Disclaimer
In 2015, under the Pregnancy and Lactation Labeling Rule (PLLR), the US Food and Drug Administration (FDA) abolished the letter rating system for drug safety in pregnant women and during lactation; the letters are to be replaced with narrative-based labeling. Drugs approved prior to 2015 have three years to comply with the new format while drugs approved thereafter must comply from the onset. Fed Regist 2014;79;72064-72103.

Video Table of Contents x
Preface xi
List of Contributors xii
User Guide xxv
Dedication xxvi
Figures and Tables xxvii
Acknowledgments xxviii

Volume 1

SECTION 1: Overview of Basic Science

0 Basic Principles of Dermatology 1
Whitney A. High, Carlo F. Tomasini, Giuseppe Argenziano, Iris Zalaudek, Marco Ardigò, Chiara Franceschini and Philipp Tschandl

1 Anatomy and Pathophysiology 47
Travis W. Vandergriff

2 Skin Development and Maintenance 58
Isaac Brownell, Cynthia A. Loomis and Tamara Koss

3 Molecular Biology 68
Amaya Virós and Thomas N. Darling

4 Immunology 81
Karin Pfisterer, Wolfgang Weninger and Thomas Schwarz

SECTION 2: Pruritus

5 Cutaneous Neurophysiology 100
Gil Yosipovitch and Brian Kim

6 Pruritus and Dysesthesia 110
Sonja Ständer, Manuel P. Pereira, Elke Weisshaar and Jeffrey D. Bernhard

7 Psychocutaneous Diseases 128
Karynne O. Duncan, Josie Howard and John Y.M. Koo

SECTION 3: Papulosquamous and Eczematous Dermatoses

8 Psoriasis 139
Peter C.M. van de Kerkhof and Lars Iversen

9 Other Papulosquamous Disorders 164
Bernard Cribier, Gary S. Wood and George T. Reizner

10 Erythroderma 177
Sean Whittaker

11 Lichen Planus and Lichenoid Dermatoses 189
Tetsuo Shiohara and Yoshiko Mizukawa

12 Atopic Dermatitis 210
Maeve A. McAleer and Alan D. Irvine

13 Other Eczematous Eruptions 232
Norbert Reider and Irina Gasslitter

14 Allergic Contact Dermatitis 246
Kalman L. Watsky, Rosemary L. Nixon, Christen M. Mowad and James G. Marks Jr

15 Irritant Contact Dermatitis 267
Emily C. Milam and David E. Cohen

16 Occupational Dermatoses 279
S. Mark Wilkinson and Faheem Latheef

17 Dermatoses Due to Plants 291
Thomas W. McGovern

SECTION 4: Urticarias, Erythemas, and Purpuras

18 Urticaria and Angioedema 309
Clive E.H. Grattan, Emek Kocatürk and Sarbjit S. Saini

19 Figurate Erythemas 327
Agustín España

20 Erythema Multiforme, Stevens–Johnson Syndrome, and Toxic Epidermal Necrolysis 339
Wolfram Hötzenecker, Anna Oschmann and Lars E. French

21 Drug Reactions 355
Christina Bergqvist, Saskia Ingen-Housz-Oro and Olivier Chosidow

22 Purpura: Mechanisms and Differential Diagnosis 385
Warren W. Piette

23 Cutaneous Manifestations of Microvascular Occlusion Syndromes 397
Warren W. Piette

24 Cutaneous Vasculitis 418
Robert G. Micheletti

25 Neutrophilic Dermatoses 450
Alex G. Ortega-Loayza and Mark D. P. Davis

26 Eosinophil-Associated Dermatoses 470
Brendon Verhave and Lisa A. Beck

27 Pregnancy Dermatoses 480
Christina M. Ambros-Rudolph

SECTION 5: Vesiculobullous Diseases

28 The Biology of the Basement Membrane 491
Kim B. Yancey

29 Pemphigus 501
Masayuki Amagai

30 Pemphigoid Group 517
Luca Borradori and Michael Hertl

31 Dermatitis Herpetiformis and Linear IgA Bullous Dermatosis 534
Bridget E. Shields, Christopher M. Hull and John J. Zone

32 Epidermolysis Bullosa 545
Jo-David Fine and Jemima E. Mellerio

33 Other Vesiculobullous Diseases 560
José M. Mascaró Jr

34 Vesiculopustular and Erosive Disorders in Newborns and Infants 568
Nicole W. Kittler, Renee M. Howard and Ilona J. Frieden

SECTION 6: Adnexal Diseases

35 Structure and Function of Eccrine, Apocrine, and Sebaceous Glands 586
Martin Schaller and Gerd Plewig

36 Acne Vulgaris 592
Andrea L. Zaenglein, Amanda M. Nelson and Leah E.B. Lalor

37 Rosacea and Related Disorders 610
Síona Ní Raghallaigh

38 Folliculitis, Follicular Occlusion Tetrad, and Other Follicular Disorders 622
Jennifer L. Hsiao, Vivian Y. Shi and Kieron S. Leslie

39 Diseases of the Eccrine and Apocrine Sweat Glands 641
Jami L. Miller

SECTION 7: Rheumatologic Dermatology

40 Autoantibodies Encountered in Patients with Autoimmune Connective Tissue Diseases 657
Jeffrey R. Gehlhausen, Heidi T. Jacobe, Richard D. Sontheimer and Sarika Ramachandran

41 Lupus Erythematosus 670
Lela A. Lee and Victoria P. Werth

42 Dermatomyositis 689
Ruth Ann Vleugels and Joseph L. Jorizzo

43 Systemic Sclerosis (Scleroderma) and Related Disorders 702
Gideon P. Smith, Anna K. Haemel and M. Kari Connolly

44 Morphea and Lichen Sclerosus 717
Martin Röcken and Kamran Ghoreschi

45 Other Rheumatologic Disorders and Autoinflammatory Diseases 732
Cédric Lenormand, Marco Gattorno and Dan Lipsker

SECTION 8: Metabolic and Systemic Diseases

46 Mucinoses 753
Franco Rongioletti

47 Amyloidosis 765
Richard W. Groves

48 Deposition Diseases 775
Sven R. Quist, Jennifer E. Quist and Harald P. Gollnick

49 Porphyria 784
Jorge Frank

50 Calcifying and Ossifying Disorders of the Skin 796
Daniela Kroshinsky and Janet A. Fairley

51 Nutritional Diseases 807
Bernice Y. Kwong, Lucero Noguera-Morel, Stephanie Ann McLeish and Chad M. Hivnor

52 Graft-versus-Host Disease 825
Jennifer T. Huang and Edward W. Cowen

53 Dermatologic Manifestations in Patients with Systemic Disease 833
Lauren M. Madigan, Kathryn Schwarzenberger and Jeffrey P. Callen

SECTION 9: Genodermatoses

54 Basic Principles of Genetics 858
Jennifer L. Hand and Angela M. Christiano

55 Genetic Basis of Cutaneous Diseases 869
Vered Molho-Pessach and Julie V. Schaffer

56 Biology of Keratinocytes 883
Peter J. Koch, Anna L. Bruckner and Maranke I. Koster

57 Ichthyoses, Erythrokeratodermas, and Related Disorders 894
Gabriele Richard

58 Palmoplantar Keratodermas 931
Dieter Metze, Kira Süßmuth and Vinzenz Oji

59 Darier Disease and Hailey–Hailey Disease 951
Daniel M. Hohl

60 Primary Immunodeficiencies 962
Julie V. Schaffer and Amy S. Paller

61 Neurofibromatosis and Tuberous Sclerosis Complex 992
Hensin Tsao and Su Luo

62 Mosaicism and Linear Lesions 1012
Julie V. Schaffer

63 Other Genodermatoses 1035
Susan J. Bayliss, Monique G. Kumar, Ángela Hernández-Martín, Bernard A. Cohen, Teresa Martínez-Menchón, Encarna Guillén-Navarro and Virginia P. Sybert

64 Developmental Anomalies 1067
Richard J. Antaya and Julie V. Schaffer

SECTION 10: Pigmentary Disorders

65 Melanocyte Biology 1086
Jean L. Bolognia and Seth J. Orlow

66 Vitiligo and Other Disorders of Hypopigmentation 1098
Julien Seneschal, Thierry Passeron, Antonio Torrelo and Jean-Paul Ortonne

67 Disorders of Hyperpigmentation 1125
Gillian K. Weston and Mary Wu Chang

SECTION 11: Hair, Nails, and Mucous Membranes

68 Biology of Hair and Nails 1155
Etienne C.E. Wang, David de Berker and Angela M. Christiano

69 Alopecias 1173
Lidia Rudnicka and Catherine M. Stefanato

70 Hypertrichosis and Hirsutism 1198
Rachel Reynolds, Kristen Corey and Francisco M. Camacho

71 Nail Disorders 1214
Antonella Tosti and Bianca Maria Piraccini

72 Oral Diseases 1232
Maryam Jessri, Kristin K. McNamara and Nathaniel Treister

73 Anogenital (Non-venereal) Diseases 1255
Susan M. Cooper

Index to Volumes One and Two I-1

Volume 2

SECTION 12: Infections, Infestations, and Bites

74 Bacterial Diseases 1273
R. Matthew McLarney, Lacy L. Sommer, Annette C. Reboli and Warren R. Heymann

75 Mycobacterial Infections 1310
Marcia Ramos-e-Silva, Maria Cristina Ribeiro de Castro and Maria Teresa Ochoa

76 Rickettsial Diseases 1333
Lucas S. Blanton and David H. Walker

77 Fungal Diseases 1343
Boni E. Elewski, Lauren C. Hughey, Katherine Marchiony Hunt and Roderick J. Hay

78 Cutaneous Manifestations of HIV Infection 1376
Roy K.W. Chan, Martin T.W. Chio and Hong Yi Koh

79 Human Papillomaviruses 1394
Reinhard Kirnbauer and Petra Lenz

80 Human Herpesviruses 1412
Joseph Jebain, Alfredo Siller Jr. and Stephen K. Tyring

81 Other Viral Diseases 1437
Anthony J. Mancini, Ayelet Shani-Adir and Robert Sidbury

82 Sexually Transmitted Infections 1461
Georg Stary and Angelika Stary

83 Protozoa and Worms 1485
Francisco G. Bravo

84 Infestations 1519
Craig N. Burkhart, Craig G. Burkhart and Dean S. Morrell

85 Bites and Stings 1533
Dirk M. Elston

SECTION 13: Disorders Due to Physical Agents

86 Ultraviolet Radiation 1553
Peter Wolf and Thomas M. Rünger

87 Photodermatologic Disorders 1564
Henry W. Lim and Cheryl F. Rosen

88 Environmental and Sports-Related Skin Diseases 1585
Sarah Hannam and Michael L. Smith

89 Signs of Substance Use Disorder 1611
Yul W. Yang and Mark R. Pittelkow

90 Skin Signs of Abuse 1622
Sharon S. Raimer, Lauren Raimer-Goodman and Ben G. Raimer

SECTION 14: Disorders of Langerhans Cells and Macrophages

91 Histiocytoses 1629
Sylvie Fraitag and Stéphane Barete

92 Xanthomas 1649
William Trent Massengale

93 Non-infectious Granulomas 1660
Misha A. Rosenbach and Karolyn A. Wanat

94 Foreign Body Reactions 1681
M. Abdel Rahim Abdallah, Mahmoud M. A. Abdallah and Marwa Abdallah

SECTION 15: Atrophies and Disorders of Dermal Connective Tissues

95 Biology of the Extracellular Matrix 1693
Alexander Nyström and Leena Bruckner-Tuderman

96 Perforating Diseases 1707
Ronald P. Rapini

97 Heritable Disorders of Connective Tissue 1714
Nigel P. Burrows, Franziska Ringpfeil and Jouni Uitto

98 Dermal Hypertrophies 1730
Salma Machan, Ana María Molina-Ruiz and Luis Requena

99 Atrophies of Connective Tissue 1741
Catherine Maari and Julie Powell

SECTION 16: Disorders of Subcutaneous Fat

100 Panniculitis 1751
Luis Requena, Heinz H. Kutzner and James W. Patterson

101 Lipodystrophies 1775
Suat Hoon Tan, Hong Liang Tey and Joel Hua Liang Lim

SECTION 17: Vascular Disorders

102 Vascular Biology 1790
Benedikt Weber, Satoshi Hirakawa and Michael Detmar

103 Infantile Hemangiomas 1801
Anita N. Haggstrom, Sheilagh M. Maguiness and Maria C. Garzon

104 Vascular Malformations 1819
Eulalia Baselga

105 Ulcers 1844
Ariela Hafner and Eli Sprecher

106 Other Vascular Disorders 1864
Robert Kelly and Christopher Baker

SECTION 18: Neoplasms of the Skin

107 Principles of Cutaneous Tumor Biology 1875
Thomas Tüting and Andreas Dominik Braun

108 Actinic Keratosis, Basal Cell Carcinoma, and Squamous Cell Carcinoma 1888
Ingrid H. Wolf, H. Peter Soyer, Erin K. McMeniman and Peter Wolf

109 Benign Epidermal Tumors and Proliferations 1911
Luis Requena, Celia Requena and Clay J. Cockerell

110 Cysts 1935
Mary Seabury Stone

111 Adnexal Neoplasms 1948
Timothy H. McCalmont and Laura B. Pincus

112 Benign Melanocytic Neoplasms and Melanotic Lesions 1973
Thomas Wiesner and Raymond L. Barnhill

113 Melanoma 2009
Lisa C. Zaba, Jennifer Y. Wang and Susan M. Swetter

114 Vascular Neoplasms and Neoplastic-Like Proliferations 2045
Paula E. North

115 Neural and Neuroendocrine Neoplasms (Other than Neurofibromatosis) 2077
Andrea Saggini, Tomoko Akaike, Paul Nghiem and Zsolt B. Argenyi

116 Fibroblastic, Myofibroblastic and "Fibrohistiocytic" Proliferations and Neoplasms of the Skin 2096
Bernadette Liegl-Atzwanger and Heinz H. Kutzner

117 Smooth Muscle, Adipose, and Cartilage Neoplasms 2116
Steven Kaddu

118 Mastocytosis 2131
Michael D. Tharp

119 B Cell Lymphomas of the Skin 2142
Lorenzo Cerroni and Isabella Fried

120 Cutaneous T Cell Lymphoma 2156
Rein Willemze and Werner Kempf

121 Other Lymphoproliferative and Myeloproliferative Diseases 2177
Cesare Massone, Harry L. Winfield and Bruce R. Smoller

122 Cutaneous Metastases 2189
Christine J. Ko and Jennifer M. McNiff

SECTION 19: Medical Therapy

123 Public Health and Dermatology 2197
Eric J. Yang, Eleni Linos and Abrar A. Qureshi

124-1 Skin Barrier 2206
Matthias Schmuth, Jason Meyer, Gopinathan K. Menon, Kenneth R. Feingold, Theodora M. Mauro and Peter M. Elias

124-2 Transdermal and Topical Drug Delivery 2211
Mark R. Prausnitz

125 Glucocorticoids 2217
Courtney R. Schadt and Scott M. Jackson

126 Retinoids 2231
Jean-Hilaire Saurat and Olivier Sorg

127 Antimicrobial Drugs 2246
Ashley N. Millard-Garcia, Alexandra Cameli Carley, Erik J. Stratman, Jack L. Lesher Jr. and R. Carol McConnell

128 Systemic Immunomodulators 2272
J. Mark Jackson and Jeffrey P. Callen

129 Other Topical Medications 2295
Mark Marchitto, Matthew Fox, Yolanda R. Helfrich and Sewon Kang

130 Other Systemic Drugs 2311
Mary P. Maiberger, Julia R. Nunley and Stephen E. Wolverton

131 Drug Interactions 2330
Lukas Koch, Birger Kränke, Lori E. Shapiro, Sandra R. Knowles and Neil H. Shear

132 Sunscreens and Photoprotection 2344
Brandon L. Adler and Vincent A. DeLeo

133 Complementary and Alternative Medicine 2354
Apple Bodemer, Raja Sivamani and Peter Lio

SECTION 20: Physical Treatment Modalities

134 Ultraviolet Therapy 2362
Herbert Hönigsmann and Thomas Schwarz

135 Photodynamic Therapy 2379
Harvey Lui and Sunil Kalia

136 Lasers and Other Energy-Based Technologies – Principles and Skin Interactions 2390

Video 159.6 Neuromodulator Treatment of Chin
Alastair Carruthers, Jean Carruthers and Ada Trindade de Almeida

Video 159.7 Neuromodulator Treatment of Axillary Hyperhidrosis
Elizabeth Tanzi

Preface

The practice of dermatology is based upon a visual approach to clinical disease, with the development of an appreciation of recurrent patterns and images. The entire spectrum of our discipline, from the generation of differential diagnoses to the orientation of rotational flaps, relies upon imagery. As a result, visualization also plays a critical role in how we integrate new information into pre-existing frameworks that serve as the hard drives of our medical memory.

In the textbook *Dermatology* there is a strong emphasis on visual learning. This commitment is reflected in the use of schematic diagrams to convey the principles of skin biology as well as cutaneous surgery, in addition to the inclusion of algorithms, which provide a logical as well as practical approach to commonly encountered clinical problems. The majority of the basic science is integrated throughout the book and appears as introductory chapters to the various sections. There is also an emphasis on clinicopathologic correlations, with photomicrographs demonstrating key histologic findings adjacent to clinical images of the same disorder. Differential diagnosis tables are weighted and there is a "ladder" approach to therapeutic interventions. Lastly, color-coding of sections allows an easy and rapid access to required information.

One goal of the *Dermatology* textbook is for it to never make its way to the bookshelf because it is being used on a weekly, or perhaps even daily, basis. Nowadays, another goal is for the app to be on the home screen of smartphones and tablets. Hopefully, this book will function as a colleague, albeit a non-verbal one, who is easily approachable and possesses the necessary expertise to provide succinct, up-to-date information that is both precise and practical. It is also our hope that the organization is intuitive and information can therefore be quickly retrieved. Realizing this goal required the time and energy of our contributors and associate editors, who have unselfishly shared their knowledge and experience with literally thousands of patients from around the world, and we thank them.

JB, JVS, and LC
2024

Contributors

The editors would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible.

M. Abdel Rahim Abdallah MD PhD

Ana María Molina-Ruiz MD PhD
Dermatologist
Private Practice
Madrid, Spain

Gary D. Monheit MD FAAD FACMS
Private Practice
Total Skin and Beauty Dermatology
Clinical Professor
Departments of Dermatology and Ophthalmology
University of Alabama at Birmingham
Birmingham, AL, USA

Dean S. Morrell MD
Clinical Professor
Department of Dermatology
University of North Carolina at Chapel Hill
Chapel Hill, NC, USA

Christen M. Mowad MD
Clinical Professor and Chair
Division of Dermatology
Geisinger Medical Center
Danville, PA, USA

Priya Mahindra Nayyar MD
Mohs Surgeon
PH Dermatology
Palm Harbor, FL, USA

Amanda M. Nelson PhD
Assistant Professor of Dermatology
Pennsylvania State University College of Medicine
Penn State Hershey Medical Center
Hershey, PA, USA

Paul Nghiem MD PhD
Professor and Interim Chair
Department of Dermatology
University of Washington School of Medicine
Seattle, WA, USA

Síona Ní Raghallaigh MB BAO BCh MRCPI MD
Consultant Dermatologist
Beaumont Hospital
Bon Secours Hospital
Dublin, Ireland

Rosemary L. Nixon AM BSc (Hons) MB BS MPH FACD FAFOEM
Director
Occupational Dermatology Research and Education Centre
Skin Health Institute
Melbourne, VIC, Australia;
Clinical Associate Professor
St Vincents Hospital Department of Medicine
University of Melbourne
Fitzroy, VIC, Australia

Lucero Noguera-Morel MD
Attending Physician
Department of Dermatology
Hospital Universitario Infantil Niño Jesús
Madrid, Spain

Paula E. North MD PhD
Professor and Chief of Pediatric Pathology
Department of Pathology
Medical College of Wisconsin
Milwaukee, WI, USA

Julia R. Nunley MD
Emeritus Professor
Department of Dermatology
Virginia Commonwealth University
Richmond, VA, USA

Alexander Nyström MS PhD
Group Leader
Department of Dermatology
Faculty of Medicine
Medical Center – University of Freiburg
Freiburg, Germany

Maria Teresa Ochoa MD
Professor of Clinical Dermatology
University of Southern California
Los Angeles, CA, USA

Vinzenz Oji MD
Assistant Professor of Dermatology
University of Münster
Münster, Germany

Suzanne Olbricht MD
Senior Dermatologist
Lahey Clinic
Burlington, MA, USA

Seth J. Orlow MD PhD
Samuel Weinberg Professor of Pediatric Dermatology
Professor of Cell Biology and Pediatrics
Chair, Ronald O. Perelman Department of Dermatology
New York University Grossman School of Medicine
New York, NY, USA

Alex G. Ortega-Loayza MD MCR
Associate Professor of Dermatology
Oregon Health and Science University
Portland, OR, USA

Jean-Paul Ortonne MD†
Professor of Dermatology
University Hospital of Nice
Nice, France

Anna Oschmann MD
Assistenzärztin
Klinik und Poliklinik für Dermatologie und Allergologie
LMU Klinikum
Munich, Germany

Amy S. Paller MD
Walter J. Hamlin Professor and Chair of Dermatology
Director, Skin Biology and Disease Resource-Based Center
Northwestern University Feinberg School of Medicine
Professor of Pediatrics
Ann & Robert H. Lurie Children's Hospital of Chicago
Chicago, IL, USA

Paola Pasquali MD
Coordinator
Department of Dermatology
Pius Hospital de Valls
Valls, Tarragona, Spain;
Department of Medicine and Medical Specialties
Universidad de Alcalá
Madrid, Spain

Thierry Passeron MD PhD
Professor of Dermatology
University Hospital of Nice
University Côte d'Azur
Nice, France

James W. Patterson MD
Professor Emeritus of Pathology
Department of Pathology
University of Virginia Health System
Charlottesville, VA, USA

Manuel P. Pereira MD PhD
Consultant Dermatologist
Institute of Allergology
Charité – Universitätsmedizin Berlin
Berlin, Germany;
Fraunhofer Institute for Translational Medicine and Pharmacology ITMP
Allergology and Immunology
Berlin, Germany;
University Hospital Münster
Center of Chronic Pruritus, Department of Dermatology
Münster, Germany

Karin Pfisterer PhD
Lecturer and Senior Scientist
Department of Dermatology
Medical University of Vienna
Vienna, Austria

Warren W. Piette MD
Professor of Dermatology
Department of Dermatology
Rush University Medical Center
Voluntary Attending Physician and Former Chair
Division of Dermatology
John H. Stroger Jr. Hospital of Cook County
Chicago, IL, USA

Laura B. Pincus MD
Professor of Dermatology and Pathology
University of California San Francisco
San Francisco, CA, USA

Bianca Maria Piraccini MD PhD
Professor and Chief of Dermatology
University of Bologna
Bologna, Italy

Mark R. Pittelkow MD
Professor and Past Chair
Departments of Dermatology and Biochemistry and Molecular Biology
Mayo Clinic Arizona
Scottsdale, AZ, USA

Gerd Plewig MD Dr. h.c.mult. FRCP
Professor of Dermatology
Ludwig-Maximilian University
Munich, Germany

Sheldon V. Pollack MD FRCPC
Associate Professor of Medicine
Division of Dermatology
University of Toronto Faculty of Medicine
Toronto, ON, Canada

Julie Powell MD FRCPC FAAD
Pediatric Dermatology
Clinical Professor of Pediatrics (Dermatology)
Université de Montréal
Centre Hospitalier Universitaire (CHU) Sainte-Justine
Montréal, QC, Canada

Mark R. Prausnitz PhD
Regents' Professor
School of Chemical and Biomolecular Engineering
Georgia Institute of Technology
Atlanta, GA, USA

Jennifer E. Quist MD MBA
Doctor
Clinic of Dermatology
Helix Medical Excellence Center
Mainz, Rhineland-Palatinate, Germany

Sven R. Quist MD PhD MSc MPharm MBA
Professor
Clinic of Dermatology
Otto-von-Guericke University
Magdeburg, Saxony-Anhalt, Germany;
Professor
Clinic of Dermatology
Helix Medical Excellence Center
Mainz, Rhineland-Palatinate, Germany

Abrar A. Qureshi MD
Professor and Chair
Department of Dermatology
Warren Alpert Medical School of Brown University
Professor of Epidemiology
Brown University School of Public Health
Providence, RI, USA

Ben G. Raimer MA MD
Professor, Retired
Department of Pediatrics
University of Texas Medical Branch at Galveston
Galveston, TX, USA

Sharon S. Raimer MD
Chair Emeritus
Department of Dermatology
Professor
Departments of Dermatology and Pediatrics
University of Texas Medical Branch at Galveston
Galveston, TX, USA

Lauren Raimer-Goodman MD
Clinical Associate Professor
Department of Pediatrics
University of Texas Medical Branch at Galveston
Galveston, TX, USA

Sarika Ramachandran MD FAAD
Associate Professor of Dermatology
Yale School of Medicine
New Haven, CT, USA

Marcia Ramos-e-Silva MD PhD
Chair and Full Professor
Sector of Dermatology
Federal University of Rio de Janeiro
Rio de Janeiro, Brazil

Ronald P. Rapini MD
Chernosky Distinguished Professor and Chair
Department of Dermatology
University of Texas Medical School and MD Anderson Cancer Center
Houston, TX, USA

Désirée Ratner MD
Clinical Professor
Department of Dermatology
New York University Grossman School of Medicine
New York, NY, USA

†*Deceased*

Annette C. Reboli MD

DISCLOSURE INDEX

The editors of the fifth edition of *Dermatology* have indicated that they have a relationship which could be perceived by some individuals as a real or apparent conflict of interest, but they do not consider that it has influenced their work on the text. Codes for the disclosure information (institution[s] and nature of relationship[s]) are provided below. All editors listed here also receive royalties from Elsevier for their work on this and, in some cases, additional texts.

Relationship Codes

A—Stock options or bond holdings in a for-profit corporation or self-directed pension plan
B—Research grants
C—Employment (full or part-time)
D—Ownership or partnership
E—Consulting fees or other remuneration received by the contributor or immediate family
F—Nonremunerative positions, such as board member, trustee, or public spokesperson
G—Receipt of royalties
H—"Speaker's bureau" including CME lectures
I – Other

Institution and Company Codes

1—American Board of Dermatology
2—Biogen
3—Eli Lilly
4—JAMA Dermatology
5—Jaypee Brothers Publishers
6—Journal of the American Academy of Dermatology
7—La-Roche Posay
8—Novartis
9—Pfizer
10—Riovant
11—Sanofi, Sanofi-Aventis, Sanofi-Regeneron
12—Serono
13—Skinceuticals
14—UpToDate

Editors

Jean L. Bolognia: G-14
Lorenzo Cerroni: Nothing to disclose
Julie V. Schaffer: C-1, E-6, G-14
Jeffrey P. Callen: E-2, E-10, E-12, F-4, G-14
Edward W. Cowen: G-14
Karynne O. Duncan: D-13
George J. Hruza: Nothing to disclose
Jonathan Leventhal: E-7, E-11
Luis Requena: Nothing to disclose
Antonio Torrelo: E-3, E-8, E-9, E-11, G-5, G-14
Thomas Wiesner: H-8, H-11

VOLUMES, SECTIONS, AND COLOR CODING

Dermatology is divided into two volumes. The book is divided into 22 sections, which are color-coded as follows for reference:

VOLUME ONE

- **Section 1** Overview of basic science
- **Section 2** Pruritus
- **Section 3** Papulosquamous and eczematous dermatoses
- **Section 4** Urticarias, erythemas, and purpuras
- **Section 5** Vesiculobullous diseases
- **Section 6** Adnexal diseases
- **Section 7** Rheumatologic dermatology
- **Section 8** Metabolic and systemic diseases
- **Section 9** Genodermatoses
- **Section 10** Pigmentary disorders
- **Section 11** Hair, nails, and mucous membranes

VOLUME TWO

- **Section 12** Infections, infestations, and bites
- **Section 13** Disorders due to physical agents
- **Section 14** Disorders of Langerhans cells and macrophages
- **Section 15** Atrophies and disorders of dermal connective tissues
- **Section 16** Disorders of subcutaneous fat
- **Section 17** Vascular disorders
- **Section 18** Neoplasms of the skin
- **Section 19** Medical therapy
- **Section 20** Physical treatment modalities
- **Section 21** Surgery
- **Section 22** Cosmetic surgery

Basic Science Chapters

Basic science chapters in the book are highlighted on the upper corner of each page with the following skin biology symbol:

Therapeutic Ladders

Therapeutic ladders have been standardized for measuring levels of evidence.

Key to evidence-based support:

(1) prospective controlled trial
(2) retrospective study or large case series
(3) small case series or individual case reports.

Dermatology Website

The accompanying eBook, which can be found at eBooks.Health.Elsevier.com, includes all of the book's content plus 1500 supplementary images and 80 supplementary tables in a searchable format, along with a collection of videos.

This book is dedicated to our families, in particular Dennis Cooper, MD, Andrew Schaffer and Ricarda Cerroni, who endured our work on this project and who unwittingly were part of the team, and to all the rest of the team at Elsevier who made it all happen.

Figures and Tables

The following figures were sourced from the **Yale Residents' Slide Collection**: Fig. 0.5, 0.8C, 0.8F, 0.8H, 0.9, 1.10A, 1.12, 7.8C, e7.2, e7.4, 8.6B, 8.8B, 8.12, 8.18, 8.19A, 8.19C, 8.20A, e8.17, 9.5A, 9.5D, 9.13A, e9.2A, e9.2B, e9.3, e9.6, e9.9, e9.19, 10.1, 10.2, 10.7, e10.1, 11.5B, 11.7B, 11.8, 11.9B, 11.9C, 11.10A, 11.12, 11.13A, 11.13C, 11.15A, 11.15B, 11.15C, 11.16A, 11.17A, 11.21A, 11.21B, 11.24A, 12.7A, 12.12, 12.15 (inset A), e12.15A, 13.4 (insets B & I), 14.7, 14.10, 14.19, 17.11C, 18.1C, 19.1A, 19.1B, 19.1C, 19.2A, 19.5A, e19.1a, e19.3, e19.6, 20.1B, 20.1C, 20.1E, 20.2, 20.3A, 20.7A, 20.7B, 20.8, 20.9A, 20.11A, 20.11B, 20.14B, 21.1B, 21.2, 21.3C, 21.7B, 21.8, 21.10A, 21.12, 21.13, 21.16E, 21.25A, e21.1A, e21.1B, e21.9, e21.11, e21.14, 22.2C, 22.7A, e22.6, 23.5C, 23.8B, 23.10A, 24.2C, 24.3A, 24.3C, 24.6A, 24.6B, 24.7C, 24.15A, 24.17B, 24.17C, 24.17D, 24.20D, e24.3, e24.5, e24.7 e24.8A, e24.8B, e24.9, e24.10, 25.8, 25.10D, 25.10E, 25.12, e25.2, 27.4A, 27.4B, 27.4C, 27.11B, e29.2, 30.2C, 30.6C, 30.18A, e30.1, e30.14, 31.2A, 31.2B, 31.2D, 31.3A, 31.10, e31.3, 32.2A, 32.4A, 32.4C, 32.8, 32.9A, 32.16B, 33.1, 33.10, 34.4A, 34.4B, 34.16, 36.8A, 37.9C, 37.10, 37.14B, e37.2, 38.3B, 38.5F, 38.15B, 38.15C, 39.8, e39.2, 41.5A, 41.5B, 41.5D, 41.5H, 41.5I, 41.5K, 41.8B, 41.9B, 41.11A, 41.12, 41.13, 41.15, 41.16A, 42.2A, 42.10A, e42.11, 43.8, e43.1, e43.4, e43.8C, 44.5A, 44.8B, e44.10, 45.1A, 46.15C, e46.7, 47.5A, 47.6, 47.7B, e47.7, e47.10A, e48.1A, 49.3A, 49.7, e49.4, 50.5C, 50.10C, 50.10D, e50.4, e50.6, e50.11, 51.6, 51.8A, 51.9A, 51.12D, 51.12E, e51.2, e51.6, e51.10, e52.8A, 53.31, 57.10A, 57.10B, 57.12C, 57.14A, 57.14B, 57.14C, 57.14D, 58.3D, 58.9B, 58.16, e58.2B, e58.6, e58.9A, e58.9B, e58.9C, 59.2B, 59.2D, 59.12, 59.14, 59.15A, 59.15B, 60.4B, e61.13, e61.22, 62.5, 62.6A, 62.7C, 62.13, 62.16A, 62.16C, e62.1A, 63.2, 63.16D, 64.4, 64.21B, 64.24, 66.17, 66.19A, 66.19D, 66.19F, 66.19H, 66.21, 66.22, 66.23A, 66.24, 66.28, 66.30A, 66.30B, e66.6, e66.9, e66.13, e66.16, e66.18, 67.4, 67.7B, 67.10 (inset), 67.20B, e67.4A, 69.12A, 69.12D, 69.24H, 69.24I, e69.15, e69.19, 70.8, e70.2, 71.2, 71.20A, 72.1 (inset), Table 72.2 (insets), e72.1, 73.13A, 73.15A, 74.8A, 74.8B, 74.12A, 74.12B, 74.12C, 74.19, 74.22, 74.29, 74.35, e74.6A, e74.6C, e74.16, e74.20, e74.22, 75.15, 75.16, 75.18B, 75.19, 75.20, 75.21, 75.23A, 75.23B, 75.23C, 75.25A, 75.26B, 76.5, 76.6, 77.4, 77.5B, 77.6E, 77.9, 77.13A, 77.13C, 77.13D, 77.13E, 77.13G, 77.16A, 77.16C, 77.22A, 77.22F, 77.26A, 77.35A, 77.35B, 77.35E, 77.35F, e77.15, e78.6, 80.6A, 80.8A, 80.8B, 80.8C, 80.14A, 80.14C, 80.14E, 80.14F, 80.20, 80.21, e80.1A, e80.21, e80.10, e80.14, e80.21, e80.23B, 81.10A, 81.10C, e81.8, 82.5B, 82.8A, 82.8C, 82.8E, 82.9A, 82.9B, 82.9C, 82.10A, 82.10B, 82.10D, 82.14, 82.23A, 82.23C, e82.1, 83.4B, 84.1, 84.3E, 84.3G, 84.5, 84.12, e84.2A, e84.4B, 85.5, 85.19, 87.24C, e87.2B, e87.10E, 88.8B, 88.18, 91.1A, 91.1C, 91.1F, 91.1I, 91.9B, 91.19A, e91.10, 92.2, 92.3A, 92.11, e92.1, 93.2A, 93.2C, 93.2D, 93.3C, 93.4, 93.9B, 93.15A, 93.18C, e93.4, e93.9, e93.16, e93.20, 94.1, e94.2B, 96.4A, 96.4B, 96.8, e96.4, 97.6B, e97.4B, e97.5, 98.1B, 98.1D, 98.9, 99.5C, e99.2, 101.9B, 103.4A, 103.9, 103.10C, e103.10B, 104.4A, 104.14A, 104.20B, 104.20E, e104.17A, 105.4, 105.5E, 105.6, 105.7A, 105.9, 105.14, 105.15B, 105.18, 105.20C, e105.9, 106.13, 106.14, 106.16, 108.5A, 108.5D, 108.9D, 108.9E, 108.10B, 108.16B, 109.3B, 109.9A, 109.9G, 109.12A, 110.2, 110.7, 110.13B, 110.16B, 110.26, 111.2, 111.4A, 111.12, 111.18A, 111.21A, 111.24A, 111.30, 111.34A, 111.36, 111.37, e111.1, e111.4, e111.5, e111.10, e111.11, e111.12B, 112.1B, 112.6A, 112.8, 112.9A, 112.31A, 113.7, 113.9, 113.29B, e113.6B, e113.8, e113.11, 114.13A, 114.19, e114.8, e114.9, e114.14, e115.5A, 116.1, 116.20, 116.22, 116.24, e116.10, 117.9, e117.1, 118.6B, 118.6C, 118.8, e118.5, e120.12, e120.16, 121.1A, 122.4B, 122.4C, e122.1, e122.2, e122.3, 127.7D, 128.2, 128.3, 128.7B, 134.6.

The following figures were sourced from the **NYU Slide Collection**: 9.5E, e9.12, 10.8, 10.9, 11.9A, 11.13B, 13.2B, 16.7, 18.13, 24.2A, 24.7B, 26.3B, 29.8D, 29.8E, 30.7A, 38.8, 44.9B, 44.9D, e44.5A, 48.4A, 57.11A, 57.11C, 64.20A, 67.3A, 67.5A, 67.5B, 69.17B, 69.25, 70.13, 72.6, 74.20C, 74.24, 74.30A, 76.8A, 76.8B, 78.11B, 81.9A, 81.9B, 82.12, 87.2B, 87.3B, e87.10C, 93.15D, e93.24, 101.16B, 116.2, 116.17, 116.32, e116.1, e116.2, 130.6A.

The following figures and tables were sourced from the ***Dermatology Essentials*** book: 0.1, 0.8, e0.1, e0.2, Table 0.4, 6.2, 12.1, 12.3, 12.15, 13.4, e13.10, Table 13.3, 21.4, e21.2, e21.3, eTable 21.3, 24.19, Table 24.8, 25.1, 29.12, Table 29.8, Table 35.1, Table 35.2, 36.1, 38.1, 42.1, 43.2, Table 43.6, Table 43.8, Table 45.4, 51.2, 52.2, Table 53.1, 66.4, 69.1, 70.11, 70.17, 70.18, Table 70.8, e74.1, Table 74.3, Table 74.13, 75.1, Table 75.5, Table 78.3, Table 78.6, 80.13, 81.2, 87.1, 88.2, 101.1, 105.8, e108.21, Table 108.8, 111.1, 112.28, 117.1.

Acknowledgments

We are grateful to the authors for sharing their expertise and putting forth their best efforts to bring up-to-date educational material to the readers. As with any endeavor, it takes a village. Jennifer Shreiner, a fellow Pennsylvanian, was the heart and soul of the fifth edition of *Dermatology*. Her organizational skills, knowledge, work ethic, and can-do attitude combined with patience were remarkable. She kept us all sane albeit to a variable degree. Glenys Norquay and Joanna Souch had the equivalent of X-ray vision and could find the one error in a haystack of figures and tables. Their skills and attention to detail were very much appreciated. Anne Collett was a multi-tasker, coordinating updates to proofs while kind-heartedly chasing errant authors. Early on, Mary Hegeler got us on the right path and Charlotta Kryhl has been the glue for the project since the beginning. We also thank Kalman Watsky, MD, for all the beautiful photographs he has contributed over more than two decades.

PAST EDITORS

We would like to acknowledge and offer grateful thanks for the input of all previous editions' editors, without whom this new edition would not have been possible:

Warren R. Heymann, 3rd edition
Thomas D. Horn, 1st, 2nd editions
Joseph L. Jorizzo, 1st, 2nd, 3rd, 4th editions
Harvey Lui, 4th edition
Anthony J. Mancini, 1st, 2nd, 3rd editions
José M. Mascaro Jr., 1st edition
James W. Patterson, 3rd edition
Ronald P. Rapini, 1st, 2nd editions
Martin Röcken, 3rd edition
Stuart J. Salasche, 1st, 2nd editions
Jean-Hilaire Saurat, 1st edition
Thomas Schwarz, 2nd, 3rd, 4th editions
Georg Stingl, 1st, 2nd editions
Mary S. Stone, 2nd edition

Basic Principles of Dermatology 0

Introduction to Clinical Dermatology 1
The Role of Dermatopathology in Clinicopathologic Correlation . . . 12
Introduction to the Use of Dermoscopy (Dermatoscopy) 32
Introduction to Confocal Microscopy 39
Introduction to Artificial Intelligence 42

INTRODUCTION TO CLINICAL DERMATOLOGY

The skin represents the largest organ of the human body. The average adult has 1.75 m^2 (18.5 ft^2) of skin that contains a variety of complex adnexal structures, including hair follicles, nails, glands, and specialized sensory structures, all of which function in protection, homeostasis, and the transmission of sensation. Dermatology is the field of medicine that deals with the macroscopic study of skin, adjacent mucosa (oral and genital), and cutaneous adnexa, while dermatopathology deals with the microscopic study of these same structures. The two fields are closely allied, as they are complementary and requisite to one another.

Multiple studies have shown that dermatologists are the most effective diagnosticians of skin disease[1,2]. This enhanced acumen reflects experience in recognizing distribution patterns and configurations, as well as subtle variations in morphology and colors, in addition to appreciating associated histopathologic findings. This chapter serves as an introduction to classification schemas and to descriptive terminologies and diagnostic tools utilized in dermatology. It also highlights additional means for studying skin, including dermoscopy (dermatoscopy), artificial intelligence, and dermatopathology, with clinicopathologic correlation between macroscopic and microscopic findings.

Etiologic Premises

All students of dermatology, whether beginners or advanced scholars, require a conceptual framework upon which to organize thousands of skin diseases. A useful analogy is that of a tree, with a trunk, major branches, minor branches, twigs, and ultimately, leaves (Fig. 0.1). Instead of memorizing thousands of leaves, a logical, progressive movement along the limbs allows for a complete and sophisticated differential diagnosis.

Inflammatory versus neoplastic

An early and major "branch point" in classifying skin diseases is deciding if a skin condition is "neoplastic" (either benign or malignant) or "inflammatory" (either infectious or non-infectious) (see Fig. 0.1). However, an experienced clinician knows that one must consider possible diagnoses along multiple limbs before narrowing the differential diagnosis, because overlap and mimicry can occur. For example, mycosis fungoides, the most common form of cutaneous T cell lymphoma, is a clonal lymphoproliferative disorder (a "neoplasm"), yet its clinical presentation resembles an inflammatory disorder (Fig. 0.2), particularly in its early stages. Conversely, sarcoidosis is an inflammatory condition, yet it may present as an isolated infiltrated plaque or nodule that may mimic a neoplasm (Fig. 0.3).

Morphology

To an engineer or material scientist, the word "*morphology*" refers to the structure and appearance of a material without regard to function. In dermatology, the term refers to the general appearance of a skin lesion, irrespective of the etiology or underlying pathophysiology. For example, a small cutaneous blister is referred to as a "vesicle," regardless of whether it is due to an infectious process, such as herpes

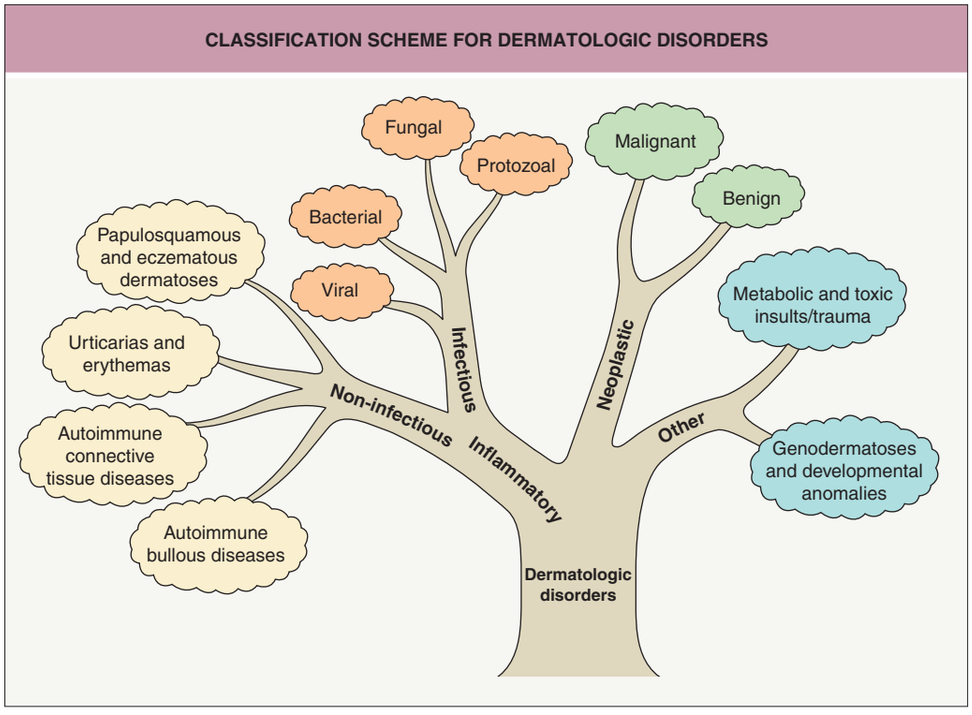

Fig. 0.1 Classification scheme for dermatologic disorders. The "trunk" of dermatology divides into the major etiologic "branches" of inflammatory, neoplastic, and other. Branches narrow and further subdivide, e.g. inflammatory into infectious and non-infectious. Branches ultimately terminate as clustered leaves, representing specific disorders.

Fig. 0.2 Mycosis fungoides, the most common form of cutaneous T cell lymphoma. Mycosis fungoides represents a neoplastic proliferation of monoclonal lymphocytes, but it presents clinically in a manner akin to that of inflammatory disorders. *Courtesy Lorenzo Cerroni, MD.*

Fig. 0.3 Sarcoidosis. It is an inflammatory disorder of uncertain etiology, most prevalent in African-Americans from the southern United States, but sarcoidosis can present as a papulonodule or infiltrated plaque, mimicking a neoplastic disorder.

Fig. 0.4 Herpes zoster, an infectious disease, versus dermatitis herpetiformis, an autoimmune bullous disease. While disparate in etiology, herpes zoster (**A**) and dermatitis herpetiformis (**B**) result in a similar morphology – cutaneous vesicles and bullae – but with different distribution patterns. *Courtesy Lorenzo Cerroni, MD.*

zoster, or an autoimmune process, such as dermatitis herpetiformis (Fig. 0.4). Proper use of morphologic terms establishes a structural framework for grouping skin diseases based upon their macroscopic appearances[3].

In essence, morphologic terms form a "native language" by which dermatologists, and other health professionals, communicate with each other to *describe* skin lesions. As such, they are key elements of our shared lexicon. Without a working knowledge of morphology, it is impossible to describe cutaneous observations in a consistent manner. Ergo, one of the initial steps in studying dermatology is to learn the basic morphologic definitions inherent to the specialty.

There exist both *primary* morphologic terms (Table 0.1), which refer to the most characteristic, representative, or native appearance of skin lesions (e.g. a "papule"), as well as *secondary* morphologic terms (Table 0.2), which augment or supplant primary morphologic terms. Secondary morphologic terms often reflect the effects of exogenous factors or temporal changes (e.g. "scales", "crusts") that evolve during the course of a skin disease.

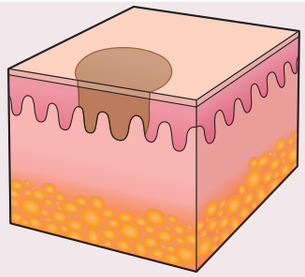
Secondary features must be considered when performing, or examining histologically, a biopsy of a skin lesion. An astute clinician will biopsy a lesion that is both "fresh" and well-developed as it most aptly demonstrates the primary pathologic process. Lesions with confounding secondary changes such as erosions, excoriations, and lichenification are avoided, if possible, as this allows the dermatopathologist the opportunity to evaluate the histologic features in their native state.

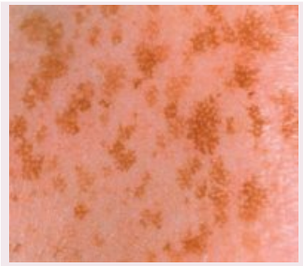
Lastly, the skin is a three-dimensional structure, and like cartographers who construct maps, there are accepted descriptors used by dermatologists to describe the topography of individual skin lesions. Examples include flat-topped (lichenoid), dome-shaped, verrucous, umbilicated, filiform, and pedunculated[3].

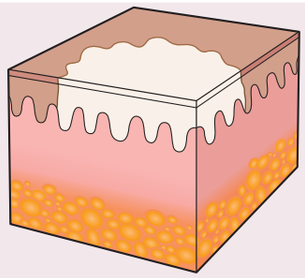
Palpation and appreciation of textural changes

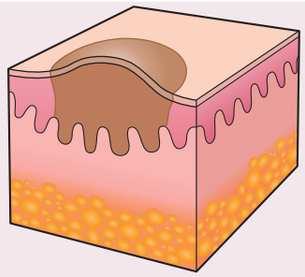
Any discussion of morphology must include textural change, and palpating a lesion often provides diagnostic clues. In dermatology, palpation can prove useful in several ways. Firstly, it helps in making a distinction amongst various morphologies (see Table 0.1). For example, the key difference between macules and papules, or patches versus plaques, is that macules and patches are flush with the surrounding skin and cannot be appreciated by palpation. On the other hand, papules and plaques, by definition, must be palpable (Table 0.3). Secondly, palpation may augment understanding of a disease process that is otherwise unimpressive or nonspecific.

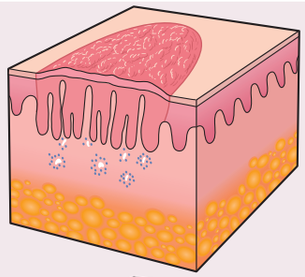
For example, in morphea, an autoimmune connective tissue disease that leads to sclerotic collagen in the dermis, the skin feels indurated (firm), yet only mild hyperpigmentation may be evident by visual inspection. The same is true for other fibrotic diseases such as systemic sclerosis. Likewise, atrophy, be it epidermal, dermal or subcutaneous,

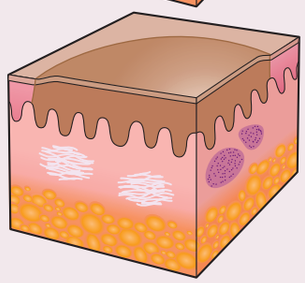


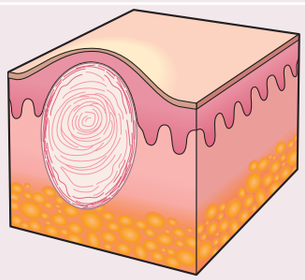








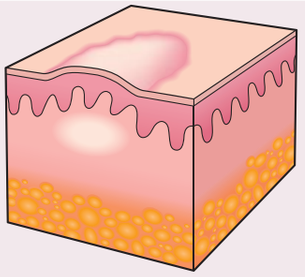


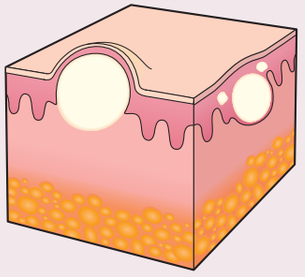


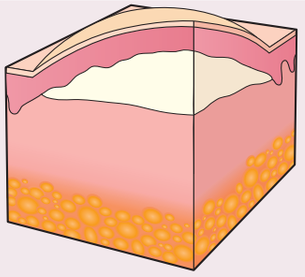
PRIMARY LESIONS – MORPHOLOGICAL TERMS				
Term	**Clinical features**		**Clinical example**	**Clinical disorders**
Macule	• Flat (non-palpable), circumscribed, differs in color from surrounding skin • <1 cm in diameter • Often hypo- or hyperpigmented, but also other colors (e.g. pink, red, violet) • It can be round, oval, or irregular in outline		 Solar lentigines	• Ephelid (freckle) • Lentigo • Idiopathic guttate hypomelanosis • Petechiae • Flat component of viral exanthems
Patch	• Flat (non-palpable), circumscribed, differs in color from surrounding skin • >1 cm in diameter • Often hypo- or hyperpigmented, but also other colors (e.g. blue, violet)		 Vitiligo	• Vitiligo • Melasma • Dermal melanocytosis (Mongolian spot) • Café-au-lait macule • Nevus depigmentosus • Solar purpura • Port-wine birthmark (early)
Papule	• Elevated (palpable), circumscribed • <1 cm in diameter • Elevation due to increased thickness of the epidermis and/or cells or deposits within the dermis • May have secondary changes (e.g. scale, crust) • The profile can be flat-topped (lichenoid), dome-shaped, umbilicated, smooth, or verrucous		 Seborrheic keratosis	• Seborrheic keratosis • Cherry angioma • Compound or intradermal melanocytic nevus • Verruca • Molluscum contagiosum • Fibrous papule (angiofibroma) • Lichen nitidus • Elevated component of viral exanthems • Small vessel vasculitis
Plaque	• Elevated (palpable), circumscribed • >1 cm in diameter • Elevation due to increased thickness of the epidermis and/or cells or deposits within the dermis • May have secondary changes (e.g. scale, crust) • Occasionally, a plaque is palpable but not elevated, as in morphea	 	 Psoriasis  Sarcoidosis	*Primarily epidermal* • Psoriasis • Lichen simplex chronicus • Nummular dermatitis *Dermal* • Granuloma annulare • Sarcoidosis • Hypertrophic scar, keloid • Morphea • Lichen sclerosus *Both epidermal and dermal* • Discoid lupus erythematosus
Nodule	• Palpable, circumscribed • Larger volume than papule, usually >1 cm in diameter • Can be compressible, soft, rubbery, or firm to palpation • Involves the dermis and/or the subcutis • Greatest portion may be beneath the skin surface or exophytic		 Epidermoid (infundibular) cyst	• Epidermoid or tricholemmal cyst • Lipoma • Rheumatoid nodule • Metastasis • Neurofibroma • Panniculitis, e.g. erythema nodosum • Lymphoma cutis

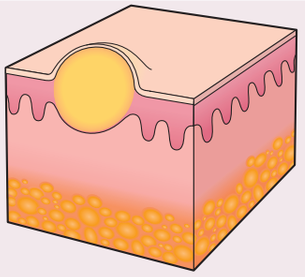
Table 0.1 Primary lesions – morphological terms.

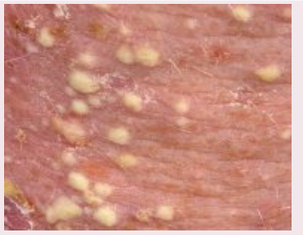
Continued









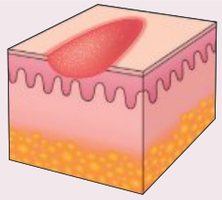


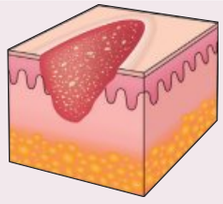
PRIMARY LESIONS – MORPHOLOGICAL TERMS				
Term	**Clinical features**		**Clinical example**	**Clinical disorders**
Wheal	• Transient elevation of the skin due to dermal edema • Often pale centrally with an erythematous rim		 Acute annular urticaria	• Urticaria
Vesicle	• Elevated, circumscribed • <1 cm in diameter • Filled with fluid – clear, serous, or hemorrhagic • May become pustular, umbilicated, or an erosion		 Herpes simplex	• Herpes simplex • Varicella or zoster • Acute allergic contact dermatitis • Dyshidrotic eczema • Dermatitis herpetiformis
Bulla	• Elevated, circumscribed • >1 cm in diameter • Filled with fluid – clear, serous, or hemorrhagic • May become an erosion		 Bullous pemphigoid	• Friction blister • Thermal burn (second-degree) • Bullous insect bite reactions • Bullous pemphigoid • Linear IgA bullous dermatosis • Bullous fixed drug eruption • Coma bulla • Edema bulla
Pustule	• Elevated, circumscribed • Usually <1 cm in diameter • From its onset, filled with purulent fluid • May be infectious or sterile		 Folliculitis	*Follicularly centered* • Folliculitis • Acne vulgaris *Non-follicularly centered* • Pustular psoriasis • Acute generalized exanthematous pustulosis • Subcorneal pustular dermatosis

Table 0.1 Primary lesions – morphological terms. *Some photographs courtesy Jean L. Bolognia, MD; Lorenzo Cerroni, MD; Louis A. Fragola, Jr, MD; Julie V. Schaffer, MD; Kalman Watsky, MD.*

SECONDARY FEATURES – MORPHOLOGICAL TERMS			
Feature	**Description**	**Clinical example**	**Disorders**
Crust	• Dried serum (serous), blood (hemorrhagic), or pus on the surface of the skin • May include bacteria (usually *Staphylococcus*)	 Secondarily infected hand dermatitis	• Eczema/dermatitis (multiple types) • Impetigo • Later phase of herpes simplex, varicella, or zoster • Erythema multiforme
Scale	• Hyperkeratosis • Accumulation of stratum corneum due to increased proliferation and/or delayed desquamation • Represents a primary rather than a secondary feature in ichthyoses	 Psoriasis	• Psoriasis (silvery [micaceous] scale) • Tinea (leading scale) • Erythema annulare centrifugum (trailing scale) • Pityriasis (tinea) versicolor (powdery [furfuraceous] scale) • Actinic keratoses (gritty scale) • Pityriasis rosea (peripheral collarette and central scale)

Table 0.2 Secondary features – morphological terms.





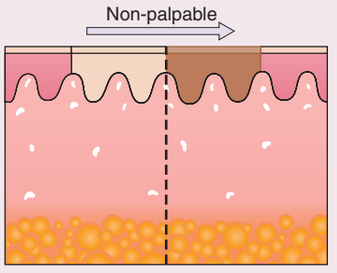
SECONDARY FEATURES – MORPHOLOGICAL TERMS			
Feature	**Description**	**Clinical example**	**Disorders**
Fissure	• Linear cleft in skin • Often painful • Results from marked drying, skin thickening, and loss of elasticity	 Hand dermatitis	• Angular cheilitis • Hand dermatitis • Sebopsoriasis (intergluteal fold) • Irritant cheilitis • Lichen sclerosus (perineum)
Excoriation	• Exogenous injury to all or part of the epidermis (epithelium) • May be linear or punctate	 Neurotic excoriations	• A secondary feature of pruritic conditions, including arthropod bites and atopic dermatitis • Neurotic excoriations • Acne excoriée
Erosion	• Partial loss of the epidermis (epithelium) • A superficial moist, oozing, and/or crusted lesion	  Pemphigus foliaceus	• Impetigo • Friction • Trauma • Pemphigus, vulgaris, and foliaceus
Ulceration	• Full-thickness loss of the epidermis (epithelium) • May have loss of the dermis or even subcutis • The size, shape, and depth should be described as well as the characteristics of the border, base, and surrounding skin • Usually heals with a scar	  Pyoderma gangrenosum	• Venous (stasis) ulcer • Neuropathic ulcer • Arterial ulcer • Decubitus ulcer • Aphthous ulcer • Pyoderma gangrenosum • Ecthyma • Ecthyma gangrenosum
Infarct	• Ischemia of tissue • Color can vary from gray–white to purple to black	 Antiphospholipid syndrome	• Can be due to vascular compromise (e.g. atherosclerosis, calciphylaxis), thrombosis, vasculitis, emboli (infectious or non-infectious), or vasospasm (see Table 0.5)
Atrophy	• Epidermal atrophy – thinning of the epidermis, leading to wrinkling and a shiny appearance • Dermal atrophy – loss of dermal collagen and/or elastin, leading to a depression (see Table 0.3)	 Striae	• Lichen sclerosus • Poikiloderma • Striae • Anetoderma • Focal dermal hypoplasia (Goltz syndrome)

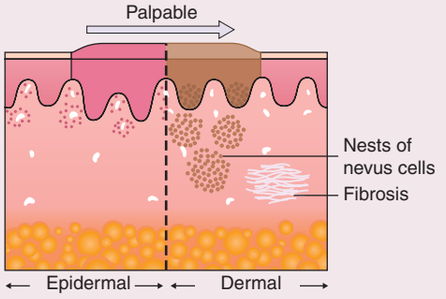
Table 0.2 Secondary features – morphological terms.

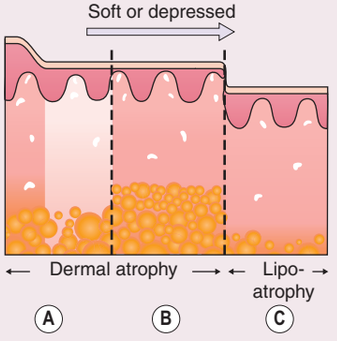
Continued

SECONDARY FEATURES – MORPHOLOGICAL TERMS			
Feature	**Description**	**Clinical example**	**Disorders**
Lichenification	• Accentuation of natural skin lines, reflecting thickening (acanthosis) of the epidermis • Often due to rubbing	 Lichen simplex chronicus	• Lichen simplex chronicus, isolated or superimposed on a pruritic condition, e.g. atopic dermatitis

Table 0.2 Secondary features – morphological terms. *Some photographs courtesy Lorenzo Cerroni, MD; Louis A. Fragola, Jr, MD; Jeffrey P. Callen, MD; Luis Requena, MD.*







USE OF PALPATION IN DEFINING CUTANEOUS LESIONS		
Types of lesion		**Examples**
Macules & patches (non-palpable)		• Solar lentigines • Idiopathic guttate hypomelanosis • Melasma • Vitiligo • Petechiae • Dermal melanocytosis
Papules & plaques (palpable)		• Psoriasis • Lichen planus • Dermatitis • Intradermal or compound melanocytic nevus • Hypertrophic scar, keloid • Morphea
Atrophy – dermal & subcutaneous		Ⓐ Anetoderma Ⓑ Focal dermal hypoplasia (Goltz syndrome) Ⓒ Lipoatrophy due to corticosteroid injections Lipoatrophy due to panniculitis

Table 0.3 Use of palpation in defining cutaneous lesions.

serves as a diagnostic clue (Fig. 0.5). Lastly, purpura is often classified as palpable or non-palpable, and this division can imply different underlying etiologies (e.g. small vessel vasculitis is aligned more with palpable purpura). Examples of useful distinctions that can be gleaned via palpation are outlined in Table 0.4.

Color

The color of skin lesions provides clues as to the nature of the disease process. Sometimes the perception of color may be modified by palpation (see Table 0.4). For example, while many dermatologic processes appear erythematous (red to purple) in color, it is important to ascertain whether this color is "blanchable" (i.e. disappears with pressure), which suggests it is due to vasodilation, or "non-blanchable," which suggests it is due to extravasation of erythrocytes into the skin. Exogenous sources of pigment, such as topical medicaments, oral drugs, and other ingestants, can also lead to skin discoloration. Table 0.5 lists frequently observed colors of skin lesions and associated disorders.

Variation in skin color within the human population

Many racial and ethnic descriptors are used in common parlance, including African, African-American, Asian, Middle Eastern, Northern European, Southern European, Native American, Pacific Islander, and Hispanic, to describe individuals with similar cutaneous characteristics and heritage. Yet even within racial/ethnic groups, gradations of skin pigmentation exist. Sometimes the term "skin of color" is used to describe all skin tones darker than those of white skin[4]. However, this term encompasses more than skin color and its response to ultraviolet

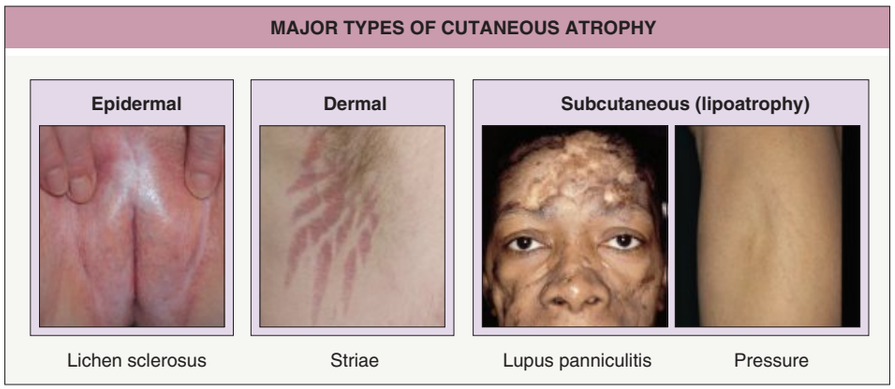


Fig. 0.5 Major types of cutaneous atrophy. *Photographs courtesy Jean L. Bolognia, MD, and Fenella Wojnarowska, MD.*

PALPATION OF CUTANEOUS LESIONS
• Soft (e.g. intradermal nevus) versus firm (e.g. dermatofibroma) versus hard (e.g. calcinosis cutis, osteoma cutis)
• Compressible (e.g. venous lake) versus non-compressible (e.g. fibrous papule)
• Tender (e.g. inflamed epidermoid inclusion cyst, angiolipoma, leiomyoma) versus non-tender (e.g. intradermal melanocytic nevus)
• Blanchable (e.g. erythema due to vasodilation) versus non-blanchable (e.g. purpura)
• Rough (e.g. actinic keratosis) versus smooth (e.g. fibrous papule)
• Mobile (e.g. epidermoid cyst) versus fixed to underlying structures (e.g. soft tissue sarcoma)
• Dermal (e.g. dermatofibroma) versus subcutaneous (e.g. erythema nodosum)
• Temperature – normal versus warmer (e.g. cellulitis) versus cooler (e.g. Raynaud phenomenon)
• Other, e.g. thrill, pulsatile

Table 0.4 Palpation of cutaneous lesions.

irradiation, as is assessed by the Fitzpatrick Scale (skin phototypes I–VI; Table 0.6). It also refers to other shared characteristics, such as hair color, hair texture, and even cutaneous reaction patterns to inflammation (e.g. follicular accentuation) or injury. The practice of dermatology requires a solid understanding and appreciation of the differences in clinical features (e.g. hues of red) amongst individuals with different skin pigmentation – the importance of this cannot be overstated[5].

Variations in skin color are a result of differences in the amount and distribution of melanin within epidermal melanocytes and keratinocytes[6], rather than the number of melanocytes (see Ch. 65). The ratio of eumelanin (brown–black) to pheomelanin (yellow–red) also influences skin color, with pheomelanin the predominant pigment in those with freckles and red hair. Exposure to ultraviolet radiation also impacts melanin production (tanning).

Mucocutaneous pigmentation influences the prevalence of certain cutaneous findings and disorders. For example, individuals with darker skin phototypes are more likely to develop longitudinal melanonychia (see Ch. 71)[7,8], pigmentation of the oral mucosa[9], persistent postinflammatory hyperpigmentation (see Ch. 67), and pigmentary demarcation lines[10] (Futcher lines or Voigt lines; see Fig. 67.12). Whether postinflammatory hypopigmentation[11] is more common or simply more apparent is a matter of debate. In addition, discoid lupus erythematosus, sarcoidosis, and keloids are seen more often in patients with darkly pigmented skin and African ancestry, but there is no known relationship of these disorders to melanocyte function.

There can also be differences in the physiologic properties of the skin. For example, the stratum corneum of black skin often retains more layers and is more compact and cohesive than that of white skin. In addition, darker skin produces less vitamin D_3 in response to equivalent amounts of sunlight, and this is postulated to have been a driving force in the evolution of more lightly pigmented skin as early humans migrated away from the equator[12].

Perhaps the most important point to remember is that erythema (redness) can be difficult to appreciate in darkly pigmented skin. Erythema is caused by vasodilation and/or increased blood flow within the dermis, and if the epidermis is deeply pigmented, the red hues of oxyhemoglobin may be less apparent. For this reason, diseases often described as decidedly erythematous (e.g. cellulitis) or violaceous (e.g. lichen planus) may have a different hue in darker skin types (Fig. 0.6)[13]. When performing diagnostic procedures that depend upon the development of overt erythema, such as patch testing for the evaluation of allergic contact dermatitis, appreciation of the influence of epidermal pigment is important. Lastly, cyanosis (blue hues indicative of poor oxygenation and a critical clinical sign) may be more difficult to appreciate when the skin is darkly pigmented.

Configuration and Distribution

After carefully considering the morphology and color of skin lesions, the dermatologist must analyze two closely related properties – configuration and distribution – in order to generate a differential diagnosis. For example, pruritic and fragile vesicles on the elbows and knees prompt consideration of dermatitis herpetiformis, whereas grouped vesicles on an erythematous base, confined to a single dermatome, mandate consideration of herpes zoster (see Fig. 0.4A) or zosteriform herpes simplex.

Configuration

The configuration or arrangement of skin lesions can provide important diagnostic clues. Examples include *annular* (e.g. tinea corporis, granuloma annulare; see Ch. 19), *serpiginous* (e.g. cutaneous larva migrans), *clustered/grouped* (e.g. piloleiomyomas, herpetiform vesicles), *reticulated* (e.g. erythema ab igne), and *retiform* (e.g. purpura fulminans, purpura due to calciphylaxis [Fig. 0.7]; see Ch. 23). The latter pattern reflects occlusion of cutaneous vasculature[14].

It is important to determine if the lesions have a *linear* configuration (Fig. 0.8). They may follow the lines of Blaschko, which reflect patterns of embryonic development (see Fig. 62.1)[15], or lesions may be confined to a dermatome, which represents an area of skin innervated by a single spinal nerve (see Fig. 80.13). Irrespective of whether lesions are along the lines of Blaschko (e.g. epidermal nevi) or are in a dermatomal pattern (e.g. herpes zoster [see Fig. 0.4A]), there is often characteristic midline demarcation. A linear arrangement can also result from trauma-induced Koebner phenomenon (an isomorphic response [Table 0.7]), as in vitiligo, lichen planus (Fig. 0.9), and psoriasis[16,17], or trauma-induced autoinoculation, as in verrucae vulgares or verrucae planae. Linear lesions are often seen in acute allergic contact dermatitis due to plants (e.g. poison ivy), reflecting a brushing of branches and leaves against skin. Lastly, papulonodules due to a range of infectious agents can align along lymphatic vessels in a sporotrichoid pattern (see Ch. 77).

On occasion, cutaneous lesions have an unusual, even "unnatural", shape that corresponds to an external (exogenous) insult, such as allergic or irritant contact dermatitis (Fig. 0.10), an accidental or purposeful injury (see Ch. 90)[18], or even ritualistic medicinal practices (e.g. "cupping" or "coining"; see Ch. 133).

Distribution

Stepping back and observing the anatomic distribution of skin lesions can also prove useful. For example, plaques of psoriasis often favor *extensor* surfaces (e.g. elbows and knees) while lichenified plaques of atopic dermatitis favor *flexural* surfaces in older children and adults

COLOR AS A CLUE TO THE CLINICAL DIAGNOSIS

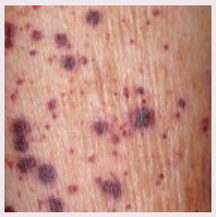
Color	Examples of diseases with this color
Pink/red Erythema (pink to red–brown, depending upon the skin phototype)  Morbilliform (exanthematous) drug eruption	• Dermatitis • Psoriasis • Morbilliform drug eruption • Viral exanthem • Any condition that causes vasodilation

Black
 
Necrosis secondary to vasculopathy from levamisole-contaminated cocaine
	• Necrosis of the skin due to:
	  • Vasculitis (e.g. granulomatosis with polyangiitis)
	  • Thrombosis (e.g. DIC, monoclonal cryoglobulinemia)
	  • Emboli (e.g. ecthyma gangrenosum)
	  • Vasospasm (e.g. severe Raynaud phenomenon)
	  • Vascular compromise (e.g. atherosclerosis, calciphylaxis)
	• Eschar (e.g. anthrax)
	• Cutaneous melanoma
	• Traumatic tattoo (e.g. asphalt)

Blue (ceruloderma)  Dermal melanocytosis	• Dermal melanocytosis (e.g. Mongolian spot, nevus of Ota) • Dermal melanocytoma (e.g. blue nevus) • Cyanosis • Ecchymosis • Venous congestion (e.g. venous malformation) • Drugs/deposits (e.g. minocycline, traumatic tattoo)

Brown
 
Melasma
	• Pigmented lesions
	  • Lentigo
	  • Seborrheic keratosis
	  • Junctional, compound, or congenital melanocytic nevus
	  • Café-au-lait macule
	  • Dermatofibroma
	  • Melanoma
	  • Pigmented AK, Bowen disease
	• Postinflammatory hyperpigmentation – epidermal (see Ch. 67)
	• Melasma
	• Phytophotodermatitis
	• Drug-induced hyperpigmentation (e.g. cyclophosphamide)
	• Metabolic (e.g. Addison disease, hemochromatosis)

Gray  Argyria	• Postinflammatory hyperpigmentation – dermal (e.g. erythema dyschromicum perstans; see Ch. 67) • Drugs/deposits (e.g. argyria, chrysiasis) • Combined melanocytic nevus • Traumatic tattoo • See Blue (above)



Color	Examples of diseases with this color
Purple (violaceous)  Palpable purpura of cutaneous small vessel vasculitis	• Purpura, non-palpable (e.g. solar purpura) • Purpura, palpable (e.g. small vessel vasculitis) • Vascular neoplasm (e.g. angiokeratoma, angiosarcoma) • Lichen planus • Lymphoma cutis • Pyoderma gangrenosum – border • Morphea – border (lilac)
White  Calcinosis cutis (systemic sclerosis)	• Absence of melanocytes or melanin production (e.g. vitiligo, piebaldism, OCA1A) • Scarring (e.g. scarring in discoid lupus erythematosus) • Vasospasm (e.g. Raynaud phenomenon, nevus anemicus) • Deposits (e.g. calcinosis cutis, gouty tophi) • Macerated stratum corneum – mucosal surfaces (e.g. leukoplakia)
Green  Onycholysis with secondary *Pseudomonas* infection	• *Pseudomonas* infection • Tattoo • Chloroma • Green hair due to copper deposits
Orange–red (salmon)  Pityriasis rubra pilaris with islands of sparing	• Pityriasis rubra pilaris • Mycosis fungoides (sometimes)
Yellow  Xanthelasma	• Solar elastosis • Carotenoderma • Xanthomas (e.g. eruptive, xanthelasma) • Xanthogranulomas • Adnexal tumors and hyperplasias with sebaceous differentiation • Necrobiosis lipoidica • Capillaritis (yellow–brown background) • Deposits/drugs (e.g. tophi, quinacrine)

Table 0.5 Color as a clue to the clinical diagnosis. AKs, actinic keratoses; DIC, disseminated intravascular coagulation; OCA1A, oculocutaneous albinism type 1A.

FITZPATRICK SCALE OF SKIN PHOTOTYPES		
Skin phototype	**Skin color**	**Response to UV irradiation**
I	White	Always burns, does not tan
II	White	Burns easily, tans with difficulty
III	Beige	Mild burns, tans gradually
IV	Brown	Rarely burns, tans easily
V	Dark brown	Very rarely burns, tans very easily
VI	Black	Never burns, tans very easily

Table 0.6 Fitzpatrick scale of skin phototypes.

(e.g. the antecubital and popliteal fossae; Table 0.8). However, to complicate matters, there is an "inverse" pattern of psoriasis in which lesions are present in major body folds, i.e. in flexural areas (see Ch. 8). Langer cleavage lines refer to natural skin tension lines used to guide the orientation of surgical excisions. The long axis of oval lesions of pityriasis rosea[19] and erythema dyschromicum perstans may follow these cleavage lines, and this pattern is often most apparent on the posterior trunk.

A *seborrheic* distribution pattern includes the head and neck as well as the upper trunk; it reflects areas rich in sebaceous glands. Seborrheic dermatitis, acne vulgaris, and pityriasis versicolor often have a seborrheic distribution pattern. The term "*photodistribution*"

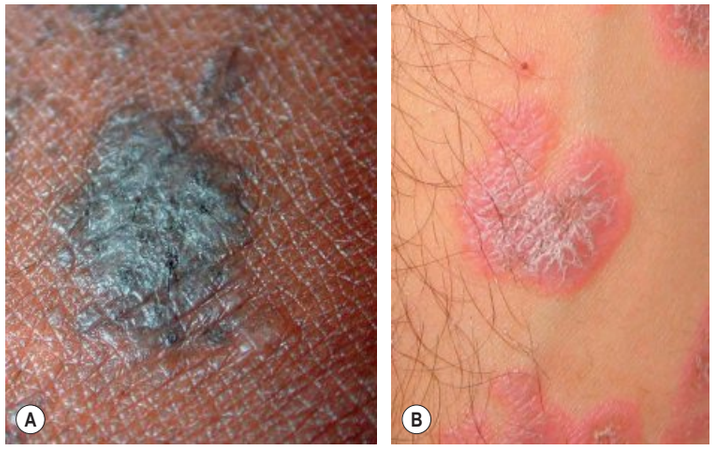

Fig. 0.6 Lichen planus presents differently in darkly pigmented versus lightly pigmented skin. A, B The erythematous to violaceous hue seen in lightly pigmented skin is more muted in darkly pigmented skin and the lesions appear brown–black in color. Wickham striae (lacy white pattern) are more easily seen in **B**.

CLINICAL ENTITIES THAT COMMONLY DISPLAY THE KOEBNER PHENOMENON (ISOMORPHIC RESPONSE)
• Psoriasis
• Vitiligo
• Lichen planus
• Lichen nitidus
• Cutaneous small vessel vasculitis
• Still disease

Table 0.7 Clinical entities that commonly display the Koebner phenomenon (isomorphic response). This is to be distinguished from *autoinoculation* or pseudo-Koebner phenomenon that is seen with verrucae or mollusca as well as *Wolf isotopic response* where a second skin disease appears at the site of an initial unrelated and often healed skin disease (e.g. granuloma annulare at the site of healed herpes zoster) or *pathergy*.

MAJOR DISTRIBUTION PATTERNS
Disseminated vs localized vs solitary
Unilateral vs bilateral
Symmetric vs asymmetric
Sun-exposed sites vs sun-protected sites
Flexural vs extensor surfaces
Intertriginous/large body folds
Acral (hands, feet, ears, nose)
Palmoplantar
Seborrheic region (head and neck, upper trunk)
Periorificial
Mucosal (mouth, anogenital)
"Linear" – also considered a configuration – see Fig. 0.9

Table 0.8 Major distribution patterns. Occasionally, the pattern represents a *locus minoris resistentiae* (see text).

Fig. 0.9 Koebernization (isomorphic response) of lichen planus secondary to trauma. As a result, the lesions have a linear configuration.

Fig. 0.10 Allergic contact dermatitis to a para-phenylenediamine-based ("black henna") temporary tattoo. The shape of the lesion clearly suggests an exogenous insult/etiology. *Courtesy Colby Evans, MD.*

describes an accentuation of lesions in areas exposed to ultraviolet irradiation. Photodermatoses include polymorphic light eruption, phototoxic drug reactions (e.g. to doxycycline), and subacute cutaneous lupus erythematosus. Of note, sometimes a disorder will display a combination of distribution patterns; for example, in dermatomyositis, lesions can be photodistributed and involve extensor surfaces (e.g. elbows, knees).

In addition to differences in the color of inflammatory lesions, individuals with darkly pigmented skin also have an increased frequency of several cutaneous disorders (see section on Color) and certain types of reaction and distribution patterns[20]. Examples of these reaction patterns include papular eczema and a follicular accentuation of atopic dermatitis and pityriasis versicolor, as well as an annular configuration of seborrheic dermatitis and facial secondary syphilis. With regard to distribution, pityriasis rosea often assumes an "inverse" pattern, in which lesions occur primarily in the axillae and groin rather than on the trunk. Although underlying pathomechanisms are not known, it is important to be aware of their occurrence[20].

Sometimes a distribution pattern is better explained by the phenomenon of *locus minoris resistentiae*, in which certain anatomic sites are more vulnerable than others to a particular disease process[21]. Examples would be cutaneous infections in a lymphedematous limb or asteatotic eczema within a skin graft site. There is also the poorly understood phenomenon of *Wolf isotopic response*, in which a second condition, such as granulomatous dermatitis or leukemia cutis, occurs preferentially in the site of a prior healed process (often herpes zoster; see Table 80.7)[22].

Augmented Examination – Wood's Lamp and Dermoscopy

A Wood's lamp emits primarily ultraviolet A radiation with a peak wavelength of 365 nm. It is often used to assist in the diagnosis of pigmentary disorders and infectious diseases (Table 0.9)[23,24]. A Wood's lamp examination is performed in a dark room, with the lamp held 4–5 inches from the area that is to be illuminated. After the target absorbs the UVA radiation, there is energy loss and as a result, the secondary emission is within the visible range due to its longer wavelength (with less energy). Dermoscopy is discussed in detail later in this chapter.

Temporal Course

Central to any medical history, including that of cutaneous disorders, is the temporal course. The patient should be queried as to duration and relative change in intensity and/or distribution over time. For example, there are some dermatoses that have a cephalocaudal progression over time, such as measles and pityriasis rubra pilaris. Of course, the time course is more prolonged in the latter as compared to the former.

The dermatologist is at an advantage because the skin is so accessible. Information provided by the patient can be readily compared to the physical examination. With experience, a dermatologist can usually determine by observation if cutaneous lesions are acute, subacute, or chronic. As an example, scale (not to be confused with crust) reflects parakeratosis, and due to epidermal transit time, it requires 2 weeks to develop. Intact tense bullae are rarely more than a week old. Lichenification, i.e. thickening of the skin with accentuation of normal skin markings, takes weeks to months to develop. If lichenification is present, the lesion has not appeared acutely, despite what the patient may believe.

In otherwise healthy individuals, there are several diseases whose cutaneous manifestations are often acute in nature, in particular urticaria, morbilliform drug eruption, viral exanthem, acute allergic or irritant contact dermatitis, and pityriasis rosea. This does not mean these skin diseases require emergent management, but rather that the rashes appear abruptly and are distinguished, particularly from neoplasms or chronic dermatoses, by temporal acuity. Of note, sometimes a more serious and potentially life-threatening cutaneous disease may present with skin findings that mimic a more common and less serious disorder, especially early on.

WOOD'S LAMP EXAMINATION OF THE SKIN	
Disorder/infection/colonization	**Fluorescent color/clinical findings**
Pigmentary disorders	
Vitiligo	Chalk-white to dull bluish-white (fluorescence of dermal collagen observed due to a marked decrease or absence of melanin within the epidermis)
Ash leaf spot	Enhancement of hypopigmentation
Hyperpigmentation due to an increase in:	
• epidermal melanin	Enhancement of brown color
• dermal melanin	Difference in color of lesional vs non-lesional skin becomes less obvious
Bacterial infections/colonizations	
Pseudomonas aeruginosa	Green
Corynebacterium minutissimum	Coral red
Cutibacterium (formerly *Propionibacterium*) *acnes*	Orange–red (in comedones)
Fungal infections	
Pityriasis (tinea) versicolor due to *Malassezia* spp.	Yellowish-white, yellow–green, golden, copper–orange
Tinea capitis due to *Microsporum* spp.	Blue–green to yellow–green
Favus due to *Trichophyton schoenleinii*	Blue–white

Table 0.9 Wood's lamp examination of the skin.

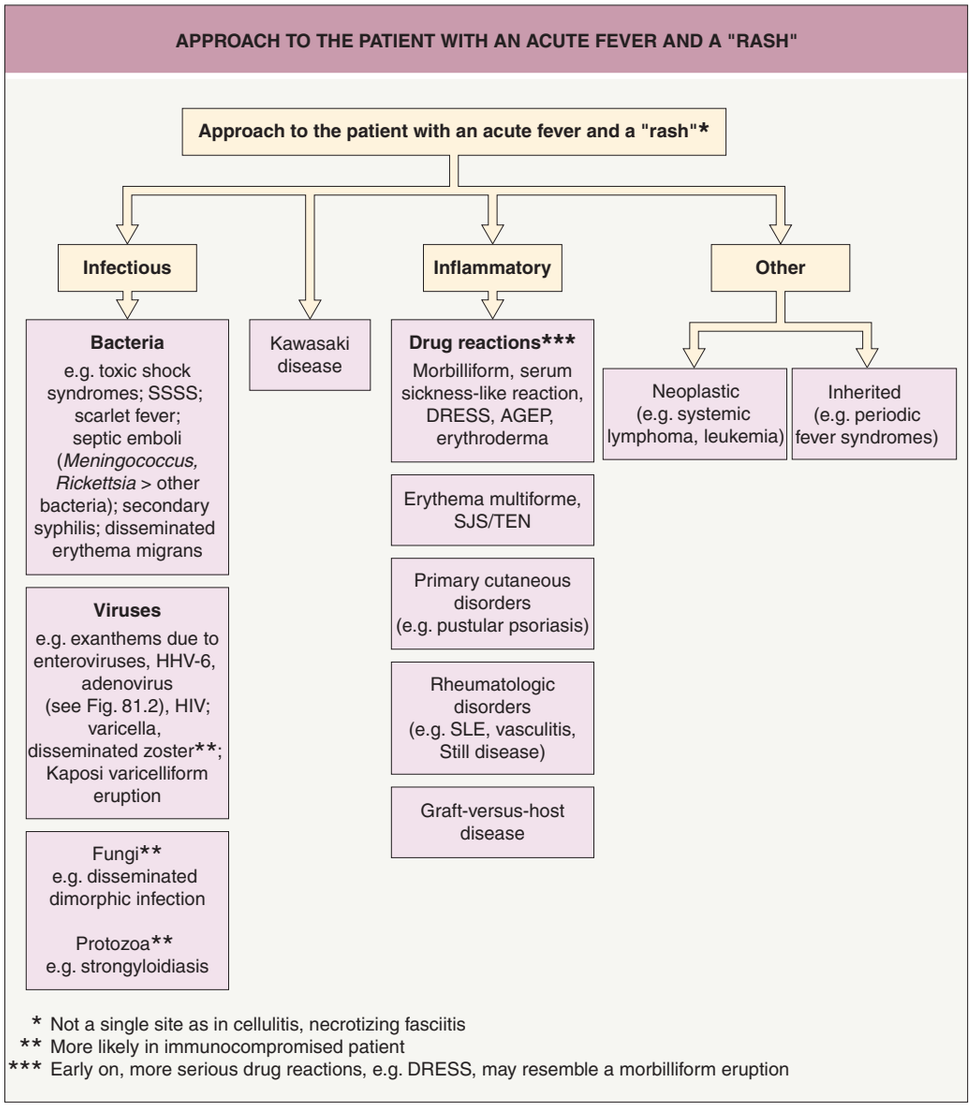

Fig. 0.11 Approach to the patient with an acute fever and a "rash." AGEP, acute generalized exanthematous pustulosis; DRESS, drug reaction with eosinophilia and systemic symptoms (also referred to as drug-induced hypersensitivity syndrome [DIHS]); HHV, human herpes virus; HIV, human immunodeficiency virus; SJS, Stevens–Johnson syndrome; SLE, systemic lupus erythematosus; SSSS, staphylococcal scalded skin syndrome; TEN, toxic epidermal necrolysis.

Finally, while emergencies in dermatology are uncommon, there are a few illnesses, particularly those that present with a rash and fever, which are true emergencies and must be recognized promptly and treated accordingly. Examples include Stevens–Johnson syndrome, toxic epidermal necrolysis, Kawasaki disease, meningococcemia (including purpura fulminans), Rocky Mountain spotted fever, necrotizing fasciitis, and endocarditis with cutaneous manifestations. An approach to critical dermatologic emergencies that present with a fever and rash is outlined in Fig. 0.11.

The next two sections of this introductory chapter focus upon basic principles of dermatopathology and dermoscopy, respectively. It is important to remember all diagnostic techniques (unaided clinical examination, histologic examination, dermatoscopy, confocal microscopy, and imaging, including ultrasound [Fig. 0.12]) are complementary. In other words, synergistic strength and clinicopathologic correlation are achieved when the techniques are used in combination. As a corollary, using any one technique, to the exclusion of the others, may be misleading and result in misdiagnosis.

THE ROLE OF DERMATOPATHOLOGY IN CLINICOPATHOLOGIC CORRELATION

Dermatopathology, the study of skin under the microscope, is uniquely related to the study of clinical dermatology, for few other medical specialties place so much emphasis on *both* the clinical and the histologic features of diseases within their realm[25]. However, this union exists not only because of overlapping subject matter, but because dermatology and dermatopathology both rely heavily upon careful observation and pattern recognition. In addition, clinical dermatology represents the "gross macroscopy" of dermatopathology, as clinical examination can be regarded akin to gross examination of biopsy specimens in other organs.

Experienced clinicians may anticipate associated histologic findings as they examine a cutaneous lesion or eruption (e.g. hyperkeratosis and/or parakeratosis when scale is present clinically, or dermal hemorrhage when there is purpura clinically). As a result, a sophisticated differential diagnosis often accompanies a skin biopsy performed by a dermatologist. Moreover, when the microscopic features are clearly delineated in a histopathology report, an experienced dermatologist can utilize clinicopathologic correlation to arrive at a final diagnosis. In a similar fashion, an experienced dermatopathologist can utilize clinical pictures to arrive at a final pathological diagnosis.

The Skin Biopsy

In no other field of medicine is the tissue of interest so readily accessible for histologic analysis. As a result, performing a skin biopsy is an integral component of medical decision-making in dermatology. A skin biopsy may be performed for a multitude of reasons, including:

- uncertainty about the clinical diagnosis
- to investigate a poor response to therapy
- to exclude or investigate the evolution of one condition into another, or
- to investigate symptoms in the absence of clinically recognizable disease.

Regardless of the rationale for performing a skin biopsy, the securing of appropriate tissue involves more than the mere mechanical procurement. Instead, a multistep process is executed, with forethought, precision and care, in order to maximize diagnostic utility[26]. Also, because a skin biopsy is often just a small sampling of a larger process, it may not always be representative of the entire disease state. Inappropriate technique or poor tissue handling may seriously limit the diagnostic yield of a skin biopsy; accordingly, clinicians must have an appreciation of the principles of histologic examination.

Site selection

Often, the first step in performing a biopsy is to identify an unadulterated *primary lesion*. Lesions with obfuscating secondary features, such as those resulting from rubbing or traumatic injury (e.g. lichenification, excoriations) or other superimposed processes (e.g. crusting and impetiginization), should be avoided, unless the purpose of the biopsy is to prove existence of such confounders.

A well-developed, "fresh" lesion is typically chosen for biopsy. Such sampling is premised on an assumption that it will demonstrate the most diagnostic histopathology. Immature lesions may not yet manifest characteristic histopathologic changes, and older lesions may be compromised by secondary features. Of course, there are exceptions to this general principle, such as the sampling of early lesions of cutaneous small vessel vasculitis (<24 hours old) or immunobullous diseases, especially when performing direct immunofluorescence.

While specimens are often taken from the center of a primary lesion, exceptions to this guideline exist, particularly in the case of bullae (see Fig. 29.12) and ulcers or when the histopathologic changes are subtle relative to uninvolved skin. For example, in atrophoderma an incisional biopsy should include both affected and unaffected skin and be sectioned longitudinally, so that subtle differences can be detected (see Ch. 99). In ulcers, nonspecific inflammation of vessels underneath the wound may be misinterpreted as a primary vasculitis, but in a biopsy specimen that includes the surrounding skin, the "vasculitis" disappears a few millimeters away from the ulcer. Biopsying the border of suspected porokeratosis is also recommended in order to best detect the diagnostic cornoid lamella. In sum, selection of a proper biopsy site will always be influenced by knowledge of the suspected underlying pathology.

Biopsy techniques

By employing the appropriate biopsy technique as well as providing adequate clinical data, the quality and amount of information a clinician obtains from a skin biopsy is maximized. A wide range of biopsy techniques exist (see Ch. 146), but those most often performed include: superficial/tangential shave, deep shave ("saucerization"), curettage, punch, and incisional/excisional biopsy (Fig. 0.13). For optimal results, the technique employed must include tissue from the level of the skin or subcutis where the pathologic changes are anticipated, while simultaneously balancing concerns of cosmesis and morbidity. For example, if panniculitis is suspected, a shave would not provide the appropriate tissue to establish or refute such a diagnosis (Table 0.10).

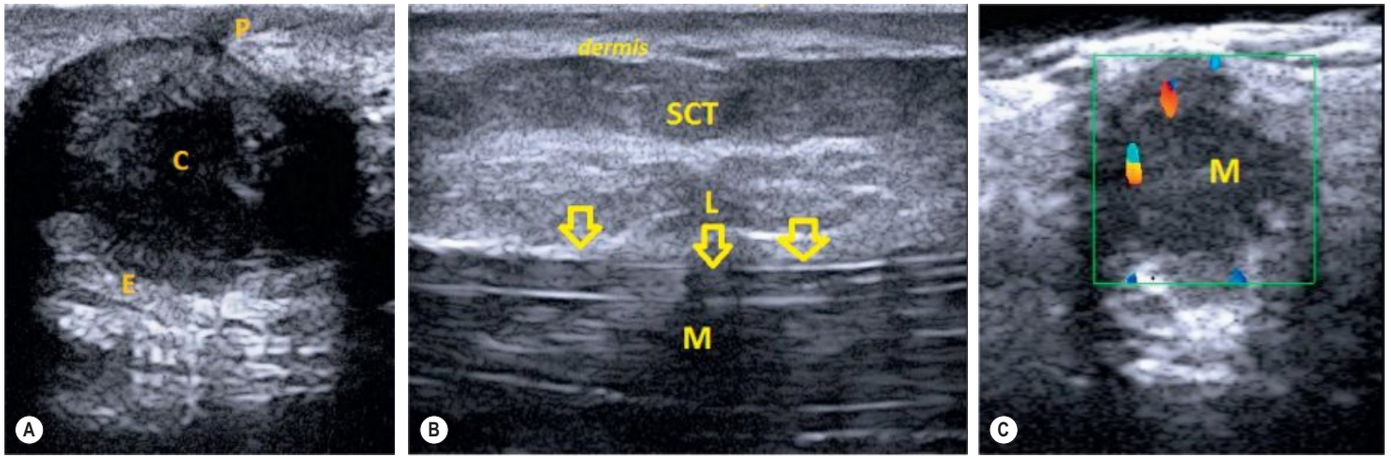

Fig. 0.12 Ultrasound of a cyst, a lipoma, and a cutaneous melanoma metastasis. A A cyst is a well-defined dermal/subcutaneous *hypo*echoic lesion (C) with heterogeneous content; posterior enhancement (E) is a common artefact and an infundibular duct or punctum (P) is usually visible. **B** A subcutaneous lipoma (L) is an ill-defined *hyper*echoic subcutaneous lesion embedded in normal subcutaneous tissue (SCT). Compression of subjacent muscle (M) is evident (arrows). **C** A well-defined, often lobulated, subcutaneous *hypo*echoic lesion (M; green box) with increased intralesional blood flow (multicolored) is characteristic of a metastasis. *Courtesy Fernando Alfageme, MD, PhD.*

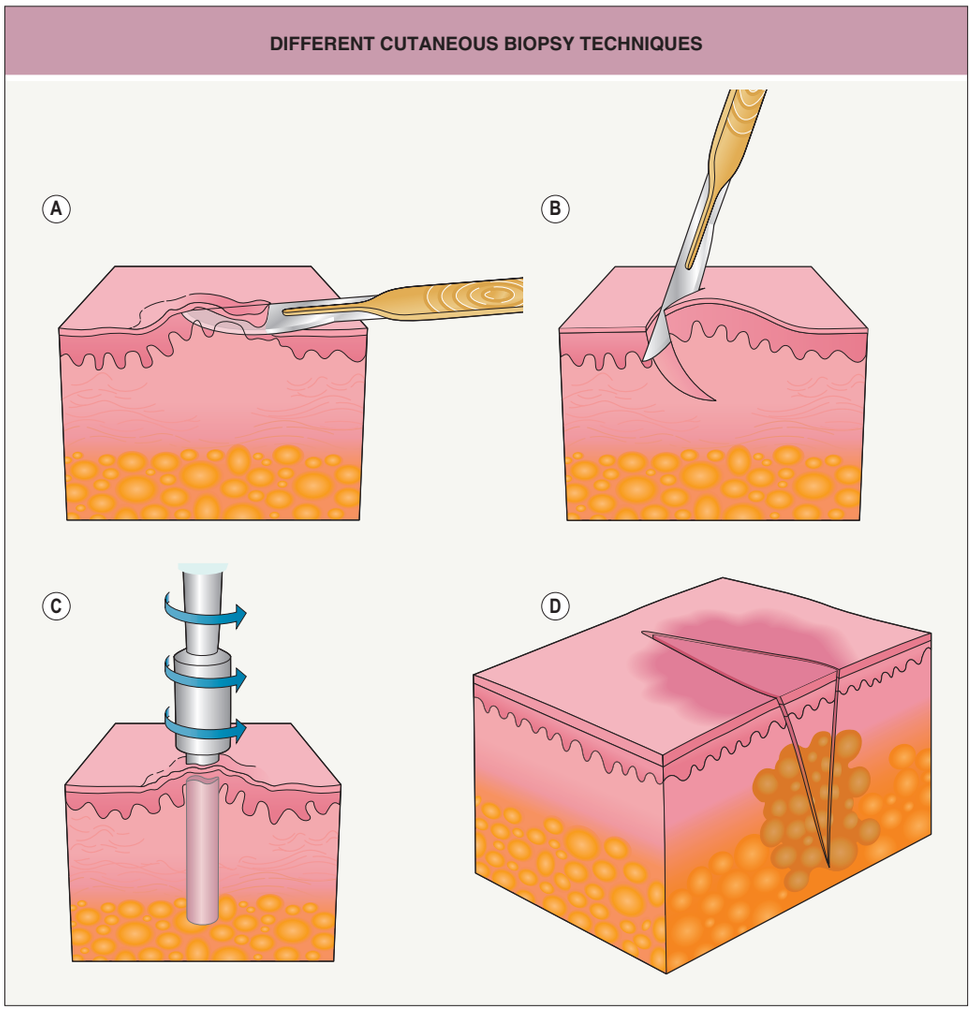

Fig. 0.13 Different cutaneous biopsy techniques. The size, topography, depth and site of the lesion, as well as the clinical differential diagnosis, influence the type of biopsy technique that is performed. **A** Superficial shave biopsy. **B** Deep shave biopsy (saucerization). **C** Punch biopsy. **D** Incisional biopsy. For more details, see text (also see Ch. 146). *Courtesy Suzanne Olbricht, MD.*

OPTIMIZING INFORMATION OBTAINED FROM A SKIN BIOPSY SPECIMEN (BASED UPON PRESUMED DIAGNOSIS)				
Inflammatory diseases				
Disorders (presumed)	***Where and when to biopsy***	***Preferred technique***	***Pitfalls***	***Ancillary techniques to consider***
Vasculitides	• Center of an early lesion • Prefer sites above the knee to avoid poor wound healing or background features due to venous hypertension	Punch or incisional biopsy (depending on the size of affected vessels)	Necrotic or ulcerated lesions may be non-diagnostic	Direct immunofluorescence of lesional skin (early lesions, not older than 24 h)
Livedo reticularis	• Center of the pale areas defined by the surrounding venous plexus network • Corresponds to the site of the ascending arteriole (see Fig. 106.1)	Punch or incisional biopsy	Biopsy of the venous plexus or a biopsy that is too superficial can lead to false-negative results	
Autoimmune connective tissue diseases	• Fully developed lesion • In DLE, biopsy areas of inflammation, not scarred areas	Primarily punch biopsy, unless panniculitis is suspected	• In DLE, biopsies of non-inflammatory scarred areas are often non-diagnostic • Changes of acute LE may be subtle	Direct immunofluorescence of lesional skin
Panniculitides	Early evolving lesion in lobular panniculitides (e.g. lupus panniculitis); fully developed lesion in septal panniculitides (e.g. erythema nodosum)	Large and deep incisional biopsy (must include subcutaneous fat)	• Failure to include enough fat • Late-stage lesions often have nonspecific findings	• Fresh tissue culture and/or PCR (if infectious etiology suspected) • Direct immunofluorescence (if vasculitis suspected)
Autoimmune blistering disorder	• An edematous papule/plaque or an early vesicle is preferred • If only large bullae are present, biopsy the edge of the bulla plus surrounding inflamed skin	Punch biopsy (e.g. 4 mm) or saucerization of: edematous papule/plaque, entire small vesicle, or edge of fresh, intact vesicle/bulla plus surrounding inflamed skin	• Biopsy of late-stage bullae undergoing re-epithelialization may lead to erroneous diagnosis • Late-stage, purulent, crusted, or ulcerated lesions may be non-diagnostic	Direct immunofluorescence of perilesional skin (see Fig. 29.12) or nearby skin (if dermatitis herpetiformis)

Table 0.10 Optimizing information obtained from a skin biopsy specimen (based upon presumed diagnosis).

Continued

OPTIMIZING INFORMATION OBTAINED FROM A SKIN BIOPSY SPECIMEN (BASED UPON PRESUMED DIAGNOSIS)				
Inflammatory diseases (cont'd)				
Disorders (presumed)	***Where and when to biopsy***	***Preferred technique***	***Pitfalls***	***Ancillary techniques to consider***
Alopecias	• Active advancing edge • Areas of perifollicular inflammation	• 4–6 mm punch biopsy oriented parallel to the direction of hair • Include subcutaneous fat	Scarred areas show only end-stage fibrosis	• Horizontal and vertical sectioning of biopsy • Direct immunofluorescence of lesional skin
Infectious diseases	• Prefer mature lesions • If ulcerated, include inflammatory border	Punch biopsy or incisional biopsy (for deep-seated infections)	• Organisms may not be appreciated in histologic sections • Fresh tissue culture and/or PCR often needed	Immunohistochemistry, fresh tissue culture, and/or PCR
Ulcerative dermatoses	Active edge of the ulcer or early lesion if the spectrum of lesions includes a pre-ulcerative stage (e.g. pyoderma gangrenosum)	Punch or incisional biopsy	Avoid center of ulcer where nonspecific changes or possible misleading secondary changes such as underlying vasculitis	Immunohistochemistry, fresh tissue culture, and/or PCR (if infectious etiology suspected)
Pigmentary disorders	Include the edge of the lesion as well as normal skin for comparison	Punch biopsy, rarely incisional biopsy	Subtle findings require clinicopathologic correlation	Special stains and/or immunohistochemistry may be necessary
Urticaria	Include the edge of the lesion as well as normal skin for comparison	Punch biopsy	Small-diameter punch biopsies may lead to false-positive results as retraction of collagen bundles may simulate interstitial edema	Direct immunofluorescence (if urticarial vasculitis is suspected)

Neoplastic processes		
Disease	***Preferred technique****	***Pitfalls***
Melanocytic neoplasms	• Excisional biopsy (preferred when melanoma is strongly suspected) • Saucerization that includes the entire lesion • When major differential diagnosis is macular seborrheic keratosis vs lentigo maligna, broad shave technique as long as no underlying induration • Other techniques may be appropriate depending upon the circumstances and the degree of suspicion	Partial (subtotal) punch biopsy or superficial shave biopsy may not be representative of the entire process
Keratinocytic neoplasms	Punch, saucerization, or excisional biopsy	Partial (subtotal) punch biopsy or superficial shave biopsy may not be representative of the entire process or allow assessment for possible dermal invasion
Dermal neoplasms	Punch, incisional, or excisional biopsy	Partial (subtotal) punch biopsy or superficial shave biopsy may not be representative of the entire process
Deep dermal and/or subcutaneous neoplasms	Excisional or incisional biopsy, depending upon size	Partial (subtotal) punch biopsy or superficial shave biopsy may not be representative of the entire process
Lymphoma cutis and leukemia cutis	• Punch or excisional biopsy • When major differential diagnosis is patch-stage mycosis fungoides vs parapsoriasis, broad saucerization may be performed	• Partial (subtotal) punch biopsy or superficial shave biopsy may not be representative of the entire process • Artifactual changes, in particular crush artifact and/or desiccation, are common when lymphocytic infiltrates are sampled via a small-diameter punch biopsy and then tweezers are used to remove the specimen and/or the specimen is placed on a gauze†

*On occasion, surgical/clinical/cosmetic constraints may, in the patient's best interest, require consideration and performance of an alternative technique, or even a subtotal biopsy, with acceptance of limitations regarding the diagnostic result.
†Tweezers should not be used to remove the biopsy specimen and the latter should be placed directly into a formalin solution.

Table 0.10 Optimizing information obtained from a skin biopsy specimen (based upon presumed diagnosis). DLE, discoid lupus erythematosus; h, hour; LE, lupus erythematosus; PCR, polymerase chain reaction. *Table created with the assistance of Dr. Stefano Titli.*

Similarly, in the case of a benign exophytic lesion, such as a verruca or skin tag, it would not be expedient, economical, or cosmetically savvy to remove the lesion via an excision with sutured closure. Artifactual changes due to the use of tweezers (crush) or placement of the biopsy specimen on gauze (desiccation) may hinder the dermatopathologist's ability to render an accurate assessment; the cells that are most susceptible to these artifactual changes are those of cutaneous lymphoma and Merkel cell carcinoma.

- **Superficial shave biopsy** – this technique is employed most often when the suspected pathology is chiefly epidermal in nature (e.g. an actinic keratosis, squamous cell carcinoma *in situ*, inflamed seborrheic keratosis), or when there is a desire to remove an exophytic benign lesion (e.g. an intradermal melanocyte nevus) (see Fig. 0.13A). If the findings of interest are suspected to lie in the mid to deep dermis (e.g. discoid lupus erythematosus) then a superficial shave biopsy will not provide diagnostically useful information.
- **Deep shave/saucerization biopsy** – this technique is simply a deeper variant of the superficial shave, where greater angling of the blade removes more of the upper to mid dermis (see Fig. 0.13B). Suspected non-melanoma skin cancer (e.g. basal cell carcinoma, squamous cell carcinoma) is often sampled by deep shave. Evidence suggests that when properly performed, the diagnostic value of a deep shave may rival that of an incisional/excisional procedure[27].
- **Curettage** – this technique is employed to remove superficial lesions that are confined to the epidermis, but it does so in a fragmented and unorientable fashion. In this regard, curettage is

less desirable for diagnostic purposes, and it is not appropriate for pigmented lesions that are suspicious for melanoma or for neoplasms of uncertain etiology.

- **Punch biopsy** – this technique is preferred when the suspected pathology lies within the dermis and when a small sampling is likely to dutifully represent the overall disease process (see Fig. 0.13C). Common punches range from 1.5 to 8.0 mm in diameter, with 4 mm being the most commonly used size for inflammatory diseases. If the sampled lesion can be contained in the punch, then the concern regarding sampling error is rendered moot. It is controversial as to whether punch biopsies, even if performed in a "stacked" fashion, can provide adequate tissue for assessment of deeply infiltrating tumors or panniculitis. Studies suggest that *partial* punch samplings of melanocytic lesions can lead to misdiagnosis or to erroneous staging and therefore should not be performed[28].
- **Incisional/excisional biopsy** – this technique involves the removal of either a portion of a lesion (incisional) or the entire visible lesion (excisional) via a scalpel, using standard surgical techniques (see Ch. 146; see Fig. 0.13D). An incision is often used for examination of the subcutaneous fat (e.g. panniculitis), while an excision is often employed to inspect the entirety of a neoplasm (e.g. a pigmented lesion that is reasonably suspicious for melanoma).

Optimal biopsy techniques based upon the suspected cutaneous disease are outlined in Table 0.10.

Handling of the specimen after biopsy

Skin specimens must be handled carefully upon extirpation. For example, excessive lateral pressure by forceps on small punch biopsy specimens can distort cellular infiltrates, particularly lymphomas and Merkel cell carcinoma, creating so-called "crush" artifact. This type of artifact may compromise the diagnostic utility of a biopsy. These two cell types are also subject to desiccation artifact when the biopsy specimen is placed onto gauze rather than into formalin solution.

For routine histologic analysis, tissue specimens are usually fixed in 10% neutral buffered formalin (NBF) solution, with a volume 10- to 20-fold that of the tissue itself. When culturing for microorganisms, the tissue specimen cannot be placed in 10% NBF; instead it must be placed in a sterile container with a small amount of non-bacteriostatic saline. For direct immunofluorescence (DIF) studies, specimens must be flash-frozen, placed in normal saline (for no more than 24–48 hours), or placed in specialized transport medium (Michel's solution). Recently, honey was shown to be an excellent transport medium for DIF studies[29]. Fixation in paraformaldehyde and glutaraldehyde in a cacodylate buffer is required for electron microscopy.

To obtain the most accurate histopathologic assessment, all biopsy specimens sent to a dermatopathologist should be accompanied by relevant clinical data such as: age and sex of the patient, anatomic site(s) involved, pertinent physical findings, and suspected clinical differential diagnosis. Prior treatments that might impact upon the histologic findings should be disclosed. Any special instructions or requests should be detailed (e.g. inking of an area of special concern in a melanocytic neoplasm, longitudinal sectioning to detect subtle changes in atrophoderma). Inclusion of drawings or clinical photographs (favored) may prove very useful, especially in difficult or complex cases.

Classification of Inflammatory Skin Diseases by Pattern Analysis

First conceived by Dr Hermann Pinkus, but more firmly established by Dr A. Bernard Ackerman[30,31], histopathologic assessment by pattern analysis has emerged as the principal means of classifying inflammatory skin diseases (Fig. 0.14). The number of patterns and the precise descriptors assigned may vary among examiners, but the core principle remains the same – a major pattern is first identified, then additional histologic features are used to further subcategorize the disease process until a final diagnosis is rendered.

The algorithmic approach of pattern analysis is reproducible, and it minimizes subjectivity. However, the method has two important limitations, namely, it is based on artificial disease categories and it cannot include every possible pattern. Furthermore, while pattern analysis clearly narrows the differential diagnosis, a final assessment may require clinical correlation and/or ancillary laboratory testing, imaging, or genetic testing[32].

The histopathologic appearance of skin disease may also vary based upon the age of the lesion, reflecting the "life of a lesion". As noted previously, histologic findings may be altered by previous treatment(s) or by secondary changes such as rubbing, scratching, or infection. Lastly, pattern analysis is not only applicable to inflammatory skin diseases, but is also used for neoplasms, primarily to distinguish benign from malignant.

Ten major patterns defined

Over the past several decades, different classification schema based upon pattern analysis have emerged. The number of patterns in any schema has varied from 9 to 28 or more, but in this introductory chapter, 10 major patterns will be discussed.

Perivascular dermatitis

Perivascular dermatitis is defined and recognized by the presence of an inflammatory infiltrate that is arranged chiefly around dermal blood vessels (Fig. 0.15). Traditionally, perivascular dermatitis has been subdivided into "superficial" and "superficial and deep" variants, and while this division has some diagnostic value, considerable overlap exists. In addition, inflammatory skin diseases can exhibit a spectrum of findings, depending in part upon severity, as well as the duration of an individual lesion (acute vs chronic). Because this pattern is shared by the majority of inflammatory skin diseases, there is a wide range of potential diagnoses.

Once a perivascular pattern is identified (see Fig. 0.14A), the next step is to: (1) determine if there are associated epidermal changes; and (2) characterize the types of inflammatory cell(s) that are present in the infiltrate (e.g. lymphocytes, neutrophils, eosinophils, plasma cells). There are disorders without detectable changes within the epidermis, such as deep gyrate erythemas (see Ch. 19), and when an inflammatory process is beginning or resolving, epidermal changes may be subtle. To further refine the diagnosis, a search is performed to detect subtle *spongiosis* (intercellular edema of the epidermis), subtle *parakeratosis* (aberrant retention of nuclei in the stratum corneum), subtle *interface* and *vacuolar changes* at the dermal–epidermal junction, or extravasated erythrocytes.

Interface dermatitis

This pattern is characterized by inflammation and/or degenerative change(s) at the dermal–epidermal junction (see Fig. 0.14B). Morphologically, this pattern may be further subdivided into primarily *vacuolar* (vacuoles between two adjacent basal cells or between basal cells and the underlying basement membrane with mild or no inflammation; Fig. 0.16) or primarily *lichenoid* (lymphocytes fill the papillary dermis in a band-like fashion and often obscure the dermal–epidermal junction; Fig. 0.17), but there is overlap between these two groups.

It is important to remember that even though an entity has lichenoid features under the microscope (e.g. fixed drug eruption), clinically, it does not have to resemble lichen planus. Also, some degree of lichenoid inflammation may be associated with a variety of benign and malignant neoplasms, such as lichenoid keratoses and melanoma. In these instances, the lichenoid inflammation represents an immunological response to the tumor.

Spongiotic dermatitis

Spongiosis (intercellular edema) is a nonspecific morphologic alteration that is observed in a variety of skin conditions. It manifests as widened spaces between keratinocytes, with elongation of intercellular bridges (see Fig. 0.14C). The degree of spongiosis may vary from microscopic foci to grossly visible vesicles or intraepidermal bullae. There is often associated *exocytosis* of inflammatory cells, with migration from the vasculature into the epidermis. It is important to note that even those spongiotic dermatitides that characteristically develop vesicles, for example acute allergic contact dermatitis, may not do so, i.e. patients have only macules and papules throughout the entire course of their disease.

Spongiotic dermatoses may be further subdivided into acute, subacute, and chronic forms. In acute spongiotic dermatitis, the spongiosis is often severe, sometimes resulting in microvesicles within the epidermis (Fig. 0.18). Parakeratosis, a histologic equivalent of scale, often overlies subacute spongiotic dermatitis. In chronic spongiotic dermatitis, the spongiosis may be more difficult to appreciate, being instead

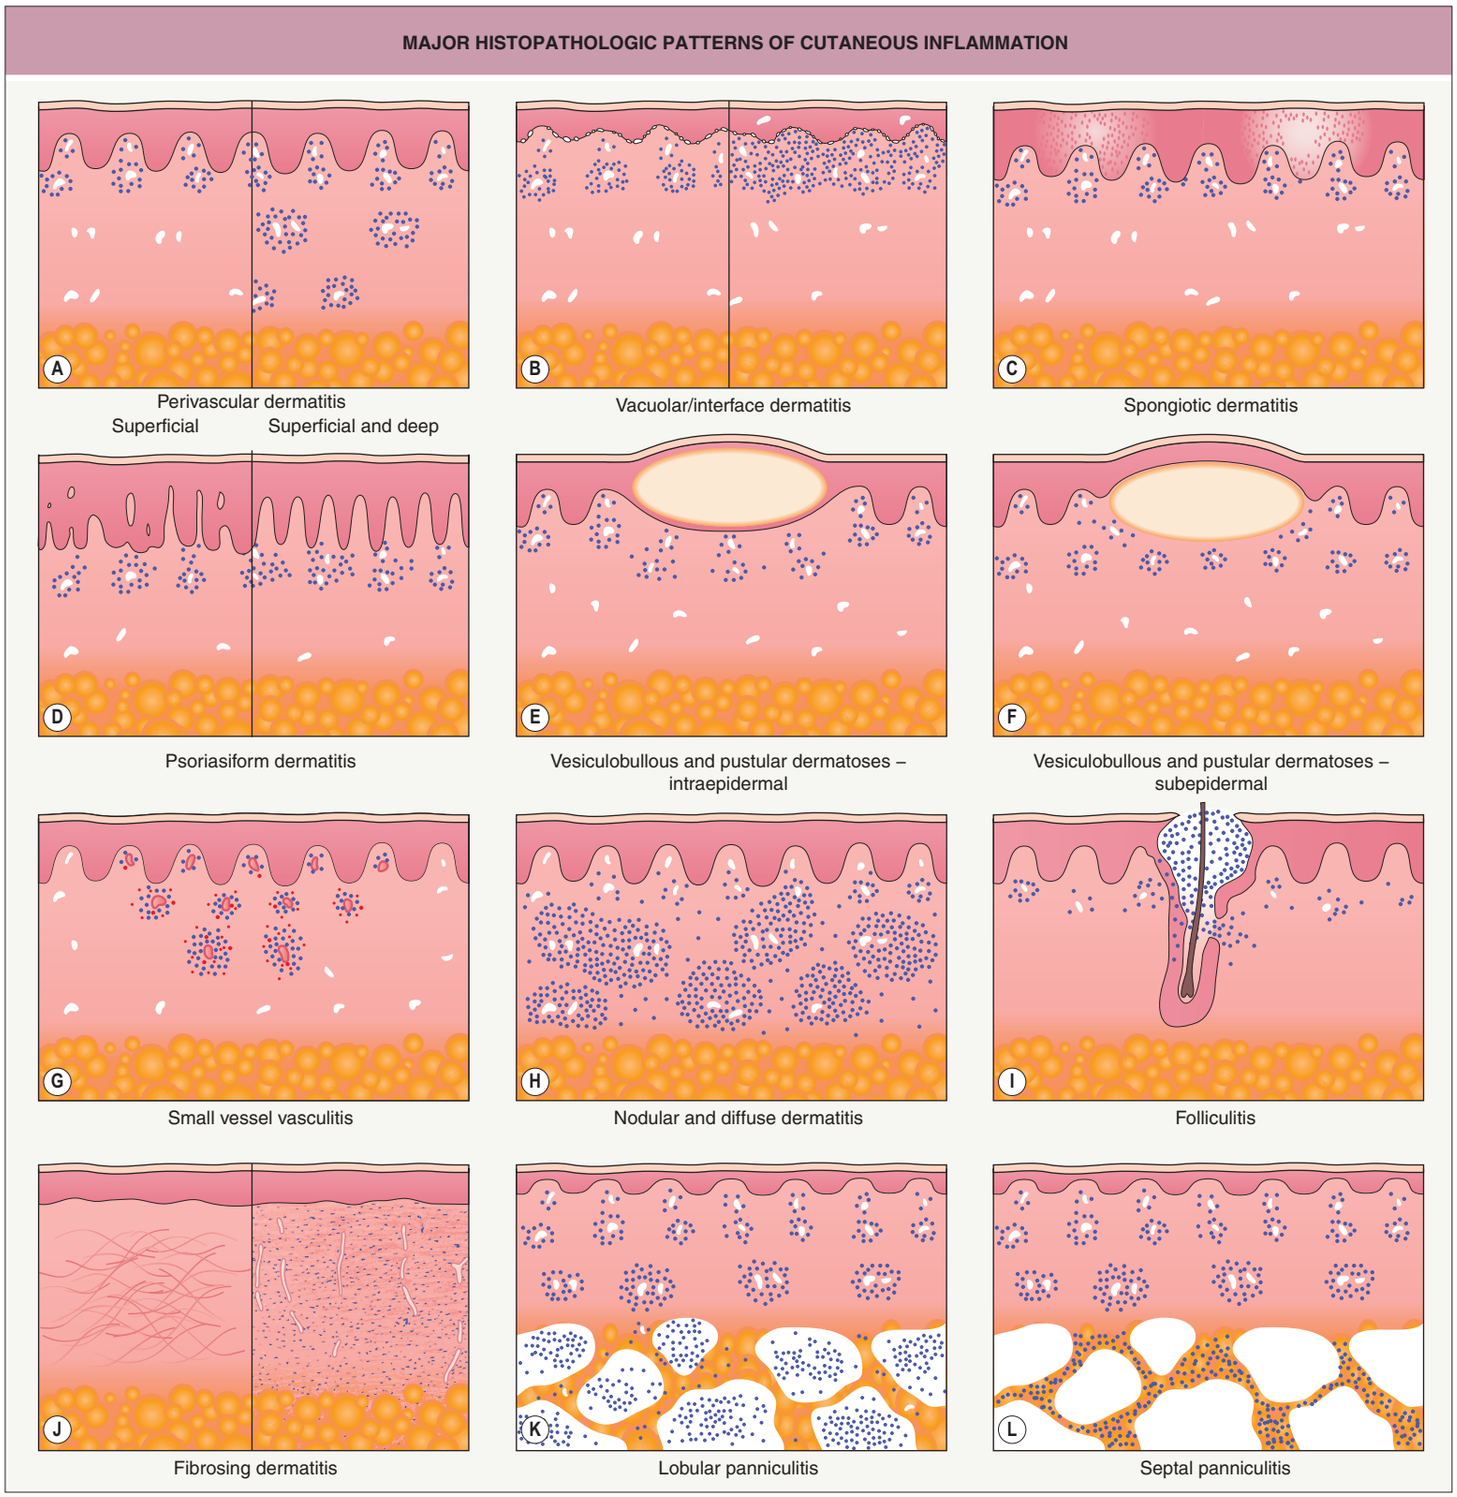

Fig. 0.14 Major histopathologic patterns of cutaneous inflammation (based upon Ackerman's classification). Basic patterns of inflammation result primarily from the distribution of the inflammatory cell infiltrate within the dermis and/or the subcutaneous fat (e.g. nodular, perivascular). It also reflects the character of the inflammatory process itself (e.g. pustular), the presence of injury to blood vessels (e.g. vasculitis), involvement of hair follicles (e.g. folliculitis), abnormal fibrous dermal and/or subcutaneous tissue, and formation of vesicles and bullae. *Adapted from Ackerman AB. Histologic Diagnosis of Inflammatory Skin Diseases: A Method by Pattern Analysis. Philadelphia: Lea & Febiger; 1978.*

overshadowed by epidermal *acanthosis* (thickening of the epidermis). Also, a predominance of certain inflammatory cells in association with spongiosis, such as eosinophils or neutrophils, may serve as a clue to a hypersensitivity component or infectious process, respectively.

Lastly, it is important to recognize that multiple cutaneous disorders with eczematous features, such as allergic contact dermatitis, atopic dermatitis, nummular dermatitis and seborrheic dermatitis, may have histologic evidence of spongiosis, but this pattern is not exclusive to those diseases. In other words, spongiosis may also be seen as a reactive epidermal component of other disorders better classified under another pattern.

Psoriasiform dermatitis

The term "psoriasiform" refers to a regular pattern of *epidermal hyperplasia* (elongation of the rete ridges; see Fig. 0.14D) that is observed not just in psoriasis, but also in a number of other, generally longstanding,

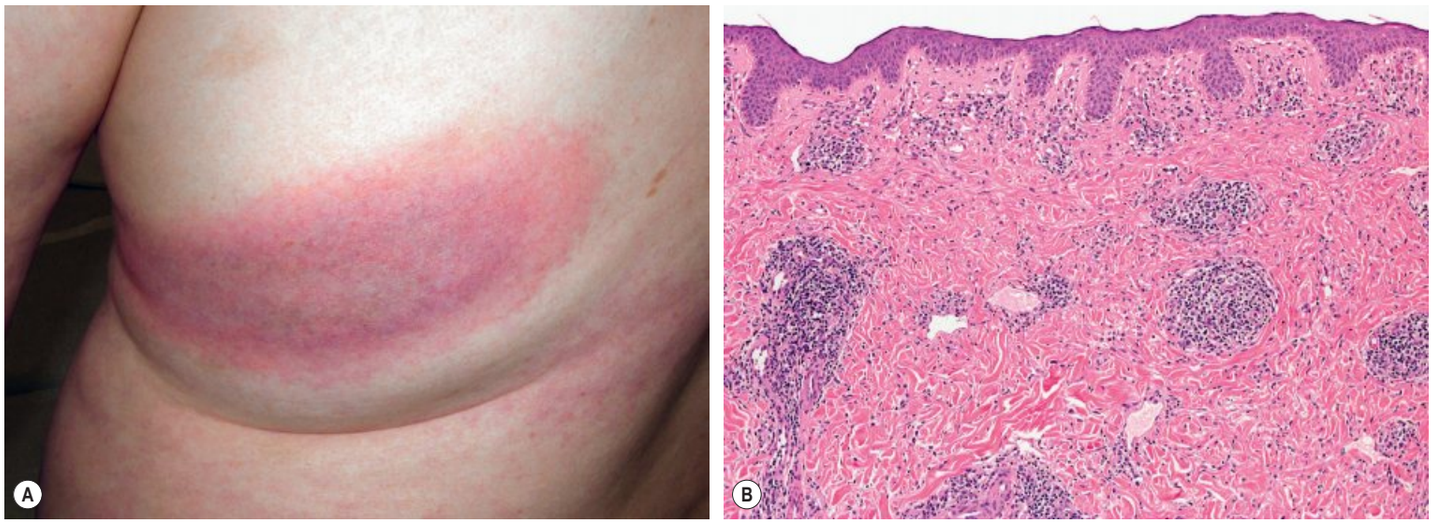

Fig. 0.15 Perivascular dermatitis. A Erythema migrans. **B** Perivascular inflammatory infiltrate composed primarily of lymphocytes. *B, Courtesy Lorenzo Cerroni, MD.*

conditions. Clinically, this group of psoriasiform disorders is characterized by thickened, scaly papules and plaques (Fig. 0.19). Psoriasiform dermatoses can be further subdivided into those diseases that are exclusively psoriasiform and those that are associated with another pattern (e.g. psoriasiform *and* lichenoid; psoriasiform *and* spongiotic).

Pseudoepitheliomatous hyperplasia represents a related benign condition due primarily to hyperplasia of adnexal epithelium. It may occur in response to a range of insults to the skin, such as chronic rubbing or scratching (e.g. lichen simplex chronicus, prurigo nodularis), or it may appear in inflammatory, neoplastic, and infectious skin diseases (e.g. hypertrophic lupus erythematosus, halogenodermas, chromoblastomycosis).

As with spongiotic dermatitis, psoriasiform dermatitis is a histologic concept, not a specific clinical diagnosis, and its presence mandates consideration of a variety of skin diseases that share this particular pattern.

Vesiculobullous and pustular dermatoses

Intraepidermal vesiculation (see Fig. 0.14E)

The concept of intraepidermal vesiculation due to spongiosis has been addressed above, but other disease mechanisms may lead to formation of intraepidermal vesicles or bullae (e.g. acantholysis, ballooning degeneration, prominent basal layer vacuolization, subepidermal edema). *Acantholysis* refers to the discohesion of keratinocytes due to disruption of *desmosomes* (intercellular connections), and this can lead to intraepidermal vesicles or bullae (Fig. 0.20).

Although acantholysis may occur at any level of the epidermis, the location of a blister cavity is often used as a clue to the underlying disorder. For example, superficial (subcorneal) acantholysis may favor pemphigus foliaceus, while acantholysis within the deeper portion of the epidermis is more characteristic of pemphigus vulgaris. *Ballooning degeneration* refers to intracellular edema in response to cytotoxic events (e.g. herpes virus infection, drug reaction), and it is identified by the presence of abundant pale cytoplasm of keratinocytes in the spinous zone. When ballooning is severe, keratinocytes rupture, resulting in reticular degeneration and epidermal necrosis.

Pustule formation (the intraepidermal accumulation of neutrophils) may be seen in a variety of infectious and non-infectious skin diseases. In early pustule formation, neutrophils are scattered within the lower portion of the epidermis, whereas later, accumulation is noted in the upper epidermis and/or beneath the stratum corneum (Fig. 0.21). In a resolving pustule, the neutrophils or their remnants may even appear within a scale-crust in the cornified layer.

In both vesiculobullous and pustular dermatoses, autoimmune and non-autoimmune mechanisms (e.g. subcorneal pustular dermatosis versus IgA pemphigus) may be histopathologically indistinguishable. As a result, direct and indirect immunofluorescence studies are of utility in determining the precise etiology.

Subepidermal vesiculation (see Fig. 0.14F)

In this subcategory of disease, vesicles or bullae form at the junction between the epidermis and dermis (Fig. 0.22), or between the mucosa and submucosa of mucous membranes. While such clefting can be the result of autoantibodies that target specific components of the dermal–epidermal junction (e.g. collagen XVII in bullous pemphigoid, linear IgA bullous dermatosis), it may be the result of an inflammatory or toxic/metabolic insult (e.g. bullous erysipelas or porphyria cutanea tarda, respectively).

The number of inflammatory cells varies within subepidermal blisters, and this variance influences the differential diagnosis. For example, some diseases such as porphyria cutanea tarda are classically pauci-inflammatory, while the majority of cases of bullous pemphigoid contain a significant number of inflammatory cells, particularly eosinophils.

However, because there is histologic overlap among blistering disorders, the final diagnosis must depend upon cumulative information, including direct and indirect immunofluorescence microscopy, ELISA, and, of course, clinicopathologic correlation.

Vasculitis/pseudovasculitis

Vasculitis refers to inflammatory damage to and destruction of blood vessels, which leads ultimately to the deposition of fibrin and/or thrombus formation (see Fig. 0.14G). The histopathologic classification of vasculitis is based upon the size of the vessel involved (small, medium-sized, or large vessel vasculitis; see Ch. 24) as well as the predominant inflammatory cell type that is mediating the damage (neutrophils, lymphocytes, eosinophils, or histiocytes).

The most common form of cutaneous vasculitis is *leukocytoclastic vasculitis* (Fig. 0.23), a process that is mediated by neutrophils and affects chiefly the postcapillary venule. Leukocytoclastic vasculitis begins with deposition of circulating immune complexes in and around blood vessel walls, with neutrophils recruited to these sites of deposition; this ultimately leads to *leukocytoclasia* (nuclear fragmentation) and vessel destruction, with resultant fibrin deposition. In the few longstanding disorders that are mediated by leukocytoclastic vasculitis, such as erythema elevatum diutinum, concentric fibrosis may develop over time.

The concept of *lymphocytic vasculitis* is less well defined and is even a controversial pattern for some authors. However, it is a term used to denote an inflammatory process in which there may be some fibrinoid necrosis of the vessel wall, but the mediating cells

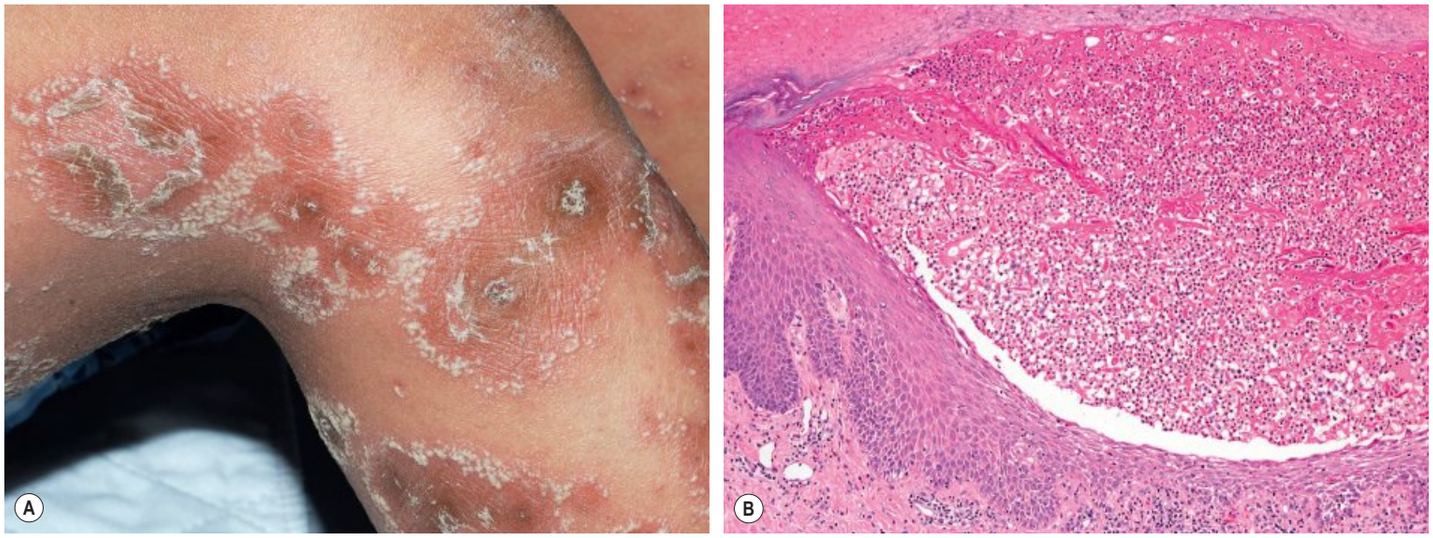

Fig. 0.21 Intraepidermal pustular dermatosis. A Annular variant of pustular psoriasis. **B** Large collection of neutrophils beneath the stratum corneum (subcorneal pustule). *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Lorenzo Cerroni, MD.*

A Nodules of cutaneous arteritis (cutaneous polyarteritis nodosa) admixed with livedo reticularis. **B** Inflammation and destruction of a subcutaneous arteriole with a dense inflammatory infiltrate composed of lymphocytes, histiocytes, and neutrophils admixed with hemorrhage. *A, Courtesy David Wetter, MD; B, Courtesy Lorenzo Cerroni, MD.*

are predominantly lymphocytes. It is postulated as a mechanism in disorders such as pernio, Sneddon syndrome, and pityriasis lichenoides et varioliformis acuta (PLEVA), although the latter lacks fibrinoid necrosis (see Table 24.2).

Granulomatous vasculitis is defined by the presence of histiocytes within and around blood vessel walls, in association with fibrin and/or degenerative and necrotic changes. Like lymphocytic vasculitis, granulomatous vasculitis is a pattern that is observed in a restricted group of diseases which includes granulomatosis with polyangiitis (formerly Wegener granulomatosis), eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome), and giant cell arteritis (formerly temporal arteritis). Occasionally, it may also represent a later evolutionary stage of another form of vasculitis, either leukocytoclastic or lymphocytic in nature.

In *medium-sized vessel cutaneous vasculitis*, there is involvement of the blood vessels at the dermal–subcutaneous junction and/or within the septa of the subcutaneous fat (Fig. 0.24). For dermatopathologists, cutaneous arteritis (formerly cutaneous polyarteritis nodosa) is the most commonly encountered entity in this disease category. Giant cell arteritis represents a form of large vessel vasculitis, but biopsies of this disorder are rarely performed by dermatologists.

Pseudovasculitis refers to a group of heterogeneous, non-inflammatory conditions that are broadly classified into *non-inflammatory purpura* (disorders that primarily cause hemorrhage) and *occlusive vasculopathies* (conditions that primarily occlude vessels) (see Chs. 22 & 23). Many of these latter disorders involve occlusion of vessels due to emboli, thrombi, vasospasm, intimal–medial hyperplasia secondary to vessel trauma, or non-inflammatory vessel wall pathology. The latter includes calcification, cholesterol emboli, and amyloid deposition.

Nodular and diffuse dermatitis

Nodular dermatitis is somewhat similar to perivascular dermatitis, but the inflammatory infiltrate has enlarged and has coalesced to form one or multiple nodules within the dermis (see Fig. 0.14H). Further expansion of these nodules can fill nearly the entirety of the dermis, yielding a diffuse pattern (Fig. 0.25).

The nodular and diffuse pattern of dermatitis may be further subdivided based upon the predominant inflammatory cell present. When *histiocytes* predominate in one or more foci, the pattern is designated *granulomatous*. This can be observed in a large family of chronic inflammatory diseases due to a wide variety of immunogenic stimuli, including infectious and non-infectious agents. If the granulomatous response is sustained, histiocytes become "epithelioid", i.e. the cells have abundant pink cytoplasm with indistinct borders and plump ovoid nuclei and they appear to touch one another reminiscent of the cells in an epithelium. Granulomas may contain other cells, including neutrophils, eosinophils, plasma cells, lymphocytes, and giant cells. Giant cells form via the fusion of histiocytes and are typically large and multinucleated. There are three major types of multinucleated giant cells whose morphologies differ: Langhans giant cells, foreign body giant cells, and Touton giant cells. None of these giant cells are exclusive to a singular disease, but some disorders are characterized by the conspicuous presence of one or more type(s) (e.g. Touton giant cells in juvenile xanthogranuloma).

Based on the constituent cells and other distinctive features, seven major histopathologic types of granulomas can be defined (Fig. 0.26):

- ***Tuberculoid granuloma*** (see Fig. 0.26A) – comprised of epithelioid histiocytes, including multinucleate forms, surrounded by a dense infiltrate of lymphocytes and plasma cells. Central caseation may be present. The *Langhans type* of multinucleated

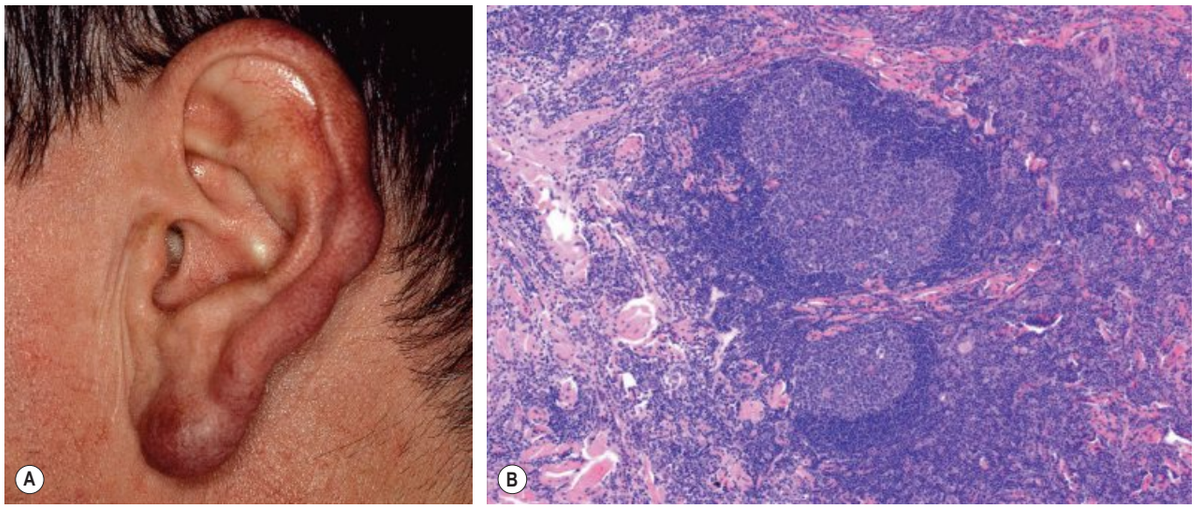

Fig. 0.25 Nodular and diffuse dermatitis, lymphocytic. A Cutaneous lymphoid hyperplasia. The earlobe is a common location. **B** Dense dermal infiltrate containing lymphoid follicles with formation of germinal centers. *B, Courtesy James Patterson, MD.*

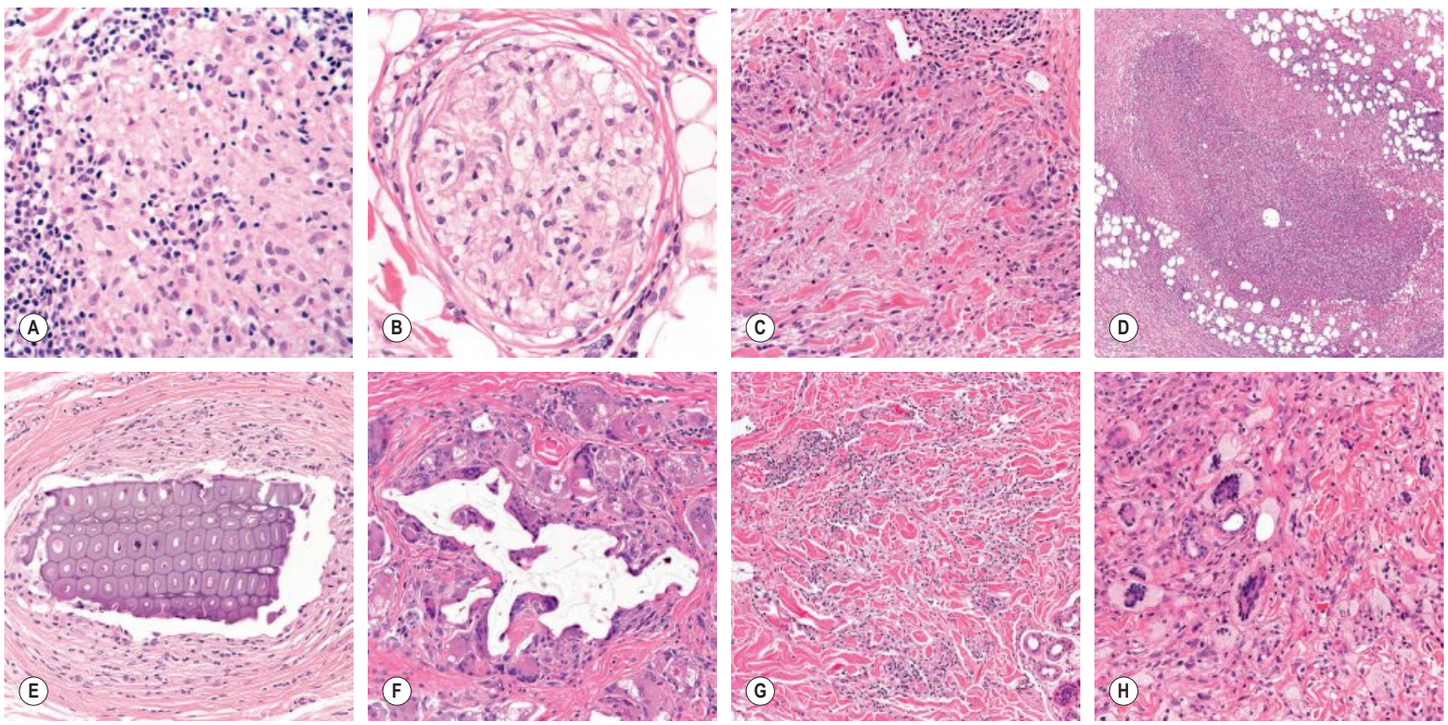

Fig. 0.26 Seven major types of cutaneous granulomas. A Tuberculoid – epithelioid granuloma rimmed by lymphocytes. **B** Sarcoidal – epithelioid granulomas with minimal peripheral lymphocytic infiltrate. **C** Palisaded – granuloma surrounding a focus of degenerated collagen. **D** Suppurative – granulomas with central dense neutrophilic infiltrates. **E** Foreign body – large foreign body representing a portion of a plant with geometric shapes surrounded by histiocytes. **F** Foreign body – irregularly shaped, apparently empty structures (corresponding to implanted aesthetic filler) surrounded by foreign body type giant cells with randomly scattered nuclei in their cytoplasm. **G** Interstitial – epithelioid histiocytes distributed interstitially among the collagen bundles, focally forming small palisades around sclerotic collagen bundles. **H** Xanthogranuloma – numerous foamy histiocytes, lymphocytes, and characteristic Touton giant cells. The latter have a central ring of nuclei and peripheral clear or foamy cytoplasm due to accumulated lipid. *Courtesy Lorenzo Cerroni, MD.*

giant cell, with a horseshoe-like arrangement of nuclei, may be observed in tuberculoid granulomas. This type of granuloma is often, but not invariably, associated with cutaneous infections (e.g. *Mycobacterium tuberculosis*).

- ***Sarcoidal granuloma*** (see Fig. 0.26B) – comprised of aggregates of epithelioid histiocytes, with sparse peripheral lymphocytes or plasma cells (i.e. "naked tubercles"). While multinucleated cells may be identified, no specific type is associated exclusively with sarcoidal granulomas.
- ***Palisaded ("necrobiotic") granuloma*** (see Fig. 0.26C) – comprised of epithelioid histiocytes aligned as a rim around a central area of degenerated collagen with different tinctorial qualities.
- ***Suppurative granuloma*** (see Fig. 0.26D) – comprised of neutrophils within, and sometimes among or surrounding, aggregates of epithelioid histiocytes. Suppurative granulomas may be induced by infectious agents or foreign body material.
- ***Foreign body granuloma*** (see Fig. 0.26E,F) – comprised of epithelioid histiocytes, variable numbers of other inflammatory cells, and large foreign body giant cells. The latter result from the fusion of multiple histiocytes and have nuclei randomly scattered throughout their cytoplasm. Foreign material, either exogenous or endogenous, may be observed within these giant cells and/or in the interstitium.
- ***Interstitial granuloma*** (see Fig. 0.26G) – typified by the predominant distribution of histiocytes between dermal collagen bundles, sometimes forming small palisades around altered collagen bundles, admixed with variable numbers of other inflammatory cells.
- ***Xanthogranuloma*** (see Fig. 0.26H) – comprised of clusters of foamy histiocytes filled with lipids, along with a variable admixture of other inflammatory cells, especially lymphocytes, and Touton giant cells. The latter have a central homogeneous cytoplasm surrounded by a ring of nuclei then a peripheral rim of foamy cytoplasm.

All granulomatous infiltrates, but particularly tuberculoid, sarcoidal and suppurative granulomas, require exclusion of infectious agents and/or foreign material by means of special stains, immunohistochemical stains, tissue culture, PCR, and/or polarization microscopy.

Nodular and diffuse infiltrates comprised chiefly of histiocytes may also be further subcategorized into *Langerhans cell* and *non-Langerhans cell histiocytoses* (see Ch. 91). In Langerhans cell histiocytosis, the cells of interest have reniform (kidney bean-shaped) nuclei and a characteristic immunohistochemical staining pattern (i.e. S100 protein$^+$, CD207$^+$, and CD1a$^+$). Non-Langerhans histiocytes, on the other hand, have a range of cytologic features (vacuolated, spindle-shaped, foamy, scalloped, oncocytic) as well as multiple admixed multinucleated giant cells (Touton type, Langhans type, foreign body type). Sometimes, the histiocytes and giant cells display a homogeneous "ground glass" cytoplasm; these cells are generally S100 protein$^-$, CD1a$^-$, CD68$^+$, and CD163$^+$. The varying histopathologic features of the non-Langerhans histiocytoses may possibly be related to the actual physiologic function of histiocytes within the granuloma[33].

Lastly, *xanthomas* are characterized by the accumulation of *lipophages* (foamy histiocytes filled with lipid) within the dermis (see Ch. 92). The lipid content may impart a yellowish hue to the lesions (Fig. 0.27). Cutaneous xanthomas can take various forms, including widespread papules (*eruptive*), nodules (*tuberous* or *tendinous*), and plaques (*xanthelasma*, *palmar*). Nowadays, intracytoplasmic lipids can be demonstrated in formalin-fixed, paraffin-embedded tissue via immunohistochemical staining with anti-adipophilin antibody. Adipophilin (perilipin-2) is associated with lipid droplets and, unlike the lipid itself, is preserved during tissue processing.

Folliculitis/perifolliculitis

Folliculitis (inflammation of a hair follicle) is defined by the presence of inflammatory cells in the wall and lumen of a hair follicle (see Fig. 0.14I); perifolliculitis refers to the presence of similar cells in the adjacent dermis. Folliculitis may be due to infections (bacterial, fungal, viral, *Demodex* mites), drugs, occlusion, or unknown etiologies (e.g. eosinophilic folliculitis).

The classification of folliculitis (and perifolliculitis) can be made on the basis of the primary inflammatory cell (lymphocytes, neutrophils, or eosinophils), the nature of the underlying pathologic process (e.g. dermatophyte infection), the temporal course (acute versus chronic), and the site of involvement along the length of the hair follicle. If the inflammatory process is severe and/or if it irreversibly damages epithelial stem cells, located in the bulge region of the follicle, permanent "scarring alopecia" may result (Fig. 0.28).

Fibrosing/sclerosing conditions

Fibrosing conditions include a wide spectrum of disorders that result from altered production of collagen, typically related to injury or an autoimmune connective tissue disease (see Fig. 0.14J). Histopathologically, the pattern is characterized by either: (1) abnormal fibrous dermal (and sometimes subcutaneous) tissue with an increased number of fibroblasts and increased, but rather unremarkable, collagen

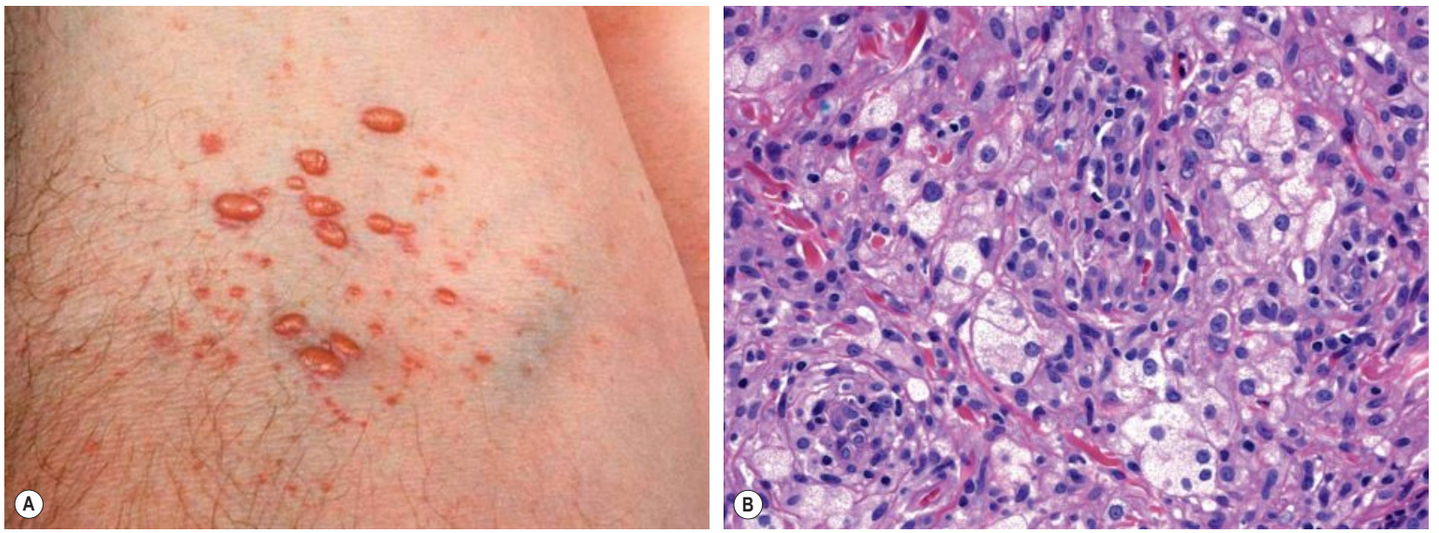

Fig. 0.27 Xanthomas. A Yellow–pink eruptive xanthomas. **B** Lipid-laden macrophages with foamy or vacuolated cytoplasm are present within the dermis. *B, Courtesy James Patterson, MD.*

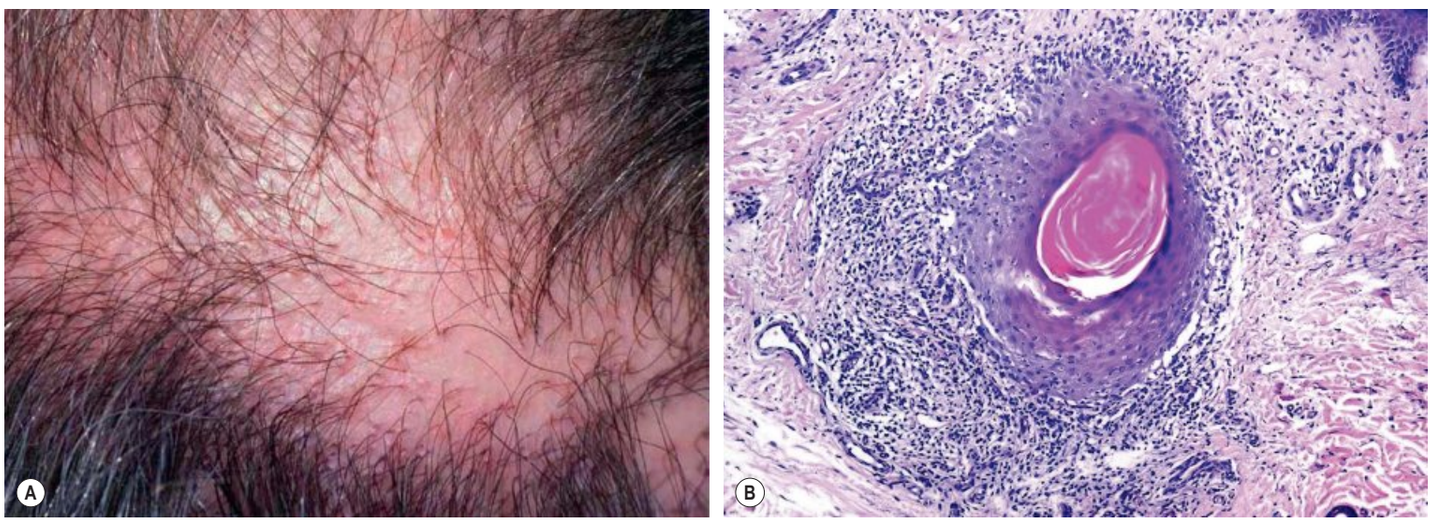

Fig. 0.28 Scarring alopecia. A Lichen planopilaris with areas of scarring alopecia and red–violet rims of inflammation around hair follicles. **B** Band-like lymphocytic infiltrate surrounding a hair follicle, with vacuolar alteration of basilar outer root sheath epithelium.

(*fibrosis*); or (2) homogenized, abnormally enlarged and eosinophilic collagen with a paucity of admixed fibroblasts (*sclerosis*). An example of the former is nephrogenic systemic fibrosis, while an example of the latter is morphea (Fig. 0.29) or systemic sclerosis. These two patterns represent the ends of the spectrum and overlap can occur.

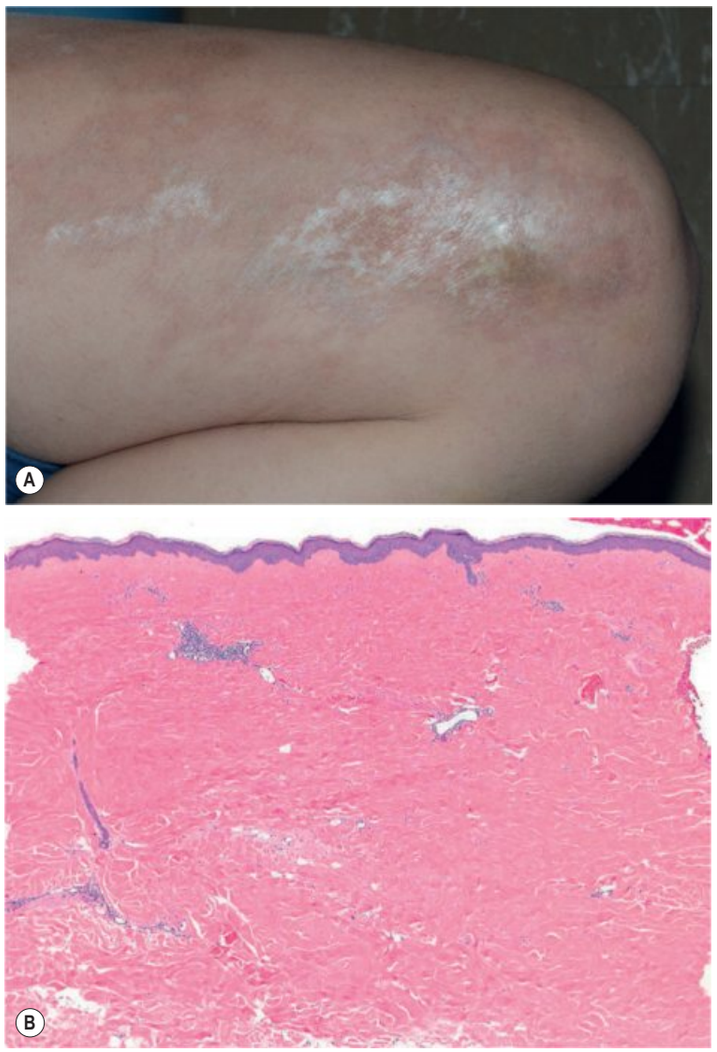

Fig. 0.29 Sclerosing disorder. A Linear distribution of coalescing sclerotic dyschromic plaques on the thigh; note the lilac-colored border. **B** Thickened and hyalinized collagen bundles, loss of adnexal structures and minimal inflammatory cell infiltrate. *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Lorenzo Cerroni, MD.*

Panniculitis

Panniculitis represents inflammation of the subcutis (see Fig. 0.14K,L) and it encompasses a wide range of disease processes (see Ch. 100). The diagnosis of panniculitides is difficult for clinicians and for dermatopathologists because the clinical presentation is often nonspecific and the histopathologic changes may vary over time and/or the changes may be nonspecific. Adding to the challenge, biopsy specimens are often inadequate, due to their being too superficial in nature, too narrow in breadth or too badly crushed by forceps, to render a definitive diagnosis.

An important first step in the subdivision of panniculitides is determination of the predominant location of the cellular infiltrate (Figs. 0.30 & 0.31). That is, does it chiefly affect the fat lobules or the septa between the fat lobules? Second, there should be an assessment as to whether a coexisting vasculitis is present or absent. If a coexisting vasculitis is detected, the size and type of the vessels affected must be determined.

With panniculitides, it is important to note the type and quality of the inflammatory infiltrate, as well as peculiarities in the pattern of fat necrosis. Early in the course of erythema nodosum, the most common panniculitis, the infiltrate may include acute inflammatory cells (neutrophils in particular), but in later stages, the infiltrate is composed primarily of chronic inflammatory cells (lymphocytes, histiocytes; see Fig. 0.30). If mononuclear cells are present, the presence or absence of cytologic atypia should be assessed, as subcutaneous panniculitis-like T cell lymphoma may mimic an inflammatory panniculitis. Lastly, peculiarities of fat necrosis, such as the hyaline changes in lupus panniculitis, the basophilic saponification in pancreatic panniculitis (see Fig. 0.31), or the pseudomembranous degeneration in lipodermatosclerosis, should be appreciated.

As is the case for granulomatous infiltrates, panniculitis requires a low threshold for performing special stains to exclude an infectious etiology and polarized light examination to identify foreign material.

Invisible dermatoses

Occasionally, one encounters a dermatosis that lacks an immediately recognizable pattern, and these types of cases are collectively referred to as "invisible dermatoses" (Table 0.11). From the perspective of the dermatopathologist, these invisible dermatoses represent cases where disease appears to exist clinically, but the histologic examination is rather unremarkable with conventional hematoxylin–eosin staining (i.e. the microscopic findings differ minimally from those of normal skin)[34].

Among the "invisible dermatoses" are: (1) diseases with subtle pathologic changes and diseases that require special stains to visualize the diagnostic pathology (e.g. disorders of elastic and collagen tissue without significant fibrosis or sclerosis) (Fig. 0.32); (2) diseases with focal pathologic processes requiring serial tissue levels to identify diagnostic features (e.g. cutaneous arteritis); and (3) diseases that require precise clinical information and/or strict clinical correlation to make the diagnosis (e.g. vitiligo, melasma, telangiectasia macularis eruptiva perstans).

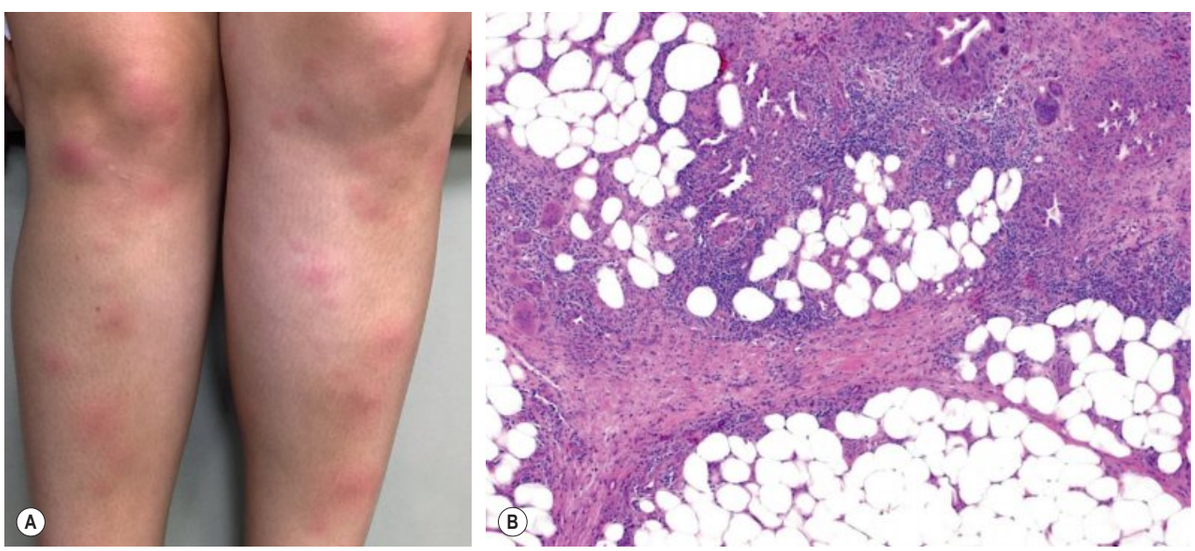

Fig. 0.30 Septal panniculitis. A Multiple pink to pink–violet nodules of erythema nodosum on the shins, admixed with healing bruise-like areas. **B** Predominantly septal granulomatous infiltrate with formation of characteristic Miescher granulomas. *A, Courtesy Julie V. Schaffer, MD; B, Courtesy James Patterson, MD.*

INVISIBLE DERMATOSES		
Microanatomic site	**Abnormality**	**Example dermatoses**
Stratum corneum, granular cell layer	Superficial infections	• Pityriasis (tinea) versicolor • Dermatophytosis • Erythrasma • Pitted keratolysis
	Keratinization disorders	• Ichthyosis • Disseminated superficial actinic porokeratosis
Basilar layer of epidermis	Pigmentation disorders	• Vitiligo • Café-au-lait macule • Melasma
Superficial dermis	Infestations	Onchocerciasis
	Mast cell infiltration	Telangiectasia macularis eruptiva perstans
	Deposition of endogenous substances	Macular amyloidosis
Superficial and deep dermis	Deposition of exogenous substances	Argyria (basement membrane of epithelial structures)
	Deposition of endogenous substances	Systemic amyloidosis (when subtle)
	Collagen abnormalities	• Collagenoma • Atrophoderma
	Elastic tissue abnormalities	• Nevus elasticus • Anetoderma (non-inflammatory) • Mid-dermal elastolysis
Absence of normal epithelial structure	Deficiency of eccrine sweat glands	Hypohidrotic ectodermal dysplasia

Table 0.11 Invisible dermatoses.

Because the histopathologic changes in "invisible dermatoses" are subtle and vexing, careful analysis is recommended. This includes careful searching for diagnostic pathology at all levels of the skin (cornified layer, epidermis, papillary dermis, reticular dermis, hypodermis, adnexa) and the use of special stains or immunohistochemical stains. Lastly, it should be remembered that causes of a seemingly invisible dermatosis may include poor selection of the biopsy site.

Deposition of Materials within the Skin

Occasionally, materials not normally present in the skin are deposited, either by exogenous or metabolic insult, and this can be appreciated histologically. In some patients, there is aberrant deposition of endogenously produced materials, such as uric acid in gouty tophi or light chain-derived amyloid due to an underlying plasma cell dyscrasia, whereas in others, exogenous material has been purposefully or accidentally inoculated into the skin (e.g. cosmetic filler material, tattoo pigment). These materials may accumulate within the dermis, the subcutaneous fat, or both. Deposits of some materials, such as the silver in patients with argyria, may be limited to cutaneous adnexa. Use of polarized light or darkfield microscopy (where light enters tissue at an angle that is not perpendicular to the slide) may be of use in identifying foreign material.

Some deposits engender a granulomatous inflammatory reaction (see Ch. 94), while others evoke no appreciable reaction at all. Deposited material is usually visualized during microscopic examination, but it may be removed during processing (e.g. siliconosis), leaving only characteristic "empty spaces" to suggest its clinical presence. Special stains may be helpful for precise identification, depending upon the suspected nature of the material. Sometimes mass spectrometry is required.

Histologic Stains

The various stains are characterized by their affinity to different pH values within tissues or to different chemical structures. The standard stain in dermatopathology is *hematoxylin and eosin*, referred to as "H&E". This stain yields a predictable pattern, with hematoxylin marking basophilic structures a blue–purple color (cellular nuclei and the granular layer of the epidermis) and eosin marking eosinophilic structures a pink–red (cytoplasm, collagen, muscle, nerve, and fibrin).

H&E staining alone enables the histopathologic diagnosis of many skin diseases, but some disorders require additional special stains to facilitate a diagnosis[35]. For example, elastic tissue, unless significantly altered by ultraviolet radiation or calcium deposits, does not stain with H&E, and special stains such as orcein or Verhoeff–van Gieson are required to identify alterations in these fibers (e.g. in anetoderma; see Fig. 0.32C,I). Similarly, special stains exist to screen for the presence of infectious agents, such as the Brown–Brenn stain (a modified tissue Gram stain) for bacteria, the periodic acid Schiff (PAS) or Grocott methenamine silver stain for fungus, and the Ziehl–Neelsen or Fite-Faraco stain for mycobacteria (see Fig. 0.32F,G). Additional special stains may be utilized to determine the type of infiltrating cell, such as the Giemsa or chloroacetate esterase stain for mast cells. Table 0.12 lists the more commonly employed histochemical ("special") stains used in dermatopathology.

Immunohistochemical Testing

Immunohistochemistry (IHC) is the use of immunologic techniques to identify cellular antigens (proteins) that are not visible in sections stained with H&E. It exploits the principle of antibodies binding specifically to

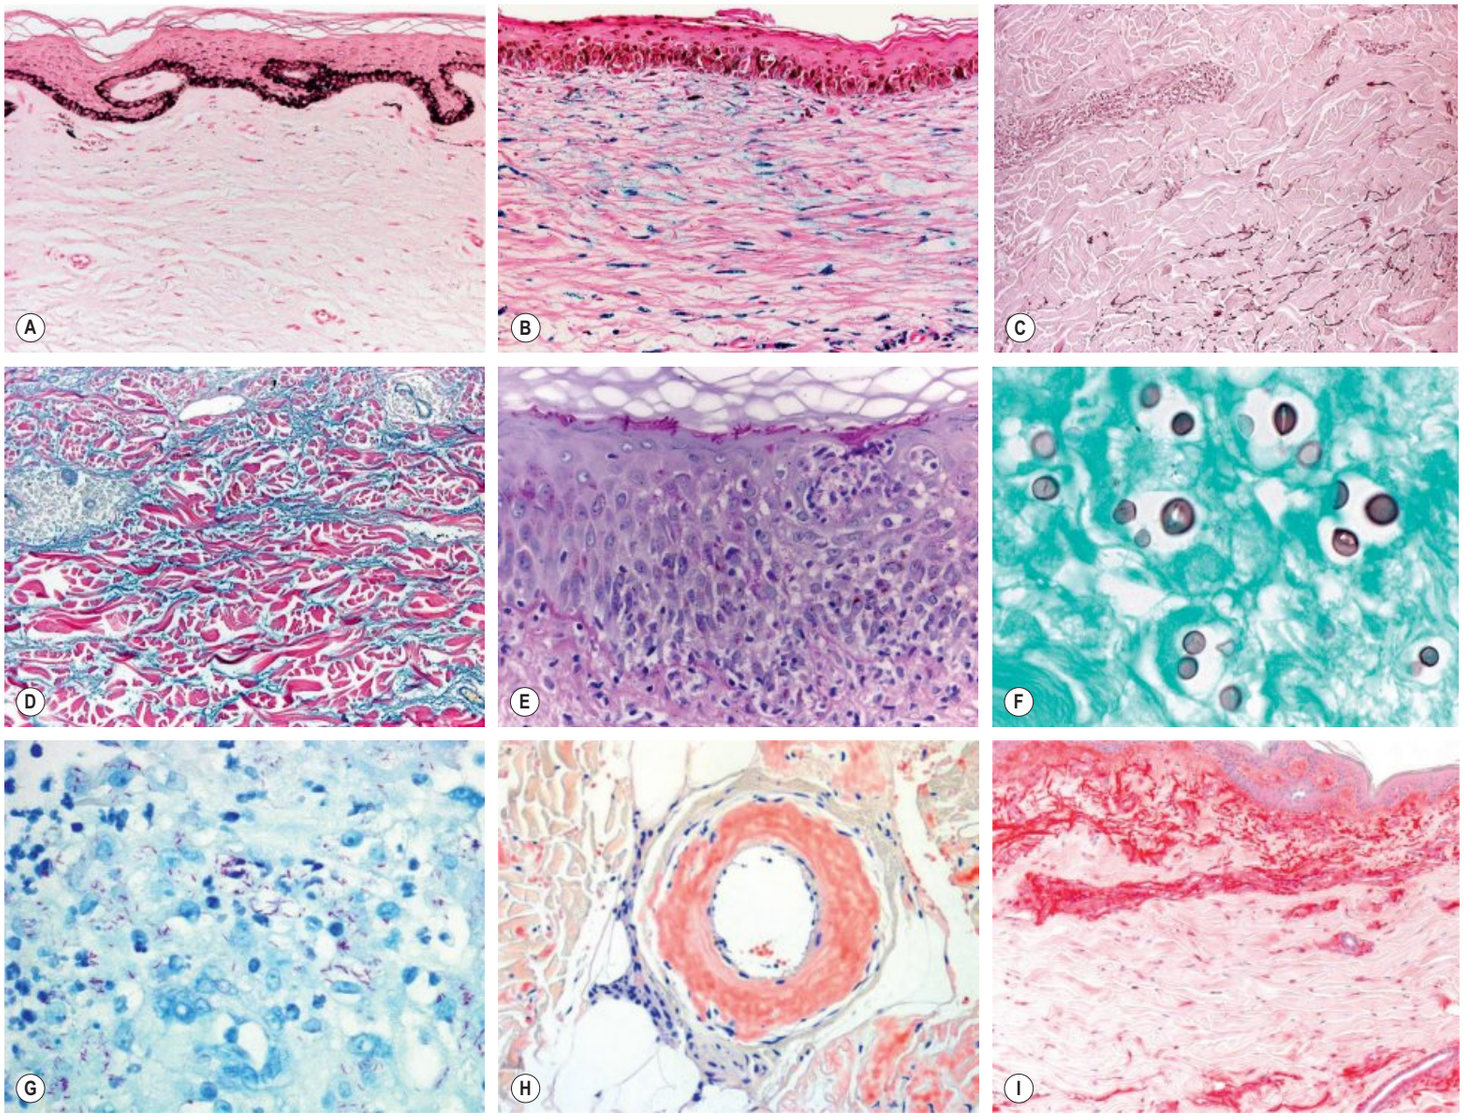

Fig. 0.32 Examples of histochemical stains. Often, histochemical stains reveal structures or substances (e.g. pigments, connective tissue elements, microorganisms) that cannot be clearly seen on H&E-stained sections. **A** Enhancement of increased *melanin* within the basal layer of the epidermis in genital melanosis (black color) – Fontana–Masson stain. **B** Demonstration of *iron* (hemosiderin) within dermal macrophages in purpura (blue color) – Prussian blue (Perls' iron) stain. **C** A near absence of dermal *elastic fibers* (upper left), compared to normal elastic fibers in the lower right, in anetoderma (black color) – orcein elastic tissue stain. **D** Increased *mucin* in the dermis in reticular erythematous mucinosis (blue color) – colloidal iron stain. **E** *Fungal hyphae* within the stratum corneum in dermatophytosis (purple–red color) – PAS stain (also note the staining of the basement membrane zone). **F** Yeast forms of *Cryptococcus neoformans* within the dermis (black color) – Grocott methenamine silver stain. **G** *Mycobacteria* within a granulomatous infiltrate in cutaneous tuberculosis (red–violet color) – Fite stain (modified acid-fast stain). **H** Amyloid deposits around dermal blood vessels in primary systemic AL amyloidosis (orange–red color) – Congo red stain. **I** Complete loss of elastic tissue in the mid dermis in mid-dermal elastolysis (red color) – immunostaining for amyloid P component. *A–F, Courtesy Lorenzo Cerroni, MD; G, Courtesy Karen Warschaw, MD.*

COMMONLY EMPLOYED SPECIAL STAINS IN DERMATOPATHOLOGY			
Stain	**Structures identified**	**Color**	**Application(s)**
Alcian blue (pH 2.5)	Acid mucopolysaccharides (glycosaminoglycans)	Light blue	Mucinoses (see Table 46.1) Lupus erythematosus Extramammary Paget disease Mucopolysaccharidoses
Alcian blue (pH 0.5)	Sulfated mucopolysaccharides (heparan sulfate, chondroitin sulfate)	Blue	
Chloroacetate esterase (Leder)	Myeloid cells and mast cells	Red	Neutrophilic dermatoses Malignant myeloid infiltrates Mastocytosis
Colloidal iron	Acid mucopolysaccharides	Blue	Mucinoses Lupus erythematosus Extramammary Paget disease
Congo red	Amyloid	Red; green in polarized light	Amyloidoses, cutaneous and systemic
Crystal violet	Acid mucopolysaccharides (glycosaminoglycans) and amyloid	Metachromatically purple with blue background	Mucinoses Amyloidoses

Table 0.12 Commonly employed special stains in dermatopathology.

Continued

COMMONLY EMPLOYED SPECIAL STAINS IN DERMATOPATHOLOGY			
Stain	**Structures identified**	**Color**	**Application(s)**
Fite–Faraco	*Mycobacterium leprae* *M. tuberculosis* MOTT (mycobacteria other than tuberculosis)	Red	Hansen disease (leprosy) Cutaneous tuberculosis Atypical mycobacterioses
Fontana–Masson (argentaffin)	Melanin	Black	Distinction between iron and melanin Discoloration due to drugs (e.g. minocycline) Evaluation of vitiligo
Giemsa	Nuclei of cells, microorganisms	Blue	Leishmaniasis Histoplasmosis Granuloma inguinale
	Mast cell granules	Metachromatically purple	Urticaria Mastocytosis
Gram (Brown–Brenn)	Gram-positive bacteria	Blue	Bacterial infections
	Gram-negative bacteria	Red	Bacterial infections
Grocott methenamine silver	Fungal cell walls	Black	Mycotic infections
Masson's trichrome	Smooth muscle	Pink	Distinguishing leiomyomas from dermatofibromas and neural tumors
	Collagen	Blue/green	Evaluating the characteristics of dermal collagen, e.g. perforating disorders
Mucicarmine	Epithelial mucin (acid mucopolysaccharides)	Red	Usually used for sialomucin (e.g. adenocarcinoma, Paget disease) and the capsule of *Cryptococcus neoformans*
Myeloperoxidase	Immature myeloid cells	Orange	Leukemic infiltrates (myelogenous leukemia)
Orcein (acid orcein–Giemsa)	Collagen	Pink	Elastic tissue disorders (e.g. PXE, anetoderma)
	Elastic tissue	Dark brown	
	Muscle and nerves	Yellow	
Pagoda	Amyloid	Orange	Amyloidoses
Periodic acid Schiff (PAS)	Glycogen, fungal walls, neutral mucopolysaccharides, fibrin, basement membranes, many clear cell neoplasms	Red	Mycotic infections Discoid lupus erythematosus (thickened epidermal basement membrane) Porphyria cutanea tarda (thickened vascular walls)
Perls' iron (Prussian blue)	Hemosiderin Ferric ions	Blue	Identification of iron as the source of pigment
Sudan black	Lipids (in frozen sections or formalin-fixed, unprocessed tissue*)	Black	Xanthomatoses Storage diseases (e.g. Fabry disease)
Sudan orange	Lipids (in frozen sections or formalin-fixed, unprocessed tissue*)	Orange	Xanthomatoses Storage diseases
Thioflavin T	Amyloid	Yellow–green by fluorescence microscopy	Amyloidoses
Toluidine blue	Acid mucopolysaccharides and mast cell granules	Metachromatically purple	Mastocytosis
Truant (auramine–rhodamine)	Acid-fast organisms	Reddish-yellow by fluorescence microscopy	Mycobacterial infections More sensitive than Fite stain
Verhoeff–van Gieson or Weigert	Collagen	Pink to red	Elastic tissue disorders (e.g. PXE, anetoderma, mid-dermal elastolysis, acquired cutis laxa)
	Elastic tissue	Black	
	Muscle and nerves	Yellow	
Von Kossa	Calcium salts	Black	Calcium deposits PXE (oxalate salts may not stain with this method) Calciphylaxis
Warthin–Starry (modified Steiner)	Bacteria	Black	Syphilis (and other diseases caused by spirochetes) Bacillary angiomatosis Granuloma inguinale, rhinoscleroma
Ziehl–Neelsen	Acid-fast bacteria	Red	Mycobacterial infections

*If processed, use anti-adipophilin stain.

Table 0.12 Commonly employed special stains in dermatopathology. In parentheses are alternative names or variations of the stain. Some of these special stains are being replaced by immunohistochemical (IHC) stains, e.g. IHC for adipophilin instead of Sudan black or Sudan orange stain. PXE, pseudoxanthoma elasticum.

antigens in biological tissues. Visualizing this antibody–antigen interaction may be accomplished in a number of ways. Most commonly, the tissue to be examined is incubated with antibodies conjugated with an enzyme that catalyzes a color-producing reaction when the antibody–enzyme conjugate is bound to the appropriate antigen within tissue; the enzyme is often peroxidase, hence the older terminology, immunoperoxidase technique.

While IHC is most often used to characterize the cellular lineage of neoplasms, it is also helpful in assessing the biological behavior of tumors and in identifying specific infectious agents that are not discernible or are difficult to detect in routine H&E-stained sections (Fig. 0.33)[36,37]. IHC is also used as a research tool to determine the distribution and localization of specific biomarkers and proteins within biological tissue. Finally, more recently, IHC has been used to verify the presence of antigens targeted by specific drugs (e.g. PD-L1).

When used rationally and appropriately, IHC is a formidable tool in diagnostic dermatopathology, but if used without insight or used excessively, it can be misleading and economically wasteful. Important factors to consider when utilizing IHC include the following: (1) almost no antibody is specific for a certain cell type, therefore a panel of antibodies should be employed to avoid premature, incomplete, or erroneous conclusions; (2) a differential diagnosis must be constructed prior to ordering an antibody panel so that the antibodies requested are appropriate; and (3) no antibody can differentiate irrefutably between a benign and malignant neoplasm (although, on occasion, evidence of an increased proliferative index or the aberrant expression of certain proteins may *support* such a conclusion).

A list of antibodies used most often in dermatopathology, the corresponding antigens, and the disease processes suggested by positive reactions is provided in Table 0.13.

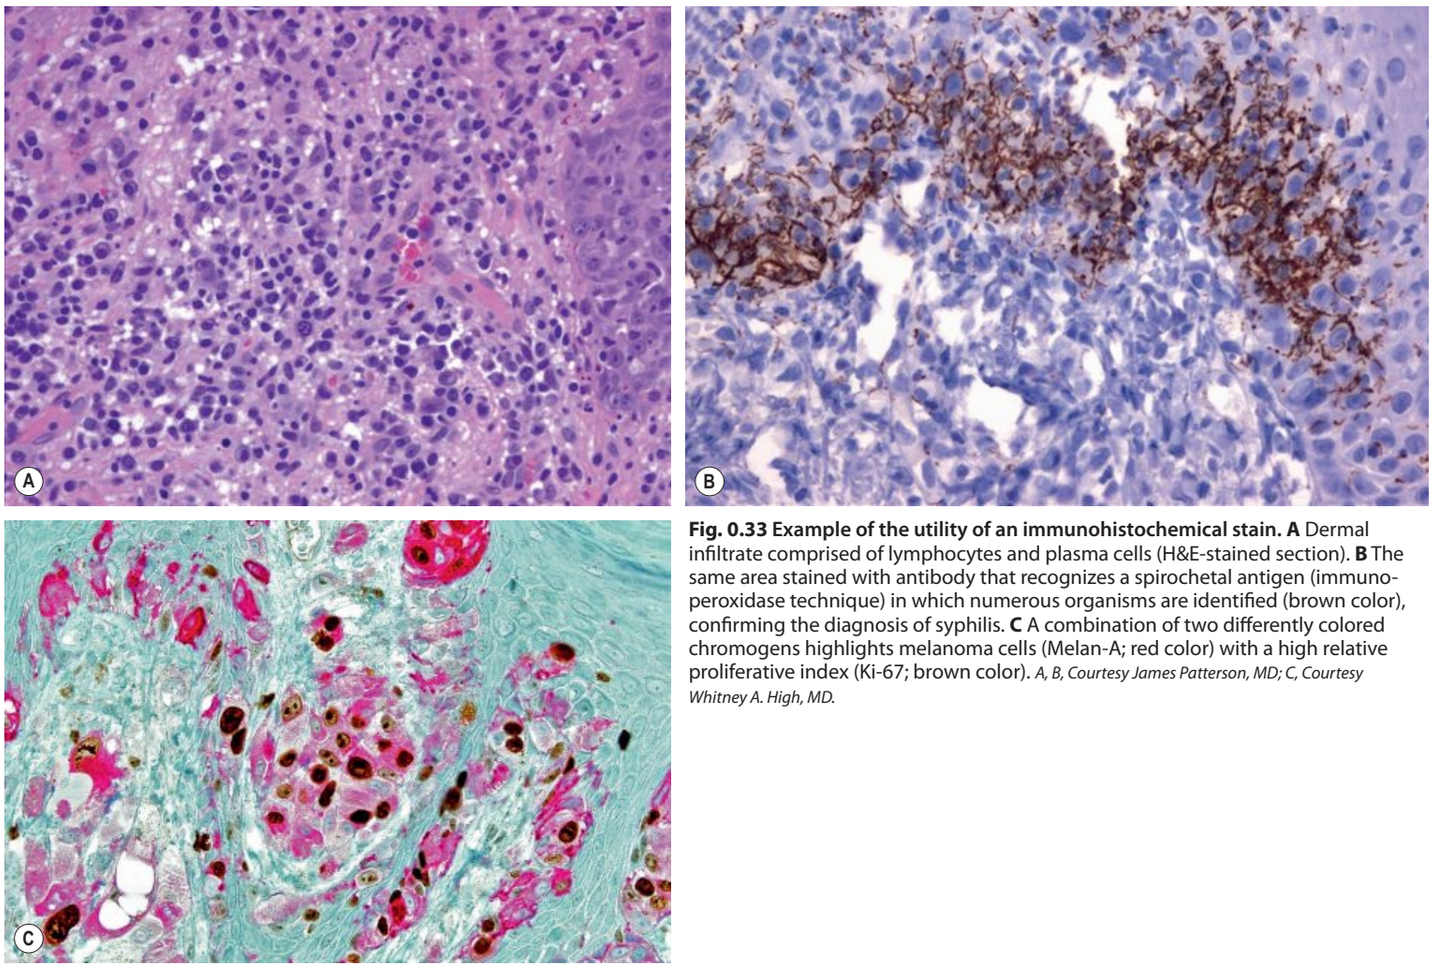

Fig. 0.33 Example of the utility of an immunohistochemical stain. A Dermal infiltrate comprised of lymphocytes and plasma cells (H&E-stained section). **B** The same area stained with antibody that recognizes a spirochetal antigen (immunoperoxidase technique) in which numerous organisms are identified (brown color), confirming the diagnosis of syphilis. **C** A combination of two differently colored chromogens highlights melanoma cells (Melan-A; red color) with a high relative proliferative index (Ki-67; brown color). *A, B, Courtesy James Patterson, MD; C, Courtesy Whitney A. High, MD.*

MOST COMMONLY EMPLOYED IMMUNOHISTOCHEMICAL (IHC) STAINS IN DERMATOPATHOLOGY		
Marker	**Definition/primary cellular expression**	**Applications/comments**
Markers for diagnosis of epithelial tumors		
Adipophilin (perilipin-2)	Marker of intracellular multilocular lipid accumulation	Diagnosis of tumors with sebaceous differentiation
Bcl2	Protein product of an oncogene which inhibits programmed cell death (apoptosis) Expressed in the basal layer of the epidermis (and lymphoid cells; see below)	Distinguishing basal cell carcinoma (diffuse staining) from trichoepithelioma (stains outermost layer)
Ber-EP4	Transmembrane glycoprotein involved in cellular adhesion Broadly distributed in epithelial cells	Distinction of basal cell carcinoma (+) from other cutaneous basaloid tumors (–)
CEA (carcinoembryonic antigen)	Expressed in a variety of epithelia, from gastrointestinal to cutaneous adnexa	Highlights tubular differentiation in epithelial tumors Diagnosis of benign and malignant adnexal neoplasms

Table 0.13 Most commonly employed immunohistochemical (IHC) stains in dermatopathology.

Continued

MOST COMMONLY EMPLOYED IMMUNOHISTOCHEMICAL (IHC) STAINS IN DERMATOPATHOLOGY		
Marker	**Definition/primary cellular expression**	**Applications/comments**
CK5/6	Intermediate-sized basic keratins Expressed in the basal layer of stratified squamous epithelia and myoepithelial cells of eccrine and apocrine secretory tubules	Spindle cell squamous cell carcinomas Myoepithelial neoplasms
CK20	Low-molecular-weight cytokeratin Expressed in simple epithelia and Merkel cells	Most specific marker for Merkel cell carcinoma (especially when combined with negative TTF-1 staining) Cutaneous metastases from different types of adenocarcinomas
EMA (epithelial membrane antigen)	High-molecular-weight transmembrane glycoprotein expressed in many epithelial cells	Highlights ductal differentiation in eccrine and apocrine tumors (benign and malignant) Positive staining in most sebaceous glands Perineurial cells
GCDFP-15 (gross cystic disease fluid protein-15)	Glycoprotein expressed by apocrine glands, eccrine glands (variable), minor salivary glands, bronchial glands, metaplastic epithelium of the breast, benign sweat gland tumors of the skin, and serous cells of the submandibular gland	Breast carcinoma metastases Sweat gland carcinoma with apocrine differentiation
MNF116	Epitope common to several cytokeratins (CK5, 6, 8, 17, and probably 19)	Spindle cell squamous cell carcinomas Adnexal and undifferentiated carcinomas
p63	p53 homolog that acts as a transcription factor Expressed in the basal layer of the epidermis and cutaneous adnexa as well as myoepithelial cells	Myoepithelial neoplasms Distinction of primary cutaneous adenocarcinomas (+) versus cutaneous metastasis from visceral adenocarcinomas (–)
Pancytokeratin AE1/AE3	Mixture of low- and high-molecular-weight cytokeratins	Screening tumors for an epithelial origin Useful for squamous cell carcinomas
MSH2, MLH1, MSH6, PMS2	Mismatch repair proteins	Loss of expression in sebaceous neoplasms; initial screening for Muir–Torre syndrome Not as sensitive or specific as germline mutational analysis and/or microsatellite instability testing
Markers for diagnosis of melanocytic and neural tumors		
S100	Family of low-molecular-weight calcium-binding proteins Neural crest-derived cells (melanocytes, Schwann cells, glial cells), chondrocytes, fat cells, macrophages, Langerhans cells, dendritic cells Some breast epithelial cells	Melanocytic nevi and melanoma Most sensitive marker for spindle cell/desmoplastic melanoma Also stains malignant peripheral nerve sheath tumors and clear cell sarcoma (melanoma of soft parts)
Melan-A (MART-1)	Protein involved in the function of the melanosomal matrix protein pmel17/gp100 Antigen present on melanocytes (and melanoma cells) recognized by cytotoxic T cells	Melanocytic nevi and melanomas Also may stain melanosome-containing keratinocytes in sun-damaged skin Cutaneous PEComas
SOX10	Transcription factor that is expressed in melanocytes Required for survival and proliferation of neural crest cells Controls MITF expression	High sensitivity for primary and metastatic melanomas (97%–100%) Expressed in all melanoma subtypes, including desmoplastic melanoma (~80%–100%) Positive staining in clear cell sarcomas and peripheral nerve sheath tumors Useful for the detection of micrometastases in sentinel lymph nodes
HMB45	Glycoprotein present in premelanosomes and melanosomes (pmel17/gp100) Expressed in melanocytes that are synthesizing melanin	Melanocytic nevi and melanomas (highly specific) Diminished staining with dermal descent more frequent in benign tumors Also may stain melanosome-containing keratinocytes Cutaneous PEComas
MITF (microphthalmia transcription factor)	Transcription factor that regulates several melanogenic enzymes, including tyrosinase, in melanocytes Plays key role in regulating melanocyte development during embryogenesis	Stains the nucleus of melanocytic nevus and melanoma cells Positive staining in most (~80%–100%) of all melanoma subtypes, including desmoplastic (~50%) Lack of staining of melanin-containing keratinocytes helpful in distinguishing solar lentigo from lentigo maligna Less specificity as can also stain non-melanocytic spindle cell tumors
Tyrosinase	Enzyme involved in the initial steps of melanin biosynthesis Expressed in melanocytes	High sensitivity and specificity (97%–100%) Sensitivity decreases with increased clinical stage and in metastases Positive staining in only a small percentage (~6%) of desmoplastic melanomas
PRAME (preferentially expressed antigen of melanoma)	A member of the family of cancer testis antigens (CTA), positive in many examples of different subtypes of melanoma and usually negative in melanocytic nevi Inhibits signaling of retinoic acid via retinoic acid receptors	In positive cases, helpful in distinguishing melanoma cells from associated nevus cells Can assist in assessment of margins in melanoma excisions
BRAF V600E	BRAF = serine/threonine-protein kinase in the MAPK pathway V600E = an amino acid substitution of glutamic acid (E) for valine (V) in the BRAF protein at position 600 due to a mutation in *BRAF* BRAF V600E (less often V600K or V600D) detected in ~50% of cutaneous melanomas This missense mutation leads to activation of the kinase	Compared to PCR, IHC staining is less sensitive Detection of BRAF V600E leads to treatment with targeted inhibitors of BRAF V600E and the MAPK pathway (see Ch. 113) BRAF V600E also present in Langerhans cell histiocytosis, Erdheim-Chester disease

Table 0.13 Most commonly employed immunohistochemical (IHC) stains in dermatopathology.

MOST COMMONLY EMPLOYED IMMUNOHISTOCHEMICAL (IHC) STAINS IN DERMATOPATHOLOGY		
Marker	**Definition/primary cellular expression**	**Applications/comments**
P75	Common receptor for members of the neurotrophins (NT) family Involved in programmed cell death Marker of Schwannian differentiation	Helpful for establishing the diagnosis of desmoplastic and neurotropic melanoma when S100 staining is weak or absent
PNL2	Detects fixative-resistant, uncharacterized melanocyte antigen	Highly sensitive and specific for melanocytic nevi and melanomas Positive staining of intraepidermal nevus cells (up to 100%) and primary and metastatic melanomas (~75%–100%), with the exception of desmoplastic melanomas which are almost invariably negative Clear cell sarcomas, PEComas, and melanocytic schwannomas may stain positively
pHH3 (phospho-histone H3)	Core histone protein Detects mitoses and distinguishes mitoses from apoptotic cells	Precise identification of mitoses within tumors
Markers for diagnosis of neuroendocrine tumors		
Chromogranin	Granules of neuroendocrine cells and sympathetic nerves	Merkel cell carcinoma Mucin-secreting sweat gland carcinoma with neuroendocrine differentiation
CK20 (see above)	Low-molecular-weight cytokeratin Expressed in simple epithelia and Merkel cells	Most sensitive stain for Merkel cell carcinoma (especially when combined with negative TTF-1 staining) Cutaneous metastases from different types of adenocarcinomas Epidermotropic metastases, e.g. secondary extramammary Paget disease
Neurofilament	Intermediate filaments in neurons and neuronal processes of central and peripheral nervous tissue	Merkel cell carcinoma Neuromas and neurofibromas
Synaptophysin	Glycoprotein of presynaptic vesicles found in neurons and neuroendocrine cells	Merkel cell carcinoma Neural tumors Mucin-secreting sweat gland carcinoma with neuroendocrine differentiation
TTF-1 (thyroid transcription factor-1)	Expressed in the epithelia of the thyroid and lung	Thyroid carcinoma Small cell lung carcinoma, visceral neuroendocrine tumors Negative in most cases of Merkel cell carcinoma
Markers for diagnosis of mesenchymal tumors		
Caldesmon	Actin and protomyosin binding protein involved in regulation of muscle and non-muscle contraction	Smooth muscle neoplasms
Calponin	Calcium-binding protein that regulates smooth muscle myosin ATPase activity Expressed in smooth muscle	Neoplasms with smooth muscle differentiation (benign and malignant)
CD99	Cell surface glycoprotein involved in leukocyte migration and T cell adhesion Expressed on most hematopoietic cells	Ewing sarcoma, peripheral neuroectodermal tumor Atypical fibroxanthoma, dermatofibroma (strong), DFSP (weaker) Some hematopoietic neoplasms
Desmin	Intermediate filament expressed predominantly by striated and smooth muscle cells	Smooth and striated muscle cell neoplasms (benign and malignant)
Factor XIIIa	Human coagulation factor XIII Expressed in subsets of dermal dendrocytes and monocytes/macrophages	Dermatofibromas (DFs) Non-Langerhans cell histiocytoses Negative in DFSP
Smooth muscle actin	Expressed in smooth muscle around blood vessels and in arrector pili muscles Expressed in myofibroblasts	Benign and malignant smooth muscle tumors Myofibroblastic tumors and pseudotumors Myoepithelial neoplasms
Vimentin	Intermediate filaments in mesenchymal cells	All mesenchymal cells/tumors Sarcomatoid (spindle cell) carcinoma
Markers for diagnosis of vascular tumors		
CD31	Platelet-endothelial cell adhesion molecule-1 (PECAM-1) Highly sensitive for endothelial cells, but poor specificity	Benign and malignant vascular neoplasms Histiocytes also stain positively
CD34	Surface glycoprotein involved in cell–cell adhesion Highly sensitive for endothelial cells, but poor specificity	Benign and malignant vascular neoplasms DFSP (negative in DFs) Many cutaneous spindle cell neoplasms so poor specificity
Podoplanin (D2-40)	Mucin-type transmembrane glycoprotein Specifically expressed by lymphatic, but not blood vessel, endothelial cells	Kaposi sarcoma, lymphangiomas, angiosarcomas with lymphatic differentiation, schwannomas Distinction of primary cutaneous carcinomas (+) from cutaneous metastases from visceral carcinomas (–)
c-MYC	Proto-oncogene Detection of MYC protein expression correlates with *MYC* translocation	Angiosarcoma (particularly post-radiation) Subset of cutaneous diffuse large cell B cell lymphomas

Table 0.13 Most commonly employed immunohistochemical (IHC) stains in dermatopathology.

Continued

MOST COMMONLY EMPLOYED IMMUNOHISTOCHEMICAL (IHC) STAINS IN DERMATOPATHOLOGY		
Marker	**Definition/primary cellular expression**	**Applications/comments**
ERG	Proto-oncogene Transcription factor expressed in vascular endothelial cells	Benign and malignant tumors derived from endothelial cells Epithelioid sarcoma (~50% of cases)
HHV-8 (human herpesvirus 8)	HHV-8 latent nuclear antigen	Kaposi sarcoma
Markers for diagnosis of histiocytic tumors		
CD1a	Transmembrane glycoprotein structurally related to MHC proteins that plays a role in antigen presentation Expressed in Langerhans cells and precursor T cells	Langerhans cell histiocytoses Some T cell lymphoblastic lymphomas
CD68	Glycoprotein that binds to low-density lipoprotein (LDL) Expressed in monocytes and macrophages, as well as myeloid cells and mast cells	Blastic NK cell lymphoma (some cases), myeloid leukemias Non-Langerhans cell histiocytoses Soft tissue tumors, e.g. some atypical fibroxanthomas, dermatofibromas, giant cell tumors of the tendon sheath
CD163	Member of the scavenger receptor cysteine-rich (SRCR) superfamily that is involved in clearance and endocytosis of hemoglobin/haptoglobin complexes Exclusively expressed by monocytes and macrophages	More specific than CD68 for identifying cells of monocyte/macrophage lineage in reactive and neoplastic conditions Non-Langerhans cell histiocytoses, e.g. juvenile xanthogranuloma, Rosai–Dorfman disease, reticulohistiocytoma Fibrohistiocytic tumors, e.g. dermatofibromas Chronic myelomonocytic leukemia, histiocytic sarcoma
CD207 (Langerin)	Transmembrane cell surface receptor expressed by Langerhans cells and localized within Birbeck granules Involved in internalization of antigens into Birbeck granules	Langerhans cell histiocytoses
S100 (see above)	Family of low-molecular-weight calcium-binding proteins Expressed in Langerhans cells and activated macrophages	Langerhans cell histiocytoses and Rosai–Dorfman disease Some lipomas and liposarcomas
Markers for diagnosis of mast cell tumors		
CD117 (c-KIT)	Receptor for stem cell factor Expressed on hematopoietic stem cells, mast cells, melanocytes Proto-oncogene	Mastocytosis Myeloid leukemia, some melanomas (especially acral or mucosal), melanocytic nevi The efficacy of KIT receptor inhibitors is determined by the location of amino acid substitutions
Mast cell tryptase	Serine protease within mast cell granules	Mastocytosis
Markers for diagnosis of cutaneous metastases (e.g. CK7, CK20, PSA) – see Table 122.4		
Markers for diagnosis of cutaneous lymphoproliferative disorders		
ALK (anaplastic lymphoma kinase)	Membrane-associated tyrosine kinase receptor Expressed in the nervous system, especially during development	Subgroup of anaplastic large cell lymphomas (nodal and very rarely primary cutaneous) Otherwise negative in primary cutaneous T cell lymphomas and other specific types of anaplastic lymphoma with CD30 positivity Also positive in some spitzoid melanocytic tumors, a subset of xanthogranulomas, and in epithelioid fibrous histiocytoma
Bcl-2	Anti-apoptosis factor for T and B cells Expressed in non-germinal center B cells and most T cells	Primary cutaneous diffuse large B cell lymphoma, leg type Distinguishes systemic/nodal follicular lymphomas with secondary skin involvement (+) from primary cutaneous follicle center lymphomas (–)
Bcl-6	Nuclear protein expressed in mature B cells within normal germinal centers Also expressed in T follicular helper cells	Primary cutaneous follicle center lymphoma Reactive lymphoid follicles T follicular helper cells
Immunoglobulin light chains (kappa and lambda)	Small polypeptide subunits of immunoglobulin Expressed in B lymphocytes and plasma cells	Plasma cell and plasmacytoid neoplasms Monotypic expression in clonal neoplasms
CD3	Surface glycoprotein involved in signal transduction to the T cell interior following antigen recognition Pan T cell marker Also expressed in NK cells (cytoplasmic staining for CD3ε)	T cell lymphomas, including HTLV-I associated adult T cell leukemia/lymphoma Reactive infiltrates with T lymphocytes
CD4	Transmembranous glycoprotein involved in T cell activation (MHC class II-restricted) Expressed in T helper cells, monocytes, granulocytes, macrophages, Langerhans cells, nTreg and iTreg cells	Most T cell lymphomas, including mycosis fungoides Blastic plasmacytoid dendritic cell neoplasm
CD5	Transmembrane glycoprotein Expressed in mature T cells, thymocytes, and a subset of mature B cells	T cell lymphomas, B cell chronic lymphocytic leukemia/small lymphocytic lymphoma, mantle cell lymphoma Reactive infiltrates with T lymphocytes
CD8	Transmembranous glycoprotein involved in T cell activation (MHC class I-restricted) Expressed in cytotoxic T cells, NK cells, thymocytes	Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T cell lymphoma Subcutaneous panniculitis-like T cell lymphoma Phenotypic variants of several CTCLs (e.g. mycosis fungoides)

Table 0.13 Most commonly employed immunohistochemical (IHC) stains in dermatopathology.

MOST COMMONLY EMPLOYED IMMUNOHISTOCHEMICAL (IHC) STAINS IN DERMATOPATHOLOGY		
Marker	**Definition/primary cellular expression**	**Applications/comments**
CD10/CALLA (common acute lymphoblastic leukemia antigen)	Membrane-associated metallo-endopeptidase Expressed in precursor B cells and germinal center cells Also expressed in follicular T helper cells	Follicle center lymphoma (both systemic and primary cutaneous) B lymphoblastic leukemia/lymphoma [Positive in most atypical fibroxanthomas but not specific]
CD15 (Lewis X)	Membrane protein that is a component of adhesion molecules that bind selectins Expressed on monocytes, granulocytes Absent on normal lymphocytes	Classic Hodgkin lymphoma (expressed on Reed–Sternberg cells) Acute myelogenous leukemia
CD20	Unglycosylated phosphoproteins expressed only on B cells Play a role in B cell activation and proliferation	Different types of cutaneous B cell lymphoma (both systemic and primary cutaneous) Reactive infiltrates with B lymphocytes
CD21	Receptor for the C3d fragment of complement and EBV in B cells and epithelial cells Expressed in follicular dendritic cells and mantle and marginal zone B cells	Follicular dendritic cell neoplasms Follicular dendritic cells within both reactive and neoplastic lymphoid follicles
CD30	Member of the tumor necrosis factor (TNF) receptor family Expressed by activated T and B cells	Anaplastic large T cell lymphoma, lymphomatoid papulosis, Hodgkin lymphoma, large cell transformation of mycosis fungoides May be expressed by a proportion of neoplastic cells in several other types of CTCL (e.g. mycosis fungoides) Expressed in activated T cells in non-neoplastic skin diseases (e.g. herpes virus infections, poxvirus infections)
CD45 (common leukocyte antigen)	Family of high-molecular-weight glycoproteins present on the surface of leukocytes (tyrosine phosphatase) Expressed by both T cells and B cells	Expressed on lymphocytes (benign and malignant, both T and B cell types)
CD56	Neural cell adhesion molecule Expressed on neural cells, NK cells, a subset of $CD3^+$ cytotoxic T cells, a subset of $CD4^+$ T cells, and monocytes	Extranodal NK/T cell lymphoma, nasal type Blastic plasmacytoid dendritic cell neoplasm Myeloma, some myelogenous leukemias, neural neoplasms
CD79a	Surface glycoprotein physically associated with immunoglobulin within the B cell membrane; involved in signal transduction after antigen binding Appears before the pre-B cell stage Expressed on immature and mature B cells, plasma cells	B cell lymphomas (can be positive in cases where CD20 is negative) Plasma cell neoplasms Reactive infiltrates with B lymphocytes
CD123	Marker of dendritic cells, including plasmacytoid	Blastic plasmacytoid dendritic cell neoplasm Positive staining of plasmacytoid dendritic cells in lupus erythematosus and other conditions
CD138	Surface glycoprotein involved in cell–cell and cell–matrix adhesion Expressed in plasma cells, plasmocytoid cells, activated T and B cells	Marginal zone B cell lymphoma, plasmacytoma, myeloma, plasmablastic lymphoma Positive staining of reactive plasma cells
Cyclin D1 (PRAD1; bcl-1)	Increased expression of cyclin D1 due to translocation of the cyclin D1/bcl-1 gene locus to the IgH promoter	Mantle cell lymphoma
EBER-1 (Epstein–Barr virus early ribonucleoprotein 1) [*in situ* hybridization]	EBV-infected cells	EBV-associated cutaneous lymphoproliferative disorders, e.g. hydroa vacciniforme, post-transplant lymphomas, extranodal NK/T cell lymphoma (nasal type), Hodgkin lymphoma
Granzyme B	Serine protease expressed specifically by activated cytotoxic T lymphocytes	Cytotoxic lymphocytes in benign and malignant lymphoid infiltrates
MUM1 (multiple myeloma oncogene-1)	Member of the interferon regulatory factor family of transcription factors Plasma cells, late B cells, and activated T cells	$CD30^+$ lymphoproliferative disorders, anaplastic $CD30^+$ lymphoma Strong expression in cutaneous diffuse large B cell lymphoma, leg type
Myeloperoxidase	Lysosomal protein most abundant in neutrophils and monocytes	Myeloid leukemias
PD-1 (programmed cell death protein 1)	Member of the CD28 family This receptor, along with its two ligands, comprises a checkpoint that downregulates immune responses Expressed primarily in activated T cells	Positive staining of T follicular helper lymphocytes Angioimmunoblastic T cell lymphoma Primary cutaneous CD4-positive small/medium T cell lymphoproliferative disorder Mycosis fungoides, Sézary syndrome Adult T cell leukemia/lymphoma
Perforin	Cytolytic protein stored in cytoplasmic granules and then released from cytotoxic T cells	Cytotoxic lymphocytes in benign and malignant lymphoid infiltrates
TCR-beta (βF1)	Beta chain of the T cell receptor	CTCLs with alpha/beta phenotype Positive staining of most reactive T lymphocytes

Table 0.13 Most commonly employed immunohistochemical (IHC) stains in dermatopathology.

Continued

MOST COMMONLY EMPLOYED IMMUNOHISTOCHEMICAL (IHC) STAINS IN DERMATOPATHOLOGY		
Marker	**Definition/primary cellular expression**	**Applications/comments**
TCR-gamma	Gamma chain of the T cell receptor	CTCLs with gamma/delta phenotype Positive staining of only a few reactive T lymphocytes
TdT (terminal deoxyribonucleotidyl transferase)	Expressed in immature, pre-B and pre-T cells	Lymphoblastic lymphoma/leukemia Variably positive in blastic plasmacytoid dendritic cell neoplasm
TIA-1	Granule-associated RNA-binding protein that defines a subset of $CD8^+$ lymphocytes with cytotoxic potential	Cytotoxic lymphocytes in benign and malignant lymphoid infiltrates
Microorganisms		
Herpes simplex virus (HSV)	Glycoproteins present within the viral envelope and core	HSV-1 or -2 infection
Varicella–zoster virus (VZV)	Glycoprotein I of VZV	Varicella or herpes zoster
Epstein–Barr virus (EBV)	EBV membrane protein encoded by *BNLF*	See EBER-1 under lymphoproliferative disorders
Cytomegalovirus (CMV)	Glycoproteins expressed during the immediate–early and early stages of CMV replication within infected cells	CMV infection
Human herpesvirus 8 (HHV-8)	HHV-8 latency-associated nuclear antigen	Kaposi sarcoma, primary effusion lymphoma, Castleman disease
Merkel cell polyomavirus (MCPyV)	MCPyV large T antigen	Expression may be associated with more favorable prognosis in Merkel cell carcinoma Anti-MCPyV-oncoprotein antibody titers used for monitoring
BCG	Anti-Bacillus Calmette–Guérin	Mycobacterial infections
Treponema pallidum	Specific for all *Treponema pallidum* antigens	Syphilis
Bartonella spp.	*Bartonella henselae, Bartonella quintana*	Bacillary angiomatosis, cat scratch disease, verruga peruana
Proliferation markers and markers for mitoses		
Ki-67	Prototypic antigen for cell cycle-related nuclear proteins, expressed by proliferating cells during the active phases of the cell cycle, but not during the resting phase (G0)	Assessment of proliferative activity
MIB-1	Peptides from recombinant fragments of the gene for Ki-67 antigen	

Table 0.13 Most commonly employed immunohistochemical (IHC) stains in dermatopathology. CD, cluster of differentiation; CK, cytokeratin; CTCLs, cutaneous T cell lymphomas; DFSP, dermatofibrosarcoma protuberans; EBV, Epstein–Barr virus; GIST, gastrointestinal stromal tumor; HTLV-1, human T cell leukemia virus 1 (human T cell lymphotropic virus 1); MAPK, mitogen-activated protein kinase; MART-1, melanoma antigen recognized by T cells; Melan-A, melanocyte antigen; MHC, major histocompatibility complex; NK, natural killer; PEC, perivascular epithelioid cell; PCR, polymerase chain reaction.

INTRODUCTION TO THE USE OF DERMOSCOPY (DERMATOSCOPY)

In the prior two sections, we reviewed the basic principles of clinical dermatology and then dermatopathology, with particular emphasis on clinicopathologic correlations. We now turn to an increasingly utilized ancillary examination technique known as dermoscopy (dermatoscopy). It is a non-invasive diagnostic technique that allows one to observe the morphologic features that are not visible to the naked eye, thus forming a link between macroscopic clinical dermatology and microscopic dermatopathology. This "sub-macroscopic" observation of colors and structures (Figs. 0.34–0.39) enhances clinical assessment by providing new diagnostic criteria for the differentiation of melanoma from other benign and malignant neoplasms, both melanocytic and non-melanocytic[38–40].

The technique of dermoscopy classically involves applying a liquid or gel to the skin surface and then inspecting the lesion using a hand-held, illuminated microscope (also called a dermatoscope), a stereomicroscope, a camera, or a digital imaging system. The magnification of these instruments ranges from 6× to 40× and even up to 100×.

The widely used dermatoscope has a 10-fold magnification, sufficient for routine assessment of skin tumors. When fluid is placed on the lesion this eliminates surface reflection and renders the cornified layer translucent, thus allowing a better visualization of pigmented structures within the epidermis, the dermal–epidermal junction, and the superficial dermis. Moreover, the size and shape of vessels within the superficial vascular plexus are better visualized with this procedure (Fig. 0.40; see Figs. 0.38 & 0.39)[41]. Subsequently, hand-held devices were introduced that utilize polarized light, which renders the epidermis translucent. With these latter devices, the use of a liquid medium is no longer required in order to visualize subsurface structures. The introduction of polarized light dermatoscopes definitively improved the dermoscopic examination of skin lesions by speeding up the process. In addition, this light mode allows the visualization of new features, such as shiny white structures, which were proved to be an additional important clue for the diagnosis of melanoma.

Nowadays, the dermatoscope is increasingly being used by dermatologists as a stethoscope equivalent. This is because it not only facilitates the diagnosis of pigmented and non-pigmented skin tumors, but it also improves recognition of a growing number of non-pigmented skin conditions. For example, dermoscopy can facilitate the diagnosis of scabies due to the presence of the pathognomonic "jet with contrail" sign[42] (see Fig. 0.40D). Additional skin infections and infestations that may be differentiated with increased confidence include pediculosis, phthiriasis, tungiasis, tinea nigra, and molluscum contagiosum (see Fig. 0.40A). For two of the more common inflammatory skin disorders – psoriasis and lichen planus – the use of dermoscopy allows the visualization of specific sub-macroscopic features, including "red dots" pattern in psoriasis and "whitish striae" pattern in lichen planus (see Fig. 0.40E,F). Scalp psoriasis and seborrheic dermatitis may also be differentiated via dermoscopy. The most notable scalp psoriasis features are red dots and globules, twisted red loops, and glomerular vessels, whereas seborrheic dermatitis is characterized by the presence of arborizing vessels and atypical red vessels, as well as featureless areas with no particular vascular pattern and no red dots or globules. In a review of the indications for dermoscopy, more than 35 different inflammatory and infectious skin diseases were listed[43], but nowadays more than 300 dermatologic conditions have been reported in which dermoscopy can be usefully applied. One of the more recent applications

Orange	keratin	epidermis
Yellow	keratin – cholesterol	epidermis – dermis
Black	melanin	stratum corneum
Brown	melanin	basal layer
Gray	melanin	papillary dermis
White	fibrosis	dermis
Blue	melanin	papillary and reticular dermis
Red	hemoglobin	papillary dermis
Purple	hemoglobin	reticular dermis

Fig. 0.34 Dermoscopy colors of keratinizing, melanocytic, and vascular tumors.

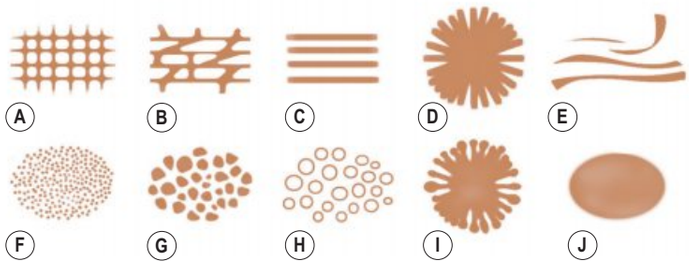

Fig. 0.35 Patterns of dermoscopy. Patterns formed by lines (upper row): **A** Reticular. **B** Branched. **C** Parallel. **D** Radial. **E** Curved lines. Patterns formed by other basic elements (lower row): **F** Pattern of dots. **G** Pattern of clods. **H** Pattern of circles. **I** Pattern of pseudopods. **J** Structureless (absence of discernible basic elements). Combinations of patterns may occur. If multiple patterns are present, they may be arranged symmetrically or asymmetrically.

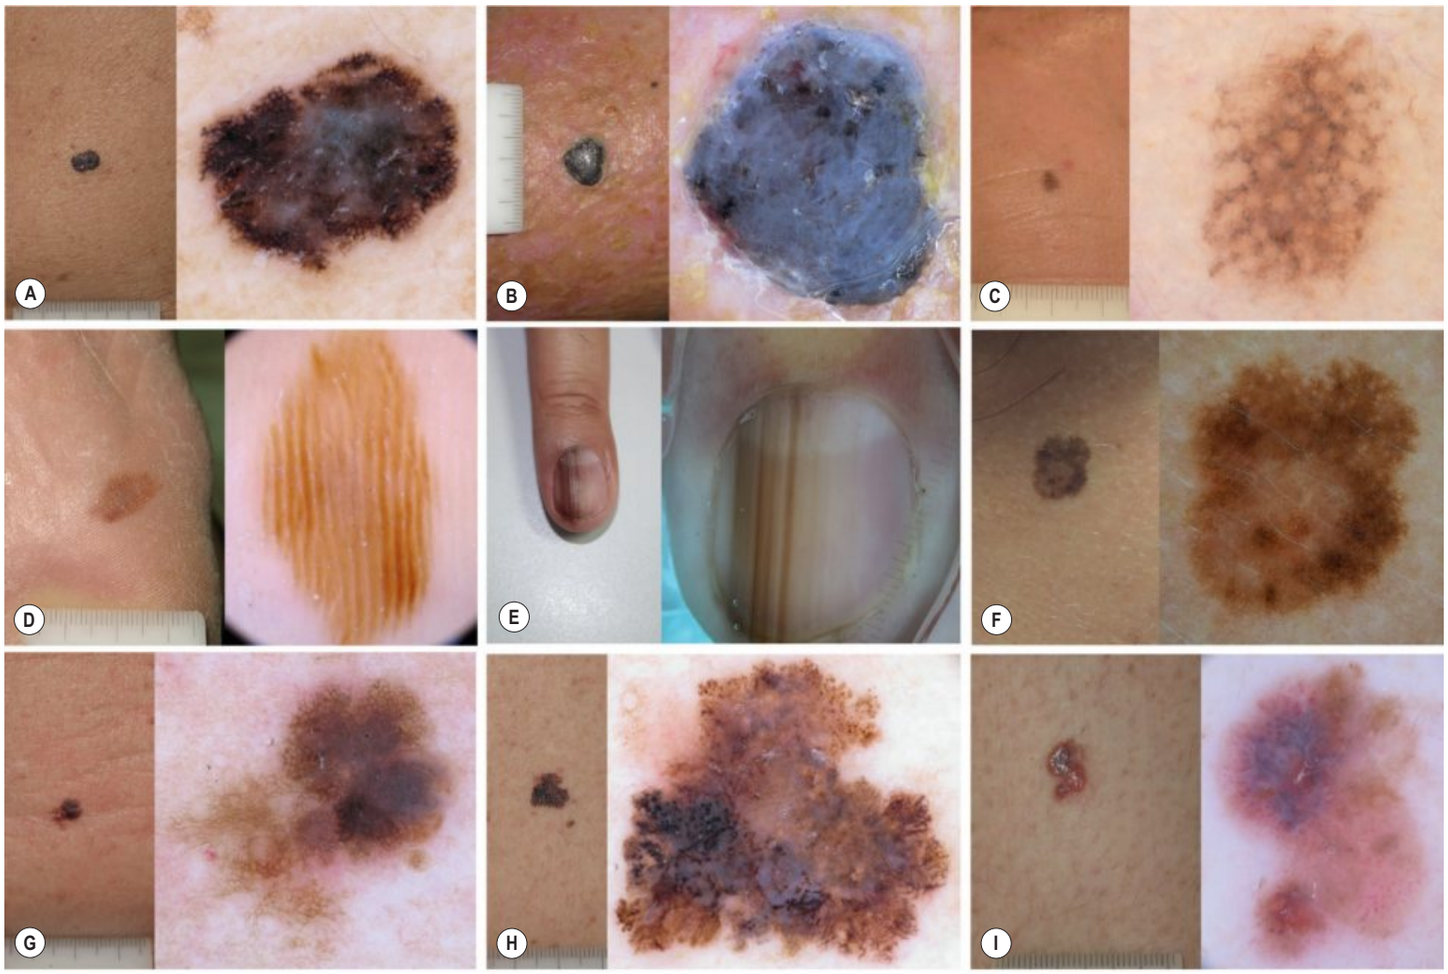

Fig. 0.36 The most common types of melanoma and examples of superficial melanomas of increasing tumor thickness. A Small superficial melanoma typified dermoscopically by asymmetry of color and structure, atypical network, and blue–white structures. **B** Larger thick melanoma with predominant blue–white veil and a few irregular black globules/areas. The combination of blue and black colors (as seen here) is highly specific for the diagnosis of nodular melanoma. **C** Small facial melanoma *in situ* (lentigo maligna) typified by gray granules around the hair follicles. **D** Acral melanoma *in situ* typified by the characteristic parallel-ridge pattern. **E** Nail apparatus melanoma characterized by a pigmented band composed of parallel lines with variable degrees of pigmentation and thickness. **F** Melanoma *in situ* typified dermoscopically by asymmetry of color and structure and atypical network. **G** Melanoma 0.5 mm in depth typified predominantly by an atypical pigment network and blue–white structures. **H** Melanoma 0.8 mm in depth typified by multiple melanoma-specific criteria including asymmetry of color and structure, irregular dots and globules, blue–white structures, and peripheral irregular streaks. **I** Melanoma 1.3 mm in depth typified predominantly by blue–white veil and atypical vascular pattern, both signs of increased tumor thickness. Remnants of an atypical pigment network and irregular brown globules are also observed.

