RICCARDI'S CLASSIFICATION OF NEUROFIBROMATOSIS	
Category	**Description**
NF1	von Recklinghausen disease
NF2	Acoustic schwannoma
NF3*	Mixed (central and peripheral neurofibromas)
NF4*	Variant
NF5*,†	Segmental café-au-lait macules, neurofibromas, or both, affecting one or more dermatomes
NF6*,‡	Café-au-lait macules only
NF7*	Late onset
NF-NOS	Not otherwise specified

*Primarily of historical/conceptual interest.
†Now referred to as mosaic (segmental) NF1.
‡Includes Legius (NF1-like) syndrome.

62 Mosaicism and Linear Lesions

*Julie V. Schaffer**

Chapter Contents

Introduction and history 1012
Patterns and pathogenesis of cutaneous mosaicism 1012
Approach to Molecular Testing for Genomic Mosaicism 1015
Functional mosaicism in X-linked germline disorders 1017
Epidermal nevi and related syndromes. 1023
Mosaicism in other autosomal dominant disorders 1027
Vascular malformations 1028
Pigmented lesions with a mosaic distribution pattern 1029
Linear inflammatory disorders 1029
Pigmentary mosaicism 1030
Chimerism 1032

Key features

- Mosaicism for genes expressed in the skin presents as a patchy distribution of affected and unaffected skin
- The classical pattern follows the lines of Blaschko but varies according to cell type and timing of mosaicism
- Epidermal nevi represent mosaicism for a variety of genes with variable associated features
- Some mosaic disorders are recognizable as segmental forms of autosomal dominant skin disorders
- If there is also gonadal mosaicism, offspring may have the corresponding generalized condition

INTRODUCTION AND HISTORY

The term "mosaic" is used to describe individuals composed of cells of different genotypes that are derived from a genetically homogeneous zygote. For example, patients with mosaic Turner syndrome have both 45,XO and 46,XX cells. Based on this traditional definition, all humans are actually mosaics due to high rates of postzygotic mutations both *in utero* and throughout life (e.g. in cutaneous neoplasms)[1a,1b]. Consequently, a recent consensus expert review proposed redefinition of a *mosaic skin abnormality* or *mosaic disorder* to specify that the genetically distinct cell populations: (1) are present *by the time of birth*; and (2) *lead to a disease phenotype*, either in the skin or the entire disorder, respectively[1c]. Of note, a *postzygotic* mutation occurs after the single-cell stage and is thus not inherited from one's parents; this is also referred to as a *somatic* mutation if it does not affect the germ cells/gametes. In contrast, a *germline* (constitutional) mutation affects the whole individual and can either be inherited from a parent or arise *de novo* (see Ch. 54).

The skin provides an ideal canvas to visualize patterns of mosaicism.In 1901, Alfred Blaschko[1] documented the characteristic lines and whorls that are followed by epidermal nevi and other skin conditions now known to result from mosaicism (Fig. 62.1A). In 1961, Mary Lyon postulated that similar striped patterns in female mice heterozygous for coat color genes on the X chromosome reflected two populations of cells, one expressing the maternal X chromosome and one the paternal X chromosome. She hypothesized that all women are *functional* mosaics with regard to the X chromosome. In 1965, Curth and Warburton[2] used the Lyon hypothesis to explain the linear pattern of skin findings in the X-linked disorder incontinentia pigmenti. A decade later, Happle recognized lyonization as the reason that skin lesions follow the lines of Blaschko in heterozygous female patients with other X-linked genodermatoses[3,4].

We now recognize that mosaicism affecting autosomes as well as X chromosomes may result from either: (1) changes in the DNA sequence due to mutations or chromosomal alterations (*genetic* or *genomic* mosaicism); or (2) changes in gene expression (*epigenetic* or *functional* mosaicism) as in lyonization[4] (Table 62.1). Autosomal mosaic conditions usually result from *de novo* postzygotic mutations and are not inherited. However, the clinical manifestations of some autosomal dominant disorders reflect a mosaic "second hit" in affected tissues, such as the skin lesions of neurofibromatosis type 1 (NF1). The unusual familial occurrences of autosomal mosaic disorders may be explained by inheritance of either an unstable "premutation" or a transposon ("jumping gene") of retroviral origin that can modulate the expression of other genes when the disorder has a genetic versus epigenetic etiology, respectively[5].

The idea that the lines of Blaschko represent the embryonic migration pathways of skin cells was first expressed in English by Douglass Montgomery, who proposed that the linear patterns of epidermal nevi "may be due to the streams or trend of growth of the tissues"[6]. Although both Montgomery and Blaschko presented their findings in May 1901, Montgomery's contribution was eclipsed by that of his German contemporary. In fact, the now widely held theory that the lines of Blaschko reflect routes of embryonic cell migration did not surface again until the late 1970s[3,7].

PATTERNS AND PATHOGENESIS OF CUTANEOUS MOSAICISM

Blaschko's original diagram (see Fig. 62.1A) omitted the midface, scalp, lateral neck, and genital area. The trajectories of the lines of Blaschko in these areas have now been established[8] (Fig. 62.1B–E), as have analogous patterns in the eyes, teeth, and oral mucosa. Considerable variability occurs in the degree of whorling on the flanks and the directions of lines on the face; the posterior midline may be shifted to the left or right, but the anterior midline tends to be sharply centered from the upper sternum to the pubis.

Mosaic skin conditions do not always follow the lines of Blaschko (Fig. 62.1F-H). Happle categorized patterns of cutaneous mosaicism into seven types[8a]: (1,2) narrow or broad bands along the lines of Blaschko; (3) checkerboard (block- or flag-like); (4) lateralization, i.e. one side of the body only; (5) phylloid (leaf- or flower-like); (6) patchy without midline separation; and (7) sash. To date, all patterns, except for sash, have been shown to be mosaic at the molecular level in at least one condition. Other patterns have also been described in genetically proven mosaic conditions, such as multiple small, relatively circular congenital melanocytic nevi. Assuming that the pattern is determined by cell migration, it depends on both the *timing* of the genetic alteration (Table 62.2) and the *cell type* affected. These two factors also contribute to other aspects of the mosaic phenotype. A mutation occurring early in embryonic development tends to affect a higher proportion of that individual's cells and a greater number of tissue types. For example, an early mutation in a vascular precursor cell can give rise to Sturge-Weber syndrome involving the skin, eyes and brain, while the same mutation

*This chapter was written by Drs Celia Moss and Fiona Browne for the previous edition of this textbook. It has been updated here by Dr Schaffer, but much of their original chapter has been retained. We remain most grateful to them both for their work on earlier editions.

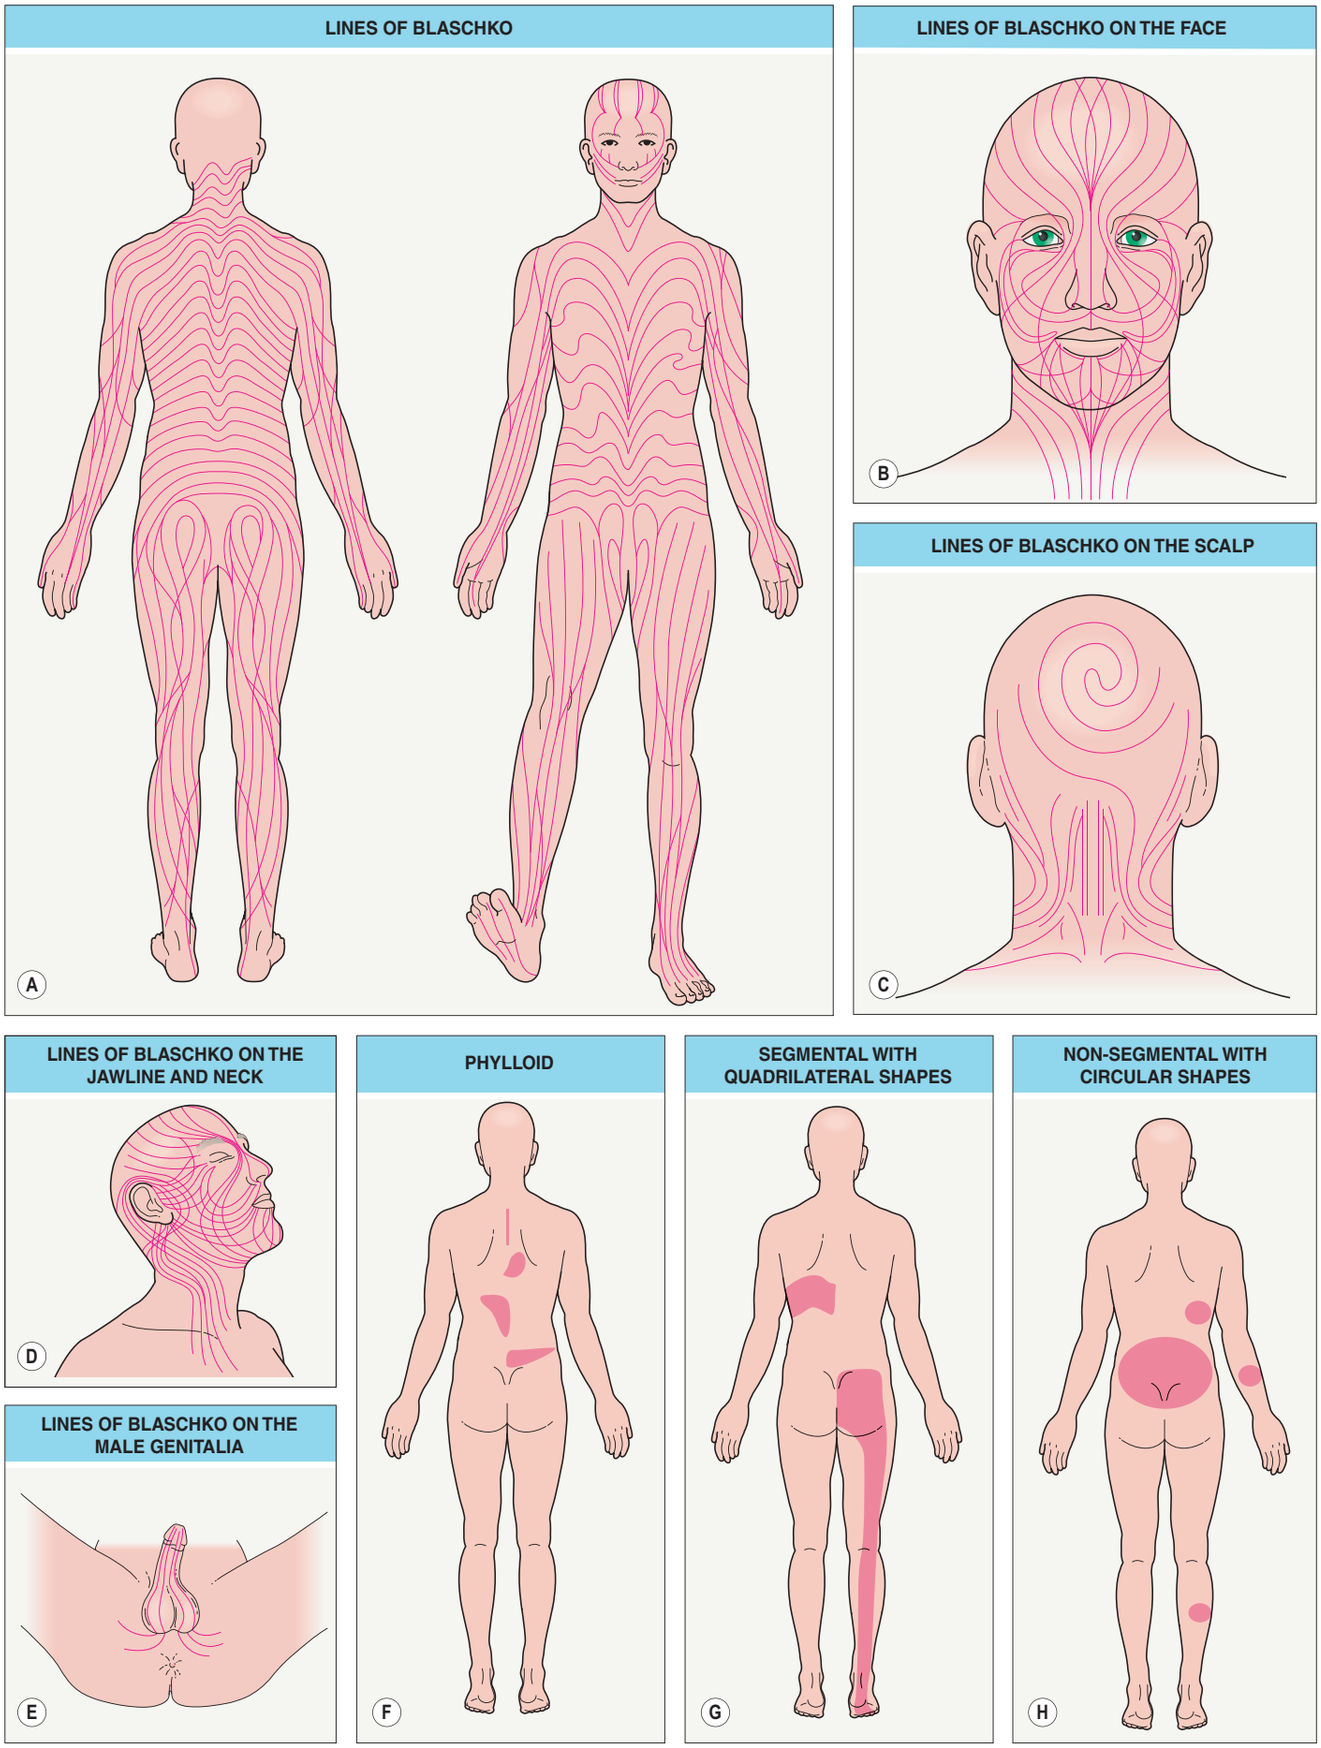

Fig. 62.1 Lines of Blaschko and other mosaic patterns. A These diagrams are taken from Blaschko's original drawings[1]. Note the S-shape of the abdominal lines and the V-shape on the central back. **B** Lines of Blaschko on the face, based on personal observations and ref. 8. **C** Lines of Blaschko on the scalp, based on ref. 8. **D** Lines of Blaschko on the jawline and neck, based on personal observations and ref. 8. **E** Lines of Blaschko on the male genitalia, based on ref. 1. **F** Phylloid pattern, with multiple "leaf-like" or "floral" lesions of different shapes and sizes, without a dominant larger lesion. Often includes linear streaks with midline demarcation. **G** Segmental pattern with quadrilateral shapes. The linear edges are often roughly parallel, with midline demarcation. Involvement may be unilateral or bilateral, ranging from a single relatively small area to an entire "quadrant" such as the arm, shoulder and upper trunk. This pattern encompasses broad bands along the lines of Blaschko and the checkerboard (flag-like) pattern. **H** Non-segmental with circular shapes (encompasses the "patchy pattern without midline separation"). The edges are rounded, and the affected areas may extend around the body, e.g. to form a bathing-trunk pattern. Lesions are of variable sizes and may be single or multiple, with or without a dominant larger lesion that may cross the midline. *F-H, Courtesy Veronica Kinsler, MD, PhD.*

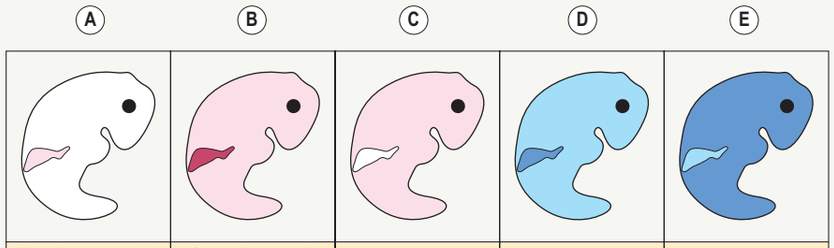
CAUSES OF MOSAICISM AND CHIMERISM			
Cause	**Timing**	**Pathogenesis**	**Consequence**
Genetic (genomic)			
Half-chromatid mutation	First meiotic division of gametogenesis	An incorrect base is added, resulting in a mismatched double strand. When this separates in mitosis, it provides two templates that are not exactly complementary, giving rise to two lines of daughter cells	An individual composed of two different cell lines in approximately equal proportions
Somatic mutation	Postzygotic (i.e. any time after fertilization); not in germ cells/gametes	Any DNA change	A mutant clone within an otherwise normal individual
Chromosomal non-disjunction	Postzygotic	Chromosomes fail to separate correctly during either meiosis or mitosis, resulting in daughter cells with aberrations in chromosome number or structure	An individual composed of two or more different cell lines
Chimerism	Pre- or post-zygotic	Fertilization of one egg by two sperm, or fusion of two zygotes	An individual composed of two cell lines with completely different genotypes
Epigenetic (functional)			
Lyonization	Early embryonic development	Random inactivation in each cell of either the paternal or maternal X chromosome, which then forms the Barr body; once this occurs, it is the same in all daughter cells	A female composed of 2 different cell lines, expressing either the maternal or paternal X chromosome
Epigenetic modification	Inherited or postzygotic	A switch in gene expression, usually involving DNA packaging, resulting from DNA methylation or histone modifications; passed on to daughter cells	Cells with gene expression different from the other cells in that individual

Table 62.1 Causes of mosaicism and chimerism.

EXPECTED PATTERN OF CUTANEOUS MOSAICISM ACCORDING TO ITS TIMING OF ONSET				
Timing	**Configuration/shape of skin lesions**	**Number of skin lesions**	**Laterality**	**Organs affected**
Meiosis	Linear	Multiple	Bilateral	Multi-organ
Very early blastocyst (includes lyonization)	Linear	Multiple	Bilateral	Multi-organ
Later blastocyst	Linear	Fewer	Uni- or bilateral	Multi-organ
Later in first trimester, pre-organogenesis	Linear or oval	Fewer	Uni- or bilateral	Multi-organ
First trimester, post-organogenesis	Linear or oval	Few or single	Uni- or bilateral	Skin only
Second/third trimester	Oval or round	Single	Unilateral	Skin only
Postnatal	Round (smaller)	Single	Unilateral	Skin only

Table 62.2 Expected pattern of cutaneous mosaicism according to its timing of onset.

at a later developmental stage may only lead to a port-wine birthmark. Likewise, the identical mutation in a keratinocyte, melanocyte or pluripotent precursor cell can result in a nevus sebaceus, nevus spilus, or both of these birthmarks, respectively.



The classic pattern defined by Blaschko is seen in disorders of epidermal cells[9], which is not surprising since Blaschko based his diagrams on epidermal nevi. Investigation of patterns in congenital pigmentary disorders led to the proposal that *narrow* bands following Blaschko's lines reflect mosaicism involving keratinocytes, but not melanocytes[9a]. For example, *KITLG* mutations in keratinocytes can result in narrow hyperpigmented bands[9b]. Embryonic keratinocytes move via directional proliferation, in more-or-less continuous lines that are affected by the complex interplay between cell migration and surface remodeling. In contrast, melanoblasts migrate from the neural crest to the skin, where they then proliferate antenatally. This as well as other characteristics of the aberrant cells and the timing of the genetic alteration may explain the *broad* bands along Blaschko's lines as well as checkerboard and phylloid patterns seen in mosaic pigmentary conditions and the patchy or garment-like distribution of larger congenital melanocytic nevi. For *melanocytic* mosaic disorders, two major patterns have been proposed: (1) *segmental* - characterized by quadrilateral shapes with midline demarcation, encompassing broad Blaschko-linear and checkerboard patterns; and (2) *non-segmental* - characterized by circular shapes without midline demarcation[9a] (see Fig. 62.1G and H).

Cutaneous blood vessels, fibroblasts, other mesodermal derivatives, and nerve cells take different routes; mosaic disorders involving these tissues typically display patterns that correspond to embryonic segments or dermatomes rather than the lines of Blaschko. For example, the patterns of facial capillary malformations and their association with ophthalmologic and neurologic involvement are thought to relate to embryonic placodes[9c]. The distribution of skin lesions along the lines of Blaschko in Goltz syndrome (focal *dermal* hypoplasia) and linear morphea are thought to reflect mutated genes that are expressed in the epidermis but lead to changes in the underlying dermis.

The phenotypic consequences of mosaicism also vary according to: (1) whether the trait is dominant or recessive; (2) whether the mutation is "forward" (pathogenic; gain- or loss-of-function) or revertant (correcting; "backward"/"back"); and (3) whether the individual's background germline genome is "normal" or contains an autosomal dominant or autosomal recessive mutation (Fig. 62.2). In individuals with a "normal" germline genome, the postzygotic mutation can result in *simple segmental mosaicism*. Such mutations are further categorized as either lethal or compatible with life if in the germline. When compatible with life, this has been referred to as *type 1 mosaicism*, defined as a postzygotic mutation in one allele of a gene that underlies an autosomal dominant disorder (e.g. epidermolytic ichthyosis) resulting in one or more regions of affected skin (Fig. 62.2A). The latter may have a linear distribution, e.g. an epidermolytic epidermal nevus. On the other hand, if the postzygotic mutation is lethal when in the germline (e.g. Proteus syndrome), there is no correlate of generalized disease.

Sometimes, a more severe segmental lesion is *superimposed* upon the background of a generalized autosomal dominant disease. This phenomenon, which has been referred to as *type 2 mosaicism*, occurs

MOSAICISM FOR AUTOSOMAL TRAITS

	Simple segmental (type 1) forward in AD	Superimposed (type 2) forward in AD	Revertant in AD	Forward in AR	Revertant in AR
Background genotype	Wild type	Heterozygous	Heterozygous	Heterozygous	Homozygous abnormal
Background phenotype	Normal	Abnormal	Abnormal	Normal	Abnormal
"Line" genotype	Heterozygous	Homozygous abnormal	Homozygous normal	Homozygous abnormal	Heterozygous
"Line" phenotype	Abnormal	Very abnormal	Normal	Abnormal	Normal
Mosaic event	Somatic mutation ("gain of heterozygosity")	Loss of heterozygosity	Reversion to normal*	Loss of heterozygosity	Reversion to heterozygous state**
Example	Type 1 linear Darier disease	Type 2 linear Darier disease	Ichthyosis with confetti	Mosaic AR congenital ichthyosis	Revertant recessive dystrophic EB

*Additional mechanisms include mitotic recombination, with crossing over of homologous chromosomes leading to homozygous mutant and homozygous normal daughter cells, and a second site mutation (e.g. that silences a dominant negative allele).

**Additional mechanisms include gene conversion (where the donating chromosome is unchanged) and a second-site mutation (e.g. that restores the reading frame, prevents a termination codon, or aff ects RNA splicing).

Fig. 62.2 Mosaic mutations in autosomal skin disease genes. The phenotype depends partly on whether the background genotype is wild type (**A**), heterozygous for a dominant condition (**B, C**), heterozygous for a recessive condition (**D**), or homozygous/compound heterozygous for a recessive condition (**E**). Mosaicism for "forward" mutations results in an abnormal streak or segment of skin (**A, B, D**), with mosaic loss of heterozygosity in an individual with a generalized dominant condition resulting in a more severely affected area (**B**). In contrast, revertant mosaicism ("back" mutation) creates a spared area (**C, E**). The revertant phenotype depends on the degree of gene reversion (complete or partial), the timing of the "back" mutation (larger or multiple areas if earlier in development versus a smaller spot if postnatally), and a selective advantage of the revertant cells (e.g. lack of blistering in revertant epidermolysis bullosa).

when an individual with a heterozygous germline mutation in the gene for an autosomal dominant disorder develops a "second hit" postzygotic mutation in the other allele that leads to loss of heterozygosity (or rarely a "double [cis]" mutation in the same allele). This results in a region (e.g. a linear streak) where the genetic burden is doubled (Fig. 62.2B). Superimposed (type 2) mosaicism has been proven on a molecular level in Hailey–Hailey disease, Darier disease[10], PTEN hamartoma tumor syndrome[11], NF1, and basal cell nevus syndrome.

Clonal loss of heterozygosity leading to clinical manifestations may also occur in carriers of autosomal recessive skin conditions such as epidermal dysplasia-skin fragility syndrome and autosomal recessive congenital ichthyosis[12,12a] (Fig. 62.2D). The opposite phenomenon – regional absence of skin disease attributed to a correcting mutation (revertant mosaicism) – can occur in both autosomal recessive and autosomal dominant conditions, including ichthyosis with confetti and several forms of epidermolysis bullosa (EB)[13,14] (Fig. 62.2C, E). Revertant mosaicism has therapeutic potential and has been employed to create pluripotent stem cells and autologous grafts for patients with recessive dystrophic EB[15,16].

Mosaic skin conditions can also be categorized based upon the nature of the corresponding generalized condition (Table 62.3). When assessing a linear skin disorder, it is helpful to consider what the most likely diagnosis would be were the condition to affect the entire skin surface. While the lesional morphology and histology of the mosaic condition are typically similar to the generalized form, the connection may not be immediately obvious due to differences in distribution and overall appearance. If no generalized disorder exists to match the linear lesions, then the patient could have a dominant mutation (autosomal or X-linked) that is only survivable in the mosaic form.

Mosaicism for autosomal dominant disorders can arise after fertilization (postzygotic/somatic mutation) or less often during gametogenesis (half-chromatid mutation). Although a simple segmental (type 1) mosaic condition itself is not heritable, there is a risk of passing on the full-blown disorder to the next generation if mutant cells are present not just in the skin but also in the gonads (gonadal mosaicism). Examples include an epidermolytic epidermal nevus (due to *KRT1* or *KRT10* mosaicism) passed on as epidermolytic ichthyosis, a porokeratotic eccrine and ostial dermal duct nevus (*GJB2* [gap junction β2]) passed on as keratitis-ichthyosis-deafness (KID) syndrome, and segmental neurofibromatosis type 1 (*NF1*) passed on as generalized NF1. A correlation between the size or site of the parent's mosaic lesion and the risk to offspring has not been established. If the parental mutation is known, prenatal diagnosis is possible if clinically appropriate, and men can theoretically undergo DNA analysis of sperm to quantify the risk to their offspring[17].

Fig. 62.3 provides an approach to the differential diagnosis of skin lesions that follow the lines of Blaschko. Selected mosaic disorders will be discussed in more detail below.

APPROACH TO MOLECULAR TESTING FOR GENOMIC MOSAICISM

Although mosaic mutations are sometimes present in the peripheral blood (especially when findings are widespread), a sample of *affected tissue* (e.g. skin biopsy specimen) is more likely to contain mutant cells. In addition to the skin biopsy, it is often recommended that a blood sample be sent for comparative analysis. For DNA-based tests (including whole-exome or whole-genome sequencing, multi-gene panels, and arrays), DNA can be extracted directly from the skin biopsy, which is typically used in its entirety if it is not known with certainty which cell type is affected (e.g. keratinocytes vs melanocytes).

Many phenotypically distinct mosaic diseases have been found to have the same genetic basis and therefore have been grouped together as part of a spectrum. For example, depending on the cell type(s) affected, manifestations of the *PIK3CA*-related overgrowth spectrum (PROS) can include vascular malformations, lipomatosis, and epidermal nevi. This enables genotype-driven targeted therapies, such as treatment of PROS with phosphatidylinositol 3-kinase (PI3K) inhibitors, when the genetic etiology has been identified[17a].

MOSAIC SKIN CONDITIONS WITH CORRESPONDING GENERALIZED CONDITIONS AND ASSOCIATED GENES			
Mosaic condition	**Generalized condition**	**Gene symbol [? = likely candidate for mosaic condition]**	**Protein**
X-linked dominant mutations: mosaic patterns in females, usually lethal in males			
Incontinentia pigmenti	(Hypomorphic mutations: hypohidrotic ectodermal dysplasia with immune deficiency)	*IKBKG (NEMO)*	Inhibitor of nuclear factor κB kinase regulatory subunit γ
Goltz syndrome	NR	*PORCN*	Porcupine homolog
Conradi–Hünermann–Happle syndrome	NR	*EBP*	Emopamil binding protein
CHILD syndrome	NR	*NSDHL*	NAD(P)-dependent steroid dehydrogenase like
Linear skin defects with multiple congenital anomalies (LSDMCA) 1 (MIDAS syndrome), 2, and 3	NR	1: *HCCS;* 2: *COX7B;* 3: *NDUFB11*	Holocytochrome c synthase; 2: cytochrome c oxidase, subunit 7B; 3: NADH:ubiquinone oxidoreductase
Oral–facial–digital syndrome type 1	NR	*OFD1*	OFD1 centriole and centriolar satellite protein
Terminal osseous dysplasia with pigmentary defects*	NR	*FLNA*	Filamin A
X-linked recessive mutations: variable mosaic patterns in females, generalized in males			
Linear hypohidrosis, alopecia/lack of adnexa, ± hyperpigmentation	Hypohidrotic ectodermal dysplasia	*EDA*	Ectodysplasin A
Incontinentia pigmenti-like lesions (stages 3 and 4)	Hypohidrotic ectodermal dysplasia with immune deficiency	*IKBKG (NEMO)*	See above
Linear hyperpigmentation	X-linked reticulate pigmentary disorder	*POLA1*	DNA polymerase-α1, catalytic subunit
Linear hyperpigmentation	X-linked dyskeratosis congenita	*DKC1*	Dyskerin
Linear hypopigmentation	Menkes disease	*ATP7A*	ATPase, copper-transporting, α polypeptide
Linear hypotrichosis and scaling	Ichthyosis follicularis with atrichia and photophobia (IFAP), X-linked keratosis follicularis spinulosa decalvans, X-linked Olmsted syndrome	*MBTPS2*	Membrane-bound transcription factor peptidase, site 2
See text for other X-linked etiologies of Blaschko-linear hypo- and hyperpigmentation			
Autosomal dominant mutations (including lethal conditions)			
Various types of epidermal and sebaceous nevi	See Table 62.6		
Linear Darier disease	Darier disease	*ATP2A2*	ATPase, calcium-transporting
Linear Hailey–Hailey disease	Hailey–Hailey disease	*ATP2C1*	ATPase, calcium-transporting
Linear porokeratosis	Porokeratosis	*MVD, PMVK*	Mevalonate diphosphate decarboxylase, phosphomevalonate kinase
Linear basal cell nevus	Basal cell nevus syndrome	*PTCH1*	Patched 1
Happle–Tinschert/Curry–Jones syndrome	NR	*SMO*	Smoothened
Segmental café-au-lait macules, lentigines, and/or neurofibromas	Neurofibromatosis type 1	*NF1*	Neurofibromin 1
Segmental café-au-lait macules and lentigines	Legius syndrome	*SPRED1*	Sprouty-related EVH1 domain-containing 1
Linear/segmental angiofibromas	Tuberous sclerosis complex	*? TSC1, TSC2*	Hamartin, tuberin
Segmental leiomyomas	Multiple cutaneous and uterine leiomyomatosis	*FH*	Fumarate hydratase
Linear trichoepitheliomas, spiradenomas, and/or cylindromas	Multiple familial trichoepitheliomas, Brooke–Spiegler syndrome, familial cylindromatosis	? *CYLD*	Cylindroma lysine 63 deubiquitinase
Venous malformation	Multiple cutaneous and mucosal venous malformations (VMCM), blue rubber bleb nevus syndrome	*TEK(TIE2)*	TIE-2 endothelial tyrosine kinase
Segmental plaque-type glomuvenous malformations	Hereditary glomuvenous malformations	*GLMN*	Glomulin
Verrucous venous malformation ("verrucous hemangioma")	NR	*MAP3K3*	MAPK kinase kinase 3
Parkes Weber syndrome/arteriovenous malformation (AVM)	Capillary malformation (CM)–AVM syndrome	*RASA1, EPHB4*	RAS p21 protein activator 1 EPH receptor B4

Table 62.3 Mosaic skin conditions with corresponding generalized conditions and associated genes.

MOSAIC SKIN CONDITIONS WITH CORRESPONDING GENERALIZED CONDITIONS AND ASSOCIATED GENES			
Mosaic condition	**Generalized condition**	**Gene symbol [? = likely candidate for mosaic condition]**	**Protein**
Sturge–Weber syndrome, port-wine stains, dermal melanocytosis, phakomatosis pigmentovascularis type II, congenital hemangiomas	NR	*GNAQ, GNA11*	Q-type G proteins, α-stimulating
Becker nevus	Baraitser-Winter syndrome, juvenile-onset dystonia**	*ACTB*	β-actin
McCune–Albright syndrome	NR for activating mutations	*GNAS*	G protein, α-stimulating
Nevus spilus, phakomatosis pigmentokeratotica	Costello syndrome**	*HRAS*	HRAS
Nevus spilus, phakomatosis pigmentovascularis type III	Noonan syndrome with multiple lentigines	*PTPN11*	Protein tyrosine phosphatase non-receptor
Classic CMN, nevus spilus-type CMN	Noonan syndrome**	*NRAS*	NRAS
Agminated melanocytic nevi; linear syringocystadenoma papilliferum; arteriovenous malformations (also *MAP2K1, KRAS*, and *HRAS*)	Cardio-facio-cutaneous syndrome**	*BRAF*	BRAF
Encephalocraniocutaneous lipomatosis; arteriovenous malformations (*KRAS*)	Craniosynostosis/skeletal dysplasia syndromes* *(FGFR1);* Noonan and cardio-facio-cutaneous syndromes* (*KRAS*)	*FGFR1, KRAS*	Fibroblast growth factor receptor 1, KRAS
Linear hyperpigmentation with syndromic findings	Smith-Kingsmore syndrome	*MTOR*	Mechanistic target of rapamycin
RHOA-related neuroectodermal syndrome	NA	*RHOA*	Ras homolog family member A
Autosomal recessive mutations			
Linear scaling and erosions	Ectodermal dysplasia with skin fragility	*PKP1*	Plakophilin 1
Linear scaling and erythema	Autosomal recessive congenital ichthyosis	*ABCA12*	ATP binding cassette subfamily A member 12

*Features hyperpigmented, atrophic (with dermal hypoplasia) facial macules and digital fibromas.
**In general, the mutations in this gene that cause generalized disease are different (e.g. less severe) than those that underlie mosaic disorders.

Table 62.3 Mosaic skin conditions with corresponding generalized conditions and associated genes. Epidermal nevi with known genetic bases are presented in Table 62.6. CMN, congenital melanocytic nevus; MIDAS, *mi*crophthalmia, *d*ermal *a*plasia and *s*clerocornea; NR, not reported (presumably lethal).

FUNCTIONAL MOSAICISM IN X-LINKED GERMLINE DISORDERS

In women heterozygous for X-linked disorders, functional mosaicism due to random X-chromosome inactivation (lyonization) may produce skin lesions following the lines of Blaschko. Sons who inherit the abnormal X chromosome carry and express the mutation in all cells; if "recessive", the disorder is generally compatible with survival (e.g. hypohidrotic ectodermal dysplasia), but if "dominant", the disorder is typically so severe that males die before birth (e.g. incontinentia pigmenti, Goltz syndrome). Occasionally, male patients present with skin lesions following the lines of Blaschko because they themselves are mosaic for an X-linked dominant disorder, and therefore, protected by the presence of some normal X chromosomes. X-chromosome mosaicism in boys and men can result from Klinefelter syndrome (where the extra X chromosome permits lyonization) or a postzygotic or half-chromatid mutation (see Tables 62.1 and 62.4).

Lyonization occurs synchronously in all cells at about the 1000-cell stage, so the two clones are intimately mixed from the beginning. Female patients with X-linked genodermatoses typically have numerous skin lesions that follow the lines of Blaschko in narrow bands. A curious exception is CHILD (*c*ongenital *h*emidysplasia with *i*chthyosiform nevus and *l*imb *d*efects) syndrome, which characteristically shows large unilateral blocks of abnormal skin. This lateralization pattern may reflect the effects of expression of the mutant versus normal X-chromosome in organizer cells that control large developmental fields. Alternatively, a deficiency in sonic hedgehog signaling (which normally helps to confer left–right asymmetry) in cells expressing the *NSDHL* mutation may result in selection against these cells on one side of the body.

Not all X-linked skin disorders follow the lines of Blaschko. For example, women who are heterozygous for the gene defects that underlie Fabry disease, Wiskott–Aldrich syndrome, and chronic granulomatous disease have either no lesions or scattered lesions in a non-linear pattern. This is likely because the cells that express the mutated gene are circulating leukocytes or non-epidermal cells (e.g. endothelial cells) for which lyonization does not produce a clinically apparent pattern. In the case of steroid sulfatase-deficient ichthyosis, where the defect is epidermal but not evident in female carriers, the steroid sulfatase gene is on a part of the X chromosome that does not undergo lyonization.

Incontinentia Pigmenti

Synonym: ■ Bloch–Sulzberger syndrome

Key features

- An X-linked dominant disorder with skin lesions that follow the lines of Blaschko
- Four cutaneous stages: (1) inflammatory/vesicular; (2) verrucous; (3) hyperpigmented; and (4) hypopigmented/atrophic
- Other ectodermal abnormalities may be present, e.g. alopecia, nail dystrophy, pegged or missing teeth
- May also have ocular (~20–40%) and neurologic (~30%) involvement
- Caused by mutations in *IKBKG* (*NEMO*)

Introduction

Incontinentia pigmenti (IP) is a multisystem disorder with an estimated birth prevalence of 1:140 000 and a female:male ratio of ~20:1. Patients may present to neonatologists, neurologists, ophthalmologists, or dentists as well as dermatologists. However, the diagnosis typically rests on recognition of the cutaneous findings[17b]. The name refers to the pathologic finding of pigmentary incontinence, i.e. dermal melanophages, in the third stage of the disease. The linear skin lesions reflect *functional* mosaicism secondary to X inactivation (lyonization).

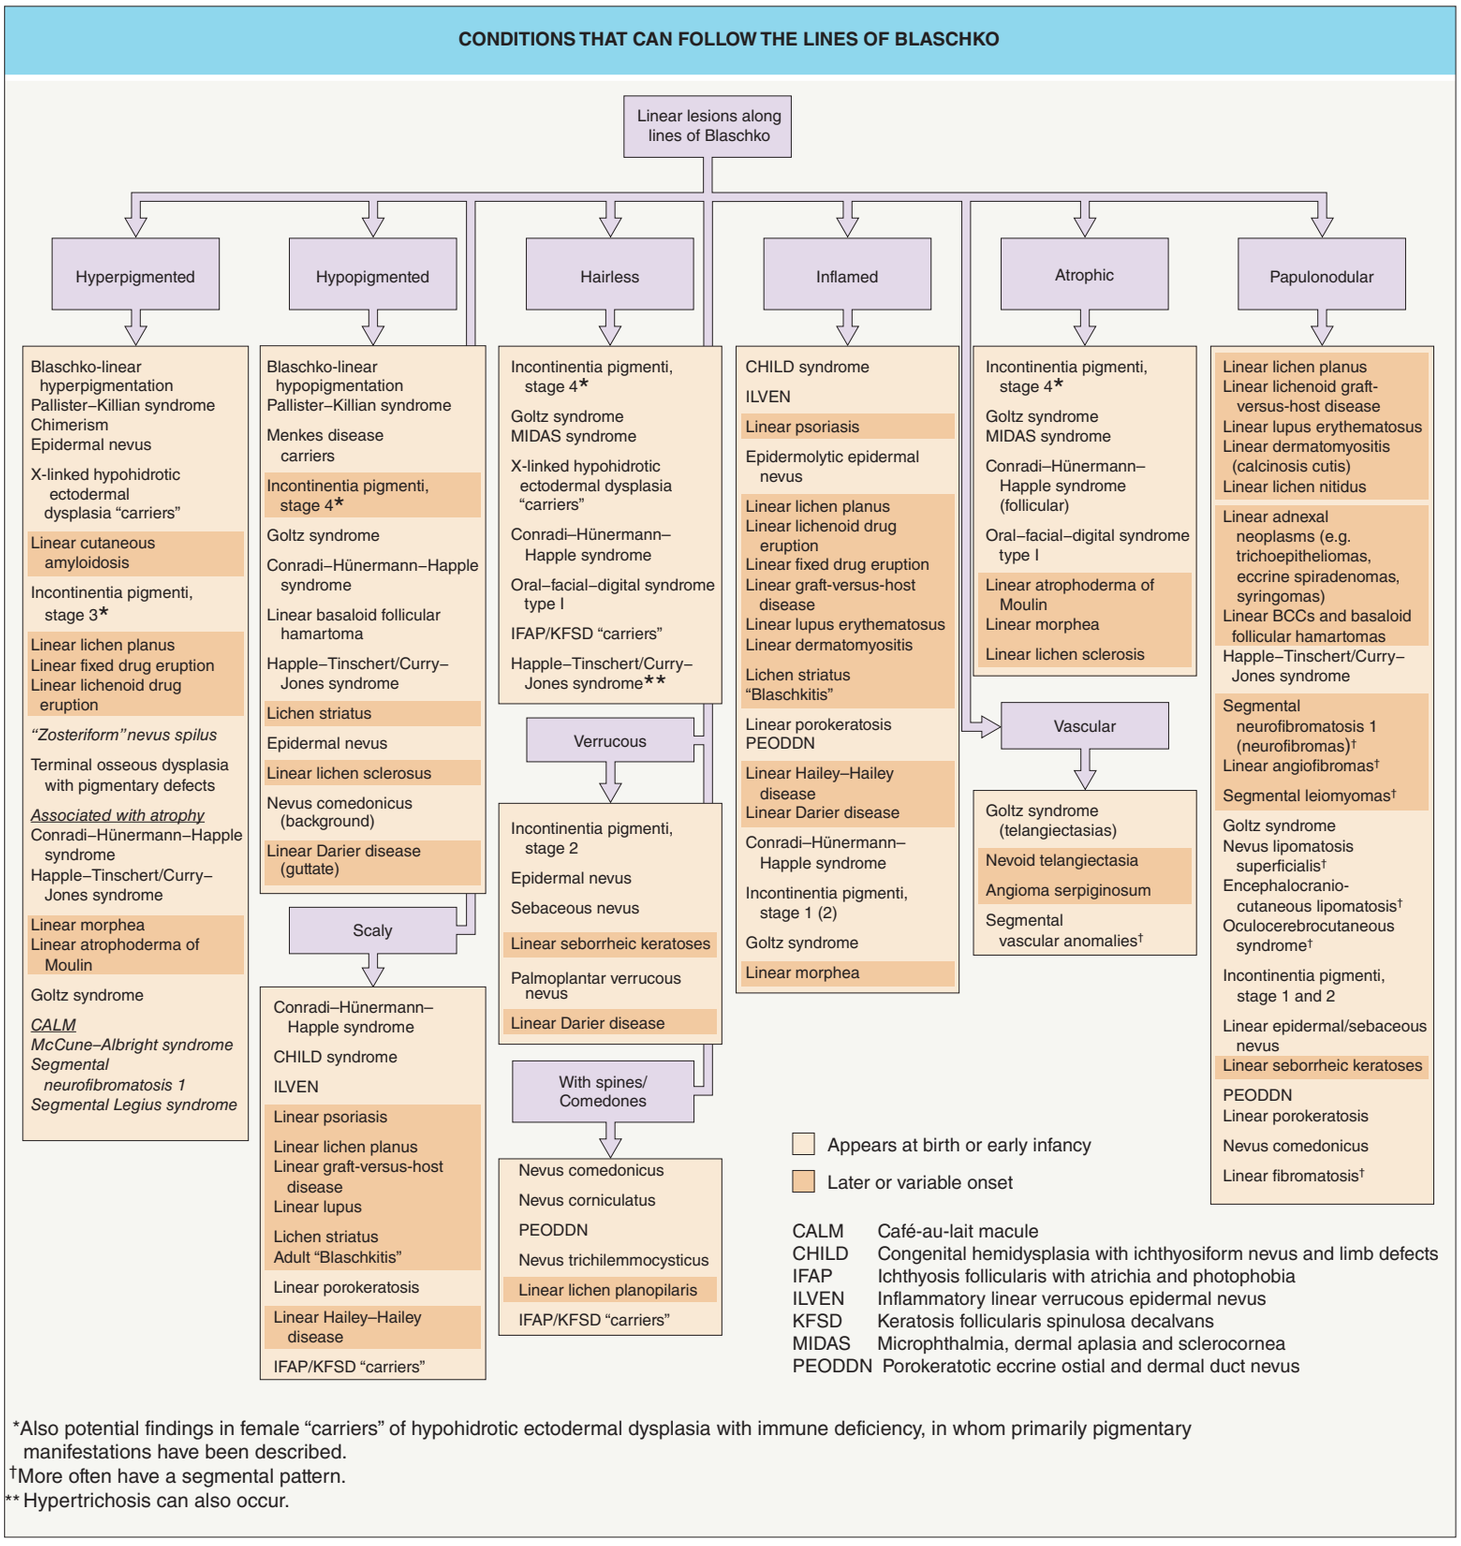


Fig. 62.3 Conditions that can follow the lines of Blaschko. Most of these conditions occur in narrow bands as shown in Fig. 62.2A-E. However, those in italics typically have the segmental pattern with quadrilateral shapes shown in Fig. 62.2G, which includes broad bands along the lines of Blaschko.

History

Although Garrod probably first described IP in 1906, Bloch's 1926 report of a "previously unreported pigment disorder" and that 2 years later by Sulzberger are remembered eponymously. In 2000, the International Incontinentia Pigmenti Consortium established that IP is caused by mutations in *IKBKG*, which encodes inhibitor of nuclear factor κB kinase regulatory subunit γ, also known as *NEMO* (*N*F-κB *e*ssential *mo*dulator).

Genetics

IP is an X-linked dominant disorder, usually antenatally lethal in boys, that is caused by mutations in *IKBKG* located at Xq28[18]. Approximately 80% of patients have a common large deletion of exons 4–10 that tends to arise during paternal meiosis (male gametogenesis). Occasional occurrences of clinically typical IP in boys are attributed to Klinefelter syndrome (~10% of male patients) or to genomic mosaicism due to a half-chromatid or postzygotic *NEMO* mutation (Table 62.4)[19]. In the latter patients, the

FINDINGS IN GIRLS AND BOYS WITH *NEMO* MUTATIONS					
	Girl with IP	**Boy with IP + Klinefelter syndrome**	**Son of mother with classic IP**	**Somatic mosaic boy with IP**	**Boy with HED-ID†**
Karyotype	XX	XXY	XY	XY	XY
***IKBKG* genotype**	Heterozygous for typical mutation*	Heterozygous for typical mutation*	Hemizygous for typical mutation*	Mosaic hemizygous for typical mutation* (half-chromatid or postzygotic)	Hemizygous for milder ("hypomorphic") mutation that does not abolish activity
Skin findings	Classic IP	Classic IP	NA	Classic IP, although may have a more limited distribution (e.g. unilateral or localized)	Hypotrichosis, hypohidrosis, recurrent pyogenic infections, extensive seborrheic- or atopic-like dermatitis, reticulated hyperpigmentation (less common)
Immunodeficiency	No	No	Yes, extremely severe	No	Yes, with dysgammaglobulinemia (↑IgM, ↓IgG)
Life expectancy	Normal	Normal	Usually lethal before birth	Normal	Typically shortened due to pyogenic and opportunistic infections; may improve with hematopoietic stem cell transplantation

*A particular large deletion that removes exons 4–10 is found in ~65% of female patients with IP; a NEMO mutation may be difficult to detect in peripheral blood samples from mosaic male patients (since mutant leukocytes are prone to apoptosis), so analysis of DNA from lesional skin may be required.
†Mother may have a mild variant of IP; affected boys typically have missing/conical teeth. An allelic variant features osteopetrosis and lymphedema, and an autosomal dominant condition with a similar phenotype can result from mutations in NF-κB inhibitor α gene (NFKBIA).

Table 62.4 Findings in girls and boys with *NEMO* mutations. HED-ED, hypohidrotic ectodermal dysplasia with immune deficiency; IP, incontinentia pigmenti; NA, not applicable; *IKBKG*, inhibitor of nuclear factor κB kinase regulatory subunit γ.

distribution of the skin lesions may be relatively limited. A large genetic biobank has been established to facilitate IP research[19a].

Pathogenesis

The NEMO protein is a subunit of a kinase that activates NF-κB, a transcription factor that protects against TNF-α-induced apoptosis (Fig. 62.4). Defective linear ubiquitination has been described in association with a truncated NEMO protein[19b]. The idea of IP as a pro-apoptotic state explains male lethality, destruction of epidermal cells, and progressive replacement of cells expressing the mutant X chromosome by those expressing the normal allele[18]. In one report, a liveborn boy whose mother had classic IP died hours after birth due to lethal hematopoietic and immunologic disturbances[20]. Milder hypomorphic *NEMO* mutations are responsible for hypohidrotic ectodermal dysplasia with immune deficiency (HED-ID) in boys, whose mothers often have relatively subtle features of IP (see Table 62.4 and Ch. 63)[21].

Clinical features

IP typically presents with linear erythema and vesicles (stage 1) during the first few weeks to months of life in an otherwise healthy baby girl (see Fig. 34.13)[22]. Vesiculobullous lesions are most common on the limbs and scalp, frequent on the trunk, and rare on the face (Fig. 62.5A). They resolve within days to weeks and are often replaced by verrucous linear plaques (stage 2) that favor the extremities (Fig. 62.5B) and usually disappear later in infancy. Streaks and swirls of reticulate grayish-brown hyperpigmentation (stage 3) develop next and have a predilection for the trunk and intertriginous sites, with scalloped edges that are thought to reflect the growth of normal keratinocytes into affected skin (Fig. 62.5B, C). Gray-brown dots in a linear array represent a characteristic dermoscopic finding of stage 3 IP. The inflammatory sequence sometimes recurs within pigmented areas during later infancy or childhood together with intercurrent febrile illnesses. In addition, acral keratotic nodules (including subungual lesions) occasionally arise after puberty (Fig. 62.5D). The hyperpigmented streaks tend to fade by adolescence, although a few areas of slate-gray pigmentation may persist lifelong. From puberty onward, linear hypopigmented bands lacking hair and sweat glands (stage 4) appear on the posterior aspects of the limbs (especially the calves; Fig. 62.5E) and may be the only stigmata of the disease during adulthood[23]. Individual stages of IP may be absent or overlap. Extracutaneous manifestations of this condition are listed in Table 62.5.

Pathology

The early inflammatory phase of IP demonstrates eosinophilic spongiosis and scattered dyskeratotic keratinocytes. The epidermis of verrucous lesions is acanthotic with hyperkeratosis and foci of dyskeratosis. In stage 3, there is pigmentary incontinence as well as variable vacuolization of basal keratinocytes, whereas stage 4 is characterized by a thinned epidermis and dermis devoid of adnexa[23].

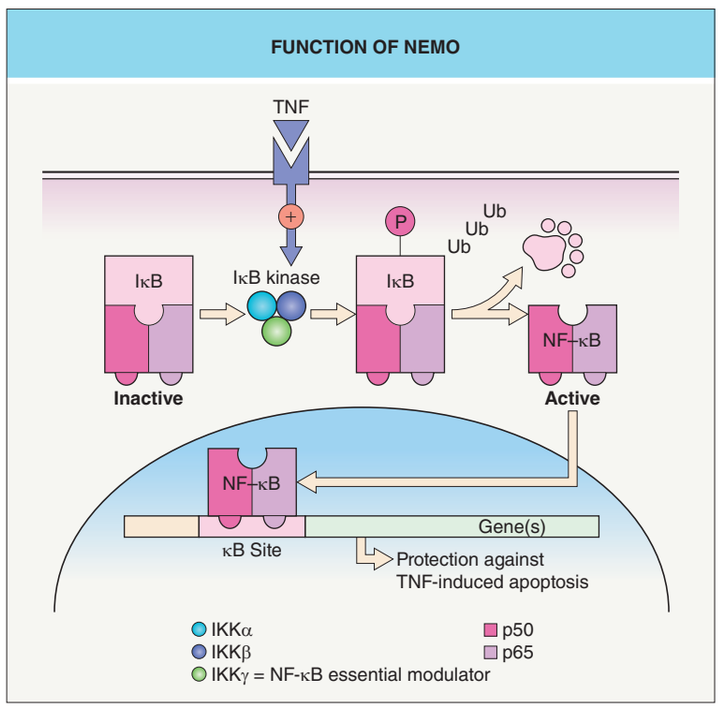

Fig. 62.4 Function of NEMO. In incontinentia pigmenti, lack of NEMO (NF-κB essential modulator; also known as IKBKG [*i*nhibitor of nuclear factor κB kinase regulatory subunit γ]) results in failure to activate NF-κB, which normally protects against tumor necrosis factor (TNF)-induced apoptosis.

Differential diagnosis

Neonatal IP can usually be distinguished from infectious conditions (e.g. herpes zoster, varicella, herpes simplex viral infections) by the wellbeing of the child and characteristic patterning of the skin lesions. Peripheral eosinophilia and leukocytosis are common in neonates with IP, and histologic examination can confirm the diagnosis. In Blaschko-linear hyper- or hypopigmentation due to pigmentary mosaicism, there is no preceding inflammatory phase, the hyperpigmentation is epidermal, and adnexa are typically normal.

Fig. 62.5 Incontinentia pigmenti. A Stage 1 with streaks of erythema and vesicles in a neonate. **B** Stages 2 (verrucous) and 3 (hyperpigmented). Note the keratotic lesions on the toes (**B**). **C** Residual stage 3 involvement in the axilla of a young girl. The scalloped edges of the hyperpigmented streaks are thought to reflect growth of normal keratinocytes into areas of apoptosis. **D** Hyperkeratotic nodules on the leg of a teenage girl. **E** Stage 4 (atrophic and hypopigmented). Note absence of hairs within the streaks on the calf. *A, Courtesy Robert A. Silverman, MD; B, E, Courtesy Celia Moss, MBBS, MA, DM.*

Treatment

Baseline and longitudinal ophthalmologic (especially during infancy) and neurologic evaluations represent the most important aspects of IP management early in life[17b]. Prompt laser therapy can reduce the likelihood of visual sequelae in patients with retinal vasculopathy[23a]. MRI and electroencephalogram are indicated for infants with neurologic symptoms, and European consensus guidelines also recommend a brain MRI at ~2 years of age in children without neurologic manifestations[17b]. Initial dental assessment is recommended at 2-3 years of age, with further intervention by specialists as indicated. The mother should be examined for subtle atrophic streaks, usually most visible on the calves, and genetic testing can assist with family planning. Rare cases of transmission from a mosaic father to a daughter have been reported[23b].

Hypohidrotic Ectodermal Dysplasia With Immune Deficiency

This condition is discussed in detail in Chapter 63.

Goltz Syndrome (Focal Dermal Hypoplasia)

Synonym: ■ Goltz–Gorlin syndrome

Key features

- X-linked dominant condition in which skin lesions follow the lines of Blaschko and consist of dermal atrophy in association with variable fat "herniation", telangiectasias, and pigmentary changes
- "Raspberry-like" papillomas favor the perioral and anogenital regions
- Nail dystrophy, ocular defects, dental anomalies, and limb malformations such as ectrodactyly (split hand/foot) are common
- Caused by mutations in *PORCN*

Introduction

This uncommon genetic disorder was first described by Goltz in 1962 and ectodermal and mesodermal structures – primarily the skin, eyes, teeth, and bones – are affected in a mosaic pattern.

ADDITIONAL MANIFESTATIONS OF INCONTINENTIA PIGMENTI
Surface ectodermal defects
• Missing and conical *teeth* (40–50% of patients) • Linear absence of *hair* (swirled at the vertex in 30–40% of patients) and *sweat glands* • Dystrophic *nails* (ridging, pitting > subungual keratoses; 10–20% of patients) • Asymmetric *breast* development or supernumerary *nipples*
Eye anomalies (20–40% of patients)
• Retinal vascular abnormalities • Strabismus • Cataracts • Microphthalmia • Optic atrophy
Central nervous system abnormalities (30–60% of patients)
• Seizures • Motor and intellectual delay • Microcephaly • Hemorrhagic stroke
Skeletal defects (uncommon)
• Skull anomalies • Scoliosis
Other organs (uncommon)
• Pulmonary hypertension

Table 62.5 Additional manifestations of incontinentia pigmenti.

Genetics

Goltz syndrome is an X-linked dominant condition caused by mutations in *PORCN*, with the mosaic distribution of skin lesions in female patients reflecting lyonization. Although Goltz syndrome is antenatally lethal in boys with non-mosaic hemizygous mutations (as in IP; see Table 62.4), male patients with genomic (e.g. due to a postzygotic mutation) or functional (in the setting of Klinefelter syndrome) mosaicism account for ~10% of affected individuals.

Approximately 95% of all Goltz syndrome cases are sporadic, which likely reflects both a decreased likelihood of reproduction by severely affected women and the lethality of *PORCN* mutations with widespread expression. Some authors have postulated that either preferential inactivation of the mutant X chromosome or a postzygotic mutation is required for survival of affected female fetuses[24]. Rare familial cases often show anticipation, with the offspring being more severely affected than the parent and having a higher proportion of cells expressing the mutant X chromosome. The possibility that an apparently normal mother is a carrier must therefore be considered.

Pathogenesis

PORCN belongs to the evolutionarily conserved porcupine gene family and is expressed in the skin, craniofacial and long bones, tooth buds, and eyes – structures affected in Goltz syndrome. PORCN is an endoplasmic reticulum protein with multiple transmembrane domains. It functions as an O-acyltransferase involved in palmitoylation and secretion of Wnt, a morphogen important in ectomesodermal tissue development[24,25]. Wnt signaling stimulates fibroblast proliferation, inhibits adipogenesis, and induces osteogenesis, explaining the dermal hypoplasia, fat "herniations", and osteopathia striata (streaks of decreased bone density) observed in Goltz syndrome. Wnt also has key roles in early limb patterning and tooth formation.

Although the primary cutaneous abnormality in Goltz syndrome is in the dermis, the distribution of skin lesions along the lines of Blaschko reflects embryonic migration pathways of epidermal cells. Ectoderm-specific deletion of *PORCN* in mice has shown that expression of this gene in the epidermis and resultant Wnt signaling regulate development of the underlying dermis and fat[26]. Of note, patients with Goltz syndrome have a thin epidermis and abnormal adnexal structures. This is not surprising considering that Wnt signaling, including β-catenin-dependent pathways, is known to have critical roles in epidermal regeneration and adnexal morphogenesis/maintenance (see Fig. 55.6).

In 3 of 24 patients in one series, a microdeletion affected both *PORCN* and the adjacent *EBP* gene responsible for Conradi–Hünermann–Happle syndrome (see below). Curiously, however, these patients showed no features of the latter disorder. This implies that the *PORCN*-related hypoplastic skin phenotype predominates over the ichthyosis and follicular changes of Conradi–Hünermann–Happle syndrome[24].

Clinical features

The phenotype of Goltz syndrome is highly variable, depending on the proportion and distribution of cells expressing the mutant X chromosome[25,27]. Streaks of vermiculate dermal atrophy and/or telangiectasias are often present from birth (Fig. 62.6A–C). Later, hypo- and hyperpigmentation as well as "herniations" of fat develop. Although "raspberry-like" papillomas with a verrucous surface and fibrovascular core may appear in any location, they favor the anogenital region as well as the lips (Fig. 62.6D), larynx, and acral sites. Limb malformations affect >80% of patients and include ectrodactyly (split hand/foot malformation), asymmetric syndactyly, oligodactyly, and long bone reduction defects. Radiographs of the midportion of the lower extremities characteristically show osteopathia striata. Eye abnormalities, often unilateral, include iritic and chorioretinal colobomas, microphthalmia, anophthalmia, and cataracts. Dystrophic nails (e.g. longitudinal fissures, hypoplasia), sparse hair, abnormal teeth (e.g. vertical grooving, hypodontia), and dysmorphic facies (e.g. notched nasal alae, pointed chin, large malformed ears) may be observed. Other reported features include aplasia cutis congenita, ventral body wall defects, cleft lip/palate, obstructive sleep apnea, gastrointestinal dysfunction, impaired hearing, intellectual impairment, and anomalies of the CNS, spine, urinary tract, or uterus.

Pathology

Affected skin shows a marked reduction in the thickness of the dermis, with fewer adnexal structures[25]. As a consequence of the decreased dermal thickness, adipose tissue may be found just below the epidermis. An increase in papillary dermal blood vessels may also be seen.

Differential diagnosis

The distinctive cutaneous and extracutaneous findings of Goltz syndrome, especially dermal atrophy/fat "herniations" and osteopathia striata, distinguish it from other X-linked dominant genodermatoses. Examples of such conditions include MIDAS (which does not involve the distal extremities), Conradi–Hünermann–Happle, and oral–facial–digital type 1 syndromes. Although an inflammatory component is occasionally observed, the skin lesions of Goltz syndrome are relatively static compared to the evolving lesions of IP.

Treatment

Treatment is supportive, with appropriate subspecialist referral based on the associated abnormalities. The telangiectasias may be improved by pulsed dye laser treatment. Troublesome exophytic papillomas can be treated with curettage or photodynamic therapy.

Conradi–Hünermann–Happle Syndrome (X-Linked Dominant Chondrodysplasia Punctata)

This rare X-linked dominant disorder presents in female neonates with ichthyosiform erythroderma characterized by feathery, adherent scale distributed along the lines of Blaschko (see Ch. 57). Characteristic extracutaneous findings include asymmetric shortening of the proximal limbs with epiphyseal stippling (chondrodysplasia punctata) and ocular anomalies such as cataracts and microphthalmia[28]. Patients often have swirled cicatricial alopecia and coarse, lusterless hair. After infancy, the skin changes evolve into follicular atrophoderma. Conradi–Hünermann–Happle syndrome is caused by mutations in the *emopamil binding protein* (*EBP*) gene[29], which lies on the X chromosome adjacent to *PORCN* and encodes an isomerase essential for cholesterol biosynthesis. The cardinal biochemical abnormality is increased plasma 8(9)-cholestenol and 8-dehydrocholesterol[28].

CHILD Syndrome (*C*ongenital *H*emidysplasia With *I*chthyosiform Erythroderma [or Nevus] and *L*imb *D*efects)

CHILD syndrome is a rare X-linked dominant disorder that presents with unilateral skeletal hypoplasia ranging from amelia to mild distal

Fig. 62.6 Goltz syndrome (focal dermal hypoplasia). A, B Hypopigmented streaks of vermiculate atrophy. Note the fat herniation (**A**). **C** Streaks of telangiectasias plus erosions on the leg. **D** Several erythematous, raspberry-like papules on the lips. The most prominent lesion is at the angle of the mouth. Similar lesions can occur in the anogenital region and may be confused with warts. *D, Courtesy Celia Moss, MBBS, MA, DM.*

defects, chondrodysplasia punctata, and occasionally defects in internal organs (see Ch. 57). Erythematous, thickened skin with yellowish scaling may have a striking unilateral distribution with sharp midline demarcation, follow the lines of Blaschko, and/or favor skin folds. With time, lipid accumulates and lesions develop features of a verruciform xanthoma. CHILD syndrome results from mutations in *NSDHL* located on Xq28, which encodes a 3β-hydroxysteroid dehydrogenase enzyme involved in cholesterol biosynthesis[30]. Pathogenesis-based topical therapy with lovastatin or simvastatin plus cholesterol is highly beneficial[31].

Linear Skin Defects With Multiple Congenital Anomalies (Including MIDAS Syndrome)

Linear skin defects with multiple congenital anomalies (LSDMCA) represents a group of X-linked dominant conditions that are antenatally lethal in males and characterized by *mi*crophthalmia, *d*ermal *a*plasia, and *s*clerocornea (MIDAS syndrome; see Table 64.4)[32]. Aplastic linear skin lesions with stellate borders are usually confined to the face and neck. Other reported features include agenesis of the corpus callosum, developmental delay, short stature, cardiac anomalies, and genital malformations. LSDMCA can be caused by mutations in several genes that encode mitochondrial enzymes – *HCCS* (holocytochrome c synthase), *COX7B* (cytochrome c oxidase), and *NDUFB11* (NADH:ubiquinone oxidoreductase subunit B11)[33].

Oral–Facial–Digital Syndrome Type I

Oral–facial–digital syndrome type I is an X-linked dominant condition characterized by cleft (or pseudocleft) lip/palate, lobulations and hamartomas of the tongue, hypertrophic oral frenula associated with alveolar clefts, digital malformations, structural brain abnormalities, intellectual disability, polycystic kidneys, facial milia (primarily during infancy), and patchy alopecia that is typically whorled at the vertex. It is caused by mutations in *OFD1*, which encodes a centrosomal protein located at the base of primary (non-motile) cilia[34]. The latter structures are present on most cells and mediate signaling pathways such as Hedgehog and Wnt during embryonic development.

X-linked Etiologies of Blaschko-Linear Hypo- and Hyperpigmentation

Several X-linked disorders can present with hypo- or hyperpigmentation along the lines of Blaschko in affected girls and women. *Börjeson-Forssman-Lehmann syndrome*, due to germline mutations in *PHF6*, presents with Blaschko-linear hyperpigmentation that favors the axillae; additional features include dental and digital anomalies, hypoplastic nails, intellectual disability, and facial features such as prominent supraorbital ridges and frontotemporal hypotrichosis[34a].

TFE3-associated neurodevelopmental disorder is characterized by linear hypopigmentation or (less often) hyperpigmentation as well as lysosomal storage disorder-like findings such as skeletal anomalies, intellectual disability, seizures, and coarse facial features. Although most affected individuals are female, there are reports of male patients with this disorder, some of whom were shown to be mosaic[34b]. The TFE3 transcription factor functions in mTOR signaling and has roles in lysosomal biogenesis and embryonic stem cell differentiation[34b].

Female-restricted X-linked syndromic intellectual development disorder-99 due to germline mutations in *USP9X* (encodes ubiquitin-specific peptidase 9) is associated with pigmentary alteration (hypopigmentation documented) along the lines of Blaschko in the majority of patients[34c]. Other features include structural brain abnormalities, facial dysmorphism, cleft palate, short stature, polydactyly, cardiac defects, breast underdevelopment, and scoliosis[34c].

X-Linked Hypohidrotic Ectodermal Dysplasia (Female Patients)

Female patients ("carriers") with the X-linked form of hypohidrotic ectodermal dysplasia may have mild dental anomalies, patchy alopecia, and variable degrees of reduced sweating, with a lack of adnexa and sometimes hyperpigmentation in a distribution corresponding to the lines of Blaschko (see Ch. 63 and Fig. 55.10).

Menkes Disease (Female Carriers)

Menkes disease, an X-linked recessive disorder caused by dysfunction of a Cu^{2+}-transporting ATPase (α-polypeptide), is discussed in Ch. 69. Female carriers may have patchy pili torti and hypopigmentation along the lines of Blaschko, attributable to functional mosaicism for cells with abnormal copper metabolism.

X-Linked Reticulate Pigmentary Disorder

X-linked reticulate pigmentary disorder is caused by mutations in *POLA1* that encodes the catalytic subunit of DNA polymerase-α, a regulator of the type I interferon response. Female patients have hyperpigmented streaks following the lines of Blaschko, whereas male patients have generalized reticulated hyperpigmentation and systemic manifestations (see Ch. 67). Histologic findings, which are similar in both sexes, include increased epidermal melanin, dermal melanophages, and necrotic keratinocytes; in some adult patients, amyloid deposits are present in the papillary dermis. The latter finding led to an initial description of the condition as "familial cutaneous amyloidosis".

EPIDERMAL NEVI AND RELATED SYNDROMES

Classification and Clinical Features of Epidermal Nevi

Epidermal nevi represent a heterogeneous group of mosaic lesions that are typically distributed along the lines of Blaschko, although those with a later developmental origin may be smaller with a round to oval shape. They may be warty, smooth, or barely palpable; brown, pink, yellow, tan, or hypopigmented (Fig. 62.7); localized or extensive; unilateral or widespread; and isolated or (for more extensive lesions) associated with extracutaneous abnormalities. The appearance is affected by both the age of the patient and the site of the lesion. Epidermal nevi are often whitish or pink in color and macerated at birth. Sometimes they first become evident later in infancy or seem to extend over time, a phenomenon parents find worrisome and difficult to reconcile with the term "birthmark".

Epidermal nevi may be purely *keratinocytic* or demonstrate *organoid* differentiation (see Chs. 109 & 111). Organoid subtypes include nevus sebaceus, Munro acne nevus, nevus comedonicus, woolly (or rarely straight) hair nevus, linear syringocystadenoma papilliferum, and porokeratotic adnexal ostial nevus (Table 62.6 and Fig. 62.8). A nevus sebaceus typically presents as a congenital hairless plaque on the scalp or face, with a characteristic yellowish-pink to orange-brown color and waxy texture (see Fig. 62.8A). These lesions tend to thicken after puberty and can become verrucous. In a patient with widespread epidermal nevi, it is not uncommon for lesions to be keratinocytic on the trunk and extremities but have sebaceous differentiation when they involve the head and neck region. In general, epidermal nevi on the scalp tend to have overlying alopecia or hair with an abnormal (e.g. woolly) texture (see Fig. 62.8B).

Keratinocytic epidermal nevi can be divided clinically into inflammatory (e.g. inflammatory linear verrucous epidermal nevi [ILVEN]) (see below and Ch. 109) and noninflammatory categories. The latter may be further classified histologically into non-epidermolytic and epidermolytic variants (Fig. 62.9), although this is not an absolute distinction and even organoid nevi occasionally display epidermolysis. Keratinocytic epidermal nevi are often thicker and more pronounced within skin folds (see Fig. 62.7B), where they can have an appearance similar to acanthosis nigricans; softening and decreased hyperkeratosis may also be observed in intertriginous sites.

Two rare epidermal nevus variants are RAVEN (*r*ounded *a*nd *v*elvety *e*pidermal *n*evus) and PENS (*p*apular *e*pidermal *n*evus with "*s*kyline" basal cell layer). RAVEN, also referred to as nevoid acanthosis nigricans, is characterized by lesions with a distinctive rounded outline arranged in a linear pattern[34d]. Patients with PENS present with congenital skin-colored or pinkish hyperkeratotic papules or small plaques that are typically circular/ovoid or polygonal in shape, with only one report to date of a lesion following the lines of Blaschko[34e,34f]. Although usually sporadic, familial cases have been reported as have associated neurodevelopmental abnormalities[34e,34f]. Characteristic histopathologic findings include basal cells with palisaded nuclei in a pattern reminiscent of a city skyline[34e].

Genetics of Epidermal Nevi

The genetic bases of multiple types of epidermal nevi have been established[35–49] (see Table 62.6). Several variants as well as their syndromic associations (see below) are caused by activating postzygotic mutations in genes that encode proteins in two major signaling pathways: (1) RAS/MAPK (mitogen-activated protein kinase), resulting in mosaic RASopathies (see Fig. 55.4); and (2) FGFR (fibroblast growth factor receptor)/PIK3CA (phosphatidylinositol-3-kinase catalytic subunit α)/AKT1, which is negatively regulated by PTEN (phosphatase and tensin homolog) (see Fig. 55.3). For example, mosaic *HRAS* or *KRAS* mutations account for ~40% of noninflammatory, non-epidermolytic keratinocytic epidermal nevi, with *FGFR2/3* or *PIK3CA* mutations in another ~50% of these lesions[35,36] (Fig. 62.10). Nevus sebaceus is also

Fig. 62.7 Non-epidermolytic verrucous epidermal nevi. A S-shaped hyperpigmented papillomatous streaks on the abdomen with sharp midline demarcation. **B** Hyperpigmented keratotic streaks accentuated in skin folds. **C** Tan lesions in a V-shaped pattern on the mid-back. **D** Velvety papillomatous streaks along the midline abdomen. **E** Extensive hypopigmented streaks with variable adherent scale, which is accentuated in the popliteal fossae, in a patient with darkly pigmented skin. *D, Courtesy Lorenzo Cerroni, MD.*

EPIDERMAL NEVI: ASSOCIATED GENES AND POTENTIAL SYNDROMIC ASSOCIATIONS				
Type of epidermal nevus (EN)	**Gene**	**Protein**	**Generalized conditions caused by germline mutations***	**Potential syndromic associations with the EN**
Verrucous (keratinocytic) epidermal nevi				
	Mosaic keratinopathies			None
Epidermolytic keratinocytic EN	*KRT1, KRT10, KRT2*	Keratin 1, 10, and 2	Epidermolytic ichthyosis, PPK (*KRT1*)	None
Palmoplantar non-epidermolytic EN	*KRT16*	Keratin 16	Pachyonychia congenita, focal PPK	None
	Mosaic RASopathies (also woolly hair and sebaceous nevi; see below)			Ocular, skeletal, neurologic
Non-epidermolytic keratinocytic EN (NEKEN)	*NRAS* (<5% of NEKEN)	NRAS	Noonan syndrome (see Table 61.3)	Cutaneous skeletal hypophosphatemic syndrome (*NRAS* or *HRAS* Q61R, *HRAS* G13R); phakomatosis pigmentokeratotica with nevus spilus (*HRAS* Q61R or G13R in both nevus types) or with agminated melanocytic nevi + focal cortical dysplasia (*BRAF*)
	HRAS (~30% of NEKEN)	HRAS	Costello syndrome (see Table 97.7)	
	KRAS (~5% of NEKEN)	KRAS	Cardio-facio-cutaneous (CFC) andNoonan syndromes	
	BRAF (K601Q; <1% of KEN)	BRAF	CFC syndrome	
	Mosaic "FiGRopathies" (also sebaceous and acneiform nevi; see below)			Craniofacial, acral skeletal, neurologic
	FGFR2 (5-10% of NEKEN)	Fibroblast growth factor receptor 2	See below	"Twisted" hair, syndactyly, overgrowth of hands/feet, macrocephaly, nevus simplex complex
	FGFR3[**,§] (~30% of NEKEN)	Fibroblast growth factor receptor 3	Thanatophoric dysplasia**, Crouzon syndrome with acanthosis nigricans, SADDAN	Garcia–Hafner–Happle syndrome: asymmetric craniofacial malformations, intellectual disability
	Mosaic "AKTopathies"			Overgrowth; vascular and adipose anomalies
	PIK3CA[§] (~10% of NEKEN)	Phosphatidylinositol 3-kinase catalytic subunit α	?Cowden syndrome variant (type 5)	CLOVE(S) syndrome: *c*ongenital *l*ipomatous *o*vergrowth, *v*ascular anomalies, *EN*, and *s*coliosis/other *s*keletal abnormalities (especially broad hands and feet); see Table 104.5
	AKT1	AKT serine/threonine kinase 1	Not reported	Proteus syndrome (see text)
	PTEN	Phosphatase and tensin homolog	PTEN hamartoma tumor syndrome (PHTS), including Cowden syndrome	"Proteus-like" features: *s*egmental *o*vergrowth, *l*ipomatosis, *a*rteriovenous *m*alformations, *EN* (SOLAMEN; due to postzygotic "second hit"); macrocephaly and other features of PHTS (see Ch. 63)
Other epidermal nevi				
Woolly hair nevus	*HRAS* (G12S)	HRAS	Costello syndrome	
	BRAF (K601Q)	BRAF	CFC syndrome	See NEKEN above
Nevus sebaceus (NS)	*HRAS* (G13R in ~90% of NS)	HRAS	Costello syndrome	Schimmelpenning syndrome (CNS, ocular, skeletal); cutaneous skeletal hypophosphatemic syndrome
	KRAS	KRAS	CFC and Noonan syndromes	
Nevus sebaceus, papillomatous pedunculated	*FGFR2* (C382R)	Fibroblast growth factor receptor 2	Craniosynostosis syndromes: Beare–Stevenson cutis gyrata, Apert***	Cleft palate
Munro acne nevus	*FGFR2* (S252W, P252R)			Acral skeletal anomalies (e.g. syndactyly, broad thumb), developmental delay
Nevus comedonicus	*NEK9*	NIMA-related kinase 9	Skeletal dysplasia (with biallelic mutations)	Digital anomalies, scoliosis
Porokeratotic adnexal ostial nevus (PAON)[¶]	*GJB2*	Connexin 26	Keratitis–ichthyosis–deafness (KID) syndrome	
Inflammatory linear verrucous epidermal nevus (ILVEN)	*GJA1*, *?NSHDL*	Connexin 43	Erythrokeratodermia variabilis, ? CHILD syndrome (mosaic skin findings)	Ipsilateral distal limb reductions (*NSHDL*)
	CARD14	CARD14	Psoriasis, CARD14-associated papulosquamous eruption	
	ABCA12	ABCA12	Autosomal recessive congenital ichthyosis (biallelic)	

*Can potentially occur in the offspring of an epidermal nevus patient who has gonadal as well as cutaneous mosaicism.
**Usually caused by the R248C activating FGFR3 mutation; thanatophoric dysplasia presents with widespread acanthosis nigricans, short-limbed dwarfism, craniofacial malformations, CNS defects, and perinatal lethality
§Somatic activating mutations are also found in seborrheic keratoses, dermatosis papulosa nigra, stucco keratoses, and solar lentigines.
***Manifestations of Apert syndrome, which is usually caused by S252W and P253R FGFR2 mutations, include craniosynostosis, digital anomalies (syndactyly, broad thumbs), severe acne, diffuse pigmentary dilution, and developmental delay.
¶Includes porokeratotic eccrine ostial and dermal duct nevus (PEODDN); spiny hyperkeratotic EN without histologic features of PAON have also been reported.

Table 62.6 Epidermal nevi: associated genes and potential syndromic associations. Mosaic RAS mutations found in epidermal nevi are often (but not always) different from those in generalized conditions, suggesting that the former represent more severe, lethal mutations rescued by mosaicism. Other mosaic genetic changes reported within epidermal nevi include *PTCH* deletion (in a nevus sebaceus), a chromosomal breakpoint at 1q23, and trisomy 6[36,37]. *ABCA12*, ATP-binding cassette subfamily A member 12; *CARD14*, caspase recruitment domain family member 14; CHILD, *c*ongenital *h*emidysplasia with *i*chthyosiform erythroderma/nevus and *l*imb *d*efects; CNS, central nervous system; FGF, fibroblast growth factor; *GJA1/B2*, gap junction α1/β2; PPK, palmoplantar keratoderma; SADDAN, *s*evere *a*chondroplasia with *d*evelopmental *d*elay and *a*canthosis *n*igricans.

Fig. 62.8 Epidermal nevi with organoid differentiation. A A small nevus sebaceus with an oval shape. **B, C** Woolly hair and epidermal nevi due to a mosaic *HRAS* mutation in a young girl. Focal areas of curly hair with a woolly texture are evident amid a background of straight hair **(B)**. A thin tan epidermal nevus with subtle elevation more evident with side lighting. **D** Comedones and cribriform scarring along the lines of Blaschko, with an inflammatory nodule in the superior portion of the lesion. *A, Courtesy Veronica Kinsler, MD, PhD.*

Fig. 62.9 Epidermolytic verrucous epidermal nevus. A Hyperpigmented streaks with central shedding of scale and associated pink color. **B** Histology shows verrucous epidermal hyperplasia with prominent compact hyperkeratosis associated with granular and vacuolar degeneration of keratinocytes in the spinous and granular layers (epidermolytic hyperkeratosis). *B, Courtesy, Luis Requena, MD.*

Fig. 62.10 Epidermal nevus due to *FGFR3* mutation and seborrheic keratoses following the lines of Blaschko. A This lesion represents a mosaic counterpart of the acanthosis nigricans in patients with thanatophoric dysplasia, perhaps reflected in its flexural prominence. **B** Unilateral seborrheic keratoses in bands following the lines of Blaschko. Seborrheic keratoses often have a somatic activating mutation in *FGFR3* or *PIK3CA*. *A, Courtesy Celia Moss, MBBS, MA, DM; B, Courtesy, Luis Requena, MD.*

primarily caused by mosaic mutations in *HRAS* and to a lesser degree *KRAS*[47]. *FGFR2* mutations have been found to underlie a less common papillomatous/cerebriform nevus sebaceus variant and the Munro acne nevus as well as a subset of keratinocytic epidermal nevi that includes RAVEN, which can also result from *FGFR3* mutations[43]. Mutations in either *HRAS* or *BRAF*, whose protein product is also in the RAS/MAPK pathway, have been identified in woolly hair nevi[49](see Fig. 62.8B), and *BRAF* mutations can result in linear syringocystadenoma papilliferum.

Epidermal Nevus Syndromes

Introduction

"Epidermal nevus syndromes" (ENSs) represent a group of heterogeneous disorders in which keratinocytic and organoid epidermal nevi are associated with ocular, neurologic, and/or musculoskeletal abnormalities[50–53]. *Schimmelpenning syndrome* can be caused by somatic mutations in *HRAS* or *KRAS*[52], and the genetic etiologies of other ENSs are presented in Table 62.6. Overgrowth syndromes resulting from activation of the PIK3CA/AKT1 pathway include Proteus syndrome, PTEN hamartoma tumor syndrome (PHTS), and the *PIK3CA*-related overgrowth spectrum (PROS). These disorders, which are discussed below and summarized in Table 104.5 can have cutaneous manifestations including lipomatosis and vascular malformations as well as epidermal nevi. Additional skin findings that have been described in association with epidermal nevi include hypo- or hyperpigmentation (e.g. café-au-lait macules [CALMs]) in a mosaic distribution, melanocytic nevi (e.g. in phakomatosis pigmentokeratotica; see below), and aplasia cutis congenita.

History and terminology

Reports of epidermal nevi occurring in conjunction with abnormalities in other organ systems date back over a century. Various authors are credited with descriptions of these associations, including Jadassohn, Schimmelpenning, Feuerstein, and Mims. Solomon and Esterly reviewed epidermal nevi and related extracutaneous findings in 1973[50], and Solomon is often credited with the term "epidermal nevus syndrome". Happle later extended ENSs to encompass multiple additional mosaic entities such as Proteus and CHILD syndromes[51], while others limited the term to the Schimmelpenning phenotype classically associated with sebaceous nevi[53].

Phakomatosis Pigmentokeratotica, Schimmelpenning Syndrome, and Cutaneous Skeletal Hypophosphatemia Syndrome

Phakomatosis pigmentokeratotica (*phakomatosis spilosebacea*) is defined as the association of a nevus spilus (see below and Ch. 112) with a nevus sebaceus, while *Schimmelpenning syndrome* is the term classically used for the association of extracutaneous findings with a nevus sebaceus. These clinical diagnoses exist on a spectrum, as they result from mosaic *HRAS* or, for a small subset of Schimmelpenning syndrome, mosaic *KRAS* mutations[34,57]. Additional cutaneous features may include keratinocytic epidermal nevi and CALMs, with the latter potentially representing a nevus spilus prior to the appearance of superimposed nevi. The distributions of the various skin findings can be overlapping or distinct.

Extracutaneous manifestations of these mosaic RASopathies most often involve the CNS (e.g. hemimegalencephaly, seizures, hemiparesis, intellectual impairment)[53], eye (e.g. [lipo]dermoids, colobomata, choristomas), and skeleton (e.g. hemihypertrophy, scoliosis). Epidermal nevi involving the head are thought to be more likely to have associated cerebral defects than those in other sites, although this has not been systematically evaluated. Neurologic abnormalities are also more likely when sebaceous nevi on the scalp are linear rather than round, presumably reflecting their earlier origin and the consequent wider tissue dissemination (see Table 62.2). Epidermal nevi due to *RAS* mutations have also been associated with extracutaneous malignancies, in particular rhabdomyosarcoma and urothelial carcinoma, which occur at increased frequency in patients with Costello syndrome due to germline *HRAS* mutations (see Table 97.7).

The *cutaneous skeletal hypophosphatemia syndrome* may occur in patients with an extensive keratinocytic and/or sebaceous nevus caused by particular *HRAS* and *NRAS* mutations[48]. Affected individuals develop vitamin D-resistant rickets due to overproduction of fibroblast growth factor 23 (FGF-23), which is normally secreted by osteocytes to regulate vitamin D and phosphate homeostasis. There are reports of successful treatment with the FGF23 inhibitor burosumab or the MEK inhibitor trametinib, with the latter also leading to improvement of the patient's nevus sebaceus[48a,48b].

PIK3CA-Related Overgrowth Spectrum (PROS)

PROS encompasses a variety of mosaic conditions with dermatologic manifestations, including: CLOVE(S) syndrome (*c*ongenital *l*ipomatous *o*vergrowth, *v*ascular malformations, *e*pidermal nevi, *s*coliosis/skeletal/spinal anomalies); megalencephaly-capillary malformation; CLAPO syndrome (*c*apillary and *l*ymphatic malformations of the tongue/neck with *a*symmetry and *p*artial *o*vergrowth); Klippel-Trenaunay syndrome; fibroadipose hyperplasia/overgrowth; and hemihyperplasia multiple lipomatosis[53a,53b]. Depending on the tissue(s) involved, characteristic findings in addition to epidermal nevi (which are present in a subset of patients) include asymmetric overgrowth, lipomatosis, and vascular malformations (see Table 104.5).

Proposed diagnostic criteria require documentation of a mosaic *PIK3CA* mutation, which can be done via genetic analysis (e.g. an overgrowth syndrome panel) of DNA extracted from a biopsy of affected skin[53a]. Although there is some clinical overlap with Proteus syndrome (see below), PROS is distinguished by congenital, less progressive overgrowth, and the cerebriform connective tissue nevi that characterize Proteus syndrome are typically absent[53a,53b].

Management of PROS depends on the types and distribution of the clinical manifestations. Patients with PROS have an increased risk of venous thromboembolism, with potential contributing factors including venous malformations, impaired mobility, decreased anticoagulant proteins, and effects of the underlying mutation on the vascular endothelium[53c]. There is debate regarding whether routine screening for Wilms tumor via serial abdominal ultrasounds until age 8 years is indicated, as only a few Wilms tumors have been reported in PROS patients[53b].

Targeted therapy with the PI3K inhibitor alpelisib is FDA-approved for patients ≥2 years of age with severe manifestations of PROS. In a retrospective study (n = 32 patients), administration of alpelisib for 24 weeks improved vascular malformations and overgrowth in ~75% of PROS patients. A 6-month course of low-dose oral sirolimus was also found to result in a small reduction in the bulk of affected tissues in PROS patients, but adverse effects (e.g. infections, cytopenias) were common.

Proteus Syndrome

Proteus syndrome is a rare mosaic disorder characterized by overgrowth of a variety of tissues due to activating mutations in *AKT1*. The 1999 diagnostic criteria were revised in 2019 to include the genotype as well as clinical manifestations[54]. A hallmark of Proteus syndrome is progressive and disproportionate postnatal overgrowth, which is distinct from the relatively stable congenital overgrowth seen in PROS. Manifestations of overgrowth in Proteus syndrome include asymmetric macrodactyly or limb gigantism, typically with abnormal bones and soft tissue in the affected areas, as well as scoliosis related to megaspondylodysplasia. Another characteristic feature is cerebriform palmar or plantar connective tissue nevi, which tend to expand and thicken during childhood and adolescence[55,56]. EN in patients with Proteus syndrome are often "soft" but have variable clinical morphologies[56]. Other cutaneous manifestations include slow-flow vascular malformations, papulonodular connective tissue nevi on the face and digits, patchy dermal hypoplasia, hyper- and hypopigmented macules/patches, asymmetric hypertrichosis, and abnormal fat deposition resulting in lipomas and/or lipoatrophy[56,56a].

Management of Proteus syndrome includes genetic analysis (e.g. an overgrowth syndrome panel) of DNA from affected tissue and radiologic evaluation to assess and monitor bony and soft tissue disease. Similar to PROS, patients with Proteus syndrome have an elevated risk of venous thromboembolism, which represents the leading cause of death in this condition and requires individualized surveillance and management[56b]. Targeted therapy with the AKT inhibitor miransertib has shown promising results in early clinical studies[56c].

Superimposed (Type 2) Mosaic PTEN Hamartoma Tumor Syndrome

The growth-promoting PIK3CA/AKT pathway that is activated in the affected tissues of Proteus syndrome patients is negatively regulated by PTEN (see Fig. 55.3). In the autosomal dominant PTEN hamartoma tumor syndrome (PHTS, including Cowden syndrome; see Ch. 63), patients have a heterozygous germline *PTEN* mutation, and the hamartomas/tumors result from a "second hit" causing loss of heterozygosity. The same mechanism, occurring earlier during embryogenesis, can lead to a "Proteus-like" phenotype distinguished from true Proteus syndrome by macrocephaly, thicker and more verrucous epidermal nevi, vascular anomalies with a fast-flow component, and a lack of cerebriform palmoplantar connective tissue nevi. This superimposed (type 2) mosaic PHTS/Cowden syndrome is also referred to as *SOLAMEN syndrome* – *s*egmental *o*vergrowth, *l*ipomatosis, *a*rteriovenous *m*alformation, and *e*pidermal *n*evus (Fig. 62.11)[11,55].

PTEN negatively regulates mechanistic target of rapamycin (mTOR) signaling downstream of AKT1. The mTOR inhibitor sirolimus has been anecdotally reported to slow overgrowth in superimposed mosaic PHTS[56], and further investigation of this agent in PHTS is in progress.

ILVEN (Inflammatory Linear Verrucous Epidermal Nevus)

ILVEN represents a spectrum of inflammatory mosaic disorders that manifest as linear, erythematous, scaly plaques that follow the lines of Blaschko and are characteristically pruritic[57] (Fig. 62.12; see Ch. 109). While occasionally present at birth, ILVEN usually appears during childhood (or, less often, adult life) and extends over months to years. It responds temporarily, if at all, to topical anti-inflammatory agents and rarely remits spontaneously.

Reported genetic etiologies of ILVEN include heterozygous postzygotic mutations in *GJA1* (encoding connexin 43; mosaic erythrokeratodermia variabilis et progressiva) and *CARD14* as well as germline plus postzygotic mutations in *ABCA12* (mosaic autosomal recessive congenital ichthyosis)[57,57a,57b]. The differential diagnosis of ILVEN includes linear psoriasis (see Fig. 62.15), which may be difficult to distinguish but tends to be less recalcitrant to therapy, and secondary inflammation within an epidermal nevus (e.g. with an underlying postzygotic *HRAS* or *KRT10* mutation). Linear porokeratosis (e.g. due to germline plus superimposed somatic *PMVK* mutations) can mimic ILVEN clinically and histologically, with potential misinterpretation of the cornoid lamella as alternating ortho- and parakeratosis[57]. In addition, some patients presenting with an ILVEN phenotype actually have a forme fruste of CHILD syndrome due to a germline *NHDSL* mutation. An alternative acronym for this variant is PEN/PENCIL (*p*soriasiform *e*pidermal *n*evus ± *c*ongenital *i*psilateral *l*imb defects)[58]. Knowing the genetic basis of these lesions can direct targeted therapies such as topical statin/cholesterol (*PMVK* or *NSDHL*) and ustekinumab (*CARD14*).

MOSAICISM IN OTHER AUTOSOMAL DOMINANT DISORDERS

Mosaicism for other autosomal dominant disorders may present with a linear or segmental distribution of cutaneous findings that are usually generalized.

Linear Darier Disease (Acantholytic Dyskeratotic Epidermal Nevus)

Linear and segmental presentations of Darier disease are usually morphologically identical to the generalized form (Fig. 62.13). Heterozygous mutations in *ATP2A2* have been found in lesional but not normal-appearing skin, documenting simple segmental (type 1) mosaic Darier disease on a molecular level[59]. Less commonly, linear streaks with an earlier onset and

Fig. 62.12 Inflammatory linear verrucous epidermal nevus. Scaly psoriasiform plaques distributed in a linear array.

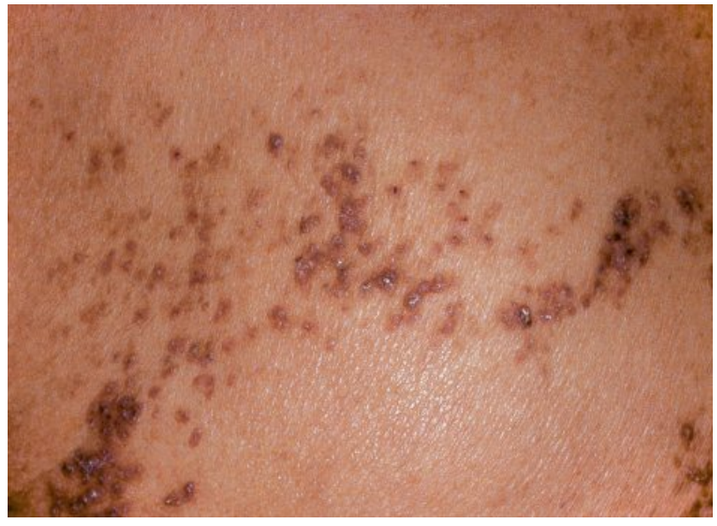

Fig. 62.13 Linear Darier disease with hyperpigmented, keratotic papules. Sometimes lesions of guttate leukoderma are also seen within the streak.

increased severity due to a "second hit" in *ATP2A2* are found in patients with generalized Darier disease, reflecting superimposed (type 2) mosaicism.

Linear Hailey–Hailey Disease (Relapsing Linear Acantholytic Dermatosis)

Linear Hailey–Hailey disease is characterized by relapsing erosions and crusting within a segmental area; histologically, acantholysis resembling a "dilapidated brick wall" is observed (see Ch. 59). Heterozygous postzygotic *ATP2C1* mutations reflecting type 1 mosaicism have been identified in such patients. Inactivation of the second *ATP2C1* allele (loss of heterozygosity) has also been found in linear regions with earlier and more severe involvement in patients with generalized Hailey–Hailey disease, confirming superimposed (type 2) mosaicism[60].

Linear Porokeratosis

Linear porokeratosis is composed of multiple plaques with keratotic borders that represent cornoid lamellae. These plaques are usually congenital and persistent, with a higher risk of developing squamous cell carcinoma than other porokeratosis variants[61]. Linear porokeratosis sometimes coexists with familial forms of porokeratosis such as disseminated superficial actinic porokeratosis (DSAP), which result from germline heterozygous mutations in genes encoding various enzymes in the mevalonate biosynthesis pathway such as *MVD* (mevalonate diphosphate decarboxylase; see Fig. 109.8). Mosaic "second hit" mutations in *MVD* and *PMVK* (phosphomevalonate kinase) have been found to underlie linear porokeratosis[61a]. Pathogenesis-directed topical treatment of linear porokeratosis with cholesterol 2%/lovastatin 2% cream or ointment has been reported[61b].

Porokeratotic Adnexal Ostial Nevus (PAON)

PAON, which includes the porokeratotic eccrine ostial and dermal duct nevus (PEODDN), features keratotic spines and/or punctate pits with keratotic plugs (see Fig. 111.40). Histologically, parakeratotic columns arise from the eccrine ducts and/or hair follicles. PAON is caused by postzygotic mutations in *GJB2*, which encodes connexin 26, and therefore represents the mosaic form of the autosomal dominant keratitis–ichthyosis–deafness (KID) syndrome[62] (see Ch. 57). Erosions during the neonatal period, development of SCC, and psoriasiform lesions have been described in association with PAON, but extracutaneous features of KID syndrome have not yet been reported.

Linear Basal Cell Nevus Syndrome

Superimposed mosaic manifestations of basal cell nevus syndrome can include congenital basaloid skin tumors and palmoplantar pits in a linear pattern. This has been confirmed on a molecular level, with identification of a germline *PTCH1* mutation in addition to a "second hit" mutation in affected skin[63]. A heterozygous mosaic *PTCH1* mutation has also been identified within multiple superficial BCCs in a Blaschko-linear distribution pattern[63a].

Curry-Jones and Happle-Tinschert Syndromes

Curry-Jones and Happle–Tinschert syndromes, which were described in 1995 and 2008, respectively, represent mosaic disorders with genotypic and phenotypic overlap[64,65]. Both conditions are caused by postzygotic activating mutations in the gene encoding Smoothened (SMO), which is inhibited by Patched in the Hedgehog signaling pathway (see Fig. 107.6)[66]. Patients present with a linear or segmental distribution of basaloid follicular hamartomas that are variably accompanied by hyperpigmentation, hypopigmentation, atrophoderma, hypertrichosis, and hypotrichosis. Extracutaneous manifestations can include dental, digital, cranial, cerebral, and gastrointestinal anomalies[64–66].

Mosaic Neurofibromatosis Type 1 and Legius Syndrome

Patients with café-au-lait macules (CALMs) and/or neurofibromas limited to a segmental distribution may have a type 1 mosaic form of NF1 or (for CALMs) Legius syndrome due to a postzygotic mutation in the gene encoding neurofibromin or SPRED1 (*sp*routy-related *E*VH1 *d*omain-*1*), respectively[67,68] (see Ch. 61). The distribution of the CALMs, which are often accompanied by lentigines, may be block-like or rarely in a broad Blaschko-linear distribution, sometimes with subtle relative hyperpigmentation of the background skin. In contrast, neurofibromas usually occur in a segmental pattern. Like other simple segmental (type 1) mosaic conditions with nonlethal underlying mutations, offspring may have full-blown NF1[69]. In addition, plexiform neurofibromas and CALMs represent manifestations of superimposed (type 2) mosaicism (i.e. due to a postzygotic "second hit") in patients with NF1 and (for CALMs) Legius syndrome.

Linear or Segmental Angiofibromas and Mosaicism in Tuberous Sclerosis Complex

Mosaicism accounts for ~5–10% of patients diagnosed with tuberous sclerosis complex (TSC) based on clinical criteria, many of whom have relatively mild clinical manifestations but not an obvious segmental distribution of skin lesions[70]. However, mosaic TSC can also present with an asymmetric distribution of facial angiofibromas[70a]. Of note, "second hit" mutations have been identified within angiofibromas, fibrous cephalic plaques, and shagreen patches in patients with TSC[70b].

Linear or Segmental Benign Tumors

Trichoepitheliomas, spiradenomas, and/or cylindromas occasionally occur in a linear distribution. These may represent mosaic forms of autosomal dominant *CYLD* cutaneous syndrome caused by heterozygous germline *CYLD* mutations, and heterozygous *postzygotic CYLD* mutations have been identified in clustered cylindromas[71]. A somatic *BRAF* V600E mutation has been associated with linear syringocystadenoma papilliferum.

Leiomyomas can occur in a segmental pattern as a manifestation of autosomal dominant hereditary leiomyomatosis and renal cell cancer due to fumarate hydratase mutations, most often representing superimposed (type 2) mosaicism (i.e. with a germline mutation plus "second hit" in the affected segment).

An autosomal dominant tendency to develop seborrheic keratoses is recognized, although no gene has yet been implicated. An adult onset of seborrheic keratoses distributed along the lines of Blaschko has also been described (see Fig. 62.10B); in one patient, activating *FGFR3* and/or *PIK3CA* mutations were variably present within the lesions, some of which showed keratinocytic atypia histologically, but were not found in the background skin[72].

Encephalocraniocutaneous Lipomatosis (Haberland Syndrome)

Encephalocraniocutaneous lipomatosis (ECCL) is a rare mosaic condition caused by postzygotic activating mutations in *FGFR1* or *KRAS*[73,74]. Patients present with cerebral malformations, ipsilateral eye abnormalities (usually choristomas), and papulonodular skin lesions including lipomas, fibromas, fibrolipomas, and angiolipomas. These lesions favor the eyelids and scalp, and alopecia overlying scalp lipomas, referred to as *nevus psiloliparus*, is occasionally associated with aplasia cutis congenita. The cranial and eye lesions are usually unilateral, but lipomas may be found on both sides of the scalp. Of note, *germline* activating *FGFR1* mutations lead to autosomal dominant craniosynostosis and skeletal dysplasia syndromes. *Oculocerebrocutaneous (Delleman–Oorthuys) syndrome* has similar clinical features and is thought to exist on a spectrum with ECCL[74].

VASCULAR MALFORMATIONS

Mosaic mutations have been identified as the cause of multiple types of sporadic and familial vascular malformations (see Ch. 104). In addition to the entities discussed below, mosaic mutations underlying lymphatic (*PIK3CA*) and arteriovenous (*MAP2K1, BRAF, KRAS, HRAS*) malformations have also been identified (see Table 104.2).

Venous and Glomuvenous Malformations

Heterozygous somatic activating mutations in *TEK*, which encodes the TIE-2 endothelial cell tyrosine kinase receptor, or *PIK3CA* are frequently

Fig. 62.14 Dermal melanocytosis (A) and port wine birthmarks (B) in phakomatosis pigmentovascularis type II. Note the block-like segmental distributions. *Courtesy Veronica Kinsler, MD, PhD.*

found in sporadic *venous malformations*. A subset of these lesions therefore represents a simple segmental (type 1) mosaic form of the autosomal dominant multiple cutaneous and mucosal venous malformation syndrome caused by *germline TEK* mutations[75]. *Verrucous venous malformations* ("verrucous hemangiomas") result from heterozygous somatic mutations in *MAP3K3* (MAPK kinase kinase 3)[76]. Large segmental plaque-type *glomuvenous malformations*, which are typically congenital, can occur as a superimposed (type 2) mosaic manifestation of hereditary glomuvenous malformations due to heterozygous germline *GLMN* (glomulin) mutations.

Capillary Malformations (Port-Wine Birthmarks)

Somatic activating mutations in *GNAQ* are found within affected tissues in most patients with *Sturge–Weber syndrome* and non-syndromic *port-wine birthmarks*[77]. This gene encodes a Q-class G protein α-subunit, activation of which increases MAPK signaling. Somatic mutations in *GNAQ* and the related *GNA11* are also found in blue nevi and nevus of Ota. It is therefore not surprising that patients with *phakomatosis pigmentovascularis type II* have the same activating *GNAQ* or *GNA11* mutation in both their port-wine stain and dermal melanocytosis[78] (Fig. 62.14). Of note, somatic activating mutations in *GNAQ*, *GNA11*, *GNA14*, and *RAS* have been identified in congenital hemangiomas (noninvoluting and rapidly involuting variants), pyogenic granulomas (*RAS*), and other vascular tumors. *GNAQ*, *GNA11*, and *GNA14* mutations have only been reported in mosaic form and are likely otherwise lethal. *RASA1* and *EPHB4* mutations are responsible for the autosomal dominant capillary malformation–arteriovenous malformation syndrome, in which lesions have been shown to demonstrate loss of heterozygosity[79].

PIGMENTED LESIONS WITH A MOSAIC DISTRIBUTION PATTERN

Congenital Melanocytic Nevi (CMN)

CMN have more recently been viewed as forms of mosaicism and are discussed in Chapter 112. In addition to *classic CMN*, which are categorized based upon their size, the *nevus spilus-type CMN* is characterized by multiple small to medium-sized CMN superimposed on a CALM-like background. A single, small classic CMN is the most common presentation. Rarely, numerous widespread classic CMN are seen. Such patients, who sometimes also have a large or giant CMN in a "cape"- or "bathing trunk"-like distribution pattern, are at risk of neurocutaneous melanocytosis and other involvement beyond the skin. Additional manifestations of this "CMN syndrome" may include non-melanotic CNS findings (e.g. Dandy-Walker malformation, arachnoid cysts), endocrine abnormalities, and characteristic facial features.

Classic CMN of all sizes are most often caused by postzygotic *NRAS* mutations (~70%; e.g. Q61K, Q61R), with *BRAF* mutations accounting for 5-10%[80,81]. Nevus spilus-type CMN most often result from *NRAS* mutations (e.g. Q61H, Q61L) that differ from those typically observed in classic CMN[82]. The same *NRAS* mutations are found in skin and CNS lesions in patients with neurocutaneous melanocytosis[80]. *SCALP syndrome* refers to the rare association of *s*ebaceous nevi, *C*NS malformations, *a*plasia cutis congenita, and *l*imbal dermoid with CMN (*p*igmented nevi) on the scalp; underlying mosaic *NRAS* and germline biallelic *DOCK6* mutations have been reported in one affected individual to date.

Nevus Spilus

Nevus spilus (speckled lentiginous nevus) is defined as CALM-like hyperpigmentation with superimposed smaller pigmented lesions that may represent lentigines or a variety of types of melanocytic nevi. The macular background hyperpigmentation is often subtle and may not be evident at birth. Subtypes of this mosaic condition include: (1) nevus spilus-type CMN due to *NRAS* mutations (see above)[82]; (2) nevus spilus due to *HRAS* mutations (primarily "papular" type), which may have superimposed Spitz nevi and can occur together with nevus sebaceus in phakomatosis pigmentokeratotica (see above)[46,83]; and (3) nevus spilus due to *PTPN11* mutations (primarily "macular" type), which can occur together with a light red-pink capillary malformation ("nevus roseus") in phakomatosis pigmentovascularis type III[83a] (spilorosea; see Table 104.4). A variant of phakomatosis pigmentokeratotica due to an activating *BRAF* mutation in both an epidermal nevus and agminated melanocytic nevi (without background hyperpigmentation) has also been reported.

Extracutaneous findings described in *PTPN11*-associated nevus spilus and PPV spilorosea include neurodevelopmental impairment, macrocephaly, scoliosis, skeletal muscle weakness, overgrowth/hemihypertrophy, and ocular pigmentation[84]. Considering that *germline PTPN11* mutations are responsible for Noonan syndrome with multiple lentigines (formerly LEOPARD syndrome), individuals with *PTPN11*-associated mosaic skin conditions may be at risk of having offspring affected by Noonan syndrome. Of note, cutaneous melanoma has been reported to arise within all subtypes of nevus spilus.

McCune–Albright Syndrome

McCune–Albright syndrome features large blocks of café-au-lait pigmentation, demarcated at the midline and sometimes following the lines of Blaschko in broad bands, together with polyostotic fibrous dysplasia of the bone and/or endocrine hyperfunction (classically precocious puberty). It is due to particular postzygotic activating mutations in *GNAS*, the gene encoding the α-subunit of the G protein that stimulates adenylate cyclase activity. This results in increased signaling in pathways where cyclic AMP acts as a "second messenger", explaining endocrine overactivities and increased pigmentation due to stimulation of tyrosinase. Associated bone involvement can be asymptomatic or present with manifestations such as pain, a limp, pathologic fractures, facial asymmetry, and FGF23-related phosphate wasting. Evaluation may include X-rays of the long bones, bone scintigraphy, and laboratory assessment of phosphate homeostasis[83b].

LINEAR INFLAMMATORY DISORDERS

Several inflammatory skin conditions are occasionally distributed along the lines of Blaschko. When generalized, these disorders are multifactorial, typically with both a genetic susceptibility and environmental contributions. Linear presentations likely result from mosaicism for a "susceptibility" mutation. In some cases, a streak of more severe disease is superimposed on a generalized background of the same condition, perhaps reflecting clonal loss of heterozygosity[85]. Such conditions provide an opportunity to identify the genes involved in multifactorial cutaneous diseases.

Fig. 62.15 Linear psoriasis. Erythema and scale are seen within the streak as well as in small scattered lesions. *Courtesy Lorenzo Cerroni, MD.*

Linear Psoriasis

Linear psoriasis is rare (Fig. 62.15)[86] and can be difficult to distinguish from ILVEN (see above). Psoriasis following the lines of Blaschko may also be confused with the Koebner phenomenon where linearity is imposed by exogenous injury. However, both can occur in the presence of generalized psoriasis, as can psoriasis superimposed on an epidermal nevus. Linear psoriasis may be "unmasked" when the generalized component clears with treatment[87].

Linear Lichen Planus

Linear lichen planus (LP) is more common than linear lupus and can occur at any age[88]. It presents as typical LP lesions distributed along the lines of Blaschko, and postinflammatory hyperpigmentation is often the most prominent feature. Histology may be required to distinguish this disorder from other causes of linear pigmentation (see Fig. 62.3). If the LP lesions extend to the end of a digit, the nail is often affected.

Lichen Striatus

This self-limited linear inflammatory condition usually occurs during childhood, most commonly on an extremity in an atopic individual (see Ch. 11)[89]. The condition is not particularly pruritic, but it has histologic features similar to those of both eczema and lichen planus. Although both lichen striatus and linear lichen planus can be associated with nail dystrophy, postinflammatory hypopigmentation points to the diagnosis of lichen striatus.

"Blaschkitis"

"Blaschkitis" refers to a rare inflammatory dermatosis that typically presents as pruritic papules and vesicles along multiple lines of Blaschko, particularly on the trunk. More common in adults than children, it follows a relapsing course, with episodes often resolving spontaneously within days. Although the histology is more eczematous and less lichenoid than in lichen striatus, they may represent variants of the same condition[90].

Other Linear Inflammatory Disorders

Several other inflammatory disorders occasionally occur in a distribution along the lines of Blaschko. These conditions include atopic dermatitis, lupus erythematosus (with morphea-like/"sclerodermiform" features in one variant)[91,92], dermatomyositis, lichenoid and fixed drug eruptions[93,94], lichenoid GVHD[95], morphea[96], and atrophoderma of Pasini and Pierini (linear atrophoderma of Moulin[97]; Fig. 62.16).

PIGMENTARY MOSAICISM

Both hypo- and hyperpigmentation can occur in a linear or segmental pattern as a reflection of mosaicism. Traditionally, such presentations have been split into the disorders described below, but there is considerable overlap between these heterogeneous conditions, and distinctions can become blurred.

Fig. 62.16 Linear atrophoderma of Moulin. Hyperpigmented depressions with "cliff-drop" borders following the lines of Blaschko. The morphology of the lesions resembles that of atrophoderma of Pasini and Pierini.

Linear and Block-Like Hypo- and Hyperpigmentation

Synonyms/variants: ■ Linear nevoid hypo- and hyperpigmentation ■ Blaschkoid dyspigmentation ■ Pigmentary mosaicism ■ Hypomelanosis of Ito (becoming historical) ■ Linear and whorled nevoid hypermelanosis ■ Segmental pigmentation disorder ■ Incontinentia pigmenti achromians (historical)

Key features

- Descriptive terms rather than specific diagnoses, with a variety of genetic etiologies
- Hypo- or hyperpigmentation following the lines of Blaschko or in a block-like pattern can be evident at birth or appear later
- Variable extracutaneous involvement, which can include CNS, musculoskeletal, and ocular abnormalities

Introduction

Hypo- or hyperpigmentation following the lines of Blaschko reflects *epidermal* mosaicism and has a wide variety of genetic etiologies[98]. Block-like hypo- or hyperpigmentation, which has been referred to as "*segmental pigmentation* disorder"[99], is also presumed to result from mosaicism. Associated extracutaneous findings are found in a minority of affected individuals with either distribution pattern[99–101].

History

The first published description of hypopigmentation along Blaschko's lines was by Ito in 1951, resulting in the eponym "hypomelanosis of Ito." This term is becoming historical and should be reserved for patients with extracutaneous manifestations due to the presence of the mosaic abnormality in tissues other than the skin[98,100,101].

Epidemiology

Linear and block-like pigmentary alterations affect both sexes and are typically easier to see in darkly pigmented skin. The areas of patterned hypo- or hyperpigmentation may be apparent at birth or become evident during childhood, especially in those with lightly pigmented skin.

Genetics and pathogenesis

Blaschko-linear hypo- or hyperpigmentation can have a variety of genetic etiologies, which range from mosaic chromosomal alterations (up to 50% of cases; e.g. trisomy 18 or 20) or point mutations (e.g. *MTOR*) to *germline* X-linked conditions (e.g. Börjeson-Forssman-Lehmann syndrome; see above) and rarely chimerism (see below)[102,103]. The pattern of narrow bands along Blaschko's lines is thought to reflect mosaicism at the level of keratinocytes, with the pigmentary changes resulting from interactions between altered keratinocytes and neighboring melanocytes[9a,102]. This is supported by the identification of

postzygotic mutations in genes such as *TP63* and *KITLG*, which are primarily expressed by keratinocytes, in patients with Blaschko-linear hyperpigmentation[9b].

Clinical features

Streaks and swirls of hypo- or hyperpigmentation along the lines of Blaschko can occur anywhere on the cutaneous surface, with unilateral or bilateral involvement. Superimposed lentigines, hypertrichosis, and alopecia are occasionally observed. Only a small proportion (<15–30%) of children with Blaschko-linear hypo- or hyperpigmentation who present to a pediatric dermatologist at a tertiary referral center have extracutaneous abnormalities, which generally became apparent during infancy[100,101]. The extracutaneous abnormalities are highly variable, depending on the genetic etiology and tissues affected; they most often involve the CNS, eyes, and musculoskeletal system. In a recent series, neurodevelopmental abnormalities were significantly more common in children with Blaschko-linear hypopigmentation affecting ≥4 vs <3 of 5 body areas[101a].

Block-like hypo- or hyperpigmentation favors the trunk, but any site can be affected. Midline demarcation is more often present ventrally than dorsally, and the lateral borders tend to be less distinct. Segmental hyperpigmentation occasionally coexists with a light red-pink capillary malformation ("phakomatosis melanorosea"). Associated extracutaneous findings are uncommon, affecting <2–5% of patients[99].

Some patients have linear streaks of both hypo- and hyperpigmentation or a combination of linear and block-like hypopigmentation. When involvement is extensive, it may be difficult to determine whether the lighter or darker skin represents the background color.

Associated syndromes

The most common known single-gene cause of Blaschko-linear *hypopigmentation* is mosaic activating *MTOR* mutations. In a recent French series of 71 patients with "hypomelanosis of Ito", 15 (21%) had an underlying mosaic *MTOR* mutation[103a]. Additional findings in affected individuals can include macrocephaly, (hemi)megalencephaly, intellectual disability, seizures, facial dysmorphism, ocular anomalies, and asymmetric overgrowth[103b]. *RHOA-related neuroectodermal syndrome* results from mosaic mutations that lead to inactivation of a RAS-related Rho GTPase. Clinical features include Blaschko-linear *hypopigmentation* (Fig. 62.17), scarring alopecia, leukoencephalopathy (usually asymptomatic), facial dysmorphism, and hemihypoplasia as well as digital, dental, and ocular anomalies[103c]. X-linked syndromes that present with Blaschko-linear hypo- or hyperpigmentation are discussed above.

Pallister-Killian syndrome due to mosaic tetrasomy 12p, which usually results from gonadal mosaicism in a parent, is a distinct disorder that presents with *hypopigmentation* following the lines of Blaschko or in an irregular pattern. Frontotemporal alopecia and hypohidrosis represent additional cutaneous manifestations. Extracutaneous features include facial dysmorphism, intellectual disability, and broad first digits in addition to cardiac, renal, genitourinary, and gastrointestinal abnormalities[104].

Phylloid hypomelanosis in a pattern of leaf-like and floral shapes represents a distinct entity due to mosaic copy number variation involving chromosome 13[105]. Additional features may include telangiectatic macules, thick eyebrows, long eyelashes, intellectual disability, agenesis of the corpus callosum, conductive hearing loss, colobomas, and digital anomalies. A few patients with phylloid hypermelanosis have also been reported, with variable extracutaneous manifestations and underlying mosaic chromosomal aberrations (e.g. involving 5p)[105].

Pathology

Hypopigmented skin may appear normal or have a reduced number of melanocytes, while hyperpigmented skin shows increased epidermal pigmentation.

Differential diagnosis

Fig. 62.3 shows the differential diagnosis of hypo- and hyperpigmented lesions following the lines of Blaschko. Diagnostic considerations for block-like hyperpigmentation may include McCune–Albright syndrome, which tends to have darker, sharply demarcated lesions that follow the broad lines of Blaschko, as well as a large CALM, Becker nevus, and early nevus spilus. Block-like hypopigmentation is usually distinguishable from the amelanotic lesions of segmental vitiligo.

Fig. 62.17 Blaschko-linear hypopigmentation on the foot and leg of a child with a mosaic *RHOA* mutation. *Courtesy Veronica Kinsler, MD, PhD.*

Evaluation and management

A thorough history and physical examination should be performed to assess for extracutaneous involvement, with further evaluation directed by abnormal findings and/or recognition of distinct syndromes (see above). Growth and development should be followed in conjunction with the child's pediatrician.

In patients with extracutaneous abnormalities, identification of the underlying genetic alteration may provide better understanding of the overall diagnosis, help direct further evaluation, and potentially impact future family planning. For example, mosaic *MTOR* mutations involving the gonads have been implicated in transmission of Smith-Kingsmore syndrome, which presents with megalencephaly, seizures, and intellectual disability due to heterozygous germline *MTOR* mutations. In addition, recognizing the genetic etiology can provide the basis for targeted therapies such as sirolimus or other mTOR inhibitors.

Although mosaic mutations are sometimes present in the peripheral blood, a sample of affected tissue (e.g. a skin biopsy specimen) is more likely to contain mutant cells. If no specific single-gene disorder is suspected, genetic testing should start with an assessment for chromosomal mosaicism, which can be performed via microarray-based tests, e.g. single nucleotide polymorphism (SNP) array or array comparative genomic hybridization (CGH). If initial evaluation of DNA from a blood sample is not diagnostic, the test can be repeated on DNA extracted from a 4 mm punch skin biopsy of affected skin. The latter is generally of higher yield than the fibroblast cultures routinely performed by cytogenetics laboratories, as the mutation may not be present in that cell type. Keratinocyte cultures may be of utility when available[102], and whole exome or whole genome sequencing represents an additional testing option.

Nevus Depigmentosus

A nevus depigmentosus is another hypopigmented skin lesion that is thought to reflect cutaneous mosaicism. However, it is limited in extent and generally lacks extracutaneous associations. The most common presentation is a localized patch that breaks apart into smaller macules

at its periphery, resembling a splash of paint. Although classically evident at birth, a nevus depigmentosus sometimes becomes apparent later in childhood, especially in lightly pigmented individuals.

CHIMERISM

Block-Like Hyper- and Hypopigmentation Due to Chimerism

Chimerism differs from mosaicism in that the different clones originate from different organisms. Human chimeras can result from fusion of two zygotes (i.e. fused dizygotic twins) or fertilization of one egg by two sperm. Usually detected by hematologists as anomalous blood groups, or by endocrinologists as ambiguous sexual differentiation, chimerism is exceedingly rare. Findlay and Moores[106] studied more than a million routine blood samples and found evidence of chimerism in only two. Pigmentary variation in chimerism typically presents in a checkerboard pattern; however, streaks along the lines of Blaschko and mixtures of light and dark skin that do not correspond to recognized patterns of mosaicism have also been described[107]. In cases of XX/XY chimerism, the karyotype of dermal fibroblasts does not necessarily correspond to the overlying skin color, probably reflecting the different embryonic migration routes in the dermis and epidermis[9].

Introduction

In this chapter, a number of genodermatoses are discussed that are not covered in other chapters of this textbook (Table 63.1).

Disorders characterized by cutaneous or mucosal tumors in conjunction with a variety of extracutaneous neoplasias, both benign and malignant, as well as endocrine abnormalities are the focus of the first section. It includes multiple endocrine neoplasia types 1, 2A, and 2B in addition to PTEN hamartoma tumor syndrome (including Cowden syndrome), Gardner syndrome, and Muir–Torre syndrome. This is followed by sections on: enzyme deficiencies; premature aging syndromes and poikilodermas; and ectodermal dysplasias.

DISORDERS FEATURING TUMORIGENESIS

Susan J. Bayliss and Monique G. Kumar

MULTIPLE ENDOCRINE NEOPLASIA

Multiple endocrine neoplasia (MEN) refers to a group of disorders marked by the presence of neoplasia or hyperplasia in two or more endocrine organs, often in association with mucocutaneous findings. Three major MEN syndromes with mucocutaneous findings – termed types 1, 2A, and 2B – have been clinically and genetically defined and are described in Table 63.2[1,2].

Mucocutaneous features are most prominent in MEN types 1 and 2B. In MEN1, multiple facial angiofibromas and collagenomas are present in the majority of affected individuals (Fig. 63.1), and lipomas are another common finding[3,4]. Compared to those in tuberous sclerosis, facial angiofibromas in MEN1 tend to be smaller and fewer in number, and they are more likely to arise on the upper lip and its vermilion border in addition to the nose and medial cheeks. Although melanoma has been reported in patients with MEN1 and there is evidence that *MEN1* expression is frequently lost in sporadic melanomas[5,6], it remains unclear whether individuals with this syndrome have an increased risk of melanoma.

MEN2B is notable for multiple mucosal neuromas, especially of the conjunctivae, lips, and anterior tongue (Fig. 63.2). These lesions, which may be evident at birth or develop during early childhood, represent a relatively specific marker that can enable timely diagnosis and thyroidectomy, as medullary thyroid cancer typically develops during the first few years of life in patients with MEN2B[7,8]. However, mucosal neuromas are also occasionally observed in patients with the PTEN hamartoma tumor syndrome (PHTS; see below). Cutaneous neuromas are rare in MEN2B and when present are usually in a perinasal location.

PTEN HAMARTOMA TUMOR SYNDROME, INCLUDING COWDEN SYNDROME

Synonyms: ■ Multiple hamartoma syndrome ■ Cowden disease

Key features

- Spectrum of disorders with autosomal dominant inheritance characterized by multiple hamartomatous tumors of ectodermal, mesodermal, and endodermal origin
- Mucocutaneous findings include tricholemmomas, acral keratoses, oral papillomas, neuromas, sclerotic fibromas, genital pigmented macules, vascular anomalies, and lipomas
- Patients have especially high risks of breast, thyroid, and endometrial carcinoma
- Caused by mutations in *PTEN*

Introduction

PTEN hamartoma tumor syndrome (PHTS) refers to a spectrum of disorders with overlapping clinical features caused by mutations in the phosphatase and tensin homolog (*PTEN*) gene (Table 63.3). PHTS encompasses Cowden syndrome (CS), Bannayan–Riley–Ruvalcaba syndrome (BRRS), and SOLAMEN syndrome (segmental overgrowth, lipomatosis, arteriovenous malformation, and epidermal nevus; see Ch. 62). CS represents the most common phenotype of PHTS and is characterized by multiple hamartomas of ectodermal, mesodermal, and endodermal origin. Macrocephaly and mucocutaneous lesions (e.g. tricholemmomas, acral keratoses, oral papillomas) are the most constant and characteristic features[9]. Up to 85% of CS patients develop at least one malignant neoplasm, most often of the breast, thyroid, or endometrium[10].

GENODERMATOSES
Hereditary connective tissue disorders (Chs. 64, 95, 97, 98) Disorders of keratinization (Chs. 57–59) Hereditary epidermolysis bullosa (Ch. 32) Hereditary disorders of hair and nails (Chs. 69–71, 99) Hereditary disorders of pigmentation (Chs. 66 & 67) Hereditary vascular disorders (Ch. 104) Hereditary lipodystrophy syndromes (Ch. 101) Metabolic skin disorders (including enzyme deficiencies – see below; Chs. 48, 49, 92) Hereditary disorders of calcification/ossification (Ch. 50) Hereditary photosensitivity disorders (Chs. 49 & 87) Hereditary autoinflammatory diseases (Ch. 45) Primary immunodeficiencies (Ch. 60) Disorders featuring cutaneous cancer (Ch. 108) Disorders featuring benign tumors (Chs. 61 & 111) or multiple lentigines (Ch. 112) Mosaic skin disorders (Ch. 62)
Skin disorders associated with extracutaneous cancer • MEN1, 2A, 2B* • Cowden syndrome/PTEN hamartoma tumor syndrome* • Gardner syndrome* • Muir–Torre syndrome* • Birt–Hogg–Dubé syndrome (Ch. 111) • Peutz–Jeghers syndrome (Ch. 112) • Hereditary leiomyomatosis and renal cell cancer (Reed syndrome; Ch. 117) Ectodermal dysplasias* Premature aging syndromes* Poikilodermas* Enzyme deficiencies* • Alkaptonuria • Biotinidase & holocarboxylase synthetase deficiencies • Fabry disease & fucosidosis • Gaucher disease • Hartnup disease • Mitochondrial respiratory chain defects • Niemann–Pick disease • Phenylketonuria
*Discussed in this chapter.

Table 63.1 Genodermatoses. See also Chapter 55.

Fig. 63.1 Multiple endocrine neoplasia type 1. A Multiple large angiofibromas are a characteristic finding, including on the lips. **B** Multiple collagenomas are present on the abdomen. *A, Courtesy Edward Cowen, MD.*

History

In 1963, Lloyd and Dennis reported a multisystem disorder with characteristic mucocutaneous lesions and tumors of the breast, thyroid, and gastrointestinal tract[9]. They named the disorder "Cowden disease" after their first patient.

Epidemiology

PHTS is probably more common than is reflected by the number of cases reported, because the clinical findings can be subtle. It is inherited as an autosomal dominant trait with variable expressivity; a female predominance has been noted in some series[11]. Most of the reported patients have been White, and it is estimated to affect 1 in 200 000 individuals[12].

Pathogenesis

The PTEN protein is a lipid and protein phosphatase that plays a role in cell-cycle regulation and apoptosis[13,14]. In particular, PTEN *downregulates* the PI3K (phosphatidylinositol 3-kinase)/AKT/mTOR (mechanistic target of rapamycin) pathway that promotes cellular proliferation and survival (see Fig. 55.3). Like other autosomal dominant disorders caused by a defective tumor suppressor gene, PHTS is caused by a heterozygous germline *PTEN* mutation, with hamartomas and neoplasms resulting from a "second-hit" somatic mutation that inactivates the remaining allele of the gene (loss of heterozygosity). Lack of PTEN function leads to excessive mTOR signaling in affected tissues, in particular those with physiologic proliferation, such as the epidermis, oral and gastrointestinal mucosa, and thyroid and breast epithelium. PTEN also has phosphatase-independent activities and nuclear functions independent of the PI3K/AKT/mTOR pathway[14].

Clinical presentations of PHTS vary substantially even among patients with the same germline *PTEN* mutation, and in some families both CS and BRRS phenotypes are observed. Although genotype/phenotype correlations have not been established, mutations leading to an inactive protein may produce a more severe phenotype than those resulting in partially retained protein function[15]. Mosaicism due to a very early postzygotic *initial* mutation may produce a phenotype with disseminated findings clinically similar to germline disease[16]. Manifestations such as vascular anomalies and epidermal nevi with segmental distribution patterns can reflect an early postzygotic *second-hit* mutation (type 2 mosaicism; see Ch. 62) in a patient with a germline mutation, with different clinical findings depending on the tissue type affected.

Clinical Features

The 2013 revised clinical diagnostic criteria for PHTS are outlined in Table 63.4[17].

Mucocutaneous manifestations

Cutaneous involvement occurs in >80% of patients with PHTS and often serves as an early sign of the disorder. Characteristic mucocutaneous lesions usually begin to appear during the second to third decades of life (average, 22 years; range, birth to 75 years). Facial tricholemmomas present as multiple skin-colored to yellowish-tan, verrucous, or keratotic papules that resemble common warts[18] (Fig. 63.3A; see Ch. 111).

TYPES OF MULTIPLE ENDOCRINE NEOPLASIA (MEN)							
MEN type (synonyms)	**Mode of inheritance**	**Gene locus**	**Gene**	**Protein product**	**Location and type of mutations**	**Clinical manifestations**	
						Systemic	**Mucocutaneous**
1 (Wermer syndrome)	AD	11q13	*MEN1** [*MENIN*]	Menin (a nuclear protein)	Variable; truncating mutations in >70%	**Parathyroid**: hyperplasia or adenoma, hyperparathyroidism **Pancreas**: islet cell hyperplasia, adenoma or carcinoma, e.g. gastrinoma, insulinoma, glucagonoma **Pituitary**: prolactinoma > acromegaly, Cushing syndrome Less common: foregut carcinoid tumors, adrenocortical tumors, follicular adenomas (thyroid) Uncommon: pheochromocytoma	Multiple facial angiofibromas Collagenomas Lipomas (cutaneous and visceral) Less common: multiple gingival papules, confetti-like hypopigmented macules, CALM, possibly melanoma
2A (MEN type 2, Sipple syndrome)	AD	10q11.2	*RET*†	Tyrosine kinase receptor	Point mutations in the cysteine-rich extracellular domain, especially codon 634‡	**Thyroid**: C-cell hyperplasia, medullary carcinoma§ **Adrenal**: pheochromocytoma (50% bilateral) **Parathyroid**: hyperplasia or adenoma; hyperparathyroidism (less frequent than in MEN 1) Unusual: Cushing syndrome, Hirschsprung disease	Pruritus¶ Lichen amyloidosis¶ Notalgia paresthetica¶ Macular amyloidosis¶
2B (MEN type 3, multiple mucosal neuroma syndrome)	AD	10q11.2	*RET*†	Tyrosine kinase receptor	>95% of patients have missense mutation ($Met^{918}Thr$) in substrate-recognition pocket	**Thyroid**: medullary carcinoma (in first few years of life)§ **Adrenal**: pheochromocytoma (50% bilateral) **GI**: Diffuse ganglioneuromatosis (constipation, megacolon) Tearless crying (alacrima) Medullated corneal nerve fibers Marfanoid habitus Reduced subcutaneous fat High-arched palate Flat nasal bridge Pectus excavatum Proximal myopathy Other: Bilateral pes cavus, high patella, scoliosis, kyphosis, lordosis, joint laxity Rare: Cushing syndrome	Multiple mucosal neuromas, especially eyelid margins, conjunctivae, lips, anterior tongue > gingiva, palate, nasal and laryngeal mucosa Increased nerve fibers in normal skin Prominent, everted lips Everted eyelids Hyperpigmentation around mouth and overlying small joints of hands and feet CALM Circumoral lentigines Hypertrichosis, synophrys Rare: multiple neuromas of perinasal skin

*A tumor suppressor gene.
†Rearranged during transfection of proto-oncogene; mutations in the same gene can be responsible for Hirschsprung disease and familial medullary thyroid carcinoma.
‡Induces dimerization and activation of receptor in the absence of its ligand.
¶Onset usually prior to medullary thyroid carcinoma.
§Screen via measurement of serum calcitonin level after calcium or pentagastrin injection; prophylactic thyroidectomy prior to age 1 year is recommended for patients with MEN2B.

Table 63.2 Types of multiple endocrine neoplasia (MEN). A rare fourth type of MEN (MEN4) is caused by mutations in cyclin-dependent kinase inhibitor 1B (*CDKN1B*) and characterized by pituitary and parathyroid tumors; familial medullary thyroid carcinoma can result from *NTRK1* mutations as well as *RET* mutations. A woman with medullary thyroid carcinoma, macular amyloidosis, and multiple cutaneous neuromas in a widespread distribution (overlapping features of MEN2A and MEN2B) with a RET mutation in codon 768 has also been reported. AD, autosomal dominant; CALM, café-au-lait macules; NTRK1, neurotrophic tyrosine kinase receptor type 1.

Fig. 63.2 Multiple endocrine neoplasia type 2B. Enlarged lips and multiple neuromas on the tip of the tongue.

Both tricholemmomas and nonspecific cutaneous papules show a predilection for the central face, and they may coalesce around facial orifices (especially the nostrils) and on the ears. Papules on the head and neck of PHTS patients may also represent inverted follicular keratoses or acrochordons.

Multiple sclerotic fibromas of the skin are a relatively specific cutaneous marker of CS[19]. These lesions present as sharply circumscribed, firm dermal papules that display a strikingly uniform storiform pattern of collagen bundles on histologic examination (see Ch. 116). Punctate palmoplantar keratoses, often translucent with a central depression, are present in more than half of patients[20] (Fig. 63.4). Keratotic papules can also be seen on the heels, the dorsal aspects of the hands and feet, and the extensor surfaces of the forearms and lower legs.

Other skin and soft tissue manifestations include lipomas (especially testicular lipomatosis), angiolipomas, and vascular anomalies. The cutaneous vascular anomalies tend to be fast-flow lesions with intramuscular involvement and associated ectopic fat[21]. A distinctive "PTEN hamartoma of soft tissue" that presents as a subcutaneous and intramuscular mass with adipocytic, fibrous, and vascular (arterial, venous) components and sometimes lymphoid, bony, and neural elements has also been described[22]. Lastly, PHTS patients may have a slightly increased risk of melanoma, with a lifetime incidence of ~5%[10].

Oral lesions of PHTS appear as 1–3 mm, asymptomatic, mucosa-colored papules that often lead to a cobblestone appearance (Fig. 63.3B). They have a predilection for the lips and tongue, but extensive involvement of the entire oral cavity can occur[20].

CLINICAL MANIFESTATIONS OF PTEN HAMARTOMA TUMOR SYNDROME AND SCREENING RECOMMENDATIONS			
Clinical manifestations			
	Onset typically at birth or in childhood	**Onset typically in adolescence or adulthood**	**Variable onset**
Mucocutaneous	Pigmented macules of genitalia (glans and shaft of penis, vulva) Lipomas Vascular anomalies* PTEN hamartoma of soft tissue (see text) Neuromas (facial, acral, mucosal) Epidermal nevi Café-au-lait macules	Multiple facial papules† Multiple oral papillomas (lips, tongue)‡ Sclerotic fibromas Inverted follicular keratoses Multiple acrochordons Acanthosis nigricans	Acral/palmoplantar keratoses Scrotal tongue Perioral pigmented macules (rare)
Craniofacial and skeletal	Macrocephaly Down-slanting palpebral fissures Frontal bossing High-arched palate, long philtrum Pectus excavatum Joint hyperextensibility Hand and foot abnormalities¶		Scoliosis, kyphoscoliosis
Thyroid		Goiter and/or adenomas Carcinoma (follicular form over-represented)	
Breast		Fibrocystic disease Virginal hypertrophy Ductal papillomas Fibroadenomas Adenocarcinoma	
Gastrointestinal tract	Hepatic vascular anomalies	Adenocarcinoma (rare)	Multiple polyps (usually <5 mm in diameter)§ Ganglioneuromas Diffuse glycogenic acanthosis of esophagus
Genitourinary system		Ovarian cysts Uterine leiomyomas Menstrual irregularities Testicular lipomatosis Endometrial carcinoma Renal cell carcinoma Testicular tumors (e.g. seminoma)	
Central nervous system	Developmental delay, autism Seizures Hypotonia Developmental venous anomalies	Lhermitte–Duclos disease (LDD) – hamartomatous overgrowth of cerebellar ganglion cells that can lead to elevated intracranial pressure, ataxia, and seizures‖	Meningioma Spinal neurinoma
Ocular	Prominent corneal nerves Prominent Schwalbe lines Strabismus, amblyopia Retinal vascular anomalies Pseudopapilledema		Cataracts Myopia Angioid streaks
Muscular	Lipoid storage myopathy		
Other	Neonatal macrosomia Persistent drooling		
Screening recommendations			
• Yearly comprehensive *physical examination*, including skin, thyroid and breast, beginning at age 18 years (or 5 years before the youngest age of cancer diagnosis in the family); in women, breast examination every 6–12 months beginning at age 25 years (or 5–10 years prior to first breast cancer diagnosis in the family) in addition to monthly self-examinations • Yearly *thyroid ultrasound* starting at age 7 years • *Colonoscopy* beginning at age 35 years (or earlier if symptomatic or a family history of colon cancer before age 40 years); repeat at least every 5 years • In women, *annual mammogram and consideration of tomosynthesis and breast MRI* beginning at age 30–35 years (or 5–10 years before the youngest breast cancer diagnosis in the family) • Consider: (1) prophylactic mastectomies on an individual basis; (2) endometrial biopsy every 1–2 years and/or endometrial ultrasound beginning at menopause; and (3) renal ultrasound every 1–2 years beginning at age 40 years			
*Typically multifocal lesions with fast-flow channels, intramuscular involvement, and associated ectopic fat; may have capillary, venous, and/or lymphatic components. †Includes tricholemmomas, lesions with histologic features of verrucae, and very rarely tumors of the follicular infundibulum. ‡May represent epithelial hyperplasia, sclerotic fibromas, or glycogenic acanthosis. ¶Includes accelerated growth of the first metacarpal and first and second middle phalanges, syndactyly, and brachydactyly. §Can be hamartomatous, adenomatous, ganglioneuromatous, or inflammatory. ‖May occur as an isolated finding or in association with Cowden syndrome; patients with adult-onset LDD usually have a mutation in PTEN.			

Table 63.3 Clinical manifestations of PTEN hamartoma tumor syndrome and screening recommendations. In general, the clinical manifestations that are usually evident at birth or during childhood have classically been associated with Bannayan–Riley–Ruvalcaba syndrome and those that usually develop during adolescence or adulthood have classically been associated with Cowden syndrome.

REVISED CLINICAL DIAGNOSTIC CRITERIA FOR PTEN HAMARTOMA TUMOR SYNDROME (2013)
Major criteria

• Multiple mucocutaneous lesions (any of the following):
  • Tricholemmomas (≥3, at least 1 biopsy-proven)
  • Acral keratoses (≥3 papules or palmoplantar pits)
  • Mucocutaneous neuromas (≥3)
  • Oral papillomas, particularly on tongue & gingiva (≥3, biopsy-proven, or dermatologist-diagnosed)
• Pigmented macules on the glans penis
• Macrocephaly (>97th %ile; 58 cm in adult women, 60 cm in adult men)
• Lhermitte–Duclos disease (LDD; in an adult)
• Breast cancer
• Endometrial cancer (epithelial)
• Thyroid cancer (follicular)
• Gastrointestinal (GI) hamartomas, including ganglioneuromas, but *not* hyperplastic polyps (≥3)

Minor criteria
• Vascular anomalies, including multiple intracranial developmental venous anomalies • Lipomas (≥3) • Testicular lipomatosis • Autism spectrum disorder • Intellectual disability (IQ ≤75) • Renal cell carcinoma • Colon cancer • Esophageal glycogenic acanthosis • Thyroid cancer (papillary or follicular variant of papillary) • Thyroid structural lesions (e.g. adenoma, multinodular goiter)
Operational diagnosis in an individual: 3 major criteria including macrocephaly, LDD, or GI hamartomas –*or*– 2 major criteria + 3 minor criteria **Operational diagnosis when a family member meets diagnostic criteria or has a *PTEN* mutation:** 2 major criteria –*or*– 1 major + 2 minor criteria –*or*– 3 minor criteria

Table 63.4 Revised clinical diagnostic criteria for PTEN hamartoma tumor syndrome (2013). A scoring system incorporating age and clinical findings developed to estimate a patient's risk of having a *PTEN* mutation is available online (http://www.lerner.ccf.org/gmi/ccscore/). *Adapted from Pilarski R. PTEN hamartoma tumor syndrome: a clinical overview. Cancers (Basel) 2019;11;844.*

Extracutaneous manifestations

Multinodular goiter or thyroid adenomas occur in more than two-thirds of patients with PHTS, and the lifetime risk of thyroid carcinoma is estimated to be 10% to >30%. Fibrocystic disease and fibroadenomas of the breast affect three-quarters of female patients. Breast carcinoma develops in up to 85% of female patients with PHTS and is diagnosed at a mean age of ~40 years[10,23]; it has also been reported in affected men[24].

Multiple polyps may be found anywhere in the gastrointestinal tract but most frequently affect the colon (≥85% of patients). The lifetime risk of colon carcinoma is estimated to be ~10%[17,23]. Benign ovarian cysts and uterine leiomyomas commonly develop and endometrial carcinoma occurs in as many as 20%–30% of women with PHTS. The lifetime risk of renal carcinoma is estimated to be as high as ~30%[23].

Pathology

Histologically, tricholemmomas are characterized by a lobular proliferation of pale keratinocytes, often in association with a hair follicle. Basal keratinocytes are oriented to form a palisade, and hyperkeratosis can lead to a cutaneous horn. Demonstration of complete loss of PTEN expression within a tricholemmoma via immunohistochemical staining is suggestive that the patient has PHTS[25]. Histologically, some facial papules in patients with PHTS may simply be squamous papillomas, while others show follicular infundibular hyperplasia. Oral lesions often represent fibromatous nodules with collagen fibers arranged in whorls. On biopsy, extrafacial and palmoplantar papules tend to be hyperkeratotic papillomas, and they may have changes reminiscent of verrucae or acrokeratosis verruciformis[26].

Fig. 63.4 Cowden syndrome. Multiple palmar keratoses, many of which have a glassy appearance. A few have a central depression. *Courtesy Joyce Rico, MD.*

Differential Diagnosis

The clinical differential diagnosis of the oral papillomas of PHTS includes verrucae, focal epithelial hyperplasia (Heck disease), traumatic fibromas, mucosal neuromas of MEN2B, papillomas of Goltz

syndrome, and papular lesions of lipoid proteinosis. A combination of acral keratoses (including palmoplantar) plus oral and facial papules can also be seen in Darier disease, whereas multiple facial angiofibromas and gingival fibromas are characteristic of tuberous sclerosis. These disorders can usually be differentiated from PHTS by other characteristic features as well as histologic evaluation.

The clinical differential diagnosis of multiple facial tricholemmomas may include angiofibromas (as seen in tuberous sclerosis complex or MEN1), trichoepitheliomas, and fibrofolliculomas (Birt–Hogg–Dubé syndrome); in addition to their histologic features, the tendency of tricholemmomas to have a verrucous appearance clinically may help to distinguish them from these lesions. Common warts, seborrheic keratoses, basaloid follicular hamartoma syndrome, and epidermodysplasia verruciformis may represent additional diagnostic possibilities. Less commonly, multiple syringomas or the basal cell nevus syndrome might be considered (see Fig. 111.5).

The differential diagnosis for SOLAMEN syndrome includes the *PIK3CA*-related overgrowth spectrum and Proteus syndrome (see Table 104.5).

Treatment

Although the recognition of PHTS is based upon clinical and histologic evaluation, genetic testing allows confirmation of the diagnosis and facilitates identification of affected family members. Due to the high risk of malignancy, cancer surveillance is a critical part of PHTS management (see Table 63.3).

Agents that downregulate the mTOR pathway, such as sirolimus (rapamycin), can lead to improvement in vascular anomalies, lipomatosis, cutaneous papules, gastrointestinal polyps, and cerebellar function[27]. Facial papules respond variably to topical 5-fluorouracil, oral isotretinoin, curettage, laser ablation, or surgical excision[18].

GARDNER SYNDROME (VARIANT OF FAMILIAL ADENOMATOUS POLYPOSIS)

Synonym: ■ Familial polyposis of the colon

Key features

- Autosomal dominant disorder that is a variant of familial adenomatous polyposis (FAP) with prominent extraintestinal manifestations
- Features the intestinal polyps and adenocarcinoma that characterize FAP together with epidermoid cysts, fibromas, desmoid tumors, and osteomas
- Retinal pigment epithelial hamartomas represent an early sign
- Caused by mutations in the *APC* (adenomatous polyposis coli) gene

Introduction

The main features of Gardner syndrome are premalignant intestinal polyposis, epidermoid cysts, osteomas, and desmoid or fibrous tumors of the skin and other sites. It is considered to represent a phenotypic variant of the familial adenomatous polyposis syndrome (FAP) with prominent extraintestinal involvement[28,29].

History

In 1951, Gardner described a large family in which colonic polyps and carcinoma were associated with osteomas and "surface tumors". This FAP phenotype with prominent extraintestinal manifestations continues to bear Gardner's name.

Epidemiology

The prevalence of FAP is estimated to be 1 in 7000 to 1 in 30 000 live births. It is inherited as an autosomal dominant trait with high penetrance of the gastrointestinal manifestations but variable expressivity of extraintestinal findings, affecting men and women equally.

Pathogenesis

FAP (including Gardner syndrome) is caused by heterozygous germline mutations in the adenomatous polyposis coli (*APC*) tumor suppressor gene. *APC* encodes a protein that downregulates the Wnt/β-catenin signaling pathway, which has important functions in cellular proliferation, differentiation, and adhesion (see Fig. 55.6). Extraintestinal manifestations (especially desmoid tumors) are more likely in patients with mutations in the distal portion of *APC*[30,31].

Clinical Features

Cutaneous and soft tissue manifestations

Skin lesions appear during childhood and adolescence, frequently preceding the onset of polyposis. Cutaneous epidermoid cysts affect ~50% of patients with FAP and are often multiple[31]. The cysts typically begin to appear before puberty and favor the face, scalp, and extremities[31]. Multiple familial pilomatricomas have also been reported as a presentation of Gardner syndrome[32].

Gardner-associated fibromas may occur in the skin, subcutaneous tissues, mesentery, or retroperitoneum. The fibromas typically arise during the first two decades of life, favor the back (especially the paraspinal region), and can serve as a desmoid tumor precursor. Lipomas, leiomyomas, trichoepitheliomas, and neurofibromas are less frequently observed.

Desmoid tumors (also referred to as desmoid fibromatosis) are non-encapsulated, non-metastasizing, locally aggressive tumors that are usually rare but affect 10%–30% of patients with FAP. These lesions arise from musculoaponeurotic structures and can occur spontaneously or at surgical sites. In patients with APC, desmoid tumors most often develop within the abdominal wall or intra-abdominally following colectomy, with the latter location causing greater morbidity via obstruction of the small bowel and/or ureters. Extra-abdominal lesions affecting the shoulder girdle, chest wall, or inguinal region can also occur. Although cytologically benign, desmoid tumors represent a potential cause of mortality in FAP, e.g. due to compression of vital organs.

Other extraintestinal manifestations

Retinal pigment epithelial hamartomas (RPEH) are evident in ~75%–80% of patients with FAP. These lesions may be present at birth, serving as an early and specific sign of the disorder[33,34] (Fig. 63.5). Although often referred to as congenital hypertrophy of the retinal pigment epithelium (CHRPE), FAP-associated pigmented retinal lesions have irregular borders and a haphazard bilateral distribution that differentiate them from sporadic multifocal CHRPE[34].

Osteomas occur in ~65%–80% of patients with FAP and favor the frontal bone, mandible, and maxilla, although they can also develop in other bones of the skull and long bones. Seen in children as young as 8 years of age, osteomas are painless and can grow large enough to be clinically obvious or be detectable only by radiographic studies. Other skeletal lesions include exostoses, endostoses, and cortical thickening of the long bones. Dental anomalies are apparent in ~30% of patients with FAP and include supernumerary teeth, odontomas, unerupted teeth, and congenitally missing teeth.

Fig. 63.5 Retinal pigment epithelial hamartomas in Gardner syndrome. *Courtesy L. Tychsen, MD.*

Patients with FAP are at increased risk for the development of other tumors, including papillary carcinoma of the thyroid (particularly in women), hepatoblastoma (usually affecting children <3 years of age), pancreatic and biliary tract carcinomas, nasal angiofibromas, adrenal adenomas (or occasionally carcinomas), and sarcomas (e.g. fibrosarcoma, osteosarcoma). The association of brain tumors (most often medulloblastomas) with adenomatous polyposis in patients with heterozygous *APC* mutations has historically been referred to as Turcot syndrome type 2. The latter is distinct from the *constitutional mismatch repair deficiency syndrome* (previously referred to as Turcot syndrome type 1) that presents during childhood with brain tumors (primarily glioblastomas), colonic polyposis, hematologic malignancies, and multiple café-au-lait macules due to *biallelic* mutations in mismatch repair genes (see below and Table 61.3)[35].

Gastrointestinal manifestations

In adults, the diagnosis of FAP is commonly made when the patient presents with gastrointestinal bleeding secondary to adenomatous polyps. Other findings may include anemia, abdominal pain, diarrhea or constipation, and weight loss. Premalignant *adenomatous* polyps most commonly occur in the colorectum but are also found in the small intestine and stomach in over half of patients. Polyps are typically <1 cm in diameter and are rarely seen before the age of 10 years. By the age of 20 years, 50% of patients with FAP have demonstrable polyps. Without surgical intervention, colorectal carcinoma is inevitable; it usually develops before age 40 years and arises by early adolescence in ~5% of affected individuals[29,36]. Carcinomas of the small intestine (especially the duodenum) can also occur[29].

Pathology

Histologically, intestinal polyps show adenomatous hyperplasia of the mucosa. Cutaneous cysts in patients with FAP usually demonstrate the same microscopic changes as ordinary epidermoid cysts, with a lining of keratinizing epithelium that includes a granular layer. Pilomatricoma-like changes, with characteristic basophilic and shadow cell populations, have also been noted.

Differential Diagnosis

Although epidermoid cysts represent a common sporadic finding, multiple lesions with onset during childhood should prompt a thorough family history and evaluation for other findings of Gardner syndrome (e.g. RPEH, osteomas). Of note, mutations in the *MUTYH* base excision repair gene can cause an autosomal recessive form of colorectal adenomatous polyposis, with osteomas, RPEH, desmoid tumors, pilomatricomas, and sebaceous neoplasms (see below) having been described in affected individuals[37].

Management

The diagnosis of FAP is established by identifying a pathogenic variant in *APC* in an individual with multiple colorectal adenomatous polyps (≥100 for an adult pre-colectomy and without a relative with confirmed FAP). Genetic counseling is imperative, and family members should be evaluated for intestinal and extraintestinal signs of the disorder.

Because of the inevitable development of colorectal carcinoma, prophylactic colectomy is recommended when polyp formation becomes evident, and it is usually performed between 15 and 25 years of age. Initially, children with FAP should be monitored with sigmoidoscopy or colonoscopy every 1–2 years beginning at 10–12 years of age. Once polyps are detected, patients should undergo annual colonoscopy until a colectomy is done. Esophagogastroduodenoscopy is recommended every 6 months to 4 years (depending on polyp burden) beginning at 20–25 years of age, with careful inspection of the ampulla of Vater. Annual physical examination should include evaluation for neurologic deficits and other extraintestinal manifestations, including palpation of the abdomen (for desmoid tumors) and thyroid starting in the late teenage years. If there is a family history of desmoid tumors, abdominal CT or MRI beginning 1–3 years post colectomy and then every 5–10 years should be considered. Because of the increased risk of hepatoblastoma, some experts recommend abdominal ultrasound and measurement of serum α-fetoprotein every 3–6 months during the first 5 years of life.

Symptomatic epidermoid cysts can be surgically excised. Desmoid tumors are also treated by surgical excision, although there tends to be a high recurrence rate. Preoperative MRI of the abdomen can demonstrate the origin of the tumor and the extent of involvement. If wide surgical excision fails, radiotherapy, hormonal therapy (e.g. tamoxifen, raloxifene), chemotherapy, or a combination thereof can be tried. The osteomas of FAP may or may not be amenable to surgical intervention. Medications that affect prostaglandin metabolism, such as nonsteroidal anti-inflammatory drugs (NSAIDs), may reduce the risk of colorectal cancer and desmoids[38].

MUIR–TORRE SYNDROME (VARIANT OF LYNCH SYNDROME)

Synonym: ■ Cutaneous sebaceous neoplasms and keratoacanthomas, with gastrointestinal and other carcinomas

Key features

- An autosomal dominant disorder associated most commonly with adenocarcinoma of the colon, followed by genitourinary carcinomas
- The cutaneous manifestations are sebaceous neoplasms and keratoacanthomas
- Caused by mutations in DNA mismatch repair genes (*MSH2* >> *MLH1* > *MSH6, PMS2*)

Introduction

Muir–Torre syndrome (MTS) is an uncommon autosomal dominant genodermatosis that is characterized by sebaceous neoplasms (adenoma, sebaceoma, or carcinoma; see Ch. 111), and internal malignancies. It is considered to represent a variant of Lynch syndrome, which is also known as hereditary non-polyposis colorectal cancer (HNPCC) syndrome[39].

History

Muir in 1967 and Torre in 1968 independently reported the syndrome that bears their names. Their two patients had malignancies in several organs plus either keratoacanthoma-like lesions or multiple tumors of sebaceous origin.

Epidemiology

The male : female ratio in MTS is 3 : 2, and affected individuals present with cutaneous manifestations at a mean age of 55 years. The prevalence of Lynch syndrome in the general population is estimated to be ~1 in 350. In a study of Lynch syndrome patients, MTS was observed in 28% (14/50) of families and 9% (14/152) of individuals with a confirmed germline mismatch repair gene mutation[40].

Pathogenesis

MTS is caused by heterozygous germline mutations in one of several DNA mismatch repair (MMR) genes, including *MSH2* (90% of MTS cases), *MLH1*, and rarely *MSH6* or *PMS2*. MMR proteins are responsible for detecting and repairing DNA replication errors. In patients with MTS, somatic inactivation of the other allele of the affected gene (loss of heterozygosity) results in microsatellite instability, i.e. increased variability in the lengths of repetitive "microsatellite" sequences in the genome, as well as mutations that lead to tumor formation[41].

Clinical Features

Sebaceous tumors can present prior to (~30%), concurrently with (~10%), or after (~60%) the diagnosis of a visceral malignancy. The skin tumors sometimes appear decades before or after a visceral malignancy develops. In general, sebaceous tumors favor the head and neck region (Fig. 63.6), and sporadic sebaceous carcinomas tend to affect the

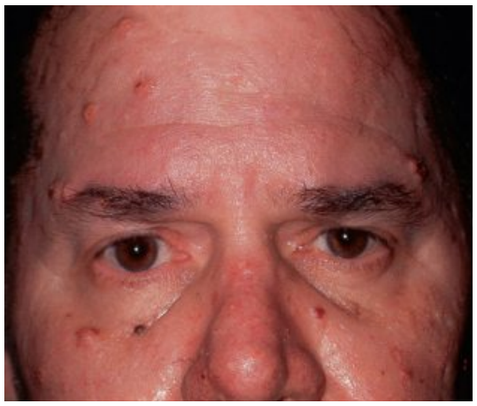

Fig. 63.6 Muir–Torre syndrome with multiple sebaceous neoplasms. *Courtesy Dan Ring, MD.*

periocular area. However, in patients with MTS, these neoplasms can occur in other locations (trunk > extremities)[42]. Sebaceous adenomas are the most common tumor type, and they present as slow-growing, yellow to pink papules or nodules, numbering from one to hundreds. Keratoacanthomas, which are keratotic skin-colored to erythematous papules or nodules that arise quickly, are seen in ~25% of patients with MTS and usually exhibit sebaceous differentiation. Fordyce granules ("free" sebaceous glands) on the vermilion lip and oral mucosa (especially the vestibule) are more common and prominent in patients with MTS than in the general population[43].

The most frequently observed malignancies in Lynch syndrome are colorectal (~50%–60% of patients with *MSH2* or *MLH1* mutations) and genitourinary (e.g. endometrium [15%–50% of women], ovary [10%–35% of women], urinary tract; highest risk with *MSH2* mutations) carcinomas[44]. Colorectal carcinoma in Lynch syndrome most often involves the proximal colon and develops at a median age of 45 years, about one decade before it typically occurs in the general population. Lynch syndrome patients are also at increased risk of neoplasms of the small intestine, stomach, pancreas, hepatobiliary system, CNS, and perhaps breast[45,46]; hematologic malignancies and sarcomas have also been reported.

RISK ASSESSMENT FOR MUIR–TORRE SYNDROME (MTS)	
Higher likelihood of MTS	**Lower likelihood of MTS**
Clinicopathologic characteristics of skin lesions	
• ≥2 sebaceous neoplasms **[2]** • Located outside of the head and neck region • Sebaceous neoplasm with high specificity for MTS, e.g. a cystic lesion or keratoacanthoma with sebaceous differentiation	• Single sebaceous neoplasm • Located in photodamaged facial skin • Sebaceous hyperplasia
Characteristics of patient and family history	
• Age <60 years **[1]** • Personal history of colorectal cancer* and/or other Lynch syndrome-related malignancies (e.g. small bowel, gastric, endometrial, bladder, ureteral, renal, biliary, pancreatic, glioblastoma) **[1]**, especially if more than one • Colorectal cancer and/or other Lynch syndrome-related malignancies in family member(s) **[1]**, especially if before 50 years of age and in first-degree relative(s)	• Elderly patient with no history of a Lynch syndrome-related malignancy • No family members with colorectal cancer/other Lynch syndrome-related malignancies
Additional analysis of sebaceous neoplasms	
• Loss of MSH2, MLH1, MSH6, and/or PMS2 expression shown by immunohistochemical staining† • Evidence of MSI in lesional tissue (more specific)‡	• Expression of MLH1, MSH2, MSH6, and PMS2 shown by immunohistochemical staining • No evidence of MSI in lesional tissue‡

*Especially if MSI-high histology – presence of tumor-infiltrating lymphocytes, Crohn disease-like lymphocytic reaction, medullary growth pattern, or signet ring/mucinous differentiation.
†MSH2 and MSH6 proteins form a heterodimer, so lack of one can lead to the absence of the other; likewise, PMS2 is unstable without a functional MLH1 protein.
‡Testing can be performed on paraffin-embedded tissue; diagnostic yield may be higher for colonic neoplasms.

Table 63.5 Risk assessment for Muir–Torre syndrome (MTS). A clinical score of ≥2 based on the sum of the applicable numbers in [ ] has a sensitivity of nearly 100% and a specificity of ~80% for predicting a germline mutation in a mismatch repair gene[48]. MSI, microsatellite instability.

Diagnosis

The diagnosis of MTS was traditionally based on the presence of at least one sebaceous tumor (or keratoacanthoma with sebaceous differentiation) and a visceral malignancy without another known predisposing factor. In the absence of a sebaceous tumor, the diagnosis can be made in a patient with multiple keratoacanthomas, multiple visceral malignancies, and a family history of MTS[47]. Findings that suggest a higher or lower likelihood of MTS in patients with sebaceous neoplasms are summarized in Table 63.5[48]. Testing for a mismatch repair gene mutation is helpful in confirming the diagnosis and facilitating identification and surveillance of affected family members.

Pathology

Skin tumors arising as part of MTS fall into two general categories: sebaceous neoplasms and keratoacanthomas. Sebaceous adenomas (with a predominance of mature sebocytes), sebaceomas (vertically oriented with a predominance of basaloid seboblastic cells), so-called sebaceous epitheliomas (inconsistently defined term used for various lesions with seboblastic differentiation), and sebaceous carcinomas may occur (see Ch. 111). A type of keratoacanthoma with sebaceous differentiation that may be specific to this syndrome has been called a sebo(kerato)acanthoma; it has the architecture of a keratoacanthoma but contains well-differentiated sebaceous lobules (Fig. 63.7)[49]. In addition, cystic sebaceous tumors, which are well-circumscribed, deep sebaceous lesions with a cystic growth pattern, occur in some MTS patients and are a strong clue for the presence of the syndrome.

Immunohistochemical (IHC) staining for MSH2, MSH6, MLH1, and PMS2 can be a valuable screening tool for MTS-associated tumors, which frequently show a lack of expression of one or more of these mismatch repair proteins (see Table 63.5)[43,45,50]. However, abnormal IHC staining is not diagnostic of MTS, as it is sometimes seen in sporadic sebaceous neoplasms, especially in immunocompromised patients; conversely, IHC staining may rarely be normal in lesions from patients with a mismatch repair gene mutation (see Ch. 111)[50,51]. PCR-based assays can also be used to demonstrate microsatellite instability (MSI) in tissue from MTS-associated neoplasms. Confirmatory testing for a germline

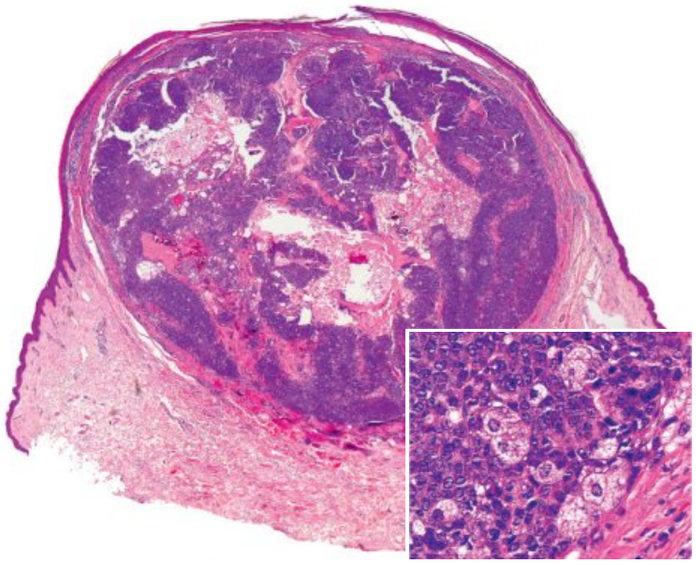

Fig. 63.7 Seboacanthoma in a patient with Muir–Torre syndrome. Well-circumscribed basaloid tumor with abundant secreted material, surrounded by a pseudocapsule of compressed fibrous tissue. Note the sebaceous differentiation (inset). *Courtesy Luis Requena, MD.*

SURVEILLANCE GUIDELINES FOR PATIENTS WITH LYNCH SYNDROME, INCLUDING MUIR–TORRE SYNDROME		
Test	**When to begin**	**Frequency**
• Comprehensive physical examination, including the skin, and neurologic assessment	• Age 20–25 years	• Yearly
• **Colonoscopy**	• Age 20–25 years • If diagnosed in a family member before age 25 years, 2–5 years younger than the earliest colon cancer in the family	• Every 1–2 years
• Consider endometrial biopsy and (in postmenopausal women) transvaginal ultrasound*	• Age 30–35 years*	• Every 1–2 years
• Consider esophagogastroduodenoscopy with biopsy of the proximal and distal stomach • Consider *H. pylori* testing and treatment when found	• Age 40 years	• Every 3–5 years, based on individual risk factors
• Consider urinalysis ± cytological examination	• Age 30–35 years	• Yearly, based on individual risk factors
• Consider prostate-specific antigen (PSA) testing and digital rectal examination	• Age 40 years	• Yearly, based on individual risk factors
*Consider hysterectomy and bilateral salpingo-oophorectomy when childbearing is completed, with timing depending on factors including menopause status, comorbidities, family history, and genetic etiology.		

Table 63.6 Surveillance guidelines for patients with Lynch syndrome, including Muir–Torre syndrome. Colonoscopy (in **bold**) is the only strong recommendation in these guidelines. For patients with a family history of pancreatic cancer, screening can be considered beginning at age 50 years (or 10 years younger than the earliest diagnosis in the family) with endoscopic ultrasound and/or magnetic resonance imaging/magnetic resonance cholangiopancreatography. Routine breast screening beyond that advised for the general population is not currently recommended. *Based on the National Comprehensive Cancer Network guidelines (http://nccn.org/professionals/physician_gls/pdf/genetics_colon.pdf) and Giardiello FM, Allen JI, Axilbund JE, et al. Guidelines on genetic evaluation and management of Lynch syndrome: a consensus statement by the US Multi-Society Task Force on Colorectal Cancer. Dis Colon Rectum 2014;57:1025–48.*

mismatch repair gene mutation should be considered in patients with abnormal lesional IHC staining for these proteins, evidence of MSI, or a strong clinical suspicion of MTS.

Differential Diagnosis

Sebaceous hyperplasia is a common finding in the general population, and sebaceous adenomas and carcinomas can occur in patients without MTS. Sebaceous adenomas and carcinomas as well as colorectal carcinomas have also been described in patients with autosomal recessive colorectal adenomatous polyposis caused by mutations in the *MUTYH* base excision repair gene[37,52]. This disorder accounts for some of the patients with sebaceous neoplasms and visceral malignancy who meet the traditional criteria for MTS, but whose tumors do not exhibit microsatellite instability. Some authors have referred to patients without evidence of microsatellite instability due to mismatch repair dysfunction as having MTS type 2[47]. Additional manifestations of *MUTYH*-associated polyposis include other malignancies (e.g. small bowel, ovarian, bladder) and findings that overlap with Gardner syndrome, such as osteomas, RPEH, desmoid tumors, and pilomatricomas[53].

Multiple keratoacanthomas may occur as an isolated finding (i.e. without visceral malignancy), especially in patients with the Ferguson–Smith (multiple self-healing) or Grzybowski (generalized eruptive) types of keratoacanthomas. However, these patients should be evaluated to exclude the possibility of MTS.

Treatment

Patients with an internal malignancy require appropriate oncologic referral and management. Recommendations for surveillance of high-risk individuals are outlined in Table 63.6. Long-term aspirin therapy may decrease the risk of colorectal carcinoma in patients with Lynch syndrome[39].

Treatment options for benign sebaceous tumors include curettage, excision, and cryosurgery. Sebaceous carcinomas have metastatic potential and require wide local excision or Mohs micrographic surgery, with the latter recommended for facial lesions. Oral retinoids with or without interferon-α may be useful in the prevention of new sebaceous neoplasms.

ENZYME DEFICIENCY DISEASES

Ángela Hernández-Martín

ALKAPTONURIA

Synonym: ■ Ochronosis

Key features

- An autosomal recessive disorder due to deficiency of homogentisate 1,2-dioxygenase
- Clinical signs include discoloration of cartilage (e.g. the helices), sclerae, and skin (e.g. the axillae)
- Extracutaneous findings include urine that darkens on standing, arthritis, and valvular heart disease

Alkaptonuria is an autosomal recessive inborn error of metabolism in which homogentisic acid (HGA), an intermediate in phenylalanine and tyrosine metabolism, cannot be further metabolized and therefore accumulates in body fluids and tissues[54]. The disorder results from a deficiency of the enzyme homogentisate 1,2-dioxygenase. It is estimated to have a prevalence of ~1 in 250 000 in most ethnic groups, but as high as 1 in 20 000 in Slovakia and the Dominican Republic due to founder effects.

The cardinal clinical features of alkaptonuria include urine that turns dark on standing, discoloration of cartilage and other connective tissues, and arthritis (Fig. 63.8). The arthritis often presents in the third or fourth decade of life with chronic back pain and stiffness, and radiographs show flattened and calcified intervertebral discs. Later involvement of large peripheral joints can resemble rheumatoid arthritis clinically but osteoarthritis radiographically. Renal complications include an increased incidence of calculi and occasionally kidney failure. Aortic stenosis is common by the sixth or seventh decade of life and coronary artery calcifications may also develop[54]. Life expectancy is normal.

The dermatologic features of alkaptonuria are rarely noted prior to 10–15 years of age and typically become apparent during adulthood, often in the fourth decade of life. Axillary skin may be one of the initial sites to develop discoloration, which can range in color from blue to yellow to brown. The classic blue–grey color associated with this disorder is often first noted in the helices of the ear and sclerae (see Fig. 63.8). Later, it may affect the palmar and plantar surfaces as well as the entire face. Dermoscopy can show speckled white globular structures overlying a grayish-blue structureless area[55]. Collagenous and elastotic marginal plaques of the hand may also develop, typically during the fourth to sixth decades of life[56]. Features that may present early in life

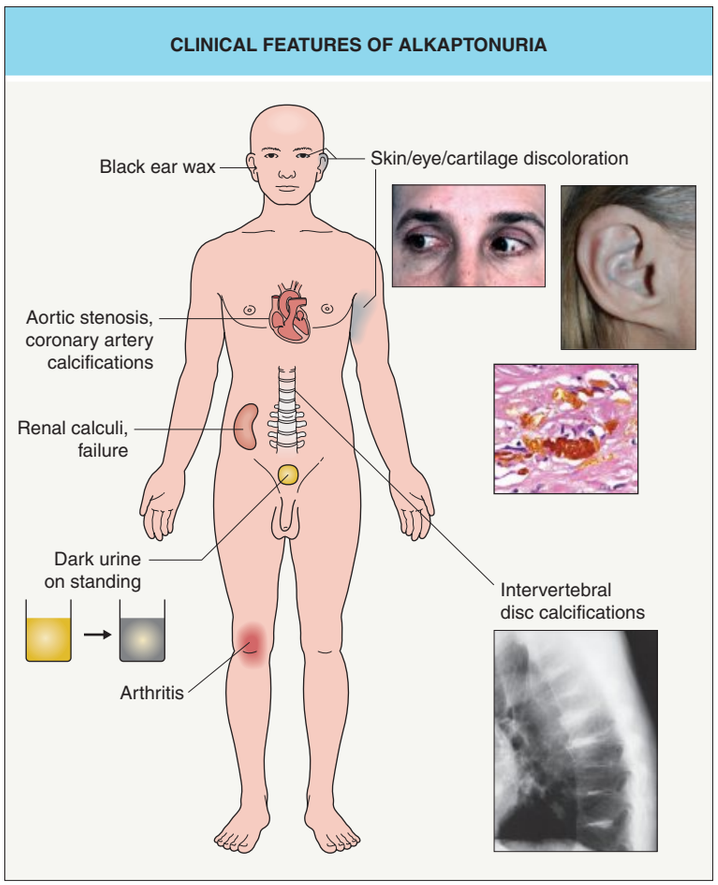

Fig. 63.8 Clinical features of alkaptonuria. *Eyes, courtesy William Gahl, MD PhD; ear, courtesy Julie V. Schaffer, MD; radiograph, courtesy Jean L. Bolognia, MD; photomicrograph, courtesy Lorenzo Cerroni, MD.*

include brownish discoloration of diapers (due to the dark urine) and cerumen that is brown to black in color. Histopathologic findings of discolored skin include orthohyperkeratosis and irregular, brownish-yellow, acellular deposits in the dermis[55].

Diagnosis of alkaptonuria can be confirmed by urine organic acid analysis. Management includes physical therapy and pain control as needed. Beginning at age 40 years, periodic cardiac assessment with echocardiography is recommended[54]. Administration of oral nitisinone, an inhibitor of HGA production, at a dose of 2–10 mg daily reduces urinary HGA excretion by >95% and has been shown to slow disease progression[57]; a low-protein diet in conjunction with this medication may help to prevent excessively high plasma tyrosine levels.

BIOTINIDASE AND HOLOCARBOXYLASE SYNTHETASE DEFICIENCIES

Synonym: ■ Late- and early-onset forms of multiple carboxylase deficiency

Key features

- As biotin is an essential cofactor for carboxylases, there is overlap in these two autosomal recessive disorders
- Cutaneous findings include alopecia, periorificial erythema and erosions (features of "nutritional dermatitis"), and sometimes flexural involvement reminiscent of seborrheic dermatitis
- Metabolic acidosis occurs in both disorders
- Biotinidase deficiency is associated with developmental delay, hearing loss, and seizures beginning during infancy or childhood, while patients with holocarboxylase synthetase deficiency classically develop encephalopathy and hypotonia within the first 3 months of life

Biotinidase deficiency and holocarboxylase synthetase deficiency are genetically distinct autosomal recessive disorders that result in multiple carboxylase deficiency; the former has its onset during infancy or childhood, while the latter presents during the first 3 months of life[58,59]. Dermatologic features, which overlap with other forms of "nutritional dermatitis" (see Fig. 51.13), occur in >50% of patients with biotinidase deficiency and a smaller proportion of those with holocarboxylase synthetase deficiency. Characteristic skin findings include progressive alopecia and a well-demarcated dermatitis with erythema and scaling that typically begins in perioral, perianal and/or flexural regions, sometimes mimicking seborrheic dermatitis, but then can become generalized. This eruption is often eroded or fissured, and superimposed candidiasis and other secondary infections may develop.

Biotinidase deficiency, a pan-ethnic disorder with an incidence of ~1 in 60 000 births, represents a defect in biotin recycling. Patients with this disorder become functionally biotin-deficient under conditions of *normal* dietary biotin intake. Since biotin is an essential cofactor for the activity of carboxylases, multiple carboxylase deficiency ensues. Both cutaneous and extracutaneous manifestations usually develop between 3 months and 2 years of age but may be delayed until later childhood. Extracutaneous features include developmental delay, hearing loss, seizures, conjunctivitis, optic atrophy, myelopathy, and metabolic acidosis[58].

Abnormalities on urine organic acid analysis are not consistently present. The diagnosis is established by an assay of biotinidase activity in blood or molecular genetic testing; prenatal diagnosis is possible via enzymatic and molecular analyses. Considering that the highly variable manifestations may go unrecognized, biotinidase deficiency is included in the newborn screening panel of many countries, including the US[58]. The clinical features of biotinidase deficiency are entirely preventable with administration of 5–20 mg of biotin daily.

Holocarboxylase synthetase deficiency is significantly less common than biotinidase deficiency. It represents a defect in biotinylation of the apocarboxylases, leading to a failure in synthesis of intact functional holocarboxylases[59]. Patients typically present within the first 3 months of life with symptoms of a metabolic encephalopathy, including poor feeding, lethargy, respiratory distress, and hypotonia. Metabolic acidosis, hyperammonemia, and organic aciduria are often observed. Definitive diagnosis is established by assays of carboxylases in leukocytes or cultured skin fibroblasts, or by molecular genetic testing; prenatal diagnosis is also possible via enzymatic and molecular analyses. Most patients exhibit significant improvement when treated with 10 mg of biotin daily.

FABRY DISEASE

Synonym: ■ Anderson–Fabry disease

Key features

- X-linked disorder due to a deficiency of α-galactosidase A
- Characteristic mucocutaneous finding is multiple angiokeratomas
- Additional features include pain and paresthesias of the extremities, hypohidrosis, and renal and coronary insufficiency

Fabry disease is an X-linked lysosomal storage disorder resulting from a defect in glycosphingolipid metabolism due to pathogenic variants in *GLA*, which encodes the enzyme α-galactosidase A (α-Gal A)[60]. It is a pan-ethnic condition that can be identified via newborn screening in ~1 in 7000 male neonates[61], including both *classic* severe disease (associated with minimal residual α-Gal A activity) and *later-onset* phenotypes with milder clinical involvement (cardiac > renal). Female heterozygotes may also be affected, with variable clinical manifestations that often have a later onset. The clinical manifestations result from accumulation of globotriaosylceramide and its deacylated form, globotriaosylsphingosine, in multiple cell types, including vascular endothelial cells, cardiomyocytes, renal podocytes, and neural cells[60]. This leads to sequelae such as apoptosis, inflammation, oxidative stress, ischemia, necrosis, and fibrosis[60,62].

Fabry disease has a wide spectrum of clinical findings with variable progression, ranging from severe multi-organ dysfunction in the classic phenotype to minimal symptoms[62]. Classic Fabry disease presents in boys during childhood or adolescence with the cardinal clinical features of acral pain (episodic or chronic), acral paresthesias, hypohidrosis, and angiokeratomas (Fig. 63.9). Characteristic whorled corneal opacities ("cornea verticillata") are evident in ~75% of both male hemizygotes and female heterozygotes by childhood or adolescence but are rarely of clinical significance. Posterior lenticular opacities and tortuous retinal or conjunctival vessels may also be observed. However, milder forms of Fabry disease with delayed onset often have subtle or absent early findings.

With increasing age, progressive renal insufficiency develops, typically leading to the need for dialysis or transplantation by the fourth or fifth decade of life in untreated men with classic disease. Cardiac sequelae such as hypertrophic cardiomyopathy, arrhythmias, myocardial fibrosis, valvular abnormalities, and coronary insufficiency occur in most men with classic disease by middle age and represent the most common cause of premature death in both men and women with Fabry disease. Manifestations in other organ systems can include transient ischemic attacks and strokes; abdominal pain, diarrhea, and vomiting (especially in children); obstructive lung disease; joint pain and osteopenia; and hearing loss[60,62]. Characteristic facial features such as periorbital fullness, bushy eyebrows, a broad nasal bridge, thick lips, prognathism, and prominent earlobes have been noted in men with Fabry disease. Although complications usually occur at a later age in female heterozygotes than in men with classic disease, some women do develop early symptoms followed by progressive organ involvement.

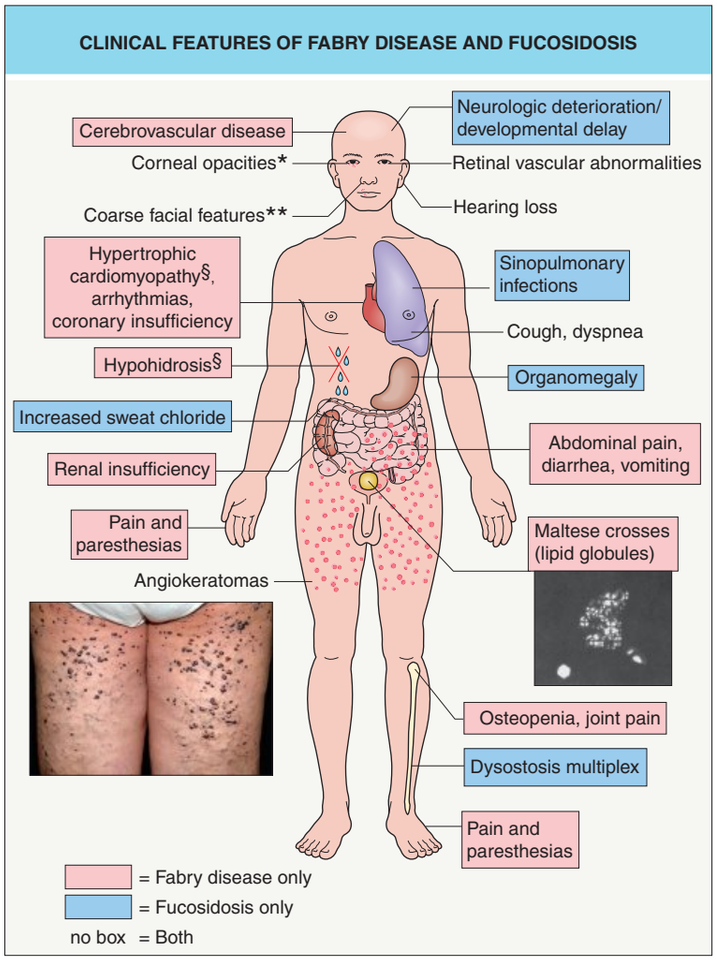

Fig. 63.9 Clinical features of Fabry disease and fucosidosis. Traditionally, polarizing microscopy of urinary sediment revealing birefringent lipid globules ("Maltese crosses") was utilized as a marker of Fabry disease. *Also lenticular in Fabry disease. **Milder in Fabry disease. §Occasionally observed in fucosidosis.
Angiokeratomas of Fabry disease, courtesy Luis Requena, MD; photomicrograph of Maltese crosses, courtesy Robert J. Desnick, MD PhD.

Angiokeratomas are one of the earliest signs of Fabry disease, typically beginning to appear during childhood or adolescence[63–65]. They develop in most male patients and ~30% of female heterozygotes. Angiokeratomas present as punctate, dark red to blue–black macules or papules (Fig. 63.10). The lesions do not blanch with pressure and may become slightly keratotic as they enlarge. The angiokeratomas of Fabry disease, referred to as angiokeratoma corporis diffusum, tend to be concentrated between the umbilicus and the knees but can develop at any cutaneous site (see Fig. 63.10); oral and conjunctival lesions are also seen. Less frequent vascular findings include linear telangiectasias favoring the face, lips, and oral mucosa; episodic acral vasospasm resembling Raynaud phenomenon, typically accompanied by pain and paresthesias; and peripheral edema and lymphedema[64,65]. Hypohidrosis is an early and almost constant feature of Fabry disease that can result in heat intolerance. Decreased body hair has also been described.

Histologically, angiokeratomas are composed of dilated capillaries in the uppermost dermis, partially enclosed by elongated rete ridges (see Ch. 114); hyperkeratosis may be seen in older lesions. In the skin, there is evidence of lipid storage in endothelial cells, pericytes, arteriolar smooth muscle, and arrector pili muscle. This can be detected by a lipid stain such as Sudan black B, or highlighted by periodic acid Schiff (PAS) staining. Lipid accumulation may also be observed in sweat gland epithelium (see Ch. 39) and perineural cells. Ultrastructural examination demonstrates characteristic cytoplasmic inclusions in all of these cell types.

The diagnosis of Fabry disease can be established by demonstration of deficient α-gal A activity in plasma, leukocytes, dried blood spots on filter paper, or cultures of amniocytes or chorionic villi obtained from prenatal testing. However, enzyme activity is within the normal range in up to a third of female heterozygotes. Molecular analysis of *GLA* can be helpful in: (1) determining disease status in females; (2) predicting disease severity in male patients via genotype–phenotype correlation; and (3) facilitating prenatal/preimplantation diagnosis and testing of at-risk family members[66,67]. Elevated plasma or urinary levels of globotriaosylsphingosine (lyso-Gb3), which correlate with disease severity, can confirm the diagnosis in individuals with a *GLA* variant of uncertain significance identified by genetic testing[61]. Although most commonly seen in association with Fabry disease, angiokeratoma corporis diffusum can also be observed in several other lysosomal storage disorders[68], as outlined in Table 63.7. Scrotal and vulvar angiokeratomas are also commonly found in older adults (see Ch. 114).

Enzyme-replacement therapy (ERT) with recombinant agalsidase-α or β is available (the latter FDA-approved) and is administered biweekly by intravenous infusion. Accumulated data indicate that it is effective in arresting progression of the disorder, especially when initiated early in the disease process. Current guidelines recommend considering ERT in all symptomatic patients, and at 7–10 years of age in asymptomatic boys with *GLA* pathogenic variants associated with classic disease[66,67,69]. Some authors recommend X-chromosome inactivation (XCI) analysis for asymptomatic girls ≥7 years of age and consideration of ERT in those with a skewed XCI pattern favoring expression of a *GLA* pathogenic variant that has been associated with classic disease[66]. Baseline assessment for organ involvement is also recommended by age 5 years and 12–15 years for asymptomatic boys and girls, respectively[66]. Controlled studies have found that treatment with migalastat, an oral pharmacologic chaperone that stabilizes specific mutant forms of α-galactosidase, may reduce renal glycosphingolipid accumulation, left ventricular hypertrophy, and gastrointestinal symptoms in Fabry disease patients with suitable mutations. Other interventions include gabapentin or carbamazepine for neuropathic pain and angiotensin-converting enzyme inhibitors to reduce proteinuria[61,70].

FUCOSIDOSIS

Key features

- Autosomal recessive disorder due to deficiency of α-fucosidase
- Multiple angiokeratomas of the skin and oral mucosa
- Extracutaneous findings include coarse facial features, dysostosis multiplex, and progressive mental and motor deterioration

Fig. 63.10 Angiokeratomas of Fabry disease. Multiple dark red to red–brown macules and papules located: (**A**) on the penis, an uncommon site for angiokeratomas in the general population, as well as on the scrotum; (**B**) on the lower trunk; and (**C, D**) in a more extensive "bathing trunk" distribution. *A,B, Courtesy Paula Luna, MD; C,D, Courtesy Edward Cowen, MD.*

Fucosidosis is a rare autosomal recessive lysosomal storage disorder resulting from pathogenic variants in *FUCA1*, which encodes the enzyme α-fucosidase. In the past, patients were classified into two groups: type I, a more severe form with onset in the first year of life; and type II, a milder form with onset in the second year or later. However, a continuous spectrum of severity is now recognized. The extracutaneous manifestations include coarse facial features, short stature, organomegaly, dysostosis multiplex, and neurologic deterioration with associated hypomyelination (see Fig. 63.9). Patients may also have corneal opacities, retinal vascular abnormalities, and frequent sinopulmonary infections[71].

Angiokeratomas virtually indistinguishable from those associated with Fabry disease are found in approximately one-third of fucosidosis patients <10 years of age and 85% of those 10–19 years of age. The lesions are distributed primarily on the trunk and lower extremities but can also develop within the mouth. Other reported cutaneous findings include telangiectasias, acrocyanosis, nevus anemicus, xerosis, and elevated sweat chloride levels[72]. The light microscopy findings of the angiokeratomas are similar to those seen in Fabry disease. Electron microscopic examination of clinically normal skin may reveal empty-appearing storage vesicles in endothelial cells, melanocytes, eccrine glands, and fibroblasts.

The diagnosis of fucosidosis is supported by demonstration of characteristic abnormalities on urine oligosaccharide analysis and established by an α-fucosidase assay utilizing leukocytes or cultured skin fibroblasts. Prenatal diagnosis is possible via enzyme analysis or genetic testing. There is no definitive treatment for fucosidosis, and the mortality rate is high, especially after the second decade of life. Hematopoietic stem cell transplantation has been attempted with some evidence of clinical improvement[73], and enzyme replacement therapy is under investigation in a canine model[71].

GAUCHER DISEASE

Key features

- Autosomal recessive disorder due to deficiency of glucocerebrosidase
- Extracutaneous findings include hepatosplenomegaly, bone disease, cytopenias, and highly variable neurologic manifestations
- Cutaneous manifestations of type 1 disease include yellow–brown pigmentation, easy tanning, and petechiae
- A subset of patients with type 2 (acute neuronopathic) Gaucher disease have ichthyosiform skin at birth

Gaucher disease is a relatively common autosomal recessive lysosomal storage disorder in which the glycolipid glucocerebroside accumulates as a result of a deficiency of the enzyme glucocerebrosidase (β-glucosidase). There are three clinical subtypes of the disorder, although the acute and chronic neuronopathic forms (types 2 and 3, respectively) are thought to exist on a continuum. Type 1 is by far the most common form of Gaucher disease and has a particularly high incidence of ~1 in 850 births in the Ashkenazi Jewish population.

Type 1 Gaucher disease is distinguished by a lack of primary involvement of the CNS, although Parkinson disease-like symptoms develop by the eighth decade of life in ~10% of affected individuals.

INHERITED METABOLIC DISORDERS ASSOCIATED WITH ANGIOKERATOMA CORPORIS DIFFUSUM				
Disorder	**Enzyme deficiency (gene)**	**Other clinical features**	**Inheritance pattern**	**Diagnostic tests***
Aspartylglucosaminuria	Aspartylglucosaminidase (*AGA*)	ID, coarse facial features, frequent respiratory infections	AR	Urine oligosaccharides; enzyme assay in leukocytes or fibroblasts
Galactosialidosis	β-Galactosidase and neuraminidase 1 secondary to a defect in cathepsin A (*CTSA*)	Coarse facial features, dysostosis multiplex, myoclonus, ataxia, neurologic deterioration, cherry-red macular spots	AR	Urine oligosaccharides; enzyme assay in leukocytes or fibroblasts
GM1 gangliosidosis	β-Galactosidase (*GLB1*)	Coarse facial features, dysostosis multiplex, neurologic deterioration, organomegaly, dermal melanocytosis	AR	Urine oligosaccharides; enzyme assay in leukocytes or fibroblasts
Fabry disease	α-Galactosidase A (*GLA*)	Pain and paresthesias of extremities, hypohidrosis, corneal and lenticular opacities, renal insufficiency, cardiac and cerebrovascular disease	X-L	Enzyme assay in plasma, monocytes or leukocytes
Fucosidosis	α-Fucosidase (*FUCA1*)	Coarse facial features, developmental regression, organomegaly, dysostosis multiplex	AR	Urine oligosaccharides; enzyme assay in leukocytes or fibroblasts
Kanzaki disease	α-*N*-Acetylgalactosaminidase (*NAGA*)	Highly variable, ranging from no other findings to lymphedema, hearing loss, and cardiomegaly; normal intelligence	AR	Urine oligosaccharides; enzyme assay in plasma or leukocytes
β-Mannosidosis	β-Mannosidase (*MANBA*)	ID, mild facial dysmorphism, hearing loss	AR	Urine oligosaccharides; enzyme assay in leukocytes or fibroblasts
Sialidosis	Neuraminidase [sialidase] 1 (*NEU1*)	Coarse facial features, dysostosis multiplex, ID, myoclonus, cherry-red macular spots	AR	Urine oligosaccharides and sialic acid; enzyme assay in fibroblasts

*Genetic testing is also available.

Table 63.7 Inherited metabolic disorders associated with angiokeratoma corporis diffusum. AR, autosomal recessive; ID, intellectual disability; X-L, X-linked (variable manifestations in female heterozygotes).

Presenting findings in type 1 may include hepatosplenomegaly, thrombocytopenia, anemia, and bone pain. The cutaneous manifestations of type 1 Gaucher disease are infrequent and relatively nonspecific[74]. They include diffuse brown or yellow–brown pigmentation of the skin and easy tanning. In addition, petechiae and ecchymoses may be observed due to the thrombocytopenia that results from infiltration of the bone marrow with glycolipid-filled macrophages (Gaucher cells) or from hypersplenism.

Type 2 Gaucher disease, the acute neuronopathic form of the disorder, is a severe and rapidly progressive condition that usually results in death before 2 years of age. Clinical manifestations develop within the first year of life and include hepatosplenomegaly, severe hypertonia, opisthotonus, oculomotor apraxia, and progressive neurologic deterioration. A subgroup of patients with this type of Gaucher disease presents at birth with a collodion baby phenotype or other ichthyosiform skin findings[75,76], suggesting that Gaucher disease should be considered in the differential diagnosis of congenital ichthyosis. Studies in a mouse model indicate that glucocerebrosidase is required to generate functionally competent membranes for normal epidermal barrier function. Electron microscopy of skin samples from patients with type 2 Gaucher disease, including those without clinically evident ichthyosis, shows immature lamellar membranes with characteristic electron-dense clefts[77]. The residual enzymatic activity present in patients with types 1 and 3 Gaucher disease is apparently adequate to protect them, since similar epidermal abnormalities are not observed in these forms. In fact, no specific cutaneous abnormalities have been described in patients with type 3 (chronic neuronopathic) Gaucher disease.

The diagnosis of Gaucher disease is established by demonstration of a glucocerebrosidase deficiency in leukocytes or cultured skin fibroblasts. Carrier detection is possible by genetic analysis, and prenatal diagnosis can be accomplished via chorionic villus sampling (CVS) or amniocentesis. Biomarkers with utility in determining prognosis and monitoring response to therapy include chitotriosidase, CC chemokine ligand 18 (CCL18), glucosylsphingosine, and ferritin[78]. There are two forms of specific treatment for Gaucher disease: (1) intravenous recombinant *enzyme-replacement therapy* for types 1 (when symptomatic) and 3; and (2) *substrate reduction therapy* with miglustat or eliglustat, inhibitors of glucosylceramide synthase, for type 1[78]. These treatments can improve organomegaly, hematologic abnormalities, and (to a variable degree) bone disease, but not the CNS manifestations of Gaucher disease.

HARTNUP DISEASE

Key features

- An autosomal recessive disorder associated with defective renal and intestinal neutral amino acid transport
- Marked aminoaciduria and tryptophan deficiency
- Typically presents with a pellagra-like dermatosis associated with photosensitivity
- Systemic manifestations include ataxia and tremors

Hartnup disease is an autosomal recessive disorder caused by pathogenic variants in *SLC6A19*, which encodes a transporter that mediates epithelial uptake of neutral amino acids in the kidneys and intestines[79]. The hallmark of the disorder is a specific hyperaminoaciduria due to diminished renal and intestinal reabsorption of neutral amino acids. Hartnup disease is one of the most common amino acid disorders, occurring in about 1 in 30 000 births. Most affected individuals, particularly those in high-income countries, remain asymptomatic throughout life, although symptoms can occur when exacerbating factors such as poor nutrition, celiac disease, or other causes of persistent diarrhea are present.

When clinical features develop, the most common finding is a recurrent photosensitive "pellagra-like" dermatosis[80]. This eruption is thought to be related to a relative niacin deficiency, as tryptophan is a precursor in niacin synthesis. It typically develops in children on exposed areas of the body and may initially resemble a sunburn or acute cutaneous lupus erythematosus. After the development of erythema following sun exposure, the affected skin becomes dry and scaly with well-defined margins; later findings include desquamation and hypo- or hyperpigmentation. The dermatosis is occasionally pruritic and blistering may occur; acrodermatitis enteropathica- and hydroa vacciniforme-like presentations have been described[80]. The second major manifestation of symptomatic Hartnup disease is intermittent ataxia, which may be accompanied by nystagmus and tremors. Psychiatric disturbances, developmental delay, and other neurologic abnormalities have been reported in some patients.

The diagnosis of Hartnup disease is established by urine amino acid analysis, which reveals markedly elevated levels of neutral amino

acids. In contrast, plasma levels of amino acids and niacin are typically normal, despite the clinical resemblance to pellagra. A high-protein diet or protein supplementation can help to prevent symptoms of Hartnup disease, and oral nicotinamide administration (50–300 mg/day) improves dermatologic and neurologic manifestations[80].

MITOCHONDRIAL DISORDERS

Synonyms: ■ Respiratory chain defects ■ Oxidative phosphorylation defects

Key features

- Marked phenotypic and genotypic heterogeneity
- 5%–10% of patients have pigmentary changes, alopecia, hypertrichosis, or hair shaft anomalies
- Myopathy, encephalopathy, cardiomyopathy, and visual impairment are frequent manifestations

Mitochondrial disorders represent a clinically and biochemically heterogeneous group of metabolic conditions characterized by impairment of the mitochondrial respiratory chain, which generates most of the adenosine triphosphate (ATP) required for cellular functioning[81]. The mitochondrial genome contains 37 genes and they encode subunits of the respiratory chain as well as the transfer and ribosomal RNAs (tRNAs and rRNAs) that translate mitochondrial DNA (mtDNA). However, some of the genes that encode respiratory chain components and other mitochondrial proteins are encoded by nuclear DNA. Mitochondrial disorders can therefore result from either maternal inheritance of mtDNA mutations or Mendelian inheritance of nuclear DNA mutations. The respiratory chain is organized into five enzyme complexes (I–V), the activity of which can be measured in muscle or other tissues to aid in the diagnosis of mitochondrial disorders. Although some mitochondrial syndromes are characterized by a particular constellation of clinical findings, there is often poor correlation between the enzyme complex involved and the clinical phenotype.

Mitochondrial disorders can present at any age and may potentially affect any organ system, but with a predilection for cells with high energy requirements such as neurons and muscle[81]. Common manifestations include developmental delay, seizures, stroke, weakness, hypotonia, and cardiomyopathy. Visual impairment, hearing loss, proximal renal tubular defects, hepatic dysfunction, poor growth, and fatigue are other frequent findings. The clinical course and progression are highly variable, even in patients with similar biochemical abnormalities[82].

A wide range of hair and skin abnormalities has been described in association with mitochondrial disorders (Table 63.8)[83]. These manifestations have been reported in about 5%–10% of patients with documented mitochondrial disorders and may develop early in the disease course. When such findings are noted in conjunction with seemingly unrelated abnormalities in other organ systems, the possibility of a mitochondrial disorder should be considered.

Biochemical and/or molecular genetic confirmation of the diagnosis of a mitochondrial disorder is rarely straightforward. Measurement of plasma lactate, plasma amino acids, and urine organic acids can be helpful in assessing mitochondrial function. Other components of the evaluation may include exercise testing, neuroimaging, muscle biopsy for histologic/histochemical evaluation, assays of respiratory chain enzyme complexes in muscle tissue or cultured skin fibroblasts, and genetic analysis[81].

Treatment of patients with mitochondrial disorders is largely symptomatic. A variety of dietary modifications have been tried and may be helpful for some patients. Coenzyme Q_{10}, L-carnitine, resveratrol, curcumin, sulforaphane, and riboflavin supplementation may also have some benefit.

CUTANEOUS MANIFESTATIONS OF MITOCHONDRIAL RESPIRATORY CHAIN DISORDERS
• Alopecia
• Hair shaft abnormalities – trichoschisis, pili torti, longitudinal grooving, trichorrhexis nodosa, trichothiodystrophy
• Hypertrichosis
• Absent or excessive sweating
• Pigmentary abnormalities – mottled or reticulated pigmentation
• Palmoplantar keratoderma (linked with deafness)
• Hypoplastic nails
• Lipomas
• Acrocyanosis
• Linear skin defects on the face and neck

Table 63.8 Cutaneous manifestations of mitochondrial respiratory chain disorders.

ACID SPHINGOMYELINASE DEFICIENCY (NIEMANN–PICK DISEASE)

Key features

- An autosomal recessive disorder due to deficiency of acid sphingomyelinase
- Rare skin involvement in type A consists of yellow–brown discoloration and facial papules
- Failure to thrive, hepatosplenomegaly, and neurologic deterioration occur in type A
- Minimal neurologic involvement and milder disease characterize type B

This is an autosomal recessive lysosomal storage disorder caused by acid sphingomyelinase deficiency, which results in the accumulation of sphingomyelin and other phospholipids[84]. There are two classic forms: type A, with an incidence of 1 in 40 000 births in the Ashkenazi Jewish population; and type B, with a lower incidence and no specific ethnic predilection. Type A (*infantile neurovisceral*) is a severe disorder associated with failure to thrive, hepatosplenomegaly, thrombocytopenia, and rapid neurologic degeneration leading to death by 2–3 years of age; cherry-red retinal spots are evident in ~50% of patients. Type B (*chronic visceral*) is characterized by little or no neurologic involvement, later onset, and survival into adult life. Progressive pulmonary infiltration may occur in either subtype, and the disease spectrum includes a *chronic neurovisceral* phenotype with intermediate severity (type A/B). Type C, which has primarily neurologic findings, results from defects in other genes (*NPC1* > *NPC2*) and is associated with an accumulation of unesterified cholesterol.

Cutaneous manifestations are typically observed only in patients with type A disease. The skin may exhibit a generalized ochre or brownish-yellow discoloration. Papular lesions, most commonly located on the face and upper extremities, may also be present. Histologically, these papules consist of foamy histiocytes, multinucleated cells, and a variable infiltrate of lymphocytes.

Diagnosis of type A or B disease is established by demonstration of deficient sphingomyelinase activity in leukocytes or cultured skin fibroblasts, or via molecular genetic analysis. Carrier detection for type A can also be performed via genetic testing, and prenatal diagnosis is available by CVS or amniocentesis. In recent clinical trials, recombinant enzyme-replacement therapy with olipudase-α has shown promising results for the non-neurologic manifestations of types A/B and B[85]. Treatment approaches utilizing gene therapy, molecular chaperones, and anti-inflammatory agents are also under investigation[84]. Lastly, hematopoietic stem cell transplantation may improve the non-neurologic features, but treatment-related complications limit its use[84].

PHENYLKETONURIA

Key features

- Autosomal recessive disorder due to a deficiency of phenylalanine hydroxylase
- Pigmentary dilution of the skin, eyes, and hair
- Atopic-like dermatitis and sclerodermatous skin changes
- Progressive developmental delay with severe intellectual disability if not treated

Fig. 63.11 Phenylketonuria (PKU). Infant with PKU and sclerodermoid skin changes. *Courtesy New York Medical College.*

Phenylketonuria (PKU) is one of the most common inborn errors of metabolism, occurring worldwide with an incidence of ~1 in 10 000 births. It is an autosomal recessive disorder resulting from a deficiency of the enzyme phenylalanine hydroxylase that is responsible for conversion of phenylalanine to tyrosine. As a result of this enzyme deficiency, phenylalanine levels rise in blood and tissues of the untreated patient on a phenylalanine-containing diet, and high levels of this amino acid are extremely toxic to the CNS. Progressive developmental delay ultimately leads to severe intellectual disability and may be accompanied by seizures, behavioral problems, and psychiatric symptoms[86].

In patients with PKU, a relative deficiency of tyrosine and/or competitive inhibition of tyrosinase by excess L-phenylalanine leads to diminished melanin production and resultant diffuse pigmentary dilution. The classic patient is described as blond and blue-eyed, although pigmentation varies depending on the family and ethnic background. Sweat with a musty or "mousy" odor can represent a clue to the diagnosis. Nonspecific dermatitis occurs with increased frequency, and early-onset atopic dermatitis affects up to half of patients with PKU. Progressive scleroderma-like skin changes that favor the proximal extremities may also be observed, often with an onset in the first year of life[87] (Fig. 63.11). This is in contrast to the acral predilection and older age of onset in systemic sclerosis.

Newborn screening for PKU is routinely performed in many countries, and the diagnosis is established by plasma amino acid analysis. Identification of affected infants at birth with early institution of a phenylalanine-restricted diet and careful control of blood phenylalanine levels prevents the development of skin changes and intellectual disability, although subtle neurocognitive consequences may be observed. Unfortunately, untreated patients are still encountered among children from low-income countries, and despite recommendations that dietary therapy be continued for life, some adolescents and adults do not adhere to the dietary restrictions, which may result in recurrent dermatologic manifestations. Dietary therapy involves not only restriction of phenylalanine, but also special medical foods containing phenylalanine-free protein substitutes. Close monitoring by an experienced nutritionist is vital. Enzyme substitution therapy with pegvaliase, a PEGylated recombinant phenylalanine ammonia lyase administered by subcutaneous injection, has been FDA-approved for adults with uncontrolled elevation of blood phenylalanine levels[88].

PREMATURE AGING SYNDROMES AND POIKILODERMAS

Bernard A. Cohen

The study of rare progeroid syndromes has led to better understanding of the normal aging process. Distinct progeroid disorders are differentiated by their time courses, associated clinical findings, and biochemical and genetic markers (Table 63.9). Inherited congenital and childhood poikilodermas, including Kindler syndrome (see Ch. 32), can also demonstrate features associated with aging and may be considered in the differential diagnosis of progeroid syndromes (Fig. 63.12).

HUTCHINSON–GILFORD PROGERIA SYNDROME

Synonyms: ■ Progeria ■ Hutchinson–Gilford syndrome

Key features

- Rare, occurring in 1 in 4 to 8 million births
- Due to mutations in *LMNA*, which encodes nuclear lamins A and C
- Normal motor and mental development
- Characteristic facies with prominent scalp veins and a beaked nose
- Wrinkled as well as scleroderma-like skin, alopecia, and poor growth
- Generalized atherosclerosis with premature death from cardiovascular and cerebrovascular disease at a median age of 14 years
- Lonafarnib, an oral farnesyltransferase inhibitor that reduces the accumulation of farnesylated mutant prelamin A ("progerin"), is an FDA-approved therapy

Introduction

Hutchinson–Gilford progeria syndrome (HGPS) is a genetic disease characterized by accelerated aging that begins during infancy[89,90]. The term "progeria" originates from the Greek word for old age, "*geras*", and was proposed by Gilford when he delineated the clinical features and course of the disorder in 1904.

History

The syndrome was first reported in 1886 by Jonathan Hutchinson, with Hastings Gilford subsequently documenting the postmortem features. In 2003, mutations in the gene that encodes lamin A were first described[90,91].

Epidemiology

HGPS is estimated to occur in 1 in 4 to 8 million births, with an overall prevalence of ~1 in 20 million people[89,92,93]. The male : female ratio is 1.2 : 1[93], and it has been reported worldwide in patients with a wide variety of ethnic backgrounds.

In the 64 cases reviewed by DeBusk[89], median and mean paternal ages were advanced, consanguinity was uncommon, and the abortion

PROGEROID SYNDROMES AND INHERITED POIKILODERMAS					
	Hutchinson–Gilford progeria syndrome	**Werner syndrome**	**MDPL syndrome**	**Penttinen syndrome**	**Néstor–Guillermo progeria syndrome**
Inheritance/gene (if known)	Sporadic AD/*LMNA*	AR/*WRN (RECQL2)* Atypical variant – AD/*LMNA*	AD/*POLD1*	AD/*PDGFRB*	AR/*BANF1*
Gender ratio	M : F = 1.2 : 1	M = F	M = F	M = F	M = F
Onset	First year	Second decade	Childhood	Infancy to childhood	Third year
Stature	Short stature, low weight for height	Short stature, central obesity	Short to normal stature, central obesity	Normal	Short stature
Facial features	Prominent scalp veins and eyes, perioral cyanosis, frontal bossing, micrognathia, thin beaked nose, small mouth, thin lips	Thin beaked nose, prominent eyes, circumoral furrows, protuberant teeth, micrognathia	Thin beaked nose, prominent eyes, protuberant teeth, micrognathia	Malar hypoplasia with retracted maxilla, pseudoprognathism, proptosis, flat occiput	Prominent scalp veins and eyes, micrognathia, thin nose, midfacial hypoplasia, thin lips
Cutaneous features	Dryness, wrinkling, scleroderma-like tautness, mottled hyperpigmentation, loss of subcutaneous fat	Atrophy (epidermal, dermal, subcutaneous), mottled hyperpigmentation, scleroderma-like tautness, keratoses and ulcers over pressure points, subcutaneous calcifications	Atrophy with lack of subcutaneous fat, telangiectasias, scleroderma-like tautness, keratoses and ulcers over pressure points	Lipoatrophy, thin translucent skin, hypertrophic scar-like lesions over pressure points	Atrophy with generalized lack of subcutaneous fat, mottled hyperpigmentation, red swollen skin on phalanges
Nails	± Dystrophy, hypoplasia	± Dystrophy	Normal	Normal or loss related to acro-osteolysis	Dystrophy
Scalp hair	Thin and lightly pigmented, progressing to diffuse alopecia	Premature canities, thinning over time	± Premature canities and thinning over time	Thin and sparse	Progressive alopecia during late childhood
Musculoskeletal	Thin with narrow thorax, prominent joints, thoracic kyphosis, coxa valga, short clavicles	Spindly extremities, osteoporosis, osteosclerosis of phalanges	Thin extremities, muscle wasting, osteopenia, joint contractures	Thin extremities, acro-osteolysis, broad thumbs and halluces, kyphoscoliosis	Marked acro-osteolysis, resorption of mandible and clavicles, severe osteoporosis, scoliosis
Metabolic/ malignancy	Growth failure, insulin resistance	Lack of growth spurt at puberty; diabetes mellitus; increased risk of sarcomas, thyroid carcinomas, melanomas	Diabetes mellitus, hyperlipidemia	None	None
Cardiovascular	Premature atherosclerosis, myocardial fibrosis	Premature atherosclerosis, calcified aortic valve	Normal	Normal	Normal
Prognosis	Average survival 12 years	Average survival ~50 years	Normal lifespan expected	Survival into adulthood	Survival into early adulthood
Other	High-pitched voice, delayed and abnormal dentition, large open anterior fontanelle, sparse or absent eyebrows and eyelashes	Bilateral cataracts (99%), high-pitched voice, hypogonadism	Sensorineural hearing impairment, high-pitched voice, dental crowding, hypogonadism in males	Corneal clouding, ocular pterygia, delayed dentition	Delayed closure of anterior fontanelle

*Acrogeric phenotypes also occur in vascular Ehlers–Danlos syndrome, which is caused by mutations in the gene encoding type III collagen, and in progeroid laminopathies due to LMNA mutations (see Table 63.10).

Table 63.9 Progeroid syndromes and inherited poikilodermas. Disorders featuring poikiloderma are shaded. Hereditary fibrosing poikiloderma with tendon contractures, myopathy, and pulmonary fibrosis results from heterozygous mutations in *FAM111B*. Variants of cutis laxa and Ehlers–Danlos syndrome with progeroid features are discussed in Chapter 97 and ataxia–telangiectasia is covered in Chapter 60. Other rare progeroid conditions include Wiedemann–Rautenstrauch (neonatal progeroid), Hallermann–Streiff, Lenz–Majewski, Fontaine progeroid, Marbach–Rustad progeroid, Ruijs–Aalfs, and SHORT (*s*hort stature, *h*yperextensibility, hernia, *o*cular depression, *R*eiger anomaly [dysgenesis of cornea and iris], and *t*eething delay) syndromes (www.ncbi.nlm.nih.gov/omim). AD, autosomal dominant; AR, autosomal recessive; *ANAPC1*, anaphase promoting complex subunit 1; *BANF1*, barrier-to-autointegration factor 1; *FERMT1*, fermitin family homolog 1; MDPL, *m*andibular hypoplasia, *d*eafness, *p*rogeroid features, and *l*ipodystrophy; *PDGFRB*, platelet-derived growth factor receptor β gene; *POLD1*, DNA polymerase δ 1; PPK, palmoplantar keratoderma; SCC, squamous cell carcinoma; *USB1*, U6 snRNA biogenesis 1.

Acrogeria (Gottron syndrome)*	Metageria	Kindler syndrome (see Ch. 32)	Cockayne syndrome (see Ch. 87)	Rothmund–Thomson syndrome (see Ch. 87)	Poikiloderma with neutropenia, Clericuzio type ("Navajo poikiloderma")
AD, AR	AR	AR/*FERMT1* (*KIND1*)	AR/*ERCC8 (CSA), ERCC6 (CSB)*	AR/*RECQL4*, AR/*ANAPC1*	AR/*USB1*
F > M	M = F	M = F	M = F	M = F	M = F
Birth	Birth	Birth	After first year	First year	First year
Normal	Tall, thin	Normal	Dwarfism, low weight for height	Short stature	Short stature
Micrognathia, thin nose with atrophic tip, proptosis	Beaked nose, prominent eyes	Normal	Sunken eyes due to periorbital fat atrophy; senile "bird-like" facies, beak-like nose, prognathism	Frontal bossing, saddle nose, prognathism	Midfacial hypoplasia
Poikiloderma, marked skin atrophy on hands and feet, easy bruising, prominent veins on trunk	*Poikiloderma* with mottled hyperpigmentation, atrophy on extremities, rarely leg ulcers	Congenital acral blistering and photosensitivity; later *poikiloderma*, atrophy, acral hyperkeratosis; occasional eczematous dermatitis	At presentation: acute photosensitivity, healing with hyperpigmentation; later: wrinkling, loss of subcutaneous fat, *poikiloderma*	At presentation: acute eruption with erythema and edema, especially on face, ± photosensitivity; later: *poikiloderma* (Fig. 63.12), acral keratoses	At presentation: erythematous papular or ichthyosiform dermatitis on the extremities and face, ± photosensitivity; later: evolution to *poikiloderma*, PPK, keratotic papules on face and forearms, calcinosis cutis, skin infections and ulcers
Dystrophy, thickening	Normal	± Dystrophy	± Dystrophy	± Dystrophy	Dystrophy (especially first toenails) with subungual hyperkeratosis (pachyonychia-like)
Normal	Fine and thin	Normal	Dry, thin; premature canities	Fine and thin, alopecia	± Thin hair
Short phalanges, acro-osteolysis	Generalized loss of subcutaneous fat	Webbing of the fingers, toes	Long limbs, disproportionately large hands and feet, joint contractures, microcephaly	Radial ray defects, metaphyseal chondrodysplasia, delayed bone formation	Normal
None	Early-onset diabetes mellitus	Possible increased malignancy risk	Cellular sensitivity to sunlight and defective DNA repair, but no increase in neoplasia	Increased risk of malignancy, especially osteosarcoma and SCC (often acral)	Myelodysplasia/ myelodysplastic syndrome; cutaneous SCC (reported in adolescents)
Normal	Premature atherosclerosis	Normal	Normal	Normal	Normal
Normal lifespan	Depends on severity of diabetes and atherosclerosis	Normal lifespan	Death by age of 30 years from neurologic degeneration	Normal to shortened life expectancy (if malignancy)	Normal lifespan
		Mucous membrane involvement with stenoses (e.g. urethral), ectropion and erosive gingivitis resulting in poor dentition	Optic atrophy, deafness, unsteady gait, demyelination	Cataracts, hypogonadism, hypodontia	Neutropenia, recurrent sinopulmonary infections, lacrimal duct obstruction, carious teeth, hypogonadism, ± developmental delay

rate in affected families was normal. These observations favored a *de novo* dominant mutation, which was later confirmed by genetic studies (see below). Since HGPS patients usually do not become sexually mature and typically succumb to the disease early in the second decade of life, familial occurrence is rare; however, it can occur in the setting of gonadal mosaicism[93]. Consanguineous families with autosomal recessive variants of HGPS have been described, but additional clinical features such as clavicular aplasia/hypoplasia in affected individuals suggest an overlap with mandibuloacral dysplasia, which is caused by biallelic mutations in *LMNA* (Table 63.10)[94,95].

Pathogenesis

The vast majority of patients with both classic and atypical forms of HGPS have a *de novo* heterozygous point mutation that affects splicing of the lamin A gene (*LMNA*)[90,96]. This gene encodes two protein products, lamin A and lamin C, that represent major components of the nuclear membrane lamina and contribute to the structural scaffolding of the nucleus. *Classic HGPS* (80%–90% of affected individuals) is caused by a particular mutation, c.1824C>T, which activates a cryptic splice site within exon 11 and leads to an internal deletion of 50 amino acids. This deletion includes a cleavage site that is necessary for the conversion of prelamin A to mature lamin A[97] (Fig. 63.13). As a result, the cells contain a dominant-mutant prelamin A ("progerin") that disrupts the nuclear scaffolding. In the patients' cells, including lymphocytes and fibroblasts, there is evidence of altered nuclear sizes and shapes, as well as lobulation of the nuclei, extrusion of chromatin, and nucleolar alterations. Such structural changes result in functional defects such as abnormal DNA damage repair, mitochondrial impairment and aberrant cell-cycle regulation, which lead to premature aging[98].

Other heterozygous progerin-producing *LMNA* mutations cause either *atypical HGPS* with clinical findings similar to classic HGPS or *autosomal dominant progeroid laminopathies* with distinct phenotypes that share some features with HGPS (see Table 63.10). The severity of these disorders correlates with the ratio of progerin to lamin A, and extremely high progerin levels have been associated with neonatal-onset progeria and death in the first few years of life[99]. In families with *autosomal recessive progeroid laminopathies*, including the *progeria–mandibuloacral dysplasia overlap syndromes*, biallelic mutations in *LMNA* may affect both lamin A and C, disrupting interactions with nuclear proteins[94,95].

Other cellular and molecular changes that contribute to the pathogenesis of HGPS include altered epigenetic regulation and gene expression, shortened telomeres, and increased cellular senescence[98]. Of note, progressively decreasing telomere length is seen with normal aging and is associated with progerin production and low levels of telomerase activity[100]. In a telomerase knockout mouse model (see Ch. 4), some clinical features of accelerated aging have also been observed. Additional abnormalities associated with the normal aging process, such as insulin resistance and decreased survival of fibroblast cultures, are seen in patients with HGPS.

Clinical Features

HGPS is a multisystem disease with prominent involvement of the skin, bones, skeletal muscle, adipose tissue, and cardiovascular structures. Although affected children usually appear normal at birth, growth failure and other clinical features typically appear rather abruptly during the first year of life[89,91,93,101]. Weight gain is very slow, with marked loss during episodes of illness. Linear growth proceeds at half the normal pace and does not undergo the normal acceleration around puberty. Sexual maturation is absent in most patients, and affected individuals have both short stature and a low weight for height.

At birth or during early infancy, patients may have thick, inelastic, scleroderma-like skin, usually on the lower abdomen, flanks, thighs, and buttocks. Following the onset of growth failure, the skin becomes thin and dry, with less hair than normal. Some areas may appear taut and shiny, whereas others (especially the fingers and toes) lax and wrinkled. Infantile fat is rapidly lost with the onset of growth failure, resulting in prominent superficial veins and the appearance of perioral cyanosis. As the aged appearance progresses, irregular brown pigmentation becomes evident in sun-exposed areas.

NUCLEAR ENVELOPATHIES	
Primary feature and associated diseases	**Inheritance**
Laminopathies – due to mutations in the *LMNA* gene which encodes the lamin A and C proteins of the nuclear membrane lamina*	
Premature aging and/or cutaneous sclerosis	
Hutchinson–Gilford progeria syndrome (classic and atypical)	AD
Restrictive dermopathy†	AD > AR
"Atypical Werner syndrome"	AD
Other progeroid laminopathies	AD > AR
Skeletal dysplasia and/or arthropathy	
Mandibuloacral dysplasia†	AR
Arthropathy, tendinous calcinosis and progeroid features	AR
Lipodystrophy‡	
Familial partial lipodystrophy, type 2 (Dunnigan type)	AD
Muscular dystrophy	
Emery–Dreifuss muscular dystrophy	AD > AR
LMNA-related congenital muscular dystrophy	AD
Early-onset myopathy with progeroid features	AD
Cardiomyopathy	
Dilated cardiomyopathy type 1A	AD
Heart–hand syndrome	AD
Dilated cardiomyopathy with hypergonadotrophic hypogonadism	AD
Neuropathy	
Charcot–Marie–Tooth type 2B1	AR
Cutaneous disorders with inner nuclear membrane dysfunction – due to mutations in the *LEMD3* gene, whose protein product associates with lamin A	
Cutaneous sclerosis and/or skeletal dysplasia	
Buschke–Ollendorff syndrome	AD
Osteopoikilosis	AD
Melorheostosis	Type 2 segmental¶

*Heterozygous mutations in the *LMNB2* gene, which encodes the lamin B2 protein of the nuclear membrane lamina, can cause "acquired" partial lipodystrophy (Barraquer–Simons syndrome).
†Can also result from recessive mutations in the *ZMPSTE24* gene, which encodes a zinc metalloproteinase involved in the processing of prelamin A into mature lamin A (see Fig. 63.13); mandibuloacral dysplasia often presents with progeroid features and lipodystrophy.
‡Generalized lipodystrophy with pubertal onset and features that overlap with atypical Werner syndrome has also been described; whitish, fibrotic papules on a background of diffuse hyperpigmentation represent an additional finding in some of these patients.
¶Germline heterozygous mutation (resulting in Buschke–Ollendorff syndrome or osteopoikilosis) with a presumed second hit in area of melorheostosis.

Table 63.10 Nuclear envelopathies. Entities in this heterogeneous group of genetic disorders share the common findings of cutaneous fibrosis and bone dysplasia. Néstor–Guillermo progeria syndrome (see Table 63.9) is also characterized by abnormalities in the nuclear membrane lamina; this autosomal recessive disorder results from mutations in the barrier-to-autointegration factor 1 gene (*BANF1*), which encodes a protein that interacts with prelamin A (and progerin). AD, autosomal dominant; AR, autosomal recessive.

At the onset of growth failure, patients begin to develop characteristic facial features, including a disproportionately large cranium, frontal bossing, a large open anterior fontanelle, pronounced scalp veins, prominent eyes due to relatively slow growth of the facial bones, a thin beaked nose with a sculpted appearance, and micrognathia. The facial stigmata tend to become marked by age 2 to 3 years, giving a "plucked-bird" appearance.

Alopecia develops during the first year of life and becomes diffuse and generalized, with later hair growth tending to be fine and lightly pigmented. Eyebrows and eyelashes are often sparse or absent. Although the nails may be normal, dystrophy in the form of small, short and

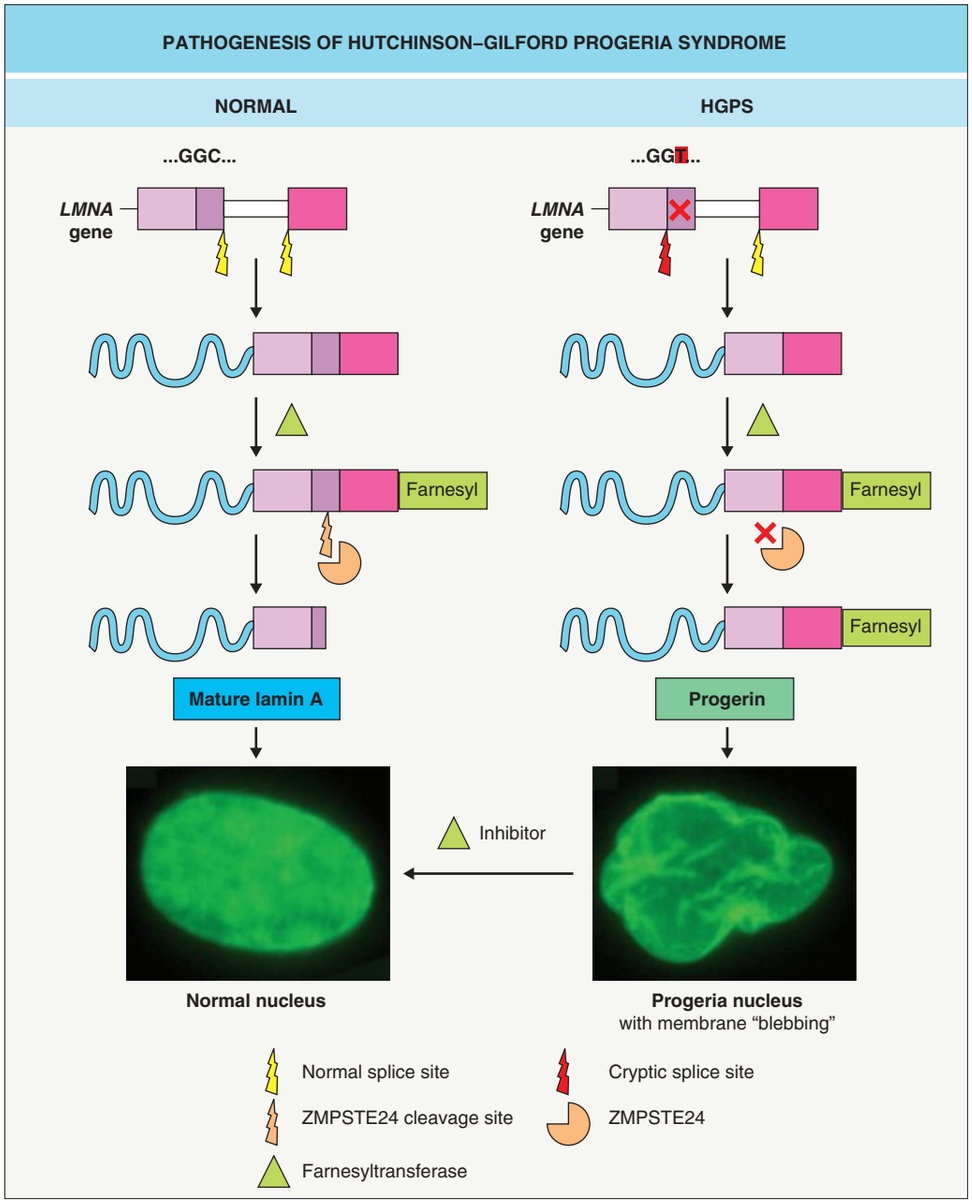

Fig. 63.13 Pathogenesis of Hutchinson–Gilford progeria syndrome (HGPS). Patients with classic HGPS have a C-to-T point mutation that activates a cryptic splice site and leads to an internal in-frame deletion of 50 amino acids. Because the deleted region includes a cleavage site for the ZMPSTE24 zinc metalloproteinase, removal of a farnesylated and methylated portion of prelamin A by this enzyme in order to produce mature lamin A does not occur in HGPS patients. Mutant "progerin" therefore remains farnesylated and, as a result, anchored to the nuclear membrane, where it disrupts nuclear scaffolding and causes blebbing. Administration of farnesyltransferase inhibitors can prevent this disruption of nuclear structure and function by progerin. Of note, *ZMPSTE24* mutations underlie some human cases of restrictive dermopathy and mandibuloacral dysplasia (see Table 63.10).

thin nails is common. Marked delay in the eruption of primary and secondary dentition has also been noted in most patients. Teeth may be crowded, rotated, overlapped and maloccluded, and the voice tends to be high-pitched and piping.

Truncal features include a narrow pyriform thorax, shoulders with thin and short clavicles, and prominent thoracic kyphosis giving a stooped appearance. Prominence of the abdomen (relative to the chest) and hypoplastic nipples also contribute to the distinctive habitus. The limbs are usually proportionate and become progressively thinner with increasing prominence of the joints, especially the knees, elbows, and small joints of the hand. Coxa valga is usually present by age 2 to 3 years and, in combination with increasing joint stiffness, contributes to a wide-based gait.

Patients are of normal intelligence and may be self-conscious about their appearance. Early onset of progressive coronary and cerebral atherosclerosis results in a median lifespan of approximately 14 years[102,103]. Other complications include osteopenia, low-frequency conductive hearing loss, corneal dryness, and hyperopia[91]. Although mild insulin resistance occurs in up to half of patients, overt diabetes mellitus is rare.

Pathology and Laboratory Findings

Cutaneous histopathology varies with the site and the age of the patient, and it is usually not helpful in diagnosing the condition[104,105]. The epidermis is fairly normal with minimal hyperkeratosis and a slight increase in melanin in the basal cell layer. Although dermal elastic tissue is normal, dermal collagen tends to be thickened and hyalinized. Adnexal structures are normal or decreased in density and arrector pili muscles are usually prominent.

Radiographic findings include hypoplasia of the facial bones, thinned cranial bones, open fontanelles, and hypoplasia of the mandible with crowding of the teeth. Progressive resorption of bone from the distal phalanges of the fingers and toes is also characteristic, but not diagnostic, of HGPS.

Differential Diagnosis

The differential diagnosis is outlined in Table 63.9 and includes Werner syndrome, "atypical Werner syndrome", Néstor–Guillermo progeria syndrome, metageria, and acrogeria[106]. In contrast to HGPS, patients with Werner syndrome have premature canities, cataracts, and an increased incidence of malignancy. HGPS should also be distinguished from the following disorders: Cockayne syndrome (Ch. 87), Rothmund–Thomson syndrome (Ch. 87), ataxia–telangiectasia (Ch. 60), Kindler syndrome (Ch. 32), Wiedemann–Rautenstrauch syndrome (neonatal progeroid syndrome), and forms of Ehlers–Danlos syndrome and cutis laxa with progeroid features (Ch. 97). Lastly, clinical overlap may be seen with other disorders that are due to mutations in *LMNA*, such as early-onset myopathy with progeroid features, restrictive dermopathy (Ch. 34), and mandibuloacral dysplasia (see Table 63.10).

Treatment

Management is directed toward the prevention and treatment of complications, particularly cardiovascular, cerebrovascular, and musculoskeletal. Regular cardiovascular monitoring is recommended and low-dose aspirin may be of benefit. No dietary regimen has been shown to alter the disease course. Although growth impairment in HGPS is not typically related to growth hormone deficiency, administration of exogenous growth hormone may increase weight and, to a lesser degree, height. Physical and occupational therapy can help to maintain joint mobility, and patients and families may benefit from psychological and genetic counseling.

Because farnesylation of the dominant-mutant progerin form of prelamin A causes it to be anchored to the nuclear membrane, thereby disrupting nuclear structure (see Fig. 63.13), inhibitors of farnesylation were identified as a potential treatment for HGPS. Initial studies found that administration of farnesyltransferase inhibitors (FTIs) restored normal nuclear morphology to human HGPS fibroblasts *in vitro*, and these inhibitors improved body weight, bone density, strength, and survival in mouse models of progeria[97,107]. Additional investigation in mouse models showed benefit from treatment with the combination of a bisphosphonate and statin, which inhibit farnesyl pyrophosphate synthase and HMG-CoA reductase, respectively. Each of these enzymes functions in the protein prenylation pathway essential to both farnesylation and the alternative pathogenic geranylgeranylation that occurs in the setting of FTI monotherapy.

Treatment of HGPS patients with the FTI lonafarnib, either alone or together with the bisphosphonate zoledronate and pravastatin, has been shown to result in small but significant increases in survival[102,108]. Mechanistic target of rapamycin (mTOR) inhibitors (e.g. sirolimus, everolimus) increase autophagic degradation of progerin[109], and a clinical trial investigating the combination of everolimus and lonafarinib is underway. Antisense oligonucleotides that reduce progerin transcript and protein levels were recently shown to partially rescue the cardiovascular phenotype and increase lifespan in an HGPS transgenic mouse model[110]. Other possible therapies being explored include inhibition of progerin–lamin A binding with the small molecule progerinin, inhibition of isoprenylcysteine carboxyl methyltransferase to mislocalize progerin away from the nuclear rim, vitamin D to potentially reduce progerin production, remodelin to inhibit N-acetyltransferase-10 and rescue nuclear shape, tocilizumab to reduce oxidative stress by neutralizing interleukin-6, and inhibition of the NLRP3 inflammasome[111–114]. Lastly, gene correction via base editing or CRISPR/Cas9-based methods is being investigated in HGPS mouse models[115,116].

WERNER SYNDROME

Synonym: ■ Progeria of the adult

Key features

- Occurs in 1 in 1 million births, with a higher incidence in Japan
- Autosomal recessive disorder due to mutations in *WRN (RECQL2)*, which encodes a DNA helicase
- Premature aging with the appearance of canities, cataracts, osteoporosis, diabetes mellitus, and atherosclerosis during the second decade
- Additional features include sclerodermoid changes, keratoses and ulcerations over bony prominences, short stature, and vascular and soft tissue calcification
- Similar facies to progeria patients, with a pinched appearance and micrognathia
- Increased risk of meningiomas, sarcomas, and (particularly in Japanese patients) thyroid carcinomas and melanomas

Introduction

Werner syndrome is a genetic disorder of accelerated aging with an onset in the second decade of life. This rare progeroid syndrome has a higher incidence in certain populations in Japan[117–121]. Although it is often referred to as progeria of the adult, Werner syndrome has some distinctive clinical findings not normally associated with aging, such as hypogonadism, laryngeal atrophy, and osteosclerosis of the distal extremities[117–120]. The discovery of underlying mutations in *WRN (RECQL2)* has allowed investigation into the molecular aspects of Werner syndrome[118].

History

In 1904, Otto Werner described a family with two brothers and two sisters between the ages 36 and 40 years who displayed clinical features of premature aging. In 1934, Oppenheimer and Kugel reported two similar cases and established the eponym Werner syndrome.

Epidemiology

Werner syndrome is a rare autosomal recessive disorder with an overall incidence of 1 in 1 million births. However, its incidence in Japan is higher and may approach 1 in 3500 in some communities owing to high rates of consanguinity. It was the study of several large Japanese families that led to identification of the gene responsible for this disorder[120]. Werner syndrome has been reported in all races and affects both sexes equally.

Pathogenesis

Werner syndrome is caused by mutations in *WRN (RECQL2)*, which encodes a homolog of the *Escherichia coli* RecQ DNA helicase. Almost all of the mutations identified to date predict a truncated protein, and over half of Japanese patients are homozygous for a specific splice-site mutation[118,122].

The Werner protein (WRN) has both exonuclease and helicase activities, and it plays a role both in optimizing DNA repair, particularly via base excision, and in suppressing illegitimate recombination. Therefore, loss of WRN activity results in genomic instability. The accumulation of senescent cells with decreasing replicative capacity and an increasing number of mutations is thought to lead to the clinical findings of premature aging and an increased risk of malignancy. Decreased heterochromatin stability is also thought to play a role in the accelerated cellular senescence of Werner syndrome as well as physiologic aging[123]. Loss of function of *WRN* may occur in the normal population as a function of age[118].

A subset of patients have "atypical Werner syndrome" and lack pathogenic changes in *WRN*. Rather, they have heterozygous missense mutations in *LMNA* (see HGPS section) that affect the heptad repeat region and are predicted to interfere with protein–protein interactions[124]. Compared to patients with *WRN* mutations, those with atypical Werner syndrome tend to have an earlier onset of disease and more severe age-related manifestations. Atypical Werner syndrome might therefore be better classified as a late-onset form of HGPS.

Clinical Features

In most affected individuals, growth progresses normally until the beginning of the second decade, when short stature and thin limbs become noticeable. Graying of the hair may first appear during childhood but characteristically develops in late adolescence or the early twenties, often accompanied by hair thinning. While other findings of Werner syndrome typically become evident during the second and third decades of life[117–120], diagnosis is often delayed until the fourth or fifth decade[125].

The typical patient is short, with an average height of 5 ft (1.5 m), and has spindly limbs but central obesity. The hands and feet are small, and the face is thin with a pinched appearance, prominent eyes, a beaked nose, circumoral radial furrows, taut lips, protuberant teeth, and micrognathia (Fig. 63.14). The voice is high-pitched and raspy.

Cutaneous changes include atrophy (epidermal, dermal and subcutaneous), scale, mottled hyperpigmentation, and tightness reminiscent of scleroderma. These findings are most prominent on the face, forearms, hands, legs, and feet. Nails may be dystrophic, hypoplastic, or absent, and plantar hyperkeratosis is common. Thick keratoses

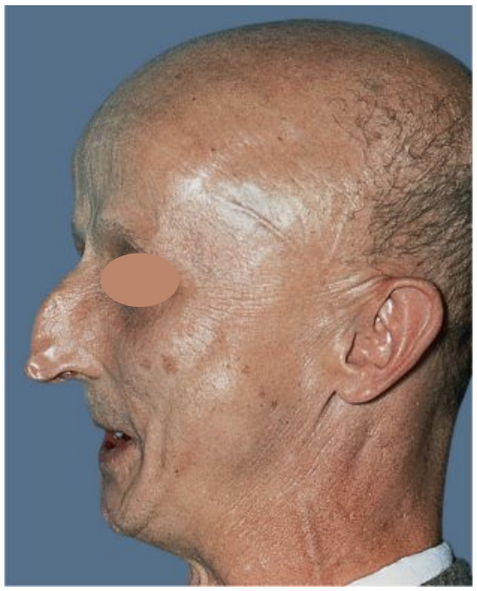

Fig. 63.14 Werner syndrome. Characteristic features include a beaked nose, taut skin, prominent veins, and micrognathia. *Courtesy Ronald P. Rapini, MD.*

develop over pressure points such as the fingers, toes, ankles, elbows and, occasionally, the ears. Removal of these keratoses by accidental or deliberate trauma leaves painful progressive ulcers. Ulcers may be resistant to therapy and prone to infection because of ischemia related to peripheral vascular disease. Dystrophic soft tissue calcification and osteomyelitis can also complicate chronic ulcers.

Other characteristic findings in Werner syndrome that reflect accelerated aging include bilateral cataracts, type 2 diabetes mellitus, hyperlipidemia, generalized atherosclerosis, osteoporosis, and less often hypertension. Additional features not normally associated with aging include hypogonadism, laryngeal atrophy, and osteosclerosis of the extremities. Affected individuals have an increased risk of meningiomas, soft tissue sarcomas, and osteosarcoma. Japanese patients are also at increased risk for thyroid follicular carcinomas and melanomas, especially in acral and mucosal locations[121].

The average lifespan is ~54 years, and death is usually related to cardiovascular and cerebrovascular disease. Some authors have postulated that heterozygous carriers may have higher rates of malignancy and myocardial infarction than the general population[118,119].

Pathology and Laboratory Findings

The epidermis is hyperkeratotic and atrophic, with focal hypermelanosis of the basal layer. Appendages are decreased in number and atrophic, and there is fibrosis and variable hyalinization of the dermis. The fat is also atrophic and often replaced by hyalinized connective tissue. Vessels may show changes typical of diabetic angiopathy.

Differential Diagnosis

A clinical diagnosis can usually be made when the characteristic skin findings, premature canities, "bird-like" facies, short stature, and bilateral cataracts are recognized. More detailed clinical diagnostic criteria are available at https://dlmp.uw.edu/research-center/werner/diagnostic-criteria, and genetic testing can be utilized to confirm the diagnosis if clinical features are inconclusive. There is considerable overlap with *m*andibular hypoplasia, *d*eafness, *p*rogeroid features, and *l*ipodystrophy (MDPL) syndrome caused by mutations in *POLD1*, which encodes DNA polymerase δ (see Table 63.9)[126]; this polymerase interacts with the Werner helicase during DNA replication and repair. However, MDPL is differentiated by frequent hearing impairment, absence of cataracts, and no predisposition to malignancy. In addition to other premature aging syndromes outlined in Table 63.9, Werner syndrome must be distinguished from ataxia–telangiectasia (see Ch. 60), prolidase deficiency (which features facial dysmorphism, telangiectasias, recalcitrant leg ulcers, and premature canities), and disorders associated with plantar keratoderma and scleroderma-like skin changes, such as Huriez syndrome (see Ch. 58).

Treatment

Genetic counseling should be provided, and prenatal diagnosis can be offered to affected families. Skin ulcers may prove resistant to therapy and should be treated aggressively and early, including with skin grafting; severe recalcitrant disease may lead to lower limb amputation[125,127]. Case reports have suggested that etidronate can ameliorate painful soft tissue calcifications. Management of diabetes mellitus and hyperlipidemia with proper diet and appropriate medications (e.g. thiazolidinediones, metformin, dipeptidyl peptidase 4 inhibitors ["gliptins"], lipid-lowering agents) can help to reduce complications, including atherosclerosis. Vitamin C supplementation was found to reverse age-related metabolic abnormalities and increase the lifespan in a mouse model of Werner syndrome, suggesting that vitamin C might be beneficial for Werner syndrome patients[128]. Other potential treatments that are under investigation include mTOR inhibitors and CRISPR/Cas9-mediated gene correction[129,130].

ECTODERMAL DYSPLASIAS

Encarna Guillén-Navarro, Teresa Martínez-Menchón and Virginia P. Sybert

Key features

- These genetic disorders share the central feature of abnormalities in at least two of the major ectodermally derived structures – hair, teeth, nails, and sweat glands
- Other ectodermal structures, such as mucous and sebaceous glands, as well as non-ectodermally derived structures may also be affected
- Different forms of ectodermal dysplasia are distinguished based on the types of ectodermal abnormalities, associated non-ectodermal anomalies, and mode of inheritance, as well as the underlying genetic defect
- Ectodysplasin, WNT, and p63 signaling pathways have been implicated in the pathogenesis of ectodermal dysplasias
- Some inherited abnormalities limited to one ectodermal structure (e.g. hair, nails) have a genetic basis related to that of ectodermal dysplasias, e.g. hypodontia due to heterozygous *WNT10A* mutations versus ectodermal dysplasia syndromes due to biallelic mutations in the same gene

Ectodermal dysplasias have long been recognized as a distinct group of inherited disorders that affect ectodermal appendages. Early descriptions of affected individuals were made by Danz in 1792, Wedderburn in 1838, and Darwin in 1875. The term "hereditary ectodermal dysplasia" was subsequently introduced by Weech in 1929. Ectodermal dysplasias are characterized by abnormalities in two or more of the major ectodermal structures – hair, teeth, nails, and sweat glands; other ectodermal structures, such as sebaceous and mucous glands, can also be affected[131–133].

