific, but mild to severe intractable pruritus is a consistent feature. Clinical findings vary from excoriations to eczematous, papular, and/or urticarial lesions that have persisted for several weeks or months (see Figs. 30.3 to 30.5). Importantly, these nonspecific skin findings may remain as the only signs of the disease. At least 20% of patients have neither obvious blisters nor erosions due to ruptured bullae at the time of diagnosis[18,20,22].

Bullous phase

The bullous stage of BP is characterized by the development of vesicles and bullae on apparently normal or erythematous skin, together with urticarial and infiltrated papules and plaques that occasionally assume an annular or figurate pattern. The blisters are tense, up to 1–4 cm in diameter, contain a clear fluid, and may persist for several days, leaving eroded and crusted areas (see Fig. 30.2). Occasionally, the blister fluid becomes blood-tinged. The lesions frequently have a symmetric distribution pattern, and they predominate on the flexural aspects of the extremities and the lower trunk, including the abdomen. Within intertriginous zones, vegetating plaques may be observed (pemphigoid vegetans; see Fig. 30.6C). The extent and degree of disease activity can be assessed by employing the BP disease area index (BPDAI)[21] or a daily blister count.

Residual postinflammatory changes include hyper- and hypopigmentation and, less commonly, milia. Involvement of the oral cavity is observed in 10%–30% of patients, more often in those with moderate to severe disease. The mucosae of the eyes, nose, pharynx, esophagus, and anogenital region are more rarely affected. In ~50% of patients, a peripheral blood eosinophilia is noted.

Clinical variants

Several clinical forms of BP have been described and are outlined in Table 30.2[18,20,22]. *Gestational pemphigoid* (pemphigoid gestationis) is also a variant of BP, which typically occurs during pregnancy (see Ch. 27).

While the individual lesions of BP in infants and in older children (*infantile* and *childhood BP*) are similar to those observed in older adults, the sites of involvement can differ (Fig. 30.7). In infants, bullae often first appear in acral locations and then can generalize to other sites, including often the face. Involvement of the genital region (e.g. *vulvar childhood pemphigoid*) as well as other mucosal sites has been observed in children[18,20].

Associated Diseases

The association of internal malignancies with BP is probably related primarily to the older age of the patient. In case–control studies, the trend towards an increased risk of malignancy was marginal[18,20] while an English national record linkage study found no overall increased risk for concurrent or subsequent malignancies in BP patients[23]. Nonetheless, individuals with BP should be up to date with age-related cancer screening tests recommended for the general population.

Rarely, BP has been described in patients with inflammatory bowel disease or other autoimmune diseases including Hashimoto thyroiditis,

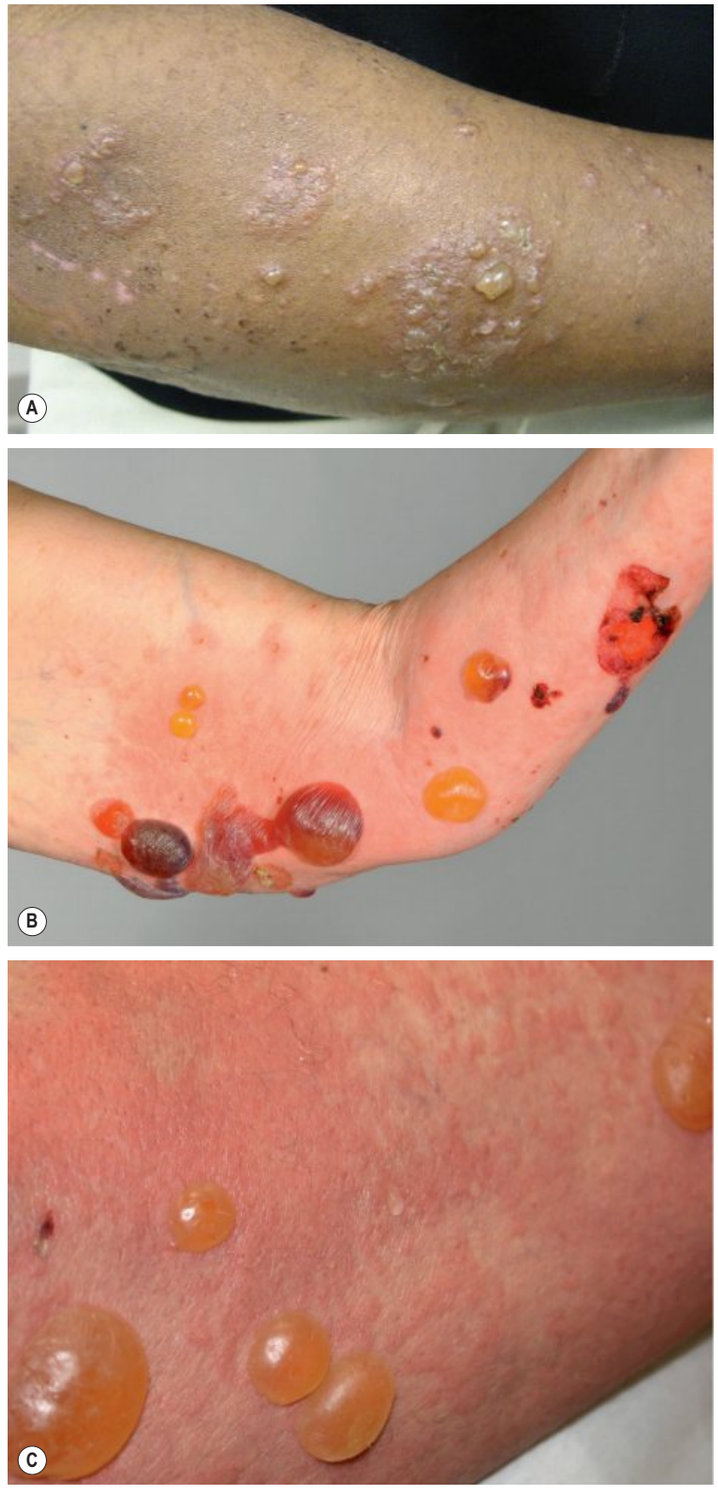

Fig. 30.2 Bullous pemphigoid – classic presentation. A–C Tense vesicles and bullae vary in size from a few mm to several cm in diameter and can arise within normal-appearing skin, areas of erythema, or urticarial plaques. The blister fluid may be serous or hemorrhagic. The flexor aspect of the extremities is a common site of involvement. As the bullae age, they become flaccid and rupture, leaving erosions and serous or hemorrhagic crusts. Biopsies of vesiculobullae for routine histology should be obtained from the edge of a fresh tense blister. *Jeffrey Callen, MD.*

Fig. 30.3 Bullous pemphigoid – urticarial presentation. Multiple, firm annular, arciform and polycyclic urticarial plaques. Note the absence of bullae.

Fig. 30.4 Bullous pemphigoid – eczematous presentation. Large pink eczematous plaques on the trunk and upper extremities.

rheumatoid arthritis, dermatomyositis, and lupus erythematosus (LE)[18,20,23,24]. These associations may be fortuitous or they could reflect a genetically determined susceptibility to develop autoimmune disorders. While one case–control study did not find an increased risk for autoimmune diseases[24], a sample analysis of US hospitalized patients with BP reported a slight risk for other autoimmune disorders[25].

In some patients, BP appears to be triggered by trauma, burns, radiotherapy or UV irradiation (including PUVA). BP has also been observed in association with certain dermatoses, in particular lichen planus and psoriasis (Fig. 30.8)[18,20]. In *lichen planus pemphigoides*, BP coexists with lichen planus (see Ch. 11). Theoretically, a dysfunction of T regulatory cells leads to both a lichenoid interface dermatitis and an autoantibody response to BP180 and BP230. In the setting of chronic inflammation at the dermal–epidermal junction, exposure of antigens to autoreactive T lymphocytes could result in a secondary immune response[26].

Finally, BP has been strongly associated with psychiatric and neurologic disorders; the latter include Parkinson disease, dementia, multiple sclerosis, and stroke[27]. It should be noted that a neuronal variant of BP230 is expressed in the central and peripheral nervous systems[19], while available data regarding the expression of BP180 are contradictory. Whether exposure to neuronal antigens, via a compromised blood–brain barrier, plays a role in the development of BP remains to be determined.

Fig. 30.5 Bullous pemphigoid – nonspecific lesions due to pruritus. Multiple excoriations and nonspecific lesions of prurigo simplex are present. Bullous pemphigoid is in the differential diagnosis of chronic pruritus associated with secondary excoriations.

Drug-induced bullous pemphigoid

In certain patients, systemic medications can lead to the development of BP (Fig. 30.9)[28,29]. There are multiple implicated drugs, in particular diuretics (e.g. furosemide), NSAIDs, antibiotics (e.g. amoxicillin, ciprofloxacin), ACE inhibitors, and TNF inhibitors. More recently, dipeptidyl peptidase-4 inhibitors (e.g. vildagliptin, linagliptin) and immune checkpoint inhibitors (e.g. nivolumab, pembrolizumab) have been strongly associated with BP. A meta-analysis suggested that exposure to aldosterone antagonists, dipeptidyl peptidase-4 inhibitors, anticholinergics, and dopaminergic medications were significantly associated with BP[28]. Therefore, a detailed history is essential. Discontinuation of the drug, or a drug holiday in the case of immune checkpoint inhibitors, may or may not lead to improvement[22,29a]. As a result, initiation of standard therapies may be required.

A number of hypotheses have been put forth to explain drug-induced BP – an underlying genetic predisposition, medication-related alteration of the antigenic properties of the BMZ[28,29], and a breakdown of immune tolerance in the case of immune checkpoint inhibitors. In dipeptidyl peptidase-4 inhibitor-induced BP, autoantibodies also recognize BP180 epitopes other than the NC16A domain.

Diagnosis

The diagnosis of BP is based upon the typical clinical presentation, compatible histologic features, and, most importantly, positive direct immunofluorescence (DIF) microscopy studies (see Fig. 29.17)[18,20–22]. Further support for the diagnosis of BP requires the detection of specific circulating IgG autoantibodies (anti-BP180, anti-BP230) via either indirect immunofluorescence (IIF) microscopy or ELISA. In the vast majority of patients, these tests allow for the correct classification of patients. However, in a minority of patients (~10%) in whom both IIF microscopy and ELISA are negative, additional immunopathological studies, e.g. n-serration *versus* u-serration pattern analysis (see below), can be employed to demonstrate indirectly an autoantibody response to BP180 and/or BP230 and thereby exclude other autoimmune bullous diseases (see Table 30.1)[12,20,22].

Light microscopy

In the non-bullous phase or in atypical variants of BP, routine histology may provide less specific information, since only eosinophilic spongiosis and/or dermal inflammatory infiltrates admixed with numerous eosinophils may be seen (Fig. 30.10)[18,20,22]. In biopsy specimens of an early bulla, a subepidermal blister accompanied by a dermal inflammatory infiltrate composed of eosinophils and mononuclear cells is typically observed. The infiltrate favors the uppermost dermis, and the cavity of the bulla contains a net of fibrin with a variable inflammatory

Fig. 30.6 Bullous pemphigoid – uncommon clinical variants. infiltrate (Fig. 30.11). Conventional electron microscopy studies have shown that subepidermal blister formation usually occurs at the level of the lamina lucida.

Direct immunofluorescence (DIF) microscopy

In almost all patients, DIF microscopy of *perilesional* skin, either normal-appearing or if inflamed 1–2 cm from a bulla, will characteristically demonstrate the presence of fine, linear, continuous deposits of IgG and/or C3 (and, more rarely, other Ig classes) along the epidermal basement membrane (see Fig. 1.9)[18,20,22]. IgG4 and IgG1 are the predominant IgG subclasses. Two additional studies are helpful in distinguishing BP from other autoimmune blistering disorders: (1) close analysis of the linear fluorescence pattern at the BMZ in order to determine if it is *n-serrated* (BP and linear IgA bullous dermatosis) versus *u-serrated* (epidermolysis bullosa acquisita)[30]; and (2) the salt-split skin assay in which perilesional skin is examined after treatment with 1 M NaCl (see Fig. 28.7)[18,20,22]. In BP, immune deposits are found in the epidermal side (roof) or in both the epidermal and dermal sides of the split. Although not routinely available, the computer-aided fluorescence overlay antigen mapping (FOAM) technique allows for more precise localization of the deposited immunoreactants.

Indirect immunofluorescence (IIF) microscopy

For IIF studies in subepidermal blistering diseases, salt-split normal human skin is the substrate of choice, rather than intact normal human skin or monkey esophagus (see Table 29.5). Circulating anti-basement membrane autoantibodies of the IgG class, and less frequently of the IgA and IgE classes, are detectable in 60%–80% of patients[18,20]. These autoantibodies typically bind to the epidermal side or, less frequently, to both the epidermal and dermal sides of saline-separated normal human skin (Fig. 30.12). In a single miniature incubation field, multiplex tests that combine IIF with BIOCHIP technology have been used to screen for autoantibodies against multiple target antigens[31].

ELISA

An increasing number of autoantibodies associated with autoimmune bullous diseases can be detected via ELISA (see Table 29.6). Target antigens include the NC16A domain of BP180 and the COOH-terminus (± the NH2-terminus) of BP230[8,9,18,20,22]. In the case of BP, these tests have been found to be fairly *specific* (≥90%); occasionally, low-titer, false-positive results are observed in healthy subjects and elderly patients with pruritic cutaneous eruptions[18]. When performed in unselected BP patients, the overall *sensitivity* of the BP180–NC16A ELISA is comparable to that of IIF (with salt-split human skin as a substrate)[9,18,20,31]. Combining the ELISA for BP230 with the BP180–NC16A ELISA increases the overall sensitivity by ~10% so the former

is only recommended in the setting of a negative BP180 ELISA[32]. A multivariant ELISA that contains multiple autoantigens and utilizes BIOCHIP technology has recently been introduced[33].

Other immunopathological studies

In immunoblot and immunoprecipitation studies of keratinocyte extracts, which are not commercially available, 60%–100% of patients' sera contain IgG autoantibodies that bind to BP180 and BP230, respectively (Fig. 30.13A,B). Patients' sera also frequently contain specific IgA and IgE autoantibodies. In general, recombinant forms of BP180 and BP230 expressed in prokaryotic or eukaryotic systems are used for the detection of autoantibodies (Fig. 30.13C)[9,10,18,20].

Differential Diagnosis

Because the clinical findings in the non-bullous forms of BP may be nonspecific, they can resemble a variety of dermatoses, including drug reactions, contact dermatitis, prurigo (simplex and nodularis), urticarial dermatoses, arthropod reactions, and scabies[18,20,22]. These disorders are usually distinguished on the basis of the clinical history and setting, pathologic features, and the negative findings with IF microscopy. The presence of bullae raises the possibility of bullous arthropod bites and the eosinophilic dermatosis of hematologic malignancy, allergic contact dermatitis, bullous drug eruptions (see Ch. 33), dyshidrotic eczema, pseudoporphyria, or porphyria cutanea tarda. In children, bullous impetigo, inherited epidermolysis bullosa, and bullous mastocytosis must also be considered.

The pemphigus group, paraneoplastic pemphigus, and dermatitis herpetiformis can be differentiated on the basis of distinctive immunopathologic findings and clinical context. In patients with a subepidermal blistering disorder associated with linear deposits of IgG or C3 along the BMZ, the presence of the following clinical criteria point to the diagnosis of BP: (1) absence of skin atrophy; (2) absence of mucosal involvement; (3) absence of head and neck involvement; and (4) age greater than 70 years[18,20,22]. Nevertheless, the distinction of BP from the following disorders can sometimes prove challenging (see Table 30.1).

- **Epidermolysis bullosa acquisita (EBA)** has a wide spectrum of clinical presentations (see below). While the classic "non-inflammatory" form of EBA is sufficiently distinctive, the "inflammatory" form closely mimics BP. As in BP, mucosal involvement may be present[18,20].
- **Linear IgA bullous dermatosis (LABD)** represents a group of subepidermal blistering diseases rather than a single entity (see Ch. 31). While features of LABD are polymorphic in adults, during childhood the condition is frequently associated with annular and polycyclic lesions, often with peripheral blisters, as well as involvement of the genital and perioral region. However, identical features are also observed in childhood BP (see Fig. 30.7B)[18,20].
- **Anti-p200 pemphigoid (anti-laminin γ1 pemphigoid)**. Although patients often have features similar to BP, they tend to be younger and are more likely to have involvement of palmoplantar and cephalic regions as well as the oral mucosa. Neutrophils are usually the predominant cells within the inflammatory infiltrate. These patients have circulating autoantibodies that bind to: (1) the dermal side of salt-split human skin; and (2) a 200 kDa protein in immunoblots of human dermal extracts. The major target antigen, detected by ~90% of sera, is laminin γ1 (see Table 30.1); additional

target antigens, which may be pathologically important, have also been identified[20,34]. Of note, anti-p200 pemphigoid and psoriasis often co-exist, especially in Japanese patients.

- **Mucous membrane pemphigoid (MMP)** is a heterogeneous group of diseases which have in common the predominant involvement of the mucosae, a chronic course, and a scarring tendency (see below)[20]. Skin lesions occur in up to 30% of patients and favor the head and upper trunk. When there is both mucosal and cutaneous involvement, distinction from BP may be difficult, but a predominance of mucosal lesions with a scarring tendency and limited skin involvement point to MMP.
- **Chronic pruritic dermatoses of the elderly and early-stage BP**. In the elderly, pruritus, alone or in combination with nonspecific skin lesions, is a common complaint. There are myriad underlying causes and a thorough assessment is often required (see Ch. 6). A dilemma arises when patients with pruritus have circulating autoantibodies to the epidermal BMZ and reactivity with BP180 and/or BP230, but routine DIF microscopy remains negative[18,35]. A small minority of these patients, with initially negative DIF microscopy findings, eventually develop BP[18]. With few exceptions, DIF remains a more definitive diagnostic test than either IIF or ELISA[22].

Prognosis

BP is a chronic disease characterized by spontaneous exacerbations. Approximately 30% of BP patients have a relapse during their first year of treatment, with extensive disease and associated dementia representing independent risk factors for relapse. Furthermore, after cessation of therapy, ~50% of patients experience a relapse, most often within the first 3 months[18,36].

Mortality is considerable among elderly patients. The estimated death rate during the first year varies between 10% and 40%, depending on the series[6,18,20,36]. Older age, dementia, history of a cerebrovascular accident (CVA), and low Karnofsky score have a negative impact on survival[6,36]. The use of systemic corticosteroids or immunosuppressive drugs is also likely to influence overall mortality. Impaired quality of life is obviously an issue for many patients given the associated symptoms[21,22].

Monitoring

The practicality of using the results of quantitative serologic tests, such as ELISA-BP180 or perhaps distinct inflammatory biomarkers[13], as a means of guiding treatment remains to be established. That said, serum

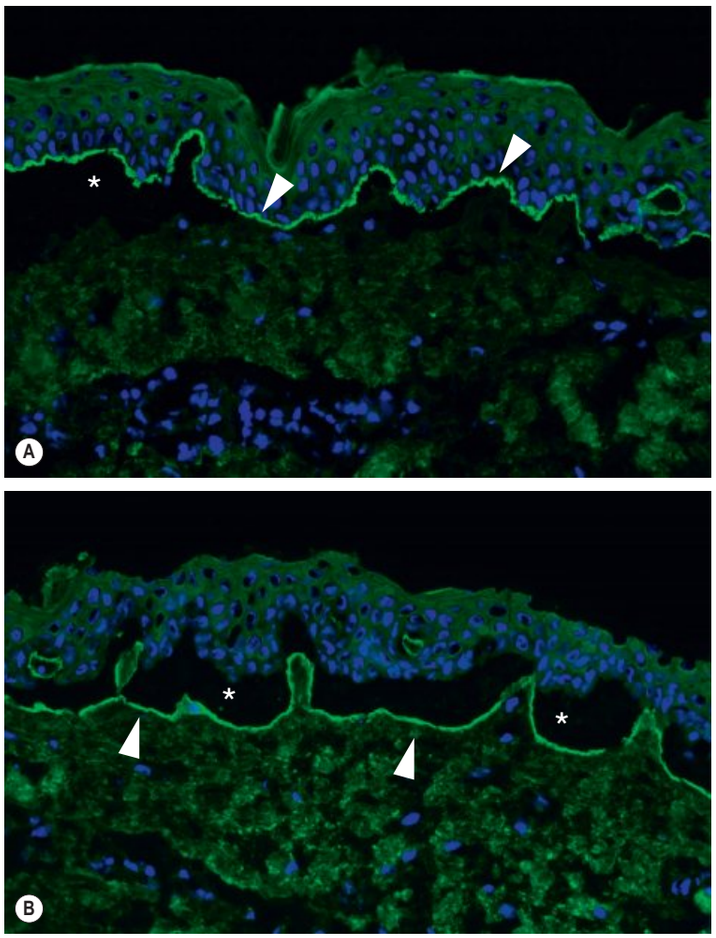

Fig. 30.12 Indirect immunofluorescence (IIF) microscopy utilizing salt-split human skin. Pas, MD.*

levels of IgG autoantibodies to BP180 correlated with disease severity in several ELISA-based studies[8,9,20,36]. Furthermore, determination of anti-BP180 IgG antibody levels by ELISA at days 0, 60, and 150 appeared to help predict disease relapse – a small (<20%) decrease in serum autoantibody levels between days 0 and 60 was associated with relapse during the first year of therapy[35]. Finally, a high BP180–NC16A ELISA score (>27 U/ml) and, to a lesser degree, positive DIF findings at cessation of therapy are both good indicators of future relapse of BP.

As noted previously, the extent and degree of disease activity can be assessed by employing the BP disease area index (BPDAI)[21] or a daily blister count.

Treatment

The choice of treatment depends on the severity of the disease and comorbidities (Tables 30.3 and 30.4)[22,37–47]. For **extensive** disease, often defined as >10 new blisters/day or inflammatory lesions involving large areas or multiple body sites, either systemic or widespread ultrapotent corticosteroids are employed. *Oral prednisone* (0.5–0.75 mg/kg/day; 1 mg/kg may result in significant side effects and increased mortality) usually controls the disease within 1–2 weeks. If there are no new lesions or pruritus for at least 2 weeks[22,39], then the dosage is progressively tapered to a low dose over a period of 4–6 months, or occasionally longer. Low-dose prednisone is then continued for an additional 3–6 months[22]. Rarely, pulse therapy with methylprednisolone is required for rapid control of the disease. In controlled trials, *ultrapotent topical corticosteroids*, e.g. clobetasol propionate 0.05% cream, had the same efficacy as oral corticosteroids, with fewer systemic side effects and reduced mortality[22,41]. Two topical regimens have been described: standard and mild, in which the starting doses are clobetasol 40 g/day and clobetasol 10–30 g/day, respectively (see Table 30.3)[41]. While ultrapotent topical corticosteroids can be tried first, cost, compliance, and ease of application in the elderly may be limiting factors.

Immunosuppressive therapies can serve as *steroid-sparing agents* and are employed when corticosteroids alone fail to control the disease, there are contraindications to the use of systemic corticosteroids, and/or comorbidities exist that limit the dosage of corticosteroid (e.g. diabetes mellitus, osteoporosis, psychosis)[22]. The most frequently employed agents are azathioprine, mycophenolate mofetil (1.5–3 g/day), methotrexate (7.5–15 mg/week), and cyclophosphamide (see Table 30.4). The dosage of azathioprine (0.5–2.5 mg/kg/day) should be adjusted according to the level of thiopurine methyltransferase, in order to increase efficacy and reduce myelosuppression (see Ch. 130). In the elderly, the dose of methotrexate requires careful monitoring as renal function is often

SURVEY OF SELECTED CONTROLLED TRIALS FOR THE TREATMENT OF PATIENTS WITH BULLOUS PEMPHIGOID						
Authors (year)	**Trial design**	**Intervention**		**Number of patients**	**Response**	**Remarks**
Guillaume et al.[37] (1993)	Randomized, multicenter	Group 1	Prednisolone (1 mg/kg/day) alone	98	At month 6, no significant difference in remission rate between group 1 (42%), group 2 (39%), and group 3 (29%)	More complications in group 2 No adjustment of doses of azathioprine based on TPMT levels
		Group 2	Prednisolone plus azathioprine (100–150 mg/day)			
		Group 3	Prednisolone plus 4 plasma exchanges			
Joly et al.[39] (2002)	Randomized, multicenter	Group 1	Topical clobetasol propionate	341	At week 3, control rates better in group 1	At year 1, topical therapy was associated with a significantly reduced mortality and complication rate
		Group 2	Prednisone (0.5–1 mg/kg/day)			
Beissert et al.[40] (2007)	Randomized, multicenter, prospective	Group 1	Methylprednisolone (0.5 mg/kg/day) plus azathioprine (2 mg/kg/day)	38	Disease control similar in the two groups	In group 1, higher incidence and severity of liver toxicity Trend for faster disease control and less total cumulative doses of corticosteroids in group 1 No adjustment of doses of azathioprine based on TPMT levels
		Group 2	Methylprednisolone (0.5 mg/kg/day) plus mycophenolate mofetil (2 g daily)	35		
Joly et al.[41] (2009)	Randomized, multicenter, prospective	Group 1	Topical clobetasol propionate *standard* regimen for 12 months (40 g daily as starting dose)	153	Time to achieve disease control similar in both groups At 1 year, trend for higher relapse rate in patients with moderate BP treated with *mild* regimen	In moderate BP treated with *mild* regimen, decrease in side effects and death Lower cumulative dose of clobetasol in *mild* regimen
		Group 2	Topical clobetasol propionate, *mild* regimen for 6 months (10–30 g daily as starting dose)	159		
Williams et al.[42] (2017)	"Pragmatic" parallel-group, randomized, multicenter, prospective	Group 1	Doxycycline (200 mg/day); localized adjuvant potent topical corticosteroids permitted during first three weeks After 6 weeks, possible switch to group 2	132	At week 6, proportion of participants with ≤3 blisters is lower in group 2 (adjusted difference favors prednisolone) At one year, severe and fatal events appear to be lower in group 1	Per authors, doxycycline noninferior for short-term blister control and better long-term safety profile Limitations include study design with possible switch in treatment and use of topical corticosteroids by some participants
		Group 2	Prednisolone (0.5 mg/kg per day) After 6 weeks, possible switch to the other therapy or adjustment of prednisolone dose	121		
Amagai[43] (2017)	Randomized, double-blind multicenter	Group 1	Add-on therapy with IVIg (2 g/kg/day) in patients with no improvement on prednisolone ≥0.4 mg/kg/day	29	Trend towards better responses in group 1 during the observation period (days 15 and 56 were time points)	Primary endpoint did not reach statistical significance (but *post-hoc* analysis of covariance demonstrated clinical significance) Compared to placebo, IVIg improved severe disease and increases in prednisolone dose not required
		Group 2	Placebo as add-on therapy in patients with no improvement on prednisolone ≥0.4 mg/kg/day	27		
Simon et al.[44] (2019)	Randomized, placebo-controlled, double-blind, single institution	Group 1	Mepolizumab (750 mg every 4 weeks for 12 weeks) in addition to standard of care: prednisolone (0.5 mg/kg/day) with discontinuation of prednisolone within 12 weeks	20	Group 1 regimen (i.e. add-on mepolizumab) did not significantly affect clinical outcome at weeks 16 and 36	For patients on prednisolone, mepolizumab did not significantly impact disease control or relapse rate compared to placebo Significantly lower number of circulating eosinophils in group 1, but no difference in tissue eosinophils Inclusion of few patients with severe disease could obscure effect of mepolizumab
		Group 2	Placebo every 4 weeks for 12 weeks in addition to standard of care with prednisolone (see group 1)	10		

Table 30.3 Survey of selected controlled trials for the treatment of patients with bullous pemphigoid. TPMT, thiopurine methyltransferase.

significantly reduced. The choice of a particular immunosuppressive drug depends on its side-effect profile, the patient's overall condition, and the experience of the physician.

For **localized** involvement or mild disease with a limited number of non-bullous inflammatory lesions, potent topical corticosteroids represent first-line therapy[21]. Tetracycline, doxycycline or minocycline, alone or in combination with nicotinamide (500–2000 mg/day), can lead to clinical improvement and may be considered as a therapeutic alternative when contraindications to corticosteroids exist[22,38]. A trial comparing doxycycline with prednisolone reported acceptable blister control and a better safety profile with doxycyline, but the latter often needed to be combined with corticosteroids during the course of the disease[42]. Unless there is glucose-6-phosphate dehydrogenase deficiency, the use of dapsone may also be warranted, particularly in the presence of mucosal involvement; topical immunomodulators (e.g. tacrolimus) are an additional option.

THERAPEUTIC LADDER FOR BULLOUS PEMPHIGOID Rx
Mild and/or localized disease
First-line
• Superpotent topical corticosteroids (1*) • Oral corticosteroids† (1) • Minocycline, doxycycline or tetracycline, alone or in combination with nicotinamide (1)
Second-line
• Topical immunomodulators (e.g. tacrolimus) (3) • Dapsone, sulfonamides (3) • Erythromycin, penicillins (3)
Extensive/persistent cutaneous disease
First-line, as primary treatment
• Superpotent topical corticosteroids (1*) • Oral corticosteroids† (1‡)
Second-line, or as adjunctive therapy
• Azathioprine (1) • Mycophenolate mofetil (1) • Methotrexate¶ (2) • Omalizumab (3) • Dupilumab (3) • IVIg (1) • Rituximab (3) • Cyclophosphamide (3) • Immunoadsorption (3)
Note: Superpotent topical corticosteroids should be considered in any patient and may be combined with a systemic therapy.
*Validated. †Prednisone doses of at least 0.5–0.75 mg/kg/day seem to be necessary to control extensive disease, with increased side effects and mortality at 1 mg/kg. For mild to moderate disease, 0.5 mg/kg/day is sufficient. ‡Validated for prednisone. ¶In elderly patients, low-dose regimen (2.5–10 mg/week) can be effective.

Table 30.4 Therapeutic ladder for bullous pemphigoid. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

In case series, both dupilumab and omalizumab have been used as monotherapy or as steroid-sparing agents with favorable responses and safety profiles (see Ch. 128)[45,46]. The pathogenic roles of IL-4 and IL-13 signaling pathways as well as IgE autoantibodies suggest that they are potential therapeutic targets in BP. In treatment-resistant cases, anti-CD20 immunotherapy (rituximab)[47] and IVIg can also be considered. Therapies under investigation include inhibitors of IL-17, IL-12/-23, IL-5Rα, eotaxin, and complement molecules (e.g. C5aR).

While the optimal duration of therapy has not been established, BP patients usually need to be treated for a range of 9–12 months, depending upon the severity of the disease and therapeutic response. The exception is steroid-resistant or steroid-dependent disease. This time period includes a maintenance phase in which low-dose oral prednisone (<10 mg/day) or topical clobetasol propionate (10 g/week) is continued for 1 to 6 months after cessation of clinically active disease[25]. Finally, in all patients with BP, it is important to minimize the complications of both the cutaneous lesions and the systemic treatment, including using osteoporosis prophylaxis and gastric protection (see Ch. 125).

MUCOUS MEMBRANE PEMPHIGOID

Synonyms (becoming historical): ■ Cicatricial pemphigoid ■ Benign mucous membrane pemphigoid

Subtypes/variants: ■ Anti-laminin 332 (mucous membrane) pemphigoid – anti-epiligrin cicatricial pemphigoid ■ Brunsting–Perry pemphigoid

Key features

- Mucous membrane pemphigoid is a chronic, autoimmune, subepithelial blistering disorder characterized by predominant involvement of the external mucosal surfaces and a tendency for scarring
- It is associated with tissue-bound and, less often, serum autoantibodies directed against distinct structural components of basement membranes in stratified and some complex epithelia: BP180, BP230, laminin 332 (laminin 5), type VII collagen, and likely integrin β_4 and α_6 subunits
- The condition should not be regarded as a clinical entity, but as a "disease phenotype" shared by a heterogeneous group of diseases with lesions that favor the mucosal surfaces and, less frequently, the skin
- As scarring frequently affects the conjunctivae, the disorder can be devastating and ultimately lead to blindness
- Diagnosis relies on immunopathologic examinations, especially DIF microscopy, and serological immunoassays

Introduction

Mucous membrane pemphigoid (MMP) is a rare autoimmune subepithelial blistering disorder characterized by predominant involvement of the mucosae, a chronic course, and a tendency towards scarring of the affected areas. The disorder should not be regarded as a clinical entity, but rather as a "disease phenotype" shared by a heterogeneous group of blistering diseases, with predilection for the mucosal surfaces[48]. The majority of patients have linear deposits of immunoglobulins and/or complement components along the epithelial BMZ of the skin and mucosae. Circulating anti-BMZ autoantibodies are detected in the serum of some patients (20%–30% by standard IIF), usually at a low titer or concentration. It is a chronic and progressive disease, which may result in serious mucosal complications. When postinflammatory atrophy or scarring affect the conjunctivae, the disorder can be devastating and ultimately lead to blindness.

History

In 1794, Wichmann first described a chronic blistering disease associated with involvement of the eyes. Civatte separated this disorder from pemphigus on the basis of peculiar histopathologic findings in 1949, and Lever later suggested the name "benign mucous membrane pemphigoid", a misnomer in view of the potentially severe complications of the disorder. During the latter part of the 20th century, the term "cicatricial pemphigoid" was used primarily. In 2012, based upon an international consensus conference, the term "mucous membrane pemphigoid" was proposed. Demonstration of immunoreactants deposited along the epithelial BMZ by IF microscopy pointed to an autoimmune origin.

Epidemiology

The annual incidence of MMP is ~1 to 2 cases per million population[49], with a calculated prevalence (in Germany) of 25 cases per million inhabitants. MMP typically occurs in the elderly, with a mean age at the time of diagnosis of between 60 and 80 years. However, isolated cases have been reported in children. Women are affected more frequently than men (estimated ratio 1.5–2:1). Although no geographic or racial predilection has been described, several studies have shown an association with specific immunogenetic HLA class II haplotypes, e.g. HLA-DQw7 (subtype HLA-DQB1*03:01), in both oral and ocular forms of the disease[50]. There is no overall association with malignancy, but in a distinct subtype associated with IgG autoantibodies directed against laminin 332 (also known as anti-epiligrin cicatricial pemphigoid), an increased relative risk for cancer has been suggested[48,51]. Although this is debated, a search of an associated solid tumor may be recommended in case of anti-laminin 332 reactivity.[48] For example, in a retrospective study of 154 patients, an association of anti-laminin 332 reactivity with malignant neoplasms was noted, with an adjusted odds ratio of 23[50a]. Recently, MMP has been observed in patients receiving immune checkpoint inhibitors.

Pathogenesis

Mucocutaneous lesions are thought to result from the binding of autoantibodies to the BMZ of stratified epithelia of mucosae and skin. These autoantibodies recognize distinct structural components of the hemidesmosomal adhesion complex. Specifically, they appear to bind predominantly to antigenic sites located extracellularly within the anchoring filament zone rather than within the hemidesmosomal plaque[52]. However, the pathogenicity of various IgG autoantibodies associated with this disease phenotype (see Table 30.1) has not yet been established unequivocally and other mechanisms may also be involved. In a minority of patients with MMP, BP180–NC16A domain-specific T cells are detectable. Increased expression of collagen-binding heat shock protein 47 (HSP47) and TGF-β1 by conjunctival fibroblasts may contribute to the conjunctival scarring seen in patients with ocular disease[53].

Based upon their autoantibody profile, patients with MMP can be divided into four distinct subgroups. The **first** subgroup includes those with autoantibodies directed against laminin 332. This subgroup was previously referred to as *anti-laminin 332 MMP* or anti-epiligrin cicatricial pemphigoid[54]. It is estimated that 18%–30% of patients with MMP belong to this subgroup[55]. Patients with anti-laminin 332 IgG autoantibodies frequently have multiple sites of mucosal involvement, including the pharynx, larynx, and trachea[48]. Their circulating IgG autoantibodies bind to the dermal side of salt-split skin and react with the α_3 chain (G domain) and, less frequently, the β_3 and/or γ_2 chain of laminin 332 ($\alpha_3\beta_3\gamma_2$) (see Fig. 28.5). Occasionally, antibody binding to the α_3 chain of laminin 311 (previously termed laminin 6 [a heterotrimer of $\alpha_3\beta_1\gamma_1$ chains]) is also observed because of the presence of cross-reacting autoantibodies. *In vitro* and *in vivo* studies have provided convincing evidence that autoantibodies to laminin 332 are pathogenic[55].

In the **second** group of patients, involvement is exclusively or predominantly ocular. IgG autoantibodies that bind to the β_4 subunit of $\alpha_6\beta_4$ integrin, a transmembrane hemidesmosomal component that interacts with laminin 332, have been described anecdotally. Some clinicians refer to this subset as *ocular MMP* (see Fig. 28.3A)[56].

A **third** subgroup of patients, who lack a specific clinical phenotype, have tissue-bound and circulating IgG antibodies that react with the same target antigens as in BP, especially BP180. These patients, who have been classified as having *anti-BP antigen MMP*, represent the largest subgroup. The antigenic regions targeted on BP180 are located within the NC16A domain and on its distal COOH-terminal portion. The latter appears to extend into the lamina densa region of the BMZ (see Fig. 28.3A)[52]. There is ample scientific evidence that anti-BP180 IgG antibodies are pathogenic[11].

The **fourth** group is rather heterogeneous. It includes patients who have variable involvement of the mucosae without involvement of the skin. While it is yet unclear whether injury occurs as a result of an autoantibody-mediated immune response against proteins of the BMZ, a few patients with an MMP phenotype have shown reactivity against type VII collagen. It has been reported that a small subset of patients with oral MMP have autoantibodies which bind to the α_6 subunit of $\alpha_6\beta_4$ integrin, but this needs to be validated[57].

Clinical Features

Mucous membranes

The two most frequently involved sites in patients with the "mucous membrane pemphigoid phenotype" are the oral and conjunctival mucosae. However, the disease may also start in, and affect, any mucosal site, including the nasopharyngeal, anogenital, laryngeal, or esophageal mucosa (in descending order of frequency)[48,58–60].

Approximately 90% of patients have oral involvement (often in the absence of skin lesions), and the oral cavity may be the only site of disease activity in up to 30% of patients. Lesions frequently involve the gingiva, buccal mucosa, and palate; the alveolar ridges, tongue, and lips are less commonly affected. A classic oral presentation is desquamative gingivitis accompanied by bleeding erosions and paresthesias (Fig. 30.14A); small intact blisters are rarely observed. Chronic inflammation may lead to periodontal ligament damage and the loss of teeth. In other areas of the mouth, transient vesicles give rise to chronic erosions, especially on the palate (Fig. 30.14B), with variable associated pain. Lesions on the tongue are usually localized to its lateral and ventral surfaces. Adhesions may develop in the area of the uvula and tonsillar fossae as well as between the tongue and the floor of the mouth. White, reticulated striations that resemble oral lichen planus may also be seen.

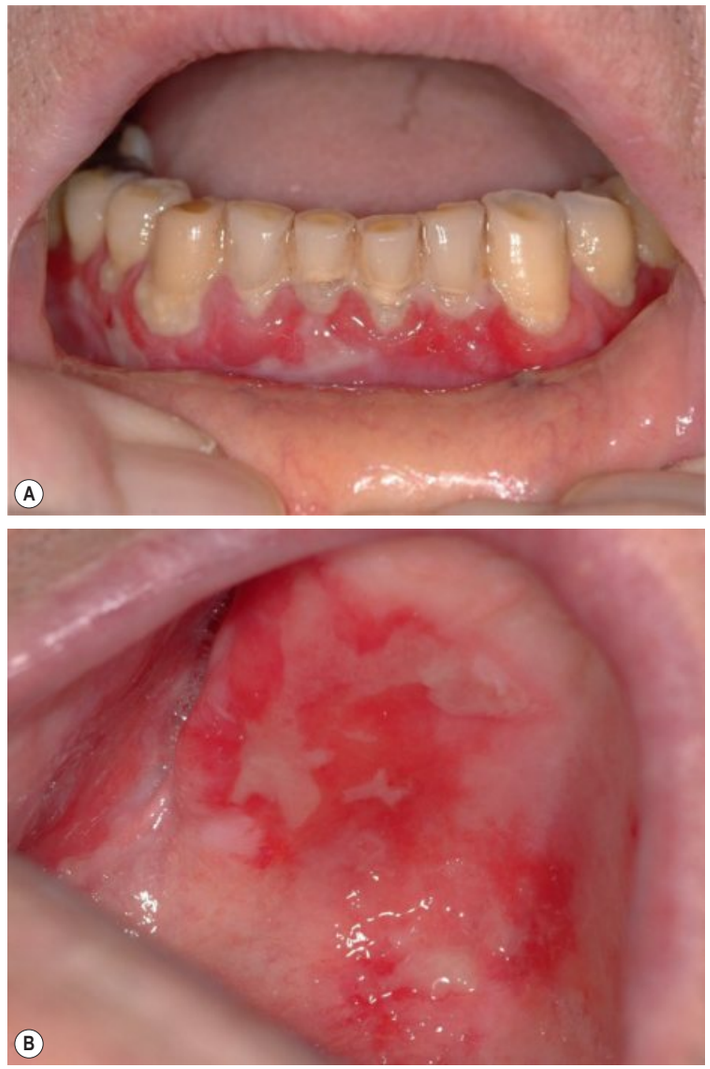

Fig. 30.14 Mucous membrane pemphigoid. A Desquamative gingivitis with erythema and erosions of the gingival margins. Note the sloughing of the mucosa with shaggy margins. **B** Chronic erosions on the hard palate with irregular borders. Sloughing of mucosa is seen superiorly.

Conjunctival involvement occurs in ~40% of patients[48,54] and can result in blindness[60]. The conjunctivae are frequently the only site affected. Although the disease may begin unilaterally, in the majority of patients, lesions appear in both eyes. Ocular involvement starts as a nonspecific chronic conjunctivitis and limbitis, with burning, soreness, foreign-body sensation, decreased vision, and/or mucus production. Periods of exacerbations and subsequent remissions are typical, with eventual progression to a scarring due to subepithelial conjunctival fibrosis (Fig. 30.15).

Conjunctival vesicles or blisters are rare on the tarsal conjunctiva. Chronic inflammation may result in progressive scar tissue formation, leading to a shortened inferior fornix and symblepharon (an adhesion between bulbar and palpebral conjunctival surfaces; Fig. 30.16) as well as ankyloblepharon. Conjunctival fibrosis can also result in trichiasis (inwardly angled eyelashes) and entropion[60]. In uncontrolled disease, trichiasis, entropion, and xerosis (due to scarring of the lacrimal ducts) eventuate in superficial corneal trauma, corneal neovascularization with subsequent corneal ulceration, and blindness[48].

Nasopharyngeal involvement occurs in a third of patients with MMP and is typically chronic and asymptomatic[48,59]. It results in crusted intranasal ulcerations, epistaxis, fibrous adhesions between adjacent mucosal surfaces, and airway obstruction. Pharyngeal involvement presents as ulcerations of the posterior or lateral pharynx and dysphagia. Laryngeal involvement is a potentially serious manifestation, presenting as hoarseness, loss of speech, and even life-threatening stenosis, which requires tracheostomy.

Although esophageal disease may be accompanied by dysphagia resulting from erosions of the esophageal mucosa, involvement can be

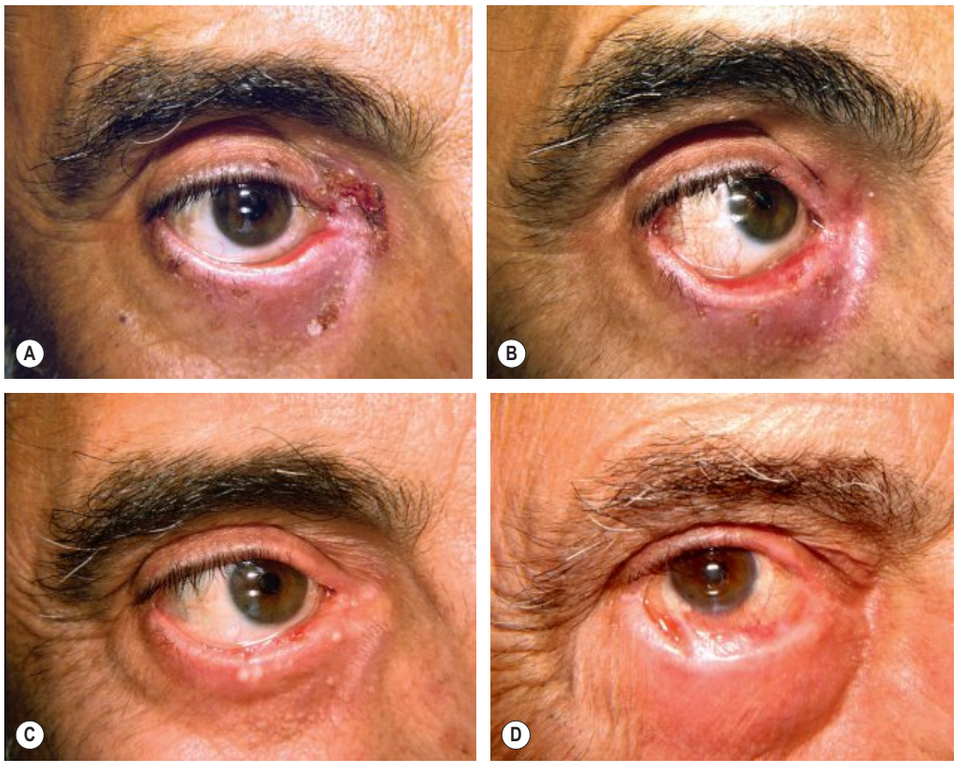

Fig. 30.15 Ocular involvement in mucous membrane pemphigoid. A Erosion and erythema of the lower medial eyelid margin plus scale-crust of the inner canthus and lower eyelid. **B** Three months later, ectropion and thickening of the lower eyelid in addition to erosions. **C** Six months later, smaller erosions but scarring and milia formation. **D** Seven years later, further scarring with significant shortening of the inferior fornix due to symblepharon. *Courtesy Louis A. Fragola, Jr, MD.*

entirely asymptomatic. Chronic inflammation can lead to strictures and stenosis, with associated dysphagia[48].

Involvement of genital and anal mucosae is relatively uncommon, but increasingly recognized. Early lesions consist of blisters and chronic erosions. In female patients, progressive disease leads to scarring and narrowing of the introitus. In male patients, adhesions can form between the prepuce and the glans penis. Anal involvement can also lead to scarring and, in severe cases, to stricture formation[48].

Cutaneous lesions

The skin is involved in 20%–35% of patients. The most frequently involved sites are the scalp, face, neck, and upper trunk. Lesions typically present as erythematous plaques, which become sites for recurrent blister formation and erosions, with subsequent scarring. Their extent and number are generally limited, but an individual patient can have a BP-like clinical presentation[48].

In the *Brunsting–Perry variant*, skin lesions are localized predominantly to the head and neck and upper trunk (Fig. 30.17A,B)[61]. Mucosal involvement is usually absent or minimal. On the scalp, significant scarring alopecia can result (Fig. 30.17C).

Diagnosis and Differential Diagnosis

The diagnosis of MMP has to be considered in all patients who have blistering or erosive lesions that predominantly involve mucous membranes and whose affected tissues show linear, continuous deposits of immunoreactants along the epithelial BMZ. Unfortunately, there is frequently a significant delay, often more than a year, before the diagnosis is established. As a result, moderate to severe scarring, especially ocular, may have already occurred.

Light microscopy and electron microscopy

The histopathologic features of MMP and BP are often similar. Examination of a fresh vesicle or bulla demonstrates subepithelial or subepidermal blister formation (without acantholysis). A mixed cellular infiltrate of variable intensity is present, with a predominance of neutrophils; the number of eosinophils is increased in older lesions, but they are still fewer than in BP. Older lesions also tend to have scarring in the submucosa or upper dermis. In oral lesions, the inflammatory infiltrate typically contains some plasma cells, a nonspecific finding related to the mouth being a mucosal site. The epithelium of affected conjunctivae is often invaded by inflammatory cells, including mononuclear cells and mast cells, while granulation tissue is found in the submucosa.

In most cases, electron microscopy studies of a fresh blister demonstrate that the dermal–epidermal cleavage occurs within the lamina lucida. In advanced conjunctival lesions with scarring, the lamina densa appears to be discontinuous, focally thickened, or duplicated.

Direct immunofluorescence (DIF) microscopy

By DIF microscopy, 80%–95% of patients with MMP have *in vivo* bound autoantibodies directed against the BMZ of mucosae and/or skin. The majority of patients exhibit continuous, fine, linear deposits of IgG, IgA, and/or C3 along the epithelial BMZ in perilesional biopsy specimens. It should be noted that DIF microscopy studies of mucosae are more frequently positive (50%–90%) than those of skin (20%–50%). IgG deposits belong primarily to the IgG4 and IgG1 subclasses; deposits of IgM and fibrin are less common. DIF microscopy of salt-split skin is of less diagnostic value. Although a combined pattern with staining of both the epidermal and dermal sides is frequently observed, reactivity with either the epidermal roof or the dermal floor of the separated skin is occasionally noted. If circulating autoantibodies are not detected, analysis of the

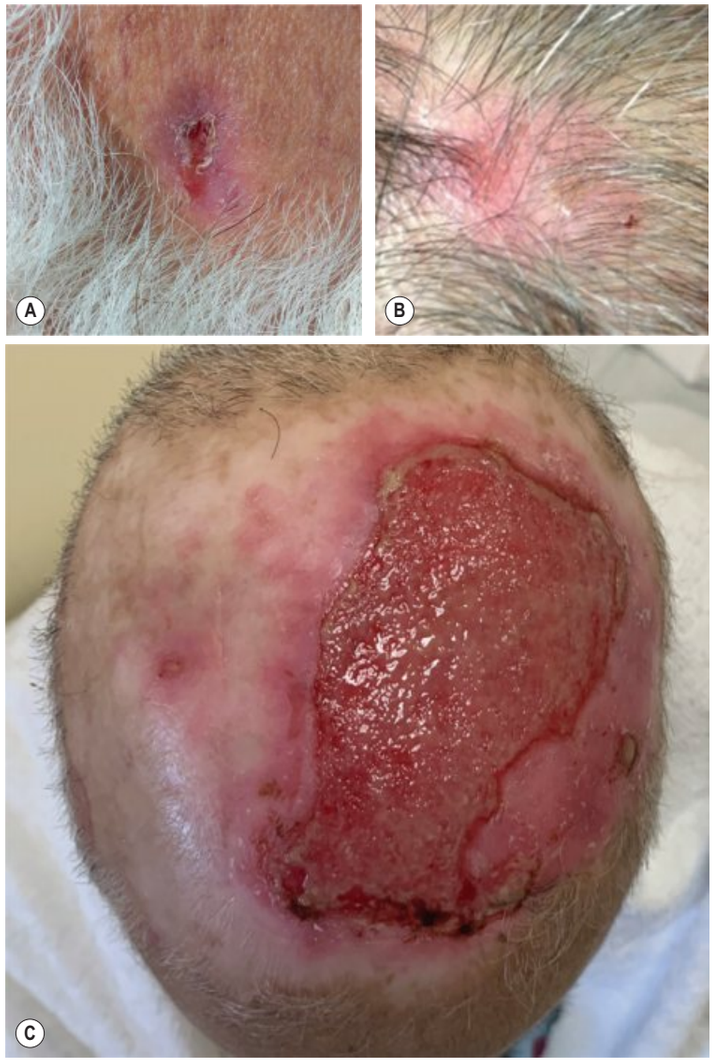

Fig. 30.17 Mucous membrane pemphigoid – Brunsting–Perry variant. Duncan, MD; C, Courtesy Michael Gowen, MD.*

linear fluorescence pattern of autoantibody deposits at the cutaneous BMZ (*n-serrated* [pemphigoid group] versus *u-serrated* [EBA]) or results of the FOAM technique (see above) may prove helpful. Of note, in mucosal specimens, the serration pattern cannot be assessed[48].

Immunoelectron microscopy

Although electron microscopy studies are not routinely available and are time-consuming, they may be particularly useful in establishing the diagnosis of MMP, especially in patients in whom standard DIF and IIF microscopic findings are negative. Direct immunoelectron microscopy studies in MMP have demonstrated immune deposits distributed either: (1) in the lower lamina lucida and above the lamina densa; or (2) on and around hemidesmosomes, with most of the labeling on the outside of basal keratinocytes below their plasma membranes[48,52].

Indirect immunofluorescence (IIF) microscopy

By standard IIF, anti-BMZ autoantibodies can be detected in serum samples from 20%–30% of patients with MMP. Antibodies are mainly of the IgG class, but circulating IgA or IgE may also be detected. Antibody concentrations are usually very low. Some authors have suggested that patients with high serum levels of IgG and IgA anti-BMZ autoantibodies have more severe disease[62]. The sensitivity of IIF can be increased either by the use of normal oral or genital mucosa and conjunctiva as substrates, or by utilizing salt-split skin. Using this latter technique, most patients with MMP have antibodies that bind to the epidermal roof, whereas MMP patients with anti-laminin 332 or anti-type VII collagen reactivity have IgG antibodies that bind to the dermal side (see Fig. 30.12). The use of salt-split oral mucosa does not improve the overall sensitivity. Distinguishing MMP with anti-laminin 332 autoantibodies from EBA may be possible by IIF microscopy using "knockout" skin substrates, i.e. substrates deficient in specific basement membrane proteins[63].

Immunochemical studies, including ELISA

Immunochemical techniques, including ELISA, immunoblots, and immunoprecipitation, have confirmed that the autoantigens targeted in patients with a MMP phenotype are heterogeneous[54,55,57,63–67]. Serum autoantibodies react with various proteins located within the epithelial BMZ, e.g. BP180, laminin 332, type VII collagen (see Table 30.1). Depending upon the patient population and specific assay, IgG anti-BP180 or anti-laminin 332 antibodies are detected in 30–70% or 15–30% of MMP patients, respectively. These targeted antigens appear to constitute serologic markers for different subgroups of MMP (see above).

Patients may have IgA autoantibodies directed against the ectodomain of BP180[6]. As a result, salivary IgG and IgA autoantibodies directed against BP180–NC16A may serve as diagnostic biomarkers. In some cases, these autoantibodies appear to preferentially bind to antigenic reactive sites present on the proteolytically cleaved and shed portion of the extracellular domain of BP180, i.e. the LABD antigen (LAD-1; see Ch. 31). Lastly, several unidentified target antigens of varying molecular weights have also been reported.

ELISAs that utilize recombinant proteins or affinity-purified native proteins (e.g. BP180, laminin 332, type VII collagen) can be useful in the search for circulating autoantibodies[31].

Differential diagnosis

Distinction from other subepidermal autoimmune bullous diseases (including BP, EBA, and LABD) may be difficult and often relies on the predominance of mucosal involvement and chronic course. In contrast, pemphigus vulgaris and non-autoimmune blistering diseases are more easily excluded via histology and IF microscopy.

If oral involvement, especially isolated desquamative gingivitis, is the sole manifestation of MMP, it can be difficult to differentiate clinically from pemphigus vulgaris or erosive lichen planus. End-stage, scarring conjunctival lesions may mimic severe chronic infectious conjunctivitis, ocular pseudopemphigoid due to ophthalmologic preparations (including pilocarpine, idoxuridine, guanethidine, β-blockers), or sequelae of Stevens–Johnson syndrome and toxic epidermal necrolysis. While the rare, generalized cutaneous form of MMP can be impossible to distinguish from BP, involvement of multiple mucosal sites favors the former.

Prognosis

MMP is a particularly chronic, potentially devastating, but rarely fatal disease. The most important complication is impairment of vision due to ocular involvement. It can also lead to weight loss as well as respiratory, sexual, or urinary complications. Even with localized involvement, this disease can have a major negative impact on quality of life. Life-threatening complications, due to severe laryngeal, tracheal or esophageal disease, are rare.

Treatment

Treatment can be difficult and at times frustrating, with therapeutic regimens based primarily on clinical experience[67].

Local therapy is crucial and, for limited involvement, it can be sufficient. Mild to moderate disease activity may be successfully treated with potent topical corticosteroids. Oral lesions can respond to topical corticosteroids (as mouthwashes or topical preparations in a gel or occlusive base supplemented by customized prosthetic devices to provide occlusion) in conjunction with tetracycline mouthwashes and professional dental hygiene. Corticosteroid sprays and inhalers may prove useful in nasal, pharyngeal, or esophageal disease. Recalcitrant lesions of both skin and mucous membranes may improve with intralesional injections of triamcinolone. Esophageal strictures may require dilatations to prevent dysphagia, while severe tracheal involvement may require a tracheostomy to prevent asphyxiation[68].

Systemic medications include dapsone (50–150 mg/day) as a first-line therapy for controlling oral and cutaneous lesions, and it may also

be used for mild ocular disease without rapid worsening. Dapsone can be particularly beneficial in patients with linear deposits of IgA at the BMZ. Cyclophosphamide (1–2 mg/kg/day) is considered the treatment of choice for rapidly progressive or severe ocular disease[60] – alone, in combination with oral corticosteroids, or as pulse therapy. Such regimens are effective in resolving severe conjunctival inflammation and preventing recurrences and secondary scarring. Azathioprine (2 mg/kg/day) and mycophenolate mofetil (2 g/day) have also been reported to be helpful in reducing the dose of corticosteroids required for control of ocular involvement and cutaneous lesions.

Systemic corticosteroids alone are generally insufficient therapy for patients with significant disease, and they are less effective for mucosal than for cutaneous disease. Patients with significant esophageal or laryngotracheal involvement should be treated aggressively with the combination of prednisone and cyclophosphamide or mycophenolate mofetil to prevent potentially life-threatening complications. Other therapies reported to be of potential value in the treatment of MMP include topical tacrolimus, a combination of tetracycline and niacinamide, minocycline, sulfapyridine, methotrexate, TNF inhibitors, IVIg, topical or systemic cyclosporine, thalidomide, and subconjunctival mitomycin[69–73]. Case series have also underscored the efficacy of rituximab in controlling progressive ocular involvement and severe extraocular complications[67,72]. When these manifestations fail to respond to cyclophosphamide plus corticosteroids or there is an intolerance or contraindication to this regimen, rituximab can be considered as second-line therapy[58].

Surgical therapy may occasionally be necessary for severe scarring involving the eye, larynx, esophagus, or genitalia. It should be performed when the disease is fully controlled by medical therapy. For ocular disease, surgical intervention includes corneal grafts, allograft limbal transplantation, amniotic membrane transplantation, and tarsorrhaphy.

EPIDERMOLYSIS BULLOSA ACQUISITA

Synonym: ■ Acquired epidermolysis bullosa; dermolytic pemphigoid

Key features

- Epidermolysis bullosa acquisita is a rare, acquired, subepidermal bullous disease associated with autoimmunity to type VII collagen, the major component of the anchoring fibrils of the dermal–epidermal BMZ
- Patients may present either with a mechanobullous disorder, mimicking dystrophic epidermolysis bullosa, or with clinical features that resemble BP or infrequently MMP, the Brunsting–Perry variant of MMP, or LABD
- Diagnosis relies on immunopathologic examinations, especially immunofluorescence microscopy, immunoserologic studies, and occasionally immunoelectron microscopy
- The disease is usually chronic and more refractory to treatment than BP

Introduction

Epidermolysis bullosa acquisita (EBA) is a rare, acquired, subepidermal bullous disease associated with autoimmunity to type VII collagen, the major component of the anchoring fibrils of the dermal–epidermal BMZ[74–77]. Patients may present with either a non-inflammatory variant, the features of which strikingly resemble those observed in patients with dystrophic epidermolysis bullosa (EB), or with an inflammatory variant that mimics BP. Infrequently, the clinical phenotype resembles MMP, the Brunsting–Perry variant of MMP, or LABD.

History

The first cases of an acquired bullous disease with clinical features mimicking hereditary dystrophic epidermolysis bullosa were described by Elliot in 1895. In the early 1970s, before the advent of cutaneous immunopathology, Roenigk and colleagues proposed the initial clinical criteria for EBA. A few years later, IF microscopy studies demonstrated that EBA patients have anti-BMZ antibodies, similar to BP patients. In the early 1980s, immunoelectron microscopy studies separated EBA from BP by demonstrating that IgG deposits in EBA were located in the sublamina densa region of the BMZ. In the 1990s it was shown that EBA autoantibodies bind to type VII collagen, the major component of anchoring fibrils[75].

Epidemiology

EBA has been reported in both children and adults and may occur at any age. It is one of the rarest subepidermal autoimmune bullous diseases in Western Europe, with an estimated annual incidence of ~0.25 per million people[49,77]. It may be more common in specific Asian populations (e.g. Koreans) as well as in African-Americans.

Pathogenesis

The pathogenic role of autoantibodies to type VII collagen is supported by several lines of evidence[76]. Patients with EBA have tissue-bound and circulating IgG autoantibodies against type VII collagen, the major component of anchoring fibrils (see Fig. 28.3A). In addition, titers of anti-type VII collagen antibodies parallel disease activity in EBA patients, and neonates of mothers with EBA can develop transient blisters due to diaplacental transfer of anti-type VII collagen IgG autoatibodies[74,77].

Type VII collagen is located within the lamina densa and sublamina densa region of the BMZ (see Fig. 28.2). It is composed of three identical α-chains, each of which consists of a central 145 kDa collagenous triple helical segment, flanked by a large 145 kDa non-collagenous NH2-terminal domain (NC1) and a short 30 kDa COOH-terminal region (NC2). Patients' autoantibodies target immunodominant epitopes within the NC1 domain of the protein. However, reactivity with either the central collagenous domain or the NC2 domain is also observed, albeit rarely. It is, as yet, unclear if binding activity to certain antigenic regions of the molecule correlates with a distinct clinical phenotype (see below).

In vitro, EBA autoantibodies, together with the complement system and neutrophil elastase and gelatinase B, are able to mediate leukocyte infiltration (via FcγRIV expression) and dermal–epidermal separation. In mice, studies involving passive transfer of antibodies or active immunization with autologous type VII collagen have shown that autoantibodies to type VII collagen are capable of inducing dermal–epidermal separation, i.e. are pathogenic[76,77].

EBA autoantibodies may also directly interfere with the association and assembly of type VII collagen molecules into anchoring fibrils and/or by critically affecting the interactions between type VII collagen and other matrix proteins such as laminin 332, fibronectin, or type IV collagen.

As in the case of other autoimmune diseases, certain HLA class II alleles appear to be more prevalent in EBA, e.g. DRB1*15:01 and DR5 in White individuals and African-Americans or DRB1*13 in Koreans. It is likely that the expression of distinct HLA alleles has a critical impact on the susceptibility to developing EBA. The observation that deficient expression of type VII collagen in patients with various forms of dystrophic EB causes skin fragility and dermal–epidermal separation demonstrates unequivocally the importance of this protein in maintaining the integrity of the epidermal BMZ[77].

Clinical Features

EBA usually occurs in adult patients, although pediatric cases have been reported. Cutaneous manifestations are heterogeneous and may mimic other bullous diseases[77,78].

The classic presentation is that of a *non-inflammatory mechanobullous disease* characterized by the development of acral blisters that heal with atrophic scarring, milia formation, and dyspigmentation[77]. Cutaneous blisters, which may become hemorrhagic, and evolving erosions appear within non-inflamed skin or on areas of scarring. They are localized to trauma-prone surfaces, especially the elbows, knees, and dorsal aspects of the hands, occiput, back, feet, and toes (Fig. 30.18). As in inherited dystrophic EB, acral involvement in EBA may be mutilating, leading to a "mitten" deformity of the digits, webbing between adjacent fingers or toes (pseudosyndactyly), nail dystrophy, and complete

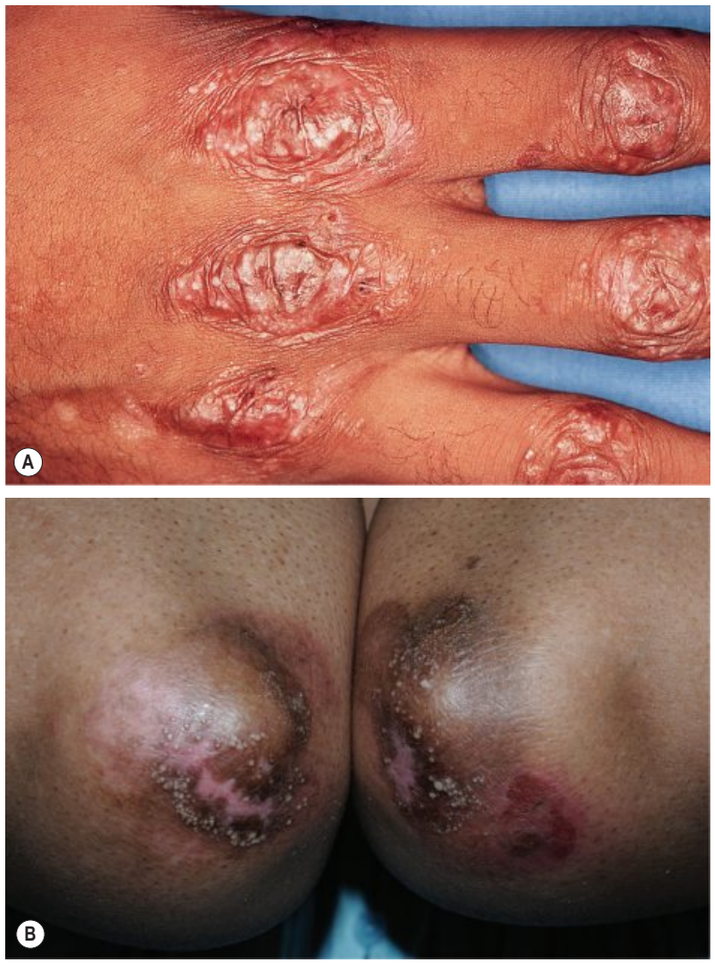

Fig. 30.18 Epidermolysis bullosa acquisita – mechanobullous presentation. **A** Milia and scarring that favor sites of trauma overlying joints, in association with skin fragility. Note the resemblance to dystrophic epidermolysis bullosa. **B** Postinflammatory hyperpigmentation, mild scarring, and milia in sites of trauma in a patient with systemic lupus erythematosus. Note the ruptured bulla on the left elbow. *B, Courtesy Kalman Watsky, MD.*

Fig. 30.19 Epidermolysis bullosa aquisita – inflammatory presentation. Widespread erythematous plaques, some of which have erosions and hemorrhagic crusts. Although there is accentuation on the elbows, the differential diagnosis would include bullous pemphigoid. *Courtesy Lorenzo Cerroni, MD.*

Fig. 30.20 Epidermolysis bullosa acquisita – oral involvement. Multiple erosions of the palate reminiscent of mucous membrane (cicatricial) pemphigoid. *Courtesy C. Prost, MD.*

nail loss. Scalp involvement occurs in up to 20% of patients, and, in isolated cases, extensive non-healing erosions with scarring alopecia have been described.

Several *inflammatory subtypes* of EBA have also been described, which may occur more frequently than the mechanobullous form[77,78]. The *BP-like presentation* is the most common inflammatory form of EBA[77–79]. It is characterized by widely distributed, pruritic vesicles and bullae on an erythematous base. Any cutaneous site may be involved, as well as the oral mucosa. Lesions heal without milia or atrophic scars (Fig. 30.19).

Other inflammatory subtypes of EBA are quite uncommon[77–79] and include those whose presentation resembles MMP, the Brunsting–Perry variant of MMP with scarring alopecia, and LABD with a polymorphous bullous eruption and a linear band of IgA deposits along the BMZ. Of note, during the course of the disease, the clinical features can convert from one variant to another or, alternatively, a mixture of inflammatory and non-inflammatory features may coexist.

Mucous membrane involvement occurs not only in MMP-like EBA, but is also observed in up to 50% of patients with the mechanobullous and BP-like presentations[77–79]. Erosions and intact vesicles may be seen in the mouth (Fig. 30.20), larynx and esophagus, and they may lead to dysphagia and laryngeal stenosis. Ocular involvement with severe cicatrizing conjunctivitis and blindness have been reported in the MMP-like phenotype[77,80]. Lastly, features of childhood EBA have substantial overlap with those observed in childhood BP and LABD.

In some reports, a number of systemic diseases have been described in association with EBA, particularly Crohn disease and ulcerative colitis (up to 30% of cases) and, more rarely, myeloma, systemic LE, rheumatoid arthritis, thyroiditis and diabetes mellitus[77].

Diagnosis and Differential Diagnosis

Light microscopy and electron microscopy

By light microscopy, biopsy specimens of bullae show a subepidermal cleavage. In the BP-like or MMP-like variants of EBA, there is a variable inflammatory infiltrate within the dermis, composed predominantly of neutrophils admixed with eosinophils and lymphocytes. In the mechanobullous non-inflammatory lesions, there is a minimal-to-absent cellular infiltrate.

Electron microscopy studies of fresh vesicles demonstrate that dermal–epidermal cleavage occurs within the sublamina densa zone. In addition, a reduction in the number of anchoring fibrils may be observed. However, in some cases, separation within the lamina lucida has been noted, most likely reflecting the formation of a subepidermal blister at the *locus minoris resistentiae*. The level of cleavage is, therefore, not always a reliable criterion for discriminating EBA from other subepidermal bullous disorders.

Direct immunofluorescence (DIF) microscopy

DIF microscopy studies of perilesional skin demonstrate IgG deposits distributed in a continuous, rather broad, linear pattern along the epidermal BMZ. Less commonly, linear deposits of C3, IgA, or IgM are found. In salt-split skin preparations of perilesional skin, the immune deposits are typically located on the dermal side of the cleavage. A u-serrated immune deposition pattern at the epidermal BMZ is very helpful in differentiating EBA from the other subepidermal bullous diseases, i.e. the "pemphigoids", which have an n-serrated pattern of immunoreactants

at the BMZ. Finally, the FOAM technique (see above), employing a confocal laser scanning microscope, localizes the immunoreactants to the level of the BMZ where type VII collagen is expressed[77].

Indirect immunofluorescence (IIF) microscopy

By standard IIF, circulating anti-BMZ antibodies can be detected in ~50% of patients with EBA. They are primarily of the IgG class, but serum IgA autoantibodies have also been reported. By IIF on salt-split skin, circulating IgG or IgA antibodies bind to the dermal side of the artificial blister[30,77,79,81]. Although not often available, testing of patients' sera either against a panel of skin substrate specimens lacking distinct basement membrane molecules (e.g. BP180, type VII collagen, laminin 332) or against HEK cells transfected with the recombinant NC1 domain of type VII collagen can prove helpful in characterizing the antigens targeted by circulating autoantibodies.

Immunoelectron microscopy

Immunoelectron microscopy has traditionally been considered the "gold standard" for diagnosing EBA, especially when circulating autoantibodies are absent and therefore cannot be characterized by IIF microscopy, immunoblot, or ELISA (see below)[77]. By immunogold techniques, which allow a more precise localization than peroxidase labeling, EBA autoantibodies specifically bind to the anchoring fibrils and the lamina densa where anchoring fibrils originate and terminate (see Fig. 28.3A).

Other immunochemical studies, including ELISA

In Western immunoblot analyses of dermal extracts, serum autoantibodies from patients with EBA were found to bind to proteins of ~290 kDa and, less frequently, 145 kDa. These proteins have been clearly shown to correspond to type VII collagen and its NH2-terminal NC1 subdomain, respectively[77,81]. Epitope mapping studies using recombinant forms of type VII collagen have demonstrated that immunodominant epitopes are located within the NC1 domain[81]. ELISAs are now available, utilizing either the recombinant NC1 domain of type VII collagen or a combination of recombinant NC1 and NC2 domains[82,83]; these assays exhibit high specificity (>96%) and are likely more sensitive than IIF microscopy studies utilizing salt-split skin[83]. Serum concentrations of collagen VII-specific IgG autoantibodies, as determined by ELISA, may correlate with disease severity[77].

Differential diagnosis

EBA may be confused with inherited dystrophic EB, BP, MMP, LABD, porphyria cutanea tarda, pseudoporphyria, or rare variants of porphyria (e.g. porphyria variegata). Clinically, the mechanobullous type of EBA most closely resembles mild dominant dystrophic EB, but the lack of a family history, late onset, and the positive DIF findings generally allow for distinction. However, some patients with inherited EB do develop autoantibodies against type VII collagen. The involvement of the hands may mimic porphyria cutanea tarda, but the latter can easily be excluded by porphyrin studies. Occasionally, patients with EBA on incriminating medications are misdiagnosed as having pseudoporphyria. The inflammatory type of EBA is clinically indistinguishable from BP, anti-p200 (anti-laminin γ1) pemphigoid, or MMP, including the Brunsting–Perry variant. These conditions may be distinguished by u-serrated versus n-serrated DIF pattern analysis, FOAM technique, ELISA, IIF with salt-split skin as a substrate, Western immunoblot analysis of both epidermal and dermal extracts, and direct immunoelectron microscopy studies[77,84].

Bullous systemic LE usually presents as a transient, widespread, inflammatory subepidermal blistering condition (see Ch. 41), and, less frequently, as a mechanobullous eruption with milia formation and scarring[75,77]. In a number of these cases, circulating autoantibodies show binding to type VII collagen and the possibility of systemic LE-associated EBA could be considered. In addition to differences in histology, adult EBA exhibits a poor response to treatment, while a significant improvement following initiation of dapsone or azathioprine therapy is generally seen in patients with bullous systemic LE[85].

Treatment

Treatment of EBA is difficult and often unsatisfactory. Because of the rarity of the condition, most data on treatment are based on anecdotal reports[67,74,77]. Systemic corticosteroids and immunosuppressive agents, such as azathioprine, methotrexate, mycophenolate mofetil, cyclophosphamide or, more recently, rituximab, are sometimes helpful in controlling the BP-like variant of EBA, which may eventually go into clinical remission. Colchicine, dapsone, and cyclosporine have also been reported to have some benefit. In patients with severe EBA unresponsive to conventional immunosuppressive therapy, IVIg ± rituximab may prove effective[77,85]. A combination of dapsone plus prednisolone has been recommended by some authors for the treatment of childhood EBA[74].

31 Dermatitis Herpetiformis and Linear IgA Bullous Dermatosis

Bridget E. Shields, Christopher M. Hull and John J. Zone

Key features

- Dermatitis herpetiformis (DH) is differentiated from linear IgA bullous dermatosis (LABD) on the basis of granular IgA versus linear IgA deposition at the basement membrane zone, as observed by direct immunofluorescence
- DH is a cutaneous manifestation of celiac disease (CD) and is associated with gluten sensitivity in virtually all cases
- DH and CD are genetic disorders strongly associated with HLA-DQ2 and DQ8 genotypes
- CD-associated IgA antibodies are directed against *tissue* transglutaminase (transglutaminase 2 [TG2]); IgA antibodies in the skin of DH patients are directed against *epidermal* transglutaminase (transglutaminase 3 [TG3])
- The intestinal and cutaneous disease in DH can be controlled by gluten restriction; both DH and LABD respond to sulfone therapy
- In adults, LABD is often drug-induced

DERMATITIS HERPETIFORMIS

Synonym: ■ Duhring disease

Introduction

Dermatitis herpetiformis (DH) is a cutaneous manifestation of gluten sensitivity. Although over 90% of DH patients have evidence of a gluten-sensitive enteropathy (GSE), only about 20% have intestinal symptoms of celiac disease (CD). Both the skin disease and the intestinal disease respond to gluten restriction and recur with institution of a gluten-containing diet.

Four findings support the diagnosis of DH:

- pruritic papulovesicles or excoriated papules on extensor surfaces
- neutrophilic infiltration of the dermal papillae with vesicle formation at the dermal–epidermal junction
- granular deposition of IgA and epidermal transglutaminase (TG3) within the dermal papillae of clinically normal-appearing skin adjacent to a lesion
- a response of the skin disease, but not the intestinal disease, to dapsone therapy.

Although DH is usually a lifelong condition, the course may wax and wane. A spontaneous remission may occur in up to 10% of patients, but most clinical remissions are related to dietary gluten restriction[1].

History

Dr Louis Duhring described DH at the University of Pennsylvania in 1884. It was the first skin disease described by an American dermatologist. The critical discoveries in our understanding of DH are listed in Table 31.1.

Epidemiology

DH occurs more commonly in people of northern European origin. It is uncommon in African-Americans and Asians. The annual incidence ranges from 0.4–3.5/100 000 and appears to be declining, likely secondary to better recognition of early celiac disease[2]. The mean age of onset is during the fourth decade, but it may first appear from age 2 to 90 years. Although adolescent and prepubescent children in the US and northern Europe are infrequently affected, this age group is more commonly affected in other countries such as Hungary and Italy. In most epidemiologic studies, DH occurs more frequently in men, in a ratio of 1.1 : 1 to 1.9 : 1[3]. From 1979 to 1996, the familial incidence of DH in Finland was studied prospectively. DH was diagnosed in 1018 patients and 10.5% of these patients had one or more affected first-degree relatives[4].

A study in Utah (1987) found a prevalence of 11.2 per 100 000. The annual incidence during the years 1978 to 1987 was 0.98 per 100 000. Mean age of onset for men was 40 years and for women was 36 years. The male-to-female ratio was 1.44 : 1[5].

Pathogenesis

Our knowledge of the pathogenesis of DH is based on a number of clinical and laboratory observations. The key observations that have been integrated into theories of pathogenesis are:

- a strong genetic association with HLA DQ2 haplotype and less often DQ8

DERMATITIS HERPETIFORMIS – HISTORIC LANDMARKS	
1884	Louis Adolphus Duhring of Philadelphia described in detail "dermatitis herpetiformis" (DH)
1888	Jean Louis Brocq of Paris renamed the condition "dermatite polymorphe prurigineuse"
1890	T Caspar Gilchrist outlined the histologic changes of DH, which were included in the 1897 edition of Duhring's textbook *Cutaneous Medicine: A Systemic Treatise on Diseases of the Skin*
1940	Sulfapyridine was reported to be an effective treatment for DH. The clinical response to sulfapyridine became a diagnostic test
1950	Dicke, a Dutch pediatrician, observed that patients with celiac disease (CD) improved during World War II when bread was in short supply, and their disease worsened when grain supplies were restored
1953	Diamino-diphenyl sulfone (dapsone), the parent compound of sulfapyridine, also proved to be effective in DH
1967	Independent accounts connected DH with CD
1969	JB van der Meer demonstrated IgA deposits in the papillae of uninvolved skin in DH
1972	Stephen Katz linked DH to the HLA-B8 antigen. This strengthened the association between CD and DH
1986	IgA class anti-endomysial antibodies discovered to be highly specific for DH and CD
1997	DH and CD found to have a common immunogenetic background with strict association with HLA alleles DQ A1*0501 and B1*02, which encode HLA-DQ2 heterodimers
2003	Sardy and colleagues identified epidermal transglutaminase as an autoantigen in DH
2012	Zone and colleagues demonstrated that transfer of DH sera or goat anti-human epidermal transglutaminase antibodies to human skin-grafted mice mimics DH immunopathology

Table 31.1 Dermatitis herpetiformis – historic landmarks.

- some degree of GSE on small bowel biopsy in virtually all patients, accompanied by a TG2-targeted immune response in the intestine in both CD and DH plus an additional anti-TG3 response in DH
- granular IgA deposition within the papillary dermis of the skin (this is essential for the diagnosis and occurs at the site of eventual inflammation)
- neutrophilic infiltration into the dermal papillae
- improvement of symptoms with dapsone therapy and worsening of symptoms with inorganic iodide ingestion.

Genetic predisposition

Specific HLA DQ2 or DQ8 genes, which encode molecules that interact with T cell receptors, are believed to provide the antigenic specificity that processes the gliadin antigen in genetically susceptible individuals. This HLA association is the same for patients with CD and DH. Genes encoding the DQ2 (A1*0501, B1*02) heterodimer are carried by 90% of CD and DH patients, while genes encoding the DQ8 (A1*03, B1*03) heterodimer are carried by the remaining DH patients[6]. Previous descriptions of associations with HLA-B8, as well as HLA-DR3 and HLA-DR5/DR7, represent class I and class II molecules that are in linkage disequilibrium with DQ2. However, it has been established that <50% of the genetic predisposition in CD and DH is due to specific HLA genes. However, genomic searches for non-HLA genes in patients with DH have to date been unsuccessful. Monozygotic twins, one with DH and the other with CD, have been reported, indicating that environmental as well as genetic factors play a role in the development of CD and/or its extraintestinal manifestation, DH[7].

Gluten-sensitive enteropathy (GSE)

In small bowel biopsies, more than 90% of DH patients have some degree of GSE. The bowel abnormality is caused by gliadin, the antigenic alcohol-soluble fraction of gluten. Gluten consists of a family of grain proteins found in: wheat, rye, barley, and hybrids of these grains (e.g. kamut, spelt, triticale). It is not found in rice, corn, sorghum, or most oats. The spectrum of intestinal involvement ranges from minimal infiltration of the lamina propria by lymphocytes (with normal villi), to minimal atrophy of the jejunum accompanied by intraepithelial lymphocytic infiltrates, to total villous atrophy of the small intestine. The enteropathy is often patchy and may require multiple small bowel samples for diagnosis. Symptomatic malabsorption occurs in ~20% of patients with DH.

The proposed pathogenesis of DH and CD is presented in Fig. 31.1. Following ingestion of gluten-containing grains (see above), one of the products of digestion is gliadin (see Fig. 31.1A). Once gliadin is absorbed via the lamina propria, glutamine residues within gliadin are deamidated by tissue transglutaminase (TG2) and covalent cross-links (isopeptidyl bonds) are formed between lysine residues in TG2 and glutamines in gliadin. Deamidation by TG2 is thought to be a critical step as it serves to optimize antigen presentation.

Deamidated gliadin peptides bind to the groove of the HLA-DQ2 molecule on dendritic antigen-presenting cells (see Fig. 31.1B), and the gliadin antigen is then presented to sensitized helper T cells in the context of HLA-DQ2 or DQ8 specificity. These helper T cells can stimulate B cells, with differentiated plasma cells producing IgA antibodies to multiple antigens, including gliadin, gliadin cross-linked to TG2, TG2, and epidermal transglutaminase (TG3). IgA anti-TG2 antibodies have become the serologic hallmark for CD.

In addition, stimulated natural killer (NK) lymphocytes cause crypt hyperplasia and villous atrophy. Elevated serum levels of interleukin (IL)-17 and IL-36 in patients with DH suggest a possible role for these cytokines in NK cell signaling and neutrophil activation[8]. The IL-31 pathway may also be involved in mediating the pruritus found in DH[9].