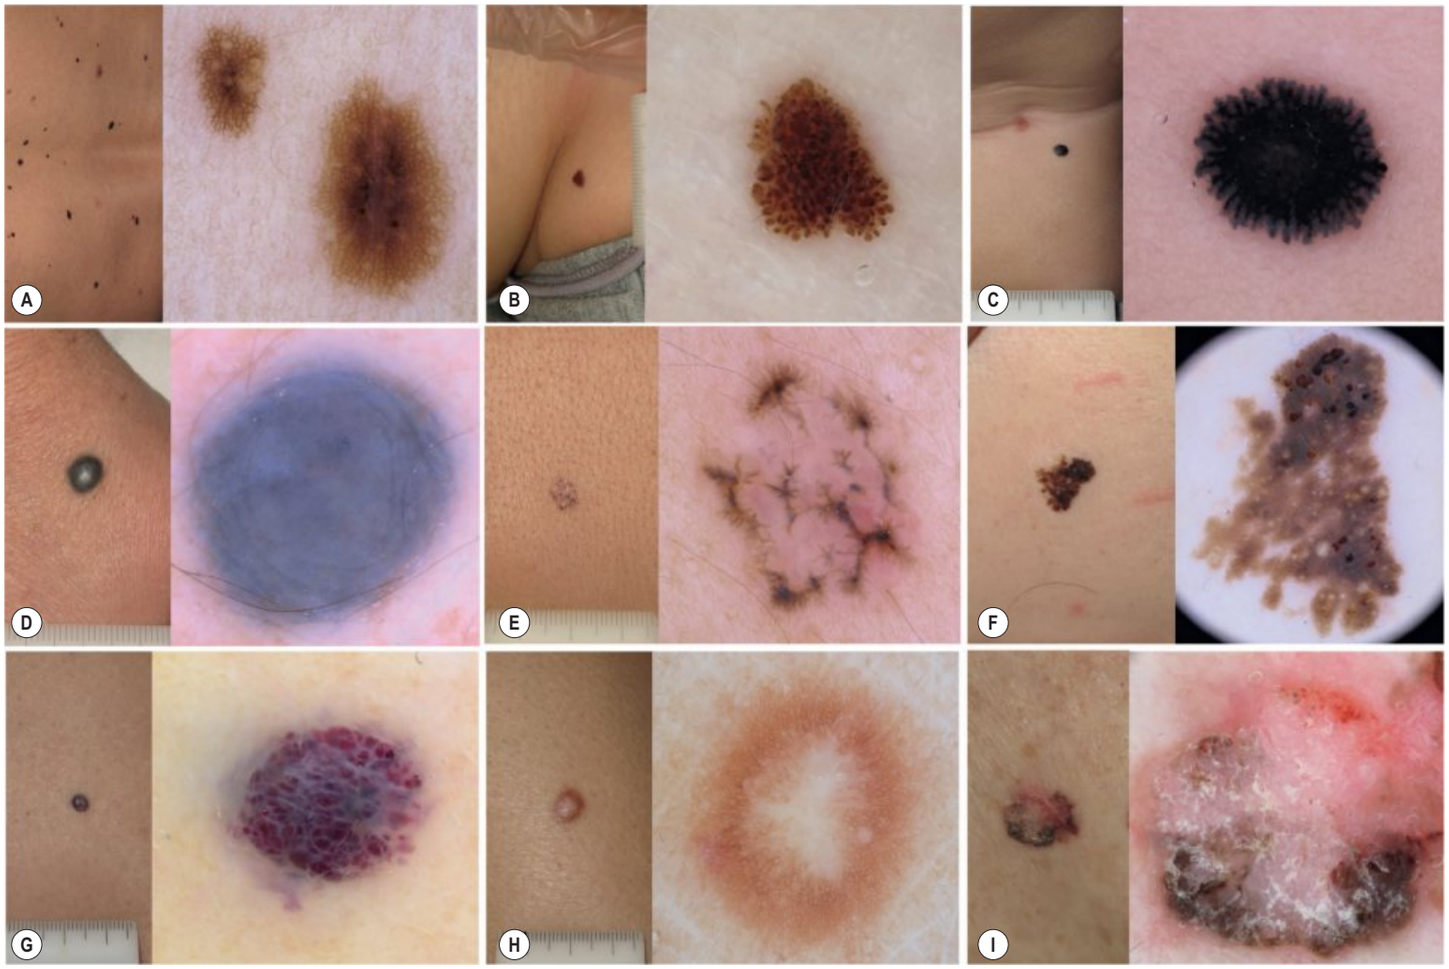

Fig. 0.37 The most common types of melanocytic nevi and non-melanocytic pigmented tumors – clinical and dermoscopic findings. A Two typical acquired nevi with a reticular pattern by dermoscopy. **B** Small congenital nevus with a globular pattern. **C** Reed nevus (pigmented spindle cell nevus) typified dermoscopically by the classic starburst pattern (regular streaks at the periphery of a heavily pigmented and symmetric small macule). **D** Classic homogeneous blue color typically found in blue nevi. **E** Pigmented basal cell carcinoma with typical leaf-like areas (islands of brown–gray color) and blue–gray globules. **F** Seborrheic keratosis with typical milia-like cysts (white shining dots/globules) and comedo-like openings (black targetoid globules). **G** Angiokeratoma with red–blue lacunae clearly visible as well-demarcated roundish structures. **H** Dermatofibroma with characteristic central white patch and peripheral delicate pigment network. **I** Squamous cell carcinoma characterized by a keratotic plaque with white structures, peripheral irregular pigmentation and atypical vessels.

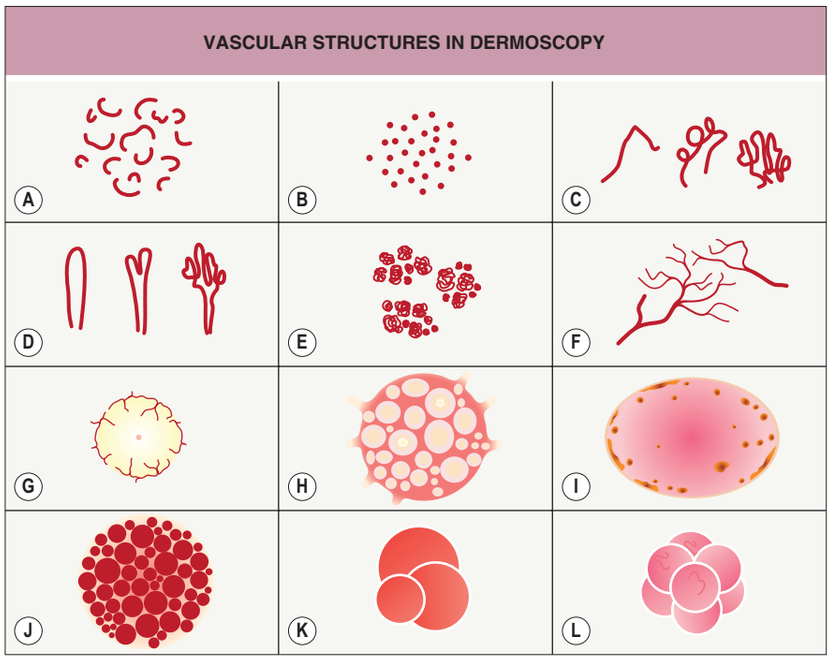

Fig. 0.38 Vascular structures in dermoscopy. (See also Table 0.16 for definitions and diagnostic significance). **A** Comma vessels – typical of dermal and congenital nevi. **B** Dotted vessels – often found in melanoma and Spitz nevi. **C** Linear-irregular vessels – typical of melanoma. **D** Hairpin vessels – most common in keratinizing tumors, such as seborrheic keratosis and squamous cell carcinoma. **E** Glomerular vessels – found in Bowen disease. **F** Arborizing vessels – typical of basal cell carcinoma. **G** Crown vessels – common finding in sebaceous hyperplasia. **H** Strawberry pattern – typical of facial actinic keratosis. **I** Multiple blood crusts over a red background – typical finding in superficial basal cell carcinoma. **J** Red lacunae – typical finding in hemangiomas. **K** Red homogeneous areas intersected by whitish lines – most common in pyogenic granuloma. **L** Milky-red areas – typical of melanoma.

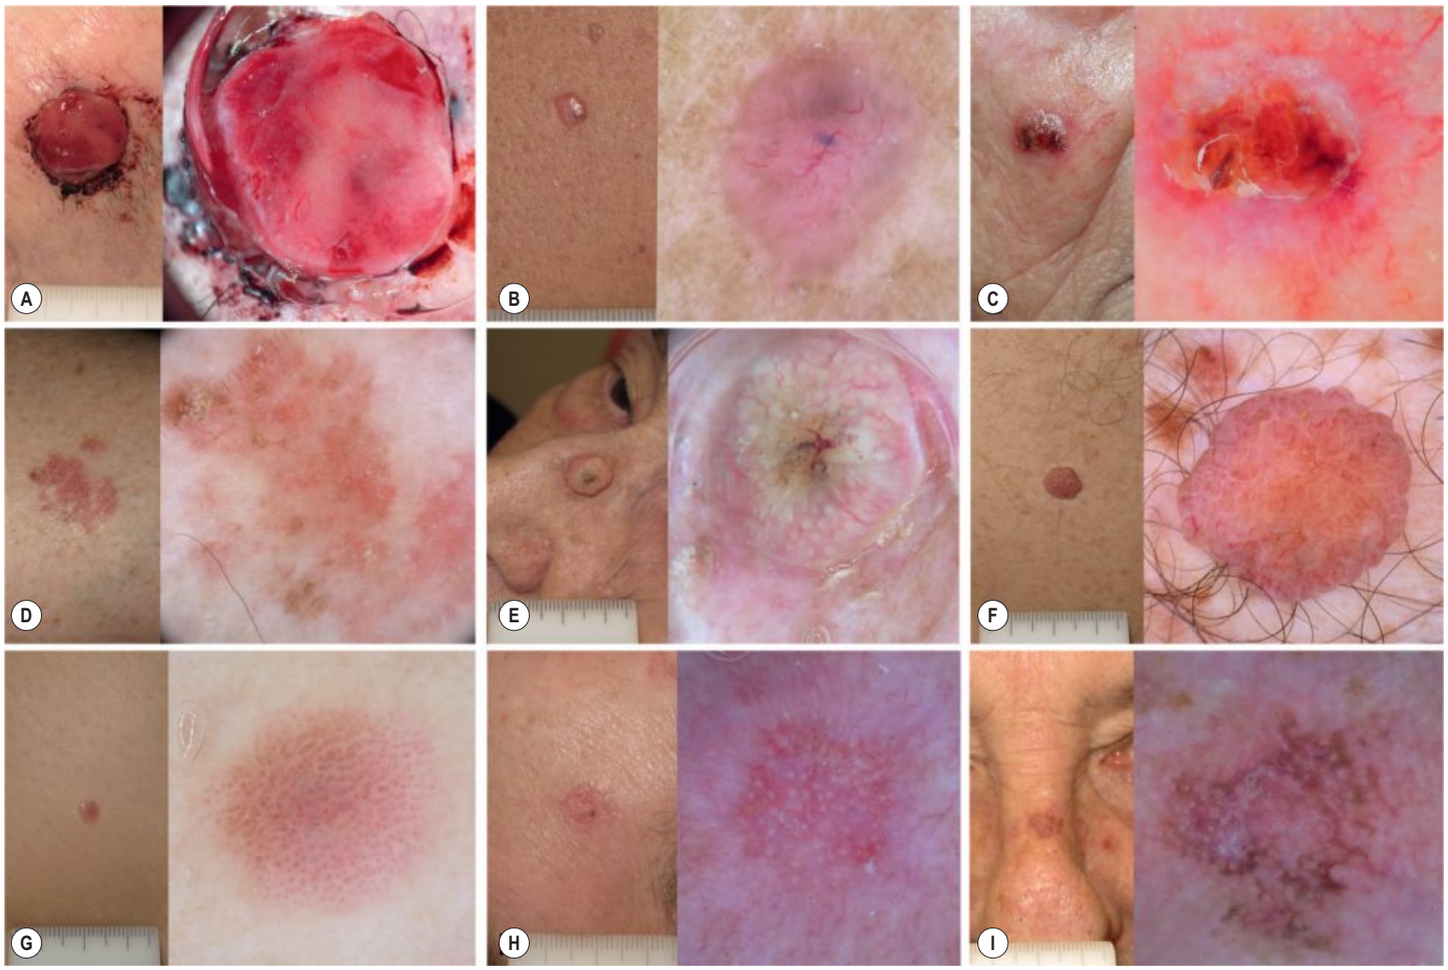

Fig. 0.39 Non-pigmented skin tumors – clinical and dermoscopic findings. A An amelanotic melanoma typified by polymorphic vascular structures and a milky-red color in the background. **B** Nodular basal cell carcinoma with obvious arborizing vessels and blue–gray globules. **C** Merkel cell carcinoma characterized by an atypical vascular pattern. **D** An example of Bowen disease with clusters of dotted/glomerular vessels; these findings in combination with superficial scales are highly specific for the diagnosis. **E** Well-differentiated squamous cell carcinoma with white keratin masses, white circles, white clods, and polymorphic vessels. **F** An intradermal melanocytic nevus with typical comma-shaped vessels. **G** Spitz nevus with dotted vessels and reticular depigmentation. **H** Strawberry pattern and scales of an actinic keratosis. **I** Pigmented variant of actinic keratosis characterized by pigmented scales and rosettes on an erythematous background.

of this technique is trichoscopy, namely the dermoscopic observation of the scalp, which can prove helpful in the differential diagnosis of hair and scalp diseases[44] (see Fig. 0.40G; see Fig. 69.7).

With regard to melanoma screening, the aim of dermoscopy is to maximize early detection while minimizing the unnecessary excision of benign skin tumors. Over the past several years, three meta-analyses and two randomized studies have proven definitively that dermoscopy improves the sensitivity for melanoma detection as compared to just the naked eye[45–49]. In a meta-analysis of dermoscopic studies performed in a clinical setting, the relative odds ratio for dermoscopic diagnosis of cutaneous melanoma (compared to naked eye examination) was 15.6 ($p=0.016$). The average sensitivities for melanoma detection by naked eye versus dermoscopic examinations were 74% and 90%, respectively. Furthermore, this improved sensitivity came about without a decrease in specificity, suggesting that better melanoma detection (16% improvement) occurred without increasing the number of unnecessary excisions of benign lesions[49]. A randomized study found that combining eye and dermoscopic examinations led to a significant reduction in the percentage of patients referred for biopsy (9% vs 15.6%; $p=0.013$)[47]. In summary, the use of dermoscopy is associated with a significant increase in the number of excised melanomas, as well as a significant reduction in the number of excised benign pigmented skin lesions[50,51].

Pattern analysis is the most well-known and reliable method for differentiating pigmented skin tumors. This is based on a two-step algorithm, where first there is recognition of basic criteria for melanocytic and non-melanocytic tumors (first step; Table 0.14) and then benign and malignant features of melanocytic nevi and melanoma, respectively (second step; Tables 0.15 & 0.16)[38]. Attempts to simplify the dermoscopic approach to diagnosing melanocytic nevi and melanoma include the ABCD rule, the Menzies method, and the 7-point checklist[38] (Tables 0.17–0.19).

In a virtual "Consensus Net Meeting on Dermoscopy"[38], 40 experts were able to correctly classify more than 95% of melanocytic lesions and more than 90% of non-melanocytic lesions, with pattern analysis producing the best diagnostic performance. The alternative algorithms (ABCD rule, Menzies method, and 7-point checklist) revealed similar sensitivities as compared to pattern analysis but ~10% less specificity. The favorable results of pattern analysis were not unexpected, as this method probably reflects the human brain's approach to categorizing morphologic images and is similar to the pattern analysis utilized in general clinical dermatology and dermatopathology (see above). That is, there is a subjective perception of the "gestalt" of a given lesion and its integration into an internalized knowledge base, which is the result of expertise on the subject; in contrast, "simplified" algorithms were designed to keep non-experts from failing to detect melanomas, even at the cost of decreased specificity.

Results of the virtual consensus study showed that three criteria (asymmetry, atypical network, and blue–white structures) were especially important in distinguishing malignant from benign pigmented skin tumors (Table 0.20). Using this 3-point dermoscopy rule as a screening test, general physicians with no prior experience in the use of dermoscopy were able to better classify skin lesions suggestive of skin cancer as compared to examination with the naked eye (referral sensitivity of 79% and 54%, respectively), without increasing the number of unnecessary expert consultations[48].

While the continued, skilled use of dermoscopy will undoubtedly aid in the early recognition of melanoma as well as the diagnosis of inflammatory disorders and other cutaneous neoplasms, there are additional technologies that may also have a significant impact on our specialty over the next decade, including confocal microscopy[52] and artificial intelligence. These topics are covered in the next two sections.

Fig. 0.40 Non-pigmented skin lesions – clinical and dermoscopic findings. A Molluscum contagiosum with peripheral arborizing vessels superimposed on a white background. Amorphous white–yellow clods are typically seen in the center. **B** Sebaceous hyperplasia characterized by aggregated yellow blotches and crown vessels. **C** Clear cell acanthoma with dotted vessels linearly arranged as strings of pearls. **D** A 6-month-old boy with scabies. By dermoscopy, a characteristic "jet with contrail" structure can be identified corresponding to the anterior part of the mite (arrow) and the burrow behind it. **E** By dermoscopy, classic psoriasis plaques exhibit regular dotted vessels. **F** The dermoscopic pattern of lichen planus is definitely different from that of psoriasis. In the former, dotted vessels are seen at the border of typical whitish lines and clods, which closely resemble the Wickham striae found in lichen planus of the oral mucosa. **G** Typical follicular yellow dots seen dermoscopically in patches of alopecia on the scalp in alopecia areata. **H** A palmar wart showing hemorrhagic dots corresponding to small intracorneal hemorrhages. **I** An early plaque of discoid lupus erythematosus showing erythema, white scales, and perifollicular whitish halo.

PATTERN ANALYSIS: FIRST-STEP ALGORITHM FOR DIFFERENTIATION BETWEEN MELANOCYTIC AND NON-MELANOCYTIC LESIONS		
Dermoscopic criterion	**Definition**	**Diagnostic significance**
Pigment network – pseudo-network*	Network of brownish interconnected lines over a background of tan diffuse pigmentation. In facial skin, a peculiar pigment network, also called a pseudo-network, is typified by round, equally sized network holes corresponding to the pre-existing follicular ostia	Melanocytic lesion
Aggregated globules	Numerous, variously sized, more or less clustered, round to oval structures with various shades of brown and gray–black. They should be differentiated from multiple blue–gray globules	Melanocytic lesion
Streaks	These have been previously described separately as pseudopods and radial streaming, but are now combined into the one term. They are bulbous and often kinked or finger-like projections seen at the edge of a lesion. They may arise from network structures but more commonly do not. They range in color from tan to black	Melanocytic lesion
Homogeneous blue pigmentation†	Structureless blue pigmentation in the absence of pigment network or other distinctive local features	Melanocytic lesion
Parallel pattern	Seen in melanocytic lesions of palms/soles and mucosal areas. On palms/soles, the pigmentation may follow the sulci or the cristae (i.e. furrows or ridges) of the dermatoglyphics. Rarely arranged at right angles to these structures	Melanocytic lesion
Multiple milia-like cysts	Numerous, variously sized, white or yellowish, roundish structures	Seborrheic keratosis
Comedo-like openings	Brown–yellowish to brown–black, round to oval, sharply circumscribed keratotic plugs in the ostia of hair follicles. When irregularly shaped, comedo-like openings are also called irregular crypts	Seborrheic keratosis
Light-brown fingerprint-like structures	Light-brown, delicate, network-like structures with the pattern of a fingerprint	Seborrheic keratosis

Table 0.14 Pattern analysis: first-step algorithm for differentiation between melanocytic and non-melanocytic lesions.

PATTERN ANALYSIS: FIRST-STEP ALGORITHM FOR DIFFERENTIATION BETWEEN MELANOCYTIC AND NON-MELANOCYTIC LESIONS		
Dermoscopic criterion	**Definition**	**Diagnostic significance**
Cerebriform pattern	Dark-brown furrows between ridges typifying a brain-like appearance	Seborrheic keratosis
Arborizing vessels	Tree-like branching telangiectasias	Basal cell carcinoma[¶]
Leaf-like structures	Brown to gray/blue discrete bulbous structures forming leaf-like patterns. They are discrete pigmented nests (islands) never arising from a pigment network and usually not arising from adjacent confluent pigmented areas	Basal cell carcinoma[¶]
Large blue–gray ovoid nests	Well-circumscribed, confluent or near confluent, pigmented, ovoid, or elongated areas that are larger than globules and not intimately connected to a pigmented tumor body	Basal cell carcinoma[¶]
Multiple blue–gray globules	Multiple globules (not dots) that should be differentiated from multiple blue–gray dots (melanophages)	Basal cell carcinoma[¶]
Spoke-wheel areas	Well-circumscribed radial projections, usually tan in color but sometimes blue or gray, meeting at an often darker (dark brown, black, or blue) central axis	Basal cell carcinoma[¶]
Ulceration[‡]	Absence of the epidermis, often associated with congealed blood, not due to a well-described recent history of trauma	Basal cell carcinoma[¶]
Red–blue lacunae	More or less sharply demarcated, roundish or oval areas with a reddish, red–bluish, or dark-red to black coloration	Vascular lesion
Red–bluish to reddish-black homogeneous areas	Structureless homogeneous areas of red–bluish to red–black coloration	Vascular lesion
None of the listed criteria	Absence of the above-mentioned criteria	Melanocytic lesion

*Exception 1: Pigment network or pseudo-network is also present in solar lentigo and rarely in seborrheic keratosis and pigmented actinic keratosis. A delicate, annular pigment network is also commonly seen in dermatofibroma and accessory nipple (clue for diagnosis of dermatofibroma and accessory nipple: central white patch).
†Exception 2: Homogeneous blue pigmentation (dermoscopic hallmark of blue nevus) is also seen (uncommonly) in some hemangiomas and basal cell carcinomas and (commonly) in intradermal melanoma metastases.
‡Exception 3: Ulceration is also seen less commonly in invasive melanoma.
¶To diagnose a basal cell carcinoma, the negative feature of pigment network must be absent and one or more of the positive features listed here must be present.

Table 0.14 Pattern analysis: first-step algorithm for differentiation between melanocytic and non-melanocytic lesions. *Adapted from Argenziano G, Soyer HP, Chimenti S, et al. Dermoscopy of pigmented skin lesions: results of a consensus meeting via the Internet. J Am Acad Dermatol 2003;48:679–93.*

PATTERN ANALYSIS: SECOND-STEP ALGORITHM FOR DIFFERENTIATION BETWEEN MELANOCYTIC NEVI AND MELANOMA		
Dermoscopic criterion	**Definition**	**Diagnostic significance**
Global features		
Reticular pattern	Pigment network covering most parts of the lesion	Melanocytic nevus
Globular pattern	Numerous, variously sized, round to oval structures with various shades of brown and gray–black	Melanocytic nevus
Cobblestone pattern	Large, closely aggregated, somehow angulated globule-like structures resembling a cobblestone	Intradermal melanocytic nevus
Homogeneous pattern	Diffuse, brown, gray–blue to gray–black pigmentation in the absence of other distinctive local features	Melanocytic (blue) nevus
Starburst pattern	Pigmented streaks in a radial arrangement at the edge of the lesion	Spitz/Reed nevus
Parallel pattern	Pigmentation on palms/soles that follows the sulci or the cristae (furrows or ridges), rarely arranged at right angles to these structures	Acral nevus/melanoma (see below)
Multicomponent pattern	Combination of three or more of the above patterns	Melanoma
Nonspecific pattern	Pigmented lesion lacking above patterns	Possible melanoma
Local features		
Pigment network	Typical pigment network: light- to dark-brown network with small, uniformly spaced network holes and thin network lines distributed more or less regularly throughout the lesion and usually thinning out at the periphery	Benign melanocytic lesion
	Atypical pigment network: black, brown or gray network with irregular holes and thick lines	Melanoma
Dots/globules	Black, brown, round to oval, variously sized structures regularly or irregularly distributed within the lesion	If regular, benign melanocytic lesion If irregular, melanoma
Streaks	These have been previously described separately as pseudopods and radial streaming. Streaks are bulbous and often kinked or finger-like projections seen at the edge of a lesion. They may arise from network structures but more commonly do not. They range in color from tan to black	If regular, benign melanocytic lesion (Spitz/Reed nevus) If irregular, melanoma
Blue–whitish veil	Irregular, structureless area of confluent blue pigmentation with an overlying white "ground-glass" film. The pigmentation cannot occupy the entire lesion and usually corresponds to a clinically elevated part of the lesion	Melanoma
Regression structures	White scar-like depigmentation and/or blue pepper-like granules usually corresponding to a clinically flat part of the lesion	Melanoma

Table 0.15 Pattern analysis: second-step algorithm for differentiation between melanocytic nevi and melanoma.

Continued

PATTERN ANALYSIS: SECOND-STEP ALGORITHM FOR DIFFERENTIATION BETWEEN MELANOCYTIC NEVI AND MELANOMA		
Dermoscopic criterion	**Definition**	**Diagnostic significance**
Hypopigmentation	Areas with less pigmentation than the overall pigmentation of the lesion	Nonspecific
Blotches	Black, brown, and/or gray structureless areas with symmetrical or asymmetrical distribution within the lesion	If symmetrical, benign melanocytic lesion If asymmetrical, melanoma
Site-related features		
Face	Typical pseudo-network (round, equally sized network holes corresponding to the pre-existing follicular ostia)	Benign melanocytic lesion
	Annular-granular structures (multiple blue–gray dots surrounding the follicular ostia with an annular–granular appearance)	Melanoma
	Gray pseudo-network (gray pigmentation surrounding the follicular ostia, formed by the confluence of annular–granular structures)	Melanoma
	Rhomboidal structures (gray–brown pigmentation surrounding the follicular ostia with a rhomboidal appearance)	Melanoma
	Asymmetric pigmented follicles (eccentric annular pigmentation around follicular ostia)	Melanoma
Palms/soles	Parallel-furrow pattern (pigmentation following the sulci superficiales)	Acral nevus
	Lattice-like pattern (pigmentation following and crossing the furrows)	Acral nevus
	Fibrillar pattern (numerous, finely pigmented filaments perpendicular to the furrows and ridges)	Acral nevus
	Parallel-ridge pattern (pigmentation aligned along the cristae superficiales)	Melanoma

Table 0.15 Pattern analysis: second-step algorithm for differentiation between melanocytic nevi and melanoma. *Adapted from Argenziano G, Soyer HP, Chimenti S, et al. Dermoscopy of pigmented skin lesions: results of a consensus meeting via the Internet. J Am Acad Dermatol 2003;48:679–93*.

VASCULAR STRUCTURES SEEN IN VARIOUS SKIN TUMORS		
Pattern	**Definition**	**Diagnostic significance**
Comma	Coarse vessels that are slightly curved and barely branching	Congenital and intradermal melanocytic nevi
Dotted	Tiny red dots densely aligned next to each other	Melanocytic lesion (often Spitz nevus and melanoma)
Linear-irregular	Linear, irregularly shaped, sized and distributed red structures	Melanoma
Hairpin	Vascular loops sometimes twisted and bending. They can be surrounded by a whitish halo	With white halo: keratinizing proliferation (seborrheic keratosis, squamous cell carcinoma, keratoacanthoma, verruca) Without white halo: melanoma
Glomerular	Variation on the theme of dotted vessels. They are tortuous capillaries often distributed in clusters mimicking the glomerular apparatus of the kidney	Bowen disease
Arborizing	Stem vessels of large diameter branching irregularly into fine terminal capillaries. The color is bright red, being sharply focused in dermoscopic images due to their location immediately beneath the surface of the tumor	Basal cell carcinoma
Crown	Groups of orderly bending, scarcely branching vessels located along the border of the lesion	Sebaceous hyperplasia
Strawberry	Pink-to-red "pseudo-network" around hair follicles of the face, frequently intermingled with fine, linear-wavy vessels. Often hair follicles are filled with yellowish keratotic plugs	Actinic keratosis
Corkscrew	Linear vessels twisted along a central axis	Thick melanoma or melanoma metastasis
Milky-red color	Globules and/or larger areas of fuzzy or unfocused milky-red color often corresponding to an elevated part of the lesion	Melanoma
Polymorphous	Any combination of two or more different types of vascular structures. The most frequent is linear-irregular and dotted vessels	Malignant tumor, including melanoma, basal cell carcinoma, squamous cell carcinoma

Table 0.16 Vascular structures seen in various skin tumors. See also Figs. 0.38–0.40.

ABCD RULE FOR THE DERMOSCOPIC DIFFERENTIATION BETWEEN BENIGN MELANOCYTIC LESIONS AND MELANOMA			
Dermoscopic criterion	**Definition**	**Score**	**Weight factor**
Asymmetry	In 0, 1, or 2 perpendicular axes; assess not only contour, but also colors and structures	0–2	×1.3
Border	Abrupt ending of pigment pattern at the periphery in 0–8 segments	0–8	×0.1
Color	Presence of up to six colors (white, red, light brown, dark brown, blue–gray, black)	1–6	×0.5
Dermoscopic structures	Presence of network, structureless (homogeneous) areas, branched streaks, dots, and globules	1–5	×0.5

Table 0.17 ABCD rule for the dermoscopic differentiation between benign melanocytic lesions and melanoma. Formula for calculating total score: (A score × 1.3) + (B score × 0.1) + (C score × 0.5) + (D score × 0.5). Interpretation of total score: <4.75, benign melanocytic lesion; 4.75–5.45, suspicious lesion (close follow-up or excision recommended); >5.45, lesion highly suspicious for melanoma. *Adapted from Argenziano G, Soyer HP, Chimenti S, et al. Dermoscopy of pigmented skin lesions: results of a consensus meeting via the Internet. J Am Acad Dermatol 2003;48:679–93*.

MENZIES SCORING METHOD FOR THE DERMOSCOPIC DIFFERENTIATION BETWEEN BENIGN MELANOCYTIC LESIONS AND MELANOMA	
Dermoscopic criterion	**Definition**
Negative features	
Symmetry of pattern	Symmetry of pattern is required across all axes through the lesion's center of gravity (center of the lesion). Symmetry of pattern does not require shape symmetry
Presence of a single color	The colors scored are black, gray, blue, dark brown, tan, and red. White is not scored as a color
Positive features	
Blue–white veil	An area of irregular, structureless confluent blue pigmentation with an overlying white "ground-glass" haze. It cannot occupy the entire lesion and cannot be associated with red–blue lacunae
Multiple brown dots	Focal areas of multiple brown (usually dark brown) dots (not globules)
Pseudopods	Bulbous and often kinked projections that are found at the edge of a lesion, connected either directly to the tumor body or to the pigmented network. They can never be seen distributed regularly or symmetrically around the lesion. When connected directly to the tumor body, they must have an acute angle to the tumor edge or arise from linear or curvilinear extensions. When connected to the network, the width of the bulbous ending must be greater than the width of any part of the surrounding network and at least double that of its directly connected network projection
Radial streaming	Finger-like extensions at the edge of a lesion which are never distributed regularly or symmetrically around the lesion
Scar-like depigmentation	Areas of white distinct irregular extensions (true scarring), which should not be confused with hypo- or depigmentation due to simple loss of melanin
Peripheral black dots/globules	Black dots/globules found at or near the edge of the lesion
Multiple (5–6) colors	The colors scored are black, gray, blue, dark brown, tan, and red. White is not scored as a color
Multiple blue/gray dots	Foci of multiple blue or gray dots (not globules) often described as "pepper-like" granules in pattern
Broadened network	A network made up of irregular thicker "cords" of the net, often seen focally thicker

Table 0.18 Menzies scoring method for the dermoscopic differentiation between benign melanocytic lesions and melanoma. For melanoma to be diagnosed, a lesion must have neither of both negative features and one or more of the nine positive features. *Adapted from Argenziano G, Soyer HP, Chimenti S, et al. Dermoscopy of pigmented skin lesions: results of a consensus meeting via the Internet. J Am Acad Dermatol 2003;48:679–93.*

7-POINT CHECKLIST FOR THE DERMOSCOPIC DIFFERENTIATION BETWEEN BENIGN MELANOCYTIC LESIONS AND MELANOMA		
Dermoscopic criterion	**Definition**	**Score**
1. Atypical pigment network	More than one type of network (in terms of color and thickness of the meshes) irregularly distributed within the lesion	2
2. Blue–whitish veil	Irregular, structureless area of confluent blue pigmentation with an overlying white "ground-glass" film. The pigmentation cannot occupy the entire lesion and usually corresponds to a clinically elevated part of the lesion	2
3. Atypical vascular pattern	Linear-irregular or dotted vessels not clearly seen within regression structures	2
4. Irregular streaks	Brown to black, bulbous or finger-like projections irregularly distributed at the edge of a lesion. They may arise from network structures but more commonly do not	1
5. Irregular dots/globules	Black, brown, round to oval, variously sized structures irregularly distributed within the lesion	1
6. Irregular blotches	Black, brown, and/or gray structureless areas asymmetrically distributed within the lesion	1
7. Regression structures	White scar-like depigmentation and/or blue pepper-like granules usually corresponding to a clinically flat part of the lesion	1

Table 0.19 7-point checklist for the dermoscopic differentiation between benign melanocytic lesions and melanoma. By simple addition of the individual scores, a minimum total score of 3 is required for the diagnosis of melanoma, whereas a total score of less than 3 is indicative of non-melanoma. *Adapted from Argenziano G, Soyer HP, Chimenti S, et al. Dermoscopy of pigmented skin lesions: results of a consensus meeting via the Internet. J Am Acad Dermatol 2003;48:679–93.*

DEFINITIONS OF DERMOSCOPIC CRITERIA FOR THE 3-POINT CHECKLIST	
Criterion	**Definition**
Asymmetry	Asymmetrical distribution of colors and dermoscopic structures
Atypical network*	More than one type of network (in terms of color and thickness of the meshes) irregularly distributed within the lesion
Blue–white structures†	Presence of any type of blue and/or white color
*Usually found in early melanoma. †Usually found in both melanoma and pigmented basal cell carcinoma.	

Table 0.20 Definitions of dermoscopic criteria for the 3-point checklist. The presence of more than one criterion suggests a suspicious lesion. *Adapted from Argenziano G, Puig S, Zalaudek I, et al. Dermoscopy improves accuracy of primary care physicians to triage lesions suggestive of skin cancer. J Clin Oncol 2006;24:1877–82.*

INTRODUCTION TO CONFOCAL MICROSCOPY

Reflectance confocal microscopy (RCM) is a non-invasive imaging technique that enables a microscopic, horizontal view of the epidermis and papillary dermis. RCM provides a "virtual" skin biopsy that allows assessment of different layers of the skin at a cellular level[53]. In clinical settings, RCM can be used for the pre-histologic diagnosis of skin tumors as a way of improving patient management. Most commonly, RCM is employed as a second-level analysis to support clinical and dermoscopic evaluation, especially when biopsies are a concern because of anatomic location (e.g. face, genitalia) or the clinical condition of the patient[54]. By increasing specificity and sensitivity, RCM improves the diagnostic accuracy of skin cancers, especially melanocytic tumors. It also reduces the number of unnecessary biopsies and excisions, guides biopsy selection in a suspicious lesion so as to provide a more accurate diagnostic specimen, and helps to define the margins of large tumors to ensure an adequate surgical excision. In addition, RCM is used to monitor and longitudinally evaluate the clinical and therapeutic evolution of neoplastic and inflammatory skin diseases[55].

LIMITATIONS OF REFLECTANCE CONFOCAL MICROSCOPY (RCM) AND POSSIBLE INTERVENTIONS			
	Influence on RCM analysis	**Possible intervention(s)**	**Effectiveness of the intervention(s)**
Body site/features			
Palmoplantar	Thick stratum corneum and acanthosis of the epidermis limits assessment	None	–
Multiple terminal hairs	Poor adherence of the lens and presence of air bubbles in the follicle ostia	Clip hairs and use handheld RCM device	+
Lesion characteristics			
Hyperkeratotic	High backscattering of laser light due to keratin	Pre-treatment with keratolytic ointment	+
Nodular	Penetration of laser is limited to the upper dermis	Evaluation of the surface of the lesion	+/–
Ulcerated or crusted	Presence of fibrin, coagulated blood, and keratin limit examination	Evaluation of the portion of the lesion that surrounds the crust or ulceration	+/–
Deep inflammation	Penetration of laser is limited to the upper dermis	None	–

Table 0.21 Limitations of reflectance confocal microscopy (RCM) and possible interventions.

RCM Principals, Technology, and Limitations

In RCM, the basic principle is to have a point source of light focused on a specific point within tissue. Due to the different refractive indices in the skin, the light is scattered back by various tissue structures. Only light reflected from the tissue focus point can pass through a pinhole-sized spatial filter into the RCM detector; it is then processed by dedicated software. The contrast in confocal images is due to differences in the reflectance index between cellular structures, subcellular structures, and their surroundings. Melanin and keratin have a high reflectance index, as do white blood cells, chromatin, and dermal fibers, but to a lesser extent. Therefore, they appear brighter than surrounding structures in RCM images[54–57]. RCM provides cellular details similar to those seen by histopathology at low magnification.

Commercially available RCM devices often use a near-infrared (830 nm) laser with low power (up to 35 mW) at the tissue level. Immersion oil or water must be applied to the skin lesion to obtain a refractive index close to that of the stratum corneum. The immersion lens is used with water/gels placed between the window and the objective lens and has a refractive index close to that of the epidermis. The laser scans a two-dimensional grid over the skin to obtain a thin horizontal optical section, and back-scattered photons from the illuminated living tissue are detected. Processed data are usually displayed as a grayscale image ("single RCM image": 500 × 500 microns field-of-view) with a lateral resolution of ~0.5 microns and an axial resolution of ~3.5 microns. For most lesions and anatomical sites, RCM examination is feasible, but there are limitations, e.g. hyperkeratotic, acral, or ulcerated lesions (Table 0.21)[54].

Currently, two different RCM instruments are commercially available. They are designed for different indications, based primarily on the clinical lesion and its anatomical site. The static-head RCM device (Vivascope® 1500, Caliber I.D. Inc.) usually employs an automated stepper in order to obtain up to 64 sequential images for a mosaic grid of 16 × 16 contiguous images in the *horizontal* plane (8 × 8 mm field-of-view[54,57]; termed "Vivablock"). By adjusting the focal length of the laser beam, a series of consecutive RCM single images can be stacked *vertically* (termed "Vivastack"), from the skin surface to the superficial dermis. A dermoscopic picture usually serves as a gross map to guide RCM imaging so as to examine the site of interest within the lesion.

The handheld RCM device (Vivascope® 3000, Caliber I.D. Inc.) allows one to investigate anatomic sites that are curved or difficult to reach, such as the nose, ears, eyelids, or mucosa. The technical characteristics are similar, but the field-of-view is smaller and limited to 0.5 × 0.5 mm[54]. The most common application of this device is examination of pigmented macules and patches in photodamaged facial skin. In addition, this handheld device can be moved easily on the skin and allows for analysis of multiple lesions in different body sites, which is particularly useful when studying inflammatory skin diseases.

CUTANEOUS TUMORS – MAJOR REFLECTANCE CONFOCAL MICROSCOPY (RCM) FEATURES		
Cutaneous tumors	**RCM feature**	**Associated diagnosis**
Melanocytic	Pagetoid round cells	Atypical melanocytic lesion, melanoma
	Pagetoid dendritic cells	Atypical melanocytic lesion, melanoma
	Dense nests	Melanocytic nevus
	Sparse nests	Atypical melanocytic lesion, melanoma
	Cerebriform nests	Nodular melanoma
	Dendritic cells around adnexal structures	Lentigo maligna
	Ringed pattern	Melanocytic nevus
	Meshwork pattern	Melanocytic nevus
	Disarray of the dermal–epidermal junction	Atypical melanocytic lesion, melanoma
Keratinocytic	Absent or irregular honeycombed pattern of epidermis	Actinic keratosis, SCC
	Parakeratosis	Actinic keratosis, SCC
	Atypical keratinocytes (different degree)	Actinic keratosis, SCC
	Polycyclic papillae and epidermal bulges	Solar lentigo, seborrheic keratosis
	Epidermal invaginations with keratin pearls	Seborrheic keratosis
	Basaloid nests – dark silhouette	BCC
	Basaloid nests – palisading	BCC
	Peritumoral clefts	BCC
	Dilated vessels	SCC, BCC

Table 0.22 Cutaneous tumors – major reflectance confocal microscopy (RCM) features. BCC, basal cell carcinoma; SCC, squamous cell carcinoma.

RCM Applications

Cutaneous tumors

The RCM criteria for melanocytic and keratinocytic skin tumors have been extensively described in the literature (Table 0.22). RCM is particularly useful for flat pigmented lesions, especially when the differential diagnosis is atypical nevus versus melanoma. It has been shown to significantly reduce the number of unnecessary skin biopsies and excisions. In the case of nodular lesions, RCM does not allow assessment of the deep cellular component, but assessment of the superficial confocal features that reflect the melanocytic proliferation is often sufficient to define the nature of the lesion.

The differential diagnosis of flat pigmented lesions in sun-exposed sites includes melanocytic skin neoplasms, in particular lentigo maligna (Fig. 0.41) and lentigo maligna melanoma, as well as non-melanocytic

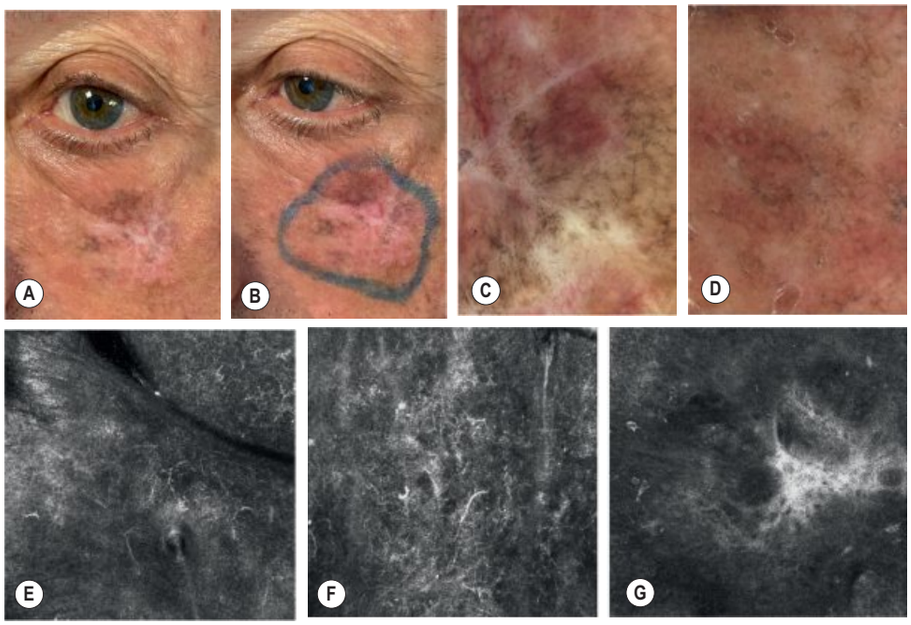

Fig. 0.41 Reflectance confocal microscopy (RCM) of relapsed lentigo maligna. A An X-shaped scar surrounded by a fragmented brown patch with an irregular border. **B** Outline of lesional margins based upon mapping with a handheld RCM device. **C, D** By dermoscopy, there is scar tissue due to the previous excision and an atypical reticular pattern as well as focal gray areas containing fine gray granules. **E, F** RCM illustrates the presence of atypical dendritic melanocytes in the epidermis and pagetoid cells. **G** Scar tissue visible as bright white dermal fibers.

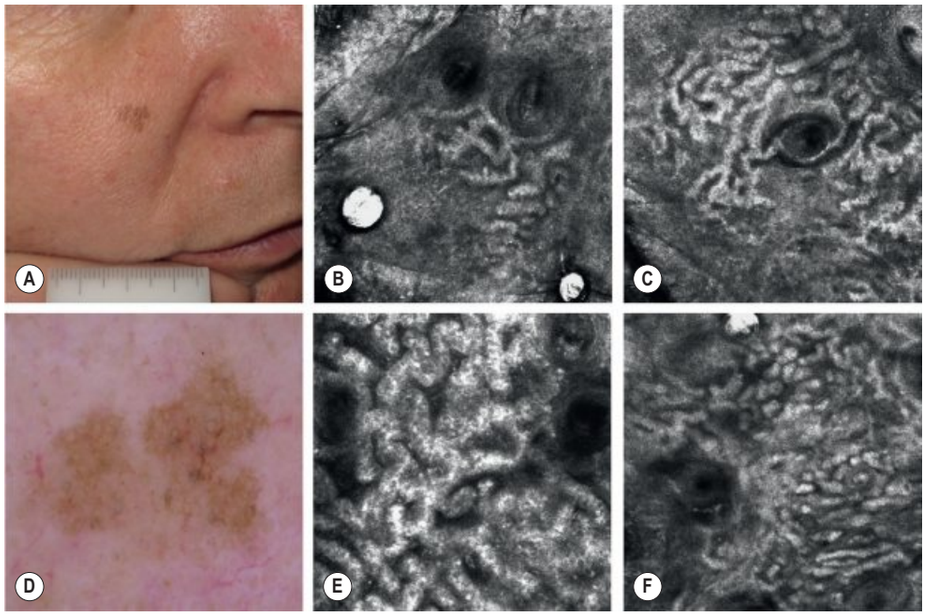

Fig. 0.42 Reflectance confocal microscopy (RCM) of a solar lentigo/macular seborrheic keratosis. A Brown macule on the cheek with a slightly irregular border. **D** By dermoscopy, sharp borders and a pseudo-network are seen. RCM demonstrates epidermal invaginations with keratin pearls (**B, C**) and polycyclic papillae and epidermal bulges (**E, F**).

neoplasms, especially solar lentigines (Fig. 0.42), pigmented actinic keratoses, and lichen planus-like keratoses[58]. When the dermoscopic diagnosis of pigmented macules proves challenging, e.g. when facial lesions have shared dermoscopic features such as a brown pseudo-network and annular granular structures, RCM is often helpful in providing a more definitive diagnosis. For lentigo maligna, RCM can support the diagnosis in addition to identifying its margins[58].

RCM is increasingly being utilized for keratinocytic skin tumors. Characteristic RCM findings of basal cell carcinoma include: dark silhouettes, bright tumor islands with peripheral palisading, cleft-like dark spaces, dendritic cells, plump-bright cells, and dilated canalicular vessels[59,60]. For scaly erythematous lesions in sun-exposed sites or on genitalia (e.g. actinic keratoses, Bowen disease), the detection of atypical keratinocytes is characteristic of a squamous cell proliferation (see Table 0.22). The histologic spectrum, from actinic keratosis (Fig. 0.43) to squamous cell carcinoma, can be assessed by RCM, with the limitation that the dermal portion of the tumor cannot be evaluated[59].

Inflammatory skin diseases

In inflammatory diseases, RCM can assist with clinicopathologic correlations and it provides additional information for confirming the diagnosis and improving therapeutic management[54,56,61]. Psoriasiform dermatitis is characterized by a thickened stratum corneum and epidermis (hyperkeratosis and acanthosis), the presence of highly refractive round-to-polygonal structures within the stratum corneum (parakeratosis), dense and enlarged dermal papillae with thin interpapillary epidermal spaces (papillomatosis), and prominent dark canalicular structures (dilated vessels). Spongiotic dermatitis is characterized by dark intercellular spaces in the epidermis (spongiosis) and oval bright cellular structures between keratinocytes (exocytosis). In acute phases of eczema, intraepidermal vesicles can be detected as well-demarcated dark spaces between keratinocytes, often filled by "floating" inflammatory cells (vesicles with inflammatory cells)[58]. Interface dermatitis is characterized by inflammatory cells within the epidermis and around adnexal structures. Inflammatory cells can be seen at the dermal–epidermal junction, with obscuring of papillary rims, as well as around blood vessels in the upper dermis[62]. Deeper inflammatory processes cannot be assessed by RCM due to the limited penetration of the laser into the skin.

RCM is also helpful in the clinical management of alopecia, thereby avoiding scalp biopsies and allowing for prompt diagnosis. Non-scarring alopecia, in particular androgenic alopecia, is characterized by miniaturization of hair shafts and follicular ostia. RCM findings in lichen planopilaris and lupus erythematosus include involvement of the dermal–epidermal junction, with obscuring of the dermal papillae,

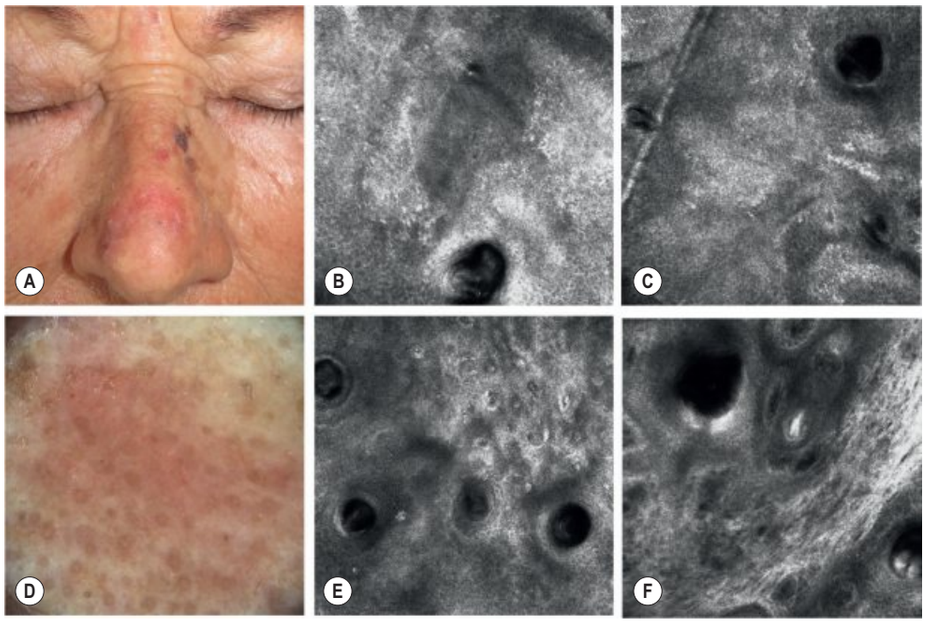

Fig. 0.43 Reflectance confocal microscopy (RCM) of an actinic keratosis on the nose. A Thin erythematous plaque with rough scale. **D** By dermoscopy, there is an erythematous background with the typical strawberry pattern and mild scaling. RCM, progressing from the stratum corneum to the papillary dermis, illustrates parakeratosis (**B**), a mildly atypical honeycombed pattern (**C**), preserved integrity of the dermal–epidermal junction (**E**), and thickening of collagen bundles due to solar damage (**F**).

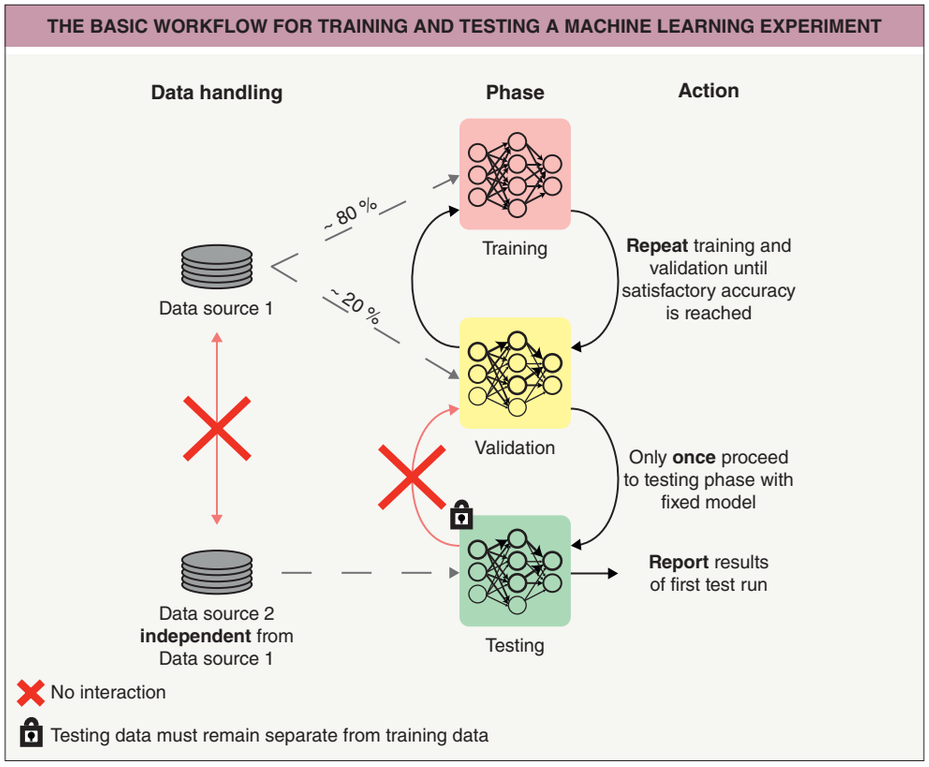

Fig. 0.44 The basic workflow for training and testing a machine learning experiment. The data for the training (pink) and validation (yellow) phases come from a single data collection (Data source 1), while the data for the testing phase (green) should be completely independent (Data source 2). After testing a model, one should not return to the training-validation circle, as this implicitly adds knowledge from the test phase into the training phase and reduces the ability to generalize reported results.

and the presence of inflammatory cells in the epidermis and around adnexal structures. Infiltration of adnexal structures represents a major criterion for lichen planopilaris[54]. Because RCM allows for assessment of the number and distribution of inflammatory cells, disease activity, including response to therapy, can be determined longitudinally[54,58,61].

INTRODUCTION TO ARTIFICIAL INTELLIGENCE

Reports of the potential benefits of artificial intelligence (AI) in healthcare, including dermatology, are rapidly increasing. This section is intended as a guide to basic AI concepts, available technologies, and current and potential future application of computer-aided dermatology. Technical concepts, which are described on an abstract level, are accompanied by instructive schematic illustrations. Clinicians should become familiar with these basic concepts, as they are similar across most models and when understood allow for critical evaluation of current and emerging clinical studies. Although "machine learning" and "AI" are not identical, these terms are used interchangeably below for simplicity. Technical implementations and mathematical concepts are reviewed in referenced publications[63].

Training and Testing AI Models

Machine learning can be viewed as training a virtual machine to solve a task without giving specific instructions but rather by providing training examples along with the known solution. The workflow should consistently follow the same step-by-step pattern (Fig. 0.44), regardless of which specific machine learning model (e.g. support vector machines,

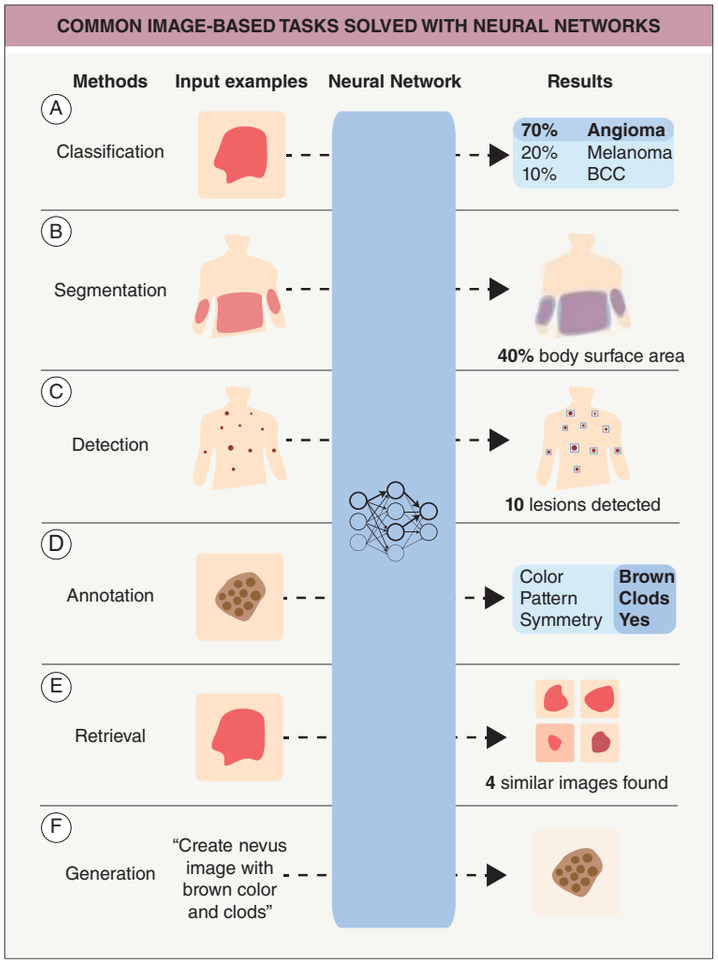

Fig. 0.45 Common image-based tasks solved with neural networks. While basically all tasks can be solved with convolutional neural networks (CNNs) of some type, the specific architecture differs between them. Standard CNNs such as ResNet- or Inception-type networks can solve classification (**A**), annotation (**D**), and retrieval (**E**) just by differing training modalities. However, other architectures are required for image generation (**F**; generative adversarial networks [GANs]) and for segmentation (**B**; e.g. U-Net), object detection (**C**; e.g. RetinaNet, SSD) or both (Mask R-CNN). BCC, basal cell carcinoma.

random forests, convolutional neural networks) is chosen. The steps are as follows:

1. Gather and prepare both **training data** and **test data** for a specified problem that are completely **independent**, e.g. from different study centers. If obtaining independent test data is not possible, ~20% of the original data are initially split off in a random, but usually stratified, fashion as this ensures that cases or patients do not overlap. Test data obtained in this manner must not be touched or examined until the very end; otherwise, the data will have lost their quality as true *test* data. Only the remaining 80% of the data are used as *training* data in steps 2 to 4.
2. **Train** the model with training data for the target task (e.g. probability of melanoma, correct specific diagnosis, affected body surface area); this step utilizes ~80% of the *training* dataset.
3. **Validation:** Measure performance of the model based on the remaining ~20% of the *training* data.
4. **Repeat** steps 2 and 3 while changing training approaches and parameters until a satisfactory performance in the "validation" step is attained.
5. **Lock** the model parameters and proceed to the test phase.
6. **Test**: Measure the model performance on the *test* data **once** and report these results.

This sequence is somewhat simplified, as there are more advanced methodologies such as using *k-fold cross-validation* instead of a fixed, single 20% validation split. However, the steps should reflect the essential concept of strict data handling and experimental workflow in order to avoid negligence or errors that can lead to misinterpretation of results. Unfortunately, the lack of a truly *independent test set* is not uncommon in machine learning and has measurable consequences when generalized, i.e., inferior performance in the real world. A meta-analysis found that studies without an independent test set had systematically different performance results[64].

Image-Based Tasks Solved with Neural Networks

What kind of tasks can a machine learning model potentially solve? Conceptually, anything where there are enough data and the performance can be parameterized as a numeric value, e.g. accuracies of diagnoses in percentages.

Classification (Fig. 0.45A) is the most well-known technique for a visual specialty such as dermatology. The concept is to predict a diagnosis or a list of differential diagnoses from a single image or a sequence of images. This technique can be performed on clinical[65], dermatoscopic[66], or histopathologic images. Utilizing modern neural networks together with large public image datasets[67], experimental, large-scale international studies[68] have shown that the models are equal or superior to dermatologists in classification tasks. Although skin cancer recognition is the most common topic in the literature, one can also automatically grade inflammatory skin diseases or predict diagnoses in general dermatology[65,69]. In addition, tedious tasks such as organizing image databases can be enhanced via classification[67]. Measurements for classification performance are usually chosen for the task at hand and are usually classic diagnostic values such as sensitivity or specificity, crude accuracy, Youden's J, area under the ROC (receiver operating characteristic) curve, or mean sensitivity across multiple diagnoses.

Segmentation (Fig. 0.45B) allows the automatic highlighting and measurement of areas of interest, e.g. affected body area with psoriasis or visual dermatoscopic patterns. In histopathology, semi-automatic and interactive segmentation could enhance the annotation speed of researchers. Well-known measurements for segmentation performance are Intersection-over-Union (IoU, "Jaccard" index) or the Dice coefficient.

Detection (Fig. 0.45C) provides one or multiple marks on an image where an object-of-interest was recognized, as well as the predicted area ("bounding box"). Relevant applications of this technique are detecting skin lesions in full-body images or detecting nuclei in histopathologic images. The detection of skin lesions in full-body images can be combined with a change-detection algorithm to automatically assess whether a lesion has changed over time. The standard measurements for performance is Intersection-over-Union and average precision at prespecified cutoffs of IoU percentages.

Annotation (Fig. 0.45D) is similar to classification, but there is the potential for multiple elements, rather than a single prediction, to be returned. A non-medical analogy would be providing multiple descriptive terms ("hashtags") for an image on social media, e.g. providing all these terms – "scenic", "mountains", "dawn", "alps" – instead of just "mountains". Metrics can be the ones employed in the field of information retrieval such as precision@k, mean reciprocal rank, or average precision.

Retrieval (Fig. 0.45E) of similar cases can be achieved by a technique called *content-based image retrieval* (CBIR), in which a neural network recognizes patterns, structures, and colors from an image, encodes them, and compares them to images in a database. Retrieved similar images can be used for education or for explaining a machine learning model. Although metrics of information retrieval can theoretically be applied to CBIR, the highly subjective nature of visual similarity makes it difficult to evaluate this technique objectively.

Generation (Fig. 0.45F) of artificial images is a more experimental technique. Special types of neural networks, such as GANs (generative adversarial networks)[70], can learn the ability to create artificial images. This application can generate high quality artificial facial and dermatoscopic images, and in the future, it may create genuinely anonymous images for clinical training and reference.

Inputs and results of the techniques mentioned above are basically straightforward, but there are, of course, more advanced applications that use other image material or combinations of data. An example would be automated analysis of histopathologic images to predict genetic changes, prognosis, or treatment efficacy. Since 2012, when Kriszevsky et al.[71] demonstrated the superior performance

of convolutional neural networks (CNNs), image-based machine learning has largely moved from manually crafted "computer vision" techniques to "deep learning", i.e. the application of multilayered neural networks. While there is extensive literature on improvements of CNN models, a detailed discussion is beyond the scope of this section; therefore, they are simply referred to as "neural networks". At the time of this writing, the most well-known modern CNN-based architectures are EfficientNet-, ResNet-, ResNeXt-, SqueezeNet-, MobileNet-, and Inception-type networks for classification and Mask R-CNN, DeepLab, YOLO, SSD, U-Net, and RetinaNet for object detection and/or segmentation.

Although dermatology is a visual domain, it is important to mention other subfields of machine learning that are not image-based but may be helpful to dermatologists. One example is *natural language processing* (NLP), a field in which texts can be analyzed, predicted, or even created. In the future, NLP could automate initial patient interviews through chat-bots, automatically extract ICD-coding from free text, provide diagnosis or management suggestions from patient summaries, automate report generation from a few keywords, or retrieve study patients from electronic health records.

AI does not need to be based on neural networks entirely. For example, another approach that uses classic logic and rule-based systems, in conjunction with a knowledge database, can generate meaningful sets of differential diagnoses from listing clinical descriptions[72].

Shortcomings and Limitations of AI

Convolutional neural networks may learn image-based pattern recognition at a similar pace compared to humans[73], but are inherently limited to the knowledge they can extract from training data. Thus, to achieve a clinically useful and robust performance, CNNs require large, diverse, comprehensive, well-curated training datasets. While such large datasets are available for images of general objects, they are mostly unavailable in dermatology. The nearly exhaustive list of usable public datasets at the time of this writing are dermatoscopic images from PH2, the ISIC archive (including HAM10000 and ISIC challenge datasets), and derm7pt, as well as clinical images from the SD-198 dataset. Except for melanoma in the TCGA, there is basically no relevant public, reusable dataset for dermatopathology at the time of this writing. This limited list highlights that clinicians and clinical researchers are in need of more published useful datasets.

What are the specific impacts of too little data? When only a few datasets are available, the rule of strict test set splitting (see above) may become impossible. Test sets will then originate from the same source as training images, skewing estimates of diagnostic performance[64]. Fewer examples of diagnoses in datasets introduce dataset **bias**. If image examples of one of the diagnoses are mostly from one single center and photographed there with one specific camera or lighting conditions, a CNN will learn to recognize this camera and lighting conditions rather than the diagnosis itself. Another example is that melanomas are often photographed with skin markings or rulers to document their size, resulting in CNNs predicting "melanoma" at a higher rate when skin markings or rulers are included in an image[74]. With techniques to control biases, such as illumination color, de-biasing images is theoretically possible but difficult to implement in practice. Lastly, academic skin cancer centers usually have more expensive equipment to document diseases and well-trained staff to provide high-quality images, both of which may not be available in future point-of-care settings where CNNs will later be deployed.

When predicting diagnoses from clinical images, there is a wide range of **possible diagnoses** in dermatology. CNNs will perform well on common, well-documented diagnoses such as psoriasis or melanoma, but may fail on the "long tail" diagnoses, which are numerous but rare, because there are fewer or even missing training examples.

Another problem is not machine learning itself, but the way it is being studied, measured, and compared to physicians. Often, ensembles of several large CNNs require large computational resources and a lot of time to make predictions. Compared to single human participants (physicians) who make decisions almost instantly, these large ensembles are rarely used in real-life situations. This is because the computing is too expensive, not feasible on smaller devices such as smartphones, or simply too time-consuming.

Target metrics to evaluate performance were briefly mentioned above but are sometimes inadequately chosen in the clinical context. For example, experimental studies measuring the area under the ROC curve for differentiating malignant from benign skin tumors may allow for comparison of differences in performance in general. However, the resulting models may not be useful for clinical applications because no specific cut-off is chosen and measured in a clinically meaningful way.

The quality of clinical endpoints is also difficult to measure. In studies of CNNs that diagnose melanocytic tumors, "ground truth" for comparisons is problematic. Even for experts, interrater reliability in histologic discrimination of melanoma from nevi is far from perfect, and this issue may only be solved by integrating clinical information and dermatoscopic evaluation. The fact that the targeted "ground truth" may not even be true is often not considered in technically focused CNN studies.

Possible Clinical Implementations of AI

The application of automated predictions carries tremendous opportunities, but also significant risks and liability as malignant diseases may be misdiagnosed. As a result, standalone applications in which patients receive an automated diagnosis directly from an AI model have not gained traction in dermatology. Instead, collaborative models involving the interaction of physicians and CNNs seem much more promising. The successful use of AI depends not only on its experimental accuracy, but even more importantly on where, how, and by whom it is used. The different implementation scenarios of AI will depend on the task at hand.

Autonomous predictions (Fig. 0.46A) aimed directly at the patients are currently best suited for low-risk tasks and monitoring, such as calculating the PASI (Psoriasis Area and Severity Index) or monitoring the severity of acne. In the field of skin cancer, direct patient education has been successfully tested, but applications for skin cancer diagnosis have been found to lack accuracy[75]. Although modern CNNs will probably be more accurate in the future, appropriately controlled prospective clinical trials demonstrating utility and safety are lacking at the time of writing.

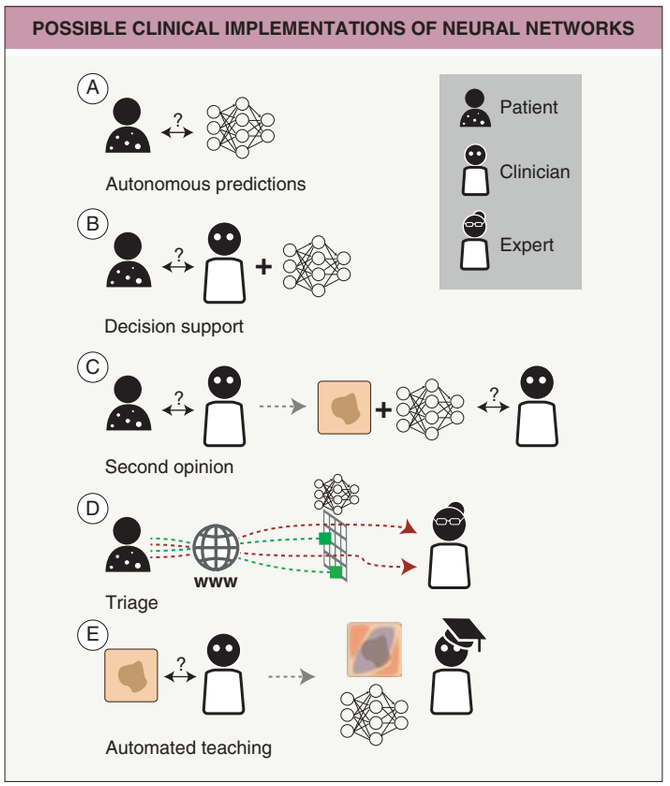

Fig. 0.46 Possible clinical implementations of neural networks. Image-based machine learning models can be implemented at multiple sites of the patient workflow, guided towards and used by different groups such as patients, clinicians, or experts. ? represents a clinical problem such as determining the correct clinical diagnosis or therapy.

Decision support (Fig. 0.46B) for when physicians are examining patients is a more nuanced implementation of automated prediction that keeps the clinicians "in the loop", avoids catastrophic events, and allows for integration of patient context, concerns, and treatment preferences. Experimental data have shown that interaction with automated multi-class predictions can increase physicians' accuracy of clinical and dermatoscopic[76] diagnoses.

Second opinion (Fig. 0.46C) will allow physicians to re-assess a case after a patient visit, similar to consulting an expert, and enable *post hoc* changes in treatment decisions. It has been shown that physicians perform fewer unnecessary biopsies after AI-guided reassessment of their own patient evaluations[76].

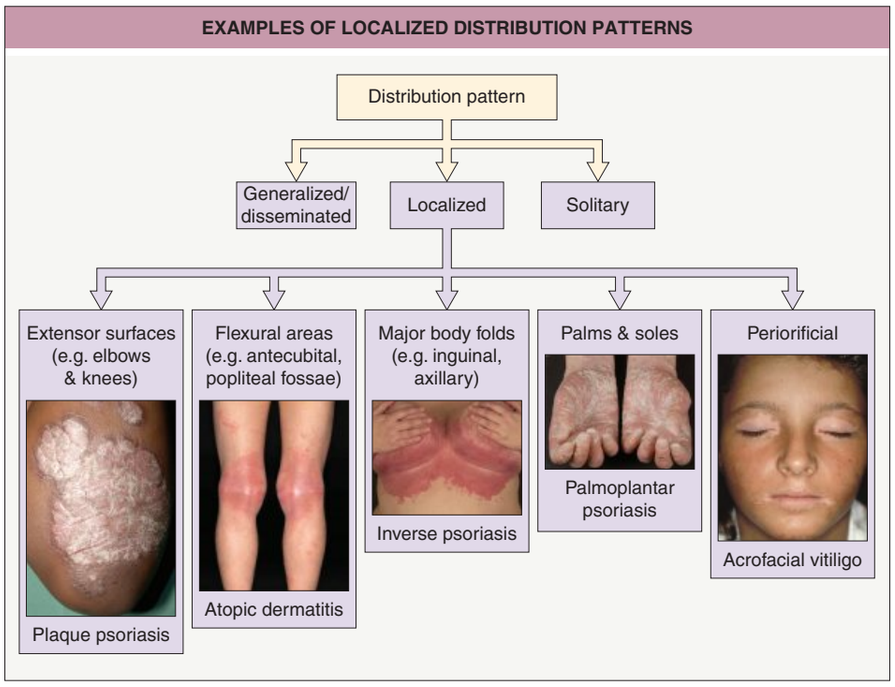
Triaging (Fig. 0.46D) patients, referrals, or cases for review is an important task when human and healthcare resources are limited. It has been shown that triage using teledermatology can reduce wait times for skin cancer patients. Patients at high risk for skin cancer can perform self-monitoring to automatically detect skin cancer with reasonable specificity; however, such applications should not be used to avoid in-person screening altogether but rather to increase screening intervals.

Automated teaching (Fig. 0.46E) represents a slower implementation of AI into healthcare and is aimed more at improving physician education. Cai et al.[77] have shown that histologic case retrieval can be improved by interactive use of a machine learning model. Other groups have successfully generated diagnosis lists with a logic-based algorithm as an education tool for building clinical differential diagnoses[72].

Future of AI

In summary, machine learning and AI will almost certainly guide and help physicians in clinical practice in the future. Maybe it will not be necessary to calculate scores like PASI by hand anymore or it will be easier to narrow down diagnostic gray areas in melanocytic lesions, conduct population-wide skin cancer screenings, and perform semi-automated telemedicine/triage. Automated predictive staging systems may replace TNM staging systems. However, what will become a reality depends on physicians and researchers, technical advances, patients, politics, companies, ethical considerations, and regulatory agencies. There are also many other applications and techniques that are not or only briefly covered here, given limitations on content. Finally, the field of machine learning is fast-paced, and critical review of relevant literature is paramount in understanding new concepts and possibilities of AI.

CONCLUSION



This chapter has sought to provide an introduction and basic structural framework to the study of dermatology by addressing terminology, morphology, pattern recognition, and a number of techniques that will all serve to enhance the practice of clinicopathologic correlation. The desired end results are more accurate diagnoses and better care of patients.

Additional figures and table, Acute cutaneous eruptions in otherwise healthy individuals, available in our eBook (see inside front cover for access code).

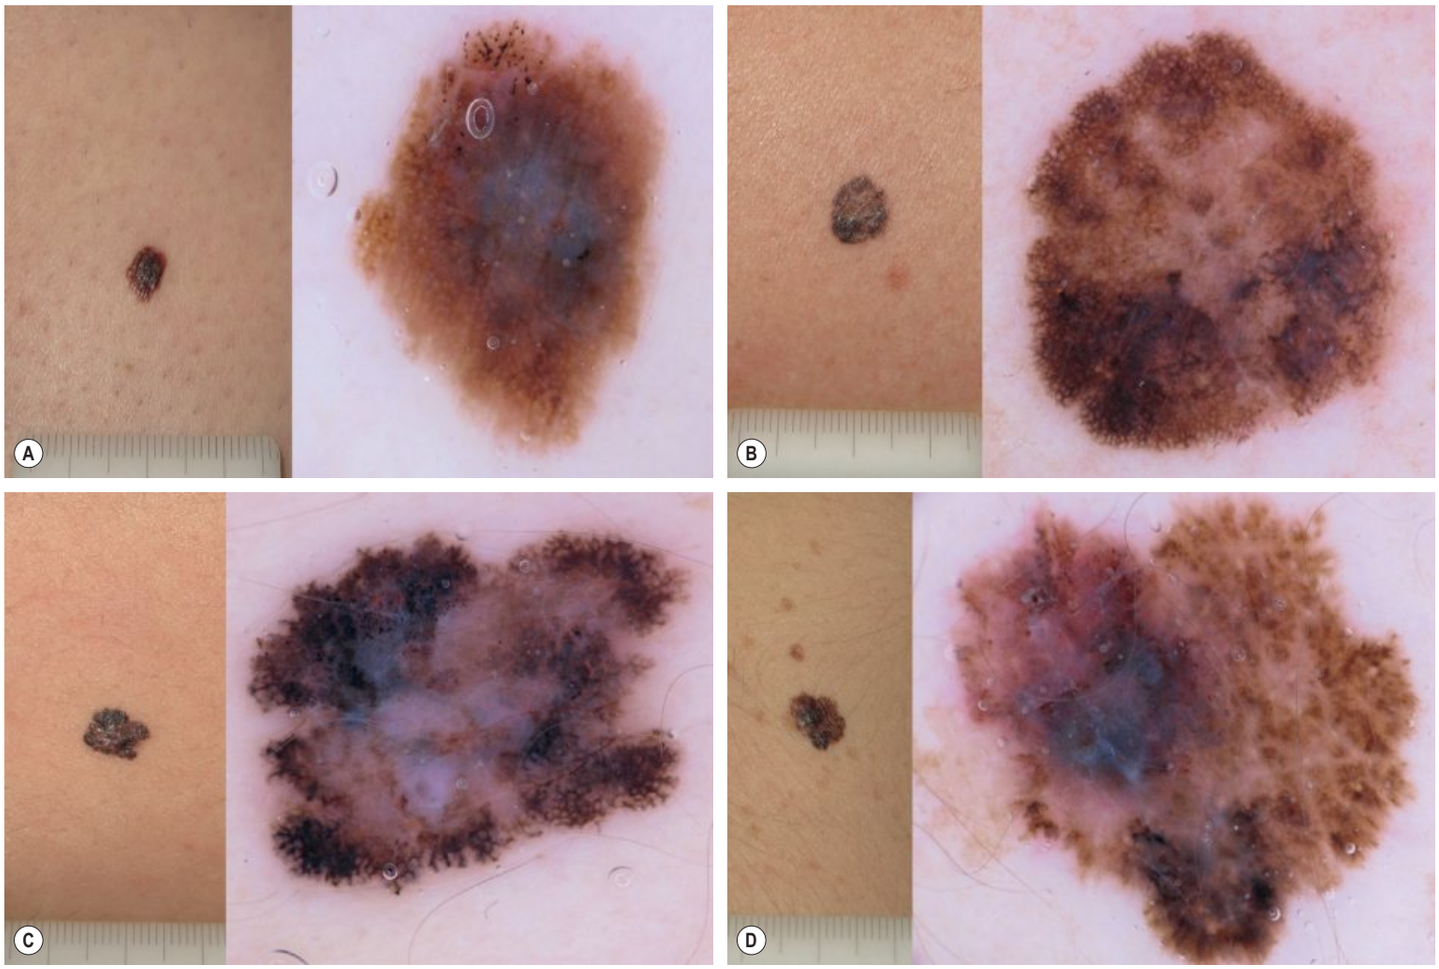
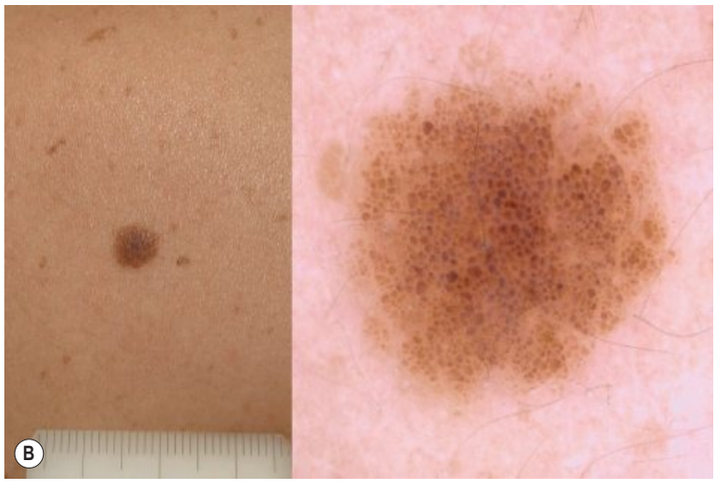
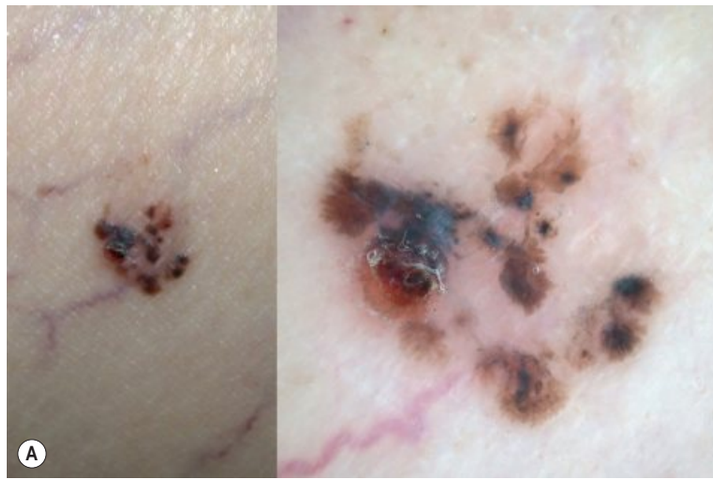
eFig. 0.1 Examples of localized distribution patterns. Additional patterns are outlined in Table 0.8. Generalized lesions are seen in morbilliform drug eruptions and viral exanthems. *Photographs courtesy Peter C.M. van de Kerkhof, MD; Thomas Bieber, MD; and Julie V. Schaffer, MD.*



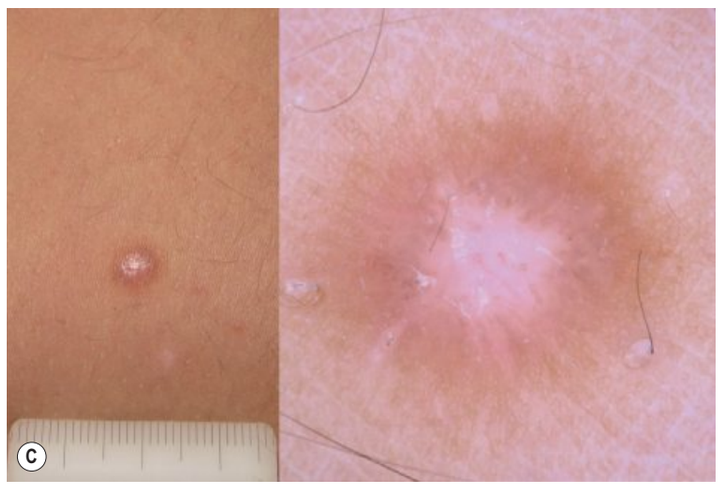
eFig. 0.2 Descriptive terms for topography. *Photographs courtesy Jennifer Choi, MD; Hideko Kamino, MD; Reinhard Kimbauer, MD; Petra Lenz, MD; Frank Samarin, MD; Julie V. Schaffer, MD; and Judit Stenn, MD.*

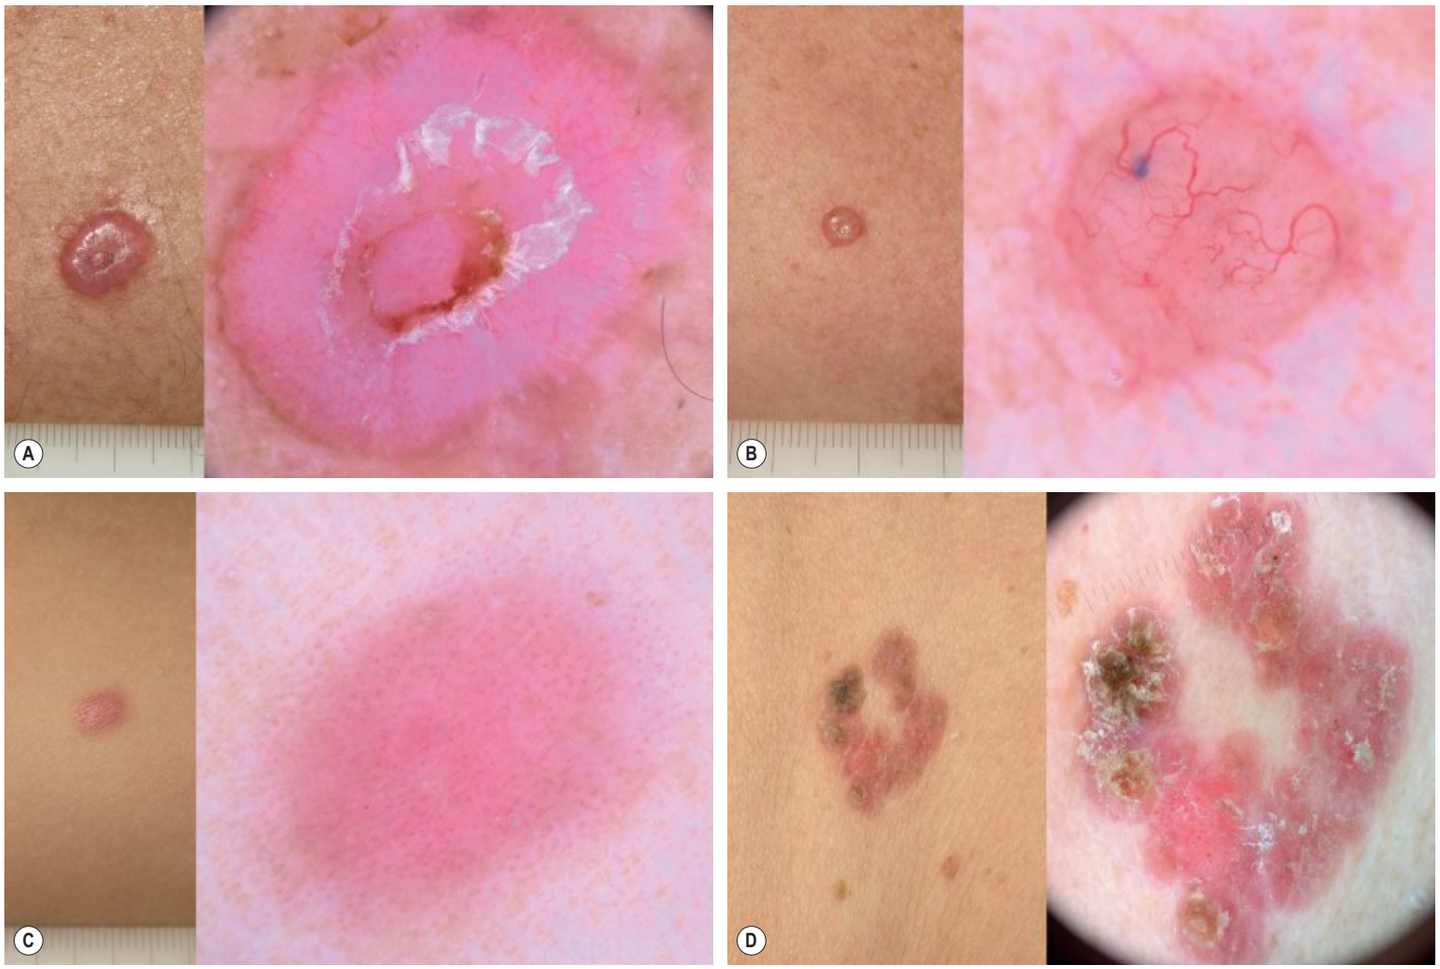


eFig. 0.3 The three most common types of melanoma. A Small superficial melanoma typified dermoscopically by asymmetry of color and structure, atypical network, blue–white structures, and irregular streaks at the periphery. **B** Large thick melanoma with predominant blue–white veil. The combination of blue color with irregular black to brown dots, globules, and blotches (as seen here) is highly specific for the diagnosis of thick melanoma. **C** Small facial melanoma *in situ* (lentigo maligna) typified by gray color and rhomboidal structures in dermoscopy.

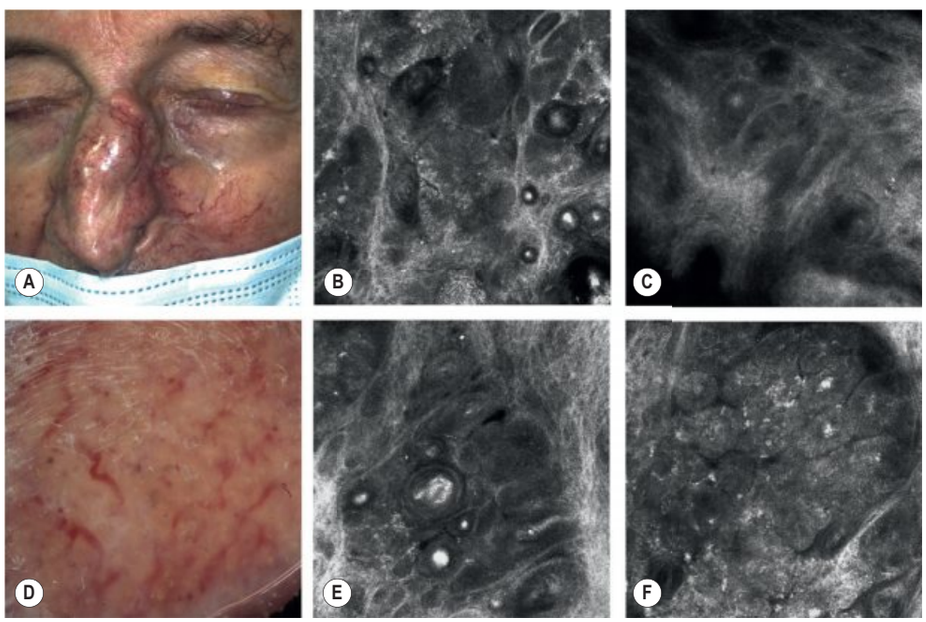


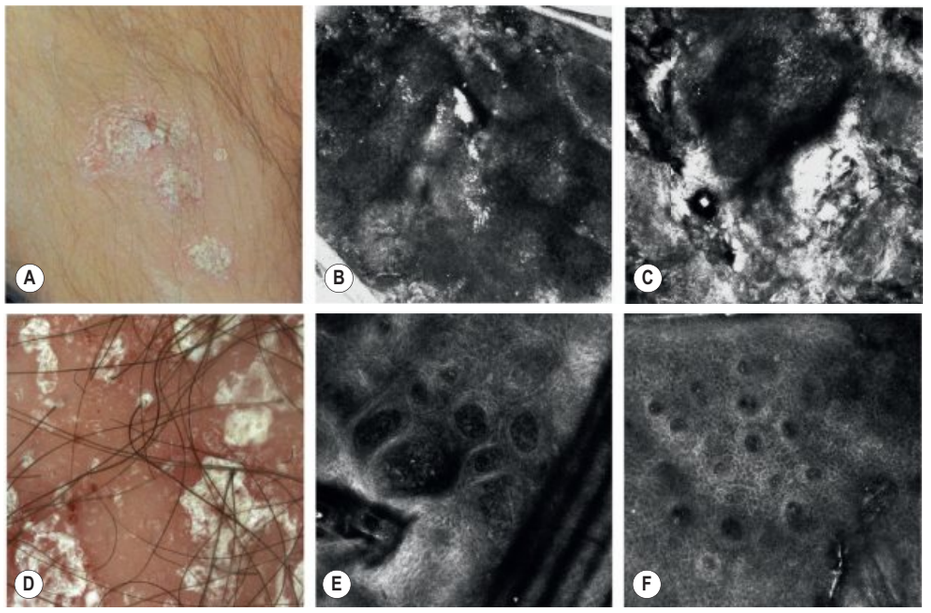
eFig. 0.4 Four examples of superficial melanomas of increasing tumor thickness. A Melanoma *in situ* typified dermoscopically by asymmetry of color and structure, atypical network, blue–white structures, and irregular black dots and globules (at the upper side of the lesion). **B** Melanoma 0.5 mm thick typified predominantly by atypical pigment network and regression structures. The latter are composed by areas of pigment loss (in the center of the lesion) and bluish pepper-like granules corresponding to melanophages. **C** Melanoma 0.75 mm thick typified by multiple melanoma-specific criteria including asymmetry of color and structure, atypical network, irregular streaks at the periphery, irregular dots and globules (upper side of the lesion), and blue–white structures especially in the center. **D** Melanoma 0.9 mm thick. Clinically, a palpable area is visible, corresponding dermoscopically to the presence of blue–white veil, a sign of increased tumor thickness. Irregular dots and globules (at the upper side), irregular streaks at the periphery, and uneven brown to black pigmented areas (blotches) are also observed.



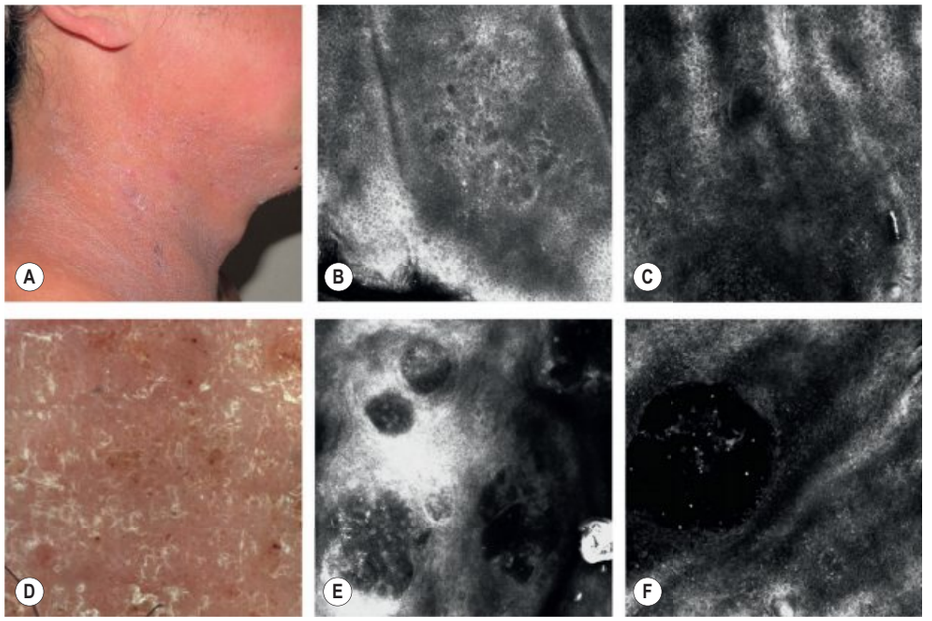


eFig. 0.5 The three most common types of melanocytic nevi – clinical and dermoscopic findings. A Typical acquired nevus with reticular pattern in dermoscopy. **B** Small congenital nevus with globular pattern. **C** Reed nevus typified dermoscopically by the classic starburst pattern (regular streaks at the periphery of a heavily pigmented and symmetric small macule).

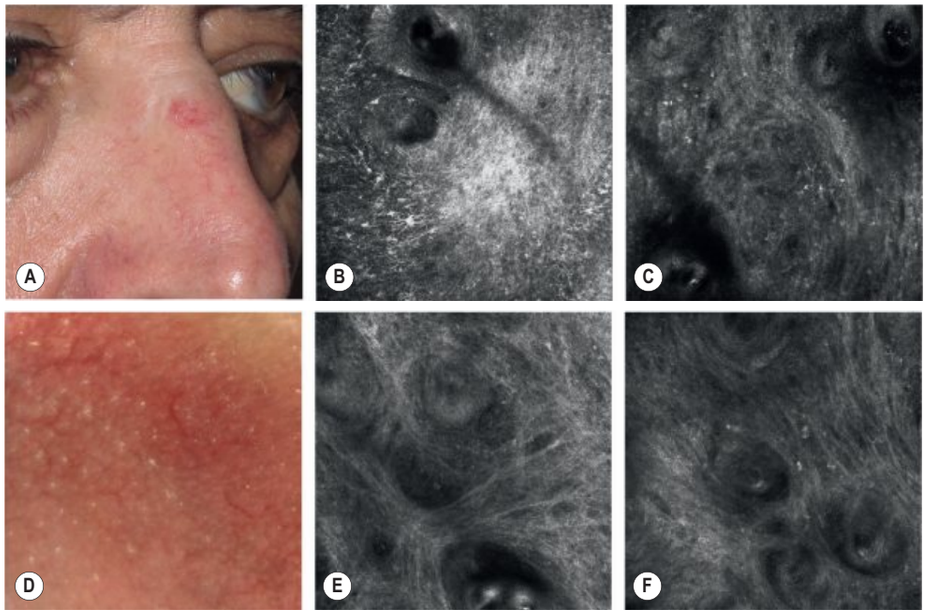




eFig. 0.6 Three non-melanocytic pigmented tumors – clinical and dermoscopic findings. A Pigmented basal cell carcinoma with leaf-like areas (islands of blue–gray color) at the periphery and a small erosion of reddish color at the left side of the lesion. **B** Angiokeratoma with red–black lacunae clearly visible as well-demarcated roundish structures. **C** A dermatofibroma with characteristic central white patch and peripheral delicate pseudo-network.

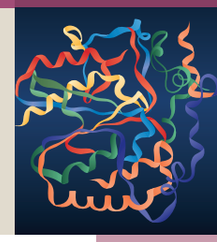


eFig. 0.7 Four non-pigmented skin tumors – clinical and dermoscopic findings. A This amelanotic melanoma is typified by a central ulceration, polymorphic vascular structures (combination of dotted and linear-irregular vessels), and milky-red color in the background. **B** Nodular basal cell carcinoma with striking arborizing vessels. **C** A Spitz nevus with dotted vessels and typical negative pigment network (reticular depigmentation) at the periphery. **D** An example of Bowen disease with clusters of glomerular vessels that in combination with superficial scales are highly specific for the diagnosis.



eFig. 0.8 Reflectance confocal microscopy (RCM) of recurrent basal cell carcinoma (BCC). A Recurrence of a BCC on the nose. **D** Telangiectasias seen by dermoscopy. RCM shows tumoral nests with palisading (**B**), dark silhouettes of tumor nests in the dermis (**C**), hyper-reflective stroma surrounding tumor nests (**E**), and peri-tumoral clefts (**F**).

eFig. 0.9 Reflectance confocal microscopy (RCM) of plaque psoriasis. A Discrete pink plaques with thick scale. **D** Diffuse dotted vessels by dermoscopy. RCM of the stratum corneum showing hyperkeratosis (**B**) with parakeratosis (**C**), then in deeper sections, dilated papillae with dilated looping vessels (**E**), and dense dermal papillae (**F**).



eFig. 0.10 Reflectance confocal microscopy (RCM) of allergic contact dermatitis of the neck. A Diffuse erythema of the neck with scaling and scattered crusts. **D** Yellow scale-crusts and pinpoint hemorrhagic crusts by dermoscopy. RCM of the epidermis with inflammatory cells and dark areas corresponding to spongiosis (**B, C**) and vesicles (**E, F**).

eFig. 0.11 Reflectance confocal microscopy (RCM) of discoid lupus erythematosus. A Single erythematous plaque on the dorsum of the nose that could be misdiagnosed as a non-melanoma skin cancer. **D** By dermoscopy, erythematous telangiectatic background with follicular hyperkeratosis. RCM shows bright white inflammatory cells around adnexal structures (**B**) and within the epidermis (**C**); follicular hyperkeratosis (**E**) and thick collagen bundles plus melanophages (large polygonal cellular structures between collagen bundles; **F**) are also seen.

ACUTE CUTANEOUS ERUPTIONS IN OTHERWISE HEALTHY INDIVIDUALS	
Disorder	**Characteristic findings**
Urticaria (see Ch. 18)	• Pathogenesis involves degranulation of mast cells with release of histamine • Primary lesion: edematous wheal with erythematous flare • Widespread distribution • Very pruritic* • Individual lesions are transient (<24 h in duration) • May become chronic (>6 weeks)
Acute allergic contact dermatitis (see Ch. 14)	• Immune-mediated and requires prior sensitization • Primary lesion: dermatitis, with vesicles, bullae, and weeping when severe • Primarily in sites of exposure; occasionally more widespread due to autosensitization • Pruritus, often marked • Spontaneously resolves over 2–3 weeks if no further exposure to allergen (e.g. poison ivy, nickel)
Acute irritant contact dermatitis (see Ch. 15)	• Direct toxic effect • Primary lesion: ranges from erythema to bullae (e.g. chemical burn) • At sites of exposure • Burning sensation • Spontaneously resolves over 2–3 weeks if no further exposure to irritant (e.g. strong acid, strong alkali)
Exanthematous (morbilliform) drug eruptions (see Ch. 21)	• Immune-mediated and requires prior sensitization • Pink to red–brown, blanching macules and papules; may become purpuric on distal lower extremities • Widespread distribution • May be pruritic • Spontaneously resolves over 7–10 days if no further exposure to inciting drug
Pityriasis rosea (see Ch. 9)	• May follow a viral illness • Primary lesion: oval-shaped, pink to salmon-colored papule or plaque with fine white scale centrally and peripheral collarette; occasionally vesicular • Initial lesion is often largest (herald patch) • Favors trunk and proximal extremities; may have inverse pattern (axillae & groin); long axis of lesions parallel to skin cleavage lines • Spontaneously resolves over 6–10 weeks; exclude secondary syphilis
Viral exanthems (see Ch. 81)	• Due to a broad range of viruses, including rubeola, rubella, enteroviruses, parvovirus, adenovirus (see Fig. 81.2) • Often associated with fever, malaise, arthralgias, myalgias, nausea, upper respiratory symptoms • Primary lesions vary from blanching pink macules and papules to vesicles or petechiae • Distribution varies from acral to widespread; may have an enanthem • Spontaneously resolves over 3–10 days
*May have burning rather than pruritus with urticarial vasculitis, and lesions can last longer than 24 hours.	

eTable 0.1 Acute cutaneous eruptions in otherwise healthy individuals.

1 Anatomy and Pathophysiology

Travis W. Vandergriff

Key features

- The relationship between structure and function of the skin is best demonstrated by presenting diseases that illustrate how skin can fail. Thus, disease reveals function, and function highlights structure
- The most obvious function of the skin is to maintain an internal environment that allows an organism to protect DNA and to reproduce it relatively faithfully
- Cutaneous structures include an *epidermis* that serves as a barrier (preventing loss from within and damage from external insults) and a *dermis* that provides mechanical support, circulation, and nutrition. Other functions provided by the cells in the skin include immune recognition and memory, the ability to repair damage, thermoregulation, and communication
- Evidence that the skin has failed includes barrier disruption, infection, autoimmunity, cancer, and an appearance undesirable to the individual

INTRODUCTION

Most reviews of the anatomy and physiology of skin begin with detailed descriptions of cellular composition, structural proteins, and extracellular matrix. Since each of these topics is covered in subsequent sections of the textbook, this chapter will briefly introduce the cells and structures, with references to the appropriate chapters for further details. We will reverse the conventional approach by examining diseases that illustrate the function of the skin in the context of the cells and structures that sustain it. This method is derived from the assertion that the structure and function of the skin are best illustrated by disease. The strength of this alternative approach may be seen in clinical vignettes easily recognized by those who care for patients with skin disease:

- a 70-year-old man with skin phototype I who works outdoors develops a lentigo maligna melanoma of the face
- a 16-year-old boy with hypohidrotic ectodermal dysplasia suffers a heatstroke while competing in outdoor athletics in Texas
- toxic epidermal necrolysis due to trimethoprim–sulfamethoxazole develops in a 40-year-old woman, leading to dehydration and sepsis
- numerous squamous cell carcinomas arise on the face and extensor forearms of a renal transplant recipient with significant cumulative sun exposure
- linear eruption of grouped vesicles due to varicella–zoster virus develops on the left flank of a young man with HIV infection

These patients and their diseases illustrate at least four of the functions of the skin: photoprotection, thermoregulation, barrier formation, and immunologic protection.

THE BASIC STRUCTURE OF SKIN

The skin is divided into three major layers: the epidermis, dermis, and subcutaneous fat (Fig. 1.1). The anatomic structures observed by light microscopy are fairly similar in most body regions (Fig. 1.2). However, specialized skin regions such as the palms, soles, genitalia, and scalp have modified forms that address regional functional requirements (Fig. 1.3).

Epidermis

In humans, the epidermis contains four major resident populations: keratinocytes (Ch. 56), melanocytes (Ch. 65), Langerhans cells (Ch. 4), and Merkel cells (Chs. 2 & 115). The most obvious function of the epidermis resides in the stratum corneum (Fig. 1.4), a semipermeable, laminated surface aggregate of differentiated (keratinized) squamous epithelial cells. The stratum corneum serves as a physiologic barrier to chemical penetration and microbiologic invasion from the environment, as well as a barrier that prevents fluid and solute loss from within[1] (Ch. 124).

Keratinocytes, the major population, are epithelial cells that originate from a stem cell pool situated in the basal layer; cells that leave this pool then differentiate as they migrate upward, ultimately forming the laminated stratum corneum. The human epidermis has an average thickness of 50 microns and a surface density of ~50 000 nucleated cells/mm^2. Under normal conditions, differentiated keratinocytes require about two weeks to exit the nucleated compartment and another two weeks to move through the stratum corneum[2]. When stimulated by injury, inflammation or disease, keratinocytes can significantly increase their proliferation and maturation rates (Ch. 8).

Melanocytes, as noted in a DOPA-stained whole mount of the epidermis, manufacture the light-absorbing pigment melanin, which plays a major role in protecting the skin from the harmful effects of ultraviolet (UV) radiation (Ch. 86). Melanosomes, with their complement of melanin, are produced by melanocytes and then transferred to nearby keratinocytes, where their preferred location is above the nucleus, providing protection for genetic material (see Fig. 65.5)[3].

Langerhans cells metabolize complex antigens into peptides, some of which are immunogenic. After activation, these cells migrate from the epidermis to regional lymph nodes, where they play a critical role in antigen presentation during the induction and regulation of immunity (see Fig. 4.13).

Merkel cells contain neuroendocrine peptides and are found in the basal layer of the epidermis, although they may not be apparent in routine histologic sections. Although these cells are thought to play a role in mechanoreceptor responses, their precise physiologic role remains an area of inquiry.

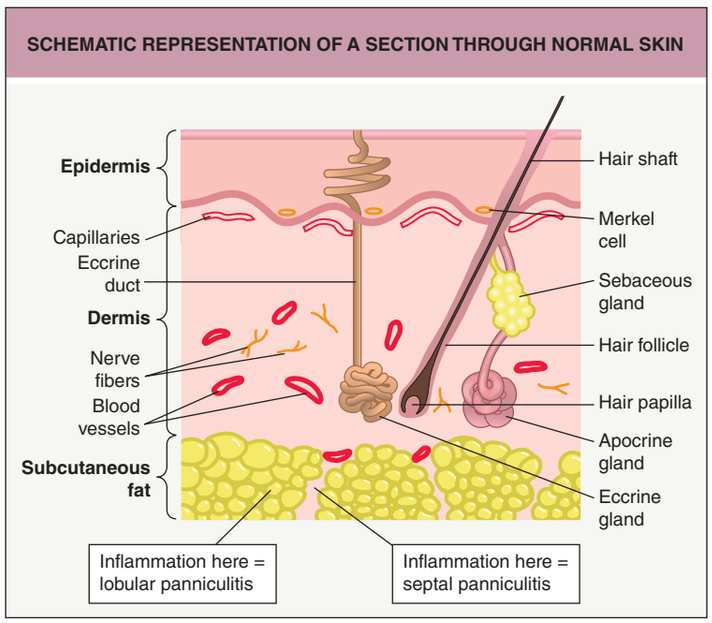


Fig. 1.1 Schematic representation of a section through normal skin. The skin is divided into 3 major layers: (1) the epidermis, which serves as a barrier to prevent loss of fluid and electrolytes and to protect against external insults such as chemicals and microbes (see Fig. 1.4); (2) the dermis, which provides structural and nutritional support (see Fig. 1.5); and (3) the subcutaneous fat. Adnexal structures, including hair follicles, sebaceous glands, eccrine glands and apocrine glands, are found within the dermis.

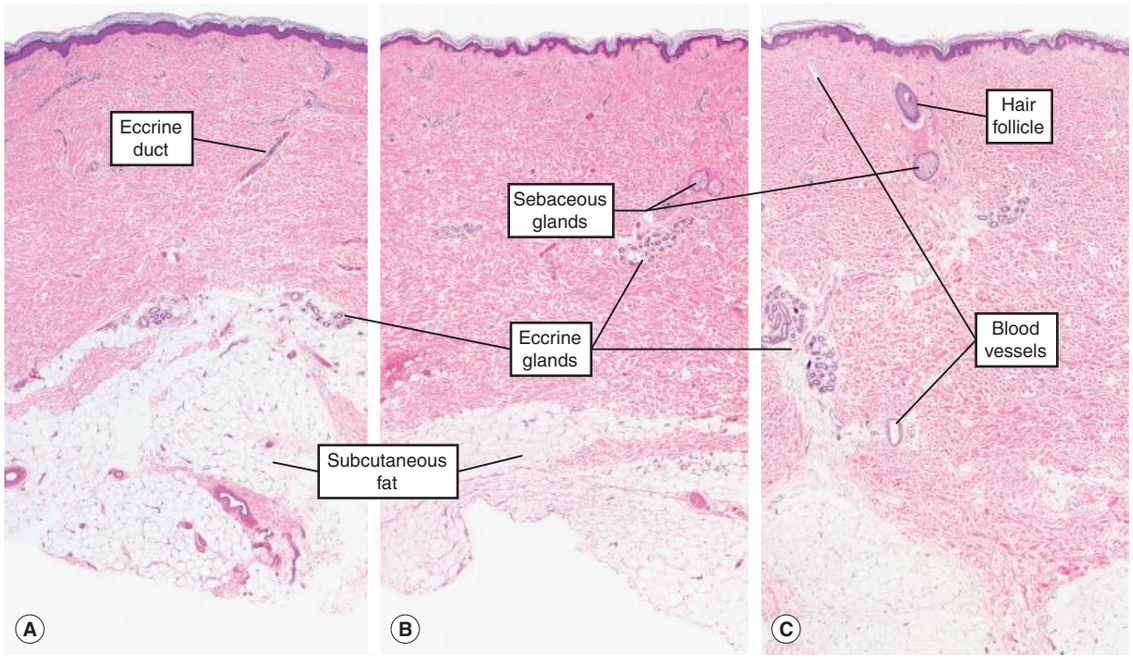

Fig. 1.2 Histopathologic features of normal skin from three different anatomic sites. Comparison of biopsy specimens from the arm (**A**), flank (**B**), and back (**C**) illustrates the increasing thickness of the dermis, but also similarity with regard to the presence of blood vessels and adnexal structures including eccrine glands. *Courtesy Lorenzo Cerroni, MD.*

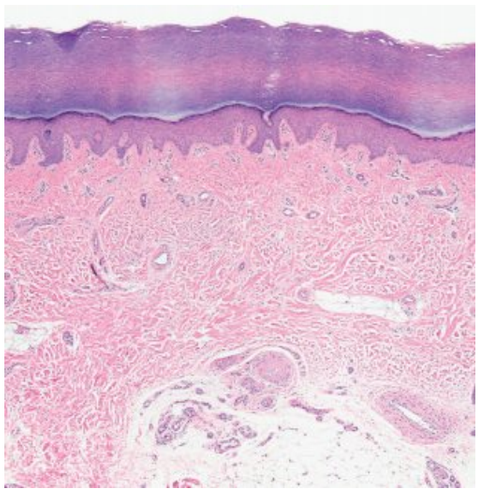

Fig. 1.3 Histopathologic features of normal plantar skin. Note the markedly thickened stratum corneum, compared to the photomicrographs in Fig. 1.2. The thickened stratum corneum protects against mechanical stress. *Courtesy Lorenzo Cerroni, MD.*

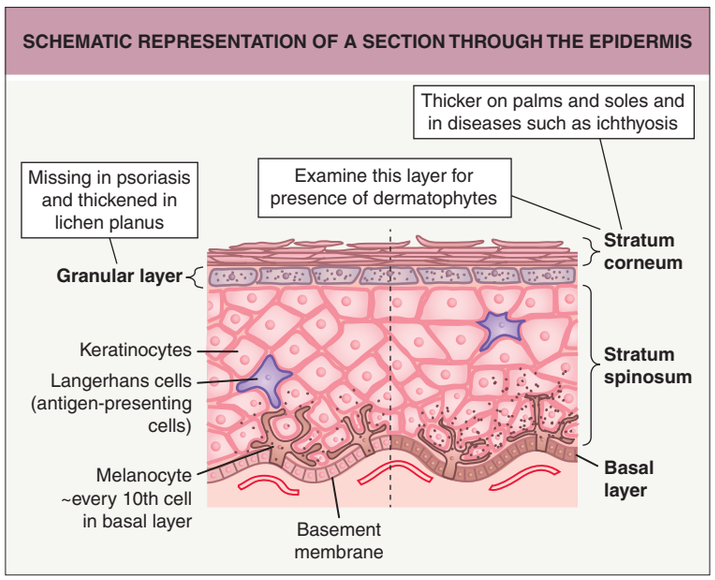

Fig. 1.4 Schematic representation of a section through the epidermis. The epidermal layers from the surface are: (1) the cornified layer (stratum corneum); (2) the granular layer (stratum granulosum); (3) the spinous layer (stratum spinosum); and (4) the basal layer (stratum basale). Under normal conditions, keratinocytes require about two weeks to exit the nucleated compartment and an additional two weeks to move through the stratum corneum. The basement membrane represents the junction between the epidermis and the dermis. Cell populations that reside within the epidermis include melanocytes along the basal layer, which transfer melanin to the surrounding keratinocytes via melanosomes, and Langerhans cells, which serve as antigen-presenting cells. On the left is lightly pigmented skin and on the right is more darkly pigmented skin.

Dermis

Beneath the epidermis, the vascularized dermis provides structural and nutritional support. The dermis is composed of a glycosaminoglycan gel held together by a fibrous connective tissue matrix containing collagen and elastin (Fig. 1.5) (Ch. 95). Vascular structures, accompanied by nerves and mast cells (Ch. 118), course through the dermis to provide nutrition, recirculating cells, and cutaneous sensation. Three additional cells, fibroblasts, macrophages, and dermal dendritic cells, complete the list of dermal residents.

In pathologic conditions such as acute inflammation, the functions and types of dermal cells change substantially, with various infiltrating leukocytes entering via the blood vessels. The composition of cutaneous infiltrates differs depending on the disease entity, providing useful diagnostic clues (Fig. 1.6).

Dermal–Epidermal Interface

The boundary between the epidermis and dermis consists of a specialized aggregation of attachment molecules and associated matrix, collectively known as the basement membrane[4] (Ch. 28). This structure is of considerable interest because various diseases originate from genetic defects in the composition of the basement membrane or from autoantibodies, which render individual components dysfunctional.

STRUCTURE AND FUNCTION OF THE SKIN AS IT RELATES TO DISEASE

We have chosen to present in this chapter a conceptual framework into which the other chapters of this textbook can be placed. This framework is derived from the assertion that knowledge of cutaneous function begins with disease. One corollary of this assertion is that there may be unrecognized skin functions, either because there is no corresponding disease yet recognized or because the disease is fatal. For example, no one would have guessed that incontinentia pigmenti

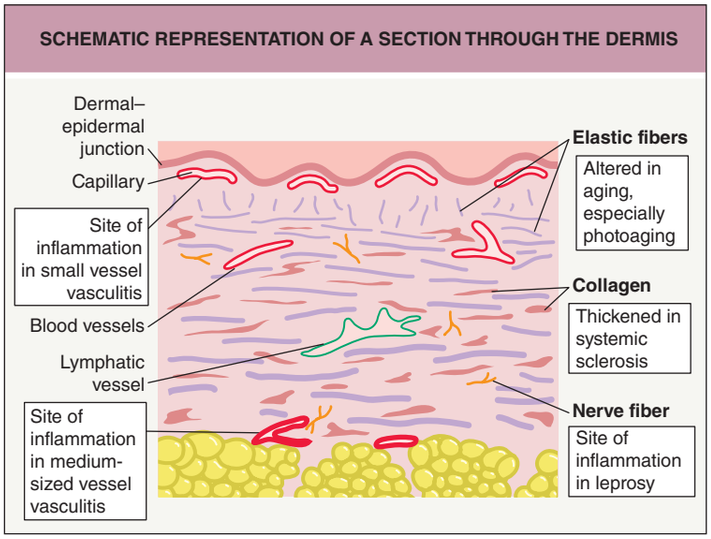

Fig. 1.5 Schematic representation of a section through the dermis. The extracellular matrix of the dermis is composed of structural proteins (collagen, elastin) and a gel-like ground substance (glycosaminoglycans). Blood vessels that supply nutrition and recirculating cells, lymphatic vessels, nerve fibers, and adnexal structures (see Fig. 1.1) are also present, with variations depending upon body site. Other cell types present in the dermis include mast cells, fibroblasts, macrophages, and dermal dendritic cells.

Fig. 1.6 Severe pustular psoriasis in an infant. The pustules represent sterile collections of neutrophils. Sterile infiltrates of neutrophils within the skin are seen most commonly in pustular psoriasis, pustular drug reactions (acute generalized exanthematous pustulosis), and neutrophilic dermatoses (see Ch. 26). *Courtesy Antonio Torrelo, MD.*

was lethal in males (likely due to widespread apoptosis of male fetuses *in utero*) had it not been for the survival of heterozygous females with this X chromosome-linked disease[5].

We deviate from the concept that physicians should always attempt to develop a single diagnosis for an illness. Rather, we believe that it is possible and even likely that two or more disease processes and/or predispositions may underlie an illness and that such simultaneous occurrences may alter the clinical presentation. Dermatologists are well aware of the unusual morphologic features of pityriasis rosea when it occurs in a patient with underlying psoriasis or when a patient with atopic dermatitis improves substantially with antibiotic therapy, even in the absence of obvious infection. Genetic factors and infectious agents also modulate the course of otherwise conventional skin diseases, e.g. a large number of viral warts or mollusca contagiosa may point to an immunodeficiency from an occult HIV infection. Thus, dermatologists have an extra assignment: to find otherwise hidden genetic, infectious, inflammatory, and environmental factors that modify the appearance and severity of cutaneous diseases.

All plants and animals have limiting membranes that define an internal space while also protecting against insults. In mammals, these membranes, which may be described functionally as "barriers", occur primarily in three organs: the respiratory tract, gastrointestinal tract, and skin (Ch. 124). Although similar in concept, the barrier properties of these organs are fundamentally different. Pulmonary and gastrointestinal barriers promote rather than retard the transfer of gases, fluids, nutrients and wastes, and because of their internal location, they are protected from many environmental influences. By contrast, and with the possible exception of UV radiation-facilitated vitamin D_3 production[6], there is no obvious benefit to skin penetration, or, at least, there are as yet no recognized diseases attributed to the failure of any material or form of energy to penetrate the skin. However, biomedical scientists continue to try to subvert the cutaneous barrier, as the skin has become a target of novel therapies based upon percutaneous penetration (Ch. 124)[7]. In addition to serving as a useful portal of entry for pharmaceutical agents, the skin can also serve as a site for immunization with gene-based materials and as a gene-driven cutaneous factory[8].

Protecting the DNA

Although we begin with the common rhetorical question: "What are the functions of skin?", it is followed by a more complicated question: "What are the requirements of skin that allow it to serve those functions?". The skin's primary function is to maintain an internal environment that allows an organism to protect its DNA and reproduce it relatively faithfully. In short, the preservation and reproduction of DNA sustains the species.

A second and highly related process is the generation of beneficial changes in DNA that adapt to new environmental circumstances. For example, skin pigmentation improves reproductive success in tropical climes by protecting folate from UV-mediated degradation, while lightly pigmented skin is advantageous for vitamin D biosynthesis in areas where UV radiation is scarce[9].

So, what are the requirements of skin to protect and replicate DNA? In fact, these requirements have not been identified merely through deductive logic; rather, as noted above, they have been identified by observing various failures that eventuate in skin disease. For this reason, we begin our survey with a listing of failures of skin (Table 1.1).

Immunologic Protection

An intricate system of immunologic recognition, both innate and adaptive, protects the skin from infection (Ch. 4)[10]. The innate immune response is the initial, rapidly deployed arm of the immune system that combats invading microbes and mediates defense against infection. It also plays a role in inflammatory conditions such as acne vulgaris and atopic dermatitis[11]. The cornerstone of adaptive immunity lies in recirculating lymphocytes and antibodies that are specifically recruited and "tuned" to recognize "foreign" materials, primarily peptides derived from infectious agents. Initial recognition occurs when sentinel dendritic cells in the epidermis (Langerhans cells) and dermis (dermal dendritic cells) are activated. Prior to activation, dendritic cells engulf particles and metabolize complex proteins into small immunogenic fragments. Once activated, motility is induced, allowing these cells to travel out of their cutaneous residence and migrate, via draining lymphatics, to regional lymph nodes (see Fig. 4.13). Thus, these residents of normal skin can travel to a distant location where reactive lymphocytes are selected and then expanded. Within a lymph node, activated T helper lymphocytes assist B lymphocytes in generating antibodies, while T helper lymphocytes and cytotoxic T lymphocytes begin to recirculate preferentially to and from the skin. A population of effector memory T lymphocytes that reside within the skin has also been identified, and these cells play a critical role in immune responses[12].

Infection

Cutaneous infections illustrate important aspects of skin function (Chs. 74–85), ranging from a structural barrier provided by the stratum corneum to immunologic recognition and protective immunity. Examining examples of defective resistance to infection, e.g. verrucae, Hansen disease, can provide insights into these functions.

Chronic and recurrent *verrucae* are often a vexing problem, especially when patients are immunocompromised or have epidermodysplasia verruciformis (Chs. 60 & 79)[13]. Trauma to the stratum corneum disrupts a physical barrier that is normally not susceptible to viral infection.

SELECTED REQUIREMENTS AND FAILINGS OF SKIN	
Requirement	**Selected failings**
Immunologic protection	Fungal, bacterial and viral infections; autoimmunity, cancer
Maintain a barrier	Infection, dehydration
Repair injury	Cancer, leg ulcers
Provide circulation	Infarction due to embolization, vasculitis, or other forms of occlusion
Communicate	Sensory neuropathy, pruritus
Provide nutrition	Vitamin D deficiency
Regulate temperature	Hypothermia, hyperthermia

Table 1.1 Selected requirements and failings of skin.

Fig. 1.7 Verrucae vulgares. A Multiple periungual warts. **B** Papillomatosis, hyperkeratosis, mounds of parakeratosis at the tips of the verrucous epidermal projections, and vacuolated keratinocytes (koilocytes) within the upper layers of the epidermis. The latter are due to a halo surrounding a shrunken nucleus. *A, Courtesy Louis A. Fragola, Jr, MD; B, Courtesy Lorenzo Cerroni, MD.*

Following a structural failure, human papillomavirus can infect the basal keratinocytes, which are viable and less resistant (see Fig. 79.3). Immunologic recognition of infected keratinocytes is usually followed by a cytotoxic cellular response, leading to destruction and resolution. When this response fails, chronic infection may ensue (Fig. 1.7). Protective immunity against warts often appears to be balanced precariously such that minor shifts in responsiveness may lead to their elimination in multiple sites simultaneously. In addition to physical destruction, therapeutic options frequently rely on modulating the immune response, including topical application of imiquimod, elicitation of contact sensitivity reactions, and intralesional injection of immunologic recall antigens such as *Candida* or mumps (see Fig. 79.26)[14].

Another example that highlights the importance of the structural integrity of the stratum corneum is *HIV infection* (Ch. 78). HIV penetrates through small tears in genital and rectal mucosae, and once the infection has occurred, the virus cannot be completely eradicated, despite a panoply of very effective therapies. With the loss of immunologic integrity, patients develop AIDS, demonstrating the role cellular immunity plays in protecting against infections by a wide variety of pathogens, including *Mycobacterium tuberculosis*, *Pneumocystis jirovecii*, and varicella–zoster (Fig. 1.8).

Hansen disease (leprosy) is also instructive in that most people exposed to its causative organism, *Mycobacterium leprae*, develop an effective immune response that seemingly clears the bacillus (Ch. 75). On the other hand, a small percentage of exposed individuals develop a chronic infection that may take any one of several forms, based on immunologic resistance. Observations in patients with Hansen disease have been important in formulating the Th1/Th2 paradigm, with each person's clinical response falling along a spectrum from tuberculoid to lepromatous (see Fig. 75.2)[15]. Associated neuropathy also illustrates the relevance of cutaneous sensation to protection against traumatic injury.

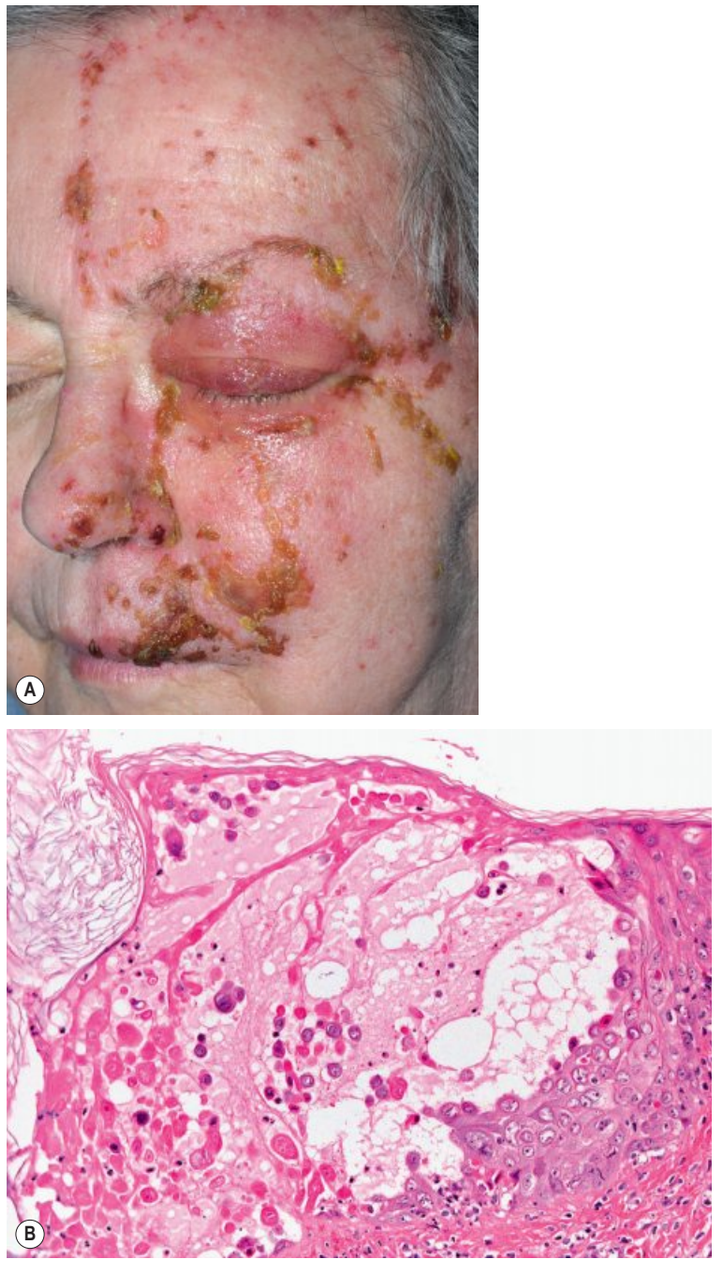

Fig. 1.8 Herpes zoster involving the ophthalmic (V1) and maxillary (V2) branches of the trigeminal nerve. A Erythema, especially of the eyelids, as well as serous and hemorrhagic crusts on the left side of the forehead, nose, cheek, and upper lip. Note the sharp midline demarcation on the forehead. **B** An intraepidermal vesicle forms as a consequence of ballooning degeneration, acantholysis, and necrosis of infected keratinocytes. Note the keratinocytes with enlarged, partly dyskeratotic nuclei or multiple nuclei in the side wall of the blister cavity, in addition to acantholytic, necrotic keratinocytes and fibrin within the blister. *A, Courtesy Kalman Watsky, MD; B, Courtesy Lorenzo Cerroni, MD.*

Autoimmunity

Whereas the principal task of the immune system is to recognize and destroy infectious organisms, autoimmunity represents a failure to distinguish "self" from "foreign", i.e. a misidentification and destruction of components of the host as if they were dangerous. Autoimmune diseases have different genetic and environmental factors promoting their development, and they may target components of the epidermis, the basement membrane, or the dermis (Table 1.2). In pemphigus vulgaris, for example, autoantibodies directed against desmogleins compromise cell–cell adhesion, resulting in intraepithelial acantholysis and widespread erosions (Fig. 1.9). It has also become apparent that autoimmunity directed against cutaneous antigens may impact other organ systems. For example, patients with paraneoplastic pemphigus have autoantibodies against both desmogleins and plakins (see Table 29.2),

COMMON AUTOIMMUNE SKIN DISEASES		
	Target antigen	**Chapter**
Diseases with identified autoantigens		
Pemphigus foliaceus	Desmoglein 1	29
Pemphigus vulgaris (Fig. 1.9A)	Desmoglein 3 and 1	29
Bullous pemphigoid (Fig. 1.9D)	Collagen XVII (BPAG2), BPAG1*	30
Epidermolysis bullosa acquisita	Collagen VII	30
Dermatitis herpetiformis	Transglutaminase-3	31
Diseases with unknown or multiple autoantigens		
Subacute cutaneous lupus erythematosus	Unknown, possibly SSA/Ro	41
Chronic cutaneous lupus erythematosus	Unknown	41
Psoriasis	Unknown	8
*Neural isoforms are referred to as dystonin.		

Table 1.2 Common autoimmune skin diseases.

which bind to adhesion molecules in keratinocytes but are also pathogenic in the lungs, leading to bronchiolitis obliterans[16,17].

Immune surveillance and cancer

Data supporting the concept that immune responses protect against malignancy are strongest for those malignancies arising in the skin and lymphatic tissues[18], especially cutaneous squamous cell carcinoma (SCC), Merkel cell carcinoma (MCC), and melanoma. Cutaneous SCC is a common complication of immunosuppression in solid organ transplant recipients[19].

Immune suppressive signals on cancer cells can prevent the immune system from attacking them. For example, the interaction of PD-L1 on cancer cells with PD-1 on T cells decreases T cell function. Immune checkpoint inhibitors such as nivolumab and cemiplimab, which block the binding of PD-L1 to PD-1, can activate the immune system and prevent immune evasion of cancer cells (see Fig. 128.9)[20]. These immune checkpoint-blocking antibodies have been used successfully to treat melanoma, MCC, and metastatic and locally advanced basal cell carcinoma and cutaneous SCC.

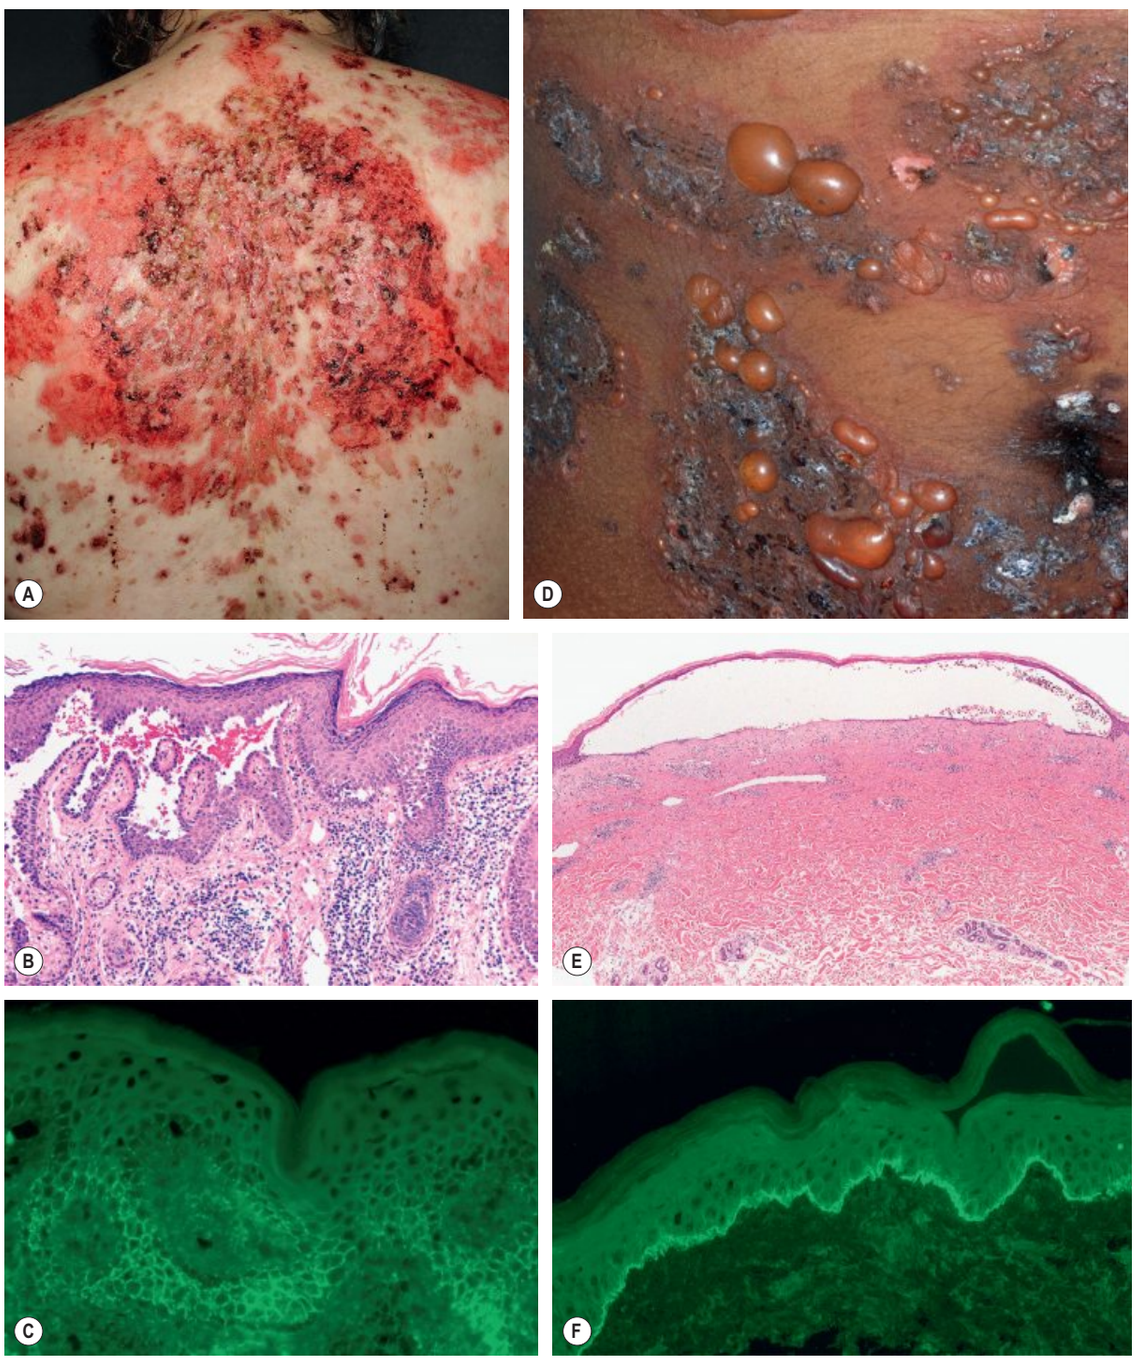

Fig. 1.9 Pemphigus vulgaris versus bullous pemphigoid. **A** In pemphigus vulgaris, fragile blisters are short-lived and rupture easily, leading to crusting and erosions that can become extensive. **B** Acantholysis and an intraepidermal split due to loss of desmosomal function from anti-desmoglein autoantibodies. Note that keratinocytes remain attached to the basement membrane via hemidesmosomes, resembling a row of tombstones. **C** Direct immunofluorescence (DIF) microscopy shows *in vivo* intercellular deposits of IgG within the lower epidermis in a "chicken wire" pattern. **D** In bullous pemphigoid, multiple tense bullae are seen; the contents of the bullae are usually serous. The bullae are longer-lasting than in pemphigus, but do eventually rupture, leading to erosions and crusts. **E** Subepidermal separation is seen. **F** DIF microscopy demonstrates linear deposits of C3 at the basement membrane. *A, B, E, Courtesy Lorenzo Cerroni, MD; C, F, Courtesy Christine Ko, MD; D, Courtesy Julie V. Schaffer, MD.*

Maintaining a Barrier

The most obvious function of the skin is to maintain a barrier that prevents the loss of fluids, electrolytes, and other molecules from within the body, while also preventing penetration by microorganisms, toxic materials, and UV radiation (Ch. 86)[21]. The stratum corneum is the key structure for barrier function. Protection against UV radiation occurs through several phenomena, including photon scattering in the stratum corneum and photon absorption by underlying melanin.

Protection against dehydration and infection

The most dramatic form of epidermal failure occurs in patients with toxic epidermal necrolysis (TEN; Ch. 20). In this drug-induced disease, rapid death of keratinocytes leads to detachment of the epidermis over large areas of the body (Fig. 1.10). TEN is most often associated with sulfonamides, aromatic anticonvulsants, and nonsteroidal anti-inflammatory drugs. The mortality rate depends on the area of skin affected, and death is not uncommon.

There is no specific treatment for TEN, but there is evidence that drug-induced triggering of massive keratinocyte apoptosis may underlie the disease[22]. Inhibition of apoptosis signaling pathways represents a potential therapeutic approach, e.g. by administration of immunomodulators such as cyclosporine and IVIg. Complications associated with significant loss of the epidermis highlight the importance of its barrier function: despite intensive treatment protocols similar to those used for burns, complications are common and include overwhelming infections with sepsis as well as fluid and electrolyte losses, leading to hypovolemia, electrolyte imbalances, and renal insufficiency.

Protection against toxic chemicals

Analysis of barrier failure includes the observation that the stratum corneum is defective in disorders of keratinization as it is less resistant to chemical penetration. In healthy adults with normal barrier function, topical application of the keratolytic salicylic acid in recommended amounts poses minimal, if any, risk of systemic toxicity. However, salicylism, which occasionally has been fatal, can occur in patients with ichthyosis (Fig. 1.11) or other cutaneous disorders with impaired barrier function[23].

Protection against UV radiation

UV radiation induces various changes in the skin, ranging from acute toxicity and immunosuppression to carcinogenesis and premature aging (Chs. 86, 87, 107 & 108). Sun protection is generally recommended to prevent adverse effects from UV radiation (Ch. 132), but at the same time, effective therapies for a number of skin diseases are based on UV radiation (Ch. 134). In addition to wearing clothing and applying topical preparations containing UV-absorbing or UV-blocking molecules, several characteristics of the skin itself limit UV radiation-induced damage. Due to its optical characteristics, the stratum corneum tends to reflect and scatter photons, and those that do penetrate the stratum corneum are usually absorbed by molecules such as melanin.

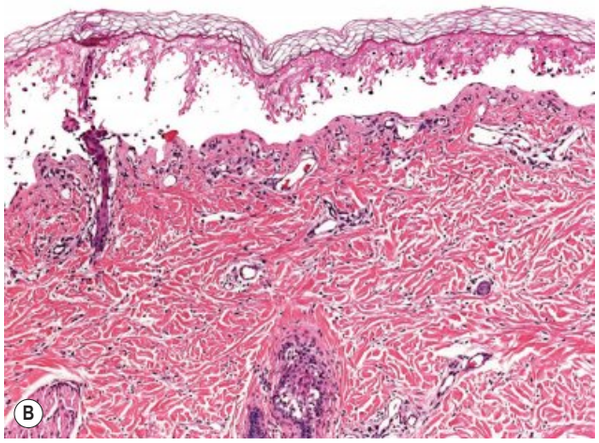

Fig. 1.10 Toxic epidermal necrolysis. A Detachment of necrolytic epidermis, leading to large areas of denuded skin. In the glistening areas, one is looking at dermis. **B** Full-thickness epidermal necrosis with a subepidermal cleft and sparse superficial inflammatory infiltrate. The normal basket-weave stratum corneum points to the acute nature of the disease process. *B, Courtesy Lorenzo Cerroni, MD.*

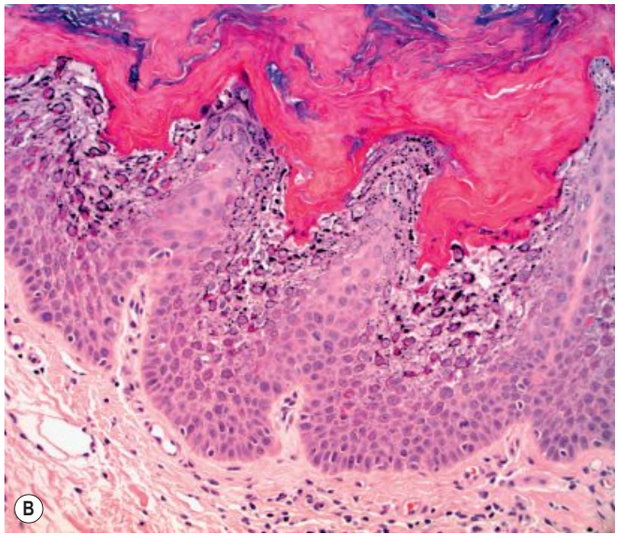

Fig. 1.11 Epidermolytic ichthyosis. A Mild background erythema with markedly thickened scale, especially near the axilla. Note the corrugated pattern of the scale. The fragility of the upper epidermis leads to peeling and erosions. **B** Marked compact orthokeratosis overlies a hyperplastic epidermis with epidermolytic change and dyskeratotic cells in its upper layers. *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Lorenzo Cerroni, MD.*

Additional mechanisms include scavenging of reactive oxygen species by antioxidants and repair of damage via DNA repair enzymes.

The importance of melanin in limiting UV penetration is best illustrated by patients with oculocutaneous albinism (OCA, Fig. 1.12). Patients with OCA have decreased melanin production and depending upon the degree of pigmentary dilution and cumulative sun exposure, they can develop multiple SCCs[24] and premature photoaging (Chs. 66 & 87). As an example, in sub-Saharan Africa, metastatic cutaneous SCC is a well-recognized cause of death in individuals with OCA.

Repairing Injury

Physical injuries to the skin are common, and repair of small breaks caused by blunt or sharp objects often goes unnoticed. A special type of injury is caused by UV radiation; this includes a variety of effects ranging from sunburn and immune suppression to accelerated aging and carcinogenesis. Thermal injuries occur when the skin is exposed to a hot object or radiant energy that heats the skin excessively, e.g. from a fire. Injury also occurs when the underlying vascular supply is interrupted. The biology of wound healing is complex and discussed in detail in Chapter 141.

Delayed wound healing

Both delayed and incomplete wound healing are disabling as well as costly. Diabetes mellitus, peripheral artery disease, and aging are risk factors for disturbed wound healing. The management of chronic leg ulcers is an important part of dermatology and rehabilitation medicine (Ch. 105). The need to address issues of chronic cutaneous ulceration led to the formation of the Wound Healing Society (www.woundheal.org), a consortium composed of clinical and basic science investigators along with representatives from industry and government.

Keloids

The formation of hypertrophic scars and keloids can be viewed as an exuberant response to injury. They reflect a unique mix of genetic and environmental factors with anatomic site. While studies have shown that transforming growth factor-β (TGF-β) activity is excessively high in fibroblasts derived from keloids[25], the pathogenesis is clearly more complex.

Fig. 1.12 An infant with oculocutaneous albinism (OCA). The scalp hairs are strikingly white. Patients with OCA are at higher risk for UV radiation-induced carcinogenesis, in particular cutaneous squamous cell carcinoma, as well as ocular abnormalities.

Xeroderma pigmentosum

An important failure occurs when UV radiation (UVR)-induced DNA damage is not effectively repaired. The archetype for this deficiency is the disease xeroderma pigmentosum. The high incidence of several types of skin cancer in these patients supports the assertion that UVR-induced DNA damage is an important cause of skin cancer in humans. This illustrates two points: (1) UVR is dangerous and the skin must protect itself from UVR's harmful effects; and (2) cancers develop more quickly when DNA repair mechanisms are disrupted.

Circulation: Providing Thermoregulation, Nutrition, Immunoregulation

Two circulatory systems mediate the movement of cells and soluble substances to and from the skin. There is a two-way *hematologic* system that conducts blood flow and a one-way *lymphatic* system; the latter returns leukocytes and interstitial fluids, first to draining lymph nodes and then, via the thoracic duct, into the central venous system. Hematologic circulation serves three major functions: nutritional support, the delivery of leukocytes, and thermoregulation. Although the movement of oxygen and solutes from the blood into interstitial tissues occurs largely by passive diffusion, the migration of cells from the vascular space occurs via an orchestrated sequence of signaling, attachment, and migratory processes (Ch. 102).

The hematologic system includes two types of vessels: (1) nutritive vessels (arteries, capillaries, and veins); and (2) anastomosing arteries and veins that participate in heat regulation. The anastomosing system includes an extensive subcutaneous venous plexus, which can hold large quantities of blood (to dissipate heat from the skin's surface), and arteriovenous anastomoses, which provide direct connections between arterial and venous plexuses. These anastomoses are prominent in areas exposed to maximal cooling, such as the volar surfaces of the hands and feet, lips, nose, and ears.

Cutaneous lymphatic drainage begins in microscopic, blind-ended, dermal vessels called lymphatic capillaries. These collect both cells and interstitial substances, which are then directed to the regional lymph nodes. As a result, lymphocytes, macrophages, and dendritic cells can travel from the epidermis through draining lymphatic vessels to the lymph nodes[26].

Embolic occlusion of arteries

The most dramatic form of blood vessel occlusion is emboli-mediated blockage, which can produce changes within hours. This is followed rapidly by ischemic necrosis of all cutaneous structures distal to that blockage. The extent of necrosis depends on the size of the vessel occluded and degree of collateral circulation. Occlusion followed by cutaneous necrosis vividly demonstrates the dependence of skin on arterial circulation.

Vasculitis

Cutaneous inflammation centered in the blood vessel wall is responsible for a spectrum of cutaneous findings that vary depending upon the size of the affected vessel (Fig. 1.13; see Fig. 24.24). Vasculitis is commonly associated with autoimmune connective tissue diseases, particularly Sjögren syndrome, rheumatoid arthritis, and lupus erythematosus (Chs. 24, 41, & 45). The critical element in terms of cutaneous structure is that the skin's survival is highly dependent upon an intact circulation.

Occlusive vasculopathy

Other disorders characterized by vascular occlusion result from thrombosis due to aberrant coagulation or cold-related "gelling" (Ch. 23). Examples of hypercoagulable disorders include antiphospholipid antibody syndrome and factor V Leiden mutation leading to activated protein C resistance (Ch. 105).

Venous insufficiency

Although listed last, venous insufficiency through partial occlusion and valvular incompetence contributes to the most common vascular problem, the development of venous stasis ulcers of the legs (Ch. 105).

Lymphatic blockage

Blockage of lymphatic drainage may also occur in certain inflammatory skin conditions. The inflammation associated with recurrent streptococcal and staphylococcal infections can lead to scarring and loss of

Fig. 1.13 Palpable purpura of the lower extremity due to cutaneous small vessel vasculitis. Immune complex deposition within postcapillary venules leads to circular purpuric macules and papules. *Courtesy Lorenzo Cerrroni, MD.*

lymphatic drainage, resulting in distal edema. With chronic infection, permanent edema may develop, associated with widespread verrucous change at the skin surface, a condition described as elephantiasis nostras verrucosa (Ch. 105). Likewise, blockage of lymphatic drainage in parasitic infections is known to cause deforming patterns of lymphedema (Ch. 83).

Communicating with External and Internal Environments

Communication within the skin occurs by three mechanisms: conventional nerve conduction via cutaneous fibers; intercellular signaling mediated by cytokines and hormones (endocrine, paracrine, and autocrine effects); and the physical movement of "message-carrying" cells from one site to another.

Communication via nerves

The skin is "wired" with afferent and efferent nerve fibers that accompany vascular structures, forming an intricate network in the dermis. They envelop the pilosebaceous apparatus, blood vessels, and sweat glands. Although the head and distal extremities are innervated most densely, the entire skin contains nerves. In the dermis, larger fibers are surrounded by a myelin sheath, but as diameters diminish, many fibers run free. Although most nerve fibers appear to end in the dermis, some small endings penetrate the basement membrane and travel into the epidermis, where they can modulate immune responsiveness[27]. Diminished or functionally impaired intraepidermal nerve fibers lead to neuropathic symptoms, including burning and pruritus[28].

Nerves also control vascular tone, as evidenced in blushing responses, and they mediate the sensations of heat, cold, itch, touch, and pain (Chs. 5 & 6). Defects in sensation and neurologic function are common and can be seen in patients with postherpetic neuralgia, uncontrolled itching, neurologic syndromes (e.g. trigeminal trophic syndrome), and excessive sweating. Intradermal injections of botulinum toxin to uncouple cholinergic nerve fibers have at least two dermatologic applications: (1) to decrease muscle tone, leading to a loss of facial lines for cosmetic purposes; and (2) to inhibit the excessive sweating that characterizes disabling axillary and palmar hyperhidrosis[29] (Ch. 159).

The sensory function of the skin plays an important role in neurologic development and social interactions. Touch reduces physiologic reactions to stress in infants[30] and plays an important role in developing cohesive social units[31]. Tactile stimulation of neonates activates the brain in areas linked to sensory perception and social-affective processing[32].

Itch and pain

Itch is a major problem for patients with skin disease (Chs. 5 & 6). We presume that acute and modest levels of itching confer some beneficial effect, but, most certainly, chronic and excessive itching can be devastating for both personal and social activities. On the other hand, there is little evidence for structural abnormalities that predispose to excessive itching. Postherpetic neuralgia is similarly important (Ch. 80), although, once again, there is no obvious structural defect in this exquisitely painful disorder.

Excessive sweating

Hyperhidrosis is a potentially debilitating disorder of sweating, which usually involves the axillae as well as the palms and soles. Accumulated evidence favors a neurologic abnormality rather than a structural abnormality[29]. Moreover, interruption of sweat gland innervation by injection of botulinum toxin provides considerable relief (Ch. 159).

Loss of sensation

The most obvious and devastating effects of altered touch and pain sensation are seen in patients with peripheral neuropathies associated with diabetes mellitus and Hansen disease[33]. The loss of sensory function results in the patient's inability to recognize, and therefore avoid, cutaneous trauma. In patients with longstanding diabetes mellitus, this can result in neuropathic ulcers in weight-bearing areas of the feet (see Fig. 105.15). Similar ulcers develop in patients with Hansen disease, along with a gradual loss of tissue. In both conditions, the loss of sensation leads to vulnerability of the skin to traumatic injury.

Communication via hormones and cytokines

Hormones

The skin plays a unique hormonal role in calcium metabolism. Vitamin D_3 (cholecalciferol) is produced in the epidermis by the action of UVR on 7-dehydrocholesterol[6]. It then leaves the skin and is hydroxylated in the liver and kidneys to the active form of vitamin D (1,25-dihydroxycholecalciferol; see Fig. 51.11).

An example of indirect hormonal influences on the skin is adrenocorticotropic hormone (ACTH), which was recognized as having systemic effects via its influence on the secretion of adrenal corticosteroids. While corticosteroids have beneficial effects on inflammatory skin disorders such as psoriasis and atopic dermatitis, other diseases like acne can worsen. Several of the clinical signs of Cushing disease (altered fat distribution, vascular dilation, and striae) result from excessive secretion of corticosteroids (Ch. 53). In contrast, diminished production of adrenocortical hormones causes excessive secretion of ACTH, which indirectly gives rise to the hyperpigmentation seen in patients with Addison disease (Ch. 67).

Cytokines

It has been increasingly recognized that cells within the skin produce an array of cytokines[34]. Keratinocytes produce IL-1, IL-8 and TGF-β, with an important physiologic function thought to be the beneficial effect of TGF-β on wound healing[35]. Langerhans cells produce a unique spectrum of cytokines and chemotactic factors related to their immunologic properties[36], and vascular endothelial cells produce IL-1β, IL-6, and IL-8[37]. Cytokine-mediated communication between cells has proven to be enormously complex[38–42], and the interplay between cytokines and cells is often reciprocal[43,44]. For example, mast cells produce tumor necrosis factor (TNF), which affects cutaneous immunity[44], but, at the same time, mast cell function is regulated by other cytokines[45].

As a result of an improved understanding of the role of cytokines in keratinocyte biology, important advances have been made in managing inflammatory skin diseases, most notably psoriasis. Aberrant levels of TNF, IL-17, and IL-23 have emerged as critical targets of immunomodulators used to treat psoriasis (Ch. 128). Similarly, targeting the dysregulated Th2 axis by blocking the IL-4 receptor now represents a treatment option for atopic dermatitis[46].

Communication via cells

In the course of their normal function, certain resident cutaneous cells depart from the skin while in possession of information that directly impacts the function of the skin. These cells include dendritic cells in particular, which, once activated, leave the skin and migrate to regional lymph nodes where they select and prime naive and resting

T lymphocytes (Ch. 4). The activation, migration, and repopulation processes have been intensely studied with the prospect of developing methods to modulate immunity.

Regulating Temperature

Regulation of core temperature is a characteristic of all mammals, which, by definition, are euthermic. For humans, core temperature is maintained at ~37°C (98–99°F). Because environmental influences can alter temperature, there is an intricate regulation system in which the skin plays a decisive role as both radiator and insulator. Temperature regulation occurs primarily through evaporative cooling following eccrine sweating (Ch. 39) and through vasodilation and vasoconstriction.

Human skin includes several million eccrine sweat glands distributed over most of its surface, with a total mass approximately equivalent to one kidney. The secretory activity of eccrine sweat glands consists of two major activities: (1) secretion of an ultrafiltrate of a plasma-like fluid; and (2) reabsorption of sodium by the duct to produce hypotonic sweat.

Effects of excessive heat

Excessive heating may be local or systemic, and when this occurs, the skin plays a cooling role to prevent injury. Cooling may be required under two circumstances: (1) in response to central heating, when heat enters the skin from the environment or when muscle activity generates sufficient energy to raise the core temperature; and (2) in response to sustained local heating, when a portion of the skin is heated to a temperature at which proteins begin to denature (45–50°C; 113–122°F; Ch. 88). The subsequent physiologic responses that lower temperature in order to prevent injury require innervation, circulation, and successful sweating. Elimination of central heat occurs via radiation from the skin surface and the evaporative cooling that follows sweating. Dispersion of local heat takes place through direct radiation to the environment and by heat transfer to other body locations via circulating blood.

The importance of sweating for inducing cooling and ultimately for survival is illustrated in the vignette of hyperthermia at the beginning of this chapter. In patients with hypohidrotic ectodermal dysplasia, the defining defect is an almost complete absence of sweat glands, in association with other features such as hypotrichosis and abnormal teeth (Ch. 63). This disease demonstrates the importance of sweating, as death from overheating during exercise may occur, especially when the environmental temperature is high.

Of note, local heat is also used therapeutically: electrocautery is a time-honored method of therapy in dermatology (Ch. 140). Heat therapy has also been used to treat skin infections, including sporotrichosis, verrucae, and leishmaniasis.

Effects of excessive cold

Cold injuries occur under two related circumstances: (1) in response to heat loss to the environment in amounts that cool the body centrally (hypothermia); and (2) in response to local exposure to sustained below-freezing temperatures that could result in direct freezing injury ("frostbite"). Apart from vascular constriction to reduce radiation of heat from the skin surface and shivering (or exercise) to increase central heating, there are no cutaneous mechanisms to protect against excessive cooling. However, humans have become quite adept at creating artificial methods to prevent cold injury through clothing and shelter. These have enabled humans to survive successfully in geographic areas of extreme temperature.

For over a century, dermatologists have successfully used local cold injury, i.e. cryosurgery, as a therapeutic tool (Ch. 138).

Interpersonal Communication: Beauty, Attention, and Self-Identity

An important function of the skin begins with the human need to communicate with each other so that personal and societal goals can be met. The skin plays an important role in interpersonal communication by conveying beauty to others, attracting attention, and contributing to the development and expression of self-identity. In virtually every society, the appearance and condition of the skin has fundamental importance. There is not sufficient space to list the physical features that are considered beautiful within each cultural context, but let us assert that the perceived loss of these features has much to do with the distress that often affects patients with acne, vitiligo, alopecia, aging, and virtually all other skin diseases.

Over the past two decades, there has been increasing attention paid to the impact of skin disease on quality of life. Myriad reports have been published describing the extent to which chronic skin diseases, including psoriasis, eczema, and pigmentary disorders, affect patients' self-perception. As dermatologists become increasingly aware of the psychosocial impact of chronic skin disease, we will better understand and treat patients with these conditions.

Finally, the skin represents a "canvas" onto which individuals can make modifications to communicate and display aspects of self-identity. Tattoos, ritual scarification, and piercings have long been seen as expressions of self-identity. Dermatologists participate in skin modification by performing procedures designed to alter a patient's appearance and to address a variety of patient concerns (Chs. 152–159).

Failures to present an attractive appearance

Concern about appearance is an intrinsic human behavior. Appropriately proportioned, symmetric, flawless skin seems to be preferred in most societies. The changes that are most undesirable vary from culture to culture, so that one cannot assume that what is considered unattractive in one culture is necessarily considered unattractive elsewhere. Although variations in norms across cultures can be remarkable, the discipline of cosmetic dermatology has arisen to address such concerns, with the goal of improving self-image.

Pigmentation disorders

Pigmentary disorders tend to be more perceptible, and thus more important, in populations with darker constitutive pigmentation. Although dermatologists care for patients with a wide range of disorders of pigmentation, two diseases predominate: vitiligo (Ch. 66) and melasma (Ch. 67). Vitiligo is characterized by the absence of epidermal melanin due to the autoimmune destruction of melanocytes (Fig. 1.14)[47]. It can be accompanied by autoimmune endocrinopathies and this association is recapitulated in patients receiving immune checkpoint-blocking antibodies for melanoma (Ch. 113). Melasma also has a higher prevalence in patients with darker skin phototypes and it can be quite distressing[48].

The preference for unblemished skin is exceedingly important in cultures in which altered pigmentation may be confused with infectious diseases such as Hansen disease (Ch. 75) or conflated with superstitions or folklore. Not only do persons with albinism face the physical consequences of reduced melanin production such as poor vision and increased risk of developing skin cancer, but they also face a variety of social injustices. In sub-Saharan Africa, where OCA is relatively prevalent, these individuals live under the threat of violence from those within their society who believe albinism is a curse[49] or the opposite, that body parts can bring luck or success.

Inappropriate hair distribution

For many individuals, the psychological contributions of hair cannot be underestimated. Scalp hair is a major social and sexual display feature for humans. Two phenomena predominate in concerns about hair: (1) too much hair in the wrong place; and (2) not enough hair in the right place. Too much hair in the wrong place occurs in congenital and acquired forms of hypertrichosis, in response to therapy with minoxidil and cyclosporine, and as a manifestation of androgen excess (Ch. 70). However, most patients who seek help for excessive hair do so primarily for cultural reasons. In terms of insufficient hair (Ch. 69), three diseases predominate: (1) androgenetic alopecia in men; (2) female pattern alopecia in women; and (3) alopecia areata (Fig. 1.15). Inflammatory scarring alopecia, while less common, also creates a significant impact on quality-of-life.

Undesirable fat distribution

With the possible exception of hemifacial atrophy and lipodystrophy syndromes, indications for the absolute removal and the movement of fat are based on psychologic needs rather than on abnormalities in the structure of the skin and subcutaneous tissues. Nevertheless, the movement or reduction of fat is becoming a fairly common procedure, and dermatologists are playing increasingly important roles in this arena (Ch. 156).

Fig. 1.14 Vitiligo in an African-American man. The digits are a common site of involvement and repigmentation of the distal fingers can be difficult due to the lack of hair follicles. Vitiligo and other pigmentary disorders are more noticeable in patients with darker skin.

Fig. 1.15 Circumscribed area of hair loss due to alopecia areata. The detrimental social impact of hair loss in patients with diseases such as alopecia areata cannot be underestimated.

An Important Corollary, with an Eye to the Future

In this chapter, we have asserted that the structure and function of the skin are revealed through careful study of skin diseases. Structure and function are also discovered by observing the outcomes of therapeutic interventions. For example, the mechanism of action of anti-tumor immune checkpoint inhibitors is immune stimulation. A wide range of cutaneous side effects, from lichenoid dermatoses to bullous pemphigoid to sarcoidosis, is providing valuable insights into the pathogenesis of these diseases. Many more such observations are bound to follow as we develop new methods of treating skin disease. Furthermore, the acuity of our power to observe changes in the skin will be aided by advances in technology, including artificial intelligence. If we remain curious about the diseases we treat, the potential for additional discoveries regarding the structure and function of the skin is endless.

Acknowledgment

The author wishes to thank Paul R. Bergstresser, MD, for his valuable contributions to this chapter in the previous editions.

INTRODUCTION

Development of the human embryo is a complex process involving highly orchestrated cell movements, proliferation, death, and differentiation. This chapter focuses on key events and regulatory mechanisms that result in skin morphogenesis, maintenance, and regeneration. The spectrum of cutaneous abnormalities that can result from mutations in genes with critical roles in skin development is discussed. Ultimately, improved understanding of the pathways and signaling cascades essential to skin development will provide the basis for therapeutic approaches for patients with acquired as well as inherited skin disorders.

EMBRYONIC ORIGIN OF THE SKIN

The skin is composed of diverse cell types of both ectodermal (e.g. keratinocytes, melanocytes, Merkel cells, neurons) and mesodermal (e.g. fibroblasts, hematopoietic cells such as Langerhans cells, endothelial cells) lineages. To understand the origins of these cells, it is important to review the early stages of embryogenesis. Immediately after fertilization, cells divide rapidly, and by the end of the first week, the embryo begins to implant into the uterine wall. During the third week, the embryo undergoes gastrulation, a complex process resulting in the formation of the three embryonic germ layers: endoderm, mesoderm, and ectoderm.

During the next stage of embryogenesis, ectodermal cells commit to either a surface ectodermal or neuroectodermal fate. The surface ectodermal cells eventually differentiate into the keratinocytes of the embryonic epidermis, whereas the neuroectodermal cells invaginate to create the neural tube in a process called neurulation. As the neural tube forms, cells in its dorsal portion separate to form the neural crest. An important neural crest-derived cell in the skin is the melanocyte. Although Merkel cells were once believed to be neural crest derivatives, it has now been established that they descend from the epidermal lineage. The lineage of the dermis depends on the body site. The dermis (and other mesenchymal structures) of the face and frontal scalp are derived from the neural crest, whereas the dermis elsewhere is derived from the mesoderm. Knowing from which germ layer and lineage different cell types in the skin derive helps one to understand the pathophysiology of cutaneous disorders such as Waardenburg syndrome in which craniofacial dysmorphism and hearing impairment as well as pigmentary abnormalities reflect disrupted migration and survival of neural crest-derived cells (see Ch. 65).

An overview of key events in the development of skin and its specialized structures is shown in Fig. 2.1.

EPIDERMAL DEVELOPMENT

The ectoderm that covers the developing embryo after gastrulation is a single-layered epithelium (Fig. 2.2A). The first step in epidermal development occurs when cells of the surface ectoderm adopt an epidermal fate[1]. Although this process does not result in major morphologic changes, it is marked by dramatic alterations in gene expression that result in the formation of the embryonic epidermis, which initially consists of a simple epithelium (Fig. 2.2B). Primitive keratinocytes subsequently generate cells of the periderm, a single cell layer that covers the developing epidermis until the cornified cell layer is formed (Figs. 2.2C–F & 2.3A,B). The periderm is believed to exchange substances across fetal skin and to protect the developing epidermis from forming interepithelial adhesions.

The embryonic epidermis begins to stratify at approximately 8 weeks' estimated gestational age (EGA)[2]. At this time, basic organogenesis is complete and bone marrow hematopoiesis commences, marking the transition from embryo to fetus. Of note, expression of *TP63* is required for epidermal stratification. During the first stage of stratification, an intermediate cell layer is formed between the basal layer and periderm (see Figs. 2.2D & 2.3B). Unlike suprabasal keratinocytes in the postnatal epidermis, the intermediate layer consists of actively proliferating cells. As a consequence, it is able to expand to accommodate the rapid growth of the embryo as well as create additional layers of intermediate cells over the next several weeks (see Fig. 2.2E). However, the intermediate cell layer is ultimately replaced by post-mitotic keratinocytes undergoing terminal differentiation.

Terminal differentiation, the process resulting in the formation of mature keratinizing epidermal cells, begins during the second trimester. Early cornification can be observed within the hair canal at approximately 15 weeks' EGA[3], but it does not commence in the interfollicular epidermis until 22–24 weeks' EGA, occurring first in the skin on the head, palms, and soles. The process begins when cells in the intermediate layer permanently withdraw from the cell cycle and differentiate into spinous and granular cells (see Fig. 2.2F). The cornified cell layer, which is composed of "dead" keratinocytes (corneocytes) held together by a matrix of proteins and lipids (see Chs. 56 & 124), subsequently starts to form and is several cells thick by 24–26 weeks' EGA. The corneocytes are a reflection of the closely regulated process of terminal differentiation that is required for normal functioning of the skin. At the time of keratinization, the periderm detaches from the underlying epidermis and is sloughed off into the amniotic fluid, with remnants contributing to the vernix caseosa that coats newborns. During the third trimester, the number of keratohyalin and lamellar granules as well as stratum corneum layers increases. By the mid third trimester, the epidermis is morphologically similar to adult skin (Figs. 2.2G & 2.3C), although it does not acquire full barrier function until a few weeks after birth.

Clinical Relevance

Genetic abnormalities affecting various stages of epidermal morphogenesis have been found to underlie inherited skin disorders in humans. However, generalized abnormalities in epidermal specification, the process through which the surface ectoderm adopts an epidermal fate, have not been identified. It is likely that generalized epidermal defects would be incompatible with survival past the first trimester. Mosaic skin conditions that result in abnormalities of the epidermis and/or its appendages often have a distribution pattern that follows the lines of Blaschko, which are thought to represent the migration pathways of epidermal cells during embryonic development. Classic examples include epidermal nevi (due to postzygotic mutations in genes encoding

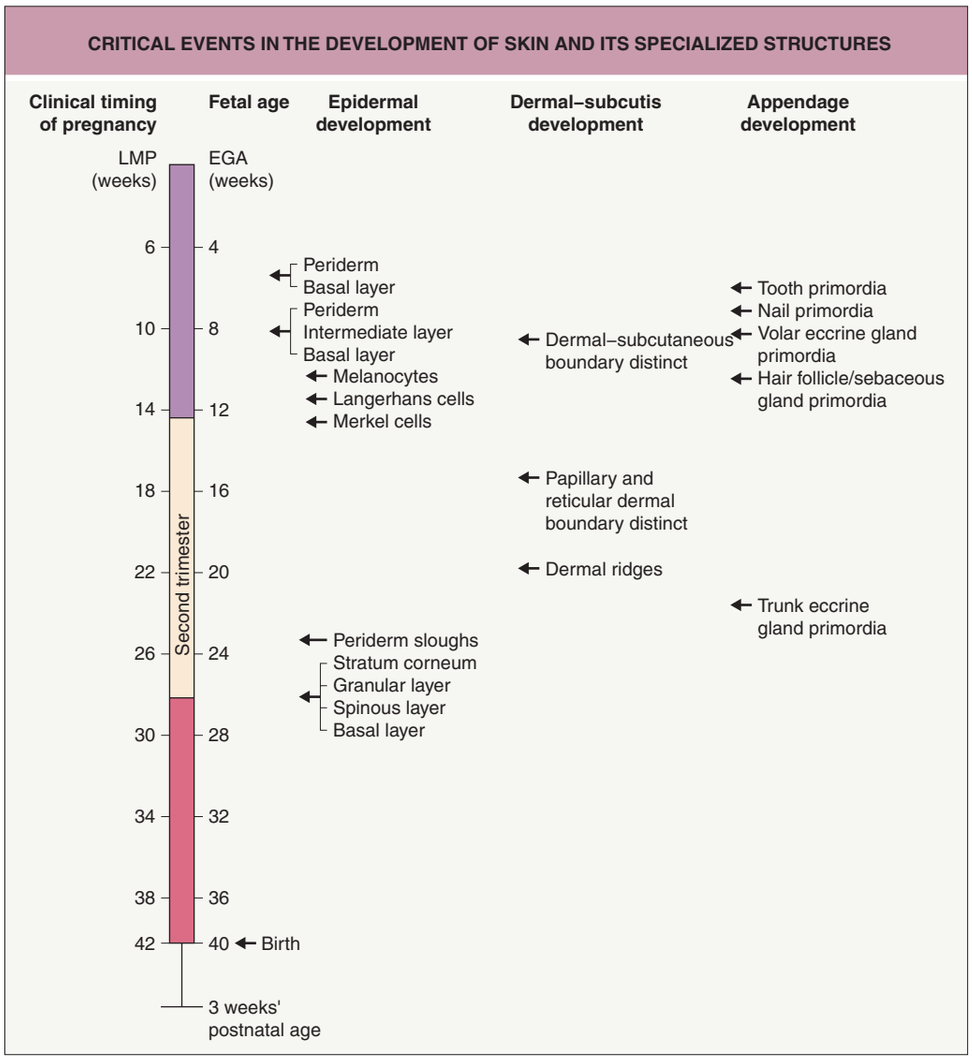

Fig. 2.1 Critical events in the development of the skin and its specialized structures. The timeline indicates the time of initiation defined by estimated gestational age (EGA) and duration of pregnancy (by last menstrual period [LMP]). Refers to skin on the back unless otherwise noted.

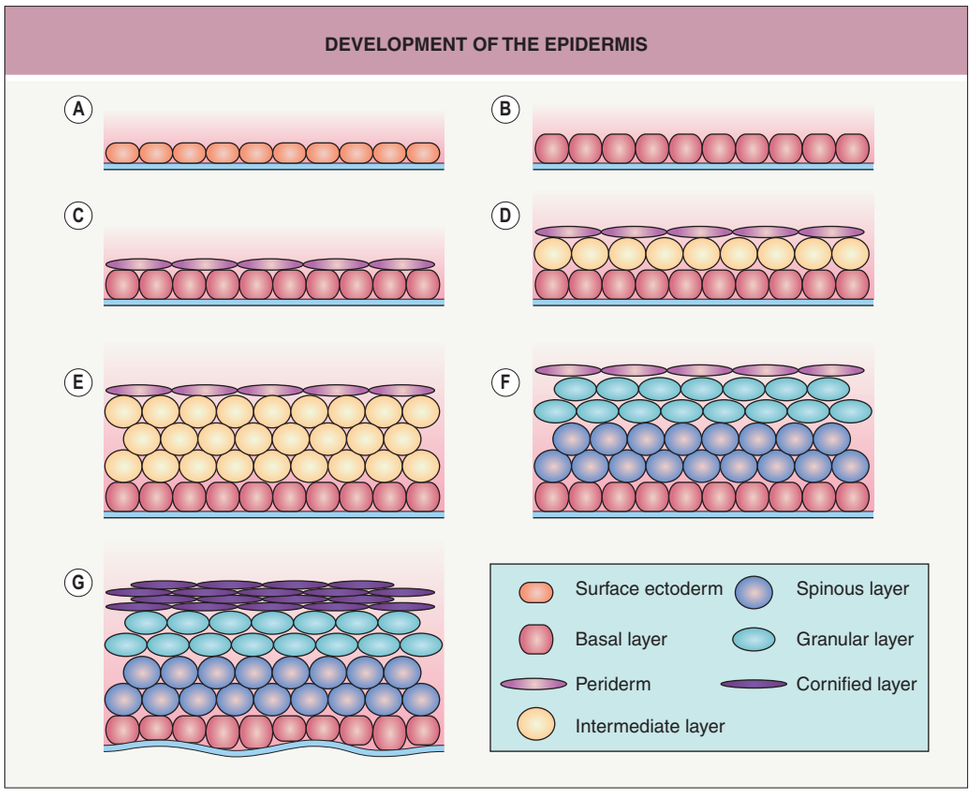

Fig. 2.2 Development of the epidermis. A The epidermis develops from the surface ectoderm, a single-layered epithelium that initially covers the developing embryo. **B** Through changes in gene expression, cells of the surface ectoderm adopt an epidermal fate. **C** Epidermal cells subsequently give rise to the periderm, a cell layer that covers the developing epidermis until cornification occurs. **D** Epidermal stratification begins with the formation of a highly proliferative intermediate layer between the basal layer and the periderm. **E** The intermediate layer becomes several cells thick over the next few weeks. **F** Intermediate cells ultimately withdraw from the cell cycle and differentiate into spinous and granular keratinocytes. **G** The periderm is replaced by the cornified cell layer.

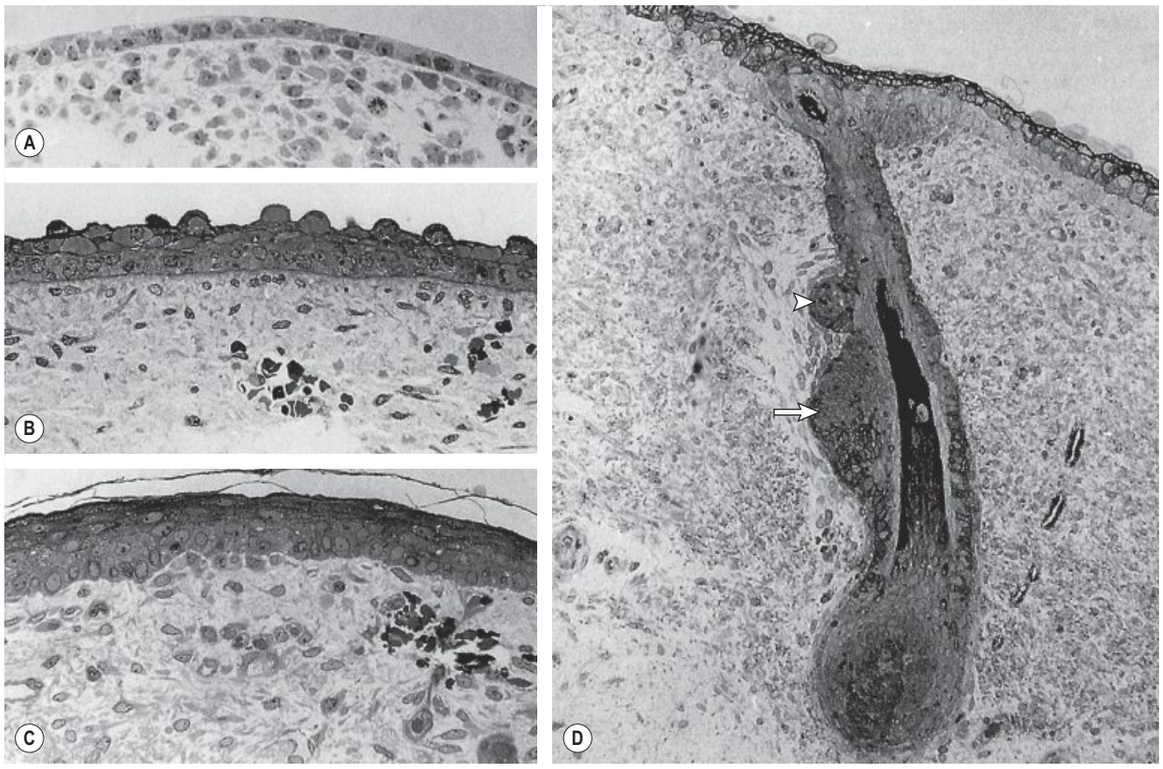

Fig. 2.3 Development of the skin. A At 36 days' estimated gestational age, the embryonic epidermis consists of two layers – a superficial periderm layer overlying a basal layer. **B** By 72 days, the basal layer has given rise to the highly proliferative intermediate cell layer. **C** A distinct granular cell layer and stratum corneum are seen in neonatal skin. **D** An early peg-stage follicle from a mid second trimester fetus. The more superficial bulge consists of the developing sebaceous gland (arrowhead), whereas the deeper bulge represents the insertion point of the future arrector pili muscle and the location of the presumptive follicular stem cells (arrow). *Photomicrographs, courtesy Dr Karen Holbrook, from Loomis CA, Koss T, Chu D. Fetal skin development. In: Eichenfield LF, Frieden IJ (eds). Textbook of Neonatal Dermatology, 3rd edn. Elsevier, 2014:2–5.*

fibroblast growth factor receptors, the phosphoinositide-3-kinase alpha subunit, Ras family members, and keratins) and sebaceous nevi (due to postzygotic mutations in *HRAS* > *KRAS*) (see Ch. 62).

There are a number of genetic disorders that result in abnormal epidermal differentiation and barrier formation. One clinical presentation of such conditions is a "collodion baby" born encased in a taut, shiny, transparent membrane that is formed by aberrant stratum corneum. After shedding the membrane, most of these infants manifest with lamellar ichthyosis or congenital ichthyosiform erythroderma, two forms of autosomal recessive congenital ichthyosis that exist on a spectrum[4]. However, following a collodion membrane, some patients develop normal or almost normal appearing skin. The "self-improving" collodion baby is an example of a dynamic epidermal phenotype that depends on environmental conditions. All of these outcomes can result from mutations in the same set of genes that encode proteins essential for formation of the epidermal barrier, including transglutaminase-1 (an enzyme that cross-links lipids to the cornified cell envelope; *TGM1*), lipid processing enzymes (*ALOXE3*, *ALOX12B*), and lipid transporters (*ABCA12*) (see Ch. 57).

More deleterious mutations in *ABCA12* cause harlequin ichthyosis (HI), an especially severe disorder of cornification characterized by aberrant epidermal maturation. Patients with HI are born with a tremendously thick, armor-like shell of hyperkeratosis, severe ectropion and eclabium, and underdevelopment of the nose and ears. The extreme phenotype of HI highlights the importance of lipid transport into lamellar bodies for epidermal formation and function.

Abnormalities in the stratum corneum are present not only in infants with ichthyosis, but also in premature infants, especially those born before 28 weeks' EGA. The immaturity of the stratum corneum results in impaired barrier function, which leads to an increased risk of infection, dehydration, and excessive absorption of topical medications or chemicals[5]. Even healthy full-term infants do not attain full skin barrier function until 3 weeks of age. The structural features of premature skin and adult skin are summarized in Table 2.1.

DEVELOPMENT OF SPECIALIZED CELLS WITHIN THE EPIDERMIS

Two populations of non-keratinocyte cells – melanocytes and Langerhans cells – migrate to the epidermis during early embryonic development. *Melanocytes* are derived from the neural crest that forms along the dorsal neural tube. Melanocyte precursors migrate away from the neural tube within the mesenchyme beneath the primitive epidermis. They follow a characteristic trajectory, moving dorsolaterally and then ventrally around the trunk to the ventral midline, anteriorly over the scalp and face, and distally along the extremities. Cutaneous melanocytes also arise from Schwann cell/melanocyte precursor cells that migrate along nerves to the skin via a distinct ventral pathway[6].

Melanocytes can be identified within the epidermis at approximately 50 days' EGA based on HMB45 immunostaining and their dendritic morphology. Epidermal melanocyte density is high early in embryonic development (~1000 cells/mm^2), and it increases further (~3000 cells/mm^2) as the epidermis stratifies (80–90 days' EGA) and the appendages begin to develop; later in gestation, the density decreases and becomes similar to that of young adults (800–1500 cells/mm^2). However, epidermal melanin production does not begin until 3–4 months' EGA, and melanosome transfer to keratinocytes is not seen until 5 months' EGA. Even though all melanocytes are functional and in place at birth, the pigmentation of the skin increases over the first few months of life; this process is most pronounced in infants with darker skin phototypes.

Active melanocytes are also present throughout the dermis during embryonic development. Eventually, most of these dermal melanocytes migrate to the epidermis or undergo apoptosis. By the time of birth, dermal melanocytes have generally disappeared, with the exception of certain anatomic sites (head and neck, dorsal aspects of the distal extremities, and sacrococcygeal area), which correspond to the most common locations for dermal melanocytoses and blue nevi (see Ch. 112).

Langerhans cell precursors appear within the epidermis during the first trimester and are detectable as early as 40 days' EGA. These cells can be distinguished by their characteristic dendritic morphology; expression of CD45, HLA-DR, and CD1c; and high levels of ATPase activity. CD1a, Langerin, and Birbeck granules are expressed by 13 weeks' EGA. The density of Langerhans cells in fetal skin remains low early in gestation and increases to typical adult levels during the third trimester.

Merkel cells, highly innervated neuroendocrine cells involved in mechanoreception, are initially identified within the epidermis during the first trimester. These cells are detected as early as 8–12 weeks' EGA in palmoplantar epidermis, and slightly later in interfollicular skin.

COMPARATIVE FEATURES OF PREMATURE, NEWBORN, AND ADULT SKIN			
	Premature	**Newborn**	**Adult**
Skin thickness	0.9 mm	1.2 mm	2.1 mm
Epidermal surface	Vernix (gelatinous)	Vernix	Dry
Epidermal thickness	~20–25 microns	~40–50 microns	~50 microns
Stratum corneum thickness	4–5 microns	9–10 microns	9–15 microns
	5–6 cell layers	>15 cell layers	>15 cell layers
Spinous cell glycogen content	Abundant	Little or none	Little or none
Melanocytes	High number of cells; few mature melanosomes	Similar number of cells to young adult; low melanin production	Numbers decrease with age; melanin production dependent on skin type, body area
Dermal–epidermal junction	All known adult antigens expressed; fewer and smaller desmosomes	Structural features and antigens similar to those of the adult	Well-developed adhesive structures; large number of antigens expressed
Papillary dermis			
• Boundary with reticular dermis	Present but not marked	Present but not marked	Marked
• Size of collagen fiber bundles	Small	Small	Small
• Cellular density	Abundant	Abundant	Moderately abundant
Reticular dermis			
• Boundary with the subcutis	Marked	Marked	Marked
• Size of collagen fiber bundles	Small	Small to intermediate	Large
• Cellular density	Abundant	Moderately abundant	Sparse
Elastic fibers	Sparse; tiny with immature structure	Small size and immature structure; distribution similar to adult	Large in reticular dermis, small and immature in papillary dermis; form network
Hypodermis	Well-developed fatty layer	Well-developed fatty layer	Well-developed fatty layer

Table 2.1 Comparative features of premature, newborn, and adult skin. *Reproduced with permission from Schachner LA, Hansen RC (eds). Pediatric Dermatology, 4th edn. London: Mosby, 2011.*

Merkel cells are identified by the presence of cytoplasmic dense core granules and the expression of cytokeratin 20 and neuropeptides. These cells are found in the basal layer of the epidermis, are often associated with appendages and nerve fibers, and are particularly dense on volar skin. The developmental origin of Merkel cells has been the subject of longstanding controversy, but genetic fate mapping studies have demonstrated that mammalian Merkel cells are derived from an epidermal rather than neural crest lineage[7].

Clinical Relevance

Several inherited pigmentary disorders result from genetic defects that lead to abnormal migration and proliferation of neural crest-derived melanocyte precursors (melanoblasts). Piebaldism and Waardenburg syndrome are characterized by achromic patches of skin on the central forehead, central abdomen, and extremities. This distribution pattern reflects the failure of melanocyte precursors to survive, proliferate, or travel to the distal points of their embryonic migration pathway. A number of different causative genes leading to this phenotype have been identified, including those encoding transcription factors (e.g. microphthalmia-associated transcription factor [*MITF*], *PAX3*, *SOX10*, *SNAI2*) as well as membrane receptors and their ligands (e.g. endothelin-3, endothelin B receptor, KIT receptor)[8] (see Ch. 66). The endothelin B receptor is found on common melanoblast/ganglion cell precursors in the developing neural crest, explaining both the Hirschsprung disease and the pigmentary abnormalities that are associated with defects in this receptor or its ligand.

DEVELOPMENT OF THE DERMIS AND SUBCUTIS

The specification of dermal mesenchymal cells is a complex process that is incompletely understood. Unlike the epidermis, which is derived exclusively from the ectoderm, the origin of the dermis varies depending on the body site. As noted above, the dermal mesenchyme of the face and anterior scalp (as well as the underlying muscle and bone) is derived from neural crest ectoderm, thereby explaining the facial dysmorphia in the neurocristopathy Waardenburg syndrome. On the other hand, the dermal mesenchyme of the back originates from the dermomyotome of the embryonic somite, and the dermal mesenchyme of the extremities and ventral trunk is thought to arise from the lateral plate mesoderm.

Dermal fibroblasts are heterogeneous, and different populations have distinct molecular signatures and functions. The rostral–caudal and proximal–distal positions of dermal fibroblasts correlate with differential embryonic expression of *HOX* genes that is maintained into adulthood. Moreover, at each site in the dermis, mesenchymal precursors differentiate into distinct dermal lineages to produce papillary dermal fibroblasts, reticular dermal fibroblasts, and adipocytes[9]. The different molecular populations influence how the skin regenerates and heals wounds[10].

By 6–8 weeks' EGA, presumptive dermal fibroblasts are situated under the developing epidermis[11]. However, at this developmental stage, there is no distinct demarcation between the cells that will give rise to the dermis and those that will give rise to musculoskeletal components. Although embryonic dermal cells are capable of synthesizing collagens (e.g. types I, III, and IV) and some microfibrillar components, these proteins are not yet assembled into complex fibers. Of note, the ratio of collagen III to collagen I is 3 : 1, the reverse of what is seen in the adult dermis.

The demarcation between the dermis and underlying skeletal condensations becomes distinct at approximately 9 weeks' EGA. By 12–15 weeks' EGA, progressive changes in matrix organization and cell morphology distinguish the fine weave of the papillary dermis located directly beneath the epidermis from the thicker, deeper reticular dermis. At this stage, the collagen proteins produced by fibroblasts start to assemble into collagen fibers, which continue to accumulate in the reticular dermis during the second and third trimesters. Electron microscopy can first detect definitive elastic fibers at approximately 22–24 weeks' EGA. As development progresses, the gelatinous, proteoglycan-rich, cellular dermis of the embryo is modified to the more rigid, fibrous, paucicellular dermis characteristic of adult skin. By the end of the second trimester, the dermis shifts from a non-scarring to a scarring form of wound repair. At birth, the dermis is still thinner and more cellular than is adult dermis.

The basic pattern of the dermal vasculature is discernible by the end of the first trimester. This pattern, however, undergoes extensive remodeling *in utero* and is not fully mature until after birth. Numerous molecular controls are involved in the regulation of angiogenesis, including the vascular endothelial growth factor (VEGF) family as well as the tyrosine kinase receptors Tie-1 and Tie-2 and their stimulatory (Ang-1) and inhibitory (Ang-2) angiopoietin ligands (see Ch. 102).

Nerve networks are formed by the mid to late first trimester but also undergo significant remodeling during later development and early postnatal life. Cutaneous nerves and vessels follow a similar pattern, with nerves dictating arterial differentiation and branching[12]. Accumulation of subcutaneous fat begins during the second trimester and continues through the third trimester, when distinct lobules separated by fibrous septae are formed.

Clinical Relevance

Mutations in genes that encode dermal structural proteins (e.g. collagens, elastic fibers) and the enzymes that process them underlie multiple forms of Ehlers–Danlos syndrome (characterized by skin hyperextensibility and fragility with poor wound healing) and cutis laxa (featuring lax, redundant skin). Genetic defects in regulatory proteins important for extracellular matrix development can lead to abnormalities in the skin and other organs. For example, mutations in the latent transforming growth factor-β (TGF-β) binding protein-4 gene (*LTBP4*) underlie a form of cutis laxa associated with severe pulmonary, gastrointestinal, and genitourinary malformations. The absence of LTBP4, an extracellular matrix protein that controls the bioavailability of TGF-β, leads to defective elastic fiber assembly in many types of tissues.

Another disorder characterized by abnormal dermal development is Goltz syndrome (focal dermal hypoplasia), an X-linked dominant disorder characterized by areas of dermal hypoplasia with fat herniation/hamartomas in a distribution following the lines of Blaschko (thought to reflect pathways of *epidermal* development) as well as skeletal defects and mucosal papillomas. Goltz syndrome is caused by mutations in *PORCN*, an effector of the Wnt signaling pathway[13]. It is likely that epidermal PORCN regulates Wnt signaling to the developing dermis, explaining the distribution of dermal hypoplasia along the lines of Blaschko.

DEVELOPMENT OF THE DERMAL–EPIDERMAL JUNCTION

The dermal–epidermal junction (DEJ) mediates adhesion between the basal keratinocytes and the dermis and provides resistance against shearing forces on the skin (see Ch. 28). The DEJ develops from a simple, generic basement membrane in the embryo to a highly complex, multilayered structure in the second-trimester fetus.

The embryonic DEJ consists of a lamina densa and a lamina lucida, and it is composed of molecules that are common to all basement membranes (e.g. type IV collagen, laminin, heparan sulfate, proteoglycans)[14]. The DEJ becomes progressively more complex, and skin-specific components of the DEJ start to appear after the embryonic–fetal transition at 8 weeks' EGA, coincident with the onset of epidermal stratification. By 12 weeks' EGA, almost all of the structures characteristic of the mature DEJ are in place (see Ch. 28). Hemidesmosomes, anchoring filaments, and anchoring fibrils are synthesized by basal keratinocytes, with type VII collagen-containing anchoring fibrils localizing to the sublamina densa; laminin 332 and the bullous pemphigoid antigens are also expressed. As development progresses, the flat embryonic DEJ acquires the rete ridges and dermal papillae that characterize the adult DEJ.

Clinical Relevance

Epidermolysis bullosa (EB) is a heterogeneous group of genetic disorders characterized by blister formation due to mechanical fragility of the skin. EB can result from mutations in genes that encode several different components of the DEJ[15]. The specific protein affected, as well as the degree to which it is altered, determine disease severity, depth of bulla formation, and involvement of extracutaneous tissues (see Ch. 32). Analogously, the pathogenesis of a number of autoimmune blistering diseases involves autoantibodies targeting components of the DEJ (see Chs. 29–31).

DEVELOPMENT OF SKIN APPENDAGES (ADNEXAE)

Skin appendages include eccrine, apocrine, and sebaceous glands as well as the hair and nails. Normal development of these structures depends on tightly regulated interactions and signaling between the early dermis and epidermis; disruption of either component or their communications leads to aberrant development. Despite the differences in the structure and function of the various types of cutaneous appendages, the developmental processes that regulate their formation are remarkably similar[16] (see Fig. 68.1).

Hair Follicle Development

The genetics and complex dermal–epidermal signaling that occur in appendageal development are best understood in hair follicle induction. Follicle formation is initiated by signals from the dermis that direct the embryonic epidermis to form focal thickenings, called placodes (see Fig. 68.2)[17]. Placodes are first seen on the scalp and face between 10 and 11 weeks' EGA; they subsequently develop in a caudal and then in a ventral direction. The epidermal placodes instruct the underlying dermal cells to condense and form the presumptive dermal papilla. The dermal papilla then directs the keratinocytes of the placode to proliferate and extend deeper into the dermis, thereby forming the hair germ (Fig. 2.4; see Fig. 68.2). By 12–14 weeks' EGA, the base of the developing hair follicle surrounds the presumptive dermal papilla, forming the hair peg (see Figs. 2.4 & 68.2). The superficial portion of the developing hair follicle has two distinct bulges. The more superficial bulge consists of the developing sebaceous gland, whereas the deeper bulge represents the insertion point of the future arrector pili muscle and the location of the presumptive follicular stem cells (Fig. 2.3D).

Hair follicles undergo further maturation during the second trimester, forming seven concentric cell layers (from outer to inner): outer root sheath; inner root sheath, composed of Henle's and Huxley's layers and a cuticle; and then the hair shaft cuticle, cortex, and medulla (see Fig. 68.5). The hair canal is fully formed by 18–21 weeks' EGA, and hair shafts begin growing shortly thereafter. The hairs continue to grow until 24–28 weeks' EGA, when they leave the active growing phase (anagen) and enter the short-lasting degenerative phase (catagen) and subsequently the resting phase (telogen). The follicles then start the second hair cycle by re-entering anagen; new hairs grow and push out the first group of telogen hairs (exogen), which are shed into the amniotic fluid (see Fig. 68.4).

Hair cycling through anagen, catagen, and telogen continues throughout life, but the hair cycles for individual follicles become asynchronous after birth. The third hair cycle is initiated perinatally, leading to the shedding of the second wave of fine lanugo hair follicles. Most hairs become thicker and coarser with subsequent growth cycles, leading to vellus and then adult-like terminal hairs on the scalp and in the eyebrows.

Many genes important for hair follicle development and cycling have been identified (see Ch. 68). Sonic hedgehog (SHH), a signaling molecule secreted by cells of the developing hair follicle, is required for the maturation of the dermal papilla and for the progression of the follicle placode to the peg hair stage. SHH also appears to be critical in mediating the transition from telogen to anagen during postnatal hair cycling. Members of the Wnt, bone morphogenetic protein (BMP), and fibroblast growth factor (FGF) families of signaling molecules are also important in hair follicle development and cycling. Transcription factors with roles in follicular differentiation have also been identified, including HOXC13 and FOXN1.

Sebaceous gland development parallels follicular development. The presumptive sebaceous gland is first seen at around 13–16 weeks' EGA as the most superficial bulge on the developing hair follicle. The outer proliferative layer of the sebaceous gland generates lipogenic cells that progressively accumulate lipid/sebum until they are terminally differentiated, at which time they disintegrate and release their products into

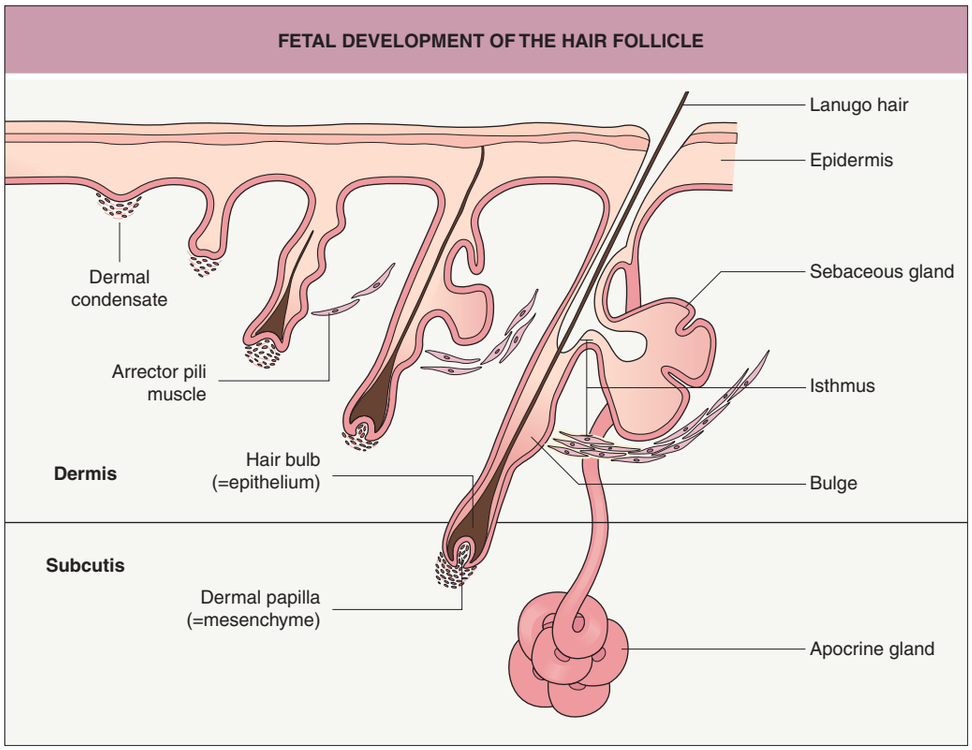

Fig. 2.4 Fetal development of the hair follicle. The hair follicle begins as a small epithelial thickening (placode) that induces a dermal condensate. Reciprocal signaling between these two structures subsequently directs the patterning and growth of a complex, multi-cylindrical, hair-forming structure with an associated dermal papilla, sebaceous gland, and apocrine gland.

the upper portion of the hair canal, contributing to the vernix caseosa. Both maternal hormones and androgen production from the "fetal zone" of the developing adrenal gland (which involutes postnatally) result in sebaceous gland hypertrophy and increased sebum production during the second and third trimesters.

Nail Development

Fingernail development begins at 8–10 weeks' EGA and is completed by the fifth month of intrauterine development (see Fig. 68.8). The flat, rectangular surface of the future nail bed on the dorsal digital tips is first demarcated by folds visible at 8–10 weeks' EGA. The nail bed on the dorsal digit is the first skin structure to keratinize, at around 11 weeks' EGA; keratinization begins distally and then continues toward the proximal nail fold. A wedge of ectoderm invaginates obliquely into the mesenchyme along the proximal end of the early nail field, forming the proximal nail fold by 13 weeks' EGA. The presumptive nail matrix cells, which will later produce the differentiated nail plate, are found ventral to the proximal nail fold. A differentiated nail plate emerges from under the proximal nail fold during the fourth month of gestation and grows distally to completely cover the nail bed by the fifth month. Toenails develop by a similar process that occurs ~4 weeks later than the fingernails.

Eccrine and Apocrine Sweat Gland Development

Like hair and nails, palmoplantar eccrine sweat glands begin to develop during the first trimester and are fully developed by the second trimester. Sweat gland development starts with the formation of large mesenchymal bulges or pads (analogous to the paw pads of other mammals) on the palms and soles between 55 and 65 days' EGA. Parallel ectodermal ridges are induced in the epidermis overlying these pads between 12 and 14 weeks' EGA. The curves and whorls formed by these ridges result in characteristic dermatoglyphics (fingerprints), which can be seen on the digit tips by the fifth month of gestation. Unlike most other mammals, the mesenchymal pads in the human fetus regress by the third trimester.

Beginning between 14 and 16 weeks' EGA, individual eccrine gland primordia bud along the ectodermal ridges at regularly spaced intervals. The buds elongate as cords of cells that enter the pad mesenchyme. By 16 weeks' EGA, glandular structures form at the terminal portion of the buds and secretory and myoepithelial cells appear. Canalization of the dermal component of the eccrine duct is also complete by 16 weeks' EGA; this occurs via a loss of the desmosomal adhesions along the innermost ectodermal surfaces, with concomitant maintenance of the adhesion between duct cells and the gland walls. Canalization of the epidermal component of the duct is not complete until 22 weeks' EGA.

Interfollicular eccrine glands and apocrine glands begin to form during the fifth month of gestation. Like sebaceous glands, apocrine glands typically arise from the upper portion of a hair follicle, whereas interfollicular eccrine glands originate independently. Glandular cords of cells elongate during the ensuing weeks, and by 7 months' EGA the clear cells and mucin-secreting dark cells characteristic of apocrine glands can be visualized. Apocrine glands function transiently during the third trimester and subsequently become quiescent in the neonate. In contrast, eccrine glands mature and begin functioning postnatally.

Clinical Relevance

Ectodermal dysplasias are a large, heterogeneous group of genetic disorders characterized by developmental abnormalities in two or more major ectodermal appendages – hair, teeth, nails, and sweat glands; other ectodermal structures (e.g. sebaceous glands) can also be affected[18] (see Ch. 63). Hypohidrotic ectodermal dysplasia (HED) is a relatively common type of ectodermal dysplasia that affects the sweat glands (hypohidrosis), hair (hypotrichosis), and teeth (hypodontia). HED is caused by mutations in genes encoding components of the ectodysplasin A (EDA) signaling pathway, which is critical for the initiation of sweat gland, hair follicle, and tooth morphogenesis. Underlying mutations can occur in the genes encoding the EDA ligand, EDA receptor (EDAR), or EDAR-associated death domain (an intracellular adaptor protein that functions in EDAR signaling). Mutations in EDA are responsible for the X-linked form of HED (XLHED), which leads to "full-blown" disease in affected males and areas of involved skin following the lines of Blaschko in heterozygous females. Because the underlying defect is in a soluble ligand that is only required for a brief period during the initiation of appendage formation, XLHED is a prime target for protein therapy. Encouragingly, studies in mice and dogs have demonstrated an almost complete correction of the XLHED phenotype upon prenatal or neonatal treatment with recombinant EDA protein[19,20]. Intra-amniotic

administration of recombinant EDA-Fc fusion protein to human fetuses with X-linked HED during the late second and early third trimesters has had positive effects on tooth development and sweating ability, and additional clinical trials are ongoing.

In addition to mutations in genes that are required for appendage development, ectodermal dysplasias can also be caused by mutations in genes that are required for epidermal development[21]. In these instances, abnormal appendages result from disruption of cross-talk between the developing epidermis and dermis. Mutations in *TP63*, a gene that is required for epidermal morphogenesis, can cause several types of ectodermal dysplasia, including the ankyloblepharon–ectodermal dysplasia–cleft lip/palate (AEC) and ectrodactyly–ectodermal dysplasia–cleft lip/palate (EEC) syndromes (see Ch. 63). The phenotypic differences between AEC and EEC are explained by underlying mutations in separate regions of *TP63*, which affect different functions and isotypes of the p63 protein.

Genetic defects in the Wnt signaling pathway, which is critical for appendageal development, underlie conditions ranging from hereditary hypotrichosis simplex to onycho-odonto-dermal dysplasia and Schöpf–Schulz–Passarge syndrome (see Fig. 55.6)[22]. The basal cell nevus (Gorlin) syndrome is caused by mutations in the *PTCH* tumor suppressor gene that result in overactivation of the sonic hedgehog (SHH) signaling pathway (see Fig. 107.6), which has important roles in neurologic and anterior–posterior axis development as well as hair follicle formation[23]. This explains the broad range of developmental anomalies, including craniofacial and skeletal defects, and the propensity for medulloblastomas, odontogenic keratocysts, and multiple basal cell carcinomas (BCCs) to arise (see Ch. 108).

SKIN STEM CELLS

Stem cells are present in each self-renewing tissue and are responsible for maintaining and repairing the tissue in which they reside. These somatic stem cells have two defining properties: (1) the ability to produce daughter cells that can differentiate to renew or repair the tissue; and (2) the ability to produce a new stem cell (self-renewal). The epidermis, dermis, appendages, and melanocytes are each maintained by different lineage-specific stem cells[24]. Stem cells often reside in a protective niche microenvironment that provides necessary signaling factors. During periods of homeostasis, stem cells generally divide very infrequently, a feature believed to protect them from acquiring mutations during cell cycle progression. After an injury, however, stem cells can divide more rapidly as part of wound healing.

One distinguishing characteristic of stem cells is that they can be maintained in culture virtually indefinitely. For example, a subset of epidermal basal cells forms highly proliferative colonies that can be passaged long-term *in vitro*; referred to as holoclones, they presumably represent stem cells[25]. Holoclones can reconstitute epidermis *in vitro*, and they have been utilized as skin grafts for the treatment of burns and inherited skin disorders (see below). Within the skin, stem cells that maintain the epidermis and hair follicles have been most extensively studied. The properties of different cutaneous stem cells, including their molecular markers, are summarized in Table 2.2.

Epidermal Stem Cells

The human epidermis renews itself every 40–56 days[26]. This constant turnover is mediated by epidermal stem cells, which reside in the basal layer[27]. Stem cells comprise a small percentage of the basal epidermis, although their precise location and number is unclear. There is conflicting evidence regarding whether palmoplantar epidermal stem cells are found at the bottom or top of rete ridges, with more protection from environmental stress in the former location. Similarly, there are two competing models – hierarchical and stochastic – to account for proliferative, undifferentiated cells in the basal epidermis (Fig. 2.5)[25].

Hair Follicle Stem Cells

The hair follicle bulge, which is located in the outer root sheath just deep to the sebaceous gland and adjacent to the arrector pili muscle attachment site, is thought to harbor hair follicle stem cells (Fig. 2.6).

CUTANEOUS STEM CELLS				
Stem cell	**Location (niche)**	**Tissue regeneration in homeostasis**	**Tissue regeneration in injury repair**	**Markers**
Keratinocyte				
Interfollicular epidermis	Basal layer	Interfollicular epidermis	Hair follicle Sebaceous gland Interfollicular epidermis	Delta 1, MCSP, α_6* and β_1 integrins, LRIG1; *low* levels of CD71
Hair follicle†	Bulge‡	Hair follicle	Hair follicle Sebaceous gland Interfollicular epidermis	Keratin 15, α_6 and β_1 integrins, CD200, PHLDA1, follistatin, frizzled homolog 1, LGR5; *low* levels of CD24, CD34¶, CD71, CD146, SOX9
Sebaceous gland§	At or near the bud of the sebaceous gland	Sebaceous gland	Sebaceous gland	Blimp1
Merkel cell§	Touch domes of hairy skin	Interfollicular epidermis	Interfollicular epidermis	α_6 integrin*, keratin 17, CD200, GLI1, SOX2, ATOH1
Melanocyte§	Lower bulge and sub-bulge region‖	Hair matrix and epidermal melanocytes	Hair matrix and epidermal melanocytes	Pax3, TYRP2; *negative* for KIT, tyrosinase, TYRP1
Eccrine gland lumen§	Suprabasilar eccrine duct	Eccrine luminal cells	Acral epidermis	Keratins 15, 18, & 19

*Also expressed by basal keratinocytes.
†Additional stem cell populations identified within the hair follicle in mice include LGR6-positive cells in the central isthmus and LRIG1-positive cells in the upper isthmus, both of which contribute to the interfollicular epidermis and sebaceous glands during homeostasis.
‡Within the outer root sheath just below the sebaceous gland, at or near the site of insertion of the arrector pili muscle.
¶Upregulated in mouse bulge cells.
§Studied primarily in mice.
‖Lowest permanent portion of the hair follicle.

Table 2.2 Cutaneous stem cells. ATOH1, atonal homolog 1; CD24, glycoprotein involved in cell adhesion and signaling; CD34, marker of hematopoietic progenitor cells and endothelial cells; CD71, transferrin receptor; CD146, melanoma cell adhesion molecule/MUC18/S-Endo-1 antigen; CD200, transmembrane glycoprotein that delivers a negative immunoregulatory signal (may be involved in maintaining immune tolerance); GLI1, GLI family zinc finger 1; LGR5/6, leucine-rich repeat-containing G protein-coupled receptor 5/6; LRIG1, leucine-rich repeats and immunoglobulin-like domains 1 (epidermal growth factor receptor antagonist and regulator of stem cell quiescence); MCSP, melanoma-associated chondroitin sulfate proteoglycan; PHLDA1, pleckstrin homology-like domain, family A, member 1; SCA1, stem cell antigen 1; SOX2/9, SRY (sex determining region Y)-box 2/9; TYRP, tyrosinase-related protein.

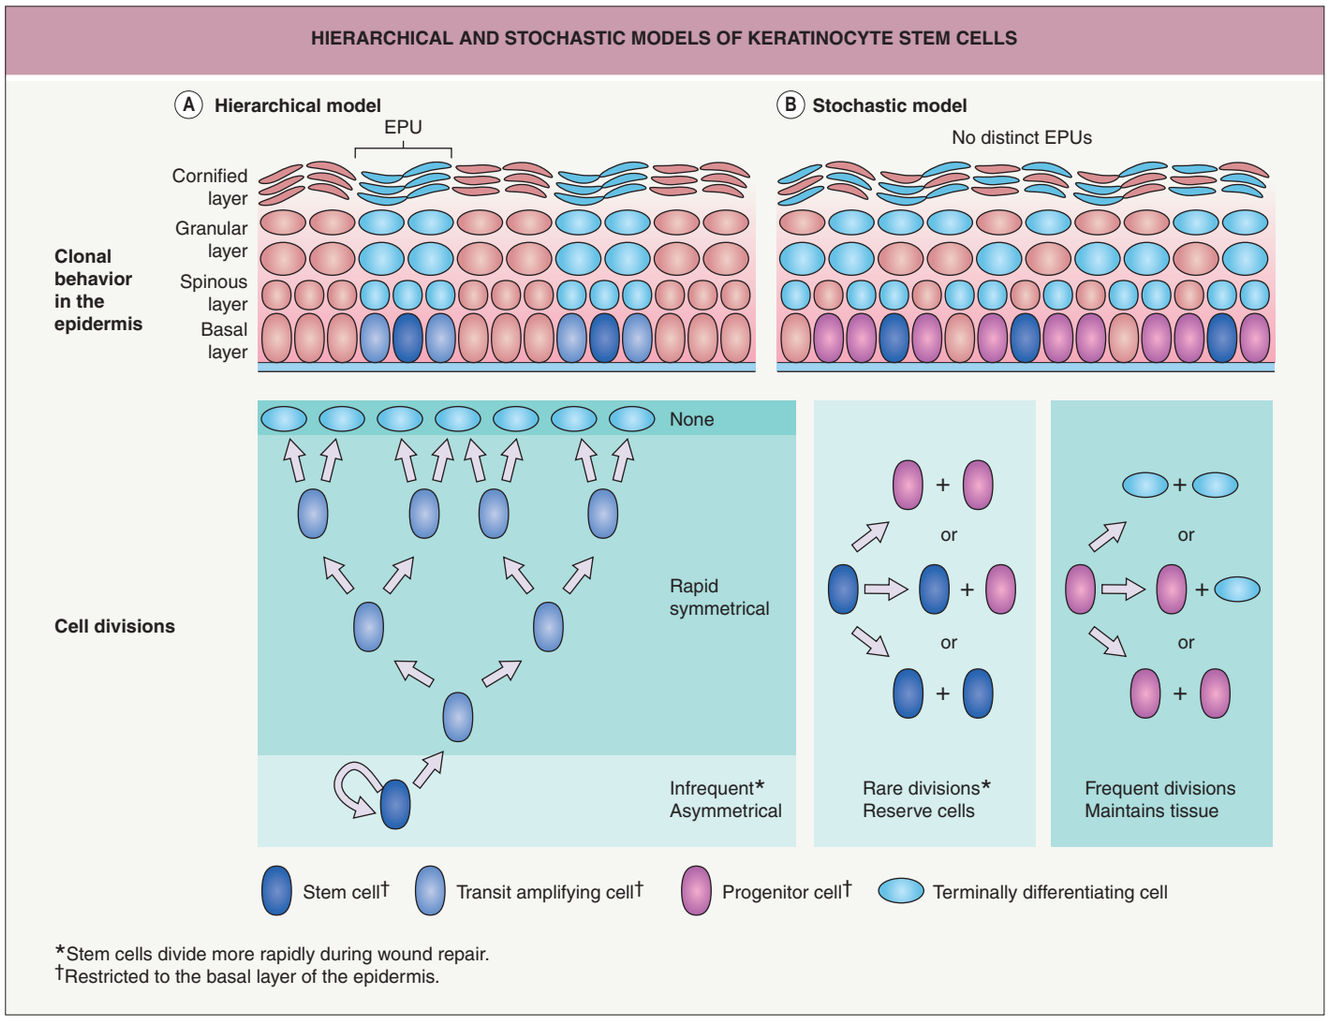

Fig. 2.5 Hierarchical and stochastic models of keratinocyte stem cells. These two models have been utilized to explain the behavior of stem cells and other proliferative cells in the basal epidermis. **A** In the *hierarchical model*, stem cells undergo infrequent asymmetric division, generating one new stem cell and one daughter transit amplifying (TA) cell. Unlike stem cells, TA cells divide frequently and symmetrically, producing two TA cells; in this model, they constitute the majority of basal keratinocytes. After a few rounds of division, TA cells withdraw from the cell cycle and move suprabasally, initiating the keratinocyte terminal differentiation program. Each epidermal stem cell and its progeny form a vertical column of progressively differentiating cells, which is known as an epidermal proliferation unit (EPU). **B** In the *stochastic model*, epidermal stem cell divisions are rare and usually asymmetrical, generating a new stem cell and a committed progenitor cell; however, random symmetric divisions resulting in either two stem cells or two progenitor cells also occasionally occur. In this model, committed progenitor cells make up the bulk of the basal layer, where they divide frequently to maintain the epidermis by producing either a new progenitor and a cell that leaves the basal layer to undergo terminal differentiation or two cells of either fate. It is possible that aspects of both stem cell models occur in the skin, depending on location or external stimuli, explaining why experimental evidence exists to support both models. Retention of a DNA label (e.g. 5-bromo-2-deoxyuridine or tritiated thymidine) is utilized as an *in vivo* marker of stem cells based on their slowly cycling nature.

The bulge represents the lowest portion of the hair follicle that does not regress during the catagen phase, and it contains morphologically undifferentiated cells[28]. Hair follicle bulge cells are slow-cycling and have a high clonogenic potential in culture, as well as being self-renewing and multipotent. *In vivo*, they typically proliferate only when the hair follicle re-enters the anagen phase, in order to regenerate the bottom two-thirds of the follicle. In addition, appendageal stem cells of the bulge and eccrine duct provide an important ectodermal reserve, allowing reconstitution of the surface epidermis after wounding.

The bulb region at the base of the anagen follicle contains self-renewing, rapidly dividing, clonogenic matrix cells that produce the hair shaft and inner root sheath. These cells have the properties of stem cells, except they regress along with the rest of the lower follicle during catagen. Whether bulb cells are best described as transit amplifying cells or committed progenitor cells is a matter of debate.

Stem Cell Plasticity

Under homeostatic conditions, epidermal and hair follicle stem cells only contribute to their respective tissues of origin. However, bulge-derived keratinocytes can also contribute to the repair of the interfollicular epidermis in response to injury[28]. Although most bulge-derived cells survive only transiently within the healing epidermis, a subpopulation of bulge cells can transdifferentiate into long-living epidermal stem cells[29]. Similarly, epidermal stem cells can contribute to new hair follicle formation in the center of large wounds[30].

Like many organs, the skin and subcutaneous fat contain rare cells that can produce sphere-like colonies when provided with multiple growth factors in three-dimensional culture. These sphere cells represent *pluripotent* stem cells that can be directed to produce many tissue types, and their use for autologous stem cell therapies is being explored. However, the *in situ* location and function of these cells in the skin remains unknown.

Along the same lines, cells in adult mammals are far more "flexible" in their potential to form other cell types than previously thought. Some cell types, particularly bone marrow cells, have the potential to incorporate themselves into diverse tissues (e.g. epidermis, heart) and adopt the fates of resident cells, contributing progeny to the tissue. Induced pluripotent stem (iPS) cells are somatic cells

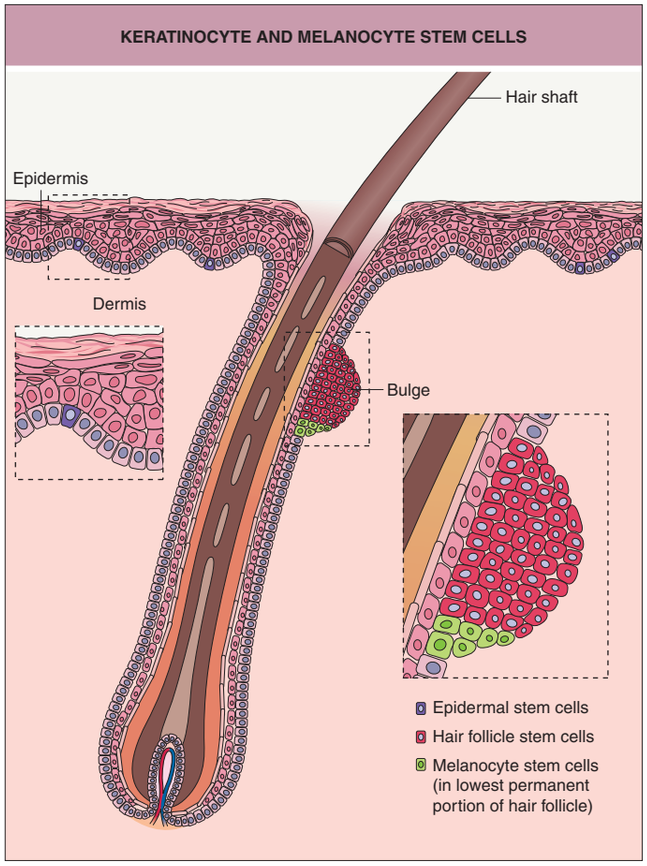

Fig. 2.6 Keratinocyte and melanocyte stem cells. Note that the bulge is continuous with the outer root sheath.

(e.g. fibroblasts) that have been reprogrammed into an embryonic stem cell-like state[31]; these cells can be stimulated to differentiate into a variety of cell types, including keratinocytes. Thus, adult cells, including different skin cell types, may be capable of dedifferentiating into pluripotent stem cells.

Stem Cell-Based Therapy for Genetic Skin Disease

Stem cells have been utilized in several strategies for gene therapy of heritable skin diseases (Fig. 2.7). Treatment via delivery of gene-corrected stem cells has the advantage of continuous protein synthesis in the skin, but it may carry a risk of oncogenesis, especially with retroviral vectors. Laminin-β3-deficient skin from patients with junctional EB has been corrected by transplantation of stem cell-enriched epidermal grafts transduced *ex vivo* with a retroviral vector encoding normal *LAMB3* cDNA. The treatment resulted in expression of functional laminin 332 and an absence of blistering in the corrected epidermis, both sustained over years of follow-up[32]. In patients with severe recessive dystrophic EB (RDEB), similar gene-corrected autologous keratinocyte grafts as well as intradermal and intravenous injections of allogeneic mesenchymal stromal/stem cells have also led to improved wound healing. In clinical trials investigating the use of allogeneic bone marrow-derived stem cell transplantation in children with severe RDEB, collagen VII deposition at the dermal–epidermal junction and variably decreased blistering were observed, with associated morbidity and mortality partially ameliorated by using reduced-intensity conditioning regimens[33]. Other investigators are studying alternative sources of stem cells for the treatment of EB, including autologous iPS cells derived from revertant keratinocytes[34].