Multiple ectodermal dysplasia classification schemes have been proposed over the years, including a descriptive clinical categorization by Pinheiro and Freire-Maia[134], a clinical–genetic model by Priolo and Lagana[135], and a functional classification by Lamartine[136]. Over the past two decades, the molecular basis of many ectodermal dysplasias has been elucidated, leading to better understanding of processes of cell signaling involved in the induction and development of ectodermal structures as well as their interactions with mesodermal structures[131,137]. International conferences were held in 2008, 2012, and 2017 with the aim of developing a classification system for ectodermal dysplasias that integrates clinical, genetic, and functional/pathway-based data and is fluid enough to incorporate new discoveries[133,138,139]. The current ectodermal dysplasia classification system recognizes approximately 100 conditions in which defects in ectodermal structures represent the major clinical features[133,133a]. Disorders recognized as within other genodermatosis groups (e.g. ichthyoses, keratodermas, skin fragility disorders) and complex syndromes with major non-ectodermal manifestations are not included in this classification[133].

Other	Dolichocephaly, frontal bossing, increased bone density	Short-limbed dwarfism, postaxial polydactyly, skeletal dysplasia; congenital heart defects	Lax, redundant skin; short proximal limbs, brachydactyly, narrow thorax; dolichocephaly, frontal bossing; nephronophthisis	Cleft lip/palate (CLPED); PPK (esp. CLPED); partial cutaneous syndactyly (EDS > CLPED)	Macular dystrophy; syndactyly, ectrodactyly, camptodactyly	Facial telangiectasias, reticulated erythema, "atrophy"; xerosis, follicular keratoses; PPK; smooth tongue	Follicular papules on scalp

*Allelic with Schöpf–Schulz–Passarge syndrome, which has an overlapping phenotype but also features eyelid hidrocystomas and PPK with histologic evidence of eccrine syringofibroadenomas. In addition, approximately 5%–15% of patients with a hypohidrotic ED phenotype have *WNT10A* pathogenic variants, with milder manifestations in heterozygotes. Multiple milia, adnexal neoplasms (e.g. poromas, tumors of the follicular infundibulum), basal cell carcinomas, and pili annulati have also been described in patients with *WNT10A* pathogenic variants.
†The pathogenesis of these conditions as well as disorders with an underlying mutation in *TP63, RIPK4* (CHANDS), or *CHUK/IKKA* (see Table 63.12 and text) is thought to involve disruption of p63 signaling.

Table 63.13 Other selected ectodermal dysplasias (EDs) with cutaneous manifestations and a known molecular basis. The ED–short stature syndrome due to biallelic pathogenic variants in *GRHL2* (grainyhead-like 2) features nail dystrophy, hypodontia with enamel hypoplasia, marginal PPK, keratoses on the dorsal hands and feet, and oral hyperpigmentation. SOFT syndrome – *s*hort stature, *o*nychodysplasia, *f*acial dysmorphism, and hypo*t*richosis – is caused by pathogenic variants in *POC1A*. Additional genes that have been implicated in ED include *KREMEN1* (kringle-containing transmembrane protein 1; AR, hair/tooth), *TSPEAR* (thrombospondin-type laminin G domain and EAR repeats; AR, hair/tooth/±hypohidrotic), *CST6* (cystatin E/M; AR, hair/hypohidrotic), and *KDF1* (keratinocyte differentiation factor 1; AD, hair/tooth/nail/hypohidrotic). AD, autosomal dominant; AR, autosomal recessive; PPK, palmoplantar keratoderma.

HYPOHIDROTIC ECTODERMAL DYSPLASIA

Synonyms: ■ Anhidrotic ectodermal dysplasia ■ Christ–Siemens–Touraine syndrome

Hypohidrotic ectodermal dysplasia (HED) refers to a group of disorders that share the following features: sparse or absent hair; missing or peg-shaped teeth; and decreased ability to sweat. The most common form is X-linked, and traditionally the term HED has referred to this condition. However, clinically similar conditions with autosomal dominant and autosomal recessive inheritance can result from molecular defects that affect the same pathway as in X-linked HED.

Epidemiology

The X-linked form of HED is estimated to affect 0.5–2 in 10 000 live-born boys and occurs in all ethnic groups. The autosomal dominant and recessive forms are much less common.

Pathogenesis

HED is caused by pathogenic variants in genes that affect the ectodysplasin signal transduction pathway[140,140a] (Fig. 63.15). Epithelial cells in the developing tooth, hair follicle, and eccrine gland utilize this pathway during morphogenesis, and errors in signaling result in aplasia, hypoplasia, or dysplasia of these structures. Activation of the ectodysplasin pathway at a critical time during development leads to translocation of the nuclear factor-κB (NF-κB) transcription factor into the nucleus of these epithelial cells, thereby altering the expression of a variety of target genes. The change in gene expression likely has an effect on both cellular proliferation and survival[141].

The *EDA* gene that is altered in X-linked HED encodes a soluble ligand, ectodysplasin A. It is secreted by a subset of epithelial cells and binds to its receptor (*ecto*dysplasin-*A* receptor; EDAR) on another group of epithelial cells. Pathogenic variants in *EDAR* can cause autosomal recessive or autosomal dominant HED[142]. Less often, autosomal recessive and autosomal dominant HED is caused by pathogenic variants in *EDARADD* (EDAR-associated death domain), which encodes an intracellular adapter protein that assists in transducing the signal from the activated receptor to the nucleus[143]. A dominant-negative mutation in *TRAF6*

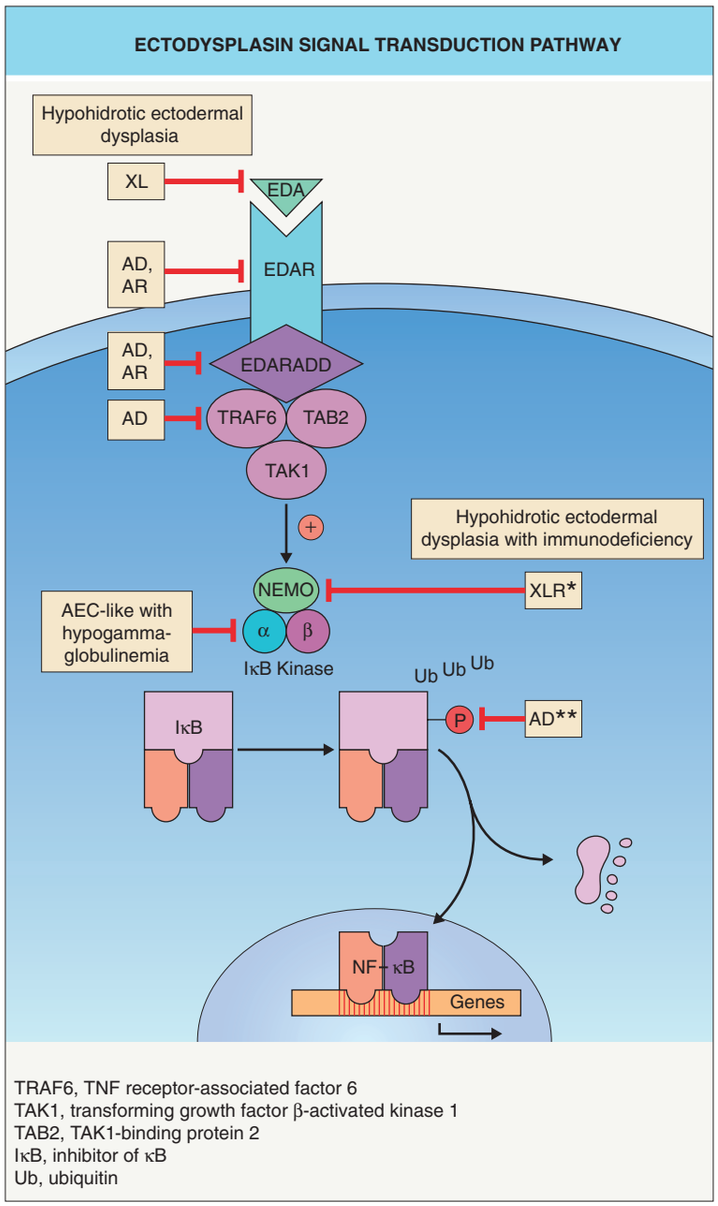

Fig. 63.15 The ectodysplasin signal transduction pathway. The IκB kinase α subunit (IKKα), which is also known as CHUK (component of IκB kinase complex), is upregulated by p63; this explains the ankyloblepharon–ectodermal defects–cleft lip/palate (AEC) syndrome-like phenotype in individuals with pathogenic variants in this gene. *Allelic with incontinentia pigmenti. **A hypermorphic mutation in the gene encoding IκBα that prevents this protein's phosphorylation (and subsequent ubiquitination/degradation) can result in continued inhibition of NF-κB and a phenotype of hypohidrotic ectodermal dysplasia with immunodeficiency. AD, autosomal dominant; AR, autosomal recessive; EDA, ectodysplasin A; EDAR, EDA receptor; EDARADD, EDAR-associated death domain adapter protein; NEMO, NF-κB essential modulator (also known as IKBKG, inhibitor of NF-κB kinase regulatory subunit γ); XL(R), X-linked (recessive).

(TNF receptor-associated factor 6), which encodes a protein that interacts with EDARADD, has also been reported in a patient with HED[144]. In addition, mutations in *WNT10A* are responsible for a subset (~5%–15%) of patients with an HED phenotype (see below and Table 63.12)[145].

Clinical Features

Affected newborns may present with a collodion-like membrane or with marked skin scaling. Scalp hair is sparse to absent (Fig. 63.16), and, when present, is usually lightly pigmented. Hair may darken at puberty and secondary sexual hairs are typically normal, although body hair is usually sparse or absent. Most male patients are unable to sweat to a detectable degree[146]. This can lead to elevation of core temperature in warm environments or with exertion, and symptomatic hyperthermia is a major problem. Affected infants often present with fever of unknown origin, and hyperthermia during the first few years of life can be fatal when HED is not recognized[146,147]. The skin is smooth and dermatoglyphics may be effaced because of absent eccrine pores. Atopy is a major cause of morbidity, with eczema affecting nearly two-thirds of HED patients. Periorbital wrinkling and hyperpigmentation are common. Sebaceous hyperplasia of the face, clinically resembling milia, can develop over time (see Fig. 63.16E). The nails are usually normal.

Both the primary and secondary dentition are affected. Teeth may be absent or reduced in number and abnormally shaped (e.g. peg-shaped). Dental radiographs are helpful in determining the extent of hypodontia, and prenatal tooth germ sonography can reliably identify affected fetuses between 18 and 28 weeks of gestation[148]. Individuals with HED typically have an alteration in their facial appearance characterized by a saddle nose, full everted lips and frontal bossing (see Fig. 63.16). Nasal secretions and cerumen are thick and viscous, and recurrent respiratory tract infections are common. The voice is frequently hoarse or raspy. Affected infants often develop gastroesophageal reflux and feeding problems. Unilateral or bilateral amastia is an occasional feature.

Female patients with the X-linked form of HED fall into one of three categories: (1) carriers with no detectable clinical features; (2) limited involvement with findings such as decreased hair density, one or more peg-shaped or missing teeth, patchy distribution of sweat glands along the lines of Blaschko, and relative hyperpigmentation of the skin that lacks adnexa (most evident on the back); or (3) full-blown features of the disorder (Fig. 63.17). Although this variability has been classically linked to the random nature of X-inactivation (see Ch. 62), hypomorphic *EDA* variants, genetic modifiers, and additional biologic mechanisms may also play a role[145].

Pathology

A skin biopsy is usually not necessary, although a scalp or palmar biopsy specimen lacking eccrine structures was traditionally considered diagnostic of HED[149]. Microscopic examination of hairs often shows small or variable shaft diameters and parallel dark bands of various lengths resembling a "bar code"[150].

Differential Diagnosis

In patients with clinical features of HED, options to confirm the diagnosis include single gene testing or a next-generation sequencing (NGS)-based multigene panel including *EDA, EDAR, EDARADD, TRAF6*, and *WNT10A*[145]. The majority of affected individuals, either male or female, have the X-linked form. *Homozygous* or *compound heterozygous* pathogenic variants in the *WNT10A* gene can give rise to an HED phenotype without associated facial dysmorphism, in addition to causing odonto-onycho-dermal dysplasia and Schöpf–Schulz–Passarge syndrome[145,151] (see Table 63.13 and Fig. 55.6). *Heterozygous WNT10A* pathogenic variants also represent a common etiology of mild HED or isolated hypodontia. At birth, HED can be confused with an ichthyosis if a collodion-like membrane is present (see Ch. 57, Table 57.4). Recurrent fevers in an infant may lead to consideration of infectious diseases before the features of HED are recognized. HED with immune deficiency (HED-ID) due to pathogenic variants in the *IKBKG* (*NEMO*) gene can be differentiated by the clinical and laboratory features of the associated immune system abnormalities and confirmed by genetic analysis (see below).

Treatment

Controlling ambient temperatures and external methods of cooling, e.g. wet T-shirts, wet headbands and cooling vests, are critical to prevent hyperthermia in children with HED. Regular use of moisturizers is helpful for dry skin. Dentures can be fitted in children as young as 3 years of age, and dental restoration through implants should be employed for older patients. Multidisciplinary care is required for treatment of other manifestations, which range from nasal concretions, asthma and recurrent respiratory infections to weight deficits and reduced salivary secretion. Patient organizations such as the National Foundation for Ectodermal Dysplasias (www.nfed.org) are also an important aspect of care, providing information and support to affected families.

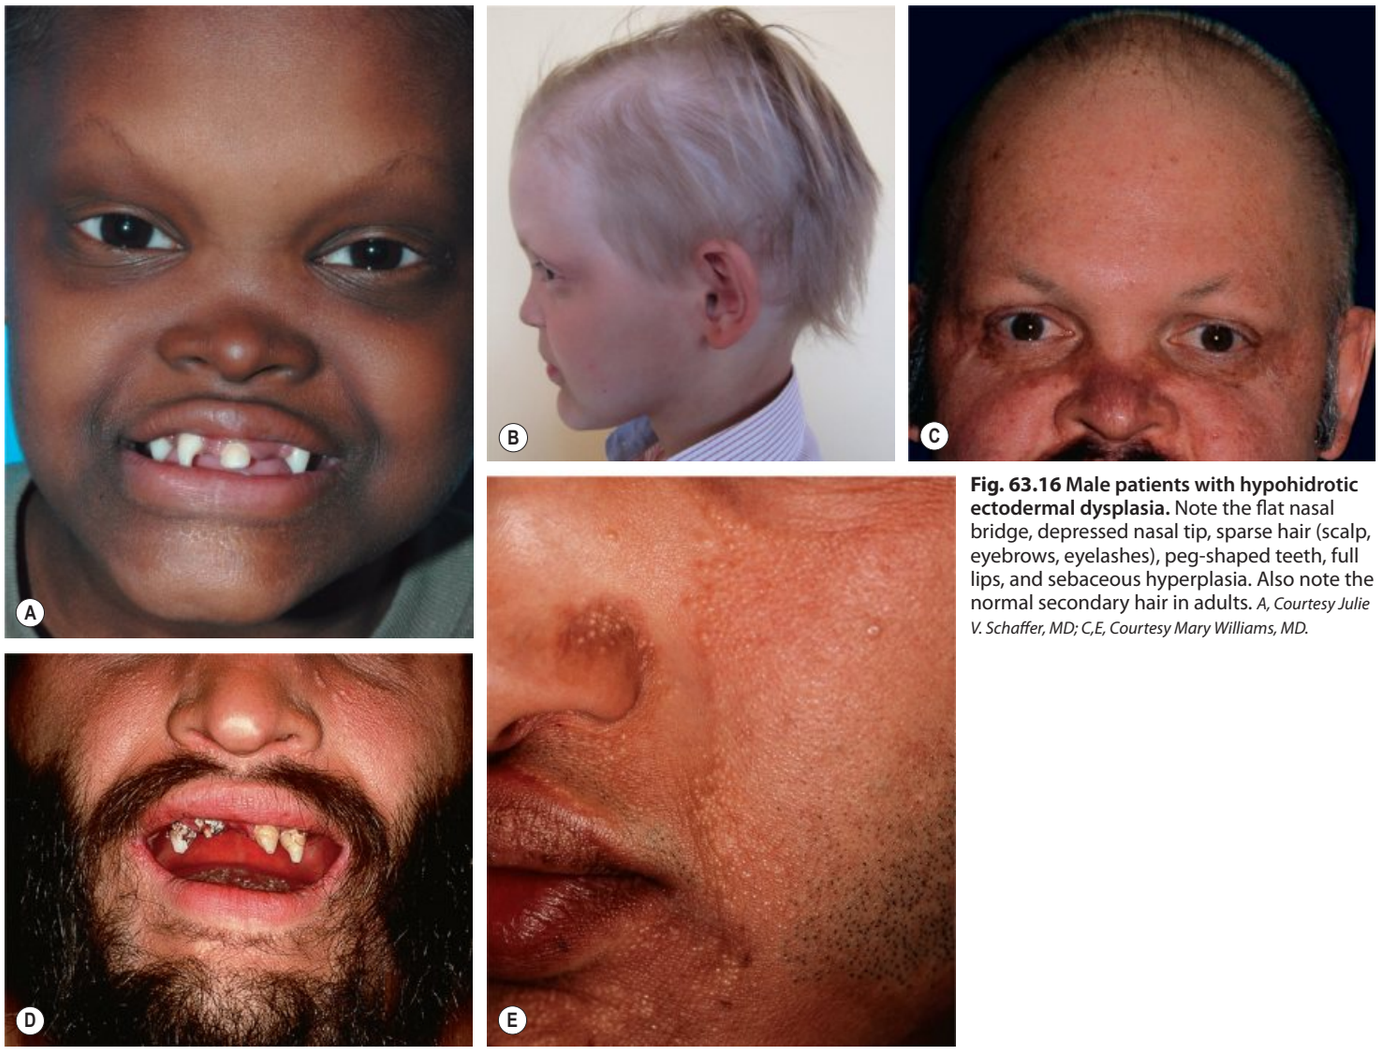

Fig. 63.16 Male patients with hypohidrotic ectodermal dysplasia. Note the flat nasal bridge, depressed nasal tip, sparse hair (scalp, eyebrows, eyelashes), peg-shaped teeth, full lips, and sebaceous hyperplasia. Also note the normal secondary hair in adults. *A, Courtesy Julie V. Schaffer, MD; C,E, Courtesy Mary Williams, MD.*

Prenatal administration of recombinant EDA protein is a promising approach to correct the X-linked HED phenotype. This method has been successfully utilized in murine and canine models[152–154]. Intra-amniotic administration of recombinant Fc-EDA fusion protein (constant domain of IgG1 plus receptor-binding portion of EDA) to three human fetuses with X-linked HED at 26 ± 31 weeks' gestation had positive effects on tooth development and restored sweating ability in the infants[155].

HYPOHIDROTIC ECTODERMAL DYSPLASIA WITH IMMUNE DEFICIENCY

HED-ID is a rare condition that shares many features with classic HED but is differentiated by the associated immune abnormalities (see also Ch. 60).

Pathogenesis

HED-ID is most commonly inherited in an X-linked recessive pattern due to hypomorphic mutations in *IKBKG* (inhibitor of NF-κB kinase regulatory subunit γ), which is also known as *NEMO* (*N*F-κB *e*ssential *mo*dulator). This gene encodes the γ subunit of a kinase that activates NF-κB downstream in the ectodysplasin (see Fig. 63.15) and tumor necrosis factor (TNF) pathways[156]. The condition primarily affects boys and is allelic to incontinentia pigmenti, which is caused by more detrimental *IKBKG* pathogenic variants that are lethal in male embryos unless in a mosaic state (e.g. due to a postzygotic mutation of Klinefelter syndrome; see Ch. 62). Patients with HED-ID have a high frequency of somatic mosaicism in their T cells, reflecting revertant mutations that are critical for survival in this cell type. An autosomal dominant form of HED-ID due to pathogenic variants in the *NFKBIA* gene has also been described[157]. These patients have decreased NF-κB signaling because the mutated α-component of the NF-κB inhibitor is resistant to degradation (see Fig. 63.15).

Clinical Features

Individuals with HED-ID often have milder abnormalities of ectodermal structures than do patients with classic HED. The findings can include hypodontia, conical teeth, hypotrichosis, and a reduced ability to sweat; frontal bossing, periorbital wrinkling, and everted lips may also be seen. A seborrheic- or atopic-like dermatitis that evolves into erythroderma may serve as a clue to the diagnosis[158], and reticulated hyperpigmentation is occasionally observed. Extracutaneous inflammatory manifestations can include colitis, which affects ~25% of patients, and chronic arthritis.

The immunodeficiency results in recurrent pyogenic bacterial infections, especially of the skin and respiratory tract, as well as opportunistic infections. It is characterized by a poor antibody response to polysaccharide antigens, dysgammaglobulinemia (typically elevated IgM and IgA but decreased IgG levels) and defective natural killer cell activity[156]. A T cell deficiency has also been described in some patients with the autosomal dominant variant of HED-ID. Occasionally, infants with X-linked HED-ID present with osteopetrosis (abnormally dense bones) and lymphedema. Female carriers, e.g. mothers of affected children, may have mild features of incontinentia pigmenti[156,159] (see Ch. 62).

Treatment

Intravenous immunoglobulin (IVIg) administration does not typically decrease the propensity to develop infections. Hematopoietic stem cell transplantation (HSCT) can correct the immune defects, although patients may experience engraftment difficulties and post-transplant complications such as worsening colitis[158,160].

Fig. 63.17 Female patients with X-linked hypohidrotic ectodermal dysplasia. Note the peg-shaped teeth, hypodontia, and full lips (**A**), as well as sparse eyelashes and periorbital hyperpigmentation (**B**) and sebaceous hyperplasia in a distribution following the lines of Blaschko (**C**). *A, Courtesy Julie V. Schaffer, MD.*

Fig. 63.18 Hidrotic ectodermal dysplasia (Clouston syndrome). Note the thickened, shortened nails with distal separation and tiny papules in a regular distribution on the fingertips.

HIDROTIC ECTODERMAL DYSPLASIA

Synonym: ▪ Clouston syndrome

Hidrotic ectodermal dysplasia was first described in a French-Canadian kindred[161] and the ancestry of many affected individuals was traced to a single founder. Subsequently, the disorder has been reported in individuals of varying ethnic backgrounds[162].

Pathogenesis

Hidrotic ectodermal dysplasia is an autosomal dominant condition that is caused by missense mutations in the *GJB6* gene, which encodes the connexin 30 protein and is thought to be regulated by the p63 transcription factor[163]. Connexins oligomerize to form gap junctions that are important for communication between cells (see Ch. 58), and *GJB6* is expressed in keratinocytes. Pathogenic variants in genes that encode other connexins cause skin disorders ranging from Vohwinkel and keratitis–ichthyosis–deafness (KID) syndromes (*GJB2*) to erythrokeratodermia variabilis (*GJB3* and *GJB4*) (see Table 58.5). Pathogenic variants in *GJB6* can also cause non-syndromic, autosomal dominant, digenic (together with a *GJB2* mutation) deafness, with normal teeth and hair in affected individuals; less often the inheritance pattern is autosomal recessive. A *GJB6* mutation has also been described in a patient with a KID syndrome-like phenotype that included congenital atrichia[164].

Clinical Features

Hidrotic ectodermal dysplasia is characterized by the triad of hypotrichosis, nail dystrophy, and palmoplantar keratoderma, with normal teeth and sweating. The hair is wiry, brittle, and pale; patchy alopecia is common. Both hair loss and nail changes may progress over time. In affected infants, the nails are typically milky white and smaller than normal with gradual thickening throughout childhood. In adults, the nail plates grow slowly, are thick, and separate from the nail bed distally (Fig. 63.18). Keratoderma with stippling of the palms and soles can also be progressive (see Ch. 58). Tiny papules in a grid-like array, corresponding to eccrine acrosyringia, or larger papules coalescing in a cobblestone-like pattern may extend from the palms and soles onto the dorsal surface of the digits, especially distally (see Fig. 63.18 and Fig. 58.11); the latter corresponds to where the dermatoglyphics are more prominent. Similar papules may also occur on the extensor surfaces of the extremities. Oral leukoplakia has been described, and sparse eyelashes may predispose patients to conjunctivitis and blepharitis.

Pathology

Histologically, the thickened palms and soles have orthohyperkeratosis with a normal granular layer. Eccrine syringofibroadenomatosis, which is characterized by proliferation of ductal structures within a fibrovascular stroma, may be observed when papular lesions are biopsied. The hair does not have specific microscopic changes.

Differential Diagnosis

The hair abnormalities in hidrotic ectodermal dysplasia distinguish it from pachyonychia congenita, which may have similar nail findings. A hidrotic ectodermal dysplasia-like phenotype plus deafness has been reported in a few patients with a *GJB2* mutation, and the dominant deafness–onychodystrophy syndrome results from pathogenic variants in *ATP6V1B2*.

Treatment

The National Foundation for Ectodermal Dysplasias can provide support to affected individuals and families. Ablation of the nail matrix is occasionally necessary for pain relief, and patients with substantial alopecia may choose to use hairpieces. Management of hyperkeratotic palms and soles is difficult; similar strategies to those used for the palmoplantar keratodermas, e.g. α-hydroxy acids, urea, soaking and paring, can be employed.

WITKOP TOOTH AND NAIL SYNDROME

Synonyms: ■ Tooth and nail syndrome ■ Witkop syndrome ■ Hypodontia with nail dysgenesis

First described in 1965, this autosomal dominant disorder is probably more common than suggested by the relatively small number of reports in the literature[165]. Affected individuals have small, thin, brittle nail plates that grow slowly, and koilonychia may be evident at birth. The toenails are usually more prominently involved than the fingernails, and nail abnormalities tend to improve with age. Thin, fine scalp hair is an occasional feature. The primary teeth may be normal or small and/or peg-shaped (Fig. 63.19). There is usually prolonged retention of primary teeth and partially or totally absent secondary dentition, especially the mandibular incisors, second molars, and maxillary canines.

A heterozygous mutation in *MSX1* (MSH homeobox 1), which is expressed in developing teeth and nail beds in mice, has been identified in at least one family with Witkop tooth and nail syndrome[166]. Pathogenic variants in *MSX1* have also been described in families with isolated tooth agenesis or non-syndromic cleft lip and/or palate. MSX1 is a transcription factor that has roles in the development of teeth and presumably nails. Fried tooth and nail syndrome represents a similar condition with autosomal recessive inheritance and more consistent hair abnormalities.

Fig. 63.19 Witkop tooth and nail syndrome. Small primary teeth, some conical, in a 7-year-old boy. Radiographs showed an absence of nearly all of the secondary teeth. *Courtesy Julie V. Schaffer, MD.*

ANKYLOBLEPHARON–ECTODERMAL DEFECTS–CLEFT LIP/PALATE SYNDROME

Synonyms: ■ Hay–Wells syndrome ■ Rapp–Hodgkin syndrome

This autosomal dominant ectodermal dysplasia, first described in 1976[167], has been reported in ethnically and geographically diverse individuals and families[168].

Pathogenesis

The ankyloblepharon–ectodermal defects–cleft lip/palate (AEC) syndrome is caused by *TP63* mutations that typically affect the sterile alpha motif (SAM) domain of the p63 protein[169]. p63, a transcription factor, is expressed within basal keratinocytes of the skin, which have a high proliferative capacity that is lost in differentiated keratinocytes. The p63 protein has multiple isotypes, with the SAM domain present in only some forms. This helps to explain the phenotypic differences between AEC syndrome and ectodermal dysplasia–ectrodactyly–clefting (EEC) syndrome (see Table 63.12 and below); the latter is usually due to mutations within the DNA-binding domain of p63[169,170].

Clinical Features

This disorder is evident at birth. Up to 90% of affected infants present with erythroderma, peeling skin, or erosions, which can result in life-threatening infectious complications (Fig. 63.20A). The scalp is almost always involved, and a chronic, erosive scalp dermatitis is a characteristic finding (Fig. 63.20B,C). The scalp hair is wiry and usually lightly pigmented and sparse, often with patchy alopecia. Some degree of nail dystrophy is typically evident, with findings ranging from hyperconvex, thickened nail plates to anonychia. Patients may have decreased sweating and heat intolerance[171,172].

Patients often develop abnormal granulation tissue and recurrent bacterial infections of the skin. Cribriform and stellate scarring tends to occur in a shawl-like distribution on the shoulders and upper trunk[171]. Progressive reticulated hyperpigmentation frequently appears in intertriginous areas, and hypopigmentation of the scalp and face may be seen in children with darkly pigmented skin.

Congenital strands of tissue between the eyelids (ankyloblepharon adnatum filiforme) are observed in approximately three-quarters of affected individuals (Fig. 63.20D). These may lyse spontaneously, even prior to birth, or require surgical correction. The lacrimal ducts may be atretic. Almost all patients with AEC syndrome are born with a cleft palate with or without a cleft lip. Malformed external ears and recurrent otitis media with secondary conductive hearing loss are common[173]. Dental abnormalities include hypodontia and misshapen (e.g. conical) teeth, and most patients have maxillary hypoplasia.

Gastroesophageal reflux develops in the majority of AEC patients, while one-quarter of affected children fail to thrive and require gastrostomy placement[174]. Hypospadias affects up to 80% of male patients, and supernumerary nipples and/or ectopic breast tissue have been described[175]. Limb abnormalities are more common in AEC syndrome than once thought[171,172,176]; these malformations, which are typically less severe than the defects seen in EEC syndrome (see below), can include syndactyly (partial or complete), camptodactyly, brachydactyly, and even ectrodactyly[175] (Fig. 63.20E).

Pathology

Hair shaft abnormalities such as pili torti and pili trianguli et canaliculi may be observed. Histopathologic changes are nonspecific and often include mild epidermal atrophy and dermal melanophages[177].

Differential Diagnosis

Rapp–Hodgkin syndrome, once considered to be a distinct entity, is now thought to fall within the AEC spectrum. Affected individuals have heterozygous pathogenic variants in *TP63*, generally affecting the SAM domain of p63. Other than a lack of ankyloblepharon, clinical findings overlap with those of AEC syndrome, including maxillary hypoplasia, cleft palate ± lip, nail dystrophy, and abnormalities of the teeth and hair[178]. The clinical features of AEC also overlap with those of *c*urly *h*air–*a*nkyloblepharon–*n*ail *d*ysplasia *s*yndrome (CHANDS), which is caused by biallelic mutations in the receptor-interacting serine-threonine kinase 4 gene (*RIPK4*) that is a direct transcriptional target of p63[179]. An AEC/EEC-like syndrome presenting with hypogammaglobulinemia as well as ankyloblepharon, cleft lip/palate, conical teeth, sparse hair, nail dystrophy, syndactyly/ectrodactyly, and hypoplastic genitalia can result from pathogenic variants in *CHUK/IKKA* (component of inhibitor of NF-κB kinase complex/inhibitor of NF-κB kinase subunit α; see Fig. 63.15), which is activated by p63[180]. The peeling erythroderma of neonates with AEC syndrome can lead to a misdiagnosis of epidermolysis bullosa or ichthyosis.

Treatment

Surgical repair of oral clefting is usually necessary. Treatment for the erosive scalp dermatitis should be gentle and non-occlusive, with surveillance for and treatment of secondary infections. Debridement often causes erosions to worsen, and skin grafts typically fail. Ulceration and granulation tissue may be very difficult to treat, and healing tends to be slow. A recent study found that topical application APR-246/eprenetapopt/PRIMA-1^{MET}, which was developed to activate mutant p53 in cancer cells, led to substantial re-epithelialization of erosions on the hands and scalp that had been present for 9–15 years in two patients with AEC[181].

A Extensive erosions in an infant who succumbed to sepsis. **B, C** Thick scale-crust and alopecia of the scalp. **D** Strands of tissue between the eyelids (ankyloblepharon adnatum filiforme). **E** Digital abnormalities (including syndactyly, brachydactyly) and nail dystrophy (yellowing and thickening of the nail plate). *B, Courtesy Jean L. Bolognia, MD; C, Courtesy Julie V. Schaffer, MD.*

ECTODERMAL DYSPLASIA–ECTRODACTYLY–CLEFTING SYNDROME

Synonym: ■ Split hand–split foot–ectodermal dysplasia–clefting syndrome

First described by Eckholdt and Martens in 1804, this disorder occurs in all ethnic groups and has been reported worldwide.

Pathogenesis

Ectodermal dysplasia–ectrodactyly–clefting (EEC) syndrome is an autosomal dominant disorder caused by pathogenic variants in the region of *TP63* that encodes the protein's DNA-binding domain[182,183]. These mutations disrupt the ability of the p63 transcription factor, which is expressed in proliferating epidermal basal cells, to regulate gene expression. *TP63* pathogenic variants also occur in several related autosomal dominant disorders, including non-syndromic split hand/foot malformation (minority of affected families), limb–mammary syndrome

Fig. 63.21 Ectodermal dysplasia–ectrodactyly–clefting syndrome. Note the characteristic split-hand (**A**) and foot (**B**) deformities in these three siblings.

and ADULT (*a*cro-*d*ermato-*u*ngual-*l*acrimal-*t*ooth) syndrome, as well as in AEC syndrome (see Table 63.12 and above). Patients with EEC syndrome usually have missense mutations within the p63 DNA-binding domain that differ from those seen in these other disorders[183].

Clinical Features

The ectodermal changes in this highly variable condition may be quite mild[184]. The scalp hair is usually light in color and coarse. It may be sparse and grow slowly. The secondary sexual hair may also be affected. Scalp folliculitis and dermatitis are rare manifestations[185,186]. Approximately 80% of affected individuals have transverse ridging, pitting, and slow growth of the nail plates. Xerotic skin and palmoplantar hyperkeratosis can occur, and sweating is usually normal.

Clefting of the palate/lip occurs in ~50% of affected individuals, and additional oral abnormalities include enamel hypoplasia, hypodontia, and premature loss of secondary teeth. Lacrimal duct defects leading to blepharitis and dacryocystitis are frequently present, and limbal stem cell deficiency can result in photophobia and keratopathy as well as corneal ulceration and scarring[187]. Secondary conductive hearing loss is also common, and choanal atresia is an occasional manifestation.

Ectrodactyly, a specific split-hand/foot malformation due to failure of normal development of the central digits, represents a defining feature of EEC syndrome (Fig. 63.21). The ectrodactyly is frequently asymmetric, usually with more severe involvement of the feet than the hands. Intrafamilial variability is marked. Genitourinary abnormalities are an under-appreciated manifestation of EEC syndrome and may be associated with dysplasia of the urogenital epithelium; renal and urogenital malformations affect more than one-third of patients and can result in hydronephrosis.

Pathology

Histologic features are neither diagnostic nor specific.

Differential Diagnosis

The presence of split-hand/foot malformations and the absence of ankyloblepharon or cutaneous erosions help to distinguish EEC syndrome from AEC syndrome. The findings that differentiate limb–mammary syndrome and ADULT syndrome from EEC are presented in Table 63.12. Other ectodermal dysplasias that feature digital abnormalities include ectodermal dysplasia–ectrodactyly–macular dystrophy (EEM) syndrome, cleft lip/palate ectodermal dysplasia, oculodentodigital dysplasia, and ulnar–mammary syndrome (see Table 63.13 and Table 64.6). Although Goltz syndrome (focal dermal hypoplasia) can present with split-hand/foot and other digital malformations, nail dystrophy, sparse hair, dental anomalies and (occasionally) cleft lip/palate, it is easily recognized based on the highly characteristic skin findings as well as ocular and additional skeletal (e.g. osteopathia striata) defects (see Ch. 62). Lastly, the popliteal pterygium syndrome, which is caused by pathogenic variants in the interferon regulatory factor 6 gene (*IRF6*) that is transcriptionally activated by p63, has features overlapping with EEC (see Ch. 64).

Treatment

As for the other ectodermal dysplasias with oral clefting and lacrimal abnormalities, management involves a multidisciplinary approach. Limb defects may be ameliorated by surgical interventions. All affected individuals should be screened with a renal ultrasound. Potential approaches to therapy include small interfering RNAs (siRNAs) that selectively silence mutant *TP63* alleles and the p53-activating compound APR-246/eprenetapopt/PRIMA-1^{MET}, which was found *in vitro* to rescue impaired epidermal and corneal differentiation in cells from EEC patients[188,189].

Acknowledgments and disclosures

The authors wish to thank Peter H. Itin, MD and Alanna F. Bree, MD for their valuable contributions to this chapter in the previous editions. The Ectodermal Dysplasia section of this chapter has been supported by the Instituto de Salud Carlos III (ISCIII), Spanish Ministry of Economy and Competitiveness (grant numbers PI/14/01259 and PI/17/00796 and PI/21/01082), FEDER funds and AADE (Spanish Association of patients with ectodermal dysplasia).

Additional figures available in our eBook (see inside front cover for access code).

Developmental Anomalies 64

Richard J. Antaya and Julie V. Schaffer

Chapter Contents

The Midline Lesion 1067
Aplasia Cutis Congenita 1075
Other Developmental Anomalies 1077

Key features

- The human neural tube is thought to close in an intermittent, multisite pattern, and neural tube defects that present as midline cutaneous lesions (e.g. cephaloceles, heterotopic brain tissue, rudimentary meningoceles) typically occur at the junction between two closure sites
- Midline lesions of the nose and scalp have a high likelihood of representing developmental defects with a potential intracranial connection, and an evaluation with CT or MRI prior to surgical intervention is critical
- The presence of a "hair collar" surrounding a lesion on the scalp is a sign of ectopic neural tissue or membranous aplasia cutis; the latter is thought to represent a forme fruste of a neural tube defect
- Cutaneous lesions overlying the spinal axis can serve as a marker for spinal dysraphism, and their presence is often an indication for radiologic evaluation
- Aplasia cutis congenita, a physical finding reflecting a disruption of intrauterine skin development, can be approached clinically based on the morphology and distribution of lesions as well as the presence or absence of associated abnormalities
- A number of other developmental anomalies affect the skin; although they usually represent isolated defects, it is important to be aware of potential associated conditions

INTRODUCTION

Developmental anomalies are a diverse group of congenital disorders that result from faulty morphogenesis. They include both *malformations*, defined as structural defects arising due to errors in embryologic development, and *disruptions*, which occur when a structure programmed to develop normally is damaged before it is fully formed. A classic example of the former is incomplete closure of the neural tube resulting in an encephalocele, while the latter process is illustrated by the anomalies associated with varicella embryopathy. Although developmental anomalies that affect the skin are often recognized at birth or during infancy, occasionally diagnosis is delayed until later in life. The cutaneous abnormalities range in severity from isolated, minor physical findings (e.g. rudimentary supernumerary digits) to deforming, potentially life-threatening defects (e.g. deep, irregular scalp aplasia cutis congenita in Adams–Oliver syndrome). Furthermore, some skin lesions that appear to be innocuous may serve as important clues to the presence of a multiple congenital anomaly syndrome or, particularly when involving the midline, the existence of a serious defect of the underlying tissues. Such associations reflect the complex interactions between various ectodermal and mesodermal elements that occur during the intricate processes of morphogenesis and differentiation.

This chapter begins with an overview of the midline lesion and its relationship to closure of the neural tube. A discussion of specific issues pertaining to midline lesions of the nose, scalp, and spine follows, including a review of the different types of anomalies that can present in these sites. An overview of aplasia cutis congenita is followed by presentation of a clinical approach based on the morphology and distribution of lesions and the presence or absence of associated abnormalities. Finally, a variety of non-midline developmental anomalies are discussed, including lip pits, accessory tragi, supernumerary nipples, skin dimples, malformations of the dermatoglyphics, rudimentary supernumerary digits, and the amniotic band sequence. Developmental anomalies that are covered in Chapter 110 include ear pits as well as branchial cleft, thyroglossal duct, bronchogenic, median raphe, omphalomesenteric duct, and urachal cysts.

THE MIDLINE LESION

A number of critical events occur during the third to fifth weeks of embryologic development (see Ch. 2). These include formation of the neural tube, separation of neuroectoderm from surface ectoderm, and interposition of mesodermal elements. Inherent in such a complicated process is the potential for error, which spans a spectrum from obvious, fulminant neural tube defects to subtle cutaneous anomalies. However, the latter may represent a sign of a significant underlying malformation.

Classically, closure of the human neural tube was thought to be a continuous process, beginning at a single focus in the cervical region and progressing bidirectionally in a "zipper-like" fashion to culminate in the closure of the anterior and subsequently posterior neuropores. However, evidence suggests that in humans as well as other mammals, the cranial segment of the neural tube closes in an intermittent or multisite pattern. Four distinct initiation sites of neural tube closure have been identified in the mouse, and a similar pattern of closure has been proposed for humans, with an additional caudal site (Fig. 64.1)[1]. In support of the multisite closure model, neural tube defects (e.g. cephaloceles, myelomeningoceles, heterotopic brain/meningeal tissue) cluster either entirely within one closure site or at the junction of two sites, such as the nasal root (2–3) or vertex (2–4; see Fig. 64.1). Neural tube

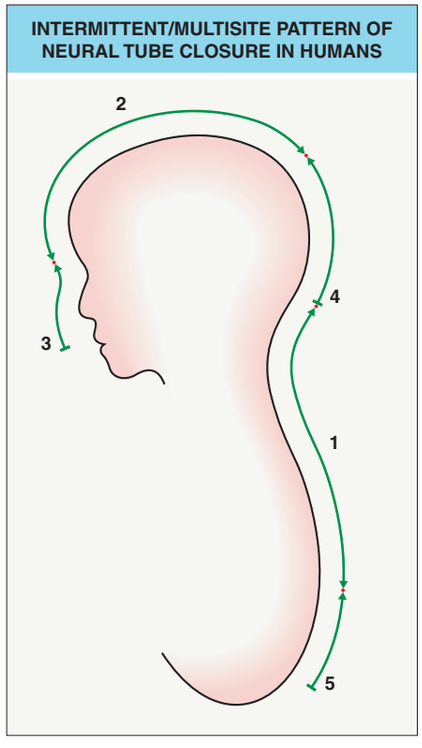

Fig. 64.1 Intermittent/multisite pattern of neural tube closure in humans. The five separate initiation sites are labeled (in chronological order, 1–5), the direction of neural tube closure is indicated by the arrows, and the junctions (where defects tend to occur) designated with dots. The 2–3 junction corresponds to the location of frontoethmoidal neural tube defects, the 2–4 junction to parietal defects, and the 1–4 junction to occipital defects. Closure in region 4 is thought to occur via membranous growth, proceeding in a superior direction; incomplete closure at this site could therefore result in a membranous defect at the 2–4 junction (i.e. the vertex).

closure in the posterior cranial area is thought to occur via a membrane rather than a midline fusion of folds, and the appearance of this site during embryologic development in animals resembles that of human membranous aplasia cutis[2]. Specific genes may control individual closure sites, explaining repetitive events within families.

Midline Lesions of the Head, Neck, and Anterior Trunk

The pathogenesis, differential diagnosis, and management of midline lesions of the nose (Fig. 64.2) and scalp are discussed below, followed by a review of the individual developmental anomalies that may present with a midline lesion on the head, neck, and anterior trunk. Midline cysts of this region (e.g. thyroglossal duct, bronchogenic) are discussed in Chapter 110.

Midline nasal lesions

It is important for physicians to recognize the potential intracranial connection of a midline nasal mass or pit[3]. Dermoid cysts, dermal sinuses, cephaloceles, and nasal glial heterotopia (nasal "gliomas") resulting from faulty embryologic development of the frontobasal skull and/or adjacent ectodermal/neuroectodermal tissues may present as congenital nasal lesions (Table 64.1). As a group, these midline nasal masses occur in ~2–5 per 100 000 live births. They are often misdiagnosed as more familiar entities such as epidermoid cysts and infantile hemangiomas.

The various congenital midline nasal masses have similar developmental origins. As the bones of the skull form during the second month of gestation, diverticula of dura mater project: (1) inferiorly into the prenasal space that extends from the base of the skull to the nasal tip, deep to the nasal bone and skin but superficial to the nasal cartilage; and (2) anteriorly through the nasofrontal fontanelle into the glabellar and inner canthal areas. These diverticula may make connections with the overlying dermis, but usually they regress completely, with subsequent bony fusion to form the base of the skull and the cribriform plate. However, if the dura mater does not separate from the dermis, an ectodermal residue, with or without a patent intracranial connection, can persist; furthermore, if faulty neural tube closure results in a bony defect, there may be herniation of brain tissue. Such ectopic elements can occur either within the prenasal space (nasoethmoidal, "intranasal") or superiorly at the glabella (nasofrontal, "extranasal")[4]. Depending on the contents of the lesion (e.g. cutaneous versus neural tissue, cyst versus tract only) and the patency of the intracranial connection, a dermoid cyst, dermal sinus, cephalocele, or nasal glial heterotopia may result (see below).

Many of these midline nasal lesions have the potential for intracranial communication and therefore present a risk for the development of serious CNS infections such as meningoencephalitis or a brain abscess. In addition, recurrent inflammation and progressive expansion of the mass may result in bony atrophy and nasal distortion. Early and complete surgical excision with repair of associated bony and dural defects is imperative. In order to prevent ascending infections, a biopsy, needle aspiration, or other preoperative manipulations should be avoided.

A thorough radiologic evaluation prior to surgery is mandatory. Ultrasound may detect some bony defects but has limited sensitivity. While CT is the most sensitive method for defining bony skull defects, false-positive studies are common in young children undergoing bone maturation. MRI is superior in demonstrating intracranial masses and other soft tissue changes and may aid in planning surgical approaches[5]. In addition, surgical exploration is often necessary to definitively exclude the presence of an intracranial connection, as small fibrous tracts may not be detectable with imaging studies.

Midline lesions of the scalp

Subcutaneous nodules of the scalp are common, and in adults they are usually acquired lesions, such as epidermoid and tricholemmal

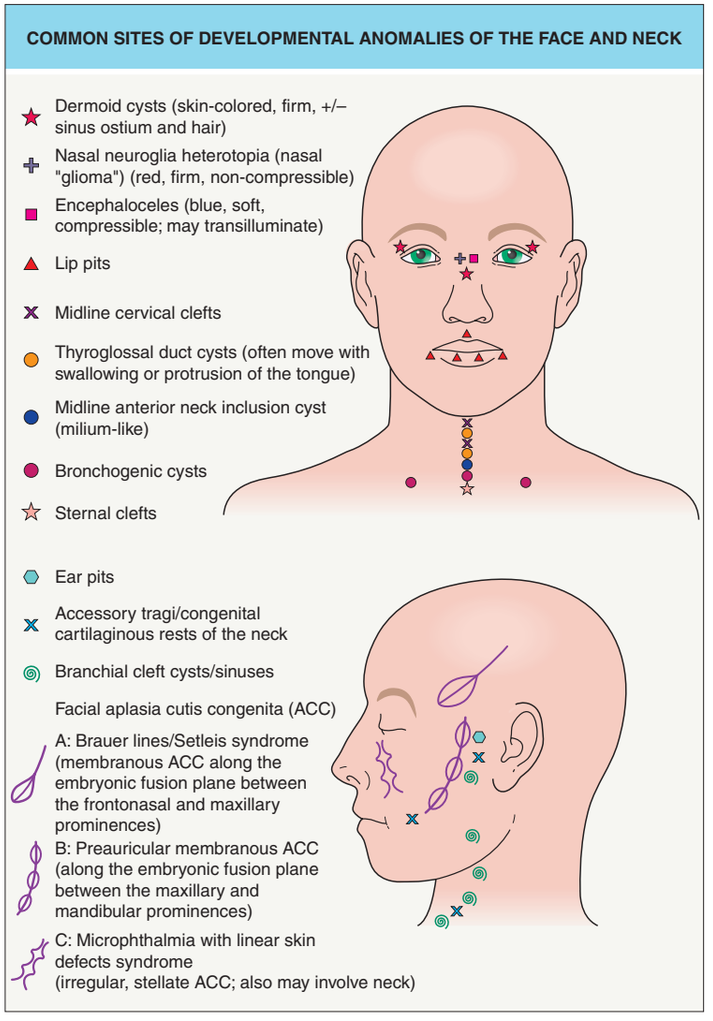

Fig. 64.2 Common sites of developmental anomalies of the face and neck.

THE DIFFERENTIAL DIAGNOSIS OF NASAL MASSES PRESENTING AT BIRTH OR DURING INFANCY
Developmental defects
• Dermoid cyst*,†
• Cephalocele (encephalocele > meningocele)*
• Nasal glial heterotopia (nasal "glioma")*
• Lymphatic malformation
• Nasolacrimal duct cyst
Other cysts
• Epidermoid cyst
• Pilomatricoma
• Ethmoid mucocele
Benign neoplasms and hamartomas
• Infantile hemangioma
• Hemangiopericytoma
• Neurofibroma
• Melanotic neuroectodermal tumor of infancy
• Hamartomas: chondromesenchymal, chondroid, lipomatous, or angiomatous
• Teratoma‡
Malignant neoplasms
• Rhabdomyosarcoma
• Fibrosarcoma
• Osteosarcoma
• Neuroblastoma
*Midline lesions.
†The most common cause of a congenital midline nasal mass.
‡May also be malignant.

Table 64.1 The differential diagnosis of nasal masses presenting at birth or during infancy.

cysts. However, midline scalp lesions that are noted at birth or in early childhood have a high likelihood of representing developmental defects, such as dermoid cysts, cephaloceles, heterotopic brain or meningeal tissue, sinus pericranii, and aplasia cutis congenita. In one series of 70 children presenting with a solitary, non-traumatic scalp nodule[6], 61% of the lesions were dermoid cysts and 4% cephaloceles. More importantly, 37% of the lesions were found to extend intracranially to the dura or brain.

In the evaluation of a patient with a subcutaneous nodule on the scalp, clinical clues that heighten suspicion of a developmental anomaly with potential intracranial extension include[7]:

- a patient who is an infant or child
- a lesion first noted at birth or during early childhood
- a family history of neural tube defects
- a history of meningitis
- the presence of neurologic signs or symptoms
- location of the lesion along the midline or over the suture lines of the scalp
- lesions that pulsate, transilluminate, or fluctuate in size with crying or straining
- lesions with a central pore in young children, who are less likely to have epidermoid cysts
- an overlying capillary malformation
- a positive hair collar sign or hair tuft (see below).

A congenital midline lesion, or a scalp nodule with other concerning features, requires imaging studies prior to surgical excision or biopsy. As noted previously, CT is superior in detecting bony defects and MRI is more sensitive in evaluating transcranial extension of soft tissue. Ultrasound is sometimes utilized as an initial study in infants, but it has a relatively high false-negative rate. A neurosurgical referral is indicated if these studies are positive and, as small communications may be missed, complete surgical removal may be prudent even if they are negative[8].

The *hair collar sign* consists of a ring of long, dark, coarse hair surrounding a congenital scalp lesion. The presence of a hair collar or a tuft of hair in the midline scalp is a relatively specific marker for ectopic neural tissue[8,9]. Hair collars are also seen in membranous aplasia cutis (Figs. 64.3 & 64.4), a disorder thought to represent a forme fruste of a neural tube defect (i.e. without the presence of ectopic neural tissue)[2]. Drolet et al.[8] hypothesized that cerebral herniation produces aberrant shearing forces during the formation of hair follicles early in development, causing them to point outward from the defect. The proximity of neuroectoderm expressing neural adhesion molecules may also alter normal epidermal–dermal interactions, thereby inducing the development of large, abnormal follicles[2]. These speculations correlate with the histologic and dermoscopic finding of numerous horizontally oriented, hypertrophic follicles emerging from the edge of scalp lesions to form the hair collar[10]. The differential diagnosis and evaluation of a positive hair collar sign is presented in Fig. 64.5.

Fig. 64.3 Hair collar sign. Membranous aplasia cutis congenita with a hair collar.

Fig. 64.4 Hair collar sign. Membranous aplasia cutis congenita with a bullous appearance and a surrounding hair collar.

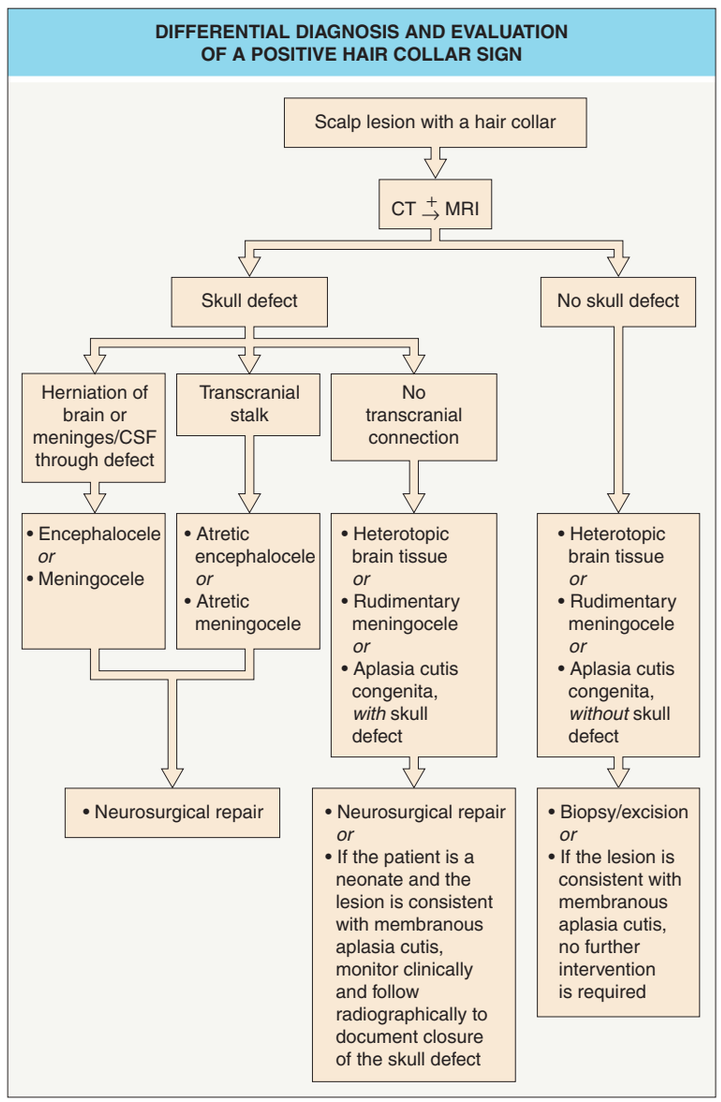

Fig. 64.5 Differential diagnosis and evaluation of a positive hair collar sign. In general, CT is the most accurate method of detecting skull defects. However, if a bony defect is detected by CT, a follow-up evaluation by MRI may be indicated to better determine whether there is extension of soft tissue transcranially.

Other developmental anomalies of the scalp

Sinus pericranii is a rare disorder characterized by a congenital, or occasionally acquired, epicranial venous malformation of the scalp that communicates with an intracranial dural sinus through dilated diploic cranial veins. The lesion is usually located near the midline, especially in the frontal region. Most are asymptomatic and appear as a compressible, fluctuant mass that varies in size with changes in intracranial pressure (Fig. 64.6). The differential diagnosis includes a simple venous or arteriovenous malformation, meningocele, and encephalocele; of note, sinus pericranii can also occur in association with heterotopic meningeal or brain tissue.

Hairless congenital scalp lesions such as a *nevus sebaceus* (see Chs. 62 & 111) and *nevus psiloliparus* (a hallmark of encephalocraniocutaneous lipomatosis; see Ch. 62) due to mosaic activating mutations may mimic developmental anomalies of the scalp.

Dermoid cysts

Dermoid cysts result from sequestration of ectodermal tissue along embryonic fusion planes during development. They are a separate entity from benign cystic teratomas, neoplasms that are also referred to as dermoids. Although dermoid cysts are congenital defects and may be recognized at birth, these lesions often escape notice until they become enlarged, inflamed, or infected. This typically occurs by early childhood, but diagnosis may be delayed until as late as the sixth decade of life. Dermoid cysts present as firm, non-compressible, non-pulsatile subcutaneous nodules that often reach a size of 1–4 cm in diameter.

Fig. 64.6 Sinus pericranii. This venous malformation involving the midline forehead and communicating with an intracranial dermal sinus was evident at birth. Fluctuations in fullness occurred with crying. *Courtesy Susan Psaila, MD.*

The lesions usually do not transilluminate. They are most commonly located around the eyes, particularly the lateral eyebrow (Fig. 64.7A), but may also be found on the nose (Fig. 64.7B), scalp (often over the anterior fontanelle or the midline occiput), neck, sternum, sacrum, and scrotum.

Dermoid cysts on the nose or midline scalp have a much higher likelihood of intracranial extension than those in a periocular location. Nasal lesions, which account for <10% of cervicofacial dermoid cysts, occur anywhere from the glabella to the tip of the nose (see above) and can result in a widened nasal bridge. The presence of a sinus ostium, which may be heralded by protruding hairs or a sebaceous discharge, increases the risk of intracranial involvement of a nasal dermoid cyst to almost 50%, versus ~25% overall[3]. A sinus ostium without an underlying subcutaneous mass may also connect with an intracranial dermoid cyst. These lesions favor the midline occipital area but can occur elsewhere on the face and scalp; recurrent drainage and inflammation may represent signs of deeper extension[11]. In addition to infectious complications, a chemical meningitis or even hydrocephalus due to release of keratinous and sebaceous material into the cerebrospinal fluid (CSF) can occur with intracranial dermoid cysts. Lastly, dermoid cysts and dermal sinuses overlying the spine may be associated with occult dysraphism (see below) and if the tract connects with the subarachnoid space, an increased risk of meningitis.

Histologically, dermoid cysts in any location are lined by keratinizing stratified squamous epithelium and contain mature adnexal structures (see Ch. 110)[12]. Treatment is by excision, and preoperative imaging studies are required for lesions located on the nose, midline scalp, or posterior axis or those with other suspicious features (e.g. a draining sinus ostium) in order to exclude a connection to the CNS.

Cephaloceles

Cephalocele is a general term for congenital herniation of intracranial structures through a defect in the skull. *Cranial meningoceles* are herniations in which the sac contains meninges and CSF, while *encephaloceles* contain both meninges and brain (Fig. 64.8). Therefore, by definition, all cephaloceles have an intracranial connection. These lesions result from faulty closure of the cephalic portion of the neural tube during development, and they are much less common than their caudal counterparts (e.g. myelomeningoceles). Cephaloceles occur in ~1–3 per 10 000 live births, with a higher incidence in those with a family history of neural tube defects and an ~5% risk of neural tube defects in subsequent siblings. They are usually midline or paramedian, occurring most frequently at the occiput or vertex (75%) (see Fig. 64.1), followed by extranasal (e.g. glabella or medial orbit; 15%) and intranasal or pharyngeal (10%) locations[4]. Encephaloceles are generally noted early in life due to the resultant deformity. Occasionally, small frontal lesions are misdiagnosed as deep infantile hemangiomas, vascular malformations, hypertelorism, or nasal polyps[3,4]; of note, the latter are almost never seen in children younger than 3 years of age.

Cephaloceles typically appear as a soft, compressible, pulsatile mass with a bluish color. They may be covered with either normal skin or a thin, glistening epithelial membrane. The size of cephaloceles varies tremendously, from 1 cm nodules to lesions containing nearly half of the brain, and the size does not necessarily correlate with the extent of the underlying bony defect. Patients with intranasal cephaloceles often present with a broadened nasal bridge but no palpable mass, whereas

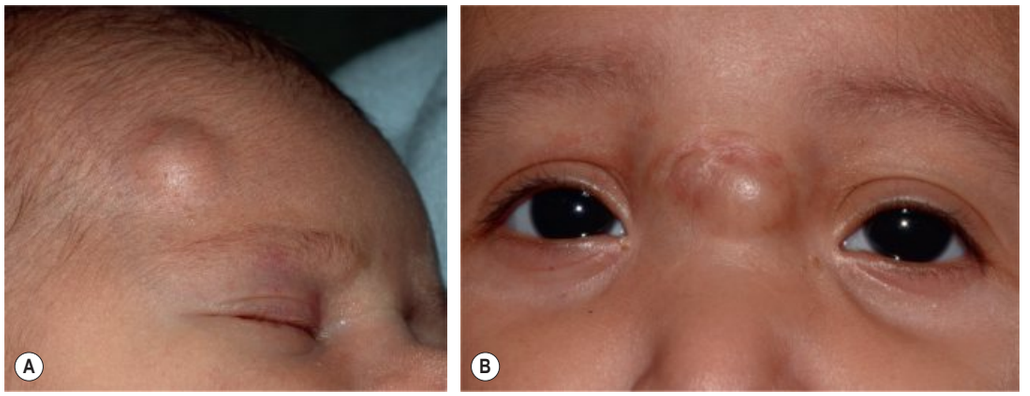

Fig. 64.7 Dermoid cysts. A This dermoid cyst presented in an infant as a firm subcutaneous nodule superior to the lateral right eyebrow. **B** Congenital firm, skin-colored nodule at the nasal root. Unlike those located in the more common lateral eyebrow location, nasal dermoid cysts have a substantial risk of intracranial extension.

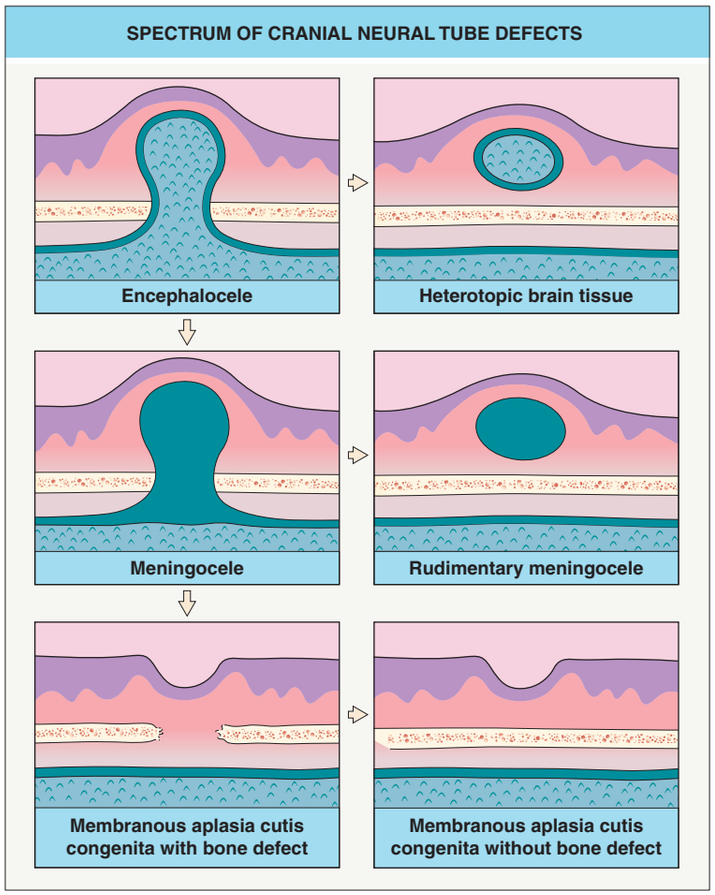

Fig. 64.8 Spectrum of cranial neural tube defects. When there is herniation of both the spinal cord and the meninges, this is referred to as a myelomeningocele.

lesions on the scalp may have an overlying capillary malformation and/or a surrounding hair collar (see above, Midline lesions of the scalp)[8]. Transillumination frequently indicates the presence of CSF; in addition, increased flow of CSF into lesions with crying, the Valsalva maneuver, or compression of the jugular veins (Furstenberg test) may result in transient expansion. Leaks of CSF can occur (e.g. CSF rhinorrhea), and patients may have a history of meningitis. Nasal cephaloceles may develop in conjunction with facial clefts and other midline defects, while encephaloceles are often associated with neurologic abnormalities.

On histologic examination, encephaloceles show mature neuroglial tissue embedded in varying amounts of fibrous stroma. Heterotopic brain tissue (see Fig. 64.8) demonstrates similar features, and these lesions cannot be reliably distinguished histologically. When a patient is suspected of having a cephalocele, imaging studies and subsequent neurosurgical repair should be performed.

Nasal glial heterotopia

Synonyms: ■ Nasal glioma ■ Nasal neuroglial heterotopia ■ Nasal heterotopic brain tissue

Nasal glial heterotopia (NGH) refers to extracranial rests of brain tissue located extranasally (e.g. at the nasal root or glabella; 60%), intranasally (30%), or both (10%)[13]. The previous term for NGH, nasal glioma, is a misnomer since this lesion represents a developmental anomaly rather than a neoplasm; it is also entirely separate from the similarly named glioma, a malignant brain tumor. NGH results when herniated brain tissue is sequestered extracranially by the bony fusion that forms the base of the skull during development (see Fig. 64.8). Although a vestigial fibrous stalk connecting with the intracranial space persists in 15%–25% of cases[13], unlike encephaloceles, there is no communication with the intracranial leptomeninges

Fig. 64.9 Nasal glial heterotopia (nasal glioma). A mass was noted on prenatal ultrasound, and this reddish, slightly pedunculated, rubbery nodule was evident at birth. *Courtesy Mary Chang, MD.*

or the CSF. NGH is present at birth, accounting for ~5% of congenital nasal midline masses[3,14], and it typically enlarges in proportion to the growth of the child.

*Extra*nasal NGH typically presents as a firm, non-compressible, non-pulsatile, non-transilluminating mass at or just lateral to the nasal root (Fig. 64.9; see Fig. 115.20). The overlying skin is often red with prominent telangiectasias, which may result in misdiagnosis as a hemangioma. *Intra*nasal NGH manifests as a widened nasal bridge or a polypoid nodule within the nasal cavity, sometimes protruding from a nostril. It occasionally causes nasal obstruction resulting in respiratory distress, and lesions involving the nasopharynx may be associated with a cleft palate[15]. Excessive lacrimation or strabismus may occur ipsilateral to the NGH[14].

Histologically, NGH demonstrates well-circumscribed nodules composed mostly of astrocytes, admixed with other glial cells and loosely textured intercellular glial substance interwoven with fibrous tissue (see Ch. 115). Neurons may or may not be present focally, and there are often prominent dilated blood vessels in the lesion and overlying skin. Immunoperoxidase staining for S100 protein and glial fibrillary acidic protein (GFAP) is positive. After imaging studies to determine whether an intracranial extension is present, NGH should be surgically excised.

Heterotopic brain tissue and rudimentary meningoceles

Synonyms: ■ Heterotopic brain tissue – neuroglial heterotopia, neuroglial choristoma ■ Rudimentary meningoceles – heterotopic meningeal tissue, sequestrated meningoceles, meningeal hamartomas, meningothelial hamartomas

Heterotopic brain tissue and rudimentary meningoceles are uncommon congenital anomalies thought to represent encephaloceles or meningoceles that have lost their intracranial attachment[8,16] (see Fig. 64.8). The bone underlying these lesions is usually intact. However, in intermediate forms known as *atretic encephaloceles* and *meningoceles*, a fibrotic stalk that extends intracranially with some degree of luminal ablation remains[8]. Heterotopic brain tissue may be located in the scalp, orbit, lip and oropharynx, as well as in the nasal area (nasal glial heterotopia; see above); rudimentary meningoceles are usually found on the scalp or overlying the spine[10,16].

Heterotopic brain tissue and rudimentary meningoceles typically present as a 1–4 cm solid or cystic subcutaneous nodule, often with a blue–red hue. Occasionally, rudimentary meningoceles have a bullous appearance and are clinically indistinguishable from membranous aplasia cutis[16]. Lesions are often located in the midline occipital or parietal scalp, where they can manifest with alopecia of the overlying skin and/or a surrounding hair collar. An overlying capillary malformation also may be present.

Histologic features of heterotopic brain tissue are as described for nasal glial heterotopia. Although classic findings such as cystic cavities lined by meningothelial cells are present in some cases of rudimentary meningocele, the histologic features are often subtle, with meningeal elements simulating the appearance of vascular or loose connective tissue. While signs such as the tendency of meningocytes to encircle collagen bundles and the presence of psammoma bodies may be helpful,

Fig. 64.10 Midline anterior neck inclusion cyst (MANIC) in an infant. *Courtesy Antonio Torrelo, MD.*

immunohistochemical staining for epithelial membrane antigen (EMA) and vimentin are critical in establishing the diagnosis[16]. Because the presence or absence of an intracranial connection cannot be reliably determined by clinical examination, imaging studies should be performed prior to surgical excision.

Midline anterior neck inclusion cyst

A midline anterior neck inclusion cyst (MANIC) presents as a congenital milia-like papule on the midline lower neck superior to the sternum. The small, superficial, yellow to white papule is not associated with underlying anomalies (Fig. 64.10). Histologically, a MANIC is lined by stratified squamous epithelium with intact keratohyalin granules, resembling an epidermoid cyst.

Midline cervical cleft

A midline cervical cleft is a rare congenital anomaly resulting from incomplete fusion of the branchial arches in the ventral midline of the neck. Approximately 200 cases have been reported worldwide, with a female-to-male ratio of 2 : 1[17]. Midline cervical clefts may be isolated or found in association with other defects, including other midline clefts (e.g. lower lip, tongue, mandible) and thyroglossal, branchial cleft, or bronchogenic cysts.

Patients present at birth with a vertically oriented, linear cleft on the midline neck at any point between the inferior edge of the mandible and the sternum. The lesion is covered with atrophic skin, which is often weeping in the neonatal period. Additional features may include a blind mucosal sinus tract inferiorly and a skin protuberance superiorly. A subcutaneous fibrous cord deep to the latter may extend upward to the chin, resulting in progressive cervical contracture and/or webbing of the neck with extension (pterygium colli medianum).

Histologically, midline cervical clefts consist of parakeratotic stratified squamous epithelium without normal adnexal structures. The subcutis often contains dense connective tissue, and fibrous cords may include bundles of skeletal muscle. Following ultrasonography to evaluate for an associated thyroglossal duct cyst (see Ch. 110), complete surgical excision and closure via Z-plasty (to reduce the risk of cicatricial contracture) should be performed during the first two years of life.

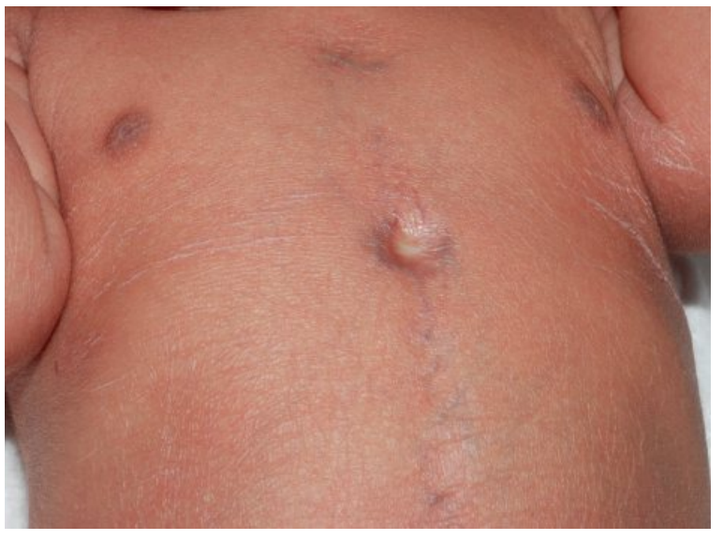

Fig. 64.11 Sternal cleft. Note the atrophic skin overlying the defect and prominent veins in the midline chest. Generalized desquamation is also evident in this 1-day-old post-term neonate. She did not develop an infantile hemangioma and had no cardiac defects or other features of PHACE syndrome.

Sternal clefts and supraumbilical raphae

Sternal clefts are rare congenital malformations that result from defective embryologic fusion of paired mesodermal bands in the ventral midline. These lesions most frequently involve the superior sternum, but inferior clefts and a complete bifid sternum can also occur. The skin overlying sternal clefts may be atrophic (Fig. 64.11), scarred, or ulcerated, and a dermal sinus tract is occasionally present. Approximately 40% of sternal clefts are associated with PHACE syndrome (*p*osterior fossa malformations; *h*emangiomas; *a*rterial, *c*ardiac and *e*ye anomalies; see Ch. 103)[18]. The sternal abnormality in PHACE syndrome may be limited to cutaneous atrophy or a pit in the presternal area, with intact underlying bone[19]. For sternal clefts associated with a substantial bony defect, surgical repair can be performed to protect the mediastinal organs and improve respiration as well as cosmesis. A supraumbilical raphe is a rare midline abdominal defect that presents as a firm, scar-like, linear protuberance extending cephalad from the umbilicus. Supraumbilical raphae often occur in association with sternal clefts, sometimes simultaneously as manifestations of PHACE syndrome.

Midline Lesions of the Spine

Spinal dysraphism refers to abnormal fusion of dorsal midline structures during embryologic development[20]. This term encompasses a wide variety of congenital spinal defects, ranging from myelomeningoceles (protrusion of the spinal cord and meninges with no overlying skin) and other overt anomalies in which neural tissue is exposed (*open spinal dysraphism*) to less obvious, skin-covered malformations (*closed* or *"occult" spinal dysraphism*). The latter include diastematomyelia (a split in the spinal cord), meningoceles, intraspinal lipomas, lipomyelomeningoceles (protrusion of the cord extraspinally into an attached lipoma), tight or fatty filum terminale, dermoid cysts, dermal sinuses, and isolated posterior spina bifida[21].

The degree of neurologic impairment associated with closed spinal dysraphism is variable. Any lesion that produces traction and/or pressure can cause progressive damage to the spinal cord, resulting in neurologic symptoms. Whereas isolated posterior spina bifida, an incidental radiographic finding in 15%–25% of the general population, is not clinically significant, other forms of dysraphism may become symptomatic during childhood or adolescence. Some patients, however, do not present until adulthood. When diagnosis is delayed, many of the aforementioned malformations can result in the tethered cord syndrome, which occurs when the conus medullaris (normally at the adult position of L1–L2 by 3 months of age) is low-lying and/or immobile. This syndrome is characterized clinically by back pain, urinary incontinence, motor and sensory deficits of the lower extremities, and orthopedic deformities (Fig. 64.12). Occasionally, an acute onset of symptoms is precipitated

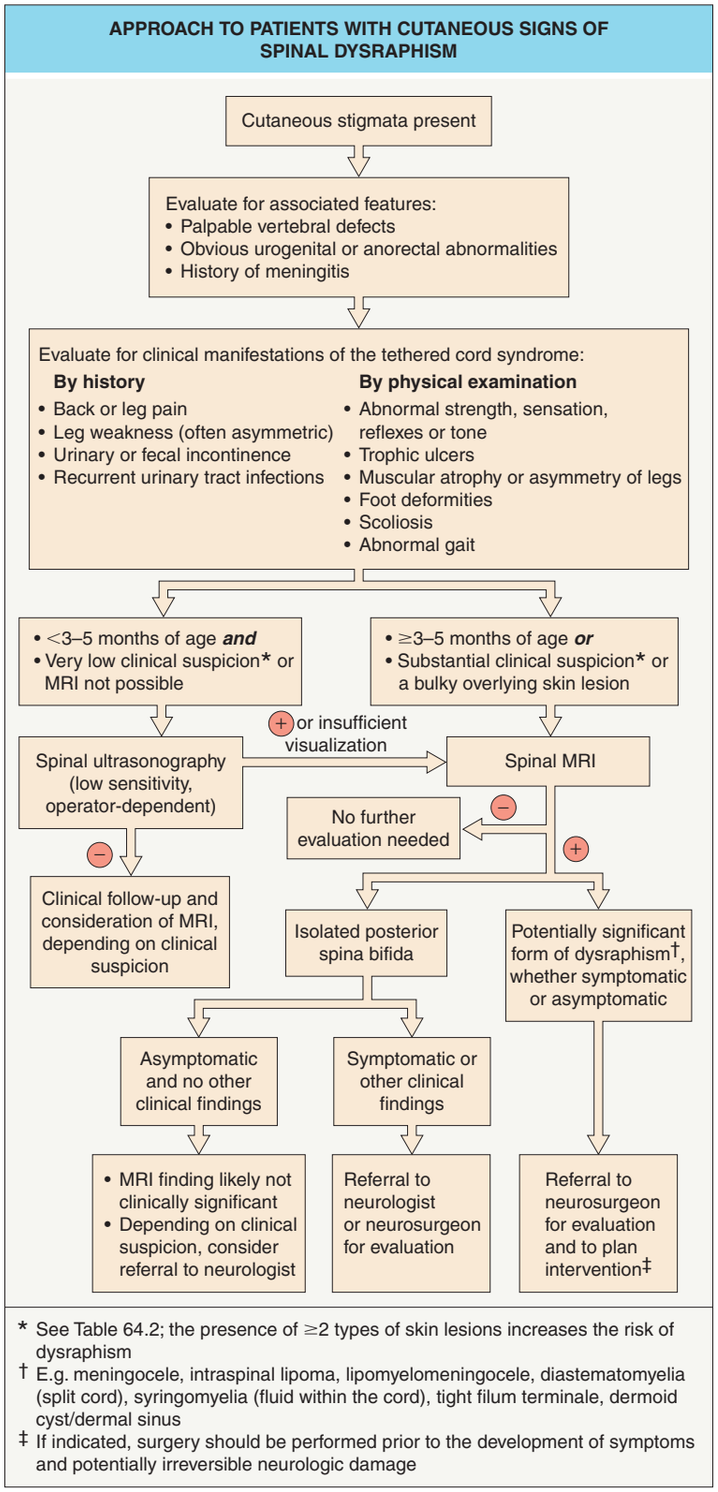

Fig. 64.12 Approach to patients with cutaneous signs of spinal dysraphism.

Fig. 64.13 Midline deep sacral dimple. The dimple was located above the gluteal cleft in association with a small tail. In contrast, a shallow dimple within the gluteal cleft is a common finding and not a sign of spinal dysraphism. *Courtesy Seth J. Orlow, MD, PhD.*

by childbirth, heavy lifting, or spinal trauma. Early diagnosis allows timely neurosurgical intervention that can halt progression and prevent potentially irreversible neurologic damage.

Because the skin and the nervous system share an ectodermal origin, concurrent anomalies of these tissues are common. Midline cutaneous lesions thus serve as a valuable marker for spinal dysraphism, and in the majority of patients, they are the finding that leads to the diagnosis. Approximately 80% of individuals with closed spinal dysraphism have paraspinal skin abnormalities, and the majority of them have more than one type of skin lesion[22,23]. In contrast, <3% of all neonates have cutaneous findings overlying the spine[24]. Shallow coccygeal dimples and deep gluteal clefts occur in an additional 4% of infants; however, in contrast to dimples located superior to the gluteal cleft (Fig. 64.13), these are considered as normal variants rather than a sign of an underlying malformation[24–26]. Most of the cutaneous lesions associated with spinal dysraphism are located in the lumbosacral area, reflecting the relative rarity of neural tube defects in the cervicothoracic region[27].

Hypertrichosis is the cutaneous marker of spinal dysraphism most often evident at birth. Affected individuals may be born with a V-shaped lumbosacral patch of long, coarse or silky hair on the dorsal midline (Fig. 64.14) known as a "faun tail"[28]. Overall, however, lumbosacral lipomas are the skin lesions most commonly associated with spinal dysraphism[22,23]. An intraspinal lipoma or lipomyelomeningocele often represents a portion of a larger subcutaneous lipoma, typically presenting as a soft mass located above the gluteal cleft and extending asymmetrically into one buttock. A curved gluteal cleft is suggestive of such a lesion, but clinical findings may be subtle initially, becoming more noticeable with time.

Infantile hemangiomas and vascular malformations located on or near the dorsal midline may also be signs of dysraphism. In addition to usually spanning the midline in the lumbosacral area, infantile hemangiomas associated with spinal dysraphism tend to have a segmental pattern and a superficial component, sometimes with minimal growth beyond reticular erythema and telangiectasias (Fig. 64.15; see Ch. 103)[29–31]. A patient with an isolated midline lumbosacral hemangioma >2.5 cm in diameter has an ~35% risk of having spinal dysraphism, which is higher if the hemangioma is larger, ulcerated, or associated with additional cutaneous markers[31]. Several acronyms have been proposed for the constellation of regional extracutaneous anomalies that can occur in individuals with segmental hemangiomas of the lower body; the most inclusive is ***LUMBAR*** *syndrome*: ***L***, *l*ower body/*l*umbosacral hemangioma and *l*ipomas or other cutaneous anomalies (e.g. "skin tags"); ***U***, *u*rogenital anomalies and *u*lceration; ***M***, *m*yelopathy (spinal dysraphism); ***B***, *b*ony deformities; ***A***, *a*norectal and *a*rterial anomalies; ***R***, *r*enal anomalies. Of note, a telangiectatic patch overlying a spinal defect may actually represent an infantile hemangioma with minimal or arrested growth.

Vascular malformations are most often an indicator of dysraphism when they occur together with other midline cutaneous lesions, most notably lipomas. In Cobb syndrome, a spinal arteriovenous malformation is associated with cutaneous involvement in the same segment; such findings may occur as a manifestation of the capillary malformation–arteriovenous malformation syndrome due to *RASA1* or *EPHB4* mutations. The cutaneous component may mimic a capillary malformation or angiokeratoma, and neurologic manifestations of cord compression can develop (see Ch. 104).

The common occipital nevus simplex ("stork bite") is *not* a marker for a spinal defect. In the lumbosacral region, nevus simplex lesions typically have rhomboidal or triangular shapes ("butterfly-like") or appear as grouped pink–red macules (Fig. 64.16), and they are frequently accompanied by nevus simplex lesions of the head, neck,

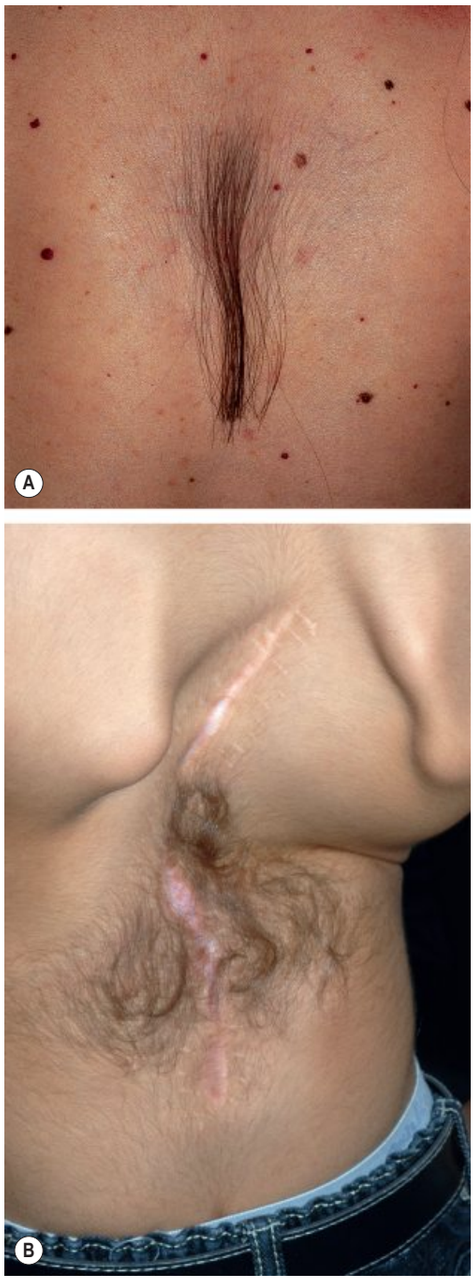

Fig. 64.14 Hypertrichosis associated with spinal dysraphism. **A** Circumscribed midline hypertrichosis overlying the lower thoracic spine in an adult with occult dysraphism. The patient periodically trims the hairs. **B** V-shaped patch of long, coarse hair on the mid back in a boy born with a large thoracic myelomeningocele. Severe scoliosis remains after multiple surgeries. *A, Courtesy Jean L. Bolognia, MD.*

Fig. 64.15 Multiple midline cutaneous stigmata overlying the sacral spine in LUMBAR syndrome. This infant with a segmental infantile hemangioma in the lumbosacral area, a large atypical dimple, a pseudotail, and a deviated gluteal cleft associated with a subcutaneous lipoma had an underlying lipomyelomeningocele.

Fig. 64.16 Nevus simplex of the lumbosacral region. Note the characteristic "butterfly-like" shape. The likelihood of spinal dysraphism is extremely low if there are no other local cutaneous findings (e.g. deviated gluteal cleft/lipoma, focal hypertrichosis, dermal sinus/pit), especially if there are additional nevus simplex lesions elsewhere.

and (occasionally) upper back. The current consensus is that regardless of spinal level, a nevus simplex without other local skin changes is rarely a sign of dysraphism, especially when there are nevus simplex lesions elsewhere[25,27]. While additional case series of lumbosacral nevus simplex have supported this expert opinion, i.e. they have not found an association with spinal dysraphism[32], a prospective study of 3623 neonates found that 1 of the 25 individuals with nevus simplex had diastematomyelia revealed by ultrasonography[33]. These neonates had no additional local skin findings, and it was not noted whether the individual with diastematomyelia had extrasacral vascular lesions.

Cutaneous lesions of the spinal axis that should alert the clinician to the possibility of dysraphism are summarized in Table 64.2. In one study[26], 39% (22/56) of neonates with "high-risk" stigmata such as hypertrichosis, subcutaneous masses, infantile hemangiomas, tails, or dimples above the gluteal cleft were found to have spinal dysraphism (see Figs. 64.14 & 64.15). The presence of *two or more skin lesions* is a particularly strong sign; in another series, 61% (11/18) of such patients had spinal dysraphism, compared to 8% (3/36) of those with only one skin lesion[34].

High-risk cutaneous stigmata overlying the spine represent an indication for radiologic evaluation, and superficial removal for cosmetic reasons is contraindicated until an underlying abnormality is excluded. MRI is highly sensitive and represents the imaging modality of choice in patients of all ages when occult spinal dysraphism is suspected. Although the vertebrae are not yet completely ossified in infants <5 months of age, ultrasonographic evaluation of the spinal cord is still less sensitive than MRI in this age group. In series comparing ultrasound to the gold standard of MRI in infants with cutaneous stigmata, ultrasound was ~75% sensitive for a low-lying conus but only 20%–40% sensitive for other findings such as a dermal sinus or abnormal filum terminale (e.g. thickened or fatty)[35]. Similarly, in a second series, ultrasound was 50% sensitive and 78% specific for detecting spinal anomalies (tethered cord, spinal lipoma > intraspinal hemangioma) in infants with lumbosacral infantile hemangiomas[31]. In infants with dysraphism associated with an anorectal malformation, spinal ultrasound had a sensitivity as low as 15%[36]. When infants are found to have anomalies with the potential to cause traction and/or pressure on the spinal cord, close follow-up is required and neurosurgical intervention may be recommended. Fig. 64.12 provides an algorithm for the approach to patients with cutaneous signs of spinal dysraphism.

SKIN LESIONS OF THE SPINAL AXIS ASSOCIATED WITH DYSRAPHISM	
Lesion	**Features**
Lipomas	Soft subcutaneous mass, asymmetric buttocks, curved gluteal cleft (Fig. 64.15)
Hypertrichosis	A V-shaped patch of long, coarse or silky hair ("faun tail") (Fig. 64.14)
Dimples	Above the gluteal cleft or >2.5 cm from the anal verge in neonates (Figs. 64.13 & 64.15); >0.5 cm in size or depth*
Dermal sinuses	Hair may be present at the ostium*
Acrochordons	May be associated with a dimple or dermal sinus
Pseudotails	Caudal protrusion due to prolonged vertebrae or hamartomatous elements, e.g. adipose tissue or cartilage (Fig. 64.15)
True tails	Persistent vestigial appendage with a central core of mature adipose tissue, muscle, blood vessels, and nerves
	May be capable of spontaneous or reflex motion
Infantile hemangiomas	Superficial, usually segmental pattern (Fig. 64.15), may be ulcerated
Telangiectasias	May represent an early, minimal/arrested growth, or regressed infantile hemangioma
Vascular malformations	Capillary malformations (CMs) are typically found together with other skin lesions
	Cobb syndrome: spinal arteriovenous malformation associated with skin involvement in the same segment mimicking a CM or angiokeratomas
Aplasia cutis congenita (ACC)	Ulcer, scar, or atrophic skin
Connective tissue nevus	Typically found together with other skin lesions
Hypo/depigmentation	May represent a nevus depigmentosus (typically found together with other skin lesions) or the residua of ACC
Hyperpigmentation	Typically found together with other skin lesions
Congenital melanocytic nevi	Spinal dysraphism has been reported in patients with neurocutaneous melanosis
Accessory breast tissue	Overlying nipple(s)
Subcutaneous masses†	May represent lipomas, meningoceles, lipomyelomeningoceles, teratomas, ependymomas, plexiform neurofibromas

*Due to a potential risk of meningitis, these lesions should not be probed.
†May result in a deviated gluteal cleft.

Table 64.2 Skin lesions of the spinal axis associated with dysraphism. The presence of two or more types of lesions increases the risk of a spinal anomaly.

APLASIA CUTIS CONGENITA

Synonyms: ■ Cutis aplasia ■ Congenital absence of skin ■ Congenital scars

Aplasia cutis congenita (ACC) is a condition in which localized or widespread areas of skin are absent or scarred at birth. It may occur as an isolated defect, in association with other developmental anomalies, or as a feature of a variety of disorders (Tables 64.3 & 64.4). There is no single underlying cause of ACC, which simply represents a physical finding that reflects an abnormality in intrauterine skin development. The many possible etiologies include genetic factors, vascular compromise, trauma, teratogens, and intrauterine infections[37,38].

As a result of its causal heterogeneity, the clinical appearance of ACC at birth is extremely variable, ranging from an erosion or deep ulceration to a scar due to healing *in utero* to a discrete ovoid defect covered by a membrane. The latter, referred to as *membranous aplasia cutis*, is the most common form. Occurring primarily on the scalp and often surrounded by a hair collar (see Figs. 64.3 & 64.4), such lesions may represent a forme fruste of a neural tube defect[2]. However, membranous aplasia cutis can also be seen along the embryonic fusion lines of the face (Table 64.4; Figs. 64.2 & 64.17)[39]. Membranous aplasia cutis typically presents at birth as a sharply marginated ("punched-out"), oval or round defect covered by a thin, translucent, glistening epithelial membrane. Lesions may contain serous fluid in the neonatal period, resulting in a bullous appearance (see Fig. 64.4). Eventually, they tend to flatten and transform into an atrophic scar (Fig. 64.18A). Dermoscopy typically shows a lack of follicular openings, telangiectatic vessels, and radially oriented hair follicles extending horizontally at the periphery ("starburst-like")[40]. Hypertrophic scarring can be a manifestation of an autosomal dominant form of scalp ACC in which mutations in the ribosomal GTPase BMS1 result in a cell cycle defect[41].

A second major type of ACC consists of stellate or angulated lesions, which are thought to result from vascular abnormalities and/or intrauterine ischemic events. Examples include irregular midline scalp defects in Adams–Oliver syndrome[42,43] and extensive, symmetric lesions on the trunk and/or extremities associated with fetus papyraceus, placental infarction, or other forms of vascular insufficiency (Fig. 64.19)[44]. These defects usually appear as ulcers of variable depth with a raw, hemorrhagic, or granulating base (Fig. 64.18B,C).

Other patterns of ACC include a lack of skin overlying embryologic malformations, either obvious or occult, and large erosions with jagged borders on the extremities of neonates with epidermolysis bullosa[45]. The latter likely result from the mechanical trauma of fetal movements in a setting of increased skin fragility. The morphology and distribution of the skin defects (see Fig. 64.19) as well as the presence or absence of associated abnormalities represent important clues to the etiology of ACC. Table 64.3 presents a classification scheme for ACC, and Table 64.4 describes several syndromes associated with ACC. However, because ACC is a physical finding that may result from *any* intrauterine event that disrupts skin development, not all cases can be neatly categorized. Unusual presentations of ACC range from an isolated defect on the ventral penis to an extreme form with absence of skin and subcutaneous tissue over >90% of the body surface area associated with extracutaneous anomalies ("systemic" ACC; see Table 64.3).

The scalp is the most common site for ACC, accounting for >85% of solitary lesions. The majority of cases of scalp ACC, whether membranous or irregular and scar-like, are located at or near the vertex, in proximity to the parietal hair whorl[46]. Approximately 25% of patients have more than one lesion, and multiple membranous lesions may occur in a linear arrangement. Most defects are 1–2 cm in diameter, although the size can range from 0.5 to >10 cm. A capillary malformation (see above, Midline lesions of the scalp) is sometimes present in the skin surrounding membranous ACC, and dilated scalp veins may also be evident, especially in patients with Adams–Oliver syndrome (see Table 64.3)[42]. Scalp ACC involves the underlying skull in 10%–30% of cases, with increased risk when the lesion has a midline vertex location, hair collar, size >5 cm, and associated capillary stain[47,48]. Large, irregular lesions are more likely to extend to deeper structures and may affect the dura and/or leptomeninges.

Histologic features of membranous aplasia cutis include an atrophic flattened epidermis, replacement of the dermis by loose connective tissue, and an absence of adnexal structures. Findings in other types of ACC vary but lesions that have healed generally show scarring, a lack of adnexa, and in some cases fragmented elastic tissue[49]. Although histologic examination may occasionally be helpful, the diagnosis of ACC is primarily clinical.

Cutaneous defects noted at birth may initially be erroneously attributed to obstetric trauma, such as injuries from forceps or fetal scalp electrodes. Evaluation of a patient with ACC is directed by the personal, obstetric, and family history as well as the physical examination; in a neonate, it may include specific investigations such as examination of the placenta and viral studies for herpes simplex and varicella zoster[50]. In patients with large, deep, irregular or membranous lesions of the scalp (Fig. 64.18B,E), especially when there is a hair collar and/or midline vertex location, imaging studies are indicated to assess for underlying bone defects, vascular anomalies, or brain malformations. Lastly, elevated α-fetoprotein in midtrimester maternal serum and amniotic fluid as well as elevated acetylcholinesterase in the amniotic fluid may represent early signs of ACC, although they are neither sensitive nor specific for this condition.

CLASSIFICATION SCHEME FOR APLASIA CUTIS CONGENITA (ACC)			
	Inheritance (Gene)	**Features**	**Associated abnormalities**
Group 1: Scalp ACC without multiple anomalies	Sporadic > AD	Usually at the vertex Membranous Hair collar	**No associated abnormalities** **Isolated abnormalities** (most often associated with membranous ACC): cleft lip and/or palate, tracheoesophageal fistula, high myopia and cone-rod dysfunction, patent ductus arteriosus, intestinal lymphangiectasia, omphalocele, polycystic kidneys, double cervix and uterus, intellectual disability, temporal triangular alopecia
	Often AD (*BMS1*)	Usually at the vertex Irregular and scar-like	
Group 2: Scalp ACC associated with Adams–Oliver syndrome	AD (*ARHGAP31*, *RBPJ*, *NOTCH1, DLL4*) AR (*DOCK6*, *EOGT*)	Midline scalp Often large, irregular lesions Skull defect Dilated scalp veins	**Adams–Oliver syndrome**: terminal transverse limb defects (e.g. reductions, syndactyly, nail dystrophy), cutis marmorata telangiectatica congenita, cardiac malformations, CNS abnormalities
Group 3: Scalp ACC associated with epidermal and sebaceous nevi (and, occasionally, congenital melanocytic nevi)	Sporadic due to mosaic RASopathy (e.g. *HRAS*, *KRAS*)	Scalp, often unilateral Membranous	**Epidermal nevus or nevus sebaceus**, usually in proximity to the ACC **Large congenital melanocytic nevus**: in a few reports* **Ipsilateral ophthalmologic abnormalities**: corneal opacities, scleral dermoids, eyelid colobomas, retinal dystrophy **CNS abnormalities**: intellectual disability, seizures
Group 4: ACC overlying embryologic malformations	Variable	Scalp, often with a hair collar if overlying a neural tube defect Lumbosacral Chest, abdomen	**Cranial malformations**: cephalocele, heterotopic brain or meningeal tissue, congenital midline porencephaly, holoprosencephaly, craniosynostosis, vascular malformation/aplasia/arteriovenous fistula **Spinal malformations**: occult dysraphism, myelomeningocele **Thoracic malformations**: sternal cleft **Abdominal malformations**: omphalocele, gastroschisis **Multiple malformations associated with generalized, lethal ACC ("systemic" ACC)**: corneal opacities, choanal atresia, hypoplastic lungs, absent greater omentum, intestinal malrotation & atresias, hepatosplenomegaly, skull defects, syndactyly, anonychia
Group 5: ACC associated with fetus papyraceus, placental infarcts, or other ischemic events	Sporadic	Scalp, chest, flanks, axillae and/or extremities (see Fig. 64.19) Multiple, symmetric Stellate/angulated configuration	**Associated fetus papyraceus** due to second-trimester death of twin/triplet or fetal reduction of higher-order pregnancies **Placental infarction**, single umbilical artery **Duodenal, ileal, and/or biliary atresias with intestinal infarction** Intracranial hemorrhage/CNS abnormalities
Group 6: ACC associated with epidermolysis bullosa (EB)	AD or AR, depending on EB type	Lower extremities ("Bart syndrome") or large areas of the extremities, trunk, and scalp	**EB simplex (EBS; especially *KLHL24*-related), junctional EB (JEB), and dystrophic EB**: blistering of skin and/or mucous membranes, skin fragility, nail dystrophy **If more widespread (most often in JEB or EBS with pyloric atresia)**: ureteral stenosis, renal abnormalities, arthrogryposis, abnormal ears and nose; may have intrauterine/neonatal death (*ITGB4*, *PLEC*)
Group 7: Localized ACC, presumably due to prenatal physical insult	Sporadic	Extremities, e.g. forearm, pretibial area	**Volkmann contracture** or **radial dysplasia** (with ACC on the forearm) **Amniotic band sequence** (see text)
Group 8: ACC caused by specific teratogens, maternal conditions, or intrauterine infections	Sporadic	Scalp with drugs Any site with congenital infections	**Methimazole (thiamazole), carbimazole**: imperforate anus, urachal malformations **Misoprostol** **Low-molecular-weight heparin** **Valproic acid** **Maternal antiphospholipid syndrome** **Intrauterine varicella, herpes simplex or rubella infection**: signs of these infections
Group 9: ACC associated with malformation syndromes	Variable	Variable	See Table 64.4

*Referred to as "SCALP" syndrome (*s*ebaceous nevus, *C*NS malformations, *A*CC, *l*imbal dermoid, *p*igmented nevus).

Table 64.3 Classification scheme for aplasia cutis congenita (ACC). Bold text in column 4 signifies main topics, followed by details. AD, autosomal dominant; AR, autosomal recessive; *ARHGAP31*, Rho GTPase activating protein 31; *BMS1*, ribosome biogenesis factor; CNS, central nervous system; *DLL4*, Delta-like 4; DOCK6, dedicator of cytokinesis 6; *EOGT*, EGF domain-specific O-linked N-acetylglucosamine transferase; *KLHL24*, Kelch-like member 24; *RBPJ*, recombination signal binding protein for immunoglobulin κ J region (transcriptional regulator for the Notch pathway). *Adapted from Frieden IJ. J Am Acad Dermatol. 1986;14:646–60, with permission.*

Most small lesions of ACC heal within the first few months of life, leaving an atrophic (see Fig. 64.18A) or, less often, hypertrophic ("lumpy") scar. In such instances, daily cleansing and application of petrolatum or a topical antibiotic ointment until healing is complete are often the only interventions required. Underlying skull defects also tend to resolve spontaneously during infancy. However, potential complications of deep ACC of the scalp include life-threatening sagittal sinus hemorrhage/thrombosis and meningitis. Because the risk of complications increases if the period of healing is prolonged, early surgical repair of large stellate scalp lesions or those associated with a dural defect or exposure of the sagittal sinus is recommended. Preoperative imaging studies are required to identify underlying vascular structures. Even without surgical intervention, residual scarred, hairless areas generally become less conspicuous as the child grows. If desired for cosmetic reasons, excision or hair transplants can be performed later in life.

SYNDROMES ASSOCIATED WITH APLASIA CUTIS CONGENITA (ACC, GROUP 9)			
	Inheritance (Gene)	**Features of ACC**	**Other features**
Facial ACC (see Fig. 64.2)			
Focal facial dermal dysplasia (FFDD) FFDD1 – Brauer FFDD2 – Brauer–Setleis FFDD3 – Setleis FFDD4 – preauricular	**FFDD1 & 2:** AD, variable expressivity **FFDD3:** AR (*TWIST2*) **FFDD4:** AR (*CYP26C1*) > AD	Round or oval, membranous, ± hair collar Linear arrangement **FFDD1–3:** bilateral temples ("forcep marks"), from lateral eyebrow to anterior hairline* **FFD4:** bilateral from preauricular cheek to angle of mouth†	**FFDD1**: sparse lateral eyebrows, distichiasis, flat nasal tip **FFDD2 & 3**: abnormal eyelashes, upward-slanting eyebrows, "leonine" facies (Fig. 64.17), imperforate anus **FFDD4**: buccal mucosal polyps
Linear skin defects with multiple congenital anomalies (LSDMCA) 1–3 LSDMCA1 – microphthalmia with linear skin defects (MIDAS)	X-linked dominant LSDMACA1: *HCCS* LSDMACA2: *COX7B* LSDMACA3: *NDUFB11*	Mid-cheek to bridge of nose, neck Stellate erosions that heal with reticulolinear scarring	Microphthalmia, sclerocornea, agenesis of the corpus callosum, genital anomalies, short stature
Scalp ACC			
Adams–Oliver syndrome (see Table 64.3, ACC group 2)			
Oculocerebrocutaneous (Delleman–Oorthuys) syndrome	Sporadic	Membranous on supra-auricular scalp (often crescentic shape) Also may occur on neck and lumbosacral area	Orbital cysts, microphthalmia, giant tectum-absent vermis, agenesis of the corpus callosum, facial appendages composed of skeletal muscle
Oculoectodermal syndrome	Mosaic (*KRAS*)	Membranous	Epibulbar dermoids, macrocephaly, truncal hyperpigmentation
UBA2-related phenotypic spectrum	AD (*UBA2*)	At/around vertex, may be multifocal	Ectrodactyly/other digital anomalies, hip dysplasia, peg-like teeth, thin hair, supernumerary nipples, hypertelorism, high forehead, developmental delay; ocular, cardiac, genital, and renal anomalies
Johanson–Blizzard syndrome	AR (*UBRI*)	Stellate or membranous	Dwarfism, hypoplastic nasal alae, hypodontia/peg-like teeth, deafness, microcephaly, hypothyroidism, pancreatic insufficiency
Scalp–ear–nipple syndrome (Finlay–Marks syndrome)	AD (*KCTD1*)	May heal with hypertrophic scarring	Nipple/breast hypo- or aplasia, abnormal ears and teeth, nail dystrophy, syndactyly, reduced apocrine secretion
Trisomy 13 (Patau syndrome)	Sporadic	Membranous Large defects	Holoprosencephaly, ocular abnormalities, deafness, cleft lip/palate, cardiac malformations, polydactyly, narrow and convex nails; early death
4p- (Wolf–Hirschhorn) syndrome	Sporadic	Midline	Microcephaly, ocular abnormalities, cleft lip/palate, preauricular pits, and accessory tragi; often early death

*Along the embryonic fusion line between the frontonasal prominence and the maxillary prominence of the first branchial arch.
†Along the embryonic fusion line between the maxillary and mandibular prominences of the first branchial arch.

Table 64.4 Syndromes associated with aplasia cutis congenita (ACC, group 9). ACC also may be found in patients with branchio-oculo-facial syndrome (see text), Goltz syndrome (focal dermal hypoplasia), encephalocraniocutaneous lipomatosis, and several types of ectodermal dysplasia, including the EEC syndrome (*e*ctrodactyly, *e*ctodermal dysplasia, *c*lefting), AEC syndrome (*a*nkyloblepharon, *e*ctodermal dysplasia, cleft lip/palate), cleft lip/palate–ectodermal dysplasia, and tricho-odonto-onychial dysplasia. In addition, there have been reports of scalp ACC in patients with Pallister–Killian syndrome (tetrasomy 12p), Opitz syndrome, popliteal pterygium syndrome, EVEN-plus syndrome, Xia–Gibbs syndrome, Marshall syndrome, and hereditary sensory and motor neuropathy type 1 (www.ncbi.nlm.nih.gov/omim). AD, autosomal dominant; AR, autosomal recessive; *COX7B*, cytochrome c oxidase, subunit 7B; *CYP26C1*, cytochrome P450 family 26 C, polypeptide 1; *HCCS*, holocytochrome c synthase; *KCTD1*, potassium channel tetramerization domain-containing 1; MIDAS, microphthalmia, dermal aplasia and sclerocornea; *NDUFB11*, NADH:ubiquinone oxidoreductase subunit B11; *UBA2*, ubiquitin like modifier activating enzyme 2; *UBR1*, ubiquitin-protein E3 component n-recognin 1.

Fig. 64.17 Facial aplasia cutis congenita. Atrophic cutaneous defect extending from the lateral eyebrow to the anterior hairline in a patient with Setleis syndrome. Note the upward-slanting eyebrows and "leonine" facial appearance. *Courtesy Seth J. Orlow, MD, PhD.*

OTHER DEVELOPMENTAL ANOMALIES

Congenital Lip Pits

Synonyms: ■ Lip sinuses ■ Congenital sinuses of the lower lip ■ Midline sinuses of the upper lip

Congenital lip pits are divided into three types based on their location: (1) commissural; (2) upper lip; and (3) lower lip. Commissural lip pits are by far the most common, occurring in 1%–2% of newborns. Lip pits likely result from defective embryologic fusion of facial processes with epithelial entrapment. They usually represent the opening of a blind sinus tract, which can extend inward through the orbicularis oris muscle to a depth of >10 mm. This tract occasionally communicates with the ducts of underlying minor salivary glands, and saliva or mucus may drain from the ostium. Lesions are sometimes associated with swelling of the lip or, particularly if located on the philtrum, recurrent infection.

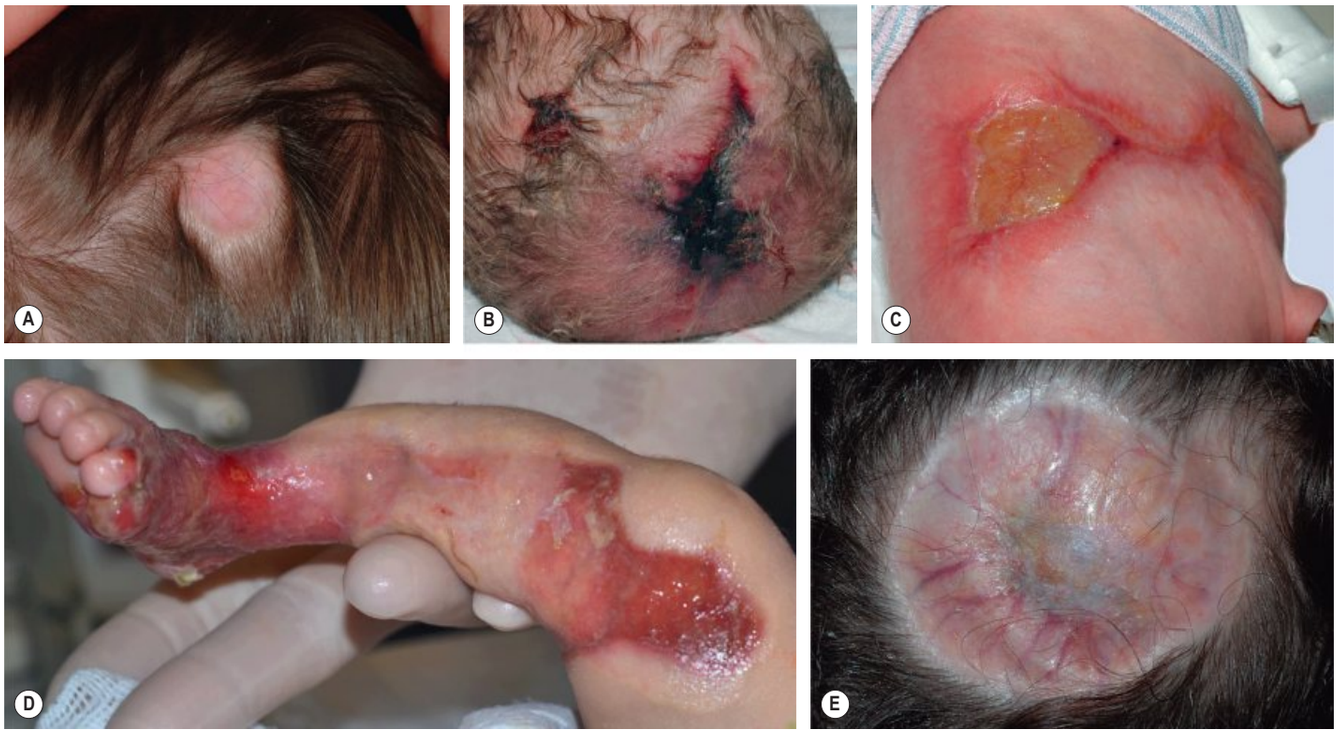

Fig. 64.18 Aplasia cutis congenita (ACC). A This hairless, round, scarred plaque on the scalp of a 6-month-old was present at birth. **B** Stellate ACC on the midline scalp of a neonate. This hemorrhagic lesion was associated with an underlying skull defect and cerebrovascular anomalies. **C** Stellate ACC on the lateral trunk of a neonate born of an initial sextuplet gestation for which fetal reduction was performed. The lesions had a bilateral, symmetric distribution. **D** ACC on the leg in a neonate with epidermolysis bullosa ("Bart syndrome"). **E** Membranous ACC associated with a large defect of the underlying skull in a patient with Goltz syndrome.
A, Courtesy Anthony J. Mancini, MD; D, Courtesy Emily Berger, MD.

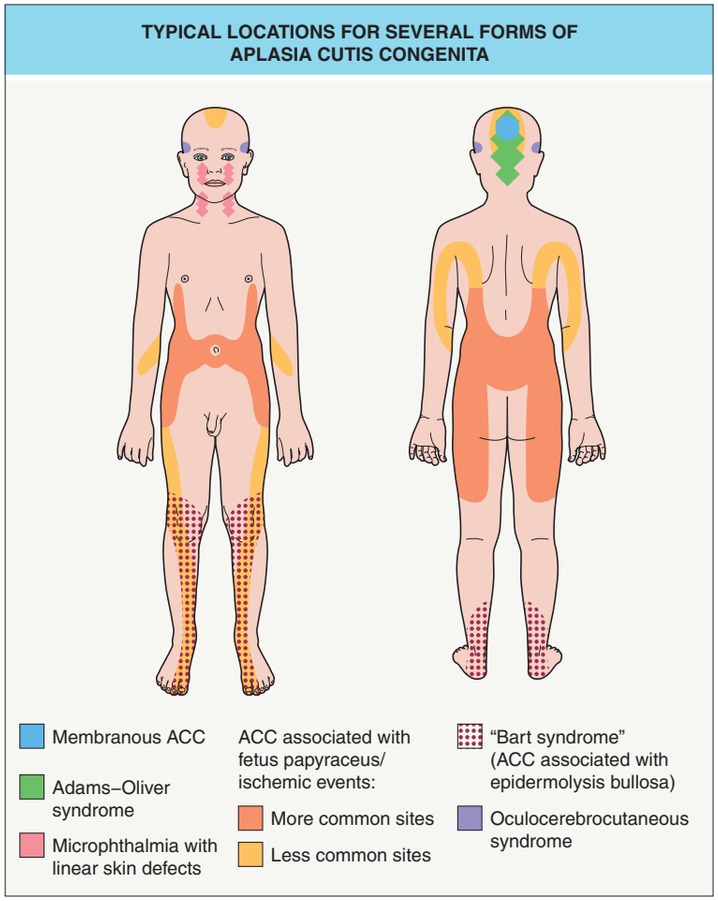

Fig. 64.19 Typical locations for several forms of aplasia cutis congenita (ACC). See Fig. 64.2 for Brauer lines/Setleis syndrome, preauricular membranous ACC, and microphthalmia with linear skin defects.

Commissural lip pits are typically found bilaterally in the mucosal surface at the angles of the mouth (Fig. 64.20A). Although most often an isolated anomaly, they may be inherited in an autosomal dominant fashion along with preauricular pits and hearing impairment in patients with a form of branchio-otic syndrome linked to chromosome 1q31[51]. Commissural lip pits also have been described in association with alveolar synechiae, ankyloblepharon filiforme adnatum (congenital adhesions between the upper and lower eyelids), and ectodermal defects.

Upper lip pits, also known as midline sinuses of the upper lip, are rare lesions that are typically located along the philtrum. Although usually an isolated defect, they may be associated with hypertelorism and other dysmorphic facial features. In addition, paramedian upper lip pits may occur (Fig. 64.20B) and are bilateral in patients with the branchio-oculo-facial syndrome (see below, Branchial Cleft Sinuses and Fistulae).

Lower lip pits may be an isolated finding or seen as a part of van der Woude syndrome, which is characterized by paramedian pits in the vermilion portion of the lower lip, cleft lip and/or palate, and hypodontia. The lip pits are usually bilateral, and they may be located on the apex of a conical elevation (Fig. 64.20C). Van der Woude syndrome, which occurs in ~1–3 per 100 000 live births, is an autosomal dominant disorder caused by mutations in the interferon regulatory factor 6 (*IRF6*)[52] or grainyhead-like 3 (*GRHL3*) gene. The popliteal pterygium syndrome is also due to *IRF6* mutations; in addition to lower lip pits, findings include cleft lip and/or palate, syngnathia, popliteal webbing, nail dysplasia, syndactyly, and genital anomalies. Lastly, lower lip pits are occasionally seen in oral–facial–digital syndrome type I (Table 64.5) and Kabuki syndrome (www.ncbi.nlm.nih.gov/omim).

Histologically, the sinus tracts associated with lip pits are lined by stratified squamous epithelium; associated salivary or mucous glands are occasionally observed. The evaluation of patients with lip pits should include a family history and a physical examination to exclude associated anomalies. If lip pits of any type are symptomatic or cosmetically undesirable, surgical excision is the treatment of choice. The extent of the sinus can be estimated preoperatively by injection of a radio-opaque contrast medium.

Fig. 64.20 Lip pits. A Bilateral commissural lip pits. **B** Unilateral right-sided upper lip pit. **C** Bilateral paramedian lower lip pits, each located on the apex of a conical elevation. All were isolated anomalies.

DISEASES AFFECTING THE SKIN THAT ARE ASSOCIATED WITH CLEFT LIP AND/OR PALATE	
Syndrome	**Other features**
Ectodermal dysplasias (see Ch. 63)	
• EEC syndrome	AD, *TP63*; ectodermal dysplasia, ectrodactyly, cleft lip/palate
• AEC syndrome	AD, *TP63*; ankyloblepharon, ectodermal dysplasia, cleft lip/palate
• Cleft lip/palate–ectodermal dysplasia	AR, *NECTIN1*; ectodermal dysplasia, pili torti, syndactyly
Branchio-oculo-facial syndrome	See text – branchial cleft sinuses
Oral–facial–digital syndrome, type 1	X-D, *OFD1*; lobulated tongue, hypertrophic oral frenula, digital malformations, whorled alopecia of the vertex, transient facial milia, polycystic kidneys, CNS anomalies
Oculocerebrocutaneous syndrome	See Table 64.4
4p- syndrome (Wolf–Hirschhorn syndrome)	See Table 64.4
Pai syndrome	Facial skin tags, nasal polyps, midline cleft lip, CNS lipomas
Basal cell nevus (Gorlin) syndrome	See Ch. 108
Goltz syndrome (focal dermal hypoplasia)	See Ch. 62
Waardenburg syndrome, type 1 or 3	See Ch. 66
Van der Woude syndrome*	See text – congenital lower lip pits
Popliteal pterygium syndrome*	See text – congenital lower lip pits
Nail–patella syndrome	See Ch. 71
Beare–Stevenson cutis gyrata syndrome	AD, *FGFR2*; craniosynostosis, cutis gyrata, acanthosis nigricans
Local lesions	
Dermal melanocytosis Encephaloceles or nasal gliomas	
*Allelic disorders.	

Table 64.5 Diseases affecting the skin that are associated with cleft lip and/or palate. Other disorders associated with cleft lip/palate that also can affect the skin include Cornelia de Lange, Roberts, Simpson–Golabi–Behmel, Pallister–Hall and CHIME (colobomas [ocular], *h*eart defects, *i*chthyosis, *m*ental retardation and *e*ar anomalies) syndromes, hemifacial microsomia, Meige disease (familial lymphedema praecox), and trisomy 13. AD, autosomal dominant; AR, autosomal recessive; CNS, central nervous system; X-D, X-linked dominant.

Accessory Tragi

Synonyms: ■ Preauricular tags ■ Preauricular appendages

Accessory tragi are relatively common congenital anomalies of the first branchial arch, and they are found in 3–6 per 1000 live births. Familial occurrence has been reported, sometimes with a consistent anatomic site within kindreds. During development, the external ear is formed by the fusion of six tubercles, three each from the first and second branchial arches; the tragus and anterior crus of the helix are the only portions of the ear derived from the former[53]. Whereas preauricular pits and cysts reflect defective fusion of the tubercles (see Ch. 110), accessory tragi represent remnants of and/or extra tubercles originating from the first branchial arch.

Accessory tragi most often manifest as skin-colored papules or nodules in the preauricular area, but they also may be found on the mandibular cheek or on the neck along the anterior border of the sternocleidomastoid muscle (also referred to as congenital cartilaginous rests of the neck, see below)[54] (Fig. 64.21). The latter locations reflect the embryologic migration of the external ear from the neck to the side of the head as the mandible develops. Accessory tragi are occasionally multiple (see Fig. 64.21B) and are bilateral in ~10% of affected individuals. They are typically covered by vellus hairs and can be either soft or firm due to a cartilaginous core[53].

Although they usually represent an isolated malformation, accessory tragi are sometimes associated with other developmental anomalies of the first branchial arch, such as cleft lip and palate[55]. Together with ipsilateral facial hypoplasia, ear deformities, epibulbar dermoids, and vertebral abnormalities, accessory tragi are a cardinal feature of hemifacial microsomia (Goldenhar syndrome). Accessory tragi may be seen in a number of other multiple congenital anomaly syndromes, including Nager acrofacial dysostosis, Townes–Brocks syndrome, Treacher Collins–Franceschetti syndrome, VACTERL association, Wildervanck syndrome, and Wolf–Hirschhorn syndrome (www.ncbi.nlm.nih.gov/omim). Controlled studies have failed to confirm purported associations between isolated accessory tragi and urinary tract abnormalities or hearing impairment.

Histologically, accessory tragi are polypoid lesions with numerous tiny, mature hair follicles, a prominent connective tissue framework within abundant subcutaneous fat, and often a central plate of elastic cartilage. When accessory tragi are surgically excised for cosmetic reasons, care must be taken to remove any protruding portion of underlying cartilage[54]. Evaluation of an infant with an accessory tragus should include assessment of hearing and examination for other dysmorphic features.

Congenital Cartilaginous Rests of the Neck

Synonyms: ■ Wattles ■ Cervical accessory tragi ■ Cutaneous cervical tabs

Fig. 64.21 Accessory tragi. A Typical small preauricular papule. **B** Multiple skin-colored papulonodules on the mandibular cheek as well as in a preauricular location. **C** Congenital cartilaginous rest of the neck, which is considered to represent a cervical subtype of accessory tragus.

Congenital cartilaginous rests of the neck are branchial arch remnants that are considered to be the cervical variant of accessory tragi (see above). The alternative term "wattle" refers to the fleshy appendage that hangs from the throat of certain animals, such as turkeys and goats. Typically located over the lower anterior border of the sternocleidomastoid muscle (see Fig. 64.21C), these asymptomatic lesions may be unilateral or bilateral, and they are neither cystic nor fistulous. They may be attached to the underlying fascia by a fibrous band, which can be safely transected if excision is desired[56].

Branchial Cleft Sinuses and Fistulae

Synonym: ■ Lateral cervical sinuses and fistulae

Branchial cleft *sinuses* most often represent remnants of the second branchial (pharyngeal) cleft. They are usually detected at birth or during the first few years of life, unlike the more common branchial cleft *cysts* that lack a primary cutaneous opening and typically present in older children and adults (see Ch. 110). The ostium of a second branchial cleft sinus is located on the lateral lower third of the neck along the anterior border of the sternocleidomastoid muscle, and there is frequently a history of mucus discharge; the associated tract extends superiorly in the subcutis and may be palpable. The less common first branchial cleft sinus can manifest with a cutaneous opening located higher on the neck or in the periauricular region. Approximately 70% of branchial cleft sinuses are located on the right and 5%–10% are bilateral. There may be a history of recurrent infection, and a skin tag, sometimes with a cartilaginous component, can mark the ostium. Most branchial sinus tracts end blindly, but occasionally there is a fistulous connection with the tonsillar fossa of the pharynx or the external auditory canal[57]. Rarely, thyroid or squamous cell carcinoma develops within branchial cleft remnants.

Although usually an isolated malformation, branchial cleft sinuses and fistulae are also features of several multiple congenital anomaly syndromes. These include the branchio-otic and branchio-oto-renal syndromes, autosomal dominant disorders that also feature ear pits, hearing loss, and, in the latter, renal anomalies. These syndromes can be caused by mutations in the *EYA1* (both conditions), *SIX1* (branchio-otic), and *SIX5* (branchio-oto-renal) genes, which encode transcription factors that interact within a complex. Atrophic, eroded, or "hemangiomatous" skin overlying branchial cleft sinuses on the neck or in the periauricular area is a distinctive feature of the branchio-oculo-facial syndrome that is due to mutations in the gene encoding transcription factor AP2-α. Additional manifestations of this disorder include cleft lip/palate, imperforate nasolacrimal ducts, eye and ear anomalies, and early graying of the hair.

Histologically, a branchial sinus may be lined by stratified squamous or pseudostratified ciliated columnar epithelium. In order to prevent infectious complications, complete surgical excision of branchial sinuses and fistulae is indicated. Imaging may be helpful in delineating the course and extent of the lesion, although recommendations vary among otolaryngologists. Preoperative options include CT fistulography and MRI; in addition, intraoperative contrast fistulography and/or injection of methylene blue dye can be considered[57,58].

Supernumerary Nipples and Other Forms of Accessory Mammary Tissue

Variants/synonyms: ■ Supernumerary nipples – accessory nipples, polythelia ■ Pseudomamma (nipple + areola) ■ Supernumerary breasts – polymastia

Supernumerary nipples and other forms of accessory mammary tissue are remnants of the embryologic mammary ridges or "milk lines", symmetric ectodermal thickenings that extend from the anterior axillary fold to the upper medial thigh (Fig. 64.22). Normally, there is further development in the pectoral region to form the nipples, while the remainder of the milk line regresses; focal areas of persistence result in accessory mammary tissue. Supernumerary nipples, the most common type of accessory mammary tissue, are found in 1%–6% of the population[59]. They usually represent a sporadic developmental anomaly, although ~10% of cases are familial. The incidence of supernumerary nipples is similar in men and women. However, in women, accessory mammary tissue often becomes more apparent at puberty or during pregnancy. Conversely, changes in supernumerary nipples may actually represent an early cutaneous sign of pregnancy.

Supernumerary nipples are most commonly seen on the inframammary chest, but they may be located anywhere along the milk lines (including the vulva) and occasionally in other sites such as the upper back, shoulder, posterior thigh, face, neck, or even foot. In addition, supernumerary nipples sometimes overlie the primary nipple or areola. Lesions are most often single, but they may be multiple and/or bilateral. Supernumerary nipples typically present as a small, soft, pink or brown papule, with or without a surrounding areola (Fig. 64.23). An areola also can also develop in the absence of a nipple, and ectopic glandular breast tissue can be isolated or associated with a nipple and/or areola. When only breast tissue is present, it is most often located in the axilla or vulva and may demonstrate all of the functional changes of normal breasts, from tenderness and swelling related to the menstrual cycle to lactation through pores in the overlying skin. Of note, a tuft of hair located along the milk lines may be a marker of underlying mammary tissue (polythelia pilosa)[60].

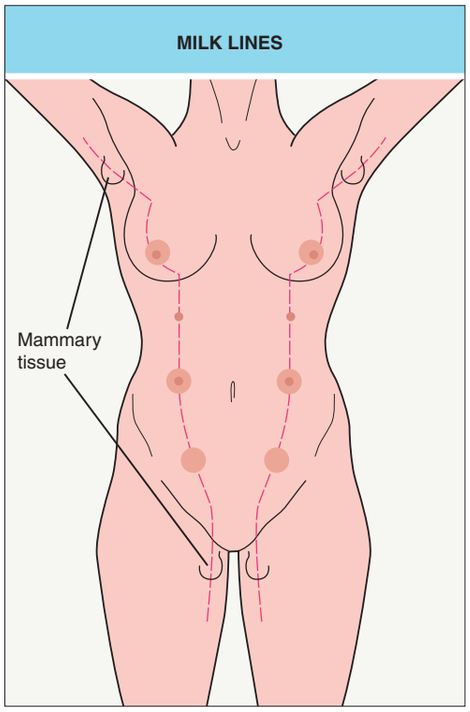

Fig. 64.22 "Milk lines". Supernumerary nipples and other forms of accessory mammary tissue represent focal remnants of the embryologic mammary ridges that extend from the anterior axillary fold to the upper medial thigh bilaterally.

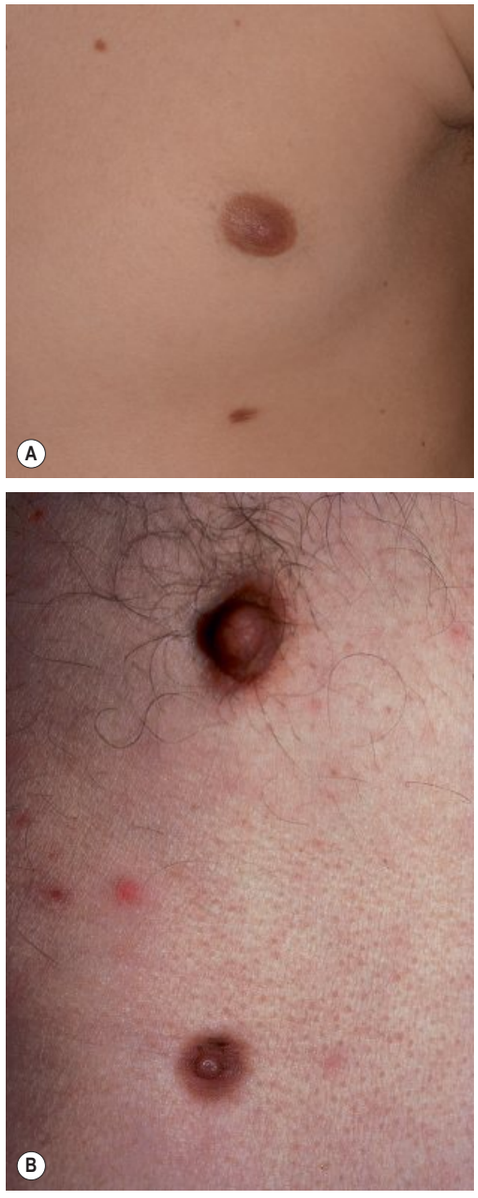

Fig. 64.23 Supernumerary nipples on the inframammary chest. A Brown papule that might be mistaken for a melanocytic nevus. **B** Nipple with a surrounding areola. *B, Courtesy Jean L. Bolognia.*

A number of other abnormalities have been described in patients with supernumerary nipples. The association between supernumerary nipples and malformations of the kidneys and urinary tract is controversial. Although early reports supported the existence of a "supernumerary nipple/renal field defect", several controlled studies failed to confirm this association[61]. However, a few studies have found supernumerary nipples to be significantly more common in patients with urogenital or renal malignancies than in control groups[62]. Supernumerary nipples have been noted in patients with Becker melanosis and are a feature of several multiple congenital anomaly syndromes (e.g. Simpson–Golabi–Behmel, Pallister–Killian), the *UBA2*-related phenotypic spectrum, cleft lip/palate–ectodermal dysplasia, and tricho-odonto-onychial dysplasia (www.ncbi.nlm.nih.gov/omim). Lastly, midline dorsal accessory breast tissue with underlying spinal dysraphism has been reported.

Histologic features of accessory mammary tissue are similar to those of normal breasts. For example, supernumerary nipples show acanthosis, pilosebaceous structures, smooth muscle, and in many cases, mammary glands. Fine-needle aspiration cytology can be helpful for evaluation of an axillary or vulvar mass suspected to represent breast tissue, although an incisional or excisional biopsy may be required for definitive diagnosis. Ectopic glandular breast tissue can develop any of the disorders that occur in normally positioned breasts, including galactorrhea, fibrocystic changes, mastitis, fibroadenomas, and carcinoma. Although such tissue does not have an increased malignant potential compared with the normal breast and prophylactic excision for cancer prevention is not required, routine screening should be performed with periodic physical examination and radiologic studies such as mammography or ultrasonography. Complete surgical excision is the treatment of choice for accessory mammary tissue that is symptomatic or cosmetically undesirable. Most authors do not recommend imaging studies to exclude an associated urinary tract malformation in asymptomatic individuals with accessory mammary tissue as an isolated anomaly.

Absent, Hypoplastic or Anomalous Nipples

Variants: ■ Athelia ■ Amastia ■ Hypomastia

Absence or hypoplasia of the nipples may occur either as an isolated developmental abnormality or together with other malformations in a variety of congenital syndromes. The Poland anomaly is a predominantly sporadic developmental field defect in which hypoplasia or absence of the nipple and/or breast is associated with ipsilateral aplasia of the sternal head of the pectoralis major muscle, patchy absence of axillary hair, and symbrachydactyly. The Becker nevus syndrome may also include hypoplasia of the ipsilateral nipple, breast, pectoralis major muscle, and/or arm; it results from mosaic mutations in the beta-actin gene that involve the mesenchymal lineage[63]. In addition, nipple and breast hypoplasia or aplasia may occur in association with ectodermal dysplasias, including X-linked hypohidrotic and tricho-odonto-onychial types, as well as the scalp–ear–nipple syndrome (see Table 64.4), limb–mammary syndrome (ectrodactyly, other hand/foot anomalies, and nail dysplasia), ulnar–mammary syndrome (Table 64.6), and ablepharon–macrostomia syndrome. In a rare, lethal form of dwarfism known as Blomstrand chondrodysplasia, loss-of-function mutations in the gene encoding parathyroid hormone receptor 1 result in lack of nipples. Mutations in *KMT2D* (lysine-specific methyltransferase 2D), *USP9X* (ubiquitin-specific protease 9, X-linked), or *PTPRF* (protein tyrosine phosphatase receptor F) can result in hypo- or athelia along with other dysmorphic features[64]. Both parathyroid hormone-related protein produced by the mammary bud epithelium and PTPRF produced by surrounding fibroblasts play a role in a Wnt-dependent pathway that regulates embryonic development of the mammary mesenchyme and is required for formation of the nipple and mammary ducts.

Inverted nipples are most often inherited as an isolated autosomal dominant trait, but they may also be found in congenital syndromes such as the congenital disorder of glycosylation type Ia. Widely spaced nipples are a feature of congenital disorders including Turner syndrome, Noonan syndrome,

DISEASES AFFECTING THE SKIN THAT ARE ASSOCIATED WITH CONGENITAL DIGITAL ANOMALIES						
	Digital anomaly (-dactyly)

Trichorhinophalangeal syndrome					x	AD, *TRPS1*; cone-shaped epiphyses, pear-shaped nose, sparse hair
Anonychia–onychodysplasia	x			x	x	AD; absent/hypoplastic distal phalanges

*Caused by mutations in the *TP63* gene; allelic disorders with overlapping manifestations (e.g. ectrodactyly, nipple hypo-/aplasia) include ADULT (acro-dermato-ungual-lacrimal-tooth) syndrome and limb–mammary syndrome.
†Patients often have macrodactyly.

Table 64.6 Diseases affecting the skin that are associated with congenital digital anomalies. Other disorders associated with digital anomalies that also may affect the skin include Cornelia de Lange, Roberts, Simpson–Golabi–Behmel, Pallister–Hall, Russell–Silver, Rubinstein–Taybi, and Hurler syndromes, trisomy 13, Fanconi anemia, and the Poland anomaly. *Syndactyly*, fused digits; *ectrodactyly*, absent digits resulting in a split hand–foot deformity ("lobster claw"); *polydactyly*, extra digits; *clinodactyly*, laterally or medially "bent" digits; *brachydactyly*, short digits. AD, autosomal dominant; AR, autosomal recessive; *CDH3*, cadherin 3; *FGFR2*, fibroblast growth factor receptor 2; *FLNA*, filamin A; *GJA1*, gap junction α1; PPK, palmoplantar keratoderma; *SMO*, smoothened; X-D, X-linked dominant.

cerebro-oculo-facio-skeletal syndrome, renal hypoplasia syndromes, and various chromosomal abnormalities (www.ncbi.nlm.nih.gov/omim).

Skin Dimples

Synonym: ▪ Skin fossae

Skin dimples are deep cutaneous depressions that are seen most commonly on the cheeks or chin, occurring in a familial pattern suggestive of autosomal dominant inheritance. Unilateral or bilateral dimples also may be found in a variety of other locations, most often overlying bony prominences such as the acromion process of the scapula, elbow, patella, tibia, and sacrum. These represent regions in which there is close proximity of the skin to the underlying bone during fetal development, and the dimples are thought to result from early fixation of the skin and deficient formation of the subcutaneous tissue.

Bilateral skin dimples on the shoulders overlying the acromion processes can be inherited in an autosomal dominant fashion as an isolated anomaly. In addition, bilateral acromial dimples are a feature of several congenital malformation syndromes, including the 18q deletion syndrome, trisomy 9p syndrome, Say syndrome, and Russell–Silver dwarfism[65]. Skin dimples also may be seen in association with skeletal abnormalities. For example, dimpling may be found overlying the tibial bend in patients with camptomelic dysplasia and over bowing convexities or exostoses of long bones in those with hypophosphatasia. Distal arthrogryposis ("whistling face") syndrome type 2A features a characteristic H-shaped dimple on the chin. Although shallow coccygeal dimples are a common isolated finding[24–26], larger or deeper midline lumbosacral dimples may represent a cutaneous sign of spinal dysraphism (see above) or a malformation syndrome[65]. Congenital dimples on the thigh have been attributed to intrauterine friction from the opposite great toenail when in the fetal position[66]. Lastly, skin dimples overlying the knees and/or elbows have been reported in association with congenital rubella, Joubert syndrome, limb–mammary syndrome, ulnar–mammary syndrome, and multiple pterygium syndrome (www.ncbi.nlm.nih.gov/omim). In other sites, an enlarging dimple in a young child may indicate an atrophic dermatofibroma or nascent lipoblastoma (see Ch. 117).

Congenital Malformations of the Dermatoglyphics

Congenital malformations of the dermatoglyphics (fingerprints) are divided into four main categories based on the appearance of the dermal ridges of which they are composed: (1) ridge aplasia (absent); (2) ridge hypoplasia (poorly formed); (3) ridge dissociation (discontinuous pattern with short segments); and (4) ridges-off-the-end (run off the end of the fingertip rather than looping around). Embryologic development of the dermal ridges occurs in conjunction with that of the eccrine glands of the palms and soles, and the sweat pores are found on the ridges. The lack of eccrine ducts and glands in the palmar skin of patients with ridge aplasia reflects this close relationship[67]. Variants in the ADAM metallopeptidase with thrombospondin motif 9 antisense RNA 2 (*ADAMTS9-AS2*) influence the whorls within dermatoglyphics[68].

Congenital dermatoglyphic malformations of all types can be inherited in an autosomal dominant fashion as an isolated defect. A non-syndromic form of adermatoglyphia ("immigration delay disease") as well as Basan and Huriez syndromes are all autosomal dominant conditions caused by mutations affecting a skin-specific isoform of SMARCAD1, a member of the SNF subfamily of the helicase protein superfamily[69]. Basan syndrome is characterized by adermatoglyphia together with neonatal acral blistering and profuse facial milia; variable features include palmoplantar keratoderma (PPK), digital contractures, nail dystrophy, and acral hypohidrosis. Huriez disease features sclero-atrophy of the hands and feet with a predisposition to acral squamous cell carcinoma as well as adermatoglyphia, PPK, and hypoplastic nails. Dermatoglyphic malformations can also occur in association with chromosomal abnormalities, malformations of the distal limbs, and ectodermal dysplasias. The latter, which may present with ridge aplasia or hypoplasia, include hypohidrotic ectodermal dysplasia, AEC syndrome (*a*nkyloblepharon, *e*ctodermal dysplasia, *c*left lip/palate), dermatopathia pigmentosa reticularis, and Naegeli–Franceschetti–Jadassohn (NFJ) syndrome (see Chs. 63 & 67). Ridge dissociation can be seen in patients with Rosenthal–Kloepfer syndrome (acromegaloid changes, cutis verticis gyrata, and corneal leukoma) and cystic fibrosis. The spectrum of abnormal dermatoglyphics includes an acquired loss as is seen in Kindler syndrome and dyskeratosis congenita (see Chs. 32 & 67) and the stippled dermatoglyphics (pachydermatoglyphia) found in Costello syndrome, KID (*k*eratitis–*i*chthyosis–*d*eafness) syndrome, and hidrotic ectodermal dysplasia (see Chs. 55, 57, & 63). Lastly, aberrant dermatoglyphic patterns have been used to screen for a predisposition to early childhood dental caries, congenital orodental anomalies, hypertension, neurodevelopmental disorders, and schizophrenia.

Rudimentary Polydactyly

Synonym: ■ Rudimentary supernumerary digits

Rudimentary polydactyly represents duplication of digital soft tissue, but without a skeletal component. It is typically found on the lateral surface of a digit, more often the ulnar side of the fifth finger (postaxial) than the radial side of the thumb (preaxial). Rudimentary polydactyly is present in ~0.5–1 per 1000 White neonates and ~3–10 per 1000 Black neonates. It usually occurs as an isolated malformation with autosomal dominant inheritance; underlying mutations have been identified in *GLI3* (GLI family zinc finger 3) and other genes. The stump remaining after intrauterine amputation of a larger structure is sometimes referred to as an *amputation neuroma*. Rudimentary polydactyly lesions are frequently bilateral and range from small, fleshy or wart-like papules (Fig. 64.24) to larger, often pedunculated nodules that may contain cartilage or a vestigial nail. Congenital ectopic nails located on the tips of the fifth fingers are regarded as a separate entity.

Histologically, rudimentary supernumerary digits often show fascicles of nerve fibers in a pattern similar to that of an acquired neuroma (see Ch. 115). When removal is desired, surgical excision is the method of choice[70]. Removal via ligation with suture material increases the risk of infection and often leaves a residual papule, which may result in a painful neuroma later in life.

Amniotic Band Sequence and Disorganization Syndrome

Synonyms: ■ Amniotic band syndrome ■ Amniotic rupture sequence ■ Congenital constriction bands ■ ADAM (*a*mniotic *d*eformity, *a*dhesions and *m*utilations) complex

The amniotic band sequence (ABS) encompasses a variety of congenital anomalies of the limbs, head, body wall, and viscera with asymmetric, seemingly random distribution patterns that do not correspond to embryonic fusion planes. Characteristic findings include constriction rings and amputations of the limbs and digits that are associated with fibrous bands. Occurring in ~1–10 per 10 000 live births, ABS is primarily a sporadic disorder, although familial cases and one patient with a mutation in *IQCK* (IQ motif-containing K) have been reported. ABS may be more common in children born to primiparous versus multiparous women[71]. *Pseudoamniotic band syndrome* is a rare complication of invasive intrauterine procedures in monochorionic twins.

There are two classic hypotheses for the pathogenesis of ABS. The *extrinsic theory* postulates that rupture and repair of the amniotic membrane during the first trimester is followed by loss of amniotic fluid and entanglement of fetal parts in fibrous strands of torn amnion, which form rings that encircle and constrict the limbs, face, or trunk. The *intrinsic theory* proposes that an abnormal endogenous developmental process leads to production of fibrous bands as well as other anomalies (e.g. internal malformations, duplicated structures) not explained by bands alone. Although the extrinsic theory has traditionally been more widely accepted, the striking similarities between ABS and the human "disorganization syndrome" as well as the mouse disorganization mutant provide support for an intrinsic mechanism[72]. The disorganization syndrome features a haphazard pattern of defects such as limb duplications, reductions, and circumferential constrictions with attached fibrous bands; hamartomatous digit-like appendages and craniofacial > truncal clefts represent additional features. Alternatively, fibrosis due to altered activation of the epithelial–mesenchymal transition process during embryogenesis has been hypothesized.

The clinical spectrum of ABS is broad, ranging from isolated minor limb anomalies to major craniofacial and visceral defects. It includes the *limb–body wall complex* characterized by body wall defects with evisceration of thoracic and/or abdominal organs, irregular anencephaly/encephaloceles, and bizarre facial clefting[73]. Variations in severity may depend upon differences in the timing of amniotic rupture or variable expressivity of genetic trait(s). Constriction rings present as circumferential grooves of variable depth on the digits, extremities, neck, or trunk; this must be distinguished from the circumferential creases of the "Michelin tire baby" syndrome (see Ch. 97). Deep lesions located on an extremity may be associated with distal lymphedema, nerve compression,

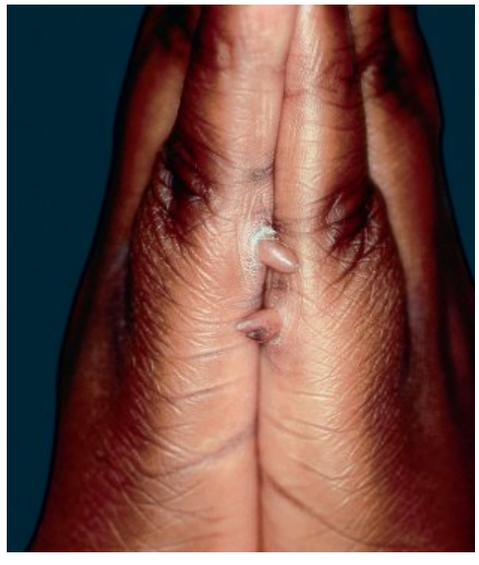

Fig. 64.24 Bilateral rudimentary supernumerary digits. The ulnar side of the fifth digit is the most common location, referred to as postaxial.

deformity, or intrauterine amputation. Acrosyndactyly can result from a constriction band that encircles adjacent digits. In addition to the distinctive fibrofatty appendages of the disorganization syndrome, other cutaneous manifestations of ABS may include aplasia cutis congenita, often with a stellate morphology, and abnormal dermatoglyphics.

Plastic surgery with wound closure via Z-plasty, anterior sheath Y–V plasty, or abdominal Scarpa fascia release is indicated for release of constriction bands that restrict growth, compress underlying nerves, or interfere with vascular and/or lymphatic circulation.

Other Developmental Anomalies Associated with Cutaneous Diseases

Skin disorders that are associated with cleft lip/palate or congenital digital anomalies are presented in Tables 64.5 and 64.6, respectively.

Chapter Contents

Origin and Function of the Melanocyte *1086*
Formation and Function of the Melanosome *1089*
Regulation of Melanin Biosynthesis *1092*

Key features

- The major determinant of normal skin color is the activity of melanocytes, i.e. the quantity and quality of pigment production, not the density of melanocytes
- Melanocytes contain a unique intracytoplasmic organelle, the melanosome, which is the site of melanin synthesis and deposition
- Compared with lightly pigmented skin, darkly pigmented skin has melanosomes that contain more melanin and are larger; once transferred to keratinocytes, the melanosomes are singly dispersed and degraded more slowly
- Tyrosinase is the key enzyme in the melanin biosynthetic pathway
- Two major forms of melanin are produced in melanocytes: brown–black eumelanin and yellow–red pheomelanin
- The production of eumelanin versus pheomelanin is influenced by the binding of melanocyte stimulating hormone to the melanocortin 1 receptor

INTRODUCTION

In order to understand the underlying pathophysiology of cutaneous disorders of hypopigmentation and hyperpigmentation, as well as the process of normal physiologic pigment production, an appreciation of the structure and function of the melanocyte is required. A classic example of basic pathogenesis is type 1 oculocutaneous albinism (OCA1), in which pigmentary dilution of the skin, hair, and eyes is due to a reduction or absence of tyrosinase activity secondary to mutations in both copies of the tyrosinase gene (*TYR*). Physiologic pigmentation is influenced by variants in multiple genes. For example, melanocytes in individuals with red hair often express variants of the melanocortin 1 receptor (MC1R)[1]. As a consequence of the altered amino acid sequences of the variant MC1Rs, their cell surface expression and interactions with melanocyte stimulating hormone (MSH) can be affected, leading to an increase in the production of pheomelanin as opposed to eumelanin. Based upon population genetics, genes that are mutated in OCA (e.g. *TYR*, *OCA2*, *TYRP1*, *SLC45A2*, *SLC24A5*) also influence normal pigment variation (Table 65.1)[2–6].

ORIGIN AND FUNCTION OF THE MELANOCYTE

The melanocyte is a neural crest-derived cell. During embryogenesis, precursor cells (melanoblasts) migrate along a dorsolateral then ventral pathway via the mesenchyme to reach the epidermis and hair follicles of the trunk (see Ch. 2). More recently, it was shown that melanocytes can also arise from neural crest-derived Schwann cell precursors that migrate along nerves to the skin via a distinct ventral pathway[7]. Additional sites of melanocyte migration include the uveal tract of the eye (choroid, ciliary body, and iris), the leptomeninges, and the inner ear (cochlea) (Fig. 65.1). Presumably, the death of melanocytes within the leptomeninges, inner ear, and skin is responsible for the aseptic meningitis, auditory symptoms, and areas of vitiligo, respectively, seen in patients with the Vogt–Koyanagi–Harada syndrome (see Ch. 66).

In the inner ear, particularly in the stria vascularis, melanocytes are thought to play a role in the development of hearing. Aberrant migration or survival of melanocytes within the inner ear, the iris, and midportions of the forehead and extremities explains the presence of congenital deafness, heterochromia irides, and patches of leukoderma, respectively, in patients with Waardenburg syndrome, the classic neurocristopathy. Also, aberrant migration or survival of enteric ganglion cells, another neural crest-derived cell population, provides an explanation for the association of aganglionic megacolon (Hirschsprung disease) with Waardenburg syndrome or rarely piebaldism.

The survival and migration of neural crest-derived cells during embryogenesis depends upon interactions between specific receptors on their cell surface and extracellular ligands. For example, KIT ligand, also known as steel factor or stem cell growth factor, binds to the transmembrane KIT receptor on melanocytes and melanocyte precursors (melanoblasts) (Figs. 65.2 & 65.3); melanoblasts require expression of the KIT receptor in order to maintain their normal chemotactic migration directed by production of KIT ligand by the dermamyotome. Heterozygous germline mutations in *KIT* that decrease the ability of the KIT receptor to be activated by KIT ligand are responsible for human piebaldism, whereas in mice, mutations in either *kit* or *steel* can lead to white spotting.

In the developing embryo, melanoblasts expressing endothelin receptor type B (EDNRB) are stimulated to migrate by endothelin-3 (ET3 [EDN3]), which is produced by the ectoderm and dermamyotome. Loss-of-function mutations in one or both copies of *EDN3* or *EDNRB* can result in Waardenburg syndrome plus aganglionic megacolon, while overexpression of both has been observed in solar lentigines (see Fig. 65.3).

Transcription factors represent another group of proteins that play an essential role during embryogenesis. Because transcription factors bind DNA and influence the activity of other genes, they are able to regulate the complex interplay of various sets of genes that is required for embryonic development. Several of the genes that, when mutated, give rise to Waardenburg syndrome encode transcription factors (e.g. *PAX3, MITF, SOX10*; see Table 66.4). Fig. 65.4 demonstrates some of these interactions, e.g. PAX3 and SOX10 can control expression of MITF[8,9]. MITF is sometimes referred to as the master regulator of melanocyte development and function given its modulation of multiple differentiation genes and its early upregulation in neural crest cells that will eventually become melanocytes and emigrate from the dorsal neural tube.

During embryogenesis, melanin-producing melanocytes are found diffusely throughout the dermis. They first appear in the head and neck region at ~10 weeks of gestation. However, by the end of gestation, active dermal melanocytes have "disappeared", except in three primary anatomic locations – the head and neck, the dorsal aspects of the distal extremities, and the presacral area[10]. Some of the dermal melanocytes have clearly migrated into the epidermis, but, given the absolute numbers of cells in the two compartments, apoptosis of pigment cells has also occurred. The three sites where active dermal melanocytes are still present at the time of birth coincide with the most common sites for dermal melanocytoses and dermal melanocytomas (blue nevi). Hepatocyte growth factor may play a role in the survival and proliferation of these dermal melanocytes as well as somatic activating mutations in one of two genes that encode G proteins. In addition to blue nevi (see Table 112.3), gain-of-function mutations in *GNAQ* or *GNA11* are also found in primary uveal melanomas.

As depicted in Fig. 65.1, melanocytes also migrate to the basal layer of the hair matrix and the outer root sheath of hair follicles. Cells that are actively producing melanin are easily recognized in the matrices of pigmented anagen hairs, whereas melanocytes within the outer root sheath are usually amelanotic and more difficult to identify[11]. It has been hypothesized that there are two populations of melanocytes in the skin, one in the interfollicular epidermis and the second in the hair follicle[12].

DISORDERS CHARACTERIZED BY DIFFUSE PIGMENTARY DILUTION IN WHICH THE GENETIC DEFECT IS KNOWN			
Disorder	**Gene**	**Protein product**	**Comments**
Oculocutaneous albinism (OCA) [~40% of patients have OCA1 and ~50% have OCA2]			
OCA1A	*TYR*	Tyrosinase	• Complete absence of tyrosinase activity and melanin production • Retention of misfolded tyrosinase protein within the ER
OCA1B	*TYR*	Tyrosinase	• Decreased tyrosinase activity; can produce pheomelanin • Variant with temperature-sensitive tyrosinase (normal activity at 35°C, but diminished at 37°C) • Additional variants: minimal pigment, platinum, yellow
OCA2	*OCA2*	P protein (*OCA2* was previously known as *P*)	• Melanosomal transmembrane protein that is also present in the ER • Implicated in the regulation of melanosomal pH which influences tyrosinase activity • May also regulate intra-organelle glutathione levels and influence folding of tyrosinase proteins
OCA3	*TYRP1*	Tyrosinase-related protein 1*	• TYRP1 stabilizes tyrosinase in mice and humans, and it can function as a DHICA oxidase • Both "mutant" TYRP1 and tyrosinase are retained in the ER and then degraded • Rufous phenotype ≫ brown phenotype; latter seen in OCA2
OCA4	*SLC45A2*	Solute carrier family 45 member 2 (also known as MATP)	• Variable phenotype, with hair ranging from white to yellow–brown; most common in Asians • Proton/glucose exporter in melanosomes that maintains deacidification in later stage melanosomes • Acidification of melanosome impairs activity of tyrosinase
OCA5	Not known	–	• Locus linked to chromosome 4q24
OCA6	*SLC24A5*	Solute carrier family 24 member 5	• Cation exchanger that is a member of K^+-dependent Na^+/Ca^{++} exchanger family • May be involved in ion transport in melanosomes
OCA7	*LRMDA* (alias *C10orf11*)	Leucine-rich melanocyte differentiation-associated protein (previously known as chromosome 10 open reading frame 11)	• Expressed in melanoblasts and melanocytes • Possible role in melanocyte differentiation
OCA8	*DCT*	Dopachrome tautomerase	• Mild pigmentary dilution • Catalyzes conversion of DOPAchrome to DHICA • Also known as TYRP2
Hermansky–Pudlak syndrome (HPS)†			
HPS1	*HPS1*	HPS1 (BLOC-3 subunit 1)	• Defective trafficking of organelle-specific proteins to melanosomes, lysosomes and cytoplasmic granules (including platelet dense granules and lytic granules in cytotoxic T lymphocytes) • Pulmonary fibrosis and granulomatous colitis‡ • Component of BLOC-3 (see Fig. 65.8)
HPS2	*AP3B1*	Adaptor related protein complex 3 subunit β1	• AP-3 recognizes sorting signals within cytosolic tails of cargo molecules and is involved in the trafficking of proteins from the trans-Golgi network to appropriate organelles (see Fig. 65.8) • Pulmonary fibrosis (some patients) • Immunodeficiency, possibly related to abnormal trafficking of CD1B, reduced perforin levels in NK cells, and reduced elastase within neutrophils
HPS3	*HPS3*	HPS3 (BLOC-2 subunit 1)	• Component of BLOC-2
HPS4	*HPS4*	HPS4 (BLOC-3 subunit 2)	• Component of BLOC-3 • Pulmonary fibrosis
HPS5	*HPS5*	HPS5 (BLOC-2 subunit 2)	• Component of BLOC-2
HPS6	*HPS6*	HPS6 (BLOC-2 subunit 3)	• Component of BLOC-2
HPS7	*DTNBP1*	Dystrobrevin binding protein 1	• Component of BLOC-1 (subunit 8) • Granulomatous colitis (some patients)
HPS8	*BLOC1S3*	BLOC1S3 (BLOC-1 subunit 3)	• Component of BLOC-1
HPS9	*BLOC1S6* (*PLDN*)	BLOC1S6 (BLOC-1 subunit 6)	• Component of BLOC-1 • Protein product also referred to as pallidin
HPS10	*AP3D1*	Adaptor related protein complex 3 δ1 subunit	• See AP-3 above • Neurologic impairment (e.g. seizures), immunodeficiency
HPS11	*BLOC1S5*	BLOC1S5 (BLOC-1 subunit 5)	• Component of BLOC-1
Chédiak–Higashi syndrome			
	LYST	Lysosomal trafficking regulator	• Abnormal vesicle trafficking and fission/fusion of lysosome-related organelles result in giant organelles (e.g. melanosomes, neutrophil granules [lysosomes], platelet dense granules)

Table 65.1 Disorders characterized by diffuse pigmentary dilution in which the genetic defect is known.

DISORDERS CHARACTERIZED BY DIFFUSE PIGMENTARY DILUTION IN WHICH THE GENETIC DEFECT IS KNOWN			
Disorder	**Gene**	**Protein product**	**Comments**
Griscelli syndrome			
GS1	*MYO5A*	Myosin Va (attaches melanosomes to actin filaments)	• In all three forms, melanosomes are retained in the body of the melanocyte rather than trafficking to the tips of dendrites for transfer to keratinocytes (see Fig. 65.10) • Silvery hair seen in all three forms • Myosin Va expressed in neurons (as well as melanocytes) and dysfunction leads to neurologic abnormalities
GS2	*RAB27A*	RAB27A (melanosomal membrane GTPase that binds melanophilin)	• GTPase also expressed in hematopoietic cells; defective release of granule contents from cytotoxic T cells leads to recurrent infections and hemophagocytic lymphohistiocytosis (HLH) • Rarely, neurologic impairment independent of HLH
GS3	*MLPH*	Melanophilin (links myosin Va and RAB27A)	• Melanophilin only expressed in melanocytes, so only pigmentary dilution in type 3
	MYO5A	Myosin Va F-exon deletion	• F-exon only expressed in melanocytes

*Recognized by Mel-5 antibody.
†Reflecting a founder effect, individuals of Puerto Rican origin have HPS1 and HPS3 (3:1 ratio); non-Puerto Ricans most commonly have HPS1, followed by HPS3 and HPS4 with ~70% of patients having one of these three types.
‡In addition to bleeding diathesis which is a characteristic finding in all types of HPS.

Table 65.1 Disorders characterized by diffuse pigmentary dilution in which the genetic defect is known. See Chapter 66 for details of clinical findings. AP-3, adaptor protein complex 3; BLOC, *b*iogenesis of *l*ysosome-related *o*rganelles *c*omplex; DHICA, 5,6-dihydroxyindole-2-carboxylic acid; ER, endoplasmic reticulum; MATP, membrane associated transporter protein; TYRP, tyrosinase-related protein.

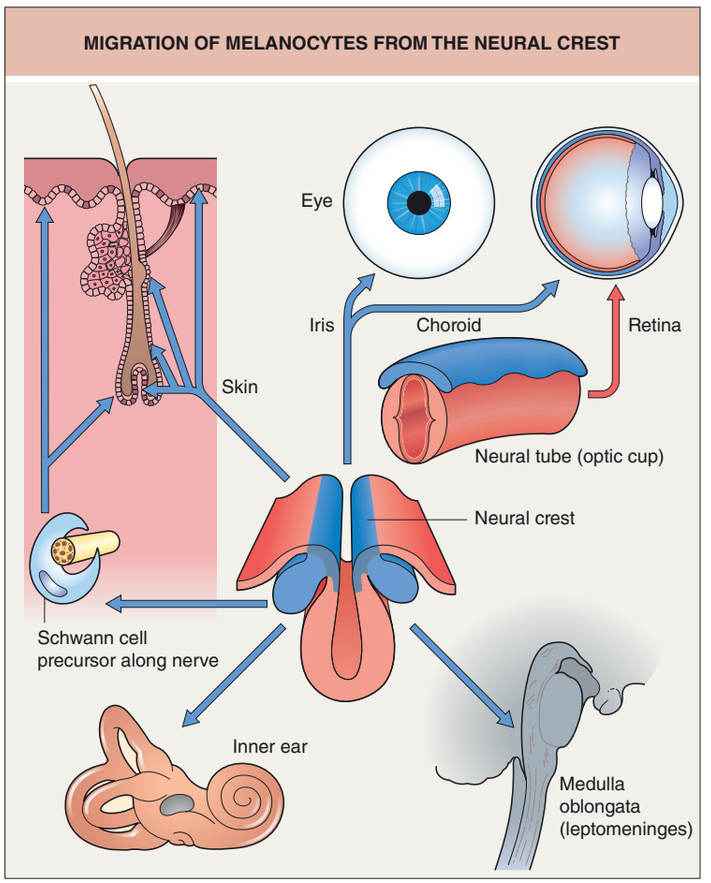

Fig. 65.1 Migration of melanocytes from the neural crest. Melanocytes migrate to the uveal tract of the eye (iris, ciliary body, and choroid), the leptomeninges, and the cochlea of the inner ear, as well as to the epidermis and hair follicle. Cutaneous melanocytes can also arise from Schwann cell precursors located along nerves in the skin, which also originate from the neural crest. The retina actually represents an outpouching of the neural tube. See Fig. 2.6 for location of melanocyte stem cells within the hair bulge.

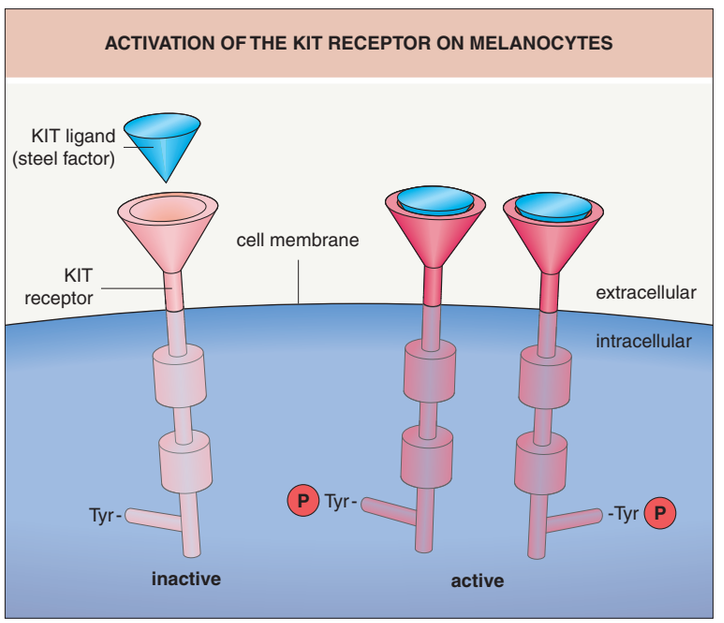

Fig. 65.2 Activation of the KIT receptor on melanocytes. Because the KIT receptor is a tyrosine kinase receptor, it has the ability to phosphorylate the tyrosine residues of other proteins as well as itself, i.e. autophosphorylation. Heterozygous germline mutations in *KIT* that prevent the activation of the KIT receptor by KIT ligand, also referred to as steel factor, lead to piebaldism, whereas somatic activating mutations in *KIT* are seen in patients with mastocytosis as well as melanomas (see Fig. 118.2). A form of familial progressive hyperpigmentation with or without hypopigmentation can result from heterozygous gain-of-function germline mutations in the gene that encodes KIT ligand[59]. P, phosphorylation; Tyr, tyrosine.

Based upon antigen expression and clinical observations, it is the former that is more sensitive to the destructive forces of vitiligo. As a result, repigmentation of patches of vitiligo in which the hairs are still pigmented relies upon activation and subsequent upward migration of the melanocytes present in the outer root sheath[11]. Of note, melanocyte stem cells have been identified within the lower portion of the hair follicle bulge, i.e. the lowermost permanent portion of the hair follicle (see Fig. 2.6). In addition, KROX20$^+$ cells, which give rise to the hair shaft, have been identified within the hair bulb. These hair progenitor cells produce KIT ligand/stem cell factor (SCF) which has been shown to be essential for hair pigmentation, i.e. mouse hairs turned white when *SCF* was deleted[13].

By immunohistochemical staining, melanocytes are identified within the fetal epidermis as early as 50 days of gestation[14]. Melanin-containing melanosomes are recognizable by electron microscopy during the fourth month of gestation. Except in benign and malignant neoplasms, melanocytes reside within the basal layer of the epidermis, a location they maintain throughout life (Fig. 65.5). Although the cell

body of the melanocyte sits on a specialized region of basal lamina, its dendrites come into contact with keratinocytes as far away as the mid stratum spinosum. This association of a melanocyte with ~30–40 surrounding keratinocytes to which it transfers melanosomes has been called the epidermal melanin unit[15]. However, melanocytes fail to form desmosomal connections with neighboring keratinocytes; their interactions with keratinocytes are via cadherins.

Although there is variation in the density of epidermal melanocytes/mm^2 when different *regions* of the body are analyzed via DOPA-stained epidermal sheets (Fig. 65.6), e.g. the density of melanocytes is greater in the genital region (~1500/mm^2) compared with the back (~900/mm^2), there are smaller differences between individuals when the same anatomic site is examined. This is despite the wide variation in pigmentation seen amongst humans. In other words, a person who has minimal baseline pigmentation and an inability to tan has a similar density of melanocytes when compared with a person whose skin is dark brown to black in color. Indeed, even patients with the most severe form of OCA, OCA type 1A, have a normal complement of epidermal melanocytes.

The major determinant of normal skin color is the activity of the melanocytes, i.e. the quantity and quality of pigment production, not the density of melanocytes[16]. Several factors play a role in determining the activity level of melanocytes; they include specific characteristics of the individual melanosomes (e.g. their dimensions) as well as both baseline (constitutive) and stimulated (facultative) levels and activity of the enzymes involved in the melanin biosynthetic pathway. The latter are influenced by receptor-mediated interactions with extracellular ligands such as MSH which then influence the expression of transcription factors including MITF (see Fig. 65.4). An example of an inhibitory signal is TGF-β1, which is expressed by adipose mesenchymal cells.

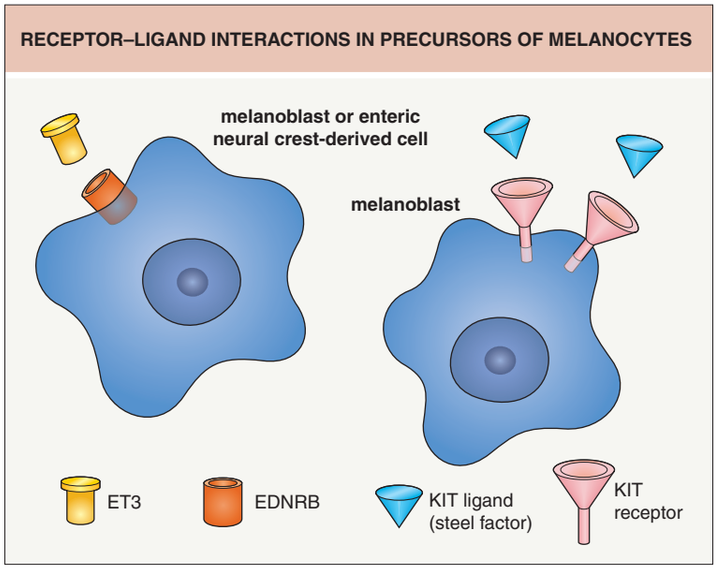

Fig. 65.3 Receptor–ligand interactions in precursors of melanocytes. In the developing embryo, melanoblasts expressing endothelin receptor type B (EDNRB) are stimulated to migrate by endothelin-3 (ET3) which is produced by the ectoderm and dermamyotome. Melanoblasts also require expression of the KIT receptor to maintain their normal chemotactic migration directed by production of KIT ligand/steel factor by the dermamyotome.

FORMATION AND FUNCTION OF THE MELANOSOME

Within the cytoplasm of melanocytes is a unique organelle known as the melanosome, in which melanin pigments are synthesized, deposited, and transported. The melanosome is most closely related to the lysosome and is referred to as a lysosome-related organelle[17]. Through compartmentalization, both organelles provide protection for the remainder of the cell – lysosomes protect against pro-enzymes such as proteases and melanosomes protect against melanin precursors (e.g. phenols, quinones) that can oxidize lipid membranes.

The melanosome contains both matrix proteins (chiefly PMEL/PMEL17/gp100), which form a scaffolding upon which the melanin is deposited, and enzymes such as tyrosinase that regulate melanin biosynthesis. Following their formation via ribosomes, all these proteins are found within the rough endoplasmic reticulum. In patients with OCA1 and OCA3, misfolded tyrosinase or aberrant tyrosinase-related protein 1 (TYRP1) plus tyrosinase polypeptides, respectively, accumulate within the endoplasmic reticulum (ER; Fig. 65.7)[18]. This retention leads to ER stress and activation of the unfolded protein response (UPR)[19]. As a result of the UPR, which acts as a form of quality control, these proteins

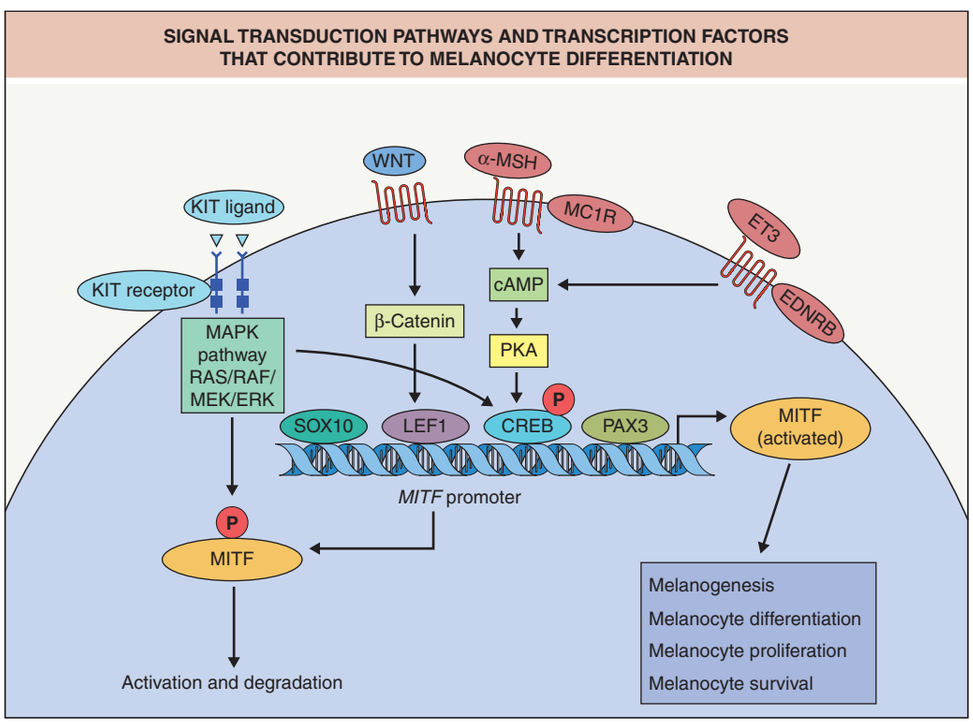

Fig. 65.4 Signal transduction pathways and transcription factors that contribute to melanocyte differentiation. MITF expression is activated early on during the transition from pluripotent neural crest cells to melanoblasts and is required for melanoblast survival[8]; mutations in *MITF* lead to Waardenburg syndrome, a classic neurocristopathy. MITF also regulates the expression of multiple pigment genes including those that encode tyrosinase, TYRP1, TYRP2, PMEL/PMEL17/gp100, and MART-1/Melan-A. Additional transcriptional targets are *CDK2*, *CDKN2A*, and *BCL-2* (whose protein product is an inhibitor of apoptosis)[9]. Small molecule inhibitors of SIK (salt-inducible kinase) can upregulate MITF, and application of these inhibitors to normal human skin led to an increase in pigmentation[60]. WNT signaling in melanocyte stem cells is critical for hair pigmentation[61]. Details of how activation of G-protein-coupled receptors leads to an increase in intracellular cAMP is shown in Fig. 65.14. Of note, EDNRB interacts with the G proteins GNAQ and GNA11, and activating mutations in the genes that encode these latter two proteins can lead to blue nevi and phakomatosis pigmentovascularis. EDNRB can also activate the MAPK pathway. Additional receptors include ET1 (activates protein kinase C), hepatocyte growth factor receptor, and GM-CSF receptor; the latter two activate the MAPK pathway. cAMP, cyclic adenosine monophosphate; CREB, cAMP response-element binding protein; ET3, endothelin-3; EDNRB, endothelin receptor type B; LEF1, lymphoid enhancer binding factor 1; MAPK, mitogen-activated protein kinase; MC1R, melanocortin 1 receptor; MITF, microphthalmia-associated transcription factor; MSH, melanoctye stimulating hormone; P, phosphorylation; PKA, protein kinase A; SOX10, SRY-box containing gene 10.

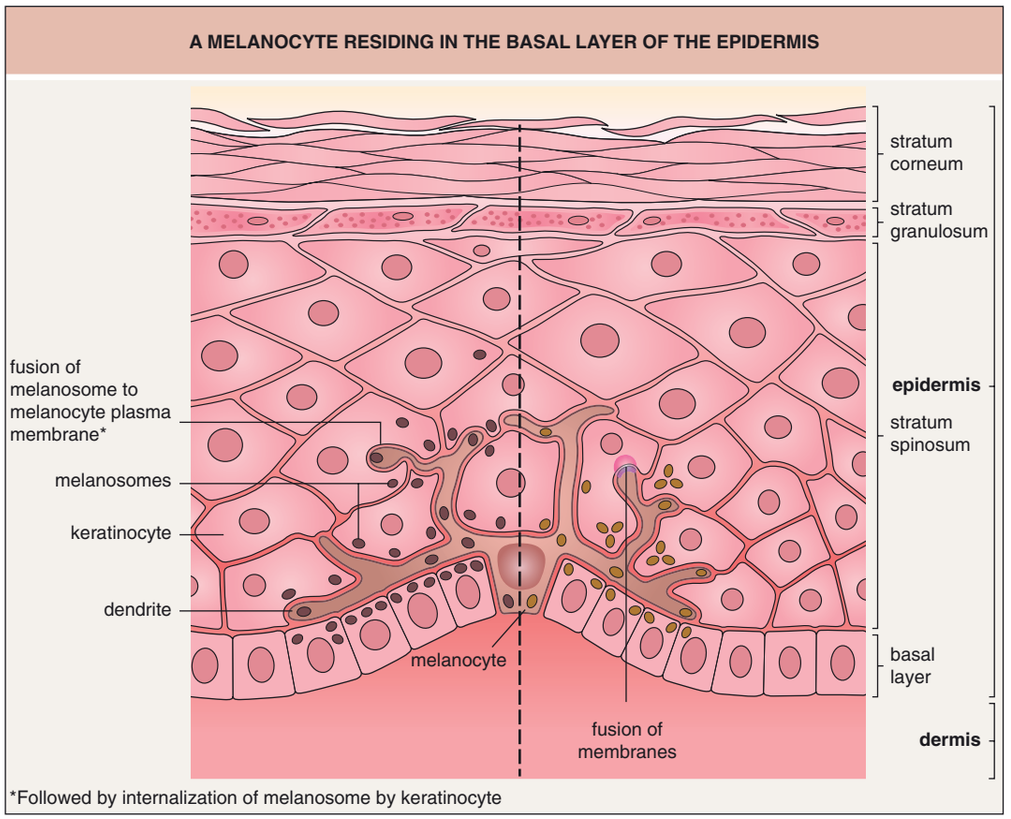

Fig. 65.5 A melanocyte residing in the basal layer of the epidermis. In normal skin, approximately every tenth cell in the basal layer is a melanocyte. Melanosomes are transferred from the dendrites of the melanocyte into neighboring keratinocytes of the epidermis, hair matrices, and mucous membranes; no transfer occurs in the pigment epithelium of the retina. The epidermal melanin unit refers to the association of a melanocyte with ~30–40 surrounding keratinocytes to which it transfers melanosomes. Note the different size and distribution of melanosomes in darkly pigmented skin (left) as compared to lightly pigmented skin (right).

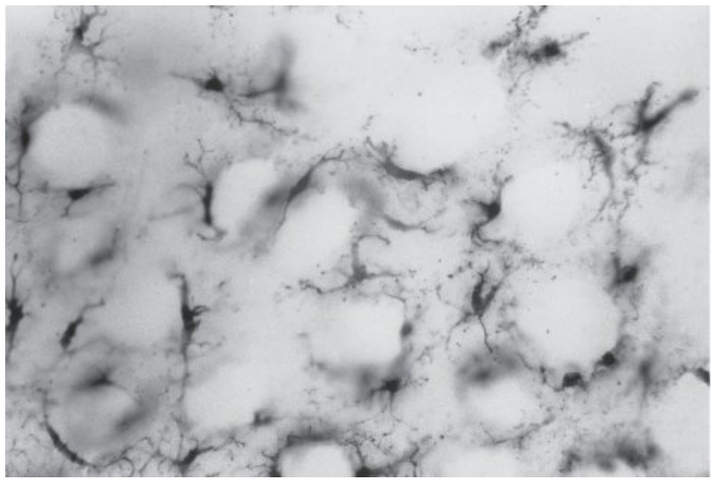

Fig. 65.6 Dihydroxyphenylalanine (DOPA)-stained epidermal sheet. Following incubation with 5 mM L-DOPA for 4–5 hours, the epidermal melanocytes turn black because they contain the enzyme tyrosinase, which converts DOPA to black DOPA-melanin. Note the multiple dendrites and regular spacing of the melanocytes.

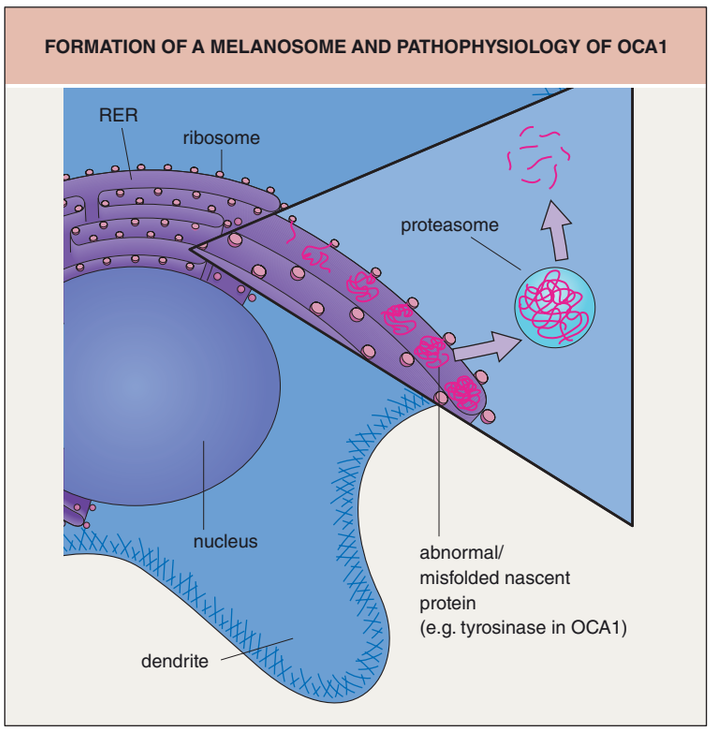

Fig. 65.7 Pathophysiology of oculocutaneous albinism type 1 (OCA1). In patients with OCA1 and OCA3, tyrosinase polypeptides are retained too long within the lumen of the RER and then become targets for destruction within proteasomes. Thus, they are not incorporated into melanosomes. RER, rough endoplasmic reticulum.

become targets for destruction by proteasomes and therefore are not incorporated into melanosomes.

Several of the enzymes in the melanin biosynthetic pathway are glycoproteins that require the attachment of sugars in order to gain full function. For this reason, they undergo post-translational modification in the ER and the Golgi apparatus and then join up with the matrix proteins (e.g. PMEL) to initiate melanogenesis. The targeting of proteins to the plasma membrane versus intracytoplasmic organelles and the targeting of specific proteins to the correct type of organelle are complicated processes. This triaging requires the equivalent of traffic police within the cell, an example of which is adaptor protein complex 3 (AP-3). Mutations in the gene that encodes the β3A subunit of AP-3 are responsible for a subset of patients with Hermansky–Pudlak syndrome (HPS2)[20]. Other forms of HPS are due to dysfunction of the proteins that serve as components of *b*iogenesis of *l*ysosome-related *o*rganelles complexes (BLOCs; Fig. 65.8)[21,22]. It then follows that these patients have dysfunction of more than one intracytoplasmic organelle, i.e. not just melanosomes but other lysosome-related organelles such as NK cell granules and platelet dense granules (see Table 65.1)[23]. The associated hypopigmentation can be explained by the failure to efficiently deliver melanogenic proteins, e.g. tyrosinase, TYRP1, to the melanosome.

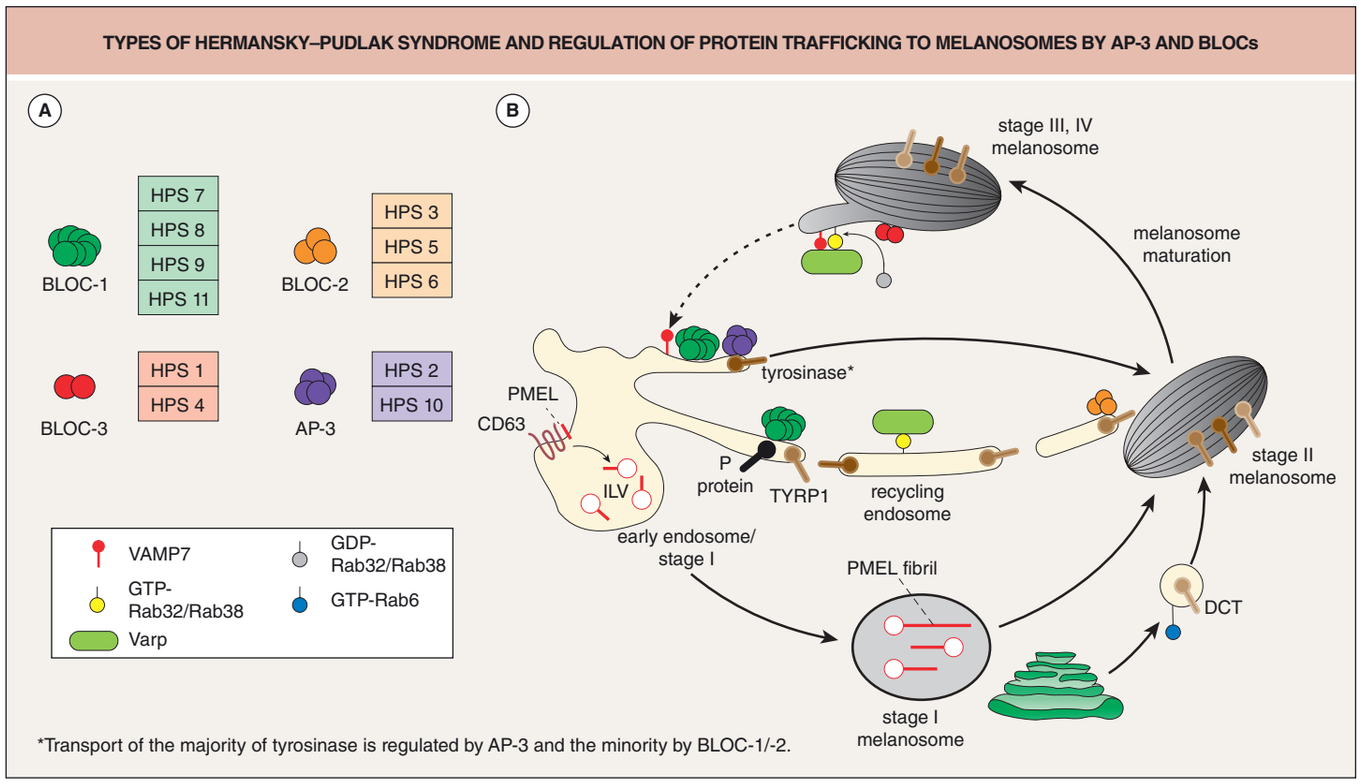

Fig. 65.8 Types of Hermansky–Pudlak syndrome and regulation of protein trafficking to melanosomes by adaptor protein complex 3 (AP-3) and biogenesis of lysosome-related organelles complexes (BLOCs). A Sorting of proteins to the correct organelles is a complex process and it requires regulators, in particular BLOCs and adaptor AP-3 in the case of lysosome-related organelles. The latter include melanosomes, platelet dense granules, and lytic granules of cytotoxic lymphocytes and natural killer cells. In Hermansky–Pudlak syndrome (HPS), there is abnormal routing of proteins to lysosome-related organelles due to dysfunction of components of BLOC-1, -2, or -3 or AP-3. **B** After glycosylation and processing within the endoplasmic reticulum and Golgi apparatus, several of the enzymes involved in the formation of melanin (including tyrosinase, TYRP1, and DCT) are packaged in vesicles and then combine with matrix proteins. The primary matrix protein is PMEL, also referred to as PMEL17 or gp100 and recognized by anti-HMB45 antibody; formation of the matrix fibers requires cleavage of PMEL by a proprotein convertase[62]. The Rab32/Rab38-Varp complex is required for the recovery of melanosomal cargoes, such as VAMP, from mature melanosomes (retrograde trafficking) and is also required for the transport of melanogenic enzymes from early endosomes to maturing melanosomes (anterograde trafficking). The dotted arrow indicates an as-yet-unidentified transport pathway. DCT, dopachrome tautomerase; ILV, intralumenal membrane vesicle; TYRP, tyrosinase-related protein; VAMP, vesicle-associated membrane protein; Varp, VPS9-ankyrin-repeat protein. *Adapted from Ohbayashi N, Fukuda M. Recent advances in understanding the molecular basis of melanogenesis in melanocytes. F1000Research 2020;9:608.*

FOUR MAJOR STAGES OF EUMELANIN MELANOSOMES

Stage	Description	Electron micrographs
I	Spherical; no melanin deposition	
II	Oval; obvious matrix in the form of parallel longitudinal filaments; minimal deposition of melanin; high tyrosinase activity	
III	Oval; moderate deposition of melanin; high tyrosinase activity	
IV	Oval; heavy deposition of melanin; electron-opaque; minimum tyrosinase activity	

Fig. 65.9 Four major stages of eumelanin melanosomes. *Courtesy Raymond Boissy, PhD.*

The progression of a melanosome from an organelle that lacks melanin to one that is fully melanized is arbitrarily divided, for convenience, into four stages (Fig. 65.9). Proteins that play a key role in the biogenesis of early-stage melanosomes are PMEL, MART-1/Melan-A, and the ocular albinism type 1 (OA1) G-protein-coupled receptor[24]. Cleavage and processing of PMEL, an amyloidogenic protein, leads to a fibrillar matrix that acts as a scaffold upon which melanin is deposited (see Fig. 65.8B)[25]. As melanin is deposited within the melanosome, the organelle migrates via microtubules into the dendrites in preparation for transfer into the neighboring keratinocytes, either within the epidermis or within the anagen hair matrix. In addition to microtubules, proteins such as kinesin and dynein are involved in the movement of melanosomes (Fig. 65.10)[26].

Within the dendrites, a specialized myosin protein, myosin Va, aids in the process of melanosome transfer by assisting attachment between the actin cytoskeleton beneath the plasma membrane and the organelle itself. RAB27A and melanophilin also play a role in ensuring this attachment. The importance of the interactions between these three proteins – myosin Va, RAB27A, and melanophilin – is illustrated by the three different forms of Griscelli syndrome in which there are mutations in the respective genes (see Table 65.1)[27,28]. The various phenotypes are explained by the tissue-specific expression of these three genes, e.g. neurons versus cytotoxic T cells. All three genes are expressed in melanocytes and as expected, the associated diffuse pigmentary dilution reflects a lack of transfer of melanosomes from the melanocytes to nearby keratinocytes. Histologically, numerous melanosomes are seen to congregate within the center of the melanocytes.

To reiterate, normal pigmentation of the skin is dependent on an orderly transfer of melanosomes from melanocytes to keratinocytes. When this transfer is disrupted, either in inherited diseases such as Griscelli syndrome or in acquired diseases such as atopic dermatitis, the result is hypopigmentation. In the former there is diffuse pigmentary dilution, whereas in the latter the hypopigmentation is circumscribed. Uptake of melanosomes by keratinocytes can be triggered by activation of the keratinocyte growth factor (KGF) receptor (KGFR/FGFR2b) by KGF, also referred to as fibroblast growth factor 7[29], as well as by activation of protease-activated receptor 2 (PAR-2)[30]. Inhibitors of PAR-2 receptor–ligand interactions, e.g. inhibitors of serine proteases, have led to cutaneous hypopigmentation in animal models[31].

In summary, the activity of melanocytes and their interactions with neighboring keratinocytes, rather than melanocyte density, is the

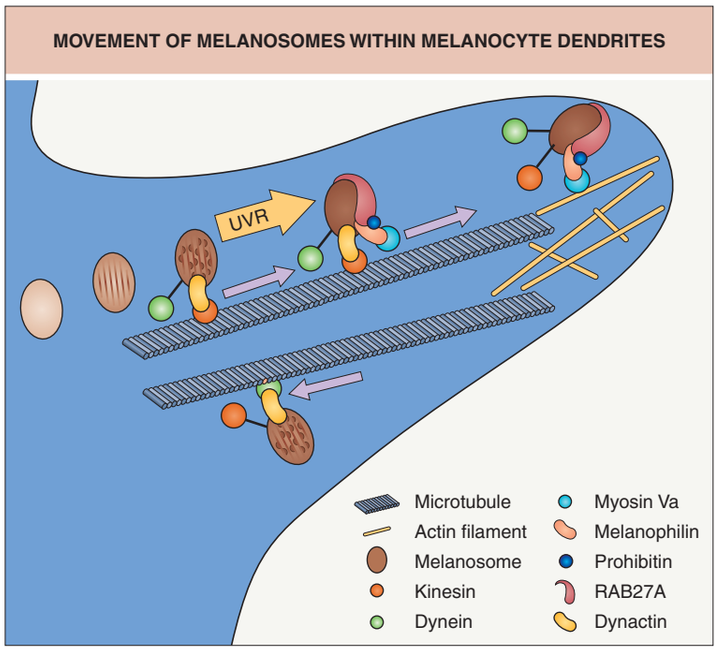

Fig. 65.10 Movement of melanosomes within melanocyte dendrites. As more melanin is deposited within the melanosomes, they migrate into the dendrites along microtubules in preparation for their transfer into neighboring keratinocytes. Kinesin and dynein serve as molecular motors for microtubule-associated anterograde and retrograde melanosomal transport, respectively, and UVR results in augmented anterograde transport via increased kinesin and decreased dynein activity. Myosin Va, which is linked to the melanosomal RAB27A GTPase by melanophilin, captures mature melanosomes when they reach the cell periphery and attaches them to the actin cytoskeleton.

VARIATION OF PREDOMINANT MELANOSOMAL STAGES WITH LEVEL OF CUTANEOUS PIGMENTATION

Pigmentation of skin	Predominant melanosomal stages	
	Melanocytes	Keratinocytes
Light	II, III	Occasional III
Medium	II, III, IV	III, IV
Dark	IV > III	IV

Table 65.2 Variation of predominant melanosomal stages with level of cutaneous pigmentation.

major determinant of normal skin color. The activity of a melanocyte is reflected in the number and size of melanized melanosomes it produces as well as in its efficiency at transferring those melanosomes to keratinocytes. For example, primarily stage II and stage III melanosomes are seen in lightly pigmented skin, whereas primarily stage IV melanosomes are seen in darkly pigmented skin (Table 65.2). An additional factor is the rate of degradation of the melanosomes once they are transferred to the surrounding keratinocytes and this is related in part to the size of the individual melanosomes. The smaller melanosomes of lightly pigmented skin are clustered in groups of two to ten within secondary lysosomes in the keratinocytes and are degraded by the mid stratum spinosum (Table 65.3)[16]. In lightly pigmented skin, increased autophagy also leads to increased degradation of melanosomes within both melanocytes and keratinocytes[32]. In darkly pigmented skin, the melanosomes are larger and singly dispersed within lysosomes of the keratinocytes; they are degraded more slowly, such that melanin granules can still be found in the stratum corneum. Melanosomes within the basal layer of the epidermis cap the nuclei and are more numerous within progenitor keratinocytes and stem cells[33].

REGULATION OF MELANIN BIOSYNTHESIS

This section begins with a review of the melanin biosynthetic pathway and then examines factors, both external and internal, that can

MELANOSOMES IN LIGHTLY PIGMENTED VERSUS DARKLY PIGMENTED SKIN

	Lightly pigmented skin	Darkly pigmented skin
Melanization	Stages II, III	Stage IV
Size (diameter)	0.3–0.5 microns	0.5–0.8 microns
Number per cell	<20	>200
Distribution of melanosomes within the lysosomes of keratinocytes	Groups of 2–10 	Single 
Degradation	Fast	Slow

Table 65.3 Melanosomes in lightly pigmented versus darkly pigmented skin.

influence the level of melanin production. The "starting material" for the production of melanin, both the brown–black eumelanin and the yellow–red pheomelanin, is the amino acid tyrosine. The key regulatory enzyme in the pathway is tyrosinase, which controls the initial biochemical reactions in this pathway (Fig. 65.11). It should then come as no surprise that the initial investigations into the molecular basis of OCA focused on the gene that encodes tyrosinase.

In OCA1A, the form of OCA where mutations in both copies of the tyrosinase gene lead to complete loss of enzyme activity, no melanin is found in the hair, skin, or eyes (see Table 65.1). However, in OCA1B, where there is decreased enzyme activity, pheomelanin is produced, especially in the hair as the patient ages. The formation of pheomelanin requires less tyrosinase activity than does the formation of eumelanin and therefore the formation of pheomelanin can be thought of as a default pathway (see Fig. 65.11).

The activity of tyrosinase is enhanced by DOPA and is stabilized by tyrosinase-related protein 1 (TYRP1) (see below). Competitive inhibitors of tyrosinase activity include hydroquinone, which is used to treat disorders of hyperpigmentation such as melasma, and L-phenylalanine. In patients with phenylketonuria (PKU), there is a diffuse pigmentary dilution due to elevated levels of L-phenylalanine resulting from a deficiency in the enzyme L-phenylalanine hydroxylase that converts L-phenylalanine to L-tyrosine[16]. The characteristic blonde hair of PKU can undergo darkening when the patient is on a low-phenylalanine diet. Of note, tyrosinase is a copper-requiring enzyme and it has two copper-binding sites. Rare cases of copper deficiency can lead to diffuse cutaneous pigmentary dilution, and in patients with Menkes disease, where a transmembrane Cu^{2+}-transporting ATPase that delivers copper to the trans-Golgi network and melanosomes is dysfunctional[34], the kinky hair is hypopigmented.

In a test tube, L-DOPA can spontaneously oxidize to form melanin, an insoluble biopolymer. For this reason, it was originally thought that tyrosinase was the sole enzyme involved in melanin biosynthesis. However, by the late 1970s, it was becoming clear that there were additional control points in the pathway (see Fig. 65.11). For example, dopachrome tautomerase, also known as tyrosinase-related protein 2 (TYRP2), which like TYRP1 shares similarities in its amino acid sequence with tyrosinase, converts DOPAchrome to 5,6-dihydroxyindole-2-carboxylic acid (DHICA). In mice and humans, TYRP1 stabilizes tyrosinase[35] and mutations in both copies of *TYRP1* lead to OCA3 (see Table 65.1).

Decreased function of yet another transmembrane protein, the P protein, leads to OCA2[36]. Based upon its amino acid sequence, a prediction was made that the P protein was involved in the transport of small molecules across the membrane of the melanosome. Originally, tyrosine, the initial precursor in the melanin biosynthetic pathway, was considered the most likely candidate for transmembrane transport. However, the P protein is now thought to play a role in increasing the internal pH of the melanosome, as acidification can reduce the activity of tyrosinase[37]. P protein may also regulate glutathione levels within the melanocyte's intracellular compartments.

Melanins represent a group of complex polymers whose functions vary from camouflage to the quenching of oxidative free radicals generated

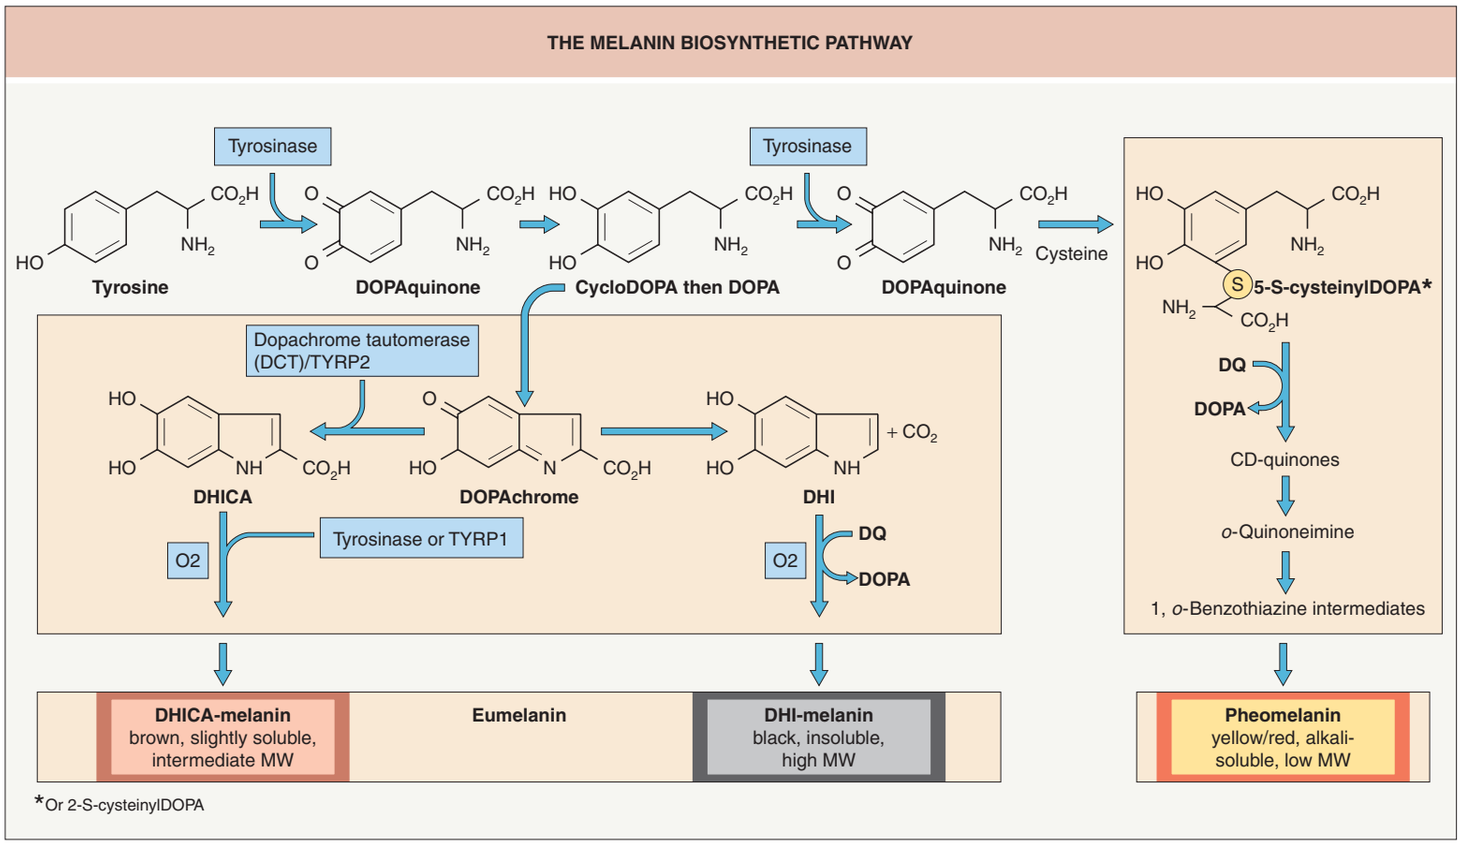

Fig. 65.11 The melanin biosynthetic pathway. The pathway includes the sites of dysfunction in OCA1 (tyrosinase) and OCA3 (TYRP1). The two major forms of melanin in the skin and hair are brown–black eumelanin and yellow–red pheomelanin. The enzymes are transmembrane proteins located within the melanosome. DHI, 5,6-dihydroxyindole; DHICA, 5,6-dihydroxyindole-2-carboxylic acid; DOPA, dihydroxyphenylalanine; MW, molecular weight; TYRP, tyrosinase-related protein.
Adapted from Hearing VJ. Determination of melanin synthetic pathways. J Invest Dermatol 2011;131:E8–E11.

via exposure to UV radiation (UVR). The level and type of melanin production is a complex interplay of the activity of the various enzymes involved in the biosynthetic pathway as well as the activity of proteins such as the P protein and those that stabilize the activity of tyrosinase (e.g. TYRP1). Several factors are known to influence the activity of these key proteins of melanogenesis, and they include α-MSH, basic fibroblast growth factor (bFGF), endothelin-1, KIT ligand, and UVR (see below).

Among the multiple protein products of the proopiomelanocortin (POMC) gene are adrenocorticotropic hormone (ACTH), β-endorphin, and the three forms of MSH (α, β, and γ) (Fig. 65.12); in humans, α-MSH represents the major biologically active form of MSH. The primary site of expression of *POMC* is the pituitary gland; however, other sites of expression include the testis, the endothelium, and, of particular importance, epidermal keratinocytes. Although MSH is classically associated with the pigmentary system, this peptide has a wide range of biologic properties, including suppression of inflammation and regulation of body weight. For example, mutations in *POMC* can result in severe early-onset obesity, adrenal insufficiency, and red hair[38]. It then follows that mutations in the genes that encode the melanocortin receptors to which the protein products of *POMC* bind can lead to similar clinical findings; for example, mutations in *MC4R* are associated with morbid obesity and variant alleles in *MC1R* are associated with red hair (see below). Of note, subcutaneous afamelanotide (4-norleucyl-7-phenylalanine-α-MSH), which has enhanced binding to MC1R compared to α-MSH, can lead to cutaneous hyperpigmentation. When subcutaneous implants of afamelanotide were administered monthly, patients with erythropoietic protoporphyria (EPP) experienced fewer phototoxic reactions and could tolerate more direct sunlight without pain while patients with vitiligo had more rapid and extensive repigmentation in response to treatment with UVB. More recently, once-daily dersimelagon, a novel oral MC1R agonist, improved sun exposure tolerance in patients with EPP[38a].

There are five major melanocortin receptors, all of which have seven transmembrane domains (Table 65.4; Fig. 65.13). Although the MC1R is present on a variety of cells within the skin, from endothelial cells to fibroblasts, the highest density of this receptor is found on melanocytes[39].

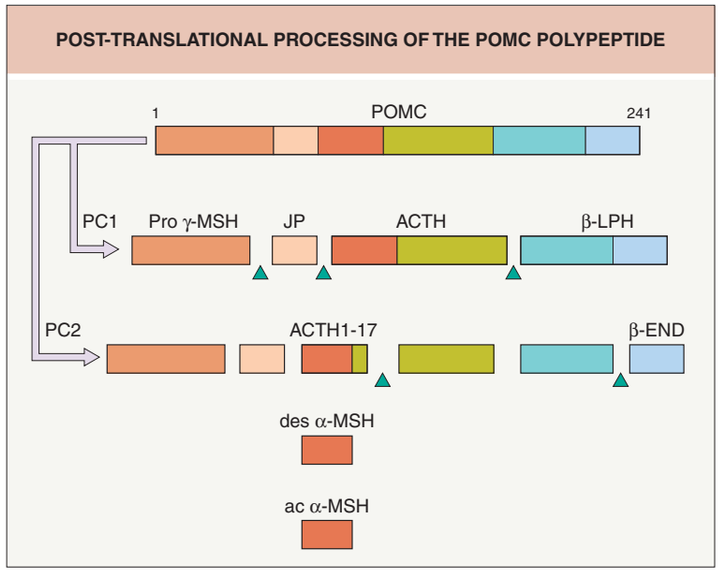

Fig. 65.12 Post-translational processing of the POMC polypeptide. Pituitary hypersecretion of ACTH and/or α-MSH can lead to generalized hyperpigmentation in patients with Addison disease. ac, acetylated; ACTH, adrenocorticotropic hormone; des, desacetyl; END, endorphin; JP, joining peptide; LPH, lipotropic hormone; MSH, melanocyte stimulating hormone; PC, prohormone-converting enzyme; POMC, proopiomelanocortin.

As in the case of the β-adrenergic receptor, the MC1R is a G-protein-coupled receptor, i.e. it uses proteins that bind guanosine triphosphate (GTP) and guanosine diphosphate (GDP) as intermediary messengers (Fig. 65.14). Following the binding of MSH to the MC1R, the protein pair interacts with a complex of G proteins. The GTP-$G_s\alpha$ subunit then

activates adenylate cyclase, leading to increased production of cyclic adenosine monophosphate (cAMP) within the melanocyte. An increase in the intracellular concentration of cAMP leads to an increase in tyrosinase activity and eumelanin production via MITF (see Fig. 65.4). If the MC1R is dysfunctional and fails to initiate a significant rise in the intracellular level of cAMP, then pheomelanogenesis is favored (Fig. 65.15). Of note, the majority of individuals with red hair are compound heterozygotes or homozygotes for a variant R allele in the gene that encodes the MC1R[1,40] (see Fig. 65.13). However, the variation in human hair color is complex, with over 120 genes identified[41].

MC1R also interacts with a protein known as the agouti protein (mouse) or agouti signaling protein (ASIP; human). Agouti is a term used to describe the banding of hairs seen in some mammals, including dogs, foxes and mice, that is due to alternating production of eumelanin and pheomelanin (Fig. 65.16). The production of agouti protein by the cells in the hair follicle papillae is cyclic, and, when the agouti protein is present, it effectively competes with MSH and the formation of pheomelanin within pheomelanosomes is favored[42,43] (see Fig. 65.15). Compared to eumelanosomes, pheomelanosomes are characterized by a more spherical shape and the presence of an unstructured matrix with vesicular bodies.

An enhancement of pigment production can be seen following exposure of melanocytes to agents that increase intracytoplasmic levels of cAMP such as cholera toxin, forskolin[44], dibutyryl cAMP, and MSH (see Fig. 65.14). The activation of protein kinase A (PKA) by cAMP leads to the phosphorylation of various proteins, which can result in their activation. One of the proteins that is phosphorylated by PKA is the *c*AMP *r*esponse-*e*lement *b*inding protein (CREB), which functions as a transcription factor, regulating the expression of other genes, including *MITF* (see Fig. 65.4). Patients with the McCune–Albright syndrome (polyostotic fibrous dysplasia) are mosaics for an activating mutation in the gene that encodes the G protein $G_s\alpha$ (see Fig. 65.14). As a result, the cAMP cascade is permanently "turned on" and, with continued transcription of CREB-controlled genes, there is hyperplasia of the bones and endocrine organs, albeit in a mosaic pattern. Presumably within the melanocytes of the segmental café-au-lait macules typical of this disorder, the increase in intracellular cAMP leads to increased tyrosinase activity and eumelanin production.

Exposure of melanocytes to phorbol esters, e.g. tetradecanoyl phorbol acetate (TPA), can lead to increased melanin formation via the activation of protein kinase C (PKC) (Fig. 65.17). Growth factors, including bFGF and KIT ligand, can also increase the pigment content within melanocytes whereas KIT receptor inhibitors (e.g. imatinib) can lead to hypopigmentation. Endothelin-1, a small peptide originally isolated from endothelial cells, is produced by keratinocytes and can lead to an increase in tyrosinase activity followed by an increase in melanin production.

In addition to ultraviolet radiation (see below), inflammation can lead to hyper- or hypopigmentation. Prostaglandin E_2/F_2 and interleukin (IL)-33, mediators produced by both keratinocytes and fibroblasts, can lead to activation of melanocytes. Inhibitors of pigment production include interferon-γ, tumor necrosis factor (TNF), IL-4, and IL-6[45].

Multiple genes have been implicated as playing a role in normal pigment variation in humans, including: (1) *MC1R* and *ASIP*; (2) several genes that play a role in OCA, e.g. *TYR*, *OCA2*, *TYRP1*, *SLC45A2*, *SLC24A5* (see Table 65.1); (3) *KITLG* which encodes KIT ligand; (4) *TPCN2* which encodes an ion channel transporter; and (5) *IRF4* which encodes interferon regulatory factor 4[2–4]. The presence of a variant (rather than the African ancestral) allele of *SLC24A5*, whose protein product is a putative cation exchanger in the melanosomal membrane, correlates with lighter skin color[5]. In addition, variants in *OCA2* are thought, at least in part, to determine the normal phenotypic variation in human eye color[2]. A haplotype with several polymorphisms in *ASIP* (and presumably a gain of ASIP function) has been associated with red or blonde hair, freckling, and a tendency to burn, while variants that lead to destabilized *ASIP* mRNA have been associated with darker skin phototypes[3,46,47]. A polymorphism in the regulatory region of *KITLG* that reduces its responsiveness to the WNT-activated transcription factor LEF1 is associated with blonde hair[48], and in mice, decreased lef1 leads to light-colored hair. Of note, some loss-of-function mutations in

MAJOR FORMS OF THE MELANOCORTIN RECEPTOR

Receptor	Distribution, major (minor)	Ligands
MC1R*	Melanocytes (keratinocytes, fibroblasts, endothelial cells, antigen-presenting cells)	α-MSH, ACTH > β-MSH
MC2R	Adrenal cortex (adipocytes)	ACTH
MC3R†	Brain (gut, placenta)	α-, β-, γ-MSH, ACTH
MC4R†	Brain	α-, β-MSH, ACTH
MC5R	Peripheral tissues, e.g. sebaceous glands, fibroblasts, adipocytes	α-, β-MSH, ACTH

*Antagonistic ligands – agouti protein (mouse) and agouti signaling protein (ASIP; human).
†Antagonistic ligand – agouti-related protein (AGRP).

Table 65.4 Major forms of the melanocortin receptor (MCR). ACTH, adrenocorticotropic hormone; MSH, melanocyte stimulating hormone.

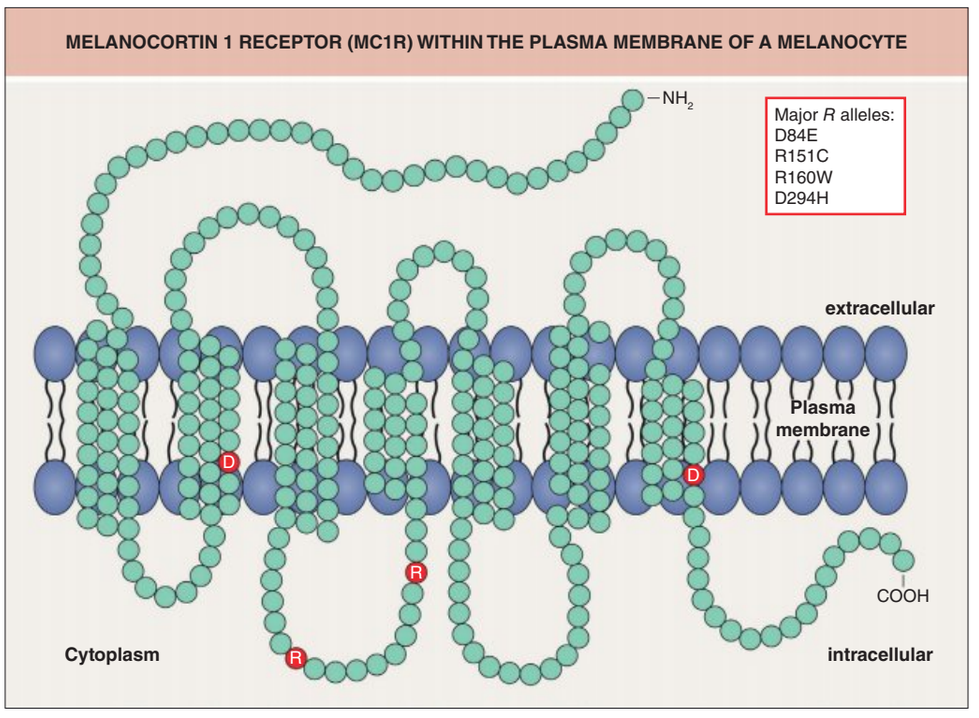

Fig. 65.13 Melanocortin 1 receptor (MC1R) within the plasma membrane of a melanocyte. MC1R has seven transmembrane domains and is a G-coupled receptor (see Fig. 65.14). There are numerous genetic variants of the MC1R. The null or hypomorphic *R* alleles D84E, R151C, R160W, and D294H have red hair odds ratios of 62, 118, 50, and 94, respectively; the low penetrance *r* alleles of V60L, V92M, and R163Q have red hair odds ratios of 6, 5, and 2, respectively[63]. In general, *R/R* individuals have red hair and lightly pigmented skin.

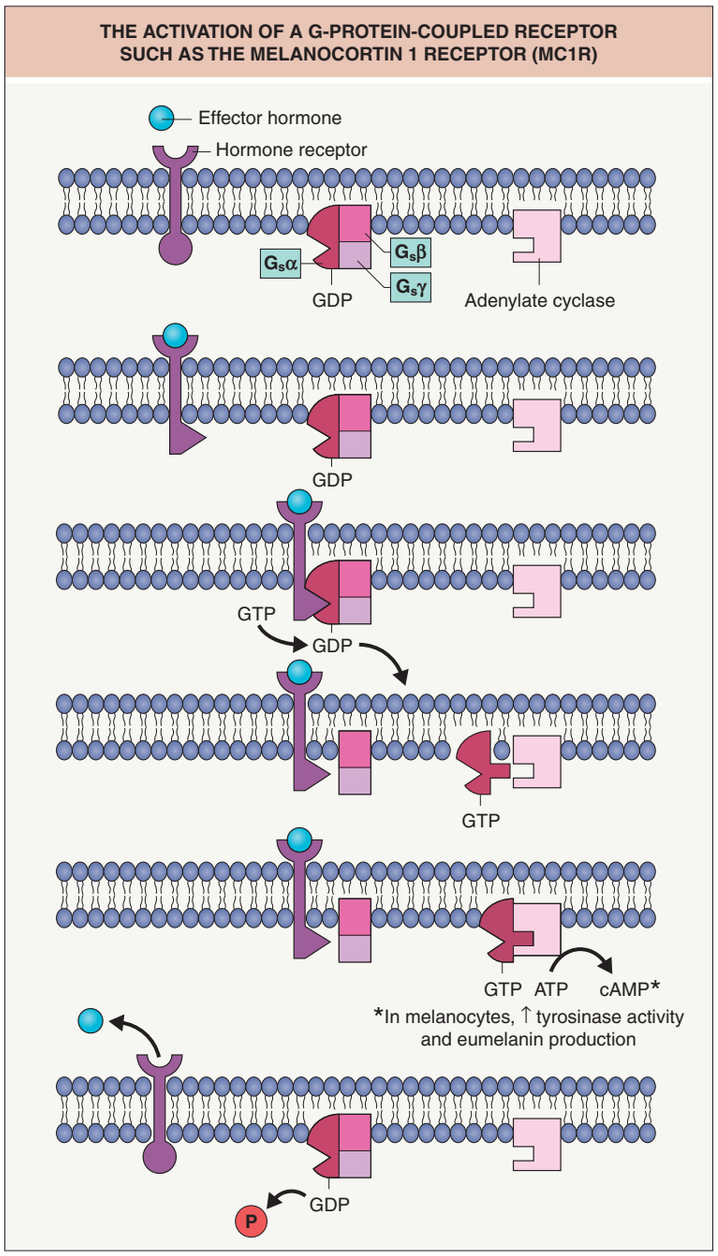

Fig. 65.14 Activation of a G-protein-coupled receptor such as the melanocortin 1 receptor (MC1R). In the case of the MC1R, the increase in the intracellular concentration of cAMP leads to an increase in tyrosinase activity and eumelanin production. GDP, guanosine diphosphate; GTP, guanosine triphosphate; P, phosphate group; S, stimulatory. *Adapted from Alberts B. Molecular Biology of the Cell. Garland Publishing; 1989.*

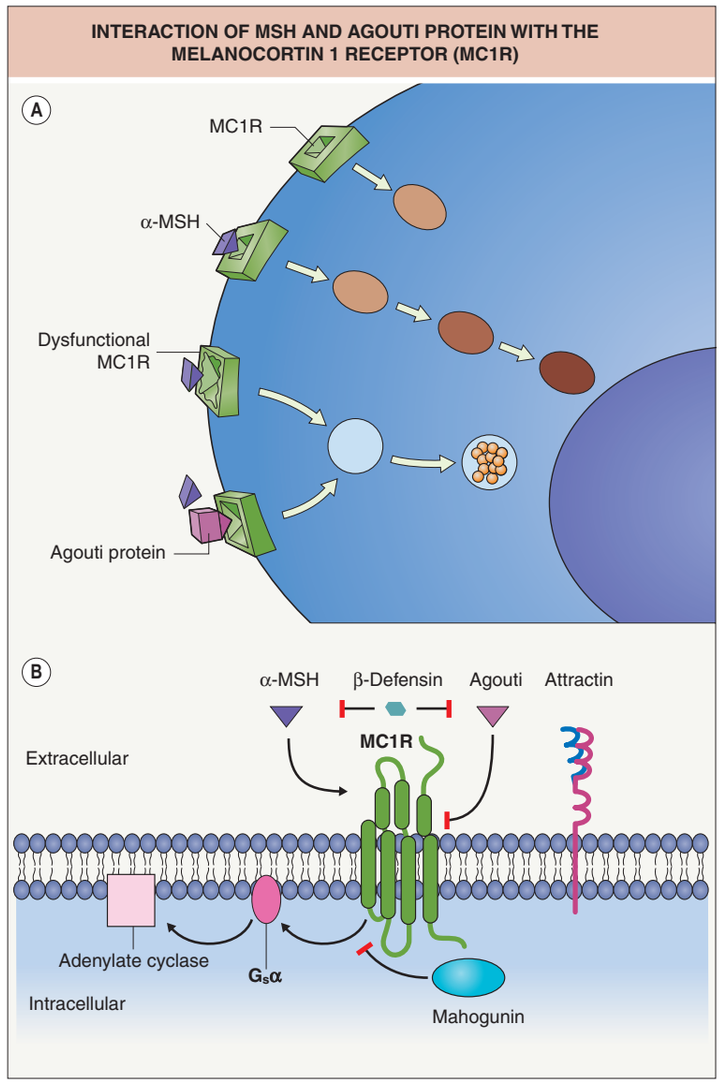

Fig. 65.15 Interaction of melanocyte stimulating hormone (MSH) and agouti protein with the melanocortin 1 receptor (MC1R). A There is baseline activity of the MC1R, enhanced by binding with MSH. Agouti protein represents an antagonist ligand for the MC1R whose binding can lead to pheomelanogenesis. Dysfunction of the MC1R can also lead to pheomelanogenesis, as in the case of humans with red hair. **B** Interactions are actually more complex, in that to be fully effective, agouti requires attractin and mahogunin; the former aids in the binding of agouti to MC1R while the latter acts on the cytosolic side. There is also a neutral agonist, β-defensin, which interferes with both agonist and antagonist binding. *Adapted from Schiaffino MV. Signaling pathways in melanosome biogenesis and pathology. Int J Biochem Cell Biol 2010;42:1094–104.*

MC1R confer a risk for developing cutaneous melanoma, independent of pigmentary phenotype[40].

In humans, graying or whitening of hair is a normal aging phenomenon. There is evidence that reactive oxygen species accumulate within affected hair follicles and lead to oxidative damage of hair follicle melanocytes[49]. Hair bulb melanocytes are thought to undergo apoptosis first, followed by depletion of precursor cells in the bulge region. However, more recent studies of graying hairs have pointed to a reduction in the migration of melanocyte stem cells from the bulge region[49a]. Hair bulb melanocytes that disappear fail to express TYRP2 and SOX10. The role of SCF production by KROX20$^+$ cells within the hair bulb was discussed previously. Lastly, hyperactivation of sympathetic nerves has been shown to drive depletion of melanocyte stem cells[50].

Ultraviolet Radiation (UVR)

Following a single exposure to UVR, an increase in the size of melanocytes can be observed, along with an increase in tyrosinase activity[16]. Repeated exposures to UVR lead to an increase in the number of stage IV melanosomes transferred to keratinocytes, as well as an increase in the number of active melanocytes. When chronically sun-exposed sites (e.g. the upper outer arm) are compared with non-sun-exposed sites (e.g. the upper inner arm), the density of melanocytes is up to two times greater in sun-exposed sites[51]. Melanocytes, like other neural-derived tissues, have a low mitotic rate, and whether this increase in number represents an increase in mitotic rate or an activation of "inactive" melanocytes or melanocyte precursors is not known. Senescent fibroblast-derived GDF15 may play a role in the hyperpigmentation of photoaged skin via β-catenin signaling[52].

Following exposure to UVA irradiation, an *immediate pigmentary darkening* can be observed, which occurs within minutes and fades over 20–30 minutes. It is clinically most obvious in darkly pigmented skin and is thought to represent oxidation of pre-existing melanin or melanin precursors. Given its transient nature, it does not provide photoprotection. *Delayed tanning* is visible within 24–72 hours after exposure to UVB and UVA radiation and represents new pigment production via an increase in tyrosinase activity. In addition to an increase in melanocyte

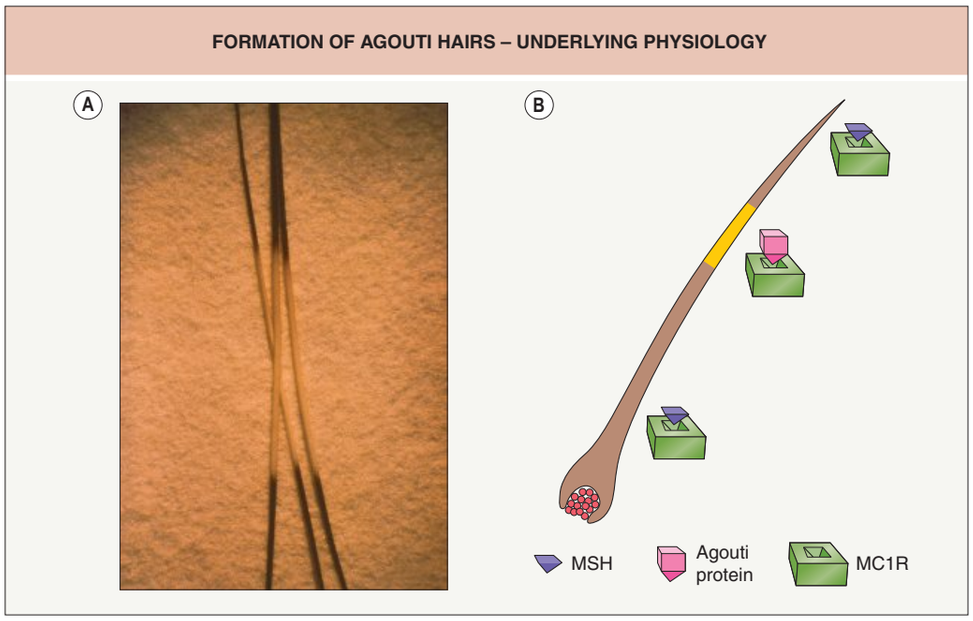

Fig. 65.16 Formation of agouti hairs – underlying physiology. A Fox hairs with alternating eumelanin and pheomelanin production within individual hairs, a pattern referred to as agouti. **B** Explanation for the agouti pattern based on different ligands interacting with the melanocortin 1 receptor (MC1R). Both gain-of-function mutations at the agouti locus and loss-of-function of MC1R can lead to yellow-haired mice. In the CNS, an abundance of agouti protein leads to obesity, and yellow mice with gain-of-function mutations at the agouti locus are also obese[64].

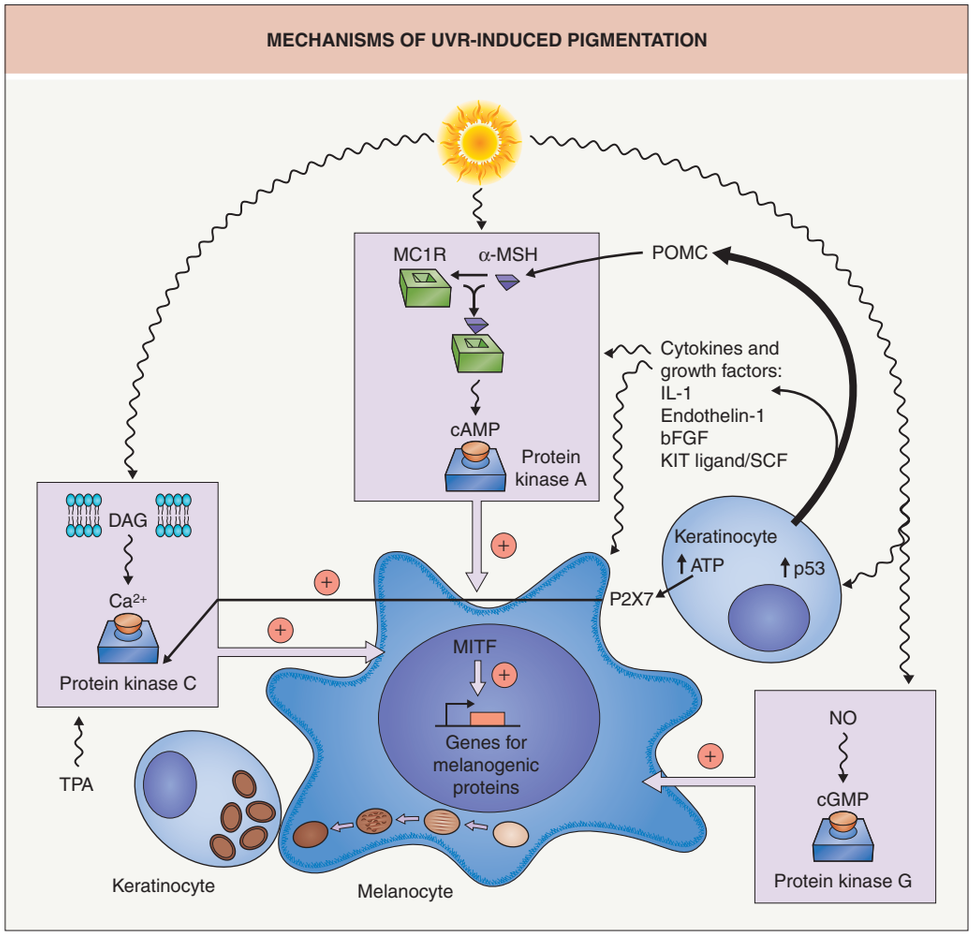

Fig. 65.17 Mechanisms of UVR-induced pigmentation. These include an increase in one or more of the following: (1) expression of proopiomelanocortin (POMC) and its derivative peptides by cells within the skin, in particular keratinocytes; (2) the number of melanocortin 1 receptors (MC1R) on melanocytes; (3) the release of diacylglycerol (DAG) from the plasma membrane, which activates protein kinase C; (4) the induction of an SOS response to UVR-induced DNA damage; (5) nitric oxide (NO) production, which activates the cGMP pathway; and (6) production of cytokines and growth factors by keratinocytes. As a result, there is enhanced transcription of the genes that encode microphthalmia-associated transcription factor (MITF) and melanogenic proteins including tyrosinase, tyrosinase-related protein 1 (TYRP1), TYRP2, and PMEL/PMEL17/gp100. In addition, melanocyte dendricity and transfer of melanosomes to keratinocytes is stimulated via increased activity of Rac1 (involved in dendrite formation), the ratio of kinesin to dynein, and expression of protease-activated receptor-2 (PAR-2; involved in melanosome transfer). Increased POMC expression in keratinocytes followed by processing to β-endorphin (in addition to α-MSH) may play a role in addiction to ultraviolet light. ATP, adenosine 5′-triphosphate; P2X7, purinergic receptors type 2 X7; TPA, tetradecanoyl phorbol acetate.

size and number, tyrosinase activity, and transfer of melanosomes to keratinocytes, the response to PUVA includes an alteration in size and aggregation pattern of melanosomes, i.e. from smaller and grouped to larger and singly dispersed (see Table 65.3).

UVR may work by increasing one or more of the following:

- transcription of the tyrosinase gene (via MITF)
- the number or activity of MC1R on melanocytes
- the expression of POMC and its derivative peptides by keratinocytes and several cell types within the dermis (e.g. endothelial cells, sebocytes, lymphocytes)
- the release of diacylglycerol from the plasma membrane, which activates protein kinase C
- an activation of the nitrous oxide/cGMP pathway
- the production of cytokines and growth factors by keratinocytes (e.g. endothelin-1)
- the induction of an SOS response to UVR-induced DNA damage[39,53,54]
- transactivation of the *POMC* promoter by p53[55,56]
- the ratio of kinesin to dynein, affecting melanosome transport (see Fig. 65.10).

The inability of the majority of red-haired individuals to develop a tan following exposure to UVR can be explained, at least in part, by dysfunction of their melanocyte MC1R. This phenomenon, along with the production of oxygen radicals following the UV irradiation of pheomelanins, probably contributes to the increased incidence of both cutaneous melanoma and keratinocyte carcinomas in persons with red hair. In addition, chemiexcitation of melanin derivatives induces DNA photoproducts long after UV exposure[57]. Based upon a large genome-wide association study in individuals of European ancestry, the ability to tan was associated with 20 loci, including ten that were not previously associated with pigment-related phenotypes[58].

Key features

- Leukoderma and hypopigmentation refer to lightening of the skin, which is classically due to decreased epidermal melanin (hypomelanosis)
- Melanocytopenic hypomelanosis, characterized by a reduction in the number of melanocytes, can result from a variety of defects in pigment cell differentiation, proliferation, migration, and/or survival
- Melanopenic hypomelanosis features a normal number of melanocytes but decreased melanin synthesis or transfer to keratinocytes, and the underlying abnormalities often involve melanosomes
- The age of onset (congenital or acquired), degree of pigment loss (hypo- versus amelanosis), presence or absence of preceding inflammation, anatomic location, and distribution pattern – circumscribed, diffuse, linear, or guttate – represent key considerations in the evaluation of a patient with hypopigmentation
- Vitiligo is a common multifactorial disorder involving the disappearance of melanocytes due to an immune disturbance; patients present with circumscribed depigmented macules and patches in a localized (including segmental) or generalized distribution
- Presentations of hereditary hypomelanosis range from congenital, stable, circumscribed areas of amelanosis in piebaldism and Waardenburg syndrome to diffuse pigmentary dilution of the skin, hair, and/or eyes in the various forms of oculocutaneous albinism and related conditions
- Postinflammatory, infectious, and chemical hypomelanosis as well as halo nevi and melanoma-associated leukoderma represent other etiologies of circumscribed hypo- or amelanosis
- Blaschko-linear hypopigmentation and idiopathic guttate hypomelanosis are the most common causes of linear and guttate hypopigmentation

INTRODUCTION

Leukoderma and hypopigmentation are general terms used to designate disorders characterized by lightening of the skin. They are classically the result of decreased epidermal melanin content (melanin-related), but they may be secondary to a decreased blood supply to the skin (hemoglobin-related). Hypomelanosis is a more specific term that denotes a reduction of melanin within the skin; amelanosis signifies the total absence of melanin. Depigmentation usually implies a total loss of skin color, most commonly due to disappearance of pre-existing melanin pigmentation, as in vitiligo. The term pigmentary dilution is used to describe a generalized lightening of the skin and hair, as in oculocutaneous albinism; this may only be apparent if the affected individuals are compared with unaffected relatives.

Cutaneous hypomelanosis is often classified into two groups:

- *melanocytopenic hypomelanosis*, caused by a reduction in the number of epidermal and/or follicular melanocytes
- *melanopenic hypomelanosis*, in which the number of epidermal and/or follicular melanocytes is normal, but the pigment cells fail to synthesize normal amounts of melanin and/or transfer it to surrounding keratinocytes.

Melanocytopenic hypomelanosis may be hereditary and/or congenital due to a defect in melanoblast differentiation, proliferation, migration, and/or survival, or it may be acquired. In the latter case, functional melanocytes can disappear as a result of their destruction from insults such as external trauma (e.g. cryosurgery) or an immune attack. The factors controlling melanocyte survival may also play a role in the postnatal disappearance of dermal melanocytes. Melanopenic hypomelanosis may result from complex pathologic mechanisms, including melanosomal abnormalities that affect biogenesis, melanization, transfer, or degradation.

Diagnosis of Leukodermas

Any patient with a leukoderma should be fully examined under visible light and using a Wood's lamp (~365 nm). The latter is particularly useful in circumscribed leukodermas, individuals who have very lightly pigmented skin (phototypes I or II), and neonates. Under visible light, it is sometimes difficult to distinguish between hypomelanosis and amelanosis, but the greater the loss of epidermal pigmentation, the more marked the contrast on Wood's lamp examination. This technique is also helpful in differentiating hypomelanotic macules from hemoglobin-related leukodermas; for example, nevus anemicus becomes inapparent.

Most leukodermas are diagnosed clinically following a complete history and physical examination. Determining whether the distribution pattern is *circumscribed* (e.g. vitiligo), *diffuse* (e.g. albinism), *linear*, or *guttate* (e.g. idiopathic guttate hypomelanosis) helps to narrow the differential diagnosis. The age of onset, presence or absence of preceding inflammation, anatomic location, and degree of pigment loss represent other pertinent features. Histologic examination of involved skin is most useful for several of the hypomelanoses associated with inflammatory processes (e.g. sarcoidosis, lichen sclerosus, mycosis fungoides).

VITILIGO

Vitiligo is an acquired disorder characterized by circumscribed depigmented macules and patches due to the loss of epidermal melanocytes. Leukotrichia within areas of involvement is due to a loss of follicular melanocytes.

Epidemiology

Worldwide, vitiligo affects ~0.5%–1% of the general population[1,2]. It may appear any time from shortly after birth to late adulthood, with an average age of ~30 years[3] at onset. Although patients with vitiligo may attribute the development of their disease to specific life events (e.g. physical injury, sunburn, emotional distress, illness, pregnancy), with the exception of the Koebner phenomenon, it has not been proven that these factors directly precipitate vitiligo.

Pathogenesis

The pathogenesis of vitiligo involves both genetic and non-genetic factors in processes that lead to the loss of epidermal melanocytes.

Genetics

Both twin and family studies point to the importance of genetic factors in the development of vitiligo[2]. For example, a survey in the US and UK found that 7% of the first-degree relatives of vitiligo probands had vitiligo. However, a 23% concordance rate in monozygotic twins supported the additional role of environmental factors[4]. Genome-wide linkage analyses have been performed in multiple patient populations, resulting in the identification of a number of susceptibility loci and candidate genes. Many of these genes are involved in melanogenesis, immune regulation, or apoptosis and have been associated with other pigmentary, autoimmune, or autoinflammatory disorders[3,5,6] (Table 66.1).

Pathogenic pathway

Multiple steps occur during the initiation and progression of vitiligo, ultimately leading to the loss of epidermal melanocytes (Fig. 66.1). With a background of genetic susceptibility, intrinsic abnormalities of melanocytes are thought to render them more vulnerable to damage from oxidative stress. Oxidative stress also results in impairment of WNT signaling; the latter normally promotes differentiation of melanocyte precursors and thereby facilitates repigmentation during vitiligo therapy[7].

In the cascade of events that leads to immune activation, an initial step is a release by melanocytes of damage-associated molecular patterns (DAMPs) such as HSP-70 (heat shock protein 70)[8] and HMGB1 (high mobility group box protein B1). This stimulates plasmacytoid dentritic cells and innate lymphoid cells in the skin to secrete interferon (IFN)-α[9,10] and IFN-γ. Activated keratinocytes produce C-X-C chemokine ligands 9 and 10 (CXCL9 & 10), which leads to the recruitment of both $CD4^+$ helper and $CD8^+$ cytotoxic T cells which express C-X-C chemokine receptor 3 (CXCR3). These T cells produce proinflammatory cytokines such as IFN-γ and tumor necrosis factor (TNF)[11,12], resulting in the destruction of melanocytes.

The recurrence of vitiligo within previously affected skin highlights the role of resident memory T cells (see Fig. 11.3). These cells have a distinct transcriptional program and express characteristic cell surface markers such as CD69, CD103 and CD49a[13], with the latter defining a subset of resident memory T cells with cytotoxic properties.

Clinical Features

Characteristics of vitiligo lesions

The most common presentation of vitiligo is totally amelanotic (milk- or chalk-white) macules or patches surrounded by normal skin. Well-developed lesions typically have discrete margins and may be round, oval, irregular, or linear in shape. The borders are usually convex, as if the depigmenting process were "invading" the surrounding normally pigmented skin[1,2,14]. However, at their onset or when actively spreading, areas of vitiligo may be more ill-defined and hypomelanotic rather than amelanotic. Vitiligo lesions occasionally have a hyperpigmented border, and a blue color can result when vitiligo develops in areas of postinflammatory dermal pigmentation.

Lesions enlarge centrifugally over time at a rate that can be slow or rapid. Vitiligo macules and patches range from millimeters to centimeters in diameter and often have variable sizes within an area of involvement. In lightly pigmented individuals, the lesions may be subtle or inapparent without Wood's lamp examination or tanning of uninvolved skin. In patients with darker skin phototypes, the contrast between vitiliginous areas and the surrounding skin can be striking (Fig. 66.2). Vitiligo is usually asymptomatic, but pruritus is occasionally noted, especially within active lesions.

Vitiligo may develop anywhere on the body. Interestingly, it frequently localizes to sites that are normally relatively hyperpigmented, such as the face, dorsal aspect of the hands, nipples, axillae, umbilicus, and sacral, inguinal, and anogenital regions (see Fig. 66.2). Typically, facial vitiligo occurs around the eyes and mouth (i.e. periorificial), and on the extremities it favors the elbows, knees, digits, flexor wrists, dorsal ankles, and shins (Figs. 66.3 & 66.4). Common sites of involvement also include areas subjected to repeated trauma, pressure, or friction (e.g. in body folds or via contact with clothing). Palmoplantar[15] and oral mucosal involvement in lightly pigmented individuals is often difficult to visualize without Wood's lamp examination. In acrofacial vitiligo, periungual involvement of one or more digits may be associated with lip depigmentation; however, either can be an isolated finding.

The incidence of body leukotrichia varies from 10% to >60%, as vitiligo often spares follicular melanocytes. The occurrence of leukotrichia does not correlate with disease activity.

One additional manifestation of vitiligo is the isomorphic Koebner phenomenon, which is characterized by the development of vitiligo within sites of trauma, such as a surgical excision or thermal burn. It is more common in patients with progressive vitiligo. There appears to be a minimal threshold of injury required, bringing into question the hypothesis that minor trauma, such as friction from clothes, can induce vitiligo lesions.