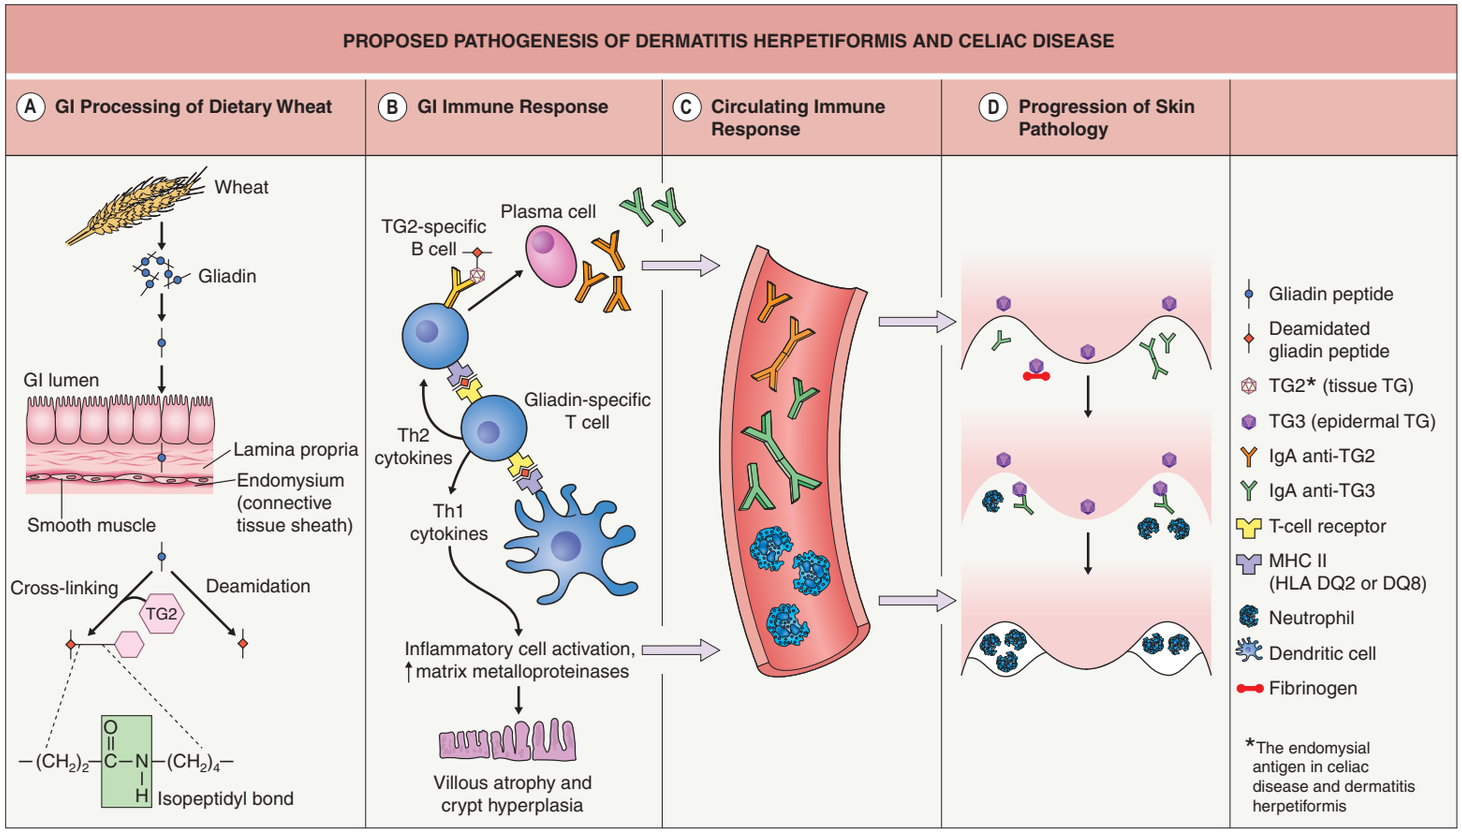

Fig. 31.1 Proposed pathogenesis of dermatitis herpetiformis and celiac disease. A Dietary wheat, barley, or rye is processed by digestive enzymes into antigenic gliadin peptides, which are transported intact across the mucosal epithelium. Within the lamina propria, tissue transglutaminase (TG2): (1) deamidates glutamine residues within gliadin peptides to glutamic acid; and (2) becomes covalently cross-linked to gliadin peptides via isopeptidyl bonds (formed between gliadin and TG2 lysine residues). **B** $CD4^+$ T cells in the lamina propria recognize deamidated gliadin peptides presented by HLA-DQ2 or -DQ8 molecules on antigen-presenting cells, resulting in the production of Th1 cytokines and matrix metalloproteinases that cause mucosal epithelial cell damage and tissue remodeling. In addition, TG2-specific B cells take up TG2–gliadin complexes and present gliadin peptides to gliadin-specific helper T cells, which stimulate the B cells to produce IgA anti-TG2. **C** Over time, IgA directed against TG3 (IgA anti-TG3) forms as a result of epitope spreading and both IgA anti-TG2 and IgA anti-TG3 circulate in the bloodstream. **D** When IgA anti-TG3 antibodies reach the dermis, they complex with TG3 antigens which have been produced by keratinocytes (epidermal TG) and then have diffused into the dermis. That is, IgA/TG3 immune complexes are formed *locally* within the papillary dermis. This leads to neutrophil chemotaxis (with formation of neutrophilic microabscesses), proteolytic cleavage of the lamina lucida, and subepidermal blister formation.

In the setting of continued exposure to gliadin, epitope spreading is thought to lead to development of IgA anti-TG3 antibodies in patients who already have IgA anti-TG2 antibodies. Patients with CD and DH have an immune response to TG2 within their intestinal mucosa, while those with DH have an additional response to TG3[10] (see Fig. 31.1B,D). Epitope spreading is a possible explanation for why DH tends to present at a later age than symptomatic CD (the latter often manifests in childhood) and why patients with CD alone tend to have more severe intestinal disease than patients with DH. Formation of IgA anti-TG3 antibodies is thought to require time and continued exposure to gluten and this would be more likely to occur in patients with less severe, relatively asymptomatic intestinal involvement. Findings in support of this theory include the presence of IgA anti-TG2 antibodies in most DH patients and a higher prevalence of IgA anti-TG3 antibodies in adults than in children with CD (i.e. developing later in the evolution of the disease). The declining incidence of DH, despite the rising incidence of CD, might further support this theory, with CD being diagnosed earlier before epitope spreading has the chance to occur[1].

The formation of IgA anti-TG3 antibodies also activates circulating neutrophils (see Fig. 31.1C). Deposition of these antibodies within the dermal papillae results in the infiltration of activated neutrophils from the circulation into the dermal papillae (see Fig. 31.1D). Degranulation of neutrophils releases proteases which disrupt the lamina lucida and produce a subepidermal blister.

Since both the skin disease and the intestinal disease resolve with dietary gluten restriction and recur with return to a regular diet, it is clear that the dietary protein gluten is central to the pathogenesis of the cutaneous eruption. In addition, it is the HLA class II antigen that acts as a gate through which gluten can reach the inflammatory cells and initiate the autoimmune process[11,12].

Circulating antibodies

The first serologic difference between DH and CD was described in 2002, with TG3 identified as the autoantigen in DH[13]. Additional studies have demonstrated that circulating IgA anti-TG3 antibodies are not only elevated in patients with DH, but can be assayed and may be helpful in monitoring response to a gluten-free diet[14,15]. TG3 was also found to co-localize with IgA in dermal papillae of DH patients and is enzymatically active in this site (see Fig. 31.5B)[13,16,17]. TG3 is expressed in many tissues of the body, including the epidermis. When IgA anti-TG3 antibodies reach the dermis, they complex with TG3 antigens which have been produced by keratinocytes (epidermal TG) and then have diffused into the dermis. In other words, IgA/TG3 immune complexes are formed *locally* within the papillary dermis (see Fig. 31.1D).

When goat anti-human TG3 antibodies (IgG) were passively transferred into SCID mice grafted with human skin, immune deposits were detected within the papillary dermis which reacted with rabbit anti-TG3 and DH sera. Transfer of sera from DH patients (who had high circulating levels of IgA anti-TG3 antibodies) led to similar granular IgA and TG3 dermal deposits[18]. In DH skin, IgA-bound deposits of TG3 are enzymatically active and therefore TG3 likely plays an important role in the covalent binding of IgA to connective tissue fibers. Enzymatically active TG3 also binds to soluble fibrinogen whose subsequent degradation may play a key pathogenic role[17]. In an animal model, evidence supported local formation of immune complexes in the papillary dermis, supplanting previous theories in which IgA complexes within DH skin were thought to represent deposits of circulating immune complexes.

Granular IgA deposition

Granular IgA deposition within dermal papillae is the hallmark of DH (see Fig. 31.5A). The deposits are composed of IgA1 antibodies directed against TG3. Circulating IgA antibodies to TG2 (an endomysial antigen) have been identified by indirect immunofluorescence (IIF) microscopy using a monkey esophagus substrate, and the presence of these antibodies correlates with the degree of GSE. IgA anti-TG3 antibodies, but not IgA anti-TG2 antibodies, are responsible for the IgA deposition in DH skin.

Iodide

Ingestion of iodide can lead to worsening of DH and topical application of iodide onto the normal skin of DH patients produces lesions that are histologically identical to spontaneous lesions. Even in normal subjects, topical iodides may produce follicular neutrophilic pustules. When potassium iodide is added to DH skin *in vitro*, the enzymatic activity of TG3 that is complexed to IgA dramatically increases[19]. It is therefore possible that the clinical worsening of DH after iodide application or ingestion is due to an iodide-induced increase in TG3 activity. In patients with refractory DH, a search for covert iodide ingestion should be undertaken as iodide can be found in medications, dietary supplements, and foods (e.g. eggs), in addition to radiographic contrast media[19a].

Associated Disorders and Malignancies

A strong association exists between DH and thyroid disease, particularly Hashimoto thyroiditis. In one study, the presence of some type of thyroid abnormality was found in 26 of 50 patients with DH[20]. Although the pathogenetic relationship between DH and thyroid disease is unknown, it may represent a coexistence of autoimmune disease[20]. The incidence of enteropathy-associated T cell lymphoma is also increased in patients with DH and warrants increased surveillance. Of note, adhering to a gluten-free diet protects against developing lymphoma, in particular after the patient has adhered to a gluten-free diet for five years. This further supports advising patients with DH to adhere to a strict gluten-free diet *ad infinitum*. Other autoimmune disorders reported to be associated with DH and CD are listed in Table 31.2.

Clinical Features

DH has a symmetric distribution and favors the elbows, knees, extensor forearms, back, and buttocks (Fig. 31.2 & 31.3). The primary lesions are pleomorphic, with urticarial plaques, papules, and vesicles. Grouped or "herpetiform" papulovesicles with an erythematous base are characteristic of this autoimmune disorder. Intense pruritus leads to secondary excoriation and crusting. Even if only hemorrhagic crusts or secondary changes from scratching are present, the diagnosis should be suspected on the basis of the distribution pattern. Less common presentations are isolated facial or scalp involvement, exclusively macular lesions, and hemorrhagic acral macules (usually palmoplantar; see Fig. 31.3C).

Pathology

For routine histology, it is optimal to capture a small, intact vesicle. If this is not available, an area of erythema should be biopsied. Areas of erythema will show dermal papillary edema and neutrophil infiltration associated with a superficial perivascular lymphocytic infiltrate. Dermal papillae filled with neutrophils, with relative sparing of the lowermost tips of the intervening rete ridges, is a characteristic finding. When an intact vesicle is biopsied, a subepidermal blister containing predominantly neutrophils is usually seen (Fig. 31.4). Sometimes only a lymphohistiocytic infiltrate or spongiosis is seen, emphasizing the important role of direct immunofluorescence (DIF) microscopy[15,21]. Also, as with other autoimmune bullous disorders, the presence of typical histologic features depends on the site and quality of the biopsy.

AUTOIMMUNE DISORDERS ASSOCIATED WITH DERMATITIS HERPETIFORMIS	
Common	
• Autoimmune thyroid disease (Hashimoto thyroiditis) • Insulin-dependent diabetes mellitus	
Uncommon	
• Pernicious anemia	
Rare	
• Addison disease • Autoimmune chronic active hepatitis • Alopecia areata • Myasthenia gravis • Sarcoidosis	• Systemic sclerosis (scleroderma) • Sjögren syndrome • Systemic lupus erythematosus • Vitiligo

Table 31.2 Autoimmune disorders associated with dermatitis herpetiformis.

Fig. 31.2 Dermatitis herpetiformis. A Pink papulovesicles, erosions, and hemorrhagic crusts on the elbow. **B** Multiple urticarial pink papules on the knee, in addition to a few erosions and small subtle intact vesicles (arrows and half-circles). **C** Pink plaques on the knee composed of grouped papules and papulovesicles, admixed with tiny hemorrhagic crusts. **D** Crusted papules as well as an intact vesicle on the elbow. *C, Courtesy Thomas Horn, MD.*

IgA Deposits

In patients with DH, dermal IgA deposits are not uniformly distributed throughout the skin. Notably, IgA deposits are present in greater amounts near active lesions. The optimal biopsy site for DIF microscopy is normal-appearing skin immediately adjacent to a lesion (see Fig. 29.12). A false-negative DIF can occur if lesional skin is biopsied, since the inflammatory infiltrate can destroy the epitopes on IgA[22]. A definitive diagnosis of DH depends upon the demonstration of dermal IgA deposits by DIF microscopy. Granular IgA deposits localized to the dermal papillae are found in 85% of cases of DH (Fig. 31.5), while continuous granular deposition of IgA along the basement membrane occurs in 5% to 10% of cases. A fibrillar pattern of IgA deposition occurs rarely although it is more commonly observed in Japanese patients[23]. Because DH represents a lifetime diagnosis with systemic and therapeutic implications, definitive immunopathologic confirmation is essential.

Although granular deposits of IgA in the skin along with serum IgA anti-TG3 antibodies is considered characteristic of DH, a recent study found that a subset of newly diagnosed CD patients without skin disease could have cutaneous IgA deposits and circulating IgA anti-TG3 antibodies[24]. It is possible that this subset of CD patients may go on to develop DH.

Laboratory evaluation

Anti-endomysial IgA antibodies are very specific for the GSE present in CD and DH. Their levels indicate the severity of GSE and reflect the degree of compliance with dietary gluten restriction. IgA anti-endomysial antibodies are found in ~80% of patients with DH and >95% of patients with active CD at the time of diagnosis. The endomysium is the connective tissue covering the smooth muscle layers of the esophagus, stomach, and small intestine (see Fig. 31.1A) and TG2 has been identified as the endomysial antigen.

Anti-TG2 and -TG3 antibodies play a key role in the pathogenesis of CD and DH (see above). The normal physiologic function of transglutaminase is to repair injured tissue by cross-linking extracellular matrix proteins in order to protect surrounding tissue from further damage. Transglutaminase facilitates the linkage of the carboxamide group of the amino acid glutamine, found in gliadin, to an ε-amino group of a lysine residue in transglutaminase located in the intestinal tract (see Fig. 31.1A). The glutamine in gliadin is especially vulnerable to cross-linkage with transglutaminase, and this linkage is perceived as a foreign antigen by the host immune system. As antibodies to transglutaminase are produced, the normal function of transglutaminase in repairing the damaged intestinal mucosa is impaired.

Fig. 31.3 Dermatitis herpetiformis. Fig. 31.5 Dermatitis herpetiformis – direct immunofluorescence. A Granular IgA deposition along the dermal–epidermal junction of normal-appearing skin adjacent to a lesion. **B** Granular deposition of epidermal transglutaminase (TG3) within the dermal papillae, which co-localizes with the IgA. *A, Courtesy Kristin Leiferman, MD.*

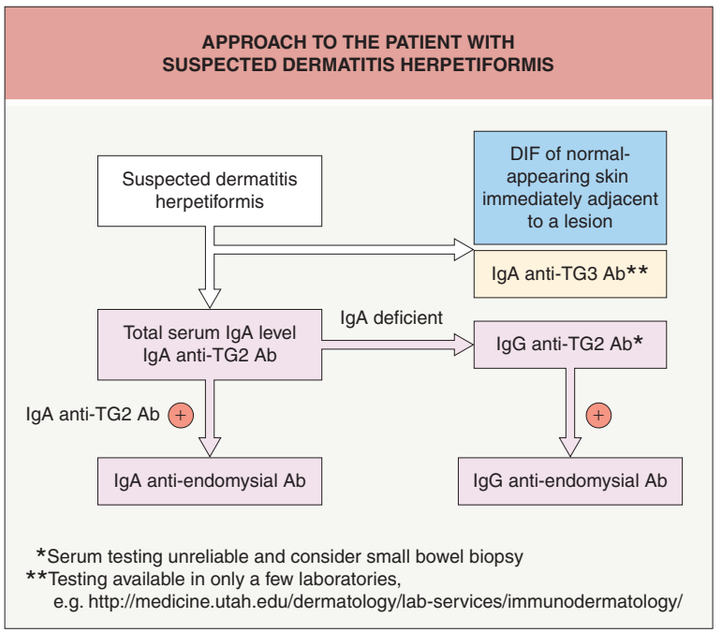

Fig. 31.6 Approach to the patient with suspected dermatitis herpetiformis. IgA anti-TG2 and anti-endomysial antibodies can be monitored over time to assess compliance with a gluten-free diet. Because the anti-endomysial antibody assay is based upon analysis of indirect immunofluorescence, it is more expensive than the IgA anti-TG2 antibody assay; thus, the recommendation that the latter assay be performed first. Anti-deamidated gliadin peptide IgG testing may have utility for individuals with IgA deficiency or weakly positive anti-TG2 IgA. Ab, antibody; DIF, direct immunofluorescence; TG, transglutaminase.

An approach to the laboratory evaluation of a patient with suspected DH is outlined in Fig. 31.6.

Differential Diagnosis

The differential diagnosis includes arthropod assault, scabies, and urticarial vasculitis, as well as erythema multiforme, bullous lupus erythematosus, linear IgA bullous dermatosis (LABD), and bullous pemphigoid. Table 31.3 outlines the clinical and histologic features that help differentiate DH from LABD and bullous pemphigoid. Erythema multiforme is characterized by target lesions that are often acral in distribution and show vacuolar degeneration and focal epidermal necrosis histologically as well as a lack of IgA deposition at the basement membrane zone (BMZ; see Ch. 20).

CHARACTERISTICS THAT DIFFERENTIATE DH, LABD, AND BP			
	DH	**LABD**	**BP**
Cutaneous lesion	Grouped papules and small vesicles, often excoriated	Small vesicles and/or large bullae	Large tense bullae
Distribution pattern	Extensor surfaces, symmetrical	Similar to DH or BP; may involve mucosae	Trunk, extremities, occasionally mucosae
Routine histology	Subepidermal bullae with neutrophilic infiltrate	Subepidermal bullae with neutrophilic infiltrate (sometimes eosinophils predominate)	Subepidermal bullae with eosinophilic infiltrate
Direct IF	Granular IgA in dermal papillae	Linear IgA at BMZ, possibly also IgG	Linear IgG and C3 at BMZ
Site to biopsy for direct IF	Adjacent normal-appearing skin	Perilesional	Perilesional
Routine indirect IF	Negative	Linear IgA at BMZ (70%)	Linear IgG at BMZ (70%)
Enteropathy	>90%	Rare	None
HLA-DQ2	>90%	30%	Normal (20%)
Dapsone responsiveness	Excellent	Good, may also require systemic corticosteroids	Minimal to moderate

SIDE EFFECTS OF DAPSONE		
Red blood cell toxicity	• Hemolytic anemia • Methemoglobinemia*	
White blood cell toxicity	• Leukopenia • Agranulocytosis	
Dapsone hypersensitivity syndrome	• Fever, fatigue, anorexia, hepatitis, lymphadenopathy	
Cutaneous reactions	• Morbilliform eruption • Urticaria • Fixed drug eruption • Erythema nodosum • Exfoliative dermatitis	• SJS/TEN • Phototoxicity • Drug-induced cutaneous lupus erythematosus
Gastrointestinal manifestations†	• Anorexia, nausea • Hepatitis • Cholestatic jaundice • Severe hypoalbuminemia	
Neurologic associations†	• Headache, dizziness • Peripheral neuropathy • Blurred vision, tinnitus • Insomnia • Psychosis	
Miscellaneous	• Fever • Nephrotic syndrome	

*Patients should be warned that arterial desaturation may be noted by pulse oximetry, even with relatively low levels of methemoglobinemia.
†In decreasing order of frequency.

Table 31.4 Side effects of dapsone. SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

Bullous lupus erythematosus presents with urticarial papules and vesicles on an erythematous base and a histologic picture similar to LABD and DH. However, the patients have clinical and serologic findings of systemic lupus erythematosus. DIF reveals multiple immunoglobulins (including IgA) in a granular or broad linear pattern along the BMZ, whereas in LABD there is a fine linear IgA deposition.

Crusted papules are also seen on the elbows and knees in patients with granulomatosis with polyangiitis and eosinophilic granulomatosis with polyangiitis, but histologic features of vasculitis are observed.

Treatment

The treatment of DH includes dapsone and a gluten-free diet, with the pruritus of DH relieved within 48–72 hours after instituting dapsone (4′,4′ diamino-diphenyl sulfone). Lesions abruptly recur within 24–48 hours of therapy discontinuation. However, dapsone has no effect on the intestinal pathology.

Dapsone is begun after screening for glucose-6-phosphate dehydrogenase (G6PD) deficiency, with initial dosages of 25–50 mg in adults and 0.5 mg/kg in children. Initiation of therapy with higher doses may precipitate severe hemolysis and cardiac decompensation in susceptible individuals. The average maintenance dose in adults on a normal diet is 50–100 mg daily. The half-life ranges from 12 to 32 hours, so divided doses are seldom of benefit. The daily dose can be regulated on a weekly basis to optimize control. One to two new lesions per week should be expected on the optimal dose. Higher doses increase toxicity with little benefit.

Outbreaks of facial and scalp lesions while on otherwise adequate treatment can occur, but are not common. Facial disease may prove refractory to dapsone therapy. Breaking the vesicles followed by application of a potent corticosteroid gel may be helpful.

Although there are many side effects of dapsone (Table 31.4; see Ch. 130), the drug is well tolerated for years in more than 90% of patients. Hemolysis occurs in virtually every patient on dapsone therapy, since sulfones produce an oxidant stress on aging red blood cells. In patients with G6PD deficiency, dapsone may produce severe hemolysis. Although most patients have evidence of drug-induced hemolysis, a compensated *hemolytic anemia* develops. Drug-induced hemolysis can be confirmed and followed by a reticulocyte count, which should show increased erythropoiesis. Of note, dapsone is secreted in breast milk and may cause hemolytic anemia in breastfed infants. In the setting of a persistent severe anemia, a search for contributing causes, such as iron, vitamin B_{12} or folate deficiencies or hereditary spherocytosis, should be pursued.

Methemoglobin is present in the blood of most patients taking 100 mg or more of dapsone daily. Although the amount of methemoglobin usually does not exceed 5%, there are patients who have maintained levels between 10% and 15%. Methemoglobinemia in the absence of cardiopulmonary symptoms does not require alteration of dapsone dose. Patients should be warned that arterial desaturation may be noted by pulse oximetry, even with relatively low levels of methemoglobinemia.

Fatal *agranulocytosis* has developed in patients with DH treated with dapsone. This drug-induced agranulocytosis usually occurs after 2–12 weeks of continuous dapsone treatment. Re-administration of dapsone then causes leukopenia within hours. A simple measure is to warn the patient to discontinue the drug and report immediately if fever, a sore throat, or other signs of infection develop.

Dapsone hypersensitivity syndrome (see Ch. 21) is a rare, but potentially severe, reaction, characterized by fever, a cutaneous eruption, and internal organ involvement. It is usually seen 2–7 weeks after initiation of therapy. The cutaneous manifestations vary from a morbilliform eruption to exfoliative dermatitis, while the systemic manifestations include fever, pruritus, lymphadenopathy, hepatitis, an elevated ESR, leukocytosis, and, rarely, eosinophilia. Among patients with leprosy, HLA-B*13:01 has been associated with the development of the dapsone hypersensitivity syndrome. Reported population frequencies of HLA-B*13:01 are 2%–20% (Chinese), 1.5% (Japanese), 1%–12% (Indians), and 2%–4% (Southeast Asians); this allele is largely absent in Europeans and Africans[25]. Patients should be educated about this syndrome and instructed to discontinue therapy and notify their medical provider if any signs or symptoms of the dapsone hypersensitivity syndrome develop.

Peripheral neuropathy induced by dapsone may occur within the first few weeks of therapy. The neuropathy was initially reported as a pure motor neuropathy (involving primarily distal extremity muscles);

however, pure motor, pure sensory, and combined motor and sensory neuropathies have subsequently been reported. Relatively high daily doses of dapsone (200–500 mg) have been implicated.

If patients are intolerant to dapsone, therapy with **sulfapyridine** can be considered. The initial dose of sulfapyridine is usually 500 mg three times daily and it can be safely increased to 2 g three times a day; however, some patients may not respond to sulfapyridine at any dose. Adequate fluid intake and alkalinization of the urine minimizes the risk of nephrolithiasis. Because sulfapyridine is currently not commercially available in the US, sulfasalazine may be used as a second alternative. Sulfasalazine is metabolized to sulfapyridine and 5-aminosalicylate by intestinal bacteria, making dosing less predictable. In adults, a standard starting dose is 500 mg four times daily.

Dapsone monitoring includes a baseline complete blood count (CBC) and liver function tests, then weekly CBCs for the first month, twice monthly CBCs for the second month, then monthly CBCs for the next 4 months, and semiannual CBCs thereafter while the patient remains on therapy. Liver function tests should be repeated at 6 months and annually thereafter. Some clinicians measure baseline G6PD activity in all patients, while others focus on those of African, Asian, or southern Mediterranean ancestry. Sulfapyridine rarely produces hemolytic anemia, but the potential for agranulocytosis does exist. Consequently, similar monitoring is recommended for chronic sulfapyridine or sulfasalazine therapy.

Patients can also be treated with a **gluten-free diet** (which includes corn, rice, and most oats). Because several months on a gluten-free diet is typically needed for a response, concurrent suppression of symptoms with dapsone is usually necessary. Most patients with granular IgA deposits respond to a strict gluten-free diet such that they can either decrease or eliminate their need for dapsone. With a prolonged gluten-free diet, IgA in the skin decreases and eventually disappears, but with the reintroduction of gluten, IgA deposits and skin disease return in the vast majority of patients. Minor fluctuations in disease severity are most likely related to oral gluten intake. The gluten-free diet is inconvenient and unacceptable to some patients.

Patient Support

The Gluten Intolerance Group and the Celiac Disease Foundation (www.celiac.org) offer information on foods and additives that should be avoided. The former patient support group has a *Quick Start Gluten-Free Diet Guide* that may be useful for patients. Their website is www.gluten.org.

LINEAR IgA BULLOUS DERMATOSIS

Synonyms: Adults: ■ Linear IgA dermatosis (LAD) ■ Linear IgA disease of adults ■ Linear IgA disease ■ Linear IgA dermatitis herpetiformis ■ Linear dermatitis herpetiformis ■ Adult linear IgA disease ■ IgA bullous pemphigoid ■ Pemphigoid linear IgA

Children: ■ Chronic bullous disease of childhood ■ Benign chronic bullous dermatosis of childhood ■ Childhood linear IgA dermatitis herpetiformis ■ Linear IgA disease of childhood

Introduction

LABD is an immune-mediated, subepidermal, vesiculobullous eruption that occurs in both adults and children. It has been defined on the basis of a unique immunopathology consisting of linear deposition of IgA along the cutaneous BMZ. In adults, the clinical findings associated with this immunopathologic pattern may resemble those of DH or bullous pemphigoid (BP) (see Table 31.3), but in children, the cutaneous features may be clinically unique.

The childhood form is frequently termed "chronic bullous disease of childhood" (CBDC). It is a subepidermal vesiculobullous disease that was initially described on the basis of its clinical findings – annular erythema and blisters (often referred to as a "crown of jewels"), which developed predominantly in flexural areas, particularly the lower trunk, thighs and groin, in preschool children (Fig. 31.7). However, it is invariably characterized by the linear deposition of IgA along the BMZ

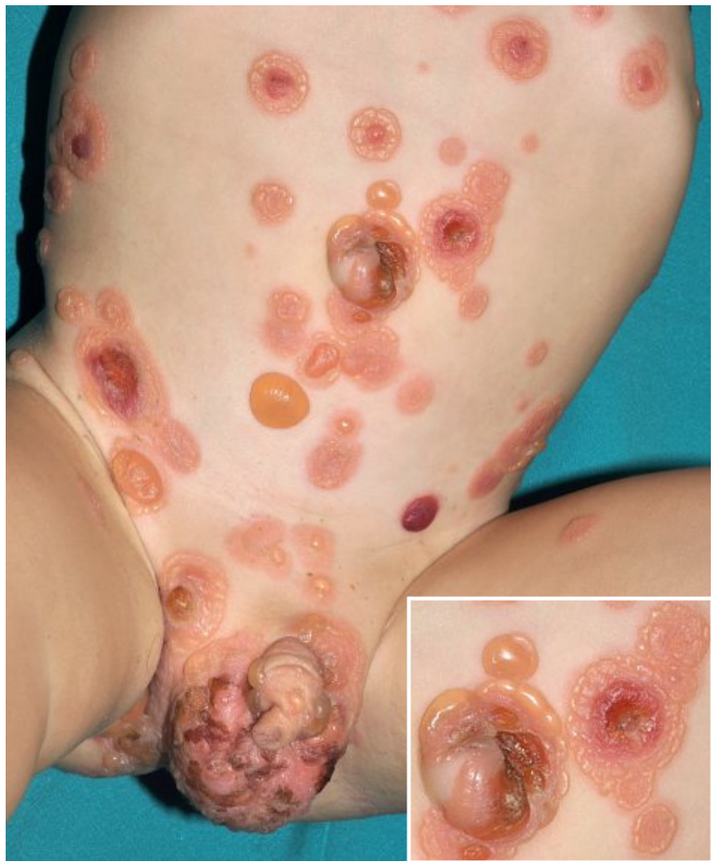

Fig. 31.7 Linear IgA bullous dermatosis. Characteristic findings in this child include the annular array of bullae (inset) and involvement of the genital region. There are also tense bullae arising on normal-appearing skin with either clear or hemorrhagic fluid and annular bullae with central crusting. *Courtesy Antonio Torello, MD.*

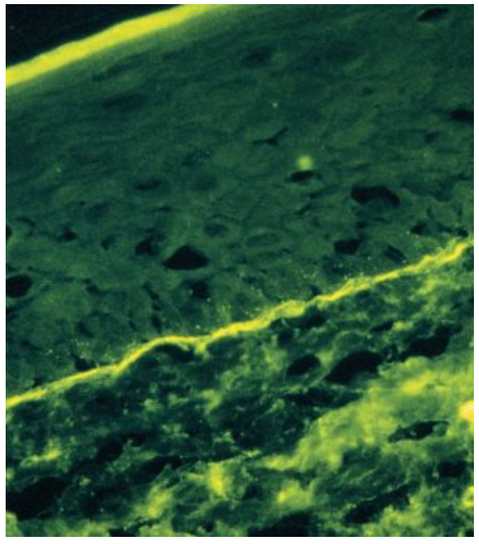

Fig. 31.8 Linear IgA bullous dermatosis – direct immunofluorescence. A linear pattern of IgA deposition is present within perilesional skin.

(Fig. 31.8) as well as circulating antibodies against the same BMZ antigens described in the adult form[26].

There are two distinct types of LABD based upon the site of IgA deposition as determined by immunoelectron microscopy: a lamina lucida type (majority) and a sublamina densa type. In adults, LABD is frequently drug-induced.

History

In 1969, it was noted that patients with vesiculobullous lesions and the histologic findings of DH could have linear rather than granular deposits

of IgA along the epidermal BMZ[27]. In 1975, Chorzelski and Jablonska[28] first suggested the term LABD and suggested that it was a separate entity based on its immunopathologic findings. Since then, there has been general agreement that LABD is a distinct disease entity from DH[29,30]. Nowadays, the term linear IgA disease (LAD) is often used as synonymous with LABD and perhaps is a preferred term, especially when there is mucosal involvement.

In 1970, Jordon et al.[31] first proposed the name "benign chronic bullous dermatosis of childhood". Subsequent investigators, using antisera specific for IgA, identified the characteristic linear IgA deposition along the epidermal BMZ in children with CBDC[32]. On a molecular basis, CBDC is the same disease as LABD in that the circulating IgA antibody found in the serum of patients with CBDC binds to the same 97 kDa proteolytic fragment of BP180 antigen described in adults with LABD[26].

Epidemiology

The annual incidence of LABD varies globally, ranging from 0.5 to 2.3 cases per million per year[33]. Incidence in the US has not been reported, but we have estimated the prevalence of LABD in Utah to be 0.6 per 100 000 adults. In adults, the average age of onset of LABD is over 60 years of age[33,34]. There appears to be a slight female preponderance, although this has not been observed in all series[33]. Childhood LABD occurs at a mean age of 4.5 years[34].

Pathogenesis

Both BP and the lamina lucida type of LABD have lamina lucida deposition of immunoglobulin and are associated with BMZ vesiculation. However, the antigenic specificity differs. In BP, the pathogenic IgG antibodies bind the MCW-1 region of the NC16 domain of BP antigen 2 (BPAG2; BP180), whereas the epitopes that have stimulated an IgA response in LABD are toward the carboxy terminus of the same molecule (Fig. 31.9)[35]. In adult and childhood LABD patients, this IgA antibody was initially found, on immunoblot, to react against a 97 kDa antigen in an epidermal extract[36]. Subsequently, there was definitive characterization of the antigenically active fragments of the physiologically cleaved BP180 ectodomain[37]. Sera from LABD patients preferentially react with two fragments that contain neoepitopes but not with intact BP180. These two fragments are LAD-1 (120 kD) and LABD97 (97 kD; see Fig. 31.9)[37]. Why BP antibodies should react predominantly with antigens near the transmembrane portion of BPAG2 and LABD antibodies react with cleaved epitopes within the collagenous domain is unclear.

IgA class antibodies from patients with the sublamina densa type of LABD have been reported to bind to type VII collagen within anchoring fibrils[38,39].

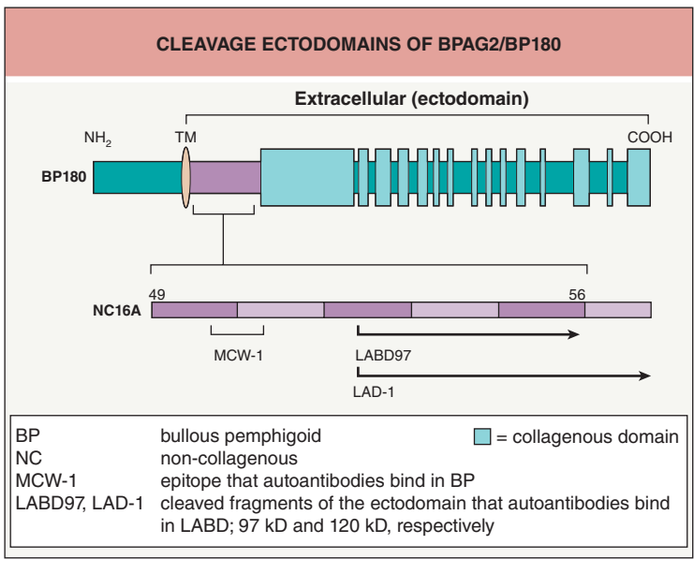

Fig. 31.9 Cleavage ectodomains of BPAG2/BP180. BP, bullous pemphigoid; COOH, carboxy terminus; LABD, linear IgA bullous dermatosis; NH_2, amino terminus; TM, transmembrane region.

There have been reports in the literature of the association of LABD with various disorders such as gastrointestinal diseases, autoimmune diseases, malignancies, and infections (see below). The significance of these associations is yet to be determined, but they may play a role in the initial stimulation of the IgA mucosal immune system.

The incidence of gluten-sensitive enteropathy in LABD has been reported in the literature to range from 0 to 24%[30,32,40]. In one case series, two of six patients with LABD had gluten-sensitive enteropathy, and two of six patients' skin lesions improved on a gluten-free diet; however, none of the patients completely cleared[40]. In contrast, a second series found no histologic evidence of gluten-sensitive enteropathy in the six patients they studied[30]. LABD clearly has a much lower prevalence of small bowel histologic abnormalities than does DH. Ulcerative colitis, Crohn disease, and gastric hypochlorhydria have also been described in association with LABD[29,41]. LABD associated with ulcerative colitis was reported to remit after colectomy[42].

Data on the association of autoimmune diseases with LABD are not sufficient to allow statistical analysis of prevalence. However, there are reports in the literature of the association of systemic lupus erythematosus and dermatomyositis with LABD, as well as thyrotoxicosis, autoimmune hemolytic anemia, rheumatoid arthritis, and glomerulonephritis[43,44].

An association between LABD and malignancy has also been described. Tumors that have been reported in patients with LABD include: B cell lymphoma, chronic lymphocytic leukemia, and carcinoma of the bladder, thyroid, colon and esophagus; single case reports of plasmacytoma, hydatidiform mole, renal cell carcinoma, and ocular melanoma have also been described[33,45–48]. In addition, LABD has been reported to be associated with several infections, including varicella zoster virus, antibiotic-treated tetanus, and upper respiratory infections. It has been postulated that the infectious agent may have triggered an immune response[49,50]. Lastly, there are reports of new-onset LABD developing after SARS-CoV-2 vaccination, but whether this represents a true association remains speculative.

There are multiple reports of drug-induced LABD; the drugs associated with LABD are listed in Table 31.5, with vancomycin being the most common inducer (Fig. 31.10)[51,52]. While IIF studies are generally

DRUG-INDUCED LINEAR IgA BULLOUS DERMATOSIS

Common

- Vancomycin*

Less common

- Penicillins
- Cephalosporins
- Captopril > other ACE inhibitors
- NSAIDs: diclofenac, naproxen, oxaprozin, piroxicam

Uncommon

- Phenytoin
- Sulfonamide antibiotics: sulfamethoxazole, sulfisoxazole

Rare

- Acetaminophen
- Allopurinol
- Amiodarone
- Amlodipine
- Angiotensin receptor blockers: candesartan, eprosartan
- Atorvastatin
- Buprenorphine
- Carbamazepine
- Cyclosporine
- Enoxaparin
- Furosemide
- Gemcitabine
- Glibenclamide
- Glyburide
- Granulocyte colony-stimulating factor
- Infliximab
- Influenza vaccination
- Interferon-α and interferon-γ
- Interleukin-2
- Lithium carbonate
- Metronidazole
- Minocycline
- Moxifloxacin
- PUVA
- Rifampin
- Somatostatin
- Tea tree oil
- Ustekinumab
- Verapamil
- Vigabatrin

*Unusual variants include toxic epidermal necrolysis-like and morbilliform.

Fig. 31.11 Linear IgA bullous dermatosis. Vesicles and bullae arising within normal-appearing skin as well as scattered annular lesions. The former can also be seen in bullous pemphigoid. *Courtesy Jeffrey P. Callen, MD.*

Fig. 31.13 Linear IgA bullous dermatosis. Striking annular vesiculobullous lesions on the thigh with central erosions and crusting. A figurate outline is seen in the area of coalescence.

negative in drug-induced LABD, addition of vancomycin to patients' sera can result in a positive IIF assay, with reactivity against the NC1 domain of type VII collagen. These novel findings suggest that vancomycin either mediates or enhances IgA autoreactivity to type VII collagen[53]. Drug-induced LABD usually remits within 2–6 weeks of cessation of the drug, although it can persist for months[52].

Clinical Features

Clinical manifestations of LABD are variable and patients can present with findings suggestive of DH as well as subepidermal tense bullae that are often indistinguishable from BP (Fig. 31.11). However, the vesiculobullous lesions often appear in a herpetiform arrangement on erythematous and/or normal-appearing skin (Fig. 31.12). Some patients present with expanding annular plaques (Fig. 31.13), while others have lesions that are scattered and asymmetric[29]. An isomorphic response, including lesions appearing at previous sites of adhesive tape, has been reported.

LABD may present as a variant of mucous membrane pemphigoid, with oral, nasal, pharyngeal, and esophageal lesions. Involvement of the tracheobronchial mucosa was reported in a severe case[54]. The ocular form of LABD is clinically indistinguishable from ocular mucous membrane pemphigoid[55].

LABD secondary to drugs, in particular vancomycin, may have a toxic epidermal necrolysis (TEN)-like or morbilliform presentation.

Pathology

LABD is a subepidermal vesicular dermatosis in which neutrophils predominate. In early urticarial papules or plaques, neutrophils are aligned along the BMZ, accompanied by vacuolar change and sometimes

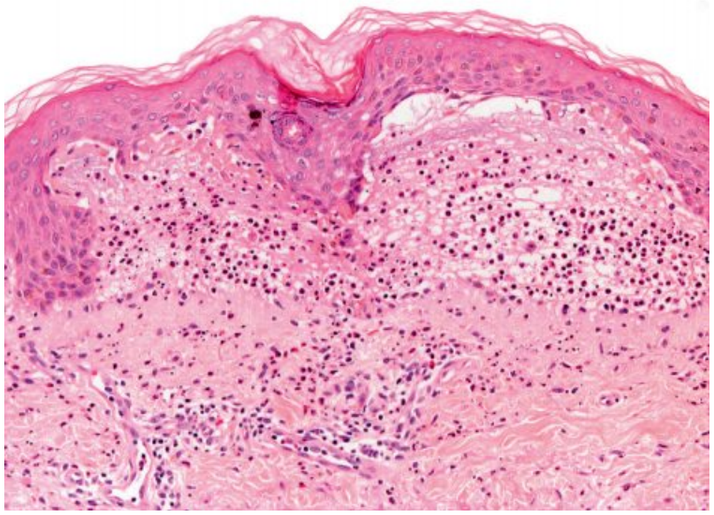

Fig. 31.14 Linear IgA bullous dermatosis – histopathologic features. Subepidermal blister filled with neutrophils. Neutrophils and a few eosinophils are also present within the underlying dermis. *Courtesy Lorenzo Cerroni, MD.*

by neutrophilic microabscesses in dermal papillae. These papillary dermal collections, if numerous enough, can resemble the picture seen in DH[29]. In fully developed lesions, there are subepidermal bullae in which neutrophils are present in the underlying dermis, either alone or with eosinophils (Fig. 31.14). Eosinophils can become more numerous over time, particularly in adults, thus mimicking the histopathologic picture of bullous pemphigoid. Although in most cases distinguishing between DH and LABD is impossible by light microscopy, a linear distribution of neutrophils along the BMZ and neutrophils at the very tips of dermal papillae favor LABD[56]. However, the latter cannot be considered a specific finding.

LABD can be subdivided on the basis of immunoelectron microscopy findings, with most patients having IgA deposits within the lamina lucida[30,57]. Less commonly, there is deposition of IgA in the sublamina densa, associated with anchoring fibrils[30]. In a few cases, deposits of IgA have been observed in both sites[58]. In one report, the deposition of IgA was initially in the lamina lucida, but later had a combined pattern[58].

Galactose-deficient IgA1 (Gd-IgA1) is implicated in the pathogenesis of IgA nephropathy and deposits of Gd-IgA1 have been detected in systemic and skin-limited forms of IgA vasculitis[59]. However, the role of Gd-IgA1 in DH and LABD remains unknown. A single case report has suggested the passive transfer of pathogenic IgA autoantibodies to a newborn from an asymptomatic mother via breast milk[59a].

Differential Diagnosis

LABD can be difficult to diagnose clinically, especially in adults, and is often confused with DH and BP. By definition, LABD is separated from DH and BP on the basis of findings by DIF (see Table 31.3). Linear IgA deposition along the BMZ in perilesional skin is characteristic of LABD (see Fig. 31.8), in contrast to either DH, which shows granular deposition of IgA in dermal papillary tips or in a continuous pattern along the basement membrane[28–30], or BP, which shows linear deposition of IgG along the epidermal BMZ. The classification of cases demonstrating both IgG and IgA along the BMZ is problematic. Some authorities include only those patients with IgA as the sole BMZ immunoglobulin under the term LABD and categorize all others as BP. Others categorize patients with both IgG and IgA along the BMZ based on the predominant immunoglobulin by DIF. Perhaps the most important point is that patients with IgA along the BMZ, alone or in combination with IgG, are more likely to respond to dapsone therapy. Distinguishing the sublamina densa form of LABD from epidermolysis bullosa acquisita is also made on the basis of the class of immunoreactant and classification can be problematic.

Circulating anti-BMZ antibodies of the IgA class can be demonstrated in 60%–70% of LABD sera. In contrast, patients with DH have not been shown to have circulating antibodies that bind to skin, and 60%–70% of patients with BP demonstrate circulating IgG class antibodies (see Table 31.3)[28]. Circulating IgA class anti-BMZ antibodies from the lamina lucida type of LABD have been shown to adhere to the epidermal side (roof) of salt-split skin, while patients with sublamina densa binding of IgA on direct immunoelectron microscopy have serum antibodies which bind to the dermal side of salt-split skin. Patients with both IgA and IgG at the BMZ demonstrate binding to the epidermal side of salt-split skin[60]. Whether or not such antibody titers correlate with disease activity has not yet been established.

For the morbilliform or TEN-like presentation of LABD due to drugs, in particular vancomycin, routine microscopy plus DIF aids in the diagnosis.

Treatment

The majority of patients with LABD respond to oral dapsone, sulfapyridine or sulfasalazine. These medications have been reviewed in detail in the section on the treatment of DH. Most patients with LABD have a clinical response within 48–72 hours. In occasional patients, it may be necessary to add oral prednisone in doses up to 40 mg daily to achieve complete control of the disease. However, the majority of our patients have been controlled by dapsone alone. It is our observation that patients in whom both IgG and IgA deposits are present in the BMZ represent those who are likely to require additional therapy with systemic corticosteroids. The average dose of dapsone required to control LABD in adults is 100 mg daily, but doses as high as 300 mg daily may be needed. If doses >200 mg per day are necessary, close monitoring should be undertaken. Children usually respond to a dose of 1–2 mg/kg daily.

Successful treatment of both adult and childhood LABD with antibiotics, including dicloxacillin, erythromycin, tetracycline (in those >9 years of age), and trimethoprim–sulfamethoxazole, has been reported. No specific microorganism was incriminated in these cases and therapeutic trials were empirical. A clinical trial of these relatively benign therapies may be undertaken, but no method of predicting a response has been identified. Mycophenolate mofetil, azathioprine, IVIg, and rituximab can be used as steroid-sparing agents in patients who do not respond to a combination of prednisone and dapsone or in patients with severe disease.

The natural course of the disease is characterized by persistence for several years with eventual spontaneous remission in many patients. Reported remission rates vary from 10%–60%, depending on the underlying trigger. There should be repeated attempts to taper systemic medications, on the chance that a spontaneous remission has occurred. Childhood LABD remits within 2–4 years.

Epidermolysis Bullosa 32

Jo-David Fine and Jemima E. Mellerio

Synonyms: ■ All forms of EB: EB hereditaria ■ EB simplex: epidermolytic EB ■ Junctional EB: EB atrophicans, EB letalis ■ Dystrophic EB: EB dystrophica

Key features

- Epidermolysis bullosa (EB) encompasses multiple clinically distinctive disorders that share three major features: genetic transmission, mechanical fragility of the skin, and blister formation
- There are four major forms of inherited EB – EB simplex, junctional EB, dystrophic EB, and Kindler EB – which differ in the ultrastructural site within which cutaneous blisters form
- EB may be diagnosed by immunofluorescence antigenic mapping, transmission electron microscopy, or genetic analysis
- Any epithelial-lined or epithelial-covered organ is at potential risk for involvement in the more severe forms of inherited EB
- In the absence of specific therapy, management is primarily focused on prevention of blisters, wound care, and treatment of extracutaneous complications

INTRODUCTION

Inherited epidermolysis bullosa (EB), the prototypic mechanobullous disease, is characterized by the development of blisters following seemingly minor or insignificant trauma or traction to the skin[1,2]. The most recent classification includes four major forms of classic EB – EB simplex, junctional EB, dystrophic EB, and Kindler EB – and at least 30 distinctive clinical phenotypes[1] (Table 32.1). Inherited EB can result from mutations within the genes that encode at least 16 structural proteins: keratins 5 and 14; the subunits of laminin 332 (formerly laminin 5); types VII and XVII collagens; plectin; $\alpha_6\beta_4$ integrin; α_3 integrin subunit; bullous pemphigoid antigen 1; kindlin-1; exophilin 5; kelch-like protein 24; and CD151 (tetraspanin 24). The current EB classification also delineates other disorders associated with skin fragility in which blistering is a relatively minor feature, with at least 23 additional genes implicated in their pathogenesis[1]. These entities include several disorders that were previously classified as suprabasal forms of EB simplex, such as acral peeling skin syndrome (transglutaminase-5; see Table 57.8), skin fragility–ectodermal dysplasia syndrome (plakophilin-1), and acantholytic erosive disorder (desmoplakin or plakoglobin).

Although most forms of EB are rare, research into their underlying pathophysiologic bases has led to major advances in our understanding of the cell and molecular biology of keratins, other keratinocyte-associated structural proteins, collagens, and the cutaneous extracellular matrix (ECM). Study of EB has also helped to elucidate mechanisms of epithelial cell adhesion, migration, and differentiation and to highlight the role of the epidermal basement membrane in health and disease. The creation of *in vitro* and animal models of EB has facilitated the development of novel translational therapeutic approaches for the treatment of EB patients[2].

HISTORY

Epidermolysis bullosa was first described in 1870 by von Hebra under the name "erblichen pemphigus"[3]. Its current name, "epidermolysis bullosa hereditaria", was coined by Koebner in 1886. Hallopeau recognized the distinct clinical features of simplex and dystrophic forms of EB in 1898. Junctional EB was first identified in 1935 by Herlitz and termed "EB letalis". Precise characterization of these three major EB types via the use of transmission electron microscopy was first achieved by Pearson in 1962[4]. In the ensuing years, additional EB phenotypes were described. Monoclonal antibody studies provided the first suggestion that specific protein defects underlie individual types and subtypes of this disease[5–8]. In 1986, the National EB Registry was established in the US by the National Institutes of Health, facilitating epidemiologic, clinical, and laboratory characterization of each major EB type and subtype[9,10]. In 1991, Bonifas et al.[11] utilized linkage analysis to demonstrate the molecular basis for EB simplex. Subsequent work by others has established the precise molecular basis for most of the EB subtypes recognized to date.

EPIDEMIOLOGY

Based on National EB Registry data[12,13], the estimated overall prevalence and incidence of EB in the US are 11.1 per 1 million population and 19.6 per 1 million live births, respectively. Carrier frequencies have also been reported[14]. The approximate prevalences and incidences, respectively, of the major types of EB are as follows: EB simplex, 6.0 and 7.9; junctional EB, 0.5 and 2.7; dominant dystrophic EB, 1.5 and 2.1; and recessive dystrophic EB, 1.4 and 3.0.

PATHOGENESIS

EB is caused by mutations within genes that encode structural proteins that reside within the epidermis (EB simplex), dermal–epidermal junction (junctional EB), or uppermost papillary dermis (dystrophic EB). The site within which each of these proteins resides determines the ultrastructural location where the blisters arise (Fig. 32.1, see Table 32.1).

EB Simplex

The most common forms of EB simplex (EBS) are transmitted in an autosomal dominant manner and are associated with blistering at the level of the basal keratinocyte. EBS most often results from a dominant-negative mutation (see Ch. 54) within the keratin 5 (*KRT5*) or 14 (*KRT14*) genes, expression of which is primarily within the basal layer of the epidermis[15,16]. The clinical severity and other phenotypic features of EBS are closely associated with the genotype. For example, mutations in the helix initiation and termination motifs of *KRT5* and *KRT14* lead to the severe subtype of EBS (severe EBS, previously known as EBS-Dowling–Meara), whereas the specific phenotype of EBS with mottled pigmentation almost always arises from a particular missense mutation in the V1 domain of *KRT5*.

Dominant stabilizing mutations in the kelch-like protein 24 ubiquitin ligase gene (*KLHL24*) lead to EBS via increased ubiquitination and degradation of keratin 14[17]. An autosomal recessive form of EBS due to mutations in the gene encoding plectin (*PLEC*) is associated with muscular dystrophy, which is not surprising considering that plectin is expressed in skeletal muscle as well as in the hemidesmosomes of basilar keratinocytes. Other EBS patients with plectin or rarely $\alpha_6\beta_4$ integrin deficiencies present with pyloric atresia, while autosomal recessive variants of EBS caused by mutations in bullous pemphigoid antigen 1/dystonin (*DYS*) or exophilin 5 (*EXPH5*) genes have also been reported.

Junctional EB

Junctional EB (JEB) is almost always transmitted in an autosomal recessive manner (see Table 32.1). The severe subtype of JEB (severe JEB,

CLASSIC EPIDERMOLYSIS BULLOSA: SIMPLEX, JUNCTIONAL, DYSTROPHIC, AND KINDLER SUBTYPES		
Subtype	**Inheritance**	**Defective protein(s)**
Intraepidermal cleavage

*One case with AD inheritance has been reported.
†Includes variants previously referred to as pretibial (DDEB & RDEB), acral (DDEB), and nails only (DDEB).

Table 32.1 Classic epidermolysis bullosa (EB): simplex, junctional, dystrophic subtypes, and Kindler EB. Entities in **bold** are the more common subtypes, and those with a darker background represent syndromic variants. AD, autosomal dominant; AR, autosomal recessive; EBS, epidermolysis bullosa simplex; DDEB, dominant dystrophic EB; RDEB, recessive dystrophic EB.

previously known as JEB-Herlitz) typically results from homozygous or compound heterozygous truncating mutations within a gene encoding one of the three subunits of laminin 332, a key component of the lamina lucida of the dermal–epidermal junction (see Ch. 28)[18]. In laryngo-onycho-cutaneous syndrome, the underlying mutations affect only the A isoform of the laminin α3 subunit. The milder intermediate form of JEB (intermediate JEB, previously known as JEB-non-Herlitz and generalized atrophic benign EB) results from mutations within the genes for either a subunit of laminin 332 or, less frequently, type XVII collagen/bullous pemphigoid antigen 2. JEB with pyloric atresia, which is much more common than EBS with pyloric atresia, is also caused by mutations within either of the two genes that encode the subunits of $\alpha_6\beta_4$ integrin. A form of JEB associated with respiratory and renal involvement results from mutations in the integrin α_3 chain.

Dystrophic EB

Dystrophic EB (DEB) is transmitted in either an autosomal dominant or autosomal recessive manner and is caused by mutations in the type VII collagen gene (*COL7A1*). Dominant DEB (DDEB) results from dominant-negative mutations, typically a missense mutation that leads to substitution of another amino acid for a glycine within the triple-helical domain of this collagen. Although the resultant protein is structurally abnormal, immunohistochemical staining for type VII collagen along the dermal–epidermal junction is usually indistinguishable from that of normal skin.

Recessive DEB (RDEB) is due to compound heterozygous or, less frequently, homozygous mutations within the type VII collagen gene[19–21]. Premature stop codons, which result in truncated proteins, are

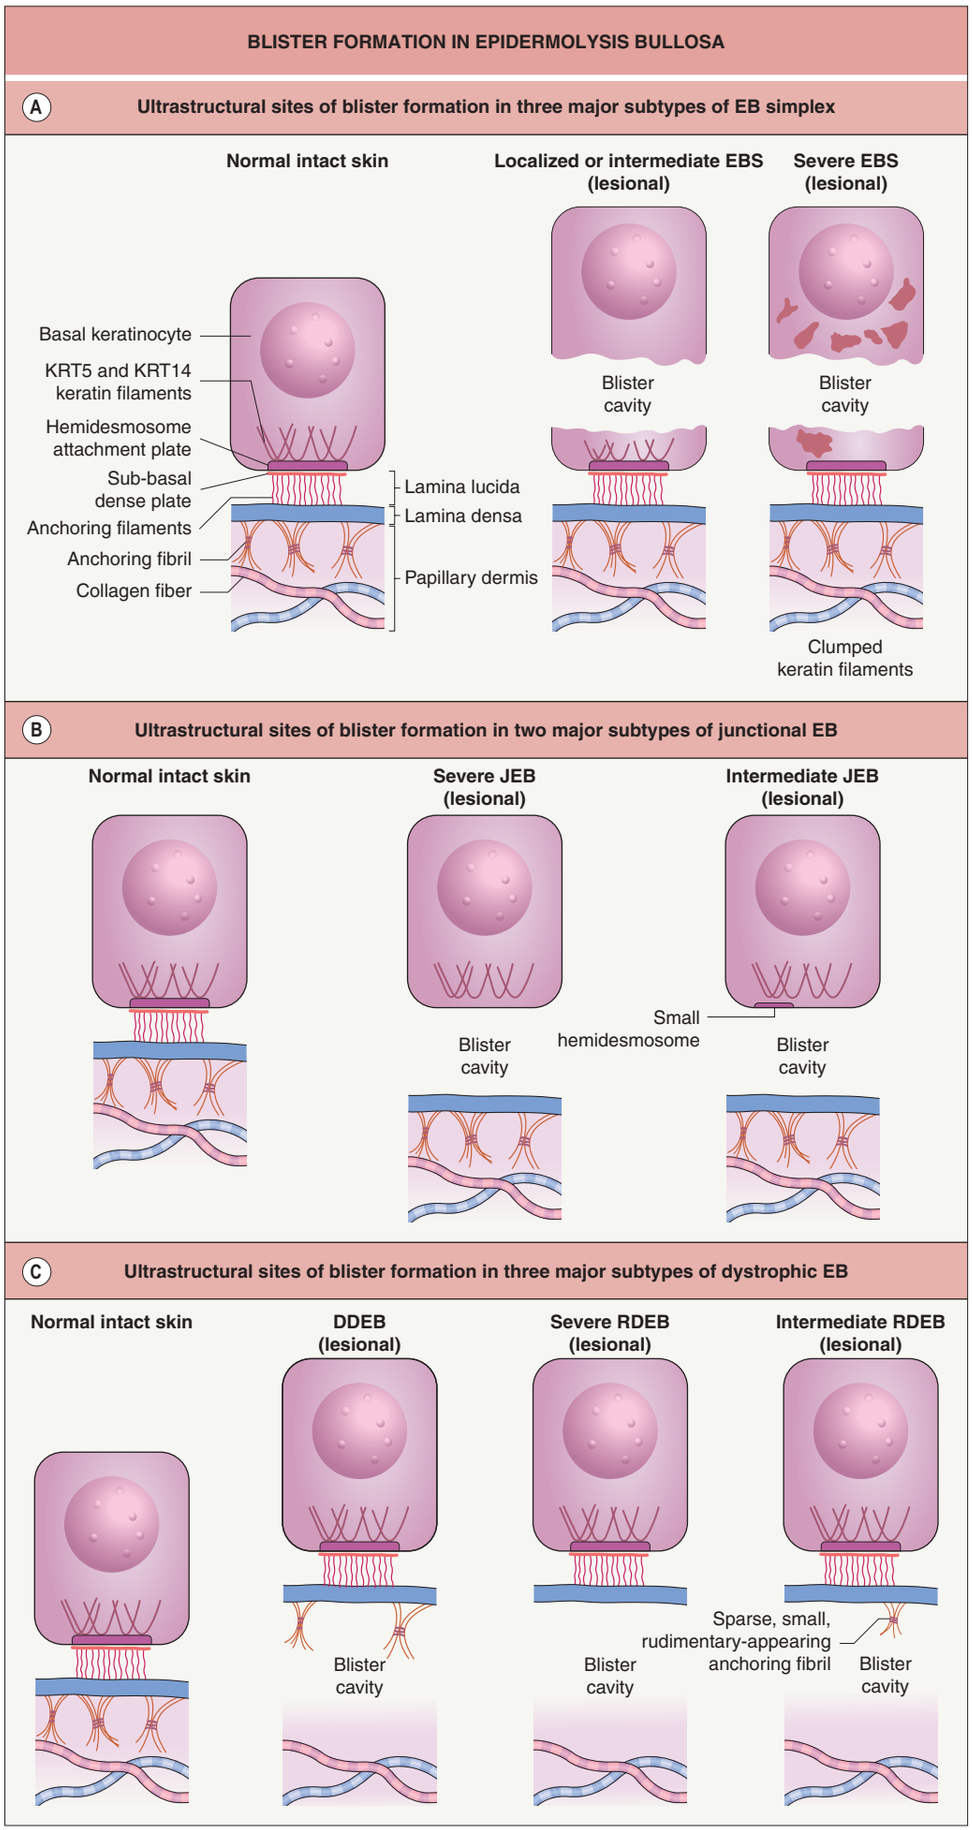

Fig. 32.1 Blister formation in epidermolysis bullosa (EB). A Ultrastructural sites of blister formation in three major subtypes of *EB simplex (EBS)*. The ultrastructure of normal intact skin is presented for comparison. In all three major subtypes of EBS – localized, intermediate, and severe – blisters arise within the lowermost intracytoplasmic portion of the basilar keratinocyte. In severe EBS, keratin filaments tend to coalesce into larger electron-dense clumps, especially in lesional skin. Keratin filaments are absent or reduced in the rare autosomal recessive form of EBS, and in EBS with muscular dystrophy there is lack of integration of keratin filaments into the underlying hemidesmosome. **B** Ultrastructural sites of blister formation in two major subtypes of *junctional EB (JEB)*. All forms of JEB are characterized by blister formation within the lamina lucida of the dermal–epidermal junction. As such, the lamina densa remains firmly attached to the dermis which forms the base of the blister cavity. Sub-basal dense plates and anchoring filaments are absent in generalized severe JEB and often attenuated in other subtypes of JEB. Hemidesmosomes are absent or extremely sparse and rudimentary in severe JEB, whereas they are normal or reduced in number and size in intermediate JEB. **C** Ultrastructural sites of blister formation in three major subtypes of *dystrophic EB (DEB)*. Blister formation occurs beneath the lamina densa in all forms of dystrophic EB. Anchoring fibrils appear normal in size and structure in dominant DEB (DDEB) skin, although they may be somewhat reduced in number. Consistent with the presence of sublamina densa cleavage, these anchoring fibrils remain attached to the blister roof, which is composed of intact epidermis and an attached basement membrane that includes the lamina densa. In contrast, anchoring fibrils are usually completely absent in lesional skin from patients with severe recessive DEB (RDEB). In intermediate RDEB, anchoring fibrils are reduced in number and rudimentary in appearance.

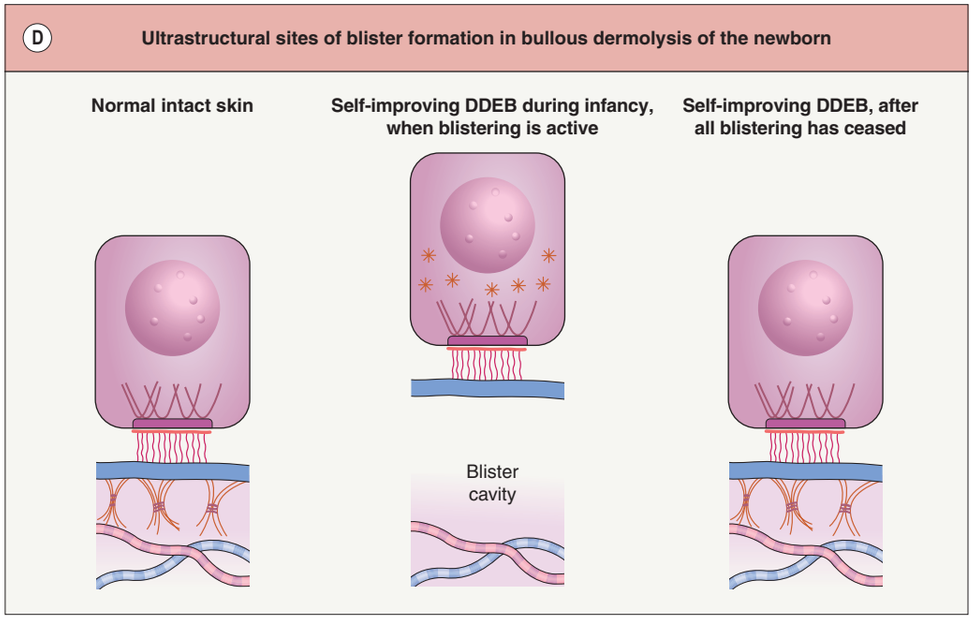

Fig. 32.1 Blister formation in epidermolysis bullosa (EB). (cont'd) D Ultrastructural site of blister formation in the form of DEB referred to as *self-improving DEB*. With age, there is improvement in the transport and deposition of type VII collagen from the keratinocyte cytoplasm to the anchoring fibrils of the basement membrane.

characteristic of the severe subtype (severe RDEB, previously known as RDEB-Hallopeau–Siemens). Consistent with the severity of these mutations, anchoring fibrils are undetectable or extremely sparse and poorly formed in skin biopsy specimens, and immunohistochemical staining with antibodies against the major epitopes of the type VII collagen molecule is absent or barely detectable. Milder forms of RDEB are associated with less severe biallelic mutations in the type VII collagen gene.

A single nucleotide polymorphism in the matrix metalloproteinase 1 gene promoter has been identified as a disease modifier in RDEB[22]. It is likely that additional modifying genes account for some of the inter- and intra-familial phenotypic variability observed in this and other forms of EB. There is also evidence for secondary effects from loss of protein expression in EB. For example, loss of collagen VII in RDEB fibroblasts leads to alterations in dermal matrix proteins, metalloproteinases, and transforming growth factor-β (TGF-β), which are thought to further influence keratinocyte adhesion, dermal–epidermal integrity, and dermal fibrosis[23,24].

Severe RDEB and (to a lesser extent) other forms of DEB, JEB, and Kindler EB are associated with an increased risk for the development of cutaneous SCCs. The pathogenesis of these tumors is multifactorial, and the cutaneous microenvironment plays a critical role in the initiation of carcinogenesis, tumor progression, and metastatic potential[2,25]. Increased dermal stiffness, bacterial colonization, chronic inflammation, and defects in the innate immune system contribute to the early development and aggressive nature of these tumors[23].

In self-improving DEB (previously known as bullous dermolysis of the newborn), inheritance is usually dominant and blistering is typically confined to the first 1–2 years of life[26–28]. Clinical expression coincides with a time during which type VII collagen is present primarily within basal keratinocytes in these patients' skin, rather than along the dermal–epidermal junction (see Fig. 32.1D). This suggests that there may be a temporary disruption in the transport of this protein from the keratinocyte cytoplasm to the underlying ECM.

CLINICAL FEATURES

Cutaneous Findings

All forms of inherited EB are characterized by mechanically fragile skin, erosions, and (with rare exceptions) macroscopic blisters (Figs. 32.2 & 32.3). Scarring is almost always atrophic and can occur in any subtype of EB (Fig. 32.4), including localized EBS. However, scarring is most frequent in the subtypes that are characterized clinically by generalized disease activity and ultrastructurally by disruption of the basement

Fig. 32.3 Intermediate epidermolysis bullosa simplex. Extensive blistering on the buttocks (**A**) and blistering in association with focal keratoderma on the soles (**B**) of a 2-year-old girl. *Courtesy Julie V. Schaffer, MD.*

membrane, particularly the lamina densa (Fig. 32.5). Whereas scarring is estimated to occur in only 15% of patients with localized EBS, it is present in essentially every patient with RDEB[29]. Other cutaneous findings that have similar variations in frequency across the major types and subtypes of EB include dystrophic or absent nails (see Fig. 32.4), milia, and scarring alopecia of the scalp.

Some cutaneous findings have diagnostic implications (Fig. 32.6)[13]. *Reticulated hyperpigmented macules* distinguish a rare subtype of EBS termed EBS with mottled pigmentation. *Grouped ("herpetiform") blisters*, often in an arcuate (Fig. 32.7) or polycyclic array, are highly characteristic of severe EBS, which is also associated with the gradual development of a diffuse palmoplantar *keratoderma* (Fig. 32.8). *Migratory circinate erythema* with vesiculation of the advancing edge has been described in patients with EBS caused by a frameshift mutation that leads to an elongated keratin 5 protein. *Excessive or exuberant granulation tissue*, usually in a symmetric distribution involving the perioricial areas, skin folds, upper back, nape of the neck, and periungual areas, is typical of severe JEB (Fig. 32.9). *Extremely pruritic papules* that can coalesce into a linear arrangement on the lower extremities, are characteristic of DEB pruriginosa (Fig. 32.10).

Distribution of skin disease activity is also useful in the subclassification of EB[29,30], although the pattern of involvement tends to be less distinctive in infants than in adults. Patients with the "inversa" subtypes of JEB and RDEB experience severe disease activity primarily in intertriginous areas such as the axillae and inguinal creases. In contrast, patients with localized JEB have involvement mainly in acral sites. Individuals with localized DEB may have lesions almost exclusively on the shins (previously referred to as pretibial DEB). A rare

Fig. 32.4 Dominant dystrophic epidermolysis bullosa. A, B Erosions, scarring and milia on the fingers. Note the partial (**A**) to almost complete (**B**) loss of the nails. **C** A discrete area of scarring on the elbow with blisters, crusting, and milia. *B, Courtesy Julie V. Schaffer, MD.*

subtype previously known as RDEB centripetalis initially features acral blistering, followed by slow progression of disease activity toward the trunk over the years.

Extracutaneous Findings

The molecular defects that affect the skin in patients with EB may also lead to manifestations in other tissues with an epithelial lining or surface, including the eye, oral cavity, and gastrointestinal, genitourinary, and respiratory tracts[31–36]. Major extracutaneous complications of EB are summarized in Table 32.2[31–33]. Although exceptions exist, extracutaneous involvement occurs most frequently in RDEB and JEB, and it can result in blisters, erosions, ulcers, and scarring. Rare subtypes of JEB and EBS present at birth with *pyloric atresia* as well as skin fragility and blistering[35]. In other forms of EB, extracutaneous disease may become apparent as early as the first few months of life. Repeated blistering of the *external eye* can result in neovascularization and blindness[34]. Chronic involvement of the *esophagus* leads to scarring, stricture formation and, rarely, even complete obstruction[35]. Involvement of the *small intestine* presents with chronic malabsorption, whereas disease activity within the *large intestine* tends to produce constipation and painful anal fissures or strictures. Recurrent *genitourinary tract* blistering may result in urethral or ureterovesical

Hydroureter and hydronephrosis		JEB-PA, sev-JEB
Nephrotic syndrome	JEB-ILD/ nephrotic	Sev-JEB
Heart		
Dilated cardiomyopathy		Sev-RDEB > JEB, intermed-RDEB
Musculoskeletal system		
Pseudosyndactyly	Sev-RDEB	Intermed-RDEB, Kindler EB
Osteoporosis or osteopenia	Sev-RDEB	Sev-RDEB, sev-JEB
Muscular dystrophy	EBS-MD	
Bone marrow		
Severe multifactorial anemia	Sev-RDEB, sev-JEB	

*Causes include renal amyloidosis and glomerulonephritis.

Table 32.2 Major extracutaneous complications of epidermolysis bullosa (EB). EBS, EB simplex; GERD, gastroesophageal reflux disease; intermed, intermediate; sev, severe; ILD, interstitial lung disease; inv, inversa; JEB, junctional EB; MD, muscular dystrophy; PA, pyloric atresia; RDEB, recessive dystrophic EB.

strictures; if persistent, the latter may eventuate in ureteric reflux and hydronephrosis. *Tracheolaryngeal* blistering and associated soft tissue edema, seen most often in infants and young children with severe JEB, may lead to potentially fatal acute airway obstruction[36]. JEB with respiratory and renal involvement is a rare subtype associated with severe interstitial lung disease.

Dental enamel hypoplasia, which occurs exclusively in JEB, is associated with pitting of the surfaces of primary and permanent teeth[37,38]. If untreated, affected individuals lose teeth during childhood due to excessive caries[39]. *Severe caries* and tooth loss also occur in severe RDEB, likely resulting from impaired clearance of food from the mouth and poor dental hygiene in the setting of intraoral injury and scarring, ankyloglossia, and microstomia.

Pseudosyndactyly ("mitten" deformities) of the hands and feet primarily affects patients with RDEB, especially severe RDEB, although it occasionally occurs to a lesser degree in DDEB and JEB[40] (Fig. 32.11B & C). Initially presenting as proximal web formation between adjacent digits, the digits may eventually become totally fused and

Fig. 32.11 Severe recessive dystrophic epidermolysis bullosa. A Area on the neck with chronic and recurrent wounds in a 7-year-old child. **B** Early proximal interdigital web formation together with atrophic scarring and loss of nails in a 5-year-old girl. **C** Partial "mitten" deformities of the hands in an older child. *A, B, Courtesy Julie V. Schaffer, MD.*

encased by scar tissue. Lack of mobility leads to progressive bone resorption and muscular atrophy, and hand function is severely compromised.

Osteoporosis, detectable by dual-emission X-ray absorptiometry (DEXA) scanning, is common in severe RDEB and severe JEB. Radiographs may demonstrate vertebral crush fractures in severe cases. EBS due to plectin deficiency is associated with mild to severe *muscular dystrophy*. Although the muscle disease presents during infancy in some patients, weakness often develops insidiously during later childhood or even early adulthood in those who are less severely affected.

Chronic renal failure occasionally develops in patients with severe forms of EB, most notably severe RDEB, which is associated with a ~10% risk of death from renal failure by age 35 years[41]. Renal disease may result from untreated outflow obstruction, glomerulonephritis, secondary systemic amyloidosis, or IgA nephropathy. *Nephrotic syndrome* associated with altered expression of laminin isoforms in renal basement membranes has been reported in an infant with generalized JEB and it occurs congenitally as a result of integrin α_3 mutations in JEB with respiratory and renal involvement. A small subset of patients with severe forms of EB, especially RDEB, develop potentially fatal dilated *cardiomyopathy*[42]. Although as yet unproven, selenium or carnitine deficiency may be a contributing factor.

Although it was a common occurrence several decades ago, potentially lethal bacterial sepsis is now relatively rare in inherited EB[43], presumably due to improved wound care and the availability and judicious use of broad-spectrum antibiotics. When sepsis does occur in EB, it tends to affect infants with severe disease[44]. In contrast, failure to thrive is still common among infants with severe JEB and may lead to death.

Cutaneous Malignancies

A major complication, usually of RDEB, is the development of multiple cutaneous SCCs[45,46]. These tumors most often arise in chronic non-healing wounds or hyperkeratotic lesions (Fig. 32.12). Histologically, they are usually well differentiated. However, the borders of the lesions are often indistinct and they are difficult to completely excise, with a tendency to recur locally. In addition, SCCs in EB patients frequently metastasize and are strikingly unresponsive to chemotherapy or radiotherapy. Indeed, they represent the leading cause of death in EB at or after mid-adolescence, with death from an SCC of cutaneous origin occurring in most patients within 5 years of the diagnosis of their first SCC[44]. These tumors occur primarily in RDEB, especially when severe, although SCCs can also develop in adults with other forms of DEB, JEB, and Kindler EB. The cumulative risk of at least one SCC in patients with severe RDEB is 7.5% by age 20 years but rises to 68%, 80%, and 90% by ages 35, 45, and 55 years, respectively[33]. In contrast, the risk of SCC in other forms of RDEB is <25% by age 45 years[44].

Melanoma occurs in a small number of children with severe RDEB, with a cumulative risk of 2.5% by the age of 12 years[43]. Although this is a relatively infrequent complication, careful surveillance during childhood is indicated. Children with EB, in particular those with intermediate JEB, can develop large, irregularly shaped, darkly pigmented melanocytic nevi ("EB nevi") (Fig. 32.13) that clinically resemble melanoma, although they are histologically and biologically benign. A large size from the onset rather than a relatively slow horizontal expansion is a clue to the diagnosis of these EB-associated nevi.

APPROACH TO DIAGNOSIS

Patients with EB are classified on the basis of the clinical phenotype, mode of inheritance, ultrastructural level of blister formation, antigenic profile in the skin, and underlying genetic defect[2,29,47]. Although skin findings play an important role in determination of the EB phenotype, different subtypes of EB have considerable overlap in their cutaneous manifestations. In addition, the severity, distribution, and type of skin findings in an individual patient may change over time, such as evolution from generalized to localized blistering (or the opposite) or delayed development of sequelae such as exuberant granulation tissue, scarring, and nail dystrophy[1,29].

Fig. 32.13 Large acquired melanocytic nevus at a site of blistering in a teenage girl with junctional epidermolysis bullosa. *Courtesy Julie V. Schaffer, MD.*

Standard light microscopy has no role in the diagnosis of classic forms of inherited EB, since it may be difficult to distinguish between even lower intraepidermal and subepidermal blister formation, let alone between intra-lamina lucida (i.e. JEB) and sublamina densa (i.e. DEB) types, without more sophisticated staining techniques[47]. The diagnostic tests employed for EB include immunofluorescence antigen mapping (IFM), transmission electron microscopy (TEM), and increasingly genetic analysis[47]. TEM can define the ultrastructural level of blister formation and provide a quantitative and qualitative assessment of specific structures, such as basilar tonofilaments, hemidesmosomes, sub-basal dense plates, anchoring filaments, and anchoring fibrils[13,47]; however, currently it is routinely performed in only a few reference laboratories. A diagnostic algorithm is presented in Fig. 32.14.

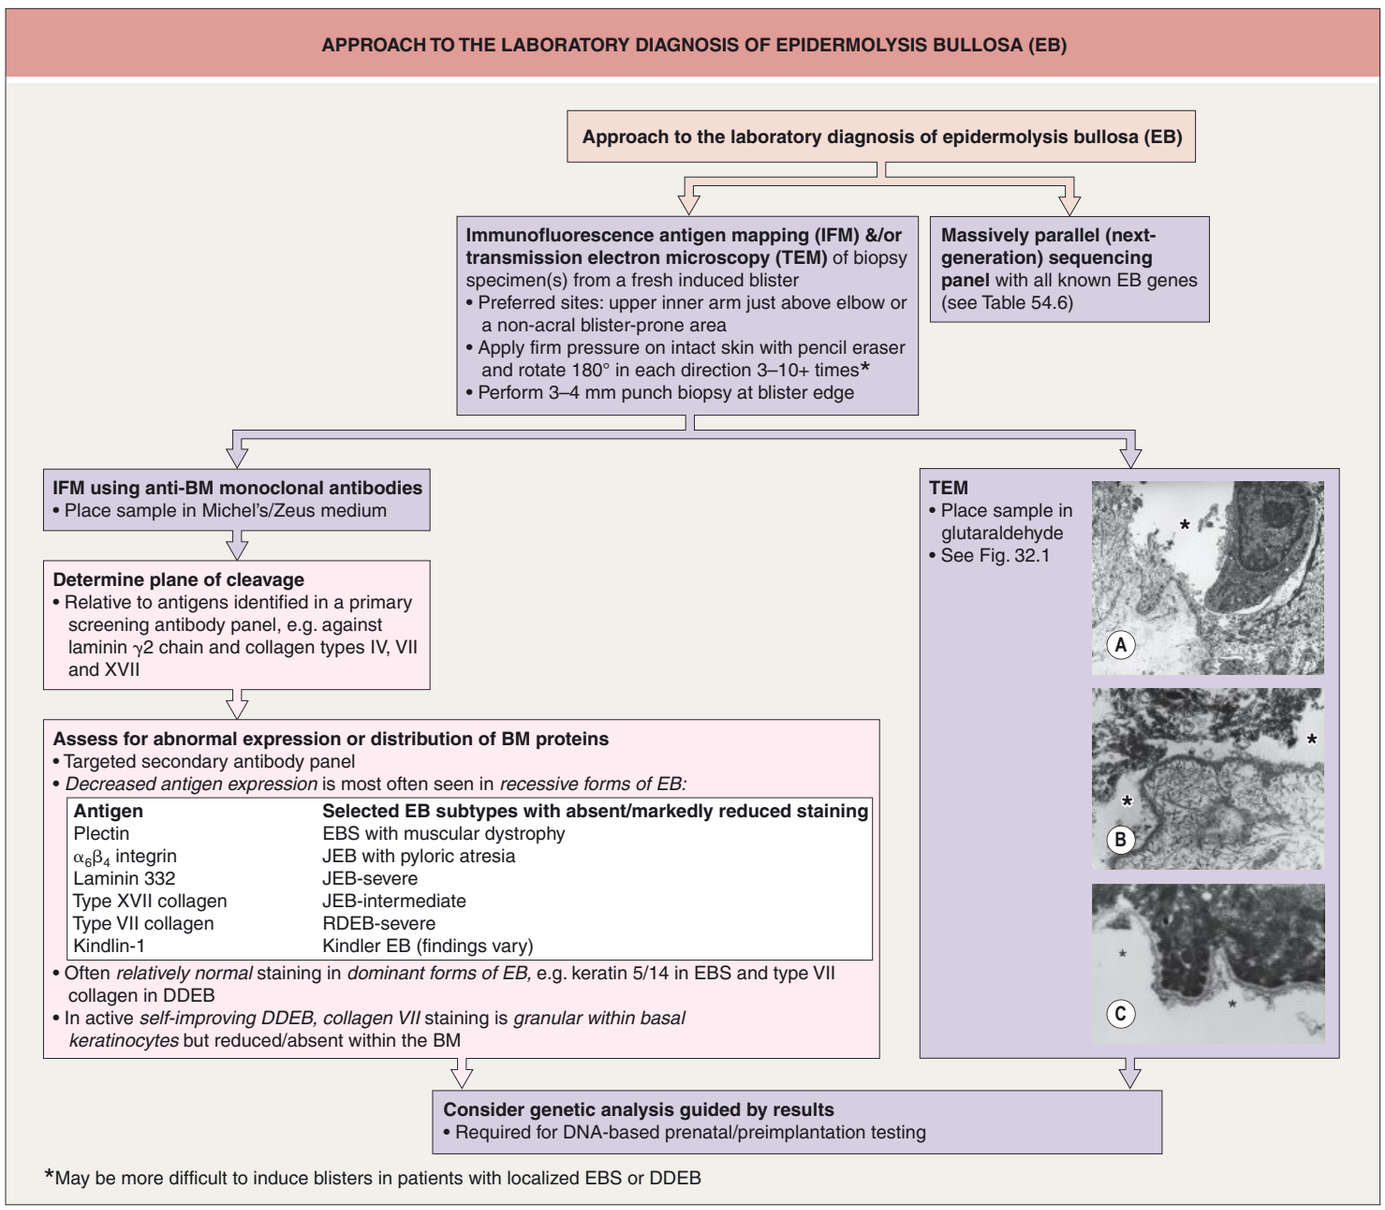

Fig. 32.14 Approach to the laboratory diagnosis of epidermolysis bullosa (EB). A Electron microscopy (EM) of an induced blister in localized EBS demonstrates skin cleavage (asterisk) within the inferior-most portion of the basilar keratinocyte. **B** EM of a spontaneous blister from a patient with the severe JEB reveals skin cleavage (asterisks) within the lamina lucida. Hemidesmosomes, sub-basal dense plates, and anchoring filaments are all absent. In contrast, anchoring fibrils are still present in normal amounts within the underlying dermis. **C** EM of the roof of a spontaneous blister from a patient with severe RDEB reveals cleavage (asterisks) beneath the level of the lamina densa. Anchoring fibrils are absent along the epidermal roof of the blister. BM, basement membrane; DDEB, dominant dystrophic EB; EBS, EB simplex; JEB, junctional EB; RDEB, recessive dystrophic EB.

Genetic analysis has become the first-line method for EB diagnosis and classification, with increasing availability and decreasing cost of massively parallel (next-generation) sequencing panels that include all known EB genes[47]. Molecular diagnosis allows more accurate genetic counseling and is required for DNA-based prenatal/preimplantation testing.

Differential Diagnosis

Although it is difficult to determine the subtype of inherited EB on the basis of clinical findings alone, the diagnosis of EB itself is usually straightforward, especially beyond early childhood. There is a limited differential diagnosis for a chronic mechanobullous disease with early onset and/or a positive family history[1,2]. Other genetic diseases that may present with blistering early in life include acantholytic erosive disorder and other skin fragility syndromes due to defects in desmosomal proteins as well as peeling skin syndromes and epidermolytic ichthyosis (see Ch. 57)[1] (Fig. 32.15A,B). Of note, the former disorders were previously categorized as forms of EBS. Genodermatoses that can be associated, at least transiently, with skin fragility or blisters and therefore potentially misdiagnosed as EB are outlined in Table 32.3. Less often, EB may be confused with acrodermatitis enteropathica, incontinentia pigmenti stage 1, pachyonychia congenita, or early lipoid proteinosis.