PRENATAL DIAGNOSIS OF GENODERMATOSES

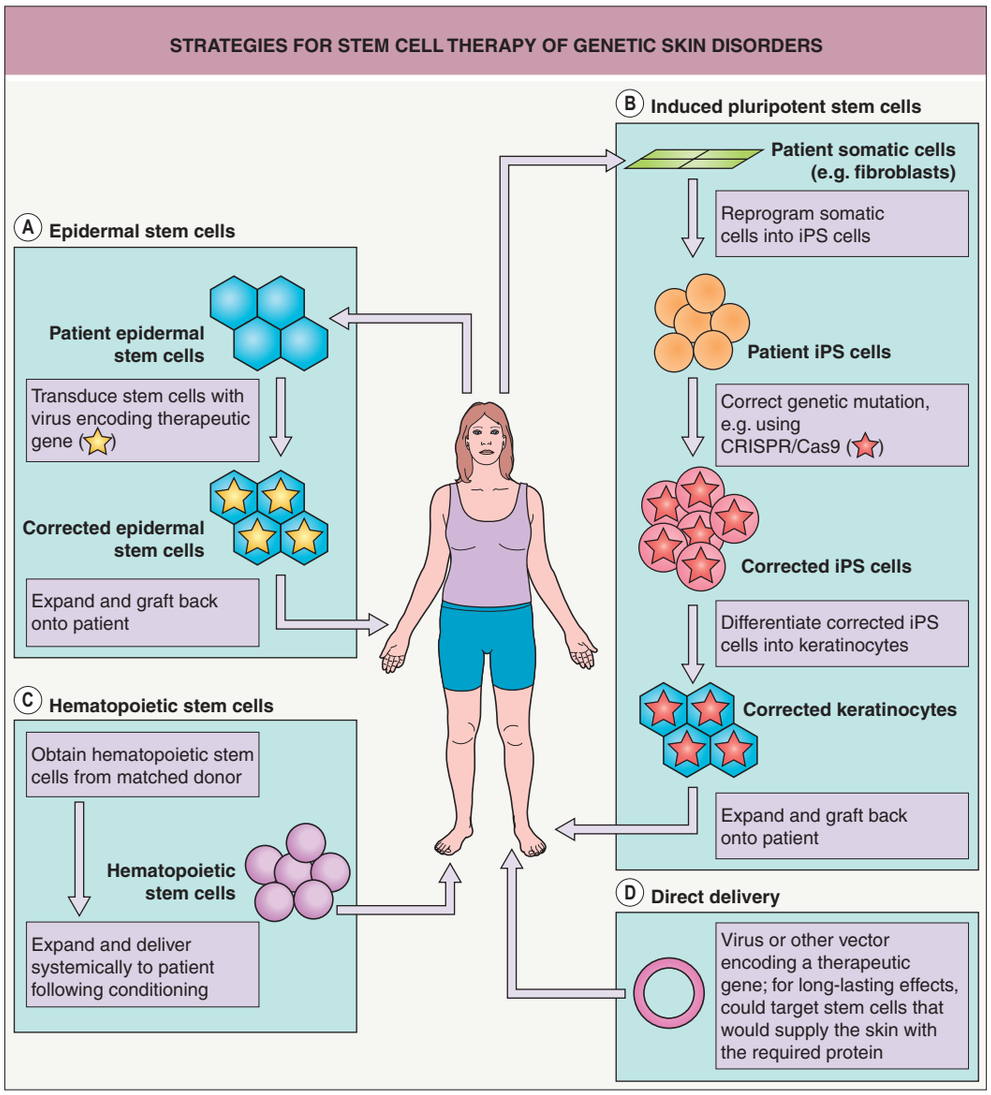
Many genodermatoses are incompatible with survival to term or are associated with significant morbidity or even mortality after birth, making prenatal diagnosis desirable. In the early 1980s, fetal skin biopsy obtained at 19–22 weeks' EGA via ultrasound guidance became the first technique available for prenatal diagnosis of inherited skin diseases. Epidermolytic ichthyosis and severe junctional EB were the first diseases diagnosed prenatally by light and/or electron microscopy of fetal skin biopsies.

As the causative genes for many genodermatoses have been discovered, DNA-based testing using material obtained from chorionic villus sampling (10–12 weeks after the last menstrual period/8–10 weeks' EGA) or amniocentesis (14–16 weeks after the last menstrual period/12–14 weeks' EGA) has largely replaced fetal skin biopsy, as these techniques can be performed earlier and pose less risk to the mother and fetus. More recently, non-invasive prenatal testing techniques utilizing circulating fetal cells or cell-free DNA have been developed[35]. With these approaches, the pathogenic mutation(s) must be identified in family members prior to prenatal testing.

Preimplantation genetic diagnosis allows for prenatal diagnosis before the embryo is implanted and pregnancy begins. This technique requires the use of *in vitro* fertilization. One or two cells are taken from the embryo at the blastocyst (6- to 10-cell) stage. The cellular DNA is amplified using PCR and analyzed for the known family mutation(s); unaffected embryos are then selected for uterine implantation. For X-linked disorders, sex determination has been utilized both in conjunction with specific genetic analysis and to identify embryos of a particular sex for selective transfer. Preimplantation genetic diagnosis obviates the need to terminate a pregnancy with an affected fetus. However, it has several disadvantages compared to chorionic villus sampling or amniocentesis, including higher cost, technical difficulties (e.g. contamination by extraneous DNA), and a low rate of completed pregnancies.

SIGNIFICANCE OF SKIN DEVELOPMENT IN POSTNATAL LIFE

Understanding skin development is essential for the appropriate diagnosis and management of congenital skin disorders. This knowledge is useful far beyond the neonatal period, however, as many of the regulatory pathways central to development are recapitulated in postnatal life. For example, hedgehog signaling through PTCH and SMO is critical for postnatal hair cycling as well as hair follicle development. In addition to the germline *PTCH* mutations that result in basal cell nevus syndrome, somatic *PTCH* mutations represent a pathogenic factor in sporadic BCCs. Knowledge of this pathway enabled the development of SMO inhibitors (e.g. vismodegib) to treat locally advanced and metastatic BCC and explains the hair loss caused by these drugs. Similarly, identifying the mechanisms controlling angiogenesis and wound healing during intrauterine development holds promise for developing new cancer treatments and wound care interventions. Furthermore, elucidating the mechanisms of cutaneous stem cell formation and maintenance will help to design potential stem cell-based therapies. Thus, advancing the understanding of skin embryology and stem cell biology may lead to life-saving or life-enhancing medical advancements.



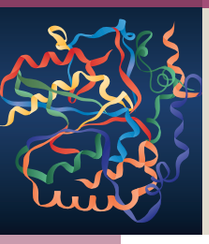


Fig. 2.7 Strategies for stem cell therapy of genetic skin disorders. A One strategy is to isolate epidermal stem cells from a patient, correct the genetic defect *in vitro* (e.g. using a viral vector), and graft epithelial sheets containing the corrected stem cells back onto the patient. **B** Gene therapy could also potentially utilize induced pluripotent stem (iPS) cells, which are generated from somatic cells (e.g. fibroblasts). The genetic defect could be corrected via techniques such as CRISPR/Cas9-based targeted genome editing in these cells (see Fig. 3.13), which would then be differentiated into keratinocytes and grafted onto the patient. **C** A third strategy involves the use of hematopoietic stem cells (HSC). Upon systemic administration (following conditioning), allogeneic HSC cells have the capacity to home to the skin (e.g. to sites of injury in patients with epidermolysis bullosa) and produce differentiated progeny cells that provide the needed skin protein (e.g. collagen VII). **D** Finally, therapeutic genes could be directly administered to patients via a virus or another vector. To achieve permanent correction, the vector must target stem cells that could supply the protein to the skin.

3 Molecular Biology

Amaya Virós and Thomas N. Darling

INTRODUCTION

Advances in molecular biology are rapidly changing our understanding of skin biology and disease. Increased knowledge is being translated into new molecular diagnostic tests that are transforming clinical practice. Molecular analyses are currently being employed to diagnose genodermatoses[1], cutaneous infections[2], melanomas[3,4], lymphomas[5], and inherited[6] or autoimmune blistering disorders[7]. This enhanced knowledge has also led to new targeted therapies, many of which require determination of the molecular basis of a disease in order to appropriately implement treatment[8]. Molecular analyses are also used to screen for drug efficacy and susceptibility to adverse reactions to certain medications[9].

To utilize these tests appropriately, dermatologists nowadays have an even greater need to understand basic concepts of molecular biology. The goal of this chapter is to explain key concepts and methods of molecular biology in order to provide practicing dermatologists with a basic understanding of the tools their colleagues are employing and developing in the laboratory to transform clinical diagnosis, patient stratification, and therapy.

EXPERIMENTAL TECHNIQUES

Tissue Processing

Dermatologists are accustomed to placing a biopsy specimen in formalin followed by paraffin embedding and then staining tissue sections with hematoxylin and eosin. However, this is just one of several possible starting points for tissue processing (Fig. 3.1). By placing the sample in formalin (for light microscopy), glutaraldehyde (for electron microscopy), or freezing a fresh sample before processing and sectioning, the sample can be analyzed histologically in various ways, including by routine staining, immunohistochemistry, or *in situ* hybridization.

Cryosections from frozen samples have lower quality tissue architecture than sections from formalin-fixed, paraffin-embedded tissues, but the former preserve DNA, RNA, and protein better than other fixation methods. Fresh or frozen tissue can also be processed directly with buffers and reagents to extract DNA, RNA, and protein from the *whole tissue*. In addition, fresh tissue can be used to prepare a suspension of *single cells* for single-cell analysis of DNA, RNA, or protein. The desired lineage of cells (e.g., keratinocytes, fibroblasts, immunocytes, endothelial cells) can be propagated *in vitro* by using selective culture media and isolation techniques.

One method for isolating a particular cell population from a tissue section is laser microdissection, which allows selection of microanatomic regions for analysis (Fig. 3.2)[10]. Alternatively, once tissue is dissociated and living cells are in a single cell suspension, flow cytometry can be used to identify populations of cells (Fig. 3.3)[11]. Individual cells pass through in a stream and through a set of lasers and electronic detectors that can measure multiple parameters for each cell. Fluorescence-activated cell sorting (FACS) utilizes an electrostatic deflection system and it can be used to obtain pure cell populations with specific desired characteristics, e.g. cells tagged by lineage-specific antibodies. The field of single-cell molecular biology is rapidly evolving, and it has become possible to analyze 40 or more parameters for each cell by combining the principles of flow cytometry and elemental mass spectrometry in a technique called mass cytometry[12].

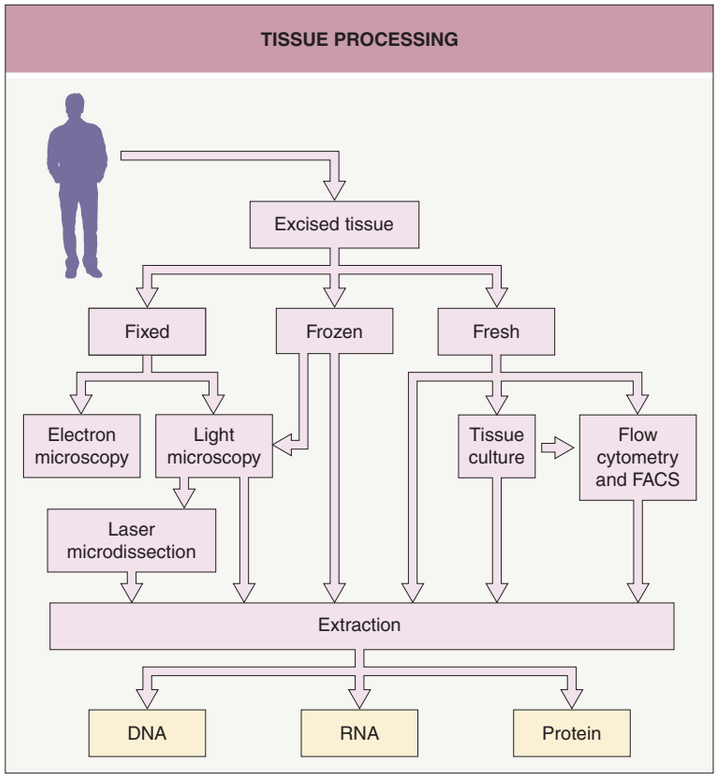

Fig. 3.1 Tissue processing. A tissue sample can be processed in various ways for the analysis of DNA, RNA, or protein. FACS, fluorescence-activated cell sorting.

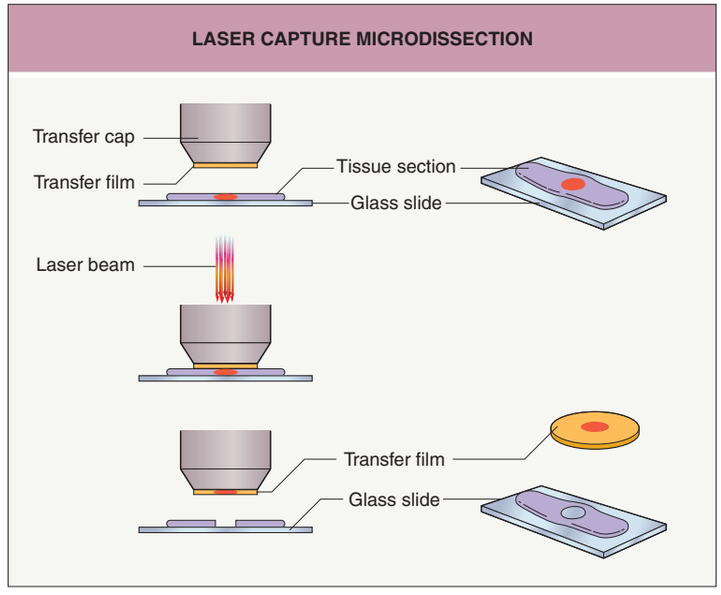

Fig. 3.2 Laser capture microdissection. Laser capture microdissection is one method of microdissection used to selectively procure individual cells or clusters of cells from tissue sections. A cap coated with a thermoplastic transfer membrane is placed directly over the tissue section. The operator visually identifies the cells of interest and triggers a low-energy infrared laser to melt the transfer film onto cells of interest. The cap is then lifted from the section to separate the selected cells from the remainder of the tissue section.

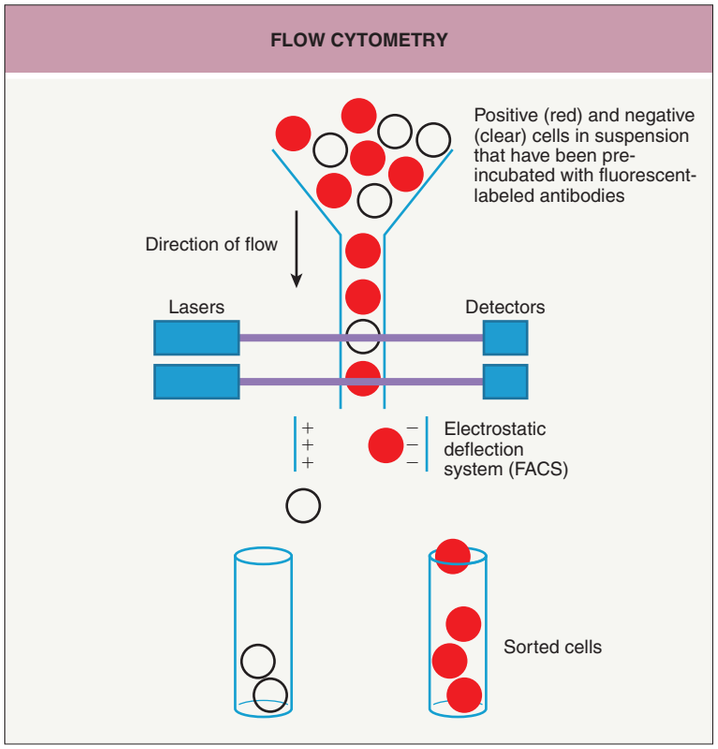

Fig. 3.3 Flow cytometry. Cells in suspension, pre-incubated with fluorescent-labeled antibodies, flow single file in a liquid stream through lasers. Detectors measure the fluorescence intensities of each cell. In fluorescence-activated cell sorting (FACS), the single cells are divided into charged droplets that are separated into different tubes based on the marker(s) of interest as they pass through an electrostatic deflection system.

The Foundations of Molecular Techniques for Analyzing DNA, RNA, and Protein

The concepts behind molecular biology are simple and unifying. In general, they consist of extracting the molecules of interest, amplifying them to measurable amounts, and then detecting them. Polymerase chain reaction (PCR) is a standard technique for amplifying *DNA* (Table 3.1; Fig. 3.4)[13]. To perform PCR, short sequences of synthetic DNA (primers) are used to hybridize to a DNA region of interest, which is then replicated through multiple cycles. The PCR-amplified DNA, typically 50 to 2000 base pairs in size depending on the primers designed, can be detected in a gel using an intercalating dye that fluoresces with ultraviolet light. The nucleotide sequence can then be determined via fluorescence sequencing techniques. This simple and relatively inexpensive approach, also called Sanger sequencing, is still widely used.

Nowadays, however, massively parallel sequencing, also known as next-generation sequencing, offers the opportunity for reading millions of DNA fragments in a single run at a marginally higher cost (Table 3.2; Fig. 3.5)[14]. The advent of massively parallel sequencing not only allows access to DNA sequences, but it also allows one to infer DNA copy number changes. This is because the final amplified DNA is proportional to the number of DNA copies in the original reaction, allowing inference of copy number variation of specific genes and genomic regions. One limitation of massively parallel sequencing is that its increased power and reading depth requires bioinformatics and sophisticated data analyses, which are challenging to standardize in clinical practice.

RNA is also easy to purify, but is more unstable and degrades much faster than DNA. Therefore, a typical first step in the analysis of RNA is to convert it into DNA using reverse transcription (RT; Table 3.3; Fig. 3.6). Following RT, the generated complementary DNA (cDNA) can be amplified by PCR, as described above. The technique of RT-PCR has also been modified to allow accurate quantitation of

POLYMERASE CHAIN REACTION
Purpose
• Amplify a specific piece of DNA from a complex mixture
Requirements
• Need to know the sequence of the DNA of interest (at least of its ends)
Underlying concepts
• Double-stranded DNA can be unwound (denatured) with a higher temperature to single strands; when cooled, the single strands come back together to form double strands (hybridize) if the nucleotide sequences are complementary • During the hybridization process, two complementary strands bind to each other. The A nucleotides bind to T nucleotides on the complementary strand, whereas C nucleotides bind to G nucleotides on the complementary strand • In PCR, short DNA strands called oligonucleotide primers are designed to hybridize to target sequences in the template DNA
Outline of method (Fig. 3.4)
• Oligonucleotide primers are designed to hybridize to specific sequences at each end of the DNA of interest. These primers are added to a reaction vessel mixture containing the template DNA along with a thermostable DNA polymerase, the nucleotides dATP (A), dTTP (T), dGTP (G) and dCTP (C), and a reaction buffer • The reaction vessel is placed in a thermal cycler, which controls the temperature of the reaction through many cycles • Each cycle contains the following steps: (1) denaturation; (2) primer annealing or primer hybridization; (3) primer extension; and (4) repeat of the complete cycle of PCR 30–40 times leading to amplification of the target sequence
Benefits
• PCR is simple, rapid, and sensitive • Each cycle increases the number of PCR products twofold. The total number of PCR products after n cycles will be 2^n
Limitations/errors
• Because of its high sensitivity, contamination can cause misleading results • Primers used for PCR can anneal to sequences that are similar, but not identical, to the sequence of interest, causing misleading results • DNA polymerase occasionally incorporates incorrect nucleotides
Experimental applications
• DNA can be amplified either for detection of a specific sequence or for cloning • PCR can be used to label DNA with fluorescent or radioactive nucleotides
Modifications/alternatives
• Quantitative PCR – the amount (number of copies) of a specific piece of DNA can be quantified by a variety of methods utilizing PCR. A relatively simple and high-throughput method, called real-time quantitative PCR, measures the amount of PCR product formed after each cycle. The higher the amount of DNA, the earlier the product can be detected.

Table 3.1 Polymerase chain reaction.

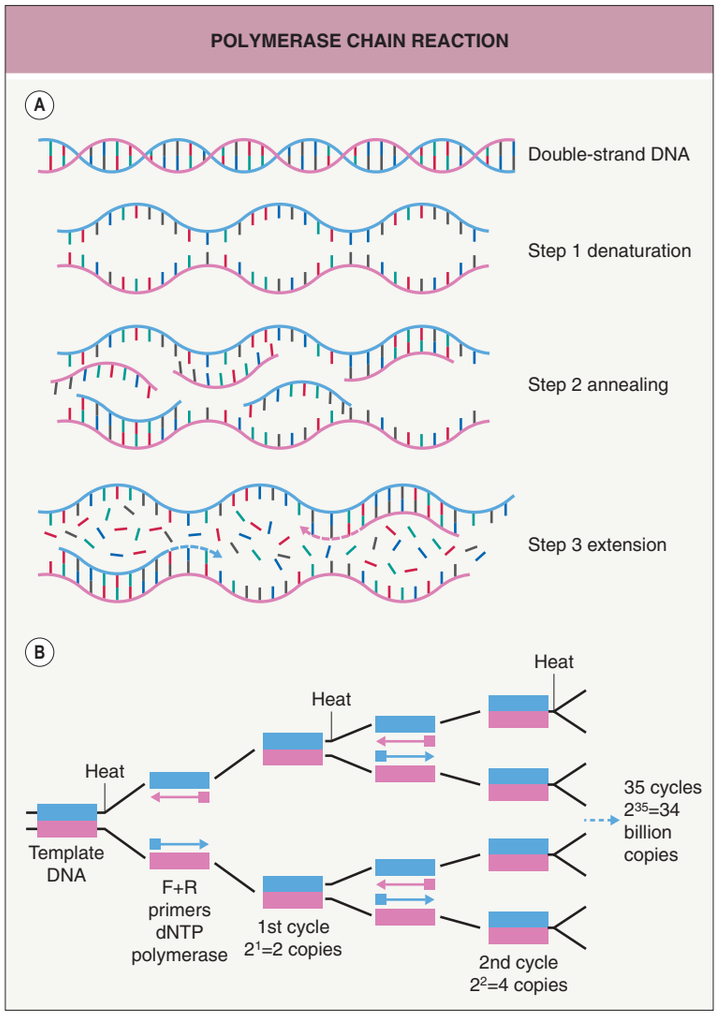

Fig. 3.4 Polymerase chain reaction. A Each cycle contains the following steps: (1) denaturation – separate the two strands of DNA by heating to >90°C; (2) primer annealing or primer hybridization – allow the oligonucleotide primers to bind to the template DNA by cooling to 50–65°C; (3) primer extension – DNA polymerase catalyzes the addition of nucleotides (A, G, C, T) that are complementary to the DNA template, beginning with the primer and extending 3′ at the optimal temperature of 72°C; and (4) repeat the complete cycle 30–40 times. **B** Each cycle increases the number of PCR products twofold. The total number of PCR products after *n* cycles will be 2^n times the original amount. F+R, forward and reverse.

MASSIVELY PARALLEL SEQUENCING
Purpose
• Determine the sequence or order of nucleotides (A, G, C, T) in a genome or parts of the genome
Requirements
• DNA to be sequenced should be high quality
Underlying concepts
• Millions of DNA fragments are sequenced simultaneously on the same solid surface with spatial separation of templates • Reversible chain termination is used to incorporate fluorescent nucleotides sequentially for optical detection of the nucleotide sequence
Outline of method (Fig. 3.5)
• Library preparation: sequencing libraries can be created using adapter ligation or multiplex PCR (amplicon sequencing). In adapter ligation, DNA is randomly fragmented followed by ligating sequencing adapters to both ends of the DNA fragments. The adapter-ligated DNA fragments may be used directly for whole-genome sequencing or enriched for specific regions of interest (target enrichment) by hybridizing to biotinylated probes that are isolated by magnetic pull-down • Sequencing: oligonucleotides complementary to the sequencing adaptors are bound on the surface of a glass slide (the flow cell). Each DNA fragment of the sequencing library that is bound to its complementary oligonucleotide on the surface of the flow cell is amplified into a clonal cluster of DNA fragments using a PCR-based method (cluster generation). Millions of clusters are simultaneously sequenced using DNA polymerase and four different fluorescently labeled reversible dNTP terminators. The nucleotide incorporated at each cycle on unique clusters is detected optically, after which the fluorescent label is enzymatically cleaved and a nucleotide is incorporated before moving to the next nucleotide for detection • Data analysis: the sequencing reads are computationally aligned to a reference genome, and various types of computational analyses are then performed to detect single nucleotide variants, insertions, deletions, translocations, and DNA copy number variations
Benefits
• Rapid sequencing of the entire genome at low cost • Targeted sequencing of all protein-coding DNA regions (exome sequencing; ~2% of the genome) or only a few selected genes (e.g. cancer-related gene panels)
Limitations/errors
• Read lengths of about 150 to 300 bp • 99.9% accuracy of reads
Experimental applications
• Identifying genomic aberrations, including mutations, copy number changes, and translocations • Sequencing of microbiomes
Modifications/alternatives
• Nanopore technology and Sanger sequencing • ChIP-seq combines massively parallel sequencing with chromatin immunoprecipitation to analyze protein interactions with DNA • ATAC-seq assesses genome-wide chromatin accessibility

Table 3.2 Massively parallel sequencing.

very low levels of mRNA[15]. Because the amount of PCR product is monitored during each amplification cycle, this technique is called "real-time" quantitative PCR.

The amount of *protein* in a cell is a complex balance of synthesis and degradation controlled at multiple steps, including efficiency of protein translation and post-translational modifications that affect protein stability. One method for measuring protein levels is the Western blot, which is also called an immunoblot because an antibody is used to detect the protein of interest (Table 3.4; Fig. 3.7). In addition to measuring protein levels, Western blot analysis can determine protein size and whether there are different forms of the protein[16]. Another common method for measuring protein levels is an enzyme-linked immunosorbent assay (ELISA; see Table 3.4), which can provide accurate quantifications of proteins[17]. In multiplex bead-based immunoassays, up to 100 analytes can be detected simultaneously (see Fig. 40.2). For this, distinct fluorophore-colored microbeads, coupled to specific antibodies, are incubated with a sample; this mixture is then exposed to secondary detection antibodies and reporters, followed by exposure to laser excitation. The technique allows for a quantitative interpretation of the amount of analyte bound to the bead.

Measuring Cells Within Tissues

For populations of cells, PCR, RT-PCR, and Western blots are useful for measuring DNA, RNA, and protein, respectively. However, to identify features at a cellular level, tissue sections can be analyzed via various assays. For example, fluorescence *in situ* hybridization (FISH) is employed to assess the presence or expression of *DNA or RNA*. This technique relies on the use of fluorescently labeled nucleic acid probes that are complementary to the DNA or RNA sequences of interest in the tissue sections (Table 3.5; Fig. 3.8). The probes are hybridized to the target sequences in the tissue, and the slide is then examined using

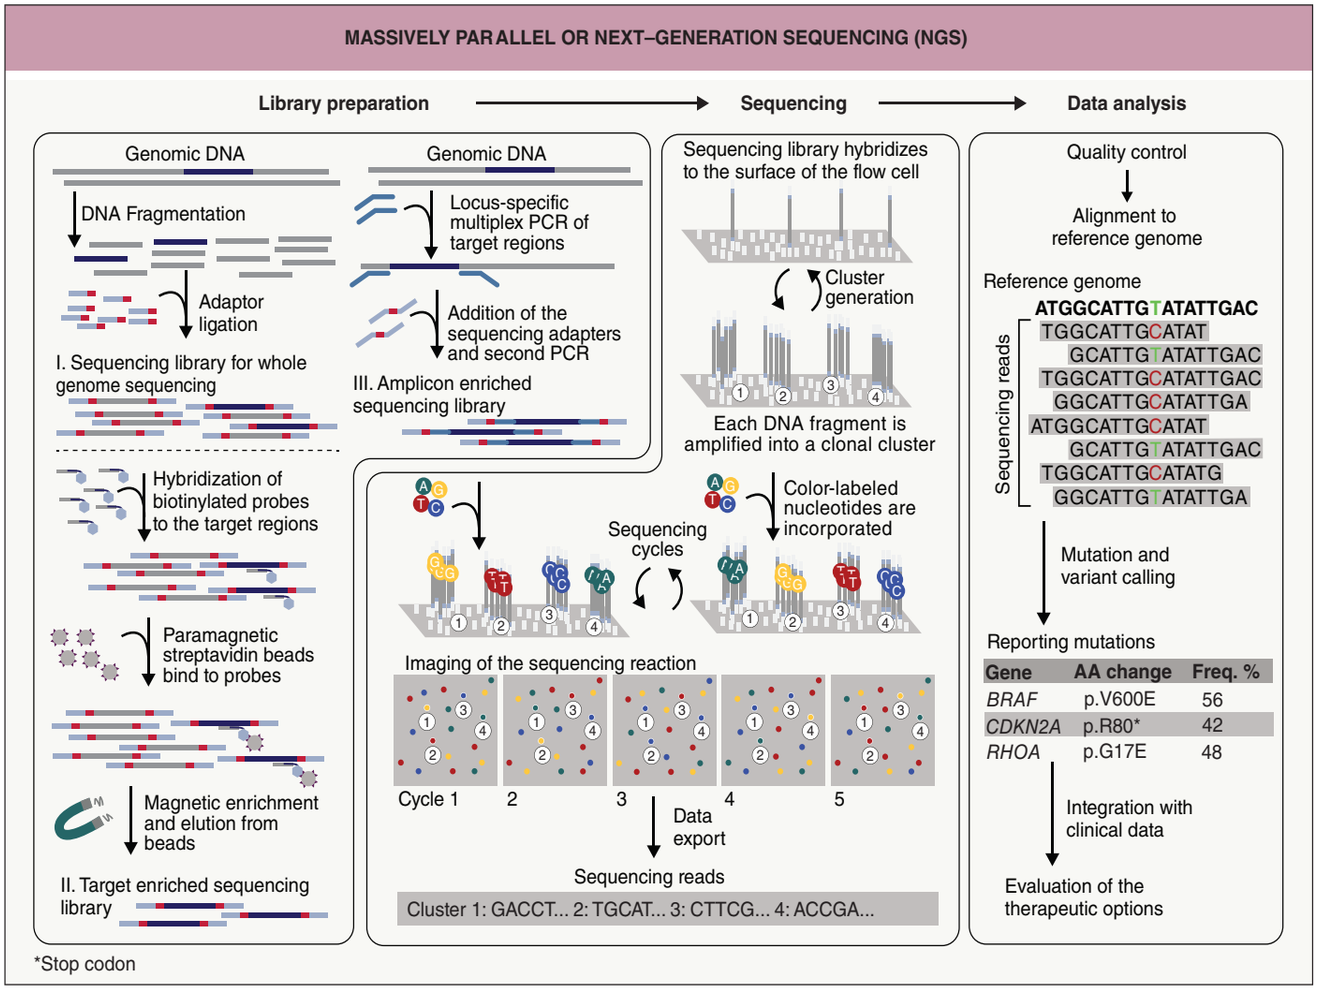

Fig. 3.5 Massively parallel or next generation sequencing (NGS). The technology used for massively parallel sequencing varies among different platforms. The workflow on Illumina platforms can be divided into three steps: (1) *library preparation* – the test DNA is flanked with sequencing adaptors either by ligation (adaptor ligation) or PCR (amplicon sequencing); (2) *sequencing* – the adaptor-flanked test DNA binds to oligonucleotides on the surface of the flow cell and DNA polymerases catalyze the incorporation of fluorescently labeled nucleotides, which are identified by imaging; after enzymatic removal of the fluorophores, a new fluorescently labeled nucleotide is incorporated and read out by imaging; (3) *data analysis* – after quality controls and alignment of the sequencing reads to reference genomes, the genetic aberrations are called and annotated using computational algorithms. Freq, frequency

fluorescence microscopy[18]. As a diagnostic tool, FISH can be used to detect genomic aberrations in single cancer cells (see Fig. 117.19).

Immunohistochemistry is employed to assess the expression of *proteins* in tissue sections. An antibody is added to a tissue section where it specifically binds to the protein of interest. The bound antibody is usually detected based on an enzymatic reaction that generates a colored product at the binding site. Immunohistochemistry can be used to determine the locations and expression level of a protein within a tissue, including proteins that mark specific cell lineages or cell states such as differentiation, activation, proliferation, or apoptosis. Of note, immunohistochemistry has evolved beyond quantitative visualization of a single protein – it can also detect specific sequences of *messenger RNA* (mRNA) in a tissue. In addition, revolutionary visualization assays allow assessment with multiple antibodies, utilizing the same principles of antibody-bound color reagents (multiplex IHC and FISH).

Measuring the Transcriptome and Proteome

There are several approaches to quantitatively analyze the expression levels of nearly all cellular genes, i.e. the *transcriptome*. RNA-seq utilizes massively parallel sequencing to evaluate gene expression levels, gene splicing, non-coding RNA, microRNA, gene fusions, and mutations[19]. Nowadays it is also possible to perform RNA-seq on single cells, an approach that is providing new insights into the complexity of human skin[20]. Additional methods are based on the hybridization of labeled sample mRNA to known oligonucleotide or cDNA sequences (representing thousands of genes) placed on chips, beads, or glass slides (arrays)[21]. The level of hybridization to the nucleotide sequence of a given gene indicates how much mRNA of that gene is present.

The *proteome* represents all cellular proteins expressed under specific conditions. Mass spectrometry provides extremely accurate measurements of protein mass by ionizing the protein and measuring the "time-of-flight" through a tube to a detector on the opposite end (Table 3.6; Fig. 3.9)[22]. In most instances, the proteins are separated by two-dimensional gel electrophoresis or capillary electrophoresis before mass spectrometry. Quantification is accomplished by labeling proteins with stable isotopes to provide internal standards or by label-free shotgun proteomic approaches that allow a faster analysis at lower costs[22]. Another technique is the use of reverse-phase protein arrays, in which whole protein lysates are spotted onto slides and probed using antibodies to specific proteins[23]. The field of proteomics promises to provide a tremendous amount of information regarding cell biology and disease states.

Mouse Models of Skin Disease

Transgenic mice are commonly used as experimental models for elucidating the *in vivo* functions of genes[24,25]. The traditional approach is to microinject the gene of interest into a fertilized mouse egg, where it randomly integrates into the mouse genome (Table 3.7; Fig. 3.10). Although the gene is present in every cell as the egg develops into a mouse, expression of the gene can be limited or targeted to specific tissues or cell types by using a promoter that is only expressed in a

REVERSE TRANSCRIPTION PCR
Purpose
• To amplify mRNA by PCR • mRNA is first converted to DNA (called complementary DNA or cDNA), followed by PCR amplification of a specific region of the cDNA to detectable levels
Requirements
• Starting material can be total cellular RNA or purified mRNA
Underlying concept
• Many methods that study RNA first convert RNA to cDNA with an enzyme called reverse transcriptase, because cDNA is more stable than RNA
Outline of method (Fig. 3.6)
• Reverse transcriptase can convert mRNA to cDNA by three different methods, depending on the primer used for the initial RT step: (1) random hexamer primers contain six nucleotides (6-mer) that have all possible sequence combinations of the dA, dG, dC, and dT nucleotides (4^6 possible combinations) and hybridize to complementary sequences in the RNA; (2) oligo dT primers contain only dT nucleotides and hybridize to the complementary string of dA nucleotides that are present at the end of mRNA molecules (poly-A tail); or (3) primer that will only hybridize to a specific mRNA sequence • After the mRNA has been converted to cDNA, primers that hybridize to specific sequences are added and PCR amplification is performed
Benefits
• RT-PCR is simple, rapid, and sensitive
Limitations/errors
• If the RNA sample is contaminated with DNA, a PCR product may be amplified from the DNA even though the corresponding mRNA for the gene is not present • RNA is fragile, and the absence of a specific mRNA transcript may result from RNA degradation during and following extraction
Experimental applications
• The mRNA gene transcripts can be amplified for subsequent cloning or sequencing
Modifications/alternatives
• Quantitative RT-PCR – by adding a reverse transcription step to quantitative PCR, the levels of mRNA transcripts can be quantified. Samples that contain fewer mRNA transcripts will require more PCR cycles, and different RNA samples can be precisely compared by measuring the number of PCR cycles needed to produce a defined amount of PCR product • Alternative methods to measure RNA levels include digital PCR, in which the sample is partitioned into individual nucleic acids

Table 3.3 Reverse transcription PCR (RT-PCR).

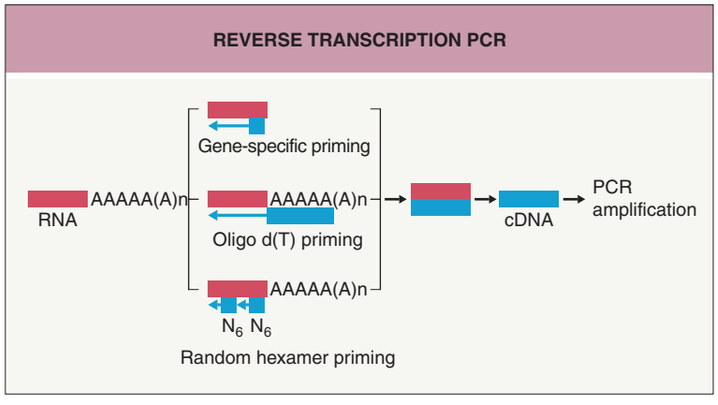

Fig. 3.6 Reverse transcription PCR (RT-PCR). Reverse transcriptase can convert mRNA to cDNA in three different ways, depending on the primer used: (1) random hexamer primers; (2) oligo dT primers; and (3) gene-specific primers. After the mRNA has been converted to cDNA, primers that can hybridize to specific nucleotide sequences are added and PCR is performed.

WESTERN BLOT
Purpose
• Determines the size and the amount of protein present in a sample
Requirements
• An antibody that is specific for the protein of interest
Underlying concepts
• Polyclonal antibodies react to several epitopes on a protein and they are obtained by injecting a protein into an animal and later isolating the antibodies from the serum • Monoclonal antibodies react to only one epitope of a protein and they are obtained by injecting a protein into an animal followed by fusing of the animal's reactive lymphocytes with an immortal myeloma cell line to create cells that are able to provide antibodies indefinitely • The primary polyclonal or monoclonal antibodies bind to the protein. The primary antibodies are detected by a secondary antibody, which is labeled with a fluorescent probe that can produce light or with an enzyme that can produce a detectable substrate by an enzymatic reaction
Outline of method (Fig. 3.7)
• A solubilized protein mix is separated on a polyacrylamide gel and transferred electrophoretically to a membrane. The membrane is then soaked in a buffer containing the antibody. Bound antibody is detected by a chromogenic or chemiluminescent assay
Benefits
• A simple and sensitive method to detect and quantify proteins • Can determine the molecular weight of a specific protein relative to standard controls
Limitations/errors
• Specific antibodies are required that recognize the protein • May contain a high background of nonspecific staining • Proteins may degrade during extraction
Experimental applications
• Detection, quantification, and characterization of a specific protein • Identification of antibody activity to a known antigen
Modifications/alternatives
• Immunoprecipitation (IP): the specific antibody is added to the protein mixture, and the resulting antibody–protein complexes are then isolated; because proteins are not denatured by IP, they can be detected in a more native configuration • IP–Western: protein–protein interactions can be studied by first immunoprecipitating the protein with one antibody, bringing down a protein complex. The protein complex is then separated on a polyacrylamide gel, followed by Western blotting to detect the members of the protein complex • Enzyme-linked immunosorbent assay (ELISA): a sensitive and specific method for quantifying the amount of a protein. The protein of interest is captured on a plate coated with a monoclonal antibody and other proteins are washed away. The protein is then detected using a second antibody that has been modified for detection using a colorimetric or luminescent assay • Immunohistochemistry: allows visualization of the cellular localization of a protein. A primary antibody that recognizes the protein of interest is applied to a tissue section. The protein is then detected using a secondary antibody coupled to an enzyme that reacts with a substrate to produce a colored precipitate

Table 3.4 Western blot.

particular cell linage. Promoters initiate mRNA expression and are located upstream of the gene's coding region. For example, a promoter that ensures that a gene is expressed only in melanocytes would be a promoter of a gene involved in melanin biosynthesis, such as tyrosinase. Although every mouse cell will contain a randomly integrated copy of this new gene, it is expressed only in melanocytes, because of the melanocyte-specific promoter. This principle can be applied to other cell lineages[24].

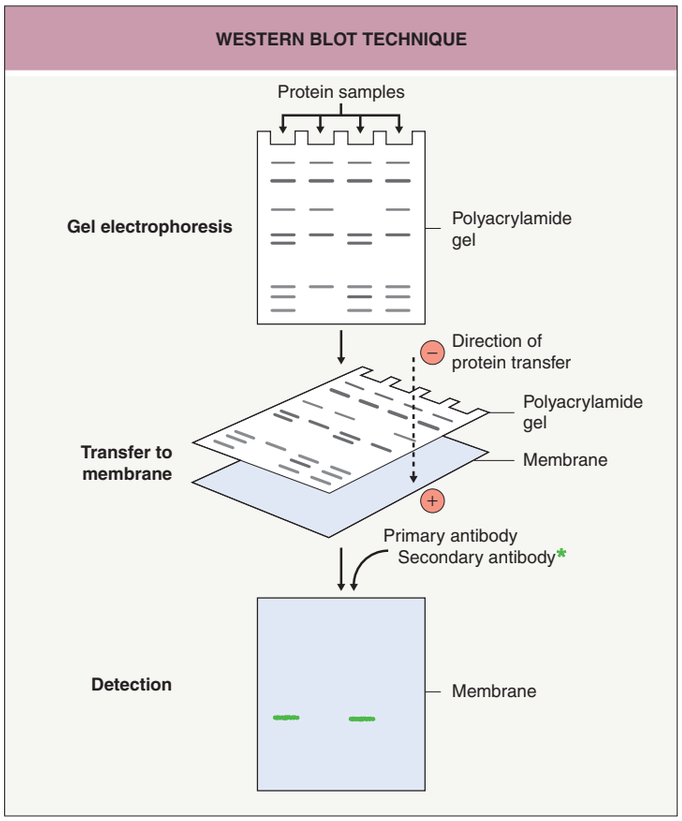

Fig. 3.7 Western blot technique. A solubilized protein mix is separated on a polyacrylamide gel and electrophoretically transferred to a membrane. The membrane is soaked in an antibody-containing buffer, and the bound antibody is detected by a chromogenic or chemiluminescent assay utilizing a labeled secondary antibody (green asterisk).

FLUORESCENCE *IN SITU* HYBRIDIZATION (FISH)
Purpose
• To visualize locations and levels of specific sequences of DNA or RNA in tissue sections
Requirements
• Tissue section of formalin-fixed paraffin-embedded tissue or fresh-frozen tissue • The target sequence must be known
Underlying concepts
• A fluorescently labeled nucleic acid probe hybridizes to complementary sequences in tissue sections
Outline of method (Fig. 3.8)
• A probe is designed that is complementary to the target sequence and is directly or indirectly labeled with a fluorochrome • Nucleic acids in the tissue section are denatured, and then the FISH probe is applied to the tissue section to hybridize to the target sequence • The unbound probe is washed away • The signal is detected using fluorescence microscopy
Benefits
• Identifies specific abnormalities in DNA, such as gene deletion, amplification, or translocation • Determines which cells are expressing a particular gene
Limitations/errors
• Subject to interlaboratory and interobserver variability • Technical issues may complicate results, such as incomplete hybridization or nonspecific binding
Experimental applications
• Identification of DNA copy number aberrations and translocations in cancer cells • Determining the spatial pattern of gene expression in a tissue
Modifications/alternatives
• Single molecule RNA FISH • FISH of metaphase preparations to diagnose chromosomal abnormalities

Table 3.5 Fluorescence *in situ* hybridization (FISH).

The functional loss of a gene can also be studied by creating a "knockout" transgenic mouse (Table 3.8; Fig. 3.11)[26]. It is also possible to *selectively* delete a gene (e.g. a tumor suppressor gene) in a specific cell type or tissue rather than deleting the gene from all cells in the mouse (Fig. 3.12)[26]. A further refinement is to trigger deletion of the gene at a particular point in time, including during development[27]. One advantage of these inducible systems over gene deletion in all mouse cells is that they may more faithfully mimic how gene deletion occurs in a specific tissue of a patient, faithfully recapitulating the hallmarks of diseases such as cancer. Inducible models can also circumvent problems that arise from gene deletion in all mouse cells, which often impact normal mouse development. In addition to using tamoxifen to control Cre expression (see Fig. 3.12), the "Tet-On/Off" system can be used to address the problem of embryonic death due to gene deletion.

The discovery of CRISPR-Cas9 genome editing tools has revolutionized and accelerated mouse model engineering, allowing for the precise introduction of mutations at targeted DNA sites (Fig. 3.13). The CRISPR-Cas9 system facilitates RNA-guided, site-specific cleavage of DNA, which results in the deletion of a DNA region following DNA repair (*knockout*); alternatively, exogenous DNA is used as a template during the repair process and this leads to a new genetic code (*knock-in*). These new techniques simplify the engineering of models for skin diseases and hold the potential to accelerate therapy development.

Gene-Based Therapy for Skin Diseases

Gene-based therapy is a therapeutic approach that holds promise as a treatment for skin diseases[28]. In gene-based therapy, DNA or RNA is manipulated to add or correct a gene in the cells of a target tissue in order to achieve a therapeutic effect (Table 3.9). Although this therapy could be administered directly to the patient's skin *in vivo*, there are concerns regarding safety and the potential for genetic alteration of the germline. Therefore, *ex vivo* techniques have been developed in which cells are grown from a skin sample, treated *in vitro*, and grafted back onto the patient (see Fig. 2.7).

Because genetic manipulation of stem cells may result in long-term engraftment and stable benefits[29], they are often preferred. However, the number of stem cells that can be obtained from adult tissues is limited, so there is considerable interest in gene therapy utilizing induced pluripotent stem (iPS) cells (see Ch. 2). Fibroblasts grown from human skin can be reprogrammed into iPS cells via exposure to transcription factors; these iPS cells are pluripotent and can be propagated *in vitro* indefinitely[30]. iPS cells from a patient may be genetically corrected and then differentiated into the desired cell type, such as keratinocytes, for grafting back to the patient (see Fig. 2.7).

In gene therapy, there are several ways to manipulate DNA. To compensate for the loss-of-function of a gene, a new copy of the gene may be introduced into cells utilizing either non-viral or viral vectors. *Sleeping Beauty* is a non-viral, cut-and-paste DNA transposon that improves long-term gene expression compared to that obtained when only DNA from the gene of interest is used. However, the DNA transposon poses risks for insertional mutagenesis because it may randomly insert near a proto-oncogene that then becomes activated[31]. Viral vectors can also be used to introduce DNA, including self-inactivating lentiviral and gamma retroviral vectors. These vectors integrate into the genome and have less risk of insertional mutagenesis compared to earlier retroviral vectors. However, viral vectors also have disadvantages such as immunogenicity, broad tropism, and limited DNA packaging capacity[32].

It may be possible to avoid the complication of insertional mutagenesis by *correcting the endogenous gene* rather than inserting a gene. Methods for targeted gene correction include the use of zinc

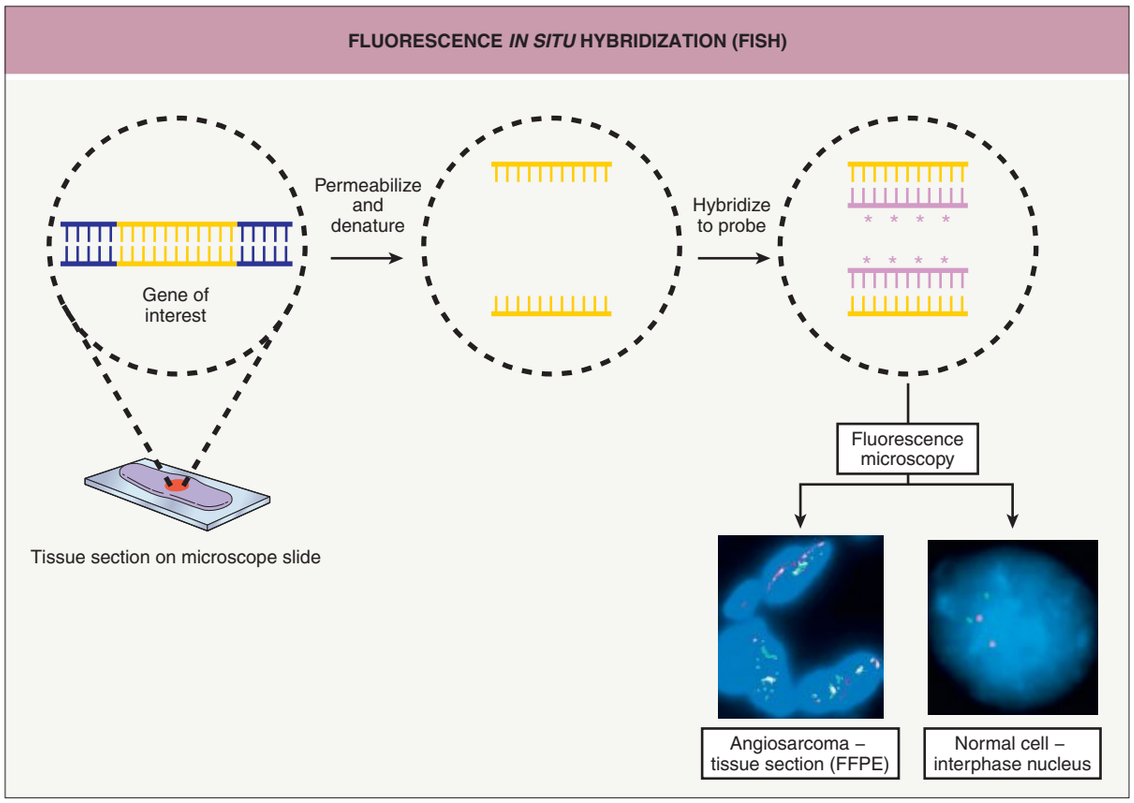

Fig. 3.8 Fluorescence *in situ* hybridization (FISH). A tissue section on a microscope slide is fixed and permeabilized. The nucleotides on the section (yellow) and the fluorescently labeled (asterisks) probes (dark pink) are denatured; then the probes are added to the section to hybridize with complementary sequences. The unbound probe is washed away, and the tissue is examined by fluorescence microscopy. Normally, two fluorescent signals appear in each nucleus for an autosomal gene, but in cancer cells, there may be only one signal, indicating a deletion, or three or more signals, indicating an amplification. Here, a normal nucleus contains two green signals and two dark pink signals for two separate autosomal genes, whereas a tissue section from an angiosarcoma shows multiple separate signals using a *MYC* break-apart probe (the probe consists of two flanking sequences in which variable breakpoints have been observed) instead of only two copies of the two signals attached to one another. FFPE, formalin-fixed, paraffin-embedded.

PROTEOMICS WITH MASS SPECTROMETRY
Purpose
• High-throughput analysis to rapidly and quantitatively assess complex mixtures of proteins present in a cell
Requirements
• A mixture of cellular proteins, or peptides derived from these proteins, is purified from a defined population of cells and then separated into proteins and/or peptides prior to mass spectrometry
Underlying concepts
• Mass spectrometry measures the size or mass of proteins and peptides by giving these peptides a positive charge (ionization) and then measuring the time required for the positively charged peptide ions to move through a tube to a detector (time-of-flight)
Outline of method (Fig. 3.9)
• The first step is to reduce the complexity of the mixture of cellular proteins or peptides to be analyzed, usually by liquid chromatography columns • The separated proteins/peptides are positively charged using lasers, electrospray ionization, or nanospray ionization. Based upon the time-of-flight of the charged peptides, the peptide mass/charge ratio can be measured and this allows identification of the peptide sequence and the protein that contained the peptide • Tandem mass spectrometry (MS/MS) can "ion trap" a given peptide ion and then sequence the peptide by fragmenting it into its component amino acids. Bioinformatics software can use this sequence information to search protein databases for rapid protein identification
Benefits
• Mass spectrometry is extremely sensitive and able to detect very small amounts of proteins/peptides
Limitations/errors
• Better technology to reduce the complexity of protein/peptide mixtures and differentially separate the proteins/peptides in a high-throughput manner is being developed • Although mass spectrometry can measure the mass of proteins/peptides very precisely, it is more difficult to measure the amount of protein/peptide quantitatively
Experimental applications
• Mass spectrometry can be used to determine the complete set of proteins present in a defined population of cells
Modifications/alternatives
• Isotope labeling approaches for quantitative mass spectrometry, including isotope-coded affinity tag (ICAT), stable isotope labeling by amino acids in cell culture (SILAC), tandem mass tags (TT), and isobaric tags for relative and absolute quantification (iTRAQ) • Label-free quantitative proteomics • Antibody protein arrays and reverse-phase protein arrays

Table 3.6 Proteomics with mass spectrometry.

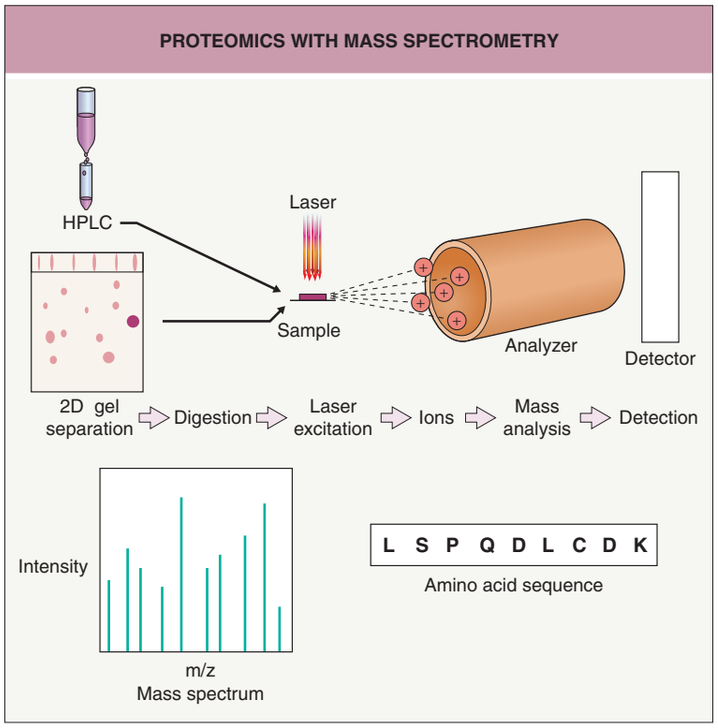

Fig. 3.9 Proteomics with mass spectrometry. The first step is to reduce the complexity of the mixture of cellular proteins or peptides to be analyzed. The two main methods to separate proteins/peptides from each other are high-performance liquid chromatography (HPLC) columns or two-dimensional (2D) gel electrophoresis. Mass spectrometry analysis is then performed by first ionizing the separated proteins/peptides into positively charged ions using lasers. Based on the time-of-flight of the charged ion, mass spectrometry can measure, record, and print out the mass/charge ratio of every peptide along with signal intensity.

finger nucleases (ZFNs), transcription activator-like effector nucleases (TALENs), and, most importantly, CRISPR-Cas9 (see Fig. 3.13)[33]. These nucleases have sequence-specific DNA-binding modules that are linked to a DNA cleavage domain and this allows them to induce a DNA double-strand break at a specified site. The double-strand break increases the frequency of homology-directed repair so that a co-delivered plasmid with extended homology arms can correct the existing gene. Correction of endogenous genes holds promise for treating genetically based diseases.

Another therapeutic approach is to target specific mRNAs for degradation. Double-stranded RNAs with a length of 21–23 nucleotides and complementary to the mRNA of interest are designed. These synthesized antisense oligodeoxynucleotides (AS-ODNs) are delivered to the cell, where they mediate sequence-specific mRNA degradation using an endogenous complex of proteins called the RNA-induced silencing complex (RISC). However, AS-ODN techniques are being replaced by synthetic vectors that deliver short interfering RNA (siRNA) and microRNA (miRNA) (Fig. 3.14). These synthetic delivery vectors include lipid-based or polymer-based nanoparticles, as well as covalent delivery systems such as dynamic polyconjugates and GalNAc conjugates[32]. These approaches have been used successfully in the laboratory and are being tested in clinical trials.

CONCLUSIONS

In this chapter, we have presented a variety of techniques used in dermatology research and clinical practice. Some of these are new, whereas others are long-established and still widely used. New technologies continue to appear and change the way research is done. These technologic advances allow experiments to be done faster and with less and less starting material. They allow the measurement of thousands of different genes or proteins in single experiments. To handle all the information

TRANSGENIC MICE
Purpose
• Investigating the effects of a transgene (the gene of interest) on a cellular, tissue, and whole animal level. The transgene can be selectively expressed in a particular cell type by using a promoter/enhancer regulatory region that is specific for that cell type
Requirements
• A gene of interest, whose biologic function is to be characterized • A regulatory region (promoter/enhancer) that will selectively express the gene of interest in a specific tissue
Underlying concepts
• After injection of a transgene into a fertilized mouse egg, the transgene randomly integrates into the genome. As the embryo develops into a mouse, the integrated transgene will be present in every cell type, tissue, and organ in the mouse. The transgene will only be expressed in cells where the promoter/enhancer regulatory region is active • Phenotypes that develop in mice can help us understand the biologic effects of the transgene
Outline of method (Fig. 3.10)
• A transgene construct, defined as the transgene (gene of interest) and a regulatory region (promoter/enhancer), is microinjected into fertilized eggs. The transgene then integrates into the genome, usually at a single site • The injected eggs are then implanted into a recipient mother, who gives birth to a heterozygous "founder" mouse. The founder mouse contains the transgene on one of the two paired chromosomes (e.g. only one copy of chromosome 7 contains the transgene, whereas the other chromosome 7 does not) • The founder mice are bred with normal non-transgenic mice of the same strain. The progeny mice will be both heterozygous transgenic and non-transgenic, according to Mendelian genetics • To derive homozygous transgenic mice that contain the transgene on both of the paired chromosomes (e.g. both copies of chromosome 7 contain the transgene), two heterozygous transgenic mice are mated. Homozygous transgenic mice will have a double dose of the transgene, which may lead to different phenotypes and biologic effects compared to heterozygous transgenic mice
Benefits
• Transgenic mouse models help us to understand the biologic effects of genes
Limitations/errors
• The regulation of the expression level as well as the timing of gene expression during development (turning the transgene on or off during development) have been relatively difficult. Advancements in transgenic design, including inducible promoters, have improved the regulation of transgene expression • When expressed in mouse tissues, a human transgene may have different biologic effects compared to its effects in human tissues • Because classic transgenic mouse models only add a new transgene to cells, they do not allow investigation of the biologic effects of gene mutations or deletions that result in loss of gene expression
Experimental applications
• Transgenic mouse models of disease can be used to test the effectiveness of new therapeutic agents
Modifications/alternatives
• More precise control of transgene expression can be achieved with promoters/enhancers that are inducible and can be regulated (i.e. turned off and on at different time points) • Programmable nuclease systems for RNA-guided genome editing such as clustered regularly interspaced short palindromic repeat (CRISPR)/CRISPR-associated protein (Cas) (CRISPR-Cas9; Fig. 3.13) • "Knockout" transgenic mouse models (Table 3.8) allow investigation of the biologic effects of gene mutations and deletions that cause a loss of specific proteins

Table 3.7 Transgenic mice.

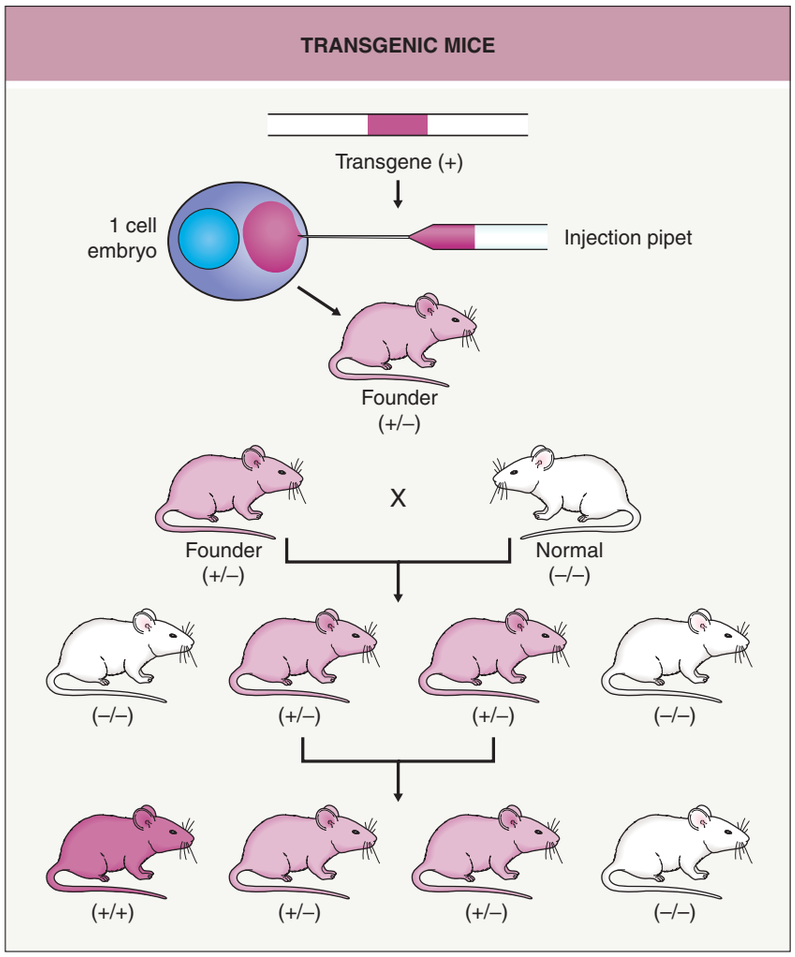

Fig. 3.10 Transgenic mice. A transgene construct, defined as the transgene and regulatory region (promoter/enhancer), is prepared for injection. The transgene is microinjected into fertilized eggs (single-cell stage) and the transgene integrates into the genome, usually at a single site. These injected eggs are then implanted into a recipient mother, who then gives birth to a heterozygous "founder" mouse. The founder mice are bred with normal non-transgenic mice of the same strain, and then two heterozygous transgenic mice are mated.

KNOCKOUT TRANSGENIC MICE
Purpose
• In knockout transgenic mice, both alleles of a normal endogenous gene are modified, mutated, or deleted so that protein can no longer be produced by that gene. Knockout transgenic can be used to study what happens to a cell or tissue when a particular gene can no longer be expressed
Requirements
• Embryonic stem cells (ES cells) capable of forming and reconstituting all tissues and organs of a mouse • A targeting construct that modifies the normal endogenous gene so that it is no longer able to express a functional protein
Underlying concepts
• In knockout transgenic mice, all cells (whole animal or targeted tissue) lack the gene that has been "knocked out" and do not express any functional protein from that gene • Technology is available to selectively target and delete an endogenous gene in its normal chromosomal location in ES cells
Outline of method (Fig. 3.11)
• A targeting construct that contains some sequences of the gene to be knocked out is created and introduced into ES cells. The targeting construct specifically hybridizes to one of the endogenous alleles, and through homologous recombination, the targeting vector modifies or deletes the endogenous gene so that no normal protein is produced • ES cells containing the "knocked out" gene are introduced into early mouse embryos, known as blastocysts, which are then implanted into recipient mothers. The progeny will be chimeric mice; all tissues and organs, including testes and ovaries, will contain a mixture of normal cells and cells that lack the "knockout" gene allele • The chimeric mice are next mated to normal mice. Depending on the degree of chimerism, a certain percentage of the offspring will be heterozygous, containing one normal allele and one allele that has been knocked out • To obtain completely "knocked out" mice, two heterozygous mice are mated
Benefits
• This approach yields mice that completely lack the gene product in all cells of the whole animal or targeted tissues
Limitations/errors
• Investigators have to ascertain that no normal gene product is being produced. It is possible that the homologous recombination process used to knock out a gene may result in a gene that encodes a mutant protein that still has biologic effects
Experimental applications
• Knockout transgenic mice make it possible to study the biologic effects from loss of gene expression, which is particularly important for examining the role of tumor suppressor genes in cancer development
Modifications/alternatives
• To more accurately mimic *in vivo* situations, the gene of interest can be selectively deleted in only one organ or tissue. These *conditional* knockout mice allow investigators to study the effects of gene loss in a particular tissue without the complications of losing gene expression in all the other tissues (Fig. 3.12) • Targeted genome editing using CRISPR-Cas9 (Fig. 3.13)

Table 3.8 Knockout transgenic mice.

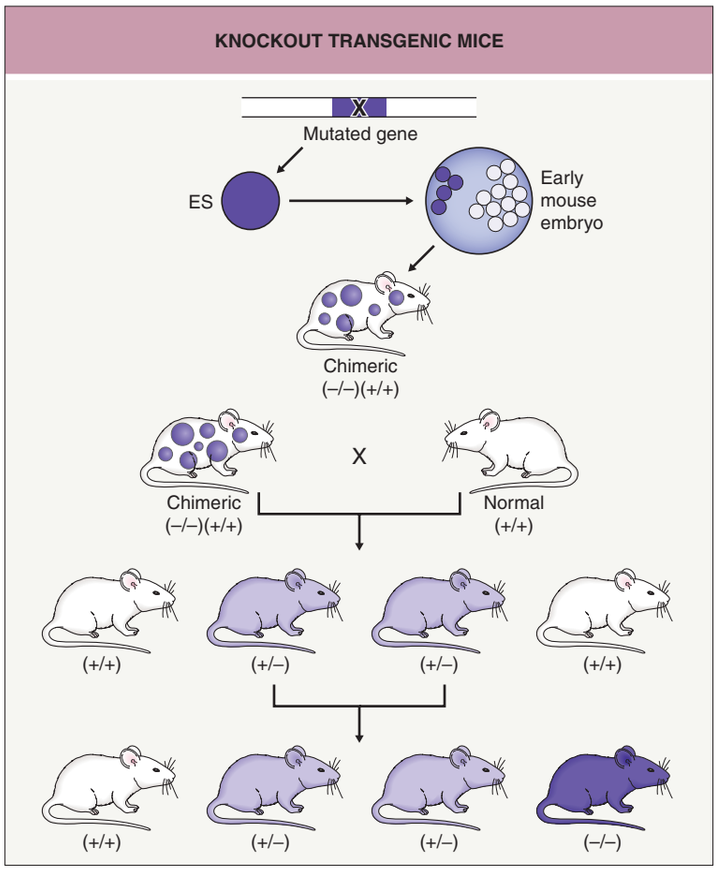

Fig. 3.11 Knockout transgenic mice. A targeting vector that contains some sequences of the gene to be targeted is created and introduced into cells. This targeting vector hybridizes to one of the endogenous alleles of a gene and modifies or deletes the endogenous gene so that no normal protein is produced. The embryonic stem (ES) cells containing the "knocked out" gene are introduced into early mouse embryos, which are then implanted into recipient mothers. The progeny will be chimeric mice, which are then mated to normal mice. To obtain completely knocked out mice, two heterozygous mice are mated.

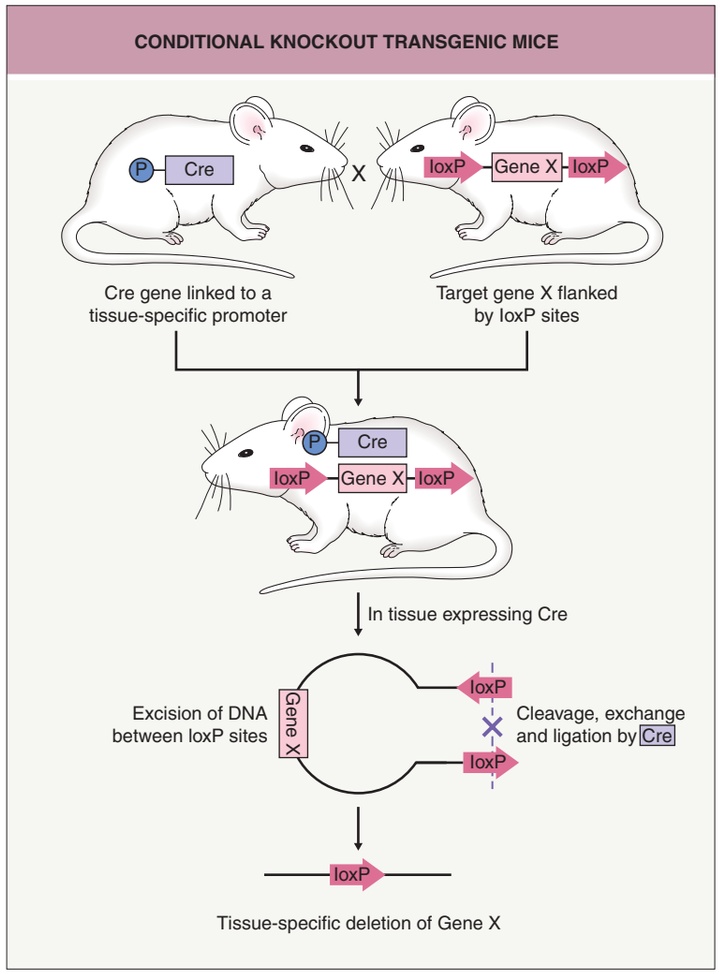

Fig. 3.12 Conditional knockout transgenic mice. In the conditional knockout model using the Cre-lox system, a target gene can be selectively deleted in a particular organ or tissue. Cre is a site-specific DNA recombinase that catalyzes recombination between two loxP sites, resulting in cleavage, exchange, and ligation; this leads to excision (and subsequent degradation) of the DNA between the loxP sites. A transgenic mouse with the Cre gene linked to a tissue-specific promoter is mated to a transgenic mouse with two loxP sites flanking the target gene. Progeny inherit both of these constructs, and the target gene is knocked out only in cells that activate the tissue-specific promoter. By adding a ligand-binding domain to the Cre recombinase, such as one that binds tamoxifen, investigators can achieve temporal control of Cre expression in these cells. The target gene can be temporally deleted, inverted, or translocated, depending on the orientation of the loxP sites.

currently being generated by life sciences, advances in computer science and bioinformatics are progressing along with the technologic advances, accelerating the pace of scientific research.

Advances in our scientific understanding also translate into new developments in disease diagnosis and management. For dermatology, this provides hope that diseases can be diagnosed more rapidly and reliably, and that individualized prognoses can be provided. Therapies have been and will continue to be developed that specifically target the genetic abnormality causing the disease. In the future, therapies may be tailored to the individual, taking into consideration the individual's genetic make-up and the individual's disease course. These future possibilities are exciting.

For discussions of types of polymorphisms and genome-wide association studies, see Chapter 54.

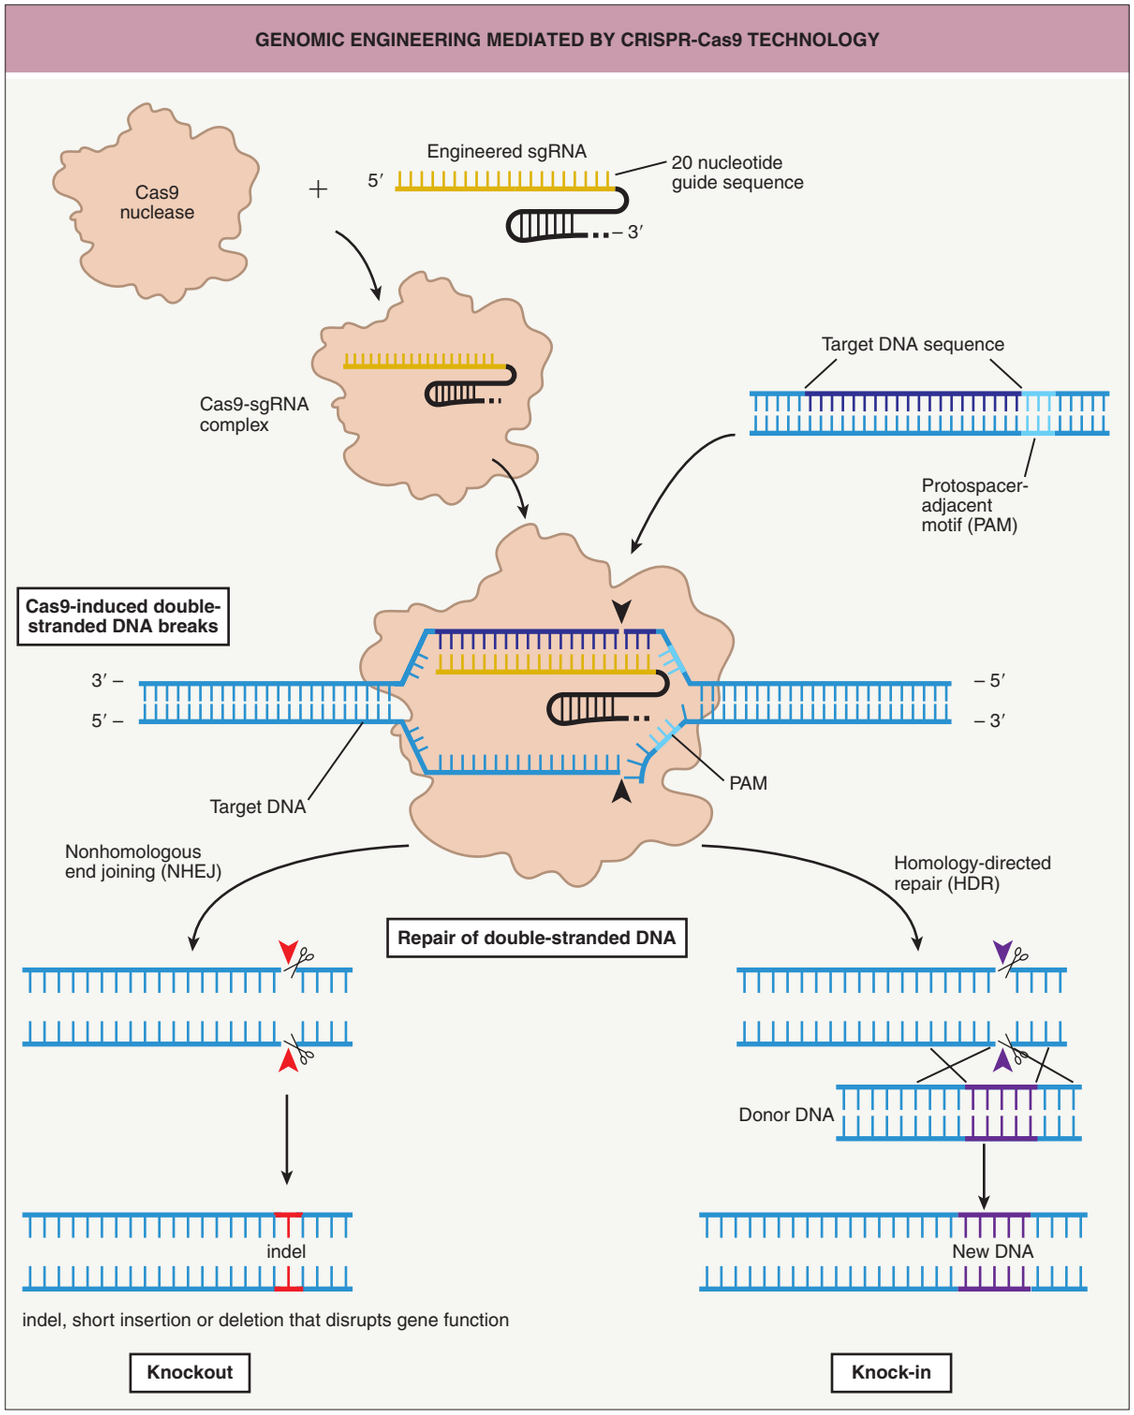

Fig. 3.13 Genomic engineering mediated by CRISPR-Cas9 technology. A single-guide RNA (sgRNA) is engineered to target genomic DNA adjacent to a protospacer adjacent motif (PAM) utilizing a 20-nucleotide guide sequence. The hairpin structure recruits Cas9 to form a complex that binds to the target sequence. Cas9 catalyzes the cleavage of both strands of DNA three nucleotides upstream of the PAM. A double-strand break may be repaired by non-homologous end-joining (NHEJ) that leads to the formation of short insertions or deletions that disrupts gene function. In the presence of a DNA-repair template, homology-directed repair (HDR) may occur to introduce exogenous DNA at the site of the break.

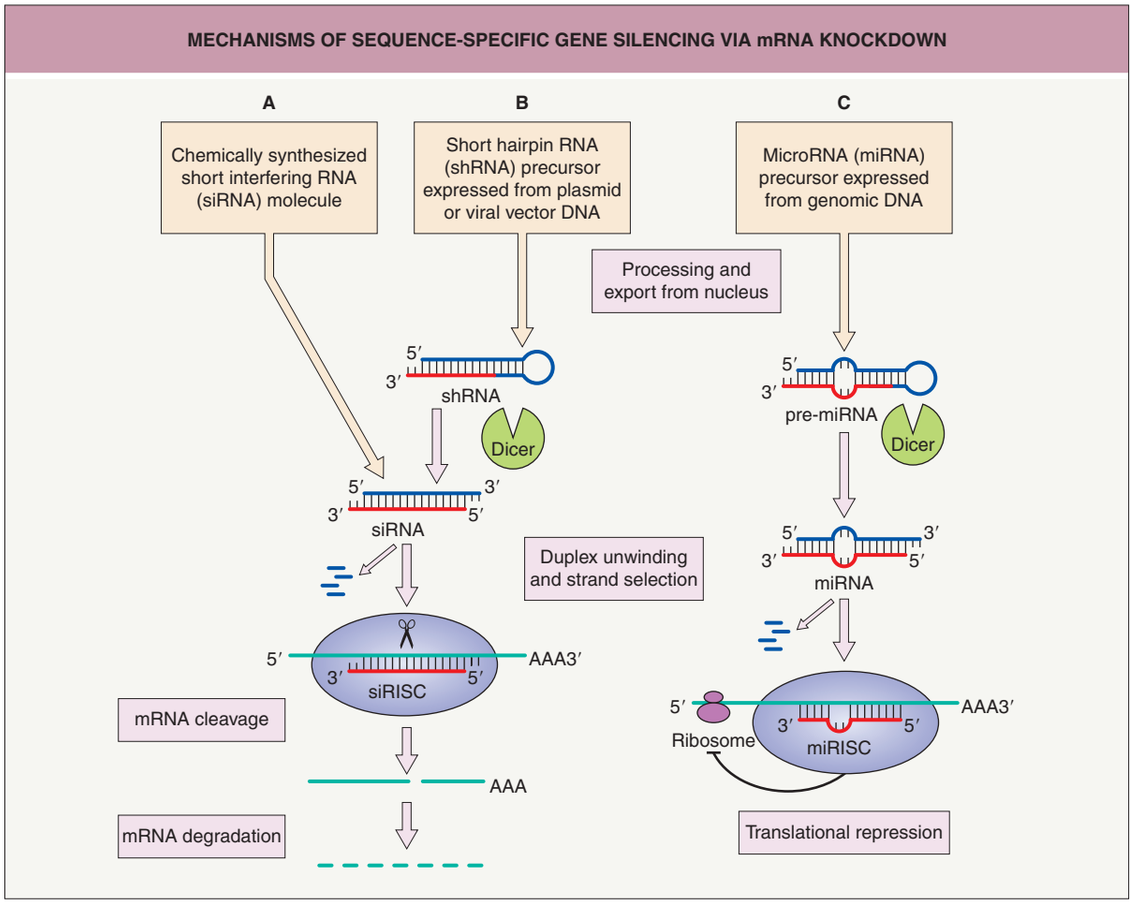
SKIN GENE-BASED THERAPY
Purpose
• Genes are introduced and expressed, corrected, or knocked down in the skin for therapeutic purposes • Skin gene therapy is a promising field that has the potential to provide new treatments for both skin and systemic diseases, in which the skin is used as a vehicle for the systemic delivery of a needed factor or substance
Requirements
• A gene that is able to achieve the desired therapeutic effect when expressed in skin cells • A delivery vector that can efficiently introduce the desired gene into cells. Both viral vectors and non-viral vectors can be used to deliver a desired gene to a target cell type

Table 3.9 Skin gene-based therapy. *Continued*

SKIN GENE-BASED THERAPY
Underlying concepts
• There are two general approaches for introducing genes into the skin: a direct *in vivo* approach and an *ex vivo* approach • Many issues need to be considered when choosing a vector and determining the best approach to deliver the desired gene to the skin. In some situations, short-term or transient expression is sufficient; in other cases, long-term expression is preferable
Outline of method
• In the direct *in vivo* approach, the desired gene is introduced directly into the skin by injection or physical methods such as gene gun or electroporation. *In vivo* approaches are simple and straightforward, but expression is usually only transient and the percentage of cells containing the desired transgene may be low • In the *ex vivo* approach, keratinocytes are removed from the donor, the desired gene is introduced into cultured keratinocytes which form a skin equivalent, and then the genetically modified keratinocytes are grafted back onto the donor. *Ex vivo* approaches are more complicated and technically demanding than *in vivo* approaches, but are superior at achieving long-term expression in a higher percentage of cells
Benefits
• As our understanding of the molecular basis of disease increases, genetic therapies will become more important • The effectiveness of skin gene therapy can be assessed in animal models
Limitations/errors
• Skin gene therapy with long-term expression of a desired gene in a high percentage of cells has been difficult to achieve in animal models • Skin gene therapy for recessive genetic skin diseases is problematic because of the development of an unwanted immune response against the normal protein • Risk of oncogenesis, especially with retroviral vectors
Experimental applications
• Treatment of genetic skin diseases and non-genetic skin diseases if a sufficient understanding of the molecular basis of the disease exists • Systemic delivery of cytokines, hormones, and growth factors • Genetic immunization
Modifications/alternatives
• Use of short (small) interfering RNA (siRNA) that targets and silences expression of dominant-negative mutant genes (Fig. 3.14) • Gene-based therapy utilizing induced pluripotent stem (iPS) cells (see Fig. 2.7)

Table 3.9 Skin gene-based therapy.



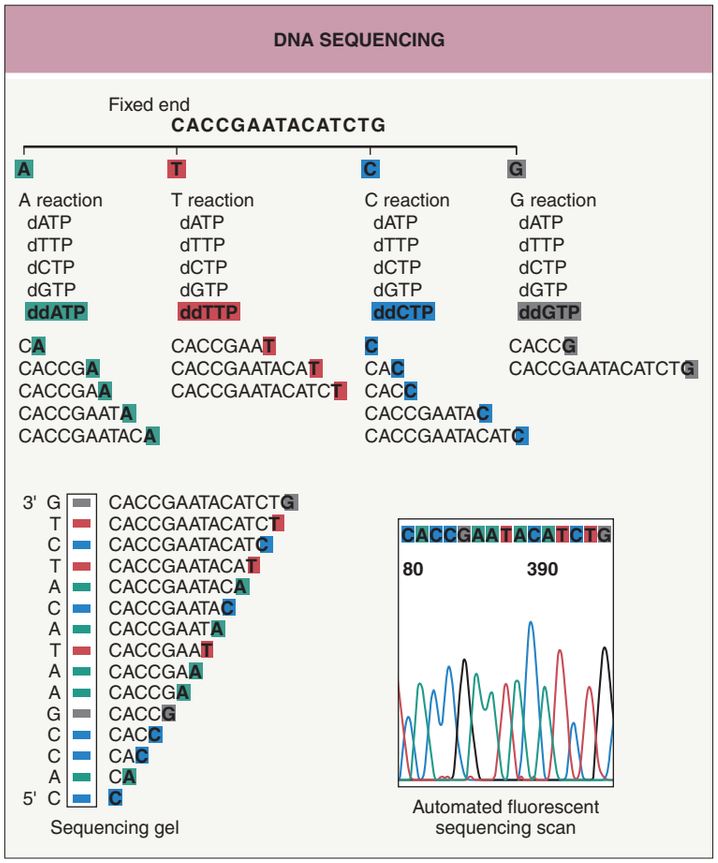


Fig. 3.14 Mechanisms of sequence-specific gene silencing via mRNA knockdown. A Short (small) interfering RNA (siRNA) is unwound, and the "guide" antisense strand is incorporated into an RNA-induced silencing complex (RISC) that degrades a specific target mRNA sequence. Processing of short hairpin RNA (shRNA; **B**) and pre-microRNA (miRNA; **C**) by the Dicer enzyme can generate siRNA and miRNA, respectively. **C** Endogenously produced miRNA regulates up to a third of human genes and tends to have less complementarity with target mRNA; it recruits RISC proteins and typically inhibits mRNA translation (rather than decreasing mRNA levels).

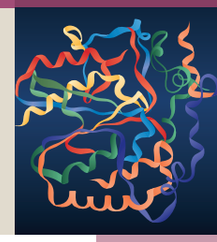
eFig. 3.1 DNA sequencing. An oligonucleotide primer hybridizes to the DNA to be sequenced, and DNA polymerase synthesizes a second complementary strand. The synthesis of the second strand is interrupted randomly by the incorporation of fluorescent nucleotide analogues (ddATP, ddGTP, ddCTP, ddTTP). The DNA fragments containing this final nucleotide analogue can be identified because each of the four ddNTPs is labeled with a different color fluorochrome. Gel electrophoresis is used to separate the different sizes of DNA fragments. The different-length DNA strands terminating with different fluorochrome-labeled nucleotide analogues pass a fluorescence detector and indicate the order of the DNA sequence.



eFig. 3.2 Nucleic acid arrays. A In the expression bead array, RNA is extracted from cells and reverse transcribed to generate cDNA. *In vitro* transcription of the cDNA in the presence of biotinylated nucleotides yields biotin-labeled cRNA. Labeled cRNAs bind to their respective 50-base probes that are linked to separate beads using additional nucleotides as an address to decode the gene. Fluorescent streptavidin is added, which strongly binds to biotin. The fluorescent intensities on different beads are related to the amount of cRNA, and the latter is a reflection of the level of expression of mRNA by specific genes. Usually, the patterns of gene expression of two samples are compared, such as normal versus tumor or treated versus untreated. **B** In the gene chip microarray, labeled cRNA molecules are hybridized to small DNA fragments chemically synthesized on a surface, with the surface containing thousands of specific sequences at different locations. **C** In a third approach using glass slides, two samples can be labeled with differently colored fluorescent probes (e.g. Cy5, Cy3) that are hybridized to an oligonucleotide array simultaneously. Arrays can also be used to analyze DNA rather than RNA; examples include single nucleotide polymorphism (SNP) arrays and array comparative genomic hybridization (CGH) (see Chs. 54 & 113).

eFig. 3.3 Skin gene therapy. In the *ex vivo* approach, keratinocytes are removed from the donor and, during *ex vivo* culture, the desired gene is efficiently introduced, usually with viral vectors. Skin equivalents or raft cultures containing these genetically modified keratinocytes (along with a dermal portion containing fibroblasts) are constructed and then grafted back onto the donor.

Abbreviations

AMP	antimicrobial peptides
APC	antigen presenting cell
CCL	C-C motif chemokine ligand
CCR	C-C motif chemokine receptor
CLA	cutaneous lymphocyte antigen
CTL	cytotoxic T lymphocyte
DAMP	danger-associated molecular pattern
DC	dendritic cell
ILC	innate lymphoid cell
iTreg	induced Treg
LC	Langerhans cell
nTreg	natural Treg
PAMP	pathogen-associated molecular pattern
pDC	plasmacytoid dendritic cell
Tc cell	cytotoxic T cell
Tcm	central memory T cell
Tem	effector memory T cell
Tfh cell	T follicular helper cell
Th cell	helper T cell
Tmm	migratory memory T cell
Treg	regulatory T cell
Trm	resident memory T cell

Key features

- The major purpose of the immune system is protection against harmful agents such as pathogens and tumor cells. This is achieved by a rapid "primitive" reaction, called the *innate immune response*, and a more highly developed specific reaction, called the *adaptive immune response*
- The characteristics of an adaptive immune response are specificity and the accumulation of memory, thus enabling improvement with each successive encounter with a particular antigen
- The key event in an adaptive immune response is antigen presentation, yielding either a cell-mediated or a humoral response. The cellular response involves primarily T cells, whereas the humoral response involves B cells that ultimately mature into antibody-secreting plasma cells
- Immune responses are not always protective and can even be pathogenic if the response induces severe tissue destruction or is directed against an autoantigen
- As a barrier organ to the external environment, the skin is endowed with the capacity and the necessary cellular components to mount an immune response

INTRODUCTION

As a major barrier against the external environment, one of the skin's major functions is defense against potential insults by microbial, chemical, and physical agents. Over the past several decades, it has become clear that the skin is not a mere passive mechanical barrier to the outside world but rather represents an active member of the body's immune system. As such, the skin is inhabited by a myriad of resident immune cells, which, together with recruited inflammatory and adaptive immune cells, protect the individual from external and internal danger signals. Accordingly, the term "skin-associated lymphoid tissues" (SALT) has been coined to reflect the importance of the cutaneous immune response in tissue homeostasis and repair[1].

The classical immune response, also referred to as the adaptive immune response, is characterized by specificity that is due to immunologic memory (specific immunity). Innate immunity is a more primitive defense system that acts in a rapid but less specific manner. Both types of responses can be generated in the skin. Adaptive immune responses in the skin, however, are not always protective but can also be harmful in nature, e.g. allergic or autoimmune reactions. Numerous skin diseases are caused by T lymphocytes and/or autoantibodies and are therefore immunologically mediated. Consequently, many dermatoses respond favorably to immunosuppressive therapy administered either systemically or topically.

INNATE IMMUNE RESPONSE

Essential components of the cutaneous innate immune system include tissue-resident cells such as mast cells, macrophages, dendritic cells (DCs), non-classical T cells, natural killer (NK) cells, and innate lymphoid cells. In addition, circulating cells, including neutrophils and eosinophils, can be rapidly recruited from the bloodstream into the skin. Innate immune cells are characterized by their capacity to immediately respond to harmful signals by virtue of expression of danger sensing receptors such as Toll-like receptors (TLRs). Soluble mediators, including cytokines and complement factors, represent effector molecules of the innate immune response. In addition, microbiota as well as antimicrobial peptides produced by the epithelium and other cells support these responses against invading pathogens. Innate immune reactions are less complicated than adaptive responses and developed earlier in evolution. Nevertheless, failures in these "primitive" immune responses may be associated with severe, even fatal, health problems.

Complement

The complement system plays an important role in innate immunity. It consists of at least 20 serum glycoproteins that are activated by an enzymatic amplifying cascade (see Ch. 60). Complement proteins sense and transmit internal danger signals originating from tissue disruption (damage-associated molecular patterns, DAMPs) or products released from microbes (microorganism-associated molecular patterns, MAMPs). Three pathways can trigger the proteolytic cascade which results in protein fragments that activate complement receptors. The classical pathway is stimulated by antigen–antibody complexes, the alternative pathway by polysaccharides derived from microbial cell walls, and the later identified lectin pathway by the interaction of microbial carbohydrates with mannose-binding proteins. All three pathways lead to activation of the central C3 component and, finally, the generation of a number of immunologically active substances. For example, C3b, the cleavage product of C3, binds to the surface of microbes. Since phagocytic cells express receptors for C3b, phagocytosis of the microorganisms is enhanced. In addition, complement components bind to antigen–antibody immune complexes, which help complement receptor-bearing antigen-presenting cells target these immune complexes.

C5a is a powerful attractant for neutrophils. C3a, C4a, and C5a, also called anaphylatoxins, induce the release of inflammatory mediators from mast cells. This increases vascular permeability, thereby enabling proteins (e.g. antibodies) to enter the tissue. Assembly of the complement components C5b, C6, C7, C8, and C9 forms the membrane-attack complex (MAC), which generates pores in cell membranes and leads to death by osmotic lysis. Human cells are much less susceptible to killing by complement than microbes, since the former express certain complement receptors that can inhibit cell lysis. For example,

human cells express complement receptor type 1 (CR1, CD35), decay-accelerating factor (DAF, CD55), and membrane cofactor protein (MCP, CD46), which inhibit C3 convertase and thereby block progression of the complement cascade. In addition, CD59 is a protein that binds to C8 and inhibits insertion of C9 into the cell membrane.

Complement fragments can also bind to complement receptors expressed on immune cells, such as NK cells, neutrophils, monocytes, macrophages, DCs, and, although still controversial, B and T cells. Complement receptor engagement induces and modifies several effector functions including phagocytosis of apoptotic cells and immune complexes, cell migration and adhesion, surface receptor and cytokine expression, tissue repair, and modification of cell signaling responses to pattern recognition receptors[2]. Furthermore, components of the complement system can crosstalk and modulate TLR signaling cascades. These synergistic interactions potentially boost immune system responses directed against invading pathogens[2].

Toll-Like Receptors

Several families of pattern recognition receptors (PRRs) mediate responses to pathogen-associated molecular patterns (PAMPs) that are conserved among microorganisms. TLRs, the mammalian homologs of the Toll receptors identified in *Drosophila*, are one such family of PRRs. To date, ten TLRs have been identified in humans (Fig. 4.1)[3], and those localized to the cell surface have the following specificities: TLR2 (in association with either TLR1 or TLR6) – recognition of lipoproteins and peptidoglycans; TLR4 – lipopolysaccharide; and TLR5 – flagellin (a component of bacterial flagella). TLR3, TLR7, TLR8, and TLR9 reside within endosomal vesicles and recognize nucleic acids[4], with TLR9 recognizing bacterial CpG DNA sequences and the other intracellular TLRs involved in the recognition of viral RNA[5].

The signaling pathway of TLRs is highly homologous to that of the receptor for interleukin (IL)-1. Upon interaction with myeloid differentiation factor 88 (MyD88), IL-1 receptor-associated kinase (IRAK) is recruited, ultimately leading to activation of the transcription factor NF-κB (see Fig. 4.1). Activation of TLRs can also result in the release of interferons (IFNs) via activation of interferon regulatory factor 3 (IRF3).

DCs express several types of TLRs. Upon activation of these receptors by microbial components, DCs mature and migrate to the lymph nodes, where they present pathogen-derived antigens to naive T cells and induce an adaptive immune response. TLRs thereby bridge the gap between the innate and adaptive immune systems. These two systems constantly interact within the skin, and therefore the innate immune system represents a potential target for modulating adaptive immune responses[6]. Different PAMPs and danger signals polarize DCs, giving them the ability to produce certain cytokines and to induce T cells to differentiate into particular subtypes.

Inflammasomes

Closely connected with the rapid recognition of danger signals are inflammasomes – innate multi-protein complexes that sense intracellular DAMPs or PAMPs. Four types of inflammasomes have been identified: Aim2 (*a*bsent *i*n *m*elanoma *2*), the *p*yrin domain-containing NLRP1 (*n*ucleotide-binding domain *l*eucine-rich *r*epeat-containing receptor *1*, also called NALP), NLRP3, and NLRC4 (*N*od-*l*ike *r*eceptor *C*ARD domain-containing 4)[7]. Aim2 is activated by double-stranded DNA resulting from either viral or bacterial intracellular pathogens, NLRP1 by muramyl dipeptide, and NLRC4 by flagellin. NLRP3 is triggered by numerous PAMPs and DAMPs and is thus the most important inflammasome (Fig. 4.2). The ultimate result of activation of inflammasomes is the cleavage of pro-IL-1β into active IL-1β, a highly potent inflammatory mediator. NLRPs are large backbone proteins of the complex which, upon assembly of the inflammasome complex, bind to ASC (*a*poptosis-associated *s*peck-like protein containing a *ca*spase *r*ecruitment *d*omain [CARD]). The latter interacts with caspase-1, resulting in its activation. Active caspase-1 cleaves and activates pro-IL-1β, as well as the proinflammatory cytokine pro-IL-18. Dysregulation of inflammasomes is the cause of a group of inherited autoinflammatory diseases called cryopyrin-associated periodic syndromes (CAPS) which are associated with recurrent episodes of fever, urticarial skin lesions, arthritis, and systemic inflammation (see Ch. 45). These disorders respond very well to IL-1 blocking drugs (see Fig. 4.2).

The Skin Microbiota and Antimicrobial Peptides

The skin microbiota is comprised of billions of bacteria, archaea, viruses, and fungi that are in symbiosis with the host. Extensive research over the past decade has shown that the commensal microorganisms on the skin are essential for training cells of the cutaneous

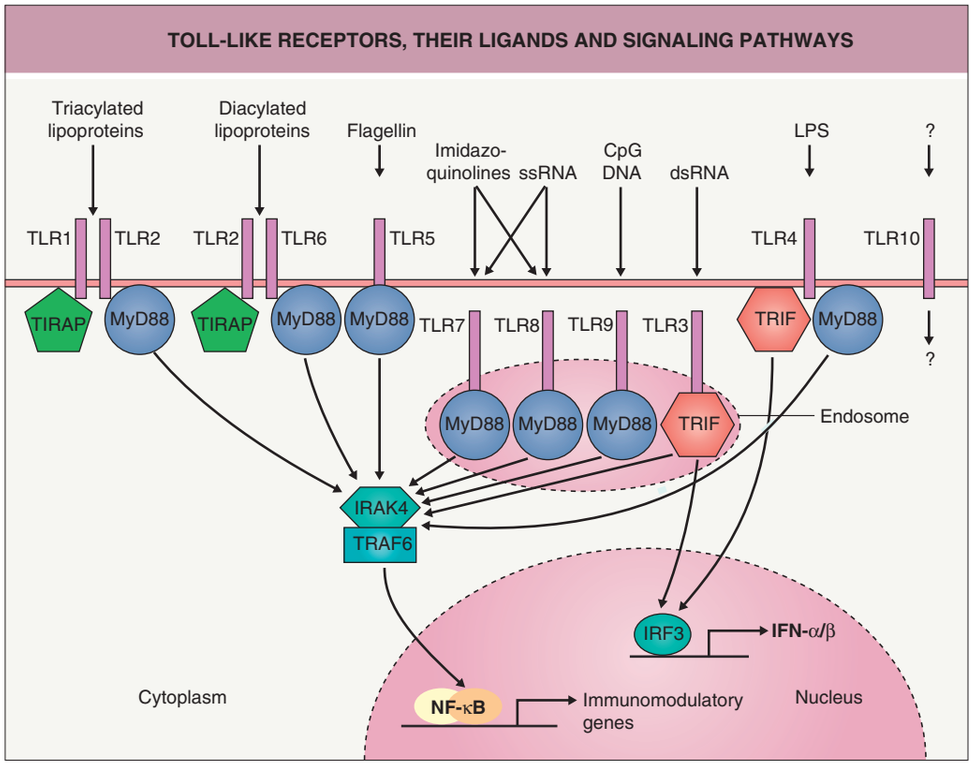

Fig. 4.1 Toll-like receptors, their ligands, and signaling pathways. Toll-like receptors (TLRs) recognize pathogen-associated molecular patterns and/or synthetic compounds in a specific fashion. A TLR2/TLR1 dimer recognizes triacylated lipoproteins, and a TLR2/TRL6 dimer interacts with diacylated lipoproteins. TLR5 recognizes flagellin and TLR4 recognizes lipopolysaccharide (LPS). These TLRs are located on the cell membrane and are internalized upon ligand interaction. TLR3, TLR7, TLR8, and TLR9 are located on intracellular membranes of endosomes and lysosomes. TLR3 recognizes viral double-stranded RNA (dsRNA); TLR7 and TLR8 viral single-stranded RNA (ssRNA); and TLR9 bacterial and viral hypomethylated DNA (CpG [5′-C-phosphate-G-3′] motifs). TLR7 and TLR8 also bind to synthetic compounds (imidazoquinolones). All TLRs except TLR3 utilize myeloid differentiation factor 88 (MyD88) for signaling, while TLR2 and TLR6 also require Toll-interleukin-1 receptor domain-containing adaptor protein (TIRAP). MyD88 signaling via IL-1 receptor-associated kinase-4 (IRAK-4) and tumor necrosis factor receptor-activated factor-6 (TRAF-6) mostly results in activation of nuclear factor κB (NF-κB), ultimately inducing transcription of genes encoding immunomodulatory and proinflammatory molecules. TLR3 and TLR4 signal via TIR-domain-containing adapter-inducing interferon-β (TRIF). The TRIF pathway induces the production of interferons (IFNs) via interferon regulatory factor-3 (IRF3). Both the ligand and signaling pathway of TLR10 are still unknown. *Adapted from Miller LS. Toll-like receptors in skin. Adv Dermatol 2008;24:71–87 and from McInturff JE, Modlin RL, Kim J. The role of toll-like receptors in the pathogenesis and treatment of dermatological disease. J Invest Dermatol 2005;125:1–8.*

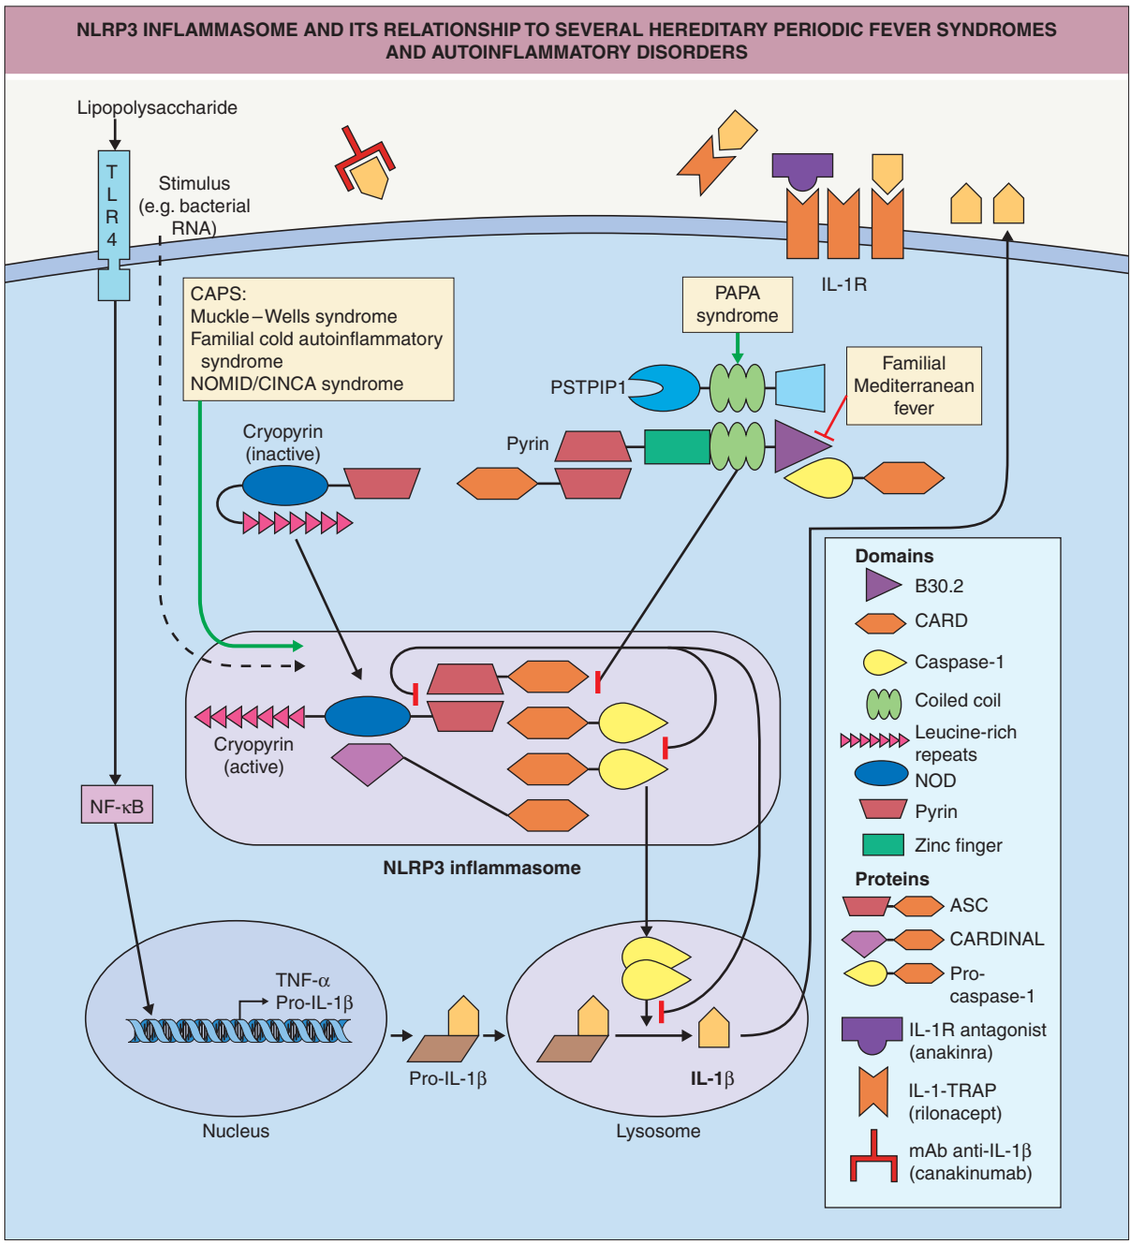

Fig. 4.2 NLRP3 inflammasome and its relationship to several hereditary periodic fever syndromes and autoinflammatory disorders. immune system as well as for protecting against invasion of pathogenic microbes[8]. Re-evaluation of the composition of the skin microbiota via next generation sequencing (see Fig. 3.5) has expanded the microbiome kingdom landscape beyond bacteria. The diversity of bacterial species and strains (see Fig. 74.1), viruses, and fungi is strongly dependent on host genetics, body site, skin pH, sebum content, moisture, and UV radiation exposure[9,10].

On healthy skin, microbiota outcompete pathogenic microorganisms by building a physical and biological barrier which contributes to the first line of defense against pathogen invasion. Some commensal bacteria can produce antimicrobial substances (e.g. antibiotics, serine proteases) while others interact with and train immune and skin cells to secrete interleukins, complement components, and antimicrobial peptides (AMPs)[8,9]. A change in the equilibrium of commensal microbiota and pathogens is an important factor in the pathogenesis of several skin disorders, most notably atopic dermatitis in which there is an overgrowth of *Staphylococcus aureus*[11].

To cope with pathogenic invaders, plants and invertebrates produce a variety of highly effective AMPs. Human epithelia, including the epidermis, also secrete AMPs as a mechanism of innate defense. The first AMP to be isolated from human skin was human β-defensin-2 (hBD-2)[12]. A number of other AMPs have subsequently been described (Table 4.1). In addition to antibacterial properties, some of these peptides possess antimycotic and, likely, antiviral activity. As demonstrated for psoriasin, which prevents *Escherichia coli* infection[13], these peptides may protect the skin from pathogenic bacterial infections.

Expression of AMPs can be induced by bacteria, bacterial products, or proinflammatory cytokines via TLRs and other mechanisms. Enhanced and reduced production of these peptides in psoriasis and atopic dermatitis, respectively, may explain why superinfections are so rare in the former disease and common in the latter[12,14]. However, enhanced expression of AMPs in atopic skin has also been reported, which may reflect disruption of the epidermal barrier[15]. Ultraviolet (UV) B radiation has been shown to induce expression of AMPs, potentially explaining the paucity of UVB-related bacterial infections despite its immunosuppressive effects (see Ch. 86)[16]. The role of microbiota in the response of the epidermis and the immune system to UV radiation has been shown experimentally in a mouse model under germ-free conditions[17].

Beta-defensins can also attract immature DCs and memory T cells via the chemokine receptor (CCR)-6, illustrating another link between innate epithelial defense and adaptive immunity[18]. The antimicrobial peptide LL-37, also known as cathelicidin antimicrobial peptide (CAMP), mediates DC activation in psoriasis by binding self-DNA and forming structures that stimulate TLR9 and thereby induce IFN production (see Fig. 4.1)[19].

Table 4.1 Skin-derived antimicrobial peptides. In the skin, antileukoprotease (ALP) is also referred to as SKALP, skin-derived ALP.

Cytokines

Cytokines represent a large, heterogeneous family of low-molecular-weight messenger substances that play a crucial role in intercellular communication. Cytokines can be secreted by almost any cell type, and they may act in an autocrine, paracrine, or endocrine manner. Cytokines exert their biologic activities by binding to specific cell surface receptors. Although the vast majority of cytokines occur in a soluble form, some can be membrane-bound. In addition, soluble cytokines can be sequestered by extracellular matrix molecules thereby becoming immobilized. The latter limits diffusion, aids in the build-up of cytokine concentration gradients within tissues, and results in increased force loads being transferred onto the cellular cytoskeleton. These intracellular forces can enhance stimulatory signals following cytokine binding resulting in increased cellular responses.

Cytokines influence the proliferation, differentiation, and activation of cells. Each cytokine exhibits multiple activities, a fact that can complicate strict categorization. Cytokines that are produced by leukocytes and exert effects preferentially on other white blood cells are called interleukins (ILs). Colony-stimulating factors (CSFs) are mediators that induce differentiation and proliferation of hematopoietic progenitor cells while IFNs interfere with viral replication. Cytokines that have chemoattractant activity are termed chemokines, and they play a crucial role in leukocyte migration. The main subgroups of chemokines are differentiated according to the position of two cysteine (C) residues compared with the other amino acid residues (X), CXC (α-chemokines) and CC (β-chemokines). Chemokines that recruit leukocytes are termed inflammatory chemokines, whereas those that regulate trafficking within lymphoid tissues are called lymphoid chemokines.

Early *innate* immune responses are dominated by cytokines with inflammatory (e.g. IL-1, IL-6, IL-10, IL-12, IL-18, tumor necrosis factor [TNF], inflammatory chemokines) and antiviral (e.g. IFN-α, IFN-β) capacities. Induction of *adaptive* immune responses is critically dependent on cytokines with immunomodulatory capacities (e.g. IL-2, IL-4, IL-5, IL-12, IL-13, IL-17, IL-22, IL-23, IFN-γ and TGF-β). However, since most of these mediators exhibit multiple and sometimes overlapping activities, a strict separation into inflammatory and immunomodulatory cytokines is not possible. Due to structural similarities, some cytokines are grouped into families, e.g. the IL-6 family (IL-6, IL-11, oncostatin M, leukemia inhibitory factor [LIF]), the IL-10 family (IL-10, IL-19, IL-20, IL-22, IL-24, IL-26), or the IL-12 family (IL-12, IL-23, IL-27).

Monocytes and Macrophages

Monocytes are short-lived mononuclear cells with proinflammatory and regulatory activities. Two main subtypes of monocytes and one intermediate stage with distinct functions have been described in human blood: classical $CD14^{++}CD16^{-}$; intermediate/transitional $CD14^{+}CD16^{+}$; and non-classical $CD14^{dim}CD16^{++}$[20]. Monocytes are derived from a common myeloid progenitor in the bone marrow, circulate in the bloodstream, and migrate into tissues to respond to inflammation and infection. Within tissue, they can give rise to inflammatory DCs and macrophages whose functions are defined by the tissue environment and tissue type[21]. Although residing in different niches, these cell types have similar functions: phagocytosis, antigen presentation to T cells, and production of cytokines.

Monocyte-derived macrophages express receptors for carbohydrates that are usually *not* expressed on vertebrate cells (e.g. mannose). Through this mechanism, macrophages can discriminate between "foreign" and "self" molecules. Furthermore, macrophages possess receptors for antibodies and complement. Hence, microorganisms that are coated with antibodies and/or complement are more readily phagocytosed[22]. After phagocytosis, the microorganisms are exposed to a variety of toxic intracellular molecules, including superoxide anions, hydroxyl radicals, hypochlorous acid, nitric oxide, lysozyme, and antimicrobial cationic proteins. Macrophages can also present processed antigens to T and B cells. However, their T cell stimulatory capacity is less effective than that of DCs.

Activated macrophages release granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF). These two cytokines induce the division of myeloid precursors in the bone marrow, releasing millions of neutrophils into the circulation.

Neutrophils

Under normal conditions, neutrophils circulate in the bloodstream, some rolling along the vascular endothelium[23]. To enter the site of an infection, neutrophils utilize a complex process that involves adhesion molecules (e.g. integrins), chemoattractants, and other surface receptors (see Chs. 25 & 102). The recruited neutrophils phagocytose organisms and kill them within phagolysosomes by using oxygen-dependent and oxygen-independent mechanisms. The former, called the respiratory burst, involves the production of hydrogen peroxide, hydroxyl radicals, and singlet oxygen. The oxygen-independent mechanism utilizes highly toxic cationic proteins and enzymes, such as myeloperoxidase (MPO) and lysozyme. Organisms that are coated with antibodies or complement components bind to Fc and complement receptors, respectively, on neutrophils (as well as macrophages) and are more effectively phagocytosed and killed.

Ectosomes are vesicles released from the plasma membrane of neutrophils upon their stimulation (e.g. by bacteria)[24]. They carry membrane surface receptors (e.g. CD15, L-selectin), phosphatidylserine, and granule proteins (e.g. CD66b, CD87, MPO, elastase, proteinase 3, defensins, lactoferrin, collagenase I). Depending on the composition, ectosomes can induce a variety of responses in their target cells which include endothelial cells, platelets, natural killer cells, and DCs.

In addition, neutrophils can release neutrophilic extracellular traps (NETs) and thereby develop into anuclear cytoplasts[24]. NETs are composed of extracellular strands of DNA bound to neutrophil-derived AMPs and proteins. Because NETs can entrap bacteria, fungi, and viruses, they may offer some antimicrobial protection. On the other hand, NETs can induce autoimmunity by stimulating immune responses against the NET-associated nuclear antigens (see Fig. 41.1). Whether formation of NETs contributes to the exacerbation of autoimmune diseases by infections remains to be determined.

Eosinophils

The major function of eosinophils is most likely to protect the host from infections by parasites, particularly nematodes. Infections with these organisms are associated with the production of antigen-specific IgE antibodies that coat the parasite. Via their low-affinity receptors (FcεRII, CD23), eosinophils bind to IgE antibodies and become activated. In contrast to macrophages and neutrophils, eosinophils are only weakly phagocytic. They harbor large granules that contain major basic protein, eosinophilic cationic protein, eosinophil peroxidase, and eosinophil-derived neurotoxin (see Fig. 26.1). Upon activation, eosinophils release these toxic products, which can kill parasites, together with prostaglandins, leukotrienes, and various cytokines[25]. Eosinophils also play an important role in the pathogenesis of allergic reactions.

Basophils and Mast Cells

Basophils (found in the blood) and mast cells (located within tissues) exhibit similar functional and morphologic characteristics. At least two populations of mast cells exist, which can be differentiated by the enzymes they contain and by their tissue location. Mucosal mast cells contain only trypsin, while connective tissue mast cells contain both trypsin and chymotrypsin (see Ch. 118). In contrast to pulmonary, uterine, and tonsillar mast cells, cutaneous mast cells express the receptor for C5a (CD88), which implies that triggering of mast cells through the anaphylatoxin C5a results in cutaneous, but not systemic, reactions[26]. Further, skin mast cells have been shown to express CD117 (c-Kit), CD26 (dipeptidyl peptidase IV), and the neural cell adhesion molecule L1[27]. Both basophils and mast cells express high-affinity receptors for IgE (FcεRI) that avidly bind IgE (see Ch. 18).

When a specific antigen binds to mast cell-bound IgE, the FcεRI becomes activated, which leads to degranulation and release of preformed mediators, including histamine and serotonin. Other mediators such as prostaglandins, leukotrienes (B_4, C_4, D_4 and E_4), and platelet-activating factor are also released, and they enhance vascular permeability, bronchoconstriction, and induction of an inflammatory response (see Ch. 18). Hence, basophils and mast cells play an important role in immediate-type allergic reactions such as urticaria and angioedema. There is also evidence that mast cells are involved in contact hypersensitivity reactions.

Innate Lymphoid Cells

Innate lymphoid cells (ILCs) are lymphoid progenitor-derived leukocytes which lack T and B cell receptors and do not express conventional hematopoietic lineage markers[28]. ILCs require the transcription factor Id2 and the cytokine IL-7 for their development. Three subgroups have been defined based upon their cytokine and transcription factor expression profiles. *ILC1s* rely on the T-bet transcription factor and secrete type 1 cytokines such as IFN-γ and TNF in response to intracellular pathogens. *ILC2s* are under the control of GATA3 and ROR-α transcription factors and produce type 2 cytokines (e.g. IL-4, IL-5, IL-9, IL-13) in response to extracellular parasite infections. *ILC3s* are under the control of the ROR-γt transcription factor and produce IL-17, IL-22, and GM-CSF. There may be some plasticity between different ILC subgroups, but this is still under investigation.

The exact role of ILC1s in physiologic and pathologic processes within the skin still remains to be determined. In contrast, there is mounting evidence to support the role of ILC2s in allergic skin diseases such as atopic dermatitis. ILC2s activate B cells to secrete IgE via class switching, increase mast cell degranulation, and induce eosinophilia. ILC3s may play a role in triggering psoriatic flares since an increase in $NKp44^+$ILC3s that release IL-17 and IL-22 have been found in the circulation and skin of psoriatic patients. Their potential pathogenic role is also supported by a significant reduction in $NKp44^+$ILC3s after successful treatment with adalimumab. These ILC subsets have distinct gene expression profiles and localize to different skin compartments[29]. For example, when they reside in compartments close to hair follicles and sebaceous glands, they negatively regulate sebaceous gland function in a TNF- and lymphotoxin-dependent manner; absence of ILCs results in overgrowth of sebaceous glands and increased fatty acid production. By controlling the production of antimicrobial lipids these cells positively influence microbiota diversity[29].

Natural Killer Cells

The major task of natural killer (NK) cells is to eliminate virally infected or malignant cells[30]. NK cells can recognize their targets in two ways. Since they express Fc receptors that bind IgG (FcγRIII, CD16), NK cells can adhere to and kill target cells that are coated with IgG. This killing process is referred to as *antibody-dependent cellular cytotoxicity* (ADCC).

The second recognition system involves killer-activating and killer-inhibitory receptors. *Killer-activating receptors* recognize molecules that are expressed by nucleated cells. This provides a signal for the NK cell to kill the target cell by secretion of perforins, which make holes in the cell membrane through which granzymes are injected. Granzymes lyse target cells by activating the apoptotic caspase cascade. *Killer-inhibitory receptors* (KIR) on NK cells recognize major histocompatibility complex (MHC) class I molecules. KIRs shut off the killer signal and thus prevent autolysis of the host. Tumor cells and viruses often downregulate MHC class I molecules to escape recognition by cytotoxic T cells, but this renders "MHC class I-low" cells susceptible to recognition by NK cells.

ADAPTIVE IMMUNE RESPONSE

The characteristic features of an adaptive immune response are its specificity and enhancement with each successive antigen encounter owing to the accumulation of cellular "memory". A crucial event during the generation of an adaptive immune response is antigen presentation.

Antigen-Presenting Cells

Various cells can present antigens, depending on how and where the antigen first encounters cells of the immune system. Professional antigen-presenting cells (APCs), such as DCs and B cells, are specialized in capturing and displaying antigens to lymphocytes. Within the epidermis, Langerhans cells (LCs) are key APCs.

Langerhans cells

In 1868, Paul Langerhans first described dendritic cells that localized within the epidermis. Because of their shape, Langerhans thought that these cells might be of neural origin. More than 100 years later, it was shown that LCs are derived from bone marrow. LCs share ontogeny

with tissue-resident macrophages, but functionally resemble DCs[31]. Formation of LCs depends on transforming growth factor-β1 (TGF-β1) and macrophage colony-stimulating factor receptor (M-CSFR) ligands (M-CSF, IL-34), which are provided in an autocrine fashion.

LCs are intimately associated with nerve fibers that extend from the dermis into the epidermis and they can modulate LC function via the release of neuropeptides such as calcitonin gene-related peptide (CGRP)[32]. Psychological stress has been shown to result in a reduction of LCs and to influence local neuropeptide expression in human skin[33], suggesting a connection between environmental influences, mental health, and skin immune homeostasis. In humans, the number of LCs is reduced on the palms and soles, genitalia, and buccal mucosa. Of note, their density decreases with age and is reduced in chronically UV-exposed skin[34].

Ultrastructurally, LCs have rod-shaped organelles termed Birbeck granules (see Fig. 91.5). A Ca^{2+}-dependent lectin with mannose-binding specificity called langerin (CD207) is associated with and responsible for the formation of Birbeck granules[35]. Birbeck granules result from the antigen-capture function of langerin, which routes antigens into these organelles and provides access to a non-classical antigen-processing pathway. Activated LCs elongate their dendrites which can then penetrate keratinocyte tight junctions and survey the area just beneath the stratum corneum for antigens[36]. These penetrating dendrites take up antigens which co-localize with langerin/Birbeck granules. By forming new tight junctions, keratinocytes rapidly close the defects produced by the penetrating dendrites, thereby maintaining skin integrity during antigen uptake.

Histochemically, human LCs can be visualized by staining for adenosine triphosphatase (ATPase), a membrane-bound, formalin-resistant, sulfhydryl-dependent enzyme. In addition to langerin, antigenic moieties present on human LCs include the pan-hematopoietic marker CD45, MHC class II antigens (HLA-DR), CD1a, S100 protein, and vimentin. CD1a is a useful marker for LCs, since within the epidermis (normal or inflamed) it is exclusively expressed on LCs, whereas HLA-DR antigens are expressed on keratinocytes in inflamed skin (Table 4.2). Since CD1a does not exist in the murine system, staining for MHC class II antigens is often used for detection of murine LCs in non-perturbed skin (Fig. 4.3)[34]. In addition, human LCs express the high-affinity IgE receptor (FcεRI)[37]. Subtle differences in the surface marker expression of resident LCs, migrating LCs, and langerin$^-$ dermal DCs have been described (Table 4.2).

Other dendritic cells

DCs are professional APCs that display an extraordinary capacity to stimulate naive T cells and initiate a primary immune response[38]. They also control skin immune homeostasis via interactions with a variety of other immune cells, such as mast cells, macrophages, and ILCs, either via direct cell–cell contact or by secreted cytokine messengers. DCs can develop from different types of progenitor cells, while the same progenitor cell can give rise to a variety of functional phenotypes of DCs[39]. The DC system is very complex, and to further complicate matters, there are a number of differences between the experimental systems used to study human and murine DCs.

In general, dermal DCs can be divided into conventional DCs (cDCs) comprising cDC1 and cDC2 cells, and plasmacytoid DCs (pDCs)[40]. cDCs are the major dermal DC type under non-inflammatory conditions and they reside mainly in the upper dermis, compared to dermal macrophages which are found primarily in the deeper, vascular-rich dermis. Human cDC1s are defined by the expression of CD141 and BDCA3 and cDC2s by CD1c[41]. The two subgroups have overlapping, but distinct, immune functions – cDC1 cells can cross-present viral antigens and self-antigens and elicit Th1 immune responses, whereas hapten- or protein-primed cDC2 cells induce Th2-specific immune responses, while reducing Th17 cytokines[41,42].

Plasmacytoid DCs (pDCs; $CD123^+$) are specialized DCs that secrete large amounts of type I IFN in response to TLR7 or TLR9 activation. As such, they are powerful defenders against viral infections, but are normally absent in healthy human skin. Although pDC numbers are quite low in healthy individuals, circulating pDCs are significantly increased in patients with systemic lupus erythematosus (SLE)[43]. In addition, pDCs have been shown to infiltrate lesions of cutaneous lupus and psoriasis and further promote inflammation[44].

In the dermis of mice, two other subsets of DCs have been described, double-negative (DN) DCs and monocyte-derived DCs. The human counterpart of the latter are $CD14^+$ dermal cells, whereas the counterpart of the former is still elusive[42]. In the skin, monocyte-derived DCs have the potential to locally present antigens by forming immune clusters and thereby activating skin-resident T cells and regulatory T cells (Tregs)[42].

In humans, lymphoid and plasmacytoid DCs induce Th2 responses while myeloid DCs generate Th1 reactions[45]. Activation of TLR7 via the immunomodulator imiquimod, an imidazoquinoline (see Fig. 4.1), drives myeloid DCs to express perforin and granzyme B and drives plasmacytoid DCs to express TNF-related apoptosis-inducing ligand (TRAIL). This enables killing of tumor cells, indicating that both myeloid and plasmacytoid DCs may be directly involved in imiquimod-induced destruction of skin cancer[46].

The type of immune response that is generated is also critically dependent on the state of maturation of the stimulating DC at the time of antigen presentation. For the induction of Th1 responses, the presence of IL-12 is crucial. DCs tend to produce IL-12 directly after an activating step in their maturation, driving T cells into a Th1 phenotype if they meet the DCs at this stage[47]. At later time points,

the production of IL-12 decreases, thereby favoring the development of a Th2 response. This process is also influenced by the innate immune system (e.g. stimulation by TLRs) and mast cells which can further skew T cells to produce Th1 and Th17 cytokines[42]. Taken together, the parameters responsible for the type of Th cell differentiation induced by DCs remain to be fully defined. Of note, immature DCs induce tolerance due to incomplete T cell activation, resulting in regulatory T cells that suppress immune responses[48].

Antigen presentation

Antigen-presenting cells: activation and migration

To initiate sensitization, antigens must be presented to T cells by APCs. For many years, LCs were thought to be the most important APC in the skin since contact sensitization could not be induced in sites that were naturally devoid of LCs (e.g. murine tail skin) or in which LCs had been depleted (e.g. by UV radiation)[49]. However, transgenic mice in which LCs are completely depleted demonstrated variably diminished but not completely abrogated sensitization responses[50]; in one such model, the sensitization response was completely normal[51]. In a different knockout mouse model characterized by constitutive and durable absence of epidermal LCs[52], an enhanced sensitization response was actually observed, suggesting that LCs may have regulatory functions. This "LC paradigm" proposes that LCs may be tolerogenic when they present antigens under steady-state non-inflammatory conditions, but sensitizing upon stimulation by inflammatory mediators. Which of these activities is the main function of LCs remains to be determined, and there is accumulating evidence that dermal DCs are equally, if not even more, important than LCs for presenting antigens to mount productive immune responses.

Cutaneous APCs actively take up antigens in the skin, but antigen presentation to lymphocytes takes place in the regional lymph nodes. In the presence of inflammation, the APCs become activated, leave the skin, and then migrate to the draining lymph nodes via afferent lymphatics. During migration, they change their phenotypic and functional behavior and develop into mature DCs. For example, molecules involved in antigen uptake and processing (Birbeck granules, Fc receptors) are downregulated on activated DCs[53]. When compared, gene expression profiles of LCs and migratory dermal DCs (e.g. cDC1s) are very similar and both have the capacity to prime naive helper T cells in lymph nodes.

In activated LCs, CD44, a hyaluronic acid receptor involved in the tissue homing of leukocytes, is upregulated. The splice variant CD44v6 supports binding of LCs to T cell-rich areas of lymph nodes[54]. Furthermore, the integrins $\alpha_6\beta_1$ and $\alpha_6\beta_4$, which exhibit affinity to the basement membrane zone, are induced on the surface of emigrating LCs[55]. The release of proteolytic enzymes like matrix metalloproteinase-9 (type IV collagenase) may enable their penetration through the basement membrane. Their dendricity becomes less pronounced, and surface molecules necessary for antigen presentation and T cell priming are upregulated (e.g. MHC class I, MHC class II, CD40, CD54, CD58, CD80, CD86). At this stage, LCs emigrating from the epidermis are almost indistinguishable from DCs obtained from lymphoid organs[53].

Antigen presentation to T cells

In contrast to B cells, T cells cannot recognize soluble protein antigens *per se*; instead, the T cell receptor (TCR) recognizes antigen-derived peptides bound to MHC locus-encoded molecules expressed on APCs. $CD4^+$ T cells recognize antigens in association with MHC class II molecules, while $CD8^+$ T cells recognize antigens in association with MHC class I molecules (Fig. 4.4).

Two pathways exist by which antigens can be "loaded" onto MHC molecules. If the antigen has been produced *endogenously* within the cell (e.g. viral or tumor proteins), it is complexed with *MHC class I* molecules through intracellular processing pathways (Fig. 4.5)[56]. The proteasome degrades cytosolic antigens produced by the cell. Resulting peptides (which consist of 8 to 12 amino acid residues) are then imported into the endoplasmic reticulum (ER) in a TAP (transporter associated with antigen processing)-dependent manner and loaded onto MHC class I molecules[57]. After binding to the MHC class I–β_2 microglobulin complex, these peptides are transported to the cell surface via the Golgi apparatus. Alternative pathways by which exogenous proteins are phagocytosed with the phagosome fusing to the ER may also exist. The proteins would subsequently be re-transported out of the ER into the cytoplasm and then degraded by the proteasome. The degraded peptides could then enter the pathway that is normally employed for endogenous proteins via the TAP protein. As the vast majority of nucleated cells express MHC class I molecules, many cell types can serve as nonprofessional APCs for MHC class I-restricted antigen presentation in a secondary immune response. This can also result in activation of effector cytotoxic T lymphocytes.

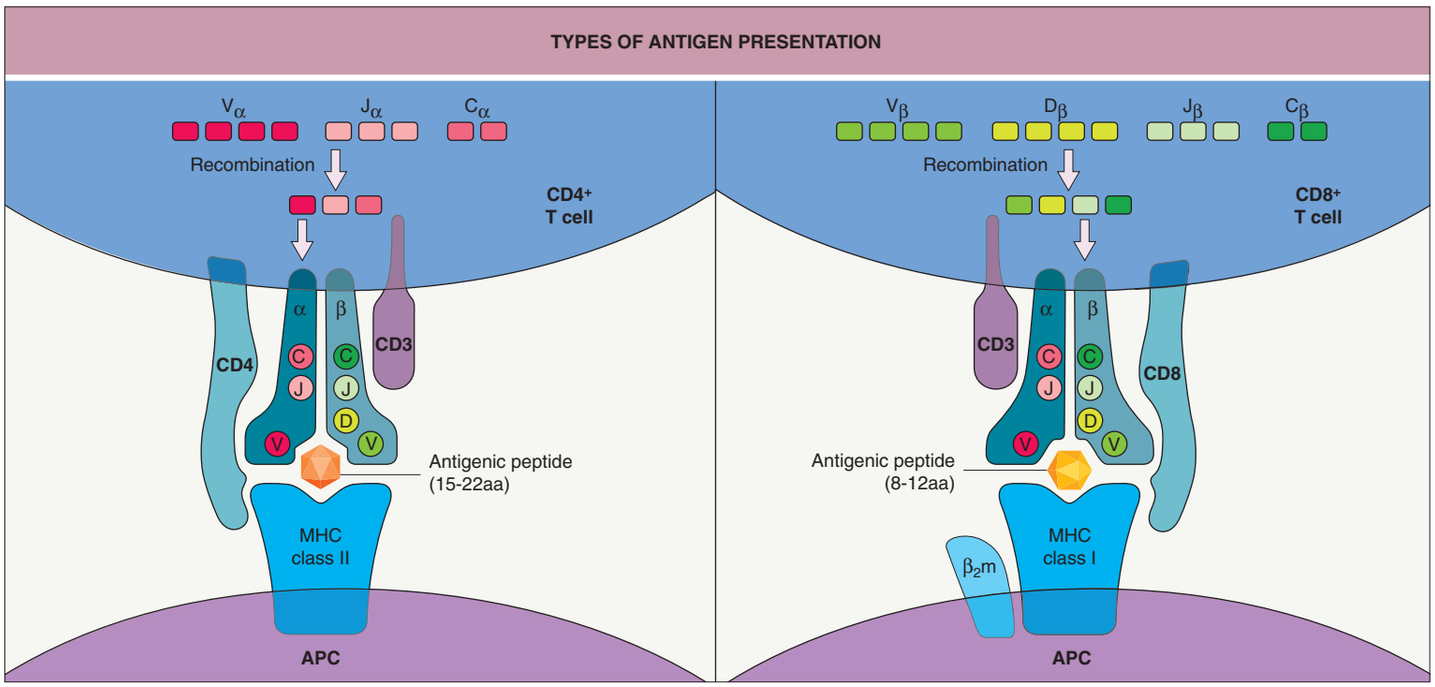

Fig. 4.4 Types of antigen presentation. Antigens are presented by antigen-presenting cells to the T cell receptor of $CD4^+$ or $CD8^+$ T cells in association with either MHC class II or MHC class I molecules. The diversity of the T cell receptors is generated by gene rearrangement. For reasons of clarity, the simplified gene rearrangement of the α-chain is shown only in the $CD4^+$ T cell and that of the β-chain in the $CD8^+$ T cell. aa, amino acids; APC, antigen-presenting cell; β_2m, β_2-microglobulin; V, variable; D, diversity; J, joining; C, constant. *Adapted from Modlin RL. Lymphocytes. In: Freedberg IM, Eisen AZ, Wolf K, et al. (eds). Fitzpatrick's Dermatology in General Medicine, vol. 1. New York: McGraw-Hill, 1999;32:400–5.*

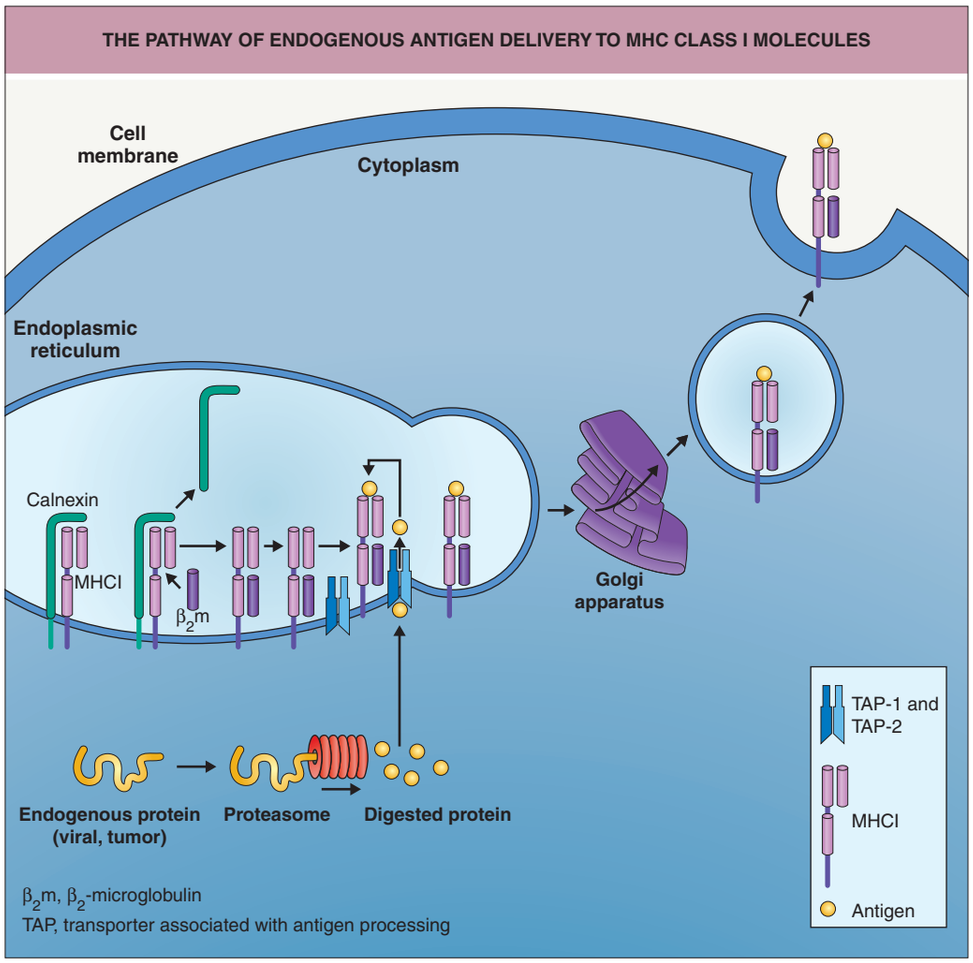

Fig. 4.5 The pathway of endogenous antigen delivery to MHC class I molecules. Newly synthesized MHC class I molecules are stabilized by calnexin. When β_2-microglobulin (β_2m) binds to the complex, calnexin dissociates. This complex associates with the TAP (transporter associated with antigen processing) protein waiting for a suitable peptide. Endogenous antigens are degraded by the proteasome and transported via TAP into the endoplasmic reticulum (ER), where they bind to the MHC class I/β_2m complex. Finally, the peptide/MHC complex is transported through the Golgi apparatus to the cell surface. Not pictured is a possible alternate pathway in which exogenous proteins are phagocytosed and the phagosome fuses to the ER. The proteins are then retransported out of the ER into the cytoplasm and degraded by proteasomes. The degraded peptides can now enter this pathway via the TAP protein.

MHC class II-dependent antigen presentation is critically dependent on DCs, B cells, and monocytes/macrophages. *MHC class II*-associated antigen presentation targets primarily *exogenous* and less frequently endogenous antigens[58]. Exogenous antigens are taken up via macro- or micropinocytosis or by receptor-mediated endocytosis (Fig. 4.6). One example of the latter is the DEC-205 receptor (CD205), which guides antigens into endocytic vesicles that reside deeper inside the cell and contain MHC class II molecules. As a consequence of this unique intracellular targeting, antigens endocytosed by the DEC-205 receptor stimulate respective T cells up to 500-fold greater than antigens taken up by pinocytosis or other receptors. Protein degradation eventually takes place in the endo-/lysosomes, yielding peptides with a typical length of 15 to 22 amino acid residues. These peptide fragments enter specialized endosomal compartments containing MHC class II molecules that are generated in the ER[59].

Newly synthesized MHC class II molecules are associated with an invariant chain, which inhibits dissociation of empty MHC class II molecules and transports the MHC class II complex from the ER to the specialized endosomal compartments where the molecules can interact with antigen peptide fragments (see Fig. 4.6). In this compartment, the invariant chain is cleaved by proteases, leaving a small fragment called CLIP (class II-associated invariant peptide) that binds to the class II molecule. Upon interaction with the antigenic peptides, the CLIP fragment is released from the complex. The MHC class II molecule with the bound antigen peptide is subsequently expressed on the cell surface, allowing antigen recognition by T cells carrying the appropriate TCR.

Classically, MHC class I molecules present self- or pathogen-derived antigens that are synthesized within the cell to $CD8^+$ T cells (see Fig. 4.5), whereas exogenous antigens derived via endocytic uptake are loaded onto MHC class II molecules for presentation to $CD4^+$ T cells (see Fig. 4.6). However, it has become evident that some DCs are also able to process exogenous antigens into the MHC class I pathway for presentation to $CD8^+$ T cells. This mechanism, referred to as cross-presentation[60], allows DCs to induce either tolerance (to self-antigens) or immunity (to exogenous pathogens).

T Cells

T cell precursors continuously migrate from the bone marrow to the thymus, where T cells develop[61]. In the thymus, T cells bearing the α/β TCR are subjected to a complex selection process. In contrast to antibodies, which represent the antigen receptor on B cells and recognize antigens in their naive form, the α/β TCR recognizes only short peptide fragments that are generated during antigen processing (see above). These processed antigens are presented to the TCR by MHC molecules on the cell surface. The amino acid sequences recognized by the TCR include those from both the MHC molecule and the antigenic peptide. Consequently, the TCR recognizes a combination of "self" MHC molecules (which are highly polymorphic) and "foreign" peptides. T cells that recognize "self" MHC molecules but *not* "self" peptides are useful for immune defense and do not lead to undesirable autoimmunity. This requirement is achieved by a complex process involving both positive and negative selection within the thymus.

T cell development

Developing T cells within the cortex of the thymus engage MHC complexes on thymic DCs. When the T cells are able to recognize these MHC molecules via their TCR, they receive a survival signal (*positive selection*). Otherwise, the T cells undergo apoptotic cell death. At this stage, more than 95% of the developing T cells die in the thymus because they are not selected due to their uselessness (i.e. inability to recognize "self" MHC molecules)[62]. In addition, T cells that express a TCR with a high affinity for the complex of a "self" peptide plus a "self" MHC molecule are eliminated by apoptosis, since they are potentially harmful. This process, called *negative selection*, takes place in the thymic medulla and involves DCs and macrophages that process and present a spectrum of "self" antigens. Positive and negative selection

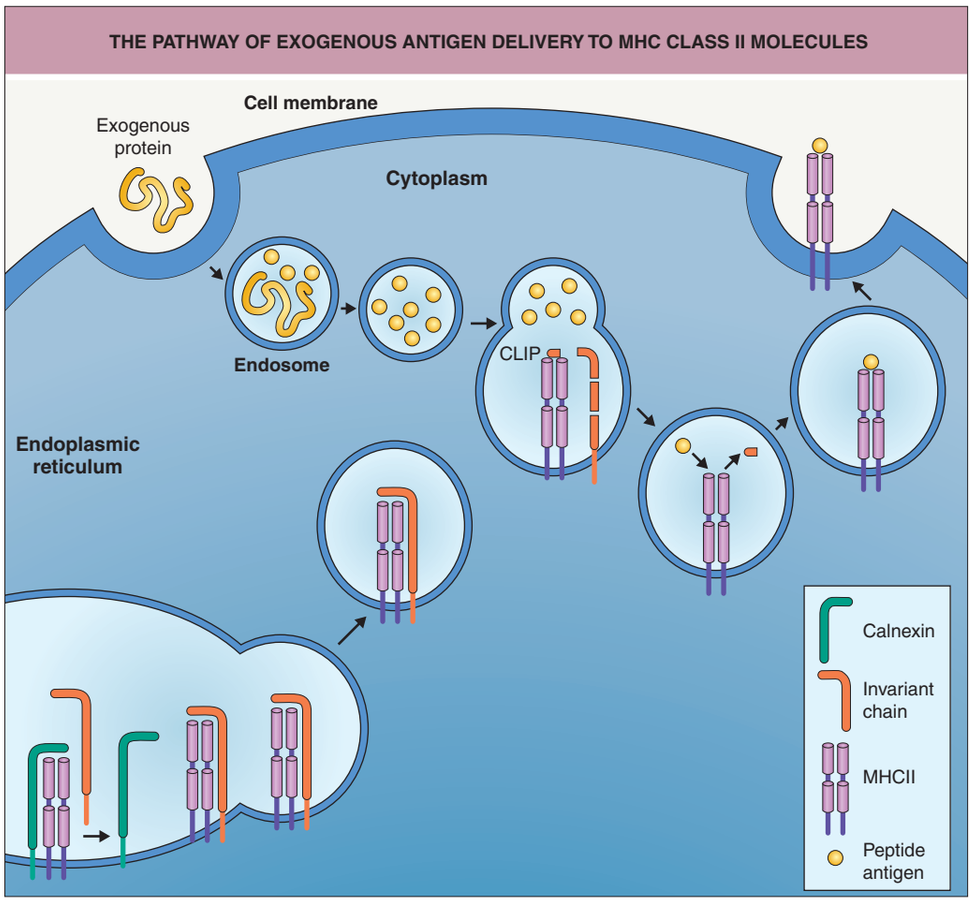

Fig. 4.6 The pathway of exogenous antigen delivery to MHC class II molecules. Exogenous antigens are taken up into the cell by endosomes. The protein is cleaved into peptides within the endosomes, which become increasingly acidic. In the endoplasmic reticulum (ER), newly synthesized MHC class II molecules bind to an invariant chain, which inhibits their disassociation while empty. During this assembly, the complex is stabilized by calnexin. The invariant chain transports the MHC class II molecule from the ER (via the Golgi apparatus) into the endosomal compartment, where the MHC class II complex meets the peptides. The invariant chain is cleaved, leaving a small fragment (CLIP) in the groove of the MHC class II molecule. Finally, CLIP is replaced by the antigenic peptide. The complex is transported to the cell membrane and expressed on the cell surface. CLIP, class II-associated invariant peptide.

allow the survival of just those T cells that recognize foreign (but not "self") peptides in the context of "self" MHC molecules and thus are useful for immune defense without causing auto-attack[63].

During thymic education, a variety of surface molecules are switched on and off. Components of the CD3/TCR complex, together with CD4 or CD8 molecules, have roles in this process. In general, $CD4^+$ T cells function as helper T cells and recognize antigens presented by MHC class II molecules, whereas $CD8^+$ T cells are usually cytotoxic and recognize antigens in association with MHC class I molecules (see Fig. 4.4). During their early stage of development within the thymus, T cells express both CD4 and CD8[64]. Upon expression of an appropriate TCR, these immature T cells exhibit the capacity to recognize antigenic peptides associated with either MHC class I or class II, since they still express both CD4 and CD8 (double-positive stage). In the subsequent process, one of these surface markers is lost, resulting in single-positive T cells expressing either CD4 or CD8.

T cell receptor

One major feature of an adaptive immune response is the recognition of specific antigens. This is achieved either by the TCR during a T cell-mediated response or by antibodies during a B cell response. TCRs are transmembrane molecules consisting of α/β (vast majority of T cells) or γ/δ (<10% of T cells) heterodimers[65]. Antigen recognition by γ/δ T cells appears to be independent of classic MHC molecules, instead utilizing other MHC-like molecules (e.g. CD1) that preferentially present certain lipid and glycolipid antigens[66].

T cell receptor diversity

An amazing feature of the immune system is that it provides specific receptors for every possible peptide antigen. B cells are capable of producing approximately 10^{16} different antibody variable regions, and T cells generate a comparable number of TCR variable regions. Remarkably, these numerous proteins are encoded by fewer than 400 genes. This tremendous diversity is created via a unique recombination process that cuts, splices, and modifies genes in the variable region[67].

Four segments of genes are involved in TCR formation: the variable (V), diversity (D), joining (J), and constant (C) regions (see Fig. 4.4). In contrast to the TCRβ and TCRδ loci (both on chromosome 7), the TCRα and TCRγ loci (both on chromosome 14) do not contain D segments. The segments are cut out by nucleases and spliced together by ligases, ultimately forming the final gene sequence that encodes the receptor molecule. The tremendous diversity is explained by the multiplicity of all these regions within the genome (e.g. ~70–80 V genes and ~60 J genes for the TCRα alone), but only one of each type is used for a particular TCR.

Each lymphocyte utilizes a different combination of V, D, and J gene segments to form the genetic code of its antigen receptor. Any one of the genes can join with any other one to form the final VDJ region, thereby creating tremendous diversity. In addition, the recombination process is subject to inaccuracies during splicing, which cause slight variations at the VDJ junctions, and additional nucleotides can be inserted by the enzyme deoxyribonucleotidyl transferase at the spliced regions. These two events increase the diversity even further. Of note, only a tiny minority of these cells will become functional over a lifetime, with the vast majority dying without ever having met their antigen.

Defects in the *r*ecombination-*a*ctivating *g*enes *RAG1* and *RAG2*[68], which encode two of the enzymes that mediate the recombination of variable-region genes in both B cells and T cells, cause a form of severe combined immunodeficiency (see Ch. 60). Affected individuals are unable to produce lymphocytes bearing functional antigen receptors[69].

T cell receptor signaling

TCRs are associated with the CD3 complex, which transmits signals upon antigen binding. CD3 consists of CD3γ, CD3δ, two molecules of CD3ε, and a disulfide-linked CD3ζ homodimer[70]. Upon binding to the peptide–MHC complexes, TCRs become cross-linked (Fig. 4.7). Aggregation of the TCRs causes phosphorylation of tyrosines in the cytoplasmic tails of the CD3 complex, which contain *i*mmunoreceptor *t*yrosine-based *a*ctivation *m*otifs (ITAMs). Phosphorylation involves kinases such as Lck (which also binds to the cytoplasmic tails of CD4 and CD8), Fyn, and ZAP70 (see Fig. 4.7)[71]. These events ultimately lead to the transcriptional activation of genes that encode cytokines and induce cellular proliferation and differentiation.

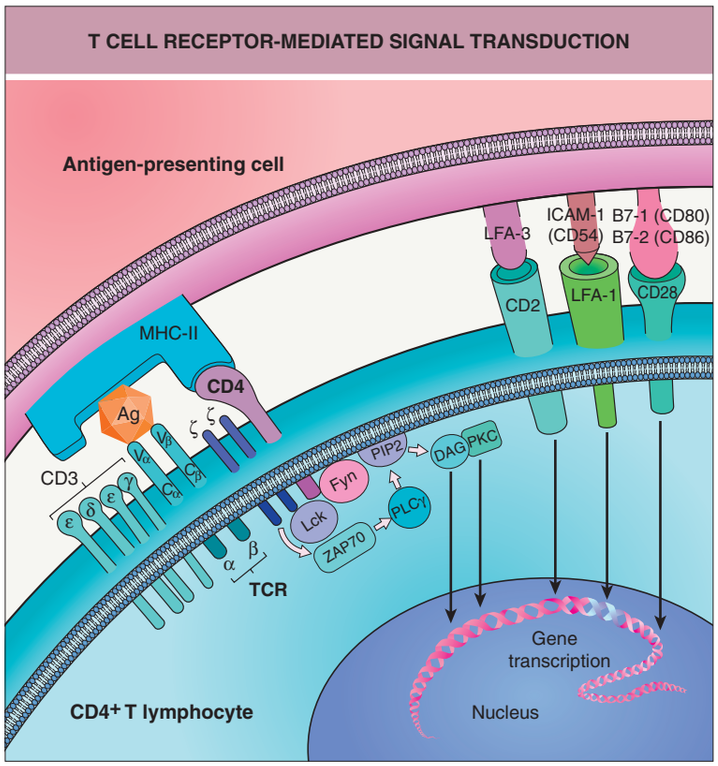

Fig. 4.7 T cell receptor-mediated signal transduction. Activation of the T cell receptor (TCR) by presentation of the appropriate antigen by antigen-presenting cells in association with MHC molecules induces a complex signal transduction cascade. The T cell receptor-associated signal transduction is primarily mediated by the CD3 complex and the ζ chain. Upon activation, the cytoplasmic tails of these molecules become phosphorylated by protein kinases (Lck, Fyn, ZAP70). This causes downstream signaling which ultimately leads to transcriptional activation of particular genes. Additional stimuli are provided by the signaling of costimulatory molecules (CD2, LFA-1, CD28). DAG, diacylglycerol; PIP2, phosphatidylinositol 4,5-bisphosphate; PKC, protein kinase C; PLC, phospholipase C.

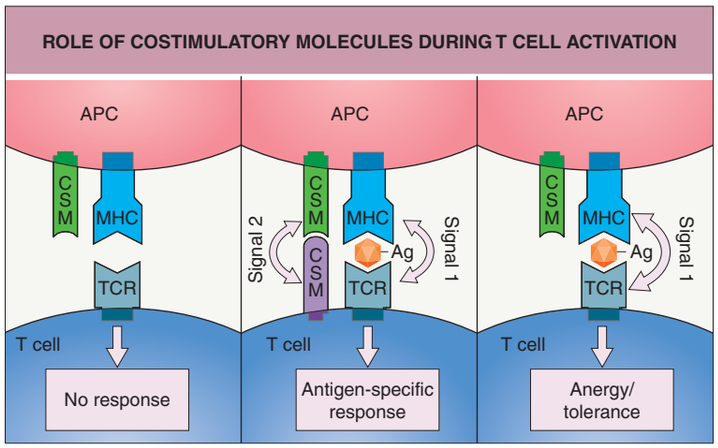

Fig. 4.8 Role of costimulatory molecules during T cell activation. Presentation of the antigen by antigen-presenting cells to the T cell receptor in association with MHC molecules delivers the first signal necessary for T cell activation. The second signal is provided by the interaction of costimulatory molecules present on antigen-presenting cells and T cells. An antigen-specific response is only induced when signal 1 and signal 2 are provided. Presentation of the antigen in the absence of signal 2 does not lead to an antigen-specific response but induces anergy and tolerance. APC, antigen-presenting cell; CSM, costimulatory molecule; MHC, major histocompatibility complex; TCR, T cell receptor.

COSTIMULATORY MOLECULES AND THEIR LIGANDS*

Receptor molecule	Expression†	Co-receptor molecule	Expression†
CD80 (B7-1)	APC	CD28, CD152 (CTLA-4)	T
CD86 (B7-2)	APC	CD28, CD152 (CTLA-4)	T
CD275 (ICOS-L, B7H2, B7h, B7RP1)	APC	CD278 (ICOS)	T
CD274 (PD-L1, B7H1)	APC	CD279 (PD-1)	T, B
CD273 (PD-L2, B7DC)	APC	CD279 (PD-1)	T, B
CD40	APC, B	CD154 (CD40L)	T
CD134 (OX40)	T	CD252 (OX40L)	APC, B
CD27	APC, T	CD70 (CD27L)	T, B
CDw137 (4-1BB)	T, B	4-1BBL	APC, B
CD265 (RANK)	APC	CD254 (RANKL, TRANCE)	APC, T
CD30	T, B	CD153 (CD30L)	T, B, APC
CD58 (LFA-3)	APC	CD2	T

*Only important costimulatory molecules and those with known ligands are included.
†Expression refers only to T cells (T), B cells (B), and antigen-presenting cells (APC) including dendritic cells and Langerhans cells.

B7 family | TNF receptor family | adhesion molecules

Table 4.3 Costimulatory molecules and their ligands. CTLA-4, cytotoxic T-lymphocyte-associated antigen-4; ICOS, inducible costimulator; LFA-3, lymphocyte function antigen-3; PD-L1, programmed death ligand 1; TNF, tumor necrosis factor.

Costimulatory signals

Signaling through the TCR complex alone is not sufficient for naive T cell activation. The presence of costimulatory signals is needed for T cells to undergo antigen-specific clonal expansion[72]. Hence, development of a productive T cell immune response requires at least two types of stimuli. The *first signal* is the interaction of the TCR with peptide–MHC complexes presented by APCs, which determines the specificity of the immune response. The *second signal* involves surface molecules and cytokines, which determine the clonal expansion of specific T cells and their differentiation into effector and memory cells (Fig. 4.8). Without these costimuli, signaling by the antigen receptors alone will either cause anergy (non-reactivity) or apoptotic cell death. The major receptors and ligands expressed on APCs and T cells that play a role in activation are listed in Table 4.3.

The most relevant accessory molecules belong to the B7-CD28 superfamily which includes the following receptor:ligand pairs – CD28/CTLA-4:CD80/CD86, ICOS:ICOS-L, and PD-1:PD-L1/PD-L2[73]. The best-investigated costimulators for T cells are B7-1 (CD80) and B7-2 (CD86)[74]. Both are induced on immature, resting APCs by various TLR ligands or by cytokines (e.g. TNF, IL-1). The CD28 receptor on T cells recognizes the B7 molecules and delivers activating signals, including the expression of antiapoptotic genes and the production of cytokines such as IL-2 (see Fig. 4.7). Interaction of ICOS (*i*nducible T cell *co*-stimulator; CD278) with ICOS-L (CD275) induces less IL-2 but promotes T helper cell differentiation and effector function through the production of IL-10, -4, -17, -21, and IFN-γ[73]. The ICOS:ICOS-L signaling pathway is also crucial for T cell-dependent B cell responses.

Cytotoxic T lymphocyte-associated antigen-4 (CTLA-4 [CD152]) also binds to the B7 molecules, with even higher avidity than CD28. However, unlike CD28 binding, cross-linking of CTLA-4 to B7 downregulates IL-2 production and cell cycle progression, whereas blockade of CTLA-4 signaling prolongs T cell activation. Hence, CTLA-4 is regarded as a T cell-associated co-receptor with negative regulatory effects[75]. PD-L1 (CD274) and PD-L2 (CD273) also deliver a co-inhibitory signal to T cells via PD-1 (*p*rogrammed *d*eath-*1*; CD279) and thus inhibit T cell proliferation and cytokine production. Through the expression of CTLA-4, PD-Ll, and PD-L2, tumor cells may escape an immune response. Neutralization of these inhibitory molecules by antibodies (e.g. anti-CTLA-4 [ipilimumab], anti-PD-1 [nivolumab, pembrolizumab, cemiplimab], anti-PD-L1 [avelumab]), referred to as immune checkpoint inhibitors, has proven to be a highly effective therapy for a variety of malignancies including metastatic melanoma (see Ch. 128). Many of the associated side effects of these therapies such as colitis, hepatitis, and hypophysitis are due to autoimmune phenomena.

If a T cell recognizes its specific antigen peptide in association with the appropriate MHC molecules and becomes activated by costimulatory signals, then cell division and clonal expansion occur. Cytokines, especially inflammatory mediators like IL-1, IL-6 and TNF, also provide costimulatory signals by themselves and, in addition, upregulate other costimulatory molecules. Hence, a T cell is much more likely to be activated if it meets its specific antigen via an APC that has been exposed to an inflammatory environment. Polarizing cytokines such as IL-4, IL-12, and IL-23 also critically influence the differentiation of naive T cells.

Memory cells

Memory T cells have a longer lifespan than effector cells and react more rapidly upon re-exposure to their specific antigen. While naive T cells express CD45RA, memory T cells are characterized by the expression of the surface molecule CD45RO. Two distinct subsets of human memory T cells have been described. Stationary, tissue-resident memory T cells that comprise resident memory T cells (Trms) and effector memory T cells (Tems). They express receptors for migration into inflamed tissues to fulfill their effector functions[76]. Both subsets express low or no levels of the lymph node homing receptor CCR7, preventing tissue egress. In contrast, $CCR7^+$ memory T cells comprise central memory T cells (Tcms) and migratory memory T cells (Tmms) and they have the potential to recirculate to lymph nodes. Tcms lack immediate effector function, but efficiently stimulate DCs to produce IL-12 and can differentiate into Tems upon secondary stimulation.

Organ-specific adhesion molecules guide memory T cells to various locations, including the skin[23,76]. It is estimated that human skin contains twice as many T cells as the blood (~20 billion T cells). In normal human skin, 2% to 3% of T cells reside within the epidermis while the bulk of T cells are in the dermis. The majority of T cells express the α/β TCR and either CD8 or CD4. Trms express the skin-homing receptor CLA (see below) as well as CD2, CD5, and CD45RO; they are CCR7-negative and can be CD4- or CD8-positive[77].

Trms play a major role in host defense against previously encountered antigens[78] and with infections can populate the entire skin surface[79]. Upon antigen encounter, Trms proliferate and clear the pathogen. Associated inflammation causes nonspecific recruitment of T cells from the bloodstream via endothelial cell activation; the few antigen-specific T cells recruited into the skin in this manner also contribute to the clearance of the pathogen. In addition, DCs carry the antigen to the skin-draining lymph nodes and present it to Tcms. This gives rise to new populations of skin-homing Tems which migrate to the skin and also participate in the clearance of the antigenic attack.

Trms differ from other memory T cells as they do not circulate back to lymph nodes once they are recruited to the skin due to encounters with pathogens. More recently, these long-lived cells have been shown to reside within human skin for a decade and are at least partially resistant to radiochemotherapy[80]. Despite their beneficial effect in rapid on-site clearing of infections, Trms have also been reported to enhance allergic and autoimmune skin diseases and play a role in skin cancer biology.

Conventional T cells

Two major types of effector T cells have been identified: $CD4^+$ T helper (Th) cells and $CD8^+$ cytotoxic T (Tc) cells. The former activate B cells and modulate important components of cell-mediated immune responses, mainly via cytokine production. $CD8^+$ Tc cells are crucial to antiviral and antitumor responses.

T helper cells

$CD4^+$ Th cells recognize "their" antigenic peptides in association with MHC class II molecules (see Fig. 4.4). Based primarily on differences in their cytokine secretion patterns, several types of Th cells have been described[81]. Naive precursor Th cells only produce IL-2 whereas preactivated precursor cells, called Th0, can release a wide variety of cytokines (e.g. IL-2, IFN-γ, lymphotoxin, IL-3, IL-4, IL-5, IL-6, IL-9, IL-10, IL-13, GM-CSF, TNF). As they develop into Th1, Th2 or Th17 cells, the cytokine secretion pattern becomes more restricted and specific (see below). More recently described Th9 and Th22 cells may represent separate types.

Morphologically, the cells in the various Th subsets are almost indistinguishable, although surface differences (especially in chemokine receptors) have been described[82]. Differentiation of naive Th cells into effector Th subsets is driven by well-defined transcription factors. However, Th cell differentiation into effector cells is not irreversible. Effector Th cells sustain plasticity and can differentiate into other subsets thereby flexibly adjusting to environmental changes[83].

Th1 cells: Typical Th1 cytokines are IFN-γ, lymphotoxin, and IL-2. IL-2 induces proliferation of $CD4^+$ cells in an autocrine manner and affects the cytokine differentiation pattern; however, it also stimulates $CD8^+$ T cell division and cytotoxicity, thereby providing "help" for $CD8^+$ Tc cells. IFN-γ activates macrophages to kill intracellular pathogens (e.g. mycobacteria, fungi, protozoa) and stimulates NK cell cytotoxicity. Therefore, Th1 cells are involved in the clearance of intracellular pathogens, and their cytokines preferentially induce a cell-mediated inflammatory response, such as the granulomatous lesions of tuberculosis or leprosy. Macrophages stimulated by IFN-γ release IL-12, the major cytokine that drives Th0 cells towards a Th1 phenotype (Fig. 4.9)[84]. In addition, the transcription factor T-bet drives differentiation towards the Th1 phenotype.

Th1 cells also promote the isotype switch of B cells to produce complement-binding antibodies and they contribute to the pathogenesis of autoimmune diseases such as rheumatoid arthritis, multiple sclerosis, allergic contact dermatitis, and psoriasis.

Th2 cells: Th2 cells are under the control of the transcription factor GATA3 and produce primarily IL-4, IL-5, and IL-13. These cytokines favor production of non-complement-binding antibodies. IL-4 switches B cells to produce IgE, and IL-5 promotes an expansion of eosinophils. Therefore, Th2 responses are often associated with allergic diseases. Comparable to the role of IL-12 in inducing Th1 responses, IL-4 is the key cytokine in driving Th2 responses (see Fig. 4.9). In addition, IL-4 suppresses Th1 and Th17 differentiation. However, IL-4 seems to exert opposing effects on $CD4^+$ T cells and DCs, since it can stimulate DCs to produce IL-12 and thus paradoxically promote Th1 development[85].

Many TLR signals and infections are strong inducers of IL-12 and therefore favor a Th1 response. However, other TLR signals to DCs and early production of IL-4 favor the generation of Th2 cells. Additional factors that influence the Th1/Th2 decision include the dose of the antigen, the APCs involved[39], the cytokines secreted (by APCs and bystander cells), the genetic background of the host, and the presence of costimulatory molecules. Of note, many immune responses are not strongly polarized in the Th1 or Th2 direction.

Th9 cells: In response to TGF-β and IL-4, $CD4^+$ T cells secrete IL-9. The development of Th9 cells depends on the IL-4-activated transcription factor PU.1. Th9 cells predominantly reside in human skin and are involved in protecting against pathogens, but also play a role in allergic and non-allergic inflammatory skin diseases[86]. In addition, they contribute to extracutaneous allergic diseases in that IL-9 is highly expressed in the lungs of asthmatic patients, especially children.

Th17 cells: $CD4^+$ T cells that produce IL-17, but not IFN-γ or IL-4, are referred to as Th17 cells[87]. Besides IL-17A, these cells also secrete IL-17F, IL-21, IL-22, IL-25 and IL-26. Whereas the heterodimeric cytokine IL-12 (consisting of a p35 chain and a p40 chain) is crucially involved in the development of Th1 cells, the IL-12-related cytokine IL-23 (consisting of a p19 chain and the same p40 chain; see Fig. 128.9) is essential for the generation of Th17 cells. Naive T cells do not express the IL-23 receptor. In mice, a combination of TGF-β and IL-6 induces expression of the transcription factor *r*etinoid acid receptor-related *o*rphan *r*eceptor-γt (ROR-γt), which stimulates transcription of the IL-17 gene and expression of the IL-23 receptor (see Fig. 4.9). IL-6 and IL-23 enhance the expression of IL-17 and IL-22 and suppress production of IL-10 and IFN-γ, thereby stabilizing the Th17 phenotype. IL-21 is also produced in large amounts by mature Th17 cells and amplifies Th17-cell differentiation[87]. In human T cells, combinations of TGF-β plus IL-21, TGF-β plus IL-6 and IL-23, or IL-6 plus IL-21 appear to be involved in the differentiation of Th17 cells by inducing the expression of ROR-c, the human analogue of murine ROR-γt.

Th17 cells are rapidly induced in response to infectious agents – in particular, bacteria and fungi. Patients with a defective Th17 response due to mutations in the gene encoding *s*ignal *t*ransducer and *a*ctivator of *t*ranscription 3 (STAT3), another transcription factor involved in Th17 cell development (see Fig. 4.9), have hyperimmunoglobulin E (hyper-IgE) syndrome and suffer from recurrent *Candida albicans* and *Staphylococcus aureus* infections of the skin and lungs (see Ch. 60)[88]. Th17 responses have important roles in chronic inflammation and in mediating autoimmune reactions. There is evidence that Th17 cells are involved in rheumatoid arthritis, psoriasis, multiple sclerosis, and inflammatory bowel diseases[87]. Genetic studies have linked variants of

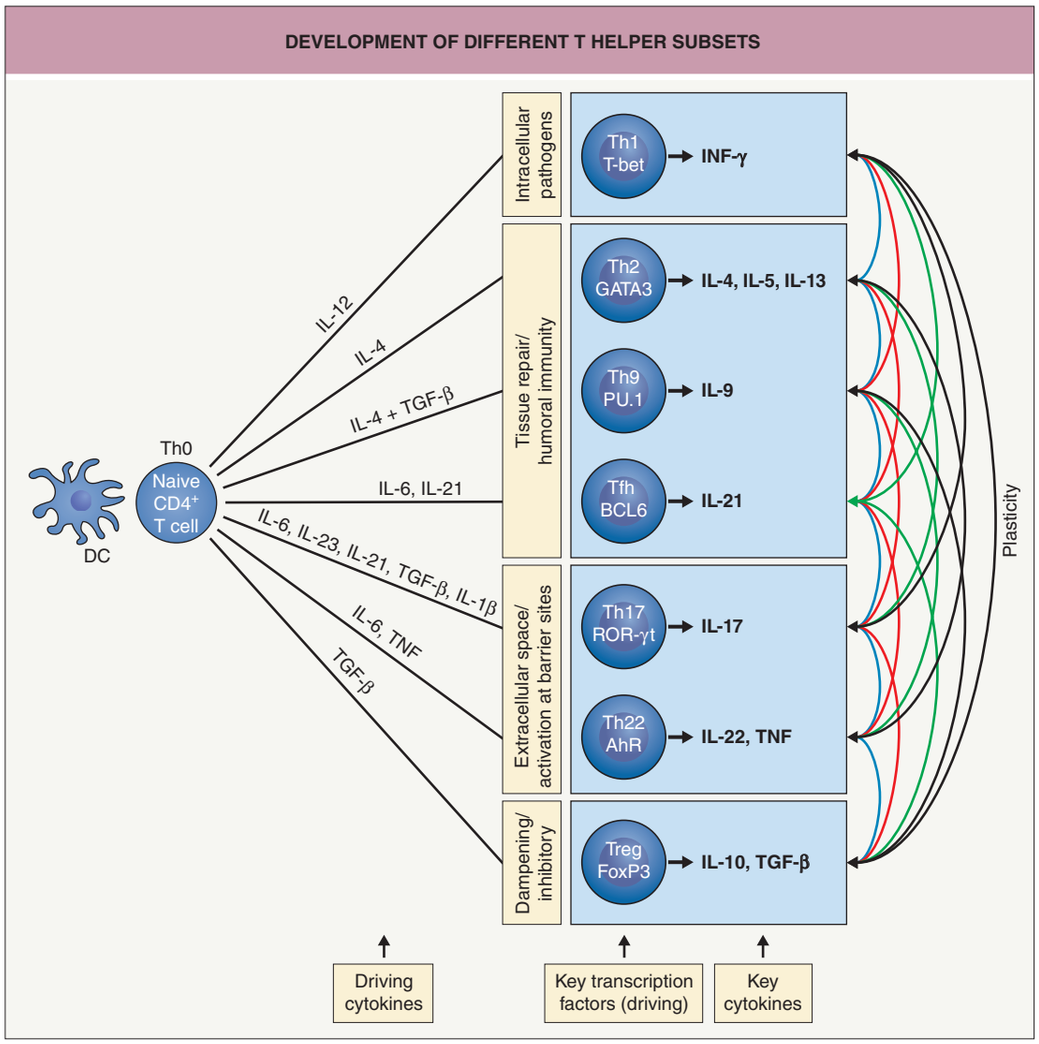

Fig. 4.9 Development of different T helper subsets. Key cytokines drive the differentiation of naive T helper (Th) cells into various Th cell subtypes. Th cell differentiation is non-linear and highly plastic, thus allowing trans-differentiation of already committed cells into other subtypes (plasticity model). Each $CD4^+$ T cell subtype is depicted with its major driving cytokines (e.g. IL-12, IL-4, TGF-β) and fate-determining transcription factors (e.g. T-bet, GATA3, PU.1, BCL6, ROR-γt, AhR), which direct differentiation. There are additional transcription factors (e.g. STAT3) that play an important role. Differentiated Th cells secrete unique cytokines that influence other immune cells. Th1 cells are crucial for T cell-mediated immunity against intracellular pathogens whereas Th2, Th9, and Tfh cells support the development of humoral immunity and provide assistance in tissue repair. Th17 and Th22 cells are activated at barrier sites, such as the skin and gut mucosa, to protect the extracellular space and are involved in chronic inflammatory and autoimmune reactions. Tregs are crucial for maintaining immune homeostasis by dampening immune reactions. AhR, aryl hydrocarbon receptor; BCL6, B cell lymphoma 6; FoxP3, forkhead box P3; GATA3, transcription factor that binds to the DNA sequence "G-A-T-A"; IL, interleukin; IFN-γ, interferon-γ; PU.1, transcription factor that binds to purine-rich DNA sequence (PU-box); ROR-γt, retinoid acid receptor-related orphan receptor-γt; T-bet, T-box expressed in T cells; Tfh, T follicular helper cell; TGF-β, transforming growth factor-β; Th, T helper, Treg, T regulatory. *Adapted from Tuzlak S, Dejean AS, Iannacone M, et al. Repositioning TH cell polarization from single cytokines to complex help. Nat Immunol 2021;22:1210–7 and O'Shea JJ, Paul WE. Mechanisms underlying lineage commitment and plasticity of helper CD4+ T cells. Science 2010;327:1098–102.*

the IL-23 and IL-23 receptor genes to susceptibility for psoriasis and psoriatic arthritis[89]. Since IL-23 enhances IL-17 production, inhibition of IL-23 is a target for therapeutic intervention. Indeed, the monoclonal antibody ustekinumab, which is directed against the common p40 chain and therefore blocks signaling by both IL-12 and IL-23, represents an effective treatment for psoriasis[90] as do guselkumab, tildrakizumab and risankizumab which target the p19 chain of IL-23; the same applies for agents blocking either IL-17A (ixekizumab, secukinumab) or the IL-17 receptor (brodalumab) (see Fig. 128.9).

Th22 cells: A subset of human $CD4^+$ Th cells characterized by secretion of IL-22 and TNF (in the absence of IFN-γ, IL-4, or IL-17) are termed Th22 cells and are potentially under the control of AhR, the aryl hydrocarbon receptor transcription factor which links extracellular signals to cellular responses via ligand-induced translocation from the plasma membrane to the nucleus[91]. IL-22, a member of the IL-10 cytokine family, binds to a heterodimeric receptor, which is expressed by non-hematopoietic cells including keratinocytes. IL-22 induces the expression of antimicrobial peptides (e.g. S100 proteins, defensins) as well as inflammatory chemokines and cytokines including IL-6. IL-22 is also involved in tissue repair by inducing epithelial cell proliferation and enhancing cell survival. IL-22 and Th22 cells appear to play an important role in psoriasis since IL-22 is highly expressed in psoriatic plaques and neutralization of IL-22 prevented the development of lesions in a murine model of psoriasis[92]. Tapinarof, an AhR agonist, was recently introduced as a topical treatment for psoriasis.

T follicular helper cells (Tfh): Tfh cells mainly produce IL-21 and this cytokine in turn drives their differentiation via the master transcription factor Bcl-6. Although Tfh cells reside primarily within secondary lymphoid organs where they aid B cell functions, skin DCs can also drive their expansion[93]. Little is known about their role in skin pathologies beyond a suggested involvement in skin fibrosis[94].

Cytotoxic T cells

Cytotoxic T (Tc) cells are $CD8^+$, recognize "their" antigenic peptides in association with MHC class I molecules, and can directly lyse their targets (e.g. virally infected or tumor cells). For example, virally infected cells present peptides derived from intracellular viral proteins on MHC class I molecules, and Tc cells that recognize this viral peptide–MHC complex are stimulated to kill the infected cell. Tc cells have at least three different pathways of killing[95], two of which involve direct contact with the target cell. In one method, Tc cells insert perforins into the membrane of the target cell; this creates pores in the membrane, through which granzymes are released from the Tc cell into the target cell. Granzymes then activate caspases which are proteolytic enzymes that induce apoptosis in the target cell. In a second mechanism, Tc cells activate the death receptor Fas (CD95) on the target cell by expressing the cognate death ligand FasL (CD95L). Activated Fas also triggers apoptosis in the target cell. The third pathway is mediated by cytokines, including TNF and IFN-γ, which are released as long as TCR stimulation continues. These mediators can affect distant cells as well as the target cell[95].

Naive $CD8^+$ T cells (Tc0 cells) can develop into Tc1, Tc2, Tc9, Tc17, and Tc22 cells[96]. Comparable to Th1 and Th2 cells, Tc1 and Tc2 cells are differentiated based on their different cytokine secretion patterns. However, their exact functional roles in skin still remain to be determined. Even though there is evidence that some $CD8^+$ T cells exhibit suppressor functions[97], most $CD8^+$ Tc1 and Tc2 cells develop a cytotoxic phenotype.

Regulatory T cells

Regulatory T cells (Tregs) were discovered by the observation that chronic activation of $CD4^+$ T cells in the presence of IL-10 induced $CD4^+$ T cell clones with a low proliferative capacity that produced high

levels of IL-10, low levels of IL-2, and no IL-4[98]. These antigen-specific T cell clones suppressed the proliferation of $CD4^+$ T cells in response to antigen and prevented T cell-mediated colitis in SCID mice. This $CD4^+$ T cell subset was designated T regulatory cells 1 (Tr1).

Another subset of $CD4^+$ Treg is characterized by the constitutive expression of the α-chain of the IL-2 receptor (CD25). Some $CD4^+CD25^+$ Tregs are generated in the thymus and become activated upon re-encountering their antigen in the periphery. Thymectomized mice that do not develop $CD4^+CD25^+$ T cells develop autoimmune diseases[99]. In turn, reinjection of such cells prevents the development of the autoimmune phenomena, indicating that the $CD4^+CD25^+$ cells prevent autoimmunity and thus can act in a suppressive fashion. FoxP3, a transcription factor whose inherited dysfunction leads to an autoimmune and inflammatory syndrome in humans (IPEX: *i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked) and mice (*Scurfy* strain), is specifically expressed in naturally arising $CD4^+CD25^+$ Tregs[100]. Retroviral gene transfer of *Foxp3* converts naive T cells toward a Treg phenotype. Thus, *Foxp3* is a key regulatory gene in the development of Tregs.

Natural Tregs (*nTregs*) are produced in the thymus as a functionally mature subpopulation of T cells and constitute ~10% of all murine peripheral $CD4^+$ T cells[101]. *Induced Tregs* (*iTregs*) can also develop from naive T cells in the periphery through several mechanisms (Fig. 4.10). Immature DCs appear to be involved in the generation of human iTregs. Upon repeated stimulation by immature DCs, allogeneic $CD4^+$ T cells have been shown to: express the negative regulatory molecule CTLA-4; lose their capacity to produce IFN-γ, IL-2, or IL-4; and differentiate into non-proliferating, IL-10-producing T cells[48]. In co-culture experiments, these T cells inhibited the antigen-driven proliferation of Th1 cells in a cell contact-dependent manner. The same may apply for damaged APCs, since the migration of UV-damaged LCs is required for the generation of Tregs by UV radiation[102].

Together, these findings show that immature and mature DCs induce different types of T cell responses: (1) mature, IL-12-producing DCs result in inflammatory Th1 cells; (2) less well-defined "DC2s" result in Th2 cells; and (3) immature or damaged DCs result in IL-10-producing iTregs. These observations provide evidence for constant control of peripheral tolerance to self-antigens[103]. In this scenario, immature DCs constantly take up proteins from normal cells as they undergo regular cell turnover. In the absence of inflammatory signals, DCs do not mature and therefore enter the regional lymph nodes in an immature stage. Self-antigens expressed on immature DCs lead to the development of Tregs, which then migrate to the respective organ where they exhibit suppressive effects. During an infection, immature DCs take up self-antigens and mature in the presence of TLR and inflammatory signals. In the regional lymph nodes, the mature DCs prime naive $CD4^+$ or $CD8^+$ T cells, which become effector T cells. These cells re-migrate to the initial site of inflammation, where they encounter the inhibitory effects of Tregs that are already present. This process normally prevents the development of autoimmunity under both normal and inflammatory conditions.

Tregs exert their suppressive functions in several ways[101] (see Fig. 4.10). They release inhibitory cytokines (e.g. IL-10, IL-35, TGF-β) and can induce apoptosis of target effector T cells via perforin and granzymes. Tregs also interfere with metabolic functions in their target T cells by depriving them of IL-2 (which results in apoptosis), increasing their intracellular levels of cAMP (which inhibits T cell proliferation and IL-2 production), and increasing pericellular levels of adenosine (which is cytotoxic). Furthermore, negative regulation of the maturation and function of APCs occurs through the interaction of CTLA-4 and lymphocyte-activation gene-3 (LAG-3) on Tregs with CD80/CD86 and MHC class II ligands, respectively, on APCs. Induction of the tryptophan-degrading enzyme indoleamine 2,3-dioxygenase (IDO) in DCs has been suggested as another mechanism by which Tregs exert suppression.

Tregs colonize the skin soon after birth, and in a mouse model, hair follicle morphogenesis and the presence of commensal microbiota within the follicles are essential for this process[104]. This hand-in-hand accumulation of bacteria and Tregs in and around skin appendages allows for induction of tolerance to commensals and is essential in maintaining skin homeostasis. Later in life, $FoxP3^+$ Tregs predominantly localize around hair follicles in both human and mouse skin. They promote hair follicle cycling via modifying stem cell activation and differentiation as well as regulating wound healing by controlling inflammatory responses at the hair follicle-stem cell niche[105,106].

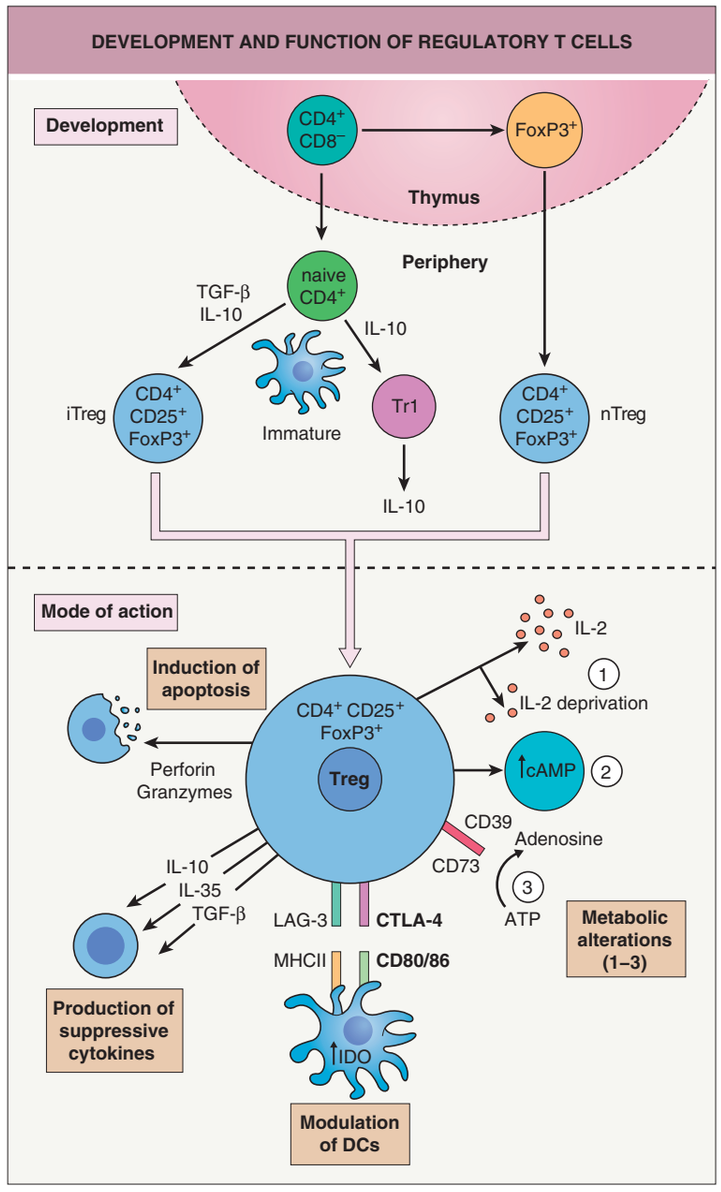

Fig. 4.10 Development and function of regulatory T cells. Natural regulatory T cells (nTregs), which express CD4, CD25 and FoxP3, develop from $CD4^+CD8^-$ T cells in the thymus. In the periphery, naive conventional $CD4^+$ T cells (in the presence of interleukin [IL]-10 and/or transforming growth factor-β [TGF-β]) can develop into $FoxP3^-$ regulatory type 1 cells (Tr1) or induced regulatory T cells (iTregs) that express CD24, CD25, and FoxP3. Tregs exert their inhibitory functions in several ways. They release inhibitory cytokines (e.g. IL-10, IL-35, TGF-β), induce apoptosis of their target effector T cells via release of granzymes and perforin, and interfere with metabolic functions of their target T cells. The latter can be accomplished by: (1) IL-2 deprivation, which triggers apoptosis; (2) transferring cAMP, which inhibits proliferation and IL-2 production, into target cells; and (3) increasing pericellular levels of cytotoxic adenosine via conversion of ATP to adenosine by CD39 and CD73, two ectonucleotidases expressed on the surface of Tregs. Tregs also modulate dendritic cell (DC) maturation and function via interaction of cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) and lymphocyte-activation gene-3 (LAG-3) on Tregs with their ligands CD80/CD86 and MHC class II, respectively, on DCs and induction of the tryptophan-degrading enzyme indoleamine 2,3-dioxygenase [IDO] in DCs. *Adapted from Workman CJ, Szymczak-Workman AL, Collison LW, et al. The development and function of regulatory T cells. Cell Mol Life Sci 2009;66:2603–22 and from Sakaguchi S, et al. Regulatory T cells and immune tolerance. Cell 2008;133:775–87.*

Unconventional T cells

Natural killer T cells

NK T cells are a distinct subset of peripheral T cells that have characteristics of both T cells and NK cells[107]. They express the NK cell marker

NK1.1 and an invariant TCR restricted to CD1d. NK T cells produce various cytokines, including IFN-γ, IL-4, and IL-10. They are present in the thymus during early stages of ontogeny and are probably involved in the differentiation of various T cell subsets, especially Th2 cells. Since NK T cells are numerically and functionally deficient in mice with autoimmune diseases, they may also play a role in the control of autoimmunity.

Invariant NK T (iNKT) cells express an invariant TCR α chain and recognize endogenous and foreign antigens, such as bacterial lipid antigens presented by CD1d. They secrete Th1-, Th2-, or Th17-specific cytokines and modulate effector functions of NK cells, DCs, macrophages, B cells, and T cells.

γ/δ T cells

Under normal conditions, the vast majority of T cells found in the skin belong to the α/β type, but a subset of T cells carries a TCR composed of γ and δ (rather than α and β) protein chains. Although in normal skin γ/δ T cells were long thought to be found exclusively within the epidermis, more recent evidence has shown that a subset resides in the dermis, where they are involved in responses against bacterial infections[108]. In certain infectious diseases such as leprosy and leishmaniasis, γ/δ T cells can account for almost one-third of the T cells infiltrating the skin. The precise functional role of γ/δ T cells remains to be determined, but they may be involved in the recognition of non-peptide moieties expressed by microbial pathogens[109]. γ/δ T cells depend on IL-7 signaling for their maintenance and predominantly recognize lipid antigens. Skin inflammation quickly results in γ/δ T cell activation and IL-17 production followed by neutrophil recruitment and bacterial clearance[110].

Dendritic epidermal γ/δ T cells

$CD3^+$ lymphocytes found in the epidermis of mice have a dendritic shape and are therefore termed dendritic epidermal T cells (DETCs)[111]. These murine DETCs express a γ/δ type of TCR with limited diversity. The same TCR configuration is detected in early thymocytes, giving rise to speculation that fetal thymocytes are the progenitors of DETCs; alternatively, maturation could take place in the skin. DETCs are thought to protect stressed keratinocytes and they exhibit NK cell function, but also downregulate T cell responses. However, despite extensive studies, to date the functional role of DETCs has not been fully elucidated, and a human equivalent of DETCs has not yet been identified.

Mucosal associated invariant T cells

Mucosal associated invariant T (MAIT) cells share features of innate and adaptive cells. MAIT cells recognize riboflavin-derived antigens that are presented by MR1, a MHC-like protein. Classical MAIT cells are present in human blood and also colonize tissues that are in cross-talk with commensal microbiota. They secrete a plethora of cytokines, including IFN-γ, TNF, IL-2, and IL-17A, and they play a role in infections, autoimmune diseases, and allergic and inflammatory disorders[112]. In human skin, MAIT cells are also important for tissue repair and require the presence of riboflavin-synthesizing bacteria in the microbiota to colonize the skin early in life[113].

Lymphocyte recruitment

A major challenge for T lymphocytes is to be at the right place at the right time in order to find and recognize cognate antigen. Naive lymphocytes encounter their antigens for the first time in secondary lymphoid organs, while memory cells can also do this in the periphery. Naive T cells continuously recirculate between the blood and lymphoid organs[114]. Expression of the surface molecule L-selectin (CD62L) allows naive T cells to attach to and roll on the inner surface of the high endothelial venules, specialized postcapillary venules within the lymph nodes and Peyer's patches. The venules express the secondary lymphoid-tissue chemokine (SLC/CCL21)[115] which interacts with the chemokine receptor CCR7. Subsequently, T cells adhere tightly to these high endothelial venules via interaction of endothelial intercellular adhesion molecule-1 (ICAM-1, CD54) with lymphocyte function antigen-1 (LFA-1, CD11a). This is followed by transmigration into the T cell areas of the lymph node. The T cells can then return to the bloodstream by leaving the lymph node via efferent lymphatics.

Upon activation by APCs presenting cognate antigenic peptides, T cells start to proliferate and begin to express activation molecules, thereby developing into effector/memory T cells. During this process, they express new surface molecules that allow them to exit the blood vessels and enter extranodal tissues[116]. A hallmark of activated T cells is their ability to "remember" the anatomic location that the lymph node was draining. Due to the expression of specific adhesion molecules, they exhibit the capacity to migrate primarily into the sites where the antigen was first encountered by the host. Hence, lymph nodes draining different organs generate distinct, "tissue-specific" memory T cells.

Memory T cells entering the skin express *cutaneous lymphocyte antigen* (CLA), whereas memory T cells found in other tissues are primarily CLA-negative. CLA is generated by modification of the pre-existing P-selectin glycoprotein ligand-1 (PSGL-1, CD162) by glycosylation enzymes[117]. The function of CLA is to allow the early tethering of T cells to the endothelium of cutaneous postcapillary venules, leading to the slowing, arrest, and then extravasation of the T cells. The endothelial ligand for CLA is E-selectin (CD62E), which is constitutively expressed at low levels on cutaneous microvessels and highly upregulated during inflammation. Although interaction between CLA and E-selectin is an important initial step, it does not suffice for transmigration. Interactions of LFA-1 and the β-integrin very late antigen-4 (VLA-4) on T cells with ICAM-1 (CD54) and VCAM-1 (CD106), respectively, on endothelial cells produce the firm adhesion required for extravasation of T cells from the blood into the skin (see Ch. 102).

CLA^+ T cells often co-express CCR4[118]. CCR4 binds the ligand CCL17, which is present in a steady state on cutaneous vasculature and upregulated on keratinocytes and dermal fibroblasts in inflammatory skin diseases, such as atopic dermatitis or psoriasis[119]. CCR4-CCL17 binding arrests rolling T cells and enhances T cell adhesion to the endothelium for efficient extravasation into tissue. Approximately 50% of skin-resident memory T cells also express the chemokine receptor CCR8. Upon exposure to dermal DCs in combination with IL-7 and IL-15, $CCR8^+$ T cells markedly proliferate, a hallmark of homeostatic proliferation of Trms[120]. CCL1, the ligand of CCR8, is expressed on epidermal LCs and vascular endothelial cells and may also be involved in homeostatic immune cell migration in healthy skin[119].

B Cells

The major task of B cells is the production of immunoglobulins (antibodies) that bind to specific antigens. Antibodies also interact with components of the innate immune system by preventing foreign organisms from adhering to mucosal surfaces, by activating complement, and by opsonizing bacteria for phagocytosis. Immunoglobulins are secreted products of mature B cells. However, during early B cell development, immunoglobulins function as antigen-specific B cell receptors on the cell membrane, equivalent to the TCR on T cells. CD19, CD20, and CD22 are the major markers currently used to identify B cells. Activation of B cells results in cell division and maturation into plasma cells, which secrete specific antibodies during humoral immune responses. Although B cells are infrequently found in healthy skin, they may play an incompletely understood role in pro- and anti-inflammatory processes associated with skin cancer, atopic dermatitis, psoriasis, and delayed-type hypersensitivity reactions[121].

Immunoglobulins

Immunoglobulins consist of two identical heavy chains and two identical light chains, linked together by disulfide bonds[122] (Fig. 4.11). The N-terminus of each chain contains a variable domain that binds the antigen through three hypervariable complementarity-determining regions (CDRs). The C-terminal domains of the heavy and light chains form the constant regions. Five classes of immunoglobulin (IgG, IgA, IgM, IgD, and IgE) are defined by the amino acid sequences of the constant regions of the heavy chains. The designation of κ or λ depends on the constant region of the light chain. The class/subclass and titer of the antibody that is formed depend on: the physical and chemical properties of the antigen; the site, duration, repetition, and amount of antigen exposure; and the individual's propensity to recognize the antigen as foreign.

Digestion of immunoglobulins with the enzyme papain yields an antigen-binding fragment termed Fab and a fragment that spontaneously crystallizes with time and thus is called the Fc portion. Immunoglobulins are divalent, since twice as many Fab fragments than Fc portions are obtained upon cleavage with papain. Digestion of

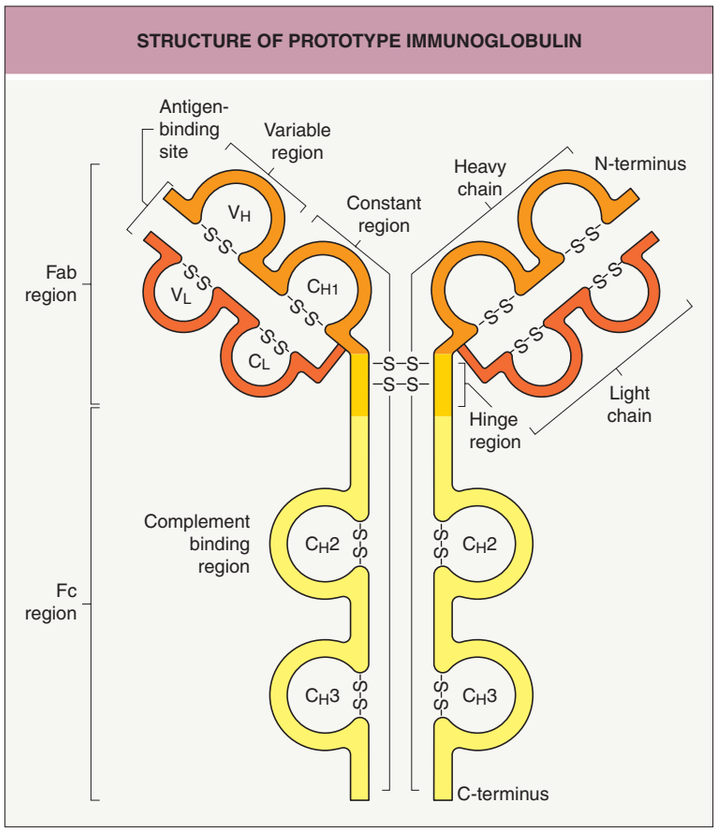

Fig. 4.11 Structure of a prototype immunoglobulin. The basic immunoglobulin structure consists of two identical light polypeptide chains and two identical heavy polypeptide chains, which are linked together by disulfide bonds. The antigen-binding site is at the N-terminal end.

immunoglobulins with pepsin provides Fab fragments that are disulfide bond-linked and thus called F(ab) fragments.

Through their CDRs, antibodies recognize the conformational structure of their epitopes. No antigen processing is required. As for the TCR, extensive gene rearrangement involving V, D, and J regions allows the generation of a nearly infinite variety of immunoglobulins specific for any putative antigen[67] (see T cell receptor diversity above). An even greater repertoire of B cell receptors than TCRs is produced, since further gene rearrangement of immunoglobulins occurs during B cell division after antigen stimulation, a process called somatic hypermutation.

The ability to induce effector functions resides in the Fc portion of the heavy chain. The Fc portion of IgG contains domains called C_H1, C_H2 and C_H3 for IgG. Complement activation is mediated via the C_H2 domain, while binding to macrophages or monocytes is mediated via the C_H3 domain. Binding of the Fc portion of IgG to phagocytic cells via their Fcγ receptors promotes phagocytosis of antibody–antigen complexes. Three receptors for human IgG exist. FcγRI (CD64) binds monomeric IgG with a high degree of affinity. FcγRII (CD32) is broadly distributed on cells and binds only complexed IgG with a low degree of affinity. FcγRIII (CD16) is expressed on macrophages, NK cells, and some T cells, and it interacts with both monomeric and complexed IgG. IgA binds only to the FcαR (CD89), while IgE can bind to three surface molecules: FcεRI, FcεRII (CD23), and the IgE-binding protein.

Immunoglobulin M

IgM is the major immunoglobulin produced in primary immune responses. With a size of ~900 Da, IgM is the largest immunoglobulin. IgM molecules are pentamers that contain one J chain in addition to light and heavy chains. Upon binding to its antigen, IgM induces agglutination and activates the classical complement pathway.

Immunoglobulin G

IgG is the most abundant immunoglobulin, accounting for ~75% of the total amount of serum immunoglobulin, and it is the major immunoglobulin of the secondary immune response. Four subclasses (IgG1, IgG2, IgG3, IgG4) are defined by the amino acid sequences of their constant region. They differ in their ability to activate complement. While IgG1 and IgG3 are potent activators of the classical complement pathway, IgG2 is less effective and IgG4 lacks such ability. In addition, IgG1 and IgG3 bind more avidly to mononuclear cells, i.e. they are more cytophilic. Most of the autoimmune dermatoses caused by autoantibodies are mediated by IgG, most often IgG4.

Immunoglobulin A

IgA is the predominant immunoglobulin present in mucosal surfaces, where it protects the host from invasion of microorganisms. IgA can activate the complement system via the alternative (but not the classical) pathway. Two subclasses of IgA exist, IgA1 and IgA2. IgA molecules can be joined by a J chain; this dimer form is mostly found in secretions, while in the serum, IgA circulates primarily as a monomer. IgA molecules can be involved in the pathogenesis of bullous autoimmune diseases.

Immunoglobulin E

IgE is the classic anaphylactic antibody that mediates most immediate allergic and anaphylactic reactions. Although in normal serum IgE is present in only small amounts (10–70 mcg/100 ml), just a few molecules appear to be required for sensitization. Mast cells and basophils express high-affinity receptors for the Fc portion of IgE (FcεRI). Antigens, anti-IgE antibodies, or other substances that cross-link at least two IgE molecules bound on mast cells induce the release of mediators such as histamine, serotonin, leukotrienes, and prostaglandins (see Ch. 18).

In addition to mast cells and basophils, several other cell types such as LCs[37], dermal DCs, and peripheral blood DCs can bind monomeric IgE via the high-affinity FcεRI[123]. Both quantitatively and qualitatively, FcεRI is the crucial serum IgE-binding structure on APCs of atopic individuals and functions as an allergen-focusing molecule. Allergens are more efficiently taken up, processed, and presented to T cells following targeting to APCs via the FcεRI. Thus, FcεRI-IgE-dependent allergen presentation may lower the threshold to elicit allergen-specific T cell responses in atopic individuals[115]. This may perpetuate allergen-specific IgE production and even modulate T cell-mediated delayed-type hypersensitivity reactions in allergen-exposed tissues.

The second IgE receptor, FcεRII (CD23), exhibits weaker binding affinity and is expressed on macrophages, eosinophils, platelets, and particular subtypes of T and B cells. Macrophages stimulated via activation of FcεRII exhibit increased phagocytic and cytotoxic activity; secrete prostaglandins, leukotrienes, and lysosomal enzymes; and generate superoxides.

Immunoglobulin D

The function of IgD is mysterious. Secreted IgD has a short half-life of 2–3 days and does not activate the complement system, but may recruit lectins[124]. More recent evidence suggests that IgD participates in respiratory immune defense[125]. It binds to basophils and mast cells, stimulating their production of antimicrobial factors. IgD may also exert proinflammatory functions, as illustrated by the hyperimmunoglobulinemia D with periodic fever syndrome (HIDS; see Table 45.2).

B cell activation

B cells can respond to some antigens in a T cell-*independent* manner[126]. Such antigens have numerous repeating epitopes (mainly polysaccharides), which bind and cross-link multiple B cell receptors and activate the B cells directly to secrete IgM. However, this response is limited to IgM and is of short duration and poor specificity due to the lack of germinal center formation, affinity maturation, Ig class switching, and memory.

Most B cell responses are activated in a T cell-*dependent* manner. Upon recognition by the specific IgM on the B cell surface, the antigen is internalized, processed, and re-expressed within the MHC class II molecule on the surface. As a result, the B cell can present the antigen to a specific T cell. Primed Th cells, in turn, secrete cytokines (IL-2, IL-4, IL-5, IL-6, IFN-γ) that function as B cell growth factors, inducing proliferation, isotype switch, and maturation to plasma cells. Activation of CD40 (expressed on B cells) by CD40 ligand (CD154; expressed on T cells) is needed for isotype switching from the initial IgM to an IgG response (Fig. 4.12). Once the switch from IgM to another isotype has occurred, some of the activated cells become long-lived memory cells

that can rapidly produce antibodies upon re-challenge with the same antigen. Mutations in the genes encoding CD40 ligand and CD40 are associated with forms of primary immunodeficiency known as hyper-IgM syndromes, which are characterized by low or undetectable levels of IgG, IgA, and IgE but elevated levels of IgM (see Ch. 60).

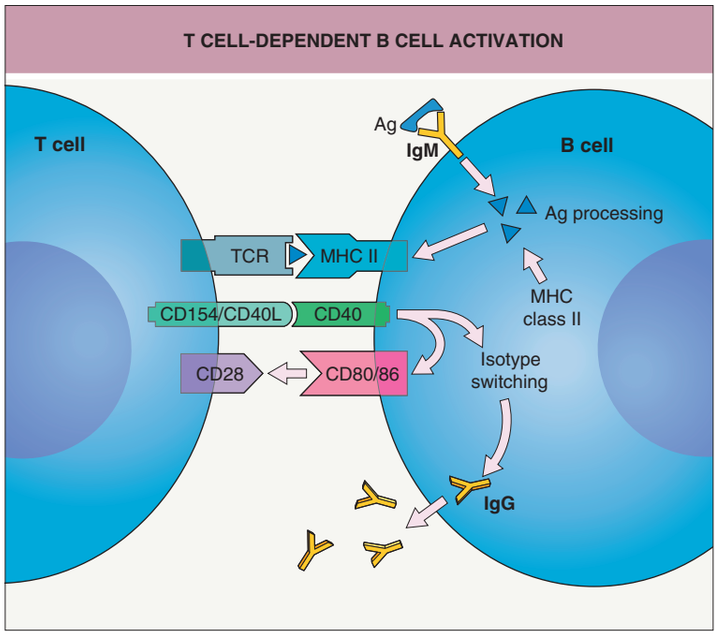

Fig. 4.12 T cell-dependent B cell activation. B cells present the antigen in association with MHC II molecules to $CD4^+$ T cells. This results in the upregulation of CD154/CD40 ligand which interacts with CD40 expressed on B cells. CD40–CD40 ligand interaction causes isotype switching of immunoglobulins and upregulation of CD80/86 which interacts with CD28 expressed on T cells. This results in further activation of T cells. Ag, antigen; CD40L, CD40 ligand; Ig, immunoglobulin; MHC II, major histocompatibility complex II.

Upon subsequent antigen exposure, B cells become activated by follicular DCs, which are located in the germinal centers of the lymph nodes. Follicular DCs bear Fc and complement receptors and bind immune complexes. In contrast to "conventional" DCs, follicular DCs do not endocytose and process antigens. Instead, they trap antigen–antibody complexes and provide intact antigen for interaction with the B cell receptor. This interaction stimulates B cell activation and differentiation. In addition, follicular DCs form immune complex-coated bodies (iccosomes) that are taken up by B cells. Upon processing, B cells present this follicular DC-derived antigen to T cells and thus may obtain T cell assistance[127].

Allergic Contact Hypersensitivity

Allergic contact hypersensitivity (CHS) is highly relevant for dermatologists, since it is the pathogenic basis for allergic contact dermatitis, a frequent inflammatory dermatosis. In addition, important basic immunologic discoveries have been made utilizing the model of CHS[128].

Induction of CHS

Most contact allergens are low-molecular-weight chemicals that, after penetrating the skin, have to couple with host proteins to be able to act as full antigens. This process is called haptenization, and the low-molecular-weight allergens are referred to as haptens. Upon epicutaneous application of a hapten in a naive host, APCs in the skin take up the hapten, migrate to the regional lymph nodes and present it to naive T cells (Fig. 4.13). Although this was previously thought to be done only by LCs, it has been established that other cutaneous APCs (e.g. dermal DCs) can present antigens, and the role of LCs as the primary APC in the skin is currently under debate (see Antigen presentation above).

During the emigration from the skin, APCs convert from a "resting" into an "activated" functional state. This process is initiated by keratinocytes, which secrete inflammatory cytokines as a result of hapten application; triggering of TLRs and direct effects of haptens on the APCs may also be involved. Furthermore, the inflammasomes within keratinocytes become activated by contact sensitizers resulting in the release of biologically active IL-1β and IL-18. It follows that

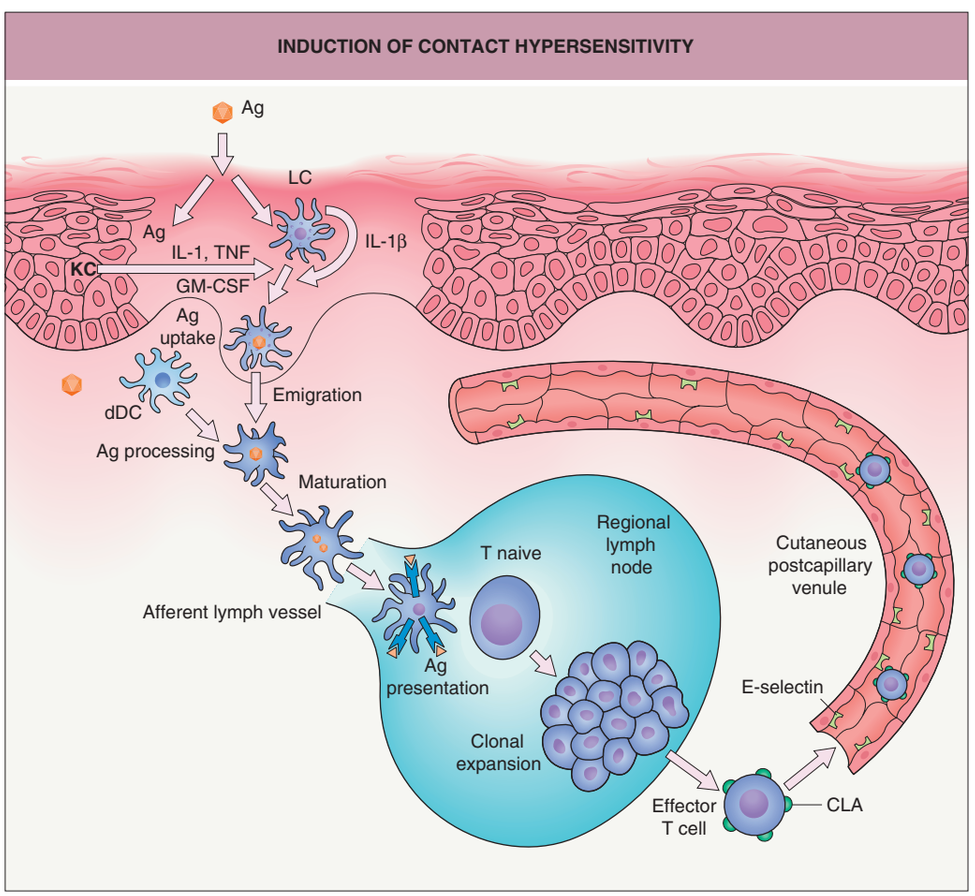

Fig. 4.13 Induction of contact hypersensitivity. Application of contact allergens (Ag) induces the release of cytokines by keratinocytes (KCs), Langerhans cells (LCs), and other cells within the skin. These cytokines in turn activate LCs and/or dermal dendritic cells (dDCs), which uptake the antigen and emigrate into the regional lymph nodes. During this process, they develop into mature antigen-presenting cells. In addition, the antigen is processed, re-expressed on the surface, and, finally, presented to naive T cells in the regional lymph node. Upon antigen presentation, T cells bearing the appropriate T cell receptor clonally expand and become effector T cells. These alter their migratory behavior due to the expression of specific surface molecules like cutaneous lymphocyte antigen (CLA). Effector T cells recirculate into the periphery, where they may later meet the antigen again.

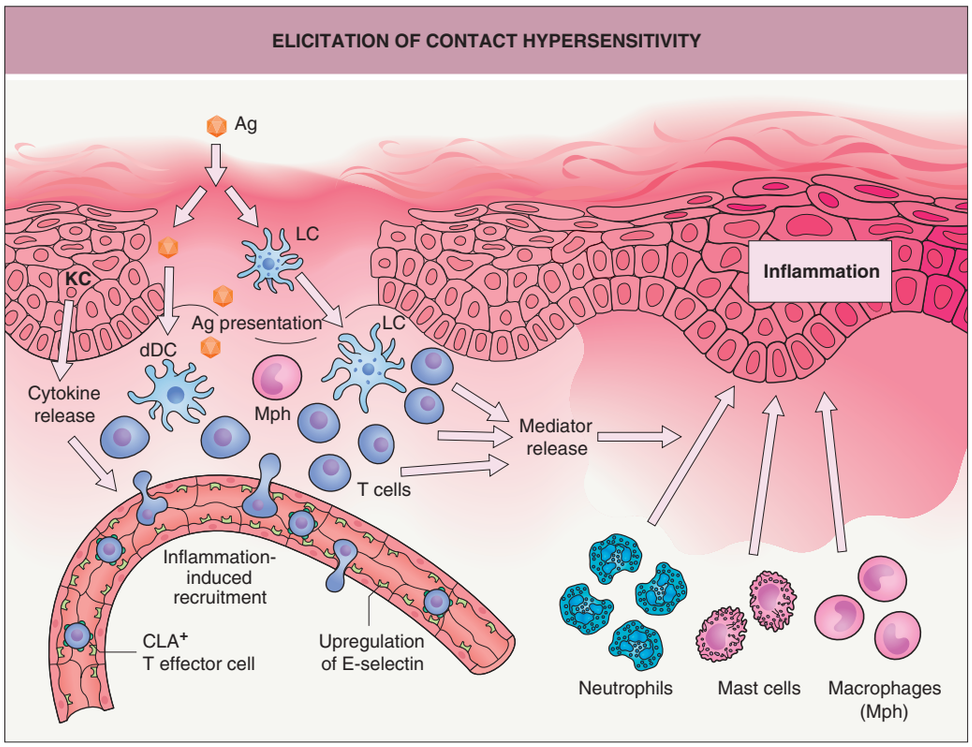

Fig. 4.14 Elicitation of contact hypersensitivity. Application of contact allergens (Ag) onto a sensitized individual causes the release of cytokines by keratinocytes (KCs) and Langerhans cells (LCs). These cytokines induce the expression of adhesion molecules and activation of endothelial cells, which ultimately attracts leukocytes to the site of antigen application. Among these cells, T effector cells are present, which are now activated upon antigen presentation either by LCs, dermal dendritic cells (dDCs), or infiltrating macrophages (Mphs). Antigen-specific T cell activation again induces the release of cytokines by T cells. This causes the attraction of other inflammatory cells, including granulocytes and macrophages, which ultimately cause the clinical manifestation of contact dermatitis. CLA, cutaneous lymphocyte antigen.

inflammasome-deficient mice (ASC- and NALP3-knockout mice) display an impaired response to contact allergens[129]. Induction of IL-1β appears to be specific for haptens, since it is not observed with irritants or tolerogens. In addition, other cytokines, including chemokines, TNF-α, and GM-CSF, may also contribute to APC activation and migration. Hence, the hapten itself, through its capacity to provoke a specific cytokine pattern, seems to be the initial trigger that activates APCs and induces sensitization (see Fig. 4.13).

Presentation of the hapten by APCs in the regional lymph nodes causes activation of naive T cells carrying the appropriate TCR and results in the generation of effector cells. In contrast to other types of delayed-type hypersensitivity responses, which are mediated by $CD4^+$ T cells, most haptens induce a T cell response of predominantly $CD8^+$ effector T cells[128]. In addition, Treg populations that inhibit the CHS response are induced. The balance between effector T cells and Tregs seems to depend on the dose of the antigen applied, since application of extremely low doses of the hapten does not result in sensitization, but rather in tolerance[97].

Elicitation of CHS

T cells that have been primed in the draining cutaneous lymph nodes express the skin-homing marker CLA and thereby exhibit the capacity to enter the skin[77]. These T cells become activated when they encounter their relevant hapten presented by APCs within the skin. However, in contrast to the sensitization phase, antigen presentation can now be effectively performed by other cells (including keratinocytes, dermal mast cells, and macrophages) that are capable of presenting antigen at least in a MHC class I-restricted fashion[128]. Alternatively, inflammatory cells that infiltrate the site of hapten application very early during the response may function as APCs.

The earliest histopathologic findings during a CHS response are mast cell degranulation, vasodilation, and an influx of neutrophils, which is followed by infiltration of monocytes and T cells (Fig. 4.14). However, the pathophysiologic events that result in allergic contact dermatitis are clearly T cell-dependent, since T cell-deficient mice are unable to mount a CHS response. Furthermore, low doses of hapten that are sufficient to stimulate hapten-specific T cells are insufficient to elicit a CHS response. This indicates that the elicitation of a CHS response requires, in addition to hapten-specific recognition, a proinflammatory stimulus that can be provided in a dose-dependent manner by the hapten itself[130].

Chapter Contents

Pruritus Pathways 100
Mediators of Pruritus 102
Chronic Itch 105
Treatments for Pruritus 106
Future Directions. 106

Key features

- At least three subsets of pruriceptive C neurons exist that respond to histamine or other pruritogens and then activate distinct spinothalamic and spinoparabrachial tract neurons
- Peripheral itch mediators include histamine, proteases, and multiple interleukins
- Central itch mediators include opioids, gastrin-releasing peptide, and B-type natriuretic peptide
- There is an overlap between chronic itch and chronic pain, including activation of multiple brain areas and associated neuromediators and receptors, e.g. nerve growth factor, neurotrophin 4, transient receptor potential (TRP) channels
- Cross-talk between cutaneous nerve fibers and the stratum corneum is a possible mechanism for the pruritus associated with impaired barrier function (e.g. xerosis, atopic dermatitis)
- Therapies with topical and systemic drugs that reduce itch sensitization by counteracting the responsible mediators represent promising treatment strategies

INTRODUCTION

The skin contains a network of highly specialized *afferent* sensory nerves that convey sensations such as pain, itch, temperature, and touch (Table 5.1). In addition, peptidergic nerve fibers release neuropeptides such as substance P, calcitonin gene related peptide (CGRP), nerve growth factor (NGF), and other neurotrophins whose effects include immune modulation. Because pruritus is largely restricted to the skin, the latter represents the major target organ of somatosensation.

Pruritus (itch) is the dominant symptom of many cutaneous diseases and is mediated by sensory nerves traditionally classified as non-peptidergic (NP). Although itch elicits scratching via a reflex arc, it is actually multidimensional with cognitive, evaluative, and motivational components. Pruritus can also occur in association with systemic diseases (e.g. chronic kidney disease, cholestasis; see Ch. 6), psychiatric conditions (see Ch. 7), and damage to nerve fibers.

The link between itch and scratching is so close that in some languages the same word refers to both itch and scratch. Although similarities to pain exist, itch is distinct – pain elicits a reflex withdrawal, whereas itch leads to a scratching response[1]. Despite being an extremely common complaint that is highly conserved across species, medical science is still struggling to understand the mechanisms of itch and how it can be inhibited.

PRURITUS PATHWAYS

The neurophysiology of itch involves specific itch mediators and nerve fibers that transmit itch both peripherally and centrally[2]. While the concept of pruritus as a sensory modality separate from pain was not generally appreciated until the mid-twentieth century, studies have clearly identified individual histaminergic and non-histaminergic C fibers that uniquely transmit itch[3]. C fibers that transmit itch have exceptionally slow conduction velocities (0.3–1.0 m/second) and innervate unusually wide territories.

Histamine-sensitive C fibers are sensitive to heat as well as pruritogenic stimuli but generally not to mechanical stimuli; in contrast, the vast majority of other C fibers, while sensitive to heat stimuli, have little or no response to histamine[3]. The co-responsiveness of itch-transmitting C fibers to temperature explains aggravation of pruritus in a warm environment. However, the ineffectiveness of oral antihistamines for most types of pruritus suggests that other fibers play important roles in itch sensation[4].

Indeed, distinct parallel pathways of *non-histaminergic C fibers* that transmit itch have been identified in the peripheral nervous system of humans and the spinothalamic tract of other primates[4,5]. Itch transmission can be elicited by spicules of the tropical legume cowhage (*Mucuna pruriens*), which produce an intense itch when rubbed, inserted, or injected into the skin, without producing a histaminergic axon reflex[5]. Cowhage spicules induce itch via release of the protease mucunain, which activates proteinase-activated receptor (PAR)-2 and PAR-4[6]. Cowhage-sensitive fibers transmit a burning sensation together with itch and are also sensitive to mechanical and other stimuli. PAR-2 receptors have been implicated in itch associated with atopic dermatitis[7] (see Ch. 12). The non-histaminergic, polymodal C fibers stimulated by mucunain may also have clinical relevance in chronic itch. In addition to C fibers, A-delta fibers contribute to cowhage-evoked itch with a more rapid onset[8].

MAS-related G protein-coupled receptor D (MRGPRD) is a β-alanine receptor that is exclusively expressed by a subset of pruriceptive C fibers classified as type 1 non-peptidergic (NP1) neurons. Similarly, the pharmacologic pruritogen chloroquine directly activates NP2 (type 2) neurons, whereas the Th2 cytokine IL-31 elicits itch via NP3 (type 3) neurons[9]. Collectively, recent studies suggest that a variety of sensory neurons respond to different itch stimuli via distinct pathways, explaining why there are so many types of itch.

Within the spinal cord, there is another layer of itch circuitry where signals from the skin are integrated and the perception of itch is then relayed to the brain. The first itch-specific receptor to be identified, gastrin-releasing peptide receptor (GRPR), is found in the spinal cord and represents a key downstream mediator of non-histaminergic itch responses. Overexpression of gastrin-releasing peptide (GRP) in cutaneous nerve fibers and GRPR in the spinal cord has been observed in mice and primates with chronic itch. B-type natriuretic peptide, an itch-selective neuropeptide found in dorsal root ganglia neurons, is believed to act upstream of the GRPR itch spinal circuit. Substance P is also expressed by a distinct population of murine dorsal horn neurons that respond to pruritic and noxious stimuli[9,10].

The perceived sensation of pruritus can vary greatly in quality. Patients may describe burning, pricking, "insects crawling" on the skin, or even a tickle, but the neurophysiologic and psychologic correlates of these qualitative differences have not yet been elucidated. However, information obtained from itch questionnaires has enabled a better understanding of the different characteristics of itch and its features in various skin diseases[11].

Central Pathways to Higher Nervous System Centers

In the spinal cord, pruriceptive C fibers synapse with secondary sensory neurons in the gray matter of the dorsal horn (Fig. 5.1). These neurons then cross over and ascend in the lateral spinothalamic tract to the

PRIMARY AFFERENT NEURONS THAT INNERVATE THE SKIN				
Fiber	**Diameter**	**Myelination**	**Conduction velocity**	**Responds to**

*Transmit pruritus accompanied by a burning sensation; also sensitive to mechanical stimuli.
†~5% of total C fibers transmit itch.
‡Separate C fibers carry both pruritogenic and thermal stimuli, but not mechanical stimuli.

Table 5.1 Primary afferent neurons that innervate the skin. BAM8-22, bovine adrenal medulla 8-22 protein; NP2/3, non-peptidergic 2/3.