Clinical classification of vitiligo

The 2012 Vitiligo Global Issues Consensus Conference recommended that "vitiligo" be used as the umbrella term for all *non-segmental* forms of vitiligo[16]. *Segmental* vitiligo would refer to a clinically unambiguous segmental distribution of depigmented lesions, while *mixed* vitiligo represented the coexistence of segmental and non-segmental vitiligo.

An additional classification scheme subdivides vitiligo into two major groups, localized and generalized (see Fig. 66.4).

Localized:

- *Segmental*: involves one or more body segments, usually with roughly quadrilateral shapes and not crossing the midline (Fig. 66.5); this form typically has rapid onset and often associated leukotrichia (Fig. 66.6)
- *Focal*: undetermined/unclassified form in which depigmented macules are localized to one area but not clearly in a segmental distribution; after 1–2 years of follow-up, more definitive classification is frequently possible
- *Mucosal*: only the mucous membranes are involved

Generalized:

- *Vulgaris*: scattered patches that are widely distributed
- *Acrofacial*: distal extremities and face
- *Universal*: complete or, more commonly, nearly complete depigmentation

Overall, >90% of vitiligo patients have vulgaris or acrofacial variants. Segmental vitiligo is more common in children than adults, accounting for ~15%–30% of pediatric vitiligo (see below).

Clinical variants

Follicular vitiligo presents with leukotrichia in the absence of depigmentation of the surrounding epidermis[17]. Although vitiligo of the scalp, eyebrows, and eyelashes usually presents as one or more localized patches of white or gray hair (poliosis; see Fig. 66.6), scattered white hairs due to involvement of individual follicles or even total depigmentation of all scalp hair may occur.

Vitiligo ponctué, an unusual clinical presentation of vitiligo, is characterized by multiple, small, discrete amelanotic macules (confetti-like), sometimes superimposed upon a hyperpigmented macule. Erythema at the margin of a vitiligo macule is referred to as *"vitiligo with raised inflammatory borders"* or *inflammatory vitiligo* (Fig. 66.7); a figurate papulosquamous variant has also been reported.

Trichrome vitiligo is characterized by a hypopigmented zone between the normal and depigmented skin. This intermediate zone has a fairly uniform hue rather than a gradual progression from white to normally pigmented skin. The number of melanocytes is also intermediate in this zone, suggesting a slower centrifugal progression compared to classic vitiligo. *Quadrichrome and pentachrome vitiligo* have also been described.

Hypochromic vitiligo has been described in patients with skin phototypes V and VI[18]. They present with persistent hypopigmented macules in a seborrheic distribution, with lesions coalescing on the face and scattered on the neck, trunk, and scalp. There was no history of prior inflammation and a few individuals had additional achromic macules. Decreased melanocyte density was noted histologically.

SELECTED SUSCEPTIBILITY LOCI AND CANDIDATE GENES FOR VITILIGO	
Candidate gene	**Defective protein**
Involved in immune regulation	
PTPN22	Protein tyrosine phosphatase, non-receptor type 22
*FOXD3**	Forkhead box D3*
IFIH1	Interferon induced with helicase C domain 1
CTLA4	Cytotoxic T lymphocyte-associated protein 4
FOXP1	Forkhead box P1
CD80	CD80 molecule
LPP	LIM domain containing preferred translocation partner in lipoma
CLNK	Cytokine dependent hematopoietic cell linker
TSLP	Thymic stromal lymphopoietin
BACH2	BTB domain and CNC homolog 2
HLA (various genes), *BTNL2*	Major histocompatibility complex classes I–III, butyrophilin-like 2
CCR6	Chemokine (C-C motif) receptor 6
SMOC2	SPARC related modular calcium binding 2
SLA	Src-like-adaptor
IL2RA	Interleukin 2 receptor α
CD44	CD44 molecule
CXCR5	C-X-C motif chemokine receptor 5
IKZF4	IKAROS family zinc finger 4
SH2B3	SH2B adaptor protein 3
VDR	Vitamin D receptor
NLRP1 (formerly *NALP1*)	NOD-like receptor family, pyrin domain containing 1
TNFRSF11A	TNF receptor superfamily member 11a (RANK)
TICAM1	Toll-like receptor adaptor molecule 1
PTPN1	Protein tyrosine phosphatase, non-receptor type 1
UBASH3A, AIRE	Ubiquitin associated and SH3 domain containing A, autoimmune regulator
XBP1	X-box binding protein 1
C1QTNF6	C1q and tumor necrosis factor related protein 6
TOB2	Transducer of ERBB2, 2
FOXP3	Forkhead box P3
Involved in apoptosis and/or cytotoxicity	
FASL	Fas ligand
RERE	Arginine–glutamic acid dipeptide (RE) repeats
SLC29A3	Solute carrier family 29 member 3
CASP7	Caspase 7
GZMB	Granzyme B
Melanocyte-related	
IRF4	Interferon regulatory factor 4
FGFR1OP, RNASET2	Fibroblast growth factor receptor 1 oncogene partner, ribonuclease T2
ZMIZ1	Zinc finger MIZ-type containing 1
TYR	Tyrosinase
PMEL	Premelanosome protein
OCA2, HERC2	Oculocutaneous albinism 2 transmembrane protein, HECT and RLD domain containing E3 ubiquitin protein ligase 2
MC1R	Melanocortin-1 receptor
ASIP	Agouti signaling protein

*In one family to date, a functional variant in the promoter of the *FOXD3* melanoblast developmental regulator gene was associated with autosomal dominant inheritance of an atypical vitiligo phenotype (early onset, widespread, progressive depigmentation).

Table 66.1 Selected susceptibility loci and candidate genes for vitiligo. There is evidence that vitiligo has significant genetic heterogeneity in different ethnic populations. Genome-wide association studies have identified other susceptibility loci, including 7p13, 7q11, 9q22, and (in Chinese patients) 4q13–q21. HLA, human leukocyte antigen.

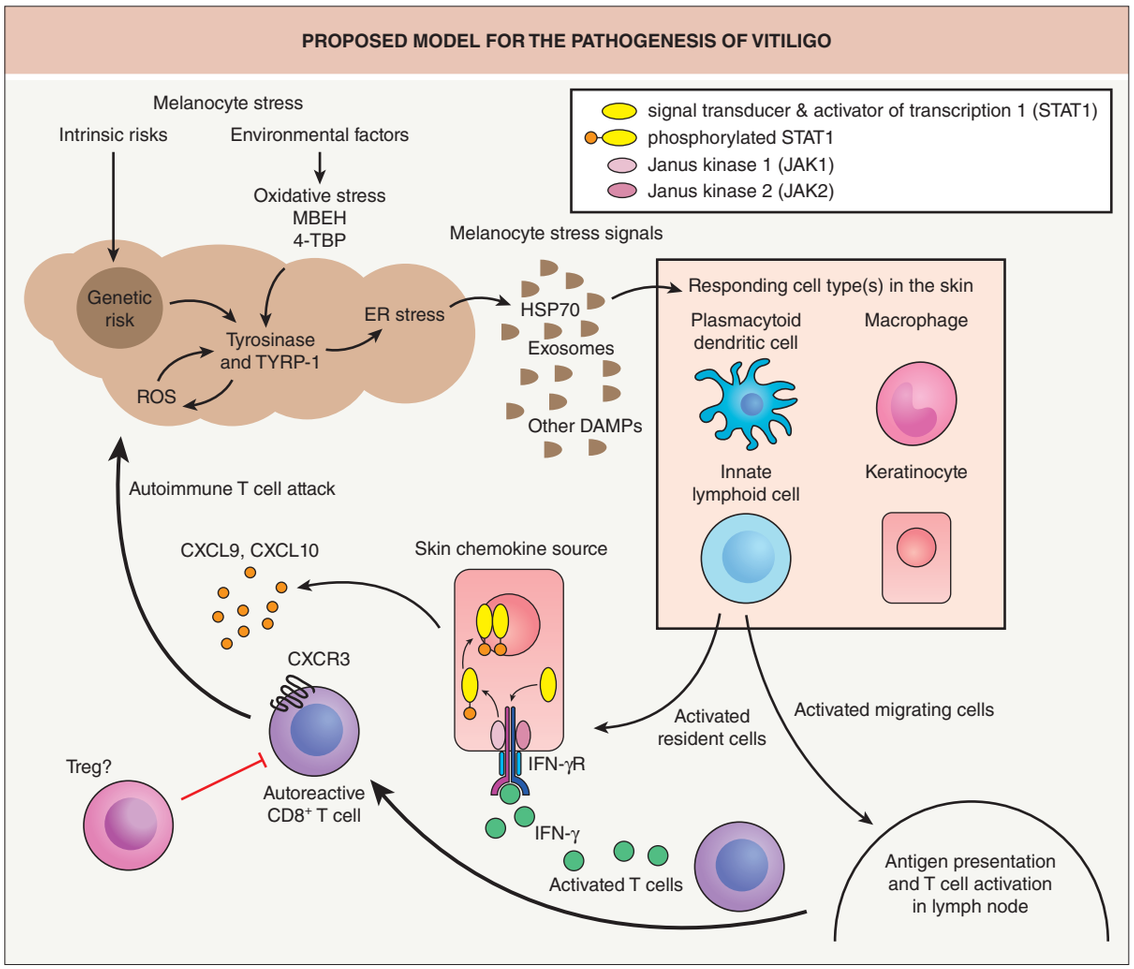

Fig. 66.1 Proposed model for the pathogenesis of vitiligo. Inherited genetic risk (see Table 66.1) and environmental insults (e.g. monobenzyl ether of hydroquinone [MBEH], 4-tertiary butyl phenol [4-TBP]) induce melanocyte stress, exemplified by endoplasmic reticulum (ER) stress. Stressed melanocytes signal to local innate and resident skin cell types via exosomes containing antigen and damage-associated molecular patterns (DAMPs), soluble heat shock protein 70 (HSP70), and other factors. These signals activate several cell types, some of which migrate to the draining lymph nodes and stimulate T cells, which secrete interferon-γ (IFN-γ). IFN-γ signals through the IFN-γ receptor (IFN-γR) on keratinocytes and/or other cells; this involves phosphorylation of the transcription factor STAT1 by Janus kinases (JAK) 1 and 2. Phosphorylated STAT1 homodimerizes and then translocates into the nucleus, where IFN-γ-dependent genes such as *CXCL9* and *CXCL10* (C-X-C chemokine ligand 9 and 10) are transcribed. Autoreactive $CD8^+$ T cells that express C-X-C chemokine receptor 3 (CXCR3) follow secreted CXCL9/10 to the skin, where they kill melanocytes. Approaches targeting this IFN-γ–STAT1–CXCL9/10 axis that drives melanocyte destruction (e.g. with JAK inhibitors or antibodies against CXCR3) can be utilized to treat vitiligo. ROS, reactive oxygen species; STAT1, signal transducer and activator of transcription 1; TYRP-1, tyrosinase-related protein 1. *Adapted from Strassner JP, Harris JE. Understanding mechanisms of autoimmunity through translational research in vitiligo. Curr Opin Immunol 2016;443:81–8.*

Fig. 66.6 Segmental vitiligo. Under normal light, vitiligo can be subtle in lightly pigmented individuals. The clue to the diagnosis is the poliosis of the eyelashes. *Courtesy Jean L. Bolognia, MD.*

Disease course

The onset of vitiligo is usually insidious. Many patients become aware of the depigmented macules and patches, especially in sun-exposed areas, during the summer when tanning increases the contrast between involved and uninvolved skin. Clinical erythema or pruritus rarely precedes vitiligo.

The course of vitiligo is unpredictable. It becomes more extensive by the appearance of new depigmented macules, centrifugal enlargement of pre-existing lesions, or both processes. Clinical features that have been associated with active progression include hypomelanotic lesions with poorly defined borders and confetti-like lesions[19–21].

The natural course of *generalized* vitiligo is usually one of slow spread, but it may stabilize for a long period of time or evolve rapidly. Rarely, total body involvement develops within a few weeks or even days. In contrast, *segmental* vitiligo usually reaches its full extent within 1–2 years and remains restricted to the initial segmental area. The presence of halo nevi and leukotrichia increases the likelihood of evolution from segmental to mixed vitiligo[22]. Some degree of sun-induced or spontaneous repigmentation of vitiligo is not uncommon, but complete and stable repigmentation is rare.

The *v*itiligo *a*rea *s*coring *i*ndex (VASI), *V*itiligo *E*uropean *T*ask *F*orce (VETF) score, and *v*itiligo *e*xtent *s*core (VES) represent validated quantitative assessment scales[14,23,24]. A *p*hysician *g*lobal *a*ssessment (PGA) that categorizes vitiligo extent and *v*itiligo *s*igns of *a*ctivity *s*core (VSAS) have also been developed[25,26].

Ocular involvement

The uveal tract (iris, ciliary body, and choroid) and retinal pigment epithelium contain pigment cells. *Uveitis* is the most significant ocular abnormality associated with vitiligo. *Vogt–Koyanagi–Harada*

Fig. 66.7 Inflammatory vitiligo. An erythematous inflammatory border is evident. Such lesions are sometimes misdiagnosed as tinea corporis.

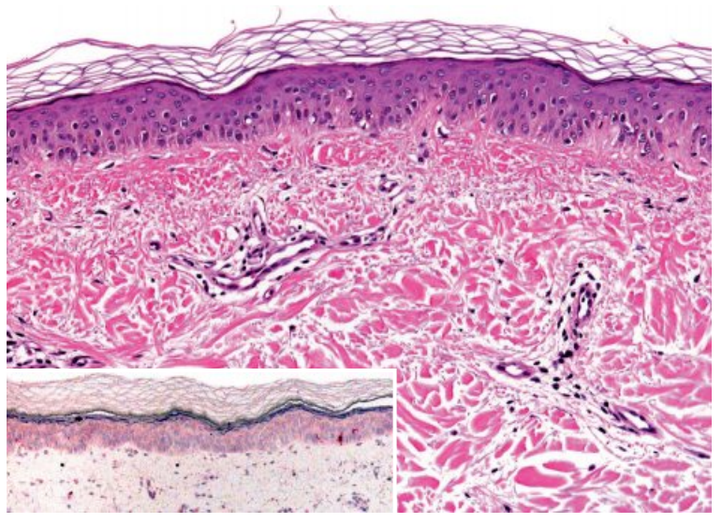

Fig. 66.8 Histology of vitiligo. The complete absence of melanocytes in the basal layer of the affected epidermis is highlighted by Melan-A (MART-1) staining (inset), in contrast to the normal number of melanocytes visible in adjacent unaffected skin on one lateral edge. *Courtesy Lorenzo Cerroni, MD.*

(VKH) syndrome is characterized by: (1) uveitis; (2) aseptic meningitis; (3) otic involvement (e.g. dysacusia); and (4) vitiligo, especially of the face or sacral region, and associated poliosis. Histologic examination of amelanotic skin, which classically appears after the extracutaneous symptoms, demonstrates an infiltrate consisting primarily of $CD4^+$ lymphocytes, suggesting a prominent role for cell-mediated immunity.

Non-inflammatory depigmented lesions of the ocular fundus are evident in some patients with vitiligo, presumably representing focal areas of melanocyte loss. An association between vitiligo and high-frequency sensorineural hearing loss has been noted in recent systematic reviews[27,28], possibly reflecting the role of cochlear melanocytes in regulation of auditory function. However, clearcut evidence of otic abnormalities remains to be demonstrated.

Alezzandrini syndrome is a rare disorder characterized by unilateral whitening of scalp hair, eyebrows, and eyelashes as well as ipsilateral depigmentation of facial skin and visual changes. In the affected eye, there is decreased visual acuity and an atrophic iris. The pathogenesis of Alezzandrini syndrome is unknown, but it is believed to be closely related to VKH syndrome.

Associated disorders

Although most vitiligo patients are otherwise healthy, generalized vitiligo is associated with an increased risk of developing additional autoimmune diseases, especially in patients with a family history of vitiligo and autoimmunity. Indeed, many vitiligo susceptibility genes are shared with other autoimmune or atopic diseases (see Table 66.1), usually with the same high-risk alleles. Up to 20% of patients with vitiligo have at least one comorbid autoimmune disorder[29], most commonly autoimmune thyroid disease, which affects ~15% of adults and ~5%–15% of children with vitiligo[27,30–33]. Other autoimmune conditions reported to be associated with vitiligo include alopecia areata (~2%–4% of vitiligo patients), pernicious anemia, type 1 diabetes mellitus, myasthenia gravis, and several connective tissue diseases – lupus erythematosus (discoid and systemic), Sjögren syndrome, and rheumatoid arthritis[27,29,34]. Epidemiologic studies have also linked vitiligo with psoriasis, atopic diseases, inflammatory bowel disease, and metabolic syndrome[27,35]. Vitiligo can also occur in the setting of chronic graft-versus-host disease. Lastly, psychosocial conditions such as depression, anxiety, and adjustment disorders also occur in patients with vitiligo[36].

Patients with the autosomal recessive *a*utoimmune *p*oly*e*ndocrinopathy–*c*andidiasis–*e*ctodermal *d*ystrophy (APECED) syndrome often develop vitiligo. The gene responsible for APECED, *AIRE* (*a*uto*i*mmune *re*gulator), encodes a transcription factor that promotes expression of tissue-specific self-antigens in the thymus, which facilitates development of peripheral tolerance. In APECED, failure to delete autoreactive T cells leads to autoimmune disease. In a mouse model, AIRE deficiency was found to result in tyrosinase-related protein-1 (TYRP1)-specific T cells that enhanced immune responses against melanoma[37].

Childhood vitiligo

Although vitiligo vulgaris is the most common clinical type observed in children, the frequency of segmental vitiligo (~15%–30%) is significantly increased compared to that in adults (<5%–10%)[38]. The incidence of associated endocrinopathies is less than in the adult vitiligo population. A family history of vitiligo is associated with an earlier age of onset[39].

Pathology

In lesions of vitiligo, melanocytes are typically absent or present in very small numbers (Fig. 66.8). The epidermal melanocyte density can be assessed with melanocyte-specific immunohistochemical stains, such as Melan-A (MART-1), MITF, and HMB45, or via incubation of biopsy specimens with dihydroxyphenylalanine (DOPA; detects tyrosinase activity; see Fig. 65.6). Although ultrastructural studies may be performed for research purposes, very few hypomelanotic disorders have specific ultrastructural findings.

Differential Diagnosis

When there is complete depigmentation/amelanosis, the differential diagnosis may include chemical or drug-induced (e.g. imatinib) leukoderma, postinflammatory depigmentation, the leukodermas associated with melanoma and scleroderma, the late stages of treponematosis and onchocerciasis, and (for congenital lesions) piebaldism. A single circular depigmented lesion on the trunk of a young person may represent a stage III halo nevus (see below). Early lesions or those with a partial loss of pigment need to be distinguished from postinflammatory hypopigmentation, idiopathic guttate hypomelanosis, tinea versicolor, and other cutaneous infections (e.g. leprosy). In addition to a decrease, rather than an absence, of pigment, nevus depigmentosus can be distinguished by its stability and early onset, although lesions may not become apparent until mid-childhood in lightly pigmented individuals. Treatment with potent topical corticosteroids can also lead to hypomelanosis.

Treatment

The major goals of vitiligo treatment are stabilization of the depigmentation process, repigmentation, and maintenance of repigmentation[39a,39b]. Immunomodulatory therapies are utilized to limit disease progression, with repigmentation requiring repopulation of epidermal melanocytes from neighboring pigmented hair follicles, surrounding uninvolved epidermis, and/or lesional interfollicular melanocyte precursors.

The therapeutic regimen depends on the extent, location, and activity of disease as well as the patient's age, skin type, and motivation for treatment. In general, a period of at least 6 months is needed to determine whether a particular treatment is effective. The face, neck, mid extremities, and trunk tend to have the best response to therapy, while the distal extremities and lips are the most resistant to treatment.

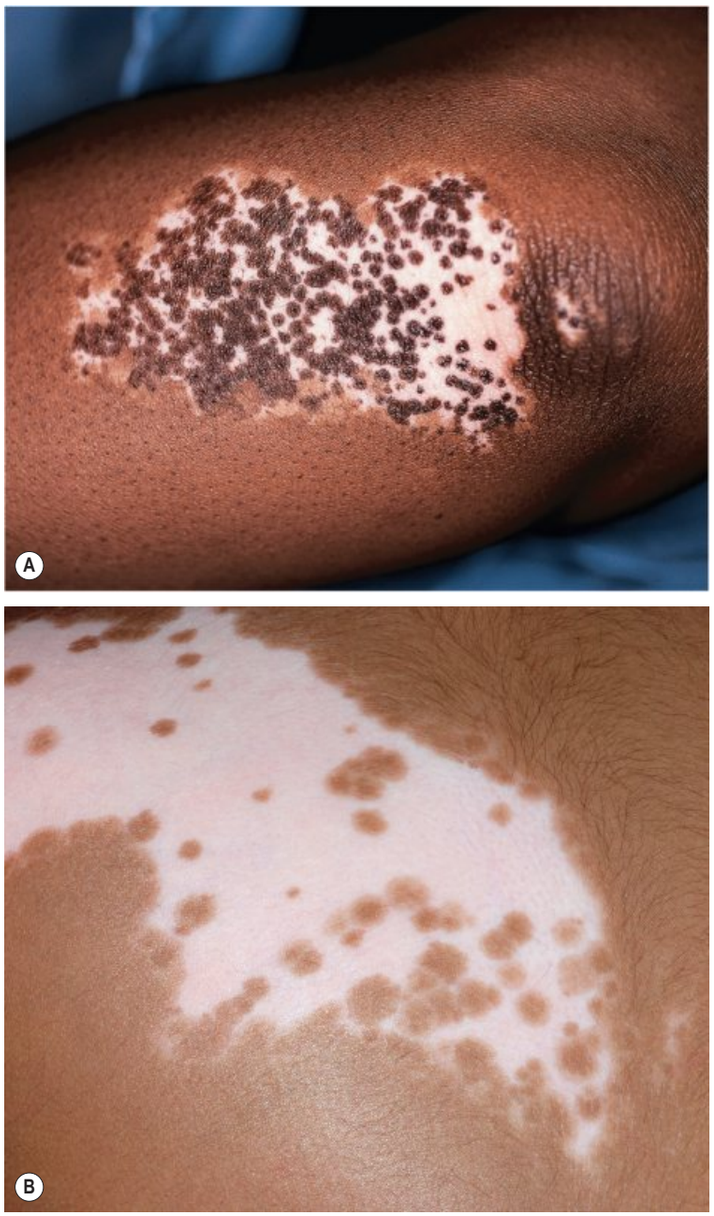

Fig. 66.9 Perifollicular repigmentation. Vitiligo on the elbow (**A**) and segmental vitiligo on the back (**B**) responding to PUVA and narrowband UVB therapy, respectively, with repigmentation in a prominent perifollicular pattern as well as from the periphery. The areas of repigmentation are darker in color than the uninvolved skin in (**A**) and have two shades (darker where well established and lighter at the expanding edge) in (**B**). *A, Courtesy Jean L. Bolognia, MD; B, Courtesy Julie V. Schaffer, MD.*

Repigmentation initially appears in a perifollicular pattern (unless the affected site is hairless or has depigmented hairs) and/or at the periphery of the lesions (Fig. 66.9). After therapeutic repigmentation, the rate of recurrent depigmentation of vitiligo lesions is ~40%[40].

Topical corticosteroids

Topical corticosteroids are useful for localized areas of vitiligo in adults and children, with the highest response rates in newer lesions and those on the face and neck. A meta-analysis showed that approximately half of patients with vitiligo affecting ≤20% of the body surface area (BSA) achieved >75% repigmentation with class 1 (superpotent) or 2–3 (high potency) topical corticosteroids; cutaneous atrophy was observed in 14% and 2% of these groups, respectively[41]. To minimize side effects, class 1 corticosteroids can be used in 6- to 8-week cycles or on a twice-weekly basis, alternating with topical tacrolimus, topical ruxolitinib, or a less potent topical corticosteroid. Treatment should be discontinued if there is no visible improvement after 4–6 months.

In general, intralesional corticosteroids are less commonly employed due to the pain associated with injection and the higher risk of cutaneous atrophy (≥30%).

Topical calcineurin inhibitors (TCIs)

For lesions on the face and neck, topical tacrolimus or pimecrolimus has similar efficacy as topical corticosteroids. A recent small randomized controlled trial (RCT) found that 65% of adults who applied tacrolimus 0.1% ointment twice daily for 24 weeks achieved ≥75% repigmentation of facial vitiligo, compared to 0% for a vehicle control[42]. However, TCIs are less effective than potent topical corticosteroids for vitiligo in extra-facial sites. In a recent systematic review (n=1499 vitiligo patients), TCI monotherapy for a median duration of 3 months produced ≥75% repigmentation in ~20% of patients overall, ~30% of children, and 35% of lesions on the face/neck versus only 2% of lesions on the trunk/extremities[43].

Combining a TCI with narrowband UVB or an excimer laser can provide a synergistic effect, resulting in repigmentation rates of ≥50%[43,44]. TCIs can also be used in conjunction with topical corticosteroids on a rotational basis (see above) or as maintenance therapy after repigmentation. In an RCT, bi-weekly application of tacrolimus 0.1% ointment to sites of previous vitiligo reduced the rate of recurrent depigmentation to 10%, compared to 40% with placebo[45].

Topical Janus kinase (JAK) inhibitors

Ruxolitinib 1.5% cream is a Janus kinase 1/2 (JAK1/2) inhibitor that was recently FDA-approved for treatment of non-segmental vitiligo involving ≤10% BSA in patients ≥12 years of age. In two phase III RCTs (total n=674 patients), ~30% of individuals treated with ruxolitinib 1.5% cream twice daily for 24 weeks achieved ≥75% improvement in the facial VASI, compared to 7%–11% for the vehicle control[46]. Acne at application sites was the most common adverse event, although the JAK inhibitor class-wide black box warning notes potential increased risks of serious infection, death, cancer, cardiovascular events, and thrombosis (see Chs. 128 & 129).

Photo(chemo)therapy

Narrowband UVB

Narrowband UVB (NB-UVB) has become first-line therapy for adults and children ≥6 years of age with generalized vitiligo[47], especially if it involves ≥15% BSA or cosmetically sensitive areas that typically respond to treatment (see Ch. 134). Several studies have demonstrated the effectiveness of NB-UVB monotherapy[48], which is superior to broadband UVB for the treatment of vitiligo.

The Vitiligo Working Group recommends initiating NB-UVB phototherapy at a dose of 200 mJ/cm^2 for all skin phototypes[49]. The dose is then increased by 10%–20% at each subsequent treatment until mild, asymptomatic lesional erythema is achieved, up to a maximum dose of 1500 mJ/cm^2 for the face and 3000 mJ/cm^2 for the body. Phototherapy is administered two to three times per week on non-consecutive days. If there is no evidence of repigmentation after 50 mildly erythrogenic exposures, then therapy should be discontinued. Short-term side effects include painful erythema, pruritus, and xerosis; to date, long-term side effects (e.g. cutaneous carcinogenesis) have not been reported. The advantages of NB-UVB over psoralen plus UVA (PUVA) therapy include shorter treatment times, no gastrointestinal side effects, reduced phototoxic reactions, less accentuation of the contrast between depigmented and normally pigmented skin, and no need for post-treatment photoprotection. In addition, NB-UVB can be used in children, pregnant or lactating women, and individuals with hepatic or kidney dysfunction. For reliable patients, home NB-UVB units represent a convenient option[50].

Psoralen plus UVA (PUVA)

PUVA consists of psoralens (usually 8-methoxypsoralen) combined with UVA light (see Ch. 134). Psoralens can be administered orally (oral PUVA) or applied topically (topical PUVA), followed by exposure to either artificial UVA light or natural sunlight (PUVASOL). Oral PUVA is no longer recommended for vitiligo therapy considering the greater efficacy, ease of administration, and lack of systemic side effects of NB-UVB[51]. Topical PUVA or PUVASOL can be useful for localized lesions[52], although there is a risk of phototoxicity with blistering or koebnerization.

A low concentration (≤0.1%) of psoralen should be used, which requires dilution of commercially available preparations, followed by an initial UVA dose of 0.25 J/cm^2 and subsequent increases in 10%–20% increments until mild erythema is achieved in the treated sites.

Excimer laser and lamp

The excimer laser and lamp deliver UVB light at a peak wavelength of 308 nm, which is similar to the 311 nm peak of NB-UVB. Compared with NB-UVB, excimer devices have equal to superior efficacy for vitiligo, typically requiring a shorter duration of treatment and avoiding darkening of unaffected skin[52]. However, excimer therapy is primarily indicated for segmental vitiligo and other forms involving <10% BSA.

Areas of vitiligo are treated two to three times weekly, typically for a total of 25 to 50 sessions; in general, the repigmentation rate depends on the total number of sessions, not their frequency[53]. Repigmentation may be enhanced by the concomitant use of treatments such as TCIs, topical corticosteroids, topical JAK inhibitors, or short-term oral corticosteroid mini-pulses (see next section).

Oral corticosteroid mini-pulse therapy

Mini-pulses of oral corticosteroids represent a treatment option for rapidly progressive vitiligo[54,55], although RCTs investigating their efficacy and safety are lacking. A typical regimen consists of oral dexamethasone 2.5–5 mg on two consecutive days each week for 3 to 6 months. This treatment has been reported to halt disease expansion in ~90% of patients[54,56], but it usually does not induce significant repigmentation. Side effects such as insomnia, agitation, weight gain, acne, and hypertrichosis frequently develop (see Ch. 125). As relapse of vitiligo often occurs after discontinuation of treatment, concomitant or maintenance therapy with other agents (e.g. NB-UVB) is recommended.

Other systemic immunomodulators

A few case reports and small studies have described improvement of vitiligo with systemic immunomodulators such as methotrexate and oral JAK inhibitors (e.g. tofacitinib, ruxolitinib, baricitinib; see Ch. 128)[55]. A recent phase II RCT in adults with active non-segmental vitiligo (n = 364 patients) found that ~20% of patients treated with the oral JAK3/TEC inhibitor ritlecitinib for 24 weeks (50 mg daily ± 100 or 200 mg loading dose daily for 4 weeks) achieved ≥75% improvement in the facial VASI, compared to ~2% for placebo[57]. Additional investigations are needed to determine the efficacy and safety of these systemic immunomodulators. Treatment strategies targeting interleukin-15 signaling are also under investigation.

Antioxidants

The rationale for this approach rests on the hypothesis that deficiencies in innate antioxidant processes play a role in vitiligo pathogenesis (Table 66.2). Oral α-lipoic acid, *Polypodium leucotomos*, *Ginkgo biloba*, and various vitamins (e.g. C, E) have been utilized as treatments for vitiligo, often in combination with phototherapy. Although individually none of these agents has strong evidence of efficacy, a recent meta-analysis concluded that oral antioxidants might have a benefit when administered in conjunction with phototherapy[58]. Small RCTs have found that administration of oral *Polypodium leucotomos* extract together with NB-UVB was associated with increased repigmentation in the head and neck region compared to NB-UVB alone[59]. In a recent small RCT, a statistically insignificant improvement in the vitiligo extent score (VES) was observed in patients treated with oral gliadin-protected superoxide dismutase plus NB-UVB compared to NB-UVB alone (20% vs 9%), suggesting potential benefit of this antioxidant[60].

Afamelanotide

Afamelanotide is an α-melanocyte stimulating hormone (α-MSH) analogue that stimulates melanogenesis and melanocyte proliferation by binding to the melanocortin-1 receptor (MC1R; see Ch. 65). An RCT found that the addition of afamelanotide (monthly subcutaneous implants) to NB-UVB therapy increased the speed and extent of repigmentation compared to NB-UVB alone in patients with generalized vitiligo, especially those with skin phototypes IV–VI[61]. However, afamelanotide-induced excessive tanning of non-lesional skin can increase the contrast with lesional skin, thereby reducing cosmetic acceptance in lightly pigmented patients[62]. Additional studies are needed to determine the indications and limitations of afamelanotide therapy for vitiligo.

Surgical therapies

For vitiligo patients who fail to respond to medical therapy, surgical treatment with autologous transplantation techniques may be an option[63,64]. The general selection criteria for autologous transplantation include stable disease for ≥6–12 months, absence of the Koebner phenomenon, no tendency for scar or keloid formation, and age >12 years. A minigraft test showing retention/spread of pigment at the recipient site and no koebnerization at the donor site after 2–3 months can also assist in patient selection.

Several methods of surgical repigmentation have been successfully utilized. *Minigrafting* is the simplest technique. Small punch grafts (1–2 mm) from uninvolved skin are implanted within achromic areas, separated from each other by 5–8 mm[65,66]. A cobblestone effect, a variegated appearance of the grafts, and sinking pits represent potential unfavorable outcomes. *Micropunch grafting* utilizes a motorized 0.8 mm punch instrument and can be used to reduce these complications[67]. Because scarring and dyspigmentation may occur at the donor sites, cosmetically insensitive areas are chosen. The advantages of *suction blister epidermal grafting* are the absence of scarring at the donor site and the possibility of reusing this area[68]. However, failure of the graft to take and koebnerization may occur. *Grafting of cultured autologous melanocytes* is an expensive technique that requires specialized laboratory expertise; grafts consist of pure melanocytes or melanocytes admixed with keratinocytes[69]. To avoid the need for *in vitro* culture, which involves mitogens to enhance cell growth, *grafting of non-cultured epidermal cell suspensions* that include melanocytes has been advocated[70]. *Grafting of individual hairs* to repigment vitiligo leukotrichia has also been successfully performed. Most of these techniques require clinical expertise.

Combination therapies

Combination therapy may produce higher rates of repigmentation compared to traditional monotherapies. Examples include phototherapy following surgical procedures as well as combining topical or systemic agents (e.g. TCIs, corticosteroids, JAK inhibitors, antioxidants) with NB-UVB or excimer laser therapy[71–76]. Of note, a recent meta-analysis did not demonstrate sufficient evidence to support the combination of excimer laser/lamp with topical vitamin D derivatives[75].

Maintenance therapies

As noted above, the relapse rate for repigmented vitiligo is ~40%[40]. There is evidence from one RCT that twice weekly application of tacrolimus 0.1% ointment can significantly reduce recurrent depigmentation in adults with successfully treated vitiligo[45]. Additional studies are needed to determine other agents and regimens that may have benefit as maintenance therapy for vitiligo.

Micropigmentation

The technique of permanent dermal micropigmentation utilizes a non-allergenic iron oxide pigment to camouflage recalcitrant areas of vitiligo. This tattooing method is especially useful for the lips, nipples, and distal fingers, which have a poor rate of repigmentation with currently available treatments. Although the color may not match perfectly with the normal surrounding skin and can fade over time, the result is immediate and can represent a dramatic aesthetic improvement.

Depigmentation

Depigmentation represents a treatment option for patients who have widespread, treatment-resistant vitiligo with limited areas of normally pigmented skin in exposed sites. The patients must be carefully chosen, i.e. adults who recognize that their appearance will be altered significantly and who understand that depigmentation requires lifelong strict photoprotection (e.g. sunscreens, clothing, umbrellas). The most commonly used agent is 20% monobenzyl ether of hydroquinone (MBEH), applied once to twice daily to the affected areas for 9–12 months or longer[77]. MBEH is a potent irritant and allergen, and an open application test can be performed before more widespread application. It typically takes 1–3 months to initiate a response, and a loss of pigment can occur at distant sites. Although depigmentation from MBEH is considered permanent, repigmentation (especially perifollicular in areas with pigmented hairs) can be seen following a sunburn or intense sun exposure. Monomethyl ether of hydroquinone (MMEH) in a 20% cream can be used as an alternative to MBEH. Side effects include contact dermatitis, exogenous

PATHOGENIC HYPOTHESES FOR VITILIGO		
Hypothesis	**Evidence for hypothesis**	**Evidence against hypothesis**
Autoimmune destruction of melanocytes	• Epidemiologic association with autoimmune disorders (see text) • Variants in immunoregulatory genes linked with vitiligo and associated autoimmune disorders (see Table 66.1) • Detection of antibodies against melanocyte proteins (e.g. TYR, TYRP1, DCT, MCHR1, SOX10) in the sera of patients with vitiligo • Destruction of melanocytes in normal human skin engrafted onto nude mice after injection with vitiligo patient sera • Infiltration of $CD8^+$ T cells into perilesional vitiligo skin • Skin-homing, melanocyte-specific cytotoxic T cells (e.g. against surface proteins such as Melan-A/MART-1) frequently detectable in the peripheral blood of vitiligo patients • Reports of generalized vitiligo following bone marrow transplantation from donors with vitiligo • T cell receptor transgenic mice that recognize an epitope of tyrosinase develop depigmented lesions with characteristics similar to human vitiligo	• Limited evidence for autoimmune pathogenesis of segmental vitiligo • Although there is strong evidence for an autoimmune etiology of generalized vitiligo, it is unclear whether a primary immune attack targets normal melanocytes or if immune activation is triggered by damage to melanocytes by an exogenous or endogenous factor

An intrinsic defect in melanocytes, their adhesive properties, and/or factors critical to their survival	• Abnormalities of cultured vitiligo melanocytes:
	  • Dilation of the rough endoplasmic reticulum
	  • Abnormal synthesis/processing of TYRP1
	• Increased sensitivity to oxidative stress (e.g. UVB)
	• Evidence for *transepidermal melanocytorrhagy* due to defective melanocyte adhesion:
	  • Detachment and transepidermal loss of melanocytes observed in *in vivo* studies of vitiligo skin
	  • Induction of detachment by mechanical stress, which could explain the Koebner phenomenon
	  • Decreased adhesion to collagen type IV and "stubby" dendrites in melanocytes cultured from perilesional skin of unstable vitiligo
	• Evidence for reduced melanocyte survival and dysregulation of melanocyte apoptosis in vitiligo:
	  • The progressive loss of hair follicle melanocytes observed in *bcl-2*$^{-/-}$ mice provides a model of apoptotic loss of melanocytes
	  • Variants in genes that regulate apoptosis associated with vitiligo (see Table 66.1)
	  • Deficiency of factors important for melanocyte maintenance (e.g. SCF, KIT, MITF) in vitiligo skin
	  • Vitiligo-like depigmentation and hair graying observed in patients treated with tyrosine kinase inhibitors that target KIT
		• Melanocytorrhagy is observed only in lesional and perilesional areas of vitiligo and appears to be a secondary process
		• No alteration in the expression of apoptosis regulatory molecules in vitiligo melanocytes compared with normal melanocytes

Defective defense against oxidative stress leading to destruction of melanocytes	• Detection of high *in vivo* levels of epidermal H_2O_2 in vitiligo skin, with potential sources including:
	  • Accumulation of oxidized pteridines, e.g. 6-biopterin (bluish fluorescence) and 7-biopterin (yellow/green fluorescence)
	  • Increased catecholamine biosynthesis in association with increased monoamine oxidase A activity
	  • Inhibition of thioredoxin/thioredoxin reductase by calcium in the setting of defective calcium transfer/homeostasis in vitiligo epidermis
	• Oxidative degradation of catalase resulting in low levels of this protective enzyme in vitiligo skin
		• Whether these abnormalities are the cause of vitiligo lesions, versus secondary consequences of immune attack or an intrinsic defect in melanocytes, has not been determined
		• No conclusive evidence of benefit from therapeutic approaches using pseudocatalase or systemic antioxidant agents in clinical studies

Table 66.2 Pathogenic hypotheses for vitiligo. A "convergence theory" that vitiligo results from a combination of several of these pathogenic mechanisms has also been proposed. Hypotheses with less support include destruction of melanocytes by neurochemical substances or a viral infection (e.g. cytomegalovirus). DCT, dopachrome tautomerase; MCHR1, melanin-concentrating hormone receptor 1; MITF, microphthalmia-associated transcription factor; SCF, stem cell factor; TYR, tyrosinase; TYRP1, tyrosinase-related protein 1; UVB, ultraviolet B.

ochronosis, and leukomelanoderma en confetti. Depigmentation via Q-switched ruby laser therapy was reported to achieve faster depigmentation than that achieved with a bleaching agent[78], and this laser has also been used in combination with topical 4-methoxyphenol to induce depigmentation[79]. Lastly, depigmentation with the Q-switched alexandrite laser has been described[80].

Psychological support

The impact of vitiligo on quality of life is severe in many affected individuals, and it is critical for physicians to recognize this aspect of the condition and address their patients' psychological needs. Although a "magic" treatment is not yet available, there is always something beneficial that can be done for vitiligo patients. They first need to know what their skin disorder is. Explaining the nature of the disease process and the potential and limits of available therapies is important and more productive than a fatalistic attitude that there is no cure and vitiligo is "only" a cosmetic disorder. Even helping patients to conceal the condition so that it is not visible can be part of the management plan. The use of support groups and, if indicated, psychological counseling are important supplementary therapies.

HEREDITARY HYPOMELANOSIS

Oculocutaneous Albinism

Oculocutaneous albinism (OCA) consists of a group of genetic disorders characterized by diffuse pigmentary dilution due to a partial or total absence of melanin pigment within melanocytes of the skin, hair follicles, and eyes[81]. The number of epidermal and follicular melanocytes is normal. Hypopigmentation involving primarily the retinal pigment epithelium is termed ocular albinism (OA).

Epidemiology

OCA is the most common inherited disorder that leads to diffuse hypomelanosis. In most populations, the estimated frequency is 1 : 20 000; however, it is as high as 1 : 1500 in some African tribes.

Pathogenesis

All well-characterized types of OCA have an autosomal recessive inheritance pattern, although a few rare families with autosomal dominant OCA have been described[82]. Based upon molecular studies, eight types of OCA have been defined (see Table 65.1). OCA type 1 (OCA1) results from reduced (OCA1B) or absent (OCA1A) tyrosinase activity; >400 distinct mutations in the tyrosinase gene (*TYR*) have been identified in patients with OCA1[83]. OCA2 is due to mutations in *OCA2* (previously *P*), which encodes the P (pink-eyed dilution) transmembrane protein present in melanosomes and the endoplasmic reticulum (ER)[84]. The P protein is thought to influence tyrosinase activity via regulation of melanosomal pH, and it may also regulate intra-organelle glutathione levels.

OCA3 results from mutations in *TYRP1* (tyrosinase-related protein 1)[85]. TYRP1 is a melanocyte-specific protein that stabilizes tyrosinase and is involved in eumelanin synthesis (see Fig. 65.11). In both OCA1 and OCA3, the abnormal protein (tyrosinase or TYRP1) never leaves the ER to become incorporated into melanosomes[86] (see Fig. 65.7). Of note, dysfunction of the P protein can also lead to abnormal processing and trafficking of tyrosinase. OCA4 is caused by mutations in *SLC45A2* which encodes solute carrier family 45 member 2 (formerly membrane-associated transporter protein [MATP]), a proton/glucose exporter that maintains the deacidification in later stage melanosomes that is required for tyrosinase activity[87,88].

OCA5 has been linked to chromosome 4q24, but the responsible gene has not yet been identified. OCA6 results from mutations in *SLC24A5*, which encodes a cation exchanger localized to the melanosomal membrane[89]. Of note, this gene was previously identified as one of the determinants of the physiologic variation in human pigmentation. Mutations in *LRMDA* (formerly *C10orf11*) underlie OCA7; the leucine rich melanocyte differentiation-associated protein is expressed in melanoblasts as well as melanocytes and is thought to have a role in melanocyte differentiation[90]. Lastly, OCA8 is due to mutations in *DCT* (*TYRP2*) which encodes DOPAchrome tautomerase, an enzyme that catalyzes tautomerization of DOPAchrome to 5,6-dihidroxyindole-2-carboxylic acid in the melanin biosynthetic pathway[91] (see Fig. 65.11).

OA type 1 is an X-linked recessive disorder caused by mutations in *GPR143* (G protein-coupled receptor 143; formerly *OA1*). This pigment cell-specific intracellular G protein-coupled receptor regulates melanosome formation and transport within melanocytes and cells of the retinal pigment epithelium[92]. Mutations in *GPR143* that lead to ocular albinism can result in retention of the aberrant protein within the ER. Autosomal recessive OA is no longer regarded as a distinct disorder, since many patients actually have OCA1B or OCA2 with subtle cutaneous findings.

Clinical features

Ocular manifestations

The many ocular manifestations of OA and OCA reflect a reduction in melanin within eye structures or misrouting of optic nerve fibers during development. The former leads to a translucent iris that transmits light upon globe transillumination, as well as a relatively hypopigmented retina and fovea that are associated with photophobia and reduced visual acuity; the severity of these findings correlates with the amount of reduction in melanin pigment. Misrouting of the optic fibers is thought to be responsible for the characteristic strabismus, nystagmus, and lack of binocular vision.

OCA1

There are two clinical subtypes of OCA1, based upon whether tyrosinase activity is reduced (OCA1B) or absent (OCA1A).

OCA1A

OCA1A corresponds to the classic "tyrosinase-negative" OCA. The melanocytes of the skin, hair, and eyes synthesize no melanin. The characteristic phenotype includes white hair, milky white skin, and blue–gray eyes at birth. With age, the skin color remains white and melanocytic nevi amelanotic, but the hair may develop a slight yellow tint due to denaturing of hair keratins. These patients have an extreme sensitivity to UV light and a strong predisposition to skin cancer. Reduced visual acuity is most severe in OCA1A, and some patients are legally blind.

OCA1B

Because the decrease in tyrosinase activity varies, the phenotype ranges from obvious to subtle pigmentary dilution when compared with first-degree relatives. One of the original OCA1B phenotypes was called "yellow albinism" because of the eventual color of the patient's hair, since the formation of yellow pheomelanin requires less tyrosinase activity. Other clinical types of OCA1B have been referred to as "minimal pigment OCA", "platinum OCA", and "temperature-sensitive OCA". All of these patients have little or no pigment at birth, but they develop some pigmentation of the hair and skin during the first and second decades of life. The majority burn without tanning after sun exposure, and some degree of iris translucency is often present. Amelanotic or pigmented melanocytic nevi can develop.

In the temperature-sensitive OCA1B phenotype, patients are born with white hair and skin and blue eyes. During puberty, scalp and axillary hairs remain white, but arm hairs turn light reddish brown and leg hairs turn dark brown. The abnormal tyrosinase enzyme is temperature-sensitive, losing its activity above 35°C. As a result, melanin synthesis does not occur in warmer areas of the body, akin to the phenotype of a Siamese cat, which also has temperature-sensitive tyrosinase activity.

OCA2

The OCA2 phenotype (in addition to OCA1B) corresponds to the classic "tyrosinase-positive" OCA. The clinical spectrum of OCA2 is broad, ranging from minimal to moderate pigmentary dilution of the hair, skin, and iris, with little to no ability to tan. The vast majority of Black individuals with "tyrosinase-positive" OCA have OCA2. With time, pigmented melanocytic nevi and lentigines may develop in sun-exposed areas (Fig. 66.10); the latter can become rather large and darkly colored (Fig. 66.11). Another phenotype previously referred to as "brown OCA" in Black populations results primarily from mutations in the *P* gene. In these individuals, the hair and skin are light brown, the irides are gray to tan at birth, and sunburns are unusual.

The hypopigmentation seen in a subset of patients with Prader–Willi syndrome (PWS) and Angelman syndrome (AS) represents a form of OCA2. PWS features hyperphagia, obesity, hypogonadism, and intellectual disability, whereas AS is characterized by severe intellectual disability, microcephaly, ataxic movements, and inappropriate laughter. Due to genomic imprinting (see Ch. 54), deletions of the 15q region (which includes *OCA2*) in the paternal chromosome lead to PWS, while deletions in the maternal chromosome give rise to AS. Approximately 1% of patients with AS or PWS also have OCA2, which occurs when the deletion of one *OCA2* allele is accompanied by a mutation in the second allele.

OCA3

OCA3 is most common in Black individuals, and phenotypes previously referred to as "rufous" (vast majority of OCA3 patients) and "brown" (more often seen in OCA2; see above) have been described. The "rufous" phenotype includes a red–bronze skin color, ginger-red hair, and blue or brown irides.

Fig. 66.10 Oculocutaneous albinism type 2 (OCA2). African patient with obvious squamous cell carcinomas on the cheek as well as multiple pigmented lentigines. *Courtesy James Nordlund, MD.*

OCA4

OCA4 is most common among individuals with albinism who are from Japan (~25% of patients), China (10%–20% of patients), or India (~10% of patients), and it accounts for ~5% of albinism in White individuals[93]. The phenotype of OCA4 is variable; hair color ranges from white to yellow or brown, and patients may or may not develop increased pigmentation of the skin and hair over time.

OCA5–8

OCA5 was described in a consanguineous Pakistani family, in which affected individuals had white skin and golden hair. OCA6 has been reported in patients from Asia, Africa, and Europe. Affected individuals have white to light brown skin with a variable ability to tan, yellow to brown hair that often darkens with age, and blue to light brown irides[89]. OCA7 has been described primarily in patients from the Faroe Islands of Denmark; affected individuals have lighter skin than their relatives and hair color ranging from light yellow to brown[90]. OCA8 presents with mild pigmentary dilution of the skin and hair, often together with more pronounced ocular findings including nystagmus, reduced visual acuity, and foveal hypoplasia[91].

Fig. 66.11 Oculocutaneous albinism type 2 (OCA2). African patient with hypopigmented hair and large pigmented lentigines. *Courtesy James Nordlund, MD.*

Ocular albinism type 1 (OA1)

Ocular albinism type 1 is characterized by a substantial reduction in visual acuity, hypopigmentation of the retina, and the presence of macromelanosomes in the eyes. Affected boys have nystagmus, photophobia, and foveal hypoplasia[92]. Their skin is usually clinically normal without notable pigmentary dilution, although hypopigmented macules have been described in affected individuals who have darkly pigmented skin. Macromelanosomes are evident on histologic examination of the skin. Female carriers of OA1 may have a "mud-splattered" fundus due to interspersed regions of pigmentation.

Pathology

Although there is a reduction in melanin content, a normal number of melanocytes are present within the epidermis.

Differential diagnosis

This is outlined in Fig. 66.12. Occasionally, patients with total body vitiligo may be thought to have OCA, but their epidermis lacks melanocytes.

Treatment

No specific treatment is available. Photoprotection (sunscreens, hats, clothing, sun avoidance) is mandatory in patients who have minimal or no pigmentation, in order to avoid cutaneous photocarcinogenesis, in particular the development of squamous cell carcinomas. The latter are a significant cause of morbidity and mortality, especially in tropical regions (see Fig. 66.10). All patients should undergo ophthalmologic evaluation early in life, with longitudinal care as required.

Nitisinone, which is FDA approved for treating hereditary tyrosinemia type 1, represents a potential therapy for OCA. In a mouse model of OCA1B, nitisinone elevated plasma tyrosine levels and led to increased pigmentation of the hair and eyes[94]. A pilot study in 5 adults with OCA1B found that visual acuity as well as skin and hair pigmentation increased after 1 year of treatment with oral nitisinone (2 mg/day)[95].

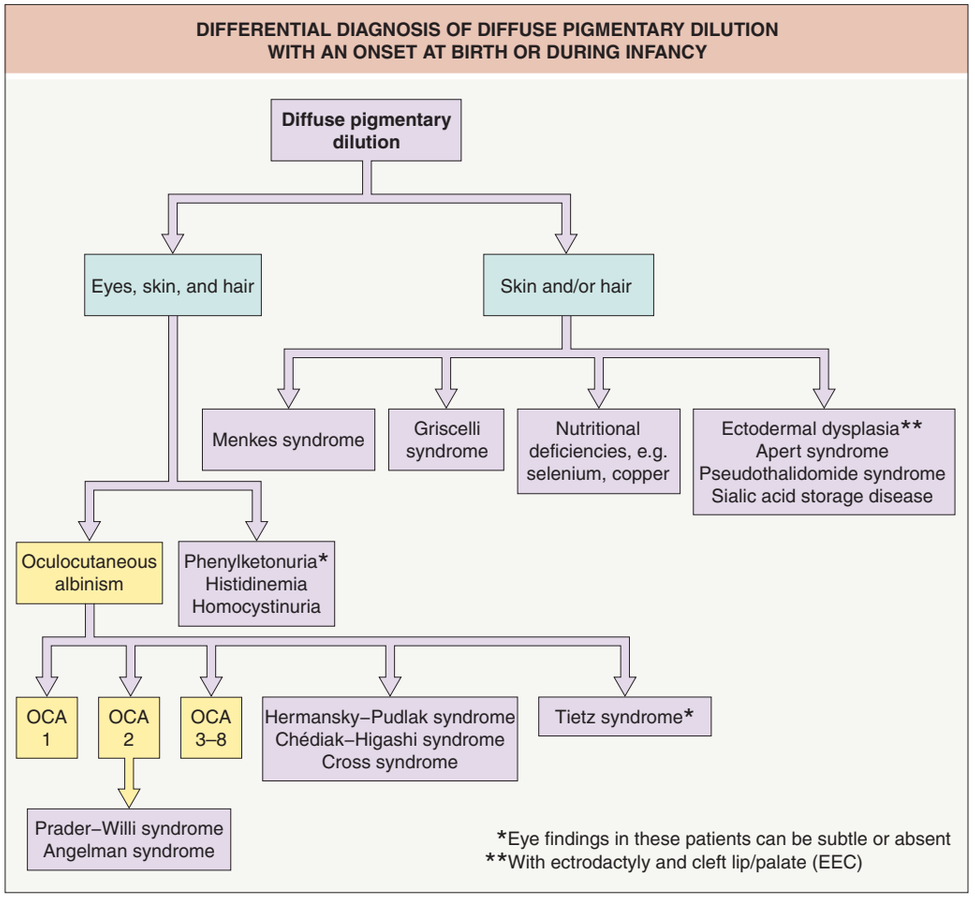

Fig. 66.12 Differential diagnosis of diffuse pigmentary dilution with onset at birth or during infancy. Patients with Griscelli syndrome and Chédiak–Higashi syndrome (CHS) have silvery hair and those with CHS can have an admixture of hyper- and hypopigmentation in chronically sun-exposed skin. Additional rare causes of diffuse pigmentary dilution include deficiency of the endosomal adaptor p14, tricho-hepato-enteric syndrome, and biallelic *KIT* mutations. *Adapted from Bolognia JL. A clinical approach to leukoderma. Int J Dermatol 1999;38:568–72.*

Piebaldism

Piebaldism is an uncommon autosomal dominant disorder characterized by poliosis and congenital, stable, circumscribed areas of leukoderma due to an absence of melanocytes within involved sites.

Epidemiology

The exact prevalence of this condition is not known, but it is estimated to occur in approximately 1 in 40 000 White individuals.

Pathogenesis

Piebaldism results from mutations in the *KIT* proto-oncogene[96], which encodes a member of the tyrosine kinase family of transmembrane receptors that is found on the surface of melanocytes (see Fig. 65.2). A functioning KIT receptor is required for the normal development of melanocytes, both immediately before melanoblast migration from the neural crest and postnatally. Although heterozygous deletion of *SNAI2* was previously identified in a few patients, this gene is no longer thought to be associated with piebaldism[97].

Clinical features

The leukoderma has a characteristic distribution pattern that favors the central anterior trunk, mid extremities, central forehead, and midfrontal portion of the scalp; the latter results in a white forelock (Fig. 66.13). The lesions are present at birth and classically spare the posterior midline. The white forelock, which is found in 80%–90% of patients, is the most familiar feature of piebaldism. However, its absence does not exclude the diagnosis. All the hairs of the forelock are white, and the underlying skin is also amelanotic. This depigmented patch is midline in location, triangular or diamond-shaped, and often symmetrical. The apex can reach the vertex posteriorly, and the affected area may extend to the root of the nose and include the medial third of the eyebrows; involvement of the nose is rare.

The areas of leukoderma are distinctive and can establish the diagnosis of piebaldism, even in the absence of a white forelock. They are irregular in shape, well-circumscribed, and milk-white in color. Normally pigmented and hyperpigmented macules and patches, ranging from a few millimeters to several centimeters in diameter, are typically apparent within the leukodermic patches (Fig. 66.14). Hyperpigmented patches also occur within uninvolved skin and should not be misinterpreted as evidence of neurofibromatosis type 1; axillary freckling has also been observed in patients with piebaldism. Poliosis of the eyebrows and eyelashes is a common finding, as are white hairs within areas of leukoderma. Limited contraction of the areas of involvement over time is occasionally observed, and premature graying of the hair is not uncommon.

Pathology

By light and electron microscopy, no melanocytes can be identified in either the interfollicular epidermis or the hair follicles of amelanotic skin[98]. The hyperpigmented macules are characterized by an abundance of melanosomes in the melanocytes and keratinocytes.

Differential diagnosis

The presence of stable amelanotic patches since birth, the characteristic distribution pattern, and the distinctive normally pigmented or hyperpigmented macules within the areas of leukoderma allow the differentiation of piebaldism from vitiligo. The differential diagnosis of circumscribed poliosis of scalp hairs is broad and includes both inherited and acquired causes (Table 66.3)[99]. Of note, an isolated white forelock can also be inherited as an autosomal dominant trait. The diagnosis of piebaldism should prompt the clinician to exclude the possibility of Waardenburg syndrome via an ocular examination and evaluation of hearing. *Albinism–deafness syndrome* (Ziprkowski–Margolis or Woolf syndrome), a rare X-linked disorder linked to Xq26.3–q27.1, presents with congenital sensorineural deafness and a severe piebald-like phenotype with extensive areas of hypopigmentation[100].

Treatment

Autografting of normal skin or melanocytes into amelanotic areas represents a therapeutic option, but this typically requires multiple procedures. Cosmetic products can be used to camouflage affected areas; protection against sunburn is also necessary.

Waardenburg Syndrome

Waardenburg syndrome (WS) is a rare autosomal dominant or less often autosomal recessive disorder that is characterized by various combinations of the following features[101]:

- achromia of the hair, skin, or both in the same pattern as piebaldism (see above)
- congenital deafness
- partial or total heterochromia irides (including isohypochromia)
- medial eyebrow hyperplasia (synophrys)
- a broad nasal root
- dystopia canthorum (increased distance between the inner canthi, with a normal interpupillary distance).

Four clinical subtypes of WS have been described (Table 66.4): WS type I, the classic form (WS1); WS type II, which lacks dystopia canthorum (WS2); WS type III, with associated limb abnormalities (WS3, Klein–Waardenburg syndrome); and WS type IV, with Hirschsprung disease (WS4, Shah–Waardenburg syndrome).

Epidemiology

The incidence of WS in the Netherlands has been estimated as ~1 in 200 000. In the US, deafness in the setting of WS afflicts 1 in 50 000. WS has been observed in various races and from all regions of the world. Men and women are equally affected.

Fig. 66.13 Piebaldism. White forelock and characteristic triangular amelanotic patch on the mid-forehead. *Courtesy Julie V. Schaffer, MD.*

Fig. 66.14 Piebaldism. Characteristic involvement of the mid extremities. Note the normally pigmented and hyperpigmented macules within the leukoderma. *Courtesy Julie V. Schaffer, MD.*

Pathogenesis

The facial dysmorphism seen in WS points to abnormal fetal development. It is therefore not surprising that several of the genes responsible for WS (*PAX3, MITF, SOX10*; see Table 66.4) encode transcription factors that, by binding DNA and regulating the expression of other genes, have important functions during embryogenesis (see Fig. 65.4). The neural crest is the source of the connective tissues of the head and neck and intestinal ganglion cells as well as melanoblasts, explaining the manifestations of this neurocristopathy. Presumably, the deafness in WS reflects the role of melanocytes in the development of the inner ear.

The PAX3 transcription factor that is mutated in WS1 and WS3 activates melanoblasts and other cells to proliferate and then migrate from the neural crest. The abnormalities of the upper extremities that characterize WS3 imply that PAX3 also regulates limb development[102]. Mutations in the *mi*crophthalmia-associated *t*ranscription *f*actor gene (*MITF*; expression of which is regulated by PAX3 and SOX10; see Fig. 65.4), which encodes a helix-loop-helix/leucine zipper transcription factor, can result in WS2. Of note, a mutation in *MITF* that affects the nuclear localization of this protein underlies Tietz syndrome (see below)[103]. In addition to its critical role in melanocyte development, MITF regulates the expression of a number of melanocyte-specific genes (e.g. tyrosinase; see Ch. 65). KIT signaling also interacts with MITF in melanocyte development (see Fig. 65.4), and biallelic mutations in *KITLG* (encodes KIT ligand) have been found to result in WS2 as well as other pigmentary phenotypes, including diffuse pigmentary dilution (skin and hair) and familial progressive hyperpigmentation ± hypopigmentation (see below)[104]. Homozygous deletion of *SNAI2* (the expression of which is regulated by MITF) is no longer thought to represent a cause of WS2[97].

The SOX10 transcription factor plays an essential role in the development of melanoblasts and ganglion cells, and mutations in this gene can cause WS4 or (if milder) WS2[105]. WS4 can also be caused by mutations in the genes encoding the endothelin B receptor and its endothelin-3 ligand[106]. The endothelin B receptor is found on melanoblast-ganglion cell precursors in the developing neural crest, and its binding to endothelin-3 is essential for the generation of these cell types (see Fig. 65.3).

DIFFERENTIAL DIAGNOSIS OF CIRCUMSCRIBED SCALP POLIOSIS
Inflammatory, autoimmune, or traumatic
• Vitiligo • Halo nevus • Alopecia areata (primarily initial cycle of growth) • Postinflammatory (e.g. discoid lupus, blepharitis [eyelashes]) • Postinfectious (e.g. zoster) • Post-traumatic • Vogt–Koyanagi–Harada syndrome • Alezzandrini syndrome • Melanoma-associated leukoderma (spontaneous or following immunotherapy)
Inherited
• Tuberous sclerosis* • Piebaldism (midline frontal) • Waardenburg syndrome (primarily midline frontal) • Isolated white forelock† • Isolated occipital white lock (X-linked recessive) • White forelock with osteopathia striata (autosomal or X-linked dominant) • White forelock with multiple malformations (autosomal or X-linked recessive) • Neurofibromatosis type 1 – overlying a neurofibroma • Prolidase deficiency and Marfan syndrome (single case reports)
Nevoid
• Angora hair nevus • Associated with nevus comedonicus • Scalp heterochromia secondary to mosaicism*
Pharmacologic agents
• Imiquimod • Latanoprost (eyelash poliosis) • Tyrosine kinase inhibitors (e.g. eyelash poliosis with cetuximab)
Idiopathic
*May be lighter than surrounding hair rather than white (e.g. blond streaks in a patient with brown hair). †Separate entity vs possible forme fruste of piebaldism.

Table 66.3 Differential diagnosis of circumscribed scalp poliosis. *Adapted from Bolognia JL, Shapiro PE. Albinism and other disorders of hypopigmentation. In: Arndt KA, et al (eds). Cutaneous Medicine and Surgery. Philadelphia: WB Saunders, 1995.*

Clinical features

Waardenburg syndrome type 1 (WS1)

A white forelock, generally similar to that of piebaldism, is the most frequently observed pigmentary abnormality in WS (20%–60% of patients). Although the forelock is usually white, patches of red, brown, or black hair have also been described. A few patients have additional areas of poliosis in the frontoparietal or occipital scalp. Premature graying can involve the scalp hair, eyebrows, and body hair, and the onset may be as early as the teens. Areas of leukoderma with an appearance, distribution pattern, and natural history similar to piebaldism have been observed in ~15% of patients. The prevalence of

DISORDERS OF MELANOCYTE DEVELOPMENT					
Human disease		**Mouse model**	**Inheritance**	**Gene**	**Protein**

*Diffuse pigmentary dilution of the skin, hair, and eyes as well as deafness and developmental delay have been described in patients with biallelic *KIT* mutations.
†Other forms of WS2 have been linked to 1p21–p13.3 (WS2B) and 8p23 (WS2C).
‡Homozygous *PAX3* mutations have been described in individuals with WS3 whose parents were affected with WS1.

Table 66.4 Disorders of melanocyte development. AD, autosomal dominant; AR, autosomal recessive.

hearing impairment ranges from 10% to >35%[107]; it may be bilateral or unilateral and severe or moderate.

Heterochromia irides, partial (sectorial) or complete, is found in >20% of patients (Fig. 66.15). Complete heterochromia irides gives rise to irides of different colors, one being whitish blue. Bilateral involvement results in bilateral pale blue eyes (isohypochromia). Hypomelanotic fundi may be present.

The eyebrows may be confluent (synophrys) or show hyperplasia of their medial portions (15%–70% of patients). The characteristic dystopia canthorum represents an increase in the distance between the inner canthi, with normal distances between the pupils and between the outer canthi. This is accompanied by a shortening in the length of the palpebral fissure (blepharophimosis) and a lateral displacement of the inferior lacrimal points, which are then situated in front of the cornea. The dystopia is usually symmetric but may be asymmetric. Dystopia canthorum is a characteristic feature of WS1 and WS3.

Waardenburg syndrome type 2 (WS2)

WS2 differs from WS1 primarily by the absence of dystopia canthorum. In addition, deafness is probably more common in patients with WS2.

Klein–Waardenburg syndrome (WS3)

WS3 is similar to WS1 but is also associated with upper limb abnormalities (e.g. hypoplasia, syndactyly).

Shah–Waardenburg syndrome (WS4)

In WS4, the characteristic findings of WS occur in association with Hirschsprung disease. In many patients, a white forelock, amelanotic macules, and heterochromia irides are present. Deafness is fairly common, but dystopia canthorum and a broad nasal root are uncommon. Additional rare manifestations (associated with *SOX10* mutations) include central nervous system dysfunction, neonatal hypotonia, and arthrogryposis.

Tietz syndrome

Tietz syndrome is a rare autosomal dominant disorder characterized by diffuse pigmentary dilution of the skin and hair together with deafness and hypoplasia of the eyebrows. Although the eyes are blue, affected individuals do not have photophobia or nystagmus and the fundi are normal. The clinical phenotype is significantly different from WS2, despite being allelic.

Pathology

As in piebaldism, the areas of involvement in WS have an absence or minimal number of melanocytes when examined by light or electron microscopy.

Diagnosis

In patients with the complete WS phenotype, the diagnosis is clear. However, there is significant clinical heterogeneity, and in some forme fruste cases the diagnosis can be difficult to establish. Examination of family members can be helpful as they may have other features of the disease.

Fig. 66.15 Waardenburg syndrome type 2. Heterochromia irides in the absence of dystopia canthorum. The white forelock is seen in the upper left corner.
Courtesy Daniel Albert, MD.

Treatment

No specific treatment is available. However, early diagnosis permits appropriate management of the deafness.

Disorders of Melanosome Biogenesis

Melanosomes are considered members of the lysosome-related organelle family, which includes platelet dense granules and the lytic granules of cytotoxic lymphocytes and natural killer (NK) cells. When the biogenesis of these organelles is disrupted, affected individuals present with the clinical findings of OCA due to their defective melanosomes together with additional symptoms (e.g. bleeding diathesis, immunodeficiency) that reflect abnormalities in other lysosome-related orgenelles[108,109]. These genetic diseases include Hermansky–Pudlak syndrome (HPS) and Chédiak–Higashi syndrome (CHS).

Hermansky–Pudlak syndrome

To date, eleven subtypes of HPS have been identified, each of which is inherited in an autosomal recessive manner (see Table 65.1)[110].

Pathogenesis

Most forms of HPS result from mutations in genes that encode components of the *b*iogenesis of *l*ysosome-related *o*rganelles *c*omplexes 1–3 (BLOC1/2/3; see Table 65.1 & Fig. 65.8). These complexes are involved in the formation of lysosome-related organelles, including melanosomes, by a mechanism distinct from that of the adaptor protein 3 (AP-3) complex. The exceptions are HPS2 and HPS10, which are caused by mutations in *AP3B1* and *AP3D1*, respectively[111]. These genes encode the β1 and δ1 subunits of the AP-3 complex, which is involved in protein sorting to lysosomes and lysosome-related organelles (see Fig. 65.8). AP-3 also functions in CD1b-associated antigen presentation and secretion of lytic granules from cytotoxic T cells, explaining the additional clinical feature of immunodeficiency in patients with HPS2 and 10. In addition, a neuron-specific AP-3 heterotetramer requires δ1 but not β1; as a result, HPS10 but not HPS2 has neurologic manifestations.

Clinical features

Compared to unaffected first-degree relatives, patients with HPS have pigmentary dilution of the skin, hair, and eyes. The degree varies, depending upon the underlying mutations and the patient's constitutive pigmentation. With age, an increase in pigmentation is usually seen, but patients still have difficulty tanning. Ocular manifestations of albinism, such as nystagmus and reduced visual acuity, are also present.

Systemic manifestations due to organelle dysfunction include a bleeding tendency (e.g. with tooth extraction or childbirth) as well as interstitial pulmonary fibrosis and granulomatous colitis secondary to ceroid lipofuscin accumulation within lysosomes. Granulomatous plaques and "knife-cut" ulcers of the vulva, intertriginous areas, and peristomal skin similar to cutaneous Crohn disease have also been described[112]. Less often, renal failure and cardiomyopathy develop, usually during adulthood. Patients with HPS2 and 10 experience recurrent bacterial infections due to neutropenia and abnormal cytotoxic T cell function, and HPS10 presents with neurodevelopmental delay and seizures.

Laboratory findings and pathology

By electron microscopy, macromelanosomes as well as stage I to III (rarely stage IV) melanosomes are seen. Although the platelet count is normal, the bleeding time and platelet function analyzer (PFA)-100 time are prolonged due to platelet dysfunction. Ultrastructurally, there is an absence of dense bodies within platelets. Ceroid deposits, derived from the degradation of lipids and glycoproteins, are found within lysosomes in affected internal organs, including the lungs and gastrointestinal tract. Presumably, this reflects a defect in lysosomal function.

Differential diagnosis

In addition to the entities in Fig. 66.12, diagnostic considerations may include the autosomal recessive *deficiency of the endosomal*

adaptor p14, which features diffuse pigmentary dilution of the skin and hair, neutropenia, and recurrent pulmonary infections.

Treatment

The development of progressive pulmonary fibrosis often leads to premature death in patients with HPS, who have an average lifespan of only 30–50 years. Although the antifibrotic agent pirfenidone appeared to slow the progression of pulmonary fibrosis in HPS1 patients in an initial controlled study, a controlled trial found no benefit of this agent in HPS1 patients with mild to moderate pulmonary disease[113]. Platelet transfusions can be administered prior to surgical procedures in HPS patients.

Cross syndrome

Cross syndrome is characterized by diffuse pigmentary dilution, silvery hair, ocular anomalies, and neurologic abnormalities (e.g. psychomotor retardation, ataxia, and spasticity). A family with overlapping features of HPS and Cross syndrome has raised the possibility that this latter syndrome may be a clinical variant of HPS[114].

Chédiak–Higashi syndrome

Chédiak–Higashi syndrome (CHS) is a rare autosomal recessive disorder characterized by OCA with a silvery-gray cast to the hair, photophobia, nystagmus, and ocular hypopigmentation; an admixture of hyper- and hypopigmentation may be evident in chronically sun-exposed skin, especially in patients with relatively dark constitutive pigmentation. Additional findings include a bleeding diathesis due to diminished function of platelet dense granules, progressive neurologic dysfunction, and severe immunodeficiency due to abnormal lytic granules in lymphocytes, NK cells, and neutrophils (see Ch. 60). A hallmark of the disorder is the presence of giant lysosome-related organelles, including melanosomes, platelet dense granules, and neutrophil granules. Examination of a peripheral blood smear for the latter represents a simple method of screening for this condition. CHS is caused by mutations in the *lys*osomal *t*rafficking regulator gene (*LYST*), which encodes a cytoplasmic protein that regulates fission/fusion of lysosome-related organelles[115].

Tricho-hepato-enteric syndrome (phenotypic diarrhea of infancy)

This autosomal recessive disorder caused by mutations in the SKI3 subunit of superkiller complex gene (*SKIC3*) can present with diffuse pigmentary dilution of the skin and hair, platelet defects (including abnormal granules) and immunodeficiency. Unlike CHS, it is also characterized by brittle hair with trichorrhexis nodosa, intractable diarrhea during infancy, primary liver disease, facial dysmorphism, and cardiac defects.

Disorders of Melanosome Transport and/or Transfer

Identification of the defective proteins in various forms of Griscelli syndrome (GS) has led to better understanding of processes of melanosome transport.

Epidemiology

Griscelli syndrome is a rare autosomal recessive disorder.

Pathogenesis

On the basis of molecular genetics (as well as clinical findings), GS has been separated into three entities, GS1, GS2, and GS3 (see Table 65.1). GS1 is due to mutations in the gene that encodes myosin Va[116]. One end of the myosin Va protein binds the actin cytoskeleton, while the other can bind an organelle, e.g. a melanosome. This linkage plays a key role in the transfer of melanosomes from melanocytes to keratinocytes. GS2 is caused by mutations in *RAB27A*[117], which encodes a small Ras-like GTPase (belonging to the Rab family) that is present in melanosomes. GS3 is due to mutations in *MLPH*, whose protein product, melanophilin, serves to link myosin Va to Rab27a[118] (see Fig. 65.10). Because *MLPH* is expressed only in melanocytes, the associated phenotype is limited to diffuse pigmentary dilution and silvery hair. On the other hand, expression of *MYO5A* in neurons explains the associated neurologic abnormalities in GS1, and expression of *RAB27A* in hematopoietic cells accounts for the immunodeficiency and hemophagocytic syndrome observed in GS2. *Elejalde syndrome* is now thought to likely represent a variant of GS1.

Clinical features

All three types of GS are characterized by pigmentary dilution of the skin and silvery-gray hair due to pigment clumping within melanocytes. As noted above, patients with GS1 exhibit primarily neurologic impairment[116], while those with GS2 have immune abnormalities due to defective release of cytotoxic lysosomal contents from hematopoietic cells. A hemophagocytic syndrome can also occur in GS2, with uncontrolled T lymphocyte and macrophage activation leading to death[117]; this process can involve the CNS in a secondary manner.

Treatment

Hematopoietic stem cell transplantation is indicated for the treatment for GS2, but not GS1 or GS3.

Tuberous Sclerosis Complex

Tuberous sclerosis complex (TSC) represents an autosomal dominant disorder characterized by hamartomas in multiple organs, most commonly the skin, brain, eye, heart, and kidney (see Ch. 61).

Clinical features

The classic TSC triad of facial angiofibromas ("adenoma sebaceum"), seizures, and intellectual disability is preceded by the appearance of white macules. In one study utilizing Wood's lamp examination, hypomelanotic macules were found in 64 of 65 patients with TSC.

Hypomelanotic macules are often evident at birth or during the neonatal period. In fact, all lesions are probably present at birth, but they may be inapparent, particularly in infants with lightly pigmented skin, until the skin is exposed to UV light or the patient is examined with a Wood's lamp. The number of lesions varies from one to >100 per patient. The vast majority of patients have 2–20 hypomelanotic macules, with 50% having <6 and 50% having ≥6 macules. Lesions may be polygonal, lance-ovate, "thumbprint-like", guttate ("confetti-like"), or (rarely) segmental (see Fig. 61.14). The most characteristic, but not the most frequent, configuration is lance-ovate (rounded at one end, pointed at the other), which resembles the leaflet of the mountain ash tree, hence the name "ash leaf spot".

Hypomelanotic macules are usually found on the trunk, particularly posteriorly, but they can be found on any cutaneous surface. They occur more commonly on the lower extremities than on the upper extremities or the head and neck; lesions on the scalp are often associated with more lightly pigmented hairs. The long axis of the lance-ovate (ash leaf) macules is predominantly in the cephalocaudal direction on the extremities and in the transverse direction on the trunk. The margins of the lesions are usually smooth but may be irregular. The macules and patches are a dull white color (hypomelanotic), not the "pure-white" color (amelanotic) of vitiligo. As a result, they may be inapparent on casual examination of lightly pigmented skin. Wood's lamp examination reveals a reduction, but not an absence, of pigmentation. The relative size and number of hypomelanotic macules do not change with age, and spontaneous disappearance does not occur. Café-au-lait macules are seen in some patients.

Pathogenesis

Circumscribed hypomelanosis in TSC does not appear to result from a reduction in the number of melanocytes but rather from decreased size and poor melanization of melanosomes, which (regardless of racial background) are grouped within the lysosomes of keratinocytes (see Table 65.3). Decreased melanosome size is not a feature of other circumscribed congenital hypomelanoses. TSC is caused by mutations in two tumor suppressor genes, *TSC1* and *TSC2*, which encode the hamartin and tuberin proteins, respectively. These proteins associate physically *in vivo*, functioning together to negatively regulate mechanistic target of rapamycin (mTOR) signaling.

Diagnosis

If an infant has three or more hypopigmented macules, especially if lance-ovate in shape, a diagnosis of TSC should be considered and (if there is no history of seizures) echocardiography performed as an initial

DIFFERENTIAL DIAGNOSIS OF GUTTATE LEUKODERMA
Idiopathic guttate hypomelanosis
Pityriasis lichenoides chronica
Lichen sclerosus
Achromic verrucae planae*
Leukoderma punctata (after PUVA therapy)
Vitiligo ponctué
Darier disease (usually admixed with keratotic lesions)
Confetti-like lesions of tuberous sclerosis
Xeroderma pigmentosum
In association with punctate palmoplantar keratoderma (Cole disease)
In association with chromosomal abnormalities
Disseminated hypopigmented keratoses (after PUVA therapy)*
Frictional lichenoid dermatitis*
Pityriasis alba
Tinea versicolor (especially on the face of children)
Clear cell papulosis*
*Minimally elevated flat-topped papules.

Table 66.5 Differential diagnosis of guttate leukoderma. Guttate hypopigmentation may also be seen in the setting of dyschromatoses (see Table 67.11). *Adapted from Bolognia JL, Shapiro PE. Albinism and other disorders of hypopigmentation. In: Arndt KA, et al (eds). Cutaneous Medicine and Surgery. Philadelphia: WB Saunders, 1995.*

Fig. 66.16 Linear nevoid hypopigmentation. Hypopigmented streaks with various widths along the lines of Blaschko on the posterior lower extremities. *Courtesy Antonio Torrelo, MD.*

Fig. 66.17 Nevus depigmentosus. Hypomelanotic patch with a decrease, but not absence, of pigmentation.

investigation (see Fig. 61.21). The combination of white macules and seizures increases the likelihood of TSC. Although the presence of only one or two hypopigmented macules or patches in an otherwise healthy infant does not exclude TSC, the diagnosis of nevus depigmentosus is much more likely.

It is usually fairly easy to distinguish vitiligo, given its characteristic distribution pattern and pure-white color. Postinflammatory hypopigmentation is typically easily excluded by the lack of preceding or concurrent inflammatory or trauma-induced lesions. Nevus anemicus is readily distinguished by its "disappearance" upon diascopy; in addition, vigorous rubbing or application of ice produces erythema in the hypopigmented lesions of TSC significantly more than in nevus anemicus. Hypomelanotic macules may be observed in patients with ataxia telangiectasia (likely reflecting "pigmentary mosaicism"). *Westerhof syndrome* is characterized by hypo- and hyperpigmented macules, possibly in association with growth retardation; autosomal dominant inheritance has been proposed, but the etiology is not known. *Familial progressive hyperpigmentation with or without hypopigmentation*, which also has autosomal dominant inheritance and features lesions ranging from small macules to large patches, is caused by heterozygous activating mutations in *KITLG*[119].

Rarely, the hypopigmentation in TSC has a segmental pattern, for which the differential diagnosis includes segmental vitiligo (which progresses over a few months to 2 years and is amelanotic) and "pigmentary mosaicism" (see below). Idiopathic guttate hypomelanosis (IGH) may resemble the confetti lesions of TSC, but IGH is an acquired disorder that usually develops in adults. The diagnosis of TSC should be considered in any child or infant with a guttate leukoderma. Other causes of a guttate leukoderma are outlined in Table 66.5.

"Pigmentary Mosaicism": Blaschko-Linear Hypopigmentation, Segmental Pigmentation Disorder, and Nevus Depigmentosus

Hypopigmentation along the lines of Blaschko reflects epidermal mosaicism characterized by streaks of skin with decreased pigment production ("pigmentary mosaicism"; see Ch. 62). The eponym "hypomelanosis of Ito" is becoming historical and should be reserved for patients with associated extracutaneous findings due to the presence of the mosaic mutation in tissues other than the skin. Although cytogenetic data are less substantial, "segmental pigmentation disorder" and nevus depigmentosus are also considered to represent manifestations of cutaneous mosaicism[120].

Clinical features

Blaschko-linear hypopigmentation may be apparent at birth or become evident during infancy or early childhood. The characteristic pattern of streaks and whorls can occur unilaterally or bilaterally (Fig. 66.16)[120]. Abnormalities of the CNS, eye, or musculoskeletal system are found in <15%–30% of patients with Blaschko-linear hypopigmentation who present to a pediatric dermatologist at a tertiary referral center.

Nevus depigmentosus occurs in 1 in 50–75 individuals. The name is a bit of a misnomer, as the areas of leukoderma are actually hypomelanotic rather than amelanotic. Most lesions measure a few centimeters in diameter and have irregular but well-defined borders, often breaking apart into smaller macules at the periphery (Fig. 66.17). A block-like variant of nevus depigmentosus, also referred to as the hypopigmented form of "segmental pigmentation disorder", typically features midline demarcation and less distinct lateral borders[121].

Phylloid hypomelanosis is a distinctive pattern of hypomelanosis that occurs in patients with mosaic forms of trisomy (or tetrasomy) 13 or 13q. The hypomelanosis consists of: (1) round or oval lesions; (2) large asymmetric areas reminiscent of the leaves of a begonia; and (3) pear-shaped or oblong macules. Additional features may include telangiectatic macules, hypertrichosis, CNS defects (especially absence of the corpus callosum), conductive hearing loss, choroidal and retinal colobomas, craniofacial anomalies, and digital malformations[122].

Pathology

The number of melanocytes in affected skin may be normal or decreased[123].

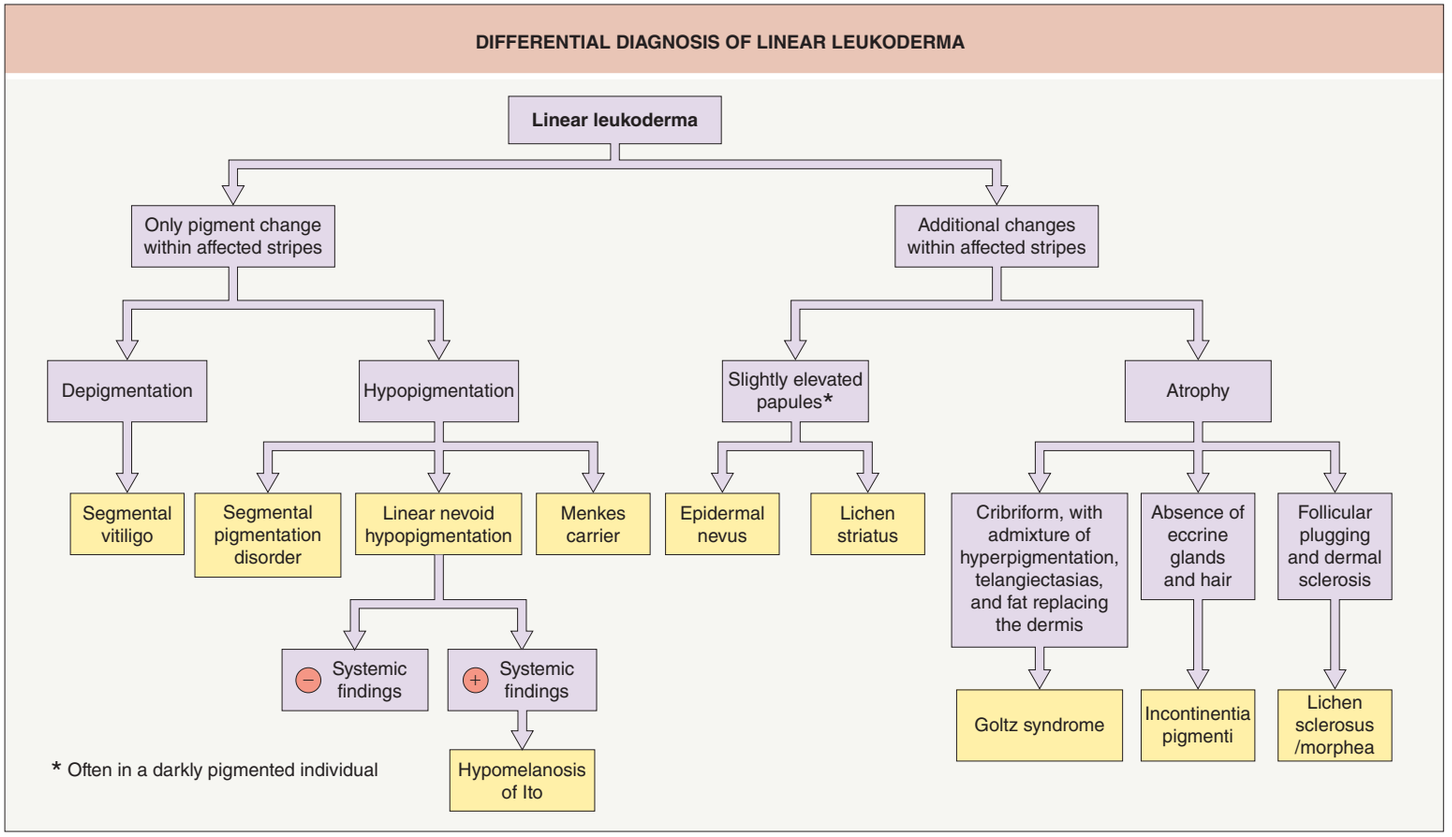

Fig. 66.18 Differential diagnosis of linear leukoderma.

Pathogenesis (see Ch. 62)

A wide variety of mosaic cytogenetic abnormalities in peripheral blood lymphocytes and/or lesional fibroblasts have been detected in patients with Blaschko-linear hypopigmentation. Single-gene causes of Blaschko-linear hypopigmentation include: (1) mosaic activating *MTOR* mutations, which are often associated with macrocephaly, (hemi)megalencephaly, and asymmetric overgrowth; (2) *RHOA-related neuroectodermal syndrome* with associated leukoencephalopathy and hemihypoplasia due to mosaic *RHOA* mutations; (3) X-linked disorders that result in functional mosaicism in female patients, e.g. *TFE3-associated neurodevelopmental disorder* with lysosomal storage disease-like features and *female-restricted X-linked syndromic intellectual development disorder-99 (USP9X)*[124] (see Ch. 62).

Diagnosis

The differential diagnosis of linear leukoderma is presented in Fig. 66.18 and Table 66.6. Diagnostic considerations for the common type of nevus depigmentosus are discussed above (see TSC).

DISORDERS WITH LINEAR HYPOPIGMENTATION
Lesions usually follow lines of Blaschko
• Blaschko-linear hypopigmentation*
• Lichen striatus
• Focal dermal hypoplasia (Goltz syndrome)
• Menkes kinky hair disease (female carrier)
• Conradi–Hünermann–Happle syndrome
• Epidermal nevus
• In association with nevus comedonicus
• Linear lichen sclerosus/morphea
• Guttate macules in linear keratosis follicularis and linear basaloid follicular hamartoma
Lesions may follow lines of Blaschko
• Segmental vitiligo
• Segmental ash leaf spot
• Fourth stage of incontinentia pigmenti
Lesions do not follow lines of Blaschko
• Linear hypopigmentation secondary to intralesional corticosteroids
• Pigmentary demarcation lines, type C
*Block-like hypopigmentation (segmental pigmentation disorder) represents another pattern of "pigmentary mosaicism" and may coexist with linear lesions; previous terms include "systematized" nevus depigmentosus with a linear configuration.

Table 66.6 Disorders with linear hypopigmentation. *Adapted from Bolognia JL, Shapiro PE. Albinism and other disorders of hypopigmentation. In: Arndt KA, et al (eds). Cutaneous Medicine and Surgery. Philadelphia: WB Saunders, 1995.*

NUTRITIONAL HYPOMELANOSIS

In *kwashiorkor*, which is due to severe protein deficiency, the skin initially becomes erythematous to red–brown in color with marked desquamation (see Ch. 51). Both hypomelanosis and patchy postinflammatory hypermelanosis can be seen, with striking pigmentary changes in florid cases. The hypomelanosis usually begins on the face. The hair is dry and lusterless, and it may become light red–brown in color. Upon resumption of dietary protein intake, the skin repigments slowly. Diffuse pigmentary dilution due to *deficiencies of copper* or *selenium* have also been reported (see Fig. 66.12).

HYPOMELANOSIS SECONDARY TO CUTANEOUS INFLAMMATION

Epidemiology

Postinflammatory hypomelanosis (PIH) represents a very common skin disorder that is more obvious in darkly pigmented or tanned individuals. A large number of dermatoses can lead to PIH[125], including seborrheic dermatitis, atopic dermatitis, lichen striatus, pityriasis lichenoides chronica, psoriasis, and lupus erythematosus (Fig. 66.19); mycosis fungoides, sarcoidosis, and lichen sclerosus can also present as hypopigmented lesions. In some patients, repeated examinations are required to identify primary inflammatory lesions.

Pathogenesis

The various steps that determine skin color, including melanogenesis, are controlled by multiple factors (e.g. growth factors, cytokines) that exert their actions directly or indirectly on keratinocytes and

Fig. 66.19 Postinflammatory hypopigmentation. Hypopigmentation secondary to psoriasis (**A**), seborrheic dermatitis in an infant (**B**), pityriasis lichenoides chronica (**C, D**), and lichen striatus (**E**). Note the subtle flat-topped papules in the latter. Complete pigment loss in patients with severe atopic dermatitis (**F**), neonatal lupus erythematosus (**G**), and discoid lupus erythematosus (**H**). *B, Courtesy Jean L. Bolognia, MD; E, G, Courtesy Julie V. Schaffer, MD.*

melanocytes. Dysregulation of these processes can induce abnormal melanocyte–keratinocyte interactions. Cutaneous inflammation, for example, is able to alter melanosome biogenesis, melanin production, melanosome transport, and especially transfer of melanosomes to keratinocytes. Severe local inflammation can lead to a loss of functional melanocytes or even melanocyte death.

Clinical features

Hypomelanosis usually follows or coexists with inflammatory lesions, but, occasionally, only hypopigmented lesions are seen, e.g. in sarcoidosis or mycosis fungoides. PIH, either localized or widespread, is usually associated with a decrease, but not absence, of pigment. Complete depigmentation is most commonly seen in the setting of severe atopic dermatitis and discoid lupus erythematosus (see Fig. 66.19F,H). Whether this lack of pigment represents koebnerization of vitiligo into areas of inflammation versus the consequence of severe inflammation is debatable.

Pathology

In certain dermatoses (e.g. sarcoidosis, mycosis fungoides), histologic examination of hypopigmented lesions can aid in establishing the diagnosis, whereas in others (e.g. pityriasis lichenoides chronica) the findings are less specific and the diagnosis is made primarily on a clinical basis.

Treatment

Once the underlying inflammatory disorder is effectively treated, PIH usually gradually resolves. Sun exposure or UVB phototherapy may be helpful, although tanning can also accentuate the contrast with normal skin. In amelanotic lesions with complete loss of melanocytes, epidermal or melanocyte grafting may be considered (see above).

Pityriasis Alba

Pityriasis alba is a very common condition, consisting of slightly scaly, round to oval, ill-defined macules and patches with mild to moderate hypopigmentation (see Ch. 12). Although it occurs in all skin phototypes, pityriasis alba is more noticeable in darkly pigmented individuals. It is generally a disorder of childhood and adolescence, and it becomes more apparent during the summer months when the surrounding skin is tanned. The lesions usually vary in size from 0.5 to 3 cm, but larger lesions can also occur.

The earliest lesions may be pink in color, but after a few weeks, the erythema fades and the cutaneous surface assumes a whitish, dry, powdery appearance, sometimes with a slightly raised, pinkish border. The face, especially the malar region, is the most frequent site of involvement. Occasionally, lesions of pityriasis alba are seen on the neck, trunk, and extremities. This dermatosis is generally asymptomatic, but some patients complain of itching and burning. With Wood's lamp examination, more lesions may become apparent and a decrease, but not absence, of pigment is observed. Although the patches of hypomelanosis often remain stationary and unchanged for several years, they usually (but not always) clear spontaneously after puberty.

Light and electron microscopy reveal reduced numbers of active melanocytes and a decrease in the number and size of melanosomes in the affected skin.

The differential diagnosis includes tinea versicolor, vitiligo (see above), "eruptive hypomelanosis" associated with viral symptoms[126], and other forms of PIH, in particular pityriasis lichenoides chronica when the lesions are extrafacial.

Topical hydrocortisone may be helpful, but emollients seem to be equally effective.

Sarcoidosis

The true incidence of leukoderma in sarcoidosis is unknown. In one series, hypopigmentation was observed in 6% of sarcoidosis patients. The female-to-male ratio is ~2:1. Lesions are described as circumscribed or poorly marginated papules or plaques that vary from one to a few centimeters in diameter, and they may or may not be indurated. In addition, dermal nodules surrounded by hypomelanosis may be seen[127]. The lesions appear most commonly on the extremities, are asymptomatic, and have no other secondary changes. They appear to carry no specific prognostic significance, and spontaneous repigmentation may occur.

Histologically, non-caseating granulomas are seen in the dermis. By electron microscopy, some melanocytes appear normal, while others have a vacuolated appearance; the number of melanosomes within keratinocytes is decreased. The clinical and histologic features of leprosy differ enough to allow a distinction.

Hypopigmented Mycosis Fungoides

Hypopigmented mycosis fungoides (MF) is a variant of early-stage MF that is most frequently observed in individuals with darkly pigmented skin (Fig. 66.20). The hypomelanotic lesions occur on the trunk or extremities and may be pruritic. Some authors distinguish patients, often children and adolescents, with primarily hypopigmented patches from those, usually adults, with classic erythematous plaques of MF admixed with postinflammatory hypopigmentation. Although the most common age range at the time of diagnosis of MF is 30–40 years, the hypopigmented variant accounts for a higher proportion (~25%–50%) of MF in children and adolescents. Successful treatment (e.g. photo[chemo] therapy or topical mechlorethamine [nitrogen mustard]) usually results in repigmentation. Routine histology shows the typical features of MF and electron microscopy demonstrates decreased numbers of melanosomes within epidermal keratinocytes. Numerous morphologically normal melanosomes are present in melanocytes. These observations suggest a defect in melanosomal transfer, a change seen in most postinflammatory hypomelanoses.

Systemic Sclerosis (Scleroderma) and Lichen Sclerosus

Patients with systemic sclerosis can develop diffuse hypermelanosis[128] with accentuation in sun-exposed sites, a mixture of hypo- and hyperpigmentation in areas of chronic sclerosis (e.g. the hands), and a characteristic leukoderma in both sclerotic and non-sclerotic skin. The latter is characterized by circumscribed areas of complete pigment loss except for perifollicular and supravenous retention of pigment (Fig. 66.21). When this peculiar leukoderma is seen, systemic sclerosis must be excluded, as it is only known to occur in two other settings: overlap syndromes (i.e. those that include systemic sclerosis) and scleromyxedema. The origin and pathogenesis of the pigmentary disturbances in systemic sclerosis are unknown.

Genital and extragenital lesions of lichen sclerosus are often hypomelanotic. Additional changes include epidermal atrophy, follicular plugging and, especially in the anogenital region, purpura. Occasionally, extragenital lichen sclerosus presents as a guttate leukoderma (see Table 66.5; Fig. 66.22). Electron microscopy reveals a loss of pigment cells or decreased number of melanocytes with degenerative changes.

Fig. 66.20 Hypopigmented mycosis fungoides. A Variant with an admixture of classic erythematous lesions and hypopigmented patches with scale on the legs in an adolescent. **B** Purely hypopigmented lesions of variable sizes on the back and buttocks of a child. *A, Courtesy Edward Cowen, MD; B, Courtesy Julie V. Schaffer, MD.*

Fig. 66.21 Leukoderma of systemic sclerosis (scleroderma). Uniform retention of perifollicular pigment within areas of leukoderma. Hyperpigmentation is also seen overlying a superficial vein.

Fig. 66.22 Guttate lichen sclerosus involving the areola.

Lupus Erythematosus

In discoid lupus erythematosus (DLE), hypomelanosis or amelanosis is almost always associated with cutaneous atrophy and scarring (see Fig. 66.19H). Hypomelanosis favors the center of the lesions, and it is often accompanied by a rim of hyperpigmentation. In chronic scarring DLE, the pigmentary changes are persistent. Histologically, in addition to a decreased number of epidermal melanocytes, changes that help to establish the diagnosis include epidermal atrophy, vacuolar degeneration of the basal layer, a variably dense inflammatory infiltrate rich in $CD123^+$ plasmacytoid dendritic cells, pigmentary incontinence, and fibrosis. Hypomelanosis is also frequently seen in the center of annular lesions of subacute cutaneous LE, but this is usually reversible.

INFECTIOUS AND PARASITIC HYPOMELANOSIS

Tinea (Pityriasis) Versicolor

The primary lesion is round to oval, hypomelanotic, and usually measures several millimeters to 1–3 cm in diameter (Fig. 66.23). Within the areas of involvement, the lesions are often coalescent centrally. Associated fine scale may be obvious or only apparent upon scratching or stretching the skin. The distribution is usually symmetric and favors the upper trunk and shoulders; lesions sometimes develop on the lower trunk, body folds, neck, and face (see Ch. 77). Of note, facial tinea versicolor may occur in association with protective mask use[128a]. While the contrast between the hypomelanotic infected skin and the surrounding normal skin is striking in darkly pigmented patients, or following a tan in lightly pigmented patients, Wood's lamp examination may be required to locate all the lesions.

In the hypopigmented skin, there is a decreased density of melanosomes within keratinocytes, but no change in the melanocyte density. Abnormal melanosome production, decreased melanin synthesis, and a partial block in melanosome transfer to keratinocytes have all been suggested as underlying defects. Azelaic acid, a competitive inhibitor of tyrosinase produced by *Malassezia furfur*, may play a role in the decreased melanin synthesis. Although the differential diagnosis may include postinflammatory hypopigmentation (e.g. secondary to parapsoriasis), progressive macular hypomelanosis, and early vitiligo, the diagnosis of tinea versicolor is easily confirmed by examination of the associated scale in a potassium hydroxide preparation.

Hypomelanosis without scaling may remain for months after spontaneous or treatment-induced eradication of the hyphal form of the organism.

Fig. 66.23 Tinea versicolor. A Hypopigmented variant with obvious scale. **B** Guttate hypopigmented lesions on the lateral cheek of a child; note the classic scaly lesions in the posterior auricular area. *B, Courtesy Julie V. Schaffer, MD.*

Hansen Disease (Leprosy)

Hypomelanotic macules may be the earliest expression of *lepromatous leprosy*. The lesions are usually small, multiple, subtle, and ill-defined; they may be difficult to recognize, particularly in lightly pigmented skin. The face, extremities, and buttocks are favored, and the warmer parts of the body are usually spared. There is little or no anhidrosis or loss of sensation. Later, plaques, nodules, or diffuse infiltration of the skin appear (see Ch. 75).

The hypopigmented patches of *tuberculoid leprosy* are much different from those of lepromatous leprosy. Tuberculoid lesions have discrete edges and can be quite large, up to 30 cm in diameter (Fig. 66.24). A raised border, uniform infiltration, or a characteristic pebbled appearance may be observed. The surface can be slightly scaly, dry, or minimally atrophic. The lesions are asymmetrically distributed on the posterolateral aspects of the extremities, back, buttocks, and face. There is associated alopecia, anhidrosis, and loss of tactile and heat sensations.

In *borderline leprosy*, plaques and annular lesions are more common than hypomelanotic macules; the latter, if present, have ill-defined borders. A "Swiss cheese" appearance with erythematous annular lesions and hypomelanotic areas, all bound by vague outer borders, characterizes this form of leprosy. In *indeterminate leprosy*, the macules are usually hypomelanotic, but they can also be erythematous; hypoesthesia may be present. They are asymmetrically distributed and favor exposed sites.

The mechanism of hypopigmentation in leprosy is unknown, and there are no histologic or ultrastructural alterations in the melanocytes. Treatment usually, but not always, results in repigmentation of the hypomelanotic macules.

Treponematoses

In *pinta*, hypomelanotic lesions occur during the late phase of the disease, a few months to several years after the appearance of secondary lesions. Irregular, vitiligo-like areas of depigmentation favor skin overlying bony prominences and are often surrounded by brown to blue–gray hyperpigmentation. Atrophy, xerosis, and alopecia may be evident. Longstanding amelanotic lesions do not typically repigment.

Fig. 66.24 Tuberculoid leprosy. Large, thin hypopigmented plaque on the elbow with a raised light pink border.

Hypomelanosis occasionally develops in untreated tertiary *yaws*. Symmetric hypomelanotic macules enlarge until an entire area is affected. The most common sites are the dorsal aspects of the wrists and hands and over the metacarpophalangeal and interphalangeal joints.

Hypomelanosis may occur in the late stages of *bejel (endemic syphilis)*. Hypomelanotic macules have well-defined borders and may be admixed with pigmented macules. The lesions are usually symmetrically distributed on the extremities, genitalia, areolae, and trunk. Early penicillin treatment results in satisfactory repigmentation.

In *secondary syphilis*, hypomelanosis is an occasional finding that is called "leukoderma syphiliticum". In the "necklace of Venus", small (1–2 mm) hypomelanotic macules are scattered within a larger area of hyperpigmentation on the neck. Hypopigmentation may also develop at sites of previously inflamed lesions, which favor the neck, proximal extremities, upper trunk, abdomen, axillae, and groin. Leukoderma syphiliticum regresses with treatment and usually disappears completely within several months to a year.

Onchocerciasis

Initially, small (punctate), yellowish, hypomelanotic macules appear on the middle third of the shin medial to the tibial crest. Later, the macules enlarge, coalesce, and undergo progressive lightening until there is amelanosis (Fig. 66.25). Pigmented macules persist within the hypopigmented patches, hence the designation "leopard skin" (see Fig. 83.31). Other sites of involvement may include the lateral aspects of the legs, groin, and skin overlying the bony prominences of the pelvis.

Post-Kala-Azar Dermal Leishmaniasis

Small hypomelanotic macules in a symmetric distribution that favors the upper trunk and arms constitute the prenodular stage of the disease. The lesions become elevated over a period of months to years. Total repigmentation following systemic treatment with antimonials is almost impossible to achieve.

Herpes Zoster

Hypo- or depigmentation is sometimes seen in the sites of previous herpes zoster. Amelanosis can result from melanocyte destruction during the inflammatory and healing process, which may also lead to atrophy and fibrosis.

HALO NEVUS AND MELANOMA-ASSOCIATED LEUKODERMA

Halo Nevus

The halo nevus phenomenon most often occurs in children and young adults with multiple melanocytic nevi (see Ch. 112); it is unusual in adults over 40 years of age. A central melanocytic nevus is surrounded by a round or oval amelanotic annulus. The lesions are asymptomatic and the most common site is the trunk, particularly the back. There are four stages in halo nevus evolution, which occurs over a period of months to ≥10 years: (1) appearance of the halo; (2) loss of pigment within the central nevus; (3) disappearance of the nevus; and (4) disappearance of the halo. Patients often develop multiple halo nevi and some have associated vitiligo. The exact relationship between halo nevi and vitiligo has been the subject of controversy.

Both nevus cells and epidermal melanocytes in the surrounding skin are destroyed, as demonstrated by histologic and ultrastructural studies. Both $CD4^+$ and $CD8^+$ T cells infiltrate halo nevi. Peripheral T cells from a patient with halo nevi were shown to lyse *in vitro* melanocytes obtained from a normal nevus, implicating T cells in the pathogenesis of halo nevi. Oligoclonality of the T cell response in patients with halo nevi further suggests that the destruction of melanocytes could represent the lysis of a distinctive cell type through an immune process mediated by a limited number of T cell clones[129].

The clinical diagnosis of halo nevus is usually fairly straightforward, but Wood's lamp examination may occasionally be required to detect the halo. The halo phenomenon can occur with a variety of types of melanocytic nevi (e.g. congenital, blue) and melanoma. Careful examination of the central lesion is therefore required. Typical halo nevi require no treatment other than reassurance. Individuals beyond 40 years of age with new-onset halo nevi should be examined carefully for melanoma (ocular and cutaneous).

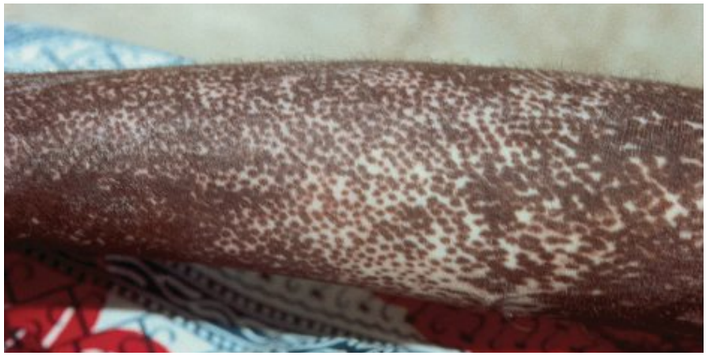

Fig. 66.25 Onchocerciasis (leopard skin). Depigmentation of the shin with follicular repigmentation or retention of perifollicular pigment, a common site for the associated leukoderma.

Melanoma-Associated Leukoderma

Vitiligo-like depigmentation can occur in patients with cutaneous or ocular melanoma. At least three types of leukoderma are associated with melanoma: (1) hypomelanosis within tumors (primary or metastatic) due to regression (see Ch. 113); (2) amelanosis around tumors (halo phenomenon; see above); and (3) vitiligo-like depigmentation remote from the tumors. In the latter, involvement of ocular melanocytes (e.g. uveitis, retinopathy, VKH-like changes) has also been reported.

Increasing evidence suggests that melanoma-associated, vitiligo-like leukoderma results from an immune reaction directed against antigenic determinants shared by normal and malignant melanocytes. Although antibodies to pigment cells are commonly found in patients with melanoma, growing evidence points towards an important role for cellular immune responses (Fig. 66.26). Vitiligo-like lesions have been observed in melanoma patients following successful immunotherapy with immune checkpoint inhibitors targeting cytotoxic T lymphocyte-associated antigen-4 (CTLA-4; e.g. ipilimumab; Fig. 66.27), programmed cell death-1 (PD-1; e.g. pembrolizumab, nivolumab), and PD-ligand 1 (PD-L1; e.g. atezolizumab); IL-2; tumor-infiltrating lymphocytes specific for tyrosinase-, gp100- or TYRP1-derived antigens; and peptide vaccines based upon these antigens. Vitiligo-like depigmentation induced by immune checkpoint inhibitors favors chronically sun-exposed areas; although most common in melanoma patients, it occasionally occurs with treatment of other malignancies. Lastly, cytotoxic T lymphocyte clones derived from melanoma patients efficiently lyse cultured human melanocytes.

Clonally expanded T cells with identical Vp regions have been identified in a primary melanoma and a depigmented halo surrounding the tumor, again suggesting a role for a T cell-mediated antitumoral response in the development of melanoma-associated, vitiligo-like leukoderma. Melan-A/MART-1-specific $CD8^+$ T cells have been identified in inflammatory hypomelanotic skin lesions following the infusion of Melan-A/MART-1-specific $CD8^+$ T cell clones in a patient with metastatic melanoma[130]. Thus, in melanoma patients, "vitiligo" may be a visible effect of a spontaneous or therapy-induced antitumoral immune response against melanocyte differentiation antigens (see Ch. 113). In addition to occasionally preceding spontaneous resolution of metastatic melanoma, the development of vitiligo-like leukoderma is associated with a survival benefit in patients receiving immunotherapy for metastatic melanoma[131].

CHEMICAL AND PHARMACOLOGIC HYPOMELANOSIS

A large number of chemical and pharmacologic agents can cause hypomelanosis of skin and hair[132,133]. The three major groups of depigmenting compounds (Table 66.7) are:

- phenols/catechols
- sulfhydryls
- miscellaneous.

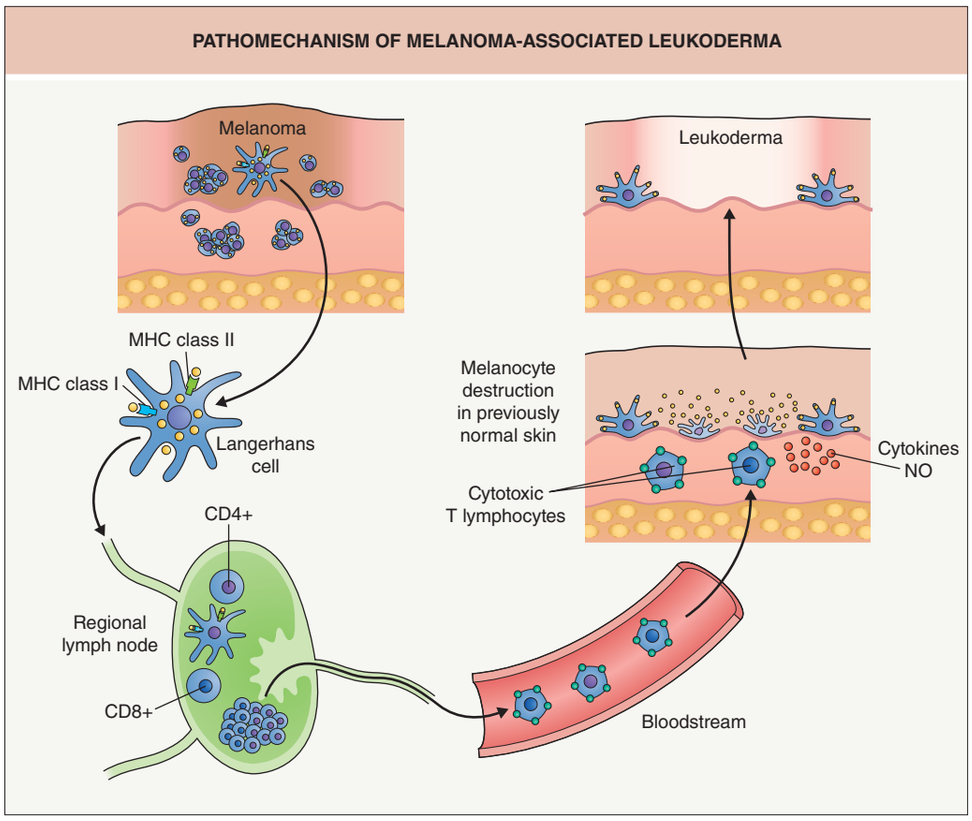

Fig. 66.26 Pathomechanism of melanoma-associated leukoderma. NO, nitric oxide. *From Schaffer JV, Bolognia JL. The biology of the melanocyte. In: Rigel DS, et al (eds). Cancer of the Skin, 2nd edn. Philadelphia: Elsevier Saunders, 2011.*

Fig. 66.27 Vitiligo-like leukoderma associated with anti-cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) therapy for metastatic melanoma. *Courtesy Jean L. Bolognia, MD.*

Hydroquinone (HQ) and its derivatives (MMEH, MBEH) are the most widely used "bleaching" agents. HQ induces a reversible hypopigmentation of the skin, and it is used to treat disorders such as melasma. In contrast, depigmentation from MBEH is often permanent and occurs not only in the areas of application but also in distant sites; as a result, its only indication is as depigmentation therapy for widespread, treatment-resistant vitiligo (see above). Of note, MMEH and MBEH were identified as depigmenting agents after outbreaks of occupational leukoderma in workers exposed to these chemicals in rubber products.

Hypomelanosis can follow the use of either topical or intralesional corticosteroids, particularly in darkly pigmented individuals. Potent topical corticosteroids are unfortunately widely used as lightening agents in many areas of the world, especially Africa and Asia. In most cases, the hypomelanosis is incomplete, but the risk of significant side effects (e.g. acne, atrophy, striae) is high. Hypomelanosis induced by intralesional or intra-articular corticosteroids can be stellate or linear, has an irregular outline, and is often ill-defined (Fig. 66.28). The cutaneous hypopigmentation appears several weeks to months after the injection. In most instances, repigmentation occurs within 1 year after discontinuation of the injections.

In any patient, particularly adults, presenting with new-onset "vitiligo" (Fig. 66.29), a detailed history to detect exposure to known depigmenting agents or use of topical or oral medications (e.g. imiquimod, imatinib) implicated in depigmentation is mandatory (see Table 66.7). Patch testing can be useful for confirming the diagnosis of chemical leukodermas, but delayed readings are essential (e.g. at 2 weeks, then again at 4–6 weeks). Spontaneous repigmentation may occur following avoidance of the causative agent, but treatment, as for vitiligo, is usually required (see above).

In chemical leukoderma induced by HQ and its derivatives, melanocytes are decreased in number or absent. Other depigmenting agents inhibit tyrosinase (thus blocking melanogenesis) or prevent melanosome transfer.

Patients treated with imatinib mesylate have been noted to develop various forms of hypomelanosis, including generalized lightening of the skin, hypopigmentation of the distal digits, difficulty in maintaining a suntan, and progression of vitiligo. These changes appear to be reversible and potentially dose-dependent, and they have been observed more commonly in darkly pigmented individuals[134]. Imatinib mesylate is a tyrosine kinase inhibitor that targets the bcr-abl fusion protein that is characteristic of chronic myelogenous leukemia; it also inhibits three other tyrosine kinases – platelet-derived growth factor (PDGF) receptor-α, PDGF receptor-β, and the KIT receptor. Imatinib mesylate-induced inhibition of the KIT receptor, which is involved in melanogenesis and melanocyte homeostasis, is the most likely explanation for the hypopigmentation. Loss of hair color has been noted in patients receiving sunitinib malate, another inhibitor of tyrosine kinase receptors (including the KIT receptor). Sunitinib-induced hair depigmentation appears to be reversible with cessation of treatment[135].

SELECTED CHEMICALS ASSOCIATED WITH LEUKODERMA
Phenol/catechol derivatives
Monobenzyl ether of hydroquinone (MBEH)
Monomethyl ether of hydroquinone (MMEH) (*p*-methoxyphenol; *p*-hydroxyanisole)
Monoethyl ether of hydroquinone (MEEH) (*p*-ethoxyphenol)
Hydroquinone (HQ) (1,4-dihydroxybenzene; 1,4-benzenediol; quinol; *p*-hydroxyphenol)
Rhododendrol
p-tert-butylcatechol (PTBC)
p-tert-butylphenol (PTBP)
p-tert-amylphenol (PTAP)
p-phenylphenol
p-octylphenol
p-nonylphenol
p-isopropylcatechol
p-methylcatechol
Butylated hydroxytoluene (BHT)*
Butylated hydroxyanisole (BHA)*
Pyrocatechol (1,2-benzenediol)
p-cresol
Sulfhydryls
β-mercaptoethylamine hydrochloride (MEA) (cysteamine)
N-(2-mercaptoethyl)-dimethylamine hydrochloride (MEDA)
Methimazole (1-methyl-2-mercaptoimidazole – MMI)
Sulfanilic acid
Cysteamine dihydrochloride
3-mercaptopropylamine hydrochloride
Miscellaneous
Mercurials
Arsenic
Cinnamic aldehyde
p-phenylenediamine (PPD)
Benzyl alcohol
Azelaic acid
Corticosteroids
Imiquimod
Methylphenidate patches
Optic preparations • Physostigmine (eserine) • Diisopropyl fluorophosphates • Thiotepa (N,N′,N″-triethylenethiophosphoramide) • Guanonitrofuracin
Systemic medications • Chloroquine • Fluphenazine (Prolixin®) • Tyrosine kinase inhibitors (e.g. imatinib mesylate, pazopanib, cabozantinib)
*Depigmentation weak or not known.

Table 66.7 Selected chemicals associated with leukoderma.

HYPOMELANOSIS FROM PHYSICAL AGENTS

Various types of physical injuries can induce cutaneous hypomelanosis or amelanosis, including thermal burns, freezing, UV radiation, lasers, ionizing radiation, and physical trauma from surgical procedures. The combination of the history of an insult, the shape of the hypopigmentation, and associated findings usually makes the diagnosis relatively straightforward.

Repigmentation is based on a host of factors, including the type and depth of the insult or injury, the anatomic location, and the presence of hair follicles and pigmented hairs.

Fig. 66.28 Hypopigmentation due to injection of corticosteroids into the anatomic snuff box. The outline is both stellate and linear.

MISCELLANEOUS

Idiopathic Guttate Hypomelanosis

Idiopathic guttate hypomelanosis (IGH) is a very common disorder, the incidence of which increases with age. It is seen in up to 80% of patients over the age of 70 years. IGH occurs in all races and skin types, but it is more striking in darkly pigmented skin. In White individuals, IGH may favor those with brown eyes and brown hair. An apparent female predominance is probably the result of heightened perception of a cosmetic problem.

The typical IGH lesion is a circumscribed, sharply defined, asymptomatic porcelain white macule[136]. The lesions are usually 0.5–6 mm in diameter and often delineated by the skin furrows; occasionally, lesions are up to 2.5 cm in size (Fig. 66.30). Once present, they do not change in size or coalesce; their surface is smooth but not atrophic. Spontaneous repigmentation has not been reported. Hairs within the lesions usually retain their pigment. In most patients, there are multiple lesions on the extensor forearms and shins; the remainder of the extremities can be affected, but rarely the face.

The most consistent histologic features of IGH are a flattening of the dermal–epidermal junction, moderate to marked reduction or focal absence of melanin granules in the basal and suprabasal layers, and a basket-weave hyperkeratosis. There is a moderate to relatively marked reduction in the number of DOPA-positive epidermal melanocytes (10%–50% compared with normal skin), but these cells are never totally

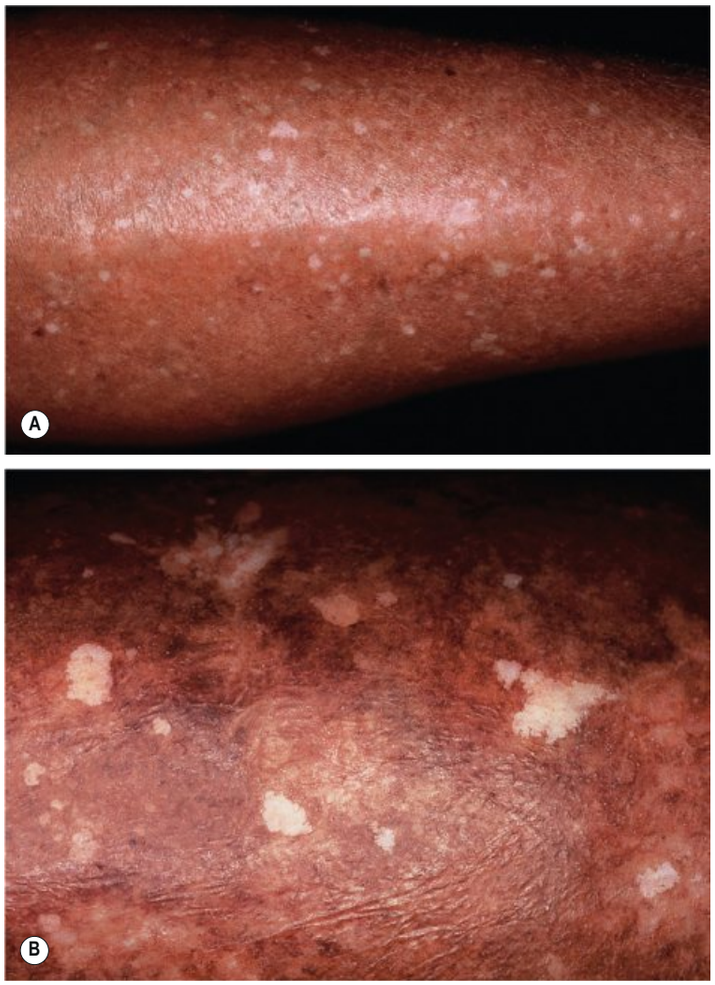

Fig. 66.30 Idiopathic guttate hypomelanosis. A Typical 1–5 mm macules on the shin. **B** Occasionally there is admixture of larger lesions.

absent. At the ultrastructural level, some melanocytes have normal melanogenic activity, while others lack mature melanosomes. The keratinocytes show marked variation in their content of melanin, which may be absent or markedly decreased.

The diagnosis of IGH is usually made clinically; the differential diagnosis of guttate leukoderma includes achromic verrucae planae, pityriasis lichenoides chronica, disseminated hypopigmented keratoses that follow PUVA therapy, and clear cell papulosis (Fig. 66.31; see Table 66.5). Although lesions of atrophie blanche favor the distal shins and ankles, these porcelain white scars are usually depressed and encircled by papular telangiectasias. The cause of IGH is unknown, but sun exposure probably plays a role.

Cryotherapy with liquid nitrogen has been described as a possible therapy for IGH. As sunlight is most likely a precipitating factor, use of sunscreens and physical barriers should be recommended.

Fig. 66.31 Guttate leukoderma. A Disseminated hypopigmented keratoses presenting as >200 guttate, minimally elevated hypopigmented papules. The lesions developed after several months of PUVA therapy. Histologically, there was no evidence of verruca plana. **B** Clear cell papulosis presenting as multiple hypopigmented, barely elevated, small flat-topped papules and macules in the suprapubic area and on the abdomen along the "milk lines" in a 2-year-old boy. Histologically, these lesions are characterized by large clear cells in the lower epidermis that have a pattern of immunohistochemical staining similar to clear cells of Toker and extramammary Paget disease. **C** Guttate hypopigmentation in sun-exposed areas on the extensor aspect of the arm in a 3-year-old Hispanic boy with xeroderma pigmentosum. Note the sparing of the proximal upper arm, which is normally covered by a T-shirt. *A, Courtesy Jean L. Bolognia, MD; B, C, Courtesy Julie V. Schaffer, MD.*

Vagabond's Leukomelanoderma

This skin disorder occurs in older persons in whom dietary deficiency is combined with lack of cleanliness and heavy infestation with *Pediculus humanus* var. *corporis*. These patients have small macules of hypomelanosis (related to scratching) superimposed on a background of diffuse hypermelanosis, especially of the wrists, axillae, groin, medial thighs, and posterior neck.

Progressive Macular Hypomelanosis

Progressive macular hypomelanosis (PMH) is a fairly common skin disorder, observed more frequently in young women with darkly pigmented skin who originate from or reside in tropical climates. The condition is characterized by poorly defined, nummular, non-scaly hypopigmented macules and small patches on the trunk, with rare extension onto the proximal extremities or head and neck region; confluence of lesions may occur centrally (Fig. 66.32)[137]. Another variant of PMH features large circular lesions. There is no associated pruritus or preceding inflammation, and patients are sometimes misdiagnosed as having residual hypopigmentation related to tinea versicolor. Histologically, there is decreased pigment in the epidermis and a normal-appearing dermis. Electron microscopy demonstrates a shift from large melanosomes in uninvolved skin to small aggregated membrane-bound melanosomes in hypopigmented skin. Proliferation of *Cutibacterium* (previously *Propionibacterium*) *acnes*, in particular the *elongatum* subspecies (phylotype III), is thought to play a role in PMH pathogenesis[138]. The fact that this strain is rarely present on the face may explain why PMH is not typically found in this location. Treatment regimens include various combinations of topical 1% clindamycin, 5%

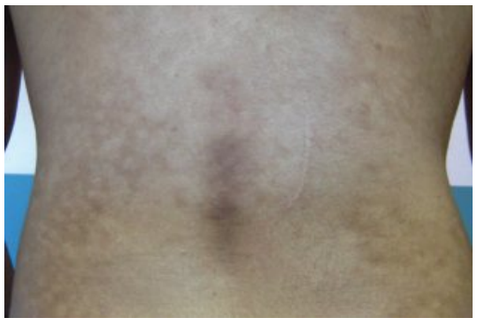

Fig. 66.32 Progressive macular hypomelanosis. Note the coalescence of the non-scaly hypopigmented macules on the center of the back.

DISORDERS ASSOCIATED WITH PREMATURE GRAYING OF SCALP HAIR
• Piebaldism
• Waardenburg syndrome
• Vitiligo
• Sudden whitening of hair
• Hereditary premature canities
• "Bird-headed" dwarfism
• Progeria
• Werner syndrome
• Ataxia telangiectasia
• Rothmund–Thomson syndrome
• Dyskeratosis congenita
• Fisch syndrome
• Myotonic dystrophy
• Prolidase deficiency (also in Table 66.9)
• Oasthouse disease

Table 66.8 Disorders associated with premature graying of scalp hair.

benzoyl peroxide, and phototherapy with NB-UVB or UVA (e.g. three times weekly for 12 weeks).

Hair Hypomelanosis

Poliosis refers to a circumscribed hypomelanosis of hair (see Table 66.3), whereas canities implies a more generalized depigmentation of hair. Graying of hair, localized or generalized, is characterized by an admixture of normally pigmented, hypomelanotic, and amelanotic hairs. Whitening of hair is the endpoint of canities and graying of hair. The graying and whitening of human hair that occurs with aging was thought to be due to defective maintenance of melanocyte stem cells[139,140], with more recent work suggesting a reduction in the migration of melanocyte stem cells from the bulge region.

A number of genetic disorders are associated with premature graying of hair (Table 66.8), while there are both hereditary and acquired causes of diffuse hypomelanosis of hair (Table 66.9). In Chédiak–Higashi and Griscelli syndromes, the scalp hairs have a silvery hue due to pigment clumping (see Fig. 60.5).

Leukodermas Without Hypomelanosis

Woronoff's ring

Woronoff's ring is a blanched halo of fairly uniform width surrounding psoriatic lesions after phototherapy or topical treatments. There is an element of vasoconstriction, but it is uncertain whether there is any decrease in pigmentation.

DISORDERS ASSOCIATED WITH DIFFUSE HYPOMELANOSIS OF SCALP HAIR
• Fanconi syndrome
• Book syndrome
• Down syndrome
• Hallermann–Streiff syndrome
• Treacher Collins syndrome
• Prolidase deficiency (also in Table 66.8)
• Hyperthyroidism
• Chronic protein loss or deficiency (e.g. due to kwashiorkor, nephrosis, ulcerative colitis, malabsorption)
• Vitamin B_{12} deficiency
• Tyrosine kinase inhibitors (e.g. sunitinib, imatinib, dasatinib, cabozantinib)
• Antimalarials (chloroquine > hydroxychloroquine)

Table 66.9 Disorders associated with diffuse hypomelanosis of scalp hair. See also Fig. 66.12.

Nevus anemicus

Nevus anemicus presents as a pale area of variable size (often 3–6 cm) with an irregular, "broken up" outline (see Ch. 106). It is usually unilateral and located on the trunk. Present since birth, the lesion is most commonly detected later in life, and it is most noticeable when there is surrounding vasodilation due to heat or emotional stress. On diascopy, the lesion becomes indistinguishable from surrounding skin. Histologically, there are no abnormalities in the melanocytes or melanin content. Nevus anemicus is caused by decreased blood flow through the capillaries in the dermal papillae, due to a localized hypersensitivity of the blood vessels to catecholamines. Although ~30%–60% of patients with neurofibromatosis type 1 (NF1) have a nevus anemicus, this skin finding is not included in the 2021 revised NF1 diagnostic criteria (see Ch. 61).

Cutaneous edema and anemia

Cutaneous edema and anemia also produce lightening of the skin and mucous membranes. In the case of anemia, it is due to decreased hemoglobin levels in the skin.

Angiospastic macules (Bier spots)

Pale macules, usually 3–6 mm in diameter, are seen primarily on the extremities and are often more noticeable on the legs (see Ch. 106). The lesions are due to localized vasoconstriction and occur most often in young women. Their appearance may be induced by a dependent position or placing a tourniquet on the limb. Prominent or widespread angiospastic macules have been described in association with pregnancy, lymphedema, cryoglobulinemia, capillary malformation–arteriovenous malformation syndrome (especially type 2 due to *EPHB4* mutations), tuberous sclerosis complex, and aortic hypoplasia. *BASCULE* syndrome features *B*ier *a*nemic *s*pots, *c*yanosis, and an *u*rticaria-*l*ike *e*ruption in association with orthostatic intolerance[141].

Skin color depends upon the amount and distribution of melanin and other pigments such as hemoglobin, which can influence light absorption, reflection, and scattering. Disorders of hyperpigmentation usually result from an increase in melanin production and, on occasion, from an increase in the density of active melanocytes. Discoloration of the skin may also be caused by deposition of exogenous substances such as drugs, drug complexes (e.g. with melanin or iron), or heavy metals within the dermis.

To aid in the clinical approach, disorders of hyperpigmentation can be divided into diffuse, circumscribed, linear, and reticulated subsets (Fig. 67.1). A discussion of each of these categories is followed by an overview of dyschromatoses, disorders characterized by both hypo- and hyperpigmentation. Keratinocytic disorders that present with hyperpigmentation are listed in Table 67.1, and benign melanocytic neoplasms are covered in Chapter 112.

DIFFUSE AND CIRCUMSCRIBED HYPERPIGMENTATION

Introduction

Diffuse and circumscribed hyperpigmentation are discussed together because both postinflammatory hyperpigmentation (PIH) and reactions to systemic drugs, two major causes of hyperpigmentation, can assume either of these patterns. Melasma is another common cause of circumscribed hyperpigmentation, whereas diffuse hyperpigmentation can also be a manifestation of metabolic diseases, sclerodermoid disorders, nutritional deficiencies, and occasionally HIV infection.

POSTINFLAMMATORY HYPERPIGMENTATION

Synonym: ■ Postinflammatory hypermelanosis

Key features

- Extremely common, especially in individuals with more darkly pigmented skin
- Develops after inflammation or injury to the skin, but preceding inflammation may be transient or subclinical
- The increased melanin can be primarily within the dermis (e.g. following lichen planus) or in the epidermis (e.g. following acne or atopic dermatitis)
- Epidermal hyperpigmentation fades more readily than dermal hyperpigmentation

Introduction

PIH represents an acquired excess of melanin pigment following cutaneous inflammation or injury. It can occur anywhere on the skin surface, including the mucous membranes and the nail unit. PIH is extremely common and can have significant cosmetic and psychosocial consequences.

Epidemiology

PIH can occur at any age and there is no sex preference. Individuals with darkly pigmented skin tend to have a greater frequency, severity, and duration of PIH than those with lighter complexions.

Pathogenesis

In the *epidermal* form of PIH, there is increased melanin production and/or transfer to keratinocytes. Inflammatory mediators (e.g. prostaglandins E_2 and D_2, IL-33) that enhance pigment production may play a role in this process. In *dermal* hyperpigmentation, melanin enters ("falls into") the dermis via a damaged basement membrane, where it is phagocytosed by and subsequently resides within dermal macrophages (referred to as melanophages). Macrophages may also migrate into the epidermis, phagocytose melanosomes, and then return to the dermis. Melanin within dermal melanophages tends to persist for long periods of time (e.g. years).

Clinical Features

Asymptomatic hyperpigmented macules and patches range in color either from tan to dark brown (epidermal melanin) or from gray–blue to gray–brown (dermal melanin). Primary lesions of the underlying inflammatory disorder may be admixed with the hyperpigmentation or present elsewhere. When primary lesions are absent, the size, shape, and distribution pattern of the hyperpigmented lesions may provide clues to the underlying etiology (Table 67.2). PIH can be exacerbated by continued inflammation, trauma, exposure to ultraviolet (UV) irradiation, or treatment-related irritation.

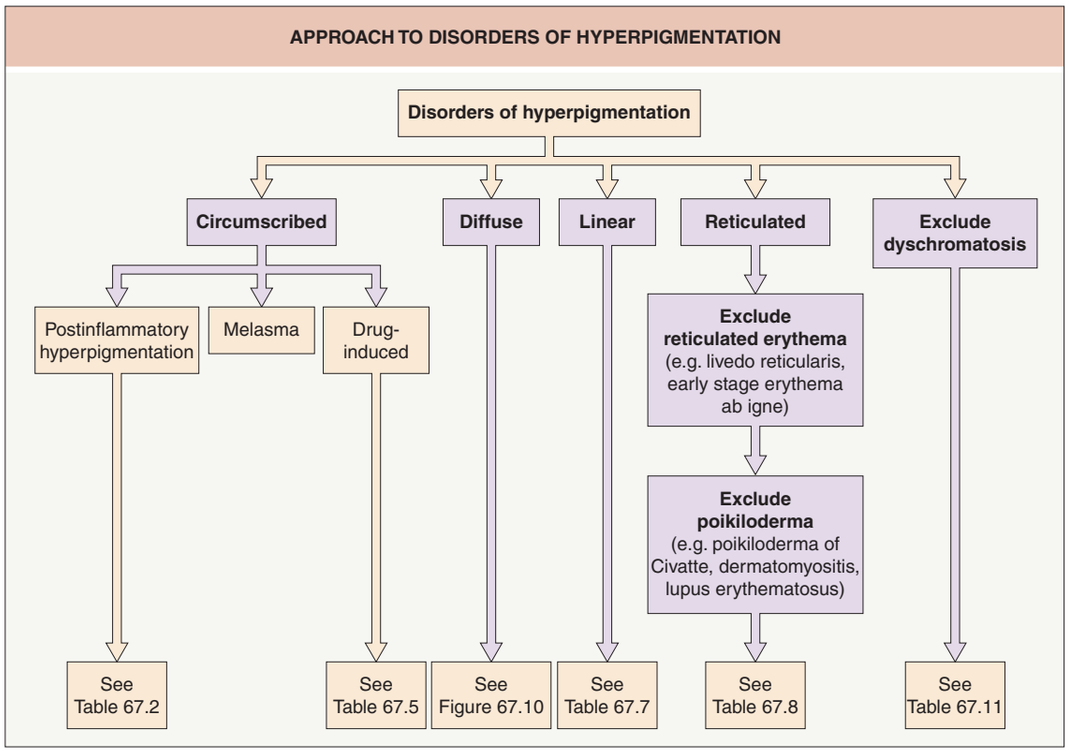

Fig. 67.1 Approach to disorders of hyperpigmentation. Hyperpigmentation can also result from keratinocytic (epidermal) disorders (see Table 67.1).

HYPERPIGMENTATION RELATED TO KERATINOCYTIC (EPIDERMAL) DISORDERS	
Disorder	**Key clinical features**
Acanthosis nigricans	Velvety and corrugated hyperpigmentation of flexural sites (e.g. neck, axillae) > extensor surfaces; often associated with insulin resistance (see Fig. 53.14)
Confluent and reticulated papillomatosis	Hyperpigmented papules and thin plaques with a corrugated and papillomatous surface; form a reticulated pattern primarily on the central trunk, neck, and axillae; onset typically around puberty (see Figs. 67.20 and 109.22)
Terra firmaforme dermatosis	Retention hyperkeratosis presenting as hyperpigmented plaques that favor concave surfaces of the face, neck, chest, and ankles; removed by wiping with 70% isopropyl alcohol pads
Nevoid hyperkeratosis of the nipple and areola	Hyperpigmentation and thickening of the areola(s), more commonly bilateral; typically begins after puberty in women or men receiving hormonal therapy (see Fig. 109.21)
Epidermal nevus	Linear hyperpigmented streaks following the lines of Blaschko (rarely hypopigmented); a variably papillomatous or verrucous texture; congenital or apparent by early childhood (see Chs. 62 and Fig. 109.18)

Table 67.1 Hyperpigmentation related to keratinocytic (epidermal) disorders. Therapeutic options are discussed in cited chapters.

Disorders that commonly lead to epidermal PIH include acne, insect bites, pyodermas, atopic dermatitis, psoriasis, and pityriasis rosea (Fig. 67.2A–C,E). In contrast, dermal PIH is associated with dermatoses characterized by degeneration of the basal layer of the epidermis and inflammation at the dermal–epidermal junction, such as lichen planus, lichenoid drug reactions, lupus erythematosus, and fixed drug eruptions (Fig. 67.2D). Upon treatment of the underlying disorder, epidermal PIH generally resolves over time, although fading may require months or years in darkly pigmented individuals. Dermal melanosis tends to persist longer and is sometimes permanent.

Pathology

Epidermal PIH is characterized by increased pigment in keratinocytes and dermal PIH by melanophages within the superficial dermis.

Differential Diagnosis

The size, shape, and distribution of the hyperpigmented lesions can provide clues to the inflammatory disease or injury that preceded PIH (see Table 67.2), and a thorough skin examination may detect active primary lesions. A history of prior inflammatory lesions and medication use (including prescription, over-the-counter, and alternative products) should be obtained. Disorders such as erythema dyschromicum perstans, melasma, tinea (pityriasis) versicolor, and atrophoderma of Pasini and Pierini should be considered in patients without evidence of preceding inflammation by history or on examination. Occasionally, a biopsy may assist in establishing the diagnosis.

Treatment

Provided that the underlying dermatosis is successfully treated, PIH eventually improves in most patients, especially those with epidermal hypermelanosis. Sun protection, including daily application of a broad-spectrum sunscreen, can help to prevent accentuation of the pigmentation by UV exposure. Topical hydroquinone (2%–4%) may lead to lightening over 3–6 months if the increase in pigmentation is limited to the epidermis. As with melasma (see below), use of a topical retinoid and corticosteroid together with hydroquinone may be more effective than monotherapy. Topical azelaic, α-hydroxy, L-ascorbic, tranexamic, and kojic acids as well as cysteamine, arbutin, licorice extracts, mequinol, niacinamide, *N*-acetyl glucosamine, and soy are additional potential therapeutic options[1]. However, it is important to avoid irritant contact dermatitis from topical agents, as this may exacerbate the hyperpigmentation. Chemical peels (e.g. with salicylic or glycolic acid) and laser therapy may be of benefit but can also result in hyper- or hypopigmentation, especially in patients with darkly pigmented skin. Laser therapy (e.g. 1927-nm non-ablative fractional thulium fiber laser, Q-switched Nd:YAG, ruby, and alexandrite lasers) are variably successful in removing dermal pigment (see Ch. 137).

ERYTHEMA DYSCHROMICUM PERSTANS

Synonyms: ■ Ashy dermatosis ■ Dermatosis cenicienta

DISORDERS ASSOCIATED WITH POSTINFLAMMATORY HYPERPIGMENTATION	
Inflammatory disease	**Clinical clues**
Common	
Acne vulgaris	Head/neck region, upper trunk; <1 cm; perifollicular
Atopic dermatitis	Atopic diathesis; face and extensor extremities in infants, then later flexural involvement; excoriations; atopic pleats; xerosis; lichenification; transverse nasal crease ("allergic salute")
Impetigo	Favors face; most common in children
Insect bites	Favor exposed areas; usually <1 cm; lower extremities common with flea bites; clustered and sometimes linear patterns ("breakfast–lunch–dinner"; see Fig. 67.2B)
Lichen simplex chronicus	Common locations: posterior neck, ankle, scrotum
Transient neonatal pustular melanosis	Black neonates; pustules precede pigmentation (see Fig. 67.2C)
Less common	
Irritant and allergic contact and photocontact dermatitis	Sites determined by etiologic agent and form of exposure; phytophotodermatitis associated with linear hyperpigmentation in sun-exposed areas
Pityriasis rosea	Favors trunk and proximal extremities; lesions follow skin cleavage lines; oval-shaped
Psoriasis	Scalp/nail involvement; knees/elbows most common sites (see Fig. 67.2E)
Seborrheic dermatitis	Favors face (especially forehead, upper eyelids, nasolabial folds, mental fold), skin folds, and presternal area; scalp/ear involvement; may also have hypopigmentation
Polymorphous light eruption	Extensor upper extremities, mid upper chest, face; seasonal (e.g. spring or early summer)
Discoid lupus erythematosus	Face and conchal bowls, with follicular plugging in latter site; oral lesions; in scarred lesions, central hypopigmentation with rim of hyperpigmentation
Lichen planus	Wrists, shins, presacral; nail/oral involvement
Erythema dyschromicum perstans (EDP; ashy dermatosis)*	Neck, proximal upper extremities, trunk; round or oval in shape with gray–brown to blue–gray color; long axis can follow skin cleavage lines (similar to pityriasis rosea); less commonly observed in fair-skinned individuals
Idiopathic eruptive macular pigmentation*	Trunk, proximal extremities, neck, face; round or oval, discrete brown macules and small patches; sometimes barely elevated plaques with a subtle velvety texture; histologically, basal epidermal hyperpigmentation ± papillomatosis, with no vacuolar alteration and relatively few dermal melanophages compared to EDP; affects primarily children and adolescents, lasting months to years
Hyperpigmented macules on the forehead in infants*	Irregular brown macules on the forehead and temples; onset at age 2–24 months, with variable fading over several years; histologically, mild lymphocytic dermal infiltrate with melanophages
Fixed drug eruption	Circular; favors perioral, acral and genital sites; recurrence at same site(s) with repeated exposure (see Fig. 67.2D)
Morbilliform drug eruption	Widespread; usually discrete lesions, history of drug exposure
Viral exanthem	Widespread, usually with discrete lesions; history of associated symptoms; chikungunya fever: diffuse or reticulated hyperpigmentation, especially in infants, that characteristically includes the tip of the nose ("chik sign")
Morphea	Trunk or extremities; large-sized except in guttate variant; may be linear; associated induration and later dermal atrophy
Atrophoderma of Pasini and Pierini	Trunk; large-sized; depressed with "cliff sign" at periphery; no induration
Neurotic (psychogenic) excoriation, acne excoriée	Favors face, scalp, extensor surface of arms, upper back (reachable areas); linear or angular shapes; multiple stages of evolution, from erosions/ulcerations to scars
Flagellate erythema	Associated with bleomycin use, shiitake mushroom ingestion, dermatomyositis, and Still disease
*Typically no preceding inflammatory phase evident clinically or histologically.	

Table 67.2 Disorders associated with postinflammatory hyperpigmentation. Cutaneous injury (e.g. thermal burn, radiation therapy) may also result in localized postinflammatory hyperpigmentation. *Adapted from Bolognia JL. Disorders of hypopigmentation and hyperpigmentation. In: Harper J, Oranje A, Prose N (eds). Textbook of Pediatric Dermatology, 2nd edn. Oxford: Blackwell Science, 2006:997–1040.*

Key features

- Most common in individuals with skin phototypes III–IV
- Gray–brown to blue–gray macules and patches in a symmetric distribution
- Favors the neck, trunk, and proximal extremities
- A consistently effective treatment is not currently available

Introduction

Ramirez first described erythema dyschromicum perstans (EDP) in 1957, referring to affected individuals as *los cenicientos* (ashen ones). This is an asymptomatic, slowly progressive eruption that is characterized by circumscribed areas of dermal pigmentation[2].

Epidemiology

Although EDP occurs worldwide, it is most common in Latin America. There is no sex preference. The disorder usually presents during the second to third decade, but it occasionally develops in younger children or older adults.

Pathogenesis

The etiology of EDP is not known. Although it has been postulated that a cell-mediated immune reaction to an ingestant, contactant, or microorganism underlies the discrete areas of pigmentary incontinence, no causal agent has consistently been identified[2]. In most patients, a trigger is never found. However, there have been reports of EDP developing in association with the ingestion of ammonium nitrate, oral X-ray contrast media, and medications (e.g. benzodiazepines, penicillin, proton pump inhibitors, epidermal growth

Fig. 67.2 Postinflammatory hyperpigmentation (PIH). The lesions were caused by pemphigus foliaceus (**A**), insect bite reactions (**B**), transient neonatal pustular melanosis (**C**), a fixed drug eruption induced by trimethoprim-sulfamethoxazole (**D**), and psoriasis (**E**). Note the residual inflammation and "breakfast–lunch–dinner" configuration in **B**.

factor receptor inhibitors, cyclin-dependent kinase 4/6 inhibitors); exposure to various pesticides, fungicides or toxins; endocrinopathies such as thyroid disease; and whipworm and HIV infections. The presence of the HLA-DR4 allele may represent a risk factor for EDP in Mexican patients.

Clinical Features

Oval, circular, or irregularly shaped macules and patches that are 0.5 to 3 cm in diameter and slate-gray to blue–brown in color develop gradually in a symmetric pattern and may coalesce (Fig. 67.3A). The initial site of involvement is often the trunk, with subsequent spread to the neck, proximal upper extremities, and sometimes the face. The mucous membranes are spared, and the palms, soles, and scalp are rarely affected. Occasionally, early lesions have a thin, raised, erythematous border, which tends to resolve over a few months, and the long axis of lesions may follow skin cleavage lines. Peripheral hypopigmentation may be seen in older lesions. Characteristic dermoscopic features of EDP include pigmentation in the crista cutis and small brown to gray dots, described as having a "Wagyu beef-like" appearance[3].

EDP is usually asymptomatic but can be mildly pruritic. The disease progresses slowly and typically does not regress in adults. However, in one study of 33 prepubertal children, the majority of whom were White children, the disease spontaneously resolved in two-thirds, with no recurrences over the ensuing 2–3 years[4].

Pathology

In early ("active") lesions, vacuolar degeneration of the basal cell layer, a perivascular mononuclear cell infiltrate and melanophages in the upper dermis, and increased epidermal melanin are seen (Fig. 67.3B). Colloid bodies (apoptotic basal keratinocytes) and dermal hemosiderin may be present. In later ("inactive") lesions, the number of melanophages in the superficial dermis is increased but hydropic changes within the basal cell layer are absent and the dermal mononuclear cell infiltrate is minimal or absent.

Differential Diagnosis

Idiopathic eruptive macular hyperpigmentation (IEMH) features discrete brown macules and small patches with a distribution similar to that of EDP but with more prominent epidermal pigment. Some reports have noted a velvety surface and papillomatosis histologically[5,6] (see Table 67.2). Considering the substantial clinical and histologic overlap of EDP, IEMH, lichen planus pigmentosus, and pigmented contact dermatitis (see Table 67.3), the umbrella term *acquired dermal macular hyperpigmentation* has been proposed for this group of disorders[7,8]. The differential diagnosis of EDP also includes PIH secondary to a lichenoid drug eruption (see Ch. 11), lichen planus, or a generalized fixed drug eruption as well as mastocytosis and (less often) infectious diseases such as leprosy or pinta.

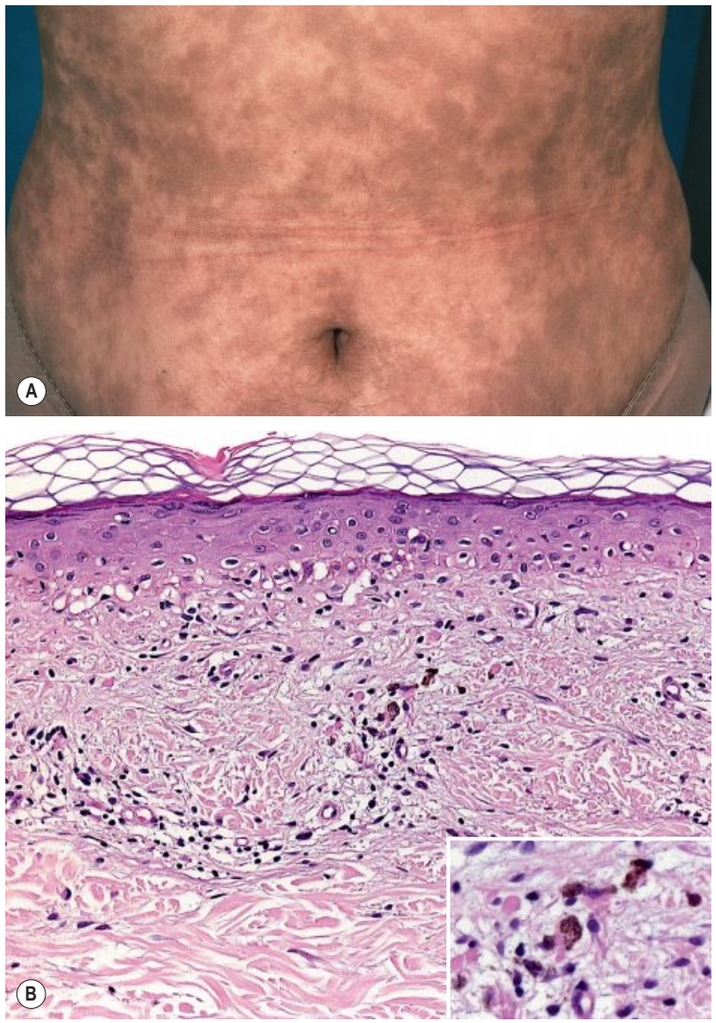

Fig. 67.3 Erythema dyschromicum perstans (ashy dermatosis). A Multiple gray–brown macules and patches on the abdomen; note the coalescence of lesions. The "ashy" color is characteristic. **B** Histopathologic features include vacuolar degeneration of the basal layer, a sparse perivascular lymphocytic infiltrate, and prominent dermal melanophages (see inset). *B, Courtesy Lorenzo Cerroni, MD.*

Treatment

There is no consistently effective therapy for EDP. Topical corticosteroids and hydroquinone are generally of no benefit. Successful treatment with topical tacrolimus, narrowband UVB phototherapy, and oral dapsone, clofazimine, or isotretinoin has been reported in small series.

LICHEN PLANUS PIGMENTOSUS

Key features

- Variant of lichen planus most commonly described in adults with skin phototypes III–V
- Gray–brown to dark brown macules and patches either in a photodistribution or in an inverse (intertriginous) pattern

Lichen planus pigmentosus (LPP) is an uncommon variant of lichen planus that most often affects young to middle-aged adults with skin phototypes III–V, including those from India, Latin America, and the Middle East[9,10]. It presents as irregularly shaped or oval, brown to gray–brown macules and patches that favor sun-exposed areas (especially the forehead, temples, and neck) as well as intertriginous zones (Fig. 67.4). It is usually asymptomatic, but some patients experience mild pruritus or burning. In contrast to EDP, early lesions with an erythematous border are not a feature of LPP.

Fig. 67.4 Lichen planus pigmentosus. Multiple coalescing brown to gray–brown macules in the axilla of a middle-aged woman.

Diffuse, reticulated, blotchy, and follicular patterns of LPP have all been described[9]. While the distribution is typically symmetric, a unilateral linear variant has also been reported. The palms, soles, nails, and oral mucosa are usually not involved. Other lichen planus variants, including frontal fibrosing alopecia, can be observed in ~15%–20% of patients with LPP[10]. Histologic findings include a flattened, often atrophic epidermis with basal cell degeneration and a variably dense, band-like, or perivascular lymphoid infiltrate in the upper dermis admixed with melanophages.

The etiology of LPP is unknown. The photodistribution in some patients suggests that UV exposure may play a pathogenic role. Possible associations with hepatitis C viral infection and the use of mustard oil, amla oil, henna, or hair dyes has also been reported[9]. The differential diagnosis includes other forms of acquired dermal macular hyperpigmentation (e.g. EDP, pigmented contact dermatitis) and PIH, especially that due to actinic and inverse variants of lichen planus or a lichenoid drug eruption (see Ch. 11). When there is facial involvement, melasma and the entities listed in Table 67.3 also need to be considered.

LPP is a chronic disorder with exacerbations and remissions. Treatment is often ineffective, although some patients may respond to topical tacrolimus, oral dapsone, and low-dose isotretinoin[9]. Depending upon the distribution, photoprotection is recommended.

MELASMA

Synonyms: ■ Chloasma ■ Mask of pregnancy

Key features

- At least 90% of patients are women
- Increased prevalence in individuals who are Hispanic, or of Asian or African descent
- Most common location is the face, followed by the forearms
- Symmetric patches of hyperpigmentation with irregular borders due to increased melanin within the epidermis and/or dermis

Introduction and Epidemiology

Melasma is a common acquired disorder characterized by symmetric, hyperpigmented patches with an irregular outline, occurring most commonly on the face. It is most prevalent among young to middle-aged women who are Hispanic, Black, or of Asian or Middle Eastern descent. Exacerbating factors include sun exposure, pregnancy, and use of oral contraceptives.

DIFFERENTIAL DIAGNOSIS OF MELASMA	
Disorder	**Key differences from melasma/comments**
Drug-induced hyperpigmentation or discoloration	• History of medication use (e.g. doxycycline, amiodarone; see Table 67.5) • Hyperpigmentation less patterned and less irregular in outline; may involve tip of nose • Discrete oval or round shape of fixed drug eruption rarely confused with melasma • May follow phototoxic drug reaction • Oral contraceptives and phenytoin may exacerbate melasma
Postinflammatory hyperpigmentation, e.g. due to cutaneous lupus erythematosus, photosensitivity reactions, contact dermatitis (e.g. irritant contact dermatitis to hydroquinone or tretinoin), or other forms of dermatitis	• History of inflammatory phase with erythema, scale, and possible pruritus or burning • Primary lesions – may be admixed or elsewhere on body
Pigmented contact dermatitis (Riehl melanosis)	• Favors sites of application of contactants, especially cosmetics; reported due to masks with a sponge insert • May be reticulated • Brown–grey color due to dermal melanin deposits • Histologic features: vacuolar degeneration of basal layer and lichenoid infiltrate in early lesions
Acquired bilateral nevus of Ota-like macules (Hori nevus)	• Asian women, usually during the fourth or fifth decade of life • Multiple brown–gray to brown–blue macules, primarily in the malar region • Less common sites: lateral forehead, temples, upper eyelids, nasal root, or alae • Lack of ocular or mucosal involvement • Histologic features: pigment-producing dermal melanocytes
Actinic lichen planus	• Fine scale overlying violaceous lesions if inflammatory phase still present • Histologic features: hydropic degeneration of basal layer, lichenoid infiltrate
Lichen planus pigmentosus	• Often begins on the temples/in the preauricular area and involves the neck • Coexistent classic lichen planus (~20% of patients) • Histologic features: vacuolar degeneration of basal layer; variable lichenoid infiltrate and epidermal atrophy
Erythema dyschromicum perstans	• Inflammatory phase with rim of erythema occasionally seen • Lesions slate-gray to blue–brown • Distribution includes sun-protected areas
Exogenous ochronosis	• History of hydroquinone application to areas of hyperpigmentation followed by progressive darkening • Superimposed small pigmented papules may also be seen • Histologic features: banana-shaped, yellow–brown deposits in the dermis (see Fig. 67.8)
Cutaneous mercury deposits	• History of use of mercury-containing soaps or creams • Dermatitis often present • Histologic features: brown–black granules free in dermis, in association with elastic fibers and within macrophages
Erythromelanosis follicularis faciei et colli	• Red–brown patches on lateral cheeks and neck • Superimposed tiny pale follicular papules
Poikiloderma of Civatte	• Presence of atrophy and telangiectasias • Favors lateral and inferior aspects of anterior neck; sparing of perifollicular skin and submental region
Acanthosis nigricans	• Velvety plaques in the hollow of the cheek and preauricular

Table 67.3 Differential diagnosis of melasma.

Pathogenesis

Although the exact pathogenesis of melasma is unknown, it is hypothesized that following exposure to UV irradiation or another inducer, hyperfunctional melanocytes within involved skin produce increased amounts of melanin[11,12]. The key role of UV irradiation is supported by fading of lesions during winter months and a distribution pattern characterized by involvement of sun-exposed regions with sparing of relatively sun-protected sites such as the philtrum. In addition to oral contraceptive use and hyperestrogenic states, other medications (e.g. phenytoin, phototoxic drugs) and disorders (e.g. autoimmune thyroid disease) have the potential to aggravate melasma. Increased expression of KIT and stem cell factor within lesional epidermis and dermis, respectively, may play a role in the hyperpigmentation of melasma[13]. Furthermore, reduced expression of Wnt-inhibitory factor 1 (WIF-1) and microRNAs may lead to tyrosinase upregulation via increased Wnt signaling[13a].

The presence of enhanced blood flow within areas of melasma has also been investigated. An increase in both blood vessel size and density has been observed that correlates with the increase in pigmentation. When compared to perilesional normal skin, increased expression of vascular endothelial growth factor (VEGF) was detected within lesional skin. These findings have led to alternative therapeutic strategies.

Clinical Features

Light to dark brown or brown–gray patches with irregular borders appear primarily on the face (Fig. 67.5). The areas of hypermelanosis are distributed symmetrically in three classic patterns: (1) *centrofacial* (most common), involving the forehead, cheeks, nose, upper lip (sparing the philtrum and nasolabial folds), and chin; (2) *malar*, affecting the cheeks and nose; and (3) *mandibular*, along the jawline. Less common sites include the extensor aspect of the forearms and mid upper chest. Lesions often first appear or are accentuated following exposure to UV irradiation or during pregnancy. In lightly pigmented individuals, this "mask of pregnancy" frequently diminishes or disappears after parturition, but it tends to persist in women with more darkly pigmented skin.

Melasma has classically been subdivided into four types based upon the primary location of the pigment: epidermal, dermal, mixed, or indeterminate (e.g. in patients with very dark skin pigmentation). In theory, lesions with increased epidermal melanin are accentuated and those with increased dermal melanin become less obvious (i.e. blend with uninvolved skin) with Wood's lamp examination. However, clinicopathologic studies utilizing adjacent uninvolved skin as controls have shown that Wood's lamp examination does not correlate with histologic findings[12,14]. Considering that epidermal pigmentation is more likely to respond to topical therapies, further studies are needed to determine the

Fig. 67.5 Various forms of melasma and melasma-like hyperpigmentation. A Malar variant. **B** Mild centrofacial type with sparing of the philtrum. **C** Extension of the hyperpigmentation onto the mandible. **D** Involvement of the extensor forearm; note the same irregular outline as is seen on the face. **E** Melasma-like appearance in a patient with previous acute cutaneous lupus erythematosus. *C–E, Courtesy Jean L. Bolognia, MD.*

clinical utility and prognostic significance of Wood's lamp examination and perhaps optical coherence tomography.

Pathology

Compared to uninvolved adjacent skin, increased melanin deposition is observed in all layers of the epidermis, particularly the basal layer. An increased number of melanophages may also be seen in the upper dermis. Epidermal melanocytes are normal to slightly increased in number, and they are enlarged with prominent dendrites[12,14].

Ultrastructurally, lesional melanocytes contain an increased number of melanosomes. In addition, the mitochondria, Golgi apparatus, and rough endoplasmic reticulum are increased in number. These findings support the theory of hyperfunctional melanocytes, presumably stimulated by UV irradiation or hormones (see Pathogenesis above).

Differential Diagnosis

The differential diagnosis of melasma is reviewed in Table 67.3. These disorders are distinguished from melasma based upon historical aspects (e.g. drug ingestion, previous inflammation), color, distribution pattern, histologic features, and, if present, primary inflammatory lesions.

Treatment

The treatment of melasma is summarized in Table 67.4. Diligent sun protection and patient motivation are necessary for any melasma treatment regimen to be successful. For epidermal melasma, 2 months of therapy are typically required to initiate lightening and 6 months of treatment are often needed to achieve satisfactory results.

ADDITIONAL FORMS OF CIRCUMSCRIBED HYPERPIGMENTATION

Segmental Pigmentation Disorder

This term was coined by Metzker et al. in 1983 and re-introduced by Hogeling and Frieden in 2010[15]. This block-like pattern of hyper- or hypopigmentation represents a type of pigmentary mosaicism, i.e. a postzygotic genetic alteration leading to a regional change in pigment production potential (Fig. 67.6; see Ch. 62). The hyperpigmented patches are evident at birth or become apparent during infancy. They favor the trunk, with midline demarcation more often evident ventrally than dorsally and less distinct lateral borders. There are usually no associated extracutaneous anomalies.

Familial Progressive Hyperpigmentation

Familial progressive hyperpigmentation is an autosomal dominant disorder characterized by hyperpigmented patches in a widespread distribution including the palms, soles, lips, and conjunctiva. The lesions begin to develop during infancy and increase in size, number, and confluence with age. Heterozygous gain-of-function mutations in the KIT ligand gene (*KITLG*) can cause this condition[16] as well as *familial progressive hyper- and hypopigmentation*, which has the additional finding of hypopigmented macules and patches.

GIST-Cutaneous Hyperpigmentation Disease

Familial gastrointestinal stromal tumors (GISTs), which are derived from the interstitial cells of Cajal in the stomach or small intestine, can result from germline heterozygous gain-of-function *KIT* mutations. Affected individuals (typically with mutations in codon 11 or 13) may also develop hyperpigmented patches or multiple lentigo-like macules, referred to as GIST–cutaneous hyperpigmentation disease[17]. The hyperpigmentation is progressive and favors the face, acral areas, the anogenital region, and sites of friction or trauma. It is usually apparent at birth or by early childhood, thus preceding the development of GIST, and may eventually become generalized. Treatment with imatinib has been reported to improve the hyperpigmentation as well as GIST[18].

Primary (Localized) Cutaneous Amyloidosis

Macular and lichenoid forms of primary (localized) cutaneous amyloidosis are associated with hyperpigmentation (see Ch. 47). The most common locations are the upper back (macular amyloidosis) or the extensor surface of the lower extremities (lichen amyloidosis), and there is a characteristic rippled pattern with parallel bands or ridges of hyperpigmentation. Areas of involvement are often pruritic, and rubbing plays a key role in the production of lesions. Histologically,

TREATMENT OPTIONS FOR MELASMA
Recommendations for all patients
• Avoidance of sun exposure and tanning beds • Daily use of broad-spectrum sunscreen (ideally SPF ≥30 with physical blocker such as zinc oxide or titanium dioxide) • Sun-protective hats and clothing • Camouflage makeup (with iron oxide to block visible light) • Discontinue oral contraceptives, if possible
Active treatment*,†
First-line topical therapies • Triple combination of HQ + retinoid + corticosteroid‡ at bedtime • 4% HQ daily, typically at bedtime • Azelaic acid (15%–20%) **Adjunctive topical therapies** • L-ascorbic acid (10%–15%) • Kojic acid (1%–4%) • Tranexamic acid (2%–5%) • Niacinamide (4%) **Adjunctive oral therapies** • Tranexamic acid (250 mg BID for 8–12 weeks)¶ **Second-line therapies** • Glycolic (start at 30% and increase as tolerated) or salicylic acid peels (20%–30%) every 4–6 weeks **Third-line therapies§** • Non-ablative fractional laser • Intense pulsed light (IPL) • Low fluence Q-switched lasers • Picosecond lasers
Long-term maintenance
• Continue daily sunscreen and sun-protective measures (see above) • Topical retinoid • Topical α-hydroxy acid (e.g. glycolic acid cream) • Other topicals, e.g. L-ascorbic acid (10%–15%), azelaic acid (15%–20%), kojic acid (1%–4%), tranexamic acid (2%–5%)
*Results from topical treatments may take up to 6 months to appreciate; depending on the patient, HQ or a combination HQ + retinoid + corticosteroid are typically used daily for 2–4 months and then decreased in frequency to 1–2 times per week; prolonged daily use can result in side effects such as perioral dermatitis and atrophy (corticosteroid) or exogenous ochronosis (HQ; see Ch. 129). †While topical HQ can cause allergic contact dermatitis, all topical agents may lead to irritant contact dermatitis, which can worsen the dyspigmentation; if this is a concern, can test on a small, non-facial site prior to widespread facial application. ‡Typically a class 5–7 topical corticosteroid is used (see Ch. 125). ¶Patients should be screened for history of and risk factors for thromboembolism. §Potential risk of post-procedural dyspigmentation; a small test site should be performed prior to widespread facial laser or light therapy.

Table 67.4 Treatment options for melasma. HQ, hydroquinone.

Fig. 67.6 Segmental pigmentation disorder. Unilateral block-like hyperpigmentation on the chest, abdomen, and upper arm of an infant. Note the midline demarcation inferiorly. *Courtesy Julie V. Schaffer, MD.*

melanophages as well as amyloid deposits that stain positively with anti-keratin antibodies are seen within the upper dermis.

Mastocytosis

Cutaneous mastocytosis is characterized by the accumulation of mast cells within the skin and sometimes other organs (see Ch. 118). The maculopapular form of mastocytosis classically features hyperpigmented lesions, with patients developing a few to several hundred brown to red–brown macules and papules ("urticaria pigmentosa"). Mastocytomas can also have a light brown color. Lesions of cutaneous mastocytosis typically urticate after they are stroked (Darier's sign), and an increased number of mast cells is seen in biopsy specimens. The hyperpigmentation in mastocytosis is thought to result from stimulation of melanocytes by mast cell-derived mediators such as KIT ligand or α-melanocyte-stimulating hormone[19]. Somatic activating mutations in *KIT* often underlie mastocytosis in both children and adults. Whereas the prognosis for childhood-onset mastocytosis is good, with spontaneous resolution by adolescence in many patients, adult-onset disease is frequently persistent (see Ch. 118).

Tinea (Pityriasis) Versicolor

Tinea versicolor is a superficial skin infection caused by the yeast *Malassezia globosa* and other *Malassezia* spp. (see Ch. 77). Hypo- or hyperpigmented macules or very thin papules and plaques covered with fine scale are usually found on the upper trunk and proximal upper extremities but may also appear in other sites such as the neck, face, and groin. There is often coalescence of lesions centrally, especially on the trunk. In light and electron microscopy studies, a similar number of melanocytes was noted in uninvolved skin as in hypo- and hyperpigmented lesions; the latter had a thickened stratum corneum that contained more organisms. The clinical differential diagnosis for the hyperpigmented form of tinea versicolor may include PIH and confluent and reticulated papillomatosis, but a KOH preparation of the scale showing both hyphal and yeast forms of *Malassezia* distinguishes tinea versicolor from these entities.

Atrophoderma of Pasini and Pierini

Atrophoderma of Pasini and Pierini is usually seen in young adults and has been postulated to represent an atrophic form of morphea (see Ch. 99). Most often, multiple oval hyperpigmented patches measuring 4–10 cm in diameter appear on the posterior trunk. There is a subtle depression of the entire lesion, but no induration or secondary changes. The depression can be appreciated by palpation of the edge of the lesion, with a characteristic "cliff sign" at the peripheral margin.

PIGMENTED LESIONS

Lentigines

Lentigines are reviewed in Chapters 109 and 112.

Café-au-Lait Macules

Café-au-lait macules (CALMs) are hyperpigmented macules or patches two to three shades darker than uninvolved skin (see Ch. 112). They are found in at least 10% of the population. CALMs may be evident at birth or, especially in individuals with lightly pigmented skin, become apparent during infancy or early childhood. The presence of multiple CALMs raises the possibility of neurofibromatosis type 1 or another genetic syndrome (see Table 61.3); Fig. 61.10 outlines an approach to a young child with multiple CALMs. A CALM is usually easily distinguished from a fully developed congenital melanocytic nevus, but in infants there may be overlap in the clinical appearance of these two entities. The differential diagnosis also includes the earliest stage of a nevus spilus (before the "speckles" appear), Becker melanosis (nevus) or smooth muscle hamartoma, and a mastocytoma; in addition, segmental CALMs and "pigmentary mosaicism" have significant overlap. Although laser treatment of CALMs is possible (see Ch. 137), responses vary and recurrence of pigmentation is common.

DRUG-INDUCED HYPERPIGMENTATION OR DISCOLORATION

Key features

- Localized or generalized hypermelanosis or discoloration may be seen
- Several medications and drug classes are known to induce hyperpigmentation or discoloration, especially minocycline, antimalarials, chemotherapeutic agents, and zidovudine
- Longitudinal, transverse, or diffuse melanonychia may also be present

Cutaneous hypermelanosis or discoloration can result from exposure to chemicals and a wide range of medications, most commonly chemotherapeutic agents, antimalarials, minocycline, and zidovudine (Table 67.5, Figs. 67.7–67.9). The underlying mechanisms vary from induction of melanin production to deposition of drug complexes or heavy metals within the dermis. The pigmentation can be circumscribed or generalized. Although it usually resolves with discontinuation of the offending drug, the course may be prolonged. Longitudinal, transverse, or diffuse melanonychia and oral mucosal pigmentation may also be observed.

ADDITIONAL FORMS OF DIFFUSE HYPERPIGMENTATION

In addition to medications, diffuse hyperpigmentation can be caused by metabolic abnormalities, nutritional deficiencies, and several inherited and acquired syndromes. An approach to the patient with diffuse hyperpigmentation is provided in Fig. 67.10.

DRUGS AND CHEMICALS ASSOCIATED WITH HYPERPIGMENTATION OR DISCOLORATION

Drug or chemical	Clinical features	Histopathology/comment
Chemotherapeutic agents (see Ch. 21)		
BCNU (carmustine)	• Hyperpigmentation at sites of topical application (not with parenteral administration)	• Hyperplasia of basal melanocytes • Increased melanin within the epidermis
Bleomycin (intravenous or intralesional)	• Linear, flagellate bands that favor the trunk and may be associated with minor trauma (see text) • Transverse melanonychia • Hyperpigmentation overlying joints/pressure points or localized to striae and palmar creases • Sclerodermoid changes	• Increased epidermal melanin but no increase in the number of melanocytes • Usually relatively few dermal melanophages
Busulfan	• Generalized hyperpigmentation resembling Addison disease; sometimes associated with drug-induced pulmonary fibrosis	• Increased melanin within basal keratinocytes and dermal macrophages
Cyclophosphamide	• Diffuse hyperpigmentation of the skin and mucous membranes • Pigment localized to the nails (transverse, longitudinal, or diffuse melanonychia), palms and soles, or teeth	• Cutaneous hyperpigmentation usually regresses within 6 to 12 months after therapy is discontinued
Dactinomycin	• Generalized hyperpigmentation, most prominent on the face	• Pigmentation fades after treatment is discontinued
Daunorubicin	• Hyperpigmentation of sun-exposed areas • Transverse brown–black melanonychia	
Doxorubicin	• Hyperpigmentation overlying the small joints of the hands and involving the palms (especially the creases), soles, and oral mucosa (buccal, tongue) • Transverse melanonychia	• Increased epidermal melanin • Increased number of melanocytes
5-Fluorouracil	• Hyperpigmentation in sun-exposed areas (~5% of patients treated systemically; often follows an erythematous photosensitivity reaction) • Increased pigmentation of skin overlying veins in which the drug was infused • Other sites include the dorsal aspects of the hands, palms/soles, and radiation ports • Transverse or diffuse melanonychia; lunular pigmentation	• Postinflammatory hyperpigmentation • Capecitabine (the 5-fluorouracil prodrug) may also lead to acral or oral hyperpigmentation
Hydroxyurea	• Reversible hyperpigmentation over pressure points and on the back • Longitudinal, transverse, or diffuse melanonychia; lunular pigmentation	• Lichenoid eruption with postinflammatory hyperpigmentation can also occur
Imatinib (also dasatinib, gefitinib)	• Localized or diffuse hyperpigmentation (<5% of patients) • Diffuse melanonychia, repigmentation of gray hair, and pigmentation of the gingiva and teeth	• Localized or diffuse hypo- or depigmentation is more common (40%–60% of darkly pigmented patients)
Mechlorethamine (nitrogen mustard)	• Topical use for cutaneous T cell lymphoma may result in generalized hyperpigmentation • More intense in lesional skin	• Disaggregation of melanosomes within keratinocytes • Increased number of melanocytes

Table 67.5 Drugs and chemicals associated with hyperpigmentation or discoloration.

Continued

DRUGS AND CHEMICALS ASSOCIATED WITH HYPERPIGMENTATION OR DISCOLORATION		
Drug or chemical	**Clinical features**	**Histopathology/comment**
Methotrexate	• Uniform hyperpigmentation in sun-exposed areas (occasionally follows an erythematous photosensitivity reaction)	• Uncommon
Antimalarials		
Chloroquine, hydroxychloroquine, quinacrine	• Gray to blue–black pigment, usually pretibial, with (hydroxy) chloroquine; face, hard palate, sclerae, and subungual areas may be involved • Diffuse yellow to yellow–brown discoloration with quinacrine • Discoloration affects up to 25% of patients	• Dermal deposition of melanin–drug complexes; hemosiderin around capillaries • May fade after discontinuation of drug, but rarely resolves completely
Heavy metals		
Arsenic	• Areas of bronze hyperpigmentation ± superimposed "raindrops" of lightly pigmented skin; favors axillae, groin, palms, soles, nipples, and pressure points • Dyspigmentation appears 1–20 years after arsenic exposure, with a strong dose–response relationship • Palmoplantar keratoses and squamous cell carcinoma typically develop after dyspigmentation (see Ch. 88)	• Dermal and epidermal deposition of arsenic • Increased epidermal melanin synthesis
Bismuth	• Generalized blue–gray discoloration of the face, neck and dorsal hands • Oral mucosa and gingivae may be involved	• Bismuth granules in the papillary and reticular dermis
Gold (chrysiasis)	• Permanent blue–gray discoloration in sun-exposed areas, particularly around the eyes	• Gold particles within lysosomes in dermal macrophages, especially in perivascular and perieccrine areas
Iron	• Permanent brown pigment at injection sites or in areas of application of ferric subsulfate (Monsel's) solution as a hemostatic agent • Dermal hemosiderin deposits (due to lysis of extravasated red blood cells and release of their iron stores) are commonly observed in the setting of venous hypertension, in pigmented purpuric dermatoses, and as a side effect of sclerotherapy of superficial veins	• Pigment coats collagen fibers and is deposited in dermal macrophages
Lead	• "Lead line" in gingival margin • Nail discoloration	• Lead line is due to subepithelial deposition of lead granules
Mercury	• Slate-gray discoloration, particularly in skin folds	• Brown–black granules free in dermis, in association with elastic fibers and within macrophages
Silver (argyria)	• Diffuse slate-gray discoloration (see Fig. 67.7A), increased in sun-exposed areas; occurs in settings of occupational exposure, alternative medications, or systemic absorption from use of silver sulfadiazine on extensive burns/wounds • The nail unit (diffuse or localized to the lunulae) and sclerae may also be affected • Sites of topical application, e.g. of silver sulfadiazine to burns or ulcers	• Silver granules in the basement membrane of eccrine glands; also often seen in elastic fibers, in the tissue around hair follicles, and in arrector pili muscles; highlighted by darkfield illumination (see Fig. 67.7B)
Hormones		
Oral contraceptives	• Melasma; increased pigmentation of nipples and nevi	• Increased melanocytes and increased melanin synthesis
ACTH/MSH (ACTH is rarely used; [NIe4-D-Phe7]-α-MSH/afamelanotide orphan drug for EPP)	• Diffuse brown or bronze hyperpigmentation, accentuated in sun-exposed sites	• Increased melanin synthesis
Miscellaneous compounds		
Amiodarone	• Slate-gray to violaceous discoloration of sun-exposed skin, especially the face (less common than erythema from photosensitivity) • Fair-skinned patients after long-term, continuous therapy	• Yellow–brown granules in dermal macrophages, mostly in a perivascular distribution • By EM, lysosomal inclusions composed of a lipid-like substance • Usually fades completely over months to years after discontinuation of drug, but sometimes persists
Azidothymidine (zidovudine, AZT)	• Longitudinal > transverse and diffuse melanonychia (up to 10% of patients); blue lunulae • Mucocutaneous hyperpigmentation (e.g. widespread diffuse, acral, oral macules); most common in patients with darkly pigmented skin, and may be accentuated in areas of friction or sun exposure	• Skin biopsy shows increased melanin in the epidermis and dermal melanophages • Fades gradually after drug is discontinued

Table 67.5 Drugs and chemicals associated with hyperpigmentation or discoloration.

DRUGS AND CHEMICALS ASSOCIATED WITH HYPERPIGMENTATION OR DISCOLORATION		
Drug or chemical	**Clinical features**	**Histopathology/comment**
Clofazimine	• Diffuse red to red–brown discoloration of skin, conjunctivae • Violet–brown to blue–gray discoloration, especially of lesional skin	• Red color secondary to drug in fat (highly lipophilic) • Blue–violet color secondary to brownish granular pigment within dermal macrophages • By EM, phagolysosomes contain amorphous granular material and lamellar structures characteristic of lipofuscin • Fades gradually after discontinuation of drug
Diltiazem (rarely amlodipine)	• Slate-gray to gray–brown discoloration of sun-exposed skin in patients with skin phototypes IV–VI; perifollicular accentuation and a reticular pattern may be observed	• Sparse lichenoid infiltrate and numerous dermal melanophages
Dioxins	• Hyperpigmentation may occur in sun-exposed areas • Chloracne is a more common skin finding	• Rare, except in accidental exposure
Eltrombopag (thrombopoietin receptor agonist)	• Subtle grey discoloration, usually on sun-exposed areas	• Dermal deposition of Fontana-Masson- and Prussian blue-positive brown granules
Ezogabine/retigabine (anticonvulsant no longer available in the US)	• Blue–gray discoloration, most often lips, face, nail beds, and hard palate • Black pigment deposits on conjunctivae	• Permanent vision changes • Perivascular and periadnexal intracellular deposits of coarse melanin granules
Gardenia fruit (herbal medicine)	• Blue–gray discoloration of face and chest • Diffuse and patchy	• Mesenteric phlebosclerosis • Dermal melanophages • Ionized genipin, a metabolite of geniposide, detected by ToF-SIMS
Hydroquinone	• Hyperpigmentation in areas of application due to irritant contact dermatitis (i.e. postinflammatory) or exogenous ochronosis; the latter may also result in small "caviar-like" papules	• In exogenous ochronosis, yellow–brown banana-shaped fibers in papillary dermis (see Fig. 67.8)* • Presumed mechanism is metabolism by melanocytes of hydroquinone into ringed structures that serve as precursors of ochronotic fibers • May fade upon discontinuation of hydroquinone; variable improvement with pigment-directed Q-switched lasers
Interferon-α	• Hyperpigmentation of the oral mucosa and face • Longitudinal melanonychia	• More common in patients with darkly pigmented skin and sun exposure
Minocycline	• *Type I:* blue–black discoloration in sites of inflammation and scars, including those due to acne or ablative laser therapy (see Fig. 127.7A) • *Type II:* blue–gray macules/patches (1 mm–10 cm in size) within previously normal skin, most often on the shins (see Figs. 67.9 & 127.7B–D); sometimes misdiagnosed as ecchymoses • *Type III:* diffuse "muddy brown" pigmentation that is most prominent in sun-exposed areas • Blue–black discoloration may also involve nails, sclerae, oral mucosa, bones, thyroid, and teeth	• Iron-containing (types I, II) or melanin-containing (type II) pigment granules within the dermis†; the former can be intra- or extracellular and may represent hemosiderin and/or a minocycline derivative plus chelated iron • Increased melanin within the basal epidermis and/or dermal melanophages (type III) • Minocycline is a highly lipid-soluble, yellow, crystalline material that turns black with oxidation • Fades after discontinuation of medication, but may take months or even years; for types I and II, treatment with Q-switched pigment-directed lasers (similar to tattoo removal) may decrease the discoloration
Nicotine (smoker's melanosis)	• Localized brown hyperpigmentation of oral mucosa, favoring gingiva and lips	• May fade upon cessation of smoking
Psoralens	• Diffuse hyperpigmentation after exposure to UVA light following oral administration (PUVA) • Circumscribed or linear streaks of hyperpigmentation can be seen with topical exposure, e.g. topical PUVA or phytophotodermatitis (exposure to psoralen-containing plants plus sunlight)	• Proliferation of follicular melanocytes, with increased synthesis and transfer of melanin • Singly dispersed melanosomes within keratinocytes • Psoralens are furocoumarin compounds originally derived from plants
Psychotropic drugs (chlorpromazine, thioridazine, imipramine, desipramine, amitriptyline)	• Slate-gray to brown (with amitriptyline) discoloration in sun-exposed areas	• Golden-brown granules in the upper dermis • Electron-dense inclusion bodies
Prostaglandin analogues (bimatoprost, latanoprost)	• Periocular reddish-brown to brown hyperpigmentation, hyperpigmentation of iris	• Increased melanin within the basal epidermis and dermal melanophages

*Similar histologic findings are seen in alkaptonuria (also referred to as ochronosis), an autosomal recessive disease caused by deficiency in homogentisic acid oxidase, which results in accumulation of homogentisic acid in the tissues; this insoluble pigment binds to collagen and leads to blue–black discoloration (e.g. of the helices and sclerae; see Ch. 63).
†Occasionally, the type I clinical pattern shows a calcium-containing melanin-like substance but no iron; in addition, both iron and melanin deposits have been described in pigmentation within pre-existing leprosy lesions.

Table 67.5 Drugs and chemicals associated with hyperpigmentation or discoloration. LINEAR HYPERPIGMENTATION

Linear hyperpigmentation can have a variety of etiologies, including postinflammatory changes, drug reactions, and mosaic genetic alterations that result in hypermelanosis along the lines of Blaschko (see Ch. 62). Pigmentary demarcation lines reflect normal dorsal–ventral patterning of the skin. In the evaluation of a patient with linear hyperpigmentation, an initial step is to determine whether or not the hypermelanosis follows the lines of Blaschko.

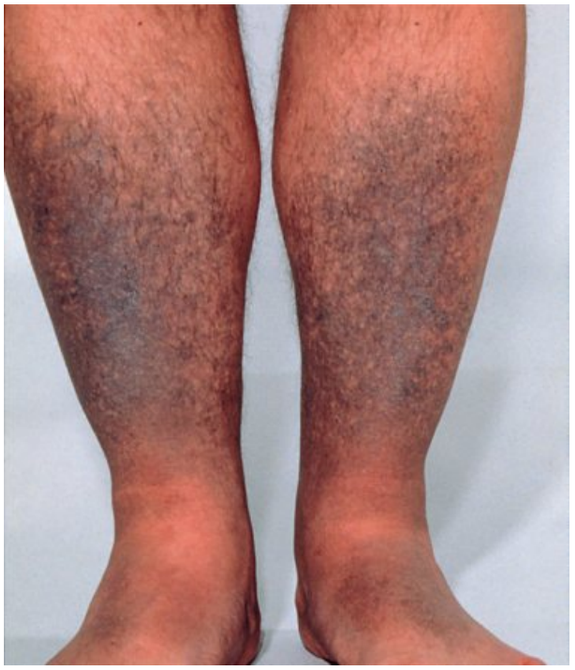

Fig. 67.9 Minocycline-induced pigmentation. The distribution on the shins and the gray–blue color can be similar to that seen with antimalarials.

PIGMENTARY DEMARCATION LINES

Synonyms: ■ Futcher lines ■ Voight lines ■ Ito lines

Key features

- Lines of demarcation between dorsal surfaces (which are relatively hyperpigmented) and ventral surfaces
- Physiologic pattern of human pigmentation
- More often apparent in individuals with darkly pigmented skin
- Most commonly seen on the anterolateral upper arm and posteromedial thigh

Introduction

In all skin types, the dorsal skin surfaces are relatively hyperpigmented compared to the ventral surfaces. In individuals with darkly pigmented skin, visible lines of demarcation between dorsal and ventral surfaces are more conspicuous, especially on the anterolateral portion of the upper arm (Fig. 67.11A). These demarcation lines are bilateral, symmetric, and present from infancy through adulthood. Additional lines occur on the posteromedial aspect of the thighs (Fig. 67.11B), upper chest (Fig. 67.11C), paraspinal region of the back, and face (Table 67.6; Fig. 67.12).

Differential Diagnosis

PIH may occasionally be confused with pigmentary demarcation lines types A, B, D, and F–H. However, in the latter there is no preceding inflammation or injury and the lines are perfectly symmetric and stable over time. Types C and E pigmentary demarcation lines may be confused with linear nevoid hypopigmentation. Linea nigra, the linear hyperpigmentation that extends from the umbilicus to the pubis in pregnant women (see Fig. 27.11A), is easily distinguished from a pigmentary demarcation line.

Treatment

These are normal pigmentation patterns, and no treatment is indicated.

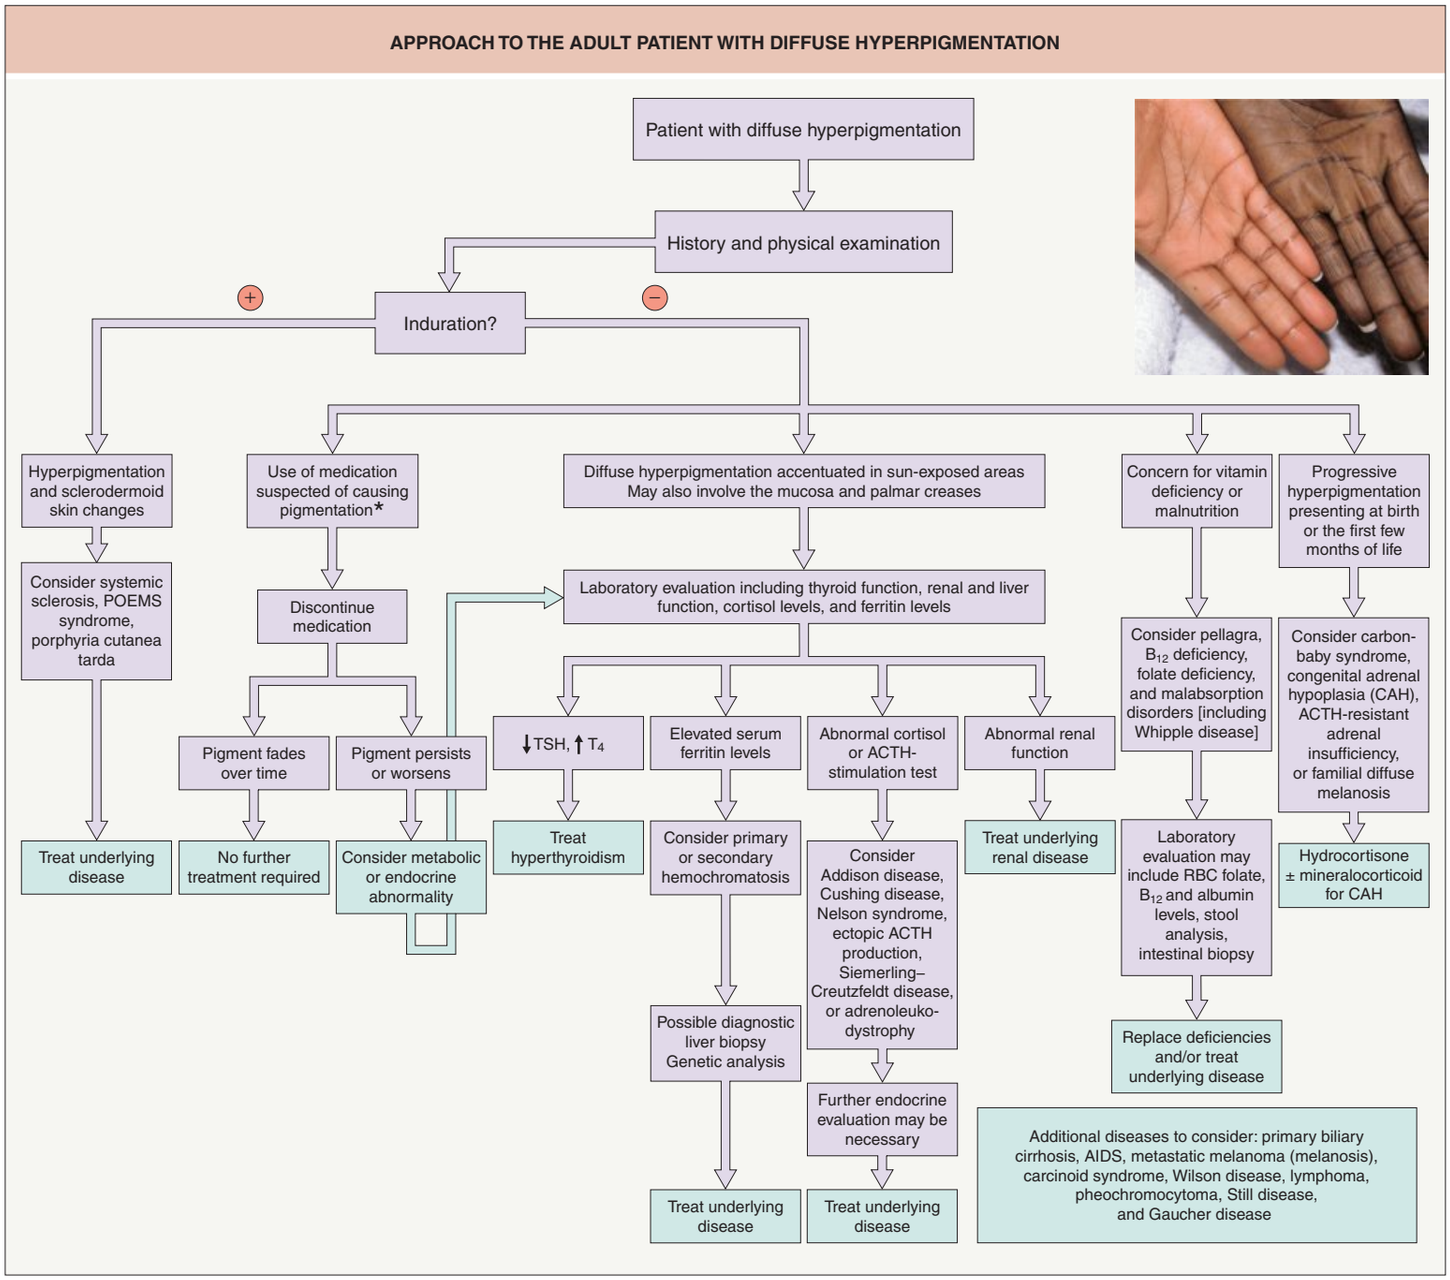

Fig. 67.10 Approach to the adult patient with diffuse hyperpigmentation. The palm on the right in the inset photograph shows diffuse hyperpigmentation in a patient with POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal gammopathy and *s*kin lesions). ACTH, adrenocorticotropic hormone; T_4, thyroxine; TSH, thyroid-stimulating hormone. *See Table 67.5 for drugs and chemicals associated with diffuse hyperpigmentation.

LINEAR POSTINFLAMMATORY HYPERPIGMENTATION

PIH is the most common cause of acquired hyperpigmentation, with the circumscribed variant (see above) seen more often than diffuse or linear forms. In general, PIH is more clinically apparent in individuals with darkly pigmented skin than in those with lightly pigmented skin.

Clinical Features

Linear PIH can occur following skin injuries, dermatitis, and other inflammatory conditions with a linear pattern, e.g. phytophotodermatitis (Table 67.7; Fig. 67.13). Occasionally, PIH follows the lines of Blaschko because the antecedent inflammatory dermatosis did so, e.g. linear lichen planus. The color ranges from brown (epidermal) to brown–gray (dermal). PIH slowly fades over time, provided that further injury to the skin does not occur. However, resolution may not occur for months to years, especially in more darkly pigmented individuals and when the melanin is primarily dermal. The pathogenesis, histology, and treatment of linear PIH are similar to those of the circumscribed form (see above).

Differential Diagnosis

Linear PIH is relatively easy to recognize when there is a history of preceding cutaneous injury or inflammation, but it is more difficult if the preceding event was transient or unnoticed. The differential diagnosis includes rare conditions such as flagellate pigmentation due to bleomycin or shiitake dermatitis (see below) as well as the common phenomenon of black dermographism. The latter occurs when metals, including those in jewelry (nickel, gold, silver), are abraded by harder substances such as powders that contain zinc oxide. The color varies from dark grey to black, and the deposits of metallic powder can be easily removed. Black lacquer deposits associated with poison ivy dermatitis can also result in linear pigmentation, but the color is jet black (see Ch. 17).

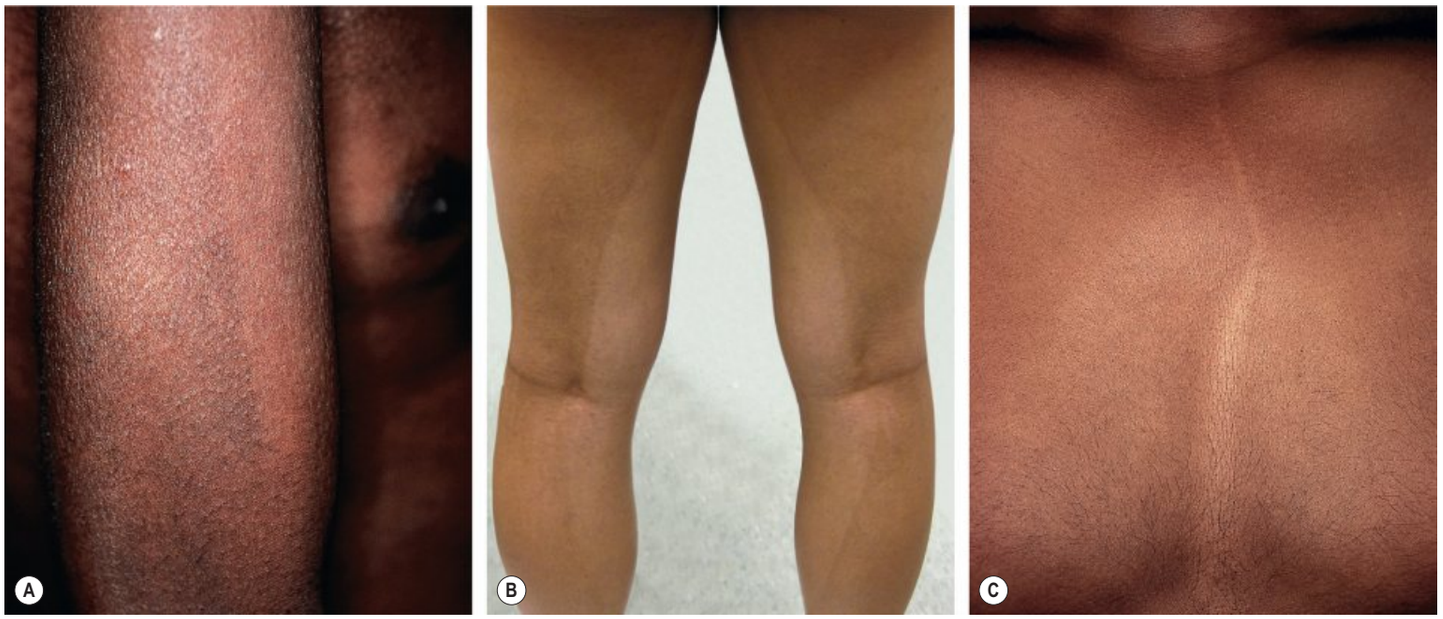

Fig. 67.11 Pigmentary demarcation lines (PDLs). A The most common PDL (type A) is on the upper arm, with relative hypopigmentation on the ventral surface. **B** Type B PDLs on the posterior thighs, with relative hypopigmentation medially. **C** Type C PDL (composed of parallel lines) may be confused with linear nevoid hypopigmentation. *A, C, Courtesy Jean L. Bolognia, MD; B, Courtesy Justin Finch, MD.*

PIGMENTARY DEMARCATION LINES: FIVE MAJOR TYPES (A–E) ANDPROPOSED FACIAL TYPES (F–H)	
Type	**Description**
A	A vertical line along the anterolateral portion of the upper arm that may extend into the pectoral region (most commonly observed type) (see Fig. 67.11A)
B	A curved line on the posteromedial thigh that extends from the perineum to the popliteal fossa and occasionally to the ankle (see Fig. 67.11B)
C	A vertical or curved hypopigmented band on the mid chest that results from two parallel pigmentary demarcation lines (see Fig. 67.11C)
D	A vertical line in a pre- or paraspinal location
E	Bilateral chest markings (hypopigmented macules and patches) in a zone that runs from the mid third of the clavicle to the periareolar skin
F & G	"V"- or "W"-shaped lines between the lateral temple and malar prominence; a curved line may extend medially in the infraorbital area
H	A diagonal line from the angle of the mouth to the lateral aspect of the chin

Table 67.6 Pigmentary demarcation lines: five major types (A–E) and proposed facial types (F–H). Also see Fig. 67.12.

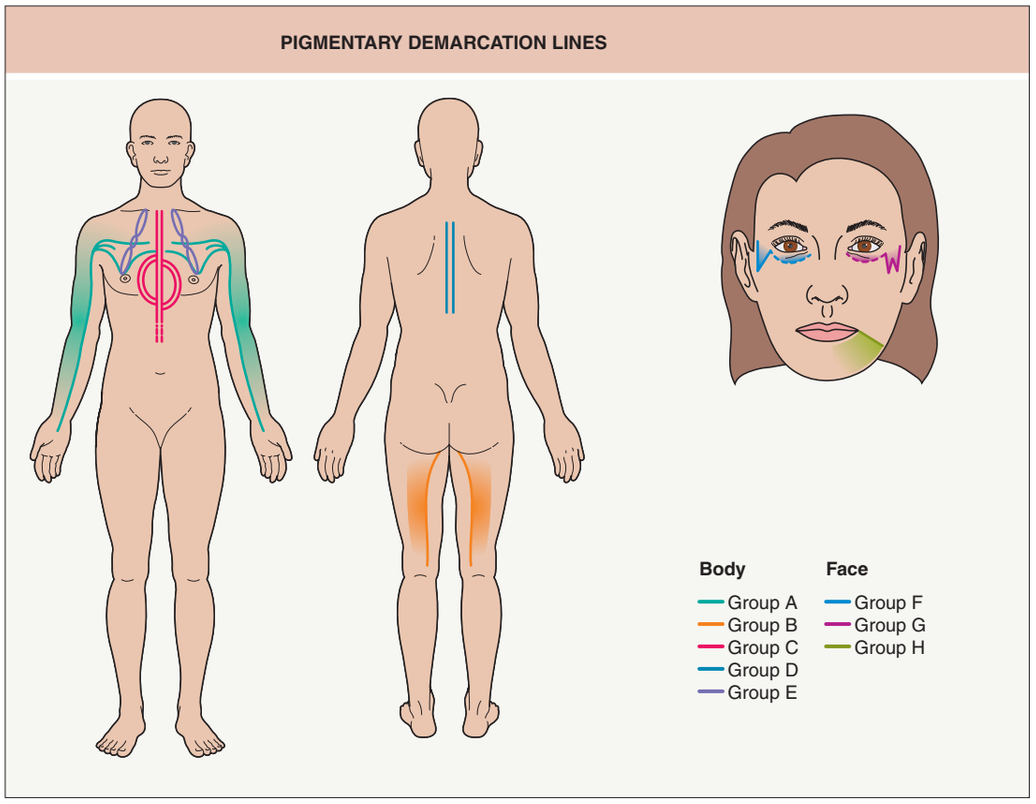

Fig. 67.12 Pigmentary demarcation lines.

DISORDERS WITH LINEAR HYPERPIGMENTATION
Follows the lines of Blaschko
Inherited/early onset
• Linear and whorled nevoid hypermelanosis ("pigmentary mosaicism"*; see Fig. 67.15) • Early or subtle epidermal nevus • Third stage of incontinentia pigmenti† (see Fig. 67.19) • X-linked reticulate pigmentary disorder† • Focal dermal hypoplasia† (Goltz syndrome; hyperpigmented macules within linear streaks, along with cribriform dermal atrophy, fat "herniation", hypopigmentation, and/or telangiectasias) • X-linked hypohidrotic ectodermal dysplasia† • Conradi–Hünermann–Happle syndrome† • X-linked dyskeratosis congenita (rare)† • Börjeson–Forssman–Lehmann syndrome† (favors axillae; also dental/digital anomalies, frontotemporal hypotrichosis, facial dysmorphism) • *TFE3*-associated neurodevelopmental disorder† (lysosomal storage disease-like findings) • Café-au-lait macules of McCune–Albright syndrome (more often broad bands or block-like) • Chimerism (more often block-like or ill-defined pattern)
Acquired/often later onset
• Linear lichen planus, lichen planus pigmentosus, erythema dyschromicum perstans, or fixed drug eruption • Linear atrophoderma of Moulin (see Fig. 67.17), possibly linear morphea • Postinflammatory hyperpigmentation due to Blaschkitis • Linear biphasic cutaneous amyloidosis‡
Does *not* follow the lines of Blaschko
• Pigmentary demarcation lines (see Figs. 67.11 & 67.12, Table 67.6) • Linea nigra (see Fig. 27.11A) • Phytophotodermatitis (see Fig. 67.13) • Sock- or mitten-line hyperpigmentation • Flagellate hyperpigmentation – e.g. from bleomycin (see Fig. 67.14), shiitake dermatitis, dermatomyositis, persistent plaques of Still disease • Serpentine supravenous hyperpigmentation, e.g. from phlebitis, intravenous drug use, systemic sclerosis, chemotherapeutic agents (e.g. 5-fluorouracil, docetaxel) • Additional causes of linear postinflammatory hyperpigmentation – excoriations, trauma/abuse, burns, allergic contact dermatitis (especially to plants), koebnerized lesions (e.g. psoriasis, lichen planus), coining
*Pigmentary mosaicism can also present with hyperpigmentation in a block-like pattern, referred to as segmental pigmentation disorder (see text). †Linear findings are found primarily in female patients due to functional mosaicism (via lyonization) in these X-linked disorders; occasionally in male patients with somatic mosaicism or Klinefelter syndrome. ‡Single case.

Table 67.7 Disorders with linear hyperpigmentation.

FLAGELLATE PIGMENTATION FROM BLEOMYCIN

Synonym: ■ Scratch dermatitis

Key features

- Occurs in 10%–20% of patients treated with systemic bleomycin
- Linear hyperpigmented streaks are most often seen on the chest and back
- Reversible once the drug is discontinued
- Additional findings may include circumscribed hyperpigmentation of the skin overlying joints, transverse melanonychia, and sclerodermoid changes

Introduction

Bleomycin is a cytotoxic antibiotic used to treat malignancies such as Hodgkin disease and testicular carcinoma. It is also occasionally used intralesionally for treatment of warts or sclerotherapy of vascular malformations. Flagellate or "streaked" hyperpigmentation due to bleomycin was first recognized in 1970[20].

Fig. 67.13 Linear hyperpigmentation due to phytophotodermatitis. Hyperpigmented streaks developed on the arms of this mother and her toddler son following contact with citrus juice on a sunny day.

Epidemiology

Flagellate hyperpigmentation is a fairly common side effect, occurring in 10%–20% of patients treated with systemic bleomycin and occasionally in those who receive intralesional bleomycin. Due to its potential pulmonary toxicity, other agents (e.g. brentuximab, immune checkpoint inhibitors) are increasingly being employed as substitutes for bleomycin in the treatment of Hodgkin lymphoma.

Pathogenesis

The pigmentation appears to be dose-dependent, but the pathogenesis is poorly understood. The pigmentation may represent a form of PIH, and preceding flagellate erythema is observed in a subset of patients. The configuration of the lesions is suggestive of a relationship to scratching. However, attempts to reproduce the lesions by scratching the skin of patients receiving bleomycin have often been unsuccessful, and some patients deny pruritus or previous scratching[21]. Other hypotheses include a bleomycin-induced local increase in melanogenesis or alteration of "pigment maturation"[20].

Clinical Features

Bleomycin-associated pigmentation can be circumscribed, diffuse, or flagellate. Circumscribed lesions are typically found over joints or in other pressure points, but hyperpigmentation can also be localized to the palmar creases, striae, or sites of adhesive electrode pads. Flagellate pigmentation usually occurs after cumulative doses of 100–300 mg; however, it has been reported after doses as low as 15 to 30 mg, including following intralesional injections of warts or vascular malformations[20,21]. Flagellate pigmentation appears from 1 day to 9 weeks after administration of the drug. Some patients have pruritus (ranging from mild to severe) or linear urticarial lesions preceding the pigmented streaks, but others have neither associated symptoms nor antecedent lesions. The linear bands or streaks are brown in color and are most commonly seen on the chest and back (Fig. 67.14).

Additional cutaneous side effects of bleomycin include painful nodules on the fingers, verrucous plaques on the knees and elbows, sclerodermoid changes, and digital gangrene due to Raynaud phenomenon. Nail changes can include melanonychia (typically transverse) as well as Beau's lines, onychomadesis, and onycholysis.

Pathology

Varying histologic findings have been reported in bleomycin-induced flagellate hyperpigmentation, from basal layer hypermelanosis to

Fig. 67.14 Flagellate pigmentation. This young man had received bleomycin as a treatment for his lymphoma. Note the linear excoriations. *Courtesy David E. Cohen, MD MPH.*

spongiosis confined to the basal layer in association with a perivascular lymphohistiocytic infiltrate admixed with melanophages. By electron microscopy, an increased number and size of melanosomes within the basal keratinocytes may be seen; the melanocytes sometimes contain enlarged mitochondria[22].

Differential Diagnosis

Linear forms of PIH should be considered in the differential diagnosis (see Table 67.7). However, a history of systemic bleomycin administration coupled with the characteristic clinical picture usually points to the correct diagnosis. Shiitake dermatitis (see below) can also present as flagellate lesions, but a history of ingestion of or occupational exposure to raw shiitake mushrooms allows a distinction to be made, as does the presence of a prominent papular component. Flagellate erythema can occur in patients with dermatomyositis, and fixed reddish-brown plaques and hyperpigmented streaks in irregular linear arrays have been observed in patients with Still disease (juvenile or adult-onset); histologically, these eruptions are characterized by an interface dermatitis (in dermatomyositis) and necrotic keratinocytes in the upper epidermis plus a dermal neutrophilic infiltrate (in Still disease).

Treatment

While there is no specific therapy, recognition that bleomycin is the culprit is important as these patients are usually receiving multiple medications. Pruritus can be treated with topical corticosteroids and oral antihistamines. The pigmentation usually fades over 3 to 4 months, once the course of chemotherapy is complete and the bleomycin is discontinued.

SHIITAKE DERMATITIS (FLAGELLATE MUSHROOM DERMATITIS)

Synonyms: ■ Shiitake mushroom dermatitis ■ Lentinan dermatitis ■ Shiitake-induced toxicoderma

Key features

- Occurs after eating large amounts of raw or partially cooked shiitake mushrooms
- Flagellate streaks initially composed of erythematous papules or petechiae develop on the face, trunk, and extremities

Introduction

Shiitake dermatitis occurs in individuals who have ingested raw or undercooked shiitake mushrooms (*Lentinula edodes*)[23,24]. It presents with linear streaks of erythematous papules or petechiae, which occasionally evolve to flagellate pigmentation similar to that induced by bleomycin[23]. Of note, occupational skin and respiratory conditions can develop in workers who cultivate shiitake mushrooms, with manifestations including protein contact dermatitis and hypersensitivity pneumonitis ("mushroom worker's disease").

History and Epidemiology

Toxicoderma caused by shiitake mushroom ingestion was first described in the Japanese literature in 1977. Since then, several hundred cases of "shiitake dermatitis" have been reported, initially mostly from Japan and Europe but nowadays globally due to the widespread popularity of East Asian cuisines. Similar eruptions due to ingestion of wood ear (*Auricularia auricula-judae*) or porcini (*Boletus* spp.) mushrooms have also been described[25].

Pathogenesis

Lentinan, a thermolabile toxin in shiitake mushrooms, is probably responsible for this dermatosis. Prick and patch tests using shiitake mushroom extract are typically negative in patients who have ingestion-related dermatitis, and oral rechallenge may be negative as well. A phototoxic mechanism has also been proposed[23].

Clinical Features

In shiitake mushroom dermatitis, pruritic erythematous papules, vesicles, and edema develop on the face, scalp, trunk, and extremities 1–2 days after mushroom ingestion. Scratching leads to long, flagellate streaks composed of erythematous papules and/or petechiae on the extremities and the trunk, with sparing of the difficult-to-reach mid upper back. This can be followed by a linear pattern of either discoloration due to hemosiderin or PIH. Diffuse erythema and edema in photo-exposed areas have been observed in half of Japanese patients with shiitake dermatitis, and fever and malaise are occasional associated findings[23].

Pathology

Spongiosis and necrotic keratinocytes are seen within the epidermis in addition to a lymphocytic dermal infiltrate, which is admixed with melanophages in cases with hyperpigmentation[23].

Treatment

The acute dermatitis can be treated with topical corticosteroids and oral antihistamines. Resolution occurs within 1 to 8 weeks if the mushrooms are avoided. Thoroughly cooking shiitake mushrooms prevents the disorder.

HYPERPIGMENTATION ALONG THE LINES OF BLASCHKO

The lines of Blaschko are characterized by a V-shape on the posterior midline, an S-shape on the abdomen, and spirals on the posterior scalp[26,27] (see Ch. 62). Dermatoses that follow the lines of Blaschko result from mosaicism.

Linear and Whorled Nevoid Hypermelanosis

Synonyms: ■ Linear nevoid hyperpigmentation ■ Reticulate and zosteriform hyperpigmentation ■ Progressive cribriform and zosteriform hyperpigmentation

Key features

- Hyperpigmentation in whorls and streaks following the lines of Blaschko
- Usually becomes apparent within the first year of life
- Associated systemic findings occur in a minority of affected individuals
- Increased melanin within the epidermis and few melanophages

Introduction

Linear and whorled nevoid hypermelanosis (LWNH), first described in the 1970s, is characterized by swirls and streaks of macular hyperpigmentation along the lines of Blaschko[28]. Occasionally, there are associated extracutaneous abnormalities.

Epidemiology

LWNH is a sporadic disorder with no sex preference. It is viewed as an uncommon condition but is probably under-recognized.

Pathogenesis

LWNH is a genetically heterogeneous, mosaic skin condition characterized by a clone of skin cells with increased pigment production[29]. A variety of underlying mosaic chromosomal anomalies have been reported. Mosaicism for a gain-of-function mutation in the KIT ligand gene (*KITLG*) was reported in a patient with extensive LWNH, thus representing a mosaic presentation of familial progressive hyperpigmentation.

Clinical features

Swirls and streaks of brown pigmentation usually appear early during the first year of life (Fig. 67.15). The full extent of skin involvement is typically apparent by the time the child is 2–3 years of age[28]. The linear hyperpigmentation tends to persist indefinitely. Occasionally, patients with "pigmentary mosaicism" will develop both hypo- and hyperpigmented streaks.

Approximately 10%–25% of patients with LWNH who present to a pediatric dermatologist have extracutaneous findings, which typically become apparent during infancy and may be neurologic, musculoskeletal, or (less often) cardiac in nature[29]. However, the exact incidence of extracutaneous abnormalities in LWNH is unknown and is likely lower in the general pediatric population.

Pathology

LWNH is characterized by increased melanin within basal keratinocytes and in some cases a slight increase in the density of melanocytes. There are a few dermal melanophages.

Differential diagnosis

The differential diagnosis includes other disorders characterized by hyperpigmentation along the lines of Blaschko (see Table 67.7; Figs. 67.16 & 67.17). The hyperpigmented stage (stage 3) of incontinentia pigmenti (IP) is distinguished by its grayish-brown color, a predominance of melanophages rather than epidermal pigment (Fig. 67.18), fading over time, and in most patients a history of previous inflammatory vesicular and verrucous stages (stages 1 and 2, respectively). Some epidermal nevi initially have minimal or no palpable component,

Fig. 67.15 Linear and whorled nevoid hypermelanosis on the trunk. This young Black girl had developmental delay. Note the distribution along the lines of Blaschko. *Courtesy Julie V. Schaffer, MD.*

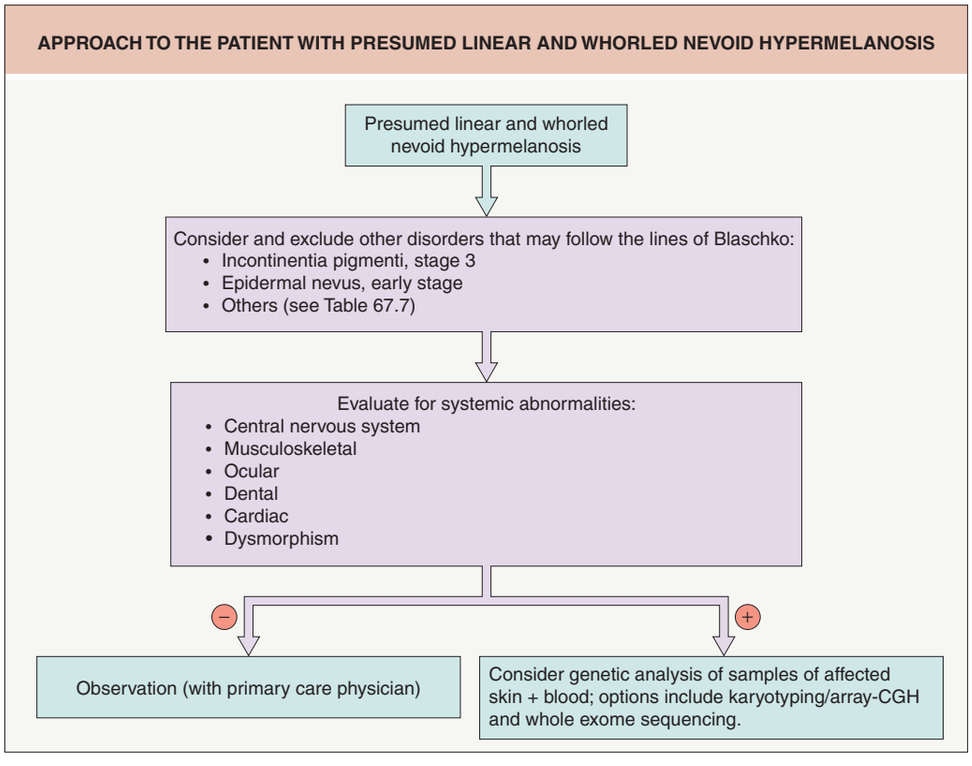

Fig. 67.16 Approach to the patient with presumed linear and whorled nevoid hypermelanosis. In general, the initial evaluation is clinical, with additional studies as indicated based on abnormalities that are evident. Karyotyping from a skin sample requires a fresh biopsy for cell culture; this is routinely done for fibroblasts, with keratinocyte or melanocyte cultures performed in specialized labs. Other tests use extracted DNA, with higher yield from a fresh biopsy than formalin-fixed paraffin-embedded tissue. CGH, comparative genomic hybridization.

but they often eventually develop some elevation. Of note, a mother and child previously reported as an example of "familial LWNH" (with histologic findings of increased epidermal melanin but no pigment incontinence in affected skin) were subsequently found to have hypohidrotic ectodermal dysplasia with immunodeficiency due to a hypomorphic *IKBKG* (*NEMO*) mutation[30].

Treatment

There is currently no effective treatment, although camouflage cosmetics may be helpful.

Incontinentia Pigmenti

A full discussion of IP can be found in Chapter 62. This X-linked dominant multisystem disorder is characterized by skin lesions distributed along the lines of Blaschko, including vesicles (stage 1), verrucous lesions (stage 2), hyperpigmentation (stage 3) and, eventually, hypopigmentation (stage 4). The third stage usually presents within the first year of life and is characterized by gray to gray–brown streaks and whorls along the lines of Blaschko (Fig. 67.19). The trunk is a common area of involvement. The pigmentation fades gradually during late childhood to adolescence, often persisting primarily in intertriginous sites. IP is due to mutations in the *IKBKG* (*NEMO*) gene. The gradual fading of stage 3 lesions reflects increased apoptosis within the affected streaks, followed by replacement with normal skin.

Fig. 67.17 Linear hyperpigmentation due to atrophoderma of Moulin. Note the subtle depression of the lesions. *Courtesy Antonio Torrelo, MD.*

RETICULATED HYPERPIGMENTATION

Disorders characterized by true reticulated macular hyperpigmentation are rare. Initial evaluation should exclude other more common entities such as confluent and reticulated papillomatosis of Gougerot and Carteaud (see Table 67.1 and Ch. 109), where the lesions are elevated and favor the neck and upper trunk (Fig. 67.20), and the hyperpigmentation of erythema ab igne, which has a widely spaced net-like pattern corresponding to the arrangement of the cutaneous venous plexus (see Ch. 88). A similar violaceous to brown-colored net-like pattern can also be seen on the lower extremities of patients with livedo reticularis. Reticulated hyperpigmentation is an occasional feature of other skin disorders, such as its occurrence on the anterolateral neck in patients with atopic dermatitis ("atopic dirty neck") and in association with epidermolysis bullosa herpetiformis.

When a true reticulated pigmentary disorder exists, the family history should be reviewed and the patient carefully examined for associated abnormalities. The following section discusses prurigo pigmentosa and six genodermatoses associated with reticulated hyperpigmentation. Additional entities that feature reticulated hyperpigmentation are listed in Table 67.8.

PRURIGO PIGMENTOSA

First described by Nagashima in 1971[31], this disorder is characterized by a markedly pruritic eruption of erythematous papules and papulovesicles on the back, neck, and chest (Fig. 67.21A). Crops of inflammatory lesions develop rapidly and then involute within a week, leaving macular reticulated hyperpigmentation (Fig. 67.21B). Recurrences tend to occur at the same site, and lesions in multiple stages are often

Fig. 67.19 Stage 3 incontinentia pigmenti in a 2-year-old child. Note the characteristic gray–brown color and the distribution along the lines of Blaschko.

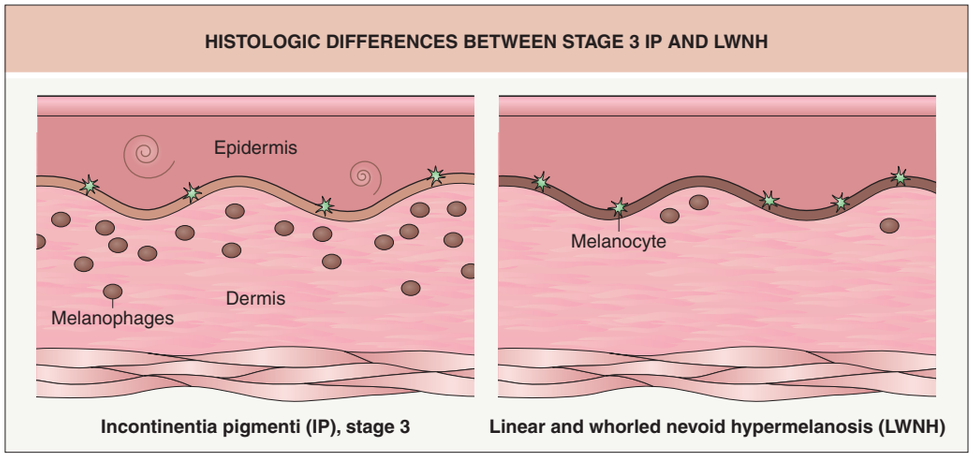

Fig. 67.18 Histologic differences between stage 3 incontinentia pigmenti (IP) and linear and whorled nevoid hypermelanosis (LWNH).

Fig. 67.20 Confluent and reticulated papillomatosis. **A** On the neck and back of a teenage girl. **B** On the chest of an older woman. *A, Courtesy Seth Orlow, MD PhD.*

DISORDERS CHARACTERIZED BY RETICULATED PIGMENTATION	
Disorder	**Key features**
Confluent and reticulated papillomatosis	See Table 67.1 and Fig. 67.20
Erythema ab igne	Widely spaced net that corresponds to vascular pattern; due to heat injury (see Ch. 88)
Atopic dirty neck	Anterolateral neck
Prurigo pigmentosa	Favors young Japanese women; may be associated with ketosis, e.g. due to a ketogenic diet or bariatric surgery; favors the back, neck, and chest; recurrent crops of pruritic papulovesicles that resolve with a reticulated pattern of hyperpigmentation (Fig. 67.21A,B)
Dyskeratosis congenita*	XLR > AD and AR forms (see Table 67.9 and Fig. 67.23); pterygium/nail dystrophy, leukoplakia, pancytopenia; increased risk of mucosal squamous cell carcinoma and leukemia
Naegeli–Franceschetti–Jadassohn syndrome	AD due to *KRT14* mutations; fading reticulated hyperpigmentation, dental anomalies, hypohidrosis, palmoplantar keratoderma, hypoplastic dermatoglyphics, nail dystrophy
Dermatopathia pigmentosa reticularis	AD due to *KRT14* mutations; persistent reticulated hyperpigmentation (see Fig. 67.24), alopecia, nail dystrophy; palmoplantar keratoderma and hypoplastic dermatoglyphics in some patients
X-linked reticulate pigmentary disorder	XLR due to *POLA1* mutations; generalized reticulated pigmentation in male patients (see Fig. 67.25); neonatal colitis, recurrent pneumonia, hypohidrosis, photophobia; amyloid deposits in adults
Dowling–Degos disease (DDD)	AD due to mutations in *KRT5*, *POFUT1*, and *POGLUT1* genes; reticulated hyperpigmentation favoring major flexures (see Fig. 67.26); may be composed of or admixed with discrete hyperpigmented macules and papules; variant associated with hidradenitis suppurativa due to *PSENEN* mutations
Galli–Galli disease	Acantholytic variant of DDD
Haber syndrome	Rosacea-like facial eruption plus the clinical features of DDD
Pigmentatio reticularis faciei et colli	Possible variant of DDD; hyperpigmentation of the face and neck plus multiple epidermoid cysts
Reticulate acropigmentation of Kitamura	AD due to *ADAM10* mutations; atrophic acral lentigo-like lesions, palmoplantar and dorsal phalangeal pitting
Epidermolysis bullosa simplex (EBS) with mottled pigmentation* and generalized EBS	AD due to *KRT5/14* mutations, with a specific P25L *KRT5* mutation usually underlying EBS with mottled pigmentation (see Ch. 32)
Mendes da Costa disease*	Traumatic bullae and hyperpigmentation, usually acral; dwarfism, atrichia
Cantu syndrome	Reticulated pigmentation of face, forearms, and feet; palmoplantar keratoderma
Reticulate genital hyperpigmentation associated with localized vitiligo*	Congenital or acquired reticulate hyperpigmentation of the genitalia, followed by the development of vitiligo in the same region
Mitochondrial disorders	Sun-exposed areas (e.g. cheeks, dorsal aspects of the forearms and hands); additional cutaneous findings include hypertrichosis, hair shaft abnormalities, and acrocyanosis (see Ch. 63)
Postinflammatory	Lichenoid dermatoses (e.g. lichen planus pigmentosus, graft-versus-host disease); contact dermatitis (e.g. due to benzoyl peroxide); chikungunya fever
Drug-induced	Diltiazem (sun-exposed areas); chemotherapeutic agents such as 5-fluorouracil, cyclophosphamide, paclitaxel, idarubicin, and cytarabine (see Table 67.5)

*Also dyschromatosis.

Table 67.8 Disorders characterized by reticulated pigmentation. Entities in the rows with a darker shade are covered in this chapter. Fanconi anemia is discussed in Table 67.10. *ADAM10; a d*isintegrin and *m*etalloproteinase *10*; AD, autosomal dominant; AR, autosomal recessive; *KRT5/14*, keratin 5 or 14; *POFUT1*, protein O-fucosyltransferase 1; *POGLUT1*, protein O-glucosyltransferase 1; *POLA1*, DNA polymerase-α1, catalytic subunit; *PSENEN*, presenilin enhancer protein 2; XLR, X-linked recessive.

Fig. 67.21 Prurigo pigmentosa. A Eroded and crusted erythematous papules and plaques. A few patches of hyperpigmentation are seen inferiorly. **B** Erythematous crusted papules admixed with reticulated macular hyperpigmentation. **C** Histopathologic features include intraepidermal vesiculation, necrotic keratinocytes, and a patchy lichenoid infiltrate. *A, Courtesy Luis Requena, MD; B, C, Courtesy Lorenzo Cerroni, MD.*

evident. The condition favors young adults, with a female : male ratio of ≥2 : 1; the majority of reported patients have been from East Asia. Prurigo pigmentosa triggered by ketosis due to bariatric surgery, a ketogenic diet, or type 1 diabetes mellitus has been reported in patients with a variety of ethnic backgrounds[32].

Three histopathologic stages have been identified: (1) neutrophilic exocytosis, spongiosis, papillary dermal edema, and a superficial perivascular infiltrate of neutrophils; (2) intra-/subepidermal vesiculation, necrotic keratinocytes, and a patchy lichenoid infiltrate of predominantly lymphocytes admixed with eosinophils (Fig. 67.21C); and (3) variable parakeratosis, acanthosis, and hyperpigmentation of the epidermis as well as dermal melanophages[33]. Treatment with oral minocycline, doxycycline, or dapsone is often effective for the inflammatory component of prurigo pigmentosa. The condition does not respond to corticosteroids (topical or systemic) or antihistamines. Prurigo pigmentosa associated with ketosis may improve with reintroduction of carbohydrates[32].

DYSKERATOSIS CONGENITA

Synonym: ■ Zinsser–Engman–Cole syndrome

Key features

- Genetically heterogeneous disorder due to defective telomere maintenance, with X-linked recessive inheritance in the most common form
- Triad of reticulated hyperpigmentation, nail dystrophy (e.g. pterygium), and leukoplakia
- Bone marrow failure resulting in thrombocytopenia, anemia, or pancytopenia
- Continuous lacrimation (epiphora) due to lacrimal duct atresia, pulmonary fibrosis, and liver cirrhosis may develop
- Predisposition to malignancy, especially mucosal squamous cell carcinoma (e.g. mouth, anus)

Introduction

First described in 1906 by Zinsser, dyskeratosis congenita (DKC) is a genetically heterogeneous disorder caused by defective telomere maintenance. DKC is characterized by progressive bone marrow failure and the mucocutaneous triad of reticulated hyperpigmentation, nail dystrophy, and leukoplakia. In addition, affected individuals have an increased risk of developing pulmonary fibrosis, liver cirrhosis, and malignancies including squamous cell carcinoma (especially mucosal) and acute myeloid leukemia[34].

Epidemiology

The most common form of DKC has an X-linked recessive pattern of inheritance, but autosomal dominant and autosomal recessive forms also exist (Table 67.9). The overall male : female ratio is ~3 : 1[34].

Pathogenesis

DKC is caused by defective telomere maintenance, which leads to the characteristic feature of markedly shortened telomeres[35]. Telomeres are repetitive nucleotide sequences that protect the ends of eukaryotic chromosomes. The enzyme telomerase prevents the progressive shortening of chromosomes that would otherwise occur with DNA replication (Fig. 67.22). Tissues with high replication rates, such as the bone marrow and skin, are particularly vulnerable when telomerase is not functioning properly. When telomeres reach a critically short length, cell cycle arrest occurs and the cells undergo either senescence or apoptosis. However, telomerase dysfunction also leads to chromosome instability, which can result in tumorigenesis.

In 1998, mutations in *DKC1*, which encodes the dyskerin protein that interacts with telomerase, were found to underlie the X-linked recessive form of DKC[36]. Since then, 11 additional genes have been implicated in both autosomal dominant and recessive forms of DKC that have variable clinical manifestations. These genes encode the telomerase RNA component (TERC) and reverse transcriptase (TERT) as well as other factors with roles in telomerase function and additional aspects of telomere protection (see Table 67.9 & Fig. 67.22). Advances in understanding of the pathogenesis of DKC and other telomere biology disorders may provide insights into telomere maintenance in general processes such as aging and cancer[35].

GENETIC ETIOLOGIES OF DYSKERATOSIS CONGENITA (DKC)				
Gene	**Gene product (see Fig. 67.22)**	**Mode of inheritance**	**Proportion of DKC patients (%)**	**Comments**
DKC1	Dyskerin (in telomerase complex)	XR*	20–30	Classic DKC, often relatively severe, in male patients; clinical manifestations in female heterozygotes are extremely rare
TINF2	Telomere repeat binding factor 1 (TERF1)-interacting nuclear factor 2 (in shelterin telomere protection complex)	AD*	10–20	Often severe with bone marrow failure in childhood; mutations in this gene also cause the Revesz syndrome variant (see text)
TERC	Telomerase RNA component	AD	5–10	Often less severe
TERT	Telomerase reverse transcriptase	AD, AR*	~5	Later onset and less severe in AD form
RTEL1	Regulator of telomere elongation helicase 1	AD, AR*	~5	Later onset in AD form
CTC1	Conserved telomere maintenance component 1 (in telomere capping complex)	AR	1–3	
WRAP53 (TCAB1)	Telomerase Cajal body protein 1 (regulates telomerase transport)	AR	<1	
NHP2, NOP10	NHP2 and NOP10 ribonucleoprotein homologs (in telomerase complex)	AR	<1	
PARN	Poly(A)-specific ribonuclease (regulates TERC interaction with telomeres)	AD, AR*	<1	
ACD (TINT1)	TINF2-interacting protein 1 (in shelterin telomere protection complex)	AD, AR*	<1	Later onset in AD form
RPA1	Replication protein A1 (functions in telomere maintenance)	AD	<1	

*Also reported to present as the more severe *Hoyeraal–Hreidarsson syndrome* variant (see text).

Table 67.9 Genetic etiologies of dyskeratosis congenita (DKC). ACD, adrenocortical dysplasia homolog; AD, autosomal dominant; AR, autosomal recessive; WRAP53, WD repeat-containing antisense to TP53; XR, X-linked recessive.

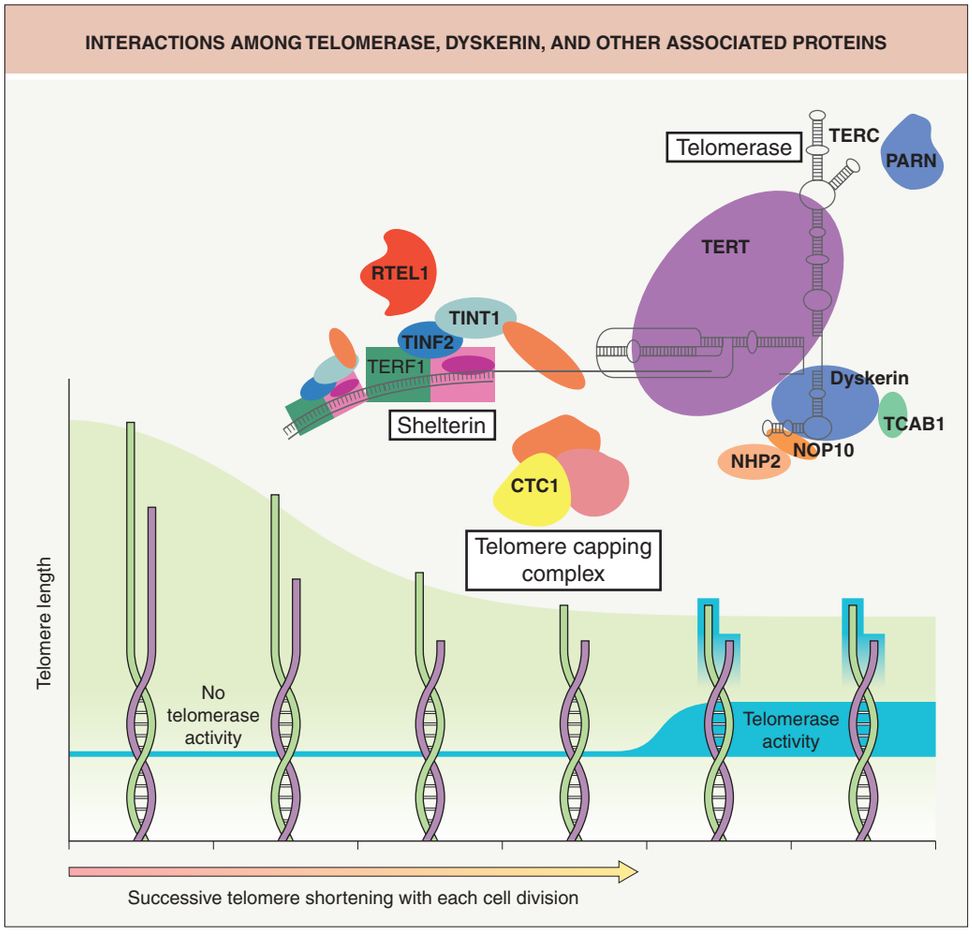

Fig. 67.22 Interactions among telomerase, dyskerin, and other telomere-associated proteins implicated in dyskeratosis congenita. Telomerase, the enzyme that protects against progressive shortening of the chromosomes with successive cell divisions, is composed of two subunits: an RNA component (**TERC**) and reverse transcriptase (**TERT**). **Dyskerin** interacts with telomerase and plays a role in its proper function. The **NHP2** and **NOP10** ribonucleoprotein homologs are also in the telomerase complex, while telomerase Cajal body protein-1 (**TCAB1**) controls telomerase trafficking. Poly(A)-specific ribonuclease (**PARN**) regulates TERC's interaction with telomeres. TERF1-interacting nuclear factor 2 (**TINF2**) and TINF2-interacting protein 1 (**TINT1**) are components of the shelterin complex that protects the ends of telomeres. **RTEL1** is a DNA helicase that regulates telomere elongation, and conserved telomere maintenance component 1 (**CTC1**) functions in a telomere capping complex. TERF1, telomere repeat binding factor 1.

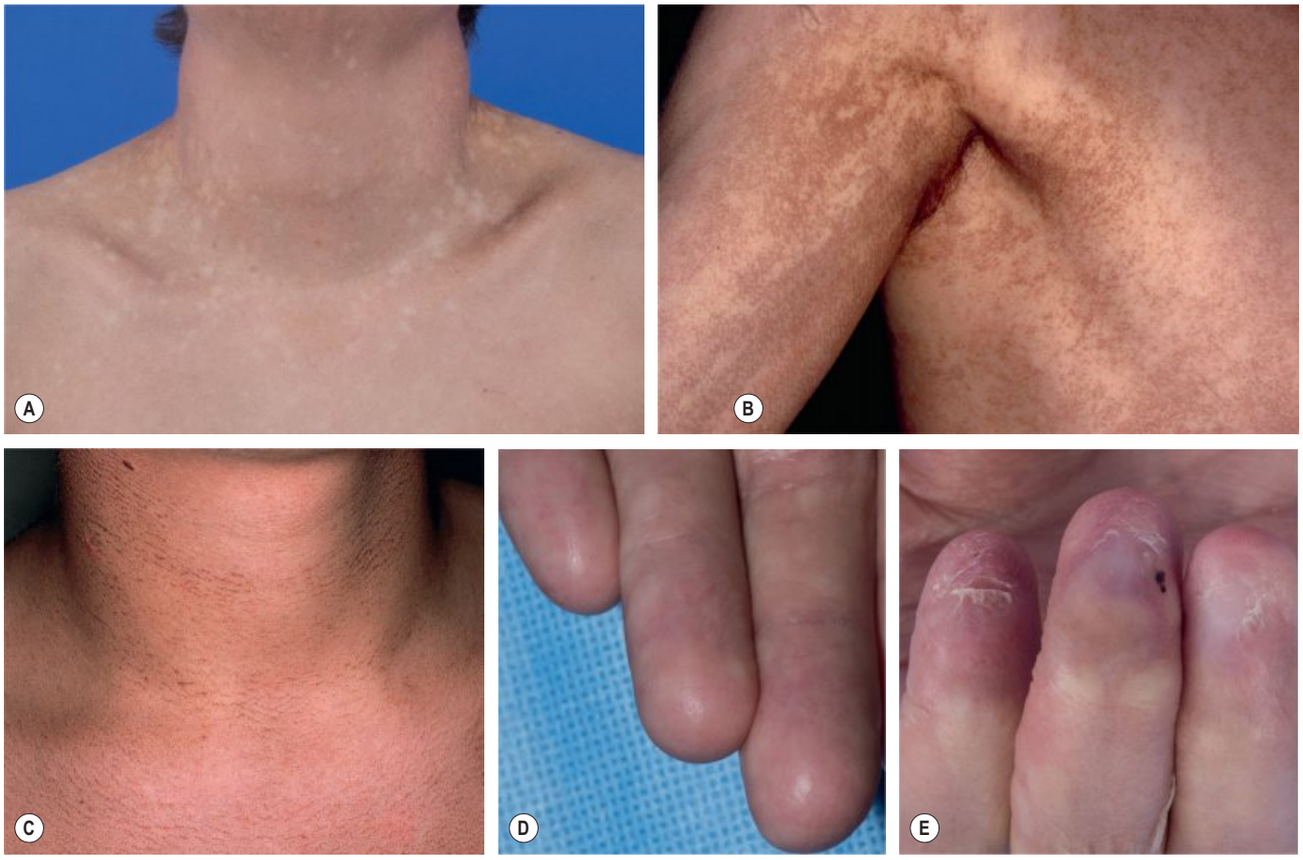

Fig. 67.23 Dyskeratosis congenita. A Diffuse and reticulated hyperpigmentation of the neck and upper chest as well as multiple hypopigmented macules. **B** More pronounced reticulated and confluent hyperpigmentation on the shoulder and axilla. **C** Reticulated hyperpigmentation on the chest and neck of a teenage boy. **D** Mild scaling and erythema of fingers as well as absent dermatoglyphics. **E** Micronychia and anonychia. *A, D, E, Courtesy Edward Cowen, MD; B, Courtesy Eugene Mirrer, MD; C, Courtesy Seth Orlow, MD PhD.*

Clinical Features

A lacy reticulated pattern of hyperpigmentation generally develops during the first decade of life. This occurs primarily on the neck, upper chest, and upper arms and is sometimes admixed with macules of hypopigmentation (Fig. 67.23A–C). Telangiectasias and epidermal atrophy may also be seen, i.e. poikiloderma. Additional cutaneous features include wrinkled skin on the extremities, dorsal aspects of the hands, and genitalia; palmoplantar hyperhidrosis and hyperkeratosis; loss of dermatoglyphics (Fig. 67.23D); frictional bullae; acrocyanosis; and premature graying of the hair.