The differential diagnosis of blisters and erosions in neonates or young infants may also include infectious diseases (e.g. herpes simplex viral infection, staphylococcal scalded skin syndrome, bullous impetigo), sucking blisters, mastocytosis, autoimmune blistering diseases, and congenital erosive and vesicular dermatosis (see Ch. 34). Diagnostic considerations in patients with acral blistering, erosions, and ulcerations with progression to digital resorption may include congenital erythropoietic porphyria (see Table 32.3 and Ch. 49) and SAVI (*S*TING-*a*ssociated *v*asculopathy with onset in *i*nfancy [Fig. 32.15C]; see Ch. 45).

Congenital localized absence of skin (CLAS), also referred to as aplasia cutis congenita, can occur in any form of EB (see Ch. 64). In patients with EB, CLAS is distinguished by the associated skin fragility and blistering as well as its frequent location on the lower extremities (referred to as Bart syndrome), although involvement may be more widespread, especially in forms of EBS or JEB associated with pyloric atresia[48].

TREATMENT

Day-to-day management of EB revolves around the prevention of mechanical trauma, wound care, and avoidance of infection. Protective bandaging, padding over bony prominences, and soft/loose-fitting clothing can be helpful. Bathing or soaking with ~0.005% sodium hypochlorite (0.5 cup household bleach [6%–8.25% sodium hypochlorite] in a full standard bathtub) or 0.25% acetic acid (1 part white vinegar [5% acetic acid] to 19 parts water) may help to reduce bacterial colonization. Antibiotics should be used judiciously, with avoidance of chronic treatment with topical mupirocin or oral antibiotics. Problematic plantar hyperhidrosis in EBS patients may be reduced by the topical application of aluminum chloride hexahydrate, although its effect on blistering is less certain, and injection of botulinum toxin A can decrease plantar blistering and associated pain in some individuals with EBS[49].

A number of dressings are available for cutaneous wounds in EB patients (Table 32.4; see Ch. 145). As a general rule, only those that are non-adhesive or "low-tack" should be applied to EB skin. Soft silicone dressings, some of which incorporate an absorbent foam backing, are widely used. Silver-impregnated dressings may be helpful for heavily colonized or infected wounds, although long-term application should be avoided to prevent excessive systemic silver absorption and cutaneous argyria. Less expensive Vaseline®-impregnated gauze is another suitable dressing for non-infected wounds. Topical therapies under investigation include diacerein 1% cream, which downregulates production of interleukin-1β and keratin 14, thereby stabilizing the keratinocyte intermediate filament network and reducing blister formation in patients with EBS[50].

Systemic drugs that may be of benefit include tetracycline or erythromycin for EBS[51] and dupilumab, thalidomide, or cyclosporine for symptomatic relief in DEB pruriginosa[52,53]. There are few reports on the use of systemic retinoids in any form of EB, although these drugs appear to be tolerated, at least in low dosage, in patients with RDEB[54]. Whether long-term treatment with low-dose systemic retinoids would

ADDITIONAL GENODERMATOSES ASSOCIATED WITH SKIN FRAGILITY OR BLISTERS		
Disorder	**Defective protein/gene (inheritance)**	**Clinicopathologic features**
Erosive skin fragility disorders		
Skin fragility–woolly hair syndrome (DSP), skin fragility–ectodermal dysplasia syndrome (PKP1), and related conditions	Desmoplakin/*DSP*, plakophilin 1/*PKP1*, or plakoglobin/*JUP** (AR)	Erosions > blisters favor extremities (Fig. 32.15B), perioral and intertriginous fissures, focal PPK with fissures; sparse and/or woolly hair, nail dystrophy; acantholysis in skin biopsy specimens; **DSP:** follicular keratoses on extensor surfaces, variable cardiomyopathy and hoarseness; **JUP***: PPK, alopecia or curly hair, cardiomyopathy
Acantholytic erosive disorder (formerly acantholytic EBS)	Desmoplakin/*DSP* or plakoglobin/*JUP* (AR)	Generalized erosions at birth; universal alopecia; acantholysis in skin biopsy specimens; **DSP:** natal teeth, anonychia and variable cardiomyopathy; **JUP:** onycholysis and infections
Peeling skin fragility disorders		
Acral peeling skin syndrome	Transglutaminase 5 (AR)	Superficial peeling and erosions on hands and feet (see Fig. 32.15A)
EBS superficialis		
EBS superficialis	Unknown	Superficial erosions; postinflammatory hyperpigmentation; subcorneal cleavage
Hyperkeratotic skin fragility disorders		
Superficial epidermolytic ichthyosis	Keratin 2 (AD)	Mauserung phenomenon (desquamation); superficial intraepidermal blistering in skin biopsy specimens
Epidermolytic ichthyosis	Keratins 1 and 10 (AD)	Blistering primarily in the first few years of life; later, corrugated hyperkeratosis; epidermolytic hyperkeratosis in skin biopsy specimens; **keratin 1**: PPK
Connective tissue disorder with skin fragility		
Syndromic connective tissue disorder with skin fragility	Lysyl hydroxylase 3 (AR)	Predominantly acral blistering; scoliosis, joint contractures, pterygia, dysmorphic facies, ocular anomalies
Additional genodermatoses with erosions or blistering		
Congenital erythropoietic porphyria (Günther disease)	Uroporphyrinogen III synthetase (AR)	Severe photosensitivity leading to blistering, deep ulcerations and facial/digital mutilation; elevated uroporphyrin I and coproporphyrin I; red urine and teeth; hemolytic anemia
Mendes da Costa syndrome	Unknown (X-linked)	Spontaneous formation of bullae (unprovoked by trauma); atrichia; acrocyanosis; dyspigmentation; microcephaly; intellectual disability
AEC (ankyloblepharon–ectodermal dysplasia–clefting) syndrome	p63 (AD)	Ankyloblepharon; ectodermal dysplasia; cleft lip and palate; erythroderma; widespread erosions in neonates; chronic erosive scalp dermatitis; patchy alopecia

*Features overlap with those of Naxos disease (see Ch. 58).

Table 32.3 Additional genodermatoses associated with skin fragility or blisters in the differential diagnosis of epidermolysis bullosa. Additional diagnostic considerations may include other peeling skin syndromes (see Table 57.8) and pachyonychia congenita (see Chs. 58 & 71). Biallelic mutations in the genes encoding desmocollin 3 and desmoglein 3 have been implicated in hypotrichosis with recurrent skin vesicles and acantholytic oral/laryngeal blisters, respectively. AD, autosomal dominant; AR, autosomal recessive; EBS, epidermolysis bullosa simplex; PPK, palmoplantar keratoderma.

DRESSINGS FREQUENTLY USED IN PATIENTS WITH EPIDERMOLYSIS BULLOSA		
Dressing type	**Use**	**Examples®,™**
Soft silicone dressings ("low-tack")	• Suitable as primary or secondary dressings in many types of EB • May have a foam backing for mechanical protection or to wick exudate away from the wound	Mepitel, Mepilex, Mepilex Transfer, Mepilex Border
Non-adherent lipido-colloid dressings	• Suitable for primary contact	Urgotul
Hydrogel dressings	• Provide moisture to drier wounds to facilitate healing • May provide relief from pain or itch	Flexigel, Curagel, ActiForm Cool
Foam dressings	• Useful to absorb moderate amounts of wound exudate	Mepilex, Allevyn
Absorptive dressings	• Useful to absorb heavy amounts of wound exudate	Eclypse, Sorbion Sana
Silver-containing dressings	• Clinically infected or highly colonized wounds • Avoid prolonged use due to risk of silver absorption	Urgotul SSD, Mepilex AG
Other antimicrobial dressings	• Clinically infected or highly colonized wounds	PolyMem, Cutimed Sorbact, Activon Tulle, Suprasorb X + PHMB

Table 32.4 Dressings frequently used in patients with epidermolysis bullosa (EB).

help to prevent the development of SCCs in severe RDEB patients remains to be determined. The angiotensin receptor blocker losartan interferes with TGF-β signaling, which is upregulated in the skin of RDEB patients and may contribute to the risk of developing SCC. Losartan was shown to reduce cutaneous fibrosis and digital fusion in a mouse model of EB and is currently under investigation in RDEB patients[55].

Although not yet in mainstream clinical practice, translational therapeutic approaches for EB utilizing cell-, protein- and gene-based methods have been a focus of attention in recent years[2,56]. In clinical trials investigating the value of allogeneic bone marrow-derived stem cell transplantation in patients with RDEB, significant clinical responses were observed, with production of collagen VII at the dermal–epidermal junction and improved wound healing[57,58]. However, there was also

substantial associated morbidity and mortality, although ameliorated to some extent by using reduced-intensity conditioning regimens. An alternative approach has been to use intradermal[59] or intravenous[60,61] injections of allogeneic mesenchymal stem cells in patients with severe RDEB, which has led to improved wound healing as well as reduced inflammation and itch. Injections of allogeneic fibroblasts into RDEB wounds also improved wound healing in a small clinical trial[62]. In addition, intradermal and intravenous delivery of recombinant collagen VII has been explored in animal models of RDEB but not yet in human studies[63].

Gene therapy for EB is currently under investigation in several clinical trials. It was first successfully performed in a man with intermediate JEB, with *ex vivo* gene correction of autologous keratinocytes to restore laminin 332[64]. A skin equivalent was generated and grafted onto the patient's legs, with amelioration of blistering that persisted for years post-procedure. Similar approaches utilizing *ex vivo*-gene correction have subsequently been employed in a child with severe JEB, with graft coverage of ~80% of his body surface area, and patients with RDEB[65,66]. *In vivo* topical gene therapy with beremagene geperpavec (B-VEC), a non-replicating *COL7A1*-containing herpes simplex virus type 1 vector, was recently shown in a randomized placebo-controlled study to induce collagen VII expression and promote healing when applied to wounds in patients with RDEB[67]. Gene editing using technologies such as CRISPR/Cas9 and base editing to restore expression of functional proteins in EB has also been explored[68,69]. Another promising method is the use of drugs such as aminoglycoside antibiotics (e.g. topical or intravenous gentamicin) to induce read-through of nonsense mutations and improve wound healing in RDEB and JEB patients[70,71].

Revertant mosaicism in the skin of EB patients represents "natural gene therapy" that can restore wild-type function to a clone of cells, providing a model for potential gene manipulation strategies and possibly explaining the tendency for improvement with age in some subtypes of EB. Mitotic gene conversion, true back mutations, and second-site mutations that prevent a premature termination codon or restore the reading frame have been shown to reverse disease-causing type XVII collagen mutations in individuals with intermediate JEB, leading to decreased blistering in discrete areas of skin[72]. Second-site nonsense mutations have also been shown to abrogate blistering by silencing a dominant-negative keratin 14 allele in those with severe EBS, and revertant mosaicism has also been observed in RDEB patients. Furthermore, patients with intermediate JEB have had successful local treatment with autologous grafts harvested from areas of revertant skin[73].

Strategies for the medical and surgical management of long-term complications of EB are outlined in Table 32.5[33,74–76]. Multidisciplinary clinics can provide care and support for the wide range of needs that patients with EB and their families have. Families can also obtain helpful information from several support group websites, in particular www.debra.org and www.debra-international.org.

KINDLER EPIDERMOLYSIS BULLOSA

Synonyms: ■ Kindler syndrome ■ Kindler–Weary syndrome ■ Bullous acrokeratotic poikiloderma of Kindler and Weary ■ Hereditary acrokeratotic poikiloderma

Introduction

Kindler EB is a rare autosomal recessive genodermatosis that features skin fragility and photosensitivity during early life as well as progressive poikiloderma, cutaneous atrophy, and mucosal inflammation[2,77–79].

History

In 1954, Theresa Kindler described a patient with acral blistering and photosensitivity during infancy, followed later in life by progressive poikiloderma and atrophy. Twenty years later, Weary reported ten members of a single family with similar findings in addition to widespread atopic dermatitis during early childhood and keratotic papules over the joints of the arms and legs that appeared in childhood and persisted indefinitely. Oral involvement and other mucosal manifestations were subsequently emphasized[77–81].

Pathogenesis

Kindler EB is characterized ultrastructurally by basement membrane reduplication and mixed planes of cleavage that can be within basal keratinocytes, through the lamina lucida, and/or below the lamina densa[2,82]. It results from mutations in the FERM domain-containing kindlin-1 gene (*FERMT1*) which encodes kindlin-1, a component of focal adhesions that connect actin filaments in basal keratinocytes to the underlying ECM[81–84] (see Ch. 28). Through integrin-mediated signaling, kindlin-1 affects the shape, polarity, adhesion, proliferation, and motility of keratinocytes[78]. There is also evidence that kindlin-1 has a role in regulating cutaneous epithelial stem cell homeostasis, with loss of kindlin-1 leading to increased risk of skin cancer as well as cutaneous atrophy due to stem cell exhaustion and premature senescence of keratinocytes[84].

Clinical Features

Erosions are occasionally present at birth, most often on the forearms and shins, and blistering during infancy is most prominent on the hands and feet. In contrast to other forms of EB, skin fragility tends to decrease considerably during childhood. Photosensitivity manifesting as an increased susceptibility to sunburn also improves over time. Reticulated hyperpigmentation and telangiectasias begin to develop in sun-exposed areas during childhood, and after puberty these findings spread to sun-protected sites. A characteristic feature in adult patients with Kindler EB is poikiloderma (Fig. 32.16A), which persists throughout life. Tissue paper-like atrophy is frequently seen, particularly on the dorsal surfaces of the hands and feet (Fig. 32.16 B,C), and mild webbing of the digits (see Fig. 32.16C) and palmoplantar hyperkeratosis may also be evident. Eczematous dermatitis, typically beginning during infancy and resolving by early childhood, occurs in some patients.

Patients with Kindler EB often have erosive gingivitis and poor dentition. Mucosal involvement may result in intraoral and corneal scarring, ectropion, colitis, and strictures of the esophagus, urethra, vagina, and anus. Patients have an increased risk of SCC of the lip and oral mucosa as well as acral skin[81].

Pathology

In older patients, skin biopsy specimens show the typical changes of poikiloderma, including epidermal atrophy, vacuolization of the basal cell layer, variable epidermal melanin content, dermal melanophages, and capillary dilation. Immunostaining of skin biopsy specimens with anti-kindlin-1 antibodies often demonstrates a marked reduction or absence of this protein[82]. Ultrastructural findings are noted above.

Differential Diagnosis

The predominantly acral distribution of the blisters and associated atrophy and photosensitivity distinguish Kindler EB from other forms of EB, although a form of JEB characterized by progressive cutaneous atrophy similar to that in Kindler EB has been described[85]. As poikiloderma becomes apparent during early childhood, the differential diagnosis may include Rothmund–Thomson syndrome and other entities outlined in Table 63.9.

Treatment

Management is akin to other forms of EB, with the addition of sun protection and assiduous oral hygiene.

Additional figures available in our eBook (see inside front cover for access code).

MANAGEMENT OF LONG-TERM COMPLICATIONS OF EPIDERMOLYSIS BULLOSA		
Complication	**Prevention and monitoring/detection**	**Management**
Oral and gastrointestinal		
Excessive caries	• Diligent oral hygiene • Antiseptic and fluoride mouthwashes • Periodic evaluation and cleaning by a dentist	• Restorative dentistry
Microstomia		• Physical therapy • "Mouth expanding" devices
Oral ulceration		• Topical antiseptics, topical NSAIDs, barrier preparations (e.g. sucralfate suspension)
Esophageal strictures	• Evaluate dysphagia with contrast studies	• Dietary modification (soft foods/purées, caloric supplementation) • Fluoroscopically guided balloon dilatation; repeated procedures are often required • In severe and recalcitrant cases, surgical options include colonic interposition
Gastroesophageal reflux disease		• Proton pump inhibitors, H_2 blockers, prokinetic agents (e.g. metoclopramide, domperidone [not available in the US])
Constipation	• Ensure adequate fluid intake and dietary fiber	• Osmotic laxatives (e.g. containing polyethylene glycol), mineral oil • Avoid suppositories and enemas
Nutritional		
Growth retardation/inadequate intake to meet nutritional needs	• Monitor height, weight and body mass index • Periodically assess serum zinc, selenium, iron, vitamin D, and carnitine levels (e.g. yearly) • Oral supplements to optimize intake of calories, protein, vitamins, and minerals	• Consider gastrostomy feedings
Hematologic		
Anemia due to iron deficiency and chronic inflammation	• Monitor CBC and measures of iron stores	• Iron supplementation (oral or IV) • Consider erythropoietin or darbepoetin alpha • Consider blood transfusion if hemoglobin ≤7–8 g/dl and/or symptomatic
Genitourinary and renal		
Urinary outflow obstruction (e.g. urethral or ureteral strictures)	• Consider annual ultrasound of the urinary tract and urodynamic studies (especially for JEB)	• Dilatation procedures as needed to treat obstruction • Avoid unnecessary instrumentation
Renal disease (e.g. hydronephrosis, post-infectious glomerulonephritis, renal amyloidosis, IgA nephropathy)	• Blood urea nitrogen & serum electrolyte levels, urinalysis and blood pressure evaluation every 6 months in RDEB patients • Adequately treat streptococcal infections	• Hemodialysis or peritoneal dialysis if renal failure develops
Musculoskeletal		
Osteopenia and osteoporosis	• Annual DEXA scan and spinal radiographs beginning at age 5 years in RDEB and JEB patients • Calcium and vitamin D supplementation	• Consider IV bisphosphonate therapy
Pseudosyndactyly of hands/feet	• Cushioned splints on hands/forearms and individual wrapping of fingers in RDEB patients	• Surgery to release contractures and webbing
Oncologic		
Cutaneous squamous cell carcinoma	• Periodic total-body skin examinations; for RDEB patients, approximately every 3–6 months beginning at age 10 years and every 3 months after age 16 years • Biopsy or monitor non-healing ulcers (see Fig. 32.13) • Consider taking serial photographs	• Excision ± skin grafting (sometimes amputation); consider MRI to assess extent of local disease • Consider staging with CT, PET-CT, sentinel lymph node biopsy • Use of EGFR and immune checkpoint inhibitors for advanced disease has been reported
Ocular		
Chronic complications include corneal scarring, symblepharon, ectropion	• Periodic ophthalmologic evaluation for patients with eye involvement • Lubricating eye drops	• Surgical procedures, e.g. division of symblepharon, amniotic membrane transplantation
Cardiac		
Dilated cardiomyopathy	• Consider annual echocardiography beginning in late childhood for RDEB patients	• Medical management • Supplement selenium and carnitine if deficient
Psychological and psychiatric		
Disrupted family unit (e.g. via divorce)	• Consider family counseling, support groups	• Psychological/family counseling
Depression and suicidal ideation/attempts	• Consider psychological counseling, support groups	• Psychiatric evaluation, antidepressant therapy

Table 32.5 Management of long-term complications of epidermolysis bullosa (EB)[33,74,75]. CBC, complete blood count; CT, computed tomography; EGFR, epidermal growth factor receptor; JEB, junctional EB; MRI, magnetic resonance imaging; NSAID, nonsteroidal anti-inflammatory drug; PET, positron emission tomography; RDEB, recessive dystrophic EB.

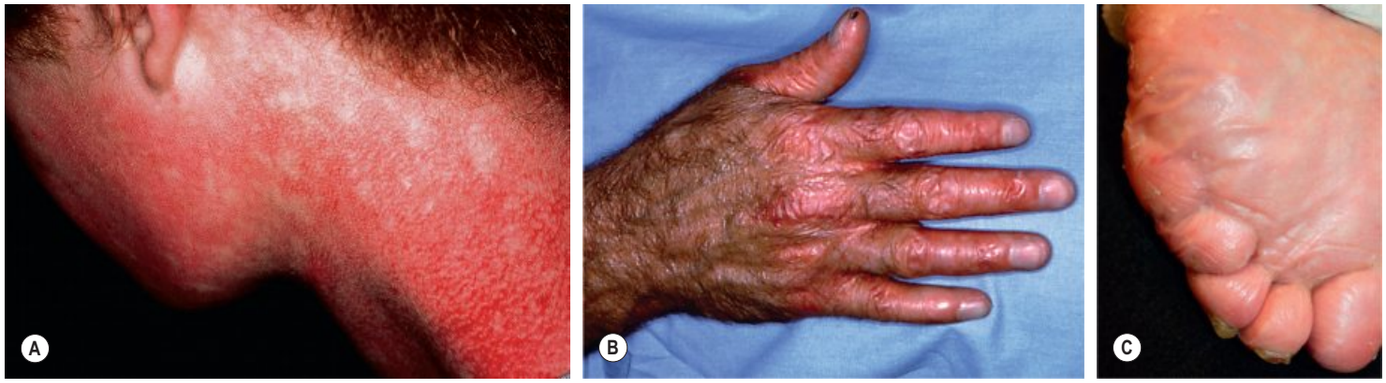

Fig. 32.16 Kindler epidermolysis bullosa. A Poikiloderma of the face and neck with "skip" areas. **B** Erythema and atrophy on the dorsal hand. **C** Progressive syndactyly of fourth and fifth toes in an adult. Note the near absence of dermatoglyphics. This patient also had ectropion and urethral strictures. *C, Courtesy Jean L. Bolognia MD.*

Bullous Insect Bite Reactions 563
Delayed Postburn/Postgraft Blisters 565
Edema Blisters 565
Additional Vesiculobullous Disorders 566

Vesiculobullous diseases of the skin encompass a wide range of entities, including autoimmune bullous diseases and inherited blistering disorders (see Chs. 28–32). This chapter focuses on the remaining non-infectious disorders in which cutaneous bullae develop and represent the primary clinical manifestation.

BULLOSIS DIABETICORUM

Synonyms: ■ Diabetic bullae ■ Bullous eruption of diabetes mellitus ■ Bullous diabeticorum

Key features

- A rare condition associated with diabetes mellitus
- Tense blisters develop on normal-appearing skin in acral sites (feet, lower legs, hands); there is often an association with peripheral neuropathy
- Histologically, intraepidermal and/or subepidermal blisters are observed
- Spontaneous healing usually occurs in 2 to 6 weeks

History

Bullosis diabeticorum was first described by Kramer in 1930. In 1967, Cantwell & Martz[1] introduced the term "bullosis diabeticorum".

Epidemiology

The exact prevalence of bullosis diabeticorum is unknown. In a retrospective study of diabetic patients, the annual incidence was 0.16%[2]. The age of onset ranges from 15 to 85 years, with a mean age of 55 years. A 2:1 male-to-female ratio has been reported, and it occurs more frequently in the setting of longstanding diabetes and neuropathy.

Pathogenesis

Although bullosis diabeticorum has been related to trauma and the microangiopathy of diabetes, little is known about its cause. Diabetic patients can develop blisters after minimal trauma, and some authors have found a reduced threshold for inducing suction blisters in these patients[3,4]. There is no evidence of an infectious etiology.

Clinical Features

Bullosis diabeticorum is characterized by a sudden and spontaneous appearance of vesicles and bullae within normal-appearing, non-inflamed skin of the distal extremities of diabetics. The most frequent locations (in decreasing order) are the feet, distal legs, hands, and forearms. Bullae are rarely seen on the trunk. The lesions are usually asymptomatic, but occasionally there is a mild burning sensation. Blisters often develop "overnight" and in the absence of known trauma. The vesicles and bullae are tense and vary in diameter from 0.5 to several centimeters (Fig. 33.1). They contain a clear, sterile fluid that can be more viscous than that found in friction blisters.

Most patients have longstanding diabetes, but occasionally bullosis diabeticorum is a presenting sign of diabetes. It is associated with both insulin-dependent and non-insulin-dependent diabetes mellitus. Many patients have an associated polyneuropathy, retinopathy, or nephropathy.

Pathology

The histopathologic findings are heterogeneous. Initial reports described intraepidermal blisters, whereas more recent publications have usually described subepidermal bullae. It seems likely that the level of cleavage is subepidermal, and that intraepidermal blisters represent older lesions undergoing re-epithelialization. Direct immunofluorescence (DIF) examination is usually negative, although a few reports have described IgG or IgM and C3 deposits within dermal blood vessel walls. By electron microscopy, subepidermal blisters with a separation at the level of the lamina lucida or below the lamina densa have been described[5].

Differential Diagnosis

In porphyria cutanea tarda (PCT) and pseudoporphyria associated with dialysis and medications, the blisters are usually <1 cm in diameter and favor the hands rather than the feet and ankles. Complications of diabetes include both chronic renal failure and atherosclerotic cardiovascular disease and, as a result, patients may be receiving dialysis

Fig. 33.1 Bullosis diabeticorum. A large, tense bulla overlying the medial malleolus. Note the absence of erythema or edema in the surrounding skin.

and/or diuretics. The distal extremity is also a common site for fixed drug eruptions, but bullae develop on an inflammatory base. Localized bullous pemphigoid and epidermolysis bullosa acquisita (EBA) are differentiated by histologic examination and DIF, as well as by an accentuation of lesions at sites of friction in patients with EBA. If there is surrounding erythema, warmth, and tenderness, the possibility of bullous cellulitis must be considered.

Treatment

Most patients have spontaneous healing of their lesions within 2 to 6 weeks. To relieve pressure or improve appearance, the blisters can be cleansed with alcohol and then a small window is placed in the most dependent portion of the blister roof. The sites should be washed daily to prevent secondary infection followed by application of petrolatum. Occasionally, a secondary soft-tissue infection does develop, requiring systemic antibiotics or surgical intervention[2].

COMA BLISTERS

Synonyms: ■ Coma bullae ■ Drug-induced coma blisters ■ Barbiturate blisters ■ Neurologic blisters

Key features

- Associated with loss of consciousness, neurologic diseases, or prolonged immobilization
- Tense blisters develop on normal-appearing skin
- Histologically, intraepidermal or subepidermal blisters are observed, with a characteristic necrosis of sweat glands
- Spontaneous healing occurs within 1 to 2 weeks

Introduction

In some comatose patients, blisters, primarily within sites of pressure, will develop within 48–72 hours of loss of consciousness. Although historically associated with barbiturate overdose, they can be seen in the setting of coma due to other causes including medications (e.g. opioids), infections (e.g. viral encephalitis), metabolic disturbances (e.g. hypoglycemia), and neurologic dysfunction (e.g. cerebrovascular accidents).

History

Coma blisters were first described in 1806 by Dominique Larrey, Napoleon's surgeon, who noticed these lesions in soldiers who had been comatose from carbon monoxide intoxication.

Epidemiology

In 1952, Holten reported the appearance of coma blisters in 4% of a series of 501 patients with barbiturate poisonings[6]. In another study, blisters were found in 6.5% of barbiturate overdoses[7]. Although a number of reported cases have been associated with barbiturate overdose, blisters have also been observed in those whose comas were induced by overdosage of other medications, including opioids, benzodiazepines, hypnotics, tricyclic antidepressants and antipsychotics, as well as alcohol intoxication[8]. Similar lesions have also been described in patients with non-drug-induced coma due to carbon monoxide poisoning, head trauma, cerebrovascular accidents, viral encephalitis, hypoglycemia, diabetic ketoacidosis, or hepatic encephalopathy[9,10]. In addition, bullous lesions have been observed following surgical procedures requiring general anesthesia[11] and in non-comatose patients, in particular those with severe neurologic disease or prolonged immobilization (e.g. secondary to accidents)[12].

Pathogenesis

The pathogenesis is unclear. A direct toxic drug effect has been implicated, particularly because of the association with drug intoxication and the frequent finding of eccrine gland necrosis (many drugs are thought to be excreted by sweat glands). However, this would not explain the non-drug-induced cases. Therefore, pressure, friction, and local hypoxia have been implicated as etiologic factors. The pressure/ischemic hypothesis is currently favored and is supported by the observation that most (if not all) lesions appear at sites of pressure.

Clinical Features

Lesions develop at body sites exposed to maximum pressure during unconsciousness or immobilization. They first appear 24 hours after the onset of coma as blanchable erythematous patches or plaques that progress to violaceous plaques. Blisters or erosions then develop within 48–72 hours after the onset of coma at these sites (Fig. 33.2). If the patient survives, the erosions usually heal spontaneously over 1 to 2 weeks. In some individuals, residual scarring can result. Compression neuropathies and non-traumatic rhabdomyolysis are additional complications that may be seen in patients with coma bullae[8–10,12,13]. As mentioned previously, the same type of blisters can occur in patients with prolonged immobilization or neurologic diseases (Fig. 33.3).

Fig. 33.2 Coma bullae. Blisters developed in an area of pressure in a previously comatose patient.

Fig. 33.3 Neurologic blisters. Tense blisters on the dorsal aspect of the fingers on the hemiplegic side in a patient with a history of a cerebrovascular accident.

Pathology

The blisters are predominantly subepidermal. However, intraepidermal blisters are also observed as the result of re-epithelialization of older lesions or epidermal spongiosis. There is a variable degree of epidermal necrosis. Sweat gland necrosis is a characteristic finding (Fig. 33.4), and focal necrosis of the epithelium of the pilosebaceous units can also be seen. There is only a sparse inflammatory cell infiltrate. DIF is usually negative, but deposits of IgG, IgM, and/or C3 have been found within the walls of dermal blood vessels[8,9].

Differential Diagnosis

In most patients, the clinical setting alone is sufficient to make the diagnosis (Fig. 33.5). A cutaneous biopsy will allow differentiation from friction blisters. An intraepidermal blister cavity just below the granular layer is seen in friction blisters, whereas a subepidermal split with sweat gland/follicular necrosis is characteristic of coma bullae. Based upon the distribution pattern, clinical appearance, and histologic findings, multiple fixed drug eruption can be excluded.

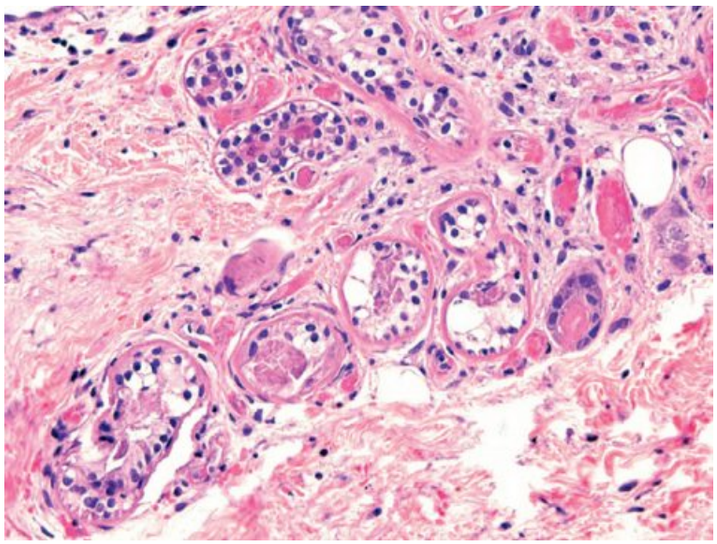

Fig. 33.4 Bulla due to prolonged immobilization ("coma blister") – histopathologic features. Following a fall and hip fracture, the patient remained immobilized on the floor for two days. Detection of the characteristic sweat gland necrosis aided in the diagnosis.

Treatment

Coma blisters heal spontaneously over 1 to 2 weeks. In non-comatose patients, frequent postural changes help to resolve and prevent the disorder.

FRICTION BLISTERS

Key features

- Friction blisters occur most commonly on the soles and heels
- They are the result of repeated friction, e.g. walking or running in ill-fitting shoes; they may also develop on the palms and fingers if a repetitive action is performed
- Histologically, blistering occurs just below the stratum granulosum

Epidemiology

Friction blisters are very common in the general population. Almost every person remembers developing such lesions when wearing a new pair of shoes. They are particularly common in young and active individuals, especially those engaged in the military and sports. In a military study at a Combat Support Hospital, the prevalence of foot friction blisters was 33% and they were more common in those who were unable to break in their boots[14].

Pathogenesis

Frictional shearing forces occur within the epidermis when the surface of an object rubs against the skin surface. Repetition of this rubbing action over a period of time can induce the appearance of blisters. Rubbing of moist skin produces higher frictional forces than with very dry or very wet skin[15]. Poorly fitting shoes, heat, and sweating are predisposing factors.

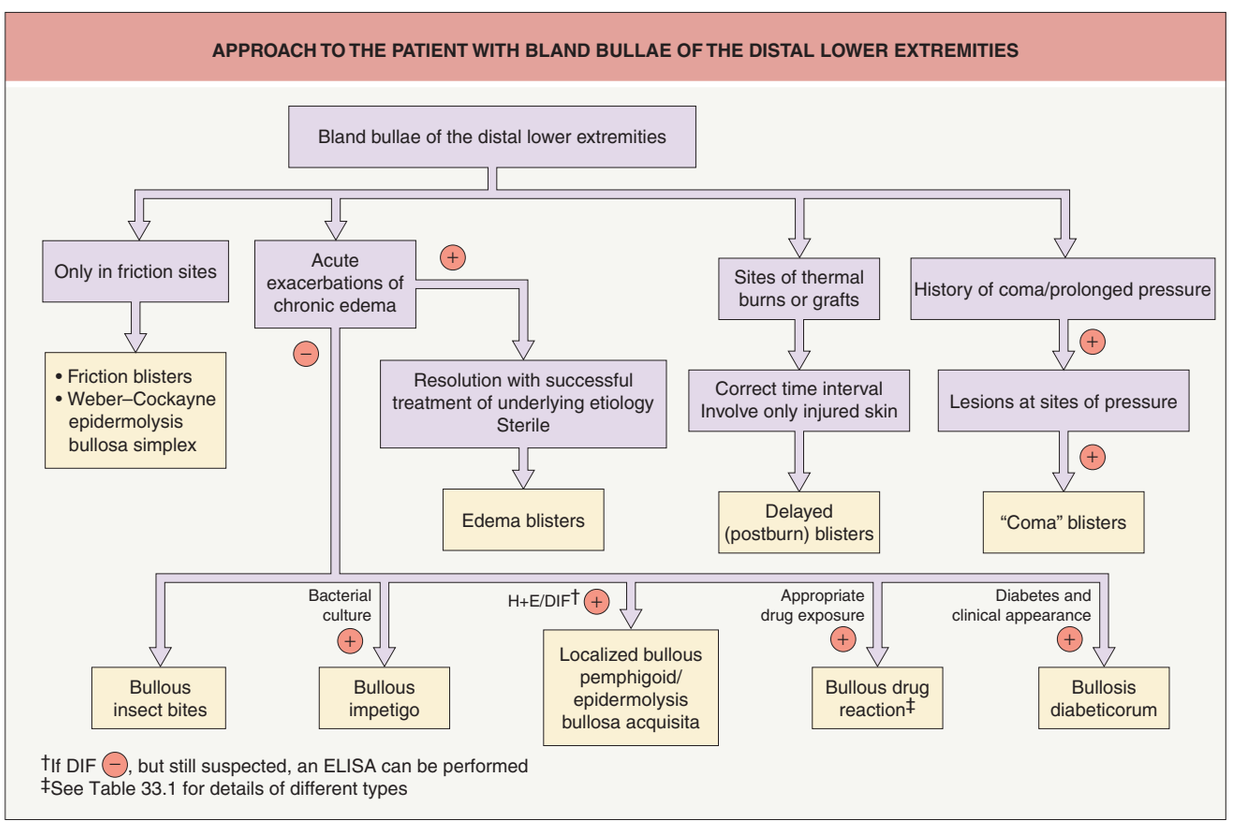

Fig. 33.5 Approach to the patient with bland bullae of the distal lower extremities.

Clinical Features

Friction blisters most frequently develop in areas with thick stratum corneum (soles, heels, palms, fingers). They are particularly common in sites where friction is intense and repeated (e.g. feet). The lesions initially begin as erythematous macules at sites of friction and later develop into blisters. The patients complain of an associated burning sensation or pain, and the blister fluid may be clear or blood-tinged.

Pathology

Friction blisters are intraepidermal blisters resulting from necrosis of keratinocytes. The level of the split is variable but usually in the stratum spinosum just below the stratum granulosum. The roof of the blister is formed by the stratum corneum, the stratum granulosum, and some cellular debris. Pale and degenerated keratinocytes that stain faintly are found within the upper portion of the floor of the blister cavity. The deeper layers of the epidermis are normal[16]. There is only a sparse perivascular inflammatory infiltrate in the superficial dermis.

Differential Diagnosis

In most patients, friction blisters can be easily diagnosed clinically. The localized variant of epidermolysis bullosa simplex (formerly Weber–Cockayne) is suspected when there is an exaggerated response to friction; histologic examination of a fresh or induced blister should show separation subepidermally or within the basal layer of the epidermis. EBA can also mimic friction blisters, but it is differentiated by histologic examination, DIF, and ELISA (see Fig. 33.5).

Treatment

Friction blisters can heal spontaneously without treatment. Drainage of blister contents via a small "window" in the blister roof relieves pressure and discomfort and prevents the accumulation of fluid; it also allows the blister roof to remain largely intact. Hydrocolloid or other dressings can also be utilized.

BULLOUS CUTANEOUS SMALL VESSEL VASCULITIS

Occasionally, patients with cutaneous small vessel vasculitis will develop superimposed vesicles and bullae, especially on the distal extremities (Fig. 33.6). These blisters are often hemorrhagic and can progress to ulceration. Edema of the lower extremities may also be present. In children, vesicles have been observed more frequently in IgA vasculitis (Henoch–Schönlein purpura) than in non-IgA vasculitis[17]. Histologically, a leukocytoclastic vasculitis is seen (in addition to a subepidermal blister with epidermal necrosis), which differentiates this entity from other blistering diseases. This may be a sign of more severe disease (see Ch. 24).

Fig. 33.6 Bullous variant of cutaneous small vessel vasculitis. *Courtesy Jeffrey P. Callen, MD.*

BULLOUS DRUG ERUPTIONS

Key features

- Some drug eruptions can present as blistering eruptions
- These eruptions can be localized or widespread
- Clinical, histologic, and immunofluorescence findings vary, depending on the type of drug eruption

Vesicles and bullae can develop in a variety of drug eruptions, which are outlined in Table 33.1 and discussed in detail in other chapters.

BULLOUS INSECT BITE REACTIONS

Synonyms (for exaggerated insect bite reactions in the setting of hematologic malignancies): ■ Eosinophilic dermatosis of hematologic malignancy ■ Eosinophilic dermatosis associated with hematological disorders

Key features

- Bullous insect bite reactions are fairly common, particularly in children, although patients often do not recall being bitten
- Severe insect bite reactions as well as insect bite-like reactions can occur in patients with hematologic malignancies, in particular chronic lymphocytic leukemia

Introduction

Although most insect bite reactions present as pruritic erythematous papules (see Ch. 85), vesiculobullous reactions are not uncommon.

History

An exaggerated reaction to insect bites in patients with chronic lymphocytic leukemia (CLL) was first described in 1965 by Robert Weed, and it has been increasingly recognized over the past two decades.

Epidemiology

There seems to be no difference in the incidence of insect bites based on sex, race, or age. Certain individuals may be bitten more frequently because of their body temperature, odor, use of perfumes, or carbon dioxide excretion. Children tend to have more severe reactions than adults because the latter tend to become desensitized by repeated exposures over time.

Patients with CLL, as well as other hematologic malignancies (e.g. non-Hodgkin lymphomas, acute leukemias, multiple myeloma), can develop both exaggerated reactions to insect bites and insect bite-like reactions[18,19]. The latter term is used to describe lesions that resemble insect bites clinically and histologically, but for which a clear link to insect bites cannot be established[20]. These exaggerated reactions can precede the diagnosis of the hematologic malignancy; in a large retrospective study of patients with CLL, the eruption preceded the diagnosis in 20% of patients[21]. Of note, no relationship to disease activity has been observed. More recently, these reactions have been referred to as "eosinophilic dermatosis associated with hematological disorders" or "eosinophilic dermatosis of hematologic malignancy"[22]; the term "eosinophilic dermatosis of myeloproliferative disease" is inaccurate, as CLL is not a myeloproliferative disorder (see Ch. 121).

BULLOUS DRUG ERUPTIONS		
Disease	**Characteristic features**	**Commonly implicated drugs**
Fixed drug eruption (see Ch. 21)	• Sharply circumscribed erythematous to dusky violaceous patches • Central blisters or erosions may appear • Often resolves with postinflammatory hyperpigmentation • Recurrence at same location(s) following drug re-exposure	Sulfonamides, NSAIDs, tetracyclines, barbiturates, aspirin, acetaminophen (paracetamol), metronidazole, phenolphthalein
Stevens–Johnson syndrome (SJS), toxic epidermal necrolysis (TEN) (see Ch. 20)	• Prodrome of fever and painful skin • Areas of dusky erythema associated with epidermal detachment (varying from <10% [SJS] to >30% [TEN]) • Mucosal involvement	NSAIDs, antibiotics (sulfonamides and β-lactams), aromatic anticonvulsants, lamotrigine, allopurinol, immune checkpoint inhibitors
Drug-induced autoimmune blistering diseases (see Chs. 29–31)	• Primarily, linear IgA bullous dermatosis, bullous pemphigoid, pemphigus • Diagnosis based on histopathologic findings, immunofluorescence studies, and drug history	• Linear IgA bullous dermatosis: vancomycin > β-lactams, captopril, NSAIDs • Bullous pemphigoid: diuretics (especially furosemide), antibiotics, immune checkpoint inhibitors, gliptins • Pemphigus: captopril, β-lactams, penicillamine, gold
Drug-induced pseudoporphyria (see Ch. 49)	• Eruption resembles porphyria cutanea tarda • Porphyrins are within normal limits	NSAIDs (especially naproxen), nalidixic acid, thiazides, furosemide, tetracyclines, voriconazole
Acute generalized exanthematous pustulosis (see Ch. 21)	• Acute onset, usually occurring within 2 days of drug exposure • Areas of erythema studded with pustules; occasionally vesicles • Fever, malaise, leukocytosis	β-lactams, macrolides, pristinamycin, terbinafine, calcium channel blockers (diltiazem), hydroxychloroquine, carbamazepine, acetaminophen, metronidazole, immune checkpoint inhibitors
Phototoxic drug eruptions (see Ch. 87)	• Limited to sun-exposed areas • Resembles exaggerated sunburn	Tetracyclines (especially doxycycline), quinolones, psoralens, NSAIDs, diuretics, voriconazole, pirfenidone, BRAF inhibitors, EGFR inhibitors
Bromoderma and iododerma (see Ch. 21)	• Acneiform lesions, papulopustules, nodules, or even vegetating lesions simulating pemphigus vegetans • Clear or hemorrhagic blisters can develop (more common in iododerma)	Bromides, iodine-containing drugs (e.g. amiodarone), radiographic contrast media
Palmoplantar erythrodysesthesia (acral variant of toxic erythema of chemotherapy [TEC]; see Ch. 21)	• Painful erythema develops primarily on the palms, soles, and digits following chemotherapy administration • The skin becomes edematous, its color changes to dark red or violet, and blisters and erosions may develop • With severe TEC, bullae can be generalized	Cytarabine, doxorubicin, capecitabine, 5-fluorouracil (especially prolonged infusions), busulfan, multikinase inhibitors (e.g. sorafenib, sunitinib), taxanes, clofarabine, pralatrexate

Table 33.1 Bullous drug eruptions. Occasionally, eczematous drug reactions (e.g. secondary to warfarin, calcium channel blockers, angiotensin converting enzyme [ACE] inhibitors, angiotensin II receptor blockers) and systemic contact dermatitis can be papulovesicular; patients with drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS) and drug-induced Sweet syndrome can also develop vesicles. Coma blisters and bullous small vessel vasculitis are discussed in the text. EGFR, epidermal growth factor receptor; NSAIDs, nonsteroidal anti-inflammatory drugs.

Pathogenesis

Most lesions are the result of an individual's immune response to insect antigens introduced by the bite. Both humoral (IgE-mediated) and cell-mediated immunity (delayed hypersensitivity) are involved. Initial bites typically do not produce significant lesions, but sensitization occurs over a few weeks. Subsequent bites then induce a stronger reaction and even bullae formation. With time, repeated bites can result in desensitization. In the case of bullous bed bug reactions, cutaneous vasculitis may be playing a role[23].

In patients with NK/T cell lymphomas, severe hypersensitivity to mosquito bites has been well documented and a possible role for the EBV-induced clonal proliferation of NK cells has been raised[24]. For patients with ALK-positive anaplastic large cell lymphoma, the possibility has been raised that insect bite-associated antigens lead to an influx of T lymphocytes, some of which bear t(2;5). The release of cytokines then results in activation of these cells, expression of NPM-ALK (nucleophosmin–anaplastic lymphoma kinase) fusion protein, and subsequent uncontrolled proliferation[25]. In patients with B cell malignancies, an increased production of IL-4 and IL-5 may explain associated tissue eosinophilia[20].

Fig. 33.7 Bullous insect bite reactions. The serous blister fluid is sterile and the ankle is a common site. *Courtesy Luis Requena, MD.*

Clinical Features

Insect bites usually appear as intensely pruritic erythematous papules or nodules. They are usually grouped, and a linear arrangement is commonly seen. However, vesicular and bullous bite reactions are not uncommon, and blisters can develop centrally within papules or as bland vesiculobullae (Fig. 33.7). Flea bites are the most likely to cause blisters, especially on the legs, and bedbug bites can also be bullous. Some insects (e.g. fire ants) can produce pustular lesions. In patients with hematologic malignancies, the exaggerated reactions consist of persistent papulonodules, vesicles, bullae, and even necrotic lesions (Fig. 33.8).

Fig. 33.8 Exaggerated insect bite-like reactions in a patient with B cell chronic lymphocytic leukemia. Both bullae and erosions at sites of ruptured bullae are present. *Reprinted with permission from Cerroni L. Skin Lymphomas: The Illustrated Guide, 5ed. Oxford: Wiley-Blackwell, 2020.*

Pathology

The typical pattern is that of a superficial and deep perivascular and periadnexal lymphocytic infiltrate with abundant eosinophils. A wedge-shaped pattern is characteristic. During the initial phase, intraepidermal spongiotic vesicles may be present and they can be associated with eosinophilic spongiosis. Pronounced dermal edema leads to the formation of subepidermal blisters. Sometimes, epidermal necrosis develops. Flame figures (extruded eosinophilic granules aggregated onto collagen fibers that are classically associated with eosinophilic cellulitis) can be observed, particularly in the exaggerated reactions seen in patients with hematologic malignancies.

Differential Diagnosis

The presence of intense pruritus and lesion distribution usually suggests a bullous bite reaction. However, these reactions can mimic bullous pemphigoid, linear IgA bullous dermatosis, bullous erythema multiforme, bullous impetigo, allergic contact dermatitis, or even viral infections.

Treatment

Most patients with bullous insect bites can be managed with drainage of blisters plus topical corticosteroids and systemic antihistamines to relieve pruritus. In the most severe reactions, a short course of systemic corticosteroids may be necessary. Systemic corticosteroids can lead to improvement of eosinophilic dermatosis of hematologic malignancy, but lesions tend to recur when the dose is reduced. Dupilumab may represent a therapeutic option in these patients[26]. Protective clothing and insect repellants are important preventative measures (see Ch. 85).

DELAYED POSTBURN/POSTGRAFT BLISTERS

Key features

- Delayed postburn and postgraft blisters represent an under-reported condition
- Tense blisters develop weeks to months after the initial injury has healed
- Blistering can persist for several weeks or months

Introduction

Delayed blisters have been observed weeks to months after the initial healing of second-degree thermal burns, donor sites of split-thickness skin grafts, and recipient sites of split-thickness skin grafts[27,28].

History

The first report of this phenomenon is attributed to Barker and Cotterill in 1980.

Epidemiology

Delayed blisters have received little attention in the literature. However, it appears to occur to some degree in almost every patient with a thermal burn involving more than 30% of the body surface area[28]. Most descriptions refer to patients with thermal burns, where delayed blisters have been observed on the spontaneously healed skin, graft donor sites, and graft recipient sites[27]. They have also been seen after skin grafting for toxic epidermal necrolysis and within laser-resurfaced skin[29].

Pathogenesis

The exact pathogenesis is not known. The antigenic components of the normal dermal–epidermal junction appear sequentially during fetal life or wound healing. Therefore, it has been hypothesized that this phenomenon is due to the enhanced fragility of a newly synthesized, "immature" dermal–epidermal junction[27,28]. In fact, in conventional scars, a subepidermal cleft is not an unusual histopathologic finding.

Clinical Features

Tense vesicles or blisters develop several weeks after the injured skin (burned, donor site, recipient site) has completely healed. In one study, blisters appeared between 19 and 55 days after the patients had sustained their burns, with an average of 37 days[28]. Blisters do not develop within uninvolved skin. Although they heal spontaneously, there is a tendency for recurrences over a period of weeks to months.

Pathology

Histologically, subepidermal blisters with minimal inflammatory infiltrate are seen. Electron microscopy has shown that the blisters occur either in the dermis (below the dermal–epidermal junction) or intraepidermally through the basal keratinocytes. DIF studies have been negative. Immunofluorescence mapping has shown a diminished or variable expression of dermal–epidermal junction antigens, including type IV and type VII collagens, laminin, and bullous pemphigoid antigen[27].

Differential Diagnosis

Blistering associated with a healed injured site can also be due to herpetic infection, ischemia (in the case of graft recipient sites), or autoimmune bullous diseases. Herpetic infection can be excluded by a negative PCR, viral culture, Tzanck smear, direct fluorescent antibody test, and/or biopsy findings; ischemia is diagnosed on the basis of clinical findings; and autoimmune blistering diseases can be excluded by histologic features, DIF/IIF examination, and ELISA.

Treatment

These blisters heal spontaneously with simple care, topical antibiotics, wound dressings, and local compression.

EDEMA BLISTERS

Synonyms: ■ Edema bullae ■ Stasis blisters ■ Hydrostatic bullae

Fig. 33.9 Edema bullae on the thigh of an infant. The bullae are tense and are surrounded by edematous skin. Desquamation from a ruptured bulla is also seen.

Key features

- Edema blisters develop in patients with an acute exacerbation of chronic edema, particularly of the lower extremities, and in the setting of anasarca
- The tense bullae are usually non-inflammatory, but are surrounded by edematous skin
- Blisters resolve when the edema resolves

Epidemiology

This phenomenon has received little attention in the literature. These blisters are not infrequent and usually develop in elderly and immobile hospitalized patients as well as in the setting of anasarca. In a study of 13 patients, the mean age was 74 years[30].

Pathogenesis

The bullae usually develop on the legs in association with an acute exacerbation of chronic edema. Edema develops when the capillary filtration rate exceeds lymphatic drainage. This can be due to hypoalbuminemia, congestive heart failure, renal disease, hepatic cirrhosis, venous occlusion (thrombosis) or drugs, particularly calcium channel blockers. Cutaneous vesicles and bullae also occur with acute exacerbations of lymphedema.

Clinical Features

Due to gravitational effects and venous hypertension, most patients develop blisters on the distal lower extremities, particularly the dorsum of the foot and ankle. With acute exacerbations of chronic edema, blisters appear and enlarge slowly to reach a diameter of up to several centimeters. The bullae are tense and asymptomatic, and the surrounding skin is edematous. The sterile blister fluid is usually clear, but it can be serous or hemorrhagic. In patients with anasarca, there is a more widespread distribution (Fig. 33.9).

Pathology

Marked epidermal spongiosis is observed, with dilated dermal blood vessels and a mild inflammatory infiltrate. The dermis is markedly edematous with wide separation of collagen bundles. In some cases, a subepidermal blister is observed. DIF is negative.

Differential Diagnosis

Blistering in the setting of acute edema is usually not difficult to diagnose. However, the possibility of bullous pemphigoid, bullosis diabeticorum, or bullous drug eruption must also be considered. The correct diagnosis can usually be established via the clinical history and physical examination (see Fig. 33.5). If needed, bullous pemphigoid can be excluded by negative DIF/IIF examinations and ELISA.

ADDITIONAL VESICULOBULLOUS DISORDERS	
Disorder	**Characteristic features**
Fracture blisters	• Tense bullae that develop within edematous skin and overlie bony fractures (Fig. 33.10) • Most common sites: distal tibia, ankle, foot, elbow, wrist • Thought to be due to shearing forces related to the injury plus post-traumatic edema
Sucking blisters	• Seen in newborns in areas accessible to the infant's mouth, e.g. forearm (see Fig. 34.8A) • Develop *in utero*
Bullous dermatitis artefacta (self-inflicted injury)[31,32]	• Can be produced by a thermal, electrical, or chemical burn as well as application of a vesicant, coolant, or "salt and ice" (see Ch. 88) • Histologic features vary depending upon etiology, but the most common pattern is a subepidermal blister with epidermal necrosis +/– dermal damage
Jellyfish stings	• Intense pain followed shortly by a burning sensation or pruritus as well as erythema and edema • Linear vesiculobullae and occasionally necrosis may also appear • Flagellate distribution corresponds to sites of contact with the jellyfish tentacles
PUVA-induced acrobullous dermatosis	• Sudden appearance of sterile, tense blisters, usually on the distal extremities • Due to weakening of epidermal–dermal cohesion plus friction or trauma • DDx: phototoxicity (more widespread) and PUVA-induced bullous pemphigoid

Table 33.2 Additional vesiculobullous disorders. Sites of frostbite can also develop vesicles. DDx, differential diagnosis.

Fig. 33.10 Fracture blisters. Multiple blisters, containing serous or hemorrhagic fluid, developed on the lower extremity following blunt trauma to the thigh. The resultant hematoma and fracture was accompanied by edema of the affected limb.

Treatment

These blisters resolve rapidly when the cause of the edema is successfully treated. Diuretics, discontinuation of calcium channel blockers, leg elevation, and compressive bandages (followed by maintenance compression hose) may prove helpful.

ADDITIONAL VESICULOBULLOUS DISORDERS

These are summarized in Table 33.2.

Additional figures available in our eBook (see inside front cover for access code).

34 Vesiculopustular and Erosive Disorders in Newborns and Infants

Nicole W. Kittler, Renee M. Howard and Ilona J. Frieden

A wide variety of conditions can cause vesicles, pustules, bullae, erosions, and ulcerations during the newborn period and infancy. Accurate and prompt diagnosis is important because some of the underlying disorders represent potentially life-threatening infections; conversely, many are benign and self-limited. Therefore, it is essential to develop a systematic approach to the evaluation and treatment of newborns and infants with these types of skin lesions. An algorithm outlining initial and subsequent investigations is presented in Fig. 34.1. This chapter highlights many causes of vesiculopustular and erosive eruptions during the first year of life, with more comprehensive lists provided in Tables 34.1 and 34.2. Most infectious etiologies are also covered in Chapters 74–82.

Key features

- Vesiculopustular eruption characterized by an eosinophilic infiltrate
- Affects nearly half of full-term neonates and resolves spontaneously over a few days
- Often involves the trunk as well as the face, proximal limbs, and buttocks
- Almost always spares the palms and soles
- Small wheals, inflammatory papules, pustules, and/or vesicles surrounded by blotchy erythema

COMMON CAUSES

Erythema Toxicum Neonatorum

Synonyms: ■ Erythema toxicum ■ Toxic erythema of the newborn

Erythema toxicum neonatorum (ETN) is a very common, benign condition. Originally described by Netlinger in 1472, it was known as "toxic erythema of the newborn" and was renamed erythema toxicum neonatorum by Leiner in 1912[1]. ETN occurs in approximately half of full-term neonates, possibly favoring those delivered vaginally, and is only rarely seen in premature infants or those weighing less than 2500 g[2,3].

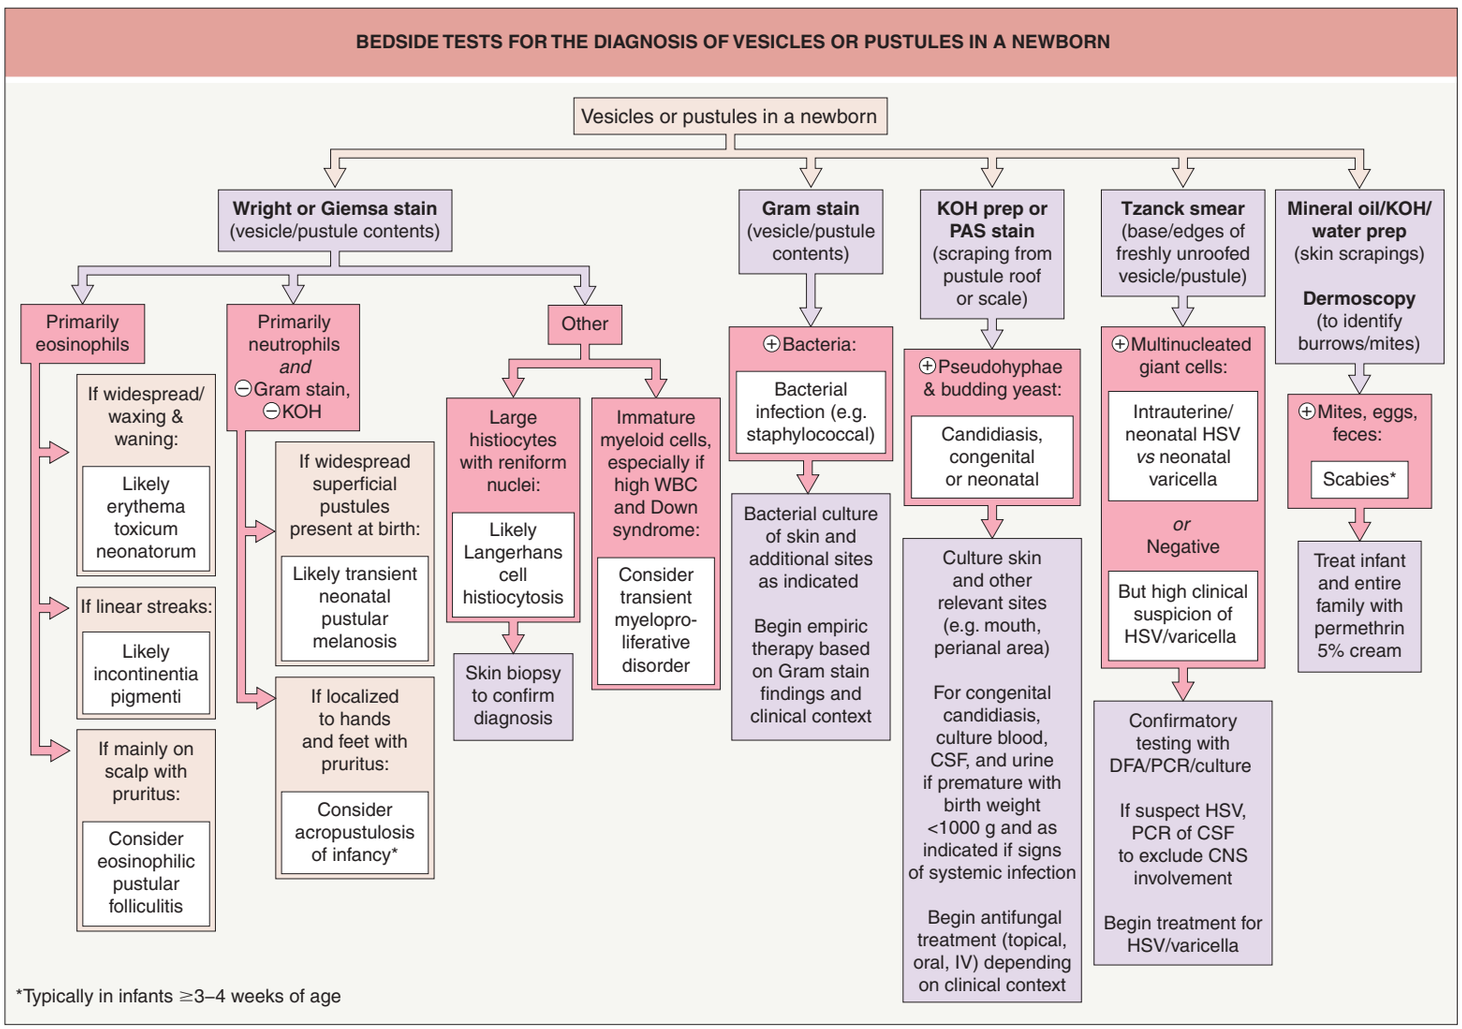

Fig. 34.1 Bedside tests for the diagnosis of vesicles or pustules in a newborn.

DIFFERENTIAL DIAGNOSIS OF VESICULOPUSTULAR DISEASES					
Disease	**Usual age of onset**	**Morphology**	**Distribution**	**Diagnostic studies (skin)**	**Comments**
Infectious diseases (more common conditions are in bold)					
Staphylococcal diseases: pyoderma and bullous impetigo (see Ch. 74) (Fig. 34.3A)	Few days to weeks or older	Pustules, bullae, occasionally vesicles; superficial erosions with collarettes of scale, crusts; furuncles	Favors diaper and periumbilical areas	Gram stain: Gram-positive cocci in clusters; bacterial culture	May occur in outbreaks
Group A streptococcal infection (see Ch. 74)	Few days to weeks or older	Isolated pustules, honey-colored crusts; moist, foul-smelling, fiery red intertriginous erythema	Any body region; may affect moist umbilical stump or skin folds	Gram stain: Gram-positive cocci in chains; rapid antigen test, bacterial culture	Occasionally cellulitis, meningitis, pneumonia
Group B streptococcal infection	Birth to first few days	Vesicles, bullae, erosions, pustules, honey-colored crusts	Any body region	Gram stain: Gram-positive cocci in chains; bacterial culture	Pneumonia, bacteremia, meningitis
Listeria monocytogenes infection (see Ch. 74)	Birth to first few hours	Hemorrhagic pustules and petechiae	Generalized, especially trunk and extremities	Gram stain: Gram-positive rods; bacterial culture	Sepsis, respiratory distress; history of maternal fever and premature labor
Haemophilus influenzae infection (see Ch. 74)	Birth to first few days	Vesicles, crusted papules	Any body region	Gram stain: Gram-negative bacilli, bacterial culture	Bacteremia, meningitis
Pseudomonas aeruginosa infection (see Ch. 74)	Days to weeks or older	Erythema, pustules, hemorrhagic bullae, necrotic ulcerations	Any region, especially anogenital area	Gram stain: Gram-negative rods; bacterial culture	Prematurity, low birth weight, immunodeficiency
Congenital candidiasis (Figs. 34.3B & 34.7)	Birth to first few days	Erythema, small papules and pustules, fine scaling; "burn-like" if extremely premature (see Table 34.2)	Any region; palms/soles often involved; nails may be affected	KOH: budding yeast; fungal culture; placental/umbilical cord lesions may be present	Prematurity, foreign body in cervix/uterus are risk factors; ascending *in utero* infection
Neonatal candidiasis	1–2 weeks of age	Beefy red patches with scale, satellite pustules and papules	Diaper area, other intertriginous zones, face	KOH: budding yeast, pseudohyphae; fungal culture	Usually otherwise healthy; acquisition during delivery or postnatally; oral thrush
Aspergillus infection (see Ch. 77)	Few days to weeks	Pustules (often clustered) rapidly evolve to necrotic ulcers	Any region, especially macerated skin in the diaper area and under adhesive tape/occlusive dressings	Skin biopsy: septate hyphae; tissue fungal culture	Extreme prematurity
Neonatal HSV infection (see Ch. 80) (Fig. 34.14)	Birth to 2 weeks, usually after 5 days	Vesicles, pustules, crusts, erosions	Any region, especially scalp, torso; may involve mucosa	Tzanck preparation, PCR, DFA or immunoperoxidase slide test, viral culture	Signs of sepsis, irritability, lethargy; must exclude herpes meningitis/encephalitis
Intrauterine HSV infection	Birth	Vesicles, pustules, widespread erosions, scars, areas of absent skin	Any body region	Tzanck preparation, PCR, DFA, or immunoperoxidase slide test, viral culture	Low birth weight, microcephaly, chorioretinitis; may mimic congenital erosive and vesicular dermatosis (see text)
Neonatal varicella (see Ch. 80)	Birth to 2 weeks	Vesicles on an erythematous base	Generalized distribution	Tzanck preparation, PCR, DFA, viral culture	Maternal primary varicella infection 7 days before to 2 days after delivery
Herpes zoster (see Ch. 80)	Typically 2 weeks or older	Vesicles on an erythematous base	Dermatomal pattern	Tzanck preparation, PCR, DFA, viral culture	Maternal primary varicella during pregnancy or up to a few days after delivery, or neonatal varicella
Scabies (see Ch. 84)	Typically 3–4 weeks or older	Papules, nodules, crusted areas, vesicles, pustules, burrows	Any region, including head and neck; especially axillae, groin, palms/soles, and wrists	Mineral oil preparation, dermoscopy	Family members may have pruritus and similar lesions

Table 34.1 Differential diagnosis of vesiculopustular diseases.

DIFFERENTIAL DIAGNOSIS OF VESICULOPUSTULAR DISEASES					
Disease	**Usual age of onset**	**Morphology**	**Distribution**	**Diagnostic studies (skin)**	**Comments**
Common transient conditions					
Erythema toxicum neonatorum (Fig. 34.2)	Typically 24–48 hours but can be birth to 2 weeks	Erythematous macules, papules, pustules > vesicles, wheals	Any region, except almost always spares palms/soles	Clinical; Wright's stain: eosinophils	Term infants >2500 g
Transient neonatal pustular melanosis (Fig. 34.4)	Birth	Pustules without erythema; collarettes of scale; hyperpigmented macules	Any region; most often forehead, neck, lower back, shins; may affect palms/soles	Clinical; Wright's stain: neutrophils, occasional eosinophils, cellular debris	Term infants; more common in infants of African descent
Miliaria crystallina (see Ch. 39) (Fig. 34.5A)	Birth to early infancy	Fragile vesicles without erythema	Forehead, upper trunk, arms most common	Clinical	Sometimes history of overheating or fever
Miliaria rubra (see Ch. 39) (Fig. 34.5B)	Typically ≥1 week	Erythematous papules with superimposed pustules	Forehead, neck, upper trunk; occluded areas most common	Clinical; Wright's stain: variable inflammatory cells but not prominent eosinophils	Sometimes history of overheating or fever
Neonatal cephalic pustulosis (neonatal "acne") (Fig. 34.6)	~5 days to 3 weeks	Papules and pustules on erythematous base	Cheeks, forehead, chin, eyelids; less commonly neck, upper chest, scalp	Clinical; Giemsa stain: yeast forms, neutrophils	Otherwise well
Uncommon and rare non-infectious diseases					
Acropustulosis of infancy (Fig. 34.10)	Typically 3–6 months, occasionally birth to weeks	Vesicles and pustules	Hands and feet; occasionally scalp, trunk	Clinical; assess for scabies infestation; skin biopsy: intraepidermal vesicle/pustule with neutrophils and occasionally eosinophils	Severe pruritus; lesions recur in crops; subset with prior scabies
Eosinophilic pustular folliculitis of infancy (Fig. 34.11)	Birth to 14 months, mean 6 months	Papules and pustules	Scalp > face > trunk, extremities	Skin biopsy: dense mixed infiltrate with eosinophils, often but not invariably centered on hair follicles	Pruritus; lesions recur in crops; often peripheral eosinophilia; *neonatal eosinophilic pustulosis* variant favors the face in premature boys
Congenital and neonatal Langerhans cell histiocytosis (see Ch. 91) (Fig. 34.12)	Birth to weeks	Vesicles, crusts, papules, nodules, petechiae	Any body region, especially flexural sites, palms/soles, scalp	Skin biopsy: $S100^{+}/CD1a^{+}$ histiocytes with reniform nuclei, focal invasion of epidermis	Occasional mucosal or extracutaneous involvement; pure cutaneous form often resolves spontaneously, but later cutaneous and systemic relapses possible
Incontinentia pigmenti (see Ch. 62) (Fig. 34.13)	Birth to weeks	Vesicles, hyperkeratotic papules along the lines of Blaschko	Vesicular lesions most common on the extremities	Skin biopsy: eosinophilic spongiosis with necrotic keratinocytes; genetic analysis (*IKBKG*/*NEMO*)	Ocular, CNS, and dental involvement common but often not evident at birth; X-linked dominant, patients usually female
Autosomal dominant hyper-IgE syndrome (see Ch. 60)	Birth to weeks	Single and grouped vesicles or papulopustules	Face, scalp, upper trunk, axillae, diaper area	Skin biopsy: intraepidermal vesicle with eosinophils, eosinophilic folliculitis; genetic analysis (*STAT3*)	Eosinophilia with variably elevated IgE levels, abscesses, pneumonias, and pneumatoceles often develop after neonatal period
Vesiculopustular eruption of transient myeloproliferative disorder in Down syndrome	Days to weeks	Vesicles and pustules	Face > trunk, extremities, sites of adhesive dressings, minor trauma	Intraepidermal spongiotic vesiculopustules, infiltrate containing immature myeloid cells	Trisomy 21 or mosaicism for trisomy 21, severe leukocytosis with immature myeloid cells, increased risk of myeloid leukemia
Erosive pustular dermatosis of the scalp	Weeks to months	Pustules, erythema with scale-crust, erosions; alopecia and scarring	"Halo scalp ring" pattern, vertex of scalp	Clinical, skin biopsy: alopecia, scarring, mixed dermal infiltrate	Prolonged labor and delivery, necrotic caput succedaneum at birth
Neonatal Behçet disease (see Ch. 26)	First week	Vesiculopustular, purpuric and necrotic skin lesions; oral and genital ulcers	Lesions favor hands and feet as well as oral and genital mucosae	Clinical	Maternal history of Behçet disease; diarrhea, vasculitis

Table 34.1 Differential diagnosis of vesiculopustular diseases.

Continued

DIFFERENTIAL DIAGNOSIS OF VESICULOPUSTULAR DISEASES					
Disease	**Usual age of onset**	**Morphology**	**Distribution**	**Diagnostic studies (skin)**	**Comments**
Pustular psoriasis, including deficiency of interleukin-36 receptor antagonist (DITRA; AR) and CARD14-mediated pustular psoriasis (CAMPS; AD) (see Chs. 8 & 45)	Weeks to months or older	Pustules and pustular lakes within areas of erythema	Often generalized with erythroderma; pustules in any body region, especially the palms/soles	Skin biopsy: spongiform pustules and micro-abscesses within the epidermis, parakeratosis, dilated dermal capillaries; genetic analysis (*IL36RN*, *CARD14*)	Occasional fever; often resistant to therapy, although DITRA often responds to IL-36 and IL-17 inhibitors
Deficiency of interleukin-1 receptor antagonist (DIRA; see Ch. 45)	Birth to weeks	Pustules within areas of erythema	Often generalized with erythroderma; oral lesions	Skin biopsy: neutrophilic microabscesses within acanthotic epidermis, parakeratosis, dilated dermal capillaries; genetic analysis (*IL1RN*)	Sterile osteolytic or hyperplastic bone lesions, neonatal distress, dramatic response to IL-1 antagonists
Perforating neutrophilic and granulomatous dermatitis associated with immunodeficiency	Birth to weeks	Papules evolve into vesicles, pustules, crusts, and ulcers	Varies: face, extremities, perineum	Skin biopsy: granulomas, neutrophilic infiltrate, transepidermal elimination of degenerated collagen and debris through hair follicles	Primary immunodeficiencies, including APLAID (autoinflammation and phospholipase C γ2-associated antibody deficiency and immune dysregulation)

Table 34.1 Differential diagnosis of vesiculopustular diseases. Additional etiologies include irritant contact dermatitis (see Table 34.2), dermatophyte infection, Sweet syndrome, and intrauterine coxsackievirus or Chikungunya virus infection. The vesicular eruption of lipoid proteinosis tends to develop after 1 year of age (see Ch. 48). AD, autosomal dominant; AR, autosomal recessive; CNS, central nervous system; DFA, direct fluorescent antibody; HSV, herpes simplex virus; KOH, potassium hydroxide examination; MAPK, mitogen-activated protein kinase; PCR, polymerase chain reaction. *Adapted from Frieden IJ, Howard R. In: Eichenfield LF, Frieden IJ, Mathes EF, Zaenglein AL (eds). Neonatal and Infant Dermatology, 3rd edition. London: Elsevier, 2015:112–115.*

DIFFERENTIAL DIAGNOSIS OF BULLAE, EROSIONS AND ULCERATIONS					
Disease	**Usual age**	**Morphology**	**Distribution**	**Diagnostic studies (skin)**	**Comments**
Infectious diseases					
Staphylococcal scalded skin syndrome (see Ch. 74) (Fig. 34.17)	Few days to weeks; rarely congenital	Erythematous patches, fragile bullae, superficial erosions, peeling in sheets	Generalized with periorificial and intertriginous accentuation	Biopsy: epidermal separation at granular cell layer; culture positive only at primary site(s) of infection (toxin-mediated)	Irritability, temperature instability; high risk of secondary sepsis, fluid/electrolyte abnormalities
Group B streptococcal infection	(see Table 34.1)				
Pseudomonas aeruginosa infection	(see Table 34.1)				
Congenital syphilis (see Ch. 82)	Birth to first few days	Bullae or erosions; erythema and desquamation	Any region, especially perioral, palms/soles	Darkfield examination of serous exudates, DFA; serologic studies (treponemal and non-treponemal)	Snuffles, hepatosplenomegaly, periostitis with pseudoparalysis
"Invasive fungal dermatitis" due to candidiasis > other fungi (see text and below) in very-low-birth-weight premature newborns (Fig. 34.7)	Birth to 2 weeks	"Burn-like" erythema with desquamation and erosions; intertriginous maceration	Any region	KOH: budding yeast; fungal culture; placental/umbilical cord lesions may be present	Risk factors: birth weight <1000 g, vaginal delivery, systemic corticosteroid administration, prolonged hyperglycemia; high risk of disseminated systemic infection
Aspergillus infection	(see Table 34.1)				
Zygomycosis, trichosporonosis (see Ch. 77)	Days to weeks	Generalized peeling and skin breakdown; cellulitis evolving into necrotic ulcer	Any body region	Skin biopsy and tissue fungal culture	Extreme prematurity
Intrauterine HSV infection	(see Table 34.1)				
Congenital (fetal) varicella syndrome (see Ch. 80)	Birth	Erosions, ulcers, scarring, aplasia cutis congenita	Any region, especially extremities; may have dermatomal pattern	Variably positive Tzanck preparation, PCR, DFA, viral culture	Maternal varicella in the first or early second trimester; limb atrophy, CNS/eye abnormalities

Table 34.2 Differential diagnosis of bullae, erosions, and ulcerations.

DIFFERENTIAL DIAGNOSIS OF BULLAE, EROSIONS AND ULCERATIONS					
Disease	**Usual age**	**Morphology**	**Distribution**	**Diagnostic studies (skin)**	**Comments**
Conditions with exogenous causes					
Sucking blisters (Fig. 34.8)	Birth	Flaccid bulla or linear erosion, most often solitary	Radial forearm, wrist, hand, fingers, occasionally foot	Clinical	Due to sucking on affected areas *in utero*
Irritant contact dermatitis	First few days to weeks or older	Glazed erythema, vesiculation, punched-out erosions	Diaper area, especially on convex surfaces	Usually clinical	Severe form referred to as Jacquet erosive diaper dermatitis
Perinatal trauma/ iatrogenic injury	Birth or neonatal period	Erosions, ulcerations, scars, atrophic lesions	Depends on cause of trauma	Usually clinical	Perinatal history of fetal scalp electrode monitor, prolonged labor and/ or vacuum or forceps delivery, history of amniocentesis, etc.
Perinatal gangrene of the buttock	Days	Sudden-onset erythema and cyanosis, then gangrenous ulcers	Buttocks	Clinical	Umbilical artery catheterization in some cases
Associated with birthmarks and related conditions					
Erosions overlying large congenital melanocytic nevi (see Ch. 112)	Birth to first few days	Erosions, ulcerations	Superimposed on the congenital melanocytic nevus, most often on the back	Clinical, skin biopsy to exclude melanoma if persistent or other unusual features	Neurocutaneous melanosis present in subset of patients
Ulcerated infantile hemangioma (see Ch. 103)	Birth to first few weeks or months	Ulcer, often with a bright red or pale, vasoconstricted border	Any site, but diaper area and lip most common	Clinical	Cause often not clinically apparent until hemangioma begins to proliferate
Aplasia cutis congenita (see Ch. 64) (Fig. 34.9)	Birth	"Bullous" form: round/oval, sharply demarcated with overlying membrane; other types with raw, full-thickness ulcer; scar	Scalp (especially vertex) or face most common; other sites depending on etiology (e.g. shins in Bart syndrome)	Usually clinical; imaging studies to evaluate underlying bone, CNS	Possible associations: CNS defects, sagittal sinus thrombosis, trisomy 13, limb-reduction abnormalities
Linear porokeratosis, porokeratotic eccrine ostial and dermal duct nevus (PEODDN) (see Chs. 62, 109, & 111)	Birth or weeks to years later	Occasionally eroded at birth; usually erythema and keratotic border or (in PEODDN) spines	Often extremities, but any site possible	Skin biopsy: cornoid lamella (may not be evident in newborn period)	Risk of squamous cell carcinoma; mosaic *GJB2* mutations in PEODDN
Uncommon and rare non-infectious diseases					
Mastocytosis (see Ch. 118) (Fig. 34.18)	Birth to weeks or months	**Discrete lesions** ("maculopapular", mastocytoma): papules, plaques or nodules with intermittent superimposed wheals, bullae, erosions; often hyperpigmented **Diffuse**: blistering and erosions superimposed on infiltrated skin with *"peau d'orange"* appearance	Any body region	Positive Darier sign; skin biopsy: increased mast cells in dermis	Variably present: flushing, irritability, diarrhea, abdominal pain
Epidermolysis bullosa (see Ch. 32)	Birth to first few days or older	Mechanically induced blisters and erosions; depending on type: mucosal erosions, aplasia cutis congenita of anterior legs, scarring, milia, nail dystrophy	Widespread or limited, depending on type; most often extremities, especially hands/feet	Biopsy of induced blister for immunofluorescence antigen mapping ± electron microscopy; genetic analysis	Difficulty feeding, failure to thrive; occasionally ocular, respiratory tract or gastrointestinal (e.g. pyloric atresia) involvement; anemia
Kindler syndrome (see Ch. 32)	Birth to weeks or older	Trauma-induced blisters and erosions; progressive poikiloderma	Bullae most common in acral sites; poikiloderma is widespread with skip areas	Skin biopsy: immunostaining with anti-kindlin-1 antibody, genetic analysis (*FERMT1*)	Photosensitivity, gingivitis, colitis, mucosal stenoses (e.g. esophageal, urethral), acquired syndactyly (toes, proximal fingers); AR inheritance
Epidermolytic ichthyosis (see Ch. 57) (Fig. 34.16)	Birth	Erythroderma with blisters and erosions	Generalized	Skin biopsy: epidermolytic hyperkeratosis; genetic analysis (*KRT1*, *KRT10*)	Risk of sepsis, fluid and electrolyte imbalances; AD inheritance

Table 34.2 Differential diagnosis of bullae, erosions, and ulcerations.

Continued

DIFFERENTIAL DIAGNOSIS OF BULLAE, EROSIONS AND ULCERATIONS					
Disease	**Usual age**	**Morphology**	**Distribution**	**Diagnostic studies (skin)**	**Comments**
Maternal autoimmune bullous disease	Birth	Depends on type of maternal disease: tense or flaccid bullae, erosions	Variable, often widespread	Skin biopsy with DIF usually diagnostic	Maternal history of blistering disease, but occasionally inactive during pregnancy
Bullous pemphigoid (see Ch. 30)	Usually ≥2 months of age	Tense bullae	Favor hands and feet but may be generalized	Skin biopsy: subepidermal bullae with eosinophils; DIF: linear pattern IgG at DEJ	
Linear IgA bullous dermatosis (see Ch. 31)	Rarely at birth, usually later infancy or childhood	Tense blisters often form rosette or sausage shapes	Widespread but often concentrated in the girdle area; usually spares mucosa	Skin biopsy: subepidermal bullae with neutrophils, DIF: linear pattern IgA at DEJ	
Neonatal lupus (see Ch. 41)	Birth (~20%) to weeks or months	Congenital erosions/ulcers, crusting, rarely bullae as well as classic annular erythematous plaques; atrophy, scarring, background of livedo reticularis	Face favored, especially the periorbital area, but can be more widespread	Skin biopsy: epidermal atrophy, vacuolar interface dermatitis, variable mucin	Mother and infant with antibodies to SSA/Ro, SSB/La, and/or U1RNP; variable heart block, cardiomyopathy, hepatobiliary disease, cytopenias
Toxic epidermal necrolysis (TEN; see Ch. 20) or TEN-like GVHD (see Chs. 52 & 60)	Usually ≥6 weeks of age, except for intrauterine GVHD	Tender erythema, bullae, epidermal sloughing/erosions	Often widespread, evolving rapidly over hours to days; mucosal involvement	Skin biopsy: subepidermal blister with epidermal necrosis (usually full thickness)	Typically in setting of Gram-negative sepsis or due to maternofetal or transfusion-associated GVHD in infants with severe combined immunodeficiency
Intrauterine epidermal necrosis	Birth	Widespread erosions and ulcerations without vesicles or pustules	Generalized, spares mucous membranes	Skin biopsy: epidermal necrosis and calcification of pilosebaceous units	Prematurity, brain infarcts, cardiomegaly, renal tubular necrosis; rapid mortality
Congenital erosive and vesicular dermatosis (Fig. 34.15)	Birth	Erosions, vesicles, crusts, "scalded skin"	Generalized with relative sparing of face, palms/soles	Clinical diagnosis, often retrospective; skin biopsy (nonspecific): epidermal necrosis, neutrophils or mixed infiltrate; exclude HSV via PCR	Prematurity; heals with supple reticulated scarring; CNS/developmental abnormalities
Pyoderma gangrenosum (see Ch. 26)	Rare reports of congenital or neonatal onset	Sharply demarcated ulcerations with undermined borders	Any site, especially groin and buttocks	Clinical; exclusion of other etiologies; skin biopsy: infiltration of neutrophils without primary vasculitis or infection	Associations include inflammatory bowel disease, chronic recurrent multifocal osteomyelitis; consider immunodeficiency and autoinflammatory syndromes
Acrodermatitis enteropathica* (see Ch. 51)	Weeks to months	Sharply demarcated, eroded erythematous plaques with scale-crust; occasionally intact vesicles/bullae	Periorificial (i.e. around mouth, nose, eyes, anus, genitalia), neck folds, hands/feet	Low serum zinc and alkaline phosphatase levels	Irritability, diarrhea, failure to thrive; onset classically after weaning if breastfed; acquired zinc deficiency: low maternal breast milk zinc or prematurity; genetic form with AR inheritance (*SLC39A4*)
Methylmalonic acidemia, other organic acidemias/aminoacidopathies* (see Fig. 51.13)	Days to weeks	Erythema with or without erosions	Periorificial or more widespread	Urine organic acid analysis; plasma isoleucine level (if restricted diet); often included in newborn screening; genetic analysis	Lethargy, hypotonia, neutropenia, metabolic acidosis; skin findings may result from therapeutic restrictions of dietary amino acids
Restrictive dermopathy	Birth	Rigid tense skin with linear erosions, tears	Generalized; skin tears most common in flexural creases	Clinical; distinguish from Neu–Laxova syndrome (intrauterine growth retardation, microcephaly, abnormal brain development, edema, parchment-like or ichthyosiform skin), genetic analysis (*ZMPSTE24* > *LMNA*)	Joint contractures, micrognathia, fixed facial expression, restrictive pulmonary disease, early mortality

Table 34.2 Differential diagnosis of bullae, erosions, and ulcerations.