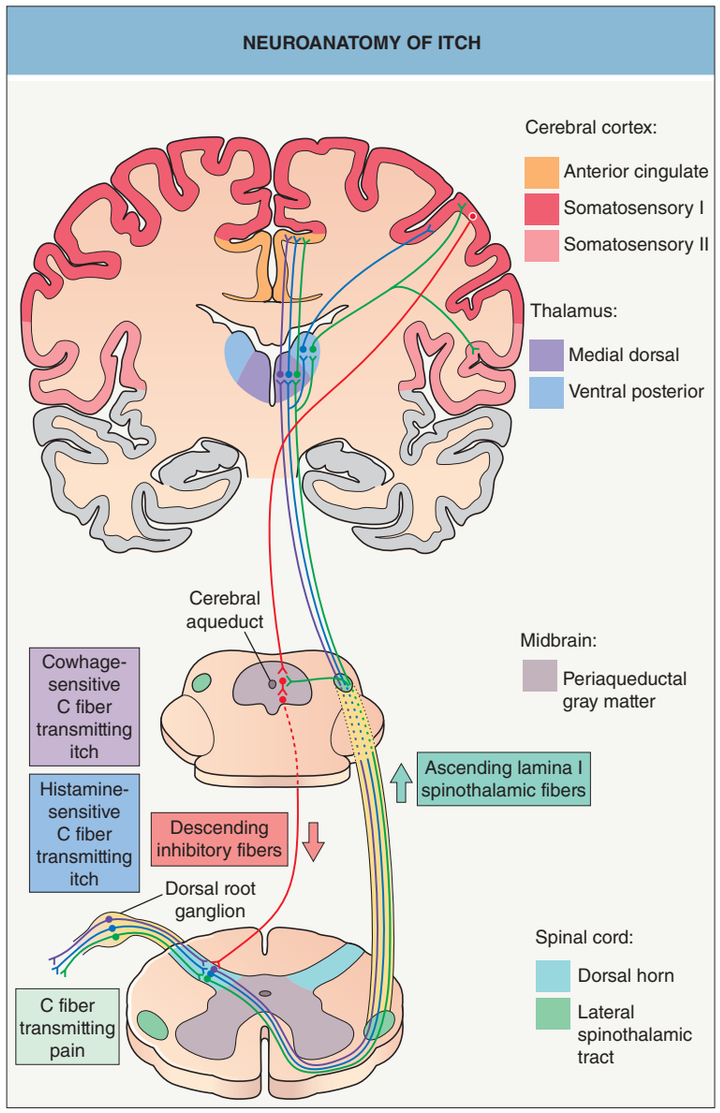

Fig. 5.1 Neuroanatomy of itch. Itch and pain transmission occur via unmyelinated C nerve fibers that excite lamina I neurons in the dorsal horn of the spinal cord. Two subsets of pruritoceptive C-fiber neurons (which respond to histamine and cowhage, respectively) are conducted through distinct lateral spinothalamic pathways, with projections to the thalamus. Processing of itch through either pathway activates several regions of the brain, which are similar to those involved in pain (see Table 5.4). Concomitant painful stimuli can reduce the sensation of itch, possibly by a descending inhibitory mechanism resulting from activation of the periaqueductal gray matter. In mice, gastrin-releasing peptide receptor-positive neurons transmit itch (but not pain) within the spinal cord; the role of such neurons in humans remains to be determined. *Adapted from Yosipovitch G. Pruritus: an update. Curr Probl Dermatol 2003;15:137–64.*

thalamus. *In vivo* studies using extracellular recordings from cats identified a subclass of lamina I spinothalamic tract neurons that are excited by iontophoretically administered histamine[12]. Neurophysiologic experiments in primates found that cowhage-induced itch stimulates a distinct population of spinothalamic tract neurons that are not involved in the transmission of histamine-mediated itch (see above)[13]. Studies in humans utilizing functional MRI or positron emission tomography (PET) have shown that histamine and cowhage activate different brain areas, providing insight into the supraspinal processing of itch[14].

In healthy individuals, induction of itch by either histamine or cowhage can elicit activation of various regions, including the anterior and posterior cingulate cortex, precuneus, somatosensory areas I and II, supramarginal gyrus, inferior parietal lobe, and insula–claustrum complex. The activation of multiple brain areas argues against a single "itch center" and underscores the multidimensionality of the itch sensation. Of note, pain shows a similar pattern of brain activation across cortical regions[15] (see Fig. 5.1). In mice, optogenetic studies, in which expression of light-induced proteins within neuronal cell membranes is measured, detected a spinoparabrachial pathway that sends itch signals to the parabrachial nucleus of the brain stem[16].

Seeing other people scratching can trigger itch and atopic dermatitis patients experience increased itch when exposed to visual stimuli[17]. Studies utilizing functional MRI showed that "contagious itch" activates many of the neural regions linked to the physical perception of itch[18]. In mice, the suprachiasmatic nucleus is a key visual organ that mediates contagious scratching behavior[19].

In addition to inhibiting activation of the cingulate cortex, scratching has been found to activate the prefrontal cortex and cerebellum. It is possible that the cerebellum plays a role in coordinating the itch–scratch cycle[20,21]. Scratching inhibits histamine-evoked activity of spinothalamic neurons in primates, but not spontaneous or pain-triggered activity[22]. Scratching also activates areas of the brain involved in reward processing, including the striatum and substantia nigra. While these responses correlate with the pleasure of scratching, activation of other areas is associated with itch relief[23].

Pruritus Receptor Units

Removal of the epidermis largely abolishes the perception of itch. Light microscopic and ultrastructural studies of human skin have shown the existence of intraepidermal nerve fibers with "free" non-specialized nerve endings extending to the stratum granulosum. A subclass of C fibers in the epidermis that express MRGPRs, in particular MRGPRX1, are involved in chloroquine-induced pruritus (see Fig. 5.2F)[24]. Cathepsin S, an endogenous protease, can cleave and thereby activate MRGPRX2 (murine MrgprC11), which leads to scratching behavior, as well as PAR-2/4 receptors[25].

Keratinocytes express a variety of neural mediators and receptors involved in the sensation of itch (Table 5.2). These include opioids, proteases, substance P, NGF, and neurotrophin 4 in addition to their respective receptors, including μ- and κ-opioid receptors, PAR-2, neurotrophic tyrosine kinase receptor type 1 (NTRK1), and transient receptor potential vanilloid ion channels (particularly TRPV1 and TRPV3). Keratinocytes also have ATP-gated ion channels and adenosine receptor ligands similar to those observed in C fibers involved in pain transmission. These structural similarities to nerve fibers suggest that keratinocytes may be involved in the transduction and generation of itch.

Table 5.2 Major mediators of pruritus: relative potencies with regard to pruritus and pain. +/–, little or no activity; +, weak activity; ++, moderately active; +++, highly active; –, no activity.

MEDIATORS OF PRURITUS

Various mediators that act centrally and/or peripherally are involved in pruritus, including histamine, proteases, substance P, opiates, NGF, and prostaglandins (Fig. 5.2A). In inflammatory skin diseases, proinflammatory mediators produce pruritus and other signs of inflammation, in particular erythema due to vasodilation and edema from increased vascular permeability. However, cytokines and other inflammatory mediators can also act directly on sensory neurons to influence itch sensation[9]. The relative potencies of the major mediators are listed in Table 5.2.

Histamine

Histamine is the archetypal mediator of inflammation, including pruritus. In the skin, histamine is contained primarily within the granules of dermal mast cells. Histamine can be released from mast cells upon activation of a range of receptors, including the high-affinity IgE receptor (FcεRI), the KIT receptor, MRGPRX2, and receptors for various neuropeptides (e.g. NGF) and complement C5a[9]. In IgE-mediated acute urticaria, histamine is released when a specific antigen/allergen cross-links adjacent receptor-bound specific IgE antibodies on mast cells. In autoimmune chronic urticaria, similar cross-linking occurs via functional circulating IgG that react with epitopes expressed on the α-chain of adjacent FcεRIs or less commonly anti-IgE autoantibodies (see Fig. 18.3). Histologically, dermal mast cells and unmyelinated neurons are juxtaposed (Fig. 5.2B,C,E), indicating a close ("synapse-like") functional relationship between the immune and nervous systems. However, evidence for histamine as the main mediator of pruritus is limited to a few skin diseases, including acute and chronic urticaria and mastocytosis.

Recognition of the histamine H4 receptor has expanded our understanding of the physiologic actions of histamine beyond the traditional H1 receptor. The H4 receptor is expressed by neurons and immune cells such as eosinophils, mast cells, dendritic cells, monocytes, and $CD8^+$ T cells. It mediates chemotaxis and plays a role in the inflammation and pruritus of atopic dermatitis. H4 antagonists are under development and have been shown to alleviate experimental pruritus. In animal models of itch, the effects of H4 antagonists are synergistic with those of centrally acting H1 antihistamines (e.g. diphenhydramine)[26,27].

Gastrin-Releasing Peptide

As noted above, itch-specific GRPR-positive neurons have been identified in the dorsal horn of the spinal cord in mice[28]. Although named for its role in regulating gastrointestinal functions, gastrin-releasing peptide (GRP) is expressed in many tissues. Whether peripheral sensory neurons express GRP is still debated[9].

B-Type Natriuretic Peptide

B-type natriuretic peptide (BNP; natriuretic polypeptide B) is a 32-amino acid peptide that is secreted by the cardiac ventricles to regulate blood pressure and fluid balance. BNP is also expressed by a subset of C fibers and may function in itch transmission in the spinal cord[9].

Proteases

Mast cells produce two proteases, tryptase and chymase. Tryptase, released by activated mast cells, cleaves PAR-2, a G protein-coupled receptor present on C-fiber terminals (Fig. 5.2B,D); this exposes a tethered ligand domain and thereby "self-activates" PAR-2, leading to itch transmission. Tryptase levels are increased four-fold in non-lesional forearm skin of atopic dermatitis patients, while expression of PAR-2 is significantly increased in the epidermis and cutaneous nerve fibers of eczematous lesions and to a lesser degree in non-lesional skin.

Kallikreins and cathepsins can also activate PAR-2 via their protease activity. In addition, kallikrein 7, which does not activate PAR-2, triggers itch in the setting of atopic dermatitis-like disease in mice and is enriched in lesional human atopic dermatitis skin[29]. Cathepsin S can evoke itch by cleaving and thereby activating MRGPRX2 as well as PAR-2 (see above). Furthermore, proteases such as cathepsin B can be found in common allergens (e.g. grass pollen, house dust mites), and *Staphylococcus aureus* can induce secretion of proteases; both of these exogenous factors are known to aggravate atopic dermatitis and itch[30].

Transgenic mice overexpressing various serine proteases exhibit severe itch and scratching (Table 5.3). In Netherton syndrome, serine protease inhibitor deficiency leads to excess epidermal protease activity, resulting in pruritus and atopic manifestations (see Ch. 57). These observations demonstrate that interactions between proteases and receptors on C fibers play key roles in itch.

Opioid Peptides

Central pruritus, which involves pruritic mediators within the CNS, can occur in both cutaneous and systemic diseases. Endogenous opioids modify the perception of pruritus via central and peripheral opioid receptors. Generalized pruritus may be induced by an imbalance between the μ- and κ-opioid systems, activation of which stimulates and inhibits itch perception, respectively[31]. κ-Opioid receptor agonists can act within the skin, spinal cord, and brain to reduce itch and are utilized as therapies for chronic pruritus[32,33].

Morphine as well as other exogenous and endogenous μ-opioid receptor agonists may cause generalized pruritus. Morphine also produces local pruritus and erythema when injected intradermally; this response is only partially inhibited by the μ-opioid receptor antagonist naloxone but is substantially inhibited by topical pretreatment with the H1 antihistamine doxepin, indicating the ability of morphine to activate mast cells[34]. Therefore, two possible mechanisms for opioid-induced itch are: (1) degranulation of cutaneous mast cells[35]; and (2) activation of μ-opioid receptors with direct central and peripheral pruritogenic effects[32,33].

Substance P

Substance P, a neuropeptide with a widespread distribution in peripheral nerves and the CNS, is involved in itch perception. Substance P is

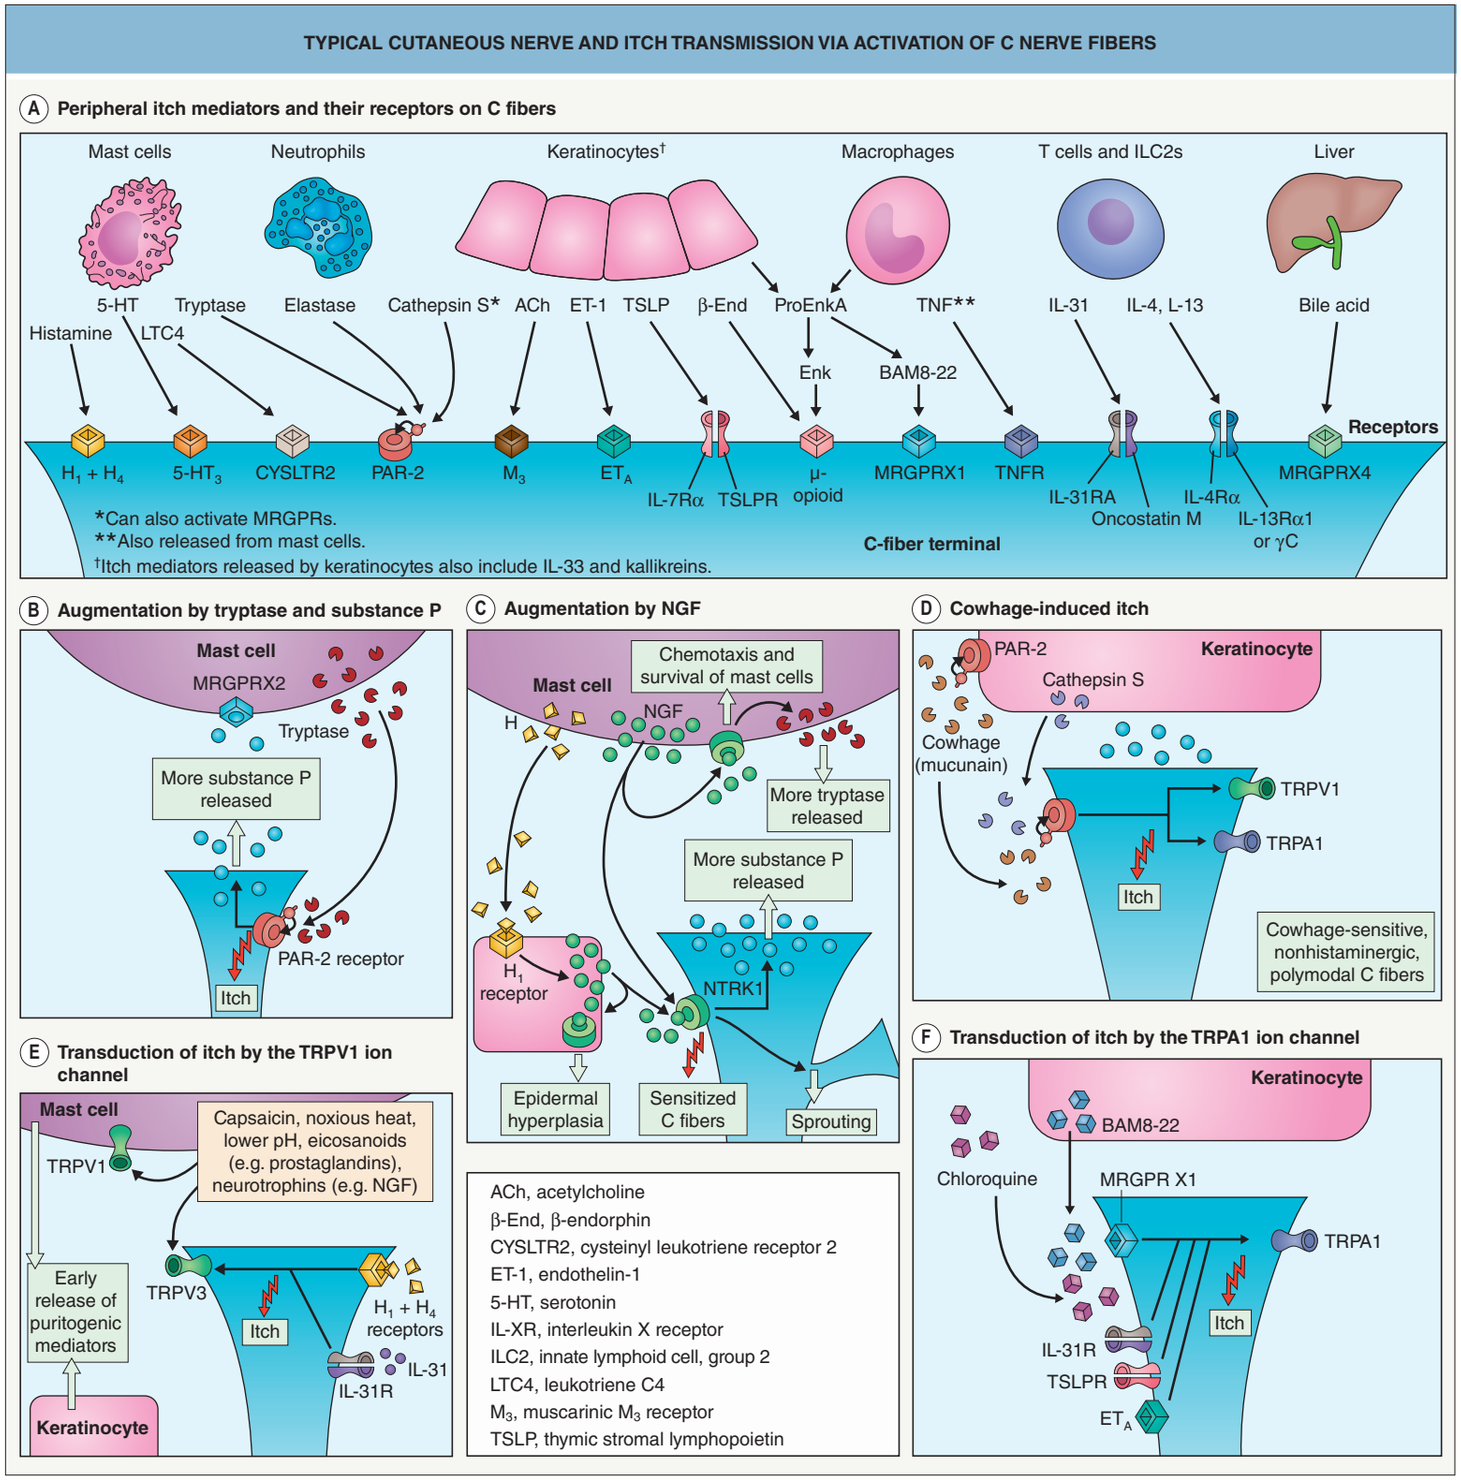

Fig. 5.2 Typical cutaneous nerve and itch transmission via activation of C nerve fibers. There are two categories of axons in a typical cutaneous nerve: (1) primary afferent Aβ, Aδ, and C fibers with cell bodies in dorsal root ganglia; and (2) sympathetic postganglionic fibers with cell bodies in sympathetic ganglia. Separate C fibers (~5% of the total) carry pruritogenic stimuli via two pathways: (1) *histamine-induced itch* that is transmitted by mechanically insensitive, capsaicin-sensitive fibers via the *t*ransient *r*eceptor *p*otential *v*anilloid receptor 1 (TRPV1); and (2) *cowhage (mucunain)-induced itch* accompanied by a burning sensation that is transmitted by polymodal fibers sensitive to both capsaicin and mechanical stimuli. **A** Peripheral itch mediators released by immune cells, keratinocytes, and the liver activate pruriceptors on C-fiber terminals in the skin. For example, activated mast cells release histamine, which triggers itch via histamine H1 and H4 receptors on histamine-sensitive C fibers. Proteases such as tryptase, elastase, and cathepsin S can cleave proteinase-activated receptor-2 (PAR-2), exposing a tethered ligand and thereby resulting in "self-activation". Proenkephalin A (ProEnkA) may be cleaved to form enkephalin (ENK) or bovine adrenal medulla 8-22 peptide (BAM8-22). **B** Self-activation of PAR-2 following tryptase cleavage results in transmission of itch by the C fibers as well as release of additional substance P, which primes mast cells via neurokinin-1 receptors (NK1Rs). **C** Nerve growth factor (NGF) released by mast cells and keratinocytes (with NGF production stimulated by histamine [H]) activates neurotrophic tyrosine kinase receptor type 1 (NTRK1 [TRKA]) on C fibers, mast cells, and keratinocytes. This induces C fiber sprouting, sensitization to cowhage-induced itch, and increased substance P release; mast cell chemotaxis, survival, and increased tryptase release; and epidermal hyperplasia. **D** Cowhage-induced itch occurs through the release of mucunain, a protease that activates PAR-2 and PAR-4 receptors (the latter not yet identified in the skin); these receptors can also be activated by endogenous proteases such as cathepsin S as well as tryptase. Activation of PAR-2/4 sensitizes TRPV1 and TRP ankyrin 1 (TRPA1) channels, resulting in cross-talk and itch transmission. **E** Activation of H1/H4 receptors and the IL-31 receptor (IL-31R) heterodimer leads to membrane depolarization of C fibers via TRPV1, which is required for transduction of histamine-induced itch. The TRPV1 ion channel on C fibers, keratinocytes, and mast cells can also be activated by capsaicin, heat, low pH, eicosanoids, and neurotrophins; although this initially stimulates transmission of itch and release of pruritogenic mediators, it may eventually lead to desensitization, neuropeptide depletion, and attenuation of itch. **F** C fibers (including those responsive to histamine) in the epidermis express MAS-related G protein-coupled receptors (MRGPRs), which can be activated by chloroquine, BAM8-22, and cathepsin S. TRPA1 is involved in transduction of itch by MRGPRs as well as other pruriceptors, including the IL-31R, thymic stromal lymphopoietin receptor (TSLPR) heterodimer, and endothelin type A receptor (ET_A).

MURINE MODELS OF ITCH		
Model	**Clinical and laboratory features**	**Pathogenesis/comments**
Transgenic mice overexpressing PAR-2	Epidermal hyperplasia and scaling as well as pruritus and scratching	
Transgenic mice overexpressing a serine protease	Pruritus and scratching	
TRPV1-deficient mice and Pirt-deficient mice	Lack of response to pruritogens	Pirt normally plays an important role in sensing itch (histaminergic and non-histaminergic) as well as pain via TRPV1 channels (and also TRPV1-independent itch)
Mrgpr-deficient mice and TRPA1-deficient mice	Lack of scratching response to chloroquine and BAM8-22, but preserved response to histamine	Mrgprs are normally activated by chloroquine and BAM8-22, so the lack of response in TRPA1-deficient mice implicates this receptor in downstream signaling
GRPR-deficient mice	Lack scratching response to pruritogens, but preserved response to painful stimuli	GRPR is expressed in the dorsal spinal cord
Bhlhb5-deficient mice	Enhanced scratching response to pruritogens	Selective loss of inhibitory interneurons in the dorsal horn that regulate pruritus
μ-Opioid receptor-deficient mice	Thinner epidermis, higher density of epidermal nerve endings, and less scratching after induction of dry skin	
Transgenic mice overexpressing interleukin-31	Pruritus, scratching, excoriations and alopecia	

Table 5.3 Murine models of itch. Bhlhb5, basic helix-loop-helix family member B5; GRPR, gastrin-releasing peptide receptor; Mrgpr, Mas-related G protein-coupled receptors; PAR-2, protease-activated receptor 2; Pirt, phosphoinositide-interacting regulator of transient receptor potential channels; TRPV1, transient receptor potential vanilloid 1.

synthesized in the cell bodies of C neurons, transported towards the peripheral nerve terminals, and released by antidromic depolarization to cause vasodilation and increased vascular permeability. High concentrations of substance P can cause immediate mast cell degranulation via MRGPRX2 receptors, whereas low concentrations specifically activate neurokinin-1 (NK-1) receptors on mast cells, leading to sensitization of these cells and increased production of tumor necrosis factor (TNF; Fig. 5.2B)[36].

Direct activation of mast cells by substance P triggers itch transmission[37,38]. When injected intradermally, it provokes neurogenic inflammation, including erythema and the wheal-and-flare reaction, in addition to itch. Levels of substance P in the serum of patients with atopic dermatitis are elevated and correlate with disease severity[39].

Neurotrophins

Neurotrophins are factors that regulate the growth and function of neurons. Members of this family include the prototypic nerve growth factor (NGF) as well as brain-derived neurotrophic factor (BDNF) and neurotrophins 3, 4, and 5[40]. Increased levels of epidermal NGF correlate with proliferation of terminal cutaneous nerves and upregulated expression of neuropeptides such as substance P[41]. NGF can also induce sprouting of nerve fibers, sensitization of nerve endings, and axonal transport in dorsal root ganglia cells (Fig. 5.2C)[42].

Keratinocytes express high levels of NGF, which is not only required for survival and regeneration of sensory neurons but also controls the responsiveness of neurons to external stimuli[43,44]. NGF is thought to act as a signaling molecule between mast cells and keratinocytes in allergic skin diseases. Mast cell-derived histamine induces keratinocytes to increase NGF production, and the latter may promote infiltration of mast cells into inflamed skin. Patients with atopic dermatitis and psoriasis have increased expression of NGF in cutaneous mast cells, keratinocytes, and fibroblasts[45,46]. Upregulation of other neurotrophins, such as neurotrophin 4, has also been observed in keratinocytes from atopic dermatitis patients[47].

Prostanoids and Leukotrienes

Prostaglandins are the products of the conversion of arachidonic acid by cyclooxygenase-1 (COX-1) or 2 (COX-2), and they enhance histamine-induced itch[48,49]. When injected into the dermis, prostaglandin E_1 (PGE_1) is not itself pruritogenic but enhances pruritus due to histamine subsequently injected into the same site[50]. It appears that only itch-mediating neurons that display lasting activation following exposure to histamine are excited by PGE_2, and mechanosensitive fibers are unresponsive to both histamine and PGE_2. PGE_2 has also been shown to have a direct, low-level pruritogenic effect in both atopic dermatitis patients and unaffected individuals without inducing protein extravasation. This suggests that prostanoids' peripheral action is not solely via histamine and that prostanoids may potentiate pruritus via other effects on nerve fibers. Although oral administration of aspirin, a cyclooxygenase inhibitor, does not generally ameliorate pruritus, topical application of aspirin may reduce chronic localized itch[50].

The role of other eicosanoids, including leukotrienes and 12-hydroxyeicosatetraenoic acid (12-HETE), in the pathogenesis of pruritus is unclear. In mice, leukotriene B_4 can provoke scratching and may be involved in skin disease-related itch[51]. More recent studies have shown that basophil- and mast cell-derived leukotriene C_4 directly activates NP3 neurons and acts as a pruritogen in acute itch flares of atopic dermatitis[52,53,53a].

Mediators That Activate Transient Receptor Potential Receptors

Neuromediators that activate ion channels in the *t*ransient *r*eceptor *p*otential (TRP) family are also involved in the sensation of itch. TRP vanilloid 1 (TRPV1) is located on C fibers (see Fig. 5.2E) and is activated by capsaicin, endogenous substances such as cannabinoids (e.g. anandamide), prostaglandins, neurotrophins, a lower pH, and temperatures >43°C (109°F). TRPV1-expressing C nerve fibers can mediate heat pain and they house many pruriceptors. In addition, experimental induction of histamine-mediated itch requires cooperation of TRPV1 ion channels[54]. Stimulation of TRPV1-positive nerve fibers also leads to the release of pruritoceptive mediators such as neuropeptides.

TRPV3 is a thermosensor of warmth (>33°C, 91°F) that is expressed in keratinocytes and dorsal root ganglion neurons. Gain-of-function missense mutations in *TRPV3* result in chronic itch, scratching, and an atopic-like dermatitis in mice and Olmsted syndrome in humans. The latter features pruritus as well as palmoplantar keratoderma and periorificial hyperkeratosis (see Ch. 58)[55]. PAR2 can induce itch via TRPV3 signaling in keratinocytes, and enhanced thermal sensitivity of TRPV3 in keratinocytes plays a role in heat-induced release of pruritogens such as thymic stromal lymphopoietin (TSLP), NGF, and PGE_2 in patients

with atopic dermatitis[56,57]. Intradermal injection of citrusinine-II, a plant-based TRPV3 inhibitor, was recently shown to attenuate itch in mouse models[58]. In contrast, TRP melastatin 8 (TRPM8) on C nerve fibers functions as a thermosensor of cool temperatures (<28°C, 82°F) and is activated by menthol and icilin, which provide a "cooling" sensation that may relieve itch.

TRP ankyrin 1 (TRPA1), a polymodal ion channel, functions as a downstream mediator of histamine-independent itch stimulated by MRGPRs in a subset of epidermal C fibers[59]. TRPA1 can be activated directly by menthol as well as via pruriceptors such as the TSLP receptor subunit[60] (see Fig. 5.2F).

Other Peripheral Mediators of Itch

Other neurotransmitters

Intradermal injection of acetylcholine, an important neurotransmitter in the autonomic nervous system, typically induces pain; however, in patients with chronic pruritus, it can induce itch. Activation of the muscarinic receptor 3 triggers itch in mice[61]. Norepinephrine, a catecholamine neurotransmitter, exerts tonic inhibition of itch signaling in the spinal cord[62]. Although serotonin can induce itch in mice, in humans it is a very mild pruritogen. Currently there are no data regarding the role of epinephrine or dopamine in itch transmission.

Other mediators with potential roles in itch

Nitric oxide may induce itch via neurogenic inflammation[63]. The bovine adrenal medulla 8-22 (BAM8-22) peptide, a proteolytically cleaved product of proenkephalin A, is a potent activator of MRGPRs and can stimulate itch, usually accompanied by a stinging or burning sensation (see Fig. 5.2F)[64]. Chloroquine can also induce itch by activating MRGPRs, which are expressed by a subset of C fibers in the epidermis.

Immune Cells as Itch Mediators and Modulators

Interactions between the nervous and immune systems in the skin play important roles in itch induction. Neuropeptides such as substance P, CGRP, and vasoactive intestinal peptide, which are released from cutaneous sensory nerves, regulate the expression of adhesion molecules and proinflammatory cytokines, thereby modulating immune and inflammatory responses[9]. These neuropeptides also influence cell proliferation and differentiation, tissue repair, and antigen presentation involving keratinocytes, mast cells, dermal microvascular endothelial cells, and Langerhans cells. These interactions are bidirectional, as cytokines and chemokines also regulate primary nerve afferents via receptor activation.

IL-31 is produced by Th2 cells and belongs to the IL-6 family. It induces pruritus by modulating the function of sensory neurons[65]. The IL-31 receptor (IL-31R) is a heterodimer composed of the oncostatin M receptor (OSMR) β protein plus the IL-31 receptor A (IL-31RA). The IL-31R is found on TRPV1$^+$/ TRPA1$^+$ cutaneous C fibers and in dorsal root ganglia.

Signaling via either the IL-31R or OSMR, a heterodimer composed of the OSMR β protein and a gp130 subunit, can result in cutaneous inflammation as well as keratinocyte proliferation, differentiation, and apoptosis. Mutations in the gene encoding the OSMR β protein underlie *familial primary localized cutaneous amyloidosis*, an autosomal dominant disorder characterized by chronic localized itching and scratching that results in deposition of keratin-derived amyloid in the dermis[66]. Of note, increased levels of IL-31 are found in the skin of patients with atopic dermatitis, prurigo nodularis, and cutaneous T cell lymphoma. In randomized controlled trials, nemolizumab, an anti-IL-31RA monoclonal antibody, reduced itch and skin lesions in patients with atopic dermatitis and prurigo nodularis. Vixarelimab, an anti-OSMRβ monoclonal antibody, is currently under investigation as a therapy for prurigo nodularis and other chronic pruritic skin conditions.

Thymic stromal lymphopoietin (TSLP) is produced by keratinocytes and promotes Th2 cell-associated responses. TSLP acts directly on TRPA1-expressing neurons to elicit itch in mice[60], and TSLP expression is increased within lesions of atopic dermatitis.

IL-4 and ***IL-13*** produced by Th2 cells contribute to the itch of atopic dermatitis via activation of JAK (Janus kinase)/STAT (signal transducer and activator of transcription) signaling cascades in sensory neurons[67]. In addition to reducing itch in patients with atopic dermatitis, both JAK inhibitors and monoclonal antibodies that target IL-4/-13 signaling (e.g. dupilumab, tralokinumab, lebrikizumab) lead to improvement of other chronic pruritic disorders such as prurigo nodularis.

IL-33 has been associated with chronic pruritus of unknown origin and mediates itch in the context of allergic contact dermatitis and xerotic skin[68].

CHRONIC ITCH

Chronic itch may occur in the setting of inflammatory itch secondary to skin diseases, neuropathic itch due to pathology in the nervous system, and systemic or psychiatric disorders (see Ch. 6). It often has a significant effect on patients' quality of life. Chronic itch and chronic pain share several features, with both potentially involving peripheral and central sensitization (Table 5.4; Fig. 5.3).

Peripheral Sensitization in Chronic Itch

Patients with chronic itch in the setting of atopic dermatitis have increased neurotrophin levels in involved skin, including NGF and neurotrophin 4. Chronic localized pain is also associated with elevated levels of the same neurotrophins, which are known to sensitize nociceptive neurons.

Central Sensitization in Chronic Itch

Chronic itch leads to sensitization of second-order neurons within the dorsal horn of the spinal cord (see Fig. 5.1). There are two forms of increased sensitivity to itch, alloknesis and hyperknesis. In *alloknesis*, stimuli that normally do not induce itch such as touch or gentle warming do so in the skin that surrounds a pruritic area. This phenomenon is analogous to allodynia, in which gentle mechanical stimuli give rise to a perception of pain. Like allodynia, alloknesis requires ongoing activity in primary afferent C fibers and is probably mediated by low-threshold myelinated mechanoreceptor Aβ fibers (see Fig. 5.2). Alloknesis is common and represents a prominent feature of atopic dermatitis, explaining pruritus associated with dressing and undressing. Expression of the channel protein Piezo2 on Merkel cells has been shown to limit alloknesis in mice[69].

Hyperknesis is characterized by more intense itch induced by a stimulus that usually produces slight itch and occurs within the skin surrounding an area of inflammation. It is similar to the phenomenon in chronic pain termed hyperalgesia. In mice, neurokinin-1

COMPARISON OF CHARACTERISTICS OF CHRONIC ITCH AND CHRONIC PAIN

	Chronic itch	Chronic pain
Peripheral sensitization	• Sensitized C nerve fibers	• Sensitized C nerve fibers
Central sensitization	• Alloknesis • Hyperknesis	• Allodynia • Hyperalgesia
Selected neuromediators	• Nerve growth factor • Neurotrophin 4	• Nerve growth factor • Neurotrophin 4
Selected chemical mediators	• Histamine • Cowhage (mucunain) • Most opioids induce itch	• Bradykinin • Most opioids reduce pain
CNS areas activated	• Anterior and posterior cingulate cortex • Premotor area • Precuneus • Supramarginal gyrus • Dorsolateral prefrontal cortex • Insula–claustrum complex • Somatosensory cortex I, II • Parabrachial nuclei	• Anterior cingulate cortex • Premotor area • Somatosensory cortex I, II • Dorsolateral prefrontal cortex • Insula–claustrum complex

Table 5.4 Comparison of characteristics of chronic itch and chronic pain.

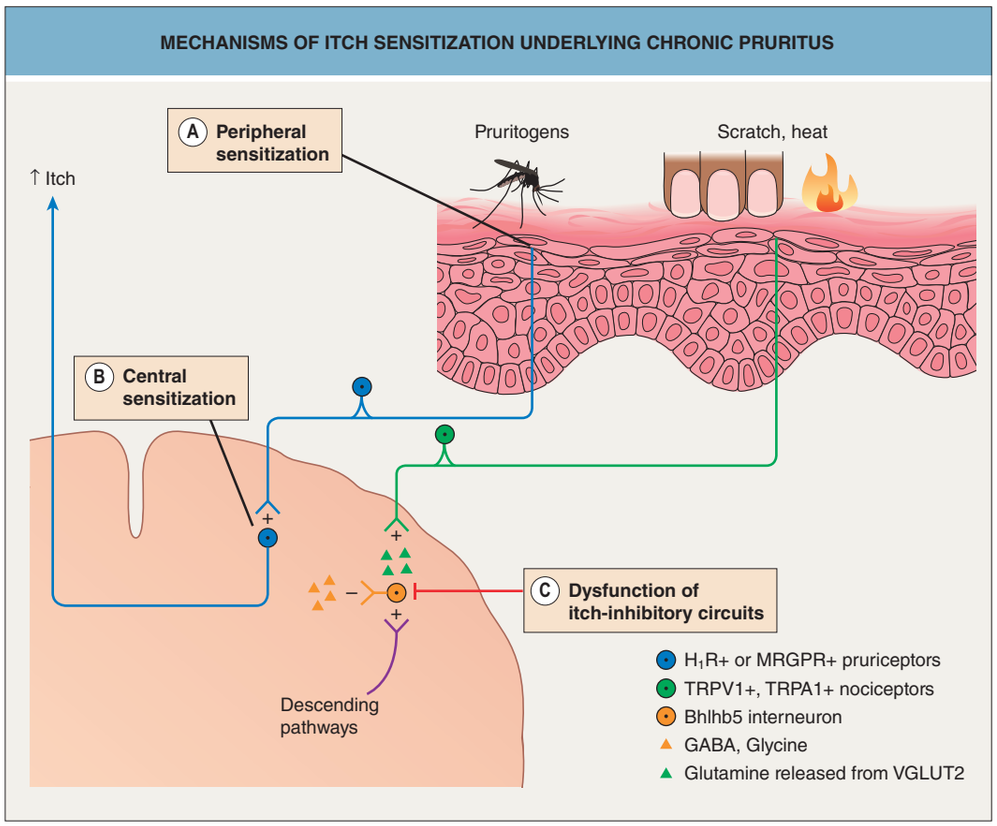

Fig. 5.3 Mechanisms of itch sensitization underlying chronic pruritus. Three main mechanisms of itch sensitization have important roles in chronic pruritus. **A** Peripheral sensitization of C-fiber pruriceptors occurs in the setting of chronic pruritus, which may be associated with increased levels of neurotrophins such as nerve growth factor (NGF; see Fig. 5.2C). PAR-2 activation in C fibers can also play a role in itch sensitization by enhancing responses to MAS-related G protein-coupled receptor (MRGPR) agonists. **B** Spinal itch-transmitting neurons are sensitized in the setting of chronic pruritus. There may be increased synaptic efficacy and signaling via additional synapses. **C** Itch-inhibitory circuits are normally driven by vesicular glutamate transporter 2 (VGLUT2)-dependent glutamate release from nociceptors as well as by descending pathways; this results in activation of itch-inhibitory Bhlhb5 interneurons, which release GABA, glycine, and/or dynorphins. Decreased function of these interneurons can result in disinhibition of itch. H_1R, histamine H1 receptor; TRPA1, transient receptor potential ankyrin receptor 1; TRPV1, transient receptor potential vanilloid receptor 1.

receptor-expressing spinal neurons play a major role in chronic itch, whereas gastrin-releasing peptide receptor-expressing spinal neurons contribute to hyperknesis, but not alloknesis or ongoing itch.

In patients with chronic itch, painful electrical and heat stimuli may be perceived as itch. An analogous phenomenon can occur in patients with chronic pain, in whom histamine iontophoresis may be perceived as painful. These findings indicate that pain-induced inhibition of pruritus may be compromised in patients with chronic itch. This may also explain why scratching aggravates itch in patients with chronic itch, thereby inducing a vicious itch–scratch cycle.

Itch Related to Impaired Skin Barrier Function

Itch is a common symptom of xerotic skin and is aggravated during the winter in cold climates when the relative humidity falls indoors. Damage to the stratum corneum and the impaired barrier function that results can induce itch even in the absence of inflammation. Environmental changes in pH, temperature, and humidity may activate C fibers to transmit the sensation of itch. Cross-talk between the stratum corneum and nerve fibers may explain the pruritus associated with impaired barrier function. Keratinocytes release neuromediators upon damage to the stratum corneum barrier, and nerve fibers sprout in the epidermis in response to this damage. Indeed, factors such as IL-33 have been shown to directly stimulate sensory neurons and evoke itch in the setting of xerotic skin[68].

Itch in Older Adults

Itch is particularly frequent in individuals over 65 years of age[68]. Although dry skin is probably the most common trigger, elderly patients can have idiopathic itch without xerosis. Other possible explanations include age-related changes in nerve fibers and central disinhibition of itch due to loss of input from pain fibers. Additional changes that may contribute to pruritus as well as xerosis in elderly patients include decreased skin surface lipids, diminished skin barrier repair, and immunosenescence (e.g. enhanced Th2 activity).

Cholestatic Pruritus

The enzyme autotaxin and its product lysophosphatidic acid (LPA), a neuronal activator, have a pathogenic role in cholestatic pruritus (see Ch. 6). Serum autotaxin levels correlate with itch intensity in patients with cholestasis. In addition, the G protein-coupled bile acid receptor-1 (Gpbar1; TGR5) has been found to have a role in cholestatic pruritus in mouse models. Murine MrgprA1 and human MRGPRX4 have been identified as itch receptors for bilirubin, suggesting another mechanism by which cholestatic itch is elicited[70,71].

TREATMENTS FOR PRURITUS

Unlike pain, for which a host of effective medications are available, there are no general-purpose, consistently beneficial antipruritic drugs. The mechanisms, uses, and adverse effects of currently available antipruritic drug treatments are outlined in Table 5.5. A number of new and emerging therapies for atopic dermatitis provide ways to treat itch by targeting the neuro-immune interface. These include agents that block IL-4/-13 and IL-31 signaling as well as JAK inhibitors. Additional pruritus treatments are likely to result from further advances in our understanding of itch biology.

FUTURE DIRECTIONS

Continued progress in itch research will help to determine how itch transmission pathways contribute to neuropathic, inflammatory, and even idiopathic forms of pruritus, providing the basis for novel therapies.

DRUG TREATMENT OF PRURITUS			
Medication	**Mechanism(s) of action**	**Uses and efficacy**	**Major adverse effects**
Topical agents			
"Barrier repair" creams, other emollients and humectants	• Diminish transepidermal water loss and decrease flux between a distended and desiccated state • Minimize microfissures that expose C nerve fibers • Agents that acidify the stratum corneum may reduce itch, as alkaline agents (e.g. bar soaps) can activate proteases and increase lipid rigidity	• Decrease itch in patients with atopic dermatitis	None

Capsaicin (active component in hot chili peppers)	• Activates and subsequently desensitizes TRPV1, a vanilloid TRP receptor
	• Causes release from C neurons and (eventually) depleted stores of neuropeptides (e.g. substance P, CGRP, somatostatin)
	• Prolonged use leads to neuronal degeneration at sites of application, which can result in a reversible decrease in epidermal nerve fiber density
		• Used primarily for localized, chronic pruritic disorders, especially those of neuropathic origin
		• Controlled studies support use for:
		  • Notalgia paresthetica
		  • Brachioradial pruritus
		  • Hemodialysis-associated pruritus
		  • Postherpetic neuralgia, with a transdermal patch FDA-approved for this indication
			• Transient burning sensation, which usually resolves after several days of consistent use; application of topical lidocaine or EMLA may be helpful

Doxepin	• Tricyclic compound with potent antihistamine effects (H1 and H2) • Also anticholinergic properties	• Shown to relieve pruritus in patients with atopic dermatitis	• Drowsiness in ~25% of patients due to percutaneous absorption • Allergic contact dermatitis, followed by risk of systemic contact dermatitis with oral doxepin
Ketamine–amitriptyline–lidocaine (10%–5%–5% compounded cream)	• Anesthetic effect; targets ion channels in peripheral nerves and NMDA receptors	• May decrease neuropathic itch and other forms of pruritus, including the itch of prurigo nodularis	• Mild burning sensation • Potential systemic absorption • Not FDA approved
Menthol	• Activates TRPM8 and TRPA1, producing a cool sensation	• Inconsistent results in controlled studies • May be especially beneficial for patients whose itch is relieved by cold showers	• Skin irritation
Pramoxine	• Anesthetic (blocks transmission of nerve impulses)	• Beneficial for histamine-induced itch and uremic pruritus in end-stage renal disease	• Allergic contact dermatitis (uncommon)
Ruxolitinib	• Inhibit JAK 1 and 2, thus decreasing signaling by IL-4, IL-31, and TSLP	• Decreases itch in patients with atopic dermatitis	• Acne at application site • Possibly nasopharyngitis
Strontium	• Calcimimetic thought to inhibit ion channels in nerve fibers	• Strontium 4% hydrogel was shown to relieve localized cowhage-induced itch	• None identified • Not FDA approved
Tacrolimus, pimecrolimus	• Calcineurin inhibitors that block production of multiple proinflammatory cytokines (see Ch. 128) • May initially activate and subsequently desensitize TRPV1	• Can decrease itch related to the inflammation of atopic dermatitis	• Transient burning sensation
Systemic agents			
Antihistamines (especially doxepin)	• Doxepin is a tricyclic compound with potent antihistamine effects (H1 and H2) and anticholinergic properties; first-generation, sedating antihistamine	• Decrease wheal formation as well as pruritus in patients with urticaria	• Sedation • Anticholinergic effects • Interaction with MAO inhibitors (for doxepin)
Aprepitant	• Antagonist of the neurokinin-1 receptor, which is activated by substance P	• Primarily used as an antiemetic in oncology patients; reports of reduced pruritus in patients with atopic dermatitis, Sézary syndrome, and other forms of CTCL as well as decreases in pruritus induced by anti-EGFR antibodies or tyrosine kinase inhibitors	• Fatigue • Hiccups
Butorphanol	• κ-Opioid receptor agonist and μ-opioid receptor antagonist*	• Relieves pruritus associated with morphine with epidural administration of both agents • May reduce severe pruritus associated with systemic disease or inflammatory skin conditions‡	• Nausea/vomiting • Sedation • Dependence (rare)
Difelikefalin, nalfurafine†	• κ-Opioid receptor agonists*	• Controlled trials show efficacy for renal pruritus; difelikefalin is FDA-approved for this indication	• Insomnia

Table 5.5 Drug treatment of pruritus.

Continued

DRUG TREATMENT OF PRURITUS			
Medication	**Mechanism(s) of action**	**Uses and efficacy**	**Major adverse effects**
Naloxone, naltrexone	• μ-Opioid receptor antagonists*	• Controlled trials show efficacy for cholestatic and renal pruritus • May be of benefit for severe pruritus of other etiologies	• Hepatotoxicity • Nausea/vomiting • Insomnia • Reversal of analgesia
Thalidomide	• Blocks neuropathic afferent pathways (peripherally and centrally) • Inhibits TNF synthesis	• May be helpful for prurigo nodularis, actinic prurigo, and pruritus of advanced age	• Teratogenicity • Peripheral neuropathy
Dupilumab, tralokinumab lebrikizumab	• Block IL-4Rα (dupilumab) on immune cells and neurons • Block IL-13 (tralokinumab, lebrikizumab)	• Decrease pruritus in patients with atopic dermatitis and prurigo nodularis	• Conjunctivitis, keratitis • Facial dermatitis • Injection site reaction
Nemolizumab	• Blocks IL-31RA	• Reduces pruritus in patients with atopic dermatitis and prurigo nodularis	• Injection site reaction • Peripheral edema
Gabapentin, pregabalin	• Structural analogues of the neurotransmitter GABA • Thought to inhibit central itch pathways	• Beneficial for neuropathic itch (e.g. brachioradial pruritus), post-burn pruritus and postherpetic neuralgia	• Peripheral edema • Sedation • Abdominal pain
Mirtazapine	• Serotonin and norepinephrine inverse agonist that reduces central itch perception	• May reduce nocturnal pruritus (at low doses, e.g. 15 mg nightly)	• Sedation • Weight gain
Omalizumab, ligelizumab	• Block IgE	• Decrease pruritus in patients with chronic spontaneous urticaria and associated with immune checkpoint inhibitor and anti-HER2 therapies	• Rare anaphylactoid reactions (epinephrine [adrenaline] autoinjector should be prescribed for all patients) • Injection site reaction
Paroxetine	• Selective serotonin reuptake inhibitor (SSRI)	• A controlled study showed benefit for pruritus related to systemic disease	• Sexual dysfunction • Sedation • Insomnia • Weight gain
Upadacitinib, abrocitinib, baricitinib	• Inhibition of JAK1 (+ JAK2 for baricitinib) in immune cells and neurons	• Decrease pruritus within 1–2 weeks in patients with atopic dermatitis	• Risk of acne, serious infections, cytopenias, thrombosis, hyperlipidemia, major cardiovascular events, cancer, and (for upadacitinib & baricitinib) gastrointestinal perforation

*Inhibit itch transmission within the central nervous system.
†Currently not commercially available in the US.
‡An intranasal spray is currently available.

Table 5.5 Drug treatment of pruritus. Topical naltrexone, aspirin, and cannabinoids may also have antipruritic effects, and injections of botulinum toxin type A have been used to treat neuropathic itch. Of note, although capable of relieving pruritus by treating inflammatory skin disease, corticosteroids are not intrinsically antipruritic. The ileal bile acid transporter inhibitors odevixibat and maralixibat are FDA-approved to treat cholestatic pruritus in patients with progressive familial intrahepatic cholestasis and Alagille syndrome, respectively. In the future, topical anti-itch medications may target serine proteases (e.g. cathepsin S), nerve growth factor, or neurotrophin 4. CGRP, calcitonin gene-related polypeptide; CTCL, cutaneous T cell lymphoma; EGFR, epidermal growth factor receptor; EMLA, eutectic mixture of local anesthetics (lidocaine + prilocaine); FDA, US Food and Drug Administration; GABA, γ-aminobutyric acid; IL, interleukin; MAO, monoamine oxidase; NMDA, N-methyl-D-aspartate; TNF, tumor necrosis factor; TRP, transient receptor potential ion channel family; TSLP, thymic stromal lymphopoietin.

INTRODUCTION

Pruritus can be defined as an unpleasant sensation that elicits a desire to scratch. The presumed biologic purpose of pruritus is to provoke scratching to remove a parasite or other harmful pruritogen. Pruritus is the most common skin-related symptom. It often arises from a primary cutaneous disorder but can be a manifestation of an underlying systemic disease in 15%–50% of affected individuals, especially when generalized[1,2]. Non-dermatologic conditions that can lead to generalized pruritus include hepatic, renal, or thyroid dysfunction; lymphoma, myeloproliferative neoplasms (e.g. polycythemia vera), and chronic lymphocytic leukemia; HIV or parasitic infections; and neuropsychiatric disorders (see Ch. 7).

A clinical classification scheme for chronic pruritus was proposed in 2007 by the International Forum for the Study of Itch[3]. In this system, there are three major groups of pruritus: (1) chronic pruritus of lesional (inflamed) skin; (2) chronic pruritus of non-lesional (non-inflamed) skin; and (3) chronic pruritus presenting with secondary scratch-induced lesions (e.g. prurigo nodularis, lichen simplex chronicus). Following initial evaluation, the etiology of the pruritus is categorized as dermatologic, systemic, neurologic, psychogenic, mixed, or other/unknown[3]. Such classification assists in planning further evaluation and treatment of the underlying disease (if possible) as well as the pruritus itself. Recent advances in our understanding of the mechanisms underlying chronic pruritus have led to the development of targeted therapies, and additional promising drugs are expected in the near future.

EPIDEMIOLOGY

It is assumed that all humans experience the sensation of pruritus at some point in their life, e.g. from insect bites (Fig. 6.1). However, relatively few studies have investigated the overall incidence and prevalence of pruritus. In a Norwegian population-based, cross-sectional study of self-reported skin morbidities, pruritus was the dominant symptom among adults, experienced within the past week by 9% of women and 7.5% of men[4]. A German population-based, cross-sectional study found that the self-reported point, 12-month, and lifetime prevalences of chronic pruritus (lasting ≥6 weeks) were 13.5%, 16%, and 22%, respectively[5]; in a follow-up cohort study, a 7% 12-month cumulative incidence of chronic pruritus was observed[6]. Women have a higher lifetime prevalence of chronic pruritus than men, and older adults are more frequently affected. Table 6.1 summarizes the prevalence of pruritus in various medical conditions[7].

EVALUATION OF THE PATIENT

A structured approach to the evaluation of patients with a chief complaint of pruritus is presented in Fig. 6.2. Pruritus is a subjective sensation, and currently its presence or severity cannot be assessed objectively. Thus, a thorough history that includes the patient's itch sensation plus a complete cutaneous examination for any evidence of skin lesions are important for correct diagnosis and allow assignment of the patient to one of the three clinical groups of pruritus (see above).

Fig. 6.1 Insect bites. Linear pruritic papules with central crusts demonstrating the "breakfast, lunch, and dinner" sign. *Courtesy Antonio Torrelo, MD.*

PREVALENCE OF PRURITUS IN SELECTED CONDITIONS	
Disorder	**Reported prevalence of pruritus**
Atopic dermatitis	100% (diagnostic criterion)
Lichen planus	~95%
Psoriasis	60%–95%
End-stage kidney disease on hemodialysis	25%–30%
Primary biliary cholangitis	80% (often the presenting symptom)
Hepatitis C viral infection	~15%
Cutaneous T cell lymphoma	60%–80% overall; >90% in Sézary syndrome
Polycythemia vera	30%–50%
Hodgkin lymphoma	≤30%
Non-Hodgkin lymphoma	≤10%
Leukemias	<5%
Herpes zoster	≤60%
Postherpetic neuralgia	≤30%
Pregnancy	~20%

Table 6.1 Prevalence of pruritus in selected conditions (see text).

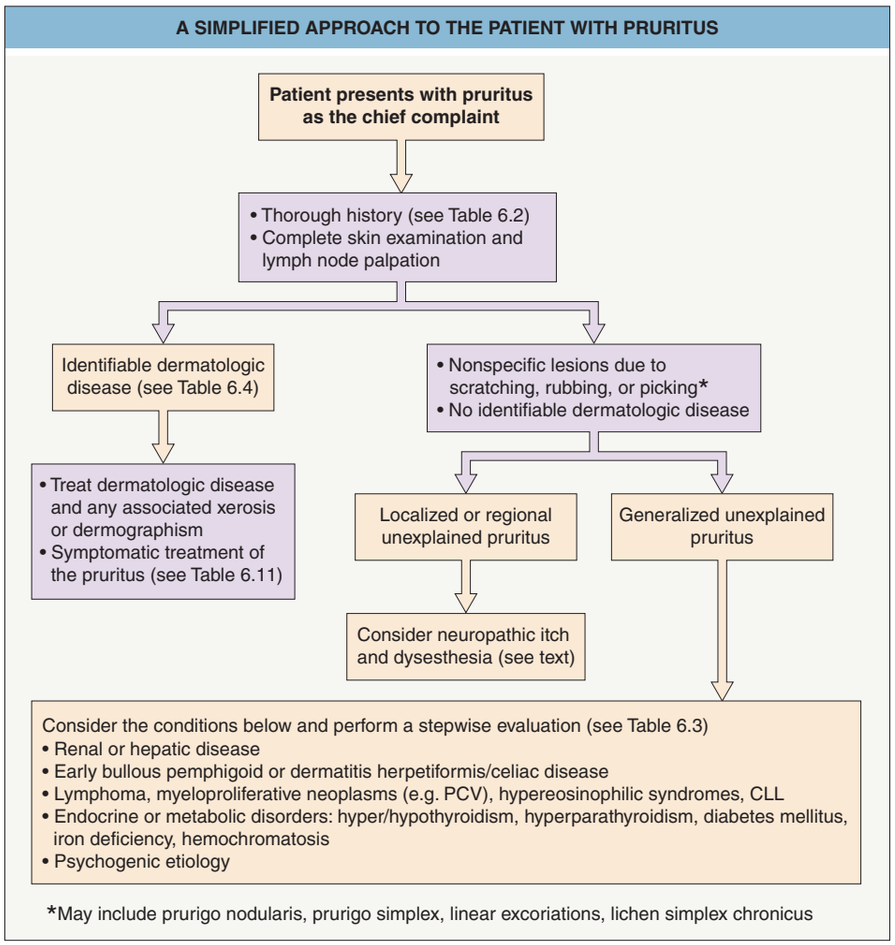

Fig. 6.2 A simplified approach to the patient with pruritus. CLL, chronic lymphocytic leukemia; PCV, polycythemia vera.

Patients with evidence of a particular skin condition should be treated accordingly, while those with no identifiable primary skin disease (i.e. an absence of or only secondary skin lesions) require further investigation to determine the etiology of their pruritus. Also, chronic pruritus can have multiple underlying factors, and a pruritic skin condition that has nonspecific clinical findings initially may over time develop diagnostic features. Therefore, longitudinal evaluation is essential.

History

A precise history may provide insight into the patient's disease processes. In addition to the patient's spontaneous description, specific questions regarding the onset, location, duration, and nature of the pruritus can help to determine its cause (Table 6.2)[8]. The use of standardized instruments to assess itch intensity (e.g. a numerical rating scale) and impairment of quality of life (e.g. ItchyQol) is recommended[9]. A medical and medication history should also be obtained. Although chronic, progressive, generalized pruritus without primary skin lesions raises suspicion of an underlying systemic disease, no particular clinical characteristics reliably predict the likelihood of a systemic etiology[8].

Examination

Careful and complete examination of the skin, nails, scalp, hair, mucous membranes (e.g. oral, conjunctival), and anogenital area at the initial visit is recommended. The morphology and distribution of primary lesions and secondary changes (e.g. excoriations, crusts, lichenification) should be assessed, with particular attention to xerosis, the presence of dermographism (Fig. 6.3), and skin signs of systemic diseases (see Ch. 53). Lesions on the mid upper back suggest a primary skin disease, since this difficult-to-reach area is typically spared (the "butterfly sign") in patients with skin lesions secondary to scratching (see Fig. 6.5A). However, this region can be accessed with "back-scratching" devices.

The examination should include palpation of major peripheral lymph node groups (e.g. cervical, supraclavicular, axillary, inguinal), especially in those with no obvious primary inflammatory skin disease. Together with a general physical examination performed by the patient's primary care physician, this may disclose an undiagnosed extracutaneous disease (e.g. lymphoma) in individuals with pruritus of unknown etiology[8].

Laboratory Investigation and Radiographic Imaging

In the setting of pruritus of unknown etiology, a stepwise approach to laboratory tests and other investigations (e.g. radiographic imaging) is recommended (Table 6.3). Microscopic examination of skin scrapings for signs of scabies or a fungal infection as well as examination of stool samples for parasites can also be considered. Biopsies of representative skin lesions, even if nonspecific clinically, are occasionally informative, and direct immunofluorescence studies of perilesional skin or normal-appearing skin (in the vicinity of lesions if present) may point to a specific dermatologic disease such as bullous pemphigoid or dermatitis herpetiformis, respectively. Radiographic examinations may be performed to exclude an underlying malignancy or other systemic condition as well as peripheral nerve impingement when neuropathic itch is suspected[8].

PRURITUS IN DERMATOLOGIC DISEASE

This section focuses on the sensation of pruritus in selected skin diseases where this symptom is a prominent feature. A more comprehensive discussion of the diseases mentioned and the many additional dermatoses in which pruritus is a characteristic feature (Table 6.4) may be found in other chapters.

Inflammatory Dermatoses

Urticaria

Urticaria is often intensely pruritic and can also produce stinging or prickling sensations. Early lesions and small superficial wheals are

DESCRIPTIVE FEATURES OF THE PRURITUS AND ADDITIONAL PATIENT HISTORY
Questions to ask regarding the pruritus
• WHEN did it start? *Duration:* days, weeks, months, years • WHERE did it start? WHERE is it now? *Location*: localized or generalized; unilateral or bilateral; within lesional (inflamed) skin or non-lesional (non-inflamed) skin • HOW did it develop? *Onset*: abrupt, gradual, progressive, prior history of pruritic episodes • HOW does it feel? *Nature:* prickling, crawling, burning, stinging • HOW intense is it? *Severity:* on numerical ranking scale (1–10); mild, moderate, severe; interference with normal activities or sleep • HOW often do you feel it? *Time course:* intermittent, continuous, cyclical, nocturnal • WHAT makes it worse? *Provoking/aggravating factors:* heat, cold, water, air, exercise, occupation, hobbies • WHAT makes it better? *Itch relief:* cold, heat, scratching/rubbing/hurting, cool/hot showering • WHAT do you think is the cause? *Patient's theory of pruritus etiology*
Additional patient history
• Skin care, bathing habits, exposure to irritants • Medications (including topical agents): prescribed, over-the-counter; duration of use and relationship to onset of pruritus • Use of nicotine, alcohol, and recreational/illicit drugs • Allergies (known and suspected): drugs, airborne, food, contact • Atopic history: atopic dermatitis, allergic rhinoconjunctivitis, asthma • Past and present medical history: thyroid, liver, or renal dysfunction; other systemic diseases; psychological disease; surgeries or accidents • Family history: atopy, skin disease, similar pruritic conditions • Occupation, hobbies, personal stress • Household and personal contacts; pets and their care • Dietary habits • Sexual history • Travel history • Prior diagnoses made by physician or patient

Table 6.2 Descriptive features of the pruritus and additional patient history.

Fig. 6.3 Dermographism. Linear streaks of urticaria induced by scratching the skin. Assessment for dermographism should be performed in all patients with pruritus.

LABORATORY AND RADIOGRAPHIC EVALUATION IN PATIENTS WITH PRURITUS OF UNKNOWN ETIOLOGY
Basic initial evaluation
• Complete blood count (CBC) with differential and platelet count • Erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) • Creatinine, blood urea nitrogen (BUN) • Liver transaminases, alkaline phosphatase, bilirubin • Lactate dehydrogenase (LDH) • Thyroid stimulating hormone (TSH) • Fasting plasma glucose • Serum ferritin, serum iron, and total iron binding capacity
Possible additional evaluation
Skin biopsy • Routine histology (if skin lesions are present) • Direct immunofluorescence studies* *Other laboratory tests* • Serum total and/or allergen-specific IgE • Serum protein electrophoresis, serum immunofixation electrophoresis • Viral hepatitis panel (including hepatitis B and C viruses); HIV testing • Parathyroid function (calcium, phosphate, parathyroid hormone levels) • Serum tryptase • Anti-BP180 and anti-BP230 bullous pemphigoid IgG antibodies; anti-tissue transglutaminase IgA antibody • Anti-mitochondrial and anti-smooth muscle antibodies • Stool for ova/parasites *Radiographic studies* • Chest X-ray or CT scan • Abdominal and pelvic ultrasonography or CT scan • Lymph node ultrasonography • Spinal X-ray or MRI (for regional pruritus) *Other investigations* • Patch testing • Prick testing for major atopy and relevant occupational allergens • Age-appropriate cancer screening (in conjunction with primary care physician) • If hydroxyethyl starch (HES)-induced pruritus is suspected, electron microscopy of a biopsy sample from normal-appearing skin
*Biopsy perilesional skin or normal-appearing skin (in vicinity of lesions if present) to assess for bullous pemphigoid and dermatitis herpetiformis, respectively.

Table 6.3 Laboratory and radiographic evaluation in patients with pruritus of unknown etiology. A general physical examination should also be performed by the patient's primary care physician. Selection of particular tests beyond the basic initial evaluation is based upon the patient's history, physical examination findings, and pruritus severity. The results of initial testing can also help to direct further evaluation[8].

particularly symptomatic[1]. Histamine plays a primary role in the pruritus of urticaria, and H1-receptor antagonists usually decrease or eliminate this sensation as well as the wheals themselves[10]. Several other mediators are involved in the pathophysiology of urticaria, and interleukin (IL)-31 levels correlate with itch intensity[11]. When refractory to higher doses of antihistamines, omalizumab, and cyclosporine represent alternative treatments for urticaria (see Ch. 18).

Atopic dermatitis

Pruritus is such an important aspect of atopic dermatitis that "the diagnosis of active atopic dermatitis cannot be made if there is no history of pruritus"[12] (see Ch. 12). The itch sensation typically comes in "attacks", which may be severe and significantly impact quality of life[13]. Often, pruritus is the first indication of a disease flare. Moreover, scratching as a response to itch leads to excoriations and lichenification, which represent additional clinical features of atopic dermatitis[14]. Pruritus can be provoked by exposure to aeroallergens or ingestion of foods to which the patient is sensitized as well as non-immunologic triggers, including emotional stress, overheating, perspiration, and contact with rough fabrics or even air (atmokinesis)[15] (Fig. 6.4). Although most affected children experience worsening of symptoms during the winter, others have exacerbations primarily during the summer[16]. Of note, pruritus may persist after resolution of inflammatory skin lesions.

The minimal effectiveness of antihistamines in alleviating the itch of atopic dermatitis indicates that histamine is probably not the predominant mediator of the pruritic sensation[17–19]. Rather, the benefit of antihistamines in atopic dermatitis is most likely due to their sedative effects. Type 2 cytokines such as IL-4, IL-13, IL-31, and thymic stromal lymphopoietin play a key role in the inflammation of atopic dermatitis. As a result, therapies that target Th2 signaling via IL-4/-13 (e.g. dupilumab, tralokinumab, lebrikizumab), IL-31 (nemolizumab), or Janus kinase (JAK) 1/2 have anti-pruritic effects[14].

Other mediators and receptors with possible roles in the pruritus of atopic dermatitis include neuropeptides (e.g. substance P, calcitonin gene-related peptide [CGRP]), neurotrophic factors (e.g. nerve growth factor [NGF], artemin [causes warmth-provoked itching]), epidermal opioid receptors (downregulated), and endothelin-1[14,18,19]. In addition, itch transmission results from kallikrein-related peptidase and mast

PRIMARY DERMATOLOGIC CONDITIONS ASSOCIATED WITH PRURITUS	
Cause	**Dermatologic disease**
Inflammation	• Atopic dermatitis • Allergic or irritant contact dermatitis • Seborrheic dermatitis, especially of the scalp • Stasis dermatitis • Psoriasis • Parapsoriasis • Pityriasis rubra pilaris • Lichen planus and its variants • Urticaria, dermographism • Mastocytosis • Papular urticaria, urticarial dermatitis • Drug eruptions, e.g. morbilliform • Polymorphous light eruption, actinic prurigo, chronic actinic dermatitis • Bullous diseases, e.g. DH, BP • Polymorphic eruption of pregnancy (PEP) • Eosinophilic folliculitis • Dermatomyositis • Prurigo pigmentosa • Lichen sclerosus • Graft-versus-host disease
Infestation/ bites & stings	• Scabies • Pediculosis • Arthropod bites
Infections	• Bacterial infections, e.g. folliculitis • Viral infections, e.g. varicella • Fungal infections, e.g. inflammatory tinea • Parasitic infections, e.g. schistosomal cercarial dermatitis
Neoplastic	• Cutaneous T cell lymphoma, e.g. mycosis fungoides, Sézary syndrome
Genetic/ nevoid	• Darier disease and Hailey–Hailey disease • Ichthyoses, e.g. Netherton, Sjögren–Larsson, and peeling skin syndromes • Pruriginosa subtype of dominant dystrophic EB • Porphyrias, e.g. porphyria cutanea tarda and erythropoietic protoporphyria • Inflammatory linear verrucous epidermal nevus (ILVEN) • Large/giant congenital melanocytic nevi, occasionally, especially in bulky lesions with neural differentiation • Multiple intestinal atresia, early-onset IBD, and combined immunodeficiency (*TTC7A* mutations)
Other	• Xerosis, eczema craquelé • Primary cutaneous amyloidosis (macular, lichenoid) • Postburn pruritus • Scar-associated pruritus • Radiation-associated pruritus • Fiberglass dermatitis (see Ch. 16)

Table 6.4 Primary dermatologic conditions associated with pruritus. BP, bullous pemphigoid; DH, dermatitis herpetiformis; EB, epidermolysis bullosa; IBD, inflammatory bowel disease.

Fig. 6.4 Atopic dermatitis. A Excoriated eczematous plaques in the popliteal fossae, a classic flexural location for atopic dermatitis. **B** Prurigo simplex, prurigo nodularis-like lesions, and angulated ulcerations; the latter two are primarily on the knees. *Courtesy Antonio Torrelo, MD.*

cell tryptase binding to protease-activated receptors (PAR-2; see Ch. 5). In atopic patients, morphologic alterations of cutaneous nerves and neuronal sensitization may also contribute to an increased itch sensation and even the perception of painful stimuli as itch[20].

Psoriasis

Although not traditionally regarded as a pruritic disease, studies have shown that up to 60%–95% of psoriasis patients suffer from pruritus, with xerosis, heat, sweating, and emotional stress serving as exacerbating factors[21]. While lesions on the scalp, back, and legs are most often pruritic, generalized pruritus can occur in plaque-type as well as erythrodermic and pustular psoriasis[21]. Patients frequently describe the pruritus as having tickling, crawling, and burning components, and antihistamines rarely provide relief. Although the pathophysiology of psoriatic itch is still largely unknown, it is thought to be multifactorial and a variety of itch mediators (e.g. substance P, NGF, protein gene product 9.5, CGRP, neuropeptide Y, IL-2, opioid receptors) have been implicated[21]. Coadministration of β-blockers, angiotensin-converting enzyme (ACE) inhibitors, or antacids may be associated with the development of psoriatic itch[22]. Successful treatment of psoriasis can reduce associated pruritus (see Ch. 8)[21,23].

Infestations

Scabies

In patients with scabies, pruritus can be localized or generalized, and it may have a burning component. It is usually more intense at night and typically spares the head. The pruritus usually begins 3–6 weeks after a first-time infestation, and within a few days in subsequent infestations; multiple family members are often affected (see Ch. 84). The itch reflects various components of the immune response against mites, eggs, and scybala[1]. Bacterial superinfection and eczematization of skin lesions may also contribute to itch in patients with scabies[24].

Pediculosis (lice)

Pruritus at the primary sites of infestation (e.g. scalp, groin) is a clue to the diagnosis of head and pubic lice (see Ch. 84). Generalized pruritus is characteristic of body lice but can also occur with other forms of lice infestation[1].

Cutaneous T Cell Lymphoma (CTCL)

Pruritus affects >60% of patients with CTCL, with an increased frequency and intensity in those with later-stage disease, especially Sézary syndrome (>90% of patients) and folliculotropic mycosis fungoides (MF)[25,26]. A variant of Sézary syndrome presenting with

generalized pruritus and minimal or no clinically evident skin disease has also been described[27]. Pruritus significantly reduces the quality of life in CTCL patients[28], and it has been associated with an increased risk of disease progression and death.

IL-31 is a putative mediator of itch in CTCL, especially in late-stage disease, and lower serum IL-31 levels have been observed in association with reduced pruritus following treatment with histone deacetylase inhibitors and mogamulizumab (anti-CC-chemokine receptor type-4 antibody)[29–31]. Other possible mediators of CTCL-related itch include IL-4, IL-5, IL-10, IL-13, substance P, NGF, endogenous opioids, and visfatin[31].

Treatment strategies for severe pruritus not responsive to disease-directed therapy in CTCL patients include gabapentin (900–2400 mg daily in divided doses) and/or mirtazapine (7.5–15 mg nightly) as well as opioid antagonists (e.g. naltrexone 50–150 mg daily)[8]. Aprepitant has also been reported to relieve intractable pruritus in patients with Sézary syndrome and other forms of CTCL, suggesting a role for neurokinin-1 (NK1) receptors and substance P in CTCL-related itch[32]. However, in a recent randomized controlled trial (RCT), aprepitant failed to demonstrate an antipruritic effect compared to placebo in patients with Sézary syndrome[33].

DERMATOSES INDUCED BY PRURITUS-ASSOCIATED SCRATCHING OR RUBBING

Prurigo Nodularis

Prurigo nodularis is associated with chronic itch (i.e. lasting ≥6 weeks), where skin lesions are produced by repetitive, focused scratching or picking of the skin[34]. Neuronal sensitization and the development of an itch–scratch cycle contribute to disease chronicity[35]. Prurigo nodularis most often occurs in adults, especially women, but can affect any age group, including children and adolescents with an atopic diathesis[36].

Multiple pruritic papulonodules are most commonly observed on the extensor aspects of the extremities, and their distribution is usually symmetric. The upper back, lumbosacral region, and buttocks may also be involved, but the difficult-to-reach mid upper back is classically spared ("butterfly sign") (Fig. 6.5A). Flexural areas as well as the face and groin are often spared.

The firm, dome-shaped papulonodules have varying degrees of central scale, crust, erosion, or ulceration (Fig. 6.5A–C). The color ranges from skin-toned to erythematous to brown, with hyperpigmentation often seen in individuals with more darkly pigmented skin (see Fig. 6.5C). Lesions can develop a verrucous or fissured surface and lichenification of adjacent skin may be observed. When crusted smaller papules are the predominant finding, the term prurigo simplex is sometimes utilized.

The etiology of the underlying pruritus varies and may include atopic dermatitis (up to 50% of patients), xerosis, another skin disorder, or a systemic disease (e.g. hepatic or renal dysfunction)[35]. Psychological afflictions (e.g. emotional distress) and neuropsychiatric conditions (e.g. obsessive–compulsive disorder, autism spectrum disorders) can also lead to repetitive scratching. Occasionally, prurigo nodularis is associated with an underlying lymphoma and less often solid tumor malignancies[37]. The clinical differential diagnosis of prurigo nodularis may include pemphigoid nodularis (Fig. 6.6), hypertrophic lichen planus, hypertrophic lupus erythematosus, scabietic nodules, persistent insect bite reactions, the pruriginous type of dominant dystrophic epidermolysis bullosa, and neoplasms such as multiple keratoacanthomas or granular cell tumors.

Histologically, there is marked epidermal hyperplasia and thick, compact hyperkeratosis[38]. Keratinocyte atypia is absent, and small areas of erosion or ulceration may be seen. Fibrosis of the papillary dermis with vertically arranged collagen fibers, increased numbers of fibroblasts and capillaries, and a perivascular or interstitial mixed inflammatory infiltrate represent additional findings.

Possibly as a result of intense scratching, pruriginous lesions demonstrate hypertrophy and an increased density of dermal nerve fibers. In contrast, the number of nerve fibers within the epidermis is reduced. There is increased expression of substance P, CGRP, and NGF receptors by the dermal nerve fibers and prominent NGF immunoreactivity in lesional dermis. The dermal neuronal hyperplasia and epidermal "small fiber neuropathy" may play a pathogenic role in perpetuating the pruritus of prurigo nodularis[20,39]. Additionally, proinflammatory

mediators such as IL-31 are upregulated in pruriginous lesions and contribute to neurogenic inflammation.

Treatment of prurigo nodularis is usually difficult and typically requires a multifaceted approach, which should be individualized depending on etiologic factors and the extent of disease[40]. Any underlying conditions (e.g. atopic dermatitis, chronic kidney disease, cholestasis) should be identified and treated if possible. Ideally, significantly reducing the pruritus would break the itch–scratch cycle, eventually leading to healing of the lesions; however, this is often not possible, especially when there is a psychological underpinning. Topical antipruritic agents (e.g. menthol, pramoxine, polidocanol) and oral antihistamines may help to decrease itch intensity. The former can be applied repeatedly as a "substitute" for scratching, and a sedating antihistamine at bedtime may be beneficial for sleep disturbances.

The skin lesions may respond to superpotent topical corticosteroids under occlusion, corticosteroid-impregnated tape, intralesional corticosteroids, phototherapy (e.g. narrowband or broadband UVB, psoralen plus UVA [PUVA]), or excimer laser treatment. Other topical treatments with potential benefit include capsaicin (0.025%–0.1% 4–6 times daily, applied locally), calcipotriene (calcipotriol), and calcineurin inhibitors. Based upon RCTs in which ~45%–50% of patients with prurigo nodularis achieved clear or almost clear skin after 24 weeks of therapy, dupilumab was FDA approved for this indication[40a]. The IL-31 receptor inhibitor nemolizumab was also found in RCTs to significantly reduce pruritus and cutaneous lesions in adults with prurigo nodularis[41].

Improvement of prurigo nodularis with gabapentinoids (e.g. gabapentin, pregabalin), μ-opioid receptor antagonists (e.g. naloxone, naltrexone), or combined μ-opioid receptor antagonist/κ-opioid receptor agonists (e.g. nalbuphine) has been described. Systemic immunosuppressive drugs such as cyclosporine or methotrexate may be of benefit, especially in patients in which the inflammatory component of the disease predominates. Treatment directed toward any underlying compulsive behavior is important. Selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants have both been employed successfully, especially when a component of depression is present. Thalidomide (50–200 mg daily) has been reported to be highly effective for patients with recalcitrant prurigo nodularis, although its use is limited by teratogenicity and the potentially irreversible side effect of peripheral neuropathy.

Lichen Simplex Chronicus

In lichen simplex chronicus (LSC), there is epidermal hypertrophy secondary to chronic, habitual rubbing or scratching of localized areas of skin. Lesions of LSC are broader and thinner than those of prurigo nodularis. LSC is most frequently observed in adults and is relatively uncommon in children, with the exception of lichenified lesions in atopic dermatitis.

Fig. 6.7 Lichen simplex chronicus. A Lichenified pink plaque on the ankle of a young man. **B** Note the increased skin markings in this hyperpigmented plaque on the posterior neck. *B, Courtesy Ronald P. Rapini, MD.*

LSC is characterized by well-defined plaques exhibiting exaggerated skin lines (lichenification) with a "leathery" appearance, coalescing papules, hyperpigmentation, and varying degrees of erythema. Lesions may be solitary or multiple, with a predilection for the posterolateral neck, occipital scalp, anogenital region (e.g. scrotum, vulva), shins, ankles, and dorsal aspects of the hands, feet, and forearms (Fig. 6.7). Predisposing factors include xerosis, atopy, psoriasis, stasis dermatitis, anxiety, obsessive–compulsive disorder, localized neuropathic itch, and pruritus related to systemic disease.

The clinical differential diagnosis may include lichen amyloidosis and hypertrophic lichen planus, both of which present with chronic pruritic plaques favoring the shins. *Lichen ruber moniliformis* is a historic condition that presents with rows of papules and cord-like fibrotic bands, which may be both pruritic and painful. Histologic features of LSC are similar to those of prurigo nodularis (see above), with compact hyperkeratosis, acanthosis with irregular elongation of rete ridges, hypergranulosis, and vertically oriented collagen bundles in the papillary dermis.

Like prurigo nodularis, lesions of LSC itch spontaneously, which leads to an "itch–rub/scratch–itch" cycle that often makes it resistant to treatment. Underlying pruritic disorders should be identified and treated if possible. Management strategies are similar to those described for prurigo nodularis (see above), with topical corticosteroids (± occlusion) and intralesional corticosteroids as the mainstays of therapy. Repeated application of a hydrocolloid dressing can lead to improvement. Informal insight-oriented psychotherapy and application

of topical antipruritic agents as "substitutes" for rubbing/scratching may be of benefit. Use of topical lidocaine 5% or capsaicin 8% patches, licensed for the treatment of postherpetic neuralgia, may be helpful in recalcitrant cases. Additional treatments may include antihistamines, gabapentinoids, antidepressants, phototherapy, transcutaneous electrical stimulation, and focused ultrasound[42].

PRURITUS IN SPECIFIC LOCATIONS

Scalp Pruritus

Skin disorders involving the scalp (e.g. seborrheic dermatitis, psoriasis, folliculitis, lichen planopilaris, dermatomyositis) may present with pruritus localized to this area. However, scalp pruritus also occurs in the absence of any objective changes including in the setting of neuropathic disorders (e.g. small-fiber neuropathy, postherpetic neuralgia) or psychogenic itch[43]. Trigger factors should be avoided and any underlying cause treated if possible. Topical corticosteroids and antipruritic agents have been employed with inconsistent efficacy[44].

Anogenital Pruritus

Pruritus ani

Pruritus localized to the anus and perianal skin occurs in 1%–5% of the general population, with a male : female ratio of ~4 : 1[45]. The onset is typically insidious, and symptoms may be present for weeks or years before patients seek medical attention.

Pruritus ani can be primary (idiopathic) or secondary in nature. Primary pruritus ani is defined as pruritus in the absence of any apparent cutaneous, anorectal, or colonic disorder; it accounts for 25%–95% of reported cases, depending upon the series. Possible causes include dietary factors such as poor personal hygiene and psychiatric disorders. Secondary pruritus ani has an identifiable etiology such as chronic diarrhea, fecal incontinence/anal seepage, hemorrhoids, anal fissures or fistulas, rectal prolapse, primary cutaneous disorders (e.g. psoriasis, lichen sclerosus, seborrheic dermatitis, allergic contact dermatitis), sexually transmitted diseases, other infections, infestations (e.g. pinworms), previous radiation therapy or trauma, and neoplasms (e.g. anal cancer)[45]. Pruritus ani (as well as pruritus vulvae or scroti) can also be neuropathic in origin and be due to compression or irritation of lumbosacral nerves from prolapsed intervertebral discs, vertebral body fractures, or osteophytic processes.

Findings on physical examination range from normal-appearing skin or mild perianal erythema to severe irritation with crusting, lichenification, and erosion or ulceration. Histologically, a nonspecific, chronic dermatitis is usually seen, but specific dermatoses (e.g. lichen sclerosus) and neoplastic disorders (e.g. extramammary Paget disease) can be excluded.

Evaluation includes a thorough history, complete cutaneous and general physical examination, and psychiatric screening. The latter is of importance considering that anxiety and depression may be aggravating factors for pruritus ani. Patch testing should be considered to exclude allergic contact dermatitis. Rectosigmoidoscopy and/or colonoscopy may be necessary, especially in patients with recalcitrant pruritus ani, in order to detect underlying conditions ranging from hemorrhoids to cancer. The possibility of pinworm infection should be considered, particularly in affected children[46]. In patients receiving chronic antibiotic therapy who have liquid stools with a pH of 8–10, *Lactobacillus* replacement therapy is recommended.

While secondary pruritus ani usually improves with treatment of the underlying disorder, management of primary disease can be very challenging. Mild cases often respond to elimination of irritants and triggers, sitz baths (e.g. with astringents such as black tea), cool compresses, and meticulous hygiene using water-moistened, fragrance-free toilet paper or a bidet. The area is then dried with blotting or a fan, with avoidance of rubbing and alkaline soaps[46] (see Ch. 153). Application of zinc oxide paste can help to protect the skin from further irritation and friction.

A mild corticosteroid cream (class 6 or 7) is often effective in controlling symptoms. However, with greater disease severity or the presence of lichenification, more potent topical corticosteroids and prolonged treatment may be required, raising the risk of cutaneous atrophy. Topical calcineurin inhibitors, including use on a rotational basis with topical corticosteroids, may be helpful when longer courses of therapy are necessary[47].

Pruritus vulvae and scroti

These common disorders, which may be incapacitating and emotionally disturbing, are solely psychogenic in only 1%–10% of patients[1]. Like pruritus ani, patients with pruritus of the vulva or scrotum typically complain of symptoms that are worse at night, and repeated rubbing or scratching leads to lichenification. The evaluation, differential diagnosis, and treatment options are similar to those for pruritus ani.

Acute pruritus of the vulva or scrotum is often related to infections such as candidiasis or scabies, but allergic or irritant contact dermatitis should also be considered. *Chronic* pruritus in these sites may be caused by dermatoses (e.g. psoriasis, atopic dermatitis, lichen sclerosus, lichen planus, LSC), malignancy (e.g. extramammary Paget disease, squamous cell carcinoma), or atrophic vulvovaginitis[46]. Scrotal pruritus secondary to lumbosacral radiculopathy has also been described[48]. In general, irritation of sensitive genital skin from cleansing and toilet habits needs to be addressed, as well as treatment of any identifiable underlying cause.

PRURITUS VARIANTS

Aquagenic Pruritus

Aquagenic pruritus is usually secondary to a systemic disease (e.g. polycythemia vera) or another skin disorder (e.g. urticaria, dermographism; Table 6.5), whereas primary (idiopathic) aquagenic pruritus is relatively uncommon. Aquagenic pruritus presents with prickling, tingling, burning, or stinging sensations within 30 minutes of water contact, irrespective of its temperature or salinity, and lasts for up to 2 hours[1]. Typically, symptoms begin on the lower extremities and then generalize, with sparing of the head, palms, soles, and mucosae[49]; on examination, specific skin lesions are not seen. The pathologic mechanism is unknown, although elevated dermal and epidermal levels of acetylcholine, histamine, serotonin, and prostaglandin E_2 have been described[1].

Treatment of aquagenic pruritus is difficult. Aspirin (300–500 mg daily) was of benefit in one RCT. Treatment with narrowband or broadband UVB or PUVA may also be effective. Based upon case reports and case series, alkalization of bath water with baking soda, capsaicin cream (0.025%–0.1% applied 3–6 times daily for ≥4 weeks), and systemic agents including β-blockers (e.g. propranolol, atenolol), clonidine, ibuprofen prior to bathing, pregabalin, H2-blockers, opioid receptor antagonists, antidepressants, and interferon-α may be helpful[8]. In secondary forms of aquagenic pruritus, treatments should target any underlying condition, e.g. antihistamines for dermographism.

DIFFERENTIAL DIAGNOSIS OF PRURITUS OR PRICKLING SENSATIONS PROVOKED BY WATER CONTACT
Disease-associated skin findings typically evident at time of visit
• Polycythemia vera (ruddy complexion; see text) • Mastocytosis (cutaneous lesions, positive Darier's sign) • Hypereosinophilic syndrome (cutaneous lesions in >50% of patients) • Hemochromatosis (diffuse hyperpigmentation)
Urticaria by history and/or challenge
• Dermographism • Cold urticaria • Cholinergic urticaria (with hot water exposure) • Aquagenic urticaria
Skin findings (other than those due to scratching) typically absent
• Hodgkin lymphoma • Myelodysplastic syndromes • Essential thrombocythemia • Testosterone-induced erythrocytosis • Drug-related (e.g. antimalarials, bupropion, clomipramine) • Aquagenic pruritus of the elderly (xerosis may be subtle) • Primary (idiopathic) aquagenic pruritus

Table 6.5 Differential diagnosis of pruritus or prickling sensations provoked by water contact. A possible relationship with lactose intolerance in a subset of patients has also been reported.

Pruritus in Scars

Scar remodeling can last from 6 months to 2 years. Pruritus associated with wound healing is common and usually resolves over time, but it is occasionally prolonged, especially in hypertrophic or keloidal scarring. The pruritus in immature or abnormal scars is most likely a consequence of physical and chemical stimuli as well as nerve regeneration. Physical stimuli include direct mechanical stimulation of nerve endings during scar remodeling. Histamine, vasoactive peptides (e.g. kinins), and prostaglandins E1/E2 may account for a "chemogenic" pruritus. Nerve regeneration occurs in all healing wounds, and a disproportionate number of thinly myelinated and unmyelinated C-fibers in immature or abnormal scars may contribute to increased itch perception. The observation of abnormalities in small nerve fiber morphology and function within keloids has raised the possibility of a small nerve fiber neuropathy[50].

Therapy includes emollients, topical and intralesional corticosteroids, cryotherapy, brachytherapy, and silicone gel sheets. Oral antihistamines do not have a significant benefit. Relief of pain and pruritus associated with giant keloids was observed with oral pentoxifylline (400 mg 2–3 times daily)[51].

Post-Thermal Burn Pruritus

Approximately 85% of patients with burns experience pruritus during the healing phase, particularly when the burns involve the limbs[52]. A gradual decrease in pruritus usually occurs, but it may persist for years. Both neuropathic and pruritogenic mechanisms are thought to contribute to the development of itch after a burn[53]. Reported predictors of pruritus include a deep dermal burn injury, female sex, and psychological distress[54]. Morphine therapy may also contribute to postburn pruritus. Emollients, topical anesthetics (e.g. lidocaine/prilocaine) or doxepin, massage therapy, bathing in oiled water or with colloidal oatmeal, extracorporeal shockwave therapy, and botulinum toxin may be of benefit[55,56]. In an RCT, oral gabapentin was found to be more effective than cetirizine for postburn pruritus[57]. Other systemic therapy options include ondansetron, opioid modulators, and antidepressants[53,58].

Fiberglass Dermatitis

Fiberglass exposure is common in individuals who work in manufacturing or construction. Deposition of fiberglass particles on the skin may provoke severe pruritus, sometimes in the absence of visible skin lesions (see Ch. 16). Involvement of the hands and other non-covered sites such as the arms, face, and upper trunk is typical. Cutaneous findings vary and include erythema, papules, vesicles, excoriations, and lichenification. The clinical presentation may resemble scabies, eczematous dermatitis, folliculitis, or urticaria. Tolerance often develops with prolonged fiberglass exposure[59].

PRURITUS IN SYSTEMIC DISEASE

Chronic Kidney Disease-Associated Pruritus (Renal Pruritus)

Pruritus is a frequent symptom in patients with advanced chronic (not acute) kidney disease, especially those requiring dialysis[7,60]. Although the term "uremic pruritus" is used synonymously, it incorrectly implies that the symptom is secondary to elevated serum urea levels. Nowadays, chronic kidney disease-associated pruritus (CKD-aP), rather than renal pruritus, is the preferred term.

CKD-aP may be localized or generalized, and the intensity and distribution often vary over time. Prurigo nodularis and other secondary skin lesions can develop due to scratching, rubbing, or picking the skin. CKD-aP represents an independent predictor of mortality in dialysis patients and is associated with sleep disturbances, depression, and impaired quality of life[61].

In general, the occurrence of CKD-aP is not associated with sex, race, duration of dialysis, or etiology of the kidney disease[7]; it is rare in children but otherwise does not correlate with age. From 25% to 45% of hemodialysis patients suffer from pruritus[7,62]; a decrease in pruritus frequency over the past few decades likely reflects improvements in dialysis procedures, such as utilization of high-permeability rather than conventional hemodialysis[63]. Patients receiving continuous ambulatory peritoneal dialysis (CAPD) appear to be slightly less or equally affected by pruritus compared to those on hemodialysis[1]. In patients receiving standard thrice weekly hemodialysis, pruritus usually peaks in the evening after 2 days without dialysis, is relatively high during dialysis, and is lowest the following day[64,65].

The etiology of CKD-aP is poorly understood. The role of mast cells and histamine is controversial, with no relationship between plasma histamine levels and the severity of pruritus[66]. This finding is supported by the failure of antihistamine therapy in most affected individuals. Another possible explanation for CKD-aP is an accumulation of compounds that cross the dialysis membranes slowly[1].

Parathyroid gland activity is commonly increased in chronic kidney disease, and dramatic relief of pruritus after subtotal parathyroidectomy has been reported in some patients[1]. However, although higher serum levels of calcium, phosphate, and parathyroid hormone (PTH) have been detected in dialysis patients with pruritus than in those without pruritus, no correlation between degree of pruritus and PTH levels has been observed[67]. Furthermore, studies have failed to demonstrate PTH immunoreactivity within the skin, PTH does not produce pruritus when injected intradermally, and pruritus is not always present in uremic patients with hyperparathyroidism.

Although dry, scaly skin is common in patients with chronic kidney disease (Fig. 6.8), the presence of pruritus does not correlate with xerosis, stratum corneum hydration, or sweat secretion[68,69]. Peripheral neuropathy affects up to 65% of patients who receive dialysis, raising the possibility that pruritus may be a manifestation of a neuropathy. Loss of itch-*inhibiting* CGRP-expressing neurons in the papillary dermis has been observed in CKD-aP patients[70]. Opioids could potentially play a role, as they accumulate with renal failure. However, this accumulation is unrelated to the duration of disease and levels are unaltered by hemodialysis[1]. A recent study found a decrease of κ-opioid receptors in the skin of hemodialysis patients with pruritus, suggesting a role of the peripheral opioid system in renal itch[68]. It has also been suggested that an immunologic alteration characterized by a proinflammatory pattern is involved in the pathogenesis of CKD-aP, and elevated serum IL-31 levels have been reported[69]. Lastly, higher serum aluminum levels have also been associated with pruritus in hemodialysis patients[71].

The management of CKD-aP is often very challenging, and currently available therapeutic options are outlined in Table 6.6. Xerosis should be addressed with gentle skin care and emollients (see Table 6.11). Treatment with topical γ-linolenic acid, pramoxine, corticosteroids, tacrolimus, or capsaicin may be helpful. Antihistamines typically have only marginal efficacy, with improvement related primarily to their sedative effects[1].

Fig. 6.8 Xerosis and scratching in a patient with end-stage kidney disease undergoing hemodialysis. There are a few papules of acquired perforating dermatosis admixed with the scratch marks. *Courtesy Jean L. Bolognia, MD.*

THERAPEUTIC LADDER FOR RENAL PRURITUS	
First-line	Gabapentin (100–300 mg po*) (1) Pregabalin (25–75 mg po*) (1) Difelikefalin† (0.5 mcg/kg iv*) (1)
Second-line	UVB narrowband or broadband phototherapy (alone or in combination with other treatments) (1)
Third-line	Naltrexone‡ (25–50 mg po daily) (2) Naloxone‡ (0.002–0.2 mcg/kg body weight/min iv × 8 hours for 3–5 days, repeated monthly) (3) Nalfurafine† (2.5–5 mcg po or iv*) (1)
Localized itch	Capsaicin cream (0.025% 3–5 times daily) (2)
Additional options	*Topical* γ-linolenic acid (2.2% cream 4 times daily) (1) Pramoxine (1% lotion 2–4 times daily) (1) Cromolyn sodium (4% cream twice daily) (1) *Systemic* Activated charcoal (6 g po daily) (1) Montelukast (10 mg po daily) (1) Cromolyn sodium (100–135 mg po 3–4 times daily) (1) Doxepin (10–20 mg po daily) (1) Ketotifen (1–2 mg po daily) (2) Sertraline (25–100 mg po daily) (2) Pentoxifylline (600 mg iv*) (3) Lidocaine (200 mg iv daily) (3) Erythropoietin (36 U/kg sc 3 times weekly) (3) Cholestyramine (4–16 g po daily in divided doses) (2)

*Typically administered post-hemodialysis; in non-dialysis-dependent patients, dose adjustments for gabapentinoids are made based upon degree of renal impairment.
†κ-opioid receptor agonist; nalfurafine is available in Japan.
‡μ-opioid receptor antagonist.

Table 6.6 Therapeutic ladder for renal pruritus[136]. Additional interventions include addressing underlying xerosis, evaluating the quality of dialysis (see text), and assessing serum parathyroid hormone (PTH) level, with treatment of hyperparathyroidism if present. The combined μ-opioid receptor antagonist/κ-opioid receptor agonist nalbuphine was found to have benefit in an RCT, but the extended release oral formulation used in the study is not currently available. General measures for pruritus management are summarized in Table 6.11. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. iv, intravenously; po, per os; sc, subcutaneously.

In patients with CKD-aP, serum PTH levels should be assessed and hyperparathyroidism treated if present. The quality of dialysis should also be evaluated to ensure that the Kt/V (urea clearance [K] multiplied by dialysis time [t] divided by volume of urea distribution [V]) is ≥1.2. If itch persists, gabapentin (100–300 mg orally) after each dialysis session can be tried; low-dose pregabalin may be equally effective[72]. Phototherapy, especially broadband or narrowband UVB, represents an alternative or adjunctive modality. Difelikefalin, a peripherally acting κ-opioid receptor agonist, was shown in an RCT to significantly reduce itch intensity in hemodialysis patients and is now an FDA/EMA-approved treatment for CKD-aP[73]. Nalfurafine (available in Japan) is another κ-opioid receptor agonist that was found to be effective in multicenter controlled studies[74]. The μ-opioid receptor antagonist naltrexone (25–100 mg orally daily) represents an additional option. Even in patients with intractable CKD-aP, renal transplantation generally leads to resolution of itch.

Cholestatic Pruritus

Nearly any liver disease can present with pruritus, but the most commonly associated entities are primary biliary cholangitis (primary biliary cirrhosis), primary sclerosing cholangitis, obstructive choledocholithiasis, carcinoma of the bile duct, cholestasis (may also be drug-induced), chronic hepatitis C viral infection, and other forms of viral hepatitis[1]. Pruritus in these settings tends to be generalized, migratory, and not relieved by scratching. It tends to be more pronounced at night and is typically worse on the hands and feet (especially the palms and soles) as well as body regions constricted by clothing. In patients with chronic cholestasis, pruritus can be an early symptom that develops years before any other manifestation of the liver disease[1].

The exact etiology of cholestatic pruritus is unknown. MRGPRX4 (Mas-related G-protein coupled receptor member X4), a bile acid receptor expressed in sensory neurons, is involved in itch transmission and may represent a therapeutic target.[75,76] However, elevated serum levels of bile acids are not always associated with pruritus, and in patients with severe cholestasis the development of hepatocellular failure tends to result in spontaneous cessation of pruritus[77]. Increased opioidergic neurotransmission or neuromodulation in the CNS is also hypothesized to contribute to cholestatic pruritus[78].

Other studies have provided evidence that lysophosphatidic acid (LPA), a neuronal activator, and autotaxin (ATX, lysophospholipase D), the enzyme responsible for production of LPA from lysophosphatidylcholine, play significant roles in cholestatic pruritus[79]. Unlike other putative mediators, ATX levels correlate with the intensity of itch in patients with cholestasis[77]. However, the factors presumably present in the enterohepatic circulation that are responsible for induction of ATX expression remain to be determined[80,81].

The disease underlying cholestatic pruritus should be treated if possible, such as gallstone removal, drug withdrawal, and therapy for chronic hepatitis C infection with direct-acting antiviral agents. A stepwise approach to the treatment of cholestatic pruritus is provided in Table 6.7[77,81]. In intrahepatic cholestasis of pregnancy (see Ch. 27), ursodeoxycholic acid (UDCA) significantly reduces itch and serum bile acid levels, probably due to improvement of hepatobiliary secretion, and it represents first-line therapy[82]. Although UCDA is also used in other cholestatic conditions, itch has not been studied as the primary endpoint. The ileal bile acid transporter inhibitors odevixibat and maralixibat are FDA-approved to treat cholestatic pruritus in patients with progressive familial intrahepatic cholestasis and Alagille syndrome, respectively[83,84]. The recommended first-line treatment for other forms of cholestatic pruritus is the anion exchange resin cholestyramine, which binds bile acids in the small intestine and results in their fecal excretion[85]. Rifampin represents a second-line option and may work by reducing ATX expression on a transcriptional level[86]. Opioid antagonists (e.g. naltrexone, naloxone) and the SSRI sertraline can also have antipruritic effects in cholestatic itch[87–89]. Fibrates, phototherapy, albumin dialysis, and plasmapheresis are additional treatment options[85]. Ultimately, liver transplantation for end-stage liver failure can improve symptoms.

Hematologic Pruritus

Significant pruritus can occur in association with a number of hematologic diseases, especially hypereosinophilic syndromes (see Ch. 25) and myeloproliferative neoplasms such as polycythemia vera and Hodgkin lymphoma, and less often essential thrombocythemia. Occasionally, patients with myelodysplastic syndrome have significant pruritus.

Iron deficiency

In patients with iron deficiency plus generalized or localized pruritus, especially of the perianal or vulvar region, improvement with iron supplementation has been described[1,90]. Of note, iron deficiency can be a sign of polycythemia vera and other malignancies or systemic diseases that themselves may cause pruritus. In addition to laboratory confirmation, the etiology of the iron deficiency should be determined, including exclusion of a gastrointestinal source of blood loss.

Polycythemia vera

Aquagenic pruritus may precede the development of polycythemia vera by several years and eventually affects ~30%–50% of polycythemia vera patients. Thus, this diagnosis should be considered in all patients with aquagenic pruritus (see above). Additional cutaneous findings include a ruddy facial complexion, erythema of the hands and feet, and conjunctival injection. Approximately 97% of patients with polycythemia vera have a somatic mutation (V617F) in the Janus kinase 2 gene (*JAK2*) that results in constitutive activation and agonist hypersensitivity in basophils, which may have a pathogenic role in their aquagenic pruritus. Platelet aggregation has also been suggested as a possible underlying mechanism, with release of serotonin and other pruritogenic factors such as histamine. In RCTs, the JAK 1/2 inhibitor ruxolitinib led to rapid improvement of polycythemia vera and its associated pruritus[91,92]. Other treatment options include hydroxyurea, aspirin (300 mg daily), UVB or PUVA phototherapy (reports of success), SSRIs (effective in small series), interferon-α-2b (approved therapy with good efficacy), and oral H1- or H2-receptor antagonists (variable results)[1,93].

TREATMENT OPTIONS FOR HEPATIC OR CHOLESTATIC PRURITUS		
	Treatment and dosing	**Specific indications**
First-line	Cholestyramine (4–16 g po daily, with 4-hour interval if taking other medications) (1)	Cholestatic pruritus
	Odevixibat* (40–120 mcg po daily, maximum 6 mg daily) (1)	Progressive familial intrahepatic cholestasis
	Maralixibat* (190–380 mcg/kg po daily) (1)	Alagille syndrome
	Ursodeoxycholic acid (13–15 mg/kg or 1 g po daily) (1)	Intrahepatic cholestasis of pregnancy
Second-line	Rifampin (150–600 mg po daily) (1)	
Third-line	Bezafibrate (400 mg po daily) (1)	Primary biliary cholangitis, primary sclerosing cholangitis
Fourth-line	Naltrexone† (25–50 mg po daily) (1) Naloxone† (0.002–0.2 mcg/kg body weight/min iv × 8 hours for 3–5 days, repeated monthly) (1) Gabapentin (300–3600 mg daily) (3) Pregabalin (75–600 mg po daily) (3)	
Fifth-line	Sertraline (75–100 mg po daily) (1)	
Additional options	Phototherapy with narrowband or broadband UVB (3) Nalmefene† (escalating twice daily po dose: 2 mg [day 1], 5 mg [day 2], 10 mg [day 3], then 20 mg; further increases as needed, maximum of 120 mg) (1) Nalfurafine‡ (2.5–5 mcg po daily) (1) Butorphanol nasal spray¶ (1–2 mg [1–2 puffs] daily) (3) Paroxetine (10–20 mg po daily) (3) Dronabinol (5 mg po nightly) (3) Phenobarbital (2–5 mg/kg po daily) (3) Lidocaine 100 mg iv daily (1) Thalidomide 100 mg po daily (3)	
Procedural interventions	Nasobiliary drainage (3) Plasmapheresis, plasma separation and anion adsorption (3) Extracorporeal albumin dialysis (e.g. MARS – molecular adsorbents recirculating system) (3)	

*Ileal bile acid transporter inhibitor.
†μ-opioid receptor antagonist.
‡κ-opioid receptor agonist; nalfurafine is available in Japan.
¶Combined κ-opioid receptor agonist and μ-opioid receptor antagonist.

Table 6.7 Treatment options for hepatic or cholestatic pruritus[136]. Antihistamines have limited benefit other than their sedating properties. Gabapentin did not have a therapeutic advantage over placebo in a controlled study. Ileal bile transporter inhibition with linerixibat was shown to be of benefit for primary biliary cholangitis in an RCT. General measures for pruritus management are summarized in Table 6.11. Potential adverse effects of rifampin include hepatitis, hemolytic anemia, and renal failure, necessitating periodic laboratory monitoring in patients with cholestasis. Potential adverse effects of bezafibrate include hepatic toxicity, rhabdomyolysis, and osteoporosis. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. iv, intravenously; po, per os.

Pruritus and Malignancy

Virtually any malignancy can induce pruritus, but the precise relationship between cancer and this symptom is unclear. In 2014, a special interest group of the International Forum on the Study of Itch[94] defined "paraneoplastic itch" as "a systemic reaction to the presence of a tumor or a hematological malignancy, neither induced by the local presence of cancer cells nor by tumor therapy". They noted that the itch usually disappears with remission of the neoplasm and returns with a disease relapse.

Paraneoplastic itch is most frequent with myeloproliferative neoplasms (e.g. polycythemia vera > essential thrombocythemia), lymphoma (Hodgkin > non-Hodgkin), and cancers of the liver or biliary system[91]. A population-based cohort study found that patients with chronic pruritus without concomitant skin findings (n = 8744; mean age, 61 years) had 2- and 3.7-fold increased risks of an incident hematologic or bile duct malignancy, respectively[92]. Another study found a 1-year absolute risk of cancer of 1.6% in patients with pruritus[95]. In pediatric patients, itch is most often associated with hematologic malignancies[96]. Thus, persistent unexplained pruritus or failure of generalized pruritus to respond to conventional therapy should warrant evaluation for an underlying malignancy, including a complete blood count and hepatic panel as well as a thorough review of systems and physical examination[10,94].

Paraneoplastic pruritus can occur in advanced disease or represent an early sign, which is sometimes present for several years prior to diagnosis. However, the intensity and extent of pruritus do not generally correlate with the extent of tumor involvement[1]. Proposed mechanisms of tumor-associated pruritus include toxic products from necrotic tumor cells entering the systemic circulation, production of chemical mediators of pruritus by the tumor, allergic reactions to tumor-specific antigens, increased proteolytic activity, and histamine release[8]. Pruritus can also be a symptom of malignancies that obstruct the biliary tree (e.g. carcinoma of the head of the pancreas or bile duct) or involve the brain ("central" pruritus)[8]. In addition, pruritus may develop due to treatment with surgery, radiotherapy, cytotoxic chemotherapy, targeted tumor therapy[94], or immunotherapy[97].

Treatment of the underlying malignancy is the most effective measure. In refractory cases, or when the tumor is not treatable, therapeutic options include antidepressants (e.g. paroxetine, mirtazapine), gabapentinoids, opioid modulators, NK1 receptor antagonists, and histone deacetylase inhibitors[8,98].

Hodgkin lymphoma

Up to 30% of patients with Hodgkin lymphoma experience pruritus. It is usually generalized and classically manifests at night in association with chills and sweating[1,8]. Severe, persistent pruritus is predictive of a poor prognosis, and return of this symptom may portend tumor recurrence. It has been proposed that pruritus should be added to the list of the "B symptoms" in this disease[1].

Factors contributing to pruritus in Hodgkin lymphoma may include eosinophilia and release of histamine (from basophils), leukopeptidases, or bradykinin. Hepatic involvement by the lymphoma may occasionally play a role. Production of IL-5 by Reed–Sternberg cells can lead to eosinophilia, but whether the eosinophil count correlates with the degree of pruritus is unclear. While the pruritus usually resolves following successful treatment of the lymphoma, based upon case reports and series, phototherapy, cimetidine, carbamazepine, mirtazapine, oral corticosteroids, and NK1 receptor antagonists may lead to some improvement[8,93].

Non-Hodgkin lymphoma

Pruritus is generally less prevalent in non-Hodgkin lymphoma than in Hodgkin lymphoma. Up to 10% of patients with non-Hodgkin lymphoma suffer from pruritus at some time during their disease course, often with improvement after successful therapy.

Leukemia

Pruritus is not a common symptom in patients with leukemia, but when it occurs, it is usually generalized. Chronic lymphocytic leukemia (CLL) and hypereosinophilic syndromes, which include patients with eosinophilic leukemia and other hematologic malignancies (see Ch. 25), are most often associated with pruritus. In addition, patients with CLL can develop exaggerated reactions to insect bites (see Ch. 33). Leukemia cutis may produce localized symptoms that include pruritus[10].

Endocrine Pruritus

Thyroid disease

Severe generalized pruritus may be a presenting symptom of hyperthyroidism. The cause is not known, but it is postulated to result from a direct effect of thyroid hormone on the skin[1]. Localized or generalized pruritus may also be seen in patients with hypothyroidism, but not as frequently. The skin in individuals with hypothyroidism is often dry, which can lead to asteatotic eczema accompanied by pruritus.

Diabetes mellitus

Generalized pruritus is a fairly common symptom of diabetes mellitus, with itch often first developing on the back[99]. Diabetic polyneuropathy is characteristically associated with pain as well as burning or prickling sensations, but it can also present with pruritus that starts on the feet and lower legs[99].

Pruritus in HIV Infection

Severe, treatment-resistant pruritus can be seen in HIV-infected individuals, and a possible correlation between intractable pruritus and increased HIV viral load has been observed[100]. Immunologic parameters associated with pruritus in HIV patients include markedly elevated IgE levels, peripheral hypereosinophilia, and a Th2-type cytokine profile.

HIV-infected individuals may develop a number of pruritic dermatoses such as pruritic papular eruption, eosinophilic folliculitis, severe seborrheic dermatitis, psoriasis, scabies, insect bite reactions, drug eruptions, xerosis, and acquired ichthyosis (see Ch. 78). Kaposi sarcoma lesions are occasionally pruritic. Patients with HIV infection may also have other causes of pruritus, such as chronic kidney disease, liver disease, and non-Hodgkin lymphoma and they can develop prurigo nodularis[101].

Treatment should be directed at any underlying dermatoses that can be identified (see above). Topical corticosteroids and antihistamines can be used symptomatically; antihistamines with anti-eosinophilic potential (e.g. cetirizine) may be more effective. UVB is an additional therapeutic option and is considered to be safe in HIV-infected individuals[102]. Although antiretroviral therapy (ART) can lead to improvement in several pruritic dermatologic diseases, a variety of infectious, inflammatory, and neoplastic skin conditions may flare when ART is started (immune reconstitution inflammatory syndrome; see Ch. 78)[101]. Thalidomide (100–300 mg daily) is used to treat pruritus and prurigo nodularis in patients with HIV infection and AIDS, as it is not an immunosuppressant[10,103].

PRURITUS IN PREGNANCY

Approximately 20% of pregnant women experience pruritus. This symptom can have multiple etiologies in a pregnant patient[104] and is discussed in Chapter 27.

PHARMACOLOGIC PRURITUS

Virtually any drug can cause a skin reaction that is associated with pruritus[1]. Pruritic drug reactions most often present as morbilliform or urticarial eruptions (see Ch. 21). Occasionally, however, pruritus is the predominant manifestation with an absence of skin findings (Table 6.8)[105,106]. Some medication effects (e.g. hepatotoxicity) that can lead to pruritus have a relatively long latency period. The primary goal is to identify and discontinue the offending drug, with supportive antipruritic therapy as needed (see Table 6.11).

COMMON PHARMACOLOGIC ETIOLOGIES OF PRURITUS

Pathomechanism	Medication(s)
Cholestasis	Erythromycin estolate, estrogens (including oral contraceptives), captopril, sulfonamides, chlorpromazine
Hepatotoxicity	Acetaminophen, anabolic steroids (including testosterone), isoniazid, minocycline, amoxicillin–clavulanic acid, halothane, phenytoin, sulfonamides
Xerosis	Retinoids, β-blockers, calcium channel blockers, hydrochlorothiazide, tamoxifen, busulfan, clofibrate
Phototoxicity	8-Methoxypsoralen
Neurologic	Methamphetamine, tramadol, codeine, cocaine, morphine*,†, butorphanol*, fentanyl*
Increased serotonin signaling	Selective serotonin reuptake inhibitors (e.g. sertraline, fluoxetine)
Increased bradykinin levels‡	Angiotensin-converting enzyme (ACE) inhibitors
Increased leukotriene levels	Nonsteroidal anti-inflammatory drugs (NSAIDs)
Histamine analogue	Betahistine
MRGPR¶ stimulation	Chloroquine (pruritus may be generalized, localized to the hands/feet, or aquagenic; most common in individuals of African descent)
T cell activation due to CTLA-4, PD-1, or PD-L1 inhibition	Ipilimumab, nivolumab, pembrolizumab, cemiplimab, atezolizumab, avelumab, durvalumab
EGFR inhibition	Cetuximab, panitumumab, erlotinib, gefitinib, afatinib, osimertinib
Selective BRAF or MEK inhibition	Dabrafenib, encorafenib, vemurafenib; binimetinib, cobimetinib, trametinib
Other tyrosine kinase inhibition	Sorafenib (especially scalp pruritus), imatinib, dasatinib, nilotinib (see Table 21.16)
Deposition	Hydroxyethyl starch
Idiopathic	Clonidine, lithium, bleomycin, gold salts

*Pruritus is more likely with intrathecal/epidural than systemic administration.
†Also causes non-immunologic release of histamine from mast cells.
‡Pruritus may precede development of angioedema.
¶MAS-related G protein-coupled receptor expressed by epidermal C-nerve fibers.

Table 6.8 Common pharmacologic etiologies of pruritus[137–141]. Itch may also occur as a direct effect of interleukin 2 therapy. CTLA-4, cytotoxic T lymphocyte-associated antigen 4; EGFR, epidermal growth factor receptor; PD-1, programmed cell death protein 1.

PSYCHOGENIC PRURITUS

Generalized pruritus can be associated with anxiety disorders, depression, anorexia, and even psychoses (e.g. delusional infestation; see Ch. 7). In true psychogenic pruritus, patients present with a purely sensory complaint (pruritus) without evidence of a delusional component, primary skin disease, or underlying medical condition. It is rare and must be separated from excoriation (skin-picking) disorder, in which a patient creates cutaneous lesions without pre-existing pruritus. The intensity of psychogenic pruritus tends to parallel the emotional state and is often exaggerated[10]. No primary lesions are seen, and secondary lesions range from lichenification to excoriations. Although the patient's sleep pattern is usually uninterrupted, sedative antipruritics (e.g. doxepin) may be utilized as therapy because topical agents alone are rarely effective. Consultation with a psychiatrist is recommended.

NEUROPATHIC ETIOLOGIES OF PRURITUS AND DYSESTHESIA

A dysesthesia is defined as an unpleasant abnormal skin sensation, such as tingling, burning, numbness, or pruritus; it can be spontaneous or evoked and may result from abnormalities in the central or peripheral nervous system. Dysesthesias, including pruritus, are usually localized or regional in distribution and can affect almost any site. For dysesthesias related to disorders of the CNS, the location of the abnormality is more important than its cause. In other words, a stroke, tumor, or multiple sclerosis plaque in the same region of the brain will generate similar neurologic signs and symptoms[107].

Neuropathic pruritus most often results from damage, compression, or irritation affecting a nerve or group of nerves[3]. These neuropathies typically present with localized pruritus and secondary skin lesions due to repeated rubbing or scratching in a circumscribed area supplied by the afflicted nerve(s) (Fig. 6.9A). Pruritus may occasionally spread beyond the initial site, likely due to sensitization mechanisms. Pruritus of neurogenic origin occurs without neuronal damage, such as increased endogenous μ-opioids leading to disinhibition of itch.

Sensory (Mono)Neuropathies with Pruritus and Dysesthesia

Sensory (mono)neuropathies that are most often brought to the attention of dermatologists are notalgia paresthetica and brachioradial pruritus. Less often, symptoms of meralgia, cheiralgia, or digitalgia paresthetica require dermatologic assessment (see Fig. 6.9). Secondary skin lesions, if present, include excoriations, crusted papules, hyperpigmentation, and lichenification; these findings are localized to the area of dysesthesias that corresponds to the receptive field of one or a few sensory nerves[108].

Treatment with topical capsaicin (0.025%–0.1%) 3–6 times daily for ≥4–6 weeks or a capsaicin 8% patch (applied for one hour under physician supervision; may be repeated every 3 months, if needed) may be helpful. Other treatment options include topical anesthetics (e.g. lidocaine, pramoxine), topical corticosteroids, oral gabapentin/pregabalin, and acupuncture.

Notalgia paresthetica

Notalgia paresthetica is a common condition in adults that is characterized by focal, intense pruritus of the upper back, especially over the medial scapular borders. Most evidence suggests that notalgia paresthetica represents a sensory neuropathy. The posterior rami of T2–T6 pursue a right-angle course through the multifidus spinae muscle that extends along the vertebral column, potentially predisposing these nerves to entrapment and injury (Fig. 6.9C). Degenerative changes of the spine corresponding to the affected dermatome(s) are present in a subset of patients[109]. Notalgia paresthetica can also represent a sign of multiple endocrine neoplasia type 2A (Sipple syndrome; see Ch. 63), especially if the onset is during childhood or adolescence.

In addition to itch, patients may occasionally report pain, dysesthesias, paresthesias, or hyperesthesias[109]. A characteristic finding on physical examination is a hyperpigmented patch due to chronic rubbing of the affected area. Dermal melanophages are evident histologically, and there is considerable overlap with macular amyloidosis (see Ch. 47).

Treatment of notalgia paresthetica is often difficult. Topical antipruritics (e.g. pramoxine) and corticosteroids are typically ineffective. Topical capsaicin may provide temporary benefit, and oxcarbazepine and gabapentin have demonstrated variable improvement in case series. Oral difelikefalin is under investigation, but currently it requires intravenous administration. Additional case reports have shown benefits from botulinum toxin A, but in an RCT, intradermal botulinum toxin A injection showed no benefit over placebo. If spinal pathology is suspected, management considerations include spinal imaging, referral for orthopedic or neurologic consultation; and treatment of the underlying cause with modalities such as physical therapy (e.g. rolling on a massage ball), nerve blocks, and surgical decompression.

Brachioradial pruritus

This chronic sensory neuropathy of the radial dorsal antebrachial cutaneous nerve is characterized by intermittent pruritus or burning

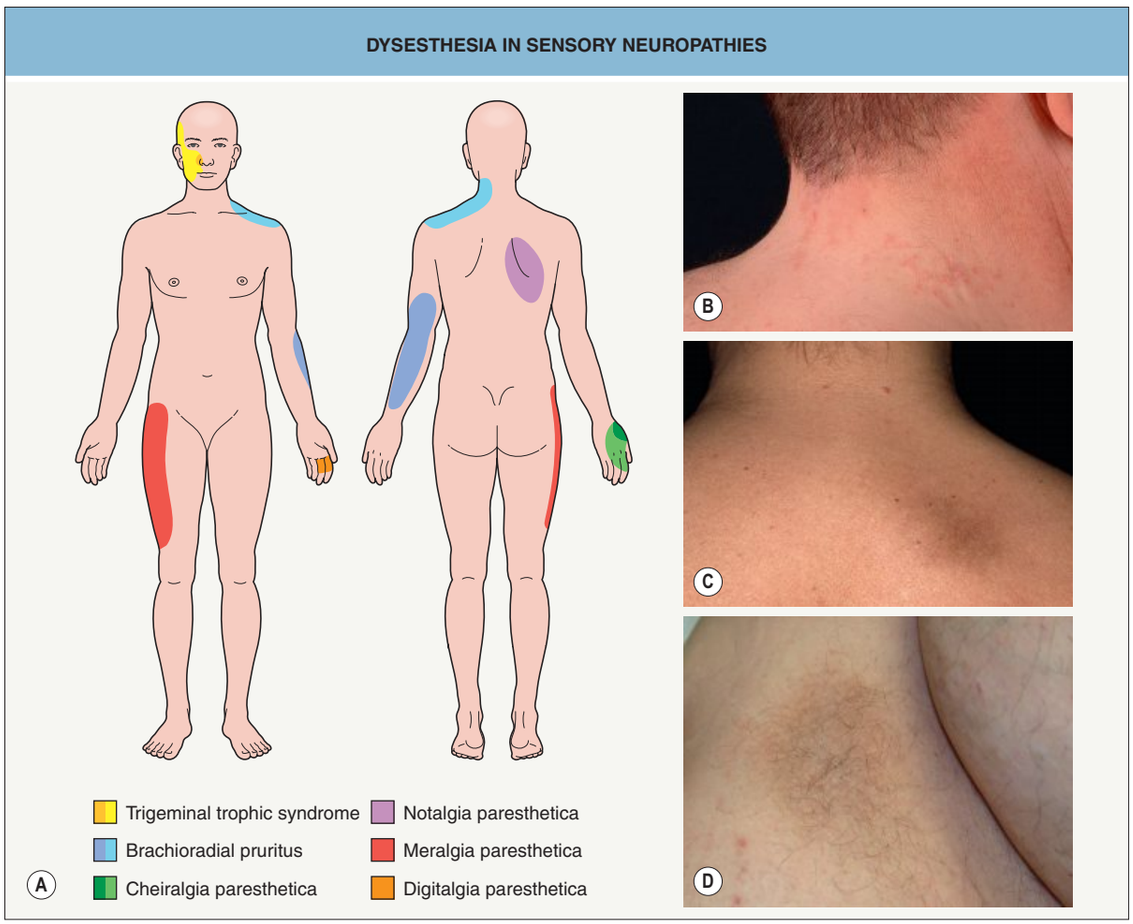

Fig. 6.9 Dysesthesia in sensory neuropathies. A Distribution of dysesthesia in selected neuropathic conditions. The names for these entities come from Greek terms, e.g. *notos* = back, *meros* = thigh, *cheiron* = hand, *algos* = pain. Darker shades indicate more common areas of involvement. **B** Secondary skin lesions on the right neck in a patient with cervical osteoarthropathy. **C** Classic notalgia paresthetica with hyperpigmentation on the right upper back at the medial scapular border. **D** Meralgia paresthetica presenting as hyperpigmentation and lichenification in a discrete area of dysesthesia on the anterior thigh. *A, Courtesy Karynne O. Duncan, MD; C, Courtesy Lorenzo Cerroni, MD.*

pain on the dorsolateral aspects of the forearms and elbows; there is sometimes more extensive involvement (e.g. of the shoulder and neck; Fig. 6.9B)[110]. More than half of patients have radiographic evidence of degenerative osteoarthritis of the spine compressing their cervical nerve roots[111], and there are rare reports of an associated spinal cord tumor. Cumulative sun exposure represents another predisposing factor. Due to hypersensitivity of cutaneous nerves, acute UV light exposure can also exacerbate the condition[1,110], and patients living in temperate climates often experience remissions during the fall and winter. Patients may relate that application of ice provides some relief.

Skin examination often reveals a variable number of excoriations, prurigo simplex or nodularis lesions, and even scars localized to the vicinity of the brachioradialis muscle. Evaluation should include a neurologic examination and, based on the results, consideration of cervical spine imaging to exclude myelopathy or tumors. In addition to the treatments noted above, diligent sun protection may be of benefit.

Meralgia paresthetica

Meralgia paresthetica presents with numbness, burning pain, tingling, and/or itching of the anterolateral thigh (Fig. 6.9D)[108]. Allodynia (increased sensitivity to light touch) is another manifestation, but cutaneous findings such as hyperpigmentation are less common than in notalgia paresthetica. Meralgia paresthetica occurs in the territory of the lateral femoral cutaneous nerve, and it results from pressure on this nerve as it passes under the inguinal ligament. Predisposing factors include obesity, pregnancy, prolonged sitting, tight clothing, and carrying heavy wallets in trouser pockets. Much less often, it results from a lumbar radiculopathy.

Cheiralgia paresthetica

Cheiralgia paresthetica is a sensory mononeuropathy of the superficial branch of the radial nerve[108]. Patients report numbness, tingling, or burning involving the dorsoradial aspect of the hand and proximal thumb (see Fig. 6.9A). The cause is usually trauma or pressure, e.g. from a tight wristwatch or handcuffs.

Digitalgia paresthetica

Digitalgia paraesthetica is a sensory neuropathy affecting digital nerves of the fingers and less often the toes[108]. It results from trauma or pressure, e.g. on the fingers from carrying heavy plastic grocery bags or on the toes from long marches or hikes.

Regional Dysesthesias with Burning or Pain

Burning mouth syndrome

Burning mouth syndrome (orodynia) is characterized by burning mucosal pain without clinically detectable oral lesions. The pain is typically bilateral, often involving the anterior two-thirds of the tongue, palate, and lower lip[112]. The buccal mucosa and floor of the mouth are rarely involved. The histology of the affected areas in primary burning mouth syndrome is unremarkable; however, secondary causes may be identified.

The condition typically affects middle-aged or older adults, with a female : male ratio of ~7 : 1[113]. Symptoms can last from a few months to several years. A classification system based on the pattern of disease over time has been described: *type 1* (35%) – absence of symptoms upon awakening, with a gradual increase in severity over the course of the day; *type 2* (55%) – constant burning, both day and night; and *type 3* (10%) – days of remission that follow no identifiable pattern[113].

The evaluation of burning mouth syndrome should include a thorough physical examination to help exclude secondary causes, although the disorder is frequently idiopathic. Localized burning or itch may be the first indication of a malignant lesion (e.g. an oral squamous cell carcinoma). Ill-fitting dentures, oral candidiasis, xerostomia, and contact dermatitis to dental work have been reported as other secondary causes. All prescription and over-the-counter medications should be reviewed to identify any that have xerostomia as a side effect. Additional precipitating factors include iron, zinc, folate, and vitamin B_{12} deficiencies as well as type 2 diabetes mellitus, hypothyroidism, and menopause[114]. Lastly, depression and anxiety are more common in patients with burning mouth syndrome than in pain-free controls[113].

Any underlying disorders should be treated, which may require referral for dental or psychiatric evaluation. In primary burning mouth syndrome, reportedly efficacious treatments include oral tricyclic antidepressants (e.g. amitriptyline, doxepin), topical or low-dose oral clonazepam (start at 0.25 mg and slowly titrate to 1–1.5 mg per day, in 3 divided doses), and gabapentinoids[115]. Antidepressant doses should be low initially and then increased slowly to minimize problematic side effects such as xerostomia and sedation. In case reports and series, successful treatments have included topical antifungal agents (even when cultures were negative), capsaicin, and anesthetics such as lidocaine or dyclonine; in addition, mouthwashes containing various combinations of anesthetics, nystatin, tetracycline, hydrocortisone, and diphenhydramine have been utilized. Cognitive behavioral therapy and α-lipoic acid (600 mg daily) may also improve symptoms[116,117].

Burning scalp syndrome

Burning scalp syndrome (scalp dysesthesia)[118,119] presents with diffuse burning pain, pruritus, numbness, or tingling of the scalp without objective findings. Secondary causes such as seborrheic dermatitis, folliculitis, lichen planopilaris, allergic or irritant contact dermatitis, and dermatomyositis should be excluded and treated if present. Burning scalp syndrome is often associated with underlying depression and anxiety. Like other dysesthesias, it can be treated with gabapentinoids, tricyclic antidepressants, and topical capsaicin[118].

Red ear syndrome

Patients have intermittent episodes of erythema involving one external ear and less often both ears. The redness can persist for minutes to hours and is associated with burning and/or pain. Triggers include heat, cold, and touch. Clinically, this disorder has been likened to erythromelalgia and associated with migraine headaches, but the precise etiology remains unclear. One hypothesis is dysregulation of sympathetic outflow, while some patients have evidence of cervical spine disease. Reported treatments include indomethacin and β-blockers as well as therapies used for other regional dysesthesias.

Dysesthetic anogenital pain syndromes

The most common causes of anal pain are hemorrhoids and fissures. Likewise, genital pain is often related to etiologies such as trauma, infection (e.g. *Chlamydia*, herpes simplex, candidiasis, mpox), and (in men) testicular torsion. Since chronic pain may be a harbinger of malignancy, a thorough evaluation is indicated. However, patients with chronic or recurrent anogenital pain but no detectable abnormalities on physical examination may have a dysesthetic anogenital pain syndrome (Table 6.9). Vulvodynia is discussed in Chapter 73. Of note, anogenital pruritus (see above) can also represent a dysesthetic state.

Trigeminal neuralgia and trigeminal trophic syndrome

Trigeminal neuralgia (tic douloureux) is characterized by recurrent paroxysms of sharp pain lasting seconds to minutes and radiating into the territory of one or more of the trigeminal sensory divisions. The pain is usually unilateral (most often right-sided) and described as a stabbing, burning, or shocking sensation. Attacks occur as often as several times per day or as infrequently as a few times per month. Potential triggers include touching or washing the face, brushing of teeth, eating, and talking. Cutaneous and neurologic examinations are

DYSESTHETIC ANOGENITAL PAIN SYNDROMES	
Syndrome	**Clinical history**
Levator ani syndrome	Brief intermittent burning pain or tenesmus of the rectal or perineal area. Aggravated by sitting or elimination
Proctalgia fugax	Sudden stabbing pain in the perirectal area. Awakens patient from sleep
Coccydynia	Intermittent or persistent pain, usually burning type, localized to the coccyx
Male genital pain syndrome	Intermittent, continuous, or episodic pain during penetration, ejaculation, micturition, or exercise
Koro syndrome	Psychogenic disorder characterized by acute anxiety, fear of death, and sensations that the genitalia are inwardly retracted and (variably) burning pain

Table 6.9 Dysesthetic anogenital pain syndromes. Vulvodynia is discussed in Chapter 73.

typically normal; if neurologic findings are present, the possibility of an underlying tumor or multiple sclerosis should be considered.

MRI should be performed to exclude secondary causes of trigeminal neuralgia ("painful trigeminal neuropathy"), such as multiple sclerosis, trauma, or a tumor. In ~80%–90% of patients with trigeminal neuralgia, high-resolution MRI with MRA demonstrates compression of the trigeminal nerve root by a vascular loop (referred to as the "classic" form)[120]. Rare familial forms have been linked to variants in genes encoding voltage-gated ion channels and transient receptor potential channels[121,122].

Regardless of etiology, carbamazepine (200–1200 mg daily) and oxcarbazepine (300–1800 mg daily) are considered first-line therapies for trigeminal neuralgia, providing relief in ~90% of patients[122]. Additional treatment options include gabapentinoids, lamotrigine, and baclofen. Botulinum toxin A injections may also be of benefit[123]. In refractory disease, surgical interventions such as microvascular decompression and ablative procedures (e.g. gamma knife radiosurgery) can be employed.

Trigeminal trophic syndrome is a self-induced ulcerative condition of the central face that classically involves the nasal ala[124,125]. Patients characteristically present with a small crust that develops into a crescentic ulcer, which may gradually extend to involve the cheek and upper lip (Fig. 6.10). The self-mutilation is triggered by dysesthesia together with hypesthesia, both resulting from damage to the sensory portion of the trigeminal nerve. The nasal tip, which is supplied by the external nasal branch of the anterior ethmoidal nerve (see Ch. 142), is typically spared. The underlying nerve damage is most often iatrogenic due to therapeutic ablation for trigeminal neuralgia; other causes include stroke, herpes zoster, trauma, and craniofacial surgery[125]. *Cervical trophic syndrome* represents a similar condition in which dysesthesia and self-mutilation occur in a cervical distribution[126].

The differential diagnosis of a non-healing facial ulcer includes malignancies (e.g. basal cell or squamous cell carcinoma, nasal NK/T cell lymphoma), infections (e.g. chronic herpes simplex, *Leishmania* spp., dimorphic fungi), inflammatory disorders (e.g. granulomatosis with polyangiitis, pyoderma gangrenosum), and factitial disease (see Table 45.3). Treatment of trigeminal trophic syndrome is challenging. Medications such as carbamazepine, gabapentinoids, amitriptyline, and pimozide have limited effectiveness. Protective barriers worn at night and patient education are important measures. Surgical repair of the defect(s) with innervated skin flaps provides the greatest chance for resolution[124,125].

Fig. 6.10 Trigeminal trophic syndrome. A Ulceration with serohemorrhagic crusting on the nasal ala, as well as excoriations, superficial ulcers, and scars on the upper lip, chin, and cheek. **B** Ulceration localized to the nasal ala and adjacent cheek. *A, Courtesy Lorenzo Cerroni, MD; B, Courtesy Edward Cowen, MD.*

Complex regional pain syndrome (reflex sympathetic dystrophy)

Complex regional pain syndrome (CRPS; reflex sympathetic dystrophy) is characterized by continuing regional pain that is seemingly disproportionate to the usual course following trauma or other insults; evidence of damage to peripheral nerves is present in a subset of patients. The upper extremities, especially the hands (Fig. 6.11), are most commonly affected, but the distal lower extremities may also be involved. Regional insult to nociceptive terminals results in a signal cascade that ultimately amplifies the pain response in the CNS. The disease was traditionally described as progressing through several stages, which were thought to be due to autonomic nervous system dysfunction[119].

Signs and symptoms within the affected region include burning pain, hyperalgesia, allodynia, vasomotor dysfunction (e.g. edema, erythema, livedo reticularis, cyanosis), hypertrichosis, hyperhidrosis, nail dystrophy, motor dysfunction, and eventually atrophy. Patients suspected to have CRPS should be referred to a neurologist for further evaluation and treatment. Physical and occupational therapy represent first-line treatment options. Therapies may be directed toward interruption of the autonomic nervous system, but they often have limited efficacy[127].

Congenital Insensitivity to Pain and Related Conditions

Congenital insensitivity to pain belongs to a group of hereditary sensory and autonomic neuropathies (HSAN) in which neurons fail to develop or degenerate[128] (Table 6.10).

Fig. 6.11 Complex regional pain syndrome with scaling and erosions of the fingertips. *Courtesy Kalman Watsky, MD.*

CONGENITAL INSENSITIVITY TO PAIN (CIP) AND RELATED HEREDITARY SENSORY AND AUTONOMIC NEUROPATHIES (HSANs)			
Features of CIP: • Oral self-mutilation due to biting of lips, tongue, and buccal mucosa • Biting of fingertips resulting in ulceration and eventual autoamputation • Bruises, cuts/wounds, burns, skin infections, joint dislocations, and fractures with resulting scars and deformities • Immunohistochemical staining for neuronal markers (e.g. PGP-9.5) shows almost complete absence of innervation to sweat glands, blood vessels, and arrector pili muscles within the skin			
HSAN type, disorder name	**Gene(s) (inheritance)**	**Protein**	**Additional clinical features**
II, Morvan disease	*WNK1, FAM134B, KIF1A* (AR)	WNK lysine deficient protein kinase 1, FAM134B, kinesin family member 1A	• Hyporeflexia, hypotonia • GI dysmotility • Acral anhidrosis, episodic hyperhidrosis
IID, CIP	*SCN9A** (AR)	Sodium voltage-gated channel α subunit 9	• Variable hearing impairment, anosmia • Variable hypohidrosis
III, familial dysautonomia (Riley–Day syndrome)	*IKBKAP* (AR)	Inhibitor of κ light polypeptide gene enhancer in B cells, kinase complex-associated protein	• Ashkenazi Jewish patients • Hyporeflexia, hypotonia • Less impaired pain/temp perception, acral sparing • No emotional tears • Postural hypotension, episodic hypertension • Vomiting crises with blotchy erythema of skin • Absent lingual fungiform papillae
IV, CIP with anhidrosis	*NTRK1* (AR)	Neurotrophic receptor tyrosine kinase 1 (high-affinity NGF receptor)	• Complete lack of pain (including visceral) and temp sensation, but normal touch and reflexes • Anhidrosis with febrile episodes • Intellectual disability • Increased susceptibility to staphylococcal infections
V, CIP	*NGF* (AR)	Nerve growth factor	• As in IV but variable anhidrosis and intellectual disability
VI	*DST* (AR)	Dystonin	• Similar to III
VII, CIP with GI dysfunction and hyperhidrosis	*SCN11A** (AD)	Sodium voltage-gated channel α subunit 11	• Diarrhea, constipation • Hyperhidrosis, pruritus • Muscular weakness
VIII, CIP	*PRDM12* (AR)	PR/SET domain 12	• Variable hypohidrosis and reduced tearing
*Gain-of-function mutations can result in hereditary neuropathies presenting with burning/episodic pain or (for *SCN9A*) erythromelalgia.			

Table 6.10 Congenital insensitivity to pain (CIP) and related hereditary sensory and autonomic neuropathies (HSANs)[128]. HSAN type I includes several autosomal dominant disorders with onset typically in later childhood or adulthood; features include motor as well as sensory neuropathy, dysesthesia with "lightning" pains, and variable hearing loss and hyperhidrosis. AD, autosomal dominant; AR, autosomal recessive; FAM134B, family with sequence similarity 134, member B; PGP-9.5, protein gene product 9.5; temp, temperature.

TREATMENT

Thus far, no antipruritic drug is indicated for relief of itch irrespective of its origin. Thus, individualized management of each patient and pruritic disease process is necessary[8,10]. General measures and specific treatments that can be selected according to the patient's complaints are discussed below and summarized in Table 6.11.

General Measures

Patient education and elimination of provocative factors are important, including wearing soft breathable clothing (i.e. no wool or rough fabrics), avoiding excessive bathing (lukewarm baths or showers with mild synthetic detergents [syndets]), using emollients on a daily basis with application immediately after bathing, and managing dermographism if present. Patients can be taught methods of interrupting the itch–scratch cycle, such as application of a cold washcloth or gentle pressure. Controlled physical exercise, relaxation therapy, and minimization of exposure to heat as well as reduction of stress and anxiety are beneficial. Avoid telling patients "don't scratch" given how difficult it is to follow this advice.

Topical Treatment

A large variety of topical compounds that have antipruritic properties are available, including corticosteroids, anesthetics (e.g. pramoxine, polidocanol), and counterirritants (e.g. menthol, camphor).

Topical anesthetic agents (e.g. lidocaine/prilocaine) decrease pain and pruritic sensations and they may relieve tingling and dysesthesias[129]. Topical doxepin has demonstrated antipruritic effects in atopic dermatitis and other eczematous dermatoses, including lichen simplex chronicus, nummular eczema, and contact dermatitis[130]. However, side effects such as drowsiness can occur when it is applied to large portions of the body or in young children. In addition, the possibility of allergic contact dermatitis to topical doxepin and potentially systemic contact dermatitis with subsequent oral administration should be considered. Compounded topical cromolyn sodium has been found to relieve allergen- and histamine-induced pruritus without blocking wheal formation, suggesting a mechanism other than prevention of mast cell degranulation.

Capsaicin is a naturally occurring alkaloid found in many species of the nightshade family (Solanaceae), especially chili peppers. Capsaicin enhances the release and secondarily inhibits the re-accumulation of neuropeptides such as substance P. It also transiently destroys intraepidermal nerve fibers. Topical capsaicin has successfully been used in several dermatologic disorders, although it is not beneficial in atopic dermatitis[131]. Concentrations usually range from 0.025%–0.1%, and it needs to be applied three to six times daily for maximal effect. While capsaicin can be safely applied to large areas of skin[132], and its side effects of stinging, burning, pain, erythema, and irritation decrease with continued use, it is typically utilized to treat localized pruritus.

Topical tacrolimus and pimecrolimus have both anti-inflammatory and antipruritic effects[133] and are successfully used in pruritic conditions including atopic dermatitis (see Ch. 128). Burning and erythema at the application site are the most commonly reported adverse events. Rapid improvement of pruritus has also been reported in patients with atopic dermatitis treated with topical ruxolitinib[134].

GENERAL MEASURES FOR THE TREATMENT OF PRURITUS AND DYSESTHESIA
Skin care
• Twice daily application of a moisturizing cream or ointment • Warm (not hot) baths/showers ≤ once daily, with minimal use of a mild soap/non-soap cleanser, and followed immediately by moisturizer application; especially in winter, consider limiting use of soap to odorous regions such as the axillae and anogenital area • Avoid wool and other rough fabrics • Keep nails cut short
Topicals
• *Cooling agents/counterirritants*: e.g. menthol, camphor • *Capsaicin* • *Anesthetics*: e.g. pramoxine, lidocaine, prilocaine, polidocanol, palmitoylethanolamine • *Anti-inflammatory agents*: corticosteroids, calcineurin inhibitors, Janus kinase (JAK) inhibitors
Systemic medications
• *Antihistamines*: especially if there is a component of dermographism or urticaria; otherwise limited efficacy beyond sedative effects • *Gabapentinoids*: gabapentin, pregabalin • *Antidepressants:* SSRIs (e.g. fluoxetine, paroxetine, sertraline, venlafaxine), tricyclics (e.g. amitriptyline, doxepin), mirtazapine • *Opioid antagonists/agonists:* e.g. naltrexone, butorphanol nasal spray, nalfurafine, nalbuphine, naloxone • *Targeted immune modulators* (especially for atopic dermatitis and prurigo nodularis): e.g. dupilumab, tralokinumab (anti-IL-4/-13); nemolizumab (anti-IL-31); JAK inhibitors • *Other:* thalidomide (especially for prurigo nodularis), aprepitant (NK1 receptor antagonist)
Physical modalities
• *Phototherapy*: UVB (broadband or narrowband), PUVA, UVA, UVA-1 • Acupuncture
Psychological approaches
• Behavior modification therapy, biofeedback • Support groups

Table 6.11 General measures for the treatment of pruritus and dysesthesia. NK1, neurokinin 1; PUVA, psoralen plus UVA; SSRI, selective serotonin reuptake inhibitor.

Systemic Treatment

Systemic drugs with antipruritic properties often act centrally and have sedating effects. With progress in understanding the pathophysiology of pruritus, treatments targeting specific mediators and pathways have become possible, such as κ-opioid receptor agonists (e.g. difelikefalin, nalfurafine) and/or μ-opioid receptor antagonists (e.g. naloxone, naltrexone); NK1 receptor antagonists (e.g. aprepitant); and antibodies targeting IL-31 signaling (e.g. nemolizumab)[135]. However, placebo responses in pruritus patients are often substantial (e.g. 66% in one study)[10], demonstrating the powerful central modulation of pruritus. Placebo-controlled studies are therefore essential to evaluate drugs with potential antipruritic effects.

Physical Treatment Modalities

UV light therapies (broadband and narrowband UVB, UVA, UVA-1, UVA/UVB, PUVA) have beneficial effects in pruritic inflammatory dermatoses, maculopapular cutaneous mastocytosis, renal and cholestatic pruritus, pruritus associated with HIV infection, aquagenic pruritus, and prurigo nodularis[102].

Transcutaneous electronic nerve stimulation has been reported as beneficial in different types of pruritus, such as that found in aged skin. This may be partially a placebo effect as it tends to decline with continued therapy[10]. Acupuncture has also been described as a successful treatment for pruritus vulvae, allergic contact dermatitis, and renal pruritus. Acupuncture was reported to decrease experimental histamine-induced pruritus but had no effect on maximal pruritus intensity or onset time[10].

Psychological Approaches

Pruritus may be precipitated, prolonged, or enhanced by a number of stress-related mediators such as histamine and neuropeptides. There are also multiple secondary psychosomatic mechanisms through which pruritus may be generated or exacerbated, e.g. sweating, alterations in cutaneous blood flow, and scratching[1]. Of note, psychological factors are thought to be able to diminish as well as augment pruritus.

Studies have shown that group psychotherapy, behavioral therapy, controlled physical exercise, support groups, and biofeedback can help to stop scratching and improve quality of life[1,10].

7 Psychocutaneous Diseases

Karynne O. Duncan, Josie Howard and John Y.M. Koo

INTRODUCTION

"Psychodermatology" refers to any aspect of dermatology in which psychological factors play a significant role in the genesis, exacerbation, or sequelae of a skin condition. At least a third of patients seen in dermatology practices require consideration of associated emotional and psychosocial factors for effective management of their cutaneous disease[1].

Many patients with psychodermatologic problems decline referral to a mental health professional, and some become upset if such a referral is suggested. Ironically, the individuals who are the most psychologically "ill" often have the least insight into the psychogenic nature of their condition and frequently refuse a psychiatric referral. The dermatologist is then faced with two choices. The first is to try to address the psychologic condition. If a dermatologist decides to take this route, it is necessary to be familiar with the approach to diagnosis, therapeutic options (both pharmacologic and non-pharmacologic, including potential side effects of medications), and limitations of what can be accomplished in a dermatology practice. The other option is to disregard the psychologic problem and allow this component of the patient's disorder to remain untreated. However, this option represents a disservice to the patient and may lead to unnecessary utilization of healthcare services and persistent psychopathology. Dermatologists can learn to effectively handle psychodermatologic issues within the limits of their training and practice setting. Although less comprehensive than treatment delivered in collaboration with a psychiatrist, in the authors' opinion, management of these issues by a dermatologist is important.

Clinically useful methods of conceptualizing and classifying psychodermatologic disorders are presented in Fig. 7.1. This incorporates updates from the fifth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5™)[2]. Selected primary and secondary psychologic conditions that are commonly encountered in a dermatologic practice are discussed in this chapter. Strategies for the evaluation and management of patients with these disorders are reviewed, including pharmacologic and non-pharmacologic treatments. Disorders characterized by pruritus and dysesthesia are covered in Chapter 6.

OVERVIEW

Psychodermatologic disorders can be conceptualized in two ways: (1) by the specific psychodermatologic condition; or (2) by the symptom complex and diagnostic pattern of the underlying psychopathology, including anxiety, depression, psychosis, and obsession–compulsion. The latter approach is useful because knowledge of the psychopathologic manifestations enables the clinician to choose the most appropriate psychopharmacologic agent (Table 7.1). For example, if the underlying psychopathology involves obsessions and/or compulsions, a selective serotonin reuptake inhibitor (SSRI; e.g. fluoxetine) would be a logical choice of therapy[3,4].

In the classification method based on psychodermatologic conditions, most patients can be grouped into one of four categories[3] (see Fig. 7.1):

- *primary psychodermatologic disorders*, in which the patient typically has no primary skin disease and cutaneous lesions are self-induced (e.g. delusional infestation, body-focused repetitive behaviors)
- *secondary psychodermatologic disorders*, in which the patient develops psychologic distress or a psychologic disorder as a result of a skin disease
- *psychogenic pruritus and dysesthesia*, in which the patient presents with a purely sensory complaint (e.g. pruritus, burning, stinging) without evidence of a delusional component, primary skin disease, or underlying medical condition (see Ch. 6)
- *psychophysiologic disorders*, in which a primary skin disorder (e.g. atopic dermatitis, psoriasis) is exacerbated by psychologic or behavioral factors (e.g. stress, anxiety)

PRIMARY PSYCHODERMATOLOGIC DISORDERS

Delusional Infestation

Synonyms: ■ Delusional parasitosis ■ Delusions of parasitosis ■ Primary delusional disorder somatic type ■ Morgellons disease

Key features

- Fixed, false belief that the skin is infested with animate organisms (e.g. insects, parasites) or inanimate materials (e.g. fibers) despite evidence to the contrary
- Occurs spontaneously and is not secondary to another medical or psychiatric condition or medication/substance use
- Requires establishment of a good patient–physician relationship and treatment with an antipsychotic medication

Introduction

The term "delusions of parasitosis" was introduced in 1946 to describe patients whose fixed false belief was that their skin was infested with what they believed to be parasites such as fleas, ticks, and various other organisms[5]. More recently, the term "Morgellons disease" has been used by patients to describe what they falsely perceive as fibers extruding from their skin[6]. To better encompass both of these conditions, which are felt to be along the same spectrum of delusional disorders, the term "delusional infestation" has been proposed and is currently more widely used.

Delusional infestation (DI) is classified as a *somatic type of delusional disorder* (previously referred to as monosymptomatic hypochondriacal psychosis) within the broad group of *schizophrenia spectrum and other psychotic disorders*[2]. *Delusions* are defined as fixed false beliefs that are not amenable to change despite conflicting evidence, and *somatic* delusions are focused on bodily functions or sensations. Individuals with DI have the isolated and fixed belief that their skin is infested by animate organisms (e.g. insects, parasites) or inanimate materials (e.g. fibers) in the absence of any objective evidence[4,7].

Epidemiology

The average age of onset is 55–60 years[8]. Among individuals over 50 years of age, women experience the disorder at least twice as often as men; however, prior to age 50, men and women are equally affected. Younger patients with this disorder are usually of a lower socioeconomic status and may have a history of substance abuse, while older patients are frequently of a higher socio-economic status.

Clinical features

Patients with DI do not meet criteria for a diagnosis of schizophrenia. However, they should fulfill the DSM-5™ diagnostic criteria for a delusional disorder, which are: (1) the delusion must be present for ≥1 month; (2) the patient does not exhibit impaired functioning or bizarre behavior apart from the impact of the delusion; and (3) the delusion cannot be attributable to the effects of a substance, medication, medical condition, or other psychiatric disorder[2]. The delusional belief

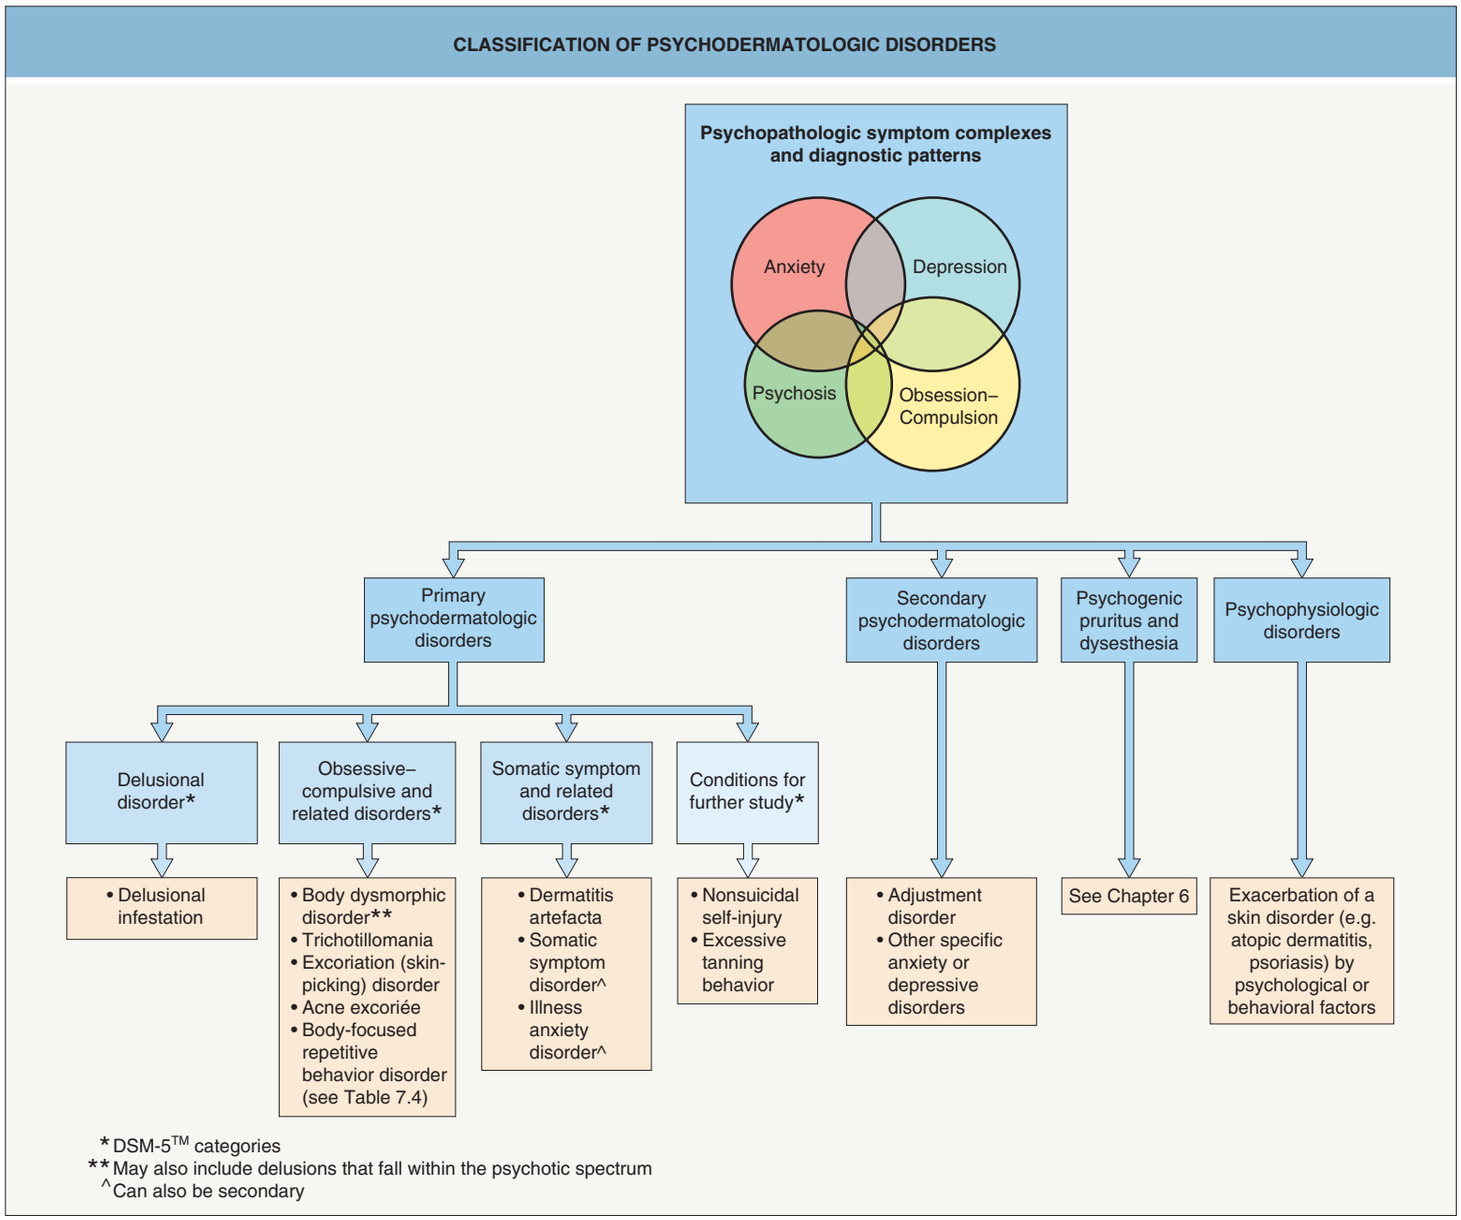

Fig. 7.1 Classification of psychodermatologic disorders. Psychocutaneous disorders can be conceptualized by: (1) the specific psychodermatologic condition and its classification; and (2) the presenting symptom complex of the underlying psychopathology. *Primary psychodermatologic disorders* are those in which the patient typically has no primary skin disease and cutaneous lesions are self-induced. *Secondary psychodermatologic disorders* are those in which the patient develops psychological distress or a psychologic disorder as a result of a skin disease. *Psychophysiologic disorders* are those in which a primary skin condition, such as psoriasis, is exacerbated by psychological or behavioral factors (e.g. stress, anxiety). A particular patient with a psychodermatologic disorder can have a presenting symptom complex with features from one or more of the four major psychopathologic patterns of anxiety, depression, psychosis, and obsessions/compulsions.

is "encapsulated", i.e. there is a narrow and specific focus on skin infestation. Patients may be able to state that others view their beliefs as irrational ("factual insight"), but they lack the true insight necessary to personally accept the valid explanation.

Individuals with DI typically present with a history of symptoms for months or even years. They have often already been evaluated by many physicians and have tried to eradicate alleged "parasites" by methods such as using pesticides, hiring exterminators, or changing their residence. Patients frequently bring in bits of skin, lint, and other samples that they believe represent "parasites"/fibers, which is referred to as the "matchbox sign" (Fig. 7.2). In addition to or in place of these samples, they may also bring in photographic documentation.

Skin findings in DI range from none to excoriations, lichenification, prurigo nodularis, and ulcerations (see Fig. 7.2). All of these are self-induced, usually resulting from the patient's efforts to dig out "parasites"/inanimate materials. Patients often report accompanying pruritus and stinging as well as biting and crawling sensations (formication).

One intriguing aspect of this disorder is the potential for a shared delusional system whereby the patient's close contacts come to believe in the delusion as well. *Folie à deux* ("craziness for two") is the term used to describe two people who share the same delusion. Occasionally, larger numbers of people harbor the same delusion, which may include the patient's parent(s) and children[9].

Differential diagnosis

By definition, DI occurs spontaneously and is not caused by another psychiatric or medical disorder; however, the term "secondary DI" is sometimes used for the latter situation. It is essential to exclude an underlying condition before making the diagnosis of "primary" DI. Conditions to consider in the differential diagnosis include: an actual skin infestation (e.g. scabies); formication due to neurologic disease; an underlying psychiatric disorder (e.g. schizophrenia) or medical condition (e.g. dementia, B_{12} deficiency, pruritus related to systemic disease); and medication/substance use (e.g. dopamine agonists, amphetamines, cocaine [see Ch. 89]). A thorough history and physical examination should be accompanied by microscopic evaluation of samples brought by the patient. When indicated, skin scrapings, skin biopsies, and laboratory evaluation are also performed.

PSYCHOPATHOLOGIC PATTERNS AND PSYCHOTROPIC MEDICATIONS USED IN DERMATOLOGY		
Underlying psychopathology and symptom complex	**Possible pharmacologic treatment**	**Comments and precautions**
Anxiety		
• Excessive anxiety and worry • Restlessness; feeling "keyed up" or "on edge" • Irritability • Fatigability • Difficulty concentrating or mind going blank • Muscle tension or feeling "shaky" • Sleep disturbance • Somatic symptoms, e.g. dizziness, sweating, palpitations, abdominal complaints	**Acute anxiety:** *Benzodiazepines* • Alprazolam (0.125–0.25 mg every 6–8 hours, as needed) • Lorazepam (0.5–2 mg every 6–8 hours, as needed) • Clonazepam (0.5–2 mg once or twice daily, as needed)	• Treatment not to exceed 4 weeks because of dependency/addiction risk • May cause sedation • Taper dosage to avoid withdrawal symptoms

	Chronic anxiety:
	• *SSRIs* (see Depression below)
	• *SNRIs*
	  • Venlafaxine, extended release (37.5–75 mg/day, up to 225 mg/day)
	• *Other*
	  • Buspirone (initial dose 7.5 mg twice a day; increase daily dose by 5 mg every 2–3 days, up to a maximum of 60 mg/day if needed)
	  • Doxepin (10–25 mg, at bedtime)
	  • Hydroxyzine (10–25 mg every 6–8 hours)
		• Onset of action often delayed 2–4 weeks
		• Do not cause dependency/addiction
		• SSRIs and SNRIs are considered as first-line treatment; therapeutic doses are similar to those used for depression
		• Buspirone often used as augmentation when partial response to antidepressant
		• Hydroxyzine and doxepin are sedating and may be helpful for pruritus

Depression		

• Depressed mood
• Anhedonia
• Unexplained weight loss/gain or appetite change
• Insomnia or hypersomnia
• Psychomotor agitation or retardation
• Fatigue, lack of energy
• Feelings of hopelessness, worthlessness
• Excessive guilt
• Difficulty with concentration, indecisiveness
• Suicidal ideation/plan
• Crying spells
• Preoccupation with physical concerns
	• *SSRIs* – start at minimal effective dose and increase every week or every other week as tolerated; if no response at 6–8 weeks, then change to a different class of antidepressants
	  • Fluoxetine (10–20 mg/day, up to 40–60 mg/day)
	  • Paroxetine (10–20 mg/day, up to 50 mg/day)
	  • Sertraline (25–50 mg/day, up to 200 mg/day)
	  • Escitalopram (5–10 mg/day, up to 20 mg/day)
	  • Citalopram (10–20 mg/day, up to 40 mg/day)
	• Bupropion XL (150–300 mg/day) can be used if sexual dysfunction is an issue/concern and if anxiety is not a prominent symptom
	• Mirtazapine (7.5–30 mg/day) may be useful in patients with insomnia or marked weight loss
		• SSRIs are typically the first-line treatment; slow onset of action, with full therapeutic response after ~6–8 weeks
		• SSRIs may cause gastrointestinal disturbances, sexual dysfunction
		• May unmask mania in patients with an undiagnosed bipolar disorder
		• Avoid abrupt discontinuation of SSRIs, as may cause dysphoria, dizziness, gastrointestinal distress
		• Citalopram and escitalopram can cause dose-dependent QT prolongation

	• *Tricyclic antidepressants (TCAs)* • Doxepin (dosage for pruritus is typically 10–25 mg at bedtime; for depression, typically start at 10–25 mg at bedtime and increase every 1–2 weeks to a therapeutic dose of 25–150 mg at bedtime or up to 300 mg in divided doses, depending on tolerance and disease severity)	• TCAs can lead to weight gain, cardiac conduction abnormalities, orthostatic hypotension, and anticholinergic side effects • Doxepin often causes sedation, especially in the elderly and smaller individuals; should be started at low doses (e.g. 10 mg/day); long-term use associated with increased risk of dementia; as dose approaches 100 mg daily, check trough serum level to guide future dose adjustments
Psychosis		
• Delusions are the most common feature that presents to dermatologists • Fixed false belief that the patient is convinced is true • Delusion is usually encapsulated (narrow focus)	• *First-generation antipsychotics* • Pimozide (start at 0.5–1.0 mg/day and increase by 0.5–1.0 mg every 2–4 weeks, as tolerated, to the lowest clinically effective dose – typically 2–6 mg/day). Once adequate clinical response, maintain dose for at least three months, followed by a gradual taper. Most patients require a 5- to 6-month treatment course	• Gradual taper to avoid withdrawal symptoms such as dyskinetic movements • Associated with QT prolongation, arrhythmias (doses ≥10 mg/day), EPS, TD (with long-term use), and drug interactions (avoid if taking opiates, citalopram, escitalopram, sertraline, macrolides, protease inhibitors, azole antifungals, grapefruit juice) • Baseline ECG often recommended when starting pimozide

	• *Second-generation antipsychotics*
	  • Risperidone (0.5 mg/day, up to 4 mg/day [Table 7.2])
	  • Olanzapine (2.5 mg/day, up to 10–15 mg/day)
	  • Aripiprazole (2 mg/day, up to 10–15 mg/day)
		• Weight gain, metabolic effects, and other side effects listed in Table 7.3
		• Risperidone is increasingly being used first-line for delusional infestation because of a lower risk of EPS and TD compared to pimozide, but has greater metabolic side effects (see Tables 7.2 and 7.3).

Obsessive–compulsive disorder (OCD)		

• Presence of intrusive obsessions and/or compulsions (see text)
• Varying degrees of insight
	• *SSRIs* (start at low dose and increase every week or every other week until reach therapeutic range)
	  • Fluoxetine (10 mg/day, up to 40–80 mg/day)
	  • Paroxetine (20 mg/day, up to 40–60 mg/day)
	  • Sertraline (25 mg/day, up to 200 mg/day)
	  • Fluvoxamine (50 mg/day, up to 200–300 mg/day)
	  • Escitalopram (5 mg/day, up to 20 mg/day)
	  • Citalopram (10 mg/day, up to 40 mg/day)
		• SSRIs are first-line pharmacologic treatment, but often need higher doses and longer time to respond (e.g. 10–12 weeks)
		• OCD is a chronic condition with rare complete remission; once a therapeutic response is achieved on a stable, tolerable regimen, most experts recommend continuation of treatment
		• If necessary or desired, a very slow taper can be attempted, with close monitoring for symptom recurrence

	• *Tricyclic antidepressants* • Clomipramine (25 mg/day, up to 100–250 mg/day)	• Clomipramine has a less tolerable side-effect profile than SSRIs, including cardiac toxicity and arrhythmias; baseline ECG; check blood levels when the dose is ≥150 mg/day
	• *SNRIs* • Venlafaxine (75 mg/day, up to 225–350 mg/day)	• Venlafaxine may cause hypertension and an increased risk of gastrointestinal bleeding

Table 7.1 Psychopathologic patterns and psychotropic medications used in dermatology. The pharmacologic treatment of psychodermatologic disorders can be chosen based on the underlying pathophysiology. This list is not exhaustive and focuses on psychotropic medications that are more frequently used in a dermatologic practice. SSRI, selective serotonin reuptake inhibitor; SNRI, serotonin-norepinephrine reuptake inhibitor; EPS, extrapyramidal side effects; TD, tardive dyskinesia.

Fig. 7.2 Delusional infestation. A Multiple excoriations and hypopigmented scars resulting from the patient's attempts to "dig out" parasites. **B** Samples of alleged "parasites" brought in by a patient ("matchbox sign" or "specimen sign"). *Courtesy Kalman Watsky, MD.*

Treatment

After assessing the differential diagnosis, the first step in management is to establish rapport and address the patients' concerns seriously without challenging their beliefs. Short follow-up visits and serial skin examinations can be helpful in building a strong therapeutic relationship. When discussing the diagnosis, communicate it in a matter-of-fact manner and refrain from making any statements that may be misinterpreted by patients as supporting their delusional ideation. It is important to validate the person's experience, without validating the delusion itself, and to ensure that the patient does not feel dismissed in the process of treatment.

The most challenging aspect of treatment is getting patients to agree to a trial of an antipsychotic agent, which is the mainstay of therapy for DI. Systematic reviews have not demonstrated superior efficacy of any particular antipsychotic agent for treatment of DI, and to date there have been no randomized controlled trials. The choice of antipsychotic therapy should take into account patient characteristics and medication side effect profiles (Tables 7.1–7.3). First-line treatment has traditionally been pimozide, which is usually effective at a very low dose and may be better accepted by patients because it has no psychiatric FDA indication (see Table 7.1). However, second-generation antipsychotics (e.g. risperidone; see Table 7.2) have more recently gained favor because of their decreased risk for EPS[7,10], but they do have potential metabolic side effects (see Table 7.3). Compared to individuals with other psychotic disorders, patients with DI typically respond to lower doses of antipsychotic agents and can often be successfully tapered off medication after 2–6 months.

General Features of Obsessive–Compulsive and Related Disorders

Several conditions included in the *obsessive–compulsive and related disorders* group have dermatologic manifestations (see Fig. 7.1). *Obsessions* are recurrent and persistent thoughts, images, or urges that are intrusive and unwanted. *Compulsions* are repetitive behaviors or mental acts that an individual feels driven to perform in order to reduce anxiety or distress, especially that arising from obsessions. In all of these disorders, the preoccupations and/or behaviors lead to significant distress or impairment in social, occupational, or other areas of functioning. Some of these conditions feature *body-focused repetitive behaviors* (e.g. hair pulling, skin picking) that continue despite repeated attempts to stop or decrease the behavior (Table 7.4; Fig. 7.3).

Body Dysmorphic Disorder

Synonym: ▪ Dysmorphophobia

Key features

- May affect as many as 10%–15% of dermatology patients
- Often begins in late adolescence or early adulthood
- Preoccupation with a non-existent or slight defect in appearance
- Frequent body sites of concern include the skin, hair, nose, breasts, and genitalia
- Typically associated with compulsive or ritualistic behaviors

Introduction

Dermatologists, particularly those performing cosmetic procedures, and plastic surgeons are often consulted by patients with body dysmorphic disorder, a distressing and socially impairing preoccupation with a non-existent or slight defect in appearance[11].

Epidemiology

The prevalence of body dysmorphic disorder in the general US population is estimated to be ~2.5% in women and 2% in men, but it is as high as 10%–15% in dermatology and cosmetic surgery patients. The mean age at onset is late teens, and the course tends to be chronic[2,4,11].

Clinical features

Patients with body dysmorphic disorder have a fundamental disturbance in their body image. They focus on perceived faults in their skin (e.g. acne, wrinkles, scars), hair (e.g. thinning, excessive), or body structures such as the nose, mouth, breasts, and genitalia. These preoccupations are time-consuming and cause significant distress, frequently leading to social isolation or functional impairment. In addition, affected individuals often adopt compulsive or ritualistic behaviors such as spending an excessive amount of time in front of a mirror or repeatedly checking for perceived imperfections. Personal insight regarding this condition is usually poor.

Treatment

The spectrum of body dysmorphic disorder includes: (1) *obsessions* with perceived inadequacies, which fall within the *obsessive–compulsive disorder (OCD) spectrum*; and (2) *delusions* (fixed false beliefs) about their appearance, which fall within the *psychotic spectrum*. For the purpose of treatment, it is useful to classify patients into one of these two categories, although the distinction is not always clear and individual patients may fluctuate between delusional and non-delusional thinking. Patients with the delusional variant have no insight into their disease and often go to extraordinary lengths, such as multiple surgeries, to correct their perceived deformity. It is important for cosmetic surgeons to recognize this disorder and avoid performing unnecessary procedures. In addition, patients with body dysmorphic disorder are often dissatisfied with the results of any procedure that is performed.

The first-line therapy for patients with the OCD variant of this disease includes cognitive behavioral therapy (CBT), typically in conjunction

USE OF RISPERIDONE IN DERMATOLOGY						
Drug properties: Second-generation antipsychotic; dopamine type 2 (D_2) and serotonin receptor ($5HT_2$) antagonist **Dermatologic indications:** Delusional disorders (e.g. delusional infestation) **Dosage:** Start at 0.5 mg/day at bedtime and increase weekly, as tolerated, to the lowest clinically effective dose (typically 2–4 mg/day dosed once or twice daily). Once an adequate clinical response has been reached, maintain therapeutic dose for at least three months, followed by a gradual taper; most patients require a 5- to 6-month course **Side effects:** See Table 7.3 **Monitoring guidelines**:						
Measure	**Baseline**	**4 weeks**	**8 weeks**	**12 weeks**	**Quarterly**	**Annually**
Personal/family history of metabolic syndrome, heart disease	X					X
Weight	X	X	X	X	X	
Waist circumference	X			X		X
Blood pressure (orthostatic measurements)	X			X		X
Fasting blood glucose/ hemoglobin A1C	X			X		X
Fasting lipid profile	X			X		X
Abnormal Involuntary Movement Scale (AIMS)*	X			X	X†	
Contraindications: Known hypersensitivity to risperidone or paliperidone; history of QT interval prolongation, arrythmias, cardiac conduction abnormalities; elderly patients, especially those with dementia-related psychosis (increased risk of death). **Pregnancy and lactation:** Use during third trimester of pregnancy can increase risk of EPS and/or withdrawal symptoms in newborns. Caution advised with breast-feeding, as it does pass into breast milk. **Drug interactions:** AVOID concomitant use of the following: medications which prolong the QT interval (e.g. macrolide antibiotics, citalopram, escitalopram); strong CYP2D6 inhibitors (*increase* the levels and effects of risperidone; e.g. fluoxetine, paroxetine, divalproex sodium, verapamil); strong CYP2D6 inducers (*decrease* the levels and effects of risperidone; e.g. carbamazepine, phenytoin, phenobarbital, rifampin).						
*For details, see qxmd.com/calculate/calculator_601/abnormal-involuntary-movement-scale-aims#; in the treatment of delusional infestation, tardive dyskinesia and EPS are rare given the use of lower dosages and relatively short duration of therapy. †If ≥50 years of age monitor the AIMS every 3 months; if <50 years of age, every 6 months.						

Table 7.2 Use of risperidone in dermatology. Compared to first-generation antipsychotics (e.g. pimozide), second-generation antipsychotics (SGAs) such as risperidone have reduced neurologic sequelae and a decreased incidence of extrapyramidal side effects (EPS) and tardive dyskinesia, but a greater risk of metabolic side effects for which monitoring is required. *Monitoring guidelines adapted from American Diabetes Association, American Psychiatric Association, American Association of Clinical Endocrinologists, North American Association for the Study of Obesity. Consensus development conference on antipsychotic drugs and obesity and diabetes. Diabetes Care 2004;27:596–601.*

SIDE EFFECTS OF PIMOZIDE AND SELECTED SECOND-GENERATION ANTIPSYCHOTIC DRUGS								
	Anticholinergic effects	**Sedation/ somnolence**	**QT prolongation**	**Increased prolactin**	**Weight gain**	**Metabolic effects***	**Extrapyramidal effects†**	**Tardive dyskinesia‡**
Pimozide (Orap®)	+	+	++	+++	+	+	+++	+++
Second-generation antipsychotic drugs

Ziprasidone (Geodon®)	+	++	+++	++	+	+	+	+
*E.g. insulin resistance/type 2 diabetes mellitus, hyperlipidemia (especially hypertriglyceridemia). †Parkinsonian symptoms, restlessness, stiffness, tremor; can be managed with benztropine 1–2 mg, 2–3×/day or diphenhydramine 25–50 mg every 6–8 hours (sedating). ‡Uncontrolled slow or jerky movements, often starting with tongue rolling and chewing; valbenazine is an FDA-approved treatment, but may be irreversible. ¶Use is limited by a 1% incidence of potentially life-threatening agranulocytosis as well as increased risks of seizures (dose-dependent), venous thromboembolism, and myocarditis. §Another second-generation antipsychotic drug, paliperidone (Invega®), represents the primary active metabolite of risperidone.								

Table 7.3 Side effects of pimozide and selected second-generation antipsychotic drugs. The use of antipsychotic drugs in elderly patients with dementia has been associated with an increased risk of mortality. A dose-dependent increased risk of sudden cardiac death has also been documented in patients receiving antipsychotic drugs. Olanzapine- and ziprasidone-induced drug reaction with eosinophilia and systemic symptoms (DRESS) has been described. With the lower doses and typically shorter duration of therapy for treating delusional infestation, tardive dyskinesia and extrapyramidal side effects are rarely seen.

BODY-FOCUSED REPETITIVE BEHAVIORS (BFRBs) AND ASSOCIATED MUCOCUTANEOUS FINDINGS	
Body-focused repetitive behavior	**Associated mucocutaneous findings**
Lip licking	Irritant contact dermatitis, secondary bacterial or yeast infections
Lip picking or biting	Multiple erosions or ulcerations, recurrent HSV
Cheek chewing or biting	Bite fibroma, morsicatio buccarum (see Fig. 72.12)
Cuticle pulling, picking, or biting (see Figs. 7.3 & 7.6)	Paronychia, nail surface irregularities
Nail biting (onychophagia) (see Fig. 7.3)	Paronychia, nail dystrophy, subungual hemorrhages
Nail picking or pulling (onychotillomania)	
Habit-tic deformity of the thumbnail (see Ch. 71)	Multiple midline Beau's lines with prominent longitudinal central depression
Thumb or finger sucking	Skin maceration, dermatitis, secondary bacterial or yeast infections
Skin biting (dermatophagia) (see Fig 7.6)	Pseudo-knuckle pads ("chewing pads")
Nose picking (rhinotillexomania)	Erosions, secondary bacterial infections
Hair pulling (trichotillomania; see Fig. 7.4)	See text
Skin picking (excoriation; see Fig. 7.6)	See text

Table 7.4 Body-focused repetitive behaviors (BFRBs) and associated mucocutaneous findings. BFRBs occur on a chronic basis and present with characteristic mucocutaneous findings, depending on the body site and behavior type. These behaviors exist along a spectrum, with habits at one end and body-focused repetitive behavioral disorders at the other end. The latter disorders continue despite repeated attempts to stop and lead to impaired functioning (e.g. social, occupational) or to distress manifesting as feelings of loss of control, embarrassment, or shame. HSV, herpes simplex virus.

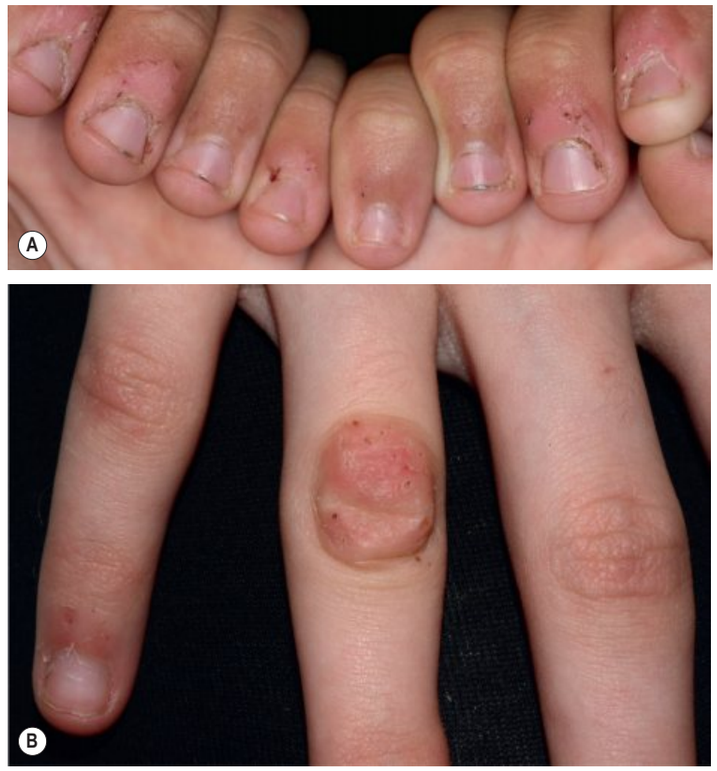

Fig. 7.3 Body-focused repetitive behaviors. A Sequelae of nail biting (onychophagia) and cuticle picking. **B** Pseudo-knuckle pad due to habitual repetitive hand movements. *B, Courtesy Julie V. Schaffer, MD.*

with an SSRI (often requiring a relatively high dose). Antipsychotics are the treatment of choice for patients who are truly delusional (see Tables 7.1–7.3)[12,13]. It is also important to treat any psychiatric comorbidities that may be contributing to the body dysmorphia, such as depression, anxiety, and panic disorder.

Trichotillomania

Synonyms: ■ Habitual hair pulling ■ Hair-pulling disorder

Key features

- Recurrent pulling out of one's hair, most often from the scalp, eyebrows, and eyelashes
- Varying lengths of hair are typically seen within areas of alopecia
- Behavior modification therapy is the mainstay of treatment

Introduction

Trichotillomania represents a body-focused repetitive behavior disorder characterized by hair pulling.

Epidemiology

The prevalence of trichotillomania in adolescents and adults in the general population is roughly 1%–2%[2]. The female:male ratio is as high as 10:1 in adults but more equal in children. The peak onset of hair pulling is around the time of puberty[14]. The majority of patients also have other body-focused repetitive behaviors such as nail biting or skin picking (see Table 7.4). In dermatologic practice, trichotillomania is usually seen in relatively psychologically intact individuals. Of note, hair pulling in toddlers and preschool-aged children is more common in boys than girls and, unlike trichotillomania in older children, tends to resolve spontaneously.

Clinical features

The DSM-5™ diagnostic criteria for trichotillomania include: (1) recurrent pulling out of one's hair, resulting in hair loss; (2) repeated attempts to decrease or stop the hair pulling; (3) significant distress or impaired functioning related to the hair pulling; and (4) no underlying medical condition or other mental disorder that explains the hair loss/pulling[2]. In dermatologic practice, the spectrum ranges from inattentive, habitual hair pulling to obvious obsessive–compulsive psychopathology involving well-planned rituals.

The most common sites of hair pulling are the scalp, eyebrows, eyelashes, and pubic region. Hair pulling typically occurs while alone or in the presence of close family members. It may be preceded or accompanied by anxiety or boredom, and some patients describe a prior tingling sensation. Pulling of the hair results in gratification, pleasure, or a sense of relief in some patients, while others display a more automatic behavior with less conscious awareness[2]. Pulling may be confined to a specific time of the day and place, with ritualized manipulation of the pulled hairs prior to discarding them. Some patients practice *trichophagy*, the chewing and swallowing of the hair that has been pulled out, which can lead to intestinal obstruction from trichobezoars. Occasionally, affected individuals pull hair from family members, pets, dolls, sweaters, or carpets.

The classic physical finding is hairs of varying lengths distributed within the area of alopecia, with uninvolved areas appearing completely normal (Fig. 7.4); the hairs are sometimes referred to as "irregularly irregular". This pattern likely reflects a hair-pulling technique of twisting multiple strands around the fingers and pulling them simultaneously. Lesions are often single and can be large; the vertex and parietal scalp are the most common sites[2]. While broken hairs and black dots are seen

Fig. 7.4 Trichotillomania. Note the hairs of varying lengths and small areas of sparing.

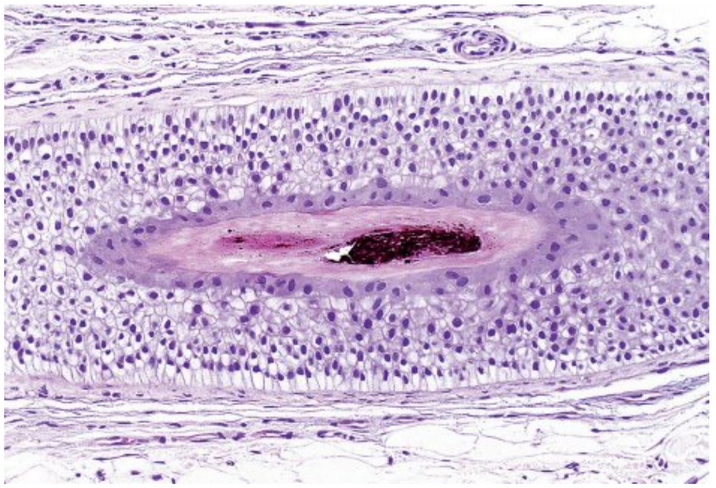

Fig. 7.5 Histopathology of trichotillomania. Pigmented follicular cast. *Courtesy Ronald P. Rapini, MD.*

by trichoscopy, more specific findings include hook, coiled, tulip and flame hairs, the V-sign, and trichoptilosis (see Ch. 69)[15]. Patients may try to conceal the hair loss with make-up, scarves, hats, or wigs.

Diagnosis and pathology

Many patients admit to hair pulling, but trichoscopy and biopsy may be helpful when the diagnosis is in doubt. Another useful test is the "clipped hair square", in which a small section of affected hair is clipped close to the scalp with scissors or shaving; too short to pull out, the hairs display uniform regrowth.

Histopathologic findings can include deformed hair shafts (trichomalacia), empty follicles, and pigmented hair casts (Fig. 7.5), which may also be seen with traction alopecia and other forms of follicular trauma. Inflammatory cells are usually sparse or absent. Perifollicular hemorrhage is sometimes found in early lesions, and perifollicular fibrosis represents a late change. If the follicle is destroyed, a vertical fibrous tract often remains at the site.

Differential diagnosis

The differential diagnosis includes other causes of circumscribed non-scarring alopecia such as alopecia areata (see Ch. 69), which occasionally coexists with trichotillomania, and tinea capitis. However, in trichotillomania there are no exclamation point hairs, scaling and pustules are absent, and fungal cultures are negative.

Treatment

The prognosis and approach to treatment of trichotillomania depend upon the age of onset and degree of underlying psychopathology. As noted above, preschool children typically outgrow the habit, and management usually involves bringing awareness to the parents and patient. Onset in the pre-adolescent to young adult years often portends a chronic, relapsing course requiring more intervention. Later adult onset is frequently associated with psychopathology that requires psychiatric referral.

Behavior modification therapy (e.g. habit reversal training, CBT) is the mainstay of treatment[16,17]. This includes awareness training, teaching the patients to do something else whenever they feel the urge to pull their hair, relaxation techniques, and positive reinforcement. In addition, a family and peer support network may be helpful. Antidepressants (especially SSRIs and clomipramine) have been reported to be effective in some studies[14]. However, two randomized controlled trials failed to show benefit of antidepressants compared to placebo, and several others found that behavioral therapy was more effective than antidepressants. In other randomized controlled studies, treatment with olanzapine or *N*-acetylcysteine (a glutamatergic agent; 1200–2400 mg/day) led to more improvement in adults with trichotillomania than did placebo[18,19].

Excoriation Disorder

Synonyms: ■ Skin-picking disorder ■ Neurotic excoriations ■ Dermatillomania ■ Psychogenic excoriations

Key features

- Recurrent picking, scratching, or rubbing that results in skin lesions
- Most often on the face, scalp, dorsal hands/forearms, and upper back but can occur on any reachable body surface
- Most commonly seen in middle-aged women

Introduction

Excoriation disorder is categorized in DSM-5™ as a body-focused repetitive behavior disorder characterized by skin picking. Some people have a tendency to inattentively but habitually pick incidental skin lesions, such as an arthropod bite, keratin plug, or lesion of acne or folliculitis. This action may be episodic or occur on a regular basis, and it can be regarded as an innocuous habit when controllable and not causing distress or psychosocial impairment. In contrast, patients with excoriation disorder have a conscious, repetitive, and uncontrollable desire to pick, scratch, or rub their skin, which results in characteristic lesions. Picking activity may begin inadvertently as the hand comes across an irregularity on the skin, or it may take place in a ritualistic fashion.

Epidemiology

The lifetime prevalence of excoriation disorder in the general population is estimated to be 1.5%, with a female : male ratio of 3 : 1[2]. Onset is most often around the time of puberty, and it frequently begins with a dermatologic condition such as acne (see Acne Excoriée below)[2]. The usual course is chronic, with waxing and waning of symptoms over a period of years. Excoriation disorder is more common in individuals with OCD and their first-degree family members, and many patients exhibit other body-focused repetitive behaviors (e.g. hair pulling, nail biting; see Table 7.4)[20]. Underlying depression may also be present.

Clinical features

The DSM-5™ diagnostic criteria for excoriation disorder, analogous to those for trichotillomania, include: (1) recurrent skin picking, resulting in skin lesions; (2) repeated attempts to decrease or stop the picking; (3) significant distress or impaired functioning related to the picking; and (4) no underlying medical condition or other mental disorder that explains the picking[2]. The psychological aspects of the skin picking are similar to those for the hair pulling of trichotillomania (see above).

Skin lesions may be created *de novo* or evolve from a pre-existing urticarial papule, acneiform lesion, or crust. Repeated picking, scratching, or rubbing of the skin can result in erosions or ulcerations with linear/angular or circular/oval shapes (Fig. 7.6). The distribution characteristically favors the dorsal hands and forearms as well as the scalp, face, upper outer arms, upper back, and buttocks. Some patients favor only "hidden" areas such as the buttocks.

Fig. 7.6 Excoriation (skin-picking) disorder. This patient continued to pick at a mosquito bite, creating a deep ulceration with raised borders. Note the sequelae of concomitant body-focused repetitive behaviors – short nails with surrounding erythema, thickening, peeling, and hemorrhagic crusts from nail biting (onychophagia) and cuticle picking.

Fig. 7.7 Acne excoriée. This patient compulsively picked at his acne lesions. *Courtesy Richard Odom, MD.*

Lesions range in size from a few millimeters to several centimeters. Several stages of evolution are often evident, from small superficial erosions to deep ulcerations with hypertrophic borders to hypo- or hyperpigmented scars. On the scalp, there may be broken hairs as well as areas of scarring alopecia. The presence of mature scars points to chronicity.

Differential diagnosis

Underlying causes of pruritus and dysesthesia should be considered (see Ch. 6). Body-focused repetitive behaviors, including skin picking and hair pulling, should not be confused with stereotypic movement disorders, which are characterized by repetitive, seemingly driven, apparently purposeless motor behaviors that typically begin during early childhood. Stereotypic movement disorders can occur in the setting of autism spectrum disorder and other neurodevelopmental conditions.

Treatment

Once causes of pruritus or dysesthesia are excluded and treatment of underlying cutaneous disorders (e.g. folliculitis) has been instituted, therapy can focus on associated pruritus (if present) and the psychological aspects of the condition. When pruritus is present, topical lotions containing pramoxine or menthol may be helpful. Cool compresses are soothing, hydrate the skin, and facilitate debridement of crusts. Antihistamines such as hydroxyzine can have beneficial sedative and antipruritic effects in some patients. Intralesional corticosteroids and flurandrenolide tape address the inflammatory component of existing lesions but not the formation of new lesions.

Doxepin, a tricyclic antidepressant with potent antihistamine properties, may be particularly useful in patients with excoriation disorder associated with pruritus, anxiety, and/or difficulty sleeping. Starting at a low dose (e.g. 10 mg) at bedtime is recommended, with a gradual titration to a beneficial effect (often 25–50 mg nightly [lower in elderly patients]). This allows one to build tolerance to associated daytime somnolence. If significant depression or anxiety is present and not controlled by low-dose doxepin, addition of an SSRI is preferred so as to avoid the potential side effects of higher doxepin doses (see Table 7.1).

Since obsessive–compulsive symptoms are associated with serotonin-mediated neural pathways, SSRIs can be helpful in patients with excoriation disorder as well as OCD itself (see Table 7.1). CBT and habit reversal training have been reported to reduce skin picking in systematic reviews[21,22]. In addition, *N*-acetylcysteine (1200–3000 mg/day) led to more improvement than placebo in a randomized controlled study of adults with excoriation disorder, with similar findings in a systematic review[23–25]. Potential side effects include occasional gastrointestinal symptoms such as flatulence.

Acne Excoriée

Synonym: ■ Acne excoriée des jeunes filles

Key features

- Subset of excoriation disorder
- Frequently seen in young women
- Ritualistic picking of acne lesions

Clinical features

Acne excoriée is a subset of excoriation disorder (see above) in which the picking is directed at acne lesions. The underlying acne is often mild but accompanied by extensive excoriations that may lead to scarring (Fig. 7.7).

Treatment

Treatment includes comprehensive therapy for the underlying acne (see Ch. 36) together with management of the obsessive–compulsive component and other psychological aspects as described above for excoriation disorder. Recurrence of even mild acne may be accompanied by resumption of picking unless the associated psychologic disorder is addressed.

Dermatitis Artefacta

Synonyms: ■ Factitial dermatitis ■ Factitious disorder

Key features

- More common in women than men
- Motive is usually subconscious and patients deny their role in causation
- Self-inflicted cutaneous lesions that are often induced by foreign objects
- Typically located in areas that are easily reached by the hands

Introduction

Dermatitis artefacta represents a type of *factitious disorder* within the broad DSM-5™ category of *somatic symptom and related disorders*[2]. Patients inflict cutaneous lesions upon themselves to satisfy a psychologic need of which they are usually not consciously aware. If asked, the patients deny having any role in creating the skin lesions. While some of these individuals create skin lesions as a maladaptive response to an acute psychosocial stress, many suffer from borderline personality disorder[4]. Because patients may dissociate in the process of creating these lesions, they are often unable to give an accurate history, making this disorder challenging to diagnose and treat. "*Factitious disorder imposed on another*" (previously known as *Munchausen syndrome by proxy*) is a related condition in which an individual surreptitiously inflicts lesions on another person in order to satisfy a subconscious psychologic need.

Epidemiology

Dermatitis artefacta is uncommon and is reported to have a female : male ratio of up to 20 : 1[4]. Although the onset is most frequently during adolescence and young adulthood, it can occur at any age. Many patients either work in or have a close family member who works in the healthcare field.

Clinical features

Dermatitis artefacta can mimic a wide variety of dermatoses. The lesions may be single or multiple and unilateral or bilateral. Although usually within easy reach of the hands, the lesions can be caused by methods such as carving with sharp instruments, applying chemicals, injecting foreign substances, thermal burns, and the "salt and ice challenge" publicized on the Internet[26,27]. The morphology ranges from vesicles and bullae to purpura to subcutaneous emphysema to erosions and ulcerations. A clue to the diagnosis is unusual shapes, particularly with angulated edges, that suggest an external method of induction (Fig. 7.8).

Pathology

Histopathologic changes seen with dermatitis artefacta vary considerably, depending upon the manner in which the lesions were produced. The findings are generally not diagnostic and can include erosion, ulceration, epidermal necrosis with multinucleated keratinocytes, hyperkeratosis, irregular acanthosis, vascular proliferation, hypertrophied nerves (as observed in prurigo nodularis), and fibroplasia[28]. Polarizing exogenous material with a variable foreign body response is occasionally evident[29].

Differential diagnosis

In addition to excluding a primary skin disorder (e.g. ecthyma), dermatitis artefacta must be distinguished from delusional infestation, excoriation disorder, and malingering; the latter is characterized by skin lesions that are self-inflicted for a *conscious* gain. In *nonsuicidal self-injury* (see below), patients acknowledge that they inflicted the lesions on themselves.

Treatment

Initially, wound care to help with healing is often indicated and the possibility of a primary dermatologic disorder needs to be excluded. There is controversy as to whether or not to confront the patient upon recognition of dermatitis artefacta, as this might acutely exacerbate their self-harm behaviors. Therefore, it is often more fruitful to provide a supportive environment early in the doctor–patient relationship and then advance to the psychological aspects of the disease at subsequent visits. Antidepressant, antianxiety, or antipsychotic medications may be indicated when affected individuals have an underlying psychiatric disorder (see Table 7.1). Children or adults in whom the lesions represent a response to a transient stress have the most favorable prognosis. Dermatitis artefacta usually has a chronic course, with waxing and waning depending upon circumstances in the affected individual's life.

Other Somatic Symptom and Related Disorders

Other conditions within the *somatic symptom and related disorders* category in DSM-5™ are characterized by somatic symptoms (either medically validated or unexplained) that are more severe than expected and associated with significant distress or functional impairment. Disorders in this category that may be seen in dermatologic practice include somatic symptom disorder and illness anxiety disorder.

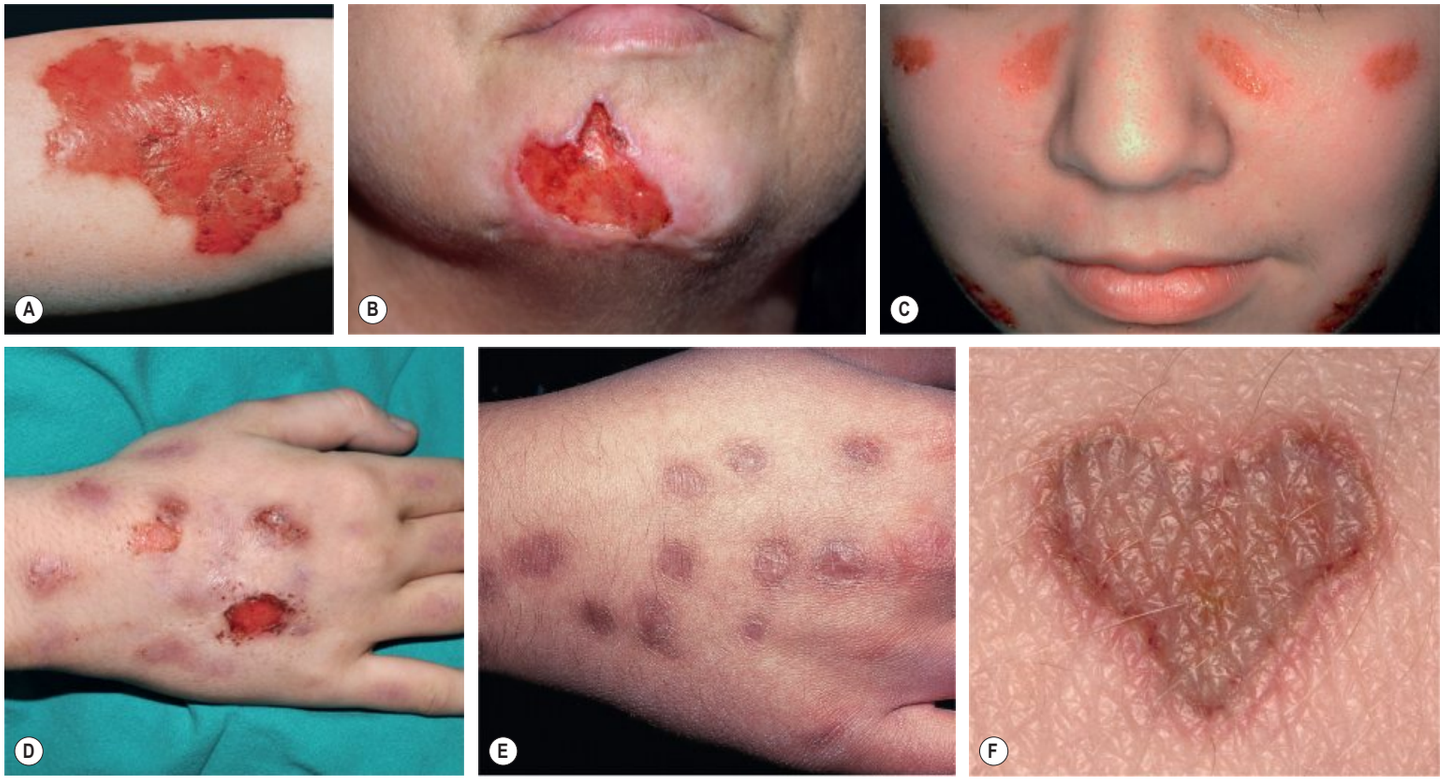

Fig. 7.8 Dermatitis artefacta. Erosion (**A**) and ulcer (**B**) with "bizarre" shapes and angulated borders, possibly created with sharp instruments. **C** Symmetric erosions on the cheeks of an adolescent girl. **D** Erosions in different stages of healing. **E** Scars from cigarette burns. **F** The patient carved this heart-shaped lesion into her skin. These patients all denied knowing how the lesions had developed or having any role in the process. *B, Courtesy Kalman Watsky, MD; D, Courtesy Antonio Torrelo, MD; E Courtesy Ronald P. Rapini, MD; F, Courtesy Department of Dermatology, Medical University of Graz.*

In *somatic symptom disorder*, affected individuals overestimate the seriousness of their symptoms, which lead to persistent thoughts, high levels of anxiety, and/or excessive expenditure of time and energy. Such patients are rarely reassured and may feel that their medical care has been inadequate. For example, a patient may interpret normal daily hair shedding as evidence of having alopecia areata, resulting in severe anxiety and substantial time spent collecting hairs.

Illness anxiety disorder is characterized by an excessive preoccupation with the idea of having or acquiring a serious illness[30]. Somatic symptoms are absent or mild, and there is an inappropriately high level of health-related anxiety. The individual may either be: (1) *care-seeking* with increased health-related behaviors, e.g. daily skin self-examinations looking for skin cancers; or (2) *care-avoidant* in a maladaptive manner, e.g. failing to go to the dermatologist for skin examinations despite a family history of melanoma.

Somatic symptom and illness anxiety disorders respond best to a combination of pharmacologic (e.g. SSRIs) and non-pharmacologic (e.g. CBT, psychotherapy) measures[30,31]. Coordination of care between providers is helpful to avoid unnecessary evaluation and treatment.

Fig. 7.9 Nonsuicidal self-injury. Repeated episodes of self-cutting with a razor blade caused these hypopigmented scars on the dorsal hand and forearm of this young woman.

Nonsuicidal Self-Injury

Synonym: ■ "Cutting"

Key features

- Repeated infliction of cutaneous injuries, e.g. via cutting, stabbing, or burning
- Represents a response to psychological distress without suicidal intent

Epidemiology and clinical features

Nonsuicidal self-injury features repeated infliction of shallow injuries to the surface of the body, typically via cutting, stabbing, or burning. There is no suicidal intent, and the purpose is usually to reduce negative emotions or resolve an interpersonal difficulty. The injury may be inflicted with a sharp object (e.g. knife, razor, needle), cigarette, or eraser that is rubbed vigorously. The most common sites are the dorsal forearms and anterior thighs. Most patients do not seek medical help and will admit that they inflicted the lesions on themselves[32]; scars are often the only visible sign of the behavior (Fig. 7.9). Onset is usually in early adolescence and can continue for many years. The overall female : male ratio is approximately 1.5 : 1[33]. Although nonsuicidal self-injury is classically associated with borderline personality disorder, depression and anxiety are more common in affected individuals.

Treatment

Initial management should focus on the patient's safety and treatment of associated psychiatric conditions. Basic tenets of treatment include determining the patient's psychologic needs and developing alternative methods to fulfill them. Dialectical behavioral therapy addressing impulse control, affect regulation, distress tolerance, and interpersonal effectiveness can be of benefit for patients with an underlying borderline personality disorder.

Excessive Tanning Behavior

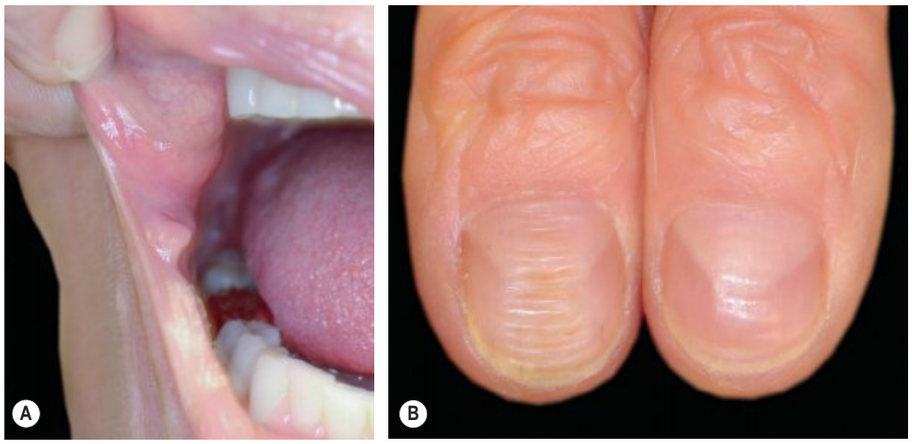
There is increasing evidence that excessive tanning can represent an addictive behavior[34–36]. It involves an impulse towards and repetition of tanning that leads to impaired psychosocial functioning and continues despite potentially serious or fatal consequences, e.g. following the diagnosis of cutaneous melanoma.

SECONDARY PSYCHODERMATOLOGIC DISORDERS

Patients often experience concern and suffering due to skin conditions that are life-threatening (e.g. melanoma), disfiguring (e.g. alopecia areata, vitiligo), intensely pruritic or painful (e.g. atopic dermatitis, hidradenitis suppurativa), or even relatively minor but troublesome. When the magnitude of the distress exceeds that which would be expected and/or there is impairment in life functioning, then a secondary psychodermatologic condition such as anxiety, depression, and/or adjustment disorder should be considered.

Adjustment Disorder

Adjustment disorders are common in medical practice and may occur in response to a dermatologic condition. DSM-5™ defines an adjustment disorder as the development of emotional or behavioral symptoms in response to an identifiable stressor that results in either marked distress out of proportion to the severity of the stressor or significant impairment in life functioning. The stress-related reaction does not meet criteria for another psychiatric disorder (e.g. depression), arises within 3 months of the onset of the stressor, and does not persist for more than 6 months after the stressor has ended. If the stressor or its consequences persist, the adjustment disorder may continue and become chronic[2]. Adjustment disorders have been associated with an increased risk of suicidal behavior and substance abuse as well as with interference in medical treatment and worsening of the medical condition.



By asking open-ended questions about patients' experiences with their skin conditions, dermatologists can recognize and address their concerns, identify pathologic psychological responses, and make appropriate referrals to mental health providers. Adjustment disorder is best managed with psychotherapy, which can often be brief and solution-oriented, focusing on coping skills and managing problems associated with the dermatologic condition. Pharmacotherapy to address anxiety and/or depression, if present, may also be helpful (see Table 7.1).

AIMS EXAMINATION PROCEDURE

SHOULD BE COMPLETED BEFORE ENTERING THE RATINGS ON THE ABNORMAL INVOLUNTARY MOVEMENT SCALE (AIMS) FORM.

Either before or after completing the Examination Procedure, observe the patient unobtrusively at rest (e.g. in waiting room).

The chair to be used in this examination should be a hard, firm one without arms.

1: Ask patient whether there is anything in his/her mouth (i.e. gum, candy, etc) and if there is, to remove it.

2: Ask patient about the current condition of his/her teeth. Ask patient if he/she wears dentures. Do teeth or dentures bother patient now?

3: Ask patient whether he/she notices any movements in mouth, face, hands, or feet. If yes, ask to describe and to what extent they currently bother patient or interfere with his/her activities.

4: Have patient sit in chair with hands on knees, legs slightly apart, and feet flat on floor. (Look at entire body for movements while in this position.)

5: Ask patient to sit with hands hanging unsupported. If male, between legs, if female, and wearing a dress, hanging over knees. (Observe hands and other body areas.)

6: Ask patient to open mouth. (Observe tongue at rest within mouth.) Do this twice.

7: Ask patient to protrude tongue. (Observe abnormalities of tongue movement.)

*8: Ask patient to tap thumb, with each finger, as rapidly as possible for 10–15 seconds: separately with right hand, then with left hand. (Observe facial and leg movements.)

9: Flex and extend patient's left and right arms, one at a time. (Note any rigidity and rate it.)

10: Ask patient to stand up. (Observe in profile. Observe all body areas again, hips included.)

*11: Ask patient to extend both arms outstretched in front with palms down. (Observe trunk, legs, and mouth.)

*12: Have patient walk a few paces, turn, and walk back to chair. (Observe hands and gait.) Do this twice.

*Activated movements.

eTable 7.1 Abnormal involuntary movement scale (AIMS).

Patient's name _____ Patient's ID information _____

Examiner's name _____

CURRENT MEDICATIONS AND TOTAL MG/DAY

Medication #1 _____ Total mg/day _____ Medication #2 _____ Total mg/day _____

INSTRUCTIONS: COMPLETE THE EXAMINATION PROCEDURE BEFORE ENTERING THESE RATINGS.

	None, Normal	Minimal (may be extreme normal)	Mild	Moderate	Severe
Facial and Oral Movements					
1. Muscles of facial expression e.g. movements of forehead, eyebrows, periorbital area, cheeks; include frowning, blinking, smiling, grimacing	☐0	☐1	☐2	☐3	☐4
2. Lips and perioral area e.g. puckering, pouting, smacking	☐0	☐1	☐2	☐3	☐4
3. Jaw e.g. biting, clenching, chewing, mouth opening, lateral movement	☐0	☐1	☐2	☐3	☐4
4. Tongue Rate only increases in movement both in and out of mouth, NOT inability to sustain movement	☐0	☐1	☐2	☐3	☐4
Extremity Movements					
5. Upper (arms, wrists, hands, fingers) Include choreic movements (i.e. rapid, objectively purposeless, irregular, spontaneous); athetoid movements (i.e. slow, irregular, complex, serpentine) DO NOT include tremor (i.e. repetitive, regular, rhythmic).	☐0	☐1	☐2	☐3	☐4
6. Lower (legs, knees, ankles, toes) e.g. lateral knee movement, foot tapping, heel dropping, foot squirming, inversion and eversion of foot	☐0	☐1	☐2	☐3	☐4
Trunk Movements					
7. Neck, shoulders, hips e.g. rocking, twisting, squirming, pelvic gyrations	☐0	☐1	☐2	☐3	☐4

SCORING:
- Score the highest amplitude or frequency in a movement on the 0–4 scale, not the average;
- Score Activated Movements the same way; do not lower those numbers as was proposed at one time;
- A POSITIVE AIMS EXAMINATION IS A SCORE OF 2 IN TWO OR MORE MOVEMENTS or a SCORE OF 3 OR 4 IN A SINGLE MOVEMENT
- Do not sum the scores: e.g. a patient who has scores 1 in four movements DOES NOT have a positive AIMS score of 4.

Overall Severity					
8. Severity of abnormal movements	☐0	☐1	☐2	☐3	☐4
9. Incapacitation due to abnormal movements	☐0	☐1	☐2	☐3	☐4
	No Awareness	Aware, No Distress	Aware, Mild Distress	Aware, Moderate Distress	Aware, Severe Distress
10. Patient's awareness of abnormal movements (rate only patient's report)	☐0	☐1	☐2	☐3	☐4
Dental Status					
11. Current problems with teeth and/or dentures?	☐Yes	☐No			
12. Does patient usually wear dentures?	☐Yes	☐No

Guy W: ECDEU Assessment Manual for Psychopharmacology - Revised (DHEW Publ No ADM 76-338), US Department of Health, Education, and Welfare; 1976

eTable 7.1 Abnormal involuntary movement scale (AIMS). The AIMS is a 12-item clinician-rated scale to assess the presence and severity of abnormal involuntary movements in patients taking antipsychotic medications. Development of such abnormal involuntary movements is unusual with the use of such medications in dermatology (e.g. for delusional infestation), as the doses are typically much lower and the durations significantly shorter than those used for other psychiatric conditions (e.g. schizophrenia). Items are scored on a 0 (none) to 4 (severe) basis. The scale provides a total score (items 1–7) or item 8 can be used alone to indicate the level of symptom severity. A positive AIMS examination is a score of 2 in two or more movements or a score of 3 or 4 in a single movement. *From Guy W. ECDEU Assessment Manual for Psychopharmacology – Revised (DHEW Publ No ADM 76-338), US Department of Health, Education, and Welfare; 1976.*

THE EFFECT OF PSYCHOTROPICS ON QTc
No effect
Brexpiprazole Cariprazine Lurasidone
Low effect (only in overdose or <10 ms increases in QTc)
*Aripiprazole**, asenapine, clozapine, haloperidol, perphenazine, prochlorperazine, *olanzapine*†, *risperidone*, loxapine, paliperidone*
Moderate effect (>10 ms QTc prolongation at clinical doses)
Chlorpromazine, iloperidone, *quetiapine*, ziprasidone
High effect (>20 ms QTc prolongation at average clinical doses)
Pimozide Any drug or combination of drugs used in doses exceeding recommended maximum
*Data on paliperidone are confusing (some suggest no effect) and recent data suggest aripiprazole prolongs QTc to a small extent and is probably torsadogenic. †Isolated cases of QTc prolongation demonstrated effect on inwardly rectifying potassium channels (IKr); other data suggest no effect on QT.

eTable 7.2 The effect of psychotropics on QTc. Drugs in *italics* are currently the most commonly prescribed antipsychotic medications in the US. ms, milliseconds; QTc, QT interval corrected for heart rate. *Modified from Taylor DM, Barnes TRE, Young AH. Maudsley Prescribing Guidelines in Psychiatry. 13th edition. Chichester: Wiley Blackwell; 2018. Reproduced with permission.*

8 Psoriasis

Peter C.M. van de Kerkhof and Lars Iversen

Key features

- Psoriasis is a chronic, immune-mediated disorder that results from a polygenic predisposition combined with environmental triggers, e.g. trauma, infections, medications, psychological stress
- The underlying pathophysiology involves various classes of T cells and their interactions with dendritic cells and cells involved in innate immunity, including neutrophils and keratinocytes
- Identification of susceptibility genes has pointed to a major role for the innate and adaptive immune systems as well as altered epidermal differentiation
- Sharply demarcated, scaly, erythematous plaques characterize the most common form of psoriasis; occasionally, sterile pustules are seen
- The most common sites of involvement are the scalp, elbows, and knees, followed by the nails, hands, feet, and trunk (including the intergluteal fold)
- Typical histologic findings include acanthosis with elongated rete ridges, hypogranulosis, hyper- and parakeratosis, dilated blood vessels, and a perivascular infiltrate of lymphocytes with neutrophils singly or within aggregates in the epidermis
- Psoriatic arthritis is the major associated systemic manifestation and the most common presentation is asymmetric oligoarthritis of the small joints of the hands and feet; other comorbidities include depression, metabolic syndrome, and cardiovascular disease in patients with moderate to severe disease
- Topical therapy is used to treat limited disease, whereas phototherapy, methotrexate, cyclosporine, and targeted immunomodulators ("biologic" therapies) that modify key immune effector cells and cytokines lead to significant clinical improvement of moderate to severe psoriasis

INTRODUCTION

Psoriasis is an immune-mediated polygenic skin disorder[1]. Various environmental triggering factors, e.g. trauma, infections, medications, may elicit disease in predisposed individuals[1]. The characteristic lesion is a sharply demarcated erythematous plaque with micaceous scale, and the plaques may be localized or widespread in distribution. Histologically, hyperkeratosis, parakeratosis, acanthosis of the epidermis, tortuous and dilated vessels, and an inflammatory infiltrate composed predominantly of lymphocytes are observed.

Psoriasis is a systemic disease process in which up to 20%–30% of patients have or will develop psoriatic arthritis. In addition, in patients with moderate to severe psoriasis, there is an increased relative risk for metabolic syndrome, atherosclerotic cardiovascular disease, and depression. Psoriasis also has a significant impact on patients' quality of life[2], and in surveys, patients feel that the current treatments, although often effective, do not provide a satisfactory long-term solution.

HISTORY

Hippocrates and his school (460–377 BCE) provided meticulous descriptions of many skin disorders. In their classification, dry scaly eruptions were grouped together under the heading "lopoi". This group probably included psoriasis and leprosy.

Between 129 and 99 BCE, the word "psora" (meaning a desquamative condition) was first used by Galen to describe a skin disorder characterized by a scaliness of the eyelids, corners of the eyes, and scrotum. The condition was pruritic and excoriations were present. Although called psoriasis, this affliction was probably a type of eczema.

It was not until the nineteenth century that psoriasis was recognized as an entity distinct from leprosy. Although Robert Willan (1809) was the first to give an accurate description of psoriasis, it would be another 30 years before Hebra (in 1841) definitively separated the clinical features of psoriasis from those of leprosy. In 1879, Heinrich Koebner described the development of psoriatic plaques at sites of skin injury. The World Health Organization (WHO) passed a resolution in 2014 recognizing psoriasis as a "chronic, noncommunicable, painful, disfiguring and disabling disease for which there is no cure".

EPIDEMIOLOGY AND GENETICS

In most reviews, the prevalence of psoriasis is said to be 2% of the world's population. However, in the US and Canada, prevalences as high as 4.6% and 4.7% have been reported, respectively. This contrasts with frequencies in Africans, African-Americans, Norwegian Lapps, or Asians of between 0.4% and 0.7%. A worldwide systematic literature review was performed by the Global Psoriasis Atlas (www.globalpsoriasisatlas.org) focusing on the epidemiology of psoriasis[3]. The incidence varied from 30 per 100 000 person-years in Taiwan to 321 per 100 000 person-years in Italy. Psoriasis proved to be more frequent in high-income countries and in regions with older populations.

One population-based study noted that 73% of affected individuals had mild to moderate psoriasis, while 27% suffered from more severe involvement[2]. In one large group of patients with psoriasis (n = 1728), 79% had nail changes[4]. Psoriatic arthritis has been found to affect 5%–30% of patients with cutaneous psoriasis, depending upon the series[1].

Psoriasis can first appear at any age, from infancy to the eighth decade of life. Two peaks in age of onset have been reported: one at 20–30 years of age and a second peak at 50–60 years. In ~75% of patients, the onset is before the age of 40 years[5–7], and in 35%–50%, it is before the age of 20 years. Although the age of onset is earlier in women than in men, the natural history is similar – chronic with intermittent remissions. In one epidemiologic study, 39% of the patients stated they had experienced remissions of 1–54 years[6].

In Europe, the overall prevalence rate for juvenile psoriasis was found to be ~0.7%, with an increase from 0.37%–0.55% in those 0 to 9 years of age to 1.01%–1.37% in those 10–19 years of age[5–8]. Plaque psoriasis is the most frequent form of the disease in children, followed by guttate psoriasis.

Genetic Factors

Depending upon the series, a positive family history has been reported by 35% to 90% of patients with psoriasis. Based on a large survey-based study in Germany, if both parents had psoriasis, the risk of their child developing psoriasis was 41%, whereas if only one parent were affected, the risk was 14%; the risk was 6% if just one sibling had psoriasis[9].

Analysis of concordance rates among monozygotic and dizygotic twins is another method for examining the influence of genetic factors on a disease. One literature review found that of 141 monozygotic twin pairs, 82 were concordant for psoriasis and 59 were discordant; of 155 dizygotic twin pairs, only 31 were concordant and 124 were discordant for psoriasis[10]. Thus, there is a two- to threefold increased risk of psoriasis in monozygotic twins as compared to dizygotic twins, implying that genetic factors are important. The distribution of the lesions, the severity, and the age of onset were similar in the monozygotic twin pairs, whereas these features differed in the dizygotic twin pairs. This observation suggested that genetic factors also play a role in the clinical course of psoriasis.

HLA studies

Histocompatibility antigens (HLA) are surface antigens on human cells, and the corresponding chromosomal region is called the major histocompatibility complex (MHC). It is situated on the short arm (p) of chromosome 6. Psoriasis is associated with HLA-Cw6, with the presence of HLA-Cw6 conferring a relative risk of 13 for developing psoriasis in the White population and 25 in the Japanese.

HLA-Cw6 is strongly linked to the age of onset of psoriasis. In one series, HLA-Cw6 was expressed in 90% of the patients with early-onset psoriasis, in 50% of those with late-onset psoriasis, and only in 7% of a control population. A specific MHC class II antigen (DRB1*0701/2) also appeared to be associated with early-onset psoriasis, and the psoriasis-associated HLA alleles were often in an extended haplotype: Cw6-B57-DRB1*0701-DQA1*0201-DQB1*0303. Individuals carrying this haplotype were found to have a 26-fold increased risk of developing early-onset psoriasis[11].

As a result, some clinicians have designated patients with early-onset psoriasis, a positive family history of psoriasis, and expression of HLA-Cw6 as having *type I psoriasis* and those with late-onset disease, no family history, and a lack of expression of HLA-Cw6 as having *type II psoriasis*[12]. While HLA-Cw6 may serve as a biomarker for clinical and therapeutic stratification[13], to date there are no treatments that specifically target HLA-Cw6. Other HLA alleles can be associated with different psoriasis variants and related conditions, e.g. the HLA-B27 allele is a marker for sacroiliitis-associated psoriasis and reactive arthritis (see below).

Genome-wide association studies

Classic genome-wide linkage analysis identified at least nine psoriasis susceptibility regions *(PSORS1–9)* in different chromosomal locations[14]. By far the most important genetic region was *PSORS1* (on chromosome 6p), which is estimated to account for up to 50% of psoriasis risk. *PSORS1* contains genes such as *HLA-C* (with the *HLA-Cw6* risk allele; see above) and corneodesmosin (*CDSN*). Due to high linkage disequilibrium in *PSORS1* (i.e. genes within this region are inherited as a block), it has been challenging to determine which gene(s) within *PSORS1* contribute to psoriasis pathogenesis.

In genome-wide association studies (GWASs), in which hundreds of thousands of *s*ingle *n*ucleotide *p*olymorphisms (SNPs) across the entire human genome are examined in thousands of patients (see Ch. 54), at least 80 risk loci have been identified[15]. It has been estimated that these loci explain ~28% of genetic heritability[15]. GWASs have led to several conclusions regarding the genetic factors in psoriasis (Table 8.1)[16,17]. First, most of the genes that have been implicated have immune-related functions, underscoring the importance of the innate and adaptive immune systems in the pathogenesis of psoriasis; in contrast, relatively few genes that encode skin-specific proteins have been associated with psoriasis. Second, thus far surprisingly few interactions among the genetic variants have been identified (with the exception of HLA-Cw6 and ERAP-1; see below). Third, associated genes encode proteins with roles in particular immunologic and signaling pathways, especially those involving tumor necrosis factor (TNF), NF-κB, interferons (IFNs), and interleukin (IL)-23/Th17 cells (see Table 8.1)[17,18]. Lastly, *ERAP1*, which encodes an aminopeptidase involved in MHC class I antigen processing, interacts synergistically with the *HLA-Cw6* risk allele, providing another argument for the role of an MHC-restricted antigen and its presentation through HLA-C in the pathogenesis of psoriasis[17].