Nail involvement is present in the vast majority of patients, typically appearing during early childhood. Initial changes include longitudinal ridging and splitting, followed by pterygia formation and occasionally complete nail loss (Fig. 67.23E). Leukoplakia occurs in most patients, usually manifesting during early adolescence. White plaques on the oral mucosa are observed most commonly, with a predilection for the lateral portions of the tongue. Involvement of the urethra, vagina, and anus may also be seen. The teeth may be malformed, missing, or have aberrant spacing or extensive caries. Epiphora (continuous lacrimation) due to lacrimal duct atresia is common.

Bone marrow failure occurs in 50%–90% of patients and is a major cause of mortality. It presents during the second or third decade with anemia, thrombocytopenia, or pancytopenia. Malignancies tend to develop during the third or fourth decade, most notably squamous cell carcinomas of the mouth, anus, cervix, vagina, esophagus, and skin. There is also an increased risk of myelodysplastic syndrome, acute myeloid leukemia, and gastrointestinal carcinomas.

Other potential systemic manifestations include pulmonary fibrosis, liver cirrhosis, developmental delay, short stature, avascular necrosis of the femoral head, esophageal or urethral stenosis, cryptorchidism, male hypogonadism, and immunologic dysfunction leading to opportunistic infections. Of note, increased severity in successive generations (anticipation) due to progressive telomere shortening has been observed in autosomal dominant forms of DKC. *Hoyeraal–Hreidarsson syndrome* is a severe variant of DKC characterized by early bone marrow failure, immunodeficiency, cerebellar hypoplasia, microcephaly, enteropathy, and growth retardation (intrauterine and postnatal). Caused by mutations in several DKC genes (see Table 67.9), it typically leads to death in early childhood. *Revesz syndrome* is another related disorder that features progressive neurologic deterioration, intracranial calcifications, and exudative retinopathy together with the manifestations of DKC; it is caused by heterozygous mutations in *TINF2*.

Pathology

Histologically, the features of poikiloderma vasculare atrophicans are seen, with telangiectasias and epidermal thinning as well as foci of increased pigment within the basal layer. In the early stage, hydropic degeneration of basilar keratinocytes and a band-like inflammatory infiltrate in the upper dermis may be evident. In the late stage, the epidermis is markedly thinned and flattened and melanophages are present in the upper dermis.

Short telomere length can be detected in leukocytes from patients with DKC by flow-fluorescence *in situ* hybridization (FISH)[37].

Differential Diagnosis

Fanconi anemia is also associated with pigmentary abnormalities, pancytopenia, and an increased risk of neoplasia (e.g. leukemia); this disorder is compared to DKC in Table 67.10. Naegeli–Franceschetti–Jadassohn (NFJ) syndrome and dermatopathia pigmentosa reticularis (DPR) differ by their lack of leukoplakia and bone marrow involvement (see below). Patients with chronic GVHD may develop poikilodermatous skin changes and lacy white patches of the oral mucosa. However, GVHD is usually easily distinguished by the history of a hematopoietic stem cell transplant (or, rarely, a solid organ transplant). Additional entities associated with poikiloderma are discussed in Chapter 63.

COMPARISON OF DYSKERATOSIS CONGENITA AND FANCONI ANEMIA		
	Dyskeratosis congenita	**Fanconi anemia (FA)**
Pigmentation	Lacy reticulated hyperpigmentation favoring the neck and upper chest, with onset during the first decade of life Sometimes admixed with hypopigmented macules Poikiloderma may be present (telangiectasias and epidermal atrophy)	More generalized, diffuse hyperpigmentation; less often reticulated Sometimes admixed with hypopigmented macules Multiple café-au-lait macules may be present
Hematologic abnormalities	Anemia, leukopenia, thrombocytopenia, pancytopenia Onset typically in 2nd decade	Anemia, leukopenia, thrombocytopenia, pancytopenia Onset typically in 1st decade
Associated malignancies	Increased risk, in particular SCC (esp. mucosal), acute myeloid leukemia	Increased risk, in particular SCC (esp. of head & neck), acute myeloid leukemia, hepatocellular cancer; increased risk of breast and pancreatic cancer with heterozygous mutations in some FA genes*
Additional clinical findings	Nail abnormalities (e.g. pterygium), leukoplakia, hyperhidrosis, palmoplantar hyperkeratosis, frictional bullae, acrocyanosis, epiphora (continuous lacrimation)	Radial ray bony defects involving the thumb, short stature, renal and cardiac malformations, hypogonadism and other endocrinopathies
Exposure of lymphocytes to mitomycin C or diepoxybutane	No chromosomal breakage; shortened telomeres via flow-fluorescence in situ hybridization (FISH)	Enhanced chromosomal breakage and rearrangement
Inheritance	12 associated genes identified (see Table 67.9); X-linked recessive > autosomal dominant or autosomal recessive	Autosomal recessive with at least 11 complementation groups; rarely X-linked recessive (1 complementation group; ~1% of patients)

*For example, BRCA2 (FAD1).

Table 67.10 Comparison of dyskeratosis congenita and Fanconi anemia. SCC, squamous cell carcinoma.

Treatment

Management of DKC patients requires multidisciplinary care. Longitudinal surveillance of all mucosal surfaces is indicated to monitor for the development of squamous cell carcinoma within areas of leukoplakia. Sun and cigarette avoidance are advisable. Bone marrow failure can be treated with supportive transfusions of blood products and the use of androgens (e.g. oxymetholone, danazol), erythropoietin, granulocyte colony-stimulating factor, and eltrombopag or romiplostim. Although hematopoietic stem cell transplantation (HSCT) can potentially cure bone marrow failure and leukemia in patients with DKC, the three-year overall survival rate following HSCT is ~65%.

NAEGELI–FRANCESCHETTI–JADASSOHN SYNDROME

Key features

- Autosomal dominant disorder due to heterozygous mutations in the keratin 14 gene
- Reticulated hyperpigmentation beginning by 2 years of age and often fading during adolescence
- Ectodermal dysplasia with hypohidrosis and heat intolerance as well as dental anomalies, including early loss of teeth
- Palmoplantar keratoderma, with absent or hypoplastic dermatoglyphics

Introduction

NFJ syndrome is a rare autosomal dominant genodermatosis that is characterized by reticulated hyperpigmentation as well as ectodermal dysplasia (primarily dental anomalies and hypohidrosis) and hypoplastic dermatoglyphics.

History

First described by Naegeli in 1927, NFJ was initially confused with incontinentia pigmenti. In 1954, Franceschetti and Jadassohn re-examined the original family and noted the autosomal dominant pattern of inheritance.

Epidemiology

Affected families have been primarily of Swiss and British descent.

Pathogenesis

NFJ syndrome is caused by truncating mutations in the non-helical head domain of the keratin 14 gene (*KRT14*) that result in haploinsufficiency (see Fig. 56.5)[38]. This leads to increased susceptibility of keratinocytes to tumor necrosis factor (TNF)-induced apoptosis, which explains the hyperpigmentation secondary to pigment incontinence observed in affected individuals. It also points to a role for the N-terminal portion of keratin 14 in regulating apoptosis during morphogenesis of cutaneous appendages.

Clinical Features

Brown or gray–brown reticulated hyperpigmentation develops by the age of 2 years, without a preceding inflammatory stage. The pigmentary changes are most often observed on the abdomen and periocular and perioral regions, with variable involvement of the neck, trunk, proximal extremities, axillae, and groin. The hyperpigmentation often fades after puberty and may eventually disappear. Some infants have bullae on their feet during the newborn period. Decreased sweat gland function with lifelong heat intolerance is a problem for many patients. Other cutaneous manifestations include absent or hypoplastic dermatoglyphics, palmoplantar keratoderma (diffuse or punctate), and onychodystrophy (onycholysis, subungual hyperkeratosis, and congenital malalignment of the great toenails). Dental anomalies are common and include abnormally shaped teeth, supernumerary teeth, and yellow spotted tooth enamel. Early total loss of teeth may occur.

Pathology

Histologically, the hyperpigmented skin demonstrates pigment incontinence, i.e. melanophages in the upper dermis.

Differential Diagnosis

The lack of leukoplakia, bone marrow failure, or an increased risk of malignancies in patients with NFJ syndrome differentiates it from *DKC*. Although NFJ syndrome lacks the prominent alopecia and more persistent hyperpigmentation that characterize *DPR*, there is significant overlap between these allelic disorders. *X-linked reticulate pigmentary disorder* often presents with hypohidrosis and dental anomalies as well as reticulate hyperpigmentation, but additional systemic manifestations as well as the inheritance pattern distinguish it from NFJ. Reticulated hyperpigmentation and palmoplantar keratoderma may develop in patients with *epidermolysis bullosa simplex* due to mutations in keratin 5 or 14, but blistering is more prominent. In addition, patients with *Kindler epidermolysis bullosa* may have absent or hypoplastic

dermatoglyphics, but they develop poikiloderma rather than reticulated hyperpigmentation (see Ch. 32). Obviously, hypohidrosis, onychodystrophy, dental anomalies, and hypoplastic or absent dermatoglyphics can be seen in other forms of ectodermal dysplasia (see Ch. 63).

Treatment

Treatment is supportive. Genetic counseling should be offered to affected individuals and families.

DERMATOPATHIA PIGMENTOSA RETICULARIS

Key features

- Autosomal dominant disorder due to mutations in the keratin 14 gene
- Persistent reticulated hyperpigmentation with truncal predominance
- Non-scarring alopecia of the scalp, eyebrows, and axillae
- Onychodystrophy
- Absent dermatoglyphics and punctate keratoderma in some patients

Introduction and Pathogenesis

DPR is a rare genodermatosis that was recognized as a distinct entity in the 1970s. Like NFJ (see above), a heterozygous truncating mutation in the non-helical head domain of the keratin 14 gene has been shown to cause DPR[38].

Clinical Features

DPR presents by the second year of life with the triad of reticulated hyperpigmentation, non-scarring alopecia, and onychodystrophy[39]. The reticulated hyperpigmentation has a predilection for the trunk but also occurs on the proximal extremities, and it persists during adulthood (Fig. 67.24). The nail involvement may result in pterygia formation. Variable features include absent dermatoglyphics, hypo- or hyperhidrosis, and a punctate palmoplantar keratoderma.

Pathology

Histologically, the hyperpigmented skin demonstrates pigment incontinence, i.e. melanophages in the upper dermis.

Fig. 67.24 Dermatopathia pigmentosa reticularis. Persistent hyperpigmentation in a reticulated pattern extending from the lower abdomen to the thigh in a young man. *Courtesy Julie V. Schaffer, MD.*

Differential Diagnosis

There is clinical overlap with the NFJ syndrome (e.g. reticulated hyperpigmentation, nail dystrophy, punctate keratoderma, absent dermatoglyphics), but the latter lacks alopecia and has less persistent hyperpigmentation. Additional diagnostic considerations are as discussed above for NFJ.

X-LINKED RETICULATE PIGMENTARY DISORDER

Synonyms: ■ Partington syndrome type II ■ Familial cutaneous amyloidosis ■ X-linked reticulate pigmentary disorder with systemic manifestations

Key features

- Reticulated hyperpigmentation along the lines of Blaschko in women and in a generalized pattern in men
- Recurrent infections and multiple systemic manifestations in male patients
- Some adult patients have amyloid deposits within the dermis

Introduction and Pathogenesis

This rare genodermatosis is characterized by reticulated brown hyperpigmentation that is generalized in male patients and along the lines of Blaschko in female patients. Affected males have severe systemic complications that may lead to premature death. The disorder was first described by Partington et al. in 1981[40], and several additional families have subsequently been identified[41–43]. It is caused by mutations in *POLA1* which encodes the catalytic subunit of DNA polymerase-α, a regulator of the type I interferon response[43].

Epidemiology

Partington's original kindred had English and Scottish heritage[40]. Other reported families had Maltese, Lebanese, Spanish, and mixed Dutch, French and German ancestries[41–43].

Clinical Features

In *female* patients with this X-linked disorder, manifestations appear to be limited to the skin. At birth or within the first few weeks of life, female infants develop lacy or reticulated areas of hyperpigmentation in streaks that follow the lines of Blaschko. Although the lesions are reminiscent of stage 3 IP, there are no preceding vesicular or verrucous stages. The hypermelanosis may fade during adulthood.

In *male* patients, the reticulated hyperpigmentation is generalized (Fig. 67.25), initially developing on the inner thighs, buttocks, or cheeks between 4 months and 5 years of age. Affected boys often have systemic manifestations, including a low birth weight, neonatal colitis, failure to thrive during infancy, seizures and hemiplegia, as well as gastroesophageal reflux, urethral strictures, and inguinal hernias. Recurrent pneumonias and chronic obstructive pulmonary disease are nearly always present in male patients and can lead to premature death. Intelligence may be normal or developmentally delayed. Additional features include dental anomalies, hypohidrosis, xerosis, photophobia, corneal clouding, and skeletal changes such as delayed bone age and shortened metacarpals. Blonde unruly hair with a frontal upsweep is a frequent clinical finding; in fair-skinned patients, the hair may become silver–gray[40–42].

Pathology

Histologic features of the cutaneous hyperpigmentation are similar in male and female patients. Findings include increased epidermal melanin, pigment incontinence with dermal melanophages, and dyskeratosis[40]. Amyloid deposits in the upper dermis (keratin-positive as in macular amyloidosis) were also noted in some adults (but not children), including those from the original Canadian family[40]. As with macular amyloidosis, deposits were not found in other tissues.

Fig. 67.25 X-linked reticulate pigmentary disorder. There is reticulated hyperpigmentation of the face and neck in this 11-year-old boy, as well as blond, coarse hair. *Courtesy K. Robin Carder, MD.*

Differential Diagnosis

In boys, other entities with reticulated hyperpigmentation should be considered (see Table 67.8), particularly DKC and NFJ syndrome, especially when there are recurrent infections (DKC), hypohidrosis (NFJ syndrome), or dental anomalies (DKC and NFJ syndrome). In female carriers, the differential diagnosis includes the disorders listed in Table 67.7 that follow the lines of Blaschko.

Treatment

Improvement of autoinflammatory manifestations with JAK inhibitor therapy has been reported[44]. Genetic counseling is indicated for affected families.

DOWLING–DEGOS DISEASE

Synonyms:
- Reticular pigmented anomaly of the flexures
- Reticulated pigmented anomaly of the flexures

Key features

- Reticulated hyperpigmentation in flexural sites
- Comedo-like lesions on the back and neck
- Pitted facial scars
- Autosomal dominant with variable penetrance
- Caused by loss-of-function mutations in the gene that encodes keratin 5

Introduction

Dowling–Degos disease (DDD) is an uncommon autosomal dominant condition characterized by acquired reticular hyperpigmentation in intertriginous sites.

Epidemiology

There is no racial or sex predilection in classic DDD, and it has been reported worldwide. A founder mutation has been observed in Jewish Ashkenazi families with DDD plus hidradenitis suppurativa.

Fig. 67.26 Dowling–Degos disease. Hyperpigmented macules forming a reticulated pattern in the axilla. *Courtesy Thomas Schwarz, MD.*

Pathogenesis

Classic DDD is often caused by loss-of-function mutations in the non-helical head domain of the keratin 5 gene (*KRT5*) (see Fig. 56.5) that lead to haploinsufficiency[45]. Interestingly, a missense mutation in the same region of *KRT5* underlies epidermolysis bullosa simplex with mottled pigmentation (see Ch. 32). The head domain of keratin 5 has been found to interact with Hsc70, a chaperone involved in vesicle uncoating, and it has been postulated that keratin 5 has a role in melanosome trafficking. In addition, a form of DDD with more prominent involvement of non-flexural sites can result from heterozygous loss-of-function mutations in *POFUT1* and *POGLUT1*, which encode O-fucosyltransferase 1 and O-glucosyltransferase 1, respectively. Both of these enzymes perform post-translational modifications that regulate the Notch signaling pathway, which has roles in controlling proliferation and differentiation of melanocytes and keratinocytes as well as their interactions with one another[46]. A variant of DDD associated with hidradenitis suppurativa is caused by mutations in the presenilin enhancer protein 2 gene (*PSENEN*), which encodes a component of the γ-secretase protein complex that functions in Notch signaling[47].

Clinical Features

Onset is typically during the third to fourth decade of life. The reticulated hyperpigmentation is admixed with and sometimes composed of lentigo-like brown macules; small brown papules with variable hyperkeratosis may also develop. These findings progressively increase over time, initially appearing in the axillae (Fig. 67.26) and groin followed by the intergluteal and inframammary folds, neck, trunk, and inner aspects of the arms and thighs. Some patients report pruritus of the affected flexural areas. Hypopigmented macules, comedo-like lesions on the back or neck, pitted perioral scars, epidermoid cysts, and hidradenitis suppurativa represent additional features in some patients[48].

Pathology

Histologically, there is increased pigmentation of the basal layer and finger-like elongation of the rete ridges with thinning of the suprapapillary epithelium. This results in an "antler-like" pattern arising from the under surface of the epidermis and hair follicles. Dermal melanophages and a mild perivascular lymphohistiocytic infiltrate are also observed[49]. *Galli–Galli disease* represents a variant of DDD (also caused by *KRT5* mutations) with prominent suprabasal non-dyskeratotic acantholysis in biopsy specimens of lesional skin in addition to the usual clinical and histologic features[50].

Differential Diagnosis

Acanthosis nigricans is distinguished clinically by velvety plaques and histologically by less pronounced elongation of the rete ridges. In

addition, there is no follicular involvement. Patients with neurofibromatosis type 1 develop lentigines (oftentimes referred to as "freckles") in the axillae and groin, but this disorder is usually easy to distinguish from DDD.

The spectrum of DDD-like disorders that feature reticulate pigmentation include reticulate acropigmentation of Kitamura (see below) and Haber syndrome. Patients with *Haber syndrome* develop a photosensitive rosacea-like facial eruption during adolescence, which is followed by the appearance of keratotic papules, comedo-like lesions, pitted scars, and reticulate hyperpigmentation on the trunk and proximal extremities as well as in the axillae.

Treatment

Topical hydroquinone, tretinoin, adapalene, and corticosteroids have been used with varying success. Improvement following treatment with the erbium:YAG or Q-switched Nd:YAG plus fractional CO_2 lasers has also been reported[48].

RETICULATE ACROPIGMENTATION OF KITAMURA

Synonym: ■ Kitamura reticulate acropigmentation

Key features

- Atrophic reticulated or lentigo-like hyperpigmentation that favors the dorsal aspects of the hands and feet and appears during childhood
- Pits on the palms, soles, and dorsal phalanges
- Autosomal dominant inheritance

Introduction and Pathogenesis

Reticulate acropigmentation of Kitamura (RAK) is a rare genodermatosis characterized by atrophic hyperpigmented macules that appear during childhood and initially have an acral distribution. Two-thirds of reported patients have been Japanese, but the condition has been described in individuals with other ethnic backgrounds. Heterozygous loss-of-function mutations in the *a d*isintegrin *a*nd *m*etalloproteinase *10* gene (*ADAM10*), which encodes a zinc metalloproteinase that activates Notch signaling (see above), have been found to underlie RAK.

Clinical Features

During childhood, slightly depressed lentigo-like hyperpigmented macules develop on the dorsal aspects of the hands and feet and often assume a reticulated pattern. These macules slowly darken over time and subsequently may spread to other sites of the body during adulthood. Sunlight may aggravate the condition. Pits are found on the palms, soles, and dorsal phalangeal surfaces, and breaks in the dermatoglyphics are often evident.

Pathology

The hyperpigmented macules show epidermal atrophy and elongated rete ridges that contain an increased amount of melanin. An increased number of DOPA-positive melanocytes are seen in the basal layer of the epidermis.

Differential Diagnosis

In contrast to the more common solar lentigines, the hyperpigmented macules of RAK are slightly atrophic and develop at an earlier age. Unlike dyschromatosis symmetrica hereditaria (see below), white macules are not admixed with the brown macules.

Treatment

Treatment options are similar to those listed above for Dowling–Degos disease.

DYSCHROMATOSES

Dyschromatoses are characterized by the presence of both hypo- and hyperpigmentation (Figs. 67.27–67.29). Often, at least one component of the dyspigmentation is guttate. The two classic dyschromatoses, dyschromatosis symmetrica hereditaria and dyschromatosis universalis hereditaria, are discussed in this section. A more recently recognized entity, acquired brachial cutaneous dyschromatosis, is also described. Additional dyschromatoses are listed in Table 67.11.

DYSCHROMATOSIS SYMMETRICA HEREDITARIA

Synonyms: ■ Acropigmentation of Dohi ■ Symmetrical dyschromatosis of the extremities

Key features

- Small, irregular hypopigmented and hyperpigmented macules on the dorsal aspects of the distal extremities, especially the hands and feet
- Autosomal dominant disorder caused by mutations in *ADAR*, which encodes an RNA-specific adenosine deaminase

Fig. 67.27 Dyschromic amyloidosis cutis. An admixture of reticulated hyperpigmentation and guttate hypopigmentation are evident. *Courtesy Seth J. Orlow, MD PhD.*

Fig. 67.28 Dyschromatosis symmetrica hereditaria. An admixture of multiple hypo- and hyperpigmented macules on the hands more so than on the forearms. *Courtesy Peter Ehrnstrom, MD.*

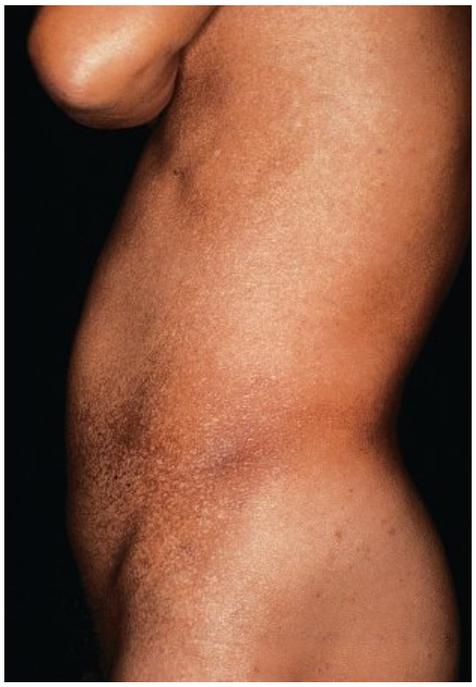

Fig. 67.29 Dyschromatosis universalis hereditaria. Both hypo- and hyperpigmentation were present in a widespread distribution. *With permission from Urabe K, Hori Y. Dyschromatosis. Semin Cutan Med Surg 1997;16:81–5.*

Introduction

Dyschromatosis symmetrica hereditaria (DSH) was first reported by Toyama in 1929. It is characterized by both hyper- and hypopigmented macules of varying size on the dorsal surfaces of the distal extremities. The vast majority of reports have come from Japan, China, and Korea, but DSH has also been described in European, Afro-Caribbean, and Indian patients[51]. The prevalence in Japan is ~1.5 per 100 000[52].

Pathogenesis

DSH has an autosomal dominant inheritance pattern with high penetrance. It is caused by heterozygous mutations in *ADAR (DSRAD)*, which encodes the RNA-specific adenosine deaminase[52–54]. Of note, biallelic *ADAR* mutations are one cause of Aicardi–Goutières syndrome (AGS), a type I interferonopathy presenting with encephalopathy and variable pernio-like skin lesions (see Table 45.7).

Clinical Features

Hyper- and hypopigmented macules arise in infancy or early childhood. The macules often increase in size and number until adolescence, when they stabilize; darkening after sun exposure may be observed. This dyschromatosis favors the distal extremities and is usually most marked on the dorsal aspects of the hands and feet (see Fig. 67.28); it spares the palms, soles, and mucous membranes. Spontaneous clearing has not been described. A few patients with dystonia and neurologic

DYSCHROMATOSES	
Disorder	**Key features**
Genetic disorders	
Dyschromatosis symmetrica hereditaria	Symmetrical dyschromatosis of distal extremities, especially dorsal aspects of hands and feet (see Fig. 67.28); palms, soles, and mucous membranes spared Usually presents by age 6 years Caused by heterozygous mutations in *ADAR*, which encodes RNA-specific adenosine deaminase Vast majority of patients are Japanese or Chinese (see text)
Dyschromatosis universalis hereditaria	Truncal or generalized hyper- and hypopigmented macules (see Fig. 67.29); can occur on palms and soles, but not mucous membranes Usually presents by age 6 years, often becoming apparent in the first year of life Subsets due to mutations in *ABCB6*, which encodes an ATP-binding cassette transporter protein, and SASH1 Most common in Japan (see text)
Xeroderma pigmentosum (XP)	Lentigines and hypopigmented macules on dorsal aspects of hands and feet, face, and other chronically sun-exposed sites (see Fig. 86.13) Actinic damage beginning in infancy and early childhood, with skin cancers often developing during the first decade of life Autosomal recessive disorder caused by defective nucleotide excision repair (complementation groups A–G) or error-free bypass (XP-variant) of UV-induced DNA damage
Dyskeratosis congenita	Reticulated hyperpigmentation can be admixed with macules of hypopigmentation; nail dystrophy and leukoplakia Predisposition to mucosal SCC and other malignancies Most common form is X-linked recessive (see Table 67.9 and text)
Epidermolysis bullosa simplex with mottled pigmentation	Acral blistering early in childhood, mottled pigmentation, punctate keratoses of the palms and soles, and dystrophic, thickened nails Typically due to a specific keratin 5 mutation (P25L; see Ch. 32)
Familial progressive hyper- and hypopigmentation (FPHH)	Generalized distribution (including face, palms, and soles) of hyper- and hypopigmented macules and patches of various sizes, with progressive development beginning in infancy; diffuse background hyperpigmentation accentuated with sun exposure Sparse lateral eyebrows, short stature Autosomal dominant due to mutations in the gene encoding KIT ligand
Wende–Bauckus/Pegum syndrome	At ~1 year of age, background hyperpigmentation (gray–brown) develops on the trunk > extremities Tiny white macules on the trunk with confluence in flexures
Ziprkowski–Margolis syndrome	Diffuse pigmentary dilution of the hair and skin, sparing the buttocks and genital region Later, multiple hyperpigmented macules appear, giving the skin a leopard-like appearance Congenital sensorineural deafness, heterochromia irides X-linked recessive inheritance
Chédiak–Higashi syndrome (CHS) and Griscelli syndrome (GS)	In addition to pigmentary dilution of the skin, patients may develop diffuse hyperpigmentation with superimposed guttate hypopigmentation in sun-exposed areas Silvery hair with clumps of melanin, bleeding diathesis (CHS), neurologic abnormalities (CHS, GS1), immunodeficiency (CHS, GS2) (see Ch. 66 and Table 60.5)

Table 67.11 Dyschromatoses.

Continued

DYSCHROMATOSES	
Disorder	**Key features**
Syndromes with ectodermal dysplasia	
Berlin syndrome	Generalized grayish-brown hyperpigmentation with superimposed guttate hypopigmented macules Sparse eyebrows with absent lateral aspect, delayed dentition/hypodontia, short stature, sexual underdevelopment in male patients, intellectual disability Described in one family (Iranians living in Israel; four affected siblings; consanguineous parents)
Lucky/Winter syndrome	Generalized hyperpigmentation with superimposed guttate hypopigmented macules most prominent in flexural sites Scant lightly pigmented hair, enamel hypoplasia (single central incisor in one patient), "digitalized" thumbs, short stature Likely autosomal dominant inheritance
Acromelanosis albo-punctata	Diffuse hyperpigmentation with superimposed guttate hypopigmentation affecting acral and flexural areas, with atrophic skin on the dorsal aspects of the hands and feet Keratotic follicular papules on the legs, pili torti, platonychia
Pigmentation defects, palmoplantar keratoderma, and cutaneous SCC	Hypo- and hyperpigmented macules on the trunk, face, and extremities develop during infancy/childhood Progressive alopecia, diffuse palmoplantar keratoderma, nail dystrophy, early loss of teeth, conjunctival telangiectasias, and cutaneous SCCs Autosomal recessive due to *SASH1* mutations (in 2 Moroccan siblings)
Exposures	
Arsenic	From systemic ingestion of inorganic arsenic Background of bronze hyperpigmentation with superimposed "raindrop"-like guttate hypopigmented macules Palmoplantar keratoses, Bowen disease, basal cell carcinoma, and SCC Increased risk of certain internal malignancies
Diphenylcyclopropenone (DPCP)	Used for topical immunotherapy for alopecia areata of the scalp Hyperpigmented patches with superimposed confetti-like hypopigmented macules occurring mainly on treated areas of the scalp, sometimes at remote untreated sites Described in four patients among 243 patients treated with DPCP
Monobenzyl ether of hydroquinone	Dyschromia with confetti-like hyper-, hypo- or depigmented macules occurring following topical application; typically used for depigmentation therapy in patients with severe vitiligo
Betel leaf (*Piper betle*)	Contact leukomelanosis on the face following application of betel leaves (used as a home remedy for hyperpigmentation) Initially described in Taiwanese patients
Photoleukomelanodermatitis of Kobori	Dyschromic drug eruption that occurs after ingestion of afloqualone, thiazides, or tetracyclines, followed by exposure to sunlight
Infections	
Secondary syphilis (necklace of Venus)	Background hyperpigmentation with superimposed white macules on neck (see Ch. 82)
Pinta	During late phases, copper-colored and slate-blue macules become admixed with depigmented macules and patches (see Ch. 74)
Other	
Dyschromic amyloidosis cutis	Generalized guttate leukoderma plus reticulated macules of hyperpigmentation (see Fig. 67.27), primarily in sun-exposed skin Onset before puberty; may have autosomal dominant inheritance Small foci of amyloid deposits in the papillary dermis
Kwashiorkor	Protein malnutrition, usually in an infant or young child Small hypopigmented macules in diaper area and on thighs, lower abdomen and back in addition to hyperpigmented areas "Flaky paint" dermatosis
Acquired brachial cutaneous dyschromatosis	Gray–brown patches with irregular borders on the extensor forearms Intermixed with the patches are hypopigmented macules and a variable number of telangiectasias Typically affects White women in the fifth to seventh decade of life and associated with chronic sun exposure

Table 67.11 Dyschromatoses. See Table 67.10 for Fanconi anemia. SASH1, SAM and SH3 domain-containing 1; SCC, squamous cell carcinoma.

deterioration associated with a particular *ADAR* mutation have been reported, and features of both DSH and AGS have been described in individuals with biallelic *ADAR* mutations.

Pathology

In the hyperpigmented macules, there is increased melanin within basal keratinocytes, while the hypopigmented macules demonstrate a decrease in the density of DOPA-positive melanocytes.

Differential Diagnosis

Reticulate acropigmentation of Kitamura lacks hypopigmented macules, while vitiligo lacks hyperpigmented macules. Patients with xeroderma pigmentosum also develop hyper- and hypopigmented macules during childhood, but the lesions are in a photodistribution that includes the face and upper trunk. In dyschromatosis universalis hereditaria (see below), the dyschromic lesions have a similar clinical appearance, but they may be present at birth in some patients and, more importantly, the distribution is primarily truncal (see Table 67.11).

Treatment

Current treatments are unsatisfactory. Strict sun avoidance may decrease the contrast between the hypo- and hyperpigmented macules[54].

DYSCHROMATOSIS UNIVERSALIS HEREDITARIA

Key features

- Hyperpigmented and hypopigmented macules in a generalized distribution, with onset in early childhood
- Most reported patients have been Japanese

Introduction and Pathogenesis

Dyschromatosis universalis hereditaria (DUH) is a rare disorder characterized by hypo- and hyperpigmented macules in a generalized distribution. Initially described in 1933, this condition is most common in Japan but has also been reported in patients from other parts of Asia and Europe. One autosomal dominant form of DUH is caused by heterozygous mutations in *ABCB6*, which encodes an ATP-binding cassette transporter protein that is expressed in keratinocytes and melanocytes[55]. Heterozygous mutations in *SASH1*, which encodes a SAM and SH3 domain-containing protein with several purported roles in melanogenesis, can result in either DUH or an autosomal dominant lentiginosis favoring sun-exposed sites[56]. In addition, biallelic *SASH1* mutations may produce a constellation of findings including palmoplantar keratoderma, alopecia, and cutaneous SCC as well as dyschromatosis (see Table 67.11). An autosomal recessive form of DUH has also been mapped to 12q21–q23.

Clinical Features

Over 80% of DUH patients develop dyschromia by 6 years of age, and ~20% have dyspigmentation at birth. Numerous hyperpigmented and hypopigmented macules of various sizes develop on the head, neck, extremities, and trunk (see Fig. 67.29). Hyperpigmented macules on the face can resemble ephelides or lentigines. The dyschromia may be accentuated in sun-exposed sites, especially in SASH1-related DUH; it can also involve the palms and soles as well as the dorsal aspects of the hands and feet, but spares the mucous membranes. There is no seasonal change or spontaneous regression with age[57]. Extracutaneous abnormalities reported in isolated cases of DUH include short stature and high-frequency deafness; abnormalities in erythrocytes, platelets and tryptophan metabolism; bilateral glaucoma and unilateral cataract; and seizures[58].

Pathology

A focal increase or decrease in the melanin content of the basal epidermal layer is seen in the hyperpigmented and hypopigmented areas, respectively[58].

Differential Diagnosis

Xeroderma pigmentosum may have similar dyspigmentation, but it is in a photodistribution and associated with premature actinic damage (see Ch. 86). Additional causes of dyschromatosis are outlined in Table 67.11.

Treatment

There is no satisfactory treatment.

ACQUIRED BRACHIAL CUTANEOUS DYSCHROMATOSIS

This acquired dyschromatosis was described in 2000[59] and primarily affects White women in the fifth to seventh decades of life. It is characterized by chronic, asymptomatic gray–brown patches with geographic borders on the dorsal aspect of the forearms[59]. Intermixed with the patches are hypopigmented macules and a variable number of telangiectasias. Affected individuals often have evidence of chronic sun exposure clinically (e.g. poikiloderma of Civatte) or histologically (e.g. solar elastosis).

Biology of Hair and Nails

68

Etienne C.E. Wang, David de Berker and Angela M. Christiano

Key features

- The pilosebaceous unit and nail apparatus are epidermal derivatives that produce two of the hardest epithelial structures in mammalian biology
- The hair follicle is the only continuously cycling organ in mammals, while the nail exhibits uninterrupted growth
- Hair and nails serve multiple functions, including protection, sensation, and social communication
- Hair shafts and nail plates largely consist of dead, terminally differentiated keratinocytes (trichocytes and onychocytes, respectively) whose durability is based on the presence of abundant keratin intermediate filaments
- The hair cycle includes phases of growth (anagen), regression (catagen), resting (telogen), and hair shaft shedding (exogen/teloptosis)
- The hair follicle is a site of immune privilege and a major reservoir for epithelial and melanocyte stem cells; immune privilege and stem cells within the nail unit are also becoming recognized
- The nail apparatus consists of the fully cornified nail plate, which is produced by the nail matrix, and other specialized epithelial tissues such as the nail bed and nail folds

PRINCIPLES OF ADNEXAL MORPHOGENESIS

Skin adnexa in mammals develop through evolutionarily conserved mechanisms. Similar processes lead to modifications of epithelial cells and proteins in order to form functional structures such as hairs, feathers, nails, glands, and teeth. In all cases, adnexa result from interactions between adjacent tissue layers, the ectoderm (epidermis) and underlying mesoderm (dermis) (Fig. 68.1). For example, the hair follicle (HF) first arises as a small epidermal bud and then, via reciprocal signaling involving the underlying dermis, progresses to form a complex, multi-cylindrical organ with associated sebaceous and apocrine glands (see Fig. 2.4). The developmental relationships among different adnexal structures is evidenced by the hair, nail, sweat gland, and tooth defects observed in ectodermal dysplasias (see Ch. 63).

The basic principles of adnexal development were defined by a series of classic tissue recombination experiments performed in the 1970s, which have served as the foundation for research in this field[1,2]. These experiments demonstrated that the dermal mesenchyme emits the initial "message" for the development of all types of skin adnexa (stage 0). The mesenchyme itself does not change morphologically but rather signals the overlying epithelium to thicken and form a placode (stage 1) (Fig. 68.2). The type of appendage that develops is determined within the epidermis, where positional and epigenetic cues dictate the ultimate phenotype[3]. Canonical β-catenin-dependent WNT (*w*ingless-type *int*egration site) signals are candidates for the dermal message, and it is thought that they precede other activators and regulators of adnexal development[4]. Recent advances in single-cell RNA sequencing and the study of increasingly smaller cellular subsets have confirmed the developmental trajectory of an early dermal condensate that drives appendageal morphogenesis[5,6].

BIOLOGY OF HAIR

Hair Follicle Morphogenesis

WNT signaling plays key roles in HF development. In mice, lack of WNT signaling through overexpression of the WNT inhibitor Dickkopf homolog 1 (DKK1) prevents HF formation[4], while overexpression of β-catenin in the epidermis (acting downstream of WNT; see Fig. 55.6) promotes conversion to a placode fate[7]. Loss-of-function mutations in *WNT10A*, which encodes an activator of WNT signaling, cause several forms of ectodermal dysplasia in humans, including odonto-onychodermal dysplasia and Schöpf–Schulz–Passarge syndrome (see Ch. 63). The spectrum of cutaneous findings that can result from *WNT10A* mutations includes hypotrichosis, nail dystrophy, palmoplantar keratoderma with eccrine syringofibroadenomatosis, and apocrine hidrocystomas[8]; in addition, *WNT10A* polymorphisms have been associated with hair shape, tooth morphology, and corneal thickness[9,10]. The APCDD1 (adenomatosis polyposis coli downregulated 1) protein normally inhibits WNT/β-catenin signaling by binding to WNT and low-density lipoprotein receptor-related proteins (LRPs) upstream of β-catenin. *APCDD1* mutations that lead to dysregulation of the WNT/β-catenin pathway result in hypotrichosis simplex characterized by hair shaft miniaturization (see Fig. 55.6)[11].

In normal mouse HF development, WNT and β-catenin activation occurs in the placode following the initial dermal signal. This induces transcription of the ectodysplasin A receptor gene (*Edar*), which mediates nuclear factor-κB (NF-κB) signaling[12]. Expression of EDAR within the primary follicle placode also suppresses inhibitory signals from the surrounding epidermis, which refines WNT/β-catenin expression within the placode. Competing gradients of WNT (activating) and DKK (inhibitory) signals within the epidermis modulate HF spacing, establishing regular intervals between follicles[13,14].

After determination of placode fate, reciprocal signaling between the mesenchyme and epithelium continue to drive HF morphogenesis through a complex interplay among secreted molecules (see Fig. 68.2). Fibroblast growth factor (FGF)-20 secreted by the placode promotes formation of a dermal condensate[15]. A second dermal signal follows,

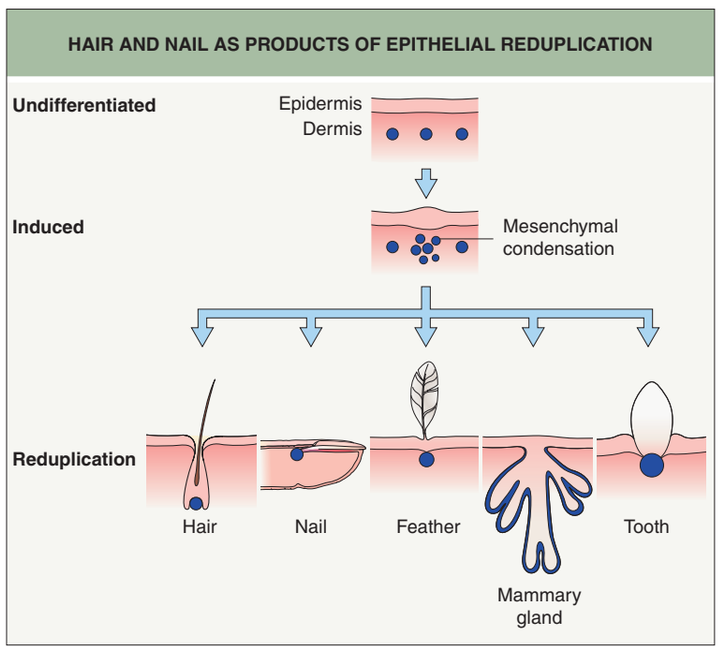

Fig. 68.1 Hair and nail as products of epithelial reduplication. *Reproduced with permission from Chuong C-M. Morphogenesis of epithelial appendages: variations on top of a common theme and implications in regeneration. In: Chuong C-M (ed). Molecular Basis of Epithelial Appendage Morphogenesis. Austin: R.G. Landes Company, 1998:3–13.*

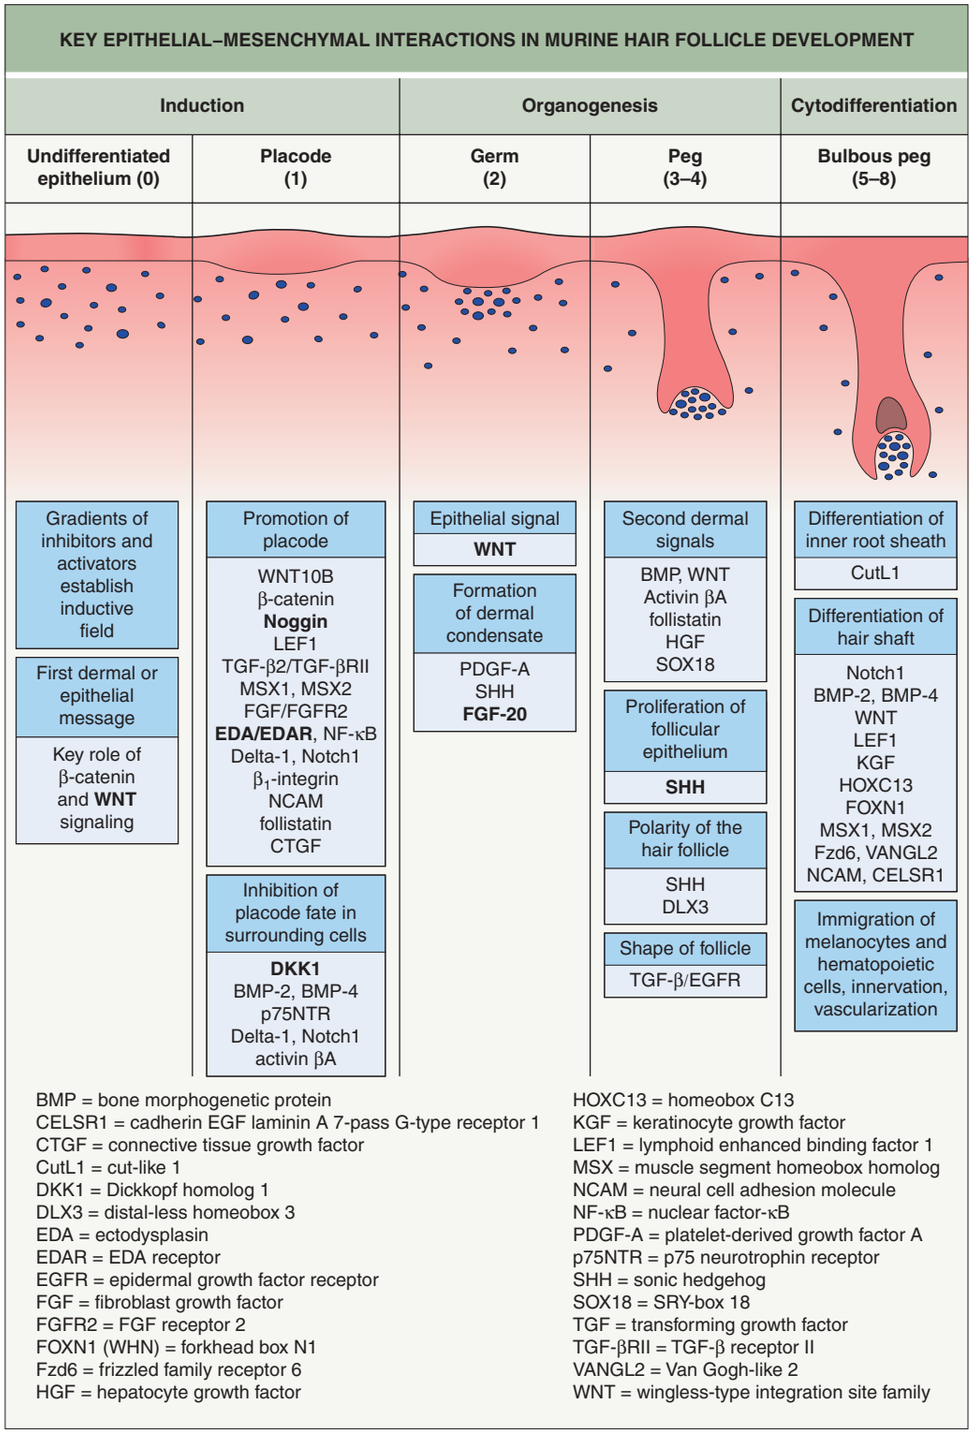

Fig. 68.2 Key epithelial–mesenchymal interactions in murine hair follicle development. The undifferentiated epithelium emits an as-yet unidentified initial signal affecting the WNT pathway, which leads to accumulation of β-catenin in the superficial dermis. Dermal cells respond with secretion of morphogens such as WNTs, ectodysplasin A (EDA), and fibroblast growth factors (FGFs) that lead to specification of the epidermal placode. The placode produces Dickkopf homolog (DKK) and bone morphogenic proteins (BMPs) that inhibit surrounding epithelial cells, thus refining the patterning. The placode matures into the primary hair germ, and its secretion of platelet-derived growth factor A (PDGF-A), sonic hedgehog (SHH), and FGF-20 promote condensation of the dermal cells. Signals from the dermal condensate include WNTs, SHH, and hepatocyte growth factor (HGF); this initiates downgrowth of the hair germ to form the peg, which envelopes the condensate and tightens the interaction interface. Subsequent cross-talk activates a host of morphogens that direct differentiation of the bulbous peg into concentric layers of keratinocytes that ultimately form the hair follicle. *Adapted from Millar SE. Molecular mechanisms regulating hair follicle development. J Invest Dermatol 2002;118:216–25.*

which induces proliferation of the epidermis and invasion of the dermis by a column of epithelial cells that forms the hair germ (stage 2), followed by the hair peg (stage 3–4) and subsequently the bulbous peg (stage 5–8) (see Fig. 68.2)[16]. WNT and EDAR signaling control the expression of sonic hedgehog (SHH), which drives downgrowth of the hair germ[17]. Primary cilia on dermal cells within the condensate coordinate SHH signaling. In mice that lack SHH or have abnormal cilia, the dermal condensate forms but proliferation and downgrowth of the epithelium are arrested[18,19]. Hemidesmosomal integrins also have a physical role in hair germ development, and mice with deficient β1 or β4 integrins have hair germs that cannot remodel their basement membrane and descend into the dermis[20,21].

During follicle development, the mesenchymal condensate is progressively engulfed by epidermal cells and becomes enclosed, thereby evolving into the dermal papilla. Although epithelial growth is initially downward, a switch to an upward differentiation program occurs in response to WNT and bone morphogenic protein (BMP) signaling from the dermal papilla. This gives rise to concentric layers of the hair shaft and inner root sheath. In human hair follicles, epithelial keratins 1, 10, 14, and 16 are expressed by 12 weeks' gestational age, with keratin 16 in proliferative regions such as the bulb; this is followed by keratin 20 expression. Epithelial cell fate depends upon the relative position of a matrix cell with respect to the dermal papilla[22]. An early effector of this signaling within the matrix is the distal-less homeobox 3 (DLX3) transcription factor, which directly regulates expression of hair keratin genes in the hair shaft and inner root sheath[23]. A dominant frameshift mutation in *DLX3* results in tricho-dento-osseous syndrome, a form of ectodermal dysplasia characterized by dystrophic hair, enamel hypoplasia, and thickening of skull and jaw bones[24]. Mutations in additional genes with key roles in hair follicle development underlie other ectodermal dysplasias as well as non-syndromic hair disorders (see Ch. 63 and Table 69.7).

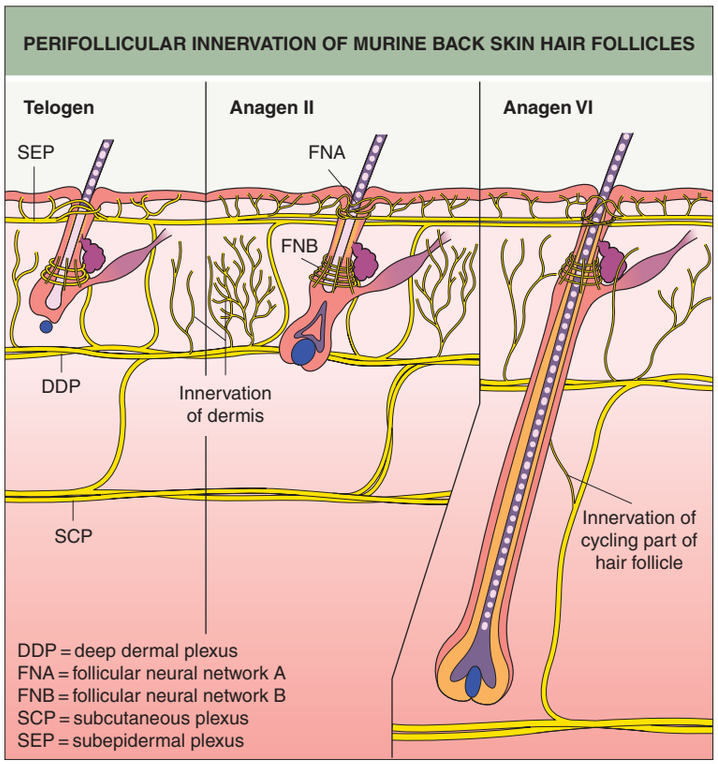

Fig. 68.3 Perifollicular innervation of murine back skin hair follicles. *Adapted from Paus R, Peters EM, Eichmüller S, Botchkarev VA. Neural mechanisms of hair growth control. J Invest Dermatol Symp Proc. 1997;2:61–8.*

Complex neural networks develop in conjunction with HF morphogenesis. Nerve fibers arrive in the skin first and are located at presumptive follicular sites, running parallel to a dense network of blood vessels (Fig. 68.3). Developing follicles become innervated around stage 5, with nerve fibers encircling the isthmus and bulge regions[25]. Neurotrophins released from the follicular epithelium regulate this innervation, and in turn the nerves may influence the stem cell niche of the HF[26]. Similarly, signaling proteins that promote angiogenesis, such as vascular endothelial growth factor (VEGF), are released from the epithelium and affect development of the vascular network surrounding HFs[27].

Hair follicle patterning

Individual mammals can produce different types of hairs that share basic architectural principles. In the dorsal skin of mice, HF development occurs in three successive waves: (1) large, straight, *primary guard* or *tylotrich* hairs, which comprise 1%–3% of total hairs and have two sebaceous glands, form on embryonic day 14.5; (2) *secondary awl* (straight, ~30% of the coat) and *auchene* (one bend, ~0.1% of the coat) hairs form on embryonic day 16.5; and (3) *tertiary zigzag* hairs, which have several bends and account for ~70% of the coat, form on embryonic day 18.5. The mouse coat therefore contains four distinct hair types, in addition to specialized hairs such as vibrissae (whiskers) and tail hairs[28]. EDAR is necessary for placode development in primary HFs[29] but not for induction of secondary HFs, which utilize signaling pathways that involve Noggin and SRY-box 18 (SOX18) expression within the dermal papillae[29–31].

In humans, hypohidrotic ectodermal dysplasia (HED) with abnormal morphogenesis of scalp hair, sweat glands, and teeth results from mutations in the genes encoding components of the EDAR/NF-κB signaling pathway, including EDAR, its ligand ectodysplasin A, and the downstream effector EDAR-associated death domain (EDARADD)[32] (see Fig. 63.15). In addition, a non-synonymous single nucleotide polymorphism (SNP) within *EDAR* is associated with increased hair thickness in Asian populations[33]. Deep deformations in the hair shaft were identified in Swedish patients with an autosomal dominant form of HED due to an *EDAR* mutation[34]. These clinical observations underscore the importance of the EDAR/NF-κB signaling pathway in human appendage development. Interestingly, mutations in human *SOX18* cause lymphedema and telangiectasias as well as hypotrichosis[35].

The hairs of the mouse dorsal coat have anterior–posterior polarity along the body axis, which contributes to formation of a sleek coat. SHH and neural cell adhesion molecule (NCAM) within the HF have an asymmetric distribution pattern, which is established by a conserved planar cell polarity (PCP) pathway during hair germ development[36]. PCP proteins VANGL2 (Van Gogh-like 2) and CELSR1 (cadherin epidermal growth factor laminin A seven-pass G-type receptor 1) respond to directional cues and are necessary for the correct polarization of follicles within the skin[36,37]. Mutations in *Vangl2* or the frizzled family receptor 6 (*Fzd6*) affect the early global alignment of HFs, resulting in germs that first grow vertically. Over time the follicles reorient themselves in competing patterns, producing characteristic whorls on the back of the mouse[38]. In *Fzd6*$^{-/-}$ mice, an additional mutation in Astrotactin2 (*Astn2*), which has roles in neuronal migration, leads to a 180-degree reorientation of the dorsal coat to a posterior–anterior polarity[39]. Hair whorls are frequently observed in mammals, such as on the occipital scalp in humans, between the eyes in horses and cattle, and on the upper chest in dogs[38]. Aberrant or displaced hair whorls are observed in a number of genetic disorders (omim.org).

Under physiologic conditions, human HF morphogenesis occurs only once. Lanugo, vellus, and terminal hairs have the same basic architecture (Table 68.1). The first "coat" is composed of fine, long, variably pigmented lanugo hair, which is shed in an anterior-to-posterior wave during the third trimester. A second coat of fine, shorter, unpigmented lanugo hair then grows in all areas except the scalp and is shed 3–4 months after birth; pigmented scalp hairs, which have variable lengths and diameters, are also shed postnatally in an anterior-to-posterior wave. Thereafter, the hair grows in an asynchronous "mosaic" pattern rather than waves. In prepubertal children, hair is terminal on the scalp, eyelashes, and eyebrows, while it is vellus on the face, trunk, and extremities. During puberty, vellus hairs in some sites become terminal hairs under the influence of androgens. Paradoxically, terminal hairs on the scalp exposed to the same androgens revert to miniaturized vellus-like hairs in androgenetic alopecia.

Congenital generalized hypertrichosis (Ambras syndrome) is characterized by a disruption in the patterning of hairs, with terminal hairs growing at sites that normally have vellus follicles[40]. A position effect that downregulates the expression of the trichorhinophalangeal syndrome I gene (*TRPS1*) was found to underlie this hypertrichosis phenotype in both humans and mice[41]. In addition, X-linked congenital generalized hypertrichosis in a Mexican family was associated with a position effect that decreased the expression of *FGF13*[42].

In most mammals, the hair pattern differs depending on the body site. While the ectoderm involved in skin and hair development is non-neural and relatively homogeneous, the mesenchyme has various origins which may explain this regionalization. The dorsal dermis is derived from the somitic dermomyotome, the ventral dermis has a somatopleural origin, and the craniofacial dermis arises from the neural crest[43,44]. The dermal progenitors at each of these sites are specified by different signaling pathways. Mice display regional differences in skin thickness as well as hair color and type. The postnatal identity of their skin is acquired by embryonic day 12.5, with the T-box 15 (TBX15) transcription factor appearing within dorsal skin to demarcate the dorsal–ventral boundary[45].

In humans, the effects of androgens on HFs depend upon the body site. Follicles in the frontal scalp are normally androgen-dependent, whereas occipital scalp follicles are hormonally insensitive and therefore less susceptible to androgenetic alopecia. When HFs from the occipital scalp are transplanted to the frontal scalp, they typically retain the pigmentary characteristics, androgen sensitivity, and growth rate of the donor site[46]. However, in other instances, transplanted hairs take on characteristics of the recipient site, such as scalp hairs moved into the eyebrow region. It remains to be established exactly which characteristics are more influenced by the recipient site versus the donor site following transplantation.

Postnatal hair follicle development

Although HF formation in general occurs prior to birth, adult mammalian skin retains the capacity for HF morphogenesis. In adult mouse and rabbit skin, WNT-dependent *de novo* HF formation occurs after wounding[47]; this is mediated by FGF-9 secreted by infiltrating γδ-T cells and wound

TRICHOLOGY TERMS	
Hair follicle (HF) cycle	Autonomous, rhythmic transformation of fully developed HFs through phases of growth, regression, and resting; controlled by the follicle itself by an as yet enigmatic "hair cycle clock", with modulation by numerous systemic/extrafollicular factors
Anagen	Growth stage of the HF cycle
Catagen	Involution of the lower two-thirds of the HF by massive keratinocyte apoptosis
Telogen	Resting phase of the HF cycle
Exogen	Phase of active hair shaft shedding (during anagen in rodents; most likely during the telogen to anagen transition in humans)
Kenogen	Telogen follicle with no club hair present
Hair bulb	Lowermost portion of the HF
Hair matrix	Rapidly proliferating keratinocytes that terminally differentiate to produce the hair shaft
Club hair/fiber	Fully keratinized proximal tip of hair shaft, formed during late catagen and telogen; brush-like appearance; characteristic of telogen follicles
Vellus hair (follicle)	Very short, non-pigmented, and usually non-medullated; absence of arrector pili muscle; tiny vellus follicles can have large sebaceous glands (face); undergo full hair cycle, yet much shorter than terminal hair
Terminal hair	Large, usually pigmented and medullated hair
Lanugo hair	Fine hair on the fetal body; shed *in utero* or during the first weeks of life
Vibrissae	Special sensory HFs found on the upper lips/snout region in non-human mammals, especially rodents; largest and most densely innervated HFs with special sinusoid blood supply; first HFs to develop
Tylotrich HF	Large sensory HFs interspersed within truncal skin of non-human mammals, most notably rodents; extra large, long hair shaft, typically associated with double sebaceous gland and an innervated epidermal Merkel cell complex (Pinkus' Haarscheibe); second type of HF to develop
Non-tylotrich pelage hair	Majority of all HFs in non-human mammals; last to develop
Effluvium	Process of excessive shedding of hair shafts
Alopecia	Result of abnormal hair loss
Hirsutism	Excessive vellus-to-terminal hair conversion in androgen-dependent areas in women
Miniaturization	Terminal-to-vellus hair conversion, e.g. on the balding scalp in androgenetic alopecia; these miniaturized follicles still have an arrector pili muscle, unlike true vellus hairs
Infundibulum of follicle	Region extending from the junction with the interfollicular epidermis to the opening of the sebaceous gland; displays cornification similar to that of the interfollicular epidermis
Isthmus of follicle	Region located between the opening of the sebaceous gland and the site of insertion of the arrector pili muscle; displays trichilemmal keratinization
Arrector pili muscle	Inserts at the level of the bulge; pulls up hair ("goose bumps")
Bulge	Segment of the outer root sheath located at the level of arrector pili muscle insertion; major seat of epithelial stem cells of the HF
Secondary hair germ	Additional seat of epithelial stem cells and site of melanocyte stem cells; located between club hair and dermal papilla in telogen HF
Dermal sheath	Special mesenchymal follicular sheath that is tightly attached to the HF basement membrane and is continuous with the follicular dermal papilla
Follicular dermal papilla (DP)	Onion-shaped, closely packed, specialized fibroblast population with inductive and morphogenic properties; hair cycle-dependent fibroblast trafficking occurs between the dermal sheath and DP; volume of DP determines size of hair bulb and, thus, hair shaft diameter
Inner root sheath (IRS)	Packages and guides the hair shaft; cornifies
Outer root sheath (ORS)	Merges distally into the epidermis and proximally into the hair bulb; provides slippage plane, nutrition, regulatory molecules, and stem cells
Follicle pigmentary unit	Melanin-producing HF melanocytes located above and around the upper one-third of the DP; transfer eu- or pheomelanosomes to differentiating HF keratinocytes in the precortical matrix; goes largely into apoptosis during each catagen phase, regenerated from melanocyte stem cells in hair germ (and possibly from non-melanogenic ORS melanocytes) during anagen

fibroblasts[48]. WNT-dependent expression of FGFs may also play a role in human hair follicle regeneration[49]. It is therefore reasonable to consider possible therapeutic interventions that would initiate *de novo* HF formation on the human scalp[50]. Trans-species end-bulb formation and hair fiber growth has been demonstrated after implantation of intact human dermal papillae onto transected mouse whisker follicles[51]. In humans, allogeneic transplantation of tissue from the dermal sheath that surrounds the dermal papilla can induce new follicle formation in the recipient, with immune privilege providing protection from rejection[52]. In addition, cultured tooth mesenchymal papilla cells from humans and rats have been shown to induce hair fiber formation in an amputated follicle, highlighting the conservation of inductive signals among different adnexa[53].

Dermal papilla cells in rodents show much more inductive potency than their human counterparts. Rodent HF papilla cells can reprogram differentiated glabrous epidermis to produce a *de novo* HF, and they are also capable of initiating transdifferentiation of amnion or even adult corneal epithelium into epidermis complete with HFs[54,55]. Human dermal papilla cells lose their inductive properties quickly in a standard monolayer culture, which hampers the utilization of these cells for hair regeneration. However, dermal papilla cells grown in a three-dimensional spheroid culture have been shown to retain their ability to induce hair growth in glabrous skin, suggesting that cellular interactions are critical to maintenance of dermal papilla identity[56].

The Mature Hair Follicle: Cycling and Anatomy

Once the mature HF is generated during embryogenesis and early postnatal life, it begins to cycle and continues to do so throughout its lifetime. The phases of the hair cycle include active growth (anagen), regression (catagen), and rest (telogen) (Fig. 68.4A). As noted above, mouse follicles cycle in a synchronous wave along the anterior to posterior axis, while human follicles cycle in a mosaic pattern. HF cycling is an autonomous phenomenon that continues even when HF units are isolated from the skin and grown in culture[57]. Signaling pathways involved in HF morphogenesis, including those mediated by WNT and FGFs, also regulate the mature hair cycle[58]. The portion of

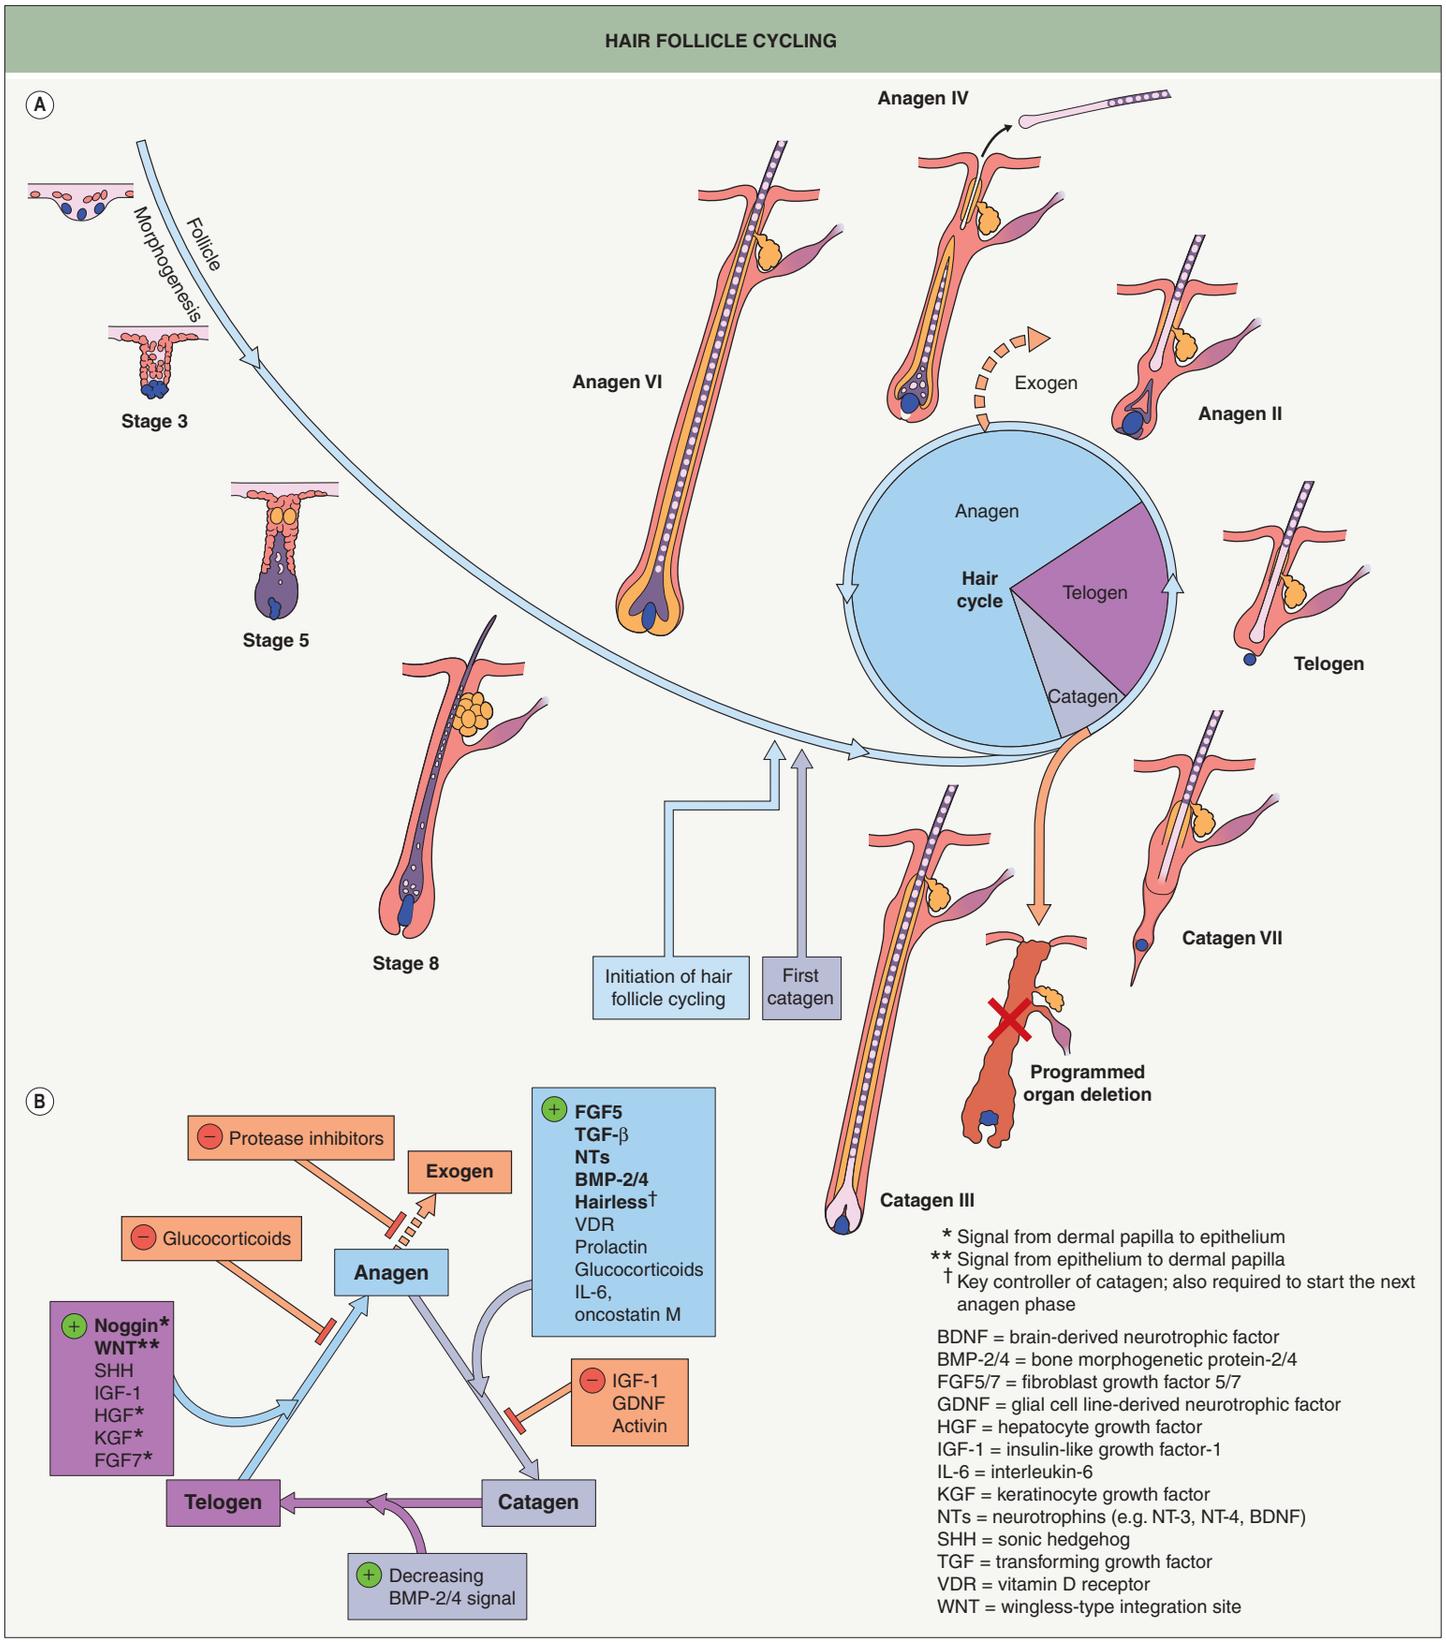

Fig. 68.4 Hair follicle cycling. A Model of hair follicle development and cycling. Although exogen is coupled to anagen in rodents, the timing of exogen in humans is less well characterized, and the club fiber is thought to usually be shed during the telogen to anagen transition. **B** Regulation of hair.

the follicle below the bulge undergoes distinct morphologic changes as it grows and regresses; in contrast, the upper region of the follicle including the sebaceous gland, isthmus, infundibulum, and hair canal remains permanent.

The process of cycling makes the HF a dynamic structure, enabling animals to have different hair lengths depending on the body site and to change their coats depending on the season for camouflage and insulation (Table 68.2). Coat changes involve two processes: (1) exogen – signals and structural changes culminating in hair shedding (teloptosis); and (2) initiation of new hair fiber growth[59]. "Kenogen" refers to a telogen follicle that has lost its club fiber but has not yet transitioned to anagen, representing the "true" resting phase of the hair cycle where metabolic activity is at a minimum.

Anagen

Anagen is the period of active hair fiber production, and its duration varies depending upon factors such as species and body site (Table 68.3). Anagen is divided into six substages, anagen I–VI; it lasts 1–3 weeks in mice and up to several years on the human scalp[60,61], explaining the longer lengths of human scalp hair. The start of anagen (anagen I), as observed in mouse skin, is associated with an increased size of the dermal papilla, due mainly to an influx of cells from the surrounding dermal sheath. Dermal sheath cells at the base of the follicle also contribute to dermal papilla regeneration after removal of the lower follicle[62,63]. The influx of cells at the start of anagen is accompanied by an increase in ECM material. This doubles the size of the dermal papilla[64], the width of which is directly proportional to the thickness of the hair shaft produced by the follicle. The degree of axial symmetry within the hair bulb determines the curvature of the final hair structure[65].

The dermal papilla provides signals to the surrounding matrix cells, whose position with respect to the dermal papilla specifies their fate, e.g. central cells become the medulla[22]. As the matrix cells begin to differentiate, they form precursor cells of the different follicle lineages. Migrating upwards, these cells undergo specialized programs of differentiation, expressing specific sets of keratins to form seven concentric epithelial lineages of the follicle, from the medulla to the companion layer (Figs. 68.5 and 68.6). In contrast, the outer root sheath (ORS), which is the outermost layer of the epidermal portion of the follicle, does not originate from upward growth of matrix cells, but rather directly from the bulge (see below)[66]. The growing HF ends up nestled in the subcutaneous fat by anagen VI. In the mouse, dermal adipocyte precursors secrete platelet-derived growth factor-A (PDGF-A), which acts on the dermal papilla to support anagen[67].

In rodents and rabbits, plucking telogen hairs can accelerate onset of the next anagen phase. The trauma of plucking causes release of chemokine C-C motif ligand 2 (CCL2) by the follicle, leading to recruitment of macrophages that secrete tumor necrosis factor (TNF), which promotes local follicles to enter anagen[68]. Osteopontin, which is produced by melanocytic nevi, also promotes anagen entry and stimulates hair growth[68a]. Other microenvironmental cues and "quorum-sensing" among HFs also likely play a role in hair cycle coordination.

FUNCTIONS OF HAIR AND NAILS
Functional properties of hair shafts
• Social and sexual communication • Camouflage • Protection against chemical and physical damage • Protection against insects • Provide sensory "antennae" • Insulation against heat loss, overheating, and desiccation • Removal from the skin surface of parasites, dirt, debris, and squames by the outward-moving hair shaft • Facilitation of sebum, apocrine sweat, and pheromone secretion • Organ of scavenging and excretion via the melanized hair shaft, which serves to deposit and extradite unwanted molecules • Hair shaft medulla can serve as a fiberoptic device for conversion of UV light into heat (polar bear)
Functional properties of pilosebaceous units
• Production, extrusion, containment, and mooring of pigmented hair shafts • Crucial stem cell reservoir, e.g. for keratinocytes and melanocytes • Reservoir for Langerhans cells • Highly sensitive tactile organs that sense hair shaft movements • Generate sebum, apocrine sweat, and pheromones
Functional properties of nails
• Social and sexual communication (color, shape, length) and aesthetic appearance • Protection of the distal phalanges of the digits from mechanical, chemical, and biological trauma • Contribute to the tactile discrimination and fine motor capacities of the fingertips • Provide the ability to scratch and groom • Rudimentary natural weapons • Contribute to pedal biomechanics essential for full motor functioning of the feet

Catagen

At the end of anagen, the follicle enters the regressive catagen phase, which is divided into eight substages (catagen I–VIII)[69]. Catagen lasts ~2 weeks in humans, regardless of the site and follicle type[61]. The initiation of catagen is characterized by a nearly 50% reduction in the volume of the dermal papilla due to loss of ECM and migration of cells into the surrounding dermal sheath, which acts as a repository that replenishes the dermal papilla in the subsequent anagen[70]. Melanocytes in the hair bulb also downregulate melanogenesis. Later, there is cessation of mitotic activity within the matrix cells of the bulb, and the remaining hair precursor cells at the base of the shaft differentiate to form a "club fiber".

The club fiber migrates up the follicle, and a germ capsule termed the trichilemmal sac forms around its base. This club fiber lacks pigmentation and is formed from cortical and cuticle cells only. The electron-dense, non-nucleated layer of trichilemmal keratin around its base has a characteristic "brush" structure that protrudes outwards and between surrounding ORS cells[71]. Abundant desmosomes between the trichilemmal keratin and surrounding tissue are thought to physically anchor the club fiber within its trichilemmal sac until it receives the signal for release[72].

As the club fiber moves up the follicle, the dermal papilla, which is initially still in the subcutaneous fat, becomes separated from the club by an epithelial strand that is surrounded by basement membrane (the glassy membrane)[73]. Apoptosis in the epithelial strand creates an "apoptotic force" that draws the dermal papilla up to just beneath the club fiber in the dermis, leaving behind a trailing dermal sheath called a fibrous streamer or stele[59]. FGF-5 produced by macrophage-like cells facilitates regression of human HFs[74], and *FGF5* mutations underlie familial trichomegaly characterized by abnormally long eyelashes[75]. Macrophages also participate in the clearance of cellular debris during catagen[76,77].

Loss-of-function mutations in the hairless gene (*HR*) can result in atrichia with papular lesions (APL)[78,79], a rare autosomal recessive disease characterized by complete hair loss early in life and later eruption of papular lesions. Hairless is a transcription factor that is required for apoptosis in the epithelial strand, which draws the dermal papilla up beneath the club fiber and secondary hair germ in a position to activate the next anagen phase. Thus, individuals with APL are born with hair, which never grows back after it is shed. Activating mutations in the upstream open reading frame of *HR* lead to another form of sparse hair, Marie Unna hypotrichosis[80]. Hairless interacts with the vitamin D receptor (VDR), which has ligand-independent functions in hair cycle control[81]. Patients with hereditary vitamin D-resistant rickets caused by *VDR* mutations present with alopecia that is not corrected by vitamin D supplementation[82].

Telogen

Telogen begins when the dermal papilla reaches the base of the permanent portion of the HF. The duration of telogen can be as short as 2 days in mice and as long as 3 months for human scalp hairs. The hair germ is derived from the bulge during the catagen-to-telogen transition and lies inferior to the bulge, separating the latter from the dermal papilla[83]. As in HF morphogenesis, epithelial–mesenchymal cross-talk is required to activate the new anagen phase. Anagen progression recapitulates the middle and later stages of HF development, and many factors that drive follicle morphogenesis (e.g. WNT, SHH, noggin) also play important roles in telogen-to-anagen transition (Fig. 68.4B). The

BASIC INFORMATION ON HUMAN HAIR FOLLICLES (HFs)	
Total number	~5 000 000 (mostly vellus)
Number of scalp HFs	~100 000 Blondes: + 20% Redheads: – 20%
Average density of hairs on the scalp*	Terminal + vellus: 1135/cm^2 (newborn) 615/cm^2 (20–30 years) 485/cm^2 (30–50 years) 435/cm^2 (70–80 years) African-Americans, Asians: lower density Terminal only: ~250/cm^2 Bald scalp (45–70 years): 330/cm^2 Highest density: cheek + forehead
Hair embryology	Development progresses at fixed intervals in cephalocaudal direction, first becoming visible in eyebrow, upper lip, and chin regions (9th week) At 16 weeks, hair shafts are formed in these regions HFs are formed in sequential waves of interspersed follicles
Hair cycle distribution for terminal scalp hair	Anagen: 85%–90% Telogen: 10%–15% Catagen: <1%
Duration of hair cycle phases	Anagen: 2–6 years Telogen: 2–3 weeks Catagen: 3 months } Terminal scalp hair
	There are substantial variations in anagen duration: Terminal mustache: 4–14 weeks Terminal on arms: 6–12 weeks Terminal on legs: 19–26 weeks Vellus: 6–12 weeks Premature anagen is induced by plucking of telogen hair shafts (depilation) Estrogens prolong anagen Thyroxine promotes growth, corticosteroids retard anagen onset
Number of lifetime cycles per scalp follicle	10–20
Physiologic hair shedding rate (scalp)	~100–200/day, with substantial interindividual and seasonal variations
Hair shaft production rate (scalp)	~0.35 mm/day, 1 cm/month Hair production is not influenced by cutting/shaving Estrogens reduce hair growth rate Androgens increase hair growth rate and hair diameter in androgen-dependent sites (e.g. beard)
Hair shaft diameter and length	Vellus: <0.03 mm; 1–2 mm Terminal: >0.06 mm; 1–50 cm Average diameter: Asian hair (circular): 120 microns Caucasian (elliptic): 50–90 microns
Hair shaft structures	Cuticle (outside), cortex, medulla (center) Cuticle maintains hair fiber integrity Cortex contains bulk of hair keratins and keratin-associated proteins Hair fiber strength is largely due to disulfide bonding Medulla consists of loosely connected trichocytes with large intercellular air spaces; provides insulation (animals)
Hair shaft pigmentation	Dark hair: predominance of eumelanin Blond/red hair: predominance of pheomelanin Melanosomes of hair cortex larger than those of epidermis
Hair graying (canities)	Generally commences in the third to fourth decade of life on the temples, spreading later to crown and occiput; by the age of 50 years, 50% of the population has at least 50% grey hair
Hair patterns	Pubic hair: horizontal (90% of women, 20% of men), acuminate (10% of women, 50% of men) Diffuse chest hair: normally grows only in men, after puberty until 6th decade Axillary: appears about 2 years after first pubic hairs, more sparse in Asians than White individuals; frequently absent in older individuals Trichoglyphics: single, clockwise parietal whirl present in 95% of individuals

Table 68.3 Basic information on human hair follicles (HFs).

bulge is relatively quiescent during telogen, traditionally referred to as the "resting" phase, due to inhibitory signals (e.g. FGF-18, BMP-6) from keratin 6-positive inner bulge cells[84]. The apparent dormancy of the HF during telogen may be an energy-efficient adaptation allowing for the maintenance of stem cells in preparation for the next anagen phase[85]. Consistent with this theory, mitochondrially localized myelin protein zero-like 3 (MPZL3) has recently been implicated in murine hair follicle cycling.[86]

The macro-environment surrounding the HF also takes part in regulating cycle transitions[87]. Immune cells surrounding the HF interact with the HF stem cell niche to control hair cycling. For example, in mice, TREM2$^+$ (triggering receptor expressed on myeloid

cells 2) macrophages produce oncostatin M, which maintains the quiescence of HF stem cells and prevents anagen entry[88]. BMPs in the subcutaneous fat maintain HFs in a "refractory" telogen, and cessation of this inhibitory signal enables the follicle to progress to a "competent" telogen with a hair germ (biochemically distinct from the bulge) that is responsive to anagen-initiation signals and capable of entering a new anagen phase[83,89]. After secondary hair germ activation, the germ cells begin to contribute to the hair matrix and concentric layers of the follicle via an upward movement, while bulge cells generate the ORS through a downward movement[90]. In follicles with a longer anagen duration, the proliferative capacity of the matrix is not sufficient to sustain growth. The "stem cell trafficking theory" proposes that a continuous migration of precursor cells from the bulge down the ORS prevents exhaustion of the germinative matrix during anagen[91].

Exogen

The stimulus for entry into catagen, and hence the formation of a club hair, typically occurs several months before the hair is shed in humans[92]. "Exogen" represents the shedding of the club fiber (teloptosis) as well as the preceding signals and structural changes in the follicle[59]. Exogen is considered to be an active proteolytic event rather than a passive process where the club fiber is dislodged due solely to mechanical forces from the new growing fiber. A gradual decrease in the adhesion of the club fiber within its epithelial silo has been observed prior to its programmed release from the follicle[93].

Structure of the hair fiber

In response to signals from the dermal papilla, the matrix cells at the base of the follicle proliferate and differentiate during anagen, forming the layers of the follicle. The three central lineages – medulla, cortex, and hair cuticle – form the hair fiber, which fulfills the primary hair-producing function of the anagen follicle. Surrounding the hair fiber are the three concentric layers that compose the inner root sheath (IRS): the IRS cuticle, Huxley's layer, and Henle's layer. The IRS undergoes a complex program of differentiation during anagen, with Henle's layer terminally differentiating shortly after formation. The IRS cuticle differentiates further up the follicle, followed by Huxley's layer; all three layers undergo desmosomal remodeling during terminal differentiation[94]. The IRS forms a mechanically supportive tube around the hair fiber and is degraded by proteolytic enzymes at the level of the isthmus[95], allowing the hair shaft to enter the hair canal and emerge from the skin surface. Heparanase expressed in the IRS during anagen

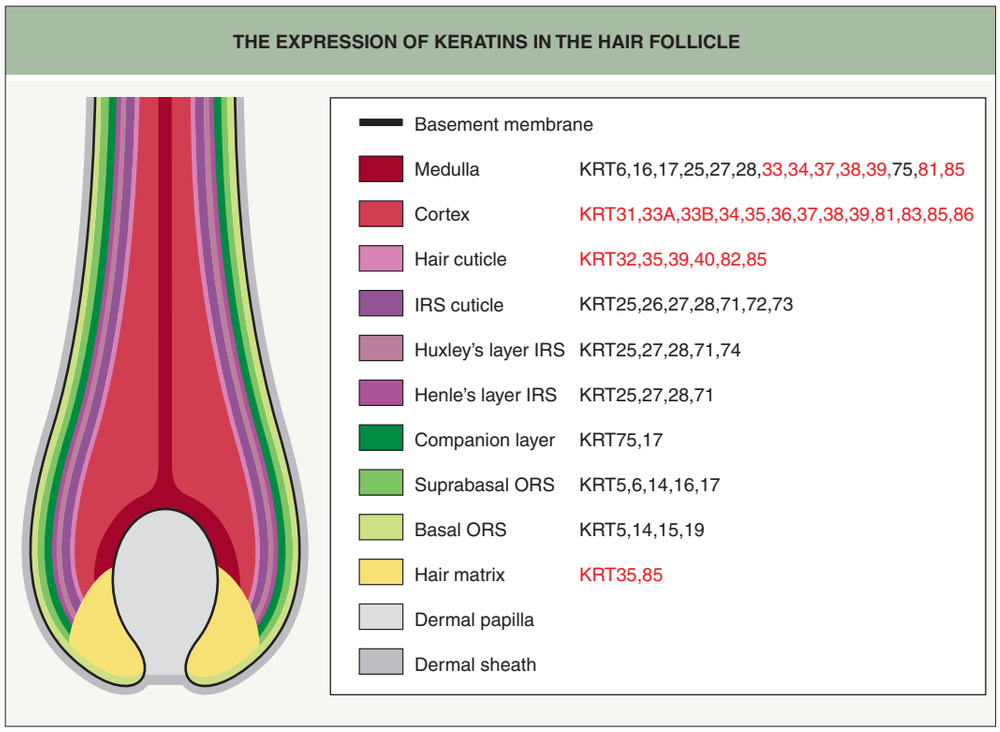

Fig. 68.6 The expression of keratins in the hair follicle. Hair keratins are in red font. KRT, keratin.

acts on heparin sulfate proteoglycans and controls IRS differentiation by influencing growth factor sequestration and diffusion[96].

The seventh concentric layer that originates from the matrix in line with the hair fiber and IRS is the companion layer, which is a single cell thick. Regarded as the "slippage plane" between the IRS and the surrounding ORS during anagen, the companion layer enables directional hair growth. It is attached to the IRS through "Flugelzellen" structures that extend from Huxley's layer through Henle's layer and link to the companion layer via numerous desmosomes[97,98]. A "barrel" of transversely oriented intermediate filaments on the inner side of the companion layer are thought to provide support for the inner root sheath, protecting it from the compressive forces of the expanding ORS[99].

Hair Keratins

The 54 functional keratin genes encode 28 type I and 26 type II keratins, which form heterodimeric pairs containing one keratin of each type[100]. There are 11 type I hair keratins, designated KRT31–KRT40, and six type II hair keratins, designated KRT81–KRT86 (see Table 56.2); the remainder are epithelial keratins[101,102]. Compared to epithelial keratins, hair keratins possess more sulfur in their head and tail domains, which allows them to form tight cross-links via disulfide bonds.

Different hair and epithelial keratins are expressed in the concentric layers of the HF, with hair keratins found primarily in the cortex and hair cuticle (see Fig. 56.6)[103]. Autosomal dominant monilethrix, which features fragile "beaded" hairs and follicular hyperkeratosis, is caused by mutations in the helix termination and initiation motifs of several type II hair keratins: KRT81, KRT86, and (less commonly) KRT83[104,105]. These keratins are highly expressed within the hair cortex and are critical to its development[104,105]. Mutations in the genes encoding KRT85 and KRT74 (see below) underlie autosomal recessive pure hair and nail ectodermal dysplasia. KRT85 is primarily expressed in the matrix of the follicle, which explains the total alopecia observed in these patients[106].

Some epithelial keratins exhibit HF specificity (see Fig. 68.6). The type I keratins KRT25, KRT27, and KRT28 and the type II keratin KRT71 are expressed within the IRS (cuticle, Huxley's layer, and Henle's layer). KRT74 is restricted to Huxley's layer, while KRT72 and KRT73 are found in the IRS cuticle[107]. Mutations in the genes encoding KRT71 and KRT74 can cause autosomal dominant woolly hair with or (for KRT74) without associated hypotrichosis[108,109], and a homozygous missense variant in *KRT25* has been implicated in autosomal recessive woolly hair[110].

The companion layer contains only one type II keratin, the epithelial KRT75, which is also expressed in the medulla of the hair shaft and the fungiform papillae of the tongue. Pseudofolliculitis barbae and loose anagen hair syndrome have possible links to defects in KRT75 in some patients[101]; KRT75 polymorphisms are also associated with reduced enamel hardness and increased risk of dental caries, highlighting the link between tooth and hair architecture[111]. The ORS expresses several keratins, including KRT5/KRT14, KRT6a/KRT16, and KRT6b/KRT17 (see Fig. 68.6). However, patients with pachyonychia congenita due to mutations in the latter keratin pairs only occasionally exhibit hair abnormalities such as pili torti (primarily with KRT17 defects)[112].

Desmosomes in the Hair Follicle

Desmosomes are specialized adhesive structures that couple neighboring cells together in a variety of tissues, with particular importance in epithelia and the myocardium[113]. Each desmosome is connected to the intermediate filament cytoskeletons of the interacting cells, which imparts resilience and resistance to mechanical stress (see Fig. 56.8). Desmogleins (Dsg1–4) and desmocollins (Dsc1–3) are desmosome-specific cadherins that interact in the intercellular space to couple the two halves of the desmosome; they are connected to intermediate filaments via the linker proteins plakoglobin, plakophilins (Pkp1–3), and desmoplakin. Mutations in genes encoding desmosomal components can result in diseases affecting: (1) the hair – woolly, fragile, and/or sparse; (2) the skin – palmoplantar keratoderma, fragility/blistering; and (3) the heart – cardiomyopathy. This leads to multisystem disorders such as Naxos disease, Carvajal syndrome, and skin fragility–ectodermal dysplasia syndrome (see Fig. 56.8 and Ch. 58).

All four desmogleins are found in the HF, with differentiation-specific expression patterns[114,115]. Dsg4 is the only desmosomal cadherin that is highly expressed in the hair shaft cortex, including the keratinizing zone in which hair keratins are abundant. Dsg4 is also present in the precortex, lower hair cuticle, upper IRS cuticle, and interfollicular epidermis (granular and cornified layers)[116]. Transcription factors that regulate the expression of both Dsg4 and hair keratins in differentiating trichocytes include LEF1 (lymphoid enhancer-binding factor), HOXC13 (homeobox C13), and FOXN1 (forkhead box N1)[117]. Dsg4 is a key mediator of keratinocyte adhesion in the HF, where it coordinates the transition from proliferation to differentiation[116]. Mutations in *DSG4* can cause autosomal recessive forms of localized hypotrichosis and monilethrix, with the pathomechanism involving a stress response due to accumulation of the mutant protein in the endoplasmic reticulum (ER)[118].

Although hair shedding and alopecia result when Dsg3 is disrupted in mice[119,120], similar hair phenotypes have not been identified in humans with Dsg3 defects. However, a homozygous mutation in *DSC3* has been reported to underlie hypotrichosis with recurrent skin "vesicles"[121]. In addition, mutations in *CDSN* which encodes corneodesmosin, a glycoprotein found in the IRS and modified desmosomes within the stratum corneum, can result in autosomal dominant hypotrichosis simplex of the scalp (see Fig. 56.8)[122]. *CDSN* mutations also cause autosomal recessive inflammatory peeling skin syndrome, reflecting the role of corneodesmosin proteolysis in desquamation[123].

Hair Follicle Stem Cells

Adult stem cells have the ability to self-renew and to regenerate tissues during homeostasis and wound repair. Given the dynamic remodeling seen with the cyclic regeneration of the HF, it has long been postulated that it contains one or more stem cell niche(s) (see Ch. 2). Studies in the 1990s showed that slow-cycling, label-retaining cells (characteristics of stem cells) are localized within the HF bulge area, which is named for the swelling evident at this site in rodents[66].

Although the bulge architecture in mice is not pronounced until 3 weeks after birth, slow-cycling bulge cells can be identified during early stages of murine HF morphogenesis by the marker SOX9[124]. During anagen in adult mouse skin, bulge stem cells express distinctive markers, including SOX9 as well as S100A4 and CD34. The molecular architecture of the bulge is not identical in mice and humans, as the human HF stem cell niche is not morphologically distinct. However, analysis of human anagen HFs have identified distinctive human bulge cells with clonogenic potential that express CD200 but, in contrast to bulge cells in mice, not CD34 (see Table 2.2)[125].

When murine follicles cycle through telogen, a secondary hair germ is formed below the bulge, just above the dermal papilla. Bulge cell progeny in this hair germ that had migrated out of the stem cell niche during the previous anagen are capable of returning and regaining stem cell characteristics[84]. Some markers are expressed in both the secondary hair germ and the bulge, including keratin 15 and (at low levels) SOX9[83] while others are only highly expressed in the former (e.g. P-cadherin, LEF1)[83]. Following wounding, bulge and hair germ cells can both contribute to the interfollicular epidermis[126]; however, this does not occur under homeostatic conditions. Cell populations that maintain the sebaceous glands and interfollicular epidermis in mice include a LGR6 (leucine protein G rich repeat coupled receptor 6)-positive population in the central isthmus[127] as well as leucine-rich repeats and LRIG1 (immunoglobulin-like domains 1)- and Blimp1-positive populations in the upper isthmus[128,129]. There is also an SCA1 (stem cell antigen-1)-positive cell population in the infundibulum that is thought to contribute to skin homeostasis[130].

The dermal papilla and dermal sheath represent a mesenchymal stem cell niche within the follicle. Under homeostatic conditions, dermal papilla cells rarely divide after formation of the initial condensate during morphogenesis, yet their gene expression profile is dynamic throughout development and the hair cycle. If removed from their niche, dermal papilla cells have the ability to differentiate into osteogenic, myogenic, adipogenic, and hematopoietic lineages[131–133]. In addition to their ability to transdifferentiate, a major function of dermal papilla cells is related to their inductive potential. Isolated and cultured dermal cells from adult follicles are capable of stimulating a range of committed epithelia to form follicles, inclusive of progenitor stem cells[55,134–136]. The potential of cultured human dermal papilla cells to induce *de novo* hair growth provides the basis for novel therapeutic approaches[56].

The Hair Follicle and the Immune System

The HF represents an immune privileged site, which is defined as a location in the body where foreign tissue grafts can survive for extended periods of time without immune rejection. Of note, other immune privileged sites include the anterior chamber of the eye, testis, brain, and placenta.

Initial evidence regarding the immune protection of the HF came from the classic "Billingham experiment" in 1971[137], in which skin from black guinea pigs was transplanted onto an immunologically incompatible strain of white guinea pigs. The grafted skin turned white, reflecting the expected immune response against the foreign epidermal melanocytes. However, pigmented hairs grew within the grafts, showing that the foreign HF melanocytes survived. Application of the contact allergen picryl chloride to mouse skin during early anagen results in an attenuated sensitization reaction compared to application during telogen[138], suggesting that the HF immune system is suppressed specifically during anagen. Features of the human anagen hair bulb that protect it from an immune response are summarized in Table 68.4.

The immune privilege of the HF was previously thought to be restricted to the matrix region during the anagen phase. However, evidence has accumulated that the bulge region has immune privilege during the entire hair cycle[139]. Since the bulge represents the HF stem cell niche, sustained immune privilege in this region may be essential for the survival of the follicle. Autoimmune attack leading to loss of the stem cells in the bulge results in cicatricial alopecia where regrowth is unlikely[140].

Two mechanisms can potentially underlie an immune reaction directed against the hair: (1) a primary attack of the immune system against the HF; or (2) a breakdown in HF immune privilege leading to a secondary attack by the immune system[141–143]. Since the hair matrix immune privilege is mainly restricted to the anagen phase[143], it has been postulated that an autoantigen from melanocytes, which are active during the anagen phase, could be responsible for initiating the immune response against the HF that occurs in alopecia areata. Indeed, antibodies against melanocyte-associated antigens have been found in patients with this condition[144,145].

The collapse of HF immune privilege is linked to upregulation of HF major histocompatibility complex (MHC) class I molecule expression, which allows presentation of autoantigens to the immune system[146]. In HFs affected by alopecia areata, there is increased expression of MICA (MHC class I polypeptide-related sequence A). $CD8^+$ T cells and natural killer (NK) cells accumulate around affected HFs and exhibit increased expression of the NKG2D activating receptor, but decreased expression of inhibitory receptors such as KIR3DL1 (killer cell

MECHANISMS CONTRIBUTING TO THE IMMUNE PRIVILEGE OF THE HAIR FOLLICLE

Mechanism of immune evasion	Function of the molecules affected
Downregulated expression of MHC class I, MICA, and β_2-microglobulin	Required for presentation of autoantigens to the immune system
Downregulated expression of MHC class II	Required for functioning of antigen-presenting cells
Upregulated expression of IL-10, transforming growth factor-β1 (TGF-β1), and α-melanocyte stimulating hormone (α-MSH)	Immunosuppressive actions
Increased production of Fas-ligand (FasL)	Induces apoptosis of activated T cells; known to be crucial for maintenance of immune privilege in the eye, brain, and fetus
Low expression of heterodimeric CD94/NKG2C and NKG2D receptors on NK cells and $CD8^+$ cytotoxic T cells as well as of the NKG2D ligand UL16 binding protein 3 (ULBP3)	These receptors activate NK cells and $CD8^+$ cytotoxic T cells upon ligand binding; NKG2D has been implicated in the immune attack on the hair follicle in alopecia areata
High expression of killer cell immunoglobulin-like receptors (KIRs) and heterodimeric CD94/NKG2A receptors on NK cells	These receptors inhibit NK cells
Increased production of indoleamine 2,3-dioxygenase (IDO)-1	Inhibits lymphocyte proliferation
Increased production of IK cytokine	Inhibits interferon-γ-induced expression of MHC class II antigens
Lack of lymphatic vessels around the hair follicle	Recruit immune cells

Table 68.4 Mechanisms contributing to the immune privilege of the hair follicle. IL, interleukin; MHC, major histocompatibility complex; MICA, MHC class I polypeptide-related sequence A; NK, natural killer.

immunoglobulin-like receptor three domains long cytoplasmic tail 1) and heterodimeric CD94/NKG2A[143,147]. ULBP3 (UL16 binding protein 3), a NKG2D ligand, is upregulated in the dermal sheath and papilla of HFs affected by alopecia areata[147]. These observations indicate that HFs in patients with alopecia areata lose their immune privilege and express danger signals in their outermost layer.

The pathogenesis of alopecia areata also involves downregulation of immunosuppressant molecules such as transforming growth factor (TGF)-β1, α-melanocyte stimulating hormone (MSH), indoleamine 2,3-dioxygenase (IDO)-1, and the IK cytokine that inhibits the functions of interferon (IFN)-γ[139,141,143]. IFN-γ plays a pivotal role by inducing the expression of MHC class II antigens, which are normally absent in the HF matrix and dermal sheath, thereby propagating the immune response and contributing to destruction of the hair follicle.

Genome-wide association studies (GWAS) in patients with alopecia areata have implicated genes that are involved in immune regulation, in particular the function of regulatory T cells, such as cytotoxic T lymphocyte-associated protein 4 (CTLA-4), interleukin (ILs)-2 and -21, the IL-2 receptor A (CD25), ULBPs, and Eos (an Ikaros transcription factor), as well as genes expressed in the follicle (e.g. syntaxin 17, peroxiredoxin 5)[147,148]. Such studies have provided insights into potential therapeutic targets. For example, treatment with inhibitors of the Janus kinase (JAK) pathway, which is involved in signaling by many of the cytokines implicated in alopecia areata, can result in significant hair regrowth[149,150].

BIOLOGY OF NAILS

Like its phylogenetic ancestors (e.g. claws, hoofs), the nail protects the distal phalanges and contributes to a variety of motor and sensory functions (see Table 68.2). Two key aspects of nail biology are how nails grow and from what part of the nail apparatus they arise. The composition and appearance of the nails and the characteristics of the surrounding tissues are other important considerations, potentially representing signs of internal disease or environmental exposures[151,152]. An understanding of these aspects of the nail unit, in addition to its anatomy and development, can maximize the clinician's ability to assess, diagnose, and treat patients with nail disorders. However, our current knowledge of the regulation of nail development and growth on a molecular level is relatively poor, and acquisition of data has been hampered by the difficulty in obtaining nail-producing tissues and growing nails and/or nail matrix keratinocytes in culture. Tools such as mouse models given the substantial homology between murine claws and human nails, organ-culturing microdissected components of the human nail apparatus, and nail-equivalent *in vitro* systems will hopefully help to better elucidate the molecular mechanisms of nail biology.

Nail Unit Anatomy

An understanding of nail biology and disease requires knowledge of the local anatomy (Fig. 68.7)[153,154]. The nail plate is a hard, semitransparent, slightly convex sheet comprised of tightly packed corneocytes termed onychocytes. It contains "hard" hair-type keratins, which are embedded in a matrix of sulfur-rich, high-cysteine and high-glycine/tyrosine proteins (see below). The dermis of the nail apparatus is a fibrocollagenous network that is sandwiched between the nail plate and the underlying bone, lacking associated subcutaneous soft tissues or pilosebaceous units. As a result, bacterial infections in this region have a relatively high risk of spread to the bone, resulting in osteomyelitis of the distal phalanx.

The nail plate is surrounded on three edges by nail folds, one proximal and two lateral. The proximal nail fold, a double layer of skin overlying the proximal part of the nail, protects this area from trauma, solvents, and infectious agents that might otherwise alter nail shape and structure. The dorsal layer of the proximal nail fold is continuous with the skin of the digit, while the ventral layer is continuous with the nail matrix. The cuticle (eponychium) is a thin strip of cornified epithelium that adheres to the nail at the edge of the proximal nail fold and acts as a seal against ingress. Damage to the cuticle results in a predisposition to inflammation of the nail fold; conversely, inflammation of the nail folds disrupts normal maturation of the epithelium and cuticle formation. Nail-fold inflammation can also disturb the underlying matrix and alter nail plate production, most often manifesting as transverse ridging. The proximal nail fold may help to mold the emerging nail, forming a relatively thin structure that grows obliquely from its point of origin in the matrix.

The longitudinal axis of nail growth is also guided by the lateral nail folds, which compress the nail plate from each side and contribute to its transverse curvature. The lateral margins of the nail bed form deep

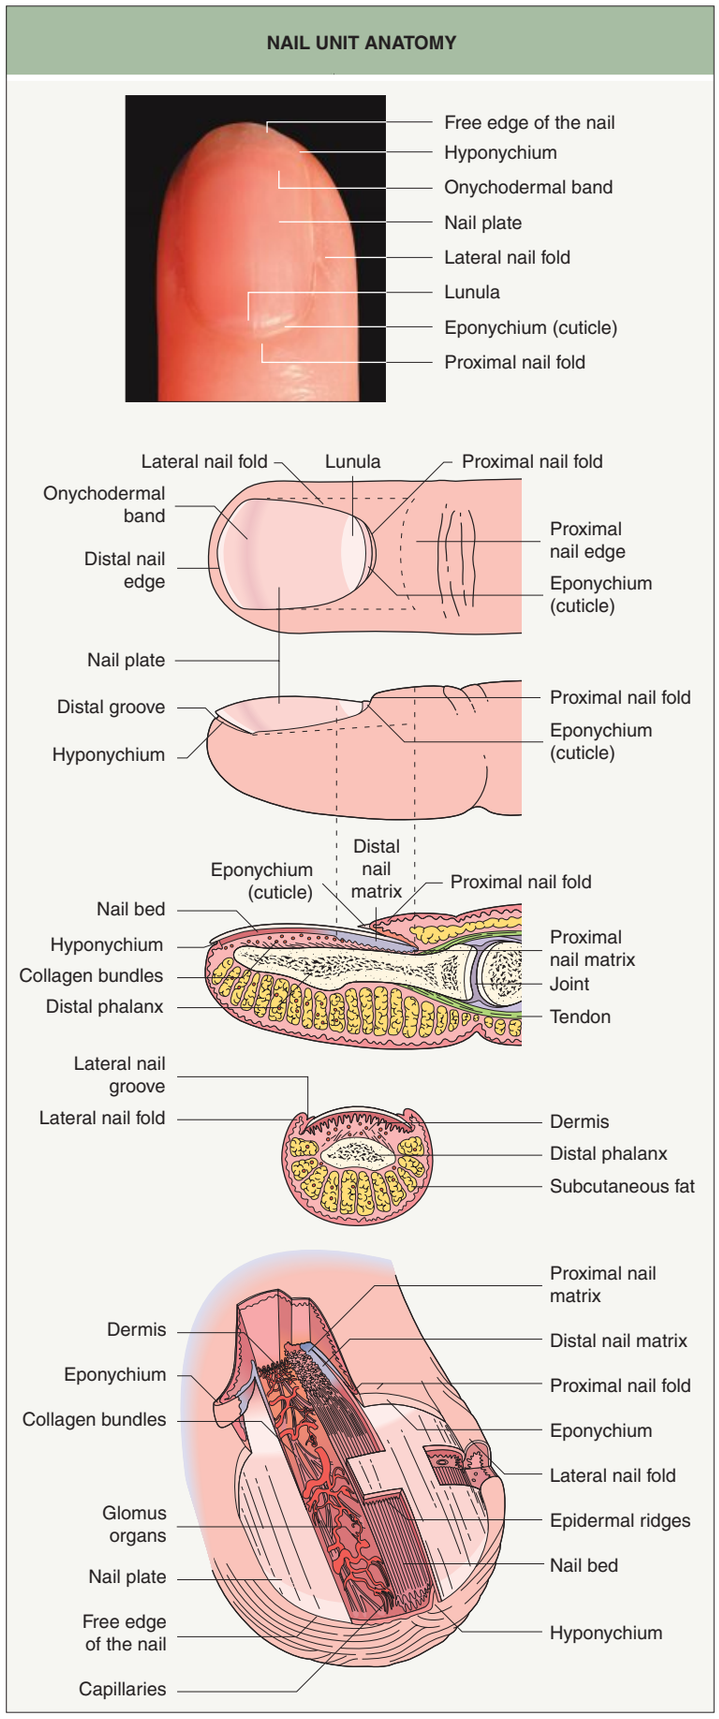

Fig. 68.7 Nail unit anatomy.

sulci that follow the curve of the distal phalanx and then fold back on themselves to produce the lateral nail folds. These sulci help to attach the nail to the soft tissues and, similar to the proximal nail fold and cuticle, provide a seal at the nail margin.

The structures bounded by the nail folds are the nail matrix proximally and the nail bed distally and medially. The half-moon-shaped lunula, which is most prominent on the thumb, demarcates the junction between the matrix and the nail bed. The lunula is less apparent, due in part to concealment by the proximal nail fold, with progression from the second to fifth finger. The lunulae of the toes are hidden by their thicker nail plates (especially for the great toes) and relatively prominent proximal nail folds, which may serve a protective function[153,154].

The nail plate is in continuity with the matrix from which it arises, while the nail bed represents its underlying support structure and extends from the distal margin of the lunula to the onychodermal band, a thin pinkish transverse strip proximal to the whitish onychocorneal band (see Fig. 68.7). A longitudinal pattern of rugose rete ridges in the nail bed increases the surface area of its attachment to the ventral aspect of the nail, which has corresponding ridges. This enhances adhesion between these surfaces and enables the free edge of the nail to be used as a levering tool without lifting the nail or causing pain. Histologically, both the nail bed and matrix normally lack a granular layer. The presence of a granular layer in these sites is a sign of pathology, such as the altered nail bed behavior associated with subungual hyperkeratosis.

The nail is in close proximity to the underlying distal phalanx, and BMPs are thought to have roles in the morphogenesis of both structures. When the distal phalanx and/or interphalangeal joint are affected by an inflammatory disease such as psoriasis, involvement of the nail matrix (and hence nail plate) often occurs. Congenital absence of part of the distal phalanx is typically accompanied by a small or otherwise altered nail (e.g. congenital onychodysplasia of the index fingers), further illustrating the relationship between these two structures[155]. In the neonatal period, digit tip regeneration can occur in humans after partial amputation. This appears to require the presence of a residual nail unit and to involve the expression of BMP-4 and the MSX1 (muscle segment homeobox 1) transcriptional repressor[156]. Overexpression of MSX1 and MSX2 is associated with increased regenerative capacity[157]. There appears to be a reciprocal interaction between nail and bone, with bone mesenchyme providing a scaffold for nail regrowth and the nail bed facilitating regeneration of underlying bone[158,159]. In later life, regeneration rarely, if ever, occurs upon partial amputation of the fingertip due to trauma or osteolysis in the setting of scleroderma, and secondary nail changes typically ensue.

Studies in adult mice suggest that LGR6-expressing nail stem cells in the proximal matrix are capable of WNT-dependent nail blastema formation, which enables digit tip regeneration[160,161]. Nerve-associated Schwann cell precursors that dedifferentiate and secrete growth factors such as oncostatin M and platelet-derived growth factor A promote expansion of the blastema and are required for murine digit regeneration[162]. The cytoskeletal protein flightless I (Flii) also enhances murine digit regeneration after amputation; although this is normally limited to distal third amputations, mice with overexpression of Flii can retain the proximal nail matrix and regenerate proximal amputations[163]. Outside of the nail unit Flii is associated with *inhibition* of epidermal stem cells and wound reepithelialization[164], suggesting that prevention of epithelialization may allow continued connective tissue proliferation and thereby enable the subepidermal repair required for greater digit regeneration. These observations in mice may help to develop therapies for human amputees in the future.

The vascular supply of the digit is through two dorsolateral and two ventrolateral arteries that lack an internal elastic lamina and have a tortuous morphology that helps them to withstand flexion and other movements. There is substantial communication between these vascular networks, particularly distally via plexuses in the proximal nail fold and digital pulp. This provides the digit with a blood supply of more than one origin and direction, which ensures continued flow in the event of trauma or a sustained grip that decreases supply from the ventral vessels. The pulp plexus is located within a recess produced by the gap between the ventral prominence of the distal phalanx and the rim of the distal interphalangeal joint[165].

In a cold environment, which leads to constriction of arterioles, arteriovenous anastomoses (Sucquet–Hoyer canals) within glomus bodies maintain sufficient blood supply to the distal digits. Glomus bodies are encapsulated oval structures containing modified smooth muscle cells that dilate upon exposure to the cold. These structures are most prominent in the subungual tissue, which represents the most common site of a glomus tumor, a benign proliferation of glomus cells[166] (see Ch. 114).

In the proximal nail fold, the dermal capillaries normally form a regular pattern of "hairpin" loops with a thin efferent limb and a more tortuous, thicker afferent limb. The organization of nail bed vessels is similar, although the hairpin turn is less evident. Dermatoscopic examination (capillaroscopy) of nail-fold vessels can help to assess a patient's acral microvascular status. The pattern and/or patency of the capillaries in the proximal nail fold and nail bed is often altered in patients with an autoimmune connective tissue disease (AI-CTD) or embolic disorder. The proximal nail folds of patients with lupus erythematosus typically show dilated, tortuous capillaries of normal density, whereas systemic sclerosis and dermatomyositis feature hemorrhages and decreased capillary density characterized by avascular areas alternating with dilated capillary loops. Acral infarction due to embolization (e.g. in the setting of endocarditis) can result in leakage of blood into the nail bed, referred to as splinter hemorrhages. These lesions can also develop secondary to trauma, AI-CTD, and psoriasis; the latter condition is associated with an increased number of papillary dermal vessels, disrupted nail integrity, and shearing forces between the nail plate and bed.

The nerve supply of the digit follows the pattern of the vascular supply, with two dorsal and two ventral branches that have some overlap distally in their sensory territories[154]. Since the fingertips have an important role in sensory perception, nerve endings that transmit pain (type I fibers), touch (Meissner and Pacinian bodies), and temperature are all abundant. The function of these nerve endings may be compromised by pressure due to relatively minor trauma and edema within the fascial envelope that encloses a finger or toe.

Nail Embryology

The nail primordium becomes evident at 8 weeks' gestational age as a transverse ridge on the distal dorsal surface of the digit (Fig. 68.8) (see Ch. 2). Over the next 4 weeks, the ridge takes a more proximal position and eventually invaginates beneath the emerging proximal nail fold. The outline of the nail unit is established by 16 weeks' gestational age, and the nail plate completely covers the nail bed during the fifth month.

The study of inherited nail diseases has provided clues regarding some of the processes that regulate the formation of the nail unit. An autosomal recessive form of anonychia congenita is caused by loss-of-function mutations in the gene encoding R-spondin 4 (RSPO4), which functions in the WNT signaling pathway[167]. Mouse studies have demonstrated expression of *Rspo4* in digit mesenchyme during embryogenesis, and it is thought to influence induction of the nail unit in the overlying epithelium. Human *WNT10A* mutations that alter β-catenin signaling can result in nail dystrophy as well as hypotrichosis, hypodontia, and palmoplantar keratoderma (see Ch. 63)[168]. In contrast, changes in claw formation have not been noted in *Wnt10* knock-out mice[169].

Nail–patella syndrome is another genetic disorder that has contributed to our understanding of nail development. The nail changes in this autosomal dominant condition include triangular lunulae and absent or hypoplastic nails, with most prominent involvement of the thumbnail and other radial digits; however, an individual nail is usually more severely affected on its ulnar side. Extracutaneous manifestations include hypoplastic patellae, iliac horns, nephropathy, and glaucoma. Nail–patella syndrome is caused by mutations in the gene encoding the LIM homeobox transcription factor 1β (LMX1B), which influences dorsoventral limb patterning[170,171]. In Clouston syndrome, a form of ectodermal dysplasia due to mutations in the gap junction β6 gene (*GJB6*) that encodes connexin 30, thickened nails with onycholysis occur in association with hypotrichosis and palmoplantar keratoderma (see Ch. 63)[172]. These genetic nail diseases illustrate the importance of communication between cells and tissues in the morphogenesis of the nails as well as other adnexal structures and organs. These messaging systems use the same code to initiate a variety of events in different tissues. Other genetic diseases affect the nails through alteration of their structural components, such as keratins or constituents of the basement membrane.

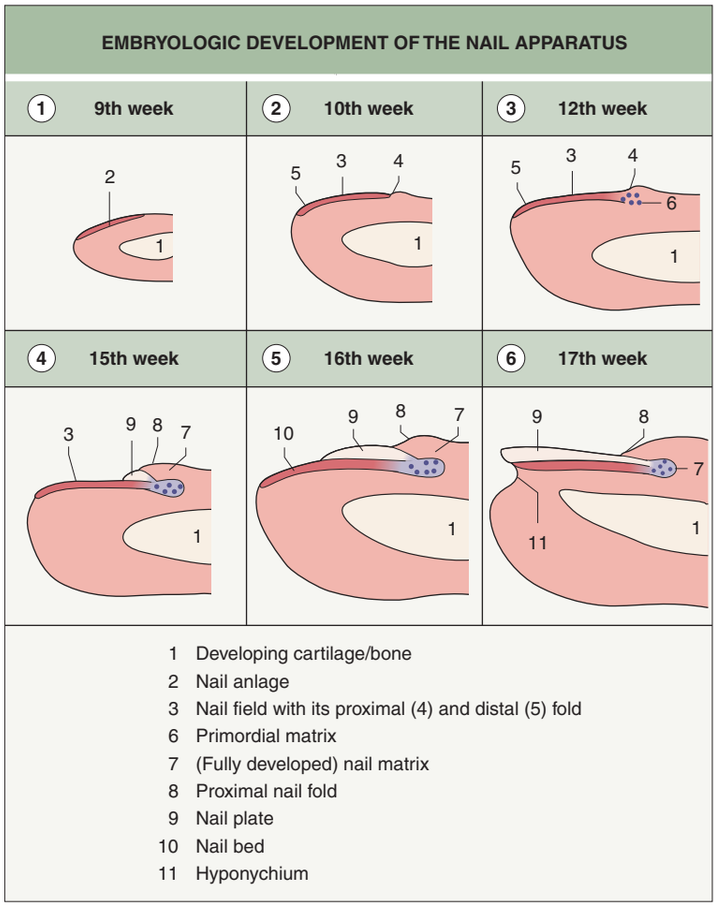

Fig. 68.8 Embryologic development of the nail apparatus.

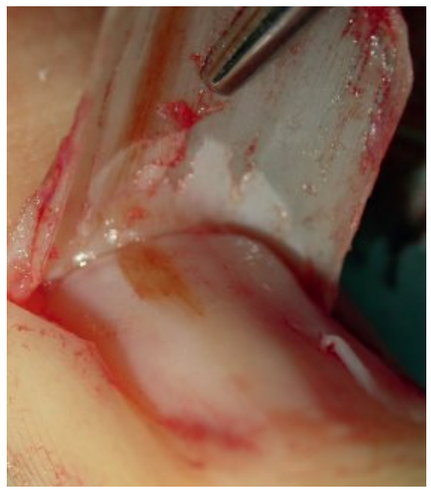

Fig. 68.9 Nail matrix biopsy to determine the etiology of longitudinal melanonychia. Note that the pigment in the nail extends to the proximal part of the matrix in the nail plate and (as seen when the nail is lifted) the matrix itself.

Nail Matrix

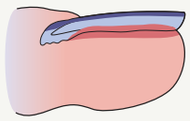
"Nail matrix" is a functional and anatomical term; although there is currently general consensus with regard to these definitions, disagreement about the precise functional role of the matrix (see below) can potentially lead to confusion about its exact anatomy.

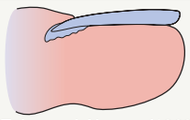
Matrix anatomy

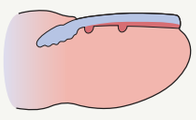
The anatomical boundaries of the classical matrix are visible during a surgical procedure in which the nail is avulsed and the proximal nail fold retracted (Fig. 68.9). This reveals two zones of tissues on which the nail rests, a proximal pale nail matrix and a distal pinker nail bed. Their arcuate junction is evident through the nail plate as the lunula (half moon). The most lateral portion of the matrix may be "buried" in the sulcus of the lateral nail fold (see Fig. 149.2); because this can be difficult to access surgically, procedures designed to remove the lateral part of the nail matrix sometimes leave behind a small piece of matrix that produces a detached spicule of nail (see Fig. 149.15). Proximally, the matrix extends to the point of flexure of the proximal nail fold, where the latter structure turns back over and protects the proximal margin of the nail (see Fig. 68.7). Compared to epidermal keratinocytes, those in the nail matrix are larger and have a higher rate of proliferation.

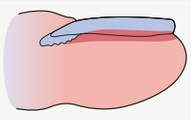
Matrix function

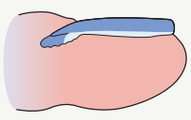
For more than 50 years, anatomists and clinical scientists have investigated the relationship between the matrix and production of the nail (Fig. 68.10). Early work by Lewis[173] used static histology of silver-stained longitudinal sections of the nail unit to delineate three layers that he postulated were derived from separate epithelial surfaces within the nail unit: (1) the ventral aspect of the proximal nail fold (upper nail plate); (2) the classical matrix as defined above (mid nail plate); and (3) the nail bed (lower nail plate). This led to the misconception that there are three areas of matrix – dorsal, ventral, and intermediate. Subsequent studies in squirrel monkeys, which have digits similar to those in humans, utilizing *in vivo* autoradiography provided evidence that most, if not all, of the nail plate is generated from the classical matrix[174]. In these experiments, systemic injection of tritiated thymidine was followed by amputations at different time points, demonstrating that the thymidine reached the nail plate via the matrix. Injection of radiolabeled glycine into the nail unit of human volunteers who then had nail biopsies also showed that the classical matrix is the main source of the nail plate[175].

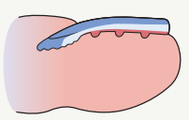












In the early 1990s, Johnson and colleagues[176] found that between the distal margin of the lunula and the end of the nail bed, the nail plate of the great toe increases in thickness by ~20%. They inferred from this observation that the nail bed contributed this proportion of the nail plate. Histologic assessment of great toe nail plates obtained via avulsion confirmed this increase in thickness but showed that the number of cells in the vertical axis of the nail plate did not increase from the proximal to distal nail bed. These results suggested that the nail plate thickens because of compaction due to distal-to-proximal compression rather than an active contribution from the underlying nail bed[177]. Walking while wearing shoes produces low-grade, repetitive trauma to the free edge of the great toenail, which would explain such an effect[177].

Immunohistochemical staining with proliferating cell nuclear antigen or Ki-67 demonstrates minimal proliferative activity in the nail bed but substantial activity in the matrix, further supporting that the matrix is the source of the nail plate[178]. The correlation between anatomy and function explains the different patterns of nail disease that result from pathology affecting the matrix versus the nail bed (see Table 71.1). It also accounts for the potential for permanent nail deformity following surgical intervention or biopsy of the matrix, but not for similar interventions involving the nail bed. Because the proximal half of the matrix produces ~80% of the nail plate, surgeries or biopsies in this area are more likely to produce nail dystrophy than those of the distal matrix. Onychocytes migrate upward and distally along an oblique axis during their maturation and differentiation; as a result, the proximal part of the matrix produces the dorsal portion of the nail plate, while the distal part of the matrix synthesizes the ventral portion of the nail plate. Abnormalities in the proximal matrix underlie clinical findings such as pitting and longitudinal ridging/splitting, whereas disruption of the distal matrix can cause true leukonychia. Interestingly, nail pitting can occur in association with alopecia areata, suggesting shared pathomechanisms.

Nail Stem Cells

Identification of label-retaining cells in the basal layer of the nail matrix has suggested that this represents the main source of nail stem cells[179], although other experimental approaches have suggested alternative nail stem cell niches[180]. In labeling studies, basal cells from the proximal nail matrix persisted longer than those from the distal matrix or nail bed[160]. Lineage tracing using HF stem cell markers (e.g. KRT15)

THEORIES ON THE ORIGIN OF THE NAIL PLATE

Origin of the nail plate	Evidence	Schematic, reference
Three portions of the nail matrix form three corresponding parts of the nail plate, which is characterized by a three-layer structure: Dorsal part = Proximal nail fold → Upper nail plate Inter-mediate part = Classical nail matrix → Intermediate nail plate Ventral part = Nail bed → Lower nail plate	Light microscopy and silver staining of human nails	 Lewis (1954)
Cells of the classical matrix are the origin of the whole nail plate	*In vivo* auto-radiography (with tritiated thymidine) in squirrel monkeys	 Zaias and Alvarez (1969)
Cells of the classical matrix produce nearly the total nail plate. Only a few cells of the nail bed in poorly defined locations take part in forming the nail plate	*In vivo* auto-radiography (with radiolabeled glycine) in human volunteers	 Norton (1971)
The regrowth of nail plates following traumatic avulsion of great toenails was investigated: approximately 20% of the nail plate's thickness was added when the nail grew over the nail bed, suggesting a nail bed contribution to the nail plate's growth	Changes in nail plate's thickness during nail growth in human volunteers	 Johnson et al. (1991,1993)
Cells of the proximal half of the matrix produce approximately 80% of the nail plate, whereas 1% or less of the nail plate is contributed by the nail bed. In psoriatic nails, the nail bed contribution may increase to over 25%	Immunohisto-chemical labeling in healthy human nails with antibodies to proliferating cell nuclear antigens and antigen Ki-67	 Healthy nail  Psoriatic nail de Berker and Angus (1996); de Berker et al. (1996)

Sites of origin and their contributions to the nail plate:

- Proximal matrix within nail fold (dorsal matrix)
- Nail bed
- Nail matrix
- Proximal half of nail matrix
- Distal half of nail matrix

Fig. 68.10 Theories on the origin of the nail plate. *Adapted fom Dawber RP, de Berker DA, Baran R. Science of the nail apparatus. In: Baran R, Dawber RP, de Berker DA, et al (eds). Diseases of the Nails and their Management. Oxford: Blackwell Science, 2001;1–47.*

identified a ring-like population of quiescent cells in the proximal nail fold that was harboring putative stem cells[181]. Much like the HF, the nail unit is likely to have more than one stem cell niche, each with distinct cellular dynamics and function.

Nail Unit Melanocytes

Melanocytes are found in the nail matrix but not in the normal nail bed. In general, foci of pigment in the nail bed that are separated from the nail folds and matrix are not melanocytic in origin[182], with possible exceptions including a metastatic melanoma and a partially amelanotic melanoma that is continuous with the matrix or nail fold. Nail matrix melanocytes are most abundant in the distal matrix and are found in suprabasal layers as well as the basal layer, which may reflect a distinct expression pattern of adhesion molecules (e.g. α_2, α_3, and β_1 integrins) that regulate interactions between melanocytes and keratinocytes[183].

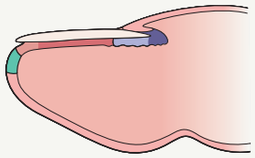
The main distribution pattern of melanin in the nail plate is pigmented bands, referred to as longitudinal melanonychia, which vary in number, intensity, and width depending on their etiology (see Ch. 71). Multiple streaks of longitudinal melanonychia due to active nail matrix melanocytes are commonly found in individuals with darkly pigmented skin, sometimes as a result of trauma or inflammation affecting the matrix. In contrast, nail matrix melanocytes in individuals with lightly pigmented skin are normally quiescent; longitudinal melanonychia in such patients, especially an isolated band in an adult with no systemic or local causative factors, usually requires a nail matrix biopsy to exclude the possibility of melanoma (see Ch. 149). Inadequate biopsy specimens (e.g. too small, non-representative) can lead to a delay in diagnosis and less favorable prognosis[184].

The Nail Immune System

The nail unit, in particular the proximal matrix, represents a site of relative immune privilege, with reduced expression of MHC class I and II antigens and decreased numbers of antigen-presenting cells. Similar to the HF, the stem cell niche of the nail unit is believed to have immune privilege to ensure its preservation in the face of constant environmental exposure. Although the immune privilege may prevent over-reactivity to environmental antigens, it may also increase vulnerability to human papillomavirus infections and their potential oncogenic effects, which can result in periungual squamous cell carcinomas[185]. Collapse of immune privilege has been suggested to underlie lichen planus of the nail unit as well as lichen planopilaris of the scalp[140].

Nail Keratins

Multiple types of keratins are expressed in the nail apparatus (Fig. 68.11), and they account for 80% of the dry weight of the nail plate. The nail plate and matrix contain "hard" hair-type keratins with a large number of sulfur-containing amino acids that facilitate cross-linking between keratin molecules. This reduces the amount of water associated with these proteins and makes them more rugged and resistant to chemical destruction compared to "soft" epithelial keratins[186]. Keratin 15 in the proximal ventral aspect of the proximal nail fold may represent a marker of a keratinocyte stem cell population[181].



The pattern of keratin expression within the nail unit explains the involvement of this structure in several genodermatoses that are caused by keratin defects[187,188]. Pachyonychia congenita (PC) is an autosomal dominant disorder caused by mutations in the genes encoding keratins 6a, 6b, 6c, 16, or 17 (see Chs. 58 & 71). These keratins are expressed in the nail bed, HF, and sebaceous gland as well as palmoplantar, injured (e.g. ulcer margins), and hyperproliferative epidermis. PC features thickening of the nail plate, much of which represents compaction of dense subungual hyperkeratosis, together with painful palmoplantar keratoderma, follicular keratoses, and variable oral leukokeratosis and cysts (e.g. steatocystoma multiplex). Nail fragility as well as alopecia characterize the pure hair–nail ectodermal dysplasia that results from mutations in the gene for keratin 85. In these patients, keratin 85 lacks two cysteine residues, which may compromise nail integrity via diminished cross-linking of amino acids within keratins.

The nail bed does not express keratins 1 and 10[188], which characterize terminally differentiated stratified epithelia such as the epidermis. It has been postulated that the presence of the nail plate overlying the nail bed inhibits further differentiation of the latter structure. Indeed, if the nail plate is avulsed, the nail bed develops a cornified layer over the next 3 to 4 weeks.

Other Nail Plate Components

In addition to keratins, the nail plate contains structural proteins high in sulfur (with elevated cysteine content) or glycine and tyrosine

DISTRIBUTION OF KERATINS AND NON-KERATIN PROTEINS IN THE NAIL APPARATUS

Anatomical region	Keratins (key examples)		Non-keratin proteins
	Soft keratins	Hard keratins	
Nail plate	KRT14, KRT16, KRT17 KRT5, KRT6	KRT31–KRT34 KRT81–KRT84	Ultra-high-sulfur proteins, high-sulfur proteins, high-glycine/tyrosine proteins, trichohyalin
Proximal nail matrix	KRT10, KRT14, KRT15, KRT16, KRT17 KRT1, KRT5, KRT6	KRT31, KRT34 KRT81, KRT85, KRT86	Actin, involucrin, filaggrin*, trichohyalin*, plasminogen activator inhibitor type II, laminin
Distal nail matrix	KRT10, KRT14, KRT20 KRT1, KRT5	KRT31	
Nail bed	KRT14, KRT16, KRT17 KRT5, KRT6, KRT7		Trichohyalin, plasminogen activator inhibitor type II, laminin
Hyponychium	KRT10, KRT14 KRT1, KRT5		Laminin
Tip	KRT16, KRT17 KRT6		
Embryonic nail unit	KRT19		*detected in monkey nails

Fig. 68.11 Distribution of keratins and non-keratin proteins in the nail apparatus. *Adapted from Dawber RP, de Berker DA, Baran R. Science of the nail apparatus. In: Baran R, Dawber RP, de Berker DA, et al (eds). Diseases of the Nails and their Management. Oxford: Blackwell Science, 2001;1–47.*

THE NAIL APPARATUS: BASIC INFORMATION AND TERMINOLOGY	
Nail plate thickness	Toenails are usually thicker than fingernails Toenails: 1.4 mm in women, 1.65 mm in men Fingernails: 0.5 mm in women, 0.6 mm in men
Growth rate	Fingernails usually grow faster than toenails Fingernails: 2–3 mm/month Toenails: 1 mm/month Complete replacement of a nail requires 6 (fingernails) to 18 months (toenails)
Nail plate	Tightly packed cornified cells (onychocytes) arranged in a lamellar pattern; weakly eosin+, strongly acid-fast+; largest on the great toe, covering ~50% of this digit; fingernails have a longer longitudinal axis compared to the transverse axis, while toenails usually have a longer transverse axis
Nail matrix	Epithelium situated above the middle part of the distal phalanx of the digits; keratinizes without a granular layer and generates the nail plate; contains many melanocytes (up to 300/mm^2), predominantly in supra-basal layers
Nail bed	Thin epithelium consisting of 2–5 cell layers with abrupt keratinization and no granular layer; typically no melanocytes
Proximal nail fold	Epithelium with a granular layer; its dorsal part corresponds to the skin of the dorsum of the digit and contains sweat glands but is devoid of pilosebaceous units; densely innervated; the ventral part is thinner and connects with the nail matrix epithelium
Hyponychium	An epithelium equivalent to the volar skin containing granular and thick cornified layers
Nail pigmentation	Banded pigmentation (longitudinal melanonychia) is common in Asian and Black individuals (~75% by age 20 years, nearly 100% by age 50 years); relatively uncommon in White individuals

Table 68.5 The nail apparatus: basic information and terminology. *Courtesy John P. Sundberg, DVM, PhD.*

(see Fig. 68.11). Other molecules and elements within the nail plate include water (normally ~10%–15%, compared to ~15%–25% for the epidermis), lipids (primarily cholesterol), and minerals (e.g. iron, zinc, calcium). The nail plate is relatively porous and ~1000-fold more permeable to water than is the epidermis; as a result, nails can be rapidly dehydrated and hydrated. Low water content in nails leads to brittleness, while nails composed of >30% water are soft and opaque. Although calcium is present in the nail plate, it does not influence the hardness of the nail. Likewise, the white "flecks" that are commonly seen in the nail plate (especially in children) have nothing to do with calcium but rather reflect small disturbances in the compaction of onychocytes, usually related to trauma.

The nail can also contain markers of various metabolic processes and exposures to exogenous substances (e.g. drugs, environmental pollutants). Biomarkers in the nail plate include glycosylated keratin in patients with diabetes mellitus[189], high sodium levels in those with cystic fibrosis[190], and increased amounts of lipids in hyperlipidemic individuals[191]. Exogenous substances that are found in the nail plate in settings of systemic exposure due to environmental contamination include arsenic, lead, and other heavy metals[192,193]. Drugs taken for medical purposes or recreationally may also be present in the nail plate, depending on their binding properties and lipid solubility. Analysis of nicotine in the toenails can be used to track exposure to cigarette smoke via inhalation[194], and a range of narcotics can be identified in nail clippings, either within deposits beneath the free edge of the nail plate due to recent direct contact or incorporated into the nail plate via systemic exposure over previous months[195]. For neonates, it is possible to measure *in utero* exposure to some drugs using nail analysis[196].

Nail Growth

Nail growth is typically measured in the longitudinal axis (e.g. using a vernier caliper) from a defined reference point to the free edge or by monitoring the movement over time of a transverse groove made at the peak of the lunula (Table 68.5)[197]; the mass of nail produced in clippings over a fixed period can also be determined. When a systemic event or local trauma disrupts nail growth for a brief period, a transverse groove reflecting the contour of the proximal margin of the matrix appears and grows outward with the affected nail, allowing the timing of the inciting phenomenon to be estimated. This clinical sign is known as Beau's lines, named after the Parisian cardiologist Justin Beau, who described these bands in patients recovering from typhoid[198].

Multiple physiologic conditions, medical disorders and drug exposures can influence nail growth (Table 68.6). The appearance of decreased nail growth is occasionally explained by substantial thickening of the nail plate that deviates the axis of growth such that nail is accumulating upwards in the vertical axis as well as outward in the longitudinal axis. Examples include onychogryphosis and yellow nail syndrome[199] (see Ch. 71), which are both accompanied by retraction of the proximal nail fold that may normally have a role in molding and flattening the early nail. In these instances, measurement of nail bulk rather than length illustrates that the nails are actually growing, but in a different direction.

FACTORS THAT CAN INFLUENCE NAIL GROWTH		
Factor/condition	**Reduction of growth**	**Acceleration of growth**
Age	Elderly	Young
Time of day	Night	Day
Seasons	Winter	Summer
Anatomic location	Toes Thumb, little finger	Fingers Middle finger
Physiologic states		Pregnancy
Extracutaneous disorders	Fever Poor nutrition Denervation, immobilization Infections (e.g. mumps, tuberculosis)	Hyperthyroidism Arteriovenous shunting
Cutaneous disorders	Onychomycosis	Psoriasis, pityriasis rubra pilaris
Drugs	L-DOPA Methotrexate Azathioprine Acitretin	Itraconazole Acitretin (in psoriasis patients)

Table 68.6 Factors that can influence nail growth.

Alopecias 69

Lidia Rudnicka and Catherine M. Stefanato

Chapter Contents

Non-Cicatricial (Non-Scarring) Alopecias *1173*
Cicatricial (Scarring) Alopecias *1186*
Hair Shaft Abnormalities *1193*
Alopecia of Sites other than the Scalp *1196*

INTRODUCTION

In this chapter, the major non-cicatricial alopecias will be reviewed first, followed by a discussion of cicatricial alopecias and then a review of structural hair shaft abnormalities. Chapter 68 reviews the structure and function of the hair follicle as well as regulation of the hair cycle. Table 69.1 outlines the information of importance in the evaluation of alopecias while Figs. 69.1 and 69.2 depict a clinical approach and the diagnostic tests that can be performed in addition to the clinical examination. The decision to perform trichoscopy, histopathology, hair shaft analysis, and blood tests is guided by the differential diagnosis.

NON-CICATRICIAL (NON-SCARRING) ALOPECIAS

Androgenetic Alopecia

Synonyms: ■ Male pattern and female pattern hair loss (MPHL and FPHL) ■ Female androgenetic alopecia (FAGA)

Key features

- Dihydrotestosterone (DHT) is a key hormone in the pathogenesis of androgenetic alopecia
- There is a conversion of terminal scalp hairs into miniaturized vellus hairs
- Treatment options include oral 5α-reductase inhibitors, topical minoxidil, and low-dose oral minoxidil

Introduction

Androgenetic alopecia (AGA) is an androgen-dependent disorder characterized by the conversion of terminal scalp hairs into miniaturized vellus hairs in a characteristic pattern. Both prevalence and severity increase with age, with up to 80% of men and 50% of women having evidence of AGA during their lifetime. Female androgenetic alopecia (FAGA) and male androgenetic alopecia share several pathogenetic, histopathologic, and trichoscopic features, but differ in their typical distribution patterns[1]. Onset can occur during adolescence, but pediatric androgenetic alopecia is rarely observed[2].

Pathogenesis

Genetic factors

In men, a polygenic basis for AGA is now generally accepted and is supported by the results of genome-wide association studies. Polymorphisms in the androgen receptor gene are thought to play a significant pathogenic role in men, but not in women. A second gene with potential importance in both men and women is *WNT10A* whose protein product is expressed in the follicular bulge during anagen. The WNT signaling pathway is known to play a critical role in hair follicle development (see Ch. 68), and loss-of-function mutations in *WNT10A* lead to several types of ectodermal dysplasia. Of note, polymorphisms in *APCDD1*, which encodes a WNT signaling inhibitor, have also been implicated in AGA. Lastly, FAGA has been associated with polymorphisms in *CYP19A1* and *ESR2*, whose protein products are an aromatase that converts C19 androgens to C18 estrogens and estrogen receptor 2, respectively[3,4].

Hormonal factors

Dihydrotestosterone (DHT) plays a central role in the pathogenesis of AGA, serving as a trigger for hair follicle miniaturization (see Fig. 157.1). The enzyme 5α-reductase, of which there are three isoenzymes (types I, II, and III), converts testosterone to DHT (see Fig. 69.10). The latter androgen may not directly miniaturize hair follicles, but rather serve as a co-mediator of hair sheath thickening, perifollicular fibrosis, and

CLINICAL APPROACH TO THE PATIENT WITH ALOPECIA
Historical information
• Increased hair shedding versus only reduction in hair density (the latter points to hair follicle miniaturization) • Shedding versus hair breakage • Expected hair length (allows identification of "hair that never grows") • Coexisting scalp symptoms (e.g. scaling, pruritus, burning, trichodynia [pain and/or paresthesias], tenderness) • Duration, including age of onset • Persistent versus intermittent with recurrent episodes of hair loss • Possible triggering factors (e.g. postpartum, medications or supplements, preceding high fever or severe illness, malnutrition, flare of systemic disease such as lupus erythematosus, significant emotional stress) • Review of symptoms to detect possible underlying systemic disease (e.g. thyroid dysfunction) • Family history of alopecia
Physical examination
• Diffuse versus patchy or patterned alopecia • Cicatricial versus non-cicatricial alopecia • Length and structure of hairs • Scalp changes (e.g. scaling, erythema, pustules, tenderness, drainage, scarring)
Diagnostic procedures
• Gentle hair pull test • Trichoscopy • Hair card test • Light microscopy of cut hair shafts (can include polarized light microscopy) • Trichogram (if telogen effluvium or loose anagen hair syndrome suspected) • Fungal culture and/or Wood's lamp examination; bacterial culture • Trichoscopy-guided biopsy for histopathology • Biopsy for direct immunofluorescence (discoid lupus versus lichen planopilaris, mucous membrane pemphigoid) • Blood tests (e.g. DHEA-S, free testosterone, TSH)
Treatment considerations
• Previous therapies, including duration and if used correctly • Psychological burden and impact on quality of life • Comorbidities and current medications (e.g. drug–drug interactions) or supplements (e.g. biotin's interference with avidin-based laboratory tests) • Expectations (e.g. halting progression, preventing relapse, degree of hair regrowth) • Commitment to long-term therapy • In women of childbearing age, discuss pregnancy plans and contraindicated medications

Table 69.1 Clinical approach to the patient with alopecia. TSH, thyroid stimulating hormone.

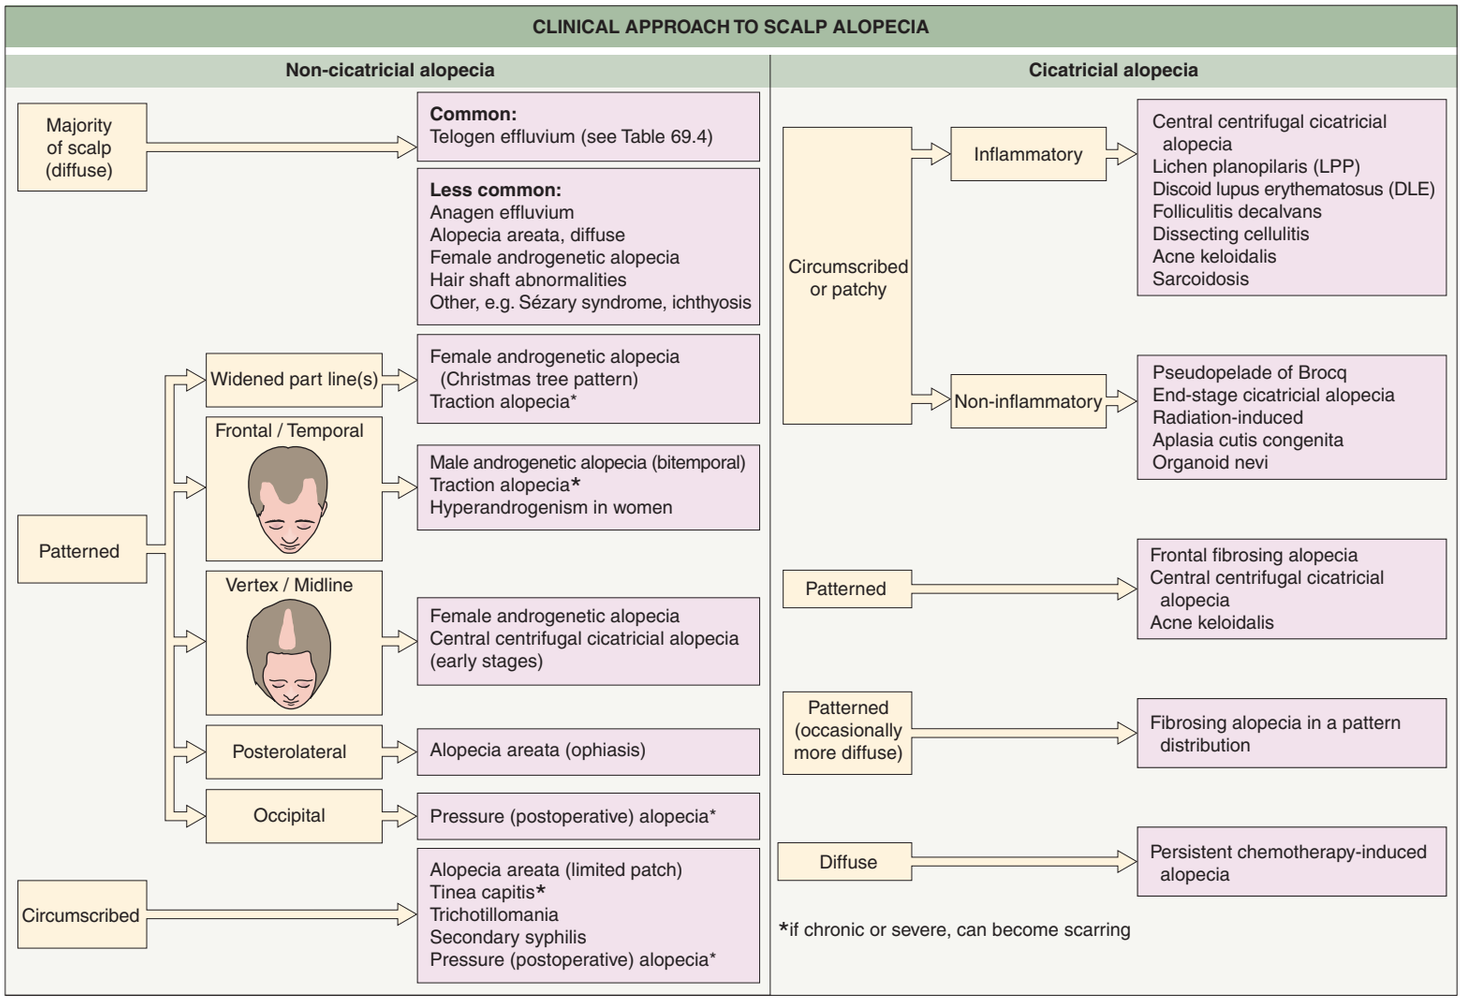

Fig. 69.1 Clinical approach to more common causes of scalp alopecia.

sometimes even calcification. These changes could then result in miniaturization via restriction of the follicle's growth space as well as its oxygen and nutrient supply[5].

In patients with AGA, 5α-reductase activity and DHT levels are increased in balding scalp skin when compared to non-balding scalp skin. Decreasing DHT levels in both the skin and the blood have been associated with a reversal of miniaturization in men with AGA. In women, a similar androgen-related pathophysiology has been postulated. However, most patients, both men and women, with AGA have normal circulating testosterone levels and signs and symptoms of systemic hyperandrogenism are unusual. Thus, AGA represents a local androgen-driven process.

Clinical features

In both men and women, the most common presentation is progressive non-synchronized hair miniaturization. The end stage of hair miniaturization is the development of vellus hairs. Because vellus hairs are short, thin, and hypopigmented, they are nearly invisible on clinical examination. Therefore, the "hair loss" in AGA represents "terminal hair loss" with retention of vellus hairs. However, prolonged disease eventually leads to follicular dropout.

The areas with the most pronounced hair miniaturization differ between men and women. In men, progressive recession of the frontotemporal hairline and diffuse thinning of the crown constitute the predominant sites of involvement (see Ch. 157). In women, the frontal hairline is usually preserved and hair loss favors the mid scalp, especially the frontal region; this can lead to a "Christmas tree" pattern of hair thinning (Fig. 69.3A). The degree to which there is widening of the central part line is also indicative of the severity of FAGA (Fig. 69.4). Occasionally, men may develop a female pattern of hair loss and vice versa[1,6]. A history of increased hair shedding may precede the clinical appearance of hair thinning.

The Hamilton and Norwood scales are most commonly used to grade and classify male AGA. They are depicted in Fig. 157.2. In female patients with AGA, the Ludwig grading system is often employed and consists of three major grades (see Fig. 157.3). The Sinclair scale represents another grading system for FAGA and it divides patients into five stages (Fig. 69.5; Table 69.2).

Diagnosis

In most men with AGA, the diagnosis is based upon clinical features and is relatively straightforward. However, additional evaluation can be helpful in women and this includes trichoscopy, i.e. dermoscopy of the hair and scalp (see Fig. 69.2)[7]. In AGA, there is heterogeneity of hair shaft thickness (Fig. 69.6) as well as a predominance of follicular units with only one terminal hair. Both findings are due to non-synchronized hair miniaturization (including within a single follicular unit). Sparse yellow dots, which represent empty hair follicles containing sebum and keratotic material, are also seen (Fig. 69.7)[8].

In the absence of signs or symptoms of hyperandrogenism, the authors do not perform screening laboratory tests[6]. However, some experts routinely order screening blood tests (e.g. serum DHEA-S, total and free testosterone; see Ch. 70) in women with AGA while others recommend detailed testing for possible androgen excess[9]. As there may be an increased risk of metabolic syndrome, cardiovascular disease, and prostate cancer in men with AGA, assessment and longitudinal evaluation for these disorders should be considered in the appropriate clinical setting[10].

In some patients, especially those with confusing clinical presentations, scalp biopsies may provide helpful information. Interpretation of the histopathologic findings requires an appreciation of the characteristic

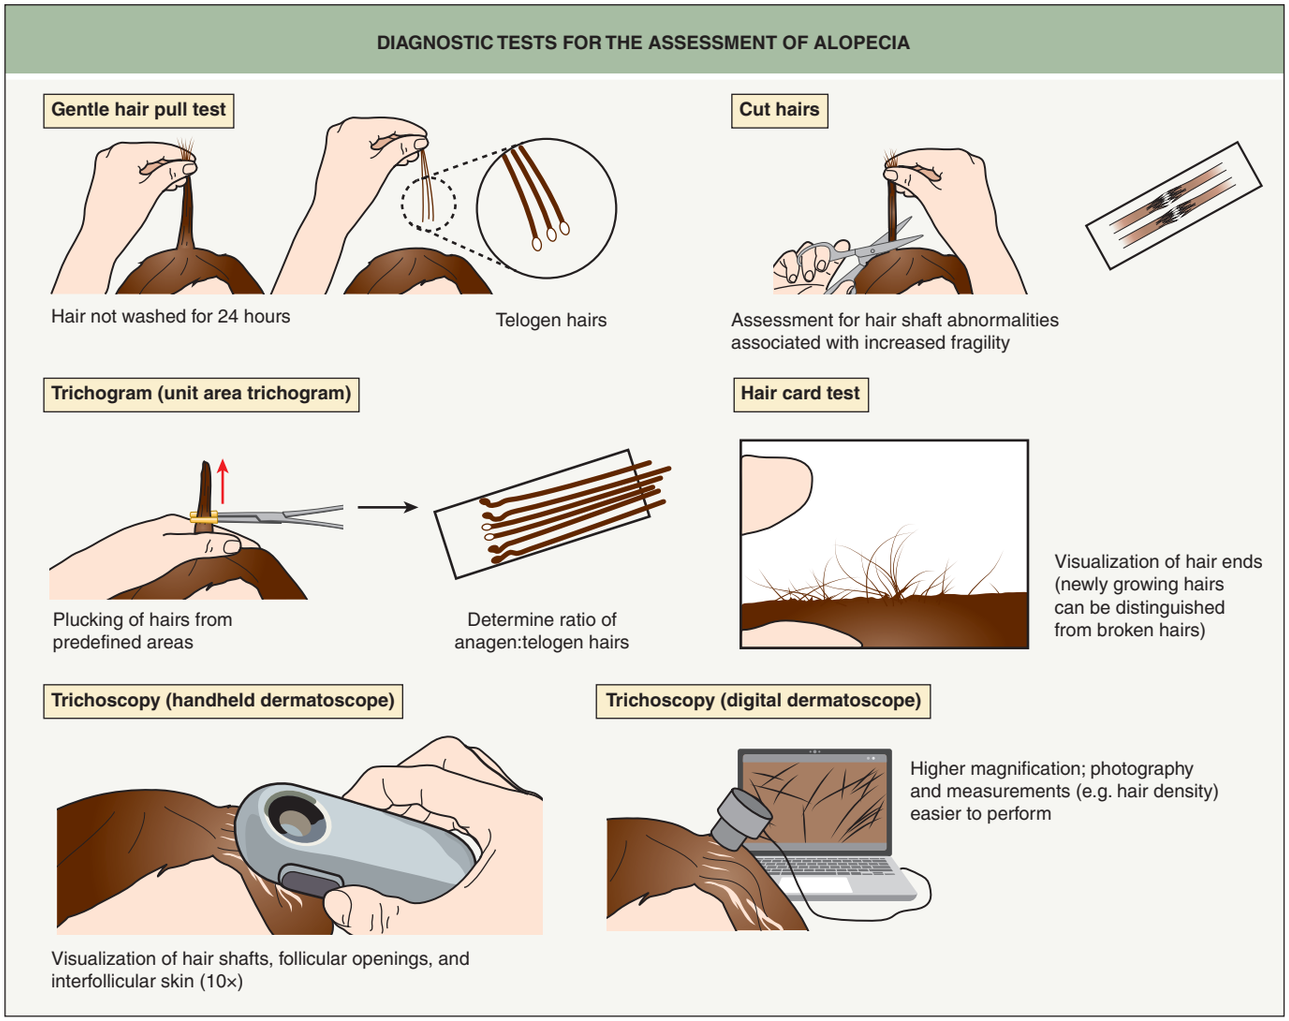

Fig. 69.2 Diagnostic tests for the assessment of alopecia. Additional investigations include fungal culture, Wood's lamp examination, scalp biopsy, polarized light microscopy of scalp hairs, and blood tests.

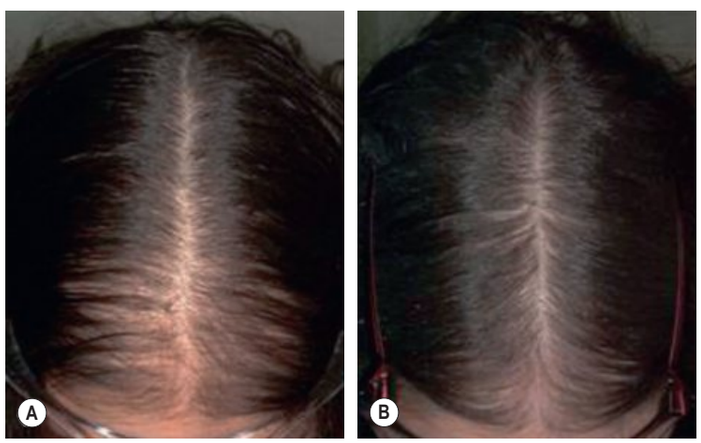

Fig. 69.3 Female androgenetic alopecia. A Prior to treatment. Note the greater hair loss anteriorly. **B** Obvious improvement following 5 years of therapy. Androgenetic alopecia may be at least partially reversible, when treated early. *Courtesy Rodney D. Sinclair, MD.*

structures at different levels within the follicular unit (Fig. 69.8). With the movement towards horizontal sections, this has become even more essential. The characteristic histopathologic findings in AGA are outlined in Table 69.3 and illustrated in Fig. 69.9A,C, & D.

Differential diagnosis

The diagnosis of AGA in men is relatively straightforward unless it is coincidentally associated with other non-scarring hair diseases such as alopecia areata or telogen effluvium. Initial recognition of FAGA may coincide with a superimposed telogen effluvium. Early-onset or severe patterned hair loss in women should suggest the possibility of pathologic hyperandrogenism, and appropriate screening laboratory tests (e.g. total and free testosterone, DHEA-S, and 17 hydroxyprogesterone) should be performed (see Ch. 70). Senile (senescent) alopecia is age-related and is due to more synchronized hair follicle miniaturization than in AGA. While the two disorders share some

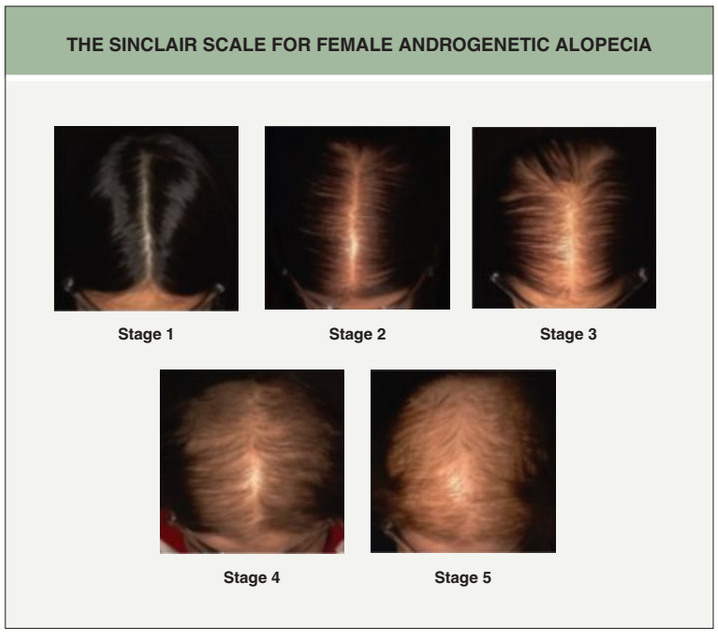

Fig. 69.5 The Sinclair scale for female androgenetic alopecia. Stage 1 – normal; Stage 2 – widening of the central part line; Stage 3 – widening of the part line with translucency of the hairs at its border; Stage 4 – development of a bald area anteriorly along the part line; and Stage 5 – advanced hair loss. *Courtesy Rodney D. Sinclair, MD.*

clinical and trichoscopic features, senile alopecia does not respond to antiandrogen therapies.

Treatment

Topical formulations of minoxidil (2% and 5%) have been approved by the US Food and Drug Administration (FDA) for the treatment of AGA in both men and women. Minoxidil-induced hair growth is commonly associated with shedding of telogen hairs and a paradoxical worsening of hair loss ~3 to 6 weeks following initiation of treatment. However, this resolves with continued treatment. Low-dose oral minoxidil is an off-label, but well documented treatment, for AGA. The optimal dose is currently being investigated, with recommended regimens ranging from 0.625 to 2.5 mg/day in women and 0.625 to 5 mg/day in men[11]. Side effects, including facial hypertrichosis, periorbital edema, lightheadness, and other potential cardiovascular effects, are reviewed in Chapter 157.

Oral finasteride, a type II 5α-reductase inhibitor (Fig. 69.10), is approved for AGA in men at a dose of 1 mg/day. It halts hair loss in 90% of men and partial hair regrowth occurs in ~65%. Continued use of the product is necessary to sustain these effects. Oral finasteride is not FDA-approved for women with AGA, but its efficacy and safety is well documented at a daily dose of 2.5–5 mg[12–14]. As there is some indirect evidence that finasteride may be teratogenic and DHT is required for development of male genitalia, adequate contraception is required for women of child-bearing age.

Possible finasteride side effects include reversible loss of libido, reduced volume of ejaculate fluid, and erectile dysfunction, which occurs in ~2% of men. There are reports of long-lasting sexual dysfunction (post-finasteride syndrome), but its incidence is unknown. While the overall incidence of prostatic carcinoma is *reduced* among elderly men who take finasteride 5 mg daily for benign prostatic hypertrophy, patients should be informed that this higher dose has been associated with an increased risk of the diagnosis of high-grade prostatic carcinoma[14]. It is uncertain if the latter represents overdiagnosis due to enhanced screening or whether it is predictive of an increased risk of metastasis and a higher mortality rate[15]. With regard to the effects of finasteride (1 mg/day) on lowering serum concentrations of prostate-specific antigen (PSA), the recommendation is to adjust the measured serum PSA concentrations upwards by 40%–50% for the purposes of prostate cancer screening[16].

EXAMPLES OF MOST COMMONLY USED ALOPECIA SCORING SYSTEMS

Scoring system	Number of grades or range of scores	Disorder
Ludwig grading system	1–3 (see Fig. 157.3)	Female androgenetic alopecia
Hamilton and Norwood classifications	I–VIII and I–VII (see Fig. 157.2)	Male androgenetic alopecia
Sinclair scale	5 (see Fig. 69.5)	Female androgenetic alopecia
Severity of Alopecia Tool (SALT)	0–100	Alopecia areata
Alopecia Areata Severity Index (AASI)	0–250	Alopecia areata
Alopecia Areata Predictive Score (AAPS)	6 (–4 to +2)* [trichoscopy-based]	Alopecia areata
Lichen Planopilaris Activity Index (LPPAI)	0–10	Based upon symptoms (30%), signs (scale, erythema; 30%), anagen pull test (25%), spreading (15%)
Frontal Fibrosing Alopecia Severity Score (FFASS)	0–25	Based upon cm of hairline recession, loss of eyebrows, perifollicular inflammation, symptoms (pruritus, pain)
Lee classification	9	Dissecting cellulitis; based upon presence/absence of intercommunicating sinus tracts and scarring plus number of involved regions
Melo classification	3 [trichoscopy-based]	Dissecting cellulitis

*Six point scoring system where points are added for upright regrowing hairs and pigtail hairs on trichoscopic exam (positive signs); points subtracted for exclamation hairs, tapered hairs, broken hairs, or black dots (negative signs; see Fig. 69.7). A final score of 1 or 2 is associated with treatment response, whereas scores of –1, –2, –3 or –4 indicate an unlikely response to treatment.

Table 69.2 Examples of most commonly used alopecia scoring systems. Additional scoring systems include: Ebling and Rook 5-stage classification, Savin's pictorial grading (9), and Olsen's classification (3) for female androgenetic alopecia and the alopecia barbae severity score (ALBAS; 0–100) for alopecia areata.

Fig. 69.6 Androgenetic alopecia – trichoscopic features. Full-thickness terminal hairs, intermediate hairs, thin hairs, and very thin (vellus) hairs are all observed simultaneously. This heterogeneity of hair shaft thickness is due to non-synchronized hair miniaturization.

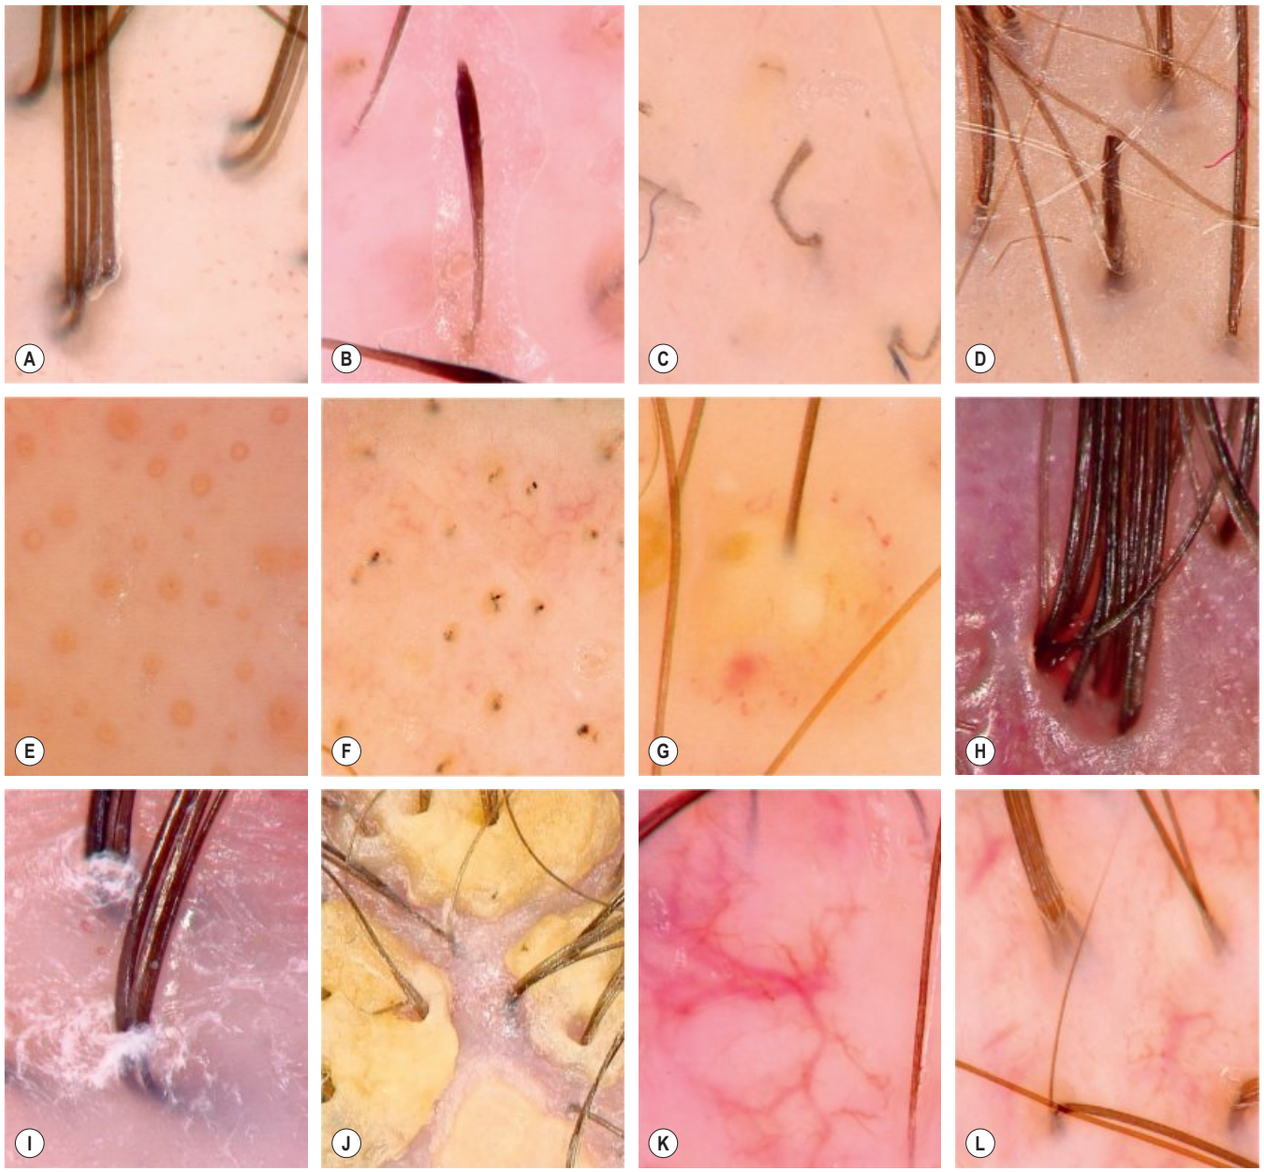

Fig. 69.7 Common trichoscopy findings. A Healthy hairs are uniform in color and shape throughout their length. The follicular units contain 1 to 4 hairs (average, 2.3). **B** Exclamation point hair – observed primarily in alopecia areata, trichotillomania, and chemotherapy-induced alopecia. **C** Comma hairs – tinea capitis. **D** Broken hair – trichotillomania, tinea capitis, and alopecia areata. **E** Yellow dots – alopecia areata and androgenetic alopecia. **F** Black dots – alopecia areata, tinea capitis, trichotillomania, and anagen effluvium. **G** Perifollicular pustule – folliculitis decalvans. **H** Hair tufts consisting of more than 5 hairs per follicular unit ("tufted folliculitis") – folliculitis decalvans. **I** Perifollicular scaling – lichen planopilaris, folliculitis decalvans, and frontal fibrosing alopecia. **J** Seropurulent exudate – dissecting cellulitis and tinea capitis. **K** Thick arborizing vessels and tortuous vessels – systemic lupus erythematosus. **L** Upright regrowing hair (healthy regrowing). Zigzag hairs can be seen in tinea capitis.

Oral dutasteride is more potent than finasteride due to its ability to inhibit 5α-reductase types I and II. It is not FDA-approved for AGA, but its efficacy is well documented at a dose of 0.5 mg/week to 0.5 mg/day[17]. In both men and women, the effectiveness of finasteride and dutasteride decreases with age. In a recent meta-analysis of oral therapies for male AGA, dutasteride (0.5 mg/day) was found to be most effective, followed by finasteride (5 mg/day) and then minoxidil (5 mg/day)[18]. Use of intralesional or topical dutasteride is currently under investigation, with topical 0.01% dutasteride solution plus microneedling leading to improvement. In a recent randomized controlled trial, topical 0.5% finasteride spray solution was shown to lead to a significant improvement in hair counts[19].

There are additional therapies that are based upon less rigorous evidence. For FAGA, these include spironolactone, cyproterone acetate plus ethinyl estradiol, and alfatradiol (17α-estradiol) (Fig. 69.3B; see Fig. 69.10)[20]. Use of low-level light therapy and platelet-rich plasma are reviewed in Chapter 157.

Hair transplantation remains a mainstay in the treatment of AGA and is combined with medical therapy for optimal results (see Ch. 157).

Telogen Effluvium

Key features

- Increased shedding of otherwise normal telogen hairs in response to an external or internal trigger (e.g. medication, high fever, malnutrition, systemic disease, significant emotional stress)
- A chronic form with no identifiable precipitating factor is observed in some women
- Laboratory evaluation is directed by history, physical examination, trichoscopy, and microscopic evaluation of plucked hairs (trichogram)

Introduction

Scalp hair grows longer than hair on other parts of the body because its anagen phase is longer. Unlike mammals that molt, hair cycling in humans is asynchronous such that shedding of each follicle is

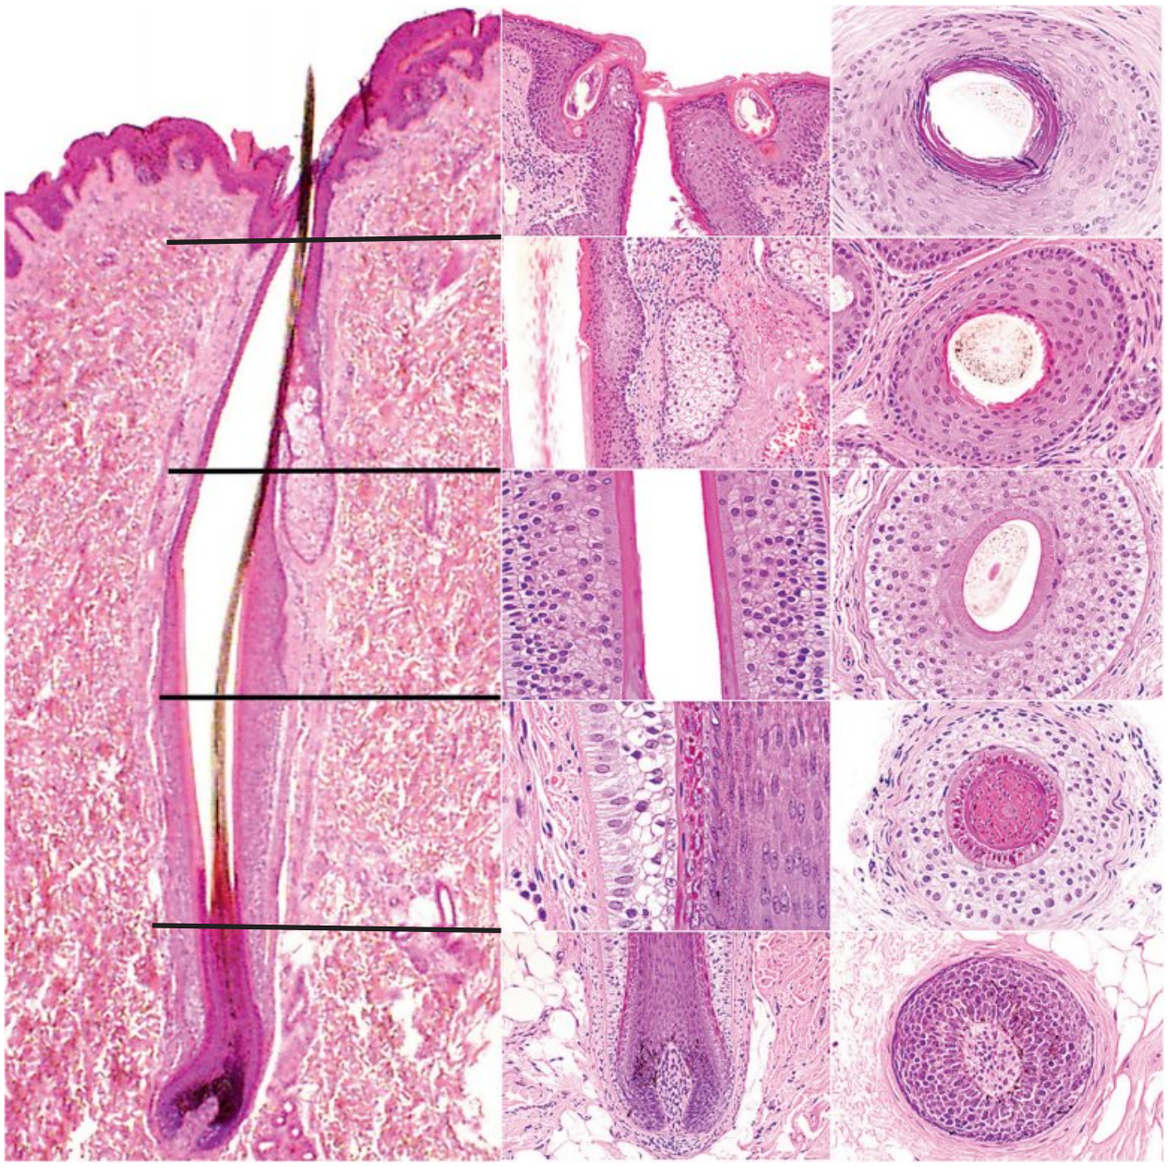

Fig. 69.8 Vertical and horizontal sections of a hair follicle cut at different levels (from bottom to top). *Bulb*: the hair bulb embraces the dermal papilla and is composed of matrical cells admixed with pigmented melanocytes; the nucleated hair shaft is surrounded by: (1) the early inner root sheath (IRS); (2) a paler outer root sheath (ORS); and (3) a dermal fibrous sheath in continuity with the dermal papilla. *Suprabulbar area*: the hair shaft is nucleated and is surrounded by (moving outwards): (1) the hair cuticle – a single layer of overlapping elongated cells; (2) the Huxley layer of the IRS – 3–4 layers of cuboidals cells with keratohyaline granules; (3) the Henle layer of the IRS – single layer of elongated cells; and (4) the pale ORS. *Subisthmus*: the IRS is completely keratinized, the hair shaft is no longer nucleated, and the ORS is less pale and more pink, resembling epidermis. *Isthmus*: upon entering the isthmus, abrupt disintegration of the keratinized IRS occurs and is replaced by tricholemmal keratinization by the ORS. *Infundibulum*: the epithelium has reached maturation and is identical to, and in continuity with, the epidermis.

independent of surrounding follicles. Consequently, a fairly uniform density of hair is maintained at all times.

In the normal scalp, there are ~100 000 hair follicles of which ~90% are in the *anagen* phase of the hair growth cycle; this phase typically lasts for 2–4 years. Hairs then enter the *catagen* phase (0.5%–1% of hair follicles), followed by a *telogen* phase (10% of hair follicles). The latter phase usually lasts for three months after which the hairs undergo conversion to *exogen* and are shed; daily ~50–200 hairs are shed (see Ch. 68)[21]. Internal or external factors that interfere with this normal hair cycle can trigger telogen effluvium. The most common disturbance is a shortened anagen phase.

Pathogenesis

Various external and internal factors may induce a simultaneous transition of a large number of hair follicles from anagen phase into telogen phase. This transition begins the hair shedding process which eventuates in clinically apparent hair loss (telogen effluvium) at the conclusion of the telogen phase, thus explaining its usual occurrence three months after the inciting cause. Potential triggers of telogen effluvium include pregnancy, medications, high fever, malnutrition, systemic diseases such as lupus erythematosus, and significant emotional stress as well as inflammatory scalp disorders (Table 69.4). Systemic infections represent an additional cause; for example, a quarter of individuals infected with SARS-CoV-2 experienced telogen effluvium within the following two months.

Although a wide range of medications have been reported to induce telogen effluvium, only a few have been proven. The severity of hair loss depends on the drug (see Table 69.4), its dosage, and patient susceptibility[8]. Lastly, a significant number of women have a chronic form of telogen effluvium that lacks any identifiable trigger[22].

Clinical features and diagnosis

Thinning and loss of terminal hairs involves the entire scalp and may also be noted on other hairy regions of the body. A trichogram will show an increased percentage of telogen hairs, with >20% diagnostic of telogen effluvium (Fig. 69.11)[23]. By trichoscopy, telogen effluvium is often a diagnosis of exclusion. An increased percentage of follicular units with only one hair is the most characteristic feature. During the regrowth phase, multiple short upright regrowing hairs can be seen.

When due to past events such as a severe illness or pregnancy, complete hair regrowth is expected. If the underlying etiology is an ongoing issue such as hypothyroidism, then the latter needs to be addressed first (see Table 69.4). While chronic telogen effluvium can continue for years or decades, it usually does not lead to baldness[24].

After a history (including medications and supplements) and physical examination have been performed and the triggering factor is still unclear, then thyroid function, complete blood count, metabolic panel, ESR, and serum ferritin level can be assessed. Serum ferritin levels should be at least 40 ng/dl, but the relationship of reduced iron stores to the hair loss still needs to be determined[24].

HISTOPATHOLOGIC FEATURES OF VARIOUS TYPES OF ALOPECIA
Androgenetic alopecia
• Normal *total* number of hair follicles when counted in the superficial dermis • Decreased number of hair follicles when counted at the dermal–subcutaneous fat junction ("miniaturization") • No significant inflammation • Increased fibrous "streamers" below miniaturized hairs • Slightly increased telogen count • Uninvolved scalp (e.g. occiput) appears normal
Telogen effluvium
• Normal *total* number of hairs • Normal number of terminal (large) hairs • Increase in the telogen count to >20% (>15% is suggestive); telogen count seldom exceeds 50%; >80% is inconsistent with telogen effluvium • Absence of inflammation and scarring
Alopecia areata
Early, progressive disease ("acute" and "subacute")
• Normal *total* number of hairs • Peribulbar mononuclear cell infiltrate (with occasional eosinophils), predominantly affecting terminal anagen and catagen hair bulbs • Occasional exocytosis of inflammatory cells into bulbar epithelium • Degenerative changes of hair matrix • Increased number of terminal catagen and telogen hairs • Increased number of miniaturized hairs • Trichomalacia and marked narrowing of hair shafts • Pigment casts
Longstanding and stable disease ("chronic")
• Majority of hairs in catagen or telogen phases • Diffuse miniaturization of hair follicles • Numerous miniaturized, "arrested", rapidly cycling hairs, referred to as *nanogen* hairs • Mild peribulbar mononuclear cell infiltrate around those nanogen hairs possessing anagen-like or catagen-like bulbs
Trichotillomania
• Follicles are normal size • Total number of hairs (both terminal and vellus) is normal • Incomplete, disrupted follicular anatomy • Increased number of terminal catagen and/or telogen hairs • Trichomalacia and pigment casts • No significant inflammation
Pressure (-induced) alopecia
• Early stage includes vascular thrombosis and inflammation within the dermis and superficial fat • Necrosis of the epidermis and eccrine coils when severe • In conjunction with alopecia, synchronized conversion of most or all of the terminal hair follicles to the catagen/telogen phase (*without* hair miniaturization) • Pigment casts, incontinent pigment within collapsed root sheaths, and trichomalacia (but not distorted follicular anatomy)
Traction alopecia
Early and progressive phases
• Increased number of telogen and catagen hair follicles • Occasional trichomalacia • No significant inflammation • Over time, drop-out of terminal hairs with retention of miniaturized hairs
Late phase
• Total number of terminal hairs is markedly reduced; residual vellus hair follicles • Distinct columns of connective tissue replace some follicles, leaving obvious "blank spaces" (follicular scars) • Sebaceous glands associated with the remaining hair follicles are still intact and sebaceous glands with arrector pili muscles persist in follicular units that seem to have lost all of their hair-producing epithelium • No significant perifollicular inflammation
Psoriasiform alopecia
• Psoriasiform epidermal changes may or may not be present • Marked increase in percentage of catagen/telogen hairs, associated with hair miniaturization • Occasional miniaturized follicle showing peribulbar chronic inflammation; plasma cells rare or absent • Marked atrophy of sebaceous glands
TNF inhibitor-induced psoriasiform alopecia
• Psoriasiform dermatitis often present • Increase in catagen/telogen hairs and miniaturization of hairs, similar to alopecia areata • Some peribulbar and superficial perivascular inflammation present, often with several eosinophils and plasma cells in the infiltrate

Table 69.3 Histopathologic features of various types of alopecia.

Continued

HISTOPATHOLOGIC FEATURES OF VARIOUS TYPES OF ALOPECIA
Lichen planopilaris
• Perifollicular band-like lymphoid cell infiltrate obscuring the interface between follicular epithelium and dermis; vacuolar alteration at the interface and hypergranulosis within affected infundibula is typical (sometimes with colloid or Civatte bodies) • Inflammation affects the *upper* portion of the follicle (infundibulum and isthmus) predominantly • Occasionally, interfollicular epidermal changes of lichen planus are found • Reduced or absent sebaceous glands • Over time, perifollicular fibrosis becomes prominent and the lymphocytic infiltrate seems to "back away" from the follicle • An artifactual cleft between epithelium and stroma is often found, with epithelium "floating" within the cleft (Max-Joseph spaces) • End-stages may show follicular "tufting" • Fragments of "naked" hair shafts in giant cells may be seen • Direct immunofluorescence shows colloid bodies (usually IgM) adjacent to the follicular epithelium and, when epidermis is involved, a linear "shaggy" band of fibrinogen is present
Central centrifugal cicatricial alopecia
• Premature desquamation of the inner root sheath in the subisthmic area • Eccentric epithelial atrophy (thinning) in the subisthmic area • Concentric lamellar fibroplasia (onion skin-like fibrosis) of affected follicles • Variably dense lymphocytic perifollicular inflammation, primarily at the level of the upper isthmus and lower infundibulum • Occasional fusion of infundibula (polytrichia) • In advanced lesions, total destruction of the follicular epithelium with retained hair shaft fragments and granulomatous inflammation • In pustular lesions ("folliculitis decalvans"), intrafollicular and perifollicular infiltrates rich in neutrophils and lymphocytes
Discoid lupus erythematosus
• Vacuolar interface alteration of the epidermis and follicular epithelium (the epidermis may be spared) • The interface change in follicles is usually vacuolar rather than lichenoid (less inflammation) • Reduced sebaceous glands • Follicular (and/or epidermal) basement membrane zone thickening present in late stages • Chronic inflammation with lymphocytes (often including plasma cells) of the eccrine sweat glands and arrector pili • Perineurial lymphoid cell infiltrate may be seen • Increased dermal mucin • Fragments of "naked" hair shafts in giant cells may be seen • Direct immunofluorescence typically shows granular deposits of IgG and C3 (less commonly IgM or IgA) at the dermal–epidermal junction and/or the junction of the follicular epithelium and dermis
Folliculitis decalvans
• Pustular neutrophilic folliculitis rich in lymphocytes and plasma cells • Early stages: perifollicular inflammation with mixed, predominantly neutrophilic, infiltrate; follicular neutrophilic abscesses • Rupture of the hair follicles with partly granulomatous inflammation • Fragments of "naked" hair shafts within giant cells may be seen • Gram-positive cocci often present • Late stages: perifollicular scarring with "tufting" and interfollicular dermal scarring
Acne keloidalis
• Perifollicular, chronic inflammation (lymphocytic and plasmacytic), most intense at the level of the isthmus and lower infundibulum • Lamellar fibroplasia, most marked at the level of the isthmus • Loss of sebaceous glands • Total follicular destruction in advanced disease
Dissecting cellulitis
• Moderately dense, perifollicular lymphocytic inflammation affecting the lower half of the dermis and extending down into the subcutaneous fat (early lesions) • Numerous intact and seemingly undamaged follicles in the upper dermis with intact sebaceous glands • Increased percentage of catagen/telogen hairs • Initially, lymphocytes dominate the infiltrate, but eventually neutrophils become more numerous, especially in longstanding, fluctuant lesions • Vascular proliferation accompanies the infiltrate as the disease evolves, and the deep dermis and subcutaneous fat begin to exhibit the histologic findings of granulation tissue • Eventually, chronic abscesses become lined with squamous epithelium derived from the overlying epidermis, and true sinus tracts are formed • When inflammation subsides, there is dense fibrosis of the dermis and the superficial fat with loss of follicles
"End-stage" cicatricial alopecia
• A decreased total number of hairs, especially terminal hairs • Loss of the sebaceous glands in zones of follicular loss • Residual, "naked" hair shafts within histiocytic giant cells surrounded by mild, granulomatous inflammation • Follicular streamers (stelae) without overlying follicles • Cylindrical columns of connective tissue representing the sites of former follicles

Table 69.3 Histopathologic features of various types of alopecia. See Fig. 69.7. Trichomalacia is characterized by pleated or twisted hair shafts within follicular infundibula.

For persistent cases of telogen effluvium, i.e. those lasting beyond 6 months, trichoscopy should be repeated and a trichoscopy-guided biopsy from the vertex area may be considered to exclude early AGA. The histopathologic findings in telogen effluvium are outlined in Table 69.3[25], with the ratio of terminal to vellus hairs at the level of the isthmus allowing for distinction from AGA[26]. That said, the coexistence of telogen effluvium and AGA is a common occurrence.

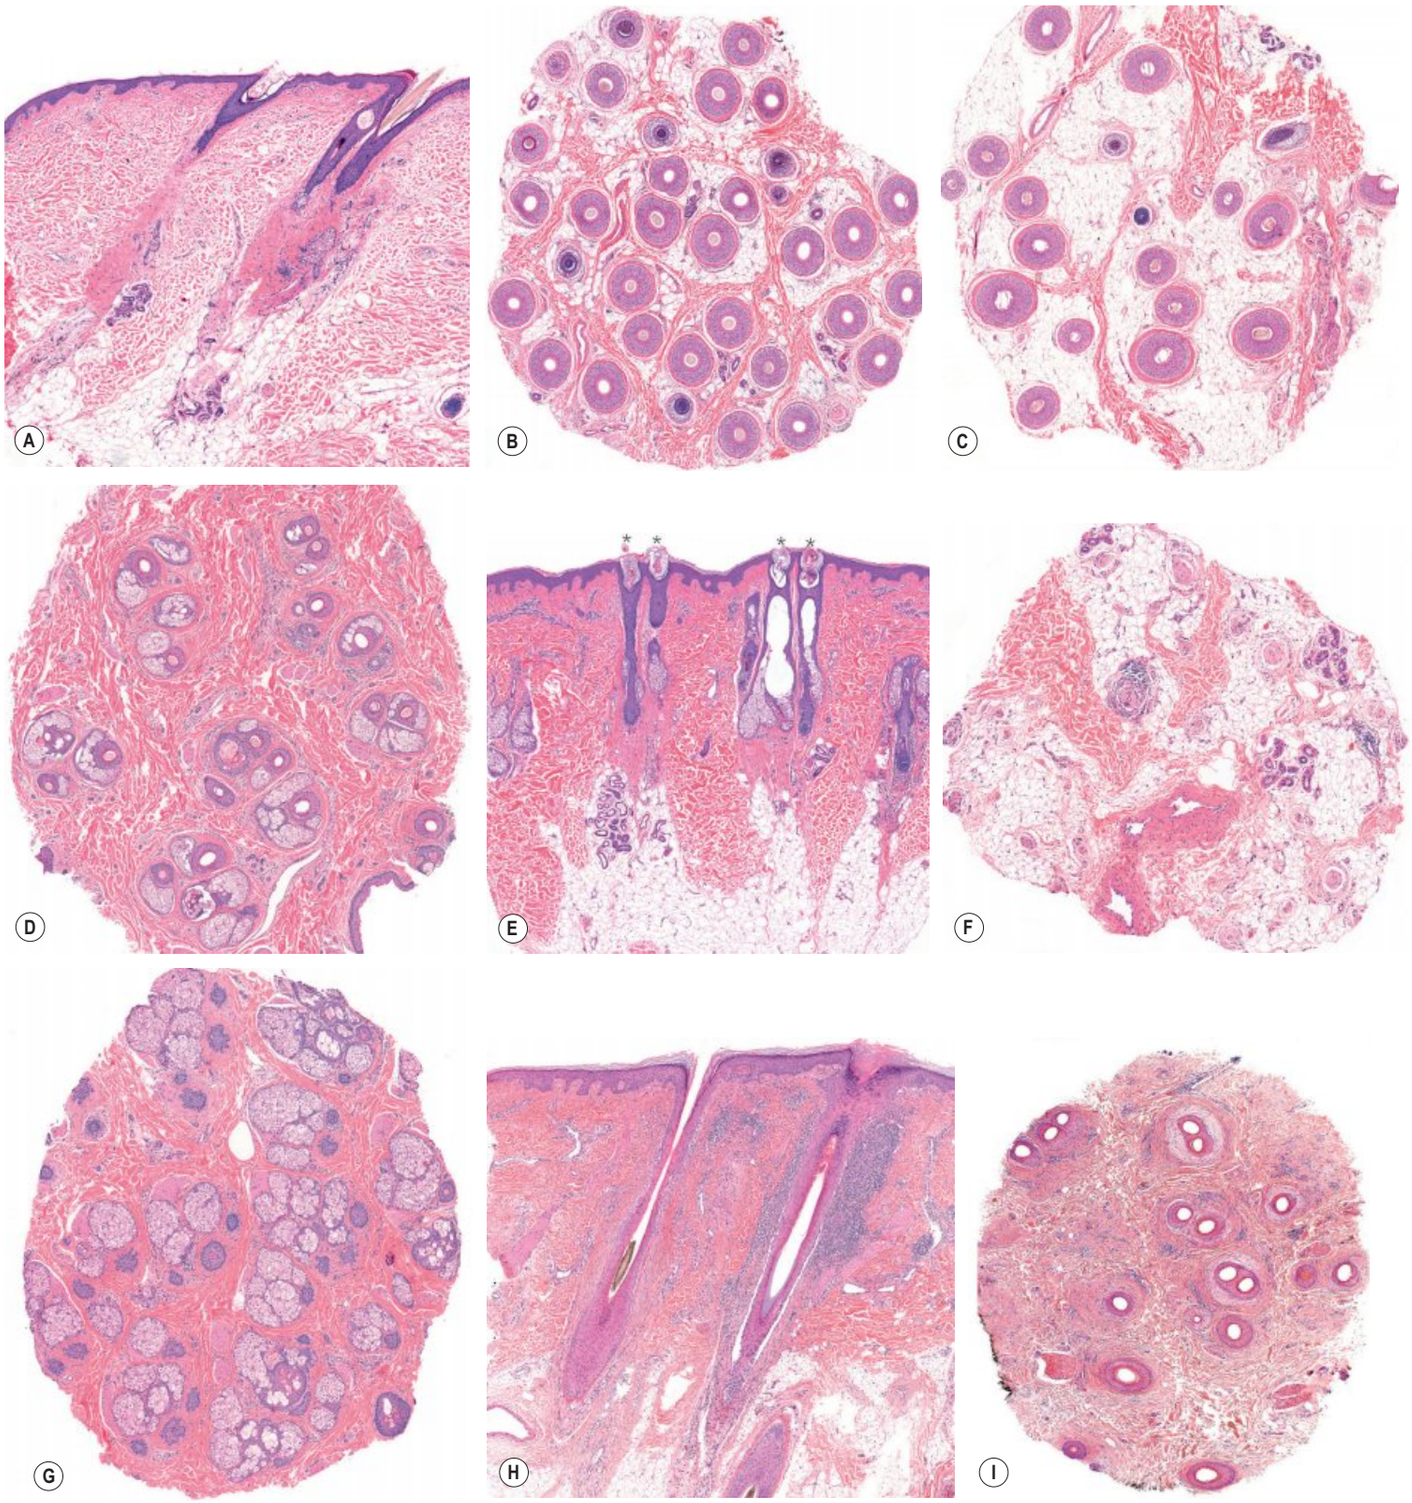

Fig. 69.9 Histopathologic features of androgenetic alopecia, alopecia areata, and lichen planopilaris. A *Androgenetic alopecia* with the characteristic miniaturization of hair follicles and fibrous streamers (vertical section). **B** Normal scalp (horizontal section). **C** *Androgenetic alopecia* with variation in hair follicle size (horizontal section; compare to B). **D** *Androgenetic alopecia* at the level of the isthmus with miniaturized vellus-like hair follicles and no significant inflammation (horizontal section). **E** *Alopecia areata* with miniaturized, vellus-like hair follicles, one of which has a peribulbar lymphocytic infiltrate (vertical section). A clue to the diagnosis is the dilatation of the follicular infundibula which corresponds to the yellow dots by trichoscopy (asterisks). **F** *Alopecia areata* with the characteristic peribulbar lymphocytic infiltrates (horizontal section). **G** *Alopecia areata* at the level of the isthmus demonstrating exclusively telogen follicles (horizontal section). **H** *Lichen planopilaris*. Focal hypergranulosis at the acrotrichium and a dense perifollicular lymphocytic infiltrate (vertical section). Note the Max-Joseph spaces between the hair follicle and the perifollicular sheath. **I** *Lichen planopilaris* at the level of the isthmus showing complete loss of sebaceous glands, perifollicular fibrosis, perifollicular lymphocytic infiltrate, and follicular tufting (horizontal section). *A–H, Courtesy Laila El Shabrawi-Caelen, MD.*

Treatment

With the exception of correcting underlying disorders or discontinuing (or substituting) medications outlined in Table 69.4, there is no well-documented treatment for telogen effluvium. Iron replacement in those with a serum ferritin level <40 ng/dl is recommended by many hair experts following determination of its etiology. Topical or low-dose oral minoxidil may be considered as an off-label, nonspecific hair growth-promoting agent[27] as can platelet-rich plasma injections.

Anagen Effluvium

Anagen effluvium develops when there is an abrupt and simultaneous inhibition of the mitotic activity of follicular matrix cells. Anagen follicles with the highest mitotic activity are most affected while those with less mitotic activity enter telogen phase. Within a few days to weeks, there is loss of actively growing anagen hairs. Of note, hair follicles in telogen phase are not affected. Chemotherapy is the most common cause but exposure to thallium, other heavy metals (e.g. arsenic, lead, bismuth), ionizing radiation, and severe nutritional deficiencies can lead to anagen effluvium[28]. Systemic medications used to treat skin diseases, such as methotrexate, azathioprine, and retinoids, are a rare cause of anagen effluvium. Anagen effluvium may be related to other hair disorders, e.g. alopecia areata.

The diagnosis is based on history and clinical appearance, with the abrupt loss of up to 90% of hair shafts a distinct finding. By trichoscopy, there are multiple black dots, terminal hairs with proximal hair thinning, and exclamation point hairs[29]. Some patients, especially those who receive taxanes and anthracyclines, can develop persistent chemotherapy-induced alopecia, which may improve with topical or low-dose oral minoxidil.

Treatment of anagen effluvium consists of discontinuation or avoidance of the causative factor. Scalp cooling during administration

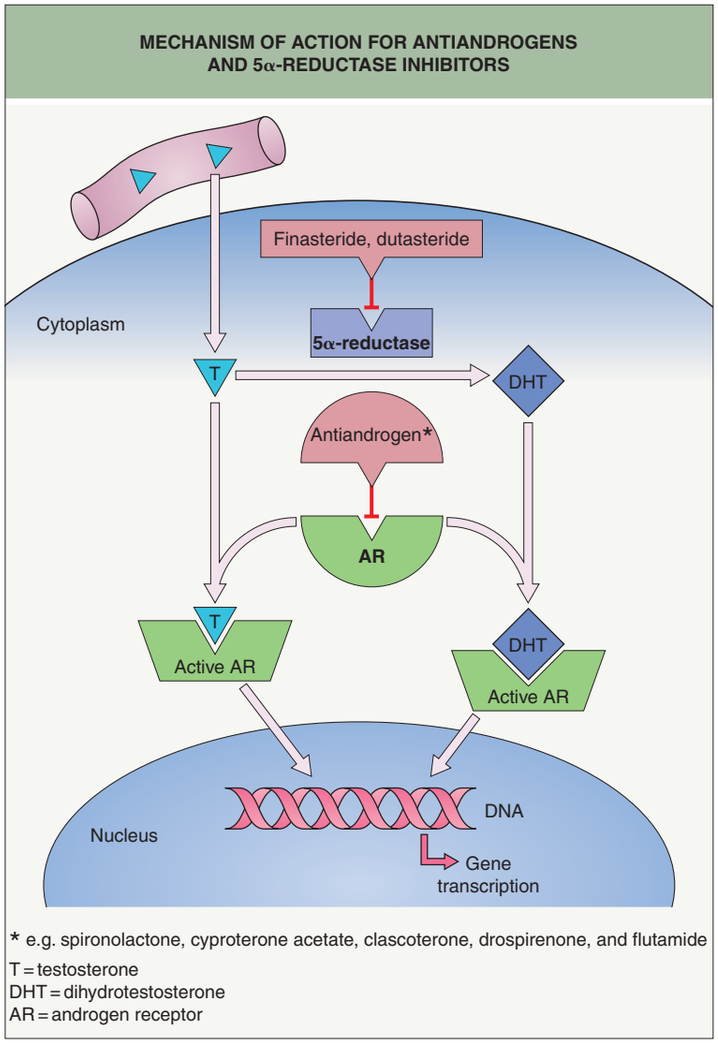

Fig. 69.10 Mechanism of action of antiandrogens and 5α-reductase inhibitors in androgenetic alopecia.

TRIGGERS OF TELOGEN EFFLUVIUM
• Shedding of the newborn (physiologic)
• Pregnancy
• High fever
• Severe infection (e.g. bacterial, viral) or illness
• Endocrinopathy (e.g. hyperthyroidism, hypothyroidism)
• Nutritional deficiencies (e.g. malnutrition, malabsorption, weight reduction diets, fad diets, post-bariatric surgery)
• Chronic systemic disease (e.g. AIDS, systemic lupus erythematosus)
• Major surgical procedure (general anesthesia)
• Acute or chronic blood loss, iron deficiency
• Medications
◦ discontinuation of oral contraceptives
◦ endocrine therapies (e.g. selective estrogen receptor modulators)
◦ retinoids (e.g. acitretin, isotretinoin) and vitamin A excess
◦ anticoagulants (especially heparin)
◦ antithyroid drugs (propylthiouracil, methimazole)
◦ lithium
◦ anticonvulsants (e.g. phenytoin, valproic acid, carbamazepine)
◦ interferon-α-2b
◦ β-blockers (e.g. propranolol, metoprolol, timolol)
◦ immunosuppressive drugs (e.g. methotrexate, azathioprine)
◦ nonsteroidal anti-inflammatory drugs (e.g. ibuprofen, ketoprofen)
◦ levodopa
◦ allopurinol
• Exposure to heavy metals (e.g. cadmium)*
• Severe, prolonged psychological stress
• Inflammatory scalp disorders (e.g. severe seborrheic dermatitis, psoriasis, allergic contact dermatitis)
*Also cause anagen effluvium.

Table 69.4 Triggers of telogen effluvium. There is also a chronic form of telogen effluvium for which there is no attributable cause or illness.

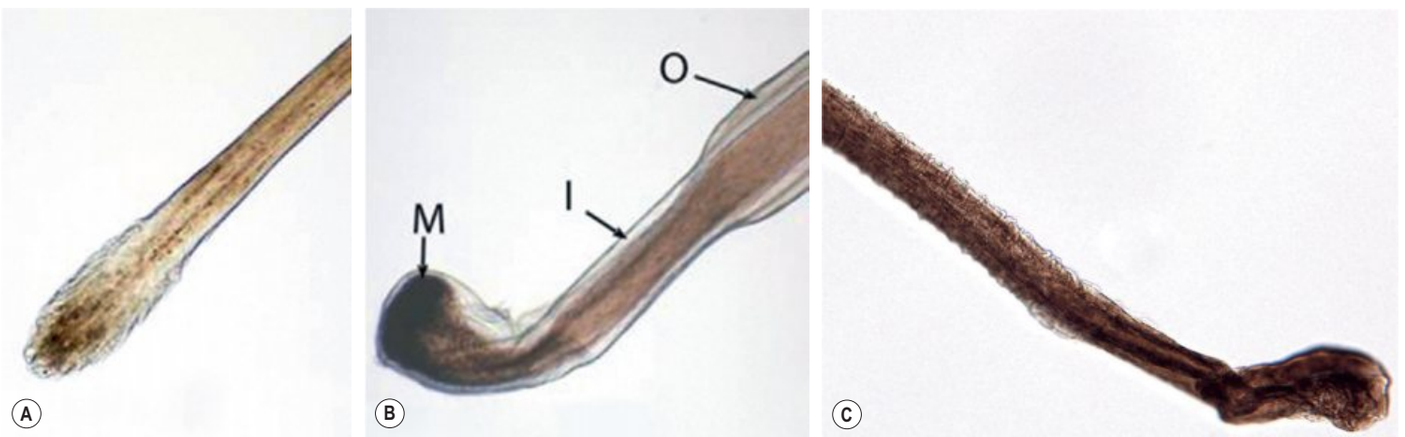

Fig. 69.11 Microscopic features of anagen and telogen hairs. A Telogen shaft showing a club-shaped bulb. **B** Anagen shaft with attached root sheaths, demonstrating a pigmented and distorted bulb. M, matrix; I, inner root sheath; O, outer root sheath. **C** Ruffled cuticle of loose anagen hair. *C, Courtesy Julie V. Schaffer, MD.*

of chemotherapy via cold caps or cooling systems has shown benefit in up 50% of patients, depending upon the chemotherapeutic regimen. To date, scalp cooling has been used primarily in breast cancer patients rather than in those with malignancies (e.g. hematologic) where there could be a theoretical reduction in chemotherapy efficacy.

Alopecia Areata

Key features

- Autoimmune disease characterized by chronic or episodic non-cicatricial hair loss
- Presents with hairless patches, most commonly on the scalp; may result in total hair loss
- Typical trichoscopic features are exclamation point hairs, black dots, and yellow dots
- Long-standing alopecia areata is associated with follicular dropout and may become irreversible

Introduction

Alopecia areata is an autoimmune disease, with genetic factors playing a role in disease susceptibility. It has a chronic relapsing course and although varying hair-bearing areas can be affected, the scalp and beard are the most common sites of involvement. The prevalence of alopecia areata in the population is ~0.1% to 0.2%, and the lifetime risk of developing alopecia areata is estimated to be ~2%[20].

Pathogenesis

The pathogenesis of alopecia areata is complex, with interactions involving immune, genetic, and environmental factors. It is an autoimmune T-cell mediated disease with a predominant Th1/IFN-γ response that leads to stimulation of $CD8^+NKG2D^+$ effector T cells. The latter infiltrate affected hair follicles, leading to upregulation of major histocompatibility complexes and subsequent loss of hair follicle immune privilege[30]. IL-15 is also upregulated in diseased hair follicles, activating IFN-γ-producing $CD8^+NKG2D^+$ cytotoxic T cells which then leads to a positive feedback loop that promotes additional IL-15 production. As a result, there is a continued autoimmune attack on hair follicles and a transition from anagen to catagen. IFN-γ and IL-15 are dependent on the JAK-STAT signaling pathway for the activation and proliferation of autoreactive T cells (see Fig. 128.11), providing an explanation for the therapeutic response to JAK inhibitors. Of note, follicular stem cells are not usually targeted, allowing for future hair regrowth via spontaneous remission or effective treatment.

For some patients, environmental factors such as viral infections, vaccines, medications, and stress have been implicated as possible triggers[30a]. From a genetic standpoint, alopecia areata is an example of a complex polygenic disease[30b,30c]. Genome-wide association studies have confirmed an association with particular HLA genes, with the HLA-DQB1*03 allele identified as an important susceptibility marker[30d,30e]. There is also a strong association with genes in the ULBP gene cluster (chromosome 6q25) which code for activating ligands of the NKG2D receptor[30f]. Patients with alopecia areata have an increased risk of other autoimmune diseases (e.g. thyroid disease, rheumatoid arthritis) and this may be due to a shared inherited autoimmune pathway. Indeed, several susceptibility loci linked to other autoimmune diseases have been identified in patients with alopecia areata, e.g. CTLA-4, IL-2/IL-21, IL-2RA[30g]. Lastly, both *PTPN22*, which encodes a lymphoid protein tyrosine phosphatase that normally suppresses T cell proliferation, and IL-1 cluster genes (IL-1RA) have been associated with severe forms of alopecia areata[30h].

Clinical features

Alopecia areata commonly presents as round or oval patches of non-scarring hair loss (patchy alopecia areata; Fig. 69.12A,B). Other presentations include alopecia totalis (loss of all scalp hair), alopecia universalis (loss of all scalp and body hair), ophiasis (band-like pattern of hair loss along the periphery of the temporal and occipital scalp), and alopecia involving the beard, eyebrows, or other hair-bearing sites (Fig. 69.12C–F). The reticular variant is characterized by recurrent patchy disease, in which the patient experiences hair loss in one area while at the same time undergoing spontaneous regrowth in other sites. An unusual variant is sisaipho (ophiasis inversus) in which the hair loss spares temporal and occipital areas. The rare diffuse variant of alopecia areata can present with widespread thinning or may primarily affect the vertex. Non-pigmented hairs may remain unaffected such that some patients with diffuse scalp involvement appear to develop rapid graying of the hair[20].

The hair loss in alopecia areata is generally reversible, but late-stage disease is characterized by progressive follicular drop-out. Prognosis worsens when alopecia areata persists beyond 5 years and hair loss can become irreversible when the alopecia persists for >10 years. However, irreversibility should not be assumed nor serve as a contraindication for a therapeutic trial[31]. The Alopecia Areata Predictive Score (AAPS) can be used to estimate the probability of hair regrowth based upon trichoscopy findings (see below)[32].

Alopecia areata, especially when severe, may be associated with nail involvement. The most common abnormality is nail pitting, often in a grid-like pattern (see Fig. 71.2). Other changes include trachyonychia (sandpaper-like roughness due to excessive longitudinal ridging; Fig. 69.12G), brittle nails, onycholysis, koilonychia, and rarely, onychomadesis[33].

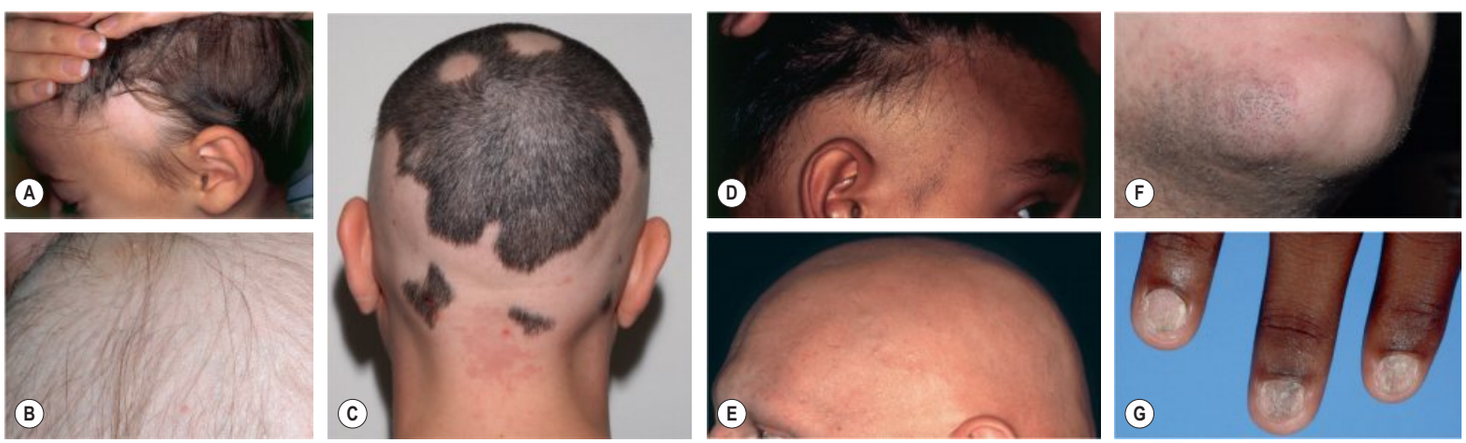

Fig. 69.12 Alopecia areata. A A circular patch of alopecia areata in a child. **B** Within a patch of alopecia areata, hair loss may be incomplete as telogen hairs remain; note the multiple exclamation point hairs. **C** Circular and confluent areas of alopecia, leading to an ophiasis pattern. There is an incidental nevus simplex. **D** Ophiasis with a band-like pattern of hair loss along the periphery of the temporal and occipital scalp. **E** Total alopecia of the scalp, eyebrows, and eyelashes in a patient with alopecia universalis. **F** Alopecia areata of the beard. **G** Trachyonychia, which is usually associated with severe alopecia areata. *B, G, Courtesy Julie V. Schaffer, MD; C, Courtesy Edward Cowen, MD; E, Courtesy Leonard C. Sperling, MD; F, Courtesy Rodney D. Sinclair, MD.*

In alopecia areata, the three most common trichoscopic findings are: (1) exclamation point hairs – proximal hair shaft thinning due to episodes of arrested mitotic activity within the germinal matrix; (2) black dots – when the exclamation point hairs break off, the residual dark hair shaft is visible in the follicular opening; and (3) yellow dots – empty hair follicles filled with keratotic material and sebum (Fig. 69.13; see Fig. 69.7B,E,F). The latter may be more subtle in prepubescent children. Tapered hairs represent very long exclamation point hairs and they indicate moderate disease activity. Pigtail (circle) and upright regrowing hairs indicate hair regrowth (see Fig. 69.7L)[34].

Comorbidities and associated disorders

Thyroid dysfunction, atopy, and systemic lupus erythematosus are the most common immune-mediated disorders associated with alopecia areata, with odds ratios of 4.4, 2.4, and 3.5, respectively[35,36]. Reported comorbidities include metabolic syndrome, depression, and anxiety. Patients with Down syndrome have an increased incidence of alopecia areata and the latter occurs in a third of individuals with the genodermatosis autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome. Some families with vitamin D-dependent rickets type II also develop alopecia areata.

Satoyoshi syndrome is a multisystem disorder in which patients can develop severe alopecia areata. Hair loss represents the syndrome's major criterion while intermittent painful muscle spasms, diarrhea, and anti-nuclear antibodies are the minor criteria (2 of 3 required for diagnosis[37]. Lastly, in a small study of patients with alopecia areata, gut dysbiosis was observed[38].

Differential diagnosis

Tinea capitis, trichotillomania, temporal triangular alopecia, traction alopecia, secondary syphilis, and loose anagen syndrome need to be considered in the differential diagnosis of alopecia areata as well as pressure-related alopecia, aplasia cutis, and "burnt-out" cicatricial alopecia. The diffuse variant may initially be confused with telogen effluvium and AGA. Usually, the history and clinical examination (including trichoscopy) is sufficient to distinguish between these conditions, but performing a scalp biopsy may prove useful for less distinctive presentations. The histopathologic features of alopecia areata are illustrated in Fig. 69.9E,F,G and are outlined in Table 69.3.

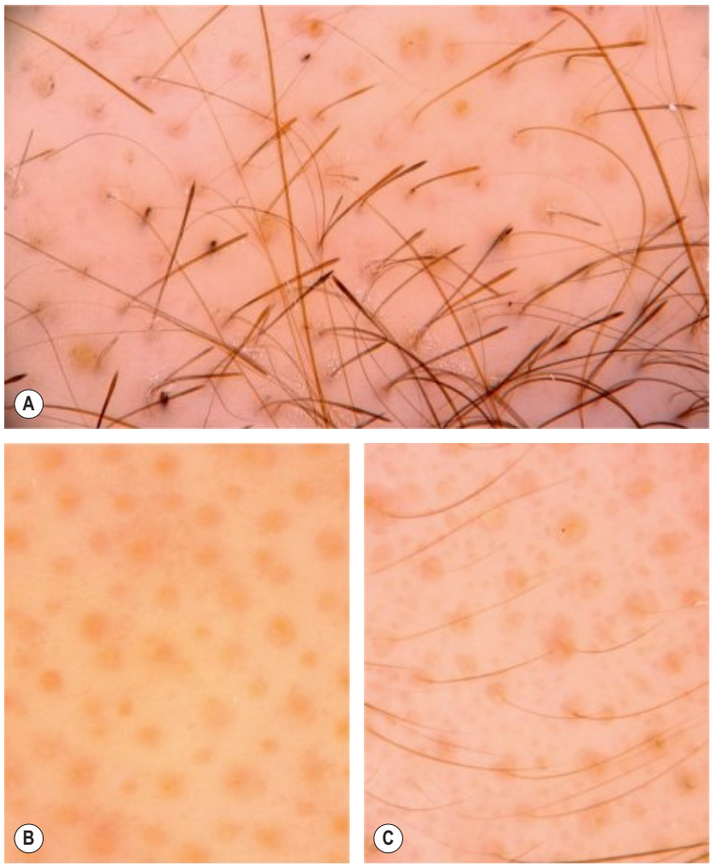

Fig. 69.13 Trichoscopy of alopecia areata. A Active disease with multiple exclamation point hairs and black dots; some yellow dots are also seen. **B** Chronic phase with only yellow dots. **C** Regrowth phase with thin hair shafts emerging from some of the yellow dots (eyebrow).

Treatment

Multiple off-label, variably successful topical, intralesional, and systemic therapies are available for the treatment of alopecia areata, with the therapeutic approach depending upon several factors such as age, extent of disease, and patient expectations. The FDA recently approved two oral JAK inhibitors for severe alopecia areata in adults (baricitinib) and for alopecia areata with extensive hair loss in individuals age 12 years and older (ritlecitinib). Most experts view a Severity of Alopecia Tool (SALT) score of >20 as an indication for systemic therapy[39].

Topical and intralesional

First-line topical therapy usually consists of an ultrapotent (class I) corticosteroid. Additional topical options include calcineurin inhibitors, minoxidil, anthralin, and especially for eyebrows, prostaglandin analogues (e.g. bimatoprost, latanoprost) and topical JAK inhibitors. Children with severe alopecia areata can be offered contact immunotherapy (e.g. diphenylcyclopropenone [diphencyprone], squaric acid dibutyl ester) before systemic therapy is considered. In all age groups, concurrent systemic immunosuppressants should be avoided as they can blunt the desired inflammatory response from contactants.

A solitary patch on the scalp is best treated with intralesional triamcinolone acetonide (2.5 to 5 mg/ml) every 3–4 weeks. Approximately 0.1 ml is injected into the mid to deep dermis, with injection sites at intervals of 1 cm apart. In an average adult, the recommended maximum dose administered during a single session is 10 to 20 mg[40].

Systemic

In adults and adolescents with severe disease, options include prednisone or prednisolone, Janus kinase (JAK) inhibitors, and cyclosporine; pulse corticosteroids (e.g. dexamethasone 0.1 mg/kg twice weekly, prednisolone 200 mg weekly, prednisolone 5 mg/kg [up to 300 mg] monthly) can also be considered in children as well as adults. When daily corticosteroids are administered for rapidly progressive disease, an initial dose of prednisolone is typically 0.4 to 0.6 mg/kg/day with a gradual taper over at least 12 weeks and a possible transition to a pulse regimen. Either cyclosporine (3 to 5 mg/kg/day) or methotrexate (15 to 20 mg weekly) may be used as a steroid-sparing agent or as monotherapy[40]. In younger patients, the methotrexate target dose is ~0.4 mg/kg/week[40]. For other steroid-sparing agents, including mycophenolate mofetil, azathioprine, dapsone, sulfasalazine, IL-17 inhibitors, apremilast and dupilumab, there are limited data regarding efficacy. The latter has been successful in patients who had concomitant atopic dermatitis.

Multiple more recent studies have demonstrated the effectiveness of oral JAK inhibitors (see Ch. 128), in particular baricitinib[41] and ritlecitinib[41a], which are now FDA-approved for the treatment of alopecia areata (see above), as well as tofacitinib and deuruxolitinib. However, maintenance therapy is necessary to avoid relapse. Topical JAK inhibitors (e.g. 2% tofacitinib, 1.5% ruxolitinib) are less effective than their oral counterparts, and use of JAK inhibitors in children (maximum daily dose of 0.625 mg [<20 kg] to 1.25 mg [20–40 kg]) is currently off-label. Irrespective of the preferred treatment, low-dose oral minoxidil can be employed as supplemental therapy.

Trichotillomania

Key features

- A body-focused repetitive behavior disorder characterized by hair pulling
- Varying lengths of hair are typically seen within areas of alopecia
- The most specific trichoscopic features are coiled hairs, flame hairs, and the v-sign
- A related disorder is trichotemnomania in which hairs are compulsively cut or shaved

Pathogenesis

Trichotillomania is defined by the American Psychiatric Association as one of the "obsessive–compulsive and related disorders" (see Ch. 7 for clinical criteria). However, individuals with trichotillomania represent a very heterogeneous group, varying from those with a mild habit to others who have an impulse-control disorder, personality disorder, or intellectual disability. Notably, many of the patients who have alopecia due to pulling their hair out do not fulfill the diagnostic criteria for psychiatric disorders.

Clinical features

Individuals with trichotillomania usually pluck scalp hair, resulting in patchy or full alopecia of the scalp (Fig. 69.14A). Some patients may also pluck from other hair-bearing regions such as the eyebrows, eyelashes, extremities, or pubic region. Patches of alopecia may have irregular shapes as well as erosions, crusts, and hairs of varying lengths. The clinical diagnosis can be supported by shaving a small area of involved scalp to demonstrate normal, dense regrowth as very short hair shafts are usually not plucked by the patient. The seven trichoscopy features with highest specificity for trichotillomania are: hook hairs; coiled hairs; the v-sign (two hairs broken at the same level in one follicle); hair powder; flame hairs (semi-transparent, wavy, cone-shaped hair residues); tulip hairs (short hairs with tulip flower-like ends); and trichoptilosis (Fig. 69.14B)[42]. Broken hairs and black dots are common, but nonspecific trichoscopic features. The histopathologic findings in trichotillomania are outlined in Table 69.3.

Treatment

No specific treatment approach has been established as effective in any large controlled study. Hypnosis, behavioral modification therapy, insight-oriented psychotherapy, and pharmacologic therapy have all been tried, but success rates are low. Habit reversal training is often used as a first-line non-pharmacologic treatment. If pharmacologic therapy is considered, N-acetylcysteine, clomipramine, or olanzapine can be tried. In preschool children, the hair pulling often resolves with no treatment[43].

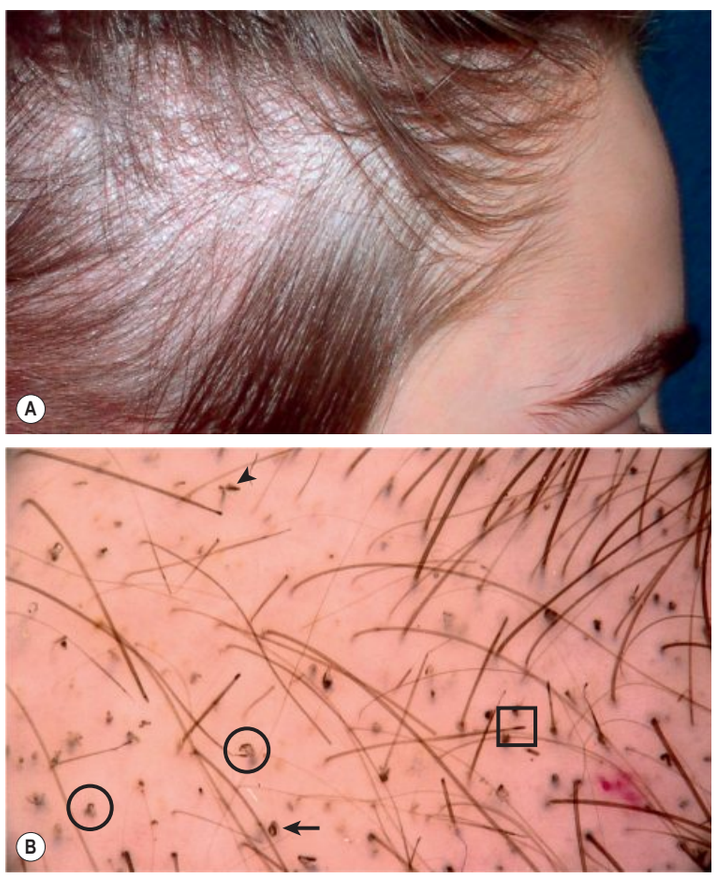

Fig. 69.14 Trichotillomania in a 14-year-old girl. A Decreased hair density in an irregularly shaped patch. **B** Trichoscopy shows multiple broken hairs of varying lengths ("irregularly irregular") and black dots. In addition, there are hook (circles), tulip (square), and coiled (arrow) hairs as well as the v-sign (arrowhead).

Pressure Alopecia (Pressure-Induced Alopecia)

Pressure alopecia usually develops following prolonged immobilization as occurs with a lengthy surgical procedure or hospitalization in an intensive care unit. Most commonly the patient is supine with the head fixed in one position on the operating table or bed and the pressure alopecia appears on the occiput. In theory, there is locally reduced microcirculation due to pressure. Although complete hair regrowth usually occurs, cases of permanent (i.e. cicatricial) hair loss have been reported[44]. Nonspecific findings are seen by trichoscopy. An analogous condition in newborns is the halo scalp ring which manifests as a self-resolving occipital band of alopecia. The ring is believed to be due to pressure from the maternal cervix during labor[45].

Temporal Triangular Alopecia

Temporal triangular alopecia (congenital triangular alopecia) presents as a hairless patch in the temporal region of the scalp (unilateral or bilateral). It may be present at birth or appear during the first decade of life. The alopecia is usually in the shape of a triangle, but oval and other shapes can be seen (Fig. 69.15). Trichoscopy shows very thin and vellus hairs within the entire patch. The alopecia is usually permanent[46].

Traction Alopecia

Traction alopecia results from repetitive and prolonged tension on scalp hairs. It usually develops from styling hair in cornrows, braids, dreadlocks, ponytails, or chignons. It may also be associated with other forms of tension, e.g. from hair extensions, and occasionally from wearing turbans. The hair loss is accentuated in areas with the greatest tension and is most commonly observed in the frontal and temporal areas (Fig. 69.16). In advanced traction alopecia, a "fringe sign" may be seen, i.e. a thin strip of retained hairs in the *original* frontotemporal hairline that is separated from the current hair-bearing margin by a 1- to 3-cm hairless band. Permanent damage to hair follicles and irreversible hair loss can occur in late-stage disease. The histopathologic findings are outlined in Table 69.3.

Trichoscopic features reflect the mechanical tension applied to the hairs, but without the chaotic arrangement that is typical of trichotillomania. A characteristic finding in traction alopecia is the Flambeau sign – perifollicular linear white tracks localized parallel to the emerging terminal hair. Vellus hairs are present in the frontal area, a feature which differentiates traction alopecia from frontal fibrosing alopecia. Hair casts and broken hairs are additional trichoscopic features of traction alopecia but they are nonspecific[47].

Fig. 69.16 Traction alopecia. Favors the frontotemporal area in African-American women and is due to traumatic types of hair styling. The arrow points to the "fringe sign". *Courtesy Leonard C. Sperling, MD.*

In traction alopecia, the major therapeutic intervention is a switch to a looser hair style with less tension and avoidance of hair styles such as tight cornrows and heavy sewn-in extensions (see Table 69.6). Hair regrowth may be stimulated with topical or low-dose oral minoxidil; topical or intralesional corticosteroids as well as antibiotics (e.g. topical clindamycin, oral doxycycline) may have some efficacy. For late-stage disease with irreversible hair loss, hair restoration may be considered (see Ch. 157)[48].

Lipedematous Scalp and Lipedematous Alopecia

Lipedematous scalp is a disease of unknown etiology that is associated with local lymphatic dilatation and edematous thickening of the subcutis and dermis. Patients have a soft, "spongy" scalp and when pressed with a finger, a depression is seen. If associated with hair loss, then it is referred to as lipedematous alopecia. Hairs are usually sparse and short (~1–2 cm). By trichoscopy, multiple thin and vellus hairs as well as linear areas of erythema with fine arborizing vessels are seen.

The primary pathologic finding is an approximate doubling of scalp thickness as a result of expansion of the subcutaneous fat layer. If there is prominent alopecia, histopathologic changes include not only a thickened adipose layer, but also replacement of hair follicles with fibrous tracts without discernible inflammation. In case reports, partial hair regrowth has been described with topical clobetasol, intralesional triamcinolone, or mycophenolate mofetil[49,50].

Psoriatic Alopecia

The most common form of psoriatic alopecia is circumscribed and non-cicatricial. It occurs within psoriatic plaques and a specific finding is hair loss in tufts as thick psoriatic scales are shed from the scalp. Although clinically apparent psoriatic alopecia is rare, a decreased hair density is frequently observed histologically in scalp psoriasis along with an increased number of telogen hair follicles. The rapid development of severe psoriatic alopecia has been described as a paradoxical phenomenon in patients whose psoriasis has otherwise been successfully treated with TNF inhibitors (e.g. infliximab, adalimumab).

Only rarely will psoriasis of the scalp lead to a cicatricial alopecia. Trichoscopy of psoriatic cicatricial alopecia shows milky-red areas with no follicular openings (dots) in addition to vascular abnormalities typical for psoriasis, i.e. regularly distributed red dots or lace-like structures in a linear arrangement as well as bushy or glomerular structures.

Syphilitic Alopecia

Unless a chancre is located on the scalp, hair loss does not occur in primary syphilis. In secondary syphilis, the most typical presentation is a "moth-eaten" pattern of alopecia with multiple, small, ill-defined hairless patches primarily in the parieto-occipital region of the scalp. Hair loss may also occur in the eyebrows, beard, and other hair-bearing sites. Diffuse scalp alopecia, as in telogen effluvium, is less common. A third type of hair loss is seen within nodulo-ulcerative skin lesions of lues maligna; they heal with scarring, leading to secondary cicatricial alopecia. In tertiary syphilis, hair loss may occur within cutaneous gummas.

Non-Cicatricial Alopecia in Systemic Lupus Erythematosus

Non-cicatricial alopecia is a common presenting sign of systemic lupus erythematosus (SLE) and can accompany a flare of the disease. It is a criterion in both the SLICC (Systemic Lupus International Collaborating Clinics) and the EULAR/ACR criteria for SLE (see Tables 41.4 & 41.5). Three clinical forms have been described: (1) diffuse hair loss that resembles typical telogen effluvium; (2) focal hair loss that resembles alopecia areata; and (3) "lupus hairs"[51]. The latter represent short hair shafts that are brittle and fragile. They are occasionally observed in other autoimmune connective tissue diseases. The trichoscopic findings include thick, arborizing and tortuous, interfollicular blood vessels (see Fig. 69.7K), decreased hair density and shaft diameter, and hair shaft hypopigmentation; randomly distributed wavy hair shafts ("lupus hairs") are also seen[29].

Congenital Atrichia with Papular Lesions

Congenital atrichia with papular lesions is a rare autosomal recessive disorder in which there are multiple, widely distributed milia-like papules in addition to a complete absence of hair that is noted within a few months of birth. Patients have hair at birth but once it falls out it is not replaced. The alopecia is non-cicatricial but non-reversible and is due to mutations in the hairless gene (*HR*), which encodes a transcriptional corepressor of multiple nuclear receptors and Notched target genes. Histologically, there is replacement of the middle and lower portions of the hair follicle by keratinizing cysts.

CICATRICIAL (SCARRING) ALOPECIAS

Introduction

"Cicatricial" (or "scarring") alopecia implies that the follicular epithelium has been replaced by fibrotic tissue. The lack of hair follicles, in particular replacement of the follicular bulge region by collagen and other extracellular matrix proteins, results in irreversible hair loss. Cicatricial alopecia may be *primary* or *secondary*. In *primary* cicatricial alopecia, the follicle is destroyed by an inflammatory process which targets the follicular unit. In *secondary* cicatricial alopecia, the follicle is merely an "innocent bystander" in the disease process. Examples of secondary cicatricial alopecia include deep burns, radiation dermatitis, cutaneous malignancies, cutaneous sarcoidosis, morphea, necrobiosis lipoidica, and certain chronic infections such as cutaneous tuberculosis. The various forms of secondary cicatricial alopecia should have distinctive clinical and histologic features typical of the underlying disease.

Performing a scalp biopsy may be helpful not only in establishing a diagnosis but also in assessing the degree of inflammation and injury to the stem cell region. Specimens should be obtained at the hair-bearing margin (guided by trichoscopy), be at least 4 mm in diameter, and extend into the fat. If the central portion is sampled, only end-stage scarring with fibrosis will be seen. Ideally, two biopsies should be performed – one for vertical sectioning, the other for horizontal sectioning. The North American Hair Research Society proposed a classification for primary cicatricial alopecias and, despite some controversies, it remains the best available working classification[52].

Lichen Planopilaris

Several distinct entities are considered to be within the broader lichen planopilaris spectrum: (1) classic lichen planopilaris; (2) frontal fibrosing alopecia; and (3) Graham Little–Piccardi–Lasseur syndrome. Some authors also consider fibrosing alopecia in a pattern distribution (FAPD) a distinct entity within this spectrum.

Classic Lichen Planopilaris

Key features

- Chronic, progressive, inflammatory cicatricial alopecia
- Trichoscopy shows perifollicular scaling and areas with no hair follicle openings
- Histologically, there is a lymphocytic infiltrate involving the isthmus and infundibulum
- Treatment consists primarily of systemic immunosuppressive drugs

Pathophysiology

In lichen planopilaris, the infundibulo-isthmic (bulge) region of the hair follicle is targeted by an immune-mediated lymphocytic infiltrate. This folliculocentric inflammatory process leads to localized fibrosis and replacement of hair follicles by fibrous tracts. The factors which trigger this disease process remain unknown.

Clinical features and diagnosis

Lichen planopilaris occurs predominantly in White women with an onset of disease between 40 and 60 years of age. Lichen planopilaris in children is rare and is usually associated with a positive family history.

Hyperesthesia of the scalp may be a premonitory symptom. A burning sensation, pain, or pruritus is usually associated with active hair loss. During the early phase, one or more small (<1 cm) patches of cicatricial alopecia appear on the vertex or in the occipital region (Fig. 69.17A). In the hair-bearing margin, there is perifollicular erythema and hyperkeratosis (Fig. 69.17B). The patches of alopecia tend to increase in size and become confluent over time[53]. Occasionally "lonely hairs" may be present in the central portion of the lesions.

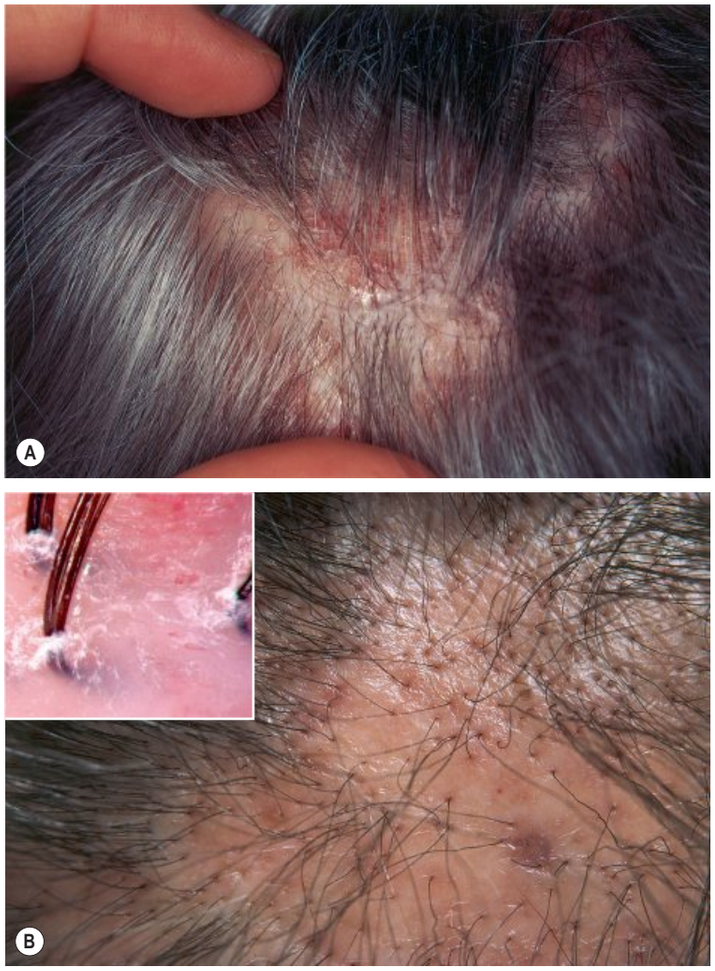

Fig. 69.17 Lichen planopilaris. A Patchy areas of alopecia with perifollicular erythema and scale at the active margins. **B** Later stage showing scarring with loss of follicular openings. By trichoscopy, there is perifollicular scaling and areas with no follicular openings (dots) due to loss of hair follicles (inset). *A, Courtesy Jean L. Bolognia, MD.*

Up to 15% of patients have coexisting mucosal lichen planus. Vulvovaginal–gingival–pilar lichen planus is a distinct entity that combines the vulvovaginal–gingival syndrome (see Ch. 11) with extensive and recalcitrant lichen planopilaris and circulating stratified epithelium-specific anti-nuclear antibodies (SES-ANA)[54].

Trichoscopy of lichen planopilaris shows perifollicular erythema and scaling, with the scales entangling hair shafts up to 2–3 mm above the scalp surface in a tubular fashion (Fig. 69.17B inset). Hair casts and elongated linear blood vessels may also be present. Late-stage disease is characterized by milky-red areas with no follicular openings[55]. The histopathologic features of lichen planopilaris are outlined in Table 69.3 and illustrated in Fig. 69.9H,I. Of note, perifollicular inflammation can be observed in areas with no clinically evident disease, raising the possibility that lichen planopilaris may be a generalized process that affects the entire scalp[56].

Treatment

The goal of treatment is to reduce pruritus and halt any further scarring. Recommended first-line treatments include hydroxychloroquine, doxycycline, and corticosteroids (intralesional or oral)[57]. Topically, potent corticosteroids and calcineurin inhibitors may be used as adjuvant therapy. Second-line therapeutic options include retinoids (acitretin and isotretinoin), mycophenolate mofetil, methotrexate, and cyclosporine[57] as well as JAK inhibitors, apremilast, and pioglitazone. Topical or low-dose oral minoxidil and 5α-reductase inhibitors may also be used as adjuvant therapy. While lichen planopilaris can burn out spontaneously, many patients have chronic progressive disease.

Frontal Fibrosing Alopecia

Key features

- Cicatricial alopecia with selective involvement of the hairline, most commonly frontotemporal
- Additional findings are a loss of eyebrows and facial papules
- Trichoscopy shows perifollicular scaling and "lonely hairs"
- Systemic immunosuppressants and 5α-reductase inhibitors may halt or slow progression of the disease

Pathogenesis

In frontal fibrosing alopecia (FFA), as in classic lichen planopilaris, the infundibulo-isthmic (bulge) region of the hair follicle is attacked by an immune-mediated inflammatory infiltrate; the latter has a predominance of $CD8^+$ T lymphocytes. The inciting factors that lead to this inflammation are unknown. Environmental exposures such as leave-on cosmetics, facial sunscreens, fragrances, haircare products, contact allergens, and diet have all been implicated as potential triggers in genetically predisposed patients, but to date there are no definitive associations.

Clinical features

Frontal fibrosing alopecia was first described by Kossard and colleagues in 1994[58]. It occurs primarily in perimenopausal women, but younger women and men may also be affected. A band-like recession of the frontotemporal hairline is typically seen, which usually progresses at a rate of ~0.3–1.5 mm per month[59]. The occipital and/or retro-auricular hairlines can also be involved[60].

Three clinical patterns of hair loss have been described: (1) linear – a clearly demarcated hairline is seen; (2) diffuse – there is a decrease in hair density in the frontal hairline; and (3) pseudo-fringe – a "fringe" of frontal hairs is isolated from the hairline by a hairless band (Fig. 69.18). In all three patterns, only full-thickness terminal hair shafts are visible within the involved hairline. Vellus hairs, which would be present in the "fringe" associated with traction alopecia, are not present because they are the first to disappear during the disease process. The skin is smooth, slightly atrophic, devoid of follicular openings, and lighter in color than the remaining skin of the forehead.

Additional clinical features of FFA include "lonely" hairs (Fig. 69.18A inset), lateral or complete eyebrow loss, partial loss of eyelashes,

Fig. 69.18 Frontal fibrosing alopecia. **A** Progressive hair loss along the anterior hairline with absence of solar lentigines (diffuse pattern). There are scattered "lonely" hairs (inset) and an eyebrow pencil has been used because of loss of eyebrow hairs. **B** Hypopigmented, atrophic band of cicatricial alopecia with a clearly demarcated, receded hairline (linear pattern) in addition to a "pseudo-fringe"; the latter is a fringe of hairs that marks the previous hair line. **C** Facial papules and loss of eyebrows; the patient also has rosacea. **D** By trichoscopy, discrete perifollicular scaling around remaining hairs and beige areas with no follicular openings (dots). *A, Courtesy Kalman Watsky, MD.*

prominent or depressed forehead veins, multiple facial papules (see Fig. 69.18C), and glabellar follicular red dots. The latter two findings are due to involvement of facial vellus hairs. In late-stage FFA, there may also be thinning of axillary, pubic, limb, and truncal hair[60]. Of note, classic lichen planus or lichen planus pigmentosus (especially in patients with darker skin phototypes) may accompany FFA. There are also rare reports of FFA coexisting with cutaneous lupus.

Treatment

Treatment options for FFA are similar to those described previously for lichen planopilaris. Of note, oral finasteride or dutasteride may be beneficial. Possible explanations for the efficacy of 5α-reductase inhibitors include an effect on coexisting androgenetic alopecia or inhibition of the conversion of terminal to vellus hair follicles, which would then lead to a reduction in the proportion of vellus hair follicles, the primary target in FFA.