DIFFERENTIAL DIAGNOSIS OF BULLAE, EROSIONS AND ULCERATIONS					
Disease	**Usual age**	**Morphology**	**Distribution**	**Diagnostic studies (skin)**	**Comments**
Focal dermal hypoplasia (see Ch. 62)	Birth	Occasional blisters, but more often hypoplasia or aplasia of skin in linear and whorled pattern; also fat "herniation", telangiectasias	Any body region	Clinical; skin biopsy: dermal hypoplasia with fat abutting epidermis; genetic analysis (*PORCN*)	Skeletal, eye, and CNS abnormalities to varying degrees
Absent dermal ridges and congenital milia (Basan syndrome; see Ch. 64)	Birth	Bullae, absent dermal ridge patterns, multiple milia	Fingers, plantar surface of feet	Clinical; genetic analysis (*SMARCAD1*)	AD inheritance
Porphyrias (see Ch. 49)	Days to months	Photosensitive erythema, blistering, erosions, scarring	Sun-exposed areas or more generalized if phototherapy for hyperbilirubinemia	Transient form: elevated plasma porphyrins; heritable forms: elevated urine, fecal, and/or plasma porphyrins ± pink/fluorescent urine	Transient form usually related to hemolytic disease; heritable forms rarely present with blistering in infancy, e.g. congenital erythropoietic porphyria
Neonatal purpura fulminans	Days	Initially purpura or cellulitis-like areas evolving to necrotic bullae or ulcers	Buttocks, extremities, trunk, and scalp	Prolonged PT/PTT, low fibrinogen, elevated FDPs, low protein C or S levels	Related to sepsis or inherited protein C or S deficiency
Ankyloblepharon–ectodermal dysplasia–clefting (AEC) syndrome (see Ch. 63)	Birth	Erythroderma, peeling skin, superficial erosions	Generalized, with prominent scalp involvement	Clinical; genetic analysis (*TP63*)	Ankyloblepharon, ectodermal dysplasia, cleft lip/palate
*An acrodermatitis enteropathica-like eruption (periorificial or more widespread), often associated with edema and hypoalbuminemia, can occur in infants (typically 3–5 months of age) with cystic fibrosis as well as in those with organic acidemias/aminoacidopathies (see Ch. 51).					

Table 34.2 Differential diagnosis of bullae, erosions, and ulcerations. AD, autosomal dominant; AR, autosomal recessive; CNS, central nervous system; CSF, cerebrospinal fluid; DEJ, dermal–epidermal junction; DFA, direct fluorescent antibody; DIF, direct immunofluorescence; FDP, fibrin degradation product; GVHD, graft-versus-host disease; PT, prothrombin time; PTT, partial thromboplastin time. Adapted from Frieden IJ, Howard R. In: Eichenfield LF, Frieden IJ, Mathes EF, Zaenglein AL (eds). Neonatal and Infant Dermatology, 3rd edition. London: Elsevier, 2015:112–115.

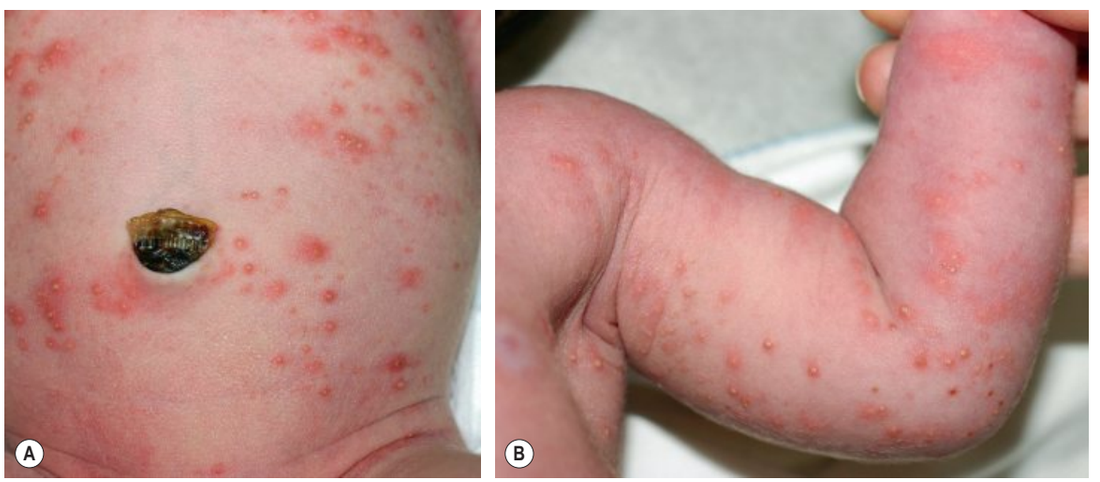

Fig. 34.2 Erythema toxicum neonatorum. Scattered papulovesicles and pustules with an erythematous flare on the abdomen (**A**) and upper extremity (**B**).

It is most commonly observed in infants with Fitzpatrick types I-II skin, although this may be related to the difficulty in perceiving erythema in infants with darker skin, and may be more prevalent in males[3,4].

Rarely presenting at birth, ETN usually begins 24 to 48 hours after delivery, followed by a waxing and waning course over the next few days. Although the onset may be as late as 1–2 weeks of age, additional diagnoses need to be considered in these cases. Five distinct components may be present in various combinations: erythematous macules, wheals, and small papules, vesicles and pustules, usually measuring 1–2 mm. The characteristic central papule with a surrounding erythematous flare is reminiscent of a flea bite (Fig. 34.2). Mechanical irritation may precipitate new lesions.

ETN most frequently affects the trunk but can also involve the face, buttocks, and proximal extremities; it almost always spares the palms and soles[2,3]. Individual lesions rarely persist for more than a day. The condition is asymptomatic and self-limited, requiring no therapy.

The diagnosis of ETN is usually made on clinical grounds. When necessary, the demonstration of numerous eosinophils via Wright stain of pustular contents can help to confirm the diagnosis. Peripheral eosinophilia is occasionally present. Histologically, pustules are intrafollicular, subcorneal, or intraepidermal and are composed of eosinophils and occasional neutrophils[5]. An eosinophilic infiltrate may also be present in the upper dermis. The pathogenesis of ETN is unknown, although an inflammatory response to microbial colonization of the follicle in the first days of life has been postulated[6].

The differential diagnosis includes other pustular disorders of the newborn, some of which may have important medical sequelae (see Table 34.1). Transient neonatal pustular melanosis (TNPM) is primarily neutrophilic, present at birth, usually affects infants with darkly pigmented skin, and resolves as pigmented macules that last weeks to months. However, overlap between ETN and TNPM has been observed (see below). Acropustulosis of infancy is an acral, rather than truncal, eruption that usually appears after the neonatal period. Eosinophilic pustular folliculitis of infancy favors the scalp and features lesions that often become crusted and recur in crops over a period of

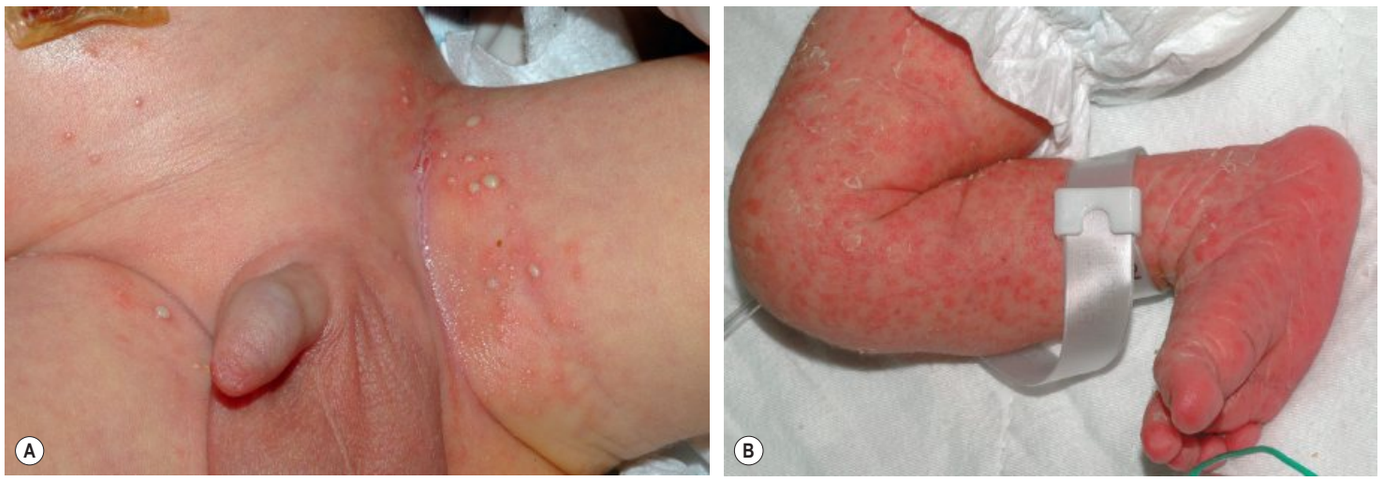

Fig. 34.3 Staphylococcal infection versus congenital candidiasis. A Multiple discrete superficial pustules with surrounding erythema in the diaper area of a 4-day-old boy due to infection with *Staphylococcus aureus*. **B** Numerous pink papules admixed with small superficial pustules and desquamation due to congenital candidiasis. Note the plantar involvement. *A, B, Courtesy Julie V. Schaffer, MD.*

months to years. Herpes simplex viral (HSV) infection presents with discrete vesicular lesions with progression to hemorrhagic crusting. *Staphylococcus aureus* infections manifest as more well-developed superficial pustules (Fig. 34.3A) or bullae that rapidly rupture, resulting in an erythematous base with a surrounding collarette. Congenital candidiasis presents with multiple tiny pustules and desquamation, with skin scrapings showing budding yeast and pseudohyphae on potassium hydroxide (KOH) examination (Fig. 34.3B). Both staphylococcal and candidal infections result in more persistent lesions that do not undergo the rapid spontaneous resolution characteristic of ETN. Miliaria rubra (prickly heat) is usually concentrated on the forehead and upper torso, with somewhat longer-lived lesions that lack a prominent erythematous flare or eosinophilic infiltrate[7].

Transient Neonatal Pustular Melanosis

Synonyms: ■ Transient neonatal pustulosis ■ Lentigines neonatorum

Key features

- Develops in ~5% of newborns with darkly pigmented skin
- Prominent superficial pustules without erythema that rupture, leaving a collarette of scale and hyperpigmentation that may last several months
- Sterile subcorneal neutrophilic infiltrate
- Favors the forehead, chin, neck, back, and shins but may be widespread

Originally described in 1961 as "lentigines neonatorum"[8], the full spectrum of TNPM was not recognized until 15 years later[9]. It occurs most commonly in infants with darker skin phototypes. There is no sexual predilection[4]. Lesions are virtually always present at birth and have three different morphologies that can coexist or occur sequentially. At delivery, superficial, 2–10 mm vesiculopustules (Fig. 34.4A) are present at sites such as the chin, forehead, nape of the neck, lower back, buttocks, and shins, and, less often, the remainder of the face, trunk, palms, and soles. These lesions may go undetected, as the fragile intra- and subcorneal pustules can be subtle or wiped away during the first bath. The second phase features slightly hyperpigmented macules with fine collarettes of scale at sites of ruptured and resolving pustules (Fig. 34.4B). Finally, residual brown macules may persist for several months. The name "lentigines" is a misnomer, as these lesions result from postinflammatory hyperpigmentation. Sometimes only the brown macules are noted at birth, suggesting that a previous pustular phase occurred *in utero*. Less commonly, infants with TNPM may present at a few weeks of age with extensive pigmented macules but no history of preceding pustules.

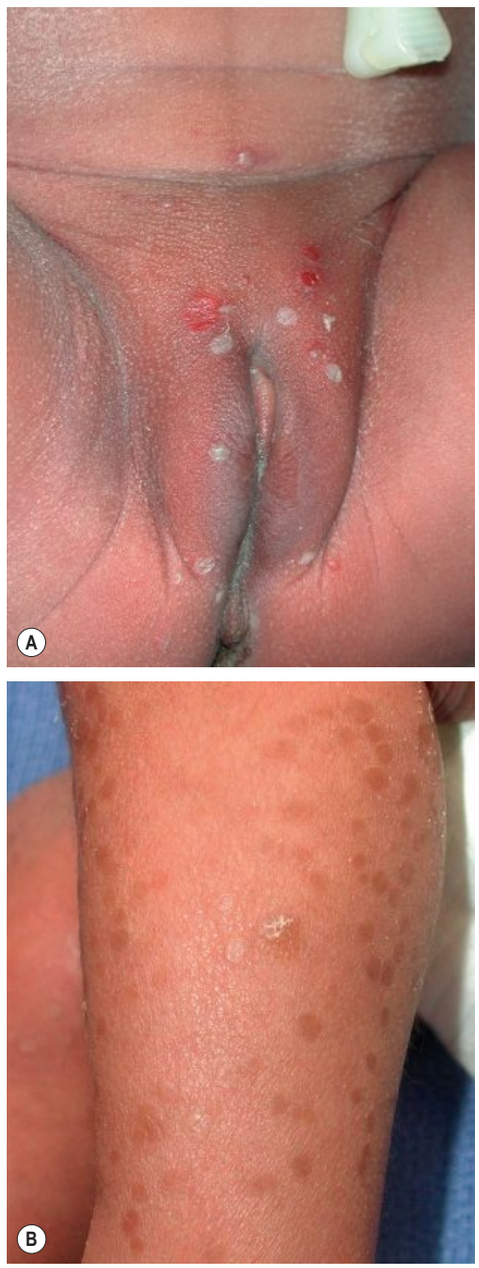

Fig. 34.4 Transient neonatal pustular melanosis in a Black neonate. A One hour after birth, flaccid vesiculopustules and superficial erosions with minimal surrounding erythema are present in the groin. **B** On the 8th day of life, hyperpigmented macules and a few collarettes of scale are evident on the lower leg.

Histologic examination is rarely necessary to make the diagnosis, but when performed on early lesions, it demonstrates intra- or subcorneal pustules containing primarily neutrophils and occasionally some eosinophils[5]. Pigmented macules show increased melanin within basal keratinocytes. The pathogenesis is unknown, and the differential diagnosis is similar to that discussed above for ETN. No treatment is necessary, and parents should be reassured of the benign and self-limited nature of the condition.

Sterile Transient Neonatal Pustulosis

It has been postulated that TNPM is simply a variant of ETN, based on their overlapping clinical and histologic features as well as reports of the two conditions coexisting in the same patient. The term *sterile transient neonatal pustulosis* has been proposed to encompass the ETN–TNPM spectrum[10]. However, most authors consider TNPM and ETN to represent separate entities.

Miliaria

Synonyms: ■ Heat rash ■ Miliaria crystallina – "dew drops" ■ Miliaria rubra – prickly heat

Key features

- Three variants: miliaria crystallina, miliaria rubra, and miliaria profunda (rare)
- Due to obstruction of eccrine sweat ducts, often in association with overheating, over-swaddling, or a fever
- Sites of predilection include the forehead, neck, upper trunk, and occluded areas
- Spontaneous resolution with cooling
- Prevention consists of avoidance of overheating and limiting excessive swaddling

Miliaria is a common condition that affects up to 15% of newborns, and it is seen more frequently in warm climates. Two types of miliaria (see Ch. 39) are typically observed in the newborn period. *Miliaria crystallina*, which is sometimes present at birth, is due to obstruction of the eccrine sweat duct as it courses through the stratum corneum. Sweat collects beneath the stratum corneum, causing clear, small, flaccid vesicles that are often likened to "dew drops" (Fig. 34.5A). *Miliaria rubra*, usually seen after the first week of life, is also caused by a blockage of the sweat ducts, but deeper within the spinous layer. The obstructed flow leads to leakage of fluid into the lower epidermis and upper dermis, resulting in an inflammatory response that produces small erythematous papules, papulovesicles, and pustules (Fig. 34.5B). *Miliaria profunda*, a variant caused by even deeper obstruction of the eccrine duct, is very rare in infants.

Both miliaria crystallina and miliaria rubra may be seen in relation to excessive warming inside an incubator, over-swaddling, fever, occlusive dressings, or a lack of air conditioning in warm climates. Lesions occur most commonly on the forehead, neck, and upper trunk as well as in areas of skin that have been occluded.

Miliaria crystallina features an intracorneal or subcorneal vesicle centered on the acrosyringium with relatively little inflammation. In miliaria rubra, intraepidermal spongiosis and vesicles are seen along with a chronic inflammatory infiltrate in the dermis[5] . An extracellular polysaccharide produced by *Staphylococcus epidermidis* present within the sweat duct may play a role[11], but this does not explain all cases, particularly congenital forms.

Miliaria resolves without treatment. Prevention is accomplished by avoidance of overheating and excessive swaddling when feasible.

Neonatal Cephalic Pustulosis

Synonym: ■ Neonatal acne

Fig. 34.5 Miliaria. A The tiny, superficial vesicles on the back and neck of this newborn are characteristic of miliaria crystallina. **B** Widespread miliaria rubra with numerous small papules and pustules. *A, From Eichenfield LF, Frieden IJ, Esterly NB, et al. (eds). Textbook of Neonatal Dermatology. © 2001 Saunders; B, Courtesy Antonio Torrelo, MD.*

Key features

- Onset usually within the first 2–3 weeks of life
- Inflammatory non-comedonal pustular eruption, most commonly observed on the cheeks, and less often on the forehead, chin, scalp, and chest
- *Malassezia* spp. have been implicated in its pathogenesis
- Spontaneous involution over weeks to months

Historically referred to as "neonatal acne", neonatal cephalic pustulosis lacks the comedones and more prolonged course that characterize infantile acne vulgaris (Table 34.3; see Ch. 36). Neonatal cephalic pustulosis develops within the first 2–3 weeks of life and resolves spontaneously by 3 months of age. Discrete papulopustules overlying variable background erythema are most commonly seen on the cheeks but may also develop on the forehead (Fig. 34.6), chin, eyelids, neck, upper chest, and scalp.

The results of some studies have suggested that an inflammatory response to *Malassezia (Pityrosporum)* spp. such as *M. furfur, M. sympodialis*, and *M. globosa* may be involved in the pathogenesis of neonatal cephalic pustulosis[12,13]. However, other studies have found no correlation between colonization of neonatal skin with *Malassezia* spp. and the presence or severity of neonatal cephalic pustulosis[14]. While these yeasts have been cultured from lesional skin in affected patients, they are part of the cutaneous microbiota in humans, and thus their exact role in the condition remains uncertain.

NEONATAL CEPHALIC PUSTULOSIS VERSUS INFANTILE ACNE		
	Neonatal cephalic pustulosis	**Infantile acne (see Ch. 36)**
Epidemiology	Common: >20%–50% of term infants Male : female = 1 : 1	Uncommon Males > females
Proposed pathogenic factors	Inflammatory reaction to *Malassezia* spp.	Androgen production
Typical age of onset	~5 days to 3 weeks	~6 weeks to 1 year
Typical duration	Weeks to 3 months	6 to 18 months
Morphology of lesions	Papules and pustules on an erythematous base	Open and closed comedones, papules, pustules, occasionally nodules
Distribution	Cheeks, forehead, eyelids, chin > neck, scalp, upper trunk	Primarily cheeks
Scarring	None	Occasionally
Treatment	Not usually necessary	More often necessary
	Topical imidazole or hydrocortisone	Topical retinoids, benzoyl peroxide, antibiotics; occasionally oral antibiotics or retinoids
Associated disease	Occasionally seborrheic dermatitis	Rarely an endocrine disorder, but need to consider when severe or other signs/symptoms (e.g. virilization, abnormal growth) Increased likelihood of severe adolescent acne

Table 34.3 Neonatal cephalic pustulosis versus infantile acne.

Fig. 34.6 Neonatal cephalic pustulosis. Papulopustules on the forehead and cheeks of a 3-week-old infant. *Courtesy Julie V. Schaffer, MD.*

A Giemsa-stained smear of pustular contents may demonstrate yeast forms, neutrophils, and other inflammatory cells; culture of *Malassezia* spp. requires specialized media[12]. The eruption can be treated with a topical imidazole or hydrocortisone, but this is not usually necessary[7].

Cutaneous Candidiasis

Key features

- *Neonatal* candidiasis is a common mucocutaneous infection acquired during delivery or postnatally, whereas *congenital* candidiasis is a relatively uncommon infection acquired *in utero*
- *Neonatal candidiasis* presents after the first week of life and is characterized by pink–red patches with satellite papules and pustules that favor the diaper area, other intertriginous sites, and face; oral thrush is often present
- When *congenital candidiasis* occurs in term neonates, it is characterized by a widespread vesiculopustular eruption, often involving the palms and soles
- In very-low-birth-weight premature newborns, cutaneous candidiasis may present as "burn-like" erythema with desquamation and erosions
- First-line therapy consists of topical anti-yeast medications (e.g. imidazoles), unless there is concern for systemic infection

Neonatal candidiasis is common and acquired during delivery or postnatally, whereas *congenital* candidiasis is uncommon and acquired *in utero*. In addition, premature newborns with a very low birth weight (often <1000 g) who develop cutaneous candidiasis prenatally or during the first two weeks of life can develop an "*invasive fungal dermatitis*" with a high risk of systemic involvement.

Neonatal candidiasis presents after the first week of life and involves primarily the diaper area and oral mucosa[7]. In some patients, other intertriginous areas and the face may be affected. Pink–red patches with satellite papules and pustules are the characteristic findings; pustules and scaling may also be present at the peripheral border.

In contrast, the relatively uncommon *congenital* candidiasis presents with a more widespread eruption, usually evident at birth but sometimes appearing as late as the 6th day of life. Congenital candidiasis is typically due to an ascent of yeast from the vagina into the uterine cavity. Risk factors include a foreign body in the uterus or cervix (e.g. retained intrauterine device, cervical cerclage), premature delivery, and a maternal history of vaginal candidiasis[15]. Skin lesions occur on the face, trunk, and extremities; the palms and soles are often involved, but the diaper area and oral mucosa are usually spared. Cutaneous findings vary and can include erythematous papules, vesiculopustules, diffuse erythema, and fine scaling[15,16]. Typically, erythematous papules appear first, followed by pustules and desquamation (see Fig. 34.3B). Nail dystrophy with yellowing and transverse ridging may be present and is occasionally the only manifestation[17].

"*Invasive fungal dermatitis*" in very-low-birth-weight newborns often presents as widespread "burn-like" erythema with desquamation and erosions (Fig. 34.7). Maceration in intertriginous areas may also be present. Additional risk factors include vaginal delivery (especially with instrumentation), invasive procedures, systemic corticosteroid administration, parenteral nutrition, and prolonged hyperglycemia. Although *Candida albicans* is the most frequent pathogen, infections with other *Candida* spp. and rarely *Trichosporon* or *Aspergillus* spp. can produce similar clinical findings.

In neonates, the differential diagnosis includes other infections (e.g. staphylococcal, streptococcal, listerial, HSV) as well as miliaria, ETN, and TNPM (see Table 34.1). Budding yeast and pseudohyphae in a KOH preparation that includes scale and/or the pustule and its roof points to the diagnosis, which can then be confirmed by culture. Cultures of blood, urine, and CSF (avoiding lumbar puncture if the skin overlying the spine is affected) should be performed in very-low-birth-weight premature infants with *congenital candidiasis* as well as in other neonates if there are signs of systemic infection (see below). When available, the placenta and/or umbilical cord should also be cultured and examined for characteristic yellow–white, bead-like papules.

For *neonatal candidiasis*, a topical anti-yeast medication (e.g. imidazole cream) is usually sufficient. Even if involvement is localized, premature neonates with very low birth weights (<1000 g) should be

Fig. 34.7 Congenital candidiasis in a neonate born at 24 weeks' gestation. This presentation is also referred to as "invasive fungal dermatitis" and has a high risk of systemic involvement. Note the "burn-like" appearance with erosions and desquamation. *Courtesy Julie V. Schaffer, MD.*

closely observed, with cultures of blood, urine, and CSF as indicated; treatment with parenteral antifungals should be considered if there are signs of worsening or systemic infection[7].

Treatment of *congenital candidiasis* is dependent on the gestational age and weight of the infant as well as the clinical presentation. Premature infants (<27 weeks' gestational age and <1000 g) are at high risk (~66%) for the development of disseminated systemic candidiasis and therefore should be treated with parenteral antifungal agents after appropriate cultures have been obtained (see above)[15,18]. Prompt initiation of a >14-day course of amphotericin B in such patients reduces the risk of disseminated infection and increases survival[18]. Infants of a more advanced gestational age with no evidence of systemic infection can be treated with topical therapy as discussed for *neonatal* candidiasis. However, regardless of gestational age, systemic antifungal therapy should be considered for infants with *congenital* candidiasis who have a "burn-like" presentation, respiratory distress, an elevated white blood cell count with a left shift, or other signs of systemic infection[15]. Oral fluconazole is an option for otherwise healthy full-term infants without evidence of disseminated candidiasis, while parenteral amphotericin B is indicated for those with high risk or signs of disseminated disease[18].

Sucking Blisters

Key features

- Caused by vigorous sucking of the affected region *in utero*
- Common locations include the radial forearm, wrist, hands, and fingers
- May present with an intact bulla, erosion, callus, or superficial ulceration on a non-inflamed base
- Usually an isolated finding without associated abnormalities
- Resolves over days to weeks and therapy is supportive

Sucking blisters are found in 1 of every 250 newborns, although they may be small and go unnoticed. They are an isolated finding caused by sucking *in utero* and are usually seen on the radial forearm, wrist, hand, or fingers (Fig. 34.8A). The flaccid bullae occur on a non-inflamed base and rupture easily, leading to linear or round erosions. Lesions are usually 5–15 mm in diameter and may be unilateral or bilateral.

The diagnosis of sucking blisters is usually straightforward and suggested by a non-inflammatory and, in most cases, solitary lesion in a typical location in a healthy infant. The lesions resolve in days to weeks without treatment.

Fig. 34.8 Physiologic skin findings in neonates. A Sucking blister on the dorsal hand. **B** Post-term desquamation is often most evident acrally. *A, Courtesy Ana Martín, MD; B, Courtesy Julie V. Schaffer, MD.*

Exogenous Causes of Erosions

Key features

- There are multiple exogenous causes for erosions, including friction from diapers and iatrogenic injury from monitors, adhesives, and procedures
- A typical location and known exposure to exogenous materials/procedures assist in diagnosis

Neonatal skin is more susceptible to erosions and ulcerations than is the skin of older infants or adults. Fragility is even more marked in preterm newborns. In full-term neonates, superficial erosions in the diaper area frequently occur within the first 2 weeks of life but then become less common. These erosions are primarily due to friction and irritation from the diaper, urine, and feces in the setting of transient neonatal skin fragility.

In neonates, iatrogenic causes of skin injury are numerous. A fetal scalp electrode monitor placed during delivery is a relatively common cause of superficial scalp erosions, but occasionally deeper lacerations or ulcers occur. Differentiation from aplasia cutis congenita (Fig. 34.9) is usually straightforward, but may be more difficult in severe cases. Pulse oximetry probes may lead to small blisters or erosions related to thermal burns or sustained pressure, especially if left in one place for more than 24 hours. Removal of adhesive materials such as tape over dressings and electrode leads can also cause erosions in fragile neonatal skin. These injuries may eventuate in anetoderma. Use of chlorhexidine-impregnated catheter-site dressings can result in irritant contact dermatitis, which may present with geometric erosions[19]. Puncture wounds from "heel sticks", a common method of phlebotomy utilized in the newborn nursery, are a potential cause of acral erosions; the medial or lateral (versus midline) location and procedural history are clues to the diagnosis[7]. Occasionally, heel-stick sites eventually develop calcinosis cutis (see Fig. 50.3).

Fig. 34.9 Aplasia cutis congenita (ACC) of the forearm. ACC in this location can be associated with underlying neurologic impairment, referred to as congenital Volkmann ischemic contracture, or bone abnormalities. The angulated borders help to distinguish it from intrauterine HSV or VZV infection. *Courtesy Julie V. Schaffer, MD.*

Fig. 34.10 Acropustulosis of infancy. Multiple vesiculopustules with an erythematous base on the medial ankle of an infant. *Courtesy Julie V. Schaffer, MD.*

UNCOMMON AND RARE CAUSES

Acropustulosis of Infancy

Synonym: ■ Infantile acropustulosis

Key features

- Onset usually between 3 and 6 months of age in the classic form
- A postscabetic variant also occurs
- Pruritic acral vesiculopustular eruption
- Recurs in crops, typically every 3–4 weeks, with decreased frequency and severity over time; the classic form usually resolves completely by ~3 years of age
- Symptomatic therapy with potent topical corticosteroids and oral antihistamines

Classic acropustulosis of infancy (AI) is an uncommon skin condition of unknown etiology that usually develops around 3–6 months of age but occasionally begins earlier. It affects all races but is more common in Black infants and boys. An association with atopy has also been observed[7]. More commonly, the same clinical findings occur in infants and children following scabies infestation. This is particularly frequent in international adoptees and has been referred to as "postscabetic acropustulosis" or, especially in younger patients, AI[20].

AI is characterized by outbreaks of pruritic vesicles and pustules in acral sites, in particular the palms, soles, dorsal aspects of the hands and feet, lateral fingers and toes, and, less often, wrists and ankles (Fig. 34.10). Occasionally, lesions are also found on the scalp, trunk, or proximal extremities. Vesiculopustules typically appear in crops that last 7–14 days and recur every 3–5 weeks. In both classic AI and the postscabetic variant, the flares decrease in frequency and severity over time. Spontaneous involution of classic AI usually occurs by 3 years of age.

A smear of pustular contents reveals numerous neutrophils, occasional eosinophils, and no bacteria or fungal elements. Histologic examination of lesional skin, while generally unnecessary, can help to confirm the diagnosis of AI. Histologic features include subcorneal pustules filled primarily with neutrophils; some mononuclear cells and eosinophils may be present[5].

The major challenge in the diagnosis of AI is distinguishing it from active scabies (see Ch. 84). Linear burrows are pathognomonic of active scabies; genital or more widespread lesions and pruritic eruptions in family members are also suggestive findings. Mineral oil examination of skin scrapings for mites, eggs, and scybala should be performed in all infants or toddlers with acral vesicles and pustules. Dermoscopy can also be used for *in vivo* visualization of mites and to increase the efficiency of skin scrapings. In uncertain cases, empiric treatment for scabies may be warranted. Other conditions with clinical overlap include dyshidrotic eczema and pustulosis palmaris et plantaris – both of which are rare in infancy. Congenital candidiasis is usually not limited to acral skin, and transient neonatal pustular melanosis is not pruritic, does not favor acral locations, and does not recur.

Symptoms can usually be controlled with intermittent application of potent or superpotent topical corticosteroids and administration of oral antihistamines[21].

Eosinophilic Pustular Folliculitis of Infancy

Synonyms: ■ Neonatal eosinophilic pustular folliculitis ■ Infantile eosinophilic pustular folliculitis ■ Eosinophilic pustular folliculitis in infancy ■ Eosinophilic pustulosis of infancy ■ Neonatal eosinophilic pustulosis

Key features

- Recurrent pruritic crops of follicular vesiculopustules
- Favors the scalp and face; occasionally involves the trunk and extremities
- Therapy is symptomatic; spontaneous resolution usually occurs by 3 years of age

Eosinophilic pustular folliculitis (EPF) of infancy is an uncommon entity with a mean age of onset at 6 months. It is occasionally present at birth and almost always develops before 15 months of age[22]. The male : female ratio is 4 : 1[22].

EPF of infancy is characterized by recurrent eruptions of sterile papules, pustules, and vesicles on an erythematous base. Lesions are located primarily on the scalp but can also occur on the face, especially in the brow region; the trunk and extremities are less commonly affected. Pruritic pustules often evolve into hemorrhagic crusts (Fig. 34.11) and occasionally result in scarring. The waxing and waning course persists for several months to years, usually with spontaneous resolution by three years of age. Because of its occasional acral involvement, cyclical recurrences, and self-limited nature, EPF of infancy has been thought to be related to AI; their coexistence has also been reported. Other

Fig. 34.12 Congenital Langerhans cell histiocytosis. Numerous erosions with crusting on the face and trunk of a newborn.

authors have suggested that EPF of infancy represents a clinicopathologic reaction pattern with heterogeneous underlying causes rather than a distinctive inflammatory dermatosis[7].

A smear of the contents of the intraepidermal pustules demonstrates primarily eosinophils, without bacteria or yeast forms. Histologically, there is a dense eosinophilic infiltrate around follicles, within the outer root sheath, and/or in the dermal interstitium. Because not all biopsies show follicular involvement[22], some authors have suggested that the term "eosinophilic pustulosis of infancy" may be more appropriate. Peripheral blood eosinophilia is often present. The differential diagnosis may include ETN, TNPM, acropustulosis of infancy, bacterial folliculitis, tinea capitis, scabies, reactions to arthropod bites, and incontinentia pigmenti. Since the histologic findings of EPF are similar to those of the vesicular and papulopustular lesions seen in association with autosomal dominant hyper-IgE syndrome[23] (see below), this diagnosis should also be considered, especially in more severe cases.

Symptomatic therapy is similar to that for acropustulosis of infancy, with options including mid-potency topical corticosteroids, topical tacrolimus, and oral antihistamines[7,22]. Oral dapsone and other antibiotics are occasionally used as anti-inflammatory agents in patients with severe, recalcitrant EPF of infancy.

Congenital and Neonatal Langerhans Cell Histiocytosis

Synonym: ■ Classic terms for congenital self-limited variant: Hashimoto–Pritzker disease, congenital self-healing reticulohistiocytosis

Key features

- Crusted papules, vesiculopustules, erosions, or nodules; occasionally petechiae or purpura
- May be limited to the skin; less commonly associated with extracutaneous involvement
- Cutaneous infiltrates of $S100^+/CD1a^+$ Langerhans cells
- Purely cutaneous form often resolves spontaneously within weeks to months
- Both cutaneous and extracutaneous relapses may occur; patients require longitudinal evaluation

Langerhans cell histiocytosis (LCH) is a rare condition that can be evident at the time of birth or present during the neonatal period with crusted papules, pustules, papulovesicles, nodules, erosions, and ulcerations (Fig. 34.12; see Ch. 91). Hemangioma-like papules, petechiae, purpura, atrophy, milia, and mucosal erosions may also be seen. Lesions are often widespread but can be solitary, and they may continue to develop and evolve over the first days to weeks of life. LCH lesions can develop anywhere on the skin surface, including the palms and soles[7]. The differential diagnosis includes neonatal varicella or HSV infection, congenital candidiasis, congenital syphilis, intrauterine GVHD, and the early-onset form of AI.

Histologically, a proliferation of Langerhans cells – large, ovoid cells with "coffee bean" nuclei – is present in the superficial dermis and occasionally in the epidermis (epidermotropism). These cells exhibit positive staining with S100, CD1a, and CD207 (Langerin). Ultrastructurally, they contain characteristic Birbeck granules[24].

In an infant diagnosed with congenital or neonatal-onset cutaneous LCH, a prompt evaluation for systemic involvement is indicated, including a complete physical examination, chemistry panel including liver function tests, complete blood cell count with differential, urine osmolality, abdominal ultrasound, skeletal survey, and chest X-ray[25]. Referral to oncology with consideration of bone marrow aspiration or biopsy is recommended. Distinction between purely cutaneous and multisystem disease is not possible based solely on the skin findings. In fact, the histologic and immunohistochemical features of "congenital self-healing reticulohistiocytosis" and disseminated Langerhans cell histiocytosis are indistinguishable. These entities are now thought to represent different ends of the LCH clinical spectrum[26].

In patients whose disease is limited to the skin, lesions usually resolve spontaneously over a period of weeks to months and the prognosis is very good. However, relapses of cutaneous or extracutaneous disease (e.g. diabetes insipidus due to pituitary involvement) may occur months or years later, highlighting the importance of longitudinal evaluation of these patients. The prognosis of multisystem congenital LCH is less favorable, and systemic therapy is generally required[7]. In the majority of patients with LCH, lesional Langerhans cells harbor somatic activating mutations in *BRAF* V600E or genes that encode additional kinases in the RAS–MAP–kinase pathway (see Ch. 113). The *BRAF* V600E mutation is more frequent in younger children and has been associated with multisystem disease and a greater likelihood of relapse[27]. Although traditional therapy for multisystem LCH involves a combination of vinblastine and prednisone, there is an emerging role for targeted treatment with BRAF and MEK inhibitors[28,29].

Incontinentia Pigmenti

Synonym: ■ Bloch–Sulzberger syndrome

Key features

- X-linked dominant multisystem disease, usually lethal in male fetuses
- Cutaneous lesions are characterized by four phases: vesicular, verrucous, hyperpigmented, and hypopigmented/atrophic
- Extracutaneous manifestations are most commonly dental, ophthalmologic, and neurologic

Incontinentia pigmenti (IP) is an uncommon X-linked dominant multisystem disease that presents within the first 2 weeks of life in 90% of patients and is lethal in male fetuses unless they have X chromosome aneuploidy (e.g. Klinefelter syndrome) or genomic mosaicism (see Ch. 62). IP is caused by mutations in *IKBKG* (inhibitor of NF-κB kinase regulatory subunit γ), which is also known as *NEMO* (NF-κB essential modulator). Its protein product confers protection against apoptosis induced by the tumor necrosis factor family of cytokines (see Fig. 130.4).

Cutaneous lesions follow the lines of Blaschko and occur in four classic phases (see Fig. 62.5). The vesicular first phase usually lasts 1–2 weeks, with intermittent recurrences for up to a year and occasionally later in childhood in association with febrile illnesses. Streaks of vesicles most often develop on the extremities and scalp but can also appear on the trunk (Fig. 34.13A–C); the face is usually spared. The verrucous second phase of IP features hyperkeratotic linear plaques. The third phase, characterized by linear and whorled grayish-brown hyperpigmentation, occurs most often on the trunk and in some patients represents the only cutaneous feature (see Fig. 67.19). The first three phases typically resolve during infancy or childhood. The fourth phase, consisting of subtle atrophic, hypopigmented thin streaks favoring the calves, may persist indefinitely. Clinical stages of IP can overlap, occur *in utero*, or occasionally be skipped entirely. Additional cutaneous findings may include patchy scarring alopecia (typically at the vertex), areas of woolly hair, nail dystrophy, and anhidrosis within atrophic linear streaks. The most common extracutaneous manifestations are: (1) *dental* abnormalities such as hypodontia and conical teeth; (2) *CNS* involvement resulting in seizures, delayed psychomotor development, or spastic paralysis; and (3) *ocular* disease characterized by retinal vascular abnormalities with potential for blindness. During the vesicular phase, patients often have peripheral blood leukocytosis and eosinophilia.

Skin biopsy is often helpful in confirming the diagnosis. Histologically, lesions from the vesicular stage of IP demonstrate eosinophilic spongiosis with scattered or grouped necrotic keratinocytes (Fig. 34.13D). A dermal infiltrate composed predominantly of eosinophils is also present[5].

The cutaneous lesions generally do not require therapy. All affected infants should be referred for baseline and longitudinal ophthalmologic examinations and should have periodic neurodevelopmental and dental evaluations. Genetic testing is available.

Autosomal Dominant Hyperimmunoglobulin E (Hyper-IgE) Syndrome

Synonyms: ■ Job syndrome ■ STAT3 hyper-IgE syndrome

Fig. 34.13 Incontinentia pigmenti stage 1. A Admixture of erythematous streaks containing vesicles and yellow–brown streaks with scale on the lower extremity. **B, C** Vesicles and erythema in a linear and whorled configuration on the trunk, extremities, and ear of female neonates. **D** Histopathology showing eosinophilic spongiosis and dyskeratotic keratinocytes. *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Luis Requena, MD; C, Courtesy Antonio Torrelo, MD and Luis Requena, MD; D, Courtesy Laura B. Pincus, MD.*

Key features

- Primary immunodeficiency syndrome with autosomal dominant inheritance due to *STAT3* mutations
- Characteristic neonatal papulopustular and vesicular eruption with crusting favoring the face, scalp, and neck as well as the axillae and diaper area
- During the first few weeks to months of life, serum IgE levels may not yet be elevated and other features such as "cold" abscesses, eczematous dermatitis, and recurrent infections are often absent

Autosomal dominant hyperimmunoglobulin E syndrome (AD-HIES) is a primary immunodeficiency caused by mutations in the *s*ignal *t*ransducer and *a*ctivator of *t*ranscription *3* gene (*STAT3*; see Ch. 60)[30]. Approximately 70%–80% of patients present with a papulopustular or vesicular eruption at birth or during the first month of life, with mean onset at 7 days of age[31]. The lesions are usually concentrated on the head and shoulders, but they can also affect the axillae and diaper area. AD-HIES is classically associated with high circulating levels of IgE (>2000 IU/ml) and peripheral eosinophilia. However, the IgE level may not yet be elevated in neonates and can fluctuate independently of skin disease severity. Histologic features of the vesicular and papulopustular lesions include intraepidermal vesicles containing eosinophils, perivascular infiltrates of eosinophils, and an eosinophilic folliculitis similar to that seen in eosinophilic pustular folliculitis[23].

Beyond the neonatal period, AD-HIES is associated with "cold" abscesses (see Fig. 60.8), pruritic chronic eczematous dermatitis, recurrent pneumonias with pneumatocele formation, osteopenia, and retention of deciduous teeth. Autosomal recessive variants of HIES have also been described, including dedicator of cytokinesis 8 (DOCK8) deficiency (see Ch. 60)[32]. The latter shares some features with HIES, including chronic eczematous dermatitis, recurrent sinopulmonary and staphylococcal skin infections, elevated serum IgE levels, and peripheral eosinophilia. However, DOCK8 deficiency is associated with severe viral skin infections and does not typically present with a neonatal vesiculopustular eruption[32].

VERY RARE DISORDERS

Neonatal Behçet Disease

Neonatal Behçet disease has been described in infants born to mothers with active Behçet disease during pregnancy (see Ch. 26), and it is thought to result from placental transfer of pathogenic maternal immunoglobulins. Cutaneous findings in these infants develop during the first week of life and resolve by 2–3 months of age. Manifestations include ulcerations of the oral and genital mucosae as well as vesiculopustular, purpuric, and necrotic skin lesions on the hands and feet; sites of trauma are favored, reflecting pathergy. Most infants have no additional symptoms, although there are isolated reports of colitis and other systemic involvement[7]. The differential diagnosis includes neonatal HSV infection (Fig. 34.14; see Table 34.1) and a monogenic autoinflammatory disease (see Ch. 45). A neonatal onset of pediatric Behçet disease has rarely been reported and is distinguished by the lack of a maternal history of Behçet disease, persistence beyond the neonatal period, and a higher likelihood of multisystem disease[33,34].

Vesiculopustular Eruption in Transient Myeloproliferative Disorder of Down Syndrome

There are a number of reports of a vesiculopustular eruption in neonates with trisomy 21 or mosaicism for trisomy 21. It begins during the first few days to weeks of life (rarely beyond 1 month) in the setting of transient myeloproliferative disorder, a congenital leukemoid reaction due to somatic *GATA1* mutations that affects ~10% of neonates with Down syndrome[35]. Vesicles and pustules develop initially and most prominently on the face but usually spread to involve the trunk and extremities[35]. As a consequence of pathergy, lesions have a predilection for sites of minor trauma or adhesive dressings[35]. Histologically, intraepidermal spongiotic vesiculopustules are present in association with a perivascular infiltrate. The infiltrate includes immature myeloid cells, which may be evident in a Tzanck smear of vesiculopustules and are usually also present in the peripheral blood[35,36].

Fig. 34.14 Neonatal HSV infection. Note the clustering of the vesicles on an erythematous base. *Courtesy Julie V. Schaffer, MD.*

Although the skin lesions tend to resolve spontaneously within weeks to months as the leukemoid reaction subsides, affected patients are at increased risk for the development of myeloid leukemia during the first few years of life and thus should be followed by a pediatric oncologist[35]. Considering that infants who are mosaic for trisomy 21 may not have phenotypic features of Down syndrome, an unexplained pustular eruption in a neonate accompanied by leukocytosis should prompt evaluation for transient myeloproliferative disorder and mosaic trisomy 21[37].

Congenital Erosive and Vesicular Dermatosis

Approximately 40 cases of "congenital erosive and vesicular dermatosis" (CEVD) have been reported since it was first described by Cohen and colleagues in 1985[38]. At birth, the neonates – almost all premature – have widespread erosions, vesicles, crusting and "scalded skin"-like erythematous areas affecting up to 75% of the body surface area (Fig. 34.15A). Reported associated findings include a collodion-like membrane, transparent areas of skin, livedo reticularis-like vascular patterns, and ulcerations. The face, palms, and soles are usually relatively spared. The lesions heal in 1 to 2 months with characteristic supple and reticulated scars that often cover large areas of the skin (Fig. 34.15B)[39]. Later on, scarring alopecia of the scalp and eyelashes, scarring of the tongue, absent or hypoplastic nails, and heat intolerance with hypohidrosis may be seen; mild ongoing blistering is occasionally observed[39]. Neurodevelopmental abnormalities, brain atrophy, hemiparesis, sensorineural hearing loss, and retinal scars have also been reported[39,40].

The cause of the condition remains unknown, but an intrauterine infection has been suspected. Although CEVD is diagnosed after exclusion of other etiologies, intrauterine HSV infection can mimic the findings of CEVD and likely accounted for a significant subset of reported cases, many of which predated widespread clinical use of HSV PCR[39,41]. The extracutaneous findings associated with CEVD overlap with those of congenital HSV infection, and recurrent HSV outbreaks during the first year of life were noted in 20% of reported CEVD cases[39,41].

Biopsy specimens from the acute phase have demonstrated epidermal necrosis, subepidermal vesiculation, or an eroded epidermis with a neutrophilic or mixed dermal infiltrate and no evidence of vasculitis or thrombosis[38,42]. Later in the course, biopsy specimens have shown scar formation with loss of eccrine structures[38,42].

Fig. 34.15 Congenital erosive and vesicular dermatosis. A Widespread bright red, irregularly shaped erosions on the back, buttocks, and extremities of a 2-week-old infant. Note the jagged outline of the healing lesion on the back. **B** Residual supple and reticulate scarring in a 9-month-old child. *A, Courtesy Anthony J. Mancini, MD; B, Courtesy Julie V. Schaffer, MD.*

Fig. 34.16 Epidermolytic ichthyosis. Diffuse scaling and a large erosion with scale-crust in a neonate. Histologically, epidermolytic hyperkeratosis was seen.

In addition to HSV infection (see above), which can be confirmed via PCR testing, the differential diagnosis includes other intrauterine infections, epidermolysis bullosa, epidermolytic ichthyosis (Fig. 34.16), acute intrauterine GVHD, and intrauterine epidermal necrosis (see Table 34.2). Infants with CEVD should be followed for evidence of diminished sweating and neurologic defects. Treatment is supportive with meticulous wound care, as no specific therapy is available.

Fig. 34.17 Staphylococcal scalded skin syndrome. Perioral and periorbital erythema and scale-crusts in a neonate (see Table 34.2). *Courtesy Julie V. Schaffer, MD.*

Fig. 34.18 Bullous mastocytosis. Tense bulla on the wrist and flaccid bullae on the dorsal hand as well as pink plaques on the trunk in a 1-month-old infant (see Table 34.2).

Pyoderma Gangrenosum

Rarely reported in infants and newborns, pyoderma gangrenosum in this age group most often involves the perineum, possibly because of pathergy. Otherwise, the clinical features of the ulcer, including an undermined violaceous border, are similar to those seen in older children and adults[43,44]. Biopsy specimens show a sterile neutrophilic infiltrate, but the diagnosis is often one of exclusion after other causes of ulceration such as infection, immunodeficiency, thrombosis, and vasculitis are eliminated. In recent reviews, up to 45% of infants with PG have an underlying disorder[44] (see Ch. 25). Intralesional or systemic corticosteroids are usually first-line treatment; other systemic agents such as dapsone, cyclosporine, and TNF inhibitors have also been used[44,45].

Restrictive Dermopathy

Restrictive dermopathy is a rare disease characterized by rigid, tense skin with erosions and linear tears that occur most commonly in

flexural creases[46]. The disorder results in a fetal akinesia or hypokinesia deformation sequence characterized by multiple flexion joint contractures, dysmorphic facies with a fixed facial expression, and polyhydramnios with reduced fetal movements; the latter results in premature delivery, most often at 30–33 weeks' gestation. Other features include translucent skin with prominent vessels, micrognathia, sparse/absent eyelashes, natal teeth, large fontanelles, dysplasia of the clavicles, and poorly expanded lungs as a result of the restrictive skin changes. Most affected newborns die from restrictive pulmonary disease within the first week of life. Restrictive dermopathy represents a lethal neonatal laminopathy, typically caused by either dominant *de novo* mutations in *LMNA*, which encodes nuclear lamin A/C proteins, or, more commonly, recessive null mutations in *ZMPSTE24*, which encodes a zinc metallopeptidase essential for lamin A processing (see Ch. 63)[47].

Noma Neonatorum

Two forms of noma have been described in the newborn period. The first is a manifestation of infection, usually *Pseudomonas aeruginosa* septicemia, and has been reported almost exclusively in low-income countries[48]. Infants present with an abrupt onset of gangrenous ulcerations of the nose, lips, mouth, eyelids, anus, and scrotum. In severe cases, the ulcerations can destroy underlying bony structures and cause extensive deformity. Predisposing factors include premature birth, low birth weight, malnutrition, and previous illness, although infectious noma has been reported in previously healthy term infants[49]. Some authors suggest that this form of noma neonatorum may represent a variant of neonatal ecthyma gangrenosum[50].

The second form of noma has been seen in Native American infants who present with perineal and oral ulcerations in the setting of severe combined immunodeficiency[51]. The presence of oral and perineal ulcerations in newborns and infants should prompt an evaluation for infection and immunodeficiency. Of note, neonatal nasal ulcerations are a characteristic feature of *p*hospho*l*ipase Cγ2 (*PLCG2*)-associated *a*ntibody deficiency and *i*mmune *d*ysregulation (PLAID)[52].

Perinatal Gangrene of the Buttock

This rare condition is characterized by the sudden onset of erythema and cyanosis of the buttocks, followed by progressive development of gangrene and ulceration. Although some cases have been associated with umbilical artery catheterization, others were spontaneous[53]. Occlusion or spasm of the internal iliac artery has been postulated as a potential cause[54]. Considerations when evaluating a neonate with hemorrhagic bullae and gangrenous soft tissue infarction also include purpura fulminans due to congenital coagulopathies (e.g. protein C or S deficiency) or infection.

35 Structure and Function of Eccrine, Apocrine, and Sebaceous Glands

Martin Schaller and Gerd Plewig

Chapter Contents

Eccrine and Apocrine Sweat Glands 586
Sebaceous Glands 588

ECCRINE AND APOCRINE SWEAT GLANDS

Key features

- Eccrine sweat glands are widely distributed, with the highest density in palmoplantar skin; they are activated by emotional and thermal stimuli and are necessary for thermoregulation
- The eccrine secretory unit consists of a coiled secretory portion that drains into a long, thin duct whose apical portion (acrosyringium) opens to the skin surface
- Innervation of eccrine glands consists of postganglionic sympathetic fibers that have acetylcholine as their main neurotransmitter
- Apocrine glands are located primarily in the axillae, anogenital and periumbilical regions, and nipples; their apical portion (acrosyringium) drains into terminal hair follicles
- Apocrine glands continuously secrete a sterile, odorless, viscous fluid that is rich in precursors of odoriferous substances; they are androgen-dependent in their development and have an unclear function in humans

Introduction

Humans have both eccrine and apocrine sweat glands, which are distinct from one another structurally, developmentally, and functionally (Table 35.1, Fig. 35.1). Disorders of sweating are common and can be due to dysfunction of central sweat centers; sympathetic ganglia and their pre- and postganglionic fibers; or secretory glands and excretory ducts. Clinical manifestations include hyperhidrosis, hypohidrosis, and sweat retention (e.g. miliaria). Knowledge of the structure and function of sweat glands is important for proper diagnosis and treatment of sweating disorders (see Chs. 39 & 159).

ECCRINE SWEAT GLANDS

Structure

In the human body, there are ~1.5 to 4 million eccrine sweat glands and they are widely distributed, sparing only the skin of the external auditory canals, vermilion lips, clitoris, labia minora, and glans penis. The highest density is found on the palms and soles. The eccrine secretory unit consists of a proximal coiled secretory portion in the lower dermis and subcutaneous tissue. This drains into a long, thin duct with an apical portion (acrosyringium) that opens directly onto the skin surface (see Fig. 35.1)[1,2]. The secretory coils contain two cell types interspersed within a single cell layer: (1) large clear cells responsible for the gland's secretion of electrolytes and water; and (2) dark cells, of unknown function, with basophilic granules that are thought to produce sialomucin. Both cell types are surrounded by myoepithelial cells, which probably function to enhance the delivery of sweat to the skin surface. The ductal epithelium is composed of two or more layers of cuboidal cells without surrounding myoepithelium. The intraepidermal portion of the duct, the acrosyringium, is twisted like a corkscrew with similar coils in the stratum corneum[2]. Stem cell markers (e.g. prominin-1/CD133) are expressed in the secretory and ductal portions of eccrine glands[3].

The eccrine glands are innervated by postganglionic sympathetic fibers that have acetylcholine (not norepinephrine) as their primary terminal neurotransmitter (Table 35.2). These sympathetic fibers are controlled by the hypothalamic sweat center[2]. The sweat center responds to its own temperature (as a reflection of core body temperature) and to neural stimuli from the periphery.

Development

During embryogenesis, at 3 months' gestation, sweat glands begin to develop as cords of epithelial cells arising from the epidermal ridges on the palms and soles. By 5 months' gestation, similar structures have developed in the remainder of the body. Functional eccrine glands are present at birth and react to thermal and emotional stimuli. Unlike apocrine glands, they have no developmental relationship with the pilosebaceous follicle[2,4].

Function

Eccrine sweat is a sterile, dilute electrolyte solution that contains primarily sodium chloride (NaCl), potassium, and bicarbonate. Other components include antimicrobial peptides (e.g. dermcidin)[5], proteolytic enzymes, glucose, pyruvate, lactate, urea, ammonia, calcium, amino acids, epidermal growth factor, cytokines, and immunoglobulins. In addition, other organic compounds and heavy metals such as arsenic, cadmium, lead, and mercury are excreted in sweat[6]. One study demonstrated that sweat activates NF-κB, ERK, and JNK pathways in keratinocytes, resulting in the upregulation of interleukin (IL)-8 and IL-1β production[7]. Keratinocyte outgrowths from eccrine sweat glands also play a central role in re-epithelializing wounds[8].

The quantity and quality of eccrine sweat secretion varies widely in response to emotional and environmental stimuli. There are several methods for measuring sweat production, e.g. gravimetry, starch–iodine reaction (see Ch. 39). At maximal stimulation, the body can produce

CHARACTERISTICS OF SWEAT GLANDS		
	Eccrine	**Apocrine**
Localization	Entire body skin, highest density on palms and soles	Axillae, anogenital, periumbilical, nipples, and areolae
Morphology	Long, thin duct opens to skin surface	Short, thick duct opens into upper part of follicular canal
	Secretory coil with narrow lumen	Secretory coil with wide lumen
Cell types in secretory coil	Large secretory clear cells, dark cells, and myoepithelial cells	Epithelial (typically cuboidal) and myoepithelial cells
Main innervation/ neurotransmitter	Sympathetic fibers/ acetylcholine	Unclear/possible humoral effects of β-adrenergic receptor agonists
Development	Present at birth	Present at birth
	No relationship to pilosebaceous follicle	Associated with terminal hair follicle
Function/ pathogenesis	Thermoregulation/ dysfunction in hyperhidrosis, hypohidrosis, and miliaria	Possible role in olfactory communication/dysfunction in Fox–Fordyce disease

Table 35.1 Characteristics of sweat glands.

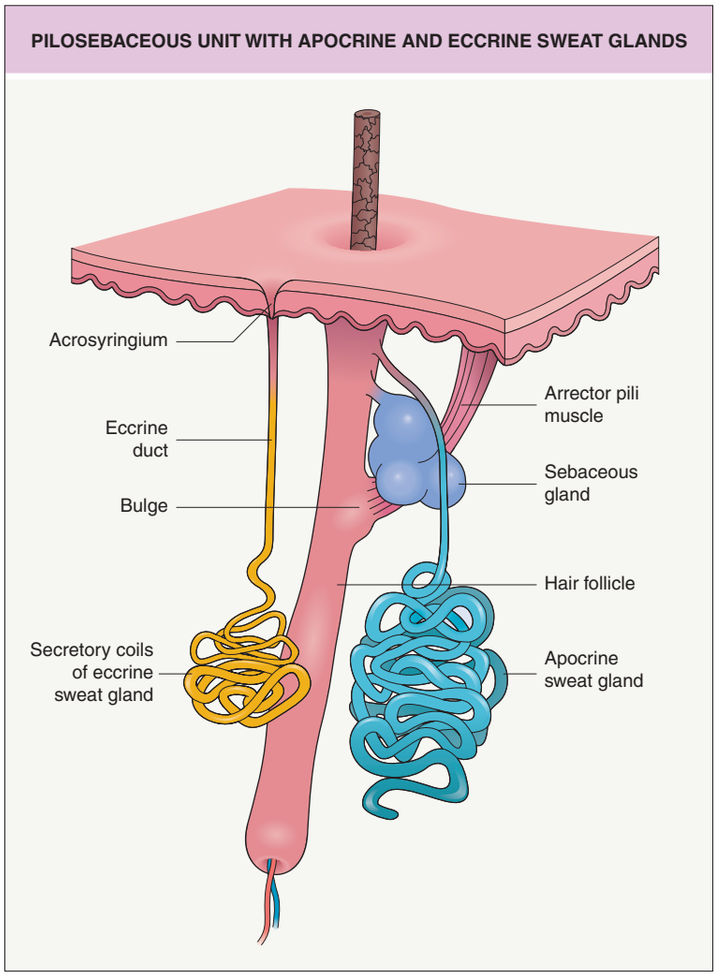

Fig. 35.1 Pilosebaceous unit with apocrine and eccrine sweat glands. Pilosebaceous unit with an associated apocrine sweat gland and a nearby eccrine sweat gland.

INNERVATION AND RECEPTOR PROFILES OF SWEAT GLANDS		
	Eccrine	**Apocrine**
Nerve fibers near gland	+	±
Cholinergic muscarinic (M_3) receptors	++	±
α_1-adrenergic receptors	+	–
β_2- > β_3-adrenergic receptors	+	+
Purinergic receptors	+	+

Table 35.2 Innervation and receptor profiles of sweat glands.

3 liters in 1 hour. Sweat is formed in two steps[9]: (1) release of nearly isotonic primary sweat by the secretory coil; and (2) partial reabsorption of NaCl by duct cells, resulting in the delivery of a hypotonic fluid to the skin surface. The final concentration of NaCl may be higher when sweat is produced at a more rapid rate. The neuropeptide galanin and its receptors regulate transepithelial ion transport and fluid secretion from human eccrine sweat glands[10].

Sweat secretion provides mechanisms for thermoregulation via evaporative heat loss, maintenance of electrolyte balance, and keeping the stratum corneum moist to ensure fine tactile skills and pliability of the palms and soles. The excretory function of the sweat gland can be instrumental in the delivery of systemically administered drugs to the stratum corneum (e.g., fluconazole, griseofulvin), and it provides an explanation for cutaneous side effects of certain chemotherapeutic drugs. Botulinum toxin can be used to treat eccrine hyperhidrosis. After dermal injection, botulinum toxin taken up by the nerve terminal interferes with proteins required to release acetylcholine at the neuroglandular junction (see Fig. 159.1).

Fig. 35.2 Toxic erythema of chemotherapy (palmar erythrodysesthesia). Erythema and blister formation, most notably on the distal portion of the first and second digits and the digital creases (arrows).

Pathophysiology

Disorders affecting eccrine function involve modifications of sweat quantity or quality; these can be localized (e.g. distribution of the auriculotemporal nerve in Frey syndrome [see Ch. 39]) or generalized (e.g. hypohidrotic ectodermal dysplasia). The sweat glands are also affected in cystic fibrosis (CF). Individuals with CF lose excessive amounts of salt (NaCl) when they sweat, and the most common screening test for CF measures the amount of Cl^- in the sweat.

Hyper- and Hypohidrosis

Increased activity of eccrine glands is typically due to enhanced cutaneous sympathetic outflow in response to mental and thermal stimuli. The secretory clear cells of eccrine glands represent the major source of sweat in hyperhidrosis[4]. In the emotional form of hyperhidrosis, excessive sweating primarily affects the palms, soles, and axillae[11]. Stimulation of eccrine sweat glands may also occur in association with menopause-related hypoestrogenemia and a number of neurologic, infectious, neoplastic (e.g. lymphomas), and endocrine diseases (see Ch. 39).

Increased sweating can lead to overhydration and even maceration of the skin. This may be accompanied by secondary bacterial and fungal infections (see Chs. 74 & 77). Proteolytic activity by resident and transient skin microbiota can lead to odor-producing substances (e.g. ammonia, short-chain fatty acids); this is referred to as eccrine bromhidrosis.

Hypohidrosis or anhidrosis may be congenital, e.g. due to a reduced number of eccrine glands in patients with hypohidrotic ectodermal dysplasia. It can also be acquired, e.g. due to poral occlusion in patients with ichthyosis or administration of medications with anticholinergic effects.

Drug-Related Eccrine Disorders

Drugs known to be secreted into eccrine sweat include chemotherapeutic agents (e.g. cyclophosphamide, cytarabine), antibiotics (e.g. ciprofloxacin, β-lactams) and antifungals. In patients receiving chemotherapy, excretion of toxic components into eccrine sweat is thought to play a role in the production of neutrophilic eccrine hidradenitis and other forms of toxic erythema of chemotherapy (Fig. 35.2). Toxic insult to the eccrine ductal cells from chemotherapy leads to the histologic finding of eccrine squamous syringometaplasia (see Ch. 21).

Disorders of Sweat Retention

Occlusion of the eccrine ducts can result from a parakeratotic plug of PAS-positive material, which then leads to sweat retention. Miliaria may be triggered by a high environmental or body temperature, excessive sweating (especially under occlusive clothing or dressings), and an increased density of resident bacteria (e.g. *Staphylococcus epidermidis*). Ductal plugs within the stratum corneum lead to superficial miliaria (miliaria crystallina), while intraepidermal and dermal duct occlusion induce miliaria rubra and profunda, respectively (see Ch. 39).

APOCRINE SWEAT GLANDS

Structure

Apocrine sweat glands are confined to certain anatomic sites (axillae, anogenital region, periumbilical area, areolae, nipples, vermilion border of the lip) and are larger than eccrine glands. Modified forms of apocrine glands are found in the external auditory canals (ceruminous glands) and on the eyelid margins (glands of Moll). Apocrine glands consist of a secretory portion located in the deep dermis and subcutaneous fat, and a stretched duct that opens into the upper portion of the follicular canal, i.e., the apocrine acrosyringium (see Fig. 35.1). The secretory unit is a convoluted tube with a single layer of epithelial cells (typically columnar) surrounded by myoepithelial cells. The duct consists of a double layer of cuboidal cells, as well as myoepithelial cells that support the movement of secretions to the skin surface.

Differentiating the *secretory* portion of apocrine glands from those of eccrine glands is relatively easy based simply upon morphologic (histopathologic) features, e.g. large lumina and "decapitation" secretion. However, the *excretory* ducts of the two types of sweat glands cannot be distinguished by either histopathologic features or immunohistochemistry; the only difference is that eccrine ducts end "free" in the epidermis, whereas apocrine ducts open into the upper portion of the follicular canal.

Apocrine gland secretion increases in response to local or systemic administration of catecholamines and cholinergic agonists, but the mechanisms controlling physiologic secretion are poorly understood. In a study of normal axillary skin, secretory coils of apocrine glands were found to have β-adrenergic and purinergic, but not cholinergic, receptors (see Table 35.2)[12]. Nerve fibers were found near eccrine glands but not apocrine glands, suggesting that catecholamines stimulate the latter through humoral mechanisms[12].

Development

Embryologically, apocrine sweat glands derive from the primary epithelial germ layer, which also gives rise to the sebaceous glands and hair follicles. In the embryo, apocrine sweat glands are present throughout the entire skin, but most of them subsequently disappear, resulting in the characteristic distribution found in adults. Enlargement of the glands occurs with the onset of puberty due to hormonal stimulation, primarily by androgens.

Function

Apocrine glands continuously secrete small quantities of an oily fluid. This sweat is sterile, odorless, and viscous, with a pH between 5.0 and 6.5. It is rich in precursors of odoriferous substances such as cholesterol, triglycerides, fatty acids, cholesterol esters, and squalene. It also contains androgens, carbohydrates, ammonia, and ferric iron. *Apocrine* or "decapitation" secretion refers to the "pinching off" and release of the luminal portion of secretory cells; apocrine glands also employ *merocrine* (exocytosis of vesicles) and *holocrine* (rupture of the plasma membrane) secretion.

In animals, apocrine glands are the source of pheromones, which act as chemical signals that instigate behavioral responses (e.g. sexual attraction) or mark territorial boundaries. In humans, apocrine glands do not have a clear function but may play a role in olfactory communication.

Pathophysiology

Although apocrine sweat is initially sterile and odorless, bacteria on the skin surface modify and degrade the secreted substances, resulting in rancid (*Corynebacterium* spp.) or sweaty (*Micrococcus* spp.) body odor, i.e. bromhidrosis. Insufficient body and textile hygiene will worsen the condition. Of note, some androgenic steroids have an odor similar to natural axillary odor.

Apocrine chromhidrosis refers to the secretion of pigmented (yellow, green, or black) sweat. It is a reflection of the rich lipofuscin content of apocrine sweat. Pseudo- or extrinsic apocrine chromhidrosis results from staining of the sweat by chromogenic bacteria, especially *Corynebacterium* spp., or colored garments. Hormonal factors are thought to play a role in the occlusion of apocrine ducts by a keratinous plug in Fox–Fordyce disease (see Ch. 39).

SEBACEOUS GLANDS

Key features

- Sebaceous glands produce sebum via holocrine secretion and have multiple biological functions, including hormonal (e.g. androgen synthesis) and immune modulation
- Except for ectopic or free sebaceous glands of the vermilion lips, orogenital mucosa, areolae, and eyelids, sebaceous glands are associated with hair follicles
- Sebum consists of free fatty acids, wax and sterol esters, triglycerides, and squalene
- Sebum production is a sensitive indicator of androgenic activity; it increases during puberty and decreases in later adulthood, particularly in postmenopausal women
- Sebaceous follicles are rich in microorganisms such as *Malassezia* spp., *Staphylococcus epidermidis*, and *Cutibacterium* spp.

Introduction

Except for the free sebaceous glands found on the vermilion lips and oral mucosa (Fordyce spots or granules), eyelids (meibomian glands), areolae (Montgomery tubercles), and labia minora and prepuce (Tyson glands), sebaceous glands are associated with hair follicles (Fig. 35.3). Sebaceous glands produce sebum, which is released into the infundibular portion of the hair follicle. Sebum production increases at the time of puberty and is a critical factor in the pathogenesis of acne vulgaris[13–15]. Sebaceous

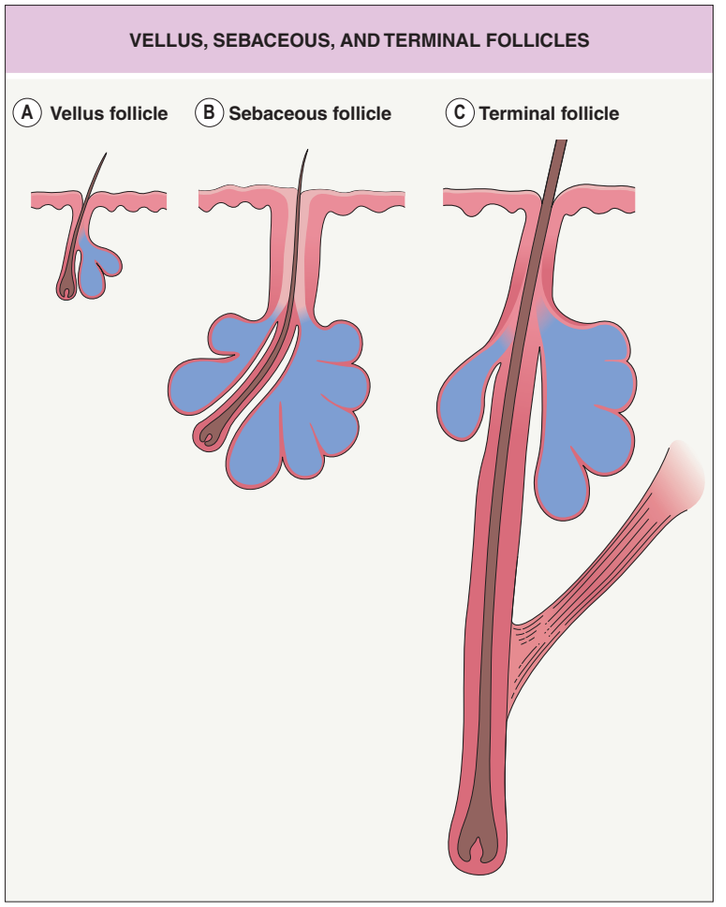

Fig. 35.3 Vellus, sebaceous, and terminal follicles. Three different types of pilosebaceous units. **A** Vellus follicle with a small sebaceous gland and short thin hair. **B** Sebaceous follicle with a large multilobular sebaceous gland and mid-sized hair. **C** Terminal follicle with a fairly large sebaceous gland and thicker hair. *Adapted from Plewig G, Melnik B, Chen W. Plewig and Kligman´s Acne and Rosacea, 4th ed. Berlin: Springer, 2019.*

glands also play an important role in cutaneous endocrine function, including the hypothalamic–pituitary–adrenal-like axis of the skin and androgen metabolism. As outlined in Table 35.3 and Fig. 35.4, the pathogenesis of acne involves interactions of the sebaceous gland with neuropeptides, androgens, and the innate immune system, including the production of antimicrobial peptides.

Structure

The distribution of sebaceous glands within the skin is variable. However, they are particularly well developed on the face, scalp, upper back, and chest. There are three different types of pilosebaceous units: vellus, sebaceous, and terminal (see Fig. 35.3).

A sebaceous follicle consists of four parts: the keratinized follicular infundibulum, the hair, the cauliflower-like convoluted sebaceous gland, and the sebaceous duct which connects the gland with the infundibulum (see Fig. 35.1). The infundibulum is divided into two parts. The distal portion (*acroinfundibulum*) has an epidermal keratinization pattern with a granular layer and corneocytes (squames) shedding into the lumen. In contrast, the lower part (*infrainfundibulum*) has a tricholemmal keratinization pattern with no granular layer.

The resident microbiota, i.e. normal flora, of sebaceous follicles is complex and includes both bacteria (e.g. *S. epidermidis*, *Cutibacterium* spp. such as *C. acnes*) and fungi (e.g. *Malassezia* spp.) (Fig. 35.5). These follicles also harbor *Demodex* mites, which increase in number in older adults and are rarely seen in prepubertal children.

Development

Sebaceous glands are derived from the epidermis as buds from developing hair follicle root sheaths and grow downward into the dermis. Sebaceous glands are present at birth, and sebum production is relatively high at this time. It soon declines and remains low until puberty, when it again increases. Androgens, in particular 5α-dihydrotestosterone (DHT), appear to be the major factor that controls gland development and sebum production. The level of sebum production at the end of puberty remains constant until mid-adulthood. Sebum production declines in women after menopause, and in men during the sixth to seventh decades of life.

Although stem cells in the hair follicle bulge can regenerate sebaceous glands following injury, under homeostatic conditions bulge cells do not appear to contribute to the formation of sebaceous glands[16].

ROLES OF THE SEBACEOUS GLAND IN PATHOGENESIS OF ACNE VULGARIS AND ROSACEA

Sebaceous gland component	Actions in sebaceous glands	Observations in sebaceous glands of patients with AV and R
A – Hypothalamic–pituitary–adrenal-like and other hormonal axes		
Corticotropin-releasing hormone (CRH)* and CRH receptors (CRH-Rs)	↑ lipid and androgen synthesis ↑ production of IL-6, IL-8 (CRH-R2)	↑ levels of CRH and (in sebaceous ducts) CRH-R1 in **AV**
α-Melanocyte stimulating hormone (MSH)* and melanocortin-1 & -5 receptors (MC1-R, MC5-R†)	↑ sebocyte differentiation and lipid synthesis (MC5-R)	↑ levels of MC1-R in **AV**
Growth hormone and insulin-like growth factor-1 (IGF-1) receptors	↑ sebocyte proliferation ↑ lipid and androgen synthesis	Association of high glycemic-load diets and intake of insulinotropic dairy products with **AV**
B – Other neuropeptides		
Substance P	↑ sebocyte proliferation/differentiation ↑ production of inflammatory cytokines	↑ substance P-containing nerves in **AV**
C – Androgens		
Testosterone* and dihydrotestosterone (DHT)*	↑ sebocyte proliferation/differentiation and lipid synthesis (especially DHT) May ↑ infundibular keratinization	↑ conversion of testosterone to DHT in **AV** Association of hyperandrogenic disorders with **AV**‡
D – Sebum components and derivatives		
Monounsaturated fatty acids (MUFAs), lipoperoxides (LPs), other proinflammatory lipids (e.g. generated via 5-lipoxygenase), linoleic acid (LA)	↑ infundibular keratinization (MUFAs, LPs, *deficient* LA) ↑ cytokine production, chemotaxis, and PPAR activation (MUFAs, LPs)	↑ overall sebum production, MUFAs, and LPs in **AV** ↑ 5-lipoxygenase in **AV** ↓ linoleic acid in **AV**
E – Innate immune system		
Toll-like receptors (TLRs, especially TLR2)	Upon stimulation (e.g. by *C. acnes*), ↑ production of IL-1, IL-8, IL-12, TNF (TLR2)	↑ expression of TLR2 and TLR4 in **AV** Possible ↑ expression of TLR2 in **R**
Defensins, cathelicidins, MUFAs (e.g. sapienic acid)	Antimicrobial properties ↑ cytokine production and chemotaxis	↑ levels of LL-37 via proteolysis of cathelicidin by kallikrein 5 in **R**, leading to proinflammatory and vasoactive effects
F – Organisms		
Cutibacterium (formerly *Propionibacterium*) *acnes*¶	↑ production of antimicrobial peptides & inflammatory cytokines/chemokines, especially IL-1β and IL-17, via stimulation of TLR2 and the NLRP3 inflammasome ↑ free fatty acids (e.g. via lipase activity) May ↑ infundibular keratinization	↑ *C. acnes* in **AV**
Demodex folliculorum	May stimulate or carry bacteria (e.g. *Bacillus oleronius*) that stimulate innate and adaptive immune reactions	↑ density of *D. folliculorum* and reactivity to *B. oleronius* in R

*Can be produced locally by the sebaceous gland as well as remotely.
†Marker of sebocyte differentiation.
‡Most AV patients have normal levels of circulating androgens.
¶Different phylogenetic clusters of *C. acnes* vary in their ability to induce immune responses.

Table 35.3 Roles of the sebaceous gland in pathogenesis of acne vulgaris (AV) and rosacea (R). IL, interleukin; PPAR, peroxisome proliferator-activated receptor; TNF, tumor necrosis factor.

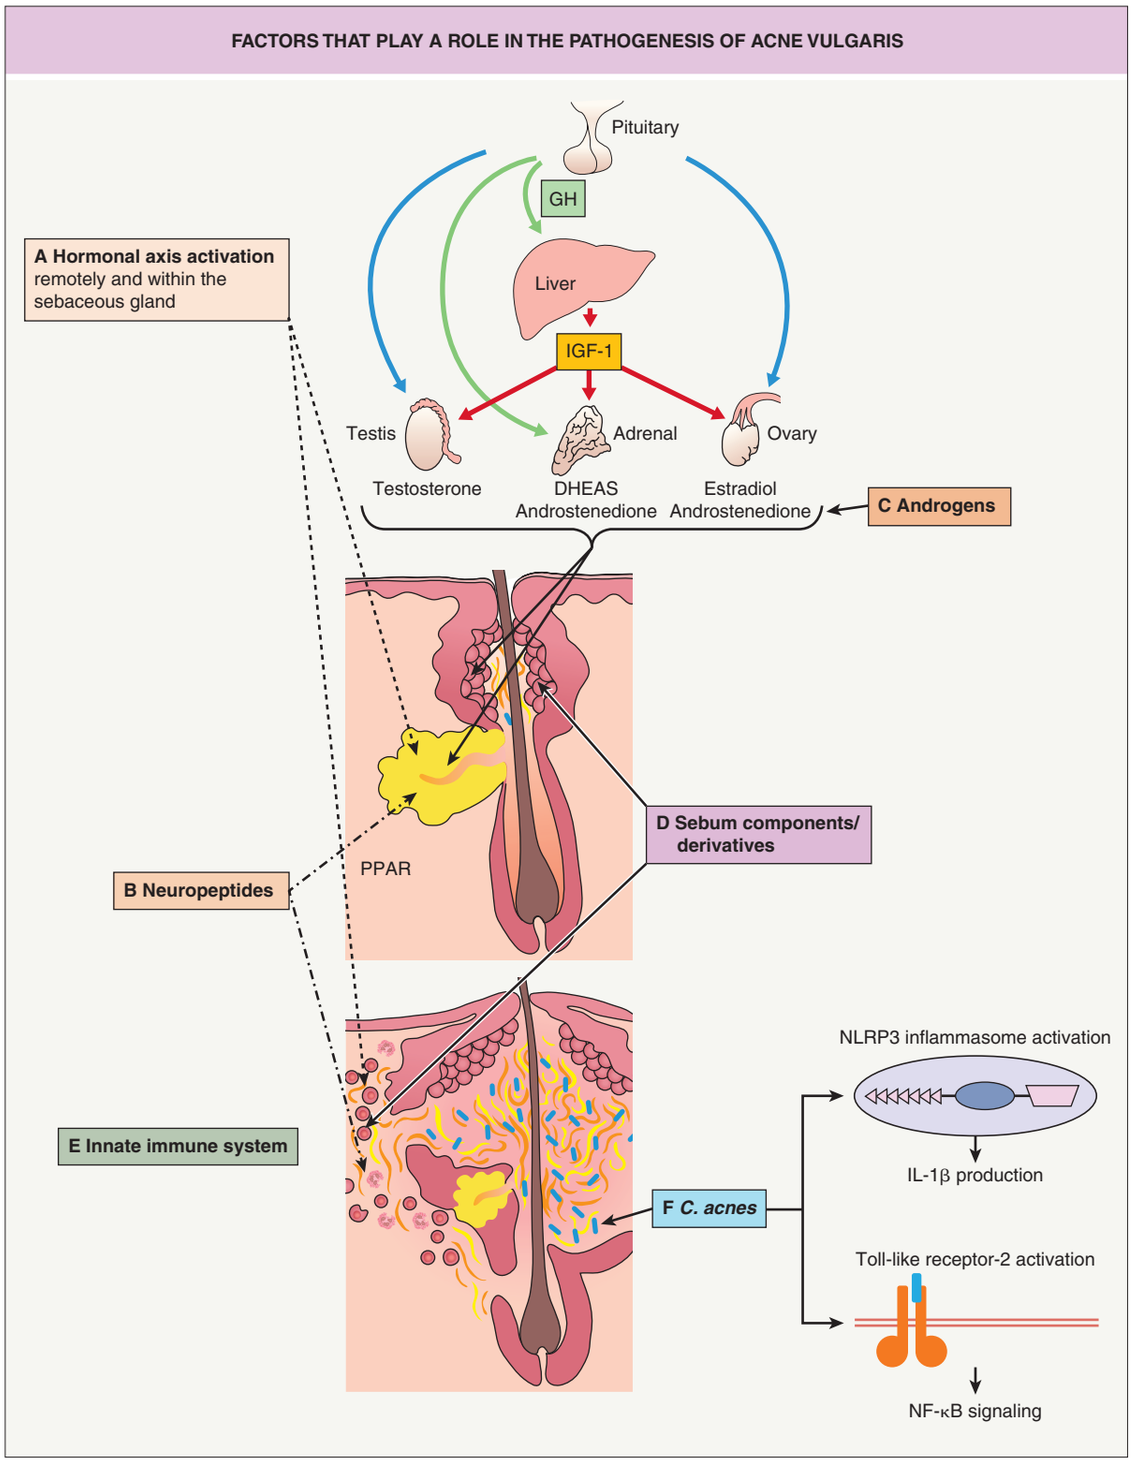

Fig. 35.4 Factors that play a role in the pathogenesis of acne vulgaris. **A–F** correspond to the sections of Table 35.3. DHEAS, dehydroepiandrosterone sulfate; GH, growth hormone; IGF-1, insulin-like growth factor-1; IL, interleukin; NLRP3, NOD-like receptor pyrin domain-containing protein 3; PPAR, peroxisome proliferator-activated receptor.

Immortalized cells derived from the human sebaceous gland can differentiate into both sebocytes and interfollicular epidermal cells, suggesting a bipotential stem cell function[17]. In cultured human sebocytes and an *in vivo* mouse model, overexpression of c-Myc stimulated *sebaceous* differentiation, whereas overexpression of β-catenin induced *epidermal* differentiation[17]. Expression of the stem cell marker keratin 15 has been observed in human basal sebocytes[16]. Blimp-1 (*B-l*ymphocyte-*i*nduced *m*aturation *p*rotein-1) was found to be a marker for sebocyte progenitor cells in mice, but in humans it is expressed by terminally differentiating cells of the sebaceous gland, hair follicle, and interfollicular epidermis[17].

Function

Sebum is a light yellow viscous fluid. It is composed of triglycerides, free fatty acids, squalene, wax and sterol esters, and free sterols. The admixture of ceramides, mostly derived from epidermal lipids, occurs in the acroinfundibulum before the sebum mixture reaches the skin surface. Secretion of sebum is holocrine, that is, the sebocytes disintegrate and thereby release their sebum as they migrate towards the central gland and sebaceous duct. Sebocyte turnover time is ~14 days, and the flow of sebum is relatively continuous. The amount of sebum produced varies among individuals and ethnic groups, but the average rate in adults is ~1 mg/10 cm^2 every 3 hours[18].