More recently, greater insights into the genetics of pustular psoriasis have been made. In patients with generalized pustular psoriasis, several groups identified homozygous or compound heterozygous loss-of-function mutations in *IL36RN*, which encodes the IL-36 receptor antagonist[19]. Patients with the autoinflammatory disorder DITRA (deficiency of IL-36 receptor antagonist) present with widespread psoriasiform plaques whose edges contain sterile pustules (see Figs. 45.11B & 45.12). Based upon susceptibility loci and transcriptomics, a significant IL-36 signature was also observed in patients with plaque psoriasis[20].

Functional genomic studies

Microarray technology has been utilized to obtain a comprehensive picture of the genes expressed in psoriatic skin[21]. More than 1300 genes were found to be differentially expressed when compared to normal human skin. This group of genes included known markers of psoriasis in the skin, but it also contained numerous genes not known to be expressed in the skin. These analyses confirmed (on a genomic scale) the involvement of T cells and dendritic cells (DCs) and also implicated a role for comorbidity-associated genes involved in atherosclerosis signaling and fatty acid metabolism.

Another important gene family differentially expressed in psoriatic epidermis encodes antimicrobial peptides. These peptides are expressed at high levels in psoriatic skin but at low levels in skin affected by atopic dermatitis[22]. Additionally, complete functional impairment of the IL-36 receptor antagonist secondary to null mutations in *IL36RN* has highlighted the importance of repressing IL-36-dependent activation of the NF-κB pathway[23]. Such insights led to the recent introduction of an interleukin-36 receptor inhibitor for the treatment of generalized pustular psoriasis.

PATHOGENESIS

Because it primarily affects the interfollicular epidermis, psoriasis was long regarded as an epidermal disease in which the fundamental biochemical or cellular defect resided within the keratinocyte. Accordingly, prior to the early 1980s[24], a number of biochemical mediators, enzymes, and pathways involved in epidermal function were incriminated as being abnormal in psoriasis, including cyclic AMP, eicosanoids, protein kinase C, phospholipase C, polyamines, and transforming growth factor (TGF)-α. Although associated immunologic abnormalities were reported in the late 1970s[25], a major paradigm shift occurred when T cell suppressive agents such as cyclosporine were found to result in dramatic improvement of psoriasis[26]. Over the past three decades, psoriasis has been regarded as a T cell-driven disease[1]. The role of lymphocyte subsets as well as cytokines involved in chemotaxis, homing, and activation of inflammatory cells has been extensively investigated, culminating in the development of novel therapeutic approaches[1]. In sum, psoriasis is a chronic, inflammatory, autoimmune skin disease elicited by environmental factors or autoantigens in genetically predisposed individuals and it involves complex interactions amongst the innate and adaptive immune systems as well as keratinocytes and other cells residing within the skin.

Immunopathogenesis

Role of T cells and dendritic cells

A pathogenic role for antigen-presenting cells and T cells is strongly suggested by the association of psoriasis with particular MHC alleles, e.g. *HLA-Cw6*, as well as (in individuals who carry such alleles) variants in *ERAP1*, which encodes an aminopeptidase involved in antigen processing. The presence of specific T cell subsets within the epidermis and dermis of lesional skin is well documented (Fig. 8.1A). Also, a number of compounds that affect T cell function (e.g. by targeting the IL-2 receptor, CD2, CD11a, or CD4) were found to result in clinical improvement of psoriasis[27]. Another argument supporting involvement of the adaptive immune system is the disappearance or development of psoriasis following hematopoietic stem cell transplantation[28]. In addition, analysis of lesional T cells has shown oligoclonality, indicating potential antigen-specific expansion of T cell subpopulations, possibly triggered by exogenous microbial or viral antigens or cross-reacting autoantigens, e.g. keratins. Other implicated autoantigens include the antimicrobial peptide LL37 (cathelicidin)[29] and the melanocyte antigen ADAMTSL5[30].

Animal models for psoriasis have also demonstrated the importance of T cells. In xenograft models in which uninvolved psoriatic skin was transplanted onto immunodeficient mice, donor immune cells (in particular resident T cells) were capable of expanding and inducing the complete lesional phenotype[31]. Induction of psoriatic lesions in these models was also shown to be dependent on TNF and on IFN-α derived from plasmacytoid DCs (pDCs)[32]. These experiments demonstrated that T cells can trigger psoriasis in a suitable patient-derived environment.

In humans, several cell types have been implicated in the initiation and maintenance of psoriatic lesions (see Fig. 8.1A). Most of the epidermal T cells are $CD8^+$, whereas the dermal infiltrate is a mixture of $CD4^+$ and $CD8^+$ cells. The majority of the cells in both locations are memory T cells that express cutaneous lymphocyte antigen (CLA; the skin homing receptor) and chemokine receptors such as CCR4. Expression of $\alpha_1\beta_1$ integrin (VLA-1) on psoriatic T cells, which allows

their interaction with basement membrane collagen IV, is key for the entrance of these cells into psoriatic epidermis and establishment of the psoriatic epithelial phenotype[33]. Unconventional T cells also contribute to the pathogenesis of psoriasis via secretion of proinflammatory cytokines and chemokines. These include natural killer (NK) T cells, gamma delta (γδ) T cells, and innate lymphoid cells (ILCs).

DCs are present in both uninvolved and lesional psoriatic skin, and because of their potent immunostimulatory capacity, they are likely to be involved in its pathogenesis. There is an increased number of dermal DCs in psoriatic skin, and they have an enhanced ability to activate T cells when compared to DCs from normal skin. The role of DCs in psoriasis has been validated by the presence of a prominent genomic DC signature and the decrease of DCs during effective targeted therapy.

Based upon studies in humans and a xenograft model, a subtype of DC, the pDC, was shown to initiate psoriasis via the production of IFN-α[32]. Complexes of self DNA or RNA (from keratinocytes) plus antimicrobial peptide LL37 trigger IFN-α release by pDCs via a Toll-like receptor 9 (TLR9)-dependent mechanism (see Fig. 8.1A). This leads to

a breaking of tolerance to self nucleic acids and potentially explains the start of the inflammatory cascade in psoriasis[34,35].

The presence of neutrophils in the epidermis, either in spongiform pustules of Kogoj or in microabscesses of Munro, is a typical histopathologic feature of psoriasis, especially acute or pustular forms. Neutrophils are typically prominent in active lesions and in the marginal zone of expanding plaques, but, in contrast to T cells, they are not a consistent feature of lesional skin. Although activated neutrophils could contribute to its pathogenesis, they are not considered to be the primary cause of psoriasis.

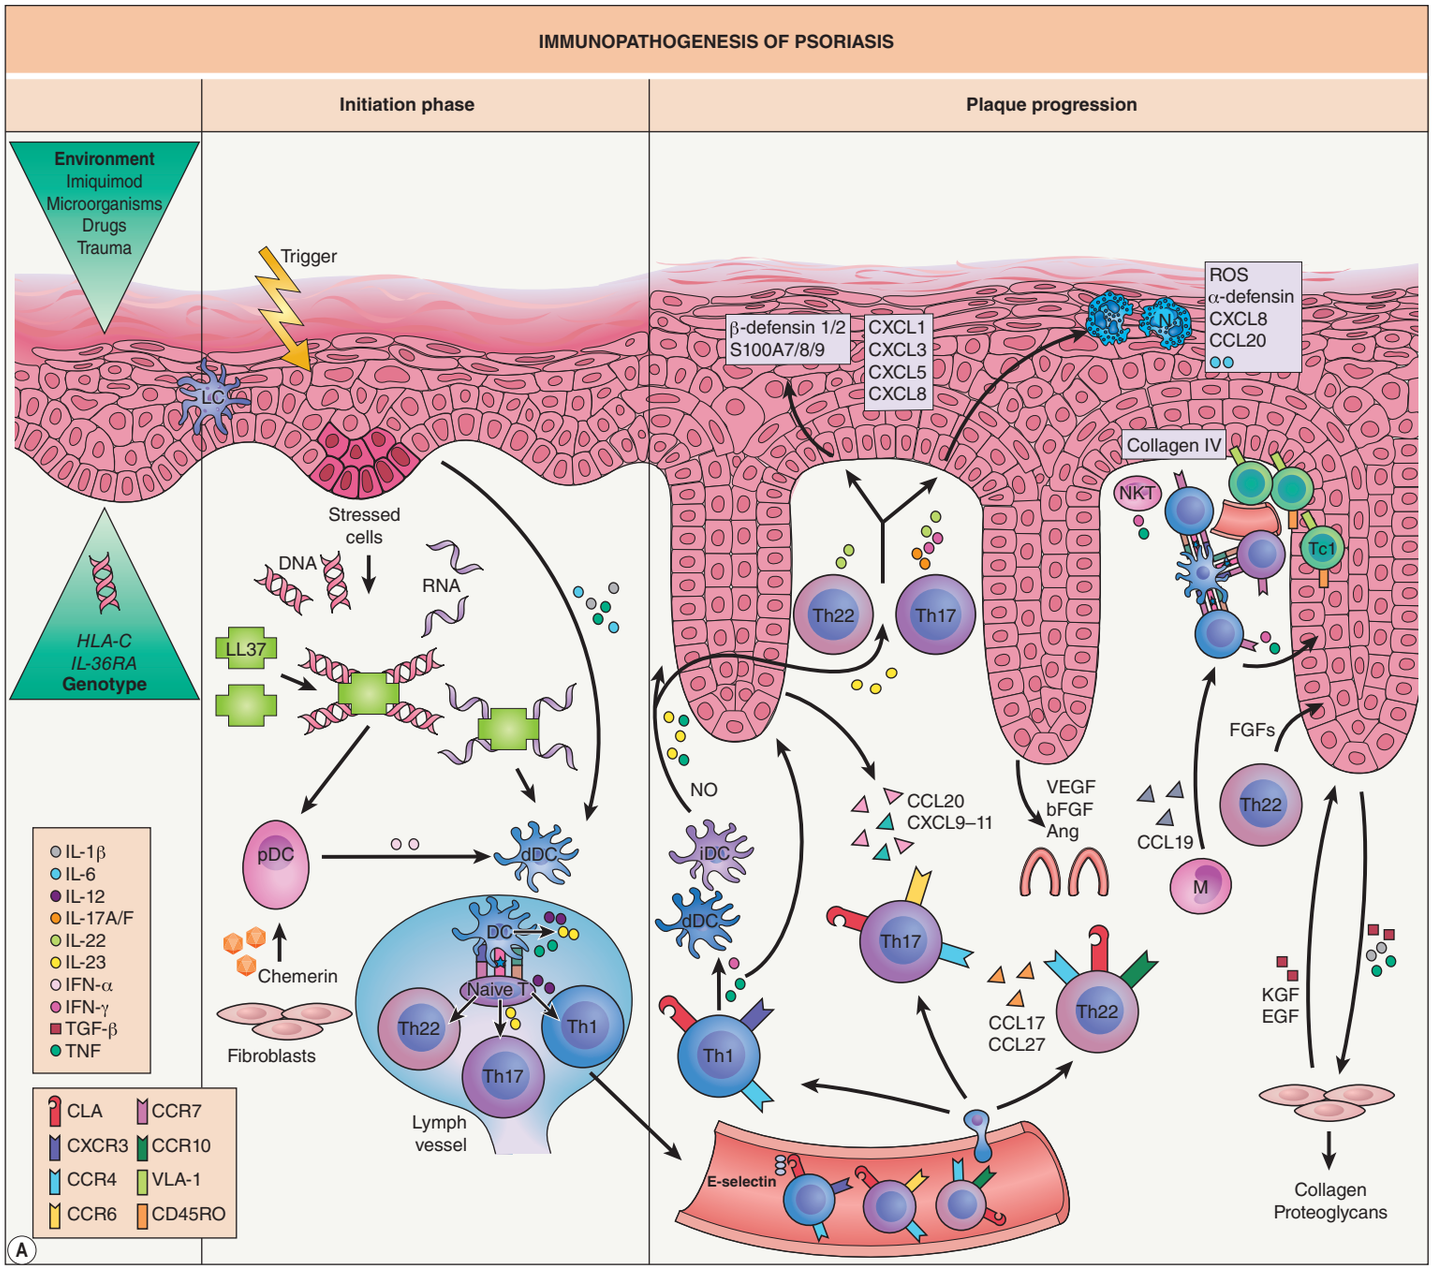

Fig. 8.1A Immunopathogenesis of psoriasis. The occurrence of triggering environmental factors in genetically predisposed individuals, carrying susceptibility alleles of psoriasis-associated genes, results in disease development. During the initiation phase, stressed keratinocytes can release self DNA and RNA, which form complexes with the cathelicidin LL37 that then induce interferon-α (IFN-α) production by plasmacytoid dendritic cells (pDCs; recruited into the skin via fibroblast-released chemerin), thereby activating dermal DCs (dDCs). Keratinocyte-derived interleukin-1β (IL-1β), IL-6, and tumor necrosis factor (TNF) also contribute to the activation of dDCs. Activated dDCs then migrate to the skin-draining lymph nodes to present an as-yet-unknown antigen (either of self or of microbial origin) to naive T cells and (via secretion of different types of cytokines such as IL-12 and IL-23 by DCs) promote their differentiation into T helper 1 (Th1), Th17, and Th22 cells. Th1 cells (expressing cutaneous lymphocyte antigen [CLA], CXC-chemokine receptor 3 [CXCR3], and CC-chemokine receptor 4 [CCR4]), Th17 cells (expressing CLA, CCR4, and CCR6), and Th22 cells (expressing CLA, CCR4, and CCR10) migrate via lymphatic and blood vessels into psoriatic dermis, attracted by the keratinocyte-derived chemokines CCL20, CXCL9–11, CCL17, and CCL27; this ultimately leads to the formation of a psoriatic plaque. Th1 cells release IFN-γ and TNF, which amplify the inflammatory cascade, acting on keratinocytes and dDCs. Th17 cells secrete IL-17A and IL-17F (and also IFN-γ and IL-22), which stimulate keratinocyte proliferation and the release of β-defensin 1/2, S100A7/8/9, and the neutrophil-recruiting chemokines CXCL1, CXCL3, CXCL5, and CXCL8. Neutrophils (N) infiltrate the stratum corneum and produce reactive oxygen species (ROS) and α-defensin with antimicrobial activity, as well as CXCL8, IL-6, and CCL20. Th22 cells secrete IL-22, which induces further release of keratinocyte-derived T cell-recruiting chemokines. Moreover, inflammatory DCs (iDCs) produce IL-23, nitric oxide (NO) radicals, and TNF, while natural killer T (NKT) cells release TNF and IFN-γ. Keratinocytes also release vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and angiopoietin (Ang), thereby promoting neoangiogenesis. Macrophage (M)-derived chemokine CCL19 promotes clustering of Th cells expressing chemokine receptor CCR7 with DCs in the proximity of blood vessels, with further T cell activation. At the dermal–epidermal junction, memory $CD8^+$ cytotoxic T cells (Tc1) expressing very-late antigen-1 (VLA-1) bind to collagen IV, allowing entry into the epidermis and contributing to disease pathogenesis by releasing both Th1 and Th17 cytokines. Cross-talk between keratinocytes, producing TNF, IL-1β and transforming growth factor-β (TGF-β), and fibroblasts, which in turn release keratinocyte growth factor (KGF), epidermal growth factor (EGF) and TGF-β, and possibly Th22 cells releasing FGFs, contribute to tissue reorganization and deposition of extracellular matrix (e.g. collagen, proteoglycans).

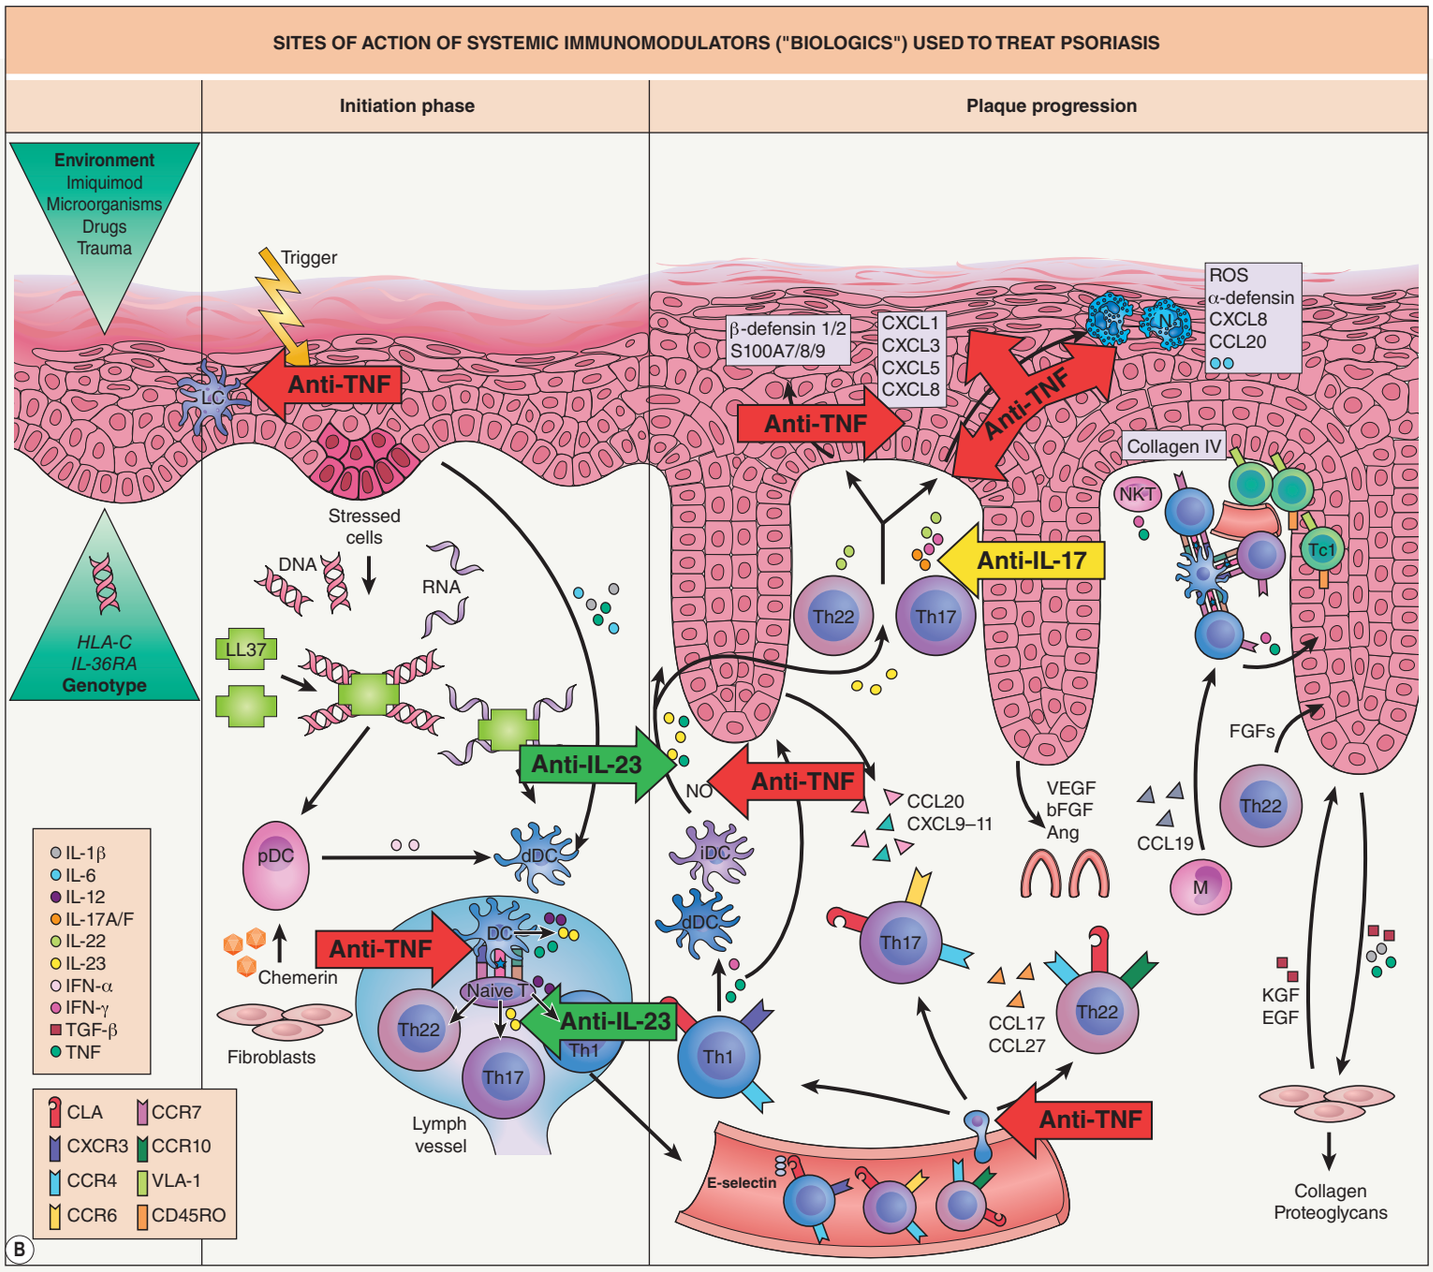

Fig. 8.1B Sites of action of systemic immunomodulators ("biologics") used to treat psoriasis. Note the multiple sites for TNF inhibitors while anti-IL-17 and -IL-23 antibodies are more selective. In the epidermis of psoriatic lesions, IL-17A, IL-17F, and IL-22 induce host defense proteins and several proinflammatory cytokines, including IL-36; there is greater expression of IL-36 in patients with generalized pustular psoriasis and in those with a loss-of-function mutation in the gene that encodes the IL-36 receptor antagonist. Recently, the first anti-IL-36 receptor antibody was approved by the FDA to treat patients with flares of generalized pustular psoriasis. LC, Langerhans cell. *Courtesy Dr Paola DiMeglio.*

Prominent angiogenesis is observed within plaques of psoriasis. There is increased expression of vascular endothelial growth factor (VEGF)[36], and anti-VEGF therapy leads to improvement in mouse models of psoriatic inflammation.

Cytokines, chemokines, and transcription factors

Psoriasis is considered to be a disease with prominent involvement of T helper cell subsets and their secreted *cytokines*[37]. This is supported by the significant clinical responses observed following administration of monoclonal antibodies that target specific cytokines (Fig. 8.1B). Increased amounts of Th1 (IFN-γ and IL-2), Th17 (IL-17A and -17F), and Th22 cytokines (IL-22) are observed, whereas levels of the anti-inflammatory cytokine IL-10 are reduced. The concerted action of these cytokines leads to proliferation of keratinocytes and dermal inflammation (see Fig. 8.1A)[38].

Following activation of pDCs, large amounts of type I IFN are produced, leading to maturation and activation of dDCs. The latter cells then secrete IL-23, which together with other cytokines (e.g. IL-6, TGF-β), drives naive T cells in a Th17 direction. Within the skin-draining lymph nodes, a naive T cell can differentiate into a Th1, Th17, or Th22 cell. After migrating into the skin, these cells release their signature cytokines; release of IL-17A and IL-17F leads, often in synergy with TNF, to an activation of the MAPK and NF-κB signaling pathways in keratinocytes[39] and other skin resident cells. This creates a "feed-forward" inflammatory response that can be self-amplifying and result in activation and recruitment of Th1 and Th22 cells into the psoriatic lesion[40,41].

Any model of pathogenesis has to also account for the dramatically increased proliferation rate of keratinocytes. Within psoriatic plaques, keratinocytes express the transcription factor STAT3, and in a transgenic animal model, epidermal expression of STAT3 (in cooperation with T cells) was found to induce psoriasis-like lesions. STAT3 induces upregulation of a number of psoriasis-relevant genes (e.g. *ICAM1*, *TGFA*), with TGF-α having been shown to stimulate proliferation of keratinocytes in psoriasis via an autocrine loop. Furthermore, STAT3 activation occurs downstream of several cytokines involved in the pathogenesis of psoriasis such as IL-6, IL-22, and IL-23[42]. In addition,

STAT3 activation induces differentiations of Th17 cells[43] and it directly activates the promoters of *IL17A* and *IL17F*[44].

IFN-γ is released by activated T cells and NKT cells within the epidermis, and it activates members of the STAT transcription factor family, which drive the expression of a large number of immune-related genes that have roles in psoriasis pathogenesis (see above). The IFN-γ-activated pathway is a key feature of psoriasis and explains several phenotypic alterations such as vasodilation (by the induction of nitric oxide synthase [iNOS]) and accumulation of T cells (via the expression of various chemokines). The innate immune cytokines IL-1, IL-6, and TNF are also upregulated in psoriatic skin. TNF is a particularly relevant cytokine and its importance is underscored by the therapeutic efficacy of TNF inhibitors (see Fig. 8.1B).

Chemokines are important mediators in the trafficking of leukocytes, and the increase in several chemokines and their cognate receptors within psoriatic lesions has been extensively documented. CXCL8 is thought to mediate the often-prominent infiltration by neutrophils. CCL17, CCL20, CCL27, and CXCL9–11 are implicated in attracting T cells to the psoriatic plaque. A pDC-attracting chemokine, chemerin, is increased in psoriatic skin and might contribute to the early recruitment of pDCs into psoriatic lesions[45].

Lastly, there is significant overlap between the cytokines, transcription factors, and subsequent signaling pathways discussed in this section and the psoriasis susceptibility genes outlined in Table 8.1.

Innate immunity and role of keratinocytes

In the skin, various cell types are involved in innate (non-adaptive) immune response pathways. These include DCs (myeloid DCs and pDCs), NKT cells, γδT cells, ILCs, and neutrophils, as well as epidermal keratinocytes. For example, keratinocytes constitutively express antimicrobial proteins such as β-defensin-1 (hBD1) and secretory leukocyte protease inhibitor (SLPI), which have direct antimicrobial activity against a broad spectrum of pathogens. In addition, keratinocytes can be stimulated to express a wide variety of other inducible antimicrobials such as hBD2, the cathelicidin LL37, and SKALP/elafin[46]. In addition to these effector molecules, keratinocytes express TLRs and secrete signaling molecules such as IL-1, IL-6, IL-8, and TNF (see Fig. 8.1A). Interestingly, the antimicrobial effector protein hBD2 was also shown to have chemotactic activity via CCR6 and to bind to TLR4. Since most of these proteins are highly expressed in lesional psoriatic skin, it is likely that they are involved in the initiation or control of the inflammatory process; however, their precise roles remain to be determined.

Disease memory

It is well known that psoriasis often relapses at previously affected body sites after treatment cessation[47]. The origin of this disease memory is unknown, but both tissue-resident memory T cells[48] and epithelial stem cells[49] have been proposed as candidate cells responsible for this phenomenon. The hypothesis that disease memory develops when lesions become chronic has led to the speculation that early and intensive interventions could avoid this phenomenon[50].

Triggering Factors

Triggering factors, both external (directly interacting with the skin) and systemic, can elicit psoriasis in genetically predisposed individuals.

External triggering factors

The Koebner or isomorphic phenomenon, i.e. the elicitation of psoriatic lesions by injury to the skin, is observed in ~25% of patients with psoriasis. A particular patient may be "Koebner-negative" at one point in time and later become "Koebner-positive". The Koebner phenomenon suggests that psoriasis is a generalized skin disease that can be triggered locally. Psoriatic lesions can also be induced by other forms of cutaneous injury, e.g. sunburn, morbilliform drug eruption, viral exanthem. The lag time between the trauma and the appearance of skin lesions is usually 2–6 weeks.

Systemic triggering factors

Infections

Infections, particularly bacterial infections, may induce or aggravate psoriasis. Provoking infections have been observed in up to 45% of psoriatic patients. Streptococcal infections, especially pharyngitis, are the most common offenders. In the palatine tonsils of psoriasis patients, immune responses have been shown to be dysregulated, with elevated expression of CLA and the IL-23 receptor[51]. Streptococci can also be isolated from other sites of infection, e.g. dental abscesses, perianal cellulitis, impetigo. Recently, group A streptococcal infections were shown to induce clonal expansion of CD1a-restricted T cells that can drive autoreactivity in psoriasis[51a].

HIV

HIV infection has also been shown to aggravate psoriasis (see Ch. 78).

Endocrine factors

Hypocalcemia has been reported to be a triggering factor for generalized pustular psoriasis. Although active vitamin D_3 analogues improve psoriasis, abnormal vitamin D_3 levels have not been shown to induce psoriasis. Pregnancy may alter disease activity, e.g. 50% of the patients in one series reported improvement during pregnancy. However, pregnant women may develop pustular psoriasis, also referred to as impetigo herpetiformis, and sometimes in association with hypocalcemia. As in pustular psoriasis in non-pregnant individuals, the pustules in impetigo herpetiformis are sterile.

Psychogenic stress

Psychogenic stress is a well-established systemic triggering factor in psoriasis, with a heightened cortisol response to stress having been demonstrated in affected patients[52]. Stress is associated with initial presentations of the disease as well as flares of pre-existing psoriasis. In a prospective study, cognitive and behavioral patterns of worrying and scratching were both independently related to an increase in disease severity and pruritus 4 weeks later[53].

Drugs

Several drugs have been incriminated as inducers of psoriasis, in particular lithium, IFNs, anti-PD-1 antibodies, β-blockers, and antimalarials. The association with immune checkpoint inhibitors may be related to increased levels of IL-6[54]. A rapid taper of systemic corticosteroids can induce pustular psoriasis as well as flares of plaque psoriasis. Patients receiving TNF inhibitors, e.g. for Crohn disease or rheumatoid arthritis, may experience new-onset or worsening of psoriasis, including pustulosis of the palms and soles (see Fig. 21.24). In addition, patients with atopic dermatitis who receive dupilumab can develop psoriasiform lesions, presumably due to a phenotypic shift from predominantly Th2-mediated inflammation to a Th1 immune response.

Alcohol consumption, smoking, and obesity

Obesity, increased alcohol consumption, and smoking have all been associated with psoriasis. In one analysis, smoking appeared to have a role in the onset of psoriasis, while obesity appeared to be a consequence of psoriasis. However, other studies have suggested that weight gain often precedes the development of psoriasis. Some studies have found that the prevalence of psoriasis in a population of individuals who stop smoking or who lose weight eventually reverts to background levels.

CLINICAL FEATURES

The extent to which psoriasis represents a spectrum of different manifestations of a single disease versus several separate disease entities remains a matter of debate. As knowledge regarding genotypes expands, will entities be defined by the associated genetic findings (e.g. in *CARD14* or *IL36RN*) or will there continue to be classifications based upon different phenotypes? Either way, recognition of characteristic skin findings remains essential.

Chronic plaque psoriasis, the most common variant of psoriasis vulgaris, presents as sharply demarcated and erythematous papulosquamous lesions. Less often, nearly all of the body surface is involved (*erythrodermic psoriasis*) or numerous, small, widely disseminated papules and plaques are seen (*guttate psoriasis*).

Given the spectrum of cutaneous manifestations, at any one point in time, different variants may coexist in a single individual. However, the skin lesions all share the same important hallmarks: erythema, thickening, and scale. As previously noted, there is also significant interindividual variability. For example, in patients with chronic plaque psoriasis, those with type I disease (HLA-Cw6$^+$) have an earlier onset,

Fig. 8.2 Annular plaques of psoriasis due to central clearing. *Courtesy Julie V. Schaffer, MD.*

more widespread disease and frequent recurrences, compared to those with type II psoriasis.

Although the size of a lesion may vary from a pinpoint papule to over 20 cm in diameter, the outline of the lesion is usually circular, oval, or polycyclic (the latter indicating that the lesion is derived from several smaller units). The configuration of psoriatic lesions due to the Koebner phenomenon reflects the etiology of the trauma. In addition to their highly characteristic sharp demarcation, psoriatic lesions are sometimes surrounded by a pale blanching ring, which is referred to as *Woronoff's ring*.

The classic findings of erythema, thickening, and scale are reflections of the histologic findings of elongated dilated capillaries that are close to the skin surface, epidermal acanthosis plus cellular infiltrates, and abnormal keratinization, respectively. If the superficial silvery white (micaceous) scales are removed, then a wet surface is seen with characteristic pinpoint bleeding. This finding, called Auspitz sign, is the clinical reflection of elongated vessels in the dermal papillae together with thinning of the suprapapillary epidermis.

During exacerbations, psoriatic lesions often itch. Pinpoint papules surrounding existing psoriatic plaques indicate that the patient is in an unstable phase of the disease. In addition, expanding psoriatic lesions are characterized by an active edge with a more intense erythema. Inflamed lesions may even be slightly tender. The involution of a lesion usually starts in its center, resulting in annular psoriatic lesions (Fig. 8.2).

Chronic Plaque Psoriasis

In chronic plaque psoriasis, there is a relatively symmetric distribution of sharply defined, erythematous, scaly plaques (Figs. 8.3 & 8.4). The degree of body surface area involvement can vary, from limited to extensive. The scalp, elbows, knees and lumbosacral area are sites of predilection, as are the hands and feet (Figs. 8.5 & 8.6). The genitalia are involved in up to 45% of patients (Fig. 8.7; see Ch. 73).

Plaques can persist for months to years at the same locations. In contrast, periods of complete remission do occur and remissions lasting for at least 5 years have been reported in ~15% of patients. When the disease is flaring, including in response to a triggering factor, pinpoint papules and deep erythematous rims may develop. The latter serve as clues the psoriasis has entered an unstable phase and occasionally sterile pustules may be observed. Differentiation of unstable psoriasis with pustule formation from generalized pustular psoriasis can be difficult.

Because the percentage of body surface area involved does not reflect the severity of the individual lesions with respect to erythema, induration, and scaling, the Psoriasis Area and Severity Index (PASI) was formulated (Table 8.2). This is a single calculated score that is based on the body surface area involved (in each of four anatomic areas – head, upper extremities, trunk, and lower extremities) and clinical grading of lesional erythema, induration, and scaling. The PASI is a cumbersome calculation and is more commonly utilized for clinical trials than for the routine management of patients with psoriasis. Other outcome measures of disease severity include the Palmoplantar Psoriasis Physician Global Assessment[55], Psoriasis Scalp Severity Index[56], Nail Psoriasis Severity Index[57], and Static Physician Global Assessment of Genitalia[58].

Fig. 8.4 Multiple large plaques of psoriasis. There is obvious symmetry of the plaques on the upper extremities. Some patients have associated pruritus and hemorrhagic crusts due to scratching. *Courtesy Luis Requena, MD.*

Guttate Psoriasis

Guttate psoriasis is more commonly seen in children and adolescents and is frequently preceded by an upper respiratory tract infection (Fig. 8.8). In over half of the patients, an elevated antistreptolysin O,

Fig. 8.5 Palmar psoriasis. Well demarcated scaly plaques of the volar wrist and palms. Comparison of the color of the plaques in a lightly pigmented (**A**) versus darkly pigmented (**B**) patient. *Courtesy Kalman Watsky, MD.*

anti-DNase B, or streptozyme titer is found, indicating a recent streptococcal infection (see previous section).

Erythrodermic Psoriasis

This variant of psoriasis is characterized by generalized erythema and scaling, and its onset can be gradual or acute. Although there are many causes of erythroderma (see Ch. 10), clues to the diagnosis of psoriatic erythroderma include previous plaques in classic locations, characteristic nail changes, and central facial sparing.

CARD14-associated papulosquamous eruption

In patients with CARD14-associated papulosquamous eruption that is due to *CARD14* mutations, there are features of both psoriasis and pityriasis rubra pilaris (PRP)[59]. Features include an early age of onset, prominent involvement of the cheeks, chin, and ears, a family history of psoriasis or PRP, minimal response to conventional topical and systemic psoriasis therapies, and improvement with ustekinumab (Fig. 8.9). NF-κB is upregulated in the skin of those with this disorder and *CARD14* mutations, resulting in an increase in IL-8 and CCL20 which recruit and activate inflammatory cells. The latter leads to production of IL-23 by dendritic cells and IL-17 and IL-22 by T cells. This provides an explanation for the therapeutic response to ustekinumab.

Pustular Disease

Generalized pustular psoriasis

In generalized pustular psoriasis, infiltration of neutrophils dominates the histologic picture, explaining the bright erythema and sterile pustules (Fig. 8.10). It is an unusual manifestation of psoriasis, and triggering factors include pregnancy, rapid tapering of corticosteroids (or other systemic therapies), hypocalcemia, infections, and, in the case of the localized pattern, topical irritants. Generalized pustular psoriasis during pregnancy is also referred to as *impetigo herpetiformis*.

Fig. 8.6 Palmoplantar psoriasis. Diffuse involvement with erythema and scaling of the palmar (**A**) and plantar surfaces (**B**).

Of note, some patients with the phenotype of pustular psoriasis have an autoinflammatory disorder with a distinct genotype (see Tables 45.6 & 45.7). This group includes DIRA (deficiency of IL-1 receptor antagonist; see Figs. 45.11A & 45.12A) and DITRA (deficiency of IL-36 receptor antagonist; see Figs. 45.11B & 45.12B). Future pathogenetic discoveries may lead to additional discrete entities.

Pustular psoriasis has four distinct phenotypic patterns:

- **von Zumbusch pattern**. This is a generalized eruption starting abruptly with erythema and pustulation (see Fig. 8.10). The skin is painful during this phase, and the patient has a fever and feels ill. After several days, the pustules usually resolve and extensive scaling is observed. Sometimes, chronic plaques of psoriasis, if present, can resolve. In the original case report by von Zumbusch (1910), nine episodes of pustulation occurred over a period of 10 years.
- **Annular pattern**. The eruption is characterized by annular lesions, consisting of erythema and scaling with pustulation at the advancing edge (Fig. 8.11). The lesions enlarge by centrifugal expansion over a period of hours to days, while healing occurs centrally.

CALCULATION OF THE PSORIASIS AREA AND SEVERITY INDEX (PASI)				
Severity of psoriatic lesions				
[0, none; 1, slight; 2, moderate; 3, severe; 4, very severe]				
	Head	***Trunk***	***Upper limbs***	***Lower limbs***
Erythema	0 to 4	0 to 4	0 to 4	0 to 4
Induration	0 to 4	0 to 4	0 to 4	0 to 4
Scaling	0 to 4	0 to 4	0 to 4	0 to 4
Total score = ❶	Sum of the above	Sum of the above	Sum of the above	Sum of the above
Area of psoriatic involvement				
[0, none; 1, <10%; 2, 10 to <30%; 3, 30 to <50%; 4, 50 to <70%; 5, 70 to <90%; 6, 90%–100%]				
Degree of involvement = ❷	0 to 6	0 to 6	0 to 6	0 to 6
Multiply ❶ × ❷	❶ × ❷	❶ × ❷	❶ × ❷	❶ × ❷
Correction factor for area of involvement = ❸	0.10	0.30	0.20	0.40
❶ × ❷ × ❸	**A**	**B**	**C**	**D**
A + **B** + **C** + **D** = total PASI				

Table 8.2 Calculation of the Psoriasis Area and Severity Index (PASI). The PASI ranges from 0 to 72.

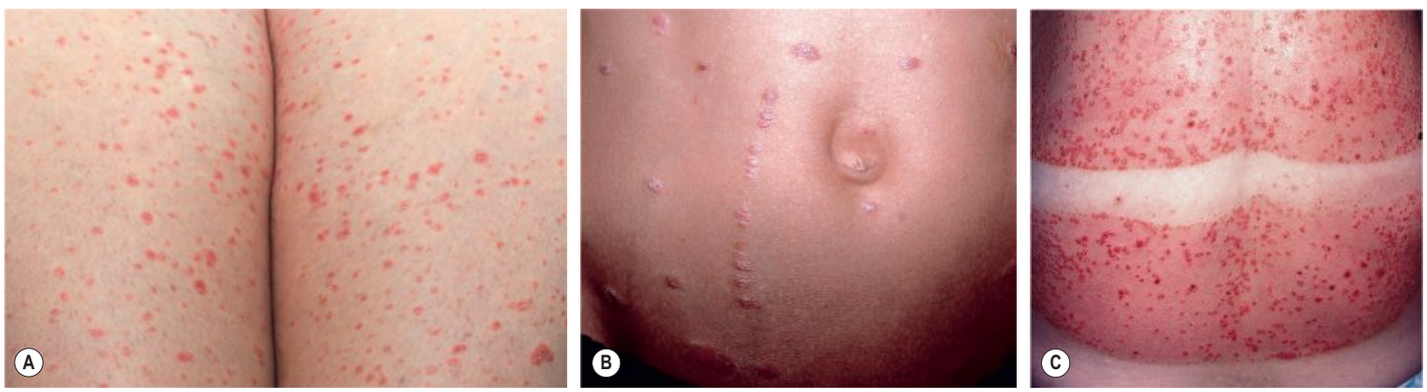

Fig. 8.8 Guttate psoriasis. A Numerous, small, discrete papules with scale on the thighs. **B** This adolescent has evidence of a linear Koebner phenomenon in addition to more widely scattered guttate lesions. **C** Numerous papules due to a sunburn-related Koebner phenomenon. *A, Courtesy Kalman Watsky, MD; C, Courtesy Ronald P. Rapini, MD.*

- **Exanthematic type**. This is an acute eruption of small pustules, abruptly appearing and disappearing over a few days. It usually follows an infection or may occur as a result of administration of specific medications, e.g. lithium. Systemic symptoms usually do not occur. There is overlap between this form of pustular psoriasis and pustular drug eruptions, also referred to as acute generalized exanthematous pustulosis (AGEP; see Ch. 21).
- **"Localized" pattern**. Sometimes pustules appear within or at the edge of existing psoriatic plaques. This can be seen during the unstable phase of chronic plaque psoriasis and following the application of irritants, e.g. tars, anthralin.

Pustulosis of the palms and soles

Pustulosis of the palms and soles is characterized by "sterile" pustules of the palmoplantar surfaces admixed with yellow–brown macules (Fig. 8.12); scaly erythematous plaques may also be seen. A minority of patients have chronic plaque psoriasis elsewhere. In contrast to the natural history of generalized pustular psoriasis, the pustules remain localized to the palmoplantar surfaces and the course of this disease is chronic. Focal infections and stress have been reported as triggering factors and smoking may aggravate the condition. Pustulosis of the palms and soles is one of the entities most commonly associated with sterile inflammatory bone lesions within the context of SAPHO

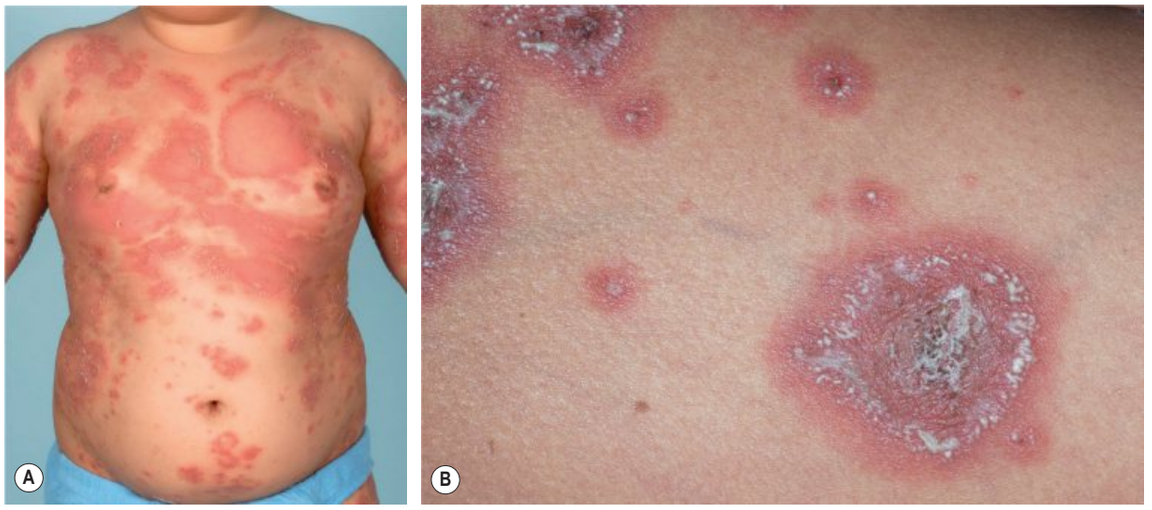

Fig. 8.11 Annular pustular psoriasis. A, B Multiple annular inflammatory plaques whose active borders are studded with pustules followed by desquamation. As these lesions enlarge, there is central clearing. The intensity of erythema can vary and the color is influenced by the skin phototype. *A, Courtesy Marieke M. B. Seyger, MD, PhD; B, Courtesy Julie V. Schaffer, MD.*

syndrome, which consists of *s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis and *o*steitis. Several neutrophilic dermatoses are associated with SAPHO (see Table 25.18). As noted previously, pustulosis of the palms and soles can occur as a paradoxical reaction in patients receiving TNF inhibitors for disorders such rheumatoid arthritis or inflammatory bowel disease (see Fig. 21.24).

Acrodermatitis continua of Hallopeau

This is a rare manifestation of psoriasis. Clinically, pustules are seen on the distal portions of the fingers (Fig. 8.13) and occasionally the toes. Pustulation is often followed by scaling and crust formation. Pustules may also form in the nail bed (beneath the nail plate), and there may be shedding of nail plates. Transition into other forms of psoriasis can

Fig. 8.14 Scalp psoriasis with extension onto the neck. Note the involvement of the external auditory canal.

occur and acrodermatitis continua may be accompanied by annulus migrans of the tongue (see below).

Special Locations

Scalp psoriasis

The scalp is one of the most common sites for psoriasis. Unless there is complete confluence, the individual lesions are discrete, in contrast to the less well-defined areas of involvement in seborrheic dermatitis. At times, however, it is not possible to distinguish seborrheic dermatitis from psoriasis, and the two disorders may coexist. The lesions of psoriasis often advance onto the periphery of the face, the retroauricular areas and the posterior upper neck (Fig. 8.14). The scales sometimes have an asbestos-like appearance and can adhere to hair shafts in clumps (pityriasis amiantacea). Although pityriasis amiantacea can also be seen in patients with seborrheic dermatitis, secondarily infected atopic dermatitis, and tinea capitis, psoriasis is the most common cause. Alopecia occasionally develops within involved areas, including in the setting of TNF inhibitor-induced psoriasis (see Ch. 69). In addition, patients with dermatomyositis involving the scalp may have lesions that resemble psoriasis.

Flexural psoriasis

Flexural lesions are characterized by shiny, pink to red, sharply demarcated thin plaques (Fig. 8.15). There is much less scale than in untreated chronic plaque psoriasis. Often a central fissure is seen. The most common sites of involvement are the retroauricular fold, intergluteal cleft, inguinal crease, axilla, and inframammary region. When flexural areas are the only sites of involvement, the term "inverse" psoriasis is sometimes used. Localized dermatophyte, candidal, or bacterial infections can be a trigger for flexural psoriasis.

Oral mucosa

Migratory annular erythematous lesions with hydrated white scale (annulus migrans) have been observed in patients with acrodermatitis continua of Hallopeau and generalized pustular psoriasis. The most common location is the tongue, and the clinical (and histologic) appearance is similar to geographic tongue (see Fig. 72.3). Occasionally, lesions are observed on the buccal mucosa.

Nail psoriasis

Nail involvement has been reported in 10%–80% of psoriatic patients, depending upon the series. The fingernails are more often affected than the toenails (Fig. 8.16). In a survey from the Netherlands, 79% of patients reported involvement of their nails, with 52% experiencing associated pain and 14% major restrictions in daily life due to the nail changes. Patients with nail involvement appear to have an increased incidence of psoriatic arthritis.

Fig. 8.16 Nail psoriasis. Nail plate pitting, distal onycholysis, oil drop changes, and subungual and proximal hyperkeratosis are seen. There is also proximal nail-fold inflammation with loss of the cuticle, especially of the forefingers. *Courtesy Marcel C. Pasch, MD.*

Psoriasis affects the nail matrix, nail bed, and hyponychium. Small parakeratotic foci in the proximal portion of the nail matrix lead to pits in the nails (see Fig. 71.2). Leukonychia and loss of transparency (less common findings) are due to involvement of the midportion of the matrix. If the entire nail matrix is involved, a whitish, crumbly, poorly adherent "nail" is seen. Psoriatic changes of the nail bed result in the "oil drop" or "salmon patch" phenomenon, which reflects exocytosis of leukocytes beneath the nail plate (see Fig. 71.13). Splinter hemorrhages are the result of increased capillary fragility, and subungual hyperkeratosis and distal onycholysis are due to parakeratosis of the distal nail bed. Vigorous removal of distal subungual debris may be an exacerbating factor.

Psoriatic Arthritis

Psoriatic arthritis occurs in 5%–30% of patients with cutaneous psoriasis[1], with some clinical investigators suggesting that classic studies of psoriatic arthritis may have underestimated its prevalence. In a minority of patients (10%–15%), the symptoms of psoriatic arthritis appear before involvement of the skin. Currently, there are no specific serologic tests for establishing the diagnosis of psoriatic arthritis, but an important hallmark is erosive change radiographically, which may occur years after the presenting peri-articular inflammation. Psoriatic arthritis is more prevalent among patients with relatively severe psoriasis. Risk factors for a more severe course of the arthritis include: initial presentation at an early age, female sex, polyarticular involvement, genetic predisposition, and radiographic signs of the disease early on. The five major forms of psoriatic arthritis are outlined in Table 8.3[60].

In one study involving 1511 patients with chronic plaque psoriasis, ~20% of the affected individuals had psoriatic arthritis[61]. DIP

FIVE MAJOR TYPES OF PSORIATIC ARTHRITIS	
Type	**Clinical findings**
Mono- and asymmetric oligoarthritis (most common type)	• Inflammation of the DIP and PIP joints of the hands and feet (Fig. 8.17) • Involvement of the PIP or both the DIP and PIP joints of a single digit can result in the classic "sausage" digit (Fig. 8.18) • MCP joint involvement unusual (unlike RA) • May be accompanied by inflammation of larger joints
Arthritis of the distal interphalangeal joints	• Exclusive involvement of the DIP joints • Classic but uncommon presentation • The joints may become fixed in a flexed position
Rheumatoid arthritis-like presentation (difficult to distinguish from RA clinically*)	• *Symmetric* polyarthritis that involves small and medium-sized joints, in particular the PIP, MCP, wrist, ankle, and elbow • Most patients are seronegative for RF
Arthritis mutilans† (least common type)	• Severe, rapidly progressive joint inflammation that results in destruction of the joints and permanent deformity • Digits become shorter, wider, and softer to palpation because of osteolysis and a telescoping phenomenon
Spondylitis and sacroiliitis (also have peripheral joint involvement)	• Spondylitis resembles that seen in ankylosing spondylitis, with axial arthritis as well as involvement of the knees and sacroiliac joints • Patients are often HLA-B27-positive and may have associated inflammatory bowel disease and/or uveitis

*Whether some seropositive patients have an overlap of the two disorders is possible.
†Also occurs in multicentric reticulohistiocytosis (see Fig. 91.17D).

Table 8.3 Five major types of psoriatic arthritis. Patients with psoriatic arthritis can have tendonitis, enthesitis, and dactylitis. DIP, distal interphalangeal; MCP, metacarpophalangeal; PIP, proximal interphalangeal; RA, rheumatoid arthritis; RF, rheumatoid factor.

involvement was observed in ~40% of the patients with arthritis, and 5% suffered from arthritis mutilans[61]. Patients with psoriatic arthritis can have involvement of juxta-articular tendons (tendonitis) and the sites where they insert into bone (enthesitis) as well as swelling of the fingers (dactylitis). Enthesitis and dactylitis have been reported in ~20% and 15%–30%, respectively, of patients with "probable" or definite psoriatic arthritis. In patients with psoriasis, nail involvement is a strong predictor of concomitant psoriatic arthritis[62].

Early diagnosis of psoriatic arthritis is important, as disease progression often results in loss of function and irreversible joint destruction.

Disorders Related to Psoriasis

A few disorders share important clinical and histologic features with psoriasis, but are distinct disease entities based upon genetic, epidemiologic, or clinical features.

Fig. 8.18 Psoriatic arthritis. Asymmetric involvement of the distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints. A "sausage" digit (third digit bilaterally) results from involvement of both the DIP and PIP joints. Note the yellowing, thickening, and crumbling of several fingernails.

Fig. 8.19 Reactive arthritis (formerly Reiter disease). A, B Plantar lesions of keratoderma blennorrhagicum. The amount of scale can vary and when sterile pustules form, they are often admixed with yellow–brown macules. **C** Papulosquamous lesions on the glans and shaft of the penis. *B, Courtesy Eugene Mirrer, MD.*

Inflammatory linear verrucous epidermal nevus (ILVEN)

ILVEN is characterized by linear psoriasiform lesions (i.e. scaling and erythematous plaques) that follow the lines of Blaschko (see Ch. 62). Based upon its chronicity and resistance to therapy, ILVEN is thought to be an entity separate from linear psoriasis. However, a subset of patients were found to have mosaicism for heterozygous missense variants in *CARD14*.

Reactive arthritis

This syndrome features urethritis, arthritis, ocular findings, and oral ulcers, in addition to psoriasiform skin lesions. The disorder is uncommon in children and occurs more frequently in men than in women. The urethritis may be mild or severe and accompanied by complications such as cystitis, cervicitis, and salpingitis. *Chlamydia trachomatis* is a major cause of urethritis and may trigger the entire syndrome, as may other infections such as shigellosis. Conjunctivitis is a common eye finding in affected patients, although iritis, uveitis with glaucoma, and keratitis may also occur. Polyarthritis and sacroiliitis are the most frequent joint manifestations. Cutaneous lesions occur in ~5% of reactive arthritis patients, with a predilection for the soles, extensor surfaces of the legs, penis, dorsal aspects of the hands, fingers, nails, and scalp (Fig. 8.19). The lesions on the plantar surface usually have thick yellow scale and are often pustular (keratoderma blennorrhagicum). Psoriatic plaques on the penis are referred to as balanitis circinata.

Reactive arthritis has a strong association with HLA-B27. Although the course is often self-limited, lasting weeks to months, some patients have disease that is chronic and disabling. Of note, HIV-infected patients can also develop this disorder and it may be severe.

Sneddon–Wilkinson disease (subcorneal pustular dermatosis)

This disorder is characterized by annular or polycyclic lesions, usually commencing in the flexures (Fig. 8.20A). Very superficial (subcorneal) sterile pustules are the hallmark of Sneddon–Wilkinson disease, hence its second name (Fig. 8.20B). There may be a gravity-induced demarcation in some vesiculopustules, with clear fluid superiorly and pus inferiorly. This disease has a cyclic course, i.e. as the pustules resolve they are replaced by superficial scaling and then new pustules form again. Some patients with Sneddon–Wilkinson disease have an associated IgA paraproteinemia. Its response to dapsone, combined with subcorneal pustules (in the absence of spongiform pustules), provide support for this condition being a disease entity distinct from pustular psoriasis, although some authors have questioned the existence of Sneddon–Wilkinson disease as a distinct entity. Of note, immunofluorescence studies are required to distinguish the subcorneal pustular dermatosis type of IgA pemphigus from Sneddon–Wilkinson disease.

Fig. 8.20 Sneddon–Wilkinson disease. A Annular and polycyclic plaques in the axilla with small pustules, erosions, and scale in the border. **B** Numerous, fragile, subcorneal pustules arising within a background of erythema. There is dependent pooling of the pustular contents in some of the larger lesions. There is significant overlap with pustular psoriasis. *B, Courtesy Department of Dermatology, Medical University of Graz.*

Associations Between Psoriasis and Other Diseases

Associations with skin diseases

There is a pronounced under-representation of allergic skin diseases in psoriatic patients as compared to age-matched controls without psoriasis. The frequencies of atopic dermatitis, asthma, urticaria, and allergic contact dermatitis have been found to be lower in psoriatic patients. For example, in one study atopic dermatitis was seen ~50 times less often in psoriatic compared with non-psoriatic patients[1]. An obvious explanation is the immunologic difference between these two conditions, with a predominantly Th1 and Th17 response in psoriasis and a predominantly Th2 response in atopic dermatitis. However, in patients with psoriasis in atypical locations and/or treatment-resistant lesions, the possibility of allergic or irritant contact dermatitis as a triggering factor needs to be considered.

A bi-directional relationship exists between lichen simplex chronicus (LSC) and psoriasis. If a psoriatic lesion is pruritic, superimposed

LSC may develop and the surface becomes shiny with increased skin markings. Because the LSC itself is pruritic, the resultant rubbing may worsen the psoriasis (Koebner phenomenon). The patient then enters a vicious cycle. Therapeutic regimens must address both disorders.

Seborrheic dermatitis is characterized by pink to red patches with yellowish, sometimes greasy, scales (see Ch. 13). The sites of predilection are the scalp, central face, ears, presternal area, and intertriginous zones. As the clinical features of psoriasis and seborrheic dermatitis can be seen in the same patient, some authors use the term "sebopsoriasis", especially when diagnostic lesions of psoriasis are not present elsewhere.

Infections

In contrast to atopic dermatitis, psoriatic lesions are seldomly impetiginized, i.e. secondarily infected by bacteria. One explanation for this resistance to secondary bacterial infections is increased production of skin-derived antimicrobial peptides, e.g. defensins, SKALP/elafin (see Pathogenesis).

The prevalence of onychomycosis, due to *Candida* species or dermatophytes, is increased in psoriatic patients (average, ~18%), compared to control groups[63]. In flexural psoriasis, concomitant *Candida* infections are frequently observed and have been incriminated as a local triggering factor.

Cancer

Patients with psoriasis may have a slightly higher incidence rate of all malignancies compared to the general population[64]. With the exception of a significantly higher rate of non-melanoma skin cancer in those who had received phototherapy (type not specified), differences in rates were minimal when various systemic therapies were compared[64]. It has been shown that psoriatic patients who have had >200 PUVA treatments are at increased risk for the development of skin cancers, especially squamous cell carcinomas (SCCs). Of note, the use of cyclosporine in patients previously treated with PUVA significantly increases the number and rate of appearance of SCCs. Lastly, there is controversy as to whether PUVA-treated patients have an increased risk of cutaneous melanoma.

Association with internal diseases (including comorbidities)

Cardiovascular diseases, e.g. myocardial infarctions, peripheral arterial disease, cerebrovascular accidents, are more common in patients with severe psoriasis. The latter is associated with a threefold increased risk for myocardial infarction and a 3.5- to 4.5-year reduction in life expectancy. This is largely due to an increased risk for having metabolic syndrome (see Table 53.5)[65–67]. In Mendelian randomization studies, it has been shown that the presence of cardiovascular disease can have a significant causal effect on psoriasis, but not vice versa, in that systemic inflammation (which causes cardiovascular disease) can increase the risk of psoriasis[67a]. In patients with psoriatic arthritis, serum levels of C-reactive protein (CRP) have been reported to be elevated (as compared to healthy controls), and elevated CRP levels represent a risk factor for the development of cardiovascular disease. It has also been shown that TNF and IL-6 can target adipocytes and induce dyslipidemia. Several studies have found that treatment with methotrexate and/or targeted immunomodulators ("biologics") may reduce the risk of atherosclerotic cardiovascular disease. Patients with psoriasis may also be at increased risk for the development of venous thromboembolism.

Non-alcoholic steatohepatitis, characterized by fatty infiltration, periportal inflammation, and focal necrosis, is more commonly observed in patients with psoriasis. In a study of 142 adults with psoriasis, non-alcoholic fatty liver disease was detected in 59%, and it correlated with the presence of obesity, hyperlipidemia, the metabolic syndrome, an AST:ALT ratio >1, and psoriatic arthritis[68]. Chronic administration of methotrexate is associated with a significant risk for hepatic damage in patients with psoriasis, whereas similar methotrexate dosages in patients with rheumatoid arthritis do not pose such hepatotoxic potential. Although the reason for this difference is not known, several possible explanations have been put forward, including a genetic predisposition, increased alcohol consumption by psoriasis patients, and a higher incidence of non-alcoholic fatty liver disease.

Crohn disease, ulcerative colitis, and psoriasis share an association with sacroiliitis and HLA-B27 positivity. In genome-wide association studies of Crohn disease and psoriasis, shared susceptibility loci were identified[69]. Additional disorders that share susceptibility genes with psoriasis are listed in Table 8.1. Of note, patients with psoriasis have also been shown to be at increased risk of depression, anxiety, and suicidal ideation[70]. Lastly, in a population-based cohort study, an association between psoriasis and kidney disease was suggested[71].

Patients with both psoriasis and lupus erythematosus, Sjögren syndrome, or dermatomyositis have been reported in the literature. It is not clear whether this is true-true related or true-true unrelated. However, the presence of a coexisting autoimmune connective tissue disease does have therapeutic implications in an individual patient[72].

DIFFERENTIAL DIAGNOSIS

Although both seborrheic dermatitis (see above) and LSC are in the differential diagnosis of psoriasis, it is important to remember that either can coexist with psoriasis. Due to the Koebner phenomenon, psoriasis can also develop within areas of contact dermatitis. When there is a single or limited number of erythematous plaques, especially if they are treatment-resistant, the possibility of SCC *in situ* (e.g. Bowen disease, erythroplasia of Queyrat) needs to be excluded via histologic examination. Occasionally, a biopsy is necessary to distinguish chronic plaque psoriasis from mycosis fungoides. Clinical features suggestive of the latter include wrinkling due to epidermal atrophy and progression to infiltrated plaques. Dermatomyositis can involve the scalp, elbows and knees, as well as the hands, and initially may be diagnosed as psoriasis.

When plaques of psoriasis involve the shins, they may be misdiagnosed as hypertrophic lichen planus, but characteristic violaceous lesions elsewhere and mucosal involvement usually point to the correct diagnosis. There is clinical overlap between palmoplantar plaque psoriasis and keratotic eczema of the palms and soles, and both may have fissures and be exacerbated by repeated trauma. Sharp margination of the lesions favors psoriasis and examination of the remainder of the skin surface can provide clues to the diagnosis, e.g. involvement of the scalp or intergluteal fold with psoriasis. Elsewhere, chronic lesions of dermatitis may develop an appearance that is similar (clinically and histologically) to partially treated psoriasis and vice versa. However, over time, characteristic lesions often become apparent. When plaques of psoriasis develop pronounced hyperkeratosis (rupioid psoriasis), the possibility of concomitant hypothyroidism should be considered.

In addition to psoriasis, there are other causes of erythroderma, including Sézary syndrome, pityriasis rubra pilaris, and drug reactions (see Ch. 10). For guttate psoriasis, the differential diagnosis may include small plaque parapsoriasis, pityriasis lichenoides chronica, secondary syphilis, and pityriasis rosea. The lesions of guttate psoriasis rarely involve the palms or soles and are often more erythematous than those of parapsoriasis. When lesions are limited in number or have an annular configuration, the possibility of tinea corporis is raised, and when the upper trunk is the predominant site of involvement, pemphigus foliaceus may be considered.

Psoriasis of the flexures is one cause of intertrigo (see Figs. 13.4 & 13.12). Other etiologies include seborrheic dermatitis, contact dermatitis, cutaneous candidiasis, tinea incognito, erythrasma, and extramammary Paget disease. Although KOH examination of associated scale allows a narrowing of the differential diagnosis, psoriasis and candidiasis can coexist (see above). In infants (more so than adults), the possibility of Langerhans cell histiocytosis needs to be considered. In these patients, there may also be scalp involvement with scaling and crusts. Occasionally, tinea capitis is in the differential diagnosis of scalp psoriasis.

When there are widespread pustules on a background of erythema, the possibility of a pustular drug eruption, also referred to as AGEP, needs to be considered (in addition to generalized pustular psoriasis). The histologic findings of these conditions can be similar, including spongiform pustules of Kogoj and microabscesses in the stratum corneum. If eosinophils are also present, a pustular drug eruption is favored. Autoinflammatory disorders, in particular DIRA and DITRA (deficiency of IL-1 or -36 receptor antagonist), can also present with a phenotype similar to pustular psoriasis (see Tables 45.6 & 45.7). In patients with pustulosis of the palms and soles and acrodermatitis continua, the initial evaluation includes the exclusion of a dermatophyte infection or secondarily infected dermatitis. The differential diagnosis of the annular form of pustular psoriasis includes Sneddon–Wilkinson disease and other causes of subcorneal pustules (Table 8.4). Reactive arthritis needs to be considered in any patient with the diagnosis of arthritis in the setting of psoriasiform skin lesions.

DIFFERENTIAL DIAGNOSIS OF SUBCORNEAL/INTRAEPIDERMAL NEUTROPHILIC PUSTULES	
Disorder	**Histologic clues**
Impetigo	Gram-positive cocci in bulla cavity
Superficial candidiasis	Yeast and pseudohyphae in stratum corneum
Dermatophyte infection	Branching hyphae in stratum corneum
Superficial folliculitis	Pustule at follicular orifice and in infundibulum
Pemphigus foliaceus, pemphigus erythematosus	Acantholytic cells; DIF, IIF: intercellular IgG deposits; anti-desmoglein 1 antibodies
IgA pemphigus, subcorneal pustular dermatosis type	DIF > IIF: intercellular IgA deposits; anti-desmocollin 1 antibodies
Sneddon–Wilkinson disease (subcorneal pustular dermatosis)	May be indistinguishable from IgA pemphigus, but negative DIF
Pustular psoriasis	Spongiform pustules*
Acute generalized exanthematous pustulosis	Mild spongiform pustulation (less prominent than in pustular psoriasis), eosinophils*
Amicrobial pustulosis of the folds	Spongiform pustules*
Transient neonatal pustular melanosis	Subcorneal and intracorneal pustules, few eosinophils*
Acropustulosis of infancy	Intraepidermal or subcorneal pustules, few eosinophils*
Pustular miliaria	Pustules centered upon an intraepidermal sweat duct
Erosive pustular dermatosis	Erosion and dense, mixed dermal inflammatory infiltrate in addition to subcorneal pustules
Eosinophilic pustular folliculitis (Ofuji disease)	Large numbers of eosinophils within the pustules, epithelium, and dermal inflammatory infiltrate
*Not all cases.	

Table 8.4 Differential diagnosis of subcorneal/intraepidermal neutrophilic pustules. DIF, direct immunofluorescence; IIF, indirect immunofluorescence.

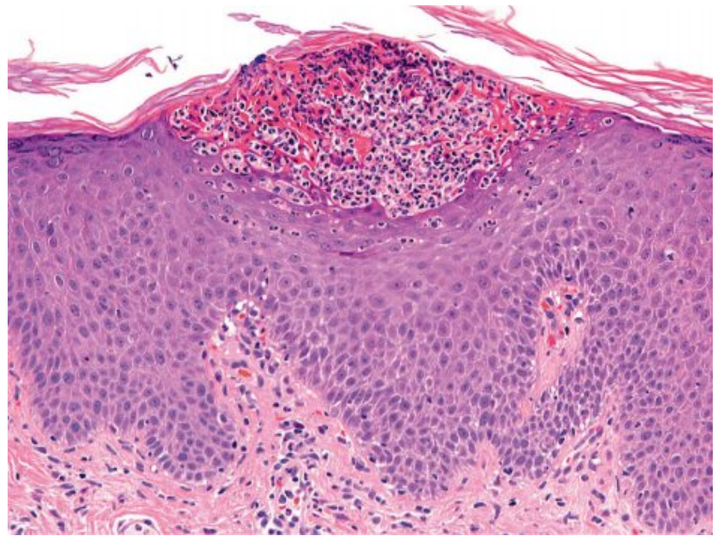

Fig. 8.21 Spongiform pustule of Kogoj. A collection of neutrophils is seen within the upper stratum spinosum. *Courtesy Lorenzo Cerroni, MD.*

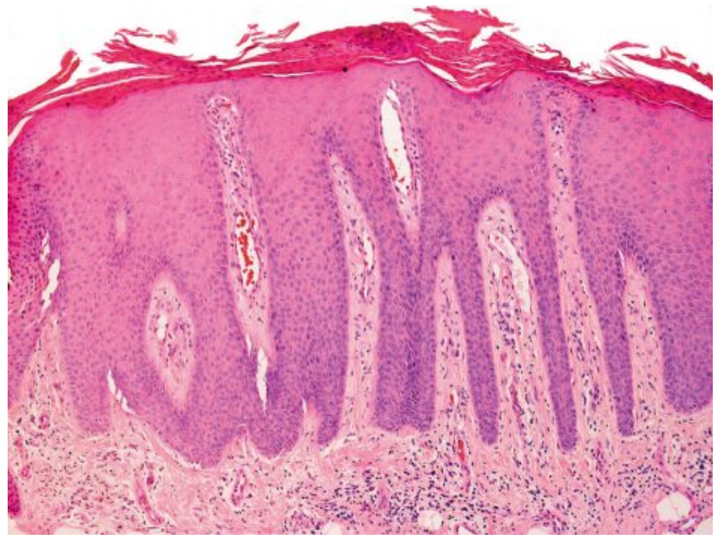

Fig. 8.22 Stable plaque psoriasis. Hyperplasia of the epidermis with "squared-off" rete ridges, elongation of the dermal papillae, dilated superficial blood vessels, hypogranulosis, and parakeratosis plus remnants of neutrophils (microabscess of Munro). *Courtesy Lorenzo Cerroni, MD.*

PATHOLOGY

Papulosquamous Lesions

Initial lesion

In the initial lesion, i.e. a pinhead-sized papule, the histopathologic features are not yet diagnostic. A superficial perivascular infiltrate of lymphocytes and histiocytes is seen in the dermis along with papillary edema and a dilation of capillaries. In acute eruptive guttate lesions, mast cell degranulation is a constant feature.

There is mild epidermal acanthosis without parakeratosis and the keratinocytes have a swollen appearance. Histiocytes (detected by CD68 staining) and lymphocytes appear within the epidermis, accompanied by mild focal spongiosis. In this early phase, neutrophils are not yet detectable.

Active lesion

A fully developed guttate lesion or the marginal zone of an enlarging psoriatic plaque is designated as an "active lesion". The histopathologic findings in an active lesion are diagnostic for psoriasis.

In the papillary dermis, the capillaries are increased in number and length and they have a tortuous appearance. Edema is seen, especially at the tops of the papillae. There is a mixed perivascular infiltrate of lymphocytes, histiocytes, and neutrophils.

The epidermis is acanthotic with focal accumulations of neutrophils and lymphocytes. At these sites, the epidermis is variably spongiotic. Above these foci, the granular layer is absent and the stratum corneum still contains flattened nuclei (parakeratosis). The accumulation of neutrophils within a spongiotic pustule is referred to as a "spongiform pustule of Kogoj" (Fig. 8.21) and the accumulation of neutrophils and/or neutrophil remnants in the stratum corneum, surrounded by parakeratosis, as a "microabscess of Munro". These two findings are pathognomonic for psoriasis and AGEP.

Stable lesion

In the papillary dermis, the capillaries are elongated and tortuous, extending upward into elongated club-shaped dermal papillae; only a small suprapapillary plate of epidermal cells covers the tip of these dermal papillae. This micromorphology explains the "Auspitz" phenomenon (see earlier). A modest perivascular infiltrate is seen that consists primarily of lymphocytes and histiocytes. The psoriatic lesion is heterogeneous, consisting of active areas (hot spots) and chronic nonspecific areas (cold spots).

The hyperproliferation of the epidermis now has reached its characteristic pattern (Fig. 8.22). The rete ridges are elongated and have a squared-off appearance. The bases of some of the rete ridges also coalesce. The horny layer has parakeratotic foci with an absence of the stratum granulosum. In some lesions, micropustules of Kogoj and microabscesses of Munro may be seen.

Pustular Psoriasis

In pustular psoriasis, accumulation of neutrophils is the predominant feature. The epidermis is usually acanthotic. Numerous neutrophils accumulate between eosinophilic strands of keratinocytes. In the stratum corneum, large accumulations of neutrophils are observed, surrounded by parakeratosis (see Fig. 0.21B). As a result, exaggerated spongiform pustules of Kogoj and microabscesses of Munro, the histologic hallmarks of "active" psoriasis, are seen in pustular psoriasis.

TREATMENT

Care of the psoriatic patient needs to focus not only on the skin, but also on the comorbidities that exist or might develop. An appropriate treatment regimen for a particular patient is selected from available topical and systemic medications as well as phototherapies. In clinical trials, single agents are usually evaluated, but in practice most patients receive combination therapy. To date, no treatment has been shown to cure this disease, so counseling of the patient and family members regarding its natural history and management strategies is essential.

The management of psoriasis requires individualization of therapy, with consideration of the extent of the disease and its effects on the patient's quality of life as well as the likely benefits and potential side effects of specific treatments. The chronic nature of psoriasis necessitates adoption of a long-term approach with avoidance of dramatic short-term "fixes" that may actually produce a more reactive disease state (see below).

Topical Treatments

Guidelines of care for the treatment of psoriasis with topical therapies have been developed by the American Academy of Dermatology[73].

Corticosteroids

Since their introduction in the early 1950s, topical corticosteroids have become a mainstay in the treatment of psoriasis. They are first-line therapy in mild to moderate psoriasis and in sites such as the flexures and genitalia, where other topical agents can induce irritation. Chapter 125 provides detailed information on mechanisms of action, pharmacologic aspects, and side effects of corticosteroid therapy.

Corticosteroids are available in various vehicles, from ointments, creams, and lotions to gels, foams, sprays, and shampoos[74]; ointment formulations, in general, have the highest efficacy (see Ch. 125). By increasing lipophilicity via masking of hydrophilic 16- or 17-hydroxy groups or by introducing acetonides, valerates or propionates, their anti-inflammatory properties have been significantly improved. Application under plastic or hydrocolloid occlusion also enhances the penetration. Once-daily application has been shown to be as effective as twice-daily application, and long-term remissions may be maintained by applications on alternate days[75]. The indications and contraindications of topical corticosteroids for the treatment of psoriasis are summarized in Table 8.5.

At least 80% of patients treated with high-potency topical corticosteroids experience clearance. In fact, the maximum improvement is usually achieved within 2 weeks. With maintenance therapy consisting of 12 weeks of intermittent applications of betamethasone dipropionate ointment (restricted to weekends), 74% of patients remained in remission, compared with 21% of the patients receiving a placebo ointment[75]. Unfortunately, no efficacy data are available on prolonged treatment for more than 3 months. As tachyphylaxis and/or rebound can occur fairly rapidly, i.e. within a few days to weeks, intermittent treatment schedules (e.g. once every 2 or 3 days or on weekends) are advised for more prolonged treatment courses. Combination topical therapy can take advantage of both the rapid effect of topical corticosteroids plus the prolonged benefits of long-term treatment with topical agents such as vitamin D_3 analogues.

Vitamin D_3 analogues

In the early 1990s, vitamin D_3 analogues became available as a topical treatment for psoriasis. When the epidermis is hyperproliferative, vitamin D_3 inhibits epidermal proliferation, and it induces normal differentiation by enhancing cornified envelope formation and activating transglutaminase; it also inhibits several neutrophil functions. Due to their therapeutic efficacy and limited toxicity, calcipotriene (calcipotriol) and other vitamin D_3 analogues have become a first-line therapy for psoriasis[76].

For a detailed description of topical vitamin D_3 analogues, the reader is referred to Chapter 129. Table 8.6 summarizes the major characteristics of commercially available vitamin D_3 analogues. Calcipotriene monotherapy has been shown to result in an ~60% reduction of PASI after 8 weeks of treatment, but in practice combination therapy with topical corticosteroids is commonly employed, both during the clearing phase as well as intermittently during long-term treatment. When calcipotriene and betamethasone dipropionate are combined, an ~70% reduction in PASI has been observed (ointment or foam formulation)[77,78], as has clearing/minimal disease in ~70% of patients with scalp psoriasis (gel formulation)[79].

Anthralin

Anthralin (dithranol) has been available since 1916; it is still used as a treatment for psoriasis, although it was more commonly utilized in the past (see Ch. 129). It has marked epidermal effects, including an anti-hyperproliferative effect. Anthralin also inhibits mitogen-induced T lymphocyte proliferation and neutrophil chemotaxis. In Europe and other regions outside the US, it is used most often in day-care centers and the inpatient setting[80].

The indications and contraindications for the use of anthralin in the treatment of psoriasis are summarized in Table 8.7. In the authors' experience, total clearing of psoriasis in at least 80% of patients occurs with 3–5 weeks of treatment in an inpatient setting or day-care center. If the anthralin treatment is performed at home, the efficacy is substantially less.

Topical retinoids

All-*trans*-retinoic acid and 13-*cis*-retinoic acid, although effective in the treatment of acne, are not effective for psoriasis. However, topical tazarotene, an acetylene retinoid that selectively binds retinoic acid receptor (RAR)-β and RAR-γ, can be used to treat psoriasis. Tazarotene has been shown to decrease epidermal proliferation and it inhibits psoriasis-associated differentiation (e.g. transglutaminase expression, K16 expression). It is manufactured in cream and gel formulations and is usually applied once daily.

Indications and contraindications of tazarotene for the treatment of psoriasis are summarized in Table 8.8. In view of its modest efficacy as monotherapy, it is usually prescribed as a second-line therapy. Irritation of the skin with burning, pruritus, and erythema can limit the use of tazarotene. For this reason, combination therapy with topical corticosteroids (e.g. halbetasol) is useful. The maximal area that can be treated with tazarotene is 10%–20% of the body surface, and safety data are available for up to 1 year of treatment.

INDICATIONS AND CONTRAINDICATIONS FOR TOPICAL CORTICOSTEROIDS

Indications

- Mild to moderate psoriasis: first-line treatment as monotherapy or in combination
- Severe psoriasis: often in combination with a vitamin D_3 analogue, a topical retinoid, anthralin, or tar; also as an adjunct to systemic therapy or photo(chemo)therapy
- Monotherapy for flexural and facial psoriasis (usually mild strength)
- Recalcitrant plaques often require occlusion (plastic, hydrocolloid)

Contraindications

- Bacterial, viral, and mycotic infections
- Atrophy of the skin
- Allergic contact dermatitis due to corticosteroids or constituents of the formulation

Table 8.5 Indications and contraindications for topical corticosteroids. Maximal quantities: 50 g/week of a superpotent corticosteroid; 100 g/week of a potent corticosteroid.

VITAMIN D_3 ANALOGUES			
	Calcipotriene/calcipotriol	**Calcitriol**	**Tacalcitol**
Concentration	50 mcg/g	3 mcg/g	2 mcg/g; 4 mcg/g
Formulations	Ointment, cream, lotion, solution, foam	Ointment	Ointment, lotion
Frequency	BID	BID	BID; daily
Maximum weekly amount*	100 g	200 g	70 g; 70 g†
Chemical structure	26,27-cyclo-vitamin D_3 22,23 double bond Transposition of the 25-OH to the 24 position	1α,25-dihydroxy vitamin D (active natural vitamin D_3)	1α,24-dihydroxy vitamin D_3
Inactivating enzymes	22,23-reductase; 24-oxido-reductase	24-hydroxylase	25-hydroxylase

*To avoid hypercalcemia.
†Maximum weekly amount for 8 weeks of treatment.

Table 8.6 Vitamin D_3 analogues. Calcipotriene is the US Adopted Name (USAN) and calcipotriol is the International Nonproprietary Name (INN). These medications should be avoided or limited in patients with abnormalities in bone or calcium metabolism (e.g. sarcoidosis) or renal insufficiency. If used in recommended weekly amounts, they are considered safe in pregnancy (pregnancy category C in previous classification). If used in conjunction with phototherapy, need to apply after UV irradiation or at least several hours prior, because they may reduce UV penetration into the skin. BID, twice daily.

INDICATIONS AND CONTRAINDICATIONS FOR ANTHRALIN
Indications
• Mild to moderate or severe* psoriasis: second-line treatment as monotherapy or in combination
Contraindications
• Unstable plaque psoriasis in a phase of progression • Pustular psoriasis • Erythrodermic psoriasis
*Severe psoriasis usually treated in day-care center or inpatient setting.

Table 8.7 Indications and contraindications for anthralin. To minimize irritation, concentration and application time are gradually escalated; neither should be increased more often than once every 3 days, given that peak erythema is seen 3–4 days following application.

INDICATIONS AND CONTRAINDICATIONS FOR TOPICAL TAZAROTENE
Indications
• Mild to moderate psoriasis: second-line treatment as monotherapy or in combination with a topical corticosteroid (e.g. halbetasol)
Contraindications
• Unstable plaque psoriasis in a phase of progression • Erythrodermic psoriasis • Allergic contact dermatitis to tazarotene or constituents of the formulation • Pregnancy or lactation

Table 8.8 Indications and contraindications for topical tazarotene.

Additional topical treatments

If the psoriatic plaques have thick scale, this needs to be reduced in order to enhance penetration of topical medications and ultraviolet (UV) light. Options include salt-water baths, topical salicylic acid, and oral retinoids. *Salicylic acid* 5%–10% has a substantial keratolytic effect and, in the case of scalp psoriasis, salicylic acid can be formulated in an oil or ointment base. Application of salicylic acid to localized areas can be done daily, but, for more widespread areas, two to three times per week is preferred. This is to prevent systemic intoxication (see Ch. 129), especially in infants or those with reduced renal function.

Coal tar has a range of anti-inflammatory actions and is effective as an antipruritic. Although crude coal tar may be the most effective tar available for the treatment of psoriasis (see Ch. 129), a distilled and alcohol-derived tar product, liquor carbonis detergens (LCD), is also used. In view of its mutagenic potential, tar is contraindicated in pregnant or lactating women. However, guidelines on the use of tar products may differ between countries.

Calcineurin inhibitors are used to treat facial and flexural psoriasis. Randomized, placebo-controlled studies have demonstrated efficacy and safety for this indication[81,82].

Recently approved topical treatments

Tapinarof cream is a first-in-class aryl hydrocarbon receptor (AhR) modulating agent. It reduces proinflammatory Th17 and Th22 cytokines, upregulates antioxidant activity, and promotes epidermal barrier restoration by filaggrin. In phase 3 studies, 35%–40% of patients reached Physician Global Assessment (PGA) 0 after 12 weeks and 35%–47% of patients reached PASI 75[83]. Up to 6% of patients have discontinued topical tapinarof due to dermatitis, folliculitis, or nasopharyngitis.

Roflumilast cream is a PDE-4 inhibitor with the same mechanism of action as apremilast (see Fig. 130.4). In a phase 2b, double-blind, randomized trial, 28% of the patients were clear or almost clear after 6 weeks of daily application of roflumilast 0.3% cream[84]. Improvement of intertriginous psoriasis in ~70% of patients has also been reported. In two phase 3 trials, there was a 65%–70% improvement in the Dermatology Life Quality Index (DLQI). Potential side effects include diarrhea (3%), headache (2%), and application site pain (1%)[84a].

Photo(chemo)therapy and Systemic Medications

Evidence-based guidelines for the treatment of psoriasis with photo(chemo)therapy and classic systemic medications have been developed by various dermatologic organizations[84–87], and the tables in this chapter are adapted from these recommendations.

Photo(chemo)therapy

Photo(chemo)therapy represents a mainstay in the treatment of moderate to severe psoriasis. Phototherapy with broadband or narrowband ultraviolet B (UVB) and photochemotherapy with ultraviolet A (UVA) following ingestion of or topical application of a psoralen are classic treatment options. In the late 1970s, monotherapy with erythemogenic doses of broadband UVB was proven to be an effective approach; later on, narrowband UVB (311 nm) was developed and is the optimal irradiation currently available. Monochromatic 308 nm light from an excimer laser or equivalent source can be used to target individual psoriatic plaques.

Photo(chemo)therapy is discussed in detail in Chapter 134, and its indications and contraindications for psoriasis are summarized in Table 8.9.

Methotrexate

In 1971, amethopterin (methotrexate; MTX) was approved by the FDA as a treatment for psoriasis. The effect of MTX on lymphocytes, circulating and cutaneous, is a likely explanation for its antipsoriatic activity.

MTX is a first-line systemic therapy for psoriasis as it is highly efficacious for severe disease and all clinical variants of psoriasis. In chronic plaque psoriasis, initial improvement is observed between 1 and 7 weeks and maximum improvement can be expected after 8–12 weeks of treatment. Based upon an international consensus, MTX should be administered weekly as a single dose, usually orally but switched to subcutaneously if there are gastrointestinal adverse effects or insufficient efficacy[88]. Occasionally, it is administered intramuscularly. The recommended

INDICATIONS AND CONTRAINDICATIONS FOR PHOTO(CHEMO)THERAPY FOR PSORIASIS
Indications
• Moderate to severe psoriasis: first-line treatment as monotherapy or in combination
Contraindications (absolute or relative)
• Genetic disorders characterized by increased photosensitivity or an increased risk of skin cancer (UVB and PUVA)*
• High cumulative number of PUVA treatments, i.e. >150–200 individual treatments (PUVA)*
• Concurrent treatment with cyclosporine (UVB and PUVA)*
• Previous history of skin cancer (UVB and PUVA; * if current skin cancer, especially SCC or melanoma)
• Pregnancy or lactation (PUVA)*
• Skin type I (UVB and PUVA)†
• Photosensitive dermatoses (UVB and PUVA)†
• Unavoidable phototoxic systemic or topical medications (UVB and PUVA)†
• Vitiligo (UVB and PUVA)†
• Previous history of arsenic exposure, ionizing irradiation, or excessive photo(chemo)therapy (UVB and PUVA)
• Immunosuppressive medication (UVB and PUVA)
• Atypical melanocytic nevi (UVB and PUVA)
• Seizure disorder (risk of fall/injury; UVB and PUVA)
• Poor compliance (UVB and PUVA)
• Men and women in reproductive years without contraception (PUVA)
• Impaired liver function or hepatotoxic medication (PUVA)
• Cataracts (PUVA)
*Absolute contraindication. †Need to adjust the dose and monitor closely.

Table 8.9 Indications and contraindications for photo(chemo)therapy for psoriasis. Some clinicians use UVA alone. PUVA, psoralen + ultraviolet A; SCC, squamous cell carcinoma; UVB, ultraviolet B.

INDICATIONS AND CONTRAINDICATIONS FOR METHOTREXATE
Indications

• Severe psoriasis
  • Chronic plaque psoriasis (>10%–15% BSA or interference with employment or social functioning)
  • Pustular psoriasis (generalized or localized)
  • Erythrodermic psoriasis
  • Psoriatic arthritis (moderate to severe)
  • Severe nail psoriasis

• Psoriasis not responding to topical treatments, photo(chemo)therapy and/or systemic retinoids
Contraindications (absolute or relative)
• Severe anemia, leukopenia, and/or thrombocytopenia*
• Significant liver function abnormalities, hepatitis (active and/or recent), severe fibrosis, cirrhosis, excessive alcohol intake*
• Impaired kidney function (creatinine clearance <60 ml/min)†
• Concomitant medications that increase MTX levels, e.g. daily trimethoprim–sulfamethoxazole*
• Significantly reduced pulmonary function*
• Pregnancy or lactation*
• Currently planning to have children (male and female patients)‡
• Severe infections* or active infections
• Peptic ulcer (active)* or gastritis
• Hypersensitivity to MTX*
• Unreliable patient*
• Pleural effusion or ascites†
• Concomitant hepatotoxic medications
• Immunodeficiency syndromes
• Concomitant radiation therapy
*Absolute contraindication. †Requires significant reduction in dosage. ‡Because of possible mutagenic risk and teratogenicity, discontinue MTX 3 months prior to attempts to conceive; continue contraception during these 3 months.

Table 8.10 Indications and contraindications for methotrexate (MTX). BSA, body surface area.

maximum weekly dosage is 15 mg (children) or 25 mg (adults), with supplemental folic acid administered 24 hours after the MTX[88]. Depending on the dosage regimen, the percentage of patients reaching PASI 75, i.e. a 75% reduction in the PASI score, ranges from 25% (low starting dose) to 60% (high starting dose) after 12–16 weeks of treatment[89,90].

Potential side effects restrict its use to moderate to severe disease resistant to topical treatments and phototherapy and/or situations in which these are contraindicated. However, provided that the guidelines are carefully followed, MTX can be employed as an effective long-term therapy. Hepatotoxicity is one of the well-known side effects, but a correlation between the cumulative dose of MTX and liver fibrosis could not be established[91]. The use of folic acid supplementation during MTX administration is recommended as it reduces side effects, including gastrointestinal. Guidelines for MTX usage vary depending on the country and disease state.

Chapter 130 describes the mechanism of action, pharmacology, and safety issues of MTX, with Fig. 130.7 outlining the monitoring guidelines for MTX-related hepatotoxicity. Tables 8.10 and 8.11 summarize indications and contraindications as well as side effects of MTX.

Cyclosporine

Cyclosporine is a cyclic undecapeptide that was isolated from the fungus *Tolypocladium inflatum*. Based on large controlled studies, cyclosporine is a highly effective treatment for the severe manifestations of psoriasis. As a calcineurin inhibitor, it prevents T lymphocyte activation from being translated into the release of effector cytokines such as IL-2. Cyclosporine can be used safely, provided that the guidelines are strictly followed. In view of its nephrotoxic effects (e.g. reduced glomerular filtration rate, tubular atrophy), cyclosporine should be given for several-month courses (i.e. maximally 1 year, although this duration is still debated) and alternated with other therapies. An alternative is an intermittent schedule using multiple short courses of a few weeks' duration.

The indications and contraindications of cyclosporine are summarized in Table 8.12. Cyclosporine can produce dramatic rapid improvement of psoriasis, but this must be balanced by the requirement for an appropriate replacement therapy, given the need to ultimately stop cyclosporine therapy.

Guidelines for pre-cyclosporine screening and long-term evaluation during cyclosporine administration are outlined in Chapter 130. An important aspect is assessment of renal function, and creatinine clearance should be estimated using the Cockcroft–Gault formula:

$$\frac{(140 - \text{age in years}) \times (\text{weight in kg})}{\text{serum creatinine}\,(\text{mg}/100\,\text{ml}) \times 72}$$

In elderly patients and patients with a history of hypertension, the risks of renal impairment and hypertension are increased.

Cyclosporine treatment in psoriatic patients has been reported to increase the frequency of SCCs, especially in those previously treated with PUVA. The underlying mechanism is not mutagenesis but a decrease in immunosurveillance of the skin. In particular, psoriatic patients who have been exposed to high cumulative doses of UV radiation are at risk for development of cutaneous malignancies. Although cyclosporine is an immunosuppressive agent, no increase in serious infections has been reported in patients treated with cyclosporine alone. Other side effects include gastrointestinal discomfort, hypertrichosis, paresthesias, gingival hyperplasia, headache, vertigo, muscle cramps, and tremor[94]. Metabolic side effects include hyperkalemia, hypomagnesemia, hyperuricemia (due to decreased clearance of uric acid), and elevated cholesterol and triglycerides.

The efficacy of cyclosporine for psoriasis has been clearly shown in multiple controlled and uncontrolled studies. For example, the European multicenter dose-finding studies found that doses of 1.25, 2.5–3, and 5 mg/kg/day of cyclosporine resulted in reductions of the PASI of 35%, 57%, and 86%, respectively[95]. An improvement in the PASI of 75% was achieved in 24%, 52%, and 88% of the patients[95]. Of note, because the criteria for these studies were different from those used for FDA approval of targeted immunomodulators ("biologic" therapies), the PASI numbers are not directly comparable. Efficacy of cyclosporine has been demonstrated in all variants of psoriasis (including nail psoriasis), but less so for psoriatic arthropathy. In general, a reduction of the

SIDE EFFECTS OF METHOTREXATE		
Subjective symptoms	**Hematopoietic†**	**Mucocutaneous**
*Most frequent**,† Nausea Vomiting Abdominal pain Fatigue Headache *Occasional* Loss of libido Impaired memory	Leukopenia‡ Thrombocytopenia Anemia	Oral erosions† Alopecia Delayed phototoxicity Tenderness and/or necrosis of plaques due to overdose Rarely, urticaria, angioedema, vasculitis
Hepatic	**Pulmonary**	**Fetal development**
Hepatitis† Cirrhosis¶	Interstitial pneumonitis (acute-onset cough, dyspnea)	Birth defects: cranial and absence of digits
Carcinogenesis§	**Idiosyncratic reaction**	
In rheumatoid arthritis patients, increased risk of lymphoma Risk factor for cutaneous SCC in PUVA-treated patients	Early in course with full dosage Severe pneumonia Gastrointestinal hemorrhage Pancytopenia	
Opportunistic infections	**Additional/unusual**	
Pneumocystis jirovecii pneumonia Cryptococcosis Disseminated histoplasmosis Disseminated herpes zoster	Osteopathy (pain, osteoporosis, compression fractures) Ventricular cardiac arrhythmias Lowered seizure threshold	

*Same day or 2–3 days following MTX administration; may respond to folic acid, dose reduction, or antiemetic drug.
†May be reduced by folic acid (5 mg, 24 hours after MTX dose).
‡Up to 10% of patients on oral regimens.
¶Up to 25% of patients receiving long-term therapy.
§No increased risk of malignancy was observed in large series of psoriasis patients[92,93].

Table 8.11 Side effects of methotrexate (MTX). PUVA, psoralen + ultraviolet A; SCC, squamous cell carcinoma.

PASI of 60%–70% can be reached within 4 weeks of treatment. During long-term treatment, there are no signs of tachyphylaxis.

Systemic retinoids

By the 1930s, vitamin A deficiency was known to cause hyperkeratosis of the skin (phrynoderma). Thirty years later, modifications of the vitamin A molecule resulted in the discovery of the so-called first generation of retinoids, including all-*trans*-retinoic acid (tretinoin) and 13-*cis*-retinoic acid (isotretinoin). Further research resulted in the development of the second generation of retinoids, the mono-aromatic retinoids, etretinate and its free metabolite acitretin.

Acitretin is an effective treatment for psoriasis, but a major problem with systemic retinoids is their teratogenicity, making contraception mandatory in women of childbearing age during treatment and (depending on the drug half-life) for a period of 1 month (isotretinoin) to 3 years (acitretin) after discontinuing therapy. Chapter 126 provides a description of the modes of action, pharmacologic aspects, and side effects of systemic retinoids.

The indications and contraindications for the use of acitretin in the treatment of psoriasis are summarized in Table 8.13, and the recommended initial and ongoing evaluations are outlined in Table 8.14.

In patients with chronic plaque psoriasis, 0.5 mg/kg/day is the initial dosage, which can be increased depending upon the clinical response and side effects. For erythrodermic psoriasis, the initial dosage is 0.25 mg/kg/day, and in pustular psoriasis, the dose should be maximized, i.e. up to 1 mg/kg/day. In patients with chronic plaque psoriasis, mild cheilitis (just perceivable by the patient) is the goal, whereas in patients with pustular psoriasis, a dose that causes a clinically apparent but tolerable cheilitis is an endpoint.

INDICATIONS AND CONTRAINDICATIONS FOR CYCLOSPORINE
Indications
• Severe psoriasis • Conventional therapies (topical treatments, photo(chemo)therapy, acitretin, methotrexate) ineffective or inappropriate
Contraindications
• Impaired renal function* • Uncontrolled hypertension* • Past or present* malignancy • History of excessive photo(chemo)therapy (>200 PUVA treatments) or concurrent photo(chemo)therapy* • Concomitant drugs affecting cyclosporine pharmacokinetics† • Radiotherapy* • Severe infections* or active infections • Hypersensitivity to cyclosporine* • Unreliable patient* • Primary or secondary immunodeficiency • Concomitant immunosuppressive therapy • History of arsenic exposure • Pregnancy or lactation • Concurrent methotrexate administration • Significant hepatic disease • Hyperuricemia, hyperkalemia • Vaccination with live vaccines • Seizure disorder • Poorly controlled diabetes mellitus • Severe chronic organ dysfunction • Alcohol and drug abuse • Malabsorption
*Absolute contraindications. †Requires dose adjustment and careful monitoring; cyclosporine is inactivated by the cytochrome P450 3A isoform.

Table 8.12 Indications and contraindications for cyclosporine. The recommended starting dose is 3 mg/kg/day in two divided doses; at 2-week intervals, dosage can be increased to a maximum of 5 mg/kg/day. PUVA, psoralen + ultraviolet A.

INDICATIONS AND CONTRAINDICATIONS FOR ACITRETIN
Indications
• Severe psoriasis that cannot be managed by topical treatments or photo(chemo)therapy • Monotherapy is indicated for erythrodermic or pustular psoriasis • Combination therapy is indicated for chronic plaque psoriasis
Contraindications
• Severe liver dysfunction* • Severe kidney dysfunction (elimination reduced)* • Pregnancy or lactation* • Women of childbearing potential who cannot guarantee adequate contraception during and up to 3 years following discontinuation of acitretin* • Hyperlipidemia, especially hypertriglyceridemia, that cannot be controlled* • Excessive alcohol intake* • Unreliable patient* • Concomitant medications that interfere with retinoid bioavailability or whose metabolism is altered† • Concomitant hepatotoxic drugs, e.g. methotrexate‡ • Poorly controlled diabetes mellitus • History of pancreatitis • Atherosclerosis
*Absolute contraindications. †Requires dose adjustment and careful monitoring, e.g. phenytoin competes for plasma protein binding. ‡Reserved for treatment-resistant patients.

Table 8.13 Indications and contraindications for acitretin. Blood donation is contraindicated in patients receiving acitretin. Patients who wear contact lenses need to use lubricants or may need to switch to glasses.

The efficacy of acitretin monotherapy in chronic plaque psoriasis is limited, with ~70% of patients achieving a moderate or better response. In one study, 23% of patients treated with 50 mg of acitretin daily for 8 weeks achieved ≥75% improvement in their PASI[96]. Combination

treatment with photo(chemo)therapy and/or vitamin D_3 analogues results in a substantial improvement in clinical response. Maximal therapeutic efficacy is reached after 2–3 months. Acitretin has been shown to be an effective maintenance therapy. As monotherapy, acitretin is highly effective in erythrodermic and pustular psoriasis. Its efficacy in nail psoriasis and psoriatic arthritis is only modest.

JAK and TYK2 inhibitors

Oral JAK inhibitors (e.g. tofacitinib, upadacitinib) have been approved for psoriatic arthritis and several are currently in phase 3 trials for plaque psoriasis. There are four JAK enzymes – JAK1, JAK2, JAK3, and TYK2 – and depending upon the drug, one or more enzymes are inhibited. Oral deucravacitinib, a selective TYK2 inhibitor, was recently approved for plaque psoriasis based upon two phase 3 trials in which it was compared to apremilast or placebo. A PASI 75 improvement was observed in 55%–60% of patients who received deucravacitinib, compared to 35% and 13% for apremilast and placebo, respectively[97].

Inhibition of the JAK/STAT pathway eventually leads to a reduction in IL-17- and IL-23-mediated inflammation and type I IFN-driven responses. The mechanisms of action and side effects of this group of medications are reviewed in Chapter 128.

Apremilast and other systemic therapies

Apremilast is an oral phosphodiesterase 4 inhibitor that prevents cyclic AMP degradation within keratinocytes, dendritic cells, monocytes, and neutrophils. Increased intracellular cAMP levels then lead to a reduction in proinflammatory mediators (see Fig. 130.4). Chapter 130 reviews the dosages and side effects of apremilast. In a third of patients with plaque psoriasis, apremilast leads to a PASI 75 improvement and it significantly decreases pruritus. Scalp psoriasis may have a relatively better response.

Additional systemic therapies that have been reported as beneficial in the management of psoriasis are outlined in Table 8.15. In general, they are used less often than the other medications described in this chapter, and there are regional differences in their use.

Targeted immunomodulators ("biologic" therapies)

Beginning in 2000, targeted immunomodulators were introduced for the treatment of psoriatic arthritis and moderate to severe psoriasis. Their targets are cytokines, including TNF, IL-12, IL-17, and IL-23 (see Fig. 8.1B). Table 8.16 lists the biologic agents that are currently commercially available and Chapter 128 provides a description of their modes of action, dosages, side effects, and monitoring recommendations. Guidelines, including European S3-Guidelines and those developed by the American Academy of Dermatology and National Psoriasis Foundation, have been proposed for the treatment of psoriasis patients with TNF inhibitors (adalimumab, etanercept, certolizumab, infliximab)

ACITRETIN – EVALUATION PRIOR TO AND DURING TREATMENT
Pre-acitretin screening
• History to exclude contraindications • Complete blood count • Liver function tests (AST, ALT, γGT, alkaline phosphatase, bilirubin) • Serum triglycerides, cholesterol, HDL • Glucose • Serum creatinine • Pregnancy test • Consider spinal X-ray (often initially performed during the first 3 months of therapy if long-term treatment is anticipated)
Evaluation during acitretin treatment
• Monitor mucocutaneous side effects • Serum triglycerides, cholesterol/HDL, and liver function tests (every month for the first 2 months then every 2–3 months) • Serum creatinine (elderly patients or patients with mild to moderate renal dysfunction) • Monitor for development of hyperostosis by history (twice yearly) and by X-ray of spine (e.g. once yearly or every other year in patients receiving long-term treatment)* • Pregnancy test (twice yearly throughout treatment)*
*Frequency varies amongst clinicians.

Table 8.14 Acitretin – evaluation prior to and during treatment. ALT, alanine aminotransferase; AST, aspartate aminotransferase; γGT, gamma glutamyl transpeptidase; HDL, high-density lipoproteins.

ADDITIONAL SYSTEMIC THERAPIES FOR PSORIASIS	
Medication	**Side effects**
Fumarates[98]	Renal impairment, flushing, gastrointestinal disturbances, headache, fatigue, Fanconi syndrome, progressive multifocal leukoencephalopathy (rare)
Mycophenolate mofetil[99]	See Ch. 130
Oral calcitriol (0.5–3 mcg/day)[100]	Hypercalcemia, hypercalciuria
6-thioguanine (40–160 mg/day)	Myelosuppression, hepatotoxicity, gastrointestinal disturbances
Hydroxyurea	See Table 130.10

Table 8.15 Additional systemic therapies for psoriasis. BID, twice daily.

COMMERCIALLY AVAILABLE BIOLOGIC AGENTS FOR THE TREATMENT OF PSORIASIS INCLUDING GENERALIZED PUSTULAR PSORIASIS			
Biologic agent	**Target**	**Molecule**	**Approved***
Etanercept	TNF†	Human fusion protein	FDA + EMA
Infliximab	TNF‡	Chimeric antibody	FDA + EMA
Adalimumab	TNF‡	Human antibody	FDA + EMA
Certolizumab	TNF‡	Humanized antibody	FDA + EMA
Ustekinumab	p40 subunit of IL-12/23	Human antibody	FDA + EMA
Secukinumab	IL-17A	Human antibody	FDA + EMA
Ixekizumab	IL-17A	Humanized antibody	FDA + EMA
Bimekizumab	IL-17A, IL-17F	Humanized antibody	EMA
Brodalumab	IL-17 receptor	Human antibody	FDA + EMA
Guselkumab	IL-23	Human antibody	FDA + EMA
Risankizumab	IL-23	Humanized antibody	FDA + EMA
Tildrakizumab	IL-23	Humanized antibody	FDA + EMA
Spesolimab	IL-36 receptor	Humanized antibody	FDA + EMA

*By registration authorities for the treatment of psoriasis as of June 2023. Biosimilar products, e.g. adalimumab-atto, etanercept-szzs, infliximab-dyyb, are also commercially available.
†Soluble form.
‡Soluble form and transmembrane TNF receptor.

Table 8.16 Commercially available biologic agents for the treatment of psoriasis including generalized pustular psoriasis. See Ch. 128 for details. EMA, European Medicines Agency; FDA, Food and Drug Administration; IL, interleukin; TNF, tumor necrosis factor.

as well as anti-IL-12/23 (ustekinumab), -IL-17 (secukinumab, ixekizumab, brodalumab), and -IL-23 (guselkumab, tildrakizumab, risankizumab) antibodies[86,101–103]. The evidence in these guidelines is based upon both short-term clinical trials (12- to 16-week efficacy and safety data) and long-term clinical trials (up to 5-year efficacy and safety data).

Based upon a network meta-analysis, the relative efficacies of multiple biologic agents are outlined in Table 8.17[104]. With regard to *short-term* efficacy, there is significant overlap amongst first-generation (TNF inhibitors) and second-generation (ustekinumab) biologic agents, photo(chemo)therapy, and classic systemic medications such as MTX and cyclosporine. However, third-generation (anti-IL-17 antibodies) and fourth-generation (anti-IL-23 antibodies) biologic agents are associated with a significant enhancement in short-term efficacy. The latter has led to assessments of PASI 90, not just PASI 75, with 60%–70% of patients achieving at least PASI 90.

In the treatment of psoriasis, *long-term* efficacy also matters. With the introduction of TNF inhibitors and ustekinumab came a dramatic reduction in both inpatient and day-care units dedicated to treating psoriasis. Data from clinical trials that included 5-year follow-up periods for first- to fourth-generation target immunomodulators demonstrated that clinical improvements were maintained long-term[105–107]. In addition, long-term safety data were reassuring.

Because clinical trials often enroll selective populations, it is important to assess real-world efficacy and safety. Real-world data have confirmed effective and safe long-term control by TNF inhibitors and ustekinumab, with a 50% drug survival over 2–6 years[108]. The improved efficacy profile of anti-IL-17 and -IL-23 antibodies has also proved to be sustainable[109]. In a recent analysis of five of the more commonly used antibodies (adalimumab, guselkumab, ixekizumab, secukinumab, ustekinumab), guselkumab had the highest drug survival[110].

At the time of writing, bimekizumab, a dual-inhibitor of IL-17A and IL-17F, has been EMA, but not yet FDA, approved for the treatment of plaque psoriasis[111]. Of note, spesolimab-sbzo, an interleukin-36 receptor inhibitor, was recently approved for the treatment of generalized pustular psoriasis[112].

More so in the past, biologic agents were prescribed primarily for "high-need" patients in whom some or all classic systemic treatments were either contraindicated or had led to insufficient improvement. This stepwise approach has gradually been replaced by the use of targeted immunomodulators early on in order to control disease activity. Of course, the latter recommendation has to be balanced against the high cost of these medications. Both indications and contraindications for currently commercially available therapies are outlined in Table 8.18.

Therapeutic Management

General considerations

Before considering a specific treatment in an individual psoriatic patient, it is important to exclude triggering factors. Aggravating factors such as focal infections, medications, and psychological stress have been described above. As psoriasis is a systemic disease, comorbidities and disease-modifying factors need to be addressed. These include arthritis, nail disease (a prognostic marker for the development of arthritis), metabolic syndrome with its associated cardiovascular disease and obesity, depression, and smoking. Furthermore, it is also crucial to assess the various aspects of disease severity, in particular[113]:

- The areas of involvement and the degree of erythema, induration, and desquamation of the cutaneous lesions (see Table 8.2).
- The impairment of quality of life. The visibility of the lesions and symptoms such as pruritus are relevant factors, and psycho-emotional stress and the response of family and friends to the psoriasis should also be considered. Impact of psoriasis on quality of life can be measured by questionnaires (e.g. Dermatology Life Quality Index [DLQI], Skindex-29).
- The responsiveness to previous treatments. Individual patients report a wide variation with respect to their clinical response to various treatments. For example, some patients, even those with widespread disease, may experience excellent improvement with a mild topical therapy, whereas patients with localized disease may prove recalcitrant to even high-dose systemic treatments.

Relative and absolute contraindications to the various treatment options have to be recognized, especially in the case of photo(chemo) therapy and systemic medications. Because psoriasis is a chronic condition, patients have to cope not only with their disease, but also with the various treatments and their costs for prolonged periods of time. For example, individual circumstances may restrict the time available for intensive daily treatments. Also, some patients cannot accept a few coin-sized lesions in visible sites, while for others this is less of a problem. Therefore, treatment selection is a multivariable decision-making process and not a simple stepwise therapeutic ladder.

In addition, classically assessing disease severity as mild, moderate, or severe can sometimes prove challenging as no consensus has been reached on their definitions based upon PASI, PGA, or DLQI. The International Psoriasis Council has redefined disease severity in practice-driven rather than data-driven terms: psoriasis patients should be classified as candidates for either topical therapy (mild disease) or systemic therapy (severe disease). The latter group should meet at

SENSITIVITY ANALYSIS: GLOBAL TRIALS ONLY						
Treatment	**PASI 75 Posterior median, 95% CrI**		**PASI 90 Posterior median, 95% CrI**		**PASI 100 Posterior median, 95% CrI**	
Risankizumab 150 mg	89.4%	(87.2%, 91.3%)	71.7%	(67.8%, 75.4%)	41.1%	(36.9%, 45.6%)

Comparison of biologics and oral treatments for plaque psoriasis: A meta-analysis. JAMA Dermatol 2020;156:258–69.*

INDICATIONS AND CONTRAINDICATIONS FOR COMMERCIALLY AVAILABLE TARGETED IMMUNOMODULATORS ("BIOLOGIC" AGENTS)
Indications
General indications
• Patients with moderate to severe psoriasis, eligible for a systemic treatment • Patients with psoriatic arthritis, particularly those who have failed other disease-modifying antirheumatic drugs (DMARDs)
Restricted indication
• Patients with moderate to severe psoriasis who are not candidates for topical treatments, photo(chemo)therapy, or classic systemic treatments because of insufficient efficacy or contraindications†
Contraindications
(The exact contraindications vary by agent [see Ch. 128]; some listed below are relative, while others are absolute [*])
• Significant viral, bacterial, or fungal infection, including active *Salmonella* or dimorphic fungal infection* • Increased risk for developing sepsis* • Active tuberculosis* • Allergic reaction to the biologic agent* • *Selective for TNF inhibitors:* ANA+ (especially if high titer) or autoimmune connective tissue disease, blood dyscrasias, congestive heart failure (NYHA grade III or IV), or demyelinization disorders (the latter also if in first-degree relative)* • *Selective for ustekinumab:* BCG vaccination within the past 12 months (mode of action expected to increase susceptibility to mycobacterial infections) • *Selective for secukinumab, ixekizumab, and brodalumab:* active Crohn disease (may cause exacerbation of bowel disease) • History of hepatitis B viral (HBV) infection‡ • History of hepatitis C viral infection (risk of activation)¶ • Immunosuppressed patient • Pregnancy (TNF inhibitors appear to be safe) • Breastfeeding • Malignancy within the past 5 years (does not include adequately treated cutaneous squamous or basal cell carcinoma) • Excessive chronic sun exposure or photo(chemo)therapy
*Absolute contraindications. †Guttate, pustular, or erythrodermic psoriasis are not established indications, but there is anecdotal evidence for efficacy and safety. ‡If HBsAg-positive, measure HBV DNA and treat with antiviral agent (e.g. tenofovir, entecavir, telbivudine) prior to immunosuppressive therapy. Monitor for reactivation in those with anti-HBs or -HBc antibodies who are HBsAg-negative). ¶Need to monitor liver function tests and viral load.

Table 8.18 Indications and contraindications for commercially available targeted immunomodulators ("biologic" agents). Administration of live vaccines (see Table 128.8) is contraindicated in patients receiving biologic agents for psoriasis. BCG, bacillus Calmette–Guérin; NYHA, New York Heart Association.

least one of the following criteria: (1) body surface area (BSA) >10%; (2) disease involving special sites; and (3) failure of topical therapy[114].

Management with topical agents

It is important before instituting topical therapy that the patient understands that due to the Koebner phenomenon, trauma (e.g. from scratching or debriding lesions) can negate therapeutic interventions. Although it may seem obvious, patients should also be told that topical agents do not prevent new lesions from appearing at additional sites. For patients with mild disease, topical treatments are the first choice. Patients with more widespread involvement may also be treated with a topical agent; however, a high degree of compliance is required and this can be difficult to achieve.

Evidence for the efficacy of various topical treatments was reassessed in a meta-analysis[115]. From this analysis, it was concluded that only very potent topical corticosteroids tended to be more effective than monotherapy with the vitamin D_3 analogue calcipotriene. In ambulatory patients, calcipotriene was more effective than anthralin, coal tar, the other vitamin D_3 analogues (tacalcitol and calcitriol), and the retinoid tazarotene. The efficacy of coal tar and anthralin are difficult to assess, as the success of these topicals is highly dependent on the treatment setting. A day-care or inpatient setting is optimal, as it allows the patient to more easily cope with the side effects of staining, stinging, and irritation.

Combination treatment is advised for the vast majority of patients, thereby increasing efficacy and reducing side effects[116]. For example, a fixed combination of calcipotriene and betamethasone dipropionate applied once daily proved to be superior to twice-daily calcipotriene or twice-daily betamethasone dipropionate monotherapy. Nonetheless, one common initial approach is to apply either calcipotriene twice daily or a potent corticosteroid once daily for a period of 4 to 8 weeks (except for sensitive skin areas and the scalp). If this regimen is not successful or if rapid clearing is required, then both calcipotriene and a potent topical corticosteroid can be applied for 4 to 8 weeks. In the case of an insufficient response, another vitamin D_3 analogue or tazarotene may be tried as monotherapy or in combination with a topical corticosteroid. In addition, a topical corticosteroid under hydrocolloid occlusion can be used for a few recalcitrant plaques, especially when there is superimposed LSC.

A trial of tar or anthralin may be tried, especially in patients with longstanding disease and incomplete responses or fast relapses. These treatments often require a day-care or inpatient facility as their use in the ambulatory setting is inconvenient and disappointing. With regard to maintenance therapy, some patients prefer only intermittent clearing courses with no intervening therapy, while other patients want continuous treatment. Daily use of a topical vitamin D_3 analogue (below the maximum allowed weekly dosage) provides a safe long-term form of maintenance therapy. If the therapeutic response is insufficient, additional intermittent application of a topical corticosteroid (once or twice weekly) is helpful.

Certain body areas may require a more site-specific approach, e.g. roflumilast cream or a topical calcineurin inhibitor, rather than a potent topical corticosteroid, for psoriasis involving major body folds. If topical therapies do not provide adequate improvement, then treatment with photo(chemo)therapy or a systemic agent is indicated.

Management with photo(chemo)therapy and classic systemic medications

For patients with more severe involvement, topical therapies may be ineffective or impractical. On a chronic basis, patients with widespread disease often cannot manage their psoriasis with topical treatments and become frustrated and non-compliant. Evidence for the efficacy of photo(chemo)therapy and classic systemic treatments has been reassessed in a meta-analysis[117]. PUVA had the highest percentage of patients with clearance (70%), followed by UVB (68%) and cyclosporine (64%). However, PUVA has become a seldomly used therapy for psoriasis due to its potential for cumulative carcinogenicity.

In the selection of a systemic treatment for an individual patient, the existence of relative and absolute contraindications has to be considered. For example, photo(chemo)therapy would not be chosen for patients with a history of excessive exposure to UV radiation, but these same patients could be excellent candidates for retinoid therapy (considering its anticancer effects). Methotrexate is contraindicated in patients with excessive alcohol intake or active hepatitis, while cyclosporine is contraindicated in those with renal insufficiency or hypertension.

As noted previously, some guidelines recommend a stepwise approach utilizing less expensive treatments first, i.e. UVB phototherapy initially, followed by one of the classic systemic medications. Because of psoriasis' chronicity, maintenance therapy also needs to be addressed. While cyclosporine should not be used long-term, methotrexate, acitretin, and fumarates (available in some European countries) can be, as long as the potential for cumulative toxicity is monitored. However, increasingly, targeted immunomodulators have become first-line therapy for moderate to severe disease, with the goal of complete or nearly complete clearance as well as a reduction in systemic inflammation[118].

Management with targeted immunomodulators ("biologic" therapies)

Several biologic therapies are currently available worldwide for the treatment of psoriasis and/or psoriatic arthritis (see Table 8.16). Relative response rates are reviewed in Table 8.17 with indications and contraindications outlined in Table 8.18. In addition to moderate to severe disease, there may be other situations in which targeted immunomodulators become first-line therapy, e.g. acute arthritis, severe depression, suicidal ideation.

The side effect profiles are very different from those of photo(chemo) therapy and classic systemic medications, as there is no indication of cumulative toxicity. Because a 1-year course of biologic therapy costs up to $60 000 in the US and up to €35 000 in Europe (with costs varying depending upon the country), national health authorities and managed care insurance companies have adopted a restrictive approach. Therefore, in many countries, biologic agents are available exclusively for those patients with severe psoriasis who cannot be treated adequately with the classic treatments. However, an improvement in quality of life and the possible impact on comorbidities also need to be considered.

Combining treatments

Enhanced clinical response and a possible reduction in side effects are the goals of combination therapy. However, for safety reasons, some combinations are contraindicated.

Beneficial combinations

For topical treatments, systematic literature reviews have been published[115,116]. As noted previously, the combination of calcipotriene with potent topical corticosteroids has been shown to be more effective than either treatment as monotherapy. The irritation caused by vitamin D_3 analogues and tazarotene can be reduced by the addition of a medium- or high-strength corticosteroid. While not comprehensively investigated in controlled studies, topical therapies are often used for persistent lesions in patients receiving systemic agents. Those biologic agents that can induce autoantibodies (e.g. adalimumab, infliximab) may be combined with MTX.

Contraindicated combinations and combinations with restricted use

The combination of acitretin and cyclosporine carries the risk of accumulation of cyclosporine, because cyclosporine is inactivated by the cytochrome P450 system, which is inhibited by acitretin. The combination of cyclosporine and methotrexate has been viewed as high risk because both are immunosuppressants. However, this combination has been used with success by rheumatologists, and, in recalcitrant psoriasis, the combination has proved to be very effective without major side effects. The combination of methotrexate and acitretin has been used in those patients in whom all treatments have failed[119]. Although this combination can be very effective, severe hepatotoxicity has been reported; therefore, careful monitoring is mandatory. If a patient has received PUVA therapy in the past, the use of cyclosporine should be avoided.

Management of childhood psoriasis

The efficacy and safety of treatment modalities in children have been reviewed[120]. Only two randomized controlled trials were identified; one examined topical calcipotriene and the other etanercept. Of note, since then, ustekinumab and ixekizumab have been studied in controlled trials. The authors recommended topical calcipotriene as first-line therapy for mild to moderate juvenile psoriasis, combined with mild- to moderate-strength topical corticosteroids (if necessary). For treatment-resistant flexural and/or facial psoriasis, tacrolimus 0.1% ointment can be added to the treatment regimen. In some countries, anthralin is then considered if this treatment regimen is not effective or if the psoriasis is moderate to severe. The next step is to recommend treatment with narrowband UVB, especially in adolescents, with attention to the number of treatments. Although controversial, the use of antibiotics can be considered in patients with guttate psoriasis where there is suspicion of a streptococcal infection.

Of the systemic medications, methotrexate is regarded as the treatment of choice, with retinoids considered in pustular and erythrodermic psoriasis. Cyclosporine is occasionally utilized for exceptional cases[120]. Four systemic immunomodulators – etanercept, ustekinumab, secukinumab, and ixekizumab – have been approved by the FDA for use in children from the ages of 4, 6, 6, and 6 years, respectively. The EMA has also approved these four medications as well as adalimumab (in children ≥4 years of age), but its age for etanercept is ≥6 years. The EMA has also approved adalimumab for children 4 years of age or older. National recommendations for the treatment of psoriasis in children have also been published by Italian and German expert groups[121,122].

Management of psoriasis in patients with comorbidities

Comorbidities, in particular metabolic syndrome, are often observed in patients with more moderate to severe forms of psoriasis. Recommended therapies for patients with various comorbidities are summarized in Table 8.19.

SYSTEMIC TREATMENT OF PSORIASIS IN THE SETTING OF COMORBIDITIES

Comorbidity	MTX	CSA	Acitretin	Apremilast	JAK, TYK2 inhibitor	Anti-TNF	Anti-IL -12/23, -23	Anti-IL -17, -17R
Psoriatic arthritis	+	+/–	+/–	+	+	+	+	+
Crohn disease	+	+	+/–	+	+	+	+	–
Congestive heart failure (higher grades)	+	+	+	+	+/–(cardiac events)	–	+	+
Multiple sclerosis	+	+	+	+	+	–	+	+
SLE	+	+	+	+	+	+/–	+	+
Depression	+	+	+	+/–¶	+	+	+	+ IL-17 / – IL-17R
Clotting disorder (e.g. DVT, PE)	+	+	+	+	–	+	+	+
Significant infection, active tuberculosis	–	–	+	+	–	–	–	–
Latent tuberculosis*	+/–	+/–	+	+	+/–	+/–	+	+
Hepatitis B† or C viral infection	–	+/–	–	+	+/–	– Hep B / + Hep C	+/–	+/–
History of internal malignancy (e.g. lymphoma, lung cancer)‡	+/–	–	+	+	–	+/–	+/–	+/–

*Begin treatment for latent tuberculosis prior to initiating systemic therapy.
†If HBsAg-positive, measure HBV DNA and treat with antiviral agent (e.g. tenofovir, entecavir, telbivudine) prior to immunosuppressive therapy. Monitor for reactivation in those with anti-HBs or -HBc antibodies who are HBsAg-negative.
‡Especially within last five years; consider consultation with hematologist/oncologist prior to biologic therapy.
¶Consider consultation with psychiatrist or mental health care professional.

Table 8.19 Systemic treatment of psoriasis in the setting of comorbidities. Note (+) indicates preferred agents; (–) indicates agents that should be avoided; (+/–) indicates agents that can be used with caution or agents that are not preferred (e.g. there are not enough data, benefits of use outweigh the risks for an individual case). When there is a history of an internal malignancy and anti-IL-12/23, -23, -17, or -17R antibodies are available, they are preferred over anti-TNF agents. CSA, cyclosporine; DVT, deep venous thrombosis; IL, interleukin; JAK, Janus-associated kinase; MTX, methotrexate; PE, pulmonary embolus; R, receptor; SLE, systemic lupus erythematosus; TNF, tumor necrosis factor; TYK2, tyrosine kinase 2.

Treatment of elderly patients

To address the efficacy and safety of systemic medications in older patients (≥65 years of age), a systematic literature review was conducted[123]. The effectiveness of acitretin, etanercept, adalimumab, and secukinumab did not correlate with age. For other systemic therapies, studies with age group comparisons were not available. Elderly patients often have a greater number of comorbidities, in addition to those associated with psoriasis. As a result, they may require altered dosing as well as more frequent laboratory and clinical monitoring. More real-world evidence and age-based (sub)analyses in prospective cohort studies are needed given the rise in this patient population.

Additional figures, tables, Therapeutic options for psoriasis and relevant safety information for use during pregnancy, Management of psoriasis at specific sites, and Topical treatment and ultraviolet B phototherapy in the setting of comorbidities, and references available in our eBook (see inside front cover for access code).

THERAPEUTIC OPTIONS FOR PSORIASIS AND RELEVANT SAFETY INFORMATION FOR USE DURING PREGNANCY

(M)RHD: (Maximum) Recommended Human Dose
Green: Use or limited use of drug is safe in pregnancy.
Orange: Limited use is likely safe if medically necessary or is recommended for specific indications.
Yellow: Use with caution in pregnancy due to limited safety data.
Blue: Use with caution in pregnancy due to potential adverse fetal effects.
Red: Use is contraindicated in pregnancy.

Dermatologic medication	Implications for use during pregnancy	Former FDA category
Topical agents		
Vitamin D analogues (calcipotriene)	No well-controlled studies in pregnant women. Calcium imbalance, skeletal and bone ossification abnormalities seen in animal studies. **Safe** in pregnancy with topical application of doses <100 g/week.	C
Corticosteroids (hydrocortisone, triamcinolone, fluocinonide, clobetasol)	No well-controlled studies in pregnant women. No associations with malformations in large studies. Fetal growth restriction reported only with extensive use of potent topical corticosteroids in the third trimester and with extensive use (particularly >300 g). **Limited use is safe** in pregnancy. Mild-to-moderate potency corticosteroids are preferred over potent corticosteroids, but potent corticosteroids may be used for a limited period of time.	C
Calcineurin inhibitors (tacrolimus, pimecrolimus)	No well-controlled studies in pregnant women. Low systemic absorption with topical application. Teratogenic and embryotoxic (decreased weight and viability) effects with oral use and high maternal doses in animal studies. **Limited use is safe** with topical application in pregnancy.	C
Salicylic acid	No well-controlled studies in pregnant women. Teratogenic in animal studies. Low systemic absorption with topical application. **Limited use is safe** in pregnancy. Avoid occlusive dressings.	C
Coal tar	Limited data in pregnant women. No increased risk of teratogenicity in a series of pregnant women. Associated with spontaneous abortions and congenital disorders in animal studies. **Limited use is safe** in 2nd and 3rd trimester of pregnancy.	N/A
Anthralin/dithranol	Limited data in pregnant women. Lack of animal studies. **Not recommended** in pregnancy.	C
Roflumilast	Limited data in pregnant women. Lack of animal studies. Oral administration at doses higher than MRHD resulted in teratogenicity in animal studies. **Not recommended** in pregnancy until further studies are available.	N/A
Tapinarof	Limited data in pregnant women. No teratogenicity in animal studies. **Not recommended** in pregnancy until further studies are available.	N/A
Tazarotene	Teratogenic (retinoid malformations, spina bifida, hydrocephaly, heart defects) and embryo-toxic (reduced fetal body weight and skeletal ossification) in animal studies. Healthy deliveries have been reported with topical tazarotene use. **Contraindicated** in pregnancy; embryo-fetal toxicity warning.	X

eTable 8.1 Therapeutic options for psoriasis and relevant safety information for use during pregnancy.

Dermatologic medication	Implications for use during pregnancy	Former FDA category
Phototherapy		
Narrowband UVB/ broadband UVB	No associated fetal abnormalities or premature deliveries. Avoid overheating/burns. **Safe** in pregnancy.	N/A
Psoralen plus UVA (PUVA)	Psoralen has a theoretical risk of teratogenic and mutagenic effects on a fetus due to the inhibition of DNA synthesis and cell division. Animal studies are lacking. Few case reports have demonstrated premature labor and fetal abnormalities. **Avoid** in pregnancy.	C
Oral agents		
Cyclosporine	No well-controlled studies in pregnant women. Low risk for teratogenicity, but premature labor and infants who are small for gestational age have been reported. Embryo-fetal toxicity (reduced fetal weight, skeletal growth delay) seen at maternally toxic doses, but no teratogenic effects found in animal studies. **Use recommended** only for severe maternal disease.	C
Apremilast	No associated congenital defects or adverse fetal outcomes in human studies. Embryo-fetal toxicity (fetal loss and incomplete skeletal ossification) at higher than MRHD, but no teratogenicity in animal studies. **Use with caution** due to potential adverse fetal effects and limited safety data.	C
Deucravacitinib	No well-controlled studies (pregnant women were excluded from initial studies). No teratogenic effects in animal studies. Other JAK inhibitors have demonstrated adverse fetal effects at higher than MRHD in animal studies. **Use with caution** due to limited safety data.	N/A
Methotrexate	Associated with spontaneous abortions, congenital malformations (skull anomalies, facial dysmorphisms, central nervous system abnormalities, limb abnormalities, cardiac anomalies), and intellectual impairment with first trimester exposure. Associated with intrauterine growth restriction and functional abnormalities with second and third trimester exposure. Potential risk in fetus with preconception exposure. **Contraindicated** in pregnancy. Use effective contraception during and 6 months after final dose. If administered intramuscularly, use preservative-free formulations, when possible, to avoid benzyl alcohol toxicity.	X
Acitretin	Fetal exposure may lead to "retinoic acid embryopathy", which is characterized by malformations of the central nervous system (e.g. meningomyelocele, meningoencephalocele) and thymic structures as well as craniofacial and cardiac alterations. **Contraindicated** in pregnancy. Recommended to discontinue at least 3 years before conceiving a child.	X
Biologic agents		
TNF inhibitor (certolizumab)	Negligible placental transfer. No teratogenic effects or embryo-fetal toxicity in animal studies. **Likely safe** in pregnancy. Preferred choice biologic because pegylation of antibody prevents placental transfer.	N/A
Other TNF inhibitors (etanercept, infliximab, adalimumab)	No teratogenic effects or embryo-fetal toxicity in animal studies. **Use recommended** for severe, recalcitrant disease during pregnancy. Consider discontinuation after 30 weeks of gestation as monoclonal antibodies are actively transferred across placenta in third trimester. Avoid live vaccines in exposed infants for the first 6 months of life.	B
IL-17 & IL-17R inhibitors (secukinumab, ixekizumab, brodalumab)	Limited studies in pregnancy. No clear patterns of congenital abnormalities or spontaneous abortions were identified in pregnant women in post-marketing surveillance data for this class. In animal studies, no teratogenicity or embryo-fetal toxicity seen with secukinumab, but embryo-fetal toxicity seen at higher than MRHD with ixekizumab. **Use with caution** due to limited safety data. Consider discontinuation after 30 weeks of gestation as monoclonal antibodies are actively transferred across placenta in third trimester. Avoid live vaccines in exposed infants for the first 6 months of life.	B (secukinumab) N/A (ixekizumab, brodalumab)
IL-12/23 & IL-23 inhibitors (ustekinumab, guselkumab, risankizumab, tildrakizumab)	No adverse effects reported in infants exposed to ustekinumab during pregnancy. No teratogenicity, embryo-fetal toxicity or adverse developmental effects in animal studies seen with ustekinumab, but neonatal deaths at higher than MRHD found with guselkumab. **Use with caution** due to limited safety data. Consider discontinuation after 30 weeks of gestation as monoclonal antibodies are actively transferred across placenta in third trimester. Avoid live vaccines in exposed infants for the first 6 months of life.	B (ustekinumab) N/A (all others)

MANAGEMENT OF PSORIASIS AT SPECIFIC SITES	
Specific sites	**Special considerations and practical treatments**
Scalp	• Remove scale with topical 10%–15% salicylic acid • Apply potent or ultrapotent corticosteroids in a lotion, gel, foam or shampoo formulation, either alone or in combination with calcipotriene
Face; groin, axilla, and other body folds	• First-line: mild topical corticosteroids • Second-line: topical calcineurin inhibitors, roflumilast cream, tapinarof cream, or tacalcitol/calcitriol in combination with a mild topical corticosteroid
Nail (see Ch. 71)	• Differentiate proximal versus distal nail unit pathology due to nail matrix versus nail bed pathology, respectively; consider coexisting onychomycosis • For distal nail unit pathology: vitamin D_3 analogues topically (limited evidence) • For proximal pathology: intralesional corticosteroids and/or systemic antipsoriatic therapies

eTable 8.2 Management of psoriasis at specific sites. These sites do improve with systemic therapies, but involvement of these sites alone is usually not a sufficient indication for a systemic therapy.

TOPICAL TREATMENT AND ULTRAVIOLET B PHOTOTHERAPY IN THE SETTING OF COMORBIDITIES

SMALL PLAQUE PARAPSORIASIS

Synonyms: ■ Chronic superficial [scaly] dermatitis ■ Digitate dermatosis

Key features

- Chronic, asymptomatic, erythematous scaly patches
- Lesions are generally <5 cm in diameter or digitate
- Histologically, mild, nonspecific spongiotic dermatitis with parakeratosis is seen
- There is a predominance of $CD4^+$ T cells in the lymphocytic infiltrate
- A dominant T cell clonality is demonstrable in some cases

Introduction and History

Since the introduction of the term "parapsoriasis" by Brocq in 1902[1], there has been much confusion and debate regarding this controversial topic[2]. For example, the term "parapsoriasis en gouttes" is no longer used as it specifically refers to the entity pityriasis lichenoides. In addition, it can be difficult to clearly define the term "parapsoriasis en plaques", as the lesions vary in size from small to large and are often patches rather than plaques. Since the 1990s, many authors have proposed that *large plaque parapsoriasis* represents either the early patch stage of mycosis fungoides (MF), which has an indolent course and excellent prognosis, or is a precursor of MF[2]. Because the vast majority of patients have a benign clinical presentation and course, *small plaque parapsoriasis* is considered a separate entity[3]. Reports of patients with small plaque parapsoriasis progressing to MF are quite rare[4].

Epidemiology

Small plaque parapsoriasis is more common in middle-aged and elderly individuals, but it may also occur in children. Parapsoriasis peaks during the fifth decade of life and occurs in all racial groups and geographic regions. There is a male predominance (male : female ratio ~3 : 1).

Pathogenesis

The etiology of small plaque parapsoriasis is unknown. It is characterized by sparse lymphoid infiltrates within the superficial dermis (with variable exocytosis into the epidermis) that are composed primarily of $CD4^+$ T cells[5]. In some cases of small plaque parapsoriasis, T cell clonality has been demonstrated within the cutaneous infiltrate[5,6], and a clonal population may also be detected in the blood[7]. However, determining the significance of these findings can prove difficult. In most patients, molecular genetic studies demonstrate an oligoclonal or pseudo-monoclonal pattern[5].

Clinical Features

Despite inclusion of the word "plaque" in the terminology, small plaque parapsoriasis is a disease composed of patches with fine scales. The lesions are chronic and generally asymptomatic or mildly pruritic. They may wax and wane early on during their clinical course, but they typically become persistent and can slowly progress to become more extensive. Some cases regress fully, either spontaneously or after therapy, but this may require several months or years. Lesions can be widespread on the trunk and extremities or more limited in their distribution. In the latter instance, they often favor more sun-protected sites.

Small plaque parapsoriasis typically presents as round to oval patches that are generally <5 cm in diameter (Fig. 9.1A). They are variably erythematous (but often less intense than psoriasis) and covered with a fine scale. Some have a yellow hue, hence the historic term "xanthoerythrodermia perstans"[1]. A distinct and perhaps the most typical presentation is "digitate dermatosis", which presents as elongated, finger-like patches symmetrically distributed on the flanks[3] (Fig. 9.1B). These lesions are an exception to the 5-cm rule in that they may measure 10 cm or more along their long axis. Progression to MF is very rare, with <20 cases reported to date in the literature[4,5].

Pathology

Patches of small plaque parapsoriasis exhibit a mild, nonspecific spongiotic dermatitis with focal parakeratosis. Exocytosis of lymphocytes is variable but usually present. There are neither Pautrier microabscesses nor atypical lymphocytes, but haloed lymphocytes within the basal layer can be seen[5].

Differential Diagnosis

The diagnosis of small plaque parapsoriasis is based on clinicopathologic correlation, with other tests of minimal value. It is distinguished from large plaque parapsoriasis primarily on the basis of clinical features. The principal entities in the differential diagnosis are listed in Table 9.1.

Pityriasis rosea is distinguished from small plaque parapsoriasis by the presence of a herald patch and spontaneous resolution within a few months. Psoriasis and secondary syphilis are excluded on the basis of clinicopathologic and serologic features. Patients with pityriasis

PRINCIPAL DIFFERENTIAL DIAGNOSIS OF SMALL PLAQUE PARAPSORIASIS AND LARGE PLAQUE PARAPSORIASIS/ EARLY STAGE MYCOSIS FUNGOIDES

Small plaque parapsoriasis	Large plaque parapsoriasis/ early stage mycosis fungoides*
Pityriasis rosea	Drug eruption, in particular mycosis fungoides-like
Drug eruption, in particular pityriasis rosea-like	Psoriasis
Pityriasis lichenoides chronica	Poikilodermatous autoimmune connective tissue disease (e.g. dermatomyositis)
Psoriasis, including guttate	Poikilodermatous genodermatoses (see Table 63.9)
Mycosis fungoides	Chronic radiodermatitis
Secondary syphilis	
Nummular dermatitis	

*While some authors believe that large plaque parapsoriasis represents an entity distinct from mycosis fungoides (MF) or a potential precursor of MF, many authorities in the field of cutaneous lymphomas consider it to be an early manifestation of MF.

Table 9.1 Principal differential diagnosis of small plaque parapsoriasis and large plaque parapsoriasis/early stage mycosis fungoides.

Fig. 9.1 Small plaque parapsoriasis. A Small (<5 cm), dull pink, slightly scaly patches on the trunk. **B** Digitate dermatosis with elongated finger-like lesions on the flank that are pink–brown to yellow–brown in color. *A, Courtesy Lorenzo Cerroni, MD.*

THERAPEUTIC LADDER FOR SMALL PLAQUE PARAPSORIASIS AND LARGE PLAQUE PARAPSORIASIS/ EARLY STAGE MYCOSIS FUNGOIDES	
Small plaque parapsoriasis	**Large plaque parapsoriasis/ early stage mycosis fungoides* (see Ch. 120)**
• Topical corticosteroids, mid- to high-potency (2) • Sunlight (2) • Ultraviolet B (UVB) phototherapy – broadband or narrowband (2) • PUVA (psoralen plus UVA) phototherapy (2) • UVA1 phototherapy (2) • Antihistamines†	• Topical corticosteroids, high-potency (2) • Ultraviolet B (UVB) phototherapy – broadband or narrowband (2) • PUVA (psoralen plus UVA) phototherapy (2) • UVA1 phototherapy (2) • Topical bexarotene (2) • Topical imiquimod (3) • Topical nitrogen mustard (3) • Antihistamines†
*While some authors believe that large plaque parapsoriasis represents an entity distinct from mycosis fungoides (MF) or a potential precursor of MF, many authorities in the field of cutaneous lymphomas consider it to be an early manifestation of MF. †If pruritus is present.	

Table 9.2 Therapeutic ladder for small plaque parapsoriasis and large plaque parapsoriasis/early stage mycosis fungoides. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

lichenoides, acute and chronic, have lesions that are smaller and more widely distributed than do patients with small plaque parapsoriasis. Drug eruptions resembling pityriasis rosea or MF need to be considered and excluded.

Treatment

All therapeutic approaches are based primarily on uncontrolled case series, case reports, or anecdotal evidence (Table 9.2). Patients with small plaque parapsoriasis should be reassured that the risk of developing MF is extremely low. Patients may be followed without treatment if they prefer. Standard therapy includes topical corticosteroids and narrowband ultraviolet B (NB-UVB) therapy[8,9]. Clinical improvement is usually observed, but recurrences are common[9]. The role of phototherapy in terms of preventing progression to MF is uncertain[10].

LARGE PLAQUE PARAPSORIASIS

The exact nosology of large plaque parapsoriasis is still debated. While some authors believe that it represents an entity distinct from MF or a potential precursor of MF (see Ch. 120), many authorities in the field of cutaneous lymphomas consider it to be an early stage of MF. The clinical morphology (erythematous patches) and location (sun-protected sites) are similar to those of early MF, and the histopathologic features of untreated lesions can be indistinguishable from those of MF. The treatment options are the same as in early lesions of MF, and as in stage 1 A MF, a minority of patients progress to life-threatening disease and as a group they have the same survival as the general population. It should be emphasized that a diagnosis of early MF should be based on convincing clinicopathologic findings, eventually corroborated by molecular analysis of T cell receptor gene rearrangements.

PITYRIASIS LICHENOIDES

Synonyms: ■ Pityriasis lichenoides et varioliformis acuta (PLEVA) ■ Mucha–Habermann disease (PLEVA) ■ Pityriasis lichenoides chronica (PLC) ■ Guttate parapsoriasis (PLC)

Key features

- Pityriasis lichenoides et varioliformis acuta (PLEVA) and pityriasis lichenoides chronica (PLC) are two ends of a disease spectrum
- Both entities are characterized by recurrent crops of spontaneously regressing erythematous papules
- Lesions of PLEVA are crusted and occasionally vesiculopustular, whereas in PLC they are scaly
- Individual patients may show intermediate or mixed lesions
- Histologically, an interface dermatitis with necrotic keratinocytes is seen
- The infiltrate is predominantly T cells that are often monoclonal

Introduction

Pityriasis lichenoides is an uncommon disorder that encompasses pityriasis lichenoides et varioliformis acuta (PLEVA), the febrile ulceronecrotic Mucha–Habermann disease (FUMHD) variant of PLEVA, and pityriasis lichenoides chronica (PLC). These acute and chronic forms of pityriasis lichenoides exist on a disease spectrum with variable presentations that can pose diagnostic and therapeutic challenges[11,12]. They are papular, often clonal T cell disorders that may rarely be associated with MF[13].

History

The two major variants of pityriasis lichenoides – PLEVA and PLC – were described as the 19th century ended and the 20th century began[11]. Pityriasis lichenoides was included in Brocq's 1902 treatise[1] on a group of chronic, idiopathic dermatoses that he termed "parapsoriasis". Nowadays, however, it is considered a separate entity.

Epidemiology

Pityriasis lichenoides is more prevalent in the pediatric population[12], but it affects patients in all age groups, races, and geographic regions. There is a male predominance.

Pathogenesis

The etiology of pityriasis lichenoides is unknown. It has been postulated to be a response to foreign antigens such as infectious agents and drugs. There is some evidence to support PLEVA being associated with viral infections, especially varicella–zoster virus[14], and in a few reports, HIV[15], parvovirus B19[16], and Epstein–Barr virus. Additional reports have described its association with medications (e.g. estrogen–progesterone, infliximab, adalimumab, statins), radiocontrast dye, and vaccines[17,18].

Both PLEVA and PLC contain lesional T cell infiltrates, sometimes with dominant T cell clonality. The concept of pityriasis lichenoides as a T cell lymphoproliferative disorder may help to explain its occasional association with other lymphoproliferative disorders such as MF[13]. In addition, this would account for the variants of pityriasis lichenoides that have numerous $CD30^+$ cells[19] or γδ T cells[20] as well as the subgroups that have been referred to as atypical pityriasis lichenoides[21] and lymphomatoid pityriasis lichenoides[22]. Because differentiation from T cell lymphomas is sometimes difficult, patients with pityriasis lichenoides and an aberrant T cell phenotype should undergo longitudinal evaluation, with the final diagnosis based upon repeated clinicopathologic correlation, including phenotypic and molecular studies of T cell clonality[21].

Clinical Features

Pityriasis lichenoides presents as recurrent crops of spontaneously regressing erythematous to purpuric papules (Fig. 9.2). The acute form (PLEVA) and the chronic form (PLC) exist on a disease continuum. Many patients have intermediate or mixed manifestations, either serially or concurrently. In patients with PLEVA, individual lesions develop crusts, ulcers, and occasionally vesicles or pustules, which

Fig. 9.2 Clinical spectrum of pityriasis lichenoides. A–C In the acute form (PLEVA), widespread erythematous papules and papulovesicles are admixed with crusted lesions; sometimes, there can be an ulcerative component (**C**). **D** Individuals with the chronic form (PLC) develop multiple dull red–brown papules, some of which have scale and may be hypopigmented. **E** In some patients the majority of lesions are characteristic of one end of the spectrum, e.g. PLEVA, but with scattered lesions suggestive of PLC. **F** Rarely, a more severe potentially life-threatening form of PLEVA, termed febrile ulceronecrotic Mucha–Habermann disease (FUMHD), may occur *de novo* or in the setting of pre-existing PLEVA. *A, D, Courtesy Julie V. Schaffer, MD; B, Courtesy Thomas Schwarz, MD; C, F, Courtesy Lorenzo Cerroni, MD.*

may heal with varioliform scars if dermal damage is extensive. Lesions are usually asymptomatic and typically resolve within weeks. Disease manifestations are confined to the skin, except rarely, when acute lesions are associated with malaise, fever, lymphadenopathy, arthritis, and/or bacteremia. The term *febrile ulceronecrotic Mucha–Habermann disease (FUMHD)* has been used to refer to such severe variants in which large, confluent necrotic skin lesions (see Fig. 9.2F) as well as mucosal, gastrointestinal, and pulmonary involvement can be observed[23,24]. In the latter group, an associated mortality rate of up to 15% has been reported[23].

In PLC, the papules are erythematous to red–brown and scaly (see Fig. 9.2D). They pursue a more indolent course, regressing over weeks to months. When these lesions subside, there may be residual hypopigmented macules; the latter are more obvious in individuals with darker skin phototypes and may be the presenting complaint (Fig. 9.3). Pityriasis lichenoides can resolve spontaneously after weeks to months or it may pursue a chronic relapsing course, sometimes interspersed with long periods of remission. Some studies have suggested that the distribution of skin lesions is more important than their acute or chronic nature in predicting outcome[25]. The average course of disease was shorter in patients with a diffuse distribution, while those with a peripheral distribution had the longest clinical course. Compared to adults, children tend to have a more persistent course and widespread distribution of lesions[26].

Fig. 9.3 Chronic form of pityriasis lichenoides (PLC) presenting as macules of hypopigmentation. This is more common in individuals with darker skin phototypes. *Courtesy Antonio Torrelo, MD.*

Pathology

Pityriasis lichenoides exhibits a superficial perivascular interface dermatitis in all cases (Fig. 9.4). Those lesions at the acute end of the spectrum contain a denser infiltrate that may be top-heavy and wedge-shaped. There is commonly an infiltration of lymphocytes into the adnexal epithelia, both follicular and eccrine[27]. Lymphocytes predominate in the infiltrate, although neutrophils may be admixed. The epidermis shows parakeratosis and evidence of damage ranging from edema to extensive epidermal necrosis in well-developed lesions. Extravasation of erythrocytes is a frequent finding. While a perivascular lymphocytic infiltrate is a constant feature, a true lymphocytic vasculitis with fibrinoid necrosis of blood vessels is uncommon, occasionally occurring in PLEVA. All of these changes are blunted in the more chronic skin lesions, where the principal microscopic features include parakeratosis and a milder interface lymphocytic infiltrate that is accompanied by focal keratinocyte necrosis and mild erythrocyte extravasation.

Lymphoid atypia is not a standard feature of pityriasis lichenoides. What has been referred to as atypical pityriasis lichenoides was defined by conventional clinical and histologic features but with an aberrant T cell phenotype[21]. Some pathologists allow occasional atypical lymphocytes or $CD30^+$ lymphocytes[19], whereas others regard this as a sign of lymphomatoid papulosis[22]. Patients with small papules that resemble pityriasis lichenoides clinically but have Pautrier microabscesses histologically were described as having "pityriasis lichenoides-like mycosis fungoides"[28], but no patients in that series evolved into typical MF. Controversies regarding T cell lymphoproliferative disorders, however, still remain.

Differential Diagnosis

The diagnosis of pityriasis lichenoides is made by the correlation of clinical features with lesional histopathology. The principal differential diagnostic considerations for pityriasis lichenoides are listed in Table 9.3. For the more acute form (PLEVA), the primary entities in the clinical and histopathologic differential diagnosis include lymphomatoid papulosis, arthropod reactions, cutaneous small vessel vasculitis, varicella, and drug eruptions[29]. For the chronic form (PLC), the principal differential diagnosis includes guttate psoriasis, lichen planus (exanthematous), pityriasis rosea, secondary syphilis, lymphomatoid papulosis, drug eruptions, and papular dermatitis. All of these alternative diagnoses can usually be excluded on the basis of key historical, clinical, pathologic, and laboratory findings. More than one biopsy specimen, T cell immunophenotyping, and molecular studies of T cell clonality may be required to achieve clinicopathologic correlation. PCR, direct fluorescent antibody (DFA), and serologic testing as well as immunohistochemical staining are helpful in excluding varicella and syphilis.

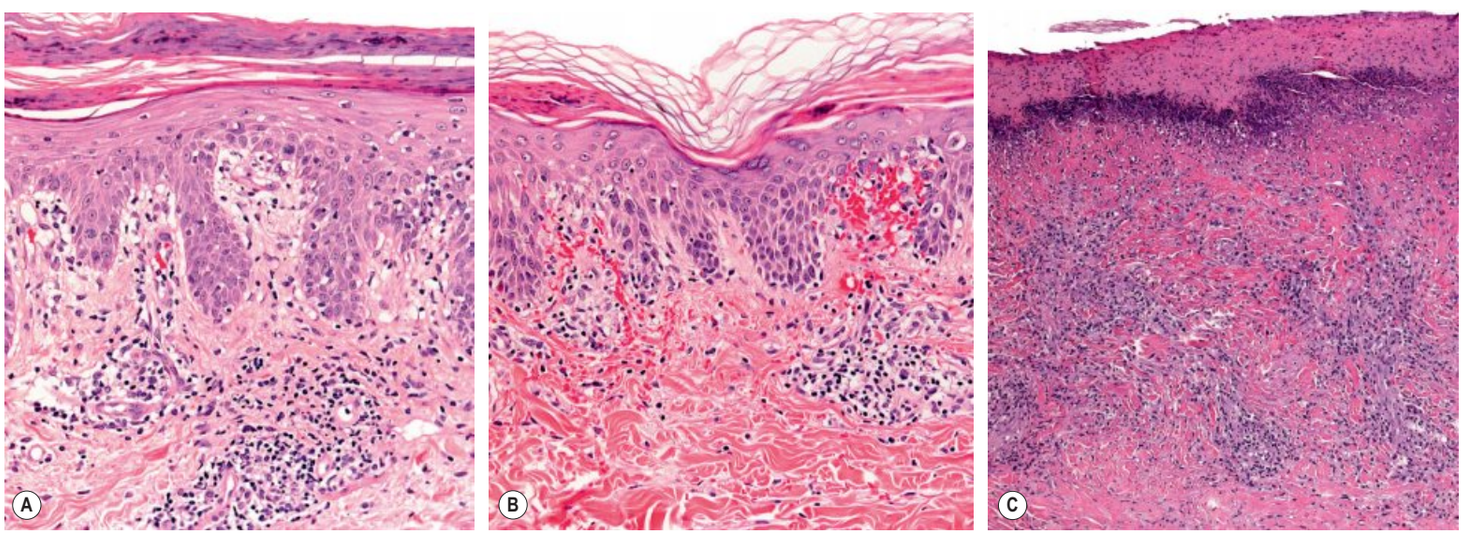

Fig. 9.4 Pityriasis lichenoides – histopathologic features. A In the chronic form (PLC), parakeratosis may be more prominent than in the acute form, but the epidermal destruction is less intense. **B** In the acute form (PLEVA), scattered necrotic keratinocytes are seen in addition to parakeratosis. The perivascular lymphoid infiltrates in the dermis are accompanied by extravasated erythrocytes, which are even present within the epidermis. As with the clinical presentations, there is a continuous histologic spectrum. **C** In the ulceronecrotic form, there is complete ulceration covered by crust. An intense lymphocytic infiltrate is seen within the dermis. *Courtesy Lorenzo Cerroni, MD.*

DIFFERENTIAL DIAGNOSIS OF PITYRIASIS LICHENOIDES	
Acute form (PLEVA)	**Chronic form (PLC)**
Lymphomatoid papulosis	Small plaque parapsoriasis
Cutaneous small vessel vasculitis	Guttate psoriasis
Varicella, enteroviral exanthems	Lichen planus (exanthematous)
Arthropod reactions	Pityriasis rosea
Erythema multiforme	Secondary syphilis
Lichenoid drug eruption	Lymphomatoid papulosis
PLEVA-like drug eruption (e.g. immune checkpoint inhibitors)	Papular dermatitis
Folliculitis	Lichenoid drug eruption
Dermatitis herpetiformis	PLC-like drug eruption (e.g. immune checkpoint inhibitors)
	When hypopigmented, extrafacial pityriasis alba

Table 9.3 Differential diagnosis of pityriasis lichenoides.

THERAPEUTIC LADDER FOR PITYRIASIS LICHENOIDES
Topical corticosteroids (2)
Topical calcineurin inhibitors (2)
Oral erythromycin (2)
Oral tetracyclines (2)
Oral azithromycin (3)
Ultraviolet B (UVB) phototherapy – broadband or narrowband (1)
PUVA (psoralen plus UVA) phototherapy (1)
Methotrexate (2)
Oral retinoids (3)
Dapsone (3)
Special treatments (3):
Antihistamines*
Systemic antibiotics†
Systemic corticosteroids‡, IVIg‡, cyclosporine‡ or TNF inhibitors‡
For recalcitrant FUMHD, JAK inhibitors or IL-6 inhibitors
*If there is pruritus.
†If there is secondary infection.
‡If there is fever, arthritis, or other systemic findings.

Table 9.4 Therapeutic ladder for pityriasis lichenoides. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

Treatment

All treatments for pityriasis lichenoides are based primarily on uncontrolled case series, case reports, or anecdotes (Table 9.4)[30]. If a drug association is suspected, trial discontinuance of the suspected agent is warranted. First-line therapy includes topical corticosteroids (limited efficacy), tetracyclines, macrolide antibiotics (e.g. erythromycin, azithromycin) and various types of phototherapy (most effective; e.g. narrowband UVB)[31]. Oral antibiotics are used for their anti-inflammatory effects, with macrolides favored in younger children. A several-month course is often required, followed by a gradual taper.

More fulminant cases may require low-dose weekly methotrexate. Those rare cases associated with fever and arthritis may benefit from systemic corticosteroids, IVIg or cyclosporine, once infection has been excluded. There are also reports of the efficacy of TNF inhibitors.

PITYRIASIS RUBRA PILARIS

Synonyms: ■ Lichen ruber pilaris ■ Devergie disease ■ Lichen ruber acuminatus

Key features

- Follicular papules with an erythematous base are a characteristic finding, including on the proximal dorsal fingers
- There is a coalescence of orange–red plaques, but with obvious islands of sparing
- An orange–red waxy keratoderma of the palms and soles is often seen
- Of the six types described, the classic adult form is the most common
- The classic types (adult and juvenile) typically resolve within 3–5 years
- Type V, the atypical juvenile form, is frequently due to *CARD14* mutations
- Histologically, there is alternating ortho- and parakeratosis, both vertically and horizontally

History

Pityriasis rubra pilaris (PRP) was first described in 1835 by Claudius Tarral as a variant of psoriasis and it was given several names during the 19th century. Devergie called it "pityriasis pilaris", and later Besnier recommended the name "pityriasis rubra pilaris" in the first comprehensive illustrated article on the disease.

Epidemiology

Although PRP shows no sex bias, affecting both men and women equally, ethnic variations may exist. The incidence of this uncommon disease has two major peaks, one during the first and second decades and the second during the sixth decade[32].

Most cases are acquired, but there are familial forms, primarily autosomal dominant and less frequently autosomal recessive. The dominantly inherited form of PRP is associated with heterozygous gain-of-function mutations in *CARD14*, which encodes the caspase recruitment domain family member 14[33]. Except for the latter group of patients and those with the non-classic forms, PRP appears to be a self-limited disease process, resolving within 3 to 5 years in almost all cases.

Pathogenesis

Excluding inherited PRP due to *CARD14* mutations, infections, UV exposure, and various minor traumas to the skin have been reported to precede the onset of PRP. Autoimmunity (e.g. associated thyroid disease) or an abnormal immunologic response to particular antigens may play a role, as in patients with HIV-associated PRP (type VI). Paraneoplastic PRP has also been described in individuals with solid-organ malignancies such as renal cell, bronchogenic, and hepatocellular[34]. Rarely, drugs or vaccines have been implicated in triggering PRP, including infliximab, tyrosine kinase inhibitors (e.g. ponatinib, imatinib), and antivirals (e.g. sofosbuvir)[35].

Clinical Features

The clinical features of classic PRP are helpful in making the diagnosis. Follicular hyperkeratosis on an erythematous base is a key finding (Fig. 9.5). This results in rough papules, especially on the dorsal aspect of the proximal fingers, reminiscent of a nutmeg grater. These papules are also seen on the trunk and extremities, and they can coalesce to form large salmon-colored to orange–red plaques with distinctive "islands of sparing". The plaques can then progress to an erythrodermic appearance with varying degrees of exfoliation (see Figs. 10.7 & 10.8). The palms and soles are commonly involved with a distinctive orange–red waxy keratoderma (Fig. 9.6). Erythema with a fine diffuse scale is often seen on the scalp. Of note, scalp disease that mimics seborrheic dermatitis is a common initial clinical manifestation of adult PRP, and rapid progression to erythroderma can occur over several weeks.

Fig. 9.5 Pityriasis rubra pilaris. A Orange–red follicular papules with coalescence into large scaly plaques, in addition to islands of sparing; follicular hyperkeratosis is often easier to appreciate within the relatively spared islands. **B** On the dorsal aspects of the digits, clustered keratotic follicular papules can resemble a "nutmeg grater". **C** The islands of sparing may be sharply demarcated; note the salmon color of the plaques. Both photoaggravated and phototriggered forms of PRP exist. Patients can eventually become diffusely erythrodermic, but follicular accentuation of the scale (**D**) and small islands of sparing (**E**) can provide clues. *B, Courtesy Antonio Torrelo, MD; C, Used with permission of the Mayo Foundation for Medical Education and Research.*

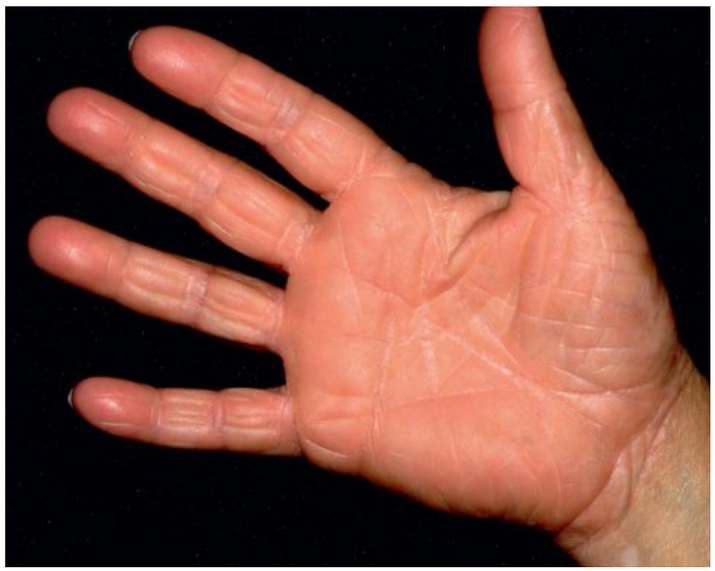

Fig. 9.6 Pityriasis rubra pilaris. The orange–red color of the skin, including that of the palmar keratoderma, aids in the clinical diagnosis. *Courtesy Luis Requena, MD.*

Nail involvement is characterized by a thickened plate with a yellow–brown discoloration and subungual debris. The mucous membranes are rarely involved, but they may show features similar to oral lichen planus.

The most common form of PRP (type I) usually begins in the head and neck region and then progressively advances caudally. Pruritus and burning have been reported in 20% of patients with PRP. Although less common than in atopic dermatitis or Darier disease, Kaposi varicelliform eruption can occur in patients with PRP. As with other forms of erythroderma (see Ch. 10), eruptive seborrheic keratoses may appear. Both photoaggravated and phototriggered forms of PRP can also occur (see Fig. 9.5C). Resolving PRP may have a clinical appearance that resembles erythema gyratum repens (see Fig. 19.9).

The classification of the different forms of PRP is based upon age, duration, and type of cutaneous involvement (Fig. 9.7)[36]. Type I (classic adult) PRP is the most common form and is typically self-limited, clearing within 3 years in 80% of patients. Type II differs from type I by a palmoplantar keratoderma with a coarse and lamellated scale, a more ichthyosiform scaling on the lower extremities, occasional alopecia, and a protracted clinical course.

PRP types III–V are seen in children and adolescents. Type III, the classic juvenile form, closely resembles the classic adult form and

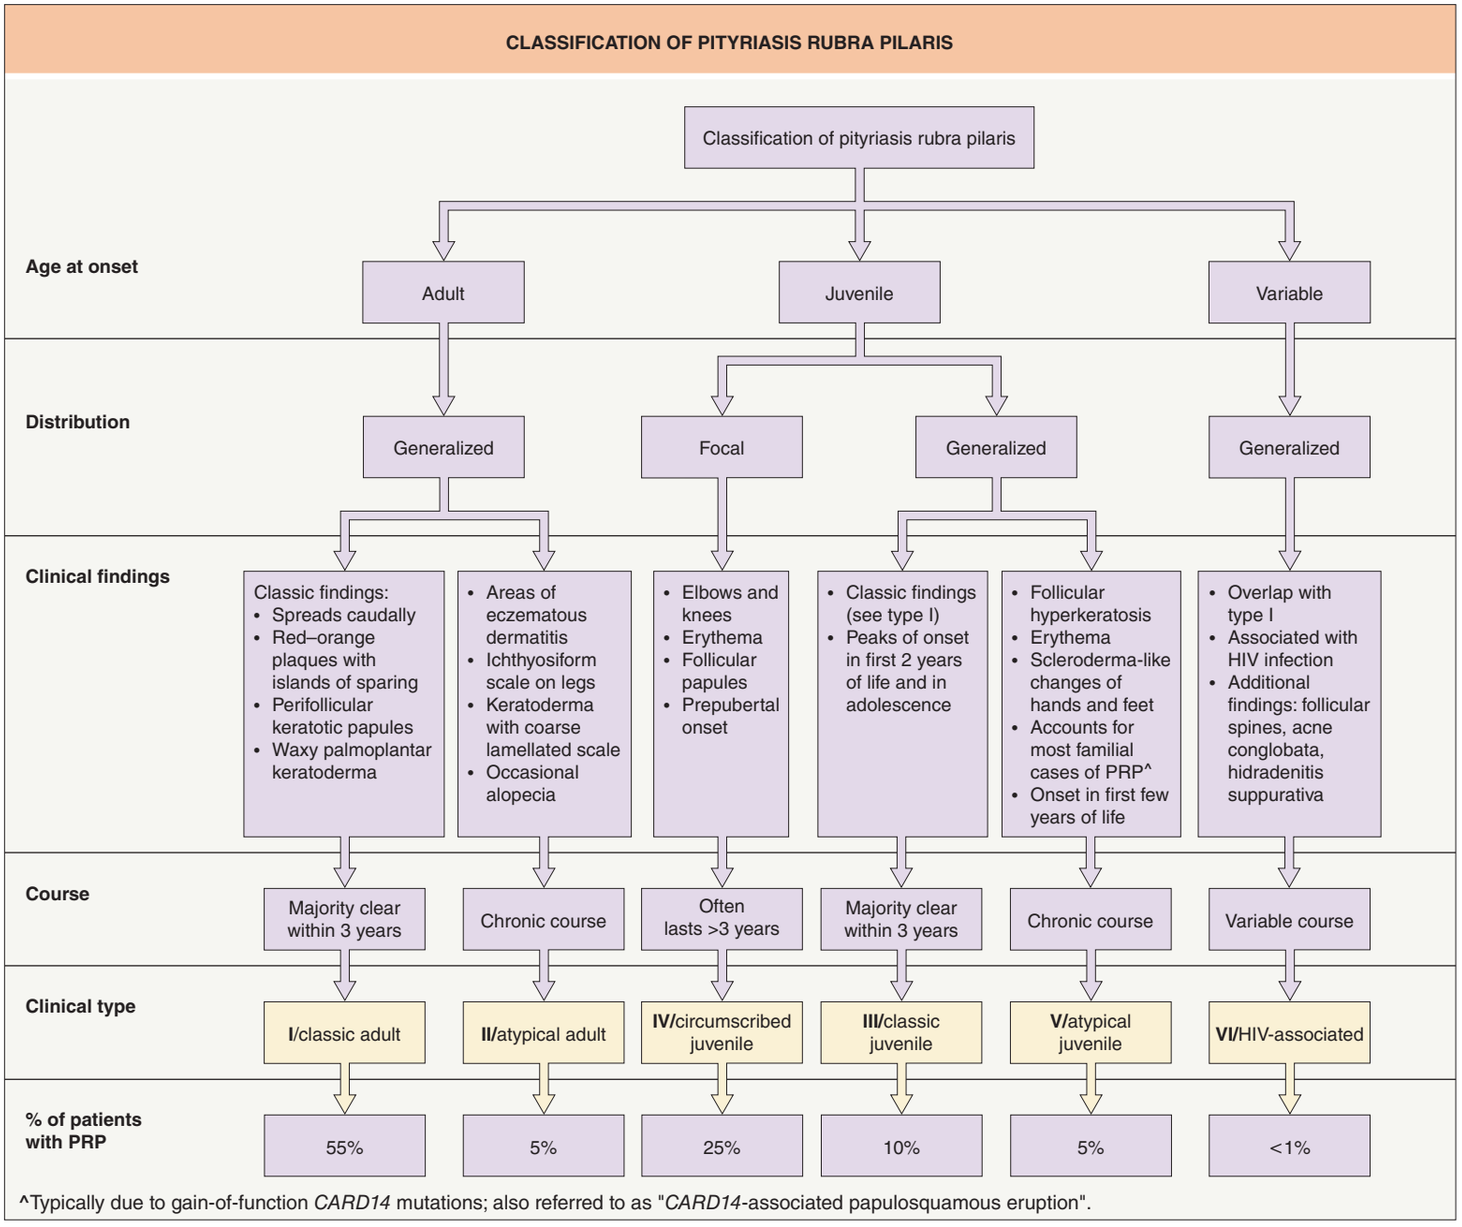

Fig. 9.7 Classification of pityriasis rubra pilaris (PRP). Type VI PRP is also referred to as HIV-associated follicular syndrome.

also typically clears within 3 years. Type IV (circumscribed) is the most common of the juvenile forms, and its focal nature sets it apart from the other clinical presentations (Fig. 9.8). Type V, the atypical juvenile form, is frequently due to *CARD14* mutations; it has features similar to type II but with more ichthyosiform scaling and a chronic course (see Fig. 8.9). Patients with *CARD14* mutations tend to present with clinical features observed in both PRP (often resembling type V PRP but sometimes with classic "islands of sparing") and psoriasis. These patients have been referred to as having "*CARD14*-associated papulosquamous eruption (CAPE)". In addition to a family history of PRP or psoriasis, characteristic features of CAPE include an early age of onset; prominent involvement of the cheeks, chin, and ears; involvement of the palms and soles; and a chronic course with a variable response to conventional treatments[33]. Gain-of-function *CARD14* mutations have rarely been detected in other types of PRP[37].

PRP type VI is associated with HIV infection, and while it often fails to respond to conventional therapy for PRP, it may improve with antiretroviral therapy. These patients can have erythematous follicular papules and keratotic spines as well as nodulocystic lesions of acne conglobata and hidradenitis suppurativa. In addition, coalescence of inflammatory plaques into an erythroderma may occur, as in PRP type I.

Pathology

Psoriasiform dermatitis with irregular hyperkeratosis and alternating vertical and horizontal ortho- and parakeratosis ("checkerboard pattern") is distinctive (Fig. 9.9A). The hair follicles are dilated and filled with a keratinous plug, while the "shoulder" of stratum corneum surrounding the follicular opening frequently shows parakeratosis (Fig. 9.9B). The interfollicular epidermis often exhibits hypergranulosis as well as thick, shortened rete pegs. A sparse lymphohistiocytic perivascular infiltrate is seen in the underlying dermis. Acantholysis and focal acantholytic dyskeratosis within the epidermis have also been described and can be helpful in distinguishing PRP from psoriasis. In CAPE, histopathologic features are more similar to PRP than to psoriasis, including alternating checkerboard parakeratosis and orthokeratosis and follicular plugging[38].

Differential Diagnosis

The major entity in the differential diagnosis is psoriasis. The distinctive orange–red palmoplantar keratoderma plus the keratotic follicular papules with a nutmeg grater appearance, the classic islands of sparing of the trunk, and a finer scale (see Fig. 10.7), help differentiate PRP from psoriasis. The presence of oil-drop changes, small pits, and marginal

onycholysis of the nails favor psoriasis. Microscopically, acantholysis and focal acantholytic dyskeratosis, if present, are especially useful in diagnosing PRP rather than psoriasis. A thickened granular cell layer, short thicker rete pegs, limited vascular dilation in the dermal papillae, and the absence of both neutrophilic migration towards the epidermis and Munro microabscesses further help distinguish PRP from psoriasis. Histopathologic features of PRP may be seen in patients with what has been described as facial discoid dermatosis.

Early PRP of the scalp can mimic seborrheic dermatitis. The relative recalcitrant nature of scalp PRP may serve as a clue to the diagnosis. A PRP-like eruption can be seen in patients with dermatomyositis (Wong type) and cutaneous T cell lymphoma, as can erythema and scaling of the scalp. Children with acute-onset PRP may be misdiagnosed as having Kawasaki disease, and, occasionally, PRP is confused with erythrokeratodermia variabilis et progressiva or ichthyosis with confetti.

Keratotic follicular papules are also seen in keratosis pilaris and lichen spinulosus, but the lesions are more limited in scope and the other manifestations of PRP are absent. The various disorders that can present as an erythroderma are discussed in Chapter 10.

Fig. 9.8 Circumscribed juvenile pityriasis rubra pilaris (type IV). Symmetric pink plaques with scale are present on the dorsal aspect of the fingers, metacarpophalangeal joints, and knees. There are follicular keratotic papules on the knees. *Courtesy Antonio Torrelo, MD.*

Treatment

Therapy for PRP is primarily empiric, based upon case series and case reports, and often involves a combination of topical and systemic therapies. *Topical therapies* alone are typically insufficient for most patients with PRP, unless there is limited disease. Topical high-potency corticosteroids, tar, calcipotriene (calcipotriol), keratolytics (e.g. urea, salicyclic acid), and retinoids (e.g. tazarotene, tretinoin) can be used as adjuncts to systemic therapy.

Systemic retinoids represent a first-line treatment for PRP in both adults and children; an excellent response is seen in >40% of patients[39]. Isotretinoin (0.5 to 1 mg/kg/day) and acitretin (0.5 mg/kg/day) are the two most commonly prescribed retinoids, with scattered reports of some efficacy with alitretinoin. There are reports of the occasional use of higher doses of isotretinoin, but in the opinion of the authors, this is not recommended. Significant clearing is usually seen within 3–6 months of instituting therapy.

Methotrexate (5–25 mg/week) is considered second-line therapy for PRP, in particular for patients who have failed or cannot tolerate systemic retinoids. A response rate of >90% and complete clearance in ~40% of patients has been observed[40]. As with retinoids, clinical responses are usually seen within 3–6 months. Hepatotoxicity and myelosuppression are well-known potential side effects (see Ch. 130).

In severe cases of PRP, a combination of methotrexate (5–25 mg/week) plus a systemic retinoid (acitretin) has been utilized. Both agents can be given at the onset of therapy, or the second medication can be added if the response to the first is inadequate. In this situation, an increased risk for hepatotoxicity must be kept in mind.

Based upon case reports and small case series, TNF inhibitors (e.g. etanercept, infliximab, adalimumab), secukinumab, and ustekinumab have led to improvement of PRP[41]. A marked to complete response was noted in 50%–80% of patients. In a small series of patients, ixekizumab was reported to be moderately successful[42]. Ustekinumab, often at higher doses, has been reported as beneficial in patients with CAPE. Due to limited data as well as the natural history of PRP, precise efficacy is difficult to assess.

Other anecdotal potential therapies include systemic immunosuppressives (e.g. azathioprine, prednisone, cyclosporine), apremilast, and IVIg, with variable results observed. Although UV light therapy runs the risk of exacerbating the disease, there are some reports of success with narrowband UVB, UVA1, or PUVA in combination with an oral retinoid[36,43].

Less toxic regimens are recommended for the classic juvenile form of PRP, given the high likelihood of spontaneous remission and the potential long-term effects of aggressive systemic therapies.

PITYRIASIS ROSEA

Synonym: ■ Pityriasis rosea Gibert

Key features

- A self-limited papulosquamous eruption that is occasionally pruritic
- Seen primarily in adolescents and young adults, favoring the trunk and proximal extremities
- Herald patch followed by lesions that are usually oval in shape and oriented with their long axes along Langer cleavage lines
- Less common variants include inverse, vesicular, purpuric, and pustular

Introduction

Pityriasis rosea is a common, "acute", self-limited papulosquamous eruption that favors otherwise healthy adolescents and young adults. Its striking appearance often prompts a request for medical evaluation. There is an absence of significant systemic manifestations, and its spontaneous resolution provides great consolation to the patient. Although the classic presentation is readily recognized, atypical forms may present a greater challenge. A viral etiology has been postulated, but this remains unproven.

History

Robert Willan described "roseola annulata" in 1798 as a self-limited eruption in otherwise healthy children. In 1860, the French physician Camille Melchior Gibert first named the condition pityriasis (scaly) rosea (pink). This aptly conveyed the clinical features and remains the name that is still used today.

Epidemiology

Most cases of pityriasis rosea occur in young healthy persons, the majority of whom are between the ages of 10 and 35 years[44]. Its peak incidence is during adolescence, and it is rarely diagnosed before the age of 2 years. There is no racial predilection and it is found worldwide. There may be a slight female predominance. The typical eruption lasts 6 to 8 weeks, though exceptionally it can persist for 5 months or longer. Some authors report a modest seasonal variation with peaks in the spring and fall or in some countries during the rainy season.

Pathogenesis

The precise cause of pityriasis rosea remains elusive, and although a viral etiology is frequently proposed, this remains controversial[45]. While attention has focused on human herpesvirus-7 (HHV-7) and, less so, on HHV-6, some studies have shown no difference in the prevalence of DNA from HHV-6 or HHV-7 in peripheral blood mononuclear cells of patients with pityriasis rosea. An association with HHV-8, H1N1 influenza virus, and SARS-CoV-2 has also been reported[46]. Proponents of a viral etiology point to the prodromal symptoms experienced by some patients, the clustering of cases, and the rarity of recurrent episodes, suggesting an immunologic defense against an infectious agent. Pityriasis rosea is considered a prototypic paraviral exanthem, i.e. a characteristic skin disease associated with a possible viral infection or reactivation, but without virus identified in the cutaneous lesions[47,48].

Clinical Features

Although classic pityriasis rosea is usually easily recognized, the more unusual variants can be more challenging to diagnose[49]. In the classic presentation, a solitary lesion appears on the trunk and enlarges over several days (Fig. 9.10)[49,50]. Less often, this initial lesion is seen on the neck or proximal extremities. It predates the remainder of the eruption by hours to days and is referred to as the "herald patch" because it heralds the onset of the disease. Its incidence varies, but in most series it has been seen in over 50% of cases. Multiple herald patches have also been reported.

The herald patch is a pink- to salmon- to pink–brown-colored patch or plaque with a slightly raised advancing margin (Fig. 9.11). The size commonly varies from 2 to 4 cm, but it can be as small as 1 cm or as large as 10 cm. The center shows the characteristic small fine scales

Fig. 9.10 Pityriasis rosea with a herald patch on the left breast. Numerous symmetrically distributed pink papules on the trunk that are round or oval in shape; associated scale is most obvious on the neck and breasts. Fewer lesions are noted on the flexor surfaces of the arms.

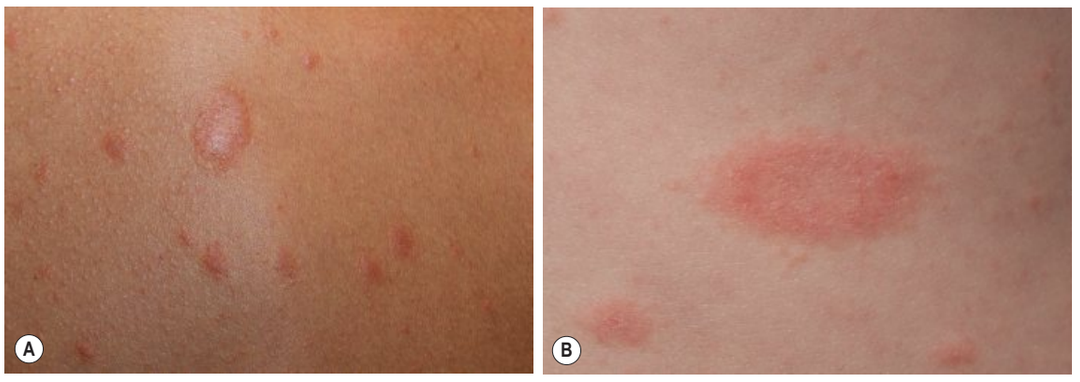

Fig. 9.11 Pityriasis rosea. A, B Herald patches in two patients with different skin phototypes. Either central or peripheral white scale can be seen. *A, Courtesy Kalman Watsky, MD; B, Used with permission of the Mayo Foundation for Medical Education and Research.*

of pityriasis rosea, and the margin has a larger, more obvious trailing collarette of scale with the free edge pointing inwards. There may be a mild prodrome with headache, fever, arthralgias, or general malaise. On occasion, the herald patch appears simultaneously with the more widespread eruption.

Typically, within the next few days, there is a blossoming of lesions on the trunk and proximal extremities. These numerous smaller thin papules and plaques are reminiscent of the larger herald patch that predated them; in more darkly pigmented skin, the lesions tend to be more papular, folliculocentric, and hyperpigmented (Fig. 9.12). Again, there is a subtle advancing border, central fine scaling, and the characteristic collarette of scale (Fig. 9.13A,B). The lesions are usually round to oval in shape, with their long axis following Langer cleavage lines (Fig. 9.13C). On the posterior trunk, such an orientation leads to what is often referred to as a "fir tree" or "Christmas tree" pattern. Minute pustules can also be seen during this initial phase of pityriasis rosea. The face, palms, and soles are usually (but not always) spared. When all these features are present, the diagnosis is easiest to establish.

The eruption of pityriasis rosea usually persists for 6–8 weeks and then spontaneously resolves; however, occasional patients have lesions that may last 5 months or longer[49]. In the latter situation, the possibility of pityriasis lichenoides chronica arises. Most patients with pityriasis rosea experience few symptoms, but in some individuals, pruritus is noted that is mild to severe.

Atypical forms of pityriasis rosea require a more astute observer. Inverse pityriasis rosea involves the axillae and inguinal areas (see Fig. 9.13B) and sometimes the face. It is more common in younger children and in those with darker skin phototypes. Oral lesions are also uncommon, but they may be underreported and palmoplantar involvement is unusual. Urticarial, erythema multiforme-like, vesicular, pustular, and purpuric variants have also been described.

Fig. 9.12 Follicular accentuation of pityriasis rosea in darkly pigmented skin. Note the central hyperpigmentation and the small follicular papules. *Courtesy Aisha Sethi, MD.*

Pathology

The microscopic features of pityriasis rosea include spongiotic dermatitis, along with elongation of the rete ridges and enlargement of the dermal papillae. Small mounds of parakeratosis and a predominantly papillary dermal infiltrate comprised of lymphocytes and histiocytes are also common features (Fig. 9.13D). There may be mild erythrocyte extravasation with scattered intraepidermal erythrocytes. In severe cases, these features are more pronounced, including the rare formation of intraepidermal pustules.

Most patients with pityriasis rosea do not have biopsies performed, because the clinical picture is quite characteristic.

Differential Diagnosis

Pityriasis rosea can sometimes be difficult to distinguish from secondary syphilis. The presence of cutaneous signs such as split papules and condyloma lata points to syphilis, as does the history or presence of a primary chancre. Patients with secondary syphilis usually have more systemic complaints, and they often have peripheral lymphadenopathy. Histologically, the absence of plasma cells favors pityriasis rosea and immunohistochemical staining for spirochetal antigens can also be done (see Ch. 0). Serologic testing allows the diagnosis of secondary syphilis to be confirmed.

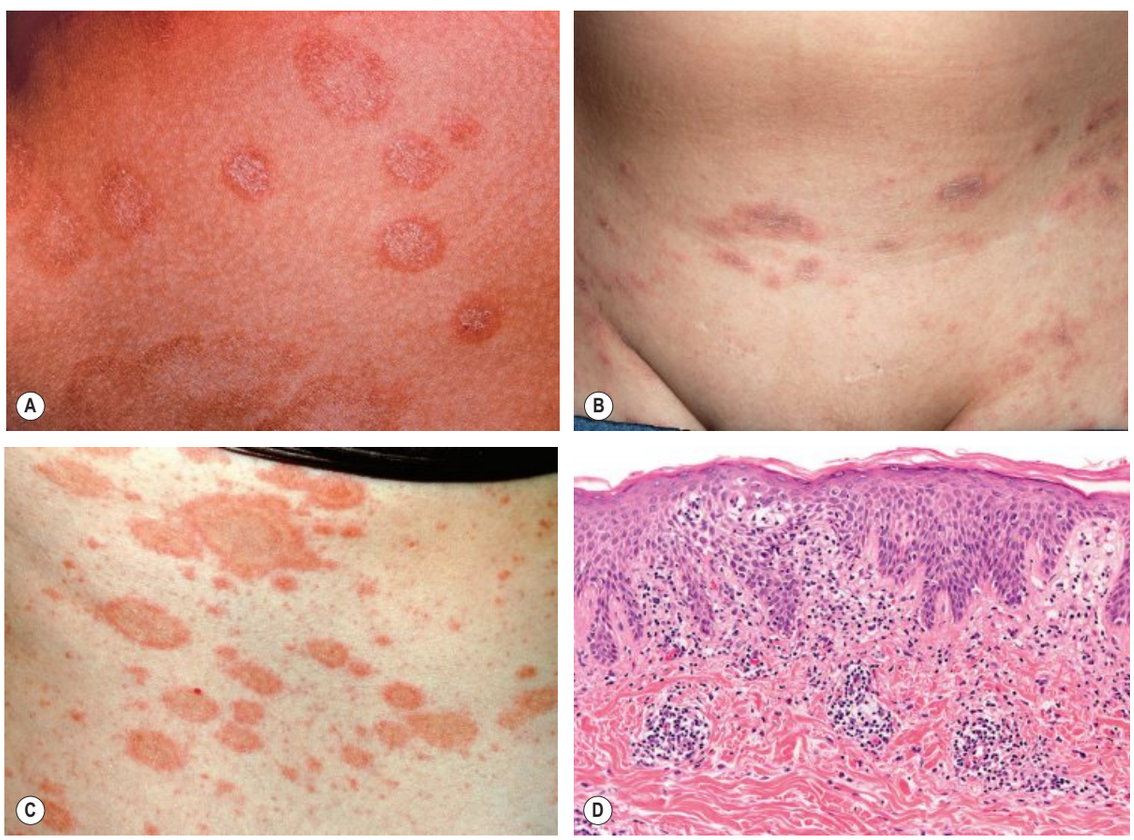

Fig. 9.13 Pityriasis rosea. A Both oval and round plaques can be seen as well as central fine scale. **B** A collarette of scale can also be seen and when lesions are limited to the pelvic region and/or axillae, the pattern of involvement is termed *inverse*. **C** A more inflammatory border may be seen and the long axes of the oval plaques follow skin cleavage lines. **D** Histopathologically, parakeratosis, mild spongiosis associated with exocytosis of lymphocytes into the epidermis, perivascular dermal lymphocytic infiltrates, and extravasated red blood cells are seen. *B, Courtesy Luis Requena, MD; C, Courtesy Julie V. Schaffer, MD; D, Courtesy Lorenzo Cerroni, MD.*

There are drug eruptions that can mimic pityriasis rosea; they have been reported in patients receiving angiotensin-converting enzyme (ACE) inhibitors, β-blockers, metronidazole, and isotretinoin, as well as arsenic, bismuth, gold, barbiturates, clonidine, hydrochlorothiazide, imatinib, omeprazole, terbinafine, TNF inhibitors, NSAIDs, and multiple vaccines[51]. A drug-induced pityriasis rosea-like eruption is often slower to resolve than the idiopathic form.

The herald patch or generalized eruption can resemble tinea corporis, tinea versicolor, or nummular dermatitis. The presence of the collarette of scale, the orientation of the lesions, and the history can help distinguish pityriasis rosea from nummular dermatitis. Guttate psoriasis usually has a thicker scale, smaller size, and lacks the fir-tree distribution. Other papulosquamous disorders such as pityriasis lichenoides should also be considered, especially when lesions last longer than 4 months.

Treatment

Because pityriasis rosea is often asymptomatic and self-limited, patient education and reassurance represent a satisfactory treatment plan. In patients with pruritus, counterirritant antipruritic lotions or low- to medium-strength topical corticosteroids may be needed for symptomatic relief. In more severe cases, UVB phototherapy (broadband or narrowband) or natural sunlight exposure and oral antihistamines can be used[52]. Rarely, a brief course of systemic corticosteroids may be required. In a 2019 Cochrane review, oral acyclovir was found to lead to "good or excellent" improvement of lesions with inconclusive effect on pruritus and oral erythromycin was shown to decrease pruritus[53]. However, a pathogenetic explanation for these findings is not clear.

Lastly, in pregnant women, there is a possible association between the development of pityriasis rosea and spontaneous abortion when there is active HHV-6 infection, in particular during the first 15 weeks of gestation[54].

PITYRIASIS ROTUNDA

Synonyms: ■ Tinea circinata ■ Pityriasis circinata

Key features

- Asymptomatic dermatosis seen primarily in the Far East and Mediterranean basin and in individuals of African descent
- There are large circular and polycyclic scaly patches with sharp margins that are typically hyperpigmented > hypopigmented and localized to the trunk and proximal extremities
- Histologic features are similar to those of ichthyosis vulgaris

Introduction

Pityriasis rotunda is an unusual dermatosis that can occur alone or in association with a number of unrelated conditions. There are familial cases that may represent a minor acquired ichthyosis.

History

Pityriasis rotunda was first described by Toyama in 1906 as "tinea circinata" and was later named pityriasis rotunda by Matsura.

Epidemiology

Pityriasis rotunda is most commonly observed in adults in their 30s and in children and has a slight female predominance[55,56]. It has been described in the Far East (Japan and China), the Mediterranean basin (Morocco, Italy, and Israel), and in Africans, African-Americans, and Afro-Caribbeans.

Pathogenesis

No clear unifying cause has been identified. In adults, possible associations include malnutrition, mycobacterial diseases (tuberculosis and leprosy), malignancies (e.g. hepatocellular carcinoma, gastric carcinoma, multiple myeloma), and hepatic cirrhosis[57]. However, the majority of patients, especially children, are in good health[58]. An absence of profilaggrin N-terminal domain and decreased expression of filaggrin-2 have been observed in some patients[59].

Fig. 9.14 Pityriasis rotunda. Circular, well demarcated, thin plaque with scale. *Courtesy Richard M. Haber, MD.*

Clinical Features

Pityriasis rotunda is typically asymptomatic and is characterized by large circular and polycyclic lesions that are often 10 cm (but may be up to 30 cm) in diameter (Fig. 9.14). They have associated fine scale and are moderately hyperpigmented with a sharp margin and no inflammation. The trunk and extremities are favored. A hypopigmented halo has been described in some patients, and sometimes the entire lesion can be hypopigmented.

Grimalt proposed categorizing pityriasis rotunda into two groups[60]. Type I is seen primarily in Black and Asian individuals as hyperpigmented lesions, possibly in association with malnutrition or internal malignancy but with no family history. Type II occurs in younger White individuals with numerous (>30) lesions who sometimes have a family history, but no associated diseases.

Pathology

Pityriasis rotunda has microscopic features of ichthyosis vulgaris, i.e. an absent or diminished granular cell layer and moderate hyperkeratosis without parakeratosis[59]. Increased pigmentation of the basal cell layer, pigment incontinence, a perivascular lymphohistiocytic infiltrate, and follicular plugging may also be observed. Special stains for fungi are negative.

Differential Diagnosis

The differential diagnosis includes tinea corporis, tinea versicolor, leprosy, and MF. The combination of fungal culture and routine histology excludes major entities in the differential diagnosis. The hypopigmented variant of pityriasis rotunda can resemble one variant of progressive macular hypomelanosis, which has no associated scale and lacks the histologic features of ichthyosis vulgaris.

Treatment

Pityriasis rotunda is relatively difficult to treat. Trials with topical lactic acid, urea, tars, emollients, and corticosteroids have provided little benefit. Topical tretinoin cream can result in modest improvement and systemic retinoids warrant consideration for patients with more extensive disease. Spontaneous remission is possible[55].

GRANULAR PARAKERATOSIS

Synonyms: ■ Axillary granular parakeratosis ■ Intertriginous granular parakeratosis

Key features

- Brownish-red keratotic papules that can coalesce into plaques
- Adult form occurs more often in women and favors the axillae over other intertriginous areas
- Infantile form is associated with diaper wearing or chemical irritation (e.g. use of benzalkonium chloride) and presents as bilateral inguinal plaques or erythematous geometric plaques underneath diaper pressure points
- Histopathology is distinct, with retention of basophilic keratohyaline granules within areas of parakeratosis in the stratum corneum
- A defect in processing profilaggrin to filaggrin is a proposed mechanism

Introduction

Granular parakeratosis is an acquired, typically pruritic disorder of the axillae and other intertriginous sites, e.g. the groin and inframammary and abdominal folds. It has distinct histopathologic findings, suggesting a disorder in keratinization[61].

History

Northcutt and colleagues[61] first described granular parakeratosis in 1991. Multiple cases have been described since then in various clinical settings, suggesting a multifactorial reactive condition[62].

Epidemiology

Granular parakeratosis is observed most commonly in middle-aged women[62]. Although it is less common in young adults, there are reports in infants and children linked to diaper-wearing and exposure to benzalkonium chloride in laundry rinse aids[63]. Granular parakeratosis has been observed in all skin phototypes.

Pathogenesis

Granular parakeratosis is an acquired keratotic dermatosis originally linked to maceration and the use of various personal hygiene products, such as deodorants and antiperspirants. More recently, occlusion from diapers or chemical irritation from benzalkonium chloride (see above) has been implicated[63].

A disorder of keratinization characterized by a basic defect in the processing of profilaggrin to filaggrin has also been proposed, based upon ultrastructural and immunohistochemical studies, i.e. retention of keratohyalin granules within the stratum corneum due to a defect in filaggrin metabolism[64]. This suggests a distinctive reactive pattern rather than a specific entity[65].

Clinical Features

The primary lesions are keratotic, brownish-red papules that can have a conical shape. They may coalesce into larger, well-demarcated plaques with various degrees of maceration secondary to local occlusion (Fig. 9.15). Lesions can persist for months or longer and recur. Pruritus is the most common complaint, but irritation is also a problem if there are erosions or fissures. Some patients experience a flare with an increase in ambient temperature and sweating. The axilla is the most common site of involvement, followed in frequency by other major body folds (e.g. inguinal, inframammary). Occasionally granular parakeratosis develops in the genital area[66].

In infants, bilateral plaques within the inguinal folds or erythematous geometric plaques underlying pressure points from the diaper can be seen. Larger lesions in other intertriginous sites have been observed in older children[63].

Pathology

The characteristic feature is an unusual form of parakeratosis. The stratum corneum is thickened and compacted with increased eosinophilic staining (Fig. 9.16). Retained nuclei are present throughout this keratin layer, creating parakeratosis. The most unusual feature is the visible retention of basophilic keratohyalin granules within these areas of parakeratosis[61,64]. Because clinically similar lesions may not have these characteristic histologic features, the encompassing term "hyperkeratotic flexural erythema" has been proposed[65].

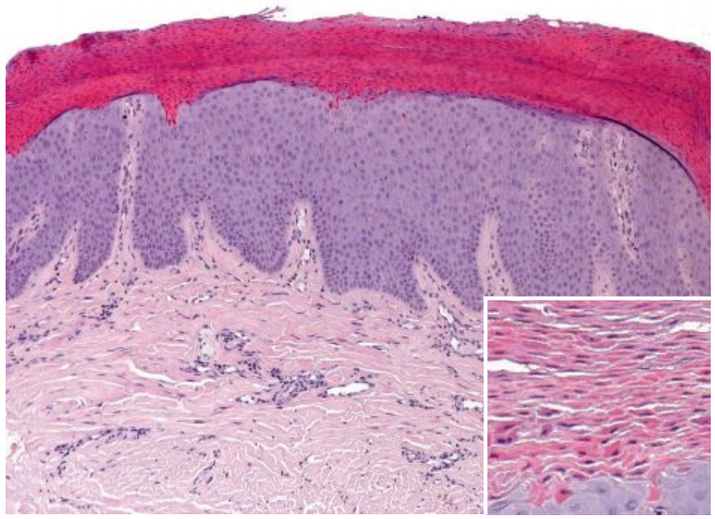

Fig. 9.16 Axillary granular parakeratosis – histopathologic findings. Marked, compact parakeratosis with small bluish granules within the stratum corneum representing keratohyaline granules (inset). *Courtesy Lorenzo Cerroni, MD.*

Differential Diagnosis

The differential diagnosis includes the most common causes of intertrigo (e.g. seborrheic dermatitis, candidiasis, inverse psoriasis, erythrasma) as well as Hailey–Hailey disease, Darier disease, and pemphigus vegetans. Irritant or allergic contact dermatitis also needs to be considered in some patients. A biopsy will confirm the diagnosis of granular parakeratosis.

Treatment

Based upon case reports and small series, therapeutic success has been reported with topical corticosteroids, vitamin D analogues, retinoids, ammonium lactate, and antifungals. In addition, cryotherapy, laser therapy[67], and oral isotretinoin or antibiotics have been used[65]. Spontaneous resolution has also been observed (including in infants), as have relapses.

Erythroderma 10

Sean Whittaker

Synonyms: ■ Exfoliative dermatitis ■ Exfoliative erythroderma ■ Red man syndrome (becoming historical term)

Key features

- Erythroderma is clinically defined as erythema and scaling involving >80% of the body surface area
- Systemic manifestations include peripheral edema, tachycardia, loss of fluid and proteins, and disturbances in thermoregulation
- Erythroderma has multiple etiologies; in adults, the most common causes are psoriasis, drug reactions, atopic dermatitis, and cutaneous T cell lymphoma (CTCL)
- Establishing the correct diagnosis requires consideration of initial sites of involvement, additional clinical findings, histopathologic and molecular features, and associated systemic abnormalities, as well as a complete medical history
- Despite an intensive evaluation, the cause remains unknown (idiopathic) in ~25% of patients; some of these patients eventually develop CTCL
- Treatment strategies should address the dermatologic disease as well as the underlying etiology and the systemic complications of the erythroderma

INTRODUCTION

Erythroderma is defined as generalized erythema and scaling involving >80% of the body surface area (BSA). However, it does not represent a defined entity, but rather is a striking and severe clinical presentation that can arise from a variety of diseases. Most commonly, erythroderma is due to generalization of pre-existing dermatoses (such as psoriasis or atopic dermatitis), drug reactions, or cutaneous T cell lymphoma (CTCL). Although up to 50% of the patients have a history of more localized skin lesions prior to the onset of the erythroderma, identification of the underlying disease process represents one of the most complex challenges in dermatology. Sustained efforts during longitudinal evaluation may lead to the precise identification of the etiology. In approximately one-quarter of the patients, no specific etiology is found, and these cases are called "idiopathic erythroderma".

Attention should also be focused on the potential systemic complications of acute erythroderma. Hypothermia, peripheral edema, and loss of fluid, electrolytes and albumin with subsequent tachycardia and cardiac failure are serious threats to the erythrodermic patient. In addition, chronic erythrodermas may be accompanied by cachexia, diffuse alopecia, palmoplantar keratoderma, nail dystrophy, and ectropion.

HISTORICAL PERSPECTIVE

The term "erythroderma" was introduced in 1868 by Hebra to describe an exfoliative dermatitis involving more than 90% of the skin surface. Based upon the clinical course, erythroderma was classified into chronically relapsing (Wilson–Brocq), chronically persisting (Hebra), and self-limiting epidemic (Savill) variants. However, these subdivisions are no longer employed. Even though originally more strictly defined as erythema and scaling involving >90% of BSA, nowadays the term erythroderma is often more liberally applied when there is >80% of BSA involvement.

EPIDEMIOLOGY

No precise data exist regarding the prevalence or incidence of erythroderma as most reports are retrospective but an overall incidence of 1 per 100 000 has been proposed. Large series of patients have focused on male-to-female ratios, average age, and underlying diseases[1–7]. Men are more commonly affected, with the male-to-female ratio ranging from approximately 2:1 to 4:1. An even higher ratio can be found in the subset of idiopathic erythroderma, also referred to as "red man syndrome" (not to be confused with the acute cutaneous reaction to rapid infusion of vancomycin). The average age at onset of erythroderma in these series was 52 years, with an average of 48 years in those including children, and 60 years in series excluding them[1,3,4,6].

Based upon several large series of patients, dermatitis (24%), psoriasis (20%), drug reactions (19%), and CTCL (8%; including Sézary syndrome and erythrodermic mycosis fungoides [MF]) represented the most common underlying causes of erythroderma[1–7]. In a more recent prospective study of over 300 patients, CTCL was diagnosed in a higher proportion of patients (18%)[8], but this could represent tertiary care referral bias or greater access to molecular diagnostics[9]. When categories within the dermatitis group were examined, atopic dermatitis (9%) was the most common type, followed by contact dermatitis (6%), seborrheic dermatitis (4%), and chronic actinic dermatitis (3%)[1,3,4,6]. With regard to etiology, no specific geographic differences have been noted[7,10]. In adults with erythroderma, overall relapse rates at one year range from 20% to 30%.

For adults, uncommon causes include pityriasis rubra pilaris, ichthyoses, bullous dermatoses (usually pemphigus foliaceus), graft-versus-host disease (GVHD), infestations (most often scabies), and autoimmune connective tissue diseases (acute lupus erythematosus, juvenile dermatomyositis). Table 10.1 lists additional unusual causes, from paraneoplastic (e.g. lymphoma, solid organ malignancies) to inflammatory (e.g. sarcoidosis) and neoplastic (e.g. hypereosinophilic syndrome). Despite multiple skin biopsies, an in-depth clinical investigation and a detailed medical history, the underlying cause of erythroderma is not found in at least 25% of patients. Unfortunately, cases of idiopathic erythroderma tend to be chronic and are more likely to recur after treatment[7].

Erythroderma in neonates and infants is rare and causes include inherited ichthyoses, dermatitides, psoriasis, immunodeficiencies[12] (e.g. Omenn syndrome), and consequences of infection (e.g. staphylococcal scalded skin syndrome) (Table 10.2)[13]. In addition, the possibility of drug-induced erythroderma should always be considered.

PATHOGENESIS

The pathogenetic mechanisms of the underlying diseases will be discussed in the respective chapters. The pathways involved in the *de novo* genesis of erythroderma or the generalization of pre-existing skin lesions are not well understood. The number of germinative keratinocytes as well as their mitotic rate is increased in erythrodermic skin, and the transit time of cells through the epidermis is shortened. Consequently, scales consist of material normally retained by the skin (nucleic acids, amino acids, soluble protein), and the daily loss of scales increases from 500–1000 mg to 20–30 g[14]. In acute erythroderma, the desquamated material usually has marginal metabolic significance, but in chronic erythroderma protein loss can be significant, leading to hypoalbuminemia and contributing to anemia of chronic disease. Given that the peak age of onset is during the 6th to 7th decade of life, it is possible that age-related immune senescence is a contributory factor in the development of idiopathic erythroderma. Likewise, the striking presentation of erythroderma in children with immunodeficiencies supports a role for immune dysregulation. Erythroderma in neonates often has a genetic basis and molecular diagnostics can play an important role in identifying causative mutations[15].

Underlying disease	**Clinical clues**	**Histologic clues**	**Additional hints**
Common			
Psoriasis (Ch. 8)	• Pre-existing psoriatic plaques or lesions of pustular psoriasis • Often spares the central face • Nail changes (oil-drop, pits, onycholysis) • Subcorneal pustules • Inflammatory arthritis	• Confluent or focal parakeratosis • Epidermal hyperplasia with bottleneck-like rete ridges • Tortuous vessels in a slightly edematous papillary dermis • Neutrophils within epidermis; sparse lymphohistiocytic infiltrate within dermis • Often reduced or absent granular layer	• Personal or family history of psoriasis • Withdrawal of corticosteroids, methotrexate, cyclosporine or targeted immunomodulators ("biologics") • Receiving medication that can exacerbate psoriasis (e.g. lithium, hydroxychloroquine, dupilumab)
Atopic dermatitis (Ch. 12)	• Pre-existing lesions (flexures) • Severe pruritus • Lichenification, including eyelids • Prurigo nodularis	• Mild to moderate acanthosis • Variable spongiosis • Dermal eosinophils • Parakeratosis • Variable lymphohistiocytic infiltrate with exocytosis of lymphocytes • Variable dermal edema	• Elevated serum IgE, eosinophilia • Personal or family history of atopy (e.g. asthma, allergic rhinitis, atopic dermatitis) • Cataracts/keratoconus
Drug reactions (Ch. 21)	• Preceded by morbilliform or scarlatiniform exanthem • Facial edema • In dependent areas, may become purpuric	• Variable patterns, including perivascular, lichenoid, spongiotic, and pseudolymphomatous • Eosinophils can be present, irrespective of pattern • Vacuolar degeneration of basal layer • SJS/TEN: apoptotic keratinocytes at all levels of epidermis • DRESS/DIHS: spongiotic and lichenoid patterns	• No history of skin diseases • More acute onset • Usually resolves within 2–6 weeks after withdrawal of responsible drug; possible exception is DRESS/DIHS • More common in HIV-infected patients • Specific HLA alleles increase risk (see Table 21.3)
Idiopathic erythroderma	• Elderly men • Chronic, relapsing • Severe pruritus • Palmoplantar keratoderma • Dermatopathic lymphadenopathy	• Nonspecific • Acute forms – parakeratosis, spongiosis, and a moderate lymphohistiocytic infiltrate • Chronic forms – compact ortho- and/or hyperparakeratosis, psoriasiform acanthosis, and expanded papillary dermis	• Consider less commonly associated drugs (see Table 10.3) • Continue to re-evaluate for cutaneous T cell lymphoma, including serial skin biopsies
Less common			
Cutaneous T cell lymphoma (Sézary syndrome > erythrodermic mycosis fungoides) (Ch. 120)	• Intense pruritus with excoriations; can develop lichenification or prurigo nodularis • Deep purple–red hue; pigmentary changes (melanoerythroderma) • Infiltration and/or edema; leonine facies • Painful, fissured palmoplantar keratoderma • Alopecia • Lymphadenopathy • Nail dystrophy	• Cerebriform pleomorphic lymphocytes • Clustering of atypical cells within epidermis uncommon • Band-like and occasionally lichenoid infiltrate • Cutaneous histology is non-diagnostic in at least 30% of patients with Sézary syndrome	• Sézary syndrome: peripheral blood $CD4^+$ lymphocytosis (≥1000 Sézary cells/mm^3; CD4/CD8 ratio ≥10; ≥40% $CD4^+/CD7^-$; or ≥30% $CD4^+/CD26^-$) • Sézary syndrome: detection of identical clonal T cell population in skin and lymph node/blood • Erythrodermic MF: variable presence of T cell clone in blood • Erythrodermic MF: lower levels or no Sézary cells (see Table 120.4) • Can mimic several other causes of erythroderma
Dermatitis (non-atopic), including contact (Chs. 14 and 15) and stasis with autosensitization (Ch. 13)	• Pre-existing localized disease • Distribution of initial lesions	• Variable spongiosis	• Occupation and hobbies • Patch testing • Review oral medications (systemic contact dermatitis)
Uncommon			
Pityriasis rubra pilaris (Ch. 9)	• Salmon-colored erythema • Islands of sparing (nappes claires) • Waxy keratoderma • Perifollicular keratotic papules	• Psoriasiform epidermal hyperplasia • Granular layer is normal • Alternating parakeratosis and orthokeratosis, both vertically and horizontally • Follicular plugs with "shoulder parakeratosis" • No neutrophils	• Flare after sun exposure • Cephalocaudal progression • Appearance of erythema gyratum-like lesions as erythroderma improves
Paraneoplastic erythroderma	• Fine scaling • Melanoerythroderma • Cachexia	• Nonspecific changes (skin does not contain malignant cellular infiltrates)	• Lymphoproliferative disorders, including lymphomas other than Sézary syndrome, and rarely thymomas • In the case of solid-organ malignancies, usually late-stage

Table 10.1 Causes of erythroderma in adults.

CAUSES OF ERYTHRODERMA IN ADULTS			
Underlying disease	**Clinical clues**	**Histologic clues**	**Additional hints**
Bullous dermatoses (Chs. 29 and 30) and inherited ichthyoses (Ch. 57)			
Pemphigus foliaceus	• Pre-existing lesions, often on upper trunk • Impetigo-like erosions and vesicles • Moist scale-crust; cornflake scale	• Acantholysis within the superficial epidermis • DIF, intercellular IgG	• IIF, intercellular • Anti-DSG1 Ab
Bullous pemphigoid	• Urticarial plaques • Tense bullae • Elderly patients	• Interface dermatitis and spongiosis; subepidermal blisters may be present • Many eosinophils, in part along the DEJ • DIF, BMZ C3 and IgG	• IIF, BMZ • Anti-BP180/BP230 Ab for longitudinal evaluation
Paraneoplastic pemphigus	• Mucosal erosions and hemorrhagic crusts • Erythema multiforme-like lesions • Mucocutaneous lichenoid lesions	• Interface dermatitis with necrotic keratinocytes • Parakeratosis • Focal acantholysis • DIF, intercellular and BMZ IgG	• IIF, intercellular and BMZ (+ IIF rat bladder)
Inherited ichthyoses	• Present from birth or early infancy (see Table 10.2)	• See Table 10.2	• See Table 10.2
Rare			
Papuloerythroderma of Ofuji	• Widespread, pruritic, flat-topped, red–brown papules that can become confluent • Sparing of skin folds ("deck-chair" sign) • Favors elderly men	• Dense perivascular infiltrate of lymphocytes and eosinophils in the upper to mid dermis	• Multiple etiologies, including CTCL > atopy, other lymphomas; drugs (e.g. DDI, aspirin); infections (e.g. HIV, hepatitis C virus); paraneoplastic phenomenon • May have peripheral eosinophilia, lymphopenia
Chronic actinic dermatitis (Ch. 87)	• Initial lesions in photodistribution • Allergic airborne contact dermatitis to *Compositae*	• Lichenoid infiltrate of lymphocytes and epidermal exocytosis • Acanthosis of epidermis and compact hyperkeratosis • Possible lymphocyte nuclear pleomorphism	• Drug history • UVA, UVB and visible light phototesting • Photopatch testing
Other unusual causes			
• Crusted (Norwegian) scabies • Dermatophyte infection • Leprosy • Toxic shock syndrome (usually staphylococcal) • Toxic exfoliative shock syndrome associated with SARS-CoV-2[11] • Primary immunodeficiencies • Lichen planus • Autoimmune connective tissue disease (e.g. acute or subacute cutaneous lupus erythematosus, juvenile dermatomyositis [adolescents])		• GVHD • Sarcoidosis • Hypereosinophilic syndrome • Other T cell hematologic malignancies (e.g. adult T cell leukemia/lymphoma, angioimmunoblastic T cell lymphoma, T cell prolymphocytic leukemia) • Mastocytosis • Langerhans cell histiocytosis	

Table 10.1 Causes of erythroderma in adults. Ab, antibody; BMZ, basement membrane zone; DDI, dideoxyinosine; DEJ, dermal–epidermal junction; DIF, direct immunofluorescence; DIHS, drug-induced hypersensitivity syndrome; DRESS, drug reaction with eosinophilia and systemic symptoms; GVHD, graft-versus-host disease; HIV, human immunodeficiency virus; IIF, indirect immunofluorescence; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

CAUSES OF ERYTHRODERMA IN NEONATES AND INFANTS			
Underlying disease	**Clinical clues**	**Histologic clues**	**Additional findings**
Inherited ichthyoses (Ch. 57)			
Non-syndromic			
Congenital ichthyosiform erythroderma	• Collodion baby • Generalized scaling involving flexures • Cicatricial alopecia, nail dystrophy, often palmoplantar hyperkeratosis • Ectropion	• Non-diagnostic	• Autosomal recessive • Mutations in multiple genes, e.g. *TGM1*, *ALOXE3*, *ALOX12B* (encode transglutaminase 1 and arachidonate lipoxygenases); see Table 57.1 for complete list
Epidermolytic ichthyosis	• Formation of superficial blisters and erosions during the first days of life • Later, corrugated hyperkeratosis in flexural areas	• Classic epidermolytic hyperkeratosis	• Autosomal dominant, very rarely autosomal recessive • Mutations in *KRT1* and *KRT10* (encode keratins 1 and 10)

Table 10.2 Causes of erythroderma in neonates and infants.

Continued

CAUSES OF ERYTHRODERMA IN NEONATES AND INFANTS			
Underlying disease	**Clinical clues**	**Histologic clues**	**Additional findings**
Syndromic			
Netherton syndrome	• Atopic-like dermatitis • Food allergies • Immune deficiency • Erythroderma in neonates • Erythroderma may persist or ichthyosis linearis circumflexa develops • Examine eyebrows and eyelashes as well as scalp hairs for trichorrhexis invaginata ("bamboo hair") • Failure to thrive	• Routine histology – non-diagnostic • Loss of tissue LEKTI expression	• Autosomal recessive • Elevated serum IgE levels • Mutations in *SPINK5* (encodes serine peptidase inhibitor, Kazal type 5, also known as lympho-epithelial Kazal-type-related inhibitor [LEKTI])
Conradi–Hünermann–Happle syndrome (X-linked dominant chondrodysplasia punctata)	• Linear and swirled pattern • Skeletal (chondrodysplasia punctata) and ocular anomalies (cataracts)	• Hyperkeratosis, reduced granular layer, follicular plugging with dystrophic calcification	• Mutations in *EBP* (encodes emopamil binding protein [sterol isomerase])
• Other rare ichthyoses and related disorders, e.g. trichothiodystrophy, keratitis–ichthyosis–deafness (KID) syndrome, Sjögren–Larsson syndrome, neutral lipid storage disease with ichthyosis, ichthyosis with confetti, ichthyosis prematurity syndrome, generalized inflammatory peeling skin syndrome, severe dermatitis–multiple allergies–metabolic wasting (SAM) syndrome, other desmosomal disorders, inflammatory skin and bowel disease*			
Immunodeficiencies (Ch. 60)			
Omenn syndrome	• Onset in neonatal period • Exfoliative erythroderma with diffuse alopecia • Lymphadenopathy and hepatosplenomegaly • Recurrent infections • Diarrhea	• Apoptosis of keratinocytes • Vacuolization of basal keratinocytes • Dense dermal infiltrate (predominantly T cells) • Acanthosis, parakeratosis • Degeneration of subcutaneous fat lobules	• Leukocytosis, peripheral eosinophilia • Hypogammaglobulinemia • Elevated serum IgE levels • Lymph nodes: disruption of germinal centers and abundant $S100^+$ interdigitating reticulum cells • Classically, *RAG1* or *RAG2* mutations, but this phenotype can also result from mutations in other genes causing SCID (see Ch. 60)
Other forms of SCID, agammaglobulinemia, complement deficiencies (e.g. C3, C5), IPEX syndrome	• "Leiner phenotype" of exfoliative dermatitis, chronic diarrhea, and recurrent infections	• Non-diagnostic	• See Ch. 60 • Many different genetic etiologies
Wiskott–Aldrich syndrome	• Primarily affects boys • Petechiae, ecchymoses • Atopic-like dermatitis • Recurrent sinopulmonary infections	• Non-diagnostic	• Microthrombocytopenia • Lymphopenia, peripheral eosinophilia • Elevated serum IgE levels • Mutations in *WAS*
• Other primary immunodeficiencies, e.g. DiGeorge syndrome and hyper IgE syndromes • GVHD (e.g. maternal–fetal or transfusion-related) in the setting of SCID (see Fig. 10.11; Ch. 52)			
Primary dermatoses			
Atopic dermatitis (Ch. 12)	• Crusted eczematous lesions on extensor surfaces, face, scalp • Spares diaper area • Pruritus • Onset week 6–16	• See Table 10.1	• See Table 10.1
Seborrheic dermatitis (Ch. 13)	• Greasy, scaling plaques and satellite papules on scalp and in skin folds • Diaper area involvement • Non-pruritic • Early onset (week 2–12)	• Psoriasiform hyperplasia of the epidermis with parakeratosis • Nonspecific inflammatory infiltrate	
Psoriasis (Ch. 8)	• Silvery white scaling and sharply demarcated plaques on face, elbows, and knees • Diaper area involvement • Nail pits • Usually later onset	• See Table 10.1	• Family history of psoriasis • See Table 10.1 • Familial erythrodermic psoriasis (and PRP) can be due to activating mutations in *CARD14* and may respond to ustekinumab • Generalized pustular psoriasis seen in DITRA and (together with sterile osteolysis and neonatal distress) DIRA (see Table 45.7)
• Other primary dermatoses, e.g. pityriasis rubra pilaris and CARD14-associated papulosquamous eruption (Ch. 9)			

Table 10.2 Causes of erythroderma in neonates and infants.

CAUSES OF ERYTHRODERMA IN NEONATES AND INFANTS			
Underlying disease	**Clinical clues**	**Histologic clues**	**Additional findings**
Drug reactions (Tables 10.1 and 10.3)			
Infections			
Staphylococcal scalded skin syndrome	• Temperature instability/low-grade fever • Irritability • Skin-fold accentuation • Large areas of tender erythema • Superficial bulla formation followed by desquamation • Radiating perioral scale-crusts • Extracutaneous staphylococcal infections often responsible	• Blister roof consists of the cornified layer and parts of the granular layer • Subcorneal blisters contain sparse acantholytic keratinocytes and only a few neutrophils and lymphocytes	• Positive culture for *Staphylococcus aureus* (conjunctivae, nares, throat, umbilicus, rectum) • Identification of exfoliative toxins (ET-A & ET-B) via slide latex agglutination, double immunodiffusion, or ELISA (see Ch. 74) • ET-A produced by *S. aureus* specifically cleaves desmoglein 1
Neonatal "toxic shock-like" exanthematous disease	• Generalized diffuse macular erythema or morbilliform eruption with confluence • Minimal scaling • Fever • Occurs during first week of life		• Colonization of umbilical stump, nasopharynx or skin with TSST-1-producing MRSA • Thrombocytopenia • Reported primarily in Japan
Congenital cutaneous candidiasis	• Maternal vaginal *Candida* infection with intrauterine spread • Pustules, collarettes of scale • Oral cavity spared • May have paronychia and nail dystrophy	• Yeast and pseudohyphae in the stratum corneum (PAS) • Subcorneal and spongiform pustules within the epidermis	• KOH examination, fungal culture
• Other infections and infestations, including viral exanthems (e.g. parechovirus), syphilis, and scabies			
Others			
• Ectodermal dysplasias*, e.g. ankyloblepharon–ectodermal dysplasia–clefting (AEC) syndrome, hypohidrotic ectodermal dysplasia with immune deficiency (Ch. 63), neonatal inflammatory skin and bowel syndrome type 1 due to *ADAM17* mutations (psoriatic erythroderma) • Nutritional and enzyme deficiency diseases such as kwashiorkor, organic acidurias, cystic fibrosis, specific deficiencies (e.g. zinc, essential fatty acids, biotin), and Gaucher disease (Chs. 51 and 63)			
*Desmosomal disorders characterized by erythrokeratodermia, ectodermal dysplasia, and/or skin fragility may also present with neonatal erythroderma (Chs. 56 and 57)			

Table 10.2 Causes of erythroderma in neonates and infants. CARD14, caspase recruitment domain family member 14; DIRA, deficiency of interleukin-1 receptor antagonist; DITRA, deficiency of interleukin-36 receptor antagonist; ELISA, enzyme-linked immunosorbent assay; IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked; MRSA, methicillin-resistant *Staphylococcus aureus*; SCID, severe combined immunodeficiency; TSST-1, toxic shock syndrome toxin 1.

CLINICAL FEATURES

Cutaneous Manifestations

Erythroderma is clinically defined by the presence of erythema and scaling involving more than 80% of the skin surface. Based upon its clinical course, erythroderma can be classified into primary or secondary types. In the primary form, the erythema (often initially on the trunk) extends within a few days or weeks to involve the entire skin surface, accompanied by the development of scaling (Fig. 10.1). The secondary form of erythroderma is defined as a generalization of a preceding localized skin disease – for example, psoriasis or atopic dermatitis. An acute onset most commonly occurs when the underlying cause is a drug reaction or dermatitis.

With the exception of very slowly progressing secondary erythroderma, erythema precedes the development of exfoliation by 2–6 days. The associated scaling varies extensively in size and color depending upon the stage of the erythroderma and nature of the underlying disease. During acute phases, scales are usually large and crusted, whereas in chronic states they tend to be smaller and drier. Occasionally, the cause of the erythroderma is suggested by the character of the scale – for example, fine in atopic dermatitis or dermatophytosis, bran-like in seborrheic dermatitis, crusted in pemphigus foliaceus, and exfoliative (i.e. peeling) in drug reactions. The color of the skin can also vary, from pink or red to reddish brown to deep red or purple.

Pruritus, the most frequent complaint, is observed in up to 90% of patients and it varies according to the underlying cause, but is most severe in patients with dermatitis or Sézary syndrome[16]. Given the itch–scratch cycle, the skin may become thickened, and areas of lichenification are seen in one-third of cases. Patients, especially those with a chronic erythroderma, may develop dyspigmentation, with hyperpigmentation (40/90 patients, 45%) observed more frequently than hypo- or depigmentation (18/90 patients, 20%) in one series[4]. Palmoplantar keratoderma appears in ~30% of erythrodermic patients and is often an early sign in pityriasis rubra pilaris[16]. Keratoderma with scale-crust can point to crusted scabies, whereas a painful and fissured keratoderma can occur in Sézary syndrome.

Fig. 10.1 Erythroderma with desquamation. Obvious exfoliation of scale with underlying erythema.

In cases of pre-existing dermatoses, nail changes may precede the erythroderma (e.g. pits in psoriasis or horizontal ridging in atopic dermatitis), whereas others develop subsequently. Nail changes are said to be present in ~40% of patients. Most often "shiny" nails are observed, but discoloration, brittleness, dullness, subungual hyperkeratosis, Beau's lines, paronychia, and splinter hemorrhages can be seen. The nails may even be totally shed. Diffuse non-scarring alopecia of the scalp or other sites appears in 20% of patients with chronic erythroderma, including those with CTCL. Cicatricial alopecia can also develop in the setting of Sézary syndrome or erythrodermic MF.