Graham Little–Piccardi–Lasseur Syndrome

The Graham Little–Piccardi–Lasseur syndrome (Graham Little syndrome) was first described by Piccardi in 1913. The description by Ernst Graham Little (in a mutual patient with Lasseur) appeared in 1915 and was the inspiration for the eponym "Graham Little syndrome". The syndrome consists of a triad of lichen planopilaris of the scalp, non-cicatricial alopecia of the axilla and groin, and follicular lichen planus of the body (see Ch. 11).

Fibrosing Alopecia in a Pattern Distribution

Fibrosing alopecia in a pattern distribution (FAPD) is a more recently recognized type of cicatricial alopecia that has characteristics of both lichen planopilaris and AGA[61]. It is considered by many to be a subtype of lichen planopilaris. Although the etiology is not well understood, FAPD is thought to be due to an exaggerated inflammatory response to damaged hair follicles, perhaps triggered by AGA. It occurs primarily in androgen-dependent areas of the scalp in which there has been hair follicle miniaturization. Clinically and by trichoscopy, there is both perifollicular inflammation (e.g. erythema, scaling) and fibrosis with loss of follicular ostia. Sometimes FAPD is misdiagnosed as AGA plus seborrheic dermatitis, but histologic examination of early-stage sites of scalp inflammation can help confirm the diagnosis. Although there are no well-documented treatments, a combination of an anti-inflammatory drug (see Lichen Planopilaris, Treatment), antiandrogen medication (see AGA, Treatment), and hair growth-promoting agent (e.g. minoxidil) has been recommended.

Classic Pseudopelade (Pseudopelade of Brocq)

Classic pseudopelade is a non-inflammatory or minimally inflammatory form of cicatricial alopecia that most commonly affects middle-aged and older women. It most likely represents a distinct clinical entity that falls within the spectrum of lichen planopilaris. The hair loss usually begins on the vertex and is characterized by multiple, small (<2 cm), smooth, slightly depressed, asymptomatic hairless patches described as appearing like "footprints in the snow" (Fig. 69.19). Over time, these lesions can become confluent and form larger areas of alopecia. While pseudopelade is classified as a cicatricial alopecia (Table 69.5), there is debate as to whether the hair follicles undergo atrophy rather than being replaced by fibrotic tissue.

Pseudopelade is usually slowly progressive but in some patients may be self-limiting[62]. Treatment options are similar to those described previously for lichen planopilaris, with the caveat that immunosuppressive drugs are less likely to be effective in the absence of significant inflammatory infiltrates.

Central Centrifugal Cicatricial Alopecia

Key features

- Slowly progressive, symmetric cicatricial alopecia centered on the mid scalp or vertex
- Most often develops in Black women; in some patients has been associated with mutations in *PADI3*
- Treatment includes topical or intralesional corticosteroids, oral tetracyclines, and adjuvant immunosuppressive drugs

Fig. 69.19 Classic pseudopelade (pseudopelade of Brocq). Irregularly shaped areas of scarring alopecia along the midline. Despite no visible features of inflammation, the disease is usually progressive. Trichoscopy shows milky-red areas of cicatricial alopecia, sparse terminal hairs, and no features of inflammation (inset). *Courtesy Kalman Watsky, MD.*

THE NORTH AMERICAN HAIR RESEARCH SOCIETY PROPOSED WORKING CLASSIFICATION OF PRIMARY CICATRICIAL ALOPECIA WITH MINOR MODIFICATIONS
Lymphocytic
Lichen planopilaris (see Ch. 11) • Lichen planopilaris • Frontal fibrosing alopecia • Graham Little syndrome • Fibrosing alopecia in a pattern distribution (FAPD) Classic pseudopelade (pseudopelade of Brocq) Central centrifugal cicatricial alopecia Chronic cutaneous lupus erythematosus (discoid lupus erythematosus) (see Ch. 41) Alopecia mucinosa* (see Ch. 46) Keratosis follicularis spinulosa decalvans (see Ch. 38)
Neutrophilic
Folliculitis decalvans Dissecting cellulitis (perifolliculitis capitis abscedens et suffodiens)
Mixed
Acne keloidalis (see Ch. 38) Folliculitis (acne) necrotica Erosive pustular dermatosis (see Chs. 25 & 87)
Nonspecific (end-stage)
*Primary form not considered a classic form of cicatricial alopecia by some experts.

Table 69.5 The North American Hair Research Society proposed working classification of primary cicatricial alopecia with minor modifications[52].

Pathophysiology

Recent insights into the underlying pathophysiology of central centrifugal cicatricial alopecia (CCCA) include the discovery of mutations in *PADI3* in some patients. The latter encodes peptidyl arginine deiminase type III, which modulates hair structural proteins including filaggrin and trichohyalin via deimination. Perifollicular lymphocytic infiltrates also play a significant pathogenic role in that they induce premature desquamation of the inner root sheath which facilitates hair loss. In addition, hair styling practices that cause traction have been implicated as potential triggers as have infectious etiologies and autoimmunity, but they remain unproven.

Clinical features

The disease begins and remains most severe on the vertex and/or mid-scalp, expanding outward in a centrifugal manner (Fig. 69.20). Most patients note mild, episodic pruritus or tenderness in the involved areas. A few isolated hairs or tufts of hair may be stranded in the otherwise denuded central zone. Perifollicular pustules may also be present[63]. By trichoscopy, there is loss of follicular openings, mild perifollicular scaling, small hair tufts, and in darkly pigmented skin, fibrotic white dots.

Differential diagnosis

All conditions that can result in a progressive pattern of alopecia affecting the crown can mimic CCCA. These include AGA, lichen planopilaris, folliculitis decalvans, and even unusual cases of discoid lupus erythematosus. Other entities in the differential diagnosis are tinea capitis (kerion) and true bacterial infections of the scalp.

Treatment

Most authors suggest that the management should begin with reduction in chemical straightening and traction-producing hair styles as well as instituting healthy hair practices (Table 69.6). Corticosteroids (potent topical or intralesional triamcinolone) are usually employed as first-line treatment. Once stabilization is achieved, maintenance therapy can consist of less frequent application of a potent topical corticosteroid. Oral doxycycline or minocycline are frequently prescribed while other possible therapeutic options include low-dose oral minoxidil as well as hydroxychloroquine, thalidomide, cyclosporine, or mycophenolate mofetil. These systemic medications can be supplemented by topical minoxidil and calcineurin inhibitors. There are anecdotal reports of the use of oral JAK inhibitors.

Discoid Lupus Erythematosus

Synonym: ■ Chronic cutaneous lupus erythematosus, discoid form

Key features

- Early lesions are characterized by erythema, scaling, and dilated, plugged follicular ostia
- Inflammatory lesions are gradually replaced by cicatricial alopecia
- The diagnosis is based on clinical evaluation, trichoscopy, histopathology, and, if needed, direct immunofluorescence (DIF) of lesional skin
- Antimalarial drugs and intralesional corticosteroids represent first-line therapies

Introduction

Discoid lupus erythematosus (DLE) can be an isolated disease or it can occur in the setting of systemic lupus erythematosus (SLE). Among patients with skin disease only, the majority will have lesions limited to the head and neck region and most do not develop systemic disease (see Ch. 41). There is, however, an increased risk of SLE in those individuals who have lesions beyond the head and neck, i.e. disseminated DLE.

Clinical features

DLE is one of the four entities classified as chronic cutaneous LE (see Fig. 41.4), and the vast majority of patients are women. Early lesions are characterized by erythema, scaling, and dilated, plugged follicular ostia. Central hypopigmentation and peripheral hyperpigmentation are commonly seen in individuals with darker skin phototypes. The inflammatory lesions are gradually replaced by cicatricial alopecia, which develops in the central portion of the lesion and progresses outwards (Fig. 69.21)[1].

Diagnosis

By trichoscopy, there are large yellow dots, thick arborizing vessels, and fine scaling (Fig. 69.21 inset). Scattered dark-brown to bluish discoloration is seen in patients with darker skin phototypes. In late-stage disease, features are similar to those observed in other cicatricial alopecias, e.g. milky-red or white areas with no follicular openings (dots) (see Fig. 69.19 inset)[55].

The clinical diagnosis of DLE should be confirmed by histologic examination (see Table 69.3). If distinction from lichen planopilaris or other disorders in the differential diagnosis is not possible, DIF of the active peripheral edge of a lesion can be performed. It is recommended that application of topical corticosteroids be suspended for at least several days to proposed biopsy sites[64].

HEALTHY HAIR PRACTICES AND TOPICAL THERAPIES FOR AFRO-TEXTURED HAIR

• Wash hair once a week or every other week
• Consider using a moisturizing, leave-in conditioner (e.g. with dimethicone, glycerin) after hair washing
• Use oil treatments (e.g. coconut oil, jojoba oil, avocado oil) or moisturizers (e.g. shea butter) on a regular basis
• Use caution with relaxers as these chemical straighteners remove fatty acids bound to the cuticle – limit use to every 2–3 months
• Use caution with thermal styling (e.g. ceramic combs, flat irons) – limit use to ~weekly*
• To limit traction alopecia, avoid tension from tight braids, cornrows, weaves, or extensions
  • crochet braids may have less tension
  • consider braids that have a higher hair base to width of braid ratio
  • weaves that are sewn into multiple corn rolls (parallel not perpendicular to frontal hairline) or a net overlying corn rolls may have less tension
  • change hairstyle every 2–3 months
• Topical therapies
  • oil-based topical corticosteroid (e.g. fluocinolone acetonide)
  • minoxidil solution (not foam) followed by moisturizer
  • zinc pyrithione or ciclopirox shampoo

*Blow dryer less damaging than flat iron.

Table 69.6 Healthy hair practices and topical therapies for Afro-textured hair.

Treatment

Photoprotection and avoidance of sun exposure are important preventive measures. Active, inflammatory discoid lesions usually respond to oral antimalarial drugs (e.g. hydroxychloroquine) and corticosteroids (topical, intralesional). Second-line therapies for antimalarial-resistant cutaneous disease, such as systemic retinoids, methotrexate, dapsone, mycophenolate mofetil, thalidomide, lenalidomide, and IVIg, are outlined in Table 41.11. Monoclonal antibodies, e.g. anifrolumab, litifilimab, daxdilimab, that inhibit production or actions of type I interferons and are usually prescribed for SLE can also improve associated mucocutaneous disease. There are scattered reports of JAK inhibitors and ustekinumab being effective in severe cases of recalcitrant DLE[65].

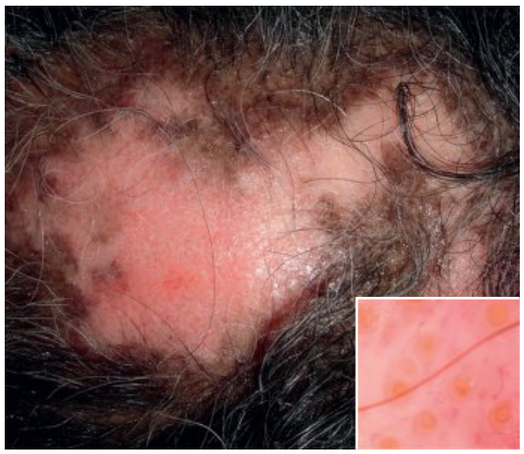

Fig. 69.21 Discoid lupus erythematosus. Coalescing areas of cicatricial alopecia in which there is obvious erythema. Central hypopigmentation is accompanied by peripheral hyperpigmentation. Trichoscopy shows follicular plugs (large yellow dots) and arborizing vessels (inset). *Courtesy Leonard C. Sperling, MD and Rodney D. Sinclair, MD.*

Follicular mucinosis

Synonym: ■ Alopecia mucinosa (clinical term)

Alopecia mucinosa is characterized histologically by the accumulation of mucin within the pilosebaceous unit. Patches, plaques, and papules commonly develop in the head and neck region. When the scalp is involved, well-defined areas of hair loss, usually 2–6 cm in diameter, can be seen; they are often accompanied by inflammation. Grouped erythematous follicular papules can also be observed within the hairless patches (see Fig. 46.15).

With the exception of urticaria-like follicular mucinosis in which there is no associated alopecia, patients with alopecia mucinosa are subdivided into primary and secondary forms (see Ch. 46). Primary disease favors children and adolescents and often resolves within 1–2 years, including hair regrowth. In adults, a greater number of lesions that are more persistent may be seen. However, excluding a secondary cause, in particular mycosis fungoides, is important in this latter group. In addition to primary alopecia mucinosa and an association with cutaneous lymphomas, deposition of mucin within hair follicles (follicular mucinosis) can be observed as an incidental finding in a number of disorders including eczematous dermatoses, SLE, and medications (e.g. imatinib). Trichoscopy shows multiple enlarged follicular openings filled with keratotic material.

In secondary follicular mucinosis, treatment focuses on the underlying disease, including phototherapy. Topical, intralesional, or oral corticosteroids may be used for primary disease, realizing that, especially in children and adolescents, the disease may resolve spontaneously[66]. Other treatment options include hydroxychloroquine, minocycline, dapsone, indomethacin, and isotretinoin.

Keratosis Follicularis Spinulosa Decalvans

Key features

- Rare X-linked recessive disorder within the spectrum of keratosis pilaris atrophicans
- Keratosis pilaris-like papules favor the scalp and face
- Follicular atrophy and scarring alopecia can follow resolution of papules

Keratosis follicularis spinulosa decalvans is a rare genodermatosis with an X-linked recessive (XLR) pattern of inheritance when due to mutations in *MBTPS2* (see Table 38.2). It is allelic with the XLR form of ichthyosis follicularis with atrichia and photophobia (IFAP) syndrome. The disease usually becomes apparent during infancy or early childhood and remains active through adolescence. Keratosis pilaris-like papules favor the face and scalp, but are sometimes more widespread. Additional findings include facial erythema, palmoplantar keratoderma, and keratitis (see Table 38.2). Hypotrichosis is often noted early on and progression of lesions leads to cicatricial alopecia of the scalp, eyebrows, and eyelashes.

Histologically, there is follicular hyperkeratosis and follicular destruction with a mixed lymphohistiocytic infiltrate as well as perifollicular and interfollicular fibrosis. In the one case described to date, trichoscopic findings (e.g. perifollicular scaling) were similar to those seen in lichen planopilaris. Oral medications, including isotretinoin, dapsone, and antibiotics, have been tried with varied results[67].

Folliculitis Decalvans

Key features

- Neutrophilic cicatricial alopecia
- It may possibly represent an altered immune response to the follicular microbiome
- When active, follicular pustules and hair tufts are the most characteristic findings
- The most common treatment is long-term oral antibiotics

Pathophysiology

Folliculitis decalvans is a neutrophilic primary cicatricial alopecia[68]. The presence of *Staphylococcus aureus* has been observed in 20%–75% of patients[44]. It has been suggested that folliculitis decalvans may result from an abnormal immune response to the follicular microbiome, with the inflammation leading to permanent follicular damage.

Clinical features

This disease typically affects young and middle-aged adults, predominantly men. The vertex and occipital area of the scalp are most often involved. During its early phase, there are recurrent follicular pustules; perifollicular erythema, scaling, erosions, and hemorrhagic crusts may also be seen. A hallmark of folliculitis decalvans is the presence of hair tufts (5–20 or more hairs in one follicular unit; Fig. 69.22), sometimes referred to as "tufted folliculitis". Although this is a characteristic finding in folliculitis decalvans, hair tufts also develop following repeated follicular injury in other inflammatory cicatricial alopecias (e.g. acne keloidalis, dissecting cellulitis). With progression, hairless patches develop that can coalesce to form large areas of cicatricial alopecia. In addition to hair tufts, active inflammation (e.g. erythema, follicular pustules, scaling, crusting) may be present at the margins of the alopecic lesions[69].

By trichoscopy, tufted hairs surrounded by perifollicular hyperplasia in a starburst pattern are seen. Previously described changes associated with inflammation may also be observed. The typical histopathologic features are outlined in Table 69.3. Occasionally, patients will have clinical features of both folliculitis decalvans and lichen planopilaris, either simultaneously or sequentially[70]. Of note, EGFR inhibitor-induced scarring alopecia can resemble folliculitis decalvans.

Treatment

In a recent analysis, a 10-week course of clindamycin plus rifampin led to the longest period of disease remission while doxycycline or azithromycin were associated with shorter remission times. Such courses of antibiotics may be repeated, if needed. Some authors prefer continuous treatment with antibiotics, either as monotherapy or in combination with immunosuppressive drugs. Isotretinoin may sometimes be effective, but its use in folliculitis decalvans remains controversial. There is a low level of evidence for other treatment options, including TNF inhibitors (e.g. adalimumab, infliximab), secukinumab, cyclosporine, apremilast, trimethoprim–sulfamethoxazole, JAK inhibitors, and photodynamic therapy. Topical corticosteroids and calcineurin inhibitors may be used as supplemental therapy.

Fig. 69.22 Folliculitis decalvans. Note the multiple hairs arising from a single inflamed follicular orifice ("tufted folliculitis") within the area of scarring alopecia. Trichoscopy shows hair tufts composed of multiple hairs and tubular perifollicular scaling (inset). *Courtesy Damon McClain, MD.*

Acne Keloidalis

Synonyms: ■ Acne keloidalis nuchae ■ Folliculitis keloidalis

Key features

- Persistent folliculitis on the nape of the neck with formation of keloid-like scars and cicatricial alopecia
- Most common in Black men, but can occur in women and White individuals
- Treatment options include intralesional triamcinolone, oral antibiotics (e.g. doxycycline), low-dose isotretinoin, and surgical excision

Pathophysiology

The etiology of acne keloidalis is still under investigation. It may be triggered by chronic follicular occlusion or trauma due to friction (e.g. rubbing from shirt collars or helmets), heat, humidity, or hair cutting practices. Other possible contributory factors include autoimmunity, infection, androgens, and medications (e.g. cyclosporine). Hypothetically, acute perifollicular inflammation leads to weakening of the follicular wall. Naked hair shafts then act as foreign bodies, with development of granulomatous inflammation and ultimately fibrosis[71].

Clinical features

Acne keloidalis typically affects young Black men and less often young Black women. It is significantly less common in White individuals. Papules, admixed with occasional pustules, appear in a band-like distribution on the posterior neck and lower occipital scalp (see Fig. 38.12). The initial papules are small (2–4 mm), smooth, and firm. Over time, they can coalesce to form larger, keloid-like, hairless plaques (see Fig. 38.13). Descriptions of trichoscopic features are limited, but include white halos around normal and dilated hair follicle openings, follicular ostia filled with keratin, and tufted hairs. The histopathologic findings are outlined in Table 69.3[106] and illustrated in Figure 38.14.

Treatment

Treatment options are discussed in detail in Chapter 38.

Dissecting Cellulitis

Synonym: ■ Perifolliculitis capitis abscedens et suffodiens

Key features

- Neutrophilic cicatricial alopecia
- May coexist with hidradenitis suppurativa, acne conglobata, and pilonidal sinus/cyst ("follicular occlusion tetrad")
- Scalp nodules appear first then develop into interconnecting, boggy, fluctuant, oval and linear ridges
- Isotretinoin and oral antibiotics are first-line therapies

Clinical features and diagnosis

Dissecting cellulitis is part of the "follicular occlusion triad" that includes hidradenitis suppurativa and acne conglobata (see Ch. 38) or "tetrad" that also includes pilonidal sinus/cyst. However, isolated scalp disease is often seen. Dissecting cellulitis most commonly affects young men, especially Black men. It occurs less commonly in White individuals and women.

Lesions begin as multiple, firm scalp nodules, most commonly on the mid and posterior vertex and the upper occiput (Fig. 69.23A). The hairless nodules rapidly develop into interconnecting, boggy, fluctuant, oval and linear ridges that eventually discharge purulent material (Fig. 69.23B). Over time the nodules become fibrotic, resulting in cicatricial alopecia. By trichoscopy, yellow structureless areas, 3D-shaped black dots, yellow dots, and dystrophic hair shafts are seen[55]. The histopathologic findings are listed in Table 69.3.

Treatment

Isotretinoin (0.5–1.5 mg/kg daily until 4 months after achieving a clinical remission) may be the most effective therapy, but this disease can prove difficult to treat. Additional therapeutic options include: antimicrobials (e.g. clindamycin, rifampin, ciprofloxacin, trimethoprim–sulfamethoxazole, metronidazole); TNF inhibitors (e.g. adalimumab, infliximab); other systemic retinoids (acitretin, alitretinoin); dapsone and colchicine. Corticosteroids (oral or intralesional) may be used to halt the inflammatory process. Some patients have been treated with laser therapy (e.g. 1064 nm Nd:YAG), photodynamic therapy, and external beam radiation therapy. Surgical therapy may be helpful in managing disfiguring, scarring, and recalcitrant disease.

Fig. 69.23 Dissecting cellulitis. A Earlier stage with multiple interconnected, inflammatory, alopecic nodules admixed with pustules and crusts. By trichoscopy, there are 3D ("bubble") black dots (inset). **B** Tender nodules with alopecia, draining sinuses, broad scarring, and linear scars. *B, Courtesy Jeffrey P. Callen, MD.*

Acne Necrotica

Synonyms: ■ Necrotizing lymphocytic folliculitis ■ Acne necrotica varioliformis

The etiology of this disease is unknown, but an altered immune reaction to microorganisms within the skin has been suggested. It primarily affects adults, with the face and scalp the most common sites of involvement followed by the neck and upper trunk. Acne necrotica can have a chronic or recurrent course lasting decades.

Lesions begin as umbilicated follicular vesicles or papulovesicles that then become pustular. Over time, hemorrhagic crusts develop and eventually varioliform scars. During a flare, the affected areas may be quite inflamed with significant erythema and numerous follicular lesions[72]. Based upon case reports and expert recommendations, long-term treatment with antibiotics (e.g. doxycycline) or isotretinoin is recommended combined with oral corticosteroids when needed.

Erosive Pustular Dermatosis of the Scalp

Erosive pustular dermatosis of the scalp is an inflammatory disease, and in some patients, it can lead to cicatricial alopecia. The disease occurs primarily on the central scalp in older adults within sites of significant photodamage (see Ch. 25). Less often lesions develop on the lower extremities in those with venous insufficiency or at sites of injury, including in neonates (see Table 34.1).

Clinically, there are erosions and they can be covered with thick keratotic crusts (see Fig. 87.24I). When the crusts are removed, purulent discharge may be present. On the scalp, the background skin is often atrophic and fragile with evidence of AGA, which represents a risk factor for the associated photodamage. Thus, unlike with other types of cicatricial alopecia, the inflammatory lesions are not limited to hair-bearing margins, but may involve the entire area of alopecia[73].

Trichoscopy shows follicular pustules, serous exudates, black crusts, follicular hyperkeratosis, and areas with an absence of follicular openings. In areas of skin atrophy, hair bulbs may be visible. Histologic findings during the early stage include laminated orthokeratosis and psoriasiform hyperplasia of the epidermis with mixed inflammatory infiltrates in the dermis. Late-stage disease is characterized by extensive fibrosis with atrophy, absence of sebaceous glands, and moderate mixed inflammatory infiltrates.

Multiple treatment options are outlined in Chapter 25.

Nonspecific (End-Stage) Cicatricial Alopecia

In patients with progressive cicatricial alopecia, "burnt-out" or "end-stage" disease presents with scalp fibrosis, which may be limited to

one or a few hairless patches or may involve the entire scalp. Clinically, no inflammation is apparent at this stage, and it is not possible to identify the preceding disease which led to the fibrosis. This clinical presentation should not be confused with the histopathologic pattern of "end-stage" disease; the latter can be seen when an older, inactive area is sampled even when there is active disease elsewhere on the scalp.

HAIR SHAFT ABNORMALITIES

Hair shaft abnormalities, both acquired and inherited (Table 69.7), are divided into two broad categories – those associated with increased hair fragility and those *not* associated with increased hair fragility (Fig. 69.24). The former group can lead to various degrees of alopecia while alteration of the clinical appearance of the hair (usually in the absence of alopecia) characterizes the latter group. The analysis of hair shaft abnormalities is best performed via trichoscopy (high magnification, if available) or light microscopy of cut hair shafts. Reflectance confocal microscopy and transmission or scanning electron microscopy are additional diagnostic modalities. When trichothiodystrophy is suspected, amino acid analysis can be performed to confirm low sulfur levels. Other than preventive hair care measures (e.g. conditioning, low tension hair styling), there are currently no specific treatments for inherited hair shaft abnormalities. Topical or low-dose oral minoxidil may stimulate hair regrowth but has no documented effect on hair shaft structure.

Hair Shaft Abnormalities Associated With Increased Hair Fragility

"Bubble hair"

This distinctive hair shaft abnormality is usually seen in young women with a localized area of uneven, fragile hairs. By trichoscopy or light microcopy, the hair shafts contain large irregularly spaced "bubbles" that expand and lead to thinning of the hair cortex (see Fig. 69.24F). Hair fractures occur at the site of larger bubbles.

Bubble hairs can develop when wet hair is exposed to hair care techniques that involve heat, including high-temperature hair dryers, hair straighteners or flat irons, and electric curlers. When wet, a hair shaft can expand up to 30% in diameter with retention of water within the shaft; exposure to heat can then lead to formation of expanding and destructive bubbles. Once the damaged hair is trimmed, the condition resolves completely with gentle hair styling[74].

Monilethrix

Synonym: ■ Beaded hair

In monilethrix, hair shafts have regular, periodic elliptical nodosities that alternate with shaft thinning and a tendency to fracture at the latter sites (see Fig. 69.24C). This disorder is usually inherited in an autosomal dominant fashion with variable expression and is due to heterozygous mutations in one of three hair cortex-specific keratin genes – *KRT86*, *KRT81*, or *KRT83*. There is also an autosomal recessive form due to mutations in *DSG4*, which encodes desmoglein 4.

Affected individuals usually have normal-appearing hair at birth, but within the first few months of life these fibers are replaced by short, fragile, brittle hair (Fig. 69.25). Patients may state "I have hair that never grows". The phenotype is variable, ranging from clinically normal hair to mild occipitotemporal hair loss to nearly total alopecia. Additional manifestations include keratotic follicular papules, primarily on the occiput, as well as syndactyly and nail (e.g. brittle, koilonychia), ocular (e.g. juvenile cataracts, decreased visual fields), and dental abnormalities[75].

By trichoscopy and light microscopy, there is variation in hair shaft thickness with uniformly spaced elliptical nodosities and intervening constrictions. Hairs are bent with a tendency to fracture at constriction sites[76]. Monilethrix-like hair shafts may be observed in other hair disorders, such as alopecia areata or chemotherapy-induced alopecia, but their clinical courses differ[29]. In pseudomonilethrix, there is irregular, square-shaped, flattening of hair shafts. Whether pseudomonilethrix is a true disease or an optical artifact is a matter of debate[29].

Pili torti

Pili torti is characterized by a flattening and 180° twisting of the hair shaft on its own axis (see Fig. 69.24G). The twists are typically narrow and occur in groups of three to ten twists, giving the hair shaft a spangled appearance. When *inherited*, pili torti can be an isolated abnormality or it may be a feature of other disorders, including Menkes disease (see Ch. 51), Björnstad syndrome, Bazex–Dupré–Christol syndrome, and several ectodermal dysplasias[29]. Hairs may be sparse or abnormal from birth or early childhood (early-onset, Ronchese type) or they may become brittle and fragile around puberty (late-onset, Beare type).

Acquired pili torti may be drug-induced (e.g. epidermal growth factor receptor inhibitors, retinoids), associated with perifollicular inflammation or fibrosis (e.g. cutaneous T cell lymphoma, cicatricial alopecia), or due to malnutrition[77]. The inherited form of pili torti can improve at puberty while resolution of the acquired form is dependent upon its etiology.

Trichorrhexis invaginata

Trichorrhexis invaginata ("bamboo hair") is a clinical feature of Netherton syndrome (see Ch. 57). This inherited disorder is due to pathogenic variants in *SPINK5*, which encodes a serine protease inhibitor, LEKTI. The hair abnormality usually becomes evident during infancy with the development of short, sparse, and very fragile hair. In scalp or eyebrow hairs, the breakage points consist of intussusceptions of the distal shaft ("ball") into the proximal shaft ("socket") due to defective cornification of the cortex (see Fig. 69.24B). Fracture of the shaft may leave the proximal shaft with a golf tee-shaped end.

Trichorrhexis nodosa

Trichorrhexis nodosa is the most common of all the structural hair abnormalities. It is characterized by hair shaft fractures in which the individual cortical cells and their fragments splay out, appearing like the ends of two brushes pushed into one another (see Fig. 69.24A). This abnormality is presumably caused by damage to the cuticular cells of the shaft and subsequently to the intercellular cement substance that normally binds cells together. Trichorrhexis nodosa may be congenital or acquired, with the congenital form occurring as an isolated finding (primary genetic) or in association with other inherited disorders, e.g. argininosuccinic aciduria, citrullinemia, trichohepatoenteric syndrome[78].

The acquired variant is most commonly caused by repeated trauma to the hair shaft. This can result from chemical relaxation, excessive heat (e.g. hair dryers, hair straighteners [flat irons, hot combs]), frequent brushing, or chronic scratching. Three clinical variants of acquired trichorrhexis nodosa have been described: (1) proximal – usually due to damage from chemicals and heat; (2) distal – due to cumulative cuticular damage; and (3) circumscribed – occurs in the scalp, moustache, or beard. Chronic use of masks may explain some cases of beard involvement. Trichorrhexis nodosa can also be seen in patients with other hair shaft abnormalities associated with increased hair fragility.

Trichothiodystrophy

Trichothiodystrophy is primarily an autosomal recessive disorder characterized by sulfur-deficient hair. By light microscopy and trichoscopy, hair shafts have transverse fractures (trichoschisis; see Fig. 69.24D) and alterations in their cuticles. Polarized light is required to visualize the alternating light and dark bands, i.e. the pathognomonic "tiger tail sign" (see Fig. 69.24E). Currently, based upon underlying genetic bases, there are nine types of trichothiodystrophy (TTD; www.omim.org). TTD1–3 have associated photosensitivity and are reviewed in Table 87.4 whereas TTD4–9 do not have photosensitivity, including X-linked recessive TTD5. The acronym PIBIDS has been used to describe possible findings in patients with TTD1–3: P (photosensitivity), I (ichthyosis), B (brittle hair), I (intellectual impairment with low IQ), D (decreased fertility), and S (short stature). Some patients may exhibit spasticity, tremors and ataxia, nail dystrophy, dental caries, cataracts, and bony and immune defects. The hair usually does not improve with age.

Hair Abnormalities Not Associated With Increased Hair Fragility

Acquired progressive kinking of the hair

The term encompasses acquired conditions characterized by curling of the scalp hair. It classically presents with curly, frizzy, and lusterless

INHERITED DISORDERS WITH HYPOTRICHOSIS AND/OR HAIR SHAFT ABNORMALITIES		
Disorder	**Mode of inheritance**	**Gene or gene product**
Alopecia, neurologic defects, and endocrinopathy syndrome	AR	RNA binding motif protein 23 (RBM23)
Argininosuccinic aciduria	AR	Argininosuccinate lyase
Atrichia with papular lesions	AR	Hairless (zinc finger transcription factor)
Bachmann-Bupp syndrome	AD	Ornithine decarboxylase
Björnstad syndrome	AR	BCS1-like (mitochondrial membrane protein)
Cartilage–hair hypoplasia (Ch. 60)	AR	RNA component of mitochondrial RNA-processing endoribonuclease
Giant axonal neuropathy 1 with curly hair	AR	Gigaxonin
Hypohidrotic ectodermal dysplasia (Ch. 63)	XLR	Ectodysplasin A
	AD	Ectodysplasin anhidrotic receptor gene or the EDAR-associated death domain gene
Hypotrichosis-lymphedema-telangiectasia	AR	SYR-box transcription factor 18
Hypotrichosis, Mari type	AR	Lipase H
Hypotrichosis, Marie Unna type,1	AD	5′ upstream open reading frame of *HR* (hairless) gene
Hypotrichosis simplex	AD	Adenomatosis polyposis down-regulated 1 gene
	AD	Small nucleotide RNP polypeptide E
	AD	Ribosomal protein L21
Hypotrichosis simplex of the scalp	AD	Corneodesmosin
Hypotrichosis with juvenile macular dystrophy	AR	Cadherin 3 (P cadherin)
Hypotrichosis with recurrent skin “vesicles”	AR	Desmocollin 3
Keratosis follicularis spinulosa decalvans (Ch. 38)	XLR	Membrane-bound transcription factor peptidase, site *2*
Ichthyosis, hystrix-like with deafness (Ch. 57)	AD	Connexin 26
Laron syndrome (pituitary dwarfism II)	AR	Growth hormone receptor
Localized autosomal recessive hypotrichosis	AR	Desmoglein 4
	AR	C3orf52 (cofactor for lipase H)
Menkes disease (Ch. 51)	XLR	Cu^{2+}-transporting P-type ATPase 7A
Monilethrix	AD	Keratin 81, Type II
	AD	Keratin 83, Type II
	AD	Keratin 86, Type II
	AR	Desmoglein 4
Netherton syndrome (Ch. 57)	AR	Serine protease inhibitor LEKTI
Pure hair nail ectodermal dysplasia (Ch. 63)	AD	Keratin 85
		Keratin 74
	AR	Homeobox C13
T cell immunodeficiency and congenital alopecia (Ch. 60)	AR	Forkhead box N1 (winged helix nude)
Trichothiodystrophy (TTD) (Chs. 57 & 87; TTD4-9 are non-photosensitive)	AR	XPB/TTD2; TFIIH subunit, DNA helicase (functions in nucleotide excision repair and as a basal transcription factor)
	AR	XPD/TTD1; TFIIH subunit, DNA helicase (functions in nucleotide excision repair and as a basal transcription factor)
	AR	General TFIIH, subunit 5 (TTD3; functions in nucleotide excision repair and as a basal transcription factor)
	AR XLR (TTD5)	TTD4: M-phase specific PLK1 interacting protein; TTD5: ring finger protein 113A; TTD6: general transcription factor IIE subunit 2; TTD7: threonyl-TRNA synthetase 1; TTD8: alanyl-TRNA synthetase 1; TTD9: methionyl-TRNA synthetase 1
Vitamin D-dependent rickets with alopecia	AR	Vitamin D receptor
Woolly hair	AR	Keratin 25
	AD	Keratin 74
Woolly hair with hypotrichosis	AD	Keratin 71
Woolly hair +/– hypotrichosis	AR	Lysophosphatidic acid receptor 6
	AR	Lipase H
Woolly hair in Naxos disease (Ch. 58)	AR	Plakoglobin
		Desmocollin 2
Woolly hair in Carvajal syndrome (Ch. 58)	AR > AD	Desmoplakin
Skin fragility/woolly hair syndrome (Ch. 32)	AR	Desmoplakin

Table 69.7 Inherited disorders with alopecia and/or hair shaft abnormalities. Hair and/or nail abnormalities can also be observed in patients with disorders of keratinization, epidermolysis bullosa, and ectodermal dysplasias (see Table 32.1). AD, autosomal dominant; AR, autosomal recessive; RNP, ribonucleoprotein; TFIIH, transcription factor IIH; XP, xeroderma pigmentosum; XLR, X-linked recessive.

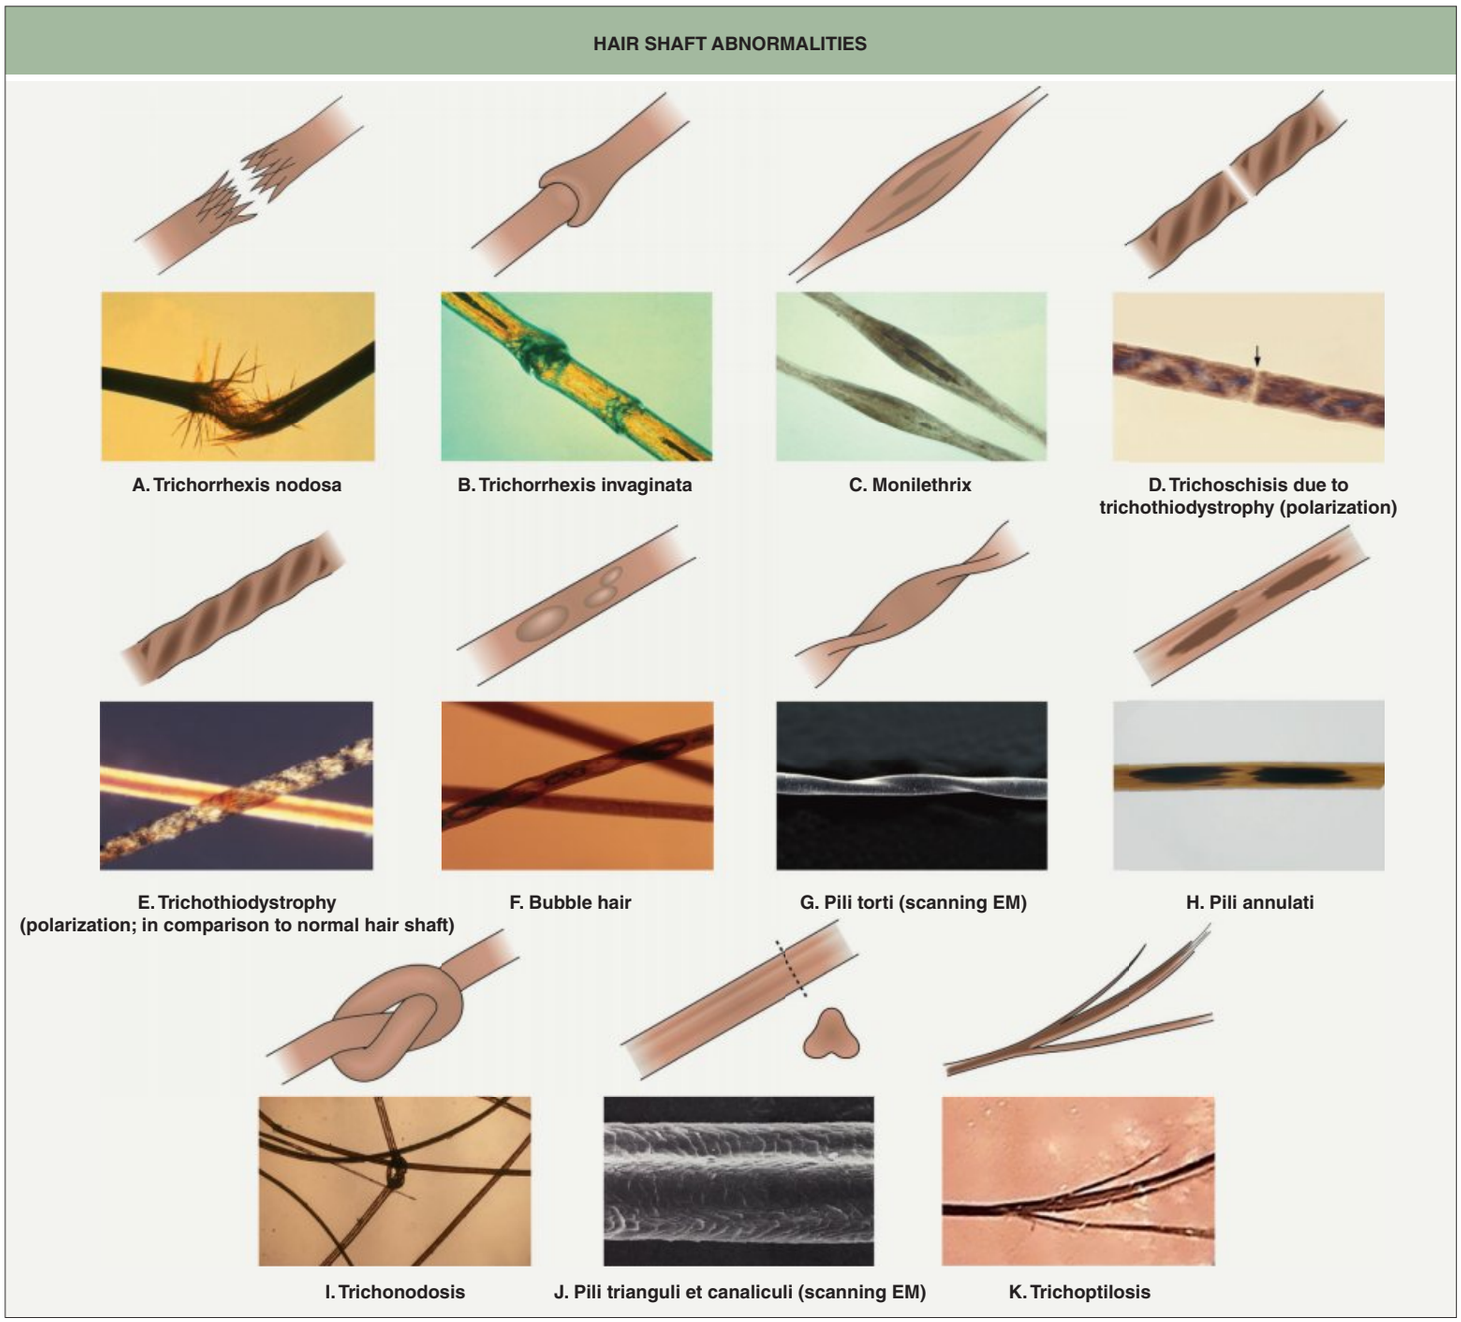

Fig. 69.24 Hair shaft abnormalities. EM, electron microscopy. *A, B, Courtesy Maria K. Hordinsky, MD; C–E, G, J, Courtesy Leonard C. Sperling, MD; F, Courtesy Jean L. Bolognia, MD.*

hair in the frontotemporal region or vertex of the scalp. There is often progression to AGA, but whether it is a harbinger of very early-onset AGA has been debated. Localized and diffuse forms of acquired hair kinking that are not associated with hair thinning have also been described.

Loose anagen hair syndrome

The classic presentation of loose anagen hair syndrome is a young girl with fairly short blond hair who has diffuse or patchy alopecia. There is no increase in hair fragility, but anagen hairs can be easily and painlessly pulled from the scalp. Because of the limited maximum hair length, patients may state "I have hair that never grows".

Microscopic examination reveals a ruffled proximal cuticle, absence of the root sheath, and a bent matrix (see Fig. 69.11C). Structural abnormalities that appear to disturb the normal supportive and anchoring functions of the inner root sheath are seen, presumably resulting in a loose attachment of the hair shaft to the anagen follicle. With trichoscopy, rectangular black granular structures are visible. Gradual improvement occurs with aging. In addition to telogen effluvium, alopecia areata, and trichotillomania, the differential diagnosis includes short anagen hair syndrome. The latter is seen primarily in children and is characterized by an increased number of telogen hairs, a shortened anagen phase with limited maximum hair length, and oftentimes a history of not requiring haircuts. If there is no improvement over time, some clinicians prescribe low-dose oral minoxidil (see Alopecia Areata, Treatment).

Pili annulati

Pili annulati (ringed hair) is characterized by hair shafts that have bright and dark bands when viewed by reflected light (see Fig. 69.24H). The bright bands are related to light scattered from periodically occurring clusters of abnormal, air-filled cavities within the hair. The condition may be sporadic or seen as an autosomal dominant trait. On microscopic examination of a hair mount, the air-filled cavities are seen as dark regions. By trichoscopy, there is alternating white and dark bands, with the former subtle, cloudy, and shorter than the remaining dark portions of the hair shaft. Approximately 20%–80% of the hairs are affected and the bands tend to disappear distally[29].

Fig. 69.25 Monilethrix. Fragility of the hair shafts leads to short broken hairs. Small perifollicular papules with scale are also present. By trichoscopy, the hair shafts have a beaded appearance (see Fig. 69.24C).

Pili bifurcati

This hair fiber anomaly is characterized by bifurcation of the hair fiber at multiple irregular intervals along the shaft, forming separate rami, which then again fuse. Each ramus has its own cuticle. As with other hair shaft disorders, the bifurcations may affect only a proportion of hairs and abnormal hairs may not be noticeable clinically.

Pili multigemini

The term pili multigemini is associated with multiple hair shafts arising from one papilla. Each hair fiber has its own inner root sheath, but all the fibers are surrounded by a common outer root sheath. Multigeminate hairs are usually found in the beard region, often in association with some perifollicular erythema. The differential diagnosis includes trichostasis spinulosa.

Uncombable hair (spun-glass hair)

This entity is also known as pili trianguli et canaliculi and refers to a rare hair abnormality in which hair has a "spun glass" appearance due to the reflection of light from variably oriented, flattened hair surfaces. Hair is characteristically stiff and difficult to comb. Abnormal keratinization of the internal root sheath is postulated to cause the irregularly shaped hair shafts, which have a triangular shape on cross-section and a longitudinal groove that is best seen by scanning electron microscopy (see Fig. 69.24J). Homozygous or compound heterozygous mutations have been identified in three genes that encode proteins involved in hair shaft formation – peptidylarginine deiminase 3 (*PADI3*), transglutaminase 3 (*TMG3*), and trichohyalin (*TCHH*).

Woolly hair

Human hair may at times develop a woolly appearance. The presence of woolly hair may be congenital and can be inherited as either an autosomal dominant or recessive trait. Some patients present with a circumscribed patch of woolly hair (woolly hair nevus). Microscopic examination may reveal elliptical cross-sections, axial twisting, and occasional trichorrhexis nodosa. With trichoscopy, hair shafts have a "crawling snake" appearance, with short wave cycles[79].

Wooly hair can be associated with several genetic disorders (see Table 69.7), including Naxos disease and Carvajal syndrome, which present with cardiomyopathy and either diffuse or striate palmoplantar keratoderma (PPK), respectively. It has also been observed in Noonan syndrome and cardio-facio-cutaneous syndrome. Kinky (but not truly woolly) hair is a feature of axonal neuropathy and tricho-dento-osseus-syndrome.

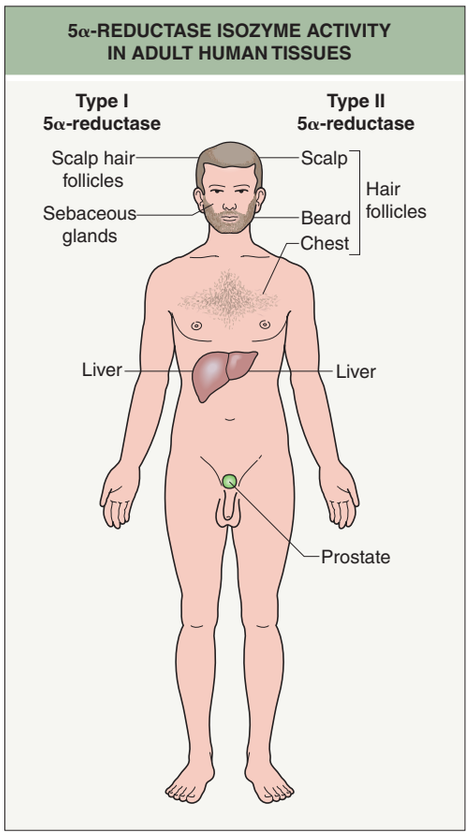
In Table 69.7, additional inherited disorders with alopecia are listed. Those genetic diseases associated with alopecia areata were discussed previously.

ALOPECIA OF SITES OTHER THAN THE SCALP

While alopecia of the scalp is the primary focus of this chapter, alopecia can occur in any hair-bearing site. Involvement of the eyebrows and/or eyelashes (madarosis) may be observed in alopecia areata, trichotillomania, and frontal fibrosing alopecia. Hypotrichosis of the lateral third of the eyebrows may serve as a clue to hypothyroidism or may be due to chronic rubbing or scratching.

Hair loss in the beard area is a common finding in patients with alopecia areata. Loss of body hair can develop in alopecia universalis and occasionally in patients with anagen effluvium. Non-scarring alopecia in the axillae and groin is a characteristic finding in Graham Little–Piccardi–Lasseur syndrome. Although the etiology is unknown, symmetric patches of alopecia on the anterolateral shins and thighs can also occur and are more obvious in men.

Acknowledgment



The authors wish to thank Leonard C. Sperling, MD, Rodney D. Sinclair, MD, and Laila El Shabrawi-Caelen, MD, for their valuable contributions to this chapter in the previous editions.

Additional figures and tables on Comorbidities and diseases associated with alopecia areata, Topical immunotherapy for alopecia areata, and DSM-5 diagnostic criteria for trichotillomania (hair-pulling disorder), available in our eBook (see inside front cover for access code).

eFig. 69.24 Central centrifugal cicatricial alopecia – trichoscopy. Findings include loss of follicular openings, mild perifollicular scaling, and small hair tufts as well as fibrotic white dots in patients with darkly pigmented skin. *Courtesy Rodrigo Pirmez, MD.*

COMORBIDITIES AND DISEASES ASSOCIATED WITH ALOPECIA AREATA		
Comorbidity or associated disease	**Odds ratio (compared to general population)**	**Prevalence**
Atopic dermatitis	2.36	9.6%
Systemic lupus erythematosus	3.46	0.7%
Iron deficiency anemia	2.78	7.5%
Thyroid dysfunction (including subclinical hypothyroidism or subclinical hyperthyroidism)	4.36	12.5%
Metabolic syndrome	4.97	1.4%
Coronary artery disease	3.13	5.5%
Depression	2.27	18.9%
Anxiety	2.00	27.1%

eTable 69.1 Comorbidities and diseases associated with alopecia areata[35,36].

TOPICAL IMMUNOTHERAPY FOR ALOPECIA AREATA
Treatment protocol for diphencyprone (DPCP) or squaric acid dibutyl ester (SADBE)*

• Sensitize with a 2% solution in acetone applied to a 4×4 cm area on one side of the scalp
• After 1 week (2 weeks if the initial reaction is severe), a 0.001% solution is applied to all affected areas on the same side of the scalp
• Each week, DPCP or SADBE is applied to the same side of the scalp
  • The *concentration* is titrated according to the severity of the reaction the previous week, with a goal of maintaining a low-grade, tolerable degree of erythema, scaling, and pruritus for 24–36 hours after application
  • *Concentrations* are increased incrementally as follows: 0.001%, 0.01%, 0.025%, 0.05%, 0.1%, 0.25%, 0.5%, 1%, 2%
• Once hair growth is established, the other side is also treated
• Initial responses are usually seen after 12 weeks, and therapy is discontinued if there is no response by 24 weeks
• Frequency of treatment can be decreased in the presence of full regrowth

Additional information

• Acetone solutions should be applied using a generous amount of cotton at the end of a wooden stick†
• Following application:
  • The sensitizer is left on the scalp for 48 hours, then washed off
  • *Patients* should avoid touching the scalp for 6 hours
  • The *scalp* should be protected from light to avoid degradation of DPCP
• SADBE must be refrigerated
• Side effects include lymphadenopathy, severe or widespread eczematous reactions, and postinflammatory pigment alterations (particularly in patients with darkly pigmented skin)

Contraindications
• Pregnancy (although teratogenicity has not been established) • Malignancies and blood dyscrasias
*Both not FDA-approved. †Application by medical personnel is recommended.

eTable. 69.2 Topical immunotherapy for alopecia areata.

DSM-5 DIAGNOSTIC CRITERIA FOR TRICHOTILLOMANIA (HAIR-PULLING DISORDER)
A. Recurrent pulling out of one's hair, resulting in hair loss B. Repeated attempts to decrease or stop hair pulling C. The hair pulling causes clinically significant distress or impairment in social, occupational, or other important areas of functioning D. The hair pulling or hair loss is not attributable to another medical condition (e.g. a dermatological condition) E. The hair pulling is not better explained by the symptoms of another mental disorder (e.g. attempts to improve a perceived defect or flaw in appearance in body dysmorphic disorder)

eTable 69.3 DSM-5 diagnostic criteria for trichotillomania (hair-pulling disorder). It is DSM-5 disorder 312.39 (F63.3).

70 Hypertrichosis and Hirsutism

Rachel Reynolds, Kristen Corey and Francisco M. Camacho

Key features

- Hypertrichosis refers to excessive growth of hair anywhere on the body, whereas hirsutism represents excessive hair growth within androgen-dependent sites in girls and women
- Hypertrichosis may be generalized or localized, with etiologies ranging from genodermatoses to underlying hamartomas to repeated trauma
- Hirsutism is related to hormonal factors, in particular an increase in circulating androgen levels and/or enhanced sensitivity of hair follicles to androgens
- In women, the major sources of androgens are the adrenal glands and the ovaries; dysfunction of these organs must be considered when a patient presents with hirsutism
- Depending on its etiology, treatment of hirsutism may include oral contraceptives, antiandrogens, gonadotropin-releasing hormone agonists, glucocorticoids, and insulin-lowering agents, combined with topical medications and physical measures (e.g. laser hair removal)

HYPERTRICHOSIS

Introduction

Hypertrichosis describes the growth of excessive hair anywhere on the body. The term is frequently confused with hirsutism, which should only be applied to women with excessive growth of terminal hairs in androgen-dependent sites (i.e. a "male pattern") due to hyperandrogenemia or increased end-organ sensitivity to androgens[1–3]. Hypertrichosis can be classified based on its distribution (generalized versus localized), the age of onset (congenital or programmed from birth versus acquired), and the type of hair (lanugo or vellus versus terminal).

Clinical Features

Generalized hypertrichosis

In generalized hypertrichosis, there is lanugo hair, excess vellus hair, or terminal hair over much of the cutaneous surface, including an acquired transformation of terminal hair into lanugo hair (Fig. 70.1)[4]. Lanugo is the non-pigmented, non-medullated, fine hair that covers the fetus and can grow up to several centimeters in length; it is normally shed *in utero* at ~7–8 months' gestation or during the first few weeks of life and replaced by vellus hair on the body and terminal hair on the scalp. Some neonates, especially if born prematurely, transiently retain lanugo hairs diffusely and shed them during the first few weeks of life.

Congenital generalized hypertrichosis

A number of distinctive but rare genetic syndromes are associated with congenital generalized hypertrichosis (Table 70.1). While the majority of these disorders have extracutaneous manifestations such as gingival hyperplasia or facial dysmorphism, some have primarily hypertrichosis, including universal hypertrichosis. However, this latter entity is sometimes viewed as constitutional, i.e. simply exaggerated normal hairiness that may be familial. Genetic abnormalities associated with congenital generalized hypertrichosis lead to dysfunction of several proteins, ranging from those known to be involved in hair follicle development to membrane transporters (see Table 70.1).

The possibility of intrauterine exposure to medications (e.g. minoxidil) also needs to be considered in infants with congenital generalized hypertrichosis. The differential diagnosis also includes inherited disorders in which hypertrichosis can involve multiple sites and may appear early in life (Table 70.2).

Prepubertal hypertrichosis

Prepubertal hypertrichosis is a relatively common finding in otherwise healthy infants and children, most often occurring in individuals of Mediterranean or South Asian descent. Pigmented hair is present in a widespread, diffuse distribution and becomes more obvious during childhood. There is involvement of the face (especially the forehead, temples, and preauricular area), proximal extremities, and back; hairs in the latter location assume an "inverted fir tree" pattern. Bushy eyebrows and a low anterior hairline represent additional features.

The facial distribution pattern of prepubertal hypertrichosis can overlap with that of familial hirsutism (see below), and there may be a family history of excessive hairiness. Mildly elevated levels of total and free testosterone have been observed in a subset of girls with prepubertal hypertrichosis, while others have a normal androgen profile[12]. These findings suggest multiple etiologies for this clinical pattern of hypertrichosis, including androgen excess as well as an increased constitutional propensity for hair growth.

Acquired generalized hypertrichosis

Acquired generalized hypertrichosis is most often related to drug ingestion (Table 70.3). Drug-induced hypertrichosis is characterized by slow growth of terminal hair of medium thickness. The findings are most evident on the forehead, temples, flexor aspects of the extremities, and trunk. Drug-related hypertrichosis is usually reversible, and differs in distribution from drug-induced hirsutism.

Acquired generalized hypertrichosis can also represent a sign or consequence of a variety of systemic conditions, including disorders of the CNS (e.g. traumatic brain injuries), juvenile hypothyroidism, juvenile dermatomyositis, acromegaly (especially of the lower face), malnutrition (including anorexia nervosa), POEMS syndrome, and advanced HIV disease.

Acquired hypertrichosis lanuginosa

This is considered to be a paraneoplastic phenomenon as it is associated with internal malignancies, most often of the lung, colon, or breast. Occasionally, acquired hypertrichosis lanuginosa may precede the diagnosis of the neoplasm. In addition, it may be associated with other paraneoplastic dermatoses, such as acanthosis nigricans, palmoplantar keratoderma, the sign of Leser–Trélat, and acquired ichthyosis (see Ch. 53). The lanugo hair appears over the entire body within a short period of time, although in mild forms it may be localized to the face, leading to a "simian" appearance. Lanugo hair may even develop in areas of androgenetic alopecia.

Localized hypertrichosis

Most cases of localized hypertrichosis involve a switch from vellus to terminal hair in sites that do not usually bear terminal hair. Localized hypertrichosis can develop as a component of a hamartoma, as an isolated congenital lesion, as a manifestation of a systemic disease (inherited or acquired), or as a consequence of cutaneous trauma or inflammation.

Congenital localized hypertrichosis

Hamartomas, including those with delayed clinical presentation, and congenital abnormalities characterized by hypertrichosis of a specific anatomic site (Figs. 70.2 and 70.3; Tables 70.4 & 70.5) are included in this category.

Congenital melanocytic nevi and plexiform neurofibromas

Congenital melanocytic nevi often have associated hypertrichosis. The increased hair growth may be noted at birth, but often becomes

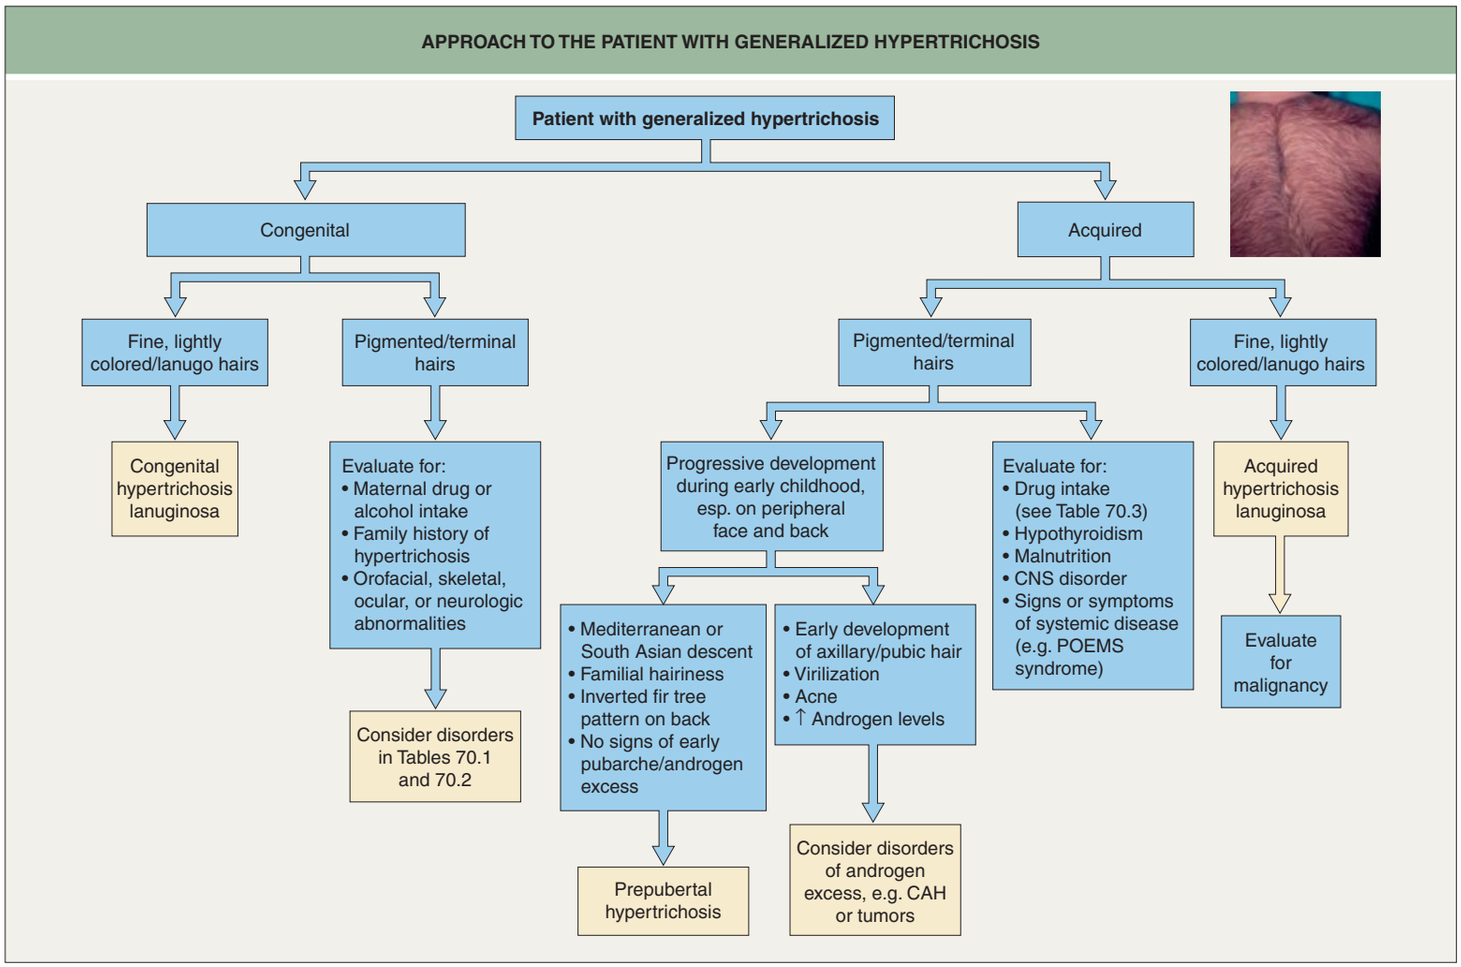

Fig. 70.1 Approach to the patient with generalized hypertrichosis. CAH, congenital adrenal hyperplasia; POEMS, *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal gammopathy, *s*kin lesions. The photograph is an example of universal hypertrichosis, which some authors view as simply exaggerated normal hairiness that may be familial.

more prominent during infancy or early childhood. Hypertrichosis can be seen in all sizes of congenital melanocytic nevi (see Ch. 112). A particularly dense growth of terminal hairs may accompany scalp nevi. Plexiform neurofibromas can also have associated hyperpigmentation and hypertrichosis.

Becker melanosis (nevus)

This is a hamartoma characterized by macular hyperpigmentation with irregular borders, most commonly located on the upper lateral trunk (anterior or posterior) (see Ch. 112). Some patients have associated hypertrichosis while others do not. The pigmentation usually arises during the first decade of life, whereas the hypertrichosis typically appears in the second decade (Fig. 70.5). Becker melanosis is most often diagnosed in boys and men. Postzygotic mutations in the *ACTB* gene encoding β-actin have been found to underlie Becker melanosis and associated anomalies (referred to as Becker nevus syndrome; see below) as well as smooth muscle hamartomas (see Ch. 117 and below)[15].

Occasionally, asymmetry of the extremities and hyperplasia or hypoplasia of the affected areas is evident, especially ipsilateral mammary hypoplasia in women or, less often, the Poland anomaly (unilateral chest wall hypoplasia and ipsilateral hand syndactyly). Rarely, there may be an association with genitourinary tract abnormalities (SNUB syndrome: supernumerary nipples, uropathies, Becker melanosis)[16]. Because of its benign nature, surgical removal of Becker melanosis is not recommended. Epilation can be performed by various techniques, but attempts at decreasing pigmentation via laser therapy are often not successful.

Smooth muscle hamartomas, which exist on a spectrum with Becker melanosis, may present as circumscribed hypertrichotic plaques with variable hyperpigmentation. A rare generalized form is characterized by extensive hypertrichosis and folding of the skin which has been reported under the term "Michelin tire baby" (see Table 97.7). Lastly, the hypertrichosis observed in the setting of hemimaxillofacial dysplasia (with facial asymmetry due to unilateral maxillary enlargement, gingival hyperplasia, and hypoplastic teeth) is often associated with Becker melanosis or smooth muscle hamartoma.

Other hamartomas and infantile tumors

Hypertrichosis can also overlie the following skin lesions: plaque-type blue nevus, neurocristic hamartoma, fibrous hamartoma of infancy, dermal dendrocyte hamartoma, eccrine angiomatous hamartoma, and tufted angioma.

Nevoid hypertrichosis

This is an uncommon congenital alteration characterized by the growth of terminal hairs in a circumscribed area. In general, there are no extracutaneous associations in *primary nevoid hypertrichosis*; the skin within the affected area is normally pigmented and there is no underlying hamartoma (Fig. 70.6). Table 70.4 outlines specific sites of localized hypertrichosis that can be familial. To date there is a report of one family with primary multifocal localized hypertrichosis[17]. Nevoid hypertrichosis has also been observed to follow the lines of Blaschko, as reported in female carriers of X-linked hypertrichosis (see Table 70.1).

Secondary nevoid hypertrichosis can be associated with lipodystrophy, hemihypertrophy, scoliosis, and abnormalities of the underlying vasculature. Nevoid hypertrichosis also occasionally occurs together with epidermal nevi or nevoid hypopigmentation, and it can represent a manifestation of Proteus and Happle–Tinschert syndromes.

Spinal dysraphism and the hair collar sign

Dysraphism is defined as an alteration of the formation of a fold or elevation which is constituted in the midline of the human body during

HEREDITARY DISORDERS CHARACTERIZED BY CONGENITAL GENERALIZED HYPERTRICHOSIS		
Disorder	**Inheritance (genetic basis/gene)**	**Other key features**
Increased hair is the major feature		
Congenital hypertrichosis lanuginosa	AD	• Fetal lanugo hair is not replaced by normal hair and continues to grow • Fine, downy, silvery-gray to blond lanugo hair that may be up to 10 cm in length • Involves entire body surface (except for the palms, soles, dorsal surface of distal phalanges, and prepuce) but hair may be shed over the first year of life • Occasional dental anomalies; rarely other associations (e.g. ear defects, glaucoma, pyloric stenosis, photophobia, ID)
Universal hypertrichosis	AD	• Thicker, longer hair most prominent on the back, proximal extremities and the frontal, temporal, and preauricular areas of the face* • Increases during infancy and tends to persist • Considered by some authors to be simply exaggerated normal hairiness that may be familial
Ambras syndrome (hypertrichosis universalis congenita, Ambras type; HTC1)[5,6]	AD (8q22–q24 breakpoints; position effect downregulates *TRPS1* expression)	• Fine, silky, lightly colored, long vellus hair involving the entire body but primarily the face, ears, and shoulders • Uniformly distributed on the face, including the nose • Persists for life • Minor facial dysmorphism, dental anomalies, supernumerary nipples
Generalized hypertrichosis with extracutaneous features		
X-linked hypertrichosis (congenital generalized hypertrichosis; HTC2)[7]	XLD (Xq27.1; palindrome-mediated interchromosomal insertion; position effect downregulates *FGF13* expression)	• Curly, shorter, dark hair most prominent on the face and upper body • Anteverted nostrils, prognathism; occasional dental anomalies, deafness • Female carriers may have nevoid hypertrichosis following lines of Blaschko
Congenital generalized hypertrichosis with or without gingival hyperplasia (HCT3)[8]	AD or AR (17q24.2–q24.3 microdeletion or microduplication [AD]; position effect downregulates *SOX9* expression; also *ABCA5* [AR])	• Dark terminal hairs on the peripheral face, central back, and extremities • In addition to gingival hyperplasia, coarse facies, ID, seizures
FHEIG syndrome	AD (*KCNK4*)	• *F*acial dysmorphism, *h*ypertrichosis, epilepsy, *I*D, *g*ingival overgrowth
Cantú syndrome (hypertrichotic osteochondrodysplasia)	AD (*ABCC9*)	• Coarse facies, osteochondrodysplasia, macrosomia at birth, cardiomegaly
Zimmermann–Laband syndrome	1: AD (*KCNH1*) 2: AD (*ATP6V1B2*) 3: AD (*KCNN3*)	• Gingival hyperplasia, coarse facies, hypoplastic nails and distal phalanges, joint hyperextensibility, splenomegaly, ID
Coffin–Siris syndrome†	1: AD (*ARID1B*) 2: AD (*ARID1A*) 3: AD (*SMARCB1*) 4: AD (*SMARCA4*) 5: AD (*SMARCE1*) 8: AD (*SMARCC2*) 9: AD (*SOX11*)	• Sparse scalp hair, coarse facies, hypoplastic fifth fingernails and toenails, GD, ID
Schinzel–Giedion midface retraction syndrome	AD (*SETBP1*)	• Midfacial vascular stain, midfacial retraction, hyperconvex nails, hypoplastic distal phalanges and dermatoglyphs, GU anomalies, GD, ID
Fontaine progeroid syndrome (includes Gorlin–Chaudry–Moss syndrome)	AD (*SLC25A24*)	• Craniofacial dysostosis with midfacial hypoplasia, hypoplastic distal phalanges, ocular and dental anomalies, genital hypoplasia, GD
Adducted thumbs syndrome	AR	• Arthrogryposis, craniosynostosis, myopathy
Barber–Say syndrome	AD (*TWIST2*)	• Lax skin, ectropion, macrostomia, coarse facies, hypoplastic nipples, GD

*This pattern of distribution is also observed in prepubertal hypertrichosis (see text).
†Protein products of mutated genes are subunits of the SWI/SNF complex.

Table 70.1 Hereditary disorders characterized by congenital generalized hypertrichosis. Autosomal recessive disorders presenting with congenital amaurosis or cataracts in addition to hypertrichosis have also been reported in individual families. ABC, ATP-binding cassette transporter; AD, autosomal dominant; AR, autosomal recessive; ARID, AT-rich interaction domain; ATP6V1B2, ATPase H^+ transporting V1 subunit B2; FGF, fibroblast growth factor; GD, growth delay; GU, genitourinary; HTC, hypertrichosis; ID, intellectual disability; KCN, potassium voltage-gated channel; SLC, solute carrier family; SMARC, SWI/SNF related, matrix associated, actin dependent regulator of chromatin; TRPS1, transcriptional repressor GATA binding 1/tricho-rhino-phalangeal syndrome 1 protein; TWIST, twist family BHLH transcription factor 2; XLD, X-linked dominant.

the union of two lateral portions. In spinal dysraphism, abnormal closure of the neural tube leads to defects in the vertebral column and/or spinal cord (see Ch. 64). Skin lesions marking a hidden vertebral defect are usually located in the dorsal midline. The faun tail is most often a sign of spina bifida occulta or diastematomyelia (split spinal cord), and is typically located in the lumbosacral region. In addition, a ring of hypertrichosis on the scalp, referred to as the hair collar sign, can surround membranous aplasia cutis or ectopic neural tissue, reflecting the origin of these midline lesions as incomplete neural tube defects.

Localized hypertrichosis in hereditary and acquired systemic diseases

There are multiple genetic diseases characterized by the presence of localized hypertrichosis as a major or secondary diagnostic feature (see Table 70.2). For example, hypertrichosis within sun-exposed areas is one of the signs of the porphyrias – in particular, porphyria cutanea tarda (Fig. 70.7) and hepatoerythropoietic porphyria. Likewise, the low frontal hairline and synophrys ("unibrow") in the Cornelia de Lange syndrome are important diagnostic features of that entity. Localized hypertrichosis

HEREDITARY DISEASES AND CONGENITAL SYNDROMES ASSOCIATED WITH REGIONAL HYPERTRICHOSIS		
Disorder	**Sites of hypertrichosis**	**Other key features**
Dysmorphic syndromes		
Cornelia de Lange syndrome	• Forehead, lateral face, shoulders, back • Low anterior hairline, synophrys, trichomegaly	• Distinctive facies, upper extremity anomalies, microcephaly, GD, ID, "growling cry" • AD (1,3,4): *NIPBL* > *SMC3*, *RAD21* • XLD (2,5): *SMC1A*, *HDAC8*
Rubinstein–Taybi syndrome	• Lateral face, shoulders, back • Thick eyebrows, trichomegaly	• Midfacial vascular stains, keloids, pilomatricomas • Broad thumbs/halluces, beaked nose, high-arched palate, short stature, ID • AD; *CREBBP* > *EP300*
KINSSHIP syndrome	• Extremities	• Horseshoe *ki*dney, *N*ievergelt/Savarirayan mesomelic dysplasia, *s*eizures, *h*ypertrichosis, *I*D, *p*ulmonary anomalies • AD (*AFF3*)
Disorders with primary cutaneous features		
Porphyrias	• Sun-exposed areas • Favors lateral face in PCT, HEP, VP • Face, trunk, extremities in CEP	• See Ch. 49
Lipodystrophy syndromes (e.g. Berardinelli–Seip syndrome, leprechaunism)	• Face, neck, extremities • Low hairline	• See Ch. 101
Superficial epidermolytic ichthyosis (SEI)*, erythrokeratodermia variabilis et progressiva (EKVP)	• Extremities (SEI); trunk and extremities (EKVP)	• See Ch. 57
Dystrophic epidermolysis bullosa*	• Areas of previous blistering	• See Ch. 32
Metabolic disorders		
Mucopolysaccharidoses†	• Trunk, extremities	• See Ch. 48
Congenital hypothyroidism	• Back, extremities	• See Ch. 46
Mitochondrial disorders		
Leigh syndrome due to *SURF1* mutations	• Forehead, extremities	• Progressive neurodegeneration
MELAS syndrome	• Lower extremities	• *M*itochondrial encephalopathy, *l*actic *a*cidosis, and stroke-like episodes
Intrauterine exposures‡		
Fetal hydantoin syndrome	• Face, back, extremities	• Gingival hyperplasia, coarse facies, hypoplastic nails and distal phalanges, GD
Fetal alcohol syndrome	• Face, back, extremities	• Midfacial hypoplasia, GD, CNS anomalies
Morpheaform or sclerodermoid disorders		
MONA (*m*ulticentric *o*steolysis, *n*odulosis, and *a*rthropathy; previously known as Winchester syndrome)	• Hypertrichosis and hyperpigmentation overlying areas of skin thickening	• Gingival hyperplasia, carpal/tarsal osteolysis, osteoporosis, coarse facies, GD • AR; *MMP2* (matrix metalloproteinase-2)
Histiocytosis-lymphadenopathy plus syndrome¶ (including H syndrome)[9–11]	• Lower trunk and lower extremities (in association with areas of *h*yperpigmentation & induration) • Histologic features in areas of induration include a polyclonal perivascular lymphohistiocytic infiltrate with numerous plasma cells in the dermis and subcutis	• Sensorineural *h*earing loss, short *h*eight, *h*eart anomalies, *h*epatosplenomegaly, scrotal masses, hypergonadotropic *h*ypogonadism, antibody-negative insulin-dependent diabetes mellitus, facial telangiectasias • AR; *SLC29A3* (encodes nucleoside transporter hENT3 which localizes to lysosomes and mitochondria)
Stiff skin syndrome	• Variable	• See Ch. 43
Linear melorheostosis (isolated melorheostosis)§	• Overlying affected skin and bone	• Hyperostosis ("candle wax" appearance) with overlying scleroderma • Isolated cases due to *LEMD3* mutations

*Hypertrichosis is an uncommon feature.
†Hypertrichosis may also be observed in other lysosomal storage diseases, e.g. Krabbe disease and GM1-gangliosidosis, as well as sialuria.
‡Also minoxidil and diazoxide.
¶Includes pigmented hypertrichosis with insulin-dependent diabetes mellitus (PHID) syndrome, sinus histiocytosis with massive lymphadenopathy (SHML), and Faisalabad histiocytosis as well as H syndrome.
§Hypertrichosis has also been described overlying linear scleroderma in the absence of melorheostosis.

Table 70.2 Hereditary diseases and congenital syndromes associated with regional hypertrichosis. Varying degrees of hypertrichosis (predominantly facial or generalized) have also been observed in children with chromosomal anomalies, e.g. partial trisomy of 1q, 3q, 4p, or 17q. Autosomal recessive palmoplantar keratoderma and exuberant curly scalp hair due to *FAM83G* mutations has also been reported. *NIPBL*, *SMC1A*, *SMC3*, and *RAD21* encode components of the cohesin complex. *RAD21* and *EP300* encode a histone acetyltransferase and a histone deacetylase, respectively. AD, autosomal dominant; *AFF3*, ALF transcription elongation factor 3; AR, autosomal recessive; CEP, congenital erythropoietic porphyria; GD, growth delay; HEP, hepatoerythropoietic porphyria; ID, intellectual disability; PCT, porphyria cutanea tarda; VP, variegate porphyria; XLD, X-linked dominant.

may also be observed in acquired systemic diseases, such as infrapatellar hypertrichosis in juvenile dermatomyositis or hypertrichosis overlying pretibial myxedema, indurated plaques of Rosai–Dorfman disease, and areas affected by the complex regional pain syndrome.

Acquired localized hypertrichosis

After repeated trauma, friction, irritation, or inflammation, the hair within affected areas of skin may become longer and thicker (e.g.

HYPERTRICHOSIS DUE TO DRUGS	
Antibiotics	
• Streptomycin	
Anticonvulsants	
• **Phenytoin**	
Anti-inflammatory drugs	
• Benoxaprofen	• Corticosteroids
Antiseptic agents	
• Hexachlorobenzene	
Chelators	
• Penicillamine	
Diuretics	
• Acetazolamide	
Immunosuppressives	
• **Cyclosporine**	• Mycophenolate mofetil
Psoralens	
• Methoxypsoralen	• Trimethylpsoralen
Vasodilators	
• Diazoxide • **Minoxidil**	• Prostaglandin E1
Other	
• Interferon-α • Fenoterol	• EGFR inhibitors (e.g. cetuximab, panitumumab, erlotinib, gefitinib) • IL-17 inhibitors (e.g. secukinumab, ixekizumab)

Table 70.3 Hypertrichosis due to drugs. Most common drugs are in **bold**. EGFR, epidermal growth factor receptor.

HEREDITARY HYPERTRICHOSIS AFFECTING SPECIFIC ANATOMIC SITES			
Condition	**Inheritance**	**Onset**	**Other features**
Hypertrichosis cubiti (Fig. 70.2)	AD	Birth to early childhood	• Short stature* • Wiedemann–Steiner syndrome: short stature, facial dysmorphism, ID; *KMT2A*
Hairy palms and soles	AD	Birth	
Hypertrichosis of the auricle	AD†	Childhood or adolescence	• Primarily affects males
Hypertrichosis of the eyebrows	?	Adolescence	
Trichomegaly of the eyelashes	AR	Childhood	
Hypertrichosis of the nasal tip	?	Adolescence	• Primarily affects males
Anterior cervical hypertrichosis[13] (Fig. 70.3)	AD‡	Birth to early childhood	• Sensory and motor neuropathy, ID* • Hallux valgus*
Posterior cervical hypertrichosis	AD	Birth	• Kyphoscoliosis
Polythelia, including the hairy variant¶[,14]	AD§	Adolescence	• Urinary tract anomalies*

*Occasional finding.
†Shown not to be Y-linked in a cohort of Indian men; congenital hypertrichosis of the pinna can be seen in the offspring of diabetic mothers and in individuals with XYY syndrome.
‡Possible AR inheritance in a consanguineous family.
¶Tuft of hair along the "mammary line".
§Approximately 10% of cases are familial.

Table 70.4 Hereditary hypertrichosis affecting specific anatomic sites. Localized hypertrichosis as a sign of spinal dysraphism is discussed in Ch. 64. AD, autosomal dominant; AR, autosomal recessive; ID, intellectual disability; KMT2a, lysine-specific methyltransferase 2 A.

HYPERTRICHOSIS OF THE EYEBROWS AND EYELASHES
Synophrys ("unibrow")
• Isolated trait • Waardenburg syndrome (see Ch. 66) • Cornelia de Lange syndrome (see Table 70.2) • Zimmerman–Laband syndrome (see Table 70.1) • Mucopolysaccharidoses (see Ch. 48)
Inherited and/or congenital trichomegaly
• Trichomegaly due to *FGF5* mutations (AR) • Oliver–McFarlane syndrome* • Cornelia de Lange and Rubinstein–Taybi syndromes (see Table 70.2) • Congenital hypertrichosis lanuginosa and Ambras syndrome (see Table 70.1) • Cantú, Coffin–Siris, and Barber–Say syndromes (see Table 70.1) • Hermansky–Pudlak syndrome (see Ch. 66) • Kabuki and floating harbor syndromes† • Fetal alcohol syndrome (see Table 70.2)
Acquired trichomegaly
• HIV infection • Systemic medications: cyclosporine, EGFR inhibitors (e.g. cetuximab, gefitinib; Fig. 70.4), topiramate, tacrolimus, interferon-α • Ophthalmic medications: latanoprost, bimatoprost • Hypothyroidism • Porphyrias • Dermatomyositis, systemic lupus erythematosus • Malnutrition, anorexia nervosa
Distichiasis (double row of eyelashes)
• Lymphedema–distichiasis syndrome‡ • Setleis syndrome (double upper and absent lower lashes; see Ch. 64)
*Autosomal recessive (AR) disorder also featuring sparse scalp hair, intellectual disability, short stature, and retinal pigmentary degeneration. †Autosomal dominant (AD) disorders featuring distinctive facies, growth delay, and, in the former, intellectual disability. ‡AD condition due to FOXC2 mutations (see Ch. 104).

Table 70.5 Hypertrichosis of the eyebrows and eyelashes. EGFR, epidermal growth factor receptor.

hypertrichosis of the back in sack carriers, hypertrichosis of a fractured limb after the application of a plaster cast, hypertrichosis of the posterior neck in people who bear heavy weights; Fig. 70.8)[18]. Chronic rubbing or scratching can also lead to localized hypertrichosis. Transient localized hypertrichosis has been observed within vaccination sites and varicella scars as well as sites of wart removal and laser epilation[19]. In addition, hypertrichosis has been described overlying lipoatrophy following lupus panniculitis and within resolving lesions of psoriasis and morphea. Extractable hairs mimicking hypertrichosis are often evident within a pilonidal sinus (cyst), which is usually located within the gluteal cleft.

Fig. 70.5 Becker melanosis (nevus) on the mid back in a young man. In addition to hyperpigmentation, there is marked hypertrichosis. The degree of hypertrichosis can vary (see Ch. 112). When it is marked as in this patient, the clinical differential diagnosis includes congenital melanocytic nevus, especially when there is an underlying smooth muscle hamartoma.

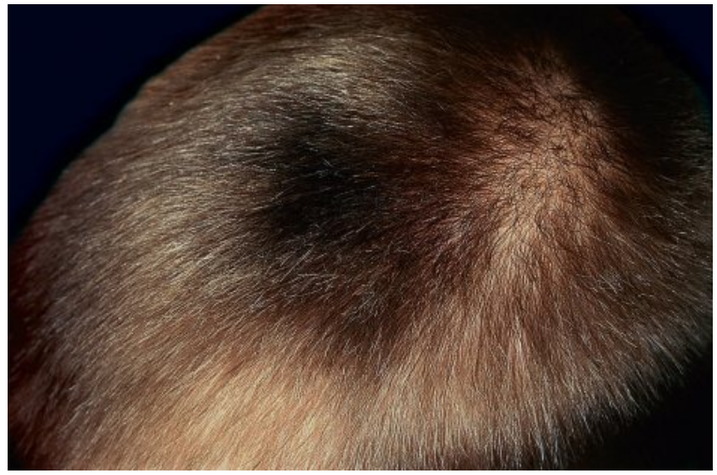

Fig. 70.6 Nevoid hypertrichosis (nevus pilosus) of the scalp in a young boy. There was no underlying melanocytic nevus or hyperpigmentation. *Courtesy Jean L. Bolognia, MD.*

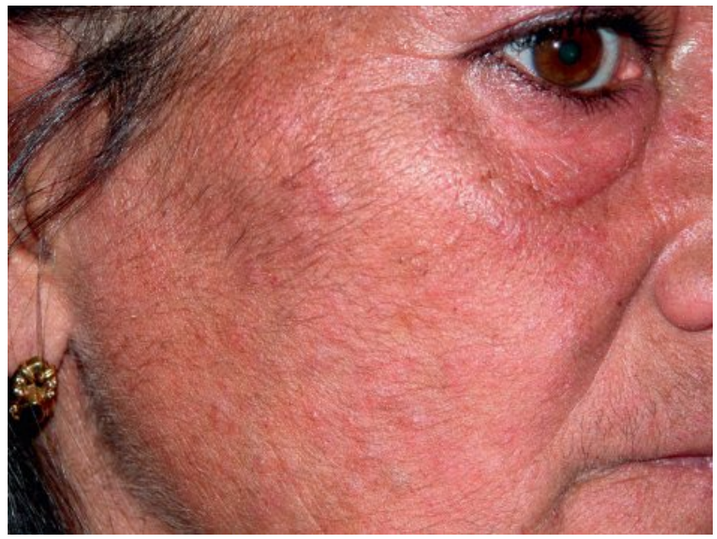

Fig. 70.7 Facial hypertrichosis in a woman due to porphyria cutanea tarda. *Courtesy Luis Requena, MD.*

Fig. 70.8 Acquired localized hypertrichosis. Hypertrichosis, hyperpigmentation, and epidermal hyperplasia at the site of friction.

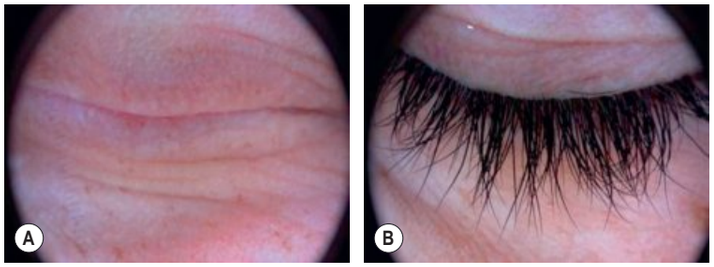

Fig. 70.9 Treatment of eyelash alopecia in a patient with alopecia universalis. A Prior to treatment. **B** Following daily application of topical latanoprost ophthalmic 0.005% solution for 6 months, there was regrowth of eyelashes.

Localized hypertrichosis has been reported after PUVA therapy. Sites of application of potent topical corticosteroids, tacrolimus, and creams containing mercury or iodine can also develop localized hypertrichosis, as can sites of repeated irritation from anthralin. Prostaglandin F-2α analogues (e.g. latanoprost, bimatoprost), which are topical agents used for the treatment of glaucoma, can induce trichomegaly of the eyelashes as well as brown iris pigmentation. The FDA has approved bimatoprost 0.03% solution for the stimulation of eyelash growth, and latanoprost has also been used off-label for this purpose (Fig. 70.9)[20].

Treatment

Methods available to treat hypertrichosis include chemical depilatory agents, electrolysis (see Ch. 140), and laser hair removal (see Ch. 137). Systems utilized for photoepilation include Nd:YAG, diode, and alexandrite lasers as well as intense pulsed light (IPL) sources (see Ch. 137). Barium sulfate depilatory creams have been shown to be especially effective, but they are odiferous and more irritating than calcium thioglycolate depilatory creams. Shaving and other physical methods (e.g. tweezing, waxing, threading, sugaring) may also be employed[21].

HIRSUTISM

Introduction

The term "*hirsutism*" is defined as excessive terminal hair growth in women that is within androgen-dependent sites (e.g. upper lip, chin, mid sternum, abdomen, back, buttocks; Fig. 70.10), representing a male distribution pattern. It reflects either hyperandrogenemia (an increase in circulating androgens) or an enhanced end-organ response to androgens[22–25]. Additional signs of hyperandrogenemia may include acne, a female pattern of androgenetic alopecia (see Ch. 69), irregular menstruation, and virilization. Virilization, which is uncommon and occurs with more severe hyperandrogenemia, also manifests with deepening of the voice, clitoromegaly, increased muscle mass, and male pattern hair loss (see Table 70.7).

Fig. 70.10 Idiopathic (constitutional) hirsutism. This patient had *s*eborrhea, *a*cne, *h*irsutism, and *a*lopecia, termed SAHA syndrome.

Epidemiology

Hirsutism, as defined by an abnormal score on the modified Ferriman and Gallwey scoring system (mFG; Fig. 70.11), affects ~5%–10% of women of reproductive age in the general population and rarely postmenopausal women[26,27]. In a study of North American women, 35% had terminal hairs on the linea alba, 17% in the periareolar area, 16% in the lumbosacral area, and 10% in the upper pubic triangle[23,24]. Androgen excess is present in >80% of premenopausal women with hirsutism, and ~70%–80% of these individuals have polycystic ovary syndrome (PCOS)[28]. Other women without hyperandrogenemia have idiopathic (constitutional) hirsutism, which tends to be relatively mild. Additional causes of hirsutism include drug intake, non-classic congenital adrenal hyperplasia, other endocrinopathies, and rarely androgen-secreting tumors (adrenal or ovarian; <0.3%) (Table 70.6). Women with rapid onset of hirsutism or signs of virilization are more likely to have an androgen-secreting tumor.

Classification

For clinical and therapeutic purposes, hirsutism can be classified according to the underlying causes (see Table 70.6)[23,24,29,30].

Clinical Features

Idiopathic (constitutional) hirsutism

Idiopathic (constitutional) hirsutism is a diagnosis of exclusion that is characterized by normal menses, normal ovaries on ultrasound, and no evidence of other causes. Androgen levels are usually normal but occasionally minimally elevated. Possible contributing factors include altered peripheral androgen activity and obesity[31], and this condition may be familial (Fig. 70.12). Approximately 5%–20% of all women with hirsutism and 50% of those with *mild* hirsutism have the idiopathic form[28]. Some women have acne and androgenetic alopecia as well as hirsutism, in association with slight increases in serum androgen levels (e.g. testosterone and dehydroepiandrosterone sulfate [DHEAS]). This constellation of findings has been referred to as *SAHA – s*eborrhea, *a*cne, *h*irsutism, and *a*ndrogenetic alopecia – *syndrome* (see Fig. 70.10)[32,33].

Ovarian hirsutism

Ovarian hirsutism can be of non-tumoral or tumoral origin. Non-tumoral etiologies include PCOS and ovarian hyperthecosis, with the former most common in premenopausal women and the latter typically occurring after menopause. A variety of benign or malignant ovarian tumors can also cause hirsutism, with malignant etiologies more likely to present with an abrupt onset of hirsutism, virilization, and markedly elevated testosterone levels.

Non-tumoral ovarian hirsutism

Polycystic ovary syndrome (PCOS)

This common syndrome, first described by Stein and Leventhal in 1935, affects ~5%–15% of women who are of reproductive age. It is

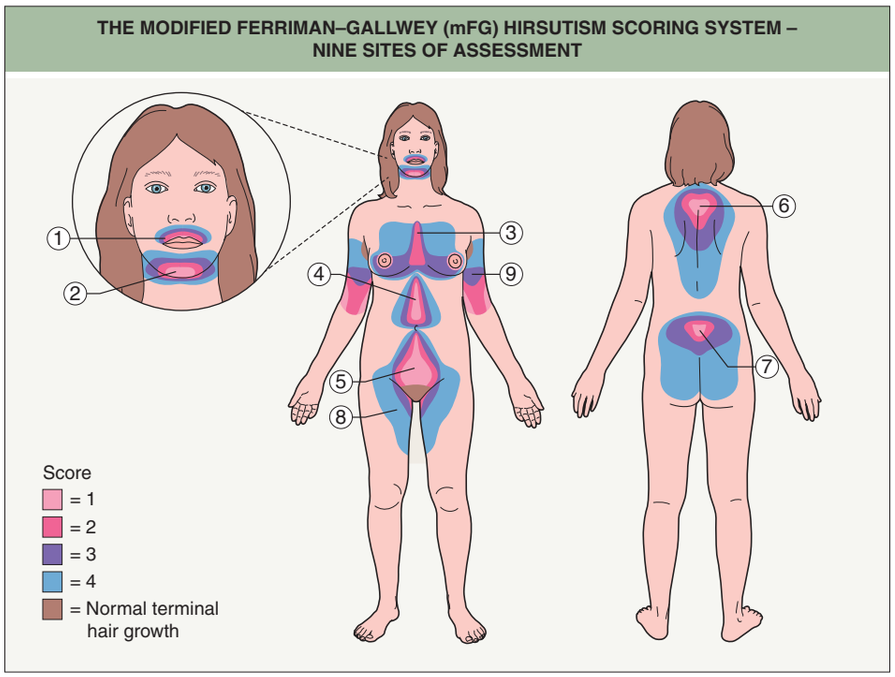

Fig. 70.11 The modified Ferriman–Gallwey (mFG) hirsutism scoring system – nine sites of assessment. The modified Ferriman and Gallwey score is based upon the sum of the values (graded from 0 to 4 points) for each of the nine body areas illustrated as follows: 0 points (no terminal hairs); 1 point (minimal terminal hairs); 2 points (hair growth is more than minimal but not yet that of a man); 3 points (hair growth is that of a man who is not very hairy); and 4 points (equivalent to a very hairy man). Total mFG scores that define hirsutism in reproductive-aged women vary depending upon race/ethnicity and are as follows: US and United Kingdom White or Black women, ≥8 (8–15 generally considered mild, 16–25 moderate, and >25 severe hirsutism); Mediterranean, Middle Eastern and Hispanic women, ≥9–10; South American women, ≥6; and Asian women, ranging from ≥2 for Han Chinese women to ≥7 for Southern Chinese women.

characterized by three major features (Rotterdam criteria): (1) oligo- or anovulatory cycles; (2) clinical or biochemical signs of hyperandrogenism (Fig. 70.13); and (3) ultrasonographic evidence of polycystic ovaries. Diagnosis requires two of these three criteria as well as exclusion of other causes of hirsutism (Fig. 70.14)[34]. Biochemically, there is typically a decrease in follicle-stimulating hormone (FSH) and an increase in luteinizing hormone (LH), as well as elevated serum levels of estrone and testosterone. Occasionally, serum prolactin levels are also increased.

After a normal menarche, patients develop persistent oligo- or amenorrhea that is frequently accompanied by infertility. Acne is present in 70% of patients and hirsutism in 90%. The associated hirsutism is usually lateral (i.e. on the breasts and lateral aspects of the face and neck) as well as on the central abdomen (see Fig. 70.13). Androgenetic alopecia in a female or male pattern is also commonly evident, but there are no signs of genital virilization. At least 50% of patients are obese, and some develop acanthosis nigricans and acrochordons in association with insulin resistance (see below). Patients with PCOS have large ovaries with a pearly gray surface, a thickened capsule and cysts with hyperplasia of the internal theca, but no signs of activity in the granulosa.

Women with PCOS have a higher prevalence of insulin resistance[35], dyslipidemia, hypertension, and obesity, which represent components of the "metabolic syndrome" that confers increased risk of atherosclerotic cardiovascular disease. Patients should be screened and followed for these conditions as well as non-alcoholic fatty liver disease (recently renamed metabolic dysfunction-associated steatotic liver disease), sleep apnea, endometrial cancer, and mood disorders, depending upon risk assessment (see Fig. 70.14)[34,36,37]. Although obesity, insulin resistance, and hyperandrogenemia are interconnected components of PCOS[37], it is important to note that insulin resistance also frequently occurs in non-obese patients with PCOS[38]. *HAIR-AN syndrome* characterized by hyperandrogenemia (*HA*), insulin resistance (*IR*), and acanthosis nigricans (*AN*) is now considered to represent a more severe subtype of PCOS that is more likely to result in type 2 diabetes, hypertension, and cardiovascular disease[39].

PCOS is oftentimes familial, but it is clearly a heterogeneous disorder. Attempts to identify its genetic basis have led to several possible candidate genes that could play a role in insulin resistance and androgen production, including those which encode cytochrome (CYP) 17, CYP 11A1, and insulin receptor substrate 1[37].

Ovarian hyperthecosis

This rare entity, which occurs primarily in postmenopausal women, is characterized by severe hyperandrogenism and insulin resistance. It results from differentiation of ovarian interstitial cells into steroidogenically active luteinized theca cells that overproduce testosterone. Women typically present with acne and hirsutism and are often virilized (Fig. 70.15). Serum testosterone levels are greatly elevated and result in increased peripheral estrogen production, which can increase the risk of endometrial carcinoma.

Tumoral ovarian hirsutism

Androgen-secreting ovarian tumors (e.g. Sertoli–Leydig cell, Leydig cell, steroid cell, and granulosa cell tumors) account for <5% of all ovarian neoplasms and can result in markedly elevated serum testosterone levels. Patients typically present with sudden onset and rapid progression of virilization in addition to hirsutism.

Adrenal hirsutism

Adrenal hirsutism can also be of non-tumoral or tumoral origin. The most frequent non-tumoral etiology is non-classic (mild) congenital adrenal hyperplasia. Androgen-secreting adrenal tumors are much less common and typically present in older women with abrupt onset and rapid progression of hirsutism and virilization[23–25].

Non-tumoral adrenal hirsutism – adrenal hyperplasias

Congenital adrenal hyperplasia (CAH) refers to a group of autosomal recessive disorders caused by genetic defects in enzymes involved in adrenal hormone production (Fig. 70.16). The most common type (≥95%) is *21-hydroxylase deficiency (21-OHD)* due to *CYP21A2* mutations, which has a broad range of clinical manifestations depending on the underlying *CYP21A2* defect. The classic (severe) form of 21-OHD CAH occurs in ~1:15 000 live births worldwide, whereas the non-classic (milder) form has a prevalence of ~1:200 to 1:2000 and is more common in certain ethnic groups, including women of Ashkenazi Jewish, Middle Eastern, and Indian heritage[40–43]. Other rare forms of CAH include those caused by defects in 11β-hydroxylase and 3β-hydroxysteroid dehydrogenase.

Classic CAH presents during the first 2 weeks of life with dehydration and electrolyte abnormalities (salt wasting) due to aldosterone as well as cortisol deficiency in ~75% of affected neonates. Female neonates with both salt-wasting and simple virilizing forms of classic CAH typically have ambiguous genitalia, while male neonates may manifest with subtle hyperpigmentation of the genitals, flexural areas, and palmoplantar creases. The US and many other countries have universal newborn screening programs for classic CAH based on detection of elevated levels of 17-hydroxyprogesterone, the preferred substrate for 21-hydroxylase[40,41]. As a result, affected neonates rarely present to a dermatologist[40,41].

CLASSIFICATION OF TYPES OF HIRSUTISM		
Type	**Notable lab abnormalities**	**Clinical findings/comments**
Idiopathic (constitutional) hirsutism		
Idiopathic hirsutism	Normal to slightly elevated serum androgen levels (testosterone, DHEAS)	• Normal ovaries on ultrasound • Normal menses • No identifiable cause • Idiopathic form often associated with obesity
Familial hirsutism (see Fig. 70.12)	Normal serum androgen levels	
Ovarian hirsutism		
Polycystic ovary syndrome (PCOS)	Normal to ↑ testosterone Normal DHEAS ↓ SHBG LH:FSH > 3	Defined by the presence of ≥2 of the following (see Fig. 70.14): • Chronic anovulation • Clinical or laboratory evidence of hyperandrogenism • Polycystic ovaries on ultrasound
Ovarian hyperthecosis	↑↑ testosterone Normal DHEAS	• Post- > premenopausal • Progressive severe hirsutism, virilization
Androgen-secreting ovarian tumor	↑↑ testosterone Normal DHEAS	• Rapid onset and progression of hirsutism, often with virilization • Post- > premenopausal
Adrenal hirsutism		
Classic (severe) congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency	↑↑ 17-OH progesterone ↑ androstenedione ↓ cortisol	• Presents during the neonatal period • Ambiguous genitalia in girls • May develop signs and symptoms of PCOS in adolescence if poorly controlled
Non-classic (mild) congenital adrenal hyperplasia (NCAH) due to 21-hydroxylase deficiency	↑17-OH progesterone Normal to slightly ↓ cortisol	• Clinical findings overlap with those of PCOS • Increased prevalence in certain ethnic groups (e.g. Ashkenazi Jews)
Androgen-secreting adrenal tumor	↑ to ↑↑ testosterone ↑↑ DHEAS ↑ cortisol ↓ ACTH	• Rapid onset and progression of hirsutism, often with virilization (carcinoma > adenoma)
Endocrinopathies that may be associated with hirsutism*		
Cushing syndrome	↑ to ↑↑ ACTH (pituitary adenoma or ectopic ACTH [e.g. small cell lung cancer, carcinoid tumor]) ↓ ACTH (adrenal tumor, adrenal primary nodular hyperplasia) ↑ DHEAS ↑ cortisol	• More rapid appearance when due to an adrenal carcinoma or malignancy • Acne, central obesity, moon facies, buffalo hump, striae distensae, hypertension, impaired glucose tolerance
Acromegaly	↑ growth hormone ↑ insulin-like growth factor 1 (IGF-1)	• Coarse facial features, macrognathia, enlarged hands and feet, deepened voice, hyperhidrosis
Hyperprolactinemia	↑↑ prolactin	• Amenorrhea, galactorrhea, infertility
Thyroid disorders	↓ SHBG (hypothyroidism) Abnormal TSH	• Menstrual dysfunction • Thyroid dysfunction
Insulin resistance disorders (obesity-related and genetic syndromes)	↑ insulin (fasting) ↑ triglycerides Hyperglycemia	• Severe insulin resistance, impaired glucose tolerance • Acanthosis nigricans, acrochordons, virilization • Amenorrhea, infertility • Often polycystic ovaries on ultrasound • Metabolic syndrome
Drug-induced hirsutism		
• Exogenous androgens (topical, oral, injections) (e.g. danazol, testosterone, DHEA) • Anabolic steroids • Corticotropin (ACTH) • Glucocorticoids • Metyrapone • Progestins • Valproic acid		• Also consider the use of topical androgens by a patient's partner
*Rarely present with isolated hirsutism.		

Table 70.6 Classification of types of hirsutism. More common entities are in **bold** font. Patients with liver disease can have a decrease in sex hormone binding globulin (SHBG), and a subsequent increase in free testosterone, which may exacerbate other causes of hirsutism. There is also conversion of androgens (e.g. Δ-4-androstenedione > testosterone) into estrogens in the ovaries and peripheral sites (adipose tissue, liver). In theory, a reduction in this conversion could lead to an increase in circulating androgens. ACTH, adrenocorticotropic hormone; DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone.

Non-classic CAH (NCAH) presents postnatally, typically with onset during childhood or early adulthood; 17-hydroxyprogesterone levels are elevated but not high enough to be detected via newborn screening. Hirsutism represents the only manifestation in ~40%–60% of women with NCAH, which accounts for ~4% of all women with hirsutism. Premature pubarche is the most common presentation in children with NCAH, whereas female adolescents and women often develop acne, androgenic alopecia, irregular menses, and infertility as well as hirsutism.

Polycystic ovarian morphology may also be observed in NCAH; although virilization (Table 70.7) is more frequently evident in women with NCAH than in those with PCOS, measuring the serum 17-hydroxyprogesterone level is typically required to distinguish these two entities. Boys and men with NCAH less frequently seek medical attention for signs of androgen excess (e.g. early beard growth, large phallus)[40,41].

Tumoral adrenal hirsutism

Virilizing adrenal adenomas and carcinomas most often develop in postmenopausal women and may result in rapid onset and progression of hirsutism and virilization. Androgen-secreting carcinomas are more common than adenomas and typically produce both androgens and cortisol. Clinical findings may also include acne, androgenetic alopecia, amenorrhea, and features of Cushing syndrome (see below). Serum

Fig. 70.12 Familial hirsutism. Prolongation of the preauricular hair implantation line with terminal hairs of the lateral lower face and neck.

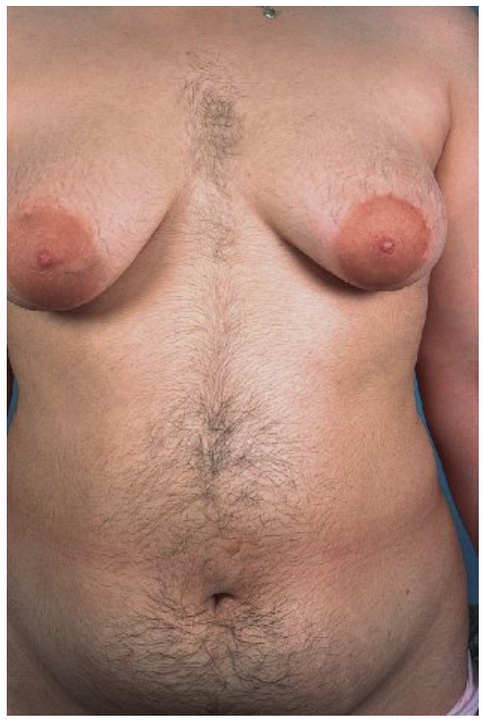

Fig. 70.13 Hirsutism in a young woman with polycystic ovary syndrome. Both lateral and central patterns are present.

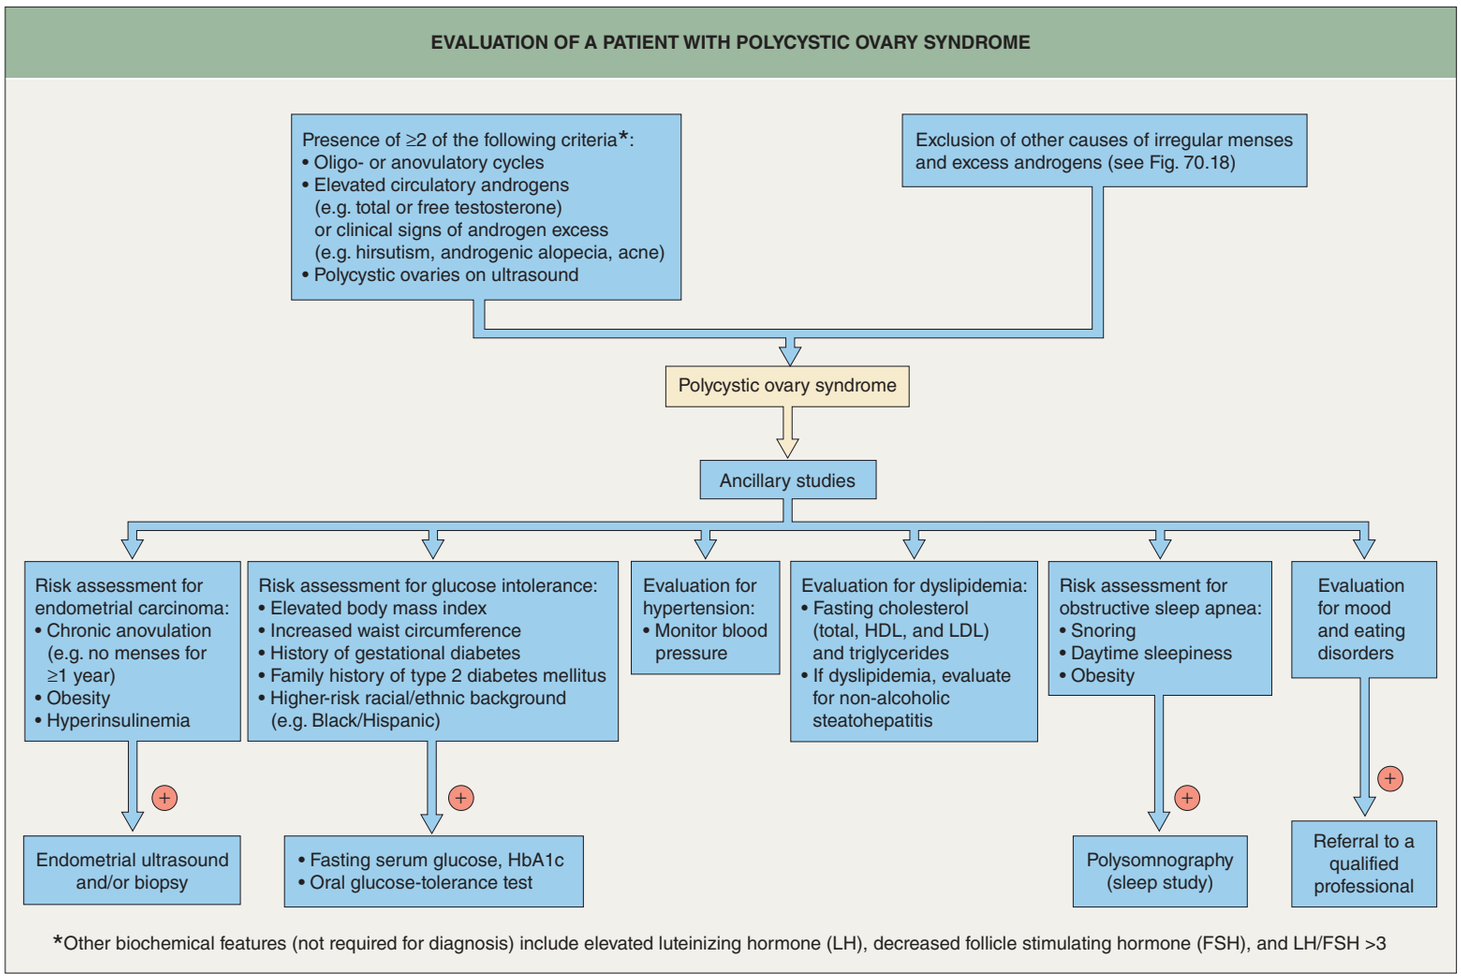

Fig. 70.14 Evaluation of a patient with polycystic ovary syndrome. Hb, hemoglobin; HDL, high-density lipoprotein; LDL, low-density lipoprotein. *Adapted from Ehrman DA. Polycystic ovary syndrome. N Engl J Med 2005;352:1223–36.*

levels of testosterone and DHEAS levels are markedly elevated, and serum cortisol may also be increased.

Other endocrinopathies associated with hirsutism

Other endocrinopathies in which women may develop hirsutism together with disease-specific manifestations include Cushing syndrome, hyperprolactinemia, acromegaly, thyroid disorders, and insulin resistance disorders[28]. Pregnant women may also present with hirsutism as a result of ovarian and placental androgen production.

Hypercortisolism (Cushing syndrome)

Cushing syndrome may be associated with either high plasma ACTH levels (pituitary hyperproduction or "ectopic ACTH syndrome") or a nearly complete lack thereof (adrenal primary nodular hyperplasia, adrenal adenoma, or adrenal carcinoma). All patients have an increase in plasma cortisol, which is the cause of the major clinical features: central obesity with "moon facies" and "buffalo hump", hypertension, glucose intolerance, purple striae, and ecchymoses. Patients with adrenal hyperplasia (usually due to ACTH hyperstimulation by a pituitary adenoma) or adrenal adenomas typically have an insidious onset of symptoms, but with an adrenal carcinoma or ectopic ACTH production by a malignant tumor, manifestations appear more rapidly. If there is significant production of androgens, which is not the norm for adrenal adenomas, virilization with hirsutism will be present in addition to the typical manifestations of Cushing syndrome.

Hyperprolactinemia

Hirsutism represents a rare manifestation of hyperprolactinemia, which is most often caused by pituitary adenomas and drugs (e.g. dopamine antagonists). This etiology of hirsutism should be considered in women <50 years of age who present with galactorrhea together with oligomenorrhea, amenorrhea, or infertility ("amenorrhea–galactorrhea syndrome").

Acromegaly

Acromegaly results from excess secretion of growth hormone (GH), most commonly by a pituitary adenoma. The clinical features reflect elevated serum concentrations of both GH and insulin-like growth factor 1 (IGF-1), which is GH dependent. Long-term excess of GH

DIFFERENCES BETWEEN DEFEMINIZATION AND VIRILIZATION	
Defeminization	**Virilization**
• Acne • Female pattern hair loss • Menstrual alterations (e.g. oligomenorrhea) • Breast atrophy and loss of female body contours • Decreased rugosity of the vaginal columns • Infertility	• Hirsutism • Male pattern hair loss • Amenorrhea • Muscle mass increased • Clitoromegaly • Coarsening of the voice

Table 70.7 Differences between defeminization and virilization.

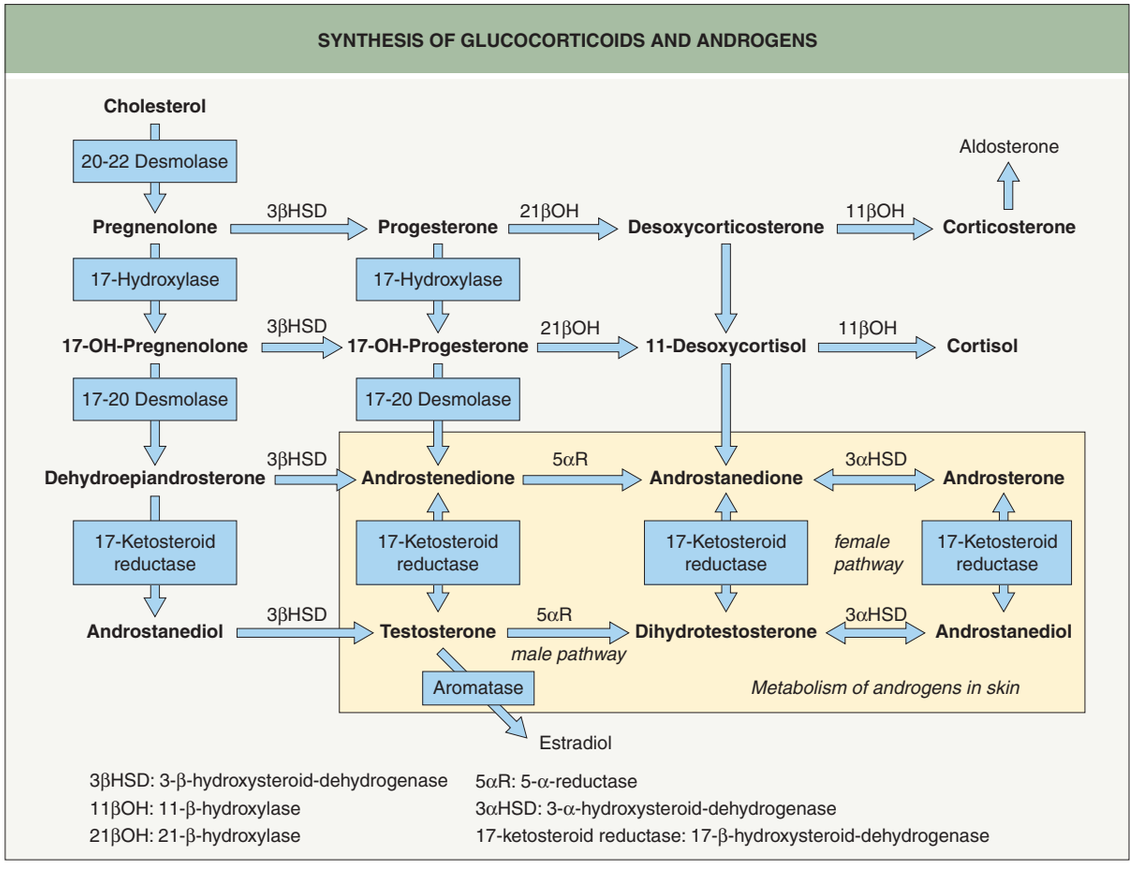

Fig. 70.16 Synthesis of glucocorticoids and androgens. The most common cause of congenital adrenal hyperplasia is 21-hydroxylase deficiency. This leads to an accumulation of 17-OH-progesterone.

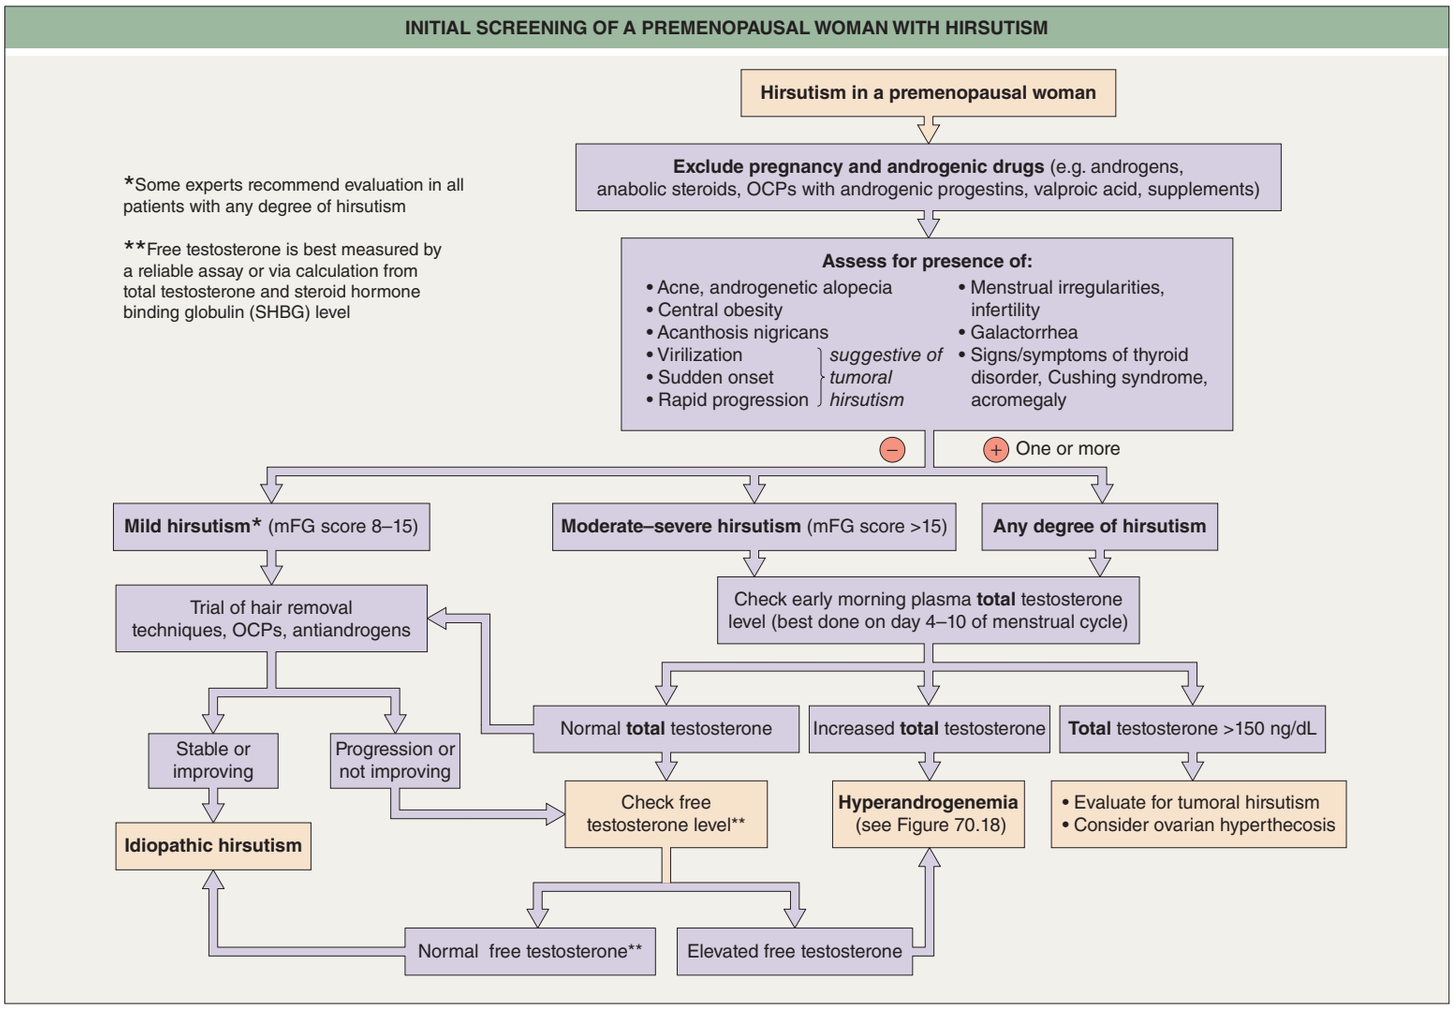

Fig. 70.17 Initial screening of a premenopausal woman with hirsutism. mFG, modified Ferriman and Gallwey; OCPs, oral contraceptives.

and IGF-1 results in overgrowth of many tissues and organs, including skin thickening as well as the classic findings of enlarged hands and feet, macrognathia, and macroglossia. Additional cutaneous manifestations can include hirsutism, hypertrichosis, hyperhidrosis, acanthosis nigricans, acrochordons, and cutis verticis gyrata.

Thyroid disorders

Thyroid dysfunction interferes with sex hormone metabolism and can result in irregular menstruation. Hypothyroidism can also cause cystic ovarian changes and decreased levels of sex hormone-binding globulin (SHBG), which increases the amount of free circulating testosterone.

Insulin-resistance disorders

Disorders of severe insulin resistance (e.g. obesity-related, insulin receptor mutations [*type A syndrome*], anti-insulin receptor antibodies [*type B syndrome*]) are often associated with hyperandrogenism, hirsutism, and even virilization[44,45]. Marked hyperinsulinemia results in ovarian hyperandrogenism, presumably via receptors for insulin and IGF-1 on ovarian theca cells. Insulin also decreases SHBG levels, thereby increasing the amount of free circulating testosterone. Ovaries often show a polycystic pattern on ultrasound.

Drug-induced hirsutism

Several drugs have been associated with the development of hirsutism (see Table 70.6). Identifying such culprit drugs and stopping them will typically result in reversal of the hirsutism.

Diagnosis

Hirsutism is a clinical diagnosis and a potential indicator of a hyperandrogenic disorder that may require treatment and have associated comorbidities such as metabolic syndrome or fertility issues. In a premenopausal woman with hirsutism, the mFG score (see Fig. 70.11) should be determined and assessment for associated findings initiated (Fig. 70.17). Additional evaluation of women with hyperandrogenemia for signs of PCOS are outlined in Figs. 70.18 and 70.14.

It is important to inquire about the age of onset (premenopausal vs postmenopausal), progression (rapid vs gradual), and emotional and psychosocial impact of the hirsutism. Patients should also be asked about their menstrual history (e.g. oligo- or amenorrhea), medications (see Table 70.6), comorbidities (e.g. insulin resistance disorders), ethnicity, and family history. Physical examination should determine if true hirsutism (versus hypertrichosis) is present as well as its severity (see Fig. 70.11). In addition, patients should be evaluated for additional findings of hyperandrogenism (e.g. acne, androgenic alopecia), virilization (see Table 70.7), acanthosis nigricans, central obesity, and manifestations of other endocrinopathies associated with hirsutism (see Table 70.6). An abrupt onset and rapid progression of hirsutism or the presence of virilization should raise suspicion for a more serious cause of androgen excess (e.g. an androgen-secreting tumor). Premenopausal women with hirsutism are most likely to have PCOS, idiopathic hirsutism or NCAH, whereas postmenopausal women with new onset hirsutism are more likely to have an androgen-secreting tumor or ovarian hyperthecosis.

In a *premenopausal* woman with hirsutism, serum total testosterone is recommended as the initial biochemical study[28]. Additional considerations include measuring the serum 17-hydroxyprogesterone level (e.g. in women at higher risk of NCAH based on ethnicity or family history) and transvaginal pelvic ultrasonography to assess for PCOS. Additional evaluation based upon these results and the clinical presentation are outlined in Figs. 70.17 and 70.18. Of note, in women taking an oral contraceptive (OCP) or spironolactone, the results of laboratory testing

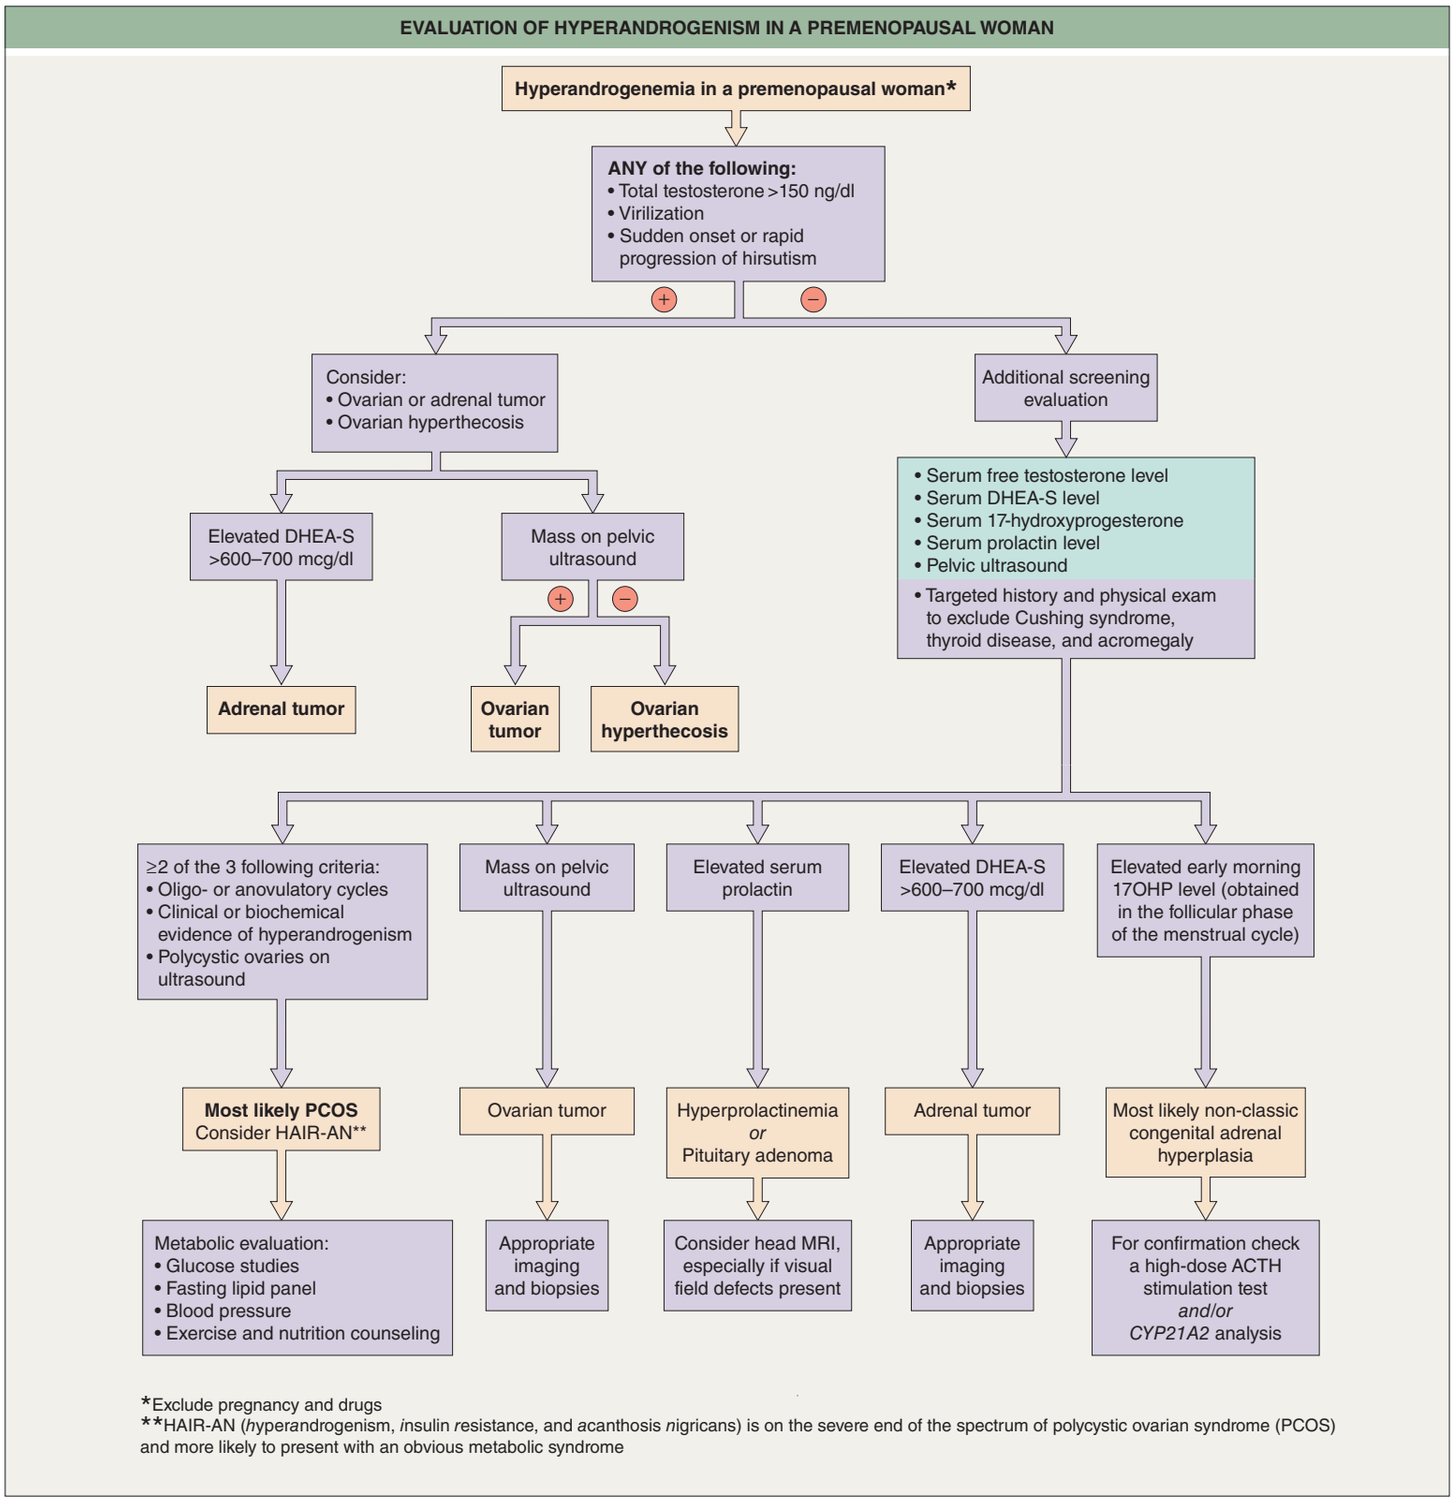

Fig. 70.18 Evaluation of hyperandrogenemia in a premenopausal woman.

will not be reliable. If an evaluation is desired, then discontinuation of the medications for at least 8–12 weeks is recommended.

The most useful biochemical tests to evaluate a *postmenopausal* woman with hirsutism are serum total testosterone and DHEAS levels. Serum total testosterone levels >150 ng/dl are suggestive of an androgen-secreting tumor, with higher testosterone levels typically associated with an ovarian source and DHEAS >700 mcg/dl suggestive of an adrenal source. Hyperandrogenism due to PCOS or NCAH can persist into menopause, and a serum 17-hydroxyprogesterone level should be considered if not evaluated previously. Other laboratory testing depends upon the presence of signs or symptoms suggestive of another endocrinopathy (see Table 70.6).

Treatment

The impact of hirsutism on a woman's quality of life should be assessed and regardless of the mFG score, treatment should be initiated if it is causing distress to the patient ("patient-important" hirsutism)[28]. Management of premenopausal and postmenopausal hirsutism involves a combination of systemic pharmacologic therapies (Table 70.8) and direct hair removal methods, both of which should be offered to women with "patient-important" hirsutism. Bilateral oophorectomy can be considered in the management of ovarian hyperthecosis. In the case of ovarian and adrenal tumors, surgical intervention is usually required.

TREATMENT OF HIRSUTISM AND HYPERANDROGENISM – SYSTEMIC AGENTS AND CLINICAL SCENARIOS		
Systemic agents		
Combined oral contraceptives (cOCPs)* • All cOCPs appear to have similar effectiveness for treating hirsutism • For women at higher risk for VTE (e.g. obesity, age ≥40 years), select a cOCP with the lowest effective dose of ethinyl estradiol (usually 20 mcg) and a low-risk progestin (e.g. norethindrone, norgestimate) **Antiandrogens**† • Spironolactone 100–200 mg/day (usually given in divided doses, twice daily; see Ch. 36) • Cyproterone acetate 50–100 mg/day (given on days 5–15 of menstrual cycle)‡ • Finasteride 2.5–5 mg/day • Bicalutamide 50 mg/day (occasional hepatotoxicity) • Flutamide (not recommended because of hepatotoxicity risk) **Gonadotropin-releasing hormone (GnRH) agonists** (risk of severe estrogen deficiency; *typically reserved for severe hirsutism [e.g. ovarian hyperthecosis] that is unresponsive to combined OCPs + antiandrogen therapy*) **Insulin-lowering agents** – metformin > thiazolidinediones (improve metabolic syndrome and reproductive function but not useful as monotherapy for hirsutism) **Glucocorticoids** – e.g. low-dose hydrocortisone, prednisone, or dexamethasone (*second-line treatment for NCAH*)		
Clinical scenarios and recommended treatment¶		
Premenopausal female	**First-line**§: cOCP **Second-line**: cOCP + spironolactone or cyproterone acetate‡	**Severe or refractory:** finasteride or GnRH agonist plus cOCP or other contraceptive method
Postmenopausal female	**First-line**: spironolactone or cyproterone acetate‡	
NCAH	**First-line:** cOCP ± spironolactone or cyproterone acetate‡ **Second-line or if seeking ovulation induction**: glucocorticoid	

*Avoid in women with a history of VTE, inherited thrombophilia, smoking (if age >35 years), migraine with aura, or an estrogen-dependent neoplasm.
†Because of teratogenicity, not recommended as monotherapy in sexually active women of reproductive age unless a reliable contraceptive method is used.
‡CPA is not available in the United States; ethinylestradiol 20–35 mg is also typically given on days 5–25 of the menstrual cycle in premenopausal women.
¶A waiting period of 6 months is recommended after initiating a treatment and before adding or changing medications.
§In patients with severe hirsutism causing emotional distress and/or previous history of treatment failure with combined OCP, consider first-line treatment with a cOCP + antiandrogen.

Table 70.8 Treatment of hirsutism and hyperandrogenism – systemic agents and clinical scenarios. For hirsute women with obesity, including those with polycystic ovary syndrome (PCOS), lifestyle changes (e.g. diet, exercise) are also recommended. NCAH, non-classic congenital adrenal hyperplasia; VTE, venous thromboembolism.

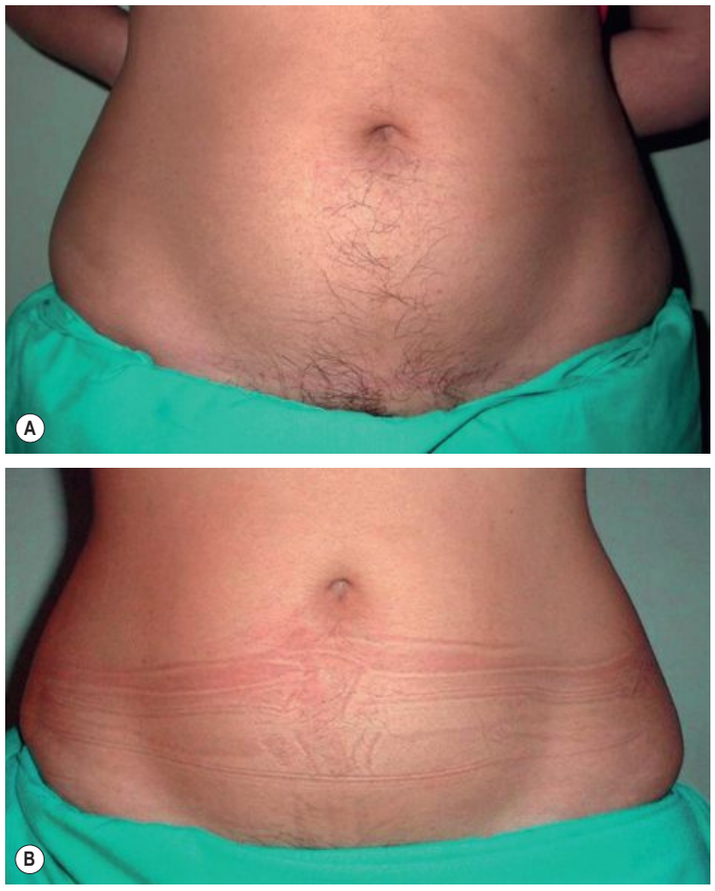

Fig. 70.19 Hirsutism before (A) and after treatment (B) with antiandrogen therapy. This patient had the SAHA (*s*eborrhea, *a*cne, *h*irsutism, and *a*lopecia) syndrome and achieved clinical improvement in hirsutism after one year of antiandrogen therapy.

Systemic therapy

The 2018 Endocrine Society clinical guidelines[28] recommend initial treatment with systemic pharmacologic therapy in *premenopausal* "patient-important" hirsutism that persists despite cosmetic measures. They suggest a combined estrogen–progesterone OCP as first-line treatment, as long as fertility is not immediately desired and there are no contraindications (e.g. history of venous thromboembolism [VTE], inherited thrombophilia, smoking if age >35 years, migraine with aura, estrogen-dependent neoplasm). Combined OCPs (cOCPs) suppress LH secretion and thus ovarian androgen production. They also stimulate the production of SHBG, which results in a decrease of circulating free androgen levels. The Endocrine Society guidelines do not recommend one cOCP over another for treating hirsutism based on a meta-analysis of effectiveness[28,46,47]. Although cOCPs containing antiandrogenic progestins (e.g. drospirenone, cyproterone acetate [not available in the US]) have been shown in some studies to lower mFG scores slightly more than other combined OCPs, the difference is not thought to be clinically important[46]. A cOCP containing the lowest effective dose of ethinyl estradiol (usually 20 mcg) and a low VTE-risk progestin (e.g. norgestimate, norethindrone) is recommended in women at higher risk for VTE (e.g. obesity, age ≥40 years)[28]. Although levonorgestrel is associated with a low VTE risk, this progestin is the most androgenic and may have adverse metabolic effects, making it less suitable for patients with PCOS[28].

If the clinical response is not achieved after 6 months of a cOCP, then an antiandrogen (e.g. spironolactone) can be added (see Ch. 36). A trial of at least 6 months is suggested before making dose adjustments or medication changes (Fig. 70.19)[28]. Antiandrogen monotherapy is not advised unless the patient is using adequate contraception, given the risk of impact on a developing fetus. If the hirsutism is severe or previous use of a cOCP has been unsuccessful, then initial therapy with both a cOCP and antiandrogen can be considered.

Additional systemic treatment options for hirsutism are summarized in Table 70.8. Flutamide and bicalutamide are nonsteroidal androgen receptor blockers that are approved for the treatment of prostate cancer. Although both of these agents have been utilized for the treatment of hirsutism, flutamide is not recommended for this indication because of its higher potential for hepatotoxicity. Insulin-lowering

medications (e.g. metformin) have not shown efficacy as monotherapy for hirsutism[28]. Management of PCOS comorbidities are outlined in Fig. 70.14. Lifestyle modifications (e.g. diet, exercise) are recommended for all hirsute women with obesity[28,31]. Lastly, for women with NCAH, glucocorticoids may be utilized to treat hirsutism that does not respond adequately to a cOCP ± antiandrogen or to induce ovulation.

In *postmenopausal* women with "patient-important" hirsutism and no evidence of an androgen-secreting tumor, treatment typically includes an antiandrogen plus direct hair removal methods (see Table 70.8).

Topical therapy

Topical antiandrogen therapy (e.g. canrenone [active metabolite of spironolactone], finasteride) is generally not recommended for treatment of hirsutism because of limited evidence of efficacy. A newer topical antiandrogen, clascoterone, has been approved for the treatment of acne but has yet to be studied for hirsutism.

Eflornithine HCL 13.9% cream is FDA-approved for the reduction of unwanted facial hair in women; it was discontinued by the original manufacturer in 2023. It irreversibly inhibits ornithine decarboxylase, an enzyme that catalyzes the rate-limiting step in follicular polyamine synthesis, which is necessary for hair growth. In a randomized vehicle-controlled study in 594 women, it was shown to reduce hair length and mass by ~25%[48]. Because eflornithine HCL slows hair growth rather than removes hair, it is best used and more effective in conjunction with other direct hair removal methods (e.g. laser or intense pulsed light [IPL])[49]. Results can take up to 8 weeks to become evident, and hair gradually returns to pretreatment levels upon discontinuation.

Direct hair removal methods

Direct hair removal methods can either remove a portion of the hair from above the skin's surface (depilation) or the entire hair shaft (epilation)[50]. Epilation methods may result in temporary or potentially permanent hair reduction. Each hair removal option has advantages and disadvantages[50].

Depilation methods include trimming, shaving, dermaplaning, and chemical depilatories. Shaving is easy and inexpensive but must be done frequently and can cause skin irritation. Contrary to popular belief, shaving does not change the texture, color, or growth rate of hair. It does, however, create a blunt tip upon regrowth that can give the illusion of thicker hair. Chemical depilatory agents, which dissolve the hair shafts via breakage of disulfide bonds, can be used for large areas but often cause skin irritation.

The results of epilation typically last longer than those of depilation. Tweezing, threading, waxing, and sugaring are effective temporary epilation techniques, but they are painful and often impractical for larger areas. Potentially permanent options include electrolysis and photoepilation utilizing a laser or IPL. Although effective, electrolysis is painful, time-consuming, and not practical for treating large areas (see Ch. 140). Photoepilation, which can treat larger areas in a shorter amount of time, represents the preferred option for long-term hair removal[27]. It utilizes pulses of light absorbed by melanin to destroy pigmented terminal hair follicles through thermal damage. Photoepilation systems include alexandrite, diode, and Nd:YAG lasers and various IPL sources, which are selected based upon the patient's skin and hair color (see Ch. 137). Clinical trials have shown ~40%–80% hair reduction, depending upon the device used and the number of treatments provided[51,52]. Photoepilation is ineffective for blond, white, or gray hairs and can be costly and painful, with potential side effects including pigmentary changes and rarely scarring or paradoxical hypertrichosis[19].

Additional figures and tables on Abraham's classification of hirsutism, and Methods to reduce unwanted hair, available in our eBook (see inside front cover for access code).

eFig. 70.5 "Pseudo"-hypertrichosis occurring in an umbilical pilonidal sinus (cyst). Localized "pseudo"-hypertrichosis can occur within a pilonidal sinus (cyst), usually located within the gluteal cleft and rarely elsewhere, e.g. umbilicus, as seen here (**A**). However, hairs are easily extracted (**B**). *Courtesy Karynne O. Duncan MD*.

eFig. 70.6 The modified Ferriman–Gallwey (mFG) hirsutism scoring system – nine sites of assessment. The modified Ferriman and Gallwey score is based upon the sum of the values (graded from 0 to 4 points) for each of the nine body areas illustrated as follows: 0 points (no terminal hairs); 1 point (minimal terminal hairs); 2 points (hair growth is more than minimal but not yet that of a man); 3 points (hair growth is that of a man who is not very hairy); and 4 points (equivalent to a very hairy man). Total mFG scores that define hirsutism in reproductive-aged women vary depending upon race/ethnicity and are as follows: US and United Kingdom White or Black women, ≥8 (scores between 8 and 15 generally considered mild, 16–25 moderate, and >25 severe hirsutism); Mediterranean, Middle Eastern and Hispanic women, >9–10; South American women, ≥6; and Asian women, ranging from ≥2 for Han Chinese women to ≥7 for Southern Chinese women.

METHODS TO REDUCE UNWANTED HAIR		
Camouflage	**Direct hair removal methods**	**Retardation of hair growth**
• Lightening of hair with bleaching product	***Depilation***	• Eflornithine HCL (13.9%) cream (best used in conjunction with other hair removal techniques); discontinued by the original manufacturer
	Chemical • Barium sulfate creams* • Calcium thioglycolate creams ***Mechanical*** • Trimming • Shaving • Dermaplaning	
	Epilation	
	• Tweezing • Waxing • Threading • Sugaring • Electrolysis† • Thermolysis† • Lasers (e.g. Nd:YAG, diode, alexandrite) or IPL	
*More effective than calcium thioglycolate but more irritating and odiferous. †Potential for permanent hair removal.		

eTable 70.2 Methods to reduce unwanted hair. The results of epilation typically last longer than those of depilation. Chemical depilatories work by dissolving hair shafts via breakage of disulfide bonds. IPL, intense pulsed light.

ANATOMY

Key features

- Nail matrix → nail plate production
  proximal matrix → dorsal nail plate
  distal matrix (lunula) → ventral nail plate
- Proximal nail fold → nail matrix protection
- Nail bed and hyponychium → nail plate adhesion and distal detachment
- Nail growth rate: fingernails: 3 mm/month; toenails: 1 mm/month

The nail plate is a fully keratinized structure produced by the germinative epithelium of the nail matrix. As it grows, the nail plate emerges from the proximal nail fold and progresses distally, lying across and strictly adhering to the nail bed (Fig. 71.1). As the nail plate approaches the tip of the digit, it detaches from the underlying tissues, forming the hyponychium. Proximally and laterally, the nail plate is surrounded by the nail folds. The proximal nail fold consists of two layers of epithelium – a dorsal layer, which is the distal continuation of the skin of the dorsum of the digit, and a ventral layer, which is continuous with the nail matrix.

The nail matrix is responsible for the production of the nail plate and consists of an epithelium that keratinizes without the formation of a granular layer. Nail matrix keratinization occurs along an oblique axis, reflecting the upward and distal movement of cells during the process of maturation and differentiation[1]. For this reason, the proximal portion of the nail matrix produces the dorsal portion of the nail plate, while the distal matrix is responsible for the production of the ventral nail plate (see Fig. 149.2). The distal portion of the nail matrix is visible through the transparent nail plate as a white, distally convex half-moon known as the lunula. The matrix contains melanocytes that are normally quiescent; however, they may become activated and synthesize melanin, which is transferred to the surrounding keratinocytes. Distal migration of melanin-containing keratinocytes then gives rise to a hyperpigmented nail plate (melanonychia).

Nail plate production occurs continuously, proceeding from the 15th week of embryonic life until death. Under normal conditions, the mean growth rate of a fingernail is 3 mm/month and that of a toenail is 1 mm/month. Nail growth rate can be influenced by several factors, including age, systemic diseases, and medications.

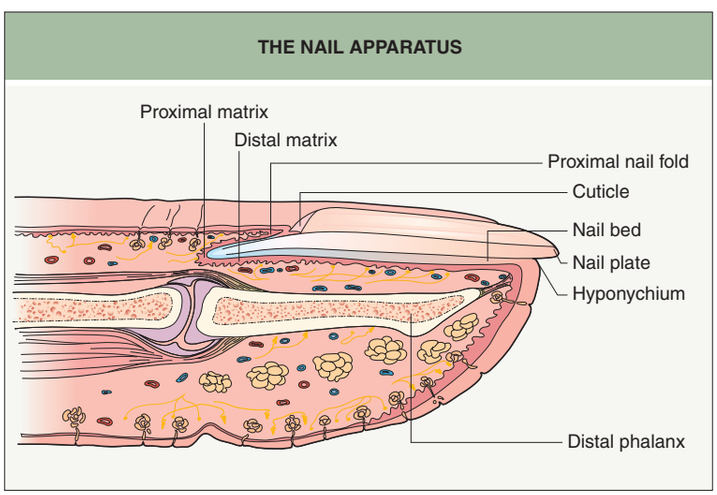

Fig. 71.1 Schematic drawing of the nail apparatus in longitudinal section. For additional details, see Figs. 149.1 & 149.2.

NAIL SIGNS

The clinical signs of various nail disorders depend upon the component of the nail apparatus that has been affected: nail plate alterations are due to matrix damage whereas nail plate detachment and/or uplifting arise from dysfunction of the hyponychium or nail bed (Table 71.1). Paronychia represents inflammation of the nail fold, which can lead to secondary matrix damage. The nail plate can develop a wide range of structural changes, from thickening to fissuring to atrophy, in addition to discoloration (Fig. 71.2).

Nail signs can be schematically divided into three major categories:

- signs due to abnormal nail matrix function
- signs due to nail bed disorders
- signs due to deposition of pigment within the nail plate.

Nail Signs Due to Abnormal Nail Matrix Function

Beau's lines

Key features

- Transverse depressions that are more evident in the central portion of the nail plate
- Most often due to trauma
- Involvement of multiple digits suggests a systemic cause

CORRELATION OF NAIL FINDINGS WITH ANATOMIC SITE OF NAIL DAMAGE	
Affected site	**Clinical manifestation**
Proximal matrix	Beau's lines Pitting Longitudinal ridging Longitudinal fissuring Trachyonychia
Distal matrix	True leukonychia
Proximal + distal matrix	Onychomadesis Koilonychia Nail plate thinning Onychauxis (nail plate hypertrophy or thickening)
Nail bed	Onycholysis Subungual hyperkeratosis Apparent leukonychia Splinter hemorrhages

Table 71.1 Correlation of nail findings with anatomic site of nail damage.

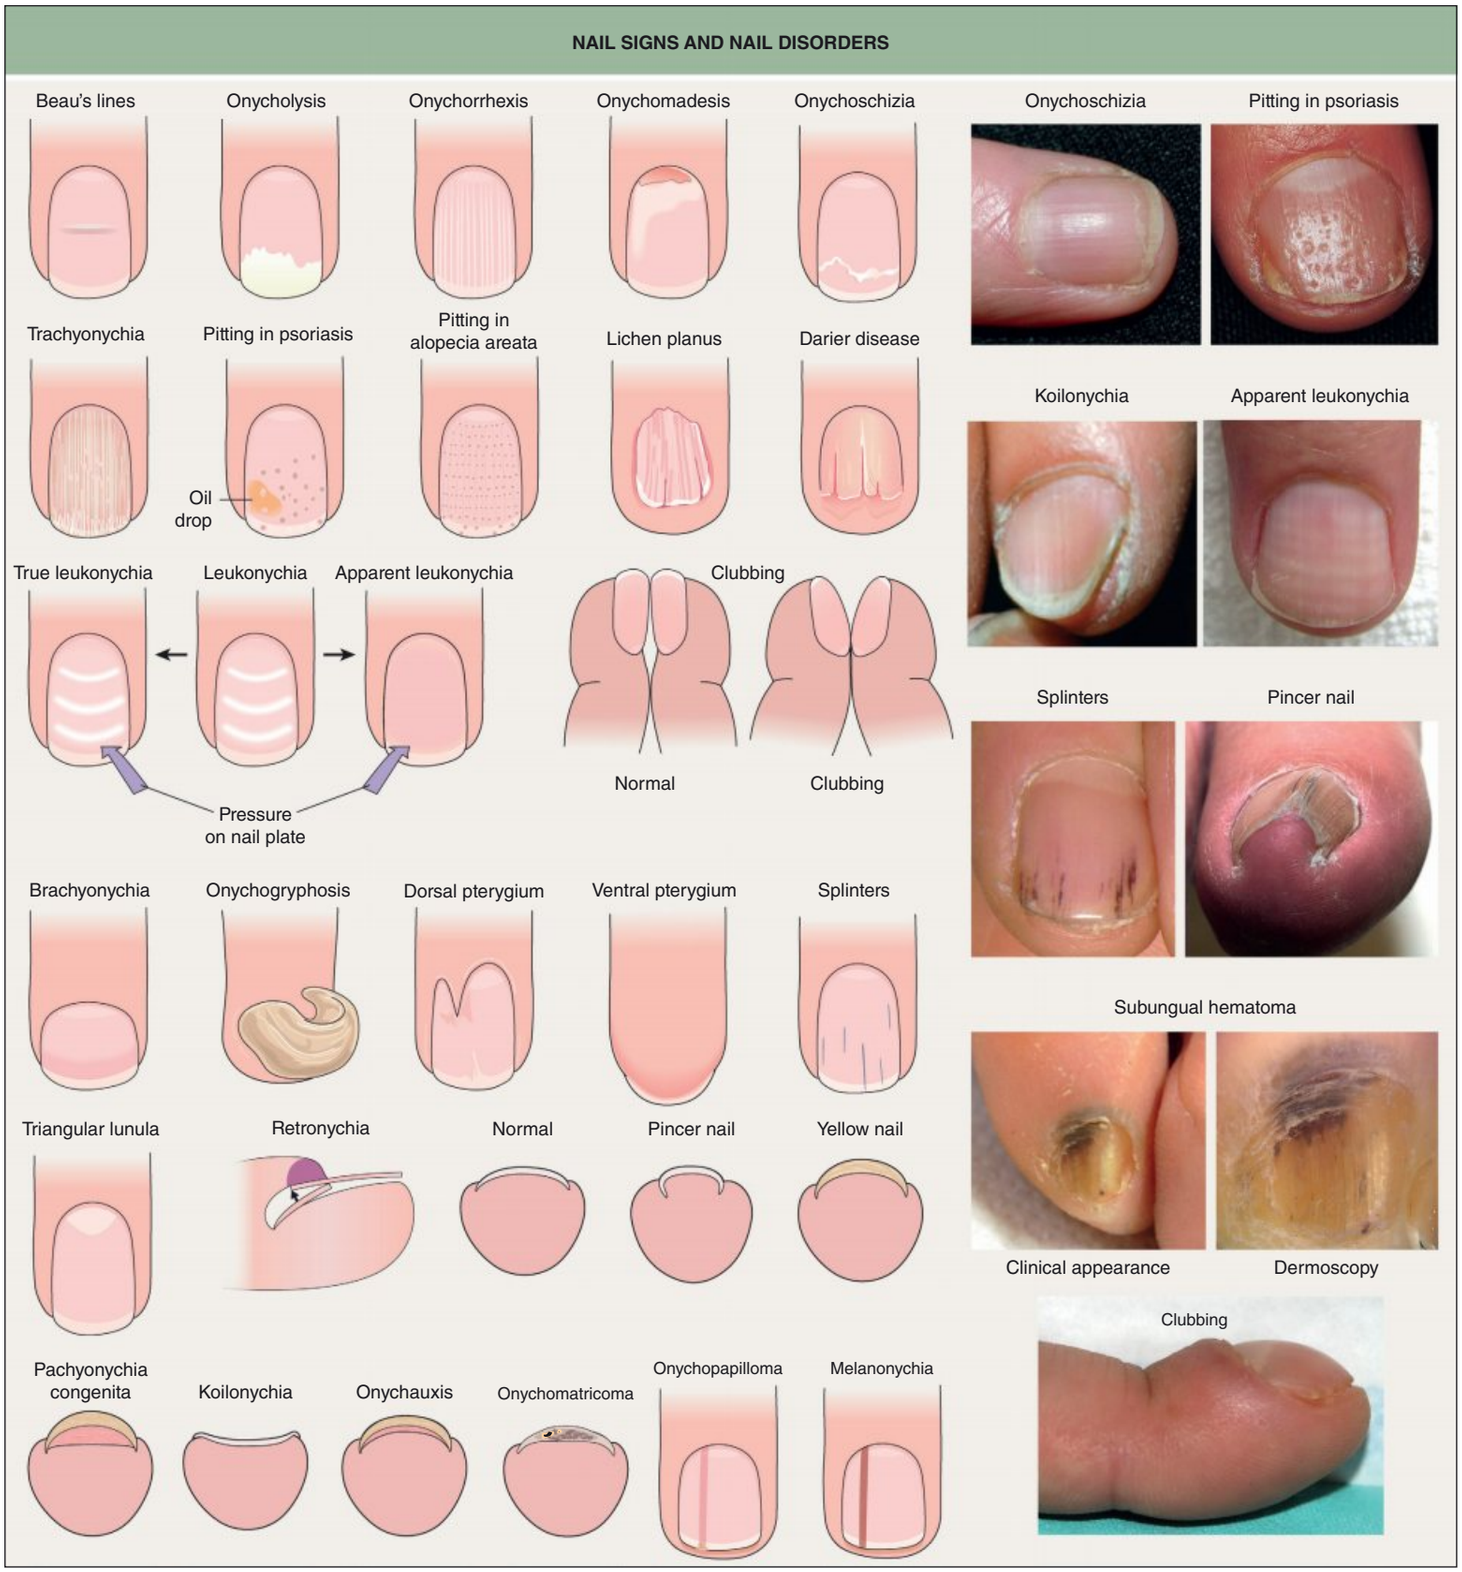

Fig. 71.2 Nail signs and nail disorders. In *apparent* leukonychia (e.g. Muehrcke's lines due to hypoalbuminemia and presumed secondary edema), the transverse white lines disappear with pressure, but not in *true* leukonychia (e.g. Mees' lines due to parakeratosis). Terry's nails and half-and-half nails are additional examples of apparent leukonychia. Dermoscopy of a subungual hematoma shows small red longitudinal splinter hemorrhages and dark purple pigmentation under the proximal nail fold and nail plate due to accumulated blood, with a typical fringed distal edge. *Photographs courtesy Jean L. Bolognia, MD; Leonard J. Swinyer, MD; Kalman Watsky, MD; and authors.*

First described by Beau in 1846, these transverse depressions of the nail plate surface result from a temporary interruption of the mitotic activity of the proximal nail matrix. The depth of the depression indicates the extent of the damage within the matrix; the width of the depression indicates the duration of the insult. Beau's lines migrate distally along with nail plate growth, with multiple lines indicating repeated damage (Fig. 71.3). Most commonly, Beau's lines are caused by mechanical trauma (e.g. manicures, onychotillomania) or dermatologic disease of the proximal nail fold (e.g. eczema, chronic paronychia). The presence of Beau's lines at the same level in all nails suggests a systemic cause (e.g. severe or febrile illness, cytotoxic drugs, erythroderma).

Fig. 71.3 Beau's lines. Multiple transverse depressions due to repeated traumatic insults to the proximal nail matrix from aggressive manicures. The depressions are more evident in the central portion of the nail plate.

Fig. 71.4 Onychomadesis of the fingernails following hand-foot-and-mouth disease due to coxsackievirus A6 infection.

Onychomadesis (nail shedding)

Key features

- Proximal detachment of the nail that is most often due to trauma
- Similar involvement of multiple digits suggests a systemic cause

The term *onychomadesis* describes the detachment of the nail plate from the proximal nail fold and is due to a severe insult that produces a complete arrest of nail matrix activity. Onychomadesis appears as a sulcus that replaces the proximal nail plate. The causes of onychomadesis include those that produce Beau's lines (see above)[2]. Retrospectively, it can indicate a previous infection, most typically hand-foot-and-mouth disease (Fig. 71.4), but also scarlet fever or Kawasaki disease. In addition, onychomadesis may appear in the setting of pemphigus vulgaris or Stevens–Johnson syndrome.

Pitting

Pitting describes the presence of punctate depressions of the nail plate surface that can have an irregular outline (see Fig. 71.2). Pits are due to foci of abnormal keratinization of the proximal nail matrix which result in clusters of parakeratotic cells within the dorsal nail plate. In the proximal plate, these clusters appear as nontransparent collections of scales. Over time, shedding of the parakeratotic cells leads to the appearance of pits. These pits migrate distally with nail growth.

Diseases that produce nail pitting include psoriasis, alopecia areata, and eczema. Fig. 71.2 demonstrates how patterns of the pits can differ. Psoriatic pits vary in size and depth and have an irregular distribution, whereas in patients with alopecia areata, the pits are small, superficial, and geometrically distributed.

Fig. 71.5 Trachyonychia (twenty-nail dystrophy). The nails appear to be sandpapered in a longitudinal direction.

Onychorrhexis

Onychorrhexis is characterized by longitudinal ridging and fissuring of the nail plate (see Fig. 71.2). The depth of the ridges can vary as can the extent of involvement, i.e. a portion versus the entire nail plate, and one or several nails may be involved. It is often associated with nail thinning, indicating damage to the nail matrix. Diseases commonly responsible for onychorrhexis include lichen planus (several nails), conditions that lead to impaired vascular supply, trauma, and tumors that compress the nail matrix (typically a single nail). The differential diagnosis includes the common phenomenon of increased longitudinal ridging of the nail plate that is age-related.

Trachyonychia (twenty-nail dystrophy, sandpapered nails)

Key features

- Nail roughness
- Associated with thinning, koilonychia, and cuticular hyperkeratosis
- Conditions that may cause trachyonychia include alopecia areata (common), lichen planus (uncommon), psoriasis (rare), and eczema (very rare)

Trachyonychia is a specific nail plate surface abnormality characterized by diffuse homogeneous roughness (Fig. 71.5)[3]. In most patients, the affected nails are opaque, lusterless, and rough; the nail plate surface has longitudinal ridging due to fine superficial striations distributed in a regular, parallel pattern (sandpapered nails). A less common variant, referred to as shiny trachyonychia, is characterized by multiple small punctate depressions distributed in a geometric pattern within parallel, longitudinal lines. Trachyonychia is a reflection of mild, diffuse damage to the proximal nail matrix by inflammatory disorders (see above). It can also be a presenting sign of systemic AL amyloidosis.

True leukonychia

Key features

- White opaque discoloration that is punctate, striate, or diffuse
- Punctate and striate leukonychia most often due to trauma to the distal nail matrix
- Needs to be distinguished from *apparent* leukonychia (nail bed discoloration that fades with pressure) and friable *pseudo-leukonychia* due to superficial white onychomycosis or nail fragility

Fig. 71.6 True leukonychia – diffuse variant. The nail plate is completely or almost completely opaque and white. It may be inherited due to mutations in *PLCD1*, *GJA1* (also keratoderma and hypotrichosis), or *GJB2* (also deafness, keratoderma and knuckle pads); the latter two genes encode connexins 43 and 26, respectively.

The nail plate has a normal surface but loses its transparency and looks white because of the presence of parakeratotic cells within its ventral portion. True leukonychia is caused by diseases that disturb distal nail matrix keratinization and it presents with three morphologic variants:

- **Punctate leukonychia**. The nail plate has small opaque white spots that move distally with nail growth and sometimes disappear before reaching the distal nail. It is caused by trauma and is most commonly observed in the fingernails of children.
- **Striate leukonychia**. The nail plate has one or more transverse, opaque white, parallel lines that migrate distally with nail growth. It is frequently observed in the fingernails of women, due to matrix trauma secondary to manicures. Striate leukonychia may also occur in great toenails as a consequence of trauma from shoes. It is also typical of Mees' lines, the white transverse bands seen in arsenic and thallium poisoning[4].
- **Diffuse leukonychia (porcelain nails, leukonychia totalis)**. The nail plate is completely or almost completely opaque and white (Fig. 71.6). Diffuse true leukonychia is rare and may result from mutations in *PLCD1* (encodes phosphoinositide-specific phospholipase C delta 1 subunit, a key enzyme in phosphoinositide metabolism expressed in the nail matrix) or *GJA1* (encodes connexin 43). Patients with *GJA1* mutations also have keratoderma and hypotrichosis. Bart–Pumphrey syndrome, in which patients have deafness, knuckle pads, and palmoplantar keratoderma in addition to leukonychia, is due to mutations in *GJB2* (encodes connexin 26; see Ch. 58).

Koilonychia (spoon nails)

The nail plate is thinned and depressed centrally with upward eversion of its lateral and distal edges, leading to a concave spoon-like shape (see Fig. 71.2). Koilonychia, especially of the 2nd–4th toes in young children (1–4 years of age), is physiologic and eventually resolves spontaneously. Isolated koilonychia is unusual and occurs in association with severe iron deficiency[5] or from contact with chemicals that damage the nail plate. More commonly, koilonychia accompanies other nail abnormalities (e.g. trachyonychia), including in the setting of inflammatory diseases such as lichen planus.

Nail Signs Due to Nail Bed Disorders

Onycholysis

The distal nail plate is detached from the nail bed and usually appears white because of the presence of air in the subungual space. If an exogenous pigment is present, the nail may appear yellow (fungi and exudate) to green–black (pyocyanin). In addition to environmental trauma, the nail bed disorders that most commonly produce onycholysis are psoriasis and onychomycosis (Fig. 71.7). Drug-induced onycholysis/photo-onycholysis involves several nails and may have associated subungual hemorrhage (e.g. taxanes)[6].

Subungual hyperkeratosis

The nail plate appears thickened due to an accumulation of subungual scales. Subungual hyperkeratosis results from excessive proliferation of the keratinocytes in the nail bed and hyponychium. It is commonly seen in inflammatory disorders such as psoriasis and contact dermatitis as well as in distal subungual onychomycosis.

Apparent leukonychia

Key features

- White discoloration that fades with pressure
- Nail plate transparency maintained
- Often due to drugs (e.g. chemotherapeutic agents) or systemic diseases (e.g. hypoalbuminemia)

The nails appear white because of abnormalities in the color of the nail bed and this is usually due to nail bed edema. Apparent leukonychia does *not* move distally with nail growth and the white discoloration fades with pressure (see Fig. 71.2). See section on Systemic Diseases for discussion of the three major forms.

Splinter hemorrhages

Splinter hemorrhages appear as one or more red–brown to purple–black, thin longitudinal lines, and they are most commonly seen in the distal portion of the nail (see Fig. 71.2). The shape of the subungual hemorrhages is due to the longitudinal orientation of nail bed capillaries. Onychoscopy allows better visualization of the hemorrhages which typically have a deep red to black color with peripheral fading.

The most common cause of splinter hemorrhages is trauma, followed by psoriasis, onychomycosis, and occasionally medications. Proximal splinters are rare and possible indicators of systemic diseases, including endocarditis (infectious and marantic), vasculitis (including septic vasculitis), trichinosis, and the antiphospholipid antibody syndrome.

Approximately 30% of patients with tuberous sclerosis complex have "red comets", i.e. short red longitudinal streaks of the nail with an enlarged distal end (see Fig. 61.17)[7]. They are partially blanchable and are thought to represent telangiectasias plus extravasated blood.

Nail Signs Due to Deposition of Pigment

Key features

- Exogenous → convex proximal border
- Endogenous → concave proximal border (distally convex)
- Subungual deposition → nail bed discoloration with a transparent nail plate

Causes of nail pigmentation include: (1) staining from external pigment; (2) pigment under the nail plate or in the nail bed dermis; and (3) deposition of pigment within the nail plate. Nail pigmentation from *external* staining typically follows the shape of the proximal nail fold. Common examples are yellow–brown nail discoloration due to nicotine in smokers or darkening of the nail plate due to hair dyes in hairdressers. *Subungual* deposition of pigment is often seen with *Pseudomonas* colonization, where the green discoloration of the nail results from the production of pyocyanin by the bacteria. Dermatophytes usually cause a yellow–white subungual color. Occasionally, there can be deposition of heavy metals or medications (e.g. minocycline) within the nail bed dermis. In melanonychia, the nail appears brown–black due to the incorporation of nail matrix-produced melanin into the *nail plate* itself (see below).

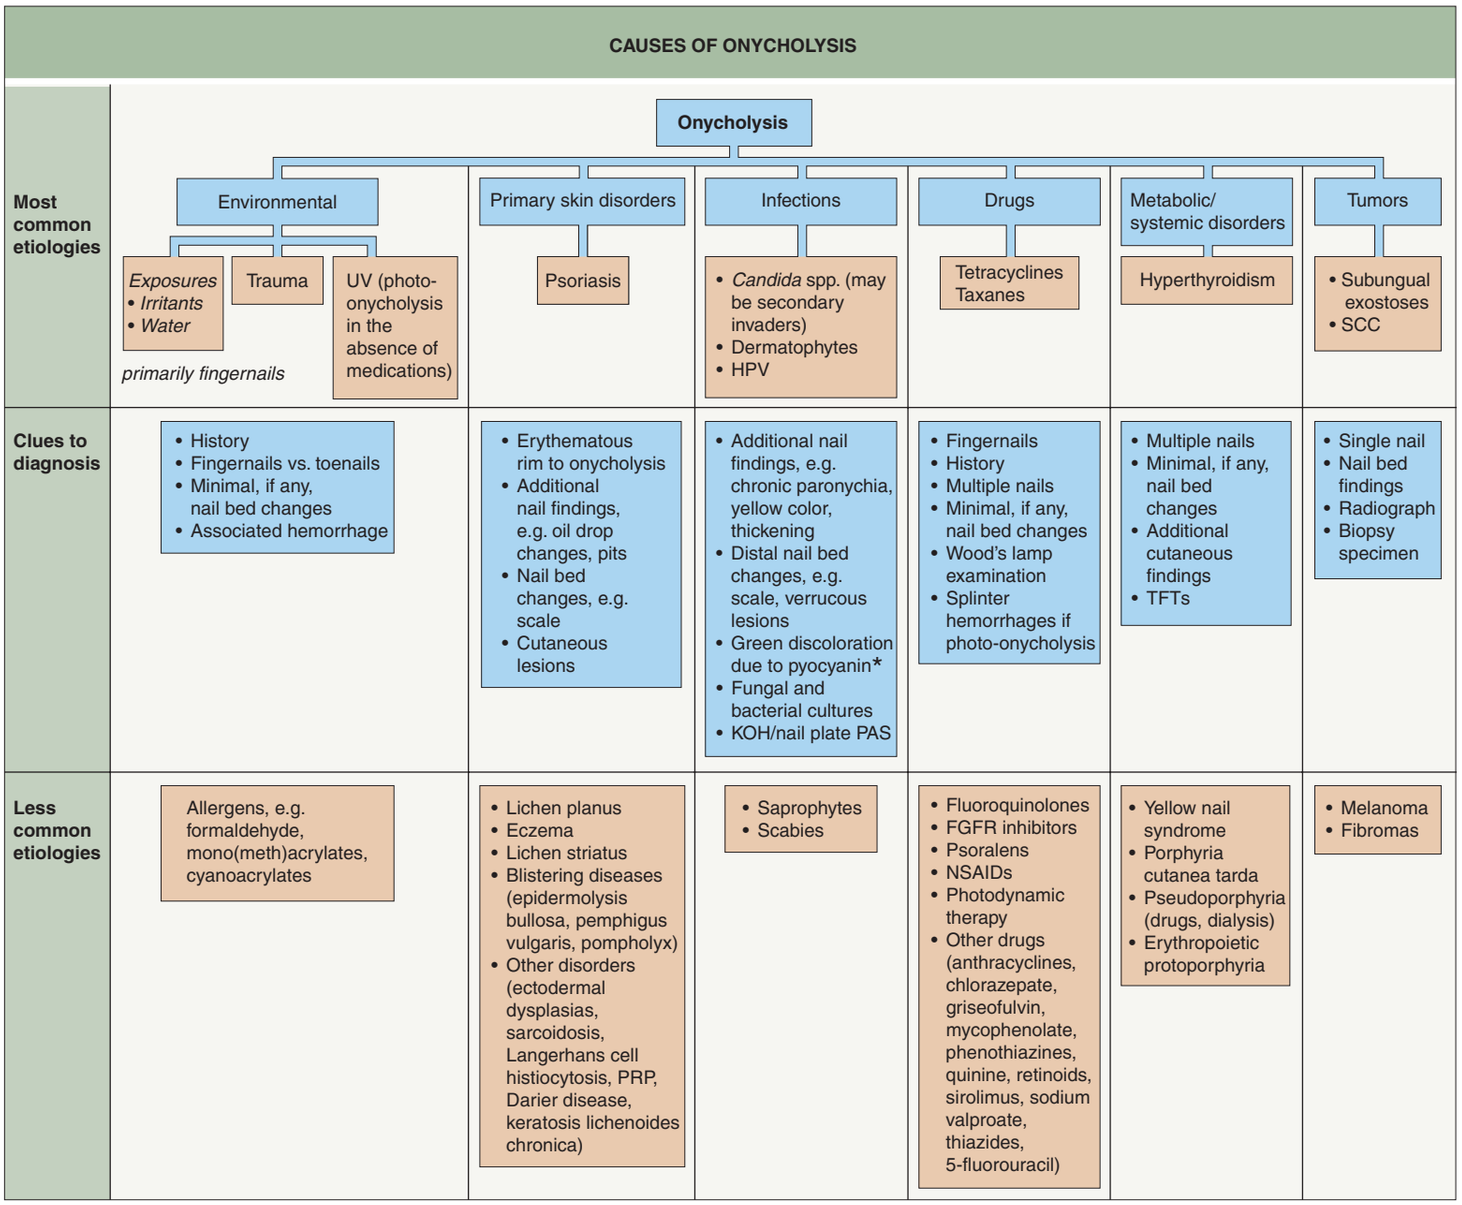

Fig. 71.7 Causes of onycholysis. *Due to secondary colonization with *Pseudomonas aeruginosa*. Serrated onycholysis is a characteristic finding in onychomycosis. FGFR, fibroblast growth factor receptor; HPV, human papillomavirus infection; NSAIDs, nonsteroidal anti-inflammatory drugs; PRP, pityriasis rubra pilaris; PAS, periodic acid Schiff (stain); SCC, squamous cell carcinoma; TFTs, thyroid function tests.

Longitudinal melanonychia

Key features

- Longitudinal brown to black band extending from the proximal nail fold to the distal margin
- Common in darkly pigmented individuals
- Single band may be a sign of melanocyte activation or proliferation (nevus, melanoma)
- Multiple bands point to physiologic, trauma/onychotillomania, drugs, or systemic disease

Longitudinal melanonychia results from melanin production by nail matrix melanocytes and is most commonly due to simple activation of these melanocytes. It can also result from melanocyte hyperplasia as is found in a lentigo, nevus, or melanoma[8]. Clinically, melanonychia presents as one or more longitudinal pigmented bands extending from the proximal nail fold to the distal margin (Fig. 71.8). The band of melanonychia can vary in color from light brown to black and the pigmentation may be homogeneous or variable. The width ranges from a few millimeters to the width of the whole nail. Melanonychia of several digits is usually due to melanocyte activation and is common in patients with darkly pigmented skin (Table 71.2). When melanonychia presents during adulthood in a single digit and there are no systemic or local causative factors, it is important to consider the possibility of nail melanoma. Fig. 71.9 outlines an approach to the patient with longitudinal melanonychia.

Dermoscopic criteria for benign and malignant nail melanocytic lesions have been proposed[9], but nail dermoscopy is not always feasible nor is it completely reliable in the evaluation of nail pigmentation[10]. For example, it cannot be performed when the nail is totally black or very thick such that the lines and borders appear blurred. Additionally, dermoscopic evaluation may give false results, as irregular lines may sometimes be seen with benign pigmentation, especially in children[11]. In addition, hyponychial brush pigmentation (distal fibrillar pattern) is seen in 25%–30% of pediatric patients with longitudinal melanonychia, especially if congenital or early-onset. Histopathologic examination, when clinically warranted, remains the gold standard for the evaluation of nail pigmentation. A detailed description of biopsy procedures for longitudinal melanonychia is found in Chapter 149.

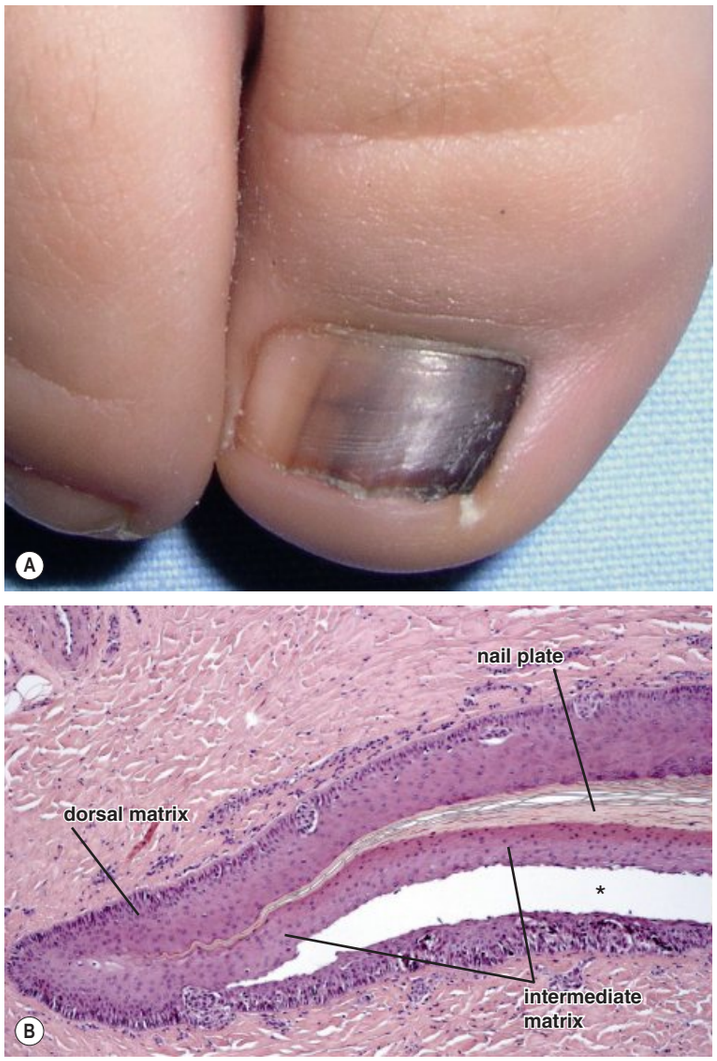

Fig. 71.8 Longitudinal melanonychia due to a congenital melanocytic nevus of the nail matrix. A The pigmentation involves approximately 75% of the nail plate and the color varies from light brown to black. **B** The biopsy specimen shows nests of melanocytes within the basal layer and lower portion of the nail matrix epithelium. The cleft (*) represents an artifact.

Green nail syndrome

The yellow–green to green–black nail plate discoloration is due to the production of the pigments pyocyanin and pyoverdin by *Pseudomonas aeruginosa* (see Ch. 74). This discoloration is most often present in the subungual space created by onycholysis and less often in the lateral nail plate in the setting of chronic paronychia. Predisposing factors include prolonged exposure to water, use of detergents and soaps, nail trauma, and other causes of onycholysis or paronychia. Not surprisingly, this disorder is seen in barbers, dishwashers, bakers, and medical personnel.

Pseudomonas colonization can be eliminated from the nail surface by applying a few drops of 2% sodium hypochlorite solution (or household chlorine bleach diluted 1 : 4 in water) and from the subungual space by soaking the affected digits in the same solution for 5 minutes per day for 20–30 days. The underlying nail disorder must also be addressed, e.g. clipping back the detached nail plate if there is onycholysis.

CONGENITAL AND HEREDITARY NAIL DISEASES

The congenital and hereditary nail diseases include a number of conditions in which nail abnormalities may be present at birth or develop during infancy. A delayed onset can also occur as in Darier disease. In some patients, the nail abnormalities are key features for the diagnosis of genetic syndromes, e.g. congenital anonychia due to mutations in the gene that encodes R-spondin 4 (*RSPO4*) or PLACK syndrome in which there is peeling skin, leukonychia, knuckle pads, and acral keratoses (Table 71.3).

CAUSES OF LONGITUDINAL MELANONYCHIA	
Melanocyte activation	Racial Trauma • manicure • nail biting/onychotillomania • friction, primarily in toenails Drugs • cancer chemotherapeutic agents • zidovudine (AZT) • psoralens Radiation Pregnancy Laugier–Hunziker syndrome Peutz–Jeghers syndrome Addison disease HIV infection Postinflammatory • lichen planus • pustular psoriasis, psoriasis • onychomycosis (*T. rubrum* and *Scytalidium* spp.) • cutaneous lupus erythematosus
Non-melanocytic tumors	Bowen disease Onychopapilloma Onychomatricoma
Melanocyte hyperplasia/ neoplasia	Nail matrix lentigo Nail matrix nevus Nail matrix melanoma

Table 71.2 Causes of longitudinal melanonychia.

Congenital Malalignment of the Great Toenails

Congenital malalignment of the great toenails is possibly caused by an abnormality in the ligament that connects the matrix to the periosteum of the distal phalanx. The nail plate of the hallux is laterally deviated with respect to the longitudinal axis of the distal phalanx. This results in nail matrix damage with Beau's lines and onychomadesis (Fig. 71.10). The nail plate is often thickened and transversely overcurved. Congenital malalignment of the great toenails is frequently bilateral and is the most common cause of ingrown toenails in children and adolescents.

Congenital Hypertrophy of the Lateral Fold of the Hallux

Hypertrophic lateral nail folds are usually present at birth. There is an overgrowth of the soft tissue of the internal portion of the lateral nail fold, resulting in a hypertrophic lip that partially covers the nail plate. This abnormal growth may deviate the nail laterally and/or cause nail embedding with an acute inflammatory reaction and pain. The abnormality is usually bilateral and may regress spontaneously after a few years[12].

Racquet Thumbs (Brachyonychia)

Racquet thumb is a common congenital malformation due to shortening of the distal phalanx. It is usually inherited as an autosomal dominant trait. The nail is shortened and abnormally wide (see Fig. 71.2). Racquet nails are usually an isolated finding and radiologic examination demonstrates a short distal phalanx.

Nail–Patella Syndrome (Oncho-Osteodysplasia; Fong Disease)

Nail–patella syndrome is an autosomal dominantly inherited condition due to mutations in *LMX1B*, which encodes a transcription factor that regulates collagen synthesis. The condition most frequently involves the thumb and may also involve the other fingers but to a lesser extent

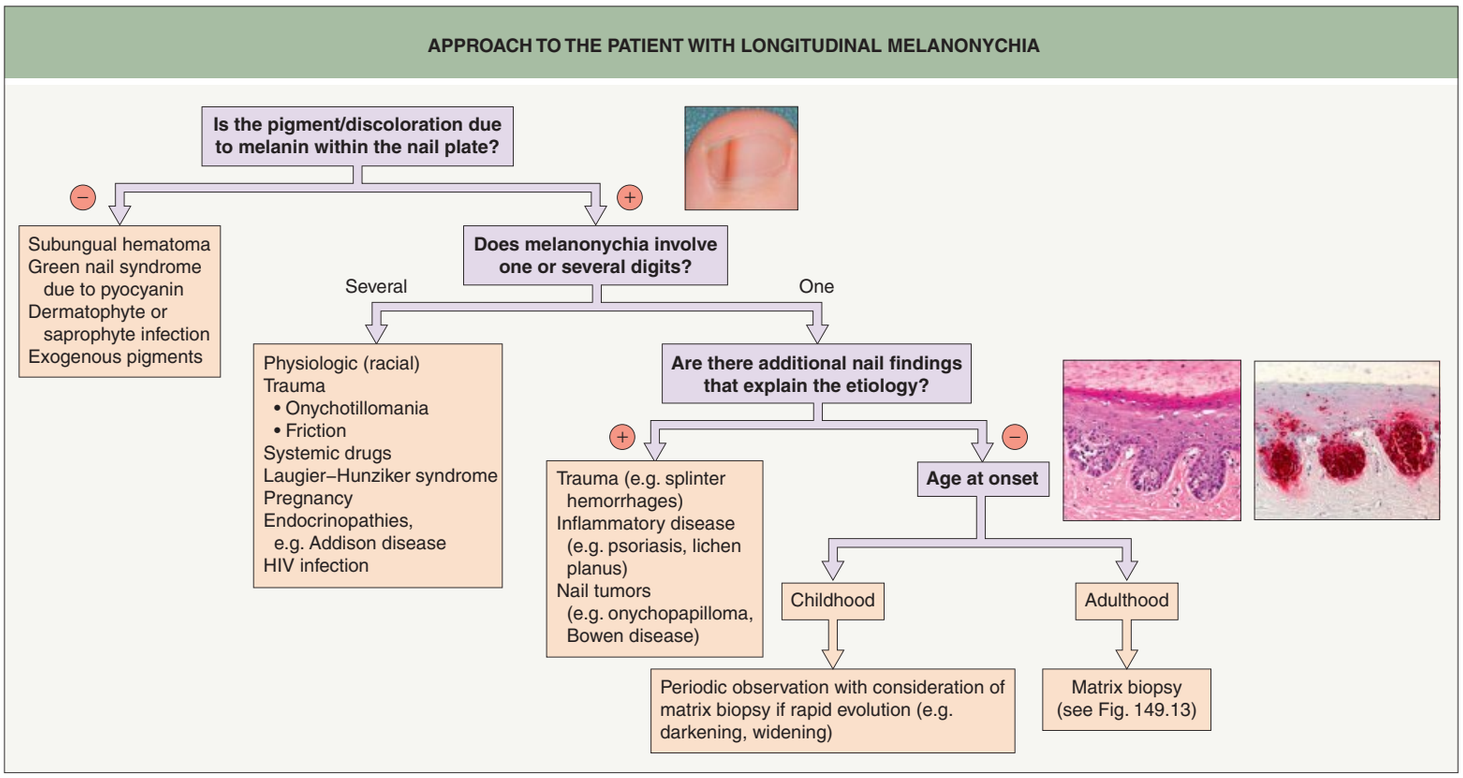

Fig. 71.9 Approach to the patient with longitudinal melanonychia. See Table 71.2 for a more extensive list of etiologies.

SELECTED HEREDITARY DISORDERS OF THE NAILS		
Disorder	**Mode of inheritance**	**Gene or gene product**
Anonychia congenita	AR	R-spondin family, member 4
Isolated AR nail dysplasia	AR	Frizzled 6
Isolated congenital nail clubbing	AR	Hydroxyprostaglandin dehydrogenase 15-(NAD)
Isolated toenail dystrophy	AD	Collagen VII, α1 chain
Leukonychia totalis	AD, AR	Phospholipase C delta 1 Connexin 43
Bart-Pumphrey syndrome	AD	Connexin 26
PLACK syndrome	AR	Calpastatin
Nail–patella syndrome	AD	LIM homeobox transcription factor 1β
Pachyonychia congenita-6a	AD	Keratin 6a
Pachyonychia congenita-16	AD	Keratin 16
Pachyonychia congenita-6b	AD	Keratin 6b
Pachyonychia congenita-17	AD	Keratin 17
Pachyonychia congenita-6c (mild nail involvement, limited to toenails)	AD	Keratin 6c
Tricho-rhino-phalangeal syndrome 1	AD	*TRPS1* (zinc finger protein)

Table 71.3 Selected hereditary disorders of the nails. Nail abnormalities can also be observed in patients with disorders of keratinization, ectodermal dysplasias, and epidermolysis bullosa. Pachydermoperiostosis is discussed in Ch. 98. PLACK, peeling skin, leukonychia, acral punctate keratoses, cheilitis, and knuckle pads.

(Fig. 71.11). The nails are absent or hypoplastic, and the dystrophy is usually more marked on the radial side of the digit. A triangle-shaped lunula is commonly observed. The nail changes are typically associated with bony abnormalities, including absent or hypoplastic

Fig. 71.10 Congenital malalignment of the great toenails. The longitudinal axis of the nail plate is deviated laterally. Note the Beau's lines and initial lateral ingrowing of the nail plate.

patellae, radial head dysplasia, and iliac crest exostoses ("horns"). In children, the diagnosis is best confirmed by the presence of iliac horns on pelvic X-ray.

Nephropathy develops in ~40% of patients. This leads to renal insufficiency in up to 8% of patients.

Epidermolysis Bullosa

Nail abnormalities are common in all forms of epidermolysis bullosa (EB), and nail involvement is one of the items scored to assess degree of severity of EB[13]. Repeated, trauma-induced blistering produces onycholysis with shortening and thickening of the nail due to nail bed scarring. Involvement of the matrix can result in nail thinning and atrophy as well as pterygium. Dystrophic or absent nails with periungual granulation tissue are characteristic of most subtypes of junctional EB and laryngo-onycho-cutaneous syndrome.

Fig. 71.11 Nail hypoplasia in nail–patella syndrome. There is hypoplasia of the nails of the first and second digits. This gradient of severity of nail involvement is characteristic. Note the triangular lunulae of the third and fourth fingernails.

Ectodermal Dysplasias

Nail abnormalities are an important sign in many of the ectodermal dysplasia syndromes, where they are associated with hair, teeth, and/or eccrine gland abnormalities (see Ch. 63). Most frequently, the nails are short and thickened with onycholysis. All the fingernails and toenails are usually affected.

Pachyonychia Congenita

Patients with pachyonychia congenita (PC) are currently classified on the basis of the mutated keratin gene (*KRT*). PC-K6a, PC-K6b, PC-K16, and PC-K17 are due to dominant-negative mutations in *KRT6a*, *KRT6b*, *KRT16*, and *KRT17*, respectively. *KRT6c* mutations can lead to both isolated palmoplantar keratoderma and PC (see Ch. 58).

Nail abnormalities are frequently present and in general are more marked in PC-K6a and PC-K16. However, the number of nails affected can vary and in some patients with specific mutations in PC-K16, the fingernails may be spared. The characteristic finding is a thickened nail with an increased transverse curvature due to severe nail bed hyperkeratosis (see Figs. 71.2 & 58.12). Affected nails are extremely hard and difficult to trim. Associated findings include hyperhidrosis, oral leukokeratosis, follicular hyperkeratosis, hoarseness, and palmoplantar keratoderma, with pain on ambulation. Multiple pilosebaceous cysts are observed most frequently in PC-K17. There are case reports of the successful use of EGFR inhibitors (e.g. oral erlotinib) that target the overactive EGFR signaling observed in pachyonychia congenita[13a].

Darier Disease (Follicular Dyskeratosis)

Key features

- Red and white longitudinal streaks
- V-shaped indentation (notching) of the distal margin
- Giant cells in the nail bed epithelium

Nail abnormalities of Darier disease are both common and diagnostic. The nail plate has multiple red and white longitudinal streaks (Fig. 71.12). Distally, wedge-shaped subungual hyperkeratosis and fissuring of the free margin of the nail plate are also seen (see Fig. 71.2). The latter occur in conjunction with the white and red bands. Similar nail abnormalities may be seen in patients with Hailey–Hailey disease.

A single, red longitudinal band (longitudinal erythronychia) with distal subungual hyperkeratosis is not sufficient for diagnosing Darier disease of the nails, since single bands may be due to a subungual benign tumor (e.g. onychopapilloma, glomus tumor) and, less often, Bowen disease[14].

Fig. 71.12 Darier disease. Longitudinal red and white streaks, fissuring, and V-shaped notching of the distal margin accompanied by focal subungual hyperkeratosis.

THE NAIL IN DERMATOLOGIC DISEASES

A number of skin diseases have associated nail abnormalities that often aid in establishing the proper diagnosis.

Psoriasis

Key features

- Several nails affected
- Diagnostic signs (usually fingernails): irregular pitting, "oil drop" sign (salmon patch), onycholysis with an erythematous border
- In toenails, psoriasis is usually clinically indistinguishable from onychomycosis
- Often associated with psoriatic arthropathy
- The Koebner phenomenon worsens nail symptoms

Nail abnormalities are present in up to 50% of patients with psoriasis and may be the only manifestation of the disease. Nail psoriasis is often associated with psoriatic arthritis and enthesitis[15]. Clinical findings that are diagnostic for nail psoriasis include irregular pitting, nail bed "oil drops", and onycholysis with an erythematous border. These signs are often seen together and are usually localized to the fingernails. Psoriatic pits are large, deep, and irregularly scattered within the nail plate (see Fig. 71.2); they may be covered by whitish, easily detachable scales. The "oil drop" sign (salmon patch) appears as an irregular area of yellow–orange discoloration visible through the nail plate (Fig. 71.13). Onycholysis surrounded by an erythematous border is also typical in nail psoriasis. Patients with psoriasis often have other nail abnormalities that are not diagnostic, as they are commonly seen in other conditions. These include splinter hemorrhages, subungual hyperkeratosis, nail plate thickening and crumbling, and paronychia.

Diseases that should be differentiated from nail psoriasis are listed in Table 71.4.

Treatment

Nail psoriasis usually does not respond to topical treatment and can be aggravated by sun exposure. Treatment measures are reviewed in Table 71.5.

Acrodermatitis Continua of Hallopeau (Hallopeau's Acrodermatitis, Dermatitis Repens)

In most patients, a single digit is involved. There are recurrent episodes of acute painful inflammation with pustules around and under the nail plate (Fig. 71.14). In addition, onycholysis as well as scaling of the nail bed and periungual skin may be seen[16]. Acrodermatitis continua of the

Fig. 71.13 Nail psoriasis. The nails show "oil drop" changes (salmon patches) and onycholysis with an erythematous border.

DIFFERENTIAL DIAGNOSIS OF NAIL PSORIASIS	
Disorder	**Comments**
Onychomycosis	• Psoriasis of the toenails may be difficult to distinguish from onychomycosis without mycologic or histologic examination of nail clippings
Idiopathic or traumatic onycholysis	• The area of onycholysis is not surrounded by erythema and there is an absence of subungual hyperkeratosis (see Fig. 71.7) • By dermoscopy, there is a linear proximal edge (in onychomycosis, this edge is ragged with spikes)
Alopecia areata	• Pits are small and geometrically distributed (see Fig. 71.2)
Acrokeratosis paraneoplastica (Bazex syndrome; paraneoplastic acrokeratosis)	• The psoriasiform eruption has a typical acral distribution with involvement of the nose and ears

Table 71.4 Differential diagnosis of nail psoriasis. Additional entities to consider are pityriasis rubra pilaris (may have subungual hyperkeratosis, onycholysis, splinter hemorrhages, longitudinal ridging) and lichen planus.

nail is, in most cases, not associated with cutaneous plaques of psoriasis vulgaris. Occasionally, proximal spread of the disease or acro-osteolysis of the distal phalanx occurs.

The differential diagnosis of acrodermatitis continua is outlined in Table 71.6. Of note, patients with palmoplantar or generalized pustular psoriasis may develop acute inflammation of multiple nails with pustule formation.

Treatment

- Topical: vitamin D_3 analogues (calcipotriene [calcipotriol], calcitriol), or the combination of calcipotriene plus a class I corticosteroid. Distal nail bed disease is most easily treated with a solution or lotion as the vehicle.
- Injection of corticosteroids into the proximal (matrix disease) or lateral nail folds (nail bed disease) of 1–4 digits.
- Systemic (severe cases): acitretin (0.3 mg/kg/day for 4–6 months), methotrexate (15 mg/week for 6–12 months), targeted immunomodulators ("biologics", e.g. ixekizumab)

Parakeratosis Pustulosa

Parakeratosis pustulosa is seen exclusively in children and is usually limited to one digit, most often the thumb or index finger. Nail changes, in particular distal onycholysis and subungual hyperkeratosis, are accompanied by psoriasiform lesions of the fingertip. The disease usually regresses spontaneously, but some children develop psoriasis.

THERAPEUTIC LADDER FOR NAIL PSORIASIS
Topical therapies
• Avoid trauma (3) • Clip onycholytic part of nail – nail bed psoriasis (3) • Topical vitamin D_3 analogues: calcipotriene (calcipotriol) – nail bed psoriasis (2) • Topical tazarotene* 0.1% gel – nail bed psoriasis (2) • Topical calcipotriene plus Class I corticosteroid ointment – nail bed psoriasis (2) • Topical tacrolimus 0.1% ointment – nail bed psoriasis (3)
Intralesional therapies
• Intralesional corticosteroid (e.g. 2.5–10 mg/ml triamcinolone acetonide in saline) – nail matrix psoriasis (1)
Systemic therapies

• Acitretin (0.2–0.4 mg/kg/day) – nail matrix and nail bed psoriasis (1)
• Methotrexate (15 mg once weekly) – if indicated for additional manifestations (2)
• Targeted immunomodulators – if indicated for additional manifestations (1):
  • IL-17 inhibitors (e.g. ixekizumab, secukinumab)
  • TNF inhibitors (e.g. etanercept, adalimumab, infliximab, certolizumab, golimumab)
  • IL-12/23 or -23 inhibitors (e.g. ustekinumab, guselkumab)
  • Janus kinase inhibitor (e.g. tofacitinib, deucravacitinib)
  • PDE-4 inhibitors (apremilast)
• Cyclosporine – if indicated for additional manifestations (2)

*May be used in combination with topical corticosteroids.

Table 71.5 Therapeutic ladder for nail psoriasis. If nail involvement is mild or affecting relatively few nails (≤3), quality of life is not significantly impacted, and psoriatic arthritis is absent, then topical therapies are typically first-line therapeutic options. Systemic therapies are best considered when nail involvement is more severe or numerous nails involved (>3), topical therapy has failed, quality of life is impaired, or psoriatic arthritis or other manifestations of psoriasis are present. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. *Based on Rigopoulos D, Baran R, Chiheb S, et al. Recommendations for the definition, evaluation, and treatment of nail psoriasis in adult patients with no or mild skin psoriasis. A dermatologist and nail expert group consensus. J Am Acad Dermatol 2019;81:228–40.*

Fig. 71.14 Acrodermatitis continua of Hallopeau. Recurrent pustular eruption of the nail bed and distal finger.

Treatment

Treatment includes topical corticosteroids and/or calcipotriene.

Lichen Planus

Nail abnormalities are present in ~10% of patients with lichen planus (see Fig. 11.15). However, nail lichen planus is most frequently seen in the absence of skin, scalp, or mucosal involvement. Clinical findings that are diagnostic include nail thinning, longitudinal ridging and fissuring, and dorsal pterygium (due to scarring) (Fig. 71.15)[17]. The combination of

DIFFERENTIAL DIAGNOSIS OF ACRODERMATITIS CONTINUA OF HALLOPEAU	
Disorder	**Comments**
Acute contact dermatitis	• Lesions are usually vesicular rather than pustular, with palmar and/or plantar involvement
Bacterial or viral paronychia	• A relapsing course is not typical of bacterial infection; relapses are seen in HSV infection, but the nail heals completely between episodes
Onychomycosis due to non-dermatophyte molds	• May be associated with periungual or subungual inflammation and a purulent discharge • Toenails are most commonly affected and the nail shows signs of fungal infection (e.g. onycholysis, subungual hyperkeratosis, yellow–orange discoloration of the nail plate) • KOH and fungal culture required for distinction
Parakeratosis pustulosa	• Favors young children (females > males) • Generally painless • Pustules are transient and appear early in course

Table 71.6 Differential diagnosis of acrodermatitis continua of Hallopeau.

Fig. 71.15 Nail lichen planus. Note the nail thinning, atrophy, and dorsal pterygium. The index finger has an "angel's wings" deformity.

fissuring plus atrophy can lead to a deformity likened to "angel's wings" and when the nail is viewed *en face* it has been likened to a "pup tent".

Several nails are usually affected. The presence of onychorrhexis and thinning indicates matrix involvement and the need for prompt treatment to avoid scarring. Dorsal pterygium results from adhesion of the proximal nail fold to the nail bed due to matrix destruction and disappearance of the nail plate. Nail bed lichen planus produces nonspecific nail changes such as onycholysis, nail thickening, and yellow discoloration. The toenails can present with abnormalities that resemble those seen in the yellow nail syndrome.

When isolated, this diagnosis may be difficult to establish, and histologic evaluation is required. The differential diagnosis of nail lichen planus is outlined in Table 71.7.

Treatment

Treatment with systemic corticosteroids may be required to avoid pterygium formation. Intralesional injections of corticosteroid (2.5–5 mg/ml triamcinolone acetonide in saline) may be utilized when the disease involves a few nails[18]. Additional treatments for lichen planus are outlined in Table 11.5.

Trachyonychia (Twenty-Nail Dystrophy, Sandpapered Nails)

In trachyonychia, there is nail plate roughness due primarily to excessive longitudinal ridging[3]. Several nails are usually affected, and in some patients, all the nails are dystrophic. Trachyonychia may be idiopathic or associated with an inflammatory skin disease, in particular alopecia areata (12% of children and 3% of adults with severe alopecia areata).

DIFFERENTIAL DIAGNOSIS OF NAIL LICHEN PLANUS	
Disorder	**Comments**
Systemic amyloidosis (AL)	• Thinning and fissuring are associated with splinter hemorrhages • Histologic examination demonstrates amyloid deposits within the nail matrix and nail bed dermis
Lichen striatus	• The lichenoid nail changes are restricted to one or two digits and often limited to one side of the nail plate
Dyskeratosis congenita	• Lichenoid nail changes are associated with oral leukoplakia and reticulated hyperpigmentation
Graft-versus-host disease	• Similar nail changes, but specific clinical setting and additional cutaneous manifestations
Nail pterygium due to bullous diseases	• The history differs and there are often associated cutaneous and/or mucosal lesions
Nail pterygium due to digital ischemia	• The digits are typically cold and there is a history of Raynaud phenomenon
Additional entities: psoriasis, onychomycosis, and yellow nail syndrome	

Table 71.7 Differential diagnosis of nail lichen planus.

In *opaque* trachyonychia, the nails appear lusterless and give the impression of having been sandpapered in a longitudinal direction, i.e. vertically striated (see Fig. 71.5). *Shiny* trachyonychia is less severe and the nails are rough because of multiple small punctate depressions distributed in a geometric pattern within parallel, longitudinal lines. The cuticles are often hyperkeratotic. Trachyonychia is fairly asymptomatic and patients or their parents primarily complain of brittleness and the cosmetic appearance. In addition to alopecia areata, trachyonychia is occasionally caused by several inflammatory diseases that mildly disturb nail matrix keratinization, including lichen planus, eczema, and psoriasis. A nail biopsy is not recommended because of the benign nature of the disease and the tendency for the majority of patients to spontaneously improve.

Systemic corticosteroids and systemic retinoids can improve associated trachyonychia when used to treat hair and cutaneous manifestations in patients with alopecia areata and psoriasis, respectively. Janus kinase inhibitors (e.g. tofacitinib, baricitinib) may also lead to improvement.

Alopecia Areata

Nail abnormalities are present in ~20% of adults and 50% of children with alopecia areata. Signs that are characteristic of nail alopecia areata include geometric pitting and trachyonychia. The pits are small, superficial, and regularly distributed in a geometric pattern (grid-like; see Fig. 71.2). Additional nail abnormalities observed in alopecia areata include punctate leukonychia, erythema of the lunula, and onychomadesis. Trachyonychia is more common in children and most frequently seen in male patients with alopecia totalis or universalis.

Eczema (Dermatitis)

Hand eczema is often associated with nail changes. In acute eczema, there are vesicles and erythema of the proximal nail fold and the hyponychium. Nail matrix damage produces irregular pitting and Beau's lines; onychomadesis can occur in severe cases. Chronic eczema frequently localizes to the hyponychium, resulting in subungual hyperkeratosis, onycholysis, and fissuring of the hyponychium. Chronic eczema of the proximal nail fold can lead to chronic paronychia. In atopic dermatitis, the nail plate frequently shows mild superficial abnormalities such as irregular pits and Beau's lines. Controlling the skin disease results in gradual improvement of the nails.

THE NAIL IN SYSTEMIC DISEASES

Abnormalities of the nails have been anecdotally reported in a number of systemic diseases, but most of these abnormalities are nonspecific. In this chapter, we will discuss only those nail changes that are useful in the diagnosis of systemic disorders.

SYSTEMIC CONDITIONS ASSOCIATED WITH CLUBBING	
Congenital/genetic	
Cardiovascular disorders	Congenital heart disease (usually cyanotic) Pulmonary arteriovenous malformations (often in the setting of hereditary hemorrhagic telangiectasia)
Bronchopulmonary disease	Cystic fibrosis
Other	Pachydermoperiostosis (primary hypertrophic osteoarthropathy; see Ch. 98)
Acquired	
Bronchopulmonary diseases	Neoplasms (primary or metastatic cancers, pleural tumors) Chronic infections (abscesses of the lungs, tuberculosis) Bronchiectasis Pulmonary fibrosis Sarcoidosis
Cardiovascular diseases	Aneurysm or dialysis fistula (unilateral clubbing) Congestive heart failure Bacterial endocarditis
Gastrointestinal diseases	Inflammatory bowel disease Carcinomas Infestations, e.g. amebiasis, ascariasis Liver disorders, e.g. chronic active hepatitis, cirrhosis
Infection	HIV infection Arterial graft sepsis (clubbing limited to perfused extremities)
Endocrine diseases	Thyroid disease (primarily hyperthyroidism)* Secondary hyperparathyroidism
Other	POEMS syndrome Laxative abuse Hemiplegia (unilateral) Trauma, median nerve injury (unidigital)

*Most often in the setting of thyroid acropachy (clubbing together with digital swelling and periosteal reaction) in patients with autoimmune thyroid disease.

Table 71.8 Systemic conditions associated with clubbing.

Clubbing (Watch-Glass Nails, Hippocratic Fingers, Drumstick Fingers)

First described by Hippocrates in the first century BCE, clubbing may be congenital or acquired. Acquired clubbing is uncommon and in 80% of patients is associated with pulmonary diseases.

Clubbing is caused by enlargement of the soft tissue of the distal digit, leading to a bulbous appearance. The nail plate is enlarged and excessively curved, with widening of the angle between the proximal nail fold and the nail plate to greater than 180° (Lovibond's sign; see Fig. 71.2). In hypertrophic osteoarthropathy, clubbing is associated with hypertrophy of the extremities and painful pseudoinflammatory joint disease. Systemic conditions associated with clubbing are outlined in Table 71.8.

Yellow Nail Syndrome

The yellow nail syndrome was first described by Samman and White in 1964. It is uncommon and its pathogenesis is still unknown. Linear nail growth is arrested or greatly reduced. The nails are thickened and transversely and longitudinally overcurved with disappearance of the cuticle. The nail color varies from pale yellow to dark yellow–green (Fig. 71.16). Onycholysis and onychomadesis are frequently seen. In most patients, all 20 nails are involved.

Characteristically, the nail abnormalities are associated with lymphedema and respiratory tract involvement, including chronic bronchitis, bronchiectasis, sinusitis, pleural effusions, and rarely malignancies. The diagnosis of yellow nail syndrome, however, requires only the presence of the typical nail changes.

Fig. 71.16 Yellow nail syndrome. Note the overcurvature of the nail, both transversely and longitudinally, and loss of the cuticle, in addition to the yellow discoloration.

Fig. 71.17 Muehrcke's nails in a patient undergoing chemotherapy. There are multiple parallel transverse white bands that will fade with pressure (apparent leukonychia). Note the associated melanonychia.

Treatment

Treatment is not effective in all cases and must be prescribed for several months[19]:

- vitamin E 1200 IU/day
- pulse itraconazole (200 mg twice daily for 1 week a month) or fluconazole (150 mg daily for 1 week a month)

There are case reports of improvement following treatment of a coexisting malignancy.

Apparent Leukonychia

In apparent leukonychia, there is white discoloration of the nail that fades with pressure and nail transparency is maintained. On the basis of the pattern of the nail discoloration, three different types of apparent leukonychia can be distinguished.

- **Muehrcke's nails** were described by Muehrcke in 1956 in patients with hypoalbuminemia (nephrotic syndrome). They are a very common finding in patients receiving combination chemotherapy. The nail has multiple transverse whitish bands, parallel to the lunula (Fig. 71.17).

- **Half-and-half nails**. First reported by Bean in 1963, half-and-half nails are detected in up to 25% of patients with chronic renal disease who are undergoing hemodialysis. The apparent leukonychia affects the proximal half of the nail. Half-and-half nails may also be seen in normal individuals.
- **Terry's nails** were described by Terry in 1954 as a common sign of liver cirrhosis, occurring in up to 80% of patients. The leukonychia affects the whole nail except for a 1- to 2-mm distal band. Terry's nails are also frequently seen in normal individuals.

Autoimmune Connective Tissue Disorders

Abnormalities in the proximal nail fold capillaries are frequently seen in three major autoimmune connective tissue disorders[20]. Roughness, hemorrhages, and necrosis of the cuticles are common in *dermatomyositis* and *systemic sclerosis*, where capillaroscopy shows reduced capillary density in which avascular areas alternate with dilated capillary loops. In *systemic lupus erythematosus*, capillaroscopy shows a normal capillary density with dilated tortuous capillaries. Ventral pterygium (pterygium inversus unguis) is characterized by the adhesion of the distal nail plate to the hyponychium, resulting in pain during nail trimming. Ventral pterygium is a distinctive sign of systemic sclerosis related to impaired peripheral perfusion. In systemic sclerosis, ischemic changes and bone resorption may result in a parrot beak nail with bending of the nail plate around the shortened fingertip (see Fig. 43.5).

HIV Infection

Onychomycoses are common in HIV-infected patients who are in clinical stages 2 to 4 (see Ch. 78). Dermatophytes are most commonly responsible, but *Candida* spp. and molds are also often isolated[21]. Although numerous nail abnormalities have been reported in association with AIDS[22], only a few clinical entities can be considered typical of this disease.

- **Proximal subungual onychomycosis** due to *Trichophyton rubrum*. This variety of onychomycosis is considered a marker of immunosuppression and at-risk populations include solid organ transplant recipients and those with untreated HIV infection. The proximal nail plate is opaque and white due to the presence of fungi in its ventral portion (see Ch. 77).
- ***Candida* onychomycosis**. *Candida* does not invade the nail plate of immunocompetent individuals, and the diagnosis of true *Candida* onychomycosis indicates immunosuppression, including that due to HIV infection, or chronic mucocutaneous candidiasis.
- **Longitudinal melanonychia**. Usually, several nails are involved, and it is often associated with cutaneous hyperpigmentation.
- **HPV-induced squamous cell carcinoma** (SCC). Longstanding periungual warts in HIV-infected patients should always raise the suspicion of SCC and be examined histologically. HPV type 16 has most commonly been detected in such lesions.

Drug-Induced Nail Abnormalities

Drug-induced nail changes usually involve several or all nails (Table 71.9). The pathogenesis is most often toxic in nature[23].

- Cancer chemotherapeutic agents, due to their cytotoxic properties, are the most frequent cause of nail changes (see Ch. 21). These include Beau's lines, onychomadesis, fragility, onycholysis, paronychia, and vascular complications, including subungual hemorrhages, hematomas, and ischemia. Painful onycholysis with subungual hemorrhages is typically seen with taxanes (e.g. paclitaxel, docetaxel). Chemotherapy can also induce multiple bands of longitudinal or transverse melanonychia as well as diffuse nail pigmentation and Muehrcke's nails (see Fig. 71.17).
- Paronychia associated with (pseudo)pyogenic granulomas is a side effect of epidermal growth factor receptor (EGFR) inhibitors. Nail changes appear from 1 to 3 months after starting treatment and disappear after interruption of treatment. Fibroblast growth factor receptor (FGFR) inhibitors can lead to severe onycholysis while brittle nails occur in patients receiving Bruton's tyrosine kinase (BTK) inhibitors.
- Oral retinoids are frequently responsible for nail abnormalities, in particular nail fragility, paronychia, onychocryptosis, and periungual pyogenic granulomas.

DRUG-INDUCED NAIL ABNORMALITIES	
Nail abnormality	**Responsible agents**
Beau's lines and onychomadesis	Chemotherapeutic agents
True leukonychia	Chemotherapeutic agents
Nail thinning and brittleness	Chemotherapeutic agents Retinoids
Onycholysis/photo-onycholysis (see Fig. 71.7)	Chemotherapeutic agents, particularly taxanes Fibroblast growth factor receptor inhibitors Tetracyclines Psoralens NSAIDs
Apparent leukonychia (e.g. Muehrcke's nails)	Chemotherapeutic agents
Melanonychia	Chemotherapeutic agents Psoralens Zidovudine (AZT)
Discoloration (non-melanin)	Minocycline Antimalarials Gold Silver
Paronychia and periungual pyogenic granulomas	Retinoids Antiretroviral drugs (e.g. indinavir, efavirenz, lamivudine) Epidermal growth factor receptor (EGFR) inhibitors (e.g. cetuximab, gefitinib, erlotinib, panitumumab) Methotrexate Capecitabine (prodrug of 5-fluorouracil) Sirolimus, everolimus
Ischemic changes	β-blockers Bleomycin
Splinter hemorrhages	Tyrosine kinase inhibitors and VEGF inhibitors
Pincer nails	β-blockers
Lunula discoloration	Tetracyclines (yellow), hydroxyurea (blue), AZT (blue), silver (blue–gray), lithium (brown–black)

Table 71.9 Drug-induced nail abnormalities. VEGF, vascular endothelial growth factor.

Fig. 71.18 Multiple periungual pyogenic granulomas in a patient taking indinavir.

- Antiretroviral drugs can cause nail pigmentation, paronychia, and pyogenic granulomas (Fig. 71.18).
- Although uncommon, photo-onycholysis is a characteristic side effect of tetracyclines, psoralens, and photodynamic therapy (see Fig. 71.7).
- Certain drugs (e.g. anticoagulants, anticonvulsants) taken during pregnancy may impair the development of the digits, leading to congenital nail hypoplasia.

INFECTIONS

Acute Paronychia

Key features

- Painful whitlow
- Recurrent when due to herpes simplex virus (HSV)
- Viral and bacterial cultures are mandatory

The affected digit becomes swollen, red, and painful and typically there is involvement of one of the nail folds. Compression of the nail fold may produce purulent drainage. Acute paronychia is most commonly due to bacteria, in particular *Staphylococcus aureus* or *Streptococcus pyogenes*, and it follows minor trauma to the nail. Recurrent episodes of acute paronychia in the same digit should raise the suspicion of an HSV infection. A Tzanck smear, along with PCR, direct immunofluorescence assay or viral culture, can confirm the diagnosis[24].

Treatment

Drainage of the abscess, followed by systemic or topical antibiotics or systemic antivirals when due to HSV.

Warts

Periungual warts are common in nail biters, in whom they are multiple and involve several nails (see Ch. 79). The warts appear as keratotic papules, and when localized to the proximal nail fold, they frequently produce periungual hyperkeratosis simulating a hyperkeratotic cuticle. For subclinical presentations, dermoscopy can aid in diagnosis[25]. Nail bed warts lead to uplifting of the nail plate with onycholysis and subungual hyperkeratosis. SCC can arise in or mimic a verruca; therefore, suspicious lesions must be further evaluated.

Treatment

Therapeutic options are outlined in Table 71.10.

Onychomycosis (Tinea Unguium)

See Chapter 77.

ENVIRONMENTAL NAIL DISORDERS

Brittle Nails (Fragility, Onychoschizia)

Brittle fingernails are very common and usually affect women[26]. Nail brittleness results from dehydration of the nail plate as a result of environmental factors such as frequent handwashing. In onychoschizia, there is lamellar exfoliation in which the distal nail plate splits horizontally into multiple layers (see Fig. 71.2). Other signs of nail brittleness include splitting, softening, onychorrhexis, and keratin degranulation. The latter occurs in persons who wear nail polish continuously; it is characterized by whitish discoloration and fragmentation of the superficial layers of the nail (Fig. 71.19).

Treatment

- Avoidance of water and chemical exposure.
- Biotin (2.5–5 mg/day). Inform the patient that biotin should be held for several days prior to having bloodwork done as it can interfere with tests that use biotin–streptavidin technology (e.g. TSH).
- Topical moisturizers and humectants, e.g. 12% lactic acid, 10% urea.

Chronic Paronychia

Chronic paronychia commonly involves the fingernails of adult women. Although the pathogenesis is still debated, there is accumulating evidence that the condition represents a contact reaction to irritants or allergens[27]. Occupational chronic paronychia is common in food handlers. Chronic paronychia is characterized clinically by longstanding inflammation of the proximal nail fold with erythema, edema, and absence of the cuticle. One or several fingernails are affected, in particular the thumb and second or third fingers of the dominant hand. Damage to the nail matrix results in nail plate surface abnormalities such as Beau's lines. *Pseudomonas* colonization of the brittle nail surface may induce a green discoloration. Recurrent, self-limited episodes of acute exacerbation are common.

Treatment

- Avoidance of water and chemical exposure.
- Topical corticosteroids and topical imidazoles, but not systemic antifungals.
- Topical antiseptics (e.g. 4% thymol in 95% ethanol).

Idiopathic Onycholysis

Idiopathic onycholysis frequently involves the fingernails as a consequence of repetitive water immersion and exposure to irritants (see Fig. 71.7). The affected nail is detached from the nail bed and usually appears white because of air in the subungual space. Secondary microbial colonization of the subungual space can lead to discoloration, e.g. green due to pyocyanin. An absence of subungual hyperkeratosis is characteristic.

Treatment

- Avoidance of water and chemical exposures.
- Clipping of the detached nail plate and topical antiseptics.

THERAPEUTIC LADDER FOR PERIUNGUAL WARTS ℞

- Keratolytics (2)
- Cryotherapy (2)
- Topical 0.7% cantharidin (2)
- Topical 5% imiquimod (2)
- Intralesional injection of *Candida*, *Trichophyton*, or mumps skin test antigens (1)
- Topical immunotherapy† (2)
- Topical (1%–3%) or intralesional (15 mg/ml) cidofovir (2)
- Intralesional bleomycin (2)
- Topical (5%) or intralesional 5-fluorouracil (2, 1)
- Laser: CO_2, Er:YAG, pulsed dye (2)
- Photodynamic therapy (2)
- Ablative CO_2 fractional laser followed by PDT* (2)

*With methyl 5-aminolevulinic acid and red light.
†For details, see Table 129.10.

Table 71.10 Therapeutic ladder for periungual warts. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. PDT, photodynamic therapy.

Fig. 71.19 Keratin degranulation of the fingernails due to prolonged wearing of nail lacquer. The distal nail plate is opaque and fragile due to multiple small areas of breakage on its surface.

NAIL CHANGES ASSOCIATED WITH A MANICURE OR PEDICURE	
Nail abnormality	**Etiology**
Beau's lines	Matrix damage from cuticle removal
True leukonychia (transverse)	Matrix damage from cuticle removal
Nail brittleness (onychorrhexis, onychoschizia, keratin granulation*)	Nail varnish solvents; electric drills
Nail brittleness (keratin granulation*)	Prolonged nail polish wearing
Distal onycholysis ("roller coaster")	Mechanical (nail tools utilized to clean the nail plate free edge)
Diffuse onycholysis	Mechanical (artificial nails acting as a lever)
Diffuse onycholysis	Chemical (acrylic nails, gel polish manicure)
Discoloration (yellow/orange)	Nail varnishes
Acute paronychia Chronic paronychia Periungual pyogenic granulomas Periungual warts	Periungual cuts from sharp instruments Contact allergy Constant cuticle removal Periungual wounds Mechanical trauma to the cuticle
Pterygium inversum unguis	Gel polish manicure
*Also referred to as superficial granulation.	

Table 71.11 Nail changes associated with a manicure or pedicure.

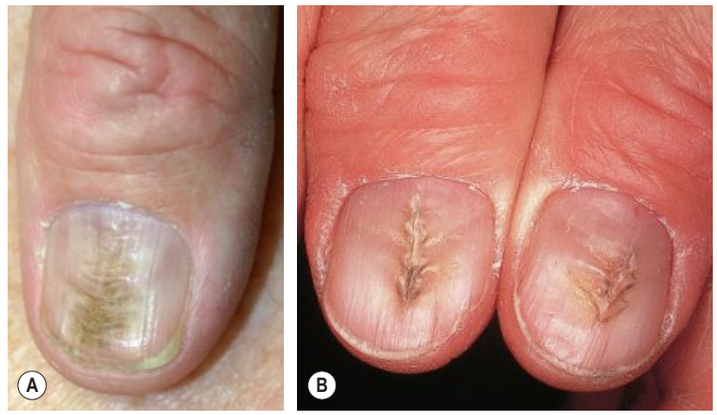

Fig. 71.20 Habit-tic deformity (A) and median canaliform dystrophy of Heller (B). A The multiple midline Beau's lines resemble a washboard. **B** A central longitudinal split with an inverted fir tree pattern. In both, deposits of exogenous pigments can be seen.

Fig. 71.21 Onychotillomania. In four of the nails, the nail plate is damaged or absent. The hemorrhagic crusts on the nail bed and proximal nail fold serve as a clue to the diagnosis.

TRAUMATIC NAIL ABNORMALITIES

Mechanical insults or exposure to chemicals can lead to nail injury. These may be accidental, self-induced, or due to attempts at adornment (e.g. manicures, pedicures; Table 71.11).

Onychotillomania

Key features

- Cuticle absent and proximal nail fold inflamed
- Nail plate surface abnormalities, e.g. midline transverse ridging
- Melanonychia
- Hemorrhages and crusts

Self-induced nail abnormalities are common, but often not recognized due to the wide range of nail signs and the difficulty in obtaining a correct clinical history.

- **Nail biting** may affect the nail plate and/or the proximal nail fold; the trauma often produces nail matrix damage with secondary nail plate abnormalities, including surface irregularities and longitudinal melanonychia.
- **Habit-tic deformity** affects the thumb and is due to the nervous habit of rubbing and pushing back the midportion of the cuticle of the thumb with the index finger. The nail plate of the thumb shows multiple midline Beau's lines that resemble a washboard (Fig. 71.20A). **Median canaliform dystrophy of Heller** (solenonychia) is considered a separate entity in which there is central longitudinal split with an inverted fir tree pattern (Fig. 71.20B); it is also probably caused by trauma.
- Nail destruction associated with psychiatric disorders. The clinical picture is variable, with nail plate destruction, hemorrhages, and periungual crusts and erosions (Fig. 71.21). Instruments (scissors, clippers, etc.) are often utilized to destroy the nails.

Treatment

- Topical preparations that taste unpleasant and bandages.
- Serotonin reuptake inhibitors (fluoxetine, paroxetine, sertraline), N-acetylcysteine.

Subungual Hematoma

Acute hematomas occur after trauma severe enough to damage subungual blood vessels, leading to accumulation of blood under the nail plate. Acute hematomas are typically associated with pain, and compression of the matrix may cause secondary nail plate dystrophy. An X-ray of the digit may be advisable to exclude a bone fracture. Repeated microtrauma or a bleeding diathesis can lead to asymptomatic small subungual hematomas of the nails that are incorporated within the ventral nail plate.

Subungual hematomas migrate distally with nail growth and this may be demonstrated by gently pushing back the cuticle. The color of subungual hematomas ranges from purple–red to black. Onychoscopy is useful for differentiating hematomas from melanin deposition (see Fig. 71.2)[28].

Treatment

Acute hematomas require prompt drainage of the blood by creating a hole through the nail plate.

Traumatic Toenail Abnormalities

Traumatic toenail abnormalities are most commonly seen in women who wear high-heeled pointed shoes, but can also be seen in athletes. They are often bilateral.

- Traumatic onycholysis of the hallux is the most common clinical presentation (Fig. 71.22). The onycholysis may be *distal*, where the detachment is caused by compression of the distal pulp by poorly fitting shoes, or *lateral*, when there is overlapping of the second toe onto the first. Clipping of the detached nail plate reveals a normal

Fig. 71.22 Traumatic onycholysis of the nail of the first toe. Age-related lateral deviation of the hallux (hallux valgus) plays a role. Although the two entities can coexist, it is often misdiagnosed as lateral onychomycosis.

nail bed. The differential diagnosis includes onychomycosis, but here the onycholysis is associated with subungual hyperkeratosis and the proximal margin of the detachment has a jagged edge by onychoscopy[29].

- Transverse leukonychia of the hallux results from repeated microtrauma by shoes to untrimmed, long, great toenails. Multiple bands of true leukonychia move distally with nail growth.
- Frictional melanonychia affects the toenails of the fourth and/or fifth digits of women. It is due to activation of nail matrix melanocytes by friction from shoes or from the adjacent digit. The bands may be multiple and black in color.
- Retronychia is caused by embedding of the nail into the proximal nail fold following trauma and may present with inflammation of the proximal nail fold.

Onychogryphosis

Onychogryphosis is common in elderly persons and almost exclusively affects the toenails, usually the hallux. The nail acquires a typical ram's horn shape due to asymmetric growth (see Fig. 71.2). The nail plate is thick, hard, and yellow–brown. Multiple transverse striations are often present. Nail hardness and self-neglect may lead to monstrous deformities.

Pincer Nails (Trumpet Nails)

Pincer nails are usually seen on the toes and may be hereditary or acquired; the latter is most commonly due to ill-fitting shoes. The nail plate displays an excessive transverse overcurvature, especially in its distal portion (see Fig. 71.2). This results in compression (pinching) of the distal nail bed and can be associated with severe pain. Subungual exostosis should be excluded by X-ray examination. Consider drug-induced pincer nails (e.g. from β-blockers) when several nails, including fingernails, are involved.

Treatment

Lateral chemical or surgical matricectomy is the treatment of choice for pincer nails (see Ch. 149).

Ingrown Toenails (Onychocryptosis)

Lateral ingrowing usually affects the hallux of young adults with congenital malalignment of the great toenails. Precipitating factors in all patients include improper or aggressive nail cutting and trauma. In addition, hyperhidrosis contributes to fragmentation of the distolateral edge. Penetration of nail plate spicules into the lateral nail fold epithelium causes painful inflammation. Chronic inflammation then leads to formation of granulation tissue that eventually undergoes epithelialization.

Distal embedding is a common complication of nail avulsion. The nail plate growth is blocked by the pulp, which forms a distal rim. Distal embedding can also occur in young infants but it resolves spontaneously.

Retronychia describes ingrowth of the proximal nail plate into the proximal nail fold, with one to three nail plates misaligned beneath the uppermost nail plate (see Fig. 71.2)[30]. There may be associated proximal nail fold erythema and swelling as well as proximal periungual pyogenic granulomas.

Treatment

- Prevention through patient education.
- Removal of the embedded spicule.
- Uplifting of the lateral nail plate with cotton, dental floss, slit tubes, or cotton casts.
- Granulation tissue may be reduced by topical antibiotics and topical corticosteroids or chemical cauterization (e.g. silver nitrate) or removed via curettage.
- Chemical (phenol, sodium hydroxide or trichloroacetic acid), laser, or excisional surgical removal of the lateral matrix is advisable in severe cases.
- In retronychia, surgical avulsion of the nail plate/s is necessary.

NAIL TUMORS

Nail surgery is discussed in Chapter 149.

Benign Tumors and Proliferations

Pyogenic granuloma (botryomycoma)

Pyogenic granulomas commonly appear within the nail apparatus, where they may be periungual or subungual and rarely under the proximal nail fold. While pyogenic granulomas of the nail unit often follow penetrating trauma, other common causes include ingrown toenails, systemic drugs (e.g. retinoids, EGFR inhibitors), peripheral nerve damage, and frictional onycholysis due to prolonged walking[31]. The tumor appears as a bleeding, friable, soft red nodule (see Fig. 71.18). When subungual, it is associated with onycholysis. The differential diagnosis includes amelanotic melanoma and treatment is surgical.

Fibromas/fibrokeratomas

Isolated periungual and subungual fibromas are not rare in the general population. Multiple lesions occur in 50% of patients with tuberous sclerosis complex (Koenen tumors). Periungual fibromas appear as pink or skin-colored, fusiform-shaped papules originating from the proximal nail fold (see Ch. 61). The fibroma may compress the nail matrix and produce a longitudinal groove in the nail plate. Subungual fibromas that grow underneath the nail plate produce longitudinal erythronychia or onycholysis. A fibrokeratoma is characterized by a hyperkeratotic tip and may be surrounded by a collarette of raised skin.

Subungual exostosis

Subungual exostoses, first described by Dupuytren in 1847, are benign bony proliferations associated with nail abnormalities. Subungual exostoses are commonly precipitated by trauma and usually seen on the great toe of young patients. An exostosis produces a hard, tender, subungual nodule that elevates the nail plate (Fig. 71.23A). The nodule may ulcerate or become hyperkeratotic. The diagnosis is confirmed by X-ray examination (Fig. 71.23B)[32] and the treatment is surgical.

Myxoid cyst (mucous cyst, digital mucous cyst)

Myxoid cysts are a common finding and favor middle-aged women (see Ch. 110). Typically located in the proximal nail fold of the fingernails, they appear as small, soft, skin-colored papulonodules that often spontaneously drain a viscous jelly-like fluid. Compression of the matrix produces nail plate depression and longitudinal grooves (Fig. 71.24). Occasionally, the cysts are subungual. These cysts are connected to the distal interphalangeal joint by a tract, and osteoarthritis of the distal joint is a frequent association[33].

Treatment

Possible treatments for myxoid cysts include sclerotherapy, cryosurgery, and intralesional corticosteroid injections. All of these procedures are

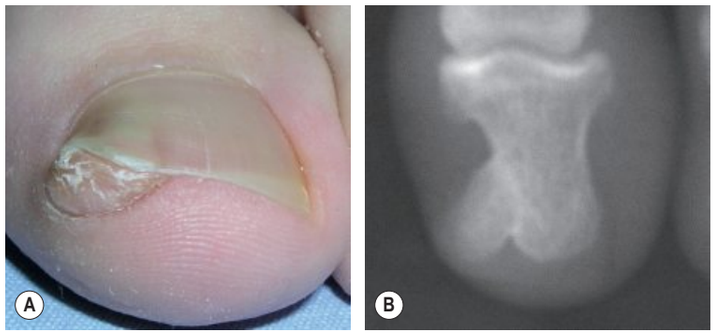

Fig. 71.23 Subungual exostosis. A Skin-colored subungual nodule elevating the nail plate. **B** Radiograph of the digit demonstrating the subungual bony proliferation.

Fig. 71.24 Myxoid cyst. The longitudinal nail groove is a result of the compression of the nail matrix by the cyst.

associated with a high frequency of relapses. Definitive cure of myxoid cysts requires a surgical procedure that includes ligation of the pedicle that connects the cyst to the joint.

Glomus tumor

A glomus tumor arises from the neuromyoarterial glomus cells of the nail bed dermis. It is typically associated with severe pain that radiates proximally and is often aggravated by physical (e.g. compression) or thermal stimuli (especially cold). Subjective symptoms typically exceed clinical signs. The tumor may not be clinically apparent or may appear as a red–bluish nail bed macule visible through the transparent nail plate (see Fig. 114.33). MRI allows the diagnosis (see Fig. 114.34).

Onychomatricoma

First described by Baran and Kint in 1992, onychomatricoma is an uncommon neoplasm that produces localized or diffuse thickening of the nail plate in which multiple longitudinal hollows contain the digitating tumor (Fig. 71.25). The affected nail is thickened and yellow–white in color, with transverse overcurvature and multiple splinter hemorrhages. In an *en face* view of the distal nail, multiple holes in the thickened free margin are typically seen (see Fig. 71.2).

Histologically, the tumor is characterized by multiple fibroepithelial projections that extend into the thickened nail plate. The tumor epithelium is identical to that of the normal nail matrix and keratinizes without a granular layer. Histopathologic examination of a simple nail clipping is sufficient for diagnosis[34].

Onychopapilloma

Onychopapilloma is a benign tumor that grows under the nail plate and has a thin filiform shape. It arises from the distal matrix/proximal

Fig. 71.25 Onychomatricoma of the left third fingernail. A longitudinal, thickened yellowish band is seen extending from the cuticle to the distal nail plate. Proximal splinter hemorrhages are also visible. Onychoscopy of the distal nail plate reveals the diagnostic finding of localized nail thickening with a honeycomb appearance (inset).

Fig. 71.26 Onychopapilloma of the left first fingernail. A thin longitudinal band of erythronychia is seen extending from the lunula. Onychoscopy reveals the crescent-shaped proximal origin of the erythronychia (lower inset) and a small subungual mass can be appreciated on the free edge of the nail (upper inset).

nail bed and extends to the distal nail margin. Small tumors produce thin longitudinal erythronychia while larger onychopapillomas induce thinning of the overlying nail plate and distal fissuring. Splinter hemorrhages are an associated finding. Examination of the free margin reveals a keratotic mass that adheres to the ventral nail plate (Fig. 71.26). Less often the tumor manifests as longitudinal leukonychia or melanonychia.

By dermoscopy, the origin (lunula) and the end (distal margin) of the thin red band can be appreciated, as can splinter hemorrhages and the distal keratotic mass. A nail clipping demonstrates a localized asymmetric keratotic thickening on the underside of the nail plate, corresponding to the location of the filiform tumor[35].

Melanocytic nevi of the nail matrix

Melanocytic nevi of the nail matrix are an uncommon cause of longitudinal melanonychia (see Table 71.2). They usually develop during childhood and often involve the fingers, especially the thumb[36,37]. Clinically, a band of melanonychia that is brown to black in color

Fig. 71.27 Bowen disease. The lateral portion of the nail plate is absent. The nail bed shows hyperkeratosis with scaling and fissuring of the epithelium.

Fig. 71.28 Amelanotic melanoma. Note the diffuse nail destruction and ulceration as well as swelling of the proximal nail fold. The tumor can resemble granulation tissue. *Courtesy Lorenzo Cerroni, MD.*

involves a portion of the nail or its entirety. The color, width, and pigment distribution may vary considerably and it is not unusual to observe fading or darkening of the pigmentation over time in an individual patient. Pigmentation of periungual tissues is also possible because nests of nevus cells can be present in the proximal nail fold or hyponychium. When dark brown or black in color, bands are often visible through the cuticle (pseudo-Hutchinson sign). The age at onset represents the most important clue to the diagnosis. Histologically, a lentigo or junctional nevus is usually seen (see Fig. 71.8B).

Treatment

Optimal management of nail matrix nevi is still debated. See Fig. 71.9 for an approach to longitudinal melanonychia, including in children.

Malignant Tumors

Malignant tumors of the nail are summarized below. For further details regarding these malignancies and their treatment, see Chapters 108 and 113.

Bowen disease (squamous cell carcinoma in situ)

Bowen disease of the nail is uncommon and is seen most often in middle-aged men. Fingers of the left hand are most commonly involved[38]. Clinically, it may be difficult to differentiate Bowen disease from warts. The affected digit shows periungual or subungual verrucous lesions with onycholysis and/or longitudinal melanonychia (Fig. 71.27). Predisposing factors include HPV infection and chronic X-ray exposure.

Keratoacanthoma

Keratoacanthoma of the nail is extremely rare and usually affects a single digit. It appears as a painful, subungual, keratotic nodule that grows rapidly over a period of weeks. Deep invasion with bone destruction frequently occurs and typically there is evidence of osteolysis on X-ray examination. A history of trauma is often reported. In contrast to cutaneous keratoacanthomas, keratoacanthomas of the nail do not regress spontaneously[39].

Squamous cell carcinoma

Squamous cell carcinoma (SCC) is the most common malignant tumor of the nail apparatus. It often affects the fingernails of middle-aged men. A number of studies have confirmed a causative role for HPV, usually HPV-16, in the development of this tumor. Clinically, it may present as slowly growing periungual or subungual verrucous mass or nodule that may ulcerate and bleed[40]. Compared to cutaneous SCC elsewhere, nail SCC tends to more quickly become invasive, but metastases are rare. Bone invasion occurs in <20% of patients and the osteolysis detected on X-ray examination is more often due to compression rather than true bone invasion.

Verrucous carcinoma (carcinoma cuniculatum, epithelioma cuniculatum)

Verrucous carcinoma is a rare, low-grade variant of SCC characterized by locally aggressive clinical behavior but low potential for metastasis. It rarely involves the nail apparatus. Clinically, the tumor appears as a rapidly growing verrucous nodule that often destroys the nail. Bone resorption is common.

Melanoma

Nail melanoma is rare, accounting for 0.7%–3.5% of all melanomas. It most frequently involves the thumb of middle-aged individuals, and patients often report a history of trauma. Diagnosis is often delayed, and in 25% of patients the tumor is amelanotic. Historically, the 5-year survival is only 15%. From a clinical standpoint, nail melanoma may have the following presentations:

- Longitudinal melanonychia[41]. Melanoma should be suspected when a single band arises during adulthood without another plausible explanation (see Fig. 71.9). The pigmented band is usually dark brown or black in color, with blurred margins and a width >3–4 mm. An ABCDEF "rule" has been proposed to aid in diagnosis[42]: A) **A**ge – peak incidence fifth to seventh decades with **A**fricans, **A**sians, and Native **A**mericans (more darkly pigmented individuals) accounting for up to one-third of all cases; B) **B**lack or **b**rown with band width of 3 mm or more; C) **C**hange in the nail or lack of improved change with treatment; D) **D**igit most commonly involved (thumb, great toe, index); E) **E**xtension of pigment onto the proximal or lateral nail fold (Hutchinson sign); and F) **F**amily or personal history of dysplastic nevus or melanoma. Except for criterion F, these represent validated clinical criteria.
  When longitudinal melanonychia is due to nail melanoma, dermoscopically the band typically has nonhomogeneous pigmentation, blurred borders, and nonparallel interrupted lines of different colors. However, for diagnosis, onychoscopy alone is not completely reliable, especially if the nails are thick or the bands are black. Moreover, sometimes the lines are regular in nail melanoma. Therefore, integration of the history, clinical appearance, and dermoscopic findings is required[9–11].
- Amelanotic nodule that ulcerates and bleeds, resembling a pyogenic granuloma (Fig. 71.28).

The presence of: (1) Hutchinson sign – pigmentation of periungual tissues due to radial spread of the tumor; or (2) micro-Hutchinson sign – pigmentation visible only by dermoscopy is a strongly suggestive clinical feature.

Additional figures and table on the ABCDEF rule for subungual melanoma, available in our eBook (see inside front cover for access code).