Sebaceous gland function is influenced by genetic factors and levels of circulating hormones. The cells within sebaceous glands contain androgen receptors that bind DHT and are then translocated to the nucleus[15,19]. They also express functional receptors for neuropeptides such as corticotropin-releasing hormone (CRH), melanocortins, and substance P[13,20]. These receptors contribute to proliferation and differentiation of cells in the sebaceous gland (sebocytes) and modulate

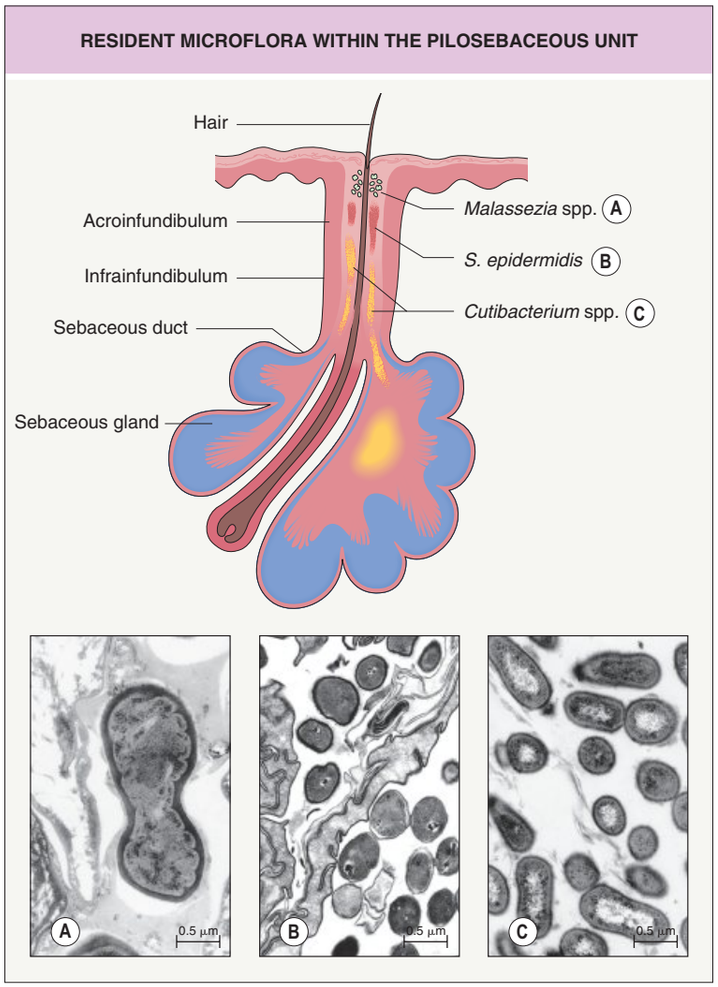

Fig. 35.5 Resident microflora within the pilosebaceous unit. Localization of resident microflora within the pilosebaceous unit and electron microscopic view of organisms: **A** *Malassezia* spp.; **B** *Staphylococcus epidermidis*; **C** *Cutibacterium* spp., including *C. acnes*, *C. granulosum*, and least often *C. parvum*.

their production of lipids, androgens, and cytokines in response to stimuli such as emotional stress (see Table 35.3). Sebaceous glands produce the majority of skin surface lipids, which not only promote barrier function but also possess both pro- and anti-inflammatory properties[15].

Pathophysiology

Sebum production of less than 0.5 mg/10 cm^2 every 3 hours is associated with *sebostasis* or dry skin, while 1.5–4.0 mg/10 cm^2 every 3 hours is considered excessive and is referred to as *seborrhea*. The presence of well-developed sebaceous follicles on the face and upper portions of the chest and back corresponds to the distribution of acne vulgaris. Clinically, these areas tend to be oilier than the rest of the body. In general, acne patients have larger sebaceous glands and produce more sebum than individuals without acne.

Growth of sebaceous glands and increased sebum production are both induced by androgens, particularly DHT. In men, DHT is mainly derived from testosterone, while in women, androstenedione is the main precursor. The conversion of testosterone to DHT is 30 times higher in skin affected by acne than in normal skin. Eunuchs, who lack testicular function, do not develop acne. However, increased sebum production alone is insufficient to cause acne vulgaris, as evidenced by the marked seborrhea but lack of acne in patients with Parkinson disease.

Sebaceous glands play several major roles in the pathogenesis of acne vulgaris and may also contribute to the pathogenesis of rosacea (see Table 35.3, Fig. 35.4, and Fig. 37.1)[19,21]. Sebum in sebaceous glands and ducts is sterile and contains no free fatty acids, but the microenvironment of the infundibulum favors the growth of *C. acnes* and *S. epidermidis*[22]. In patients with acne vulgaris, the resident microorganisms, especially *C. acnes*, are quantitatively increased in sebaceous follicles. Their lipases split di- and triglycerides, producing free fatty acids that alter the pattern of keratinization within the infundibulum. Abnormal keratinization is one of the first pathogenic steps in acne vulgaris, with increased proliferation and retention of corneocytes in the infundibulum resulting in a microcomedo. In addition, free fatty acids are chemotactic and attract neutrophils. Modulating the transcriptome of the skin microbiota can also promote acne, e.g. high-dose vitamin B_{12} supplementation was found to increase the production of inflammation-inducing porphyrins by *C. acnes*.

The infrainfundibulum of acne patients responds to a variety of physiologic and exogenous stimuli more readily than that in individuals without acne. For example, acne patients are more susceptible to the comedogenic effects of agents such as halogenated cyclic hydrocarbons, tar products, and some cosmetics[18]. Follicular acneiform eruptions also develop in patients receiving inhibitors of the *e*pidermal growth *f*actor *r*eceptor (EGFR), including antibodies that block interaction of EGF with its receptor (e.g. cetuximab) as well as inhibitors of EGFR tyrosine kinase activity (e.g. gefitinib; see Ch. 21). EGFR is highly expressed in keratinocytes and in cells of eccrine and apocrine glands. Inhibition of the EGFR disturbs the normal differentiation and morphogenesis of hair follicles, with induction of excessive follicular hyperkeratosis, follicular plugging, and growth of microorganisms in the dilated infundibula[23].

METHODS FOR EVALUATING SWEAT PRODUCTION
• Visualization of sweat by the starch–iodine reaction (see Figs. 39.3, 39.4B, 39.6 & 39.7) or quinizarin method • Measurement of electric potential and resistance of the skin • Measurement of skin temperature (e.g. infrared thermography) • Gravimetry (e.g. weighing filter paper before and after application to the skin) • Measurement of evaporative water loss from the skin

eTable 35.1 Methods for evaluating sweat production.

36 Acne Vulgaris

Andrea L. Zaenglein, Amanda M. Nelson and Leah E.B. Lalor

Synonym: ■ Acne

Key features

- A multifactorial disorder of the pilosebaceous unit
- Significant psychological and ecownomic impact
- Clinically characterized by comedones, papules, pustules, and nodules
- Potential sequelae include persistent erythema and postinflammatory hyperpigmentation as well as scarring

INTRODUCTION

Acne vulgaris is a multifactorial disorder of the pilosebaceous unit. The clinical picture can vary significantly, from mild comedonal acne to fulminant systemic disease. Although all age groups may be affected by its many variants, the peak incidence is during adolescence. Acne has an undeniable psychosocial impact, and affected individuals have an increased likelihood of self-consciousness, social isolation, anxiety disorders, depression, and even suicidal ideation[1,2]. Insights into the pathogenesis of acne have aided significantly in further defining the subtypes of acne and establishing effective treatment regimens.

HISTORY

In the sixth century CE, the term "acne" was first used by the Emperor Justinian's physician, Aetius Amidenus. It was later translated from Greek into Latin, and through these translations confusion arose regarding its original meaning. The debate continues as to whether its origin is from the Greek *acme*, meaning peak, or whether acne was actually the original term. Its use became obsolete until the 1800s, when "acne" regained a place in medical dictionaries. In 1842, Erasmus Wilson separated acne simplex (acne vulgaris) from acne rosacea[3].

EPIDEMIOLOGY

Acne vulgaris affects ~40–50 million individuals each year in the US alone, leading to an estimated annual cost in the US of at least $2.5 billion. Globally, acne accounts for ~0.3% of the total and ~15% of the dermatologic disease burden[4]. With a peak incidence during adolescence, acne affects ~85% of young people between 12 and 24 years of age and is therefore a physiologic occurrence in this group. With the general trend over the past few decades for an earlier onset of puberty, preadolescent acne affecting children 7 to 11 years of age has also become more common[5,6]. While typically thought of as a disease of youth, acne often continues to be problematic well into adulthood. In a survey-based study in the US, 35% of women and 20% of men reported having acne in their 30s, while 26% of women and 12% of men were still affected in their 40s[7]. White boys and men have a tendency to have more severe nodulocystic disease than other groups.

Individuals at increased risk for the development of acne include those with an XYY karyotype or endocrine disorders such as polycystic ovarian syndrome, hyperandrogenism, hypercortisolism, and precocious puberty. Patients with these conditions tend to have more severe acne that is less responsive to standard therapy.

Genetic Factors

The precise role of genetic predisposition in the multifactorial pathogenesis of acne remains to be determined. The number, size, and activity of sebaceous glands is inherited. In addition, the concordance rate for the prevalence and severity of acne among identical twins is extremely high. It is widely believed that the tendency to have substantial acne (including the nodulocystic variant) runs in families, and an association between moderate-to-severe acne and a family history of acne has been observed in several studies[8]. Genes found to have a possible link to acne via genome-wide association studies (GWAS) and other methods include those encoding components of the tumor transforming growth factor-β (TGF-β) pathway, other inflammatory mediators, and regulators of androgen metabolism[6,9,10].

Dietary Factors

The relationship between diet and acne remains controversial. Several observational studies in different ethnic groups have found that the intake of milk, especially skim milk, is positively associated with acne prevalence and severity[11,12]. Exacerbation of acne with the use of whey protein supplements for bodybuilding has also been reported[13]. Vitamin B_{12} supplementation can potentially trigger the development of acne or an acneiform eruption by altering the transcriptome of skin microbiota, leading to increased production of proinflammatory porphyrins by *Cutibacterium acnes*.

PATHOGENESIS OF ACNE

The development of acne involves the complex interplay of four main factors: (1) follicular hyperkeratinization; (2) hormonal influences on sebum production and composition; (3) inflammation; and (4) *C. acnes* residing in the sebaceous follicle (Fig. 36.1). Appreciating the anatomy and physiology of the pilosebaceous unit is essential to understanding the pathogenesis of acne and designing effective treatment regimens. Genetics and exogenous factors such as diet, medications, and environmental exposures can also play a role in acne pathogenesis. The structure and function of sebaceous glands are reviewed in detail in Chapter 35, with summaries of their roles in acne in Table 35.3 and Fig. 35.4.

Follicular Hyperkeratinization

The *microcomedo* is thought to be the precursor of all clinically apparent acne lesions. It forms in the upper portion of the follicle within the lower portion of the infundibulum, the infrainfundibulum. Corneocytes, which are normally shed into the hair follicle lumen and extruded, accumulate due to increases in both follicular keratinocyte proliferation and corneocyte cohesiveness, leading to the development of a hyperkeratotic plug that acts as a bottleneck. In acne patients, non-invasive high-resolution imaging of facial skin has confirmed that follicular dilation and accumulation of a keratotic plug precede the appearance of an inflammatory papule[14]. The exact inciting event for microcomedo formation is unknown, but data support a putative role for interleukin-1α (IL-1α) and increases in skin pH[15].

Hormonal Influences on Sebum Production and Composition

The sebaceous gland expresses multiple receptors including androgen, estrogen, progesterone, retinoid, and peroxisome proliferator-activated receptors (PPARs; see Table 35.3)[16–18]. Sebum production is controlled primarily by androgens, with additional influences from other hormones and neuropeptides. Androgens are produced both outside the pilosebaceous unit, mainly by the gonads and adrenal glands, and locally within the sebaceous gland via the action of androgen-metabolizing

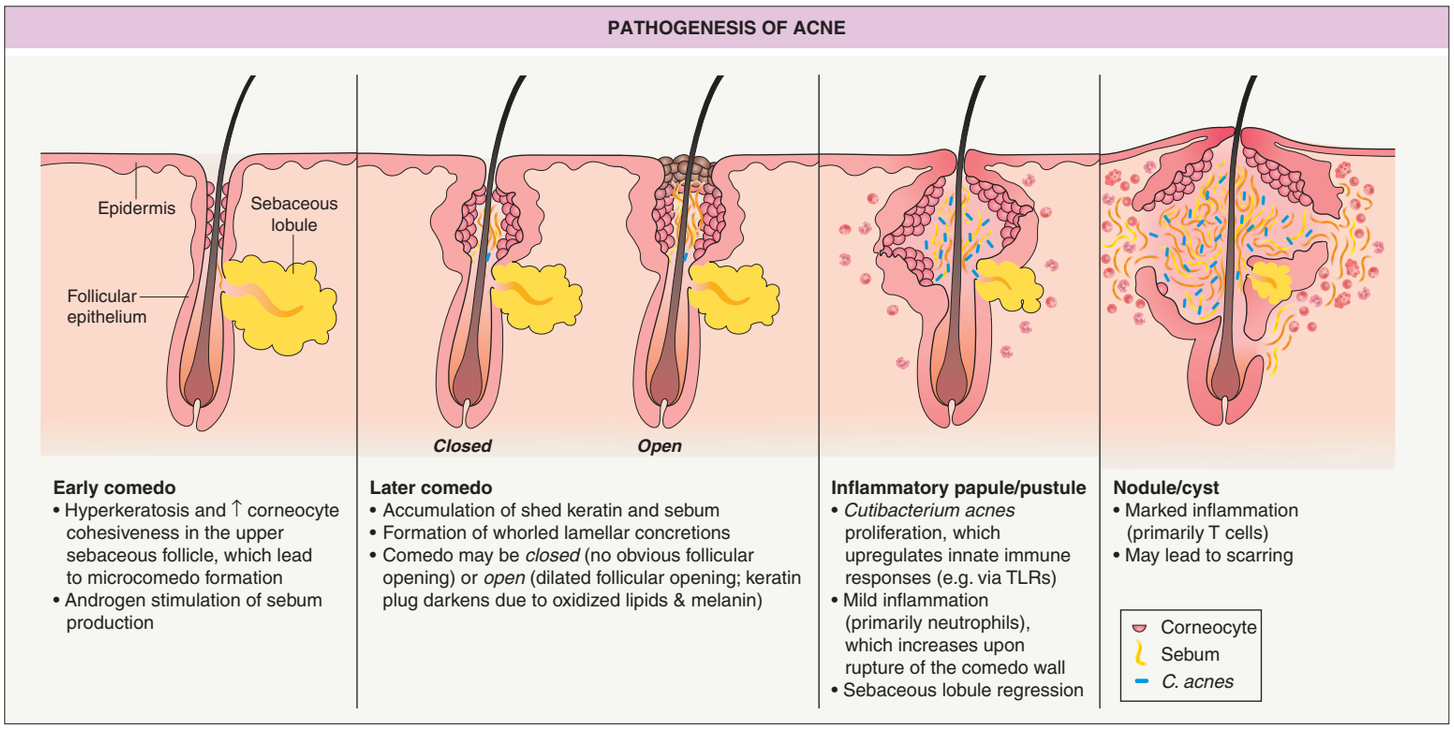

Fig. 36.1 Pathogenesis of acne.

enzymes such as 3β-hydroxysteroid dehydrogenase (HSD), 17β-HSD and 5α-reductase (see Fig. 70.16). Androgen receptors, found in the cells of the basal layer of the sebaceous gland and the outer root sheath of the hair follicle, are responsive to testosterone and 5α-dihydrotestosterone (DHT), the most potent androgens. DHT has a 5- to 10-fold greater affinity than testosterone for the androgen receptor and is the principal androgen mediating sebum production.

The impact of androgens on sebaceous gland activity begins during the neonatal period. From birth until approximately 6–12 months of age, infant boys have elevated levels of luteinizing hormone (LH), which stimulates testicular production of testosterone. In addition, both male and female infants exhibit increased levels of dehydroepiandrosterone (DHEA) and DHEA sulfate (DHEAS) secondary to a large, androgen-producing "fetal zone" in the adrenal gland that involutes during the first year of life. Sebaceous gland activity in infants is not the result of persistent maternal hormonal stimulation, as was previously hypothesized. Both testicular and adrenal androgen production decrease substantially by 1 year of age and remain at a stable nadir until adrenarche.

With the onset of adrenarche, typically at 7–8 years of age, circulating levels of DHEAS begin to rise due to its production by the adrenal gland. This hormone serves as a precursor for the synthesis of more potent androgens within the sebaceous gland (see Fig. 70.16). The rise in DHEAS serum levels in prepubescent children is associated with increased sebum production and often the initial development of comedonal acne[19]. Although the overall composition of sebum is similar in adolescents irrespective of the presence or absence of acne, the sebum in those with acne tends to have higher levels of squalene monounsaturated fatty acids and less linoleic acid. In infants with facial acne, the skin surface lipid composition has also been shown to differ from those without acne[20].

The physiologic role of estrogens and progesterone in modulating sebum production is not fully understood. Estrogens, when administered systemically in sufficient amounts, decrease sebum production[21], although the dose needed is greater than the dose required to suppress ovulation and increases the risk of thromboembolic events. However, acne often responds to treatment with lower-dose oral contraceptives containing 20–50 mcg of ethinyl estradiol or its esters because suppression of ovulation itself inhibits ovarian androgen production. Postulated mechanisms for estrogen-mediated downregulation of sebogenesis include direct opposition of androgens within the sebaceous gland, a negative feedback loop that decreases androgen production via inhibition of pituitary gonadotropin release, and regulation of genes that affect sebaceous gland activity. Although the role of progesterone in human sebum production remains to be fully determined, it can increase sebum production in both male and female rats, likely via modulation of the androgen receptor[22].

Inflammation in Acne

Although tremendous progress has been made in our understanding of acne as an inflammatory process, several questions remain regarding inflammation during acne lesion development. It is clear that when a follicle involved with acne ruptures, it exudes keratin, sebum, *C. acnes*, and cellular debris into the surrounding dermis, thereby intensifying inflammation. However, inflammation is also seen early in acne lesion formation. For example, in acne-prone sites, the number of $CD4^+$ T cells and levels of IL-1 are increased perifollicularly prior to hyperkeratinization[23]. In addition, insulin-like growth factor-1 has been found to increase the expression of inflammatory markers and sebum production in cultured sebocytes. TREM2 macrophages induced by lipids such as squalene have been shown to promote inflammation in acne lesions and block oxidative killing of *C. acnes*[23a].

The type of inflammatory response determines the clinical lesion observed. If neutrophils predominate (typical of early lesions), suppuration occurs and a pustule is formed. Neutrophils also promote the inflammatory response by releasing lysosomal enzymes and generating reactive oxygen species; levels of the latter in the skin and plasma may correlate with acne severity[24]. An influx of lymphocytes (predominately T helper cells), foreign body-type giant cells, and neutrophils results in inflamed papules, nodules, and cysts. The type of inflammatory response also plays a role in the development of scarring. Early, nonspecific inflammation results in less scarring than does a delayed, specific inflammatory response[25].

Cutibacterium acnes colonization and activities

C. acnes (previously known as *Propionibacterium acnes*) is a Gram-positive, anaerobic/microaerophilic rod that is found on the skin surface and within the sebaceous follicle[26], often together with smaller numbers of *C. granulosum*. In adults, *C. acnes* is the predominant organism in the microbiome of facial and other sebaceous skin. *C. acnes* produces porphyrins (primarily coproporphyrin III) that fluoresce with Wood's lamp illumination.

C. acnes is considered a commensal organism of the skin rather than a pathogen *per se*[27]. Although studies have documented increased levels

of *C. acnes* on the facial skin of acne patients, the *C. acnes* density does not correlate with clinical severity[28]. In a comparison of the microbiome of facial skin in adults with and without acne, *C. acnes* ribotypes 4 and 5 were more frequently found in acne patients, suggesting that these strains are either more capable of inducing acne or better suited to survive in an acne environment[29]. In addition, acne-associated *C. acnes* phylotypes (IA-2, IB-1, IC) stimulated peripheral blood monocytes to produce the proinflammatory cytokines IL-17 and IFN-γ, whereas phylotypes found in healthy skin (II [RT6], III) preferentially induced monocytes to secrete the anti-inflammatory cytokine IL-10[30]. However, another study found that while isolated peripheral blood monocytes from patients with acne exhibited a more robust release of inflammatory cytokines in response to *C. acnes* stimulation than did monocytes from individuals without acne, no differences were observed when *C. acnes* strains isolated from acne lesions were compared to strains from the normal skin of unaffected adults[31].

The pathogenicity of *C. acnes* includes the direct release of lipases, chemotactic factors, and enzymes that contribute to comedo rupture, as well as stimulation of inflammatory cells and keratinocytes to produce proinflammatory mediators and reactive oxygen species. Interactions between the skin's *innate* immune system and *C. acnes* play an important role in acne pathogenesis. One mechanism is via Toll-like receptors (TLRs), a class of transmembrane receptors that mediates the recognition of microbial pathogens by immune cells (monocytes, macrophages, and neutrophils) as well as by keratinocytes (see Ch. 4). TLR2, which recognizes lipoproteins and peptidoglycans as well as CAMP factor 1 produced by inflammatory strains of *C. acnes*[32], is found on the surface of macrophages surrounding acne follicles[33]. *C. acnes* has also been shown to increase expression of TLR2 and TLR4 by keratinocytes. Through activation of the TLR2 pathway, *C. acnes* stimulates the release of proinflammatory mediators such as IL-1α, IL-8, IL-12, tumor necrosis factor (TNF), and matrix metalloproteinases[33–35]. IL-8 leads to neutrophil recruitment, the release of lysosomal enzymes, and subsequent disruption of the follicular epithelium, while IL-12 promotes Th1 responses (see Ch. 4).

C. acnes has been shown to activate NLRP3 inflammasomes in neutrophils and monocytes, resulting in the release of proinflammatory IL-1β[36]. As noted above, *C. acnes* also stimulates Th17 responses within acne lesions[37]. Lastly, *C. acnes* can induce monocytes to differentiate into two distinct innate immune cell subsets: (1) $CD209^+$ macrophages, which more effectively phagocytose and kill *C. acnes* and whose development is promoted by tretinoin; and (2) $CD1b^+$ dendritic cells that activate T cells and release proinflammatory cytokines[24].

CLINICAL FEATURES

Acne is typically found in sites with well-developed sebaceous glands, most often the face and upper trunk. Despite evidence that inflammation is present in even the earliest comedones, acne lesions are divided into non-inflammatory and inflammatory groups based upon their clinical appearance. Non-inflammatory acne is characterized by open and closed comedones (Fig. 36.2). The histologic features of these follicular-based lesions are reflected in their clinical appearance. Closed comedones (whiteheads) are generally small (~1 mm), skin-colored papules with no apparent follicular opening or associated erythema. These lesions may be subtle and better appreciated upon palpation, stretching, or side-lighting of the skin. In contrast, open comedones (blackheads) have a conspicuous dilated follicular opening that is filled with an inspissated core of shed keratin (see Fig. 36.4). Melanin deposition and lipid oxidation within the debris may be responsible for the black color. Larger macrocomedones are deep-seated and may be cystic.

Inflammatory acne is characterized by papules, pustules, and nodules of varying severity (Figs. 36.3–36.6). Erythematous papules typically range from 1 to 5 mm in diameter. Pustules tend to be approximately equal in size and are filled with white purulent material and normal microbiota, including *C. acnes*. As the severity of lesions progresses, nodules form and become markedly inflamed, indurated, and tender. The pseudocysts of acne are deeper and filled with a combination of pus and serosanguineous fluid. In patients with severe nodulocystic acne, these lesions frequently coalesce to form large, complex, inflamed plaques that can include sinus tracts.

Early treatment of acne is essential for the prevention of lasting cosmetic disfigurement due to scarring. Erythema and

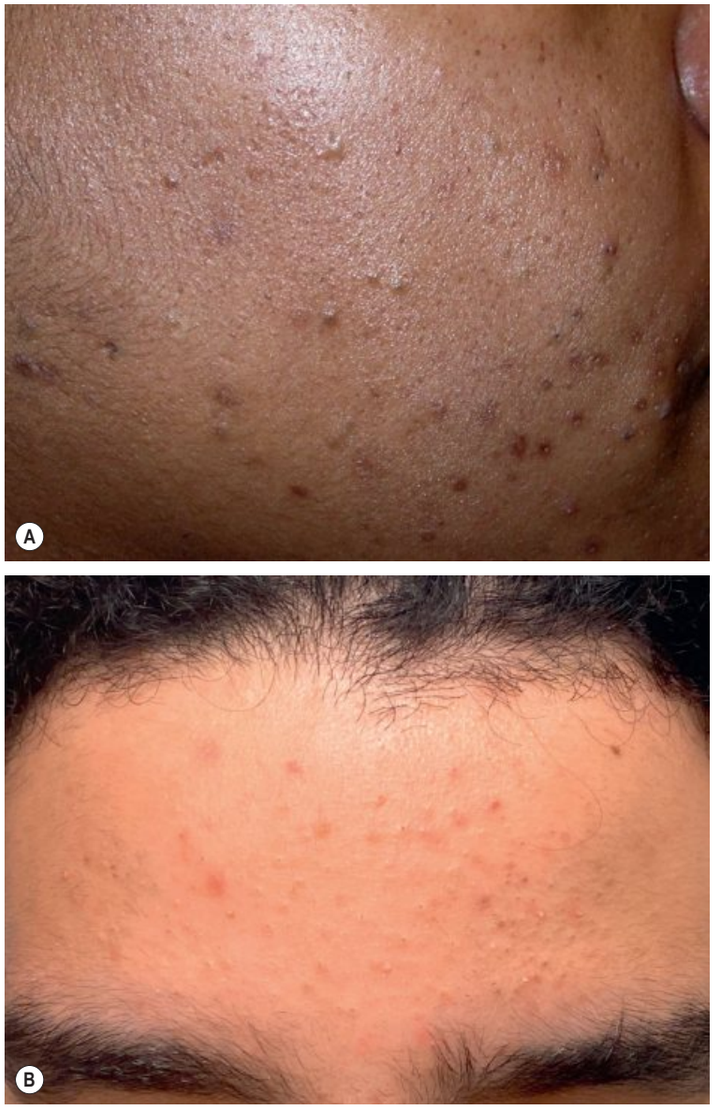

Fig. 36.2 Comedonal acne vulgaris. On the cheek (**A**) and forehead (**B**), there are open and closed comedones as well as postinflammatory hyperpigmentation (**A**) and inflammatory papules (**B**). *B, Courtesy Kalman Watsky, MD.*

Fig. 36.3 Moderate acne vulgaris. Scattered papulopustules and papulonodules are present on the cheek. *Courtesy Kalman Watsky, MD.*

postinflammatory hyperpigmentation (Fig. 36.7) often persist after resolution of inflammatory acne lesions. Although the pigmentary changes usually fade over many months if the acne is brought under control, occasionally they can be permanent. Unfortunately, pitted scars (Fig. 36.8A) or hypertrophic scars (most commonly on the trunk; Fig. 36.8B,C) are often sequelae of nodulocystic acne. Skin-colored, dome-shaped papules on the nose and chin with histopathologic features indistinguishable from angiofibromas represent an additional form of acne scarring that has a predilection for male patients with darkly pigmented skin (Fig. 36.9)[38].

Fig. 36.4 Moderate to severe acne vulgaris. Inflammatory papules and pustules as well as both open and closed comedones are evident on the cheek, forehead, and chin. Note the nodular lesion on the temple and open comedones in the concha of the ear. Scarring is present in the preauricular area.

Acne Variants

Post-adolescent acne in women

Inflammatory acne beyond 25 years of age is most common in women and may be associated with a high level of psychological stress[11]. The majority of affected women present with findings similar to those of adolescent acne, with a mixture of inflammatory and comedonal lesions involving various facial sites and sometimes the trunk[39]. Although the mandibular area is involved in ~80% of women with acne, a distinct smaller subset has inflammatory papules, pustules, and nodules exclusively in this location. Half of women report persistence of their acne since its onset, often during adolescence, while one-quarter describe periods of remission followed by recurrences. Premenstrual flares are common[40], but only ~20% of women with acne have irregular menses. Up to 30% of those in the latter group have other signs of hyperandrogenism, such as hirsutism and androgenetic alopecia (see below). A predominantly comedonal, adult-onset form of acne that is associated with smoking has also been described[41].

Acne fulminans

Acne fulminans is the most severe form of acne and is characterized by the abrupt development of nodular and suppurative acne lesions in association with systemic manifestations. This uncommon variant primarily affects boys 13–16 years of age. Patients typically have mild to moderate acne prior to the onset of acne fulminans, when numerous microcomedones suddenly erupt and become markedly inflamed. There is rapid coalescence into painful, oozing, friable plaques with hemorrhagic crusts (Fig. 36.10). The face, neck, trunk, and arms are all affected. Lesions tend to ulcerate and can lead to significant scarring.

Osteolytic bone lesions may accompany the cutaneous findings; the clavicle and sternum are most commonly affected, followed by the ankles, humerus, and iliosacral joints. Systemic manifestations include fever, arthralgias, myalgias, hepatosplenomegaly, and severe malaise. Erythema nodosum may also arise in association with acne fulminans. Laboratory abnormalities vary and include an elevated ESR, proteinuria, leukocytosis, and anemia. Laboratory studies are not required to establish the diagnosis, but their evolution may parallel the clinical course and response to therapy. The related *s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis, and *o*steitis (SAPHO) syndrome, which can accompany acne fulminans, is discussed in detail in Chapter 26. Acne fulminans has also been associated with late-onset congenital adrenal hyperplasia and anabolic steroid use, including therapeutic testosterone.

Recommended treatment of acne fulminans includes prednisone 0.5–1 mg/kg/day as monotherapy for at least 2–4 weeks, followed by initiation of low-dose isotretinoin (e.g. 0.1 mg/kg/day) after the acute inflammation subsides; after at least 4 weeks of this combination, the isotretinoin dose can be slowly increased and the prednisone tapered over a period of 1–2 months[42]. Paradoxically, an acne fulminans-like flare occasionally develops during the first few weeks of isotretinoin therapy

Fig. 36.5 Moderate to severe acne vulgaris. Multiple coalescing papules, papulopustules, and small nodules are present on the cheeks (**A,B**) and temple (**A**). Early scarring is evident laterally (**A**). *B, Courtesy Kalman Watsky, MD.*

Fig. 36.6 Severe to very severe nodular acne. **A** Numerous nodules. **B** Acne conglobata with coalescence of purulent nodules on the forehead, with associated eyelid edema. This form is best treated with prednisone and a low dose of isotretinoin initially. *B, Courtesy Julie V. Schaffer, MD.*

for acne[43]; this may be avoided by starting with a low dose of isotretinoin and concomitant administration of oral corticosteroids at the first sign of a flare or possibly preemptively in high-risk patients (see Ch. 126). Additional treatment options for acne fulminans include topical or intralesional corticosteroids, oral antibiotics (generally of limited efficacy), TNF inhibitors, IL-1 antagonists, and immunosuppressive agents (e.g. azathioprine, cyclosporine). Dapsone may be particularly beneficial in the treatment of acne fulminans associated with erythema nodosum[44].

Acne conglobata and associated conditions

Acne conglobata (see Fig. 36.6B) is a severe form of nodulocystic acne that may have an eruptive onset but without systemic manifestations. This recalcitrant acne variant is part of the follicular occlusion tetrad, along with dissecting cellulitis of the scalp, hidradenitis suppurativa, and pilonidal sinus (see Ch. 38).

The association of sterile *p*yogenic *a*rthritis, *p*yoderma gangrenosum, and *a*cne conglobata can occur in the context of an autosomal dominant autoinflammatory disorder referred to as PAPA syndrome, which can be caused by mutations in *PSTPIP1* which encodes *p*roline–serine–*t*hreonine *p*hosphatase *i*nteracting *p*rotein 1[45]. Dysfunction of PSTPIP1, which has a role in actin reorganization and interacts with the pyrin protein (defective in familial Mediterranean fever), compromises the physiologic signaling required for maintenance of a proper inflammatory response. *PSTPIP1* mutations have also been identified in some patients with *p*yogenic *a*rthritis, *p*yoderma gangrenosum, *a*cne, and *s*uppurative *h*idradenitis (PAPASH) and *p*yoderma gangrenosum, *a*cne, and *s*uppurative *h*idradenitis (PASH) syndromes[46,47]. Of note, a possible association between nodulocystic acne and inflammatory bowel disease may potentially confound links that have been observed between the latter disorder and acne therapies such as tetracyclines and isotretinoin[48].

Solid facial edema

An unusual and disfiguring complication of acne vulgaris is solid facial edema (Morbihan disease). Clinically, there is a distortion of the midline face and cheeks due to soft tissue swelling (Fig. 36.11). The woody induration may be accompanied by erythema. Impaired lymphatic drainage and fibrosis (potentially induced by mast cells) in the setting of chronic inflammation are thought to be involved in the pathogenesis of solid facial edema, and a report of its occurrence in identical twins with acne suggests that genetic factors may also have a role. Similar changes have been described in patients with rosacea (see Table 36.2). Although fluctuations in severity are common, solid facial edema does not usually resolve spontaneously. Treatment with isotretinoin (0.2–1 mg/kg/day) for 4–6 months has been reported to lead to improvement, although a more extended course of 9–24 months is often required[49]. Combination of isotretinoin with ketotifen 1–2 mg/day (not available in the US) or prednisone 10–30 mg/day may have additional benefit[50].

Neonatal cephalic pustulosis (neonatal acne)

Neonatal cephalic pustulosis occurs in more than 20% of healthy newborns (see Ch. 34). Lesions usually appear at about 2 weeks of age and generally resolve within the first 3 months of life. Small papulopustules, but not comedones, arise primarily on the cheeks, forehead, eyelids and chin, although the neck and upper trunk can also be involved (see Fig. 34.6).

An inflammatory response to *Malassezia* spp. (e.g. *sympodialis, furfur*) has been proposed as the etiology by some investigators. Additional support for this view comes from the clinical response to treatment with topical imidazoles (e.g. ketoconazole 2% cream). Active sebaceous glands in neonates and their relatively high sebum excretion rate (see Pathogenesis) are also thought to play a role. The substantial decline in sebum production after the first few months of life helps to explain the limited duration of neonatal cephalic pustulosis. Given the

transient and benign nature of this eruption, parental reassurance alone is usually adequate. However, as noted previously, therapy with topical imidazoles can be effective.

Infantile acne

Infantile acne typically has its onset at 2–12 months of age[5]. In contrast to neonatal cephalic pustulosis, comedo formation is prominent and pitted scarring may develop in up to half of patients (Fig. 36.12)[51]. Deep, suppurative nodules are occasionally seen. Its pathogenesis reflects the androgen production intrinsic to this stage of development (see Pathogenesis), including elevated levels of LH that stimulate testicular production of testosterone in boys during the first 6–12 months of life and elevated levels of DHEA produced by the infantile adrenal gland in both boys and girls. These androgen levels normally decrease substantially by 12 months of age and remain at nadir levels until adrenarche. Patients with infantile acne should be assessed for signs of hyperandrogenism, precocious puberty, or abnormal growth; if these findings are present, endocrinologic evaluation including a hand/wrist X-ray to determine bone age and laboratory testing of hormone levels should be performed.

Infantile acne usually resolves within 6–18 months and remains quiescent until around puberty, with an increased risk of severe acne during adolescence having been observed[5]. Topical retinoids (e.g. tretinoin, adapalene) and benzoyl peroxide are first-line treatments for infantile acne. Oral antibiotics (e.g. erythromycin, azithromycin) can be helpful for patients with a more severe inflammatory component, and isotretinoin is occasionally required for recalcitrant or nodulocystic presentations[52].

Mid-childhood acne

Acne presenting between 1 and 6 or 7 years of age is categorized as "mid-childhood acne"[5]. Because this is an uncommon time for acne development due to quiescent androgen production, the possibility of an underlying hyperandrogenic condition such as premature adrenarche, congenital adrenal hyperplasia, or an androgen-secreting tumor should be considered. In addition to a thorough history and physical examination to assess for signs of hyperandrogenism (see below) and precocious puberty, the child's growth curve should be carefully reviewed and a hand/wrist bone age X-ray performed if there are signs of accelerated growth. A complete endocrine evaluation is required if any abnormalities are present[53]. Treatment strategies are the same as for infantile acne.

Preadolescent acne

It is common for acne to begin to develop with the onset of adrenarche, typically between 7 or 8 to 11 years of age, which is often prior to other signs of pubertal maturation[5]. Preadolescent acne tends to be primarily comedonal and favors the forehead and central face ("T-zone"). Polycystic ovary syndrome (PCOS) and other endocrinologic abnormalities should be considered when the acne is unusually severe or accompanied by

Fig. 36.12 Infantile acne. Presentations can range from numerous open comedones (**A**) to primarily papulopustules (**B**). *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Kalman Watsky, MD.*

signs of hyperandrogenism. Treatment is similar to that for adolescent acne, although tetracycline courses of >21 days should be avoided in children <8 years of age.

Acne excoriée

Acne excoriée occurs more often in young women, in whom it may be referred to as acne excoriée des jeunes filles. Typical comedones and inflammatory papules are systematically excoriated in a ritualistic manner, leaving crusted erosions that may scar (see Ch. 7). Linear erosions suggest self-manipulation, and an underlying psychiatric component should be considered. Individuals with an anxiety, obsessive–compulsive, or body dysmorphic disorder are particularly at risk, and antidepressants or psychotherapy may be helpful in these patients.

Acne associated with endocrinologic abnormalities

Although most patients with acne do not have overt endocrinologic abnormalities, hyperandrogenism should be suspected in women and late adolescent girls with irregular menstrual periods. Acne in such patients is often severe or more difficult to treat, and the onset can be fairly abrupt. Other signs and symptoms of hyperandrogenism in women and children include hirsutism (see Ch. 70), coarsening of the voice, a muscular habitus, androgenetic alopecia, clitoromegaly with variable posterior labial fusion, and increased libido. *I*nsulin *r*esistance and *a*canthosis *n*igricans can occur in association with *h*yper*a*ndrogenism in the HAIR-AN syndrome. These patients are at increased risk for accelerated cardiovascular disease and diabetes mellitus, and they should be followed by appropriate medical specialists.

The evaluation of patients suspected of having hyperandrogenism includes a thorough history and physical examination; the age of the patient and pubertal status are also important parameters. Prepubertal children, adolescent girls, and women with signs of hyperandrogenism should undergo appropriate evaluation, and laboratory studies should not be performed while the patient is taking oral contraceptives. Initial tests typically include serum levels of total and free testosterone, DHEAS, and 17-hydroxyprogesterone. Patients with clinical findings suggestive of hypercortisolism should also be initially assessed with either a late-night salivary cortisol level, 24-hour urine cortisol level, or low-dose dexamethasone suppression test[54]. In prepubertal children, growth charts should be assessed and X-rays of the hand and wrist performed to evaluate bone age (see Mid-childhood acne).

Understanding pathways of hormone production is essential in the evaluation of hyperandrogenic states (see Fig. 70.18). For example, an elevated serum DHEAS or 17-hydroxyprogesterone level indicates an adrenal source of excess androgen production. The degree to which levels of these hormones are increased is then useful in discerning an etiology. DHEAS values in the range of 4000–8000 ng/ml or 17-hydroxyprogesterone levels >3 ng/ml may be indicative of congenital adrenal hyperplasia. Defects in adrenal enzymes, most commonly 21-hydroxylase and less often 11-hydroxylase, lead to this condition. Patients with severe deficiencies of these enzymes become symptomatic during infancy, whereas those with partial deficiencies present in adolescence. If the serum DHEAS is >8000 ng/ml, with or without an elevated testosterone level, an adrenal tumor should be suspected.

If the testosterone levels (total and free) are elevated and the DHEAS level is relatively normal, an ovarian source is likely. Polycystic ovary syndrome (PCOS) is the most common condition associated with an elevated serum testosterone, with levels typically ranging from 100 to 200 ng/dl. An increased LH/FSH ratio (>2–3) is also commonly observed. Symptoms of PCOS include irregular menstrual periods, hirsutism, obesity, insulin resistance, and reduced fertility (see Fig. 70.14). When levels of serum testosterone exceed 200 ng/dl, an ovarian tumor should be considered.

Acne associated with genetic syndromes

Apert syndrome (acrocephalosyndactyly type I) is an autosomal dominant disorder that features disfiguring synostoses of the bones of the hands and feet, vertebral bodies, and cranium. Affected individuals have an increased incidence of severe, early-onset acne that tends to be nodulocystic and have a more widespread distribution than in classic acne, often involving the entire extensor aspects of the arms, buttocks, and thighs[55]. Acne in patients with Apert syndrome is typically resistant to therapy, although isotretinoin has been reported to be beneficial[56]. Other cutaneous findings in this disorder can include marked seborrhea, nail anomalies (e.g. a single nail for the second through fourth digits), and diffuse pigmentary dilution of the hair and skin. Of note, Apert syndrome results from activating mutations in *FGFR2*, which encodes fibroblast growth factor receptor 2; mosaicism for the same *FGFR2* mutations has been found to underlie the Munro acne nevus (see Ch. 62). FGFR2 signaling has been shown to have effects on follicular keratinocyte proliferation, sebaceous lipogenesis, and inflammatory cytokine production.

Frank–ter Haar syndrome (Borrone dermato-cardio-skeletal syndrome), an autosomal recessive disorder caused by *SH3PXD2B* mutations that affect epidermal growth factor signaling, is characterized by dysmorphic facies, thick skin, severe acne, vertebral abnormalities, and mitral valve prolapse[57]. Early-onset, severe acne and hidradenitis suppurativa have been reported in patients with Patau syndrome (trisomy 13). *PAPA syndrome* and related conditions are discussed in the section on acne conglobata.

Acneiform Eruptions

Drug-induced acne

Acne or acneiform eruptions (e.g. folliculitis) can be seen as a side effect of a number of medications (Table 36.1). An abrupt, monomorphous eruption of inflammatory papules and pustules is often observed in drug-induced acne (Fig. 36.13), in contrast to the heterogeneous morphology of lesions seen in acne vulgaris. When a history of prescription medication use is not elicited, a comprehensive review of all over-the-counter medications and supplements, as well as recent medical procedures, may reveal the responsible agent (see Table 36.1). Bodybuilders and athletes should be questioned about the use of anabolic steroids as well as protein supplements. It is important to

CAUSES OF DRUG-INDUCED ACNE	
Common	**Uncommon**
Anabolic steroids (e.g. danazol, testosterone)	Azathioprine
Bromides*	Checkpoint inhibitors (e.g. anti-PD-1; see Ch. 21)
Corticosteroids (see Fig. 36.13)	Cyclosporine
Corticotropin	Disulfiram
EGFR and EGFR/MEK inhibitors** (see Fig. 36.14 and Ch. 21)	Elexacaftor-tezacaftor-ivacaftor***
Iodides†	Ethosuximide
Isoniazid	Other kinase inhibitors (e.g. vemurafenib, ibrutinib)
JAK inhibitors (e.g. upadacitinib)	Phenobarbital
Lithium	Propylthiouracil
MEK inhibitors (e.g. trametinib; see Ch. 21)	Psoralen + ultraviolet A
mTOR inhibitors (e.g. sirolimus)	Quinidine
Phenytoin	Quetiapine
Progestins (see text)	TNF inhibitors
	Vedolizumab
	Vitamins B_6 and B_{12}

*Found in sedatives, analgesics, cold remedies, and ipratropium bromide inhalers.
**3rd generation EGFR inhibitors are less likely to induce an acneiform eruption.
***Used to treat cystic fibrosis; necrotizing infundibular crystalline folliculitis may be evident histologically.
†Found in contrast dyes, cold/asthma remedies, kelp, and combined vitamin–mineral supplements.

Table 36.1 Causes of drug-induced acne. EGFR, epidermal growth factor receptor.

Fig. 36.13 Acneiform eruption secondary to high-dose dexamethasone. Abrupt eruption of monomorphous follicular papules and pustules on the chest.

note that gender-affirming hormonal therapy (e.g. testosterone) can exacerbate acne in transgender patients[58]. In one study, a third of transgender patients receiving masculinizing hormonal therapy had acne[59].

High-dose intravenous or oral corticosteroids commonly induce characteristic acneiform eruptions with a concentration of lesions on the chest and back (see Fig. 36.13). Steroid-induced acne (and rosacea) can also result from the inappropriate use of topical corticosteroids on the face. Inflamed papules and pustules develop on a background of erythema that favors the distribution of corticosteroid application. Lesions eventually resolve following discontinuation of the corticosteroid, although "steroid dependency" can lead to prolonged and severe flares post-withdrawal (see Ch. 37).

Fig. 36.14 Acneiform eruptions due to epidermal growth factor receptor inhibitors. Numerous monomorphous follicular pustules on the face of an adolescent boy treated with erlotinib.

Epidermal growth factor receptor (EGFR) inhibitors, kinase inhibitors (e.g. MEK inhibitors), and immune checkpoint inhibitors (e.g. anti-PD-1, -PD-L1, -CTLA-4) can induce acneiform papulopustular eruptions[60] (Fig. 36.14; see Tables 21.16 & 21.18). Janus kinase (JAK) inhibitors (e.g. upadacitinib, tofacitinib) have also been associated with exacerbation of acne. Eruptions of comedo-like and cystic lesions similar to chloracne have been described in patients receiving the BRAF inhibitor vemurafenib[61].

Occupational acne, acne cosmetica, and pomade acne

Exposure to insoluble, follicle-occluding substances in the workplace is responsible for occupational acne (see Ch. 16). Offending agents include cutting oils, petroleum-based products, chlorinated aromatic hydrocarbons, and coal tar derivatives. Comedones dominate the clinical picture, with varying numbers of papules, pustules, and cystic lesions distributed in exposed as well as typically covered areas. Primarily comedonal facial acne, with a predominance of closed comedones, can also develop in sites chronically exposed to follicle-occluding cosmetics (*acne cosmetica*) or hair products. The latter, referred to as *pomade acne*, favors the forehead and temples. Face mask-induced acneiform eruptions ("maskne") became more common during the SARS-CoV-2 pandemic[62].

Chloracne (metabolizing acquired dioxin-induced skin hamartomas [MADISH])

Chloracne results from systemic exposure to halogenated aromatic hydrocarbons, which accelerate keratinization and convert sebocytes to keratinocytic differentiation via activation of the aryl hydrocarbon receptor and induction of cytochrome P450 1A1 expression. Chloracne typically develops several weeks after exposure, which can occur via percutaneous absorption, inhalation, or ingestion. The following agents, found in electrical conductors and insulators, insecticides, fungicides, herbicides and wood preservatives, have all been implicated: polychlorinated naphthalenes, biphenyls, dibenzofurans and dibenzodioxins; polybrominated naphthalenes and biphenyls; tetrachloroazobenzene; and tetrachloroazoxybenzene.

Comedo-like lesions and yellowish cysts with relatively little associated inflammation most commonly affect the malar and retroauricular areas of the head and neck (see Fig. 16.13), as well as the axillae and scrotum. The extremities, buttocks, and trunk are variably involved. Cystic lesions can heal with significant scarring, and the condition may persist for several years following cessation of exposure. Additional findings may include hypertrichosis and grayish discoloration of the skin.

Initial management is aimed at removal of the source of exposure. Topical or oral retinoids may be beneficial, but chloracne is often recalcitrant to therapy.

Acne mechanica

Acne mechanica is due to repeated mechanical and frictional obstruction of the pilosebaceous outlet. Comedo formation is the result. Mechanical factors include rubbing by helmets, chin straps, suspenders, and collars as well as friction between the inner thighs[63]. Orthopedic causes include acne mechanica in the axillae due to the use of crutches and on amputee stumps due to friction from prostheses[64]. A classic example of acne mechanica is fiddler's neck, where repetitive trauma from violin placement on the lateral neck results in a well-defined, lichenified, hyperpigmented plaque interspersed with comedones. Linear and geometrically distributed areas of involvement suggest acne mechanica. Treatment is aimed at eliminating the inciting forces.

Tropical acne

Tropical acne is a follicular acneiform eruption that results from exposure to heat and humidity. This can occur in tropical climates or secondary to scorching occupational environments, as in furnace workers. Historically, tropical acne caused significant morbidity among military troops. Markedly inflamed nodulocystic acne involving the trunk and buttocks is typically seen, and secondary staphylococcal infection is a frequent complication. Treatment is often of limited efficacy until the patient returns to a more moderate climate.

Radiation acne

Radiation acne is characterized by comedo-like papules occurring at sites of previous exposure to therapeutic ionizing radiation. The lesions begin to appear as the acute phase of radiation dermatitis starts to resolve. The ionizing rays induce epithelial metaplasia within the follicle, creating adherent hyperkeratotic plugs that are resistant to expression.

"Pseudoacne" of the nasal crease

The transverse nasal crease is a horizontal anatomical demarcation line found in the lower third of the nose, which corresponds to the separation point between the alar cartilage and the triangular cartilage. Milia, cysts, and comedones can line up along this fold (Fig. 36.15A)[65]. These acne-like lesions are not hormonally responsive and arise during early childhood prior to the onset of puberty. Treatment consists of mechanical expression or topical therapy with a retinoid or benzoyl peroxide as needed.

Idiopathic aseptic facial granuloma (idiopathic facial aseptic granuloma)

This painless nodule with an acneiform appearance typically develops on the cheeks of young children (mean age, ~3.5 years), although older children are occasionally affected[66]. Multiple lesions are uncommon. Histopathologic evaluation reveals a dermal lymphohistiocytic infiltrate with foreign body-type giant cells. In general, cultures are negative and the lesions do not respond to antibiotic therapy. Eventually, after an average of one year, the lesions resolve spontaneously[67]. It has been suggested that this entity represents a form of childhood rosacea as >40% of patients have at least two other clinical signs of rosacea including recurrent chalazions, facial flushing, telangiectasias, or papulopustules[67,68].

Fig. 36.15 Disorders in the differential diagnosis of acne vulgaris. A Pseudoacne of the transverse nasal crease in a young child. Note the milia and comedones located along this anatomical demarcation line. **B** Demodicosis presenting as pustules on the nose of a healthy child. An increased number of *Demodex* mites was observed in a scraping. **C** Acneiform follicular mucinosis on the cheek of a woman. **D** Follicular mycosis fungoides that presented as numerous lesions with a comedonal appearance on the chest, abdomen, and back. *A, B, D, Courtesy Julie V. Schaffer, MD; C, Courtesy Lorenzo Cerroni, MD.*

Childhood flexural comedones

This entity is characterized by discrete, double-orifice comedones localized to the axillae and, less commonly, the groin[69]. The majority of patients have a single lesion and the average age at diagnosis is 6 years, with boys and girls equally affected. Occasionally, the condition is familial. There is no association with hidradenitis suppurativa, acne vulgaris, or precocious puberty. In addition to hidradenitis suppurativa, the differential diagnosis includes comedones associated with resolving molluscum contagiosum or pseudoxanthoma elasticum.

PATHOLOGY

Histopathologic examination of acne lesions demonstrates the stages of acnegenesis that parallel the clinical findings (see Fig. 36.1). In early lesions, microcomedones are seen. A mildly distended follicle with a narrowed follicular opening is impacted by shed keratinocytes. The granular layer at this stage is prominent. In closed comedones, the degree of follicular distension is increased and a compact cystic structure forms. Within the cystic space, eosinophilic keratinaceous debris, hair, and numerous bacteria are present. Open comedones have broad, expanded follicular ostia and greater overall follicular distension. The sebaceous glands are typically atrophic or absent. A mild perivascular mononuclear cell infiltrate encircles the expanding follicle.

As the follicular epithelium distends, the cystic contents inevitably begin to rupture into the dermis (Fig. 36.16). The highly immunogenic cystic contents (keratin, hair, and bacteria) induce a marked inflammatory response. Neutrophils first appear, creating a pustule. As the lesion matures, foreign body granulomatous inflammation engulfs the follicle and end-stage scarring can result.

In acne fulminans, there is massive inflammation with varying degrees of overlying necrosis. Comedones are rarely observed. Severe scarring may be seen in resolving lesions.

DIFFERENTIAL DIAGNOSIS

Although classic acne vulgaris is usually easily recognized clinically, the differential diagnosis of acneiform eruptions is broad and depends upon the age of onset, lesional morphology, and location (Table 36.2; see Fig. 36.15). During the neonatal period, acne must be differentiated from other common dermatoses. Sebaceous hyperplasia occurs in the majority of healthy neonates, presenting as transient yellowish papules on the cheeks, nose, and forehead. Miliaria rubra is also very common during the neonatal period, when overheating and bundling can cause temporary eccrine duct obstruction that leads to the formation of small inflammatory papulopustules. Small, white milia are often apparent on the cheeks and nose of neonates, but they generally resolve within a few months.

Predominantly comedonal acne vulgaris needs to be differentiated from comedonal eruptions caused by follicular occlusion or friction, including acne mechanica, acne cosmetica, pomade acne, and occupational acne (see above); history as well as location can help to make the diagnosis of these forms of "contact acne". Sebaceous hyperplasia, a very common finding in adults, is relatively uncommon in adolescents. These yellowish, lobulated papules arise primarily on the forehead and cheeks.

A solitary enlarged comedo is better classified as a dilated pore of Winer; such lesions rarely represent a large-pore basal cell carcinoma. Multiple open comedones are clustered in the lateral malar region in Favre–Racouchot syndrome (see Ch. 87) or appear in a linear array in nevus comedonicus (see Chs. 62 & 109). If multiple vellus hairs arise from a dilated follicular orifice in association with keratinous debris, trichostasis spinulosa is the likely diagnosis. The most common location is the nose.

Angiofibromas and appendageal tumors of follicular origin, e.g. trichoepitheliomas, trichodiscomas and fibrofolliculomas, often present as multiple facial papules (see Ch. 111). They are typically non-inflammatory, and trichoepitheliomas are concentrated in the nasolabial folds. Non-inflammatory, closed cystic papules and nodules on the central chest and back characterize steatocystoma multiplex (see Ch. 110). This autosomal dominant disorder must be differentiated from a related entity, eruptive vellus hair cysts. These smaller cysts may become inflamed and, as the name implies, contain multiple vellus hairs that can be easily visualized microscopically.

The follicle-based inflammatory papules and pustules of acne vulgaris must be distinguished from the many forms of folliculitis, including staphylococcal, Gram-negative, and eosinophilic variants (see Fig. 38.1). In folliculitis, the lesions are relatively monomorphous and comedones are not present. Gram-negative folliculitis can complicate acne vulgaris treated with oral antibiotics for a prolonged period; the inflammatory lesions typically appear on the central face, including the upper lip, and cheeks. In contrast, *Pseudomonas* ("hot tub") folliculitis favors the lower trunk and other sites covered by a bathing suit. *Malassezia* (*Pityrosporum*) folliculitis, which may develop in acne patients receiving antibiotic therapy, presents with fine papules and pustules favoring the forehead and upper trunk[70]. Eosinophilic folliculitis usually occurs in the setting of immunosuppression (e.g. HIV infection) and is markedly pruritic.

Pseudofolliculitis barbae and acne keloidalis nuchae most often affect men with Afro-textured hair (see Ch. 38). The papular component of rosacea favors the malar region, chin, and forehead; the presence of telangiectasias, an absence of comedones, and a history of easy flushing can aid in diagnosis (see Ch. 37). Rosacea typically occurs at a later age than acne, but both can develop in a single individual. Prolonged use of topical corticosteroids on the face may lead to rosacea-like lesions or periorificial dermatitis, and patients treated with oral corticosteroids can develop an eruption of monomorphous papulopustules that favors the trunk ("steroid folliculitis"; see Fig. 36.13). This can occur at any age and resolves upon discontinuation of the corticosteroid. Lastly, psychogenic (neurotic) excoriations and factitial dermatitis concentrated on the face, chest, and back can mimic acne, particularly acne excoriée. Linearity and the lack of clinically detectable primary lesions are clues.

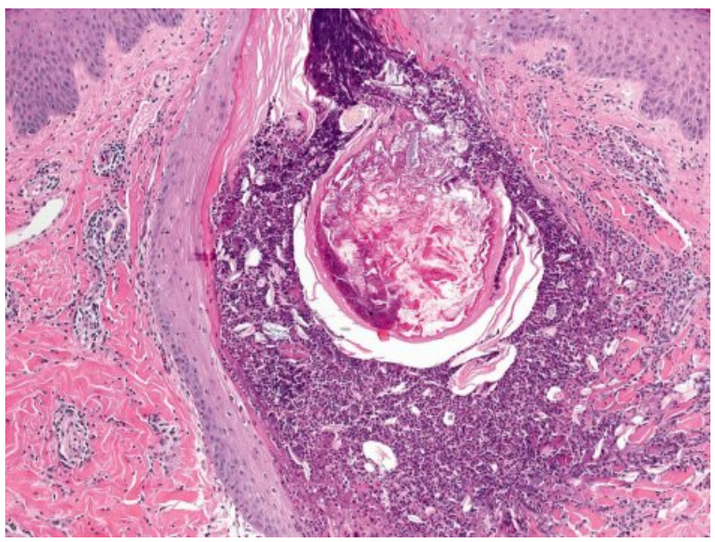

Fig. 36.16 Histology of an inflamed comedo. There is disruption of the pilosebaceous unit and secondary inflammation. *Courtesy Lorenzo Cerroni, MD.*

TREATMENT

A thorough history and physical examination are key to developing an appropriate and maximally effective treatment plan[71] (Table 36.3). The physician should review with the patient all prescription and over-the-counter medications used for acne or other conditions, noting the response to acne treatments. A review of cosmetics, sunscreens, cleansers, and moisturizers is also helpful. In female patients, a menstrual and oral contraceptive history is important in determining hormonal influences on acne. Some patients may report an improvement following sun exposure while others experience an exacerbation.

On physical examination, lesional morphology should be assessed, including the presence of comedones, inflammatory lesions, nodules, and cysts. Secondary changes such as scarring and postinflammatory pigmentary changes are also important clinical findings. The patient's skin color and type can influence the chosen formulation of a topical medication. For example, patients with oily skin tend to prefer the more drying gels and lotions, whereas those with drier skin types may prefer creams.

Table 36.4 provides an overview of the approach to acne therapy. Lack of adherence to the recommended acne treatment plan is a frequent

DIFFERENTIAL DIAGNOSIS OF ACNE	
Acne vulgaris – comedonal	
Closed	***Open***
• Milia • Osteoma cutis • Sebaceous hyperplasia • Pseudoacne of the nasal crease (see Fig. 36.15A) • Syringomas • Trichoepitheliomas* • Trichodiscomas, fibrofolliculomas • Eruptive vellus hair cysts†, steatocystoma multiplex† • Colloid milium • Acne exacerbated by systemic corticosteroids‡ or anabolic steroids • Contact acne (occupational, pomade, cosmetica, mechanica; chloracne) • Follicular keratosis of the chin/face • Follicular mucinosis (see Fig. 36.15C) • Follicular mycosis fungoides (see Fig. 36.15D) • Comedonal Darier disease	• Contact acne (see Closed) • Acne exacerbated by systemic corticosteroids‡ or anabolic steroids • Trichostasis spinulosa (see inset) • Favre–Racouchot syndrome • Pseudoacne of the nasal crease (see Fig. 36.16A) • Nevus comedonicus • Basaloid follicular hamartoma syndrome • Familial dyskeratotic comedones • Comedonal Darier disease • Dowling–Degos disease • Radiation-induced comedones • Molluscum-induced comedones • Childhood flexural comedones (often a single double-orifice lesion) • Dilated pore of Winer (single lesion) • Trichofolliculoma (usually a single lesion) • Follicular spines – in settings such as viral-associated trichodysplasia¶, type VI pityriasis rubra pilaris¶, multiple myeloma, demodicosis¶, follicular mucinosis, follicular porokeratosis, and drug-induced (e.g. BRAF inhibitors, cyclosporine¶, acitretin)
Acne vulgaris – inflammatory	
• Rosacea • Perioral/periorificial dermatitis • Demodicosis (adults > children¶; see Fig. 36.15B) • Folliculitis – culture-negative, staphylococcal, Gram-negative, eosinophilic¶, *Malassezia* • Acne/acneiform eruptions due to topical or systemic corticosteroids‡, anabolic steroids, or other medications (e.g. lithium, EGFR inhibitors; see Table 36.1) • Pseudofolliculitis barbae, acne keloidalis nuchae • Pseudoacne of the nasal crease • Furuncle/carbuncle • Idiopathic aseptic facial granuloma (in children) • Papulopustular eruption of Behçet disease • Neutrophilic dermatoses, neutrophilic eccrine hidradenitis, and neutrophilic sebaceous adenitis	• Keratosis pilaris • Follicular keratosis of the chin/face • Viral-associated trichodysplasia (trichodysplasia spinulosa)¶ • Lupus miliaris disseminatus faciei • Psychogenic (neurotic) excoriations, factitial lesions • Follicular mucinosis (see Fig. 36.15C) • Follicular mycosis fungoides (see Fig. 36.15D) • Tinea faciei • Molluscum contagiosum (especially inflamed lesions) • Angiofibromas • Angiofibroma-like papules of the nose and chin • Dowling–Degos disease (especially the Haber syndrome variant) • Follicular porokeratosis • Cutaneous Rosai–Dorfman disease • Granulomatosis with polyangiitis • Syndromes associated with acne, e.g. PAPA, (PA)PASH, SAPHO, Apert syndrome
Neonatal cephalic pustulosis (neonatal acne)	
• Sebaceous hyperplasia • Milia • Miliaria rubra (especially pustular variant)	• Candidal infection • Papulopustular eruption of hyper-IgE syndrome • Vesiculopustular eruption of transient myeloproliferative disorder
Solid facial edema secondary to acne vulgaris	
• Solid facial edema secondary to rosacea • Melkersson–Rosenthal syndrome, sarcoidosis (e.g. Heerfordt syndrome), lepromatous leprosy • Lymphoma (B or T cell), leukemia cutis, angiosarcoma • Scleromyxedema, myxedema, self-healing (juvenile) cutaneous mucinosis • Autoimmune connective tissue disease (e.g. dermatomyositis, lupus erythematosus, Still disease)	• Angioedema (lasts <24–72 hours), C1 esterase inhibitor deficiency (lasts 2–3 days), blepharochalasis/Ascher syndrome • Sweet syndrome or cellulitis – more abrupt onset • Superior vena caval obstruction • Lymphatic malformation • Pachydermoperiostosis and other genetic disorders with coarse facies • Other – trichinosis, primary systemic amyloidosis

*Early or small-sized.
†In the differential diagnosis of cystic lesions of the trunk.
‡Can also lead to rosacea-like picture (see Ch. 37).
¶Often in the setting of HIV infection or other immunocompromised states.

Table 36.2 Differential diagnosis of acne. EGFR, epidermal growth factor receptor; PAPA, *p*yogenic *a*rthritis, *p*yoderma gangrenosum, and *a*cne conglobata; (PA)PASH, (*p*yogenic *a*rthritis), *p*yoderma gangrenosum, *a*cne, and suppurative *h*idradenitis; SAPHO, *s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis, and *o*steitis.

reason for therapeutic failure. Some strategies to help improve outcomes are listed in Table 36.5.

Topical Treatments

Topical retinoids

The anti-acne activity of topical retinoids involves normalization of follicular keratinization and corneocyte cohesion, which aids in the expulsion of existing comedones and prevents the formation of new ones. Topical retinoids also have significant anti-inflammatory properties and therefore may be used as monotherapy for acne with both comedonal and mild inflammatory components. In addition, concurrent use of a topical retinoid can enhance the efficacy of benzoyl peroxide and topical antibiotics by increasing the penetration of the latter medications into the sebaceous follicle. Topical retinoids used for acne include tretinoin, adapalene, tazarotene, and trifarotene (see Ch. 126); topical products that combine tretinoin with clindamycin or benzoyl peroxide and adapalene with benzoyl peroxide are also available.

HISTORY AND PHYSICAL EXAMINATION OF THE ACNE PATIENT	
History	**Physical examination**

• Age
• Sex or gender identity
• Impact of acne on quality of life
• Motivation and goals for treatment
• Lifestyle, occupation, hobbies
• Current and previous treatments
• Use of cosmetics, sunscreens, cleansers, astringents, moisturizers, masks, scrubs, cleansing brushes
• Menstrual history
• Medications
  • Corticosteroids
  • Hormonal contraceptives, anabolic steroids, gender-affirming therapy
  • Other (e.g. lithium, EGFR inhibitors; see Table 36.1)
• Nutritional supplements
• Concomitant illnesses
• Family history (including severity of acne, polycystic ovary syndrome)
	• Skin type (e.g. oily versus dry)
	• Skin phototype
	• Distribution of acne
	  • Face (e.g. "T-zone", cheeks, jawline)
	  • Neck, chest, back, upper arms
	• Overall degree of involvement (mild, moderate or severe; see Table 36.4)
	• Lesion morphology
	  • Comedones
	  • Papules, pustules
	  • Nodules
	  • Cysts
	  • Scarring
	  • Atrophic, pitted
	  • Hypertrophic, keloidal
	  • Papular
	  • Sinus tracts
	  • Persistent erythema
	  • Postinflammatory hyperpigmentation

Table 36.3 History and physical examination of the acne patient. EGFR, epidermal growth factor receptor.

The most common side effect of topical retinoids is local irritation resulting in erythema, dryness, peeling, and scaling. This tends to peak after 2–4 weeks of treatment and improves with continued usage; transient application of a low-potency topical corticosteroid may be of benefit for patients with significant irritation[72]. Delivery systems have been developed to permit a greater concentration of retinoid while decreasing irritancy, primarily through controlled slow release, e.g. tretinoin impregnated into inert microspheres or incorporated within a polyolprepolymer. An acne flare may occur during the initial month of treatment with a topical retinoid, but resolves spontaneously with continued usage. Although not true photosensitizers, if a retinoid causes skin peeling or irritation, this may increase the user's susceptibility to sunburn. Appropriate use of sunscreens should therefore be advised.

Tretinoin (all-*trans*-retinoic acid), a naturally occurring metabolite of retinol, was the first topical comedolytic agent used for the treatment of acne. To decrease the potential for irritation, treatment is often started with a lower-concentration cream formulation of tretinoin and the strength later increased (see Table 126.5). Alternate-night to every-third-night application may be necessary initially, with increased frequency as tolerated. Because the standard generic tretinoin formulation is photolabile, night-time application is recommended to prevent early degradation; it is also inactivated by concomitant application of benzoyl peroxide, so the two medications should not be used at the same time. However, specialized microsphere formulations of tretinoin are not photolabile and can be applied together with benzoyl peroxide without degradation.

Although epidemiologic studies have not shown an increased risk of birth defects in infants of mothers using topical tretinoin during the first trimester, sporadic case reports of birth defects have been published[73,74]. Because of this and the fact that systemic retinoids are known teratogens, the use of topical tretinoin in pregnancy is discouraged. That said, dietary intake of vitamin A has been shown to have a greater influence on serum retinoid levels than facial application of tretinoin[75].

The third-generation synthetic retinoid *adapalene* is an aromatic naphthoic acid derivative (see Fig. 126.1). In the skin, it primarily binds the retinoic acid receptor γ (RARγ), whereas tretinoin binds to both RARα and RARγ. Unlike tretinoin, adapalene is light-stable and resistant to oxidation by benzoyl peroxide. Table 126.5 outlines the currently available formulations.

Tazarotene is a synthetic acetylenic retinoid that, once applied, is converted into its active metabolite, tazarotenic acid. Like adapalene, this metabolite selectively binds RARγ but not RARα or RXR (see Ch. 126). Both daily overnight application of tazarotene and short contact therapy regimens have been shown to be effective in the treatment of comedonal and inflammatory acne. Per the FDA, topical tazarotene is contraindicated during pregnancy (formerly FDA category X), so contraceptive counseling should be provided to women of childbearing age who are prescribed this medication. Like adapalene, it is light-stable and can be applied together with benzoyl peroxide.

Trifarotene is a fourth-generation topical retinoid that is selective for RARγ. A 0.005% cream formulation was recently approved for the treatment of moderate acne on the face and back in patients ≥9 years of age[76].

Antimicrobial agents

Benzoyl peroxide is a potent bactericidal agent that reduces *C. acnes* within the follicle. It also has mild comedolytic properties and is particularly effective when used in combination with other therapies. In contrast to topical antibiotics, microbial resistance to benzoyl peroxide has not been reported. Many preparations for all skin types are available in both over-the-counter and prescription formulations. These include bar soaps, washes, gels, lotions, creams, foams, and pads in concentrations ranging from 2.5% to 10% as well as products that combine benzoyl peroxide with clindamycin, erythromycin, adapalene, or tretinoin. Benzoyl peroxide's bactericidal properties are not concentration dependent, although irritation is more common with higher strengths. As benzoyl peroxide is a bleaching agent, whitening of clothing and bedding can occur. Development of allergic contact dermatitis to benzoyl peroxide and its metabolite benzoic acid is also possible, and this should be suspected in patients who develop marked erythema or vesiculation with its use.

Topical antibiotics are widely used for the treatment of acne and are available alone as well as in combination with benzoyl peroxide or a retinoid. Topical formulations of *clindamycin*, *erythromycin*, and *minocycline* utilized for acne include creams, gels, foams, solutions, and pledgets (see Ch. 127). Of note, *C. acnes* commonly develops resistance to clindamycin and erythromycin, with rates of >50% in some countries[77]; as a result, topical antibiotic monotherapy for acne is not generally recommended.

Azelaic acid is a naturally occurring dicarboxylic acid with both prescription (15%–20%) and over-the-counter (10%) formulations (see Table 127.2). By inhibiting the growth of *C. acnes*, azelaic acid reduces inflammatory acne. It also reverses altered follicular keratinization and thus demonstrates some comedolytic properties. In a randomized controlled study, azelaic acid 15% gel had non-inferior efficacy and greater tolerability than adapalene 0.1% gel in maintenance therapy for inflammatory acne in women[78]. In addition, azelaic acid can help to lighten postinflammatory hyperpigmentation[79].

Sodium sulfacetamide is a well-tolerated topical antibiotic that is thought to restrict the growth of *C. acnes* through competitive inhibition of the condensation of para-aminobenzoic acid with pteridine precursors (see Ch. 127). It is formulated as a lotion, suspension, foam, and cleanser, either alone or in combination with 5% sulfur. Tinted formulations are also available. When used together with benzoyl peroxide, sodium sulfacetamide can cause an orange discoloration of fabrics[80].

Topical *dapsone* 5% and 7.5% gels are FDA-approved for the treatment of acne vulgaris in patients ≥12 and ≥9 years of age, respectively[81]. In two randomized controlled trials (RCTs) (total n = 4340), 30% of patients ≥9 years of age with moderate acne treated with dapsone 7.5% gel once daily were clear to almost clear at week 12, compared to 21% for placebo ($p<.001$)[81]. Of note, a temporary yellow–orange staining of the skin and hair occasionally occurs with concomitant application of topical dapsone and benzoyl peroxide. Methemoglobinemia has been reported in cases of misuse or ingestion[82,83].

Clascoterone 1% cream is a topical androgen receptor inhibitor that was recently approved for treatment of acne in patients ≥12 years of age. However, in two RCTs (total n = 1440) in patients ≥9 years of age with moderate to severe acne, 18%–20% of patients treated with clascoterone 1% cream twice daily were clear or almost clear after 12 weeks versus 6%–9% with the vehicle control ($p<.001$)[84].

Other topical medications

Salicylic acid is a widely used comedolytic agent (see Ch. 153 and Table 129.7). Salicylic acid is available over the counter in concentrations of up to 2% in numerous delivery formulations, including gels,

TREATMENT OF ACNE VULGARIS		
Acne activity	**Treatment**	
	Initial	**Follow-up**
Mild: Several papules, pustules, and/or comedones; no nodules. 	**First-line** Topical retinoid or BPO ± topical antibiotic[†] or Topical retinoid + BPO ± topical antibiotic[†] **Alternative topicals** Dapsone Clascoterone Azelaic acid[*]	**For additional control:** Increase strength of topical retinoid or Change from wash to leave-on BPO or Add or replace with another topical agent
Moderate: Multiple papules and pustules; few scattered nodules; variable comedones 	**First-line** Topical retinoid + BPO ± topical antibiotic, oral antibiotic[‡], and/or oral hormonal therapy[¶] (female patients) **Alternative topicals** Dapsone Clascoterone Azelaic acid[*]	**For additional control:** See above for topical options Add oral antibiotic[‡] and/or hormonal therapy[¶] (female patients) or Change to isotretinoin
Severe: Numerous papules and pustules; multiple nodules; variable comedones 	**First-line** Topical retinoid + BPO + oral antibiotic[‡] ± hormonal therapy[¶] (female patients) or Isotretinoin **Consider alternative topical (see above)**	**For additional control:** Change to isotretinoin
Very severe: Numerous nodules with conglobate or hemorrhagic lesions; ± systemic symptoms (acne fulminans) 	Prednisone ± isotretinoin (low-dose initially)	Isotretinoin (slow dose escalation)

[*]Especially when postinflammatory hyperpigmentation is present.
[†]Topical antibiotics with level I evidence include clindamycin, minocycline, and erythromycin; sodium sulfacetamide represents another option.
[‡]Oral antibiotics with level I evidence include doxycycline, minocycline, sarecycline, and azithromycin.
[¶]Combined oral contraceptive and/or spironolactone.

Table 36.4 Treatment of acne vulgaris. Lack of response to therapy should prompt consideration of non-adherence, exacerbating factors (e.g. medications [see Table 36.1], endocrinologic abnormalities), or another diagnosis (e.g. Gram-negative or *Malassezia* folliculitis; see Table 36.2). In general, monotherapy with a topical or oral antibiotic should be avoided. There is currently level I evidence for topical retinoids, dapsone, clascoterone, azelaic acid, benzoyl peroxide, and antibiotics (the latter two especially in combination) as well as oral antibiotics, isotretinoin, spironolactone, and combined contraceptives; see footnotes for additional information. Procedural treatments include comedo extraction and (especially for nodular and cystic lesions) intralesional triamcinolone. Therapeutic options for pregnant women (in consultation with their obstetrician) include topical agents (azelaic acid, clindamycin, erythromycin), oral antibiotics (azithromycin, cephalexin), and intralesional triamcinolone. BPO, benzoyl peroxide.

TIPS FOR TOPICAL ACNE THERAPY
Educate on how to use medications, how they work, and treatment expectations
• Inform patients that it will take 6–8 weeks of treatment for substantial improvement • Address potential for postinflammatory hyperpigmentation and scarring • Explain that topical medications (especially retinoids) should be used to the entire acne-prone region rather than as "spot treatment" of individual lesions • Provide instructions on where to apply the medication and how much to use
Improve adherence – avoid compromise due to patients having busy schedules and quitting when the response is not rapid
• Ask about current skin care routine (e.g. when they shower and wash their face, if they moisturize, products used) • Simplify the regimen: once daily when possible; consider combination products (e.g. benzoyl peroxide + adapalene, tretinoin, or clindamycin; tretinoin + clindamycin) • Ask specifically about adherence: "Out of 7 nights, how many times do you apply the medication?"
Minimize irritation – most common in patients with atopic dermatitis and adults
• Note that using too much medication or applying it too frequently can increase irritation • Devise a gradual initial approach to improve tolerance in patients with sensitive skin; for example, a single agent may be used for the first 2–3 weeks (starting every other day for retinoids), followed by slow introduction of a second medication (e.g. transitioning from alternate days to daily) • Advise to avoid harsh scrubs and other irritating agents (e.g. toners, acne products that are not part of the regimen) • Suggest use of a non-comedogenic sensitive skin moisturizer if dryness occurs
Avoid exacerbation
• Review all skin care products and cosmetics; having patients bring everything that they apply to their face to a visit may help to determine the source of problems • Advise non-comedogenic products (e.g. moisturizers, sunscreens, make-up) and to avoid having oily hair or using pomades that may contribute to acne • Instruct patients not to pick or manipulate lesions
Reinforce the plan
• Recognize that patients often forget what is recommended and are bombarded by advertising and false information about acne (especially on social media platforms) • Provide a written handout with specific instructions https://pedsderm.net/site/assets/files/1028/1_spd_acne_short_web_final.pdf • Recommend additional reliable educational resources about acne and its treatment https://www.aad.org/public/diseases/acne www.webmd.com/skin-problems-and-treatments/acne/default.htm

Table 36.5 Tips for topical acne therapy.

creams, lotions, foams, solutions, and washes. Side effects of topical salicylic acid include erythema and scaling.

Niacinamide (nicotinamide) is a common ingredient in over-the-counter acne products. It can decrease sebum and increase ceramide production in the skin[85,86]. Although data on its efficacy for acne are limited, comparative studies have found nicotinamide 2% gel to be non-inferior to clindamycin 1% gel in the treatment of moderate acne[87].

Systemic Therapies

Antibiotics

First-line therapy for moderate to severe inflammatory acne includes use of oral tetracyclines, primarily doxycycline, minocycline, or sarecycline. Details regarding the mechanism of action, recommended dosages, and side effects of these antibiotics are reviewed in Chapter 127. Resistance of *C. acnes* to all the antibiotics used for acne has been documented and patterns vary significantly worldwide[88]. Acne management guidelines recommend that courses of oral antibiotics be limited to 3 to 4 months[71,77,89] and not be administered as monotherapy. In multiple clinical trials, combination of an oral antibiotic with a topical retinoid ± benzoyl peroxide resulted in greater improvement of acne than the antibiotic alone, and continuing these topicals after completion of the antibiotic course was found to be beneficial[71,90,91].

Tetracyclines suppress the growth of *C. acnes*, thereby reducing bacteria-mediated inflammation, and they have intrinsic anti-inflammatory properties via downregulation of proinflammatory cytokines (e.g. TNF, IL-1, IL-6)[92]. *Doxycycline* and *minocycline* are deemed equally effective in the treatment of the inflammatory component of moderate to severe acne[93]. Subantimicrobial doses of doxycycline (20 mg twice daily or 40 mg daily) have similar efficacy but fewer adverse effects than doxycycline 100 mg daily[94–96]. While doxycycline-related phototoxicity and gastrointestinal upset can be problematic, minocycline is associated with a higher incidence of serious adverse events, including a minocycline-induced hypersensitivity syndrome (see Ch. 21) and autoimmune reactions (hepatitis, lupus erythematosus-like syndrome, and cutaneous polyarteritis nodosa). As a result, some international guidelines recommend doxycycline over minocycline as the first-line oral antibiotic for acne[97–99]. *Sarecycline* has a narrower antimicrobial spectrum than other tetracycline derivatives and is approved for treatment of acne in patients ≥9 years of age[100].

Oral macrolide antibiotics, *erythromycin* and *azithromycin*, can be used for acne in patients who are unable to tolerate tetracyclines, pregnant, or <8 years of age. Although controlled studies have found that azithromycin has efficacy comparable to that of doxycycline[101], the high risk of bacterial resistance limits utilization of macrolides for acne. *Trimethoprim-sulfamethoxazole* may also be of benefit for acne, but its use is discouraged due to the greater risk of severe adverse reactions[71].

Hormonal therapy

Hormonal therapy can be an effective acne treatment for female patients, irrespective of their serum androgen levels. Combined oral contraceptive pills, which contain an estrogen (usually ethinyl estradiol) plus a progestin (variable), block both ovarian and adrenal production of androgens. A meta-analysis found that oral contraceptives, which are especially helpful for inflammatory acne, are equivalent to oral antibiotics in reducing the number of acne lesions after 6 months of therapy[102]. Most progestins have intrinsic androgenic activity, which is decreased in second-generation (e.g. ethynodiol diacetate, norethindrone, levonorgestrel) agents and even lower in third-generation agents (e.g. desogestrel, norgestimate, gestodene). Fourth-generation progestins (e.g. drospirenone, dienogest) and cyproterone acetate actually have *anti*androgenic properties.

Three oral contraceptives are currently FDA-approved for the treatment of acne, although others also have evidence of efficacy[103] (Table 36.6). Side effects from oral contraceptives include nausea, vomiting, abnormal menses, weight gain, and breast tenderness. Agents containing drospirenone have antimineralocorticoid properties (equivalent to ~25 mg of spironolactone) and can lead to elevations in serum potassium levels, but this is generally not clinically significant. While monitoring of serum potassium levels is not necessary in otherwise healthy individuals, it is recommended in patients with renal disease or those taking an angiotensin-converting enzyme (ACE) inhibitor, angiotensin-II receptor antagonist, potassium-sparing diuretic, potassium supplementation, heparin, aldosterone antagonist, or NSAID[104].

Rare but more serious complications from oral contraceptives include hypertension and thromboembolism (e.g. deep venous thrombosis, pulmonary embolism). The increase in risk of venous thromboembolism ranges from 2- to 4-fold with levonorgestrel or norethindrone to 3.5- to 7-fold with desogestrel, drospirenone, and cyproterone acetate; risk of thrombosis is greatest early on during treatment[105–107]. Overall the risk is highest for women over the age of 35 years, smokers, and those with other prothrombotic risk factors such as hereditary thrombophilia[108].

The antiandrogen *cyproterone acetate* is currently marketed in Europe and Canada but is not available in the US. Its anti-acne effects are mediated primarily through androgen receptor blockade. The standard contraceptive formulation combines cyproterone acetate (2 mg) with ethinyl estradiol (35 or 50 mcg). This preparation is widely used in Europe as the treatment of choice for sexually active women

ROLES OF COMMONLY USED CONTRACEPTIVES FOR ACNE	
Oral contraceptive®	**Estrogen mcg/progestin mcg**
FDA-approved as treatment for acne vulgaris	
Ortho Tri-Cyclen, Tri-Estarylla, Tri-Linyah, Tri-Sprintec, Tri-Previfem, Trinessa	Ethinyl estradiol 35/norgestimate 180, 215, 250
Estrostep, Tilia, Tri-Legest	Ethinyl estradiol 20, 30, 35/norethindrone 1000
Yaz, Gianvi, Jasmiel, Loryna, Lo-Zumandimine, Nikki, Vestura, Beyaz*	Ethinyl estradiol 20/drospirenone 3000
Clinical data to support use for acne (selected products)	
Alesse, Aubra, Aviane, Lutera, Orsythia, Vienva	Ethinyl estradiol 20/levonorgestrel 100
Diane-35†	Ethinyl estradiol 35/cyproterone acetate 2000
Yasmin, Ocella, Syeda, Zarah, Zumandimine, Safyral*	Ethinyl estradiol 30/drospirenone 3000
Natazia	Estradiol valerate 1000, 2000, 3000/dienogest 2000, 3000
May worsen acne	
Combined oral contraceptives containing more androgenic progestins (e.g. norgestrel, levonorgestrel)	
Progestin-only depot injections, subdermal implants, and progestin-containing intrauterine devices	

*Also contains levomefolate calcium for protection against neural tube defects.
†Not available in the US.

Table 36.6 Roles of commonly used contraceptives for acne.

Fig. 36.17 Cutaneous complications of isotretinoin therapy. **A** Impetigo in a patient treated with isotretinoin. Multiple serous crusts are evident. **B** Pyogenic granuloma-like healing on the chest of an adolescent boy on his third month of isotretinoin therapy. This is more likely to occur when isotretinoin therapy is started at a full dose rather than a lower initial dose, especially in teenage boys.

with hormonally responsive acne. Formulations of cyproterone acetate alone are also available. Approximately 75%–90% of patients treated with either the standard contraceptive formulation or higher doses of 50–100 mg daily (with or without ethinyl estradiol 50 mcg) show substantial improvement[109]. The most frequent side effects are breast tenderness, headache, nausea, and irregular menses; hepatotoxicity and thromboembolism represent uncommon complications.

Spironolactone functions as an androgen receptor blocker and, in doses of 50–100 mg twice daily, has been shown to reduce sebum production and improve acne[110,110a]. In two retrospective studies, 66% of women (261/395) and 23% of female adolescents (18/80) treated with spironolactone achieved ≥90% improvement in their acne[111,112]. Spironolactone side effects are dose-related and include irregular menstrual periods, breast tenderness, headache, and fatigue. These potential sequelae can be minimized if therapy is initiated at a low dose (25–50 mg/day). Hyperkalemia is rare and monitoring of potassium levels is not required in young healthy patients[113]. Although breast tumors have been reported in rodents given spironolactone, this drug has not been directly linked to the development of cancer in humans[114]. Because it is an antiandrogen, there is a risk of feminization of a male fetus if a pregnant woman takes this medication. As with other hormonal therapies, a clinical response may take 3–6 months. Effective maintenance doses range from 25 to 200 mg/day, and long-term use appears to be well-tolerated[115].