Patients with erythroderma can develop multiple seborrheic keratoses, which may be pale in color compared with the background erythema. Colonization of the skin with *Staphylococcus aureus* is common and can lead to secondary cutaneous infections as well as bacteremia. Bilateral ectropion and purulent conjunctivitis can also develop as ocular complications (Fig. 10.2). Lastly, an exacerbation of erythroderma may follow UV irradiation or drug ingestion; this is not necessarily restricted to patients with photosensitive eczema or drug-induced erythroderma[4].

Systemic Manifestations

An awareness of potential systemic complications of erythroderma is essential. Pedal or pretibial edema is observed in ~50% of patients (182/380)[1,3–5], and results from hypoalbuminemia and a shift of fluid into extracellular spaces. In patients with CTCL-associated or drug-induced erythroderma, generalized anasarca can develop. Because of the markedly increased blood flow through the skin and increased fluid loss by transpiration, tachycardia affects 40% of patients, and there is a risk of high-output cardiac failure, particularly in the elderly. Furthermore, increased skin perfusion leads to thermoregulatory disturbances. Although hyperthermia is more frequently observed than hypothermia, most patients describe chilly, rigor-like sensations[1,2,4,6,7,10]. The chronic and excessive loss of heat can lead to compensatory hypermetabolism with subsequent development of cachexia. Anemia, reflecting both iron deficiency and chronic disease, may also be observed in patients with chronic erythroderma.

The most common extracutaneous manifestation of erythroderma is peripheral lymphadenopathy, which is found in approximately half of the patients. Even in the absence of an underlying lymphoproliferative disorder, lymphadenopathy may be prominent and, if so, histologic and molecular examination of a lymph node is recommended (in particular, immunophenotypic studies and T cell receptor gene analysis)[17]. A core or excisional lymph node biopsy is preferable to a fine needle aspirate as the former provides sufficient tissue for accurate assessment of nodal architecture and cellular morphology. The major differential diagnosis is between lymphomatous involvement and reactive dermatopathic lymphadenopathy. Prior to histopathologic examination of an enlarged lymph node, a CT or PET-CT scan can identify the most morphologically abnormal and/or fluorodeoxyglucose (FDG)-avid node.

Hepatomegaly occurs in 20% of the cases (113/578), with a slight predominance in erythroderma due to drug-induced hypersensitivity. Splenomegaly is rarely seen and occurs most often in association with systemic lymphoma[1–4,6].

Fig. 10.2 Ectropion in the setting of erythroderma.

Specific Findings of the Underlying Disease

In addition to the general features previously discussed, the clinical presentation may have features suggestive of the underlying etiology (see Tables 10.1 and 10.2).

Psoriasis

Psoriasis is the most common underlying disorder in adults with erythroderma. Invariably, psoriatic erythroderma is preceded by typical psoriatic lesions (see Ch. 8). Its onset is most often due to withdrawal of potent topical or oral corticosteroids, cyclosporine or methotrexate; occasionally, widespread flares follow a systemic infection, phototoxicity, an irritant contact dermatitis to topical medications such as tar, or withdrawal of targeted immunomodulators ("biologics"). After generalization of the erythema, the typical features of psoriasis are often lost (Fig. 10.3), and generalized pustular psoriasis with disseminated sterile subcorneal pustules may develop (see Fig. 1.6). Due to a slower turnover rate, nail changes, such as oil-drop changes, onycholysis or nail pits, may still be visible and provide clues to the diagnosis of psoriatic erythroderma. Treatment of the erythroderma may result in the subsequent reappearance of characteristic psoriatic plaques.

Atopic dermatitis

Although occurring at any age, erythroderma develops most frequently in patients with a history of moderate to severe atopic dermatitis (Fig. 10.4). As a result, well-established pre-existing lesions can be found, especially when the erythroderma is of recent onset. The pruritus is intense, and secondary excoriations or prurigo-like lesions are frequently observed. Lichenification is often prominent and atrophy of the skin due to topical corticosteroids may be seen. Increased serum IgE and eosinophilia may accompany other signs and symptoms of atopy.

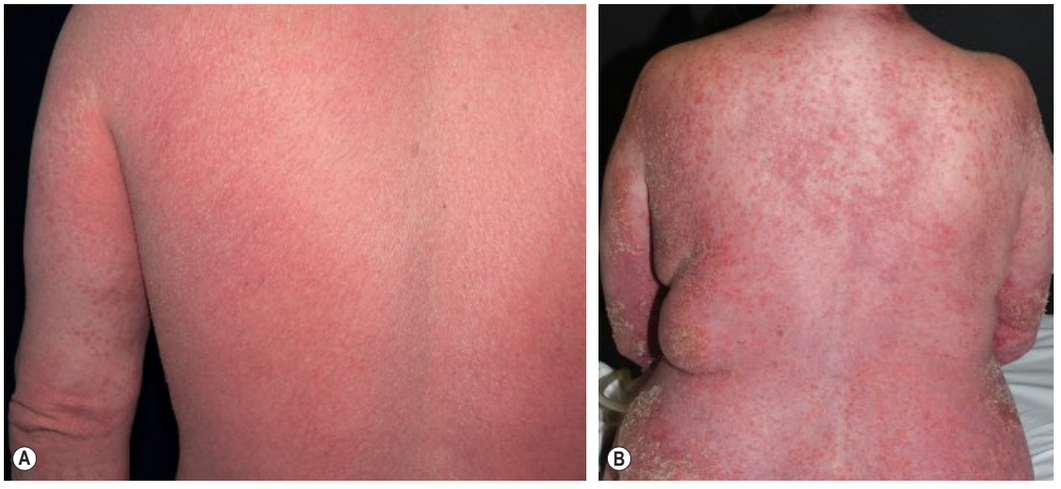

Fig. 10.3 Psoriatic erythroderma. **A** There is diffuse involvement of the trunk but a clue to the diagnosis is the individual lesions on the arm. **B** Significant exfoliation of the lateral trunk and arms. *A, Courtesy Luis Requena, MD; B, Courtesy Lorenzo Cerroni, MD.*

Fig. 10.4 Erythroderma due to atopic dermatitis. **A** Widespread erythema with fine white scaling and excoriations. **B** Fine white scaling and obvious pruritus in addition to circumoral pallor. *A, Courtesy Lorenzo Cerroni, MD; B, Courtesy Antonio Torrelo, MD.*

Drug reactions

The number of drugs implicated as causes of erythroderma is staggering (Table 10.3; see also Ch. 21)[18]. Whereas erythroderma resulting from topical medications usually begins as an irritant or allergic contact dermatitis, erythroderma due to systemic drugs often begins with the acute onset of a morbilliform or scarlatiniform exanthem. There are occasional exceptions such as the chronic eczematous eruptions associated with calcium channel blockers. In areas of greatest hydrostatic pressure (distal lower extremities), the eruption may become secondarily purpuric. While drug-induced erythrodermas have the shortest duration, usually resolving 2–6 weeks after withdrawal of the responsible drug, rarely erythroderma persists despite withdrawal of the putative drug and such cases may then be designated as idiopathic. Occasionally, there is a pseudolymphomatous presentation which can be associated with a transient peripheral blood lymphocytosis[19].

A minority of patients with DRESS (drug reaction with eosinophilia and systemic symptoms) syndrome, also referred to as drug-induced hypersensitivity syndrome (DIHS), become erythrodermic[20]. In addition to fever, these patients can develop peripheral blood eosinophilia, hepatitis, and peripheral lymphadenopathy (see Table 21.9).

Idiopathic erythroderma

In ~25% of erythrodermic patients, no underlying disease is detectable. This group consists primarily of elderly men with a chronic pruritic erythroderma in association with dermatopathic lymphadenopathy and extensive palmoplantar keratoderma (Fig. 10.5); this constellation is often referred to as "red man syndrome" or "l'homme rouge" (not to be confused with the infusion reaction ["red man syndrome"] that accompanies rapid intravenous infusions of vancomycin). When this group was compared with the entire group of erythrodermic patients, lymphadenopathy (68% vs 44%) and peripheral edema (54% vs 40%) were found to be more common than in other types of erythroderma, and hypothermia exceeded hyperthermia[21].

In one series of patients with idiopathic erythroderma, atopic dermatitis, drug-induced, and CTCL were the most common etiologies eventually identified[2]. In a second series, in which detection of a clonal T cell population in the skin was a diagnostic criterion for CTCL, the latter was the most common underlying disease[22]. However, it is important to note that in the absence of additional clinicopathologic features, the sole presence of a T cell clone in the skin is insufficient for the diagnosis of CTCL. Furthermore, peripheral blood T cell clones can be detected in elderly individuals and may reflect a diminished T cell receptor repertoire due to immune senescence rather than CTCL. Nonetheless, the detection of identical T cell clones in multiple biopsy specimens can serve as an important diagnostic clue for CTCL. Lastly, chronic actinic dermatitis should be considered in this group of patients.

DRUGS ASSOCIATED WITH ERYTHRODERMA	
Common	
• Allopurinol • β-lactam antibiotics • Carbamazepine/oxcarbazepine • Gold • Phenobarbital	• Phenytoins • Sulfasalazine • Sulfonamides* • Zalcitabine
Less common	
• Captopril/lisinopril • Carboplatin/cisplatin • Cytarabine • Cytokines (IL-2/GM-CSF) • Dapsone • Diflunisal • Dupilumab • Fluindione • Hydroxychloroquine/chloroquine • Immune checkpoint inhibitors† • Isoniazid	• Isotretinoin/acitretin • Lithium • Mercury compounds • Minocycline • Omeprazole/lansoprazole • Ribavirin • Telaprevir • Thalidomide • Tocilizumab • Vancomycin‡
Rare¶	
• Abacavir • Amiodarone • Aspirin (ASA) • Aztreonam • β-blockers • Chlorpromazine • Cimetidine • Ciprofloxacin • Clofazimine • Codeine • Erythropoietin • Fluorouracil • Imatinib • Indinavir • Lamotrigine • Methotrexate	• Mitomycin C • Nifedipine/diltiazem • Other antiretrovirals (e.g. efavirenz) • Other NSAIDs • Penicillamine • Pentostatin • Pseudoephedrine • Rifampin • St John's wort • Sulfonylureas • Tear gas (CS gas) • Terbinafine • Tobramycin • Tramadol • Vinca alkaloids • Zidovudine
*Includes furosemide. †Including ipilimumab, nivolumab, pembrolizumab. ‡Not to be confused with the infusion reaction ("red man syndrome") due to rapid infusion of drug. ¶For additional drugs, see ref. 18.	

Table 10.3 Drugs associated with erythroderma.

Cutaneous T cell lymphoma (Sézary syndrome and erythrodermic mycosis fungoides)

CTCL can mimic other causes of erythroderma and is frequently a significant diagnostic challenge. Erythroderma due to CTCL is subdivided into Sézary syndrome and erythrodermic MF (see Ch. 120). Sézary syndrome is defined by the triad of erythroderma, generalized lymphadenopathy, and peripheral blood lymphocytosis with morphologically abnormal Sézary cells; however, patients may have more limited skin involvement prior to the development of erythroderma[23]. Additional clinical features include a painful and fissured keratoderma, diffuse alopecia, edema, and leonine facies. The skin is often infiltrated or hyperpigmented (melanoerythroderma) and severe pruritus is common (Fig. 10.6).

To distinguish between Sézary syndrome and erythrodermic MF, revised criteria were proposed by the International Society of Cutaneous Lymphomas and the Cutaneous Lymphoma Task Force of the EORTC for the diagnosis of Sézary syndrome, namely erythroderma and evidence of an identical T cell clone in the blood and skin plus one of the following: (1) ≥1000 Sézary cells/mm^3; (2) a CD4:CD8 ratio of ≥10:1; or (3) an increased percentage of CD4$^+$ cells with an abnormal phenotype (≥40% CD4$^+$/CD7$^-$ or ≥30% CD4$^+$/CD26$^-$) by peripheral blood flow cytometry (B_2 in the TNMB classification; see Table 120.4). The latter cellular analysis provides a more objective measure of circulating tumor burden[24]. Erythrodermic MF can also have an identical T cell clone in the skin and blood, but flow cytometry results are normal or demonstrate low-level blood involvement (B_0 or B_1). In addition, diagnosis of erythrodermic MF can be challenging because the histopathologic findings are not diagnostic in at least one-third of patients.

Longitudinal evaluation, including repeated skin biopsies and PET-CT scans as well as lymph node biopsies and peripheral blood flow cytometry, is required to distinguish CTCL from idiopathic erythroderma. Identification of identical dominant T cell clones via more sensitive and specific high-throughput T cell receptor sequencing may prove helpful. Rarely patients with other hematologic malignancies, in particular angioimmunoblastic T cell lymphoma, adult T cell leukemia/lymphoma or T cell prolymphocytic leukemia, can present with erythroderma due to cutaneous infiltration of malignant T cells.

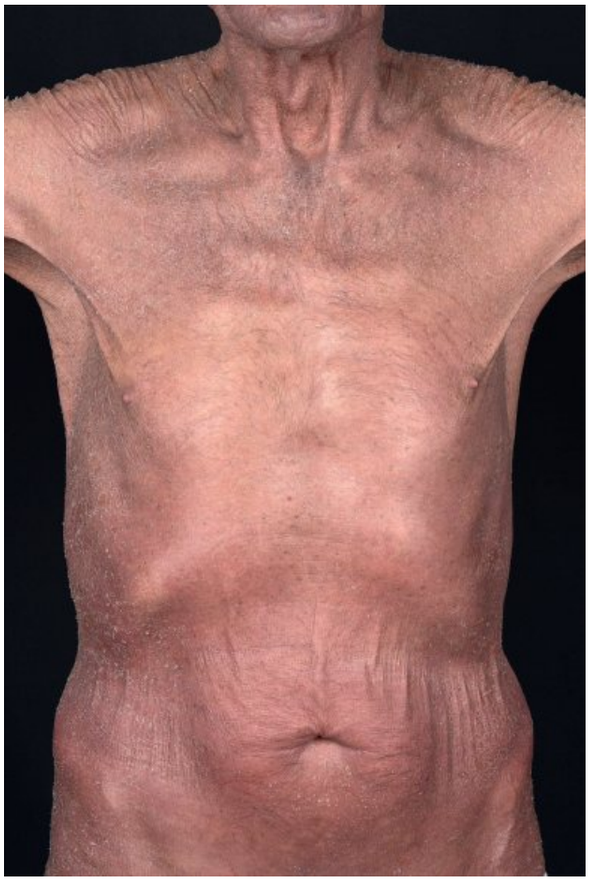

Fig. 10.5 Idiopathic erythroderma. This is the type of patient who requires longitudinal evaluation to exclude the development of cutaneous T cell lymphoma. *Courtesy Lorenzo Cerroni, MD.*

Pityriasis rubra pilaris

Erythrodermic pityriasis rubra pilaris (PRP) can be observed in children and adults (see Ch. 9). Usually, the lesions have a salmon to orange–red color. The degree of scaling varies, but it can be marked with large scales (Fig. 10.7). The combination of follicular keratotic papules on the knees, elbows and dorsal aspects of the fingers plus nappes claires (islands of uninvolved skin within the erythroderma) favors the diagnosis of PRP (Fig. 10.8). When the classic histologic features are present (see below), this is also helpful in distinguishing PRP from psoriasis. Occasionally, CTCL and the Wong type of dermatomyositis can have an appearance similar to PRP.

Papuloerythroderma of Ofuji

This represents a distinctive reaction pattern most often described in older men. Pruritic, monomorphic reddish brown papules often become confluent, with sparing of skin folds ("deck-chair" sign). In one review of

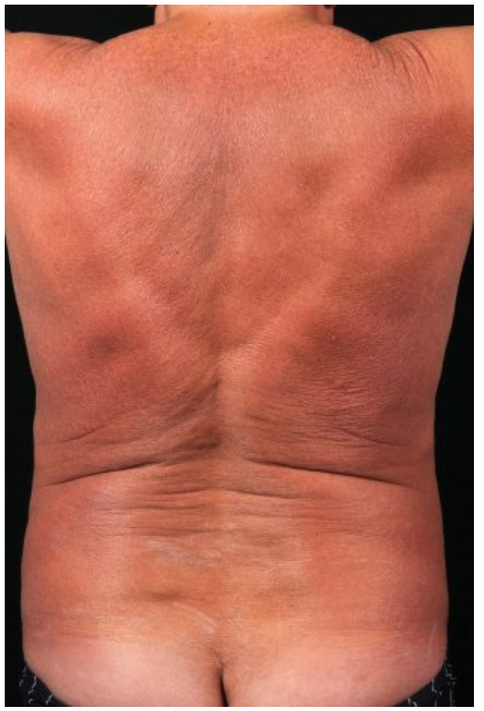

Fig. 10.6 Sézary syndrome. Diffuse erythroderma with a red–brown color. Note the evidence of scratching on the lower back. *Courtesy Lorenzo Cerroni, MD.*

Fig. 10.7 Erythroderma due to pityriasis rubra pilaris. Large thin scales are seen as well as the characteristic orange–red color.

Fig. 10.8 Erythroderma secondary to pityriasis rubra pilaris. Islands of sparing are noted on the flank and breast. Note the salmon color.

Fig. 10.9 Erythroderma due to pemphigus foliaceus. Generalized erythema with widespread scale-crusts and large areas of erosion.

170 reported cases, a causative factor was not identified in the majority of patients. Of the remaining individuals, CTCL represented the most common underlying etiology and thus needs to be excluded (see Table 10.1 for additional etiologies)[25].

Paraneoplastic erythroderma

Paraneoplastic erythroderma is most commonly associated with lymphoproliferative disorders, including systemic lymphomas and rarely thymomas. In patients with solid organ malignancies, erythroderma is rare and usually only appears during the late stages of the disease. Of note, in these patients the skin does not contain malignant cellular infiltrates. Fine scales and erythema can be accompanied by a brownish hue (i.e. melanoerythroderma). Additional signs of malignancy, such as cachexia or fatigue, may be seen.

Bullous dermatoses

Among the bullous dermatoses, pemphigus foliaceus is the one most likely, albeit rarely, to present as erythroderma; erythrodermic forms of paraneoplastic pemphigus and bullous pemphigoid have also been reported (see Table 10.1; see also Chs. 29 and 30). In pemphigus foliaceus, impetigo-like blisters and erosions are followed by collarettes of scale and scale-like crusts (Fig. 10.9). The erythroderma is usually preceded by localized lesions on the face and upper trunk.

Ichthyoses

Erythroderma due to one of the syndromic or non-syndromic inherited ichthyoses is usually present from birth or infancy (see Table 57.1)[26,27]. In neonates, congenital ichthyosiform erythroderma (CIE; previously referred to as non-bullous CIE), epidermolytic ichthyosis (previously referred to as bullous CIE), and Netherton syndrome should be considered (see Table 10.2). As a rule, CIE presents as a collodion baby (90% of the cases)[28], and within a few days after birth, an erythroderma with fine white scaling appears. Epidermolytic ichthyosis initially presents as generalized erythema with superimposed superficial blisters and erosions. This disorder may be mistakenly diagnosed as staphylococcal scalded skin syndrome or as a form of epidermolysis bullosa. Later, children develop spiny, corrugated hyperkeratoses, particularly in flexural areas, and blisters and erosions become less prevalent. Netherton syndrome manifests as an ichthyosiform erythroderma in neonates. It is associated with trichorrhexis invaginata ("bamboo hair"), elevated serum levels of IgE, and an immune defect that can result in life-threatening infections, particularly within the first years of life. Later, either the ichthyosiform erythroderma persists or ichthyosis linearis circumflexa develops, which is characterized by garland-like scaly eruptions. Because there are very rare ichthyoses that can present with an ichthyosiform erythroderma as well as multiple genes associated with a specific ichthyosis (see Table 57.1), molecular diagnostics consisting of next generation sequencing of large gene panels or whole exome sequencing have become an important evaluation tool[15].

Staphylococcal scalded skin syndrome

Staphylococcal scalded skin syndrome (SSSS; see Ch. 74) is seen primarily in children (<5 years of age), and it is due to a circulating exfoliative toxin produced by *S. aureus*. Since desmoglein 1 is cleaved by exfoliative toxin A, pemphigus foliaceus and SSSS exhibit clinical similarities, with the latter often becoming erythrodermic. Common foci for the initial infection include the nares, nasopharynx, conjunctivae, and umbilicus. After a period of 1–2 days of a low-grade fever, large areas of tender erythema develop. The skin appears tense and subcorneal blisters appear, which subsequently desquamate. A very similar syndrome, the toxic shock syndrome, can be caused by staphylococcal or streptococcal exotoxins, but more commonly affects adults and acral exfoliation has a delayed appearance, usually 2 weeks later.

Omenn syndrome

Omenn syndrome represents an autosomal recessive form of severe combined immunodeficiency (SCID; see Table 60.16). It is characterized by failure to thrive, leukocytosis with prominent eosinophilia, hypogammaglobulinemia, and elevated serum IgE levels. Cutaneous findings, which appear in neonates, are generally the first sign of the syndrome and include an erythroderma with diffuse alopecia. Systemic manifestations include prominent lymphadenopathy, hepatosplenomegaly, and recurrent diarrhea. In the absence of hematopoietic stem cell or bone marrow transplantation, severe infections lead to early death. Additional forms of SCID can also cause exfoliative dermatitis in neonates (see Table 60.16).

PATHOLOGY

Although sometimes subtle, histopathologic features of the underlying disease are present in about two-thirds of patients (see Tables 10.1 and 10.2)[29]. As a result, biopsy specimens in one-third of individuals with erythrodermic MF or Sézary syndrome are non-diagnostic[30]. Of note, epidermotropism of neoplastic lymphocytes is less commonly observed in these two disorders than in conventional MF[29]. Diagnostic findings are frequently found in psoriatic erythroderma[31], but less often in PRP.

It is important to remember that concurrent topical or systemic therapies as well as superimposed phenomena, e.g. atopic diathesis, contact dermatitis, impetiginization, can modify the histopathologic findings. In addition, multiple and sequential biopsies are often necessary in the evaluation of erythroderma.

DIFFERENTIAL DIAGNOSIS

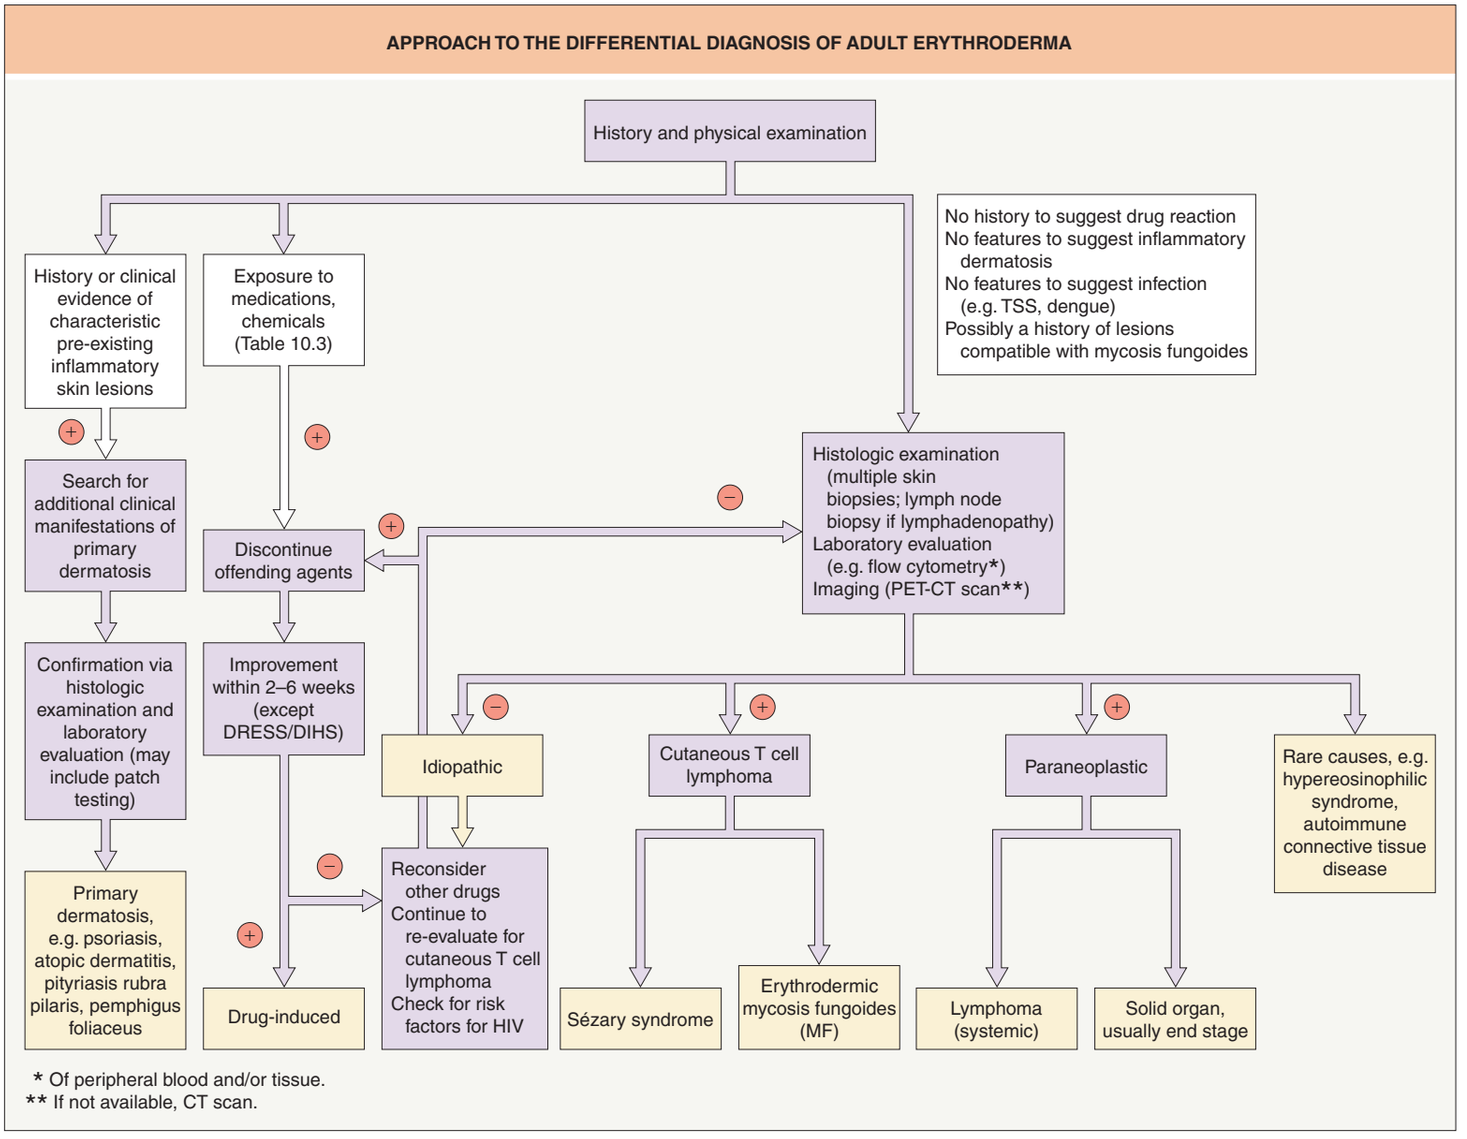
Erythroderma is a clinical presentation for a variety of diseases, and identification of the underlying etiology represents one of the most complex challenges in dermatology (Figs. 10.10 and 10.11; see Tables 10.1 and 10.2). The evaluation starts with a complete medical history: up to 45% of the patients will have a prior history of a more localized skin disease, and ~20% of cases represent drug reactions[1–6]. A comprehensive clinical examination may reveal additional clues to the underlying disease. However, it is important to recognize that pre-morbid susceptibilities may modify the clinical morphology of an erythroderma, e.g. a drug reaction in an atopic individual may appear lichenified. Once the number of possible underlying diseases is reduced, further laboratory investigation can aid in establishing the final diagnosis. Hopefully in the future, specific diagnostic biomarkers will emerge that can assist in establishing a precise etiology[32]. For erythroderma in neonates and young children, molecular diagnostics represent a critical laboratory investigation (see above)[15].

TREATMENT

Erythroderma can represent a serious medical threat to the patient and therefore hospitalization may be required. Regardless of the underlying disease, the initial management consists of nutritional assessment, correction of fluid and electrolyte imbalances, prevention of hypothermia, and both prevention and treatment of secondary infections. Sedating oral antihistamines may ease severe pruritus[16]. Systemic corticosteroids may be necessary in idiopathic erythroderma and drug reactions. With an initial prednisone dose of 1–2 mg/kg/day and a maintenance dose of 0.5 mg/kg/day or less, rapid clearing of the erythroderma can be achieved. Caution must be exercised upon tapering, as rebound may occur. Topical therapy includes open wet dressings and bland emollients or low-potency corticosteroid ointments. High-potency topical corticosteroids should be reserved for lichenified areas, and because of enhanced transcutaneous absorption via erythrodermic skin, chronic, extensive application should be avoided. Coal tar ointments and phototherapy may aggravate the condition.

In neonates and children with erythroderma, management of fluid and electrolyte balance is critical in order to prevent hypernatremic dehydration. Emollients, topical antibiotics and, depending upon the extent and severity of the secondary infections, systemic antibiotics are administered. Due to increased transcutaneous absorption, topical salicylic and lactic acid should be avoided[33].

Treatment of specific underlying diseases is outlined in the respective chapters (see Tables 10.1 and 10.2). In the case of psoriatic erythroderma, administration of methotrexate, acitretin, cyclosporine or targeted immunomodulators ("biologics") is preferred over systemic corticosteroids, given the risk of a pustular flare when corticosteroids are tapered[34]. For drug reactions, discontinuation of all non-essential drugs and all suspected drugs will usually lead to



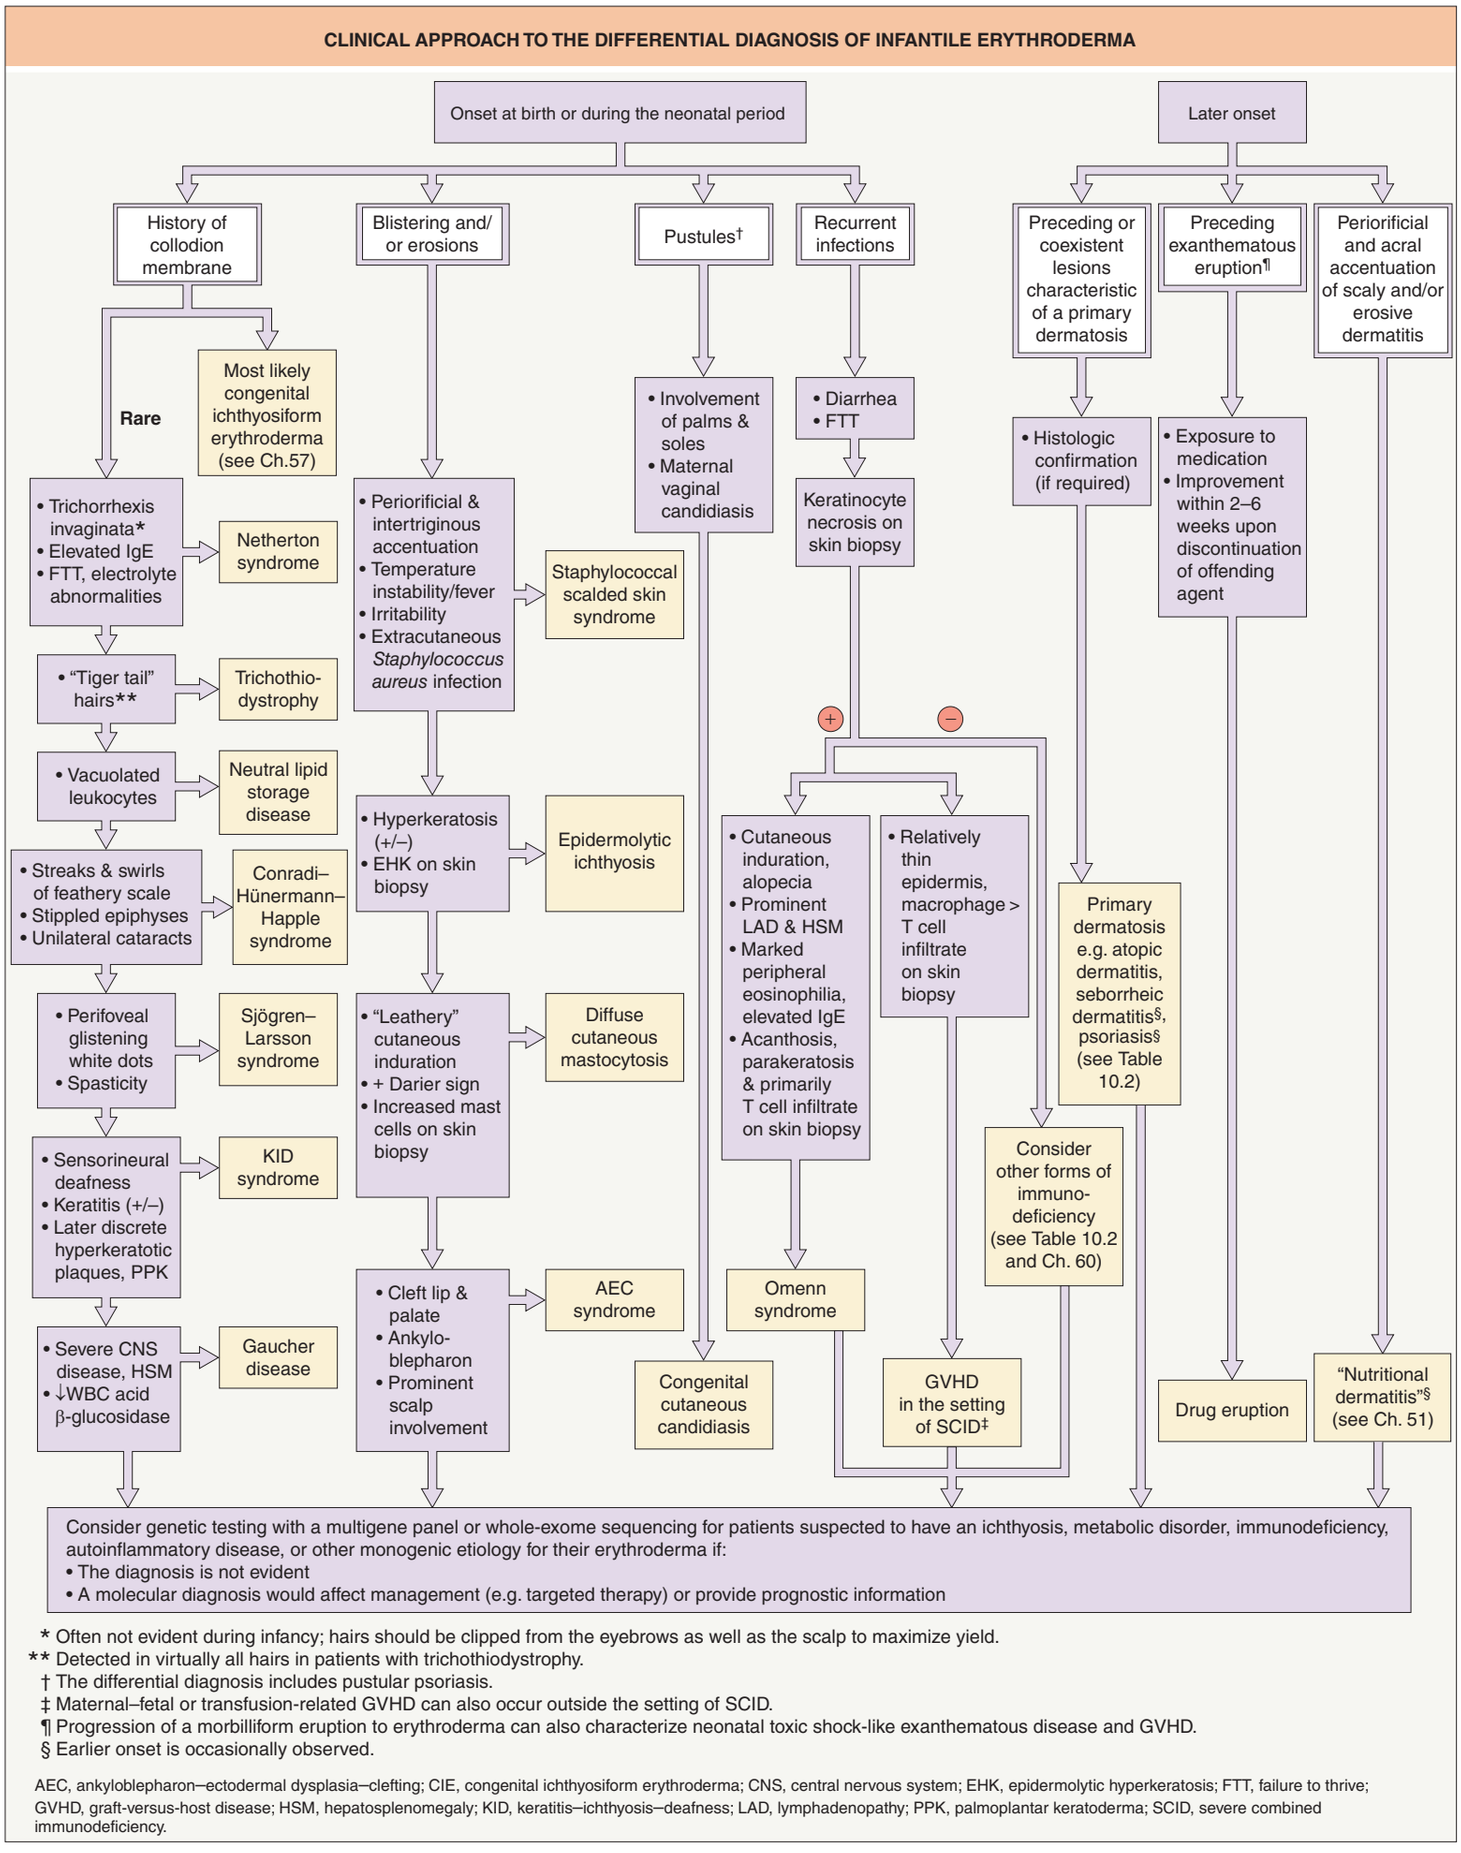


Fig. 10.10 Approach to the differential diagnosis of adult erythroderma. CT, computed tomography; DRESS/DIHS, drug reaction with eosinophilia and systemic symptoms/drug-induced hypersensitivity syndrome; PET, positron emission tomography; TSS, toxic shock syndrome.

* Often not evident during infancy; hairs should be clipped from the eyebrows as well as the scalp to maximize yield.
** Detected in virtually all hairs in patients with trichothiodystrophy.
† The differential diagnosis includes pustular psoriasis.
‡ Maternal–fetal or transfusion-related GVHD can also occur outside the setting of SCID.
¶ Progression of a morbilliform eruption to erythroderma can also characterize neonatal toxic shock-like exanthematous disease and GVHD.
§ Earlier onset is occasionally observed.

AEC, ankyloblepharon–ectodermal dysplasia–clefting; CIE, congenital ichthyosiform erythroderma; CNS, central nervous system; EHK, epidermolytic hyperkeratosis; FTT, failure to thrive; GVHD, graft-versus-host disease; HSM, hepatosplenomegaly; KID, keratitis–ichthyosis–deafness; LAD, lymphadenopathy; PPK, palmoplantar keratoderma; SCID, severe combined immunodeficiency.

Fig. 10.11 Clinical approach to the differential diagnosis of infantile erythroderma.

improvement within 2–6 weeks (with the exception of some patients with DRESS/DIHS). However, systemic prednisone (1–2 mg/kg/day) or even the co-administration of IVIg may be useful in severe cases. After careful exclusion of any underlying cause, idiopathic erythroderma may be treated with low-potency topical corticosteroids and oral antihistamines. In refractory cases, cyclosporine has been used successfully, with an initial dosage of 5 mg/kg/day, and subsequent reduction to 1–3 mg/kg/day. Additional steroid-sparing agents include methotrexate, azathioprine and mycophenolate mofetil, all of which have been used anecdotally, with dosages similar to those for recalcitrant atopic dermatitis.

LICHEN PLANUS

Synonym: ■ Lichen ruber planus

Key features

- Idiopathic inflammatory disease of the skin, hair, nails and mucous membranes, seen most commonly in middle-aged adults
- Flat-topped violaceous papules and plaques favoring the wrists, forearms, genitalia, distal lower extremities, and presacral area
- Clinical variants include actinic, annular, atrophic, bullous, hypertrophic, inverse, linear, ulcerative, vulvovaginal–gingival, lichen planopilaris, lichen planus pigmentosus, and drug-induced
- Some lichenoid drug eruptions have a photodistribution, while others are clinically and histologically indistinguishable from idiopathic lichen planus
- The most commonly incriminated drugs include angiotensin-converting enzyme (ACE) inhibitors, thiazide diuretics, antimalarials, quinidine, and, especially in the past, gold
- In most patients, the therapeutic approach to immune checkpoint inhibitor (ICI)-related lichenoid eruptions consists of topical corticosteroids and continuation of the ICI; systemic corticosteroids and a brief drug holiday may be required when the eruption is severe or recalcitrant
- Histologically, there is a dense, band-like lymphocytic infiltrate and keratinocyte apoptosis with destruction of the epidermal basal cell layer
- In this T cell-mediated autoimmune disorder, basal keratinocytes express altered self-antigens on their surface

Introduction

Lichen planus (LP), the prototype of lichenoid dermatoses, is an idiopathic inflammatory disease of the skin and mucous membranes. Classic LP is characterized by pruritic, violaceous papules that favor the extremities[1]. Histologically, a dense, band-like lymphocytic infiltrate is seen underlying an acanthotic epidermis with hypergranulosis, apoptosis, and destruction of the basal cell layer. The etiology and pathogenesis of LP are not fully understood, but the disorder has been associated with multiple environmental exposures, including viral infections, medications, vaccinations, and dental restorative materials.

LP-like lesions that resemble idiopathic LP may also develop in chronic GVHD, where alloreactive T cells that recognize foreign major histocompatibility complex (MHC) molecules are central effectors (see Ch. 52). This lends support to the hypothesis that an autoimmune reaction against epitopes on lesional keratinocytes that have been modified by viral or drug antigens may be responsible for LP.

A number of clinically distinct inflammatory dermatoses have in common varying elements of a lichenoid tissue reaction, and they are referred to as lichenoid dermatoses (Table 11.1).

History

The term lichen planus was initially introduced by Erasmus Wilson in 1869 to describe the condition that had been previously named leichen ruber by Hebra[1].

Epidemiology

Although its incidence varies depending upon geographic locale, cutaneous LP has been reported to affect from 0.2% to 1% of the adult population[1], whereas oral lesions have been observed in up to 1%–4% of the population. There is no overt racial predisposition. LP most commonly has its onset during the fifth or sixth decade, with two-thirds of patients developing the disease between the ages of 30 and 60 years. It is rare in both infants and the elderly and, typically, only 1%–4% of patients are children. However, more recent studies have suggested that LP may actually be more common in children, especially in Arab populations. Oral LP is also quite uncommon in young people and it usually affects middle-aged to elderly individuals (mean age at diagnosis being 52 years). Although LP is frequently thought to have no gender predilection, some studies have found that women were affected nearly twice as often as men.

Mucosal involvement, particularly oral lesions, is observed in up to 75% of patients with cutaneous LP, but the former can be the only manifestation of the disease. Only 10%–20% of patients whose initial presentation is oral LP will eventually develop cutaneous LP. Although reports of familial LP are rare, it may occur more frequently than previously thought; for example, LP occurs in up to 10% of first-degree relatives of affected patients. Cases of familial LP tend to have an earlier age of onset, a higher relapse rate, and more frequent oral mucosal involvement. Of note, reports of concurrent LP in monozygotic twins who were living together suggest an environmental trigger. Lastly, individuals with Good syndrome, a primary immunodeficiency that is associated with thymomas, there is an increased risk of developing lichen planus.

Pathogenesis

There is a growing body of evidence that LP represents T cell-mediated autoimmune damage to basal keratinocytes that express altered self-antigens on their surface.

Target antigens

Clinical observations and anecdotal evidence have long suggested a relationship between exposure to a number of exogenous agents (e.g. viruses, medications, contact allergens) and the development of LP (see Table 11.1). In theory, T cells that normally do not respond to skin (epidermis)-restricted antigens are primed by exogenous agents when the latter possess cross-reactive antigens that can activate autoreactive T cells via molecular mimicry. In other words, the T cell receptors on the T cells that induce mucocutaneous LP could cross-react with exogenous antigens.

Hepatitis C virus

Of the many potential exogenous antigens, significant attention has been focused on the possible role of viruses, particularly hepatitis C virus (HCV). In several case–control studies, the prevalence of HCV

(3.5%–38%) was 2- to 13.5-fold higher in patients with LP than in controls. This association seems to be strongest in Japanese and Mediterranean populations, probably due to the high prevalence of HCV infection in these countries. In the US, one case–control study found that 12 (55%) of 22 patients with LP had anti-HCV antibodies, and this was significantly higher than the 25% of 40 psoriatic patients or the 0.17% of blood donors who tested positive[2]. However, a systematic review and meta-analysis of existing epidemiologic studies demonstrated that an association between LP and HCV infection did exist in certain geographic regions (e.g. East and Southeast Asia, South America, the Middle East, Europe), but not in others (e.g. North America, South Asia, and Africa)[3].

An increased frequency of the HLA-DR6 allele has been reported in Italian patients with HCV-associated oral LP[4], raising the possibility that $CD4^+$ T cells activated upon recognition of HCV-encoded peptides bound to HLA-DR6 molecules could be directly involved in the pathogenesis of LP. In support of this possibility, HCV tetramer analysis has shown that HCV-specific $CD4^+$ and/or $CD8^+$ T cells are present with higher frequency in oral LP lesions compared with the circulating compartment, suggesting that they play a role in the pathogenesis of LP[5].

Of the various types of LP, it is the oral form that is most commonly viewed as a manifestation of HCV infection. By PCR, HCV RNA was detected in 93% of oral LP lesions[6], suggesting HCV replication within LP lesions. However, these PCR results were not confirmed by other studies. In patients receiving anti-HCV therapy, originally interferon and ribavirin and more recently direct-acting antiviral agents that target nonstructural proteins, the effects on mucocutaneous LP have varied[7]. Lesions have improved in some patients while others experienced a flare of disease activity.

Other viruses

With regard to the role of other viruses in LP, human herpesvirus *(HHV)-6* and *HHV-7* DNA has been detected in some LP lesions[8]. Remission of LP was associated with decreased HHV-7 protein expression, in particular within infiltrating plasmacytoid dendritic cells[9]. There have been multiple reports that either *SARS-CoV-2* (COVID-19) infection or COVID-19 vaccines can trigger LP[10]. Of note, in two recent systematic reviews, a stronger association was observed between LP and COVID-19 vaccination as compared to COVID-19 infection[10a,10b].

There are also sporadic case reports of LP lesions developing in areas recently affected by herpes simplex virus (*HSV*) or varicella–zoster virus (*VZV*) infections[11,12] (see Table 80.7). Possible explanations include a nonspecific Koebner phenomenon or isotopic response or an immune reaction to the virus. In an immunohistochemical study involving eight patients, VZV-gE antigen was detected within the eccrine epithelia of LP lesions if they were in a dermatomal (zosteriform) pattern but not if they were in a linear array along the lines of Blaschko[12]. Two of the patients with the dermatomal pattern reported no preceding episode of herpes zoster, leading the authors to speculate if LP could be triggered by subclinical VZV reactivation. A link between human papillomavirus (*HPV*) and oral LP has also been suggested based upon the identification of a clonal expansion of HPV-16-specific $CD8^+$ T cells within the lesions[13].

While measurements (via PCR) of viral genomes within lesional skin or blood have been inconclusive, as noted above, virus-specific T cells have been detected within lesions. This suggests that the pathology is a direct consequence of immune responses, perhaps to virally induced alterations in the antigenicity of epidermal cells rather than the viruses themselves. However, it is also possible that virus-specific T cells are nonspecifically trapped within sites of inflammation, having been activated systemically or locally at distant sites, and then they expand and mediate tissue damage "accidently" due to cross-reactivity with other antigens (e.g. drugs)[14].

Vaccines

In addition to COVID-19 vaccines (see above), a number of reports have described the appearance of LP after administration of influenza vaccines, rabies vaccines, and different types of HBV vaccines[15]. The time interval between the initial dose and the development of cutaneous or mucosal lesions has varied from a few days to 5 months. One recommendation is that patients who develop LP before completing their vaccination series should avoid further injections because of an increased risk of developing severe LP lesions, including the bullous variant.

Bacteria

Investigations regarding a relationship between bacteria and cutaneous LP have been limited. In tissue and saliva samples, the diversity and composition of microbial communities differed when patients with oral LP were compared to healthy controls, suggesting a possible role for the local microbiome.

Contact allergens

The role of contact allergy to a variety of metals in the exacerbation or induction of oral LP has been well described, based on exposure to metallic dental restorations or constructions, positive patch test results, and then regression or complete clearing after removal of the sensitizing metal and replacement with other materials. However, improvement has also been observed after removal of metals in patch test-negative patients. The metals reported to aggravate oral LP include amalgam (mercury), copper, and gold.

Of note, the development of contact allergy to metals within dental restorations in patients with LP could be explained by easy penetration of the metal via damaged mucosa.

Drugs

Cutaneous eruptions similar or even identical to LP, both clinically and histologically, have been linked to a variety of drugs. The terms "lichen planus-like" and "lichenoid" are often used to describe this phenomenon[16,17]. A wide variety of drugs have been associated with lichenoid drug eruptions and the list of such drugs steadily increases (Table 11.2). However, recurrence of the lesions subsequent to drug rechallenge has not been documented for the majority of these drugs.

Autoantigens, including tumor antigens

In occasional patients, LP has been reported as a possible autoimmune reaction triggered by an underlying neoplasm. Also, a lichenoid tissue reaction is seen in patients with paraneoplastic pemphigus. The temporal relationship between LP and the underlying neoplasm in the

Table 11.2 Drugs implicated in lichenoid drug eruptions. More commonly associated drugs are in **bold**. Topical medications, e.g. imiquimod, can exacerbate LP. CTLA-4, cytotoxic T lymphocyte-associated antigen; NSAIDs, nonsteroidal anti-inflammatory drugs; PD, programmed cell death protein; PD-L, programmed cell death ligand.

reported patients suggests that the neoplasms may have stimulated a cell-mediated immune response against tumor antigens that led to the generation of autoreactive T cells that cross-reacted against antigens expressed on epidermal cells.

Although numerous case reports describe patients with both LP and autoimmune diseases, studies with larger numbers of patients with LP have shown no increased incidence of autoimmune diseases. Multiple investigators have described a significant association between specific HLA antigens (e.g. HLA-DR1, -DR6, -DR9) and LP. However, a true association with a particular HLA allele has been difficult to establish because of significant geographic heterogeneity and clinical patient selection.

A murine model of LP has been established by employing autoreactive T cells capable of producing interferon-γ (IFN-γ) and tumor necrosis factor (TNF-α) (Fig. 11.1)[18]. Intradermal inoculation of $CD4^+$ autoreactive T cell clones into the footpads of syngeneic mice can induce local histologic changes similar to LP or lichenoid skin diseases. In this model, the autoreactive T cells can respond to self MHC class II antigens constitutively expressed on macrophages and Langerhans cells, and they migrate into the epidermis, resulting in epidermal injury. These T cells, therefore, can induce LP-like lesions without any alteration in the antigenicity of the epidermis. In subsequent studies, desmoglein-specific T cells were also capable of inducing LP-like changes histologically[19]. Thus, LP could be induced by different types of T cells – those that specifically target antigens constitutively expressed in the epidermis but also T cells that target antigens not expressed within the epidermis.

Additionally, in the natural disease process, exogenous agents (e.g. viral infections, drugs) could induce alterations in the antigenicity of epidermal cells and trigger the activation of T cells. Of note, such autoaggressive reactions could function to eliminate abnormal keratinocytes altered by these exogenous agents. However, in the situation where T cells initially responding to self-antigens modified by exogenous agents subsequently become cross-reactive with some self-epitopes, these T cells would then chronically respond to the previously ignored self-epitopes, leading to perpetuation of an autoimmune attack by such T cells[18] rather than elimination of the abnormal keratinocytes.

Effector cells

There are conflicting data regarding the phenotype of the inflammatory infiltrate in LP lesions. Although initial immunohistochemical studies showed that the cellular infiltrate contained an increased ratio of $CD4^+$:$CD8^+$ T cells[20], other investigators found a predominance of $CD8^+$ T cells, particularly in older lesions. Evidence to support the crucial role of $CD8^+$ T cells in autoimmune damage to basal keratinocytes has been provided by $CD8^+$ T cells isolated from lesional skin; these T cells exhibited specific cytotoxic activity against autologous lesional and normal keratinocytes[21].

Cellular damage, as evidenced by apoptotic DNA fragments, is greatest within the basal layer of the epidermis. A possible mechanism is as follows: IFN-γ produced by $CD8^+$ T cells upregulates Fas expression by keratinocytes, rendering them susceptible to T cell-mediated, Fas ligand-driven apoptosis. This interaction triggers a cascade of intracellular enzymatic reactions resulting in DNA fragmentation (see Ch. 107). In addition to Fas, death receptor-induced apoptosis involves signaling processes via TNF-R1, TRAIL-R1 and 2, and DR3 or DR6. Because type 1 helper T cells (Th1), such as the autoreactive $CD4^+$ T cells in the murine model (see Fig. 11.1), can produce large amounts of IFN-γ and lymphotoxin-α (TNF-β) upon activation and thereby induce or enhance the expression of apoptosis-associated proteins such as Fas and TRAIL, they may also play a role in extensive epidermal damage by promoting apoptotic death of keratinocytes. More recent studies have shown that granule exocytosis with release of perforin and granzyme B, rather than the Fas/Fas-ligand system, is the main pathway of cytotoxicity mediated by $CD4^+$ and $CD8^+$ T cells in humans[22]. However, a combination of the two mechanisms is most likely, with predominance depending upon the particular stage in the disease process.

The innate immune system, regulatory T cells (Tregs), and Th17 cells

Recent studies have provided evidence for the involvement of Toll-like receptor (TLR) signaling in the induction of autoimmunity. As depicted in Figure 4.1, certain TLRs recognize viral RNA as well as imidazoquinolones (e.g. imiquimod). Interestingly, topical application

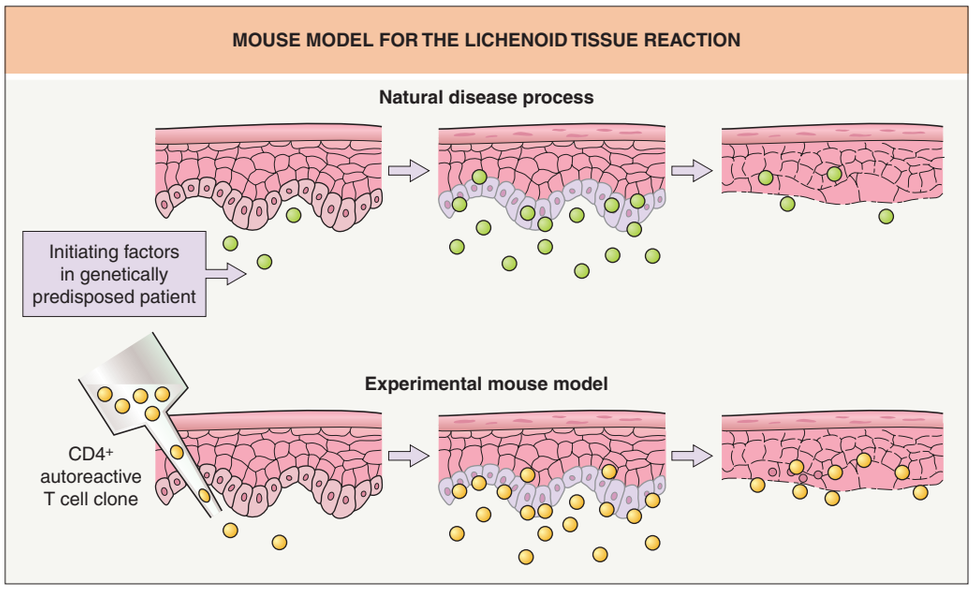

Fig. 11.1 Mouse model for the lichenoid tissue reaction. Because in humans all the analyses are performed on existing skin lesions (after the inflammatory response is underway), it is difficult to provide insight into initiating events and to establish whether the T cells present are indeed relevant to the pathogenesis. This experimentally induced animal model has the advantage that the orchestrated series of events resulting in epidermal injury can be examined from the onset and over time. Of note, injection of suboptimal or supraoptimal doses of T cells can lead to the histologic features of fixed drug eruption or toxic epidermal necrolysis, respectively.

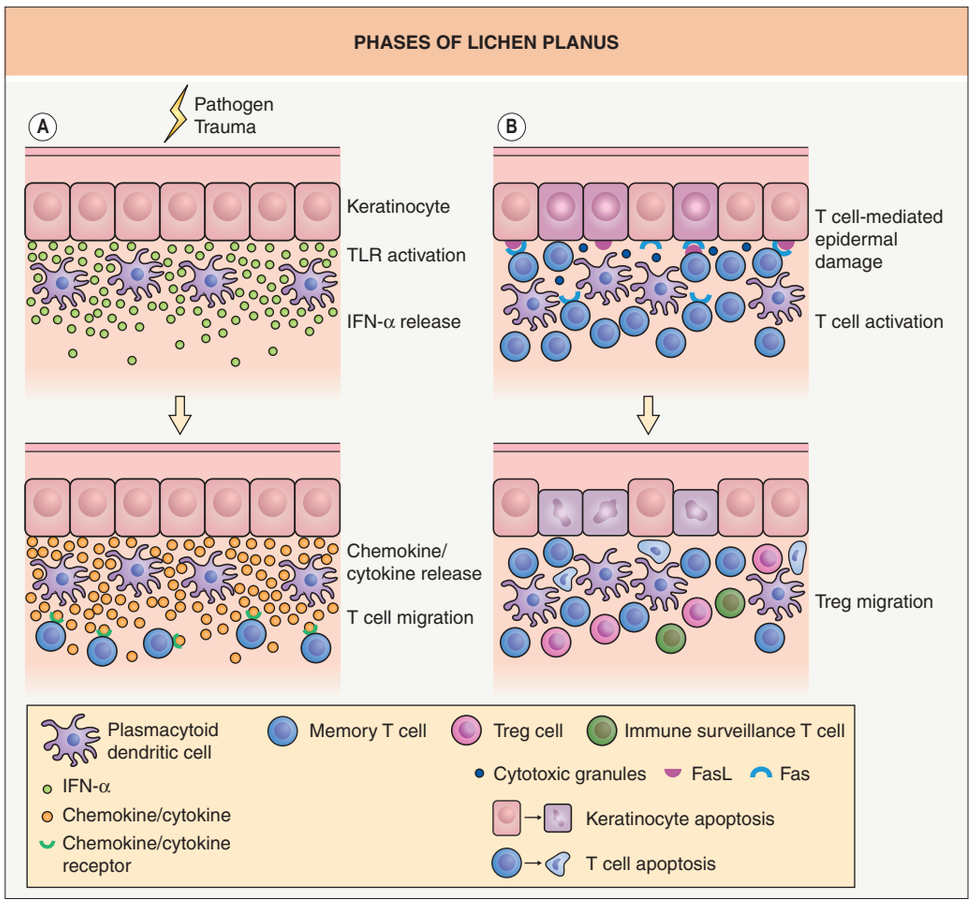

Fig. 11.2 Phases of lichen planus. A In the *induction phase*, keratinocytes and plasmacytoid dendritic cells (pDCs), upon stimulation of their Toll-like receptors (TLRs) by pathogens or endogenous ligands, can release type 1 IFNs (e.g. IFN-α); this represents an early event in the cascade leading to T cell-mediated epidermal damage. Activated keratinocytes, via production of IL-1β and TNF-α, can induce activation and migration of DCs. Chemokines, such as IP-10/CXCL10, released locally by pDCs, serve to attract CXCR3-expressing $CD8^+$ or $CD4^+$ effector memory T cells (which have differentiated from naive T cells within lymph nodes following presentation by DCs of self-peptides modified by exogenous antigens [viruses, medications and contact allergens]). Additional chemokine and chemokine receptor pairs have also been implicated in this process (see Table 11.3), and the precise mix of chemokines and cytokines released into the tissue plays an important role in determining the composition of the inflammatory infiltrates. **B** In the *evolution phase*, effector T cells (Te) that come to express skin-homing receptors (E-selectin ligands) migrate into the inflammatory site and upon recognition of antigens, are activated and release proinflammatory cytokines and cytotoxic granules, which in turn cause epidermal injury. In addition, Fas/FasL interactions can trigger cell death of both lymphocytes and keratinocytes with possible elimination of potentially harmful autoaggressive T cells. "Inflammatory" and "homeostatic" chemokines produced by keratinocytes direct the traffic of not only "pathogenic" T cells (Te) but also "immune surveillance" T cells (Ts) or regulatory T cells (Treg) into the sites; the relative balance of chemokines produced may determine the outcome of the T cell-mediated immune responses. FasL, Fas ligand.

of imiquimod, which can lead to enhanced migration and maturation of dermal dendritic cells, followed by increased production of proinflammatory cytokines and activation of antigen-specific $CD8^+$ T cells, may exacerbate lesions of LP.

In some autoimmune diseases, T cell differentiation may shift from Treg cells (immune suppression) to Th17 cells (see Ch. 4), but an increase in both populations has been found in LP lesions. However, the functionality of the Treg cells within these lesions has been questioned.

Effector T cells' access to the epidermis

A critical event in the initiation of immune responses in LP lesions is for memory T cells to migrate from the circulation into a particular skin site. Release of type 1 IFNs, such as IFN-α, from activated plasmacytoid dendritic cells (pDCs) and keratinocytes may be critical in inducing skin-directed migration of effector memory T cells (Fig. 11.2A). Stimulation of TLRs expressed on pDCs and keratinocytes by pathogens or endogenous ligands (released via skin damage) represents one of the earliest events and it is sufficient to induce type 1 IFN production. Type 1 IFN signaling and type 1 IFN-inducible chemokines (e.g. IP-10/CXCL10) then serve to recruit chemokine receptor CXCR3-expressing effector memory T cells (Th1 cells) into the skin via CXCR3/IP-10 interactions (Table 11.3). A number of other molecular interactions, such as CCR4/TARC, CCR10/CTACK and LFA-1/ICAM-1 expressed on T cells and keratinocytes, respectively, have also been implicated in

CHEMOKINES AND CHEMOKINE RECEPTORS INVOLVED IN T CELL MIGRATION INTO THE SKIN		
Chemokines*	**Chemokine receptors**	**Functional type of chemokines/T cells attracted†**

*Cytokines that have chemoattractant activity; two major groups are differentiated based on the position of two cysteine (C) residues compared with the other amino acid residues (X): CXC- or α-chemokines and CC- or β-chemokines.
†"Inflammatory" chemokines are produced at sites of cutaneous inflammation and mediate skin-directed migration of memory T cells (Th1, Th2); "homeostatic" chemokines are constitutively produced within non-inflamed skin and mediate skin-directed migration of memory T cells with an "immune surveillance" function.

Table 11.3 Chemokines and chemokine receptors involved in T cell migration into the skin. Binding of MCP-1 (CCL2) to CCR2 on monocytes plays an important role in their recruitment to sites of cutaneous inflammation. CCR, receptor for CC chemokines; CTACK, cutaneous T cell-attracting chemokine; CXCR, receptor for CXC chemokines; IP-10, interferon-inducible protein 10; I-TAC, interferon-inducible T cell α-chemoattractant; MCP-2, monocyte chemoattractant protein 2; MDC, macrophage-derived chemokine; MEC, mucosal-associated epithelial chemokine; MIG, monokine induced by interferon-γ; MIP-1α, macrophage inflammatory protein 1α; RANTES, regulated on activation normal T cell expressed and secreted; TARC, thymus- and activation-regulated chemokine.

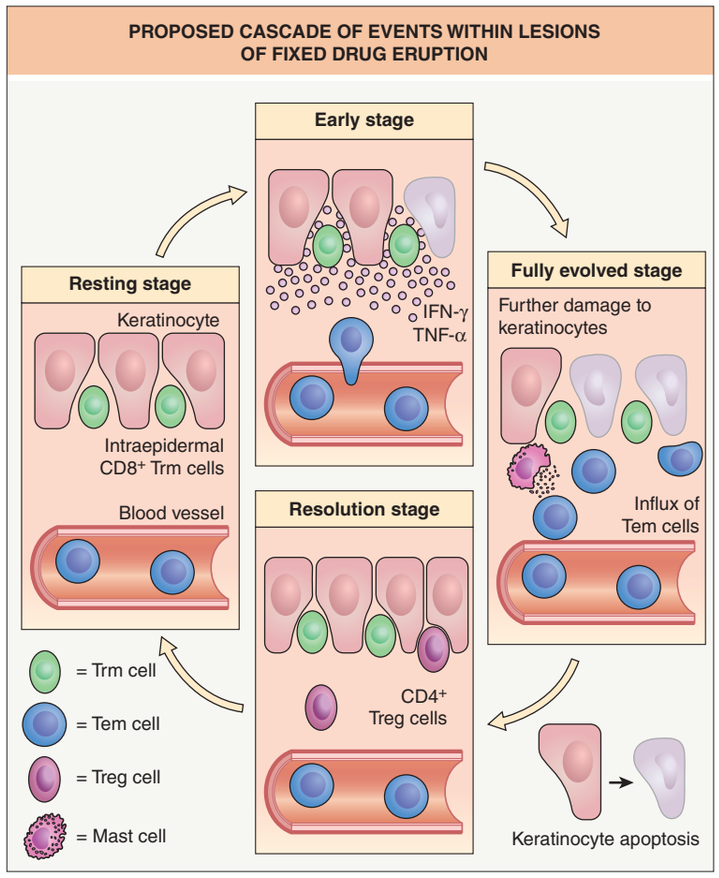

Fig. 11.3 Proposed cascade of events within lesions of fixed drug eruption. Skin tissue-resident memory T cells (Trm cells) and effector memory T cells (Tem cells) both play a role in producing tissue damage. In the resting stage, a stable population of $CD8^+$ Trm cells resides within the epidermis without exerting their cytotoxic potential (the physiologic role of these cells includes local protection against pathogens). When stimulated by cross-reactive antigens such as drugs, Trm cells then display cytolytic activity towards surrounding keratinocytes. The Trm cells also release IFN-γ and TNF-α into the local environment, leading to the recruitment of $CD4^+$ and $CD8^+$ Tem cells from the circulation into the skin. This leads to additional tissue damage. During the resolution stage, Treg cells are recruited into the site of inflammation, in part due to the release of preformed cytokines, including IL-16, by mast cells. Although the majority of activated cell populations are removed by apoptosis (see Fig. 11.2), a proportion of Trm cells are prevented from undergoing apoptosis by IL-15 produced by surrounding keratinocytes.

the recruitment of memory T cells and pDCs to the dermal–epidermal junction[23–25]. Because IFN-α from pDCs induces IFN-γ production by T cells and IFN-γ also sustains IFN-α production, a positive feedback loop may be operational within LP lesions. This ordered sequence of events provides a possible explanation for why LP lesions develop within traumatized sites and virally induced lesions.

Although chemokines produced at inflammatory skin sites are thought to regulate the composition of the Th1- or Th2-driven cellular infiltrates, memory T cells with a "surveillance" function can also migrate to skin sites under non-inflamed conditions (Fig. 11.2B). "Homeostatic" chemokines constitutively produced under non-inflamed conditions can mediate the skin-directed migration of these "immune surveillance" T cells (see Table 11.3), leading to clearance of invading pathogens such as viruses. In addition, Treg cells that have the capacity to suppress activated T cells are also able to enter inflamed skin sites. However, in LP lesions, there is no definitive means of distinguishing "immune surveillance" T cells or protective Treg cells from "pathogenic" T cells. Lastly, identification of the cells responsible for LP is further complicated by the presence of both skin tissue-resident memory T cells (Trm cells) and effector memory T cells (Tem cells) within skin lesions, with the former, whose physiologic role includes local protection against pathogens, becoming a mediator of tissue damage.

Of note, while the epidermotropic migration of effector T cells leading to epidermal damage in lichenoid tissue reactions is clearly a complicated, multistep process, the latter can be bypassed (at least in part) in the case of fixed drug eruptions (FDE). This is because effector $CD8^+$ T cells responsible for the epidermal damage persist as a stable population within previously affected sites, even when the skin becomes normal-appearing[26]. In particular, $CD8^+$ Trm cells (see above) populate the epidermis of "resting" FDE lesions and although these cells are the principal mediators of localized tissue damage, $CD4^+$ and $CD8^+$ Tem cells, recruited from the circulation, also contribute to the epidermal damage (Fig. 11.3).

Sweating disturbance

Sweat contains interleukin (IL)-1, IL-6, IL-8, and TNF-α, proinflammatory cytokines that have been implicated in the induction of T cell recruitment into the skin[27–29]. In theory, extravasated sweat could explain the syringotropic T cell migration occasionally seen in the early lesions of LP. Recent studies have shown that leakage of sweat into the dermal–epidermal junction initiates a complex sequence of events which leads to syringotropic T cell migration[29].

Clinical Features

The characteristic primary lesion of LP is a small, polygonal-shaped, violaceous, flat-topped papule (Fig. 11.4); occasionally papules are umbilicated. The surface is slightly shiny or transparent, and a network of fine white lines called "Wickham striae" or small gray–white puncta are also seen. The latter correspond histologically to focal thickening of the granular layer. Wickham striae are readily apparent by dermoscopy (see Ch. 0). Postinflammatory hyperpigmentation is also a common finding (Fig. 11.5).

The papules of LP may be widely dispersed or they may cluster or coalesce into larger plaques. LP is usually pruritic. Although the Koebner phenomenon (i.e. isomorphic response) is commonly seen in LP (Fig. 11.6), excoriations and impetiginization are unusual. A linear array of lesions can be seen as a consequence of the Koebner phenomenon or an isotopic response at the site of healed herpes zoster, as well as in the linear variant of LP which follows the lines of Blaschko.

The most common sites of involvement are the flexor wrists and forearms, the dorsal hands, the shins, and the presacral area. Mucous membranes, especially the oral mucosa (see below), are affected in more than half of patients, and this is often the only site of disease. Lesions are also commonly seen on the glans penis (Fig. 11.7A), where they can have an annular or figurate configuration and may become erosive.

The duration of the disease can vary depending upon the LP variant. While the lesions of exanthematous LP typically resolve within a year, hypertrophic, oral, and nail LP tend to be more persistent. In particular, ulcerative oral LP may be a lifelong affliction.

Actinic LP

This variant is reported under a variety of names, including LP actinicus, LP subtropicus, LP tropicus and lichenoid melanodermatitis. Although the majority of reported patients have been from Middle Eastern countries, this variant has been observed worldwide. Most patients are young adults or children, but there is no sex predilection. Lesions primarily involve sun-exposed skin of the face, followed by the neck and dorsal surfaces of the hands and arms. They usually consist of red–brown plaques with an annular configuration, but melasma-like hyperpigmented patches have been observed. In temperate climates, spontaneous improvement may occur during the winter months.

Acute (exanthematous) LP

Because lesions are usually widely distributed and disseminate rapidly, this form is also known as exanthematous or eruptive LP. The commonly affected areas include the trunk (Fig. 11.8), the inner aspects of the wrists and the dorsal feet. Reports in the literature of this variant probably include lichenoid drug eruptions. The clinical course is usually self-limited, and in general lesions resolve with hyperpigmentation within 3 to 9 months.

Annular LP

This form is thought to occur when papules spread peripherally and the central area resolves. The annular edge is slightly raised and typically

Fig. 11.7 Annular lichen planus. A On the penis, the lesions have a figurate outline with a thin pale violet border and central hyperpigmentation. **B** On the trunk, the lesions have a thin hyperpigmented rim. *A, Courtesy Frank Samarin, MD.*

purple to white in color, while the central portion is hyperpigmented or skin-colored (see Fig. 11.7). Lesions can resemble porokeratosis, tinea or if there is minimal scale, granuloma annulare. Annular lesions occur in ~10% of patients with LP and are usually scattered among more typical lesions (see Fig. 11.4C), but the former may represent the predominant finding. The most common site of involvement is the axilla, followed by the penis, extremities, and groin. While some have pruritus, most patients are asymptomatic.

Fig. 11.8 Exanthematous lichen planus. Papulosquamous lesions on the back.

Atrophic LP

Atrophic LP may represent a resolving phase of LP, given the history of the lesions: papules coalesce to form larger plaques that over time become atrophic centrally, with residual hyperpigmentation. The clinical appearance of atrophic LP is likely a result of thinning of the epidermis rather than degeneration of elastic fibers, and the epidermal atrophy may be accentuated by the use of potent topical corticosteroids. Common sites of involvement include the intertriginous zones and the lower extremities (Fig. 11.9A).

Bullous LP and LP pemphigoides

In *bullous LP*, vesicles and bullae develop within pre-existing lesions of LP as a result of intense lichenoid inflammation and significant epidermal damage (Fig. 11.9B). This leads to epidermal–dermal separation, i.e. exaggerated Max-Joseph spaces. In contrast, patients with *LP pemphigoides* have circulating IgG autoantibodies directed against the 180 kDa BP antigen (BP180; BPAG2), as in idiopathic BP. However, compared to BP, LP pemphigoides has a younger age of onset. In this variant, bullae can arise either within LP lesions or previously uninvolved skin (Fig. 11.9C), but the diagnosis of LP usually precedes the LP pemphigoides.

These findings suggest that damage to the basal layer by a lichenoid infiltrate may expose hidden antigens to the autoreactive T cells, leading to the formation of autoantibodies and subepidermal bullae. Indeed, LP pemphigoides evolving into pemphigoid nodularis has been described. There are conflicting results regarding the autoantigen in LP pemphigoides, but one study suggested a novel epitope within the C-terminal NC16A domain of BP180 (see Fig. 31.9)[30].To date, no reactivity against the 230 kDa BP antigen, type VII collagen, or the laminin-5 subunits has been detected. An additional difference between these two disorders is the finding of abundant VZV antigen-bearing monocytes and mast cells in the upper dermis of bullous LP lesions as opposed to such cells being rare in LP pemphigoides.

Hypertrophic LP

This variant is also referred to as LP verrucosus (Fig. 11.10). Extremely pruritic, thick, hyperkeratotic plaques are seen primarily on the shins or dorsal aspect of the feet and may be covered by a fine adherent scale. The lesions are usually symmetric and tend to be chronic because of repetitive scratching. The average duration of hypertrophic LP in patients whose lesions had cleared was reported to be 6 years. Chronic venous stasis frequently contributes to the development of this condition. As in hypertrophic LE, squamous cell carcinoma (SCC) may arise within longstanding hypertrophic LP, and distinguishing pseudoepitheliomatous hyperplasia from SCC can be difficult. In one retrospective review, the presence of an increased number of eosinophils pointed to the diagnosis of hypertrophic LP[31].

Inverse LP

In this unusual variant, an inverse distribution pattern is observed. Pink to violaceous papules and plaques appear in intertriginous zones (axillae > inguinal and inframammary folds) and less often in the popliteal

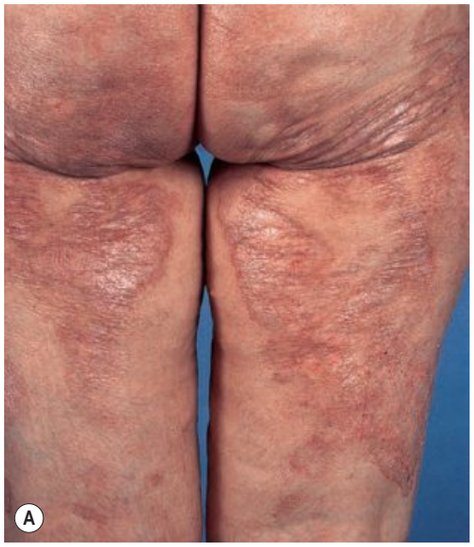

Fig. 11.9 Unusual variants of lichen planus. A Atrophic lichen planus of the lower extremities. **B** Bullous lichen planus on the shin. **C** Lichen planus pemphigoides in a patient with anti-BP180 autoantibodies.

and antecubital fossae (Fig. 11.11). Occasionally, there are LP lesions elsewhere on the body. Hyperpigmentation is usually present as well and it may be the sole manifestation, leading to overlap with LP pigmentosus.

LP pigmentosus

LP pigmentosus typically presents as brown to gray–brown macules in sun-exposed areas of the face and neck, usually with no preceding erythema and often evolving into diffuse or reticulated pigmentation (see Ch. 67). This variant favors individuals with skin types III and IV, in particular those from South Asia, Latin America, and the Middle East. Involvement of intertriginous sites is occasionally observed (Fig. 11.12), and a linear distribution following the lines of Blaschko has also been described. In the photodistributed form, topical application of mustard oil, which contains a potential photosensitizer, has been implicated as a possible trigger.

Given the similarity of histologic findings, distinction from erythema dyschromicum perstans (EDP) is based primarily upon clinical features.

Fig. 11.12 Lichen planus pigmentosus – intertriginous variant. The initial clinical presentation was that of multiple hyperpigmented macules and patches within the axillary vaults.

In EDP, there is often truncal involvement, a younger mean age of onset, and lack of either diffuse pigmentation or the occasional coexisting LP lesions. Of note, small nests of keratinocytes can be seen within the basal layer and these may be confused with nests of melanocytes.

Lichen planopilaris

In lichen planopilaris, involvement of the hair follicle is observed, both clinically and histologically. This variant is also called follicular LP and LP acuminatus. Multiple, keratotic plugs surrounded by a narrow violaceous rim are observed primarily on the scalp, although other hair-bearing areas can also be affected (Fig. 11.13). The inflammatory process may result in scarring and loss of follicular structure, i.e. a permanent alopecia. Over time, the areas of involvement often "burn out" centrally and are indistinguishable from other causes of "end-stage" cicatricial alopecia (see Ch. 69). However, examination of the periphery may reveal the primary lesions. Women are more frequently affected than men, and this form may occur alone or with typical LP lesions elsewhere.

A variant of lichen planopilaris known as Graham-Little–Piccardi–Lassueur syndrome is characterized by the triad of: (1) non-cicatricial loss of pubic and axillary hairs and disseminated spinous or acuminated follicular papules (see Fig. 11.13B); (2) typical cutaneous or mucosal LP; and (3) scarring alopecia of the scalp with or without atrophy (see Fig. 11.13C). These features need not be present simultaneously. Another more recently recognized variant of LP of the scalp is frontal fibrosing alopecia which occurs more commonly in older women and can affect the eyebrows as well (see Ch. 69); patients may also have LP pigmentosus and papules on the face.

Linear LP

Although linear lesions frequently occur in sites of scratching or trauma in patients with LP as a result of the Koebner phenomenon, the term linear LP (Fig. 11.14) is usually reserved for lesions that appear spontaneously within the lines of Blaschko (see Fig. 11.13A). This form has also been referred to as zosteriform, but with the exception of LP developing within the site of previous herpes zoster, the distribution pattern of linear LP is generally not dermatomal. The possibility exists that when LP has a strictly dermatomal pattern, it may have been preceded by "zoster sine herpete". As noted previously (see Pathogenesis), in a case series, VZV antigen was detected in the zosteriform variant of LP but not in the linear variant[12]. Attempts to determine genetic differences between involved and uninvolved skin are ongoing[32].

Discoid lupus erythematosus/lichen planus overlap syndrome

Patients whose lesions have overlapping features of both LP and lupus erythematosus (LE) have been reported. These lesions are preferentially located in acral sites, particularly the palms and soles. Histologic and

Fig. 11.13 Lichen planopilaris. A Keratotic spines surrounded by a violaceous rim in the linear variant. **B** Multiple clusters of follicular keratotic plugs on the leg admixed with small violaceous papules, some of which are folliculocentric. **C** Cicatricial alopecia with "end-stage" changes centrally, but perifollicular inflammation at the margins.

direct immunofluorescence (DIF) microscopic findings show features of both LP and LE. Whether systemic immunologic abnormalities such as high titers of ANA are present in these patients is controversial, but case reports suggest that some patients have disease at the chronic cutaneous LE end of the clinical spectrum while others meet the criteria for systemic LE (see Ch. 41).

Nail LP

The nails are affected in ~10% of patients with LP and usually several nails are affected (see Ch. 71). The characteristic nail abnormalities include lateral thinning (Fig. 11.15A), longitudinal ridging, and

fissuring (Fig. 11.15B). These changes are manifestations of matrix damage, which can lead to scarring and dorsal pterygium formation if left untreated (Fig. 11.15C). Nonspecific changes in the nail bed include yellow discoloration, onycholysis, and subungual hyperkeratosis. In some patients, twenty-nail dystrophy may represent a variant of LP. Nail LP presenting as twenty-nail dystrophy is much more common in children than in adults, although other forms of nail involvement are extremely rare in children.

Fig. 11.14 Linear lichen planus. Coalescence of violaceous lesions with Wickham striae along the lines of Blaschko on an extremity. Note the postinflammatory hyperpigmentation proximally. *Courtesy Joyce Rico, MD.*

Oral LP

Oral LP can appear in at least seven forms, which occur separately or simultaneously: atrophic, bullous, erosive, papular, pigmented, plaque-like, and reticular. The most common and characteristic form of oral LP is the reticular pattern (Fig. 11.16A). It is characterized by slightly raised, whitish linear lines in a lace-like pattern or in rings with short radiating spines. This form is usually asymptomatic and the most common site of involvement is the buccal mucosa; lesions are often bilateral and symmetric. Gingival involvement is common, and oral LP affecting the gingivae exclusively is seen in ~10% of cases. It typically presents as chronic desquamative gingivitis (see Fig. 72.7). Gingivitis also occurs as a component of the "vulvovaginal–gingival syndrome" (see below).

Atrophic, erosive, and bullous lesions are associated with symptoms ranging from mild discomfort to severe pain (Fig. 11.16B). There is a higher incidence of plaque-like lesions among tobacco smokers. For unknown reasons, oral LP is very uncommon in young patients, and in some studies, women have been affected about twice as often as men.

Patients with oral LP should be questioned about symptoms related to esophageal involvement[33] and examined for other mucosal lesions, particularly genital lesions, and vice versa, because ~70% of patients with mucosal vulvovaginal LP have clinical signs of oral LP. Esophageal LP has been increasingly recognized. It tends to be chronic and is associated with the development of dysphagia, strictures, stenosis, and even SCC.

Reportedly, the erosive or ulcerative type of oral LP is less frequently associated with cutaneous LP than are all other types of oral LP. Such mucous membrane lesions are more therapy-resistant and less likely to

spontaneously remit than cutaneous lesions. Malignant transformation of longstanding, non-healing oral LP has been reported, but it must be distinguished from pseudoepitheliomatous hyperplasia. The WHO has defined oral LP as a "premalignant condition" because of this risk.

Several studies have reported a relationship between oral LP and chronic liver disease, particularly that due to HCV infection (see Pathogenesis)[4,6]. In the HCV-positive oral LP group, oral lesions were more frequently located on the tongue, labial mucosa, and gingivae[34].

Ulcerative LP

Ulcerations can occur within palmoplantar lesions of LP, particularly those on the soles. Palmoplantar LP is not as rare as was once thought and usually appears between the third and fifth decade of life. Although palmoplantar LP is more common in men than in women, ulcerative LP prevails in female patients. Typical LP lesions may be present in additional sites of the body. The ulcers are intensely painful and often recalcitrant to conventional therapy. Chronic ulcerative lesions are at risk of developing SCC.

Vulvovaginal LP

LP of the vulva can present with several clinical variants, but the most common appears to be erosive disease[35]. Vaginal involvement occurs in up to 70% of women with erosive vulvar LP, and because there is often oral mucosal involvement as well, the term "vulvovaginal–gingival syndrome" has been introduced. The differential diagnosis of vulvar and vulvovaginal LP includes lichen sclerosus and blistering diseases, respectively (see Ch. 73). Since scarring may be a sequela of vulvovaginal LP, patients should be carefully monitored for the development of SCC, including after the resolution of active disease[36]. Less often an ano-gingival variant is observed.

Lichenoid drug eruption (drug-induced LP)

Despite the significant overlap between LP and lichenoid drug eruption (Fig. 11.17), there are both clinical and histologic clues that favor one diagnosis over the other (Table 11.4)[37].

There is usually a latent period of several months from drug introduction to the appearance of the cutaneous eruption. In a series of 17 patients with lichenoid eruptions induced by a variety of drugs, the mean latent period was 12 months[16]. The latent period varies depending not only on the offending drug, but also on other factors such as the frequency of drug administration, the dosage, and the intensity of the patient's individual reaction to the offending drug. For example, the latent period has been reported to be between 2 months and 3 years for penicillamine, ~1 year for β-blockers, and 4–6 weeks for quinacrine. In contrast to morbilliform eruptions, the time course between drug cessation and lesional resolution can be several weeks to months.

A wide range of cutaneous eruptions have been observed in patients receiving TNF inhibitors; they include new onset or paradoxical worsening of psoriasis (including palmoplantar pustulosis), eczematous eruptions, interstitial granulomatous dermatitis, cutaneous small vessel vasculitis, cutaneous LE, and lichenoid eruptions. The latter are not limited to any particular TNF inhibitor, and while some patients have clinical features similar to idiopathic LP, others have less specific skin lesions clinically, but on histologic examination lichenoid interface changes are seen. The time interval between initiation of TNF blockade and appearance of the lichenoid eruption varies from 3 weeks to 16 months. In some patients, complete resolution or significant improvement followed discontinuation of the TNF inhibitor, whereas in others, clearance occurred despite continued administration of the drug. In that TNF inhibitors are used to treat severe LP, a possible explanation for the paradoxical induction of lichenoid eruptions is a tipping of the balance between Th1 vs Th2 immune responses, Treg vs Th17 cellular responses, or IFN-α vs IFN-γ production. Perhaps inhibition of TNF allows for upregulation of other cytokines such as IFN-α.

Lichenoid granulomatous dermatitis

"Lichenoid granulomatous dermatitis," also referred to as "giant cell lichenoid dermatitis," is usually drug-related and is characterized by a lichenoid dermatitis with a granulomatous infiltrate composed of histiocytes and multinucleated giant cells[38]. In addition to being

FEATURES FOR DISTINGUISHING LICHENOID DRUG ERUPTION FROM LICHEN PLANUS

Feature	Lichenoid drug eruption	Idiopathic lichen planus
Mean age	65 years	50 years
Location	More generalized (including the trunk) and symmetric; often spares the "classic" sites of LP	Wrists, flexor forearms, dorsal hands, presacral area, lower legs, genitalia
Morphology	More eczematous, psoriasiform or pityriasis rosea-like	Shiny, flat-topped, polygonal, violaceous papules
Wickham striae	Uncommon	Present
Hyperpigmentation	Very common, sometimes persistent	Common
Photodistribution	Frequency varies*	Unusual
Mucous membranes	Usually spared	Often involved
Histology	Varying degree of eosinophilic and/or plasma cell infiltrates	Eosinophils and plasma cells uncommon
	Deep perivascular infiltrate may be present (<50% of cases)	Dense band-like infiltrate of lymphocytes in the papillary dermis
	Focal parakeratosis and focal interruption of the granular layer	Parakeratosis uncommon
	Cytoid bodies in cornified, granular and upper spinous layers	Cytoid bodies in lower spinous layer

*Very common with photosensitizing medications such as hydrochlorothiazide.

Table 11.4 Features for distinguishing lichenoid drug eruption from lichen planus. Drugs implicated in lichenoid drug eruptions are listed in Table 11.2.

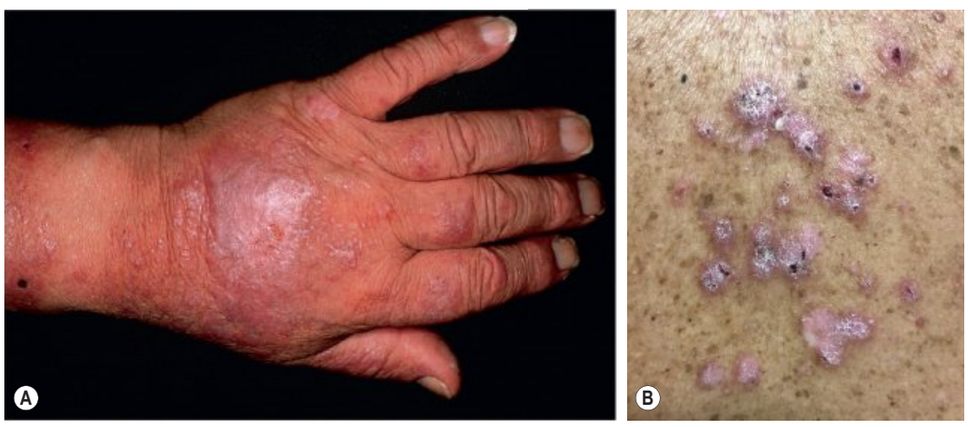

Fig. 11.17 Lichenoid drug eruption. A Photodistributed lichenoid eruption due to hydrochlorothiazide (note sparing under watchband). **B** Lichenoid dermatitis secondary to anti-PD-1 antibody therapy for non-small cell lung cancer that is characterized by pink–violet papules and plaques with white scale and crusts on the back. *B, Courtesy Jonathan S. Leventhal, MD.*

drug-induced, it can be associated with cutaneous T cell lymphoma, rheumatoid arthritis, sarcoidosis, and viral infections. Patients present with red–purple papules and plaques, and the diagnosis is based upon histologic features. The implicated drugs include antibiotics, ACE inhibitors, β-blockers, lipid-lowering agents, phenolphthalein, and nonsteroidal anti-inflammatory drugs (NSAIDs).

Immune checkpoint inhibitor-induced lichenoid eruption

Immune checkpoint inhibitors (ICIs) include monoclonal antibodies that bind cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), programmed cell death protein 1 (PD-1), or programmed cell death ligand 1 (PD-L1). They are increasingly being employed for a wide range of malignancies, with the development of *i*mmune-*r*elated *a*dverse *e*vents (irAEs) correlating with therapeutic response. Cutaneous irAEs occur in at least 50% of patients and they can appear early on, i.e. within 1 to 2 months. In addition to pruritus, maculopapular, psoriasiform, eczematous, and lichenoid eruptions are the most frequently observed cutaneous irAEs. In some patients, lichenoid eruptions arise *de novo* while in others they evolve from a maculopapular rash[39], typically after several months of ICI therapy. Of note, eruptions can have a delayed onset and may even appear after discontinuation of the ICI.

ICI-induced lichenoid eruptions range from classic LP to exanthematous. Histologically, compared to classic LP, there are eosinophils and a variable number of histiocytes. Given the clinical scenario, the goal is to use topical and systemic corticosteroids, phototherapy, or other medications (e.g. acitretin, methotrexate, apremilast) to allow either continuation of the ICI or a brief drug holiday. If a severe cutaneous adverse reaction develops, e.g. Stevens–Johnson syndrome, the ICI is discontinued.

Pathology

Despite its different clinical manifestations, the histopathology of LP is relatively uniform. The primary features are hyperkeratosis without parakeratosis, focal increases in the granular cell layer, irregular acanthosis with a "sawtooth" appearance, vacuolar degeneration of the basal cell layer, and a band-like lymphocytic infiltrate at the dermal–epidermal junction (Fig. 11.18). Colloid bodies representing apoptotic or dyskeratotic keratinocytes (also referred to as Civatte, hyaline, or cytoid bodies) are usually present in the lower levels of the epidermis and the superficial dermis. Vacuolar changes within the basal cell layer may become confluent and result in small separations between the epidermis and the dermis, termed "Max-Joseph spaces". There is often incontinence of pigment with multiple dermal melanophages.

The number of epidermal Langerhans cells is usually increased in active lesions. The majority of cells in the inflammatory infiltrate are lymphocytes, mainly $CD3^+$ T cells (see Pathogenesis). However, exocytosis of lymphocytes into the epidermis is usually not abundant in LP. Plasma cells, macrophages, eosinophils, and mast cells may be seen within the dermis, but not frequently. Occasionally, inflammation and destruction of the distal and proximal ends of the sweat ducts are also seen.

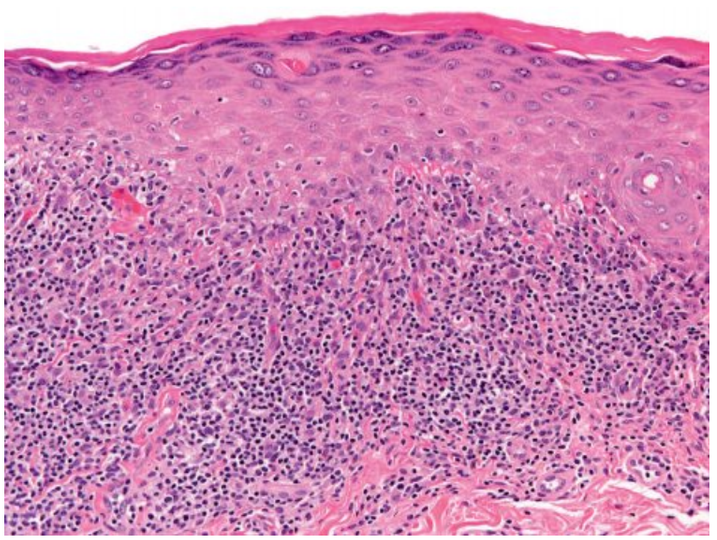

Fig. 11.18 Lichen planus – histopathologic features. Hyperkeratosis, focal increase in the granular layer, sawtoothing of the epidermis with keratinization of the basal layer, and a lichenoid infiltrate. Apoptosis of keratinocytes is also present. *Courtesy Lorenzo Cerroni, MD.*

Oral LP lesions often show parakeratosis rather than hyperkeratosis, and the epithelium may become atrophic in late stages. Lesions of lichen planopilaris are characterized by an inflammatory cell infiltrate around the hair follicles even at an early stage (see Ch. 69). Most of the inflammation involves the upper half of the follicle, with the isthmus affected in one-third of patients. Destruction of the follicles with fibrosis represents a later stage. In LP pemphigoides, a primary histologic feature of the bullous lesions is a subepidermal separation with an abundance of eosinophils (occasionally neutrophil-rich infiltrates), whereas the papular lesions have the usual features of LP.

In a nonspecific "sponge-like" manner, colloid bodies often stain for IgM, IgA, IgG or C3, and this is the characteristic finding by DIF microscopy. In lichen planopilaris lesions, IgM, IgG and IgA are found in varying combinations along the follicle–dermal interface.

The histologic changes in lichenoid drug eruption are very similar to those in idiopathic LP (see Table 11.4). In a retrospective study of 15 patients with idiopathic LP and 15 with a lichenoid drug eruption, no single histologic feature was significantly more likely to occur in the latter than in the former[37]. Although eosinophils were observed exclusively in the lichenoid drug eruptions, they were found in only 2 of the 15 cases. These results indicate that the absence of eosinophils cannot be interpreted as a sign of idiopathic LP. In addition, a few eosinophils may occasionally be seen in conventional LP. Therefore, it would be ill-advised to make the diagnosis of lichenoid drug eruption solely on the basis of histologic criteria.

Differential Diagnosis

LP can be viewed as one of the major reaction patterns in response to various exogenous agents such as drugs, viruses, and contact allergens. Before labeling patients as having "idiopathic LP", an in-depth search should be undertaken to identify any such inducing factors, because there are no definite criteria (either clinical or histologic) for differentiating drug-induced LP from idiopathic LP. Patients with oral LP lesions in apposition to metallic dental restorations should undergo patch testing with relevant metals (see Ch. 14). These metals include amalgam (mercury), copper, and gold. A lichenoid "id" reaction can be seen in children with contact dermatitis to nickel, e.g. in metal snaps in pants.

Other inflammatory conditions that are in the clinical differential diagnosis include LE and erythema dyschromicum perstans, as well as other papulosquamous disorders including pityriasis rosea, psoriasis and secondary syphilis and other lichenoid dermatoses including lichen nitidus, lichen striatus, keratosis lichenoides chronica, lichenoid GVHD, and in the anogenital region, lichen sclerosus. Hypertrophic LP needs be distinguished from lichen simplex chronicus, but in some patients the latter may be superimposed on the former. Patients with paraneoplastic pemphigus can have clinical features of a mucocutaneous lichenoid eruption (see Ch. 29). Multiple lichenoid keratoses arising in sun-damaged skin may be misdiagnosed as a lichenoid drug eruption.

Distinguishing LP from LE can be difficult, especially when there are only oral or scalp lesions, and it may require longitudinal observation, additional biopsies, and DIF studies. Granular or homogeneous bands of immunoglobulin in the basement membrane zone have been demonstrated in lesional mucosa in those with systemic LE (100%) or discoid LE (73%), but only rarely in LP (4%)[40]. The situation becomes even more complicated when there is a flare of disease in a patient with cutaneous LE who is receiving an antimalarial drug, one of the more common causes of a lichenoid drug eruption (see Table 11.2).

When LP affects the mucosal surface of the vulva, the lesions may be difficult to differentiate clinically or histologically from other inflammatory diseases, especially lichen sclerosus. While LP typically involves the inner aspects of the labia minora and consists of a glazed erythema that may easily bleed on touching, lichen sclerosus is typically observed on the outer aspects of the labia minora, and the vagina and oral mucosa are usually not involved (see Ch. 73). This mucosal vulvar variant of LP affects adult women and has not been reported before puberty, while

lichen sclerosus is frequently seen in children. Both lichen sclerosus and LP can involve perianal skin.

Treatment

It is difficult to evaluate the efficacy of different forms of therapy in LP because the majority of therapeutic recommendations are based upon small case series or anecdotes (Table 11.5). In addition, spontaneous remission of cutaneous and oral LP can occur after varying amounts of time. For example, spontaneous remission of cutaneous LP has been observed in up to two-thirds of patients after 1 year, whereas the reported mean duration of oral LP is about 5 years and the erosive form rarely spontaneously resolves[34].

In all instances, the possibility that LP is drug-induced should be considered before embarking on therapy. The diagnosis of lichenoid drug eruption is confirmed by withdrawal of the suspected drug followed by gradual disappearance of the lesions and their recurrence upon re-exposure to the drug. However, rechallenge is often not performed. There are reports of patch testing and *in vitro* tests that involve incubation with the offending drug (e.g. lymphocyte stimulation and macrophage migration inhibition tests) being used to identify the causative drugs[16], but they remain of limited value in confirming the diagnosis.

The next step is to determine which drug – or drugs, if multiple drugs are prescribed – should be withdrawn. The degree of difficulty depends upon the ability to substitute an unrelated but equally effective drug. Lastly, both the patient and the physician who prescribed the medication must be advised that withdrawal of the causative drug may not lead to quick resolution of the skin eruption and that therapies utilized for idiopathic LP may be required.

Well-described therapies for LP include topical, intralesional and systemic corticosteroids, systemic retinoids, narrowband UVB, PUVA, topical calcineurin inhibitors, antimalarials and, for severe or treatment-resistant cases, oral immunosuppressive agents (see Table 11.5). For mild disease, symptomatic treatment includes topical corticosteroids and oral antihistamines for reducing pruritus. Topical corticosteroids are particularly popular for children. Hypertrophic LP lesions may benefit from intralesional corticosteroids or topical corticosteroids under occlusion. Vulvovaginal LP is best treated with topical superpotent (class I) corticosteroids and calcineurin inhibitors[41] plus intravaginal corticosteroids, but if they fail, oral immunosuppressive drugs (e.g. methotrexate, azathioprine, mycophenolate mofetil) and/or low-dose oral prednisone may be required. Inhaled forms of corticosteroids are sometimes used for oral LP. Of note, despite their worldwide use as a mainstay of therapy, the efficacy of topical corticosteroids in cutaneous LP has not been systematically evaluated.

In several studies, tacrolimus 0.1% ointment was found to be effective in reducing the symptoms of oral LP unresponsive to more conventional therapies, including erosive disease. Most patients experienced symptomatic improvement in less than 1 month following twice-daily application. However, in one study, the median relapse time was 5 weeks (range, 2 to 20 weeks), and patients often require intermittent therapy as maintenance to prevent subsequent flares[42]. Symptoms of burning did resolve with continued use of the ointment. To date, serious adverse effects from long-term use (>1 year) have not been reported. However, given the FDA warning regarding topical calcineurin inhibitors and a possible increased risk of cutaneous carcinomas plus the increased risk of developing SCC in the setting of erosive oral and vulvar LP, continued safety monitoring is recommended.

In a more recent small case series, topical rapamycin (sirolimus) resulted in a complete (4/6 patients) or partial (2/6 patients) remission by 3 months in individuals with refractory erosive oral LP. In an open-label, randomized, controlled trial, topical calcipotriene (calcipotriol) and betamethasone valerate had equal efficacy. There are also reports of improvement with an oral suspension of apremilast (two 30 mg tablets crushed; swish and swallow). Maintaining oral hygiene is essential for patients with oral LP (see Ch. 72).

Systemic therapies

In severe, acute LP, systemic *corticosteroids* remain a commonly employed intervention. Although different dosage regimens have been proposed, the minimal effective daily dose of prednisone is usually 15 to 20 mg[1]; treatment is continued for 2–6 weeks and then gradually tapered over several weeks. Rebound and relapses may occur, but long-term maintenance therapy with systemic corticosteroids should be avoided. One study demonstrated that the median time to clearing was 18 weeks in the corticosteroid-treated group and 29 weeks in the placebo group[43].

Acitretin is the only systemic retinoid that has a relatively good level of evidence regarding its efficacy in the treatment of cutaneous LP.

*Implicated in lichenoid drug eruptions.
†Often a first-line therapy for severe, acute cutaneous LP.
‡Short-term for severe disease.

Table 11.5 Therapeutic ladder for lichen planus. Systemic treatments are usually reserved for more severe disease. Recently, oral minoxidil has been used to increase the thickness of remaining scalp hairs in lichen planopilaris (LPP). Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

A therapeutic regimen consisting of acitretin 30 mg/day for 8 weeks resulted in significant improvement or remission in 64% of those in the treatment group, compared with 13% in the placebo group[44]. In case reports, alitretinoin, up to 25 mg/day for 4 weeks, was reported to clear oral, esophageal, and cutaneous LP.

Long-term (3 to 6 months) administration of *griseofulvin* was reported to result in a complete response in 86% of patients with LP[1]. In particular, oral erosive lesions have been reported to respond favorably to this drug. As a result, griseofulvin is often tried in such patients. A complete response or significant improvement (79%) of generalized LP (mean duration of disease, 3.5 months) was observed with *metronidazole*, 500 mg twice daily for 20 to 60 days[45]. More recently, in a retrospective study, *hydroxychloroquine* (200 mg twice daily) was shown to improve both lichen planopilaris and frontal fibrosing alopecia[46]; the latter is also treated with oral 5-α-reductase inhibitors, tetracyclines, and mycophenolate mofetil. Oral *sulfasalazine* administered in increasing doses from 1.5 to 3 g/day for at least 4 weeks was reported to be effective for cutaneous LP but not for mucosal LP. A randomized, double-blind, placebo-controlled trial utilizing a maximum of 2.5 g/day of sulfasalazine observed cutaneous improvement (>50%) in 82.6% vs 9.6% of patients at six weeks[47].

Based upon a case series, weekly low-dose *methotrexate* was noted to improve oral LP[48]. Efficacy of methotrexate for generalized LP has also been described.

Based on a small case series, oral *cyclosporine* was reported as useful in inducing a remission in severe cases of LP resistant to systemic retinoids and corticosteroids[49]. Complete responses were observed with doses of cyclosporine ranging from 1 to 6 mg/kg/day. The majority of patients experienced a relapse during follow-up periods of several months, and a rebound in disease activity can occur upon discontinuation of cyclosporine. Similar results were described in lichen planopilaris; alleviation of symptoms, resolution of clinical activity, and halting the progression of hair loss was achieved within 3 to 5 months[50]. However, long-term use of cyclosporine can be associated with renal toxicity, hypertension, and an increased risk of developing cutaneous SCCs (see Ch. 130).

Mycophenolate mofetil, an immunosuppressive agent which specifically and reversibly inhibits the proliferation of activated T cells, was reported to be effective in the management of disseminated, erosive, hypertrophic and bullous variants of LP as well as lichen planopilaris[51]. It may be preferable to other immunosuppressive drugs such as cyclosporine because of its safer side-effect profile. *Thalidomide* has also been reported to be an effective therapy.

TNF inhibitors have been used in scattered patients with severe recalcitrant LP. Paradoxically, TNF inhibitors can induce LP-like eruptions (see above), usually within two months of initial administration[52]. However, resolution was observed in a few patients despite continued use of the drug.

An open-label pilot study of *apremilast*, an oral phosphodiesterase IV inhibitor, in 10 patients with moderate to severe LP demonstrated statistically significant clinical improvement in all of the patients after 12 weeks[53]. In a patient with steroid-refractory oral LP, improvement was observed after 2 cycles of IVIg (0.4 g/kg/day for 5 days), in combination with oral prednisolone (20 mg/day). *Janus kinase (JAK) inhibitors*, both topical and systemic, are emerging as a new therapeutic tool for cutaneous diseases[53a]. Oral JAK inhibitors, including tofacitinib, upadacitinib and baricitinib, have resulted in marked improvement in erosive LP, as well as nail LP, lichen planopilaris, and hypertrophic LP[54–57,57a].

Phototherapy

In patients with resistant longstanding LP, significant improvement has been observed after bath or systemic PUVA. However, the risk of promoting carcinogenesis, especially in patients with skin types I and II, has to be balanced against the benefits. The usefulness of PUVA prompted evaluation of extracorporeal photopheresis (ECP) for recalcitrant LP. One case series demonstrated that erosive oral LP cleared in all seven patients after an average of 24 sessions of ECP (two consecutive days per month) and follow-up at 24 months revealed no recurrences[58]. The use of narrowband UVB for recalcitrant LP has also been reported. In an open prospective trial in 10 patients with recalcitrant LP, complete clearance occurred after 30 exposures (mean cumulative dose, 17.7 J/cm^2) in five patients, while partial responses were observed in the remainder. The excimer laser (308 nm) was used to treat oral LP unresponsive to conventional therapies and was reported to produce excellent results[59]. Remission times ranged from 2 to 17 months. Of note, the only poor responder in the study had chronic active HCV infection.

LICHEN STRIATUS

Synonyms: ■ Linear lichenoid dermatosis ■ *B*laschko *l*inear *a*cquired *i*nflammatory *s*kin *e*ruption (BLAISE)

Key features

- An asymptomatic, linear dermatosis that primarily affects children
- The primary lesion is a small, flat-topped papule that ranges in color from pink to skin-colored to tan (hypopigmented)
- Multiple lesions appear over the course of days to weeks along the lines of Blaschko and usually on an extremity
- Spontaneously resolves over months to a few years
- Digital involvement may result in nail dystrophy

Introduction

Lichen striatus is an asymptomatic, uncommon, self-limited, linear dermatosis of unknown etiology that generally affects children. The diagnosis is usually made clinically based upon the appearance of the primary lesions and the distinctive developmental pattern. Its distribution along the lines of Blaschko plus the age of the patient usually narrows the differential diagnosis rather quickly. Occasionally, there is overlap with linear LP and "blaschkitis" (see Ch. 62).

History

In 1898, Balzer and Mercier first described a peculiar linear papular eruption that they termed "lichenoid trophoneurosis". Forty years later, Senear and Caro proposed the name "lichen striatus". Ever since the condition was first described, the pathogenesis of its linearity has been the subject of debate.

Epidemiology

Lichen striatus is seen primarily in children between the ages of 4 months and 15 years, although the disorder occasionally occurs in adults. The median age of onset is 2 to 3 years and the vast majority of cases occur in preschool-age children[60]. The reported female : male ratio has varied from 1.6 : 1[61] to 2 : 1[60].

Pathogenesis

Although the distribution of lichen striatus along the lines of Blaschko points to somatic mosaicism (see Ch. 62), neither the gene(s) involved nor the triggering factors are known. Environmental agents, particularly viruses, have been implicated, given the predominance of the disorder in young children and its seasonal variation (it appears more commonly during spring and summer). However, to date, a viral association has not been proven via serologic testing or cultures. Concurrent familial occurrence of lichen striatus in a mother and child has been touted as evidence for a viral trigger.

In theory, during early fetal development, aberrant clone(s) of epidermal cells produced by somatic mutation migrate out along the lines of Blaschko. Exposure to an infectious agent (e.g. virus, BCG vaccine) or other precipitant could then break previous tolerance to the aberrant clone by inducing a novel membrane antigen. The presence of CD8$^+$ T cells scattered or in clusters around necrotic keratinocytes supports a cell-mediated immunologic reaction by which cytotoxic T cells would attack and eliminate the mutated or virally modified keratinocyte clones. A similar mechanism has been proposed for linear LP, and a post-transplant loss of tolerance could explain linear GVHD.

Lichen striatus may represent a manifestation of an atopic diathesis with the abnormal immune responses usually associated with atopy being a predisposing factor. The timing and relative infrequency

of lichen striatus suggests that an infectious agent acts as a trigger in genetically predisposed individuals. Lastly, there are scattered reports of lichen striatus occurring at sites of injury (e.g. the periphery of a burn scar[61]) rather than along the lines of Blaschko, but this could also be explained by a break in tolerance.

Clinical Features

Lichen striatus is typically asymptomatic, but intense pruritus can occasionally occur. The eruption consists of a continuous or interrupted band composed of discrete or clustered pink, skin-colored or tan (hypopigmented) papules that are flat-topped, smooth or scaly, and range in size from 2 to 4 mm. Infrequently, vesicles may be present. Often, there is a single, unilateral streak on an extremity along the lines of Blaschko (Fig. 11.19); occasionally, there is a bilateral distribution pattern and/or multiple parallel bands. It is uncommon for lichen striatus to involve the trunk or head and neck region. There are reports of the eruption spreading distally from the trunk down an extremity, as well as observations of proximal extension along an extremity[62]. Although lichen striatus does not usually recur, relapses may occasionally occur, either in the same site or on the same side of the body[60].

The eruption usually appears suddenly, develops fully over days to weeks, and after several months to a year or more, undergoes spontaneous resolution. Postinflammatory hypopigmentation may be seen, particularly in those with more darkly pigmented skin. In the latter individuals, the eruption is often first noticed as linear hypopigmentation. When lesions involve the nail apparatus, onycholysis, splitting, fraying and total nail loss may result.

Fig. 11.19 Lichen striatus. A Linear streak on the leg that follows the lines of Blaschko. It is composed of numerous small, tan (hypopigmented), flat-topped papules. **B** Three linear streaks on the lower extremity composed of multiple pink papules, some of which are flat-topped with scale. The primary differential diagnosis would be blaschkitis. *A, Courtesy Antonio Torrello, MD.*

Pathology

The histologic features of lichen striatus are variable and depend upon the age of the lesion at the time the biopsy is performed. In addition, different sites within the same streak can have different findings. In general, there is a lichenoid tissue reaction in addition to varying degrees of involvement of the hair follicles and sweat glands and ducts (Fig. 11.20). Even though the lichenoid inflammation that may be present around hair follicles is indistinguishable from that seen in lichen planopilaris, sweat gland and hair follicle involvement can still be a helpful diagnostic feature of lichen striatus[61]. Exocytosis, parakeratosis, dyskeratosis, and focal or diffuse vacuolar degeneration can be seen in the epidermis overlying the lichenoid infiltrate. Occasionally, older lesions may have features similar to LP.

By immunohistochemistry, $CD3^+$ T cell infiltrates were noted in which $CD8^+$ T cells surrounded necrotic keratinocytes and infiltrated vesicles filled with Langerhans cells. Depending upon the age of the lesions, Langerhans cells were either decreased (earlier lesions) or increased (later phase due to an influx of precursor cells).

Differential Diagnosis

Although the differential diagnosis includes other inflammatory diseases that can assume a linear pattern, such as linear porokeratosis, linear psoriasis, inflammatory linear verrucous epidermal nevus, linear lichen sclerosus and linear Darier disease, the primary differential

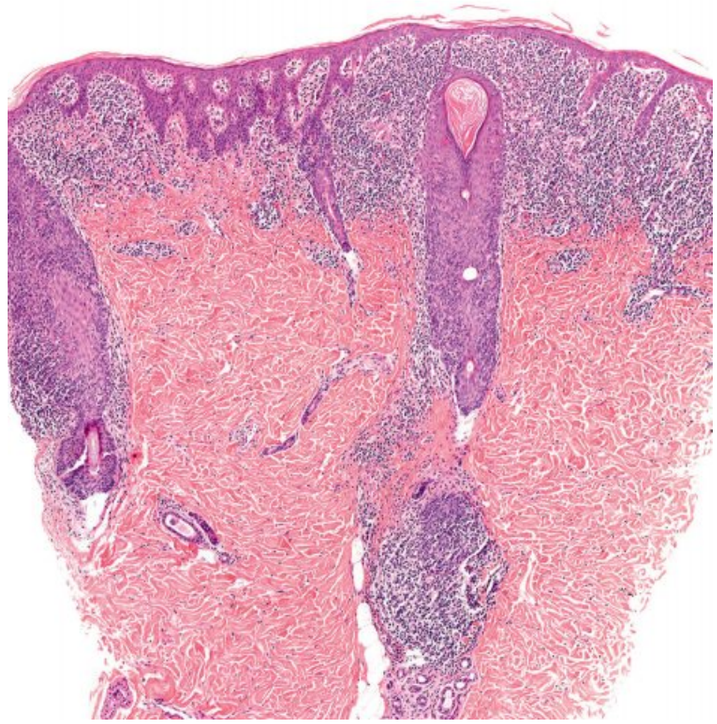

Fig. 11.20 Lichen striatus – histopathologic features. In addition to hyperkeratosis with focal parakeratosis, both a lichenoid and a perivascular and periadnexal lymphocytic infiltrate extending into the deeper dermis is seen. *Courtesy Lorenzo Cerroni, MD.*

diagnosis is linear LP, blaschkitis, and linear GVHD. The latter occurs in a specific clinical setting, while blaschkitis favors the trunk, is usually seen in adults, often consists of multiple streaks, recurs, and can have features of dermatitis. Although linear LP and lichen striatus can occasionally be indistinguishable histologically, the primary lesions usually differ in size and color, and hypopigmentation is a frequent sequela of lichen striatus, while, in general, hyperpigmentation appears in the wake of LP. In lichen nitidus, linear lesions reflect previous traumatic injury to the skin.

Treatment

Treatment of lichen striatus is usually not needed because it is self-limited, usually resolving within 1 to 2 years. Topical corticosteroids under occlusion can be used to hasten spontaneous resolution. In scattered case reports, topical calcineurin inhibitors have also been reported to be effective, including for the nail dystrophy. Obviously, with any purported therapy, the natural history of lichen striatus must be kept in mind.

LICHEN NITIDUS

Key features

- The eruption consists of multiple, tiny, discrete, shiny papules, often in clusters
- Favored sites of involvement include the flexor aspects of the upper extremities, the genitalia, and the anterior trunk
- Linear arrays of papules occur secondary to the Koebner phenomenon
- The histologic correlate of the papule is a well-circumscribed infiltrate composed of lymphocytes and epithelioid cells confined to the width of two to three dermal papillae

Introduction

Lichen nitidus is an uncommon chronic eruption consisting of multiple, tiny, discrete, skin-colored papules that are often arranged in larger clusters. The papules have a distinctive histology with a dense, well-circumscribed, lymphohistiocytic infiltrate closely apposed to the epidermis. There has been considerable debate, however, as to whether lichen nitidus represents a distinct and separate entity or should be regarded as an unusual variant of LP; their coexistence has certainly been reported and progression from lichen nitidus to LP has also been observed. It is generally accepted that lichen nitidus has no relationship to any systemic illness. Only a few authors believe that it may be a cutaneous manifestation of Crohn disease[63].

History

In 1901, Pinkus first described a peculiar papular eruption he termed "lichen nitidus" and suggested that it was a distinct entity histologically.

Epidemiology

Reliable epidemiologic data are difficult to accumulate because of the relative rarity of lichen nitidus. In a US study of 43 patients, primarily Caucasians and African-Americans, the disorder was not found to be restricted to any specific population group based on race, sex, or age[64]. Other authors have observed that lichen nitidus is more prevalent among children or young adults, and a female predominance has been described in the generalized variant. It has also been reported in patients with Down syndrome. Familial lichen nitidus, including in identical twins, is very rare.

Pathogenesis

Although much attention has been focused on the relationship of lichen nitidus to LP, there has been limited recent research regarding its pathogenesis. Lichen nitidus was initially thought to represent a tuberculous lesion or tuberculid because of its histologic features. However, no causative infectious agents have ever been demonstrated, even by repeated inoculations of tissue into animals.

Even though LP and lichen nitidus can coexist in the same patient and they share some similar clinical features (Table 11.6), most authors believe that lichen nitidus is a separate entity because of its distinctive clinical and histologic features. The possibility exists that the two conditions represent different responses to a similar triggering factor, e.g. hepatitis B vaccine. An additional example would be a patient who had Crohn disease in whom LP and lichen nitidus developed over different time frames[63].

Clinical Features

Lichen nitidus is characterized by numerous tiny, discrete, skin-colored, uniform, pinhead-sized papules (Fig. 11.21A). Individual papules are usually flat with a shiny surface (Fig. 11.21B); occasionally they have a central depression. There may be pruritus, but it is an uncommon feature. Although most often skin-colored, the papules can exhibit a variety of hues, from pink or yellow to red–blue or brown. In darkly pigmented individuals, the papules tend to be hypopigmented, but sometimes they are hyperpigmented; marked hyperpigmentation has rarely been reported.

COMPARISON OF CLINICAL AND HISTOLOGIC FEATURES OF LICHEN NITIDUS VERSUS LICHEN PLANUS

	Lichen nitidus	Lichen planus
Clinical		
Size	Pinhead	Pinhead to larger plaques
Color	Skin-colored	Violaceous
Number	Multiple to numerous	Multiple
Distribution	Upper extremities (flexor aspects), genitalia, chest, abdomen	Wrists, flexor forearms, presacral area, dorsal hands, shins, genitalia
Oral involvement	Rare*	Common (>50%)
Nail involvement	<5%–10%	~10%
Wickham striae	Absent	Common
Hyperpigmentation	Uncommon	Common
Hypopigmentation	Common†	Unusual
Koebner phenomenon	Common	Common
Pruritus	Sometimes	Common
Histologic		
Parakeratotic cap	Common	Rare
Granular layer	Thin to absent	Focally increased
Dermal infiltrate	Lymphocytes, epithelioid histiocytic cells, and occasional Langhans giant cells; usually confined to width of 1–3 dermal papillae; "ball and claw" configuration due to hyperplastic rete ridges	Band-like infiltrate of lymphocytes
Deposits of immunoreactants	Absent	Globular deposits of IgG, IgA, IgM, and/or C3 in the papillary dermis

*May be underestimated.
†Especially in individuals with darker skin phototypes.

Table 11.6 Comparison of clinical and histologic features of lichen nitidus versus lichen planus.

The lesions are usually distributed on the flexor aspects of the upper extremities as well as the chest, abdomen, dorsal aspects of the hands, and genitalia (Fig. 11.21A,C). Less commonly, the face, neck, lower extremities, palms, soles, and mucous membranes are involved. Oral lesions are thought to be rare but are probably underestimated; they appear as minute, flat, gray–white papules on the soft mucosa or white plaques on the tongue and hard palate. Nail involvement is observed in up to 10% of patients (primarily adults) and the changes include pitting, rippling, longitudinal ridging, terminal splitting, and increased longitudinal linear striations.

Lichen nitidus is one of several diseases that exhibit the Koebner phenomenon. Vesicular and hemorrhagic lesions are found in some patients, and they are often admixed with the more typical papules. Several other clinical variants have been described, including palmoplantar, linear, and follicular spines. A perforating variant has also been reported, usually in association with LP. In the generalized form, lesions occasionally coalesce. According to one study, the duration in two-thirds of the patients was 1 year or less and the longest duration was 8 years[64].

Pathology

The constellation of histologic features in lichen nitidus is very distinctive. As a result, the clinical diagnosis can be confirmed histologically.

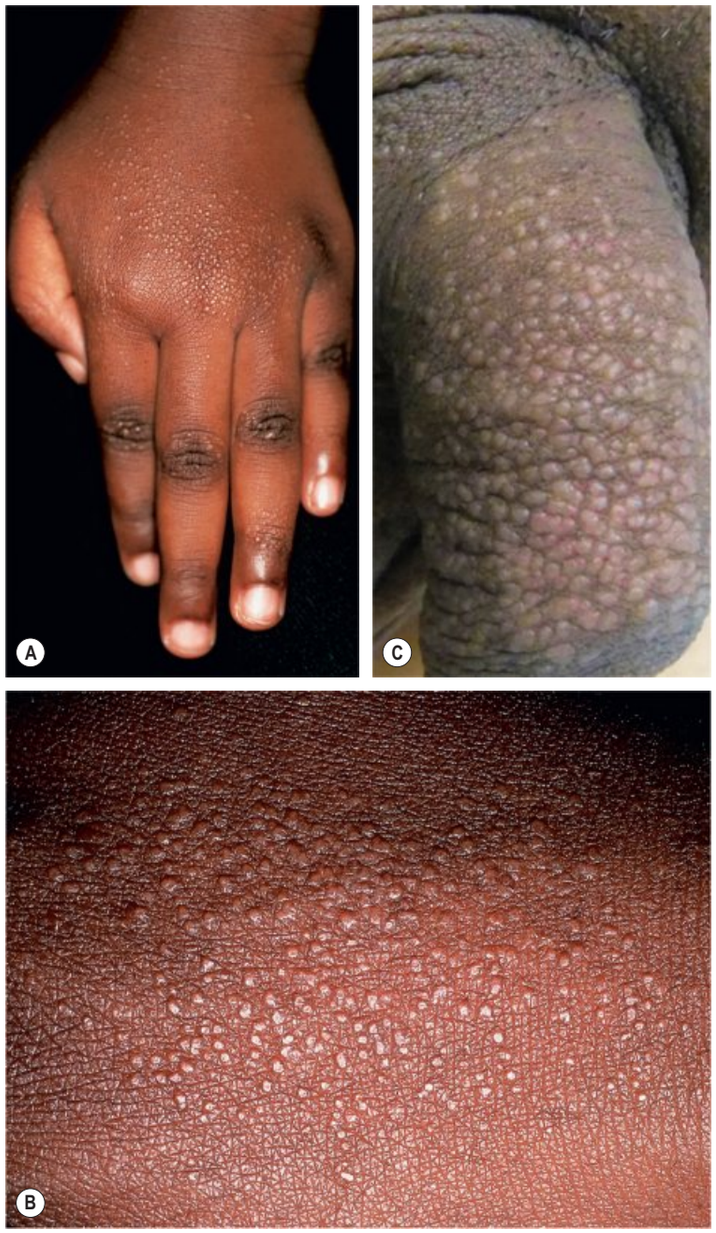

Fig. 11.21 Lichen nitidus. A Numerous tiny flat-topped papules on the hand. **B** A close-up view shows the shiny surface. **C** Numerous pink lesions on penis. *C, Courtesy Kiran Motaparthi, MD.*

A well-circumscribed infiltrate composed of lymphocytes, epithelioid cells, and occasional Langhans giant cells is typically "clutched" by the surrounding hyperplastic rete ridges in a "ball and claw" configuration (Fig. 11.22). In most lesions, the infiltrate is confined to the width of one to three dermal papillae.

The overlying epidermis is usually atrophic and frequently exhibits a parakeratotic "cap" centrally. Absence or thinning of the overlying granular layer is seen and vacuolar degeneration of the basal layer is consistently observed, often accompanied by incontinence of melanin pigment. Civatte bodies are occasionally seen. A Max-Joseph-like space, i.e. focal separation of the epidermis and dermis secondary to vacuolar degeneration, is sometimes observed. The lichenoid infiltrate closely apposes the epidermis and is thought to play a role in inducing reactive epidermal hyperplasia of the surrounding rete ridges. In perforating lichen nitidus, transepidermal elimination is observed (see Ch. 96).

The predominant cell types in the dermal infiltrate are lymphocytes and epithelioid histiocytic cells, and in some cases, epithelioid cells predominate. Immunohistochemical studies have shown a marked predominance of $CD4^+$ T cells over $CD8^+$ T cells[65], as well as the presence of large numbers of $CD1^+$ Langerhans cells in the dermal infiltrates. Of note, the pattern in lichen nitidus lesions of a mixed cellular infiltrate characterized by macrophages and a helper T cell response with few *c*utaneous *l*ymphocyte *a*ntigen-positive (CLA^+) cells is different from that seen in LP[66].

Differential Diagnosis

The differential diagnosis includes LP, guttate lichen sclerosus, lichen spinulosus, frictional lichenoid dermatitis (elbows and knees), and papular eczema (especially in skin phototypes V and VI), as well as verruca plana, lichen scrofulosorum, lichen striatus, papular sarcoidosis, and the lichenoid variant of secondary syphilis. All of these diagnoses, except LP and perhaps lichen scrofulosorum, can usually be excluded relatively easily on the basis of clinical plus histologic findings. It is not always possible to differentiate early tiny papules of LP because they may be clinically and histologically indistinguishable from lichen nitidus (see Table 11.6). Furthermore, lesions identical to lichen nitidus can be found in 25% to 30% of patients with LP. In such cases, the lack of variation in size, the absence of a violaceous color or Wickham striae, and no deposits of immunoglobulin in dermal papillae would suggest the diagnosis of lichen nitidus.

Periadnexal inflammation is more typical of lichen striatus, but patients with the latter have been described where both periadnexal inflammation and superficial features of lichen nitidus were present, suggesting a morphologic spectrum. Lichen spinulosus is characterized by follicular keratotic papules, 1–3 mm in size with a central horny spine, that are grouped into patches on the neck, arms, abdomen and buttocks. The possibility of the spinous follicular variant of lichen

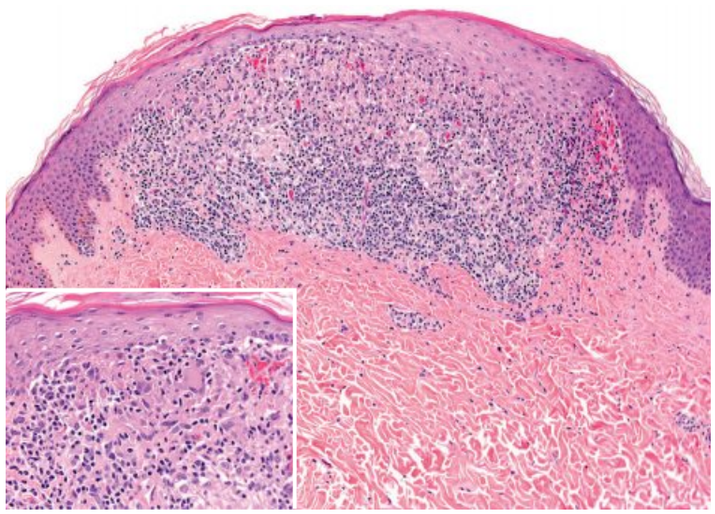

Fig. 11.22 Lichen nitidus – histopathologic features. Note the typical "ball and claw" configuration for the infiltrate and epidermis, respectively. There is thinning of the epidermis that overlies the infiltrate. Several Langhans giant cells are within the infiltrate (inset). *Courtesy Lorenzo Cerroni, MD.*

nitidus should be kept in mind when a patient presents with spiny keratotic papules plus typical histologic features of lichen nitidus. Lastly, lichen nitidus-like lesions can be seen in a photodistribution in summertime actinic lichenoid eruption, also referred to as actinic lichen nitidus (see below).

Treatment

Since the majority of patients experience spontaneous clearing within one or several years, treatment is primarily symptomatic. When significant pruritus is present, topical corticosteroids and oral antihistamines may be helpful. Anecdotally, topical calcineurin inhibitors have been reported as an effective therapy in children with lichen nitidus. Generalized lichen nitidus that had failed to respond to topical corticosteroids has been successfully treated with either narrowband UVB or PUVA[67]. One patient with peripheral $CD4^+$ T cell lymphocytopenia and lichen nitidus who was treated with topical dinitrochlorobenzene (DNCB) developed a pruritic erythematous eruption followed by resolution of the lesions of lichen nitidus[68].

ERYTHEMA DYSCHROMICUM PERSTANS

Synonyms: ■ Ashy dermatosis ■ Ashy dermatitis

Key features

- Slowly progressive appearance of gray, gray–blue or gray–brown, oval-shaped macules and patches
- Occasionally, there is a peripheral rim of erythema
- As in pityriasis rosea, the long axis of oval lesions can follow skin cleavage lines
- Seen most commonly in Latin American patients with skin phototypes III and IV
- Histologic examination demonstrates primarily dermal melanophages

Introduction

This entity was first described in 1957 by Ramírez as an asymptomatic, slowly progressive, ashy-colored, macular hyperpigmentation and was referred to as "dermatitis cenicienta". The disorder was subsequently renamed erythema dyschromicum perstans (EDP) or ashy dermatosis. Some authors consider EDP to be a variant of LP because of the overlapping clinical and histologic features (see LP pigmentosus). However, flat-topped violaceous papules and plaques are not seen in patients with EDP, and in this textbook, they are viewed as separate entities.

History

In 1957, Ramírez referred to these patients as *los cenicientos* (the ash-colored ones) and named the condition "dermatitis cenicienta". Subsequently, five patients from Venezuela were reported who were believed to be similar to those described by Ramírez. These authors suggested calling the disorder "erythema chronicum figuratum melanodermicum" because they considered it to be a new variant of erythema perstans. Sulzberger then proposed a less cumbersome and more descriptive term, "erythema dyschromicum perstans".

Epidemiology

Although it has been observed that EDP occurs most often in more darkly pigmented Latin Americans, there have been occasional reports in Asians and Caucasians. The disorder clearly favors individuals with skin phototypes III and IV. In general, no sex predilection exists, although a few authors reported that women were more commonly affected than men. While the age of onset is variable, EDP frequently appears during the first to third decade of life.

Pathogenesis

In 1973, Pinkus[69] speculated that an as-yet-unidentified set of pollutants in the environment, either contactants or inhaled or ingested substances, may be the cause of EDP in certain predisposed individuals. Indeed, there have been sporadic case reports of temporal associations with: the ingestion of ammonium nitrate, benzodiazepines, or penicillin; exposure to pesticides or toxins; whipworm infestation; and HIV seroconversion. In one patient, characteristic lesions occurred suddenly after a radiographic study using orally administered contrast medium (barium sulfate). However, to date, a rigorous epidemiologic study examining potential triggers has not been performed. Lastly, the possibility has been raised that some patients with multiple lesions of FDE or lichenoid drug eruptions are misdiagnosed as having EDP[70], emphasizing the need to carefully review all medications, including over-the-counter drugs and herbal remedies.

Clinical Features

Most patients present with a slow progression of gray, gray–brown or gray–blue macules and patches (Fig. 11.23). The presence of an erythematous, peripheral margin measuring 1–2 mm in width is actually uncommon. When present, these borders eventually disappear after several months. Most lesions measure between 0.5 and 2.5 cm but can be larger. Although the lesions may vary in shape, many are oval with their long axes following skin cleavage lines, thus assuming a pattern similar to that of pityriasis rosea.

The macules may slowly enlarge or multiply to involve large areas of the body. The most common sites of involvement are the neck, trunk and proximal arms, and the distribution is usually symmetric. Occasionally, asymmetric lesions, usually located on the face or neck, have been observed as have lesions along the lines of Blaschko. Characteristically, there is sparing of the palms, soles, scalp, and mucous membranes. Although spontaneous clearing can occur, especially in prepubertal children (~70% within 2–3 years), the lesions usually slowly progress and then persist for years in adults. The persistence is a reflection of the lack of response to various therapies.

Pathology

The histologic findings vary depending on the phase in the life of the lesion. In the border of active lesions, vacuolization of the basal layer, occasional colloid bodies, and a very mild lichenoid lymphocytic infiltrate are typically seen. These histologic findings may be seen even in the perilesional normal-appearing skin, suggesting that the pathologic processes have already begun in these areas. In inactive ashy-colored lesions, a considerable amount of pigment incontinence with variable epidermal change, including atrophy and effacement of the normal pattern of rete ridges, is seen. These changes are indistinguishable from those observed in other types of postinflammatory hyperpigmentation.

Fig. 11.23 Erythema dyschromicum perstans. Numerous oval to polygonal, gray–brown macules and patches on the lower extremities. *Courtesy Wake Forest University.*

DIF microscopy studies of the active border have demonstrated IgM, IgG, fibrinogen, and C3 staining of colloid bodies, as in LP. However, positive staining for fibrinogen at the dermal–epidermal junction is often the only finding. Immunopathologic studies have shown the dermal infiltrate (when present) to be composed of $CD4^+$ and $CD8^+$ T cells, a common pattern in LP.

Differential Diagnosis

The clinical differential diagnosis includes primarily postinflammatory hyperpigmentation secondary to a lichenoid drug eruption, pityriasis rosea, small plaque parapsoriasis, LP, or generalized FDE. Although the lesions of pityriasis rosea are often oval, the resultant hyperpigmentation is predominantly epidermal, not dermal. In patients with generalized FDE, there is incontinence of pigment histologically, but clinically the shape of the lesions is usually more circular and the color more brown. Less common entities in the differential diagnosis are macular urticaria pigmentosa, pinta, and leprosy.

There is a lack of consensus as to whether idiopathic eruptive macular pigmentation is a variant of EDP seen more commonly in children or a distinct entity. Distinguishing EDP from a lichenoid drug eruption can prove quite difficult and a search for incriminating drugs is essential.

Treatment

In general, proposed treatments for EDP are unsuccessful; they include sun protection, topical corticosteroids, calcineurin inhibitors, retinoids and vitamin C, chemical peels, oral antibiotics, vitamin A, dapsone, antimalarials, griseofulvin, and systemic corticosteroids. On the basis of a case series, clofazimine was reported as a successful treatment. In a systematic review, NB-UVB was also determined to be effective and laser therapy ineffective[71]. Spontaneous remission can occur, but unfortunately many patients have the disease for years.

KERATOSIS LICHENOIDES CHRONICA

This entity was first described in 1895 by Kaposi. He used the term "lichen ruber acuminatus verrucosus et reticularis" to describe a patient with a linear, warty lichenoid eruption. Since his original description, patients with similar lesions have been reported, but with a confusing nomenclature which includes lichen verrucosus et reticularis, porokeratosis striata lichenoides, keratosis lichenoides chronica, lichenoid trikeratosis, and Nékam disease[72]. Over time, keratosis lichenoides chronica has become the most consistently used name for this disorder.

Keratosis lichenoides chronica is characterized by violaceous, keratotic, lichenoid papules that are arranged in a characteristic linear and reticulated pattern (Fig. 11.24A). Lesions are usually symmetrically distributed on the limbs (Fig. 11.24B) and the trunk[72]. Another prominent feature is a greasy and scaly eruption involving the upper portion of the face which has been described as a seborrheic dermatitis-like mediofacial eruption or psoriasiform scaling plaques (Fig. 11.24C). Keratotic papules are sometimes present on the palms and soles, and the nails and scalp may also be affected. Although the clinical course of keratosis lichenoides chronica is usually chronic and progressive, occasionally, regression of individual lesions during the summer or with aging has been reported.

The histologic features of keratosis lichenoides chronica are very similar to those seen in LP. Furthermore, there are no significant differences in immunofluorescence or immunopathologic findings between keratosis lichenoides chronica and idiopathic LP, suggesting that it may be an unusual variant of LP or an unusual isomorphic response. Treatment should be symptomatic and it is usually unsatisfactory. Topical and systemic corticosteroids, methotrexate, cyclosporine, etretinate, oral vitamin A, and PUVA have all been tried but with little success, although a beneficial effect from UVB or etretinate plus PUVA has been reported. Nowadays, acitretin would be prescribed instead of etretinate.

ACTINIC LICHEN NITIDUS (SUMMERTIME ACTINIC LICHENOID ERUPTION)

Summertime actinic lichenoid eruption was first described by Bedi[73] in 1978. Since its initial description, the disorder has been reported under a variety of names, including LP subtropicus, LP tropicus, lichenoid melanodermatitis, LP atrophicus annularis, and LP actinicus. Of note, the last-mentioned is synonymous with actinic LP and the first three terms have also been used to describe actinic LP, so although many authors have regarded summertime actinic lichenoid eruption as synonymous with actinic LP, Bedi considered it to be a separate entity. The former typically occurs in young adults with skin phototypes IV or V following prolonged exposure to the summer sun and presents with pinhead-sized lichenoid papules that are almost exclusively confined to sun-exposed areas.

Isaacson et al.[74] broadened the clinical spectrum of summertime actinic lichenoid eruption to include several types of lichenoid eruptions: annular hyperpigmented plaques, melasma-like patches, grayish-white

Fig. 11.24 Keratosis lichenoides chronica. **A** Linear and stellate keratotic plaques. **B** Symmetrical distribution of linear and reticulated keratotic plaques admixed with small, violaceous lichenoid papules. **C** Crusted psoriasiform scaling plaques on the face. *B, Courtesy Kathryn Schwarzenberger, MD; C, Courtesy Jiro Arata, MD.*

pinhead-sized papules, and typical LP-like papules/plaques. As a result, their description of the histologic findings varied according to the morphology of the different types of clinical lesions. Hussain[75] then proposed that the designation "summertime actinic lichenoid eruption" should be limited to papular eruptions exclusively in sun-exposed areas with lichen nitidus-like histologic features, while the term actinic LP should be used to describe annular lesions with classic histopathologic features of LP. In addition, he suggested abolishing the term summertime actinic lichenoid eruption and replacing it with actinic lichen nitidus or lichen nitidus actinicus. This view has been supported by other authors. In addition to actinic LP, the differential diagnosis includes micropapular polymorphous light eruption and response to hydroxychloroquine has been reported.

ANNULAR LICHENOID DERMATITIS (OF YOUTH)

Annular lichenoid dermatitis of youth was first described in 2003 by Annessi and colleagues[76]. They observed, in a series of young patients, peculiar annular lesions whose clinical features appeared to overlap with those of inflammatory morphea, mycosis fungoides, inflammatory vitiligo, and figurate erythemas. In the initial reports, the annular lichenoid dermatitis occurred primarily in children and young adults (age range, 5–22 years), with no sex predilection. However, in a more recently reported series of six patients, four were adult men, ranging in age from 33 to 45 years[77].

Patients present with erythematous macules that enlarge into annular patches with a reddish-brown, non-scaling border and central hypopigmentation. The lesions are usually 5 to 15 cm in diameter, involve primarily the groin and flanks, and are either solitary or multiple (range, 2–12 lesions; mean, 3).

Histologically, there is a band-like lymphocytic infiltrate within the papillary dermis, along with vacuolar changes of the epidermal basal layer and epidermotropism of lymphocytes. Although variable in number, apoptotic keratinocytes are localized to the tips of the rete ridges (so-called squaring of rete ridges, a finding that distinguishes this entity from mycosis fungoides where squaring of the rete ridges is only rarely observed). Neither spongiosis nor changes in the horny and granular layers are observed. The infiltrate is composed primarily of $CD4^+$ or $CD8^+$ T cells, with few B cells and macrophages. A normal number of melanocytes is present in the hypopigmented areas, a finding that is helpful in differentiating annular lichenoid dermatitis from inflammatory vitiligo. The absence of T cell receptor rearrangements aids in excluding indolent mycosis fungoides[77,78].

The disease follows a chronic course, with some lesions spontaneously resolving while others are quite persistent. Topical or systemic corticosteroids and phototherapy have led to marked improvement or complete regression of the lesions.

VARIANTS OF LICHEN PLANUS		
Type	**Clinical aspects**	**Comments**
Actinic LP	Sun-exposed sites, especially face, neck, dorsal aspect of arms Red–brown annular plaques or melasma-like appearance	Middle East Young adults, children
Acute (exanthematous; eruptive) LP	Abrupt onset Widespread distribution	Usually self-limited (3–9 months) Exclude lichenoid drug eruption, pityriasis rosea, secondary syphilis
Annular LP	Thin raised border, with hyperpigmented or skin-colored center	Favors axillae, groin/penis, extremities
Atrophic LP	Large plaques with epidermal atrophy Later stage of disease	**DDx:** lichen sclerosus Annular variant with loss of elastic fibers centrally
Bullous LP	Bullae within pre-existing lesions	Separation of epidermis from dermis with underlying lichenoid lymphocytic infiltrate
Hypertrophic LP	Favors shins and dorsal feet Thick pruritic plaques with scale Can develop SCC	Average duration – 6 years **DDx:** lichen amyloidosis and LSC
Inverse LP	Violaceous plaques Axillae > inguinal or other major body folds	Overlap with LP pigmentosus as lesions resolve with hyperpigmentation
LP pemphigoides	Variable distribution of vesicobullae, including previously uninvolved skin	Routine histology and DIF of bullous lesions – similar to BP; IIF: autoAb to BPAG2
LP pigmentosus	Brown to gray–brown macules and patches in sun-exposed areas of the face and neck *or* intertriginous zones Inflammatory phase usually absent	Skin phototypes III and IV Coexisting LP lesions in 20% of patients **DDx:** erythema dyschromicum perstans
Lichen planopilaris	Keratotic plugs within hair follicles with narrow surrounding red to violet-colored rim Hair-bearing sites, especially the scalp	A form of scarring alopecia Variant – frontal fibrosing alopecia **DDx** for scalp: discoid LE
Linear LP	Need to distinguish Koebner phenomenon from lesions following lines of Blaschko	**DDx:** lichen striatus if along lines of Blaschko
LP/LE overlap	Lesions favor acral sites Overlapping features	Spectrum – from only cutaneous LE to systemic LE
Nail LP	Lateral thinning, longitudinal ridging, fissuring Dorsal pterygium	Variant – twenty-nail dystrophy (more common in children)
Oral LP	Reticular form – white lacy lines or circle with short radiating spikes (buccal mucosa) Erosive form* – includes chronic desquamative gingivitis	Patients can have both gingival and vulvovaginal involvement May be associated with HCV infection
Ulcerative LP	Plantar surface > palms	
Vulvovaginal LP	Inner aspects of labia minora Glazed erythema that easily bleeds	**DDx:** lichen sclerosus

*If erosive variant plus lichenoid cutaneous lesions, DDx includes paraneoplastic pemphigus.

eTable 11.1 Variants of lichen planus. AutoAb, autoantibody; BP, bullous pemphigoid; BPAG2, bullous pemphigoid antigen 2 (type XVII collagen); DIF, direct immunofluorescence; HCV, hepatitis C virus; IIF, indirect immunofluorescence; LE, lupus erythematosus; LSC, lichen simplex chronicus; SCC, squamous cell carcinoma.

12 Atopic Dermatitis

Maeve A. McAleer and Alan D. Irvine

Synonym: ■ Atopic eczema

Key features

- Common inflammatory skin condition that typically begins during infancy or early childhood and is often associated with other atopic disorders such as asthma, allergic rhinoconjunctivitis, food allergies, and eosinophilic esophagitis
- Complex genetic disease with environmental influences
- Characterized by intense pruritus and a chronic or chronically relapsing course
- Acute inflammation and involvement of the cheeks, scalp and extensor aspects of the extremities predominates in infants, shifting to chronic inflammation with lichenification and a predilection for flexural sites in children and adults
- Associated with a predisposition to skin infections, especially with *Staphylococcus aureus* and herpes simplex virus
- A proactive approach to management is recommended, including avoidance of trigger factors, regular use of emollients, and anti-inflammatory therapy to control subclinical inflammation as well as overt flares; targeted immunomodulatory therapy is available for more severe disease

INTRODUCTION

Atopic dermatitis (AD) is the most common chronic inflammatory skin disease, and its increasing prevalence presents a major public health problem worldwide[1]. Characteristic features of AD include pruritus and a chronic or chronically relapsing course, usually beginning during infancy (early onset) but occasionally first developing in adulthood (late onset)[2]. AD is a complex genetic disease and is often accompanied by other atopic disorders such as allergic rhinoconjunctivitis, asthma, food allergies, and less often eosinophilic esophagitis. These conditions may appear simultaneously or develop in succession. AD and food allergy have a predilection for infants and young children, while asthma favors older children and rhinoconjunctivitis predominates in adolescents. This age-dependent sequence, referred to as the "atopic march"[3] (Fig. 12.1), represents one of many potential pathways to atopic multimorbidity in children with AD[4]. Given that atopic disease usually starts with AD, management should not be concentrated solely on the treatment of acute flares, but also be directed towards ameliorating the underlying genetically determined epidermal barrier dysfunction and preventing active dermatitis via maintenance therapy.

HISTORY AND DEFINITIONS

The association of AD with allergic rhinitis and asthma was recognized by Besnier in 1892. The term "atopy" originates from the Greek word *atopos* meaning strange or unusual; it was first applied to this triad in the 1920s, including the use of "atopic eczema". A decade later, Hill and Sulzberger proposed the name "atopic dermatitis". The list of characteristic features proposed by Hanifin and Rajka[5] in 1980 helped to unify the clinical concept of AD. In 1994, Williams and co-workers[6] simplified Hanifin and Rajka's criteria to establish the UK Working Party's Diagnostic Criteria for AD, which were validated for the purpose of clinical studies; these criteria were modified slightly by Williams in 2005[2]. In 2003, a consensus conference, spearheaded by the American Academy of Dermatology, suggested revised Hanifin and Rajka criteria that are more streamlined and applicable to the full range of patient ages (Table 12.1).

According to the consensus nomenclature by the World Allergy Organization (WAO)[7], the term "atopy" is tightly linked to the presence of allergen-specific IgE antibodies in the serum, as documented by positive fluorescence enzyme immunoassays (previously radioallergosorbent [RAST] tests) or skin prick tests. Thus, an *IgE-associated* or *allergic* form of dermatitis, formerly known as *extrinsic AD*, corresponds to AD in the strict sense. The remaining 20%–30% of patients with the clinical phenotype of AD who have no evidence of IgE-sensitization are categorized as having a *non-IgE-associated* or *non-allergic* form of dermatitis, formerly known as *intrinsic AD*. However, IgE-associated/allergic "true" AD and non-IgE-associated/non-allergic dermatitis have substantial overlap and cannot be considered as two separate diseases; for example, the latter often represents an early transitional form of IgE-associated AD.

EPIDEMIOLOGY

The current prevalence of AD in most high-income and some low-income countries is ~10%–30% in children and 2%–10% in adults. This represents a two- to threefold increase over the past several decades[1]. In general, the prevalence of AD in rural areas and low-income countries is significantly lower than in their urban and high-income counterparts. More recently, however, the prevalence of AD appears to be plateauing in many high-income countries, where there tends to be an inverse socioeconomic gradient in prevalence. These patterns illustrate the importance of lifestyle and environment in the pathogenesis of atopic disease.

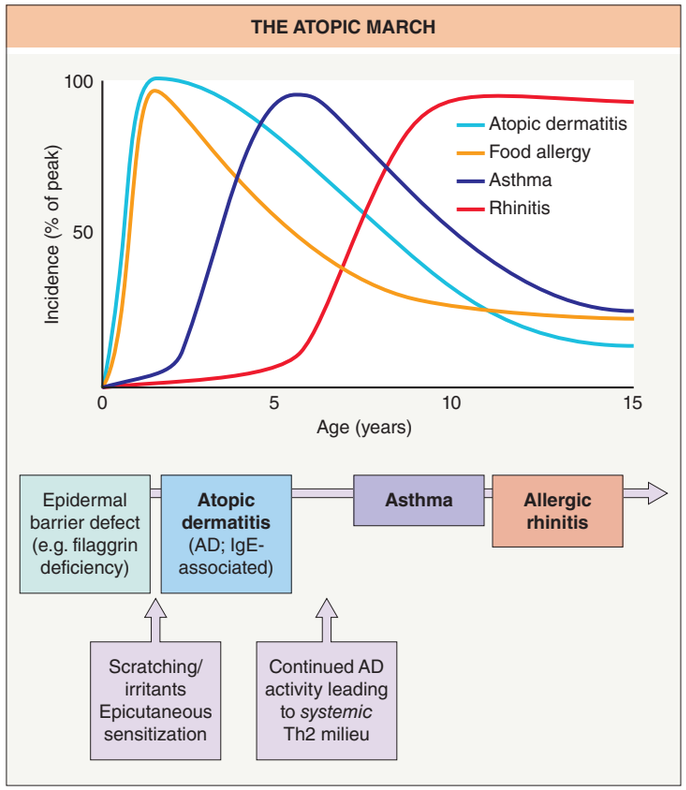

Fig. 12.1 The atopic march. This characteristic sequence represents one of many possible pathways to atopic multimorbidity in children with AD.

DIAGNOSTIC FEATURES AND TRIGGERS OF ATOPIC DERMATITIS (AD)
Essential features: must be present and are sufficient for diagnosis

• Pruritus
  • Rubbing or scratching can initiate or exacerbate flares ("the itch that rashes")
  • Often worse in the evening and triggered by exogenous factors (e.g. sweating, rough clothing)
• Typical eczematous morphology and age-specific distribution patterns (see Fig. 12.3)
  • Face, neck, and extensor extremities in infants and young children
  • Flexural lesions at any age
  • Sparing of groin and axillae
• Chronic or relapsing course

Important features: seen in most cases, supportive of diagnosis
• Onset during infancy or early childhood • Personal and/or family history of atopy (IgE reactivity) • Xerosis   • Dry skin with fine scale in areas *without* clinically apparent inflammation; often leads to pruritus
Associated features: suggestive of the diagnosis, but less specific (see Figs. 12.3 & 12.15)
• Other filaggrin deficiency-associated conditions: keratosis pilaris, hyperlinear palms, ichthyosis vulgaris • Follicular prominence, lichenification, prurigo lesions • Ocular findings: recurrent conjunctivitis, anterior subcapsular cataract; periorbital changes: pleats, darkening • Other regional findings, e.g. perioral or periauricular dermatitis, pityriasis alba • Atypical vascular responses, e.g. midfacial pallor, white dermographism*, delayed blanch
Triggers

• *Climate:* extremes of temperature (winter or summer), low humidity
• *Irritants:* wool/rough fabrics, perspiration, detergents, solvents
• *Infections:* cutaneous (e.g. *Staphylococcus aureus*, molluscum contagiosum, herpes simplex) or systemic (e.g. URI)
• *Environmental allergies:* e.g. to dust mites, pollen, contact allergens
• *Food allergies:*
  • Trigger in small minority of AD patients, e.g. 10%–30% of those with moderate to severe, refractory AD
  • Common allergens: egg > milk, peanuts/tree nuts, (shell)fish, soy, wheat
  • Detection of allergen-specific IgE (via blood and skin prick tests) does *not* necessarily mean that allergy is triggering the patient's AD

*Stroking the skin leads to a white streak that reflects excessive vasoconstriction.

Table 12.1 Diagnostic features and triggers of atopic dermatitis (AD). URI, upper respiratory infection. *Adapted from the American Academy of Dermatology Consensus Conference on Pediatric Atopic Dermatitis (Eichenfield LF, Hanifin JM, Luger TA, et al. J Am Acad Dermatol 2004;49:1088–95).*

Although it is clear that the incidence of AD peaks in infancy and chronic disease is frequently observed, clinical expression over time varies considerably. Recognized AD trajectories include transient, relapsing-remitting, and chronic persistent disease[8,9]. Predictors of persistence into adulthood include a young age at onset, concurrent asthma and/or allergic rhinoconjunctivitis, low socioeconomic status, non-White ethnicity, and filaggrin mutations (see Pathogenesis below). However, it is unclear if these predictors are independent of disease severity[10,11]. Three subsets of AD based on age of onset have been described based on epidemiologic studies:

- *early-onset AD*: defined as AD beginning in the first 2 years of life. This is the most common type of AD, which develops during the first 6 months of life in 45% of affected individuals, during the first year of life in 60%, and before 5 years of age in 85%. Approximately half of children with disease onset during the first 2 years of life develop allergen-specific IgE antibodies by 2 years of age. About 60% of infants and young children with AD go into remission by 12 years of age, including a group with resolution by 4–6 years of age[8,9], while in others disease activity persists into adolescence and adulthood.
- *late-onset AD*: defined as AD that starts after puberty. There are few epidemiological studies on AD with an onset in adulthood. Approximately 30% of AD patients overall are in the non-IgE-associated category, and among adults, the vast majority of such patients are women.
- *AD in the elderly*: a subset of AD that begins after 60 years of age[12].

PATHOGENESIS

The pathogenesis of AD can be divided into three major categories: (1) *epidermal barrier dysfunction*; (2) *immune dysregulation*; and (3) alteration of the *microbiome*. These mechanisms interact with each other and are modulated by both genetic and environmental factors (Fig. 12.2).

Genetic Factors

Genetic factors account for a large proportion of susceptibility to early-onset AD[13], with a significantly higher concordance rate in monozygotic twins (77%) compared to dizygotic twins (15%)[14]. Although the entities in the atopic triad cluster together in families, a parental history of AD is a stronger risk factor for the development of AD than either asthma or allergic rhinitis, supporting the existence of genes specific to AD susceptibility[15]. Genes that encode proteins important to the epidermal barrier and immunologic functions have been implicated in AD pathogenesis (Table 12.2). AD is a complex genetic disease, and both gene–gene and gene–environment interactions have important roles[16].

Epidermal Barrier Dysfunction

A defective epidermal permeability barrier represents a consistent feature of AD and is evident in non-lesional as well as lesional skin of affected individuals[17]. Manifestations of epidermal barrier dysfunction include increases in transepidermal water loss (TEWL), pH and permeability, as well as altered lipid composition[18–23]. The level of TEWL in non-lesional skin of children with AD correlates with disease severity[24,25]. Epidermal barrier dysfunction permits an easier entry for irritants, allergens, and microbes, which trigger immune responses that include the release of proinflammatory cytokines[26]. In infants, greater TEWL is associated with an increased likelihood of epicutaneous sensitization to aeroallergens, which could potentially play a role in the development of asthma and allergic rhinoconjunctivitis[16,27,28]. Factors that contribute to the impaired cutaneous barrier in AD are discussed next.

Filaggrin and other structural proteins

Filaggrin is a keratin *fil*ament-*aggr*egating prote*in* that serves as a major structural component of the stratum corneum. *FLG* loss-of-function (LOF) variants represent the strongest known genetic risk factor for AD and are also responsible for ichthyosis vulgaris[29–32] (see Ch. 57), with carrier frequencies of up to 10% in European and ~3% in East Asian populations[33–35]. Approximately 20%–50% of European and Asian children with moderate-to-severe AD have at least one *FLG* LOF variant; the penetrance of AD is ~40% for one and ~90% for two LOF alleles[30]. This implicates epidermal barrier dysfunction in the initiation of AD, with subsequent development of Th2-biased immune responses[34]. Although *FLG* LOF variants also play a role in the pathogenesis and persistence of AD in children of African descent, they appear to be rare in individuals from sub-Saharan Africa[36–40]; however, technical limitations may have reduced detection of uncommon *FLG* variants in earlier studies[36–38]. Of note, filaggrin expression is also affected by intragenic copy number variation and reduced by increased local pH, protease activity, and Th2 cytokine levels[32,41].

FLG mutations are associated with early-onset AD, greater disease severity, and persistence into adulthood as well as enhanced epicutaneous sensitization and an increased risk of irritant contact dermatitis, hand eczema, herpes simplex virus (HSV) infections, and food allergy[30,35,42]. *FLG* mutations have also been linked to an increased risk for the development of asthma and greater asthma severity; however, these effects are only seen in patients with pre-existing AD[43]. Since filaggrin is not found in the gastrointestinal or bronchial mucosa, the association of *FLG* mutations with food allergy and asthma strongly suggests that epicutaneous sensitization and/or cutaneous inflammation can contribute to the development of systemic atopic disease[44].

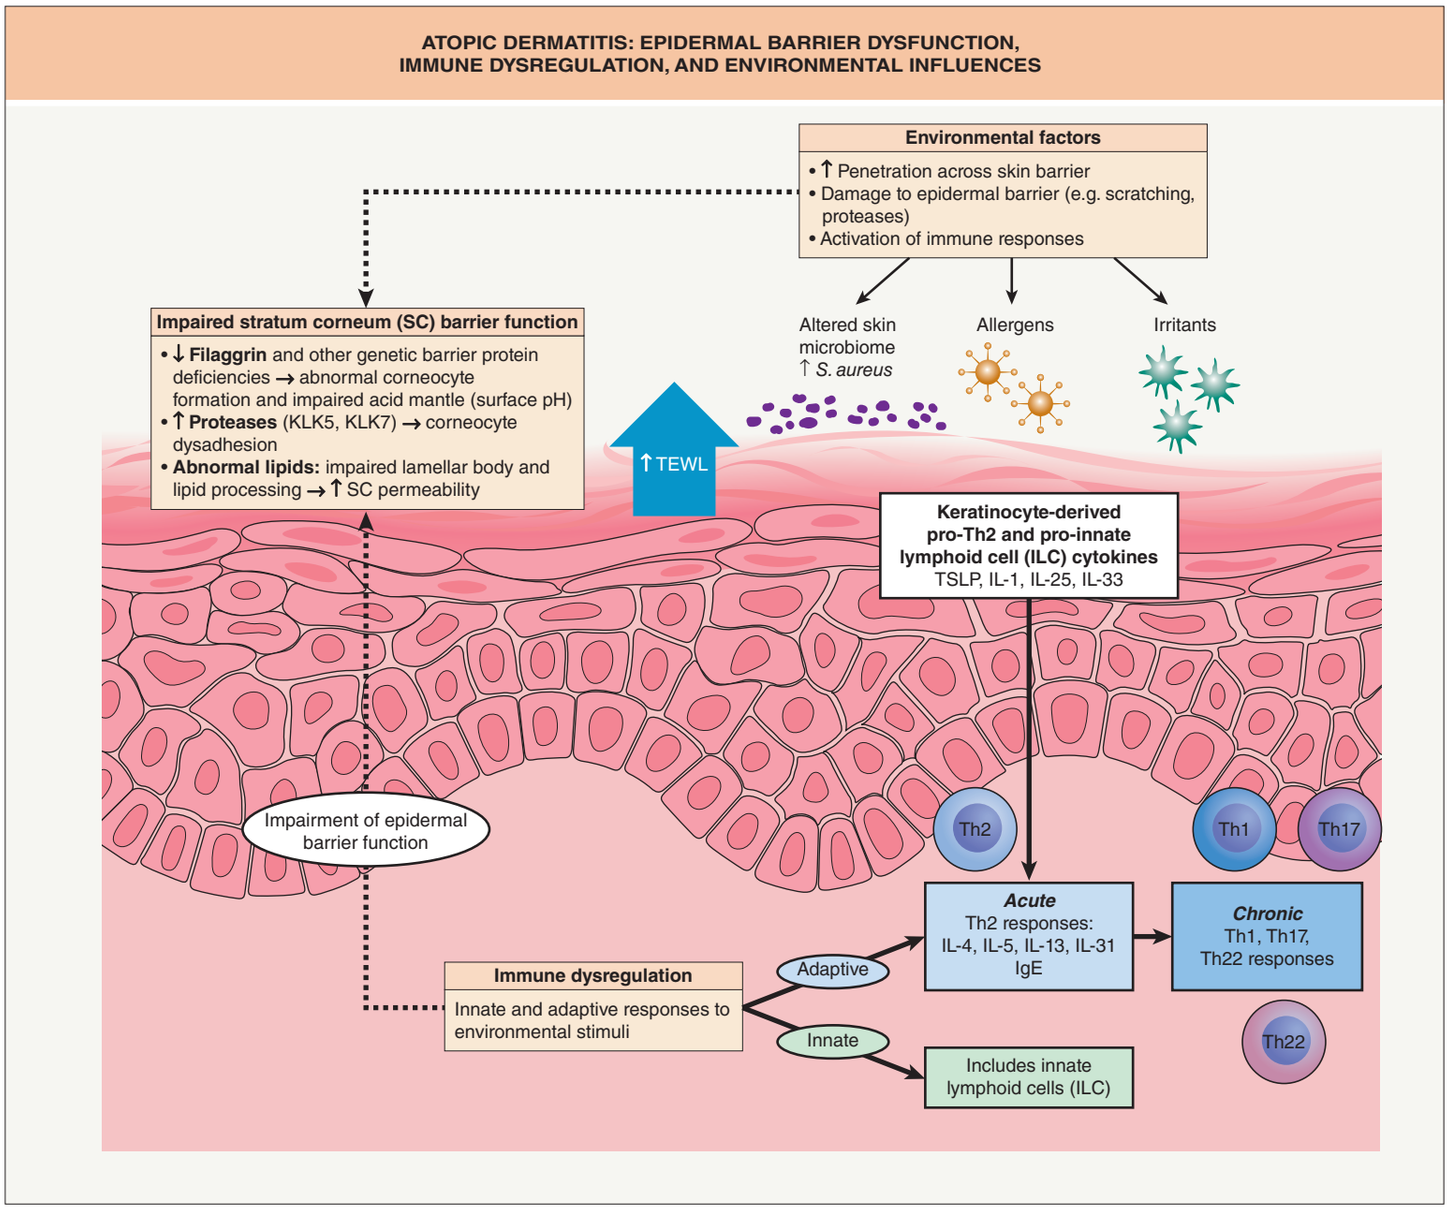

Fig. 12.2 Atopic dermatitis results from defects in epidermal barrier function, immune dysregulation, and environmental influences. SC, stratum corneum; KLK, kallikrein; TEWL, transepidermal water loss; TSLP, thymic stromal lymphopoietin. *Courtesy Harvey Lui, MD.*

Filaggrin breakdown products such as histidine contribute to epidermal hydration, acid mantle formation, lipid processing, and barrier function[30,42]. Gene expression profiling and immunohistochemical analysis of lesional and non-lesional skin from AD patients have shown broad defects in terminal differentiation, with downregulation of other epidermal barrier proteins such as loricrin, corneodesmosin, involucrin, small prolene rich proteins 3/4 (SPRR3/4), claudin-1, and late cornified envelope protein 2B[45–49].

Stratum corneum lipids

The composition, organization, and biochemical processing of stratum corneum lipids are critical determinants of epidermal permeability barrier function (see Ch. 124). In AD, a filaggrin-deficient cytoskeletal scaffold contributes to abnormal loading and secretion of lamellar bodies, with subsequent defects in post-secretory lipid organization and processing[50–52]. Disruption of the skin's acidic mantle leads to reduced activity of lipid-processing enzymes such as β-glucoscerebrosidase and acid sphingomyelinase[53,54]. Th2 cytokines also negatively affect generation of stratum corneum lipid components[52,55,56]. Lastly, *Staphylococcus aureus* colonization of the skin affects lipid composition and contributes to epidermal barrier impairment[21].

Proteases and protease inhibitors

Lesional AD skin demonstrates elevated levels of endogenous serine proteases, e.g. kallikrein 5 and 7 (KLK5/7), due to an imbalance in the activities of these proteolytic enzymes and protease inhibitors, such as the lymphoepithelial Kazal-type trypsin inhibitor (LEKTI) encoded by *SPINK5*. Biallelic loss-of-function *SPINK5* mutations underlie Netherton syndrome, which features profoundly compromised barrier function and atopy (see Ch. 57), while *SPINK5* polymorphisms have been linked to increased risk of AD in some populations[57]. Other factors that enhance proteolysis include increased skin surface pH and exogenous proteases from allergens (e.g. house dust mites, pollens), *S. aureus*, and *Malassezia*[58].

LEKTI deficiency results in excessive degradation of the corneodesmosomal component desmoglein-1 (Dsg1), causing abnormal stratum corneum detachment and thereby disrupting the epidermal barrier[59]. The *S. aureus* extracellular V8 protease, which has a sequence similar to those of *S. aureus* exfoliative toxins, is also thought to degrade Dsg1[60]. In addition, unrestrained protease activity leads to degradation of lipid-processing enzymes and antimicrobial peptides as well as activation of proinflammatory cytokines[58,61].

SELECTED CANDIDATE GENES FOR ATOPIC DERMATITIS	
Candidate gene(s)	**Defective protein(s)**
Genes encoding epidermal proteins	
FLG	Filaggrin (loss-of-function variants; see text)
FLG2	Filaggrin family member 2
SPINK5	Serine protease inhibitor LETKI
KLK5/SCTE, KLK7/SCCE	Kallikrein-related peptidases 5 & 7/stratum corneum tryptic & chymotryptic enzymes
CLDN1	Claudin-1
SPRR3	Small proline-rich protein 3
TMEM79	Transmembrane protein 79 (mattrin)
KIF3A	Kinesin family member 3A
Genes encoding immunologic proteins	
FCER1A	Fc fragment of high-affinity IgE receptor I, α chain
TLR2, 4, 6, 9	Toll-like receptor-2, -4, -6, and -9
IRF2	Interferon regulatory factor 2
IL4, 5, 12B, 13, 18, 31	Interleukin-4, -5, -12B, -13, -18, and -31
IL4RA, IL5RA, IL13RA	Interleukin-4, -5, and -13 receptors, α subunits
GM-CSF	Granulocyte–macrophage colony-stimulating factor
CD14	Monocyte differentiation antigen CD14
DEFB1	β-defensin 1
GSTP1	Glutathione S-transferase P1
CMA1	Mast cell chymase
CCL5/RANTES	Chemokine (C-C motif) ligand 5/RANTES
TSLP	Thymic stromal lymphopoietin
CARD11, CARD14	Caspase recruitment domain family members 11 and 14
RETN	Resistin
MIF	Macrophage migration inhibitory factor
VDR	Vitamin D receptor
CYP27A1, CYP2R1	Cytochrome p450 family members 27A1 and 2R1

Table 12.2 Selected candidate genes for atopic dermatitis. LETKI, lymphoepithelial Kazal-type-related inhibitor; RANTES, regulated on activation, normally T cell expressed and secreted; *SPINK5*, serine peptidase inhibitor Kazal type 5.

Immune Dysregulation

Both innate and adaptive immune systems play dynamic interrelated roles in the pathogenesis of AD. The inflammatory profile is diverse, with activation of skin-resident inflammatory dendritic cells, group 2 innate lymphoid cells, and Langerhans cells[62]. Acute AD lesions have a predominance of Th2 cytokines, but there is subsequent evolution to a chronic phase characterized by Th1 and Th22 cytokine profiles, as well as variable levels of Th17 cytokines in both acute and chronic AD[63]. The acute phase features IL-4, IL-5, and IL-13; activation of eosinophils and mast cells; and production of allergen-specific IgE[64,65]. Keratinocyte-derived cytokines, including IL-1, thymic stromal lymphopoietin (TSLP), IL-25 (IL-17E) and IL-33, promote a Th2 immune response. Th2 cytokines inhibit expression of major terminal differentiation proteins such as loricrin, filaggrin, and involucrin as well as β-defensin-2/3 antimicrobial peptides[23,46,66,67].

Thymic stromal lymphopoietin (TSLP)

TSLP is an IL-7-like cytokine that is known as the "master-switch of allergic inflammation" due to its central role in evoking a Th2 response via dendritic cell activation[61,68–70]. Exposure to allergens, viral infections, trauma, and other cytokines (e.g. IL-1β, TNF) can trigger TSLP production by keratinocytes, fibroblasts, and mast cells[71]. TSLP is highly expressed in acute and chronic lesions of AD, but not in the non-lesional skin of patients with AD or in unaffected individuals[72].

IL-4 and IL-13

IL-4 has a key role in driving Th2 cell differentiation, IgE production, and eosinophil recruitment[73,74]. Transgenic mice overexpressing IL-4 in their epidermis develop atopic dermatitis-like lesions, pruritus, an altered microbiome, and elevated IgE levels[75]. The heterodimeric receptors for IL-4 and IL-13 both contain the IL-4 receptor α subunit (IL-4Rα; see Fig. 128.9C) and activate signal transducer and activator of transcription 6 (STAT6), which promotes the differentiation of naive T cells into Th2 effector cells[76]. Although IL-4 and IL-13 share 25% sequence homology and effector functions, studies in human subjects, and human keratinocyte cell lines, support an independent role for IL-13 in AD pathogenesis. Monoclonal antibodies that target IL-4/-13 represent effective treatments for AD[77] (see Ch. 128 and below).

Other cytokines

Th17 cells are important in the regulation of innate immunity, in particular neutrophil recruitment, and have also been implicated in allergic disorders[78]. Th17 cells are found in acute as well as chronic AD lesions[79], and production of IL-17 and IL-19 is especially characteristic of new-onset pediatric AD[80]. IL-26, which is also produced by Th17 cells, induces production of Th2- and Th17-associated cytokines, thereby potentially acting as a bridge between Th2 and Th17 responses[81].

IL-31 is a Th2 cytokine that is highly expressed in lesional skin and serum of patients with AD as well as in other pruritic skin disorders such as prurigo nodularis[82–84]. Cutaneous exposure to staphylococcal superantigen rapidly induces IL-31 expression in atopic individuals, establishing a link between staphylococcal colonization of the skin and pruritus. The heterodimeric receptor for IL-31 is expressed by keratinocytes, eosinophils, activated macrophages, cutaneous C nerve fibers, and dorsal root ganglia (see Ch. 5)[85,86]. Randomized, placebo-controlled trials (RCTs) have shown that nemolizumab, a humanized monoclonal antibody against the IL-31 receptor A subunit, can significantly reduce pruritus in patients with moderate to severe AD, although improvements in disease severity scores were modest[87].

IL-33, a member of the IL-1 cytokine family, protects against helminth infection by promoting a Th2-type immune response. IL-33 expression is increased in AD lesions compared to the skin of unaffected individuals[88], and AD therapies targeting IL-33 are under development.

Innate lymphoid cells

The innate lymphoid cell (ILC) family includes natural killer cells and three groups of non-cytotoxic ILCs that orchestrate immunity, inflammation, and homeostasis in multiple tissues[89]. The group 2 ILC (ILC2) population is expanded in AD lesions and stimulated by TSLP, IL-25 (IL-17E), and IL-33[90–92]. ILC2s interact with other immune cells (e.g. mast cells, eosinophils) in the skin to promote Th2-type inflammation in a T cell independent manner.

The Cutaneous Microbiome

The cutaneous microbiome represents a complex and highly diverse community of pathogenic and commensal bacteria, fungi, and viruses that play a critical role in epidermal homeostasis, with microbial dysbiosis contributing to the pathogenesis of AD. More than 90% of patients with AD have skin colonized with *S. aureus*, compared to about 5% of unaffected individuals, presumably reflecting the disrupted acid mantle, decreased antimicrobial peptides (e.g. cathelicidins, defensins), and altered cytokine milieu of AD skin[93]. During AD flares, bacterial diversity decreases and the proportion of the microbiome accounted for by *Staphylococcus* spp. increases from ~35% to ~90%[94]. Conversely, normalization of the microbial population correlates with clinical improvement in AD[95].

Superantigens can promote the development of a Th2 immune response, and exotoxins with superantigenic properties are produced by up to 65% of the *S. aureus* strains that colonize AD patients[96]. Compared to unaffected controls, an IgE response to the *S. aureus* superantigens enterotoxin A and enterotoxin B occurs more frequently in patients with AD[97]. The *S. aureus* δ-toxin also stimulates mast cell degranulation and Th2 inflammation[98]. In addition, filaggrin deficiency increases the susceptibility of keratinocytes to *S. aureus* α-toxin-induced cytotoxicity[99]. Lastly, *Malassezia* spp. may also contribute to inflammation in AD, and adults with severe head and neck disease often display IgE reactivity to *Malassezia* antigens[100–102].

Alterations in the skin microbiome of AD patients related to the use of cleansers and topical immunomodulatory or antimicrobial agents may

have potential effects on cutaneous inflammation and barrier function. Topical administration of coagulase-negative *Staphylococcus* strains with antimicrobial activity or the Gram-negative commensal *Roseomonas mucosa* has been shown to markedly reduce *S. aureus* colonization in AD patients[103,104]. *R. mucosa* application was also associated with decreased AD severity and topical corticosteroid requirement[104], providing the basis for bacteriotherapy as a potential AD treatment.

CLINICAL FEATURES

Age-Related Cutaneous Findings

AD has a broad clinical spectrum that varies depending upon the age of the patient. It is divided into infantile, childhood, and adolescent/adult stages (Fig. 12.3). In each stage, patients may develop acute, subacute, and chronic eczematous lesions, all of which are intensely pruritic and often excoriated. Acute lesions predominate in infantile AD and are characterized by edematous, erythematous papules and plaques that may exhibit vesiculation, oozing, and serous crusting. Subacute eczematous lesions display erythema, scaling, and variable crusting. Chronic lesions, which typify adolescent/adult AD, present as thickened plaques with lichenification as well as scale; prurigo nodule-like lesions can also develop (see below). Perifollicular accentuation and small, flat-topped papules (papular eczema) are particularly common in Black or Asian patients (Fig. 12.4). In any stage of AD, a generalized exfoliative erythroderma may develop in the most severely affected patients (see Ch. 10). All types of AD lesions can leave postinflammatory hyper-, hypo-, or occasionally depigmentation upon resolution (Fig. 12.5).

Infantile AD (age <2 years) typically develops after the second month of life, often initially appearing as edematous papules and papulovesicles on the cheeks, with sparing of the central face; the lesions may evolve to form large plaques with oozing and crusting (Fig. 12.6). The scalp, neck, extensor aspects of the extremities, and trunk may also be involved, usually with sparing of the diaper area (Fig. 12.7). In the first

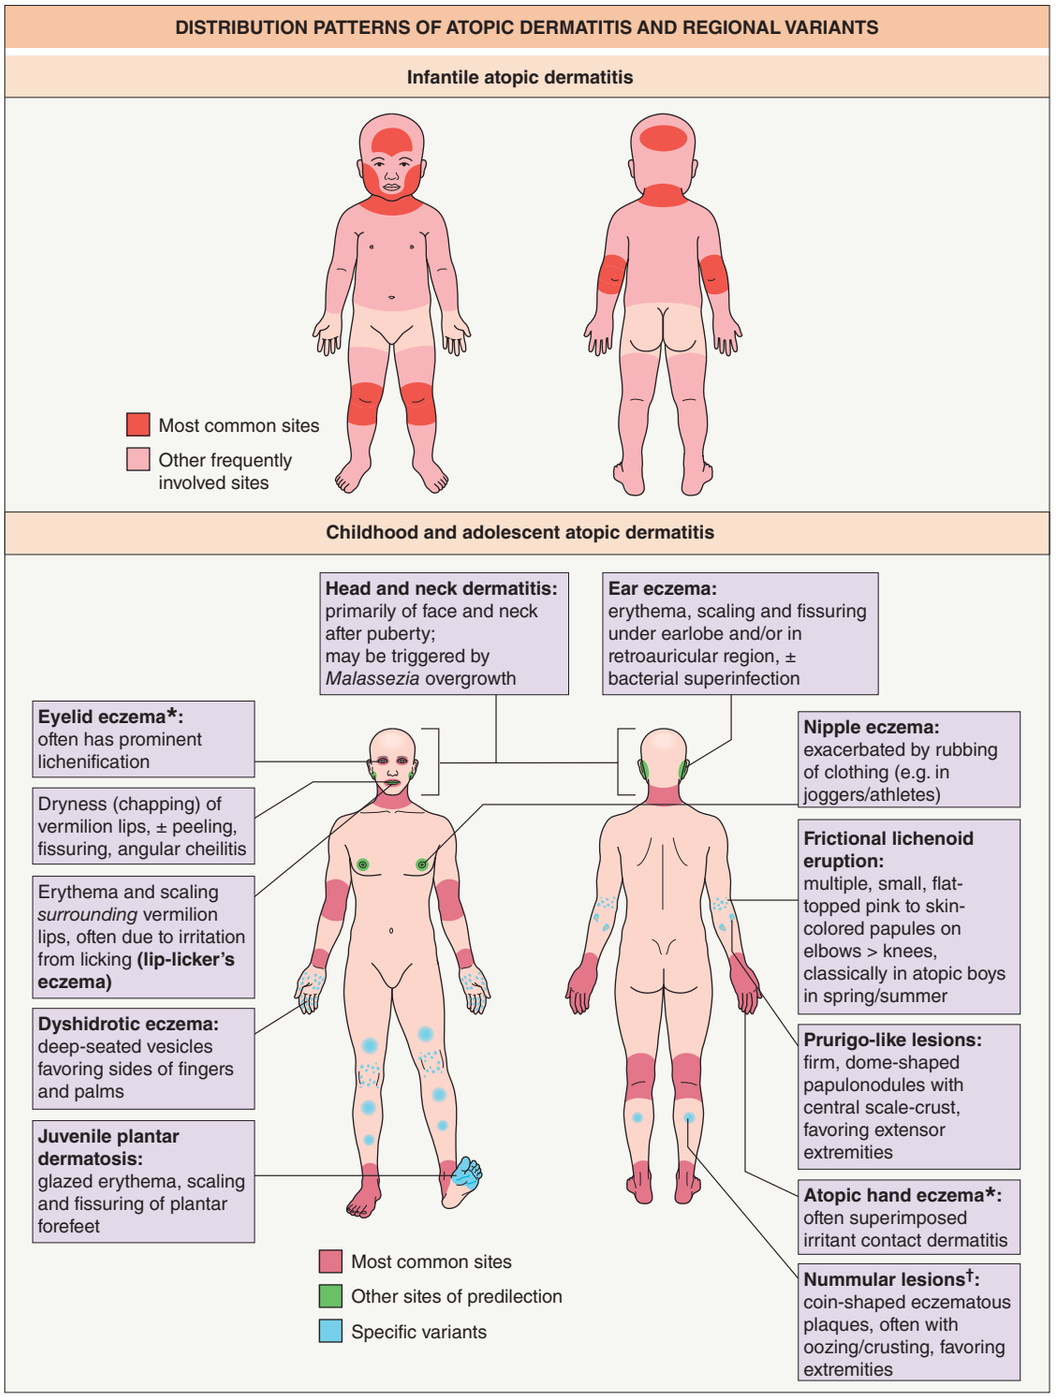

Fig. 12.3 Distribution patterns of atopic dermatitis (AD) and regional variants. *May be the only manifestation of AD in adults. †Not to be confused with nummular eczema occurring outside the setting of AD.

Fig. 12.4 Atopic dermatitis – papular pattern. This clinical variant is more commonly observed in patients with more darkly pigmented skin. There is also lichenification in the antecubital fossae. *Courtesy Gail Todd, MD.*

Fig. 12.6 Infantile atopic dermatitis on the face. A Erythema with scale-crust on the cheeks. Note the sparing of the central face. **B** More severe, widespread facial dermatitis with accentuation of scale-crust around the mouth. *A, Courtesy Julie V. Schaffer, MD.*

6 months of life, the face is affected in >90% of patients with AD[105]. Young infants may attempt to relieve itch through rubbing movements against their bedding, whereas older infants are better able to directly scratch affected areas.

In ***childhood AD (age 2 to 12 years)***, the lesions tend to be less exudative and often become lichenified. The classic sites of predilection are the antecubital and popliteal fossae (flexural eczema) (Fig. 12.8). Other common locations include the wrists, hands, ankles, feet, neck, and eyelids, although any area can be involved (Fig. 12.9). Xerosis typically becomes pronounced and widespread.

Adult/adolescent AD (age >12 years) also features subacute to chronic, lichenified lesions, and involvement of the flexural folds typically continues (Fig. 12.10). However, the clinical picture may also change. Adults with AD frequently present with chronic hand dermatitis that has both endogenous and exogenous components (Fig. 12.11), while others have primarily facial dermatitis (Fig. 12.12), often with severe eyelid involvement (see below). Patients who have suffered from continuous AD since childhood are more likely to have extensive disease that is resistant to treatment. Such individuals may also have severe excoriations and chronic papular skin lesions because of habitual scratching and rubbing (Fig. 12.13A).

AD in the elderly (age >60 years) is characterized by marked xerosis. Most of these patients do not have the lichenified flexural lesions typical of AD in children and younger adults[12].

Regional Variants of Atopic Dermatitis

Several regional variants of AD can occur in isolation or together with the classic age-related patterns of involvement described above (see Fig. 12.3). The face is a frequent location for site-specific manifestations. Eczema of the lips, referred to as ***cheilitis sicca***, is common in AD patients, especially during the winter (Fig. 12.14A). It is characterized by dryness ("chapping") of the vermilion lips, sometimes with peeling and fissuring, and may be associated with angular cheilitis. Patients try to moisten their lips by licking, which in turn may irritate the skin around the mouth, resulting in so-called ***lip-licker's eczema***. Another common feature of childhood AD is ***ear eczema***, presenting as erythema, scaling, and fissures under the earlobe and in the retroauricular area, sometimes in association with bacterial superinfection. ***Eyelid eczema*** can represent the only manifestation of AD, especially in adults. In contrast to eyelid eczema due to other causes, it is characterized by lichenification of the periorbital skin.

"Head and neck dermatitis" represents a variant of AD that typically occurs after puberty and primarily involves the face, scalp, and neck. When older children and teenagers present with this form of AD, it usually persists into adulthood. *Malassezia* yeasts, which are members of the skin microbiome in the head and neck area, may be an aggravating factor for this presentation[106], and systemic antifungal treatment with itraconazole or fluconazole may be of benefit.

Eczema variants also occur in acral sites. ***Juvenile plantar dermatosis*** presents with "glazed" erythema, scale, and fissuring on the balls of the feet and plantar aspect of the toes in children with AD (see Ch. 13). ***Atopic hand eczema*** (see Fig. 12.11) affects ~60% of adults with AD and may be the only manifestation of the condition. *FLG* mutations are associated with increased likelihood of hand eczema in children

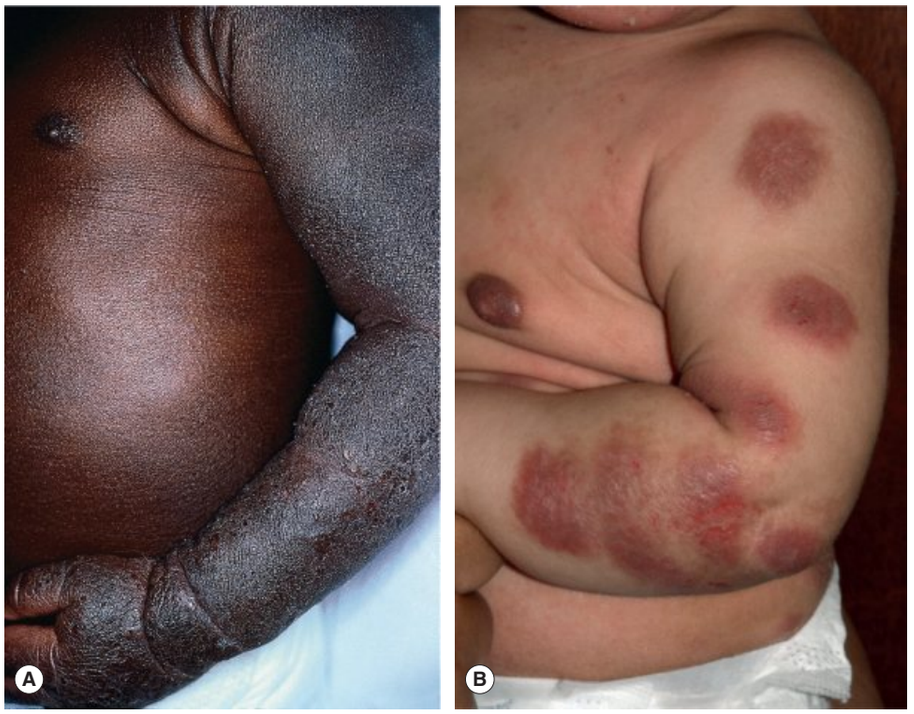

Fig. 12.7 Infantile atopic dermatitis on the extensor arms. **A** Chronic diffuse involvement of the extensor arms with scaling and hyperpigmentation. and adults[107], and frequent exposure to water and other irritants in household or occupational settings represents another risk factor. Atopic hand eczema typically involves the volar wrists and dorsum of the hands. The palms and sides of the fingers may develop the deep-seated vesicles of ***dyshidrotic eczema*** (see Ch. 13).

The ***prurigo form of AD*** favors the extensor aspects of the extremities and is characterized by firm, dome-shaped papules and nodules with central scale-crust, similar to prurigo nodularis lesions in non-atopic patients (Fig. 12.13B). ***Nummular (discoid) lesions*** also tend to develop on the extremities in children and adults with AD, appearing as coin-shaped eczematous plaques, usually 1 to 3 cm in diameter and often with prominent oozing and crusting (Fig. 12.13C; see Fig. 12.7B). They are similar in appearance to nummular dermatitis occurring outside the setting of atopy (see Ch. 13). ***Frictional lichenoid eruption*** has a predilection for atopic children and presents as multiple small, flat-topped, pink to skin-colored papules on the elbows and (less often) knees and dorsal hands. Lastly, chronic ***nipple eczema*** can develop in children and adults with AD (Fig. 12.14B).

Associated Cutaneous Features

Pruritus

Intense pruritus is a hallmark of AD. The itch is often worse in the evening and may be exacerbated by exogenous factors such as sweating or wool clothing. Rubbing and scratching in response to pruritus can initiate flares or exacerbate existing dermatitis, explaining why AD is known as the "itch that rashes". Excoriations (linear or punctate) are frequently present, providing evidence of scratching (Fig. 12.15; see Figs. 12.8–12.10). With repeated rubbing and scratching, the skin becomes thickened and leathery with exaggerated skin markings, referred to as lichenification (see Fig. 12.10 & 12.11).

Atopic stigmata

Physical findings other than dermatitis that are frequently observed in patients with AD are presented in Table 12.3 and Figs. 12.16–12.18.

Pityriasis alba

Pityriasis alba frequently affects children and adolescents with AD. It is characterized by multiple, ill-defined, hypopigmented macules and patches, usually 0.5 to 2 cm in diameter, with fine scaling. The lesions are typically located on the face, especially the cheeks (see Fig. 12.18), but occasionally appear on the shoulders and arms. Pityriasis alba is most obvious in individuals with darkly pigmented skin and/or following sun exposure. It is thought to result from a low-grade eczematous dermatitis that disrupts the transfer of melanosomes from melanocytes to keratinocytes.

Fig. 12.13 Atopic dermatitis variants. Fig. 12.14 Regional variants of atopic dermatitis. A Atopic cheilitis involving both the vermilion lip and surrounding skin (lip-licker's eczema). **B** Nipple eczema in an adolescent. *Courtesy Julie V. Schaffer, MD.*

Similar hypopigmented lesions can appear upon resolution of more overtly inflamed, erythematous lesions of AD. The differential diagnosis of pityriasis alba also includes postinflammatory hypopigmentation secondary to other dermatoses such as seborrheic dermatitis or pityriasis lichenoides chronica. Tinea versicolor is typically more sharply demarcated, with small lesions that may coalesce centrally in involved areas, and vitiligo is also sharply demarcated and depigmented rather than hypopigmented. Hypopigmented mycosis fungoides may occasionally represent a diagnostic consideration if there is extrafacial involvement. Regular use of sunscreens and other forms of photoprotection may minimize the appearance of pityriasis alba.

Infectious Complications

Bacterial and viral infections represent the most common complications of AD. Considering that *S. aureus* colonizes the skin of the vast majority of patients with AD, it is not surprising that ***impetiginization***, which can also be caused by *Streptococcus pyogenes*, occurs frequently (Fig. 12.19). Bacterial infections may exacerbate AD by stimulating the inflammatory cascade, e.g. via *S. aureus* exotoxins that act as superantigens (see above).

Eczema herpeticum represents rapid dissemination of a herpes simplex viral infection over the eczematous skin of AD patients. It initially develops as an eruption of vesicles, but affected individuals more often present with numerous monomorphic, punched-out erosions with hemorrhagic crusting (Fig. 12.20). Eczema herpeticum is frequently widespread and may occur at any site, with a predilection for the head, neck, and trunk. It is often associated with fever, malaise, and lymphadenopathy, and complications may include superinfection with *S. aureus* or *S. pyogenes* as well as herpetic keratoconjunctivitis and meningoencephalitis[108]. Patients with mutations in the filaggrin gene and those who have both severe AD and asthma have an increased risk for eczema herpeticum, and decreased production of antimicrobial peptides may have a pathogenic role. Patients with AD are also predisposed to the development of widespread ***molluscum contagiosum*** (see Ch. 81).

Impact on Quality of Life

AD has profound and multifaceted adverse impacts on the quality of life of affected children and adults as well as their families and caregivers[109,110]. Intense pruritus and stigmatization often result in sleep disturbances, psychological distress, social isolation, disrupted family dynamics, and impaired functioning at school or work. Children with AD experience greater impairment in their quality of life than those with diabetes mellitus or epilepsy[111], and detrimental effects on productivity have also been documented in adults[112,113].

Associated Extracutaneous Disorders

Ocular manifestations

In addition to allergic rhinoconjunctivitis, the spectrum of atopic eye disease includes chronic manifestations such as atopic keratoconjunctivitis, which typically affects adults, and vernal keratoconjunctivitis that favors children living in warm climates. Symptoms include ocular itching, burning, tearing, and mucus discharge, often in association with conjunctival injection and blepharitis manifesting as swelling and scaling of the eyelids. Vernal keratoconjunctivitis features large, cobblestone-like papillae on the upper palpebral conjunctiva, and atopic keratoconjunctivitis is more prone to scarring. Additional infrequent ocular complications of AD include keratoconus and subcapsular cataracts, with anterior cataracts more specifically related to AD and posterior cataracts occurring more commonly[114]; rarely there is retinal detachment.

Psychiatric disease and psychosocial burden

AD is associated with an increased risk of depression, anxiety, suicidal ideation, sleep disorders, and (in children) attention deficit hyperactivity disorder[115–118]. Sleep deprivation, pruritus, visible disease, stress, and low self-esteem contribute the psychosocial burden of AD.

Cardiovascular complications

A recent meta-analysis of cohort studies found that AD is associated with an increased risk of cardiovascular complications such as angina and myocardial infarction, cerebrovascular accidents, and heart failure during adulthood[119].

DIAGNOSTIC CRITERIA AND SEVERITY SCORES

Several authors and groups have suggested guidelines to assist in establishing the clinical diagnosis of AD. Major features in these sets of criteria include pruritus, eczematous skin lesions in typical age-specific distribution patterns, a chronic or chronically relapsing course, early age at onset, and a personal and/or family history of atopy (see Table 12.1). Atopic stigmata, especially xerosis, are also recognized as supporting features (see Table 12.3 and Fig. 12.15). The Diepgen score represents another validated set of diagnostic criteria that are separated into objective, subjective, and laboratory features[120].

Validated scores to assess the severity of AD include the EASI (Eczema Area Scoring Index), SCORAD (SCORing Atopic Dermatitis), and POEM (Patient-Oriented Eczema Measure) (see Appendix)[121]. The vIGA-AD (Validated Investigator Global Assessment scale for AD) that is required by the FDA as the primary end point for clinical trials is a rapid and simple assessment. However, it does not include body surface area affected by AD and thus omits an important aspect of disease severity[122].

The use of heterogeneous outcome measures makes it difficult to pool and compare AD study data, thereby hampering evidence-based clinical decision-making. This issue has been addressed by the Harmonizing Outcome Measures for Eczema (HOME) initiative, which recommends that POEM be utilized as the core instrument in all future clinical trials, potentially in conjunction with other measures of interest[123]. In addition, the HOME in Clinical Practice Initiative recommends using POEM and/or the Patient Oriented-SCORAD (PO-SCORAD) for

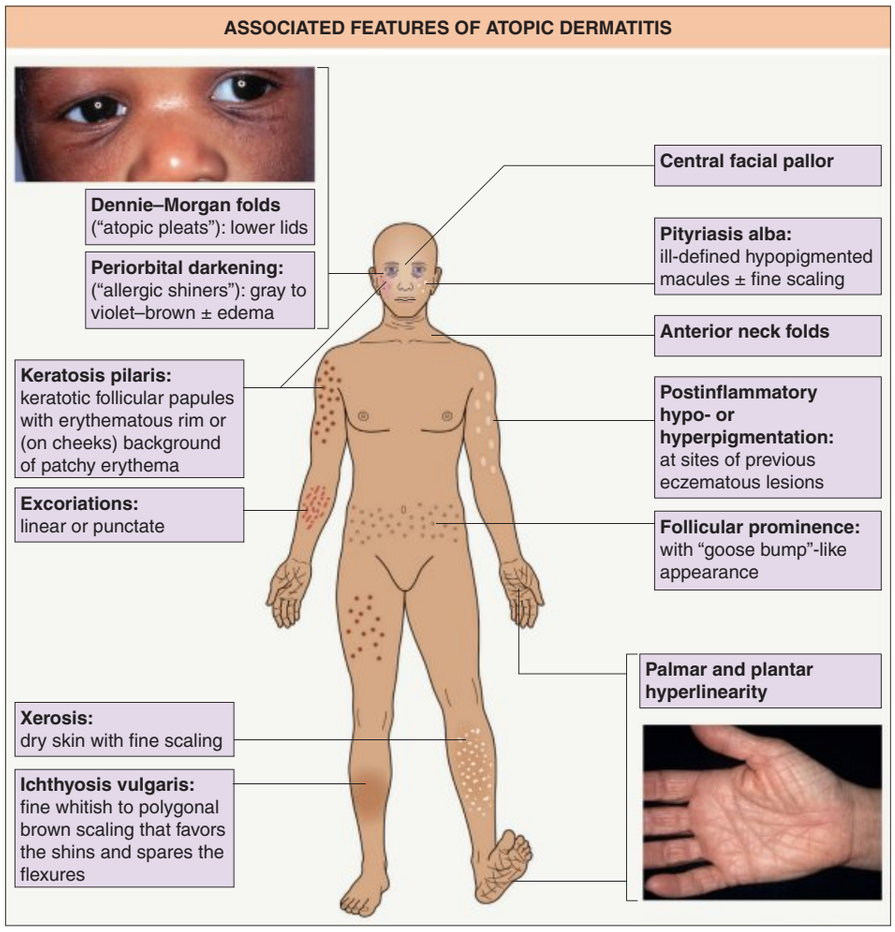

Fig. 12.15 Associated features of atopic dermatitis. See Table 12.3. *Inset of hand: Courtesy Jean L. Bolognia, MD.*

measuring AD symptoms in patient care settings[124], anticipating that they will assist in treatment choices[125].

PATHOLOGY

The histologic features of AD depend upon the clinical stage of the lesion sampled. *Acute*, exudative eczema is characterized by marked spongiosis, with intraepidermal fluid collection leading to the formation of vesicles (micro and macro) or even bullae. Some dermal edema may also be present, together with perivascular lymphocytes that extend into the epidermis and a variable number of eosinophils (Fig. 12.21A). In *subacute* lesions, vesiculation is absent whereas acanthosis, hyperkeratosis, and parakeratosis become evident (Fig. 12.21B). In *chronic*, lichenified AD, epidermal thickening is more pronounced in a pattern that may be either irregular or regular (psoriasiform). Changes in the granular layer vary from thickening secondary to rubbing, as seen in lichen simplex chronicus, to thinning when there is a psoriasiform pattern, seen in some nummular lesions. Spongiosis and inflammation are less conspicuous, but there may be an increased number of mast cells and dermal fibrosis.

These features are not specific, as similar findings are observed in other eczematous dermatoses such as allergic contact dermatitis. There are occasionally histologic clues to the etiology, such as individually necrotic keratinocytes that suggest an irritant contact dermatitis. However, a skin biopsy is usually more helpful in excluding other entities that can mimic AD clinically, such as mycosis fungoides.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of AD is broad and includes other chronic dermatoses, infections, infestations, and malignancies as well as metabolic, genetic (e.g. primary immunodeficiencies), and autoimmune disorders (Table 12.4).

In infants, AD is often preceded and/or accompanied by seborrheic dermatitis, which commonly presents during the first month of life as yellowish-white, adherent scale-crusts on the scalp. In contrast to the typical distribution of infantile AD on the extensor surfaces of the extremities and cheeks as well as the scalp, infantile seborrheic dermatitis has a predilection for the skin folds, where lesions tend to lack scale, and the forehead. Scabies in infants often has generalized involvement and can mimic AD; in addition to the presence of burrows or identification of the mite or eggs via dermoscopy or skin scrapings, scabies can usually be distinguished by the predominance of discrete small crusted papules, involvement of the axillae and diaper area, and the presence of acral vesiculopustules. Other less common conditions that occasionally represent a diagnostic consideration in infants, such as primary immunodeficiencies, are listed in Table 12.4.

Adolescents and adults without a history of atopy who present with an eczematous eruption should have a thorough history and consideration of patch testing to assess for allergic contact dermatitis. This diagnosis should also be considered in children and adults with established AD who fail to respond as expected to treatment or who develop lesions in an atypical distribution pattern. Components of emollients or topical corticosteroid preparations represent potential allergens in these individuals. Protein contact dermatitis has a predilection for atopic individuals and can also present as a chronic eczematous dermatitis. Causes include a variety of foods and animal products (Table 12.5; see Ch. 16), and it is diagnosed by prick testing or observation of an urticarial reaction within 30 minutes of patch testing on previously affected skin.

Mycosis fungoides (MF) should be considered in adolescents and adults with chronic dermatitis poorly responsive to topical corticosteroid treatment. Because the histologic findings of early MF may be difficult to distinguish from those of AD, multiple biopsies are recommended, preferably from untreated areas of skin since corticosteroids

ASSOCIATED FEATURES OF ATOPIC DERMATITIS ("ATOPIC STIGMATA")	
Xerosis	• Important feature that is present in most patients with AD • Often most prominent on the lower legs; may be generalized • Dry skin with fine scale in areas without clinically apparent inflammation • Typically worse during the winter • Impaired epidermal barrier function from decreased water content in the stratum corneum leads to easier entry of irritants, which can promote pruritus and initiate an inflammatory response
Ichthyosis vulgaris	• Autosomal semidominant disorder with incomplete penetrance caused by mutations in the filaggrin gene (*FLG*; see text and Ch. 57) • ~15% of patients with AD have moderate-to-severe ichthyosis vulgaris; conversely, >50% of patients with ichthyosis vulgaris have AD • Excessive fine, whitish to brown scaling that favors the lower legs (especially the shins) and spares the flexures
Keratosis pilaris	• Common condition that affects >40% of patients with AD and ~75% of those with ichthyosis vulgaris • Onset typically in childhood; may improve after puberty (especially facial involvement) • Affects the lateral aspect of the upper arms, thighs, and lateral cheeks (especially in children) > trunk and extensor aspects of the distal extremities • Keratotic follicular papules, often with a rim of erythema (see Fig. 12.17A) or a background of patchy erythema (especially on the cheeks) • The *keratosis pilaris rubra (KPR)* variant features numerous tiny, "grain-like" follicular papules superimposed on prominent confluent erythema (see Fig. 12.17B); often widespread on face & ears > trunk & proximal extremities, and tends to persist after puberty; presence of erythema rather than hyperpigmentation differentiates KPR from erythromelanosis follicularis faciei et colli, and a lack of atrophy in KPR differentiates it from keratosis pilaris atrophicans (see Ch. 38) • Keratolytic agents and topical retinoids are sometimes used to decrease the hyperkeratotic component, but the benefit is limited and these agents can be irritating, especially in AD patients; treatment with vascular lasers (e.g. pulsed dye laser) can sometimes improve associated erythema
Palmar and plantar hyperlinearity	• Increased prominence of the palmar and, less often, plantar creases • Associated with ichthyosis vulgaris and *FLG* mutations
Dennie–Morgan lines	• Symmetric, prominent horizontal fold(s) (single or double) just beneath the margin of the lower lid, originating at or near the inner canthus and extending one-half to two-thirds the width of the lid
Periorbital darkening ("allergic shiners")	• Skin around the eyes appears gray to violet–brown, while the rest of the facial skin is rather pale • Periorbital edema and lichenification may also be seen
Anterior neck folds	• Horizontal folds across the middle of the anterior neck
Hertoghe sign	• Absence or thinning of the lateral eyebrows
White dermographism	• Stroking the skin leads to a white streak that reflects excessive vasoconstriction • Most apparent on the forehead • Midfacial pallor and a delayed blanch response represent additional manifestations of aberrant vascular reactivity in patients with atopic dermatitis
Follicular prominence	• "Goose bump-like" appearance of the skin, most often on the trunk (see Fig. 12.7) • More commonly observed in children with darkly pigmented skin

Table 12.3 Associated features of atopic dermatitis ("atopic stigmata"). AD, atopic dermatitis. See Fig. 12.15.

can eliminate the epidermotropic T cells that point to the diagnosis of MF. Longitudinal evaluation of such individuals is required, especially when the clinical and/or histologic features are not classic for AD, with additional biopsies as indicated.

TREATMENT

General Approach

Because AD is a chronic, relapsing disease, the traditional approach was reactive management targeting acute flares with short-term treatment regimens. Based on insights into the underlying skin barrier defect and its relationship to inflammatory processes in the skin and other organs, a proactive approach that includes long-term maintenance therapy is now recommended (Fig. 12.22)[126]. This treatment strategy may modify the overall disease course and possibly prevent the development of atopic comorbidities. Management of AD includes education of patients/parents, gentle skin care, moisturizer use, and anti-inflammatory therapy to control subclinical inflammation as well as overt flares. Topical agents represent the mainstay of treatment. Severe disease may require phototherapy or systemic medications, usually in conjunction with continued topical therapy (Table 12.6)[126]. Factors that can potentially exacerbate AD should be identified and, if possible, avoided (see Table 12.1).

Educational interventions

Education of patients and families to promote AD self-management has been shown to improve outcomes[127–129]. Knowledge of disease mechanisms and course, potential triggers, appropriate use of therapies, and the goals of management can increase treatment adherence and reduce fear and misconceptions[130–133]. Parents often seek an eradicable cause for their child's AD and have difficulty accepting "control" rather than a "cure" for the condition. Addressing their specific concerns and acknowledging the stresses associated with this chronic disease, as well

as noting the improvement in pruritus and sleep disturbances likely to result from treatment, can lead to more effective care. Educational approaches include counseling clinic visits with a team approach/multidisciplinary input, online resources (e.g. nationaleczema.org), and structured teaching programs ("eczema schools"). Written action plans have also been shown to be beneficial in AD management[134–136]. Psychological interventions to aid in coping with AD may prove useful, with reported approaches including biofeedback, cognitive-behavioral therapy, and stress management[137].

Bathing

Bathing can hydrate the skin and remove scale, crust, irritants, and allergens. Although there is a paucity of objective data on optimal bathing practices for AD, it is generally recommended that patients bathe or shower once daily for 5–10 minutes in warm (not hot) water, with use

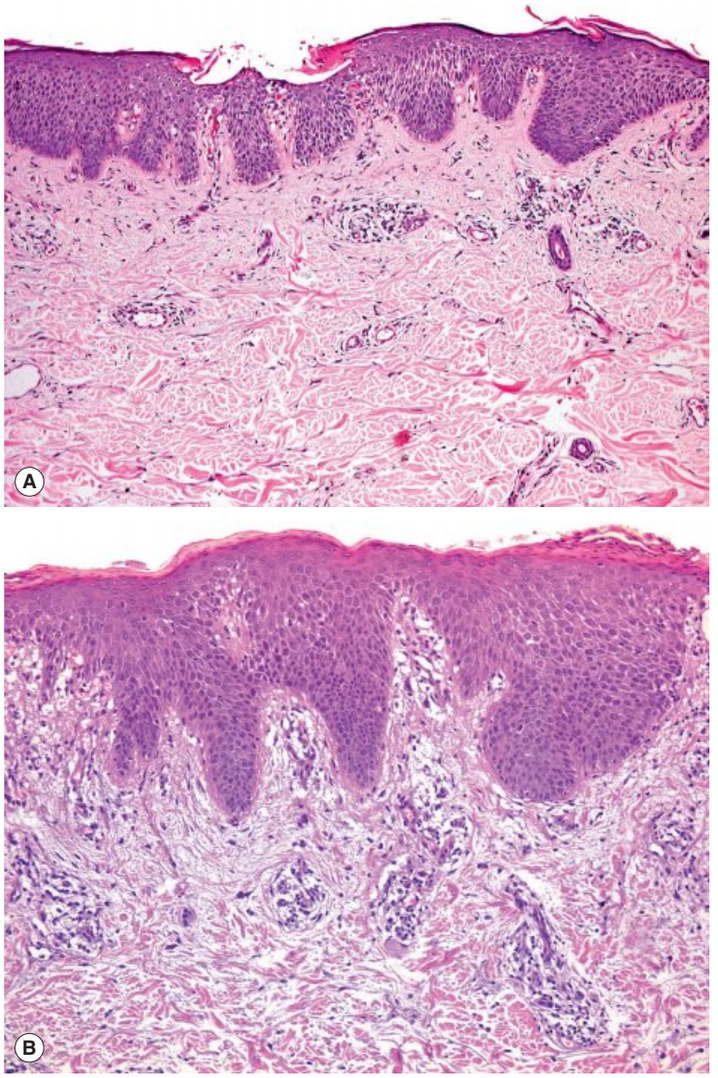

Fig. 12.21 Histologic features of acute and subacute atopic dermatitis. A Acute lesion showing prominent spongiosis, epidermal hyperplasia, and a mild inflammatory infiltrate in the upper dermis. **B** Subacute lesion with parakeratosis and less spongiosis. *A, Courtesy Lorenzo Cerroni, MD.*

of a fragrance-free non-soap cleanser with a neutral to low pH as needed (e.g. syndets; see Ch. 153)[126,138,139]. Application of a moisturizer shortly after bathing is essential to maintain skin hydration[140]. If treatment with a topical corticosteroid or other anti-inflammatory agent is needed, it should be applied immediately after bathing, prior to the moisturizer; this has been referred to as the "soak and smear" technique[138]. With the exception of bleach (see below), there are no RCTs to support the use of bath oils, other bath additives, acidic spring water, or water-softening devices for AD[126,141].

Moisturizers

Daily use of moisturizers to counteract dry skin and reduce transepidermal water loss is a cornerstone of AD management that helps to prevent disease flares[142]. Moisturizer application can reduce xerosis, pruritus, erythema, fissuring, and lichenification[126], thereby decreasing the amount of anti-inflammatory medication required for disease control[143]. Standard moisturizers contain varying amounts of emollient agents that lubricate the skin, occlusive agents that prevent water loss, and humectants that attract water[126]. Preparations should be free of dyes, fragrances, food-derived allergens such as peanut protein, and other potentially sensitizing ingredients[144]. Factors in selecting the formulation of the moisturizer include the degree of xerosis, the sites of application, acceptance by the patient, and the season. Ointments (e.g. petrolatum) contain higher concentrations of lipids, have occlusive properties, and are typically preservative-free; although they tend to cause less stinging when applied to inflamed skin, the greasiness of ointments is bothersome to some patients[126,142]. Creams may be a more acceptable option for such individuals, whereas lotions contain a higher water content and are not ideal for the xerosis of AD. Products with higher concentrations of urea or α-/β-hydroxy acids, which can decrease scaling, may also sting when used in children and on acutely inflamed or excoriated skin.

There are limited data on the optimal amount and frequency of moisturizer application or comparing the effectiveness of different moisturizing products, and no particular preparation has been shown to be superior[142,143,145]. Weekly use of 150–200 g of moisturizer in young children and 250–500 g in older children/adults has been recommended, with liberal and frequent application[139]. Prescription emollient devices (PEDs) that aim to improve the defective skin barrier of AD include preparations that contain specific ratios of lipids (e.g. cholesterol, fatty acids, ceramides), palmitoylethanolamide, glycyrrhetinic acid, and other hydrolipids[126]. There is currently no evidence that these agents are superior to over-the-counter preparations.

Topical Anti-Inflammatory Therapy

Topical corticosteroids

Topical corticosteroids represent first-line pharmacologic therapy for AD. These agents have anti-inflammatory, antiproliferative, immunosuppressive, and vasoconstrictive actions, with effects on cutaneous T cells, macrophages, and dendritic cells (see Ch. 125)[126,142]. The efficacy of topical corticosteroids in AD has been verified in >100 RCTs[146], and they have been shown to decrease the acute and chronic inflammation of AD as well as associated pruritus[126]. Topical corticosteroids are used to treat acute flares of AD and as maintenance therapy to prevent relapse.

Factors in selecting the potency and vehicle of the topical corticosteroid include the location, type (e.g. acute versus chronic), thickness, and extent of the AD lesions; patient age and preference as well as the cost and availability of different preparations represent additional considerations. The corticosteroid should have an appropriate potency to quickly gain control of the flare, and continuation of daily therapy until the active dermatitis is completely clear can minimize the likelihood of a rebound. Long-term daily use of an inadequately potent topical corticosteroid can result in a greater risk of side effects as well as less control of the eczema than relatively brief use of a more potent agent. RCTs in children and adults with AD have demonstrated that the risk of relapse can be significantly reduced by proactive maintenance with twice-weekly application of a mid-potency topical corticosteroid to the usual areas of involvement when clear, with no evidence of cutaneous atrophy after up to 40 weeks of treatment[126,147–149].

For the face and body folds, high potency corticosteroids (especially long-term use) should be avoided if possible due to risk of cutaneous atrophy and (for the face) acneiform eruptions. However, short-term use of a potent agent (e.g. mometasone furoate ointment) may be required to clear thick, exuberant lesions on the cheeks of infants. More potent corticosteroids (e.g. class 1–2) are often needed for lichenified plaques, nummular or prurigo-like lesions, and involvement of the palms and soles. Corticosteroid ointments (which minimize stinging) and creams are generally preferred considering the dryness of the skin in AD patients and the moisturizing effects of these vehicles. Application immediately after bathing improves cutaneous penetration and also decreases stinging. Corticosteroid solutions, foams, and oils represent options for AD on the scalp.

Systematic reviews have concluded that topical corticosteroids have a favorable safety profile with short-term (up to several weeks) daily use and long-term intermittent use (see Ch. 125)[150]. However, aversion or hesitancy regarding use of topical corticosteroids ("steroid phobia") is very common among AD patients and their parents, and it often leads to delayed and inadequate treatment[151–153]. It is essential that these fears and incorrect beliefs about topical corticosteroids are addressed to ensure adherence to the treatment plan.

When AD does not respond as expected to topical corticosteroid therapy, adherence should be assessed, including the amount (grams/tubes) and duration (consecutive days) of use. If possible, in-patient therapy for patients with severe AD can allow direct observation and

DIFFERENTIAL DIAGNOSIS OF ATOPIC DERMATITIS		
Chronic dermatoses		
C > A	Seborrheic dermatitis	Common
B	Contact dermatitis – allergic* or irritant	Common
B	Psoriasis	Common
A > C	Nummular dermatitis	Uncommon (although nummular lesions can be seen in AD, nummular eczema outside this setting is uncommon)
A	Asteatotic eczema	Common
A > C	Lichen simplex chronicus (secondary to pruritus of variable etiology)	Common
Infections and infestations		
B	Scabies	Common
B	Dermatophytosis*	Common
B	HIV-associated dermatoses	Variable
C	HTLV-1-associated "infective dermatitis"	Variable
C	Chronic mucocutaneous candidiasis	Rare
C	Neonatal mucocutaneous candidiasis	Variable
B	Impetigo	Variable (nummular lesions of AD can mimic impetigo)
C	Congenital syphilis	Variable
Primary immunodeficiencies		
C	Wiskott–Aldrich syndrome	Rare
C	Hyperimmunoglobulin E syndromes	Rare
C	IPEX (*i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked) syndrome and IPEX-like conditions	Rare
C	Omenn syndrome	Rare
C	DiGeorge syndrome (congenital thymic aplasia)	Rare
C	Immunodeficiency 23	Rare
C	Immunoglobulin deficiencies: X-linked hypogammaglobulinemia, common variable immunodeficiency, IgA deficiency	Variable
Malignancies		
A > C	Mycosis fungoides and Sézary syndrome	Uncommon
C	Langerhans cell histiocytosis	Rare
Metabolic and genetic disorders		
C	Netherton syndrome, generalized inflammatory peeling skin syndrome	Rare
C	Ectodermal dysplasias	Rare
C	*S*evere dermatitis–*a*llergies–*me*tabolic wasting (SAM) syndrome	Rare
B	Keratosis pilaris	Common
C	Hartnup disease	Rare
C	Phenylketonuria	Rare
C	Prolidase deficiency	Rare
B	Acrodermatitis enteropathica, glucagonoma syndrome, pellagra, riboflavin deficiency	Rare
C > A	Other causes of "nutritional dermatitis", e.g. biotin deficiency, essential fatty acid deficiency, organic acidurias, cystic fibrosis	Rare
Autoimmune disorders		
A > C	Dermatitis herpetiformis	Uncommon
A > C	Pemphigus foliaceus	Uncommon
B	Dermatomyositis	Uncommon (but often misdiagnosed as AD in children)
A > C	Lupus erythematosus	Uncommon
Other		
B	Drug eruptions	Uncommon (although drug eruptions are common, those resembling atopic dermatitis are uncommon)
A > C	Photoallergic contact dermatitis	Uncommon
A	Chronic actinic dermatitis	Uncommon
B	Graft-versus-host disease	Uncommon

*More common causes of disseminated eczema ("id reaction"), which is especially frequent in the setting of stasis dermatitis + allergic contact dermatitis.

Table 12.4 Differential diagnosis of atopic dermatitis. A, adults; B, both; C, children/infants.

intensive education. Potential complicating factors should be investigated, such as disease exacerbation by superinfection, irritants, or allergens. The latter can include immediate hypersensitivity reactions to foods and aeroallergens as well as delayed hypersensitivity to contact allergens, including components of moisturizers and topical mediations[142].

Topical calcineurin inhibitors

Two topical calcineurin inhibitors (TCIs) have been FDA-approved for the treatment of AD: (1) tacrolimus 0.03% and 0.1% ointment for moderate to severe disease; and (2) pimecrolimus 1% cream for mild to moderate disease (see Ch. 129). These agents suppress T cell activation and modulate the secretion of cytokines and other proinflammatory mediators; they also decrease mast cell and dendritic cell activity[144,154]. The efficacy of TCIs in the treatment of AD has been proven in large clinical trials in adults and children ≥2 years of age and, for pimecrolimus, infants ages 3–23 months, although it is not currently approved for the latter group[155].

TCIs are particularly useful for AD affecting the face and intertriginous areas, sites where corticosteroid-induced skin atrophy is of increased concern and TCI therapy is especially effective[142]. TCIs are also beneficial in patients with frequently flaring or persistent AD that would otherwise require almost continual use of topical corticosteroids. Randomized controlled studies have shown that the proactive application of tacrolimus ointment 2–3 times weekly as maintenance can prevent flares of AD without increasing the overall amount of medication used[156].

The most common adverse effects with TCIs are local stinging and burning. These symptoms lessen after several applications, or if TCI use is preceded by a short topical corticosteroid course. For both topical tacrolimus and pimecrolimus, there has been no short-term or intermediate-term (>15 years) evidence of systemic immunosuppression in either clinical studies or post-marketing surveillance, and long-term data collection is ongoing[157,158]. In 2006 the FDA introduced black box warnings for both drugs concerning a theoretical cancer risk; this was based on the occurrence of lymphomas in mice exposed to systemic levels 30- to 50-fold greater than the highest recorded blood levels in human patients. Pharmacokinetic studies in children and adults with AD have demonstrated minimal systemic absorption of TCIs, with transient detectable but low blood levels occasionally observed in patients with severe AD involving a large portion of the body surface area. Of note, recent meta-analyses found no association between TCI use and overall cancer or skin cancer (keratinocyte carcinoma, melanoma) risk, with a slight increase in lymphoma risk in adults that may potentially be explained by early cutaneous T cell lymphoma being misdiagnosed as AD and treated with TCIs[157,158].

Crisaborole

Crisaborole 2% ointment is a phosphodiesterase-4 (PDE-4) inhibitor that is FDA-approved for the treatment of mild to moderate AD in patients ≥3 months of age. In large RCTs, ~30% of such individuals achieved clear/almost clear skin with a ≥2-grade improvement after 4 weeks of twice daily treatment[159]. PDE-4 degrades cAMP, which leads to increased production of cytokines including IL-10 and IL-4 (see Fig. 130.3). The most common side effect is stinging or burning in the area of application.

Topical JAK inhibitors

Ruxolitinib 1.5% cream is a Janus kinase 1/2 (JAK1/2)-selective inhibitor that was recently FDA-approved for short-term or non-continuous chronic treatment (using ≤60 g/week) of mild to moderate AD in patients ≥12 years of age. In RCTs (total n=1249), 50%–55% of individuals treated with ruxolitinib 1.5% cream twice daily for 8 weeks had clear/almost clear skin with a ≥2-grade improvement, compared to 7%–15% for the vehicle control[160]. Mean plasma concentrations were

CAUSES OF PROTEIN CONTACT DERMATITIS
• Fruits (banana, fig, kiwi, lemon, pineapple)
• Grains (barley, rye and wheat flours)
• Latex
• "Meats" (fish, seafood, beef, pork, poultry)
• Mites and insects (rice flour beetle, dust mite, storage mite)
• Nuts (almond, hazelnut, peanut)
• Spices (caraway, curry, dill, garlic, paprika, parsley)
• Vegetables (carrot, cauliflower, celery, cucumber, lettuce, mushroom, onion, parsnip, potato)
• Animal dander, hair, saliva or urine (cow, deer, goat, dog, cat, rodents, hedgehog, rabbit, giraffe)

Table 12.5 Causes of protein contact dermatitis.