Oral Manifestations of Systemic Disease 1251

Introduction

From both a clinical and histologic standpoint, the oral cavity is a diverse anatomic region reflecting its various functions and environmental interactions. Sites that are exposed to the friction of mastication, such as the hard palate and attached gingivae, are bound to the underlying periosteum and are referred to as *attached mucosa* or *keratinized mucosa* (Fig. 72.1). Histologically, these anatomic sites have prominent rete ridge formation and a thick layer of keratin. The dorsal tongue has the thickest epithelium within the oral cavity and its specialized functions include taste, mastication, and deglutition. The filiform, fungiform, foliate, and circumvallate papillae are distributed on the dorsal tongue, with pigmentation of the fungiform papillae a normal variant (Fig. 72.2A). All other oral mucosal sites, including the soft palate, labial mucosa, and floor of the mouth, are "unattached" and represent *non-keratinized mucosa*. Numerous salivary glands are present within the connective tissue (submucosa) beneath the non-keratinized mucosa. In the buccal mucosa, there are variable numbers of heterotopic sebaceous glands (Fordyce granules).

COMMON BENIGN CONDITIONS OF THE ORAL CAVITY

Fordyce Granules

Synonyms: ■ Ectopic sebaceous glands ■ Heterotopic or anomalous sebaceous glands ■ Fordyce spots

Key features

- Common variation of normal sebaceous glands
- Multiple yellowish papules of the buccal mucosa and vermilion zone of the upper lip

Introduction

Fordyce granules represent sebaceous glands that are present in the vermilion portion of the lips and the buccal mucosa. Although historically considered as ectopic, Fordyce granules are simply regarded as a variation of normal anatomy. "Free" sebaceous glands (see below) can also be found on the eyelids (meibomian glands), areolae (Montgomery tubercles), labia minora, and prepuce (Tyson glands).

Epidemiology

Fordyce granules are found in 70%–85% of the adult population, with no sex predilection[1]. They are uncommon in children and a surge in prevalence occurs around puberty followed by an incremental increase with age[2].

Clinical features

Fordyce granules characteristically present as multiple asymptomatic, yellow to yellow–white macules and papules. They usually measure 1–2 mm in diameter but may become confluent. The most common sites are the buccal mucosa bilaterally and the vermilion zone of the upper lip (Fig. 72.2B,C).

Pathology

Fordyce granules are similar to sebaceous glands found in the skin, but they are not associated with hair follicles, i.e. they are "free" sebaceous glands[1].

Treatment

Because Fordyce granules are a normal anatomical variant, no treatment is required. However, patients may express a cosmetic concern when lesions appear on the vermilion lip.

Geographic Tongue

Synonyms: ■ Benign migratory glossitis ■ Oral erythema migrans ■ Glossitis areata migrans ■ Stomatitis areata migrans ■ Erythema areata migrans ■ Benign migratory stomatitis

Key features

- Red, well-demarcated patches on the lateral and dorsal tongue with scalloped, thin white borders
- Psoriasiform mucositis of unknown etiology
- No treatment is generally necessary

Introduction

Geographic tongue is a benign inflammatory condition of unknown etiology that primarily affects the tongue and tends to recur.

Epidemiology

Geographic tongue affects 1%–3% of the general population, with no sex predilection[2]. In up to one-third of patients, concomitant fissured tongue has been observed. An increased incidence in atopic individuals has been reported as well as an association with psoriasis and reactive arthritis. In some patients, mutations in *IL36RN*, a causative gene for generalized pustular psoriasis, have been identified in tissue biopsies[3].

Clinical features

Geographic tongue typically presents on the dorsum of the tongue as one or multiple depapillated areas which gradually enlarge to form slightly atrophic patches with peripheral erythema and a yellowish-white serpiginous border (Fig. 72.3). In addition to migration, lesions often wax and wane and can involve other mucosal sites including the floor

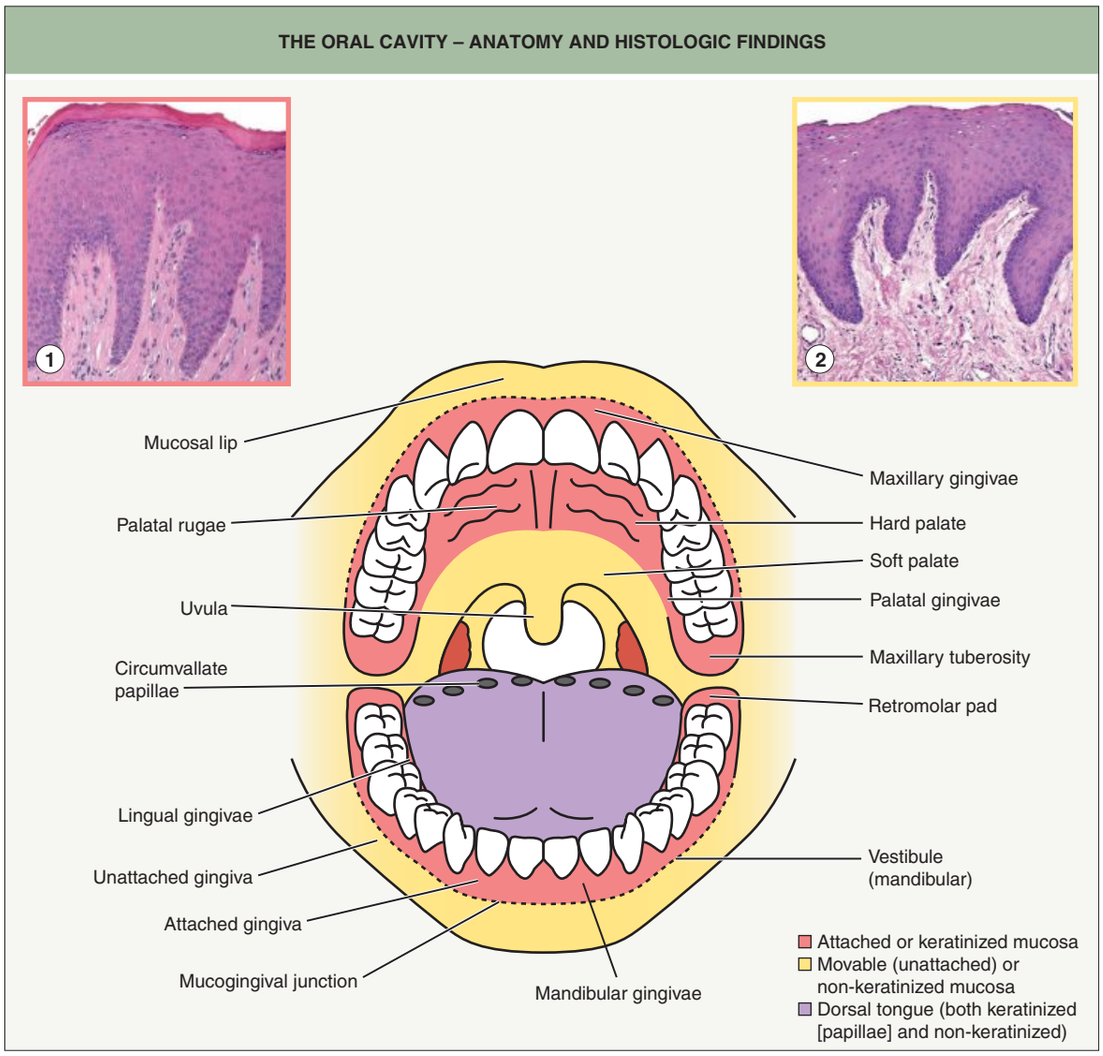

Fig. 72.1 The oral cavity – anatomy and histopathologic findings. Pink represents attached (keratinized) mucosa, yellow represents movable (non-keratinized) mucosa, and purple the dorsal tongue. Inset 1: Histologic features of the palate with prominent rete ridge formation, a granular layer, and orthohyperkeratosis; the attached gingivae have similar findings. Inset 2: Histologic features of the buccal mucosa with less pronounced rete ridges, minimal parakeratosis, and no orthokeratosis; the soft palate, labial mucosa, ventral tongue, and floor of mouth exhibit similar histologic features.

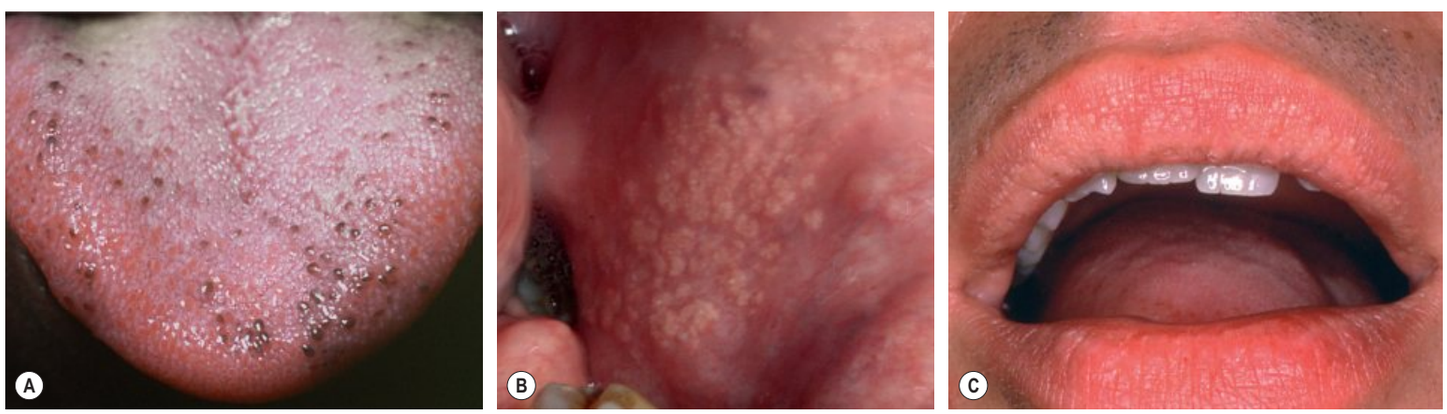

Fig. 72.2 Variations of normal anatomy – Fordyce granules and pigmented papillae of the tongue. A Multiple, tiny, brown papules representing pigmented fungiform papillae are seen on the tip and lateral aspects of the tongue; they represent a normal variant in individuals with darker skin phototypes. The more numerous keratotic projections represent normal filiform papillae. **B, C** Multiple yellowish 1–2 mm papules on the buccal mucosa and upper vermilion lip, representing "free" sebaceous glands.

of the mouth, buccal mucosa, and labial mucosa. Because geographic tongue is frequently asymptomatic, most patients are unaware of its existence. While generally an incidental finding during a routine oral examination[4], there may be associated symptoms such as a burning sensation or sensitivity to hot or spicy foods.

Pathology

Since the histopathologic features are similar to those of psoriasis, it is also referred to as "psoriasiform mucositis". At the edge of the lesion, there is a characteristic loss of the papillary surface morphology of the tongue, elongation of rete ridges, varying parakeratosis, and spongiosis, along with numerous, typically confluent, superficial intraepithelial neutrophilic microabscesses[2].

Treatment

When asymptomatic, geographic tongue requires no treatment other than assuring the patient that it represents a benign condition. If symptoms interfere with the patient's lifestyle, application of viscous

Fig. 72.3 Geographic tongue. Multiple depapillated areas which have gradually enlarged to form slightly atrophic patches with peripheral erythema and a yellowish-white serpiginous border. *Courtesy Carl M. Allen, DDS, MSD and Charles Camisa, MD.*

lidocaine, diphenhydramine, or in more severe cases, topical corticosteroids may provide relief.

Fissured Tongue

Synonyms: ■ Scrotal tongue ■ Plicated tongue ■ Lingua plicata ■ Furrowed tongue

Introduction

Fissured tongue is a common, benign condition of unknown etiology that affects the dorsal tongue. It may occur in isolation or accompany another oral condition (e.g. geographic tongue) or a genetic syndrome (e.g. Down and Cowden syndromes, pachyonychia congenita). The etiology is unknown but there may be an hereditary component, either polygenic or autosomal dominant with incomplete penetrance. Lastly, fissured tongue is a clinical feature of Melkersson–Rosenthal syndrome (see below).

Epidemiology

Fissured tongue affects both sexes. The prevalence increases with age and ranges from 2%–30%, depending on the population studied[4]. There may be an increased incidence in patients with acromegaly.

Clinical features

Fissured tongue typically presents as multiple 2–5 mm deep grooves or furrows on the dorsal tongue (Fig. 72.4). These grooves may develop on the entire surface of the dorsal tongue, present as a central fissure with or without a smaller branching fissure, or affect just isolated areas of the dorsolateral tongue. Although most patients are asymptomatic, some may report mild soreness or burning.

Pathology

Histopathologic features include hyperplastic rete ridges, loss of keratin overlying filiform papillae, deep fissures accompanied by exocytosis of neutrophils and intraepithelial microabscesses, and mixed inflammation within the lamina propria.

Treatment

Fissured tongue is a benign condition requiring no treatment.

Hairy Tongue

Synonyms: ■ Coated tongue ■ Black hairy tongue ■ Lingua villosa nigra

Fig. 72.4 Fissured tongue. Numerous asymptomatic furrows and grooves on the dorsal tongue. *Courtesy Carl M. Allen, DDS, MSD and Charles Camisa, MD.*

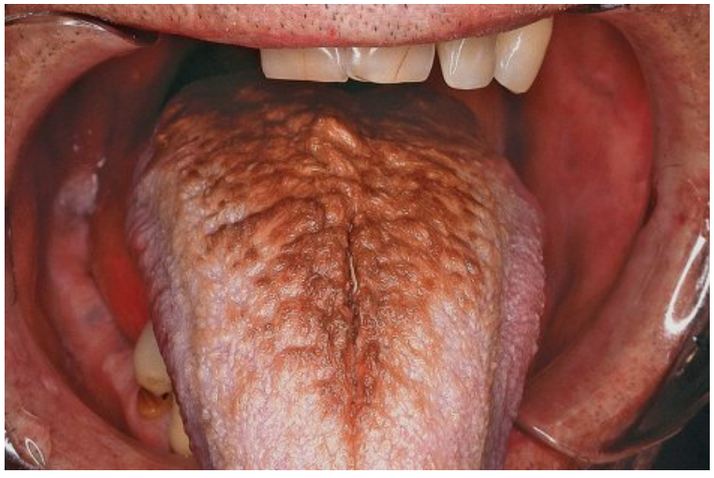

Fig. 72.5 Hairy tongue. The filiform papillae of the dorsal tongue have a marked accumulation of keratin, along with a brown discoloration. *Courtesy Carl M. Allen, DDS, MSD and Charles Camisa, MD.*

Key features

- Retention of keratin on the tips of filiform papillae
- Not due to yeast infection
- Best managed using a tongue scraper

Introduction

Hairy tongue is a benign acquired condition that reflects a reduced rate of desquamation and subsequent accumulation of keratin over the filiform papillae. Predisposing factors include a reduction in food intake, dehydration, and adherence to a primarily soft or liquid diet as well as smoking, hyposalivation, poor oral hygiene, use of oxidizing mouthwashes, and frequent consumption of hot beverages.

Epidemiology

Hairy tongue affects both sexes, with a prevalence reported as 0.5%–5% of the population.

Clinical features

Hairy tongue is usually asymptomatic and favors the midportion of the dorsal tongue (Fig. 72.5). The elongated papillae are usually yellow to brown–black, although a wide range of colors may occur due to differential exogenous staining from food, tobacco, or chromogenic bacteria. Some patients complain of bad breath, a bad taste, or a gagging sensation. A distinctly different entity is pigmented papillae of the tongue, a normal variant in which multiple uniformly spaced, tiny brown papules (representing normal fungiform papillae) are seen on the tip and lateral aspects of the tongue in darkly pigmented individuals (see Fig. 72.2A). Pseudo-back hairy tongue refers to black discoloration of the tongue due to bismuth.

Pathology

Microscopic examination reveals pronounced accumulation of parakeratosis at the tips of otherwise normal filiform papillae. Often, bacteria can be seen colonizing the surface.

Treatment

Hairy tongue is usually a self-limiting condition requiring no treatment. Better hydration, a diet containing fresh fruits or vegetables and more coarse foods, cessation of habits such as smoking or using alcoholic mouth rinses, and gentle exfoliation of the tongue with a soft toothbrush or tongue scraper can lead to improvement. Anecdotally, consumption of fresh pineapple may be recommended due to its acidity and high content of fiber and bromelain (bromelin).

Central Papillary Atrophy

Synonyms: ■ Median rhomboid glossitis ■ Erythematous candidiasis

Key features

- Red, well-demarcated area in the midline of the posterior dorsal tongue
- Consistently associated with candidiasis
- Responds partially or completely to antifungal therapy

Introduction

Central papillary atrophy, also referred to as median rhomboid glossitis, was originally thought to be a developmental defect resulting from failure of the embryonic tuberculum impar to be covered by the lateral processes of the tongue. However, it is seen more often in adults than in children and there is a frequent association with chronic candidal infection.

Epidemiology

The lesion is seen in up to 1% of adults, with no sex predilection.

Clinical features

Central papillary atrophy appears as a variably symptomatic, well-demarcated, diamond- or oval-shaped area of erythema and atrophy in the midline of the dorsal tongue (Fig. 72.6), anterior to the circumvallate papillae. The surface may be smooth or lobulated. It may be the sole clinical finding or there may be other sites of involvement – the hard and soft palate (kissing lesions) and/or the angles of the mouth (angular cheilitis) – as a reflection of chronic multifocal candidiasis.

Pathology

In the setting of active infection, histopathologic features include loss of the filiform papillae and pseudohyphae of *Candida albicans* embedded within parakeratosis. The diagnosis is usually a clinical one, with confirmation via demonstration of pseudohyphae in a potassium hydroxide (KOH) preparation or a PAS-stained exfoliative cytologic preparation.

Fig. 72.6 Central papillary atrophy. On the dorsal tongue anterior to the circumvallate papillae, there is a well-demarcated, smooth area with loss of filiform papillae.

Treatment

Topical antifungals include nystatin rinses and pastilles, clotrimazole troches, and in some countries, miconazole gel and amphotericin lozenges (see Table 77.15). First-line systemic therapy consists primarily of oral fluconazole. Following appropriate anti-candidal therapy, the mucosal alterations normally resolve partially or completely. Recalcitrant disease may be due to persistence of risk factors or possibly drug resistance (see Ch. 77).

SYNDROMES OF THE HEAD AND NECK

Basal Cell Nevus Syndrome

Synonyms: ■ Nevoid basal cell carcinoma syndrome ■ Gorlin syndrome

Basal cell nevus syndrome (BCNS) is an autosomal dominant disorder due to *PTCH1*, or rarely *PTCH2* or *SUFU*, mutations (see Ch. 107). However, up to 50% of patients may have *de novo* mutations[5]. Major clinical criteria include multiple basal cell carcinomas (BCCs) and palmoplantar pits as well as skeletal anomalies and odontogenic keratocysts (OKCs) of the jaws (see Table 108.3). OKCs typically develop in the posterior body of the mandible and appear radiologically as radiolucent cystic lesions with well corticated borders. Careful and complete excision of OKCs is recommended as recurrences and significant complications may follow incomplete removal.

Gardner Syndrome

Synonym: ■ Familial colorectal polyposis

Gardner syndrome is a variant of *familial adenomatous polyposis*, an autosomal dominant disorder due to mutations in the adenomatous polyposis coli gene (*APC*). Up to 30% of patients may have *de novo* mutations. In addition to premalignant intestinal polyps, patients can develop desmoid or fibrous tumors of the skin and early-onset epidermoid cysts (see Ch. 63). Osteomas occur in the majority of patients and favor the mandible as well as other bones of the skull. Osteomas, along with bilateral CHRPE (*c*ongenital *h*ypertrophy of the *r*etinal *p*igment *e*pithelium), represent early manifestations of this syndrome. Screening, dental anomalies, and treatment recommendations are discussed in Chapter 63.

Multiple Endocrine Neoplasia Syndrome Type 2B

Synonyms: ■ Multiple endocrine neoplasia type 3 ■ Multiple mucosal neuroma syndrome

Multiple endocrine neoplasia syndrome type 2B (MEN 2B) is a rare autosomal dominant disorder due to missense mutations in the *RET* proto-oncogene. It is associated with early-onset medullary thyroid carcinoma, diffuse gastrointestinal ganglioneuromatosis, and pheochromocytomas (see Table 63.2)[6]. Multiple soft mucosal neuromas of the lips, anterior tongue, and eyelid margins may be present at birth or develop during early childhood thus serving as an important diagnostic finding (see Fig. 63.2). Of note, however, patients with PTEN hamartoma tumor syndrome also occasionally develop mucosal neuromas.

Analysis of the *RET* gene should be performed in patients with clinical evidence of the disease as well as in asymptomatic individuals with an affected parent. Based upon the specific *RET* mutation detected, the recommended age for prophylactic thyroidectomy varies from infancy to 10 years.

PERIODONTAL AND DENTAL DISEASE

Necrotizing Ulcerative Gingivitis

Synonyms: ■ Trench mouth ■ Acute necrotizing ulcerative gingivitis (becoming historic given lack of chronic form) ■ Necrotizing gingivostomatitis ■ Vincent infection ■ Fusospirochetal gingivitis

Key features

- Painful, hemorrhagic, necrotic gingivae with classic "punched-out" interdental papillae
- Mixed bacterial infection in susceptible hosts with predisposing risk factors
- Predisposing risk factors include immunosuppression, malnutrition, stress, smoking, and poor oral hygiene

Introduction

Necrotizing ulcerative gingivitis (NUG) is characterized by pain, bleeding, and necrosis of interdental gingival papillae. The infection is due to a mixed population of bacteria, including spirochetes (e.g. *Treponema*), *Prevotella intermedia*, *Fusobacterium* and *Selenomonas* spp., and *Porphyromonas gingivalis*.

Epidemiology

NUG affects <0.1% of the population, is primarily seen in young to middle-aged adults, and does not have a sex predilection. Predisposing factors include immunosuppression, malnutrition, poor oral hygiene, physical stress, and smoking.

Clinical features

NUG is characterized by inflamed, edematous, and hemorrhagic interdental papillae. However, unlike generalized severe gingivitis, the affected papillae in NUG have a blunted appearance with "punched-out", crater-like areas of necrosis and ulceration. Generally, patients present with halitosis, severe pain, spontaneous bleeding from the gingivae, and accumulation of necrotic debris on the teeth and gingival surfaces. Systemic signs and symptoms may include fever, malaise, and lymphadenopathy.

Pathology

The histopathologic features are nonspecific and include ulceration of the epithelium that is covered by fibrinous debris and a mixed inflammatory infiltrate in the lamina propria. Bacterial colonization is common but because the primary etiologic agents represent normal oral flora, bacterial culture results are not very helpful.

Treatment

The most appropriate therapy is provided by a periodontist and includes debridement of the necrotic tissue to reduce inflammation and microbial load as well as investigation of the underlying cause(s). Chlorhexidine oral rinses (0.12%) may reduce the bacterial load. Broad-spectrum antibiotics are prescribed, especially when there are systemic signs of infection.

Desquamative Gingivitis

Key features

- A clinical descriptor for oral manifestations of an underlying immune-mediated vesiculoerosive disease
- Characterized by diffusely smooth, red, and sometimes painful gingivae
- Histopathologic and immunofluorescence studies are required for appropriate diagnosis and subsequent treatment of the underlying condition

Introduction

Desquamative gingivitis is a nonspecific clinical term used to describe superficial sloughing of the gingival epithelium. It is nearly always a manifestation of a vesiculoerosive disease such as lichen planus (see Ch. 11), mucous membrane pemphigoid (see Ch. 30), or pemphigus vulgaris (see Ch. 29). Fig. 72.7 outlines the multiple causes of desquamative gingivitis.

Epidemiology

Desquamative gingivitis primarily affects women over the age of 40 years.

Clinical features

Desquamative gingivitis primarily affects the maxillary and mandibular gingivae, either focally or diffusely (see Fig. 72.1). Affected areas are friable, denuded, and erythematous with occasional ulceration (Fig. 72.8). The gingivae may be the sole site of involvement or the gingivitis may be accompanied by erosions elsewhere in the mouth, on the lips, or in other mucosal sites. Patients often report soreness and sensitivity and, depending on the severity, diet and maintaining oral hygiene may be adversely impacted. Intact vesicles of the gingivae are rarely seen.

Pathology

The specific histopathologic and immunopathologic features of desquamative gingivitis depend on the underlying vesiculoerosive disease. Diagnosis is established via an incisional biopsy processed for both routine histology and direct immunofluorescence (DIF)[7]. In addition, when indicated, indirect IF (IIF) testing or an enzyme-linked immunosorbent assay (ELISA) can be utilized to detect circulating autoantibodies (see Fig. 72.7).

Treatment

Once a diagnosis is established, appropriate treatment for the responsible condition can follow. Meticulous dental prophylaxis (cleaning), oral hygiene instructions, and longitudinal evaluation are recommended. Reducing bacterial plaque often decreases the severity of lesions and is an important adjunct to medical therapy[7].

Sequelae of Dental Caries

Key features

- Dental infections can spread beyond the periapical region of teeth
- Periapical abscess, osteomyelitis, cellulitis, intraoral dental sinus, and cutaneous sinus are potential sequelae
- Emergent cases require immediate treatment to avoid airway obstruction or possible sepsis

Introduction

Dental caries is due to a microbial process that causes localized destruction and loss of mineralized tissues. This may result in infection of the pulp with extension to the periapical region of the tooth. In immunocompromised hosts or with particularly virulent bacteria, there may be spread of the infection to bone and soft tissues or further localized destruction. The latter can lead to a cutaneous sinus of dental origin (Fig. 72.9).

Clinical features

Dental caries is defined as localized loss of the mineralized structure of the tooth (enamel, dentin, or cementum) due to an infectious process. It may present as any one or a combination of the following: cavitation of enamel, brown discoloration, whitened chalky appearance, or soft scrapable tooth structure. Sequelae from spread of the bacterial infection beyond the tooth structure vary from contained asymptomatic bone destruction to severe facial cellulitis.

A periapical abscess forms when there is a localized accumulation of inflammatory cells and bacterial debris in the periapical space of a non-vital tooth; the abscess may be acute or chronic and symptoms range from none to severe pain. When the infection erodes through cortical bone to create a path for drainage, a "sinus tract" or "parulis" forms. An *intraoral dental sinus tract* is characterized by a soft, non-tender, erythematous papule that develops on the alveolar process, typically in the same region as the apex of the offending non-vital tooth. If the infection tunnels through the skin, a *cutaneous sinus tract of dental origin* forms which can present as an ulceration, a fibrosed depression, or an erythematous, sometimes eroded, papule (see Fig. 72.9).

DIFFERENTIAL DIAGNOSIS OF DESQUAMATIVE GINGIVITIS

Differential diagnosis of desquamative gingivitis*

Lichen planus (LP) Lichenoid drug reaction Lupus erythematosus (LE) GVHD	Autoimmune bullous disorder – mucous membrane (cicatricial) pemphigoid, pemphigus vulgaris, paraneoplastic pemphigus (PNP) > EBA, BP, LABD	Erythema multiforme, fixed drug eruption	Chronic ulcerative stomatitis	Contact dermatitis, allergic or irritant	Lichenoid contact stomatitis, lichenoid foreign body gingivitis
• Lacy white plaques (e.g. Wickham striae) of oral &/or other mucosae • Correct clinical setting for LE or GVHD • Appropriate medication history	• Erosions, ulcers, & occasionally vesicles/ bullae of oral &/or other mucosae • Ragged ulcers → pemphigus; smooth but irregular ulcers → mucous membrane pemphigoid	• Erosions, ulcers, & occasionally vesicles/ bullae of oral &/or other mucosae** • Recurrent episodes	• Clinically, resembles oral erosive LP, but asymmetric distribution of lesions & striae less sharply defined	• Need to look for unusual causes (e.g. nail polish in nail biters, sucking on metal objects) • See Table 72.1	• Lesions may result from exposure to cinnamon flavoring agents in food, beverage, and oral hygiene products; embedded particles from dentifrices and dental restorative materials in foreign body gingivitis
H&E: interface-lichenoid inflammation; may be minimal in GVHD **DIF:** nonspecific, e.g. shaggy fibrinogen at BMZ in LP; granular IgG and/or IgM, C3 at BMZ in LE **IIF:** negative	**H&E:** (edge of erosion): acantholysis & intraepithelial (suprabasal) cleft versus subepithelial cleft; pleomorphic pattern in PNP† **DIF/IIF:** see Chs. 29 31	**H&E:** interface-lichenoid inflammation, apoptotic keratinocytes **DIF:** nonspecific **IIF:** negative	**H&E:** nonspecific, patchy interface mucositis **DIF:** staining of basal/ parabasal cell nuclei (necessary for diagnosis) **IIF:** positive – similar pattern to DIF	**H&E:** spongiosis, eosinophils in allergic form **DIF:** negative **IIF:** negative	**H&E:** interface-lichenoid inflammation **DIF:** nonspecific **IIF:** negative

*Some entities may have cutaneous lesions.

**Other mucosae (genital, ocular) – more so for erythema multiforme.

†The pleomorphic pattern in paraneoplastic pemphigus includes features of pemphigus and erythema multiforme as well as lichenoid inflammation.

Fig. 72.7 Differential diagnosis of desquamative gingivitis. If the gingivae are painful, hemorrhagic, and necrotic with punched-out interdental papillae, then necrotizing ulcerative gingivitis is the most likely clinical diagnosis. For presumed chronic ulcerative stomatitis, the detection of circulating anti-p63 antibodies via ELISA may assist in diagnosis. BP, bullous pemphigoid; BMZ, basement membrane zone; DIF, direct immunofluorescence (IF); EBA, epidermolysis bullosa acquisita; GVHD, graft-versus-host disease; IIF, indirect IF; LABD, linear IgA bullous dermatosis.

Fig. 72.8 Desquamative gingivitis due to oral erosive lichen planus. Erosions and prominent, fairly well-defined areas of erythema of the attached (keratinized) gingivae. Histopathologic examination plus DIF (and occasionally IIF or ELISA) are needed to establish the etiology (see Fig. 72.7).

Fig. 72.9 Cutaneous sinus of dental origin. A Dull pink papule and adjacent indentation on the jawline. **B** An ulceration in a similar location. These sinuses originated from periapical dental abscesses in the mandible that then channeled through the overlying skin to drain. They may be mistaken for a pyogenic granuloma, neoplasm, or cutaneous infection. *A, Courtesy Carl M. Allen, DDS, MSD and Charles Camisa, MD.*

In addition to sinus tracts, cellulitis and occasionally osteomyelitis may develop and both usually have associated pain. Patients with cellulitis can also have fever, chills, and lymphadenopathy while a foul-smelling drainage may accompany osteomyelitis. There are two potential complications that represent a particular danger to patients and demand immediate attention. *Ludwig's angina* presents as swelling of the submandibular, submental, and sublingual spaces. Urgent attention is required for this form of cellulitis as it can rapidly spread to the retropharyngeal space, obstructing breathing, and even spread to the mediastinum. *Cavernous sinus thrombosis* due to a dental abscess may initially present as swelling of the canine space. Infraorbital, ocular, and eventually CNS involvement may develop.

Treatment

Treatment involves elimination of the focus of infection, which often requires incision and drainage, endodontic "root canal" therapy or extraction of the involved tooth, appropriate antibiotic therapy, and airway management, if necessary. Microbiological testing assists in the choice of antibiotics and allows exclusion of cervicofacial actinomycosis.

PHYSICAL AND CHEMICAL INJURIES

Fibroma

Synonyms: ■ Bite fibroma ■ Irritation or traumatic fibroma ■ Fibrous hyperplasia or nodule

Key features

- Smooth, pink, soft to rubbery nodule, typically on the buccal mucosa
- Asymptomatic unless persistently irritated or traumatized

Introduction

A fibroma is the most common "tumor" of the oral cavity. It most likely represents reactive hyperplasia of fibrous connective tissue in response to local trauma, including repeated biting.

Epidemiology

Fibromas most commonly occur during the fourth to sixth decades, with no sex predilection.

Clinical features

The typical lesion is a sessile, soft, smooth-surfaced papule or nodule similar in color to the surrounding normal mucosa. Depending on the location and extent of acute and chronic trauma, fibromas may be ulcerated or have a white keratotic surface. These papulonodules are usually <1.5 cm in diameter and are most commonly observed along the bite line of the buccal mucosa. However, they can also occur in other easily traumatized sites such as the lower labial mucosa and the anterolateral aspects of the tongue.

Pathology

Histologically, there is an unencapsulated mass of hyperplastic fibrous connective tissue with varying vascularity and minimal inflammation. The overlying epithelium may be ulcerated, atrophic, or hyperkeratotic secondary to friction or biting.

Treatment

Surgical excision is curative and histopathologic examination allows confirmation of the clinical diagnosis.

Contact Stomatitis

Key features

- Can be allergic or irritant
- Irritant contact stomatitis is the result of direct contact with a caustic agent
- Allergic contact stomatitis can be acute or chronic and has a range of signs and symptoms

Introduction

Contact stomatitis is a broad term that encompasses clinical findings secondary to exposure of the oral mucosa to a known contactant. It is subdivided into irritant contact stomatitis (ICS) and allergic contact stomatitis (ACS). As in the skin, the former results from direct mucosal injury by an irritant and when pronounced is referred to as a chemical burn; the latter is characterized by delayed type hypersensitivity to an allergen.

Epidemiology

Contact stomatitis may present at any age, but is more common in adults. While ICS does not have a sex predilection, ACS has a female predominance.

Clinical features

In mild ICS, erythema and textural changes of the mucosa may be seen. Direct placement of a caustic agent such as an aspirin or alendronate onto the mucosa can lead to more severe disease, with erythema appearing shortly after exposure. Depending on the duration of exposure and irritancy potential of the contactant, ICS may present as edema, sloughing of the epithelium, and even painful necrotic ulcers (Fig. 72.10)[8].

A wide range of allergens can induce ACS including flavorings such as cinnamon and peppermint in dentifrices, mouthwashes, and chewing gum and dental restorative materials (e.g. amalgam) (Fig. 72.11; Table 72.1). The clinical findings of acute ACS range from varying degrees of erythema with or without edema to superficial ulcerations and in rare cases, vesicle formation. In chronic ACS, sites of involvement may be erythematous, keratotic, or erosive and in some patients resemble lichen planus. The most common symptom of both ACS and ICS is burning within the mouth which may be generalized or limited to the affected area.

Pathology

The range of clinical presentations results in varying histopathologic findings. In ACS, epithelial spongiosis and submucosal inflammatory infiltrates that contain eosinophils and plasma cells can be seen. Ulcerations from ICS or ACS have coagulative necrosis of the epithelium with variable extension into the underlying connective tissue. In lichenoid contact stomatitis, e.g. due to contact with metals contained in dental amalgam, a lichenoid inflammatory reaction is seen that is indistinguishable from oral lichen planus. Metal particles within the lamina propria (particularly amalgam), if present, are a clue to lichenoid contact stomatitis.

Treatment

A thorough history may identify the responsible contactant and its elimination is often curative. In the case of ACS, patch testing can

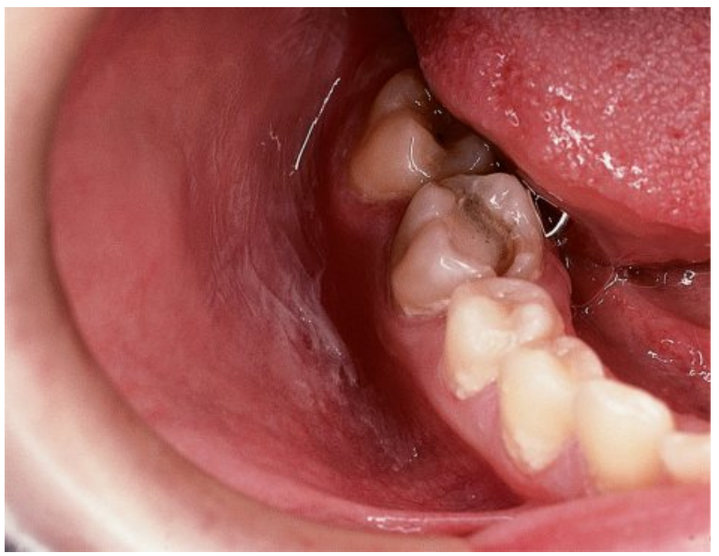

Fig. 72.10 Irritant contact stomatitis (aspirin burn). To relieve a toothache, this patient placed an aspirin in the mouth adjacent to the symptomatic tooth. Note the wrinkled white membrane that represents superficial epithelial necrosis.
Courtesy Carl M. Allen, DDS, MSD and Charles Camisa, MD.

Fig. 72.11 Allergic contact stomatitis from artificial cinnamon flavoring. Shaggy, white keratotic plaque of the left buccal mucosa caused by the use of artificial cinnamon-flavored gum. *Courtesy Carl M. Allen, DDS, MSD and Charles Camisa, MD.*

POTENTIAL CAUSES OF CONTACT STOMATITIS OR CHEILITIS
Allergic
• **Flavorings**: cinnamon, mint, menthol, vanillin • **Fragrances**: *Myroxylon pereirae* (Balsam of Peru), cinnamic aldehyde • **Dental metals**: nickel, mercury, gold, palladium, copper, silver, cobalt, chromium, beryllium, tin, zinc • Dental adhesives: acrylic resin monomers, eugenol (combined with zinc oxide) • Topical anesthetics: benzocaine • Essential oils: clove, lemon, orange • For additional causes of allergic contact cheilitis, see Fig. 72.15
Irritant
• **Aspirin** • Dental chemicals: eugenol, peroxides, phenol, sodium hypochlorite • Chlorhexidine mouth rinse • Silver nitrate stick • Sodium lauryl sulfate and sodium pyrophosphate (in toothpaste)

Table 72.1 Potential causes of contact stomatitis or cheilitis. Most common offenders in **bold** (see Chs. 14 & 15). Contact lichenoid reactions also occur (e.g. metals, spices, acrylic resin monomers), and heat or traumatic injuries can lead to irritation.

identify the responsible allergen (see Ch. 14). Application of emollient pastes or topical anesthetics as a palliative measure may provide temporary relief.

Morsicatio Mucosae Oris

Synonyms: ■ Chronic bite keratosis
Variants: ■ Morsicatio buccarum (buccal mucosa) ■ Morsicatio labiorum (labial mucosa) ■ Morsicatio linguarum (tongue)

Key features

- Factitial habit
- Shaggy white lesions of the anterior buccal mucosa, lateral tongue, or lower labial mucosa
- No treatment indicated

Introduction

Morsicatio mucosae oris (MMO) is a benign condition that is due to repetitive chewing, biting, or nibbling of the oral mucosa[2].

Fig. 72.12 Cheek chewing (morsicatio buccarum) – clinical and histopathologic findings. Repetitive nibbling of the superficial layers of the epithelium resulted in these changes. Note that the characteristic shaggy, white lesion approximates the area where the upper and lower teeth meet. Inset: Oral epithelium exhibiting acanthosis and prominent parakeratosis, with a ragged surface architecture and superficial colonization by bacteria. *Courtesy Carl M. Allen, DDS, MSD and Charles Camisa, MD.*

Epidemiology

MMO usually affects individuals during or after their fourth decade of life.

Clinical features

The most common site for MMO is the buccal mucosa followed in frequency by the ventrolateral tongue and lower labial mucosa. MMO classically presents as bilateral shaggy white lesions of the anterior buccal mucosa that approximate the area of chronic trauma (Fig. 72.12).

Pathology

Histopathologic findings are nonspecific and include acanthosis, marked parakeratosis, an irregular, shaggy surface of the epithelium with fissures and clefts, and varying degrees of vacuolization and spongiosis in the superficial portion of the epithelium (Fig. 72.12 inset). Surface colonization by bacteria is also a frequent feature.

Treatment

Because MMO is a benign condition, it requires no treatment.

Traumatic Ulcer

Key features

- Acute or chronic injury to the oral mucosa may cause a traumatic ulcer
- Commonly occurs on the tongue, lips, or buccal mucosa
- Simple traumatic ulcers are self-limiting and heal within a week following removal of the etiologic agent
- Traumatic ulcerative granuloma with stromal eosinophilia may mimic oral squamous cell carcinoma

Introduction

Acute or chronic mechanical injury, e.g. biting or trauma from sharp foods or objects such as the sharp edge of a fractured tooth, may result in laceration of the oral mucosa. Simple traumatic ulcers (STUs) usually heal within days. However, sometimes there is progression to a chronic variant which is referred to as traumatic ulcerative granuloma with stromal eosinophilia (TUGSE) as well as eosinophilic ulceration, traumatic granuloma, and eosinophilic granuloma of the tongue. These ulcers may mimic oral squamous cell carcinoma (OSCC).

Epidemiology

TUGSE has a bimodal peak prevalence: (1) infants between 1 week and 1 year of age (Riga–Fede disease); and (2) adults. TUGSE is uncommon in older children and adolescents.

Clinical features

Traumatic ulcers most commonly affect the tongue, followed by the lips and buccal mucosa. An STU presents as a central ulcer with a variable degree of surrounding erythema and it heals within 7–10 days. TUGSE often presents as a central ulcer with a yellow fibrinous base whose border is rolled, white, and keratotic with mild erythema (Fig. 72.13). Because these ulcers may persist for months, they can mimic OSCC.

Riga–Fede disease is associated with neonatal teeth and most commonly involves the anterior ventral or dorsal surface of the tongue due to mandibular or maxillary incisors, respectively.

Pathology

In an STU, there is a sharply demarcated ulcer with overlying fibrin and neutrophils and a variable nonspecific inflammatory infiltrate at its base. The adjacent epithelium is normal or hyperplastic. TUGSEs are characterized by a dense, diffuse inflammatory response composed of eosinophils, lymphocytes, plasma cells, and pleomorphic mononuclear cells that extend deeply into the submucosal tissue and underlying striated muscle. Although $CD30^+$ cells are a common finding, TUGSE is not associated with EBV infection and should be distinguished from EBV^+ mucocutaneous ulcer.

Treatment

For STU, avoidance of injury or elimination of the obvious causative agent(s) is usually curative. Given the clinically suspicious presentation, TUGSEs often undergo incisional or excisional biopsy which may trigger healing. Application of topical corticosteroids can accelerate healing and provide symptomatic relief; however, some cases may require more aggressive therapy including intralesional corticosteroids or surgical excision.

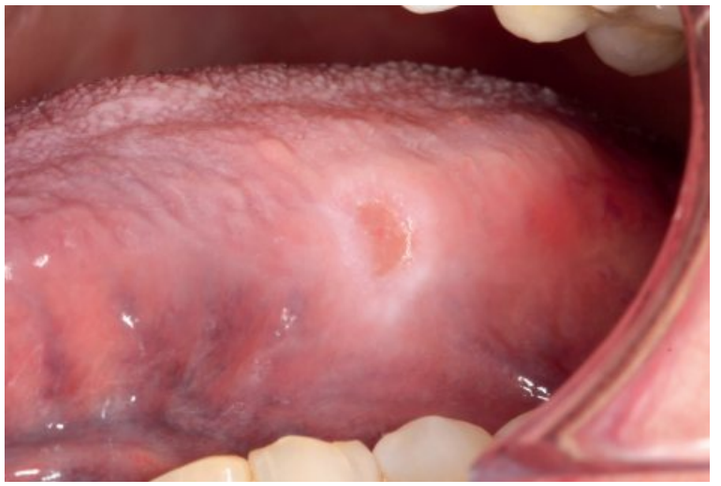

Fig. 72.13 Traumatic ulcer of the lateral tongue. The ulceration has a yellow fibrinous base with a blended white hyperkeratotic border. Compare this to the ulcerated leukoplakia with well-defined keratotic borders depicted in Fig. 72.21A and the exophytic, ulcerated mass depicted in Fig. 72.21B, which represent oral squamous cell carcinomas. *Courtesy Carl M. Allen, DDS, MSD, Charles Camisa, MD, and Kristin K. McNamara, DDS, MS.*

Drug-Related Gingival Hyperplasia

Synonyms: ■ Medication-related gingival hyperplasia ■ Drug-related gingival overgrowth ■ Drug-related gingival enlargement

Key features

- Enlargement of the gums occurs during the first year of drug administration
- Most commonly associated with phenytoin, nifedipine, and cyclosporine
- Severity correlates with patient susceptibility and level of oral hygiene

Introduction

Drug-related gingival hyperplasia is characterized by abnormal growth of the gingivae in response to a systemic medication. Multiple medications have been associated with gingival enlargement, in particular phenytoin, nifedipine, and cyclosporine (Table 72.2). Although a dose-dependent association is still controversial, the overgrowth definitely correlates with poor oral hygiene. Other causes of gingival hyperplasia are outlined in Table 72.2.

Epidemiology

The most common age for presentation depends upon the epidemiology of the condition being treated by the culprit medication. While drug-related gingival hyperplasia due to the use of phenytoin is more common in those under the age of 25, cases secondary to calcium channel blockers mainly occur in middle-aged or older adults.

Clinical features

Evidence of gingival hyperplasia can be noted as early as one month after drug initiation, with the interdental papillae the most common initial site of involvement. The hyperplasia may extend over part or all of the involved teeth. Although edentulous areas are usually spared, significant hyperplasia under poorly maintained dentures has been reported. The enlarged gingiva is usually normal in color, firm, and nodular or lobulated. However, associated inflammation can lead to a red, edematous, or friable appearance.

CAUSES OF GINGIVAL HYPERPLASIA (ENLARGEMENT, OVERGROWTH)

Systemic medications	
Common	
Anticonvulsants (**phenytoin**, phenobarbital, lamotrigine, vigabatrin, ethosuximide, topiramate, primidone, valproate)	
Calcium channel blocking agents (**nifedipine**, amlodipine, diltiazem, felodipine, verapamil)	
Cyclosporine*	
Uncommon	
Antibiotics (clarithromycin, erythromycin, trimethoprim-sulfamethoxazole [co-trimoxazole])	Sertraline
Lithium	Oral contraceptives, estrogens
Amphetamines	Vemurafenib
Additional causes	
• Local inflammatory factors – poor oral hygiene, periodontal disease • Hormone-related – pregnancy, acromegaly • Granulomatous disorders – primary orofacial granulomatosis (cheilitis granulomatosa), Crohn disease, sarcoidosis • Granulomatosis with polyangiitis (formerly Wegener granulomatosis) • Vitamin C deficiency (scurvy) • Gingival fibromatosis/multiple gingival fibromas – tuberous sclerosis complex, Cowden syndrome, hereditary gingival fibromatosis • Leukemia – acute monocytic leukemia, acute myelomonocytic leukemia > other types of myelogenous or lymphocytic leukemias • Other malignancies – Kaposi sarcoma; metastases, in particular carcinoma of the breast, prostate, colon, kidney, or lung • Deposition – primary systemic amyloidosis, infantile systemic hyalinosis, mucopolysaccharidoses, fucosidosis, Fabry disease	
*There is evidence that substitution of tacrolimus for cyclosporine may lead to resolution or reduce the risk of recurrence after surgical removal of the hyperplastic tissue.	

Table 72.2 Causes of gingival hyperplasia (enlargement, overgrowth). Most common drugs in **bold**.

Pathology

Microscopically, the redundant tissue is of normal composition or exhibits fibrovascular hyperplasia. When the specimen is clinically inflamed, there is increased vascularity and a chronic inflammatory cell infiltrate.

Treatment

A rigorous regimen of oral hygiene consisting of frequent professional cleaning and home plaque control utilizing chlorhexidine rinses is recommended. Discontinuation of the suspected offending drug or even substitution with another drug of the same class may result in cessation or some regression of the gingival hyperplasia. If discontinuation of the suspected medication does not lead to improvement, gingivectomy may be considered.

ALLERGIC AND IMMUNOLOGIC DISEASES

Recurrent Aphthous Stomatitis

Synonyms: ■ Recurrent oral aphthae ■ Aphthous ulcers ■ Canker sores
Variants: ■ Minor aphthae ■ Major aphthae ■ Herpetiform aphthae ■ Complex aphthosis

Key features

- The etiopathogenesis is unknown, but immunologic factors may play a role
- Although individual ulcers often heal spontaneously, topical corticosteroids and systemic medications can be used to address disease activity

Introduction

Recurrent aphthous stomatitis (RAS) is a relatively common ulcerative disorder of the oral cavity. While the etiology remains obscure, it is likely multifactorial and influenced by a host of predisposing factors. Although most commonly idiopathic, RAS can be associated with Behçet disease, inflammatory bowel disease, cyclic neutropenia, HIV infection, and possibly hematinic (iron, folate, or vitamin B_{12}) deficiencies (Table 72.3)[9]. Complex aphthosis is defined as nearly constant disease with ≥3 oral ulcers +/− genital ulcers and requires a search for an underlying disease or syndrome.

Epidemiology

RAS is a common disorder affecting >20% of the population. Idiopathic disease usually presents during the second or third decades of life, with severity and frequency diminishing with age.

Clinical features

Four clinical subtypes of RAS have been described: minor, major, herpetiform, and complex (severe). *Minor aphthae*, the most common form, are characterized by round to ovoid, shallow, painful ulcers that are usually <1 cm in diameter (Fig. 72.14). The ulcers are typically limited to the non-keratinized ("movable") oral mucosa, with common sites of involvement including the labial and buccal mucosa, floor of the mouth, ventral surface of the tongue, soft palate, and oropharyngeal mucosa. These lesions usually heal without scarring within 1–2 weeks.

Major aphthae are characterized by larger, deeper ulcers, typically >1 cm. They persist for up to 6 weeks and may heal with scarring. Lesions are associated with considerable oral pain and are sometimes accompanied by fever and malaise. *Herpetiform aphthae* are uncommon, consisting of multiple (>10) small, painful ulcers that resemble primary HSV infection. They are typically confined to non-keratinized mucosa and after coalescing can mimic major aphthae. In *complex aphthosis* (*severe aphthae*), there are continuous recurrences of minor aphthae (see definition above)[10,11].

Pathology

Histopathologic features are relatively nonspecific. They include an ulceration with overlying fibrin and neutrophils and an underlying inflammatory infiltrate. In most patients, however, the appearance and distribution of lesions allow for the diagnosis to be made clinically.

Treatment

The primary goals of therapy are promotion of healing, management of pain and nutrition, and prevention of recurrence[12]. Typically, analgesia and topical corticosteroids significantly reduce pain and time to healing. The frequency of episodes is often reduced following topical corticosteroid therapy. Patients with complex aphthosis may require systemic therapy (Table 72.4).

Behçet Disease

Synonym: ■ Behçet syndrome

Key features

- Recurrent oral and genital aphthae
- Anterior or posterior uveitis and/or retinal vasculitis
- Erythema nodosum-like and papulopustular lesions

Behçet disease is a rare chronic multisystem disorder that is more prevalent in individuals whose ancestry includes regions along the ancient Silk Route (see Ch. 26)[12,13]. Disease activity may be intermittent, with exacerbations and remissions of unpredictable duration

RECURRENT APHTHAE – ETIOLOGIES AND DIFFERENTIAL DIAGNOSIS
Etiologies
• Idiopathic (immune-mediated) • Related to an underlying systemic disorder: inflammatory bowel disease, celiac disease, systemic lupus erythematosus, HIV infection, Behçet disease, MAGIC syndrome (*m*outh *a*nd *g*enital ulcers with *i*nflamed *c*artilage), reactive arthritis*, cyclic neutropenia, PFAPA (*p*eriodic *f*ever, *a*phthous stomatitis, *p*haryngitis and *a*denitis) syndrome, certain hereditary periodic fever syndromes (e.g. HIDS, NOMID) • Medications (e.g. mTOR inhibitor) • Possibly related to an underlying nutritional disorder (controversial): vitamin B_{12}, folate, or iron deficiency
Differential diagnosis
• Recurrent erosions and ulcerations due to an inflammatory disorder, e.g. erythema multiforme, fixed drug eruption, contact stomatitis, autoimmune bullous disease – less pain at onset, less peripheral erythema • Recurrent herpes simplex viral infection – only involves keratinized mucosa (hard palate, attached gingiva) in immunocompetent hosts (see Fig. 72.1) • Trauma – less pain at onset, less peripheral erythema, more ragged edges
*Previously referred to as Reiter disease.

Table 72.3 Recurrent aphthae – etiologies and differential diagnosis. Potential triggers are stress and specific foods (e.g. nuts, citrus, or acidic foods). HIDS, hyperimmunoglobulinemia D with periodic fever syndrome; HIV, human immunodeficiency virus; NOMID, neonatal-onset multisystem inflammatory disease.

Fig. 72.14 Recurrent aphthous stomatitis. Adjacent minor aphthous ulcers arising in non-keratinized mucosa. The ulcerations are shallow with a creamy white surface and surrounded by an intensely red halo, a characteristic finding. *Courtesy Carl M. Allen, DDS, MSD and Charles Camisa, MD.*

and frequency. Multiple oral aphthae are often the first sign of the disease and are present in the vast majority of patients[13].

Systemic manifestations, clinical criteria for the diagnosis of Behçet disease, and treatment options are outlined in Tables 25.12, 25.14 and 25.15, respectively.

Autoimmune Bullous Diseases

Multiple erosions or ulcerations occur in several autoimmune bullous diseases, most commonly pemphigus vulgaris, but also mucous membrane pemphigoid, paraneoplastic pemphigus, bullous pemphigoid, epidermolysis bullosa acquisita, and linear IgA bullous dermatosis (see Chs. 29–31). The differential diagnosis includes multiple fixed drug eruption, herpetic infections, *Mycoplasma pneumoniae*-induced rash and mucositis (MIRM), and hemorrhagic bullous angina. The latter is an idiopathic or trauma-induced disorder that presents with recurrent hemorrhagic bullae within the oral cavity (usually the soft palate).

THERAPEUTIC LADDER FOR COMPLEX APHTHOSIS
Local therapy (agents may be used in combination)
Local anesthetics (2) Topical doxycycline hyclate (1) Superpotent topical corticosteroids (1*/2) or corticosteroid inhalers (2) Intralesional corticosteroids (2) Topical tacrolimus (3) Silver nitrate (1)
Systemic therapy
Intermittent prednisone (e.g. 20–40 mg/day × 4–7 days, 25 mg/day then taper over 2 months; up to 3 cycles/year) (3,1) Colchicine (1†/2) Dapsone (1†/2) Combination of colchicine and dapsone (2) Apremilast (1†/2) Thalidomide (1) Montelukast (1) TNF inhibitors (e.g. etanercept, adalimumab, infliximab, golimumab) (3)
*Clobetasol propionate in an adhesive denture paste. †In patients with Behçet disease.

Table 72.4 Therapeutic ladder for complex aphthosis. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. *Adapted from Letsinger JA, et al. J Am Acad Dermatol 2005;52:500–8, with permission.*

CHEILITIS

Key features

- A general term used to describe inflammation of the lips
- Depending on the underlying cause, the clinical presentation and treatment may vary

Introduction

Cheilitis is an umbrella term used to describe inflammation of the lips, which may involve both the vermilion zone and the perioral region. It is caused by a variety of internal and external factors, most commonly contact dermatitis (irritant > allergic) and chronic UV exposure (Fig. 72.15 & 72.16).

Eczematous cheilitis

Eczematous cheilitis can be due to atopic dermatitis as well as irritant and allergic contact dermatitis. A combination of these dermatitides is also commonly seen. It typically presents with xerosis, scaling, erythema, and fissuring of the lips. Burning and pruritus are common symptoms.

Irritant contact cheilitis often results from chronic lip licking (lip-licker's dermatitis) as well as from environmental factors such as cold, wind, and low humidity (see Fig. 72.16A). Additional causative factors include irritants in cosmetics, foods, and oral hygiene products (see Ch. 15). Typically, the upper and lower lips are involved, with frequent

DIFFERENTIAL DIAGNOSIS OF CHEILITIS*

Common	Less common	Less common
Actinic cheilitis Lower >> upper vermilion lip (Fig. 108.4) Background of photodamage History of AKs, BCC, SCC May have diffuse hyperkeratosis and/or discrete AKs	**Allergic contact dermatitis** Both upper and lower lip involved (Fig. 14.7) Allergens include: fragrances/flavorings (e.g. oral hygiene products, cosmetics), preservatives, sunscreens (Fig. 72.16B) > topical antibiotics (e.g. neomycin), metals (e.g. nickel; perioral > vermilion lips), propolis, topical corticosteroids	**Lichen planus, LE & GVHD** Lacy pattern on lips and oral mucosa (Fig. 72.16C) Oral and lip ulcerations (Fig. 72.16D–F) Lesions of lichen planus or GVHD elsewhere
Irritant contact dermatitis Both lower & upper lip involved Often extends onto cutaneous lip Lip licking most common cause (Fig. 72.16A)	**Candidal cheilitis** Predisposing factors: dentures/orthodontic appliances, inhaled/oral corticosteroids, diabetes mellitus, HIV infection, deep oral commissure grooves, drooling Scattered white plaques on vermilion lip (Fig. 77.22B) May have erosions Angular fissures and plaques (Fig. 77.22C) More likely to have oral thrush (Fig. 77.22A) When severe, can become verrucous	**Cheilitis granulomatosa** Diffuse enlargement of lip (Fig. 72.16G) Superimposed processes may lead to secondary changes May be associated with scrotal tongue and 7th nerve palsy in Melkersson–Rosenthal syndrome Sarcoidosis and Crohn disease are causes of secondary orofacial granulomatosis
Atopic dermatitis Atopic diathesis Lesions of atopic dermatitis elsewhere Xerosis Angular fissures (Fig. 12.14A)		**Other** Medications, in particular retinoids Nutritional deficiencies (see Table 51.2) Kawasaki disease, MIS-C Plasma cell cheilitis

*Often a combination, e.g. atopic dermatitis plus irritant contact dermatitis.

Fig. 72.15 Differential diagnosis of cheilitis. Uncommon causes include exfoliative cheilitis, cheilitis glandularis, and associations with other cutaneous disorders (e.g. cutaneous lupus erythematosus, actinic prurigo, lichen sclerosus), systemic disorders (e.g. Crohn disease, sarcoidosis, syphilis), and genetic disorders (e.g. Down syndrome, KID syndrome). AKs, actinic keratoses; BCC, basal cell carcinoma; GVHD, graft-versus-host disease; MIS-C, multisystem inflammatory syndrome in children; SCC, squamous cell carcinoma. *Courtesy Jean L. Bolognia, MD.*

A *Irritant contact dermatitis* due to lip licking with involvement of the vermilion and cutaneous lips as well as the perioral region. **B** *Allergic contact dermatitis* to oxybenzone with involvement of the upper and lower vermilion lips. **C** *Lichen planus* with a white lacy pattern of the lower lip and central upper lip. **D** Erosive *lichen planus* of the vermilion and mucosal lower lip. **E** Multiple jagged erosions limited to the lower vermilion lip in a patient with cutaneous *lupus erythematosus*. **F** Chronic *graft-versus-host disease* in which gray-white plaques are at the periphery of broad erosions. **G** Secondary *orofacial granulomatosis* characterized by diffuse enlargement of the lower > upper lip in an adolescent girl with Crohn disease. Note the coalescing tiny pink papules of the lower cutaneous lip and upper chin. *A, Courtesy Jeffrey P. Callen, MD; B, D, Courtesy Kalman Watsky, MD; C, F, G, Courtesy Julie V. Schaffer, MD; E, Courtesy Luis Requena, MD.*

extension onto the cutaneous lip. *Atopic* cheilitis occurs in individuals with atopic dermatitis or an atopic diathesis and characteristically presents with xerosis and angular fissures in addition to erythema and scaling (see Fig. 12.14A). A number of allergens (see Fig. 72.15) can lead to *allergic* contact cheilitis (see Fig. 72.16B)[14]. Women are more commonly affected than men, presumably due to greater exposure to lipsticks and cosmetics. Patients typically present with erythema, scaling, edema, fissuring, and superficial erosions on both the upper and lower lips, oftentimes with extension to the perioral cutaneous regions. In addition to careful history-taking, patch testing can assist in identifying culprit allergens (see Ch. 14).

Treatment involves removal and future avoidance of any known or suspected irritants or allergens. Simple emollients, such as white petrolatum, should be used frequently. Low- to mid-potency topical corticosteroids or topical calcineurin inhibitors can be applied twice daily for 2–3 weeks. Prolonged use of topical corticosteroids should be avoided, as it can exacerbate perioral dermatitis.

Actinic Cheilitis (see below)

Angular Cheilitis

In angular cheilitis (perlèche), there is inflammation of the skin and adjacent labial mucosa at the lateral commissures (angles or corners) of the mouth. Moist, macerated erythematous patches may be accompanied by erosions, angular fissures, and soreness (see Fig. 77.22C); oral thrush and candidal cheilitis may also be present. It is caused by excessive moisture that accumulates in the oral commissure grooves along with secondary infection with *Candida albicans*, and less commonly *Staphylococcus aureus*. It can occur at any age but is most often seen in older individuals with deep oral commissure grooves due to recession of the alveolar ridges, including those who are edentulous and wear dentures. In young children, excessive drooling and thumb sucking are common causes.

Diagnosis is usually made clinically, but in more difficult cases a lesional swab for bacterial and fungal culture can be obtained. Treatment involves addressing predisposing factors (e.g. poorly fitting dentures) as well as treating secondary fungal and bacterial infections. A topical antifungal cream (e.g. ketoconazole, clotrimazole) +/– topical mupirocin ointment applied twice a day for 1–3 weeks is often used, and oral thrush, if present, is treated. Maintenance therapy includes nighttime use of a barrier emollient such as white petrolatum or zinc oxide paste.

Drug-Induced Cheilitis

Several medications have been associated with cheilitis, most notably systemic retinoids, indinavir, sorafenib, and anticholinergic medications. Systemic retinoids routinely cause xerosis, peeling, and fissuring of the lips, and the effect is dose-dependent (see Fig. 126.8). Some implicated medications cause xerostomia with associated dryness of the lips. Management while on the medication includes liberal use of emollients (e.g. white petrolatum).

Exfoliative Cheilitis

In exfoliative cheilitis, there is persistent exfoliation of the vermilion lips, with scaling, desquamation, crusting, and hyperkeratosis. It is thought to be caused by chronic injury, most often from excessive licking, biting, picking, or sucking of the lips. It is most common in women under the age of 30 and many patients deny or are not aware of the habit. Exfoliative cheilitis is a diagnosis of exclusion. Topical emollients (e.g. white petrolatum), corticosteroids, and calcineurin inhibitors may be helpful in reducing symptoms, but psychiatric care to address underlying obsessive-compulsive tendencies or anxiety is often needed.

Plasma Cell Cheilitis

Plasma cell cheilitis is a rare disorder that typically presents as a well-circumscribed, eroded, erythematous plaque on the lower > upper lip. It is clinically and histologically similar to Zoon balanitis/vulvitis and the diagnosis is made upon histopathologic features. Treatment is difficult and often involves a trial of potent topical or intralesional corticosteroids.

Cheilitis Glandularis

Cheilitis glandularis is a rare condition characterized by inflammatory hyperplasia of the minor salivary glands of the lower lip and it may occur in association with actinic cheilitis. The secretory ducts of these hyperplastic salivary glands become dilated and inflamed and appear as pinpoint orifices from which a sticky mucous substance can be extracted. In mild cases, sunscreen and topical corticosteroids may be helpful, while in severe cases, vermilionectomy and dissection of the hyperplastic minor salivary glands has been described.

Orofacial Granulomatosis (OFG)

Key features

- Persistent non-tender swelling of the lip and/or face
- Non-caseating granulomatous inflammation
- Both primary (idiopathic) and secondary subtypes
- Primary OFG includes cheilitis granulomatosa and Melkersson–Rosenthal syndrome

Introduction

Orofacial granulomatosis (OFG) is a term introduced in 1985 to describe a spectrum of diseases characterized by non-necrotizing, non-infectious granulomatous inflammation of the face and mouth *in the absence of systemic disease*[15]. More recently, the term OFG has been used more loosely to describe a group of disorders characterized by non-caseating granulomatous inflammation involving the face and mouth including systemic disorders such as sarcoidosis and Crohn disease. In order to reconcile these different viewpoints, it is best to consider OFG as either *primary* (idiopathic) or *secondary*. *Primary* OFG would include cheilitis granulomatosa (CG) and Melkersson–Rosenthal syndrome (MRS). *Secondary* OFG would then include localized and systemic associations such as allergic contact dermatitis, foreign body reaction, sarcoidosis, and Crohn disease (see Fig. 72.16G).

Epidemiology

CG is rare and primarily occurs in young adults without sex predilection. The etiology is unknown and multiple factors have been implicated, including allergy to foods, additives or flavorings, genetic predisposition, and infection.

Clinical features

CG is a chronic process that initially can present as intermittent (hours to days) swelling of either the upper or lower lip mimicking angioedema. With progression, the episodes of swelling increase in duration and lead to persistent, often disfiguring swelling that may involve both lips and occasionally the face. Rarely, CG is associated with recurrent facial palsy and/or lingua plicata (fissured tongue), termed Melkersson–Rosenthal syndrome (MRS).

Diagnosis is made upon clinicopathologic correlation and exclusion of other entities, including angioedema (improves spontaneously in 24–48 hours), Crohn disease, sarcoidosis, foreign body reaction, allergic contact dermatitis, and infection (e.g. tuberculosis, Hansen disease [leprosy], histoplasmosis, cutaneous leishmaniasis).

Pathology

The most striking feature of OFG is the presence of non-necrotizing, epithelioid granulomas; in many cases the granulomas are sparse.

Treatment

Treatment of CG is difficult with a tendency for relapse and incomplete remission. Topical or intralesional corticosteroids are typically first-line therapy. Weekly (×3) intralesional triamcinolone injections (40 mg/ml) into the lips is one reported regimen[16]. Other anecdotal treatment options include systemic corticosteroids, oral antibiotics (e.g. minocycline, metronidazole, clofazimine), adalimumab, methotrexate, and dapsone[17]. Refractory cases have been managed surgically, with reduction cheiloplasty.

Granulomatosis with Polyangiitis (Formerly Wegener Granulomatosis)

Key features

- Necrotizing granulomatous vasculitis of the upper and lower respiratory tract and necrotizing glomerulonephritis
- Destructive ulcerated lesions of the oral and nasal cavity
- Pathognomonic friable "strawberry gums" may be seen
- Up to 90% of patients have anti-neutrophil cytoplasmic antibodies (ANCA)

Fig. 72.17 Granulomatosis with polyangiitis – strawberry gums. The affected areas of the gingiva are red–purple, micropapular and friable, with a resemblance to ripe strawberries. *Courtesy Carl M. Allen, DDS, MSD and Charles Camisa, MD.*

Introduction

Granulomatosis with polyangiitis (GPA) is an uncommon necrotizing granulomatous disease of unknown etiology (see Ch. 24). Clinically, there is both limited GPA (without renal involvement) and generalized GPA (see Fig. 40.6).

Epidemiology

Although individuals with GPA include children and the elderly, middle-aged adults are most commonly affected; there is no sex predilection.

Clinical features

Because GPA commonly involves the nose, nasopharynx, and paranasal sinuses, patients can present with epistaxis, sinusitis, or nasal ulcerations and obstruction. Destruction of the nasal cartilage may result in perforation of the nasal septum and/or saddle nose deformity[18]. The most characteristic oral manifestation is erythematous, friable gingival hyperplasia that easily bleeds, referred to as *strawberry gingivitis* (Fig. 72.17)[19,20]. Oropharyngeal, lingual, or gingival ulcerations may also be seen and tend to occur later in the course of the disease.

Pathology

For the gingival hyperplasia, histopathologic findings include papillary hyperplasia, granulation tissue, and a focal giant cell reaction. Histopathologic features of the cutaneous lesions are reviewed in Chapter 24.

Treatment

The treatment of classic GPA includes systemic corticosteroids, pulse cyclophosphamide, and rituximab[21]; oral lesions typically respond to these regimens (see Table 24.10).

EPITHELIAL PATHOLOGY

Oral Leukoplakia and Proliferative Verrucous Leukoplakia

Key features

- Leukoplakia and proliferative verrucous leukoplakia represent *clinical* diagnoses
- Leukoplakia is the most common potentially malignant disorder of the oral cavity
- Biopsy is mandatory in order to assess the degree of dysplasia and to exclude invasive SCC

Introduction

The World Health Organization (WHO) defines *oral potentially malignant disorders* (OPMDs) as "clinical presentations that carry a risk of cancer development in the oral cavity, whether in a clinically definable precursor lesion or in clinically normal oral mucosa"[22]. The major OPMDs are leukoplakia (including proliferative verrucous leukoplakia), erythroplakia, erythroleukoplakia, oral lichen planus and discoid lupus erythematous, oral submucous fibrosis, smokeless tobacco keratosis, palatal lesions associated with reverse smoking, chronic candidiasis, and actinic cheilitis.

Oral leukoplakia is defined as "a white plaque of questionable risk having excluded (other) known diseases or disorders that carry no increased risk for cancer"[23]. In addition to smoking, excessive alcohol intake, betel nut use, older age, and male sex represent risk factors. Individuals who are immunocompromised or have genetic syndromes such as dyskeratosis congenita or Fanconi anemia also have an increased risk of developing oral leukoplakia. Proliferative verrucous leukoplakia (PVL) was first described in 1985 as a subset of leukoplakia. While sharing some features with leukoplakia, the transformation rate of PVL is far higher such that many consider PVL a distinct entity warranting a separate classification.

Epidemiology

Oral leukoplakia is the most common OPMD. It has a male predominance with a peak incidence after 50 years of age. In contrast, PVL is more common in older women and the majority have few to none of the traditional risk factors for leukoplakia and OSCC.

Clinical features

Oral leukoplakia presents as a white plaque or patch and is usually asymptomatic. Although leukoplakia can involve any site within the oral cavity, the tongue, floor of the mouth, gingivae, and buccal mucosa are the most commonly affected sites (Fig. 72.18)[24]. Based upon clinical presentation, oral leukoplakia is classified as: (1) *homogenous leukoplakia* – well-demarcated white plaque or patch that is mainly smooth-surfaced with varying degrees of surface fissuring; and (2) *non-homogenous leukoplakia*. The latter has three subtypes: (a) *erythroleukoplakia* – varying amounts of erythema within a well-demarcated, mostly white plaque and a patchy or speckled pattern; (b) verrucous leukoplakia – a rough surface that at times appears leathery and most commonly occurs on the gingivae; and (c) nodular leukoplakia – nodular surface, at least focally.

PVL is characterized by the progressive development of white, often verrucous and fissured, patches and plaques in multiple non-contiguous sites or as a single large lesion. Although the seventh decade represents the average age at the time of diagnosis, many patients have had the condition for years. Dysplasia is regarded as the best predictor of transformation, but a meta-analysis found that only 12% of dysplastic lesions transformed to OSCC. That said, as many as 70% of patients with PVL eventually develop OSCC despite their lack of traditional risk factors and benign histopathologic features in early stages.

Fig 72.18 Leukoplakia. Non-homogenous, sharply demarcated white plaque involving the left ventrolateral tongue.

Pathology

The diagnosis of both leukoplakia and PVL is clinically based, i.e. independent of the presence or absence of dysplasia. Nonetheless, biopsies are routinely obtained due to concern regarding OSCC. Histopathologic features vary from only hyperkeratosis to dysplasia to frank OSCC. Major features of dysplasia include irregular, altered epithelial architecture with loss of basal cell polarity, as well as nuclear pleomorphism, dyskeratosis, hyperchromasia, and an increased number of mitoses with superficial and atypical mitotic figures[22]. Dysplasia is graded from mild to severe, depending on the portion of the involved epithelium (lower third or more). A band-like inflammatory infiltrate can be seen in the upper lamina propria (lichenoid dysplasia) and should be differentiated from oral lichen planus.

Differential diagnosis

Entities in the differential diagnosis include leukoedema, in which the white to gray–white discoloration disappears with stretching (Fig. 72.19), white sponge nevus due to mutations in *KRT4* and *KRT13*, the leukokeratosis seen in patients with pachyonychia congenita (see Ch. 58), and oral lichen planus. Oral white plaques can also be seen in hereditary benign intraepithelial dyskeratosis, a disorder that occurs primarily in Native Americans.

Treatment

A baseline incisional biopsy is considered the gold standard for management of leukoplakia and PVL. Although complete excision of the lesion (via scalpel, CO_2 laser, or cryosurgery) has been proposed as first-line therapy by some authors, removal of OPMDs has not been proven to prevent the onset of OSCC[25,26]. When possible, surgical removal of the entire lesion is performed to avoid sampling error and to exclude OSCC. Habit cessation (in particular tobacco use), longitudinal evaluation by an oral medicine specialist, and repeat biopsies as indicated are recommended for all patients.

Erythroplakia

Key features

- Erythroplakia is less common than leukoplakia but is also a clinical diagnosis
- High likelihood of dysplasia or invasive SCC at the time of diagnosis

Introduction

The WHO defines erythroplakia as "a fiery red patch that cannot be characterized clinically or pathologically as any other definable disease"[22]. Similar to leukoplakia, erythroplakia is an OPMD that is strongly associated with traditional risk factors for OSCC. A diagnosis of erythroplakia is only established after exclusion of other red lesions of the oral cavity.

Epidemiology

A rare condition that most commonly affects middle-aged and elderly men with traditional OSCC risk factors.

Clinical features

Erythroplakia typically presents as an asymptomatic, rather sharply circumscribed, velvety red patch or thin plaque. The most commonly involved sites are the floor of the mouth, tongue, soft palate, and buccal mucosa.

Pathology

Advanced dysplasia (see leukoplakia above) or invasive OSCC is found in >90% of lesional biopsies. In addition to a lack of keratinization and atrophy of the epithelium, varying degrees of cellular and architectural findings consistent with OSCC (see below) or dysplasia (see leukoplakia above) are seen in these cases.

Treatment

A baseline biopsy should be performed, with treatment based upon the histopathologic diagnosis. Patients with OSCC are referred to head and neck surgeons or oncologists. When possible, complete surgical removal of dysplastic lesions is performed to avoid sampling error and to exclude OSCC. Habit cessation (in particular tobacco use), longitudinal evaluation by an oral medicine specialist, and repeat biopsies as indicated are recommended.

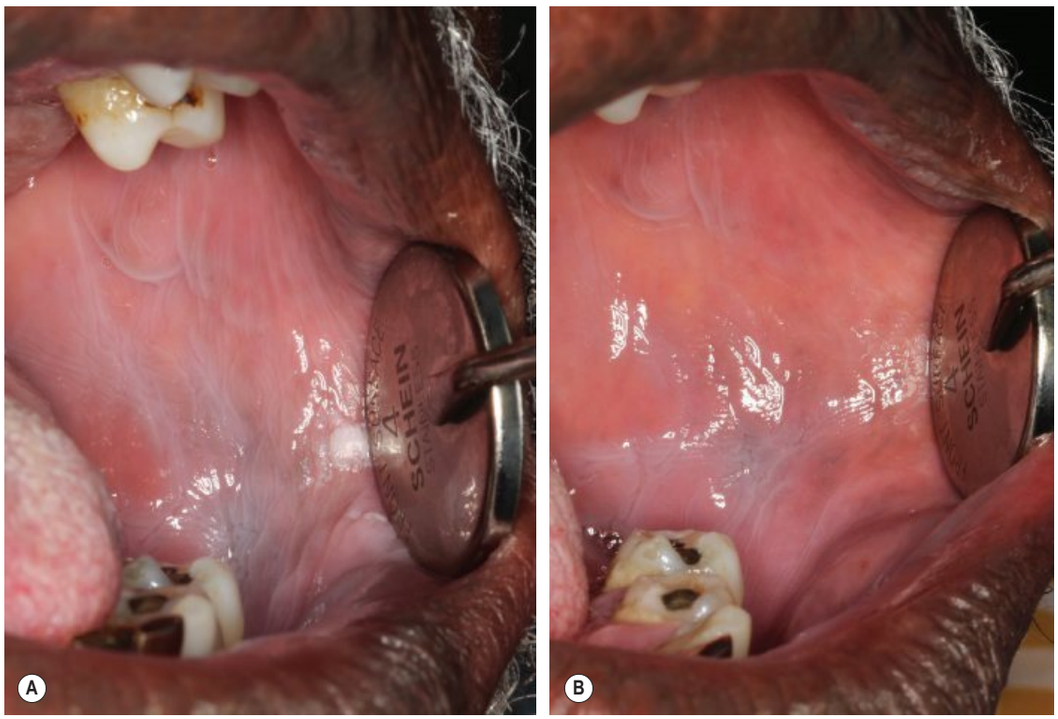

Fig 72.19 Leukoedema. A Diffuse grayish-white and wrinkled appearance of the left buccal mucosa. **B** These findings disappear when the cheek is stretched.

Nicotinic Stomatitis

Synonyms: ■ Nicotine stomatitis ■ Stomatitis nicotina

Key features

- Gray–white mucosa with umbilicated papules
- Caused by exposure of the palatal mucosa to intense heat from smoking, not nicotine

Introduction

Nicotinic stomatitis is most commonly observed in pipe, cigar, and reverse smokers. However, the resultant inflammation of the palatal mucosa is more closely linked to exposure to the intense heat from smoking rather than nicotine, as the name has erroneously implied. For example, identical lesions are observed in hot beverage drinkers[27]. The exact etiology in e-cigarette users is less clear and may be related to nicotine or other chemical compounds (e.g. strawberry flavoring) added to the liquid[28].

Epidemiology

Nicotinic stomatitis most frequently affects men in the fifth decade of life.

Clinical features

The palatal mucosa is thickened and has a diffuse gray or white discoloration. In addition, there are scattered 1–3 mm umbilicated papules with central red puncta which represent inflamed salivary gland orifices (Fig. 72.20). These changes are more prominent toward the posterior hard palate and anterior soft palate.

Pathology

The histopathologic features include hyperkeratosis, parakeratosis, acanthosis, and mild chronic sialodochitis, but the diagnosis is usually made on clinical grounds.

Treatment

Since habit cessation typically leads to resolution, it is necessary to exclude true leukoplakia or erythroplakia if any white or red plaque persists after habit cessation.

Fig. 72.20 Nicotinic stomatitis. Gray–white palatal mucosa with numerous umbilicated papules representing inflamed palatal salivary glands. *Courtesy Carl M. Allen, DDS, MSD and Charles Camisa, MD.*

Actinic Cheilitis

Synonyms: ■ Actinic cheilosis ■ Solar cheilosis

Key features

- Primarily affects the vermilion zone of the lower lip in fair-skinned individuals
- Indicator of photodamage from cumulative sun exposure

Introduction

Actinic cheilitis is a common OPMD that has the same etiology as actinic keratoses (see Ch. 108). Given its relationship to chronic UV exposure, the vermilion zone of the lower lip is the primary mucosal site of involvement.

Epidemiology

Actinic cheilitis is most common in men over 40 years of age with skin phototypes I–II[29]. It reflects significant photodamage from cumulative exposure to UV irradiation.

Clinical features

Early features include loss of normal dermatoglyphics, atrophy, and blurring of the margin between the vermilion zone and the skin. Signs of progression to precancerous actinic cheilitis include scaling and roughness, sometimes in conjunction with leukoplakia (see Fig. 108.4). Although often localized initially, over time multifocal involvement is characteristic. Fissuring and erosions may also be present as the condition worsens. Some patients have concomitant cheilitis glandularis (see above).

Pathology

There is hyperkeratosis and variable thickness of the spinous layer as well as dysplasia of the lower part of the epithelium. Actinic cheilitis may be observed in contiguity with SCC *in situ* or invasive SCC.

Treatment

Actinic cheilitis frequently represents a "field change", and while worrisome clinical features may appear focal in nature, the photodamage and epithelial dysplasia are more extensive. Treatment options include topical 5-fluorouracil or imiquimod, photodynamic therapy, and cryosurgery. When severe or treatment-resistant, vermilionectomy with histopathologic examination is a therapeutic option. Any site suspicious for SCC should be biopsied, including prior to CO_2 laser ablation.

Oral Squamous Cell Carcinoma

Key features

- The most common malignancy of the oral cavity
- Develops primarily in middle-aged or elderly men
- Significant association with the use of tobacco and alcohol
- In contrast to oropharyngeal SCC, only a small percentage of oral SCCs are associated with HPV infection, particularly types 16 and 18
- Most common intraoral sites are the lateral and ventral surfaces of the tongue, floor of the mouth, and soft palate

Fig. 72.21 Squamous cell carcinoma. A Ulcerated leukoplakia of the ventrolateral tongue. **B** Ulcerated, indurated, exophytic mass involving the right lateral border of the tongue. Both are typical presentations for this tumor. *Courtesy Carl M. Allen, DDS, MSD, Charles Camisa, MD, and Kristin K. McNamara, DDS, MS.*

Introduction

SCC is the most common malignancy of the oral cavity, and may or may not be preceded by an OPMD. OSCC risk factors include tobacco use, excessive alcohol consumption, betel nut chewing (primarily in the Indian subcontinent and Southeast Asia), chronic immunosuppression, and genetic syndromes such as dyskeratosis congenita and Fanconi anemia. Human papillomavirus (HPV) infection, especially types 16 and 18, has been implicated in the etiopathogenesis of oropharyngeal SCC, with HPV-positive tumors associated with a more favorable outcome[30,31].

Epidemiology

OSCC accounts for >90% of all malignant neoplasms of the mouth. It is typically a disease of middle-aged or elderly men; however, an increasing incidence of oral SCC among women and younger patients has been noted. Globally, the overall age-adjusted incidence is 4 per 100 000 individuals, but there is marked variation depending upon geographic location[22,32]. For example, the Indian subcontinent has recorded an incidence as high as 22 per 100 000 and worldwide accounts for one-third of all OSCCs.

Clinical features

While any intraoral site may be affected, the most common locations are the lateral and ventral surfaces of the tongue, floor of the mouth, and soft palate. OSCC may present as an ulcer, a white plaque, an exophytic mass, or an endophytic process with varying degrees of induration (Fig. 72.21). The surface is typically irregular, rough, or granular. Early on lesions are often painless, but with disease progression and local invasion, patients may experience pain, paresthesia, dysphagia, dysphonia, or difficulty moving the tongue[33].

In comparison to cutaneous SCC, OSCC is significantly more aggressive and has a less favorable prognosis. The five-year survival rates for stage I or II disease approach 80%, while the 5-year survival rate for stages III and IV is <40%[34].

Pathology

OSCCs are histologically similar to those occurring elsewhere (see Ch. 108).

Treatment

Because treatment depends upon the clinical stage, computed tomography (CT), positron emission tomography (PET), and/or magnetic resonance imaging (MRI) may be required to determine the extent of local and distant disease. In general, smaller tumors (stages I and II) are surgically excised +/− sentinel lymph node biopsy or cervical lymph node dissection. For stages III and IV, various combinations of surgery, radiotherapy, chemotherapy, and immune checkpoint inhibitors are employed[35]. Patients have a 3%–7% annual risk of developing a second primary SCC of the upper aerodigestive tract after treatment of their original tumor[36].

Verrucous Carcinoma

Subtype/synonyms: ■ Oral verrucous carcinoma ■ Oral florid papillomatosis ■ Ackerman tumor

Key features

- Uncommon, low-grade variant of SCC
- Exophytic mass with a papillary or verrucous topography
- Characterized by slow, persistent growth

Introduction

Verrucous carcinoma is a rare, low-grade variant of SCC that may involve the oral, laryngeal, sinonasal, esophageal, or genital mucosa as well as the plantar surface of the foot (see Ch. 108). Oral verrucous carcinoma has been associated with the use of snuff and chewing tobacco. Although HPV-6, -11, -16, and -18 have sometimes been isolated from these tumors, the precise etiologic role of HPV remains unclear.

Epidemiology

Verrucous carcinoma typically affects men over 55 years of age.

Clinical features

The tumor location often corresponds to the site where intraoral tobacco has been chronically placed. Therefore, tumors most commonly develop in the mandibular vestibule, buccal mucosa, tongue, and gingiva. In populations where tobacco is placed under the tongue or in the maxillary vestibule, the floor of the mouth and hard palate are commonly affected.

Verrucous carcinoma presents as a slowly growing, exophytic, papillomatous, or warty proliferation with well-demarcated margins. The color depends on associated inflammation and degree of hyperkeratosis but is most often white. If left untreated, local destruction of underlying bone, muscle, and salivary glands may occur; metastases are rare.

Pathology

Histologically, there is hyperkeratosis, acanthosis, and a papillary or verrucous surface[37]. The epithelium is well differentiated, with minimal atypia and rare mitotic figures. A dense infiltrate of chronic inflammatory cells is frequently present in the superficial connective tissue. Multiple sections are recommended because up to 20% of verrucous carcinomas show foci of conventional OSCC (hybrid carcinoma).

Treatment

Compared to conventional OSCC, verrucous carcinoma has a better prognosis. The 5-year survival rate is 85%–90% with prognosis based upon stage at diagnosis. The treatment of choice is surgical excision[38]. Although cervical lymph node metastases are rare, sentinel lymph node biopsy can be performed. In contrast, hybrid carcinomas may metastasize and should be managed as conventional OSCC. Treatment failure has been attributed to extensive involvement, delayed diagnosis, comorbidities, and failure to identify hybrid carcinomas.

SALIVARY GLAND DISEASES

Mucocele

Synonyms: ■ Mucous cyst of oral mucosa ■ Mucous extravasation phenomenon

Key features

- Disruption of a minor salivary gland duct with resultant leakage of mucus into the submucosal tissue
- Fluid-filled, dome-shaped mucosal swelling ranging from a few millimeters to 1–2 cm
- Most commonly seen on the lower labial mucosa
- May require surgical excision

Introduction

Mucocele is a common disorder that results from disruption of a salivary gland duct and escape of mucus into the adjacent submucosal connective tissue (see Ch. 110). Although the term mucocele is sometimes used to describe both retention and extravasation mucoceles, these two conditions differ in location, etiology, and histopathology. The preferred term for a retention mucocele is salivary duct cyst. Herein, the term mucocele refers exclusively to extravasation mucocele.

Epidemiology

While the majority of mucoceles are detected in younger individuals (second through fourth decades), they can present at any age and are usually due to trauma. Patients with chronic oral GVHD can develop superficial mucoceles, primarily on the palate.

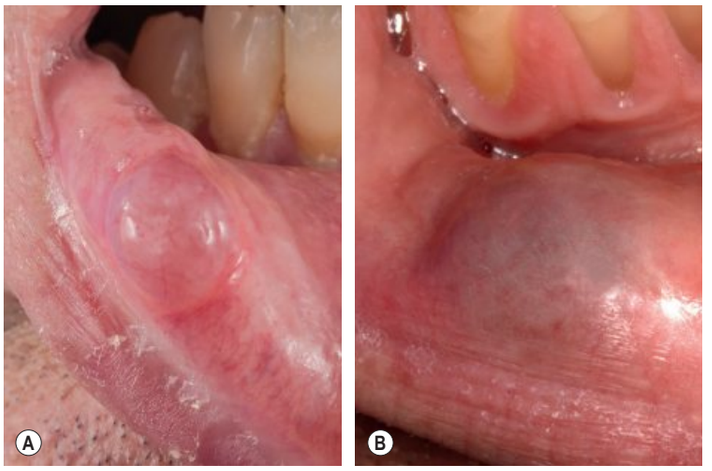

Fig. 72.22 Mucoceles of the mucosal lower lip. A Superficial mucocele that is translucent and has a vesicular appearance. **B** Slightly deeper mucocele presenting as a soft nodule with a bluish hue. This lateral location is commonly observed. *A, Courtesy Edward Cowen, MD.*

Clinical features

Mucoceles present as dome-shaped, mucosal swellings ranging from 1–2 mm to a few centimeters in size. Their color depends on the depth of the swelling relative to the surface mucosa, with very superficial lesions often appearing vesicular and slightly deeper mucoceles having a bluish tinge (Fig. 72.22); the deepest lesions have no discernible color change. In general, mucoceles are asymptomatic and undergo multiple cycles of swelling, rupturing, and then refilling. While the lower labial mucosa is the most common site of involvement, any oral mucosal area that contains minor salivary glands can potentially be affected[39]. In particular, mucoceles may develop on the ventral tongue, buccal mucosa, and posterior hard palate. A mucocele on the floor of the mouth and confined to sublingual tissues superior to the mylohyoid muscle is referred to as a *ranula*.

Pathology (see Ch. 110)

Treatment

While some mucoceles may resolve spontaneously, others require surgical excision. Other therapeutic modalities are outlined in Chapter 110.

Necrotizing Sialometaplasia

Key features

- Uncommon ulcerative process of the hard palate thought to be due to ischemia
- Frequently misdiagnosed as a malignancy, both clinically and histologically

Introduction

Necrotizing sialometaplasia is an uncommon, locally destructive disease that is most likely due to an interruption of the blood supply to salivary gland tissue, leading to ischemic necrosis[40]. While such a disruption in blood supply can follow local trauma, in most patients the cause of the ischemic injury is unknown. Very infrequently, a submucosal malignancy may occlude the palatal blood vessels[41,42].

Epidemiology

The condition is almost always seen in adults, with a slight male predominance.

Clinical features

The patient will typically report a sudden onset of swelling of the hard palate, in addition to localized pain, paresthesia, or anesthesia. Within 1–2 weeks, the ischemic tissue sloughs and the patient will often state that

"part of the roof of my mouth fell off". This leads to a well-demarcated ulcer with a smooth or minimally elevated border. By palpation, the ulcer has no underlying induration. A malignancy is often suspected clinically and therefore a biopsy is performed to exclude OSCC or a salivary gland tumor.

Pathology

Early on, acinar necrosis is seen, followed by squamous metaplasia of the salivary ducts, spillage of mucin into the surrounding connective tissue, and an associated inflammatory infiltrate. When present, preservation of the lobular architecture of the gland helps to distinguish necrotizing sialometaplasia from mucoepidermoid carcinoma and squamous cell carcinoma.

Treatment

Once a diagnosis of necrotizing sialometaplasia is established, additional treatment is not required. The condition resolves spontaneously within 5–6 weeks.

Sjögren Syndrome

Key features

- Autoimmune disorder characterized by keratoconjunctivitis sicca and xerostomia
- Primarily affects women

Introduction

Sjögren syndrome (SjS) is a chronic autoimmune connective tissue disease in which lacrimal and salivary gland dysfunction leads to dry eyes (keratoconjunctivitis sicca) and mouth (xerostomia) (see Ch. 45). While the etiology and pathogenesis of SjS remain unclear, patients do produce several autoantibodies, in particular anti-SSA/Ro and -SSB/La (see Ch. 40). Patients with SjS have a 40-fold increased risk of lymphoma, predominantly extranodal B cell non-Hodgkin type[43]. Diagnostic criteria for SjS are outlined in Table 40.4.

Epidemiology

SjS primarily affects women in their 50s and 60s.

Clinical features

Both the major and minor salivary glands may be involved, leading to reduced salivary production. Major gland involvement is clinically evident in fewer than one-half of affected patients, presenting as firm, diffuse, non-tender or slightly tender glandular enlargement that is usually bilateral.

Patients have variable degrees of ocular and oral dryness[44,45], usually with a gradual onset of symptoms. There may be changes in either quality (frothy) or quantity (reduced) of saliva and most patients have a lack of the usual pooling in the floor of the mouth. Affected patients may present with difficulty swallowing, dysgeusia, halitosis, dental caries along the gum line, difficulty wearing dentures, coated or hairy tongue, and oral candidiasis.

Pathology

An SjS diagnostic criterion is one or more foci of inflammatory cells (≥50 lymphocytes) in 4 mm^2 of minor salivary gland tissue (see Table 40.4)[45]. In major salivary glands, there are intraglandular infiltrates of lymphocytes as well as hyperplasia and metaplasia of salivary duct epithelia, forming the characteristic *epimyoepithelial islands*.

Treatment (see Table 40.5)

Salivary Gland Tumors

Key features

- Most commonly occur in the parotid gland
- Benign salivary gland tumors are more common than malignant tumors

THE DIFFERENTIAL DIAGNOSIS OF INTRAORAL TUMORS AND TUMOR-LIKE LESIONS	
Developmental lesions	

• Congenital inclusion cysts
  • Bohn nodules (alveolar ridge)
  • Epstein pearls (palate)
• Torus palatinus, torus mandibularis
• Lingual thyroid
	• Dermoid cyst
	• Enteric duplication cyst
	• Nasoalveolar (nasolabial) cyst
	• Lymphoepithelial cyst
	• Lymphatic/vascular malformation

Reactive/inflammatory conditions	
• Mucocele • Fibroma* • Oral melanoacanthoma • Eosinophilic ulcer	• Pyogenic granuloma • Peripheral giant cell granuloma • Necrotizing sialometaplasia • Nodular fasciitis
Benign salivary gland neoplasms	
• Pleomorphic adenoma • Lymphomatous papillary cystadenoma	• Monomorphic adenoma
Other benign neoplasms	
• Squamous papilloma • Infantile hemangioma • Angiomyoma • Myofibroma, hemangiopericytoma • Granular cell tumor† • Neurofibroma	• Schwannoma • Palisaded encapsulated neuroma • Melanotic neuroectodermal tumor of infancy • Ameloblastoma • Lipoma
Malignant salivary gland neoplasms	
• Mucoepidermoid carcinoma • Acinic cell carcinoma	• Adenoid cystic carcinoma
Other malignant neoplasms	
• Squamous cell carcinoma • Melanoma • Lymphoma^ • Kaposi sarcoma	• Rhabdomyosarcoma • Osteosarcoma • Fibrosarcoma • Liposarcoma
*Ossification may occur. †A congenital epulis represents a granular cell tumor of the alveolar ridge. ^Both B- and T-cell lymphomas can involve the mouth as can less common entities such as plasmacytomas and EBV^+ mucocutaneous ulcers.	

Table 72.5 The differential diagnosis of intraoral tumors and tumor-like lesions.

Introduction

Salivary gland tumors (SGTs) can occur in both minor and major salivary glands. They are considered primary epithelial neoplasms and there exists a wide array of distinct benign and malignant salivary gland tumors.

Epidemiology

The low incidence, ever-evolving classification, and disparities between old and new studies are some of the obstacles in estimating the true incidence of SGTs. Pleomorphic adenoma followed by lymphomatous papillary cystadenoma (Warthin tumor) are the most common benign SGTs and mucoepidermoid carcinoma followed by acinic cell carcinoma are the most common malignant SGTs (Table 72.5). SGTs account for <10% of head and neck tumors, with radiation, smoking, viral infections, and environmental exposures (e.g. nickel compounds) implicated in their development.

Clinical features

The parotid gland is the most frequent site of SGTs, and the majority (>70%) are benign. SGTs involving major glands present as a painless, rubbery to firm, slowly growing swelling. Less frequently, SGTs develop within submandibular, sublingual, or minor salivary glands. They can present as a painless submucosal mass or mucosal ulceration, most commonly of the posterior hard palate/anterior soft palate followed by the upper lip or buccal mucosa[46,47]. When malignant, SGTs occur most often in the sublingual gland followed by minor salivary glands.

Pathology

For a definitive diagnosis of SGT, histopathologic examination is required which demonstrates different features, depending upon the type of tumor. Ultrasound-guided fine needle biopsy may be performed prior to surgical intervention. For staging information, see https://cancer.net/cancer-types/salivary-gland-cancer/stages-and-grades.

Treatment

The treatment of benign SGTs consists of conservative surgical excision. Malignant tumors usually require more extensive surgery and postoperative radiation therapy.

ORAL MANIFESTATIONS OF HEMATOLOGIC/ONCOLOGIC DISEASE

Oral Mucositis

Key features

- Chemotherapy-induced oral mucositis usually develops in patients who have been treated with cytotoxic drugs and subsequently develop neutropenia
- Radiotherapy-induced oral mucositis most commonly occurs in patients treated for head and neck malignancies
- Erosions, ulcerations, and hemorrhagic crusting of the oral mucosa are seen
- Self-healing, but recurrent, in patients receiving multiple cycles of chemotherapy

Introduction

Oral mucositis (OM) is a common side effect of conventional chemotherapy, head and neck radiation therapy, immunotherapy, and targeted therapies (see Tables 21.15–21.18).

Epidemiology

A systematic review estimated the incidence of all grades of chemotherapy-associated OM to be 70%–87% in patients receiving myeloablative therapy prior to hematopoietic stem cell transplantation (HSCT) and 100% in patients who received radiation therapy for oral and oropharyngeal cancer[48]. Patients receiving conventional dose cytotoxic chemotherapy or targeted therapy are at a relatively lower risk for developing OM[49,50].

Clinical features

OM typically develops within a few days after conventional chemotherapy administration and within the second to third week of radiation therapy. While radiation-associated OM generally corresponds to the site of radiation, chemotherapy-induced OM characteristically involves non-keratinized surfaces (i.e. buccal mucosa, floor of the mouth, ventrolateral tongue, and soft palate). A white discoloration followed by atrophic mucosa with a loss of keratin are often the initial findings. The mucosa may also appear edematous, erythematous, and friable. Eventually a removable yellowish, fibrinopurulent membrane can form.

Oral side effects from immune checkpoint inhibitors (ICIs) may have a delayed onset and can present as lichenoid reactions with erythema, ulceration, reticulation, and hyperkeratosis. Oral erosions can also be seen in patients who develop ICI-associated erythema multiforme major, Stevens–Johnson syndrome, or bullous pemphigoid (see Table 21.18)[51,52]. Acute-onset salivary gland hypofunction has also been reported. In addition, patients receiving various classes of targeted anticancer therapies can have a range of oral side effects, including lichenoid, hyperkeratosis, and aphthous-like ulcers (see Table 21.16).

Regardless of the triggering therapy, OM is commonly associated with pain, burning, and discomfort. Xerostomia, dysgeusia, dysphagia, and difficulty speaking can occur and negatively impact patients' oral intake, oral hygiene, or quality of life. Patients with severe OM may require intravenous hydration and parenteral nutrition and, given their immunocompromised status, may develop secondary infections.

Treatment

OM typically resolves within 2–3 weeks post completion of chemotherapy or radiation therapy. Pain management with topical and systemic analgesics, nutritional support, and maintaining good oral hygiene represent standard treatments. Other interventions to reduce pain and discomfort include cryotherapy (placement of ice chips in the mouth) during bolus doses of chemotherapeutic agents, photobiomodulation, and mouthwashes that contain a topical anesthetic, Maalox®, and diphenhydramine[53,54]. Keratinocyte growth factor (palifermin) is FDA-approved for those receiving myeloablative therapy prior to HSCT but is not commonly used[55]. ICI-related lichenoid reactions may respond to topical or systemic corticosteroids.

Leukemia

Key features

- Associated intraoral findings include infections and gingival hemorrhage
- Gingival enlargement occurs most commonly with monocytic and myelomonocytic leukemias

Introduction

Approximately one-third of patients with acute and 10% with chronic leukemia develop one or more oral manifestations at some point during the course of their disease[56]. More commonly, they are infectious (e.g. herpes simplex, candidiasis) or inflammatory (e.g. GVHD) rather than neoplastic.

Clinical features

Patients often experience bruising or spontaneous and persistent hemorrhage due to thrombocytopenia. Leukopenia results in poor healing and an increased prevalence of bacterial and fungal infections while lymphopenia increases the risk of viral infections. The tissues may exhibit an overall pallor of anemia or ulcerative gingivitis. Diffuse, firm, non-tender gingival enlargement can result from infiltration of the gingival connective tissue by leukemic cells, primarily in patients with monocytic or myelomonocytic forms of leukemia.

Treatment

Multi-agent chemotherapy and allogeneic HSCT are most commonly used to treat acute leukemias. Leukemic infiltrates generally respond to therapeutic regimens for the underlying leukemia.

Lymphoma

Key features

- Non-Hodgkin lymphomas (NHLs) account for over 80% of lymphomas
- Relatively uncommon within the oral cavity, where it presents as extranodal disease

Introduction

Unlike Hodgkin lymphoma, up to 40% of NHLs may arise in extranodal sites, including the oral cavity. NHL is the second most common malignancy of the oral cavity, accounting for ~3.5% of all oral cavity malignancies. HIV-infected individuals appear to have a greater risk of developing oral NHL.

Clinical features

The head and neck region is the second most common extranodal site for NHL, after the gastrointestinal tract. The Waldeyer ring (oropharyngeal lymphoid ring that includes the tonsils) is the most commonly affected head and neck site, and the most common *intraoral* sites include the palate, buccal mucosa, tongue, and floor of the mouth. Lymphomas in these latter areas present as a soft to rubbery-firm, slowly growing, mucosa-colored to purplish swelling or mass. Ulceration may be present, mimicking OSCC, as well as overlying telangiectasias. Pain is usually not a prominent feature.

Pathology

NHLs of the oral cavity are primarily of the B cell type. However, involvement of the oral mucosa can be seen in patients with several types of cutaneous T cell lymphoma.

Treatment

Depending on type and stage, treatment options consist of chemotherapy, radiation therapy, targeted therapy (e.g. rituximab), chimeric antigen receptor therapy (CAR-T), and autologous or allogeneic HSCT.

Melanoma

Key features

- Oral mucosal melanomas are rare, constituting <1% of all melanomas
- Approximately one oral melanoma is detected annually per 10 million individuals in the US
- Predominantly affects men, with an average age of 55 years

Introduction

In contrast to cutaneous melanomas, *BRAF* mutations are present in <10% of oral melanomas while *c-KIT* (CD117) is overexpressed in a majority (~80%). The etiology of oral melanoma is unknown and UV exposure is not considered a risk factor. Oral mucosal melanomas account for <1% of all oral malignancies.

Clinical features

Oral melanoma can exhibit all the clinical features of cutaneous melanoma, including usually being painless. The preferred site is the hard palate, followed by the maxillary-attached gingiva. The differential diagnosis includes foreign body tattoo (Fig. 72.23), blue nevus, oral melanotic macule, physiologic pigmentation, drug-related pigmentation (Table 72.6), and melanoacanthoma. Occasionally these melanomas are amelanotic and then resemble erythroplakia, pyogenic granuloma, or OSCC.

Pathology

Histopathological features are similar to those of melanoma arising at other sites. PRAME positivity can be used to confirm the diagnosis and can assist in distinguishing melanoma from melanosis, although negativity may be rarely observed. For lesions devoid of melanin, the diagnosis may be confirmed by immunohistochemistry (e.g. SOX10; see Ch. 113). Of note, these mucosal melanomas are usually in a vertical growth phase at the time of diagnosis with the majority apparently having a minimal associated radial growth phase.

Treatment

The treatment of choice for oral melanoma is wide surgical excision with adequate negative margins[58]. Sentinel lymph node biopsy also provides useful prognostic information[59]. Targeted and immunotherapies may improve survival (see Ch. 113), but historically the overall 5-year survival rate for oral mucosal melanoma is only ~15%, with a median survival of <2 years.

ORAL MANIFESTATIONS OF SYSTEMIC DISEASE

Amyloidosis

Key features

- Systemic or localized deposition of fibrillar proteins
- May be primary or secondary
- Internally, most commonly affects the kidney and heart
- Amyloid deposits within the tongue can occur and may produce macroglossia

Introduction

In amyloidosis, there is extracellular deposition of pathologic insoluble fibrillar proteins (see Ch. 47). Systemic amyloidosis can be primary (e.g. associated with a plasma cell dyscrasia) or secondary (e.g. due to a chronic inflammatory disease). There are also inherited and age-related forms of amyloidosis.

Clinical features

Macroglossia, a classic feature observed in ~20% of patients with primary systemic amyloidosis, is characterized by firm enlargement of the tongue[60]. Scalloping of its edge can occur and sometimes secondary ulceration develops (see Fig. 47.8B). Translucent and hemorrhagic papules and plaques may also be seen on the tongue or in other oral mucosal sites (see Fig. 47.8A). Taste disturbances have been noted with or without macroglossia, and xerostomia can result from involvement of the salivary glands. Cutaneous and systemic features are discussed in Chapter 47.

DRUGS ASSOCIATED WITH ORAL MUCOSAL PIGMENTATION	
• Amlodipine	• Hydroxychloroquine
• Busulfan	• Hydroxyurea
• Capecitabine	• Imatinib mesylate
• Chloroquine	• Irinotecan
• Chlorpromazine	• Ketoconazole
• Clofazimine	• Minocycline
• Cyclophosphamide	• Phenolphthalein
• Doxorubicin	• Quinacrine
• Estrogen	• Quinidine
• 5-Fluorouracil	• Tetracycline
• Golimumab	• Zidovudine (AZT)

Table 72.6 Drugs associated with oral mucosal pigmentation[57].

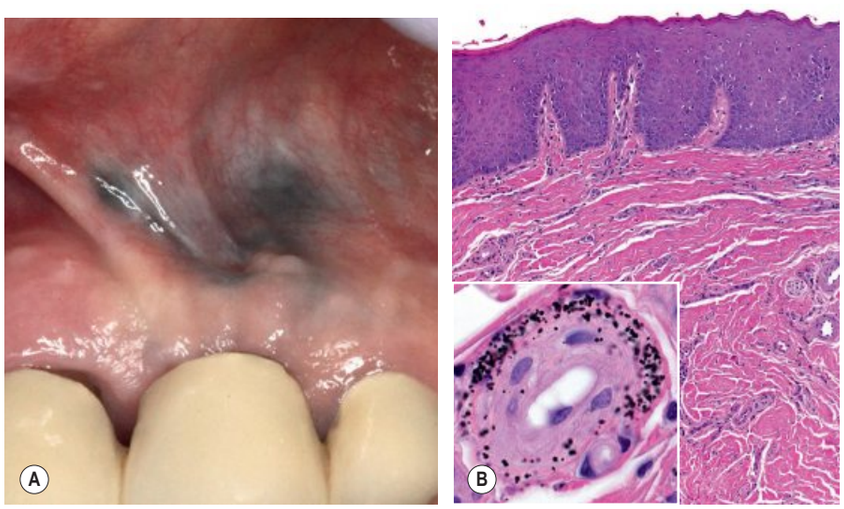

Fig. 72.23 Amalgam tattoo. Foreign body tattoos are the most common cause of acquired oral pigmentation, and most of them are due to iatrogenic implantation of dental amalgam. In this case (**A**), the amalgam was used to seal the apices of endodontically treated teeth, resulting in tattooing of the maxillary vestibule. **B** Histologically, darkly staining deposits are seen within the submucosa. Inset: black granular pigment within the secretory coil of a salivary gland. *A, Courtesy Carl M. Allen, DDS, MSD and Charles Camisa, MD; B, Courtesy Lorenzo Cerroni, MD.*

Pernicious Anemia

Key features

- Most common cause of vitamin B_{12} deficiency
- Immunologically mediated condition with antibodies directed against intrinsic factor and parietal cells of the stomach
- Tongue may appear smooth and beefy red

Introduction

Pernicious anemia is an autoimmune disorder characterized by megaloblastic hematopoiesis and/or neuropathy due to vitamin B_{12} deficiency. It is associated with atrophic gastritis and the production of autoantibodies directed against intrinsic factor and gastric parietal cells. The malabsorption of vitamin B_{12} results from intrinsic factor deficiency. B_{12} deficiency also occurs post-gastrectomy, in vegetarians, and in individuals with tapeworm infections.

Epidemiology

Pernicious anemia is a relatively common disorder, occurring in up to 2% of adults over 60 years of age. The disease occurs 20 times more frequently in close relatives, suggesting a genetic predispostion[61].

Clinical features

Pernicious anemia typically has an insidious onset, with patients eventually presenting with symptoms of anemia. Peripheral neuropathies are frequently observed, along with CNS involvement that ranges from demyelination to axonal degeneration.

Oral manifestations consist primarily of glossitis and stomatitis[62], and these changes may occur in the absence of symptomatic anemia. Atrophic glossitis manifests as a smooth, "beefy-red" tongue, with patchy, ill-defined areas of erythema gradually evolving to more diffuse dorsal tongue involvement (Fig. 72.24). Some patients experience a generalized sore mouth or burning sensation. Taste disturbances have also been reported. The differential diagnosis of atrophic glossitis includes other nutritional deficiencies (e.g. folate, iron, niacin, riboflavin) and candidiasis.

Treatment

Vitamin B_{12} replacement often leads to rapid improvement of oral signs and symptoms.

Crohn Disease

Key features

- Chronic granulomatous disorder affecting any segment of the gastrointestinal tract from the oral cavity to the anus
- Most commonly affects the distal ileum and/or proximal colon
- Oral involvement is uncommon and usually presents as linear ulceration of the buccal vestibule, although persistent swelling of the labial or buccal mucosa may be seen

Introduction/epidemiology

Crohn disease represents an idiopathic chronic granulomatous disorder of the gastrointestinal tract. The condition has also been termed "regional enteritis", due to the alternating of affected areas with unaffected areas. Crohn disease is usually diagnosed before the age of 30 years, with peak prevalence in the second and third decades; a second diagnostic peak is composed of patients over 50 years of age. There is no significant sex predilection, but White individuals are affected more frequently than other ethnic groups[63] and there is familial clustering. Oral involvement occurs in 5%–15% of patients and it precedes gastrointestinal manifestations in up to 30% of those with disease in both sites.

Clinical features

Linear fissures and/or ulcers of the vestibule are the most common clinical presentation (Fig. 72.25). Patients may also present with persistent, firm, painless swelling of the labial or buccal mucosa. Thus, there is a resemblance to cheilitis granulomatosa, both clinically and histologically. Cobblestone lesions of the buccal mucosa and vestibule, oral aphthae, and pyostomatitis vegetans are additional findings. Sequelae include oral fibrosis and adhesions.

Pathology

Histologically, non-necrotizing epithelioid inflammation is seen in the submucosa.

Treatment

Oral lesions typically respond to systemic therapies for gastrointestinal disease (e.g. sulfasalazine, TNF inhibitors, corticosteroids), but topical and intralesional corticosteroids can be employed for oral manifestations.

Pyostomatitis Vegetans

Key features

- Typically associated with inflammatory bowel disease
- Multiple "snail-track" pustules superimposed upon diffuse mucosal erythema

Introduction

Pyostomatitis vegetans is a rare mucocutaneous disorder that is often associated with an underlying gastrointestinal disorder such as ulcerative colitis or, less commonly, Crohn disease. Pyostomatitis vegetans may represent an oral mucosal variant of pyoderma gangrenosum.

Epidemiology

Most commonly diagnosed in individuals 20 to 60 years of age, with men affected more frequently than women.

Clinical features

Pyostomatitis vegetans is characterized by multiple, tiny, creamy-yellow pustules within a background of diffuse intense erythema. The pustules are often arranged in a linear serpentine fashion and are described as having a "snail-track" appearance. The pustules are easily ruptured, leading to shallow erosions and ulcerations (see Fig. 26.9A). While any area of the oral cavity may be affected, the labial, gingival, and buccal mucosa are most commonly involved. The dorsum of the tongue is usually spared.

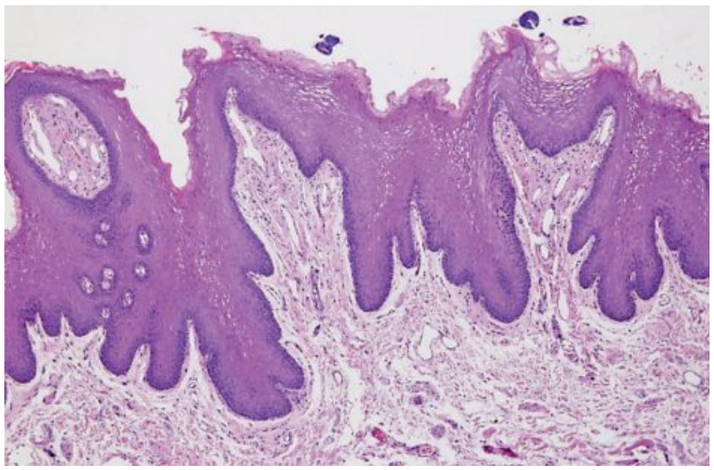
Pathology

Intraepithelial and/or subepithelial microabscesses containing numerous eosinophils as well as neutrophils are seen.

Treatment

Treatment focuses on controlling any underlying gastrointestinal disease with management of the latter often resulting in improvement of the oral lesions. Application of topical corticosteroids may also prove beneficial.

Oral Manifestations of HIV Infection



This subject is reviewed in Chapter 78.

Additional figures and tables on Topical care for oral inflammatory conditions, and Systemic diseases with oral manifestations, available in our eBook (see inside front cover for access code).

TOPICAL CARE FOR ORAL INFLAMMATORY CONDITIONS
Oral hygiene
• Soft toothbrush • Water pick, soft-tipped gum pick, or waxed tape-type dental floss to remove plaque • Non-alcohol-based mouthwash • Avoid trauma, e.g. biting cheeks, sharp/rough dental restorations/appliances • Rinses with baking soda +/– salt diluted with water (1 tsp of each in 4 cups of water)
Topical anesthetics for erosions/ulcers
• 2% viscous lidocaine (to surface of ulcers or as swish and spit) • "Magic mouthwash" with equal parts of: (1) 2% viscous lidocaine; (2) diphenhydramine 12.5 mg/5 ml; (3) magnesium and aluminum hydroxide plus sulcralfate (Maalox®) • Dyclonine lozenges
Topical anti-inflammatory medications
• Corticosteroids, e.g. clobetasol 0.05% gel/ointment, fluocinonide 0.05% gel/ointment, triamcinolone 0.1% paste (can be placed on gauze or in trays) • Dexamethasone elixir 0.5 mg/5 ml, swish and spit 5 ml BID–TID (leaving in mouth for 5 minutes)* • Corticosteroid inhaler • Tacrolimus 0.1% ointment • Tacrolimus 1 mg capsule dissolved in 0.5–1 L of water, swish and spit 5 ml BID (leaving in mouth for ≥2 minutes)*
Prevention of secondary infection†
• Clotrimazole 10 mg troches 4 times/day • Nystatin suspension (400,000–6000,000 units), swish and swallow 4 times/day • Chlorhexidine 0.12% oral rinse, swish and spit BID • Dilute hydrogen peroxide (one part 3% solution, 2 parts water), swish and spit BID
*Especially for patients with more widespread involvement. †Consider for patients with extensive oral erosion/ulceration, especially if using topical or systemic immunosuppressive agents.

eTable 72.1 Topical care for oral inflammatory conditions. *Courtesy Julie V. Schaffer, MD.*

SYSTEMIC DISEASES WITH ORAL MANIFESTATIONS	
Disease	**Characteristic oral findings**
Endocrinologic disorders	
Addison disease	Diffuse oral mucosal pigmentation
Diabetes mellitus	Severe periodontal disease, oral candidiasis, enlarged parotid glands
Genodermatoses	
Chronic mucocutaneous candidiasis/APECED syndrome	Thick white plaques due to candidiasis, enamel defects
Autosomal dominant (STAT3-deficient) hyper-IgE (Job) syndrome	Retention of primary teeth, candidiasis, high-arched palate
Cowden syndrome	Multiple mucosal-colored papules favoring the tongue, gingivae, lips, and buccal mucosa
Darier disease	Whitish papules and plaques favoring palate and gingivae
Dyskeratosis congenita	Leukoplakia may be premalignant or malignant and favors the tongue and buccal mucosa; may be preceded by bullae and erosions
Ectodermal dysplasias	Hypodontia, cone-shaped teeth, xerostomia
Epidermolysis bullosa	Fragility and vesicles/bullae; scarring results in reduced depth of the labial vestibule, microstomia, and ankyloglossia
Gardner syndrome	Osteomas of the maxilla and mandible, supernumerary and impacted teeth
Hereditary benign intraepithelial dyskeratosis	Diffuse thick white plaques favoring the buccal mucosa and labial mucosa
Hereditary hemorrhagic telangiectasia	Multiple red papules (AVMs) of the vermilion lip and oral mucosa; blanch with diascopy and can bleed
Incontinentia pigmenti	Hypodontia, cone-shaped and hypoplastic teeth, delayed dental eruption
Lipoid proteinosis	Diffuse infiltration or cobblestoned papules that favor the lips and tongue/frenulum, xerostomia
Multiple endocrine neoplasia type 2B	Mucosal neuromas favoring the lips and tongue
Basal cell nevus syndrome	Odontogenic keratocysts of the mandible > maxilla
Pachyonychia congenita	Thick white plaques favor the lateral and dorsal tongue
Peutz–Jeghers syndrome	Lentigines of the lips and oral mucosa
Tuberous sclerosis complex	Oral fibromas, dental enamel pits
White sponge nevus	Diffuse, bilateral, thick white plaques that favor the buccal mucosa
Xeroderma pigmentosum	Squamous cell carcinoma of the lower lip and tip of the tongue

eTable 72.2 Systemic diseases with oral manifestations.

Continued

SYSTEMIC DISEASES WITH ORAL MANIFESTATIONS	
Disease	**Characteristic oral findings**
Hematologic disorders	
Agranulocytosis	Necrotizing deep ulcerations that favor the gingivae, buccal mucosa, tongue, and palate
Aplastic anemia	Gingival hemorrhage plus petechiae, purpura, and ecchymoses due to thrombocytopenia, mucosal pallor, infections
Cyclic neutropenia	Recurrent episodes of oral ulcerations, especially of the gingivae, lips, tongue, and buccal mucosa
Extranodal NK/T cell lymphoma, nasal-type	Ulceration of the hard palate
Langerhans cell histiocytosis	Loosening of teeth, gingival erythema, ulcerations and bleeding, gingival papulonodules
Leukemia, especially (myelo)monocytic forms	Gingival hemorrhage, infections, gingival enlargement due to leukemic infiltration
Plasma cell dyscrasias, including multiple myeloma	In some patients with primary systemic amyloidosis, amyloid deposits can lead to macroglossia with scalloping of the tongue edge (due to dental impressions) as well as hemorrhagic papulonodules and ulcerations, xerostomia
Extramedullary plasmacytomas	Upper respiratory tract is common site; occasionally arise within oral cavity
Neutropenia	Infections, particularly bacterial, oral ulcerations
Non-Hodgkin lymphoma, including mycosis fungoides	Non-tender, boggy swellings favoring the buccal vestibule, posterior hard palate, or gingivae
Thrombocytopenia	Petechiae, purpura, ecchymoses, and spontaneous gingival hemorrhage
Immunologic disorders	
Behçet disease	Oral aphthous-like ulcers
Chronic ulcerative stomatitis	Oral erosions and ulcerations plus white striae
Systemic sclerosis, including CREST syndrome	Telangiectasias, microstomia, gingival recession, firm tongue, xerostomia
Erythema multiforme major, Stevens–Johnson syndrome	Oral erosions and ulcerations, hemorrhagic crusting of the vermilion zone of the lips
Graft-versus-host disease	White striae that resemble oral lichen planus, xerostomia, leukoplakia, mucocele
Lichen planus (LP) > lichenoid drug eruption or LP pemphigoides	Interlacing white lines (Wickham striae), oral erosions and ulcerations, desquamative gingivitis
Lupus erythematosus	White striae that resemble oral lichen planus, erythema, erosions, ulcerations; red and white plaques of the midline hard palate
Mucous membrane pemphigoid	Oral erosions and ulcerations, with vesicles or bullae occasionally seen, desquamative gingivitis
Paraneoplastic pemphigus	Oral ulcerations and hemorrhagic crusting of the vermilion zone of the lips
Pemphigus vulgaris	Ragged erosions and ulcerations, desquamative gingivitis
Sarcoidosis	Orofacial granulomatosis, xerostomia, salivary gland enlargement
Sjögren syndrome	Xerostomia
Granulomatosis with polyangiitis (Wegener granulomatosis)	Gingival hemorrhage with a friable micropapular surface (“strawberry gums”); non-healing ulcerations
Inflammatory bowel disease	
Crohn disease	Orofacial granulomatosis, linear ulcerations of buccal vestibule, aphthous-like ulcers, oral mucosal cobblestoning
Ulcerative colitis > Crohn disease	Pyostomatitis vegetans with oral pustules and erosions in a “snail-track” arrangement
Nutritional deficiencies	
Iron deficiency and B_{12} deficiency	Atrophic glossitis, stomatitis
Vitamin C deficiency (scurvy)	Gingival enlargement, hemorrhage, and erosions
Other	
Kawasaki disease	Cheilitis, diffuse oropharyngeal erythema, and strawberry tongue
MIS-C secondary to SARS-CoV-2 infection	Cheilitis, oral erosions, strawberry tongue

eTable 72.2 Systemic diseases with oral manifestations. AVM, arteriovenous malformation; CREST, calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, telangiectasias; MIS-C, multisystem inflammatory syndrome in children.

INTRODUCTION

The diagnosis and management of skin diseases in the anogenital region may be complex. The juxtaposition of urinary, genital, and alimentary tracts gives rise to special considerations at this site (Fig. 73.1), and disease of any of these major systems may present with cutaneous manifestations. A number of systemic diseases such as Crohn disease and zinc deficiency preferentially affect the anogenital area. Local factors, including warmth, moisture, irritants, friction, and the effects of body fluids, are important in this region, contributing to skin problems.

Skin conditions may be more difficult to diagnose in the anogenital region than at other cutaneous sites, as the typical appearance of a particular skin disease may be lacking and there may be a hesitation to perform biopsies. Examination of the scalp, nails, mouth, and extragenital skin frequently assists in diagnosis. Special considerations apply to treatment, as the natural occlusion of this area may increase the percutaneous absorption of topical corticosteroids, with the potential for cutaneous atrophy and/or hypothalamic–pituitary–adrenal axis suppression. Warmth and moisture increase the risk of bacterial and yeast infections.

Only a limited number of symptoms in the anogenital area are possible, and pruritus and genital pain may be the presenting feature of a wide variety of diseases.

LICHEN SCLEROSUS

Synonyms: ■ Lichen sclerosus et atrophicus ■ Balanitis xerotica obliterans (men) ■ Kraurosis vulvae (women)

Key features

- Chronic inflammatory disease with a predilection for the anogenital region
- Pruritus is the most frequent symptom
- Major clinical signs are pallor, atrophy, fissures, and foci of hyperkeratosis
- Scarring may cause loss of the normal architecture of the vulva in women and phimosis in men

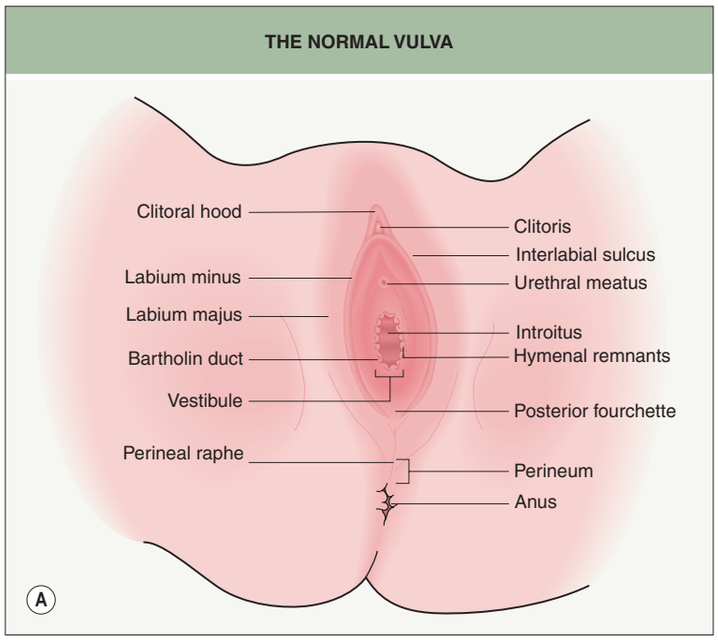
Introduction

Lichen sclerosus is a chronic inflammatory disease that preferentially affects the anogenital region, although any cutaneous site may be affected; 15%–20% of patients with genital lichen sclerosus will have extragenital disease. Symptoms may be longstanding as there is frequently a delay in diagnosis. Patients require long-term evaluation due to the risk of scarring and the risk of developing squamous cell carcinoma (SCC)[1].

Epidemiology

Lichen sclerosus is 6–10 times more prevalent in women than in men. The disorder may occur at any age, but the two peaks of onset are childhood and after menopause (or in the 4th or 5th decade in men). Although most studies have centered on White European patients, there are reports of lichen sclerosus occurring in Africans and Asians. Powell et al.[2] calculated a prevalence of 1 in 660 women and an annual incidence of 52/100 000 in postmenopausal women. The incidence of lichen sclerosus in boys may be underestimated; when foreskins of circumcised boys were examined, 14% were found to have the characteristic features of lichen sclerosus[3].

Etiology



The cause of lichen sclerosus is unknown. In women, there is evidence to support an association with autoimmunity and heritability. Autoantibodies to extracellular matrix protein 1 (ECM1) are found in the majority of women with lichen sclerosus, but their role in pathogenesis is uncertain. A heritable risk is suggested by the occurrence of familial cases, as well as an association with HLA-DRB1*12 (and the related haplotype DRB1*12/DQB1*0301/04/09/010)[4] and autoimmune disorders such as thyroid disease[5]. However, in male patients, familial cases are uncommon, and HLA and autoimmune associations are rarely observed[6].

An infectious etiology has been proposed, but *Borrelia* or other spirochetal infection has not been confirmed in large studies. Local friction or rubbing may induce lesions of lichen sclerosus via the Koebner phenomenon, and some cases of early-onset lichen sclerosus may be associated with the antiandrogenic oral contraceptive pill. In men, chronic exposure of susceptible epithelium to urine due to naviculomeatal dysfunction (microurinary incontinence) has been proposed as causative[7]. Of note, lichen sclerosus of the penis does not occur in men circumcised at birth[6]. Whether urinary dysfunction plays a role in women and children is not known.

Clinical features

Both male and female patients may present with pruritus or soreness, but rarely are entirely asymptomatic[1,8]. Dyspareunia is frequently reported. Children with lichen sclerosus are more likely to present with urinary or bowel symptoms (e.g. constipation), purpura, or even hemorrhagic bullae, which may lead to a misdiagnosis of child abuse[8].

In women and girls, the characteristic clinical findings are vulvar hypopigmentation and thin, wrinkled, atrophic skin in a figure-of-eight distribution encircling the vulvar and perianal region (Fig. 73.2). Focal areas of hyperkeratosis, erosions, and fissures are frequently seen, with the perineum a common location for fissures. Additional cutaneous features that are helpful in identification are purpura (Fig. 73.3), telangiectasias, and rarely, hemorrhagic bullae. The hemorrhagic component can occasionally be so pronounced that it mimics a vascular lesion. Because lichen sclerosus is a scarring disease, architectural change is common (Fig. 73.4). Burying of the clitoris secondary to midline fusion or fusion of the labia minora to the labia majora may occur. In untreated or severe disease, there may be total loss of the labia minora

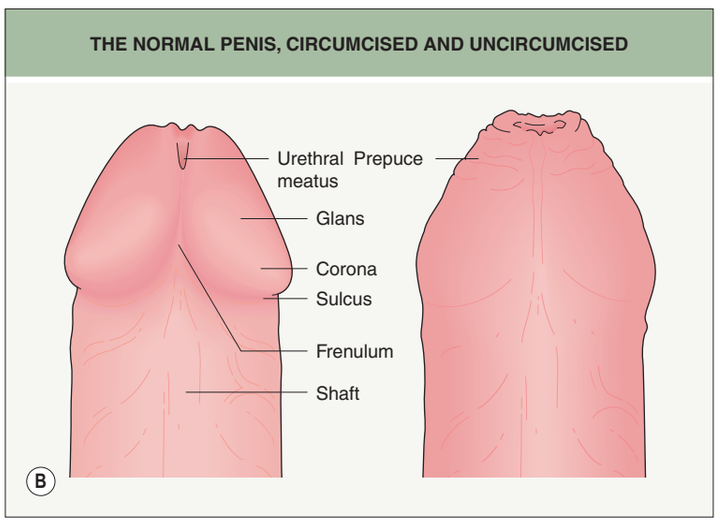


Fig. 73.1 Genital anatomy. A The normal vulva. **B** The normal penis, circumcised and uncircumcised.

Fig. 73.2 Anogenital lichen sclerosus in a girl. Hypopigmented, shiny skin in a figure-of-eight configuration with purpura, multiple erosions, and foci of hyperkeratosis. *Courtesy Julie V. Schaffer, MD.*

Fig. 73.3 Lichen sclerosus of the vulva with characteristic purpura. *Courtesy Kalman Watsky, MD.*

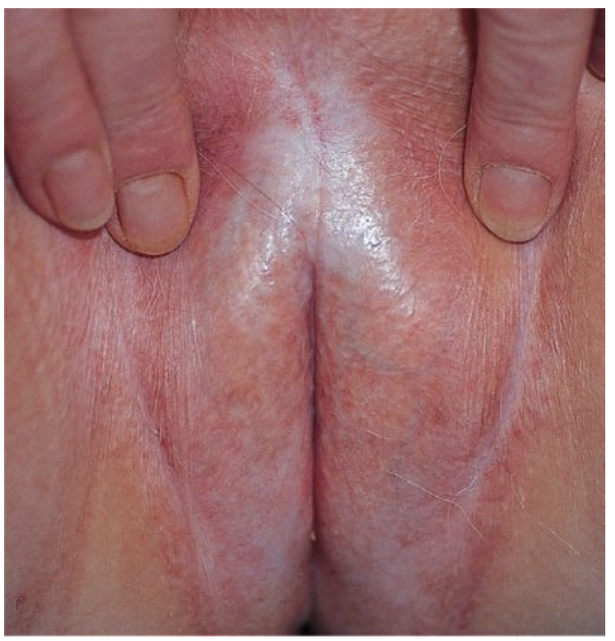

Fig. 73.4 Lichen sclerosus of the vulva. There is marked architectural change with loss of the labia minora and marked midline fusion.

and narrowing of the introitus. Darkly pigmented lentigines with an irregular outline may arise within areas of involvement.

Lichen sclerosus affects the glans penis and foreskin of men and, in contrast to women, involvement of the perianal region is uncommon. The disease usually presents with pruritus, pain, and dyspareunia[9]. Affected boys may have recurrent balanitis and a poor urinary stream, and circumcision is sometimes required. Men may report painful erections or erectile dysfunction as well as dysuria and spraying, dribbling, or poor flow of urine. Clinically, gray–white discoloration, purpura, and scarring can be seen (Fig. 73.5), leading to phimosis, paraphimosis, or constrictive posthitis. Additional architectural changes include coronal adhesions, reduced coronal sulcus and rim, and narrowing of the urethral meatus.

Extragenital lichen sclerosus favors the submammary region, as well as the shoulders, neck, and wrists, presenting as asymptomatic, hypopigmented, wrinkled patches with follicular plugging (see Ch. 44); occasionally, there are multiple guttate lesions. The diagnosis is established by a combination of the characteristic clinical and histologic findings.

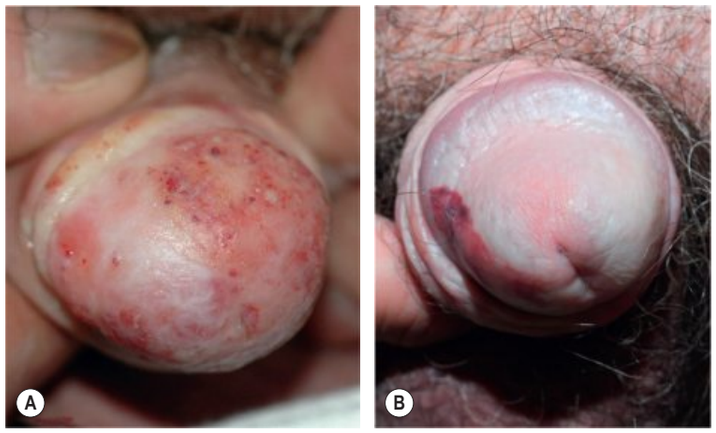

Fig. 73.5 Lichen sclerosus of the penis. A Erythematous and white plaque on the glans. **B** Shiny hypopigmented plaques of the glans in addition to purpura. *A, Courtesy Luis Requena, MD; B, Courtesy Kalman Watsky, MD.*

Pathology

The principal histologic findings are compact orthokeratosis, follicular plugging (in non-mucosal sites), a thinned epidermis, vacuolization of the basal layer, and hyalinization of the papillary dermis. A dense band-like lymphocytic infiltrate is often observed. Squamous hyperplasia may be present and may be associated with an increased risk of SCC. In bullous lichen sclerosus, there is extensive vacuolar degeneration of the basal layer with clefting and hemorrhage. Early on, the papillary dermis may be edematous and homogenous, but, with time, hyalinization and sclerosis are observed.

Histologic examination of the skin is recommended as it can be difficult to distinguish lichen sclerosus from mucous membrane (cicatricial) pemphigoid or erosive lichen planus on the basis of clinical appearance alone. Occasionally, despite marked clinical changes, the disease cannot be confirmed histologically and repeat biopsies over time may be needed to establish the diagnosis. Of note, in genital lesions, a dense band-like lymphoid infiltrate with several intraepithelial lymphocytes may be the only histopathologic finding, with hyalinization of the superficial collagen absent or only present focally. In lesions that have been treated with potent topical corticosteroids, ascertaining the diagnosis histologically may also prove challenging.

Differential diagnosis

Very mild or early disease may be confused with dermatitis. The presence of genital scarring necessitates the exclusion of other scarring disorders such as erosive lichen planus and mucous membrane pemphigoid. The absence of oral or vaginal mucosal involvement helps to distinguish lichen sclerosus from erosive lichen planus. In children, sexual abuse must be considered, as lichen sclerosus and sexual abuse are not mutually exclusive. Associated pruritus and topical therapies can lead to superimposed lichen simplex chronicus as well as allergic or irritant contact dermatitis. Histologically, the presence of a dense lymphoid infiltrate may be misdiagnosed as mycosis fungoides; the latter diagnosis, especially in the genital region, requires compelling evidence, particularly in children.

Treatment

The main aim of therapy is to bring the disease under control as quickly as possible with the fewest side effects. For induction treatment (after the diagnosis is established), a superpotent topical corticosteroid such as clobetasol propionate 0.05% ointment is prescribed until signs and symptoms improve, typically 1 to 3 months[1,9–13]. This alleviates symptoms in the majority of patients, often within weeks. Subsequently, the corticosteroid is tapered over 2–3 weeks and clinical remission maintained by limited (typically twice weekly) application of a higher potency corticosteroid or daily application of a lower potency topical corticosteroid. In some women, there is complete resolution of signs as well as symptoms, with the exception of scarring, which is irreversible[8]. Beyond preserving clinical remission, maintenance therapy has been associated with a reduced occurrence of SCC[12].

In the management of vulvar lichen sclerosus without secondary SCC, there is no longer a role for vulvectomy. For longstanding disease in which narrowing of the introitus has resulted in dyspareunia, surgical refashioning with division of adhesions may be helpful. Vaginal dilators may also be needed, in addition to psychosexual counseling to address the psychological distress that frequently accompanies lichen sclerosus.

In male patients, first-line therapy consists of potent topical corticosteroids, with cotton swab/bud application for meatal involvement[9]. Those with urinary symptoms should be evaluated by a urologist. If treatment does not lead to improvement or a tight phimosis is present, circumcision is often necessary.

Longitudinal evaluation is essential for patients with lichen sclerosus because both men and women are at increased risk of developing genital SCCs (estimates of the risk are 2%–6%)[9,11,12]. Women with childhood-onset lichen sclerosus may be particularly at risk of developing genital SCC, and notably the myth that childhood lichen sclerosus resolves at puberty has been debunked[14]. Women with lichen sclerosus may develop *differentiated* vulvar intraepithelial neoplasia (VIN), which has a higher risk of developing into invasive SCC when compared to high-grade squamous intraepithelial lesion (HSIL); the latter is an HPV-associated disease and was previously known as undifferentiated VIN. Men are at risk of penile intraepithelial neoplasia. Non-healing fissures, ulcers, or nodules must be examined histologically. Written educational material and patient support groups are very helpful. It is essential that patients who notice any features of malignancy seek prompt medical assessment.

The first- and second-line therapies for anogenital lichen sclerosus are outlined in Table 73.1.

MANAGEMENT OF ANOGENITAL LICHEN SCLEROSUS ℞

General

- Soap substitutes and regular use of emollients* (e.g. white petrolatum) (3,2)
- Apply white petrolatum prior to urinating, to minimize dysuria (2)
- Silk or cotton underwear
- Consider nighttime sedation, until pruritus controlled, to minimize scratching (3)
- Estrogen replacement (topical or systemic [if not contraindicated]) for postmenopausal women with atrophic vulvovaginal disease (2)
- Circumcision for phimosis or paraphimosis (2)
- Regular (at least yearly) examination for SCC

First-line

Induction

- Superpotent (Class I) topical corticosteroid* (e.g. clobetasol 0.05% ointment) applied once to twice daily until signs and symptoms resolve (typically 1–3 months) (1), then taper to maintenance

Maintenance†

- Superpotent (Class I) topical corticosteroid* twice weekly at bedtime (1)
  – *OR* –
- Potent (Class II, e.g. mometasone furoate 0.1% ointment) topical corticosteroid* twice weekly (1) – *OR* –
- Midpotency (Class V) topical corticosteroid* daily (2)
- Topical calcineurin inhibitors 2–3 times a week‡ (1)

Second-line

- Intralesional triamcinolone acetonide (e.g. 5–10 mg/cc monthly) (1)
- Oral retinoids (e.g. acitretin 10–50 mg/day for >6 months) (1)
- Methotrexate (2)
- Hydroxychloroquine (3)
- JAK inhibitors
- UVA1 (50 J/cm^2) (1)
- Photodynamic therapy (2)
- Fractional CO_2 laser (especially for hyperkeratotic plaques) (3)
- Circumcision, if unresponsive to medical treatment (3)
- Surgery to correct narrowing of introitus and reverse clitoral burying (3)

*Ointments are preferred over creams because they are less irritating.
†Ongoing maintenance, regardless of symptoms, has been shown to decrease the development of SCC.
‡Adding in tandem after topical corticosteroids rather than concurrently may reduce associated burning; some clinicians avoid chronic use because the long-term risk is unknown and there is an increased risk of secondary SCC in lichen sclerosus.

Table 73.1 Management of anogenital lichen sclerosus. Topical JAK inhibitors and dupilumab have been used for extragenital lichen sclerosus. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. SCC, squamous cell carcinoma.

LICHEN PLANUS

Synonyms: ■ Vulvovaginal gingival syndrome/vulvo-vaginal-gingival syndrome (erosive lichen planus in women) ■ Peno-gingival syndrome in men ■ Mucosal lichen planus

Key features

- Four distinct forms of genital lichen planus are observed: (1) papules or plaques in the setting of generalized cutaneous lichen planus; (2) erosive disease; (3) hypertrophic disease; and (4) lichen planopilaris
- Although cutaneous disease is often self-limiting, mucous membrane disease is more persistent
- The classic findings in cutaneous disease are violaceous, flat-topped papules and plaques; lacy white streaks typically occur on the genitalia as well as the oral mucosa
- Erosive lichen planus often involves multiple mucous membrane sites – in particular, the vulva, vagina, and oral mucosa

Introduction

Approximately 50% of women and 25% of men with cutaneous lichen planus have genital involvement. The classic violaceous papules and plaques typically affect the labia minora and majora or the mons pubis in women and the glans or shaft of the penis in men. Erosive lichen planus is a distinct subtype of the disease, characterized by severe, scarring erosive disease of the vestibule, introitus, vagina, and oral cavity[13,15]. Hypertrophic genital lichen planus and lichen planopilaris are the least frequent forms.

Epidemiology

Lichen planus is more common in women, generally presenting in the sixth decade. The exact prevalence is unknown, but it is likely that some cases of genital involvement in cutaneous lichen planus may be missed.

Etiology

Lichen planus probably represents T cell-mediated damage to epidermal cells that express altered self or foreign antigens on their surface, but the exact etiology is unknown (see Ch. 11). There is an autoimmune phenotype (see Lichen sclerosus above) in female patients with vulvar lichen planus and an association with autoimmune disease[5]. While some cases of lichen planus may be drug-induced, there are no definite associations with genital disease. Infectious triggers, particularly hepatitis C viral infection, may be associated with mucosal lichen planus in certain parts of the world such as the Mediterranean basin and Japan.

Clinical features

There are four distinct presentations of genital lichen planus[15,16], as follows:

- In *classic* lichen planus, the genital lesions are similar to those in other cutaneous sites, but lacy reticulation may be very prominent. Genital involvement is usually limited to the mons pubis and the labia majora and minora in women or the glans penis and shaft in men (see Fig. 11.4B). Penile plaques are frequently annular (Fig. 73.6A). Scarring is not a feature of classic lichen planus. Severe cutaneous pruritus is the usual presenting symptom, but genital lesions may be asymptomatic. Lesions are usually self-limited.
- *Erosive* lichen planus occurs much more frequently in women than in men. Pain and dyspareunia are the most common complaints. In female patients, extensive erosions occur around the vaginal orifice, edged by lacy white reticulations; similar lesions may also occur on the labia (Fig. 73.6B). Erosive lichen planus frequently leads to scarring, resulting in distortion of the vulvar architecture[13]. In severe cases, there may be complete obliteration of the vaginal canal and urinary retention. Vaginal involvement can present with a discharge, erythema and contact bleeding of the vaginal mucosa, and/or scarring with adhesions. Oral involvement is frequently observed, usually in the form of a desquamative gingivitis, but lacy white reticulations and erosions may also occur. Erosions limited to the perianal area alone have been described.
- In the *hypertrophic* form of lichen planus, hyperkeratotic white plaques on the vulva or shaft of the penis may be seen.
- In *lichen planopilaris*, follicular keratotic papules are limited to the hair-bearing labia majora and the mons pubis, but may also be seen on the scalp and trunk and in the axillae.

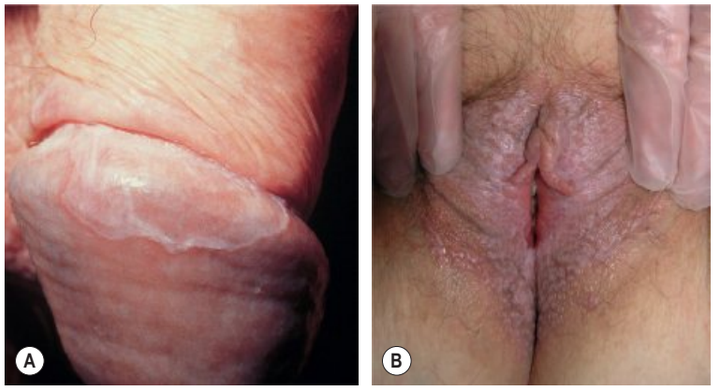

Fig. 73.6 Lichen planus. A An annular band is seen on the glans of the penis. This is a typical finding. **B** Erosive lichen planus of the vulva with fissures and an extensive white lacy pattern. *A, Courtesy R. Turner, MD.*

Pathology

The typical histologic findings are irregular epidermal acanthosis, accentuation of the granular layer, liquefactive degeneration of the basal layer, and a band-like dermal infiltrate of lymphocytes. It is more difficult to interpret biopsy specimens of mucous membranes, where these findings are more variable. Because there is loss of the epithelium in erosive disease, the specimen should include the edge of the erosion as well as the surrounding lacy reticulated skin. Despite this, it is sometimes difficult to unequivocally confirm the disease, but histologic evaluation can aid in excluding other disorders in the differential diagnosis.

Differential diagnosis

The principal entities in the differential diagnosis are lichen sclerosus; autoimmune bullous disease, including mucous membrane pemphigoid; Zoon (plasma cell) vulvitis; Behçet disease; graft-versus-host disease; and high-grade squamous intraepithelial lesion (HSIL; previously referred to as undifferentiated vulvar intraepithelial neoplasia) or SCC. Direct immunofluorescence may be necessary to exclude an autoimmune bullous disease. Orogenital ulceration raises the possibility of Behçet disease (see Ch. 26). For oral lesions, lupus erythematosus is in the differential diagnosis, but this would be unusual in the anogenital region. Early lichen planus may be confused with vulvar eczema and there may be superimposed lichen simplex chronicus. For hypertrophic disease, HSIL, SCC, and lichen simplex chronicus are the major entities in the differential diagnosis.

Treatment

The treatment of genital lichen planus is outlined in Table 73.2. Potent or moderately potent corticosteroid ointments will control most symptoms of classic genital lichen planus, as the disease is usually self-limiting. Hypertrophic disease may require intralesional corticosteroids.

The management of erosive lichen planus is more difficult, as the disease is often more persistent[15–17]. The majority of patients will respond to a 3-month course of topical clobetasol propionate 0.05% ointment (as described for lichen sclerosus) and thereafter can be maintained on moderately potent corticosteroids or twice weekly application of the potent corticosteroid. A combination of a moderately potent corticosteroid with a topical antifungal cream (e.g. econazole) may be as effective as more potent corticosteroids, particularly for maintenance therapy. For refractory disease, anecdotal case reports describe benefit from intralesional corticosteroid injections, topical calcineurin inhibitors, oral hydroxychloroquine, systemic immunosuppressants, and acitretin (see Table 73.2). Tricyclic antidepressants can be used to treat associated vulvodynia. Erosive vaginal disease requires

MANAGEMENT OF ANOGENITAL LICHEN PLANUS Rx
General
• Soap substitutes and regular use of emollients* (e.g. white petrolatum) (3) • Apply white petrolatum prior to urinating, to minimize dysuria (3) • Consider nighttime sedation, until pruritus controlled, to minimize scratching (3) • Estrogen replacement (topical or systemic [if not contraindicated]) for postmenopausal women with atrophic vulvovaginal disease (3)
First-line
Induction
• Superpotent (Class I) topical corticosteroid* (e.g. clobetasol 0.05% ointment) applied once to twice daily until signs (e.g. erosions) and symptoms resolve (1), then taper to maintenance • Intravaginal corticosteroids (*for vaginal disease*) nightly until controlled and then taper to maintenance (2); consider combining with weekly oral fluconazole (150–200 mg/week) for vulvovaginal candidiasis prophylaxis (3)
Maintenance
• Superpotent topical corticosteroid* (twice weekly) or combined moderately potent corticosteroid/antifungal/antibacterial preparations (3) • Intravaginal corticosteroids† (*for vaginal disease*) at bedtime, at minimum frequency needed for control ± weekly fluconazole (150–200 mg/week) for vulvovaginal candidiasis prophylaxis (3) • Regular use of vaginal dilators to prevent stenosis (3)
Second-line
• Topical calcineurin inhibitors (2) • Intralesional triamcinolone acetonide (e.g. 5–10 mg/cc monthly; hypertrophic disease, recalcitrant erosions) (3)
Recalcitrant or severe disease
• Prednisone (40–60 mg/day) – short course for rapid control and while initiating corticosteroid-sparing agent (2) • Hydroxychloroquine (2) • Systemic immunosuppressants (e.g. methotrexate (2), mycophenolate mofetil (2), azathioprine (3), TNF inhibitors (3)) • Acitretin (hypertrophic disease) (3) • Systemic antibiotics (tetracyclines ± nicotinamide) (3) • Photodynamic therapy (requires sedation) (1) • Surgery to correct narrowing of introitus and reverse clitoral burying in women or circumcision in men (3)
*Ointments are preferred over creams because they are less irritating. †Compounded vaginal suppositories that contain 200–300 mg of hydrocortisone acetate can be inserted nightly until control achieved, then frequency tapered.

Table 73.2 Management of anogenital lichen planus. Topical and oral JAK inhibitors as well as dupilumab have been used for extragenital lichen planus. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

intravaginal corticosteroids and regular use of vaginal dilators to prevent stenosis; surgery to lyse adhesions may be required.

Long-term evaluation of these patients is advised because of the risk of developing SCC[18]; the incidence of the latter has been estimated to be ~2.4%[16]. For further details on the treatment of lichen planus, including systemic agents for severe, refractory disease, see Chapter 11.

ZOON BALANITIS/VULVITIS

Synonyms: ■ Plasma cell balanitis/vulvitis ■ Vulvitis/balanitis circumscripta plasmacellularis ■ Zoon's erythroplasia

Key features

- Male predominance
- Erythematous, moist, speckled, discrete thin plaques
- Involvement of adjacent surfaces produces "kissing" lesions in men
- In men, cured by circumcision

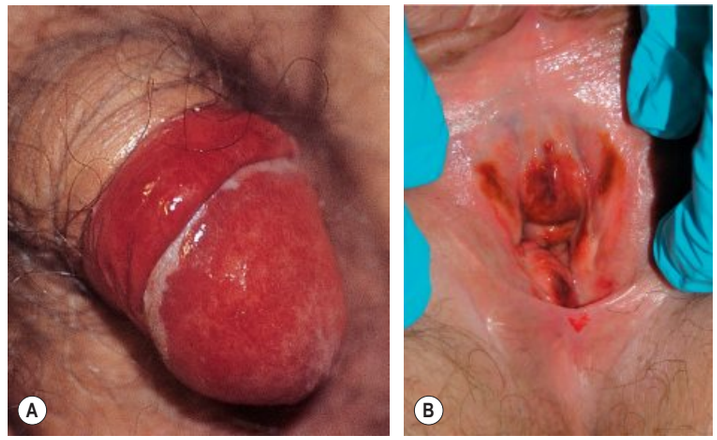

Fig. 73.7 Zoon balanitis and vulvitis. A There are moist red "kissing" lesions on adjacent surfaces of the glans and prepuce. **B** Light to dark red patches of the clitoris, vestibule, introitus, and labia.

Introduction

While most authorities believe this condition occurs in men, its existence as a separate entity in women has been questioned. This is because many of the clinical features in women are indistinguishable from those of erosive lichen planus, mucous membrane pemphigoid, or lupus erythematosus, and the lichenoid features histologically overlap with erosive lichen planus and lichen sclerosus.

Epidemiology

Zoon balanitis/vulvitis may occur at any age but is usually seen from the third decade onwards in uncircumcised men and in postmenopausal women.

Etiology

The etiology is unknown, but poor penile hygiene or chronic irritation from warmth or rubbing has been suggested. Zoon balanitis has not been observed in circumcised men. In women, the vulvitis may represent a reactive process secondary to trauma or reflect a postmenopausal hypoestrogenic state.

Clinical features

In men, the lesions on the glans penis may be asymptomatic or give rise to pruritus or dysuria. The lesions are erythematous, discrete, moist thin plaques with a "cayenne pepper" speckled appearance and a deep red to reddish-brown hue. "Kissing" lesions with involvement of adjacent, touching areas, e.g. around the urethral meatus, are a characteristic finding (Fig. 73.7A). Shallow erosions may resolve slowly, leaving a rusty color. In women, thin erythematous plaques similar to those in men may be seen anywhere on the vulva (Fig. 73.7B). Lesions may be asymptomatic or cause burning, dyspareunia, dysuria, pruritus, or pain.

Pathology

The typical histologic picture is a dense lichenoid infiltrate in the upper and mid dermis with a predominance of plasma cells. Additional features include "lozenge-shaped" keratinocytes, vascular proliferation, hemosiderin deposition, and erythrocyte extravasation.

Differential diagnosis

In order to establish the diagnosis, a biopsy is usually performed. The major disorder in the differential diagnosis is erosive lichen planus, but the possibility of cutaneous malignancy (e.g. SCC *in situ*, extramammary Paget disease) must be considered.

Treatment

In men, a circumcision will almost always cure the disease. Potent topical corticosteroids or topical calcineurin inhibitors may provide some symptomatic relief[19,20]. Vaginal estrogen may be helpful for some women.

EPITHELIAL DISORDERS OF THE ANOGENITAL REGION

Dermatitis

Key features

- Appearance ranges from mild erythema to marked lichenification
- Pruritus and soreness are the main complaints
- A mixed etiology is common
- Exogenous irritants and allergens must be sought

Introduction

Although anogenital dermatitis has traditionally been subdivided into endogenous dermatitis (e.g. seborrheic dermatitis, atopic dermatitis), lichen simplex chronicus, and exogenous dermatitis (e.g. allergic or irritant contact dermatitis), in practice it is often difficult to distinguish between subtypes. A mixed picture, in which endogenous dermatitis is worsened by exogenous irritants or allergens, is common. Lichen simplex chronicus may develop secondarily to other anogenital diseases such as candidiasis, psoriasis, and lichen sclerosus.

Pathogenesis

The majority of patients with vulvar dermatitis have an endogenous predisposition, having either an atopic background or seborrheic dermatitis. The anogenital area is susceptible to irritants, and allergic contact dermatitis is very prevalent in this site; the latter is usually due to topical medications or personal hygiene products. Psychological issues and local environmental problems such as heat, sweating, and over-cleansing may contribute.

Clinical features

The cutaneous features are varied, ranging from mild, usually poorly demarcated erythema to severe lichenification (Fig. 73.8). Symptoms include pruritus (Figs. 73.9 & 73.10), pain, and superficial dyspareunia in women. In lichen simplex chronicus, scratching or rubbing is associated with unremitting pruritus. Fissuring is common, especially perianally. The typical anogenital sites affected are the labia majora and the mons pubis in women, the crura and scrotum in men, and the perianal area in both sexes. Lichenification is most often seen on the scrotum in men and the labia majora in women. Signs of seborrheic dermatitis (e.g. a scaly scalp, greasy scaling and erythema of nasolabial folds and eyebrows), as well as erythema at other flexural sites such as the inframammary crease, intergluteal fold, and axilla, should be sought. Atopic dermatitis at other sites will usually be obvious from the history or examination. Any contribution from dermatographism can also been assessed.

Fig. 73.8 Vulvar dermatitis. Lichenification is prominent. The underlying diagnosis was atopic dermatitis.

Differential diagnosis

The key to making the diagnosis is a thorough dermatologic examination. The diagnosis is usually made on the basis of clinical appearance, but a skin biopsy can be helpful in excluding other diagnoses. For example, plaques of psoriasis are more well-circumscribed than those of dermatitis. Extramammary Paget disease should also be considered, but these lesions are also sharply demarcated and usually asymmetric. It is important to identify irritants and possible allergens through a careful history and possibly patch testing. In addition, bacterial and *Candida* cultures should be performed to exclude superimposed infection, which is common in the anogenital region. Early lesions of lichen sclerosus may be indistinguishable from dermatitis.

Treatment

The regular use of bland emollients and the substitution of an emollient for soap is recommended. Exacerbating factors, including stress, heat, excessive washing, use of premoistened personal hygiene wipes ("wet wipes"), and candidiasis, should be identified. A major therapeutic aim is reduction of pruritus and soreness. If the area is acutely inflamed, potent topical corticosteroids, often in combination with topical

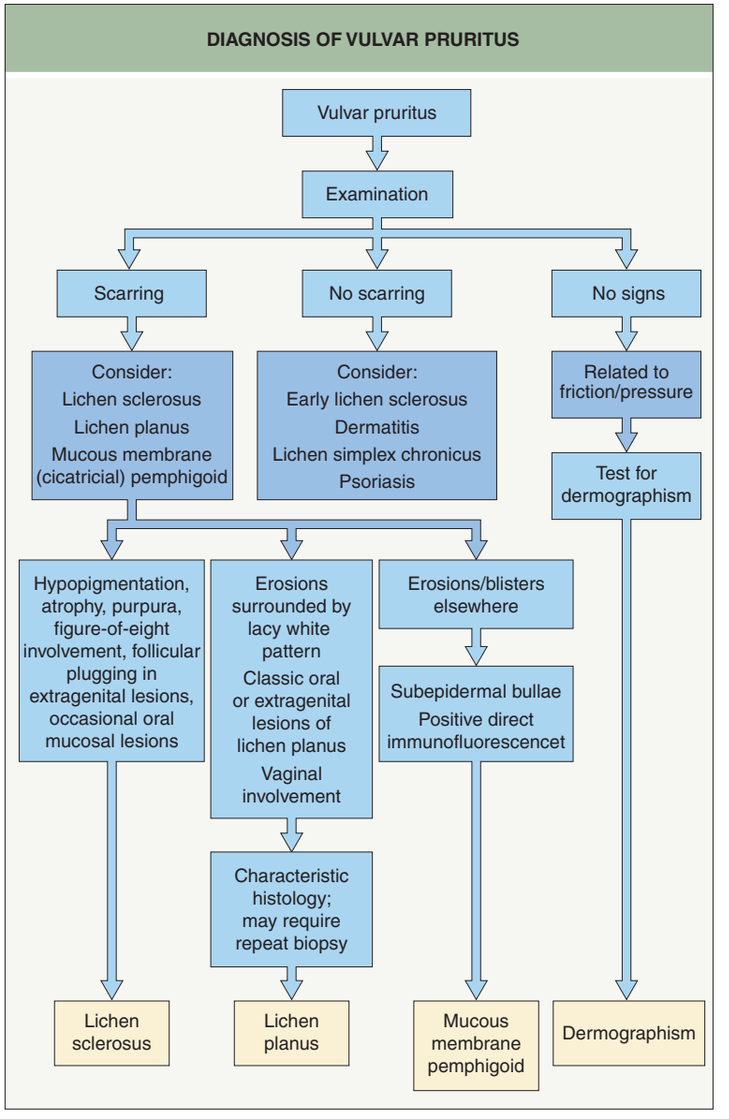

Fig. 73.9 Diagnosis of vulvar pruritus.

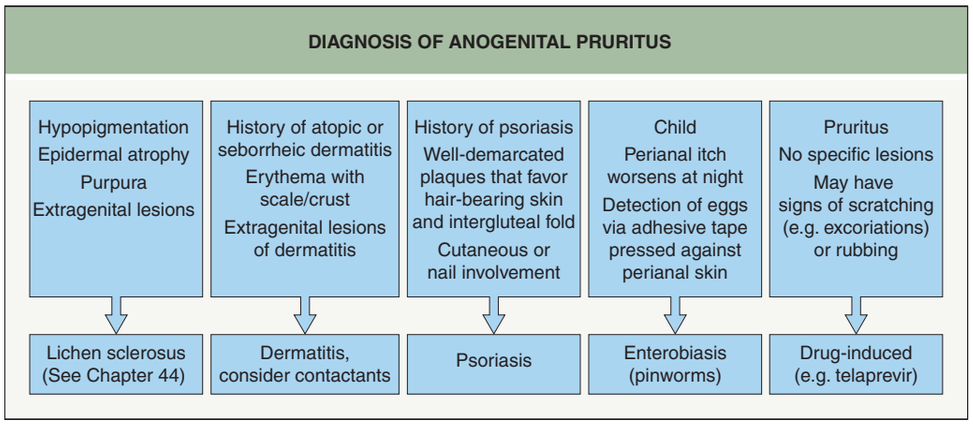

Fig. 73.10 Diagnosis of anogenital pruritus. Histologic evaluation may be required to confirm the clinical diagnosis (e.g. lichen sclerosus) or to exclude more unusual etiologies (e.g. extramammary Paget disease).

antifungal agents, topical antibacterial agents, and/or topical immunomodulators, are helpful. Over a period of a few weeks, the topical corticosteroid can be tapered to one that is less potent. When lichenification is present, it is especially important to break the itch–scratch cycle. Additional therapies include sedative antihistamines or tricyclic antidepressants, usually doxepin, at bedtime (see Ch. 6).

Contact Dermatitis

It is important to consider the possibility of contact dermatitis in any patient with dermatitis, a history of reactions to topical medications, or treatment-resistant disease. Contact dermatitis of the anogenital region may be irritant or allergic (see Chs. 14 & 15)[21]. Irritant contact dermatitis is seen in infants as diaper dermatitis and in older patients as a consequence of overzealous cleaning, urinary or fecal incontinence, or chronic diarrhea.

Allergic contact dermatitis is diagnosed by patch testing and can often arise as a treatment-related secondary condition. Topical medications are the most common cause of allergic contact dermatitis in the anogenital region[22]. Relevant allergens include preservatives, topical anesthetics, topical antibiotics, corticosteroids, fragrances, lanolin, and rubber chemicals. In perianal dermatitis, medications (topical, per anum), hemorrhoidal creams, and toilet wipes are common culprits. In addition to contact dermatitis, type I immediate hypersensitivity reactions to latex and seminal fluid may occur.

Psoriasis

Key features

- Erythematous well-defined plaques
- Evidence of psoriasis elsewhere on total body skin examination
- Intergluteal cleft frequently affected

Psoriasis of the anogenital region may appear quite different from psoriasis at other sites (see Ch. 8). The typical silvery scale is lost, as in other flexural sites such as the axillae and submammary region.

Clinical features

In women, erythematous, smooth, clearly demarcated plaques typically affect the labia majora and the mons pubis. Psoriasis is usually confined to the hair-bearing areas, so the labia minora are unaffected. Men may have circumscribed plaques on the glans penis and shaft of the penis (Fig. 73.11). Persistent, painful fissuring of the perianal area and the intergluteal cleft can be a severe problem in both sexes.

Differential diagnosis

Often the diagnosis is very straightforward, established from a combination of the clinical appearance in the genital region plus typical lesions elsewhere on the body or classic nail changes. Seborrheic dermatitis may be difficult to distinguish from psoriasis, and sometimes, clear features of both psoriasis and seborrheic dermatitis are seen in the same patient, where the term "sebopsoriasis" seems appropriate. The differential diagnosis includes tinea cruris (especially if there are pustules, an active border, extension of lesions onto the buttock or upper inner thigh, and/or concomitant tinea pedis or unguium), and erythrasma. In patients with reactive arthritis, lesions identical to those of psoriasis may be seen on the penis.

Fig. 73.11 Psoriasis of the penile shaft. Well-demarcated erythematous plaque with slight scale. Similar lesions can be seen in patients with reactive arthritis (formerly Reiter disease). *Courtesy Jean L. Bolognia, MD.*

Treatment

Unfortunately, topical therapy for anogenital psoriasis is not entirely satisfactory. Many topical agents suitable for use on the body, such as coal tar, anthralin, vitamin D derivatives, or retinoids, may be too irritating in flexural sites. Moderately potent topical corticosteroid–antibiotic–antifungal combinations remain the most useful therapy; however, in intertriginous sites, corticosteroid-induced atrophy remains a concern. Topical tacrolimus, pimecrolimus, or roflumilast may be helpful in such occluded sites. Some patients will improve when a systemic agent is used (e.g. methotrexate, cyclosporine, TNF inhibitors, systemic immunomodulators such as ixekizumab), usually for widespread disease.

RED SCROTUM SYNDROME/RED VULVA SYNDROME

The red scrotum syndrome (RSS) and red vulva syndrome (RVS) typically present in older individuals as persistent erythema of the scrotum or vulva with associated burning, pruritus, and/or pain. The precise etiology is unclear but possible contributing factors include rebound vasodilation resulting from prolonged use of topical corticosteroids and neurogenic inflammation[23]. Another theory is that it represents a form of localized erythromelalgia.

Because both RSS and RVS are diagnoses of exclusion, other entities including atopic, seborrheic or contact dermatitis, inverse psoriasis, superficial infections (e.g. tinea, candidiasis, erythrasma), fixed drug eruption, and extramammary Paget disease need to be considered. However, given the possible contribution of topical corticosteroids, RSS and RVS may be superimposed on another cutaneous disease. Treatment is challenging and includes the taper and then discontinuation of topical corticosteroids, thus attempting to avoid a rebound with more burning and erythema. This approach is similar to that employed in patients with steroid-induced rosacea. Based upon case reports, improvement has been observed with topical (e.g. timolol) and oral (carvedilol [6.25 mg three times weekly]) β-blockers[24], topical calcineurin inhibitors, oral doxycycline, and oral gabapentinoids (e.g. gabapentin, pregabalin).

PREMALIGNANT AND MALIGNANT LESIONS

Squamous Intraepithelial Neoplasia (Vulvar, Penile, Anal)

Synonyms: ■ Bowenoid papulosis ■ Bowen disease (squamous cell carcinoma *in situ*) ■ Erythroplasia of Queyrat

Key features

- High-grade squamous intraepithelial lesion (HSIL) of the vulva, previously known as usual type or undifferentiated vulvar intraepithelial neoplasia (uVIN), and most cases of PeIN (penile intraepithelial neoplasia), and AIN (anal intraepithelial neoplasia) are associated with human papillomaviruses
- Lichen sclerosus and lichen planus are predisposing factors for differentiated type VIN (dVIN)
- Despite treatment there is a high recurrence rate

Introduction

The term "squamous intraepithelial neoplasia" defines an intraepithelial change within anogenital epithelium that is premalignant. There have been several iterations of nomenclature but no universal agreement exists amongst all medical specialties. The International Society for the Study of Vulvovaginal Disease (ISSVD) divides vulvar squamous intraepithelial lesions (SIL) into: (1) high-grade squamous intraepithelial lesion (HSIL) – formerly referred to as usual type or undifferentiated vulvar intraepithelial neoplasia (uVIN); and (2) differentiated VIN (dVIN)[25]. The term for squamous intraepithelial neoplasia in men is penile intraepithelial neoplasia (PeIN), and for anal disease, anal intraepithelial neoplasia (AIN).

It is now recommended that the terms Bowen disease, erythroplasia of Queyrat, and Bowenoid papulosis not be used for lesions in the anogenital area. However, dermatologists still recognize a distinct clinical variant, Bowenoid papulosis, characterized by discrete papules in a younger age group and a tendency for spontaneous regression. Additionally, some authorities believe that erythroplasia of Queyrat and Bowen disease remain useful terms in men.

Epidemiology

It may occur at any age, but the incidence in young women is rising. Early evidence suggests that rates of HSIL may be falling in HPV-vaccinated populations.

Pathogenesis

Oncogenic human papillomaviruses, chiefly HPV types 16 and 18, are implicated in most cases of squamous intraepithelial neoplasia, especially HSIL, PeIN, and AIN. There is also an association with smoking and immunosuppression, including HIV infection. Lichen sclerosus and lichen planus are predisposing factors for dVIN.

Pathology

Intraepithelial neoplasia is characterized by nuclear hyperchromasia, disordered maturation of keratinocytes, and coarse nuclear chromatin. Multiple mitotic figures are usually visible above the basal layer.

Clinical features

The clinical presentation is varied. Erythematous well-demarcated plaques that look similar to plaques of Bowen disease in extragenital sites may occur on the vulva or the keratinized epithelium of the penis in men. Alternatively, warty white plaques, erosions, or hyperpigmented patches may be seen. Shiny erythematous plaques may occur on the glans and prepuce of the uncircumcised male (erythroplasia of Queyrat; Fig. 73.12). In patients with Bowenoid papulosis-type lesions, distinct red–brown papules are seen on the genitalia (Fig. 73.13A), which may extend to the inner thighs (Fig. 73.13B). Differentiated VIN usually presents as small ulcers or keratotic plaques.

Differential diagnosis

Intraepithelial neoplasia must be distinguished from inflammatory conditions such as lichen sclerosus, as well as condyloma acuminatum, Zoon balanitis/vulvitis, and cutaneous malignancies, in particular early invasive SCC.

Treatment

Treatment options depend on the site, the extent of disease, the age of the patient, and the type of intraepithelial neoplasia, but recurrence is a problem with all treatment modalities. In localized disease, a biopsy to establish the diagnosis, followed by local excision, is preferred, so long as the surgery is not too mutilating. In uncircumcised men, circumcision may reduce the risk of progression to invasion. Observation may be an option in selected cases if treatment is not feasible; however, if progression is observed, then surgical excision is necessary. Differentiated VIN associated with lichen sclerosus or lichen planus has a high risk of progression to invasive disease and must be excised. Cryosurgery is rarely indicated in the opinion of the author, as recurrence rates are very high; laser therapy also has a high recurrence rate. Topical imiquimod or fluorouracil may be helpful in some cases, especially when the disease is multifocal, although local side effects may limit their use. In some, but not all, patients, imiquimod

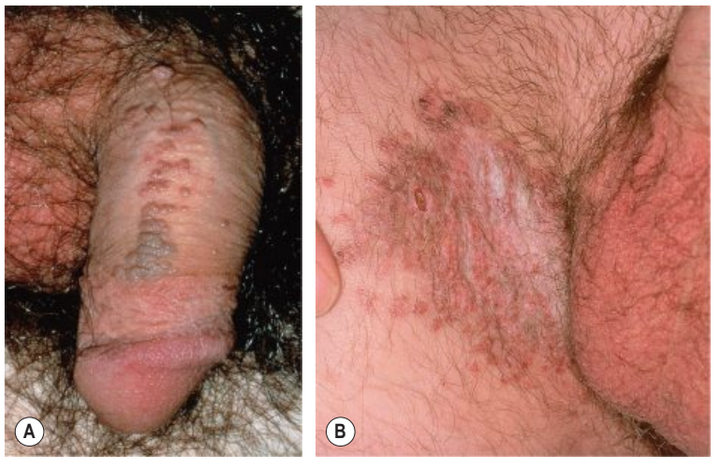

Fig. 73.13 Bowenoid papulosis variant of intraepithelial neoplasia. A Multiple red–brown to brown papules on the shaft of the penis. **B** Coalescence of red–brown to brown papules on the upper inner thigh. *B, Courtesy Robert Hartman, MD.*

can lead to histologic regression of disease and viral clearance[26,27]. In widespread disease, simple vulvectomy has been performed, but only after exhaustion of all other options.

Long-term evaluation is recommended and should include serial examinations and cervical and anal cytology, especially in the setting of HIV infection. Examination of sexual partners is advised.

Prevention

Vaccines are available to prevent infection with high-risk HPV subtypes (see Ch. 79). They are 97% effective in a population naive to these viruses at the time of the first vaccination. Cessation of cigarette smoking should be advised as this is a known risk factor for recurrence.

Pseudoepitheliomatous Keratotic and Micaceous Balanitis

This is a rare condition that occurs in elderly circumcised men[28]. Thick keratotic plaques develop on the glans penis. This condition may progress to verrucous carcinoma or SCC.

Invasive Squamous Cell Carcinomas

Key features

- Most common malignant tumor in the anogenital region
- Etiology is different from SCCs arising in actinically damaged skin

Epidemiology

Squamous cell carcinoma most frequently occurs in the elderly, although it may occur in young adults (see Ch. 108). The incidence of genital SCC in women is rising.

Pathogenesis

HPV infection and lichen sclerosus account for the majority of SCC of the anogenital region. HPV-associated tumors tend to arise in younger adults, while lichen sclerosus-related tumors occur in postmenopausal women and older men. Smoking and immunosuppression are also risk factors. SCC is very rare in circumcised men; the presence of a foreskin, which can lead to trapping of smegma and low-grade inflammation, may predispose to the development of carcinoma. SCC of the genital region is rarely due to cumulative UV light exposure, although there have been reports of SCC of the penis and scrotum in men who had received multiple PUVA treatments. Tar, chimney soot, asbestos, and petroleum products are known carcinogens in the case of scrotal SCC.

Clinical features

In men, the majority of lesions present as ulcers or plaques on the glans, the coronal sulcus, or the prepuce (Fig. 73.14). Ulcers often have a heaped-up edge. In the uncircumcised man, delay in diagnosis may occur because of associated phimosis masking the tumor. Although any area on the vulva may be involved, the labia are the most frequent sites. The clinical presentation varies from non-healing ulcers or fissures to nodules and plaques. Invasive anal carcinoma may arise from the anal margin or from within the lower anal canal.

Differential diagnosis

SCC must be distinguished from other tumors such as amelanotic melanoma or basal cell carcinoma. It is important to biopsy any suspicious lesion that develops in the anogenital region.

Treatment

Treatment is usually surgical, with the extent of surgery dependent on both the size and depth of invasion[29]. Microinvasive tumors (≤1 mm invasion and a maximum diameter of 2 cm) are removed via wide local excision. Sentinel lymph node biopsy is sometimes performed in patients with earlier stage SCC. For more advanced disease, inguinofemoral lymphadenectomy may be recommended. If the SCC arises within a background of lichen sclerosus, it is important to continue maintenance therapy with topical corticosteroids as this appears to reduce the recurrence rate of SCC[30].

Fig. 73.14 Invasive squamous cell carcinoma of the foreskin. This patient with psoriasis had received PUVA therapy without genital protection.

Anogenital Melanoma

Key features

- Rare tumor not related to UV exposure
- Delayed diagnosis is common resulting in greater depth of invasion
- Mucosal lentiginous melanoma is the most common histologic type
- Associated with a poor prognosis

Introduction

Although anogenital melanoma is a rare tumor, melanoma is the second most common primary malignant tumor of the vulva in women.

Epidemiology

Female genital tract melanomas account for <3% of melanomas diagnosed in women but ~20% of all mucosal melanomas[31]. Vulvar melanomas outnumber vaginal melanomas. Compared with cutaneous melanomas, vulvar and penile melanomas occur in an older population, typically in the seventh decade, although they may appear at any age. While the incidence of cutaneous melanoma is increasing, the incidence of urogenital tract melanoma in women is stable.

Pathogenesis

Melanoma is a multifactorial disease, but two of the major risk factors – sun exposure and melanocytic nevi – play a minimal (nevi) or no known (UV) role in anogenital melanoma. Current evidence suggests that the behavior of vulvar melanoma is similar to that of cutaneous melanoma and thus should be staged and initially managed in a similar manner. However, comparative genomic hybridization has shown a greater frequency of *KIT* mutations and fewer *BRAF* mutations in mucosal melanomas as compared to cutaneous melanomas (see Ch. 113)[32], and this does impact the choice of targeted therapy for metastatic disease. Tumor molecular profiling also includes other genes that have been detected in vulvovaginal melanomas (e.g. *NRAS*, *TP53*). Of note, 15% of patients with vulvar melanoma report a family history of cutaneous melanoma.

Clinical features

In women, melanomas may present with bleeding, pruritus, or a nodule. Amelanotic melanomas account for up to 10% of vulvovaginal melanomas. Tumors can arise throughout the genital tract, including the cervix and the vagina, as well as any site on the vulva. The labia minora, followed by the labia majora/clitoris, are the most common tumor sites. In men, a crusted nodule is the most frequent presentation, with most melanomas arising on the glans penis, although they may occur at any site, including the scrotum[33].

Because anogenital melanomas are often diagnosed at a more advanced stage, overall prognosis is significantly worse when compared

to more common cutaneous melanomas. Reported 5-year survival rates have varied from 5% to 25% for vulvovaginal melanomas, 10% for penile melanomas[31], and 5%–35% for anorectal melanomas[34]. Greater depth of invasion at the time of diagnosis may be due to a less noticeable location or the rich vascular and lymphatic network of the urogenital tract. Although these factors contribute to early spread and development of metastases, it remains to be determined whether anogenital melanomas are fundamentally more aggressive.

Pathology

On genital skin, mucosal lentiginous melanoma is the most frequent histologic type of melanoma. Nodular and superficial spreading melanomas occur less frequently. Mucosal lentiginous melanomas share some histologic features with cutaneous lentigo maligna melanomas. As with cutaneous melanoma, prognosis is determined by tumor thickness at presentation.

Differential diagnosis

For macular lesions, the major differential is mucosal melanosis. Palpable pigmented melanomas must be distinguished from atypical-appearing seborrheic keratoses, melanocytic nevi, or Bowenoid papulosis. Melanocytic nevi superimposed on lichen sclerosus may have an atypical clinical appearance and histopathologic features of a persistent nevus. Anorectal melanoma may initially be misdiagnosed as a hemorrhoid or adenomatous polyp.

Treatment

Due to the rarity of the tumor, there have been no randomized therapeutic trials. Vulvar and penile melanomas are staged and treated similarly to cutaneous melanoma. Surgical resection is the treatment of choice. Based upon recent consensus guidelines, the goal of surgical management of anogenital melanomas is to achieve microscopically clear (>1 mm) margins in the least radical fashion[34]. Lymphadenectomy is limited to clinically evident metastatic regional nodal disease, with sentinel lymph node biopsy recommended if it directs adjuvant treatment or clinical trial entry. Approximately one-third of patients have nodal disease at the time of presentation.

Immunotherapy (e.g. anti-CTLA-4 antibodies, anti-PD-1/PD-L1 antibodies) may improve survival rates and, depending upon the presence of specific mutations, targeted KIT or selective BRAF inhibitors may also be considered. Palliative radiotherapy has been tried for extensive local disease and can be considered in conjunction with immunotherapy.

Basal Cell Carcinoma

Basal cell carcinoma may occur in the anogenital area and is usually diagnosed clinically as SCC prior to biopsy or excision. Rarely, it has been reported to metastasize.

Genital Lymphoma

The anogenital region is a rare site of involvement for lymphoma. Several different types of lymphoma have been reported, including diffuse large B cell and other non-Hodgkin lymphomas. The usual presentation is that of a solid non-tender nodule. Plaques and tumors of mycosis fungoides (MF) can also be seen in this location, but MF *restricted* to the anogenital region should be seriously questioned and alternative diagnoses (e.g. pseudolymphomatous lichen sclerosus) considered.

Extramammary Paget Disease

Key features

- Rare intraepithelial adenocarcinoma
- May be primary (80%–90% of patients) or secondary to an underlying malignancy (10%–20% of patients)

Introduction

Extramammary Paget disease (EMPD) is a rare intraepithelial adenocarcinoma that develops primarily in apocrine-rich sites, with the vast majority arising in the anogenital region. Rarely EMPD occurs in the axillae or locations such as the eyelid, umbilicus, or external auditory canal. EMPD can either be *primary* (of cutaneous origin) or *secondary* (of non-cutaneous origin); the latter represents intraepithelial spread of neoplastic cells from an underlying internal malignancy. EMPD may become invasive and spread via the lymphatic system.

Epidemiology

Elderly White women most commonly develop this malignancy, but in Japan there is a male predominance.

Etiology and classification

The histogenesis of primary cutaneous EMPD has been long debated but appears in some patients to be of apocrine origin. Recurrent mutations in chromatin remodeling genes have recently been identified in both EMPD and mammary PD[35], along with the importance of the Msi1–mTOR pathway. Primary (type 1) EMPD can be divided into three subtypes: 1a – non-invasive; 1b – invasive; and 1c – associated with pagetoid spread from an underlying adnexal carcinoma. Secondary EMPD consists of either epidermotropic metastases or direct extension of a gastrointestinal tract (type 2) or urothelial tract (type 3) malignancy.

Clinical features

The vulva in women and the perianal region in men are the most commonly affected sites[36]. There may be associated pruritus or burning or the lesions may be asymptomatic. A slowly expanding, asymmetric erythematous plaque is typical, with a sharp demarcation between normal and involved skin (Fig. 73.15A–C). Scattered areas of white scale and erosion can give rise to a "strawberries and cream" appearance. Occasionally, lesions are pigmented.

Pathology

The diagnosis must be confirmed by histologic examination. Vacuolated pagetoid cells in the epidermis are distinctive (Fig. 73.15D), but immunohistochemical staining is necessary to exclude pagetoid melanoma and pagetoid Bowen disease, as well as to help differentiate between primary and secondary EMPD (Fig. 73.16)[37]. The diagnosis of primary EMPD requires a search for an underlying cutaneous adnexal carcinoma.

Differential diagnosis

EMPD is most often clinically misdiagnosed as psoriasis or dermatitis, leading to a delay in diagnosis. Histopathologically, the differential diagnosis consists primarily of melanoma and Bowen disease, but may include pagetoid dyskeratosis, clear cell papulosis, and Langerhans cell histiocytosis.

Evaluation

A thorough review of systems and complete physical examination, including lymph nodes, should be performed. Because the initial site of EMPD often correlates with the type of underlying malignancy, screening studies include the following: (1) perianal EMPD – upper and lower endoscopy +/– CT scan, cystoscopy, urine cytology, prostate-specific antigen (PSA, in men); (2) penoscrotal EMPD – colonoscopy, cystoscopy, PSA; and (3) vulvar EMPD – pelvic examination, Pap smear, colposcopy, cystoscopy, abdominal/pelvic CT scan. In women, breast examination and mammography are also recommended. Serum carcinoembryonic antigen (CEA) levels can be measured to monitor tumor status. Of note, the value of routine screening for primary intraepithelial (type 1a) EMPD has recently been questioned[38].

Treatment

It is important to distinguish between primary and secondary EMPD, and when possible determine if the malignancy is invasive (see Fig. 73.16). For localized disease in the anogenital region, wide local excision is usually performed. However, because of the multifocal nature of EMPD and the presence of clinically inapparent extension of disease, recurrences are very common. Mohs micrographic surgery often represents a preferred surgical option[37]. Additional treatment options include topical imiquimod, topical 5-fluorouracil, topical rapamycin, radiotherapy, photodynamic therapy, and CO_2 laser ablation, with

Fig. 73.15 Extramammary Paget disease. A Erythematous plaque with hydrated scale at the base of the scrotum. **B** Well-demarcated perianal plaque with both erosions and scale, giving rise to a "strawberries and cream" appearance. **C** Extensive, well-demarcated disease of the vulva with multiple foci of hydrated white scale. **D** Photomicrograph demonstrating pagetoid cells within the epidermis, both as single cells and in nests. *B, Courtesy Kalman Watsky, MD; D, Courtesy Lorenzo Cerroni, MD.*

combination therapy often employed. Long-term follow-up is recommended because invasive disease can occur.

DYSESTHETIC GENITAL PAIN SYNDROMES

The term "dysesthetic genital pain syndrome" encompasses a number of disorders in which the clinical appearance is normal despite the patient's experience of severe disabling pain (Fig. 73.17). Because these diagnoses require the absence of a clinically identifiable neurologic disorder (e.g. a radiculopathy), a neurologic examination is a prerequisite. Unmedullated C fibers transmit pain and touch, and it is now recognized that these nerve fibers can be remodeled after a stimulus has passed, explaining why perception of subsequent stimuli may be altered. Relatively minor inflammation or trauma, often unrecalled, may precipitate the onset of pain. The ISSVD has published a classification scheme for vulvar pain (Table 73.3)[39]. Of note, these pain disorders often have a profound effect on a patient's well-being and sexual functioning.

General Principles of Management

Simple measures, self-help, and patient education often lead to improvement. For more severe or long-standing symptoms, a multidisciplinary approach that includes physiotherapists, pain management specialists, psychologists, and psychosexual counselors is often required. The key interventions are patient education, pain modification (via local anesthetics, amitriptyline, gabapentinoids), physical therapy to address hypertonic pelvic floor muscles that can exacerbate pain, and psychological and psychosexual support[40].

Localized Vulvodynia (Vestibulodynia)

Key features

- Superficial dyspareunia
- Tenderness on localized pressure within the vulvar vestibule
- Occurs in young, sexually active women

Introduction

"Localized vulvodynia" is now the preferred term for this specific subtype of the vulvar pain syndrome, characterized by superficial dyspareunia and point tenderness within the vestibule, often at 5 and 7 o'clock.

Clinical features

This particular localized pain syndrome occurs in the young, premenopausal, sexually active woman whose main complaint is one of dyspareunia on penetration. Insertion of tampons may be impossible. The vulva looks entirely normal but there is pain when the vestibular area is pressed by a cotton-tipped applicator.

Differential diagnosis

Localized vulvodynia must be differentiated from other causes of vulvar pain (see Table 73.3). Hymenal and posterior vestibule fissures and herpes simplex viral infection must be excluded. Fungal culture should be obtained to eliminate *Candida* infection, and digital examination of the vagina is performed to exclude vaginismus. Sometimes these disorders can coexist.

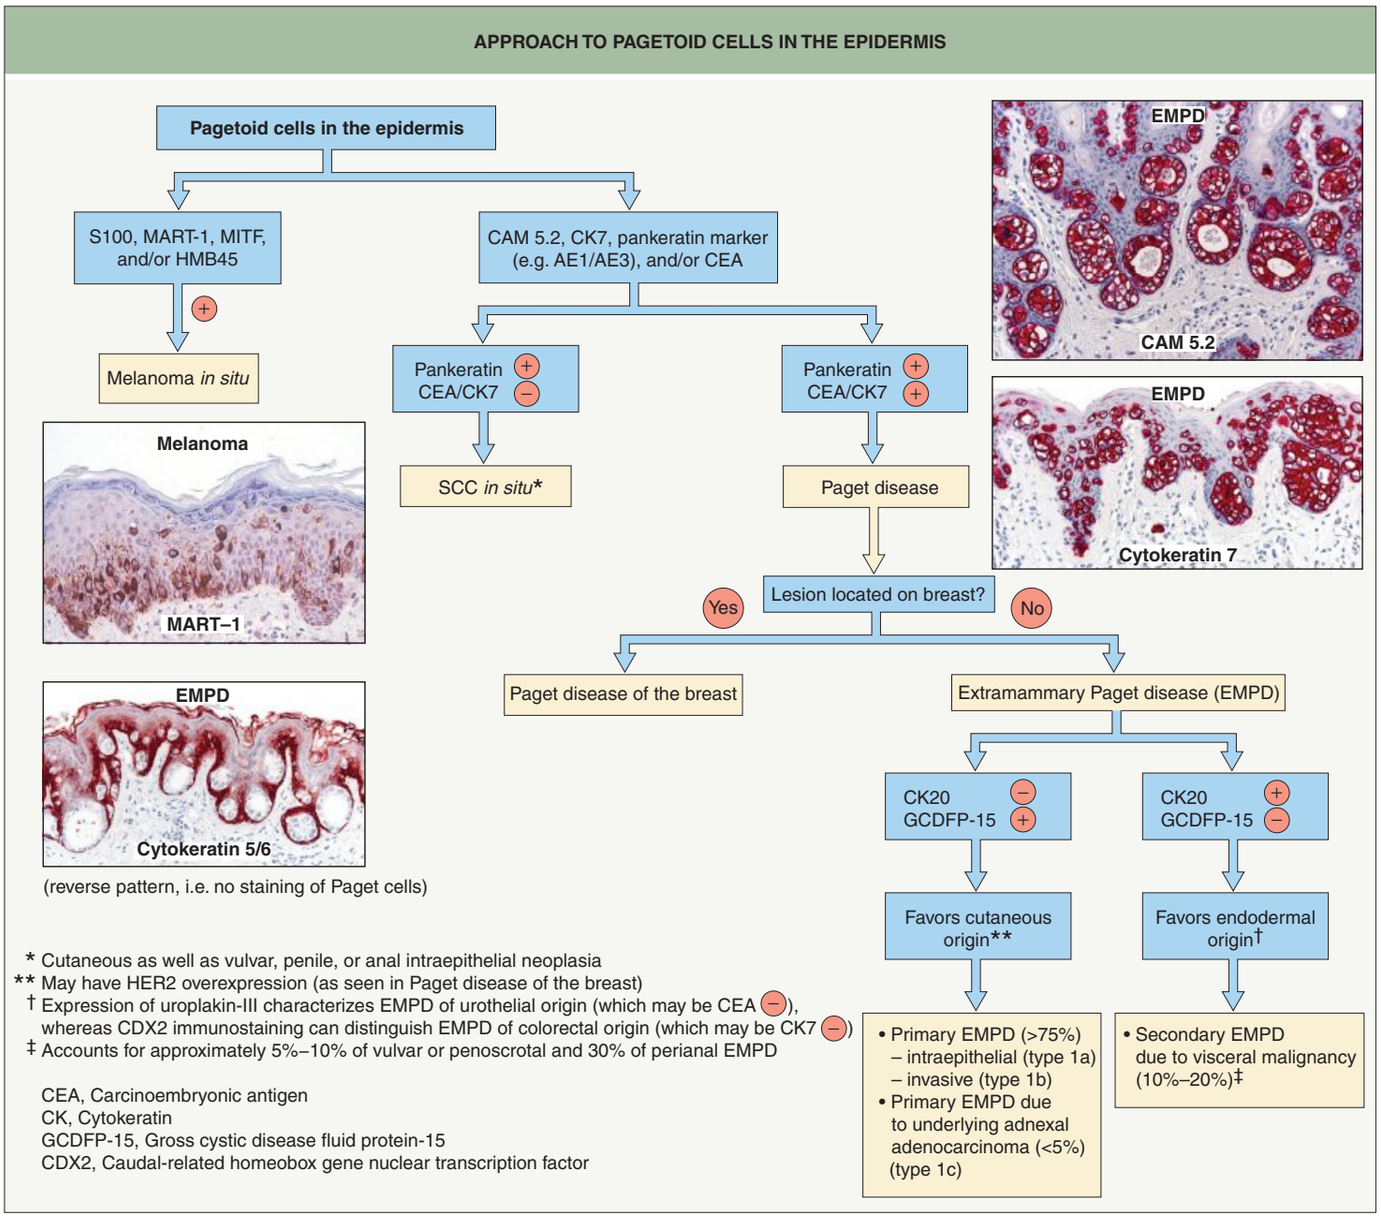

Fig. 73.16 Algorithm for the approach to pagetoid cells in the epidermis. The CAM 5.2 immunohistochemical stain is positive in >95% of Paget disease (mammary and extramammary) and approximately one-third of Bowen disease; it stains low-molecular-weight keratins. AE1 stains most subfamily A keratins (but not 12, 17, and 18) while AE3 stains subfamily B keratins. The differential diagnosis also includes pagetoid dyskeratosis (e.g. of the hand), Zuska disease, and clear cell papulosis.

Treatment

Topical local anesthetic agents (e.g. 5% lidocaine) applied before intercourse may be beneficial. Pelvic floor exercises, vaginal dilator training, and pelvic floor electromyography with biofeedback may prove useful. For a small number of women, surgery (e.g. modified vestibulectomy) might be helpful, but the role of surgery remains controversial[41].

Generalized Vulvodynia/Scrotodynia (Dysesthetic Vulvodynia/Scrotodynia)

Key features

- Burning and/or pain
- Clinical examination of vulva or scrotum is normal

Introduction

Persistent burning pain is characteristic and patients have often consulted many doctors before the correct diagnosis is made. Depression may be a feature of any chronic pain syndrome.

Scrotodynia is probably analogous to vulvodynia; however, there is less published on the subject[42]. Precipitating events include sexual activity, exercise, friction, and heat. Pain may also affect the penis.

Clinical features

Pain, often accompanied by a burning sensation, is felt over the entire vulva, scrotum, or penis, and it may extend down the thighs. The genital area may hurt even when nothing is touching it. Often, symptoms are worse on sitting or walking up stairs. Wearing of underwear may be impossible. On inspection, the scrotum or vulva looks entirely normal.

Differential diagnosis

Other causes of genital pain, e.g. infection (bacterial, viral, or fungal), lichen sclerosus, or lichen planus, must be excluded by examination before the diagnosis can be made. A potassium hydroxide (KOH) preparation and/or fungal culture to exclude candidiasis is essential. It is important to test for dermographism, as treatment with antihistamines may greatly benefit these patients.

Treatment

Treatment strategies are very similar to those for localized vulvodynia or scrotodynia (see above)[40]. Treatment with pain-modifying medications,

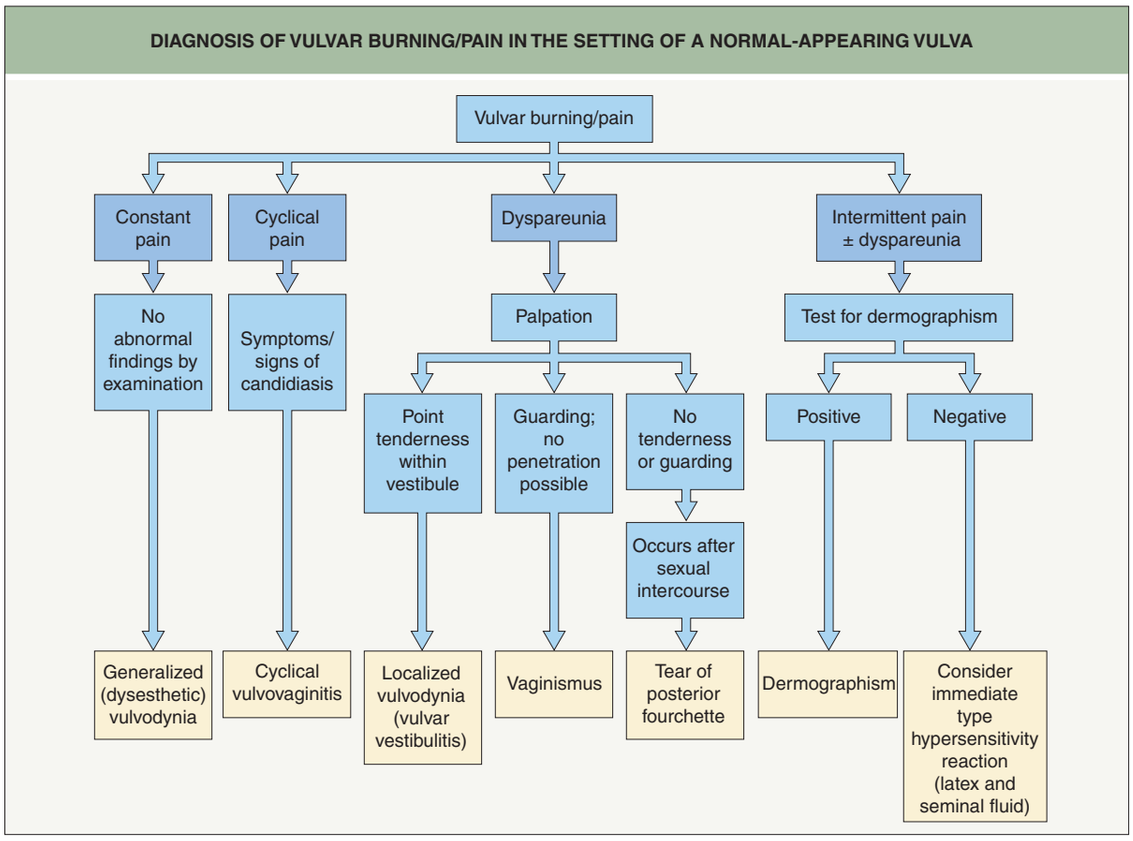

Fig. 73.17 Diagnosis of vulvar burning/pain in the setting of a normal-appearing vulva.

ISSVD TERMINOLOGY AND CLASSIFICATION OF PERSISTENT VULVAR PAIN
Vulvar pain caused by a specific disorder*
• Infectious (e.g. candidiasis, HSV infection) • Inflammatory (e.g. lichen planus, lichen sclerosus, immunobullous disorders) • Neoplastic (e.g. Paget disease, squamous cell carcinoma) • Neurologic (e.g. post-herpetic neuralgia, spinal nerve compression, neuroma) • Iatrogenic (e.g. postoperative, post-chemotherapy, post-radiation) • Trauma (e.g. cutting, obstetrical) • Hormonal deficiencies (e.g. genitourinary syndrome of menopause [vulvovaginal atrophy], lactational amenorrhea)
Vulvodynia†
Descriptors
• Localized (e.g. vestibulodynia, clitorodynia, hemivulvodynia) *or* generalized *or* mixed (localized and generalized) • Provoked (e.g. insertional, contact) *or* spontaneous *or* mixed (provoked and spontaneous) • Onset (primary or secondary) • Temporal pattern (intermittent, persistent, constant, immediate, delayed)
*Women may have both a specific disorder (e.g. lichen sclerosus) and vulvodynia. †Vulvar pain of more than 3 months' duration without clear identifiable cause; may have potential associated factors.

Table 73.3 International Society for the Study of Vulvovaginal Disease (ISSVD) terminology and classification of persistent vulvar pain (2015).

BENIGN LESIONS OF THE GENITALIA	
Common	
• Angiokeratomas • Bartholin cysts • Epidermoid cysts, milia • Fordyce spots • Melanocytic nevi	• Mucosal melanosis • Pearly penile papules • Urethral caruncle • Vestibular papillomatosis
Less common	
• Endometriosis • Fox–Fordyce disease • Hidradenoma papilliferum • Idiopathic calcinosis of the scrotum	• Papular acantholytic dyskeratosis* • Perineal pyramidal protrusion • Steatocystomas • Syringomas
*Somatic mutations in *ATP2A2* and *ATP2C1* detected.	

Table 73.4 Benign lesions of the genitalia. Papules can also be due to infections, e.g. mollusca contagiosa and condylomata acuminata. If a firm penile lesion is linear, consider sclerosing lymphangitis.

e.g. amitriptyline, gabapentin, is most likely to be beneficial in this disorder. Despite a variety of treatments, there remains a group that fails to respond.

Anal Pain

Anal pain may occur in both men and women and it shares many features with vulvodynia and scrotodynia. Associated depression is frequent.

BENIGN LESIONS

A wide variety of benign lesions can be found in the anogenital area (Table 73.4). Some of the more important lesions are discussed below.

Epidermoid Cysts

Epidermoid cysts are frequently encountered on the glabrous labia majora and scrotum, and may be multiple. They are yellow, vary in size, and may become inflamed. Treatment is by excision, but this is only necessary if the cyst is symptomatic.

Vestibular Papillomatosis

Papillomas within the vestibule are found in ~45% of premenopausal women and 10% of postmenopausal women. They are pink, asymptomatic, fine projections. Women should be reassured that the finding is normal.

SYSTEMIC DISEASES THAT MAY PRESENT IN THE ANOGENITAL REGION	
Systemic disease	**Clinical findings in the anogenital region**
Behçet disease	Recurrent aphthous ulcers (see text and Ch. 26)
Crohn disease	Recurrent abscesses, sinuses, and fistulas; linear (knife-cut) fissures; firm swelling of the labia or scrotum; firm anal "skin tags" (see Ch. 93)
Graft-versus-host disease	Fissures, erosions, ulcerations Can resemble anogenital lichen sclerosus or lichen planus Men: balanitis, phimosis Women: labial fusion, vaginal scarring with stenosis
Langerhans cell histiocytosis	Multiple red–brown papules and nodules, extending to thighs (usually children) Intertrigo-like erythema of the inguinal creases that may become erosive (see Ch. 91)
Neutrophilic dermatoses (e.g. Sweet syndrome)	Red to purple papules and nodules in association with fever
Zinc deficiency • Inherited • Acquired	Periorificial erythema, erosions, and crusting (see Ch. 51) Superimposed candidal infections

Table 73.5 Systemic diseases that may present in the anogenital region.

THE ANOGENITAL REGION AND SYSTEMIC DISEASE

There are a number of systemic disorders that may initially present in the anogenital region (Table 73.5). For example, Behçet disease is a rare multisystem inflammatory disorder in which recurrent oral aphthae are often accompanied by genital erosions or ulcers, in addition to arthritis, uveitis, neurologic disorders such as cranial nerve palsies and mono- and hemiparesis, arterial and venous thromboses, and pathergy (see Ch. 26). The disease is more prevalent in individuals from the Mediterranean basin, Japan, and Korea; it typically presents in young adults in their third or fourth decade of life. Recurrent flares and remissions are to be expected. Treatment options are outlined in Table 26.15.

INFECTIONS

Sexually transmitted infections (see Chs. 78 & 82) and condylomata acuminata (see Ch. 79) are described elsewhere, but miscellaneous infections that favor the anogenital region are discussed below.

Perianal Streptococcal Disease

The typical presentation is that of a 3- or 4-year-old boy with erythema and sometimes crusting of the perianal area[43] (see Ch. 74). Constipation is frequent because of discomfort. Similar findings may extend from the vaginal introitus onto the vulva in girls and less often around the urethral meatus in boys. The disease can be associated with guttate psoriasis and is frequently misdiagnosed as irritant dermatitis or candidiasis. Specimens for bacterial culture must be obtained. Group A β-hemolytic streptococci are responsible. Treatment is with oral penicillin, amoxicillin, or a first-generation cephalosporin.

Recurrent Toxin-Mediated Perineal Erythema

Recurrent toxin-mediated perineal erythema is an unusual condition that presents 2–3 days after a throat infection as a fine diffuse macular erythema of the perineal region[44]. Marked local edema may be present and the hands may be similarly affected. Desquamation follows the erythema and the condition can be recurrent. Streptococcal or staphylococcal pharyngitis is the most common cause and the erythema is toxin-mediated. Long-term prophylactic penicillin may be beneficial in some patients.

Kawasaki Disease

Kawasaki disease may be triggered by bacterial toxins or viral antigens, but the exact cause has not been elucidated. It is a disease of children. In up to two-thirds of cases, perineal erythema may be a presenting feature (see Ch. 81); additional findings include strawberry tongue, fissured lips, fever, and lymphadenopathy, followed by desquamation of the hands and feet. Coronary artery aneurysms may be life-threatening. Treatment is with aspirin and IVIg. Perineal erythema has also been observed in multisystem inflammatory syndrome in children (MIS-C) due to SARS-CoV-2 infection.

Fournier Gangrene

Fournier gangrene is a severe necrotizing infection of the external genitalia, perineum, or perianal area that occurs in patients with an underlying predisposition such as diabetes or immunosuppression[45] or who are receiving SGLT2 inhibitors. The infection is polymicrobial. Extensive surgical debridement with prolonged systemic antibiotics is necessary.

Erythrasma

Erythrasma is characterized by pigmented patches or thin plaques with fine scale that tend to occur in flexural areas, including the groin. Coral pink fluorescence under Wood's lamp examination is diagnostic. Distinction from dermatophytosis is usually possible clinically, as scaling is diffuse in erythrasma and there is no tendency toward central clearing.

Dermatophytosis

Chronic, slowly advancing, scaly erythematous lesions may be seen in the groin (tinea cruris) or the medial buttocks in addition to the upper thighs. Central clearing is often present and pustules may be seen; there is usually (if not always) concomitant tinea pedis and/or unguium. The diagnosis is made by microscopy and culture of skin scrapings.

Genital Candidiasis

Key features

- *Candida* spp. are normal commensals
- *Candida albicans* is responsible for 80%–90% of infections
- Underlying factors must be sought, e.g. diabetes, corticosteroids, systemic antibiotics
- In female patients usually seen during the reproductive years; occurs in infants but is uncommon in children or after menopause unless a risk factor is present

Introduction

It is important to confirm the infection by microscopy (KOH preparation) and culture because many genital skin problems in men and women are erroneously attributed to candidiasis.

Epidemiology

Candida spp. are normal commensals of the mucosal surfaces of the gastrointestinal and female genital tracts and may be found in small numbers in moist areas of skin[46]. There are at least 20 *Candida* spp. that can cause infections but evidence regarding their pathogenicity is conflicting. Resistance to imidazoles is an emerging problem.

Etiology

Candidiasis is more commonly seen in diabetics, especially when glycemic control is poor, and the immunosuppressed, as well as during treatment with systemic corticosteroids or broad-spectrum antibiotics. Candidiasis can be sexually transmitted and this is probably most important in recurrent infections. Polymorphisms in the mannose-binding lectin 2 gene (*MBL2*) have been implicated in some cases of severe recurrent candidiasis[47].

Clinical features

In men, balanitis, balanoposthitis, or rarely, widespread involvement of the perianal area, perineum, and groin is seen (see Ch. 77). Balanitis is more common in the uncircumcised man. The skin is erythematous and glazed with yellow pustules and erosions. In severe infections, edema may prevent retraction of the foreskin.

Women with candidiasis complain of pruritus and non-offensive vaginal discharge. Creamy white curds are visible on the vaginal walls, and there is vulvar erythema and sometimes fissuring. In severe cases swelling and pustules may be seen.

In both sexes, candidiasis may affect the perianal area with sheet-like erythema and fissuring. The inguinal–scrotal fold in men is a frequent site of involvement, and here, in addition to the erythema, the skin focally may appear white due to maceration of the accompanying scale. Satellite lesions, including pustules, are often seen.

In babies, candidiasis is a common cause of diaper dermatitis. There may be rapid spread of erythema and pustules that typically affect the skin creases, unlike the more common irritant dermatitis. Rarely, a nodular ulcerated variant may occur.

Differential diagnosis

Many inflammatory conditions of the genitalia are treated initially as a "yeast" infection. The presence of pseudohyphae alone is not sufficient to make the diagnosis; the appropriate clinical signs must also be present. Subcorneal pustules and erosions are also seen in impetigo, but this is excluded by a bacterial culture. In women, other causes of a vaginal discharge, including bacterial vaginosis, *Trichomonas* infection and desquamative inflammatory vaginitis, need to be considered. Some cases are mistakenly diagnosed as vulvar eczema.

Treatment

Topical polyene or imidazole antifungals may suffice in localized balanitis or intertrigo (see Ch. 127). The addition of a mild topical corticosteroid may help ameliorate symptoms. For vulvovaginal candidiasis, intravaginal imidazoles and single-dose oral fluconazole 150 mg are equally effective; in severe acute infections or in complicated infections (e.g. associated diabetes, immunocompromised state), these therapies should be repeated after 3 days. For non-*C. albicans* infections, nystatin pessaries or boric acid suppositories are recommended. Sexual partners only need treatment if they are symptomatic. An essential intervention is rectifying underlying causes such as uncontrolled diabetes.

Recurrent Candidiasis

Recurrent candidiasis is defined as more than four episodes of candidiasis per year. Precipitating factors must be identified, including hormone replacement therapy. Advice should be given on foreskin hygiene and keeping the perineal area cool with cotton underwear. In women, premenstrual exacerbations are typical. Possible regimens include oral fluconazole 150 mg weekly for 6 months or clotrimazole 500 mg vaginal tablet weekly for 6 months.

Schistosomiasis

Granulomatous lesions of the genitalia are primarily a manifestation of *Schistosoma haematobium* infection. Men may present with epididymitis, dysuria, or prostatitis and women with dyspareunia, dysmenorrhea, or contact bleeding.

EROSIVE GENITAL DISEASE

Erosions and ulcerations are seen in a wide variety of conditions (Table 73.6). Genital aphthae and HSV infections are common. Erosions may occur after scratching or rubbing or as a result of blister formation. To determine the cause of the erosions, it is essential to take a careful history and perform a full examination of the skin, including other mucosal surfaces. For example, a white lacy pattern on the buccal mucosa may suggest a diagnosis of lichen planus. Further investigations will be determined by the clinical appearance, but swabs for bacterial and fungal culture are often necessary. Biopsies of lesional skin for light microscopy and perilesional skin for direct immunofluorescence are indicated if an autoimmune blistering disorder is suspected.

CAUSES OF GENITAL EROSIONS AND ULCERATIONS
Lichen sclerosus
Erosive lichen planus
Genital aphthae/aphthosis*
Infection • Candidiasis • Herpes simplex or herpes zoster • Impetigo (*Staphylococcus*/*Streptococcus*) • Primary syphilis, chancroid • Epstein–Barr virus (EBV)†,‡, cytomegalovirus†, *Mycoplasma pneumoniae*†,¶ • Tuberculosis
Intraepithelial neoplasia
Squamous cell carcinoma and other malignancies
Trauma
Zoon balanitis/vulvitis
Acquired bullous diseases (see Table 73.7)
Drug reactions • Fixed drug eruption • Stevens–Johnson syndrome • Toxic erythema of chemotherapy • Other (e.g. penile/foscarnet, scrotal/multi-kinase inhibitors)
Inherited bullous diseases • Hailey–Hailey disease • Epidermolysis bullosa
Complex aphthosis – Behçet disease, inflammatory bowel disease
Crohn disease
Extramammary Paget disease
Langerhans cell histiocytosis
Pyoderma gangrenosum
Necrolytic migratory erythema, acrodermatitis enteropathica
Papular acantholytic dyskeratosis§
*Includes reactive non-sexually related acute genital ulcers which can be triggered by a variety of viral and bacterial infections. †Cause/trigger of reactive non-sexually related acute genital ulcers. ‡Primary EBV infection diagnosed via EBV IgM antibodies or PCR. ¶Trigger for *Mycoplasma*-induced rash and mucositis (MIRM)/reactive infectious mucocutaneous eruption (RIME). §Papules more common than erosions; it can occur in the setting of Hailey–Hailey disease or be associated with a somatic mutation in *ATP2C1* or *ATP2A2*.

Table 73.6 Causes of genital erosions and ulcerations. Infection-related disorders include erythema multiforme major, *Mycoplasma*-induced rash and mucositis (MIRM), and reactive non-sexually related acute genital ulcers.

Primarily in adolescent girls, reactive non-sexually related acute genital ulcers, sometimes referred to as Lipschutz ulcers, may be seen (Fig. 73.18). These ulcers can be large and deep and are triggered by a variety of viral or bacterial infections, including Epstein–Barr virus, *Mycoplasma*, cytomegalovirus, influenza, and streptococci. However, a cause is not always identified.

Acquired Autoimmune Bullous Diseases

Immunofluorescence (direct and indirect) is an essential investigation in suspected autoimmune bullous diseases as it may be very difficult to distinguish between the different blistering disorders on clinical grounds alone (Table 73.7)[48]. The most common autoimmune bullous diseases seen in the genital region are bullous pemphigoid, including the childhood variant[49], and mucous membrane pemphigoid. Unless blisters are seen or described, anogenital mucous membrane pemphigoid is often indistinguishable from erosive lichen planus; thus, histology and immunofluorescence are essential (Fig. 73.19). The extent and severity of the disease determine the treatment, which usually consists of a combination of topical and systemic anti-inflammatory and immunosuppressive agents. Great symptomatic relief can be gained from the use of potent topical corticosteroids, either as sole treatment in localized disease or as an adjunct to systemic treatment in widespread or more severe disease.

Fig. 73.18 Reactive non-sexually related acute genital ulcers associated with primary EBV infection. Extreme pain with urination required placement of a Foley catheter in this 13-year-old girl. EBV-related genital ulcers are often misdiagnosed as a genital herpes simplex viral infection. *Courtesy Julie V. Schaffer, MD.*

Fig. 73.19 Mucous membrane pemphigoid of the vulva. Ulcerations and scarring of the perianal area and perineum (positive direct immunofluorescence distinguished this from erosive lichen planus).

CLINICAL CHARACTERISTICS OF AUTOIMMUNE BULLOUS DISEASES THAT MAY PRESENT IN THE ANOGENITAL REGION			
Disease	**Age group**	**Clinical features**	**Chapter**
Bullous pemphigoid	Older adults; rare in children	Tense blisters that favor flexural sites, including the vulva in girls No scarring	Ch. 30
Mucous membrane (cicatricial) pemphigoid	Middle-aged and older adults	In the anogenital region, erosions and scarring but rarely blisters Involvement of oral and ocular mucosae	Ch. 30
Linear IgA bullous dermatosis	Children and adults	Trunk and limbs most common sites, but often face and genitalia in children Annular and polycyclic lesions composed of vesiculobullae	Ch. 31
Epidermolysis bullosa acquisita	Adults > children	Mechanobullous form with scarring more common than inflammatory form	Ch. 30
Pemphigus vulgaris	Peak age = 50–60 years	Initially mucosal involvement with primarily painful erosions Fragile cutaneous blisters and erosions may then develop	Ch. 29
Pemphigus vegetans	Peak age = 50–60 years	May have flexural accentuation, including inguinal	Ch. 29
Paraneoplastic pemphigus	Adults ≫ children	Erosive mucosal involvement that is severe & recalcitrant	Ch. 29

Table 73.7 Clinical characteristics of autoimmune bullous diseases that may present in the anogenital region.

Acquired Inflammatory Bullous Diseases

Erythema multiforme and Stevens–Johnson syndrome

Erythema multiforme (EM, primarily the major form) and Stevens–Johnson syndrome (SJS) may present as a bullous eruption in the genital region. In recurrent EM, HSV infection should be sought, remembering that there may be a delay of up to 2 weeks from infection to appearance of the lesions. In recurrent cases, a trial of prophylactic oral anti-HSV therapy may be indicated. Confluent dusky macular lesions point to SJS, in which drugs are the most common etiology. Prominent mucosal involvement also occurs in *Mycoplasma*-induced rash and mucositis (MIRM)/reactive infectious mucocutaneous eruption (RIME); see Ch. 20).

Fixed drug eruption

Recurrent erythematous or eroded plaques may occur on both skin and mucous membranes[50] (see Ch. 21). Often, cutaneous lesions are strikingly round, but this may not hold true in mucous membrane sites. The lesions recur in exactly the same site with each exposure to the drug. Bullous genital lesions frequently present as erosions. Common culprits are acetaminophen (paracetamol), tetracyclines, trimethoprim–sulfamethoxazole, and nonsteroidal anti-inflammatory drugs.

Inherited Bullous Disease

Hailey–Hailey disease

Patients with autosomal dominant Hailey–Hailey disease have recurrent involvement of flexural areas (see Ch. 59). Expanding erythematous plaques with superimposed erosions and sometimes vesicles and pustules are seen. In the inguinal creases, there is a particular tendency to form hypertrophic plaques. Secondary infection with bacteria, fungi, and HSV is a frequent problem and must be excluded in any exacerbation; for recurrent disease, suppressive therapy may be considered. Topical corticosteroids in combination with antifungal/antibacterial agents can ease symptoms. Low-dose naltrexone or CO_2 laser ablation may also prove helpful.

Additional figures and table on the 2015 International Society for the Study of Vulvovaginal Disease (ISSVD) terminology of vulvar squamous intraepithelial lesions, available in our eBook (see inside front cover for access code).

Key features

- Roughly 20% of outpatient dermatology visits are for bacterial skin infections
- Staphylococci and streptococci cause the majority of bacterial skin conditions, which range from common infections (e.g. impetigo) to multisystem disorders (e.g. toxic shock syndrome)
- Methicillin-resistant *Staphylococcus aureus* (MRSA) remains a concern
- Various systemic diseases and immunodeficiency states predispose patients to bacterial skin infections that can be severe and refractory to treatment

THE CUTANEOUS MICROBIOTA

Hundreds of species of bacteria, along with fungi and viruses, collectively form a dynamic ecosystem known as the cutaneous microbiota (flora). The microbiota composition depends on the anatomic location – *Cutibacterium* (formerly *Propionibacterium*) spp. dominate in sebaceous sites, whereas *Staphylococcus* and *Corynebacterium* spp. thrive in moist skin folds (Fig. 74.1)[1,2]. Together these organisms help prevent skin infections by providing competition against pathogenic microbes and hydrolyzing lipids of sebum to produce free fatty acids, which are toxic to many pathogenic bacteria. The ecology of particular areas of the skin is determined by the availability of moisture, presence of sebaceous lipids, and gaseous environment. Disruption of the delicate balance between host and microorganisms can result in skin disorders or infection. The nomenclature of cutaneous bacterial infections reflects the site, depth, and extent of the infection as well as the organism involved.

GRAM-POSITIVE BACTERIA

STAPHYLOCOCCAL AND STREPTOCOCCAL SKIN INFECTIONS

Impetigo

Synonyms: ■ Bullous impetigo: pemphigus neonatorum ■ Impetigo contagiosa ■ Non-bullous impetigo: crusted impetigo ■ Staphylococcal impetigo ■ Streptococcal impetigo

Key features

- *Staphylococcus aureus* and, to a lesser degree, group A β-hemolytic streptococci are the major causes of impetigo
- Represents the most common bacterial skin infection in children
- Nasal carriers of *S. aureus* are at particular risk of developing impetigo
- Treatment decisions should consider resistance patterns of *S. aureus*

Introduction

Impetigo is a common, contagious, superficial skin infection that can present in non-bullous and bullous forms (Fig. 74.2). The most common pathogen in both non-bullous and bullous impetigo is *Staphylococcus aureus*. Group A β-hemolytic streptococcus (*Streptococcus pyogenes*) represents another important cause of non-bullous impetigo. Table 74.1 compares the clinical characteristics and complications of bullous and non-bullous impetigo.

Epidemiology

Impetigo occurs frequently in children, especially those <6 years of age, and it represents the most common bacterial skin infection in this group. Adults most commonly acquire impetigo through contact with infected children. Impetigo is extremely contagious, spreading rapidly via direct person-to-person contact or through fomites. In temperate climates, peak incidence is in the summer months. Predisposing factors include a warm ambient temperature, high humidity, poor hygiene, an atopic diathesis, scabies, skin trauma, and participation in contact sports[3]. Nasal, pharyngeal, axillary, and/or perineal colonization with *S. aureus* increases the risk for developing impetigo and other staphylococcal infections.

Pathogenesis

Non-bullous impetigo is usually caused by *S. aureus* or group A β-hemolytic streptococci. Infection typically occurs at sites of scratching (e.g. insect bites, atopic dermatitis), minor trauma (e.g. an abrasion, laceration, or burn) or other skin infections/infestations (e.g. pediculosis, scabies). Disruption of the skin barrier allows the bacteria to adhere, invade, and establish infection.

Bullous impetigo results from the local production of exfoliative toxins (ETA, ETB) by phage group II *S. aureus* at the site(s) of cutaneous infection; systemic elaboration of the same toxins is the cause of staphylococcal scalded skin syndrome (SSSS; see below). In both diseases, blister formation is mediated by exfoliative toxin binding to the desmosomal protein desmoglein 1 and cleaving its extracellular domain, thus leading to acantholysis within the epidermal granular layer. *S. aureus* can be cultured from fluid within the blisters of bullous impetigo, but

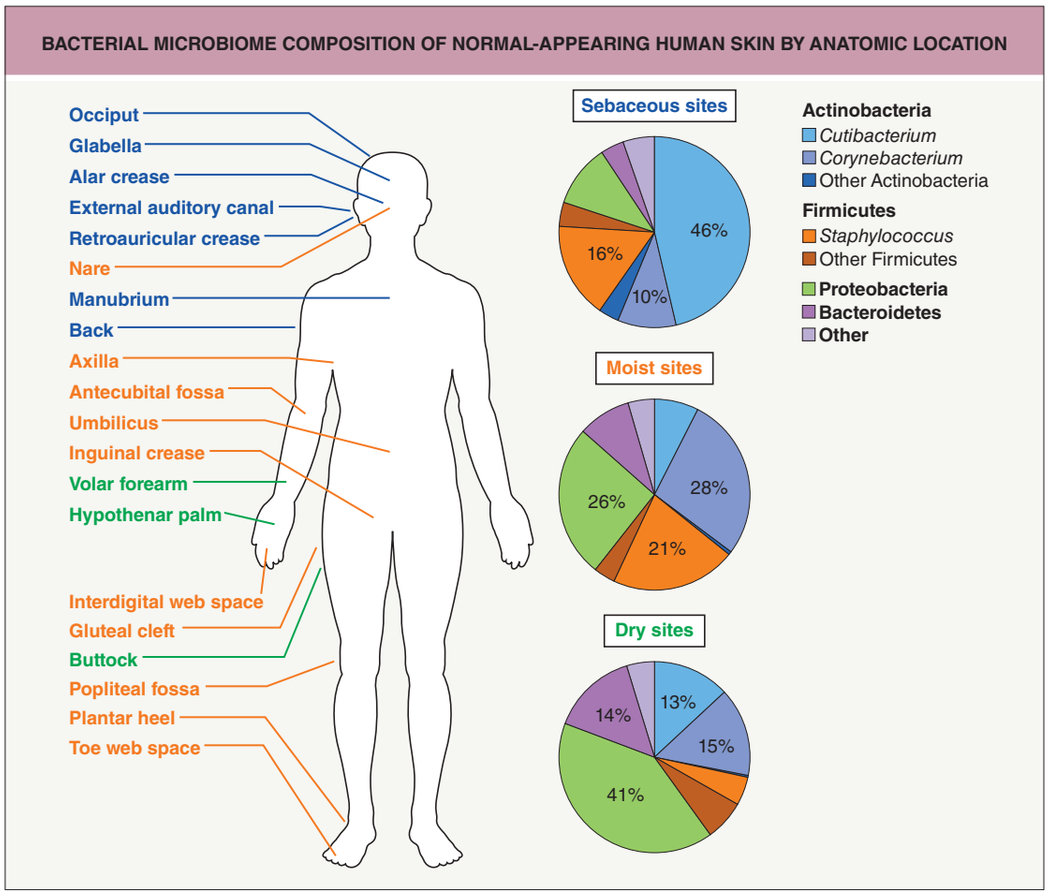

Fig. 74.1 Bacterial microbiome composition of normal-appearing human skin by anatomic location. *Adapted from Chen YE, Tsao H. The skin microbiome: Current perspective and future challenges. J Am Acad Dermatol 2013;69:143–55. Figure 3.*

Fig. 74.2 Staphylococcal impetigo. A Honey-colored crusts on the chin of a child with non-bullous impetigo. **B** Multiple small superficial erosions with crusting around the nares and on the chin in association with folliculitis in an adult. **C, D** Superficial round to oval erosions with central thin crusting and a peripheral collarette due to bullous impetigo in the axilla and on the neck. CHARACTERISTIC FEATURES OF BULLOUS AND NON-BULLOUS IMPETIGO		
	Non-bullous impetigo	**Bullous impetigo**
Epidemiology	• 70% of all cases of impetigo • Children most often affected	• Less common • Often occurs in neonates (see Ch. 34) and children
Clinical lesions	• Early: single 2–4 mm erythematous macule that rapidly evolves into a short-lived vesicle or pustule • Late: superficial erosion with a typical "honey-colored" yellow crust and rapid direct extension of infection to surrounding skin	• Early: small vesicles enlarge into 1–2 cm superficial bullae • Late: flaccid, transparent bullae measuring up to 5 cm in diameter; after rupture there is a collarette of scale, but no thick crust; usually little surrounding erythema
Distribution	• Face (around the nose and mouth) and extremities	• Face, trunk, buttocks, perineum, axillae, and extremities
Associated findings	• Mild lymphadenopathy may be present	• Usually no systemic symptoms but can be associated with weakness, fever, and diarrhea
Clinical course	• Usually a benign, self-limited process • Usually resolves within 2 weeks without scarring if untreated	• Usually resolves in 3–6 weeks without scarring if not treated
Complications	• In 5% of cases, non-bullous impetigo caused by *Str. pyogenes* (M protein types 1, 4, 12, 49, 55, 57, 60) results in acute post-streptococcal glomerulonephritis (APSG)* • Risk of APSG is not altered by treatment with antibiotics • Impetigo has not been linked to a risk of rheumatic fever	• In infants/young children and adults with immunodeficiency or renal failure, exfoliative toxin may disseminate and cause staphylococcal scalded skin syndrome
*Associated with anti-DNase B and antistreptolysin O (ASO) antibodies.		

Table 74.1 Characteristic features of bullous and non-bullous impetigo.

not those of SSSS. Compared to non-bullous impetigo, the bullous form is more likely to develop on clinically intact skin, especially in intertriginous sites.

Clinical features

The clinical features of impetigo are outlined in Table 74.1[4,5].

Pathology

In *non-bullous impetigo*, small neutrophilic vesiculopustules are present within the epidermis. Spongiosis frequently underlies the pustule. The upper dermis contains an intense infiltrate of neutrophils and lymphocytes. Gram-positive cocci are present within the vesiculopustules.

In *bullous impetigo*, there is cleavage of the upper epidermis, typically within the granular layer. Acantholysis mimicking pemphigus foliaceus may be observed. Relatively few inflammatory cells are present within the blister cavity, and a neutrophilic infiltrate is often found in the upper dermis. Gram-positive cocci may be evident.

Diagnosis and differential diagnosis

The diagnosis of impetigo is usually made clinically; exudate from beneath the crust or fluid from intact bullae can be sent for culture to confirm the diagnosis and determine susceptibility to antibiotics. Leukocytosis is seen in approximately half of patients with impetigo and regional lymphadenopathy is common. The differential diagnosis of non-bullous and bullous impetigo is presented in Table 74.2.

Treatment

For healthy patients with a few superficial lesions and no systemic symptoms, topical mupirocin, retapamulin, ozenoxacin, or fusidic acid (not available in the US) are often equally (if not more) effective than oral antibiotics[6]. However, *S. aureus* can develop resistance to each of these agents[7]. Treatment should also include cleansing the affected area and removing crusts, which can be facilitated by wet dressings.

The extent of skin involvement, the presence of complications (e.g. cellulitis, lymphangitis, bacteremia), comorbid conditions (e.g. atopic dermatitis, varicella), the patient's immune status, and local drug-resistance patterns (e.g. the prevalence of community-associated methicillin-resistant *S. aureus* [CA-MRSA]) should be considered when deciding whether topical, oral, or intravenous therapy is the most appropriate treatment (Table 74.3). The risk of developing post-streptococcal glomerulonephritis following streptococcal impetigo is not affected by treatment and is greater with certain subtypes of group A β-hemolytic streptococci (see Table 74.1)[4,6,8]. In contrast to pharyngitis, a link between streptococcal pyoderma and acute rheumatic fever has not been established. Methods for "decolonizing" the nares and skin of patients with recurrent staphylococcal impetigo are discussed in the folliculitis section below.

DIFFERENTIAL DIAGNOSIS OF NON-BULLOUS AND BULLOUS IMPETIGO		
	Most common	**Less common**
Non-bullous impetigo	• Insect bites • Eczematous dermatoses • Herpes simplex viral infection • Candidiasis	• Inflammatory tinea corporis/faciei • Varicella • Scabies • Pediculosis • Pemphigus foliaceus
Bullous impetigo	• Bullous insect bite reactions • Thermal burns • Herpes simplex viral infection • Acute contact dermatitis (allergic or irritant)	• Autoimmune bullous dermatoses • Bullous erythema multiforme • Stevens–Johnson syndrome • Bullous mastocytosis

Table 74.2 Differential diagnosis of non-bullous and bullous impetigo.

Bacterial Folliculitis

Introduction

Bacterial folliculitis is a superficial or deep infection of the hair follicle. A furuncle develops when the entire follicle and surrounding tissue are involved (see below).

Epidemiology and pathogenesis

S. aureus is the most common infectious cause of folliculitis (see Ch. 38). Gram-negative folliculitis occasionally develops in acne vulgaris patients treated with prolonged courses of oral antibiotics. In addition, *Pseudomonas* or (less often) *Aeromonas* folliculitis can result from the use of improperly chlorinated hot tubs and swimming pools[9]. Predisposing factors for staphylococcal folliculitis include occlusion, maceration, and hyperhydration of the skin; shaving, plucking, or waxing hair; use of topical corticosteroids; hot and humid weather; atopic dermatitis; and diabetes mellitus.

Clinical features

Staphylococcal folliculitis most frequently involves the face (especially the beard area), scalp, chest, back, axillae, and buttocks (see Ch. 38). The appearance depends on the depth of follicular involvement. Superficial folliculitis (impetigo of Bockhart) presents with small (1–4 mm) pustules or crusted papules on an erythematous base. The lesions are frequently clustered and heal without scarring. Sycosis barbae, a type of deep folliculitis, appears as large erythematous papules, often with a central pustule and sometimes coalescing to form plaques studded with pustules and crusts. Bacterial folliculitis may be pruritic or tender (especially if there is deeper involvement)[10].

EMPIRIC TREATMENT OF CUTANEOUS STAPHYLOCOCCAL AND STREPTOCOCCAL INFECTIONS IN ADULTS	
Organism/situation	**Suggested antibiotics**
Streptococcal infection	• Dicloxacillin 500 mg PO four times a day • First generation cephalosporin (see below) • Nafcillin or oxacillin 1–2 g IV four times a day, if severe
Suspected MSSA infection • e.g. impetigo requiring systemic treatment or non-purulent cellulitis	• First-generation cephalosporin, e.g. cephalexin 250–500 mg PO three or four times a day • Dicloxacillin 250–500 mg PO four times a day
Suspected MRSA infection (see Table 74.4) • e.g. furuncles/abscesses, purulent cellulitis, or infections that failed to respond to treatment with an antistaphylococcal β-lactam	• Doxycycline 100 mg PO two times a day* • Trimethoprim–sulfamethoxazole 1 or 2 double-strength tablets PO twice a day* • Clindamycin 300–450 mg PO four times a day (although some MRSA strains are clindamycin-resistant)
	Other oral options • Minocycline* • Linezolid† or tedizolid‡,† • Delafloxacin†
	Intravenous options for severe disease • Vancomycin (first line) • Daptomycin‡ • Telavancin‡, oritavancin‡, or dalbavancin‡ • Ceftaroline‡
Penicillin-allergic patients	• Clindamycin (see above) • Clarithromycin 250 mg PO two times a day

Additional special considerations	• Furuncle/abscess: incision and drainage (without packing) is a key component of successful treatment
	• If recurrent infections, address carrier state:
	  • Mupirocin 2% nasal ointment twice a day for 5 days
	  • Mupirocin 2% cream to major body folds (e.g. axillae, groin, inframammary) and umbilicus twice a day for 5 days
	  • Wash body with chlorhexidine or dilute bleach¶ 2–3 times per week
	• Address fomites including sports equipment, keyboards, and remote controls
	• Consider close human contacts or pets as source of infection

*Does not provide coverage of group A streptococci; if coverage of the latter is desired, a β-lactam should also be prescribed. †Intravenous form also available. ‡Their cost-effective role in treatment of MRSA has not been established. ¶e.g. 0.5 cup of household bleach (6%–8.25% sodium hypochlorite) in a full 40-gallon bathtub, or 0.5–1 teaspoon per gallon in a spray bottle.	

Table 74.3 Empiric treatment of cutaneous staphylococcal and streptococcal infections in adults. Treatment duration is usually 5–14 days, depending on the severity and clinical response. Initial choice of antibiotic is dependent on known resistance patterns in a given community. Topical treatments for localized superficial infections (e.g. impetigo) include mupirocin 2% ointment/cream, retapamulin 1% ointment, ozenoxacin 1% cream, and fusidic acid 2% cream (not available in the US). The contents of pustules or exudate (e.g. underlying a crust) should be sent for culture and sensitivities prior to beginning therapy. Systemic quinolones (other than delafloxacin) and macrolides are not optimal, as staphylococcal resistance is common and may develop rapidly. IV, intravenously; MSSA, methicillin-sensitive *Staphylococcus aureus*; MRSA, methicillin-resistant *Staphylococcus aureus*; PO, orally.

Diagnosis and differential diagnosis

The diagnosis of bacterial folliculitis is usually made based on the clinical findings. Gram staining and bacterial cultures can help to identify the causative organisms, which is especially useful in severe, recurrent, or treatment-resistant cases. The differential diagnosis includes other forms of folliculitis (see Ch. 38), acne vulgaris, rosacea, chloracne, pseudofolliculitis barbae, and keratosis pilaris.

Treatment

Superficial staphylococcal folliculitis can be treated with antibacterial washes that contain chlorhexidine or sodium hypochlorite. Topical antibiotics such as mupirocin or clindamycin may also be used for 7–10 days to treat localized lesions. When staphylococcal folliculitis is widespread or recurrent, oral β-lactam antibiotics (e.g. a β-lactamase-resistant penicillin or first-generation cephalosporin), tetracyclines, trimethoprim–sulfamethoxazole (TMP-SMZ), macrolides, or linezolid (depending on local resistance patterns) can be prescribed (see Table 74.3).

The carrier state should be addressed in patients with recurrent staphylococcal folliculitis and their close contacts (see Table 74.3). Application of mupirocin 2% ointment twice daily to the nares for 5–10 days can be used to eradicate nasal carriage of *S. aureus*. Methods to decolonize the skin (e.g. axillae, umbilicus, perineum/groin, submammary area) include topical mupirocin, washes containing chlorhexidine, and dilute sodium hypochlorite baths (e.g. 0.5 cup household bleach [6%–8.25% sodium hypochlorite] in a full standard bathtub). However, mupirocin resistance has been increasing, especially among MRSA isolates[11]. Elimination of bacterial contamination of potential fomites such as keyboards, toys, and sports equipment (e.g. shoulder pads, wrestling mats) should also be considered, e.g. by using ethanol- or sodium hypochlorite-based disinfectants.

Abscesses, Furuncles, and Carbuncles

Introduction

Abscesses and furuncles (boils) are collections of pus that are "walled-off" from the surrounding tissues. Whereas an abscess can occur anywhere in or on the body, a furuncle, by definition, involves a hair follicle. A contiguous collection of furuncles is termed a carbuncle.

Epidemiology and pathogenesis

Furuncles most often occur in adolescents and young adults. *S. aureus* is usually the causative organism, although anaerobic bacteria are occasionally cultured from recurrent furuncles in the anogenital region. Predisposing factors include chronic *S. aureus* carriage, close personal contact with affected individuals (e.g. households, athletic activities), diabetes mellitus, obesity, poor hygiene, immunodeficiency syndromes (e.g. chronic granulomatous disease, hyperimmunoglobulin E syndrome), and hereditary sensory and autonomic neuropathy due to defects in nerve growth factor β or its high-affinity receptor (see Table 6.10)[12].

Clinical features

Abscesses are localized collections of pus that are usually inflamed. They can arise in any cutaneous site. Furuncles are acute, inflammatory abscesses of individual hair follicles and the surrounding tissue and, as such, occur only in hair-bearing skin. The most common locations are the face, neck, axillae, buttocks, thighs, and perineum. Sites prone to friction or minor trauma, such as the area under a belt, are also susceptible. Furuncles usually begin as firm, tender, red nodules that progressively enlarge, becoming painful and fluctuant (Fig. 74.3);

rupture results in decreased pain. Systemic symptoms are usually absent, although regional lymphadenopathy may develop. Furunculosis (multiple or recurrent furuncles) can be associated with chronic *S. aureus* carriage.

Carbuncles are collections of furuncles that extend deep into the subcutaneous tissue. The surface usually displays multiple draining sinus tracts and occasionally ulcerates. They usually occur in areas with thicker skin (e.g. nape of neck, back, thigh). Systemic symptoms are often present. Carbuncles are slow to heal and lead to scarring.

Pathology

Biopsy specimens reveal a dense neutrophilic infiltrate in the subcutaneous tissue. Furuncles are characterized by an acute, suppurative reaction involving the follicle below the infundibulum, as well as perifollicular necrosis with fibrinoid debris.

Fig. 74.3 Furuncles secondary to methicillin-resistant *Staphylococcus aureus*. Fluctuant erythematous nodules with a central pustule on the ankle (**A**) and finger (**B**). *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Frank Samarin, MD.*

Diagnosis and differential diagnosis

Diagnosis is based primarily on clinical appearance. Gram stains and cultures from the lesion support the diagnosis. Extensive furuncles and carbuncles can be associated with leukocytosis. A ruptured epidermoid or pilar cyst, hidradenitis suppurativa, "cold" abscesses in immunodeficiency syndromes (see Fig 60.8A), and cystic acne should be considered in the differential diagnosis.

Treatment

For simple furuncles, warm compresses may promote maturation, drainage, and resolution. Larger or deeper fluctuant lesions typically require incision and drainage. Systemic antibiotic therapy is recommended (in conjunction with incision and drainage if possible) in the following situations: (1) furuncles around the nose, in the external auditory canal, or in other locations where drainage is difficult (e.g. elsewhere on the face, hands, genitalia); (2) severe or extensive disease (e.g. multiple sites); (3) lesions with surrounding cellulitis/phlebitis or associated with signs/symptoms of systemic illness; (4) lesions not responding to local care; and (5) patients with concerning comorbidities or immunosuppression[13,14]. Given the high proportion of furuncles that are caused by MRSA, empiric coverage with antibiotics such as doxycycline, TMP-SMX, or (depending on local resistance patterns) clindamycin should be considered (see Table 74.3 and below). Large controlled studies found that administration of a systemic antibiotic (TMP-SMX or clindamycin) following incision and drainage of a solitary, uncomplicated cutaneous abscess increases the cure rate and decreases the likelihood of recurrence[15,16]. However, this benefit must be weighed against the potential for antibiotic side effects. Patients with recurrent furunculosis may benefit from eradication of *S. aureus* from the nares, axillae, umbilicus, and perineum (see Table 74.3).

Methicillin-Resistant *Staphylococcus aureus* Infection

Introduction

Methicillin resistance was first noted in isolates of *S. aureus* in 1961. Although initially associated with nosocomial infection (healthcare-associated [HA]-MRSA), community-associated (CA)-MRSA has become a growing problem among individuals without predisposing factors[17]. Table 74.4 compares CA- and HA-MRSA. In the US, rates of HA-MRSA infection have fallen in recent years while CA-MRSA rates have stayed relatively stable[18]. Although there is considerable regional variation, overall, MRSA represents the most common cause of purulent skin and soft tissue infections presenting

COMPARISON OF COMMUNITY-ASSOCIATED (CA) AND HEALTHCARE-ASSOCIATED (HA) METHICILLIN-RESISTANT *STAPHYLOCOCCAL AUREUS* (MRSA)

	CA-MRSA	HA-MRSA
Epidemiology	• Favors children and young adults	• Favors adults age >65 years
Risk factors	• Close interpersonal contact (e.g. athletes, military personnel, prison inmates, children attending daycare) • Men having sex with men • Injection drug use • Recent antibiotic use • Homelessness • HIV infection • Skin trauma (e.g. lacerations, abrasions, tattoos, body shaving/piercing) • Dermatologic conditions (e.g. atopic dermatitis*)	• Underlying comorbidities (e.g. diabetes mellitus) • Recent surgery or hospitalization (especially if prolonged or in an ICU) • Residence in a long-term care facility • Dialysis • Indwelling percutaneous medical devices and catheters • Chronic wounds
Typical sites/types of infection	• Skin and soft tissue, especially furuncles/abscesses or purulent cellulitis	• Skin and soft tissue, especially in surgical sites • Urinary tract • Respiratory tract • Bloodstream
Molecular characteristics	• SCC*mec* types IV and V • Panton–Valentine leucocidin (PVL) genes • USA300 or USA400 PFGE	• SCC*mec* types I–III • USA100 or USA200 PFGE
Antibiotic susceptibility	• Usually multiple agents	• Limited

*Increased risk of staphylococcal infections, but not generally in the proportion due to MRSA.