Flutamide, a nonsteroidal androgen receptor blocker approved by the FDA for the treatment of prostate cancer, may be of benefit for acne in women at doses of 62.5–500 mg/day. However, severe dose-related hepatotoxicity limits its use.

Isotretinoin

Since 1971, oral isotretinoin (13-*cis*-retinoic acid) has been available in Europe for the treatment of acne. In the US, it was FDA-approved in 1982 for patients with severe, nodulocystic acne refractory to treatment including oral antibiotics. Over time, other clinical forms of acne have also been shown to benefit greatly from the use of isotretinoin[116]. These include significant acne that is resistant to therapy (including oral antibiotics), relapses quickly, and/or results in scarring, as well as Gram-negative folliculitis, pyoderma faciale, and acne fulminans. The mechanism of action of isotretinoin, as well as dosing regimens, side effects and monitoring protocols, are discussed in detail in Chapter 126.

Isotretinoin is a highly effective acne therapy, with ≥95% of patients achieving a good clinical response after 20 weeks of treatment[117]. Standard isotretinoin dosing for acne is 0.5–1 mg/kg/day taken with a fatty meal to increase gastrointestinal absorption. One formulation, lidose–isotretinoin, can be taken without food[118]. Patients occasionally experience an initial acne flare, usually during the first month of treatment, with risk factors including macrocomedones and a higher starting dose[119,120]. Severe, isotretinoin-induced acne fulminans is a rare complication occurring more frequently in younger adolescent boys (Fig. 36.17; see above)[121]. Starting with a lower dose (≤0.5 mg/kg/day) during the first month of treatment reduces isotretinoin-induced flaring and allows the patient to adjust to dose-dependent side effects[122].

Reaching a cumulative isotretinoin dose of 120–150 mg/kg (e.g. 1 mg/kg/day × 4–5 months after an initial month of 0.5 mg/kg/day) has been shown to reduce the risk of acne relapse[123]. However, a 6-month course of lower-dose isotretinoin (e.g. 0.25–0.4 mg/kg/day [40–70 mg/kg cumulative]) can be effective in the treatment of moderate acne, with fewer side effects[124]. Some authors recommend treatment until 1–3 months after clearance of acne is achieved[124a]. Patients with PCOS and women with less severe acne are less likely to respond to isotretinoin, while male sex, young age, short treatment duration, and low

cumulative dose are associated with acne recurrence after isotretinoin therapy[123,125–127]. Maintenance with a topical retinoid ± benzoyl peroxide following completion of isotretinoin therapy may reduce the recurrence rate[127a]. Associated scarring and sinus tracts do not respond to isotretinoin but may improve with surgical modalities.

The most common adverse effects of isotretinoin involve the skin and mucous membranes and are dose-dependent. These include cheilitis, dryness of the oral and nasal mucosa, generalized xerosis, and skin fragility. Other cutaneous side effects such as excessive granulation tissue, paronychia, and cutaneous infections (in particular with *Staphylococcus aureus*) can also occur (see Fig. 36.17).

Teratogenicity is a serious potential complication (see Table 126.7), and female patients of childbearing potential must have at least one (two in the US) negative pregnancy test(s) before starting treatment and practice effective contraception for 1 month prior to, during, and for 1 month after completing therapy. In the US, prescription of isotretinoin requires physicians and patients to register with a pregnancy risk management program (iPLEDGE™), which mandates monthly office visits for all patients that include counseling not to share the medication as well as monthly pregnancy testing for patients with childbearing potential.

Isotretinoin therapy increases serum triglyceride and/or cholesterol levels in ~20%–50% of patients; however, severe elevations that require dose modification are rare and typically develop within the first two months of therapy[128,129]. Elevated serum creatine kinase levels and rhabdomyolysis have been reported in patients on isotretinoin and are more common in athletes[130]. Other potential side effects involve the musculoskeletal system (myalgias, low back pain), eyes, liver (occasional mild elevation in transaminases), and central nervous system (see Table 126.8 and Ch. 126). To date, no firmly established causal association with depression or suicide attempts has been demonstrated. Meta-analyses have not shown an association between isotretinoin treatment and increased risk of depression; instead, acne therapy led to a decreased prevalence of depression[131]. Current data do not support an association between isotretinoin and inflammatory bowel disease[132–134].

Surgical Treatment

Comedo extraction can improve the cosmetic appearance of acne and may aid in therapeutic responsiveness to topical comedolytic agents. The keratinous contents of open comedones can be expressed using a comedo extractor. The Schamberg, Unna, and Saalfield types of comedo expressers are most commonly used. Nicking the surface of a closed comedo with an 18-gauge needle or a #11 blade allows easier expression. Extraction is especially beneficial for deep, inspissated, and persistent comedones. This procedure should be used in conjunction with a topical retinoid or other comedolytic treatment for maximum benefit. Comedo extraction should not be performed on inflamed comedones or pustules because of the risk of scarring. Light electrocautery and electrofulguration (see Ch. 140) have also been reported as effective treatments for deep comedones. In selected patients, cryotherapy represents another surgical option for the treatment of comedonal acne (see Ch. 138).

Photodynamic therapy utilizing topical 5-aminolevulinic acid together with various light sources (e.g. blue, red, intense pulsed) or lasers (e.g. pulsed dye, 635 nm red diode) as well as methyl aminolevulinate plus red light have been successfully used to treat acne (see Ch. 135). In addition, blue or intense pulsed light alone and lasers such as the pulsed dye, the 1320 nm neodymium:YAG, and especially the 1450 nm diode may be of therapeutic benefit for inflammatory acne (see Ch. 137).

Intralesional injection of corticosteroid (triamcinolone acetonide 2 to 5 mg/ml, ~0.1 ml per lesion) can quickly improve the appearance and tenderness of deep, inflamed nodules and cysts. Larger cysts may require incision and drainage prior to injection. The risks of corticosteroid injections include hypopigmentation (particularly in darkly pigmented skin), atrophy, telangiectasias, and yellow–white dermal deposits of the medication.

Low-concentration chemical peels are also beneficial for the reduction of comedones. Common peeling agents include α-hydroxy acids (including glycolic acid), salicylic acid, and trichloroacetic acid. These lipid-soluble comedolytic agents act by decreasing corneocyte cohesion at the follicular opening and assist in comedo plug extrusion. Such agents are generally well tolerated by most skin colors and types, and they can be used by the patient at home or in the dermatologist's office. Higher-concentration glycolic acid peels (20%–70%, depending on the patient's skin type) and the less predictable phenol peel may also be performed in the office setting (see Ch. 154). Risks of chemical peels include irritation, pigmentary alteration, and scarring.

One of the most distressing consequences of acne vulgaris is scarring. Surgical treatments should be aimed at the type of scarring present. Laser resurfacing (fractionated as well as traditional), dermabrasion, and deeper chemical peels seek to reduce the variability of the skin surface and smooth out depressed scars that improve when the skin is stretched. For discrete depressed scars, soft tissue augmentation can be temporarily beneficial. Filler substances used include poly-L-lactic acid, calcium hydroxylapatite, and autologous fat (see Ch. 158). Surgical subcision is also used for management of acne scars and punch grafting is an option for patients with "ice-pick" scarring. For larger hypertrophic scars, aggregated pitted scars, and sinus tracts, full-thickness surgical excision may result in improved scar placement and a better cosmetic appearance.

eFig. 36.2 Pathways of C19 steroid metabolism. Dehydroepiandrosterone (DHEA) is a weak androgen that is converted to the more potent testosterone by 3β-hydroxysteroid dehydrogenase (HSD) and 17β-HSD. 5α-reductase then converts testosterone to dihydrotestosterone (DHT), the predominant hormonal effector on the sebaceous gland. Both DHEA and testosterone can be metabolized to estrogens by the enzyme aromatase. The sebaceous gland expresses each of these enzymes.

37 Rosacea and Related Disorders

Síona Ní Raghallaigh

INTRODUCTION

The term "*rosacea*" encompasses a constellation of clinical findings, with either fixed centrofacial erythema in a characteristic pattern that may periodically intensify or phymatous changes classified as diagnostic features[1,2]. Other common features are papules and pustules, flushing, telangiectasia, and ocular manifestations such as blepharitis and chalazia. Many patients report increased facial skin sensitivity and dryness, often identifying specific aggravating triggers. The progression of rosacea is variable and at times unpredictable, with sporadic periods of exacerbations and remissions. For some patients, the psychosocial impact of this disorder can be marked.

HISTORY AND EPIDEMIOLOGY

Robert Willan is credited with the earliest medical descriptions of "acne rosacea" in the early 1800s, focusing on the papulopustular presentation. Nonetheless, estimating the true prevalence of rosacea has been limited over the years by discrepancies in disease definition, diagnostic methods, and study populations. Although some epidemiologic studies have reported a prevalence of 10% or higher in White adults[2], a systematic review of 32 studies examining 41 populations found a global adult prevalence of 5.5%[3]. In previous studies, women were observed to be affected by rosacea more often than men[4], but this systematic review found that rosacea affected both sexes equally. Notably, phymatous rosacea is rare in women.

Rosacea occurs primarily in adults older than 30 years of age, with the highest prevalence in individuals aged 45–60 years. While rosacea is rare in children, rosacea-like conditions such as periorificial dermatitis and steroid-induced rosacea are relatively common. Although described as a disease that predominantly affects individuals of Northern European descent with skin phototypes I and II[5], rosacea is likely underdiagnosed in individuals with darker skin phototypes in whom flushing, telangiectasia, and erythema are less perceptible[6].

Systemic comorbidities that may be associated with rosacea include inflammatory bowel disease, neurologic disorders (e.g. migraine, Alzheimer disease), and autoimmune diseases (e.g. multiple sclerosis, rheumatoid arthritis)[7]. A possible explanation is shared genetic, environmental, and/or pathophysiologic factors but further investigations are needed.

PATHOGENESIS

Several different but interrelated pathomechanisms have been proposed for rosacea (Fig. 37.1), with predominant pathways reflecting clinical features.

Genetic Factors

Rosacea is more common in individuals of Northern European descent and concordance in monozygotic twins has been demonstrated. A genome-wide association study identified two single-nucleotide polymorphisms and three HLA alleles associated with rosacea[8].

Dysregulated Cutaneous Immunity

Dysregulation of the cutaneous innate immune system can lead to abnormal inflammatory responses to environmental stimuli and commensal microorganisms. Triggering this innate immune system leads to the release of antimicrobial peptides such as cathelicidin (LL-37). After LL-37 propeptide is secreted by keratinocytes and other epithelial cells, it is cleaved into its active form by proteases (e.g. kallikrein-5). Active cathelicidin peptides then induce both proinflammatory and angiogenic activity. In the facial skin of individuals with rosacea, there are abnormally high levels of LL-37 (see Fig. 37.1)[9]. Also, LL-37 has been shown to contribute to inflammation via activation of the NLRP3 inflammasome (see Fig. 4.2)[10].

Toll-like receptors (TLRs) are pathogen-associated molecular pattern sensors that are involved in cutaneous innate immunity (see Fig. 4.1). In rosacea, keratinocytes express elevated levels of TLR2, leading to increased expression and activity of kallikrein proteases and thus cathelicidins[11]. In addition, matrix metalloproteinases, which activate kallikrein 5, are up-regulated in patients with rosacea[12]. Mast cells, which also release cathelicidin, are increased in number within the dermis of rosacea patients[13]. Lastly, in addition to dysregulated innate immunity, an abnormal adaptive immune response has been observed in rosacea, with Th1/Th17 polarized inflammation and macrophage infiltration[14].

Neurogenic Inflammation

Patients with rosacea often report sensations of stinging or burning of their skin, with affected individuals exhibiting lower heat pain thresholds when compared to controls[15]. When cutaneous nerve endings expressing transient receptor potential vanilloid (TRPV) cation channels are stimulated by trigger factors (e.g. spicy food, heat, alcohol), this can lead to dysesthesia, flushing, and erythema[16]. Heightened TRPV activity has been detected in the skin of rosacea patients and it leads to neurogenic inflammation, i.e. an inflammatory response induced by sensory nerves in which neuromediators are released at the site of inflammation. These neuromediators can result in vasodilation, extravasation of plasma proteins, and recruitment of inflammatory cells (see Fig. 37.1).

Vascular Alterations

Several clinical features of rosacea, including transient erythema, persistent centrofacial erythema, telangiectasias and flushing, point to the role the vascular system plays in its pathogenesis. An increase in blood flow within skin lesions of rosacea has been demonstrated[17], and patients with rosacea flush more readily in response to heat. Histopathologic studies of lesional skin found an elevated expression of vascular endothelial growth factor (VEGF), CD31, and the lymphatic endothelial marker podoplanin (D2-40), implying increased stimulation of vascular and lymphatic endothelial cells[18].

Ultraviolet Radiation (UVR)

Exposure to UVB can induce angiogenesis and increase secretion of angiogenic factors (e.g. VEGF) from keratinocytes[19]. UVR also induces production of reactive oxygen species, which upregulate matrix metalloproteinases that lead to vascular and dermal matrix damage[20]. Although clinically the erythema and telangiectasias of rosacea can resemble telangiectatic photoaging, a case–control observational study provided evidence that they are distinct entities[21], but as expected can overlap.

Epidermal Barrier Dysfunction

Several clinical features of rosacea imply skin barrier dysfunction. Rosacea patients often report facial dryness, and studies have confirmed a lowered threshold for skin irritancy[22]. In rosacea skin, there is increased transepidermal water loss, a marker of epidermal barrier dysfunction. It has been suggested that disruption or abnormalities of the stratum corneum allow penetration of sensory irritants[23]. In addition, patients with papulopustular rosacea have an abnormal skin surface fatty acid

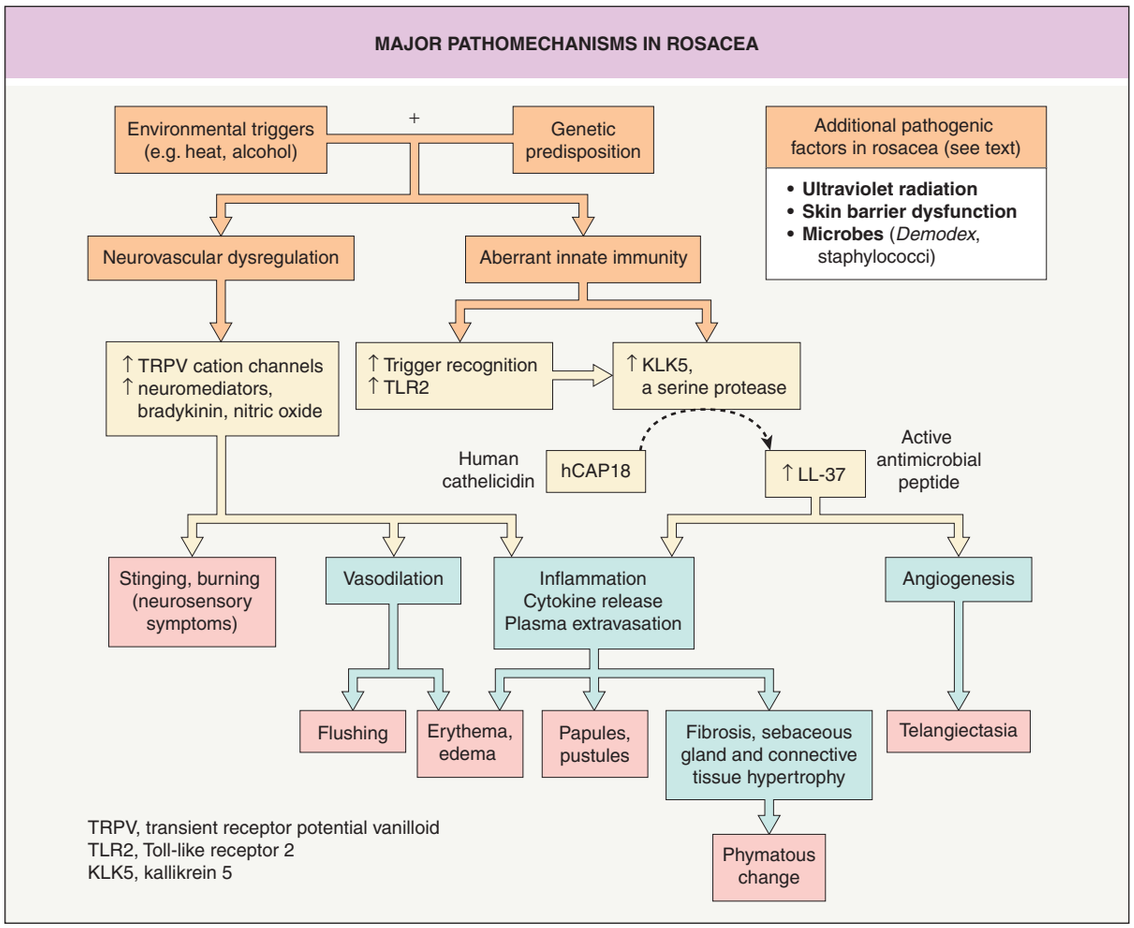

Fig. 37.1 Major pathomechanisms in rosacea. In genetically predisposed individuals (e.g. HLA-DRB1*03:01, HLA-DQA1*05:01, HLA-DQB1*02:01, SNP rs763035), environmental factors can trigger neurovascular dysregulation and an aberrant innate immune response, both of which can lead to cutaneous inflammation, including the clinical manifestations of rosacea. *Adapted from Steinhoff M, Buddenkotte J, Aubert J, et al. Clinical, cellular, and molecular aspects in the pathophysiology of rosacea. J Invest Dermatol Symp Proc. 2011;15:2–11.*

profile[24] as well as reduced epidermal hydration levels. The latter have been shown to improve following treatment with minocycline and resolution of inflammatory lesions[25].

Microorganisms

Demodex mites (*folliculorum* and *brevis*) are normally present on the face as commensal microbes, but in rosacea, greater numbers of these mites are detected by skin surface biopsy techniques[26,27]. In routine histologic sections, the mites often appear prominently within pilosebaceous follicles, and follicular infestation with multiple mites can be associated with an intense perifollicular infiltrate of predominantly CD4 T helper cells[28]. In addition, antigenic proteins from a bacterium (*Bacillus oleronius*) isolated from *Demodex* mites can stimulate inflammation in patients with papulopustular rosacea[29]. It has been suggested that *Demodex* mites and their associated bacteria upregulate local proteases, thereby potentiating dysregulation of the cutaneous innate immune response (see above)[30].

Study results differ as to whether *Helicobacter pylori* infection of the upper gastrointestinal tract plays a role in the pathogenesis of rosacea. A meta-analysis of 14 observational studies did not find statistically significant associations between either *H. pylori* infection and rosacea or *H. pylori* eradication therapy and symptomatic improvement of rosacea[31].

CLINICAL FEATURES

In 2002, a classification scheme divided rosacea into four main subtypes – erythematotelangiectatic, papulopustular, phymatous, and ocular – based upon the predominant lesion morphology[32]. However, it did not account for the frequent co-occurrence of more than one subtype nor the potential progression of one subtype to another. Recognizing these potential shortcomings, a revised classification of rosacea was recommended by the global ROSacea COnsensus (ROSCO) panel in 2016 and by the National Rosacea Society Expert Committee in 2017 (Table 37.1)[1,2].

PHENOTYPIC CLASSIFICATION OF ROSACEA (2017)
Diagnostic phenotypes
Fixed centrofacial erythema in a characteristic pattern that may periodically intensify
Phymatous changes
Major phenotypes
Papules and pustules
Flushing
Telangiectasia
Ocular manifestations*
Secondary signs and symptoms
Burning or stinging
Facial edema
Dry appearance of the skin
Ocular manifestations†
*Lid margin telangiectasia, interpalpebral conjunctival injection, spade-shaped infiltrates in the cornea, scleritis and sclerokeratitis. †Honey-crust and collarette accumulation at the base of the lashes, irregularity of the lid margin, evaporative tear dysfunction (rapid tear breakup time).

Table 37.1 Phenotypic classification of rosacea (2017). A diagnosis of rosacea may be considered in the presence of at least one diagnostic or two major phenotypes. Secondary signs and symptoms may appear concomitantly with one or more diagnostic or major phenotypes. *Adapted from Tan J, Almeida LM, Bewley A, et al. Updating the diagnosis, classification and assessment of rosacea: recommendations from the global ROSacea COnsensus (ROSCO) panel. Br J Dermatol. 2017;176:431–8; and Gallo RL, Granstein RD, Kang S, et al. Standard classification and pathophysiology of rosacea: the 2017 update by the National Rosacea Society Expert Committee. J Am Acad Dermatol 2018;78:148–55.*

Both groups agreed that either one of the following two phenotypes are diagnostic of rosacea: (1) fixed centrofacial erythema in a characteristic pattern that may periodically intensify; and (2) phymatous changes. They also concluded that in the absence of one of these two *diagnostic phenotypes*, the presence of two or more of the following four *major phenotypes* can be diagnostic: (1) papules and pustules; (2) flushing; (3) telangiectasia; and (4) ocular manifestations. Secondary signs and symptoms that may also occur in conjunction with one or more diagnostic or major phenotypes include burning and stinging, facial edema, dry appearance of the skin, and other ocular manifestations.

Diagnostic Phenotypes (Table 37.2)

Fixed centrofacial erythema in a characteristic pattern that may periodically intensify

Persistent erythema of the central face is the most common presentation of rosacea in patients with skin phototypes I–III (Fig. 37.2). Of note, it may be more difficult to appreciate in darker skin phototypes. In addition, it can be challenging to differentiate from telangiectatic photoaging, although there are relative differences (see Table 37.4)[21]. In addition, other entities that can cause persistent facial erythema should be considered, e.g. lupus erythematosus, seborrheic dermatitis.

Fig. 37.2 Fixed facial erythema due to rosacea. There was greater involvement of the medial cheek. *Courtesy Frank C. Powell, MD.*

CLINICAL FEATURES AND MANAGEMENT OF ROSACEA

Predominant phenotype	Predominant clinical features	Severity		Management
		Grade	Features	
Erythema and telangiectasia (formerly termed erythematotelangiectatic)	• Persistent centrofacial erythema • Flushing • Telangiectasia • Skin sensitivity	1	Occasional mild flushing; faint persistent centrofacial erythema; few telangiectasias	• General recommendations for facial skin care (see Table 37.5) • Reduce flushing • Minimize irritation • Topical treatments used in papulopustular rosacea may cause irritation • Laser therapy of prominent blood vessels in grades 2 and 3 disease
		2	Frequent troublesome flushing; moderate persistent centrofacial erythema; several distinct telangiectasias	
		3	Frequent severe flushing; pronounced persistent centrofacial erythema; many prominent telangiectasias; possible edema	
Papules and pustules (previously termed papulopustular)	• Persistent centrofacial erythema • Papules • Pustules/papulopustules • Overlap with other subtypes may occur	1	Few papules and/or papulopustules; mild persistent centrofacial erythema	• Topical or systemic medications for grades 1 and 2 disease • Systemic medications for grade 3 • May require repeated courses or gradual taper
		2	Several papules and/or papulopustules; moderate persistent centrofacial erythema	
		3	Extensive papules and/or papulopustules; pronounced persistent centrofacial erythema; inflammatory plaques or edema may be present	
Phymatous	• Thickened, nodular skin • Prominent pores • Can affect nose (rhinophyma), chin (gnathophyma), forehead (metophyma), ears (otophyma), eyelids (blepharophyma) • May be associated with other features of rosacea or occur in isolation	1	Puffiness; mildly patulous follicles; no clinically apparent hypertrophy of connective tissue or sebaceous glands; no change in contour	• Surgical or laser therapy for grades 2 and 3 rhinophyma • Other phymas are more difficult to treat but may improve with systemic treatments, if an inflammatory component is present
		2	Moderate swelling; moderately dilated patulous follicles; clinically, mild hypertrophy of the sebaceous glands or connective tissue; change in nasal contour without nodular component	
		3	Marked swelling; large dilated follicles; distortion of contour due to hypertrophy of the sebaceous glands and/or connective tissue, with a nodular component	
Ocular	• Dry, gritty sensation • Blepharitis • Conjunctivitis • Chalazia and hordeola • Keratitis, episcleritis, scleritis, iritis (rare)	1	Mild itch, dryness, or grittiness; fine scaling of eyelid margins; telangiectasia of eyelid margins; mild conjunctival injection	• Topical medications for grade 1 • Systemic medications for grade 2 • Refer to ophthalmologist for persistent grade 1 or 2 disease or suspected grade 3 disease
		2	Burning or stinging; crusting, irregularity, erythema and/or edema of eyelid margins; definite conjunctival injection; chalazion or hordeolum	
		3	Pain, photosensitivity, blurred vision; severe eyelid changes with loss of lashes, severe conjunctival inflammation; corneal changes, with potential loss of vision; episcleritis, scleritis; iritis	

Table 37.2 Clinical features and management of rosacea. *Adapted from Pelle MT, Crawford GH, James WD. Rosacea: II. Therapy. J Am Acad Dermatol 2004;51:499–512.*

Fig. 37.3 Rhinophyma. Hypertrophy of sebaceous glands and connective tissue as well as patulous follicles are seen. The changes are more prominent in the mid to lower nose. In addition, there is evidence of papulopustular rosacea. *Courtesy Kalman Watsky, MD.*

Fig. 37.4 Tortuous, telangiectatic vessels on the distal aspect of the nose contribute to its hyperemic appearance. This hyperemia may predispose to the subsequent hypertrophic changes of rhinophyma. Note the early sign of patulous follicles ("dilated pores"). *Courtesy Frank C. Powell, MD.*

TYPES OF PHYMATOUS ROSACEA	
Phyma	**Clinical features**
Rhinophyma	• Apparent initially as dilated patulous follicles at the distal end of the nose • When marked, can lead to debilitating nasal deformity
Gnathophyma	• Rare occurrence, with central chin typically involved • May give rise to asymmetrical swelling
Otophyma	• Usually affects the lower half of the helices and lobes of the ears
Metophyma	• Cushion-like, firm swelling of central forehead
Blepharophyma	• Swelling of the eyelids • Usually seen as a component of edematous rosacea but may accompany severe papulopustular or ocular rosacea

Table 37.3 Types of phymatous rosacea.

Fig. 37.5 Moderate papulopustular rosacea of the forehead. Note the superficial nature of the inflammatory lesions. *Courtesy Frank C. Powell, MD.*

Phymatous changes

These changes include sebaceous gland hypertrophy, patulous follicles, a bulbous appearance on the distal portion of the nose, and eventual fibrosis. Rhinophyma is by far the most common clinical presentation, occurring primarily in men (Fig. 37.3). Involvement of other anatomic sites has been reported, but it is rare (Table 37.3). Patients with rhinophyma may have other features of rosacea, usually mild to moderately severe papules and pustules. However, phymatous changes may arise *de novo* without any preceding skin changes and therefore should not be viewed as "end-stage rosacea"[33].

The earliest clinical sign of rhinophyma is the appearance of patulous follicles on the distal portions of the nose. It has been suggested that telangiectatic vessels in this same location may predispose to hypertrophic changes (Fig. 37.4). In severe cases of rhinophyma, the tissue hypertrophy leads to nasal distortion, with soft fleshy nodular growths resulting in significant disfigurement. Although basal cell carcinomas have been reported to arise in skin affected by rhinophyma, there is insufficient evidence to suggest that this condition predisposes to malignant change.

Major Phenotypes

Papules and pustules

Patients typically have a centrofacial eruption of multiple small (<3 mm), dome-shaped, erythematous papules and/or pustules that appear singly or in crops (Fig. 37.5 & 37.6). Individual lesions last about two weeks and are then replaced by blotchy postinflammatory erythema which gradually fades. Residual scarring is not a feature of papulopustular rosacea. A halo of erythema may surround larger inflammatory lesions and tiny telangiectatic vessels may be visible within this rim. Occasionally, when there is more severe disease, scaling or superficial crusting may be seen and this has been referred to as rosacea dermatitis (Fig. 37.7). Lastly, some patients will have some degree of persistent erythema of the cheeks that may represent a combination of postinflammatory erythema, telangiectasias, and vasodilation.

Flushing

Frequent flushing and blushing are common in patients with rosacea and occur in response to neurostimulation by various triggers (e.g. heat, alcohol consumption, certain social situations). Although quite noticeable in skin phototypes I–IV, flushing may be less visible in darker phototypes but rather experienced as a sensation of increasing warmth in the face. In addition, when patients complain of significant flushing, other causes of flushing should be considered as outlined in Tables 106.2 & 106.3.

Telangiectasia

Telangiectasias are common and involve primarily the central face, including the chin, in patients with lighter skin phototypes. They need to be distinguished from telangiectatic photoaging (see Table 37.4) and are less common as well as less perceptible in individuals with darker skin phototypes.

Fig. 37.6 Papulopustular rosacea – spectrum of severity in different skin phototypes. A Mild disease with scattered lesions on the cheek. **B** Moderate disease with increased number of lesions and areas of background erythema. **C** Severe disease with characteristic centrofacial distribution. Note the associated xerotic scale. *A, B, Courtesy Kalman Watsky, MD.*

Fig. 37.7 Rosacea dermatitis. When there is more severe disease, scaling and superficial crusting may be seen as on the cheek of this woman. *Courtesy Kalman Watsky, MD.*

Fig. 37.8 Inflammatory rosacea with edematous changes. An intensely erythematous plaque is present on the medial aspect of the cheek. This may improve once the underlying inflammation is treated appropriately. *Courtesy Frank C. Powell, MD.*

Ocular manifestations

Ocular manifestations of rosacea are discussed below.

Secondary Signs and Symptoms

Burning and stinging

Burning and stinging of the facial skin is a common complaint in patients with rosacea while pruritus is unusual. These sensations often occur within a background of erythema and sometimes scale. Patients also report significant sensitivity to and irritation from many products that are applied to the skin.

Facial edema

Facial edema may occur along with or result from prolonged erythema or flushing of the face and is thought to develop from post-capillary extravasation due to inflammation[2]. The soft edematous changes that are sometimes seen in patients with severe inflammatory rosacea (Fig. 37.8) should not be confused with phymatous rosacea. Such changes, unlike those of phymatous rosacea, often improve following successful management of the inflammatory lesions. Solid facial edema is discussed below.

Dry appearance

The centrofacial skin may sometimes appear dry and scaly, almost resembling a type of eczematous dermatitis. Such a presentation is often accompanied by burning and stinging sensations as well as significant sensitivity to topical products. When present, consideration should be given to the concomitant diagnosis of seborrheic dermatitis, which often coexists (see Table 37.4).

Other ocular manifestations

Ocular manifestations of rosacea are discussed below.

Other Clinical Rosacea Presentations

Ocular rosacea

This entity may or may not be accompanied by cutaneous changes of rosacea. Without cutaneous manifestations, the diagnosis of ocular

Fig. 37.9 Ocular rosacea. A Tiny concretions of keratin (conical dandruff) are visible at the bases of some of the eyelashes of the lower eyelid. There is also evidence of blepharitis of the lower eyelid and conjunctival injection. **B** Erythema of the mucosal portion of the lower eyelid and ectropion. **C** Marked injection of the conjunctivae, leading to the appearance of red eyes. Ectropion is also present. *A, Courtesy Frank C. Powell, MD.*

rosacea can be difficult to establish with certainty (Fig. 37.9). Symptoms are often nonspecific and include dryness, a gritty sensation, an inability to wear contact lenses, tearing, and sometimes pruritus. Patients usually do not associate these ocular symptoms with their rosacea and may not volunteer such information unless specifically asked.

Signs that strongly suggest a diagnosis of ocular rosacea include eyelid margin telangiectasias, interpalpebral conjunctival injection, and on slit lamp examination, corneal spade-shaped infiltrates, scleritis, and sclerokeratitis (see Table 37.1)[2]. Other common, but less specific, signs include honey crusting and mild scaling of the eyelid margin, tiny concretions at the bases of the lashes (conical dandruff; see Fig. 37.9A), and irregularity of the eyelid margin. When the disease is more active, there is evidence of blepharitis, often with eyelid swelling and conjunctival injection (see Fig. 37.9C). Cysts arising from the meibomian glands (chalazia) present as firm non-tender swellings of the cutaneous tarsal surface, while hordeola (styes) are often painful. Severe ocular disease (e.g. keratitis, corneal neovascularization, uveitis, scleritis, iritis) is rarely seen in patients with rosacea.

Granulomatous rosacea

In *granulomatous rosacea*, there are monomorphic, persistent, skin-colored to dull red–brown facial papules that are dome-shaped, favor the central face, and usually measure 1–3 mm in diameter (Fig. 37.10). This variant occurs in both children and adults and it may resolve spontaneously a few years after lesions first appear and not recur. Extrafacial lesions (e.g. on the scalp, neck, and upper trunk) are seen more often with the granulomatous variant. Histologically, non-caseating epithelioid granulomas are present within the dermis (see Pathology).

Some authors consider *lupus miliaris disseminatus faciei* (LMDF) to be a severe form of granulomatous rosacea[34], with a predilection for the periocular region (as well as the central face) and an "apple-jelly" appearance on diascopy. However, the dermal granulomas seen in biopsy specimens often have central caseation necrosis, thus explaining why this disorder was initially considered a tuberculid. More recently, *facial idiopathic granulomas with regressive evolution* (FIGURE) was proposed as an alternative term for LMDF. Unfortunately, significant facial scarring can be a permanent sequela. Occasionally, there is extrafacial involvement, which may be confused with other granulomatous

Fig. 37.10 Granulomatous rosacea, lupus miliaris disseminatus faciei variant. Monomorphous, discrete skin-colored to brown papules scattered on the face that are more persistent than the lesions of papulopustular rosacea. Histologically, granulomas with central caseation necrosis were observed, which led to the diagnosis of lupus miliaris disseminatus faciei.

diseases such as sarcoidosis, cutaneous tuberculosis, or the necrobiotic form of granuloma annulare.

Some authors consider both *rosacea conglobata*, which is characterized by an eruption of inflammatory cystic lesions that heal with scarring, and *rosacea fulminans* (pyoderma faciale) to be within the rosacea spectrum. In rosacea fulminans, an explosive onset of inflammatory papules and pustules is superimposed on a background of facial erythema, usually occurring in young women and sometimes during pregnancy[35].

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for each of the diagnostic and major phenotypic subtypes of rosacea are outlined in Table 37.4.

PATHOLOGY

Histopathologic changes in erythematous and telangiectatic rosacea may be subtle and are often limited to vascular ectasia and mild edema (Fig. 37.11A). In the inflammatory papules and pustules, a more prominent perivascular and perifollicular lymphohistiocytic infiltrate appears (Fig. 37.11B). Sebaceous hyperplasia may be prominent in some patients. Comedo formation is notably lacking. In the granulomatous form of rosacea, non-caseating epithelioid granulomas are seen within the dermis (Fig. 37.11C). Phymatous rosacea shows dilated hair follicles, marked hyperplasia of sebaceous glands, and a variably dense lymphohistiocytic inflammatory infiltrate.

TREATMENT

General skin care recommendations for all rosacea patients are outlined in Table 37.5 and they represent an important component of the overall therapeutic regimen[36,37]. Currently available treatment options for the various subtypes of rosacea are listed in Table 37.6[38,39]. Grading the predominant features of rosacea into mild, moderate, and severe (grades 1–3) assists in guiding initial therapeutic interventions and in monitoring the clinical response (see Table 37.2)[40]. At the initial consultation, the patient should be made aware of the chronic relapsing nature of rosacea and the need for maintenance therapy even when in remission[5].

Transient and Persistent Erythema and Telangiectasia

A skin care regimen aimed at reducing skin sensitivity and improving epidermal barrier function is particularly important in these patients (see Table 37.5). In addition, strict photoprotection is advised, as UV exposure may potentiate dermal matrix and vascular damage. Topical application of vasoconstrictive adrenergic agonists, such as brimonidine (selective α_2) or oxymetazoline (selective α_{1A} and partial α_2), may help to diminish persistent erythema[41,42]. Patients should be instructed on the proper application of these agents and informed of side effects including rebound erythema, a burning sensation, and irritant contact dermatitis.

Topical antibiotics such as metronidazole may reduce erythema in a select group of patients, but they can cause irritation (see Table 37.6).

DIFFERENTIAL DIAGNOSIS OF ROSACEA	
Rosacea phenotype and differential diagnosis	**Distinguishing feature(s) from rosacea**
Erythema and telangiectasia (previously termed erythematotelangiectatic)	
Actinic damage (telangiectatic photoaging)	• Also characterized by facial telangiectasias and erythema, but the latter favors the lateral more than the central face • There tends to be less transient and non-transient erythema • Some patients have both disorders
Seborrheic dermatitis	• Erythema with greasy scale in the eyebrows, nasolabial folds, auditory meatus, retroauricular sulcus, and scalp • Involvement of eyelid creases • Patients often have both disorders
Keratosis pilaris rubra	• Onset usually during adolescence • Background erythema of the lateral cheeks with superimposed tiny follicular papules
Acute cutaneous lupus erythematosus	• Absence of inflammatory papulopustules and ocular changes • At least 75%–80% of patients have systemic signs/symptoms of SLE • Often more well-demarcated edematous plaques with sparing of the nasolabial fold
Dermatomyositis	• Violaceous erythema that favors the eyelids and central face, including the nasolabial folds • Eyelid edema can be pronounced
Flushing (idiopathic or secondary)	• Intermittent erythema and warmth • Flushing in patients with rosacea is usually limited to the face • Consider other common etiologies (e.g. menopause, anxiety disorder) or a tumor-related phenomenon (carcinoid syndrome, occult pheochromocytoma, mastocytosis) when additional anatomic sites are involved or there are associated symptoms such as tachycardia and sweating
Papules and pustules (previously termed papulopustular)	
Acne (vulgaris)	• Onset at a younger age • Comedones, both open and closed, and cysts • Greater involvement of the upper trunk
Periorificial dermatitis and steroid-induced rosacea	• See text
Demodicosis	• Spectrum includes *Demodex* folliculitis (see Ch. 38) and pityriasis folliculorum (see text) • Patients may be immunosuppressed (HIV infection, leukemia) • Involves face, especially the nose, and upper chest • Responds to topical ivermectin or permethrin ± oral ivermectin or metronidazole (see Table 38.1)
Tinea incognito, candidiasis	• Both can mimic rosacea, especially if topical corticosteroids have been used • KOH examination demonstrates hyphae or budding yeasts
Acneiform (papulopustular) eruptions due to EGFR inhibitors and other targeted therapies (e.g. MEK inhibitors, HER2 inhibitors)	• Occurs in up to 90% of patients on these drugs (see Fig. 37.15) • Abrupt onset • May also involve scalp, neck, and trunk
Follicular mucinosis	• Multiple papules but not pustules • Erythematous plaques and alopecia
Ocular rosacea	
Seborrheic dermatitis	• Involvement beyond the eyelid margin; may be accentuated in the eyelid creases
Drug-induced ocular rosacea	• Eyedrops used to treat other ocular disorders, e.g. glaucoma
Phymatous rosacea	
Lupus pernio (sarcoidosis)	• Violaceous indurated plaque of the distal nose
Discoid lupus erythematosus	• Erythema, scaling, follicular plugging, and tendency for scarring
Lupus vulgaris (cutaneous TB)	• See Table 75.7
Neoplasms	• Basal cell carcinoma, lymphoma, angiosarcoma, cutaneous metastases (“clown nose”)

Table 37.4 Differential diagnosis of rosacea. Occasionally, trichostasis spinulosa has associated erythema, but detection of multiple hairs within the follicular orifice by dermoscopy or microscopic examination of follicular contents establishes the diagnosis. EGFR, epidermal growth factor receptor; HER2, human epidermal growth factor receptor 2; MEK, mitogen-activated protein kinase kinase; SLE, systemic lupus erythematosus; TB, tuberculosis.

Use of nonselective β-blockers (e.g. propranolol, carvedilol) to treat rosacea-associated flushing can be beneficial in selected individuals. Laser therapy (e.g. pulsed dye, potassium titanyl phosphate) and intense pulsed light can be used to ameliorate telangiectasias and improve erythema (see Ch. 137).

Papules and Pustules

In general, patients with inflammatory papules and pustules are treated with topical and/or systemic antibiotics (see Table 37.6)[43]. Although many of the antibiotics used to treat these lesions are the same as those used for acne vulgaris, the treatment course for rosacea is usually shorter (4–8 weeks as opposed to 3–4 months) and subantimicrobial doses may be effective. Sometimes successful treatment of the papulopustules may unmask background telangiectasias which then need to be addressed. Following successful clearance of inflammatory lesions, maintenance therapy (usually topical) should be instituted to avoid a likely relapse. Many patients with moderate and severe (grades 2 and 3) disease require repeated courses of systemic antibiotic therapy, but subsequent courses can often be shorter in duration, i.e. 3 to 4 weeks.

Topical ivermectin, which has both anti-inflammatory and antiparasitic properties, has become an important first-line therapy, as are

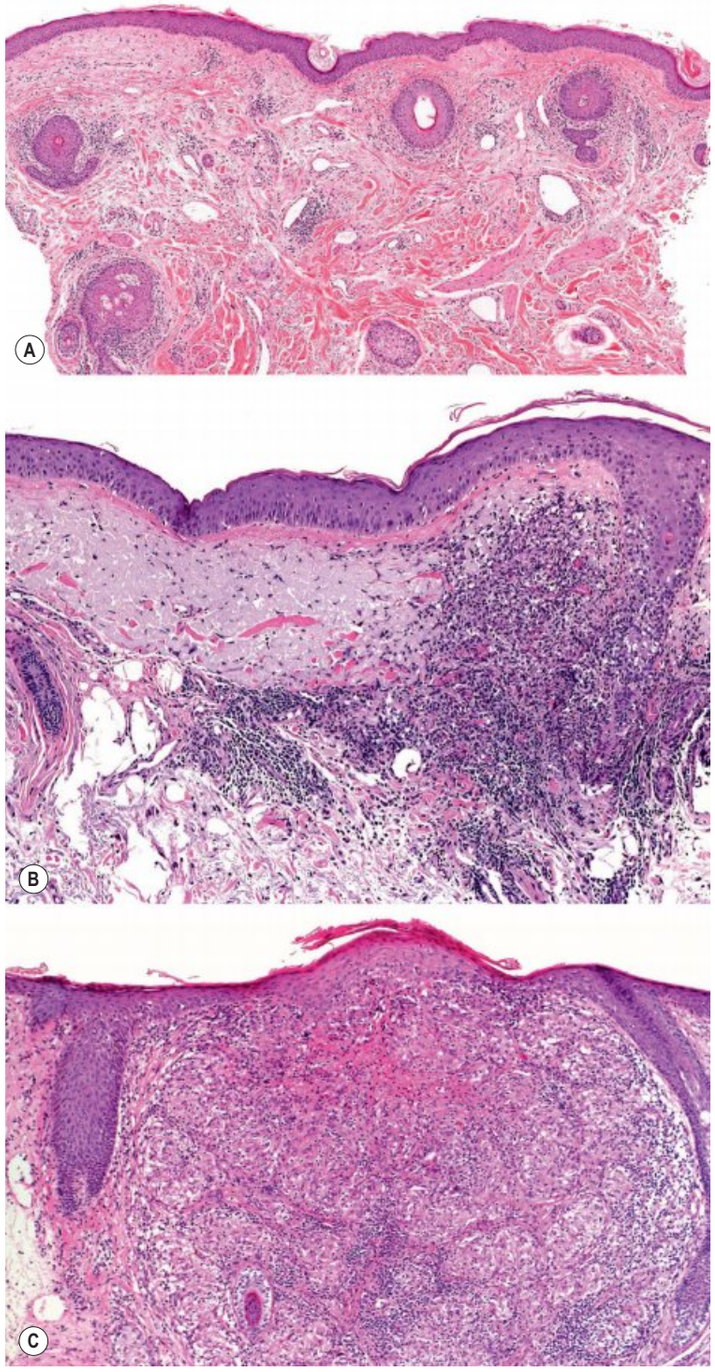

Fig. 37.11 Rosacea – range of histopathologic features. A *Erythema and telangiectasia* subtype with multiple dilated blood vessels as well as minimal perifollicular and perivascular lymphocytic infiltrates. **B** *Papules and pustules* subtype with a dense dermal infiltrate of lymphocytes, predominantly surrounding an involved hair follicle. There is also marked solar elastosis. **C** *Granulomatous variant* of rosacea with a nodular granulomatous infiltrate composed of histiocytes, histiocytic giant cells, and admixed lymphocytes filling the upper interfollicular dermis. *Courtesy Lorenzo Cerroni, MD.*

GENERAL RECOMMENDATIONS FOR FACIAL SKIN CARE AND EDUCATION IN PATIENTS WITH ROSACEA
Facial skin care
• Wash with lukewarm water and use soap-free cleansers or synthetic detergents (syndets) that are pH balanced • Cleansers are applied gently with fingertips • Use sunscreens with both UVA and UVB protection and an SPF ≥30 • Sunscreens containing the inorganic filters titanium dioxide and/or zinc oxide are usually well tolerated • Use cosmetics and sunscreens that contain protective silicones • Water-soluble facial powder containing inert green pigment helps to neutralize the perception of erythema • Moisturizers containing humectants (e.g. glycerin) and occlusives (e.g. petrolatum) help to repair the epidermal barrier • Avoid astringents, toners, and abrasive exfoliators • Avoid cosmetics that contain alcohol, menthols, camphor, witch hazel, fragrance, peppermint, and eucalyptus oil • Avoid waterproof cosmetics and heavy foundations that are difficult to remove without irritating solvents or physical scrubbing • Avoid procedures such as glycolic peels or dermabrasion
Patient education
• Reassure the patient about the benign nature of the disorder and the rarity of rhinophyma, particularly in women • Emphasize the chronicity of the disease and the likelihood of exacerbations • Direct patients to information websites such as those of the National Rosacea Society (www.rosacea.org) or the American Academy of Dermatology (www.aad.org) • Advise avoidance of recognized triggers • Explain the importance of compliance with topical regimens • Educate on the importance of sun avoidance

Table 37.5 General recommendations for facial skin care and education in patients with rosacea.

topical metronidazole and azelaic acid[44]. Other topical agents include sodium sulfacetamide +/− sulfur, minocycline[45], clindamycin, benzoyl peroxide[46], retinoids, and permethrin. Low-dose isotretinoin[47] and photodynamic therapy[48] are treatment options in patients whose lesions prove resistant to first-line therapies.

Other Forms of Rosacea

Rhinophyma is the type of phymatous rosacea most amenable to treatment (see Table 37.6). Mild disease may be responsive to low-dose isotretinoin, although conclusive evidence of efficacy is lacking. More severe (grades 2 and 3) disease responds best to physical modalities such as CO_2 laser therapy, electrosurgery, or surgical excision (see Fig. 140.7). Longitudinal evaluation of patients treated with CO_2 laser therapy suggests that improvement persists long-term[49]. Other sites of phymatous rosacea are very rare and there are no established therapeutic interventions.

Ocular rosacea is a common entity that is frequently underdiagnosed[50]. Patients with mild ocular rosacea (grade 1 disease) often respond to washing of the eyelid margins with gauze soaked with dilute, tear-free baby shampoo. This is combined with an oily tear replacement. Burning or stinging with crusting of the eyelid margins or the formation of a chalazion or hordeolum are manifestations of moderate (grade 2) disease and treatment consists of topical and/or systemic antibiotics (see Table 37.6). Pain, photophobia, and visual disturbances are features of severe (grade 3) disease. Such symptoms require prompt referral to an ophthalmologist.

Granulomatous rosacea is difficult to treat, and no consensus exists regarding first-line therapies. Anecdotally, options include dapsone, minocycline, isotretinoin, hydroxychloroquine, and the 1450-nm diode laser. Anecdotally, apremilast has been reported to improve LMDF.

While some authors consider *rosacea fulminans* (pyoderma faciale; Fig. 37.12) and *rosacea conglobata* to be within the rosacea spectrum, others view them as variants of acne vulgaris. Nonetheless, systemic corticosteroids are required to control the aggressive inflammation observed in both disorders, followed by the use of oral isotretinoin. Scarring can be a sequela despite these interventions.

ROSACEA-LIKE DISORDERS

- *Periorificial dermatitis*, originally termed perioral dermatitis, bears a superficial resemblance to rosacea, but the distribution pattern (perioral, perinasal, and/or periocular rather than centrofacial) and lesional morphology differ. In periorificial dermatitis, there are monomorphous superficial pinpoint pustules and/or pink papules as well as patches and thin plaques, some of which have fine scale (Fig. 37.13). A history of topical or inhaled corticosteroid use may be elicited. Overuse of cosmetics and moisturizers has also been

MEDICAL AND SURGICAL THERAPIES FOR ROSACEA	
Treatment	**Comments and/or doses**
Erythema and telangiectasia (previously termed erythematotelangiectatic)	
Facial skin care recommendations (see Table 37.5)	Particularly useful as this subtype is prone to skin irritation and "sensitivity"
Photoprotection	UVR may potentiate dermal matrix damage
Topical agents, e.g. azelaic acid, metronidazole	May reduce erythema, but their use is often limited by their irritant effects
Topical brimonidine tartrate (0.33% gel)*,†	Selective α_2-adrenergic agonist that improves erythema; effects are temporary and possible rebound erythema
Topical oxymetazoline HCl (1% cream)*	Selective α_{1A}-adrenergic agonist and partial α_2-adrenergic agonist that improves erythema; temporary effects are temporary and possible rebound
Laser therapy†	Use of vascular lasers (e.g. pulsed dye, potassium titanyl phosphate) as well as intense pulsed light may improve grades 2 and 3 (see Ch. 137)
Papules and pustules (previously termed papulopustular)	
Topical	
Ivermectin (1% cream)*,† once daily	More effective than placebo and slightly more effective than topical metronidazole in randomized controlled trials
Metronidazole (0.75% gel, cream, or lotion; 1% gel or cream)*,† once or twice daily	Can be used as initial treatment to clear inflammatory lesions or as indefinite maintenance therapy
Azelaic acid (15% gel and foam)*,† twice daily	Appears to be more effective than topical metronidazole but with more side effects, e.g. irritation Azelaic acid (20% cream twice daily) is a non-FDA-approved alternative dose
Sodium sulfacetamide (10%) ± sulfur (5%) lotion* or both in a cream*, gel*, foam*, or cleanser (wash, pads)* once or twice daily	Gel and cleanser formulations may include 10% urea
Minocycline (1.5% foam)* once daily	More effective than vehicle foam in reduction of inflammatory lesion count at 12 weeks[45]; well tolerated
Erythromycin (2% gel and solution) twice daily	Alcohol in gel and solution may reduce tolerance
Clindamycin (1% lotion) once daily	
Benzoyl peroxide 5% cream	Microencapsulated formulations* may be better tolerated[46]
Benzoyl peroxide 2.5%–5% plus clindamycin 1%–1.2% daily	May cause skin irritation
Tretinoin (0.025% cream; 0.05% cream; 0.01% gel) daily	Alters epidermal keratinization and may improve photodamage Poorly tolerated by some patients
Permethrin (5% cream) daily–weekly	As effective as topical metronidazole for the treatment of papules and erythema
Pimecrolimus (1% cream) or tacrolimus (0.03%, 0.1% ointment) twice daily	Some studies have shown improvement in erythema, but there have been reports of exacerbations and induction of rosaceiform dermatitis
Systemic	
Doxycycline (low-dose)	40 mg daily (30 mg immediate release and 10 mg delayed release)*,† for 4–8 weeks; as effective as the 100 mg dose but with fewer adverse effects 20 mg twice daily for 4–8 weeks may be more cost-effective
Doxycycline	50–100 mg once or twice daily for 4–8 weeks
Minocycline	50–100 mg twice daily or sustained action formula (1 mg/kg) daily for 4–8 weeks‡
Tetracycline†	250–500 mg twice daily for 4–8 weeks
Erythromycin	250–500 mg once or twice daily for 4–8 weeks
Azithromycin	250–500 mg (5–10 mg/kg) thrice weekly for 4–8 weeks
Metronidazole	200 mg once or twice daily for 4–8 weeks
Isotretinoin†	10–20 mg daily for 4–6 months
Phymatous	
Isotretinoin	May reduce nasal volume and halt the progression of rhinophyma
Electrosurgery	Can effectively debulk and resculpt the nose
CO_2 laser	
Surgical excision	
Ocular	
Eyelid hygiene and artificial tears	Frequently used to treat mild disease Useful for maintaining remission following treatment of grades 2 and 3 disease with systemic antibiotics
Topical antibiotics (metronidazole 0.75% gel, erythromycin 0.5% ophthalmic ointment, azithromycin 1% ophthalmic solution)	
Cyclosporine 0.5% ophthalmic emulsion†	More effective than artificial tears
Systemic antibiotics (see above section)	For grade 2–3 disease

*FDA-approved treatments for rosacea (evidence-based support = 1).
†In a Cochrane review of randomized controlled trials conducted for moderate to severe rosacea, these were the treatments shown to be effective[38].
‡In a 16-week trial, minocycline 100 mg daily was non-inferior to doxycycline 40 mg daily[54].

Table 37.6 Medical and surgical therapies for rosacea. If moderate to severe flushing persists despite avoidance of triggers, beta-blockers (e.g. carvedilol, nadolol) can be tried (see Ch. 106). Ophthalmic corticosteroids (e.g. dexamethasone, fluocinolone) can be used short-term to treat severe eyelid inflammation. UVR, ultraviolet radiation.

implicated in exacerbating periorificial dermatitis, and intolerance of sunlight and hot water are common symptoms.

A 4- to 8-week course of oral antibiotics (e.g. doxycycline, erythromycin, tetracycline, minocycline, often at subantimicrobial doses) is usually effective in clearing the skin; azithromycin 500 mg three times weekly for 4–8 weeks represents an alternative therapy (see Table 37.6). If topical corticosteroids are implicated in causing perioral dermatitis, they should be discontinued. However, a reduction in the strength and frequency of application of the topical corticosteroid, as opposed to an abrupt discontinuation, may help to avoid a significant rebound flare of the disease. Clearance is usually not followed by a subsequent relapse unless the patient is re-exposed to the inciting trigger. A variant seen in children is referred to as chronic granulomatous periorificial disease of children.

Fig. 37.12 Rosacea fulminans (pyoderma faciale). Sudden onset of tender plaques on the chin studded with pustules. The patient was pregnant and had no history of rosacea or acne vulgaris.

- *Steroid-induced "rosacea"* is a facial eruption in which erythema, papules, and pustules, and in some patients atrophic changes such as telangiectasias, develop from the repeated application of moderate to high potency topical corticosteroids (Fig. 37.14). As with periorificial dermatitis, reducing the strength of the topical corticosteroid as well as the frequency of application (rather than an abrupt discontinuation) is advisable to reduce a rebound flare. Systemic doxycycline, tetracycline, minocycline, azithromycin or erythromycin may also be required for 4 to 8 weeks. Although they have been reported to induce rosaceiform dermatitis, topical calcineurin inhibitors can also be used to reduce inflammation.
- *Rosaceiform dermatitis* is a term usually employed to describe a cutaneous reaction to a drug that clinically resembles rosacea. It is due primarily to topical or systemic corticosteroids and topical calcineurin inhibitors[51], and it is characterized by facial erythema plus small papules and numerous pustules. The distribution on the face is usually widespread, although there are exceptions. Abundant *Demodex* mites have been found on the facial skin of some of these patients, possibly the result of the immunomodulating effects of the inciting medications. This term is also used by some clinicians to describe patients with features of both rosacea and facial dermatitis.
- *Acneiform papulopustular eruption due to epidermal growth factor receptor (EGFR) inhibitors and other targeted therapies* – see Table 37.4 and Fig. 37.15.
- *Idiopathic facial aseptic granuloma* (IFAG) usually presents with a single erythematous nodule on the cheek of a child which persists for several months then spontaneously resolves. One theory is that it represents a form of childhood granulomatous rosacea.

Fig. 37.13 Periorificial dermatitis (often referred to as perioral dermatitis). A–C Pink papules, patches, and thin plaques as well as pinpoint superficial pustules around orifices, i.e. in a perioral, perinasal, and/or periorbital distribution pattern. In contrast to papulopustular rosacea, the papules are classically at the same stage of evolution. **D** Close-up of the characteristic pinpoint pustules (arrows). **E** Granulomatous periorificial disease in a child with monomorphous pink papules that have become confluent around the mouth. The eruption, which had previously worsened upon treatment with topical and oral corticosteroids, resolved with a 6-week course of azithromycin. *A, Courtesy Frank C. Powell, MD; B–D, Courtesy Kalman Watsky, MD; E, Courtesy Julie V. Schaffer, MD.*

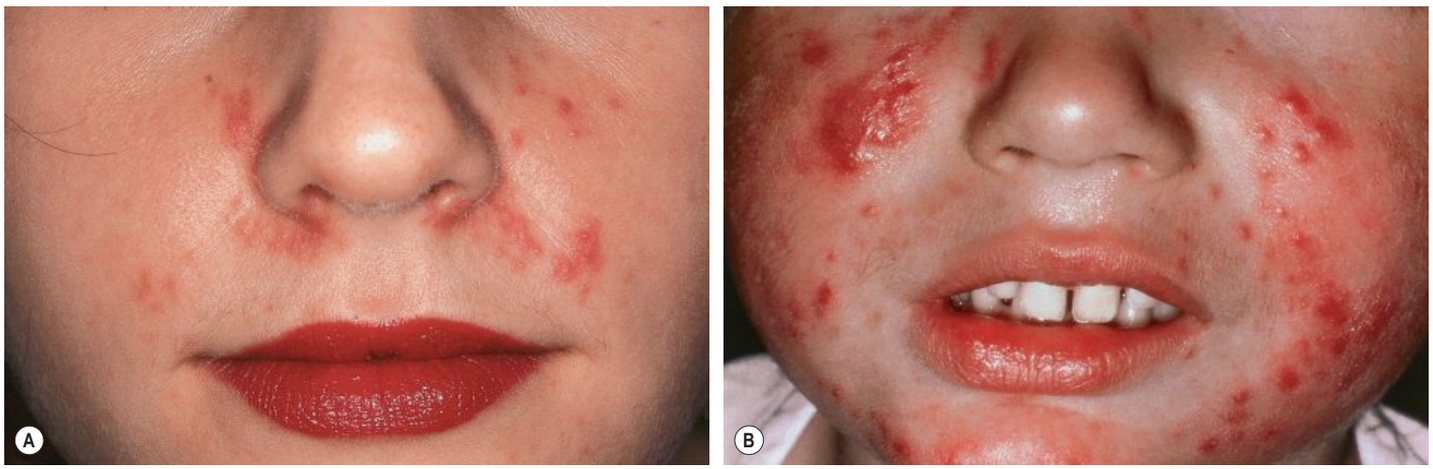

Fig. 37.14 Steroid rosacea. A Milder disease in an adult with scattered erythematous papules and papulopustules of the central face. **B** Severe disease in a child with confluence of erythematous papulopustules. *A, Courtesy Kalman Watsky, MD.*

Fig. 37.15 Papulopustular eruption due to an epidermal growth factor receptor (EGFR) inhibitor. There is a resemblance to rosacea but the onset is more abrupt. *Courtesy Frank C. Powell, MD.*

Fig. 37.16 Morbihan disease. Erythematous, firm, non-pitting, asymptomatic swelling of the upper midface. Areas of greatest involvement can acquire a "peau d'orange" appearance. *Courtesy Frank C. Powell, MD.*

- *Demodicosis* encompasses *Demodex* folliculitis (see Ch. 38) and pityriasis folliculorum. The latter is a poorly recognized disorder that primarily affects women in the 20- to 40-year age group who rarely allow water to contact their face and who instead often apply moisturizing and cleansing creams as well as cosmetic preparations. There is a roughened, whitish scaling skin surface on a background of faint erythema, along with some scattered fine papules and pustules that are not limited to the central face. The patient usually complains of increased skin sensitivity. KOH examination of skin scrapings demonstrates multiple dead and some live *Demodex* mites. Nightly application of topical ivermectin for 4 to 6 weeks is usually effective when combined with a facial washing routine.
- *Morbihan disease* (solid facial edema) is a rare facial disorder characterized by a progressive and persistent, asymptomatic, firm non-pitting swelling of the central upper face that is associated with fixed facial erythema (Fig. 37.16). Lymphedema in this location can result from a number of initiating factors, from injuries to contact allergy[52] to acne vulgaris. While rosacea has also been associated with Morbihan disease[53], there are patients with no history of a facial dermatosis. Histologically, it may be indistinguishable from other forms of rosacea, including presenting with granulomatous features. Lymphedema can also be seen. There is no consistently effective therapy, but prolonged courses of antihistamines and low-dose oral isotretinoin have been reported as helpful in individual patients.
- Patients with *Haber syndrome*, currently viewed as a subtype of Dowling–Degos disease with comedones of the trunk and pitted scars, can also have early-onset, rosacea-like facial erythema.

Acknowledgment

The editors wish to thank Dr. Frank C. Powell for his valuable contributions to this chapter in the previous editions.

Chapter Contents

Superficial Folliculitis 622
Disorders of Follicular Keratinization 629
Trichostasis Spinulosa 631
Viral-Associated Trichodysplasia Spinulosa 631
Deep Folliculitis 632
Follicular Occlusion Tetrad. 635

INTRODUCTION

This chapter reviews both superficial and deep forms of folliculitis as well as disorders of follicular keratinization. Examples of superficial folliculitis include those due to *Staphylococcus aureus* or *Pseudomonas aeruginosa* infections, whereas acne keloidalis and pseudofolliculitis barbae are examples of deep forms. Hidradenitis suppurativa, a major entity within the follicular occlusion tetrad, is increasingly being recognized as a systemic inflammatory disorder. The disorders of follicular keratinization represent a varied group of dermatoses that have in common prominent keratotic follicular plugs. Some of these disorders are reviewed in other chapters, e.g. lichen planopilaris, pityriasis rubra pilaris (PRP) and keratosis pilaris, while others are discussed here, e.g. lichen spinulosus and erythromelanosis follicularis faciei.

SUPERFICIAL FOLLICULITIS

Synonym: ▪ Impetigo of Bockhart

Key features

- Folliculocentric papules and pustules, often arising on an erythematous base
- Favors areas with terminal hairs and a greater density of sebaceous glands, such as the scalp, beard, and upper trunk, as well as the buttocks and lower extremities
- Bacterial culture of pustular contents most commonly reveals normal flora, followed by *Staphylococcus aureus*
- Treatment depends on the particular type of folliculitis

Introduction

Folliculitis is a very common disorder characterized by follicular papules and pustules with varying degrees of inflammation. It occurs most commonly in adolescents and adults. Folliculitis can be secondary to a wide range of infectious agents, or be induced by irritants or drugs (Fig. 38.1). While potential pathogens include bacteria, fungi, viruses, and parasites, culture of pustular contents most commonly reveals normal flora ("culture-negative"), followed by *Staphylococcus aureus*.

Clinical features

Follicular pustules are usually accompanied by an erythematous rim (Fig. 38.2). If no pustules are present, follicular-based erythematous papules or a superimposed collarette of scale serve as clues to the diagnosis. Comedones are not typically seen unless the patient also has acne vulgaris. Lesions may be pruritic or even tender or painful. Generalized pruritus can accompany more widespread disease.

Folliculitis occurs most commonly in the head and neck region (especially the scalp and beard area), upper trunk, buttocks, and legs, as well as in the axillae and groin (Fig. 38.3). It favors areas that are occluded and/or have a greater density of terminal hairs. In addition, shaving can predispose to folliculitis.

Pathology

The early inflammatory infiltrate consists primarily of perifollicular neutrophils with extension into the follicular epithelium and follicular ostium. This is soon followed by an admixture with lymphocytes and macrophages. Late-stage changes include follicular rupture and a granulomatous response. Deeper inflammatory reactions may lead to scarring alopecia.

Tissue Gram stain may reveal pathogenic organisms. Occasionally, cytopathic changes due to herpes simplex or zoster viral infections are seen within the follicular epithelium (see Ch. 80). In dermatophyte infections, hyphae can be seen within hair shafts or in the follicular ostium (see Fig. 77.13G). The presence of *Demodex* organisms (see Fig. 38.5H) or yeast forms requires clinicopathologic correlation as they are commensal organisms.

Differential diagnosis

In addition to the various forms of folliculitis listed in Table 38.1, the differential diagnosis also includes acne vulgaris, pseudofolliculitis barbae, and occasionally, rosacea. Dermoscopy can assist in confirming that the papules are folliculocentric, allowing distinction from other disorders such as Grover disease. Microscopic examination of follicular contents may provide a clue to the type of folliculitis as can microbial cultures and histologic examination. In patients who are confined to bed, folliculitis may develop predominantly on the posterior trunk and thus needs to be distinguished from other disorders exacerbated by occlusion including Grover disease, miliaria rubra, and cutaneous candidiasis.

Treatment

Superficial folliculitis may be self-limited, especially if exacerbating factors are addressed. The treatment chosen depends upon the culture results and severity (see Chs. 74 & 127). For patients whose cultures fail to demonstrate a pathogenic microbe, the treatments, as in acne, include topical benzoyl peroxide, topical antibiotics, and oral antibiotics (e.g. doxycycline), with the anti-inflammatory properties of these antibiotics likely playing a role. This should be combined with measures to reduce overhydration of the skin, occlusion, and irritation.

Malassezia (*Pityrosporum*) Folliculitis

Malassezia (*Pityrosporum*) folliculitis is most commonly associated with *M. globosa*, *M. furfur*, and *M. sympodialis* (see Ch. 77). These commensal yeasts favor sebaceous-rich skin and typically become pathogenic under certain favorable conditions – a warm, humid climate, excessive sebum production or sweating, occlusion from emollients, use of systemic antibiotics, and immunosuppression. Yeast lipases can cleave sebaceous triglycerides, with the resultant free fatty acids serving as potential irritants and proinflammatory mediators.

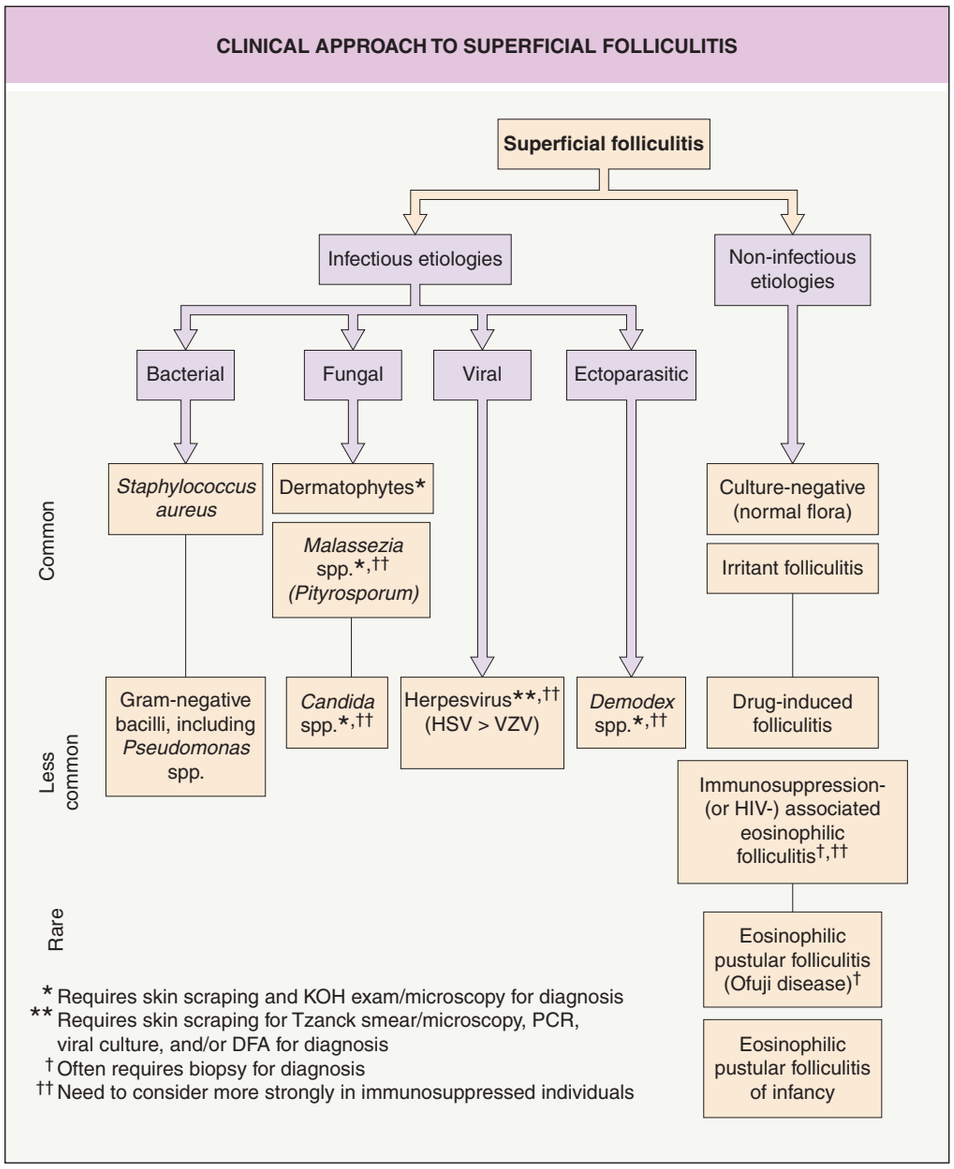

Fig. 38.1 Clinical approach to superficial folliculitis. Edematous lesions of folliculitis are most suggestive of eosinophilic folliculitis, *Demodex* folliculitis, and *Pseudomonas* "hot tub" folliculitis. See Table 38.1 for medications that can cause drug-induced folliculitis. *Courtesy Jean L. Bolognia, MD.*

Fig. 38.2 Folliculitis (culture-negative). Follicular pustules with an erythematous rim on the buttocks of a 3-year-old who wore "pull-ups" at night. *Courtesy Julie V. Schaffer, MD.*

Malassezia (Pityrosporum) folliculitis presents as multiple monomorphic, oftentimes pruritic, small follicular papules and occasionally pustules. A central keratin plug may be present. Lesions favor the upper trunk of teenagers and young adults (Fig. 38.5D), but may also appear on the shoulders, neck, and face (especially the forehead and anterior hairline). Diagnosis can be established via KOH examination of follicular contents, which demonstrates spherical yeast forms. In addition to addressing predisposing factors, treatment options include topical antifungal creams or lotions and selenium sulfide shampoo. For more widespread disease or topical therapy failure, oral fluconazole can be used, e.g. 150–300 mg once weekly for 1–2 months.

Eosinophilic Folliculitis

Three major forms of eosinophilic folliculitis have been described – eosinophilic pustular folliculitis (Ofuji disease), immunosuppression (or HIV)-associated eosinophilic pustular folliculitis, and eosinophilic pustular folliculitis of infancy.

Eosinophilic pustular folliculitis

Synonyms: ▪ Ofuji disease ▪ Eosinophilic folliculitis

Fig. 38.3 Folliculitis of the axilla and beard area due to *Staphylococcus aureus*. **A** Numerous follicular pustules with an erythematous rim emanating from the axillary vault. **B** Discrete papulopustules are seen posteriorly, while centrally there is deeper involvement with plaque formation (sycosis barbae). *A, Courtesy Kalman Watsky, MD.*

Key features

- Follicular papulopustules as well as erythematous patches and plaques with superimposed coalescent pustules; central clearing leads to figurate lesions
- Most commonly involves the face, followed by the upper extremities and trunk
- Often moderate to severe pruritus
- Recurrent crops of lesions typically involute over 7–10 days
- Peripheral blood eosinophilia also present
- Histologically, intrafollicular and perifollicular eosinophil-rich infiltrates

Introduction

Eosinophilic pustular folliculitis is characterized by recurrent episodes of eruptive, intensely pruritic, follicular papulopustules, often in association with peripheral blood eosinophilia. It typically affects "acne-prone" areas of the body such as the face, back, and extensor surface of the arms[1]. To date, this disorder has not been associated with systemic disease.

History

In 1965, Ise and Ofuji[2] were the first to report a patient who had repeated episodes of follicular pustules on the face and back along with peripheral blood eosinophilia. Of note, this disorder is not to be confused with papuloerythroderma of Ofuji (see Ch. 26).

Epidemiology

Eosinophilic pustular folliculitis is a relatively rare entity, with most of the cases reported from Japan. The majority of patients are Asian adults, with an average age of onset between 20 and 40 years. The ratio of men to women is ~5:1 amongst Japanese patients and ~1:1.6 in Singapore[3]. There have been occasional reports of eosinophilic pustular folliculitis in children, often with clinical features similar to the infantile form (see below).

Pathogenesis

The etiology of eosinophilic pustular folliculitis remains unclear. Proposed mechanisms include hypersensitivity reactions to various antigenic stimuli (e.g. infectious agents, medications), Th2 pathway skewing, and immune dysfunction[4]. The presence of $CD163^+$ M2 macrophages, which play a role in parasitic infections, as well as $pSTAT6^+$ and IL-10-producing cells within lesional skin point to Th2 polarization[5]. Via GATA3, STAT6 in concert with STAT5 induces Th2 cells to secrete IL-4, IL-5, and IL-13; these cytokines are known to play a key role in the recruitment of eosinophils. In addition, elevated serum levels of the chemokine TARC have been observed in eosinophilic pustular folliculitis[6], as in other disorders with peripheral eosinophilia such as drug reaction with eosinophilia and systemic symptoms (DRESS). Prostaglandin D2 may also play a role in the activation of pilosebaceous units and recruitment of eosinophils. This provides a possible explanation for the therapeutic response to indomethacin, a COX inhibitor that inhibits prostaglandin synthesis[7].

Clinical features

Recurrent crops of intensely pruritic, grouped, follicular pustules and papulopustules erupt in a rapid fashion. In addition, there may be erythematous patches and plaques with superimposed coalescent pustules; central clearing and centrifugal extension produce annular and figurate lesions. Typically, areas with "sebaceous" follicles, such as the face, back, and extensor surface of the arms, are affected. However, the digits, palms, and soles may be involved, proving that not all lesions are follicular. Lesions last 7–10 days and tend to relapse every 3–4 weeks. Because this disorder most commonly occurs in individuals with darker skin phototypes, postinflammatory hyperpigmentation is a common finding. The patients have no accompanying systemic symptoms.

Pathology

Involved follicles show spongiosis with exocytosis of eosinophils ("eosinophilic spongiosis"), admixed with variable numbers of lymphocytes and neutrophils. Micropustular aggregation develops, followed by the hallmark finding of infundibular eosinophilic pustules[8]. While these findings are particularly prominent in the infundibular region, they are accompanied by perifollicular inflammatory infiltrates with a similar cellular composition.

Differential diagnosis

Clinically, some of the lesions may resemble other forms of superficial folliculitis (see previous section), acneiform eruptions, and other figurate erythemas, in particular eosinophilic annular erythema, hydroxychloroquine-induced generalized pustular figurate erythema, and pustular psoriasis. However, the explosive crops, annular plaques with central clearing, intense pruritus, peripheral blood eosinophilia, and histologic findings typically enable differentiation from clinically similar entities. Rarely, early eosinophilic pustular folliculitis may have a symmetric, butterfly rash-like presentation that resembles acute cutaneous lupus erythematosus.

Treatment

Potent topical corticosteroids, tacrolimus ointment, topical indomethacin[9], and oral antihistamines can be prescribed for the associated pruritus as well as for mild localized disease. Oral indomethacin (50 mg/day) is recommended as first-line systemic therapy. Second-line therapies include UVB phototherapy, oral minocycline (100 mg twice daily), oral dapsone (100 to 200 mg/day for ≥2 weeks), systemic corticosteroids, and colchicine (0.6 mg twice daily). Oral cyclosporine or isotretinoin may be considered in patients with refractory disease.

LESS COMMON SPECIFIC FORMS OF FOLLICULITIS		
Etiology/risk factors	**Clinical features**	**Therapy**
Irritant folliculitis		
Usually occurs following the application of irritating topical medications (e.g. tar preparations), topical keratolytics, or chemical peels Exacerbated by application in a direction opposite that of hair growth	• Follicular papules and pustules in the sites of application or exposure to irritant • Favors areas with terminal hairs	• Discontinue inciting topical agent • Apply medications in the same direction as hair growth • Topical corticosteroids
Gram-negative folliculitis		
Due primarily to *Klebsiella, Escherichia coli, Enterobacter* and *Proteus* spp. Usually seen in patients with acne vulgaris receiving long-term antibiotic therapy Can occur in setting of primary immunodeficiency (e.g. HIV) or α-1-antitrypsin deficiency	• Papules and pustules in the facial T-zone and in a perinasal distribution • Adult men with oily skin • Organisms isolated from nares as well as cutaneous lesions	• Topical: gentamicin, benzoyl peroxide • Systemic: quinolones (e.g. ciprofloxacin), ampicillin or trimethoprim/sulfamethoxazole • If severe or recurrent: isotretinoin, 0.5–1 mg/kg/day for up to 16 weeks
Hot tub folliculitis, due primarily to *Pseudomonas aeruginosa* Follows exposure to contaminated water in hot tubs or whirlpools > swimming pools	• Typically appear 12–48 hours after exposure • Edematous, pink to red follicular papules and pustules, primarily on the trunk > extremities (Fig. 38.4) • Often pruritic and resolves spontaneously in immunocompetent patients • May lead to serious illness in immunocompromised patients (e.g. ecthyma gangrenosum)	• Generally self-limited; can use antibacterial soap • If severe or immunocompromised host: ciprofloxacin, 500 mg po twice daily for 7–14 days • Prevention: adequate chlorine levels, e.g. 2–4 mg/L for swimming pools, 3–5 mg/L for hot tubs, and pH of 7.2–7.4
Dermatophyte folliculitis		
Tinea barbae – usually due to zoophilic dermatophytes *Trichophyton mentagrophytes* or *T. verrucosum* Risk factors include occupational or recreational exposure to infected animals	• Inflammatory papules and pustules in the beard area more often than the mustache, with crusting • Loosened hairs can be removed without pain	• Topical antifungals (may be ineffective) • Terbinafine, 250 mg/day po for 2–4 weeks • Microsized or ultramicrosized griseofulvin, 500–1000 mg/day or 500–750 mg/day po, respectively, for 4–8 weeks • Fluconazole, 150 mg po once weekly for 2–4 weeks • Itraconazole, 200 mg po twice daily for 1 week per month, for 2 pulses
Majocchi granuloma – a follicular infection most commonly due to *T. rubrum* Can have perifollicular granulomatous inflammation Risk factors include shaving of legs, use of potent topical corticosteroids, occlusion, and immunosuppression	• Follicular pustules and follicular papules or nodules (Fig. 38.5A-C), most often located on the lower extremities • Often arises within expanding lesions of tinea corporis, cruris or pedis • Also arises in the setting of tinea incognito where scale is absent but KOH examination is floridly positive	• Oral antifungal medications recommended, with treatment regimens similar to tinea barbae (see above) • Immunosuppressed patients may need a longer course of therapy
***Candida* folliculitis**		
Most commonly caused by *Candida albicans* Predisposing factors include diabetes, obesity, immunosuppression, intravenous drug use, recent use of systemic corticosteroids or broad-spectrum antibiotics, occlusion, heat and humidity	• Pruritic satellite pustules surrounding areas of intertriginous candidiasis • Facial lesions may mimic tinea barbae or acne rosacea • KOH examination: budding yeasts and pseudohyphae	• Prevent skin-to-skin contact in intertriginous areas • If possible, discontinue antibiotics and/or corticosteroid therapy • Mild to moderate disease: topical antifungals • Recalcitrant or severe disease: fluconazole 150 mg po once weekly for 4 weeks, or 100 mg po daily for 1 week then every other day for 1 month
Herpetic folliculitis		
Herpetic sycosis is usually seen in men with a history of recurrent localized facial herpes simplex infection who shave with a blade razor Widespread or unusual presentations of herpes simplex folliculitis may be seen in HIV-infected or otherwise immunosuppressed individuals as well as in the setting of eczema herpeticum Often seen in herpes zoster	• Rapid development of individual and grouped follicular pustules and vesicles on an erythematous base • If due to herpes simplex, occurs most commonly on the face • When due to herpes zoster, can be associated with entities in Table 80.7 • A Tzanck smear or biopsy reveals multinucleated giant cells • Positive PCR or DFA	• Acyclovir 200 mg po 5 times per day for 5–10 days • Famciclovir 250–500 mg po three times per day for 5–10 days • Valacyclovir 500 mg po three times per day for 5–10 days • IV acyclovir 5–10 mg/kg every 8 hours can be used for extensive disease, especially in the context of immunosuppression
***Demodex* folliculitis (demodicosis)**		
Most commonly caused by *Demodex folliculorum* and *D. brevis* May be associated with immunosuppression	• Erythematous follicular papules and pustules on the face, especially the nose, and neck; may have a background of diffuse erythema (Fig. 38.5E,F) • Less common presentations include blepharitis, madarosis, and demodectic frost of the ear • Skin scrapings reveal numerous *Demodex* mites (Fig. 38.5G)	• Topical: ivermectin 1% cream, metronidazole 1% cream, permethrin 1% or 5% cream, sodium sulfacetamide 10%/sulfur 5% lotion, crotamiton 10% cream or lotion, benzyl benzoate 10% lotion • Systemic: ivermectin 200 mcg/kg po once weekly for 1–2 weeks, metronidazole 250 mg po TID for 7–14 days, ornidazole*, isotretinoin

Table 38.1 Less common specific forms of folliculitis.

LESS COMMON SPECIFIC FORMS OF FOLLICULITIS		
Etiology/risk factors	**Clinical features**	**Therapy**
Drug-induced folliculitis (acneiform eruption)		
Most common in acne-prone patients and age groups Corticosteroids, androgenic hormones, inhibitors of EGFR, BRAF, MEK and HER2, anticonvulsants, bromides, iodides, isoniazid, lithium, sirolimus, vitamin B_{12} supplementation Can develop within 2 weeks of starting the offending agent, but the risk is often proportional to the dose and duration of therapy	• Acute eruption of monomorphic erythematous follicular papules and pustules on the face, trunk, shoulders, and upper arms (see Figs. 21.21B & 36.13) • Multiple papulopustules of the face and scalp, sometimes admixed with scale-crust (see Figs. 21.21C & 36.15) • Unlike acne vulgaris, comedones are rarely present (with the exception of androgens)	• Discontinue or lower the dose of the offending drug, if possible • Topical: benzoyl peroxide, clindamycin, erythromycin, retinoids; corticosteroids (EGFR-induced eruptions; see Ch. 21) • Systemic: tetracycline, doxycycline, minocycline; if secondarily infected, antibiotic based upon culture; isotretinoin
Necrotizing infundibular crystalline folliculitis		
Yeasts (e.g. *Malassezia* spp.) and Gram-positive bacteria (e.g. *Cutibacterium acnes*) in affected follicles	• Waxy folliculocentric papules with predilection for the forehead, neck, and back • Birefringent, filamentous, crystalline deposits within follicular ostia • Thought to be microbial-induced crystallization of sebum	• Topical or systemic antimycotics • Topical or systemic antibiotics
Actinic folliculitis		
Seasonal, possibly caused by ultraviolet A radiation and local heat Follows initial summer sun exposure	• Monomorphic follicular papules and pustules in sun-exposed sites – face, neck, upper trunk, and arms • Arises 4–30 hours after sunlight exposure	• Sun avoidance as sunscreens will not prevent lesion formation • Usually resolution within 5–10 days after discontinuation of sunlight exposure • Topical mid-potency corticosteroids or retinoids • Isotretinoin 0.35–0.5 mg/kg/day for 3–6 months if severe
*Not an FDA-approved drug.		