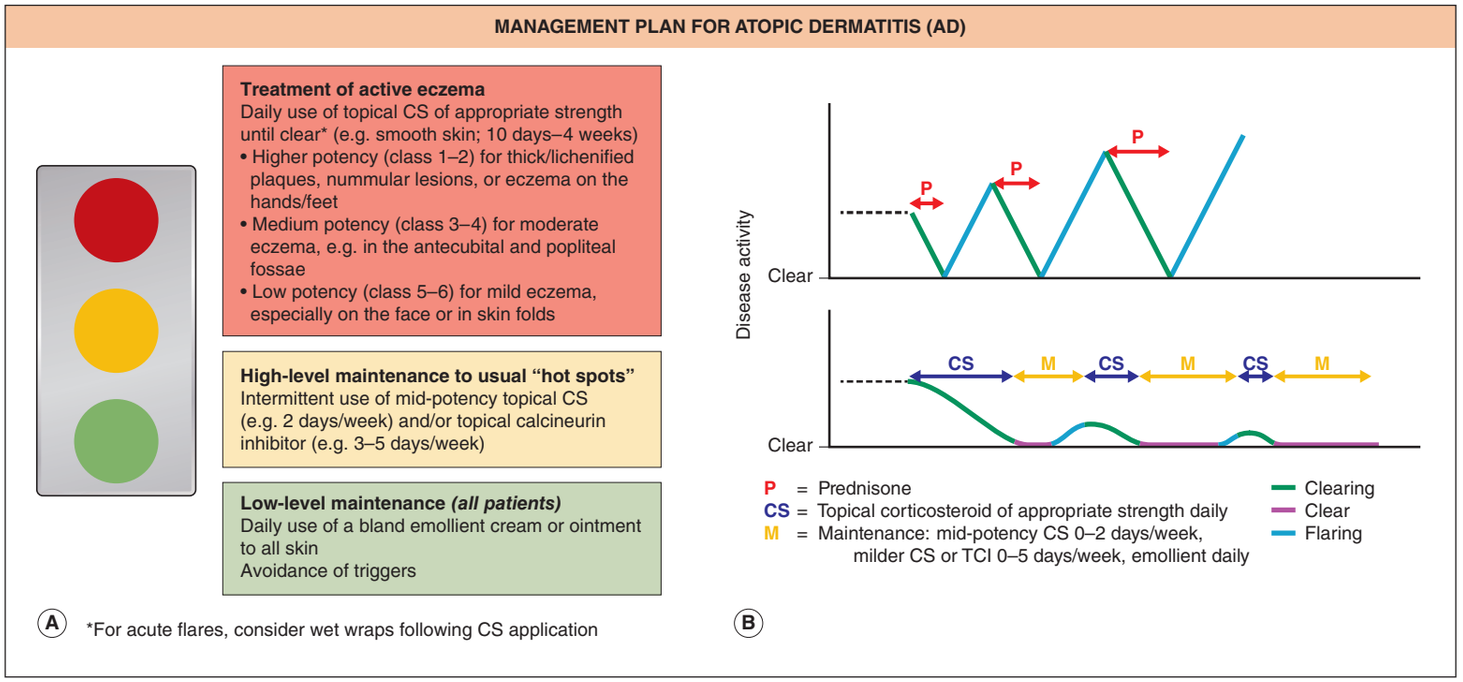

Fig. 12.22 Management plan for atopic dermatitis. A The therapeutic regimen should include both treatment of active eczema and maintenance that includes the low-level in all and the high-level in some patients. **B** Intermittent courses of a systemic corticosteroid result in rebound flares and worsening of disease over time. In contrast, a proactive regimen utilizing topical corticosteroid leads to longer clear periods and milder disease over time.

THERAPEUTIC LADDER FOR ATOPIC DERMATITIS (AD)	
Topical therapies	**Evidence**
Moisturizers	1
Corticosteroids	1
Calcineurin inhibitors	1
Crisaborole	1
JAK inhibitors e.g. ruxolitinib (FDA-approved), delgocitinib (approved in Japan)	1
Phototherapy	
Narrowband UVB, UVA–UVB, UVA1	1
Systemic therapies	**Evidence**
Dupilumab	1
IL-13 inhibitors, e.g. tralokinumab, lebrikizumab	1
JAK inhibitors, e.g. upadacitinib, abrocitinib, baricitinib	1
Cyclosporine (short-/intermediate-term)	1
Azathioprine	1
Mycophenolate mofetil/enteric-coated mycophenolate sodium	1/2
Methotrexate	1/2
Systemic corticosteroids (short-term for severe acute flares; "rebound" exacerbations often occur upon discontinuation)	2
Omalizumab	2*
Nemolizumab† (anti-IL-31 receptor A; not currently FDA-approved)	1†
Rituximab	2
Interferon-γ	‡
IVIg	2*
Adjunctive therapies	
Wet wraps, open wet dressings, or soaks combined with topical corticosteroids for acute flares	
Dilute sodium hypochlorite (bleach) baths	
Treatment of associated bacterial, viral, or fungal infections	
Oral antihistamines for associated conditions (e.g. dermographism, rhinoconjunctivitis) and sedative effects	
Leukotriene antagonists¶	
Sodium cromoglycate (topical or oral)¶	

*No significant benefit was found in a small controlled trial.
†Benefit for pruritus in patients with moderate to severe AD.
‡Although found to be effective in one randomized controlled trial, results of other studies have been inconsistent (see Ch. 128).
¶Inconsistent demonstration of efficacy in controlled trials.

Table 12.6 Therapeutic ladder for atopic dermatitis (AD). Key to evidence-based support: (1) prospective controlled trial; (2) retrospective trial or large case series; (3) small series or individual case reports.

<15% of the whole blood IC_{50} for JAK2 inhibition[160]. However, the JAK inhibitor class-wide black box warning notes potential increased risks of serious infection, death, cancer, cardiovascular events, and thrombosis (see Chs. 128 & 129). Delgocitinib 0.5% ointment (pan-JAK inhibitor; approved in Japan for AD in adults) has shown greater efficacy than vehicle in phase 2 and 3 RCTs in AD patients ≥2 years of age[161,162].

Wet wrap therapy

Wet wrap therapy may be helpful in severe recalcitrant AD or during an acute flare. These moist, occlusive dressings increase skin hydration, act as a barrier to scratching, and enhance the penetration of topical corticosteroids. However, because of the latter effect, care should be exercised when using moderate and potent topical corticosteroids with wet wraps, and a possible increased risk of bacterial skin infections has been noted[163]. The wraps consist of application of a topical corticosteroid (sometimes diluted), followed by an inner wet layer and outer dry layer of cotton gauze or garments; they are left in place 8–24 hours per day, and the treatment duration should not exceed 2 weeks.

Phototherapy

Narrowband UVB, UVA1, and *UVA combined with UVB* have each been shown to improve atopic dermatitis and associated pruritus[164–166]. The immunomodulatory effects of phototherapy occur via induction of T cell apoptosis, reduction of dendritic cells, and decreased expression of Th2 cytokines such as IL-5, IL-13, and IL-31 (see Ch. 134). In addition, treatment with UVB has been shown to reduce *S. aureus* colonization of the skin in AD patients. Narrowband UVB and UVA1 can both be helpful for chronic AD lesions, and UVA1 may also be useful in the treatment of acute flares. Phototherapy can be combined with topical corticosteroids, especially in the initial phase of treatment. The side effect profile of phototherapy is favorable compared to systemic immunosuppressive agents, with potential "sunburn" and, with long-term treatment, photoaging and possibly an increased risk of skin cancer. The time required to travel several times a week to a phototherapy center may disrupt school or work for some patients, and a home UV unit may be an option for those receiving chronic treatment. In young children, phototherapy may be difficult for practical reasons, e.g. lack of cooperation.

Systemic Anti-Inflammatory Therapy

Systemic anti-inflammatory medications may be employed for children and adults with moderate to severe AD that has failed to respond adequately to optimized topical treatment[164]. The risk–benefit profile should be carefully considered before starting an immunosuppressive agent, and patients receiving these medications require close monitoring for side effects (see Chs. 128 & 130). Combination of systemic treatment with topical corticosteroid therapy is frequently required to maximize benefit. In addition to the medications discussed below, a number of promising targeted immunomodulatory therapies are under investigation.

Interleukin-4/-13 receptor inhibitors

Dupilumab is a human monoclonal antibody that targets the IL-4Rα subunit of heterodimeric IL-4 and IL-13 receptors (Fig. 128.9C). It blocks signaling by these cytokines and the resulting Th2-mediated inflammation. Dupilumab is FDA-approved for the treatment of patients ≥6 months of age with moderate to severe atopic dermatitis that is not adequately controlled with topical therapy. Large RCTs have demonstrated a significant benefit in this patient population, with ~40%–50% of adolescents or adults who received dupilumab alone and ~55%–70% of infants, children or adults who received dupilumab plus topical corticosteroids achieving a 75% improvement in their EASI score after 16 weeks of treatment, with sustained efficacy through 52 weeks[77,165–168a].

Dupilumab is administered via subcutaneous injection. Adults receive a 600 mg loading dose followed by 300 mg every 2 weeks. Pediatric patients have weight-tiered dosing: the adult regimen if ≥60 kg; a 400 mg loading dose then 200 mg every 2 weeks if 30–59 kg; a 600 mg loading dose then 300 mg every 4 weeks if 15–29 kg (with no loading dose if <6 years of age); and 200 mg every 4 weeks if 5–14 kg. Dupilumab has a favorable side effect profile, with injection site reactions occurring in ~10% of patients and conjunctivitis in ~10% and ~25% of patients in clinical trials and real-world settings, respectively[169,170]. Ocular surface disease appears to be an AD-specific drug–disease interaction and can often be managed with topical therapies while continuing dupilumab. Some patients develop facial erythema distinct from their usual AD, with possible etiologies including rosacea, allergic contact dermatitis, and *Malassezia*-related dermatitis[171]. Lastly, dupilumab therapy for AD is associated with a decreased risk of skin infections including eczema herpeticum[172,173].

Interleukin-13 inhibitors

Tralokinumab is a human monoclonal antibody that binds to free IL-13, blocking its interaction with IL-13Rα1 and IL-13Rα2 (see Fig. 128.9C)[174]. It was recently FDA-approved for the treatment of adults with moderate to severe atopic dermatitis that is not adequately controlled with topical therapy. In large RCTs, tralokinumab monotherapy and combination therapy with topical corticosteroids were superior to placebo at 16 weeks, with ~30% and 55% of patients achieving a 75% improvement in their EASI score, respectively[175,176]. The majority of responders maintained their response at 52 weeks, and side effects included conjunctivitis[175,176]. *Lebrikizumab* is a human monoclonal antibody that also binds to soluble IL-13 and blocks its interaction with IL-4Rα, preventing heterodimerization with IL-13Rα1 and resultant IL-13 signaling (see Fig. 128.9C). In RCTs, ~55% of adolescents and adults with moderate to severe AD treated with lebrikizumab achieved a 75% improvement in their EASI score at 16 weeks[176a], and ~80% of these individuals maintained this response at 52 weeks.

Oral JAK inhibitors (see Ch. 128)

The oral JAK1-selective inhibitors *upadacitinib* and *abrocitinib* were recently FDA-approved for the treatment of recalcitrant, moderate to severe AD that is not adequately controlled with other systemic medications in patients ≥12 years of age (with weight ≥40 kg) and ≥18 years of age, respectively. In large RCTs involving adolescents and adults with moderate to severe AD, these medications were superior to placebo, with a 75% improvement in the EASI score in 65% (15 mg) and 75% (30 mg) of those who received upadacitinib daily for 16 weeks, and 40% (100 mg) and 60% (200 mg) of those who received abrocitinib daily for 12 weeks[177–180]; efficacy was sustained through 52 weeks of treatment[181]. The 15 mg and 100 mg daily starting doses for upadacitinib and abrocitinib, respectively, can be doubled if the response is not adequate. *Baricitinib* is a JAK1/2-selective inhibitor approved in Europe for treatment of adults with moderate to severe AD, with RCTs demonstrating a 75% improvement in the EASI score in 18% (2 mg) and 23% (4 mg) of such individuals[182].

Oral JAK inhibitor therapy for AD has a rapid onset of action, typically with reduction in pruritus within 1–2 weeks and improvement of clinical signs within 2–4 weeks. Laboratory monitoring is required and possible adverse effects include acne, serious infections (e.g. bacterial pneumonia, herpes zoster, tuberculosis), cytopenias, thrombosis, hyperlipidemia, major cardiovascular events, and for upadacitinib and baricitinib, gastrointestinal perforation (see Ch. 128). Long-term studies are needed to better establish the risk–benefit ratios of oral JAK inhibitors with different selectivity profiles.

Conventional immunosuppressive agents (for details see Ch. 130)

Cyclosporine typically leads to rapid improvement of AD in adults and children, and its efficacy has been established in RCTs[146,183]. However, because of potential side effects such as nephrotoxicity and hypertension, it is mainly used as a short-term treatment for AD, serving as a bridge between other therapies. Doses utilized for AD range from 3 to 6 mg/kg/day; treatment is often initiated at 5 mg/kg/day with subsequent tapering.

Azathioprine can be an effective treatment for moderate to severe AD in children and adults, with modest benefit documented in RCTs[184–186]. When dosages are based upon thiopurine methyltransferase (TPMT) activity and/or genotyping for *TPMT* polymorphisms, the risk of myelotoxicity is reduced (see Table 130.6). It has a slow onset of action, with clinical improvement after 1–2 months and full benefit requiring 2–3 months of treatment[142].

Methotrexate can lead to improvement of refractory AD in adults and children at a weekly dose of 7.5–25 mg or 0.3–0.5 mg/kg, respectively, together with folic acid supplementation[187]. This regimen is well tolerated, with a clinical effect typically seen after 2–3 months of therapy[188]. *Mycophenolate mofetil* (MMF) may also be of benefit for recalcitrant AD in adults and children, with 2–3 months of treatment typically required for maximum effect[189]. Dosing generally ranges from 1 to 3 g/day in adults and 30–50 mg/kg/day in children[164].

Continuous or chronic intermittent use of *systemic corticosteroids* for AD is not recommended due to a propensity for significant rebound flares upon their discontinuation and the unacceptable side effects of long-term administration (see Fig. 12.22 and Ch. 125)[190]. However, a short course of systemic corticosteroids may occasionally be considered for a severe, debilitating acute flare of AD while phototherapy or immunomodulatory treatment is being initiated.

Adjunctive Therapy

Antimicrobials and antiseptics

Although skin colonization and infection with *S. aureus* can play a role in triggering AD flares, there is no evidence to support the use of topical antibiotics or antiseptic agents to treat AD, with the possible exception of "bleach baths". In an initial RCT, bathing in 0.005% sodium hypochlorite (0.5 cup of household bleach [6% sodium hypochlorite] in a full 40-gallon bathtub) twice weekly together with a monthly 5-day course of intranasal topical mupirocin for 3 months led to greater improvement of moderate to severe, superinfected AD than placebo; both groups initially received a 2-week course of oral cephalexin and continued their topical anti-inflammatory regimen[191]. Subsequent controlled studies evaluating "bleach baths" in AD patients without a recent superinfection have had inconsistent results regarding efficacy for eczema; no decreases in *S. aureus* colonization or effects on skin barrier function have been observed[192].

The routine use of systemic antibiotics for AD is not recommended. However, systemic antibiotics can be utilized when AD patients display clinical evidence of bacterial infection, such as pustules, a purulent exudate, or furuncles. Similarly, systemic antiviral agents should be used to treat eczema herpeticum.

Antihistamines

The role of histamine in the itch of AD is unclear[139]. Topical antihistamines are not effective for AD and are associated with risks of allergic contact dermatitis and systemic side effects[126]. Routine use of oral antihistamines to treat AD is not recommended[142,193]. Non-sedating antihistamines are not useful in the absence of additional conditions such as urticaria, dermographism, or allergic rhinoconjunctivitis[164]. Short-term use of sedating antihistamines may be employed during an acute AD flare associated with significant sleep disturbance.

Melatonin

Reduced nocturnal melatonin is associated with sleep disturbance and disease severity in pediatric AD. RCTs have demonstrated that melatonin supplementation can improve sleep and decrease AD activity in children[194,195].

Omalizumab

The anti-IgE monoclonal antibody omalizumab is FDA-approved for chronic idiopathic urticaria in patients ≥12 years of age and for asthma in patients ≥6 years of age (see Ch. 128). It is administered every 2–4 weeks via subcutaneous injection, and potential side effects include a risk of anaphylaxis. Although observational studies have reported positive effects of omalizumab in AD, small RCTs found that omalizumab was no more effective than placebo[196,197].

Systemic immunotherapy

Allergen-specific immunotherapy to abrogate allergic sensitizations has been employed to treat asthma and allergic rhinoconjunctivitis. The benefit of sublingual or subcutaneous immunotherapy for AD with allergens such as dust mites has also been investigated, but heterogeneous studies with poor methodologies make the results difficult to interpret[198,199]. A Cochrane review concluded that there was no evidence of a benefit for specific allergen immunotherapy in AD, and this treatment approach is currently not recommended[200].

Dietary manipulation and supplements

In unselected children with AD, there is no high-quality evidence to support dietary manipulation. However, controlled trials have demonstrated significant improvement in AD following exclusion diets in individuals with confirmed egg and cow's milk allergies[201]. There is also no substantial evidence that oral supplementation with probiotics

(e.g. *Lactobacilli*), prebiotics (oligosaccharides that promote growth of desirable bacteria), or synbiotics (probiotics plus prebiotics) leads to improvement of AD[202]. Meta-analyses have demonstrated significantly lower vitamin D levels in children with AD compared to controls and vitamin D supplementation is recommended for AD patients with vitamin D insufficiency or deficiency[203]. Nonetheless, a systematic review concluded the evidence was weak for vitamin D supplementation decreasing AD severity in children[204].

Complementary Therapies

In systemic and meta-analyses as well as two RCTs, there was no evidence of a benefit for Chinese herbal medicines in AD[205,206]. In one report, analysis of "herbal creams" noted by parents in the UK to improve their children's AD revealed that 80% contained a corticosteroid, more than half of which represented clobetasol propionate[207]. Currently there also is no evidence that homeopathic treatment is of benefit for AD[208].

Management of Coexisting Disease

Food allergies

Food hypersensitivity affects up to 30% of infants and young children with AD, and ~90% of reactions in this population are caused by five allergens: eggs (most often linked to AD exacerbations), milk, peanuts, soy, and wheat. Reactivity to peanuts as well as tree nuts, fish, and shellfish tends to persist, but children usually outgrow sensitivities to other foods. In infants with AD, introduction of age-appropriate peanut-containing food as early as 4–6 months of age is recommended to reduce the risk of peanut allergy, with prior peanut-specific IgE and/or skin prick testing advised in those with severe AD[209]. Exposure to food allergens may exacerbate eczema in ~10%–30% of infants and young children with AD, especially those with severe, recalcitrant disease[210]. However, food allergens more often produce an immediate/IgE-mediated reaction with urticaria, flushing, or itch within 1–2 hours of exposure.

The National Institute of Allergy and Infectious Diseases (NIAID) recommends consideration of limited food allergy testing in children <5 years of age with moderate to severe AD if they also have: (1) persistent AD activity despite optimized management; or (2) a reliable history of an immediate allergic reaction after ingestion of a specific food[211,212]. Allergen-specific IgE assays and skin prick tests have high negative predictive values (>95%) but low specificities and positive predictive values (40%–60%)[213]. The clinical history and (in selected instances) provocation tests should be used to determine the *relevance* of positive laboratory and skin prick tests, since these allergens may not necessarily be exacerbating the patient's AD. When relevant food allergens are identified and avoided, skin-directed AD therapy is still crucial. It is important that parents and/or patients understand that coexistent food allergies are not the "cause" of AD. Even in patients with a clinically relevant allergy, elimination diets can prevent immediate hypersensitivity but are less likely to affect the course of the AD[214]. The potential benefits must be balanced with the possible adverse sequelae from unnecessarily restrictive diets, and modified diets should be supervised by a pediatric dietician to assure that they are nutritionally adequate.

Aeroallergen reactivity

Aeroallergen reactivity increases with age and is more prevalent in those with moderate to severe AD[215]. Common aeroallergens include dust mites, pollens, animal dander, and fungi. Exacerbation by aeroallergens should be considered when AD is more severe in exposed areas, and direct skin contact with aeroallergens may trigger the development of eczematous lesions in some patients. Evaluation includes assessment of specific IgE antibodies and skin prick testing[131].

Allergic contact dermatitis (ACD)

Patch testing to assess for contact sensitivity should be considered in AD patients with findings suggestive of ACD, a distribution pattern atypical of AD, sudden worsening, or recalcitrance to treatment. Common contact allergens in AD patients include components of topical medications and skin care products, such as fragrance, preservatives, lanolin, propylene glycol, cocamidopropyl betaine, bacitracin, neomycin, and sometimes corticosteroids (see Ch. 14)[216–218].

Prevention

Although the therapeutic armamentarium available for AD can successfully control the disease in most patients, primary prevention of AD represents a highly desirable goal. There is no evidence that maternal food allergen avoidance during pregnancy or lactation protects against the development of AD in the child[219]. For infants with a family history of atopy, exclusive breastfeeding during the first 3–4 months of life may potentially decrease the risk of AD[220]. However, exclusive breastfeeding for 6 months versus 3–4 months does not confer additional protection against the development of AD[221]. A Cochrane review concluded that there was no evidence for short- or long-term feeding with hydrolyzed formula compared with cow's milk formula for the prevention of AD in infants[222]. Timing of introduction of allergenic foods during infancy also appears to have no effect on AD risk[223].

While high intake of fish rich in anti-inflammatory long-chain polyunsaturated fatty acids (LC-PUFAs) during infancy may have a protective effect on the development of AD, meta-analyses found no significant association between either fish intake during pregnancy or maternal (during pregnancy or lactation) or infant PUFA supplementation and AD risk[224–227]. Low maternal prenatal vitamin D levels may be associated with an increased risk of early-onset AD during infancy[228]. However, there is no evidence that vitamin D supplementation during pregnancy, breastfeeding, or early infancy prevents allergic diseases[229].

Probiotics and prebiotics

Overall, studies investigating the effects of prebiotics, probiotics, and synbiotics on AD risk lack high-quality evidence due to methodological heterogeneity, differing definitions, and the wide variety of supplementations used. A systematic review and meta-analysis found no significant effect of prebiotic supplementation in pregnant women, breastfeeding mothers, or infants on the incidence of allergic disease[230]. Further investigation is required to determine whether pro-/prebiotic agents are beneficial for AD prevention and, if so, which agents as well as the optimal time of administration[231].

Emollients

Two large RCTs found that daily emollient application ± adding oil to the bath water during the first 8 to 12 months of life did not reduce the incidence of AD; in one of the studies, emollient use was associated with a mildly increased rate of skin infections[232,233]. Further investigations are needed to determine whether skin care interventions during infancy promote or prevent AD and whether they influence the risk of food allergy[234].

In addition to contact and atopic dermatitis, there exists a heterogeneous group of inflammatory skin diseases that obviously share the hallmarks of eczema, but display characteristic additional features. Their pathogenesis is generally less well understood, but most exhibit distinctive etiologic features.

SEBORRHEIC DERMATITIS

Key features

- Infantile and adult forms
- Lesions favor the scalp, ears, face, central chest, and intertriginous areas
- Etiologic links with active sebaceous glands, abnormal sebum composition, and *Malassezia* (*Pityrosporum*) spp.
- Can be a cutaneous sign of HIV infection

Introduction

Seborrheic dermatitis is a common, mild, chronic eczema typically confined to skin regions with high sebum production and the large body folds. Although its pathogenesis is not fully elucidated, there is a link to sebum overproduction (seborrhea), the commensal yeast *Malassezia*, and individual susceptibility.

History

Seborrheic dermatitis was first described by Unna[1], who also suspected *Malassezia furfur* (*Pityrosporum ovale*) as a causative factor. The nosologic position of seborrheic dermatitis was widely discussed for decades, the focus resting on dysfunction of the sebaceous glands and the high amounts of *M. furfur* present in scales of seborrheic dermatitis. In 1984 it was shown that seborrheic dermatitis could be suppressed by systemic ketoconazole[2]. This finding was corroborated by later studies[3], and it became clear that seborrheic dermatitis was strongly linked to these yeasts. Today, it is accepted that several species of *Malassezia*, including *M. furfur*, play a direct role in seborrheic dermatitis (see Table 77.3)[4].

Epidemiology

There are infantile and adult forms, with the former being self-limited and most prevalent the first 3–4 months of life, while the latter is chronic with a peak in the fourth to sixth decades. The prevalence of seborrheic dermatitis is estimated to be 5%, but its lifetime incidence is likely much higher. Men are afflicted more often than women. Extensive and therapy-resistant seborrheic dermatitis is an important cutaneous sign of HIV infection. It is more commonly observed in patients with neurologic diseases (e.g. Parkinson disease, cerebrovascular accidents)[5] or who are immunosuppressed. Additional contributing factors include nutritional deficiencies, impaired epidermal barrier, and occasionally medications (e.g. neuroleptics, atypical antipsychotics). Seborrheic dermatitis-like eruptions have also been reported with dupilumab and antineoplastic agents (e.g. tyrosine kinase inhibitors).

Pathogenesis

Malassezia

The genus *Malassezia* consists of lipophilic yeasts that are part of the normal resident skin flora[6,7]. Studies on the predominance of certain *Malassezia* spp. have revealed conflicting results[8,9]. *M. furfur* may behave as an opportunistic pathogen (e.g. fungemia in neonates receiving intravenous lipid emulsions) or cause or aggravate a spectrum of skin diseases: pityriasis versicolor, *Malassezia (Pityrosporum)* folliculitis, seborrheic dermatitis, and possibly atopic dermatitis.

Malassezia *and seborrheic dermatitis*

M. furfur and related species can be regularly isolated from lesions of seborrheic dermatitis, including infantile seborrheic dermatitis (whereas healthy prepubertal children are not colonized to a significant degree). This coincides with the presence of enlarged sebaceous glands during the neonatal period. There is no simple quantitative relationship between yeast number and severity of seborrheic dermatitis, and unaffected skin may carry a load of organisms similar to seborrheic dermatitis lesions. Even in the scalp, where *M. furfur* predominates amongst the resident flora, only twice as many yeasts may be recovered from areas of seborrheic dermatitis as from normal controls[6]. Amongst patients with AIDS, harboring of *Malassezia* spp. is equivalent, irrespective of the presence or absence of seborrheic dermatitis clinically; however, there is a difference in the amount of yeasts[10].

Active sebaceous glands and seborrheic dermatitis

Seborrheic dermatitis occurs predominantly in areas of the skin with active sebaceous glands and is often associated with sebum overproduction, which in turn can facilitate the growth of *Malassezia*. In infants, sebum is produced for a few weeks after birth, and the adult form of seborrheic dermatitis does not develop before puberty. This argues for a role for sebaceous gland activation by androgens. However, patients with seborrheic dermatitis may have normal sebum production and those with excessive sebum production are often free of seborrheic dermatitis. Thus, the amount of sebum produced alone does not appear to be the decisive risk factor.

It has been proposed that the composition of the skin surface lipids is the relevant factor[11]. In patients with seborrheic dermatitis, triglycerides and cholesterol are elevated but squalene and free fatty acids are significantly decreased. Free fatty acids (which have a known antimicrobial effect) are formed from triglycerides by bacterial lipases produced by the lipolytic *Cutibacterium* (formerly *Propionibacterium*) *acnes*. A major constituent of the resident microbial skin flora, *C. acnes* has been found to be greatly reduced in seborrheic dermatitis[12]. Seborrheic dermatitis may thus be linked to an imbalance of the microbial flora.

Immune responses to Malassezia *in seborrheic dermatitis*

An etiologic role for immune mechanisms against *Malassezia* – particularly in view of the prominence of seborrheic dermatitis in HIV-infected individuals – has been suspected but never convincingly proven. Intrinsic host factors, such as changes in sebum production and a defective epidermal barrier, could favor overgrowth of *Malassezia* spp. which

then incites a host inflammatory response[13]. However, additional studies on cellular immunity have yielded contradictory results[6,7]. The inflammation seen in seborrheic dermatitis might be irritant, caused by toxic metabolites, lipase, and reactive oxygen species[6,13].

Clinical Features

Seborrheic dermatitis is defined by clinical parameters, including:

- sharply demarcated patches or thin plaques that vary from pink–yellow to dull red to red–brown with bran-like to flaky "greasy" scales; vesiculation and crusting may occur but are rare and mostly due to irritation
- a predilection for areas rich in sebaceous glands – scalp, face, ears, presternal region – and, less often, the intertriginous areas
- a mild course with little or moderate discomfort.

Seborrheic dermatitis is most often limited in extent, but generalized and even erythrodermic forms can occur, albeit rarely.

Infantile seborrheic dermatitis

This form usually begins about one week after birth and may persist for several months. Initially, mild greasy scales adherent to the vertex and anterior fontanelle regions arise which may later extend over the entire scalp. Inflammation and oozing may finally result in a coherent scaly and crusty mass covering most of the scalp ("cradle cap"; Fig. 13.1A). Lesions of the axillae, inguinal creases, neck, and retroauricular folds are often acutely inflamed, oozing, sharply demarcated, and surrounded by satellite lesions (Fig. 13.1B). Superinfection with *Candida* spp. or occasionally bacteria (e.g. group A *Streptococcus*) can occur. A disseminated eruption of scaly papules with a psoriasiform appearance ("psoriasiform id reaction") may develop on the trunk, proximal extremities, and face in association with exuberant or superinfected seborrheic dermatitis, especially of the diaper area.

Fig. 13.1 Infantile seborrheic dermatitis. A Involvement of the scalp with thick adherent yellow scale overlying mild inflammation is often referred to as "cradle cap". **B** Glistening red plaques of the neck, axillary and inguinal folds as well as the penis and umbilicus. Note disseminated lesions on the trunk and extremities. *A, Courtesy Antonio Torello, MD; B, Courtesy Robert Hartman, MD.*

Adult seborrheic dermatitis

In adults, seborrheic dermatitis is generally found on the scalp and, usually of milder intensity, on the face; less often, lesions occur on the central upper chest and the intertriginous areas. Erythrodermic seborrheic dermatitis has been described as a rarity.

Pityriasis simplex capillitii (dandruff) is defined as a diffuse, slight to moderate, fine white or greasy scaling of the scalp and terminal hair-bearing areas of the face (beard area), but without significant erythema or irritation. Scales accumulate visibly on dark clothing. This common condition may be considered the mildest form of seborrheic dermatitis of the scalp.

In seborrheic dermatitis of the scalp, there is inflammation and pruritus in addition to dandruff. The vertex and parietal regions are predominantly affected, but in a more diffuse pattern than the discrete plaques of psoriasis. Towards the forehead, the erythema and scaling are usually sharply demarcated from uninvolved skin, with the border either at the hairline or slightly transgressing beyond it. Pruritus is usually moderate but may be intense, particularly in patients with male pattern alopecia; folliculitis, furuncles, and meibomitis are not uncommon complications, elicited by scratching and rubbing.

Seborrheic dermatitis of the facial skin is often strikingly symmetric, affecting the forehead, medial portions of the eyebrows, upper eyelids, nasolabial folds and lateral aspects of the nose, retroauricular areas, and occasionally the occiput and neck (Fig. 13.2). Lesions are yellowish-red, with a typical bran-like scale. Non-purulent otitis externa is often observed. If present, lesions of the trunk are preferentially found in the presternal and intertriginous areas (Fig. 13.3); those on the central chest can have a petaloid appearance. Seborrheic dermatitis, like inverse psoriasis, is a cause of intertrigo (Fig. 13.4).

In patients with seborrheic dermatitis, the skin is sensitive to irritation, and exposure to sun or heat, febrile illnesses, and overly aggressive topical therapy may precipitate flares and dissemination. Rebound flares can also follow tapers of systemic corticosteroids. Seborrheic dermatitis is more common during the winter in patients with skin phototypes I–II, most likely a reflection of increased xerosis and decreased epidermal barrier function[14].

Irritated seborrheic dermatitis lesions can become bright red and erosive. *Malassezia (Pityrosporum)* folliculitis is another complication characterized by pruritic erythematous follicular papules, sometimes pustules, typically in sites rich in sebaceous glands.

Adult seborrheic dermatitis has a chronic relapsing course. Patients feel well and systemic signs are absent. Extensive and severe seborrheic dermatitis, however, should raise the suspicion of underlying HIV infection. Among patients with seborrheic dermatitis tested for HIV infection, 2% were found to be positive, frequently in a late stage of their disease[15]. In patients with Parkinson disease, seborrheic dermatitis is a common finding, along with seborrhea. Its severity, however, is not correlated with that of the Parkinson disease[16]. The facial immobility of patients with Parkinson disease might result in a greater accumulation of sebum on the skin, resulting in a permissive effect on the growth of *Malassezia*[16,17]. Seborrheic dermatitis may also be more common in patients with other causes of immobility such as cerebrovascular accidents.

Pathology

Acute seborrheic dermatitis displays spongiosis with a superficial perivascular and perifollicular lymphocytic infiltrate composed mainly of lymphocytes. Older lesions show irregular acanthosis and focal parakeratosis. The latter may appear similar to psoriasis, but exocytosis of neutrophils, Munro microabscesses, and confluent parakeratotic horny layers are absent.

Differential Diagnosis

Infantile seborrheic dermatitis is distinguished from *atopic dermatitis* by its earlier onset, different distribution pattern, and, most importantly, by the absence of pruritus, irritability, and sleeplessness. In contrast to

Fig. 13.2 Adult seborrheic dermatitis of the face, ear and scalp. A Rather sharply demarcated pink plaque with flaky white and greasy scale. Note the fissure in the retroauricular sulcus. **B** Sharply demarcated pink–orange thin plaques with yellow, greasy scale, especially in the nasolabial fold. When this degree of severity is seen, the possibility of underlying HIV infection needs to be considered. **C** Symmetric red–brown to violet plaques of the central forehead, nasal bridge, and medial cheeks with an associated hypopigmented peripheral and figurate rim. **D** Involvement of the upper eyelids, medial canthal regions, and infraorbital creases; seborrheic dermatitis confined to the major crease in the outer canthal region can also be seen. *C, Courtesy Jeffrey P. Callen, MD; D, Courtesy Kalman Watsky, MD.*

Fig. 13.3 Seborrheic dermatitis of the presternal region in an adult. It sometimes resembles the petals of a flower.

atopic dermatitis, infants with seborrheic dermatitis generally feed well and are content. *Irritant diaper dermatitis* is confined to the diaper area and tends to spare the skin folds (see below). *Candidiasis* of the diaper area can result from colonization with fecal yeast and some infants have seborrheic dermatitis with a superimposed candidal infection. The differential diagnosis also includes *streptococcal intertrigo* (see Fig. 13.12). *Infantile psoriasis* may be difficult to distinguish from psoriasiform seborrheic dermatitis. Although psoriasiform diaper dermatitis can represent the initial manifestation of psoriasis, many affected infants do not subsequently develop psoriasis elsewhere.

Rare conditions to be considered are Langerhans cell histiocytosis, "nutritional dermatitis" (e.g. acrodermatitis enteropathica; see Fig. 51.13), and Leiner disease. The last-mentioned is a questionable entity, once thought to be the maximal variant of infantile seborrheic dermatitis, but nowadays viewed as erythroderma in the setting of underlying immunosuppression (see Chs. 10 & 60).

When scalp scaling is present in prepubertal, especially Black, children, the possibility of *tinea capitis* due to *Trichophyton tonsurans* should be considered. In *pityriasis amiantacea*, thick asbestos-like scales adhere to tufts of scalp hairs; up to a third of the affected children and adolescents eventually develop psoriasis.

A number of entities are included in the differential diagnosis of **adult** seborrheic dermatitis. Distinction of seborrheic dermatitis *of the scalp* from psoriasis can be difficult, and there may be an overlap in some patients ("sebopsoriasis"). However, the plaques of psoriasis tend to be thicker, with silvery white scale, more discrete, less pruritic, and unassociated with seborrhea. In addition, features of psoriasis may be found elsewhere. Dry scaling of the scalp, along with dry brittle hair (as opposed to greasy hair), is a symptom of xerotic skin (e.g. in atopic dermatitis), frequently mistaken for (and mistreated as) seborrheic dermatitis. Mild erythema and scale of the posterior scalp, often with demonstrable hair loss, can be seen in dermatomyositis[18].

Seborrheic dermatitis *of the face* may closely resemble both early rosacea and the butterfly lesions of systemic lupus erythematosus. Lupus erythematosus rarely affects the nasolabial folds and often has a clearly demonstrable photodistribution. Notably, seborrheic dermatitis and rosacea frequently coexist. The facial dermatitis seen in patients receiving dupilumab may resemble seborrheic dermatitis. The differential diagnosis of seborrheic dermatitis *of the trunk* includes pityriasis rosea (but in this latter entity the lesions are ellipsoid in shape, have collarette-like scaling, and there is no predilection for the central chest) as well as superficial eruptive psoriasis and subacute cutaneous lupus erythematosus.

Seborrheic dermatitis *of the intertriginous areas* must be distinguished from inverse psoriasis, erythrasma, intertriginous dermatitis, candidiasis, and, rarely, Langerhans cell histiocytosis (see Fig. 13.4).

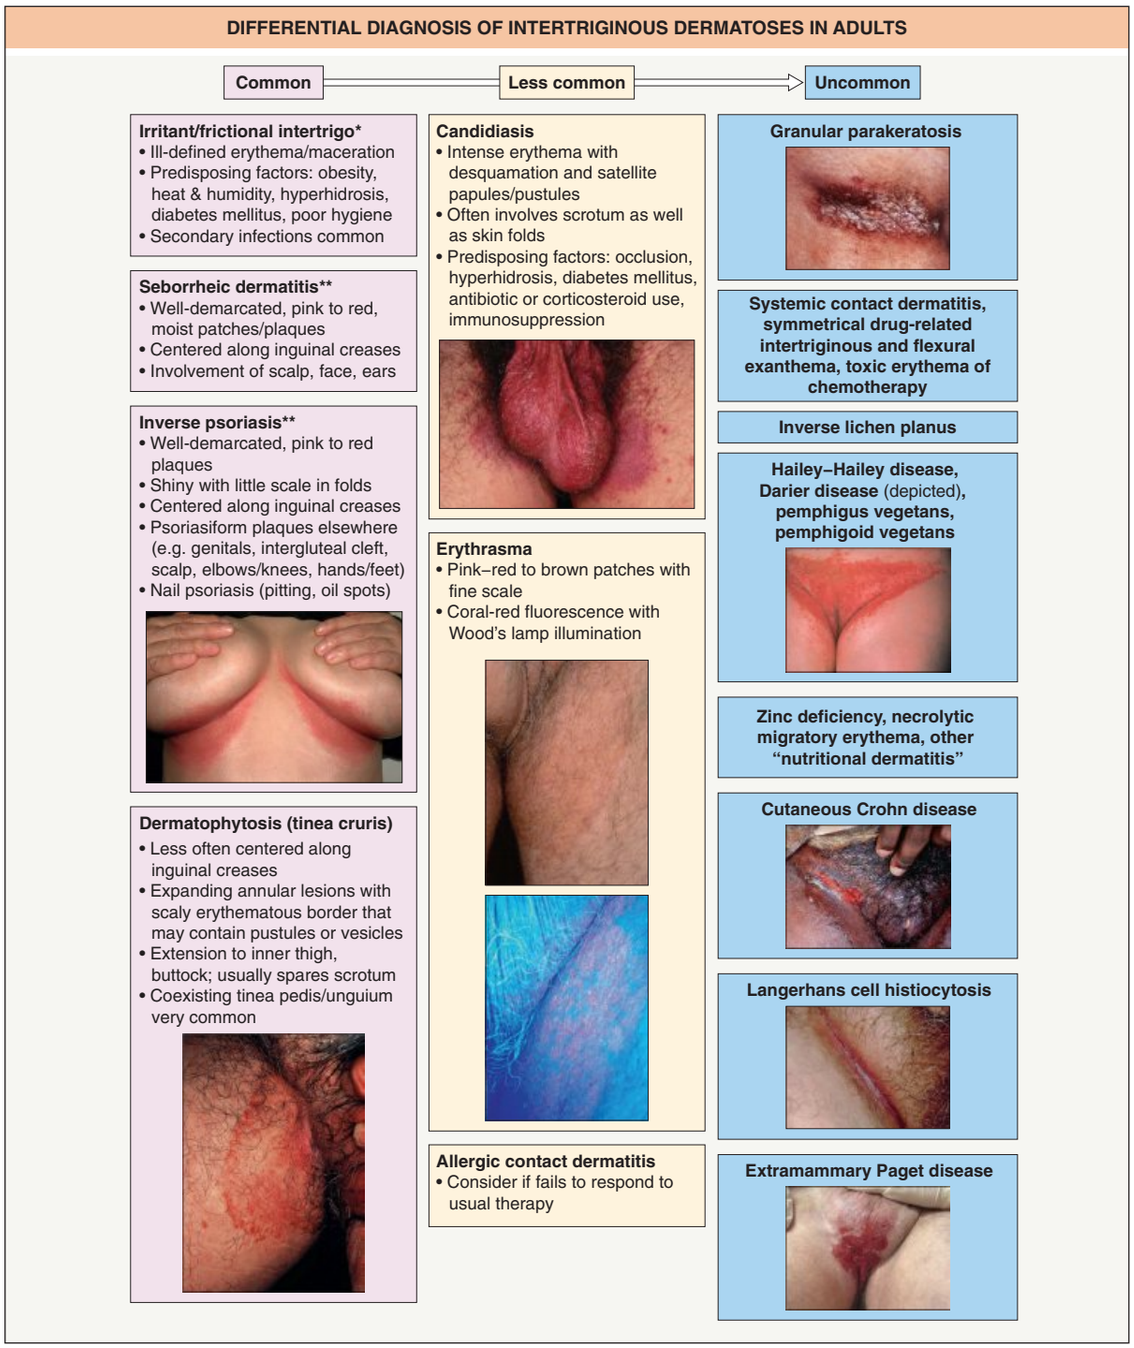

Fig. 13.4 Differential diagnosis of intertriginous dermatoses in adults. Individual patients often have multiple disorders superimposed upon one another. Bullous impetigo and streptococcal intertrigo are considerably more common in children than adults. *Also referred to more nonspecifically as intertriginous dermatitis or intertrigo. **The term "sebopsoriasis" may be used when features of both seborrheic dermatitis and psoriasis are present. *Insets: Courtesy Luis Requena, MD; Eugene Mirrer, MD; Louis A. Fragola, Jr, MD; David Mehregan, MD; Julie V. Schaffer, MD.*

Treatment

Infantile seborrheic dermatitis

Infantile seborrheic dermatitis usually responds satisfactorily to bathing and application of emollients. Ketoconazole cream (2%) is indicated in more extensive or persistent cases[19]. Short courses of low-potency topical corticosteroids may be used initially to suppress inflammation. Mild shampoos are recommended for the removal of scalp scales and crusts. Avoidance of irritation (e.g. the use of strong keratolytic shampoos or mechanical measures to remove the scales from the scalp) is important.

Adult seborrheic dermatitis

The mainstay of therapy is the use of topical azoles (e.g. ketoconazole), either as shampoos (scalp) or as creams (body). The high response rate (75%–90%) of this treatment has been documented in double-blind trials[3]. Ciclopirox olamine has antifungal and anti-inflammatory activities and has also been shown to be effective as a shampoo or cream in double-blind, randomized trials. Seborrheic dermatitis tends to relapse if a maintenance regimen is not instituted. As *M. furfur* has a slow proliferation rate, an interval of two to several weeks will pass until relapses appear. The intervals of topical therapy should follow this rhythm.

Additional measures, particularly in the initial stages of treatment, include emollients and low-potency topical corticosteroids; the latter were found to be equally efficacious as topical azoles in a Cochrane analysis[20]. Second-line treatment options include zinc pyrithione, selenium sulfide, and tar shampoos as well as topical calcineurin inhibitors. Systemic antimycotics (e.g. weekly fluconazole) should only be used in cases of severe findings or frequent recurrences.

ASTEATOTIC ECZEMA

Synonyms: ■ Eczema craquelé ■ Winter eczema ■ Winter itch ■ Desiccation dermatitis

Key features

- Dry, rough, scaly, and inflamed skin with superficial cracking that resembles a "dried riverbed"
- Sites of predilection are the shins, lower flanks, and posterior axillary line
- Associated with aging, xerosis, low relative humidity, and frequent bathing

Introduction

Dry skin (xerosis, asteatosis, exsiccosis) may result from both exogenous and endogenous causes: a dry climate or low indoor humidity; excessive exposure to water, soaps, and surfactants; marasmus and malnutrition; chronic kidney diseases and hemodialysis; hypothyroidism; HIV infection; and heritable conditions such as ichthyosis vulgaris and atopic dermatitis. Asteatotic eczema also arises in patients with reduced sweat gland function (e.g. chronic graft-versus-host disease) or in sites of edema due to hypoalbuminemia from hepatic cirrhosis or nephrotic syndrome. That said, the most common cause of xerosis is aging. Rarely, but especially when widespread and refractory to therapy, asteatotic eczema may be related to an underlying neoplasm, including lymphoma[21].

History and Epidemiology

Asteatosis as the cause of "nummular eczema" was first mentioned by Gross[22] in the late 1940s. Dry skin probably occurs in everyone over the age of 60 years, but its severity is strongly linked to the exogenous and endogenous factors mentioned above.

Pathogenesis

Xerosis of aging skin is not caused by deficient sebum production, but by a complex dysfunction of the stratum corneum (see Ch. 124)[23]. There is a decrease of intercellular lipids with a deficiency of all key stratum corneum lipids[24] and an altered ratio of esterified fatty acids to ceramide 1[25]; this, plus a persistence of corneodesmosomes[26] and premature expression of involucrin and formation of the cornified envelope[27], results in corneocyte retention and marked impairment of barrier recovery[24]. The water-binding capacity of the stratum corneum is reduced owing to decreased synthesis of "natural moisturizing factor" (NMF) as well as decreased intercellular lipids and glycerol content[28]. Consequently, the stratum corneum desiccates, loses its pliability, and forms small cracks, which render the skin surface dull, rough, and scaly.

Mild xerosis is asymptomatic, but if more pronounced, the skin conveys unpleasant sensations such as pruritus and stinging. Inflammation is enhanced by the release of proinflammatory cytokines secondary to barrier perturbation, mechanical factors (scratching, rubbing), and the application of irritating or sensitizing substances in topical preparations and skin care products.

Occasionally, eczema craquelé can appear in the setting of acute edema[29], e.g. from congestive heart failure or the re-feeding of patients with anorexia nervosa. One theory is that this is related to the rate of distention of the skin.

Clinical Features

Xerosis first arises on the shins. Later it may spread to the proximal extremities and trunk, but spares the face and neck as well as the palms and soles. It develops insidiously over many years, whereas asteatotic eczema often has a more subacute to acute onset.

Xerotic skin is dry and dull, with fine bran-like scales that may be released as powdery clouds when patients take off their stockings. If more advanced, the skin exhibits a criss-cross pattern of superficial cracks and fissures of the horny layer ("crazy-paving", eczema craquelé, "dried riverbed") and appears pink to light red in color (Fig. 13.5). The skin becomes rough, and it may develop an appearance similar to ichthyosis vulgaris ("pseudo-ichthyosis"). In more advanced stages of asteatotic eczema, there is a dull erythema as well as oozing, crusting, and abundant excoriations; disseminated nummular lesions are frequently seen. Vesiculation and lichenification are not regular features except when irritant or allergic contact dermatitis is superimposed. Hemorrhage into the fissures is occasionally observed.

Fig. 13.5 Asteatotic eczema (eczema craquelé). A On the shins, a criss-cross pattern of superficial cracks, fissures, and hemorrhagic crusts said to resemble a dried riverbed. **B** Xerosis with adherent white scales (pseudo-ichthyosis) and inflammation as well as the criss-cross pattern of superficial cracks and fissures. *A, Courtesy Kalman Watsky, MD; B, Courtesy Louis A. Fragola, Jr, MD.*

Pathology

Histologically, xerotic skin appears rather normal except for a compact and slightly irregular stratum corneum. Asteatotic eczema in addition exhibits mild focal spongiosis, focal parakeratosis, and a sparse inflammatory infiltrate in the superficial dermis.

Differential Diagnosis

Conditions that need to be distinguished from asteatotic eczema include stasis dermatitis, adult atopic dermatitis (which may overlap with asteatotic eczema), allergic contact dermatitis, nummular dermatitis, and scabies.

Treatment

Asteatotic eczema usually clears within a few days of the application of topical corticosteroid ointment. Proper attention must be given to the care of xerosis in order to avoid relapses: regular use of petrolatum, water-in-oil emollients, urea-, ceramide- or lactic acid-containing preparations, use of bath oils, and the elimination of factors that aggravate dry skin (see above). Topical calcineurin inhibitors have also been used. Coexisting stasis dermatitis should be treated as well (see below).

DISSEMINATED ECZEMA (AUTOSENSITIZATION)

Synonyms: ■ Autosensitization dermatitis ■ Autoeczematization ■ Generalized eczema ■ Id reaction

Key features

- Secondary lesions of eczema distant from the primary site of exposure or involvement
- Symmetric distribution pattern
- Most often associated with allergic contact dermatitis and stasis dermatitis

Introduction

Dermatitis caused by exogenous agents initially arises at the site of contact. Not infrequently, additional patches of eczema develop at distant sites. This phenomenon, termed secondary dissemination, has puzzled dermatologists for decades. It is most often observed in allergic contact dermatitis, particularly if associated with stasis dermatitis (see Fig. 13.8), but may occur with uncomplicated stasis dermatitis, other forms of eczema, and, occasionally, severe tinea pedis.

Disseminated eczema appears later than the primary lesions by a few days to weeks, tends to follow a strikingly symmetric distribution pattern, and shows a predilection for analogous anatomic sites (e.g. extensor aspects of the lower and upper extremities, palms, and soles). It may even arise in the absence of and without a preceding "primary" eczema, e.g. in nummular dermatitis (see below). Disseminated eczema must be distinguished from atopic dermatitis, which arises *a priori* in a disseminated fashion.

History and Pathogenesis

The phenomenon of secondary dissemination of eczemas was first described by Whitfield[30], but its pathogenesis is still not fully elucidated. The orderly and symmetric distribution pattern may reflect systemic (hematogenous) dissemination and argues against simple spread of contact irritants or allergens on the body surface. It is unclear, however, as to exactly what is disseminated via the bloodstream. It could be allergens; for example, the ingestion of allergens such as nickel has been shown to elicit disseminated eczema in sensitized individuals[31,32].

Hematogenous dissemination of microbial products leading to a variety of (non-infectious) manifestations distant from the site of infection, such as "tuberculids" and "bacterids", was an accepted pathogenic model in the first half of the twentieth century and was extrapolated to the phenomenon of disseminated eczema. Dyshidrotic eczema of the soles, for example, was interpreted as an "id" reaction associated with tinea pedis, and nummular eczema as an "id" reaction caused by "focal" infections of the tonsils. Because disseminated eczema could hardly be attributed solely to infections, attention shifted to an "autosensitization" to epidermal antigens mediated by cytotoxic autoantibodies. This hypothesis, however, has never been verified.

Instead, it became clear both from animal experiments[33] and from routine patch testing ("excited skin syndrome", "angry back")[34,35] that inflammatory processes of the skin, both allergic and irritant or caused by infections, lower the irritancy threshold of distant skin and thus facilitate the development of an eczematous reaction. Obviously, circulating activated memory T cells may play an additional role in disseminated eczema associated with allergic contact dermatitis, including that seen with rebound poison ivy dermatitis following a short, rapid taper of systemic corticosteroids. It remains to be determined which factors regulate the symmetric distribution of disseminated eczema.

Epidemiology

An estimated two-thirds or more of patients with contact dermatitis associated with stasis dermatitis develop episodes of disseminated eczema. The incidence is much lower in the other types of eczema or tinea pedis.

Clinical Features

Disseminated eczema associated with allergic contact dermatitis is characterized by moderately to poorly demarcated patches of eczema, most often on the extremities (Fig. 13.6A). Lesions are also found on the face, and less so on the trunk (Fig. 13.6B). The areas of involvement vary greatly in size and number and may consist of discrete papules which are often excoriated. Disseminated eczema in patients with seborrheic and asteatotic eczema differs slightly in predilection sites and morphology (see above).

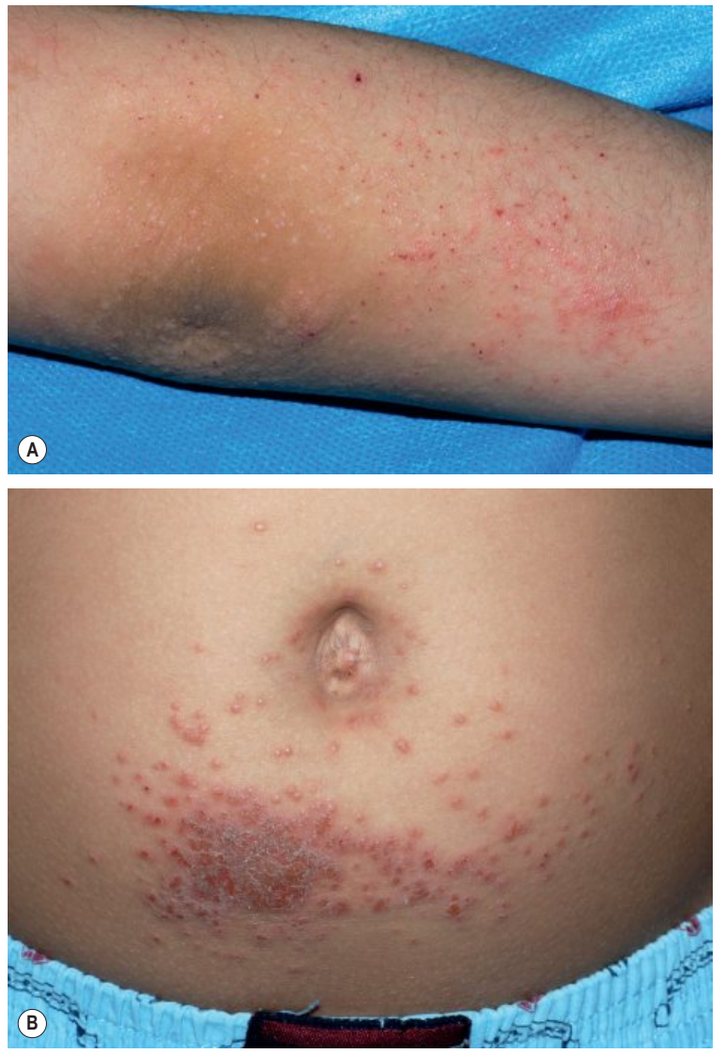

Fig. 13.6 Id reactions in children due to allergic contact dermatitis (ACD) to nickel. **A** Multiple flat-topped papules, several of which have been excoriated, in addition to patches of eczema. **B** Square-shaped area of ACD due to nickel in a buckle with an associated id reaction. The latter consists of edematous crusted papules that are separate from the area of direct nickel contact. *Courtesy Julie V. Schaffer, MD.*

Pathology

In biopsy specimens of disseminated eczema, the histologic findings are those of an acute or subacute eczematous dermatitis (see section "Stasis dermatitis").

Differential Diagnosis

Conditions to be distinguished are those eczemas that can arise in a widespread or disseminated fashion: atopic dermatitis, airborne contact dermatitis, contact dermatitis caused by constituents of textiles, photoallergic dermatitis, and eczematous drug eruptions (e.g. calcium channel blockers). Other conditions to be considered are mycosis fungoides and Sézary syndrome.

Treatment

Topical corticosteroids and systemic antihistamines are the mainstay of therapy. Short courses of systemic corticosteroids may be required, but identification and aggressive topical treatment of the inciting dermatosis is necessary to help prevent recurrences or a rebound flare.

NUMMULAR DERMATITIS

Synonyms: ■ Nummular eczema ■ Discoid eczema ■ Microbial eczema

Key features

- Coin-shaped, disseminated, eczematous lesions
- Usually very pruritic
- Chronic course

Introduction

Nummular dermatitis is an uncommon, disseminated eczema characterized by its coin-shaped lesions. Because such lesions can occur as a feature of atopic dermatitis, asteatotic eczema, and stasis dermatitis, the nosologic position of nummular dermatitis as an independent clinical entity has been questioned.

Epidemiology

Nummular lesions of eczema are not uncommon. However, in the literature there are widely discrepant data on the prevalence of nummular dermatitis, ranging from 0.1% to 9.1%[36]. Some of this variability may reflect the degree to which a distinction is made between nummular dermatitis and coin-shaped lesions observed in patients with other forms of eczema. Men are affected slightly more often and at a later age than women (>50 vs <30 years, respectively).

Pathogenesis

Nummular lesions of dermatitis are not infrequently associated with contact sensitization as well as with xerosis and venous hypertension. In a study of ~30 000 consecutive patients with different types of eczema who underwent patch testing, 3.5% were diagnosed as having nummular dermatitis; 32.5% of these individuals had at least one positive patch test reaction, most often to nickel sulfate, potassium dichromate, and cobalt chloride[36]. Clinical and laboratory signs of atopy are absent in "true" nummular dermatitis.

Clinical Features

Nummular dermatitis is defined as an eruption of round (discoid) eczematous patches almost exclusively of the extremities, often the lower legs in men and the forearms and dorsal aspects of the hands in women (Fig. 13.7A)[36]. The lesions are well demarcated and measure 1–3 cm, only occasionally being larger (Fig. 13.7B,C). They may be acutely inflamed with vesicles and weeping, but are often lichenified and hyperkeratotic. Pruritus may be intense and excoriations are often prominent. Nummular dermatitis usually takes a very chronic course. A particularly therapy-resistant variety has been termed "oid-oid" disease, also referred to as exudative discoid and lichenoid chronic dermatitis or Sulzberger–Garbe syndrome.

Pathology

Histologically, the changes of subacute to chronic eczematous dermatitis are seen (Fig. 13.7D; see section "Stasis dermatitis").

Differential Diagnosis

Nummular dermatitis must be distinguished from nummular lesions of atopic dermatitis and dissemination secondary to contact dermatitis or stasis dermatitis. Other conditions to be considered are psoriasis, inflammatory tinea corporis, mycosis fungoides, and Bowen disease.

Treatment

Options include medium- to high-potency topical corticosteroid ointments, topical tacrolimus or pimecrolimus, and emollients. Tar preparations have also been used successfully. However, a number of patients will require phototherapy to clear the lesions. Methotrexate has led to long-term improvement in children, and dupilumab is a therapeutic option for recalcitrant disease[37].

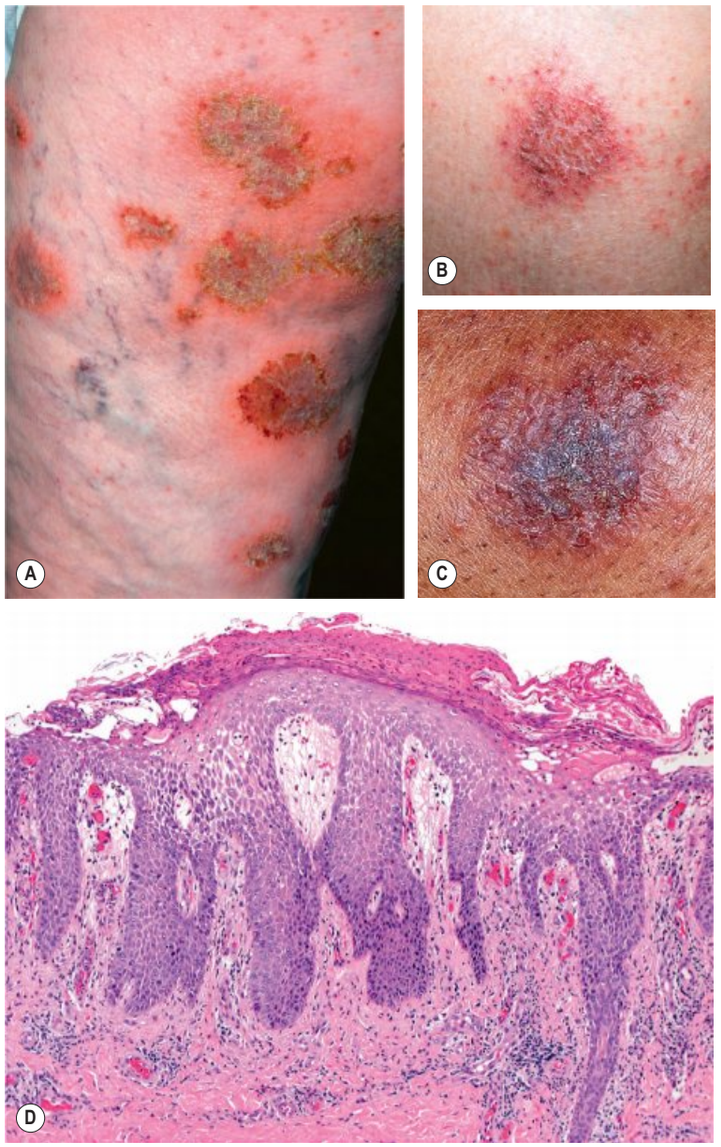

Fig. 13.7 Nummular dermatitis – clinical and histopathologic features. A Multiple coin-shaped lesions of acute and subacute dermatitis on the leg that are fairly well demarcated. There is often marked pruritus. **B, C** Coin-shaped eczematous plaques with scale-crust in two patients with different skin phototypes. Patients may report oozing of lesions. **D** Irregular acanthosis of the epidermis is accompanied by marked spongiosis as well as parakeratotic scale and crust. A lymphohistiocytic infiltrate is present in the dermis with a few lymphocytes within the epidermis. Edema is present in the papillary dermis. *B, C, Courtesy Kalman Watsky, MD; D, Courtesy Lorenzo Cerroni, MD.*

See Chapter 12.

HTLV-ASSOCIATED INFECTIVE DERMATITIS

Key features

- Rare dermatologic disorder of childhood and adolescence
- Association with human T-cell lymphotropic virus type I (HTLV-1)
- Eczema of the scalp, axillae, and groin; watery discharge of the nose
- Prompt response to antibiotics

Introduction and Pathogenesis

Human T cell lymphotropic virus type I (HTLV-1), also referred to as human T cell leukemia virus type I and adult T cell lymphoma virus type 1, was first detected in 1980[38], and it can infect T cells, B cells, and monocytes. HTLV-1 is transmitted primarily via breastfeeding, but also by sexual intercourse, blood transfusion, and needle sharing in intravenous drug users. It has been associated with adult T cell leukemia/lymphoma (ATLL), myelopathy/tropical spastic paraparesis, and infective dermatitis. Presumably, HTLV-1-induced dysregulation of the immune system leads to immunosuppression and subsequent infections with *Staphylococcus aureus* or β-hemolytic streptococci[39]. There is also a potential role for genetic factors, low socioeconomic status, and malnutrition.

The activity of HTLV-1 in infected subjects appears to be low – more than 90% of carriers remain asymptomatic[40] and the majority of disease symptoms (other than infective dermatitis) emerge during adulthood. HTLV-1 induces spontaneous T cell proliferation independent of exogenous stimuli, followed by interleukin (IL)-2 receptor expression (CD25), increased IL-2 secretion, and induction of interferon-γ, IL-5, and IL-10. In symptomatic patients, levels of tumor necrosis factor and IL-6 are elevated[41]. In addition to bacterial infections, affected individuals are more susceptible to parasitoses such as scabies and strongyloidiasis[42].

History and Epidemiology

Major endemic areas of HTLV-1 infection include sub-Saharan Africa, northern South America, the Caribbean basin, southern Japan, and Iran, affecting 10–20 million people worldwide. Infective dermatitis was first described in 1966 by Sweet[43], and a year later Walshe[44] suggested an underlying immune defect was present because relapses of the dermatitis frequently occurred, even after a prompt initial response to antibiotic treatment. In 1990, the association with HTLV-1 was first reported[39]. The probability of developing infective dermatitis was estimated to be 2% amongst HTLV-1-infected children[45], with cutaneous manifestations typically appearing only after protective maternal antibodies had disappeared.

Clinical Features

Infective dermatitis presents as an exudative and crusty eczematous dermatosis, affecting primarily the head and neck region, including the scalp, ears, eyelid margins, and paranasal skin, as well as the axillae and groin[40]. A generalized fine papular rash is occasionally observed and there is usually secondary infection with *Staphylococcus aureus* or β-hemolytic streptococci. Complications include parasitic infestations, corneal opacities, and progression to more severe HTLV-1-associated disorders (e.g. ATLL). Infective dermatitis rarely persists into adulthood. However, in a series of adult patients in Bahia with HTLV-1-associated ATLL, 44% had a history of infective dermatitis[46]. Diagnosis is established by major and minor criteria (Table 13.1)

Differential Diagnosis

The major entity in the differential diagnosis is atopic dermatitis. Apart from serologic evidence of HTLV-1 infection, lesions of infective dermatitis are more exuberant and obviously infected, but pruritus is less intense. Crusting of the nasal vestibule and blepharoconjunctivitis are more prominent than in atopic dermatitis. Furthermore, it is not associated with atopy. Other disorders to consider include seborrheic dermatitis and impetigo.

Treatment

Antibiotics (e.g. sulfamethoxazole–trimethoprim, cephalexin, erythromycin) result in improvement of the skin lesions but do not prevent relapses. Topical treatments include antibiotics (including intranasal), corticosteroids, and bleach baths.

CRITERIA FOR THE DIAGNOSIS OF HTLV-ASSOCIATED INFECTIVE DERMATITIS
Major
• Eczema of the head and neck region, including the scalp, ears, eyelid margins, and paranasal skin, as well as the axillae and groin
• Chronic watery nasal discharge and/or crusting of the anterior nares
• Chronic relapsing dermatitis which responds quickly to antibiotics but relapses promptly after withdrawal
• Onset during early childhood
• **Seropositivity for HTLV-1**
Minor
• Positive cultures for *Staphylococcus aureus* and/or β-hemolytic streptococci from the skin or anterior nares
• Generalized fine papular rash
• Anemia, elevated erythrocyte sedimentation rate
• Hyperimmunoglobulinemia
• Elevated $CD4^+$ and $CD8^+$ T cell counts; elevated CD4/CD8 ratio

Table 13.1 Criteria for the diagnosis of HTLV-associated infective dermatitis. To establish the diagnosis, four major criteria are required, with mandatory inclusion of human T-cell lymphotropic/leukemia virus type I (HTLV-1) seropositivity. For the first major criterion, the involvement of at least two body regions is required. *Adapted from La Grenade L, Manns A, Fletcher V, et al. Clinical, pathologic, and immunologic features of human T-lymphotrophic virus type I-associated infective dermatitis in children. Arch Dermatol 1998;134:439–44.*

REGIONAL ECZEMATOUS DISORDERS

Stasis Dermatitis

Synonyms: ■ Gravitational dermatitis ■ Varicose eczema ■ Congestion eczema

Key features

- Often associated with other signs of venous hypertension
- Can be complicated by allergic contact dermatitis
- One of the most common causes of disseminated eczema (autosensitization dermatitis)

Introduction

Stasis dermatitis is a common component of the clinical spectrum of chronic venous insufficiency of the lower extremities (see Ch. 105). It may arise as an early sign of chronic venous insufficiency, but can persist or recur throughout all stages and is often most prominent when ulcers are present. There is little doubt that chronic venous hypertension *per se* is the initial trigger for stasis dermatitis[47]. Over time, additional etiological factors may act in concert, most importantly contact sensitization to ingredients of topical therapies. Stasis dermatitis is one of the most common causes of secondary dissemination of dermatitis, and is therefore a complex and multifactorial condition.

History

The term "stasis dermatitis" was introduced by Pillsbury[48], and the term "gravitation dermatitis" by Belisario[49].

Epidemiology

The prevalence of chronic venous insufficiency is variable among different ethnic groups and societies. In Central Europe, ~15% of the adult population has symptoms of chronic venous insufficiency and about 1% suffers from venous ulcers. Prevalence rates clearly rise with age.

Pathogenesis

Venous hypertension of the lower limbs is linked to the upright position and is caused by multiple factors, most importantly valvular incompetence of the deep leg veins (see Fig. 105.2). With venous hypertension, there is a slowing of blood flow within the microvasculature, distension of capillaries, and damage to the capillary permeability barrier, allowing the passage of fluid and plasma proteins into the tissue (edema) and extravasation of erythrocytes (stasis "purpura" and hemosiderin deposition). These processes lead to microangiopathy, with serious consequences (Table 13.2)[58].

Both microangiopathy and chronic inflammation are likely to be responsible for stasis dermatitis. Stasis dermatitis typically occurs in the same (i.e. the medial supramalleolar) regions where microangiopathy is most intense, and the patches of dermatitis arise preferentially

PATHOGENETIC FACTORS IN STASIS DERMATITIS	
Factor	**Consequence**
Chronic venous insufficiency and the microvasculature	
Deposition of proteins, particularly fibrin, around vessels as hyaline cuffs	• Deposits inhibit oxygen diffusion and metabolic exchange in combination with interstitial edema
Slow blood flow	• Upregulation of ICAM-1 and VCAM-1 on endothelia[50] • Activation of neutrophils and macrophages[51] • Expression of L-selectin on neutrophils[52] • Neutrophils attracted into and trapped within affected areas, notably the medial supramalleolar region[53]
Release of inflammatory mediators, free radicals, and proteases by neutrophils	• Pericapillary inflammation
Free iron ions released from hemosiderin deposits	• Increase in free radical production and lipid peroxidation • Activation of matrix metalloproteinases[54]
Platelet accumulation within the microvasculature	• May trigger focal thrombosis
Fibrosis and tissue remodeling due to imbalances within the capillary network	• Lipodermatosclerosis – dermal sclerosis and septal sclerosis that present as sclerosing panniculitis • Lymphatic dysfunction • "Atrophie blanche" – stellate sclerotic areas depleted of capillaries with the formation of peripheral giant capillaries • May lead to the formation of venous ulcers
Elevated plasma levels of homocysteine[55]	• Hyperhomocysteinemia is associated with an increased risk of thromboses
Complicating factors	

Allergic contact dermatitis	• Sensitizers are often in topical agents used to combat pruritus, xerosis, and presumed infection[56,57]
	  • Antibiotics, e.g. bacitracin, neomycin
	  • Lanolin derivatives
	  • Corticosteroids
	  • Fragrances, e.g. Balsam of Peru
	  • Preservatives
	  • Emulsifiers
	  • Antiseptics, e.g. iodine*
	  • Chemicals of plant origin, rubber in pressure stockings
	  • Wound dressing components
	• Patients with chronic venous insufficiency often exhibit multiple contact allergies

Irritant contact dermatitis	• The exudate from draining ulcers leads to maceration, increased inflammation, and bacterial colonization of surrounding skin • Infectious eczematous dermatitis may occur
*More commonly, irritant contact dermatitis.	

Table 13.2 Pathogenetic factors in stasis dermatitis. See Fig. 105.3.

CUTANEOUS SIGNS OF CHRONIC VENOUS HYPERTENSION
• Edema, often tender • Varicosities, including venulectasias of the instep • Petechiae superimposed on a yellow–brown discoloration due to hemosiderin deposits (stasis purpura) • Stasis dermatitis • Lipodermatosclerosis, acute and chronic • Stasis ulcerations, in particular above the medial malleolus • Acroangiodermatitis (pseudo-Kaposi sarcoma) • Livedoid vasculopathy ("atrophie blanche"): porcelain-white scars surrounded by punctate telangiectasias and painful ulcerations*
*Need to exclude causes of hypercoagulability/thrombophilia (see Table 105.9).

Table 13.3 Cutaneous signs of chronic venous hypertension. See Figs. 105.4, 105.5 and 105.7.

Fig. 13.8 Autosensitization dermatitis in a patient with venous ulceration. Note the involvement of the extensor surfaces of the upper extremities in this patient with an allergic contact dermatitis to neomycin, as well as stasis dermatitis and venous ulceration. *Courtesy Jean L. Bolognia, MD.*

over dilated varicose veins. Also, dermal inflammation is known to induce epidermal dysfunction, including barrier impairment.

Sometimes, patients report intense pruritus that even develops before the eczema. Pruritus may be caused by repeated congestion and decongestion, as well as by the release of inflammatory mediators within the dermis. Scratching or rubbing worsens and perpetuates the dermatitis. In addition, patients often apply topical agents to combat the pruritus and xerosis, increasing the risk of contact dermatitis (see Table 13.2).

Clinical features

The first sign of chronic venous insufficiency is usually a cushion-like pitting edema of the medial aspects of the shin and calf around and proximal to the ankle, corresponding to the location of the major communicating veins (Table 13.3). Edema is more pronounced in the evening and resolves overnight. Bouts of stasis purpura lead to areas of hemosiderin deposition. At this stage, stasis dermatitis is mild or absent; the skin may be dry and pruritic. Later, the edema extends to the distal third of the calf and subfascial edema arises, often accompanied by inflammation which may mimic cellulitis (acute lipodermatosclerosis; "pseudoerysipelas"). Over a period of years, the skin, subcutaneous adipose tissue, and deep fascia become progressively indurated and mutually adherent (chronic lipodermatosclerosis). A firm circular cuff is formed which appears to strangle the distal calf, creating an inverted wine bottle appearance. The skin may show intense hemosiderin pigmentation and changes of atrophie blanche. In this setting, venous ulcers develop spontaneously or are triggered by scratching or other trauma. They arise most often in the supramalleolar region, but may later expand (see Ch. 105).

Often stasis dermatitis appears when lipodermatosclerosis develops (see Fig. 105.5). Erythema and scaling are most pronounced around the inner malleoli, but may extend to involve the entire distal lower extremity. Stasis dermatitis is markedly pruritic, as evidenced by multiple excoriations which lead to oozing and crusting. Episodes of vesiculation occur infrequently, always raising the suspicion of superimposed contact sensitization. Chronic lesions of stasis dermatitis invariably exhibit considerable lichenification. Once ulcers form, stasis dermatitis frequently becomes highly irritated, oozing, and erosive (see Fig. 105.4).

Contact sensitization often leads to secondary dissemination. Patches of eczema arise in a strikingly symmetric distribution pattern, particularly on the anterior aspect of the contralateral leg, the anterior thighs, and the extensor surface of the upper extremities (Fig. 13.8); lesions may generalize to involve the trunk and face.

Pathology

The histologic features of eczema, including stasis dermatitis, vary according to the stage of the lesion. In *acute* eczematous eruptions, intraepithelial edema (spongiosis) predominates, with focal fluid accumulation as micro- or macrovesicles, accompanied by lymphocytes in a perivascular array in the superficial dermis and exocytosis of lymphocytes into the epidermis. There is usually focal parakeratosis. In the *subacute* phase, spongiosis is still evident, but may be more subtle and intraepidermal vesicles are less prominent. The epidermis thickens variably and parakeratosis is present focally (see Fig. 13.7D). Lymphocytes persist in the dermis and epidermis. In both acute and subacute stages, edema may be present in the papillary dermis.

In the *chronic* phase, thickening of the epidermis (acanthosis) is more pronounced and it occurs in a regular, psoriasiform pattern or, more often, has a more irregular profile. Inflammation and spongiosis are mild and may be absent. Changes in the granular layer are variable, from thickening, simulating lichen simplex chronicus, to thinning, where the pattern more closely approaches psoriasis; the latter is seen more often in nummular eczema. Ascribing a specific cause of the dermatitis based upon this constellation of histologic findings is impossible.

In stasis dermatitis, biopsy specimens display the histologic features just outlined, as well as signs of venous hypertension: an increased number of capillaries which are dilated and surrounded by cuffs of fibrin, hemosiderin deposits, and hyperplastic (and at times thrombotic) venules (Fig. 13.9). The increase in vessel number can be marked so as to mimic a vascular proliferation. In later stages, there is fibrosis of the dermal connective tissue and sclerosis of the adipose tissue (see Ch. 100).

Differential diagnosis

Stasis dermatitis is a straightforward diagnosis if the cutaneous signs of venous hypertension are present (see Table 13.2). Difficulties may arise in differentiating the individual etiologic components, such as asteatotic eczema and irritant or allergic contact dermatitis. Patch testing is required to exclude the latter. Plaques of stasis dermatitis may be mistaken for nummular eczema, psoriasis, or even mycosis fungoides.

Treatment

The major aim of therapy is the management of venous hypertension – a complex goal which is reviewed in Chapter 105. Basic measures include the regular use of adequate compression bandages or stockings to improve venous return, lifestyle changes, and exercise of the calf muscles. If indicated, surgical strategies are undertaken (see Ch. 155).

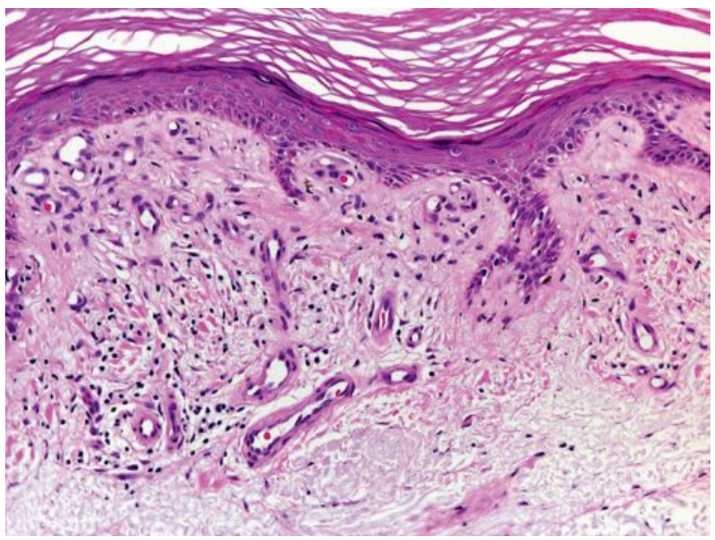

Fig. 13.9 Stasis dermatitis – histologic features. Orthohyperkeratosis and minimal spongiosis in the epidermis. There is an increased number of blood vessels surrounded by a fibrin cuff in a slightly fibrotic papillary dermis. Note also extravasation of erythrocytes and a mild lymphocytic infiltrate. *Courtesy Lorenzo Cerroni, MD.*

However, these surgical approaches do not replace the need for ongoing compression therapy. Topical treatment is the same as for other types of eczemas: judicious use of topical corticosteroids and emollients.

Dyshidrotic Eczema

Synonyms: ■ Pompholyx (larger vesicles and bullae) ■ Acute and recurrent vesicular hand dermatitis

Key features

- Firm, pruritic vesicles of the palms, soles, and lateral and medial aspects of the fingers and toes
- Association with atopic dermatitis and contact dermatitis (allergic and irritant)
- No disturbance of sweat gland function

Introduction

Dyshidrotic eczema is a not-infrequent, chronic, relapsing palmoplantar eczematous dermatosis characterized by firm, pruritic vesicles and bullae. While the vesicles are due to spongiosis within the epidermis, their intact nature is explained by the thick tear-proof horny layer in these sites. Dyshidrotic eczema is not an independent disease entity because it is often a manifestation of other types of eczema, especially atopic dermatitis and irritant or allergic contact dermatitis.

Pathogenesis

Although the formation of vesicles is not linked to sweat gland dysfunction or trapping of sweat within the epidermis (as the term may suggest), hyperhidrosis can be an aggravating factor in some patients. Notably, treatment of hyperhidrosis with onabotulinumtoxin A may ameliorate dyshidrotic eczema[59].

Dyshidrotic eczema is frequently an expression of atopic dermatitis, particularly as a late-stage manifestation. In these patients, its intensity is usually low to moderate with a protracted and relapsing course, and it is accompanied by only a few other signs of atopic dermatitis. Less often, dyshidrotic eczema is a manifestation of acute or subacute allergic contact dermatitis. Flares can also result from exposure to known irritants (see Ch. 15).

Occasionally, administration of IVIg is followed by acute episodes of dyshidrotic eczema. The role of ingestants, in particular nickel and cobalt, has been debated, but improvement with a low-nickel diet (in nickel-sensitive patients with a positive oral provocation test) has been observed. Lastly, flares can also follow periods of emotional stress as well as exposure to hot climates and rarely sunlight.

Clinical features

Dyshidrotic eczema is characterized by symmetric, firm, deep-seated vesicles of the palms, the lateral and medial aspects of the fingers, and less often the soles and toes (Fig. 13.10A). The size of the vesicles may vary from pinhead-sized to several centimeters ("pompholyx"). When smaller lesions are clustered, they have been likened to tapioca pudding (Fig. 13.10B). While the markedly pruritic vesicles initially contain clear fluid, they have a tendency for purulent superinfection. Dyshidrotic eczema resolves via desquamation of characteristically thick scales.

Dyshidrosis lamellosa sicca (also referred to as keratolysis exfoliativa) is a minimal variant which displays no blisters but only small annular collarettes of white scale (see Fig. 39.13).

Pathology

Histologically, a spongiotic dermatitis is seen with the formation of micro- and macrovesicles within the epidermis (Fig. 13.10C). There is no association with sweat glands.

Differential diagnosis

Inflammatory tinea manuum and pedis, scabies, and palmoplantar pustular psoriasis need to be considered as well as dyshidrosiform pemphigoid, dyshidrotic cutaneous T cell lymphoma, erythema

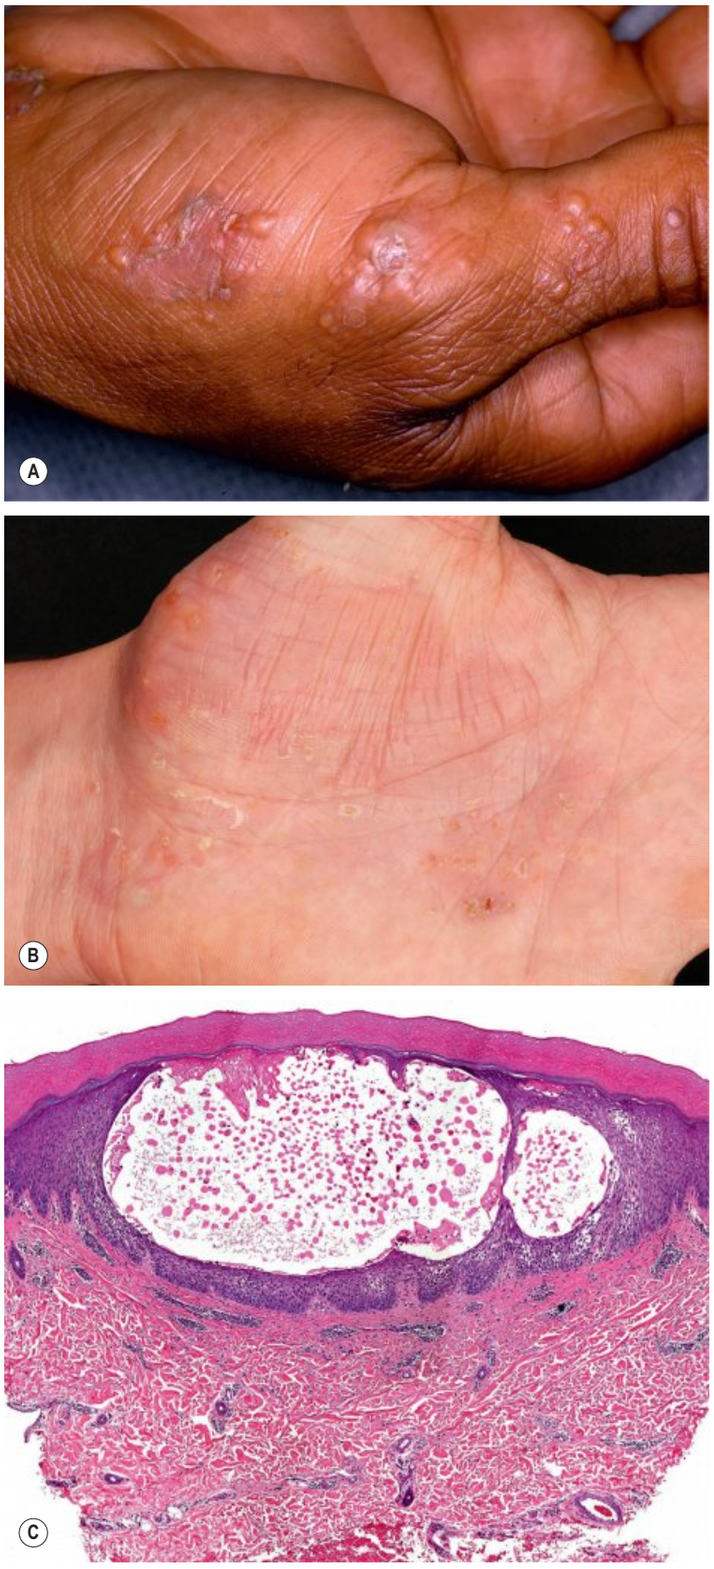

Fig. 13.10 Dyshidrotic eczema – clinical and histopathologic features. A Firm vesicles are seen along the side of the thumb and thenar eminence. Some of them are deep-seated. **B** Clusters of tiny vesicles and annular collarettes of scale where the vesicles have ruptured superimposed on plaques of dermatitis. **C** Histologically, spongiosis within the epidermis is accompanied by macrovesicles; the thick stratum corneum points to an acral location. *A, Courtesy Louis A. Fragola, Jr, MD; B, C, Courtesy Lorenzo Cerroni, MD.*

multiforme, fixed drug eruption, and, in children, infantile acropustulosis. Distinguishing between an id reaction involving the palms or soles and dyshidrotic eczema can sometimes be difficult and some clinicians view them as overlapping entities.

Treatment

Topical emollients and corticosteroids are the mainstay of treatment. Other topical treatments such as calcineurin inhibitors, retinoids, and PUVA (bath > systemic) may also be helpful. An underlying allergic or irritant contact dermatitis needs to be considered and addressed. In chronic relapsing or recalcitrant cases, systemic therapy (e.g. retinoids, oral corticosteroids, or other immunosuppressants such as cyclosporine) may be considered[60].

Infectious Eczematous Dermatitis

This entity is regarded as an eczematous reaction to a localized infection with purulent drainage, most often due to *Staphylococcus* or *Streptococcus* spp. It is thought to result from a sensitization to bacterial antigens. Clinically, pustules and vesicles spread from an infectious nidus. More advanced stages are characterized by crusting, scaling, and oozing[61]. In children, the nares, ears, and face are the most common sites of involvement, whereas in adults, the distal lower extremities are most often affected. Milder forms can be treated with open wet dressings, topical antibiotics, topical corticosteroids, and emollients whereas more severe disease usually requires the addition of oral antibiotics and sometimes oral corticosteroids.

Infectious eczematous dermatitis should be distinguished from eczema due to autosensitization, in which lesions develop at a distance from the primary site. Lastly, this disease should not be confused with HTLV-associated infective dermatitis (see above).

Juvenile Plantar Dermatosis

Synonyms: ■ Atopic winter feet ■ Forefoot dermatitis ■ Dermatitis plantaris sicca ■ Moon-boot foot syndrome ■ Sweaty sock dermatitis

Key features

- Dry, scaly, glazed and fissured plantar surface of the forefoot
- Prepubertal children are affected
- Association with atopy and exogenous factors

Introduction

The feet are a fairly common site for various eczematous dermatoses (Table 13.4). Juvenile plantar dermatosis is a characteristic condition that occurs primarily (but not exclusively) in children with an atopic diathesis.

History

Juvenile plantar dermatosis was first reported by Mackie and Husain[62].

Epidemiology

Juvenile plantar dermatosis occurs in prepubertal children, from the age of 3 years and upwards, when shoes are worn for longer periods of time. It is only occasionally seen in adults. There is seasonal variation, with worsening during the winter, and boys are affected slightly more often than girls.

Pathogenesis

An atopic disposition is clearly a risk factor, but exogenous factors play an equally important role, including plastic- and rubber-constructed sports shoes that youngsters often wear all day long. The humid environment leads to hydration of the horny layer, making it much less resistant to wear and tear. When the stratum corneum is rubbed off by friction, this leads to a characteristic glazed and thinned appearance of the skin. As involved areas become xerotic, cracks are formed. The inherently dry skin of atopic individuals may be a predisposing factor. Adults have a much thicker horny layer of their plantar skin and are thus less at risk of developing the condition.

Clinical features

The balls of the feet and the toe pads exhibit strikingly symmetrical changes: fairly well demarcated shiny, reddish, tender, dry lesions with

DIFFERENTIAL DIAGNOSIS OF DERMATITIS OF THE FOOT
Allergic contact dermatitis (footwear dermatitis)
• Dermatitis of the dorsal aspects of the feet and toes (allergen contained in the "top" of the shoes) • Dermatitis of the weightbearing areas of the soles (allergens contained in the sole of the shoes) • Most common allergens: dichromate, rubber accelerators, colophony, dyes, formaldehyde resins; also consider topical antibiotics, e.g. bacitracin • Association with atopy and hyperhidrosis • Distinguish from sock and stocking dermatitis where lesions extend more proximally (popliteal area, thighs) – most common allergen is azo dyes
Tylosis
• Mechanically induced hyperkeratosis, dryness, and fissuring • Predilection sites: heels and weightbearing areas of the soles • In middle-aged to elderly individuals • Associated with obesity and hyperhidrosis
Acquired plantar keratoderma (keratoderma climactericum)
• Same as tylosis but more intense • Typically occurs in women over the age of 45 years, but may also be seen in men • Similar lesions may appear on palms
Juvenile plantar dermatosis
See section in this chapter
Tinea pedis (athlete's foot)
• Dermatophyte infections of the plantar skin are usually accompanied by involvement of the interdigital spaces as well as lateral aspects of the foot • Often symmetric, accompanied by onychomycosis • Lesions on the lateral and dorsal aspects of the feet have well-demarcated circinate borders • Occasionally vesicular variant
Psoriasis (see Ch. 8)
• Well-circumscribed plaques or diffuse erythema with thick adherent scales, dryness, and fissuring • Psoriatic plaques found elsewhere on the body • Nail involvement, e.g. pitting and oil-drop changes
Dyshidrotic eczema
See section in this chapter
Recurrent focal palmar and plantar peeling (keratolysis exfoliativa)
• Probably represents a mild form of dyshidrosis • Dry, circinate, thin scales of palms and soles • Vesicles are absent
Pustulosis of the palms and soles (see Ch. 8)
• A neutrophilic dermatosis, possibly related to pustular psoriasis • Chronic course with crops of non-pruritic, short-lived, superficial pustules, particularly of the instep • Yellow–brown macules admixed with pustules
Sézary syndrome (see Ch. 120)
• Palms and soles are tender and exhibit scaling, which can be quite thick • Associated with hypertrophic onychodystrophy and erythroderma
Other
• Atopic dermatitis • Irritant contact dermatitis (e.g. due to occlusive footwear) • Palmoplantar lichen planus • Pityriasis rubra pilaris • Acrokeratosis paraneoplastica • Keratoderma blennorrhagicum • Inherited palmoplantar keratodermas (see Ch. 58) • Palmoplantar keratoderma associated with hypothyroidism • Crusted scabies

Table 13.4 Differential diagnosis of dermatitis of the foot.

some scaling (Fig. 13.11), and often accompanied by painful cracks and fissures. The dorsa of the feet, the interdigital spaces, and the instep are typically spared. Less often, similar lesions are found on the hands.

Fig. 13.11 Juvenile plantar dermatosis in a child. Erythema and scaling of the plantar surface of the great toes and fifth toes as well as the ball of the foot bilaterally. Note the glazed appearance of the skin of the left foot. *Courtesy Kalman Watsky, MD.*

Pathology

Histologically, the features of a chronic eczematous dermatitis are seen (see section "Stasis dermatitis").

Differential diagnosis

Juvenile plantar dermatosis needs to be distinguished from *allergic contact dermatitis* to chemicals contained in leather (e.g. chromates, dyes) or rubber. However, the latter is uncommon in children and, if present, often involves the dorsa of the feet as well. *Tinea pedis* is equally uncommon in children, and the interdigital spaces are usually predominantly affected. Patch testing and KOH preparations may help in establishing the diagnosis.

Treatment

Juvenile plantar dermatosis is a chronic but self-limiting condition. Patients should be advised to avoid wearing impermeable socks and shoes, and the application of emollients, keratolytics, and/or paraffin-type ointments is beneficial. When shoes are removed, socks, if damp, should also be removed and replaced by dry socks.

Diaper Dermatitis

Key features

- Frequently, an irritant dermatitis of the diaper area due to occlusion and prolonged exposure to urine and feces
- Secondary infection with *Candida albicans* often occurs
- May be associated with seborrheic dermatitis and psoriasis

Epidemiology

Diaper dermatitis develops in at least 50% of infants, and it is responsible for a considerable percentage of dermatologic consultations in infants and toddlers. Seborrheic dermatitis is a predisposing factor.

Pathogenesis

Diaper dermatitis is the cumulative result of several factors, in particular dampness and exposure to urine and feces. In the past, ammonia derived from the urea in urine was held as primarily responsible for diaper dermatitis. More recently, the blame has been placed on the (alkaline) pH of the urine and the role of fecal bacteria. Enzymes produced by fecal bacteria, as well as residual pancreatic proteases and lipase in the stool, act as irritants and these enzymes are also activated in the

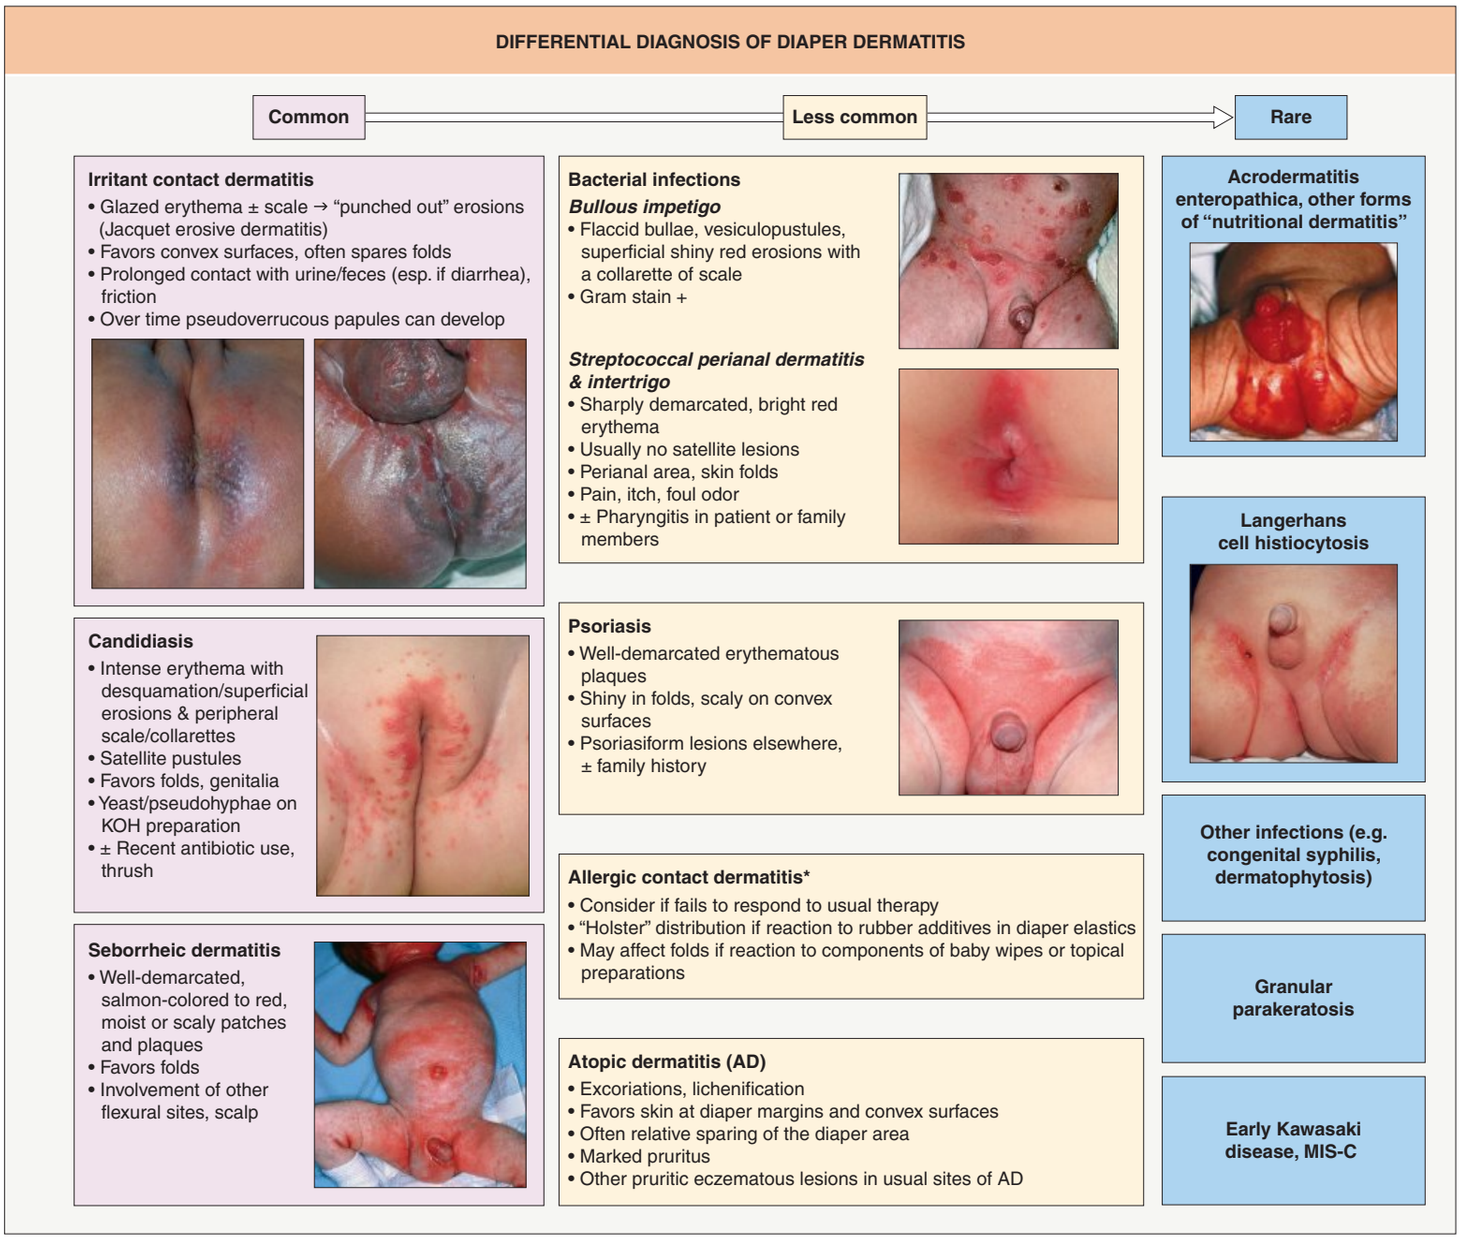

Fig. 13.12 Differential diagnosis of diaper dermatitis. While the most common etiologies are irritant contact dermatitis, cutaneous candidiasis and seborrheic dermatitis, patients often have a combination with one disorder superimposed on another. The spectrum of "erosive papulonodular dermatosis" due to chronic irritation in the diaper area includes granuloma gluteale infantum, pseudoverrucous papules, and Jacquet erosive dermatitis. Discrete papules or nodules are seen in scabies, whereas congenital syphilis often presents with erosions and even ulcerations, MIS-C, SARS-CoV-2-related multisystem inflammatory syndrome in children. *Potential allergens include sorbitan sesquioleate (an emulsifier in diaper balms), fragrances, disperse dyes, rubber additives (e.g. mercaptobenzothiazole), and preservatives in baby wipes (e.g. iodopropynyl butylcarbamate). *Insets: Courtesy Robert Hartman MD; Julie V. Schaffer, MD.*

alkaline milieu[63,64]. In addition, ureases are produced by fecal bacteria, resulting in a further increase of the urinary pH. This explains why diaper dermatitis is more likely to appear in cow milk-fed than in breast-fed infants: cow milk formulas are colonized by a greater number of urease-producing bacteria[65].

Prolonged use of diapers, dampness, and the factors detailed above lead to the breakdown of the horny layer barrier function. An alkaline pH also facilitates the development of secondary *C. albicans* infection.

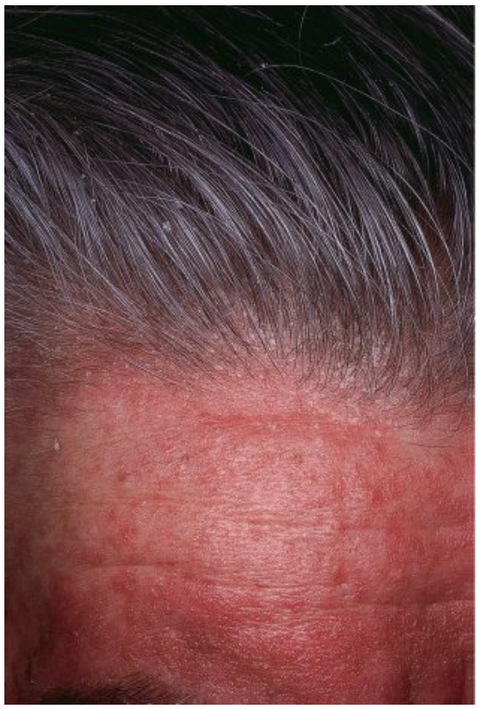
As diaper dermatitis tends to be most prominent on the inner parts of the thighs, genitalia, and buttocks, friction between the skin and the diaper material likely acts as a physical factor that leads to further irritation. In addition, chemical constituents of the diaper and/or topical preparations and baby wipes may lead to contact sensitization.

Clinical features

Diaper dermatitis is strictly confined to the diaper area, presenting with mild to pronounced erythema, erosions, and scaling. In the common form due to irritant contact dermatitis, genitocrural folds are typically spared. Depending on whether there is a secondary infection or an underlying dermatosis (e.g. seborrheic dermatitis, psoriasis), the clinical picture can vary (Fig. 13.12).

Differential diagnosis

The differential diagnosis is outlined in Fig. 13.12.



Treatment

In the acute phase, mild corticosteroid preparations are helpful. Topical imidazole creams are added for secondary infection with *Candida* spp. The major goal of long-term management is avoidance of the causative factors. Frequent changing of highly absorbent disposable diapers is associated with a lower incidence and severity of diaper dermatitis, and it leads to a more physiologic pH[66]. Emollients containing white paraffin (Vaseline®) or soft zinc pastes provide both protective and soothing effects.

14 Allergic Contact Dermatitis

Kalman L. Watsky, Rosemary L. Nixon, Christen M. Mowad and James G. Marks Jr

Synonyms: ■ Contact dermatitis ■ Contact eczema

Key features

- Allergic contact dermatitis (ACD) is a pruritic, eczematous reaction
- Acute ACD and many cases of chronic ACD are well demarcated and localized to the site of contact with the allergen
- ACD can also have a diffuse or patchy distribution, depending on the allergen and/or the development of disseminated eczema (autosensitization dermatitis)
- The prototypic reactions are ACD caused by nickel, poison ivy, and related plants
- ACD may coexist with irritant contact dermatitis, contact urticaria, and different forms of endogenous eczema
- Patch testing remains the gold standard for accurate and consistent diagnosis unless the exposure is quite obvious as in poison ivy

INTRODUCTION

When the skin comes in contact with external agents, many adverse events can occur including contact dermatitis, which can be either allergic or irritant. Irritant contact dermatitis (ICD) accounts for ~80% of all contact dermatitis (see Ch. 15), with allergic contact dermatitis (ACD) accounting for the remainder[1]. ACD is a delayed-type hypersensitivity reaction that is elicited when the skin comes in contact with a chemical to which an individual has previously been sensitized.

The cutaneous responses of ACD are dependent on the particular chemical, the duration and nature of the contact, and individual host susceptibility. The chemicals that cause contact dermatitis may be found in jewelry, personal care products, plants, topical medications (prescription, over-the-counter or herbal), clothing, and home remedies, as well as chemicals the individual comes in contact with at work, during avocations, or via contact with another individual (e.g. consort contact dermatitis).

ICD and ACD, especially the chronic forms, can take on similar clinical appearances. The classic picture of contact dermatitis is a well-demarcated, erythematous, vesicular, and/or scaly patch or plaque with well-defined margins corresponding to the area of contact (Fig. 14.1A). The distribution can be linear, when an object such as a leaf or branch is rubbed against the skin (Fig. 14.1B), or localized to the site where there has been contact with the offending chemical or product, e.g. hand dermatitis caused by ACD to epoxy resin or foot dermatitis due to ACD to the components of shoes (Figs. 14.2–14.4). Because ICD and ACD are not always discernible clinically, patch testing is required to help identify an allergen or exclude an allergy to a suspected allergen. While patch testing remains the gold standard for diagnosing ACD, it is important to note that ICD and ACD may coexist.

Patients with the most common clinical presentations of ACD often do not seek medical attention. Those who have earring dermatitis or erythema and pruritus under a ring may simply diagnose themselves as having an allergy to jewelry. An individual who is gardening over the weekend may never present to a physician because the "poison ivy rash" is so familiar. Nickel (worldwide) and poison ivy (US; see Ch. 17) are among the most common etiologies of ACD and are often not further investigated because the cause is obvious. However, oftentimes, the clinical picture and history are not sufficiently specific to identify the causative allergen, and patch testing is then necessary. For example, the patient with chronic hand dermatitis or eyelid dermatitis who comes to the office for treatment is often unaware that a personal care product could be the cause of the problem. These are the patients who can be most helped by a thorough history and cutaneous examination, as well as the diagnostic procedure of patch testing.

HISTORY OF PATCH TESTING

Jadassohn has been credited with describing the technique of patch testing over 100 years ago. In 1931, Sulzberger and Wise[2] formally brought the technique to the US and described its use as a diagnostic tool for identifying a causative allergen responsible for dermatitis. This technique has been further developed over the years on a worldwide basis, with standardized allergens, testing devices, and protocols as well as numerous regional baseline series.

EPIDEMIOLOGY

ACD can affect individuals in all walks of life. It can affect the old, the young, and individuals of all races and both sexes. Differences between

Fig. 14.1 Allergic contact dermatitis (ACD). A This erythematous plaque with vesiculation developed in a 14-month-old boy following the application of neomycin ointment. **B** Erythematous streaks with linear vesicles caused by ACD to poison ivy. *A, Courtesy Anthony J. Mancini, MD; B, Courtesy Joyce Rico, MD.*

Fig. 14.3 Persistent hand dermatitis due to chronic allergic contact dermatitis. The allergen was epoxy resin.

Fig. 14.4 Allergic contact dermatitis to shoes – acute versus chronic. A Extremely pruritic erythematous papules and papulovesicles appeared within days of wearing new sneakers; note the distribution pattern. **B** Pebbled and lichenified plaques with both hypo- and hyperpigmentation. The patient had a positive patch test to potassium dichromate. *Courtesy Louis A. Fragola, Jr, MD.*

sexes may be seen but are generally based upon exposure patterns, such as nickel allergy occurring more frequently in women, presumably because of their greater exposure to jewelry[3]. Occupations and avocations also play an important role in the epidemiology of ACD (see Ch. 16). Allergens, and therefore patch test results, differ from region to region, e.g. preservatives used in personal care products can vary based on government legislation. While quaternium-15 is a cosmetic preservative that commonly causes ACD in the US, some have argued that it is not even needed in the European Baseline Series[4]. In addition, even in a particular locale, some allergens can increase in clinical importance over time while others decrease due to usage patterns, and new allergens are continually being introduced.

PATHOGENESIS

ACD is a delayed-type hypersensitivity response. It is an allergen-specific reaction that requires prior sensitization of the individual to the chemical in question. The pathogenesis of ACD involves an initial sensitization phase when the patient first comes in contact with the chemical, which penetrates the skin and then elicits a cascade of events that results in sensitization (see Fig. 4.13 for details). The subsequent re-exposure of the skin leads to the presentation of the responsible allergen to an already primed T cell milieu, causing the release of multiple cytokines and chemotactic factors and resulting in the clinical picture of eczema (see Fig. 4.14). Once sensitized, all that is needed to elicit a reaction is contact with a low concentration of the causative chemical.

CLINICAL FEATURES

In order to diagnose ACD and treat it adequately, the clinician needs to be familiar with its clinical presentations. The typical appearance is often a well-demarcated pruritic eczematous eruption, which may be acute (blistering, weeping and/or edema, e.g. Figs. 14.1, 14.5 & 14.6) or chronic (lichenified or scaly plaques, e.g. Figs. 14.2, 14.3, 14.4B, 14.7 & 14.8). This reaction is typically localized to the area of skin that comes in contact with the allergen (Fig. 14.9A,B). However, the clinician must also be aware that patchy or diffuse distributions can also be seen, depending on the nature of the causative allergen (Fig. 14.9C,D & 14.10). For example, body washes or shampoos that are rinsed over the body may cause a more patchy or diffuse clinical dermatitis. Other less common presentations of allergic contact dermatitis are listed in Table 14.1.

PATHOLOGY

Although the diagnosis of ACD is in large part a clinical one aided by the diagnostic procedure of patch testing, histology can sometimes be helpful. This is especially true when excluding other diagnoses, such as mycosis fungoides. The pathology of ACD is most helpful in acute

Fig. 14.5 Acute vesiculobullous allergic contact dermatitis (ACD). A The allergen was neomycin from a topical antibiotic ointment. **B** The allergen was urushiol in poison ivy; this distribution pattern is seen in patients who wear gloves. *A, Courtesy Jonathan Chan, MD.*

Fig. 14.7 Allergic contact dermatitis due to aloe-containing cream. The degree of involvement on the upper and lower lips is similar, as opposed to actinic cheilitis. In the latter scale is predominantly on the lower vermilion lip.

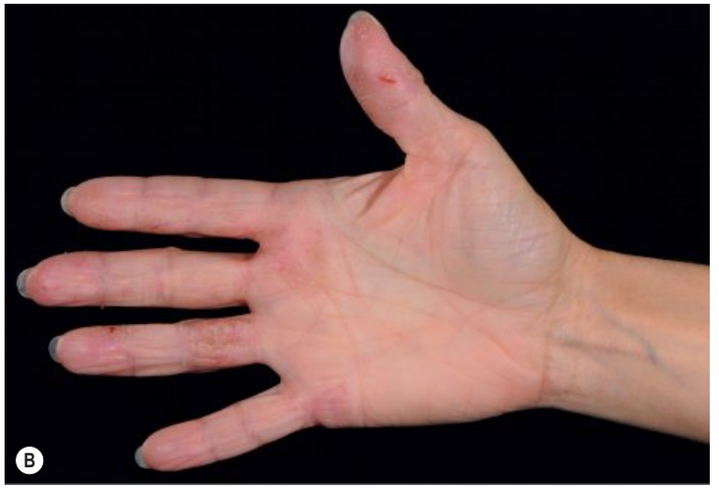

Fig. 14.8 Persistent hand dermatitis due to chronic allergic contact dermatitis. A In this machine operator, the allergen was black rubber. **B** The allergen was methylisothiazolinone in sanitary wet wipes.

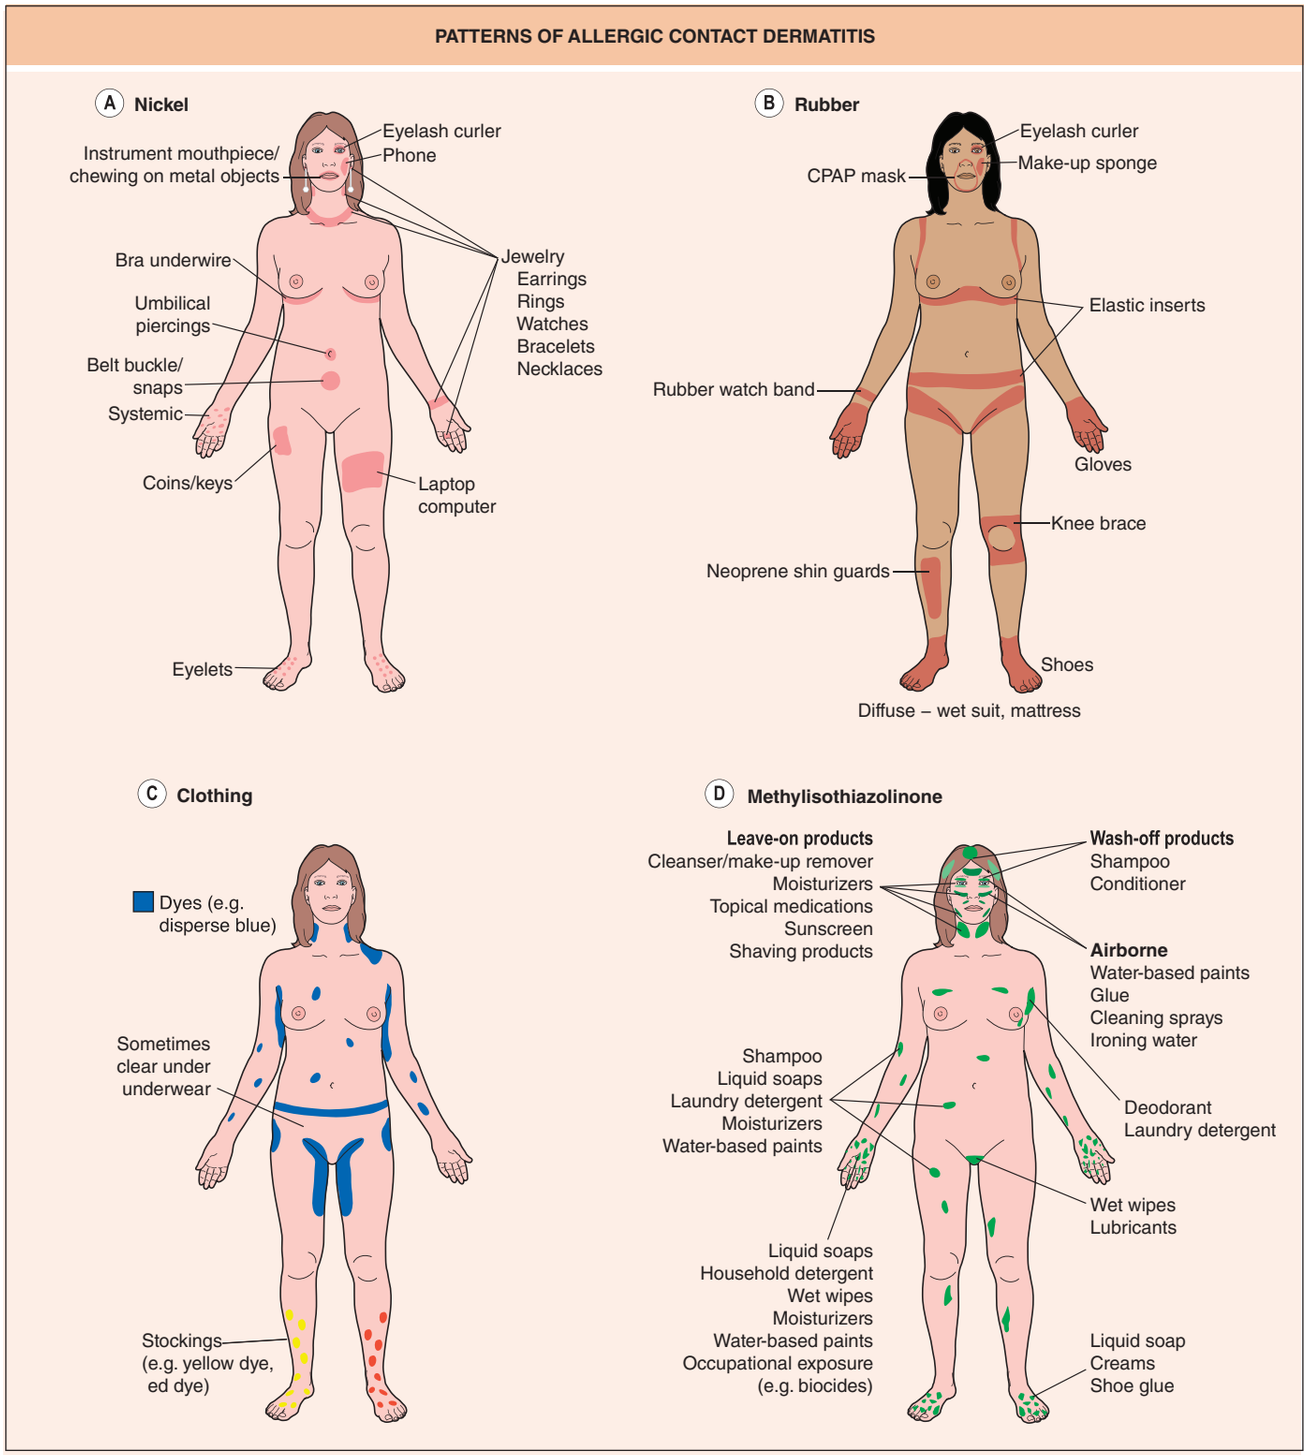

Fig. 14.9 Patterns of allergic contact dermatitis. A Due to nickel; lesions can also arise from metal braces and on the back at the site of bra clasps. **B** Due to rubber. **C** Due to dyes and resins in clothing. **D** Due to methylisothiazolinone. Some exposures can affect multiple sites and cause generalized dermatitis. CPAP, continuous positive airway pressure.

lesions, as subacute or chronic lesions often produce confusing patterns that are not diagnostic. Histologically, ACD is the prototype of spongiotic dermatitis. In the acute stage, there is a variable degree of spongiosis, with a mixed dermal inflammatory infiltrate containing lymphocytes, histiocytes, and a variable number of eosinophils. In moderate to severe reactions, marked spongiosis results in intraepidermal vesiculation (Fig. 14.11A). In subacute to chronic stages, epidermal hyperplasia, often psoriasiform, develops (Fig. 14.11B).

However, even when spongiotic dermatitis is present, clinicopathologic correlation is always required, as ACD is not the only cause of this reaction pattern. In addition, as with any dermatitis, the application of topical corticosteroids may alter the histologic findings. Occasionally, other histopathologic patterns are seen in ACD, as outlined in Table 14.1.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of ACD includes many other forms of dermatitis, such as ICD, protein contact dermatitis, atopic dermatitis, stasis dermatitis, and seborrheic dermatitis, as well as the erythematous form of rosacea. Hand and foot ACD also needs to be distinguished from endogenous dermatitis, psoriasis, and tinea (see Table 13.4 & Fig. 15.7). Of note, these conditions may coexist, which can make clinical assessment complicated. In general, when evaluating regional dermatoses (e.g. eyelid, hand, and foot), other disorders common to the area need to be considered as well as allergens specific to that area (Table 14.2). If there is widespread disease, either because of widespread contact with an allergen or autosensitization, additional causes of erythroderma (see Ch. 10), e.g. Sézary syndrome, enter the differential diagnosis.

Fig. 14.10 Allergic contact dermatitis due to cashew nut shell oil. This represented an occupational exposure.

RARE TO UNCOMMON PRESENTATIONS OF ALLERGIC CONTACT DERMATITIS	
Based primarily upon morphology	**Based primarily upon distribution and/or pathogenesis**
• Pigmented (e.g. fragrances, bactericides; often facial) • Lichenoid (e.g. color film developers, dental acrylates) • Erythema multiforme (e.g. tropical woods, *p*-phenylenediamine, poison ivy*) • Pigmented purpura (e.g. rubber diving suits) • Pseudolymphomatous (e.g. Compositae) • Granulomatous (e.g. zirconium) • Pustular (e.g. fragrances)	• Photoinduced (photoallergic contact dermatitis; see Ch. 87) • Airborne contact dermatitis • Systemic contact dermatitis (see Table 14.12) • Baboon syndrome – symmetric erythema of the gluteal and inguinal area in addition to other flexural sites†
*The lesions of erythema multiforme may favor sites previously unaffected by poison ivy. †Overlap with systemic contact dermatitis and clinical overlap with *s*ymmetrical *d*rug-*r*elated *i*ntertriginous and *f*lexural *e*xanthema (SDRIFE; see Table 21.14).	

Table 14.1 Rare to uncommon presentations of allergic contact dermatitis (ACD). Contact urticaria, both immunologic and non-immunologic, can also complicate the clinical picture.

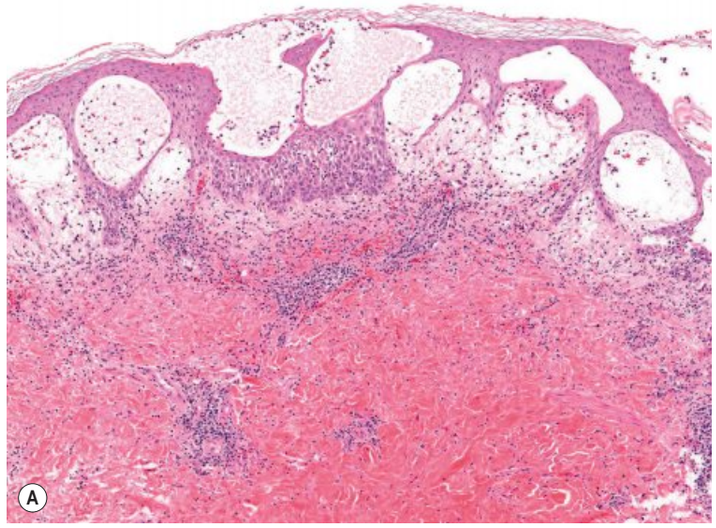

Fig. 14.11 Allergic contact dermatitis (ACD) – histologic features. A Acute ACD with marked spongiosis leading to intraepidermal vesiculation. There is a perivascular infiltrate of lymphocytes and eosinophils as well as exocytosis of these cells into the epidermis. **B** Chronic ACD with irregular psoriasiform epidermal hyperplasia and significantly less spongiosis. There is also a primarily perivascular infiltrate of lymphocytes admixed with eosinophils. *Courtesy Lorenzo Cerroni, MD.*

Deciphering and differentiating these diseases can sometimes be a challenge. Distribution and history can be helpful (see Figs. 14.1, 14.4, 14.5), as can simple tests such as a KOH preparation. In addition, dermatoses are sometimes multifactorial, and ACD may be superimposed on atopic dermatitis or stasis dermatitis. However, in order to diagnose ACD, the clinician must first consider the possibility, then ask the right questions, and, finally, use the appropriate allergens to diagnose this condition. What follows will hopefully provide the clinician with an outline to the appropriate questions to ask and procedures to use when investigating ACD.

Patch Testing

Patch testing is a deceptively simple office procedure upon which the diagnosis of ACD often rests. Although the procedure is straightforward, deciding when and what to patch test requires training and experience. Unfortunately, patch testing is still underutilized. In 2010 in the US, only 22% of dermatology program directors and 27% of chief residents reported having a specific patch testing rotation[5].

The T.R.U.E. TEST®, which is approved by the US Food and Drug Administration (FDA), consists of panels with pre-impregnated allergens, allowing for increased ease of use and perhaps resulting in increased patch testing. However, it currently screens for 35 allergens, in addition to a negative control, and although this is helpful, extended testing beyond these allergens has been shown to improve diagnostic accuracy[6–8]. With extended testing, 37%–76% more positive reactions were detected, and 47% of the patients had positive reactions *only* to non-screening allergens[6–8] (these latter allergens come in multi-use syringes or tubes [see Appendix]). Lastly, when patch testing was performed with 28 T.R.U.E. TEST® allergens, only 27.6% of patients had completely detected allergens[8].

Prior to the application of the patch tests, the clinician should ask questions about exposures both at home and at work, and attempt to understand the mechanics of the work environment. The effect of vacations and time away from work or home should also be ascertained. In addition, all personal care products should be inventoried and hobbies explored. The information gained can help to direct allergen selection more appropriately.

Technique

Although the T.R.U.E. TEST® now has 35 allergens (plus control) and the European Baseline Series[9] 30 allergens plus 13 recommended additions (Table 14.3), referral centers with patch test clinics routinely patch test to an "expanded" series of 60+ allergens. Such panels include the American Contact Dermatitis Society Series (updated in 2020)[10], the North American Contact Dermatitis Group 70 (which includes allergens "of interest" primarily for research purposes), and

EYELID DERMATITIS – DIFFERENTIAL DIAGNOSIS AND MOST COMMONLY ASSOCIATED ALLERGENS	
Differential diagnosis	
Endogenous	
• Atopic dermatitis – lichenification common • Seborrheic dermatitis – scaling of eyelid margins & accentuated in creases • Ocular rosacea – eyelid margin^ • Dermatomyositis >> cutaneous lupus – may have associated edema	
Exogenous	**Allergens most commonly associated with ACD of the eyelids***
• Allergic contact dermatitis (ACD) – occasionally airborne • Irritant contact dermatitis (ICD) – topical medications (e.g. for acne), anti-aging creams, cosmetics, occupational exposures	• Fragrances, including *Myroxylon pereirae* (balsam of Peru) • Preservatives – quaternium-15, DMDM hydantoin, methylchloroisothiazolinone, methyldibromoglutaronitrile • Topical antibiotics – neomycin • Metals – nickel, cobalt chloride, gold sodium thiosulfate • Surfactants – cocamidopropyl betaine, amidoamine

^May co-exist with periorificial dermatitis.
*Adapted from North American Contact Dermatitis Group (2003–2004). *Dermatitis*. 2007;18:78–81.

Table 14.2 Eyelid dermatitis – differential diagnosis and most commonly associated allergens. There is often a combination of endogenous plus exogenous causes. This nail salon technician had allergic contact dermatitis to 2-hydroxyethylmethacrylate (HEMA) which is found in nail polish and nickel; note the involvement of the fingertip.

the Australian Baseline Series (updated in 2021). This is in addition to more specific allergen panels, e.g. the hairdressing tray, dental tray or florist tray, which contain allergens unique to a particular occupation. The companies from which these allergens and other supplies can be obtained are listed in the Appendix. Although these expanded series of allergens are not FDA-approved, they are often required to establish the precise etiology of the patient's dermatitis.

Substances brought by patients to the dermatologist should *not* be tested in a blinded fashion. The physician should be aware of the chemical ingredients of the product, or severe irritation such as a burn or ulceration could occur. Therefore, no unknown product or chemical should be applied as a patch test. Material safety data sheets (MSDS) can sometimes help in further evaluating the chemical. However, not all ingredients are listed on these forms: those chemicals that represent a small percentage and fall below a certain threshold do not need to be listed, even though they may be the causative allergens. Identification of the latter requires communication with the manufacturer, so that full disclosure of the chemical ingredients can be obtained.

When patients bring all their personal care products to the office for patch testing, special attention is required. The general rule regarding testing of these products is that products intended to be left on the skin (so-called "leave-on" products), such as moisturizers and make-up, may be tested "as is". Products that are intended to be diluted by water or rinsed off (so-called "rinse-off" products), such as soaps and shampoos, need to be diluted prior to patch testing (often to 1%–10% in water). There are helpful guides for determining appropriate patch test concentrations for numerous chemicals[11]. When these nonstandard allergens are tested, controls (including vehicles) must be tested to evaluate for the possibility of ICD.

After allergen selection has been finalized, appropriate technique is necessary to ensure adequate testing. The most common site is the upper back. The patient should not have a sunburn in this area and should not have applied topical corticosteroids to the sites of patch testing for 1 week[12,13]. Systemic and longer-lasting injectable corticosteroids should also be avoided for at least 1–2 weeks[14]. (If necessary for disease control, the daily oral AM dose of corticosteroids should not exceed the equivalent of 20 mg of prednisone during testing.) Any one of these factors may decrease the individual's ability to elicit a reaction when challenged by an allergen, resulting in a false-negative test[12–14]. Other immunosuppressants (e.g. methotrexate, mycophenolate mofetil) and targeted immune modulators ("biologics") may also impact patch testing results[15,16].

A nurse or technician in the office can be trained to apply the patches, and this leads to improved efficiency. Either the pre-packaged allergens are placed on the back as in the case of the T.R.U.E. TEST®, or the allergens are dispensed into chambers. There are a number of different patch test systems, including Finn Chambers® (SmartPractice®) which are adhered to Scanpor® tape (Norgesplaster, Norway; available in the US from SmartPractice®); allergEAZE® chambers (SmartPractice®; Fig. 14.12); and IQ, IQ Ultra™, or IQ Ultimate™ chambers (Chemotechnique Diagnostics; distributed by Dormer Laboratories, Inc.). These patches are applied to the back, reinforced with more Scanpor® tape if required, and the patient is sent home with instructions to keep the back dry and the patches secured until the second visit at 48 hours. Patients should also be told to avoid excessive sweating and to avoid heavy lifting, as the patches may come loose. Antihistamines can be prescribed, as they will not affect the outcome of the testing. A map of where the allergens were placed should be constructed for future reference.

When the patient returns at 48 hours, the patches need to be examined to ensure that the testing technique was adequate. Initial inspection can determine that the patches are still in place. Confirmation comes from observing whether the chambers have adhered adequately so as to leave an impression in the skin (see Fig. 14.14G). As the patches are removed, their sites of application should be marked in order to identify the location of the particular allergens (Fig. 14.13). Two types of marking pen are recommended for this procedure: either a permanent surgical marker or a fluorescent highlighter. Highlighters are less messy and do not rub off as easily as the permanent marker. Because of the latter property, permanent markers can soil clothing and make interpretations at the second reading more difficult. Any positive reactions are scored according to the International Grading System (Table 14.4; Fig. 14.14). The patient is again asked to keep the back dry until the second reading, which can be performed from 72 hours to 1 week after the initial application of patches.

When the patient returns for the second reading, the map is used to identify any positive reactions. If a fluorescent marker has been utilized, a Wood's lamp may be needed to identify the markings. Positive reactions are again graded according to the standard system (see Table 14.4). This later reading is necessary as patch test responses to some allergens such as gold, neomycin, and corticosteroids may be delayed. The actual products the patient uses in his or her work and/or home environment are examined and the ingredients compared with the positive reactions. In so doing, products can be divided into groups: those that are free of the suspected allergen(s) and are safe to use and those that contain these chemical(s) and should be avoided. There will usually be some products with no ingredients listed, and these will have to be further investigated by the patient or physician by contacting companies and inquiring about ingredients.

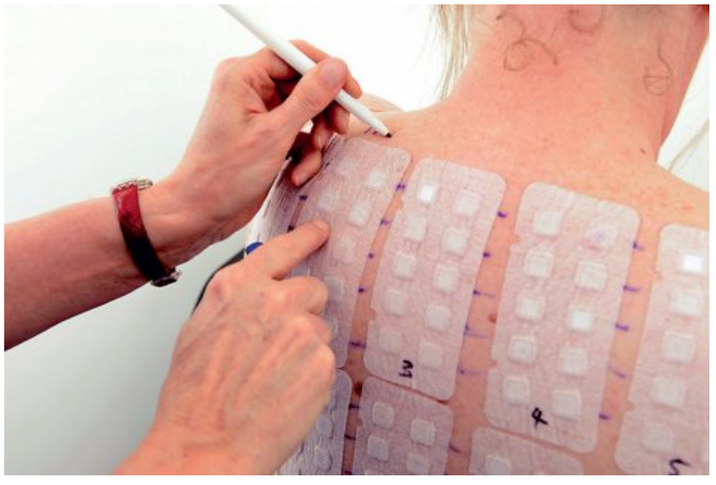

Fig. 14.12 Placement of allergens to the patient's back utilizing allergEAZE® chambers.

Fig. 14.13 Sites of specific patch tests labelled for future reference following removal of the chambers.

INTERNATIONAL GRADING SYSTEM FOR PATCH TESTS	
+/–	Doubtful reaction, faint macular erythema
+	Weak, non-vesicular reaction with erythema, infiltration and papules
++	Strong, vesicular reaction with erythema, infiltration and papules
+++	Spreading bullous reaction
–	Negative reaction
IR	Irritant reaction

Table 14.4 International Grading System for patch tests. See Fig. 14.14.

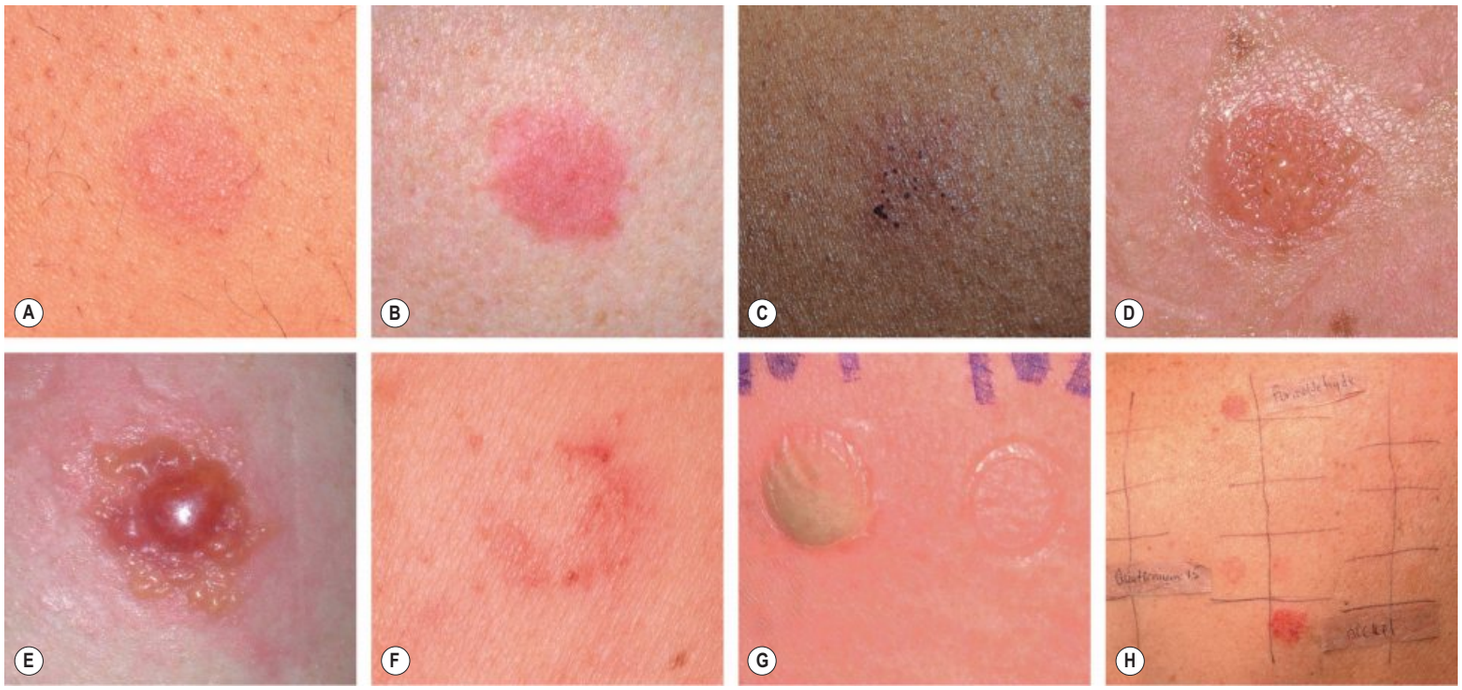

Fig. 14.14 Patch test reactions. A +/– to + reaction. **B, C** + reaction. **D** ++ reaction. **E** +++ reaction. **F** Erythematous papules at the edge of the Finn chamber application site (rim or edge effect). **G** Pustular irritant reaction at the site of the application of a metalworking fluid. The adjacent skin impression of a chamber reflects good adherence. **H** Three different patch test reactions: +/– to quaternium-15, + to formaldehyde, and ++ to nickel.

Interpreting the test

Through the process of reviewing exposures and products, the clinical *relevance* of positive test results can be determined. Allergens may have past relevance. For example, a patient who presents with a known allergy to nickel and reactions to costume jewelry is found on patch testing to have a positive reaction to nickel. The nickel may have past relevance to the patient's problem with costume jewelry but no current relevance to the chronic hand dermatitis. Relevance may also be determined to be current. For example, a positive reaction to tuliposidase A (see Ch. 17) in a florist who has hand dermatitis and contact with *Alstroemeria* when arranging flowers would have present relevance. In some individuals, relevance may be unknown, as in a patient with an eyelid dermatitis and a positive reaction to thimerosal but no history of current or past exposure; sensitization may have occurred from a vaccine.

TREATMENT AND PATIENT EDUCATION

Once allergens are positively identified, the patient should be given written information on all of these chemicals. The information sheets should contain data regarding the name of the chemical, possible synonyms, typical uses for the chemical, how to avoid exposure, and, when appropriate, substitutions. The sheets can be individually composed or obtained from books and copied for patient use[17]. In addition, the American Contact Dermatitis Society website (www.contactderm.org) is an excellent resource for allergen and product information, including patient information sheets (Table 14.5). The Contact Allergen Management Program (CAMP) is another feature of the website (available to members of the society): this allows the user to input the known allergens and the database assembles a list of products free of the allergens entered. With this CAMP-generated list, the patients can then purchase products that lack the ingredients to which they are allergic. In addition, this website contains a Contact Dermatitis Alternatives Database which assists both patients and physicians with regard to appropriate substitutions for known allergens.

The patient should also be instructed on how to read the labels of any new or old products not reviewed, in order to avoid future exposure. Each time the patient considers buying a product, he or she should utilize updated information sheets, because ingredients in a given product can change over time. In addition, ingredients in a particular product can change from location to location (e.g. between countries, or between the East and West Coast of the US) without a change in the packaging.

After identifying the substances to which the patient is allergic, the most important step a physician can take is to educate the patient regarding the names of the allergens and how to avoid them. This empowers the individual and allows the physician to transfer to the patient the responsibility for avoiding said chemicals. When trying to identify allergens in the patient's environment, one must also consider allergens transferred from other sources – so-called consort dermatitis (e.g. from spouse to spouse, such as the cologne on the husband causing a reaction on the face of his wife).

Treatment of ACD primarily involves identification of the causative allergens. Once the allergens have been identified, the physician should try to clear the dermatitis with appropriate treatments, such as topical or, if necessary, systemic corticosteroids. The educated patient then needs to be diligent in avoiding the identified allergens. It may take 6 weeks or more to see complete and prolonged clearing, even when allergens are being avoided (Fig. 14.15). If the ACD is superimposed upon another dermatosis (e.g. stasis dermatitis, atopic dermatitis, ICD), then the latter will also need to be addressed via appropriate skin care including avoidance of skin irritants and moisturizing creams.

If a patient is unable to undergo patch testing for some reason, or confirmation of patch test results is desired, a repeat open application test may be performed. This open use test, sometimes referred to as the "poor man's patch test", can prove useful. In an open use test, the patient applies the product in question to the same predetermined location (where there is no dermatitis) twice daily for 1–2 weeks; a common site is the antecubital fossa or flexor forearm. If dermatitis develops, it can be concluded that the patient is reacting to that product. Unfortunately, this type of testing does not allow the identification of individual ingredients. Repeat open application tests are also used to establish clinical relevance of the patch test results, e.g. a patient reacts to a fragrance, but the concentration of the fragrance in a particular product was so low that it did not react on initial patch testing.

ALLERGENS

The top 10 allergens, as identified by the North American Contact Dermatitis Group (NACDG) in 2017–2018 were nickel sulfate, methylisothiazolinone (MI), methylchloroisothiazolinone/MI, fragrance mix I, hydroperoxides of linalool, formaldehyde, benzisothiazolinone, *Myroxylon pereirae* (balsam of Peru), cobalt chloride, and *p*-phenylenediamine (Table 14.6)[7]. For patients with active dermatitis awaiting

METHYLCHLOROISOTHIAZOLINONE/METHYLISOTHIAZOLINONE		
Other names:		
5-chloro-2-methyl-4-isothiazolin-3-one and 2-methyl-4-isothiazolin-3-one, Kathon CG, Euxyl K100, or Groton K		
What is it?		
Methylchloroisothiazolinone and methylisothiazolinone (MCI/MI) are used alone or together as preservatives. They are active against bacteria, yeast, fungi, and algae. They are widely used in personal, household, and industrial products.		
Where might it be found?		
Personal care products		
Shampoo	Facial cleanser, scrub, mask	Facial moisturizer, anti-aging
Hair conditioner, detangler	Make-up remover	Sunscreen, sunless tanner
Hair styling mousse, foam, gel	Moist towelettes, wet wipes	Foot scrub
Hair color	Baby wipes, baby shampoo	Bubble bath
Body or hand soap, cleanser	Moisturizer, cream, lotion	
Household care and other products		
Laundry detergent	Fountain, cooling tower water	Jet fuel, anti-static
Fabric softener, stain remover	Bubble blowing solutions	Pesticide, weed killer
Household shampoo, cleaners	Dehumidifier	Pet spray, pet shampoo
Pre-moistened mop, sponge	Adhesive, glue, binding agent	Printing ink, coloring agents
Wax, polish	Cutting fluid, metalworking	Paper mill anti-slime
Paint, enamel, primer, sealer	Milk sampling	
Latex emulsions	Flax spinning	
How to avoid it:		
• To avoid MCI/MI check the complete ingredient list of each product you use. For products already at home with no ingredient list, go to the store and inspect the original box or package. Some products' ingredient lists are available on the internet at the manufacturer's website or the store's website. • You may be exposed to MCI/MI by coming in contact with products your partner is using. • Ask your hairdresser, aesthetician, and others to avoid using MCI/MI in your care. • Tell your physician about your allergy. • Some prescriptions (e.g. halobetasol and crotamiton) may contain MCI/MI. • Some items with these brand names contain MCI: Eucerin, Nivea, Moisturel, Purpose, Aveeno, Neutrogena, Nu-Skin, Herbal Essences, Dove, Pantene, Suave, and Dep. • MCI is in Cottonelle, Kleenex, Wal-Mart, Walgreens, and CVS flushable wipes. • Safe wipes are Charmin Freshmates, Wet Ones, and White Cloud Unscented; be sure to check the ingredients list. • To identify possible workplace exposure, check the complete ingredient list of everything encountered. You may need to contact the manufacturer to find out if a commercial product contains this preservative; Material Safety Data Sheets may be incomplete. • If you must come into contact with MCI/MI in your work or care for children, elders, or pets, wear protective gloves made of rubber, nitrile, or vinyl.		

Table 14.5 American Contact Dermatitis Society (ACDS) exposure information sheets: methylchloroisothiazolinone(MCI)/methylisothiazolinone (MI). Patient information sheets for several common allergens as well as the Contact Allergen Management Program (for members) are available at www.contactderm.org.

Fig. 14.15 Allergic contact dermatitis to fragrance found in cologne. A Patient at the time of diagnosis. **B** Patient after avoidance of fragrances and his cologne.

TOP TEN ALLERGENS AS IDENTIFIED BY THE NORTH AMERICAN CONTACT DERMATITIS GROUP		
Test substance	**Allergic reactions (%)**	**Relevant reactions (%) (definite, probable, possible [combined])**
Nickel sulfate, 2.5% pet	16	49
Methylisothiazolinone, 0.2% aq	15	88
Methylchloroisothiazolinone/ methylisothiazolinone, 0.02% aq	11	90
Fragrance mix I, 8% pet	9	87
Hydroperoxides of linalool, 1% pet	9	87
Formaldehyde, 2% aq	7	78.5
Benzisothiazolinone, 0.1% pet	7	52
Myroxylon pereirae (balsam of Peru), 25% pet	7	85
Cobalt, 1% pet	7	46.5
p-Phenylenediamine, 1% pet	6	64.5
Data from DeKoven JG, Silverberg JI, Warshaw EM, et al. North American Contact Dermatitis Group Patch Test Results: 2017–2018. *Dermatitis*. 2021;32:111–23.		

Table 14.6 Top 10 allergens as identified by the North American Contact Dermatitis Group. aq, aqueous; pet, petrolatum.

patch testing, avoidance of common allergens such as these can be a useful temporizing measure[18]. Table 14.7 provides a list of additional important allergens (and the frequently identified routes of exposure). Of note, ACD in children is becoming increasingly recognized, and the most common allergens, as identified by the NACDG in this age group[19], are outlined in Table 14.8. The modern era has brought us new products and new exposures to allergens, e.g. isobornyl acrylate in glucose sensors, alkyl glucosides in leave-on and rinse-off personal care products, and cyanoacrylates in surgical glues[20–25]. Additional examples are outlined in Table 14.9, including exposure to the preservative MI (see Fig. 14.9D)[27]. MI has served as a substitute for older preservatives such as parabens; the latter were eliminated from many products due to concerns regarding non-cutaneous side effects, but as a reflection of the low allergenicity of parabens they were designated the 2019 (non) allergen of the year by the ACDS[28].

The following section will briefly discuss pertinent information regarding several key allergens.

Nickel

Nickel ranks as the most common allergen tested by the NACDG, with up to 20% of patch test clinic patients reacting to it. In patch test clinics worldwide, nickel is the most common allergen, but it is often not relevant to the dermatitis in question[19]. However, upon questioning, past relevance may be discovered (e.g. previous mid-abdomen dermatitis). Nickel is a strong silver-colored metal that is commonly used in jewelry, buckles, and snaps, as well as other metal-containing objects (Fig. 14.16).

It has been proposed that the high rate of nickel sensitivity, which in some patch test clinics approaches 30%–40%, can be attributed in large part to ear piercing. Studies have shown that the metal posts used in ear piercing release varying amounts of nickel, allowing for direct exposure to an injured cutaneous surface[29]. Traditionally, the prevalence of nickel sensitivity has been higher in women; however, with newer trends toward piercing multiple body sites by both men and women, a sex difference may become less apparent[3]. In Europe, there has been a significant reduction in nickel allergy as a result of legislation limiting nickel release from items in contact with the skin[30].

Clinically, nickel dermatitis most commonly occurs at sites of contact with earrings, necklaces, and the backs of watches (see Fig. 14.9A, Fig. 14.16A). Dermatitis of the mid-abdomen caused by a belt buckle or snap is common (see Fig. 14.16C) and eyelid dermatitis from metal eyelash curlers or eyeglasses can also be seen. Facial dermatitis due to ACD to nickel and chromate within cellular phones has been described as has a generalized eruption caused by nickel from an iPad[31].

Concomitant reactions to nickel and cobalt have been reported and may be due to the frequency with which the two metals are used in combination[32]. Of note, sweating can increase the amount of metal leached from a product. A useful test to determine whether a particular item contains nickel is the dimethylglyoxime test (see Appendix), which identifies objects that release nickel using a pink color indicator (see Fig. 14.16D).

Individuals with nickel allergy should avoid costume jewelry. They can usually wear jewelry made of stainless steel, platinum or gold, but not white gold. Some clinicians advocate coating nickel-containing surfaces such as snaps on jeans with clear nail polish (e.g. Beauty Secrets Hardener) to prevent leaching by sweat onto the skin. However, the nail polish can rub off and should be reapplied if it is effective.

Methylisothiazolinone (MI)

By 2014, patch test clinics around the world were reporting that MI was becoming their most common allergen[33]. MI was previously used in combination with methylchloroisothiazolinone (MCI) in a ratio of 3 : 1 in rinse-off products, and its concentration was <3.75 ppm. In 2005, however, regulatory changes allowed its concentration to increase to 100 ppm, and this was followed by the current epidemic. While there is increasing recognition that use of sanitary wet wipes can lead to ACD of the anogenital region and hands (see Fig. 14.8B), it should be noted that MI has also been found in make-up removal wipes (see Fig. 14.6B), sorbolene lotions, liquid soaps, shampoos, deodorants, and a number of other personal care items (see Fig. 14.9D)[34]. Paints containing MI have been associated with occupational ACD as well as airborne ACD[35].

Fragrance Mix

Fragrances are ubiquitous in our environment. They are used to provide a pleasant odor and have been used extensively for centuries. According to the NACDG, fragrances are a common allergen, with a rate of up to 12%[7].

The detection of a fragrance allergy was made easier with the introduction of a fragrance mix in the 1970s. Prior to that, fragrance allergy was identified primarily through testing with balsam of Peru, which detected only about 50% of those affected[36]. The current fragrance mix I contains eight different fragrance components (at 1% each; Table 14.10).

Fragrance mix I is the most useful tool for detecting fragrance allergy[37]. However, the composition of fragrance-containing products continually changes. Therefore, by including additional allergens such as those in fragrance mix II (see Table 14.10), the detection rate of fragrance allergy can be increased. It is estimated that ~25% of patients allergic to fragrance would be missed if fragrance mix II were not used[38].

In product formulations, fragrances can be used to provide a pleasant odor. However, they can also be used to mask an unpleasant odor – a so-called masking fragrance. This often occurs in products labeled "unscented". Patients who are identified as being allergic to fragrance must be instructed to read all labels and to avoid any product that lists a fragrance, is labeled "unscented", or has an obvious scent (see Fig. 14.15). They should be instructed to look instead for "fragrance-free" products. Unfortunately, there are several fragrance ingredients that have other purposes, i.e. they act as a preservative or emollient. These covert fragrances, e.g. balsam of Peru, benzylaldehyde, benzyl alcohol, bisabolol[39], can be used in a product and the product may still be labeled fragrance-free as long as the potentially allergenic ingredient has been identified as being used for a purpose other than fragrance. Obviously, this causes significant problems for the individual with fragrance allergy who is trying to avoid fragrances. Label reading may not always be enough unless the patient is educated about some of these practices. Complete disclosure on labels of all ingredients regardless of intended function would be helpful, but this is not yet part of industry practice in the US; by contrast, in Europe 26 fragrances must be included in the product label[40]. For the individual allergic to fragrances, repeat open application testing is very helpful in screening for an allergy to new or old products.

Hydroperoxides of Linalool and Limonene

Recently, the discovery that the hydroperoxides of linalool and limonene are more sensitizing than their parent chemicals has led to increased

ADDITIONAL IMPORTANT ALLERGENS	
Allergens	**Uses/found in**
Preservatives	
Iodopropynyl butylcarbamate	Preservative/cosmetics, personal care products
Parabens	Preservative/cosmetics, personal care products; rare allergen
Polyhexamethylene biguanide (polyaminopropyl biguanide, PHBG)	Preservative, disinfectant/cosmetics, wet wipes, wound dressings, cleaning agents (including contact lens solutions)
Preservatives – formaldehyde releasers	
2-Bromo-2-nitropropane-1,3-diol (Bronopol®)	Preservative/cosmetics, personal care products
Diazolidinyl urea	Preservative/same as above
Imidazolidinyl urea	Preservative/same as above
DMDM hydantoin	Preservative/same as above
Components of rubber products	
Carba mix	Rubber accelerator/especially gloves
Mercaptobenzothiazole (MBT), mercapto mix	Rubber accelerator/especially gloves
Thiuram mix	Rubber accelerator/especially gloves
Mixed dialkyl thioureas	Rubber accelerator/rubber, neoprene, photocopying, photography
Black rubber mix	Rubber additives (antioxidants)/black rubber products (household, sports)
Hair and nail allergens	
Glyceryl thioglycolate	Alters disulfide bonds/permanent wave solutions (“acid”, “heat”); can persist for months
Tosylamide formaldehyde resin	Film former/nail polish
Acrylates	Artificial nails/nail glues
Textile allergens	
Ethyleneurea/melamine formaldehyde resin	Thermosetting resin/permanent press clothing
Disperse blue 106 and 124	Textile dyes/darkly colored > lightly colored clothing
Adhesive allergens	
Colophony (colophonium)	Resin/adhesives, cosmetics, topical medications
Epoxy resin	Resin/adhesives
p-tert-Butylphenol formaldehyde resin	Resin/adhesives
Other	
Alkyl glucosides	Surfactants/leave-on and rinse-off cosmetics
Benzocaine	Anesthetic/topical preparations
Budesonide	Corticosteroid/topical creams, ointments
Cinnamic aldehyde	Fragrance/flavoring
Cocamidopropyl betaine	Surfactant/shampoos, cosmetics
Amidoamine	Contaminant of cocamidopropyl betaine
Dimethylaminopropylamine	Contaminant of cocamidopropyl betaine
Compositae mix	Includes *Tanacetum vulgare* (tansy) and *Ambrosia* spp. (ragweed)
DL-alpha tocopherol	Synthetic vitamin E/ointments, creams
Ethylenediamine dihydrochloride	Antihistamine/topical creams
Hydroxyethyl methacrylate	Dental restorative materials, lacquers, artificial nails, adhesives, teeth whiteners
Lanolin (wool alcohol)	Emollient/topical creams, lotions
Oleamidopropyl dimethylamine	Emulsifier/cosmetics, shampoos, baby lotions
Potassium dichromate	Metals, leather, cement
Propolis	Botanical/cosmetics, cosmeceutical, naturopathic, and homeopathic products
Propylene glycol	Emulsifier/cosmetics, topical medicaments, e-cigarettes
Sesquiterpene lactone mix	Screen for Compositae allergy
Shellac	Resin/varnishes, food coating, cosmetics
Sodium gold thiosulfate	Metal/jewelry, dental implants (clinical relevance can be difficult to determine)
Tixocortol-21-pivalate	Corticosteroid/topical creams, ointments

Table 14.7 Additional important allergens. See Table 14.6 for ‘Top 10’ allergens identified by the North American Contact Dermatitis Group.

TOP 20 ALLERGENS IN CHILDREN AND ADOLESCENTS (<18 YEARS OF AGE) AS IDENTIFIED BY THE NORTH AMERICAN CONTACT DERMATITIS GROUP	
Metals	Nickel sulfate Cobalt chloride* Potassium dichromate†
Preservatives	Quaternium-15 Formaldehyde Methylchloroisothiazolinone/methylisothiazolinone 2-Bromo-2-nitropropane-1,3-diol (Bronopol®)
Topical antibiotics	Neomycin sulfate Bacitracin
Fragrances	Fragrance mix I Fragrance mix II *Myroxylon pereirae* (balsam of Peru)
Components of rubber products	Carba mix
Other	Lanolin alcohol Propylene glycol *p*-Phenylenediamine Carmine Propolis Decyl glucoside (surfactant) Compositae mix

*Also contained in ceramics (see text).
†Also contained in leather.
Data from Zug KA, Pham AK, Belsito DV, et al. Patch Testing in Children From 2005–2012: Results from the North American Contact Dermatitis Group. *Dermatitis.* 2014;25:345–355.

Table 14.8 Top 20 allergens in children and adolescents (<18 years of age) as identified by the North American Contact Dermatitis Group.

recognition of the importance of these allergens in many fragranced products, and relatively high levels of relevant reactions have been reported (see Table 14.6). However, patch testing with these fragrances is also associated with a number of doubtful and irritant reactions[41–43].

Myroxylon pereirae

Myroxylon pereirae (balsam of Peru) is a naturally occurring fragrance and one of the more common allergens identified by the NACDG[7] (see Table 14.6); however clinical relevance is often lacking[44,45]. Because it is infrequently found in topical pharmaceuticals or fragrances, positive reactions usually relate to previous exposure to fragrances, with allergy to balsam of Peru most commonly observed in those with fragrance allergy[44,45].

Patients with a positive reaction to balsam of Peru should be counseled to avoid fragrances. Some patients suspected with clinical features of systemic contact dermatitis may benefit from a restrictive diet avoiding balsams, cinnamon, cloves, and vanilla[44].

Formaldehyde

Formaldehyde is ubiquitous. It is a colorless gas that can be found in the workplace as well as in cosmetics, medications, nail hardeners, textiles, paints, cigarette smoke, paper, and formaldehyde resins (e.g. plastic bottles)[46]. Formaldehyde can cause several different types of reactions, including ICD, ACD, contact urticaria, and mucous membrane irritation, especially of the conjunctiva and respiratory tract. Formaldehyde is present in the air, as it is released in cigarette smoke, automobile exhaust, and even hair-straightening products.

Today, formaldehyde is rarely used in personal care products or cosmetics. However, allergy to formaldehyde is commonly seen in association with other formaldehyde-releasing preservatives, such as quaternium-15, imidazolidinyl urea, diazolidinyl urea, DMDM hydantoin, 2-bromo-2-nitropropane-1,3-diol, and tris(hydroxymethyl) nitromethane, and therefore formaldehyde-sensitive individuals should generally avoid these substances[46].

Textile dermatitis can be caused by formaldehyde resins, because the latter are used as a finish on "wash-and-wear" or wrinkle-resistant clothes. Of the various textiles, 100% polyester is believed to have the least amount of formaldehyde[17]. A study of many fabrics showed that some free formaldehyde was present in all of those tested[17]. Washing clothes, especially those that are "permanent press" or "drip dry", several times prior to wearing will decrease the amount of formaldehyde present but will not eliminate it.

As formaldehyde is so widespread, avoidance is often difficult. Clinical relevance can sometimes be difficult to determine.

ALLERGIC CONTACT DERMATITIS IN THE MODERN ERA		
Product(s)	**Allergen(s)**	**Clinical presentation**
Wet wipes, personal care products (including contact lens solution for PHMB)	Methylisothiazolinone, polyhexamethylene biguanide (PHMB)	Anogenital dermatitis (all ages) Hand dermatitis in caregivers (see Fig. 14.8B)
Glucose sensors, insulin pumps	Isobornyl acrylate, other acrylates, colophony	Dermatitis at the site of the device
Continuous positive airway pressure (CPAP) therapy	Dialkyl thioureas Components of cleansing agents	Dermatitis at edge of mask ICD more common
"Natural" botanical products resurgence plus grooming practices, e.g. beeswax-containing lip balm	Propolis	Cheilitis of both the upper and lower lip
Temporary tattoos	*p*-Phenylenediamine	Allergic reaction at site of temporary tattoo (see Fig. 14.17)
Sunscreen products	Benzophenone-3	Photoallergic contact dermatitis in sun-exposed areas, cheilitis
Surgical masks	Formaldehyde & formaldehyde releasers, nickel, rubber, aluminum, polypropylene	Facial and ear dermatitis ICD and flares of acne & rosacea more common
Personal electronic devices – mobile (cellular) phones, tablets, iPad, laptop computers, e-cigarettes	Nickel, chromate	Facial dermatitis, generalized dermatitis (see Fig. 14.9A)
Anti-mold sachets inside leather products to prevent mold formation during shipping (e.g. couches, chairs, shoes) [historical]	Dimethylfumarate	When heated, fumes are created which penetrate through leather and clothing, leading to dermatitis of the back, buttocks and posterolateral thighs if in furniture

Table 14.9 Allergic contact dermatitis in the modern era. For orthopedic implants, see Fig. 14.20. For hand dermatitis, especially in children, also consider ICD to homemade "slime"[26]. ICD, irritant contact dermatitis.

Quaternium-15

Quaternium-15 is a quaternium compound that is used as a preservative. It is an effective biocide against *Pseudomonas aeruginosa* and *P. cepacia*, as well as other bacteria and fungi. Although quaternium-15 is used in several industries, the incidence of associated occupational contact dermatitis is very low[46]. Quaternium-15 more typically plays a role as an allergen in personal care products such as shampoos, moisturizers, conditioners, and soaps. In the past, quaternium-15 and formaldehyde were reported to be the most common cosmetic preservatives to cause ACD in the US, but they have been overtaken by MI. The allergenicity of quaternium-15 can be due to its release of formaldehyde[47]. Studies have shown that up to 80% of those reacting to quaternium-15 are also formaldehyde-sensitive[44,48]. Allergy to quaternium-15 is often relevant to the patient's dermatitis[44,48].

Fig. 14.16 Allergic contact dermatitis to nickel. Schaffer, MD.*

COMPONENTS IN FRAGRANCE MIX I AND FRAGRANCE MIX II	
Fragrance mix I	**Fragrance mix II**
• α-Amyl cinnamic aldehyde • Cinnamic aldehyde • Cinnamyl alcohol • Eugenol • Geraniol • Hydroxycitronellal • Isoeugenol • Oak moss absolute	• Citral • Citronellol • Coumarin • Farnesol • Hexyl cinnamic aldehyde • Lyral®

Table 14.10 Components in fragrance mix I and fragrance mix II. Lyral® is hydroxyisohexyl-3-cyclohexene carboxaldehyde.

In addition to coexisting with formaldehyde sensitivity, allergy to quaternium-15 can be seen in association with other formaldehyde-releasing preservatives, such as imidazolidinyl urea, diazolidinyl urea, 2-bromo-2-nitropropane-1,3-diol, DMDM hydantoin, and tris(hydroxymethyl)nitromethane[17,46,47,49]. Avoidance of quaternium-15 is possible through careful label reading. If the individual allergic to quaternium-15 is not allergic to the other formaldehyde-releasing preservatives mentioned above, they need only avoid quaternium-15. Obviously, avoidance of the other formaldehyde-releasing preservatives may be necessary depending on the patch test results. Quaternium-15, formaldehyde, diazolidinyl urea, and imidazolidinyl urea are present in T.R.U.E. TEST®. However, other formaldehyde-releasing preservatives may be missed if expanded patch testing beyond the T.R.U.E. TEST® is not performed (see Table 14.3). As a group, the quaternium amino compounds are infrequent sensitizers and the other quaternium compounds can be safely used in those allergic to quaternium-15[46].

p-Phenylenediamine

Paraphenylenediamine (PPD) is the most commonly used permanent hair colorant and it is recognized as a common cause of ACD. Once fully oxidized, the disperse dye is no longer allergenic, but in reality the chemical is not always fully oxidized. Since 1998, PPD has been found in some temporary tattoos in concentrations higher than those present in hair color products[50]. As a result, PPD has resurfaced as an allergen in a new population (Fig. 14.17). When ACD is due to PPD in permanent hair colorants, it involves primarily the forehead, neck and scalp.

Benzisothiazolinone

Isothiazolinone derivatives have potent bactericidal, fungicidal, and algicidal properties and are primarily used in non-personal care products such as household detergents and water-based paints. Of the isothiazolinone derivatives, sensitization potential is greatest for MCI > MI followed by benzisothiazolinone > octylisothiazolinone[51].

Cobalt

Cobalt is a metal that is often used in conjunction with other metals in order to add hardness and strength. It is frequently combined with nickel, chromium, molybdenum, and tungsten. This may be the explanation for the frequent finding of sensitization to cobalt in patients

Fig. 14.17 Allergic contact dermatitis to *p*-phenylenediamine in a temporary tattoo.

who are also allergic to either nickel or chromium. Specifically, ~80% of individuals with a cobalt sensitivity have a co-sensitivity to nickel (more common in women) or chromate (more common in men)[17].

Exposure to cobalt is typically through a metal, most often in jewelry, snaps, buttons, or tools. However, cobalt is also found in cosmetics, hair dyes, orthopedic implants, ceramics, and enamel as well as in cement, paints, and resins[17]. Exposure can come from hobbies such as pottery making and occupations such as bricklaying.

When patch testing to cobalt, one may see a particular reaction, described as "poral", that appears as erythematous to violaceous dots. This is not an allergic reaction but is believed to result from the allergen residing within the acrosyringia[48]. A cobalt spot test has recently been released, based on disodium-1-nitroso-2-naphthol-3,6-disulfonate[52].

Chromium

Allergic contact dermatitis to chromium occurs from two main sources, leather tanned with chromate and cement. European legislation mandating the addition of ferrous sulphate to cement has reduced the amount of hexavalent chromium in cement to less than 2 parts per million, with a dramatic decline in the number of cases of allergic contact dermatitis. Trivalent chromium is less soluble and has a low degree of skin permeation. Allergic contact dermatitis to chromium in cement has a notoriously bad prognosis[53].

Topical Antibiotics

Neomycin is an aminoglycoside that is prescribed as a topical rather than an oral medication because it has poor gastrointestinal absorption. It is the most commonly used topical antibiotic and is the most common sensitizer among the topical antibiotics[7,17]. Neomycin is found in many over-the-counter (OTC) preparations, including antibacterial ointments, hemorrhoid creams, and otic and ophthalmic preparations (see Table 14.2). It is frequently used in conjunction with other antibacterial agents, such as bacitracin and polymyxin B (e.g. Neosporin®)[49], as well as with topical corticosteroids.

Bacitracin is a topical antibiotic with activity against Gram-positive bacteria and spirochetes. It is also used in topical antibacterial creams or ointments as well as in otic and ophthalmic preparations. As noted previously, bacitracin is frequently combined with neomycin, and although the two antibacterial agents are chemically unrelated, they often show co-reactivity. This is believed to be due to sensitization to both, given how commonly they are combined in OTC products (e.g. Neosporin®)[49]. Another common combination is bacitracin plus polymyxin B (Polysporin®)[54]. In addition to ACD, bacitracin rarely causes anaphylaxis and/or contact urticaria[55].

Thimerosal

Thiosalicylic acid and ethylmercuric chloride are the two components that are combined to form thimerosal – sodium ethylmercurithiosalicylate – a preservative that is used in a few products. It is believed that the most likely cause of sensitization to thimerosal comes from its use as a preservative in vaccines[56]. Reports of sensitivity to ethylmercuric chloride and thiosalicylic acid have been published and both compounds have been found to be capable of inducing a delayed hypersensitivity reaction[56].

Many positive reactions to thimerosal are found on patch testing. Clinical relevance may be found in patients who use otic or ophthalmic drops, but in general relevance is low. Currently, thimerosal is in neither the NACDG 70 Series nor the European Baseline Series (see Table 14.3), but is still present in the T.R.U.E. TEST®.

Gold

Worldwide rates of positive gold reactions vary, and with routine testing they range from 0.8% to 10%[57,58]. In one NACDG series, 90% of gold-allergic patients were women, and there appeared to be a higher rate of nickel (33.5%) and cobalt allergies (18%) in patients with gold allergy than in the general population (14% and 9%, respectively)[59]. Similar findings have been reported in other studies[58].

When relevant, the most common clinical presentation is that of a hand, facial, or eyelid dermatitis[57,59]. One of the difficulties with gold patch testing is that the relevance of positive reactions is usually difficult to determine[57–59]. Gold sodium thiosulfate is currently not included in the NACDG 70 Series or the European Baseline Series[19].

Corticosteroids

Corticosteroids are administered in many different forms: topical, intralesional, oral, intramuscular, intravenous, inhalational, and intra-articular. They are anti-inflammatory agents and have been shown to cause ACD in 0.2%–6% of patients[60]. Corticosteroids have been reclassified into three groups based on patch test results and molecular modeling, with group 1 corticosteroids producing the most allergic reactions[61] (Table 14.11). It is suspected that ACD to these agents may be underdiagnosed, either because of insufficient testing to the allergens or perhaps owing to incomplete testing, as a later reading is often necessary because of the anti-inflammatory nature of these compounds[60]. Clinical scenarios that should raise the question of a possible allergy to topical corticosteroids include chronic dermatitis, failure to clear with topical corticosteroids, and exacerbation of dermatitis after use of topical corticosteroids.

The combination of tixocortol-21-pivalate and budesonide provides reasonable screening for corticosteroid allergy (see Table 14.11), with ~75% of corticosteroid allergic reactions detected with these allergens in one large study[60]. Positive patch test reactions to corticosteroids are often unexpected in routine testing, but are usually relevant. They are often seen with other positive reactions. Fig. 14.18 may help direct the clinician in approaching the patient suspected of having an ACD to topical corticosteroids.

In addition to the anti-inflammatory nature of corticosteroids complicating patch test interpretation, an edge effect has also been observed. During the first reading, there may be erythema only at the rim of the test chamber, with a clear center that may later become involved. This is believed to be due to the anti-inflammatory effect of corticosteroids. In the center, the corticosteroid may be concentrated, inhibiting a reaction, but be less concentrated at the rim, where a reaction may occur more readily[62].

TEXTILE DERMATITIS

Textile dye dermatitis often goes undetected because of low suspicion and a lack of routine testing with screening allergens. The allergens most likely to cause textile dermatitis are not the synthetic or natural fibers from which the textiles are made, but rather the dyes used to color them and the resins (e.g. ethyleneurea/melamine formaldehyde resin, dimethylol dihydroxyethyleneurea) used to make clothes less likely to wrinkle or shrink[63,64]. Textile dermatitis typically occurs in areas where clothing fits more tightly (see Fig. 14.9C), and it is more

CORTICOSTEROID CLASSES AND PATCH TEST CONCENTRATIONS	
Drug	**Concentration (%)***
Group 1: non-methylated, most often non-halogenated molecules (formerly A, D2, and budesonide)

‡Budesonide R-isomer may cross-react with acetonides in group 2.
¶Available without prescription in the US.

Table 14.11 Corticosteroid classes and patch test concentrations. Most allergic reactions are due to corticosteroids in Group 1. *Adapted from Immediate and delayed allergic hypersensitivity to corticosteroids: practical guidelines. Contact Dermatitis. 2012;66:38–45.*

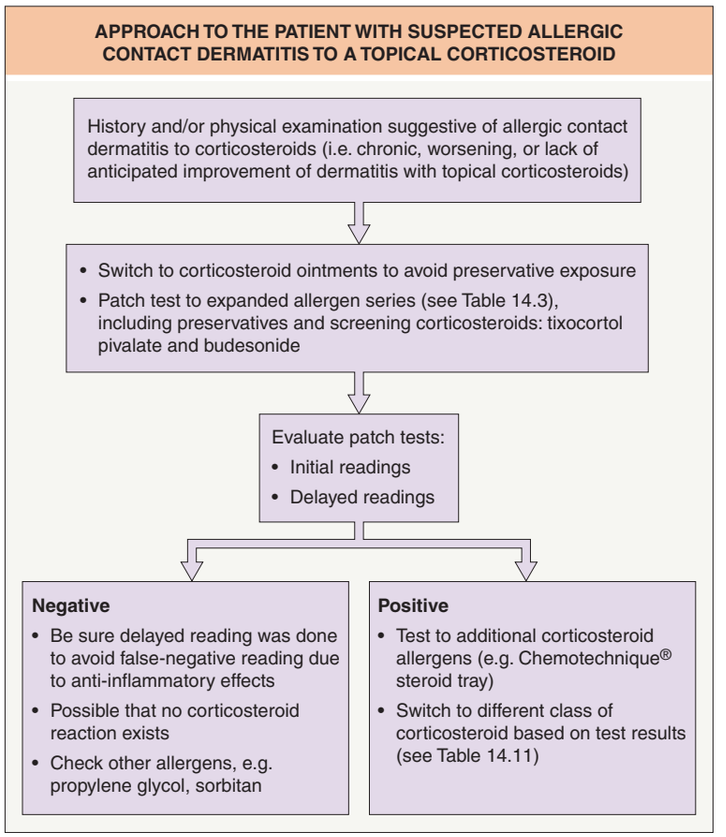

Fig. 14.18 Approach to the patient with suspected allergic contact dermatitis to a topical corticosteroid.

common in women[63]. Dyes, particularly disperse blue dyes 106 and 124, have been found to be a common cause of textile dermatitis and can be used as screening agents[63]. They frequently cross-react and positive patch test reactions can be delayed up to 7–10 days[64]. Although *p*-phenylenediamine is a disperse dye, it is not a good screening allergen for textile dye dermatitis[64]. Testing with an individual's moistened garment can also produce a relevant positive patch test reaction.

RUBBER CHEMICALS

Rubber accelerators are important causes of hand dermatitis caused by gloves, particularly in healthcare workers. Allergens include thiurams, carbamates, mercaptobenzothiazole and its derivatives, and thioureas. Of note, there is some evidence of declining frequencies of reactions to rubber accelerators[65]. ACD to rubber may coexist with an immediate hypersensitivity to natural rubber latex protein (see Ch. 16).

SYSTEMIC CONTACT DERMATITIS

Systemic exposure to a chemical may result in a widespread dermatitis. This reaction generally involves a chemical to which the patient has had a prior contact allergy; the patient is then exposed to the same chemical (or one that cross-reacts) via a systemic route, such as with an injection or oral, intravenous, or intranasal administration. This reaction is believed to be due to a delayed T cell-mediated immune response. Historically, one of the most common examples of systemic contact dermatitis was the patient with a history of ACD to ethylenediamine who then developed a diffuse dermatitis secondary to intravenous aminophylline, which contains ethylenediamine (Fig. 14.19).

Other causes of systemic contact dermatitis due to ingestion of allergens that have previously caused an ACD include antibiotics, corticosteroids, plants/plant products, propylene glycol, sorbic acid, and importantly, metals[66–73]. Marks et al.[66] reported the ingestion of cashews tainted with oil from the cashew nut shell resulting in a systemic contact dermatitis in patients with a prior history of poison ivy dermatitis. In addition, ingestion of a pesto sauce made with cashew nuts resulted in systemic contact dermatitis in the form of the "baboon syndrome" (symmetric, sharply demarcated erythema of the gluteal or inguinal area plus other intertriginous or flexural sites)[67]. Ingestion of both cashews and mangoes has been shown to cause reactions in patients sensitive to poison ivy and poison oak, as they are all members of the Anacardiaceae family (see Ch. 17).

Fig. 14.19 Systemic contact dermatitis. This patient, who was previously sensitized to ethylenediamine, received intravenous aminophylline.

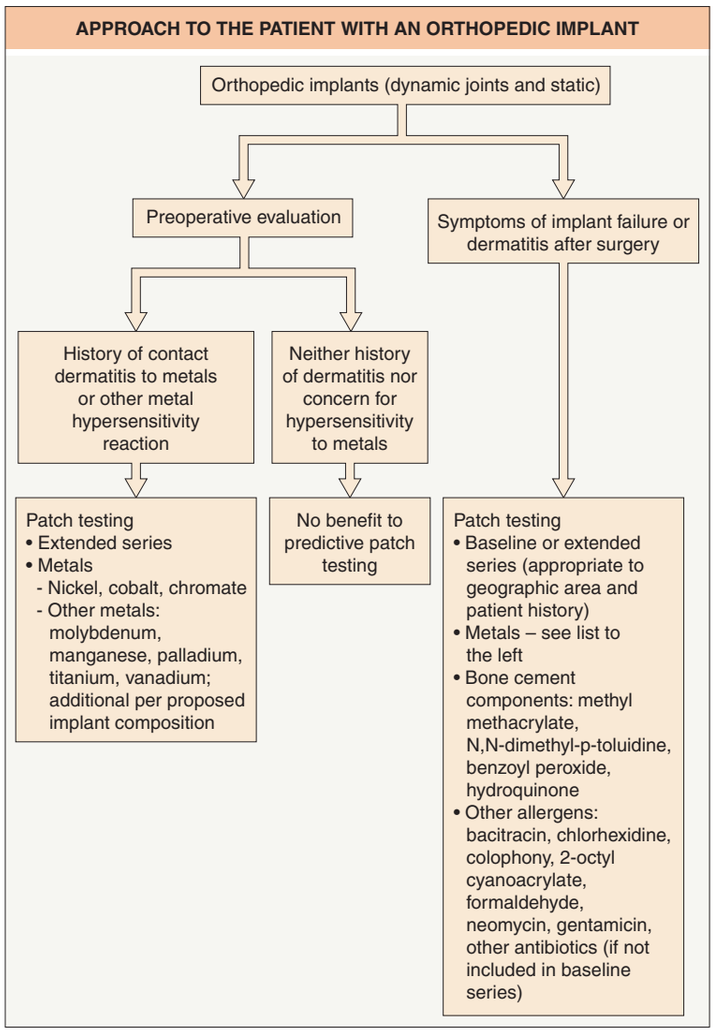

Fig. 14.20 Approach to the patient with an orthopedic implant. *Adapted from Schalock PC, Menné T, Johansen JD, et al. Contact Dermatitis. 2011;66:4–19.*

In the proper clinical setting, patch tests demonstrating a sensitivity to balsam of Peru or fragrance mixture can support the diagnosis of a systemic contact dermatitis due to balsam-related foods or spices. A diet avoiding such foods or spices may result in an improvement of the dermatitis[44,45,73].

The ingestion of metals can also cause systemic contact dermatitis, and nickel is the metal most commonly implicated[68,69]. However, the use of low-nickel diets to treat dermatitis in patients with positive patch tests to nickel is controversial, although there is increasing interest[74].

EXAMPLES OF TOPICAL ALLERGENS THAT MAY RESULT IN SYSTEMIC CONTACT DERMATITIS AFTER SYSTEMIC EXPOSURE	
Cutaneous allergen	**Systemic exposure**
Medications	
Ethylenediamine hydrochloride	Aminophylline (IV), hydroxyzine/cetirizine (po)
Quinolones	Quinolones (IV, po)
Ampicillin	Ampicillin-containing surgical solution
Neomycin	Gentamicin, streptomycin, kanamycin (IM, IV)
Topical corticosteroids	Systemic corticosteroids, e.g. prednisone, dexamethasone (IA, IL, IM, INH, IV, po)
Thiuram	Disulfiram
Metals	
Nickel and other metal salts	Nickel (and other metal salts) in food, nickel from catheter hub
Plants	
Poison ivy/oak	Cashews, mangoes
Sesquiterpene lactones	Herbal teas or food containing chamomile, chrysanthemum, wild feverfew (*Parthenium hysterophorus)*
Myroxylon pereirae (balsam of Peru)	Foods (tomatoes, citrus), sodas, spices, cough syrup, mouthwashes, toothpaste
Foods	
Formaldehyde	Aspartame (artificial sweetener)
Sorbic acid	Sorbic acid (preservative)
Propylene glycol	Emulsifier in foods and medications
Carmine[77]	Food coloring

Table 14.12 Examples of topical allergens that may result in systemic contact dermatitis after systemic exposure. IA, intraarticular; IL, intralesional; IM, intramuscular; INH, inhaled; IV, intravenous; po, oral.

The possibility of systemic contact dermatitis to metals in orthopedic implants has also been suggested, along with proposed screening recommendations (Fig. 14.20)[75]. Nonetheless, for several reasons, including the likelihood that immune reaction pathways are different for implants compared to the skin, the role of lymphocyte transformation testing remains unclear, and patch testing may neither predict future problems nor aid in the decision to remove an existing implant, this remains a topic of debate. Lastly, Fowler reported a patient with systemic contact dermatitis following ingestion of chromium picolinate, a nutritional supplement[76]. Patch testing was positive to potassium dichromate, and upon discontinuation of the chromium picolinate, the dermatitis subsided.

Examples of other cutaneous allergens and their common sources of systemic exposure are listed in Table 14.12. An extensive chapter on this subject is in *Fisher's Contact Dermatitis* textbook[68] and the reader is referred there for additional information.

AIRBORNE CONTACT DERMATITIS

When airborne allergens have contact with the skin, they may cause ACD or ICD, with a resemblance (or overlap) with photoallergic contact dermatitis and phototoxic contact dermatitis (see Fig. 87.15). Ragweed dermatitis, a good example of an airborne contact dermatitis, is most noticeable on the face (see Ch. 17)[78]. Prolonged and repetitive exposure to airborne allergens generally produces an ACD that is lichenified and dry and is predominantly located in the exposed portions of the skin: especially the eyelids, but also the face, V of the neck, arms, and legs[79]. The most common causative agents are plants, especially Compositae, fragrances, woods, rubber, preservatives, glues, metals, epoxy resins, and acrylates (Fig. 14.21A,B)[80,81].

While there are many common sources of airborne contact dermatitis, more obscure causes have been reported such as essential oils volatilized during aromatherapy or thyme dust in farmers[82–84]. There has been an increasing number of reactions to paints, especially to those

Fig. 14.21 Airborne contact dermatitis. A, **B** The allergen was an epoxy resin. Note the involvement of the eyelids. **C** The detected allergens were decyl glucoside, fragrance, thiuram, and carba mix.

containing MI or MCI[84,85], as well as to baby wipes[86]. Occupationally induced reactions appear to be the most common cause of airborne contact dermatitis. Dermatoses in exposed areas should raise the possibility of a possible airborne contact allergy, leading to a series of questions regarding possible exposure sources and to appropriate patch testing when indicated (Fig. 14.21C).

Additional figures and tables, on Simple interventions prior to patch testing, ACDS-composed exposure information sheet, and Alternatives to *p*-phenylenediamine (PPD) in hair dyes, available in our eBook (see inside front cover for access code).

SIMPLE INTERVENTIONS PRIOR TO PATCH TESTING FOR THE PATIENT WITH ACTIVE DERMATITIS
For all patients
• Instruct the patient to avoid the most common allergens (see Table 14.6), especially fragrance and methylisothiazolinone (e.g. switch to personal care products such as those made by Free & Clear™ or Vanicream™), and avoid irritants, especially in the occupational setting*.
• Fragrances may be found in perfumes, moisturizers, shampoos, deodorants, essential oils, diffusers, and hand washes and should be avoided where possible.
• Methylisothiazolinone may be found in shampoos, lotions, and hand washes and should be avoided where possible.
Specific tips for facial dermatitis
• Make the patient aware of the risk of airborne contact dermatitis (e.g. avoid hair sprays, scented candles, fragrance diffusers).
• Use open wet dressings followed by a medium potency, low allergenicity topical corticosteroid (group 3, formerly C & D1; see Table 14.11) for 1–2 weeks then taper.
• Ensure that the patient uses only white petrolatum as an emollient or another product that has been confirmed safe by repeat open application testing†.
• Patch test as soon as possible.
Specific tips for hand dermatitis
• Obtain an occupational and vocational history especially related to wet work and exposures; advise the patient to avoid wet work or use plastic gloves when wet work is unavoidable. Examine other sites, in particular the feet, to assess for endogenous dermatoses.
• Consider a course of oral antibiotics to treat secondary infection if fissures or crusts are present.
• Use high potency, low allergenicity topical corticosteroid (group 3, formerly C & D1; see Table 14.11) for 1–2 weeks nightly, preferably under occlusion with loose fitting plastic gloves‡; if tolerated, then taper.
• Ensure that the patient uses only white petrolatum as an emollient or another product that has been confirmed safe by repeat open application testing†.
• Patch test as soon as possible.
*See Tables 15.1 and 15.4. †Repeat open application testing (ROAT) consists of daily application of a small amount of the suspect product to an area of clear skin on the volar forearm or lateral neck for 1–2 weeks. Erythema at the site would represent a positive result that should be further evaluated by patch testing. ‡Two schools of thought regarding placing cotton gloves under plastic gloves.

eTable 14.1 Simple interventions prior to patch testing for the patient with active dermatitis.

ACDS-COMPOSED EXPOSURE INFORMATION SHEET: *MYROXYLON PEREIRAE* (BALSAM OF PERU)		
Other names		
Myroxylon pereirae, black balsam, *Toluifera pereirae* balsam, Honduras balsam, China oil		
This complex substance contains many potential allergens: benzoic acid, benzyl acetate, benzyl benzoate, benzyl cinnamate, cinnamic acid, cinnamic alcohol, cinnamic aldehyde, cinnamyl cinnamate, eugenol, farnesol, isoeugenol, nerolidol, and vanillin		
What is it?		
Balsam of Peru is a sweet-smelling natural substance derived from the bark of a tree native to Central America. For decades it has been added to topical preparations for its aroma and its antibacterial effect.		
Where might it be found?		
Hemorrhoid treatment	Rectal suppository	Diaper or medicated ointment
Burn treatment or wound spray	Analgesic rub, liniment	Baby powder
Antiseptic lotion or cream	Deodorant	Feminine hygiene spray
Chinese ointment, Tiger balm	Aromatherapy product	Consecrated oil, incense
Dental cement	Hair tonic or pomade	Shampoo, conditioner
Shaving lotion, aftershave	Perfume, cologne	Cosmetic with fragrance
Sunscreen, tanning lotion	Toothpaste, mouthwash	Lip balms, chewing gum
Cough medicine, lozenges	Scabies treatment	Tincture of benzoin
Scented cleaning product	Scented candle	Air freshener, deodorizer
Scented paper product	Pet care product	Pesticide
Violin rosin	Histology slide fixative	Scented tobacco, coffee, tea
How to avoid it:		
• Fragrances, flavorings, and natural substances are not always listed on ingredient labels. You may need to **avoid using any product with a scent or fragrance**. Be especially suspicious of things in your environment with a cinnamon, vanilla, or clove aroma. *Choose only "fragrance-free" products, since "unscented" ones may actually contain a masking fragrance*! • Read complete ingredient lists. Check the original box or package. Some products' ingredient lists can be found on the internet at the manufacturer's website or the store's website. • For possible workplace exposure, check the ingredient labels of all products encountered. Often commercial products contain a small amount of fragrance but do not list it. You may need to contact the manufacturer to find out. • Ask your doctor, nurse, attendant, hairdresser, masseuse, and others not to use fragranced products in your care. Be cautious of exposure from contact with a partner who uses fragranced products. If you must use fragranced products as you care for children, elders, or pets, wear protective rubber, nitrile, or vinyl gloves. • If there is a particular perfumed product you must use, ask your doctor how you can perform a repeat open application test (ROAT). • If you are not successful in clearing your skin rash by strictly avoiding contact with this allergen, your doctor may recommend you go on a special diet for one month to eliminate foods that may contain balsam of Peru in flavors and spices.		
Dietary restrictions to avoid *Myroxylon pereirae* (balsam of Peru)		
Avoid the following: **citrus fruits** and products that contain citrus flavor, peel, zest, or oil; **tomatoes** and tomato-containing products; **spices** such as cinnamon, cloves, vanilla, curry, nutmeg, allspice, anise and ginger as well as spicy condiments; **sweet flavorings**; **colas**, i.e. soft drinks, such as Dr Pepper, that may contain sweet flavorings and spices; and **liquors** such as wine, beer, gin and vermouth		
Related substances		
You may show a cross-reaction to some closely related substances that are derived from plants. If you are not successful in clearing your skin rash by strictly avoiding sources of balsam of Peru, you may also need to avoid these:		
Beeswax	Benzaldehyde	Benzoic acid
Benzoin	Benzyl salicylate	Colophony
Coniferyl alcohol	Coniferyl benzoate	Coumarin
Diethylstilbestrol	Resorcin monobenzoate	Resorcinol
Propolis	Storax	Tolu balsam
Wood tars		

eTable 14.2 American Contact Dermatitis Society (ACDS)-composed exposure information sheets: *Myroxylon pereirae* (balsam of Peru).

ALTERNATIVES TO *P*-PHENYLENEDIAMINE (PPD) IN HAIR DYES		
PPD-free (but may contain chemicals which can cross-react with PPD)	**Temporary dyes**	**Plant-based dyes (most include henna)**
Aveda Full spectrum protective (TDS, aminophenol)	*Truhair® by Chelsea Scott* Color & Lift	*As I am* Henna Happiness
Biokap® Nutricolor (TDS)	*Clairol* Natural Instincts (MePPD)	*Desert Shadow* Indigo shadow (indigo)
Hair Wonder Colour & care (TDS)	*ColorMark* Touch back	*Hairprint* True Color Grey Hair Restorer (no henna)
Hennaplus Long Lasting Colour (TDS, aminophenol)	*Goldwell* Elumen	*Matrix* Biolage Hair Color (henna)
Madison-Reed Radiant hair color (TDS, aminophenol)	*Hennaplus* Colour cream	*Light Mountain Natural* Hair Color (henna)
Napro Palette (TDS, aminophenol)	*SanoTint®* Reflex temporary natural hair dye	*Palette by Nature™* (henna, indigo)
L'Oreal Paris Casting crème (TD, aminophenol)	*Schwarzkopf* Keratin Color	*Sante* (indigo)
Schwarzkopf Brilliance luminance Live salon permanent Color ultime (TDS)	*Sebastian* Cellophanes	*Surya* (henna)
Wella Koleston perfect (MePPD)		**Other** (for men)
		Clubman Pinaud Black gel (beard) (iron oxides) Youthair (lead acetate) Youthair lead-free (bismuth citrate)
		Grecian Formula 16 liquid with conditioner (new formulation has bismuth citrate not lead acetate)

eTable 14.3. Alternatives to *p*-phenylenediamine (PPD) in hair dyes. MePPD, methyl-phenylenediamine; TD, toluenediamine; TDS, toluene diamine sulfate.

Irritant Contact Dermatitis 15

Emily C. Milam and David E. Cohen

Synonyms: ■ Irritant reaction ■ Irritant dermatitis ■ Irritant dermatitis syndrome ■ Irritant contact dermatitis syndrome ■ Toxic contact dermatitis ■ "Irritation" ■ "Chemical burn"

Key features

- Irritant contact dermatitis (ICD) is a localized, non-immunologically initiated, cutaneous inflammatory reaction. Its clinical characteristics are polymorphous and include erythema, scaling, edema, vesiculation, and erosions in acute cases, with erythema, lichenification, hyperkeratosis, and fissures in chronic cases
- ICD results from a direct cytotoxic effect due to single or repeated application of a chemical substance or physical insult to a cutaneous site
- ICD is a common disorder and represents an important spectrum of clinical presentations in both general and occupational dermatology, occurring when the normal epidermal barrier is disrupted and secondary inflammation develops
- Despite different pathogeneses, allergic contact dermatitis and ICD have similar clinical appearances, especially their chronic variants
- ICD is a multifactorial syndrome determined by the properties of the irritating substance as well as host and environmental factors; a dose–response relationship is related to exposure parameters such as concentration, pH, temperature, occlusion, repetition, and duration of contact
- Strong or absolute irritants such as strong acids and alkalis, as well as oxidants, produce erythema, edema, vesicles that may coalesce into bullae, oozing, and, in severe cases, necrosis and ulceration. The latter is vernacularly termed a "chemical burn"
- ICD is most often caused by cumulative exposure to weak irritants such as soap and water
- The clinical features of chronic ICD from repeated exposure to low-grade or marginal irritants (e.g. soaps, solvents, cleansers, weak acids and bases) include erythema, lichenification, excoriations, scaling, and fissures

INTRODUCTION

There are two major forms of contact dermatitis: irritant and allergic. Irritant contact dermatitis (ICD) is a cutaneous inflammatory disorder resulting from activation of the innate immune system by the direct cytotoxic effect of a chemical or physical agent, whereas allergic contact dermatitis is a delayed-type hypersensitivity immune reaction mediated by hapten-specific T cells[1].

Contact dermatitis is a matter of public health importance[1], with total direct costs exceeding an estimated $1.5 billion in the US in 2013[2]. Occupational contact dermatitis represents a significant cost to society when accounting for medical costs, workers' compensation, decreased productivity, and lost time from work[3–6]. A National Health Interview Survey suggested that in 2010, 15 million Americans were affected by occupational dermatitis[6], a figure 100-fold higher than in prior reports by the US Bureau of Labor Statistics. Overall, the impact of occupational skin diseases on both society and the individual is formidable in light of both prevalence and economic factors.

HISTORY

One of the earliest documented irritant skin reactions is in the writings of Celsus around 100 CE, who described skin ulceration resulting from corrosive metals[7]. The first accounts of occupational skin diseases focused on ill health among miners, and in 1556, Georg Agricola detailed the deep ulcers observed among metal workers. Eleven years later, Paracelsus discussed the etiology, pathogenesis, and therapy of skin changes caused by salt compounds. In 1700, Bernardino Ramazzini published a detailed treatise on the diseases of tradespeople in which he described skin disorders incurred by bath attendants, bakers, gilders, midwives, millers, and miners[7]. Physicians began to more widely recognize occupational irritant dermatitis during the Industrial Revolution with the development of new materials and chemicals, both natural and synthetic, for industrial and household use[8]. Germany and France were the first to enact laws compensating workers for industrial skin diseases.

EPIDEMIOLOGY

ICD is the most common form of occupational skin disease, estimated to constitute between 70% and 80% of all occupational skin disorders (Table 15.1)[9]. Data from the North American Contact Dermatitis Group indicate that in groups of patients with contact dermatitis, ICD (as a primary diagnosis) accounts for 9%–10% of those screened for allergic contact dermatitis via patch testing, and when hands are affected, ICD predominates over all other causes of contact dermatitis[10,11].

The US Bureau of Labor Statistics data show that occupational skin diseases accounted for a consistent 30%–45% of all patients with occupational illnesses from the 1970s through the mid-1980s. However, occupational skin disease rates have since fallen dramatically, e.g. from an average rate of 16.2 events/10 000 full-time workers in 1972 to 2.8 events in 2013[12].

Although skin disease accounted for only 17% of all recorded nonfatal occupational illnesses in 2007[13,14], it still ranks second and is only surpassed by musculoskeletal disorders. The incidence of occupational contact dermatitis in several other countries is similar to that in the US, with a range of 50 to 70 cases/100 000 workers/year[15]. In Europe, the decreasing incidence of occupational contact dermatitis has been attributed to more recently enacted legislation that limits occupational exposure to chemical agents, though a causal relationship has not been confirmed[16,17]. In 1996, the United Kingdom created a voluntary reporting system that combined information from the EPIDERM study with the occupational physicians' reporting activity (OPRA). The annual incidence of occupational contact dermatitis reported by dermatologists was 0.9 per 10 000 workers, and for occupational physicians, it was 3.1 per 10 000 workers[1,18].

In 2010, the National Institutes of Occupational Safety and Health sponsored the National Health Interview Survey which utilized a sample cohort of 27 157 individuals (to represent 229 million US civilian adults), the majority of whom were employed or recently employed[6]. The overall prevalence of dermatitis was 10.2%, ranging from 7.3% in those who never worked to 9.8% in currently employed workers to 11.8% in those recently, but not currently, employed.

In addition to manufacturing, industries with the highest nonadjusted and adjusted rates of dermatitis include healthcare and social assistance; arts, entertainment, and recreation; and accommodations and food services. Rubber chemicals, soaps and cleansers, wet work, resins, acrylics, and nickel are some of the more common sources for irritant and allergic contact dermatitis. Additional high-risk occupations are discussed in Chapter 16[1,18].

EXPOSURES TO IRRITANTS BY OCCUPATION	
Occupation	**Irritants**
Agriculture workers	Artificial fertilizers, disinfectants, pesticides, cleaners, gasoline, diesel oil, plants/grains
Artists	Solvents, clay, plaster
Automobile and aircraft industry workers	Solvents, cutting oils, paints, hand cleansers
Bakers and confectioners	Flour, detergents
Bartenders	Wet work, detergents
Bookbinders	Solvents, glues
Butchers	Detergents, meat
Cabinet makers and carpenters	Glues, detergents, thinners, solvents, wood preservatives
Cleaners	Detergents, solvents, wet work
Coal miners	Dust (coal, stone), wet conditions
Construction workers	Cement
Cooks and caterers	Detergents, vegetable juices, wet work
Dentists and dental technicians	Detergents, hand cleansers, wet work
Dry cleaners	Solvents
Electricians	Soldering fluxes
Electroplaters	Acids, alkalis
Floor layers	Solvents
Florists and gardeners	Manure, artificial fertilizers, pesticides, wet work
Hairdressers	Permanent wave solutions, shampoos, bleaching agents, wet work
Homemakers	Detergents, cleansers, foods, wet work
Hospital workers	Detergents, disinfectants, foods, wet work
Jewelers	Detergents, solvents
Mechanics	Oils, greases, gasoline, diesel fuel, cleaners, solvents
Metal workers	Cutting oils, solvents, hand cleansers
Nurses	Disinfectants, detergents, wet work
Office workers	Paper products, solvents in cleaners, adhesives, and photocopiers/toner
Painters	Solvents, thinners, wallpaper adhesives, hand cleansers
Photography industry workers	Solvents, wet work
Plastics workers	Solvents, acids, styrene, oxidizing agents
Printers	Solvents
Rubber workers	Solvents, talc, zinc stearate
Shoemakers	Solvents
Tannery workers	Acids, alkalis, reducing and oxidizing agents, wet work
Textile workers	Fibers, bleaching agents, solvents
Veterinarians and slaughterhouse workers	Disinfectants, wet work, animal entrails and secretions

Table 15.1 Exposures to irritants by occupation. *Adapted from Tovar R, Leikin JB. Irritants and corrosives. Emerg Med Clin North Am 2015;33:117–31.*

Clinical manifestations of ICD are highly variable and determined by the properties of the irritating substance as well as host and environmental factors. These include concentration, pH, mechanical pressure, temperature, humidity, and duration of contact. Low ambient humidity and cold are important factors in decreasing the water content of the stratum corneum and, consequently, increasing the permeability to irritants such as soaps, detergents, acids, bases, and solvents. Cold alone may also reduce the plasticity of the horny layer, with consequent cracking of the stratum corneum. However, in one study, the application of cold had a protective effect on the development of ICD if applied during the provocative exposure, in this case to sodium lauryl sulfate[19]. Occlusion, excessive humidity, and maceration increase the water content of the stratum corneum and compromise the stratum corneum's protective lipid bilayers, with consequent enhanced percutaneous absorption of water-soluble substances (Fig. 15.1)[20]. In addition, irritated skin may become more susceptible to superimposed allergic sensitization.

Important predisposing characteristics of the individual include age, sex, pre-existing skin disease, anatomic region exposed, and sebaceous activity. There are age-associated changes in the skin that can alter the skin's response to irritants. Both infants and the elderly are more often affected by ICD because of their less robust epidermal barrier, and they also develop more severe symptoms. While skin irritation may be seen more often on the upper extremities of women than men, this higher prevalence of ICD may be due to increased frequency of exposure rather than inherent sex differences. Genetic factors also play a role in the development of ICD, as shown in studies with monozygotic twins[21]. Patients with a history of atopic dermatitis have a 13.5 times greater risk of developing occupational dermatitis[22], and a reduction in epidermal filaggrin can reduce the inflammatory threshold for irritants[23]. Lastly, the most commonly affected sites are exposed areas such as the hands and the face, with hand involvement seen in ~80% of patients and facial involvement in 10%[15]. Excessive exposure to water, soaps and detergents, common causes of ICD, play a critical role given that wet work (immersion in water for >2 hours, occlusive protective gear, and/or hand washing >20 times/day) represents one of the most important risk factors for developing irritant dermatitis[24].

PATHOGENESIS

ICD is due to direct contact of a chemical or physical agent with the skin, which triggers activation of the innate immune response without the need for prior sensitization. Although the cellular mechanisms of ICD remain elusive, increasing evidence suggests that activated keratinocytes act as signal transducers in the control of host homeostatic responses to exogenous stimuli and they serve as key immunoregulators. An irritant chemical's ability to induce cutaneous damage may serve to trigger pattern recognition receptors (PRR), including Toll-like receptors, providing the necessary impetus to activate the innate immune system[25]. While other mediators such as prostaglandins, leukotrienes, and neuropeptides may possibly play a role, cytokines carry the most interest in ICD as they are the central mediators in T-cell recruitment and inflammation.

Several pathomechanisms have been associated with ICD, including denaturation of epidermal keratins, disruption of the permeability barrier (see Ch. 124), damage to cell membranes, and direct cytotoxic effects, with different mechanisms at work with different irritants

Fig. 15.1 Bilateral irritant contact dermatitis of the feet and ankles due to chronic occlusive footwear.

IRRITANTS AND MECHANISMS OF TOXICITY	
Irritant	**Mechanisms of toxicity**
Detergents	Barrier disruption, protein denaturation, membrane toxicity
Acids	Protein denaturation, cytotoxicity
Alcohols	Protein denaturation
Alkalis	Barrier lipid denaturation, cytotoxicity through cellular swelling
Oils	Disorganization of barrier lipids
Organic solvents	Solubilization of membrane lipids, membrane toxicity
Oxidants	Cytotoxicity
Reducing agents	Keratolysis
Water	If barrier is disrupted, cytotoxicity through swelling of viable epidermal cells

Table 15.2 Irritants and mechanisms of toxicity.

(Table 15.2). The mechanisms involved in the acute and chronic phases of ICD are fundamentally different. Acute reactions involve direct cytotoxic damage to keratinocytes, while repeated exposures to solvents and surfactants cause slower damage to cell membranes by removing surface lipids and water-retaining substances.

The pathogenic pathway in the *acute phase* of ICD, common to many chemically unrelated irritants, begins with penetration of the irritant through the permeability barrier (stratum corneum), mild damage or stress to keratinocytes, and the release of mediators of inflammation with resultant T cell activation[20]. In this manner, once activation is initiated via epidermal cells, continuous T cell activation independent of the exogenous agent may be maintained and barrier dysfunction perpetuated[26]. Tumor necrosis factor (TNF) and interleukin (IL)-1α are the major mediators, and they are capable of inducing production of other cytokines, chemokines, and adhesion molecules, leading to leukocyte recruitment to the site. Specifically, TNF, IL-6, and IL-1β upregulate expression of intercellular adhesion molecule-1 (ICAM-1)[27]. This is a predominant feature of ICD. In addition, IL-1 receptor antagonist (IL-1RA) and IL-8 increase substantially after exposure to the common irritant sodium lauryl sulfate.

In the *chronic phase* of ICD, the stratum corneum barrier is disrupted. Damage to the stratum corneum lipids (which mediate barrier function) is associated with loss of cohesion of corneocytes, desquamation, and an increase in transepidermal water loss (TEWL). TEWL is one of the triggering stimuli that promote lipid synthesis, keratinocyte proliferation, and transient hyperkeratosis during the restoration of the cutaneous barrier. However, damage with a solvent can disrupt this protective mechanism by occlusion and blockage of water evaporation, thus halting lipid synthesis and barrier recovery. After chronic exposure, the result is increased epidermal turnover manifested clinically by the chronic eczematoid irritant reaction[28].

CLINICAL FEATURES

Several different types of ICD have been described[29] (see below). Consequences of the myriad forms of ICD range from postinflammatory pigmentary changes to poorly healing ulcers (Table 15.3).

CLINICAL FEATURES SUGGESTING AN IRRITANT OR TOXIC ETIOLOGY		
Clinical feature	**Possible irritant or toxin**	
Ulcerations	Inorganic acids (chromic, hydrofluoric, nitric, hydrochloric, phosphoric, sulfuric) Strong alkalis (calcium oxide, sodium hydroxide, potassium hydroxide, ammonium hydroxide, calcium hydroxide, sodium metasilicate, sodium silicate, potassium cyanide, trisodium phosphate, sodium carbonate, potassium carbonate) Salts (arsenic trioxide, dichromates) Solvents (acrylonitrile, carbon bisulfide) Gases (ethylene oxide, acrylonitrile)	
Folliculitis or acneiform lesions	Oils and greases Tar and asphalt Chlorinated naphthalenes and polyhalogenated biphenyls Arsenic trioxide Glass fibers	
Miliaria	Occlusive clothing and overheating Adhesive tape Ultraviolet and infrared radiation Aluminum chloride	
Pigmentary changes		
• Hyperpigmentation	Any irritant or allergen, especially phototoxic agents such as psoralens, tar, asphalt, psoralen-containing plants Metals, such as inorganic arsenic (systemically), silver, gold, bismuth, mercury Radiation: ultraviolet, infrared, microwave, ionizing	
• Hypopigmentation	*p*-Tert-amylphenol	*p*-Cresol
	p-Tert-butylphenol	3-Hydroxyanisole
	Hydroquinone (HQ)	Butylated hydroxyanisole
	Monobenzyl ether of HQ	1-Tert-butyl-3, 4-catechol
	Monomethyl ether of HQ	1-Isopropyl-3, 4-catechol
	p-Tert-catechol	4-Hydroxypropriophenone
Alopecia	Borax Chloroprene dimers	
Urticaria	Animals (arthropods, caterpillars, corals, jellyfish, moths, sea anemones) *Myroxylon pereirae* (balsam of Peru) Cosmetics (e.g. sorbic acid) Drugs (alcohol [ethanol], benzocaine, camphor, capsaicin, chloroform, iodine, methyl salicylate, resorcinol, tar extracts) Foods (cayenne pepper, fish, mustard, thyme) Fragrances and flavoring agents (cinnamon oil, cinnamic acid and aldehyde, benzaldehyde) Metals (cobalt) Plants (seaweed, stinging nettles), woods Preservatives (benzoic acid) Textiles (e.g. blue dyes)	

Table 15.3 Clinical features suggesting an irritant or toxic etiology.

Acute Irritant Contact Dermatitis

Acute ICD, commonly seen with occupational accidents, develops when the skin is exposed to a potent irritant. The latter is capable of profound reactions on the skin surface: oxidation, reduction, desiccant, vesicant, or ion disruption[30]. The acute reaction reaches its peak quickly, usually within minutes to hours after exposure, and then starts to heal. This is termed the decrescendo phenomenon. Symptoms of acute ICD include burning, stinging, and soreness of the directly affected sites. Physical signs include erythema, edema, bullae, and possibly necrosis. These lesions are restricted to the area where the irritant or toxicant damaged the tissue, with sharply demarcated borders and asymmetry pointing to an exogenous cause. If there is no dermal injury, healing should be complete[31].

The potent irritants that most frequently lead to ICD are acids and alkalis, resulting in chemical burns.

Acute Delayed Irritant Contact Dermatitis

Acute delayed ICD is a retarded inflammatory response characteristic of certain irritants, such as anthralin (dithranol), benzalkonium chloride (preservative/disinfectant), and ethylene oxide. Adverse reactions to these chemicals are considered idiosyncratic, except when they are applied to previously injured skin, e.g. sites of xerosis or atopic dermatitis[31]. Clinically visible inflammation is not seen until 8 to 24 hours (or more) after exposure, and thus may mimic allergic contact dermatitis; however, the associated symptom is more frequently burning rather than pruritus. Sensitivity to touch and water is elicited. This form of ICD is commonly seen during diagnostic patch testing.

Irritant Reaction Irritant Contact Dermatitis

Irritant reaction ICD is a type of subclinical irritant dermatitis in individuals exposed to wet chemical environments, such as hairdressers, caterers, metal workers, or those with frequent exposures to soap and water. It is characterized by one or more of the following signs: scaling, redness, vesicles, pustules, and erosions, often beginning under occlusive jewelry (e.g. rings) and then spreading onto the fingers and then the hands and the forearms. It may simulate dyshidrotic dermatitis and ultimately result in cumulative ICD if exposure is prolonged; however, ICD tends to resolve if exposure is discontinued.

Cumulative Irritant Contact Dermatitis

Cumulative ICD is a consequence of multiple sub-threshold skin insults, without sufficient time between them for complete restoration of skin barrier function (see Fig. 16.4). It may be due to a variety of stimuli or frequent repetition of one factor, e.g. exposure to water both at the workplace and at home. Clinical symptoms develop only after the cumulative damage exceeds an individually determined manifestation or elicitation threshold, which may decrease with progression of the disease. Weak irritants do not lead to clinical ICD if they are encountered far enough apart to allow for restoration of skin barrier function. However, if the same irritant exposures follow each other closely in time, or when the manifestation threshold is reduced (e.g. in a patient with active atopic dermatitis), cumulative ICD can develop. The properties of the irritating substance, e.g. pH, solubility, detergent action, physical state, are also important. In contrast to acute ICD, the lesions of chronic ICD are less sharply demarcated. Pruritus and pain due to fissures of hyperkeratotic skin are symptoms of chronic ICD. Signs may include xerosis, erythema, and vesicles, but lichenification and hyperkeratosis predominate.

Asteatotic Dermatitis

Asteatotic dermatitis, also referred to as asteatotic eczema, eczema craquelé, or exsiccation eczematid ICD, is a special variant seen primarily during dry winter months. Elderly individuals who frequently bathe without remoisturizing are at particular risk of developing asteatotic dermatitis. Intense pruritus is common, with the skin appearing dry with ichthyosiform scale and characteristic patches of superficially cracked skin (see Ch. 13).

Traumatic Irritant Contact Dermatitis

Traumatic ICD may develop after acute skin trauma, such as from burns, lacerations, or acute ICD. Patients should be asked whether they have cleansed the skin with strong soaps or detergents. It is characterized by eczematous lesions, most commonly on the hands, that last for weeks to months with persistent redness, infiltration, scale, and fissuring in the affected areas.

Pustular and Acneiform Irritant Contact Dermatitis

Pustular and acneiform ICD results from exposure to certain irritants, such as metals, croton oil, mineral oils, tars, greases, cutting and metal working fluids, and naphthalenes (see Table 15.3 and Ch. 16). This syndrome should be considered in conditions in which folliculitis or acneiform lesions develop in settings outside of typical acne, particularly in patients with atopic dermatitis, seborrheic dermatitis, or prior acne vulgaris. The pustules are "sterile" and transient. Miliarial reactions, which may become pustular, can develop in response to occlusive clothing, adhesive tape, or ultraviolet and infrared radiation.

Non-erythematous Irritant Contact Dermatitis

Non-erythematous ICD may be defined as a subclinical form of ICD with early stages of skin irritation seen as changes in the stratum corneum barrier function without a clinical correlate.

Subjective or Sensory Irritant Contact Dermatitis

Subjective or sensory ICD is characterized by reports of a stinging or burning in the absence of visible cutaneous signs of irritation. Irritants capable of eliciting this reaction include propylene glycol, hydroxy acids, ethanol, and topical medications such as lactic acid, azelaic acid, benzoic acid, benzoyl peroxide, mequinol, and tretinoin. Sorbic acid, a preservative in concentrations of up to 0.2% in foods, cosmetics, and drugs, may also produce sensory irritation in predisposed individuals. This reaction to irritants such as lactic or sorbic acid may be reliably reproduced with dose responsiveness in double-blinded exposure tests.

Airborne Irritant Contact Dermatitis

Airborne ICD develops in irritant-exposed sensitive skin of the face and periorbital regions. While this often simulates photoallergic reactions, involvement of the upper eyelids, philtrum, and submental regions in patients with airborne ICD may aid in distinguishing between these two entities. Airborne ICD results from exposure to floating dusts, fibers (particularly fiberglass), fragrances, woods, and volatile solvents and sprays[32].

Frictional Irritant Contact Dermatitis

Frictional ICD is a distinct ICD subtype resulting from repeated low-grade frictional trauma. It is often acknowledged to also play an adjuvant role in allergic contact dermatitis and ICD. The frictional response includes hyperkeratosis, acanthosis, and lichenification, often progressing to hardening, thickening, and increased toughness. It often involves the fingers of the dominant hand. Frictional ICD has been associated with repetitive handling of paper, carbon, fabric and plastic bags; driving (due to repetitive gripping of the steering wheel and gear stick); and rubbing from clothing or sports equipment, as in golf and fishing[33].

Contact Urticaria

Contact urticaria is divided into non-immunologic and immunologic subtypes (see Ch. 16), with the former occurring more frequently and in the absence of previous exposure. Irritants that can produce *immunologic* contact urticaria include parabens (preservatives), henna, ammonium persulfate (oxidizing agent), and latex. *Non-immunologic* contact urticaria can be caused by a number of exposures, from caterpillars and jellyfish to stinging nettles and foods (see Table 15.3)[34]. Risk factors include atopy, hand dermatitis, previous mucosal exposure to latex (e.g. urinary catheterization), and allergies to fruits (e.g. kiwi, avocado; see Table 16.6).

PATHOLOGY

The histopathologic features of ICD vary according to the nature of the irritant, but often include variable spongiosis, necrosis of keratinocytes, and an inflammatory infiltrate rich in neutrophils. The combination of a neutrophil-rich superficial perivascular infiltrate plus widely scattered necrotic keratinocytes is most typical; sometimes there is even full-thickness epidermal necrosis and subepidermal clefting. Mild ICD can resemble allergic contact dermatitis. Over time, additional histologic findings include acanthosis with mild hypergranulosis and hyperkeratosis. In aggregate, these elements are not specific, and they cannot be confidently differentiated from either chronic allergic contact dermatitis or other types of chronic eczemas[35].

CLASSIFICATION OF IRRITANT CHEMICALS

Acids

A variety of both inorganic and organic acids can be corrosive to the skin. Acids cause epidermal damage via protein denaturation and cytotoxicity. Principally, all strong acids give the same clinical features, including erythema, vesication, and necrosis (Fig. 15.2).

Inorganic acids are commonly used in industry, especially hydrofluoric, sulfuric, hydrochloric, chromic, nitric, boric, and phosphoric acids (Table 15.4). Hydrofluoric acid and sulfuric acid cause the most severe

Fig. 15.2 Chemical burn due to hydrochloric acid. Development of erythema, edema, and bullae, some of which are hemorrhagic. *Courtesy Eugene Mirrer, MD.*

burns, even at low concentrations, and significant absorption may lead to systemic toxicity[36].

In general, organic acids tend to be less irritating. Among the organic acids, acetic, acrylic, formic, glycolic, benzoic, and salicylic acids are the most common irritants, particularly after prolonged exposure. The uses and properties of *acrylic acid* and *formic acid* are outlined in Table 15.4. *Acetic acid* is a constituent of vinegar, flavoring agents, and astringent mouthwashes, whereas *glycolic*, *benzoic*, and *salicylic acids* are mild irritants whose properties can be harnessed for therapeutic and cosmetic purposes, when used in low concentrations.

Alkalis

Alkalis or bases often cause more painful and severe damage than most acids, with the exception of hydrofluoric acid. There are generally no vesicles, but rather necrotic skin that first appears dark brown, then black, and ultimately becomes hard, dry, and cracked. Alkalis disrupt barrier lipids and denature proteins with subsequent fatty acid saponification, thus subjecting the cell to edema and resultant cytotoxicity. The emulsifying effect of soaps formed in the process facilitates the further penetration of the alkali into the deeper layers of the skin. Strong alkalis include sodium, ammonium, calcium, and potassium hydroxide; sodium and potassium carbonate; and calcium oxide, used primarily in the manufacture of bleaches, dyes, vitamins, pulp, paper, plastics, and soaps and detergents[37,38]. Calcium hydroxide is liberated from wet cement, which has an initial pH of 10–12 that rises to 12–14 as the cement sets (see Table 15.4).

Metal Salts

Metals represent an important and commonly encountered group of irritants, with irritant reactions to metal salts ranging from folliculitis and pigmentary changes to ulceration (see Table 15.4).

Solvents

A wide variety of solvents are used daily in processes such as chemical reactions, hydraulic systems, metal refining, dry cleaning, and metal degreasing. Nearly all are primary irritants to varying degrees (see Table 15.4), with only a few, such as turpentine, also being able to elicit allergic sensitization. Solvents act mainly by dissolving the intercellular lipid barrier of the epidermis, thereby substantially compromising barrier function. Prolonged skin contact can result in severe dermatitis as well as symptoms and even death from systemic absorption, making early recognition of skin manifestations important in the prevention of systemic toxicity. After repeated exposure, the hands, and occasionally the hands and face, develop erythema, scaling and dryness, eventually evolving into eczema (Fig. 15.3). The irritating capacity of organic solvents, attributed mainly to their lipophilicity, follows the order: aromatic > aliphatic > chlorinated > turpentine > alcohols > esters > ketones[39]. In the common clinical scenario of solvent then soap and water exposure, there is a synergistic degradation of epidermal barrier function, pointing to the importance of personal protection and hygiene[40].

Alcohols/Glycols

Alcohols are used widely as solvents, disinfectants, preservatives in cosmetics, and penetration enhancers in drug delivery systems; most have only mild irritating effects. Alcohols are the safest known topical antiseptic compounds, providing bactericidal activity against most Gram-positive and Gram-negative bacteria as well as many fungi and viruses. Most appropriate for this use are diluted solutions of ethyl alcohol, propyl alcohol, and isopropyl alcohol, which act by means of protein denaturation. In cosmetics, alcohol is used as a preservative to prevent microbial contamination and to decrease viscosity. The principal mechanism by which alcohols enhance percutaneous absorption is hypothesized to be the extraction of intercellular lipids from the stratum corneum[41,42].

Glycols, or diols, such as ethylene glycol and propylene glycol, are aliphatic alcohols commonly used in cosmetic products as solvents, emulsifiers, humectants, or keratolytics. Propylene glycol can produce both allergic and irritant contact dermatitis and sources of exposure include personal care products, topical corticosteroids, and other topical medications[43]. Of note, propylene glycol is typically used in cosmetics in concentrations <50%[44].

Detergents and Cleansers

A detergent includes almost any surface-active agent (surfactant) that concentrates at oil–water interfaces and holds both cleansing and emulsifying properties. Detergents most commonly cause chronic forms of ICD and are present in skin cleansers, cosmetics, and household cleaning products. With normal use, ICD is rare from skin cleansers, the exception being in individuals with susceptible skin. Detergents' cleansing actions are derived from their ability to lower the surface tension between two non-mixable phases due to their hydrophilic (polar head) and lipophilic (apolar tail) components. Skin toxicity arises from their damaging influence on the stratum corneum, which impairs barrier function (Fig. 15.4). Surfactants concomitantly bind to keratin and cause protein denaturation. When the stratum corneum is disrupted, detergents can damage viable epidermis and papillary dermal structures.