Table 74.4 Comparison of community-associated (CA) and healthcare-associated (HA) methicillin-resistant *Staphylococcal aureus* (MRSA). ICU, intensive care unit; PFGE, pulsed-field electrophoresis pattern.

to emergency departments in the United States[17,19]. MRSA also represents one of the ESKAPE pathogens that have emerged due to widespread overuse of antibiotics (Table 74.5); these organisms have become problematic sources of nosocomial infections, especially among burn victims.

Clinical features

Furunculosis is the most frequent manifestation of CA-MRSA infection (see Fig. 74.3). These lesions can evolve into large abscesses, cellulitis, or necrotic plaques which may be misdiagnosed as spider bites. Less often, impetigo, SSSS, and folliculitis are seen, and life-threatening complications such as septic shock, toxic shock syndrome, and necrotizing fasciitis occasionally develop.

Pathogenesis

Methicillin resistance is caused by the production of an altered penicillin-binding protein 2a (PBP2a) that has decreased affinity for β-lactam antibiotics. PBP2a is the protein product of the *mecA* gene, which is located within a specific mobile genetic element called the staphylococcal cassette chromosome *mec* (SCC*mec*). Acquisition of different SCC*mec* elements by *S. aureus* led to the emergence of HA-MRSA (usually SCC*mec* types I–III) and CA-MRSA (usually SCC*mec* types IV and V) strains; methicillin-resistant coagulase-negative staphylococci are thought to represent a reservoir of SCC*mec* for CA-MRSA. Many CA-MRSA strains also encode virulence factors such as Panton–Valentine leukocidin (PVL), a pore-forming cytotoxin that can cause destruction of leukocytes and tissue necrosis.

As a reflection of their distinct SCC*mec* elements, CA-MRSA and HA-MRSA have different patterns of antibiotic resistance. CA-MRSA is typically susceptible to multiple non-β-lactam antibiotics, whereas HA-MRSA is usually resistant to several antimicrobial classes, including aminoglycosides, macrolides, and clindamycin. However, some isolates of the USA300 clone, which currently causes most CA-MRSA skin infections in the US have developed resistance to macrolides, clindamycin, tetracycline (less often doxycycline), quinolones, and mupirocin[20].

Resistance to macrolides in staphylococci may result from: (1) active drug efflux via a pump encoded by the *msrA/msrB* gene (frequent in MRSA isolates); (2) synthesis of macrolide-inactivating enzymes; or (3) modification of the bacterial ribosome by the erythromycin ribosomal methylase encoded by *erm* genes, which produces cross-resistance to clindamycin[21]. Erythromycin stimulates expression of *erm*, which leads to clinically relevant resistance. If initial sensitivity testing shows resistance to erythromycin and susceptibility to clindamycin, resistance to clindamycin will still develop if *erm* is present, since bacterial variants with constitutive *erm* expression commonly arise and are selected for during clindamycin therapy. This "inducible resistance" can be assessed with the D-test (double-disk diffusion) (Fig. 74.4).

THE ESKAPE PATHOGENS
Enterococcus faecium
Staphylococcus aureus
Klebsiella pneumoniae
Acinetobacter baumannii
Pseudomonas aeruginosa
Enterobacter species

Table 74.5 The ESKAPE pathogens

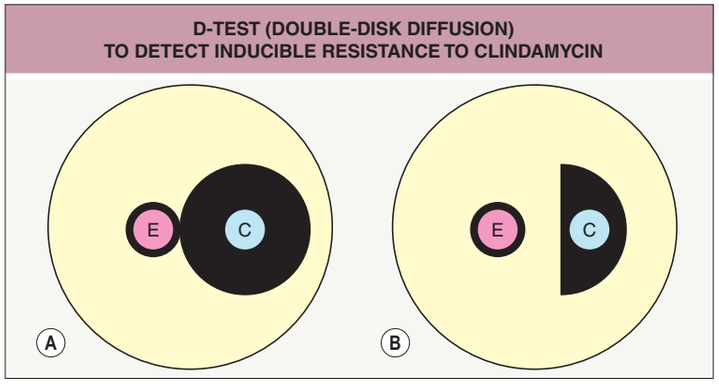

Fig. 74.4 D-test (double-disk diffusion) to detect inducible resistance to clindamycin. Erythromycin (E) and clindamycin (C) disks are placed 15–17 mm apart on an agar plate inoculated with the organism. Following incubation, the zones of inhibition around the disks are evaluated. If the zone around the clindamycin disk is circular in shape and of sufficient size (**A**), the organism is negative for inducible resistance. However, if the portion of the zone adjacent to the erythromycin disk is "flattened", producing a "D" shape (**B**), the organism is positive for inducible resistance to clindamycin.

Diagnosis and treatment

When *S. aureus* infection is suspected, culture and susceptibility testing should be performed, whenever feasible, to guide antibiotic selection. Prior to obtaining sensitivity results, empiric antibiotic therapy can be chosen based on the prevalence of MRSA and resistance patterns in a given community, as well as the severity of the infection (see Table 74.3). Vancomycin should be considered for patients with severe infections, especially in geographic regions where CA-MRSA is prevalent and in individuals with a history of MRSA colonization or injection drug use[17]. PCR-based (e.g. BD Max™ StaphSR) and bacteriophage-based (e.g. cobas® vivoDx) assays are also available for rapid detection of MRSA from nasal or potentially skin swab samples, but they do not provide other drug susceptibility information[22].

Blistering Distal Dactylitis

Blistering distal dactylitis is a localized infection of the volar fat pad of a finger or, less often, a toe, with occasional involvement of the nail fold or more proximal portion of the digit. Darkening of the skin is often observed for several days to a week before blister formation (Fig. 74.5). The infection most commonly occurs in children aged 2–16 years.

Group A beta-hemolytic streptococci or *S. aureus* are usually the causative organisms. Inoculation may follow local skin trauma or autoinoculation from nose picking[23]. The differential diagnosis includes herpetic whitlow, a thermal or chemical burn, acute paronychia, bullous impetigo, and frictional bullae.

Drainage and a 10-day course of an oral antistaphylococcal antibiotic are recommended. Although topical therapy with mupirocin has been described, systemic therapy can prevent development of new sites of infection as well as local extension.

Ecthyma

Ecthyma is a deep variant of non-bullous impetigo characterized by extension into the dermis to produce a shallow ulcer that heals with scarring (Fig. 74.6). It can be caused by a primary infection with group A beta-hemolytic streptococci or a streptococcal superinfection, e.g. of an excoriated insect bite. Outbreaks of ecthyma have occurred among infantry units where skin trauma, poor hygiene, and crowded living conditions facilitate disease spread[24]. Table 74.6 summarizes the clinical aspects and treatment of ecthyma[25].

Staphylococcal Scalded Skin Syndrome

Synonyms: ■ Ritter's disease ■ Pemphigus neonatorum

Fig. 74.5 Blistering distal dactylitis. Large vesiculopustule due to infection with group A *Streptococcus*. *Courtesy Julie V. Schaffer, MD.*

Fig. 74.6 Ecthyma. Ulceration with hemorrhagic crust on the wrist (**A**) and leg (**B**) due to infection with group A streptococci. *A, Courtesy Kalman Watsky, MD; B, Courtesy Michal Kidacki, MD, PhD.*

CLINICAL FEATURES OF ECTHYMA	
Clinical findings	• Usually fewer than 10 lesions, most commonly on the lower extremities • An initial vesiculopustule enlarges (0.5–3 cm in diameter) over several days, and develops a hemorrhagic crust • The ulcer has a "punched-out" appearance and a purulent, necrotic base • Lesions are slow to heal and produce scarring
Risk factors	• Young age (children), lymphedematous limbs, poor hygiene, neglect (including the elderly), immunosuppression, scratching (e.g. of insect bites), trauma
Complications	• Lesions are often contaminated with staphylococci • Systemic symptoms and bacteremia are rarely seen • Cellulitis and osteomyelitis are extremely infrequent
Diagnosis	• Clinical appearance • Culture of moist, purulent base; skin biopsy with deep-tissue Gram stain and culture occasionally required
Differential diagnosis	• Ecthyma gangrenosum • Ulcers due to vasculitis, vasculopathies, other causes (see Ch. 105)

Table 74.6 Clinical features of ecthyma. This deeper form of non-bullous impetigo is due to a group A streptococcal infection.

Introduction

Staphylococcal scalded skin syndrome (SSSS) is caused by hematogenous dissemination of the same exfoliative toxins that lead to bullous impetigo when produced locally. Cleavage of the epidermis through the granular layer results in the formation of tender, flaccid bullae[26].

Epidemiology

SSSS is primarily a disease of infants and young children, who have decreased renal toxin clearance (especially neonates) and/or a lack of toxin-neutralizing antibodies. Adults with predisposing conditions such as renal insufficiency, diabetes mellitus, substance abuse, and cancer are occasionally affected[27]. Outbreaks occurring in neonatal nurseries are usually secondary to asymptomatic carriage of a toxigenic strain of *S. aureus* by healthcare workers or parents. A male predominance exists, with a 2:1 male:female ratio in sporadic cases and 4:1 in epidemics.

Pathogenesis

Most cases of SSSS are caused by *S. aureus* phage group II types 55 and 71, which can be methicillin-sensitive or resistant. These organisms produce exfoliative (also known as epidermolytic) toxins (ETs). ETA (chromosomally encoded) and ETB (plasmid encoded) are serine proteases that bind and cleave desmoglein-1 (Dsg1). This causes splitting of the desmosomes, which leads to disruption of the epidermal layer and bulla formation. Dsg1 is targeted by autoantibodies in pemphigus foliaceus, which has identical histologic features to SSSS. Young children have a relatively low amount of Dsg1 and less renal clearance of ETs, contributing to their increased risk of SSSS, whereas adults are more likely to have anti-ET antibodies.

In contrast to bullous impetigo, where the effects of the ETs are limited to the site(s) of infection, in SSSS the toxin diffuses from the nidus of infection and spreads hematogenously to produce widespread effects. In children, the infectious focus is usually in the nasopharynx or conjunctivae, whereas staphylococcal pneumonia or bacteremia may be present in adults[28].

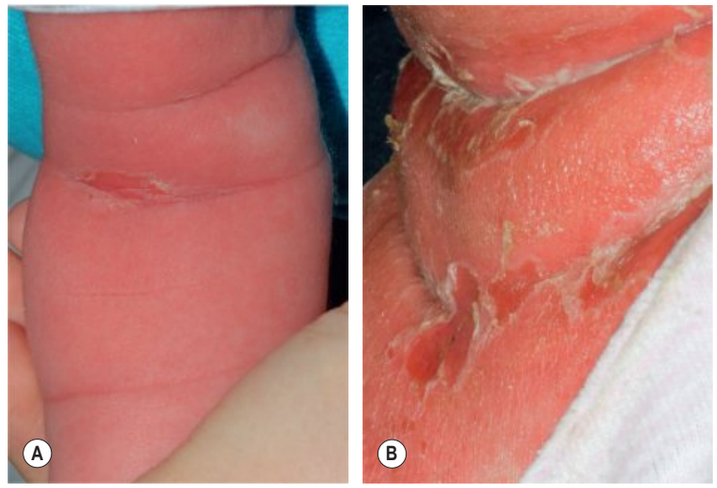

Fig. 74.7 Staphylococcal scalded skin syndrome. A Diffuse erythema with an early superficial erosion in the antecubital fossa. **B** More extensive involvement on the neck with a wrinkled appearance of the erythematous skin in addition to peeling and multiple erosions. *Courtesy Julie V. Schaffer, MD.*

Clinical features

There is often a prodrome of malaise, fever, irritability, and skin tenderness. The patient may have purulent rhinorrhea or conjunctivitis as a manifestation of the underlying staphylococcal infection. Erythema typically first appears on the head (accompanied by variable facial edema) and in intertriginous sites, often with generalization within 48 hours. The skin subsequently develops a wrinkled appearance owing to the formation of flaccid, sterile bullae within the superficial epidermis (Fig. 74.7). The Nikolsky sign is positive. Classically, the flexural areas are the first to exfoliate, leaving behind moist skin and thin, varnish-like crusting. Patients also demonstrate characteristic periorificial (e.g. perioral, periocular) crusting and radial fissuring (see Figs. 34.17 & 81.17). Intraoral lesions do not occur.

Scaling and desquamation continue for the next 3–5 days, followed by re-epithelialization without scarring. With proper treatment, SSSS resolves in 1–2 weeks, usually without sequelae. The mortality rate is ≤4% for children but may approach 50% in adults[29].

Pathology

Histologic examination shows a sharply demarcated zone of cleavage at or below the stratum granulosum. There are usually no inflammatory cells in the bullae. The upper dermis also lacks an inflammatory infiltrate, and no organisms are seen on Gram stain of biopsy specimens.

Diagnosis and differential diagnosis

SSSS is generally a clinical diagnosis. Although cultures taken from intact bullae are negative, *S. aureus* may be cultured from the conjunctiva, nasopharynx, perianal area, or pyogenic foci on the skin. Blood cultures are almost always negative in children but may be positive in adults. The leukocyte count can be elevated or normal. Examination of frozen sections is occasionally helpful in confirming the level of the split in the bullae. Slide latex agglutination, double immunodiffusion, or enzyme-linked immunosorbent assay (ELISA) tests can identify the toxins responsible for SSSS.

COMPARISON OF TOXIC EPIDERMAL NECROLYSIS AND STAPHYLOCOCCAL SCALDED SKIN SYNDROME		
	TEN	**SSSS**
Cause	Usually drug-induced	Infection with toxin-producing *S. aureus*
Age	Primarily adults	Primarily infants and young children
Histology	Dermal–epidermal separation with epidermal necrosis; dermis has a variable inflammatory infiltrate	Granular layer split in epidermis; dermis lacks inflammatory infiltrate
Distribution of rash	Areas of sparing often present	Generalized with flexural accentuation
Mucous membranes	Involved, erosions	Uninvolved
Nikolsky sign	In some areas, difficult to elicit	Present in seemingly uninvolved skin
Face	Vermilion lip erosions and crusting	Perioral and periocular crusting and radial fissuring with mild facial swelling
Treatment	IVIg, cyclosporine, corticosteroids (short course), and TNF inhibitors Supportive care (similar to a burn victim)	Antibiotics (β-lactamase-resistant ± clindamycin) and supportive care

Table 74.7 Comparison of toxic epidermal necrolysis (TEN) and staphylococcal scalded skin syndrome (SSSS). Also see Fig. 81.17. *Adapted from Habif T. Clinical Dermatology: A Color Guide to Diagnosis and Therapy. New York: Mosby-Year Book, 1996: 256–7, 570–4.*

The differential diagnosis may include a drug reaction, a viral exanthem, sunburn, Kawasaki disease, extensive bullous impetigo, toxic shock syndrome, graft-versus-host disease (GVHD), and pemphigus foliaceus. Differentiation from toxic epidermal necrolysis (TEN) and Stevens–Johnson syndrome (SJS) is outlined in Table 74.7 and Fig. 81.17, respectively.

Treatment

Patients with severe, generalized forms of SSSS require hospitalization and parenteral antibiotics (e.g. vancomycin). Oral treatment with a β-lactamase-resistant penicillin or first-generation cephalosporin for a minimum of 1 week is usually sufficient for milder disease, although SSSS is occasionally caused by MRSA. Clindamycin administration may help to reduce bacterial toxin production, but up to 50% of strains implicated in SSSS are clindamycin resistant, so monotherapy with this agent is not recommended[29]. Identification and decolonization of *S. aureus* carriers (see Table 74.3) are important, especially in hospital-acquired cases[26].

Toxic Shock Syndrome

Introduction

Toxic shock syndrome (TSS) is an acute multisystem disease caused by a *S. aureus* exotoxin (Table 74.8).

Epidemiology and pathogenesis

In the early 1980s, there was an outbreak of TSS in young women using highly absorbent tampons ("menstrual" TSS). The incidence of menstrual TSS then declined following changes in tampon manufacturing and use, and by the early 2000s it accounted for approximately half of TSS cases[30]. TSS can occur in patients who have undergone surgical procedures. In addition, it may develop in association with cutaneous pyodermas, postpartum infections, abscesses, burns, and infections associated with nasal packing or insulin pump infusion sites. Non-menstrual TSS affects both sexes equally.

TSS is due to infection or colonization with strains of *S. aureus* that produce toxic shock syndrome toxin-1 (TSST-1). This toxin is thought to act as a "superantigen" that binds to major histocompatibility complex (MHC) class II molecules of antigen-presenting cells (APCs) and the Vβ region of T cell receptors in a non-antigen-specific manner, which leads to massive release of cytokines and chemokines as well as clonal T cell expansion (see section on Streptococcal TSS)[28]. In addition to TSST-1, *S. aureus* can produce other superantigens, including at least 15 enterotoxins. The hyperinflammatory "cytokine storm" response to bacterial superantigens involves invariant natural killer T cells, mucosa-associated invariant T (MAIT) cells, and interleukin-17A-producing effector memory T cells[31,32]. Of note, the *neonatal TSS-like exanthematous disease* (see Ch. 10) occurs during the first week of life due to colonization with TSST-1-producing *S. aureus* (usually methicillin-resistant) and has a relatively mild course due to the relatively anergic state of T cells in newborns[33].

CASE DEFINITIONS FOR THE TOXIC SHOCK SYNDROMES
Toxic shock syndrome

• Fever: temperature >102°F (or >38.9°C)
• Rash: diffuse macular erythroderma
• Desquamation: 1–2 weeks after the onset of illness (especially palms and soles)
• Hypotension: systolic blood pressure <90 mmHg for adults (<5th percentile for children)
• Involvement of three or more of the following organ systems:
  • Gastrointestinal
  • Muscular
  • Central nervous
  • Renal
  • Hepatic
  • Mucous membranes (erythema)
  • Hematologic (platelets <100 000/mm^3)

• Negative results for the following tests (if done):
  • Blood and cerebrospinal fluid cultures (blood culture may be positive for *Staphylococcus aureus*)
  • Serologic tests for Rocky Mountain spotted fever, leptospirosis, measles

Streptococcal toxic shock syndrome
• Isolation of group A streptococci from a normally sterile site* (e.g. blood, cerebrospinal fluid, tissue biopsy, surgical wound) *or* • Isolation of group A streptococci from a non-sterile site† (e.g. throat, sputum, vagina, superficial skin lesion) *and* • Hypotension: systolic blood pressure <90 mmHg for adults (<5th percentile for children) *and*

• Two or more of the following signs:
  • Renal impairment
  • Coagulopathy (platelets <100 000/mm^3 or disseminated intravascular coagulation)
  • Liver impairment
  • Acute respiratory distress syndrome
  • Generalized erythematous macular rash ± desquamation
  • Soft tissue necrosis (e.g. necrotizing fasciitis, myositis, gangrene)

*Defined as a definite case. †Defined as a probable case, excluding any other possible etiology.

Table 74.8 Case definitions for the toxic shock syndromes. See https://ndc.services.cdc.gov/case-definitions/toxic-shock-syndrome-2011/ and https://ndc.services.cdc.gov/case-definitions/streptococcal-toxic-shock-syndrome-2010/ for details.

Clinical features

TSS is characterized by the sudden onset of high fever with myalgias, vomiting, diarrhea, headache, and pharyngitis. Rapid progression to hypotensive shock can occur, but the clinical spectrum ranges from mild to fulminant fatal disease. The dermatologic manifestations are more extensive and predictable in staphylococcal TSS than in streptococcal TSS (Table 74.9). Patients usually develop diffuse erythema

TOXIC SHOCK SYNDROMES		
	Staphylococcal	**Streptococcal**
Typical patient	Young (15–35 years) and healthy	Young (20–50 years) and healthy
Diffuse macular erythroderma	Very common	Less common
Vesicles and bullae	Rare	Uncommon (5%)
Localized extremity pain	Rare	Common
Soft tissue infection	Rare	Common
Hypotension	100%	100%
Renal impairment	Common	Common
Predisposing factors	Surgical packing, surgical meshes, abscesses, contraceptive sponge, tampon	Lacerations, bites, bruises, varicella
Positive blood cultures	<15%	>50%
Mortality	<3%	30%–60%

Table 74.9 Toxic shock syndromes (staphylococcal versus streptococcal).

or a scarlatiniform exanthem that starts on the trunk and spreads to the extremities (Fig. 74.8). Additional findings include erythema and edema of the palms, soles, and oral mucosa as well as a strawberry tongue, conjunctival hyperemia, and (with disease progression) generalized non-pitting edema. Desquamation of the hands and feet occurs 1–3 weeks after the onset of symptoms.

After recovery, Beau's lines and nail shedding can be seen. In severe cases, telogen effluvium may occur. With proper treatment, the majority of patients completely recover. However, complications include decreased renal function, prolonged weakness and fatigue, protracted myalgias, vocal cord paralysis, upper extremity paresthesias, carpal tunnel syndrome, arthralgias, amenorrhea, and gangrene.

Pathology

Biopsy specimens of the eruption show an infiltrate of neutrophils and lymphocytes in the superficial dermis. Papillary dermal edema as well as epidermal spongiosis and exocytosis may be noted. Hair follicles and eccrine sweat glands display similar findings.

Diagnosis and differential diagnosis

A high index of suspicion is required in order to make a timely diagnosis. Table 74.8 outlines the case definition of TSS. The possibility of streptococcal TSS (see Table 74.9 and below) should also be considered. TSS can have clinical overlap with Kawasaki disease, scarlet fever, SSSS, early TEN, Rocky Mountain spotted fever, and leptospirosis.

Treatment

Severe cases of TSS require intensive monitoring and supportive therapy. Hypotension can be treated with intravenous fluids and vasopressor agents. Foreign bodies (e.g. surgical mesh, nasal packing, tampons) that may represent a nidus of infection should be removed and abscesses drained. Beta-lactamase-resistant penicillins and first-generation cephalosporins are traditionally used to eradicate the toxin-producing staphylococci; although MRSA is responsible for only a small proportion of TSS cases, vancomycin or linezolid can be considered, depending upon local resistance patterns[30]. Some advocate using antibiotics that suppress protein (and thereby toxin) synthesis, such as clindamycin or linezolid. Administration of intravenous immunoglobulin (IVIg) may help to neutralize the toxin[34]. In severe cases of shock unresponsive to antibiotics, low-dose corticosteroids have been used[35].

Scarlet Fever

Synonym: ■ Scarlatina

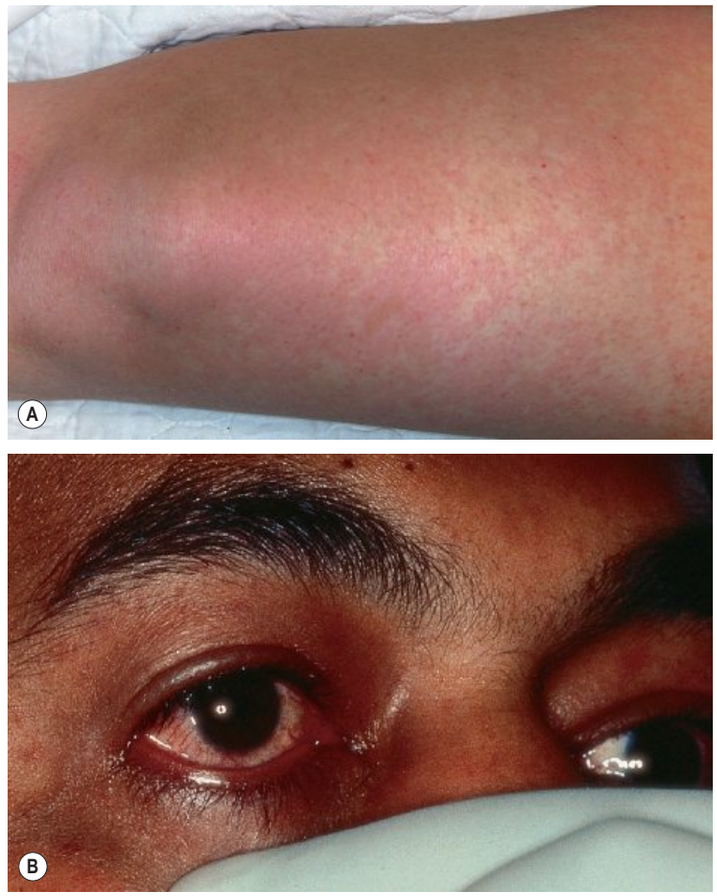

Fig. 74.8 Toxic shock syndrome due to *Staphylococcus aureus* infection. A Blotchy erythema is evident on the thigh. **B** Hyperemia of the conjunctiva is seen.

Introduction

Primarily a disease of children, scarlet fever was often fatal in the pre-antibiotic era. The erythematous exanthem and enanthem are due to toxins produced by group A β-hemolytic streptococci.

Epidemiology and pathogenesis

Scarlet fever is caused by streptococcal pyrogenic exotoxins (SPEs) types A, B, and C (also referred to as erythrogenic toxins), which are produced by group A streptococci and lead to immune activation. The majority of cases occur between 1 and 10 years of age; by the age of 10 years, 80% of the population has developed anti-SPE antibodies that prevent development of the eruption. Scarlet fever usually follows tonsillitis or pharyngitis and is most common during the late fall, winter, and spring in temperate climates. However, it occasionally develops as a complication of wound ("surgical scarlet fever"), post-burn, pelvic, or puerperal infections[36].

Clinical features

Scarlet fever is typically preceded by the sudden onset of a sore throat, headache, malaise, chills, anorexia, nausea, and high fevers. Patients, especially young children, may experience vomiting, abdominal pain, and seizures. The eruption begins 12–48 hours later as blanchable erythema on the neck, chest, and axillae. There is subsequent generalization (usually within 12 hours) and development of tiny superimposed papules with a sandpaper-like texture ("sunburn with goose pimples"). Pastia's lines (linear petechial streaks) are seen in the axillary, antecubital, and inguinal areas. The cheeks are flushed with circumoral pallor. The throat is red and edematous, developing an exudate after 3–4 days; palatal petechiae and tender cervical adenopathy are often evident. The tongue is initially white with bright red papillae, but later becomes beefy red ("strawberry tongue"). Desquamation occurs after 7–10 days, most prominently on the hands and feet (Fig. 74.9), and can last for 2–6 weeks. Possible complications of scarlet fever and the underlying streptococcal infection include otitis, mastoiditis, sinusitis, pneumonia, myocarditis, meningitis, arthritis, hepatitis, acute glomerulonephritis, and rheumatic fever[28].

Fig. 74.9 Desquamation of the foot following scarlet fever. *Courtesy Eugene Mirrer, MD.*

Pathology

Biopsy specimens reveal engorged capillaries and dilated lymphatics, most prominent around hair follicles. Dermal edema, perivascular neutrophilic infiltrates and small areas of hemorrhage represent additional findings. Spongiosis and parakeratosis are seen during the desquamative stage.

Diagnosis and differential diagnosis

Clinical diagnosis is usually not difficult. There is typically an elevated leukocyte count with a left shift. Eosinophilia of 10%–20% is often seen after 2–3 weeks of convalescence. Hemolytic anemia can occur, and mild albuminuria and hematuria may be present early in the disease. Nasal and/or throat cultures grow group A streptococci. Detection of antistreptolysin O (ASO) and anti-DNase B antibodies can also be useful in confirming the streptococcal infection.

The differential diagnosis of scarlet fever may include a drug eruption, a viral exanthem, TSS, early SSSS, Kawasaki disease, recurrent toxin-mediated perineal erythema, and infection with *Arcanobacterium haemolyticum*[37].

Treatment

As with other group A streptococcal infections, penicillin (or amoxicillin) is the drug of choice; a 10- to 14-day course is usually sufficient. A clinical response can be expected within 24–48 hours. Antibiotic treatment as long as 10 days after the onset of symptoms will prevent the development of rheumatic fever. In penicillin-allergic patients, a first-generation cephalosporin (if no history of an immediate-type reaction), clindamycin, azithromycin, or clarithromycin can be used; of note, some strains of group A streptococci are resistant to macrolides.

Streptococcal Toxic Shock Syndrome

Synonyms: ■ Streptococcal toxic shock-like syndrome ■ Toxic streptococcal syndrome

Introduction

Streptococcal TSS is a rapidly progressive, life-threatening illness caused by infection with toxin-producing group A and rarely group G streptococci[38].

Epidemiology and pathogenesis

Streptococcal TSS mainly affects healthy individuals between 20 and 50 years of age but can also occur in children (mean age, ~5 years)[39]. A disruption of the cutaneous barrier usually serves as the portal of bacterial entry. In contrast to the occult infections that predominate in staphylococcal TSS, many cases are associated with invasive soft tissue infections (e.g. necrotizing fasciitis) with virulent (e.g. M types 1 and 3) strains of group A streptococci, and the majority of patients are bacteremic[40]. Toxins that have been implicated include SPEs A, B, and C as well as the more potent streptococcal mitogenic exotoxin Z[41]. Streptolysin O may also act synergistically with SPE-A.

Similar to staphylococcal TSS, the clinical manifestations of streptococcal TSS result from massive cytokine release due to superantigen activity of bacterial exotoxins[41]. Superantigens bind directly (without intracellular processing) to MHC class II molecules on APCs (outside the antigen-presenting groove) and the Vβ region of the T cell receptor (Fig. 74.10), thereby stimulating T cells in a relatively nonspecific manner. A given superantigen–T cell interaction may lead to the activation of 5%–30% of the entire circulating T cell population, compared to ~0.01% for conventional antigens. This leads to production of huge amounts of cytokines, especially tumor necrosis factor (TNF), interleukin-1 (IL-1), and IL-6; there is also upregulation of Toll-like receptors (TLRs) 2 and 4, which augments deleterious effects of endotoxin from Gram-negative bacteria (e.g. those colonizing the gut) as well as streptococci, resulting in further elaboration of proinflammatory mediators. As a consequence, patients develop clinical manifestations such as fever, erythematous eruptions, vomiting, hypotension, and tissue injury in multiple organ systems[28]. The use of nonsteroidal anti-inflammatory drugs (NSAIDs), which lessen fever and other signs of infection, might delay the diagnosis and treatment of a streptococcal soft tissue infection, allowing TSS to occur[42].

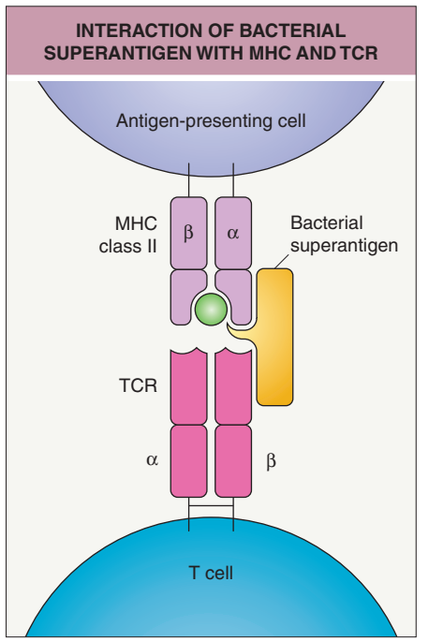

Fig. 74.10 Interaction of bacterial superantigen with the major histocompatibility complex (MHC) and the T cell receptor (TCR). *Adapted from Janeway CA, Travers P, Walport M, Shlomchik M. Immunobiology: The Immune System in Health and Disease, 6th edn. New York: Garland Science, 2004.*

Clinical features

Streptococcal TSS is defined as a group A streptococcal infection with an early onset of shock and organ failure (see Table 74.8). The most common initial symptom is severe local pain in an extremity. Although 50% of patients display signs of a soft tissue infection (e.g. swelling, tenderness, erythema), some present with only pain and no obvious physical findings. The development of a violaceous hue, bullae, or necrosis points to a deeper infection, such as necrotizing fasciitis or myositis, and portends a worse outcome.

The disease may begin insidiously with nonspecific flu-like symptoms, such as fever, chills, myalgias, and diarrhea. Symptoms of encephalopathy (e.g. confusion, altered consciousness) are commonly seen. A generalized blanching macular erythema is observed much less often than in staphylococcal TSS, but blistering is more likely to occur. Desquamation on the hands and feet eventually appears in 20% of patients. Shock and multiorgan failure usually develop 48–72 hours after the onset of symptoms. Complications of streptococcal TSS include renal failure, disseminated intravascular coagulation, and acute respiratory distress syndrome. The mortality rate for streptococcal TSS ranges from 30% to 60%.

Pathology

Biopsy specimens from skin lesions may show spongiosis, necrotic keratinocytes, subepidermal blister formation, and a neutrophilic and/or lymphocytic perivascular infiltrate in the dermis[43].

Diagnosis and differential diagnosis

Published criteria require isolation of group A streptococci from a sterile site for a "definite" diagnosis, combined with hypotension and clinical or laboratory abnormalities in two or more organ systems (see Table 74.8). Serum creatinine often rises early in the course, and creatine phosphokinase is elevated in the setting of necrotizing fasciitis or myonecrosis. The white blood cell count may be increased or normal with a substantial

left shift. Although staphylococcal and streptococcal TSSs share some common features, major differences exist (see Table 74.9).

Treatment

Most cases require intensive supportive therapy. Hypotension should be treated with aggressive intravenous fluid and vasopressors. Empiric broad-spectrum antibiotic coverage should be administered until infection with streptococci is confirmed. Clindamycin inhibits the production of bacterial toxins and is a component of first-line antimicrobial treatment (together with penicillin) for streptococcal TSS; linezolid also blocks toxin production, and administration of IVIg to neutralize toxins may be of benefit[44]. Early surgical intervention (e.g. drainage, debridement, fasciotomy, amputation) is crucial for necrotizing soft tissue infections and can be life-saving[14].

Erysipelas

Synonym: ▪ St Anthony's fire

Introduction

Erysipelas is a superficial variant of cellulitis caused primarily by group A streptococci that affects the dermis with prominent lymphatic involvement; in contrast, classic cellulitis is centered in the deep dermis and subcutaneous tissues[45].

Epidemiology and pathogenesis

Erysipelas is usually a disease of the very young, the aged, the debilitated, and those with lymphedema or chronic cutaneous ulcers. Women outnumber men, but boys are more commonly affected than girls in the pediatric age group. Erysipelas is usually caused by group A streptococci; groups G, B, C, and D streptococci are occasionally implicated. *S. aureus*, *Pneumococcus* spp., *Klebsiella pneumoniae*, *Yersinia enterocolitica*, *Campylobacter jejuni*, and *Haemophilus influenzae* type b can also cause an erysipelas-like infection[46].

Clinical features

After an incubation period of 2 to 5 days, there is an abrupt onset of fever, chills, malaise, and nausea. A few hours to a day later, a sharply marginated erythematous plaque with a ridge-like border develops and progressively enlarges. Clear demarcation from the surrounding skin is a characteristic feature (Fig. 74.11A,B). The plaque is hot, tense, indurated, and painful to palpation, with non-pitting edema and sometimes an associated burning sensation. Regional lymphadenopathy is usually present, with or without lymphangitis. Pustules, vesicles, bullae, and small areas of hemorrhagic necrosis may also form. Complications of erysipelas are uncommon and usually occur

Fig. 74.11 Cutaneous streptococcal infections. A, B Sharply demarcated erythema on the upper arm and chest (**A**) and buttocks (**B**) in two patients with erysipelas. **C** Streptococcal intertrigo presenting as a sharply demarcated, bright pink, moist plaque in the axilla of an infant. **D** Bright red erythema extending from the anal verge in a young boy with streptococcal perianal disease. *A, Courtesy Lorenzo Cerroni, MD; B, Courtesy Mary Stone, MD; C, D, Courtesy Julie V. Schaffer, MD.*

in patients with underlying disease[45]. When the infection resolves, desquamation and postinflammatory pigmentary changes may ensue.

Pathology

Biopsy specimens reveal diffuse edema and a neutrophilic infiltrate in the dermis. Dilation of the lymphatics, foci of suppurative necrosis, and dermal–epidermal separation are often seen. There is no primary necrotizing vasculitis, thrombosis, or leukocytoclasis.

Diagnosis and differential diagnosis

Diagnosis is based primarily on clinical findings. Laboratory evaluation shows an elevated leukocyte count with a left shift. Blood cultures are positive in ~5%–10% of cases. Although cultures from pustules or bullae may be helpful, the sensitivity of cultures of skin biopsy specimens is low, especially in immunocompetent hosts. Anti-DNase B and ASO titers are useful indicators of the streptococcal etiology. Direct immunofluorescence and latex agglutination tests can be used to detect streptococci within skin specimens.

The differential diagnosis of erysipelas includes other forms of cellulitis and soft tissue infections (e.g. erysipeloid, necrotizing fasciitis) as well as inflammatory causes of "pseudocellulitis" (Table 74.10).

Treatment

A 10- to 14-day course of penicillin is the treatment of choice for erysipelas caused by streptococci. Although macrolides (e.g. erythromycin) or clindamycin may be used in penicillin-allergic patients, some strains of *Str. pyogenes* are resistant to these agents. Erysipelas may recur in patients with abnormal local circulation (e.g. lymphedema), and penicillin prophylaxis is occasionally required[47]. The development of an effective vaccine against *Streptococcus* spp. could dramatically change the epidemiology of the infections caused by this microorganism[47].

Streptococcal Intertrigo

Intertrigo caused by group A streptococci is an under-recognized entity that usually affects infants and young children[48]. Infants are particularly vulnerable due to irritation and friction in moist, deep skin folds of the neck, axillae, antecubital and popliteal fossae, and inguinal region. Sharply demarcated, intensely erythematous patches or thin plaques are observed in an intertriginous site, often accompanied by a foul odor (Fig. 74.11C). In contrast to intertriginous candidiasis, satellite lesions are uncommon. Affected children occasionally exhibit irritability, low-grade fevers, and bacteremia. In genetically predisposed children, cutaneous streptococcal infection may trigger psoriasis[41]. Bacterial culture can confirm the diagnosis, which should be considered when simple intertrigo fails to respond to barrier creams and other measures to reduce friction and minimize moisture. A 10-day course of oral penicillin or amoxicillin is usually effective.

CAUSES OF "PSEUDOCELLULITIS"	
Infections and bites	**Other inflammatory disorders**
• Arthropod bite reactions (e.g. insect, spider) • Erythema migrans (see Fig. 74.15) • Herpes zoster • Toxin-mediated erythema (e.g. recurrent toxin-mediated perineal erythema)	• Allergic contact dermatitis (including airborne and dermal), stasis dermatitis • Phytophotodermatitis • Well syndrome • Panniculitis, e.g. lipodermatosclerosis, erythema nodosum • Bursitis • Thrombophlebitis • Angioedema • Interstitial granulomatous dermatitis, patch type granuloma annulare • Inflammatory morphea • Acute inflammatory edema
Neutrophilic dermatoses	**Metabolic disorders**
• Sweet syndrome, neutrophilic panniculitis • Familial Mediterranean fever, other autoinflammatory syndromes	• Gouty arthritis
Drug reactions	**Malignancy**
• Fixed drug eruptions (especially non-pigmenting) • Vaccine/injection site reactions • Toxic erythema of chemotherapy (e.g. due to gemcitabine), neutrophilic eccrine hidradenitis*	• Erysipeloid skin metastases (especially breast carcinoma)
*Occasionally develops prior to onset of leukemia or due to infection.	

Table 74.10 Causes of "pseudocellulitis".

Perianal and Vulvovaginal (Perineal) Streptococcal Infection

Synonyms: ■ Perianal – perianal streptococcal disease, perianal cellulitis, perianal streptococcal dermatitis ■ Vulvovaginal – perivaginal streptococcal disease, streptococcal vulvovaginitis

Perianal group A streptococcal infection presents as sharply demarcated, bright erythema extending 1–3 cm around the anal verge (Fig. 74.11D); similar findings can extend from the vaginal introitus onto the vulva in girls and, less often, around the urethral meatus in boys. Patients may complain of pruritus or irritation; painful defecation or dysuria; and blood-streaked stools or vaginal discharge. Systemic symptoms are generally absent. Children ages 2–7 years, especially boys (for perianal disease), are most commonly affected[49]. Perineal infection may be preceded by symptomatic pharyngitis and is frequently associated with a positive pharyngeal culture for group A streptococci even in asymptomatic patients; patients often have family members with a recent streptococcal infection. Assessment for perineal streptococcal infection should be performed in children with an outbreak of guttate psoriasis.

Other causes of perineal erythema or pruritus include contact dermatitis (irritant or allergic), *S. aureus* infection, candidiasis, seborrheic dermatitis, pinworm infestation, inflammatory bowel disease, lichen sclerosus, child abuse, and the early phase of Kawasaki disease. Perineal streptococcal infection can be diagnosed with skin culture or group A streptococcal rapid testing, although the latter is less specific. In a randomized controlled study, a 7-day course of cefuroxime was found to be more effective than a 10-day course of penicillin in the treatment of perianal streptococcal disease[50].

Cellulitis

Introduction

Cellulitis is an infection of the deep dermis and subcutaneous tissue that manifests as areas of erythema, swelling, warmth, and tenderness.

Epidemiology and pathogenesis

Cellulitis in immunocompetent adults is most often caused by group A streptococci or *S. aureus*, and the latter organism is the most frequent etiology in children. Cellulitis caused by *H. influenzae* is now rare due to routine vaccination against *H. influenzae* type B[51]. A mixture of Gram-positive cocci and Gram-negative aerobes and anaerobes is often implicated in cellulitis surrounding diabetic and decubitus ulcers[52]. Bacteria typically gain access to the dermis via a break in the skin barrier in immunocompetent individuals, but a bloodborne route is common in immunocompromised patients. Lymphedema, alcoholism, diabetes mellitus, injection drug use, and peripheral vascular disease are all risk factors for cellulitis. Recurrent bouts of cellulitis may result from damage to the lymphatic system, e.g. via prior lymph node dissection, saphenous vein harvest, or previous episodes of cellulitis.

Clinical features

Cellulitis is often preceded by systemic symptoms such as fever, chills, and malaise. The affected area displays all four of the cardinal signs of inflammation: rubor (erythema), calor (warmth), dolor (pain), and tumor (swelling). The borders are usually ill-defined and non-palpable. In severe infections, vesicles, bullae, pustules or necrotic tissue may be present (Fig. 74.12). Ascending lymphangitis and regional lymph node involvement may occur. In children, cellulitis most often affects the

Fig. 74.12 Bullous and necrotizing cellulitis. A Extensive soft tissue infection of the lower extremity due to group A streptococcal infection. **B** Edema and confluent bullae. **C** Multiple areas of necrotic crusting and focal purulence due to streptococcal cellulitis.

head and neck, whereas in adults it tends to involve the extremities. Cellulitis due to injection drug use typically affects the upper extremities, the usual sites of drug injection. Complications are uncommon but may include acute glomerulonephritis (if caused by a nephritogenic strain of *Streptococcus*), lymphadenitis, infectious endocarditis, and recurrences related to disrupted lymphatic damage.

Pathology

A mild or moderate inflammatory infiltrate composed of lymphocytes and neutrophils can be seen throughout the dermis, often extending into the subcutaneous fat (Fig. 74.13). Additional findings include edema, which occasionally leads to subepidermal bullae, and dilation of lymphatics and small blood vessels. With special stains, the causative organism may be identified.

Diagnosis and differential diagnosis

The diagnosis of cellulitis is usually clinical (Fig. 74.14). The leukocyte count is often normal or only slightly elevated. Blood cultures are almost always negative in immunocompetent hosts. An exception is *H. influenzae* cellulitis, where there is usually an increased leukocyte count with a left shift and positive blood cultures. Atypical organisms are more common in children and immunocompromised patients, and needle aspiration or skin biopsy may help to identify the infectious etiology. The differential diagnosis of lower extremity cellulitis includes deep vein thrombosis and inflammatory diseases such as stasis dermatitis, superficial thrombophlebitis, lipodermatosclerosis, and other

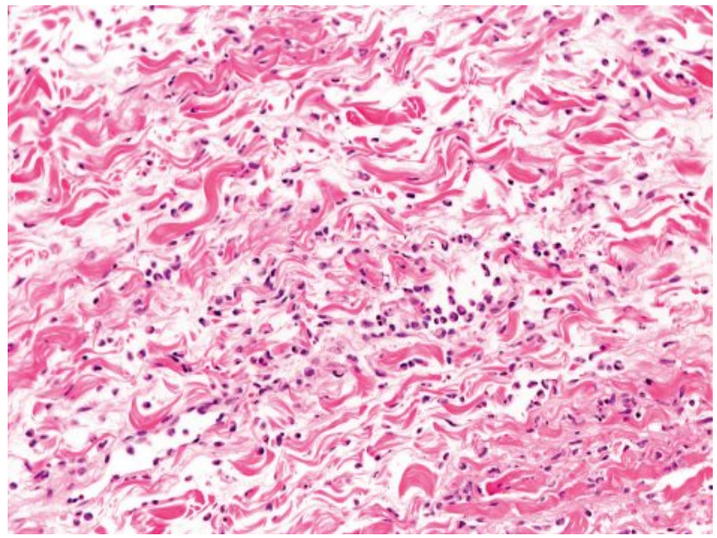

Fig. 74.13 Histopathology of cellulitis. Dermal edema and a neutrophilic infiltrate are evident. *Courtesy Lorenzo Cerroni, MD.*

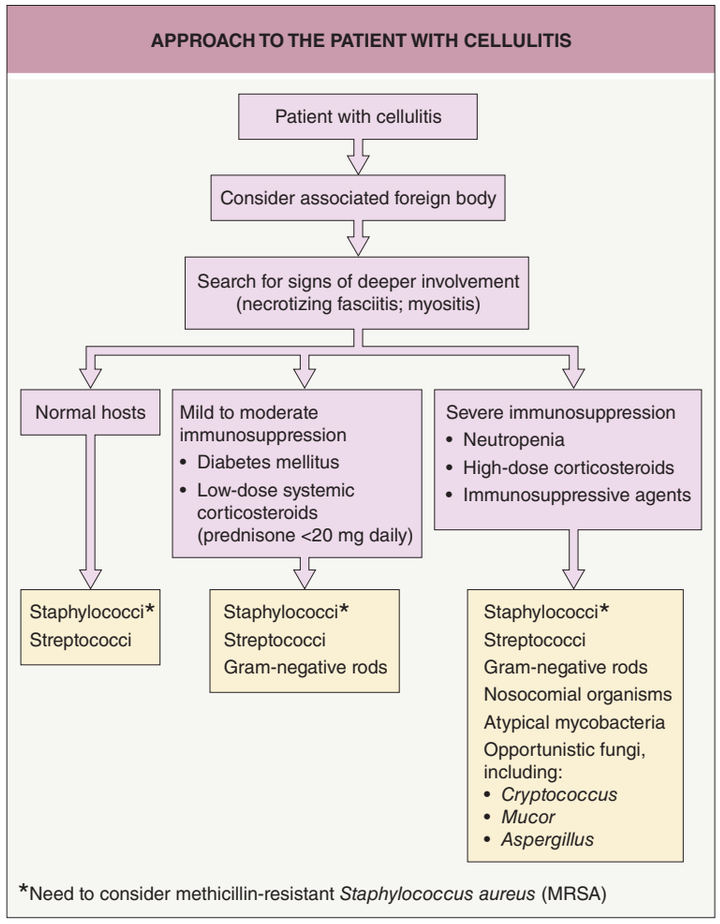

Fig. 74.14 Approach to the patient with cellulitis.

forms of panniculitis. While superficial thrombophlebitis often presents with redness and tenderness, the absence of a fever and the presence of a palpable cord aid in the diagnosis. Misdiagnosis of lipodermatosclerosis as cellulitis often leads to unnecessary hospitalizations. Additional causes of "pseudocellulitis" are listed in Table 74.10 and illustrated in Fig. 74.15. The ALT-70 score based on asymmetric involvement, leukocytosis, tachycardia, and older patient age aids in differentiating cellulitis from pseudocellulitis of the lower extremities up to 48 hours after presentation in the emergency department[53].

Fig. 74.15 Pseudocellulitis – clinical examples. A Erythema migrans with erosion following rupture of a central bulla. Inking of the skin reflects initial diagnosis of cellulitis. **B** Extravasation reaction following infusion of docetaxel. **C** Excessive limb swelling (ELS) following injection of multiple vaccines. This reaction does not preclude future immunizations. **D** Acute gout with abrupt onset of severe pain, warmth and erythema of the left great toe with difficulty in weight bearing. **E** Acute inflammatory edema with erythematous, edematous plaque sparing the inguinal fold. *A, Courtesy Kalman Watsky, MD; B, Courtesy Edward Cowen, MD; C, D, Courtesy Karynne O. Duncan, MD.*

Treatment

Treatment of cellulitis is typically targeted against group A streptococci and *S. aureus*, and a 5–10 day course of an oral antibiotic is appropriate for uncomplicated cases. Coverage for MRSA does not improve outcomes for non-purulent cellulitis[54]. For purulent cellulitis (e.g. presence of an abscess or pustules) or in patients with risk factors for MRSA, agents such as TMP-SMX, doxycycline, or clindamycin should be considered (see Tables 74.3 and 74.4). An agent with activity against both streptococcal and MRSA infections should be used when group A streptococcal infection is a possibility. Hospitalization and parenteral antibiotics may be necessary for patients with systemic manifestations (e.g. fever, tachycardia, tachypnea), facial involvement, significant comorbidities, or failure to respond to oral therapy. Broad spectrum antimicrobial coverage (e.g. vancomycin plus piperacillin/tazobactam, imipenem, or meropenem) should be provided for patients with severe non-purulent cellulitis and immunocompromised status, hypotension, or rapid progression[55]. Diabetic or decubitus ulcers complicated by cellulitis also require broad-spectrum coverage, such as piperacillin/tazobactam or, in penicillin-allergic patients, metronidazole plus ciprofloxacin. Adjunctive measures include immobilization and elevation of an affected extremity and the application of wet dressings to areas with bullae or exudate. NSAIDs may mask the signs and symptoms of deeper necrotizing infections and should be avoided when treating cellulitis.

Duration of therapy should be based on the clinical response. If signs and symptoms do not improve after 36–48 hours of treatment, then pseudocellulitis and atypical organisms should be considered. The clinical features and treatment of other types of cellulitis (e.g. *Erysipelothrix rhusiopathiae*, *Vibrio vulnificus*) are discussed below.

Preventive measures include regular foot examinations, treatment of tinea pedis and/or onychomycosis, and control of lymphedema. Compression therapy for lymphedema and prophylactic low-dose penicillin have both been shown to decrease the risk of recurrent lower extremity cellulitis; however, the protective effects diminish upon discontinuation of therapy[56,57].

Pyomyositis

Pyomyositis is a primary bacterial infection of the skeletal muscles that is caused by *S. aureus* in ~90% of cases. Other reported etiologies include: *Str. pyogenes*, *S. pneumoniae*, *Escherichia coli*, *Yersinia enterocolitica*, *Aeromonas*, *Fusobacterium*, and *H. influenzae* as well as mycobacteria and fungi; polymicrobial infections can also occur in immunocompromised patients. Once referred to as tropical myositis, pyomyositis also occurs in temperate climates. Predisposing factors include trauma, diabetes mellitus, HIV infection, injection drug use, and other forms of immunosuppression. Patients often present with a 1- to 2-week history of low-grade fevers, myalgias, and progressive firmness, pain, and enlargement of a deep soft tissue mass. Palpation of the affected area reveals "woody" induration. Muscle abscess formation occurs during the second stage of disease, and septicemia may follow.

MRI is the diagnostic modality of choice for early infection; ultrasound-guided aspiration may be helpful later in the course. Treatment of staphylococcal pyomyositis includes incision and drainage as well as appropriate intravenous antibiotics until clinical improvement is noted, followed by oral therapy[58].

Botryomycosis

Synonyms: ■ Granular bacteriosis ■ Bacterial pseudomycosis

Introduction

Botryomycosis was named for its characteristic groups of granules that resemble grapes. It is a rare, chronic, purulent and granulomatous bacterial infection that primarily affects the skin and is most often caused by *S. aureus*.

Epidemiology and pathogenesis

Botryomycosis is found worldwide, and over two-thirds of patients have only skin involvement. The disease affects all ages and has a slight male predominance. Although most often due to infection with *S. aureus*, it can also be caused by *Pseudomonas*, *Proteus*, *Moraxella*, *Serratia*, and *Corynebacteria* spp. Defects of cellular immunity, particularly low T lymphocyte counts, have been associated with the development of botryomycosis[59].

Clinical features

Botryomycosis presents as cutaneous and subcutaneous nodules, ulcers, or verrucous plaques. Multiple sinuses and fistulas may discharge purulent fluid or yellow granules composed of bacterial masses. Most patients have localized involvement of an extremity following trauma; disseminated cutaneous disease is rare[60]. The lesions may be pruritic or tender, and they may affect the underlying muscle or bone. Systemic symptoms are infrequent. Visceral botryomycosis, most often affecting the lungs, has been reported primarily in immunocompromised patients or following surgery[59].

Pathology

Biopsy specimens reveal a chronic inflammatory reaction with fibrosis and foreign body giant cells. The most distinctive feature is 1–3 mm granular bodies (grains) that represent bacteria, cells, and debris (Fig. 74.16). Grains have basophilic centers and a homogeneous, eosinophilic, hyaline periphery thought to be secondary to a host immunoglobulin response (Splendore–Hoeppli phenomenon). The granules stain with PAS, Gram, and Giemsa.

Diagnosis and differential diagnosis

When botryomycosis is suspected, bacterial, mycobacterial, and fungal cultures should be obtained and a skin biopsy performed for histopathologic examination as well as culture. Microscopic examination (fresh mount or 20% KOH) shows coarsely lobulated granules with club-like projections. Gram staining of crushed granules usually displays masses of staphylococci. The differential diagnosis of cutaneous botryomycosis includes mycetoma, actinomycosis, a ruptured epidermoid cyst, a staphylococcal abscess, orf, tuberculosis, and dimorphic fungal or atypical mycobacterial infections.

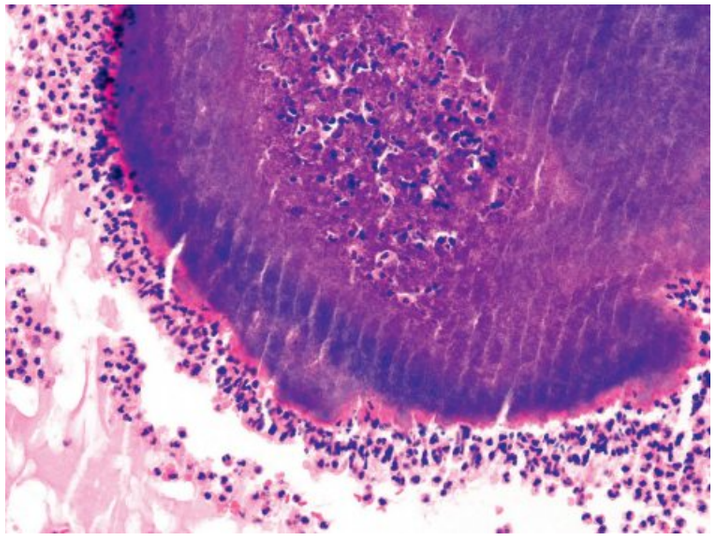

Fig. 74.16 Histopathology of botryomycosis. Note the basophilic center and eosinophilic, hyaline periphery of the granular body (grain). *Courtesy Luis Requena, MD.*

Treatment

Botryomycosis is typically treated surgically with debridement or excision in conjunction with antibiotic therapy. If possible, reducing immunosuppression may be of benefit.

Necrotizing Fasciitis

Synonyms: ■ Type 1 – polymicrobial necrotizing fasciitis ■ Type 2 – group A streptococcal necrotizing fasciitis ■ "Flesh-eating bacteria" syndrome ■ Fournier gangrene ■ Synergistic necrotizing cellulitis

Introduction

Necrotizing fasciitis is characterized by rapidly progressive necrosis of subcutaneous fat and fascia, which can be life-threatening without prompt recognition, aggressive surgical intervention, and immediate antibiotic therapy. It is classified into two major subtypes: (1) *type 1*, a polymicrobial infection including at least one anaerobe (e.g. *Bacterioides*, *Peptostreptococcus*) in addition to facultative anaerobes such as streptococci and Enterobacteriaceae; and (2) *type 2*, a monomicrobial infection, most often with group A streptococci. Some authors also distinguish *type 3* due to Gram-negative marine organisms (e.g. *Vibrio* and *Aeromonas* spp.) and *type 4* due to fungi (e.g. post trauma or in immunocompromised patients).

Epidemiology and pathogenesis

Approximately 700–1200 cases of necrotizing fasciitis are reported each year in the US. Risk factors include diabetes mellitus, immunosuppression, cardiac or peripheral vascular disease, renal failure, and therapy with medications such as sodium-glucose co-transporter 2 (SGLT2) inhibitors or bevacizumab[61], but it can also occur in young, previously healthy individuals. Necrotizing fasciitis may follow penetrating or blunt injury or develop in the absence of preceding trauma. Other predisposing factors include injection drug use, recent surgery, varicella, and decubitus or ischemic ulcers.

Mortality rates range from 20% to 60%. Higher mortality is associated with female sex, older age, malnutrition, greater extent of infection, delay to first debridement, an elevated serum creatinine or lactic acid level, disease due to group A streptococci, and a greater degree of organ dysfunction at the time of admission to hospital. Diabetes mellitus can also result in higher mortality, particularly if renal dysfunction or peripheral arterial disease is also present.

In children, necrotizing fasciitis is most commonly caused by group A streptococci. In adults, it often follows trauma or surgery and is due to a polymicrobial infection with bacteria such as streptococci, *S. aureus*, *Escherichia coli*, *Bacteroides*, and *Clostridium* spp. Less common pathogens include *V. vulnificus* (associated with sea water injuries; see below), *Aeromonas hydrophila* (associated with fresh water injuries; high mortality and amputation rates), *Pseudomonas aeruginosa*, and *H. influenzae* type B[62]. Opportunistic fungal infections, including zygomycosis, can cause necrotizing fasciitis in immunocompromised patients[63].

Clinical features

Infection begins with an area of exquisite tenderness, erythema, warmth, and swelling that does not respond to antibiotics. The skin appears shiny and tense. Initially, severe pain may be out of proportion to skin findings. The disease progresses at an alarming rate, with the skin changing from red and purple to a characteristic gray–blue color in ill-defined patches within 36 hours of onset (Fig. 74.17). Violaceous discoloration and/or hemorrhagic bullae may develop. Necrosis of the superficial fascia and fat produces a thin, watery, malodorous fluid. The area may later become anesthetic as cutaneous nerves are destroyed. The subcutaneous tissues may feel hard and "woody" on palpation. Patients can become extremely toxic, with fever, chills, malaise, leukocytosis, tachycardia, and shock. The most common site of involvement is the extremities, although the trunk is often affected in children. When necrotizing fasciitis involves the perineum and genitalia, it is referred to as Fournier gangrene, which is typically a polymicrobial infection[62,63].

Pathology

Gangrene of the subcutaneous tissues, with spread along fascial planes, is followed by involvement of the overlying skin. Fibrinoid necrosis is

Fig. 74.17 Necrotizing fasciitis. Tense, woody edema of the forearm with purple–gray areas of necrosis and bullae with watery discharge. Intravenous drug use was a predisposing factor. *Courtesy Luis Requena, MD.*

present in the media of vessels passing through the destroyed fascia, and fibrin thrombi are evident. The epidermis, dermis, and skin appendages in the area of gangrene undergo coagulation necrosis. Infiltration with neutrophils and mononuclear cells as well as numerous bacteria occurs in upper layers of the dermis.

Diagnosis and differential diagnosis

Early in the disease course, it is often difficult to differentiate necrotizing fasciitis from cellulitis. The presence of severe pain or anesthesia suggests a deeper component, and an MRI can delineate the depth of tissue involvement. Other clues that suggest necrotizing fasciitis rather than cellulitis include rapidly spreading tense edema, hemorrhagic bulla formation, grayish discoloration, foul-smelling discharge and an elevated creatine phosphokinase level. The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score based on routinely performed laboratory tests has a high specificity but lower sensitivity, and thus should not be used to exclude necrotizing fasciitis[64]. Fig. 74.18 outlines an algorithm for assessing and treating suspected necrotizing fasciitis. Conditions that can mimic necrotizing fasciitis include trauma with hematoma formation, neutrophilic dermatoses, clostridial myonecrosis, pyomyositis, phlebitis, bursitis, and arthritis (see Fig. 25.7B).

Treatment

Extensive surgical debridement (fasciotomy) is the mainstay of effective treatment. Additional surgery may be necessary 24 hours later to ensure adequate debridement, and amputation is occasionally necessary. Empiric therapy should be initiated with broad-spectrum coverage against streptococci, staphylococci (including MRSA), Gram-negative bacilli and anaerobes – e.g. vancomycin plus piperacillin/tazobactam[14]. In a patient with true penicillin allergy, empiric therapy with ciprofloxacin plus metronidazole or clindamycin can be used. Coverage of *Pseudomonas* is particularly important for neutropenic patients. Once the microbial etiology has been determined, antibiotic coverage can be narrowed appropriately.

Hyperbaric oxygen therapy remains controversial, though it may be beneficial for a subset of patients with anaerobic Gram-negative necrotizing fasciitis; however, surgery and antimicrobial therapy should never be postponed. Although IVIg may be useful for patients with severe group A streptococcal infections, a randomized placebo-controlled trial failed to show benefit of IVIg administration in intensive care unit patients with necrotizing soft tissue infections[65]. Nutritional support is crucial for enhancing postoperative wound healing. Eventually, reconstructive surgery is often necessary[14].

Bacteremia/Septicemia

Staphylococcal septicemia may occur in the absence of any cutaneous or internal focus of infection. Immunocompromised states, erythroderma (especially secondary to Sézary syndrome), injection drug use, and the presence of central venous catheters or abnormal/prosthetic heart valves represent risk factors for Gram-positive bacteremia. A large percentage of patients with late-stage cutaneous T cell lymphoma eventually succumb

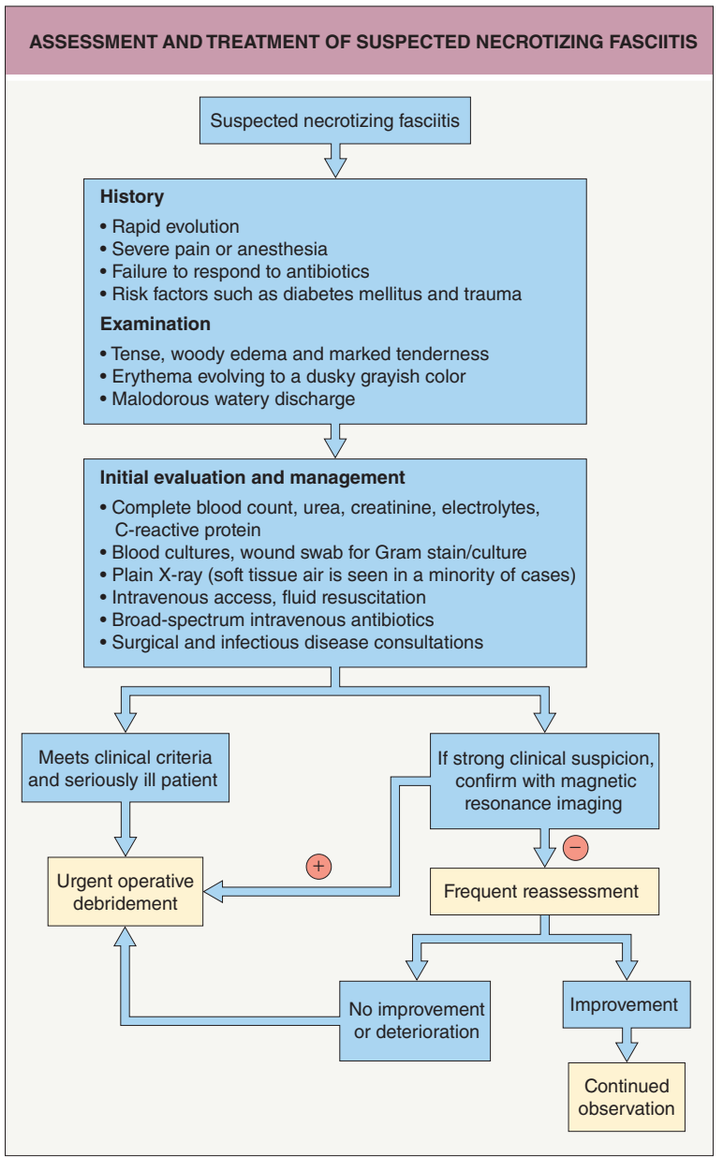

Fig. 74.18 Algorithm for assessment and treatment of suspected necrotizing fasciitis.

to septicemia, especially staphylococcal. The skin lesions of *S. aureus* septicemia are classically pustular petechiae, purulent purpura, and subcutaneous abscesses that probably represent hematogenous spread of the infection to the skin. Biopsy specimens show nonspecific inflammation, often with a positive Gram stain, and cultures grow *S. aureus*. When *S. aureus* bacteremia leads to endocarditis, a number of other characteristic skin signs may appear, including petechiae and splinter hemorrhages; Osler nodes resulting from immune complex deposition and small vessel vasculitis; and Janeway lesions that represent septic emboli with microabscess formation. Osler nodes are tender, erythematous papules and nodules with white centers that favor the finger pads and thenar/hypothenar eminences, whereas Janeway lesions are painless, small hemorrhagic macules or papules on the palms and soles (Fig. 74.19)[66]. Both staphylococcal bacteremia and endocarditis are treated with prolonged courses of intravenous antibiotics.

CLOSTRIDIAL SKIN INFECTIONS

Clostridia are spore-forming Gram-positive rods that are ubiquitous soil saprophytes and part of the normal intestinal flora. *Clostridium perfringens*, the most frequent cause of trauma-associated gas gangrene, is an obligate anaerobe and thus proliferates in hypoxic or ischemic tissue. *Clostridium septicum* is much more aerotolerant, requires a smaller infective dose, and is associated with spontaneous gas gangrene in patients with neutropenia or gastrointestinal malignancy[14].

C. perfringens produces two membrane-active toxins, alpha and theta (perfringolysin O), which have synergistic effects. Alpha toxin possesses biologic activity akin to phospholipase C and sphingomyelinase, while theta toxin disrupts endothelial cell integrity, impairs recruitment of phagocytes, and induces intravascular platelet aggregation, leading to reduced arteriolar blood flow. Impaired oxygen delivery then results in tissue hypoxia and anaerobic glycolysis of muscle tissues. Production of hydrogen sulfide and CO_2 accounts for the characteristic "gas" gangrene visualized on radiographic imaging. Local progression results in myonecrosis, whereas shock and multi-organ failure can occur when the toxins enter the systemic circulation.

The majority of cases of anaerobic cellulitis (a necrotizing subcutaneous infection) and myonecrosis (gas gangrene) are caused by clostridia. These diseases are compared and their treatment outlined in Table 74.11. Soft tissue crepitus, evidence of gas on plain films, or a foul-smelling brownish discharge ("dirty dishwater") should prompt the clinician to suspect a clostridial infection, especially following trauma or surgery in patients with diabetes mellitus and peripheral vascular disease[58].

Fig. 74.19 Palmar lesions due to staphylococcal endocarditis.

CORYNEBACTERIAL SKIN INFECTIONS

Corynebacteria are Gram-positive rods that account for nearly half of the cutaneous flora. A warm, moist local environment represents a risk factor for infection of the skin with non-diphtherial corynebacteria.

Erythrasma

Erythrasma is a superficial and often chronic skin infection caused by excessive proliferation of *Corynebacterium minutissimum* within the stratum corneum. The organism's growth is favored by moist, occluded intertriginous areas, including the groin, axillae, intergluteal fold, inframammary region, umbilicus, and web spaces between the toes. Other predisposing factors include a warm humid climate, poor hygiene, hyperhidrosis, obesity, diabetes mellitus, advanced age, and immunosuppression.

Lesions are pink to red, well-defined patches that are covered with fine scales and have associated wrinkling. With time, the red color fades to brown (Fig. 74.20A,C). The condition is asymptomatic or mildly pruritic. Interdigital erythrasma is the most common bacterial infection of the foot and the most frequent form of erythrasma. It presents as asymptomatic, chronic maceration with fissuring or scaling of interspaces. A "disciform" variant can occur in a more widespread distribution outside the usual intertriginous locations (Fig. 74.20D); this is occasionally the presenting manifestation of type 2 diabetes mellitus. Progression to cellulitis or bacteremia in immunocompromised patients has been reported.

When lesions are illuminated with a Wood's lamp, bright coral-red fluorescence appears as a result of porphyrin produced by the bacteria (Fig. 74.20B). Gram staining of the scale demonstrates Gram-positive filaments and rods, and *C. minutissimum* can be cultured on Tissue Culture Medium 199. The differential diagnosis of intertriginous erythrasma includes tinea, seborrheic dermatitis and cutaneous candidiasis, while interdigital erythrasma needs to be distinguished from tinea pedis and complex toe web infections[67].

Topical therapies include 20% aluminum chloride, clindamycin, erythromycin, mupirocin, fusidic acid, azole antifungals, and Whitfield ointment (salicylic and benzoic acids). Oral erythromycin, tetracyclines,

CLOSTRIDIAL ANAEROBIC CELLULITIS AND MYONECROSIS		
	Anaerobic cellulitis*	**Myonecrosis (gas gangrene)**
Risk factors (for both conditions)	Trauma (penetrating, "crush" injuries) or surgery, with improper/incomplete debridement or contamination of the wound Diabetes mellitus, peripheral vascular disease Injection drug use Colonic disease or malignancy (*C. septicum* myonecrosis)	
Organism†	*C. perfringens* > other anaerobic bacteria (e.g. *Bacteroides, Peptostreptococcus*, *Prevotella* spp.)	*C. perfringens* (~80%) > *C. novyi*, *C. septicum*
Incubation period	>3 days	12–24 hours
Course	Rapid	Very rapid
Exudate	Thin, dark gray–brown, foul-smelling ("dirty dishwater")	Thin, dark gray–brown, foul-smelling ("dirty dishwater")
Overlying skin changes	Minimal	Dark yellow to bronze discoloration, necrosis, bullae
Swelling	Minimal	Severe
Crepitus	Usually present (with abundant gas in subcutaneous tissues and along fascial planes)	Sometimes present
Pain	Absent or mild	Severe
Fever	Low-grade	Low-grade
Toxemia	Absent or mild	Present (e.g. tachycardia, hypotension, oliguria)
Bacteremia/laboratory findings	Usually absent/minimal	Bacteremia in ~15%; marked leukocytosis, hemolytic anemia
Treatment (for both conditions)	• Early, aggressive surgical debridement (repeated every 24–48 hours until clinical resolution) • The causative clostridial organisms are typically sensitive to penicillin; however, because the infections may be polymicrobial, broad-spectrum coverage (e.g. with clindamycin plus piperacillin–tazobactam or ticarcillin–clavulanate) is indicated until culture results are available • Adjunctive hyperbaric oxygen therapy	

*Can progress to myonecrosis.
†Infections may be polymicrobial, which can lead to overlap with necrotizing fasciitis.

Table 74.11 Clostridial anaerobic cellulitis and myonecrosis[139].

or single-dose clarithromycin can be used for widespread or recalcitrant cases. Use of antibacterial soaps may help to prevent recurrences[68,69].

Pitted Keratolysis

Synonyms: ■ Keratolysis plantare sulcatum ■ Ringed keratolysis

Introduction

Pitted keratolysis is a non-inflammatory bacterial infection of palmoplantar skin.

Epidemiology and pathogenesis

Pitted keratolysis occurs worldwide in temperate and tropical climates. Hyperhidrosis, prolonged occlusion, and increased skin surface pH are predisposing factors. Most infections are caused by *Kytococcus sedentarius* (formerly *Micrococcus sedentarius*), but other bacteria such as *Dermatophilus congolensis*, *Corynebacterium* spp., and *Actinomyces* spp. have been implicated. *K. sedentarius* produces two serine proteases (K1 and K2) that degrade keratin in the stratum corneum. Sulfur-containing compounds released by the bacteria lead to a characteristic associated malodor.

Clinical features

Small (1–7 mm), crater-like depressions are present within the stratum corneum on weight-bearing regions of the soles (Fig. 74.21) and rarely the palms. These pits may coalesce into large craters or rings of craters. There is usually no associated erythema, and the condition may go unnoticed by the patient or result in bothersome malodor[70].

Pathology

Well-defined "pits" extend approximately two-thirds of the way into the stratum corneum. Gram, PAS, and Gomori methenamine silver stains reveal bacteria in the walls and at the bottom of the craters. No inflammation is observed.

Diagnosis and differential diagnosis

The diagnosis of pitted keratolysis is usually clinical. There is no fluorescence on examination with a Wood's light. The differential diagnosis includes plantar warts, tinea pedis, palmoplantar punctate keratoderma, pits of basal cell nevus syndrome, Darier disease, and circumscribed palmoplantar hypokeratosis (see Table 58.7).

Treatment

Topical benzoyl peroxide, erythromycin, clindamycin, mupirocin, tetracycline, chlorhexidine, and azole antifungals have all been reported to lead to a rapid resolution of pitted keratolysis. Aluminum chloride 20% solution, topical glycopyrrolate, or (in recalcitrant cases) botulinum toxin can be used to treat associated hyperhidrosis[71,72].

Trichomycosis Axillaris, Pubis, and Capitis

Synonym: ■ Trichobacteriosis axillaris, pubis, and capitis

Trichomycosis is a superficial corynebacterial infection that results in concretions on the shafts of axillary and less often pubic hairs; occasionally scalp hairs in infants are affected. The hair shafts develop adherent yellow, red, or black nodules or cylindrical sheaths that can be seen with the naked eye (Fig. 74.22). There is a characteristic odor, and the sweat occasionally takes on a red color and stains clothing. However, like pitted keratolysis, the condition frequently goes unnoticed. Wood's lamp examination reveals a pale yellow fluorescence, and Gram staining of the concretions shows Gram-positive rods. The differential diagnosis includes white piedra, black piedra, nits, and hair casts (see Ch. 77). Shaving the affected hair provides an instant cure, and use of antimicrobial cleansers can prevent recurrences. Additional treatment options include benzoyl peroxide and topical erythromycin or clindamycin[73].

Cutaneous Diphtheria

Cutaneous diphtheria can be caused by both toxigenic (i.e. capable of producing systemic disease) and non-toxigenic strains of *Corynebacterium diphtheriae* and *Corynebacterium ulcerans*. It is endemic in some tropical countries and in several urban poor populations, e.g. in Vancouver, Latvia, Russia, and Ukraine[74], where it is spread by person-to-person contact in a highly contagious manner. *C. ulcerans* can also be transmitted by domestic animals. Development

Fig. 74.21 Pitted keratolysis of the plantar surface of the foot. Multiple small (**A**) and larger coalescing (**B**) craters with decreased stratum corneum that favor pressure points on the plantar surface. *Courtesy Kalman Watsky, MD.*

Fig. 74.22 Trichomycosis axillaris. Cylindrical sheaths and beading of the axillary hairs. A yellow color is seen most commonly.

Fig. 74.23 Ecthyma diphthericum. Punched-out ulcer with a black eschar on the upper lip. *Courtesy Joyce Rico, MD.*

of cutaneous diphtheria in non-endemic regions is typically related to travel, and European outbreaks have occurred in refugees from East Africa and the Middle East.

For children living in endemic regions, cutaneous diphtheria represents a form of immunization, as toxin is absorbed slowly from skin lesions and induces high levels of antibodies. In addition to children, elderly and immunocompromised individuals are most commonly affected, with predisposing factors including poor hygiene, injection drug use, and skin trauma. Vaccination prevents toxin-mediated manifestations but not bacterial infection or transmission.

Cutaneous diphtheria most commonly presents as an ulcer (*ecthyma diphthericum*) with a punched-out appearance and variable gray "pseudomembranous" eschar (Fig. 74.23). Acral sites are favored, and a pustule or crusted dermatitis may also be observed. Lesions are commonly co-infected with *S. aureus* or *Str. pyogenes*. Local lymphadenopathy and toxin-mediated complications, such as myocarditis and polyneuritis, are rare.

Gram stain of ulcer exudate and culture on specialized media can establish the diagnosis. The lab should be notified in suspected cases, as *Corynebacteria* otherwise may be reported as normal skin flora[75]. Toxigenicity can be assessed utilizing a modified Elek immunoprecipitation test, a rapid enzyme immunoassay, or PCR-based methods. Treatment includes a 10-day course of oral antibiotics, with erythromycin and penicillin representing first-line agents; additional measures include thorough cleansing of the wound site, application of a topical antibiotic, and (for toxigenic strains) intravenous diphtheria antitoxin. Contacts should be screened and asymptomatic carriers treated.

OTHER GRAM-POSITIVE SKIN INFECTIONS

Cutaneous Anthrax

Introduction and epidemiology

The name *Bacillus anthracis* is derived from the Greek word for coal, *anthrakis*, reflecting the black, coal-like eschars. *B. anthracis* is an aerobic, sporulating, Gram-positive rod measuring 1–1.5×3–5 microns. The bacterium causes disease in humans via three routes: inhalation, ingestion, and cutaneous inoculation. While the latter produces the least severe form of anthrax, it accounts for ~95% of infections. Anthrax is primarily a disease of animals (e.g. sheep, cows, horses, goats) that is endemic in parts of Africa and the Middle East. Most human cases are due to occupational exposure to infected animals or their carcasses, including hides and wool ("woolsorter's disease"). Two thousand cases are reported annually worldwide, with <10 per year in the US.

History

The fifth and sixth plagues of Egypt that are described in the book of Exodus are thought to have been anthrax. *B. anthracis* was the first bacterium proven to be the etiologic agent of a specific disease,

independently demonstrated by Dr. Robert Koch and Dr. Louis Pasteur. Anthrax was first used as a biologic weapon during World War I. Accidental release of anthrax from a biologic weapons complex in the Soviet Union in 1979 resulted in 68 fatalities. In 2001, anthrax spores were sent through the US mail as a terrorist weapon, resulting in 22 cases of inhalational or cutaneous anthrax and 5 fatalities[76].

Pathogenesis

Anthrax spores are environmentally hardy and can survive for decades in the soil. Full virulence requires the presence of an antiphagocytic capsule and three toxin components (protective antigen, lethal factor, and edema factor) that combine to form both lethal toxin and edema toxin. Edema toxin impairs neutrophil function and affects water homeostasis, leading to edema; lethal toxin causes release of TNF and IL-1β[77].

Clinical features

The clinical features of cutaneous anthrax are outlined in Table 74.12. Additional key points include the following:

- The lack of pain despite a necrotic eschar helps to differentiate cutaneous anthrax from the bite of a brown recluse spider.
- A pustular primary lesion is unlikely to be cutaneous anthrax, although "cloudy" vesicles may form a "pearly wreath" around the eschar. The term "malignant pustule", which is often attributed to anthrax, is therefore a misnomer.
- Vesicles may discharge serosanguineous fluid containing numerous organisms, which are evident on Gram stain.
- Lymphangitis and painful lymphadenopathy with systemic symptoms (fever, malaise, headache) occur rarely.
- Antibiotic therapy does not alter the progression from vesicle to ulcer to eschar, as the process is toxin-mediated.
- Multiple lesions, when present, tend to cluster in the same area of the body.
- Palpebral anthrax manifests with eyelid swelling and necrosis, often resulting in cicatricial ectropion[78].

Pathology

Spongiosis, papillary dermal edema, and a superficial and deep inflammatory infiltrate with abundant neutrophils are observed. Substantial hemorrhage is often evident, and the inflammatory infiltrate may involve nerves. Extensive ulceration and coagulative necrosis can be seen in older lesions. Elongated Gram-positive bacilli are present, often in small clusters. Spores grow readily on all routine culture media at 37°C, with a "jointed bamboo-rod" cellular appearance and a unique "curled-hair" colonial morphology.

Diagnosis and differential diagnosis

Gram staining of exudate or touch preparations can aid in rapid diagnosis. The organism grows in culture within 6–24 hours; however, antibiotic administration for more than 24 hours prevents the recovery of pathogens in culture.

Laboratory personnel must be alerted to the possibility of anthrax to ensure that the *Bacillus* isolate is not assumed to be *B. cereus* and that further speciation is performed. Definitive diagnosis of anthrax requires specific testing such as detection of lethal factor, PCR-based analysis, and immunohistochemical staining. Serologic assays can become positive as early as 10 days after onset of symptoms, with peak titers at 40 days.

The differential diagnosis includes cutaneous infection with *Bacillus megaterium*, a brown recluse spider bite, the eschar of several rickettsial diseases, cellulitis, ecthyma gangrenosum, orf, milker's nodule, opportunistic bacterial and fungal infections, and entities in the ulceroglandular category (e.g. tularemia; see below)[79].

CUTANEOUS ANTHRAX – CLINICAL CHARACTERISTICS
• Incubation period averages 7 days (range 1–12 days)
• Purpuric macule or papule develops in an exposed area (e.g. forearm, neck, chest, finger); the papule may resemble an insect bite and can be pruritic
• Within 48 hours of the lesion's appearance, a vesicle (1–3 mm) forms with surrounding non-pitting edema
• The central vesicle ulcerates and small vesicles may form around the ulcer
• The lesion becomes hemorrhagic and depressed, and a *painless*, black necrotic eschar forms centrally with an increase in the surrounding erythema and edema
• The eschar dries, loosens, and sloughs over the next 1–2 weeks, with no permanent scar

Table 74.12 Cutaneous anthrax – clinical characteristics. *Adapted from Carucci JA, McGovern TW, Norton SA, et al. Cutaneous anthrax management algorithm. J Am Acad Dermatol 2002;47:766–9.*

Treatment

Without antibiotic treatment, mortality from cutaneous anthrax may be as high as 20% (usually from septicemia), but that number falls to almost zero with proper antimicrobial therapy. Although antibiotics do not alter the evolution of the cutaneous lesions (which are toxin-mediated), the likelihood of systemic illness is reduced. When cutaneous anthrax is associated with a concomitant inhalational exposure, the Centers for Disease Control and Prevention (CDC) recommend antibiotic therapy for at least 60 days, compared to a 7- to 10-day course for a purely cutaneous exposure to an animal-based source. Quinolones and doxycycline are first-line agents, with clindamycin and (if susceptible) penicillin or amoxicillin as alternatives[77].

An anthrax vaccine, consisting of an inactivated cell-free filtrate of a non-encapsulated, attenuated strain of *B. anthracis*, is available. The recommended five-dose pre-exposure series includes administration at 0, 1, 6, 12, and 18 months, followed by yearly boosters. For post-exposure prophylaxis, three vaccine doses can be given at 0, 2, and 4 weeks together with antimicrobial treatment. Raxibacumab and obiltoxaximab are recombinant human immunoglobulin monoclonal antibodies targeting the *B. anthracis* protective antigen. Either of these antibodies or polyclonal anthrax immune globulin may be administered as a single intravenous infusion (in conjunction with antibiotics) for the treatment and post-exposure prophylaxis of inhalational anthrax.

Bacillus cereus Infection

Bacillus cereus is a large Gram-positive rod best known for causing food poisoning. However, it can produce primary cutaneous disease in immunocompetent and immunosuppressed patients as well as pneumonia, meningitis, and necrotizing fasciitis in immunocompromised individuals. An outbreak of skin infections in neonates due to contamination of equipment used during delivery has been reported[80]. Skin infection typically presents as a single necrotic bulla, which may occur in association with high fevers and negative blood cultures in neutropenic individuals. Vancomycin is considered the drug of choice, but quinolones and imipenem may also be used.

Erysipeloid

Synonyms: ■ Diamond skin disease ■ Erysipeloid of Rosenbach (localized cutaneous form) ■ Pseudoerysipelas

Erysipeloid is an acute cutaneous infection caused by *Erysipelothrix rhusiopathiae* (formerly *insidiosa*), a Gram-positive, non-motile, smooth or curved bacillus. It is caused by traumatic inoculation of the organism into the skin, which most often occurs in fishermen or persons who prepare meat, poultry, or fish. It has also been reported following animal bites[81]. There are two types of erysipeloid, localized and generalized, and they usually occur within 1 week of inoculation. The *localized form* is characterized by an erythematous to violaceous area of non-suppurative cellulitis (Fig. 74.24), which can be pruritic or painful. Hemorrhagic vesicles may develop. Although the classic finding is involvement of the finger webs with sparing of the terminal phalanges, other sites may be affected. Constitutional symptoms are unusual in localized erysipeloid, which is typically a self-limited condition. However, the *generalized form* presents with fever and arthralgias in addition to widespread cutaneous lesions. The latter range from perifollicular papules to erythematous plaques to macular purpura and necrosis. Complications can include bacteremia, endocarditis, septic arthritis, and cerebral and other visceral abscesses. The organism is often difficult to culture, and PCR-based assays can help to establish the diagnosis[82]. Erysipelas, cellulitis, spider bites, and fixed drug eruptions may simulate localized erysipeloid (see

Table 74.10). Most patients with untreated localized disease recover spontaneously. Penicillin is the drug of choice; erythromycin, cephalosporins, clindamycin, linezolid, and quinolones are alternatives. The best means of prevention is using gloves when preparing fish or meat.

Listeriosis

Listeria monocytogenes is a motile Gram-positive bacillus that represents a common veterinary (e.g. cattle, sheep) and zoonotic pathogen. Infection is usually acquired by eating contaminated food (e.g. soft cheeses, ice cream). Listeriosis primarily affects the elderly, pregnant women, and immunocompromised individuals. Manifestations include meningitis and gastroenteritis accompanied by fever, myalgias, and bacteremia. Pregnant women are at risk of miscarriage, stillbirth, and premature delivery. Neonatal septicemia and meningitis due to vertical transmission can occur and may be associated with disseminated vesiculopustules, purpura, or granulomatous papules and nodules (*"granulomatosis infantiseptica"*)[83]. Primary cutaneous listeriosis can present as grouped papulopustules, an abscess, or cellulitis. Transmission may occur via skin exposure to bovine products of conception in veterinarians and farmers, but this has decreased in recent years due to safer occupational practices[83]. In otherwise healthy individuals, primary cutaneous listeriosis may be self-limited. The first-line treatment for listeriosis is ampicillin, and TMP-SMX represents an alternative; *L. monocytogenes* is resistant to cephalosporins.

Fig. 74.24 Erysipeloid. Erythema and edema with vesicle formation on the hand and fifth digit.

GRAM-NEGATIVE BACTERIA

Table 74.13 outlines selected Gram-negative infections that present with systemic symptoms (e.g. fever) and skin findings.

NEISSERIA MENINGITIDIS

Acute and Chronic Meningococcemia

Introduction

Meningococcemia is characterized by fever and a petechial eruption, and it has acute and chronic forms. The causative organism, *Neisseria meningitidis*, is an aerobic Gram-negative diplococcus.

Epidemiology and pathogenesis

Meningococcal infections occur worldwide and affect primarily infants (6 months to 1 year), adolescents, and young adults. There is a male predominance, with a male : female ratio of 3–4 : 1. Most cases develop in the winter and spring. Risk factors include HIV infection and asplenia; deficiencies in complement component C3 (which may be associated with partial lipodystrophy), terminal complement components (C5–C9), properdin, factor D or H, and immunoglobulins (see Ch. 60)[84]; and treatment with terminal complement inhibitors (e.g. eculizumab, ravulizumab) and potentially TNF inhibitors. In addition, there is evidence that patients with low TNF production, high IL-10 or plasminogen activator inhibitor 1 production, or homozygosity of certain alleles at the IL-1 locus are at increased risk of a fatal outcome[85,86].

Thirteen clinically significant *N. meningitidis* serogroups are distinguished by their capsular polysaccharide virulence factors. Serogroups A, B, C, X, Y, and W-135 are most often implicated in human disease. Proliferation of *N. meningitidis* in contact with host cells increases the production of a bacterial transferase that adds phosphoglycerol onto its type IV pili; this modification results in bacterial detachment and

UNCOMMON GRAM-NEGATIVE INFECTIONS THAT PRESENT WITH FEVER AND SKIN FINDINGS

Infection	Common organism(s)	Transmission/other factors	Skin findings and other characteristic features
Infection with *Vibrio vulnificus*	*Vibrio vulnificus*	See Table 74.16	• Hemorrhagic bullae with cellulitis
Tularemia	*Francisella tularensis*	Infected rabbits; deer fly or tick (e.g. *Amblyomma americanum*) as vector	• Ulcers associated with lymphadenopathy • May show sporotrichoid pattern
Glanders	*Burkholderia mallei*	Direct contact with infected animals (horses, mules, donkeys)	• Nodule, pustule, or vesicle surrounded by erythema • Sporotrichoid pattern
Plague	*Yersinia pestis*	Contaminated food or water; fleas can be the vector	• Bubonic form due to inoculation: pustule or ulcer with painful regional lymphadenopathy; may have a sporotrichoid pattern • Septicemic form: emboli can present as vesicles, petechiae/purpura, or abscesses
Melioidosis	*Burkholderia pseudomallei*	Contact with contaminated soil or water; ingestion or inhalation; sexual intercourse; fleas can be the vector	• Abscesses, granulomatous lesions, purpura, pustules, urticaria, ecthyma gangrenosum
Rat-bite fever (Haverhill fever)	*Streptobacillus moniliformis* > *Spirillum minus*	Close contact with infected rodents or contaminated food, water, or raw milk (Haverhill fever)	• Acral palmoplantar eruption of macules, papules, petechiae, vesicles, pustules, and/or crusts • Migratory polyarthritis mimicking rheumatoid arthritis in 50% of patients
Brucellosis	*Brucella abortus*	Consumption of unpasteurized milk products	• Malodorous perspiration • Erythema nodosum • Vasculitis
Typhoid fever	*Salmonella typhi*	Contact with infected persons	• Rose spots: 2–8 mm pink, blanching papules, often in clusters of 5–15 on the anterior trunk • Erythema multiforme, Sweet syndrome, hemorrhagic bullae, pustules

Table 74.13 Uncommon Gram-negative infections that present with fever and skin findings. Next-generation sequencing assays are available to detect microbial cell-free DNA from >1000 infectious organisms in a peripheral blood sample, which may help to diagnose systemic infections with cutaneous manifestations.

migration across the epithelium, a prerequisite for dissemination and invasive disease[87]. The bacteria elaborate an endotoxin that triggers inflammatory processes leading to shock, multi-organ failure, and purpura fulminans.

The only known reservoir is the human nasopharynx. Rates of asymptomatic carriage in the US range from 5% to 15%[88]. Transmission is by the respiratory route, with an incubation period of 2–10 days. Active or passive exposure to tobacco smoke, as well as concurrent viral infection of the upper respiratory tract, disrupts the integrity of the respiratory mucosa, thereby increasing the risk of invasive meningococcal disease.

Clinical features

Infection with *N. meningitidis* most often results in an asymptomatic carrier state, which leads to lifelong immunity against that subgroup. Upper respiratory symptoms as well as bacteremia without sepsis may also occur. When acute meningococcemia develops, one-third to one-half of patients present with a petechial eruption, typically in association with a fever, chills, myalgias, and headache. Retiform purpura and ischemic necrosis may follow (Fig. 74.25). Bullous hemorrhagic lesions occasionally arise, most commonly on the trunk and lower extremities. In a minority of patients, only a transient, blanchable morbilliform eruption is seen. Hypotension, meningitis, meningoencephalitis, pneumonia, arthritis, pericarditis, myocarditis, and progression to disseminated intravascular coagulation (DIC) can develop.

Chronic meningococcemia comprises less than 5% of invasive meningococcal disease cases and is defined by blood cultures positive for *N. meningitidis* and symptom duration >7 days, without either meningitis or shock. Typical symptoms include recurrent fevers, migratory arthralgias, and the development of polymorphous erythematous macules and papules 12–24 hours after the onset of fevers. The skin lesions may develop into tender nodules with indistinct borders. Petechiae, retiform purpura, pustules, and erythema multiforme-like lesions have also been described. The fever and rash of chronic meningococcemia tend to resolve concurrently and then recur within 2–10 days[89].

Pathology

Biopsy specimens from patients with acute meningococcemia show leukocytoclastic vasculitis and thrombosis; organisms can be visualized with Gram stain in 70% of cases. In chronic meningococcemia, a perivascular infiltrate composed of lymphocytes and a few neutrophils can be appreciated; leukocytoclastic vasculitis may be seen in petechial lesions, and Gram or silver staining is often negative.

Diagnosis and differential diagnosis

The initial diagnosis is often clinical. Time is of the essence in diagnosing patients with meningococcemia and initiating treatment, as rapid decompensation occurs in acute infections. Culture of *N. meningitidis* from the skin or a normally sterile body fluid (e.g. blood, cerebrospinal fluid [CSF], synovial fluid) can establish the diagnosis; however, the sensitivity may be low, especially after administration of antibiotics. Latex agglutination tests that detect group A, B, C, Y, and W-135 antigens in the CSF and urine have good specificity but low sensitivity. PCR-based assays are also specific and have better sensitivity, which may be higher in skin biopsy specimens than blood or CSF samples, but bacterial culture is still necessary for susceptibility testing[90].

Fig. 74.25 Acute meningococcemia. Purpura with irregular outline and central gunmetal gray color. *Courtesy Kalman Watsky, MD.*

Acute meningococcemia must be differentiated from enteroviral infections (which can present with meningitis and a petechial exanthem), Rocky Mountain spotted fever, septic vasculitis due to acute bacteremia and endocarditis, TSS, purpura fulminans, leptospirosis, and various non-infectious vasculitides. The differential diagnosis of chronic meningococcemia includes bacterial endocarditis, Sweet syndrome, Henoch–Schönlein purpura, rat-bite fever, erythema multiforme, and chronic gonococcemia. The rash and arthralgias associated with chronic meningococcemia must not be confused with inflammatory diseases, as administration of corticosteroids or other immunosuppressive medications could provoke progression of the infection.

Treatment

While early institution of appropriate therapy for acute meningococcemia is essential, if possible, blood and CSF samples should be obtained prior to antibiotic administration. A third-generation cephalosporin is the recommended treatment for suspected (e.g. Gram stain with Gram-negative diplococci) or culture-proven acute meningococcemia prior to obtaining susceptibility results. Chloramphenicol and quinolones are alternatives in patients with a history of immediate-type hypersensitivity to penicillins, although quinolone-resistant strains have been reported[91]. Chronic meningococcemia is treated with similar antibiotics. All close contacts should receive prophylactic treatment with ciprofloxacin, rifampin, or ceftriaxone. Experimental therapies that have been tried in small numbers of patients include activated protein C, anti-endotoxin monoclonal antibodies, tissue plasminogen activator, antithrombin III infusion, topical nitroglycerin, plasmapheresis, and extracorporeal membrane oxygenation[92]. To date, these interventions have not proven to be effective in decreasing mortality.

Several meningococcal vaccines are approved for use in the US: three quadrivalent vaccines effective against serogroups A, C, W, and Y; a bivalent vaccine effective against serogroups C and Y plus *H. influenzae* type b; and two monovalent vaccines effective against serogroup B. The duration of immunity for these vaccines is ~3–5 years. A quadrivalent conjugated vaccine is routinely given to children at age 11–12 years with a booster at age 16 years; this vaccine is also administered to other individuals at high risk for infection, such as college students living in dormitories and military recruits, as well as patients ≥2 months of age at increased risk of severe meningococcal infection due to conditions such as complement deficiencies and asplenia. The monovalent serogroup B vaccine is recommended for patients ≥10 years of age in the latter high-risk group; in addition, it is offered to teens, preferably at age 16–18 years.

PSEUDOMONAS AERUGINOSA

Pseudomonas aeruginosa is a ubiquitous Gram-negative, strictly aerobic, motile bacillus. It is widely distributed in the soil and on plants, growing especially well in aqueous environments. This organism has relatively low virulence and usually requires a local anatomic or immunologic defect to cause disease. Primary cutaneous infection with *P. aeruginosa* can occur in otherwise healthy individuals in areas exposed to high levels of moisture in conjunction with skin barrier disruption; these infections have a very good prognosis. In contrast, cutaneous manifestations of *Pseudomonas* sepsis in immunocompromised individuals are associated with a grave prognosis.

Green Nail Syndrome

In green nail syndrome (chloronychia), green–blue to green–black discoloration of the nail develops due to pyocyanin, a blue–green pigment produced by *P. aeruginosa* (Fig. 74.26). There is typically associated distal onycholysis and sometimes proximal chronic paronychia. Predisposing factors include frequent or prolonged exposure to water, excessive use of detergents and soaps, nail trauma, onychomycosis[93], and other causes of onycholysis (see Ch. 71). The diagnosis of green nail syndrome is usually clinical; if necessary, it can be confirmed by Gram stain and culture of exudate and nail fragments. The differential diagnosis includes a subungual hematoma, melanocytic nevus, melanoma, and *Aspergillus* infection. Treatment involves avoidance of

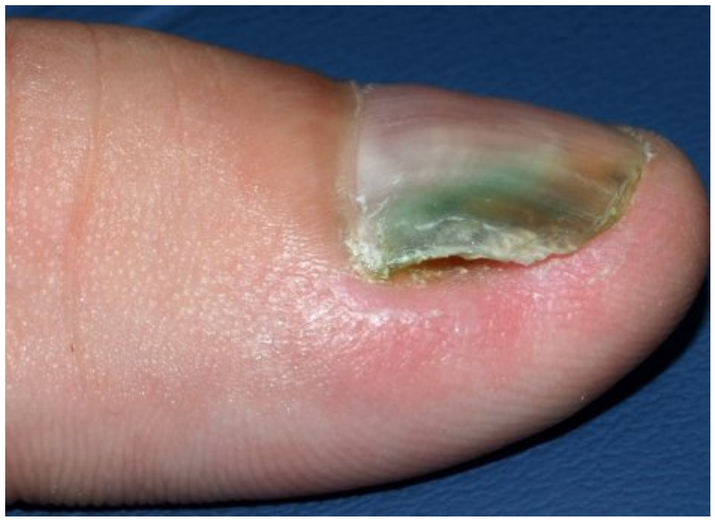

Fig. 74.26 Green nail syndrome. Blue–green discoloration of the nail due to pyocyanin produced by *Pseudomonas aeruginosa*. Note the associated onycholysis. *Courtesy Julie V. Schaffer, MD.*

Fig. 74.27 Superficial infection of the skin with *Pseudomonas*. Note the maceration, erosions, and moth-eaten appearance of the skin. *Courtesy Kalman Watsky, MD.*

predisposing factors, clipping the nail, and topical application of 2% sodium hypochlorite (household bleach diluted 1:4; see Ch. 71), a quinolone, or aminoglycoside (e.g. tobramycin) solution for 1–4 months. Treatment of coexistent onychomycosis may help prevent recurrence. In refractory cases, removal of the affected nail may be required.

Pseudomonal Pyoderma and Blastomycosis-Like Pyoderma

Pseudomonal pyoderma is a superficial infection of the skin with *P. aeruginosa*. Features include a blue–green purulence, a "grape juice-like" or "mousy" odor, and a moth-eaten appearance of the skin. The borders are often macerated and eroded (Fig. 74.27). Pseudomonal pyoderma can complicate burns, decubitus ulcers, and other chronic cutaneous ulcers. Pseudomonal pyoderma often plays a role in Gram-negative toe web infections and in "infectious eczematoid dermatitis" on the hands and feet or in the anogenital region[94].

Blastomycosis-like pyoderma is a rare reactive condition that occurs in the setting of a long-standing localized infection, presenting as large verrucous plaques with multiple pustules and elevated borders. Histologic examination reveals pseudoepitheliomatous hyperplasia with intraepidermal abscess formation; fungi are not seen, and fungal cultures are negative. This condition usually occurs in immunocompromised patients, and other bacteria (e.g. *S. aureus*) have also been implicated.

Treatment of these conditions includes systemic antipseudomonal antibiotics, topical antimicrobial and drying agents, and debridement of the hyperkeratotic rim in web space infections. Additional treatment options for blastomycosis-like pyoderma include acitretin, saturated solution of potassium iodide, surgical excision, electrodesiccation and curettage, and ablative laser therapy[95].

Otitis Externa and Necrotizing (Malignant) Otitis Externa

P. aeruginosa colonizes 1%–2% of normal ear canals. However, pseudomonal infection can result in otitis externa ("swimmer's ear"). Predisposing factors include eczema and psoriasis of the ear, swimming, mechanical trauma, hearing-aid use, and ear irrigation. In this condition, the external auditory canal is swollen and macerated with a green, purulent discharge. The tympanic membrane is uninvolved, and manipulation of the pinna results in extreme pain. An exudative dermatitis of the external ear and retroauricular area may also be present. Treatment includes removal of canal debris, antibiotic eardrops (preferably those that cover *S. aureus* co-infection), and possibly the instillation of a cotton wick. Oral therapy is only occasionally required, but recurrences can occur[96].

Necrotizing (malignant) otitis externa refers to infection that progresses to affect the temporal bone and adjacent structures. It is seen most often in elderly diabetic patients and those with HIV infection or other immunodeficiencies. Manifestations include severe pain, persistent drainage, and granulation tissue within the ear canal. Local lymphadenopathy and parotid swelling may be present. Deeper invasion can result in osteomyelitis of the skull, nerve palsies, mastoiditis, sepsis, and sigmoid sinus thrombosis. Treatment includes extended courses of intravenous antipseudomonal penicillins or cephalosporins as well as oral ciprofloxacin; surgical intervention may be required.

Auricular chondritis secondary to *Pseudomonas* spp. has been associated with piercing of the cartilaginous portion of the pinna[97].

Pseudomonal Folliculitis

Pseudomonal folliculitis ("hot tub folliculitis") is associated with the use of whirlpools, hot tubs, and (less often) swimming pools with low chlorine levels; transmission from fomites such as nylon bath towels and rubber gloves has also been reported. Erythematous, edematous perifollicular papules and papulopustules arise 8–48 hours after exposure and resolve spontaneously in 7–14 days (see Ch. 38). The lesions frequently occur in sites covered by bathing suits, and the face and neck are usually spared. Associated symptoms (which do not reflect systemic spread of *P. aeruginosa*) may include pruritus, painful eyes, earaches, a sore throat, headache, fever, painful swollen breasts, malaise, rhinorrhea, nausea, vomiting, and abdominal pain.

The diagnosis can be confirmed by isolation of *P. aeruginosa*, especially serotype O-11, from lesions. The differential diagnosis includes other forms of folliculitis (e.g. due to *S. aureus*) and papular urticaria. Treatment is generally not indicated in immunocompetent hosts, as it is usually a self-limited process. Warm compresses with 2% acetic acid and application of topical polymyxin B or gentamicin may be of benefit. In the case of widespread eruptions, recurrences, an immunosuppressed host, or associated systemic symptoms, an oral quinolone can be used[98].

Pseudomonas Hot-Foot Syndrome

Pseudomonas hot-foot syndrome occurs after swimming or wading in pool water that contains high concentrations of *P. aeruginosa*. The soles may be diffusely erythematous, and extremely painful, red-to-purple, 1–2 cm nodules develop on weight-bearing surfaces (Fig. 74.28); palmar involvement occasionally occurs. Systemic symptoms are uncommon.

Fig. 74.28 Pseudomonas hot-foot syndrome. Tender erythematous nodules on the heel. *Courtesy Justin J. Green, MD.*

Histologic examination of the nodules shows perivascular and periecrine neutrophilic infiltrates with microabscess formation. The condition is self-limiting and requires only symptomatic treatment. Idiopathic palmoplantar hidradenitis (see Ch. 39) has identical clinical features and may be pathogenically related to pseudomonas hot-foot syndrome. Additional diagnostic considerations may include pernio, symmetric lividities, and erythema nodosum[99].

Ecthyma Gangrenosum

Ecthyma gangrenosum represents an infectious vasculitis that causes skin necrosis. The most common clinical scenario is *Pseudomonas* bacteremia in a neutropenic patient. However, it may also occur in previously healthy individuals, sometimes as the initial presentation of immunodeficiency (e.g. X-linked agammaglobulinemia in young boys; see Ch. 60). Clinically identical lesions can result from other bacteria (e.g. *E. coli, Klebsiella pneumoniae, Aeromonas, Stenotrophomonas, Citrobacter, S. aureus)* or fungi (*Candida, Mucor, Fusarium, Scytalidium, Aspergillus*). Although ecthyma gangrenosum usually occurs in the setting of bacteremia (or fungemia), a localized anogenital form without identifiable bacteremia has also been described.

Lesions are usually few in number and begin as erythematous or purpuric macules, most commonly located in the anogenital area or on the lower extremities. They then evolve into hemorrhagic vesicles or bullae, which rupture and become necrotic ulcers with a central black eschar. The surrounding tissue is erythematous and tender (Fig. 74.29).

Histologic examination shows a necrotizing hemorrhagic vasculitis, and Gram-negative rods or other causative organisms can be seen in the medial and adventitial walls of deeper vessels. The intima is characteristically spared. Multiple lesions, prolonged neutropenia, and a delay in antibiotic treatment portend a poor prognosis. Once the diagnosis is suspected, biopsy and tissue culture of a skin lesion (as well as blood and urine cultures) should be performed, followed by prompt initiation of intravenous therapy (e.g. with an aminoglycoside and an antipseudomonal penicillin). Surgical debridement is often necessary[100]. Ecthyma gangrenosum in a previously healthy patient should prompt a search for an underlying immunocompromised state.

BARTONELLA

Bartonella are small, pleomorphic, facultative intracellular Gram-negative bacilli (closely related to *Brucella*) that are capable of infecting erythrocytes and endothelial cells. Although there are >30 known species of *Bartonella*, *B. henselae* (cat scratch disease), *B. quintana* (trench fever), and *B. bacilliformis* (Carrion disease) represent the three major human pathogens. Both *B. henselae* and *B. quintana* also cause bacillary angiomatosis and endocarditis. Transmission occurs via close contact between animals and humans, arthropod vectors, and possibly blood transfusions. Depending on factors such as the immune status of the infected individual, a particular *Bartonella* species can cause either acute or chronic infection and manifestations ranging from vascular proliferation to suppuration[101,102]. There is no therapeutic regimen that guarantees eradication of *Bartonella*.

Fig. 74.29 Ecthyma gangrenosum. Embolic lesion of *Pseudomonas aeruginosa* on the chest. Note the necrotic center and inflammatory border.

Bartonellosis

Synonyms: ■ Carrion disease ■ Oroya fever ■ Verruga peruana

Introduction

Bartonellosis is a potentially life-threatening biphasic infection caused by *Bartonella bacilliformis*. Two distinct clinical forms may occur independently or sequentially: (1) Oroya fever, an acute febrile disease with associated hemolytic anemia and transient immunodeficiency; and (2) verruga peruana (Peruvian wart), a chronic disease characterized by cutaneous vasoproliferative lesions.

History

The biphasic nature of bartonellosis was first described in 1540 by Miguel de Steta. In 1885, a Peruvian medical student, Daniel Carrion, died of complications of Oroya fever after inoculating himself with blood derived from a lesion of verruga peruana, proving a common causality for the two disease states[103].

Epidemiology and pathogenesis

The disease is transmitted by the bite of female Phlebotomine sand flies (*Lutzomyia verrucarum*). It occurs in mountain valleys of Peru, Ecuador, and southwestern Colombia, where the vector resides. There is no racial, sex, or age predilection, but the disease tends to be milder in children than in adults. The incubation period varies between 3 and 14 weeks.

Clinical features

The onset of *Oroya fever* is often sudden, with dyspnea, weakness, pallor, tachycardia, fever, thirst, anorexia, arthralgias, and headache. A precipitous drop in hemoglobin may occur secondary to invasion of erythrocytes, and hyperbilirubinemia and hemoglobinuria can result. After the initial septicemia, a variable degree of immunodeficiency ensues. During this phase, a third of patients develop secondary bacterial infections; when death occurs, it is often secondary to an enteropathic bacterial infection, especially *Salmonella enterica*. Lymphadenopathy, splenomegaly, and megaloblastic hyperplasia of the bone marrow are seen in severe cases. Patients with Oroya fever usually require 8–10 weeks for full recovery.

Most patients who recover from Oroya fever develop cutaneous nodules during or after their convalescent period, but *verruga peruana* can also appear in previously asymptomatic individuals and in those

treated with antibiotics for acute infection. Bright red papules and nodules measuring 2 mm to several centimeters in diameter appear within small erythematous patches. Lesions may be sessile or pedunculated and are usually located on the head and extremities. Hemorrhage, ulceration, and secondary bacterial infection can occur. In the absence of complications, lesions usually heal without scarring but may recur and serve as a reservoir for further transmission[104].

Pathology

The histologic features of verruga peruana vary and can resemble those of a pyogenic granuloma or Kaposi sarcoma. Masses of intracytoplasmic *Bartonella* organisms (Rocha–Lima inclusions) are present within swollen endothelial cells as well as in red blood cells; the bacilli are also found extracellularly. Thrombosis and occlusion of vessels occurs.

Diagnosis and differential diagnosis

The presence of organisms within red blood cells or within the cytoplasm of endothelial cells is diagnostic. *B. bacilliformis* can be isolated from blood cultures; immunologic testing (e.g. ELISA, immunoblot) and PCR-based assays for blood or tissue samples are also available[105]. The differential diagnosis of verruga peruana includes multiple pyogenic granulomas, bacillary angiomatosis, warts, molluscum contagiosum, and yaws.

Treatment

Table 74.14 outlines the treatment recommendations for bartonellosis.

Cat Scratch Disease

Synonyms: ■ Cat scratch fever ■ Subacute regional lymphadenitis ■ Inoculation lymphoreticulosis ■ English–Wear infection

Introduction

Cat scratch disease (CSD) is caused by infection with *Bartonella henselae*. In immunocompetent hosts, it is a benign, self-limited illness characterized by tender regional lymphadenitis that lasts for weeks to months. Over 90% of patients report a recent scratch and/or bite from a cat.

Epidemiology and pathogenesis

CSD occurs worldwide, and ~12 500 cases are diagnosed annually in the US[106]. Exposure to cats is the primary factor for CSD. Although flea-vectored transmission to humans has not been documented, it could explain some cases in which there is no history of exposure to cats.

Clinical features

CSD is a common cause of persistent lymphadenopathy (>3–4 weeks) in children and adolescents. Lymphadenopathy usually presents 2–4 weeks after a scratch and can last 2–6 months, or even longer if fibrosis occurs. A single, large (1–10 cm), tender, mobile lymph node, with erythema and swelling of the overlying skin, is most often noted in the axilla. Suppuration occurs in only 10%–25% of patients. A skin lesion (e.g. a red or crusted pustule) develops at the inoculation site in most patients. Other skin findings can include a morbilliform eruption, erythema multiforme, granuloma annulare, and erythema nodosum[107].

Although most patients are otherwise well, the lymphadenopathy can be accompanied by fevers, malaise, fatigue, weakness, and headaches. Additional manifestations such as encephalopathy, hepatic granulomas, osteomyelitis, and pulmonary involvement develop in up to 15% of patients. The oculoglandular syndrome of Parinaud – unilateral conjunctivitis and ipsilateral preauricular lymphadenopathy – occurs in ~5% of individuals with CSD. Immunosuppressed patients (e.g. those with HIV infection) are prone to a more severe and complicated disease course.

Pathology

Affected lymph nodes display central necrosis surrounded by histiocytic and epithelioid cells with an inner palisading layer. Giant cells with a peripheral zone of lymphoid cells are also evident. The primary skin lesion can show similar changes, albeit less well developed. The Warthin–Starry silver stain demonstrates bacilli within areas of necrosis.

Diagnosis and differential diagnosis

For patients who present with regional adenopathy and a history of a recent cat scratch, the diagnosis is usually made clinically. A sensitive and specific assay for *B. henselae* antibodies is available, and antibody titers are usually high during the first few weeks after the onset of lymphadenopathy; PCR-based testing can also be performed. Culture is difficult and not routinely recommended. Other causes of lymphadenopathy such as infections (bacterial, fungal, or viral), reactive hyperplasia, drug reactions, or malignancy can be excluded by fine-needle aspiration histology or biopsy and culture of lymph node tissue.

Treatment

Table 74.14 outlines current recommendations for the treatment of CSD.

Bacillary Angiomatosis

Synonyms: ■ Epithelioid angiomatosis ■ Disseminated cat scratch disease

Introduction

Bacillary angiomatosis is caused by infection with *B. henselae* or *B. quintana*. Vascular proliferation is the predominant feature of this condition, which most often affects HIV-infected individuals.

History

The disorder was first described in 1983 as subcutaneous vascular proliferations in individuals with AIDS. Electron microscopy and Warthin–Starry-stained sections of the lesions revealed small bacilli. In 1989, LeBoit and colleagues coined the name "bacillary angiomatosis" and proposed histologic criteria for the disorder. In the early 1990s, *Rochalimaea quintana* and *R. henselae* (subsequently reclassified in the genus *Bartonella*) were recognized as the causes of bacillary angiomatosis (see Table 74.14).

Epidemiology and pathogenesis

Bacillary angiomatosis is an uncommon disease that is most often seen in HIV-infected patients when their $CD4^+$ count is <200 cells/mcl (see Ch. 78). Fortunately, with the advent of effective antiretroviral therapy (ART), the prevalence of bacillary angiomatosis has decreased substantially. The associated vascular proliferation may reflect aberrant vascular endothelial growth factor (VEGF) signaling in endothelial cells[108]. Only 20% of patients with bacillary angiomatosis due to *B. henselae* report a preceding cat scratch or bite, compared to 90% of those with CSD.

Clinical features

Cutaneous lesions of bacillary angiomatosis may present as superficial angiomatous papules and nodules, violaceous lichenoid plaques, or deep subcutaneous nodules. The papules and nodules resemble pyogenic granulomas (Fig. 74.30A) and may be smooth-surfaced, pedunculated, or surrounded by a collarette of scale. These lesions may display central umbilication, crusting, or ulceration. Subcutaneous nodules are often several centimeters in diameter and skin-colored; overlying erosions or ulcerations may develop. Less commonly, bacillary angiomatosis presents as a cellulitic erythematous plaque that can involve the underlying bone. The host immune status largely determines the number and distribution of the lesions. Immunocompetent patients may have a single lesion at the site of inoculation, whereas the entire cutaneous surface can be affected in those who are severely immunocompromised.

Extracutaneous bacillary angiomatosis may occur with or without cutaneous disease and can affect any organ. Bacillary peliosis hepatis caused by *B. henselae* (but not *B. quintana*) presents with nausea, vomiting, diarrhea, abdominal pain, hepatosplenomegaly, and elevated liver enzymes. Bacillary peliosis splenis may lead to pancytopenia and require splenectomy. Patients can also present with malaise and night sweats.

Pathology

Biopsy specimens reveal lobular proliferations of capillaries and venules, plump and protuberant endothelial cells, and a marked neutrophilic infiltrate with evidence of leukocytoclasis throughout the interstitium

MAJOR HUMAN DISEASES CAUSED BY *BARTONELLA* SPECIES AND THEIR TREATMENT				
Species	**Disease**	**Vector**	**Reservoir/host**	**Epidemiology**
B. bacilliformis	Bartonellosis (Carrion disease, Oroya fever, verruga peruana)	Phlebotomine sand fly (*Lutzomyia verrucarum*)	Human	• Andean mountain valley regions of Peru, Ecuador, and southwestern Colombia (altitudes of 2500–8000 feet) • More common in immunologically naive tourists and transient workers • Milder in children
B. henselae	Cat scratch disease	Cat flea (*Ctenocephalides felis*)	Cat	• Primarily seen in young people (<18 years) in the fall and winter • Immunocompetent > immunocompromised
	Bacillary angiomatosis			• Immunocompromised (e.g. common in HIV)
	Bacillary peliosis hepatis			• Immunocompromised
	Bacteremia (chronic afebrile)		*(Cat exposure not a risk factor in bacteremia)*	• Immunocompetent or immunocompromised
	Endocarditis			• Late complication of chronic bacteremia
B. quintana	Trench fever "Five day fever" "Urban trench fever" "Quintan fever"	Human body louse (*Pediculosis humanus*)	Human	• First reported in troops, now seen with homelessness and poor hygiene ("urban trench fever")
	Bacillary angiomatosis			• Immunocompromised (e.g. common in HIV)
	Bacteremia (chronic afebrile)			• Immunocompetent or immunocompromised
	Endocarditis			• Late complication of chronic bacteremia
*Gray baby syndrome can develop in premature neonates who receive chloramphenicol.				

Table 74.14 Major human diseases caused by *Bartonella* species and their treatment. Fever and splenomegaly due to bacteremia with *Bartonella rochalimae* (a recently recognized species) has also been described.

(Fig. 74.30B). In H&E-stained sections, interstitial clumps of bacilli appear as purplish granular material. Bacteria can be readily identified with a Warthin–Starry stain (see Fig. 74.30B, inset).

Diagnosis and differential diagnosis

PCR-based assays are a rapid and sensitive method to identify *Bartonella* from tissue specimens. Culture of *B. henselae* or *B. quintana* on chocolate or supplemented agar may take 20 to 40 days. Testing to detect antibodies against *B. henselae* (but not *B. quintana*) is sensitive and specific.

The clinical differential diagnosis includes pyogenic granulomas, Kaposi sarcoma, cherry angiomas, angiokeratomas, verruga peruana, and a disseminated non-tuberculous mycobacterial infection. Histologically, bacillary angiomatosis can be confused with verruga peruana, Kaposi sarcoma, pyogenic granuloma, and angiosarcoma.

Treatment

Cutaneous lesions begin to improve within 1 week of appropriate antibiotic therapy and resolve completely within 4 weeks. At least 3 months of treatment is recommended, as therapeutic failures and relapses can occur with shorter courses. Immunosuppressed patients with disease relapses may require maintenance therapy. Surgical excision of solitary cutaneous lesions, although effective, is usually not necessary. Table 74.14 outlines treatment recommendations for bacillary angiomatosis.

OTHER GRAM-NEGATIVE SKIN INFECTIONS

Brucellosis

Synonyms: ■ Undulant fever ■ Malta fever ■ Bang disease

Brucellosis is a chronic granulomatous disease caused by *Brucella*, a genus of Gram-negative coccobacilli. It is the most common zoonosis worldwide, with >500 000 cases annually. Endemic regions include the Middle East, Mediterranean basin, Central Asia, and Indian subcontinent. Transmission occurs through the consumption of contaminated unpasteurized milk products (commonly raw goat's milk and cheese), direct contact with infected animal parts, or inhalation of aerosolized particles. Infection is rare in the US (~100 cases per year) and is primarily an occupational disease of farmers, laboratory personnel, butchers, and veterinarians. Children tend to have a more benign course, with fewer complications and better response to treatment, whereas pregnant women with brucellosis have a substantial risk of miscarriage[109].

Brucellosis demonstrates substantial clinical variability (Fig. 74.31). Acute disease is characterized by fevers, chills, headache, arthralgias, myalgias, back pain, and hepatosplenomegaly. Additional manifestations can include peripheral arthritis, spondylitis, epididymo-orchitis, endocarditis, and depression. Malodorous perspiration is highly characteristic. Skin lesions occur in <10% of patients, most often presenting as a disseminated eruption of violaceous papulonodules. Other cutaneous manifestations of brucellosis include erythema nodosum-like lesions, extensive purpura, and morbilliform eruptions. Endocarditis represents the major cause of death.

Acute brucellosis may mimic mononucleosis, influenza, malaria, typhoid fever, typhus, tularemia, tuberculosis, or sarcoidosis. The chronic form can be confused with rheumatologic, neurologic, or psychosomatic conditions. Multidrug regimens are recommended for brucellosis, with six weeks of doxycycline plus streptomycin, gentamicin, or rifampin representing a first-line treatment regimen; quinolones and TMP-SMX are other possible components of combination therapy. There is some concern regarding the use of rifampin in areas with a high prevalence of tuberculosis, as resistance may develop[110].

Recommended treatment	First-line	Second-line	Notes
• Oroya fever	• Chloramphenicol* plus β-lactam antibiotic • Quinolone (norfloxacin, ciprofloxacin) [>6 years of age, non-pregnant]	• Amoxicillin–clavulanate or ceftriaxone (first-line in children and pregnant women) • Trimethoprim–sulfamethoxazole • Macrolide • Doxycycline	• Successful treatment does not eliminate risk for developing verruga peruana • Adjunctive treatment needed with chloramphenicol, as treatment failures have been seen with monotherapy • Death occurs in ~40% of untreated individuals
• Verruga peruana	• Azithromycin	• Rifampin • Ciprofloxacin • Streptomycin [traditional]	• Only 5% of patients recall an acute febrile illness • Disappearance of skin lesions within 1 month with treatment
• Mild to moderate, uncomplicated	• Supportive care • Needle aspiration of painful suppurative lymph nodes • Azithromycin (antibiotic treatment is optional)	• Clarithromycin • Rifampin	• Azithromycin shown to decrease lymph node volume but not effective in preventing dissemination or complications
• Severe, complicated	• Doxycycline *plus* rifampin	• Azithromycin or trimethoprim–sulfamethoxazole, *plus* rifampin	• Severe disease includes retinitis, encephalopathy, visceral spread
• Mild, uncomplicated bacillary angiomatosis	• Doxycycline • Erythromycin	• Azithromycin • Clarithromycin	• Jarish–Herxheimer-like reaction may occur • Treatment failures seen with quinolones, trimethoprim–sulfamethoxazole, narrow-spectrum cephalosporins • Use of IV antibiotics recommended for GI intolerance or poor absorption states • Doxycycline *plus* rifampin recommended for CNS disease because of better CNS penetration
• Severe, complicated bacillary angiomatosis	• Doxycycline *plus* gentamicin	• Doxycycline *plus* rifampin • Azithromycin *plus* gentamicin	

Glanders

Glanders is principally a disease of horses, mules, and donkeys that is caused by *Burkholderia mallei* (formerly *Pseudomonas mallei*), a non-motile, strictly aerobic, facultative intracellular, Gram-negative bacillus. Human disease occurs chiefly in those with direct contact with infected animals and laboratory personnel. A naturally occurring human case has not been reported in the US since 1934, but infections still occur in East Asia, South America, Eastern Europe, North Africa, and the Middle East. Use of *B. mallei* as a biological weapon has been documented. Tissue damage results from production of exotoxins, including pyocyanin (interferes with electron transfer), lecithinase (causes cell lysis), collagenase, lipase, and hemolysin.

Glanders has four clinical forms – septicemic, localized, pulmonary, and chronic. Acute *septicemic* glanders is characterized by malaise, anorexia, chills, fever, diarrhea, and joint pains. Patients may have flushing, cyanosis, a disseminated pustular eruption, cellulitis, lymphangitis, erythroderma, and/or jaundice. Multi-organ failure ensues, and the mortality rate is ~50% (>90% without treatment).

In the *localized* form, a nodule, pustule, or vesicle surrounded by hemorrhagic edema appears at the inoculation site after approximately 1 to 5 days. The superficial portion of the lesion sloughs, producing an ulcer with a gray–brown base. Glanders may also involve the nose and cause ulceration or perforation of the nasal septum or palate.

Chronic glanders features malaise, myalgias, and often fevers. Painful subcutaneous and intramuscular abscesses may appear at any site and can ulcerate, drain, or extend into joints, periosteum, and bone. Multiple subcutaneous and intramuscular nodules ("farcy buds") appear along the draining lymphatics, and the term "farcy pipes" refers to the firm cords that result from lymphatic involvement.

Glanders should be considered when localized cutaneous abscesses and secondary lesions appear in the path of lymphatic drainage (see Table 77.17). Definitive diagnosis requires isolation of *B. mallei*, but serological, PCR-based, and indirect hemagglutination assays are also available[111]. For localized disease, a 60- to 150-day course of oral amoxicillin/clavulanate, doxycycline, or TMP-SMX can be prescribed; the regimens recommended for melioidosis represent another option (see below). Alternatives include ciprofloxacin, streptomycin, and gentamicin.

Melioidosis

Synonym: ▪ Whitmore disease

Melioidosis is caused by *Burkholderia pseudomallei*, a mobile, obligately aerobic, intracellular, non-spore-forming bacillus found in soil and water. The name melioidosis is derived from the Greek words *melis*, meaning "donkey distemper", and *eidos*, meaning "resembles glanders". Melioidosis is endemic in Southeast Asia and northern Australia, but it also occurs in Africa, the Middle East, and Central and South America. *B. pseudomallei* has been identified in the environment along the Gulf Coast of the US, with two reports of local transmission of melioidosis in Texas; contaminated imported products (e.g. aromatherapy spray from India) have also been implicated in melioidosis outbreaks in the US[112]. Infection develops via direct contact of abraded or lacerated skin with contaminated soil or water as well as through ingestion, inhalation, or sexual intercourse. Cases peak during the rainy season, likely due to aerosolization of bacteria. It is more common in adults with underlying medical conditions, especially diabetes mellitus, alcohol use, chronic lung disease, and chronic kidney disease.

Acute melioidosis can produce localized cutaneous infections, genitourinary infections, pneumonia, or septicemia. *Subacute* melioidosis, primarily a pulmonary disease, is frequently confused with tuberculosis. *Chronic* melioidosis is characterized by abscesses and granulomas in

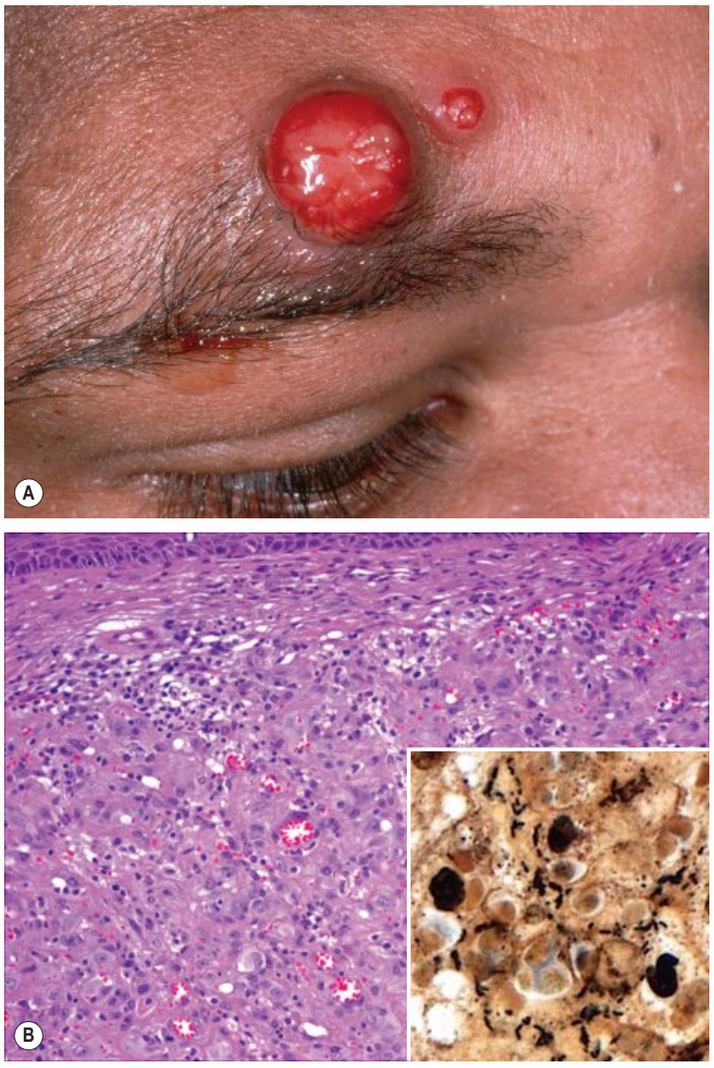

Fig. 74.30 Bacillary angiomatosis. A Bright red nodule and papule on the forehead. **B** Histologically, a dermal proliferation of vessels with plump endothelial cells is evident and scattered neutrophils are present in the accompanying infiltrate. Bacilli (in this case *Bartonella henselae*) are identified with the Warthin–Starry stain (inset). *B, Courtesy James Patterson, MD.*

multiple sites. Cutaneous manifestations may include cellulitis, subcutaneous abscesses, granulomatous lesions, ecthyma gangrenosum, purpura, pustules, Sweet syndrome, and urticaria.

Bacterial culture represents the standard for diagnosis of melioidosis, but the sensitivity is as low as 60%. Multiplex PCR-based assays are more sensitive as well as species-specific[113]. Both complement-fixing and agglutinating antibodies appear within 4 to 6 weeks after infection, but serologic testing alone is inadequate in endemic regions[114].

Treatment of melioidosis is difficult, and susceptibility testing should be performed. Current guidelines recommend an initial intensive phase with intravenous administration of ceftazidime or a carbapenem for at least 10–14 days, followed by an eradication phase with oral TMP-SMX or amoxicillin/clavulanate for ≥3 months. Of note, *B. pseudomallei* has shown resistance to quinolones, macrolides, and aminoglycosides. Melioidosis-associated sepsis has a mortality rate of 50%–90%; however, intensive supportive care lowers this to ~20%. Melioidosis has a relapse rate of ~10%, and *B. pseudomallei* can remain latent in the body for decades.

Because *B. mallei* and *B. pseudomallei* represent potential agents of bioterrorism, attempts are underway to develop vaccines for these infections.

Cutaneous Malacoplakia (Malakoplakia)

Cutaneous malacoplakia, from the Greek *malakos* ("soft") and *plakia* ("plaque"), is a chronic infectious condition that is characterized by granulomatous inflammation with distinctive macrophages that are unable to kill bacteria effectively. It occurs primarily in immunocompromised hosts, including solid organ (especially kidney) transplant recipients, people living with HIV, and children with primary immunodeficiencies[115]. Malacoplakia is most commonly due to *E. coli*, although *Pseudomonas, Proteus, Klebsiella, Staphylococcus, Shigella, Enterococcus, Rhodococcus*, and *Mycobacterium* spp. have also been implicated.

Malacoplakia most often affects the genitourinary tract but rarely involves the skin. Cutaneous lesions usually develop in the perianal region and can present as ulcerations, abscesses with multiple draining sinuses, yellow-to-pink soft papules, and erythematous indurated nodules.

Histologic examination of involved tissue shows highly characteristic findings. *Michaelis–Gutmann bodies* are intracytoplasmic laminated concretions that represent accumulations of calcified, iron-containing phagolysosomes; they stain with PAS, von Kossa, Perls', and Giemsa stains. The presence of such concretions is noted in other conditions by different names (e.g. Schaumann bodies in sarcoidosis) and thus not pathognomonic for malacoplakia. *Von Hansemann cells* are large macrophages that contain Michaelis–Gutmann bodies and stain positively for CD68, lysozyme, and alpha-1 antitrypsin. The histopathologic differential diagnosis may include sarcoidosis, infectious granulomas, Langerhans cell histiocytosis, granular cell tumor, and fibrous histiocytoma.

The treatment of malacoplakia is difficult. Localized disease may be amenable to surgical excision. Prolonged courses of antibiotics such as quinolones, TMP-SMX, penicillins, and clofazimine may be of benefit. Ascorbic acid and bethanechol chloride can be employed to improve macrophage function. In severe cases, reducing the dosage of immunosuppressive therapy (if possible) may be of benefit. Lesions may spontaneously regress after ~6 months but can also be recalcitrant to therapy[116].

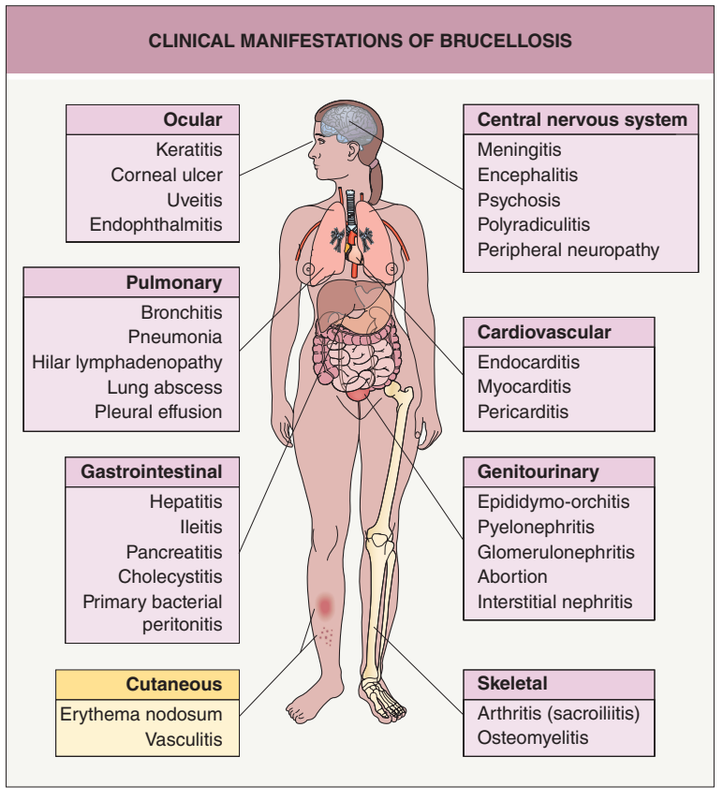

Fig. 74.31 Clinical manifestations of brucellosis. *With permission from Slack MPE. Gram-negative coccobacilli. In: Armstrong D, Powderly WG (eds). Infectious Diseases. Edinburgh: Mosby, 2004.*

Tularemia

Synonyms: ■ Deer fly fever ■ Rabbit fever ■ Pahvant Valley plague

Tularemia is a bacterial infection caused by *Francisella tularensis*, a Gram-negative, non-motile coccobacillus. First described in 1911 as a plague-like illness, there were ~2100 cases reported in the US from 2011 to 2020. Transmission to humans may occur via direct contact with mucous membranes or eroded skin, ingestion of contaminated food or water, inhalation of infectious particles, or bites from ticks or deer flies. Rodents and rabbits are the main reservoirs of disease, which may also affect domestic cats and sheep[117].

Tularemia occurs in six clinical forms according to the mode of transmission – ulceroglandular, glandular, oculoglandular, oropharyngeal/gastrointestinal, typhoidal/septicemic, and pneumonic (Fig. 74.32). Ulceroglandular tularemia is the most common form and is characterized by lymphadenopathy and an erythematous, indurated, punched-out ulcer at the site of cutaneous exposure that may last for weeks. Regional lymph nodes can become fluctuant and suppurate. Occasionally, ulceration or lymphadenopathy occurs in isolation. Other rare cutaneous manifestations include buboes, a morbilliform or vesicular eruption, erythema nodosum, and erythema multiforme.

Because of concern regarding the potential use of *F. tularensis* as a biologic weapon, tularemia is a reportable disease in the US. Diagnostic methods include direct fluorescent antibody testing (available in designated reference laboratories), immunohistochemical staining of tissue samples, and PCR-based assays. Attempts to culture *F. tularensis* are usually not made due to its high infectivity, risk to laboratory workers, and inability to grow on most media. The differential diagnosis of ulceroglandular tularemia includes other ulceroglandular entities (e.g. bubonic plague, tuberculous chancre, rat-bite fever, glanders), anthrax, soft tissue infections (i.e. *Staphylococcus*, *Streptococcus*, *Pasteurella multocida*), and infectious causes of a sporotrichoid pattern (see Ch. 77).

Treatment recommendations include a 10-day course of streptomycin (the classic first-line agent), gentamicin, or ciprofloxacin; a 14- to 21-day course of doxycycline is another option that results in a higher risk of relapse. A Jarisch–Herxheimer-like reaction may occur following the initiation of therapy. There are ongoing efforts to develop a safe and effective vaccine.

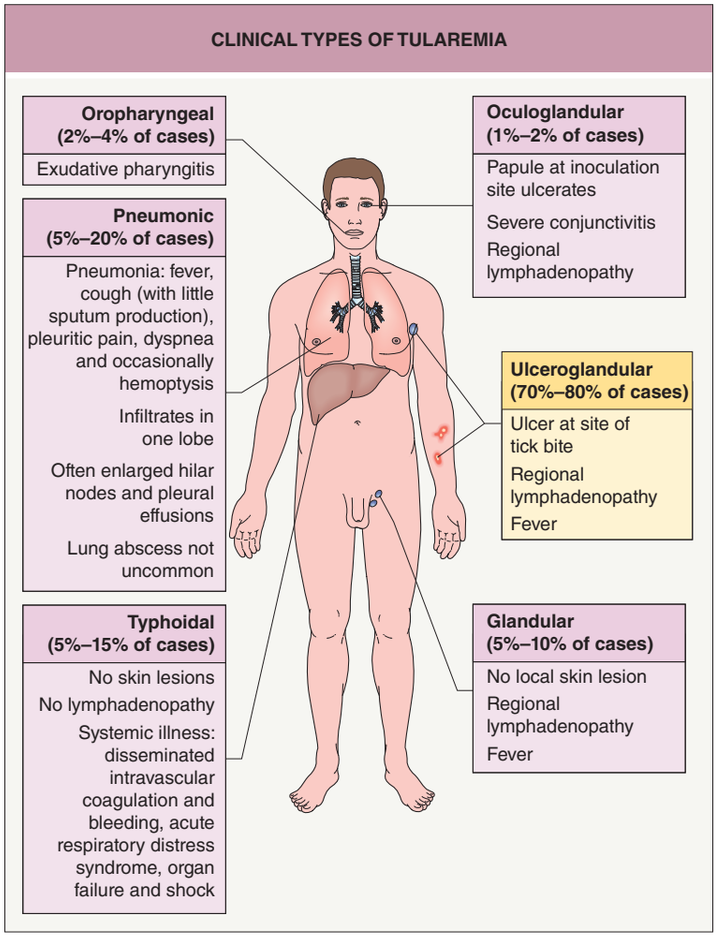

Fig. 74.32 Clinical types of tularemia. *Adapted with permission from Slack MPE. Gram-negative coccobacilli. In: Armstrong D, Powderly WG (eds). Infectious Diseases. Edinburgh: Mosby, 2004.*

Haemophilus influenzae Cellulitis

Haemophilus influenzae is a Gram-negative coccobacillus that can cause facial cellulitis with a violaceous hue in infants and young children (usually 6–24 months of age) following an upper respiratory tract infection. It favors the buccal and periorbital areas and is often associated with high fevers, an increased leukocyte count with a left shift, and positive blood cultures. If diagnosis is delayed, systemic spread may lead to meningitis. Routine vaccination of children against *H. influenzae* type b has greatly reduced the incidence of this form of cellulitis[51]. However, *H. influenzae* type f and non-typeable (unencapsulated) strains have been reported to cause cellulitis of the extremities in patients immunized to *H. influenzae* type b. First-line therapy for severe *H. influenzae* infections is a third-generation cephalosporin; selection of empiric antibiotic therapy for cellulitis is discussed above.

Rhinoscleroma

Rhinoscleroma is a slowly progressive, chronic granulomatous infection involving the nose and upper respiratory tract. It is caused by *Klebsiella rhinoscleromatis*, a short, immotile Gram-negative coccobacillus that is a subspecies of *Klebsiella pneumoniae*. Endemic foci exist in Central Europe, Egypt, India, Indonesia, Mexico, Central America, and tropical Africa. Rhinoscleroma is acquired via inhalation of contaminated droplets. Ineffective macrophage killing of *K. rhinoscleromatis* results in large, vacuolated, non-lipidized histiocytes with intracellular bacteria (Mikulicz cells)[118]. Clinical features, diagnostic techniques, the differential diagnosis, and treatment recommendations are outlined in Table 74.15. Recurrence after treatment is common. Histologic findings mimicking Rosai–Dorfman disease have been observed in cutaneous lesions and lymph nodes of patients with rhinoscleroma[119].

Salmonellosis

Salmonellosis refers to the spectrum of infections caused by Gram-negative aerobic bacilli in the genus *Salmonella*. Resultant forms of enteric fever include typhoid fever due to *S. typhi* and paratyphoid fever due to *S. paratyphi*. *S. typhi* is spread via direct contact with persons who have typhoid fever or are chronic carriers. In contrast, paratyphoid fever is most commonly acquired from inadequately cooked poultry or eggs as well as other contaminated food products or water, resulting in gastroenteritis.

Typhoid fever is characterized by fever, headache, malaise, myalgias, cough, sore throat, nausea, vomiting, and diarrhea or constipation. The characteristic cutaneous sign, "rose spots", are pink, blanching, slightly elevated papules that measure 2–8 mm and are usually found on the anterior trunk in groups of 5–15 lesions. They occur in up to 30% of patients with typhoid fever and less often in non-typhoidal enteric fever. Rose spots often occur in crops during the second to fourth weeks of the illness, and *Salmonella* spp. can usually be cultured from these lesions. Other cutaneous manifestations of salmonellosis include erythema multiforme, Sweet syndrome, hemorrhagic bullae, pustular dermatitis, and a generalized erythematous eruption known as erythema typhosum. Hemophagocytic lymphohistiocytosis represents a rare complication of salmonellosis[120].

A history of travel to endemic areas (e.g. Southeast Asia, Africa), persistence of fevers, and positive cultures aid in distinguishing typhoid fever from influenza and other viral infections. Culture of *Salmonella* spp. from the bone marrow is the most sensitive diagnostic procedure but is rarely used in clinical practice. Blood cultures are less sensitive and PCR-based detection is limited by the low concentrations of microbial DNA in clinical samples. Since the late 1980s, *S. typhi* has developed resistance to the drugs that were previously used as first-line treatments (e.g. chloramphenicol, TMP-SMX, and ampicillin). Current treatment options include azithromycin, carbapenems, and (depending on resistance patterns) quinolones and third-generation cephalosporins[121]. Typhoid conjugate vaccines are available and are recommended for travelers to endemic areas.

RHINOSCLEROMA – CLINICAL FEATURES, DIFFERENTIAL DIAGNOSIS, AND TREATMENT	
Risk factors	• Poor hygiene, poor nutrition, and living in overcrowded conditions
Stage one: rhinitic/catarrhal; lasts weeks-months	• Nonspecific rhinitis • Purulent rhinorrhea and crusting • Nasal obstruction
Stage two: granulomatous/ infiltrative; lasts months–years	• Granulomatous nodules form in the nose, pharynx, and larynx • Dysphonia, anosmia, and anesthesia of soft palate may occur • Epistaxis, deformity of the nose, destruction of the nasal cartilage (Hebra nose) • Mikulicz cells readily identified on histopathology
Stage three: sclerotic/cicatricial	• Nodules replaced by fibrous tissues with resultant extensive scarring and stenosis often requiring surgical intervention (e.g. tracheotomy, reconstruction of the airway)

Diagnosis	• Presence of Mikulicz cells and Russell bodies on routine histology
	  • *Mikulicz cells*: large, vacuolated, non-lipidized histiocytes with intracellular bacteria
	  • *Russell bodies*: plasma cells with aggregates of condensed immunoglobulins
	• PAS, Giemsa, silver, and Gram stains are reliable
	• Immunoperoxidase studies are sensitive and specific
	• Cultures are positive in only ~50% of cases
	• "Crypt-like" irregularities of the trachea can be seen on computed tomography

Differential diagnosis (see Table 45.3)	• Mucocutaneous (New World) leishmaniasis, paracoccidioidomycosis (and other dimorphic fungal infections), rhinosporidiosis, leprosy, yaws, tertiary syphilis, nasal tuberculosis, sarcoidosis, granulomatosis with polyangiitis, nasal T cell/natural killer cell lymphoma, basal cell and squamous cell carcinoma, extranodal Rosai–Dorfman disease
Treatment	• Antimicrobial therapy for 6 months or until nasal biopsy is negative; tetracycline is first-line therapy along with surgical correction of obstructed airway • Rifampin and ciprofloxacin are alternative antibiotics • Sclerotic lesions respond to ciprofloxacin • Bacterial superinfection is common, requiring treatment with clindamycin or a third-generation cephalosporin

Table 74.15 Rhinoscleroma – clinical features, differential diagnosis, and treatment.

Rat-Bite Fever

Synonyms: ■ Haverhill fever ■ Sodoku ■ Erythema arthriticum epidemicum

Rat-bite fever is most often due to infection with *Streptobacillus moniliformis* in North America and *Spirillum minus* in Asia, where it is known as sodoku. Infection results in an acute illness characterized by fever, arthritis, and a rash. While the disorder is usually caused by a bite (rat-bite fever), it can also occur from close contact with rodents or ingestion of contaminated food, water, or raw milk (Haverhill fever).

The incidence of rat-bite fever is highest in urban areas with poor sanitation resulting in a large rat population, but it can also occur from exposure to pet rats or laboratory rats. Approximately half of cases are in children. Erythema, edema, abscess formation, ulceration, and secondary infection may develop at the site of the bite. Regional lymphadenopathy is common. Paroxysms of fever interspersed with afebrile periods as well as headaches, nausea, vomiting, and myalgias may occur. In infants and children, weight loss and diarrhea can be significant. One of the hallmarks of the disease is a migratory polyarthritis that occurs in 50% of patients and may mimic rheumatoid arthritis. At 2 to 4 days following the onset of fever and arthritis, most patients with rat-bite fever develop an acrally distributed eruption involving the palms and soles. Erythematous macules and papules, petechiae, vesicles, pustules, and crusts may be seen.

Rat-bite fever can be diagnosed by culturing *Streptobacillus moniliformis* from blood, synovial fluid, or abscess aspirates, which requires an environment free of sodium polyanethol sulfonate[122]; *Spirillum minus* does not grow in culture. PCR-based assays may also be utilized. The triad of fever, arthritis/arthralgias, and a rash can be caused by a variety of infectious diseases, including viral infections (e.g. enteroviruses, EBV, parvovirus B19), Rocky Mountain spotted fever, acute or chronic meningococcemia, acute rheumatic fever, and secondary syphilis. Non-infectious causes include Still disease, systemic lupus erythematosus, serum sickness-like drug reactions, and Sweet, Schnitzler, and periodic fever syndromes.

Penicillin is the drug of choice for rat-bite fever and is usually administered for a week, although patients with septicemia may require up to 6 weeks of parenteral therapy. Ceftriaxone, tetracyclines, and streptomycin represent additional options; erythromycin and clindamycin have also been used, but studies of their efficacy are lacking. Although most infections resolve spontaneously within 2 weeks, 10%–15% of untreated cases are fatal.

Plague

Plague is caused by *Yersinia pestis*, a Gram-negative, rounded, bipolar bacillus transmitted predominantly by fleas (Fig. 74.33). Peru, Democratic Republic of the Congo, and Madagascar are currently the most plague-endemic countries. There are typically <10 cases reported yearly in the US, with most occurring in two regions: (1) northern New Mexico, northern Arizona and southern Colorado; and (2) California, southern Oregon and far western Nevada.

Three clinical forms of plague are recognized – bubonic, septicemic, and pneumonic. The symptoms of *bubonic* plague are variable. Constitutional symptoms range from absent to severe. In approximately 10% of patients, the inoculation wound develops into a pustule or ulcer. This is followed by painful regional lymphadenopathy (bubo); suppuration and discharge from the lymph nodes may occur. In *septicemic* plague, vesicles, carbuncles, petechiae, and purpura may be seen. Necrotic lesions and hemorrhage from the nasopharynx or gastrointestinal tract have also been described. In *pneumonic* plague, the patient develops acute pneumonitis. Apathy, delirium, coma, and seizures occur in seriously ill patients. Bubonic plague may simulate tularemia, rat-bite fever, sporotrichosis, tuberculosis, streptococcal ecthyma, syphilis, or lymphogranuloma venereum. Septicemic plague must be differentiated from typhus, typhoid fever, tularemia, malaria, and other bacteremias. *Y. pestis* produces a virulence factor that reduces pyrin activity, explaining why individuals with familial Mediterranean fever (*MEFV*) gene variants that result in increased pyrin activity demonstrate resistance to plague[123].

Untreated bubonic plague has a 40%–60% fatality rate, while untreated septicemic or pneumonic plague is nearly always fatal. Streptomycin and other aminoglycosides (e.g. gentamicin) are first-line treatments for plague. Doxycycline and quinolones may be used when oral therapy is acceptable. Chloramphenicol (which attains high concentrations in the cerebrospinal fluid) is the drug of choice for plague meningitis or endophthalmitis. Postexposure prophylaxis with doxycycline or ciprofloxacin, if taken within 6 days, is effective in preventing disease. Live vaccines are utilized for prevention of plague in some parts of the world, but they have poor safety profiles. There are ongoing efforts to develop a safe and effective *Y. pestis* vaccine.

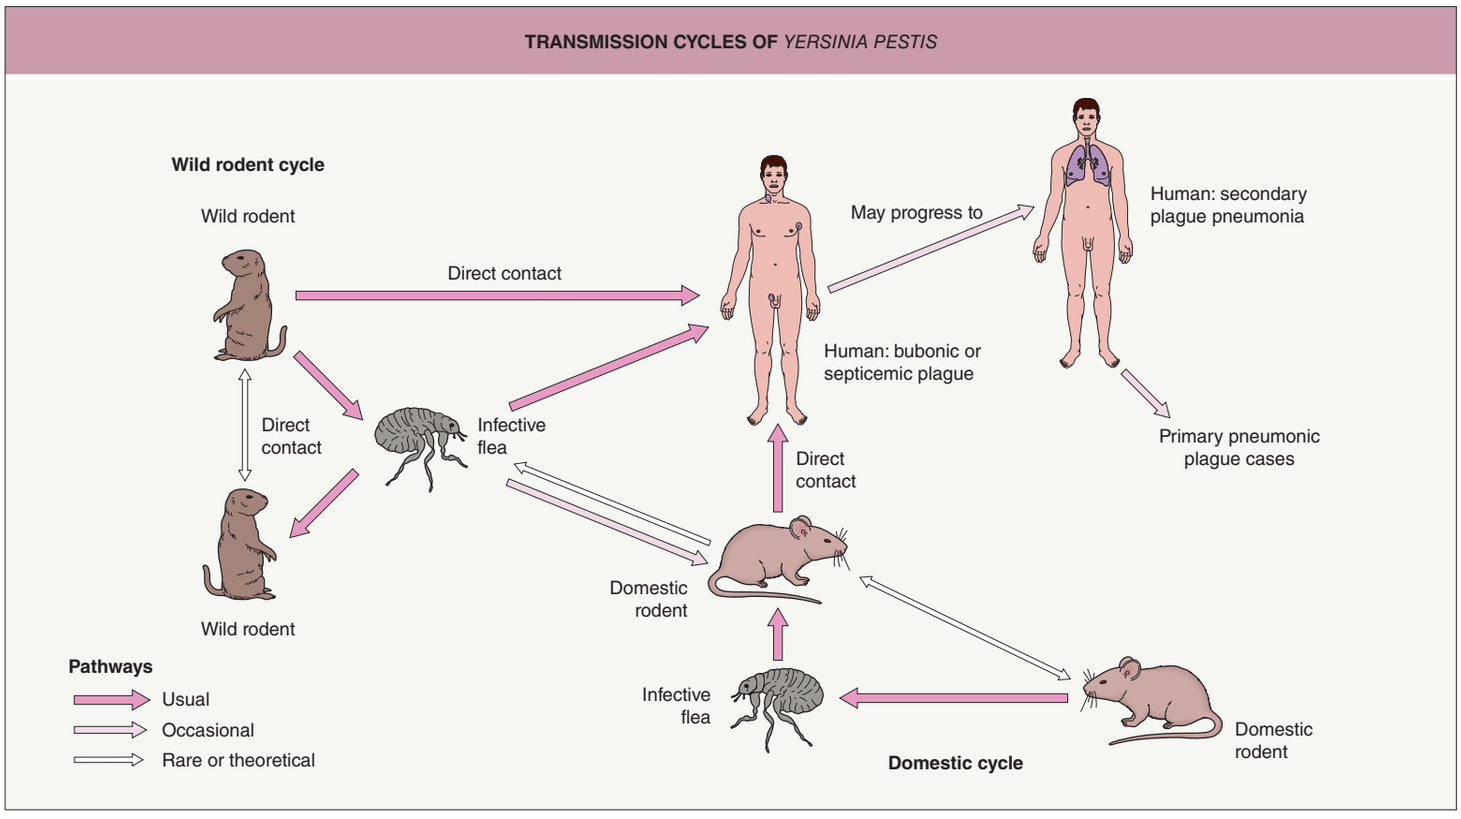

Fig. 74.33 Transmission cycles of *Yersinia pestis*. *With permission from Dennis DT, Gage KL. Plague. In: Armstrong D, Powderly WG (eds). Infectious Diseases. Edinburgh: Mosby, 2004.*

RISK FACTORS FOR *VIBRIO VULNIFICUS* INFECTION
Acquisition of infection
Cutaneous exposure to contaminated seawater and/or shellfish
• Exposure to warm coastal salt water • Handling shellfish • New injury to the skin or a pre-existing wound predisposes to a primary cutaneous infection, which can lead to cellulitis, necrotizing fasciitis, and/or septicemia in susceptible hosts (see below)
Consumption of contaminated raw/undercooked seafood
• Raw oysters, clams, crabs, and other shellfish • Leads to an acute gastrointestinal illness in immunocompetent individuals and septicemia in susceptible hosts (see below)
Underlying medical conditions that predispose to severe infections
Liver disease

• Hemochromatosis or iron overload in the setting of thalassemia
  • *V. vulnificus* is ferrophilic and requires higher levels of iron than other pathogens
  • Patients have decreased hepcidin antibacterial activity
• Alcoholic cirrhosis or chronic hepatitis

Diabetes mellitus
• Peripheral neuropathy predisposes to cutaneous wounds that serve as a portal of entry
Gastrointestinal disease
• Peptic ulcer disease   • Antacid use may lead to increased survival of *V. vulnificus* • Gastrointestinal surgery
Immunosuppression
• HIV infection • Leukemia or lymphoma • Treatment with corticosteroids, chemotherapy, and other immunosuppressive agents
Chronic kidney disease

Table 74.16 Risk factors for *Vibrio vulnificus* infection. Infections are most common in men >40 years of age.

Vibrio vulnificus Infection

The genus *Vibrio* constitutes a group of Gram-negative anaerobic bacteria, among which *V. vulnificus* is the most common cause of cutaneous disease. *V. vulnificus* infections occur most commonly in men over 40 years of age who have chronic liver disease, diabetes mellitus, or immunosuppression plus a history of exposure to warm seawater or raw/undercooked seafood. "*Vibrio* season" traditionally lasts from May to October in the US, but climate change has elongated this to the later fall and expanded the bacterium's geographic range[124]. Additional risk factors are listed in Table 74.16.

The clinical presentation of *V. vulnificus* septicemia includes fever, chills, nausea, vomiting, diarrhea, abdominal cramps, and hypotension. Skin lesions develop in 75% of these patients, with progression from erythematous and purpuric macules to vesicles and hemorrhagic bullae (Fig. 74.34) and then to necrotic ulcers in a manner reminiscent of purpura fulminans. Wounds acquired in or contaminated by seawater can also lead to *Vibrio* cellulitis that is erythematous, edematous, and painful, typically with rapid evolution to hemorrhagic bullae. Progression to necrotizing fasciitis or myositis occasionally occurs. First-line treatment is doxycycline (oral or intravenous) plus a third-generation cephalosporin (intravenous or intramuscular). Necrotic lesions may require surgical debridement[125].

EHRLICHIOSIS AND ANAPLASMOSIS

These infections are discussed in Chapter 76.

SPIROCHETES

BORRELIA BURGDORFERI

Lyme Disease

Synonym: ■ Lyme borreliosis

Lyme disease is a multisystem disorder with prominent skin findings that is caused by *Borrelia* species of spirochetes. Although found

Fig. 74.34 Hemorrhagic bullae of the leg secondary to *Vibrio vulnificus* infection.

worldwide, it has a particularly high incidence in North America and Europe, representing the most common tick-borne disease in the US. Lyme disease can occur year-round, but most cases present in the summer. If diagnosed in its early stages, it is a completely curable illness.

The species of *Ixodes* tick vector differs depending on the geographic region, e.g. *I. pacificus* in the western US, *I. scapularis* (also called *I. dammini*) in the eastern US and Great Lakes region, *I. ricinus* in Europe, and *I. persulcatus* in Asia. *B. burgdorferi* is the predominant etiologic organism in the US, whereas *B. garinii* and *B. afzelii* are the predominant causes of Lyme disease in Europe[126]. This may explain the occurrence of borrelial lymphocytoma and acrodermatitis chronica atrophicans in Europe, but not the US. Once the spirochete is in the midgut of the tick vector after feeding on an infected host (e.g. white-tailed deer), it produces outer surface protein C, which enables it to traverse the midgut epithelium, enter the hemocoel, and make its way to the salivary glands. *B. burgdorferi* is ultimately transmitted to humans via the tick's saliva. The rate of transmission is extremely low during the first 48 hours of tick attachment[127].

Chapter 19 describes the clinical features and treatment of Lyme disease, in particular erythema migrans (see Fig. 74.15), and Table 74.17 outlines the extracutaneous manifestations of Lyme disease. The next sections discuss borrelial lymphocytoma and acrodermatitis chronica atrophicans.

Borrelial Lymphocytoma

Synonyms: ■ Lymphadenosis benigna cutis ■ Lymphocytoma cutis ■ Cutaneous lymphoid hyperplasia ■ Spiegler–Fendt lymphoid hyperplasia, pseudolymphoma of Spiegler and Fendt, sarcoidosis of Spiegler and Fendt

Lymphocytoma is a benign, reactive form of lymphoid hyperplasia that can be attributed to various stimuli, including *Borrelia* infection. Borrelial lymphocytoma usually appears during the early disseminated stage of Lyme disease (see Ch. 19). Because it is caused by *B. afzelii* and *B. garinii*, neither of which is found in North America, borrelial lymphocytoma is virtually never seen in those who have not traveled outside of the US. However, it occurs in approximately 1% of patients with Lyme disease in Europe, with a predilection for children.

The formation of a lymphocytoma following a tick bite was first reported in 1950, but it was not until 1986 that *Borrelia* was cultured from such a lesion. A firm, bluish-red, occasionally tender nodule or plaque appears most commonly on the earlobes in children and the nipple/areola in adults, less often developing on the genitalia, trunk, or extremities. It may be associated with regional lymphadenopathy or concomitant erythema migrans.

MAJOR EXTRACUTANEOUS FEATURES OF LYME DISEASE	
General	Fever, malaise, headache, regional lymphadenopathy, non-productive cough
Eyes	Conjunctivitis, keratitis, iritis, episcleritis, retrobulbar neuritis
Neurologic	Meningitis, encephalitis, Guillain–Barré syndrome, Bell's palsy, psychiatric syndromes, optic atrophy, ataxia
Cardiac	Heart block, arrhythmias, pericarditis, myocarditis, cardiomyopathy, congestive heart failure
Rheumatologic	Arthralgias, tendinitis, oligoarthritis, bone calcifications and cysts
Genitourinary	Orchitis, softening of the testes, proteinuria, microhematuria

Table 74.17 Major extracutaneous features of Lyme disease.

Histologically, the epidermis is normal and separated from the dermal infiltrate by a Grenz zone. The dense dermal infiltrate of lymphocytes forms a pattern that closely resembles the architecture of a lymphoid follicle. The histologic differential diagnosis includes an arthropod bite reaction and cutaneous lymphoma, with the presence of Bcl-2 protein within follicular cells and monoclonality by PCR favoring the latter (see Ch. 119). Of note, *B. burgdorferi*-associated B cell lymphomas have rarely been described[128]. Borrelial lymphocytoma responds to the antibiotics used for Lyme disease (see Ch. 19).

Acrodermatitis Chronica Atrophicans

Synonym: ■ Herxheimer disease

Acrodermatitis chronica atrophicans (ACA) is a cutaneous manifestation of chronic Lyme disease. First described in Europe in 1883 by Buchwald as "idiopathic atrophy", it is most commonly due to an infection with *B. afzelii*, although it has also been associated with *B. burgdorferi* and *B. garinii*. As a result, it is extremely rare in the Americas but is seen in up to 10% of patients with Lyme disease in Europe.

ACA occurs months to years after the initial infection, predominantly in women 40–70 years of age, and appears to be associated with persistence of *Borrelia* organisms in the skin. It is a biphasic disorder consisting of an early, easily treatable, inflammatory stage and a late, treatment-resistant, atrophic stage. Initially, erythematous to violaceous plaques and nodules develop on the acral portion of the extremities, often insidiously. The skin is frequently doughy and swollen. This early stage follows a waxing and waning course for weeks to years. In the late stage, the skin has a glistening ("cigarette-paper") appearance with prominent blood vessels (Fig. 74.35). Fibrous nodules may form on extensor surfaces (ulnar or tibial bands). Hypopigmentation, hyperpigmentation, pain, pruritus, hyperesthesia, paresthesias, and scaling may also be present. Rarely, the condition may be complicated by the development of basal cell or squamous cell carcinoma.

In biopsy specimens of early lesions, a dermal perivascular lymphocytic infiltrate with plasma cells, telangiectatic endothelial-lined spaces, and mild epidermal atrophy are seen. Histologic examination of late lesions shows an atrophic epidermis and an interstitial lymphocytic infiltrate with plasma cells and occasional histiocytes and mast cells. The dermis may be attenuated, with periadnexal fibrosis. *Borrelia* DNA may be detected by PCR in skin biopsy specimens. The differential diagnosis may include eczematous dermatitis (e.g. due to stasis), cold injury, atrophy secondary to chronic use of potent topical corticosteroids, severe photodamage, and, in the case of fibrotic lesions, scars, morphea, and fibromatoses[129].

NON-VENEREAL (ENDEMIC) TREPONEMATOSES

Yaws, pinta, and bejel (endemic syphilis) are caused by organisms that are morphologically and antigenically identical to the causative organism of venereal syphilis, *Treponema pallidum* (see Ch. 82). All three diseases have chronic relapsing courses with major dermatologic

Fig. 74.35 Acrodermatitis chronica atrophicans. The acral skin is atrophic, shiny, and wrinkled, with prominent superficial veins.

Fig. 74.36 Cutaneous yaws on the knee of an adolescent from Indonesia. *Courtesy Peter Ehrnstrom, MD.*

manifestations. The primary route of transmission is person-to-person via skin, mucous membrane, or possibly fomite contact. With the exception of pinta, children are most often affected.

The diagnosis of yaws, pinta, and bejel is based primarily upon clinical features. The same serologic assays used for venereal syphilis can be used to diagnose the endemic treponematoses, but a positive test does not differentiate among the four diseases. Treponemal tests (e.g. TPHA, FTA-ABS, MHA-TP) are specific for treponemal infections (see Ch. 82) and may remain positive for life, regardless of treatment. The non-treponemal tests (e.g. VDRL, RPR) may indicate a current or recent infection, or a biologic false-positive result (in 1%–3% of the population). The vast majority of false-positive sera have antibody titers of <1 : 4. The quantitative non-treponemal tests are particularly useful in the evaluation of patients following therapy; a fourfold decrease in antibody titers indicates successful treatment, while a fourfold rise indicates reinfection or relapse. Diagnosis can also be made through darkfield examination of exudates from lesions.

For over 50 years the primary treatment for patients with endemic treponematoses was benzathine penicillin, given as a single intramuscular dose of 1.2 million units in individuals ≥10 years of age and 0.6 million units in children <10 years of age. A single high dose of oral azithromycin (30 mg/kg, maximum 2 g) was shown to be non-inferior to benzathine penicillin for the treatment of active and latent yaws. Due to the ease of administration and safe use in patients with penicillin allergy, azithromycin is now recommended as the first-line treatment for yaws by the WHO, with goals of mass treatment and disease eradication (see below)[130,131]. To date, no formal trials have studied azithromycin efficacy for pinta and bejel.

Yaws

Synonyms: ■ Pian (French) ■ Frambösie (German) ■ Buba (Spanish) ■ Parangi (Malay)

Yaws is a three-stage infection caused by *T. pallidum* subspecies *pertenue* and represents the most common and severe endemic treponematosis. It occurs in tropical climates, most often in the Pacific islands, Southeast Asia, and Africa. Yaws most commonly involves the lower extremities of children <15 years of age (Fig. 74.36). A "mother yaw", the main lesion of the *primary* stage, occurs at the site of inoculation within 10 days to 3 months. It begins as an erythematous, infiltrated, painless papule that over time enlarges peripherally to become 1–5 cm in diameter, then ulcerates and develops an amber-yellow crust. The lesion is rich in treponemes and eventually heals spontaneously over 3 to 6 months.

"Daughter yaws", the lesions of *secondary* yaws, are smaller and more widespread than the primary lesion. They usually occur adjacent to body orifices, such as the nose and mouth, and can expand or ulcerate. Both types of lesions are highly infectious. Patients may then enter a latent phase with reactive serology but absent clinical findings. Only 10% of patients progress to the final stage, during which abscesses form, become necrotic, and ulcerate. The ulcers may coalesce into serpiginous tracts, which heal with significant scarring and produce crippling deformities. Yaws can also cause periostitis, dactylitis, and osteitis, with the latter potentially leading to curvature of the tibia ("saber shins").

Histologic examination of early yaws lesions demonstrates spongiosis, acanthosis, and papillomatosis. A moderate to dense dermal inflammatory infiltrate composed mostly of plasma cells and lymphocytes can be seen. Silver stains easily identify treponemes in specimens. Clinically, the skin lesions of yaws can resemble venereal syphilis, chancroid, eczema, psoriasis, verrucae, calluses, scabies, tungiasis, sarcoidosis, and vitamin deficiencies[132].

Renewed eradication efforts against yaws began in 2012, and in 2016 India was the first country to be declared free of yaws by the WHO. However, the emergence of azithromycin-resistant yaws in Papua New Guinea threatens eradication efforts[133].

Pinta

Pinta affects the skin exclusively and is caused by an infection with *T. carateum*. The disease is found only in the western hemisphere (Central and South America) in semiarid, warm climates. All ages are equally affected. The *primary* lesions occur 7 days to 2 months after inoculation, most often on the lower extremities. They begin as tiny macules or papules surrounded by an erythematous halo. Over a period of months, they develop into poorly defined, erythematous, infiltrated plaques that measure 10–12 cm in diameter. *Secondary* lesions ("pintids") start as small, scaly papules, subsequently enlarging and coalescing into psoriasiform plaques. They are initially red but later become slate-blue, brown, gray, and black. The primary and secondary lesions are highly infectious. *Tertiary* pinta is characterized by symmetric depigmented, vitiligo-like lesions, which may be atrophic or hyperkeratotic and are not considered to be infectious.

Biopsy specimens of primary and secondary lesions reveal moderate acanthosis, slight spongiosis, and a superficial dermal inflammatory infiltrate consisting of lymphocytes, plasma cells, and neutrophils around dilated blood vessels. Some lesions show lichenoid changes, with hyperkeratosis, hypergranulosis, and vacuolar degeneration of the basal layer. The depigmented lesions of late pinta have epidermal atrophy and a complete absence of melanin. Except for longstanding, late depigmented lesions, treponemes can be visualized in biopsy specimens with silver stains. Early pinta is difficult to differentiate from venereal syphilis, yaws, and bejel. The early lesions can also be confused with eczema, psoriasis, leprosy, lichen planus, lupus erythematosus, and tinea corporis. The lesions of late pinta are frequently mistaken for vitiligo[132].

Bejel

Synonym: ■ Endemic syphilis

Bejel is caused by an infection with *T. pallidum* subspecies *endemicum*. Most cases are seen in the arid, warm climates of North and West Africa and the Arabian Peninsula. Children <15 years of age are most

commonly affected. Bejel is usually acquired via skin-to-skin or oral contact but can be transmitted sexually. In contrast to yaws and pinta, a *primary* lesion is rarely noticed. It usually consists of an inconspicuous small papule or ulcer in the oropharynx or on the nipples of breastfeeding women. *Secondary* bejel may present with findings similar to venereal syphilis, such as patches on mucous membranes, split papules, angular stomatitis, non-pruritic papular skin eruptions, and generalized lymphadenopathy. Condylomata lata are also frequently present. During the secondary stage, some patients experience osteoperiostitis of the long bones, which can cause nocturnal leg pain.

Six months to several years after inoculation, some patients develop the *tertiary* stage of bejel. Gumma formation may lead to gross mutilation of the skin, mucous membranes, muscle, cartilage, and bone. Without treatment, disfiguring lesions of the palate and nasal septum may occur, leading to difficulty in articulation and swallowing. The eyes and bones can also be severely affected in late-stage bejel.

The histologic picture closely resembles that of venereal syphilis. In the early stages, biopsy specimens demonstrate a perivascular dermal infiltrate of mostly plasma cells and lymphocytes. Oral lesions may resemble venereal syphilis, aphthosis, perlèche, vitamin deficiencies, and primary herpes simplex viral infection. The mutilating nasopharyngeal lesions of bejel can be mistaken for tertiary venereal syphilis, leprosy, rhinoscleroma, mucocutaneous leishmaniasis, paracoccidioidomycosis, and tuberculosis (see Tables 45.3 & 74.15)[132].

LEPTOSPIROSIS

Synonyms: ■ Fort Bragg fever ■ Pretibial fever ■ Weil's disease

Leptospirosis is a worldwide zoonosis caused by spirochetes in the genus *Leptospira*. It is transmitted via contact of non-intact skin or mucous membranes with urine or other body fluids (with the exception of saliva) from infected mammals, either directly or from drinking or swimming in contaminated water. Veterinarians, farmers, slaughterhouse or sewer workers, and recreational water sport participants are most often affected. Leptospirosis occurs in an anicteric form (~90% of cases) and a more severe icteric form (~10% of cases). After an incubation period of 7–12 days, an initial "septicemic" stage of fevers, chills, and myalgias lasting 3–7 days is followed by an "immune" stage (during which serologic tests are positive) that can result in meningitis, uveitis, and renal, hepatic, and/or pulmonary dysfunction. Cutaneous manifestations include erythematous macules, papules, patches, and/or plaques in a widespread distribution or (especially with *L. interrogans* serovar Autumnalis) localized to the shins, as well as petechiae and purpura secondary to vascular involvement. Although most cases are self-limited, antibiotics may decrease the duration of illness and reduce shedding of organisms in the urine. Oral doxycycline, amoxicillin, or azithromycin and (for more severe disease) intravenous penicillin or third-generation cephalosporins have been used[134].

BACTERIA PREVIOUSLY CLASSIFIED AS FUNGI

ACTINOMYCOSIS

Introduction

Actinomycosis is a subacute or chronic bacterial infection characterized by suppurating abscesses, granulomatous inflammation, and sinus formation. *Actinomyces israelii*, an anaerobic or microaerophilic Gram-positive, non-acid-fast actinomycete, is the most common causative organism. Cervicofacial (accounting for two-thirds of infections), pulmonary/thoracic, gastrointestinal, and pelvic forms exist.

Epidemiology and pathogenesis

Actinomycosis is seen worldwide, and men are affected more often than women. Humans are the only known reservoir for *Actinomyces* spp. *A. israelii* is part of the normal flora of the oral cavity and is also found in the gastrointestinal and female genital tracts. *Actinomyces* spp. are not considered particularly pathogenic, and their virulence is enhanced by co-infection with other organisms. In actinomycotic mycetoma, species of *Actinomyces* other than *A. israelii* are usually responsible for the formation of sulfur granules (see Ch. 77).

Fig. 74.37 Cervicofacial actinomycosis or "lumpy jaw". Soft tissue swelling and draining erythematous nodules are seen. The discharge contained sulfur granules. *Courtesy Joyce Rico, MD.*

Clinical features

In patients with *cervicofacial* actinomycosis ("lumpy jaw"), there is usually a history of poor dental hygiene, dental disease, or a previous orofacial injury or dental procedure. Additional risk factors include chronic tonsillitis and radiation therapy. An initial bluish swelling in the mandibular area progresses to brawny erythematous nodules, which become indurated (Fig. 74.37). Further progression leads to development of sinus tracts which drain purulent material with characteristic yellow "sulfur granules" that represent clumps of bacteria. Fever, pain, and leukocytosis may develop. Lymphadenopathy is usually absent. Once actinomycosis may spread via direct extension or hematogenous dissemination. Destruction of surrounding bony structures can result in facial deformity, and central nervous system involvement may lead to brain abscesses[135].

Pulmonary actinomycosis (15%–20% of patients) occurs after bacteria gain access to the lung through the aspiration of infected oral material. Pulmonary cavities are usually seen at the bases of the lungs. Extension to the pleura and chest wall may occur, and pleurocutaneous fistulas can develop. *Gastrointestinal* actinomycosis is usually preceded by trauma or inflammatory disease but may occur spontaneously. Granulomatous lesions involving the bowel can eventually extend to the abdominal wall, producing an erythematous mass with draining sinus tracts. *Pelvic* actinomycosis in women is often associated with intrauterine contraceptive devices. Actinomycosis may also involve the musculoskeletal system, gastrointestinal tract, and heart.

Pathology

An intense neutrophilic infiltrate is followed by the development of granulomatous inflammation with giant cells. Histiocytes, plasma cells, and epithelioid cells can be seen at the periphery of the abscess, while granules representing microcolonies of *Actinomyces* are seen centrally. Histologically these "sulfur granules" have a basophilic center and acidophilic periphery; they measure up to 30 microns in diameter.

Diagnosis and differential diagnosis

Microscopic examination of purulent material should be performed to detect the sulfur granules that are characteristic of actinomycosis (or actinomycotic mycetoma). They are composed of Gram-positive, branching filaments that fragment into diphtheroid forms and coccobacilli; acid-fast staining is negative. *Actinomyces* grows slowly, so cultures should be held for ≥2 weeks. Cervicofacial actinomycosis may resemble symbiotic anaerobic (e.g. *Eikenella corrodens*) and aerobic bacterial infections, scrofuloderma, dimorphic fungal infections, dental sinus tracts, and even neoplasms[136].

Treatment

The drug of choice for actinomycosis is penicillin G or ampicillin. Deep-seated, chronic infections should be treated with 2–6 weeks of intravenous therapy followed by 3–12 months of oral penicillin. For acute infections, 2–3 weeks of oral penicillin plus incision and drainage and surgical excision of sinus tracts is sufficient. Doxycycline, minocycline, and clindamycin are acceptable alternatives for penicillin-allergic patients. Imipenem has been shown to be effective in treatment-resistant cases. In order to avoid relapse, therapy should be extended beyond the resolution of symptoms[137].

NOCARDIOSIS

Introduction

Nocardiosis is caused by various species of *Nocardia*, a filamentous, Gram-positive, acid-fast organism. *Nocardia* is recognized as an opportunistic pathogen in immunocompromised individuals, causing disseminated or systemic disease; in contrast, cutaneous nocardiosis commonly occurs in immunocompetent hosts.

Epidemiology and pathogenesis

Nocardiosis has a worldwide distribution and affects all age groups. Men are affected more often than women, and children may be more prone to developing lymphocutaneous disease[138]. *Nocardia* spp. are ubiquitous in the soil. Localized trauma (e.g. puncture wounds), occupational exposures (e.g. farmers, gardeners), and immunodeficiency are risk factors for contracting nocardiosis.

Clinical features

The three major forms of primary cutaneous nocardiosis are: (1) mycetoma (see Ch. 77); (2) lymphocutaneous nocardiosis; (3) superficial cutaneous nocardiosis. Secondary skin infection may also develop after hematogenous dissemination, often from a pulmonary source. Table 74.18 details the various clinical presentations of *Nocardia* infection.

Pathology

Histologically, an intense neutrophilic infiltrate with abscess formation is seen. Sulfur granules are observed in *Nocardia* mycetoma but are absent in other forms of cutaneous nocardiosis. Organisms are not visible in routinely stained sections but appear as branching filaments on Gram stain. *Nocardia* also stains with methenamine silver and acid-fast stains.

Diagnosis and differential diagnosis

Nocardia grows easily on all common laboratory media. However, growth is slow, so cultures should be held for ≥2 weeks. Nocardiosis should be suspected in patients with sporotrichoid lesions or trauma-associated superficial cutaneous infections that do not respond to routine treatment. It should also be considered in patients at risk for opportunistic infections.

FOUR MAJOR CLINICAL FORMS OF CUTANEOUS NOCARDIOSIS	
Primary	
Actinomycotic mycetoma	• Half of all cases of actinomycotic mycetoma are due to *Nocardia* species* • Traumatic inoculation causes a painless nodule that enlarges, suppurates, and drains via sinus tracts • Purulent discharge contains sulfur granules • The foot is the usual site of involvement • May involve underlying muscle and bone
Lymphocutaneous	• Occurs days to weeks after trauma • Appears as a crusted pustule or abscess resistant to antibiotics • Ascending lymphatic streaks, a sporotrichoid pattern of papulonodules, and tender palpable lymph nodes may be seen
Superficial cutaneous	• Traumatic implantation of foreign objects (including soil and gravel) into the skin, which may result in pustules, abscesses, cellulitis, and ulcers • The diagnosis is based on a high index of suspicion, lack of response to routine antibiotic treatment, and laboratory results
Secondary	
Pulmonary/systemic	• Subcutaneous abscesses of the chest wall • Pustules, nodules, cutaneous fistulae • Almost universally fatal if left untreated • Most commonly caused by *Nocardia asteroides*

*In Mexico and Central and South America, *N. brasiliensis* is the etiology of 90% of actinomycotic mycetomas, whereas in the United States, most mycetomas are caused by true fungi.

Table 74.18 Four major clinical forms of cutaneous nocardiosis.

Treatment

Sulfonamides are the drugs of choice for nocardiosis. Minocycline is an effective alternative for sulfonamide-allergic patients, and linezolid may be added in resistant cases. For subcutaneous abscesses, surgical treatment is often required. Local forms of nocardiosis should be treated for 6–12 weeks, whereas immunocompromised patients and those with disseminated disease require 3–12 months of antimicrobial therapy.

ALT-70 CELLULITIS PREDICTIVE MODEL – CALCULATION OF THE ALT-70 SCORE		
Criterion	**Definition**	**Score**
Asymmetry	Unilateral lower extremity involvement	3
Leukocytosis	White blood cell count ≥10 000/mcl	1
Tachycardia	Heart rate ≥90 bpm	1
Age	≥70 years	2
Total score: 0–2: favors pseudocellulitis 3–4: may benefit from dermatology consultation ≥5: favors cellulitis		

eTable 74.1 The ALT-70 cellulitis prediction model – calculation of the ALT-70 score. This represents a prospectively validated clinical decision support tool that incorporates objective clinical and laboratory measures to distinguish between lower extremity cellulitis and "pseudocellulitis" at the time of presentation in the emergency department and up to 48 hours later[53]. bpm, beats per minute.

THE LABORATORY RISK INDICATOR FOR NECROTIZING FASCIITIS (LRINEC) SCORE		
Parameter	**Range**	**Score**
Hgb	>13.5 g/dl	0
	11–13.5 g/dl	1
	<11 g/dl	2
WBC	$<15 \times 10^3$/mcl	0
	$15–25 \times 10^3$/mcl	1
	$>25 \times 10^3$/mcl	2
Sodium	<135 mEq/l	2
Creatinine	>1.6 mg/dl	2
Glucose	>180 mg/dl	1
C-reactive protein	≥150 mg/l	4
Total score: ≤5: <50% risk of necrotizing fasciitis (low)* 6–7: raises suspicion of necrotizing fasciitis (intermediate) ≥8: strongly predictive of necrotizing fasciitis; >75% risk (high)		
*Clinical suspicion for necrotizing fasciitis should overrule a low LRINEC score in order to avoid delay in evaluation and management.		

eTable 74.2 The laboratory risk indicator for necrotizing fasciitis (LRINEC) score. The LRINEC tool was devised to identify and distinguish early cases of necrotizing fasciitis from other soft tissue infections using laboratory parameters[64]. Although initially found to have a high specificity and negative predictive value, subsequent studies showed a relatively low sensitivity. Hgb, hemoglobin; WBC, white blood cell count.

75 Mycobacterial Infections

Marcia Ramos-e-Silva, Maria Cristina Ribeiro de Castro and Maria Teresa Ochoa

Chapter Contents

Hansen Disease (Leprosy) 1310
Cutaneous Tuberculosis 1318
Non-tuberculous Mycobacterioses 1324

In 1896, the name "mycobacteria" was given to a large group of bacteria that produce filamentous pellicles similar to molds when grown in liquid media. These organisms are thin, slightly curved to straight, non-motile and non-spore-forming, with a waxy coating that makes them resistant to most stains. Mycobacteria are also acid-fast, which means they are not readily decolorized by acid after staining[1–3]. Of the >170 species in the genus *Mycobacterium*, a number of them may or may not be pathogenic depending on the immunologic state of the host[2,4], whereas *M. leprae* and *M. tuberculosis* are virulent and constitute an important world health problem. Research on Hansen disease (leprosy) has been greatly hampered by the inability to culture the organism, which has the longest doubling time of all known bacteria, but the discovery of the genomic sequence of *M. leprae* in 2001 was a significant advancement[5].

Although the classic mycobacterioses – Hansen disease and tuberculosis – have been known since antiquity, over the past few decades there has been a worldwide explosion in the incidence of mycobacterial infections. Several factors have played a role in this increase, including the emergence of resistant strains of *M. tuberculosis* and a rise in the number of immunocompromised hosts, including those with AIDS[3]. In Table 75.1, the different species of mycobacteria that are associated with cutaneous disease are outlined utilizing Runyon's classification scheme[1,3,6].

This chapter addresses the mycobacterial species that are of greatest interest to dermatologists: *M. leprae, M. tuberculosis*, and non-tuberculous mycobacteria that cause cutaneous infections.

HANSEN DISEASE (LEPROSY)

Key features

- Chronic infectious disease caused by *Mycobacterium leprae* or *M. lepromatosis*, intracytoplasmic bacteria that parasitize macrophages and Schwann cells
- Slowly progressive condition characterized by granulomas and neurotropism, with a predilection for the skin as well as peripheral nerves
- The primary skin lesion is erythematous or hypopigmented, and it is often anesthetic
- Based upon the clinicopathologic findings, which reflect the degree/type of immunity, Hansen disease is divided into two major forms – lepromatous with a predominantly Th2 response and tuberculoid with a predominantly Th1 response
- In the lepromatous form of Hansen disease, multiple organisms are present in the dermis, whereas in the tuberculoid form, there are only a few organisms

Introduction

Hansen disease is a chronic infectious disease that is caused by *Mycobacterium leprae* or *M. lepromatosis* and has a predilection for the skin and nerves[7,8]. It is divided into two major forms depending upon the degree and type of immunity – lepromatous with a predominantly Th2 response and tuberculoid with a predominantly Th1 response. Hansen disease is classified by the World Health Organization (WHO) as a "neglected tropical disease" that represents a public health concern in a number of low-income countries. Once worldwide in distribution, Hansen disease is now seen primarily in tropical and subtropical regions of Asia, Africa, and Central and South America (Fig. 75.1). Early diagnosis and prompt therapy are key components in the strategy to control this chronic infectious disease[9].

History

The first written descriptions of leprosy may date back to as early as 600 BCE in India, and to 200 BCE in China and Japan. Many of the cases mentioned in the Bible may actually have been psoriasis, vitiligo, or other skin disorders rather than leprosy. The earliest scientific evidence of leprosy has come from an Egyptian skeleton and two Coptic mummies from the second century BCE and the fifth century CE, respectively. One theory was that leprosy was brought from India to the Mediterranean basin by Alexander the Great's soldiers between 327 and 326 BCE and then spread throughout the Greek and Roman Empires. Recent studies utilizing comparative genomics have shown that all extant cases of leprosy are attributable to a single clone, and the disease appears to have originated in the Near East or eastern Africa[10]. During the Middle Ages, leprosy reached epidemic proportions in Europe and then spread to the New World via the wave of exploration in the late fifteenth and sixteenth centuries[11]. Independent of geographic location, the afflicted have frequently been ostracized by their communities and families.

During the nineteenth century, Danielssen and Boeck provided the first modern description of leprosy, and in the 1870s, a third Norwegian, Gerhard Henrik Armauer Hansen, identified *M. leprae*. The term Hansen disease is commonly used nowadays and may help to decrease the stigma associated with this infection. Mitsuda created the skin test for leprosy in 1919[12], and the value of sulfones in the treatment of leprosy was reported in 1942[13]. In 1966, Ridley and Jopling suggested a classification of leprosy based on the immunologic status of the patient (see below)[14].

Epidemiology

In the early 1980s, 11–15 million people worldwide were estimated to have Hansen disease. Introduction of multidrug therapy (MDT) has substantially reduced the number of affected individuals. The number of new cases per year decreased from >500 000 in 2003 to <150 000 in 2021, with only ~130 000 patients requiring treatment remaining worldwide[15,16]. However, the incidence remains relatively high among patients <15 years of age. The goal of the WHO is a prevalence rate of <1 case per 10 000 persons, which has been achieved in all but a few countries[17]. In 2021, Brazil (especially western Amazonia), India, and Indonesia accounted for ~75% of new cases, with other countries that have high infection rates located primarily in Southeast Asia and Africa (see Fig. 75.1). In the US, ~150–200 new cases are reported yearly. Recent evidence suggests that Hansen disease may be endemic in Florida[17a].

Although men and women are equally affected, the lepromatous form of Hansen disease is seen more often in men than in women (~1.5 : 1). Hansen disease affects all races and ages, with the highest incidences in individuals 10–15 and 30–60 years of age[18]. Key factors in the acquisition of Hansen disease are close contact of a susceptible person (e.g. based on genetic predisposition; see below) with a contagious individual (e.g. with multibacillary disease). The risk of acquiring the disease from household contacts is 25%, emphasizing the public health importance of domicile control[19]. The incubation period varies widely, from months to >30 years, but it is usually 4–10 years[18]. *M. leprae* is spread

predominantly by patients with multibacillary disease via nasal and oral droplets and much less often from eroded skin[12,20].

Although Hansen disease primarily affects humans, it can be found in nine-banded armadillos (southern US from Texas to Florida, Brazil) and red squirrels (British Isles)[9,21]. In one study, ~40% of patients with Hansen disease from the southeastern US were infected with one of two *M. leprae* genotypes associated with wild armadillos, suggesting that Hansen disease represents a zoonosis in this region[22].

MYCOBACTERIA THAT CAUSE CUTANEOUS DISEASE		
Group and pigment	**Rate of growth**	**Pathogens**
Slow growers		
Photochromogens*	2–3 weeks	*M. kansasii, M. marinum, M. simiae*
Scotochromogens†	2–3 weeks	*M. scrofulaceum, M. szulgai, M. gordonae, M. xenopi*
Nonchromogens‡	2–3 weeks	*M. tuberculosis, M. avium, M. intracellulare, M. ulcerans, M. haemophilum, M. malmoense, M. terrae, M. genavense, M. bovis*¶, *M. nonchromogenicum*
Rapid growers	3–5 days	*M. fortuitum, M. chelonae, M. smegmatis, M. abscessus*§, *M. immunogenum, M. goodii, M. wolinskyi, M. cosmeticum, M. mucogenicum, M. mageritense*
Non-cultured (to date)		*M. leprae*

*Capable of yellow pigment formation upon exposure to light.
†Capable of yellow pigment production without light exposure.
‡Incapable of pigment production.
¶Including bacillus Calmette–Guérin.
§Including *M. abscessus* subsp. *massiliense* and *M. abscessus* subsp. *bolletii*.

Table 75.1 Mycobacteria that cause cutaneous disease. Modified classification of Runyon[1,3,6].

Pathogenesis

M. leprae and *M. lepromatosis* are very small, slightly curved rods that are characteristically acid-fast. They are obligate intracellular microorganisms with a predilection for macrophages and Schwann cells. The major sites of involvement are the peripheral nerves, skin, mucous membranes, bones, and viscera (e.g. testes, liver). In animal models, these bacilli grow best at a temperature of 27–33°C, and they thus prefer cooler regions of the body (e.g. nose, testicles, ear lobes) as well as regions where the peripheral nerves are close to the skin[18,23].

The fact that the majority of exposed individuals do not develop disease implies that there is variability in susceptibility/resistance, depending upon genetic and environmental factors. For example, susceptibility and the type of immune response appear to correlate with specific HLA types, such that individuals with HLA-DR2 and HLA-DR3 are more likely to develop the tuberculoid form and those with HLA-DQ1 the lepromatous form[18].

Polymorphisms in the genes that encode interleukin (IL)-6, 10, 12, and 17A/F; tumor necrosis factor (TNF); lymphotoxin-α (a low-producing allele linked to early-onset Hansen disease); and the IL-23 receptor, vitamin D receptor (VDR), and Toll-like receptors (TLRs) 1 and 2 have been shown to be related to either overall Hansen disease susceptibility or the particular form of Hansen disease that develops[24–27]. The genetic factors implicated vary in different populations. For example, in Vietnamese and Brazilian populations, variants in the shared regulatory region of the *PRKN* (encoding Parkin, an E3 ubiquitin protein ligase) and *PACRG* genes have been associated with susceptibility to Hansen disease[28]. Genome-wide association studies in Chinese populations have linked variants in genes encoding proteins in the NOD2 (nucleotide-binding oligomerization domain containing 2) pathway with susceptibility to Hansen disease, especially the multibacillary form[29]. The NOD2 pathway, along with the VDR, TLRs, and Parkin, play key roles in the innate immune response, as do several additional proteins encoded by genes associated with Hansen disease, e.g. *MBL* (mannose-binding lectin), *MRC1* (mannose receptor C-type 1), *SLC11A1* (solute carrier family 11 member 1), and *KIR* (killer cell immunoglobulin-like receptor). TLRs, NOD2, and MRC1 have been associated with modulation of autophagy, whereas Parkin and LRRK2 (leucine rich repeat kinase 2) have roles in the regulation of host cell apoptosis.

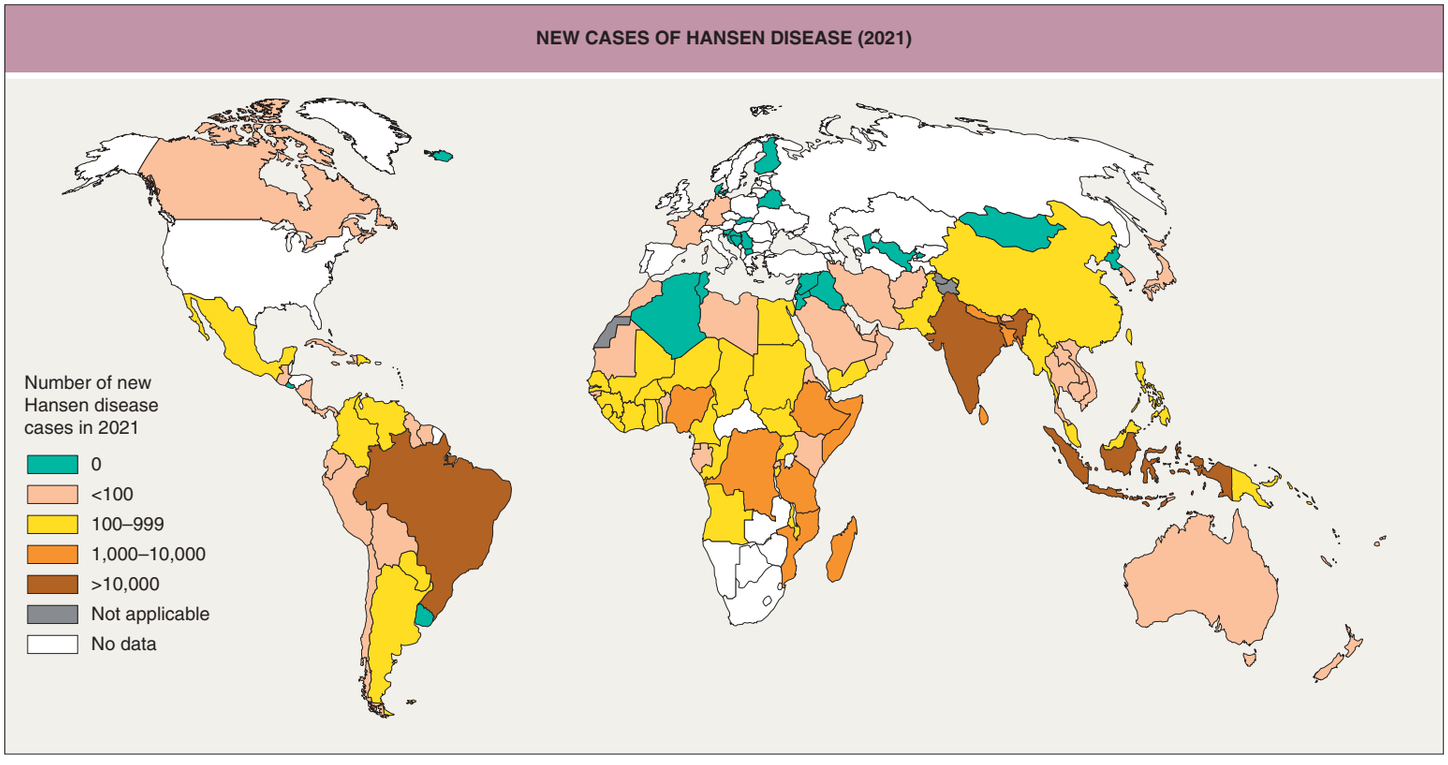

Fig. 75.1 New cases of Hansen disease, 2021. The World Health Organization (WHO) has achieved its goal of a prevalence rate of less than 1 case per 10 000 persons in all but a few countries. Over half of cases in the US are from seven states – Florida, Louisiana, Texas, California, New York, Hawaii, and Georgia. *Reproduced from the World Health Organization, https://apps.who.int/neglected_diseases/ntddata/leprosy/leprosy.html*

Presentations of Hansen disease exist on a clinical–immunologic spectrum. At one end, patients with the *tuberculoid* form of Hansen disease have specific cell-mediated immunity (CMI), as reflected in a positive lepromin test (Mitsuda reaction; see below). At the other end, patients with the *lepromatous* form of Hansen disease have a negative lepromin test and minimal CMI, while humoral immunity is increased (Fig. 75.2)[9]. For example, serum levels of antibodies against phenolic glycolipid-1 (PGL-1), an *M. leprae*-specific antigen, are highest in patients with the lepromatous form[30].

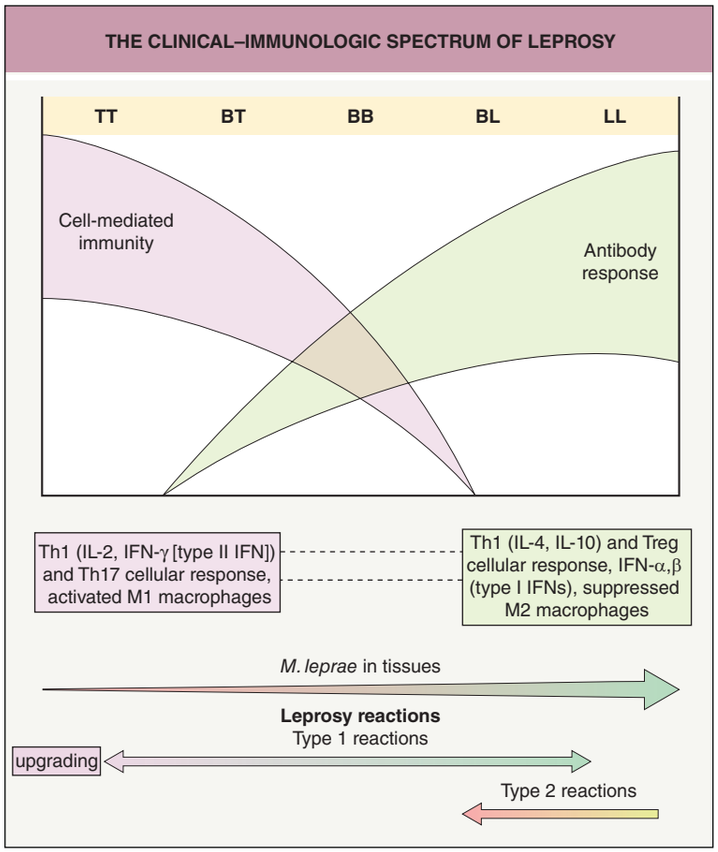

Fig. 75.2 The clinical–immunologic spectrum of Hansen disease. This reflects the underlying host immunity as measured by the T lymphocyte and antibody responses to *Mycobacterium leprae*. TT, tuberculoid leprosy; BT, borderline tuberculoid leprosy; BB, mid-borderline leprosy; BL, borderline lepromatous leprosy; LL, lepromatous leprosy; IFN, interferon; IL, interleukin. *Adapted from Britton WJ. Leprosy. In Cohen J, Powderly WG (eds). Infectious Diseases. London: Mosby, 2003. With permission of Elsevier.*

Macrophages play an important role in the body's attempt to eliminate *M. leprae*, activating a type I interferon (IFN) response and producing IL-1, TNF, and IL-12. Patients with the *tuberculoid* form maintain this inflammatory response and an effective CMI. They display a Th1 $CD4^+$ T cell response that produces IL-2, IFN-γ (type II IFN), and lymphotoxin-α in addition to involvement of $CD8^+$ cytotoxic T cells, γ/δ T cells, CD1a-restricted T cells, and Th17 cells. In patients with the *lepromatous* form, a predominantly Th2 response leads to the release of different cytokines – IL-4, IL-5, IL-10, and IL-13; these cytokines suppress macrophage activity[23,31]. $CD4^+$ regulatory T cells, $CD8^+$ suppressor T cells, and type I IFNs predominate in these patients[32]. The cell wall of *M. leprae* contains lipid complexes, including PGL-1, which may suppress T cell responses and IFN-γ production as well as the organism's invasion of Schwann cells in a laminin-2-dependent pathway[23,33,34].

$CD4^+$ T cells that express the antimicrobial protein granulysin have been detected at a sixfold greater frequency in tuberculoid as compared to lepromatous skin lesions[35]. Tuberculoid lesions also have stronger expression of TLR2 and TLR1, activation of which can induce differentiation of macrophages and dendritic cells. $CD1b^+$ dendritic cells, which promote T cell activation and secretion of proinflammatory cytokines, were not detected in lesions from patients with the lepromatous form of Hansen disease[36]; instead, these lesions had upregulation of genes belonging to the leukocyte immunoglobulin-like receptor (LIR) family. LIR-7 has been shown to suppress innate host defense by several mechanisms, including blocking antimicrobial activity triggered by TLRs[37].

Clinical Features

There is a wide spectrum of clinical findings in Hansen disease, and several classification schemes have been utilized. The Ridley and Jopling classification is based on an immunopathologic spectrum (Table 75.2; see Fig. 75.2), with lepromatous (LL) at the end with the least effective immune response, tuberculoid (TT) at the end with strong CMI, and three types of borderline leprosy in between: borderline lepromatous (BL), borderline–borderline (BB, in the middle), and borderline tuberculoid (BT) (Fig. 75.3)[12,14,18].

In addition, the WHO created an operational system to facilitate the classification and treatment of Hansen disease in endemic areas. Per the WHO, the diagnosis of Hansen disease is based on the presence of at least one of the following cardinal features: (1) anesthesia in a hypopigmented or erythematous skin lesion; (2) enlarged peripheral nerve with associated loss of sensation and/or weakness; and (3) the presence of acid-fast bacilli in a slit-skin smear or biopsy. The current WHO classification system (revised in 2017) divides Hansen disease into two main groups: (1) *paucibacillary leprosy* – one to five skin lesions, without demonstrated presence of bacilli in a slit-skin smear or biopsy when assessed; and (2) *multibacillary leprosy* – more than five skin lesions, nerve involvement (pure neuritis or with any number of skin lesions),

CLASSIFICATION OF HANSEN DISEASE						
Clinical findings	**LL**	**BL**	**BB**	**BT**	**TT**	**I**
Type of lesions	Macules, papules, nodules, diffuse infiltration	Macules, papules, annular plaques, infiltration	Annular plaques with a "Swiss cheese" appearance; dome-shaped, punched-out lesions	Infiltrated plaques, often larger than those of TT	Erythematous or hypopigmented patch or plaque with raised border	Macules, often hypopigmented
Number of lesions	Numerous	Many	Many	Single, usually with satellite lesions, to 5	One or few (≤5)	One or few
Distribution	Symmetric	Tendency to symmetry	Usually symmetric	Asymmetric	Localized, asymmetric	Variable
Definition	Vague, difficult to distinguish normal versus affected skin	Ill-defined borders	Well-defined inner border, less defined outer border	Compared to TT, less defined borders	Well-defined, sharp borders	Not always defined
Sensation	Not affected	Diminished	Diminished	Absent	Absent	Impaired
Bacilli in skin lesions	Many (globi)	Many	Many	Few (1+), if any, detected	None detected	Usually none detected

Table 75.2 Classification of Hansen disease. LL, lepromatous leprosy; BL, borderline LL; BB, mid-borderline leprosy; BT, borderline TT; TT, tuberculoid leprosy; I, indeterminate. *Adapted from A Guide to Leprosy Control, 2nd ed. Geneva: World Health Organization, 1988:27–8.*

or the presence of bacilli in a slit-skin smear or biopsy (with any number of skin lesions)[38]. This classification is commonly employed worldwide.

Certain peripheral nerves are more commonly affected, based primarily upon their more superficial location. Palpation of these nerves is an integral component of the physical examination of a patient with Hansen disease (Fig. 75.4). The clinician should determine whether there is a decrease in sensation to pain, temperature, and/or touch. This is in addition to inspection for neuropathic changes (e.g. muscle atrophy, flexion contractures of the fourth and fifth fingers), vasomotor alterations, and secretory disturbances (e.g. dry skin and eyes)[12,18].

The *lepromatous* form of Hansen disease, the form with the least cellular immunity and greatest number of bacilli, is characterized initially by multiple, poorly defined, erythematous macules, papules, nodules, and plaques (Fig. 75.5A). Lesions are widespread and usually symmetric in distribution. The most common sites of involvement are the face, buttocks, and extremities. Infiltration of the skin of the forehead can lead to leonine facies (Fig. 75.5B). Additional signs and late sequelae include madarosis, saddle nose, infiltration of both earlobes, and acquired ichthyosis on the lower extremities (Fig. 75.6). Anesthesia in a stocking or glove distribution may develop, often together with enlarged peripheral nerves and neuropathic changes. Ocular manifestations such as lagophthalmos (inability to completely close the eyes) and corneal and conjunctival anesthesia due to involvement of branches of the facial and trigeminal nerves, respectively, are sometimes present in severe cases[18].

Histoid leprosy is a clinically distinct form of multibacillary disease that some authors classify as a variant of the lepromatous form. It is characterized by the development of dermatofibroma-like papules and nodules. *Lucio leprosy* is a non-nodular, diffuse form of lepromatous leprosy most commonly seen in Mexico and Central America that results from *M. lepromatosis* infection[39].

Borderline leprosy, as its name implies, has features that are intermediate between the two ends of the spectrum. The severity of the cutaneous and peripheral nervous system manifestations depends upon whether the patient is "leaning" towards the lepromatous pole (BL) or the tuberculoid pole (BT; see Table 75.2). BT cutaneous lesions are usually asymmetric and are typically larger in size with less defined borders than those of the tuberculoid form (see Fig. 75.3A). Affected areas are hypoesthetic and have decreased sweating. BB leprosy characteristically presents with annular plaques that can have a "Swiss cheese" appearance (Fig. 75.7; see Fig. 75.3B). The cutaneous lesions of BL leprosy are more numerous and symmetric, with variable morphologies.

The *tuberculoid* form of Hansen disease usually presents with a few patches or plaques that have sharply demarcated, slightly raised borders. The color of these lesions ranges from erythematous to hypopigmented, with the latter especially common in patients with darkly pigmented skin (Fig. 75.8). Lesional alopecia and anesthesia or hypesthesia can represent clues to the diagnosis. Unilateral neuropathic changes, especially of the extremities (e.g. digital resorption), may be seen[14]. Occasionally, only neural involvement is present ("pure neuritic [neural] leprosy").

The development of reactions complicates the course of Hansen disease in ~30%–50% of patients, especially during treatment (see Fig. 75.2). These are characterized by acute inflammation that appears suddenly before, during, or after treatment (Fig. 75.9 & 75.10). *Type 1 reactions* can affect patients with any form of Hansen disease (except for the early indeterminate form), but there is a predilection for borderline categories. *Type 2 reactions* most often occur in lepromatous or BL leprosy. In addition to the administration of antimicrobial drugs, the most frequent triggers for reactions are pregnancy, other infections, and mental distress. The immunopathogenesis, clinical manifestations, and treatment of the two major types of inflammatory reactions are outlined in Table 75.3[40].

Type 1 (reversal) reactions are due to a change in the immunologic state of the patient and are often associated with neuritis. When there is an increase in cell-mediated immunity, this is referred to as an "upgrading" reaction (see Fig. 75.10A). *Type 2 reactions* are due to the formation of immune complexes in association with neutrophil recruitment[41].

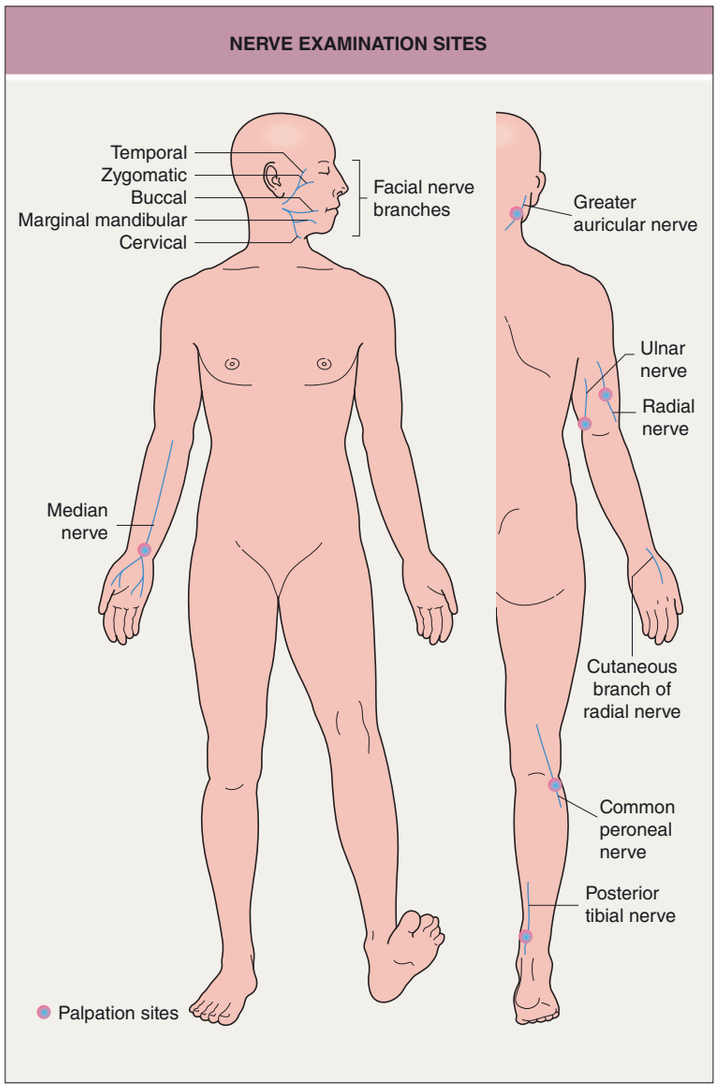

Fig. 75.4 Nerve examination sites.

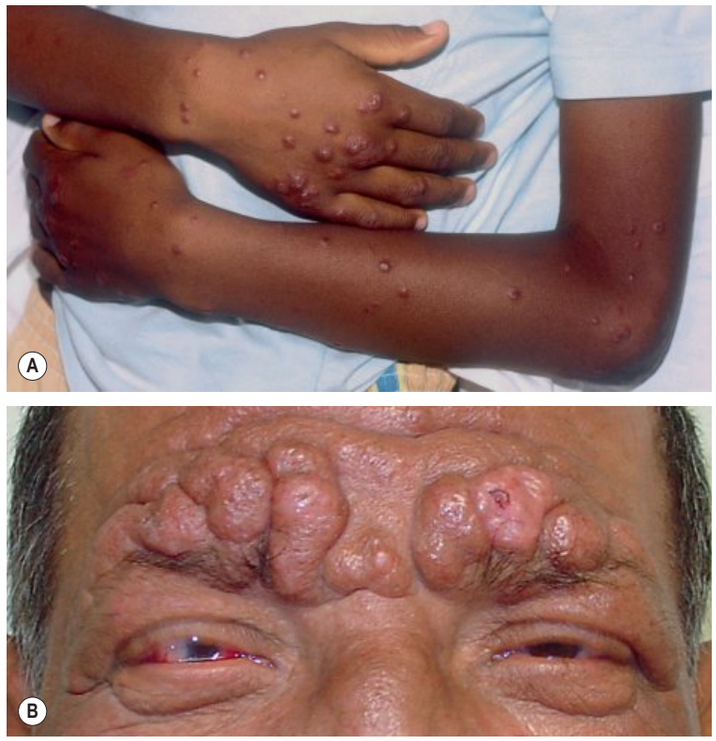

Fig. 75.5 Lepromatous form of Hansen disease. A Numerous erythematous papules and nodules on the forearms and hands. **B** Infiltrated nodules coalescing on the forehead with leonine facies and madarosis. Note the ocular involvement.

A type 2 reaction can result in cutaneous and systemic small vessel vasculitis (e.g. erythema nodosum leprosum; see Fig. 75.10B,C)[12,18,23]. Patients with the diffuse form of lepromatous leprosy, who are usually from Central or South America, may develop the *Lucio phenomenon*, a reactional state characterized by thrombosis associated with antiphospholipid antibodies in addition to a vasculopathy and/or necrotizing cutaneous small vessel vasculitis (Fig. 75.10D). On a worldwide basis, Hansen disease is a common cause of cutaneous vasculitis, especially in low-income countries[42].

Pathology and Laboratory Evaluation

There are three basic histopathologic patterns observed in Hansen disease: lepromatous, tuberculoid, and borderline. In the *lepromatous* pattern, an infiltrate may be seen in the dermis, subcutis, lymph nodes, abdominal organs (e.g. kidney, liver), testicles, and bone marrow. The infiltrate contains Virchow cells, which are macrophages with numerous bacilli as well as lipid droplets in their cytoplasm. In H&E-stained sections, these cells have a foamy appearance. The bacilli in Hansen disease can be detected by a Fite–Faraco stain (more sensitive) or Ziehl–Neelsen stain, both of which stain the bacilli a bright red color. For lesions in which bacilli are usually scant, it is recommended that at least six sections be examined before declaring them negative[12].

A band of normal-appearing dermis (Unna band or Grenz zone) separates the epidermis from the dermal infiltrate, which is composed of plasma cells and a few lymphocytes in addition to foamy macrophages containing globi (clumps of bacilli) (Fig. 75.11). Following successful therapy, the organisms fragment and become granular. Cutaneous nerves demonstrate lamination of the perineurium, producing an onion-skin appearance. In the histoid variant, a well-circumscribed proliferation of spindle cells contains numerous bacilli, which typically line up along the long axis of the cell.

In the *tuberculoid* pattern of Hansen disease, a dermal granulomatous infiltrate is seen and may have a linear pattern following the course of a nerve (Fig. 75.12). Epithelioid cells and Langhans giant cells are surrounded by lymphocytes. The cutaneous nerves are edematous, and organisms are absent or rare, even with special stains. Inflammation and fragmentation of nerve fibers in the tuberculoid form differentiate it from sarcoidosis and other granulomatous disorders.

The *borderline* pattern contains histologic features of both the lepromatous form (e.g. Virchow cells) and tuberculoid form (e.g. granulomas). Predominance of the former versus the latter is dependent upon whether the patient has the BL, BB, or BT form of borderline leprosy.

Indeterminate Hansen disease is usually difficult to diagnose histologically. Only a patchy infiltrate of lymphocytes or histiocytes around blood vessels or appendages is seen[9]. There are no granulomas or Virchow cells[12], and organisms are usually absent.

When Hansen disease is suspected, the diagnosis can be confirmed by finding bacilli in a biopsy or a slit-skin smear. Samples for the slit-skin smear may be obtained from the earlobes, elbows, knees, and cutaneous lesions. To avoid bleeding, a fold of skin is firmly squeezed between the finger and thumb of the examiner or with forceps, and a small incision is made with a scalpel blade. The liquid obtained is smeared onto a slide and allowed to dry. The smear is usually stained by the Fite–Faraco method and a search is made for red rods (against a blue background) at 100× with oil immersion[9]. Organisms are found in 100% of patients with the lepromatous form, 75% of those with borderline leprosy, and only 5% of those with the tuberculoid form. A biopsy specimen of the skin lesions should be obtained, especially in patients with suspected tuberculoid leprosy (see above). Where available, fluorescent microscopy with auramine rhodamine staining has been shown to be more sensitive than the Fite–Faraco method for detecting organisms in skin biopsy specimens[43].

PCR can be utilized to amplify genes that encode antigenic proteins (e.g. 36 kDa proline-rich antigen, Ag85B, 16 s) as well as *M. leprae*- or *M. lepromatosis*-specific repetitive repeat sequences (RLEP region). Molecular methods (e.g. analyzing RLEP region) can distinguish *M. leprae* from *M. lepromatosis* and are particularly helpful in

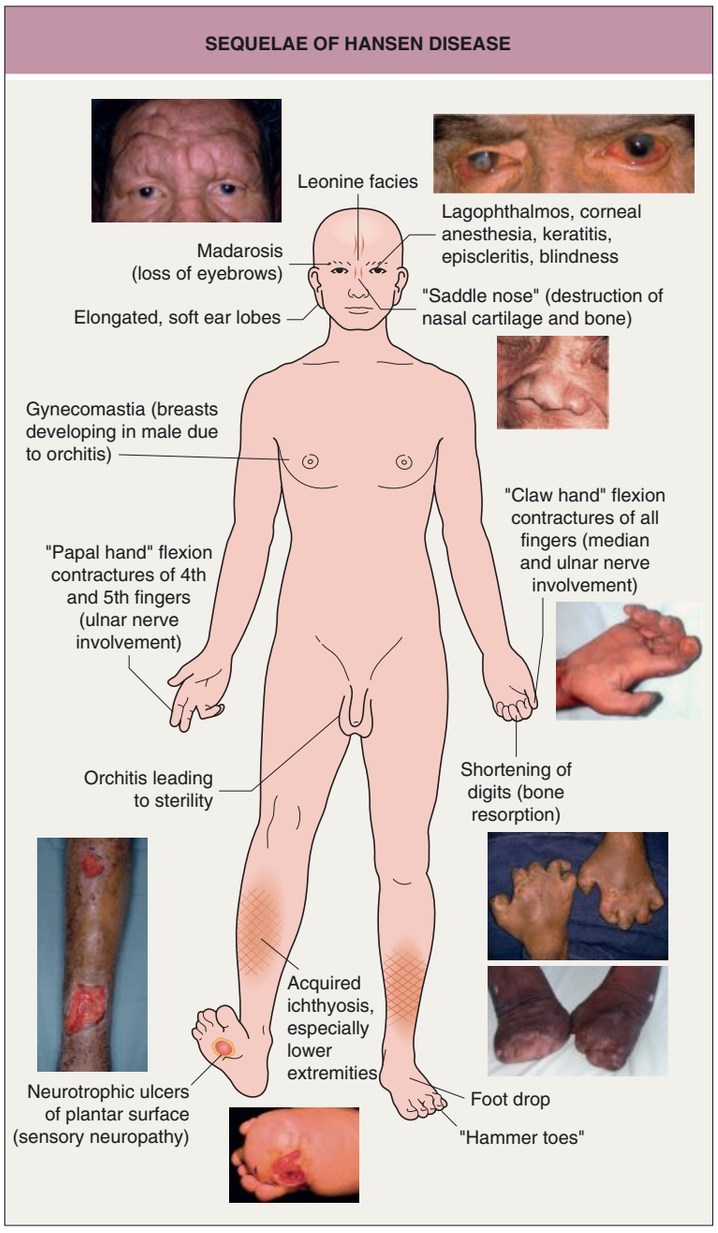

Fig. 75.6 Sequelae of Hansen disease. *Insets, Courtesy Louis A. Fragola, Jr, MD and Joyce Rico, MD.*

paucibacillary and pure neuritic leprosy[44]. PCR can also be performed on slit-skin smears and fresh, frozen[45], or paraffin-embedded skin biopsy specimens (Table 75.4). In a study utilizing RLEP real-time PCR, *M. leprae* DNA was detected in 38 (75%) of 51 paraffin-embedded skin biopsy specimens from patients with paucibacillary leprosy[46,47]. In addition, immunohistochemical staining of biopsy specimens for the PGL-1 antigen may prove helpful in paucibacillary disease.

Serologic assays for anti-PGL antibodies are only sensitive for the diagnosis of multibacillary disease. However, measurement of these antibodies can help to classify patients, monitor the response to treatment, and predict leprosy reactions[48]. Serum levels of anti-PGL-1 IgG and IgM antibodies are highest in lepromatous disease and lowest (or absent) in BT or tuberculoid disease, therefore representing a marker of mycobacterial "load". Elevation of anti-PGL-1 IgM antibody levels is also associated with reactions and impairment of nerve function[30].

The lepromin (Mitsuda) test consists of an intradermal injection of 0.1 ml of a suspension of heat-killed *M. leprae*. The response is positive when a nodule forms at the site of injection 3 to 4 weeks later, indicating that the patient can mount a specific cell-mediated response to the bacilli. The test provides prognostic, but not diagnostic, information. It is positive in TT and BT leprosy[9].

Lastly, Hansen disease, especially LL and BL, is one of the causes of biologically false-positive anti-nuclear antibodies (ANA) or rheumatoid

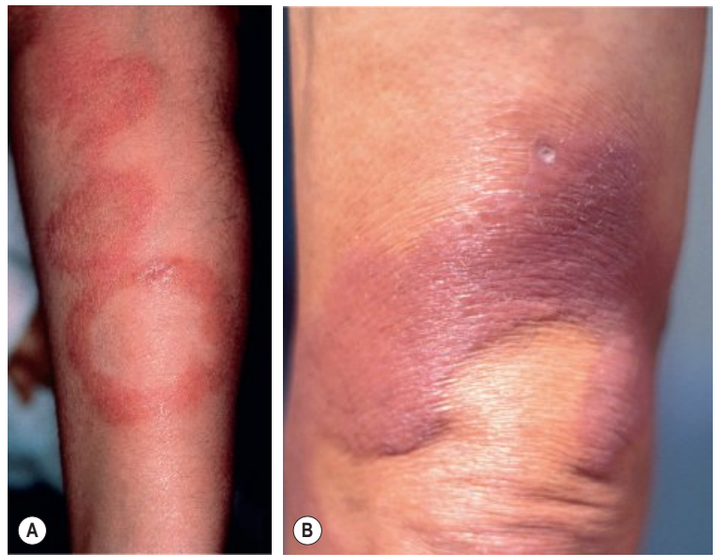

Fig. 75.7 Borderline borderline leprosy. Erythematous plaques with central clearing leading to annular (**A**) and arcuate (**B**) lesions. Note the ill-defined outer borders and well-demarcated inner borders.

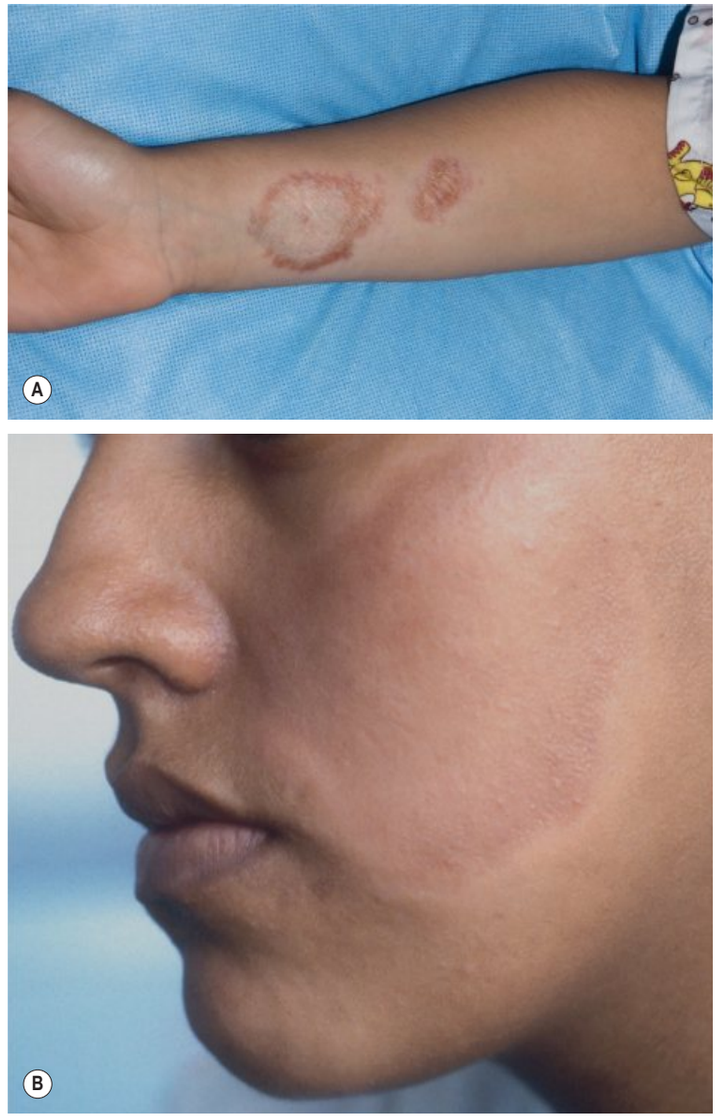

Fig. 75.8 Tuberculoid form of Hansen disease. A Two plaques on the forearm of a child that have dull pink–brown raised borders and central atrophy with hypopigmentation. **B** Large annular lesion on the cheek with a red–brown color and rim of hypopigmentation. *A, Courtesy Edward Cowen, MD.*

factor as well as Venereal Disease Research Laboratory (VDRL) and fluorescent treponemal antibody absorption (FTA-ABS) assays for syphilis (see Ch. 82).

An important goal in the management of Hansen disease is the prevention of disability. The WHO divides Hansen disease-related disability into three categories: grade 0, normal protective sensation; grade 1, loss of protective sensation of hands, feet, or eyes; and grade 2, visible deformities including ulcers, claw hand, foot drop, bone resorption, and lagophthalmos. Early detection of neuropathy is critical to prevent disability, but unfortunately the diagnosis of Hansen disease is often delayed for 1–2 years[48a]. Methods to detect nerve damage range from simple tests such as light touch with a cotton swab or monofilament to techniques such as nerve conductive studies, high resolution ultrasound, and MRI[48b].

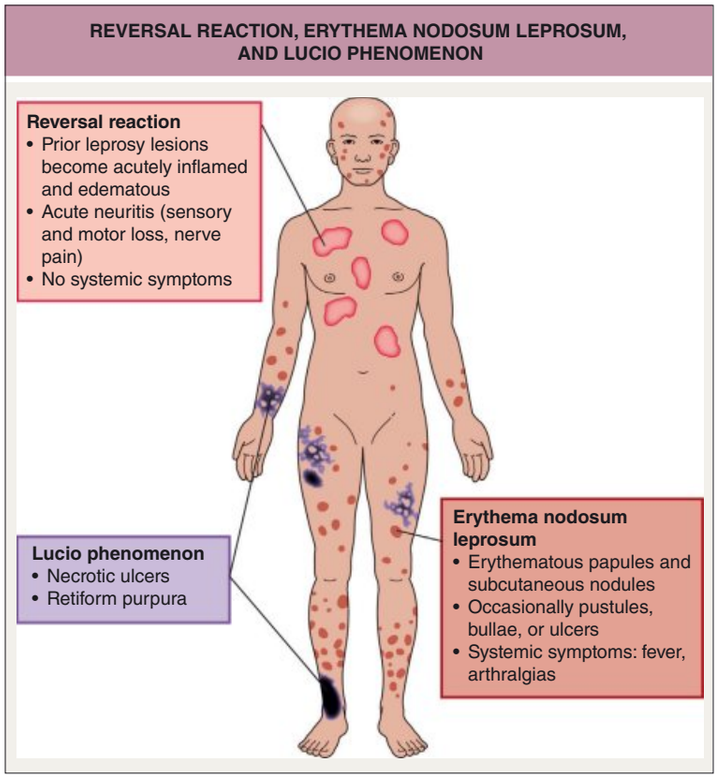

Fig. 75.9 Leprosy reactions – reversal reaction (type 1), erythema nodosum leprosum (type 2), and Lucio phenomenon.

TWO MAJOR TYPES OF LEPROSY REACTIONAL STATES		
	Type 1 – reversal reaction	**Type 2 – erythema nodosum leprosum**
Immune mechanism	Delayed-type hypersensitivity reaction with a Th1 cytokine pattern	Excessive humoral immunity with a Th2 cytokine pattern and formation of immune complexes; may be accompanied by increased cell-mediated immunity and neutrophils
Leprosy category	Borderline (BT, BB, BL) or tuberculoid with immunologic recovery (upgrading)	Lepromatous and BL > BB; especially patients with a high bacterial index
Clinical characteristics	• Increased inflammation in established skin lesions; in severe form, swelling and ulceration of facial lesions • Acute nerve pain or tenderness (neuritis) and loss of function • Recent (<6 month history) or progressive neurologic impairment in the absence of painful nerves • "Hot" abscess of nerve*	• New papular or nodular skin lesions • Fever, myalgias, malaise • Severe joint swelling and pain • Iridocyclitis • Lymphadenitis • Hepatosplenomegaly • Orchitis • Glomerulonephritis • Mild disease – low-grade fever, few ENL lesions of extremities, no internal organ involvement • Severe disease – high fever, numerous recurrent ENL nodules which can be pustular or ulcerative, internal organ involvement
Treatment	Prednisone: 40 mg per day tapered over 12 to 36 weeks, depending upon whether paucibacillary vs multibacillary and specific protocol†	Thalidomide: for severe disease, 400 mg po daily then taper to 300 mg po daily once reaction under control followed by taper to the lowest dose without a flare; latter dose then continued 2–3 months

*As opposed to "cold" abscess of nerve in TT leprosy.

PCR TESTING FOR *MYCOBACTERIA LEPRAE* AND *M. LEPROMATOSIS*	
Skin biopsy specimen	**Comments**
• 4–5 mm punch biopsy that includes subcutaneous fat	• Ensures that involved nerves, often within the deep dermis, are included
• Preferred site of biopsy is active margin of lesion	
• Formalin-fixed, paraffin-embedded tissue block – *or* – tissue within formalin*	• Testing *cannot* be performed on tissue sections on a slide
• Drug resistance can also be assessed	
*Requires expedited delivery to avoid prolonged exposure to formalin.	

Table 75.4 PCR testing for *Mycobacteria leprae* and *M. lepromatosis*. In addition to PCR, secondary histopathologic review is performed. This evaluation is provided free-of-charge to patients and submitting facilities within the USA and its territories by the National Hansen's Disease Program in Baton Rouge, LA (consultation request form is available online at www.hrsa.gov/sites/default/files/hrsa/hansens-disease/skin-biopsy-protocol-form.pdf).

Differential Diagnosis

Skin diseases that may be confused with the different cutaneous presentations of Hansen disease are outlined in Table 75.5.

Treatment

Safety, effectiveness, and ease of administration represent key considerations in multidrug therapy for Hansen disease. The WHO 2018 guidelines recommend a three-drug regimen consisting of rifampin (rifampicin), dapsone, and clofazimine for all patients with Hansen disease, with a treatment duration of 6 months for paucibacillary (PB) disease and 12 months for multibacillary (MB) disease (Table 75.6)[38]. This change from only two drugs (rifampin and dapsone) for PB disease in the previous WHO guidelines was based on better outcomes with three drugs as well as simplification of treatment (e.g. only one type of blister pack) and reducing the impact of misclassification of MB as PB disease. Of note, Chinese patients with a HLA-B*13-01 polymorphism are at high risk of hypersensitivity to dapsone[49].

In the US, the National Hansen Disease Program recommends a longer duration of treatment (1 year for PB, 2 years for MB), with no clofazimine for PB disease and the option of daily (rather than monthly) rifampin administration[50]. For patients with PB disease, therapy with *r*ifampin, *o*floxacin, and *m*inocycline ("ROM scheme"), including a single dose for individuals with a single lesion, has also produced good results[51,52].

Multidrug therapy is extremely effective. Importantly, after the first dose, the patient is no longer infectious to others. Granular or beaded bacilli may be found in biopsy specimens following initiation of treatment but are considered to be non-viable. Hansen disease relapses are rare in the setting of recommended therapy/treatment regimens, affecting <5% of patients over a 5–10 year follow-up period. In a study of 1932 patients from endemic countries with MB disease, molecular evidence of resistance to rifampin, dapsone, and/or ofloxacin was present in 8% of cases[53]. Antimicrobial resistance to rifampin and dapsone is due primarily to mutations in *rpoB* (encodes DNA-directed RNA polymerase β subunit) and *folp1* (encodes dihydropteroate synthase), respectively.

Alternative antibiotics such as minocycline, clarithromycin, and ofloxacin can be used when there is resistance to or intolerance of first-line agents (see Table 75.6). Drugs that may play a significant role in the treatment of Hansen disease in the future include other quinolones (e.g. moxifloxacin) and ansamycins[54–56]. Rifapentine (a rifampin derivative) has higher peak serum concentrations, a longer serum half-life, and more bactericidal activity against *M. leprae* than rifampin. In addition, moxifloxacin appears to be more bactericidal than ofloxacin. Thus, the combination of rifapentine, moxifloxacin, and minocycline (PMM) may be superior to rifampin, ofloxacin, and minocycline (ROM)[56].

For the two major inflammatory reactions, additional medications are often required. Oral prednisone is used for type 1 (reversal) reactions, while thalidomide is the principal therapy for type 2 reactions (erythema nodosum leprosum; see Table 75.3). Systemic corticosteroids are also recommended for the Lucio phenomenon. Although thalidomide

CLINICAL DIFFERENTIAL DIAGNOSIS OF HANSEN DISEASE	
Hypopigmented lesions	• Mycosis fungoides, including the hypopigmented variant • Sarcoidosis, but the hypopigmented variant is usually more papulonodular • Postinflammatory hypopigmentation, pityriasis alba • Tinea versicolor
Circinate (annular) plaques	• Mycosis fungoides and other forms of cutaneous lymphoma • Sarcoidosis • Psoriasis • Reactive granulomatous dermatitis • Granuloma annulare, erythema annulare centrifugum • Tinea corporis
Infiltrated plaques/ nodules	• Lymphoma • Sarcoidosis • Other infections (e.g. dimorphic fungal infection, tuberculosis, leishmaniasis, syphilis) • For DDx of leonine facies, see Table 46.5
Neurologic findings	• Peripheral neuropathy due to other disorders (e.g. diabetes mellitus, Guillain–Barré syndrome, nutritional deficiencies, Lyme disease, syringomyelia)
Deforming acral features	• Systemic sclerosis • Tabes dorsalis • Dupuytren contracture
Type 1 reaction	• Acute cutaneous lupus erythematosus • Cellulitis and pseudocellulitis • Drug reaction • Misdiagnosis as worsening of disease
Type 2 reaction	• Sweet syndrome • Medium-vessel vasculitis • Panniculitides, e.g. erythema nodosum*, lupus panniculitis • Infections, including other mycobacterial, bacterial, dimorphic fungal, and other opportunistic fungal
*Lesions favor the shins, erythema nodosum leprosum lesions are widespread.	

Table 75.5 Clinical differential diagnosis of Hansen disease.

remains the treatment of choice for type 2 reactions, teratogenicity is a major limitation and it is unavailable in many countries where Hansen disease is endemic. Lenalidomide and pomalidomide are thalidomide analogues with different side-effect profiles (e.g. more myelosuppression, less neuropathy), with potential utility in the treatment of type 2 reactions. Cyclosporine and methotrexate have been used in both type 1 and type 2 reactions, and additional drugs with possible benefit for type 2 reactions include phosphodiesterase 4 inhibitors (e.g. apremilast), TNF inhibitors, high-dose clofazimine, chloroquine, and pentoxifylline[56–58].

Although Hansen disease is now considered a curable disease with a good prognosis and excellent survival rate, it can still be incapacitating and stigmatizing. It is very important to make the diagnosis as soon as possible and to examine contacts, since early treatment prevents disability. The WHO 2018 guidelines recommended chemoprophylaxis with a single dose of rifampin to adults and children ≥2 years of age in contact with Hansen disease patients[38]. However, concerns about cost-effectiveness, stigma, and drug resistance have prevented implementation[59]. A single dose of rifapentine has also been shown to prevent Hansen disease in household contacts[59a]. Recognition of Hansen disease in its initial phases by healthcare professionals as well as the general population in endemic countries is essential in order to reduce the impact of this disease[9].

CUTANEOUS TUBERCULOSIS

Key features

- Infection of the skin due to *Mycobacterium tuberculosis*, an acid- and alcohol-fast bacillus
- A resurgence of tuberculosis (TB) in the late 1980s and early 1990s resulted from the HIV epidemic, emergence of resistant strains of *M. tuberculosis*, and a decline in TB control efforts
- Exogenous exposure produces primarily the tuberculous chancre and TB verrucosa cutis
- Endogenous infection can lead to scrofuloderma, miliary TB, and lupus vulgaris
- Tuberculids include a papulonecrotic eruption, lichen scrofulosorum, and erythema induratum

WHO 2018 GUIDELINES FOR THE TREATMENT OF HANSEN DISEASE				
Recommended first-line regimen				
Age group	***Drug***	***Dosage and frequency***	***Duration***	
			MB	***PB***
Adult	Rifampin	600 mg monthly	12 months	6 months
	Clofazimine	300 mg monthly + 50 mg daily		
	Dapsone	100 mg daily		
Children ages 10–14 years and weight ≥40 kg	Rifampin	450 mg monthly	12 months	6 months
	Clofazimine	150 mg monthly + 50 mg every other day		
	Dapsone	50 mg daily		
Children age <10 years or weight <40 kg	Rifampin	10 mg/kg monthly	12 months	6 months
	Clofazimine	100 mg monthly + 50 mg twice weekly		
	Dapsone	2 mg/kg daily		
Recommended regimens for drug-resistant disease (adult doses)				
Resistance type	Treatment for first 6 months (daily)		Treatment for next 18 months (daily)	
Rifampin resistance	Ofloxacin 400 mg* + minocycline 100 mg + clofazimine 50 mg		Ofloxacin 400 mg* – *or* – minocycline 100 mg + clofazimine 50 mg	
	Ofloxacin 400 mg* + clarithromycin 500 mg + clofazimine 50 mg		Ofloxacin 400 mg* + clofazimine 50 mg	
Rifampin and ofloxacin resistance	Clarithromycin 500 mg + minocycline 100 mg + clofazimine 50 mg		Clarithromycin 500 mg – *or* – minocycline 100 mg + clofazimine 50 mg	
*Ofloxacin 400 mg can be replaced by levofloxacin 500 mg or moxifloxacin 400 mg.				

Table 75.6 WHO 2018 guidelines for the treatment of Hansen disease[38]. Rifampicin is another name for rifampin. MB, multibacillary; PB, paucibacillary. *Adapted from World Health Organization. Introduction

Tuberculosis (TB) has affected humans since prehistoric times. There was, however, a worldwide explosion in its incidence in the late 1980s and early 1990s, and consequently a resurgence of cutaneous TB[2,60–63]. This phenomenon has been attributed to the HIV epidemic, the emergence of resistant strains of *Mycobacterium tuberculosis*, increased use of immunosuppressive therapies, more migration of people around the world, and a decline in TB control efforts[61,62], superimposed on the pre-existing factors of poverty and malnutrition.

History

There are paleopathologic findings that suggest there were *M. tuberculosis* infections as early as 3700 BCE in Egypt, and 2500–1500 BCE in Europe. Utilizing PCR, *M. tuberculosis* DNA was detected in mummified remains from ancient times. In 1826, Laennec first reported cutaneous TB in the form of a "prosector's wart". Rokitansky and Virchow subsequently described the histologic features of cutaneous TB in detail. The discovery of *M. tuberculosis* by Koch in 1882 and the advances in descriptive pathology during the nineteenth century helped establish cutaneous TB as part of the spectrum of this infectious disease[62,63].