Table 38.1 Less common specific forms of folliculitis. DFA, direct immunofluorescence assay; EGFR, epidermal growth factor receptor; HER2, human epidermal growth factor receptor 2; HIV, human immunodeficiency virus; MEK, mitogen-activated protein kinase kinase (MAPK); mTOR, mechanistic target of rapamycin; PCR, polymerase chain reaction.

Immunosuppression-associated eosinophilic pustular folliculitis

Synonyms: ■ AIDS-associated eosinophilic folliculitis ■ HIV-associated eosinophilic folliculitis ■ Immunosuppression-associated eosinophilic folliculitis

Key features

- Markedly pruritic follicular papules, urticarial and/or pustular, that favor the face, scalp, and upper trunk
- Occurs in the setting of immunosuppression, including from HIV infection or systemic medications and following allogeneic hematopoietic stem cell transplantation
- In HIV-infected patients, the CD4 count is usually <200 cells/mm^3; it may also be a manifestation of IRIS (immune reconstitution inflammatory syndrome)
- Histopathologic findings, consisting of spongiosis and exocytosis of eosinophils and lymphocytes into the follicular epithelium, are similar to those in other types of eosinophilic pustular folliculitis

Introduction and history

A pruritic papular eruption with histologic features similar to eosinophilic pustular folliculitis (Ofuji disease) was originally described in HIV-infected patients, many of whom fulfilled the criteria for AIDS. Eosinophilic folliculitis has subsequently been observed in patients with myeloproliferative disorders, as well as in those who have undergone allogeneic hematopoietic stem cell transplantation; hence, the use of the term *immunosuppression-associated eosinophilic pustular folliculitis*. However, in contrast to Ofuji disease, coalescent pustules and figurate lesions would be unusual, and the individual lesions tend to be more persistent.

Fig. 38.4 *Pseudomonas* "hot tub" folliculitis. Edematous follicular papules of the flank that began to develop 2–3 days following the use of a hot tub. *Courtesy Kalman Watsky, MD.*

Epidemiology

Although the early descriptions of HIV-associated eosinophilic folliculitis were in men, it can also occur in women[10]. The majority of these patients are 20–50 years of age, while there is a wide range of ages in non-HIV-related cases, reflecting the age of onset of associated hematologic malignancies. Development of HIV-associated eosinophilic folliculitis correlates with a low CD4 count (in particular <200/mm^3 or CD4:CD8 ratio <0.5) and clinical improvement has been observed as the CD4 count rises due to antiretroviral therapy (ART). However, there are instances where eosinophilic folliculitis develops within 3 to 6 months of initiating ART, implying an association with the immune reconstitution inflammatory syndrome (IRIS; see Ch. 78).

A Dermatophyte folliculitis of the shin within a lesion of tinea corporis; the lower leg is a common location. **B** Dermatophyte folliculitis on the buttocks arising within subtle tinea corporis (arrow). A few papulopustules admixed with both erythematous papules that have a collarette of scale and healed lesions. **C** Dermatophyte folliculitis with firm follicular papules in the setting of extensive tinea corporis. **D** *Malassezia* (*Pityrosporum*) folliculitis of the chest with multiple pruritic, monomorphic follicular papules; KOH examination of the follicular contents showed abundant yeast. **E** Numerous papules and papulopustules of *Demodex* folliculitis on the face and neck; note the edematous nature of several of the lesions. **F** Facial papules and papulopustules of *Demodex* folliculitis in a child with acute lymphocytic leukemia. **G** Histopathologic features of *Demodex* folliculitis with several organisms within the follicular ostium. **H** Microscopic findings of follicular contents obtained via scraping of *Demodex* folliculitis. *A, Courtesy Karynne O. Duncan, MD; B, Courtesy Edward Cowen, MD; D,F, Courtesy Julie V. Schaffer, MD; E, Courtesy Angela Hernández-Martin; G, Courtesy Lorenzo Cerroni, MD.*

Pathogenesis

Little is known about the exact pathogenesis of immunosuppression-associated eosinophilic folliculitis. However, as in other eosinophilic diseases, a Th2 immune response has been implicated. In patients with AIDS, elevated levels of interleukin (IL)-4, IL-5, RANTES (CCL5), and eotaxin (CCL11) mRNA were detected within lesional skin (see Ch. 26)[11]. Elevated serum levels of three additional chemokines, CCL17, CCL26 (eotaxin-3) and CCL27, have also been observed in patients with HIV-associated eosinophilic folliculitis[12].

Clinical features

Immunosuppression-associated eosinophilic folliculitis is characterized by recurrent, intensely pruritic papules and pustules in acne-prone areas, i.e. the face, scalp, and upper trunk (Fig. 38.6A). The papules are

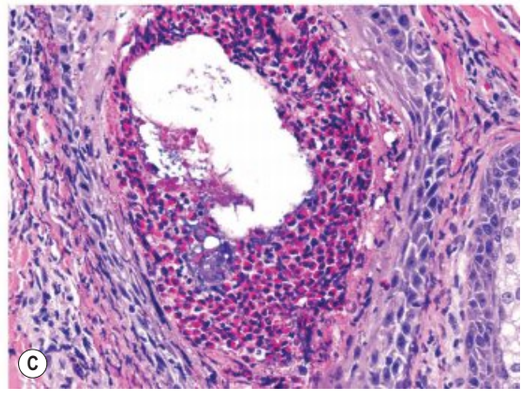

Fig. 38.6 Immunosuppression-associated eosinophilic folliculitis. **A** Multiple follicular papules on the anterior trunk in a patient who had received an allogeneic hematopoietic stem cell transplant. Note the edematous nature of some of the lesions. Very few pustules were present. **B** In some patients, multiple follicular pustules are seen. **C** A dilated hair follicle with an intrafollicular collection of eosinophils; a few eosinophils are also present within the follicular epithelium. *A, Courtesy Dennis Cooper, MD; B,C, Courtesy Luis Requena, MD.*

often slightly edematous and pustules may or may not be present (Fig. 38.6B). The associated pruritus is often intense. Some patients may also have lymphopenia.

Pathology
The histologic features are similar to those of Ofuji disease (see above; Fig. 38.6C)

Differential diagnosis
The differential diagnosis includes more common causes of folliculitis (see above) as well as the entities outlined in Table 38.1, especially *Demodex* folliculitis. Microscopic examination of follicular contents as well as performance of a biopsy may be necessary to establish the diagnosis (see Fig. 38.1). Additional disorders to consider, especially when there are no pustules and it is uncertain if lesions are follicular-based, are HIV-associated pruritic papular eruption[13], papular dermatitis, or arthropod bites and other causes of a "dermal hypersensitivity reaction".

Treatment
Although HIV-associated eosinophilic folliculitis can be refractory to treatment, institution of ART often leads to improvement; however, a flare may be seen in the setting of IRIS. In the latter patients, ART should be continued as the IRIS-related disease activity gradually subsides. Temporary interruption of ART is not required if eosinophilic folliculitis is the primary manifestation of IRIS.

For all patients, oral and topical antipruritics in combination with topical corticosteroids can be tried. Additional therapies include topical tacrolimus, topical permethrin, oral itraconazole (200–400 mg daily), oral metronidazole (250 mg three times daily), other oral antibiotics, and isotretinoin (0.5–1 mg/kg/day)[14]. UVB phototherapy may be tried when the folliculitis is extensive or recalcitrant.

Eosinophilic pustular folliculitis of infancy

Synonyms: ▪ Eosinophilic pustular folliculitis in infancy ▪ Infantile eosinophilic pustular folliculitis ▪ Neonatal eosinophilic pustular folliculitis ▪ Eosinophilic pustular folliculitis in childhood ▪ Eosinophilic pustulosis (of the scalp) in childhood

Eosinophilic pustular folliculitis of infancy is a rare, self-limiting disorder (see Ch. 34). It presents as pruritic, follicular-based pustules and vesiculopustules with an erythematous rim. The scalp is the most common site of involvement; less often lesions are seen on the face and neck, followed in frequency by the upper trunk and extremities. A cyclical course, with recurrences at intervals ranging from 1 to 12 weeks, is characteristic. Disease onset is nearly always prior to age 15 months, with a male-to-female ratio of 4:1. It differs from eosinophilic folliculitis in adults by primarily involving the scalp, frequently developing secondary crusting, and the lack of an annular configuration. Although there can be some clinical overlap, the hands and feet are the primary sites of involvement in infantile acropustulosis.

This disorder is currently viewed as a reaction pattern to a variety of triggers such as arthropod bites. Histologically, there is eosinophilic spongiosis as well as clusters of eosinophils and neutrophils within the hair follicle, especially its infundibular region. A perifollicular mixed inflammatory infiltrate can also be seen. The disease is benign and self-limited, with the majority of children experiencing resolution by 3 years of age. Topical corticosteroids can be used for relief of pruritus.

Disseminate and Recurrent Infundibulofolliculitis

Synonyms: ▪ Hitch and Lund disease ▪ Recurrent disseminated infundibulofolliculitis

Key features
- Seen primarily in young adults with darkly pigmented skin
- Numerous uniform, skin-colored papules that have been likened to "goose bumps"
- Favored sites of involvement are the trunk, neck, and upper extremities
- May last for months to years and can be pruritic
- Histologically, there is perifollicular edema and a mild inflammatory infiltration of lymphocytes within the follicular infundibulum

Disseminate and recurrent infundibulofolliculitis (DRIF) was first described by Hitch and Lund in 1968[15]. Most affected individuals have skin phototypes V or VI. DRIF is characterized by numerous 1–2 mm, pruritic, skin-colored, folliculocentric papules. Parallel rows of lesions correspond to the distribution pattern of hair follicles. The trunk is involved most often, followed by the neck, buttocks, and arms. The lesions may last for weeks, months, or years.

DRIF most closely resembles papular eczema, which also favors darker skin phototypes. Other diseases in the differential diagnosis include lichen nitidus and folliculitis (see above), but the follicular pattern and the lack of erythema or pustules exclude these two entities, respectively. The lack of keratotic plugs or spines within the hair follicles distinguishes this disorder from keratosis pilaris, pityriasis rubra pilaris (PRP), lichen planopilaris, and the disorders discussed in the next section (e.g. phrynoderma).

Although low serum vitamin A levels have been reported[16], the etiology remains unclear. Histologically, the principal findings are in the infundibular portion of the hair follicle. There is perifollicular edema and a slight infiltration of lymphocytes with occasional neutrophils[17]. Spongiosis of the follicular epithelium is usually absent or minimal.

Topical corticosteroids may provide symptomatic relief and lactic acid preparations (12%) or 20% urea may be helpful. If topical medications prove unsuccessful, doxycycline, vitamin A (50 000 IU twice daily), isotretinoin (0.5 mg/kg/day for 16 weeks), and PUVA (with twice monthly maintenance) have also been tried with mixed results.

DISORDERS OF FOLLICULAR KERATINIZATION

Although this group of dermatoses has a wide spectrum of clinical presentations, all are characterized by a prominent plug of keratin within the follicular orifice. For most of these entities, the cause of the abnormal keratinization is unknown. The dermatoses are usually distinguished on the basis of the size, extent, and distribution of the keratotic lesions, as well as the presence or absence of perifollicular erythema and associated scarring. Disorders in this group that are discussed in other chapters include keratosis pilaris (Ch. 12), PRP (Ch. 9), and lichen planopilaris (Ch. 11).

Erythromelanosis Follicularis Faciei

Synonym: ▪ Erythromelanosis follicularis faciei et colli

Key features

- An uncommon disorder that involves the lateral cheeks and sometimes the neck
- Multiple tiny follicular papules are superimposed on a red–brown patch; the papules often appear relatively hypopigmented
- May be accompanied by keratosis pilaris

Introduction

Erythromelanosis follicularis faciei was first described in 1960 by Kitamura and associates in Japanese men. It can begin during the second decade of life and is characterized by background erythema and hyperpigmentation as well as tiny follicular papules.

Epidemiology and Pathogenesis

Although the disorder was initially reported in Japanese men, it is now known to affect all races and both sexes[18]. However, the literature suggests it favors people of Asian ancestry. The pathogenesis is unknown.

Clinical features

Erythromelanosis follicularis faciei typically involves the lateral cheeks, including the preauricular area, with extension onto the neck. Involvement of the eyebrows, chin, submandibular region, and pinnae has also been described[18]. Numerous pinhead-sized follicular papules, which appear relatively hypopigmented, are superimposed on reddish-brown patches. The latter are due to a combination of vasodilation and hyperpigmentation, and by dermoscopy blue–gray peppering is seen with a reddish-brown background, along with an appreciation of keratotic follicular plugs[19]. In skin type I patients, there may be only erythema, leading to significant overlap with keratosis pilaris rubra. Patients may also have keratosis pilaris of the upper outer arms (see Ch. 12).

Pathology

There is slight follicular hyperkeratosis with increased epidermal pigmentation. Diameters of the hair shafts and outer root sheaths are decreased, as is the thickness of the inner root sheath. The adnexa are often surrounded by a lymphocytic infiltrate. Both the thickness and the compactness of the horny layer are usually increased. By quantitative histopathology, an increase in the percent area of superficial blood vessels was observed which correlated with visual grading of the associated erythema[20].

Differential diagnosis

The differential diagnosis of erythromelanosis follicularis faciei includes keratosis pilaris rubra as well as a combination of melasma plus telangiectatic erythema from photodamage (poikiloderma of Civatte). However, the former lacks hyperpigmentation and favors children, and while the telangiectasias in poikiloderma spare the perifollicular skin thus creating "hypopigmented" follicular papules, follicular hyperkeratosis is absent.

Less often, two disorders within the spectrum of keratosis pilaris atrophicans, ulerythema ophryogenes and atrophoderma vermiculatum, may be considered (Table 38.2). Although ulerythema ophryogenes is characterized by small follicular papules, they are erythematous, usually appear during early childhood, and favor the eyebrows. In addition, there is associated follicular atrophy and scarring alopecia of the lateral eyebrows. Atrophoderma vermiculatum affects the cheeks but presents with honeycomb scarring or a worm-eaten appearance (see Ch. 99).

Treatment

Various topical keratolytic agents have been tried, including urea cream (10%–20%), ammonium lactate lotion (6%–12%), tretinoin cream (0.025%–0.1%), adapalene (0.1%–0.3%), and an ammonium lactate plus hydroquinone (4%) cream combination. In a series of 11 patients, topical tacalcitol ointment (daily for 12 weeks) reduced roughness and scaling, but had a limited effect on facial erythema[21]. Both salicylic acid peels (20%–30%) and glycolic acid peels have been employed. When severe, limited courses of isotretinoin (0.1–1 mg/kg/day) have been tried. Laser treatment of the background erythema and/or hyperpigmentation may be attempted, but it requires multiple sessions. In a split-face study (n = 12), >50% improvement in the treated side was observed in five patients following five treatments with 585 nm PDL plus 1064 nm Nd:YAG lasers[22].

Keratosis Pilaris Atrophicans

Keratosis pilaris atrophicans encompasses a group of disorders in which the abnormality in follicular keratinization is accompanied by atrophy and scarring alopecia. The key features of ulerythema ophryogenes, atrophoderma vermiculatum, keratosis follicularis spinulosa decalvans, and folliculitis spinulosa decalvans are outlined in Table 38.2. Treatment with keratolytics, topical retinoids, topical or intralesional corticosteroids, oral antibiotics, and phototherapy has limited efficacy, but combination therapy may benefit individual patients and, anecdotally, oral retinoids, pulsed dye laser, and intense pulsed light have been reported to lead to improvement. In later stages, laser resurfacing, dermabrasion, and/or dermal fillers may help to improve the appearance of atrophic scarring.

Lichen Spinulosus

Synonyms: ▪ Keratosis spinulosa ▪ Keratosis follicularis spinosa (of Unna)

Key features

- Clusters of multiple follicular papules, each with a central keratotic spine
- Texture likened to that of a nutmeg grater
- Usually asymptomatic, arises suddenly, and enlarges over a week
- Appears most often in children and adolescents; favors the neck, extensor arms, abdomen, and buttocks
- Can persist indefinitely

THE SPECTRUM OF KERATOSIS PILARIS ATROPHICANS							
Disorder	**Mode of inheritance**	**Gene/ genetic locus**	**Age at onset**	**Distribution**	**Cutaneous features**	**KP***	**Other occasional features and associations**
Keratosis pilaris atrophicans faciei (ulerythema ophryogenes)	AD ≫ AR	18p11.2 (AD) *LRP1* (AR)	Infancy	Eyebrows, particularly the lateral third > temples, cheeks, forehead (Fig. 38.7)	• Skin-colored to erythematous follicular papules with central keratotic plugs, eventuating in follicular atrophy • Scarring alopecia of the lateral eyebrows	+	• Associated with Noonan syndrome, cardio-facio-cutaneous syndrome, monosomy 18p, woolly hair, and Swyer and Cornelia de Lange syndromes
Atrophoderma vermiculatum (see Ch. 99)	?AD	?	Childhood (usually between 5 and 12 years)	Cheeks (see Fig. 99.8) upper lip, forehead, ears	• Pitted, atrophic depressions in a vermiculate pattern ("worm-eaten" or "honeycomb" appearance)†	–	• Associated with Loeys–Dietz, Rombo, and Nicolau–Balus syndromes • Unilateral form has been associated with ipsilateral congenital cataract
Keratosis follicularis spinulosa decalvans, X-linked (KFSDX)	XLR	*MBTPS2*‡	Childhood (inflammation often remits at puberty)	Scalp, face, limbs, trunk	• Erythematous follicular papules with central keratotic plugs, eventuating in follicular atrophy • Scarring alopecia of the scalp, eyebrows, and eyelashes • Facial erythema • Palmoplantar keratoderma • Nail dystrophy (e.g. thickening, crumbling)	++	• Keratitis, blepharitis, corneal dystrophy, photophobia
Keratosis follicularis spinulosa decalvans (folliculitis spinulosa decalvans)	AD	?	Childhood; exacerbation after puberty	Scalp, face > trunk, extremities	• Compared to KFSDX: facial erythema and nail dystrophy more common; more severe scalp inflammation with pustules • Otherwise, features similar to KFSDX	++	• Blepharitis, conjunctivitis

*Associated keratosis pilaris (KP) on the extremities and trunk.
†May be preceded by erythematous keratotic follicular papules.
‡MBTPS2 (membrane-bound transcription factor peptidase, site 2) is a zinc metalloprotease required for cleavage of sterol regulatory element-binding proteins (SREBPs) and is essential for cholesterol homeostasis and the endoplasmic reticulum stress response; mutations in *MBTPS2* also underlie XLR IFAP syndrome (see Table 38.3).

Table 38.2 The spectrum of keratosis pilaris atrophicans. AD, autosomal dominant; AR, autosomal recessive; LRP1, low-density lipoprotein (LDL) receptor-related protein 1; XLR, X-linked recessive; +, mild to moderate; ++, severe.

History and epidemiology

First described by Crocker in 1883, lichen spinulosus is characterized by grouped, skin-colored, keratotic follicular papules. In one series, the average age at onset was 16 years[23].

Pathogenesis

Although several factors, such as atopy, infections and heredity, have been proposed as playing a role in lichen spinulosus, the exact etiology is unknown and most patients do not have associated systemic abnormalities. There are reports of lichen spinulosus-like lesions arising in the setting of HIV infection[24]. The terms *HIV-associated follicular syndrome* and *type VI PRP* have been proposed to encompass the constellation of HIV infection, nodulocystic acne, and lesions with follicular spines, including PRP and lichen spinulosus. Additional (likely coincidental) associations reported in the literature include seborrheic dermatitis, a drug reaction (omeprazole), Hodgkin lymphoma, Crohn disease, syphilis, and an id reaction to fungal infections.

Clinical features

Typical lesions measure 2–6 cm in diameter (Fig. 38.8) and are composed of grouped skin-colored, keratotic follicular papules, each of which has a central horny spine. Lichen spinulosus favors the neck, shoulders, and extensor surfaces of the arms, as well as the abdomen, buttocks, and popliteal fossae, and the distribution pattern may be symmetric. The hands and feet are usually spared. Lesions often arise suddenly in crops, enlarge over a week, and then remain stationary. Idiopathic lichen spinulosus usually appears during childhood and adolescence and is sometimes pruritic. Spinulosis of the face (tiny follicular keratotic spicules of the cheeks) may be a manifestation of lichen spinulosus.

Pathology

Histologically, lichen spinulosus most resembles keratosis pilaris, with follicular plugging of the infundibulum and a mild perivascular and perifollicular lymphocytic infiltrate in the upper dermis.

Differential diagnosis

The differential diagnosis of lichen spinulosus includes phrynoderma, keratosis circumscripta, follicular ichthyosis, and juvenile pityriasis

rubra pilaris (Table 38.3), in addition to folliculotropic mycosis fungoides[29]. Facial spines can also be seen in the setting of HIV-associated follicular syndrome (see above), viral-associated trichodysplasia, demodicosis, follicular mucinosis, and in patients with multiple myeloma. Lastly, widespread follicular plugging has been reported as a side effect of BRAF inhibitors and systemic lithium therapy.

Treatment

Topical therapies such as lactic acid, urea, and salicylic acid may improve the texture. There are case reports of successful treatment with adapalene gel, tacalcitol cream[30], glycolic acid peels, and tretinoin gel plus hydroactive adhesive applications[31].

Phrynoderma

Phrynoderma, which means "toad skin", is rarely seen in developed countries, except in settings such as intestinal malabsorption due to bariatric surgery and malnutrition from anorexia nervosa or fad diets (see Ch. 51). Phrynoderma is seen most often in association with vitamin A deficiency, but some patients may have measurable deficiencies in other vitamins and/or proven malnutrition[32]. Skin-colored to hyperpigmented acuminate follicular papules with central keratotic plugs favor the extensor surfaces of the extremities (see Fig. 51.7). Lesions of the face, hands, or feet would be unusual to rare[33]. Associated systemic findings (e.g. ocular, CNS), histologic features, diagnosis via measurement of serum vitamin A levels, and treatment are discussed in Chapter 51.

Fig. 38.8 Lichen spinulosus. Grouped, skin-colored follicular papules on the extensor surface of the arm. Central keratotic plugs can be seen.

TRICHOSTASIS SPINULOSA

Trichostasis spinulosa is a common, but often underdiagnosed, follicular disorder of unknown etiology. Comedo-like lesions that contain keratin and multiple vellus hairs are seen, primarily on the mid to lower central portion of the face, including the nose (see Table 36.2). Lesions can develop on the trunk, most commonly the interscapular region, and less often the axillae and scalp, including within an isolated collagenoma[34] and after application of minoxidil[35]. The differential diagnosis is outlined in Table 36.2. Histologically, within a dilated hair follicle, there are multiple, small vellus hairs and keratinous debris; a perifollicular, mild mixed inflammatory infiltrate may be present. Therapeutic options include keratolytics, topical tretinoin, depilatories, adhesive strips, and lasers (e.g. long-pulsed alexandrite, short-pulsed alexandrite, pulsed diode).

VIRAL-ASSOCIATED TRICHODYSPLASIA SPINULOSA

Synonyms: ■ Viral-associated trichodysplasia ■ Viral-associated trichodysplasia of immunosuppression ■ Trichodysplasia spinulosa

Viral-associated trichodysplasia (see Ch. 81) is associated with drug-induced immunosuppression, most often in organ transplant recipients, and it reflects infection with the *t*richodysplasia *s*pinulosa-associated *p*oly*o*ma*v*irus (TSPyV)[36] (see Ch. 81). The virus' small T antigen may play a role in disrupting the cycling of follicular keratinocytes[37]. Skin-colored to

DIFFERENTIAL DIAGNOSIS OF LICHEN SPINULOSUS	
Keratosis circumscripta[25–27] (psoriasis circumscripta with palmoplantar keratosis)	• Age at onset usually 3–5 years and described primarily in Africans • Well-circumscribed lesions consisting of grouped folliculocentric papules, with or without palmoplantar hyperkeratosis • Lesions favor the elbows and knees, neck, hips, sacrum, and posterior axillary folds • Some authors argue that this is a variant of psoriasis as the histologic findings are similar to those of plaque-type psoriasis
Follicular ichthyosis[28]	• Onset during early childhood • Keratotic papules with follicular plugging and prominent follicular ostia • Favors the head and neck region, but may also involve the extensor surfaces of the extremities, especially the fingers, elbows, and knees
Ichthyosis follicularis with atrichia and photophobia (IFAP) syndrome (Ch. 57)	• XLR (*MBTPS2* mutations, allelic with keratosis follicularis spinulosa decalvans; see Table 38.2) or AD (*SREBF1* mutations) • In female carriers, linear streaks consisting of follicular keratoses, scaling, and/or hypotrichosis • In affected males, generalized congenital non-scarring alopecia, photophobia, follicular keratoses, and psoriasiform plaques (see Fig. 55.11)
Hereditary mucoepithelial dysplasia	• AD with more widespread follicular keratoses and non-scarring alopecia (similar to IFAP; also *MBTPS2* mutations) • Severe keratitis, erythema of the oral mucosa (paucity of desmosomes and dyskeratotic cells histologically), and psoriasiform plaques that favor intertriginous zones, especially the perineal area
Juvenile pityriasis rubra pilaris (Ch. 9)	• Especially type IV (circumscribed), in which lesions favor the elbows and knees
Keratosis pilaris (Ch. 12)	• Perifollicular erythema in addition to follicular plugging • Favors the upper outer arms and the thighs, but lacks discrete clusters • May be more widespread in keratosis pilaris-like drug eruptions (e.g. sorafenib)
Lichen planopilaris (Ch. 11)	• Follicular keratotic plugs are surrounded by a narrow violaceous rim • Scarring alopecia of the scalp most common presentation but follicular lesions may be disseminated
Folliculotropic mycosis fungoides (Ch. 120)	• Acneiform lesions may be seen, including comedones (see Fig. 36.16B,C); they may be clustered
Phrynoderma (vitamin A deficiency; Ch. 51)	• Follicular papules with a central keratotic plug favor the extensor surfaces of the extremities and buttocks • Generalized xerosis, sparse fragile hair, night blindness, xerophthalmia

Table 38.3 Differential diagnosis of lichen spinulosus. Viral-associated trichodysplasia is discussed in the text and Chapter 81. The differential diagnosis also includes the spinous variant of lichen nitidus and follicular keratosis (of the chin). AD, autosomal dominant.

pink follicular papules and follicular spines favor the central face (see Fig. 81.16) and may be accompanied by loss of the eyebrows and eyelashes; extrafacial lesions with associated alopecia may also develop. Histologically, enlarged and distended anagen-type follicles have a high number of inner root sheath cells with excessive amounts of trichohyaline granules. If immunosuppressive therapy cannot be reduced, topical cidofovir or tazarotene gel or oral valganciclovir (900 mg once or twice daily) may be helpful.

DEEP FOLLICULITIS

The major forms of deep folliculitis are furuncles (see Ch. 74), sycosis (barbae [see Fig. 38.3B], lupoid, mycotic [Fig. 38.9]; Table 38.4), pseudofolliculitis barbae, acne keloidalis, and hidradenitis suppurativa. The lesions are firm, tender, erythematous papules or nodules. Deep lesions should never be manipulated (i.e. squeezed) by the patient, because this may cause bacteremia or seeding of the heart valves (endocarditis), brain (abscess), or bones (osteomyelitis).

Fig. 38.9 Mycotic sycosis. Firm plaque of the upper cutaneous lip studded with multiple pustules due to a zoophilic dermatophyte. *Courtesy Kalman Watsky, MD.*

FORMS OF SYCOSIS	
Type	**Characteristics**
Barbae	• Bacterial folliculitis of the beard and/or mustache areas, usually caused by *Staphylococcus aureus* • Deep-seated, edematous, perifollicular papules and pustules that may coalesce to form crusted plaques studded with pustules (see Fig. 38.3B) • Subacute to chronic course with frequent relapses
Lupoid	• Scarring form of deep folliculitis, typically affects the beard area; may be caused by *S. aureus* (although cultures often fail to reveal pathogenic organisms) • Peripheral extension of perifollicular papules and pustules with central scarring alopecia; appearance can be reminiscent of lupus vulgaris • Chronic course, refractory to treatment
Mycotic	• Dermatophyte folliculitis of the beard area, usually caused by zoophilic organisms • Inflammatory perifollicular papules and pustules coalesce to form nodules and plaques with crusts, purulent discharge from patulous follicles, and loose hairs that can be painlessly removed (Fig. 38.9)
Herpetic	• See Table 38.1

Table 38.4 Forms of sycosis. Sycosis is defined as chronic inflammation of hair follicles, especially of the beard.

Pseudofolliculitis Barbae

Synonyms: ■ Shave bumps ■ Razor bumps ■ Barber's itch ■ Folliculitis barbae traumatica ■ Scarring pseudofolliculitis of the beard ■ Chronic sycosis barbae ■ Ingrown hairs

Key features

- A common chronic disorder occurring most often in the beard area of men who shave
- It favors Black men with tightly curled hair
- Distal tips of hairs curve back into the skin after having been shaved
- Lesions range from inflammatory papules and pustules to firm papules and keloidal scars
- Although the only reliable way to cure the disease is to stop shaving, shaving techniques can be optimized and laser therapy can significantly reduce severity

Introduction

Pseudofolliculitis barbae is a common chronic inflammatory disorder of terminal hair-bearing sites, occurring most often in the beard area of men who shave and have tightly curled hair.

Epidemiology

Although pseudofolliculitis barbae can occur in any racial group, it primarily affects Black men. The incidence in African-American men varies from 45%–85%, depending upon the particular study. Pseudofolliculitis barbae is less common and is usually milder in those with straight hair. Women may also develop pseudofolliculitis following shaving or plucking of hairs in the groin, axillae, or a hirsute face.

Pathogenesis

The disorder is thought to be caused by re-entry of the distal portion of tightly curled hairs into the skin. In individuals with tightly curled hair, the hair follicles sit at an oblique angle and when shaved, a sharp tip is created at the distal end of the hair. Fig. 38.10 illustrates extrafollicular and transfollicular forms of hair penetration. Once the hair penetrates the dermis, an inflammatory reaction ensues.

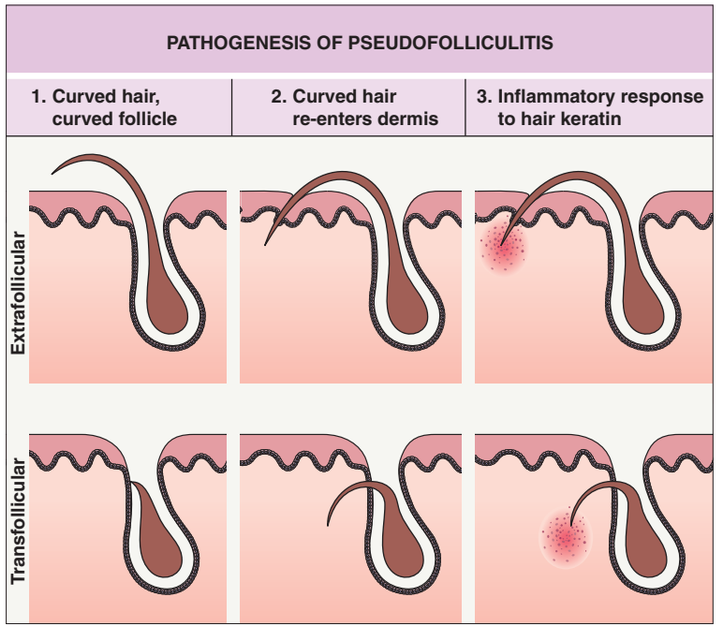

Fig. 38.10 Pathogenesis of pseudofolliculitis. In individuals with tightly curled hair, the hair follicles sit at an oblique angle and when shaved, a sharp tip is created at the distal end of the hair. There are two proposed mechanisms for hair penetration: (1) *extrafollicular* – the cut hair grows normally from the follicular orifice but then curves downward and penetrates the skin surface 1–2 mm distally from where the hair exits; and (2) *transfollicular* – the distal tip of the cut hair shaft pierces the follicular epithelium and penetrates the dermis instead of normally exiting the follicular orifice. *Courtesy M. A. Abdallah, MD.*

The presence of a single nucleotide polymorphism in the 1 A α-helical subdomain of the hair follicle companion layer-specific keratin K6hf (KRT75) has been reported to be an additional genetic risk factor for pseudofolliculitis barbae[38]. In women, hyperandrogenism may be a contributing factor[39].

Clinical features

Skin-colored to red-brown papules or pustules develop in hair-bearing sites that have been shaved (Fig. 38.11). These lesions are most commonly observed within the beard area. Postinflammatory hyperpigmentation and scarring, including keloid formation, are potential sequelae. Chronic lesions may cause the hair to create grooves in the skin; the anterior neck and submandibular areas are particularly prone to this complication. Once the grooves have formed, shaving becomes extremely difficult.

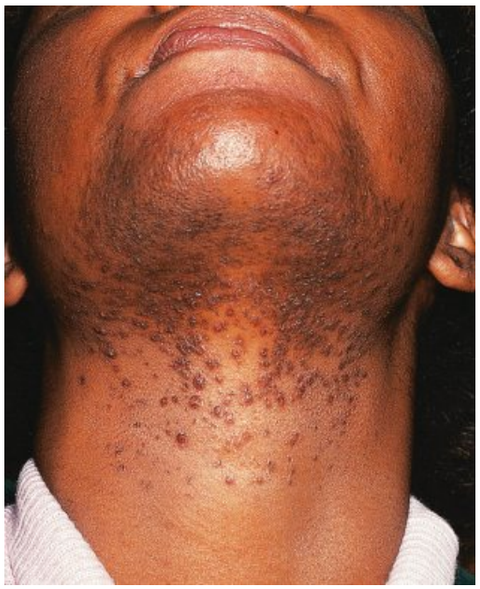

Fig. 38.11 Pseudofolliculitis barbae. Multiple firm hyperpigmented papules on the lower face and neck (beard distribution). *Courtesy Paul Kelly, MD.*

Pathology

The sharp cut end of the hair initially causes an invagination in the epidermis, which is accompanied by inflammation and frequently by an intralesional microabscess. As the hair penetrates the epidermis, a heavy mixed inflammatory cell infiltrate develops as a reaction to the downgrowth of the epidermis in an attempt to ensheathe the hair[40]. This is accompanied by abscess formation within the pseudofollicle and a foreign body giant cell reaction at the tip of the invading hair. Naked hair shafts surrounded by acute and chronic inflammation or a primarily fibrotic dermis are commonly observed.

Differential diagnosis

Facial acne vulgaris is similar in appearance, but differs by having open or closed comedones and a distribution beyond the beard region. In sycosis barbae, which also commonly occurs in the beard region, the lesions tend to be more confluent rather than discrete. Histologically, the foreign body reaction needs to be differentiated from cutaneous sarcoidosis.

Treatment

Before therapy is initiated, the patient should be given a candid explanation regarding the cause of pseudofolliculitis barbae. It should be stressed that the only reliable way to cure the disease is to stop shaving, but there are several treatments that may control the process, including laser therapy. In those with severe disease, a hiatus of several months without shaving is recommended. When patients resume shaving once the inflammatory lesions have completely cleared, they need to be given advice on shaving methods (Table 38.5).

Except for very mild cases, pseudofolliculitis barbae requires medical intervention during its acute phase, when it is often painful and/or pruritic.

THERAPEUTIC APPROACH TO PSEUDOFOLLICULITIS BARBAE	
Advice on shaving methods	
Important points	
• Do not pull the skin taut • Use a sharp razor each time (single-edged with protective foil preferred*) or an electric razor • Take short light strokes and do not shave over the same areas more than twice • For severe disease: discontinue shaving until all inflammatory lesions have cleared and all "ingrown hairs" are released; during this period, the patient can trim beard to a minimum length of 5 mm using scissors or electric clippers	
Method	
• Remove pre-existing hairs with electric clippers, leaving approximately 1–2 mm of stubble (only step if this length is acceptable to the patient) • Wash area with warm water, non-abrasive soap, and a soft brush or sponge • Rinse area with warm water or apply warm compress • Using shaving cream, massage moderate amount of lather on area to be shaved 5–10 minutes prior (do not allow lather to dry; if it does, reapply it) • Use a sharp blade* and shave the hair using short even strokes with minimal tension (and no more than twice over one area) • Traditionally, patients were advised to shave in the direction of hair growth ("with the grain"), but shaving against the grain may not worsen the disease[41] • After shaving, rinse with tap water and then apply a soothing aftershave preparation. If significant burning or itching ensues, apply a topical corticosteroid cream or lotion (1%–2.5% hydrocortisone)	
Treatment recommendations	
Compresses	• Warm tap water, saline, or Burow's solution (aluminum acetate) compresses for 10 minutes three times daily to soothe lesions, remove any crusts, reduce drainage secondary to inflammation and/or excoriations, and soften the epidermis to allow easier release of "ingrown hairs"
Topical and intralesional therapy	• Low-potency topical corticosteroid lotion, topical antibiotics (e.g. clindamycin), and/or topical retinoids should be applied after compresses and freeing of embedded hairs • Topical glycolic acid 8% lotion • Intralesional triamcinolone acetonide injections (5–10 mg/ml)
Secondary bacterial infection	• Appropriate systemic antibiotic should be prescribed, based upon bacterial cultures
Recalcitrant disease	• Topical eflornithine cream twice daily may be helpful† • Laser hair removal (utilizing appropriate laser for skin color) with goal of permanent hair reduction (see Ch. 137)
Postinflammatory hyperpigmentation	• Hydroquinone ± topical retinoids and corticosteroids, azelaic acid, kojic acid • Chemical peels (see Ch. 154)
*However, in one study, there was no difference in disease activity between single- versus multi-blade razors[72]. †Based upon case series.	

Table 38.5 Therapeutic approach to pseudofolliculitis barbae. *Courtesy A. Paul Kelly, MD.*

Although antibiotics, topical or systemic, are not particularly beneficial (unless secondary infection is present), they may provide some anti-inflammatory effect. The recommended therapeutic approach is outlined in Table 38.5. Adjunct treatments such as topical keratolytics (e.g. retinoids, α-hydroxy acids) and benzoyl peroxide washes may be used in patients with mild to moderate pseudofolliculitis barbae. However, those with severe and chronic disease usually have only slight improvement with these therapies.

Laser hair removal can lead to a significant reduction in disease severity. For example, the 1064 nm Nd:YAG laser can be used with a long pulse duration and continuous contact cooling, even in patients with skin types V or VI, as can a modified 810 nm super-long-pulsed diode laser. Treatment is given at 3- to 4-week intervals for two to three sessions. Care must be taken when selecting the laser fluence, especially in patients with darkly pigmented skin[42]. Additional therapeutic options are chemical depilatories and eflornithine cream; application of eflornithine cream twice daily between laser hair removal sessions led to better outcomes when compared with laser alone[43]. Prior to application of chemical depilatories, the beard should be trimmed and, to avoid irritation, treatments should be limited to twice weekly.

Acne Keloidalis

Synonyms: ■ Acne keloidalis nuchae ■ Folliculitis keloidis nuchae ■ Nuchal keloid acne ■ Folliculitis keloidalis ■ Dermatitis papillaris capillitii (historical)

Key features

- Begins as inflamed follicular papules or pustules on the posterior neck and occipital scalp
- With time, keloidal papules and plaques develop
- Vast majority of affected individuals are Black men

Introduction

Acne keloidalis refers to the presence of keloid-like papules and plaques on the occipital scalp and posterior neck. This disorder occurs primarily in Black men. The patients usually develop a chronic folliculitis and perifolliculitis of the posterior scalp and neck, which then heals with keloid-like papules. Over time, these papules may coalesce to form one or several large plaques, which gradually enlarge over a period of years. The lesions are usually pruritic and may also be painful and cosmetically disfiguring. Early intervention may prevent progression to disfiguring disease.

History

The disorder was first described by Hebra in 1860 as "sycosis framboesiformis". In 1869, Kaposi termed it "dermatitis papillaris capillitii". Three years after Kaposi's publication (1872), Bazin named the condition "acne keloidalis".

Epidemiology

In the US, acne keloidalis occurs most often in African-American men. Acne keloidalis may also occur in women, but the male:female ratio is at least 20:1. Development prior to puberty or after the age of 55 years is rare. An association with metabolic syndrome[44] and hidradenitis suppurativa has been observed in population-based studies.

Pathogenesis

The cause of acne keloidalis is unknown, and no specific genetic factor has been identified. Histologically, fragments of naked hair shafts, surrounded by microabscesses and/or granulomatous inflammation, can be seen within a fibrotic dermis[45]. A possible explanation is skin injury. In one study, the mast cell density of the neck/occipital scalp was increased compared with the anterior scalp; these mast cells may prompt rubbing and other physical manipulation of the skin, thereby predisposing this location to the development of acne keloidalis. Chronic irritation from high-collared shirts or helmets could also play a role. Perhaps acne keloidalis represents a primary form of scarring alopecia triggered by an aberrant cutaneous immune reaction[45].

Clinical features

Acne keloidalis often begins as a posterior scalp and/or neck folliculitis, followed by the development of 2–4 mm, dome-shaped, firm follicular papules that may or may not be pruritic (Fig. 38.12). Pustules may also be present within the same area but are usually short-lived because they are traumatized when the hair is combed or brushed or are easily ruptured by scratching. In contrast to acne vulgaris, comedones are not present.

As the disease progresses, more hard papules develop and slowly enlarge. Some coalesce and form keloid-like plaques, which are often arranged in a band-like distribution near the posterior hairline (Fig. 38.13). The plaques are usually only a few centimeters in diameter but may grow to more than 10 cm. Even when only papules are present, a large portion of the posterior scalp may be involved.

When the area of involvement is significant, there is usually associated patchy alopecia or complete hair loss. Occasionally, the scarring process may extend onto the vertex and/or parietal scalp. The upper borders of large lesions are often fringed with tufted hairs that resemble the hair on a doll's head, as seen in other scarring alopecias such as folliculitis decalvans (see Ch. 69). As in dissecting cellulitis, subcutaneous abscesses with draining sinuses may occasionally be present, and they may emit a malodorous discharge.

Fig. 38.12 Acne keloidalis. An admixture of follicular pustules, crusted papules and firm fibrotic hyperpigmented papules on the posterior neck and occipital scalp. There is associated alopecia.

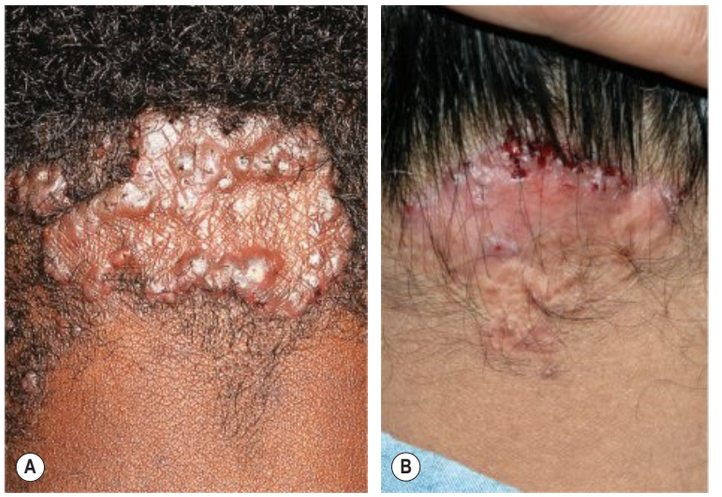

Fig. 38.13 Acne keloidalis. A Keloidal papulonodules and a large plaque of the occipital scalp, associated with scarring alopecia. Note the tufts of hair at the superior border of the scar. **B** Although the disorder is seen less often in Hispanic patients, the clinical findings are similar. *A, Courtesy Paul Kelly, MD; B, Courtesy Luis Requena, MD.*

Pathology
Inflammation begins in the upper one-third of the hair follicle. Descriptions of the initial infiltrate vary from it being composed of neutrophils and lymphocytes to predominantly plasma cells[46]. In more advanced lesions, hair follicles are disrupted, and fragments of naked hair shafts surrounded by microabscesses and/or granulomatous inflammation may be noted (Fig. 38.14). Dermal fibrosis is also present at this stage, and the collagen fibers resemble those seen in scar tissue rather than those seen in keloids. The lower portion of the follicle, including the matrix, is usually spared until later in the disease process. There is complete disappearance of sebaceous glands in late stages of the disease.

Differential diagnosis
Clinically, the initial lesions may resemble culture-negative or staphylococcal folliculitis (see above), while later-stage lesions may be mistaken for keloids or hypertrophic scars secondary to trauma. On the neck there may be overlap with pseudofolliculitis barbae, and when there is more extensive or severe scalp involvement, folliculitis decalvans and dissecting cellulitis may enter the differential diagnosis.

Treatment
Avoidance of exacerbating factors is the first line of defense. Those who have acne keloidalis should not wear any kind of head-dress or head gear that causes mechanical irritation of the posterior hairline. In addition, they should avoid wearing shirts or sweaters that irritate the posterior scalp and neck.

The sooner therapy is initiated, the less likely the patient is to develop large lesions and scarring. Twice-daily application of topical tretinoin and a mid- to high-potency corticosteroid may be sufficient to improve inflammatory papules and help flatten non-inflamed lesions. Topical or systemic antibiotics, as for acne vulgaris, may clear pustules but do not soften or clear the secondary keloidal lesions. A bacterial culture should be obtained from any site with oozing or drainage, followed by the appropriate systemic antibiotic. Triamcinolone acetonide (5–20 mg/ml) can be injected into persistent inflammatory or keloidal papules, taking into account hypopigmentation and atrophy as potential side effects.

If keloidal papules persist, they often need to be removed by a punch excision with a hair transplant trephine followed by either a primary closure or healing by second intention. The punch must extend below the level of the hair follicle to be successful. In addition, a 50:50 mixture of 2% lidocaine with epinephrine (adrenaline) and triamcinolone acetonide (40 mg/ml) may be employed for local anesthesia in order to help prevent recurrence. Excisions can be closed with silk rather than rigid sutures to prevent suture ends from piercing the surrounding skin.

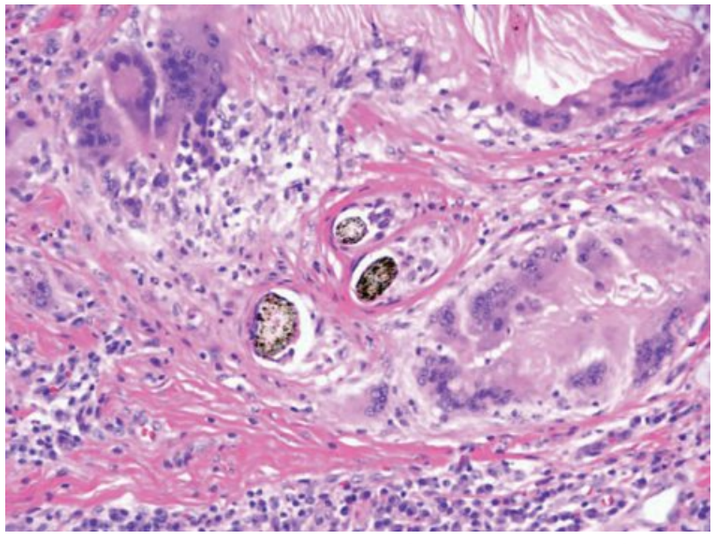

Fig. 38.14 Acne keloidalis – histopathologic features. Naked hair shafts in the dermis with perifollicular fibrosis and surrounding granulomatous inflammation with multinucleated giant cells.

For plaques 1.0–1.5 cm in vertical diameter, excision with primary closure is the treatment of choice, with the depth extending below the base of the hair follicles to reduce recurrence risk. Lesions >1.5 cm in vertical diameter should not be closed primarily because the postoperative scar usually spreads to the width of the excisional defect, producing a hairless flat scar. For these lesions, the area of acne keloidalis should be excised to the level of the fascia or deep subcutaneous tissue and left to heal by second intention. The horizontal surgical ellipse must include the posterior hairline[47], and it normally takes 8–12 weeks for the defect to close. During this healing phase, injection of corticosteroids may interfere with wound contracture. Excision with a CO_2 laser is another option and for large lesions, a staged excision.

The long pulsed Nd:YAG and diode lasers have been reported to be effective, particularly in decreasing the number of papular lesions[48]. Targeted UVB therapy was shown to decrease mean lesion count in a split-scalp comparison study of 11 patients[49]. Cryotherapy is also sometimes used, but in individuals with darkly pigmented skin, it may cause hypopigmentation. Based on case reports, a course of oral isotretinoin may prove helpful in severe recalcitrant inflammatory cases of acne keloidalis.

FOLLICULAR OCCLUSION TETRAD

In 1956, Pillsbury, Shelley and Kligman coined the term "follicular occlusion triad" for the association of acne conglobata (see Ch. 36), hidradenitis suppurativa, and dissecting cellulitis of the scalp (see Ch. 69). They proposed that the pathologic event unique to each disease was follicular hyperkeratinization[50]. In 1975, a fourth component, pilonidal sinus, was added, creating the follicular tetrad. Most commonly located within the superior portion of the natal cleft, a pilonidal sinus contains keratinous debris and often multiple hairs. There can be associated granulomatous inflammation, pustular discharge, and even abscess formation. It is also referred to as a pilonidal cyst or sacrococcygeal fistula and treatment involves surgical excision.

Hidradenitis Suppurativa

Synonyms: ■ Acne inversa ■ Verneuil disease ■ Velpeau disease ■ Apocrine acne
Advanced disease: ■ Fox-den disease ■ Pyoderma fistulans sinifica

Key features
- An inflammatory keratinization disorder characterized by follicular occlusion
- Associated with systemic inflammation, metabolic and polycystic ovary syndromes, and autoinflammatory disorders
- Predilection for intertriginous zones, especially the axillary, anogenital, and inframammary regions
- Recurrent painful inflamed nodules and abscesses; with increasing severity, formation of chronic draining tunnels, scars, and potentially squamous cell carcinoma
- Histologically, follicular dilatation and hyperkeratinization, with concomitant inflammation of the sweat glands in a minority of cases

Introduction
Hidradenitis suppurativa (HS) is a chronic cutaneous disorder that preferentially affects intertriginous skin, in particular the axillae and anogenital regions. It is characterized by recurrent inflammatory nodules and abscesses that may progress to form draining sinus tracts and scars.

History
In the 1830s, Velpeau and Verneuil conceptualized HS as a specific disease. Although apocrine gland dysfunction was initially considered to be the underlying cause, it is now believed that occlusion of the follicular

infundibula followed by follicular rupture is the inciting event, and apocrine gland involvement is secondary.

Epidemiology

In the US, the female : male ratio is 3 : 1 and African-Americans are 3–7 times more likely to be diagnosed with HS[51]. However, these statistics can vary, e.g. in South Korea the female : male ratio is 1 : 2[51]. Up to 25% of patients present prior to age 18 years ("early-onset" HS) and most commonly they are teenage girls 15–17 years of age. A prepubertal onset raises the possibility of an endocrine disorder, e.g. precocious puberty.

Pathogenesis

HS is a multifactorial inflammatory disease that is a consequence of follicular occlusion and immune dysregulation and is influenced by genetics/epigenetics, the cutaneous microbiome, and hormones.

The term *follicular occlusion* encompasses the predilection of HS for major skin folds, i.e. sites prone to friction and occlusion, as well as the follicular dilatation and hyperkeratinization that occurs microscopically. The latter is thought to be an inciting event, but actually may be a consequence of subclinical inflammation[52]. Follicular rupture, with release of keratin and bacteria into the dermis, follows comedone formation. An exuberant inflammatory response with abscess formation then ensues.

Immune dysregulation involves a host of cytokines and chemokines, including TNF, IL-1 α/β, IL-6, G-CSF, and various isoforms of IL-17[53,54]. Recruited neutrophils produce tissue damage via reactive oxygen species, proteases, and neutrophil extracellular traps (NETs); they also recruit macrophages, which produce additional proinflammatory cytokines, and activate complement (e.g. C3a, C5a). Degrading enzymes such as matrix metalloproteinases contribute to the thinning, fragility, and subsequent rupture of the follicular epithelium with generation of epithelial strands and tunnels.

Historically, a role for *genetics* was supported by up to 40%–50% of HS patients having a family history of HS[55] as well as an increased incidence of HS in patients with genetic disorders such as Dowling–Degos disease and the PASH (*p*yoderma gangrenosum, *a*cne, and suppurative *h*idradenitis) autoinflammatory disorder. More recently, mutations in one of three genes – *NCSTN, PSEN1*, or *PSENEN* – were shown to underlie inherited nonsyndromic ("pure") HS (Table 38.6)[56]. These genes encode three of the four components of the γ-secretase complex which cleaves proteins such as amyloid precursor protein and Notch. Of note, mice deficient in Notch 1 and 2 phenotypically mimic mice deficient in γ-secretase, with cyst formation and both epidermal and follicular defects, pointing to a role for the Notch cell signaling pathway in HS[57]. Additional possible candidate genes are outlined in Table 38.6[58].

Epigenetic changes include: (1) decreased expression of DNA hydroxymethylation regulators (e.g. TET1) in HS lesional skin; (2) inflammatory stage-dependent changes in expression of different microRNA (miRNA), which are involved in gene silencing via repression of mRNA translation (see Fig. 3.14); and (3) differential expression of RNA-induced silencing complex (RISC) components[58].

Regarding the *cutaneous microbiome*[59], a decreased relative abundance of skin commensal bacteria (specifically *Cutibacterium)* and an increased relative abundance of mixed anaerobic bacteria (e.g. *Prevotella, Porphyromonas*, *Peptoniphilus* spp.) have been observed in lesional skin when compared to either non-lesional or healthy control skin. Increased bacterial diversity and relative abundance of anaerobic bacteria both positively correlate with HS severity. When compared to healthy control skin, unaffected HS skin folds were also found to have an increased relative abundance of anaerobic bacteria. *Staphylococcus aureus* abundance in non-lesional skin positively correlates with overall HS clinical severity.

Fig. 38.15 Hidradenitis suppurativa. A Papulopustules, nodules, sinus tracts and scarring in the axilla (Hurley stage II). **B** Multiple tunnels and scarring in the axillary region. **C** Nodules, draining sinus tracts, and marked scarring (Hurley stage III). **D** Double-ended comedones that serve as a clue to the diagnosis, even in the absence of active disease. **E** Multiple interconnecting sinus tracts, one of which has developed granulation tissue (Hurley stage III). **F** Severe disease with inflammatory nodules, hypertrophic scarring, draining fistulae and sinus tract formation of the perianal region, buttocks, and upper thighs. This is the type of patient who is at risk for the development of squamous cell carcinoma and secondary amyloidosis. **G** Cribiform and atrophic scarring due to severe facial disease. *A, Courtesy Kalman Watsky, MD; C, Courtesy Marco Romanelli, MD; F, Courtesy A. Paul Kelly, MD.*

NONSYNDROMIC HIDRADENITIS SUPPURATIVA – ASSOCIATED GENES		
Gene	**Protein product**	**Proposed function related to HS**
Familial acne inversa (ACNINV) -1, -2, -3		
NCSTN	Nicastrin (γ-secretase complex)	Regulation of epidermal and follicular keratinocyte differentiation
*PSENEN**	Presenilin enhancer-2 (γ-secretase complex)	
PSEN1	Presenilin 1 (γ-secretase complex)	
Other genes implicated in HS pathogenesis		
TNF	Tumor necrosis factor	Promotion of inflammation
BCL2	Anti-apoptotic regulatory protein	Maintenance of homeostasis in outer root sheath cells of hair follicles
IL12Rβ1	Subunit of the IL-12 and IL-23 receptors (see Fig. 128.9D)	Regulation of T cell subset differentiation

*Allelic with Dowling–Degos disease and patients may have features of both disorders.

Table 38.6 Nonsyndromic hidradenitis suppurativa (HS) – associated genes. The fourth protein in the γ-secretase complex is anterior pharynx-defective 1. Additional implicated genes include DEFB (encodes β-defensin), *MYD88*, and *ABCC11* (affects apocrine sweat gland secretion).

COMORBIDITIES IN PATIENTS WITH HIDRADENITIS SUPPURATIVA	
Organ system	**Comorbidity**
Articular	Spondyloarthritis
Cardiovascular	Hypertension Myocardial infarction Cerebrovascular accident
Cutaneous	Acne vulgaris and acne conglobata* Dissecting cellulitis of the scalp* Pilonidal disease* Pyoderma gangrenosum
Gastrointestinal	Crohn disease Ulcerative colitis
Metabolic/endocrine	Metabolic syndrome (includes dyslipidemia, hypertension, insulin resistance; see Table 53.5) Obesity Diabetes mellitus Thyroid disease
Psychiatric	Depression Generalized anxiety disorder Suicidal ideation Substance use disorder
Reproductive	Polycystic ovarian syndrome Sexual dysfunction
Other	Smoking

*Components of follicular occlusion tetrad.

Table 38.7 Comorbidities in patients with hidradenitis suppurativa (HS).

Biofilm formation has been shown to play a role in the development of acute lesions, as well as the maintenance of chronic tunnels. The gut microbiome alterations in HS are less well characterized[60], but in smaller series findings were similar to those in patients with inflammatory bowel disease and metabolic syndrome, e.g. more abundant *Bilophila* and *Holdemania* genera and less abundant *Lachnobacterium* and *Veillonella* genera.

With regard to *hormonal factors*, there is a temporal relationship between HS onset and the rise in sex hormones during puberty. In addition, HS patients have an increased incidence of metabolic syndrome and polycystic ovary syndrome. The effect of pregnancy on HS disease activity is mixed, with women reporting improvement, no change, or exacerbation[61]. Of note, HS has been found to be a risk factor for adverse pregnancy and maternal outcomes[61a].

Clinical features

Typical lesions include comedones (including double-ended comedones; Fig. 38.15D), inflammatory papules and nodules, abscesses, tunnels (both sinus tracts and skin fistulae), and scars. Less often pyogenic granuloma-like lesions and ulcers are seen. Lesions favor major body folds including the axillae, groin, buttocks, and inframammary areas (Fig. 38.15A–C). Occasionally, the face (Fig. 38.15G), post-auricular region, neck, and trunk are involved. Initially, patients have recurrent inflammatory papulonodules and abscesses that are tender and extremely painful. Over time, tunnels (Fig. 38.15E) and scars (Fig. 38.15C,F) may develop. This can be accompanied by chronic, malodorous drainage, leading to a marked degree of frustration, embarrassment, and self-consciousness. The discharged fluid is often a mixture of serous exudate, blood and pus, in varying proportions. Of note, patients may also experience pruritus[62].

Complications include soft tissue infections, lymphedema, and scarring so severe as to lead to strictures of the urethra, anus, and rectum as well as limb contractures[63]. Rarely, squamous cell carcinoma (SCC) arises within chronic HS lesions, primarily in gluteal, perianal and perineal areas, and it has a high risk of morbidity and mortality[64]. Systemic complications include anemia, spondyloarthritis, SAPHO syndrome (see Table 25.18) and secondary AA amyloidosis with nephrotic syndrome. Depression, anxiety, sexual dysfunction, social isolation, and a limited ability, or complete inability, to work or participate in daily activities are additional psychosocial issues. Comorbidities identified in patients with HS are outlined in Table 38.7[65].

As noted previously, HS is associated with a variety of uncommon genetic and autoinflammatory disorders including Dowling–Degos disease, Down syndrome[66], KID syndrome, or PASH and its variants.

Staging and outcome measures

The three major clinical grading systems are listed in Table 38.8. While some of the scoring systems are useful for measuring outcomes, others (e.g. Hurley staging system) are less adept at capturing treatment-related changes. The Hidradenitis Suppurativa Clinical Response (HiSCR) represents a dynamic measure of the percent reduction in lesional count compared to baseline[69].

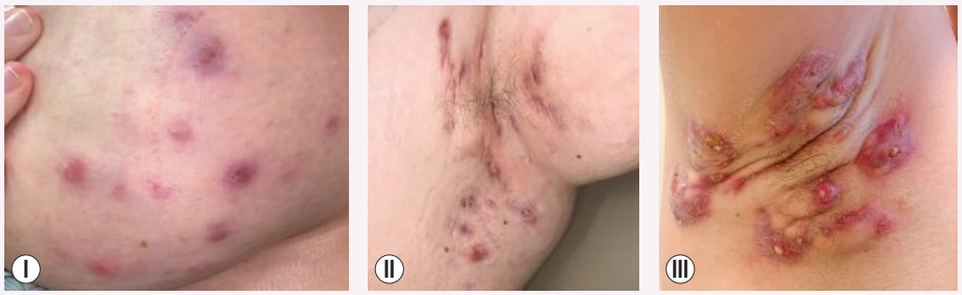
HS-associated pain can be measured using an 11-point Visual Analog Scale that ranges from 0 (no pain) to 10 (worst pain). Patient-reported outcome measurement tools[70] include: (1) Hidradenitis Suppurativa Impact Assessment (HSIA) for assessing a range of daily activities; (2) Hidradenitis Suppurativa Symptom Assessment (HSSA) tool for evaluating the burden of 9 physical symptoms, e.g. pain, drainage, tenderness, warmth, odor, pruritus; and (3) Hidradenitis Suppurativa Quality of Life (HiSQOL) scale.

Pathology

A mixed inflammatory infiltrate is present within the dermis and sometimes subcutaneous tissue along with dilated, often ruptured hair follicles and sinus tracts. Abscesses are observed in active cases[71]. Granulation tissue with inflammatory cells and occasional foreign body giant cells may be present. The sinus tracts contain inflammatory cells and keratinous debris (Fig. 38.16). In chronic disease, there is extensive fibrosis and scarring with destruction of pilosebaceous follicles and sweat glands.

Differential diagnosis

Early nodular lesions of HS may resemble acne cysts, but involvement of the face is unusual in HS as are double-ended comedones in acne; epidermoid cysts when only a few lesions are present; *staphylococcal* furunculosis; and a Bartholin cyst. Later on, a combination of inflammatory nodules, sinus tracts, and scars may resemble cutaneous infections (e.g. due to mycobacteria, *Nocardia*, *Klebsiella granulomatis*) and inflammatory disorders (e.g. cutaneous Crohn disease). Lymphedema secondary to HS should be differentiated from other causes (see Ch. 105).



THREE MAJOR GRADING SYSTEMS FOR HIDRADENITIS SUPPURATIVA
Hurley staging system

• Stage I – one or more abscesses with no sinus tract or scar formation • Stage II – one or more widely separated recurrent abscesses, with sinus tract and scar formation • Stage III – multiple interconnected sinus tracts and abscesses throughout an affected region; more extensive scarring
Sartorius grading system[67]
• Anatomical regions involved: axilla (left/right), groin (left/right), gluteal (left/right) or other region (e.g. inframammary): 3 points per region involved • Number and scores of lesions for each region: nodules = 1; fistulae = 6 • The longest distance between two relevant lesions*, i.e. nodules and fistulae, in each region: <5 cm = 1; 5–10 cm = 3; >10 cm = 9 • Are all lesions clearly separated by normal skin? In each region – yes 0/no (Hurley III) 9
International Hidradenitis Suppurativa Severity Score System (IHS4)[68]
IHS4 (points) = number of nodules × 1 + number of abscesses × 2 + number of draining tunnels × 4 Mild HS: ≤3 points Moderate HS: 4–10 points Severe HS: ≥11 points
*Or size if only one lesion.

Table 38.8 Three major grading systems for hidradenitis suppurativa (HS). A refinement of the Hurley staging system in which stages I and II are subdivided into A, B, C subtypes is also utilized. In the Revuz modification of the Sartorius grading system, five regions (axilla, breast, inguino-femoral, perianal, perineal) are scored, with additional modifications including the addition of abscesses to fistulae. The Hidradenitis Suppurativa Physician Global Assessment (HS-PGA) is a 6-point scale with scores from 0 (clear) to 5 (very severe) based upon counts of inflammatory nodules, abscesses, and draining fistulae.

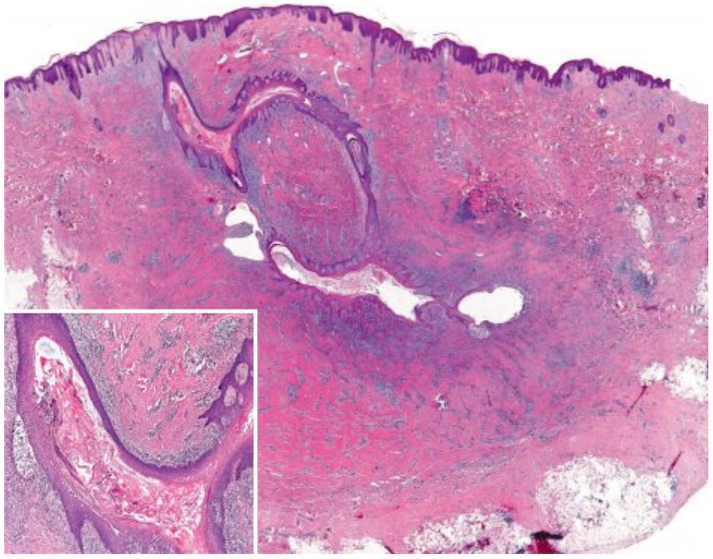


Fig. 38.16 Hidradenitis suppurativa – histopathologic features. A keratin-filled sinus tract (inset) is seen within the dermis, extending into the subcutaneous fat. It is surrounded by marked fibrosis and mixed inflammatory infiltrates. *Courtesy Lorenzo Cerroni, MD.*

Treatment

A multidisciplinary approach that addresses psychosocial issues as well as comorbidities is recommended[72–74]. A therapeutic approach to HS, based on disease severity, is outlined in Table 38.9. Individualized care is also required, e.g. a woman with pre-menstrual flares of HS may benefit from spironolactone, whereas a systemic immunomodulator may be optimal for the patient with concomitant moderate to severe HS and psoriasis (e.g. adalimumab).

Acknowledgment

The authors wish to thank the late A. Paul Kelly, MD, for his valuable contribution to this chapter in the previous editions.

Additional figures and tables on Therapeutic interventions on acne keloidalis, and Syndromic hidradenitis suppurativa and genetic disorders in which hidradenitis can be an associated finding, available in our eBook (see inside front cover for access code).

HIDRADENITIS SUPPURATIVA THERAPEUTIC LADDER	
Indication	**Therapeutic interventions**
General measures	• Discuss pain management, smoking cessation, and a healthy diet • If obese or overweight, weight reduction is recommended and may require enrollment in a weight loss program or if morbidly obese, bariatric surgery • Assess patient's mental health and refer to specialist if needed • Recommend wearing soft, breathable fabrics and loose undergarments to reduce friction and moisture • Recommend antiseptic soaps, e.g. benzoyl peroxide or chlorhexidine washes • Provide and educate patient on wound care • Consider laser hair reduction
Mild disease (Hurley stage I) (see Table 38.8)	• Intralesional triamcinolone (5–10 mg/ml) injections into inflamed lesions • Topical therapies: resorcinol, clindamycin, dapsone • Oral antibiotics*: tetracyclines (doxycycline, minocycline), clindamycin, rifampin, trimethoprim-sulfamethoxazole, metronidazole, moxifloxacin • Hormonal therapies: spironolactone, oral contraceptive pills with antiandrogenic or low androgenic progestins, metformin, finasteride • Oral retinoids (especially if patient also has cystic acne): acitretin, isotretinoin • Complementary and alternative medicine: oral zinc • Surgical treatments†; deroofing, limited local excisions

Moderate disease (Hurley stage II) (see Table 38.8)	• Medical therapies for mild disease, alone or in combination with the following:
	  • Systemic immunomodulators ("biologics"): TNF inhibitors (adalimumab‡, infliximab), ustekinumab, IL-17 inhibitors[75,76,76a], IL-23 inhibitors[77,78], anakinra
	  • Other systemic immunomodulators/immunosuppressants: apremilast[79], colchicine (in combination with minocycline), cyclosporine, corticosteroids¶
	• Surgical treatments†; deroofing, local excisions, Nd:YAG laser, CO_2 laser ablation

Severe disease (Hurley stage III) (see Table 38.8)	• Medical treatments outlined for mild and moderate disease, alone or in combination with the following: • Intravenous antibiotics: ertapenem¶ • Surgical treatments†; deroofing, wide surgical excision of involved areas, CO_2 laser excision

*Combinations of oral antibiotics shown to be helpful: clindamycin + rifampin (for disease that is at least mild-to-moderate in severity) and rifampin + moxifloxacin + metronidazole (for moderate-to-severe disease); in a prospective international cohort study comparing oral tetracyclines versus clindamycin + rifampin, there was no significant difference in efficacy[74a].
†Incision and drainage is recommended only to provide acute relief for larger abscesses; it is not a definitive treatment measure given high rate of recurrence.
‡FDA-approved adult dosing regimen: 160 mg on Day 1 -or- 80 mg daily on Days 1 and 2, followed by 80 mg on Day 15 then 40 mg weekly -or- 80 mg every 2 weeks beginning on day 29. There is a weight-tiered dosing regimen for adolescents (12 years and older, weighing at least 30 kg).
¶Systemic corticosteroids may be considered for short-term rescue therapy during a severe flare, and systemic corticosteroids or intravenous ertapenem may be used as bridge therapy to a long-term therapeutic option.

Table 38.9 Hidradenitis suppurativa (HS) therapeutic ladder. Additional reported therapies include bermekimab[80], botulinum toxin A and B injections[81], JAK inhibitors[81a,81b], photodynamic therapy[82], and cryoinsufflation[83].

THERAPEUTIC INTERVENTIONS FOR ACNE KELOIDALIS	
Indication	**Therapeutic interventions**
Mild to moderately inflamed papules	Topical potent corticosteroid ± topical tretinoin twice daily
Inflamed lesions with pustules	Topical antibiotic (e.g. clindamycin solution) Consider bacterial culture and appropriate systemic antibiotic
	If severely inflamed, consider course of oral isotretinoin
Small keloidal papules	Topical potent corticosteroid and/or topical tretinoin twice daily
	Intralesional triamcinolone acetonide (5–20 mg/ml)
	Punch excision to a depth below the level of the hair follicles followed by either primary closure or second intention healing
	Laser hair removal for permanent hair reduction
Plaques ≤1.5 cm in vertical diameter	Excise and close primarily
Larger plaques and nodules (>1.5 cm in vertical diameter)	Excise with horizontal ellipse (include the posterior hairline)
	Extend excision to level of fascia or deep subcutaneous tissue
	Allow to heal by second intention
	Do not inject corticosteroids into postoperative site
	Laser excision is an alternative to scalpel excision

eTable 38.1 Therapeutic interventions for acne keloidalis. *Courtesy A. Paul Kelly, MD.*

SYNDROMIC HIDRADENITIS SUPPURATIVA AND GENETIC DISORDERS IN WHICH HIDRADENITIS SUPPURATIVA CAN BE AN ASSOCIATED FINDING	
Genes/chromosomes	**Encoded protein**
Syndromic hidradenitis suppurativa **– to date, genes are only implicated in pathogenesis**	
PASH and PAPASH, including variants PASS and PsAPASH	
Inflammasone activity (see Fig. 4.2)	
PSTPIP1	Proline-serine-threonine phosphatase-interacting protein 1
NLRP3	Cryopyrin
IL1RN	IL-1 receptor antagonist
MEFV	Pyrin
NFκB signaling pathway	
NOD2	Nucleotide-binding oligomerization domain-containing protein 2; plays a role in Crohn disease
Regulation of keratinocyte differentiation	
NCSTN	Nicastrin (γ-secretase complex)
Immunoproteosome component	
PSMB8	Proteosome 20 S subunit beta 8
Genetic disorders in which HS can be an associated finding	
Dowling–Degos disease	
PSENEN	Presenilin enhancer-2 (γ-secretase complex)
POFUT1	Protein O-Fucosyltransferase 1
Down syndrome	
Trisomy 21	Amyloid precursor protein – competitive substrate for γ-secretase complex, along with Notch
Pachyonychia congenita (primarily steatocystomas)	
KRT6A	Keratin 6a
KRT17	Keratin 17
Familial Mediterranean fever	
MEFV	Pyrin – regulates inflammasome activity
Darier disease	
ATP2A2	Sarco/endoplasmic reticulum calcium ATPase (SERCA) 2b isoform influences folding of Notch1 receptor within SER
Keratitis–ichthyosis–deafness (KID) syndrome	
GJB2 (G12R missense mutation)	Connexin 26

eTable 38.2 Syndromic hidradenitis suppurativa and genetic disorders in which hidradenitis suppurativa can be an associated finding. HS-like lesions can develop within a nevus comedonicus. PAPASH, pyogenic arthritis, acne, pyoderma gangrenosum, suppurative hidradenitis; PASH, pyoderma gangrenosum, acne, suppurative hidradenitis; PASS, pyoderma gangrenosum, acne, suppurative hidradenitis, ankylosing spondylitis; PsAPASH, psoriatic arthritis, pyoderma gangrenosum, acne, suppurative hidradenitis.

Diseases of the Eccrine and Apocrine Sweat Glands

Disorders of the Apocrine Sweat Gland 655

SWEAT GLANDS

Eccrine Sweat Glands

Key features

- 2–5 million eccrine glands are unevenly distributed over the skin surface
- In healthy individuals, eccrine sweat is 99% water
- Sweating is a reflex sympathetic autonomic function mediated by cholinergic neurons

In humans, sweating is essential for thermoregulatory homeostasis. There are two main mechanisms for cooling the body: radiative cooling via cutaneous vasodilation and evaporative cooling via sweat. Sweat, primarily produced by the eccrine sweat glands, leads to dissipation of heat through evaporation. Few mammals except humans and horses produce sweat in sufficient quantities to affect thermoregulation. For the purposes of this discussion, the term "sweat" applies to eccrine glands and their secretory products unless otherwise specified.

Although there are 2–5 million eccrine glands distributed within the skin, none are found on the clitoris, glans penis, labia minora, external auditory canal, or lips. Eccrine glands are separate from the apocrine–pilosebaceous apparatus, and by dermoscopy, eccrine ductal orifices can be seen along the dermatoglyphic ridges of the palms and soles. The average healthy adult can produce over 0.5 liters of sweat per hour, 99% of which is water. Athletes or those acclimatized to hot environments can produce up to 3–4 liters per hour[1]. Compared to other individuals, physically fit or acclimatized persons initiate sweating earlier and conserve sodium, chloride, and other electrolytes more efficiently. Thermoregulatory control is similar in men and women and diminishes only slightly with age[2].

Sweating is a reflex function controlled primarily by the sympathetic nervous system. These nerves are anatomically sympathetic but functionally cholinergic, i.e. acetylcholine, rather than norepinephrine, is the principal terminal neurotransmitter. Neural impulses for sweating (sudomotor impulses) travel from the anterior hypothalamus via the reticulospinal tracts to the appropriate level in the spinal cord, out through the rami communicantes to autonomic ganglia, and then within sympathetic cholinergic neurons to the secretory cells of the eccrine glands. Adrenergic innervation of eccrine glands has also been demonstrated, but is not believed to be physiologically important[3]. In addition, the sweat glands, via a direct effect on the secretory cells, respond to certain drugs (e.g. cholinergic agonists) as well as to the local application of heat.

Apocrine Sweat Glands

In humans, apocrine sweat glands are confined to the eyelids (Moll's glands), external auditory meatus, axillae, areola and nipple, periumbilical region, and anogenital region, in particular the mons pubis, labia minora, prepuce, scrotum, and perianal area. At five months' gestation, apocrine glands are distributed all over the body, whereas in a full-term neonate they are limited to the above sites. In non-primate mammals, apocrine sweat glands are widely distributed but they also open into the pilosebaceous unit.

Apocrine secretion is a slow, usually continuous process analogous to milk formation in the mammary gland. The secretory product is an oily fluid composed of lipids, proteins, and sex hormones. At or near the skin surface, it mixes with sebum derived from the sebaceous gland that empties into the same pilosebaceous unit.

HYPERHIDROSIS

Key features

- Excessive sweating
- Primary hyperhidrosis is the most common type, typically affecting the palms, soles, and/or axillae
- Secondary hyperhidrosis is due to an underlying condition (e.g. infection, tumor, genetic syndrome) or medication and may be localized or generalized

Hyperhidrosis is estimated to affect 3% of the US population[4]. The most widely used classification system divides it into primary (idiopathic) and secondary types. Other classification systems separate hyperhidrosis into categories based on the source of the neural impulses that drive it: cortical (emotional), hypothalamic (thermoregulatory), medullary (gustatory), spinal cord, and local axon reflexes.

Primary Hyperhidrosis

Synonym: ■ Primary focal hyperhidrosis

Key features

- Main sites are volar (palms, soles) and axillary skin; the face may also be involved
- Hyperhidrosis arises from increased cortical stimulation and occurs *only* during waking hours (diurnal)
- Patients are otherwise healthy
- Up to 80% of affected individuals have a family history of hyperhidrosis

Primary hyperhidrosis, the most common type of hyperhidrosis, is defined as excessive sweating in localized areas (usually the palms, soles, and/or axillae) and is not associated with a systemic disorder.

Men and women of all races are equally affected. Table 39.1 lists the diagnostic criteria[5]. Between 60% and 80% of patients with primary hyperhidrosis have a family history[6], with a pattern of inheritance suggesting autosomal dominant transmission with incomplete penetrance. A locus for primary palmar hyperhidrosis was mapped to chromosome 14q in three Japanese families[7].

Intense emotion or stress can elicit sweating in anyone. It occurs most often on the palms, soles, or axillae and can also affect the face (Fig. 39.1), especially the forehead and the cutaneous upper lip. The post-orgasmic sweating observed with sexual activity may also derive from emotional stimulation[8].

Clinically significant primary hyperhidrosis occurs in two major patterns: volar (palmoplantar) and axillary, which can coexist[1], but usually one of the two sites predominates. The onset of volar hyperhidrosis is often during childhood, whereas axillary hyperhidrosis typically develops at or soon after puberty. Primary hyperhidrosis is seen in both cold and warm environments. A chronic and unremitting course is characteristic, with little or no variation in association with age, disease, or hormonal status.

Volar hyperhidrosis is the most common form of primary hyperhidrosis (Fig. 39.2), affecting ~50%–60% of patients[3,4]. The entire palm and sole, as well as the lateral aspects, tips and distal dorsal skin of the fingers, display sweating. It can clearly have an impact on quality of life.

Axillary hyperhidrosis is the second most common form of primary hyperhidrosis, affecting 30%–50% of patients[4]. The right axilla usually produces more sweat than the left (60:40). Exceptionally, one axilla may be hyperhidrotic while the opposite axilla is hypohidrotic or virtually anhidrotic. Odor (axillary bromhidrosis) is usually absent; the excessive quantities of eccrine sweat presumably rinse away or dilute odorogenic apocrine sweat droplets and bacteria.

CRITERIA FOR THE DIAGNOSIS OF PRIMARY HYPERHIDROSIS
1. Focal, visible excess sweating
2. Present for at least 6 months
3. No apparent secondary causes
4. At least two of the following:
• Bilateral and symmetric
• Impairs activities of daily life
• At least one episode per week
• Age of onset <25 years
• Positive family history
• Stops during sleep

Table 39.1 Criteria for the diagnosis of primary hyperhidrosis. *Adapted from Hornberger J, Grimees K, Naumann M, et al. Recognition, diagnosis and treatment of primary focal hyperhidrosis. J Am Acad Dermatol 2004;51:274–86.*

Fig. 39.1 Primary cortical (emotional) hyperhidrosis involving the face. Sweat droplets are evident on the upper cutaneous lip, jawline, and chin. *Reproduced from Hurley HJ. Hyperhidrosis. Curr Opin Dermatol 1997;4:105–14. Philadelphia: Rapid Science Publishers.*

Secondary Hyperhidrosis

Secondary hyperhidrosis is caused by or associated with another systemic disorder. It may be localized or generalized. There are many causes, which can be divided into categories based on the source of the neural impulse driving the response: cortical, hypothalamic, medullary, spinal cord, or local. A number of medications may also be associated with hyperhidrosis (Table 39.2).

Disorders associated with cortical (emotional) hyperhidrosis

Key features

- Several disorders of cornification and other genodermatoses affecting palmoplantar skin are associated with volar hyperhidrosis
- Patients with hereditary autonomic neuropathies can also exhibit cortical hyperhidrosis

Isolated sweating of the palms and soles is primarily due to cortical excitation by emotional or sensory stimuli. Excessive volar sweating associated with certain inherited palmoplantar keratodermas is assumed to be cortical in nature, although the pathogenic relationship between the abnormal keratinization and hyperhidrosis has not been precisely delineated. Many palmoplantar keratodermas are malodorous, likely related to sweat-induced maceration of the thickened stratum corneum and bacterial degradation of keratin. Other genodermatoses affecting the volar skin, such as epidermolysis bullosa simplex, can also have associated palmoplantar hyperhidrosis. Additional causes of cortical hyperhidrosis are listed in Table 39.3.

Fig. 39.2 Volar hyperhidrosis (primary cortical). A, B The plantar skin is moist and glistening with eccrine sweat. There are also sweat droplets. *Courtesy Jean L. Bolognia, MD.*

DRUGS THAT CAN STIMULATE ECCRINE SWEATING	
Direct-acting cholinomimetic agents	
• Acetylcholine	• Anti-xerostomia drugs (see Table 45.5)
Cholinesterase inhibitors	
• Anti-Alzheimer drugs* • Anticholinergic antidote	• Antimyasthenics
Adrenomimetic agents	
• Dopamine • Epinephrine (adrenaline) • Isoproterenol	• Norepinephrine (noradrenaline) • Phenylpropanolamine
Antidiabetic (hypoglycemic) agents	
• Insulins	• Sulfonylureas
• Biguanides	
CNS stimulants	
• Amphetamines • Caffeine	• Theophylline
Antidepressants	
• MAOIs† • SSRIs†	• Tricyclics†
Antipsychotics	
Antipyretics	
Opioids	
Other drugs	
• ACE inhibitors • Amlodipine • Atomoxetine • Dextromethorphan*,† • Ipecac • Pentoxifylline	• Phosphodiesterase inhibitors (e.g. sildenafil) • Sibutramine† • Sumatriptan† • Tramadol† • Yohimbine

*Increased sweating is infrequently observed at pharmacologic doses but represents a sign of overdose.
†Combination of MAOIs (which include linezolid as well as antidepressants) with drugs such as tricyclics, SSRIs, certain opioids, and tryptophan can result in the serotonin syndrome; the latter is characterized by mental status changes, autonomic hyperactivity (including hyperhidrosis), and neuromuscular abnormalities.

Table 39.2 Drugs that can stimulate eccrine sweating. Selective estrogen receptor modulators (e.g. tamoxifen, raloxifene) and aromatase inhibitors (e.g. anastrozole) can lead to menopausal symptoms including hot flashes with sweating. ACE, angiotensin-converting enzyme; CNS, central nervous system; MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor.

CAUSES OF CORTICAL (STRESS/EMOTIONAL) HYPERHIDROSIS
Primary hyperhidrosis (see Table 39.1)
Secondary hyperhidrosis
Disorders of cornification
• Palmoplantar keratodermas • Pachyonychia congenita • Congenital ichthyosiform erythroderma and epidermolytic ichthyosis
Other genodermatoses
• Epidermolysis bullosa: simplex > junctional • Dermatopathia pigmentosa reticularis • Dyskeratosis congenita • Pachydermoperiostosis (digital clubbing and thick, furrowed skin on the face and scalp) • Apert syndrome (craniosynostosis, digital anomalies, severe acne; *FGFR2* mutations) • Nail–patella syndrome
Hereditary sensory and autonomic neuropathies (HSANs)*
• Familial dysautonomia (Riley–Day syndrome; HSAN type III; blotchy erythema accompanies episodic hyperhidrosis of the face and trunk, decreased lacrimation, postural hypotension, and dysautonomic crises [vomiting, hypertension]) • Congenital autonomic dysfunction with universal pain loss • Congenital sensory neuropathy (HSAN type II)
*Hypothalamic (thermal) hyperhidrosis can also occur.