Epidemiology

M. tuberculosis is not particularly virulent, as only 5% to 10% of infections lead to clinical disease in immunocompetent hosts. This bacterium has a worldwide distribution (Fig. 75.13), with >6 million people newly diagnosed with TB in 2021[64]. Cutaneous involvement is relatively uncommon, accounting for ~1%–2% of extracutaneous manifestations of TB[65]. The incidence of cutaneous TB parallels that of pulmonary TB and is therefore higher in low-income countries and impoverished populations. HIV infection, immunosuppressive therapies (especially TNF inhibitors; see Ch. 128), and innate defects of the IL-12/IFN-γ axis (see Ch. 60) place individuals at greater risk for the development and reactivation of TB.

Pathogenesis

M. tuberculosis is the predominant etiologic agent of cutaneous TB. Occasionally, *M. bovis* and bacille Calmette–Guérin (BCG), an attenuated strain of *M. bovis*, may produce skin lesions[61].

M. tuberculosis is a non-motile, aerobic, non-spore-forming, filamentous rod. It is an acid- and alcohol-fast bacillus that has a waxy coating with a high lipid content, which makes the organism resistant to degradation after phagocytosis[66]. *M. tuberculosis* produces multiple proteins involved in immune system invasion, allowing it to survive inside phagocytic cells[67].

M. tuberculosis disseminates primarily via inhalation of aerosolized droplets of saliva from individuals with active disease; transmission by ingestion or inoculation can also occur[66]. Intact skin provides an effective protective barrier against invasion of the organism, but a break in the mucocutaneous barrier can facilitate entrance[68]. Untreated infected individuals who do not have underlying medical problems have a 5% to 10% lifetime risk of progression to active TB; this risk increases substantially with immunosuppression, e.g. due to HIV infection or treatment with medications such as TNF inhibitors.

Studies using a model of zebrafish infected with *M. marinum* have demonstrated that granulomas, which are classically considered as host-protective structures formed to control infection, actually contribute to early bacterial growth and facilitate spread of infection[69] (Fig. 75.14). Mycobacteria induce granuloma formation by releasing the early secreted antigenic target 6 (ESAT-6) protein, which stimulates neighboring epithelial cells to produce matrix metalloproteinase-9 (MMP-9). MMP-9 enhances recruitment of macrophages that contribute to bacterial proliferation and spread as well as maturation of the nascent granuloma[70]. Increased production of other MMPs (e.g. MMP-1, MMP-3) has been shown to drive tissue destruction in TB[71]. Eventually, development of adaptive immunity results in the curtailment, but not eradication, of bacterial growth by $CD4^+$ and $CD8^+$ effector T cells. The mature granuloma therefore represents an equilibrium between mycobacterial growth and the host immune response, and MMPs represent potential targets for antimycobacterial therapy.

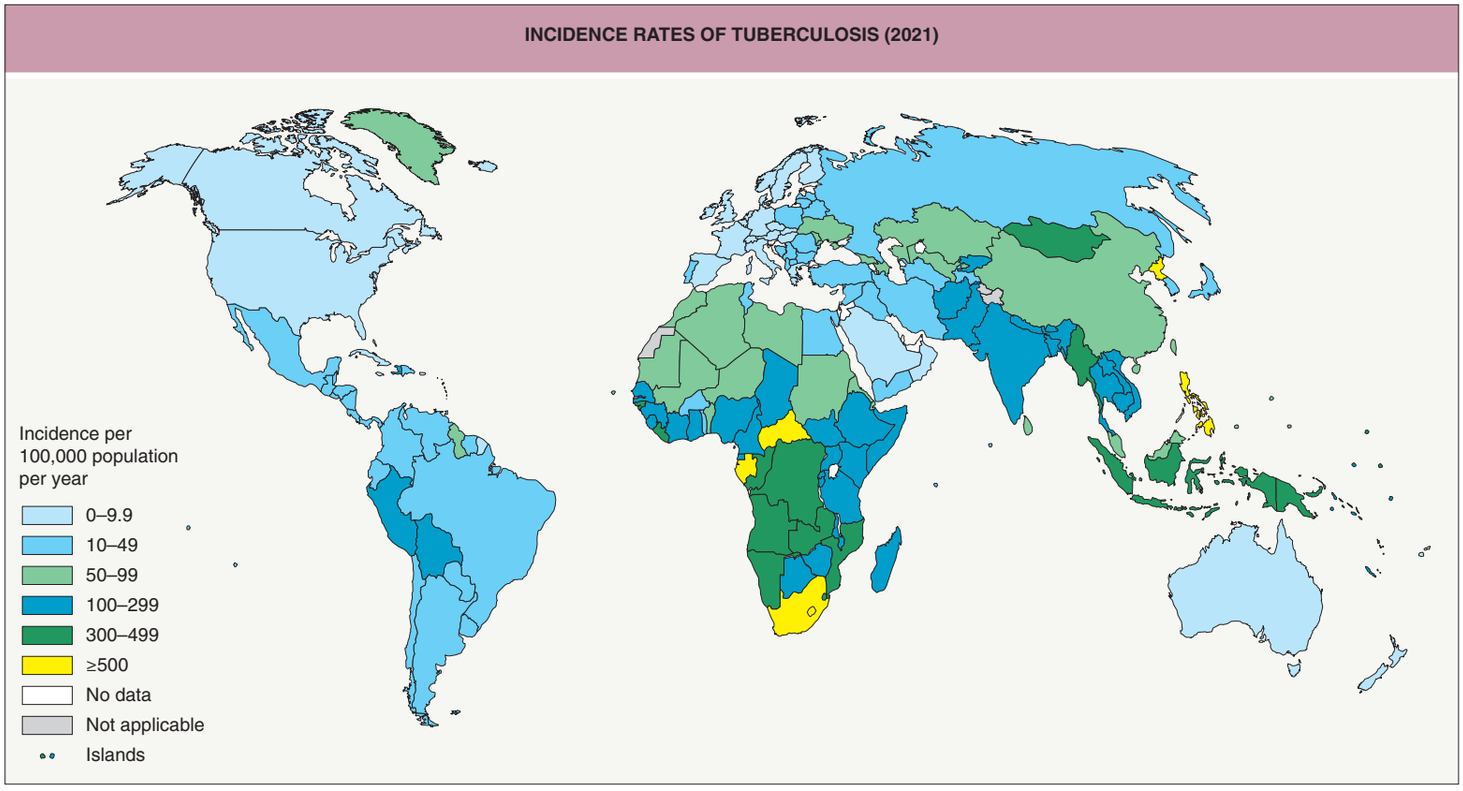

Fig. 75.13 Tuberculosis incidence rates, 2021. *Reproduced from the Global Tuberculosis Report 2022. Geneva: World Health Organization, 2022. https://www.who.int/teams/global-tuberculosis-programme/tb-reports/global-tuberculosis-report-2022/tb-disease-burden/2-1-tb-incidence*

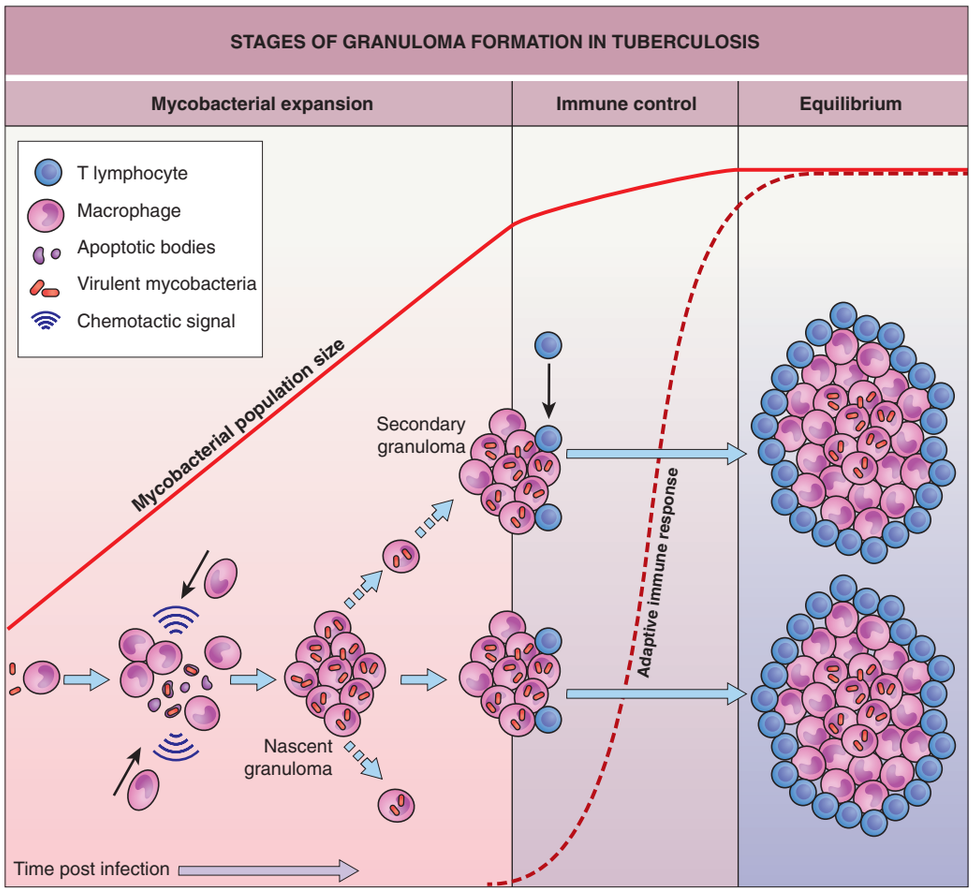

Fig. 75.14 Stages of granuloma formation in tuberculosis. The initial stage of tuberculosis is characterized by expansion of the mycobacterial population in the absence of adaptive immunity. Mycobacterial multiplication and spread are facilitated by the formation of the nascent granuloma. Infected macrophages undergo apoptosis and recruit additional macrophages, which phagocytose remnants of infected cells and their mycobacterial contents. Some of these newly infected macrophages then seed secondary granuloma formation. When adaptive immunity eventually occurs, $CD4^+$ and $CD8^+$ effector T cells curtail mycobacterial growth. Although this controls the infection, it is not eradicated. The mature granuloma therefore represents an equilibrium between mycobacterial proliferation and the host response. *Adapted with permission from Bold TB, Ernst JD. Who benefits from granulomas, mycobacteria or host? Cell 2009;136:18–19.*

The interaction of T cells and mycobacterial antigens, which are displayed on the surface of antigen-presenting cells, induces the liberation of interferons and other cytokines. These substances promote the activation and expression of MHC class II on antigen-presenting cells as well as the IL-2 receptor on T cells. During the initial sensitization, memory T cells are generated and remain for decades in lymphoid organs and the circulation[61]. In mice, the intracellular pathogen resistance 1 gene (*Ipr1*) within the supersusceptibility to tuberculosis 1 (sst1) locus encodes a protein that mediates innate immunity to *M. tuberculosis* and other intracellular organisms. Ipr1 is expressed in macrophages and limits the multiplication of *M. tuberculosis* within these cells[72]. IFN-γ-induced nitric oxide production also contributes to defense against *M. tuberculosis* by modulating macrophage responses (e.g. via activation of hypoxia inducible factor-1α) and repressing a neutrophil recruitment cascade that promotes bacterial replication[73].

The sensitization status of the host to mycobacterial antigens (e.g. previously infected versus never exposed), the degree of cell-mediated immunity of the host, the route of infection, and the pathogenicity of the infective strain of mycobacteria determine the resulting infection (Table 75.7). In immunocompromised hosts, cell-mediated immunity is impaired; as a consequence, there may be reactivation of quiescent disease[61,68].

Clinical Features and Pathology

Cutaneous TB has a wide variety of clinical presentations[3,61,63,66,74]. Direct inoculation of *M. tuberculosis* from an exogenous source can lead to tuberculous chancre, TB verrucosa cutis, and occasionally, lupus vulgaris. Skin involvement due to endogenous infection may appear as scrofuloderma, acute miliary TB, a tuberculous gumma, orificial TB, and lupus vulgaris (see Table 75.7). In addition, there are cutaneous tuberculids, which represent immune reactions against *M. tuberculosis* or its antigens.

Cutaneous tuberculosis

A *tuberculous chancre* develops 2 to 4 weeks after the inoculation of *M. tuberculosis* into the skin of an individual without a history of TB. It is a painless, firm, red–brown papulonodule that slowly enlarges, eventually eroding to form a sharply demarcated ulcer[3,61,66]. Frequently there is spread to draining lymphatics and regional lymph nodes[61]; the combination of the latter with a tuberculous chancre is analogous to the Ghon complex in the lung[61,66]. The skin lesion usually heals spontaneously within 3 to 12 months, leaving an atrophic scar and calcified regional lymph nodes. The tuberculous chancre may occasionally evolve into verrucous plaques, scrofuloderma-like lesions, or lupus vulgaris[63,66].

Tuberculosis verrucosa cutis results from exogenous inoculation of *M. tuberculosis* at sites prone to trauma in previously infected individuals[3,66]. The lesion begins as a small, asymptomatic, indurated wart-like papule with a subtle inflammatory rim (Fig. 75.15). It gradually enlarges, often in a serpiginous manner, to form a firm reddish–brown verrucous plaque. The center of the lesion may become fluctuant, with pus and keratinaceous debris expressed by slight pressure[3,63,66]. After several years, the plaque can heal spontaneously[61].

Scrofuloderma begins as a firm, deep-seated, subcutaneous nodule that has accumulated inflammatory material and necrotic tissue, best characterized as a "cold abscess". The suppurative nodule later becomes fluctuant and drains, with ulceration and sinus tract formation (Fig. 75.16). Because of the drainage, the bacilli secondarily infect the overlying dermis. The borders of the ulcers are often blue, the margins are undermined, and the base is covered with soft granulation tissue. Multiple ulcers can appear. After healing, keloids and retracted tethered scars develop at the sites of infection. The original focus of TB is usually underlying lymph nodes or bones, but it may be joints or the epididymis[3,61,63,75].

Orificial tuberculosis usually results from autoinoculation of *M. tuberculosis*, although occasionally it has an exogenous origin. Affected individuals typically have advanced systemic TB in the setting of impaired cell-mediated immunity (CMI). The mucosal or cutaneous lesions occur within or adjacent to a natural orifice that is draining an active tuberculous infection, primarily pulmonary, intestinal, or anogenital. The most common location is the mouth, especially the tongue. The initial lesion is an edematous red papule that ulcerates (Fig. 75.17) and develops undermined edges. The ulcers are painful, recalcitrant to treatment, and do not tend to heal spontaneously[3,66].

CLINICAL PRESENTATIONS OF CUTANEOUS TUBERCULOSIS							
	Tuberculous chancre	**Tuberculosis verrucosa cutis**	**Scrofuloderma**	**Orificial tuberculosis**	**Lupus vulgaris**	**Acute miliary tuberculosis**	**Tuberculous gumma**
Synonyms	Primary inoculation tuberculosis, cutaneous primary complex	Warty tuberculosis, prosector's wart, lupus verrucosus	Tuberculosis cutis colliquativa	Acute tuberculous ulcer, tuberculosis cutis orificialis	Tuberculosis luposa	Tuberculosis cutis disseminata, tuberculosis cutis acuta generalisata	Metastatic tuberculous ulcer, metastatic tuberculous abscess
Incidence	Rare except in Asia; 1%–2% of cutaneous tuberculosis	Most common form of cutaneous tuberculosis (e.g. ~40% of cases in Hong Kong)	Common in immigrants from developing countries	Rare	Low: 10%–15% of cutaneous tuberculosis; women affected 2–3 times more often than men	Rare; infants and young children, seldom adolescents or adults	Children with low socioeconomic status or immunocompromised hosts
Transmission	Inoculation into skin and/or mucosa of previously uninfected person, i.e. with no specific immunity	Inoculation into skin and/or mucosa of previously infected person with moderate or high immunity	Contiguous involvement of skin overlying a focus of tuberculosis, usually in lymph node or bone. Also reported after BCG vaccination	Autoinoculation of mucosa or skin adjacent to a natural orifice draining an active internal tuberculous infection	Direct extension; hematogenous or lymphatic spread from a tuberculous focus; reinfection; BCG vaccination	Hematogenous dissemination from primary lung focus in patient with low immunity; may follow viral infection	Acute hematogenous dissemination from a primary focus during periods of bacillemia and lowered resistance
Tuberculin skin test	Early: negative Later: positive	Positive	Usually positive	Variable, often negative	Usually positive	Usually negative	Usually negative
Histopathology	• Acute: nonspecific neutrophilic inflammation with necrosis; bacilli • Later: granulomatous inflammation with central caseation, epithelioid and Langhans giant cells; disappearance of bacilli	Acute inflammation in the epidermis, pseudoepitheliomatous hyperplasia, microabscesses in upper dermis, sparse granulomatous foci; occasionally bacilli present	Tuberculous granulation tissue and caseation necrosis in the deeper dermis; bacilli can be isolated from pus	Nonspecific inflammatory infiltrate and necrosis, some tubercles with caseation deep in dermis; bacilli easily found	Well-developed tubercles with scant caseation, nonspecific inflammatory infiltrate; no visible bacilli	Necrosis, nonspecific inflammatory infiltrate surrounded by macrophages, sometimes developing into small abscesses; abundant bacilli	Massive necrosis and abscess formation; large number of bacilli
Diagnosis	Histology and culture PCR IGRA*	Culture PCR IGRA	Culture PCR IGRA	Histology and culture PCR Presence of another focus of TB IGRA*	Histology and culture PCR IGRA	Smear, histology and culture; PCR Presence of another focus of TB IGRA*	Culture and histology PCR IGRA*
Differential diagnosis	Other pyogenic ulcers and chronic chancriform lesions, including the following: sporotrichosis, dimorphic or opportunistic fungal infections, *M. marinum* infection, nocardiosis, tularemia, syphilis, cat scratch disease	Warts, verrucous fungal infections (e.g. chromomycosis), tertiary syphilis, hypertrophic lichen planus	Dimorphic or opportunistic fungal infections, non-tuberculous mycobacterial infections, syphilitic gumma, actinomycosis, chronic bacterial osteomyelitis, adenitis with drainage, hidradenitis suppurativa, severe acne conglobata	Painful ulcerative diseases that affect orifices and perioricial skin: HSV, recurrent aphthous stomatitis, pemphigus, histoplasmosis	Sarcoidosis, discoid lupus erythematosus, dimorphic fungal infections, leishmaniasis, tertiary syphilis, squamous cell carcinoma	Varicella, enteroviral exanthems, rickettsialpox, PLEVA	Panniculitis, dimorphic or opportunistic fungal infection, syphilitic gumma, hidradenitis suppurativa

*May have an indeterminate result early in the disease course or in immunocompromised patients.

Table 75.7 Clinical presentations of cutaneous tuberculosis. BCG, bacille Calmette–Guérin; IGRA, interferon-γ release assay (e.g. QuantiFERON® TB Gold Plus, T-SPOT®.TB; see Table 75.8); PLEVA, pityriasis lichenoides et varioliformis acuta.

Lupus vulgaris is a form of cutaneous TB that occurs in previously sensitized individuals who have a strongly positive delayed-type hypersensitivity reaction to tuberculin due to intact CMI. It can develop secondarily from TB verrucosa cutis or scrofuloderma as well as from other endogenous and exogenous sources; lupus vulgaris also occasionally arises following BCG inoculation. The typical lesion is a red–brown plaque composed of papulonodules with an "apple-jelly" color on diascopy (Fig. 75.18). As the plaque expands, central scarring often develops. This can lead to substantial tissue destruction over a period of years. Clinical presentations of lupus vulgaris include: (1) plaque-type; (2) ulcerative or mutilating; (3) vegetating; (4) tumor-like; and (5) papulonodular. The head and neck region is the most commonly affected site, in particular the nose, cheeks, and ear lobes[3,63,66]. Mucosa, especially oral, can also be involved.

Fig. 75.15 Tuberculosis verrucosa cutis. A wart-like papule at the site of exogenous inoculation in a patient with immunity against *M. tuberculosis*.

Fig. 75.16 Scrofuloderma. Plaques and nodules with central ulceration as well as resultant scarring with retraction.

The initial lesions of *miliary tuberculosis* are pinhead-sized, bluish-red papules capped by minute vesicles. The vesicles develop a tiny central umbilication followed by crusting. When the papules heal, they leave a residual white scar with a brownish rim[3,61,66]. The cutaneous lesions are the result of mycobacteremia, and the primary focus is often in the lungs.

A *tuberculous gumma* is also due to mycobacteremia with cutaneous seeding. It can present as either a firm subcutaneous nodule that slowly softens or an ill-defined fluctuant swelling. The overlying skin gradually breaks down to form an undermined ulcer, often with sinus tract formation. The extremities are more often affected than the trunk[3].

A skin biopsy of early lesions of cutaneous tuberculosis typically shows a mixed infiltrate that includes lymphocytes, neutrophils, and plasma cells. This is followed after a few weeks by granulomatous inflammation (tuberculoid granulomas; see Fig. 0.26A), sometimes with central caseation. Acid-fast bacilli are usually abundant in early lesions, but are difficult to find when granulomas develop.

Tuberculids

The tuberculids represent a group of disorders that classically were associated with systemic TB. They are considered immune reactions within the skin due to hematogenous dissemination of *M. tuberculosis* or its antigens from a primary source, in an individual with strong antituberculous CMI. Often beginning as an immune complex-mediated reaction, they evolve into a granulomatous inflammatory response.

There is an ongoing debate as to the pathogenesis of tuberculids[3,63,74]. Arguments in favor of an association with *M. tuberculosis* include a positive tuberculin skin reaction in affected patients; detection by PCR of *M. tuberculosis* DNA within lesions of erythema induratum, lichen scrofulosorum, and papulonecrotic tuberculid; and improvement with antituberculous therapy. In addition, many skin lesions demonstrate granulomatous

Fig. 75.17 Orificial tuberculosis. A non-healing ulcer of the nasal mucosa. *Courtesy Louis A. Fragola, Jr, MD.*

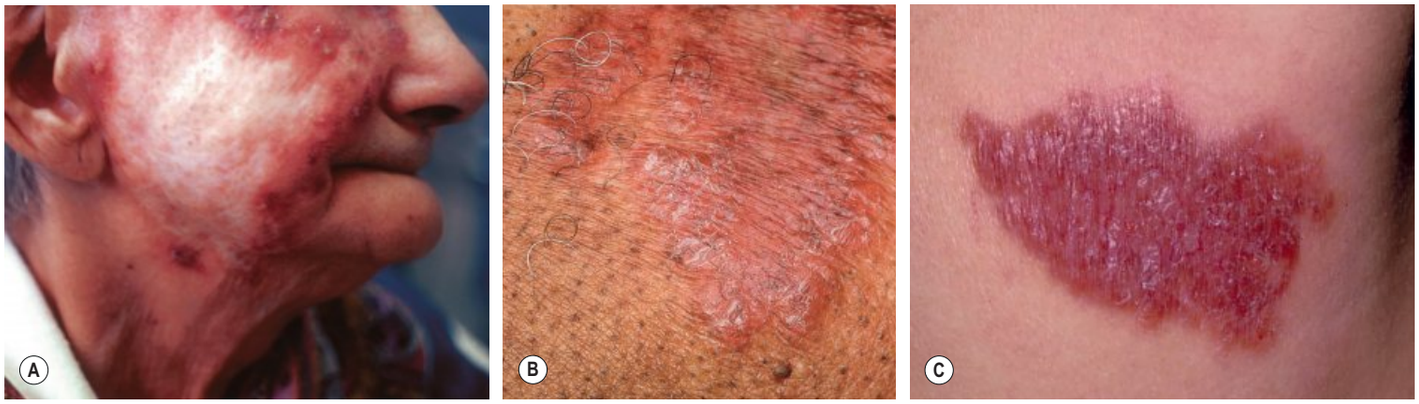

Fig. 75.18 Lupus vulgaris. A Annular granulomatous plaque with central scarring. **B** Coalescing pink–brown papules. **C** Red–brown plaque on the neck. *C, Courtesy Eugene Mirrer, MD.*

inflammation. However, there are multiple alternative causes of granulomatous inflammation and an active focus of TB is usually not found in patients with tuberculids; only a positive tuberculin test or IFN-γ release assay reflecting past exposure to TB is a consistent finding. The argument that corticosteroids can improve these eruptions is not a particularly strong one against an association, since other infectious diseases, e.g. viral hepatitis, can improve with such therapy and one would expect an antigen-driven inflammatory process to respond to corticosteroids. Although a positive PCR is not absolute proof of pathogenesis, in the setting of appropriate controls, it provides strong evidence in favor of an association.

Papulonecrotic tuberculid is seen most frequently in children and young adults. It presents with dusky red papules or papulopustules that are widely distributed in a somewhat symmetric pattern and favor the extensor aspects of the extremities and buttocks (Fig. 75.19). Individual lesions may have central necrosis and are usually asymptomatic; occasionally there is associated pruritus. Usually there is spontaneous healing of individual lesions, often with scar formation. Multiple cyclic eruptions are characteristic, even after antimycobacterial therapy. PCR for mycobacterial DNA and the tuberculin test are positive[3,63]. Histologically, there is evidence of leukocytoclastic or granulomatous vasculitis and wedge-shaped necrosis in the dermis. The history and clinical appearance aid in the diagnosis, which is bolstered by the histologic findings. The differential diagnosis often includes pityriasis lichenoides et varioliformis acuta (PLEVA) and small vessel vasculitis.

The early lesions of *lichen scrofulosorum*, a rare disorder, are firm, typically perifollicular, pink or yellow–brown, tiny flat-topped papules with variable scale. These asymptomatic papules are grouped in clusters, predominantly on the trunk. Lesions may persist for months and then disappear without scarring. Although it is seen in all age groups, children with nodal or skeletal TB are most frequently affected. This type of tuberculid has also been reported after BCG vaccination and can be triggered by tuberculin testing in highly reactive patients. Histologic examination demonstrates superficial granulomas around hair follicles and sweat ducts, with little or no caseation necrosis. No bacilli are found; however, PCR testing has demonstrated *M. tuberculosis* DNA within lesions. The clinical differential diagnosis includes lichen nitidus, lichen planus, and other lichenoid dermatoses (see Ch. 11) as well as "id" reactions, Blau syndrome, sarcoidosis, and secondary syphilis[3,63,74].

Erythema induratum (*nodular vasculitis*) is a form of lobular panniculitis associated with *M. tuberculosis* infection in a subset of affected individuals, especially in countries with a high prevalence of TB (see Ch. 100). The term *erythema induratum of Bazin* is reserved for cases related to *M. tuberculosis*. Both immune complex deposition, which may play a role in the vasculitic component, and a delayed-type hypersensitivity reaction to mycobacterial antigens are thought to be involved in the pathogenesis[74]. Women are most commonly affected (80%–90% of patients), with peaks in incidence during early adolescence and around menopause.

Symptoms often begin after exposure to low temperatures. Typically, subcutaneous nodules appear on the calves of both legs; they may involute or break down, creating irregular deep ulcers with undermined bluish borders. Healing results in atrophic hyperpigmented scars. Histologically, there is a lobular panniculitis with or without septal involvement. A neutrophilic vasculitis with mural thickening of subcutaneous arteries and veins and perivascular cuffing is often evident. Fat necrosis and granulomas can sometimes be observed. Bacilli are absent and caseation is rare[3,63].

Other entities such as erythema nodosum, lupus miliaris disseminatus faciei, granulomatous rosacea, and lichenoid tuberculid were formerly considered tuberculids, but are no longer included in this category[74].

Fig. 75.19 Papulonecrotic tuberculid. Erythematous papules and papulopustules on the heel.

BCG inoculation

BCG vaccination is performed with attenuated *M. bovis*. By increasing the degree of protection against *M. tuberculosis* infection, this vaccine has reduced the worldwide incidence of TB considerably. It can, however, cause complications, which include localized or generalized tuberculids, lupus vulgaris, scrofuloderma, and other nonspecific reactions such as fever, local inflammation, subcutaneous abscesses with or without ulceration, severe regional lymphadenitis, osteitis, and tuberculous foci in distant organs (Fig. 75.20). Rarely, it leads to a disseminated or even fatal infection, especially in individuals with a primary immunodeficiency affecting the IL-12/IFN-γ axis (e.g. Mendelian susceptibility to mycobacterial disease, hypohidrotic ectodermal dysplasia with immunodeficiency; see Ch. 60)[74]. Injections of methanol extraction residue (MER) of BCG have been used as adjuvant immunotherapy in patients with melanoma and can also result in nodules and subcutaneous abscesses (Fig. 75.21).

Diagnosis

In addition to the use of tuberculin skin tests, *M. tuberculosis* infection can be diagnosed with IFN-γ release assays (IGRAs; e.g. QuantiFERON® TB Gold Plus, T-SPOT®.TB)[76,77]. These assays determine whether exposure to recombinant peptides from *M. tuberculosis* (ESAT-6,

Fig. 75.20 Site of a BCG vaccination. Enlarging granulomatous plaque (BCGitis).

Fig. 75.21 Complication of injection of methanol extraction residue (MER) of BCG. Nodules, some of which have ulcerated, arranged in a linear "lymphatic" pattern in a patient with a high-risk extremity melanoma who had received an injection of MER of BCG as adjuvant immunotherapy.

culture filtrate protein [CFP]-10, ± TB7.7) stimulates IFN-γ production by T cells within patient blood samples. In general, IGRAs have similar sensitivity (~80%–85%, less in immunocompromised individuals) and greater specificity compared to tuberculin skin tests[76]. Current guidelines from the US Centers for Disease Control and Prevention (CDC) and National TB Controllers Association state that IGRAs may be used in place of a tuberculin skin test in all situations where the latter would be employed, with a general preference for IGRAs in patients ≥2–5 years of age with a low or intermediate risk of disease progression[76–78]. Advantages and disadvantages of these methods of TB detection as well as situations where one type of test would be preferred are listed in Table 75.8. Of note, these tests are negative in a subset of individuals with active TB disease and should not be used to exclude TB in patients with clinical evidence of infection.

Methods to detect *M. tuberculosis* in samples of respiratory secretions and infected tissues such as the skin include staining for acid-fast bacteria, culture, and PCR-based assays. The latter have variable sensitivities but are rapid and specific for organisms in the *M. tuberculosis* complex (which includes BCG). The Xpert MTB/RIF® is an automated, fast, semi-quantitative PCR method that simultaneously detects organisms in the *M. tuberculosis* complex and resistance to rifampin (rifampicin) in liquid clinical samples (e.g. sputum, lymph node aspirate) over a period of two hours. Genotyping methods based on spacer oligonucleotides (spoligotyping), mycobacterial interspersed repetitive unit-variable number tandem repeats (MIRU-VNTRs), and restriction fragment-length polymorphisms (RFLPs) can separate *M. tuberculosis* from non-tuberculous mycobacteria and detect mutants associated with drug resistance[67].

ADVANTAGES AND DISADVANTAGES OF IFN-γ RELEASE ASSAYS AND TUBERCULIN SKIN TESTING		
	Tuberculin skin test	**IFN-γ release assays**
Advantages	• Does not require a laboratory • Relatively low cost	• Requires a single patient visit • Results can be available within 24 hours • Prior BCG vaccination does not cause a false-positive result • Does not boost responses measured by subsequent tests
Disadvantages	• Requires two patient visits • Results are not available for 48 hours • Prior BCG vaccination can cause a false-positive result • May boost responses in subsequent tests • Infections with non-tuberculous mycobacteria may lead to a false-positive result	• Requires laboratory processing within 16 hours (for QuantiFERON® TB Gold Plus) or 8–30 hours (for T-SPOT®.TB; the latter if using T-cell Xtend®) • Relatively high cost • Infections with some non-tuberculous mycobacteria (e.g. *M. kansasii*, *M. szulgai*, *M. marinum*) may lead to a false-positive result
Situations where preferable	• Children <2–5 years of age	• Patient groups that historically have low rates of returning for a second visit (e.g. homeless persons, drug users) • Individuals who have received BCG

Table 75.8 Advantages and disadvantages of interferon-γ (IFN-γ) release assays and tuberculin skin testing. Both types of tests may be negative in patients with early active tuberculosis. Indeterminate IFN-γ release assay results due to failure of the internal positive control (i.e. a "low mitogen" response) are more common in immunocompromised individuals, young children, and older adults. Indeterminate results due to inappropriately high IFN-γ levels in the negative control ("high nil") can also occur. Testing with a second method after an initial negative test may be useful when the risk of infection/progression is high or when there is clinical suspicion of active tuberculosis. The QuantiFERON® TB Gold Plus test directly measures IFN-γ levels, whereas the T-SPOT®.TB test determines the number of IFN-γ-producing T cells; both use a peripheral blood sample. BCG, bacille Calmette–Guérin.

Treatment

Medications used to treat cutaneous forms of TB are the same as those for systemic TB (Table 75.9 & Fig. 75.22). Administration of appropriate therapy also assists in preventing bacterial resistance and reducing transmission of *M. tuberculosis*. In addition to the increase in *multidrug-resistant TB* that accompanied the resurgence of this disease in the late 1980s and early 1990s, *extensively drug-resistant TB* strains that are even more difficult to treat have also emerged in all regions of the world (Table 75.10). For latent TB infection, recommended regimens include isoniazid plus rifapentine weekly for 3 months, isoniazid plus rifampin daily for 3 months, and rifampin daily for 4 months[79].

In addition to "repurposing" existing antibiotics (e.g. quinolones, amoxicillin with clavulanate, linezolid, clarithromycin) for use in patients with extensively drug-resistant TB, novel drugs have been developed. *Bedaquiline*, a diarylquinoline that inhibits mycobacterial ATP synthase, was FDA-approved in 2012 as a part of combination therapy for multidrug-resistant TB. Although bedaquiline was found to increase the rate of sputum culture conversion, this drug can lead to QT prolongation and more deaths were observed when compared to the placebo group[80]. Pre-screening electrocardiography is recommended, and an initial 8-week course of bedaquiline plus linezolid for rifampin-sensitive TB was recently reported as noninferior to standard therapy, notably with limited toxic effects[81]. *Pretomanid*, a nitroimidazole, was FDA-approved in 2019 to treat extensively drug-resistant TB in combination with bedaqualine and linezolid. *Delamanid*, a dihydro-nitroimidazooxazole derivative that inhibits synthesis of the mycolic acid component of mycobacterial cell walls, was approved in Europe in 2014 for treatment of multidrug-resistant TB[82]. The antidiabetic drug metformin may have an adjunctive role in TB treatment by increasing reactive oxygen species production, enhancing specific immune responses, improving the efficacy of conventional anti-TB drugs, and decreasing detrimental inflammation[83].

The development of new TB vaccines with effective adjuvants represents a priority of the WHO[84]. Sequential administration of BCG and a recombinant modified vaccinia virus Ankara (MVA) expressing antigen 85A can induce robust antimycobacterial immunity[85]. Several TB subunit and virus-vectored vaccines are currently being evaluated in clinical trials[84,86,87]. Vaccines found to have efficacy in controlled studies include the adjuvanted protein subunit vaccine M72/AS01E (~50% efficacy after 3 years), a non-tuberculous *Mycobacterium*-derived inactivated whole-cell vaccine, an adenovirus-vectored vaccine containing three *M. tuberculosis* antigens (85A, 85B, and TB10.4), and the recombinant "next-generation" BCG vaccine VPM1002[88,89].

Although the production of nitric oxide by macrophages is known to help control infection by *M. tuberculosis*, the organisms can persist within these cells. Proper function of the mycobacterial proteosome appears to play an important defensive role, and, in the future, inhibition of proteosome function could provide a novel therapeutic approach[90].

NON-TUBERCULOUS MYCOBACTERIOSES

Synonyms: ■ Atypical mycobacterioses ■ Mycobacteria other than tuberculosis (MOTT) ■ Environmental mycobacterioses ■ Anonymous mycobacterioses ■ Opportunistic mycobacterioses

Key features

- Over a dozen species of mycobacteria, found in the natural environment and transmitted via inoculation into the skin, can produce cutaneous disease
- Clinical presentations include pustules, keratotic plaques and nodules (with or without suppuration), a sporotrichoid (lymphocutaneous) pattern, and ulcers with draining sinuses
- Disseminated infections usually occur in immunocompromised hosts
- Although suggested by a history of exposure, the diagnosis rests on isolation or identification of the responsible organism

CLASSES, ACTIVITIES AND CROSS-RESISTANCES OF THE ANTITUBERCULOUS AGENTS			
Agent	**Class of compound**	**Spectrum of activity**	**Cross-resistance to other antituberculous agents**
First-line agents			
Rifampin	Antibiotic	Broad	Other rifamycins
Isoniazid	Synthetic	Tubercle bacilli	None
Pyrazinamide	Synthetic	Tubercle bacilli	None
Ethambutol	Synthetic	Tubercle bacilli	None
Rifapentine	Antibiotic	Broad	Other rifamycins
Rifabutin	Antibiotic	Broad	Other rifamycins
Second-line agents			
Kanamycin, amikacin, streptomycin	Aminoglycoside antibiotics	Broad	Other aminoglycosides, viomycin, capreomycin
Capreomycin, viomycin	Tuberactinomycin antibiotics	Tubercle bacilli	Aminoglycosides
Levofloxacin, ofloxacin, moxifloxacin	Quinolone antibiotics	Broad	None
Ethionamide, prothionamide	Thioamides	Tubercle bacilli	Thiacetazone
Cycloserine, terizidone	Synthetic	Broad	None
para-Aminosalicylic acid	Synthetic	Tubercle bacilli	None
Third-line agents			
Clofazimine	Riminophenazine antileprotic	Mycobacteria	None
Amoxicillin/clavulonate	β-lactam antibiotic/β-lactamase inhibitor	Broad	None
Linezolid	Oxazolindinone antibiotic	Broad	None
Imipenem	β-lactam antibiotic	Broad	None
Thiacetazone	Synthetic	Tubercle bacilli	Ethionamide, prothionamide
Clarithromycin	Macrolide antibiotic	Broad	None
Bedaquiline	Diarylquinoline antibiotic	Broad	None
Delamanid	Dihydro-nitro-imidazooxazole	Mycobacteria	None
Pretomanid	Nitroimidazole	Mycobacteria	None

Table 75.9 Classes, activities, and cross-resistances of the antituberculous agents. Agents that are active against *M. tuberculosis* may also show activity against some other species of mycobacteria. Strains of *M. bovis* are naturally resistant to pyrazinamide. There are only limited data on other activities of capreomycin and viomycin. *Adapted from Grange JM, Zumla A. Antituberculosis agents. In Cohen J, Powderly WG (eds). Infectious Diseases. London: Mosby, 2003. With permission from Elsevier.*

Introduction

Non-tuberculous ("atypical") mycobacteria (NTM) were first isolated in 1931 by Pinners, who also discovered that these organisms were different from *M. tuberculosis* – they were not virulent in the guinea pig model, and they responded poorly to antituberculous therapy[91]. Their importance as human pathogens, however, was not appreciated until the 1950s[92].

These environmental mycobacteria are found in water, wet soil, house dust, dairy products, cold-blooded animals, vegetation, and human feces. NTM are transmitted by inhalation, ingestion, or percutaneous penetration, which can result in pulmonary, lymph node, or skin disease[6,91]. The type of disease depends on the species of mycobacteria, the route and degree of exposure, and the immune status of the host[1]. Individuals with innate defects of the IL-12/IFN-γ axis (≥10 genes implicated; e.g. *STAT1*, *ISG15* [IFN-stimulated gene 15]), GATA2 deficiency, and anti-IFN-γ antibodies are predisposed to severe and disseminated infections with NTM[93] (see Ch. 60).

The incidence of infections by NTM appears to be increasing due to factors such as greater use of immunosuppressive medications and more frequent surgical procedures as well as improved detection via PCR-based techniques[93]. Although these infections should be considered in patients with indolent ulcers, nodules, or plaques, especially in the setting of immunosuppression, they are often misdiagnosed because of their nonspecific or sometimes subtle clinical presentations, combined with inadequate biopsy and culture techniques[91]. The ability of some NTM to survive sterilization procedures and to even contaminate antiseptic solutions can lead to infections in surgical patients. These infections have been described in association with cutaneous surgical procedures (e.g. laser resurfacing, botulinum toxin injections, hair transplantation, liposuction), other surgical procedures (e.g. cardiothoracic, ocular, breast reconstruction), and acupuncture, body piercing, and tattooing[94–97].

Antibiotic susceptibility and therefore selection of therapy depends on the NTM species (Table 75.11)[91,98–104]. Empiric treatment with clarithromycin can be initiated while awaiting culture and sensitivity results in patients with clinical presentations suggestive of cutaneous NTM infection[105]. However, multiplex PCR-based assays (e.g. targeting 16S rRNA and hsp65) are available to more rapidly identify NTM species of clinical importance and help direct therapy[106,107].

In 1954, Runyon proposed the first classification system for NTM based upon rate of growth *in vitro* and pigment production following exposure to light (see Table 75.1). Due to advances in genomic analysis, at least 200 species of mycobacteria are now recognized[107]. Selected NTM of dermatologic interest will be discussed in this chapter.

Mycobacterium ulcerans

Synonyms: ■ Buruli ulcer ■ Bairnsdale ulcer ■ Searle's ulcer

Introduction and history

M. ulcerans is a slow-growing, acid-fast bacillus that characteristically infects the skin and subcutaneous tissues, producing indolent ulcers. After Hansen disease and tuberculosis, the "Buruli ulcer" is the third most common mycobacteriosis worldwide in immunocompetent hosts, and it is classified as a neglected tropical disease by the WHO. In 1897, Cook first described patients with huge cutaneous ulcers from the Buruli county of Uganda. It was not until the late 1940s, in Australia, that the agent was isolated and characterized by MacCallum and colleagues[1].

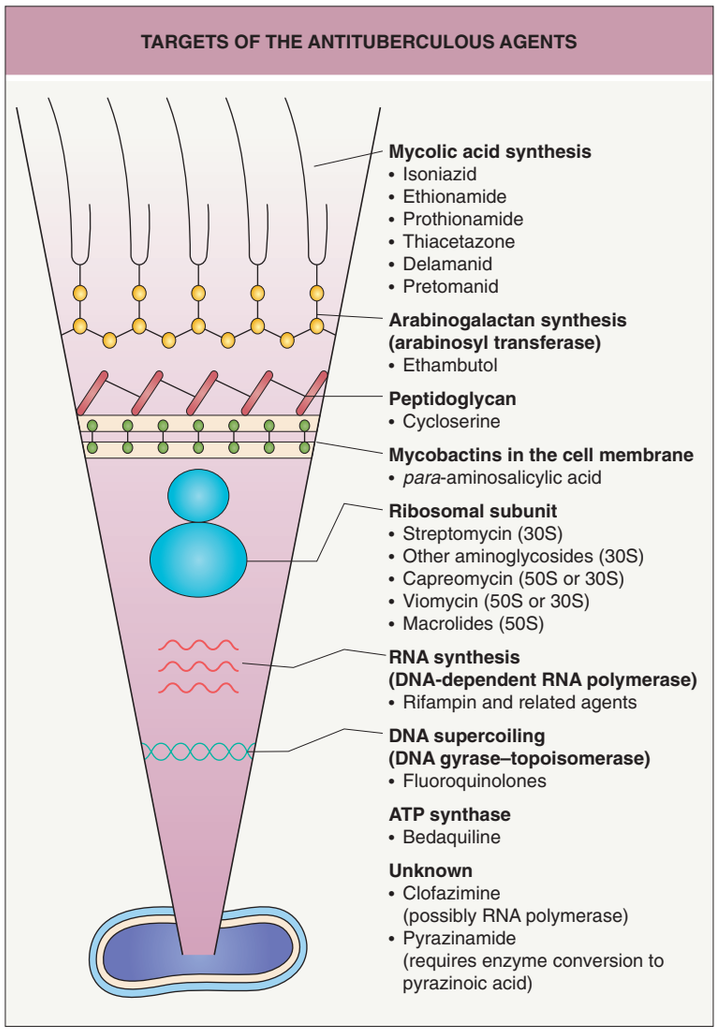

Fig. 75.22 Targets of the antituberculous agents. *Adapted from Grange JM, Zumla A. Antituberculous agents. In: Cohen J, Powderly WG (eds). Infectious Diseases. London: Mosby, 2003. With permission from Elsevier.*

Epidemiology

M. ulcerans infections have been reported in >30 countries worldwide, with primary endemic foci near freshwater wetlands in tropical and subtropical countries. Although the exact mode of transmission is not known, exposure to water or mud from rivers, ponds, or swamps is thought to play a role. The organism is harbored by snails, fish, and water insects, and it can be isolated from aquatic plants. In Australia, koalas and opossums are naturally infected.

Agricultural activities and consequent deforestation have contributed to increases in the incidence of *M. ulcerans* infections, especially in West Africa. Focal outbreaks have followed floods and human migrations, and HIV co-infection has been associated with more rapid progression into severe ulcerative stages[65,108]. The countries most affected are in Central Africa (e.g. Uganda, Democratic Republic of the Congo) and West Africa (e.g. Ivory Coast, Ghana, Benin). Japan, Southeast Asian countries, and Australia have major foci of infection, and there have been a few reports from South America and Mexico.

M. ulcerans is typically introduced into the skin by minor trauma, and the disease is rarely transmitted from patient to patient. Children under 15 years of age are most commonly affected in West Africa, but infection can occur in all age groups[92].

Pathogenesis

After inoculation into the skin, *M. ulcerans* organisms proliferate and form abundant clumps of extracellular acid-fast bacilli. The organisms

MULTIDRUG-RESISTANT AND EXTENSIVELY DRUG-RESISTANT TUBERCULOSIS
Multidrug-resistant tuberculosis (MDR-TB)
• Resistant to isoniazid and rifampin, the two most effective first-line drugs • Estimated to account for ~3% of all new TB cases worldwide in 2021, but ~20% of individuals previously treated for TB
Extensively drug-resistant tuberculosis (XDR-TB)
• Resistant to isoniazid and rifampin • Resistant to quinolones, the most effective second-line drugs • Resistant to at least one of three injectable second-line drugs: amikacin, kanamycin, or capreomycin • Estimated to account for 10% of cases of MDR-TB

Table 75.10 Multidrug-resistant and extensively drug-resistant tuberculosis.

TREATMENT OF NON-TUBERCULOUS ("ATYPICAL") MYCOBACTERIAL INFECTIONS		
Agent	**Local**	**Systemic medications: alone or combined**
M. ulcerans	For ulcers, surgical excision; local heat (40°C); hyperbaric oxygen	Rifampin plus clarithromycin, streptomycin, or a quinolone (e.g. moxifloxacin, ciprofloxacin) for 8 weeks; other drugs occasionally used in combination therapy include ethambutol, amikacin, and azithromycin
M. marinum		Clarithromycin, minocycline > doxycycline*, rifampin, ethambutol, trimethoprim–sulfamethoxazole; two agents for serious infections (e.g. clarithromycin + rifampin or ethambutol)
M. kansasii		Isoniazid (or clarithromycin) + rifampin + ethambutol ± pyridoxine; other options (depending on susceptibilities) include azithromycin, moxifloxacin, streptomycin and sulfamethoxazole
M. fortuitum	Surgical excision	Ciprofloxacin, ofloxacin, clarithromycin†, trimethoprim–sulfamethoxazole, minocycline, amikacin, meropenem, linezolid, doxycycline; at least two agents for serious infections
M. chelonae	Surgical excision	Clarithromycin; for severe infections, combine clarithromycin with linezolid, imipenem, tobramycin, amikacin, doxycycline, and/or ciprofloxacin (often resistant to latter two agents)
M. abscessus	Surgical excision	Clarithromycin or azithromycin + (for serious infections) amikacin, cefoxitin or imipenem
M. avium complex		Azithromycin (or clarithromycin) + ethambutol ± rifampin or rifabutin; second-line medications include streptomycin, amikacin, clofazimine, linezolid, bedaquiline
M. haemophilum	Surgical excision	Clarithromycin + rifampin (or rifamycin, rifabutin) ± ciprofloxacin or amikacin
M. scrofulaceum	Surgical excision	Isoniazid + rifampin, clarithromycin

*Resistance to tetracyclines has been reported.
†Often have inducible resistance to macrolides.

Table 75.11 Treatment of non-tuberculous ("atypical") mycobacterial infections[91,92,98–104]. Therapy for 3 to 6 months or more is often required. If clinical suspicion is high for a non-tuberculous mycobacterial infection, empiric treatment with clarithromycin can be considered while waiting for culture and sensitivity results.

are found at the base of the ulcer and within adjacent necrotic subcutaneous tissue as well as in surrounding normal-appearing skin.

M. ulcerans produces mycolactone, a macrolide exotoxin produced by polyketide synthases that are encoded by the virulence plasmid pMUM. Mycolactone is able to: (1) decrease inflammation via inhibition of protein translocation into the endoplasmic reticulum (ER), leading to suppression of cytokine/chemokine production, dendritic cell function, and L-selectin-mediated lymphocyte homing; (2) promote cell death via anoikis by disrupting actin dynamics through hyperactivation of the Wiskott–Aldrich syndrome protein (WASP); and (3) inhibit pain perception by binding to angiotensin II type 2 receptors on neurons, leading to potassium-dependent hyperpolarization[109]. These effects explain the severe tissue destruction with minimal pain and inflammation observed in Buruli ulcers, and different geographical lineages of *M. ulcerans* produce forms of mycolactone with varying virulence[109]. In addition, mycolactone itself represents a potential diagnostic/prognostic biomarker and therapeutic target.

Clinical features

The initial lesion is usually a single, asymptomatic, firm, non-tender, mobile subcutaneous nodule that measures 1 to 2 cm in diameter. After 1 or 2 months, the nodule becomes fluctuant and ulcerates. The resultant painless ulcer has a deep necrotic base with undermined edges, and often expands to 15 cm or more in diameter. Most lesions are on the extremities, especially the leg. There is little to no regional lymphadenopathy or systemic manifestations, although edema can develop in adjacent tissues. Without treatment, ulcers may remain small and heal as depressed scars, or they may spread rapidly over large areas of skin causing extensive scarring and deformity. Structures such as the eye, breast, or genitalia are sometimes severely damaged. Underlying bone can become involved, and progressive osteomyelitis may require amputation[92].

The WHO divides *M. ulcerans* disease into three categories of severity: (1) single lesion <5 cm in diameter; (2) single lesion (± ulceration) or area of edema 5–15 cm in diameter; (3) lesion >15 cm in diameter, multiple lesions, osteomyelitis, or joint involvement.

Pathology

Histologically, mature lesions show extensive necrosis with destruction of nerves, appendages, and blood vessels[1,92]. There are few inflammatory cells in active lesions, but a granulomatous response may develop during healing. Many acid-fast bacilli can be seen in characteristic clumps, particularly in the center of the lesion[92].

Diagnosis and differential diagnosis

Clumps of acid-fast bacilli are typically seen with Ziehl–Neelsen staining of smears and biopsy specimens from the necrotic ulcer base or undermined ulcer edge. *M. ulcerans* can be cultured, but visible growth often requires 6 to 8 weeks of incubation at 32°C[92]. PCR-based detection of the *M. ulcerans*-specific insertion sequence 2404 (IS2404), which is highly sensitive and specific, has become the gold standard for Buruli ulcer diagnosis. Additional diagnostic tests that are under development include the loop-mediated isothermal amplification (LAMP) test, thin-layer chromatography for the detection of mycolactone, and antigen detection assays[108]. In a series of 70 patients with Buruli ulcers, a modified PCR assay had a sensitivity of 98%, while the sensitivities of direct smear, culture, and histology were 42%, 49%, and 82%, respectively[110].

The differential diagnosis depends upon the stage of disease. During the initial phase, when a subcutaneous nodule is present, *M. ulcerans* infection must be differentiated clinically from other forms of panniculitis (infectious and non-infectious; see Ch. 100), cysts, nodular fasciitis, foreign body granulomas, and other granulomatous diseases. During the ulcerative phase, considerations may include fungal infections, pyoderma gangrenosum, suppurative panniculitis, and other causes of chronic ulcers (see Ch. 105)[1].

Treatment

Antibiotic therapy can be effective when used alone or in combination with surgery (debridement or more extensive procedures [see below]). Treatment with oral rifampin (10 mg/kg daily) plus clarithromycin (7.5 mg/kg twice daily or 15 mg/kg extended release daily) is now recommended as first-line treatment by the WHO. A randomized controlled trial demonstrated that 8 weeks of this regimen was not inferior to and better tolerated than the same oral rifampin dose plus intramuscular streptomycin (15 mg/kg) daily in patients with a single lesion ≤10 cm in diameter[111]. Other antibiotic protocols (e.g. in Australia) utilize rifampin plus moxifloxacin or ciprofloxacin for 6–8 weeks[112,113]. Of note, ~10%–20% of patients with Buruli ulcers (especially those associated with a high bacterial load) experience a paradoxical reaction upon initiation of antibiotic therapy, with temporary worsening of ulceration (peak at 6–8 weeks) and subsequent healing[114].

While surgical excision represents the traditional treatment of choice for ulcers (see Table 75.11), this is obviously easier to accomplish when the ulcers are small, as large ulcers often require skin grafts or, rarely, amputation[1,92]. Continuous local heating to 40°C by circulating water jackets promotes healing, even without excision[72], and hyperbaric oxygen may also be useful[1,3]. Physical therapy is important when the patient is at risk for contractures. There is no effective prophylaxis, but vaccination with BCG may lead to limited, relatively short-lived protection.

Mycobacterium marinum

Synonyms: ■ Fish tank granuloma ■ Swimming pool granuloma ■ Infection by *M. balnei*

Introduction and history

M. marinum is a free-living organism that causes disease in freshwater and saltwater fish and sporadically in humans. The latter results from exposure to contaminated water when there are breaks in the skin barrier[99]. *M. marinum* was first isolated from saltwater fish in the Philadelphia Aquarium in 1926 by Aronso[1,3]. The first report of human disease was in 1951, when the agent was found in granulomatous skin lesions of individuals who swam in a contaminated swimming pool[3]. There is scientific interest in *M. marinum* because of its phylogenetic similarity to *M. tuberculosis*[115].

Epidemiology and pathogenesis

M. marinum is found in aquatic environments, including fresh, salt, and brackish water. When cleaning fish tanks at home or in the workplace (e.g. restaurants, fish markets), trauma to the hands may result in exposure to *M. marinum*. The infection can also affect swimming pool bathers, as this organism seems to be rather resistant to chlorine[1].

Cutaneous infection with *M. marinum* requires a portal of entry, e.g. abraded or traumatized skin[1]. The incubation period is typically 2 to 3 weeks, but it can range from 1 week to 2 months[1]. In several case series of skin infections due to NTM from higher-income countries, *M. marinum* was the most common species identified[104,105].

Clinical features

The initial lesion is a single bluish-red inflammatory nodule or pustule at the site of inoculation, which is often on an upper extremity (Fig. 75.23A). It then forms a crusted ulcer, suppurative abscess, or verrucous nodule[1,3]. Multiple lesions can develop along the course of the draining lymphatics, i.e. sporotrichoid (lymphocutaneous) spread (Fig. 75.23B; see Table 77.17). Among the NTM, *M. marinum* is the most common cause of this pattern. Occasionally, deeper infections are complicated by tenosynovitis, septic arthritis, or rarely, osteomyelitis. As with other NTM, atypical or disseminated lesions can occur in immunocompromised hosts, including those treated with TNF inhibitors (Fig. 75.23C).

Pathology

The histologic features, as in other mycobacterial infections, range from acute and chronic inflammation to well-formed tuberculoid granulomas. Fibrinoid changes and caseation necrosis can occur[3]. In immunocompetent individuals, organisms are often difficult to find.

Diagnosis and differential diagnosis

The clinical features combined with a history of trauma in a wet environment or exposure to fish tanks suggests the possibility of *M. marinum* infection. The diagnosis is confirmed by culture, which is positive in 70% to 80% of cases[99]. When this infection is suspected,

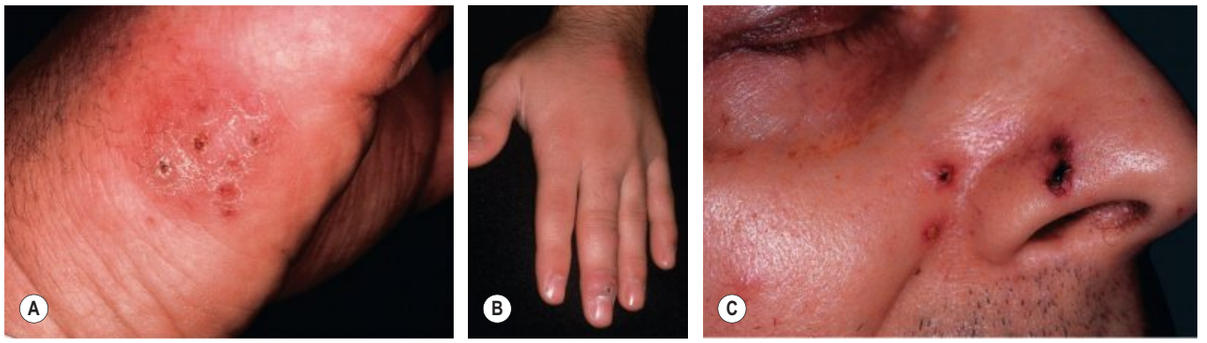

Fig. 75.23 *Mycobacterium marinum* infections. A range of presentations, including an erythematous plaque with scale-crust at the inoculation site on the lateral hand (**A**), a sporotrichoid pattern with the inoculation site on the distal third finger (**B**), and disseminated necrotic lesions on the face of an immunocompromised patient (**C**).

the laboratory should be notified in advance and care must be taken to provide proper culture conditions. *M. marinum* grows best at 31°C, in contrast to the optimal incubation temperature of 37°C for many other mycobacteria[99]; growth becomes evident after a mean of ~3 weeks, and identification of the species and its antimicrobial susceptibility pattern often requires 2 months[104]. PCR can also be performed to enable a rapid diagnosis.

Infection due to *M. marinum* should be differentiated from sporotrichosis and the entities outlined in Table 77.17 as well as tuberculosis verrucosa cutis. It is not associated with marked regional lymphadenitis.

Treatment

M. marinum is usually sensitive to the antimicrobial drugs listed in Table 75.11[91]; however, sensitivity testing should be requested as part of the laboratory evaluation[99]. Based on usual *in vitro* susceptibility patterns and clinical responsiveness, initial empiric treatment with clarithromycin (pending culture and sensitivity results) has been recommended when there is suspicion of an *M. marinum* infection[104]. A general approach is to treat with two agents (e.g. clarithromycin plus ethambutol or rifampin) until 1–2 months after resolution of clinical findings, often for a total of 3–4 months[104]; a single agent is an option for milder disease, and longer-term treatment may be necessary in immunosuppressed patients[115].

Mycobacterium kansasii

Introduction and history

M. kansasii most often causes lung disease, which can be clinically and radiologically indistinguishable from tuberculosis. There is also evidence that infection with this organism provides increased immunity against tuberculosis[92].

M. kansasii was first reported in 1953 as the "yellow bacillus". This characteristic pigmentation is due to the deposition of β-carotene crystals after exposure to light[1].

Epidemiology and pathogenesis

This organism is found throughout the world, but it is more prevalent in temperate zones within the US, South America, China, and Europe. It has been isolated from cattle and swine, but the natural reservoir may be water. Middle-class, middle-aged White men living in urban areas are most commonly affected[3,92]. Cutaneous infection is usually acquired via minor trauma such as puncture wounds[74].

Clinical features

Verrucous plaques, ulcers, and nodules are observed, and the lesions may be arranged in a lymphocutaneous (sporotrichoid) pattern. The majority of patients with cutaneous involvement have some alteration in immune status[1,3,92]. Papulonecrotic lesions and cellulitis are less common presentations[3]. Iijima and Sasaki[116] divided cutaneous mycobacteriosis due to *M. kansasii* into three types: (1) primary cutaneous chronic granulomatous; (2) primary cutaneous pyogenic; and (3) disseminated acute pyogenic, which occurs primarily in immunocompromised individuals.

Pathology

Histologic features are as variable as the clinical presentations. Typical tuberculoid granulomas may be seen, or a dense neutrophilic infiltrate may be evident, with or without abscess formation and epidermal necrosis[92]. In some patients, the findings are indistinguishable from those of *M. tuberculosis* infection[1].

Diagnosis and differential diagnosis

M. kansasii can be isolated from lesional skin biopsy specimens, and the laboratory should be advised to provide appropriate culture conditions to detect slow-growing mycobacteria[1,92]. The rarity of diagnosis of primary cutaneous *M. kansasii* infections may reflect failure to grow the organisms in culture as well as difficulties in phenotyping. PCR analysis may circumvent these potential problems because of its higher sensitivity and specificity[117].

Table 75.7 and the *M. ulcerans* section above outline the differential diagnosis of verrucous plaques and ulcers, respectively. Sporotrichosis and other NTM infections need to be considered when there is a sporotrichoid pattern (see Table 77.17). A combination of histologic examination, special stains, and culture for bacteria and fungi usually distinguishes these entities, but PCR may be required.

Treatment

A combination of antituberculous medications should be used (see Table 75.11), especially for disseminated infections. Because resistance to rifampin and other drugs may occur, sensitivity testing should be performed to optimize therapy[1,3,92].

Mycobacterium fortuitum, Mycobacterium chelonae, and *Mycobacterium abscessus*

Synonyms: ■ *M. chelonei* = *M. chelonae* ■ Turtle tubercle bacillus

Introduction and history

These rapidly growing mycobacteria are members of either the *M. fortuitum* group or the *M. chelonae/M. abscessus* complex[118]. Although the individual organisms can be distinguished on the basis of their DNA and serologic analyses, they result in infections with similar clinical features[3].

In 1903, Friedmann[68] isolated *M. chelonae*. Two subspecies (*chelonae* and *abscessus*) were initially identified, but *M. abscessus* was reclassified as a separate species in 1992[1]. Costa-Cruz used the name *M. fortuitum* in 1938 for what he believed to be a new species isolated from a skin abscess that occurred after an injection[1,119]. The *M. fortuitum* group currently includes the following additional species reported to cause human infections – *M. alvei*, *M. boenickei*, *M. conceptionense*, *M. farcinogenes*, *M. houstonense*, *M. neworleansense*, *M. peregrinum*, *M. porcinum*, *M. senegalense*, *M. septicum*, *M. setense*. The *M. chelonae/M. abscessus* complex now consists of *M. chelonae*, *M. abscessus* subsp. abscessus, *M. abscessus* subsp. bolletii, *M. abscessus* subsp. massiliense, *M. immunogenum*, and *M. salmoniphilum*[118,120].

Epidemiology and pathogenesis

The organisms exist as saprophytes, and they are found in water, soil, dust, and animals. Cutaneous infections are uncommon, and immunocompromised patients are more susceptible to severe disease caused by these species of mycobacteria[91,121].

Infections typically occur following trauma, surgery, or other procedures, including contact with contaminated medical instruments (e.g. liposuction, mesotherapy), placement of implants (e.g. prosthetic

Fig. 75.24 *Mycobacterium fortuitum* infection. Multiple eroded papulonodules and plaques within a background of erythema on the foot in a patient with an undefined immunodeficiency. *Courtesy Edward Cowen, MD.*

breast implants), and tattoo ink or acupuncture needles[96,97,122]. A post-injection abscess is another frequent presentation[3], e.g. after injection of botulinum toxin, dermal filler, phosphatidylcholine/deoxycholate, or vaccines. Furunculosis of the lower extremities has also been observed following footbaths in nail salon customers[95]. Less often, cutaneous infection is the result of dissemination from an endogenous source[91].

Clinical features

This group of mycobacteria can produce a variety of clinical diseases, including non-cavitary pneumonia, keratitis, endocarditis, lymphadenitis, osteomyelitis, and skin infections. The cutaneous manifestations range from cellulitis, abscesses, and papulopustules to sinuses and ulcers with extensive subcutaneous necrosis and serosanguineous or purulent discharge (Fig. 75.24 & 75.25A)[91]. However, the most common presentation is multiple erythematous subcutaneous nodules, frequently occurring on the distal limbs or in a sporotrichoid pattern (see Fig. 75.24)[3,119,121].

Pathology

The presence of both neutrophilic microabscesses and granuloma formation with foreign body-type giant cells is characteristic (Fig. 75.25B)[1]. Necrosis may occur[3].

Diagnosis and differential diagnosis

Culture of biopsy material must be performed. When an abscess is present, a biopsy specimen that includes the wall is preferred, rather than aspiration of pus. The organisms grow on routine bacterial culture media, such as 5% sheep blood agar or chocolate agar, within 7 days. Molecular methods utilizing PCR, gene sequencing, and matrix-assisted laser desorption ionization–time of flight mass spectrometry are available to identify these NTM[118,120].

Infection with these organisms should be considered in patients with therapy-resistant or "cold" abscesses. It can also be confused with foreign body reactions, subcutaneous mycoses, or osteomyelitis[3].

Treatment

Treatment is dependent on the type and extent of the lesions[1]. These organisms are resistant to antituberculous drugs, but nearly all *M. chelonae* and ~80% of *M. fortuitum* isolates are sensitive to clarithromycin. Excision and debridement may be required for abscesses and ulcers. Recommended antibiotics, either alone or in combination, are listed in Table 75.11[3,91,98]; prolonged courses may be required. Successful treatment of refractory pulmonary and disseminated *M. abscessus* infections by intravenous administration of engineered bacteriophages has been reported in patients with advanced cystic fibrosis lung disease[123].

Mycobacterium avium Complex (MAC)

Synonyms: ■ *M. avium* ■ *M. avium-intracellulare* (MAI) ■ *M. intracellulare*

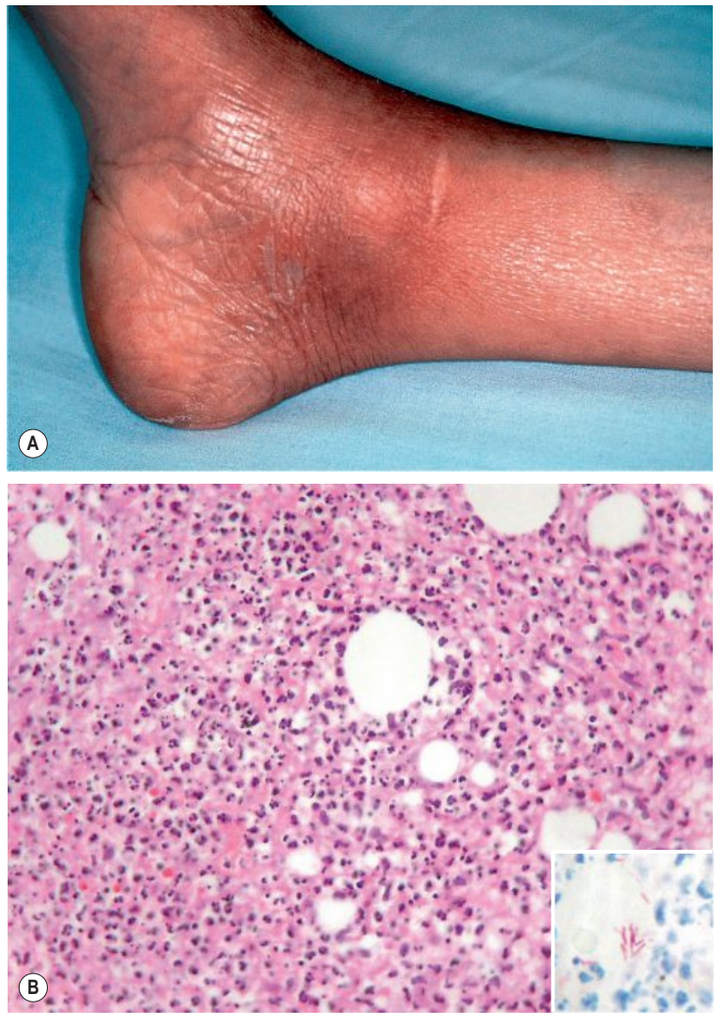

Fig. 75.25 *Mycobacterium chelonae* infection. A This immunosuppressed patient presented with an area of warmth and mild erythema on the ankle. **B** Mixed diffuse inflammatory infiltrate with granuloma formation. Curved acid-fast bacilli are seen with Fite staining (inset).

Introduction

In the 1980s, two closely related pathogens, *M. avium* and *M. intracellulare*, were designated as *M. avium-intracellulare* (MAI). Currently, the term *M. avium* complex (MAC) is utilized for these organisms as well as a growing number of additional species, including the emerging pathogen *M. chimaera* and others that have rarely been identified in human infections (*M. arosiense, M. bouchedurhonense, M. colombiense, M. marseillense, M. timonense, M. vulneris, M. yongonense*)[124].

MAC organisms are facultative pathogens that only occasionally produced human disease prior to the HIV epidemic[91], when these mycobacteria produced disseminated disease in 15%–40% of patients with AIDS[91].

Epidemiology and pathogenesis

MAC organisms are found in the environment, including fresh and salt water, soil, dairy products, and domestic animals[3,91]. They may be transmitted via inhalation into the lungs, or via water and food into the gastrointestinal tract, without person-to-person transmission[1]. As many as 30% of samples of normal human feces yield isolates of MAC[1,3].

Chronic pulmonary infection is the most common clinical manifestation of MAC infection in those who are not co-infected with HIV, followed in frequency by cervical and inguinal lymphadenitis and osteomyelitis. Lymphadenitis more frequently occurs in children. Cutaneous lesions may be primary after a traumatic inoculation, which is rare, or secondary to a disseminated infection in an immunocompromised host[3,91].

Clinical features

In patients with AIDS, there is often disseminated disease characterized by nonspecific symptoms such as fever, night sweats, weight loss, bone pain, hepatosplenomegaly, and lymphadenopathy. Serum alkaline phosphatase levels may be elevated[1]. Skin involvement is unusual and most often presents with papulopustules and multiple purulent leg ulcers[1]. Nodules with abscess formation (Fig. 75.26), panniculitis, sinus tracts, folliculitis, and granulomatous plaques may also be seen[3,91]. A papulonecrotic tuberculid-like eruption due to disseminated MAC infection has been reported in patients with AIDS[91].

Pathology

Macrophages may contain large numbers of bacilli without necrosis, and spindle cell transformation of macrophages with formation of a histoid-like lesion (as in Hansen disease) can occur[42]. The histologic features can resemble those of the lepromatous form of Hansen disease (see above) or a spindle cell neoplasm (mycobacterial spindle cell pseudotumor).

Diagnosis and differential diagnosis

In disseminated disease, the diagnosis is often established by culture of the blood or from bone marrow or liver biopsies[3]. Depending on the site(s) of involvement, cultures can also be performed on sputum or biopsies of skin and lymph nodes[99]; in addition, highly sensitive and specific PCR analysis is available.

The differential diagnosis includes pyoderma, folliculitis, other causes of panniculitis and ulcers, dimorphic fungal infections, the lepromatous form of Hansen disease, cutaneous tuberculosis, and a spindle cell neoplasm.

A Papules and nodules on the neck in a patient with interferon gamma receptor deficiency. **B** Sporotrichoid (lymphocutaneous) pattern of the coalescing nodules with abscess formation in an immunocompromised patient. *A, Courtesy Edward Cowen, MD.*

Treatment

Table 75.11 provides a list of the medications that have been used alone or in combination[1,3] to treat MAC infections. Immunocompetent patients should continue treatment until culture-negative for at least one year, whereas antimicrobial therapy should be continued for life in immunocompromised individuals with disseminated infection[3,124,125].

Mycobacterium haemophilum

Introduction

M. haemophilum is a short, slightly curved rod that occurs singly or in a cord-like arrangement. It is a fastidious organism that requires ferric ions to grow, provided as hemin, hematin, hemoglobin, or ferric ammonium citrate. In initial studies, growth was only observed with the addition of hemolyzed sheep erythrocytes; as a consequence, the organism was given the name *M. haemophilum*[92,100].

Epidemiology and pathogenesis

M. haemophilum infection occurs primarily in immunocompromised hosts, including people living with HIV, organ transplant recipients, and individuals receiving immunosuppressive medications[126]. However, this organism can also cause cervical lymphadenitis in healthy children, and cutaneous infections following tattooing (including permanent make-up) and acupuncture have been reported. The majority of affected individuals are from cities located near the ocean, the Mediterranean Sea, or the Great Lakes of North America[92,100].The natural habitat of *M. haemophilum* has not yet been identified, although water reservoirs are suspected[92,100]. *M. leprae* and *M. haemophilum* are phylogenetically related, which may explain why some individuals infected with *M. haemophilum* experience immune reconstitution events analogous to leprosy reactions (see above)[65].

Clinical features

This bacillus can produce several different types of cutaneous lesions[92]. Immunosuppressed adults typically present with one or more bluish-red tender pustules, papulonodules, or plaques, which evolve into abscesses and/or ulcers[92,102,126]. Lesions are usually located on the extremities, often overlying joints. *M. haemophilum* can also cause contiguous septic arthritis, osteomyelitis, and pneumonia. In immunocompetent individuals, cutaneous inoculation can lead to papulonodules and pustules. Immunocompetent children infected by this organism frequently have isolated cervical, submandibular, or perihilar lymphadenitis[100].

Pathology

A mixed reaction with both suppurative and granulomatous inflammation is commonly seen, but other cases have a nonspecific pattern. The bacilli are sometimes found aggregated in globi, resembling those seen in the lepromatous form of Hansen disease[92,100].

Diagnosis and differential diagnosis

The diagnosis is established by culture of the bacillus from tissue or synovial fluid; in some patients, blood cultures are positive. However, this organism requires a special environment to grow, with a source of iron and a temperature between 30°C and 32°C[92,100]. Due to these stringent requirements, it may not be isolated using routine techniques[1]. Highly sensitive and specific PCR analysis is also available.

In immunocompetent children with cervical or submandibular lymphadenitis, the possibility of MAC infection should be considered[100], along with the more common causes of lymphadenitis (e.g. EBV, CMV). The differential diagnosis of the cutaneous lesions is similar to that for infections with other NTM (see above, *M. fortuitum* and MAC).

Treatment

M. haemophilum is often resistant to antituberculous drugs, except for the rifamycins, such as rifampin and rifabutin. The combination of rifampin and clarithromycin (± amikacin) has been used successfully (see Table 75.11). The duration of therapy should be at least 6–24 months, with longer courses in immunosuppressed patients. Surgical excision is also an option when the disease is localized, e.g. adenitis in an immunocompetent child[92,100].

Mycobacterium scrofulaceum

Introduction

M. scrofulaceum was formerly grouped with MAC in a complex called MAIS (*M. avium-intracellulare-scrofulaceum*) but was separated due to its distinct clinical manifestations. *M. scrofulaceum* produces self-limited disease, particularly lymphadenitis, while MAC typically causes chronic lung disease and, less often, osteomyelitis. *M. scrofulaceum* may also cause cervical lymphadenitis with sinus formation clinically indistinguishable from scrofuloderma[74].

Epidemiology and pathogenesis

This organism is most prevalent in the southeastern US. It is widely distributed and has been isolated from raw milk, other dairy products, oysters, soil, and water[100]. Bacilli can be found in environments with: a warm temperature; low pH and dissolved oxygen level; and high soluble zinc, humic acid, and fulvic acid levels. It has also been found on the skin of healthy people and in cutaneous lesions of Hansen disease[101].

In general, infection by *M. scrofulaceum* affects children and occurs via inhalation or ingestion. Focal infection of lymph nodes due to contamination during surgical procedures may also occur. Cutaneous disease in a campground worker with corticosteroid-treated systemic lupus erythematosus and no history of preceding trauma was thought to result from subclinical bacteremia[100,101].

Clinical features

M. scrofulaceum may cause pulmonary disease and local lymphadenitis, primarily in the submandibular and submaxillary regions. It is usually a benign, self-limited condition with no systemic symptoms except for mild neck pain. The involved lymph nodes slowly enlarge over several weeks, and eventually ulceration and drainage occur with fistula formation. This organism can also produce skin lesions in a sporotrichoid pattern, but it rarely causes disseminated infection[100]. Primary cutaneous disease due to inoculation of *M. scrofulaceum* is unusual[100].

Pathology

In the lymph nodes, widespread abscess formation is the typical finding; histiocytes and granulomas may be inconspicuous. It may be difficult to differentiate *M. scrofulaceum* lymphadenitis from that due to *M. tuberculosis*[74] when there are tuberculoid granulomas with central necrosis and abscess formation. The bacilli are found within involved lymph nodes[100]. In the skin, abscess formation is typically seen.

Diagnosis and differential diagnosis

In addition to histologic examination, culture of sputum, skin, or involved lymph nodes helps to confirm the diagnosis. The infection should be distinguished from other causes of cervical lymphadenopathy (see *M. haemophilum*), particularly infection with *M. tuberculosis*[100]. However, *M. tuberculosis* usually affects tonsillar and anterior cervical nodes, while *M. scrofulaceum* typically affects submandibular and submaxillary nodes. When lesions have a sporotrichoid pattern, *M. marinum* infections and other non-tuberculous mycobacterioses should be considered (see Table 77.17)[101].

Treatment

The treatment of choice is total excision of the involved lymph nodes[74,100] because, in general, antibiotic therapy is unsatisfactory. However, promising results have been reported with isoniazid plus rifampin[101]. Successful treatment with clarithromycin has also been described (see Table 75.11)[100].

Additional figures and a table on Drug regimens for pulmonary tuberculosis, available in our eBook (see inside front cover for access code).

DRUG REGIMENS FOR CULTURE-POSITIVE PULMONARY TUBERCULOSIS (TB) CAUSED BY DRUG-SUSCEPTIBLE ORGANISMS						
Regimen	**Intensive phase**		**Continuation phase**		**Range of total doses**	**Comments**[¶,§]
	Drugs*	**Interval and doses† (minimal duration)**	**Drugs**	**Interval and doses‡,¶ (minimal duration)**		
1	INH RIF PZA EMB	7 days/week for 56 doses (8 wk) or 5 days/week for 40 doses (8 wk)	INH RIF	7 days per week for 126 doses (18 wk) or 5 days per week for 90 doses (18 wk)	182–130	Preferred regimen for patients with newly diagnosed pulmonary TB
2	INH RIF PZA EMB	7 days/week for 56 doses (8 wk) or 5 days/week for 40 doses (8 wk)	INH RIF	3 times weekly for 54 doses (18 wk)	110–94	Preferred alternative regimen in situations in which more frequent DOT during the continuation phase is difficult to achieve
3	INH RIF PZA EMB	3 times weekly for 24 doses (8 wk)	INH RIF	3 times weekly for 54 doses (18 wk)	78	Use with caution in patients with HIV and/or cavitary disease. A missed dose can lead to treatment failure, relapse, and acquired drug resistance
4	INH RIF PZA EMB	7 days/week for 14 doses (2 wk) then twice weekly for 12 doses (6 wk)[§]	INH RIF	Twice weekly for 36 doses (18 wk)	62	Do not use in HIV-infected patients or individuals with smear-positive and/or cavitary disease. If doses are missed, then therapy is equivalent to once weekly, which is inferior
5	RPT MOX INH PZA[‖]	7 days/wk for 56 doses (8 wk)	RPT MOX INH	7 days/wk for 63 doses (9 wk)	119	Patients ≥12 years of age and weighing ≥40 kg with pulmonary TB

*Other drug combinations may be appropriate in certain circumstances.
†DOT should be used when drugs are administered <7 days/week.
‡Based on expert opinion, patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month (31-week) continuation phase.
¶Pyridoxine (vitamin B6), 25–50 mg/day, is given with INH to all persons at risk of neuropathy (e.g. pregnant women; breastfeeding infants; individuals with HIV infection, diabetes, alcoholism, malnutrition, chronic renal failure, or advanced age). The pyridoxine dose should be increased to 100 mg/day in patients with peripheral neuropathy.
§Alternatively, some US TB control programs have administered intensive-phase regimens 5 days/week for 15 doses (3 weeks), and then twice weekly for 12 doses.
‖Pyrazinamide weight-based dosing: 1000 mg if 40–54 kg, 1500 mg if 55–75 kg, 2000 mg if >75 kg.

eTable 75.1 Treatment regimens for culture-positive pulmonary tuberculosis (TB) caused by drug-susceptible organisms. The effectiveness of the regimen decreases from regimen 1 to 4. With the exception of 17 weeks for regimen 5, the total duration of therapy is 26 weeks; however, the total number of doses varies. Among patients with extrapulmonary tuberculosis, regimen 1 is generally recommended as initial therapy unless the organisms are known or strongly suspected of being resistant to the first-line drugs. Doses of medications (maximum dose) when given *daily*: INH, isoniazid 5 mg/kg (300 mg); RIF, rifampin 10 mg/kg (600 mg); RPT, rifapentine 1200 mg; MOX, moxifloxacin 400 mg; PZA, pyrazinamide 35 mg/kg (2000 mg); EMB, ethambutol 20 mg/kg (1600 mg). DOT, Directly Observed Therapy. *From Nahid P, Dorman SE, Alipanah N, et al. Executive Summary: Official American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America Clinical Practice Guidelines: Treatment of drug-susceptible tuberculosis. Clin Infect Dis 2016;63:853–67.*

PROTOCOL FOR SUBMITTING SPECIMENS FOR EVALUATION OF HANSEN'S DISEASE

Submit the completed consultation request form (below) along with the biopsy sample to the National Hansen's Disease Program (NHDP).
Please clearly specify which tests should be performed by checking the appropriate boxes below (test(s) to be ordered).
Please include a copy of any related biopsy reports or clinical photos. Please send blocks with a cold pack.

The following are the requirements needed to send a biopsy for evaluation:

1. A biopsy collected with a 4 - 5 mm punch. The specimen should be deep enough to include subcutaneous fat. This depth is important because the most prominently involved nerves will most often be found in the deep dermis. As a general rule, the biopsy should be taken from an active margin of a lesion.

2. After initial fixation in 10% neutral buffered formalin (for best PCR results tissue should not remain in formalin for more than 24 hours), process tissue into a paraffin block.
   ***Initial pathology review should also be conducted prior to submitting the case to NHDP.**
   *If using an auto embedder, specimen should be re-embedded prior to sending to avoid plastic cage.

3. Slides of unstained sections - 5 unstained slides are also required for staining & histology review at NHDP.

4. Stained slides may also be submitted for histological review -- **H&E & Fite stains only.**

5. If tissue cannot be processed into a paraffin block, place specimen in 10% neutral buffered formalin, and submit for processing at the NHDP. Expedited shipping methods should be used to avoid prolonged exposure to formalin. Packages are only received during weekdays with the exception of federal holidays.
   Please note:** pathology services are conducted on a first come, first serve basis and subject to current workload/pathologist availability. Obtaining initial pathology review before sending is ***strongly recommended.

PCR TESTING--
The clinical laboratory is able to conduct PCR testing on the same formalin fixed specimen submitted for histological evaluation. Testing is limited to the identification of M. leprae and M. lepromatosis.

Requirements for PCR testing:
1. Paraffin block – required for PCR testing.
   a. If tissue is too small, PCR may not be feasible and another biopsy may be required.
   b. Please send blocks with a cold pack to prevent damage/melting during warmer months.
   c. If auto embedded, specimen will need to be re-embedded prior to sending to avoid plastic cage.

2. Formalin fixed samples may also be submitted for PCR testing if tissue cannot be processed into a block.

Reporting:
Our lab is accredited through the Joint Commission and is CLIA certified separately from the NHDP clinic. As a result, we operate as a stand-alone entity; as with any other laboratory, we are unable to release lab results to any provider/practice other than those listed on the submission paperwork. For clinical consultation purposes, please make sure to check the appropriate box below, granting the NHDP Clinic access to this report as well.

Please send specimens to the following location:
National Hansen's Disease Program
Attn: Clinical Lab (Nurah Al-Ahmed)
9181 Interline Ave.
Baton Rouge, LA 70809
Clinical Laboratory Phone: 225-756-3733; Fax: 225-756-3734; E-mail:NAL-AHMED@hrsa.gov

Rickettsial Diseases 76

Lucas S. Blanton and David H. Walker

Chapter Contents

Spotted Fever and Typhus Group Rickettsial Infections *1333*
Scrub Typhus *1340*
Human Ehrlichioses *1340*
Human Granulocytic Anaplasmosis *1341*
Q Fever *1341*

Key features

- Rickettsiae are small, obligately intracellular, Gram-negative bacteria that reside within an arthropod host (tick, flea, louse, or mite) during part of their life cycle
- The arthropod vector transmits the rickettsiae in its saliva or feces during feeding
- The major vertebrate target cells of *Rickettsia* (endothelium), *Orientia* (endothelium), *Ehrlichia* (monocytes or neutrophils), *Anaplasma* (neutrophils), and *Coxiella* (macrophages) determine to a large degree the pathogenesis of the disease
- In most spotted fever rickettsioses and scrub typhus, an eschar at the site of the vector's inoculation of organisms is an important physical sign
- A rash is the diagnostically critical clinical manifestation of Rocky Mountain spotted fever, other spotted fevers, murine typhus, and louse-borne typhus
- One of the most common rickettsial diseases in travelers is African tick bite fever

INTRODUCTION

Members of the order Rickettsiales are small, obligately intracellular, Gram-negative bacteria that reside within an arthropod host for at least part of their life cycle[1]. At least 30 bacterial species belonging to six genera (*Rickettsia, Orientia, Ehrlichia, Anaplasma, Neorickettsia, and Neoehrlichia*) as well as the related *Coxiella* genus in the order Legionellales are known agents of human diseases (Table 76.1). Cutaneous manifestations vary from nearly always present in some spotted fevers and typhus to rare in others, such as human granulocytic anaplasmosis and Q fever (Table 76.2). Clinical recognition of a rash is frequently the event that leads to appropriate antimicrobial treatment for life-threatening Rocky Mountain spotted fever (RMSF) and other rickettsioses.

SPOTTED FEVER AND TYPHUS GROUP RICKETTSIAL INFECTIONS

History

Epidemic typhus was described by Fracastorius in Italy in 1546; RMSF, by Maxey in Idaho in 1899; and boutonneuse fever by Conor in Tunisia in 1910. A rickettsial agent was first identified in 1906 in the Bitterroot Valley of western Montana by Howard Ricketts, who also recognized its transmission by ticks. In 1916, S. Burt Wolbach visualized this agent, later named *Rickettsia rickettsii*, within endothelial cells. Charles Nicolle discovered in 1909 that lice transmit epidemic typhus, which was subsequently found to be caused by *Rickettsia prowazekii*. Epidemic louse-borne typhus influenced the outcome of most European wars after 1500, including Napoleon's failed Russian invasion in 1812 and World War I, during and after which typhus affected 25 million persons and caused 3 million deaths in Russia. In 1934, recrudescent typhus (Brill–Zinsser disease) was determined to be caused by reactivation of latent *R. prowazekii* infection. Endemic or murine typhus was shown during the 1930s to have a rat reservoir and flea vector.

Epidemiology

Spotted fever group rickettsiae (SFGR) are maintained in nature principally via transmission of the bacteria in infected ova from one generation of tick, mite, or flea to the next (see Table 76.1; Fig. 76.1). During feeding, infected arthropods instill saliva containing rickettsiae into their host's skin. Thus, the seasonal and geographic distribution of each disease (Fig. 76.2) depends upon the range and the host-seeking activity

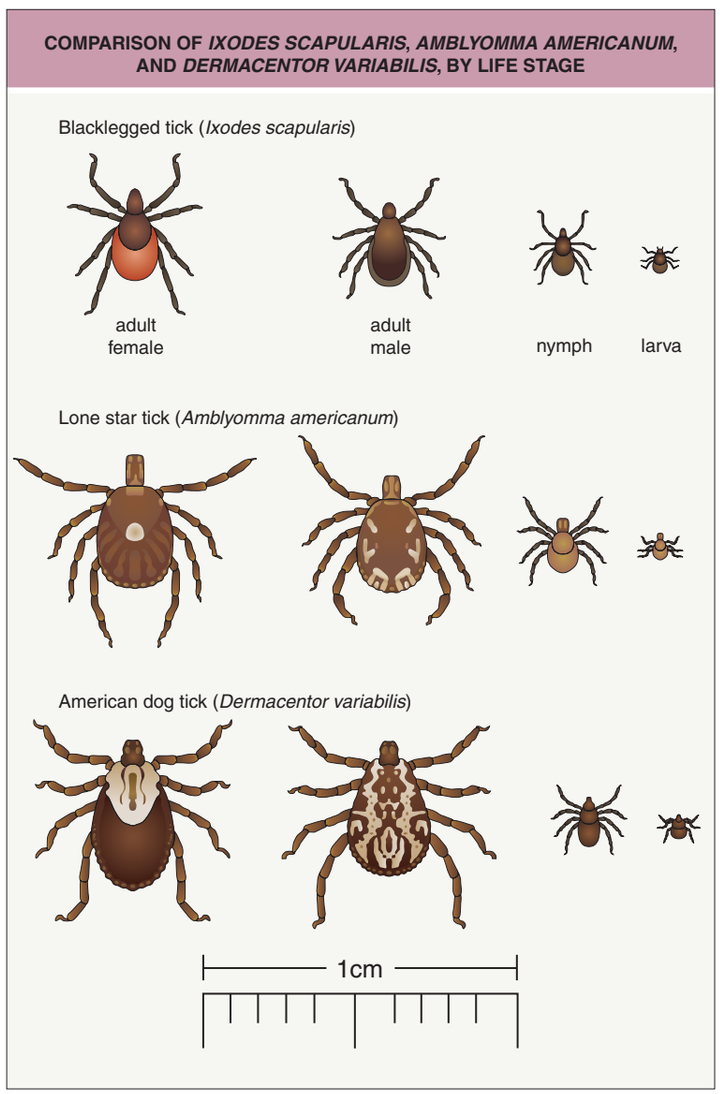

Fig. 76.1 Comparison of *Ixodes scapularis* (blacklegged tick), *Amblyomma americanum* (lone star tick), and *Dermacentor variabilis* (American dog tick), by life stage. *From Chapman AS, et al. MMWR Recomm Rep 2006;55:1–27.*

EPIDEMIOLOGY OF RICKETTSIAL AND RELATED INFECTIONS			
Agent	**Disease**	**Transmission**	**Geographic distribution**
Rickettsia rickettsii	Rocky Mountain spotted fever, Brazilian spotted fever	**Bite of tick:**	
		Dermacentor variabilis (Fig. 76.1)	Eastern two-thirds > Pacific Coast of US
		D. andersoni	Rocky Mountain states
		Rhipicephalus sanguineus	Southwestern US; northern Mexico
		Amblyomma cajennense complex, *A. aureolatum*	Mexico; Central and South America
Rickettsia akari	Rickettsialpox	**Bite of mouse mite**:	
		Liponyssoides sanguineus	North America; Eurasia
Rickettsia conorii (4 subspecies)	Boutonneuse fever (Mediterranean spotted fever), Indian and Israeli tick typhus, Astrakhan spotted fever	**Bite of tick**:	
		Rhipicephalus sanguineus	Southern Europe; Africa; western and southern Asia
		Rh. pumilio	Southern Russia
Rickettsia sibirica	North Asian and Siberian tick typhus, lymphangitis-associated rickettsiosis	**Bite of tick**:	
		Dermacentor nuttallii, D. silvarum, Haemaphysalis concinna, Hyalomma asiaticum, others	Eurasia and Africa
Rickettsia heilongjiangensis	Far Eastern spotted fever	**Bite of tick:**	
		Haemaphysalis species, D. silvarum, others	Eastern Russia, China, Thailand, Japan
Rickettsia australis	Queensland tick typhus	**Bite of tick**:	
		Ixodes cornuatus, I. holocyclus, I. tasmani	Eastern Australia
Rickettsia honei	Flinders Island spotted fever	**Bite of tick**:	
		Bothriocroton hydrosauri, others	Australia and Nepal (Flinders Island is located between Tasmania and mainland Australia)
Rickettsia japonica	Japanese spotted fever	**Bite of tick**:	
		Haemaphysalis flava, H. longicornis, Ixodes ovatus, Dermacentor taiwanensis	Japan and eastern Asia
Rickettsia massiliae	*Rickettsia massiliae* rickettsiosis	**Bite of tick:**	
		Rhipicephalus species, others	Europe, South America, Africa, Asia
Rickettsia felis	Flea-borne spotted fever	**By flea:**	
		e.g. *Ctenocephalides felis*	Worldwide
Rickettsia africae	African tick bite fever	**Bite of tick:**	
		Amblyomma hebraeum	Southern Africa
		A. variegatum	Central, eastern, and western Africa; Caribbean islands
Rickettsia parkeri	*Rickettsia parkeri* rickettsiosis (maculatum disease, American tick bite fever)	**Bite of tick:**	
		Amblyomma maculatum, A. americanum, Dermacentor parumapertus	North America
		A. triste, A. tigrinum, A. ovale	South America
Rickettsia philipii (364D)	Pacific Coast tick fever	**Bite of tick:**	
		Dermacentor occidentalis	California
Rickettsia aeschlimannii	*Rickettsia aeschlimannii* infection	**Bite of tick**:	
		Haemaphysalis concinna, Hyalomma marginatum, Rhipicephalus turanicus, others	Africa, Asia, Europe
Rickettsia slovaca, Rickettsia raoultii, or *Candidatus* Rickettsia rioja	Tick-borne lymphadenopathy, Dermacentor-borne necrosis and lymphadenopathy (DEBONEL)	**Bite of tick** (usually on the scalp):	
		Dermacentor marginatus, D. reticularis, others	Europe
Rickettsia prowazekii	Epidemic louse-borne typhus	**Feces of human body louse** (*Pediculus humanus* var. *corporis*)	South America; Africa; Eurasia
	Brill–Zinsser disease	**None (recrudescence of latent infection)**	
	Flying squirrel typhus	**Contact with flying squirrel** (*Glaucomys volans*) and its fleas and lice	North America
Rickettsia typhi	Murine (endemic) typhus	**Feces of fleas**:	
		Xenopsylla cheopis	Worldwide
		Ctenocephalides felis	North America

Table 76.1 Epidemiology of rickettsial and related infections.

EPIDEMIOLOGY OF RICKETTSIAL AND RELATED INFECTIONS			
Agent	**Disease**	**Transmission**	**Geographic distribution**
*Orientia tsutsugamushi**	Scrub typhus	**Bite of larval trombiculid mites**:	
		L. deliense, L. fletcheri, L. scutellare, L. arenicola	Southern and eastern Asia; islands of the southwestern Pacific and Indian Oceans; northern Australia
		e.g. *L. pallidum*	Japan; Korea; Russian Far East
		e.g. *L. scutellare*	China; Malaysia
		e.g. *L. deliense, L. fletcheri, L. arenicola*	Tropical regions
Ehrlichia chaffeensis	Human monocytic ehrlichiosis	**Bite of tick**:	
		Amblyomma americanum (Fig. 76.1), *Dermacentor variabilis*	Southeastern and South Central US
Ehrlichia muris eauclairensis	Ehrlichiosis (due to *Ehrlichia muris eauclairensis*)	**Bite of tick:**	
		Ixodes scapularis	Upper midwestern US
Ehrlichia ewingii	Ehrlichiosis (due to *Ehrlichia ewingii*)	**Bite of tick:**	
		Amblyomma americanum	Southeastern and South Central US
Anaplasma phagocytophilum	Human granulocytic anaplasmosis	**Bite of tick:**	
		Ixodes scapularis (Fig. 76.1)	Northern US
		I. pacificus	Far western US
		I. ricinus, I. persulcatus	Eurasia
Candidatus Neoehrlichia mikurensis	Neoehrlichiosis†	**Bite of tick:**	
		Ixodes ricinus	Europe
		Ixodes persulcatus	East Asia
Neorickettsia sennetsu	Sennetsu fever‡	**Ingestion** of infected trematode-infested raw fish or fish paste	East Asia
Coxiella burnetii	Q fever	**Aerosol** of infected products of parturition of ruminants (e.g. sheep, cattle, goats), cats, and other animals¶	Worldwide

*More recently identified causes of scrub typhus include *Orientia chuto* (Dubai, Africa) and *Candidatus* Orientia chiloensis (Chile).
†Febrile illness that may be associated with thrombosis, thrombophlebitis, and arteritis; described primarily in immunocompromised patients with a hematologic malignancy or autoimmune disease.
‡Mononucleosis-like syndrome characterized by fever, malaise, and generalized lymphadenopathy.
¶Less common means of transmission include ingestion of contaminated dairy products and tick bites (e.g. *Dermacentor* spp.).

Table 76.1 Epidemiology of rickettsial and related infections. Additional agents that have been implicated in infections with eschar and/or rash include *Rickettsia monacensis* (Europe) and *Candidatus* Rickettsia tarasevichiae (China). *Rickettsia helvetica* transmitted by *Ixodes ricinus* in Europe can also lead to "aneruptive fever" that lacks cutaneous involvement.

of the particular vector. For example, RMSF usually occurs during tick season, from late spring until the end of summer[2].

Typhus group rickettsiae are deposited on the host's skin in the feces of feeding human body lice (*R. prowazekii*) or fleas (*R. typhi*). The organisms are subsequently scratched into the skin, rubbed into mucous membranes, or inhaled. Humans who recover from louse-borne typhus remain latently infected and years later may develop recrudescent illness (Brill–Zinsser disease) and associated rickettsemia. Such individuals can infect feeding lice, which may then spread the disease to another person and ignite an epidemic. In addition, a zoonotic cycle of *R. prowazekii* is maintained in flying squirrels and their fleas and lice. *R. typhi* is maintained in natural cycles, classically in rats and oriental rat fleas as well as in opossums and cat fleas. Murine (endemic) typhus caused by *R. typhi* is prevalent in tropical and subtropical coastal regions worldwide, representing an increasingly recognized cause of febrile illness in travelers[3].

Pathogenesis

After entry into the dermis, rickettsiae spread throughout the body via the bloodstream. They attach to vascular endothelial cells by outer membrane protein B and, in the case of SFGR, also via outer membrane protein A. The organisms enter the cells by induced phagocytosis and then escape from the phagosome into the cytosol, where they obtain amino acids, nucleotides, and other building blocks for growth from the host cell and divide by binary fission. SFGR move intra- and intercellularly by stimulating propulsion via the host cell's actin, resulting

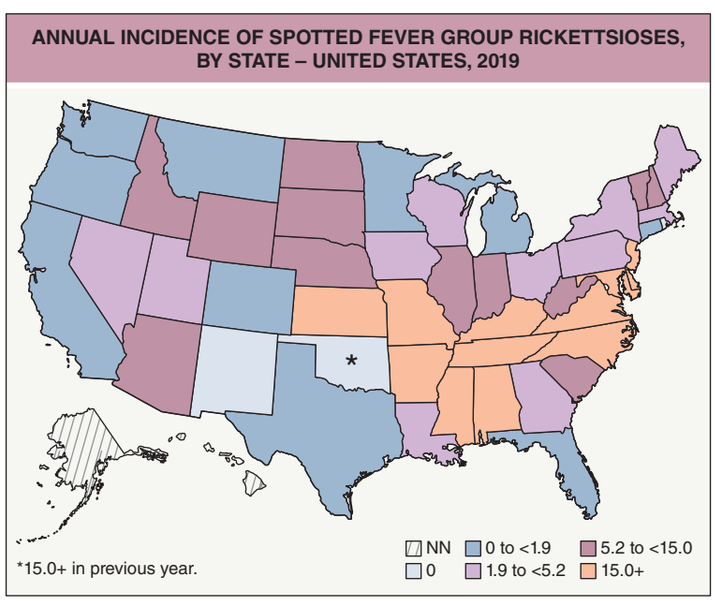

Fig. 76.2 Annual incidence (per million persons) of spotted fever group rickettsioses, by state – United States, 2019. Because serologic tests cannot reliably distinguish among spotted fever group *Rickettsia* species, since 2010 CDC reporting has combined them in a category that includes Rocky Mountain spotted fever (RMSF), *Rickettsia parkeri* rickettsiosis, Pacific Coast tick fever, and rickettsialpox. NN, not notifiable. *Courtesy US Centers for Disease Control and Prevention, cdc.gov/rmsf/stats/index.html.*

DERMATOLOGIC MANIFESTATIONS OF RICKETTSIAL INFECTIONS				
Disease	**Rash incidence (%)**	**Appearance of rash after onset of illness**	**Characteristics**	**Eschar (%)**
Rocky Mountain spotted fever, Brazilian spotted fever	90	3–5 days	Early macules, later papules; petechiae in 50% of patients; retiform purpura in severe disease	<1
Rickettsialpox	100	2–3 days	Early macules and papules; later papulovesicles and crusts	90
Boutonneuse fever and related conditions	95	3–5 days	Early macules, later papules	50
North Asian tick typhus and related conditions	100	4–5 days	Macules and papules	75
Far Eastern spotted fever	90	3–4 days	Macules and papules	90
Queensland tick typhus	90	2–6 days	Macules, papules, and vesicles	75
Flinders Island spotted fever	85	A few days	Early macules and papules, later (in some patients) petechiae	50
Japanese spotted fever	100	A few days	Early macules, later (in some patients) petechiae	90
Rickettsia massiliae rickettsiosis	75	Not reported	Macules and papules	100
Flea-borne spotted fever	80	A few days	Macules and papules; occasionally pustules	15–20
African tick bite fever	50	2–5 days	Generally relatively few lesions; macules, often vesicles	90, often multiple
Rickettsia parkeri rickettsiosis	80	2–4 days	Macules, papules, often vesicles	100
Pacific Coast tick fever	15	Not reported	Macules in region of eschar (one patient)	100
R. aeschlimannii infection	50	Not known	Macules and papules	100
Tick-borne lymphadenopathy	5	Not reported	Macules and papules	100
Epidemic louse-borne typhus	50–100	4–5 days	Early macules, later papules; petechiae	None
Brill–Zinsser disease	50	4–6 days	Macules and papules	None
Flying squirrel typhus	65	2–8 days	Macules and papules	None
Murine (endemic) typhus	50	5 days	Early macules, later papules	None
Scrub typhus	50	4–6 days	Early macules, later papules	60–90
Human monocytic ehrlichiosis	40	Median, 5 days	Macules, papules, occasionally petechiae	None
Ehrlichia muris eauclairensis ehrlichiosis	10	Not reported	Not reported	None
Human granulocytic anaplasmosis	≤5	Not reported	Erythematous rash on neck/chest; petechiae or purpura	None
Neoehrlichiosis	Rare	Not reported	Erythematous macules, erythema nodosum	None
Sennetsu fever	Rare	Not reported	Diffuse erythema, petechiae	None
Q fever	Rare	Associated with chronic infection	Macules, papules, palpable purpura; rarely erythema nodosum	None

Table 76.2 Dermatologic manifestations of rickettsial and related infections. To date, skin findings have not been described in patients with *Ehrlichia ewingii* ehrlichiosis.

in a contiguous network of infected endothelial cells that represent the source of the vascular-based disease manifestations, including skin lesions. Whereas SFGR injure the host endothelium by stimulating these cells to produce toxic reactive oxygen species, typhus group rickettsiae replicate within the infected endothelial cells until they burst[4].

The major pathophysiologic effect of rickettsial infection is increased vascular permeability, which can result in edema, hypovolemia, and hypotension. Although endothelial cells of the microcirculation are infected in every organ, the critical target organs in life-threatening infections are the lung and brain. A fatal outcome can result if increased vascular permeability leads to non-cardiogenic pulmonary edema, acute respiratory distress syndrome (ARDS), and meningoencephalitis[2].

As the infection progresses, macrophages and lymphocytes infiltrate the walls of affected vessels and act as effector cells, secreting cytokines such as interferon-γ and tumor necrosis factor. Infected endothelial cells and macrophages themselves are activated by cytokines, resulting in killing of intracellular rickettsiae by mechanisms involving nitric oxide, reactive oxygen species, and tryptophan starvation (via enzymatic degradation of this amino acid). Recruited cytotoxic T cells are critical to the apoptotic elimination of infected endothelial cells, which occurs through perforin-dependent pathways. A combination of rickettsicidal mechanisms and killing of infected endothelial cells ultimately leads to clearance of the infection. Antibodies to rickettsiae play a role in the prevention of reinfection[4].

Clinical Features

Clinical course and systemic features

Rickettsial infections typically begin with fever (>102°F [39°C]) in two-thirds of patients during the first 3 days of the illness and in 90% thereafter, accompanied by a severe headache and myalgias. Nausea, vomiting, abdominal pain, and abdominal tenderness are also frequent early symptoms. When a rash develops, it usually appears on day 3–6 of the illness (see below and Table 76.2). Cough (related to pneumonitis and/or pulmonary edema) and confusion or lethargy (related to encephalitis) may represent additional symptoms. Patients often have thrombocytopenia, although full-blown disseminated intravascular coagulation is rare, and hyponatremia frequently occurs secondary to increased antidiuretic hormone secretion in response to hypovolemia. Additional laboratory findings may include anemia, elevated liver enzymes, and abnormal renal function tests. As the clinical course progresses, hypotension, acute kidney injury, respiratory failure, and coma may develop[5].

Severe rickettsioses continue to cause death due to misdiagnosis and/or *delayed initiation* of antirickettsial treatment, with approximate mortality rates as follows: 4% for RMSF and louse-borne typhus; 2.5% for boutonneuse fever; and 0.5% for murine typhus[3]. If *not treated* with an appropriate antimicrobial agent, ~25% and 15% of patients with RMSF and louse-borne typhus, respectively, will die[2,6]. The case fatality rate is higher with older age, male sex, and comorbidities.

Fig. 76.4 Rocky Mountain spotted fever. Petechiae on the palms and soles often develop relatively late in the disease course. *Courtesy Ronald P. Rapini, MD.*

Fig. 76.5 Rocky Mountain spotted fever. Petechiae are present within erythematous papules and plaques on the buttocks. Some of the lesions have a retiform pattern.

Fig. 76.6 Rocky Mountain spotted fever. Retiform purpura on the distal lower extremity in a patient with more severe disease.

Shared cutaneous features

In many types of spotted fevers other than RMSF (see Table 76.2), an eschar consisting of central dermal and epidermal necrosis (typically 0.5–2 cm in diameter) surrounded by a zone of erythema appears during the incubation period (usually 4–10 days prior to onset of the illness) (see Figs. 76.7 and 76.8A). This represents the site of inoculation of rickettsiae by the tick or mite[7,8]. The rash typically begins as erythematous macules around the wrists and ankles (spotted fevers) (Fig. 76.3) or axillae (typhus fevers). The exanthem evolves during the course of the illness, with lesions eventually appearing on most of the body, often with relative sparing of the face. Macules and papules develop on the palms and soles in approximately half of the patients with spotted fevers, often relatively late in the disease course (Fig. 76.4). Macules reflect vasodilation related to infection of endothelial cells in the dermal microcirculation. As perivascular edema develops secondary to leakage of fluid from damaged blood vessels, macules become papules. When endothelial cell destruction leads to more severe vascular injury, petechiae appear within the lesions (Fig. 76.5), which can coalesce and become purpuric (Fig. 76.6). Cutaneous necrosis, including gangrene of the digits, extremities, ears or prepuce, occurs in ~5% of patients with RMSF and occasionally in epidemic typhus; this is due to more severe infection of the microcirculation in acral sites, which are cooler and therefore more favorable for rickettsial growth.

Features of specific diseases

RMSF usually follows the classic clinical course described above. After an incubation period of 2–14 (mean, 7) days following the tick bite (which ~40% of patients do not recall), affected individuals present with fever, myalgias, headache, and in >50% of patients, gastrointestinal symptoms. The rash typically appears 3–5 days after onset of the illness as subtle erythematous macules on the wrists and ankles, which is followed by centripetal spread to the trunk, formation of papular lesions, and eventual development of petechiae (~50% of patients). However, cutaneous findings are absent in 10%–15% of patients and may be difficult to recognize in darkly pigmented skin.

R. parkeri and *R. africae*, closely related strains of SFGR, cause two similar infections, ***R. parkeri rickettsiosis*** and ***African tick bite fever***, respectively. The former is endemic in the south central and southeastern US (the range of *A. maculatum*, the Gulf Coast tick; see Table 76.1 & Fig. 76.12B) as well as in South America, while the latter is endemic in sub-Saharan Africa and represents the rickettsial disease with the highest incidence among all international travelers returning to the US or other countries worldwide[9,10]. Patients with these conditions typically present with mild constitutional symptoms (e.g. fever, headache, myalgias), one or more eschars (Fig. 76.7), and tender lymphadenopathy in the region draining the eschar(s). In 50%–80% of affected individuals, usually 2–4 days after disease onset, a rash develops on

Fig. 76.7 African tick bite fever. Eschar at the tick bite site.

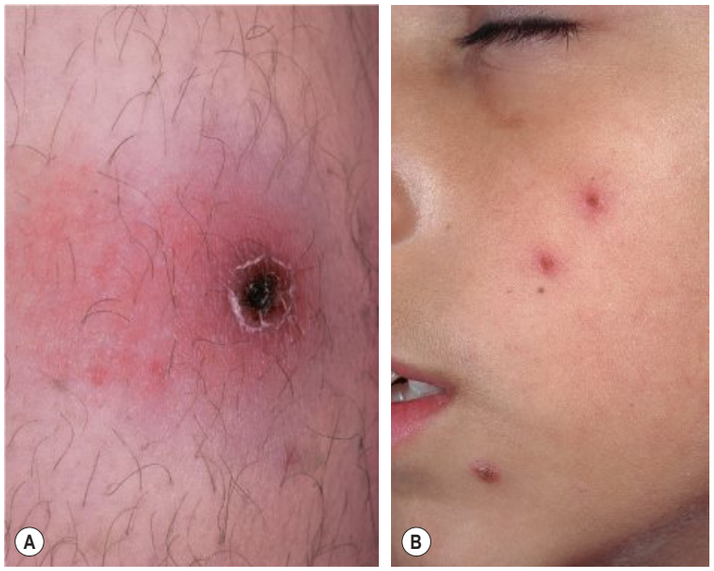

Fig. 76.8 Rickettsialpox. A Eschar at the site of the mite bite. **B** Scattered papules with hemorrhagic crusts.

the trunk and extremities, sometimes involving the palms and soles. The eruption may be relatively sparse and often features small central vesicles or pustules within erythematous macules and papules. No deaths have been reported for either type of infection. Despite the substantial difference in severity, it is likely that many *R. parkeri* infections are misdiagnosed as RMSF owing to serologic cross-reactivity with *R. rickettsii*[10].

Rickettsialpox occurs primarily in urban areas, especially in the northeastern US, and is transmitted by mites that parasitize house mice. A papulovesicle arises within 48 hours at the site of a mite bite and eventuates in an eschar with surrounding erythema and induration (Fig. 76.8A). Constitutional symptoms (e.g. fever, headache, myalgias) begin 1 to 2 weeks later, followed in 2 to 3 days by a cutaneous eruption that often involves the face (Fig. 76.8B) as well as the trunk and extremities, in no particular sequence. Approximately 20–40 skin lesions typically develop, evolving from erythematous macules and papules to papulovesicles to hemorrhagic crusts. The palms and soles are occasionally affected, and an enanthem characterized by small erosions on the tongue, palate, and pharynx may occur[3].

Pathology

Rickettsial infection is multifocal, which is reflected in the scattered distribution of cutaneous lesions. Randomly obtained tissue samples are unlikely to contain the classic finding of a lymphocytic vasculitis with extravasation of erythrocytes (Fig. 76.9), which is typically present in the center of a petechial macule or papule. The early finding of perivascular edema is difficult to identify histopathologically because of formalin-associated tissue shrinkage. Small fibrin thrombi are

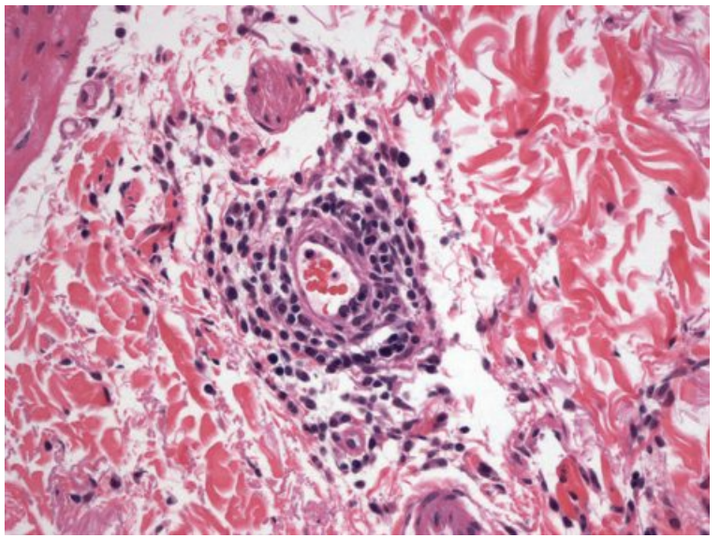

Fig. 76.9 Histologic findings in Rocky Mountain spotted fever. Typical lymphohistiocytic vasculitis involving a dermal blood vessel. *Courtesy James W. Patterson, MD.*

evident in a minority of cases. Later in the disease course, leukocytoclastic vasculitis can be detected histopathologically in the skin and other organs. Eschars reflect coagulative necrosis of the epidermis. Skin lesions of rickettsialpox show subepidermal edema associated with a mild vasculitis and dense lymphohistiocytic infiltrate. Fibrin thrombi may be observed.

Diagnosis and Differential Diagnosis

The diagnosis of rickettsiosis is based on disease signs and symptoms as well as potential arthropod exposure (Fig. 76.10)[11]. It is essential to begin empiric treatment with effective antirickettsial agents based on clinical suspicion rather than awaiting laboratory confirmation. Indeed, serologic diagnosis is usually retrospective, because antibodies do not develop until day 7 of the illness or later. Serologic confirmation requires seroconversion or a 4-fold increase between acute and convalescent antibody titers[12]. Previous exposure to non- or mildly pathogenic cross-reacting SFGR (e.g. *Rickettsia amblyommatis* within *Amblyomma americanum* [lone star] ticks) can make interpretation of single serologic specimens difficult[12,13].

Circulating rickettsiae are generally too few early in the illness to be detected in the blood by PCR-based assays, whereas PCR analysis of fresh and even formalin-fixed skin biopsy specimens is more sensitive[14] (see Fig. 76.10). Rickettsiae can also be identified by immunofluorescence or immunohistochemistry in a biopsy specimen of an eschar or a maculopapular lesion (Fig. 76.11), especially if the latter is petechial.

Prior to the onset of the rash, the differential diagnosis may include a wide variety of viral infections, ehrlichiosis, and typhoid fever. Patients with prominent nausea and vomiting are often suspected to have viral or bacterial enterocolitis. Abdominal pain and tenderness can suggest an acute surgical abdomen, which has led to exploratory laparotomies. Cough and crackles on auscultation due to pulmonary edema may lead to suspicion of bacterial or viral pneumonia. Neurologic signs and cerebrospinal fluid pleocytosis can suggest viral or bacterial meningoencephalitis, while jaundice and elevated hepatic enzymes may prompt the consideration of viral hepatitis or leptospirosis.

When the cutaneous eruption initially develops, the differential diagnosis may include a viral exanthem, a drug eruption, ehrlichiosis, Kawasaki disease, and early secondary syphilis. Exanthems due to enteroviruses, Epstein–Barr virus, parvovirus B19, adenovirus, dengue fever, and measles may have a petechial component (see Fig. 81.2). When petechial and/or purpuric lesions become more prominent, meningococcemia, small vessel vasculitis, disseminated gonococcal infection, and viral hemorrhagic fevers (e.g. dengue; see Table 81.7) may also be considered. In patients with thrombocytopenia, immune thrombocytopenic purpura or thrombotic thrombocytopenic purpura represent additional possibilities. The differential diagnosis for rickettsialpox and other rickettsial eruptions with a vesicular component

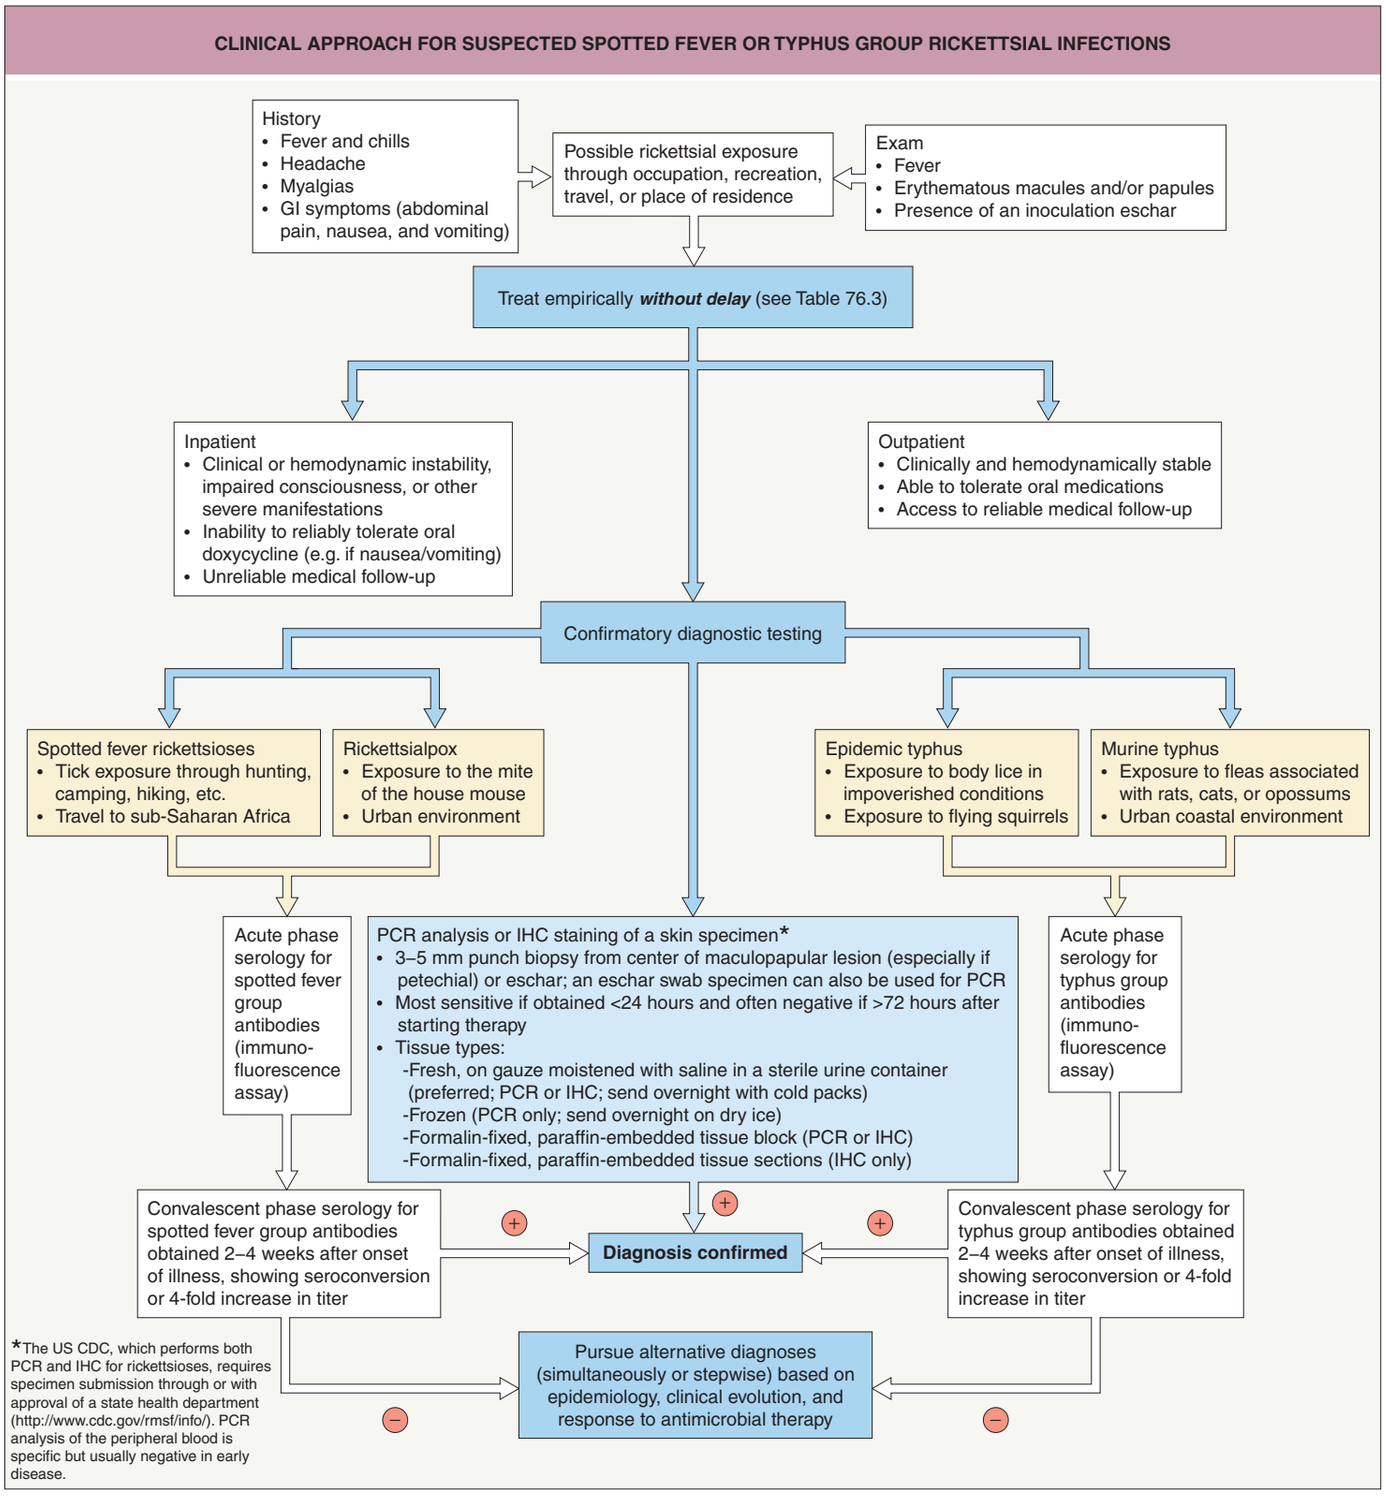

Fig. 76.10 Clinical approach for suspected spotted fever or typhus group rickettsial infections. IHC, immunohistochemical.

may include vesicular viral exanthems (e.g. due to coxsackieviruses), varicella, disseminated HSV infection, pityriasis lichenoides et varioliformis acuta (PLEVA), drug eruptions, bullous insect bite reactions, and scabies. Cutaneous necrosis resembling an eschar can be seen in spider bites, ecthyma gangrenosum (typically in immunocompromised hosts), cutaneous anthrax, *Bacillus cereus* infection, cutaneous diphtheria, tularemia, scrub typhus (see below), and primary syphilis.

Treatment

The drug of choice for rickettsial infections in nearly all patients, including young children, is doxycycline[11] (Table 76.3). Chloramphenicol is a less effective alternative, having a higher rate of fatal outcomes; in the US, oral chloramphenicol is not available and the intravenous form is difficult to obtain. Although older tetracyclines may lead to adverse effects in pregnant women and the developing fetus, doxycycline appears to be relatively safe and represents the best treatment option for severe rickettsioses (e.g. RMSF) during pregnancy[11].

Mild cases of boutonneuse fever in children have been treated with azithromycin or clarithromycin with an outcome equivalent to treatment with chloramphenicol. These antibiotics may also represent therapeutic options for mild rickettsioses during pregnancy[15]. Although fluoroquinolones have been used successfully to treat patients with boutonneuse fever, worse outcomes have been noted in those with

severe disease[16]. Fluoroquinolone or azithromycin therapy also results in delayed defervescence as compared to tetracyclines in murine typhus[3,17]. Therefore, treatment of severe rickettsial infection with macrolides or fluoroquinolones is not recommended.

SCRUB TYPHUS

Scrub typhus was described in association with red mites in China in CE 313. *Orientia tsutsugamushi* was discovered in Japan by Nagayo and Ogata in the 1920s and early 1930s. There are >70 strains of *O. tsutsugamushi*, which differs from *Rickettsia* spp. in its cell wall proteins and ultrastructure as well as by lacking lipopolysaccharide. *O. tsutsugamushi* is maintained in nature via transovarial transmission by its vector, trombiculid mites (see Table 76.1). Eggs laid by infected mites hatch with the emergence of infected larvae (chiggers) that feed on rats.

Approximately one million cases of scrub typhus occur annually, primarily affecting rural populations in Asia (from Afghanistan to Japan) and northern Australia[18]. In addition, novel *Orientia* spp. have been implicated in scrub typhus occurring in Dubai and Africa (*O. chuto*) as well as Chile (*Candidatus* O. chiloensis)[19–21]. Immunity is strain-specific and transient, resulting in reinfections. The severity of the illness is age-dependent and varies geographically.

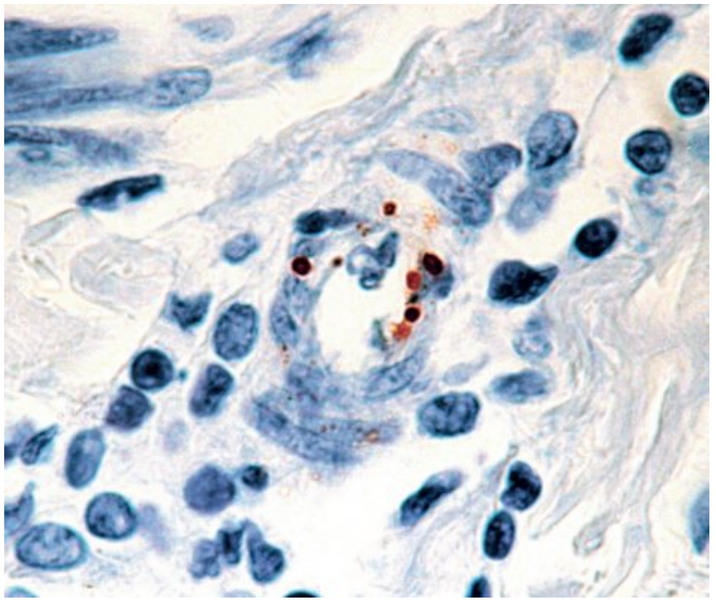

Fig. 76.11 Immunohistochemical detection of spotted fever rickettsiae. Organisms within the endothelium of a dermal blood vessel are highlighted by brown staining.

A cutaneous eschar forms at the site of chigger feeding in 60%–90% of primary infections. This is followed by regional lymphadenopathy, fever, and headache; generalized lymphadenopathy, conjunctival hyperemia, and hearing loss may also develop[18]. A rash occurs in approximately half of patients, usually appearing as erythematous macules on the trunk 4–6 days after disease onset. Lesions then become papular, with subsequent centrifugal spread. Interstitial pneumonia occurs frequently, presenting with cough, tachypnea, and radiographic infiltrates; meningoencephalitis is a less common manifestation[22]. In severe cases, ARDS, acute kidney injury, and hypotensive shock may develop.

Tetracyclines, particularly doxycycline, are generally the first-line treatment for scrub typhus. Azithromycin has similar efficacy and represents an option for pregnant women and children, whereas chloramphenicol is less effective[15]. However, reduced responsiveness of *O. tsutsugamushi* infections to doxycycline and chloramphenicol treatment has been reported in northern Thailand[23,24], and patients there have been treated successfully with azithromycin or rifampin.

HUMAN EHRLICHIOSES

Ehrlichial infections have been well known to veterinarians for >75 years, but human infection was not recognized until 1987, when an organism eventually identified as *Ehrlichia chaffeensis* was implicated as the etiologic agent of human monocytic ehrlichiosis (HME)[25]. In 1999, *E. ewingii* was found to cause human infections (most often in immunosuppressed patients) with clinical manifestations similar to HME[26]. *Ehrlichia* spp. are obligately intracellular, Gram-negative bacteria that target monocytes/macrophages (*E. chaffeensis*) or neutrophils (*E. ewingii*), within which they reside as a cytoplasmic microcolony that is occasionally visible in a peripheral blood smear. Both agents are maintained in a zoonotic cycle involving persistently infected white-tailed deer as the major reservoir and *Amblyomma americanum* as the primary vector (see Table 76.1). These ticks were originally found primarily in the south central and southeastern US, but their geographic distribution has expanded into the upper midwestern and northeastern states, overlapping with that of *Ixodes scapularis* (Fig. 76.12A)[25]. Trends of increasing temperatures with climate change are predicted to continue to shift the ranges of tick species northward[27]. *Ehrlichia muris eauclairensis*, transmitted by *Ixodes scapularis*, causes a human infection similar to HME in the upper midwestern US[28].

HME is a serious infectious disease with a ~3% case fatality rate. Its incidence is likely underestimated due to the lack of specific clinical findings[29]. Patients with HME and *Ehrlichia ewingii* ehrlichiosis typically present with fever, headache, and myalgias; common laboratory abnormalities include thrombocytopenia, leukopenia, and elevated transaminases. Progression to ARDS, meningoencephalitis, and toxic shock syndrome-like manifestations can occur. In addition, overwhelming ehrlichial infection may develop in immunocompromised hosts, such as those with HIV infection and organ transplant recipients[29,30].

TREATMENT OF RICKETTSIAL AND RELATED DISEASES

	Medication	Adult dose	Pediatric dose	Treatment duration
• First choice for virtually all rickettsial infections in children and adults*	Doxycycline	100 mg po or iv twice daily	2.2 mg/kg (max. 100 mg) po or iv twice daily	Until ≥3 days after defervescence, for a minimum total course of 5–7 days
• Alternative for non-life-threatening HME or HGA in pregnant women • Alternative for scrub typhus	Rifampin	300 mg po twice daily	10 mg/kg (max. 300 mg) twice daily	Until ≥3 days after defervescence, for a minimum total course of 7–10 days
• First choice for scrub typhus in pregnant women and potentially children • Alternative for mild rickettsioses (e.g. early boutonneuse fever) during pregnancy or in children	Azithromycin†	500 mg po daily	10 mg/kg po daily	3 days

*Other tetracyclines are also effective for rickettsial infection, but doxycycline is preferred during pregnancy, as older tetracyclines have been associated with adverse effects in this population (e.g. maternal pancreatitis, hepatitis, bone abnormalities in the developing fetus).
†Clarithromycin may also be considered.

Table 76.3 Treatment of rickettsial and related diseases. Empiric treatment with an appropriate agent should be initiated immediately when a diagnosis of Rocky Mountain spotted fever (RMSF), human monocytic ehrlichiosis (HME), human granulocytic anaplasmosis (HGA), or another potentially severe rickettsiosis is suspected clinically. Use of chloramphenicol in pregnant women is no longer recommended due to an increased likelihood of death in severe rickettsioses (e.g. RMSF) and potential risks including aplastic anemia and (when used in the late third trimester) gray baby syndrome. iv, intravenously; po, orally.

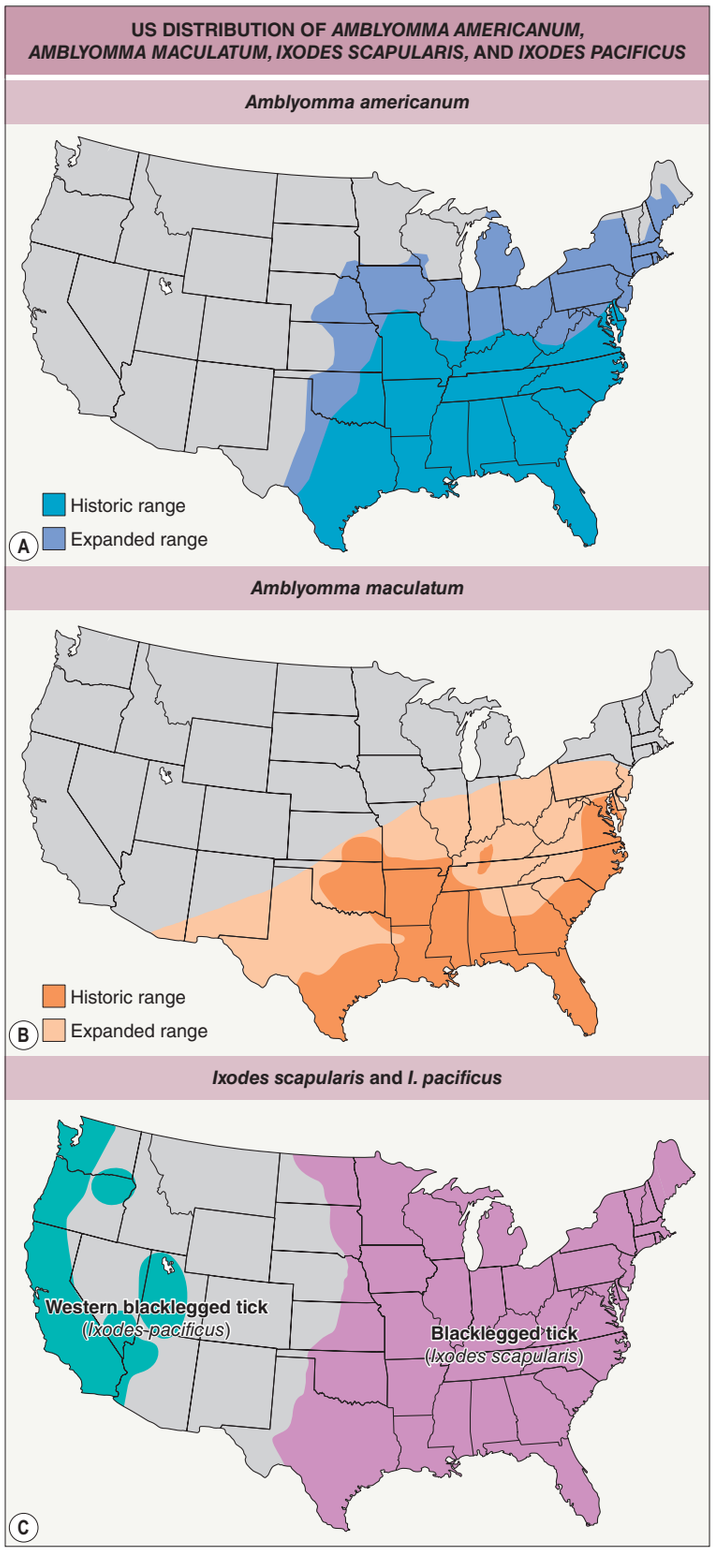

Fig. 76.12 US distribution of *Amblyomma americanum, A. maculatum, Ixodes scapularis*, and *I. pacificus*. *Amblyomma americanum* (**A**) and *A. maculatum* (Gulf Coast tick; **B**); both have original as well as extended distributions, with the latter in a second shade. **C** *Ixodes scapularis* and *I. pacificus*.

CUTANEOUS MANIFESTATIONS OF HUMAN MONOCYTIC EHRLICHIOSIS
Macular or maculopapular exanthematous eruptions
Mottled or diffuse macular erythema (transient or persistent)
Petechiae (favor the palms, soles, trunk, and palate)
Vesicles
Edema (especially of hands, feet, and scrotum)
Purpuric papules (with histologic evidence of vasculitis)
Nodules secondary to polyarteritis nodosa
Ulceration (reported on the penis)

Table 76.4 Cutaneous manifestations of human monocytic ehrlichiosis. Several types of lesions may be present simultaneously or sequentially in an individual patient.

Approximately 30%–40% of patients with HME have cutaneous manifestations, which develop a median of 5 days after the onset of the illness and may be more common in children[31]. Macular, maculopapular, and petechial eruptions involving the trunk and extremities are most often observed, but the morphology and distribution of skin lesions can vary considerably[31,32] (Table 76.4). *Ehrlichia ewingii* ehrlichiosis has not been reported to have cutaneous manifestations[26]. The differential diagnosis of ehrlichioses is similar to that of rickettsioses (see above).

Since *Ehrlichia* spp. and *Anaplasma phagocytophilum* are found within circulating monocytes or neutrophils, PCR-based assays of peripheral blood samples have greater sensitivity than for rickettsial infections[33]. However, empiric treatment should be initiated based on clinical suspicion rather than awaiting laboratory confirmation. Doxycycline is the drug of choice. *In vitro* evidence suggests that chloramphenicol is not an effective therapy for these infections.

HUMAN GRANULOCYTIC ANAPLASMOSIS

Anaplasma phagocytophilum, previously referred to as the "human granulocytic ehrlichiosis (HGE) agent", is an obligately intracellular bacterium (closely related to *Ehrlichia* spp.) that causes human granulocytic anaplasmosis (HGA; formerly known as HGE). HGA occurs in the same geographic distribution as Lyme disease (and babesiosis) owing to their transmission by the same *Ixodes* spp. tick vectors (see Table 76.1 & Fig. 76.12C). The clinical features of HGA are similar to those of HME, but HGA has a lower case fatality rate (0.5%–1%), often presents with peripheral neuropathy (but rarely meningoencephalitis), and seldom (≤5% of patients) has dermatologic manifestations other than petechiae or purpura related to thrombocytopenia[34]. Interestingly, Sweet syndrome has been described in association with HGA. As for HME, the first-line treatment is doxycycline.

Q FEVER

Coxiella burnetii are obligately intracellular bacteria categorized in the order Legionellales. Although they reside within several tick species, these organisms are transmitted to humans primarily by inhalation of aerosols generated from the placenta and birth fluids of infected animals (see Table 76.1)[35]. The bacteria target macrophages, where they thrive in acidic phagolysosomes, and their resistance to heat, desiccation, and disinfectants allows them to survive in the environment.

Acute disease typically presents as a nonspecific febrile illness, with atypical pneumonia or granulomatous hepatitis occurring occasionally. Chronic Q fever most often manifests as "culture-negative" endocarditis affecting a previously damaged heart valve. Cutaneous manifestations of Q fever are rare (see Table 76.2). A truncal maculopapular rash, an urticarial eruption, erythema nodosum, palpable purpura, palatal petechiae, and vasculitis (reported in association with mixed cryoglobulinemia) have been described.

77 Fungal Diseases

Boni E. Elewski, Lauren C. Hughey, Katherine Marchiony Hunt and Roderick J. Hay

Key features

- Cutaneous fungal infections are broadly divided into two groups: (1) those that are limited to the stratum corneum, hair, and nails; and (2) those that involve the dermis and subcutaneous tissues
- Superficial fungal infections of the skin are most often due to dermatophytes and *Candida* spp.
- "Subcutaneous" mycoses are often the result of implantation, while systemic or "deep" mycoses of the skin usually represent hematogenous spread or extension from underlying structures
- In the immunocompromised host, opportunistic fungi, e.g. *Aspergillus* and *Mucor* spp., can lead to both cutaneous and systemic infections

This chapter reviews common cutaneous fungal infections, and they are subdivided into three major groups: (1) "superficial"; (2) "subcutaneous"; and (3) "deep" or systemic (Table 77.1).

SUPERFICIAL MYCOSES

Introduction

Superficial mycoses are due to fungi that only invade fully keratinized tissues, i.e. stratum corneum, hair, and nails. They can be further subdivided into those that induce minimal, if any, inflammatory response, e.g. tinea (pityriasis) versicolor, and those that lead to more substantial cutaneous inflammation, e.g. dermatophytoses (Table 77.2).

Non-inflammatory Superficial Mycoses

Synonyms: ■ Tinea nigra: tinea nigra palmaris et plantaris, superficial phaeohyphomycosis ■ Piedra: molestia de Beigel, trichomycosis nodularis ■ Tinea versicolor: pityriasis versicolor, dermatomycosis furfuracea, tinea flava

History

In 1846, Eichstedt first noted the disease known today as tinea (pityriasis) versicolor. Over the ensuing 150 years, *Malassezia furfur* (previously known as *Pityrosporum ovale* and *P. orbiculare*) came to be recognized as the causative microbe. More recently, however, studies have pointed to *M. globosa* as a major causative organism[1]. In 1865, Beigel first described piedra after isolating a fungus, which was likely actually a contaminant, from a wig. Tinea nigra was first described in the 1890s by Cerqueira, who named it "keratomycosis nigricans palmaris"[2].

Epidemiology

Tinea nigra and piedra most often occur in tropical climates of Central and South America, Africa and Asia, but also occasionally develop in the southeastern US. While any age, ethnicity, or sex may be affected, the typical patient is a young adult. *Trichosporon* spp., which were previously collectively known as *T. beigelii*, cause white piedra and can also lead to disseminated trichosporonosis in immunocompromised individuals (see Table 77.2)[3].

Malassezia spp. are found worldwide (Table 77.3). In fact, they are part of the normal flora (microbiota) of human skin (predominantly *M. sympodialis*, *M. globosa*, and *M. restricta*). Although tinea versicolor occurs most frequently in tropical climates with high ambient temperatures and high humidity, it is also common in temperate climates. No racial or sex differences have been observed. Tinea versicolor favors adolescents and young adults but can occur at any age. *Malassezia* requires oil to grow, accounting for its predilection for sebum-rich areas of the skin. *Malassezia* has been implicated in several other skin diseases, including seborrheic dermatitis and a variant of atopic dermatitis that primarily involves the head and neck. Neonatal cephalic pustulosis (neonatal acne) may also be associated with *Malassezia* spp., particularly *M. sympodialis*[4] (see Ch. 34).

Pathogenesis

Hortaea werneckii (formerly *Exophiala werneckii*) and *Piedraia hortae* are both environmental pathogens. *H. werneckii* (tinea nigra) can be found in soil, sewage, and even shower stalls under humid conditions. The source of exposure to *P. hortae* (black piedra) is thought to be the soil. There is no known transmission of these organisms from human to human. *Trichosporon* spp. (white piedra) are also acquired from the environment; in addition, they are occasionally part of the normal flora of the mucous membranes and skin, particularly inguinal and axillary areas[5].

Malassezia spp. normally live on human skin in amounts too minute to be detectable on potassium hydroxide (KOH) examination of stratum corneum[6]. Tinea versicolor occurs when the round yeast form transforms to the mycelial form. Factors that can promote this conversion include high ambient temperatures and humidity, oily skin, excessive sweating, immunodeficiency, poor nutrition, pregnancy, and corticosteroid use. Because this yeast is lipophilic, application of oils (especially organic products such as olive oil) to the skin may also encourage its growth. Risk factors for *Malassezia (Pityrosporum)* folliculitis include chronic antibiotic use, immunosuppression, and local occlusion.

Clinical features

Piedra

"Piedra" means "stone", reflecting the fungal elements' adherence to one another to form nodules along the hair shaft. Piedra is a superficial infection that begins under the cuticle of the hair and extends outward, which can lead to weakening and breakage of the hair. As the nodules enlarge, they can even envelope the hair shaft (Fig. 77.1). The two major forms – black piedra and white piedra – are distinguished by their clinical appearance and findings on microscopic examination (Table 77.4).

Patients with black piedra develop asymptomatic brown to black nodules along the hair shaft. White piedra manifests with soft, less adherent nodules that are typically white but may also be red, green, or light brown in color. In addition to white piedra, *Trichosporon* spp., especially *T. asahii*, can cause trichosporonosis in immunocompromised patients. This serious systemic infection presents with fungemia, fever, pulmonary infiltrates, and skin lesions. The latter are typically papulovesicular and purpuric, often with central necrosis; another potential finding is creamy white plaques resembling the *in vitro* fungal colonies. *Trichosporon* endocarditis, usually involving prosthetic valves, can also occur.

Tinea nigra

After a 10- to 15-day incubation period, tinea nigra most commonly presents as a single, sharply marginated, brown to gray–green macule or patch that can be velvety or have mild scale (Fig. 77.2). There are usually no associated symptoms (e.g. pruritus), and no predisposing factors have been identified. Although most frequently seen on the palms, tinea nigra can also appear on the soles, neck, and trunk. Palmoplantar lesions are said to resemble acquired acral melanocytic nevi, but the former are usually larger, lighter in color, and lack the linear striations

of acral nevi. The advancing border of a tinea nigra lesion may also be more darkly pigmented than its center. While the disease tends to be chronic, recurrence after effective treatment is infrequent except in the case of re-exposure.

Tinea (pityriasis) versicolor

Patients usually present with multiple oval-to-round macules, patches, or thin plaques with mild, fine scale. Demonstration of this associated scale may require scratching or stretching the skin surface. The lesions are often confluent centrally within areas of involvement, which may be extensive. Seborrheic regions, in particular the upper trunk and shoulders, are the favored sites. Less frequently, lesions are seen on the face (especially in children), scalp, antecubital fossae, submammary region, and groin. Involvement of flexural areas is sometimes referred to as "inverse" tinea versicolor.

CLASSIFICATION OF CUTANEOUS MYCOSES	
Superficial	Involve stratum corneum, hair, or nails
Subcutaneous	Involve dermis or subcutaneous tissue Often due to implantation
Systemic ("deep")	Involve dermis or subcutaneous tissue
"True" pathogens	Skin involvement usually reflects hematogenous spread or extension from underlying structures
Opportunistic	Primary or secondary skin lesions in immuno-compromised hosts

Table 77.1 Classification of cutaneous mycoses.

SUPERFICIAL MYCOSES OF THE SKIN		
	Cutaneous disorder	**Pathogen(s)**
Minimal, if any, inflammation	Tinea (pityriasis) versicolor	*Malassezia furfur*, *M. globosa*
	Tinea nigra	*Hortaea werneckii*
	Black piedra	*Piedraia hortae*
	White piedra	*Trichosporon* spp.*, e.g. *T. ovoides* (especially of scalp hair), *T. inkin* (especially of pubic hair), *T. cutaneum, T. loubieri*
Inflammatory response common	Tinea capitis, barbae, faciei, corporis, cruris, manuum, pedis	*Trichophyton*, *Microsporum*, *Epidermophyton* spp.
	Cutaneous candidiasis	*Candida albicans*, other *Candida* spp.

*Formerly known as *Trichosporon beigelii*, which has been reclassified into ~50 species, at least 16 of which have clinical relevance. Invasive or disseminated trichosporonosis typically occurs in immunocompromised patients (e.g. individuals with hematologic malignancies, organ transplant recipients) and is most often caused by *T. asahii*, followed by *T. mucoides* and *T. asteroides*; in some patients, the same species is isolated from the groin. *Trichosporon* spp. may also occasionally cause onychomycosis and hypersensitivity pneumonitis.

Table 77.2 Superficial mycoses of the skin.

The most common colors are brown (hyperpigmented; Fig. 77.3A) and whitish-tan (hypopigmented; Fig. 77.3B); occasionally there is mild inflammation leading to a pink color (Fig. 77.3C). Hypopigmentation may be secondary to either reduced tanning or inhibition of melanin production by dicarboxylic acids that result from metabolism of skin surface lipids by the yeast. In general, tinea versicolor is asymptomatic and the major concern is its appearance.

Malassezia (Pityrosporum) folliculitis

This condition is most commonly seen in young women and is characterized by pruritic, monomorphic follicular papules and pustules on the upper trunk, arms, neck, and face (especially on the forehead and along the hairline). It is due to excessive growth of *M. furfur* and *M. globosa* within the hair follicle, with resulting inflammation due to yeast products as well as free fatty acids generated by fungal lipases. Only yeast forms are observed, i.e. no hyphal forms as in tinea versicolor.

Pathology and fungal culture

For black and white piedra, cut hair shafts are placed in KOH and a "crush preparation" is examined microscopically. In a black piedra nodule, dematiaceous hyphae are seen around an organized cluster of asci, each of which contains eight ascospores. The ascospores represent the sexual phase of *P. hortae*. *P. hortae* grows very slowly when cultured and yields a green to black colony with a velvety texture (asexual phase)[7].

KOH preparation of a crushed white piedra nodule reveals non-dematiaceous hyphae, blastoconidia and arthroconidia, representing the asexual state (Fig. 77.4). When cultured, *Trichosporon* spp. grow rapidly, forming moist, cream-colored, yeast-like colonies that

DIFFERENT SPECIES OF *MALASSEZIA* AND COMMON CLINICAL PRESENTATIONS	
Species of *Malassezia*	**Common clinical presentations**
M. furfur	Tinea (pityriasis) versicolor, seborrheic dermatitis, folliculitis, neonatal cephalic pustulosis, blepharitis, and systemic infections in neonates receiving intravenous fat emulsions
M. globosa	Seborrheic dermatitis, tinea versicolor, folliculitis, neonatal cephalic pustulosis
M. sympodialis	Tinea versicolor, neonatal cephalic pustulosis*
M. pachydermatis	Often isolated from domestic and wild animals; has occasionally been implicated in cases of systemic infection in humans; may play a role in chronic dermatitis and otitis externa
M. restricta	Seborrheic dermatitis, tinea versicolor
M. slooffiae	Uncommon isolate
M. obtusa	Uncommon isolate

*Most commonly isolated species in this disorder.

Table 77.3 Different species *of Malassezia* and common clinical presentations.

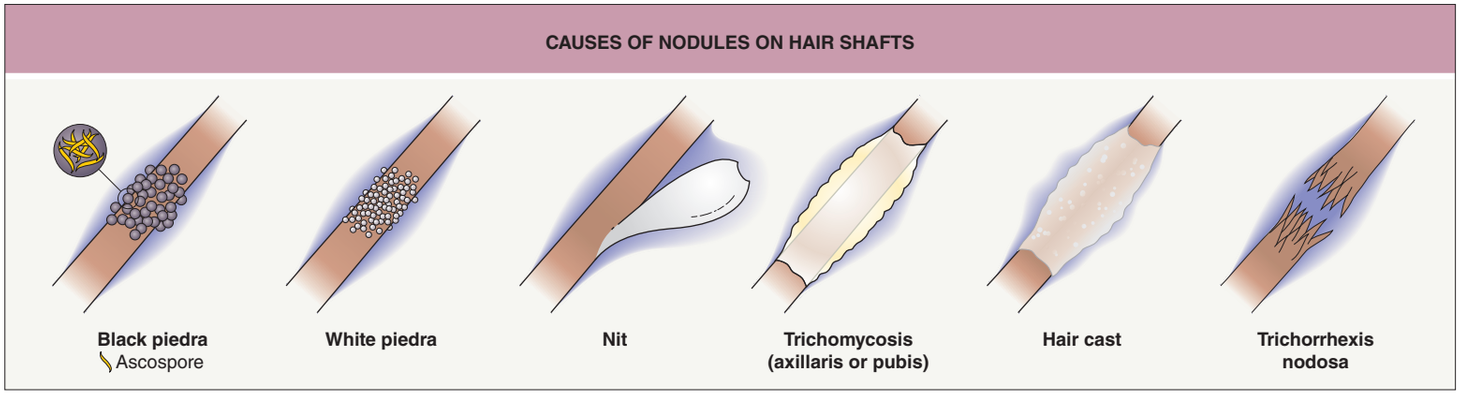

Fig. 77.1 Causes of nodules on hair shafts.

COMPARISON OF BLACK AND WHITE PIEDRA		
	White piedra	**Black piedra**
Nodule color	White (occasionally red, green, or light brown)	Brown to black
Nodule firmness	Soft	Hard
Nodule adherence to the hair shaft	Loose	Firm
Typical anatomic location	Face, axillae, and pubic region (occasionally scalp)	Scalp and face (occasionally pubic region)
Favored climate	Tropical	Tropical
Causative organism	*Trichosporon* spp.*, e.g. *T. ovoides, T. inkin*	*Piedraia hortae*
KOH examination of "crush prep" of cut hair shafts	Non-dematiaceous hyphae with blastoconidia and arthroconidia	Dematiaceous hyphae with asci and ascospores†
Culture on Sabouraud's agar	Moist, cream-colored, yeast-like colonies‡	Slow-growing, dark green to dark brown–black colonies
Treatment	Clip affected hairs, wash with antifungal shampoo	Clip affected hairs, wash with antifungal shampoo

*See Table 77.2 for the revised subdivision of the *Trichosporon* genus.
†Sexual reproduction
‡Growth inhibited by cycloheximide.

Table 77.4 Comparison of black and white piedra. *From reference 98.*

resemble "butter cream frosting". On Mycosel® agar, these organisms are inhibited by the presence of cycloheximide. When *Trichosporon* spp. are isolated from skin and nail specimens, correlation with clinical findings is necessary to determine the medical significance.

Biopsies of tinea versicolor and tinea nigra are usually not performed, as KOH examination of associated scale is typically diagnostic. In tinea versicolor, both hyphal and yeast forms are seen; although likened to "spaghetti and meatballs", the findings more closely resemble "ziti and meatballs" (Fig. 77.5A). In tinea nigra, KOH examination reveals septate pigmented hyphae. Dermoscopy of tinea nigra also shows curvilinear brown strands representing pigmented hyphae. When biopsy specimens

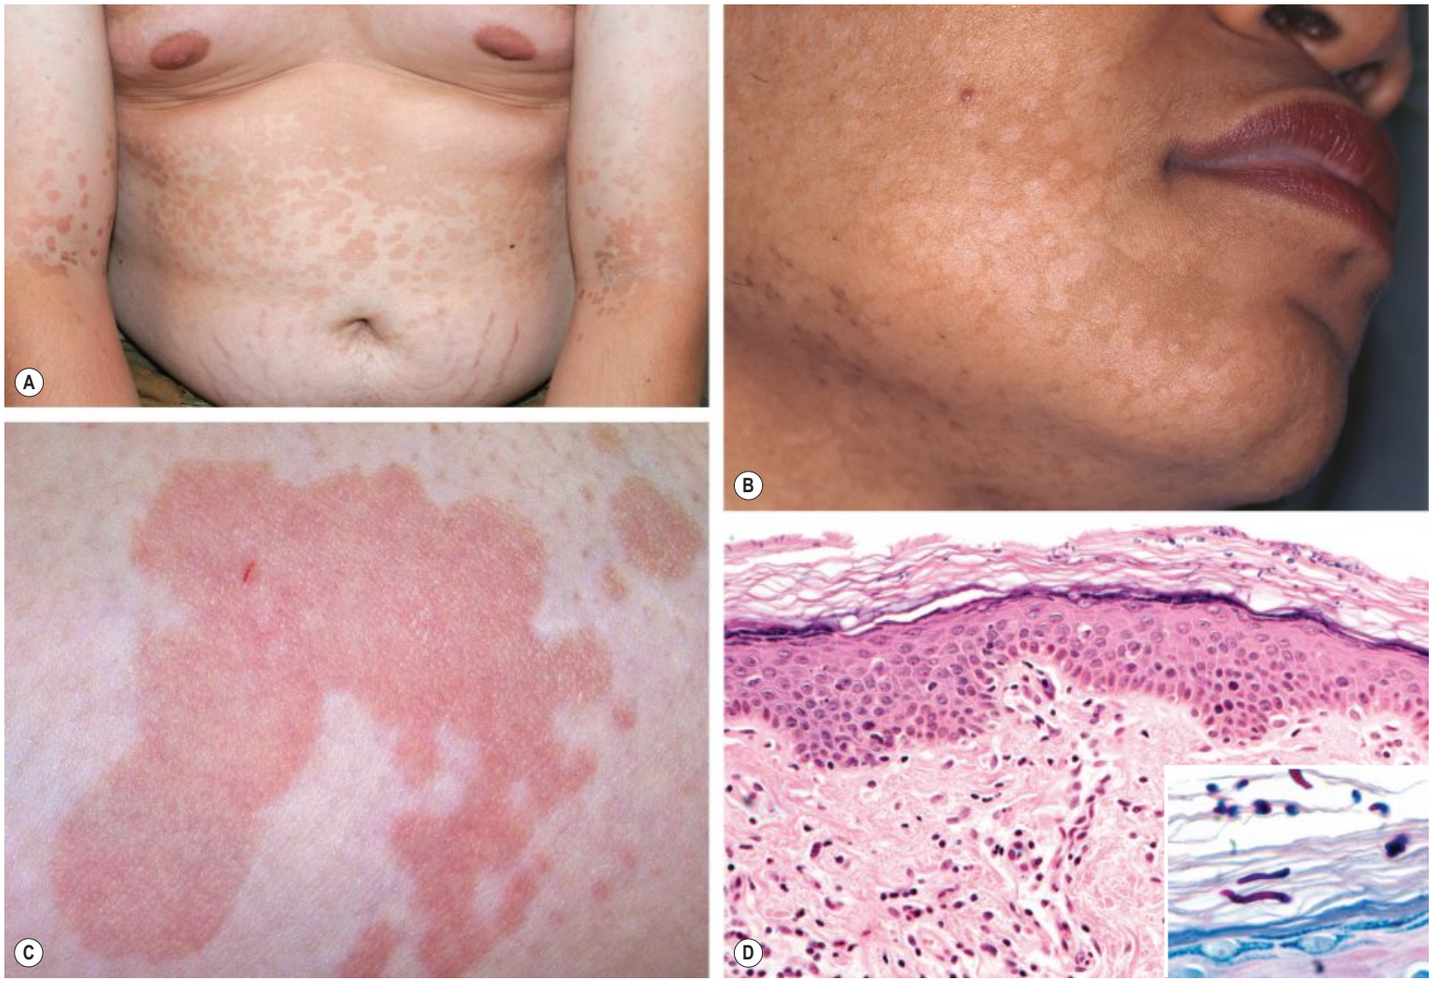

Fig. 77.3 Tinea (pityriasis) versicolor. A Hyperpigmented variant with confluence on the lower chest. **B** Hypopigmented variant on the face. **C** Coalescing pink lesions with fine scale. **D** Yeast and short hyphal forms in the stratum corneum highlighted by a PAS stain (inset). *A, B, Courtesy Kalman Watsky, MD; D, Courtesy Lorenzo Cerroni, MD.*

are obtained, similar findings are observed within the stratum corneum (Fig. 77.3D). In KOH examination of expressed follicular contents or biopsy specimens of *Malassezia (Pityrosporum)* folliculitis, only yeast forms are seen. Cultures of *H. werneckii* first appear as pasty, green–black colonies with a yeast-like appearance, and after approximately 2 weeks become a fuzzy, dematiaceous (dark in color) mold. Culture of *Malassezia* is generally not required; if necessary, the plate must be overlaid with sterile oil because of the organism's lipophilic nature.

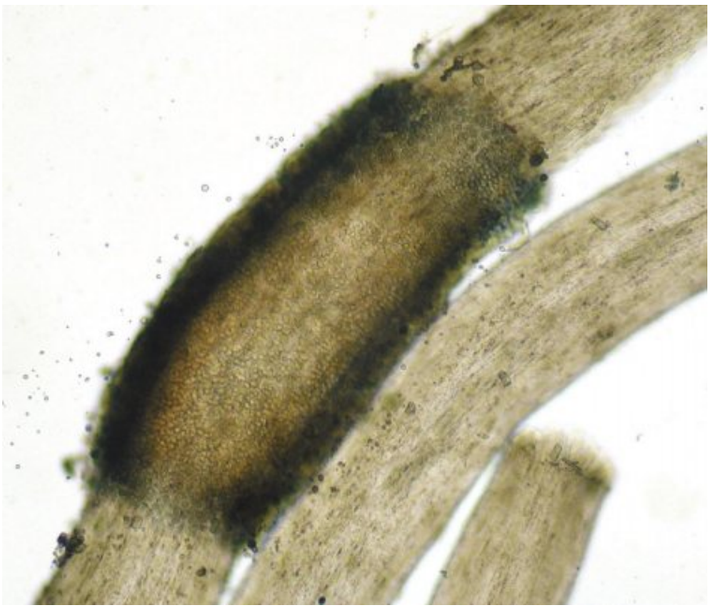

Fig. 77.4 White piedra. Potassium hydroxide preparation of a nodule on a hair shaft composed of arthroconidia and blastoconidia.

Differential diagnosis

Piedra is generally diagnosed by clinical and microscopic inspection of a hair shaft and must be distinguished from pediculosis (nits), hair casts, trichorrhexis nodosa, trichomycosis axillaris (see Fig. 77.1), and the scales of psoriasis and eczema. Unlike eczema and psoriasis, the scalp typically appears normal in piedra.

In most patients, the diagnosis of tinea nigra is made clinically and confirmed via KOH examination and/or fungal culture. Occasionally, tinea nigra could be confused with melanocytic nevi (see above), a fixed drug eruption, postinflammatory hyperpigmentation, or staining from chemicals, pigments, and dyes. Cutaneous melanoma has even been clinically misdiagnosed as tinea nigra.

Clinical examination is often sufficient to recognize tinea versicolor. However, pityriasis alba or other forms of postinflammatory hypopigmentation, vitiligo, seborrheic dermatitis, pityriasis rosea, tinea corporis, and secondary syphilis may be diagnostic considerations. Progressive macular hypomelanosis, which presents as non-scaly hypopigmented macules on the trunk of young adults and may be caused by *Cutibacterium* (formerly *Propionibacterium*) *acnes*, is often misdiagnosed as residual hypopigmentation related to tinea versicolor. Wood light examination revealing bright yellow fluorescence and then direct microscopy of scales can confirm the diagnosis of tinea versicolor. *Malassezia (Pityrosporum)* folliculitis must be differentiated from other causes of folliculitis (see Table 38.1), in particular itching folliculitis, as well as acne vulgaris.

Rapini, MD; C, Courtesy Louis A. Fragola, Jr, MD; D, Courtesy Frank Samarin, MD.*

Treatment

Clipping hairs with adherent nodules as well as shampooing the affected hairs with 2% ketoconazole shampoo is usually an effective treatment for piedra (see Table 77.4). Oral terbinafine may also be of therapeutic benefit. For treatment of tinea nigra, topical keratolytic agents such as Whitfield ointment (typically 6% benzoic acid plus 3% salicylic acid)[8] are effective, as are topical azole or allylamine antifungal medications. Several weeks of therapy may be required to prevent recurrence. Systemic therapy is generally not indicated, and griseofulvin is not effective.

Tinea versicolor usually responds to topical antifungal therapy, but oral treatment with fluconazole or itraconazole can be considered when there is more extensive involvement[9,10] (Table 77.5; see Ch. 127). Residual pigmentary changes often require weeks to months to resolve. The rate of recurrence of tinea versicolor is very high, especially in hot humid climates, and maintenance therapy may be helpful (see Table 77.5). The treatment of *Malassezia (Pityrosporum)* folliculitis is reviewed in Chapter 38.

Dermatophytoses

Synonyms: ■ Tinea corporis: ringworm, tinea circinata, tinea glabrosa ■ Tinea cruris: ringworm of the groin, eczema marginatum, jock itch, gym itch ■ Tinea barbae: tinea sycosis, barber's itch, ringworm of the beard ■ Tinea capitis: ringworm of the scalp/hair, tinea tonsurans, herpes tonsurans ■ Tinea pedis: ringworm of the foot, athlete's foot ■ Tinea unguium: ringworm of the nail, dermatophytic onychomycosis

Introduction

Dermatophytoses are fungal infections caused by three genera of fungi that have the unique ability to invade and multiply within keratinized tissue (hair, skin, and nails). These fungi, collectively called "dermatophytes", are alike in their physiology, morphology, and pathogenicity. The three genera are *Microsporum*, *Trichophyton*, and *Epidermophyton*; species within these genera that do not invade keratinized tissue in animals or humans are not considered as dermatophytes. In naming clinical infections due to dermatophytes, "tinea" precedes the Latin name for the involved body site, e.g. "tinea pedis" refers to a dermatophyte infection of the foot. Overall, ten species of dermatophytes are commonly isolated and an additional 20 are occasionally identified (Table 77.6)[11].

TREATMENT OF TINEA (PITYRIASIS) VERSICOLOR	

Initial therapy (often combination)	*Topical**
	• Antifungal shampoo applied as a body cleanser for 10–15 minutes before rinsing, twice weekly for 2–4 weeks
	  • Selenium sulfide shampoo, 1% (OTC) or 2.5%
	  • Ketoconazole shampoo, 1% (OTC) or 2%
	  • Ciclopirox olamine shampoo, 1%
	  • Zinc pyrithione shampoo
	• Antifungal cream applied several hand-widths beyond clinically visible lesions, daily to twice daily for 2 weeks
	  • Imidazole, e.g. ketoconazole 2% cream
	  • Ciclopirox olamine 0.77% cream, gel, or lotion
	Oral†
	• Fluconazole: 200 mg po daily × 5–7 days‡; 200–300 mg weekly × 2–3 weeks; or 400 mg once
	• Itraconazole: 200 mg po daily × 5–7 days

Maintenance therapy to prevent recurrence	• Treat previously affected sites with topical imidazole daily for 2 weeks prior to anticipated sun exposure • Apply antifungal shampoo (see above) 1–2 times weekly

*Treatment of all the skin from the neck down to the knees may lead to higher success rates.
†Although there are few comparative studies of oral antifungal medications, cure rates of 98%–100% have been reported in several randomized controlled trials of itraconazole 200 mg daily × 5 days and an open-label study of fluconazole 300 mg weekly × 2 weeks.
‡Based upon authors' personal experience.

Table 77.5 Treatment of tinea (pityriasis) versicolor. Oral ketoconazole is no longer indicated for treatment of superficial fungal infections due to risks of severe hepatotoxicity, QT prolongation, and serious drug interactions.

History

Dermatophyte infections have been described since ancient times. In 1910, Sabouraud published a categorization scheme that is currently employed in which dermatophytes are classified by genera. A revised and simplified nomenclature system was proposed in 2017[12].

Epidemiology

Some dermatophytes are restricted geographically, while others are found worldwide. *Trichophyton rubrum*, for example, is the most common dermatophyte and has a global distribution, while *T. concentricum* is endemic to certain parts of the South Pacific and South America. Human travel and migration, coupled with antifungal therapy and the development of drug resistance, have brought about significant changes in the geographic distribution of dermatophytes. Terbinafine-resistant *T. indotineae* (formerly *T. mentagrophytes var. VIII*), which was recognized in 2020, emerged in India with subsequent global spread[12a,12b]. One theory for its emergence is the misuse of potent topical corticosteroids in settings where they are available without a prescription. In general, dermatophyte infections are more common in tropical environments. Other important epidemiologic factors include socioeconomic status, occupation, air conditioning, and the use of footwear.

In general, dermatophytoses occur most frequently in postpubertal hosts. One major exception is tinea capitis (dermatophytosis of the scalp), which occurs primarily in children. Risk factors for the development of a dermatophyte infection during childhood include household exposure to tinea capitis or tinea pedis; environmental factors such as contaminated hats, brushes, and barber instruments; and (especially for tinea unguium) Down syndrome. Individuals with chronic mucocutaneous candidiasis, common variable immunodeficiency, or HIV infection have a propensity to develop severe, chronic, or recurrent dermatophytoses (see Chs. 60 & 78). Men more frequently have tinea pedis, tinea cruris, and tinea unguium than women.

Pathogenesis

Transmission of dermatophytes to humans occurs via three major sources, each resulting in infections with characteristic features (Table 77.7). While dermatophytes are not especially virulent and typically invade only the outer, cornified layers of the skin, they can be responsible for considerable morbidity. The first stage of infection involves contact with and adherence of the infectious elements of the fungus (arthroconidia) to the skin. The ability of certain fungi to adhere to a particular host arises from a variety of microbial mechanisms and host factors[2].

Dermatophytes, unlike most other fungi, produce keratinases (enzymes that break down keratin), which allow invasion of the fungi into the stratum corneum. Mannans in the cell walls of dermatophytes have immuno-inhibitory effects. In *T. rubrum*, the mannans may also decrease epidermal proliferation, thereby reducing the likelihood of the fungus being sloughed off prior to invasion. This mechanism is thought to contribute to the chronicity of infections caused by *T. rubrum*[13]. However, host factors such as protease inhibitors may limit the extent of invasion. If invasion is successful, disease occurs.

The severity of clinical disease is also affected by several host factors. Sebum has an inhibitory effect on dermatophytes, and the degree of disease activity may be related to the number and activity of sebaceous glands in a particular body region. Breaks in the skin barrier or macerated skin encourage dermatophyte invasion, and increased susceptibility related to immunologic factors may be inherited. Once dermatophytes invade and begin to proliferate in the skin, several mechanisms aid in limiting the infection to keratinized tissue. These include the preference of dermatophytes for the cooler temperature at the skin's surface, serum factors that inhibit dermatophyte growth (e.g. β-globulins, ferritin, other metal chelators), and the host immune response[2]. Further invasion or dissemination is extremely unusual (see below). Other conditions influencing dermatophyte infections include skin disorders that affect cutaneous barrier function, such as ichthyoses.

Clinical features

Tinea corporis

Tinea corporis is a dermatophyte infection of the skin of the trunk and extremities, excluding the hair, nails, palms, soles, and groin. The infection is generally restricted to the stratum corneum and most commonly affects exposed skin. Any dermatophyte can potentially

DERMATOPHYTES ISOLATED WORLDWIDE		
		Thallus (macroscopic) appearance* and/or microscopic findings
Most common		
Trichophyton	*mentagrophytes* (previously *mentagrophytes* var. *mentagrophytes*)	Granular front, buff reverse; pencil-shaped macroconidia, clusters of round microconidia, spiral hyphae
	interdigitale (previously *mentagrophytes* var. *interdigitale*)	Downy front, buff reverse; see above
	indotineae (previously *mentagrophytes* var. *VIII*)	Suede-like white front, yellow-brown reverse; cigar and club-shaped septate, thin-walled macroconidia; spiral and pyriform microconidia
	rubrum	White wooly front, venous blood reverse; pencil-shaped macroconidia, teardrop-shaped microconidia
	tonsurans	Granular front, mahogany reverse; pencil-shaped macroconidia, microconidia of varying sizes
	verrucosum	Convoluted, cream to gray, compact; chains of chlamydospores at 37°C
	violaceum	Creamy, waxy, becomes violet
Microsporum	*canis*	White wooly front, orange reverse; multi-celled, spindle-shaped macroconidia with thick walls and rough surface
	ferrugineum	Folded red–orange (rust-colored) front
	gypseum	Cinnamon–tan granular front; multi-celled, cucumber-shaped macroconidia with thin walls
Epidermophyton	*floccosum*	Khaki green, suede to granular; beaver tail-shaped macroconidia; no microconidia
Less common		
Trichophyton	*ajelloi*	Powdery surface, resembles *Microsporum* spp.
	concentricum	Glabrous colonies; antler-like hyphae
	equinum	Club-shaped macroconidia
	gourvilii	Waxy, pink to red front
	megninii	Pink, felt-like front with red reverse
	schoenleinii	Glabrous; antler- and nailhead-like hyphae; rat-tail-like macroconidia (media often fissured)
	simii	Club-shaped macroconidia in clusters
	soudanense	Yellow to apricot front with fringed border
	terrestre	Cream to yellow granular surface
	yaoundei	Glabrous, chocolate-brown front
Microsporum	*amazonicum*	Multi-celled, spindle-shaped, macroconidia with large inclusions
	audouinii	Flat, tan front with salmon reverse; pectinate (comb-like) hyphae
	cookei	Oval, thick-walled macroconidia
	equinum	One- to four-celled macroconidia resembling *M. canis*
	fulvum	Bullet-shaped macroconidia with spiral hyphae
	gallinae	Diffusable pink–red pigment
	nanum	Two-celled macroconidia
	persicolor	Pink to red front and reverse, resembles *T. mentagrophytes*
	praecox	Powdery front with yellow–orange reverse
	racemosum	Cream-colored powdery front
	vanbreuseghemii	Largest macroconidia

*On Sabouraud's agar.

Table 77.6 Dermatophytes isolated worldwide. *Adapted from reference 99.*

TYPES OF DERMATOPHYTES BASED ON MODE OF TRANSMISSION		
Category	**Mode of transmission**	**Typical clinical features**
Anthropophilic	Human to human	Mild to non-inflammatory, chronic
Zoophilic	Animal to human	Intense inflammation (pustules and vesicles possible), acute
Geophilic	Soil to human or animal	Moderate inflammation

Table 77.7 Types of dermatophytes based on mode of transmission.

cause tinea corporis, but *T. rubrum* is the most common pathogen worldwide, followed by *T. mentagrophytes* (Table 77.8).

Tinea corporis can result from human-to-human (including autoinoculation, e.g. from tinea capitis or pedis), animal-to-human (often transmitted by domestic animals), or soil-to-human spread (see Table 77.7). Sources include occupational or recreational exposure (e.g. military housing, gymnasiums, locker rooms, outdoor activities, wrestling) and contact with contaminated clothing or furniture[14].

There are multiple clinical presentations of tinea corporis, and they can mimic other dermatologic conditions (Table 77.9). As with most dermatophyte infections, the extent of inflammation depends on the causative pathogen and the immune response of the host. Because hair follicles serve as reservoirs for infection, hairier areas of the body may be more resistant to treatment.

The typical incubation period is 1 to 3 weeks. Infection spreads centrifugally from the point of skin invasion with central clearing of the fungus, typically resulting in annular lesions of varying sizes (Fig. 77.6A–D). Arcuate, circinate, concentric, and oval lesions can also develop (Fig. 77.6D–F). Although scale is usually present, it may be

lessened or absent if topical corticosteroids have been used (tinea "incognito") (Fig. 77.7). Pustules within the active border are suggestive of tinea (see Fig. 77.6E). Lesions are occasionally vesicular, granulomatous, or verrucous (Fig. 77.6G). Associated symptoms may include pruritus and burning.

Tinea profunda, nodular perifolliculitis (including Majocchi granuloma), and tinea imbricata represent clinical variants of tinea corporis[15]. *Tinea profunda* results from an excessive inflammatory response to a dermatophyte, analogous to a kerion on the scalp. It may have a granulomatous or verrucous appearance and be mistaken for cutaneous tuberculosis or a dimorphic fungal infection. *Nodular perifolliculitis*, usually caused by *T. rubrum*, is characterized by follicular papulopustules or granulomatous nodules that result from a deep dermatophyte folliculitis with disruption of the follicular wall (Fig. 77.8). This variant is most commonly seen in women who have tinea pedis or onychomycosis and shave their legs, and it can also occur in the setting of immunosuppression. The lesions may be extensive or even vegetating, and a prolonged granulomatous reaction (as described by Majocchi) can develop.

Tinea imbricata is a dermatophytosis caused by the anthropophilic dermatophyte *T. concentricum*. It causes chronic infections in an equatorial band encompassing the South Pacific, Asia, and Central and South America. The clinical presentation consists of concentric annular rings resembling erythema gyratum repens.

COMMON DERMATOPHYTES THAT CAUSE TINEA CORPORIS	
Dermatophyte	**Clinical features**
Anthropophilic	
Trichophyton rubrum	Commonly harbored by hair follicles; may produce concentric rings; can recur; causative organism in nodular perifolliculitis (Majocchi granuloma) and most common cause of tinea corporis
T. tonsurans	Commonly seen in adults who care for children with tinea capitis caused by this organism
Epidermophyton floccosum	Generally restricted to groin, feet; responsible for eczema marginatum
T. concentricum	Responsible for tinea imbricata; infections typically chronic
T. interdigitale (previously *T. mentagrophytes* var. *interdigitale*)	Causes interdigital tinea pedis, tinea cruris, and onychomycosis
T. indotineae (previously *T. mentagrophytes* var. *VIII*)	Terbinafine resistance leading to large annular lesions in a widespread distribution
Zoophilic	
T. mentagrophytes (previously *T. mentagrophytes* var. *mentagrophytes*)	May be associated with dermatophytid reaction; causes inflammatory tinea pedis and tinea barbae; associated with exposure to small mammals
Microsporum canis	Associated with pet exposure (cat or dog)
T. verrucosum	May mimic bacterial furunculosis; associated with exposure to cattle
T. benhamiae	Typically associated with exposure to a pet guinea pig; tinea faciei is also a common presentation
Geophilic	
M. gypseum	Frequently associated with outdoor/occupational exposure; lesions may be inflammatory or bullous

Table 77.8 Common dermatophytes that cause tinea corporis.

Tinea cruris

Tinea cruris is a dermatophyte infection of the inguinal region, in particular the inner aspects of the upper thighs (Fig. 77.9) and crural folds, with occasional extension onto the abdomen and buttocks. The three most common causative agents are *Epidermophyton floccosum*, *T. rubrum*, and *T. mentagrophytes* (Table 77.10).

This condition is more often seen in men than in women, since the scrotum provides a warm and moist environment that encourages fungal growth and men are more likely to have tinea pedis and onychomycosis as a source of dermatophytes. Other predisposing factors include obesity and excessive perspiration. Tinea cruris is frequently associated with tinea pedis because clothing that is brought over the feet is contaminated and then comes in contact with skin in the groin region.

The initial sign of infection is usually an area of erythema and pruritus in the fold between the scrotum and the inner thigh. Characteristic lesions are sharply demarcated with a raised, erythematous, scaly advancing border that may contain pustules or even vesicles. Lesions can initially be circinate and then become serpiginous. The disease may remain unilateral or become bilateral.

The duration of infection depends on the causative pathogen. Infections with *T. rubrum* and many other anthropophilic species tend to be chronic, sometimes with leathery and lichenified lesions. In contrast, the zoophilic form of *T. mentagrophytes* (previously *T. mentagrophytes* var. *mentagrophytes*) and other animal-acquired strains often cause acute infections with a prominent inflammatory component that may include pustules and vesicles (see Table 77.10). The scrotum itself is generally spared in tinea cruris. If the scrotum is involved or there are erosions or satellite pustules, cutaneous candidiasis should be considered. Measures to prevent recurrences of tinea cruris include wearing loose clothing, drying thoroughly after bathing, using topical powders, weight reduction (if obese), laundering contaminated clothing and linens, and treating concomitant tinea pedis.

Tinea manuum

Dermatophyte infections on the dorsal aspect of the hand have a clinical presentation similar to tinea corporis. However, dermatophyte infection of the palm and interdigital spaces has distinct characteristics and is referred to as tinea manuum. The reason for the two different clinical

DIFFERENTIAL DIAGNOSES OF DERMATOPHYTE INFECTIONS

Fig. 77.8 Nodular perifolliculitis (Majocchi granuloma). Perifollicular inflammation and follicular pustules on the leg due to *Trichophyton rubrum*. A few of the lowermost papules have a granulomatous appearance. *Courtesy Kalman Watsky, MD.*

pictures is thought to be related to the lack of sebaceous glands on the palms. The typical causative organisms are the same as those for tinea pedis and tinea cruris: *T. rubrum*, *T. mentagrophytes*, and *E. floccosum*. Infections with *Neoscytalidium dimidiatum* and *N. hyalinum*, two non-dermatophyte fungi, can have a tinea manuum-like appearance.

Moccasin-type tinea pedis is often present in patients with tinea manuum, and the two share clinical features such as chronicity and hyperkeratosis. Tinea manuum is usually non-inflammatory and often unilateral ("two feet and one hand syndrome") (Fig. 77.10; see Fig. 77.16A); there is hyperkeratosis of the palms and digits, including within creases, that fails to respond to emollients[16]. Tinea unguium of the involved hand can serve as a clue to the diagnosis, but infection of all the fingernails is uncommon. Other presentations include exfoliative, vesicular, and papular variants. The differential diagnosis may include psoriasis, irritant or allergic contact dermatitis, dyshidrosis, and a "dermatophytid" reaction.

Tinea barbae

Tinea barbae is a dermatophytosis that involves the bearded areas of the face and neck in men. Because the disease is often acquired from animals, the causative organisms are typically zoophilic dermatophytes, namely

Fig. 77.9 Tinea cruris. A thin, "broken-up" erythematous plaque with an arciform papular border on the upper inner thigh.

Fig. 77.10 Tinea manuum. A Diffuse scaling of the palm of one hand, with accentuation in the creases. **B** Multiple collarettes of scale reminiscent of keratolysis exfoliativa on one palm.

TINEA CRURIS: COMMON CAUSATIVE PATHOGENS	
Dermatophyte	**Clinical features**
Trichophyton rubrum	• Most common cause of tinea cruris • Infection tends to be chronic • Fungus not viable in scale (e.g. on furniture, rugs, linens) for long periods of time • Frequent extension to buttocks, waist, and thighs
Epidermophyton floccosum	• Commonly associated with "epidemics" of tinea cruris in locker rooms or dormitories • Infection is acute (rarely chronic) • Arthroconidia are viable in scale (e.g. on furniture, rugs, linens) for long periods of time • Infection rarely extends beyond groin region • Causative agent of "eczema marginatum" (well-demarcated borders with multiple small vesicles or, sometimes, vesiculopustules)
T. mentagrophytes (previously *T. mentagrophytes* var. *mentagrophytes*)	• Infection tends to be more severe and acute, with intense inflammation and pustule formation • May rapidly spread to the trunk and lower extremities, causing a severe inflammatory condition • Often acquired from animal dander

Table 77.10 Tinea cruris: common causative pathogens.

T. mentagrophytes and *T. verrucosum*. Infection with *Microsporum canis* or *T. rubrum* is uncommon. In some geographic regions, other anthropophilic dermatophytes (*T. schoenleinii, T. violaceum*, and *T. megninii*) are endemic and cause tinea barbae. With the increased use of disposable razors and disinfectants, the incidence of tinea due to contaminated razors in barbershops has been dramatically reduced.

Since zoophilic organisms are the most common culprit and affected areas often have a large number of terminal hair follicles, the clinical presentation tends to be severe, with intense inflammation and multiple follicular pustules. Abscesses, sinus tracts, bacterial superinfection, and kerion-like boggy plaques can develop. Patients may have constitutional symptoms such as malaise as well as lymphadenopathy and even scarring alopecia. A second type of tinea barbae is superficial, less inflammatory, and similar to tinea corporis; *T. rubrum* is usually the causative agent in this variant (Fig. 77.11). Alopecia may be present in the center of the lesion, but it is reversible. Other conditions that can mimic tinea barbae include bacterial folliculitis, viral infections (herpes simplex or zoster), acne vulgaris, cervicofacial actinomycosis, and a dental sinus tract. Spontaneous resolution may occur if all of the infected hairs fall out.

Fig. 77.11 Superficial form of tinea barbae due to *Trichophyton rubrum*. Several follicular pustules are evident. *Courtesy Jean L. Bolognia, MD.*

Tinea faciei

While some dermatophyte infections of the face have classic features (e.g. scale, annular configuration, pustules in the border), others can be more difficult to diagnose clinically and require a high index of suspicion (Fig. 77.12, see Table 77.9).

Tinea capitis

Tinea capitis is a common dermatophyte infection of the scalp in children (Fig. 77.13), whereas adult infection occurs infrequently. The causative pathogens are members of only two genera: *Trichophyton* and *Microsporum*. *T. tonsurans* is currently the most common cause

Fig. 77.12 Tinea faciei. A Erythema and scale on the nose and philtrum of a young child. The location and lack of central clearing may lead to the misdiagnosis of dermatitis with secondary impetiginization. **B** Child with pink papules, a few tiny pustules, and thin annular and arcuate scaly plaques in a perinasal and perioral distribution. These clinical findings could be mistaken for periorificial dermatitis. **C** Hyperpigmented lesions with subtle arcuate and annular configurations in a woman with darkly pigmented skin. There is minimal scale following the use of topical corticosteroids ("tinea incognito"). The clue to the application of topical corticosteroids is the relative hypopigmentation as compared with the more medial cheek. *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Antonio Torrelo, MD; C, Courtesy Kalman Watsky, MD.*

Fragola, Jr, MD; F, Courtesy Robert Browdell, MD; H, Courtesy Lorenzo Cerroni, MD.*

of tinea capitis in the US (accounting for >90% of cases), with a predilection for individuals with Afro-textured hair[17], and *M. canis* is the second most frequent etiology. Globally, there is significant variation in the epidemiology of tinea capitis. While *M. canis* is a common cause in many countries, *T. tonsurans* has emerged as a major agent in Europe and elsewhere. The incidence of tinea capitis due to *T. violaceum*, which is endemic in Africa, has also recently increased in some areas of the US and Europe (especially western and Mediterranean regions), likely reflecting immigration patterns. The anthropophilic dermatophyte *M. audouinii*, which was once common and then subsequently diminished secondary to social and therapeutic advances, has more recently reappeared in Europe and may also potentially re-emerge in the US.

Different clinical presentations arise from the various causative organisms. For example, *T. tonsurans* causes an endothrix infection (see below), which classically results in "black dot" tinea capitis due to hair breakage near the scalp. In contrast, *M. audouinii* is an ectothrix form of tinea capitis that typically presents with dry, scaly patches of alopecia ("gray patch" tinea capitis). Both the pathogenicity of the culprit organism and the host immune response are factors that determine the severity of disease. Tinea capitis can range from non-inflammatory scaling that resembles seborrheic dermatitis (especially with *T. tonsurans*; Fig. 77.13A) to a severe pustular reaction with alopecia, known as a kerion. Alopecia with or without obvious scale is the most common presentation of tinea capitis (Fig. 77.13B–D). The alopecia may occur in discrete patches or involve the entire scalp. Use of dermoscopy can highlight "comma", "corkscrew", and dystrophic broken hairs that represent clues to the diagnosis of tinea capitis (see Ch. 69)[18]. Many patients have posterior cervical and posterior auricular lymphadenopathy, which is helpful in differentiating tinea capitis from less inflammatory causes of alopecia, such as alopecia areata.

A kerion results from advanced disease coupled with an exaggerated host response that leads to boggy, purulent plaques with abscess formation and associated alopecia (Fig. 77.13E,F). Some patients may even become systemically ill with extensive lymphadenopathy. The hair in the affected area usually returns, but the longer the infection persists, the more likely the alopecia will be permanent. If a kerion is misdiagnosed as a bacterial abscess and treated with antibiotics following incision and drainage, the infection will likely worsen, thereby increasing the likelihood of scarring alopecia.

The "carrier state" of *T. tonsurans* refers to a clinical situation in which there are no obvious signs or symptoms of a scalp infection, yet a positive fungal culture is obtained. Although also seen in children, this typically occurs in adults who have been exposed to infected children. The carriers shed the fungus and are considered contagious[19]. Consequently, some experts advocate treating all carriers with oral or topical antifungals.

For those dermatophytes that invade hair, three patterns of invasion exist: endothrix, ectothrix, and favus (Fig. 77.14):

- The *endothrix pattern* results from infection with anthropophilic fungi in the genus *Trichophyton* and is characterized by non-fluorescent arthroconidia within the hair shaft (Fig. 77.13G). The clinical presentation varies from scaling to "black dots" with patchy alopecia to kerion formation. *T. tonsurans* and *T. violaceum* are important causes of endothrix infection.
- The *ectothrix pattern* occurs when arthroconidia are formed from fragmented hyphae outside the hair shaft (see Fig. 77.14). Cuticle destruction ensues. Ectothrix infection can be fluorescent (*Microsporum*) or non-fluorescent (*Microsporum* and *Trichophyton*), as determined by Wood's lamp examination. Clinical features vary from patchy, scaly alopecia with little inflammation that may mimic alopecia areata to kerion formation.
- *Favus* is the most severe form of dermatophyte hair infection and is most frequently caused by *T. schoenleinii*. Hyphae and air spaces are observed within the hair shaft, and a bluish-white fluorescence by Wood's light examination is typically seen. Favus presents as thick, yellow crusts composed of hyphae and skin debris ("scutula"). Scarring alopecia may develop in chronic infections (Fig. 77.15).

Fig. 77.15 Favus due to *Trichophyton schoenleinii*. Scarring alopecia with erosions and several scutula on the occipital scalp. The latter represent masses of keratin plus fungi. *Courtesy Israel Dvoretzky, MD.*

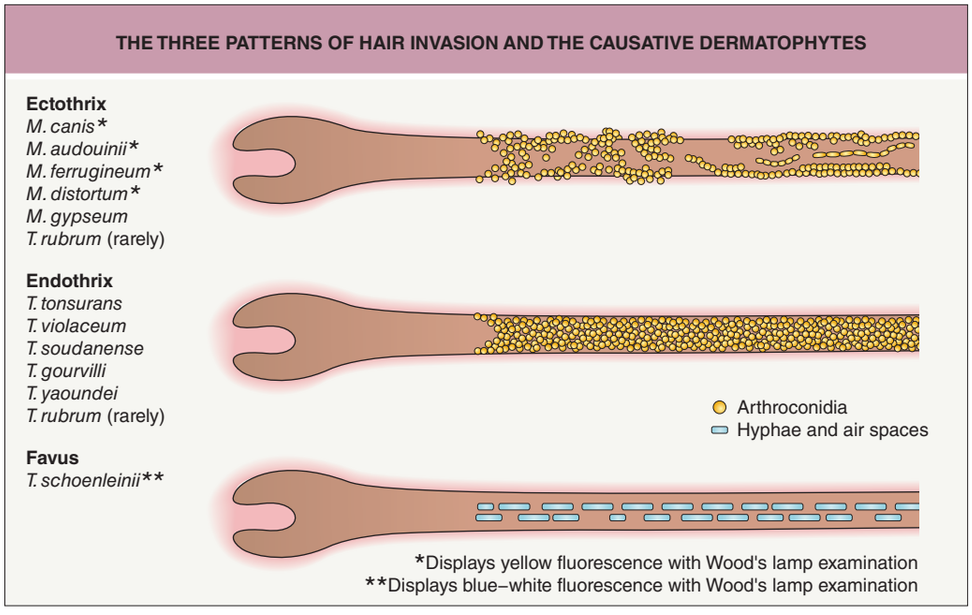

Fig. 77.14 The three patterns of hair invasion and the causative dermatophytes.

There are many scalp and hair disorders that lead to scaling or alopecia (scarring and non-scarring) that are not due to fungal infections (see Table 77.9). However, one should always consider and exclude a fungal infection (especially in children), because the treatment is typically quite simple and effective, and chronic untreated tinea capitis can lead to scarring alopecia. Oral therapy is required, as the drug must penetrate the hair follicle to be effective. Preventative measures are also important in the management of tinea capitis. Because the disease is contagious, all individuals residing with the infected patient should be examined for signs of tinea capitis and appropriately treated. Chronicity may develop if a child is continually re-exposed from untreated family members. Appropriate adjunctive treatment for household contacts as well as the patient includes regular (e.g. every other day) use of an antifungal shampoo, such as 2% ketoconazole or 2.5% selenium sulfide, until the patient is free of disease. Although routine screening in schools is difficult, screening children who have two or more infected classmates may be beneficial[20]. Combs, brushes, and headwear used by the patient should be disinfected or preferably discarded.

Tinea pedis

Tinea pedis is a dermatophyte infection of the soles and interdigital web spaces of the feet. Infection of the dorsal aspect of the foot is considered tinea corporis. The feet are the most common location for dermatophyte infections, and the majority of the US adult population has experienced tinea pedis. This condition is more common in adults than children and is found around the world, affecting both sexes. The lack of sebaceous glands and the moist environment created by occlusive shoes are important factors in the development of tinea pedis[21]. In fact, tinea pedis is uncommon in populations that do not wear shoes. However, the fungus may be acquired from going barefoot (locker rooms, gyms, public facilities).

The dermatophytes that are typically responsible for tinea pedis are *T. rubrum*, *T. interdigitale* (previously *T. mentagrophytes* var. *interdigitale)*, *T. mentagrophytes*, *E. floccosum*, and *T. tonsurans* (in children). Non-dermatophyte pathogens that produce clinical findings identical with tinea pedis include *Neoscytalidium dimidiatum* and *N. hyalinum* (moccasin and interdigital types) and, occasionally, *Candida* spp. (interdigital type). There are four major clinical types of tinea pedis, as outlined in Table 77.11: moccasin (Fig. 77.16A), interdigital (Fig. 77.16B), inflammatory (Fig. 77.16C), and ulcerative. Each type has different associated morbidities and complications that can affect diagnostic considerations and therapeutic options. These include bacterial superinfection (the "dermatophytosis complex"), dermatophytid reactions, cellulitis (especially in patients who have venous hypertension, harvested saphenous veins, and chronic edema), and

THE FOUR MAJOR TYPES OF "TINEA PEDIS" CAUSED BY DERMATOPHYTES AND NON-DERMATOPHYTES

Type	Causative organism	Clinical features	Treatment considerations
Moccasin	*Trichophyton rubrum* *Epidermophyton floccosum* *Neoscytalidium hyalinum* *N. dimidiatum*	Diffuse hyperkeratosis, erythema scaling and fissures on one or both plantar surfaces; frequently chronic and difficult to cure*; occasionally associated with immune deficiency	Topical antifungal plus product with urea or lactic acid; may require oral antifungal therapy
Interdigital	*T. interdigitale* (previously *mentagrophytes* var. *interdigitale*) *T. rubrum* *E. floccosum* *N. hyalinum* *N. dimidiatum* *Candida* spp. *Fusarium* spp.	Most common type; erythema, scaling, fissures and maceration in the web spaces; the two lateral web spaces are most commonly affected; "dermatophytosis complex" (fungal infection followed by bacterial invasion†) can develop; pruritus common; may extend to dorsum and sole of foot	Topical antifungal; may require topical or oral antibiotic if superimposed bacterial infection
Inflammatory (vesicular)	*T. mentagrophytes* (previously *T. mentagrophytes* var. *mentagrophytes*)	Vesicles and bullae on the medial foot; often associated with a dermatophytid reaction‡	Topical antifungal usually sufficient
Ulcerative	*T. rubrum* *T. interdigitale* (previously *T. mentagrophytes* var. *interdigitale*) *E. floccosum*	Typically an exacerbation of interdigital tinea pedis; ulcers and erosions in the web spaces; commonly secondarily infected with bacteria; seen in immunocompromised and diabetic patients	Topical antifungal; may require topical or oral antibiotics if secondary bacterial infection (common)

Dermatophytes Non-dermatophytes

*Because of the thickness of stratum corneum on plantar surfaces and the inability of *T. rubrum* to elicit a sufficient immune response to eliminate the fungus[22].
†Often *Pseudomonas*, *Proteus* spp., or *Staphylococcus aureus*.
‡Reaction to fungal elements presenting as a dyshidrotic-like eruption on the fingers and palms (culture negative for fungus).

Table 77.11 The four major types of "tinea pedis" caused by dermatophytes and non-dermatophytes.

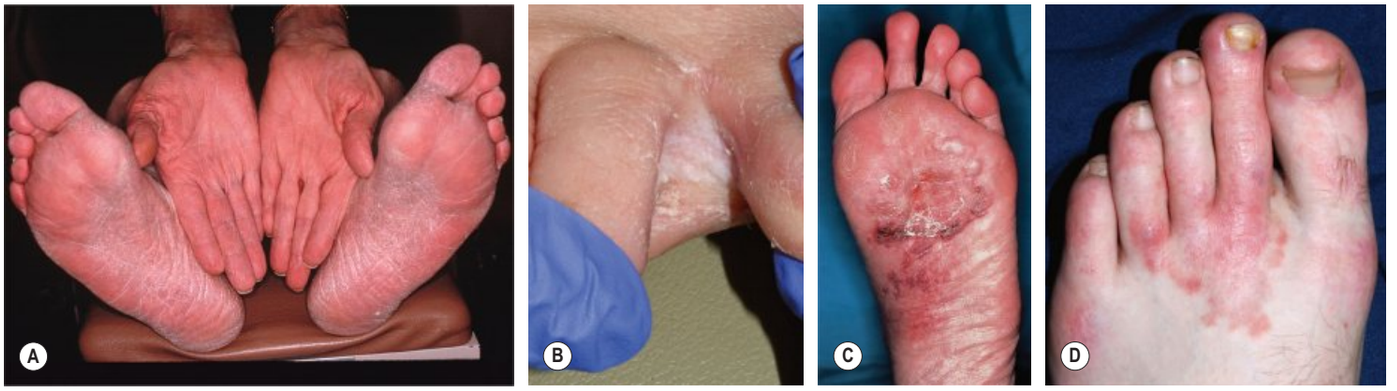

Fig. 77.16 Tinea pedis A Diffuse scaling on both feet (moccasin type) as well as on the right hand, representing "one hand–two feet" tinea. B Maceration and scaling between the fourth and fifth toes in the interdigital form. **C** Erythema, scale-crust, and bullae in the inflammatory form. **D** Extension of tinea pedis onto the dorsal foot in a serpiginous configuration of erythema and papules. Scale is minimal due to the patient's use of a potent topical corticosteroid for presumed dermatitis. *B, D, Courtesy Julie V. Schaffer, MD.*

even osteomyelitis leading to amputation in diabetics. Other conditions that can mimic tinea pedis are listed in Table 77.9. KOH examination and culture easily differentiate the moccasin and inflammatory forms of tinea pedis from these entities[22]. Erythrasma can be diagnosed with Wood's light examination because of its "coral red" fluorescence. Oral antifungal therapy should be considered in diabetics, immunocompromised patients, and those with moccasin-type tinea pedis. Finally, other dermatophyte infections often occur together with tinea pedis – in particular, tinea cruris, onychomycosis, and tinea manuum – and these sites should be examined (Fig. 77.17).

Fig. 77.17 Extensive tinea corporis emanating from tinea manuum and tinea pedis. Note the confluent involvement, serpiginous scaly borders, and associated tinea unguium of the toenails and one fingernail.

Tinea unguium (dermatophytic onychomycosis)

Onychomycosis is a term used to encompass all fungal infections of the nail and includes those due to dermatophytes as well as non-dermatophytes. It is divided into three patterns based upon the point of fungal entry into the nail unit:

- *distal/lateral subungual*, with invasion via the hyponychium (most common; Fig. 77.18A–C)
- *superficial white*, with direct penetration into (and usually confinement to) the dorsal surface of the nail plate (often due to *T. interdigitale*; Fig. 77.18D)
- *proximal subungual*, with invasion under the proximal nail fold (frequently in immunocompromised hosts)
- *mixed pattern*, with ≥2 of the above patterns in the same nail.

Onychomycosis can be challenging to manage due to difficulties in diagnosis, the requirement for long treatment periods, potential side effects of systemic medications, and frequent recurrences. Although many consider onychomycosis solely as an annoyance, patients with the condition often complain of discomfort and pain associated with trimming the nails, running, and other activities such as dancing. In addition, serious complications such as cellulitis can result from onychomycosis, especially in patients who are diabetic or immunocompromised. Infections with non-dermatophytes such as *Fusarium* spp. (see below) are of particular concern in the latter group.

Tinea unguium refers specifically to dermatophyte infection of the nail unit. It occurs worldwide, affects men more often than women, and is frequently associated with chronic tinea pedis. Trauma and other nail disorders represent predisposing factors. Although all dermatophytes can cause tinea unguium, *Microsporum* spp. do so very rarely. The most common causative pathogens are *T. rubrum*, *T. interdigitale*, *T. tonsurans* (in children), and *E. floccosum*.

Toenail infections are considerably more common than fingernail infections, and only rarely does fingernail onychomycosis occur without concurrent toenail infection. A single nail may be involved, but more frequently, multiple nails on one or both hands or feet are affected. In the *distal/lateral subungual type*, invasion of the hyponychial region leads to hyperkeratosis of the nail bed. With further progression of infection, there

Fig. 77.18 Tinea unguium. Onycholysis, yellowing, crumbling and thickening of the fingernails (**A**), thumb nails (**B**), and toenails (**C**) in the distal/lateral subungual variant. **D** White discoloration of the toenail in the superficial white variant. **E** Hyphae within a formalin-fixed, PAS-stained nail plate. *A, D Courtesy Jean L. Bolognia, MD; B, Courtesy Louis A. Fragola, Jr, MD; E, Courtesy Mary Stone, MD.*

is yellowing and thickening of the distal nail plate as well as onycholysis (see Fig. 77.18A–C), which provides an ideal environment for further proximal invasion and growth of the dermatophyte. Eventually, the entire nail bed and plate may become involved (total dystrophic pattern).

The clinical appearance of the *superficial white type* of onychomycosis can vary based on host factors (e.g. immunosuppression) and the causative organism. Discrete white patches are seen in the classic form due to *T. interdigitale* (see Fig. 77.18D). However, transverse striate bands, origination from the proximal nail fold (which may overlap with the proximal subungual type if there is also invasion under the nail fold), and deeper invasion of the nail plate can also occur. These variants are more likely to be caused by *T. rubrum*, with more invasive forms observed in healthy children as well as people living with HIV; deep invasion of the nail plate can also result from non-dermatophyte molds such as *Fusarium* spp.[23].

Although nail dystrophy can be the result of trauma, psoriasis, inherited disorders, and other conditions (see Ch. 71), an estimated 50% or more of cases are due to onychomycosis. Dermatophytes account for ~90% of cases of onychomycosis, and the remainder are due to yeasts or non-dermatophyte molds (Table 77.12). *Candida* spp. are often found in association with chronic paronychia (see Ch. 71), and infection of the nail may occur in this setting. The fingernails are usually affected, with ridging, yellow discoloration, and onycholysis. *Candida* spp. are a relatively common cause of onychomycosis in children less than 3 years of age, and nail involvement also represents a manifestation of chronic mucocutaneous candidiasis (see Ch. 60).

NON-DERMATOPHYTE MOLDS THAT CAN CAUSE ONYCHOMYCOSIS

Fungus	Key features
Fusarium spp.	Superficial white pattern*
Aspergillus spp.	Superficial white pattern*
Acremonium	Superficial white pattern*
Scopulariopsis brevicaulis	Lateral yellow–brown discoloration KOH of nail reveals lemon-shaped conidia and atypical hyphae
Neoscytalidium hyalinum	Distal and lateral nail invasion†
Neoscytalidium dimidiatum	Distal and lateral nail invasion†

*Deeper invasion of the nail plate can also occur.
†May also be associated with paronychia or tinea pedis.

Table 77.12 Non-dermatophyte molds that can cause onychomycosis.

Pathology

Tinea pedis, manuum, faciei, cruris, and corporis are usually diagnosed via KOH examination (see Fig. 77.5B) and occasionally with fungal cultures. The chlorazol black E stain can help to highlight fungal elements in KOH preparations. Use of calcofluor, a fluorescent stain specific for the chitin in the fungal cell wall, and examination with a fluorescent microscope can also demonstrate fungi (apple-green fluorescence). PCR-based assays for dermatophytes are also commercially available.

If biopsies are performed of cutaneous dermatophyte infections, hyphae are seen within the stratum corneum; the fungi are made more apparent by PAS or silver stains. In dermatophytoses affecting glabrous skin, spongiosis, parakeratosis, and pustules are often seen. In onychomycosis, hyphae and arthroconidia may be visible in the nail plate and nail bed with PAS staining, and little to no inflammation is generally present[2]. Histologic examination of formalin-fixed, PAS-stained nail plates is a quick and reliable method for diagnosing onychomycosis (Fig. 77.18E), with a sensitivity of 80% to >95%, compared with 35%–60% for culture alone[24]. Biopsy specimens of tinea capitis, Majocchi granuloma, and tinea barbae can demonstrate hyphae or arthroconidia within hair shafts and are usually done if the diagnosis is suspected but KOH examination and culture are negative. However, false-negative results are a potential problem and tissue should also be sent for culture.

Differential diagnosis

Careful clinical examination is the first and most important step in diagnosing dermatophyte infections. Because many other conditions can mimic dermatophytoses (see Table 77.9), KOH examination and/or culture are often necessary to confirm the diagnosis. Guidelines for proper specimen collection are outlined in Fig. 77.19. Because all dermatophytes have hyaline hyphae, they essentially look the same in KOH preparations. When identification of the particular species will provide helpful information or culture is needed to confirm the diagnosis, the specimen is cultured at 25–30°C (and in some instances also at 37°C) for 2 to 4 weeks.

Colonial morphology, microscopic examination of conidia (the asexual propagules formed *de novo* by the fungus), noting the growth rate/requirements, and biochemical tests allow precise identification of the dermatophyte. The presence or absence of microconidia (usually small and unicellular) and macroconidia (usually larger and multicellular) and the typical features of each (e.g. shape, cell wall texture) remain fairly consistent among genera (Fig. 77.20). Other distinguishing microscopic features include the identification of arthroconidia (infective fungal elements) and chlamydoconidia. Sometimes, conidia may not be present in culture ("sterile" organism), and the hyphal patterns (spiral,

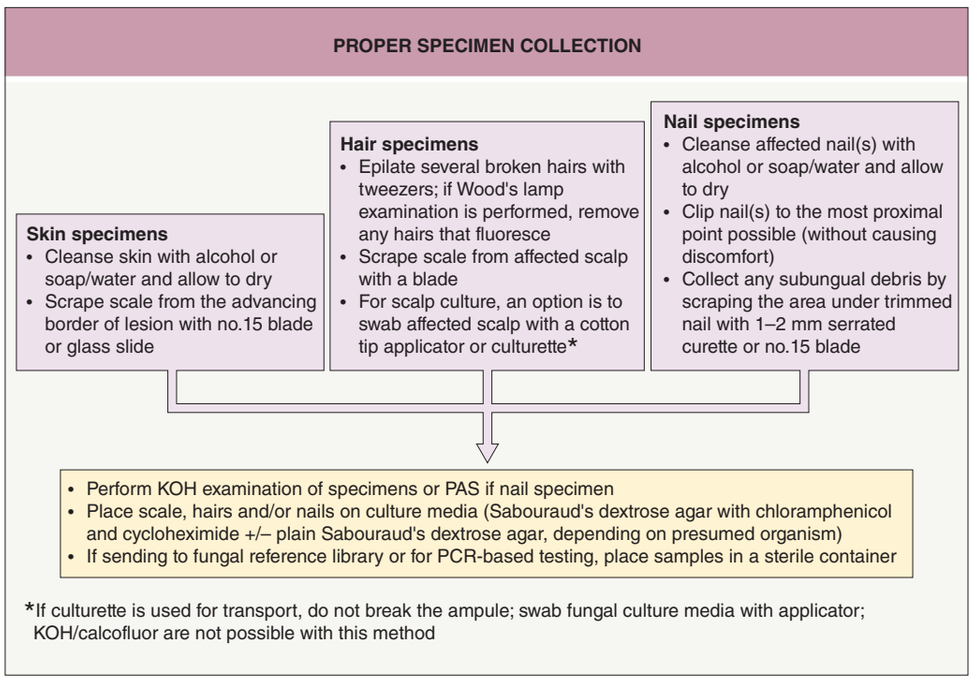

Fig. 77.19 Proper specimen collection. Proper collection of skin, hair, and nails is important. Following these simple guidelines will help the clinician to achieve the most accurate diagnosis. *Courtesy Judy Warner.*

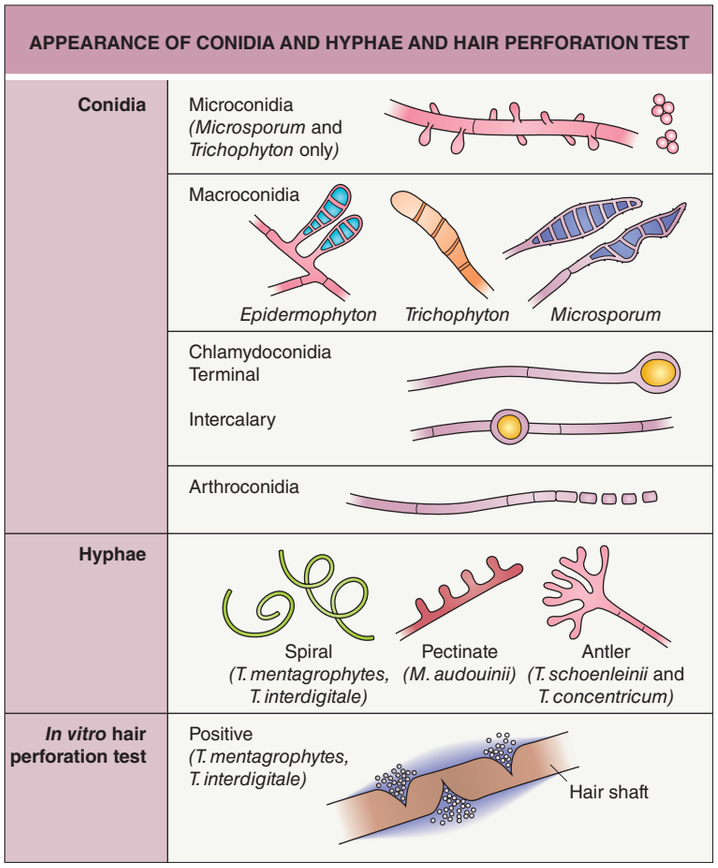

Fig. 77.20 Microscopic appearance of various forms of conidia and hyphae and the *in vitro* hair perforation test.

pectinate, antler, racquet, and nodular bodies) may be important in identification of the organism. The color, texture, and topography of the colony are features that are typical of, or even unique to, a particular species (see Table 77.6).

Dermatophytes are able to grow on media containing cycloheximide (e.g. Mycosel®, DTM [dermatophyte test medium]). However, some clinically relevant non-dermatophyte fungi do not, including *Scopulariopsis brevicaulis*, *Aspergillus* spp., *Cryptococcus neoformans*, *Candida tropicalis*, *Pseudallescheria boydii/Scedosporium apiospermum*, and *Trichosporon* spp.[25]. These can potentially be missed if specimens, in particular from nails, are grown only on cycloheximide-containing media[26].

Treatment

Topical antifungals are the first-line treatment for many patients with uncomplicated, localized cutaneous dermatophyte infections such as tinea corporis, tinea cruris, and tinea pedis (see Ch. 127). The major potential adverse reaction is irritant (or, occasionally, allergic) contact dermatitis, usually from alcohols or other components in the vehicle[27]. Systemic antifungal therapy, although associated with both a higher incidence of side effects including potentially severe adverse reactions and the potential for drug–drug interactions, is typically required to cure tinea manuum, capitis, and unguium. Suggested regimens are presented in Table 77.13[28]. In general, oral treatment is also needed for infections involving extensive areas of skin, in hairy sites other than the scalp (e.g. tinea barbae), or associated with excessive inflammatory reactions. The adjunctive use of topical products containing glycolic acid, lactic acid, or urea may help to reduce the amount of hyperkeratosis in infections such as tinea manuum and pedis.

Treatment of tinea unguium deserves special consideration. Oral antifungal therapy is usually required to achieve a complete cure (see Table 77.13), with the occasional exception of classic superficial white onychomycosis. Topical therapies that have been FDA-approved for mild to moderate onychomycosis have combined clinical and mycologic cure rates after daily application for 48 weeks ranging from 6%–10% for tavaborole 5% and ciclopirox olamine 8% solutions to 15%–20% for efinaconazole 10% solution. Although mycologic cure rates of up to 80% (or higher with prolonged therapy) have been reported with oral antifungal drugs (terbinafine, itraconazole, and fluconazole), the combined clinical and mycologic cure rates are lower, i.e. ~20%–40% after 12 weeks for toenails. Recurrent disease is common, especially in the toenails and when the degree of involvement is severe (Table 77.14)[7,29]. Preventive measures include breathable footwear and socks, antifungal or absorbent powders, frequent nail clipping, and avoiding re-exposure (e.g. not going barefoot in locker rooms). Old shoes often harbor large numbers of infectious organisms and should be discarded or treated with disinfectants or antifungal powders.

Combination therapy consisting of a topical corticosteroid plus topical antifungal has been advocated by some clinicians for the treatment of dermatophyte infections. While a reduction in inflammation can be seen, the negative effects of high-potency corticosteroids on immune defenses coupled with restrictions on treatment duration to avoid side effects such as striae lead to an unacceptable failure rate[30]. Dermatophyte resistance to antifungal therapy has emerged as a public health concern, especially with regard to squalene epoxidase mutations that lead to terbinafine resistance (see Fig. 127.9). Species affected include *T. rubrum* in the US as well as the recently recognized *T. indotineae* (*T. mentagrophytes* internal transcribed spacer [ITS] genotype VIII) that has resulted in an epidemic of resistant dermatophytosis in India, with subsequent global spread[31]. This highlights the importance of confirmatory testing and antifungal stewardship, including limiting the use of combination topical corticosteroid-antifungal products and reserving agents such as posaconazole and voriconazole for more severe infections[32].

Invasive dermatophytosis

Rarely, dermatophytes proliferate within the dermis. Invasion or dissemination of dermatophytes typically occurs in the setting of a chronic dermatophyte infection (most commonly *T. rubrum*) in an individual with a primary immunodeficiency such as CARD9 deficiency (see Ch. 60) or iatrogenic immunosuppression[33]. Hematogenous spread can lead to an acute onset of ulcerating or draining dermal and subcutaneous nodules. A more indolent process can also occur and most often presents as tender nodules on the extremities (Fig. 77.21). Currently, the recommended treatment is surgical excision (if localized) and systemic terbinafine, itraconazole, or posaconazole[34,35].

Mucocutaneous *Candida* Infections

Mucocutaneous candidiasis has a wide spectrum of clinical presentations. Early descriptions of oral candidiasis (thrush) were made by Hippocrates. In the 1940s, the association between oral antibiotic use and candidal infections was recognized. Oral candidiasis often presents as thrush, with the *pseudomembranous* form characterized by a white exudate resembling cottage cheese (Fig. 77.22A,B) and the *chronic atrophic* form by a patch of erythema; it can also lead to a *chronic hyperplastic* form with adherent white plaques or *glossitis* with painful atrophy of the dorsal tongue. Other presentations include denture stomatitis, angular cheilitis (perlèche) (Fig. 77.22C), vulvovaginitis, and balanitis (see Ch. 73). Predisposing factors for mucocutaneous candidiasis include diabetes mellitus, xerostomia, occlusion, hyperhidrosis, the use of corticosteroids or broad-spectrum antibiotics, and immunosuppression, including HIV infection[36]. In the case of angular cheilitis, deep grooves due to overlap of the skin at the angles of the mouth, which is common in edentulous and older patients, is a key contributing factor, along with the use of orthodontic appliances, drooling, atopic dermatitis, and (occasionally) iron or vitamin deficiencies (e.g. B_2).

Cutaneous *Candida* infections present with markedly erythematous, sometimes erosive, patches that are often accompanied by satellite papules and pustules (Fig. 77.22D–F). The most common sites of involvement are intertriginous zones (e.g. submammary, beneath pannus, inguinal creases, intergluteal fold) and the scrotum, as well as the diaper area in infants. Candidiasis is sometimes superimposed on intertriginous seborrheic dermatitis or psoriasis. *Candida* can also infect periungual areas (e.g. in the setting of chronic paronychia), nails (see Tinea unguium above), and the web space between the third and fourth fingers (erosio interdigitalis blastomycetica; Fig. 77.22G), especially in individuals whose hands are frequently exposed to water.

SUGGESTED SYSTEMIC REGIMENS FOR DERMATOPHYTOSES				
	Fluconazole	**Griseofulvin**	**Itraconazole***	**Terbinafine**
Tinea pedis (moccasin type)/ tinea manuum (adults)	150–450 mg/week × 4–6 weeks[28]	750–1000 mg/day (microsize) or 500–750 mg/day (ultramicrosize) × 4 weeks	200–400 mg/day × 1 week	250 mg/day × 2 weeks
Tinea pedis (moccasin type)/ tinea manuum (children)	6 mg/kg/week × 4–6 weeks	15–20 mg/kg/day (microsize suspension) × 4 weeks	3–5 mg/kg/day (maximum 400 mg) × 1 week	Daily dosing as for tinea capitis (see below) × 2 weeks
Tinea unguium (adults)	Toenail ± fingernail involvement:			
	150–450 mg/week until nails are clear[28]	1–2 g/day (microsize) or 750 mg/day (ultramicrosize) until nails are normal†	200 mg/day × 12 weeks or 200 mg BID × 1 week/month for 3–4 consecutive months	250 mg/day × 12 weeks
	Fingernail involvement only:			
	150–450 mg/week until nails are clear[28]	1–2 g/day (microsize) or 750 mg/day (ultramicrosize) until nails are normal†	200 mg/day × 6 weeks or 200 mg BID × 1 week/month for 2 consecutive months	250 mg/day × 6 weeks
Tinea unguium (children)	6 mg/kg/week × 3–4 months (fingernails) or 5–7 months (toenails), or until nails are clear	20 mg/kg/day (microsize suspension) until nails are normal†	5 mg/kg/day (<20 kg), 100 mg/day (20–40 kg), 200 mg/day (40–50 kg), or 200 mg BID (>50 kg) × 1 week/month for 2 (fingernails) or 3 (toenails) consecutive months	Daily dosing as for tinea capitis (see below) × 6 weeks (fingernails) or 12 weeks (toenails)
Tinea corporis (extensive, adults)	150–200 mg/week × 2–4 weeks	500–1000 mg/day (microsize) or 375–500 mg/day (ultramicrosize) × 2–4 weeks‡	200 mg/day × 1 week‡	250 mg/day × 1 week‡
Tinea corporis (extensive, children)	6 mg/kg/week × 2–4 weeks	15–20 mg/kg/day (microsize suspension) × 2–4 weeks	3–5 mg/kg/day (maximum 200 mg) × 1 week	Daily dosing as for tinea capitis (see below) × 1 week
Tinea capitis (adults)¶	6 mg/kg/day × 3–6 weeks	10–15 mg/kg/day (ultramicrosize; usually maximum 750 mg/day) × 6–8 weeks	5 mg/kg/day (maximum 400 mg) × 4–8 weeks	250 mg/day × 3–4 weeks§
Tinea capitis (children)¶	6 mg/kg/day × 3–6 weeks	20–25 mg/kg/day (microsize suspension) × 6–8 weeks	5 mg/kg/day (maximum 500 mg) × 4–8 weeks	62.5 mg/day (<20 kg), 125 mg/day (20–40 kg), or 250 mg/day (>40 kg) × 3–4 weeks§

*Not approved in US for use in children.
†No longer commonly used for this indication.
‡For patients with Majocchi granuloma, treatment is continued for 1–6 months depending on the disease severity and clinical response.
¶Combined with 2.5% selenium sulfide shampoo or ketoconazole 2% shampoo; "id" reaction should not be confused with a medication allergy.
§Not recommended for *Microsporum canis*, unless given at double-dose.

Table 77.13 Suggested systemic regimens for dermatophytoses. BID, twice daily.

INDICATORS OF MORE SEVERE ONYCHOMYCOSIS WITH A POOR RESPONSE TO TREATMENT	
Nail factors	• Subungual hyperkeratosis >2 mm thick* • Significant lateral involvement • Dermatophytoma† • >50% involvement of nail bed • Slow nail growth rate • Total dystrophic onychomycosis • Matrix involvement
Patient factors	• Immunosuppression • Peripheral arterial disease • Poorly controlled diabetes mellitus

*Measurement of nail plate plus nail bed.
†Streak or patch representing a subungual pocket of densely packed hyphae; removal prior to initiating antifungal therapy can be helpful.

Table 77.14 Indicators of more severe onychomycosis with a poor response to treatment. *Adapted from reference 29.*

Fig. 77.21 Invasive dermatophytosis due to *Trichophyton rubrum* in an immunocompromised host. *Courtesy Evelyn Lilly, MD.*

Mucocutaneous candidiasis is most commonly due to *C. albicans*, followed by *C. tropicalis*. The diagnosis is established by the presence of budding yeast and pseudohyphae on KOH examination (see Fig. 77.5D) and by a positive fungal culture. *C. albicans* and *C. stellatoidea* can be distinguished by their ability to form chlamydoconidia on cornmeal-Tween 80 agar. Identifying and removing predisposing factors is very important in the management of mucocutaneous candidiasis. Treatment with topical nystatin or azole antifungals is often effective[37,38]. When oral therapy is required for more extensive involvement, options include fluconazole and itraconazole (see Ch. 127). Treatment regimens for various forms of mucocutaneous candidiasis are outlined in Table 77.15.

Chronic mucocutaneous candidiasis

This is discussed in detail in Chapter 60. Chronic mucocutaneous candidiasis is not a single entity but rather a clinical manifestation of

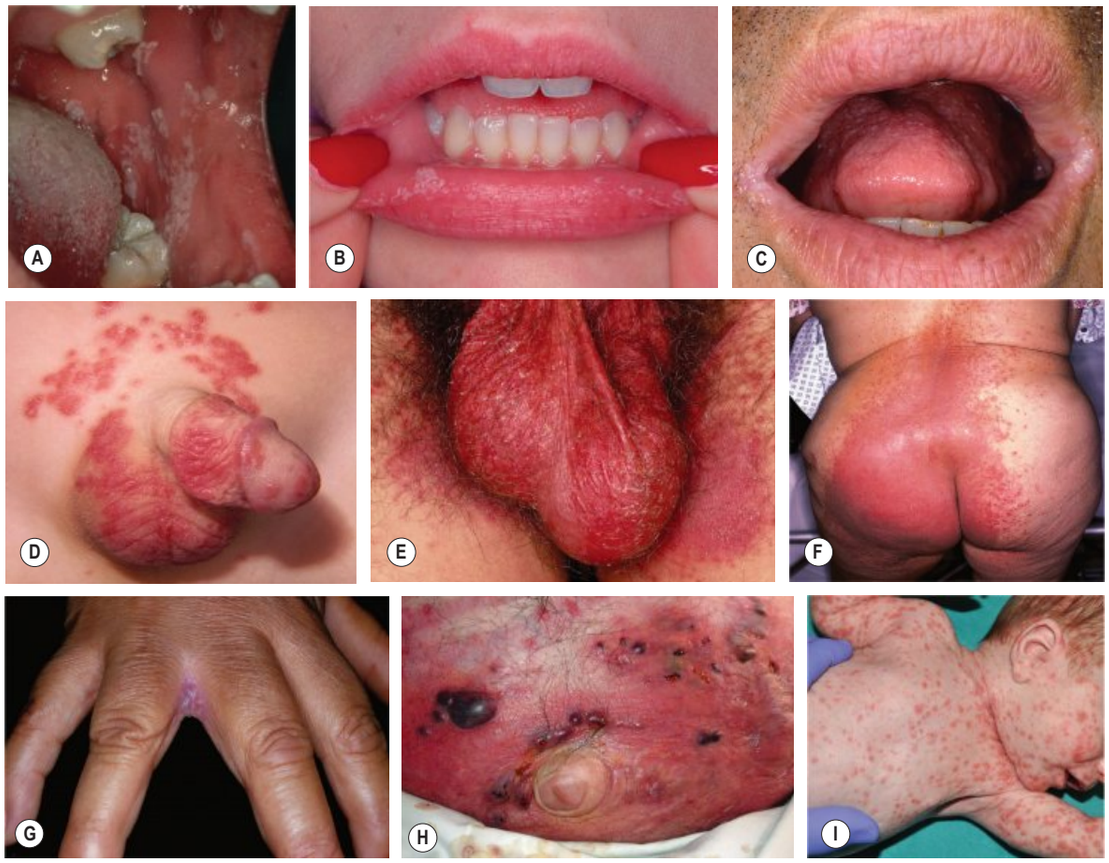

Fig. 77.22 Mucocutaneous candidiasis. A Thrush with "cottage cheese"-like exudate on the buccal mucosa in a man with AIDS. **B** Thrush and candidal cheilitis. **C** Angular cheilitis (perlèche). **D** Candidiasis of the suprapubic area and penis in a young boy. Note the collarettes of scale on the coalescing, brightly erythematous papules. **E** Candidiasis of the scrotum and medial thighs with beefy red erythema, scale, and satellite papules. **F** This infection occurred in a hospitalized patient with diabetes mellitus who was receiving broad-spectrum antibiotics. Note the multiple satellite lesions. **G** Erosive interdigital candidiasis (erosio interdigitalis blastomycetica) in the classic location between the third and fourth fingers. **H** Dermal candidiasis in an immunosuppressed patient. **I** Early-onset cutaneous candidiasis in a term neonate. Widespread pink papules, some of which have collarettes of white scale, admixed with small pustules. This typically results from intrauterine acquisition and may be present at birth or appear during the first six days of life. *B, D Courtesy Louis A. Fragola, Jr, MD; C, Courtesy Kalman Watsky, MD; E, G, Courtesy Eugene Mirrer, MD; I, Courtesy Antonio Torrelo, MD.*

a number of disorders, including primary immunodeficiencies. Patients have defects in the T helper 17 (Th17) response that prevent effective handling of *Candida* organisms, leading to chronic, recalcitrant infections of the skin (including granulomatous lesions), nails, and mucosae. Some patients have associated autoimmune endocrinopathies as well as alopecia areata and vitiligo. Therapy involves oral fluconazole and itraconazole (see Table 77.15).

Erosive Papulonodular Dermatosis: Granuloma Gluteale Infantum/Adultorum and Perianal Pseudoverrucous Papules/Nodules (see Ch. 15)

Granuloma gluteale infantum/adultorum and perianal pseudoverrucous papules/nodules are reactive conditions that occur in the setting of chronic, severe irritant contact dermatitis in the anogenital region of either infants with chronic diarrhea or children and adults with encopresis or urinary incontinence[39]. They exist within the spectrum of erosive papulonodular dermatosis, which also includes *Jacquet erosive dermatitis*, a variant with prominent punched-out erosions[40]. Erythematous to violaceous nodules and plaques, often ovoid in shape and sometimes eroded, develop on the vulva, lower buttocks, perianal region, and occasionally scrotum (Fig. 77.23). In addition to chronic irritation (e.g. from frequent loose stools), contributing factors may include candidal infection (in the past viewed as the key factor), occlusion, and topical corticosteroid use. Histologically, epidermal hyperplasia, a variably dense mixed inflammatory infiltrate in the dermis, and vascular proliferation are typically observed. Although barrier creams and topical antifungal agents may have some benefit, the condition tends to persist until the irritant trigger is eliminated (see Fig 15.6).

SUBCUTANEOUS MYCOSES

The "subcutaneous" mycoses are due to a large and diverse group of organisms that cause disease when implanted or otherwise introduced into the dermis or subcutis. Chromoblastomycosis, mycetoma, sporotrichosis, and lobomycosis are discussed in detail in this section; the first three have been designated as neglected tropical diseases (NTDs) by the World Health Organization (WHO).

Another chronic subcutaneous fungal infection is basidiobolomycosis, which is caused by *Basidiobolus ranarum*. Although this organism is an environmental saprophyte that is found worldwide, the associated infection occurs most commonly in children living in tropical and subtropical climates. The most common portal of entry is the skin, typically after arthropod bites or minor trauma. Clinically, the disease manifests as a solitary, painless, indurated subcutaneous nodule or swelling of the thigh or buttock. The classic treatment is saturated solution of potassium iodide (SSKI; see Ch. 100), although successful results have been reported with oral azole antifungals and trimethoprim–sulfamethoxazole. Surgical excision is not recommended. A related organism, *Conidiobolus coronatus*, causes an infection that has similar clinical features but typically affects the face, especially the nasal region.

Although not a true fungal disease, protothecosis is treated with antifungal agents. *Prototheca* (usually *P. wickerhamii*) is a genus of achlorophyllic algae that can be introduced into the skin via trauma, often in the setting of exposure to contaminated water. Common clinical presentations include solitary cutaneous plaques (sometimes eczematous), nodules or ulcers, as well as olecranon bursitis. The extremities are the most frequent sites of involvement. Although immunocompetent patients typically have chronic, stable disease, patients who are immunocompromised can have widespread involvement, including algemia. Protothecosis is difficult to treat; surgical excision and systemic antifungals (e.g. amphotericin B) are more effective in immunocompetent hosts.

Skin and soft tissue infections with *Pythium insidiosum*, an aquatic oomycete, may present as progressive necrotic plaques in previously healthy children and adults as well as immunocompromised individuals[41]. Pythiosis typically develops on the lower extremities or in the periocular area following exposure to stagnant water. It most often occurs in Thailand and India but has been reported worldwide, including in the southern US. These organisms resemble filamentous fungi but are more closely related to diatoms and algae. Treatment is difficult and includes surgical debridement together with antifungal and antibacterial agents.

TREATMENT OF MUCOCUTANEOUS *CANDIDA* INFECTIONS	
Type of infection	**Treatment regimen (adult doses unless otherwise indicated)**
Oropharyngeal candidiasis	**Nystatin*** 100 000 units/ml suspension: • Children and adults – 4–6 ml swish and swallow four times daily • Infants – 2 ml (1 ml inside each cheek) four times daily **Clotrimazole*** 10 mg troche five times daily **Fluconazole**† 200 mg po on day 1, then 100–200 mg po daily • Continue treatment for 7–14 days after clinical resolution
Esophageal candidiasis	**Fluconazole*** 200–400 mg po on day 1, then 100–400 mg daily **Itraconazole** 200 mg po daily **Voriconazole** 200 mg po or iv BID **Posaconazole** 400 mg po BID **Caspofungin** 50 mg po iv daily Continue treatment for 7–14 days following resolution of symptoms, for a minimum of 21 days total
Candidal vulvovaginitis‡	**Fluconazole*** 150 mg po single dose or (for severe disease or an immunosuppressed patient) three doses at 3-day intervals **Ibrexafungerp** 300 mg po, two doses 12 hours apart **Butoconazole** 2% vaginal cream, 5 g daily for 1–3 days **Clotrimazole***,¶ • 1% vaginal cream (or other topical formulation), 5 g daily for 7–14 days • Vaginal suppositories: 100 mg daily for 7 days or 200 mg daily for 3 days **Miconazole***,¶ • 2% cream, 5 g daily for 7 days • Vaginal suppositories: 100 mg daily for 7 days, 200 mg daily for 3 days, or 1200 mg single dose **Tioconazole*** 6.5% cream, 5 g single dose **Terconazole*** • 0.4% or 0.8% cream, 5 g daily for 7 or 3 days, respectively • 80 mg vaginal suppository daily for 3 days **Nystatin** 100 000 units vaginal suppository daily for 14 days *For suppression in patients with recurrent infections:* **Fluconazole** 150 mg weekly for 6 months **Oteseconazole** 600 mg po on day 1, 450 mg on day 2, then 150 mg weekly for 11 weeks (beginning on day 14) **Ibrexafungerp** 300 mg po monthly for 6 months **Clotrimazole** vaginal suppository, 200 mg twice weekly or 500 mg weekly for 6 months
Chronic mucocutaneous candidiasis	**Fluconazole** • *Eradication:* 400–800 mg po daily for 4–6 months • *Suppressive therapy*: 200 mg po daily
Candidal intertrigo or balanitis‡	Topical **imidazole** (see Table 127.12) or **ciclopirox** cream or lotion twice daily for 1–2 weeks or until resolved§ *Systemic agents for recalcitrant or severe cases:* **Fluconazole** • 50 to 100 mg po daily for 14 days • 150 mg po weekly for 2–4 weeks **Itraconazole** 200 mg po twice daily for 14 days

*Recommended as first-line treatment for immunocompetent individuals.
†Recommended as first-line treatment for people living with HIV (or other immunosuppressed individuals) who have moderate to severe disease, recurrent infection, or a CD4 count of <200 cells/mcl.
‡In cases of recurrent vulvovaginitis, treatment of the patient's sexual partner is controversial; in contrast, for recurrent balanitis, eradication of *Candida* from the sexual partner's genital tract is generally recommended.
¶Preferred treatments (with 7-day regimens) for pregnant patients.
§After clinical resolution, topical treatments may be continued twice weekly to prevent recurrence.

Table 77.15 Treatment of mucocutaneous *Candida* infections. Candidal onychomycosis can be treated with the oral fluconazole or itraconazole regimens described for tinea unguium in Table 77.13. See Table 127.17 for pediatric dosing of fluconazole. BID, twice daily; iv, intravenously; po, orally.

Chromoblastomycosis

Synonyms: ■ Chromomycosis ■ Cladosporiosis ■ Verrucous dermatitis ■ Phaeosporotrichosis ■ Pedroso disease ■ Fonseca disease

Introduction

Chromoblastomycosis presents as a "verrucous dermatosis" and is caused by several genera of dematiaceous (pigmented) fungi. Typically chronic in nature, an expanding verrucous plaque on the lower, or occasionally upper, extremity is the classic presentation. Two fungi, *Fonsecaea pedrosoi* and *Cladophialophora carrionii*, are responsible for most cases; less common causes include *Fonsecaea compacta, Fonsecaea monophora, Phialophora verrucosa*, and *Rhinocladiella aquaspersa*. The clinical presentation and colonial morphologies of each of these fungi are very similar, and differentiation is based on microscopic and conidial characteristics.

History

Pedroso first recognized chromoblastomycosis in 1911. Four years later, Medlar and Lane reported the first case in the US (in Boston)[42]. There has been confusion over the proper naming of this condition. At one point, chromoblastomycosis was thought to be closely related to blastomycosis; however, cellular division does not occur via budding ("blasto-") but rather via internal septation, hence the preference for the term "chromomycosis". Nonetheless, some authors have argued that the latter is also confusing, because it has the same meaning as phaeohyphomycosis (see below), and so they prefer the term "chromoblastomycosis".

Epidemiology and pathogenesis

Chromoblastomycosis is an NTD that is most commonly found in tropical and subtropical climates and occasionally in temperate zones such as the US, Europe, and Canada. Farmers, miners, and others working in rural areas are at increased risk. Men 20–60 years of age are most often affected, probably due to increased occupational exposure, which accounts for up to 90% of cases[43].

The fungi responsible for causing chromoblastomycosis are found in the soil and in decaying plants and wood. The disease is typically contracted from trauma to the lower extremities, including from not wearing shoes. As a result, the organism is introduced into the dermis or subcutis via implantation.

Clinical features

The disease usually presents as a papule or nodule on the leg, which progresses to form a verrucous or granulomatous plaque (Fig. 77.24). The lesion may appear annular as the central portion resolves with scarring. Several lesions may coalesce to form a multinodular mass, or multiple lesions may exist as discrete islands scattered within unaffected skin. It is thought that autoinoculation from scratching may be responsible for the spread of infection. Typically, only one extremity is affected. A subcutaneous nodule or mass is occasionally the presenting lesion. There are usually no constitutional symptoms.

Pathology

Pseudoepitheliomatous hyperplasia, intraepidermal abscesses, and suppurative and granulomatous inflammation within the dermis are the typical histologic findings (Fig. 77.24C). Pathognomonic round, pigmented "Medlar bodies" or sclerotic bodies, which are 6 to 12 microns in diameter and said to resemble "copper pennies", are present in the dermis, both extracellularly and within giant cells[2]. Organisms can also be detected via PCR of tissue samples.

Fig. 77.23 Granuloma gluteale infantum. Coalescing moist, pink papules on the vulva and suprapubic area of an infant. *Courtesy Julie V. Schaffer, MD.*

Differential diagnosis

Although characteristic reddish brown to black dots may be evident using dermoscopy, a biopsy is indicated to exclude other infectious diseases characterized by granulomatous lesions associated with scarring, such as cutaneous tuberculosis, tertiary syphilis, blastomycosis, and leishmaniasis. Mycetoma is another implantation mycosis that commonly affects the lower extremity, but edema, draining sinuses, and grains point to this diagnosis. If a biopsy is not feasible, a KOH examination of scrapings from a pigmented portion of the lesion can be performed. The presence of Medlar bodies is diagnostic (excluding other entities such as blastomycosis), but hyphae may also be seen. Culture growth at 25–30°C is slow and the different genera produce similar colonial morphologies. The major differences between genera are the microscopic features, in particular the type of conidia produced in culture. The three major types are:

- Cladophialophora-like (long branching side chains with shield cells at branch points)
- Phialophora-like (conidia resemble overflowing buds in a vase)
- Rhinocladiella-like (overall configuration similar to a mascara brush).

Treatment

Therapeutic options are limited. Some authors have advocated heat therapy based on evidence that the causative organisms will not grow at high temperatures. For small lesions, surgical excision can be attempted together with systemic antifungal treatment. 5-Flucytosine combined with either intravenous amphotericin B or an oral triazole has been reported to be efficacious. Itraconazole alone (200–400 mg/day) administered for at least 6 months may have cure rates of up to 80%–90%[44]. Successful treatment with voriconazole or posaconazole has also been described. In a small series, oral terbinafine (500 mg/day) given for at least 7 months was effective[45]. Other treatment considerations include cryosurgery and the addition of antibiotics if the lesion is secondarily infected.

Mycetoma

Synonyms: ■ Madura foot ■ Maduromycosis

Introduction

Mycetoma, often referred to as "Madura foot", is a Greek term for "fungal tumor". Due to implantation, it is a granulomatous infection of dermal and subcutaneous tissue that may extend to muscle or even bone. Mycetoma is differentiated from other mycoses by its characteristic draining sinuses containing grains (sclerotia, sulfur granules) and local edema. Two subtypes exist: (1) actinomycotic mycetoma – caused by filamentous aerobic and anaerobic organisms, e.g. *Nocardia brasiliensis*, *Actinomadura madurae*; and (2) eumycotic mycetoma – caused by true fungi. *Botryomycosis* caused by true bacteria (e.g. *Staphylococcus aureus*, *Pseudomonas* spp.) is also associated with grains, as is actinomycosis (see Ch. 74)[46].