Table 39.3 Causes of cortical (stress/emotional) hyperhidrosis. *Adapted from Moschella S, Hurley HV. Dermatology. Philadelphia: WB Saunders, 1992.*

Hypothalamic (thermoregulatory) hyperhidrosis

Key features

- Due to elevated body temperature (e.g. acute febrile illness, lymphoma, chronic infection) or direct hypothalamic stimuli (e.g. pheochromocytoma, medications, toxins)
- May be nocturnal (night sweats) or diurnal

The hypothalamus is responsible for many autonomic activities, including thermoregulation. Elevation of the temperature of the blood by 0.5°F (0.3°C) or more excites the hypothalamic nuclei and results in vascular dilation and generalized sweating responses aimed at dissipating body heat[3].

Febrile illnesses are among the most common pathologic states that cause hypothalamic sweating. At the height of the fever, notably with temperatures of 39–40°C (102–104°F) or above, sweating is absent, the apparent result of inhibition of the hypothalamic center for sweating. With defervescence, sweating characteristically ensues. Lymphomas and chronic infections (e.g. tuberculosis) can present with episodic thermoregulatory sweating, which may be described as "night sweats" (that actually follow unperceived mild febrile pulses).

Generalized sweating of hypothalamic origin can also be seen in a number of metabolic and endocrine disorders (Table 39.4). Patients with diabetes mellitus may exhibit hypohidrosis as well as various forms of hyperhidrosis. For example, hyperhidrosis is a characteristic sign of insulin-induced hypoglycemia (but not diabetic ketoacidosis), and compensatory hyperhidrosis of the trunk can develop in the setting of diabetic neuropathy affecting the extremities (see below). In addition, diabetics may exhibit gustatory hyperhidrosis, primarily of the face and neck. Troublesome sweating of the scalp can also be seen in poorly controlled diabetics, and, with regulation of the hyperglycemia, it often improves.

Disorders with vasomotor instability, such as Raynaud phenomenon, autoimmune connective tissue diseases, frostbite and other cold injuries, and complex regional pain syndrome, may be associated with excessive sweating because of disturbed autonomic function[9]. A synchronous discharge of vasoconstrictor and sudomotor impulses evokes a "cold sweat", usually of the hands and feet, producing macerated, soggy wet, violaceous skin known as symmetrical lividity.

Cerebral cortex lesions, such as a tumor, abscess or cerebrovascular accident, may be associated with a contralateral hyperhidrosis due to an impairment of the inhibitory cortical influence that normally regulates hypothalamic sudomotor activity[10]. Hypothalamic sweating is also observed in Parkinson disease and occurs as the "sweating sickness" following encephalitis. Harlequin syndrome, characterized by unilateral flushing and hyperhidrosis in association with contralateral anhidrosis, may be due to peripheral or central nervous system (CNS) abnormalities[11].

Episodic release of catecholamines from pheochromocytomas directly stimulates the hypothalamus and may elicit sweating[12]. Exposures to toxins and medications can also lead to hypothalamic hyperhidrosis, and a number of drugs that act on the CNS have increased sweating as a potential side effect (see Table 39.2). Additional causes of hypothalamic hyperhidrosis are presented in Table 39.4.

Pressure and postural hyperhidrosis may be due to hypothalamic or possibly cortical stimulation. With changes in posture or the application of pressure to one side of a supine individual, a variety of sweating patterns have been described, such as lateral hyperhidrosis, horizontal hemihidrosis, and crossed hemihidrosis. Idiopathic localized unilateral hyperhidrosis of the face and neck or forearm has been reported as an episodic disorder triggered by heat, emotional, or gustatory stimuli[13].

CAUSES OF HYPOTHALAMIC HYPERHIDROSIS						
Infection	**Tumors**	**Endocrine/ metabolic**	**Vasomotor**	**Neurologic**	**Drugs/ toxins**	**Miscellaneous**
• Acute febrile illnesses (defervescence) • Tuberculosis • Brucellosis • Malaria • Subacute bacterial endocarditis • Other	• Lymphoma • Pheochromocytoma* • Carcinoid*	• Menopause • Hypoglycemia • Obesity • Hyperthyroidism • Acromegaly • Pregnancy • Porphyria (acute intermittent) • Phenylketonuria • Gout	• Congestive heart failure† • Myocardial ischemia • Raynaud phenomenon • Acrocyanosis • Cold injury • Symmetrical lividity of the palms and soles‡ • Complex regional pain syndrome • Autoimmune connective tissue disease (e.g. rheumatoid arthritis, SLE)	• CNS tumors • Cerebrovascular accidents • Parkinson disease • Postencephalitic • Episodic spontaneous hypothermia with hyperhidrosis§ • Cold-induced sweating syndrome‖ • Familial dysautonomia‡	• Alcoholism • Alcohol or opioid withdrawal • SERMs and aromatase inhibitors • Mercury toxicity (acrodynia) • Chronic arsenic toxicity • See Table 39.2	• Compensatory hyperhidrosis (e.g. in association with miliaria, diabetic neuropathy, sympathectomy)¶ • Localized unilateral hyperhidrosis (face and neck, forearm)‡ • POEMS syndrome • Speckled lentiginous nevus syndrome • Mitochondrial disorders • Pressure and postural hyperhidrosis‡

*Via release of catecholamines (pheochromocytoma) or serotonin (carcinoid tumors, usually metastatic; see Ch. 106).
†Patients have sympathetic activation, with impaired vasodilatory responses to heating but preserved sweating.
‡Also associated with cortical hyperhidrosis.
¶Compensatory hyperhidrosis is also a feature of Ross syndrome (segmental anhidrosis, generalized areflexia and tonic pupils).
§Referred to as Hines–Bannick syndrome or, when associated with agenesis of the corpus callosum, Shapiro syndrome.
‖Autosomal recessive condition caused by mutations in the genes encoding cytokine receptor-like factor-1 and cardiotrophin-like cytokine factor-1; additional features include facial dysmorphism, flexion deformities (elbows, fingers), and scoliosis.

Table 39.4 Causes of hypothalamic hyperhidrosis. SERMs, selective estrogen receptor modulators; SLE, systemic lupus erythematosus. *Adapted from Moschella S, Hurley HV. Dermatology. Philadelphia: WB Saunders, 1992.*

Medullary (gustatory) hyperhidrosis

Key features

- Taste receptors in the mouth are the source of the afferent impulses that stimulate sweating
- *Physiologic* medullary hyperhidrosis is most commonly triggered by spicy foods, alcohol, and citrus fruits
- *Pathologic* medullary hyperhidrosis occurs when disrupted nerves for sweat aberrantly connect with nerves for salivation; this can be caused by local injury to, or disease of, the parotid gland (Frey syndrome), trauma to the sympathetic trunk, and CNS disorders (e.g. encephalitis, syringomyelia)

Physiologic medullary hyperhidrosis

Any food or drink that stimulates the taste buds may induce sweating in normal individuals, particularly of the face. This is thought to occur via a variant reflex arc in which afferent impulses from taste bud receptors travel via the glossopharyngeal nerve to nuclei within the medulla oblongata (hence the term "medullary" hyperhidrosis), but lead to provocation of sweating rather than (or in addition to) the usual response of salivation. A few minutes after ingestion of a stimulating food or beverage, sweating and erythema are seen most commonly on the upper cutaneous lip or cheeks. It may be unilateral or bilateral and may be brief or persist as long as the stimulating food or beverage is ingested. Associated vasodilation localized to the areas of sweating causes the erythema, which may be faint. Spicy or sharp-tasting foods and beverages, such as citrus fruits, alcohol and condiments, may elicit the reaction. It is most common in children and young adults and in warmer environments. A familial tendency has been described[14]. There are no other concurrent local or systemic signs or symptoms. A variant of gustatory hyperhidrosis can occur on the face in diabetics. Unusual types of gustatory hyperhidrosis involving the scalp and the knee have also been described and support the concept of a central medullary mechanism for these sweating responses[15].

Pathologic medullary hyperhidrosis

This disorder arises after disruption of nerves. During healing, nerve fibers mediating sweating aberrantly connect to nerves that mediate salivation. Impulses in parasympathetic fibers normally supplying the salivary glands are now misdirected to the sweat glands. As a result, salivary stimulation elicits sweating. Of note, thermal sweating in the areas of affected skin is reduced.

The parotid form appears weeks to months following a surgical procedure, trauma, or other disorder (e.g. abscess, herpes zoster) affecting the parotid gland. These patients experience vasodilation and sweating on the cheek and adjacent neck when salivary stimulation is induced by eating, drinking, or even chewing (Fig. 39.3). Sweating most often occurs in the distribution of the auriculotemporal nerve; at times there is also unilateral localized pain[16].

Auriculotemporal syndrome (Frey syndrome) is common after parotid surgery, developing in 40% or more of patients, although many

Fig. 39.3 Gustatory sweating in the auriculotemporal (Frey) syndrome, as a consequence of parotid surgery. The blue–black area represents sweating (starch–iodine technique). Salivary stimulation induced this sweating response. *Reproduced from Hurley HJ. Hyperhidrosis. Curr Opin Dermatol 1997;4:105–14. Philadelphia: Rapid Science Publishers.*

are not aware of it. It can also occur during infancy, frequently as a consequence of trauma to the parotid region in a forceps-assisted delivery. The infant presents with gustatory flushing, but usually no obvious sweating, and this is often erroneously attributed to food allergy. Another variant of gustatory hyperhidrosis is the chorda tympani syndrome in which salivary stimuli to the submandibular gland induce sweating on the chin and lower jaw line.

Patients with cluster headaches can have sympathetic deficits that result in impaired thermoregulatory sweating on the affected side of the forehead. In addition, ipsilateral hyperhidrosis and flushing may occur, together with excessive lacrimation, during headache attacks. This is due to misdirection of parasympathetic fibers, which normally supply the lacrimal glands, to sweat glands and blood vessels. Patients with Raeder syndrome (Horner syndrome [ptosis, meiosis ± anhidrosis] plus unilateral temporofrontal headaches and pain) may also have excessive supraorbital sweating, also referred to as lacrimal sweating.

Any condition that injures the vagus nerve and sympathetic trunk, as they lie close together in the thorax, may cause pathologic medullary hyperhidrosis (Table 39.5). Cholinergic fibers from the vagus nerve sprout into the adjacent sympathetic trunk during the healing process and can result in a gustatory hyperhidrosis with sweating on the face, neck, and portions of the trunk and upper extremities.

In patients with syringomyelia or encephalitis, gustatory hyperhidrosis is occasionally seen on the face and upper trunk. It involves the glossopharyngeal and vagus nerves. Disturbances in the brainstem apparently lead to transposition of the central medullary nuclei for salivation and sweating. There is no peripheral crossing of sympathetic and parasympathetic nerve fibers as is seen in other forms of pathologic gustatory hyperhidrosis.

Spinal (cord transection) sweating

Key features

- Spinal disorders may result in a lack of thermal sweating below the injury as well as unusual patterns of hyperhidrosis
- Mass reflex sweating may occur around the injured level

Any injury or disease process that severs or interferes with the reticulospinal tracts of the cord can disrupt the sweating reflex (see Table 39.5). Lack of a sweat response to thermal stimulation usually occurs below the level of the injury. Abnormal patterns of segmental sweating may occur in conjunction with other autonomic, sensory, and motor alterations. Onset and duration are unpredictable. Sweating can be excessive, drenching the patient in the regions involved. Bouts of "mass reflex sweating" are initiated in the skin below the level of the cord interruption. It is most intense in skin segments close to the level of the transection. Mass reflex sweating does not occur in transections below T8–T10.

Autonomic dysreflexia

Key features

- Direct stimulation (e.g. electrical, physical, or drug-induced) of a sympathetic axon can cause sweating
- May be seen with inflammatory skin diseases

Autonomic dysreflexia is a syndrome that may occur with spinal injuries at or above T6[17]. Massive episodic sympathetic discharge results in sweating above the level of the transection accompanied by headache, hypertension, facial flushing, bradycardia or tachycardia, piloerection, and paresthesias.

Direct stimulation of a cutaneous sympathetic axon with electrical and physical impulses or injections of drugs with nicotine-like effects on autonomic ganglia can induce sweating in an area ~4 cm in diameter[3]. Mediators from inflammatory skin conditions (e.g. psoriasis, dermatitis) can also elicit localized hyperhidrosis. Substance P and a number of other mediators, including kinins, dopamine, prostaglandins, angiotensin and adenine, may be involved[18].

Compensatory hyperhidrosis

Key features

- Anhidrosis in one area may cause hyperhidrosis in another
- Miliaria, diabetic neuropathy, and sympathectomy are well-known causes

The coordinated functioning of the body's eccrine sweat glands is illustrated by the phenomenon of compensatory hyperhidrosis, in which the sweat glands of one area become hyperactive in an effort to compensate for hypo- or anhidrosis in another. Apparently, a threshold number of sweat glands must be non-functional in order for the compensatory response to occur. The nature or type of the underlying process that produces the anhidrosis also appears to be important. For example, compensatory hyperhidrosis does not seem to develop secondary to the anhidrosis produced by lymphomas.

The best-known clinical forms of compensatory hyperhidrosis occur in the following three situations:

- *Miliaria*: longstanding or recurrent miliaria rubra or profunda typically results in numerous non-functional sweat glands within large areas of the trunk. This induces compensatory hyperhidrosis of the face (Fig. 39.4A), especially in response to ambient heat or exercise.
- In *diabetes mellitus*, disturbance of the autonomic nervous system due to peripheral neuropathy and microangiopathy often causes anhidrosis or hypohidrosis of the affected skin, particularly the legs. With the loss of sweating on the lower extremities, these patients may develop compensatory increases in thermal sweating on the trunk, especially the back. A second type of compensatory

OTHER CAUSES OF SECONDARY HYPERHIDROSIS			
Medullary (gustatory)	**Spinal cord**	**Axon reflex**	**Abnormal blood vessels or eccrine glands (non-neural)**
• Physiologic gustatory sweating • Frey syndrome • Chorda tympani syndrome • Cluster headaches • Sympathectomy • Sympathetic trunk and vagus nerve injury (e.g. by lung carcinoma, mesothelioma, thyroidectomy, subclavian aneurysm) • Encephalitis • Syringomyelia	• Spinal injury • Syringomyelia • Tabes dorsalis	• Inflammatory skin diseases • Drugs (see Table 39.2)	• Aquagenic palmoplantar keratoderma (see Fig. 58.19) • Eccrine nevi • Eccrine angiomatous hamartoma (see Fig. 39.5) • Maffucci syndrome • Arteriovenous fistula • Klippel–Trenaunay syndrome • Glomuvenous malformation • Blue rubber bleb nevus syndrome • Cold erythema • Granulosis rubra nasi • Pretibial myxedema

Table 39.5 Other causes of secondary hyperhidrosis. Gustatory lacrimation ("crocodile tears" syndrome) is due to transposition of autonomic fibers for lacrimation and salivation after facial nerve injury. *Adapted from Moschella S, Hurley HV. Dermatology. Philadelphia: WB Saunders, 1992.*

hyperhidrosis, gustatory in character and usually on the face and neck (Fig. 39.4B), may also be seen in diabetic patients with peripheral neuropathy of the lower extremities.

- *Post-sympathectomy*: with the loss of sweating that results from cervicothoracic sympathectomies, a thermal hyperhidrosis, usually on the trunk, is common. Sympathectomized patients may also experience gustatory hyperhidrosis.

Non-neural hyperhidrosis

Key features

- Direct stimulation of eccrine glands can cause sweating
- Triggers include local heat, drugs, and vascular tumors

Direct stimulation of eccrine sweat glands by heat or sudomimetic drugs can lead to localized sweating. Even denervated skin sweats when heat is applied[3]. Table 39.5 outlines additional non-neural causes of localized hyperhidrosis (Fig. 39.5). The rare disorder "cold erythema" affects the skin and gastrointestinal tract – exposure to cold produces local cutaneous erythema and intense pain along with a central area of hyperhidrosis. As with other entities in which local pain is a clinical feature (e.g. glomuvenous malformations), increased blood flow or an axon reflex (secondary to the pain) may be the causal mechanism for this sweating.

Diagnosis of Hyperhidrosis

Key features

- Differentiation between primary and secondary hyperhidrosis is important
- Hyperhidrosis can be documented by colorimetric and gravimetric methods

The first step is to differentiate between primary and secondary hyperhidrosis. History will elicit location, duration, and specific triggers. Other medical disorders and medications (including over-the-counter products) need to be ascertained. An extensive review of systems should point to any secondary causes.

Patients who do not fit the classic pattern of primary hyperhidrosis (see Table 39.1) should undergo further evaluation, focusing on possible etiologies (see Tables 39.2–39.5) during a complete history and physical examination. Laboratory testing and radiographic studies may be needed (Table 39.6).

Measurement of sweat can be performed. A grading scale for volar disease lists "low" as a moist palm or sole without visible sweat droplets. "Moderate" disease is characterized by sweating toward the fingertips. "Severe" cases drip sweat. Axillary involvement can be measured by the sweat stains on clothing: <5 cm is considered normal; 5–10 cm, mild; 10–20 cm, moderate; and >20 cm, severe.

Colorimetric techniques such as the starch–iodine or quinizarin methods demonstrate the sweating pattern and reveal the location of the most active sweat glands in a given area[19]. In the starch–iodine technique, iodine solution (e.g. 3.5% in alcohol) is applied to clean, shaved skin and allowed to dry. Starch powder (e.g. cornstarch) is then brushed onto the area. Sites with sweating turn blue–black (Fig. 39.6). A combination of iodine and paper impregnated with starch can also be utilized (Fig. 39.7).

Additional quantitative assessment methods are available. In order to document amounts of sweat produced, gravimetric (via weighing filter paper before and after application to the skin) and evaporative (via a device that assesses water vapor loss from the skin) measurements can be made in volar or axillary sites[19]. Infrared thermography and skin conductance measurements represent other methods of evaluating sweat gland function, allowing comparison between anatomic areas and even individual glands.

Treatment of Hyperhidrosis

Key feature

- Treatment options for hyperhidrosis include topical sweat duct blockers, topical glycopyrronium, sweat-reducing oral medications, botulinum toxin, iontophoresis, biofeedback therapy, microwave thermolysis, and surgical procedures

Treatment options available for hyperhidrosis are outlined in Table 39.7. Over-the-counter products include antiperspirants and deodorants; the latter contain antimicrobial agents while both contain odor-masking fragrances. The major active ingredient in topical antiperspirants is

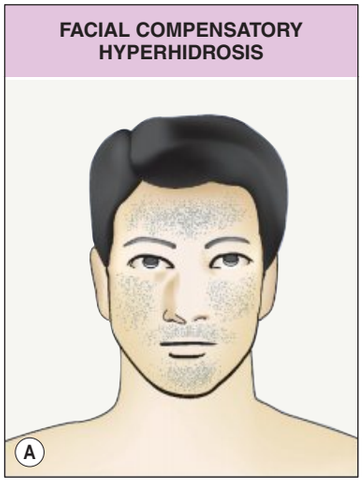

Fig. 39.4 Compensatory hyperhidrosis of the face. Fig. 39.5 Eccrine angiomatous hamartoma. Cluster of painful pink–violet papules and plaques on the thigh and knee that had been present since one year of age. There was associated hyperhidrosis, but not hypertrichosis. Histologically, an increased number of both eccrine glands and small blood vessels is seen. *Courtesy Julie V. Schaffer, MD.*

INITIAL PATIENT EVALUATION FOR SECONDARY HYPERHIDROSIS	
Laboratory test	**Disease**
Serum electrolytes, BUN, creatinine	Renal disease (rare)
Fasting blood glucose level and/or HbA1c	Diabetes mellitus
Thyroid function tests	Hyperthyroidism
Skin and/or blood tests for tuberculosis (e.g. PPD, QFTB-G)	Tuberculosis
Chest X-ray	Tuberculosis, neoplasm (e.g. lymphoma)
Complete blood count	Infection
Sedimentation rate/C-reactive protein test	Infection, neoplasm, inflammatory disease
Antinuclear antibodies	Autoimmune connective tissue disease
Urinary catecholamines*	Pheochromocytoma
*If suggestive signs or symptoms (see Ch. 106).	

Table 39.6 Initial patient evaluation for secondary hyperhidrosis. Further evaluation depends upon results and consideration of entities in Table 39.4. BUN, blood urea nitrogen; PPD, (tuberculin) purified protein derivative; QFTB-G, QuantiFERON-TB Gold.

Fig. 39.6 Delineation of area for injections of botulinum toxin A for axillary hyperhidrosis (starch–iodine technique). The blue–black area represents foci of sweating (reflected in black dots). In the case of onabotulinumtoxinA, a total of 50–100 U is injected within this area, utilizing 10 to 15 injection sites. *Courtesy Alastair Carruthers, MD, and Jean Carruthers, MD.*

metal (usually aluminum) salts which deposit within and temporarily block the sweat duct. Prescription antiperspirants contain higher concentrations of these salts. They should be applied to dry surfaces at night, when sweating is diminished. Occlusion enhances penetration of the salts. Application is recommended for three to five consecutive nights, then one to two times a week as needed to control sweating. Treated skin can be washed the following morning. Burning and irritant contact dermatitis are common side effects, particularly in women who shave their axillae and with higher salt concentrations.

Some patients who sweat significantly at night require a preliminary dose of an anticholinergic drug 1 hour before application for the first few applications (see below). This reduces sweating enough to prevent the topical solution from being rinsed away. Topical aldehyde agents such as formaldehyde and glutaraldehyde are effective, but allergic sensitization may develop that can result in cross-reactions with aldehydes in the environment (lotions, soaps, shoes).

Daily topical application of glycopyrronium tosylate via a cloth towelette is FDA-approved for the treatment of primary axillary hyperhidrosis in individuals nine years of age or older. After four weeks, 60% of treated

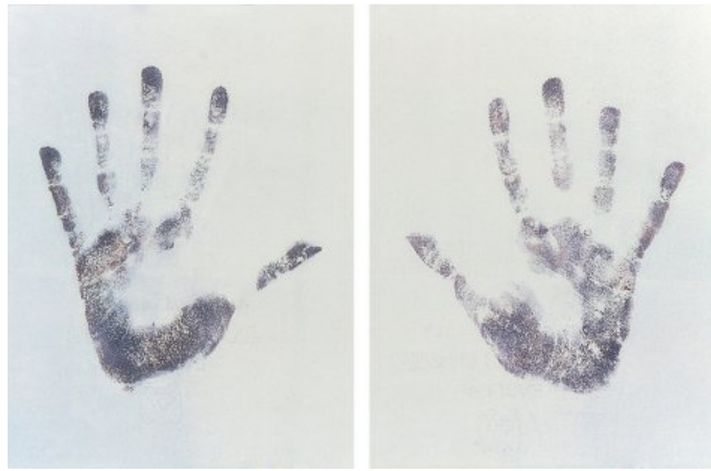

Fig. 39.7 Palmar hyperhidrosis as assessed by the semiquantitative starch paper–iodine technique. Sweating can also be demonstrated directly on palmar skin by the starch–iodine technique, as shown in Fig. 39.6 for axillary hyperhidrosis. *Courtesy Harry Hurley, MD.*

patients reported a significant reduction in sweat severity compared to 28% of those who applied the alcohol-based vehicle[20]. Botulinum liposomal cream and topical oxybutinin gel have also shown efficacy but currently are not commercially available. Table 39.7 outlines anticholinergic-related side effects. Patients with diseases that can be exacerbated by anticholinergics (e.g. glaucoma, myasthenia gravis, Sjögren syndrome, severe ulcerative colitis) should avoid their use.

Tap water iontophoresis over 20 minutes two to three times a week may be helpful. The mechanism of action is unknown but is thought to lead to blockage of the sweat duct in the stratum corneum. Side effects are minimal and include tingling of the skin during treatment. Introduction of anticholinergic medications via iontophoresis is not advised due to potential systemic absorption.

Oral anticholinergics will decrease sweating in most patients. The most commonly used agents are oxybutynin[21] and glycopyrrolate[22] (see Table 39.7 for recommended regimens). When higher doses are required to control the hyperhidrosis, unacceptable side effects can often develop, including dry eyes and mouth, insomnia, mental status changes (e.g. confusion, hallucinations), palpitations, seizures, blurred vision, bowel disturbances, urinary retention, and hypertension. More recently, a link between the long-term use of oral anticholinergic medications and development of dementia has been reported. As a result, limiting the duration of exposure to these medications has been recommended[23], and the use of calcium channel blockers as an alternative has increased.

Clonidine (an α_2-adrenergic agonist that decreases central sympathetic outflow) and phenoxybenzamine (an α-adrenergic blocker) have been used with some success in anecdotal reports[24,25]. Potential side effects include hypotension, rebound hypertension, sedation, constipation, weakness, and headache. Propranolol, a β-adrenergic blocker, is commonly used for the treatment of performance anxiety and it may improve hyperhidrosis temporarily. However, long-term use may induce hyperhidrosis.

OnabotulinumtoxinA (BTA) has been approved by the FDA for the treatment of severe axillary hyperhidrosis (see Fig. 39.6); it is also effective for volar disease. Botulinum toxins prevent the release of acetylcholine from cholinergic neurons (see Ch. 159). Injection into hyperhidrotic skin will produce near anhidrosis for 4 to 6 months (see Video 159.7). Side effects, if any, are short-lived. Muscle weakness, especially of the intrinsic muscles of the hands or feet, has been reported and resolves spontaneously over 2 to 5 weeks. Compensatory hyperhidrosis has not been observed[26]. Botulinum toxin injections should be avoided in patients who have pre-existing muscle weakness due to disorders such as myasthenia gravis and amyotrophic lateral sclerosis. To date, other botulinum toxins have not been FDA-approved for hyperhidrosis (see Table 159.1).

Surgical treatment may be offered if other therapeutic modalities have failed. Destruction of sweat glands by lasers[26], fractional microneedle radiofrequency, or microwave thermolysis can be performed[27]. Surgical dissection[28], curettage, or liposuction represent additional treatment options[29]. Excision of the sweat glands is often effective for axillary disease, but resection of the entire axillary skin causes significant scarring. However, compensatory hyperhidrosis is not seen with this form of local surgery.

TREATMENT OF HYPERHIDROSIS					
	Therapy	**Frequency & recommended dose**	**Side effects**	**Duration**	**Comments**
First-line	Topicals Aluminum chloride hexahydrate – 6.25% to 20% Aluminum chloride – 12% to 20% Aluminum sesquichlorohydrate – 15% Aluminum zirconium salts	Use nightly for 3–5 nights, then every few days as needed	Burning Irritant contact dermatitis	Days	Blocks sweat ducts Aluminum zirconium salts may be effective in axillae, but not volar surfaces
	Glycopyrronium cloth, 2.4%	At bedtime, one cloth applied to both axillae that are clean and dry	Local: erythema, burning, pruritus Systemic: dry mouth > mydriasis > urinary hesitation, blurred vision	Hours	Anticholinergic* Washing hands immediately after application avoids inadvertent eye exposure
	5% sofpironium gel	Daily			
Second-line	*Acetylcholine release inhibitors, i.e. botulinum toxins*	Every 4–6 months	Discomfort during injection Weakness of underlying muscles	Months	Prevents release of acetylcholine from neurons
	Iontophoresis	2–3 times a week	Discomfort during procedure	Days	Blocks sweat ducts
	Oral therapy†	As needed		Hours	
	Oxybutynin‡	1.25–5 mg daily - BID (IR) 5–15 mg daily (ER)	Dry mouth and urinary retention most common; also confusion and decreased mental status		Anticholinergic*
	Glycopyrrolate‡	1–2 mg BID - TID			Anticholinergic*
	Nifedipine XL	30 mg once daily with escalation to 90 mg once daily	Headache, flushing, ankle edema, hypotension		Calcium channel blocker
	Clonidine	0.1–0.3 mg BID	Hypotension, rebound hypertension		α_2-Adrenergic agonist
	Propranolol	10–40 mg BID	Hypotension, bradycardia, hyperhidrosis with long-term use		β-Adrenergic blocker
	Clonazepam	0.25–0.5 mg BID	Sedation		Anxiolytic
	Thermal ablation Nd:YAG laser Microwave thermolysis	Multiple	Expensive	Years	
Third-line	*Liposuction*	Once to more than once¶	Expensive	Semipermanent to permanent	
	Local excision	Once	Scarring	Permanent	Last resort
	Sympathectomy	Once	Compensatory hyperhidrosis Horner syndrome	Usually permanent	

*Contraindications to topical and oral anticholinergics include glaucoma, urinary retention, paralytic ileus or toxic megacolon, and myasthenia gravis.
†Combined with topical therapy.
‡A link between long-term use of oral anticholinergic medications and development of dementia has been reported.
¶May need to be performed more than once to treat glands that have regenerated or were missed.

Table 39.7 Treatment of hyperhidrosis. Examples of topical commercial products are Xerac® AC, Drysol®, and Driclor® (6.25%, 20%, and 20% aluminum chloride [AlCl] hexahydrate, respectively), Certain-Dri® (12% AlCl), and Carpe® lotion (aluminum sesquichlorohydrate 15%). Lumē is an aluminum-free product that can be used anywhere on the body. Ingredients in alternative aluminum-free products include baking soda, corn starch, tapioca starch, kaolin clay, candelilla wax, zinc oxide, and fragrances. BID, twice daily; ER, extended release; IR, immediate release; TID, three times daily.

Sympathectomy is the last resort for patients with volar hyperhidrosis. Advances in endoscopic surgery have decreased the morbidity associated with this procedure. Sympathectomy at the T2–T3 level for palmar disease and the lumbar area for plantar disease is effective. Risks of the procedure include Horner syndrome, hypotension, and pneumothorax. Compensatory hyperhidrosis of the trunk or gustatory facial sweating may occur[26] and the hyperhidrosis may gradually recur.

HYPOHIDROSIS AND ANHIDROSIS

Key features

- An inability to sweat can be life-threatening due to the development of heat-related illnesses
- Causes of hypo- and anhidrosis include central or neuropathic disruption of neural impulses, sweat gland abnormalities, and medications

Three major categories of disorders are recognized causes of anhidrosis: (1) central and neuropathic diseases or medications that disrupt neural impulses from the anterior hypothalamus to the eccrine gland; (2) peripheral (non-neural) alterations in the gland itself; and (3) idiopathic.

Central and Neuropathic Hypohidrosis

Disturbance or interruption of innervation at any level, from the sweating centers in the brain down through the descending neural tracts to the sweat glands, can result in decreased or absent sweating. Causes are listed in Table 39.8. Pontine or medullary lesions lead to unilateral facial anhidrosis on the ipsilateral side of the face and neck. Fiber tracts carrying sudomotor neurons to lower levels in the spinal cord are both crossed and uncrossed and the resultant anhidrosis of the skin may be ipsi- or contralateral.

Both peripheral neuropathies and degenerative neurologic disorders can cause anhidrosis. Chronic orthostatic (postural) hypotension may be associated with decreased sympathetic innervation of the sweat glands, and syncopal episodes in these patients are not accompanied by sweating.

CAUSES OF CENTRAL AND NEUROPATHIC HYPOHIDROSIS AND ANHIDROSIS

• Tumors, infarctions, and other lesions of the hypothalamus, pons, or medulla
• Spinal cord tumors and injuries
• Horner syndrome
• Degenerative syndromes
  • Pure autonomic failure
  • Multiple system atrophy (Shy–Drager syndrome)*
  • Ross syndrome (see text)
• Autoimmune autonomic neuropathy
• Congenital insensitivity to pain with anhidrosis
• Peripheral neuropathy due to:
  • Diabetes
  • Alcoholism
  • Leprosy
  • Amyloidosis (immunoglobulin light chain and transthyretin types)
• Drugs (see Table 39.9)

*Progressive autonomic dysfunction, parkinsonism, and ataxia.

Table 39.8 Causes of central and neuropathic hypohidrosis and anhidrosis.

DRUGS THAT CAUSE HYPOHIDROSIS AND ANHIDROSIS	
Blockade of neurotransmission	
Nicotinic acetylcholine receptor antagonists (ganglion-blocking agents)	
• Hexamethonium • Mecamylamine	• Tetraethylammonium • Trimethaphan
Muscarinic acetylcholine receptor antagonists*	
• Atropine • Glycopyrrolate	• Oxybutynin • Scopolamine
Calcium channel blockers	
α-Adrenergic blockers • Phenoxybenzamine (hypohidrosis occasionally observed) • Phentolamine†	
α_2-Adrenergic agonists‡ • Clonidine	
Dysfunction or destruction of the eccrine gland¶	
• Aldehydes (topical) • Aluminum salts (topical) • 5-Fluorouracil • Quinacrine	• Topiramate§ • Zirconium salts (topical) • Zonisamide§
*Antipsychotic drugs (e.g. phenothiazines), tricyclic antidepressants, and some antihistamines can also have anticholinergic effects, especially when administered in combination and at high doses. †Thought to suppress eccrine sweating by inhibiting ganglionic transmission. ‡Decrease sympathetic outflow from the CNS. ¶Eccrine gland necrosis is also a feature of coma bullae, which are classically associated with barbiturate overdose but can also be observed in comas induced by other drugs (see Ch. 33); syringosquamous metaplasia may result from the toxic effects of chemotherapeutic agents (e.g. cytarabine, doxorubicin) on the eccrine glands. §Decreased sweating has been attributed to inhibition of carbonic anhydrase isoenzymes in the eccrine glands.	

Table 39.9 Drugs that cause hypohidrosis and anhidrosis. Refers to systemic administration unless otherwise indicated.

This is in contrast to the sweating, pallor, and nausea seen in common vasodepressor fainting.

Ross syndrome, which consists of Adie syndrome (myotonic pupils and absent deep tendon reflexes) plus segmental anhidrosis that is typically associated with compensatory hyperhidrosis, also falls into this group. Congenital insensitivity to pain with anhidrosis (hereditary sensory and autonomic neuropathy type IV) is a rare autosomal recessive disorder which presents with recurrent fevers due to anhidrosis, self-mutilation due to insensitivity to pain, and intellectual disability. Mutations in *NTRK1*, which encodes the tyrosine kinase receptor for nerve growth factor, have been detected in these patients. Skin biopsy specimens reveal a lack of innervation of eccrine sweat glands.

Disruption of the superior cervical ganglion results in Horner syndrome, and chemical blockade of selected sympathetic ganglia will result in regional anhidrosis. Any drug that interrupts synaptic transmission in autonomic ganglia will suppress sweating (Table 39.9).

Peripheral Anhidrosis

Congenital and acquired alterations or disturbances of the sweat glands result in an absence or significant reduction in sweating (Table 39.10). Hypo- or anhidrosis is one of the clinical findings in several types of ectodermal dysplasia[30]. In patients with ichthyoses, obstruction of sweat ducts can lead to hypohidrosis.

The skin of elderly individuals may show some atrophy of the sweat glands, but overall they are preserved and continue to function with advancing age. Toxic and thermal insults to the skin and a variety of inflammatory and neoplastic disorders can destroy or produce atrophy of the sweat glands (see Table 39.10).

Diagnosis of Anhidrosis

Heat intolerance may be due to a number of underlying disorders. New symptoms such as drowsiness, fatigue, or inability to concentrate in hot environments in association with a decrease in the patient's "normal sweating" point to acquired hypo- or anhidrosis. A careful history will yield clues to the diagnosis, with special attention to new medications, recent medical events (e.g. a cerebrovascular accident), the presence of diabetes or other chronic conditions, and family history (see Tables 39.8–39.10).

Examination of the patient's skin may not reveal the presence or extent of anhidrosis. A hot environment or exercise may be required but excessive overheating must be avoided. Colorimetric or gravimetric testing (see above) and infrared thermography will demonstrate diminished or absent sweating. Local intradermal injection of cholinergic drugs to stimulate sweating in small areas can also be utilized, but the risk of side effects generally precludes their injection into large areas. Testing for axon reflex sweating with intradermal nicotine sulfate or picrate in appropriate doses (e.g. 0.001 mg) or administration of acetylcholine via iontophoresis may be performed in patients in whom peripheral neuropathies are suspected.

PERIPHERAL CAUSES OF HYPOHIDROSIS AND ANHIDROSIS DUE TO SWEAT GLAND ABNORMALITIES
Genetic disorders

• Ectodermal dysplasias
  • Hypohidrotic ectodermal dysplasia
  • Hypohidrotic ectodermal dysplasia with immune deficiency
  • Rapp–Hodgkin syndrome
  • Naegeli–Franceschetti–Jadassohn syndrome
• Incontinentia pigmenti
• Bazex–Dupré–Christol syndrome
• Fabry disease*

Destruction
• Tumors (e.g. lymphoma) • Burns • Radiation therapy, including electron beam therapy • Systemic sclerosis (scleroderma) and morphea • Sjögren syndrome† • Graft-versus-host disease • Acrodermatitis chronica atrophicans
Obstruction
• Miliaria • Ichthyoses (e.g. lamellar ichthyosis) • Psoriasis • Eczematous dermatoses • Bullous diseases (e.g. epidermolysis bullosa [inherited or acquired]) • Porokeratosis
*Hyperhidrosis (related to autonomic dysfunction) can also occur. †Hypohidrosis can also result from peripheral neuropathy.

Table 39.10 Peripheral causes of hypohidrosis and anhidrosis due to sweat gland abnormalities.

Finally, a biopsy specimen from an affected area of skin should be obtained in virtually all patients with anhidrosis to identify sweat gland abnormalities. When possible underlying etiologies have been excluded (see Tables 39.8–39.10), acquired idiopathic generalized anhidrosis should be considered (Table 39.11)[31,32].

Treatment of Anhidrosis

Treatment options for anhidrosis are limited. Offending medications should be discontinued. Keeping the patient in a cool environment is essential. For disorders due to clogged sweat ducts, gentle exfoliation may be helpful. Disorders of cornification (e.g. lamellar ichthyosis) associated with overheating should be treated aggressively. Use of water-containing spray bottles can prove useful.

ABNORMALITIES AND ALTERATIONS OF ECCRINE AND APOCRINE SWEAT COMPOSITION

Key features

- Some disorders (e.g. cystic fibrosis) lead to abnormal chemical composition of sweat
- Eccrine bromhidrosis is most commonly caused by maceration of the stratum corneum and bacterial degradation of keratin
- Apocrine bromhidrosis is related to bacterial degradation of apocrine sweat
- Eccrine chromhidrosis is due to *exogenous* chemicals that color the sweat
- Apocrine chromhidrosis is usually due to *intrinsic* causes

Abnormalities of eccrine sweat composition, as evidenced by altered electrolyte content or the presence of other anomalous substances, are recognized as disorders of eccrine function. Some of these glandular disturbances are not accompanied by clinically distinctive signs or symptoms, whereas others result in well-defined clinical entities.

ACQUIRED IDIOPATHIC GENERALIZED ANHIDROSIS
Rare disorder of unknown etiology Acquired, broadly distributed reduction in sweat production
Reported primarily in Asian populations, especially Japanese Male predominance (~80%) Most commonly presents during the 2nd to 4th decade When widespread, heat intolerance or stroke may occur
Three subtypes: • Sudomotor neuropathy • Idiopathic pure sudomotor failure (most common form) • Sweat gland failure
Diagnostic features: • By thermoregulatory sweat testing (starch–iodine test), hypohidrosis or anhidrosis involves >25% BSA and is usually symmetric • Sweating is preserved on the face, palms, and soles and in the axillae • Exclusion of other causes (e.g. medications, neurologic disorders, cutaneous diseases, Sjögren syndrome; see Tables 39.8–39.10)
Additional findings in affected areas: • Decreased sweating following local injection of acetylcholine • No induction of sweating by QSART, which assesses sweating due to the axon reflex • Marked variation in histologic findings, from normal-appearing eccrine glands to eccrine gland atrophy or absence, occlusion of proximal ducts, and periglandular inflammatory infiltrates
Treatment: • Lifestyle guidance, i.e. avoid heat if possible • Oral medications: pulse corticosteroids, cyclosporine, antihistamines

Table 39.11 Acquired idiopathic generalized anhidrosis. BSA, body surface area; QSART, quantitative sudomotor axon reflex test (acetylcholine is administered to the skin via iontophoresis and then sweating is measured). See refs. 31 and 32.

Notable among this group of disorders are those in which there is altered electrolyte concentration in sweat (Table 39.12). Cystic fibrosis, an autosomal recessive disorder caused by mutations in the *c*ystic *fi*brosis *t*ransmembrane conductance *r*egulator (*CFTR*) gene, is an important example in which all of the exocrine glands in the body are affected, leading to dysfunction of multiple organs, including the lungs, exocrine pancreas, intestines, and liver. Cystic fibrosis patients demonstrate decreased electrolyte reabsorption by the eccrine duct, which results in increased loss of sodium, chloride, and (to a lesser extent) potassium in sweat. Increased Cl^- concentration in sweat (>60 mEq/L on two separate occasions) remains the most widely used diagnostic assay for this disease; it is referred to as the sweat chloride test. Cystic fibrosis patients still produce sweat in response to heat and most pharmacologic stimuli, but the increased loss of electrolytes poses a systemic risk for them in hot environments. An absent or markedly diminished response of the eccrine glands and other exocrine glands to β-adrenergic agonists is another marker for this disorder, since the CFTR protein is a Cl^- channel activated via β-adrenergic stimulation.

Excretion of calcium in eccrine sweat has been demonstrated in patients with widespread idiopathic calcinosis cutis. In uremia, high levels of urea can produce a "uremic frost" on the skin of these seriously ill patients[33]; however, readily available dialysis has made this a rare finding. Decreased size of the sweat glands, the significance of which is unknown, has also been described in patients with uremia[34]. Many drugs, including opiates, amphetamines, anticonvulsants, antimicrobials (e.g. azole antifungals, griseofulvin), and chemotherapeutic agents, as well as metals such as copper and mercury have been shown to be secreted in sweat[35,36].

In healthy individuals, both eccrine sweat and apocrine sweat are odorless when they are secreted. Eccrine bromhidrosis can develop secondary to maceration of the stratum corneum with bacterial degradation of keratin; the odor emanates primarily from the feet and intertriginous zones, especially the inguinal region. In apocrine bromhidrosis, the odor reflects bacterial degradation of apocrine sweat into ammonia, volatile fatty acids, and thioalcohols. The types of bromhidrosis are listed in Table 39.13.

Malodorous sweat can also be caused by abnormal secretion of amino acids and their analogues or breakdown products. This occurs in several heritable metabolic disorders[37] (see Table 39.13). In addition, some foods such as garlic and asparagus can cause eccrine bromhidrosis.

Colored eccrine sweating (*eccrine* chromhidrosis) can result from hyperbilirubinemia (green), ingestion of certain foods (e.g. red due to cranberry juice), and dyes in drugs (e.g. yellow from tartrazine). Pseudochromhidrosis results from contamination of colorless eccrine sweat by pigment from microorganisms, including *Corynebacterium* spp. (blue, brown/black), *Serratia marcescens* (red/pink), *Pseudomonas*

SYSTEMIC DISORDERS THAT AFFECT THE LEVELS OF ELECTROLYTES IN SWEAT
Increased levels of electrolytes in sweat*

• Cystic fibrosis
• Endocrine disorders
  • Adrenal insufficiency (e.g. due to Addison disease or congenital adrenal hyperplasia)
  • Myxedema
  • Nephrogenic diabetes insipidus
• Familial intrahepatic cholestasis
• Malnutrition
• Metabolic disorders
  • Fucosidosis
  • Glycogen storage disease type I
• Unacclimatized individuals exposed to heat

Decreased levels of electrolytes in sweat

• Endocrine disorders
  • Aldosteronism
  • Cushing syndrome
  • Thyrotoxicosis
• Hypoproteinemic edema (e.g. due to cirrhosis or nephrotic syndrome)

*Elevated sweat electrolytes (which may result in a false-positive chloride sweat test) can also be observed in patients with skin conditions such as widespread atopic dermatitis, ichthyosiform erythroderma, or ectodermal dysplasia.

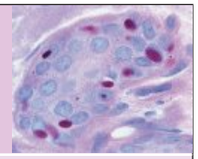
Table 39.12 Systemic disorders that affect the levels of electrolytes in sweat.

TYPES OF BROMHIDROSIS
Apocrine
• Axillary (formation of thioalcohols by *Staphylococcus hominis* a major component)
Eccrine

• Keratinogenic
  • Plantar
  • Intertriginous
• Metabolic
  • Phenylketonuria (musty or "mousy" odor)
  • Maple syrup urine disease (sweet odor)
  • Methionine adenosyltransferase deficiency ("boiled cabbage" odor)
  • Methionine malabsorption syndrome (oasthouse syndrome; "beer-like" odor)
  • Trimethylaminuria ("fishy" odor)*
  • Dimethylglycine dehydrogenase deficiency ("fishy" odor)
  • Isovaleric acidemia ("sweaty feet" odor)
• Exogenous
  • Foods, e.g. garlic, asparagus, curry
  • Drugs, e.g. penicillins, bromides
  • Chemicals, e.g. dimethyl sulfoxide (DMSO)

*Exacerbated by eating marine fish, eggs, kidney, or liver.

Table 39.13 Types of bromhidrosis.



aeruginosa (blue-green), *Bacillus* spp. (blue), and *Malassezia furfur* (blue). Miners or workers in the copper industry often exhibit blue or blue–green sweat due to external deposits of copper salts. Sunless-tanning products can result in brown sweat. Hematidrosis (bloody sweat) has been reported periodically and appears to be associated with psychiatric disease. Red sweat has been described in patients receiving clofazimine and rifampin.

In contrast, *apocrine* chromhidrosis is usually intrinsic in origin and blue or black in color, resulting from the excretion in apocrine sweat of lipofuscin in large amounts or in a highly oxidized state. Chromhidrosis, primarily axillary in location and presumably of apocrine origin, can be seen in alkaptonuria and may be a presenting sign of the disease as the excreted pigment stains the undershirts of these patients.

DIAGNOSTIC MICROSCOPIC CHANGES IN ECCRINE SWEAT GLANDS

A variety of disorders display diagnostic microscopic findings within the eccrine sweat glands, ranging from intracellular inclusions and degenerative alterations to changes in the size of the glands or their components. Table 39.14 summarizes these distinctive histopathologic features, which may be overlooked in the diagnostic evaluation of patients. Most of the findings listed can be visualized by light microscopy. By electron microscopy, viral particles from Ebola virus and severe acute respiratory syndrome (SARS) have been found in eccrine sweat ducts[38]. Although there have been reports of SARS-CoV-2 being present in the sweat of infected individuals, more recent studies have failed to detect its secretion in sweat, with no evidence that sweat can serve as a source of transmission[39].

DIAGNOSTIC MICROSCOPIC CHANGES IN ECCRINE GLANDS

Disorder	Microscopic changes
Exposures/metabolic	
Argyria	Granules in eccrine basement membrane (darkfield)
Chemotherapy (traditional)	Vacuolar degeneration of secretory cells and/or ducts; dense eccrinotropic infiltrate of neutrophils (may be sparse or lymphocytic in neutropenic patients)
Coma bullae	Necrosis of secretory cells and duct cells
Hypothyroidism	PAS-positive, diastase-resistant granules in secretory cells
Uremia	Reduced size of sweat glands
Tumors	
Mycosis fungoides, syringotropic	Dense infiltrate of atypical lymphocytes within and around eccrine glands, often with squamous syringometaplasia
Genetic disorders	
Acid maltase deficiency Adrenoleukodystrophy Mucopolysaccharidoses (e.g. Hurler, Hunter, Sanfilippo) and mucolipidoses	Membrane-bound vacuoles in secretory cells
Lafora disease	PAS-positive granules in outer layer of duct cells (inset)
Neuronal ceroid lipofuscinoses	Cytoplasmic inclusions in secretory cells
Sphingolipidoses (e.g. Fabry, Niemann–Pick, Sandhoff)	Lipid inclusions in secretory cells
Trisomy 13, 18 or 21	Differences in duct: secretory coil length
Viral infections	
Ebola hemorrhagic fever Severe acute respiratory syndrome (SARS)	Viral particles in lumen of sweat gland tubule

Table 39.14 Diagnostic microscopic changes in eccrine glands. (Inset: Lafora disease.)

INFLUENCE OF SWEAT ON SKIN DISEASES

Key features

- Wet skin is more permeable than dry skin
- Wet skin is more likely to develop contact allergies than dry skin
- Several cutaneous diseases are aggravated by sweat

That wet skin is more permeable than dry skin has been clearly established, and skin wetted by perspiration is more likely to be sensitized to contact allergens. Damp skin is also more susceptible to absorption of toxic chemicals. The macerative effect of sweat is an essential early step in the pathogenesis of sweat retention syndromes, such as miliaria. Sweat-saturated keratin, upon bacterial degradation, gives rise to plantar bromhidrosis and pitted keratolysis. Softening of the skin by sweat facilitates the entry and growth of microbes, leading to flexural candidiasis, bacterial folliculitis, bullous impetigo, superficial dermatophyte infections, tinea versicolor, verrucae, and molluscum contagiosum. Grover disease, Darier disease, and Hailey–Hailey disease are clearly aggravated by sweating. Some systemic drugs, such as antifungal agents, are excreted in eccrine sweat and diffuse from the sweat ducts to the surrounding stratum corneum, exerting inhibitory effects on microorganisms.

ADDITIONAL DISORDERS OF THE ECCRINE SWEAT GLAND

Miliaria

Key features

- Sweat retention can be caused by obstruction of the eccrine duct at various levels
- Miliaria crystallina or sudamina (superficial ductal occlusion) – clear vesicles
- Miliaria rubra or prickly heat (intermediate ductal occlusion) – erythematous papules or pustules
- Miliaria profunda or mammillaria (deeper ductal occlusion) – white papules
- Common in neonates (whose eccrine sweat ducts are not fully developed) and adults living in hot, humid climates
- Resolves with relocation to a cool environment

THREE TYPES OF MILIARIA				
Type	**Location of obstruction**	**Cutaneous lesions**	**Patient population(s)**	**Most common locations**
Crystallina	Stratum corneum	Non-pruritic, clear, fragile, 1 mm vesicles	Neonates <2 weeks of age Children and adults in hot climates	Face and trunk (Fig. 39.8)
Rubra	Mid-epidermis	Pruritic, erythematous, 1–3 mm papules; may have pustules (miliaria pustulosa)	Neonates 1–3 weeks of age Children and adults in hot climates	Neck and upper trunk (Fig. 39.9)
Profunda	Dermal–epidermal junction	Non-pruritic, white, 1–3 mm papules	Adults in hot climates; often with multiple bouts of miliaria rubra	Trunk and proximal extremities

Table 39.15 Three types of miliaria.

Fig. 39.8 Miliaria crystallina. Multiple small superficial vesicles with clear fluid.

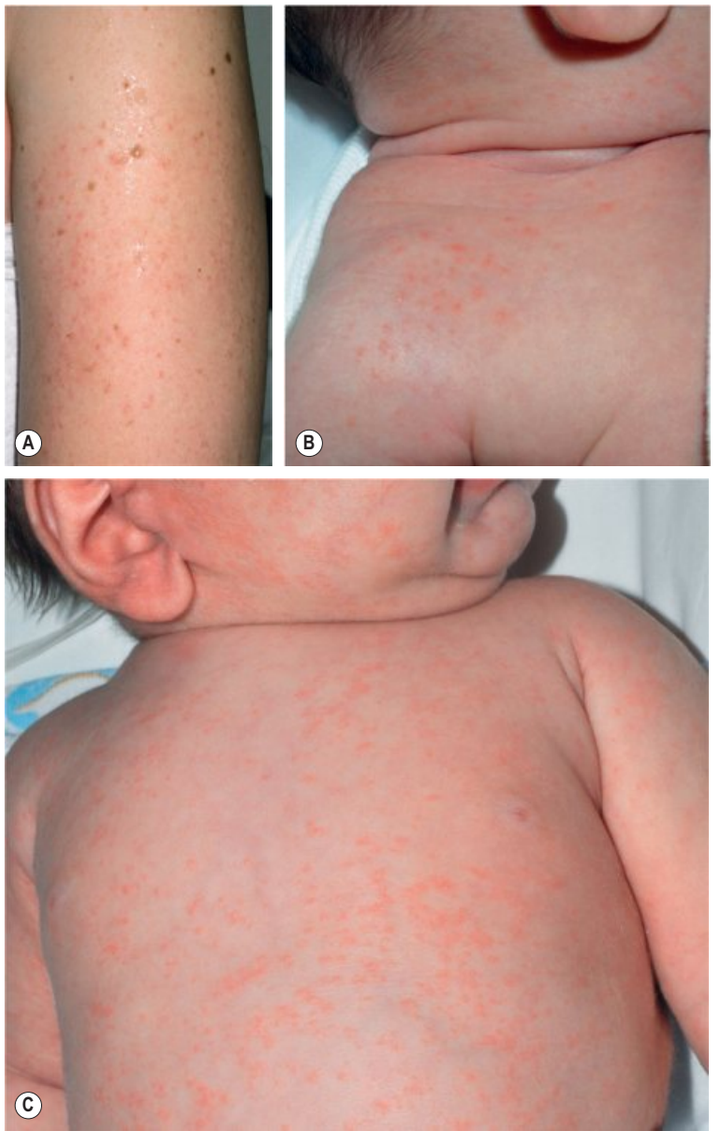


Fig. 39.9 Miliaria rubra. Multiple erythematous non-follicular papules and papulovesicles on the arm of an adult woman (**A**), on the upper trunk and neck of a neonate (**B**), and in a widespread distribution in an infant (**C**). In addition to obvious sweating, the woman also has a sunburn from recent sun exposure. Note that several of the lesions in the neonate have become pustular. *A, Courtesy Jennifer Powers, MD; B, Courtesy Julie V. Schaffer, MD; C, Courtesy Antonio Torrelo, MD.*

Miliaria encompasses a family of eccrine disorders all of which feature obstruction of the eccrine sweat duct. Three types are recognized, with each reflecting obstruction of sweat ducts at a different level, from the stratum corneum to the dermal–epidermal junction (Table 39.15). Blockage results in retention of sweat within the duct, causing a sweat retention vesicle to form.

Epidemiology and pathogenesis

Miliaria is most common in children, particularly neonates whose eccrine ducts are not fully developed. Congenital miliaria crystallina has even been described. Miliaria is also common in adults who live or work in very hot, humid environments. There is no racial or sex predisposition and it can occur in the elderly. Miliaria has not been associated with any specific underlying systemic disease.

Excessive sweating, particularly under occlusive clothing, can lead to maceration of the stratum corneum which is sufficient to cause blockage of the eccrine duct[30]. Keratinous plugs form, causing obstruction.

Clinical features

Each type of miliaria is clinically distinctive (see Table 39.15). *Miliaria crystallina* presents as small, clear superficial vesicles (Fig. 39.8) that rupture easily. It poses no systemic risk for the patient.

The most common form is *miliaria rubra*, which is characterized by small, non-follicular, erythematous macules and papules topped by a punctate vesicle (Fig. 39.9A,C). Lesions are usually pruritic and occasionally burn. Onset is within days to weeks of exposure to hot environments. Miliaria rubra may become pustular (Fig. 39.9B), especially in chronic, extensive cases. *Miliaria pustulosa*, as this variant is known, is sterile, although secondary bacterial infection may occur. Extensive cases of miliaria rubra can lead to hyperpyrexia.

When miliaria rubra is chronic or recurrent, occlusion may extend to a deeper level and produce *miliaria profunda*. Because of their deeper location, the sweat retention vesicles of miliaria profunda appear clinically as white papules, 1 to 3 mm in diameter. They start within minutes of initiation of sweating and subside within 1 to 2 hours after the sweating ceases. Lesions of miliaria profunda are asymptomatic. Only in those patients with concomitant miliaria rubra can pruritus or burning develop. When large numbers of sweat glands are occluded and essentially non-functional, these individuals are at risk for significant thermoregulatory problems and a compensatory hyperhidrosis of

the face is routinely observed (see Fig. 39.4A). Axillary and inguinal lymphadenopathy can also be seen, with resolution upon clearing of the miliaria. The term "tropical anhidrotic asthenia" has been applied to these patients.

Pathology

Biopsy specimens demonstrate ductal blockage. Keratinous obstruction of sweat ducts at the level appropriate for each type of miliaria may be seen, but several deeper sections may be required: in the stratum corneum for miliaria crystallina; the mid-epidermis for miliaria rubra; and at the dermal–epidermal junction for miliaria profunda. Sweat retention vesicles are seen underlying the respective sites of occlusion. Spongiosis in the vicinity of the epidermal sweat duct is common in miliaria rubra and miliaria profunda. Dermal inflammation is absent in miliaria crystallina, whereas perivascular lymphocytic infiltrates and vasodilation are evident in miliaria rubra. An eosinophilic cast can be seen occluding sweat ducts at the dermal–epidermal junction or intraepidermally in miliaria profunda. Periductal infiltration of lymphocytes is also seen along with mild focal spongiosis of the adjacent epidermis.

Differential diagnosis

The diagnosis is usually clinically apparent, but a simple diagnostic test consists of the puncture of a miliaria vesicle with a fine needle, resulting in release of the trapped clear sweat. In neonates, the differential diagnosis includes erythema toxicum neonatorum, neonatal cephalic pustulosis (which can involve the upper trunk as well as the face), candidiasis, and in atypical cases, other vesiculopustular diseases of the newborn (see Table 34.1). In adults, the differential diagnosis for miliaria rubra includes other conditions with a predilection for sites of occlusion and excessive sweating, such as folliculitis (with normal flora or *Staphylococcus aureus*), candidiasis, and Grover disease. The regression of miliaria profunda within hours of ceasing physical exertion and/or exposure to high temperatures distinguishes it from other papular eruptions.

Treatment

Management of all types of miliaria requires placement of the patient in a cool environment, in which sweating stops, for several days to weeks. Gradually, the obstructed sweat ducts shed their occluding keratinous plugs and normal sweating is restored. Topical anhydrous lanolin may dissolve the plugs in miliaria profunda. Anecdotally, other topicals (including corticosteroids and antibiotics) as well as oral antibiotics, retinoids, and vitamins A and C have been advocated as therapeutic options.

Multiple Sweat Gland Abscesses

Synonym: ▪ Periporitis staphylogenes

Key features

- Rare neonatal disorder
- Miliaria lesions become infected and form abscesses
- Most common on the neck, back, and buttocks
- May be associated with systemic symptoms

Multiple sweat gland abscesses represent a rare disorder of newborn infants that is likely due to a secondary staphylococcal infection of miliaria lesions. Malnourished or debilitated neonates are preferentially affected.

Clinically, erythematous papules and nodules are distributed on the occiput, neck, back, and buttocks. They are typically round or oval erythematous swellings that measure 1 to 2 cm in diameter and do not exhibit warmth, tenderness, or fluctuance. Lymphangitis and constitutional signs and symptoms such as fever and lassitude may occur with larger or more numerous lesions. Bacterial smears and cultures reveal *S. aureus*. Microscopically, abscess formation involving the sweat glands is seen.

The differential diagnosis includes furuncles or carbuncles and subcutaneous fat necrosis of the newborn. Although to date this disorder has not been associated with an immunodeficiency, primary immunodeficiencies (e.g. chronic granulomatous disease, hyper-IgE syndrome) should be considered in affected infants with recurrent cutaneous or extracutaneous infections. Systemic antibiotics, correction of the child's nutritional state, and elimination of factors encouraging the development of miliaria should be undertaken in the management of this condition.

Neutrophilic Eccrine Hidradenitis

Synonyms: ▪ Chemotherapy-associated eccrine hidradenitis ▪ Drug-associated eccrine hidradenitis

Key features

- Typically occurs following administration of chemotherapy
- Both children and adults can be affected
- Painful erythematous papules and plaques are classically found on the trunk
- Usually resolves within a few days to weeks

Epidemiology and pathogenesis

Neutrophilic eccrine hidradenitis (NEH) is a disorder of the eccrine sweat glands that occurs in both children and adults, but there may be a slight male predominance[40]. It was initially described in patients with acute myelogenous leukemia who had received cytarabine plus an anthracycline and this remains one of the most common clinical scenarios. NEH usually develops 7–14 days after initiating chemotherapy and can follow the administration of other chemotherapeutic agents including bleomycin, decitabine, and cyclophosphamide. It is generally regarded as a cytotoxic process directed at the sweat glands, e.g. via a direct toxic effect of chemotherapeutic drugs that are excreted in the sweat.

In addition, NEH has been reported after zidovudine treatment in HIV patients and following administration of granulocyte colony-stimulating factor, carbamazepine, TNF inhibitors, and targeted anti-cancer therapies including inhibitors of the epidermal growth factor receptor, KIT receptor, and BRAF[41]. In a small number of patients, NEH preceded and was believed to herald a new malignancy (usually acute myelogenous leukemia) or its relapse. An infectious form of NEH has also been described; most of the patients were immunocompromised, and the pathogenic organism (e.g. *Serratia, Enterobacter, S. aureus, Nocardia*) was often identified in tissue culture but not via light microscopy plus special stains of lesional specimens. Lastly, NEH has been observed in otherwise healthy persons.

Clinical features

Clinically, erythematous papules and plaques occur on the trunk and may also affect the extremities and face (Fig. 39.10). Polymorphic lesions, e.g. linear, annular, erythema multiforme-like, of varying sizes

Fig. 39.10 Neutrophilic eccrine hidradenitis. Erythematous plaques on the dorsal hand. *Courtesy Jeffrey P. Callen, MD.*

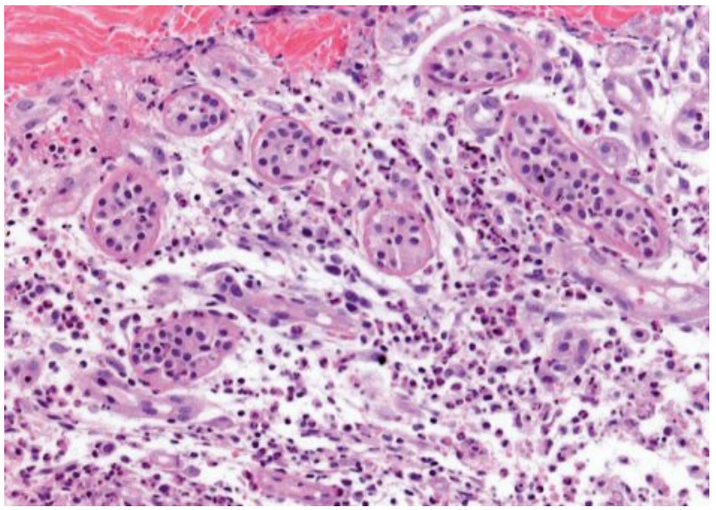

Fig. 39.11 Neutrophilic eccrine hidradenitis – histopathologic features. Neutrophils surround and infiltrate the eccrine glands and coils. There are degenerative changes of primarily secretory cells. *Courtesy Lorenzo Cerroni, MD.*

have been described, some of which were purpuric (typically in association with thrombocytopenia) or pustular. Patients are often febrile and neutropenic in the setting of chemotherapy-associated NEH.

Pathology

Histopathologic evaluation reveals eccrine sweat glands with degenerative vacuolar changes or even necrosis within secretory and (to a lesser degree) ductal cells; the process usually spares the acrosyringium. A neutrophilic inflammatory infiltrate classically accompanies these changes (Fig. 39.11). However, the infiltrate may be sparse or lymphocytic in the setting of chemotherapy-induced neutropenia. Squamous metaplasia of the cuboidal epithelial cells of the eccrine ducts, i.e. eccrine squamous syringometaplasia, is occasionally observed.

Differential diagnosis

The clinical differential diagnosis includes Sweet syndrome and infection, e.g. cellulitis, bacterial or fungal emboli. The histopathologic features of both NEH and eccrine squamous syringometaplasia can be seen in a number of chemotherapy-related entities including acral erythrodysesthesia and intertriginous eruption associated with chemotherapy. Toxic erythema of chemotherapy has been proposed as an overarching term for this spectrum of disorders[42] (see Ch. 21).

Treatment

The eruption of NEH is usually self-limited and resolves several days to weeks after cessation of chemotherapy, but may recur with subsequent cycles[34]. Because NEH usually arises in the setting of fever and neutropenia, empiric antimicrobial therapy is frequently administered until the possibility of infection is excluded. Corticosteroids seem to shorten the duration of the lesions and relieve the pain in some patients. Dapsone can be beneficial in treating NEH and preventing recurrences[42].

Idiopathic Palmoplantar Hidradenitis

Synonyms: ■ Palmoplantar eccrine hidradenitis ■ Recurrent palmoplantar hidradenitis

Key features

- Occurs primarily in otherwise healthy children
- Sudden onset of painful nodules on the palms and/or soles
- Resolves spontaneously within a few days to weeks, but may be recurrent

Fig. 39.12 Idiopathic palmoplantar hidradenitis. Erythematous papulonodules on the plantar surface. *Courtesy Michael L. Smith, MD.*

Idiopathic palmoplantar hidradenitis is primarily a disease of children and is not associated with any underlying medical conditions or medications[43]. Its onset is often preceded by vigorous physical activity. The proposed pathomechanism involves eccrine gland rupture due to mechanical and thermal trauma.

This disorder is characterized by the sudden onset of multiple, tender, erythematous nodules on the soles and less often the palms (Fig. 39.12). Neutrophilic infiltration of the secretory and ductal components of the coiled portion of the sweat glands is seen in biopsy specimens. This infiltrate is distinctly nodular, and neutrophilic abscesses may be observed. Eccrine squamous syringometaplasia is usually absent. The differential diagnosis includes the "pseudomonas hot-foot syndrome", panniculitis (e.g. erythema nodosum), pernio, and vasculitis (e.g. polyarteritis nodosa). Some have suggested that the entity "traumatic plantar urticaria" belongs within the spectrum of idiopathic palmoplantar hidradenitis.

Spontaneous resolution in a matter of days to weeks is the rule, although recurrent attacks occur in as many as half of affected children.

Granulosis Rubra Nasi

Key features

- Hyperhidrosis of the nose is followed by macular erythema; papules and vesicles can also develop
- The process may extend to the cheeks, lips, and upper chin
- Onset is during the first decade of life and usually resolves by puberty
- Autosomal dominant transmission

Granulosis rubra nasi is a rare inherited condition. It generally appears during childhood (peak incidence between ages 7 and 12 years), but adolescent or adult onset is possible. The etiology and pathogenesis of this disorder have not been elucidated. An autosomal dominant inheritance pattern has been described.

Hyperhidrosis of the tip of the nose may be present for years before the characteristic erythema develops on the nose; the latter can extend to the cheeks, chin, and upper lip. The entire area of erythema displays excessive sweating. Papules, sweat droplets, and vesicles may form at the orifices of the eccrine ducts. Cystic lesions can also develop and the nose may be cold. It may itch but is not painful. Primary hyperhidrosis of the palms and soles is a common concomitant finding, as is poor peripheral circulation with pernio or acrocyanosis. Granulosis rubra nasi usually resolves at puberty but may continue into adulthood.

Histopathologically, dilation of dermal blood and lymphatic vessels with mild inflammation around and within dilated sweat ducts (at times simulating a hidrocystoma) are seen. The epidermis, connective tissue, and pilosebaceous apparatus are otherwise normal and no heterotopic apocrine glands are found. No associated systemic disease or abnormal laboratory findings have been described.

The differential diagnosis includes rosacea, acne vulgaris, periorificial dermatitis, lupus pernio, and lupus erythematosus. Treatment can be disappointing and is limited to drying lotions, perhaps botulinum toxin injections or topical tacrolimus, and reassurance that the disorder typically resolves spontaneously at puberty.

Fig. 39.13 Keratolysis exfoliativa. Small annular collarettes of scale on the palm. *Courtesy Jean L. Bolognia, MD.*

Keratolysis Exfoliativa

Synonyms: ▪ Lamellar dyshidrosis ▪ Recurrent focal palmar peeling ▪ Dyshidrosis lamellosa sicca

Key features

- Superficial desquamation of the palms and occasionally the soles
- Non-inflammatory
- Treat with keratolytics

Keratolysis exfoliativa is a common, asymptomatic, superficial desquamative process of palmar and less often plantar skin; it usually worsens in warm weather and is occasionally associated with hyperhidrosis. Keratolysis exfoliativa is seen in healthy adults and possibly reflects low-grade damage to the thick stratum corneum of volar skin. Concurrent irritant dermatitis may also be present, and some cases may resemble or merge with pompholyx. Maceration may also be a pathogenic influence, although hyperhidrosis is not a regular feature.

Clinically, it appears as an irregular annular or circinate pattern of scaling, 2 to 15 mm in diameter (Fig. 39.13). There are no antecedent or concurrent vesicles or papules, and no fungi are recoverable from the lesions. Treatment is disappointing. Humectant and keratolytic topical products containing urea, ammonium lactate, or salicylic acid (5%–6%) may be helpful. Topical corticosteroids are not useful unless there is associated dermatitis.

Grover Disease (see Ch. 87).

DISORDERS OF THE APOCRINE SWEAT GLAND

Fox–Fordyce Disease

Synonym: ▪ Apocrine miliaria

Key features

- Caused by plugging of the apocrine sweat glands
- Occurs primarily in women 15–35 years of age
- Skin-colored follicular papules develop in the axillary, anogenital, and periareolar areas
- May be intensely pruritic

Epidemiology and pathogenesis

Fox–Fordyce disease is a chronic, pruritic disorder of the apocrine glands. It most commonly affects women between the ages of 15 and 35 years and usually remits after menopause.

Fig. 39.14 Fox–Fordyce disease. **A** Monomorphic skin-colored papules in the axillary vault, many of which are dome-shaped (inset). **B** Monomorphic hyperpigmented follicular papules with a central keratotic plug in the axillary vault. *A, Courtesy Jean L. Bolognia, MD; B, Courtesy Kalman Watsky, MD.*

The etiology of Fox–Fordyce disease is unknown, but hormonal factors are thought to play a role. Emotional and physical stimuli may also have a role in the disease course. It has occurred following the trauma of laser hair removal[44].

Clinical features

Fox–Fordyce disease presents as dome-shaped, skin-colored, discrete perifollicular papules within the axillary (Fig. 39.14), anogenital, and periareolar skin. Less common locations include the medial thighs, periumbilical area and sternal region. Loss of hair in affected areas is frequently observed. The condition is often intensely pruritic. Pregnancy and oral contraception may ameliorate the itching, while heat and emotional stress can aggravate symptoms.

Pathology

Early histologic findings of Fox–Fordyce disease include a keratin plug in the follicular infundibulum, which obstructs the entrance of the apocrine duct. This blockage leads to apocrine sweat retention and subsequent rupture of the duct at the level of the epidermis. Epidermal spongiosis and vesiculation are seen. Associated findings include a perifollicular and periadnexal mixed inflammatory infiltrate as well as perifollicular foam cells with PAS-positive cytoplasm, representing apocrine secretion material.

Treatment

Treatment of Fox–Fordyce disease is difficult. Topical and intralesional corticosteroids are often a first-line therapy, although their use may be limited by the risk of cutaneous atrophy. Topical calcineurin inhibitors may reduce pruritus and improve the appearance of skin lesions. Topical tretinoin has been shown to reduce pruritus, but has little effect on the clinical appearance of the disease and may produce irritation. Twice-daily clindamycin lotion may also be useful in minimizing symptoms. Some women respond to oral contraceptives, while other patients receive temporary relief from oral isotretinoin. Physical interventions that may be beneficial include phototherapy, electrocautery, and excision of periareolar skin.

Chapter Contents

The Fluorescent Anti-Nuclear Antibody (FANA) Test 657
Autoantibodies in Lupus Erythematosus. 662
Autoantibodies in Idiopathic Inflammatory Dermatomyopathies. 664
Autoantibodies in Systemic Sclerosis (SSc; Scleroderma) and Morphea (Localized Scleroderma) 665
Autoantibodies in Other Rheumatic Disorders Affecting the Skin 666

Key features

- Autoantibodies can play an important role in the diagnosis, management, and prognosis of autoimmune connective tissue diseases (AI-CTDs)
- The classic anti-nuclear antibody (ANA) assay remains the entrée into the world of AI-CTD serology, and understanding its limitations is critical for clinical decision-making
- While many autoantibodies are not disease-specific, certain autoantibodies have significant disease specificity and therefore are of diagnostic value
- Anti-dsDNA and anti-Smith (Sm) antibodies have high specificity for systemic lupus erythematosus (SLE)
- Anti-Mi-2, -TIF1-γ, -MDA5, -NXP-2, and -SAE antibodies are associated with different forms of dermatomyositis
- Anti-Jo-1 antibodies can be detected in antisynthetase syndrome
- Anti-topoisomerase-1 (Scl-70), -RNA polymerase III, and -centromere antibodies are associated with different clinical forms of systemic sclerosis
- Cytoplasmic anti-neutrophil cytoplasmic antibodies (c-ANCA) are often detected in granulomatosis with polyangiitis

INTRODUCTION

Autoimmune connective tissue diseases (AI-CTDs) represent polygenic clinical disorders with heterogeneous and overlapping clinical features. AI-CTDs are characterized by an immune dysregulation that includes the production of antibodies to self-antigens, termed autoantibodies (aAb). When considering the diagnosis of an AI-CTD, the most commonly requested laboratory test is the measurement of anti-nuclear antibodies (ANA). ANA are defined as aAb that target primarily nuclear components, including DNA or small nuclear ribonucleoproteins (snRNP). Elevated ANA titers are seen in multiple AI-CTDs and they reflect inflammatory processes within tissue but rarely have pathogenic potential.

Clinical laboratory testing for ANA is essential in the diagnosis and management of AI-CTD patients[1]. Each AI-CTD has aAb that are quite specific to the particular disorder as well as aAb that are shared with other diseases. Although AI-CTDs are usually distinct clinical entities, some patients may have overlapping features of two or more AI-CTDs and, as a result, an overlap in their pattern of aAb production (Fig. 40.1). Familiarity with the actual serologic tests and the disease associations of the various aAb allows one to maximize the clinical utility of aAb testing.

This chapter discusses aAb associated with AI-CTDs that have cutaneous manifestations in addition to historical and technical aspects of ANA assays. Tables 40.1–40.4 summarize the molecular identity of the various autoantigens and their clinical associations. The prevalence of the aAb in these tables represents the estimated median values reported from different cross-sectional studies using conventional clinical laboratory testing procedures. However, the results of such studies can vary widely. In addition, there can be complex relationships between the presence and relative amounts of aAb, disease diagnosis, and prognosis. Because understanding the basic principles of aAb laboratory tests such as sensitivity and specificity assists in interpreting assay results, they are also reviewed. Chapters 4, 23, and 24 discuss the related subjects of circulating immune complexes and cryoglobulins while Chapters 41–45 contain an in-depth discussion of the various AI-CTDs.

HISTORICAL PERSPECTIVE

One can better appreciate the evolution of thought in this area by considering the changes in methodologies used to identify aAb that have occurred over time[2]. In 1948, the bone marrow from a patient with SLE was noted to contain polymorphonuclear neutrophils that had phagocytosed nuclear material from degenerated cells. The presence of these cells became an indicator of SLE (SLE cell phenomenon)[3] and occurred in the presence of antibodies to DNA.

Approximately 10 years later, indirect immunofluorescence techniques were used to detect ANA, with the fluorescent anti-nuclear antibody (FANA) test providing a more sensitive assay for SLE. Another decade later, the Ouchterlony double immunodiffusion (DID) technique was used to identify and define precipitating serum aAb that reacted with saline extractable nuclear antigens (ENA) such as nuclear ribonucleoprotein (nRNP), Sm, SSA/Ro, and SSB/La[4].

In 1979, the molecularly and genetically defined ANA era began as the result of work by Lerner and Steitz, who employed immunodiffusion and Western blotting to define the molecular identities of the nRNP and Ro/La families of ribonucleoprotein autoantigens. These observations generated the notion that aAb might be more efficiently and cost-effectively assayed by using purified or recombinant forms of the different autoantigens in solid-phase immunoassays. An example of the latter is the *e*nzyme-*l*inked *i*mmuno*s*orbent *a*ssay (ELISA). While less expensive and more convenient, there are some drawbacks to employing ELISA and related immunoassay techniques to detect ANA, e.g. increased sensitivity and decreased specificity for aAb such as anti-SSA/Ro and anti-dsDNA antibodies. Newer multiplex techniques (e.g. solid-phase multiplex bead assays, proteome microarrays, Luminex® xMAP® technology) are now widely used and allow the simultaneous profiling of all relevant aAb in a patient. The principles of these assays are shown in Fig. 40.2, and their limitations are discussed in a recent review[5].

THE FLUORESCENT ANTI-NUCLEAR ANTIBODY (FANA) TEST

Although there is debate about its role in the diagnosis and management of AI-CTD, the classic fluorescent ANA assay (i.e. FANA test) is still the most clinically efficient screening test for systemic autoimmune disorders[6]. The ANA assay identifies antibodies present in serum that bind to autoantigens present in the nuclei (or cytoplasm) of mammalian cells. Both the pattern, which reflects the localization of the autoantigen, and the titer are reported. The reported titer represents the last dilution at which the ANA pattern is detectable and a titer of ≥1 : 40 is considered "positive". For the FANA test, almost all clinical laboratories currently employ a human tumor cell line such as HEp-2 for the nucleated cell substrate. aAb are detected with fluorochrome-conjugated antibodies that bind human immunoglobulin (the aAb) bound to nuclei in the HEp-2 cells (see Fig. 40.2A).

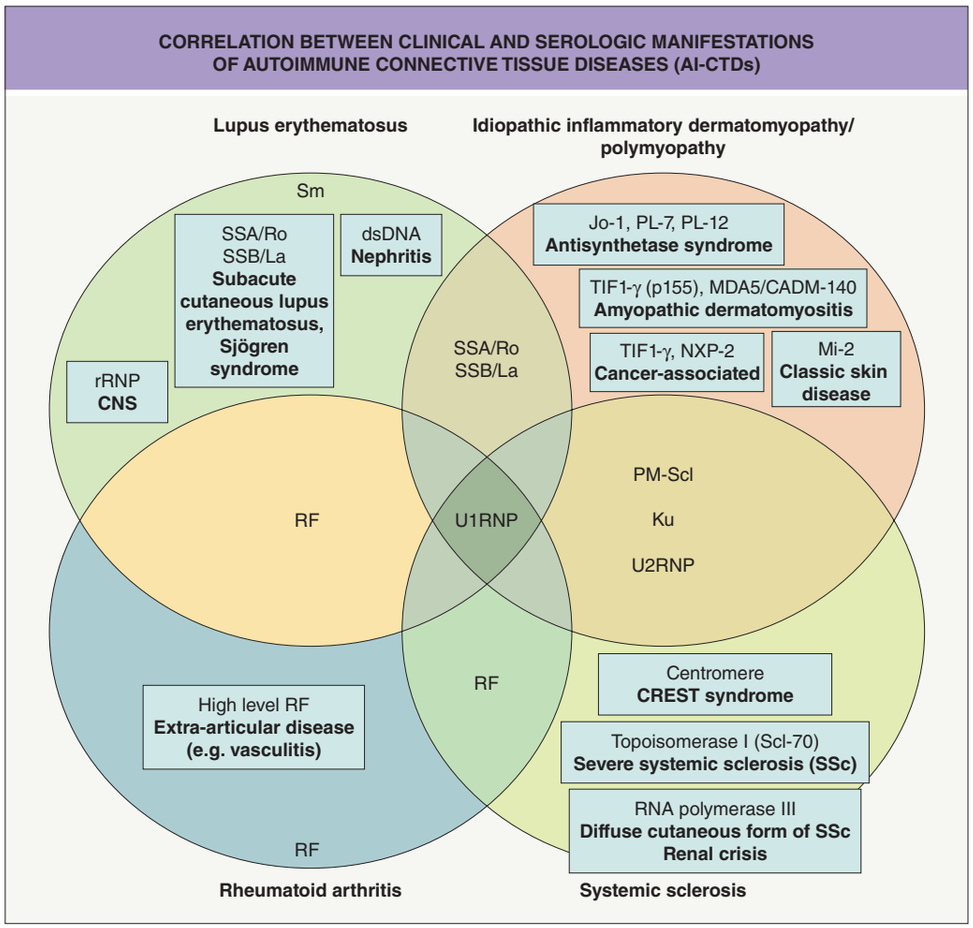

Fig. 40.1 Correlation between clinical and serologic manifestations of autoimmune connective tissue diseases (AI-CTDs). Venn diagram representation of major clinico-serologic correlations in the primary AI-CTDs that impact the skin. Some targets of autoantibodies are specific (boxed with clinical associations) while others are seen in the context of overlapping clinical features. High levels of U1RNP autoantibody with overlapping features of all four of these AI-CTDs defines the concept of mixed connective tissue disease. CADM, clinically amyopathic dermatomyositis; MDA5, melanoma differentiation-associated protein 5; p155, a 155 kDa polypeptide; RF, rheumatoid factor; RNP, ribonucleoprotein, TIF1-γ, transcriptional intermediary factor 1-gamma.

Earlier versions of the ANA assay utilized rodent cell lines that lack some of the autoantigens present in human cell nuclei (e.g. SSA/Ro). Thus, sera from SLE patients could be negative when assayed on rodent cells, especially if the predominant aAb were anti-SSA/Ro (i.e. "ANA-negative SLE"). In the past, this occurred in up to 15% of SLE patients, particularly those enriched in anti-SSA/Ro aAb-associated disorders such as subacute cutaneous LE (SCLE) and Sjögren syndrome (SjS). With the use of human HEp-2 cells, only ~1%–2% of SLE patients are ANA-negative, and "ANA-negative SLE" has almost become a historical phenomenon.

An important caveat is that the *titer* (which reflects the serial serum dilutions necessary for fluorescence to disappear) depends upon subjective interpretation by a laboratory technician. Consequently, a single serum specimen can have an ANA titer result that varies within a two-tube dilution range. In other words, a serum sample reported as having an ANA titer of 1:320 might be read as 1:160 or 1:640 upon repeat testing in the same laboratory. Although the World Health Organization tried to standardize reporting of ANA results with an international unit system (e.g. 1 IU rather than a titer of 1:160), many laboratories continue to report ANA results using a titer system. Of note, while an ANA titer of ≥1:40 is considered "positive", the 2019 European League Against Rheumatism/American College of Rheumatology (EULAR/ACR) criteria require a titer of ≥1:80 for the diagnosis of SLE (see Table 41.5).

Automated Immunoassays – Solid Phase and Bead-Based Multiplex

Automated systems have been introduced to decrease variability and increase cost-effectiveness (see Fig. 40.2B,C); however, pattern reporting remains an issue[7]. In addition, concerns exist that the results from the FANA assay may not be comparable to those of ELISA- or multiplex bead-based assays. While the FANA test has a consistently high sensitivity, this can be more variable amongst different ELISA or bead-based assays, likely due in part to the requirement of the latter to have predefined antigen combinations for ANA identification. Use of such predetermined antigen combinations is not a component of the FANA test.

Compared to the quantitative ELISA, multiplex bead-based assays have reduced labor requirements and increased throughput, but require specialized equipment. The FANA assay has the drawback of requiring significant experience for proper interpretation as well as the need for subsequent tests for antigen identification and quantitation.

"Normal" Versus "Abnormal" ANA Titers