Irritancy from detergents is best evaluated by measuring TEWL since the latter represents the surrogate measurable change indicative of irritancy damage from this group of chemicals. As a group, anionic detergents such as alkyl sulfates and alkyl carboxylate salts (soap) are more irritating than are amphoteric and non-ionic groups. Sodium lauryl sulfate, an anionic detergent, is often used as a reference irritant in studies because of its consistent, non-allergic, rapid toxic response. Amphoteric surfactants such as *cocamidopropyl betaine* – which are used in therapeutic formulations, personal care products, and cosmetics – have the lowest irritation potential[45,46]. *Cocamide DEA* (diethanolamine), a non-ionic biodegradable surfactant, is used as a viscosity booster, stabilizer, and foam booster; it is found in hand soaps, liquid shampoos, detergents, and dishwashing liquids. Of note, cocamide DEA is one of the more irritating surfactants[47], and it is commonly involved in occupation-related contact dermatitis in North American healthcare workers[48]. In contrast, *cocamide MEA* is minimally irritating and can be used in a concentration of up to 10% in leave-on products[49].

Skin cleansers may be solid or liquid, based on soap and/or synthetic detergents, and may contain solvents or abrasives, depending on use requirements (see Ch. 153). Although the primary factor that determines skin irritancy is the detergent component, skin tolerance cannot be adequately predicted from the composition of products alone. Such an assessment is largely left to trial and error or repeated skin challenges in volunteer cohorts.

Disinfectants

Most disinfectants used to destroy pathogens in the environment act as weak toxic agents and cause chronic ICD as a result of cumulative doses of subclinical irritancy (Fig. 15.5). Various compounds may be used, such as alcohols (see above), aldehydes, phenolic compounds, halogenated

IRRITANT CHEMICALS: USES, PROPERTIES AND SIDE EFFECTS		
Compound	**Uses/exposures**	**Properties and side effects**
Inorganic acids		
Chromic acid	• Metal treatments (chrome plating, copper stripping, aluminum anodizing)	• Ulcerations known as "chrome holes" • Nasal septal perforation
Hydrochloric acid	• Production of fertilizers, dyes, paints, and soaps • Electroplating, oil refining, and food processing	• Erythema, vesication, and necrosis (Fig. 15.2)
Hydrofluoric acid	• Semiconductor industry (etching glass, metal, and stone; can dissolve silicon) • Household and commercial rust, stain, and lime-scale removers	• Extremely cytotoxic agent that can lead to severe tissue damage • Penetrates intact skin due to its limited dissociation constant • Painful penetration may continue for days after exposure • With low concentrations, the onset of symptoms may be delayed for up to a day • Intense pain is due to the capacity of fluoride ions to bind tissue calcium, thereby affecting nerve conduction • Hypomagnesemia and a fluoride-mediated increase in pulmonary vascular resistance may also play a role in toxicity
Nitric acid	• Production of fertilizers and explosives; metal etching and cleaning • Fuming nitric acid – a chemical intermediate used in rocket fuels and as a laboratory reagent	• Chemical burns • Irritant contact dermatitis • Distinctive yellow discoloration • Fuming nitric acid – highly corrosive
Phosphoric acid	• Phosphate fertilizer, pharmaceuticals, water treatment, animal feeds, soaps and detergents, and cotton dyeing	• Erythema, vesication, and necrosis
Sulfuric acid	• Manufacture of fertilizers, inorganic pigments, textile fibers, explosives, pulp, and paper • Occupational risk: jewelers, electroplaters, metal cleaners, and storage battery makers	• Erythema, vesication, and necrosis
Organic acids		
Acrylic acid	• Monomer for acrylic plastics, synthetic resins, dentures, artificial nails, adhesives, and paints	• Highly irritating and corrosive • Capable of penetrating rubber gloves • Also allergic contact dermatitis
Formic acid	• Neutralizer in leather manufacturing, an antiseptic in brewing, and a coagulant in the production of natural latex	• Greatest corrosive potential of the organic acids
Alkalis		
Cement (mixed with water)	• Construction	• Acute ulcerative damage as a result of the high alkalinity of wet cement (due to liberation of calcium hydroxide) • Necrotic skin changes appear 8–12 hours after exposure • Chronic irritant cement dermatitis – develops over months to years from continued exposure; can accompany allergic contact dermatitis to chromium • Most common locations – lower limbs (kneeling, contaminated footwear), hands (glove contamination)
Metal salts		
Arsenic compounds (including arsenic trioxide)	• Aerosolized during the smelting of copper, gold, lead and other metals • Manufacture of pesticides and herbicides • Semiconductor industry and smelting operations	• Persistent folliculitis • Potential for systemic toxicity (see Ch. 88)
Beryllium	• Production of hard, corrosion-resistant alloys	• Ulcerated granulomatous skin lesions (local reaction; see Ch. 94) • Sarcoidosis-like granulomas of the skin and lung (systemic reaction)
Calcium oxide (quicklime)	• Manufacture of pulp, steel, and paper	• Releases heat on contact with water, causing painful cutaneous ulcerations
Cobalt salts	• Alloys, ceramics, electroplating, electronics, magnets, paints, varnishes, and hair dyes	• Irritant and allergic contact dermatitis
Copper salts (e.g. sulfates, oxides, cyanides)	• Used as a biostatic surface and in wood preservatives and fungicides	• Impart a greenish-black color to hair, skin, and teeth if persistent exposure to dust forms • Inhalation of copper oxides (as well as magnesium and zinc oxides) can cause metal fume fever, a brief influenza-like illness usually associated with welding operations

Table 15.4 Irritant chemicals: uses, properties and side effects.

IRRITANT CHEMICALS: USES, PROPERTIES AND SIDE EFFECTS		
Compound	**Uses/exposures**	**Properties and side effects**
Mercury, inorganic	• Products containing inorganic mercury have been banned in US since 1990 • Imported skin-lightening creams* • Limited exposure possible from old cans of latex paint	• Bluish linear pigmentation of the tongue and gums, which may serve as a marker for systemic mercury poisoning
Mercury, organic	• Phenyl mercury salts are used as preservatives in cosmetics and vaccines, as fungicides, herbicides and pesticides in agriculture, and in dental restorative materials	• Although once used as skin disinfectants, both irritant and allergic contact dermatitis have restricted its use • Positive patch tests to mercury (as well as other metals such as gold) observed in patients with oral lichenoid reactions to dental materials (see Ch. 11)
Selenium compounds (including sulfide)	• Therapeutic shampoo (selenium sulfide)	• Skin irritation, conjunctivitis
Thimerosal	• Topical medicaments, vaccines, and cosmetics	• Common cause of both allergic and irritant patch-test reactions
Solvents		
Benzene	• Manufacture of polymers, plastics, resins, adhesives, rubber, lubricants, dyes, detergents, drugs, explosives, and pesticides	• Petechial eruption of the trunk, extremities, and mucous membranes • Petechiae considered to be a marker for aplastic anemia
Chlorinated hydrocarbons (e.g. carbon tetrachloride, trichloroethylene, tetrachloroethane, methylene chloride, ethylene chloride)	• Production of vinyl chloride, which is then converted to polyvinyl chloride • Pesticides • Dry cleaning	• Cutaneous irritation • Systemic effects: liver and kidney damage, CNS depression, and carcinogenesis • Methylene chloride can hydrolyze to form hydrochloric acid, thus leading to significant cutaneous irritation (see above) • "Degreaser's flush" – sudden erythema in extensive areas of the face, neck, and shoulders; caused by alcohol ingestion shortly before or during inhalation of trichloroethylene
Coal tar derivatives (e.g. toluene, xylene, ethyl benzene, cumene)	• Medications • Solvents	• Skin drying and defatting • Exposure solely to vapors can cause xerosis
Petrochemicals (e.g. gasoline, hexane, kerosene, Stoddard solvent)	• Fuels • Insecticides • Dry cleaning • Hexanes – gasoline, glues, and for extraction of cooking oils from seeds	• Irritant contact dermatitis • Absorption of hexane via inhalation or percutaneously can cause paresthesias, hypoesthesia, and motor weakness
Disinfectants		
Aldehydes (e.g. formaldehyde, glutaraldehyde, hexamethylene-tetramine)	• Disinfectants, biocides • Tissue fixative, embalming agent • Adhesives, resins	• More irritating than alcohols • Formaldehyde – high chemical reactivity with proteins; both allergen and irritant, even at low concentrations
Ethylene oxide	• Sterilization of medical equipment	• Oxidizing agent • Severe chemical burns
Halogens – Chlorines	• Disinfectants, including wounds† • Bleach (sodium hypochlorite) • Sanitizers for swimming pools, hot tubs	• Denature proteins via deaminating or chlorinating amino acids • Oxidizing agent (sodium hypochlorite) • Acute skin and mucosal irritant reactions, particularly at high temperatures
Halogens – Iodines	• Broad-spectrum antimicrobial and sporicidal agents • Surgical scrub, shampoo, and skin cleanser (povidone-iodine in a surfactant base)	• Inhibit DNA, RNA, and protein synthesis • Irritant contact dermatitis • Contact urticaria
Phenolic compounds (e.g. Lysol® [cresol and soap solution], pentachlorophenol, chloroxylenol)	• Disinfectants • Preservative in over-the-counter products (baby powders, shampoos), especially chloroxylenol	• Irritant contact dermatitis • Chemical leukoderma (amyl- and butyl-phenol compounds; see Table 15.3)
Quaternary ammonium salts (e.g. benzalkonium chloride)	• Cosmetics, medications (e.g. ophthalmic solutions) • Antiseptics (e.g. cleaning of surgical instruments) • Detergent	• Cationic surfactants that can precipitate or denature proteins and destroy microorganisms • Local skin irritation depends on the solution concentration • Benzalkonium chloride – irritant reactions frequent during patch testing (concentration, 0.1%); can also be an allergen (e.g. healthcare workers, leg ulcer patients) so clinical correlation required

*Rarely organic mercury.
†Dakin's solution contains sodium hypochlorite; EUSOL (Edinburgh solution of lime) contains chlorinated lime and boric acid.

Table 15.4 Irritant chemicals: uses, properties and side effects. Glycols/alcohols and detergents/cleansers are discussed in the text.

Fig. 15.3 Bilateral irritant contact dermatitis of the palms secondary to repeated contact with paint solvents. Extensive patch testing excluded allergic contact dermatitis in this professional paint and crayon illustrator. *Courtesy Kalman Watsky, MD.*

Fig. 15.4 Irritant contact dermatitis caused by playing with slime composed of school glue, food coloring, and laundry detergent. Note the involvement of the web spaces. Components of homemade slime typically include glue, dye, and sodium borate (borax powder or within detergents) or boric acid. *Courtesy Emily Berger, MD.*

compounds, and quaternary ammonium salts (see Table 15.4), in addition to dyes, oxidizing agents, and mercury compounds[50–52].

Dyes of the triphenylmethane family are extensively used as topical antiseptics; they are capable of producing phototoxic dermatitis but uncommonly cause irritant reactions. Benzoyl peroxide is a common *oxidizing agent* used as a topical antimicrobial medication that is capable of causing mild irritation. Most *mercury* compounds induce skin irritation by protein precipitation, but have fallen into disuse as a result of hazards of systemic toxicity.

Plastics

Plastics are synthetic macromolecular end-products consisting of large polymers formed by the linkage of small monomers into large chain-like units. A large number of plastic resins are commercially important and they can be divided into three categories:

- thermoplastics – polyacrylates, polyethylene, polystyrene, polyvinyl chloride, and saturated polyesters
- thermosettings – epoxy resins, phenol–formaldehyde resins, and polyurethanes
- elastomers – synthetic rubbers.

Skin damage is almost exclusively attributable to the monomer ingredients, hardeners, and other additives such as stabilizers. The final hardened plastic product is generally considered inert and non-hazardous to the skin, but residual non-polymerized monomers may be the offending agents. Both irritant and allergic contact dermatitis are common, and they may only be differentiated by patch testing[53].

Fig. 15.5 Irritant contact dermatitis of the hands due to chronic exposure to disinfectants. *Courtesy Antonio Torrelo, MD.*

Food and Plants

Food and food additives often contain compounds that elicit contact sensitivity and irritation, particularly in those working in agriculture, fishing, catering, and food processing industries. Much of the work in these sectors is done without gloves under damp working conditions with frequent hand washing – factors further aggravating skin irritation. Mechanical, thermal, and climatic factors also contribute. A large majority of exposed persons in food handling and fishing professions may be affected by chronic irritant hand dermatitis[54]. Slight irritant skin changes are often accepted as "normal" for the patient's occupation and medical advice is often not sought.

Examples of foods that can lead to ICD include pineapples, which contain the proteolytic enzyme bromelain (bromelin), and garlic, which contains allicin and diallyl disulfide. Irritant dermatitis and chemical burns have occurred from the homeopathic use of garlic as well as apple cider vinegar (contains acetic acid; see Fig. 90.7)[55]. Foods can also lead to contact urticaria (see Table 15.3) and protein contact dermatitis; both of these entities are discussed in detail in Chapter 16.

Additional food-associated and plant-derived irritants are outlined in Table 15.5 and the latter are discussed in Chapter 17.

Water

Water, the universal solvent, is a particularly ubiquitous skin irritant. Wet workers such as hairdressers, hospital cleaners, cannery workers, and bartenders have an increased incidence of hand eczema, with frequent exposure to water via hand washing directly correlating with the development of irritant hand dermatitis[24]. Several mechanisms such as osmolarity, pH, hardness, and temperature might account for the irritancy of water. Stratum corneum hydration may facilitate penetration of polar and non-polar substances through connections in the lacunar network (see Ch. 124) as well as support the overgrowth of pathogenic organisms. The irritancy of water is often exacerbated by occlusion, as it changes the barrier properties of the stratum corneum[56].

Bodily Fluids

Urine, feces (especially in the setting of diarrhea), and saliva can lead to ICD. In babies, irritant diaper dermatitis is a common problem and is often characterized by glazed erythema of convex surfaces and at the diaper margins, with sparing of the skin folds; edema, scaling, and superficial erosions may also be observed (see Fig. 13.12). Chronic diarrhea and incontinence can result in similar problems in the elderly[57].

CHEMICAL COMPOUNDS IN PLANTS RESPONSIBLE FOR CHEMICAL IRRITANT CONTACT DERMATITIS			
Irritant	**Mechanism of action**	**Clinical features**	**Example of plants**
Bromelain	Proteolytic activity	Cutaneous irritation	Pineapple
Capsaicin	Binds to vanilloid receptors on sensory neurons	Cutaneous burning and erythema	Hot pepper
Isothiocyanates (mustard oils)	Readily react with amino groups of proteins in the skin and mucosae	Short-lived cutaneous burning and erythema; urticarial Ocular irritation	Mustard, cabbage, brussels sprouts, broccoli, cauliflower, radishes
Nicotine	Antagonist for nicotinic receptors in the peripheral and central nervous systems	Cutaneous irritation	Tobacco
Phorbol esters	Bind to phospholipid-dependent membrane receptors	Cutaneous pain, erythema, edema, and blistering Conjunctivitis and even blindness	Texas croton, castor bean
Protoanemonin (ranunculol)	Disrupts disulfide bonds, resulting in subepidermal separation	Cutaneous burning and erythema Irritation of conjunctivae and nasal airway	Buttercups, columbine (when wounded)

Table 15.5 Chemical compounds in plants responsible for chemical irritant contact dermatitis. For additional causes, see Table 17.6.

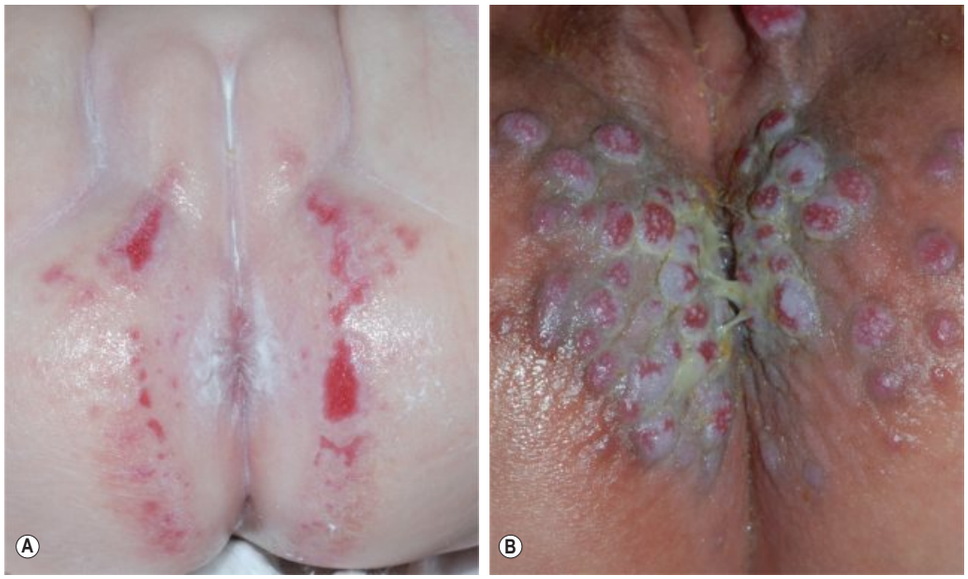

Fig. 15.6 Granuloma gluteale infantum, a form of chronic irritant contact dermatitis. Chronic exposure to urine and feces can lead to erosions and ulcerations (**A**); also referred to as Jacquet erosive dermatitis, as well as pseudoverrucous papules and nodules or erosive papulonodular dermatosis (**B**). *Courtesy Julie V. Schaffer, MD.*

In both children and adults, long-standing irritant dermatitis in the anogenital region can lead to papules and nodules (granuloma gluteale infantum [adultorum]; pseudoverrucous papules and nodules) as well as punched-out erosions and ulcerations (Jacquet erosive dermatitis) (Fig. 15.6)[58]. Predisposing factors, in addition to prolonged exposure to urine or stool, include occlusion, candidal infection, and topical corticosteroid use. Histologically, epidermal hyperplasia, a variably dense mixed inflammatory infiltrate in the dermis, and vascular proliferation are typically observed. The term erosive papulonodular dermatosis has been suggested as an overarching term to describe this spectrum of reactive changes. Of note, similar changes can be seen in submammary and peristomal skin. Although barrier creams and topical antifungal agents may have some benefit, the condition tends to persist until the irritant trigger is eliminated.

Children, more so than adults, develop the habit of lip licking. In these patients, irritant dermatitis may involve the perioral skin as well as the lips (Fig. 72.16A). In a series of 75 patients with cheilitis who were referred for patch testing, ICD was the most common cause of cheilitis[59,60]. Figure 72.15 outlines distinguishing features of the various forms of cheilitis, including that due to ICD. Periurethral ICD may be seen in patients with bladder-drained pancreatic allografts and in those receiving foscarnet.

DIFFERENTIAL DIAGNOSIS

Despite their different pathogeneses, allergic and irritant contact dermatitis, especially of the chronic type, show a remarkable similarity with respect to clinical appearance, histopathology, and immunohistology. Clinically, the reactions often look identical, with erythematous plaques, xerosis, scaling, fissures, and lichenification locally distributed and sharp borders delineating the areas of contact. In the clinical setting, the substance in question is often unknown, as is the concentration and duration of exposure. As a result, the diagnosis of ICD has remained a diagnosis of exclusion – when the dermatitis cannot be explained by a positive patch test to a known allergen. Another helpful, but not conclusive, clinical feature is the more frequent complaint of burning, pain, and stinging with ICD, in contrast to pruritus in areas of allergic contact dermatitis (Fig. 15.7).

PROGNOSIS

In many individuals, ICD resolves spontaneously even with continuous exposure, a process referred to as "accommodation" or "hardening"[61]. The exact mechanisms are still unclear, but the following changes have been observed after repetitive cutaneous exposure to irritants:

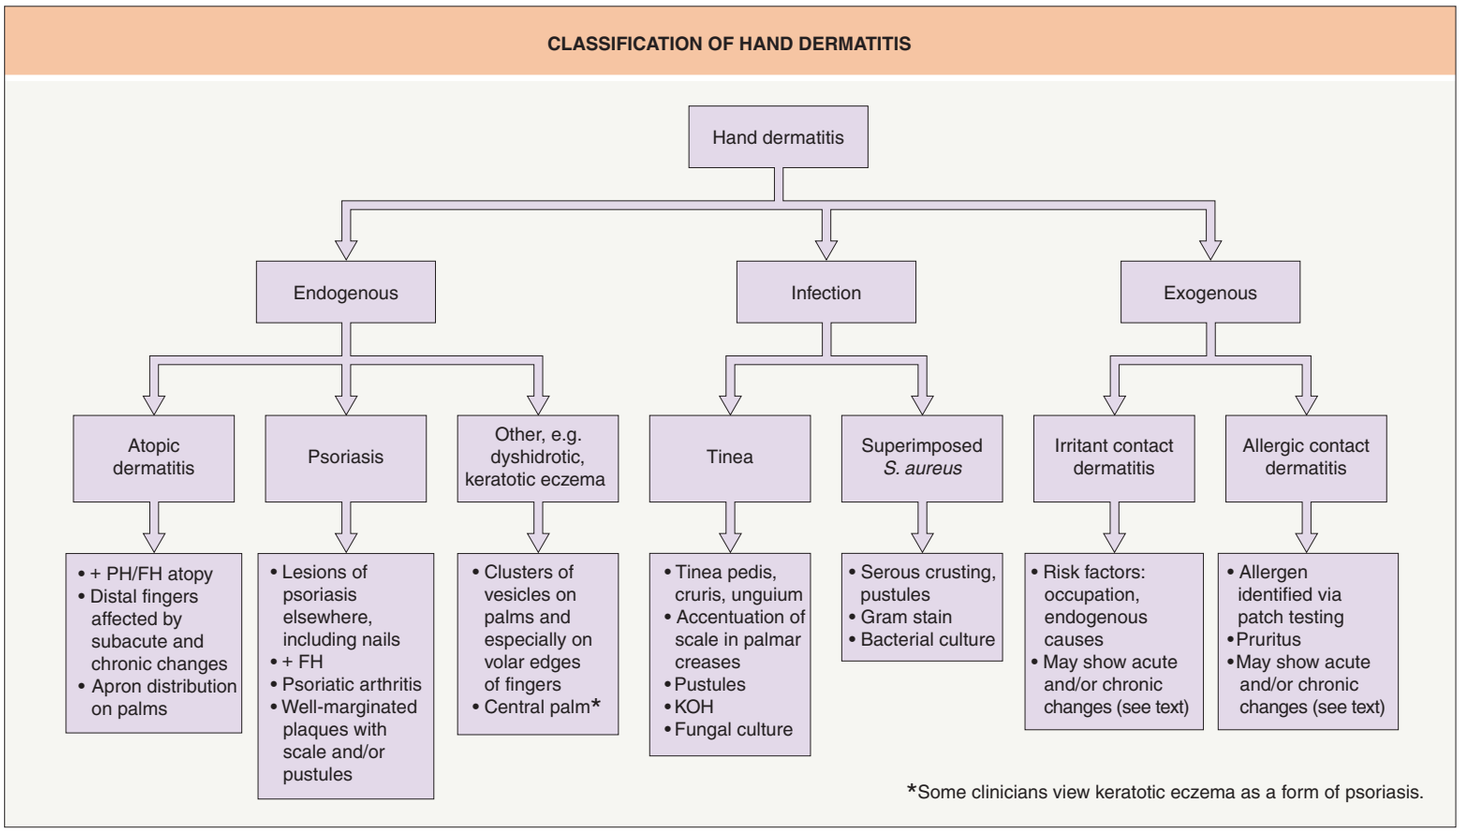

Fig. 15.7 Classification of hand dermatitis. More than one etiology may be present, e.g. atopic dermatitis plus irritant contact dermatitis. Keratolysis exfoliativa is usually not confused with hand dermatitis. Also see Figure 17.1. FH, family history; PH, personal history. (For further details, see Seidenari S, Giusti F, Pepe P, Mantovani L. Contact sensitization in 1094 children undergoing patch testing over a 7-year period. *Pediatr Dermatol.* 2005;22:1–5.)

- improvement of the physical barrier via formation of a thicker stratum corneum and a thicker stratum granulosum as well as increased production of ceramide 1
- increased skin permeability to irritants plus changes in vascular reactivity that allow faster removal of irritants
- immunologic alterations that favor an anti-inflammatory response to irritants, e.g. increased ratio of IL-1Ra (an anti-inflammatory cytokine) to IL-1α (a proinflammatory cytokine)
- a systemic hyporeactive state following repetitive exposure to low-dose irritants[61].

The time required for "accommodating" to the aggravating stimulus varies among individuals, and for some individuals, ICD can be a chronic and devastating problem. Poor prognosis is related to a previous history of atopy, female sex, and the presence of allergic contact dermatitis (as well as ICD). Factors that can potentially improve prognosis are early diagnosis, treatment, and patient knowledge about the disease[62].

TREATMENT

Avoidance of causative irritants in the home or the workplace is the primary treatment for ICD. Strategies in the prevention of ICD include the identification of irritants with appropriate substitution, the establishment of engineering controls to reduce exposure, the utilization of personal protective equipment such as gloves and special clothing, and barriers such as ointments, emollients, or creams. Other preventive strategies include emphasizing personal and occupational hygiene, establishing educational programs to increase awareness in the workplace, and providing health monitoring.

In the workplace, by far the most effective measure for reducing the incidence of contact dermatitis is technical avoidance. This can be accomplished via shielding and personal protection of the workers and limiting the use of potent irritants to closed or automated systems. Preventive skin care at the workplace may mitigate occupational hand dermatitis among vulnerable populations and involves regular use of protective creams to intact skin, removal of irritants by mild cleaning agents, and enhancement of barrier function generation by emollients or moisturizers[63,64]. Non-irritating fatty substances such as petrolatum preclude hydrophilic chemical penetration and restore barrier function. The efficacy of barrier creams for skin protection (as compared to bland emollients) remains a topic of debate[65]. In a randomized controlled trial, both barrier creams and moisturizing vehicles were found to positively influence skin status and hydration, without significant differences in efficacy[66]. Newer moisturizers containing ceramides can also improve barrier function, but further trials are necessary to ascertain their efficacy compared to traditional moisturizers[67,68]. Lastly, while new bioengineering techniques have been proposed for the assessment of individual irritant sensitivity, their value in predicting occupational ICD, especially of the cumulative type, remains unclear.

Protective gloves can reduce risk of irritant hand dermatitis when appropriately selected and worn; however, gloves worn incorrectly or produced with poor quality control can actually instigate or worsen ICD. Glove failure can result in penetration, permeation, or contamination of hazardous materials, with irritation further compounded by the gloves' occlusive environment[69,70].

The establishment of appropriate educational prevention programs is essential. A project in Finland showed a significantly better outcome for employees with occupational hand dermatitis attending an "eczema school"-like clinic run by a specialized nurse compared with an unschooled control group[71]. Another study found that most occupational skin diseases responded to effective secondary preventive measures, combining employee medical treatment with exposure analysis-based individual and group training in preventive measures[72]. Education was important in making the employees aware of initial skin changes, such as slight erythema and scaling in the interdigital folds, indicating the need to optimize skin protection and care measures in order to prevent exacerbation and chronicity.

The goal of treatment is to restore normal epidermal barrier function. Topical corticosteroids are frequently used, but their efficacy has

been controversial, as experimental studies have provided conflicting results[73]. In one double-blind, vehicle-controlled study, statistically lower values of erythema and TEWL were observed in sites irritated by sodium lauryl sulfate after 7 days of treatment with betamethasone valerate[74]. Systemic corticosteroids, although potentially helpful in reducing acute inflammation, are not useful in the treatment of chronic ICD unless corrective measures are taken to avoid the offending contactants. Narrowband ultraviolet B or photochemotherapy (PUVA) irradiation may be considered for chronic dermatitis that does not respond to any other form of therapy. Hyperkeratotic palmoplantar dermatitis from frictional or chronic ICD or a combination of dermatitis and psoriasis may benefit from the adjunctive use of systemic retinoids such as acitretin and alitretinoin or systemic immunomodulators such as methotrexate, cyclosporine, and possibly targeted immunomodulatory (biologic) therapy[75].

Additional figures and tables on Causes of cheilitis in patients who were referred for patch testing, The Hand Eczema Severity Index (HECSI), and The modified Total Lesion Symptom Score (mTLSS) for hand eczema, available in our eBook (see inside front cover for access code).

THE HAND ECZEMA SEVERITY INDEX					
Clinical signs	**Location and intensity score**				
	Fingertips	*Fingers (except tips)*	*Palm of hands*	*Back of hands*	*Wrists*
Erythema	0–3	0–3	0–3	0–3	0–3
Infiltration/ papulation	0–3	0–3	0–3	0–3	0–3
Vesicles	0–3	0–3	0–3	0–3	0–3
Fissures	0–3	0–3	0–3	0–3	0–3
Scaling	0–3	0–3	0–3	0–3	0–3
Edema	0–3	0–3	0–3	0–3	0–3
Intensity sum (range)	0–18	0–18	0–18	0–18	0–18
Extent score of clinical symptoms (Ex)	0–4	0–4	0–4	0–4	0–4
Total HESCI Score =	Intensity sum × Ex +	Intensity sum × Ex +	Intensity sum × Ex +	Intensity sum × Ex +	Intensity sum × Ex

eTable 15.2 The Hand Eczema Severity Index (HECSI). The HECSI evaluates hand eczema severity based on 6 clinical signs and 5 locations. Each location is given a score from 0 to 3 for the *intensity* of clinical symptoms, graded on the following scale: *0, no skin changes; 1, mild disease; 2, moderate; and 3, severe*. For each location (in consideration of both hands) the affected area is given a score from 0 to 4 for *extent* of clinical symptoms (*0 = 0%; 1 = 1%–25%; 2 = 26%–50%; 3 = 51%–75% and 4 = 76%–100%)*. The score given for the extent for each location is multiplied by the total sum of the intensity of each clinical feature. The total score ranges from 0 to a maximum severity score of 360. A composite HECSI score of 0 to 11 corresponds to mild disease; scores of 12 to 27 correspond to moderate disease; scores of 28 or more correspond to severe disease. *Adapted from Held E, Skoet R, Johansen JD, Agner T. Occupational Dermatoses 16

S. Mark Wilkinson and Faheem Latheef

INTRODUCTION

Given the diverse occupations that people pursue, there are thousands of chemicals and other potentially noxious insults that can impinge on the skin in many different ways[1]. Traditionally, the types of hazardous exposure are categorized as:

- mechanical – friction, pressure, vibration, mechanical disruption
- chemical – elements and chemical compounds (organic, inorganic, and proteins)
- physical – heat, cold, radiation (UV and ionizing)
- biological – organisms including viruses, bacteria, fungi, and parasites.

The types of dermatoses induced by exposure to these noxious occupational hazards can be grouped as outlined in Table 16.1. This chapter differs from most of the others in that it deals with diverse conditions, many of which are also covered in detail in specific chapters.

HISTORY

Occupational disease has existed for thousands of years. Hippocrates (c460–377 BCE) hypothesized that there were environmental causes of disease. One of the first written descriptions of occupational dermatoses was by the Italian Bernardino Ramazzini (1633–1714). He described diseases associated with a variety of occupations, including different types of ulcerations in fresh- and salt-water fishermen. During their long-distance voyages in the sixteenth century, Drake and Magellan experienced significant problems from scurvy due to the lack of vitamin C from fresh fruit and vegetables. In 1747, James Lind performed the first controlled trial demonstrating the protective effects of citrus fruits against scurvy. In 1795, the British Navy included lemon juice in ships' stores as one of the earliest forms of prevention for an occupational skin disease.

EPIDEMIOLOGY

In a UK household survey, a rate of occupational dermatosis of 15/10 000 for those who had ever been employed demonstrates the high frequency of affected individuals; in comparison, a rate of 5.1/10 000 has been reported by physicians in Denmark and Finland, where occupational disease is notifiable. Of the most common physical illnesses due to occupation, skin diseases (23%) rank second, after musculoskeletal disorders (45%)[2]. In the US in 2010 it was estimated that for private industry, the annual cost of occupational skin disease due to lost productivity, medical care, and disability payments was US$1.2 billion[3], and this accounted for 10.5% of the cost attributed to skin disorders from all causes. The average cost per claim for occupational dermatitis in the 1990s was US$3550 and the period of disability was 24 days[4]. More recently, the German statutory health insurance companies estimated the cost of hand eczema to be €9000 per case with an annual cost of €2128[1].

Based upon classification systems such as the International Standard Classification of Occupations (ISCO), the distribution of occupational skin disease reported by industry varies with the specialty of the physician (Fig. 16.1)[5]. The difference in incidence of neoplasia, as reported by dermatologists compared to occupational physicians, reflects the delay between exposure and development of disease and the fact that the majority of workers have left employment when the cancer develops. Differences in reporting also reflect the distribution of occupational health departments in industry: vehicle assembly, glass, and ceramic workers as well as scientific technicians are often seen by occupational physicians, whereas hairdressers, for example, are seen primarily by dermatologists. Over the past decade, there has been a consistent decline in the reported incidence of occupational dermatoses both in the US and in Europe[6].

THE OCCUPATIONAL DERMATOSES

Contact Dermatitis

Synonym: Contact eczema

Key features

- The most common causes of occupational *allergic* contact dermatitis are (in order of decreasing frequency): rubber, nickel, epoxy and other resins, and aromatic amines
- The most common causes of occupational *irritant* contact dermatitis are (in order of decreasing frequency): soaps, wet work, petroleum products, solvents, and cutting oils and coolants

Introduction

Contact dermatitis accounts for the majority of occupational skin disease that predominantly affects the hands. The prevalence of hand dermatitis in the population has been estimated at ~0.5%, rising in some studies to 10% when an industrial workforce has been examined. While most individuals will remain at work, over half will change jobs and a large proportion will be absent from work for a month or more.

History

In the first century CE, Pliny the Younger recorded dermatitis in individuals after they cut down pine trees, presumably representing allergic contact dermatitis to colophony in pine resin. Ramazzini in his 1700 treatise described irritant contact dermatitis of the hands and forearms in soap and laundry workers.

Epidemiology

An age-related increase in rates of occupational dermatitis is seen in men, but in women the peak age of incidence is 16–29 years with a decline thereafter. However, a comparison of rates by age within specific occupational groups suggests that the sexes follow a similar pattern. Among chefs and cleaners of either sex, higher rates are seen in young workers, whereas rates among machine tool operators increase with age, reflecting the type of occupational exposure. Materials giving rise to contact dermatitis in the United Kingdom (UK) are shown in Fig. 16.2, and the highest risk UK occupations in Fig. 16.3[7]. In contrast to the UK, in Finland and the US, the highest rate of skin disease is among agricultural workers.

Pathogenesis

The initial events of both irritant and allergic contact dermatitis (see Chs. 14 & 15) are similar. Depending upon the severity of the insult, the tissue response can reach a level at which it becomes clinically apparent as cutaneous inflammation (Fig. 16.4). If tissue perturbation is maintained via repeated insults, then chronic dermatitis ensues, while an early withdrawal of the insult may result in healing.

Clinical features

Contact dermatitis, both allergic and irritant, is morphologically indistinguishable from endogenous eczema (Fig. 16.5). Although most cases of dermatitis will result from direct exposure that leads to localized

CLINICAL CLASSIFICATION OF OCCUPATIONAL DERMATOSES
Contact dermatitis • Irritant - chemically induced - photoinduced - mechanical • Allergic
Chemical burn
Contact urticaria
Cancer • Sunlight/UV-induced • Ionizing radiation-induced • Chemically induced
Follicular disease • Acne • Folliculitis • Chloracne
Autoimmune connective tissue disease • Systemic sclerosis (silica; see Ch. 43) • Scleroderma-like (vinyl chloride, organic solvents; see Ch. 43) • Vibration-induced
Pigmentary disorders • Hypopigmentation (see Ch. 66) • Hyperpigmentation (see Ch. 67)
Foreign body reactions (see Ch. 94)
Infection • Viral • Bacterial • Fungal • Parasitic

Table 16.1 Clinical classification of occupational dermatoses.

dermatitis, there are other routes of absorption that can lead to dermatitis. In the case of solvents, inhalation may result in widespread dermatitis, often with systemic involvement.

Diagnosis of an occupational cause is dependent on a thorough dermatologic and occupational history (Table 16.2), combined with

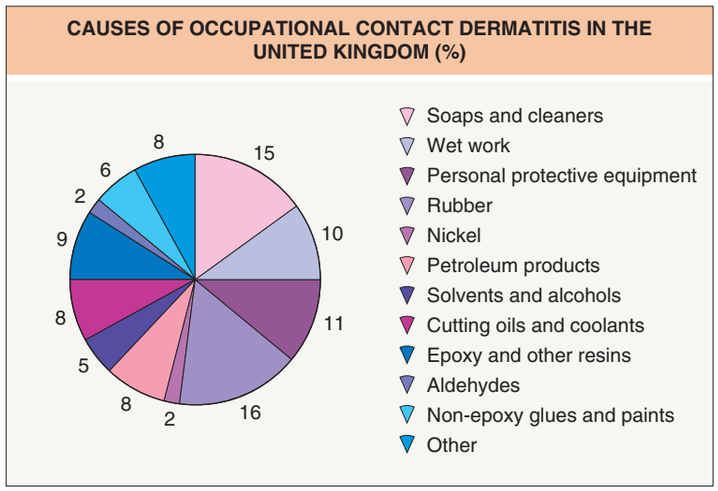

Fig. 16.2 Causes of occupational contact dermatitis in the United Kingdom (%).

examination of the entire skin. Material safety data sheets (MSDS) provide a guide to the nature of materials handled at work. They list the chemical composition and the hazards associated with the product, e.g. irritant, corrosive, contains a sensitizer. However, total reliance should not be placed on the MSDS as they may not list all ingredients of relevance, and communication with the manufacturer may prove helpful. When occupational dermatitis is suspected but a cause cannot be established from the history, a workplace visit may prove invaluable and may also elucidate the source of an allergen previously detected via patch testing.

Although the primary site is usually the hands, spread to *adjacent* areas of skin (even without primary contact) is relatively common. Spread to *distant* sites, such as the face and feet, is more frequently seen in allergic contact dermatitis than in irritant contact dermatitis. Notably, airborne allergens, e.g. from paint sprayers, can lead to a pattern of dermatitis that suggests this type of exposure. Covered areas such as the trunk and feet are unusual sites of onset of disease. Improvement of the dermatitis during periods away from work is an important clue to an occupational cause, but it should be remembered that endogenous eczema may also be exacerbated by workplace exposures. As the dermatitis becomes chronic, the relationship between work and exacerbations becomes less clear-cut.

Occupational contact dermatitis

Occupational contact dermatitis can be either irritant or allergic. Personal protective equipment (PPE) is defined as equipment that protects the wearer's body against health/safety risks at work. Although it is designed to help reduce the incidence of contact dermatitis at work, in some cases PPE itself can cause contact dermatitis. Hand dermatitis due to gloves is the most common PPE-related dermatitis, but non-glove exposures also occur[8]. Dermatitis associated with the use of face masks during the recent SARS-CoV-2 pandemic would be a prime example[9].

Allergic contact dermatitis (see Ch. 14)

Patch testing is essential for establishing the diagnosis and should be performed in any individual with a dermatitis that may be work-related or for whom a change of job is being contemplated. Testing with work materials is essential (Table 16.3) if contact allergy is not to be missed, as not all allergens are commercially available and the MSDS may not disclose all relevant ingredients. A guide to testing 5200 chemicals has been published[10]. When a reaction occurs to an unknown substance, the use of a dilutional series and the testing of ~20 controls can confirm that the reaction is allergic rather than irritant.

In an extensive surveillance report, the most common causes of occupational allergic contact dermatitis were rubber (23.4% of cases), nickel (18.2%), epoxy and other resins (15.6%), aromatic amines (8.6%), chromate (8.1%), fragrances and cosmetics (8.0%), and preservatives (7.3%)[7]. Recently, the more frequent use of long-lasting artificial nails has led to an increase in allergic contact dermatitis due to methacrylates in occupationally exposed, and sensitized, nail technicians[11].

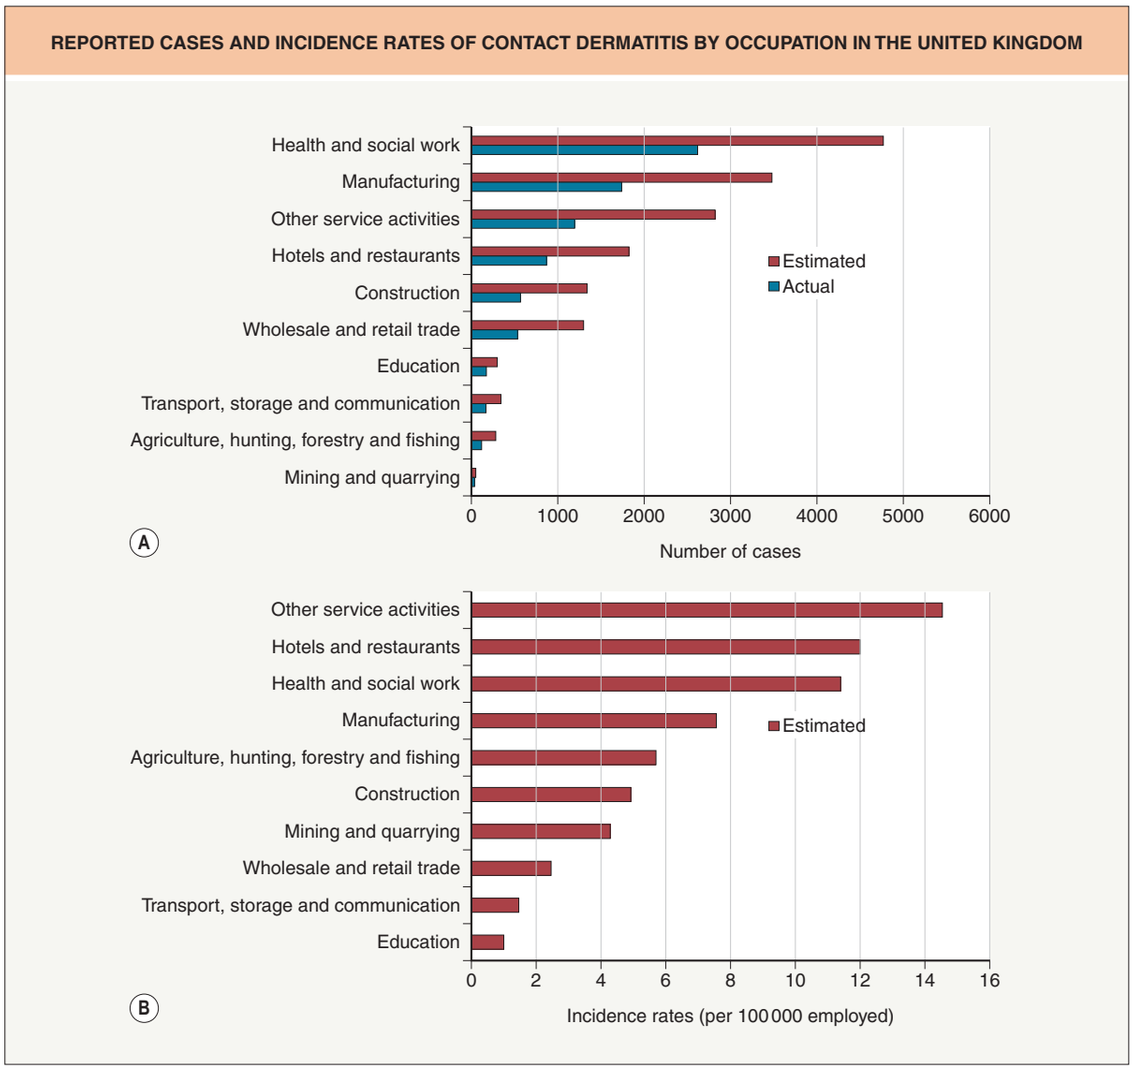

Fig. 16.3 Reported cases and incidence rates of contact dermatitis by occupation in the United Kingdom. A Actual and estimated cases of contact dermatitis, with crude data adjusted for sampling bias. **B** Contact dermatitis incidence rates (per 100 000 employed); crude data were adjusted for the size of the labor force by utilizing the labor force survey data (2002–2009) as the denominator. *Courtesy The Health and Occupation Research (THOR) network of the Centre for Occupational and Environmental Health (COEH) of the University of Manchester, UK.*

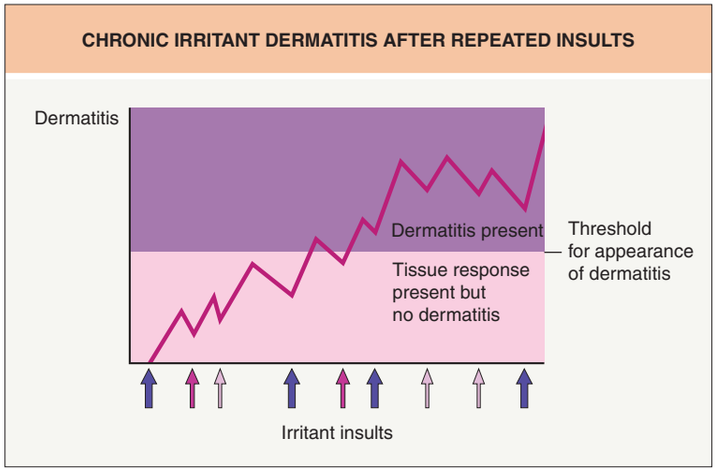

Fig. 16.4 Chronic irritant dermatitis after repeated insults. Initial subclinical response to tissue perturbation by an irritant becomes manifest as chronic irritant dermatitis after repeated insults. Each arrow represents an irritant insult of different intensity.

Fig. 16.5 Hand of a builder who presented with a dyshidrotic (pompholyx) pattern of eczema. Investigation demonstrated allergic contact dermatitis to chromate found in cement and contact urticaria to latex in the gloves he was using for hand protection.

POINTS TO CONSIDER WHEN TAKING AN OCCUPATIONAL HISTORY	
Primary (initial) site of disease • Time course	In 90%, it is the hands Is this consistent with work exposure as a cause? Does time off result in improvement?
Materials handled • Labels and material safety data sheets (MSDS) • Other persons affected • Protection provided	Irritant, corrosive, or sensitizing Suggests an irritant contact dermatitis Is it appropriate? Is there an allergy to personal protective equipment?
Previous skin disease or history of atopy	Is this a recurrence of a previous problem?
Known allergies	Is there unrecognized exposure?
Treatment	May cause allergic contact dermatitis
Hobbies	May be a more likely cause than occupation

Table 16.2 Points to consider when taking an occupational history.

Irritant contact dermatitis (see Ch. 15)

Most occupational dermatitis results from repeated exposures to weak irritants which cause cumulative damage to the skin (see Fig. 16.4). On the other hand, strong irritants are usually recognized and protection provided. Employees with previous atopic dermatitis, especially with hand involvement, are particularly at risk, as are those with mutations in the filaggrin gene[12].

Soaps (22% of cases), wet work (20%), petroleum products (9%), solvents (8%), and cutting oils and coolants (8%) are the most frequently cited causes of occupational irritant dermatitis[7].

Chemical burns

A chemical burn is an acute irritant reaction in which the injury to the skin is irreversible and cell death occurs. It can occur following a single exposure. Initial symptoms consist of burning and stinging with progressive development of erythema, blisters, erosions, and ulceration (see Fig. 15.2). Symptoms usually develop in close association with the exposure, but some chemicals, such as phenols and weak hydrofluoric acid, can have a delayed onset. Common occupational causes include[13]:

- **strong acids:** e.g. sulfuric, nitric, hydrochloric, chromic. Most coagulate skin proteins and as a result form a barrier that impedes further penetration. Hydrofluoric acid differs in that it causes a liquefactive necrosis: penetration, even down to bone, can continue for several days after exposure. Pain, which can last several days, is typical of hydrofluoric acid and other fluorides. If more than 1% of the body surface area is affected, systemic toxicity can develop
- **strong alkalis:** e.g. sodium, calcium, and potassium hydroxides; wet cement (Fig. 16.6); sodium and potassium cyanides. Degradation of lipids and saponification of the resulting fatty acids form soaps which aid the penetration of alkalis deeper into the skin. As a consequence, damage is more severe than with most acids (apart from hydrofluoric acid) and pain is also a feature
- **organic and inorganic chemicals:** e.g. dichromates; arsenates; phenolic compounds. Phenols and unhardened phenolic resins easily penetrate the skin. Nerve damage may cause anesthesia, but rarely in the absence of visible skin damage. Vasoconstriction may contribute to the necrosis that develops and following systemic absorption, shock and renal damage may ensue
- **solvents and gases:** e.g. acrylonitrile; ethylene oxide; carbon disulfide; mustine. Ethylene oxide gas is used to sterilize medical instruments, textiles, and plastic materials, and it can remain on these items for several days if not allowed to evaporate off prior to use. The possibility of exposure may therefore not be obvious.

SUGGESTED CONCENTRATIONS FOR PATCH TESTING SELECTED WORK MATERIALS		
Sample	**Dilution**	**Occupation(s)**
Personal care products		
• Leave on	As is	Hairdresser/beautician
• Wash off	1%–5% aqueous or open*	Hairdresser/beautician
Plants†		
Bulb, leaf, flower	As is	Gardener/florist Agriculture/vegetable processing
Woods – sawdust	As is/10% petrolatum	Joiner/woodworker
Dyes (clothing)	1% petrolatum	Textiles
• Cloth	As is – moistened	
Foods‡	As is	Catering/chef
Glue	10% aqueous/ petrolatum	Various
• Methacrylate monomer	1% petrolatum	Dentist/orthopedic surgeon
• Acrylate monomer	0.1% petrolatum	
• Epoxy resin	1% petrolatum	Painter – 2-part paints
• Epoxy hardener	0.1% petrolatum	
Ink	As is	Printing
• UV cured	1% petrolatum	
Oil		
• Cutting (coolant) – water miscible	10% aqueous or open	Metal machining
• Lubricant – immiscible with water	As is	Various-use machinery
Paint	10% aqueous/ petrolatum	Painter/decorator
Photographic chemicals	10% aqueous	Photographer
Solvents/thinners	10% acetone	Various

*Open test: apply the substance to a 3 cm diameter area of skin and allow to dry. Read as normal but do not occlude.
†Do not test unless the plant has been identified and is recognized not to be an irritant. There may be a risk of sensitization.
‡Prick testing is essential to exclude contact urticaria.

Table 16.3 Suggested concentrations for patch testing selected work materials. This is a guide only: the final decision must always be made in light of the information available in relation to the suspected material. Tests are usually performed on the upper back.

Fiberglass dermatitis

Glass fibers are subdivided into various types, depending on fiber diameter, and are used for their insulating (thermal, acoustic, and electrical), strengthening, and filtering abilities. They are chemically inert and the mechanism of skin injury is via direct penetration, which is directly proportional to the diameter (>3.5 microns) of the fiber and inversely proportional to its length. Histologically, eczematous changes including spongiosis are seen. Occasionally, granulomatous dermatitis is seen with birefringent fibers visible in polarized light.

Pruritus and tingling are the usual initial symptoms of fiberglass dermatitis. Subsequently, erythematous papules develop (often with follicular accentuation), either on exposed areas when there is airborne exposure or on the forearms when there is contamination of a work surface (Fig. 16.7)[14]. Contamination of clothing leads to involvement of sites where there is close contact with the skin, particularly flexural areas. Paronychia is common, and airborne exposure may also cause burning eyes, sore throat, and cough.

The diagnosis is often based on clinical findings, but can be confirmed by detecting the glass fibers either by tape stripping affected skin or by examining skin scrapings in 20% potassium hydroxide. The dermatitis resolves rapidly after cessation of exposure. In most individuals, hardening occurs and symptoms resolve over a few weeks despite continued

Fig. 16.6 Cement burns. Ulcerations on the fingertips of a construction worker exposed to wet cement. *Courtesy P. J. Coenraads, MD.*

Fig. 16.7 Fiberglass dermatitis. Multiple pruritic pink papules at the site of exposure.

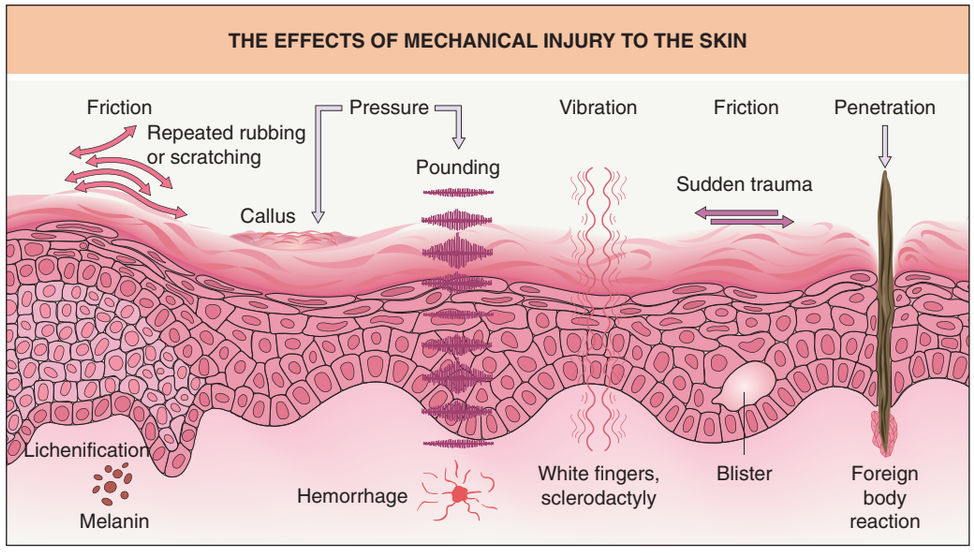

Fig. 16.8 The effects of mechanical injury to the skin. Both friction and pressure lead to callus formation. *Adapted from Adams RM. Occupational Skin Disease, 3rd ed. Philadelphia: WB Saunders, 1999:36.*

exposure; of note, the use of resins to bind glass fibers can result in an allergic contact dermatitis.

Phototoxic eruptions (see Ch. 87)

Most occupational photosensitivity is phototoxic in nature and resolves with hyperpigmentation. The most common scenario consists of outdoor workers exposed to plant-derived psoralens. This may result from direct contact or be airborne as in "strimmer" dermatitis when plant sap splatters the body of a worker inadequately protected when cutting down plants (see Ch. 17).

Coal tar and its products, including creosote, can cause a reaction known as tar/pitch smarts. A burning or stinging sensation develops after as little as 15 minutes of sun exposure.

Mechanical

Occupational marks are usually areas of lichenification or calluses and corns that develop at sites of friction and are specific to a particular job (Fig. 16.8). Mechanical injury to the skin is also thought to cause dermatitis analogous to irritant chemical damage. It may result in a keratotic hand dermatitis or post-traumatic eczema (Koebner phenomenon).

Pathology

The histopathologic features of allergic contact dermatitis and irritant contact dermatitis are discussed in Chapters 14 and 15, respectively.

Differential diagnosis

The etiology of occupational dermatitis is frequently multifactorial and coexisting endogenous eczema may contribute to the clinical appearance. Tinea manuum may resemble hand dermatitis, especially following treatment with topical corticosteroids, and scabies infestation of the interdigital spaces can simulate irritant dermatitis. Rarely, blistering of the dorsal hands due to porphyria cutanea tarda is misconstrued as contact dermatitis.

Psoriasis frequently affects the palms, resulting in keratotic plaques, sometimes with fissures. This can be difficult to distinguish from dermatitis when there are no lesions elsewhere. Furthermore, psoriasis may be exacerbated by repeated, work-related trauma leading to Koebner phenomena. Nail involvement and plaques over the interphalangeal joints are helpful clues.

Treatment

Occupational disease prevention is divided into primary, secondary, and tertiary measures (Table 16.4)[15]. During pre-employment screening, a history of severe childhood atopic dermatitis, particularly with hand involvement, indicates an individual at risk of developing dermatitis from exposure to irritants. Employment in a "dry" job should be recommended. In the workplace, the use of PPE and skin care preparations should be encouraged (Table 16.5). Use of protective creams prior to exposure may aid in the subsequent removal of irritants and application

HIERARCHY OF OCCUPATIONAL DISEASE PREVENTION	
Primary prevention	Avoid disease onset • Engineering measures • Chemical substitution • Workforce education in skin care
Secondary prevention	Detect presymptomatic or early disease • Health surveillance
Tertiary prevention	Treatment of active disease • Avoidance measures • Medical management

Table 16.4 Hierarchy of occupational disease prevention.

GUIDELINES AIMED AT PREVENTING CONTACT DERMATITIS		
Advice		**Explanation**
Do not wear rings		• Chemicals/water accumulate underneath
Hand washing	• Use lukewarm water and dry thoroughly	• Skin damage from detergent is reduced at a low temperature • Dermatitis often begins at sites that are missed, e.g. fingerwebs
Wear gloves	• For wet work	• Wet work is the major risk factor for contact dermatitis
	• For as short a time period as possible	• Glove occlusion also damages the skin
	• With a cotton inner liner if prolonged exposure	• Liners absorb moisture and reduce irritation
	• That are dry, clean, and intact	• Occlusion of chemicals inside gloves increases irritancy
Use moisturizer	• Frequently throughout the day	• Encourages barrier repair
	• To the whole hand	• Need to include web spaces
	• That is fragrance-free and preservative-free	• Prevents sensitization and development of ACD to common allergens
For antisepsis	• Use alcohol gel	• Less irritating than soaps or antiseptic detergents
Follow the same advice at home		• Domestic exposures are additive

Table 16.5 Guidelines aimed at preventing contact dermatitis. ACD, allergic contact dermatitis.

of emollients throughout the day may prevent the development of dermatitis. Education of the workforce in skin care has been shown to reduce the development of skin disease[16].

Treatment is discussed in Chapters 14 and 15. The most important aspect, however, is avoidance of the cause. Ideally, a change in the production process may avoid the need for exposure, but this may not be feasible. A practical compromise is the use of PPE and/or substitution of a particular chemical. Advice on appropriate glove type may be found on the MSDS or from glove manufacturers (e.g. www.ansellpro.com). Gloves need to be replaced regularly and each particular type of glove will have a penetration time for any given chemical. For example, acrylate glues (orthopedic surgeons, dentists), the hair dye para-phenylenediamine (hairdressers), and "acid perm" solutions containing glycerol monothioglycolate (hairdressers) rapidly penetrate latex gloves.

Initial treatment of chemical burns requires irrigation with large volumes of water. When the chemical is insoluble in water, a soap solution may be used instead. High pressures should not be used, in order to avoid splashing other areas of the body or bystanders with the corrosive material. For some chemicals, specific antidotes can then be used, e.g. 2.5% calcium gluconate gel for hydrofluoric acid; reduction of pain is a sign of successful treatment. When there is a risk of toxicity from systemic absorption, as with chromic acid, early debridement of necrotic areas reduces blood levels.

Several chemicals (e.g. hydrofluoric acid, phenolic compounds, chromic acid, gasoline) carry a significant risk of systemic toxicity even when the area of skin involved is small (~1% of body surface area). In these instances, regular monitoring of blood, liver, and kidney function plus appropriate supportive treatment (e.g. dialysis) is required. When the chemical is also a sensitizer, allergic contact dermatitis may subsequently appear on re-exposure to non-irritant concentrations, as burns and irritant dermatitis promote sensitization.

Once it has developed, the outlook for occupational contact dermatitis is poor[17], and patients frequently have persistent disease despite interventions. While a change of occupation is associated with a better prognosis, the possibility exists that the new workplace will have the same or similar chemical exposures. Prognosis is also worse when there is a contact allergy (delayed or immediate) to a chemical that is present in the domestic as well as the industrial environment. Some individuals (~10%) have persistent disease in the absence of any obvious cause, for which the term "persistent post-occupational dermatitis" has been coined.

Contact Urticaria

Synonyms: ■ Contact urticaria syndrome ■ Immediate contact reaction ■ Variant: protein contact dermatitis

Key features

- Pruritus and wheal-and-flare reaction
- Develops within 60 minutes of exposure and resolves within 24 hours
- The protein content of latex rubber is responsible for the associated contact urticaria
- In suspected cases of latex-induced contact urticaria, the specific IgE test may be negative, requiring prick testing with a commercial latex extract and a usage test

Introduction

Contact urticaria has been reported following exposure to a wide range of substances[18]. With regard to occupational skin disease, plant- and animal-derived proteins are recognized causes, especially among food handlers and agricultural, animal laboratory, and veterinary workers. In extreme circumstances, systemic symptoms (i.e. rhinoconjunctivitis, bronchospasm, and anaphylaxis) may be seen. With the introduction of universal precautions in the 1980s and increased use of natural rubber gloves, latex protein emerged as an important cause of contact urticaria, particularly in the healthcare setting.

History

Contact urticaria was first defined as a clinical entity during the 1970s but it had long been recognized.

Epidemiology

Based on official statistics, occupational causes of contact urticaria have been well classified in Finland[1]. The relative frequency of various urticants is shown in Fig. 16.9 and reflects the high prevalence of reactions in the farming community. The reactions to cow dander are probably the result of high exposure, as cattle are kept indoors from September to May/June. The prevalence varied from 140/100 000 for bakers to 2.1/100 000 for shop assistants and was higher in women, irrespective of occupation. Relative risk by occupation is shown in Fig. 16.10. The incidence of contact urticaria declines with age, and ~30% of individuals have coexistent contact dermatitis.

Pathogenesis

Contact urticaria is classified as either irritant/nonimmune-mediated or allergic/immune-mediated. An additional category includes those cases in which the mechanism is uncertain, exemplified by ammonium persulfate in hairdressing.

The mechanism of nonimmune contact urticaria is not well defined but involves the release of vasoactive mediators. It is inhibited by non-steroidal anti-inflammatory drugs but not by antihistamines, suggesting a role for prostaglandins. Symptoms develop in the majority of those exposed and are most often due to simple chemicals, e.g. sorbic acid.

Immunologic contact urticaria is mediated by allergen-specific IgE (see Ch. 18). Binding of antigen, usually protein, to mast cells in a previously sensitized individual results in degranulation and release of mast cell mediators, including histamine. Atopic individuals are at greater risk of this type of reaction.

Clinical features

Signs and symptoms range from nonspecific, i.e. pruritus, tingling and burning, to more typical urticaria with a wheal and flare, usually noted within 30 minutes of exposure at the site of contact. Resolution occurs within hours. Individuals with immunologically mediated urticaria[19] may also experience systemic symptoms with generalized urticaria, rhinoconjunctivitis, orolaryngeal and gastrointestinal symptoms, bronchospasm, and even anaphylaxis.

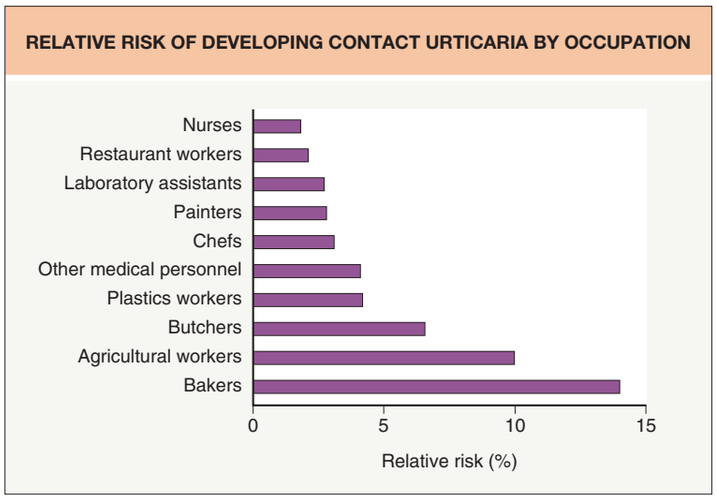

Fig. 16.10 Relative risk of developing contact urticaria by occupation. Based upon statistics from Finland. *Reproduced from Kanerva L, Elsner P, Wahlberg JE, et al. Handbook of Occupational Dermatology. Berlin: Springer Verlag, 2000.*

Foods

One of the more common causes of contact urticaria is foodstuffs, which can provoke either orolaryngeal symptoms when ingested or hand symptoms when handled (e.g. fish processors, slaughterhouse workers, individuals in the catering industry). There is a diverse range of responsible foods, including meats, fish, eggs, fruits, vegetables and flour, as well as associated enzymes such as α-amylase (found as an additive in flour). In Scandinavia, a strong association is seen between the incidence of birch pollen allergy and contact urticaria to fruits and vegetables, due to the presence of similar peptides. Birch pollen is a common aeroallergen in Scandinavia, whereas in the UK the most common aeroallergens are the house dust mite and grass pollen; this may explain why there are fewer reports of contact urticaria in food handlers in the UK. In the US, incidences of birch pollen allergy vary depending upon geographic region. If contact urticaria is confirmed, there are recognized cross-reactions between the various foodstuffs (Table 16.6)[20].

Latex

Contact urticaria to latex was first described in 1979. The term "latex" defines an aqueous dispersion of a rubber. The rubber obtained from latex by drying or coagulation is termed "latex rubber". Natural latex is derived from the sap of the tree *Hevea brasiliensis*. Natural latex contains polyisoprene (30%–40%) together with a variety of other plant chemicals, including proteins (2%).

After 1985, the demand for latex gloves for medical and dental use to prevent the transmission of infectious agents[21] more than doubled. Paralleling this rise in usage were reports of type I allergy to latex gloves. Occupational latex contact urticaria occurs more frequently in women, atopic patients (particularly those with hand eczema), and workers frequently exposed to latex gloves (e.g. hairdressers). Rates ranging from 3% to 16% have been reported among healthcare workers.

Most problems arise from items made by coating a mold with concentrated liquid latex, e.g. gloves, balloons, condoms. Nowadays, however, many gloves are manufactured by methods designed to leave lower levels of protein allergen in the final product. Latex that is allowed to dry before processing by compression molding or extrusion (e.g. syringe plungers, vial stoppers) causes fewer problems, due to degradation of the protein allergen during the manufacturing process. When latex protein is absorbed onto starch particles in gloves, it can become airborne and cause conjunctivitis, rhinitis, and asthma. Ideally, powder-free gloves should be used to avoid this risk.

In a subgroup of latex-sensitive patients, hypersensitivity reactions to bananas, avocados, chestnuts, kiwis and other fruits may also occur (see Table 16.6). Radioallergosorbent inhibition studies have shown that they contain a similar antigen. In some individuals, the primary

POTENTIAL CROSS-REACTIONS BETWEEN CAUSES OF CONTACT URTICARIA

Food/natural product	Risk (%)	Cross-reactions
Fruit (kiwi, avocado, banana)	10	Latex
Latex	35	Fruits (e.g. kiwi, avocado, banana)
A shellfish (e.g. crab)	75	Other shellfish (e.g. prawn, lobster)
A fish (e.g. salmon)	50	Other fish (e.g. swordfish, sole)
A grain (e.g. barley)	20	Other grains (e.g. wheat, rye)
A legume (e.g. peanut)	5	Other legumes (e.g. peas, beans, lentils)
Peach	55	Other Rosaceae fruit (e.g. apple, pear, cherry, plum)
Melon	90	Other fruits (e.g. watermelon, banana, avocado)

Table 16.6 Potential cross-reactions between causes of contact urticaria. If allergic to item in column 1, risk of cross-reacting with item in column 3.

sensitization is to the fruit, with latex sensitivity developing as a secondary phenomenon.

Common household sources of exposure to latex are gloves, balloons, latex contraceptives, latex mattresses and pillows, rubber bands, swimming caps, and baby pacifiers. The term "hypoallergenic glove" refers to latex gloves with reduced levels of accelerators and antioxidants (causes of allergic contact dermatitis); these gloves are not suitable for individuals allergic to latex (with immediate-type hypersensitivity).

Non-latex alternatives should be sought. Vinyl (PVC) gloves are suitable for home use. For those in the medical and dental professions, alternative gloves, typically nitrile (both sterile and non-sterile), are available from the major glove suppliers. Affected individuals should warn any doctor or dentist that they visit of their sensitivity so that measures can be taken to prevent a reaction. The most severe reactions have followed mucosal and parenteral exposures. Death has occurred following the use of a natural rubber latex cuff on a barium enema device and anaphylaxis after intraoperative, oral, or vaginal exposure to latex gloves. Use of a bracelet or necklace to alert medical professionals in the event of an emergency has been advocated.

Low-molecular-weight chemicals

Although rare, these chemicals can be important causes of occupational contact urticaria in the industrial setting. Some are also potential causes of occupational asthma. The diagnosis may prove difficult to establish because skin testing may require conjugation of the low-molecular-weight chemical with protein to form the allergen. Chemicals (and industries) associated with contact urticaria include: antibiotics (pharmaceutical industry); ammonium persulfate and para-phenylenediamine (hairdressing); phthalic anhydrides, epoxy resin systems, and polyfunctional aziridines (plastics and glue industry); and reactive dyes (textile workers).

Protein contact dermatitis

The term "protein contact dermatitis" was originally used to describe an eczematous reaction to protein-containing material in food handlers (see Table 12.5). The reactions were both allergic and non-allergic, although many had a positive prick test or the presence of specific IgE antibodies, implying an IgE-mediated mechanism. In some, positive patch tests pointed to the coexistence of delayed-type hypersensitivity. The clinical picture is usually that of a chronic eczema with episodic exacerbations following contact with the allergen[22].

Pathology

The histologic findings of contact urticaria are described in Chapter 18.

Differential diagnosis

After a detailed history and clinical examination, skin testing may be performed to confirm the diagnosis of contact urticaria. When the patient has experienced anaphylactic symptoms and a specific IgE test is available, the blood test may confirm the diagnosis, avoiding the risk of anaphylaxis as a result of skin testing. Skin testing should be performed with appropriate positive and negative controls. With an unknown allergen, exposure should be graded; an initial application test (open and subsequently occluded) is followed by a prick test and, if necessary, an intradermal test. If the patient has a positive test, control individuals should be tested; a positive response in the latter group points to the presence of a nonimmune contact urticant. While commercial allergen extracts are available, it should be remembered that, unless adequately standardized, they may not contain the relevant protein allergens, resulting in a false-negative test result. The gold standard for testing is a sample of fresh material. Skin tests should only be performed where resuscitation facilities are available.

In the case of latex, the specific IgE blood test is not sensitive and a negative test does not exclude the diagnosis (Fig. 16.11). While skin tests with glove extracts have been recommended, many gloves now contain low levels of latex protein and prick testing with these homemade extracts frequently leads to false-negative results. Prick test solutions of latex are commercially available, some of which claim >98% sensitivity and 100% specificity (Fig. 16.12). If a particular glove type appears to elicit symptoms, a so-called "prick to prick" test can be used: the suspected item itself is pricked with the lancet, after which the patient's skin is pricked with the antigen-"contaminated" lancet. The final arbiter is a usage test in which a patient wears the suspect glove on a moistened hand and is observed for any reaction.

In the absence of a latex allergy, localized symptomatic dermographism is a common cause of urticaria to gloves. Lastly, a proportion of individuals who have reactions to gloves have symptoms caused by irritation.

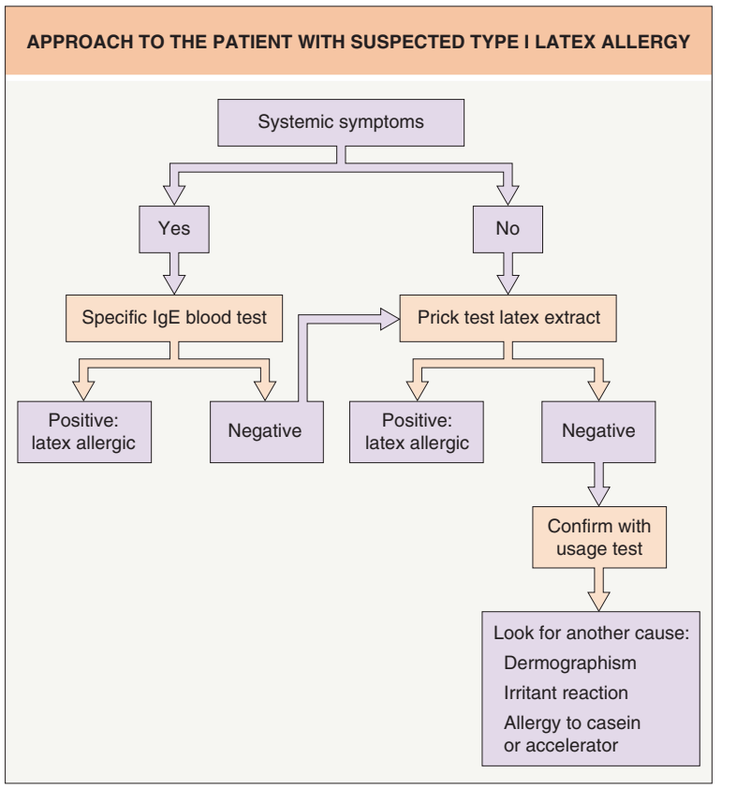

Fig. 16.11 Approach to the patient with suspected type I latex allergy. IgE-mediated immediate hypersensitivity is detected by prick tests, whereas delayed-type hypersensitivity, which manifests as allergic contact dermatitis, is detected by patch testing. In the open usage test, the patient wears the suspect glove on a moistened hand.

Fig. 16.12 Positive prick test with a commercial latex extract (L). Histamine (H; 10 mg/ml) and saline (C) controls are appropriately positive and negative. The histamine-positive control confirms that the effects of previous medications (including antihistamines) are no longer an issue and the negative control assesses for dermographism. When a standardized allergen is available for a prick test, a small drop is placed on the skin and the skin is pierced with a special lancet with a 1 mm tip. Surplus allergen is blotted off and a fresh lancet is used for each test substance to prevent cross-contamination. Reactions develop over 15 minutes and a wheal 3 mm larger than the negative control is considered positive.

Treatment

Management consists of avoidance, as desensitization for the majority of involved allergens is not available. Avoidance may be achieved by improved occupational hygiene and the use of PPE, but in extreme circumstances may necessitate a change of occupation. Treatment of the acute episode includes the use of systemic antihistamines and epinephrine (adrenaline), depending on the severity of the attack.

In the case of latex, the use of powder-free gloves containing low levels of protein has been shown to prevent the development of latex hypersensitivity by reducing the level of exposure in the at-risk population. There has also been a movement in healthcare facilities to use non-latex gloves.

Occupational Skin Cancer

Key features

- A skin cancer in which occupation has played a major etiological role
- In the workplace, the most important exposures are UV radiation, ionizing radiation, and carcinogenic chemicals (e.g. polycyclic hydrocarbons)

Introduction

Occupational skin cancers[23] have been estimated to account for <1% of all skin cancers. In a study of workers exposed to coal and diesel combustion products, the relative risk for developing non-melanoma skin cancer was 1.5%[24]. The tumor most frequently associated with occupational chemical exposure is squamous cell carcinoma (SCC).

History

The first association between occupation and cancer was made in 1775. Sir Percivall Pott, a surgeon at St Bartholomew's Hospital in London, described the occurrence of scrotal cancer in chimney sweeps. The carcinoma was often preceded by keratotic lesions known as soot warts. In 1873, von Volkmann described skin cancers from exposure to the distillation products of tar and pitch.

In the early 1800s, inorganic arsenic was associated with skin cancers, especially of the scrotum in smelter workers, but also from exposure in the mining industry and in users of end products (e.g. sheep dip). In the early twentieth century, ionizing radiation was recognized as a cause of radiodermatitis followed by skin cancer, particularly of the hands of medical workers administering radiotherapy.

Epidemiology

As carcinogens have become recognized and limits on occupational exposure introduced, solar UV exposure has risen to account for ~95% of cases of occupational skin cancer reported in the UK. In Australia, the most common cause of compensated occupational cancer (of all types) was UV exposure (22%), followed by asbestos (21%)[25]. It was estimated that 34 000 cases of non-melanoma skin cancer per year and 4% of cases of cutaneous melanoma in men were attributable to occupation. Recently, in Germany, actinic keratoses (AKs) and cutaneous SCCs were recognized and compensated as occupational diseases, provided in the case of AKs they cover at least 4 cm^2 or ≥5 separate AKs develop each year[26]. The SCCs must arise in sun-exposed skin and the worker must have been occupationally exposed to an additional 40% more UV than that of an indoor worker, e.g. at age 50 the worker would have to have spent 15 years in an outdoor occupation.

Occupations at high risk of occupational skin cancer include:

- outdoor workers, especially in agriculture and construction industries, and welders (UV exposure). Squamous cell carcinoma occurs with an odds ratio (OR) of 1.77 (95% confidence interval [CI] 1.40–2.22; p<0.001) and basal cell carcinoma with an OR of 1.43 (95% CI 1.23–1.66; p=0.0001) amongst outdoor workers[27]
- workers exposed to polycyclic hydrocarbons (e.g. tars, pitches, oil fractionation products); in addition to direct skin contact, fumes may be inhaled
- workers exposed to arsenic in glass production, copper, zinc or lead smelting, and the production of pesticides, herbicides, and semiconductors
- radiologists, dentists, X-ray technicians, and those who work with radioactive materials (ionizing radiation).

Pathogenesis

The major carcinogenic hazards include UV radiation, ionizing radiation, and carcinogenic chemicals. Occupationally induced cancers are not pathologically different from those which arise spontaneously. However, the former tend to occur at an earlier age than spontaneous tumors at the same anatomic site. They arise following repeated or continuous exposure to the carcinogen, and there is a long latency period between the exposure to the carcinogen and appearance of the tumor which can make it difficult to attribute causation.

There are two major classes of chemical carcinogens: (1) polycyclic aromatic hydrocarbons including benzo(a)pyrene; and (2) aromatic amines such as dichlorobenzidine, an intermediate in the dyestuffs industry. For many compounds, carcinogenic mechanisms are not well understood.

The molecular pathogenesis of UV radiation is discussed in Chapters 86 and 107.

Clinical features and diagnosis

In evaluating a patient with suspected UV-related occupational skin cancer, a careful history is required to establish the relative contributions of work and leisure exposure. The final judgment is essentially clinical.

With polycyclic aromatic hydrocarbons, a variety of skin changes may precede the development of cancer and aid in the clinical diagnosis. Associated changes include (in order of development) erythema and burning, folliculitis, poikiloderma, and keratotic papillomas (tar warts) within the poikilodermatous skin. The verrucous tumors may then develop into SCC, although basal cell carcinomas and keratoacanthomas also occur.

The clinical features and diagnosis of these cutaneous malignancies are discussed in detail in Chapters 108 and 113.

Pathology and treatment

The pathology and treatment of skin cancers are discussed in detail in Chapters 108 and 113.

Occupational Acne

Key features

- Open and closed comedones
- Non-inflamed nodules and cysts
- Inciting factors include exposures to oils, halogenated polycyclic hydrocarbons, and repeated frictional trauma

Introduction

Occupational acne is a form of acne resulting from various chemical exposures as well as environmental and physical factors. Chloracne is a rare acne-like skin condition caused by certain toxic chemicals and is a cutaneous sign of systemic exposure.

History

Chloracne was first reported in 1897. In 1949, the first descriptions of human exposure to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD)-contaminated chemicals were reported after a trichlorophenol reactor explosion in Nitro, West Virginia, USA. The majority of health effects have been reported among groups with high exposure, including occupational populations such as chemical production workers, pesticide applicators, and individuals who handled or were exposed to materials treated with 2,3,7,8-TCDD-contaminated pesticides. In addition, residents of communities contaminated with tainted waste oil (Missouri, USA) and industrial effluent (Seveso, Italy) have been affected[28]. During the Vietnam War, chloracne in US troops was ascribed to exposure to the defoliant Agent Orange. More recently, dioxin poisoning was implicated in the development of chloracne in the Ukrainian President Viktor Yushchenko.

Epidemiology

Oil acne is the most common form of occupational acne.

Pathogenesis

Continued exposure to oils results in reactive hyperkeratosis and subsequently follicular occlusion with typical manifestations of acne vulgaris.

Chloracne is caused by exposure to certain halogenated polycyclic hydrocarbons such as polychlorinated dibenzodioxins (PCDDs) and dibenzofurans (PCDFs)[29], which are most often found in fungicides, insecticides, herbicides, and wood preservatives. It occurs within 2 months of exposure to chloracnegens and can persist for years despite cessation of exposure. The condition is always a sign of systemic exposure to the causal agent(s), but entry may occur via percutaneous absorption as well as from inhalation or ingestion of the chemicals. After exposure of workers in a large chemical factory to hexachlorobenzene[30], blood levels in those with chloracne were compared to the levels in workers without chloracne. In the chloracne group, blood levels ranged from 1168 to 22 308 pg/g blood lipid. In the exposed but chloracne-free group, the range was from 424 to 662 pg/g. It was concluded that chloracne developed at blood levels between 650 and 1200 pg/g.

Clinical features

Oil acne and tar acne

Contact with acnegenic substances, such as creosote, oils and greases, can worsen existing acne. Oils used in industry, such as cutting oils (paraffin/oil mixtures), tars (pitch and creosote), and crude petroleum oils such as diesel oil, can all cause acne. Lesions may develop both in the usual sites for acne and in unusual sites, including beneath clothing that is saturated with oils (e.g. arms, abdomen). Oils mists can also induce acneiform eruptions.

Acne mechanica

Acne mechanica is a form of acne, usually inflammatory, that is exacerbated by repeated frictional trauma that occludes the follicle. It is localized to sites of pressure, e.g. the back in long-distance drivers, the neck in violinists, the chin in football players who wear helmets with chin straps, the face from mask-wearing during the SARS-CoV-2 pandemic[9].

Acne cosmetica

Certain cosmetic ingredients used by models and thespians, e.g. lanolin, petrolatum, some vegetable oils, can induce comedo formation.

Chloracne

Chloracne is distinguished from ordinary acne vulgaris by the predominance of open (over closed) comedones and a concentration of lesions over the malar crescent and behind the ears (Fig. 16.13). The first sign of chloracne may be excessive oiliness of the skin. This is accompanied or followed by the appearance of numerous open comedones. In mild cases, open comedones may be limited to the area around the eyes, extending across the temples to the ears. In more severe cases, they may appear more extensively on the body, especially in the malar region, other facial areas, behind the ears, and on the arms. The open comedones are usually accompanied by fluid-filled cysts and by an increased or darker growth of body hair.

As the disease progresses, milia form together with distinctive yellowish epidermoid inclusion cysts (some of which may become inflamed) on the face, behind the ears, and on the neck, buttocks, scrotum, and thighs. Some authors have proposed using the term "metabolizing acquired dioxin-induced skin hamartomas" for these dioxin-induced cysts[31]. The skin may become thicker and hyperpigmented and it may desquamate or peel. In severe cases, ulcerations and permanent scars appear. Chloracne fades slowly after exposure. Minor involvement may disappear altogether, but more severe disease may persist for years. This disorder is difficult to treat and can last for long periods without known additional exposure to chloracnegens.

In addition to conjunctivitis and "ophthalmic acne", there may be systemic manifestations including altered liver function (elevated transaminases), headaches, and peripheral neuropathy.

Acne due to halogens

Chemicals that contain iodides, bromides, and other halogens can induce an acneiform eruption similar to that due to corticosteroids (see Chs. 36 and 125); however, the iodide-induced eruptions (i.e. iododerma) may be more severe. Patients with bromoderma may also have lesions that resemble pyoderma gangrenosum.

Fig. 16.13 Chloracne. Note involvement of retroauricular skin with numerous comedones (primarily closed) and cysts. The clinical differential diagnosis includes folliculotropic mycosis fungoides.

Pathology

Histopathologic features of comedones are reviewed in Chapter 36. Small infundibular cysts and dilated infundibula filled with orthokeratotic plugs are seen in chloracne. A disappearance of sebaceous glands has been described[31].

Treatment

Treatment consists primarily of avoidance of the cause, although some forms can be persistent and require treatments designed for acne vulgaris, e.g. topical or oral retinoids (see Ch. 36). However, chloracne is particularly recalcitrant to therapy.

Vibration White Finger

Synonyms: ■ Hand–arm vibration syndrome ■ Dead finger

Key features

- Development of a white finger or fingers in response to cold
- Associated transient loss of sensation
- Possible permanent finger neuropathy and pain in the affected limb
- Associated with exposures to vibrations between 30 and 300 Hz
- Workers at risk include operators of chainsaws and pneumatic tools

Introduction

Vibration white finger is a relatively frequent disorder among operators of chainsaws, pneumatic tools, and hand grinders who work in cold climates[32]. Up to half of the exposed workforce can be affected.

History

Loriga first described the disorder in Italian marble-quarry workers in 1911. Six years later, this was followed by a description in sandstone cutters in Indiana, USA.

Epidemiology

Prevalence studies have suggested a relationship between symptoms and degree of exposure. This varies, however, with the type of tool and the work process involved. From 1972 to 1990, the prevalence amongst Finnish lumberjacks fell from 40% to 5%. This was attributed to a reduction in the weight and acceleration-induced vibration of their chainsaws[33].

It has been suggested that vibration white finger does not occur in countries with a warm climate. However, this may reflect the absence of cold temperatures that serve as a trigger for symptoms rather than the absence of vibration-induced vascular changes. In tropical countries, neurological symptoms predominate[34].

Pathogenesis

Vibrations between 30 and 300 Hz are most strongly associated with development of this disorder. While increased activity of the sympathetic nervous system is viewed as the major cause of vibration white finger, local factors are likely also important. Vibration-induced damage to endothelial vasoregulatory mechanisms with alteration in α-adrenoceptors and impaired release of nitric oxide have been described.

Smoking is known to contribute to the development of the disorder, presumably because of the vasoconstrictive effect of nicotine.

Clinical features

Onset may occur within 3 months of beginning work but more frequently it takes 2–3 years to develop. Typically, a white patch of skin develops in response to cold-induced vasospasm. It is well demarcated from surrounding areas. Reduction in sensation occurs because the touch receptors are unable to function without adequate blood supply and this results in reduced dexterity. Episodes cease upon rewarming, often with the development of reactive hyperemia. Although caused by vibrating tools, attacks are not usually triggered by work with the vibrating tool.

The condition is graded according to the severity and frequency of symptoms, starting on the tips of the fingers (stage 1) and spreading to affect the whole digit (stage 3). In the most severe form, there are trophic changes and ulceration (stage 4). To aid in the diagnosis, finger skin temperature and finger systolic blood pressure can be measured in response to cold exposure, but the results are not discriminatory.

Pathology

The histopathologic features of vibration white finger include a significant reduction in the number of unmyelinated nerve fibers containing the neuropeptide calcitonin gene-related peptide (CGRP). There also may be hypertrophy of arterial smooth muscle. However, histology is not routinely utilized in the diagnosis of vibration white finger.

Differential diagnosis

In contrast to the symmetric distribution seen in Raynaud disease, in vibration white finger the blanching is asymmetric and occurs only on those digits most exposed to vibration; the thumbs are usually spared.

OCCUPATIONAL INFECTIONS ACQUIRED FROM ANIMALS OR HUMANS WITH CUTANEOUS MANIFESTATIONS

Occupation	Infection	Organism	Animals/other humans
Healthcare Sex industry Laboratory worker	Herpetic whitlow	Herpes simplex virus	Humans
	Scabies	*Sarcoptes scabiei* var *hominis*	
	Syphilis	*Treponema pallidum*	
	AIDS	Human immunodeficiency virus	
	Hepatitis B and C viral infection	Hepatitis B virus, hepatitis C virus

Farmer Veterinarian	Tinea corporis, capitis, and barbae due to zoophilic species	*Microsporum canis*	Cats, dogs
		M. nanum	Pigs
		Trichophyton mentagrophytes	Small mammals
		T. verrucosum	Cattle
		M. (T.) gallinae	Chickens

*Slaughterhouse.

Table 16.7 Occupational infections acquired from animals or humans with cutaneous manifestations. Laboratory personnel can also acquire primary cutaneous forms of dimorphic fungal infections. AIDS, acquired immune deficiency syndrome.

However, Raynaud phenomenon can also result from repeated occupational trauma, particularly in those who use tools that require a squeezing action, e.g. farmers, mechanics.

The hypothenar hammer syndrome results from occlusion of the ulnar artery as a consequence of repeated trauma to the palms and may be misdiagnosed as Raynaud phenomenon.

Treatment

The prognosis for affected individuals is good: the disease regresses upon cessation of exposure. This is particularly true in the early stages, provided there are no other environmental or constitutional factors contributing to the disorder. As a consequence, no specific treatment may be required other than avoidance[35]. Therapeutically, topical nitroglycerin ointment or sustained-release glyceryl trinitrate patches are effective, but the condition relapses upon withdrawal. Various systemic agents used for Raynaud disease, e.g. calcium channel blockers, have also been used for symptom control (see Ch. 43).

Infections

Many occupations, particularly those involving contact with animals, are associated with exposure to infectious agents. For example, individuals with occupations that involve wet work combined with rough physical conditions, such as butchers, slaughterhouse workers, and meat and fish packers, commonly develop infections with pyogenic bacteria and human papillomavirus (butcher's warts) through cuts and abrasions. Epidemics of methicillin-resistant *Staphylococcus aureus* infection have also occurred in professional football players in the US[36].

In the metal working industry, staphylococcal folliculitis can develop as a result of exposure to contaminated work materials such as coolant fluid. In addition, outdoor workers are exposed to environmental pathogens either by direct contact or implantation with soil or plants (e.g. mycetoma, chromomycosis, sporotrichosis), as well as following inoculation, most commonly via insect bites (e.g. Lyme disease, tularemia, spotted fevers).

Common infections may also occur more frequently as a result of environmental factors in the workplace. Increased humidity may lead to bacterial and fungal infections (due to dermatophytes or *Candida* spp.) in flexural body sites along with maceration of the skin. Pitted keratolysis caused by *Corynebacterium* spp. or *Micrococcus sedentarius* occurs on the soles in association with the use of occlusive footwear.

Infectious organisms related to specific occupations are summarized in Table 16.7. Further information on these infections[37] can be obtained by reference to the relevant chapter in this book (see Section 12).

Immunologic Contact Urticaria. 292
Toxin-Mediated (Non-immunologic) Contact Urticaria. 293
Mechanical Irritant Dermatitis 294
Chemical Irritant Dermatitis. 295
Phytophotodermatitis 297
Allergic Contact Dermatitis 299
Occupational Plant Dermatoses 306
Dermatoses Erroneously Ascribed to Plants. 307

Key features

- Plant constituents cause a variety of adverse reactions, including many cases of allergic contact dermatitis
- Plant dermatoses are due to a small minority of plants
- Urticaria, mechanical and chemical irritant contact dermatitis, phytophotodermatitis, and allergic contact dermatitis are the most common plant dermatoses
- Two major plant allergens are urushiol (Anacardiaceae family which includes poison ivy) and sesquiterpene lactones (Asteraceae family which includes chrysanthemums)

Important botanical synonyms

New family name	Old family name
Apiaceae	Umbelliferae (Parsnip family)
Arecaceae	Palmae (Palm family)
Asteraceae	Compositae (Daisy family)
Brassicaceae	Cruciferae (Mustard family)
Fabaceae	Leguminosae (Pea family)
Lamiaceae	Labiatae (Mint family)
Poaceae	Gramineae (Grass family)

Rhus ≠ *Toxicodendron* or poison ivy (see text)

Non-immunologic urticaria = Toxin-mediated urticaria

INTRODUCTION

Contrary to the belief of patients, just because a product is "natural" and not "artificial", it doesn't mean it is safe. When patients discover that a "natural" skin care product is harming them, they are dumbfounded. The light only goes on in their minds when we point out that, "Poison ivy is natural, too." All the reactions described in this chapter are natural.

Plant reactions can be classified into urticaria (immunologic and toxin-mediated; see Chs. 16 & 18), irritant dermatitis (mechanical and chemical), phototoxic dermatitis (phytophotodermatitis), and allergic contact dermatitis. Table 17.1 lists the most common plant reactions.

Botanical Aspects

Becoming familiar with basic botanical nomenclature used for the over 390 000 plant species will help clinicians to better understand the literature that addresses plant-related dermatoses[1].

Poison ivy – just as allergenic despite a name change

It is occasionally necessary to change a plant's name. For example, the genus *Rhus* was once thought to be a cohesive, widespread genus that included poison ivy (previously known as *Rhus radicans* or *Rhus toxicodendron*). Research in the 1950s and 1960s revealed that poison ivy and its immediate relatives represented a distinct developmental lineage that should not be classified as *Rhus* but as a distinct genus, *Toxicodendron*, and thus the correct scientific name for common poison ivy is *Toxicodendron radicans*.

Binomial nomenclature

The nomenclatural scheme of botany and zoology gives every entity two names: a generic name followed by a specific epithet (e.g. *Toxicodendron radicans*). A reference to the person (authority) who first published the species name is often placed after the binomial name. The full binomial name of common poison ivy reads "*Toxicodendron radicans* (L.) O. Ktze". "(L.)" refers to Carl Linnaeus, who first named the plant with the specific epithet *radicans*. "O. Ktze" refers to Otto Kuntze, who transferred the epithet *radicans* from the genus *Rhus* into the genus *Toxicodendron*.

The genus, species, and any infraspecific epithets are called the "minor categories of nomenclature", and these names are used when citing a plant's name (Table 17.2). Genera are grouped into families, and if you know the family to which a plant belongs, you will probably be able to determine what kind of dermatologic manifestations (if any) it can cause.

Plant identification

The following recommendations should be followed to identify an unknown plant that you or your patient thinks is causing an eruption.

- *Collect specimens*. Herbs (low-growing plants with fleshy stems) should be collected in their entirety with their flowering and/or fruiting materials intact. For shrubs (low-growing plants with woody stems), the end of a branch (up to 60 cm) should be collected, with the leaves attached, as well as any flowering or fruiting materials present. You may press plants before submitting them for identification, or you can put them into a plastic bag with *no water added* and submit them with data on: (1) where that plant was collected; and (2) its habitat (cultivated in a garden; growing wild along a creek bank, in an open field, in high-elevation woodlands, etc.).
- *Involve a plant taxonomist*. Every US state and most Canadian provinces have an established mechanism for routine and rapid plant identification, and in most locales the service is free. In suburban and rural areas, the county or regional agricultural extension service or farm advisors are knowledgeable about the procedures for immediate plant identification, and they have access to the regional herbaria. Urban areas have similar services, usually accessed through the urban horticulturist of the state extension service, or through the local garden center or botanical garden. In other countries, look for a nearby herbarium housing a collection of flora of the region. A botanist who works there would likely be willing to help identify an unknown plant.

MOST COMMON PLANT DERMATOSES			
Binomial name	**Common name**	**Reaction type**	**Inciting agent**
Allium sativum	Garlic	ACD	Diallyl disulfide, allicin
		ICD	Probably the same
Alstroemeria spp.	Peruvian lily	ACD	Tulipalin A > B
Capsicum annuum	Hot peppers	Erythema/edema/burning	Capsaicin
Citrus latifolia	Persian lime	Phytophotodermatitis	Furocoumarins
Narcissus pseudonarcissus	Daffodils	ICD	Calcium oxalate
Opuntia spp.	Prickly pear and others	Mechanical irritant dermatitis	Glochids
Parthenium hysterophorus	Scourge of India, congress grass	ACD	Sesquiterpene lactones
Toxicodendron radicans	Poison ivy	ACD ICD (black-spot reaction)	Alkyl-catechols and resorcinols in urushiol
Toxicodendron diversilobum	Poison oak	ACD ICD (black-spot reaction)	Alkyl-catechols and resorcinols in urushiol
Tulipa spp.	Tulips	ACD	Tulipalin A > B
		ICD	Coarse hair on bulbs
Urtica dioica	Stinging nettle	Urticaria	Histamine
X *Dendranthema* cultivars	Chrysanthemums	ACD	Sesquiterpene lactones

Table 17.1 Most common plant dermatoses. These are admittedly biased by the anecdotal and unscientific observations as well as literature reviews of the author. ACD, allergic contact dermatitis; ICD, irritant contact dermatitis.

THE BASIC NOMENCLATURAL SCHEME FOR PLANTS, USING COMMON POISON IVY AS THE EXAMPLE	
Kingdom	**Plantae (Metaphyta)**
Division	Magnoliophyta (flowering plants)
Class	Magnoliopsida (dicotyledons)
Subclass	Rosidae
Order	Sapindales
Family	Anacardiaceae (sumac or cashew family)
Genus	*Toxicodendron*
Species	*radicans*
(Author's name)	(L.) O. Ktze

Table 17.2 The basic nomenclatural scheme for plants, using common poison ivy as the example. The distinctive ending for each category is underlined. Note that the minor categories of nomenclature have no special endings.

Patch Testing

Details of patch testing are beyond the scope of this chapter (see Ch. 14). The reader is also referred to the paper by Mitchell[2]. The most common allergenic plants and a proposed botanical screening tray are found in Table 17.3[3].

MOST COMMON RELEVANT BOTANICAL ALLERGENS AND PROPOSED BOTANICAL SCREENING TRAY		
Plant name	**Plant family**	**Test compound**
Achillea millefolium (yarrow) *Arnica* spp. *Chrysanthemum* cultivars *Matricaria chamomilla* (chamomile) *Tanacetum parthenium* (feverfew)	Asteraceae	Compositae mix II 6% in petrolatum, sesquiterpene lactones (SQLs) mix 0.1% in petrolatum, and parthenolide 0.1% in petrolatum
Alstroemeria spp.	Alstroemeriaceae	Alpha-methylene-gamma-butyrolactone 0.1% in petrolatum
Cananga odorata	Anonaceae	Cananga (ylang-ylang) oil 2% in petrolatum
Citrus aurantium var. *amara*	Rutaceae	Neroli oil 4% in petrolatum
Lavandula spp.	Lamiaceae	Lavender (absolute) 2% in petrolatum
Lichens (fungus–alga dual organisms)	Non-plant	Lichen acid mix 0.3% in petrolatum (contains usnic acid, atranorin, evernic acid)
Melaleuca alternifolia	Myrtaceae	Tea tree oil 5% in petrolatum
Mentha spp.	Lamiaceae	Spearmint oil 5% in petrolatum
Pelargonium cultivars	Geraniaceae	Geranium oil (Bourbon) 2% in petrolatum
Primula obconica	Primulaceae	2-methoxy-6-n-pentyl-4-benzoquinone (primin) 0.1% in petrolatum
Rosa damascena	Rosaceae	Rose oil (Bulgarian) 2% in petrolatum
Santalum album	Santalaceae	Sandalwood oil 2% in petrolatum
Taraxacum officinale	Asteraceae	Dandelion 2.5% in petrolatum

Table 17.3 Most common relevant botanical allergens and proposed botanical screening tray. This list may help to narrow down a potential botanical allergy in a patient who brings specimens into your office to examine[3]. Note this screening tray does not include urushiol. See Appendix in Chapter 14 for commercial sources of patch tests.

IMMUNOLOGIC CONTACT URTICARIA

Key features

- Atopy and frequent contact with fresh fruits and vegetables are risk factors
- May present as urticaria, pruritus, burning, or chronic dermatitis
- Oral allergy syndrome is mucosal contact urticaria caused by antigens similar to allergenic pollen
- Protein contact dermatitis represents an eczematous eruption arising from repeated urticarial reactions

Plant-induced urticarial reactions are divided into immune and non-immune (toxin-mediated [see next section]). Several cutaneous reaction patterns besides wheals are possible, e.g. erythema, dermatitis.

Epidemiology

Immunologic contact urticaria is rather uncommon. Approximately 95% of cases are work-related – long-time food handlers with underlying dermatitis are at greatest risk. However, fully half of patients with "protein contact dermatitis", a type IV eczematous eruption arising from repeated type I urticaria reactions, are not atopic.

Examples of reported urticants include common vegetables (e.g. celery, onions, potatoes, lettuce), fruits (e.g. tomatoes, bananas, lemons), herbs (e.g. parsley, dill) and nuts, as well as algae, lichens, shrubs, trees, and grasses.

Pathogenesis (see Ch. 18)

IgE-mediated release of vasoactive mediators from mast cells leads to local urticaria and, rarely, a "contact urticaria syndrome" that includes local wheals plus systemic symptoms involving the nose, throat, lungs, gastrointestinal tract, or cardiovascular system. The main cause seems to be histamine release, but prostaglandins, kinins, and leukotrienes probably augment the inflammatory response.

Clinical Features

Within 30 minutes of contact with certain fresh foods, affected individuals experience pruritus, erythema, urticarial swelling, and even dyshidrotic-like vesicles. Sometimes, individuals only develop burning or tingling without objective findings[4]. Theoretically, any plant can cause contact urticaria, especially with repeated exposures on the wet, macerated skin of food handlers. Cooking, processing, deep-freezing, or crushing fruits and vegetables generally reduces their allergenicity.

Some individuals become cross-sensitized to pollen and similar allergens in fruits or vegetables[5]. Upon eating a cross-reacting food, they experience sudden, IgE-mediated, oral cavity itching, stinging, and pain. Edema of the lips, tongue, palate, and pharynx typically ensue as the "oral allergy syndrome" (OAS) progresses. Gastrointestinal symptoms and anaphylaxis are possible if enough allergens are ingested. For example, 70% of European patients with immediate hypersensitivity to birch pollen develop OAS while eating apples, pears, cherries, peaches, plums, apricots, almonds, celery, carrots, potatoes, kiwis, hazelnuts, or mangoes. Pollen-associated foods are often, but not always, edible when heated.

The term "protein contact dermatitis" describes a chronic dermatitis in which patch tests are typically negative but prick tests to large protein allergens are positive[6]. Patients develop a chronic dermatitis – frequently on the hands and fingertips – that urticates within minutes of contact with the offending allergen (Fig. 17.1).

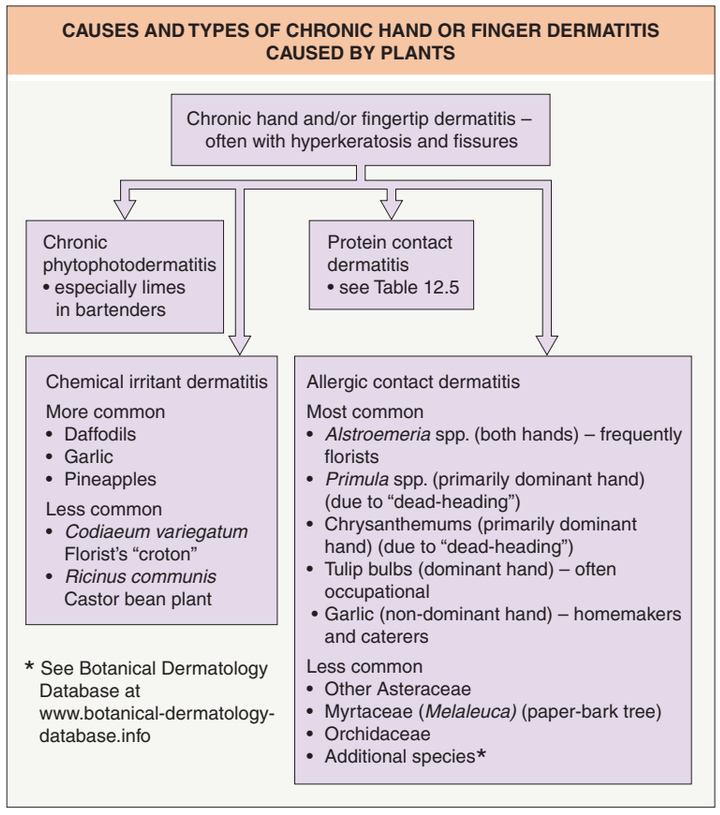

Fig. 17.1 Causes and types of chronic hand or finger dermatitis caused by plants.

Differential Diagnosis and Pathology

See Toxin-Mediated (Non-immunologic) Contact Urticaria and Chs. 16 & 18.

Treatment

Prevention is the preferred form of "treatment". Parenterally administered epinephrine (adrenaline) is required for anaphylactic reactions.

TOXIN-MEDIATED (NON-IMMUNOLOGIC) CONTACT URTICARIA

Key features

- Anyone can be affected
- Stinging nettles (*Urtica* spp.) are most common cause
- Reaction can be subjective only
- Sharp hairs on the plants can contain histamine, serotonin, and acetylcholine

History

Plants causing toxin-mediated urticaria have been used since antiquity as counterirritants in folk medicine, and Native Americans used stinging nettles to treat rheumatism, stomach upset, postpartum hemorrhage, paralysis, fevers, colds, and tuberculosis. Stinging nettle is used to produce homemade diuretics, and stem fibers were even used to make cloth until the early twentieth century.

Epidemiology

Urticaceae family members cause the majority of plant-induced contact urticaria. Because everyone exposed to the toxins develops urticaria, toxin-mediated urticaria is far more common than immunologic urticaria. Since few affected people seek medical attention, the true incidence of toxin-mediated urticaria is unknown. The most common culprit in the US is the stinging nettle (*Urtica dioica*; Fig. 17.2A)[7], which is widely scattered throughout the northern hemisphere (except in lowland tropical areas), especially in moist woods, roadsides, and on wasteland. Other common urticating plants are listed in Table 17.4.

Pathogenesis (see Ch. 18)

Inciting plants possess sharp hairs (trichomes) on leaves and stems (Fig. 17.2B,C). The proximal silicaceous hair is attached to a distal calcified portion that possesses a terminal bulb. When rubbed against, the bulb dislodges to reveal a beveled, hypodermic needle-like, hollow hair (Fig. 17.2D). The latter releases an irritant chemical cocktail (histamine, acetylcholine, serotonin) that supposedly serves as a defense mechanism against herbivores.

Clinical Features

Wheals achieve maximal size 3 to 5 minutes after contact, and erythema, burning, and pruritus last 1–2 hours. Paresthesias may last 12 hours or more. Although histamine, acetylcholine, and serotonin explain the early cutaneous reaction, they do not account for the persistent paresthesias.

Reactions to stinging nettle pale in comparison to those elicited by members of the *Dendrocnide* genus of the Urticaceae family. These trees grow up to 40 meters tall in eastern Australian rainforests. Young

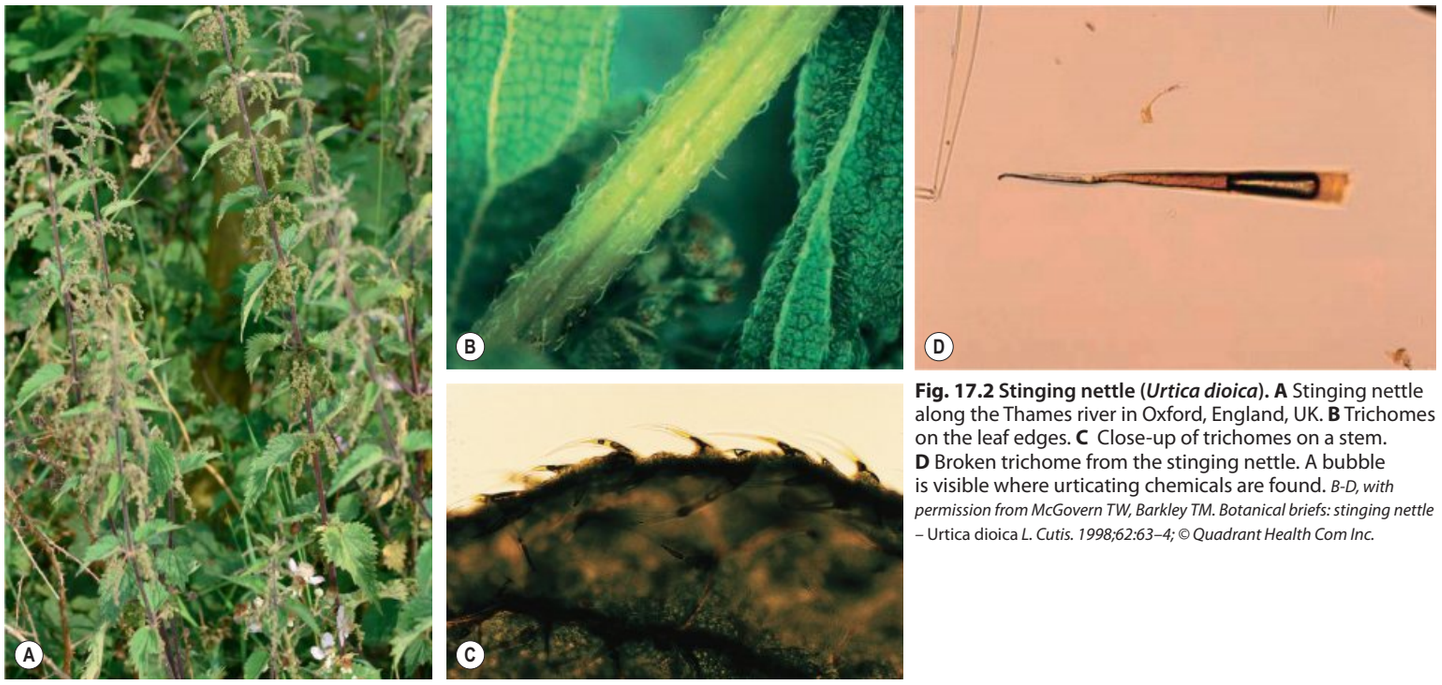

Fig. 17.2 Stinging nettle (*Urtica dioica*). A Stinging nettle along the Thames river in Oxford, England, UK. **B** Trichomes on the leaf edges. **C** Close-up of trichomes on a stem. **D** Broken trichome from the stinging nettle. A bubble is visible where urticating chemicals are found. *B-D, with permission from McGovern TW, Barkley TM. Botanical briefs: stinging nettle – Urtica dioica L. Cutis. 1998;62:63–4; © Quadrant Health Com Inc.*

THE MOST COMMON PLANTS CAUSING TOXIN-MEDIATED URTICARIA			
Family	**Genus**	**Species**	**Notes**
Urticaceae (nettle family)	*Urtica*	*dioica*, *urens*, *pilulifera*	Stinging nettles – worldwide
	Laportea	*canadensis*	"Wood nettle", 5-foot-tall perennial herb – NE USA
	Dendrocnide	*gigas*, *moroides*, *photinophylla*	Potentially deadly stinging trees – eastern Australian rainforests
Euphorbiaceae (spurge family)	*Acidoton*	*urens*	Tropical Americas
	Cnidoscolus	*stimulosus*	Spurge nettle – SE USA
		other species	Spurge nettles of tropical Americas
Hydrophyllaceae (water-leaf family)	*Wigandia*	*caracasana*, *urens*	Large-leafed shrubs – tropical Americas

Table 17.4 The most common plants causing toxin-mediated urticaria.

shoots are covered with stiff stinging hairs. Severe urticaria from these may last for weeks, and contact with water or cold objects reactivates the urticaria. Severe, intermittent, stabbing pains may follow the course of lymphatics. Human and animal deaths due to *Dendrocnide* contact have been documented.

Pathology (see Ch. 18)

Five minutes after contact with *Urtica dioica*, dermal edema and telangiectasias with or without mild spongiosis are seen. At 12 hours, the edema resolves but vasodilation persists. Some patients develop spongiosis in conjunction with a neutrophilic and/or lymphocytic infiltrate. Mast cells are observed within the papillary dermis at 12 hours, but not at 5 minutes.

Differential Diagnosis (see Ch. 18)

Although the evaluation of such patients is difficult, office testing of suspected allergens or toxin-containing plants may involve one of several methods[4]. The most sensitive tests for immunologic contact urticaria are the prick and scratch-chamber tests. For the scratch-chamber test, a 5-mm scratch is made on the back or forearm. Test material is applied and occluded with a Finn chamber for 15 minutes. The site is examined following Finn chamber removal and every 15 minutes for an hour. After reading, the chamber can be replaced for 48 hours to test for delayed hypersensitivity.

The open application test provides the most reliable way to test for toxin-mediated urticaria. Samples (0.1 ml) from a series of dilutions are each spread onto discrete 3 × 3 cm areas of skin. Sites are observed every 10–15 minutes for an hour. Maximal erythema and edema typically occur 30–40 minutes after application.

Treatment

Most stings are benign, self-limited, and require no treatment. Trichomes may be removed with glue and gauze as described in the next section. Topical pramoxine or oral analgesics may provide some symptomatic relief.

MECHANICAL IRRITANT DERMATITIS

Key features

- Large spines (modified leaves) and thorns (modified branches) cause penetrating injuries and secondary infection
- Small fishhook-shaped spines (glochids) can embed in the skin
- Prickly pears are a cause of glochid dermatitis

Epidemiology

Mechanical irritant dermatitis can affect anyone. Many plants, including most cacti, can inflict mechanical injury via small or large emergences. Generally, the amount of damage to the skin is inversely proportional to the size of the emergence. Many of the plant families that can cause mechanical irritant dermatitis are listed in Table 17.5.

COMMON PLANTS KNOWN TO CAUSE MECHANICAL IRRITANT REACTIONS		
Family	**Genus species**	**Notes**
Amaranthaceae	*Kali tragus*	Tumbleweed or Russian thistle – sharp-edged spines penetrate skin
Araliaceae	*Hedera helix*	Common ivy – leaf-borne stellate hairs detach as leaves age
Asteraceae	*Carduus* and *Cirsium* spp.	Thistles
	Lactuca serriola	Prickly lettuce
Boraginaceae	*Borago officinalis*	Borage – sharp, stiff leaf and stem hairs
Cactaceae	*Opuntia* spp.	Prickly pears; "Sabra dermatitis"
Liliaceae	*Tulipa* spp.	Coarse fibers on tulip bulb tunics cause irritant component of "tulip fingers"
Moraceae	*Ficus* spp.	Figs – abrasive bristles on leaves and fruit
	Morus spp.	Mulberries – abrasive bristles on leaves and fruit
Nyctaginaceae	*Bougainvillea*	Sharp spines on stems and spear-shaped crystals in trichomes on leaves (Brazil native)
Poaceae	Many spp.	Grasses – fine hairs, prickly spikes, and cutting leaf edges
Proteaceae	*Grevillea* spp.	Terminal, sharp points on leaves – Australia
Rosaceae	*Rosa* spp.	Thorns can cause penetrating injuries, tenosynovitis, and foreign body granulomata
Rubiaceae	*Galium aparine*	"Goosegrass" – hooked prickles on fruit, stems, leaves
Scrophulariaceae	*Verbascum thapsus*	"Mullein" or "flannel-plant" – woolly hairs on leaves used as facial rubefacient
Sterculiaceae	*Fremontodendron* spp.	"California glory" possesses stiff, stellate hairs

Table 17.5 Common plants known to cause mechanical irritant reactions. Although numerous plants possess irritant appendages, some of the well-known ones are listed here.

Pathogenesis

Whereas cacti possess large spines, their smaller glochids cause more notorious dermatologic problems. The glochids – tufts of hundreds of short, barbed or hooked hairs – arise from pincushion-like structures called "areoles", from which larger spines may also arise. The minute, barbed glochids (Fig. 17.3A) often point outward and backward like a fishhook and produce considerable irritation and pruritus after penetrating the skin. For example, *Opuntia microdasys* ("polka dot cactus", "bunny ears cactus"), a house and garden favorite, bears disarming-appearing "fluffy" clusters of 100–200 glochids on its pads (see Fig. 17.12).

Clinical Features

Prickly pear glochids from *Opuntia* spp. cause "Sabra dermatitis", a pruritic, papular eruption occurring among prickly-pear pickers and those who unwarily stumble into burglar-proof hedges of this native Mexican plant (Fig. 17.3B). The fruit contains the highest concentration of glochids (Fig. 17.3C), and the ensuing eruption can resemble fiberglass dermatitis or scabies. Prickly pears should be picked only when wetted, and harvesting should cease when it is windy, since the glochids can become airborne.

All 200 or so species of *Opuntia* are native to the New World, ranging from New England and British Columbia southward to the Straits of Magellan. Numerous species have become established in the Mediterranean basin, South Africa, South Asia, and Australia.

Spine and thorn injuries can be complicated by cutaneous inoculation of microorganisms such as *Clostridium tetani* and *Staphylococcus aureus*. Grasses, sphagnum moss, and rose thorns can transmit *Sporothrix schenckii*. Atypical mycobacteria such as *Mycobacterium kansasii* (blackberries), *M. marinum* (cactus spines), and *M. ulcerans* (spiky tropical vegetation) have also added infectious insult to mechanical injury.

Treatment

In a controlled study in rabbits, *Opuntia* glochids were most effectively removed by first detaching the larger clumps with tweezers and then applying glue and gauze to the affected area. After the glue dried, the gauze was grasped and peeled off, resulting in the removal of 95% of implanted glochids[8].

CHEMICAL IRRITANT DERMATITIS

Key features

- Calcium oxalate in daffodils is a major cause of plant-related irritant dermatitis in florists and horticulturalists
- Spurges (including poinsettias) contain irritant phorbol esters in latex
- Capsaicin in hot peppers affects cutaneous nerves, but not the skin

Fig. 17.3 Prickly pears (*Opuntia* spp.) and their glochids. A Microscopic appearance of glochids from *Opuntia microdasys*. **B** Prickly pear (*Opuntia ficus-indica*) habit. **C** Prickly pear (*Opuntia ficus-indica*) fruit. Fine spines and glochids are visible. *Courtesy Dirk Elston, MD.*

History

Plant-derived irritant chemicals have been recognized for centuries. Native Mexican Indians once used smoke from burning peppers (*Capsicum* [Solanaceae]) as a weapon against enemies, and latex from the manchineel tree (*Hippomane mancinella* [Euphorbiaceae]) was used by Caribbean people as poison for arrow tips.

Epidemiology

Several major plant families found throughout the world contain chemical irritants (Table 17.6).

Pathogenesis, Clinical Features, and Treatment (see Ch. 15)

Calcium oxalate, one of the most common chemical irritants, is found in *Dieffenbachia picta* (Araceae), a plant that decorates millions of homes and public places. Upon contact with a moist surface, the leaves release water-insoluble calcium oxalate. When leaves are chewed, salivation, burning, mucosal edema, and blistering follow. This causes hoarseness or aphonia, hence the common name "dumb cane". Treatment includes parenteral corticosteroids, antacid mouthwashes, and analgesics; antihistamines are of no benefit. The pain and edema wane over 4–12 days.

Calcium oxalate enhances the irritancy of other chemicals, including the proteolytic enzyme bromelain (bromelin) found in pineapples. Pineapple workers often develop cracks, fissures, fingerprint loss, and microhemorrhages on their hands. Calcium oxalate-induced microabrasions allow bromelain to exert its proteolytic effect on dermal blood vessels. Nitrile gloves can be worn for protection.

Bulb dermatitis, though less dramatic, is more common[9]. Daffodil sap, found not only in bulbs but also in stems and leaves, contains calcium oxalate and causes "daffodil itch", probably the most common dermatitis in florists. Dryness, scaling, fissures, and erythema develop on the fingertips, hands, and forearms. Bulbs of several other plants (e.g. tulips, hyacinths) also commonly cause dermatitis. Allergens found in garlic bulbs act as irritants at high concentrations leading to second- and third-degree burns as well as subungual hyperkeratosis and hemorrhage that can mimic nail psoriasis.

While spurges (Euphorbiaceae) are notorious for their irritant latex, they derive their common name from the purgative properties of their seeds. The milky latex contains irritant phorbol esters, diterpenes, and daphnane esters that may cause a painful, blistering dermatitis and even temporary blindness if the latex contacts the eye. Sitting under a manchineel tree in the Caribbean during a rainstorm will lead to intense cutaneous burning, erythema, and bullae, often accompanied by periocular swelling through transfer of the latex by rain. Manchineel fruit is known locally as the "apple of death". The latex of the best-known family member, the poinsettia (*Euphorbia pulcherrima*), is only mildly irritating.

Buttercups (Ranunculaceae) contain the glycoside ranunculin that is converted to protoanemonin after plant injury. Protoanemonin causes severe, linear vesiculation that may resemble early phytophotodermatitis, but no hyperpigmentation ensues. Because protoanemonin rapidly polymerizes to the non-irritant anemonin, only freshly damaged plants cause reactions.

"Chili burns" commonly occur among those who remove skins from large batches of roasted chili peppers (*Capsicum annuum*). When applied to skin, the active principle, capsaicin, depolarizes nerves causing vasodilation, smooth muscle stimulation, glandular secretion, and sensory nerve activation. Because only nerves are affected, there is erythema but no vesicles or bullae. Symptoms may be delayed and last hours to days. The best home remedy for chili burns is handwashing with soap and water followed immediately by 1 hour of immersion in vegetable oil to remove the fat-soluble capsaicin.

The "century plant" (*Agave americana*) grows in temperate, subtropical, and tropical climates and forms rosettes of tough, sword-shaped leaves with spiny margins. The marked pruritus and stinging that follows within five minutes of contact with the agave leaf is thought to be caused by latex-derived calcium oxalate crystals and saponins. Purpura may appear subsequently. Soldiers have been known to try to "earn" sick leave by rubbing broken leaves on their skin to induce a severe vesiculopustular irritant dermatitis, often accompanied by systemic symptoms[10].

PLANTS MOST COMMONLY IMPLICATED IN CAUSING CHEMICAL IRRITANT DERMATITIS

Family	Binomial name	Common name	Irritant chemical (location)
Agavaceae	*Agave americana*	Century plant	Calcium oxalate, saponins (latex throughout plant)
Alliaceae	*Allium sativum*	Garlic	Thiocyanates (bulbs)
Amaryllidaceae	*Narcissus* spp.	Daffodil, narcissus	Calcium oxalate (stems, leaves, bulbs)
Anacardiaceae	*Anacardium occidentale*	Cashew tree	Cashew nut shell oil (mesocarp [middle layer] of nut shell [irritant and allergenic])
Araceae	*Dieffenbachia picta*	Dumb cane	Calcium oxalate (leaves and fruits)
	Philodendron spp.	Philodendron	Calcium oxalate (leaves)
Brassicaceae	*Brassica nigra*	Black mustard	Thiocyanates (all parts)
	Raphanus sativus	Radish	
Bromeliaceae	*Ananas comosus*	Pineapple	Bromelain (stem > fruit) Calcium oxalate (all parts)
Euphorbiaceae	*Codiaeum variegatum*	Florist's "croton"	Phorbol esters (latex in stems, leaves, fruits)
	Euphorbia esula	Leafy spurge	
	Hippomane mancinella	Manchineel tree	Standing in rain beneath manchineel tree can transfer highly irritant latex and even cause blindness
	Euphorbia pulcherrima	Poinsettia	
Liliaceae	*Hyacinthus orientalis*	Hyacinth	Calcium oxalate (bulbs)
Polygonaceae	*Rheum rhaponticum*	Rhubarb (false, rhapontic)	Calcium oxalate (leaves)
Ranunculaceae	*Ranunculus* spp.	Buttercups	Protoanemonin (freshly damaged plant parts)
	Aquilegia spp.	Columbine	
	Caltha spp.	Marsh marigold	
Solanaceae	*Capsicum annuum*	Hot pepper	Capsaicin (placenta of fruit [no dermatitis, only erythema, edema, burning])

Table 17.6 Plants most commonly implicated in causing chemical irritant dermatitis.

PHYTOPHOTODERMATITIS

Key features

- Non-immunologic – it can happen to anyone
- Need UVA light plus topical or oral contact with photosensitizer
- Furocoumarins (psoralens and angelicins) are the most common photosensitizers
- Limes, celery, and rue (herb-of-grace) are the most common causes
- Potential photosensitizing plants of the family Apiaceae can be identified by umbel flower structure

Phytophotodermatitis connotes phototoxic reactions consisting of erythema (with or without blistering) and delayed hyperpigmentation following exposure to plants. Phototoxicity implies an inflammatory reaction caused by the combination of a topical or oral photosensitizing agent followed by exposure to the appropriate wavelength of UV radiation. Because this is not an immunologic reaction, no prior sensitization is necessary and anybody can be affected.

History

As early as 2000 BCE, vitiligo patients were encouraged to lie in the sun after picking *Ammi majus* from the Nile River valley and rubbing the juice on their skin. By 1400 BCE, Indian doctors were using boiled extracts of *Psoralea corylifolia* (scurf-pea, babchi), from which we derive the term "psoralen". Even nowadays in India, its seeds remain a source of psoralens for the treatment of vitiligo.

In 1897, Apiaceae-induced dermatitis was first reported, but the need for concomitant UV radiation went unnoticed. It would be another 40 years before Klaber introduced the term "phytophotodermatitis" to emphasize that a combination of plants ("*phyto-*") plus light ("*photo-*") is required for the reaction.

Epidemiology

Apiaceae (formerly Umbelliferae) and Rutaceae (citrus family) plants are the most common causes of phytophotodermatitis (Table 17.7 & 17.8). Members of the mulberry (Moraceae) and pea (Fabaceae) families also contain furocoumarins.

Apiaceae

A distinctive floral umbel makes family members easy to recognize: numerous small flowers form a simple umbel (a cluster of flowers on stalks of roughly equal length arising from a single point). Many small umbels can form "compound umbels" (Fig. 17.4A). Compound umbels may be umbrella-shaped or ball-shaped. The flower heads are sheathed at the base by one or more leaf-like bracts.

Common hogweed, also referred to as cow parsnip, is known by three species names: *Heracleum lanatum*, *H. maximum*, or *H. spondylium*. In North America, it naturally grows over 2 meters tall (Fig. 17.4B,C), with leaves up to 1 meter long. The larger giant hogweed (*H. mantegazzianum*) is a European native that has now invaded parts of North America. Both cause phytophotodermatitis. Fruits contain the highest concentrations of psoralens followed by leaves and stems. The greatest threat from hogweed occurs in the autumn, when the weather favors the development of many seeds. One severe case of occupational contact with giant hogweed during mid-summer roadside lawn mowing led to marked phytophotodermatitis-induced soft tissue necrosis of the leg and eventual below-the-knee amputation.

Rutaceae

The Rutaceae family includes tropical (*Citrus* spp.), subtropical, and temperate (*Ruta* spp.) plants and is the second most common plant family (after Apiaceae) that causes phytophotodermatitis (see Table 17.8). Many Rutaceae grow as shrubs or small trees and produce fleshy fruit. The rind of the Persian lime (*Citrus latifolia*), which contains ten times more 5-methoxypsoralen (5-MOP) than the pulp, is a major cause of phototoxic reactions in the US, especially in Florida and the desert Southwest. Outdoor bartenders commonly develop vesicles on their index and middle fingers from squeezing limes to make cocktails. Even the sweet orange (*Citrus sinensis*) can cause a phototoxic cheilitis after contact with the rind.

Garden rue (*Ruta graveolens*) is a bitter tasting and smelling sub-shrub native to the Mediterranean basin with a long history as a folk medicine

IMPORTANT MEMBERS OF THE APIACEAE FAMILY (FORMERLY UMBELLIFERAE) IMPLICATED IN PHOTOTOXIC REACTIONS		
Scientific name	**Common name(s)**	**Comments**
Ammi majus	False Bishop's weed	Historical and economic importance
Angelica archangelica	Angelica	Candied portions used in cakes; characteristic Benedictine flavor
Angelica sylvestris	Wild angelica	
Anthriscus sylvestris	Cow parsley, wild chervil	"Strimmer dermatitis"*
Apium graveolens	Celery	Fungus-infected plants produce more psoralens
Ficus carica	Fig	Widespread second-degree burns when used as tanning promoter (Turkey)
Foeniculum vulgare	Fennel	
Heracleum laciniatum	Tromsø palm	Scandinavia
Heracleum lanatum, H. maximum, H. sphondylium	Cow parsnip (common hogweed)	North America; most common cause of "strimmer dermatitis"*
Heracleum mantegazzianum	Giant (Russian) hogweed, wild rhubarb, hogweed tree	Giant weed naturalized and invasive across UK, Europe, Canada, US
Heracleum persicum	Persian hogweed	Iran, Iraq, Turkey
Notobubon galbanum	Blister bush	South Africa
Pastinaca sativa	Parsnip	Furocoumarins in leaves, roots, stem, fruits
Petroselinum crispum	Parsley	

*Strimmer = string trimmer, a garden tool for cutting weeds.

Table 17.7 Important members of the Apiaceae family (formerly Umbelliferae) implicated in phototoxic reactions.

PHOTOTOXIC MEMBERS OF THE FAMILY RUTACEAE	
Scientific name	**Common name(s)**
Citrus aurantiifolia	Key lime
Citrus latifolia	Persian lime or seedless lime
Citrus aurantium	Bitter orange
Citrus bergamia	Bergamot orange
Citrus sinensis	Sweet orange
Citrus limetta	Sweet lemon
Citrus limon	Lemon
Citrus paradisii	Grapefruit
Cneoridium dumosum	Coast spice bush, berry rue
Dictamnus albus	Burning bush, gas plant
Pelea anisata	Mokihana (berries used for lei in Hawaii)
Phebalium squamulosum	Blister bush, common in Western Australia
Ruta graveolens	Rue, herb-of-grace

Table 17.8 Phototoxic members of the family Rutaceae.

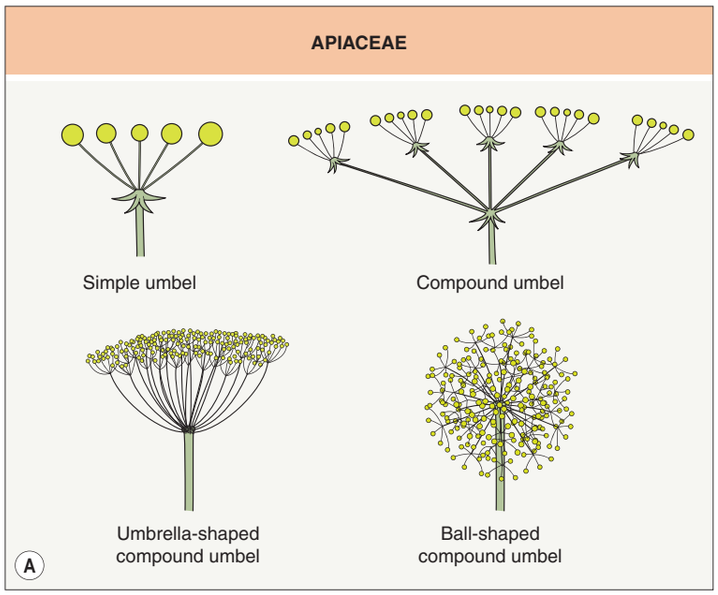

Fig. 17.4 Apiaceae. **A** Compound umbels can be umbrella-shaped or ball-shaped. **B** Cow parsnip (common hogweed; *Heracleum maximum*) habit, Mackinac Island, MI, USA. **C** Compound umbel of cow parsnip (common hogweed)

Fig. 17.5 Bullous phase of phytophotodermatitis. There was associated burning but no pruritus, and the linear bullae were replaced by hyperpigmentation. *Courtesy Jean L. Bolognia, MD.*

remedy and insect repellant. It contains 5-MOP, 8-MOP, and angelicins and is probably the most common cause of phototoxicity acquired in English gardens.

Dictamnus albus, the gas plant or burning bush, exudes an aromatic oil that can be ignited briefly without harming the plant. It has become a common yard plant in the US and Canada, and it grows wild in central and southern Europe, eastern Siberia and northern China. The seed pods have high concentrations of both 5-MOP and 8-MOP.

Moraceae

The mulberry family includes the fig tree (*Ficus carica*), a Middle Eastern native that has been widely cultivated throughout warm, temperate regions of the world. Psoralens are found chiefly in the sap of leaves and shoots but not in the fruit[11].

Other families

Eleven of 23 HIV-infected patients receiving systemic hypericin (from St John's wort, *Hypericum perforatum* [Hypericaceae]) as a potential antiretroviral agent developed severe cutaneous phototoxicity.

Pathogenesis

Furocoumarins possess linear (psoralens) or angular (angelicins) tricyclic structures (see Fig. 134.9). Bergapten (5-MOP), originally isolated from the southern European bergamot orange (*Citrus bergamia*), and 8-MOP (xanthotoxin), first isolated from the Nigerian prickly ash (*Fagara zanthoxyloides*), cause the most severe reactions.

In the presence of UVA (peak effectiveness at 320–340 nm), psoralens within the skin can interact with molecular oxygen and form reactive oxygen species that induce cytoplasmic vacuolization and membrane rupture of keratinocytes. Within 2 hours of UVA exposure, desmosomal plaques detach and degenerate leading to blister formation without the need for DNA damage[12].

UVA also excites intercalated psoralens to form covalent interstrand DNA cross-links by binding to pyrimidines (see Fig. 134.10). This leads to further keratinocyte cell death (apoptosis, "sunburn cells") and stimulates hyperpigmentation via increased melanocyte mitosis and dendricity, melanocyte hypertrophy, increased tyrosinase activity, larger melanosomal size, and enhanced distribution of melanosomes throughout the epidermis.

Furocoumarins appear necessary to defend plants from fungal attack. Healthy celery plants (*Apium graveolens*) contain 10–100 mcg/g wet weight of psoralens, but they may produce 320 mcg/g when infected with pink-rot fungus (*Sclerotinia sclerotiorum*). Disease-resistant celery unfortunately possesses high levels of furocoumarins concentrated in the leaf and stem sap.

Clinical Features

Cutaneous sensitivity to UVA light peaks 30–120 minutes after contact with furocoumarins. Bizarre configurations of erythema, edema, and bullae appear after 24 hours and peak at 72 hours (Fig. 17.5). These painful, non-pruritic reactions are more often seen in mid to late summer, when psoralen concentrations are highest in the offending plants and more skin is exposed to direct sunlight. To avoid misdiagnosis as poison ivy dermatitis, physicians must note that the initial erythematous and bullous reaction only occurs in sun-exposed areas. Hyperpigmentation appears 1–2 weeks later and lasts months to years (Fig. 17.6). Occasionally, low-dose UVA and/or psoralens cause hyperpigmentation without a preceding vesicular or erythematous eruption (see Ch. 67). Involved areas may remain hypersensitive to UV radiation for years. Wet skin, sweating, and heat enhance the phototoxic response.

Furocoumarin exposure occurs in many settings (Table 17.9). Modern power tools such as weed-whackers and strimmers (string trimmers) deliver a buckshot spray of weeds that may include phototoxic plants. "Strimmer dermatitis" appears 12–24 hours later as red, irregular

macules and papules, not bizarre linear and angular streaks, on the chest, arms, and legs if wearing shorts. Implicated species, especially in Europe, include common hogweed (cow parsnip; *Heracleum sphondylium*), giant hogweed (*Heracleum mantegazzianum*), and cow parsley (*Anthriscus sylvestris*). Berlock (or berloque, meaning trinket or charm) dermatitis is characterized by pendant-like streaks of pigmentation on the neck, face, arms, or trunk after the application of colognes containing 5-MOP.

Fig. 17.6 Phytophotodermatitis. Streaky hyperpigmentation due to contact with a psoralen-containing plant followed by exposure to sunlight. *Courtesy Lorenzo Cerroni, MD.*

Phytophotodermatitis has also been mistaken for child abuse (see Ch. 90). Parents who touch plants or fruit containing furocoumarins can transfer these chemicals to their children. A week or more later, the children may develop digitate hyperpigmentation in sun-exposed sites of parental hand contact. Multiple hues are not seen in the skin lesions, as in healing bruises. In addition, lime-induced phytophotodermatitis can be misdiagnosed as allergic contact dermatitis, impetigo, cellulitis, and infectious lymphangitis.

Celery harvesters and canners are at high risk for developing phytophotodermatitis. Only 1 mcg of 8-MOP/cm^2 of skin is necessary to produce blisters after 2.4 J/cm^2 (less than 10 minutes) of summer sunlight in Colorado. In one study of 320 randomly selected Michigan celery workers, 163 (51%) displayed various stages of vesicular and bullous dermatitis on the fingers, hands, and forearms[13]. In this study, the authors could not induce phytophotodermatitis except by using celery infected with pink-rot fungus. However, phototoxicity following the ingestion of naturally occurring psoralens is uncommon.

Phytophotoallergic Contact Dermatitis

Photoallergy due to plants is rare. A 20-year review of photopatch testing results from a tertiary medical center found reactions in eight of 69 patients, with reactions in only four patients thought to be clinically relevant[14].

Treatment

Prevention is the best treatment for phytophotodermatitis. Known furocoumarin-containing plants should not be planted near play areas. When using weed-whackers or strimmers, operators must cover their chest and extremities. If one has been in contact with a suspected phototoxic plant, prompt washing with soap and water may prevent a reaction.

ALLERGIC CONTACT DERMATITIS (SEE CH. 14)

Members of the Anacardiaceae and Asteraceae families represent the most common causes of allergic contact dermatitis due to plants.

RISK ACTIVITIES FOR PHYTOPHOTODERMATITIS	
Cosmetics	Tan promoters or perfumes containing bergamot oil (berlock [berloque] dermatitis) or a fig leaf decoction
Fruit and vegetable processing	Canning celery or stocking celery in grocery stores Making lemonade or limeade, especially if selling it outside Squeezing lime juice for margaritas and other drinks or guacamole Applying wild carrot decoction to treat foot swelling (China)
Gardening	Brushing against *Dictamnus* spp. ("gas plant/burning bush") (US, Europe, N China) or *Ruta* (UK) Cultivating celery, parsnip, or parsley Clearing weeds with a "weed whacker" (US) or "strimmer" (UK) Pruning or harvesting figs Growing *Angelica* for herbal medicine (Korea), cake decorating (when candied), tonic and flavoring in wines (esp. Benedictine, US)
Hiking	Through fields and riverbanks (*Heracleum* spp.) (Pacific NW, Europe) Hiking in southern California and Baja California (*Cneoridium dumosum*, coast spice bush [Rutaceae])
Ingestion	Ingestion of massive quantities of psoralens (esp. celery) before UVA tanning Eating selemez (wild spinach, *Chenopodium album* [Chenopodiaceae]) – native in Europe and Asia, cultivated widely; sensitizing chemical unknown
Medications	Excessive exposure to UV radiation after taking or applying psoralens for PUVA Application of rue (*Ruta* spp.) as an insect repellant
Play	Making peashooters with *Heracleum* spp. Playing among rue bushes or Apiaceae (see Table 17.7) Using psoralen-containing plants as "weapons" Wearing lei of *Pelea anisata* (Hawaii)

Table 17.9 Risk activities for phytophotodermatitis.

Epidemiology

Anacardiaceae and related families

Key features

- Poison ivy/poison oak plant identification
  - Compound leaves with three leaflets
  - Flowers or fruit arise from axillary position
  - Black dots of urushiol often present on leaves and fruit
  - Common poison ivy climbs as a vine with hairy aerial roots
- Allergens are long-chain catechols and resorcinols found in the urushiol oleoresin

Members of the Anacardiaceae family cause more allergic contact dermatitis than all other plant families combined. Most allergenic family members belong to the genus *Toxicodendron* (meaning "poison tree"). In the US, over a third of patients present during June or July[15].

Toxicodendron identification

Compound *Toxicodendron* leaves possess three or more odd-numbered leaflets[16]. Flowers and fruit arise in an axillary position in the angle between the leaf and the twig from which it arises (Fig. 17.7A,B). The leaf stalk is enlarged at its origin from the supporting twig and leaves a "U"- or "V"-shaped scar after it falls off. Green fruit turn off-white when mature. Plants cling to trees via "hairy" aerial rootlets (Fig. 17.7C,D).

Toxicodendron oleoresin contains urushiol and the enzyme laccase which oxidizes urushiol to form an insoluble, black, plastic-like polymer with great tensile strength. Black spots are commonly found on the leaves of plants (Fig. 17.7E), and the "black-spot test" helps identify toxic Anacardiaceae, but performing it also increases one's likelihood of contracting a nasty dermatitis! A stone is used to thoroughly crush plant contents, especially the leaf stalks, between folds of white paper. Urushiol turns dark brown within 10 minutes and black by 24 hours.

Allergenic Anacardiaceae

As noted in Table 17.10, there are two species each of poison ivy and poison oak and one species of poison sumac that are common to the US (Fig. 17.8). Some have multiple subspecies. Poison oak and poison ivy are weeds that grow along roads, trails, or streams; they possess three (or occasionally five) leaflets per leaf. Poison sumac contains 7–13 leaflets per leaf (see Fig. 17.7A). Young leaves are frequently red in color, and the mature fruit (drupes) are tan or cream-colored and hairless (young fruit has hair). Classically, poison ivy leaves have pointed tips and are ovate (widest point below the center). Poison oak leaves usually have rounded ends. Western poison oak has oval leaves, whereas Eastern poison oak has variable leaf appearances that can mimic white oak leaves.

Virtually all portions of the plant can induce dermatitis, even in the winter. The "winter" shape of poison ivy on fence posts resembles "Medusa heads" that are identifiable while driving down the highway. Strongly suspect any vine climbing by hairy aerial rootlets that is connected at the bottom to a tree or log. In snow, Western poison ivy grows so low to the ground that the upward, tine-like branches may be the only clue to its identification.

The cashew nut tree (*Anacardium occidentale*) grows in the tropics worldwide. The nut contains an oily, brown juice between the two layers of its shell. Contact with concentrated phenols in the nutshell and bark leads to immediate vesication. Any part of the tree, except the nut, can cause dermatitis.

Mango (*Mangifera indica*) is the most popular fruit tree in tropical and subtropical America, and some 35 species grow throughout Southeast Asia. The leaves, bark, stems, and fruit skin contain sensitizing resorcinols. Peeling the fruit before eating it typically prevents allergic contact dermatitis, although allergy to mango pulp has been demonstrated; the pulp allergens appear to be distinct from the resorcinols. Hawaiian natives rarely react to mango, perhaps because early oral exposure induces immunologic tolerance.

The Florida holly (*Schinus terebinthifolius*, Brazilian pepper tree) is probably the most common cause of allergic contact dermatitis in southern Florida. The sap and crushed berries possess a variety of sensitizing catechols and resorcinols.

Although the mango, cashew, and Brazilian pepper trees are incredibly common throughout Latin America, dermatitis to them there is rare, in contrast to the frequent reactions seen in US residents. The main allergens in toxicodendrons are catechols, whereas those in the listed trees are resorcinols, and catechols possess greater allergenicity than resorcinols. Early *cutaneous* exposure to catechols may allow

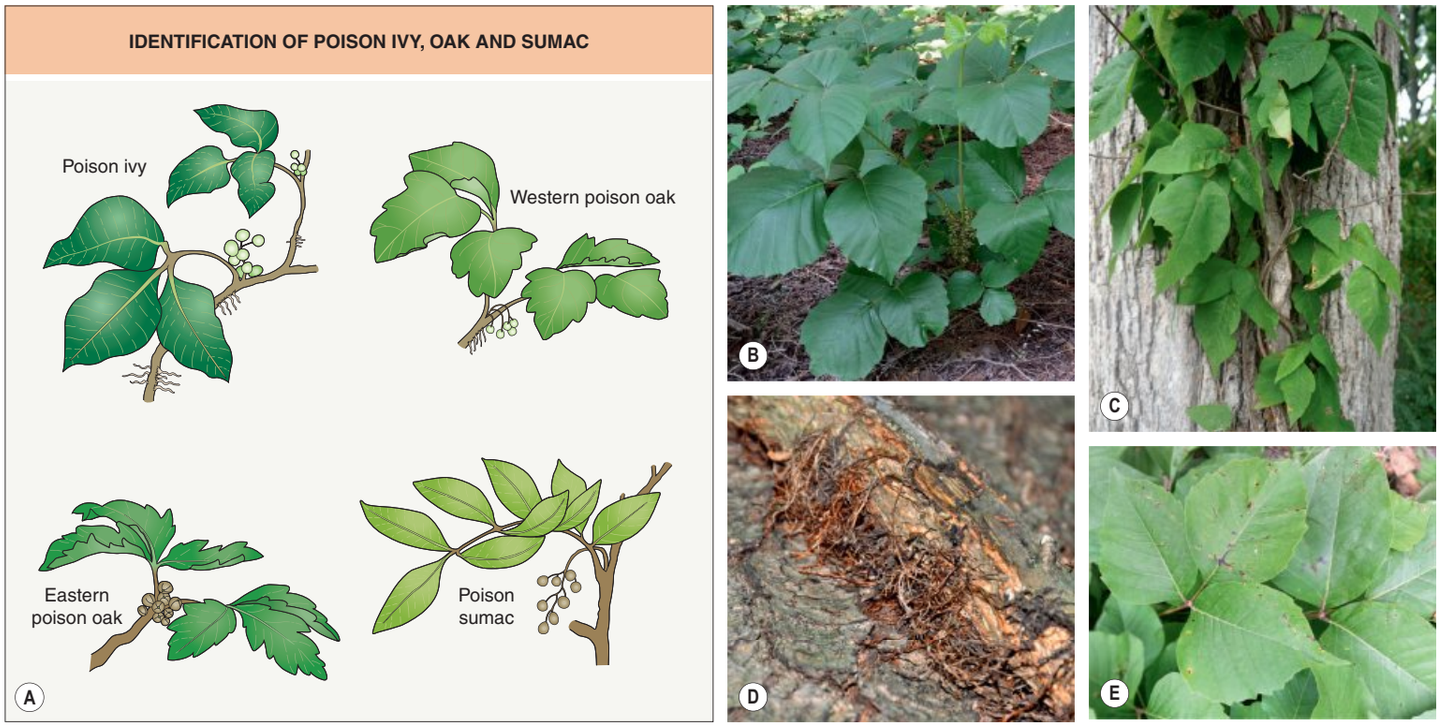

Fig. 17.7 Characteristic features useful for identifying poison ivy, poison oak and poison sumac. A Shapes and numbers of leaflets and appearance of fruit (drupes). **B** Shrub type poison ivy (*T. radicans*) with flowers arising from an axillary position just below point where leaf attaches to stem. Leaves possess three leaflets ("*Leaves of three, let them be*" or "*One, two, three, don't touch me*"). **C, D** Climbing vine of poison ivy (*T. radicans*) on an oak tree demonstrating aerial roots that anchor the vine to the tree; close-up of vine anchored to tree bark by fine hair-like aerial roots ("*Hairy rope, don't be a dope*"). **E** Shrub type poison ivy (*T. radicans*) with black spots on leaflets. Leaf trauma (e.g. wind, rain, trampling by animals or people) allows urushiol to reach the surface, oxidize, and turn black.

MOST COMMON ALLERGENIC MEMBERS OF THE ANACARDIACEAE FAMILY AND MEMBERS OF TWO OTHER PLANT FAMILIES THAT ALSO CONTAIN URUSHIOL CROSS-REACTING CHEMICALS		
Binomial name	**Common name**	**Notes**
Toxicodendron radicans	Common or Eastern poison ivy	Eastern half of USA Climbs trees with aerial rootlets Some subspecies in Mexico, Japan, China
Toxicodendron rydbergii	Northern or Western poison ivy	Western half of USA (except CA) and northern border states Non-climbing shrubs
Smodingium argutum	African poison ivy	South Africa
Toxicodendron pubescens	Eastern poison oak	Southeast USA
Toxicodendron diversilobum	Western poison oak	Pacific Coast of USA Usually a shrub but can climb
Toxicodendron vernix	Poison sumac	Eastern third of USA Not a weed Grows in standing water
Anacardium occidentale	Cashew nut tree	Tropical Americas Highest concentration of allergen in oil in middle layer of nut shell
Mangifera indica	Mango tree	Tropics (see text)
Metopium toxiferum	Poisonwood tree	Caribbean basin
Semecarpus anacardium	Indian marking nut tree	Southeast Asia, Pacific Islands, Australia Used to mark laundry in India ("dhobie mark dermatitis") and used topically as herbal remedy for dermatitis, tattoo removal
Toxicodendron verniciflua	Japanese lacquer tree Chinese lacquer tree	Japan and China Resin used to lacquer wood products
Gluta renghas	Rengas tree	Malaysia lumber source
Schinus terebinthifolius	Brazilian pepper tree or Florida holly	Native to South America, but now a problem in southern Florida, Hawaii, Central America, the Pacific Rim and Pacific Islands
Cross reactors		
Ginkgo biloba (Ginkgoaceae)	Ginkgo tree	Cultivated worldwide in temperate climates – only the seed coat is allergenic
Grevillea spp. (Proteaceae)	Spider flower, silk oak, Hawaiian tree, Kahili tree	Widely cultivated Australian natives

Table 17.10 Most common allergenic members of the Anacardiaceae family and members of two other plant families that also contain urushiol cross-reacting chemicals.

cross-reactions to other Anacardiaceae, whereas early *oral* exposure to resorcinols may induce a state of tolerance.

The 15- to 20-meter tall Japanese lacquer tree (*Toxicodendron verniciflua;* also referred to as the Chinese lacquer tree) produces a thick, self-melanizing, viscous bark sap used for varnishing wood. Because polymerized urushiol remains in the lacquer, it maintains its allergenicity for many years. Patients allergic to poison ivy usually react to Japanese lacquer tree catechols. In a survey of 232 lacquer craftsmen, 189 (81%) developed dermatitis from the lacquer, but 83% of these reactions resolved with continued lacquer exposure (natural hyposensitization)[17].

Other common urushiol-containing Anacardiaceae family members include *Smodingium argutum* (African poison ivy) in South Africa, *Toxicodendron striatum* (Manzanillo tree) in Colombia, and *Lithraea caustica* (Litre tree) in central Chile.

Cross-reactors from other families

The seed of the Ginkgo tree (*Ginkgo biloba*), the only living member of the family Ginkgoaceae, possesses the allergenic catechol ginkgolic acid. Because of the tree's large size, beauty, and resistance to air pollution, male ginkgo trees are widely grown in suburban North America and Europe. The yellowish seeds of female trees disintegrate and release rancid-smelling butyric acid. Contact with the soft outer layer (pulp) of the seed causes most allergic reactions. Dermatitis following contact with the seed kernel, seed shell, and leaves has been reported, but these parts likely only cause irritant reactions (Fig. 17.9). Handling the intact seed (without the seed pulp) does not cause dermatitis in sensitized individuals. The unique, fan-shaped leaf makes the ginkgo easy to recognize.

The genus *Grevillea* (Proteaceae) includes 250 plant species common to Australia that contain pentadecylresorcinol. Having no side-chain double bonds, it is less allergenic than poison ivy and poison oak allergens. The flower of the Hawaiian kahili tree (*Grevillea banksii*) is a significant cause of allergic contact dermatitis in Hawaii.

Asteraceae and related families

Key features

- Asteraceae (Compositae) identification
  - Flower head with all strap-like florets (e.g. dandelion)
  - Flower head with small, central tubular florets and peripheral strap-like florets (e.g. daisy, sunflower)
  - Leaf-like bracts surround undersurfaces of flowers
- Allergens are sesquiterpene lactones (SQLs)

Asteraceae identification

The compound flower heads in this largest of all plant families (~24 000 species) are composed of clusters of tiny flowers (florets) subtended by a whorl of leaf-like bracts (Fig. 17.10). In some plants, an inner "disc" of short, tubular florets is surrounded by long, strap-like "ray" florets (see Fig. 17.10A). In some plants, all the florets are similar (see Fig. 17.10C).

Allergenic Asteraceae

The daisy family includes many troublesome weeds, ornamentals, herbaceous perennials, and vegetables (Table 17.11).

In 1956, *Parthenium hysterophorus* ("congress grass"), a native of northeastern Mexico, accidentally traveled in a consignment of US wheat to India, where it found an inviting ecologic niche. It now infests approximately two million hectares within India as well as large areas of the Americas, South Africa, Madagascar, eastern Australia, and the Pacific Islands. Unlike South American *P. hysterophorus*, the Indian plant contains high concentrations of SQLs and is likely the most common cause of Asteraceae dermatitis in the world.

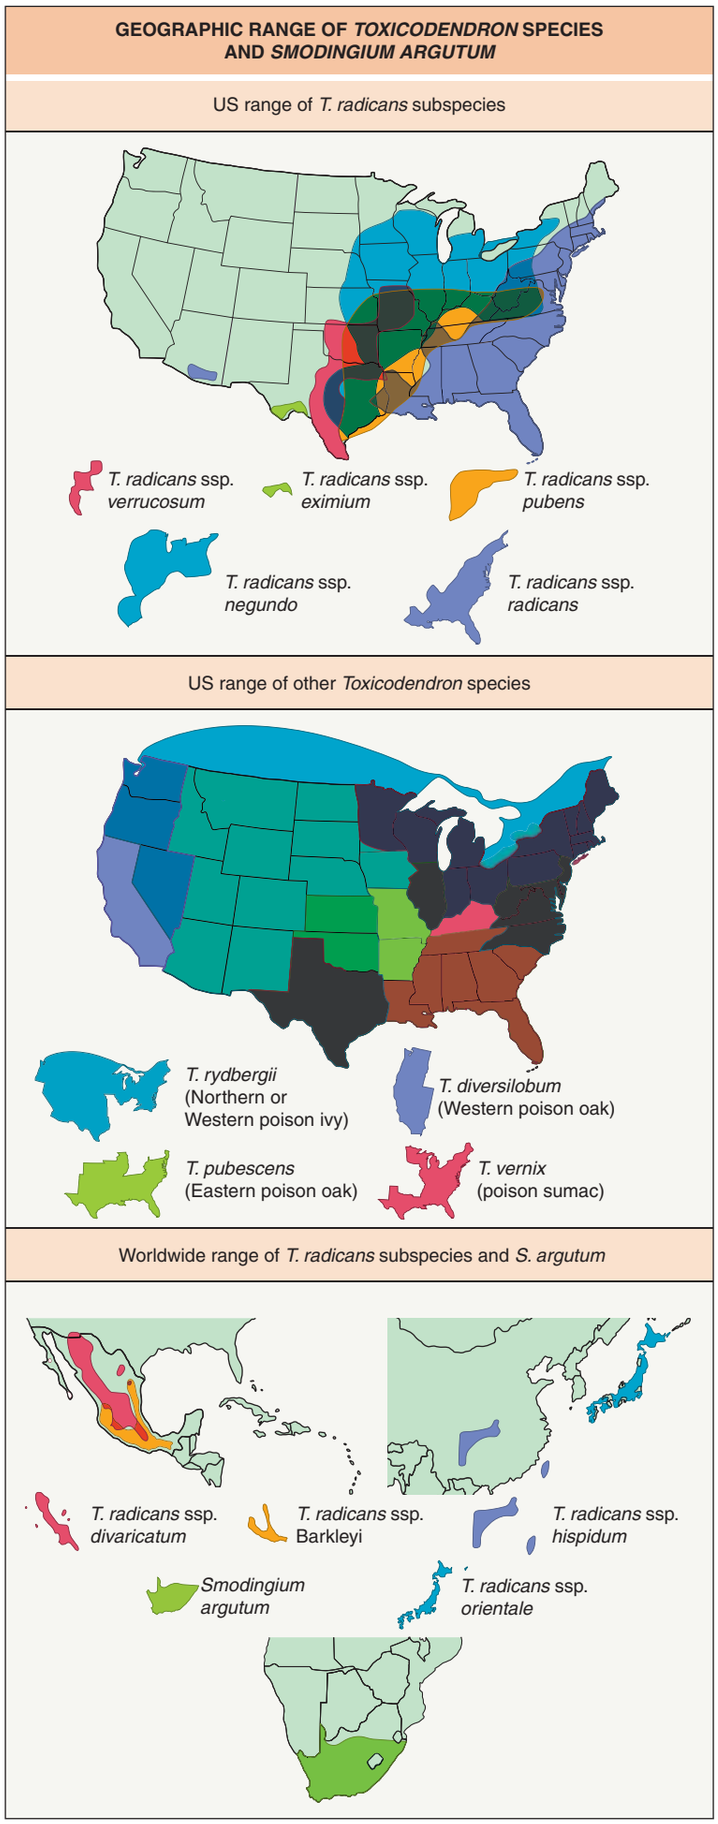

Fig. 17.8 Geographic range of *Toxicodendron* spp. and *Smodingium argutum* (African poison ivy).

Fig. 17.9 Leaves and seeds of *Ginkgo biloba*. Only the fresh seed covering contains the allergen, ginkgolic acid, which typically cross-reacts with urushiol.

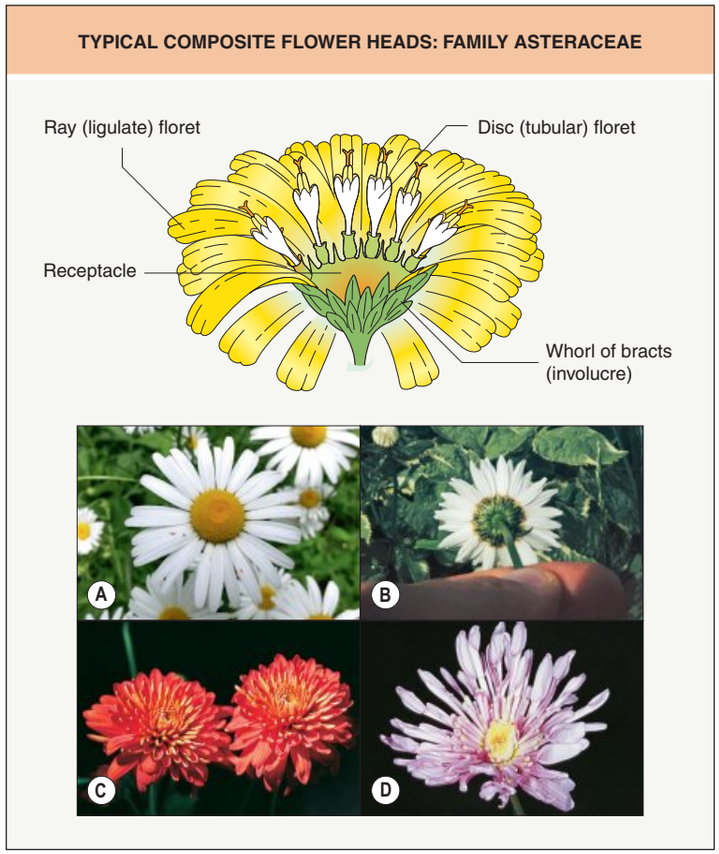

Fig. 17.10 Typical composite flower heads of members of the family Asteraceae (Compositae). Daisy (*Leucanthemum* spp.), demonstrating a composite flower head of numerous, tiny, yellow tubular florets centrally and white ray florets peripherally **(A)** as well as green leaf-like bracts beneath the flower head **(B)**, both of which are characteristic of flower heads of the family Asteraceae. **C** A cushion chrysanthemum (X *Dendranthema* cvs), demonstrating all ray, or strap-like, florets. **D** A composite chrysanthemum (X *Dendranthema* cvs), demonstrating central yellow tubular florets and peripheral ray florets.

Cross-reactors from other families

Allergic reactions to SQLs occur following contact with tulip poplar bark (*Liriodendron tulipifera*) and *Magnolia* trees (Magnoliaceae); liverworts (*Frullania* spp. [Jubulaceae]) in the Pacific Northwest; and leaves of the bay laurel tree (*Laurus nobilis* [Lauraceae]), a Mediterranean basin native.

Pathogenesis

Anacardiaceae allergens

The allergenic substance urushiol derives its name from the Japanese word for the sap (kiurushi) of the Japanese lacquer tree (*T. verniciflua*). It contains a mixture of catechols (1,2-dihydroxybenzenes) and resorcinols (1,3-dihydroxybenzenes) that avidly binds to skin[18].

Catechols and their alkyl side chains are immunologically inert. However, combining them produces potent sensitizers[19]. The

SOME OF THE MORE THAN 200 ALLERGENIC MEMBERS OF ASTERACEAE (COMPOSITAE) FOUND THROUGHOUT TEMPERATE WORLD CLIMATES			
Category	**Binomial name**	**Common name**	**Notes**
Wild flowers and weeds	*Achillea millefolium*	Yarrow, milfoil	A cause of allergic contact "strimmer" or "weed whacker" dermatitis
	Ambrosia spp.	American ragweeds	Allergic contact dermatitis throughout growing season; allergic rhinitis only during pollen season
	Arnica montana	Arnica, mountain tobacco	
	Artemisia vulgaris	Mugwort	Grows in temperate climates worldwide
	Helenium autumnale	Sneezeweed	
	Iva spp.	Marsh elder, sumpweed	
	Parthenium hysterophorus	Scourge of India, congress grass, wild feverfew	Probably most common cause of Asteraceae dermatitis worldwide; Australian "bush dermatitis"; parthenin is primary SQL
	Tanacetum cinerarilifolium	Pyrethrum	
	Tanacetum vulgare	Tansy	
	Tanacetum parthenium	Feverfew	Perhaps the best single plant to screen for SQL allergy
	Taraxacum officinale	Dandelion	Airborne contact dermatitis after mowing
Ornamental flowers	*Dahlia* spp.	Dahlia	
	X *Dendranthema* cultivars	Chrysanthemum	Common cause of SQL dermatitis; florists remove dead flowers ("dead-head") to encourage more blooms
	Helianthus annuus	Sunflower	Windblown trichomes can cause airborne contact dermatitis
	Rudbeckia hirta	Black-eyed Susan	
In herbal medicine*	*Calendula officinalis*	Pot marigold	
	Chamaemelum nobile	Sweet/Roman chamomile	
	Inula helenium	Elecampane	
Vegetables	*Cichorium endiva*	Endive	
	Cichorium intybus	Chicory	
	Cynara scolymus	Globe artichoke	
	Lactuca sativa	Lettuce	

*Also *Achillea millefolium*, *Arnica montana*, *Helianthus annuus*, *Tanacetum parthenium*, *Tanacetum vulgare*, *Taraxacum officinale*.

Table 17.11 Some of the more than 200 allergenic members of Asteraceae (Compositae) found throughout temperate world climates. SQL, sesquiterpene lactone.

immunologic activity of alkyl side chains results from weak van der Waals forces. Longer side chains increase irritancy and allergenicity; location of the catechol ring at position 3 increases antigenicity, but placement at position 6 induces tolerance. Although virtually all individuals who are allergic to poison ivy react to the C15 catechol with two double bonds (a diolefin), only 35% respond to the C15 catechol with an unsaturated side chain (pentadecylcatechol). Therefore, pentadecylcatechol, which is easily synthesized, is an inappropriate patch test allergen for Anacardiaceae sensitivity, because the diolefin is the major component in poison ivy and poison oak urushiols.

Asteraceae allergens

The major sensitizers, sesquiterpene lactones (SQLs), are found in the leaves, stems, and flowers, and they are composed of a sesquiterpene ($C_{15}H_{24}$) and a lactone ring (cyclic ester). Direct plant contact, botanical extracts in skin care products and cosmetics, and dry airborne plant parts including pollen can transfer SQLs to individuals. Over 5000 SQLs have been described, of which about 4000 are potentially allergenic. The composition of SQLs produced by any species varies according to location and weather.

Patch testing for SQL allergy has traditionally relied on the SQL mix consisting of three SQLs – costunolide, alantolactone, and dehydrocostus lactone – or the "Compositae mix" of non-standardized extracts from five species of Asteraceae. The SQL mix has a false-negative rate of 35%–65% in SQL-allergic patients, while the Compositae mix has a false-negative rate of at least 15%. The SQLs present in these mixtures poorly represent SQL structural diversity[20]. A combination of three commercially available patch tests – SQL mix, Compositae II mix, and parthenolide (also contained in Compositae II mix) – can be used as this combination detects 96% of known SQL allergic individuals[21]. Ideally, patients should be tested to portions of the suspect plant.

Clinical Features

Anacardiaceae dermatitis

Key features

- Urushiol is a partially water-soluble allergen that must be washed off quickly
- Treat for at least 2 weeks, otherwise rebound dermatitis commonly occurs
- Eruption "progresses" to "new areas" because of variability in antigen concentration and stratum corneum thickness

Lightly brushing against uninjured leaves is innocuous, since plants must be damaged to release urushiol (see Fig. 17.7E). However, in the late fall, plants spontaneously release urushiol. In addition, contaminated clothing, pets, lacquered furniture, sawdust, and smoke (potentially causing severe respiratory tract inflammation, dermatitis, and even temporary blindness) can transfer urushiol.

After urushiol contact, a sensitized person typically develops an erythematous, pruritic eruption within 2 days (range, 4–96 hours) that peaks within 1–14 days[22] . However, dermatitis may occur up to 3 weeks after primary contact or within hours of secondary contact. Streaks of erythema and edematous papules typically precede vesicles and bullae (Fig. 17.11A,B,E). If the antigen load is lower, only erythematous, edematous reactions may be seen (Fig. 17.11C,D). Although allergic contact dermatitis is the most common cause of such a streaky, vesicular dermatitis, plants may cause this picture by other means (e.g. chemical irritant dermatitis or the initial phase of phytophotodermatitis). Patch tests of bulla fluid are routinely negative. The illusion that

this fluid propagates the eruption results from variations in the time it takes for a clinical reaction to occur at different sites that have received differing antigen loads and have variable stratum corneum thicknesses.

Erythema multiforme appears to be an underreported sequela of severe poison ivy reactions that may appear 2 weeks following onset of the dermatitis (Table 17.12)[23]. Uncommonly, nephritis or eruptions resembling measles, scarlatina, or urticaria develop and are ascribed to immune complex deposition. Without treatment, poison ivy dermatitis lasts about 2–3 weeks. Prolonged postinflammatory hyperpigmentation may occur in individuals with darker skin phototypes.

Over 70% of the US population react to poison ivy allergens after patch testing, but only 50% react to plants in nature. Interestingly, only 15% of atopic persons are sensitive, and studies suggest that sensitivity is hereditary. Urushiol-sensitive AIDS patients with $CD4^+$ counts <200/mcl maintain sensitivity to poison ivy allergens[24] because the predominant effector T cells against poison ivy catechols are $CD8^+$.

In "black-spot" poison ivy dermatitis, urushiol acts as both irritant and allergen; an irritant contact dermatitis is superimposed on an allergic contact dermatitis[25,25a]. Oxidized resin creates a black discoloration on the skin (Fig. 17.11F). If urushiol stains clothing black, it cannot be washed off and will retain its allergenicity indefinitely. A more widespread spotted pattern in non-covered sites is seen if a patient has been weed-whacking areas of poison ivy (Fig. 17.11G).

Asteraceae dermatitis

Key features

- Caused by sesquiterpene lactones (SQLs)
- Most common cause for home gardeners is chrysanthemums
- Most common worldwide cause is *Parthenium hysterophorus*
- Often presents with an airborne contact pattern
- Patients frequently become photosensitive

Chrysanthemums probably cause more allergic contact dermatitis than any other home garden plant (Fig. 17.12). The flowers and leaves are more potent sensitizers than the stems, and contact is common when removing dead flowers to encourage further blooming ("dead-heading").

Middle-aged men with a history of outdoor exposure may develop Asteraceae allergy that resembles airborne contact dermatitis (ABCD) (Fig. 17.13). SQLs, though not volatile, are bound to airborne trichomes and dried leaves in sufficient concentrations to cause ABCD[26]. Typically, a single region of the body is involved for several years, flaring in the summer during the plant's growing season and disappearing during the winter. Later, all exposed areas develop a chronic pruritic and lichenified dermatitis. However, the eyelids, melolabial folds, retroauricular sulci and antecubital fossae are generally involved, unlike the situation in photosensitive dermatitis (see Fig. 87.15).

Ragweed (*Ambrosia artemisiifolia*) commonly causes ocular and airway immediate hypersensitivity reactions via pollen allergens, with the major allergen identified as Amb a 1. Although pollen can rapidly penetrate the skin[27], it contains no SQLs and has not been demonstrated to cause contact dermatitis. SQLs found in other parts of ragweed plants can induce ABCD (see above) and dyshidrotic eczema[28].

Parthenium hysterophorus allergic contact dermatitis accounts for 40% of all visits to contact dermatitis clinics in India and most commonly presents with an ABCD pattern (45%); 15% of patients have erythroderma while 10% develop chronic actinic dermatitis[29]. The remainder display a mixture of these three patterns. *Parthenium*-allergic patients sometimes demonstrate positive prick tests suggesting the

PLANTS AND PLANT PRODUCTS THAT CAN LEAD TO ERYTHEMA MULTIFORME IN THE SETTING OF SEVERE ALLERGIC CONTACT DERMATITIS

Common name (binomial name)	Family	Notes
Poison ivy, oak, sumac (*Toxicodendron* spp.)	Anacardiaceae	US and Canada
Tea tree oil (*Melaleuca alternifolia*)	Myrtaceae	Australia, exported products
Wild feverfew (*Parthenium hysterophorus*)	Asteraceae	India

Table 17.12 Plants and plant products that can lead to erythema multiforme in the setting of severe allergic contact dermatitis.

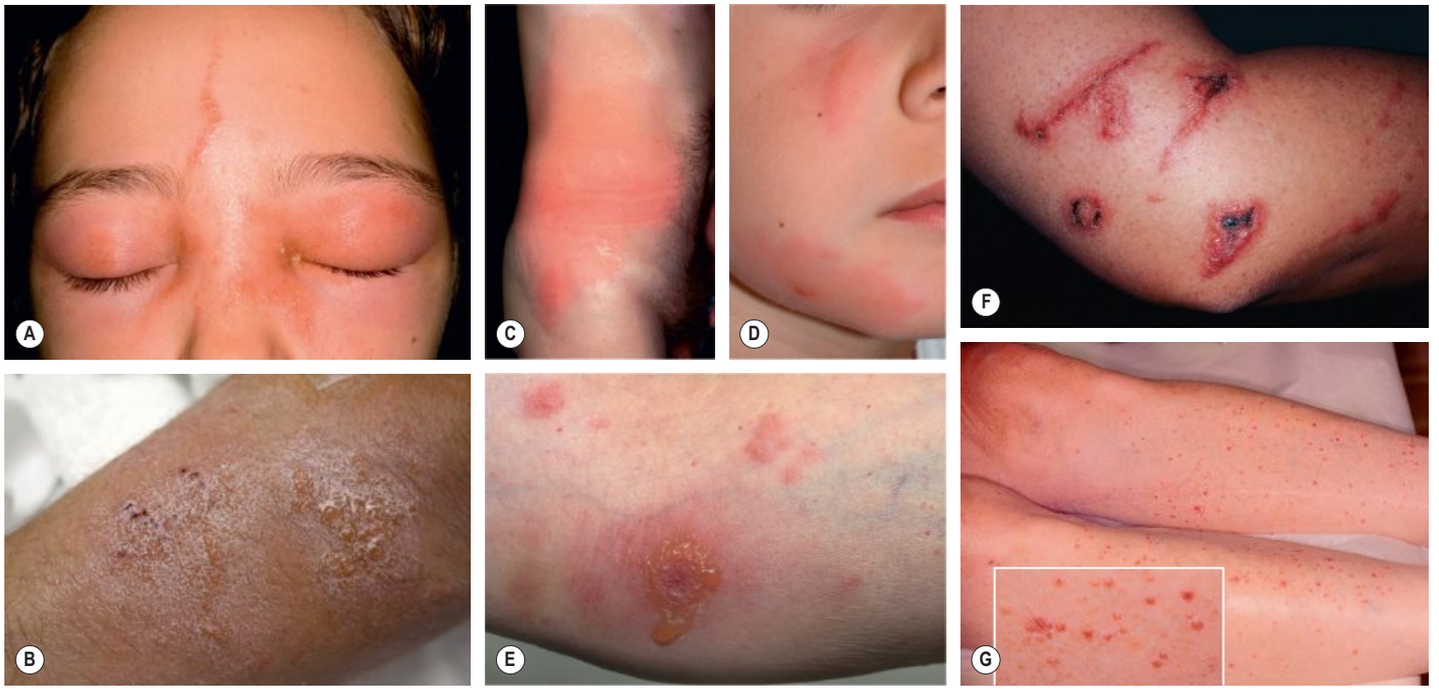

Fig. 17.11 Clinical manifestations of Anacardiaceae dermatitis. A Poison ivy (*Toxicodendron radicans*) dermatitis: acute streaks of erythema with superimposed vesicles and eyelid edema with serous crusting. **B** Poison ivy dermatitis: multiple vesicles and a few hemorrhagic crusts with superimposed zinc oxide from application of calamine lotion. **C** Widespread erythema and edema associated with intense pruritus after carrying logs of the poisonwood tree (*Metopium toxiferum*) of the family Anacardiaceae. **D** Pink edematous streaks on the face. **E** Compared to **B**, more obvious erythema in association with edema and multiloculated vesicles. **F** "Black-spot" poison ivy dermatitis: note the black discoloration in the central portion of the edematous plaques due to polymerized plant oleoresin. **G** Weed whacker dermatitis with widespread spotted pattern. *A, G, Courtesy Louis A. Fragola, Jr, MD; B, Courtesy Julia Pettersen Neckman, MD; D, Courtesy Julie V. Schaffer, MD; E, F, Courtesy Kalman Watsky, MD.*

coexistence of type I and type IV hypersensitivity reactions. Allergens found in Asteraceae plants have been shown to cause systemic allergic dermatitis which can involve both skin and mucosae[30]. Although patients are initially sensitized via skin contact, subsequent exposure to the allergen by other routes (e.g. intravenous, intramuscular, subcutaneous, inhalation, oral, mucosal) results in dermatitis in the absence of contact of the allergen with the skin.

Photosensitivity and Asteraceae allergy

SQLs possess neither phototoxic nor photoallergic properties, yet allergic patients often develop abnormally low minimal erythema and minimal phototoxic doses to wavelengths of 300–350 nm, and conversely, up to 85% of patients with chronic photosensitivity dermatoses react to Asteraceae allergens[31]. Chronic actinic dermatitis (CAD) that develops in some patients who are allergic to SQLs is thought to be an autoimmune photodermatosis mediated by sunlight-induced antigens in the skin (see Ch. 87). For example, the SQL isoalantolactone has been shown to be highly reactive with DNA in solution during UVA irradiation, and the UV action spectrum for CAD corresponds with the UV absorption peak for DNA. An interaction between SQLs and DNA in the presence of UV light may alter DNA to render it antigenic and trigger a CAD response[32].

Although α-terthienyl and various polyacetylenes with phototoxic properties have been found in some Asteraceae, no link has been established between their presence and dermatitis[32].

Treatment (Anacardiaceae and Asteraceae Dermatitis)

The primary goal of treatment is to relieve pruritus[22]. As soon as exposure to poison ivy or related plants is recognized, one approach is to thoroughly wash the entire body three times with liquid dishwashing soap and a damp washcloth – stroked in one direction, not back and forth – under very warm to hot running water[33]. If no dishwashing soap is available, washing with just water will still remove some resin.

Weepy lesions are best treated with tepid baths, wet-to-dry soaks, or bland shake lotions (calamine) that can dry the lesions. An astringent such as Burow's solution (aluminum acetate) works well to cool and dry lesions when applied as a wet-to-dry dressing or open wet dressing. Topical antihistamines, anesthetics containing benzocaine, and antibiotics should be avoided to prevent sensitization[34,34a].

Superpotent topical corticosteroids only help if applied during the earliest stages of the outbreak when vesicles and bullae are not yet present, and their abrupt discontinuation can lead to rebound inflammation. Topical calcineurin inhibitors are ineffective in treating urushiol-induced dermatitis. One surfactant product (Zanfel® wash) reportedly relieves redness and itching[35].

Systemic corticosteroids are extremely effective when indicated. Oral prednisone should be dosed at 1–2 mg/kg/day based upon ideal weight and gradually tapered over 2–3 weeks[34]. Six-day tapering courses of methylprednisolone (e.g. Medrol® Dosepak) are too short and too low dose to be effective; rebound commonly follows completion. The author routinely uses intramuscular long-acting triamcinolone acetonide (1 mg/kg) mixed with fast-acting betamethasone (0.1 mg/kg). Patients experience rapid relief and fewer side effects than with oral prednisone[34]. Such systemic treatment is also less expensive than application of high potency topical corticosteroids[15]. Soporific oral antihistamines often induce poor-quality sleep while doing nothing for the itch, since histamine is not responsible for the pruritus.

Hyposensitization programs for Anacardiaceae- and Asteraceae-allergic individuals have generally failed. Patients develop pruritus ani, generalized pruritus, or urticaria and comment that the "treatment is worse than the disease". It appears that hyposensitization after becoming cutaneously sensitized to the potent allergens in poison ivy and poison oak is difficult, but not impossible, as demonstrated by Japanese lacquer craftsmen (see above) and one study of *Parthenium*-allergic individuals in which 70% of patients who underwent oral hyposensitization improved symptomatically[29].

A recent study in guinea pigs suggests that vaccination may be possible. Intramuscular administration of water-soluble derivatives of certain urushiol components not only desensitized previously sensitized animals, but also prevented sensitization of naive animals[36].

Applying 5% quaternium-18 bentonite lotion before touching poison ivy reduces allergic reactions, but currently the once commercially available product is no longer available. Of note, toxicodendron allergens pass through rubber gloves, but not heavy-duty vinyl gloves.

In chronic actinic dermatitis or other widespread Asteraceae-induced dermatitis, potent topical corticosteroids and oral prednisone are relatively ineffective unless employed early (before year-round dermatitis occurs). Very-low-dose PUVA with initial oral corticosteroid coverage[37], azathioprine, or mycophenolate mofetil may be necessary to control the disease (see Ch. 87 for details).

Other Plant Families Causing Allergic Contact Dermatitis

Alliaceae

The genus *Allium* includes onions, garlic, and chives. Garlic is the most frequent cause of fingertip dermatitis in cooks. It typically presents on the thumb, index, and middle fingertips of the non-dominant hand with hyperkeratosis, desquamation, and fissuring. Patch testing to whole garlic should never be done because of its irritant properties. The most important irritant and allergen is diallyl disulfide. Onion (*Allium cepa*) dermatitis is rare. Common disposable gloves, such as vinyl, latex, polyethylene, and nitrile, do not protect sensitized individuals who handle garlic or onions. Reusable domestic rubber gloves are protective.

Alstroemeriaceae and Liliaceae

"Tulip fingers" is a combined allergic and irritant contact dermatitis caused by tulip bulbs (*Tulipa* spp.). Erythematous, scaly plaques appear on the fingertips and periungual skin, particularly on the first and second fingers of the dominant hand, but a diffuse, xerotic hand dermatitis often develops after prolonged exposure. Pulpitis, paronychia, and dissemination to the face, neck, arms, and anogenital area may ensue. Tuliposide A, a glycoside, is found in the white epidermis of bulbs. Acidic hydrolysis converts it to tulipalin A, the allergen. Tuliposide B is also found in tulips, but its hydrolytic product, tulipalin B, is a much weaker sensitizer.

Since their popularization in Holland in 1963, Peruvian lilies (*Alstroemeria aurantiaca* and *A. ligtu*) have become incredibly popular in floral arrangements. Handlers remove individual flowers, thread wire through the stems, and/or cut off leaves (Fig. 17.14A). These workers can develop erythema, fissuring, vesicles, hyperkeratosis, and exfoliation of the fingertips, greater on the dominant hand (Fig. 17.14B)[38]. Most often, allergic reactions present with non-inflamed distal finger fissuring and hyperkeratosis. Unfortunately, the allergen passes through vinyl (polyvinyl chloride) gloves[38]. Although nitrile (synthetic rubber) gloves are protective, few florists will wear them. Tuliposide A and B are found in virtually all portions of the plant. The flowers have more allergen than the stems, and the leaves have the least amount.

Myrtaceae

Since the early 1990s, oil distilled from the leaves of *Melaleuca alternifolia* (the Australian tea tree) has been increasingly reported as a cause of allergic contact dermatitis. At least two-thirds of Australians have been exposed to it, and between 2% and 7% of them are allergic to it. While tea tree oil possesses broad-spectrum antimicrobial, anti-inflammatory, and antihistaminic effects, at least 16 different constituents are strong sensitizers. Because most sensitizers are degradation products formed after exposure of tea tree oil to light, warmth, and moisture, fresh tea tree oil is a weak sensitizer[39].

Botanical products

Hundreds of botanical extracts are added to skin care products for fragrance and purported healing properties. Fifty to 60% of patients with a presumed contact allergy to botanical extracts display at least one relevant positive reaction[3,40]. In a 2004 report, the most common culprit was tea tree oil, followed by feverfew (Asteraceae family) and lichen acid mix (found in deodorants)[3]. A more recent analysis of allergic contact dermatitis due to the use of herbal remedies found that Asteraceae plants were the most common source of botanical allergens[40].

Balsam of Peru (*Myroxylon* spp.), fragrance mix, Compositae mix, and SQL mix are poor screens for botanical allergy in that they uncover only 33%, 30%, 20%, and 7% of relevant allergic reactions, respectively[3]. A *repeat open application test* performed by applying the suspected allergenic product to the antecubital fossa twice daily for seven days will help diagnose an allergy to botanical extracts.

Table 17.13 lists plant dermatoses most commonly observed by dermatologists in various countries from around the world.

OCCUPATIONAL PLANT DERMATOSES

Bakers

Bakers and food processors have high rates of immunologic contact urticaria[41]. Flours, grains, and feeds ranked third behind cow dander and latex as the causes of such urticaria[2]. Omalizumab has allowed at least one baker to maintain his job when protein contact dermatitis to wheat threatened his livelihood[42].

Florists and Horticulturalists[43–45]

Irritant dermatitis outweighs allergic contact dermatitis in frequency and importance. Estimates of hand dermatitis in florists range from an 8% point prevalence to a 25%–30% annual incidence to a nearly 50% lifetime incidence, especially amongst floral designers. Although most cases of hand dermatitis are mild, periodic, and self-limited, because florists' hands are often wet, primary irritant reactions may lead to sensitization over long periods of time.

For florists, the most common sensitizers are sesquiterpene lactones, tulipalin A, and primin (*Primula obconica*). Daffodil itch (caused by calcium oxalate), from handling stems and bulbs, is probably the most common cause of irritant contact dermatitis in florists. In one series,

Fig. 17.14 Allergic contact dermatitis in a florist. **A** Florist with fingertip *Alstroemeria* allergic contact dermatitis showing how he holds a Peruvian lily while cutting off the leaves. **B** Index finger of the same florist, showing the chronic, lichenified, hyperkeratotic dermatitis caused by allergy to Peruvian lily and tulipalin A. *Photos with permission from the American Journal of Contact Dermatitis 1999;10:172–6.*

10% of 250 horticultural workers were allergic to Asteraceae[45] and one-third developed urticaria. An atopic family history increased one's likelihood of developing urticaria[45].

Food Handlers

Food handlers are at increased risk for immunologic contact urticaria and protein contact dermatitis (see above)[46]. Of those who develop protein contact dermatitis, over 60% need to change jobs. Among grocery store workers, contact with fresh celery combined with indoor tanning increases the prevalence ratio for phytophotodermatitis to >40 as compared to those with neither risk factor.

Outdoor Workers

Among outdoor workers, poison ivy and poison oak (*Toxicodendron* spp.) are the main causes of occupational contact dermatitis. *Toxicodendron* contact accounts for 10% of all lost-time injuries for the US Department of Agriculture Forest Service. Foresters, especially when fighting forest fires, have virtually no control over avoiding these plants. Up to 25% of firefighters need to leave the fire line because of severe *Toxicodendron* dermatitis.

Forestry workers in the American and Canadian Pacific Northwest may develop "woodcutter's eczema", an allergic contact dermatitis caused by airborne or rainwater-dispersed SQLs from liverworts (*Frullania* spp.) growing on trees and rocks. The dermatitis is worse in wet winter months and presents in a pseudo-photodistribution, involving the upper eyelids while sparing the submental area.

DERMATOSES ERRONEOUSLY ASCRIBED TO PLANTS

Organisms that are neither animal nor plant belong to one of the following kingdoms:

- Monera – unicellular prokaryotes (anuclear); includes bacteria and blue-green algae (cyanobacteria)
- Fungi – multicellular, heterotrophic (absorb food) eukaryotes (possess nuclei); lack cilia or flagella
- Protista – unicellular eukaryotic protozoans and algae

Reactions to these organisms can be falsely ascribed as reactions to plants.

Lichen Dermatitis[47]

Lichens are composite organisms consisting of a fungus and a photosynthetic partner, usually a green or blue-green alga. In the Pacific Northwest, the fungal component of lichens growing on trees, rocks, or soil disperses usnic acid, atranorin, and everinic acid onto foresters or other passersby via either direct contact or rainwater. This leads to allergic contact dermatitis in a pseudo-photodistribution. These three lichen acids are found in the common fragrance constituent oak moss absolute, and they can also cause photoallergic contact dermatitis. Oak moss absolute is one of eight ingredients in the fragrance mix I and is responsible for almost 40% of positive reactions to this fragrance mix.

Chlorella Photodermatitis

Ingestion of *Chlorella*, a nutritional supplement grown in Taiwan and Japan, can cause photodermatitis. *Chlorella* is a single-celled green alga that produces pheophorbide A, a photosensitizing breakdown product of chlorophyll that has been used experimentally for photodynamic therapy.

Seaweed Dermatitis[48]

While there are over 3000 species of seaweed, the unicellular blue-green alga *Lyngbya majuscula* is the primary species that causes a chemical irritant contact dermatitis (due to aplysiatoxin and debromoaplysiatoxin). Usually growing in fine blackish-green to olive-green strands up to 30 cm long, it looks like matted hair or felt and can get caught under bathing or wet suits. Within minutes of contact, genitalia and buttocks develop erythema, pruritus, and edema. Pustules and several days of desquamation often follow.

Seaweed dermatitis is primarily a problem during algal blooms stimulated by pollution and overfishing. In temperate and tropical oceans around the world, *Lyngbya* has been observed in intertidal zones up to a depth of 30 meters.

Pseudo-Phytodermatitis From Plant Hitchhikers

Allergic and irritant chemical reactions may occur from insecticides and other chemicals used to prevent horticultural or agricultural damage. Contaminating arthropods such as the hay itch mite (*Pyemotes* spp.) found in grains can cause pruritic wheals in dock workers, farmers,

Urticaria and Angioedema 18

Clive E.H. Grattan, Emek Kocatürk and Sarbjit S. Saini

Synonyms: ■ Wheals – hives, nettle rash ■ Angioedema – Quincke edema, angioneurotic edema

Key features

- Urticaria is characterized by transient skin or mucosal swellings due to plasma leakage. Superficial dermal swellings are wheals, and deep swellings of the skin or mucosa are termed angioedema. Wheals (hives) are characteristically pruritic and pink or pale in the center, whereas angioedema is often painful, less well-defined, and shows no color change
- There are several recognizable clinical patterns of urticaria and different causes. The latter include allergy, autoimmunity, drugs, dietary pseudoallergens, and infections. Many cases of spontaneous urticaria remain unexplained ("idiopathic") even after an extensive evaluation; they may also be multifactorial
- C1 esterase inhibitor deficiency and angiotensin-converting enzyme (ACE) inhibitors need to be considered as causes of recurrent angioedema without wheals
- Diagnosis is based primarily on the history and clinical examination. Determination of the etiology or triggers, as well as exclusion of other diagnoses, may require further investigations, including blood tests, physical and dietary challenges, skin tests, and skin biopsy
- Urticaria is a common disorder that may cause considerable distress and last for years, but the symptoms can usually be alleviated by appropriate management

INTRODUCTION

Urticaria is a common reason for patients to present to primary care practitioners, emergency rooms, dermatologists, and allergists. It is characterized by the rapidity of its fluctuation. As a rule, individual wheals last no more than 24 hours, but the entire affliction usually lasts much longer. With nearly all clinical patterns of urticaria, wheals may be accompanied by angioedema, but the occurrence of isolated angioedema (without wheals) is of special significance because some of these patients will have a deficiency of C1 esterase inhibitor (C1 inh). The latter is due to bradykinin formation rather than release of mast cell mediators. C1 inh deficiency is a rare disorder that is often inherited and because it can prove fatal without treatment must be considered in any patient with isolated angioedema. Urticarial vasculitis is an important disorder to exclude in patients with chronic urticaria. It is a systemic disease defined by damage to small blood vessels rather than transient vasodilation and vascular permeability (see Ch. 24). Urticarial vasculitis sometimes presents with wheals or angioedema that, without confirming a duration of more than 24 hours (by serial examination of marked lesions) and a lesional skin biopsy, can be indistinguishable from chronic spontaneous urticaria (CSU). While urticaria rarely progresses to anaphylaxis, wheals are often a feature of that condition. Good management of urticaria depends on a thorough understanding of etiologies, triggers, and aggravating factors, in addition to the most appropriate drug therapies.

Definition of Urticaria

Urticaria is often used as a descriptive term for recurrent wheaing of the skin, with angioedema being viewed as a physical sign. However, there is increasing acceptance that the term "urticaria" also defines an entity that may be acute or chronic. Thus, when viewed as a disease, urticaria may present with wheals, angioedema, or both.

Wheals are pruritic, pink or pale swellings of the superficial dermis that have an initial erythematous flare around them (Fig. 18.1). Lesions may be a few millimeters in diameter or as large as a hand, and the number can vary from a few to numerous. The hallmark of wheals is that, by definition, *individual* lesions come and go rapidly, generally within 24 hours. However, larger coalescing wheals may take longer to resolve.

Angioedema swellings occur deeper in the dermis and in the subcutaneous or submucosal tissue. They may also affect the oropharynx and rarely the bowel in hereditary angioedema. The areas of involvement tend to be normal or faint pink in color, painful rather than pruritic, larger, and less well-defined than wheals, and they often last for 2 to 3 days (Fig. 18.2).

EPIDEMIOLOGY

Depending on the age range and method of sampling, estimates of the lifetime prevalence of acute and chronic urticaria in the general population range from 8% to 22%[1]. In a recent meta-analysis, chronic urticaria had overall lifetime and point prevalence rates of 1.4% and 0.7%, respectively[2]. The prevalence of specific subtypes of chronic urticaria, e.g. the inducible urticarias, is lower[3].

Urticaria is a worldwide disease and may present at any age, with the peak incidence dependent upon etiology. The proportion of cases due to different etiologic agents is likely related to the frequency of environmental exposures, such as infections and allergens, in different countries, but estimates of this are not available. It is also often difficult to prove a cause and effect, and so an underlying condition may be inappropriately "blamed" for causing urticaria. Overall, urticaria is more common in women, with a female : male ratio of ~2 : 1 for CSU, but the ratio varies with the different physical urticarias. For example, women outnumber men in dermographism and cold urticaria, but more men develop delayed pressure urticaria. Hereditary angioedema has an autosomal dominant inheritance pattern and occurs in ~1 in 50 000 individuals, with a range that varies from 1 in 20 000 to 1 in 60 000.

PATHOGENESIS

The Mast Cell

Distribution and diversity

The mast cell is the primary effector cell of urticaria. Mast cells are widely distributed throughout the body but vary in their phenotype and response to stimulation. This may explain why systemic features, such as those seen in anaphylaxis, do not accompany the activation of cutaneous mast cells in urticaria. The majority of mast cells in the skin and intestinal submucosa contain the neutral proteases tryptase and chymase (MC_{TC}), whereas those in the bowel mucosa, alveolar wall, and nasal mucosa contain only tryptase (MC_T). Both types, however, express high-affinity IgE receptors (FcεRI) and are therefore capable of participating in IgE-dependent allergic reactions[4]. There is conflicting evidence on the number of cutaneous mast cells in chronic urticaria, but there is agreement that they may be more likely to degranulate in response to certain stimuli, such as intradermal codeine injection, and in this sense may be in general more "releasable". Little is known about the beneficial effects of mast cells, but there is evidence that they are involved in the innate immune response to infection, wound healing, and the neuroendocrine system. They have also been shown to help initiate the extracellular matrix formation and angiogenesis required for neurofibroma development.

Fig. 18.1 Wheals. A, B Wheals can vary in size from small to large as well as be annular, but they still retain the classic central pallor and erythematous flare. **C** Occasionally, more uniform edematous plaques are seen.

Fig. 18.2 Angioedema. The swelling is deeper than wheals and may affect mucosal surfaces. Note the swelling of the lips and periorbital region and the lack of erythema.

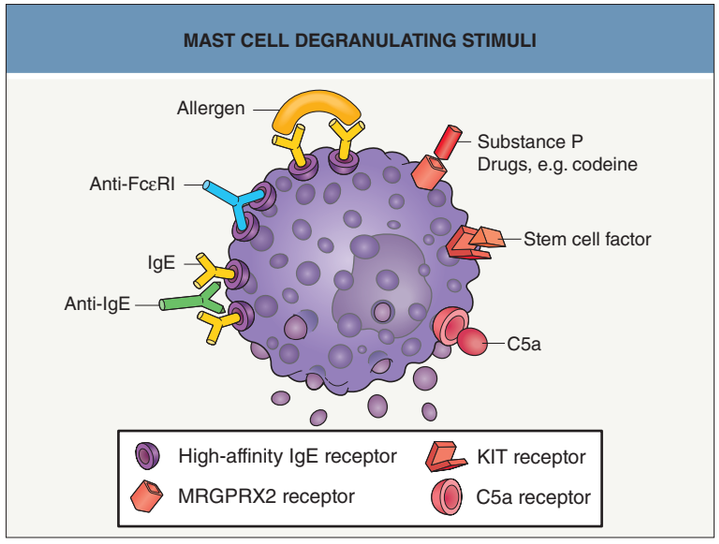

Fig. 18.3 Mast cell degranulating stimuli. Both immunologic and non-immunologic stimuli can lead to release of mediators. Substance P also binds to neurokinin 1 receptor; stem cell factor is also known as KIT ligand. MRGPRX2, MAS-related G-protein coupled receptor X2.

Degranulating stimuli

Cross-linking of two or more adjacent FcεRI on the mast cell membrane will initiate a chain of calcium- and energy-dependent steps leading to fusion of storage granules with the cell membrane and externalization of their contents. This is known as degranulation. Classic immediate hypersensitivity reactions involve binding of receptor-bound specific IgE by allergen. There are also several recognized immunologic degranulating stimuli that act through the IgE receptor, such as IgG anti-IgE and anti-FcεRI antibodies (Fig. 18.3).

Autoantibodies against FcεRI (IgG > IgM, IgA) are associated with disease markers of CSU[5], but the degree to which they mediate release of histamine from mast cells or basophils *in vitro* can vary. In addition, because anti-IgE and anti-FcεRI autoantibodies have been identified by immunoassays (but not functional assays) in patients with other diseases such as systemic lupus erythematosus[6] and occasionally in healthy controls, the role of autoantibodies in the pathogenesis of urticaria has been debated. Stimuli that can lead to mast cell degranulation independent of FcεRI activation include C5a, stem cell factor, and agents that bind MRGPRX2 (MAS-related G-protein coupled receptor X2; see Fig. 18.3); the latter include substance P and drugs such as opioids[7,8].

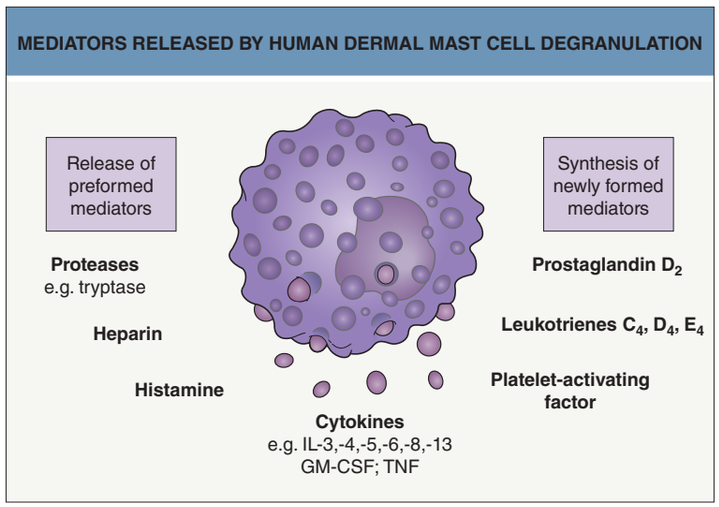

Fig. 18.4 Mediators released by human dermal mast cell degranulation. Both preformed and newly synthesized proinflammatory mediators are released from mast cells.

Proinflammatory mediators

Mast cell granules contain preformed mediators of inflammation, the most important of which is histamine (Fig. 18.4). A wide range of cytokines has been identified in human mast cells from different tissues, including tumor necrosis factor (TNF), interleukins (IL)-3, -5, -6, -8, and -13, and granulocyte–macrophage colony-stimulating factor (GM-CSF). Synthesis and secretion are upregulated following FcεRI stimulation. TNF is expressed constitutively in resting human cutaneous mast cells. Prostaglandins and leukotrienes are synthesized from arachidonic acid derived from cell membrane phospholipids. The

most important *proinflammatory* eicosanoids are prostaglandin (PG) D_2 and the leukotrienes (LT) C_4, D_4, and E_4 (slow releasing substance of anaphylaxis). PGE_2 has inhibitory effects on immunologic mast cell degranulation and may therefore have a protective role in urticaria. Increased levels of TNF, IL-1β, -6, -10, -12p70, -13, and B cell activating factor (BAFF) have been detected in the sera of urticaria patients[9].

Blood Vessels

Histamine and other proinflammatory mediators released upon degranulation bind receptors on postcapillary venules in the skin, leading to vasodilation and increased permeability to large plasma proteins, including albumin and immunoglobulins. Furthermore, histamine, TNF, and IL-8 upregulate the expression of adhesion molecules on endothelial cells, thereby promoting the migration of circulating inflammatory cells including eosinophils, basophils, neutrophils, and Th0 cells from the blood into the urticarial lesion[10].

Blood

Autoantibodies

Based upon *in vitro* assays, functional IgG autoantibodies that release histamine (and other mediators) from mast cells and basophils have been detected in the serum of 30%–50% of patients with CSU[11]. The *majority* of these autoantibodies bind the extracellular *α subunit of FcεRI*. Those recognizing the α_2 domain compete with IgE for the binding site, whereas non-competitive autoantibodies directed against the terminal α_1 domain are able to bind the receptor in the presence of IgE (Fig. 18.5). Increased serum levels of IgM anti-FcεRIα autoantibodies have also been found in patients with CSU and have been linked to features of autoimmune CSU[5]. Approximately 10% of chronic urticaria sera contain functional autoantibodies directed against the *Fc portion of IgE itself* (see Fig. 18.3). Binding of the autoantibodies to mast cells may initiate complement activation with the generation of C5a anaphylatoxin, which in turn facilitates or augments degranulation[12].

Circulating IgE autoantibodies directed against a range of autoantigens such as thyroid peroxidase (TPO), thyroglobulin, tissue factor, and IL-24 have been detected in patients with CSU[13–16]. However, healthy individuals and patients with disorders such as atopic dermatitis also have these IgE autoantibodies[17]. In patients with CSU and IgE anti-TPO antibodies, skin testing with recombinant TPO can elicit a wheal and flare reaction, indicating potential functionality, but it is still unclear as to why such patients develop only local wheals rather than systemic anaphylaxis[18].

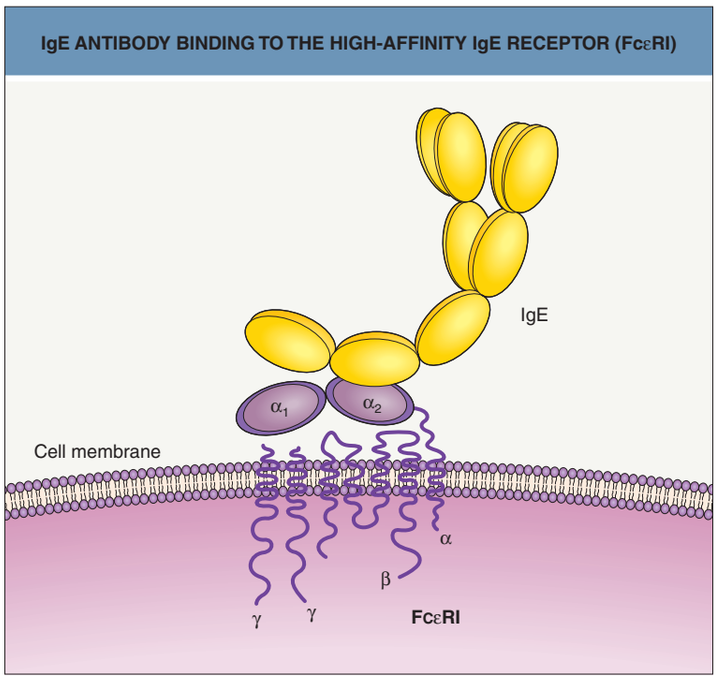

Fig. 18.5 IgE antibody binding to the extracellular α subunit of the high-affinity IgE receptor (FcεRI). Histamine-releasing autoantibodies directed against the terminal α_1 domain are able to bind the receptor in the presence of IgE and are therefore non-competitive, whereas those recognizing the α_2 domain compete with IgE for the binding site.

Other mast cell activating factors may also exist in urticaria sera, e.g. a non-IgG "mast cell-specific factor" has been described, although its identity remains unknown[19]. There is currently no evidence that characterized cytokines cause mast cell degranulation in urticaria. Evidence from small series of CSU patients treated with plasmapheresis[20] or cyclosporine[21] indicates that functional autoantibody levels correspond to disease severity.

Leukocytes

The importance of peripheral blood leukocytes in the pathogenesis of urticaria is becoming clearer. In general, blood ***basophils*** from CSU patients are less responsive *in vitro* to anti-IgE antibodies as an immunologic stimulus, possibly through desensitization, and these cells are reduced in number[22]. CSU patients can be further classified into responders and non-responders based upon the release of histamine by their basophils in response to anti-IgE antibodies or the flow cytometry-based basophil activation test (BAT). This basophil functional phenotype appears to remain stable during the course of the active illness, but then, during disease remission, the basophils become more responsive to anti-IgE antibodies[23]. Expression of the negative regulator SHIP (*s*rc *h*omology 2-containing *i*nositol *p*hosphatase) is increased in the basophils from anti-IgE non-responders[24], although the significance of this to the pathogenesis of chronic urticaria is unknown.

Evidence has emerged that basophils are recruited into urticaria wheals[25] and may sustain the inflammatory response by releasing histamine and other mediators, analogous to the delayed phase of immediate hypersensitivity reactions. A correlation between disease severity and the degree of reduction in circulating basophil counts has been observed[26]. This basopenia can normalize following successful treatment with omalizumab, providing support for the role of basophil migration into lesional skin during periods of disease activity[27].

In addition to basopenia, circulating eosinopenia may be present in those CSU patients who have greater disease activity and a lack of response to H1 antihistamines[28]. ***Eosinophils*** can contribute to the persistence of wheals by generating LTC_4, LTD_4, and LTE_4 and by releasing toxic granule proteins, including major basic protein (MBP); the latter can induce release of histamine from basophils and trigger mast cells via MRGPRX2[8]. Interactions between eosinophils and mast cells also include expression of tissue factor by eosinophils which then leads to activation of mast cells via protease activated receptors (PARs).

While ***lymphocyte*** numbers are normal in the peripheral blood of CSU patients, these cells are often present in biopsy specimens from spontaneous wheals. In one study, ~50% of the cells in the perivascular cellular infiltrates were T cells and ~20% were monocytes. Additional investigations in CSU patients noted the dermal infiltration of $CD4^+$ helper T cells, the majority of which co-expressed HLA-DR antigen; T cell activation in the peripheral blood as well as lesional and nonlesional skin; and increased expression of Th2-initiating cytokines in lesional skin[29]. Lastly, autoreactive $CD4^+$ T cells specific for FcεRIα were detected in the peripheral blood of patients with CSU[30].

Nerves

Substance P and other neuropeptides release histamine from mast cells *in vitro* and can induce a wheal and flare reaction in human skin when injected intradermally. Vasoactive intestinal polypeptide (VIP) caused a greater wheal reaction in those with chronic urticaria than did other skin-tested neuropeptides, but the relevance of this to urticaria is still uncertain. Elevated levels of brain-derived neurotrophic factor, β-endorphin, and substance P have been detected in patients with chronic urticaria[31–33]. Because several of these neuropeptides can bind MRGPRX2 on mast cells[34], the roles of neuro-immuno-cutaneous factors and neurotransmission in chronic urticaria require further clarification.

Mechanisms of Urticaria Formation

Mast cell-dependent urticaria

Potential mechanisms for mast cell-dependent urticaria are included in Table 18.1. Cross-linking of the Fab portion of specific IgE on mast

ETIOLOGIES AND PATHOMECHANISMS OF WHEALS AND/OR ANGIOEDEMA
Idiopathic
Immunologic
• Autoimmune (autoantibodies against FcεRI or IgE) • IgE-dependent (allergic) • Immune complex (vasculitic) • Kinin- and complement-dependent (C1 esterase inhibitor deficiency)
Non-immunologic
• Direct mast cell-releasing agents (e.g. opioids) • Vasoactive stimuli (e.g. nettle stings) • Aspirin, other nonsteroidal anti-inflammatory drugs, dietary pseudoallergens • Angiotensin-converting enzyme inhibitors

Table 18.1 Etiologies and pathomechanisms of wheals and/or angioedema. It is often difficult to know the exact pathogenesis of individual cases of urticaria, and many cases remain idiopathic after evaluation.

cells by percutaneous or circulating allergen undoubtedly accounts for some cases of acute or episodic urticaria, especially in children (see Fig. 18.3), but this is probably never the cause of adult chronic continuous urticaria. Examples of the former would be contact urticaria from natural rubber latex and acute urticaria from foods, including nuts, fish, and fruit. However, the majority of acute urticaria cases do not relate to allergen exposure.

IgE has been implicated in the pathogenesis of symptomatic dermographism, cold urticaria, and solar urticaria, but the mechanism by which it renders skin mast cells more sensitive to physical stimulation is not certain. It is proposed that the physical stimulus in these patients induces a neoantigen that reacts with specific IgE antibody bound to mast cells. An additional mechanism, such as neuropeptide release, could initiate or potentiate mast cell activation (see above). Using electron microscopy, localized platelet clumping has been demonstrated in cold urticaria, and the release of platelet mediators, including platelet-activating factor (PAF) and platelet factor 4/CXCL4, could contribute to wheal formation. A mutation in *F12*, which encodes the coagulation protein factor XII, has been identified in familial cold urticaria and a bradykinin-dependent, rather than mast cell-dependent, pathomechanism has been proposed (see below). Cold-induced urticarial lesions also occur in familial cold autoinflammatory syndromes (FCASs) due to mutations in *NLRP3, NLRP12*, or *PLCG2*, thus implicating a role for the cryopyrin inflammasome and its production of IL-1β (see Tables 45.2 & 45.7)[35].

Cholinergic urticaria develops in response to stimulation of cholinergic sympathetic innervation of the sweat glands. How release of acetylcholine from the nerve endings leads to mast cell activation and histamine release is unknown. An allergy to sweat has been demonstrated by one group of investigators[36]. It has been proposed that pressure-induced wheals may be due to a late-phase reaction, but an antigen has never been identified. In three Lebanese families with autosomal dominant vibratory urticaria, a missense gain-of-function variant was detected in *ADGRE2* which encodes adhesion G protein-coupled receptor E2. This was thought to lead to destabilization of the inhibitory interaction between the alpha and beta subunits of ADGRE2, leading to sensitization of mast cells to vibration-induced degranulation[37].

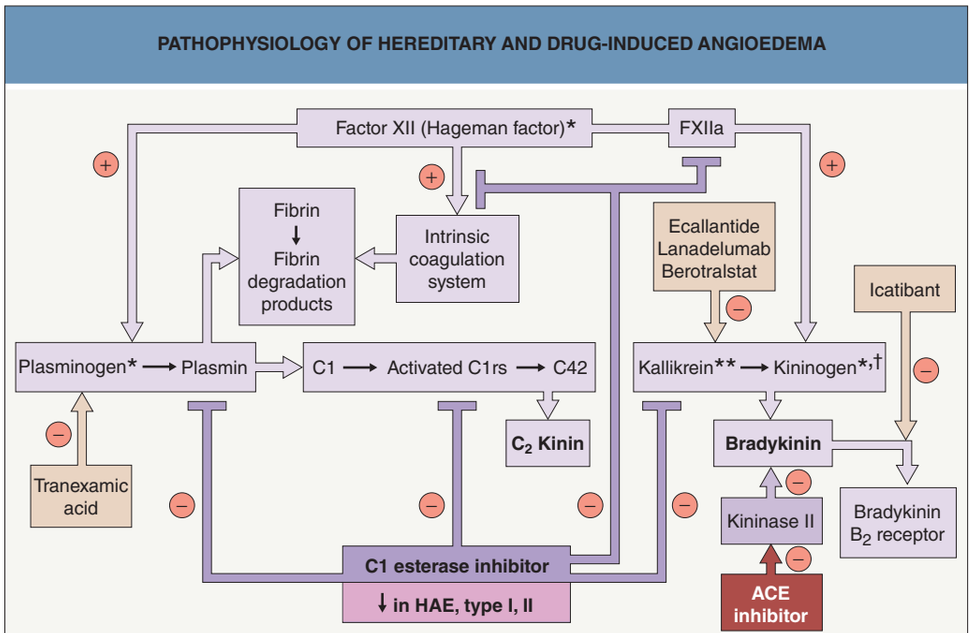
The initiating event for spontaneous urticaria wheals is unclear but may involve plasma leakage due to local factors such as heat or pressure, which allows the extravasation of autoantibodies or IgE-directed antigens that then activate the IgE receptor, thus leading to mast cell degranulation and a subsequent urticarial response. As functional autoantibodies cannot be detected in ~70% of chronic urticaria sera by currently available tests, other mechanisms may operate in "non-autoantibody" urticaria, which, nevertheless, has a similar clinical presentation[38]. Increased plasma levels of prothrombin fragment 1 + 2 (F 1 + 2) and D-dimer (a measure of fibrinolysis) have been demonstrated in CSU[39] and relate to disease severity, but the contribution of coagulation abnormalities to the pathogenesis remains unclear. There are other serum factors in CSU patients that can activate mast cell lines *in vitro* and lead to endothelial activation, independent of IgE receptors on mast cells and the presence of IgG[40].

A popular hypothesis is that dietary food additives and natural salicylates as well as nonsteroidal anti-inflammatory drugs (NSAIDs) may cause urticaria via the diversion of arachidonic acid metabolism from prostaglandin to leukotriene formation. How this leads to urticaria is not clear, but it is known that intradermal injections of LTC_4, LTD_4, and LTE_4 cause wheaing by a direct action on small blood vessels. There is some evidence from studies of rat peritoneal mast cells that PGE_2 can have inhibitory effects on immunologic mast cell degranulation[41], so a reduction in their formation may facilitate the latter. Aspirin can *aggravate* urticaria in up to 30% of patients with chronic disease, and while some clinical studies of dietary pseudoallergen avoidance have given encouraging results, the proportion of complete responders confirmed by rechallenge is small[42]. Aspirin allergy as a *cause* of urticaria is much less common, and the proportion of patients with urticaria due solely to pseudoallergens is probably low. Tolerance to NSAIDs is thought to be achievable in many CSU patients who are well controlled by H1 antihistamines[43].

Understanding "idiopathic" urticaria remains an important challenge. From a clinical perspective, it should be regarded as a multifactorial problem, and searching for aggravating factors is just as important as looking for causes.

Mast cell-independent urticaria

There are several recognized circumstances where angioedema or wheals are due to mechanisms that do not involve mast cells. These need special consideration because their management and prognosis are different. For example, prostaglandins are involved in the pathogenesis of some patterns of non-immunologic contact urticaria (e.g. to benzoic acid), and the latter can be suppressed by NSAIDs[44]. In the cryopyrin-associated periodic syndromes (CAPS; see below), patients often develop urticarial lesions. Systemic symptoms, such as fever, help to distinguish patients with autoinflammatory syndromes from those with CSU (see Ch. 45). The significant improvement that results from the administration of *anakinra*, an IL-1 receptor antagonist[45], *rilonacept*, a fusion protein that contains the extracellular domain of the IL-1 receptor and functions as an IL-1 trap[46], or *canakinumab*, a human anti-IL-1β monoclonal antibody[47], points to the role of the cryopyrin inflammasome and its production of IL-1β (see Figs. 4.2 & 45.13).



C1 esterase inhibitor (C1 inh) deficiency

C1 inh deficiency is usually hereditary but may be acquired. Two major forms of *hereditary* angioedema (HAE), types I and II, are primarily caused by mutations in one allele of the structural gene for C1 inh (*C1NH/SERPING1*) and are inherited in an autosomal dominant pattern. These mutations result in reduced levels of C1 inh (85% of cases; type I) or reduced C1 inh function (15% of cases; type II). Because these heterozygous mutations lead to levels that are 5%–30% of normal (rather than the expected 50%) in patients with type I HAE, it is thought that there is *trans* inhibition of the normal allele or increased catabolism of C1 inh. Rare families with autosomal recessive severe HAE and homozygous mutations have been reported.

Deficiency of C1 inh leads to loss of inhibition of factor XII (FXII; Hageman factor), resulting in the generation of bradykinin by the action of kallikrein on high-molecular-weight kininogen (Fig. 18.6). Activation of the C1 component of complement by proteolytic enzymes, including plasmin and FXIIa, leads to low levels of C4 in the serum, which is an almost constant feature between and during attacks in untreated patients.

HAE with normal C1 inh activity, also known as nC1-INH-HAE and previously referred to as type III HAE[48], is currently subclassified as HAE3 to HAE8 based upon underlying genetic mutations. HAE3 is due to *gain-of-function* mutations in one allele of the gene that encodes FXII, leading to increased formation of bradykinin (see Fig. 18.6). A positive feedback loop between kallikrein and FXII also contributes to the pathogenesis. One possible explanation for the preponderance of women with HAE3 is enhanced transcription of *F12* by estrogens. Mutations in *PLG*, *ANGPT1*, *KNG1*, *MYOF*, and *HS3St6* which encode plasminogen, angiopoietin-1, kininogen 1, myoferlin, and heparan sulfate 3-O-sulfotransferase 6 have also been described in HAE with normal C1 inh activity.

Acquired deficiency of C1 inh may result from activation of C1q and the complement cascade in patients with B cell lymphoproliferative disorders and plasma cell dyscrasias, or in those with autoimmune connective tissue diseases. This leads to *consumption* of C1 inh plus low

*HAE with normal C1inh is subdivided based upon molecular analysis with three groups having mutations in *F12*, *PLG*, or *KNG1* which encode factor XII, plasminogen, and kininogen 1, respectively; additional mutated genes in these patients include *ANGPT1*, *MYOF*, and *HS3St6* which encode angiopoietin 1, myoferlin, and heparan sulfate 3-O-sulfotransferase 6, with the seventh subgroup consisting of those without a known mutation.

**Kallikrein is formed from prekallikrein.
†High-molecular-weight.

Fig. 18.6 Pathophysiology of hereditary and drug-induced angioedema. Angiotensin-converting enzyme (ACE) inhibitor-induced urticaria is believed to result from the inhibition of endogenous kininase and a subsequent increase in bradykinin. Intravenous C1 inh concentrate (derived from human plasma) or recombinant C1 inh (derived from milk of transgenic rabbits), subcutaneous icatibant (a decapeptide that is a specific bradykinin B_2 receptor antagonist), and subcutaneous ecallantide (a 60-amino acid recombinant kallikrein inhibitor) are options for the *emergency* treatment of hereditary angioedema (HAE). Subcutaneous or intravenous C1 inh (every 3–4 days), subcutaneous plasma kallikrein inhibitor lanadelumab (every 2 weeks), and oral kallikrein inhibitor berotralstat (150 mg daily) are options for *prevention* of attacks. ACE, angiotensin-converting enzyme; HAE, hereditary angioedema; inh, inhibitor.

serum levels of C1q as well as C4 (acquired, type I) or the formation of *inhibitory autoantibodies* directed against the C1 inh (acquired, type II).

Angiotensin-converting enzyme (ACE) inhibitor-induced urticaria is believed to result from the inhibition of endogenous kininase II (also known as ACE), which leads to increased production of bradykinin via inhibition of its metabolism (see Fig. 18.6). It usually presents with angioedema, which is usually orofacial and may be life-threatening.

CLINICAL FEATURES

Clinical Diversity

It is important to distinguish *urticaria* from *urticarial dermatoses*, such as urticarial drug eruptions, eosinophilic cellulitis, and the urticarial phase of pemphigoid. The individual wheals of urticaria are "here today and gone tomorrow" (i.e. they generally last <24 hours), whereas with urticarial dermatoses, the individual lesions may last for days or longer. Although urticarial vasculitis is often included in classifications of urticaria because the wheals resemble urticaria, it is actually an urticarial dermatosis. Clinically, the lesions last longer than 24 hours (as determined by circling and observing individual wheals), and histologically there is evidence of leukocytoclastic vasculitis (see Ch. 24).

Wheals may be small or large, as well as single or multiple. In the physical urticarias, the distribution pattern and morphology can be helpful in separating the different clinical types (see Inducible Urticarias). Angioedema can merge with wheals and these two can be difficult to separate, especially around the eyelids. Angioedema may also be a feature of anaphylaxis, if the throat is involved. In this sense, wheals, angioedema, and anaphylaxis form parts of a clinical spectrum resulting from mast cell activation.

Classification

Because the etiology is often unknown at the time of the first consultation, the most practical classification of urticaria relies on clinical characteristics rather than etiology when defining groups of patients (Table 18.2). Mostly, spontaneous urticaria can be considered to behave in an ordinary manner (i.e. fluctuating wheals which may be accompanied by angioedema) whatever its etiology or duration, unless it has a predominantly physical trigger, has evidence of vasculitis, or is caused by exogenous contact. If no cause for spontaneous urticaria can be defined, it is called idiopathic, but the use of this label as an automatic prefix to chronic urticaria is no longer tenable as a significant number of these patients are considered to have an autoimmune etiology as evidenced by functional basophil histamine release and activation assays (Table 18.3) or flow cytometry-based BAT. Elevated thyroid antibodies are also suggestive of autoimmune urticaria. It is worth separating angioedema without wheals from the other patterns of urticaria, because some of these cases will be due to HAE, acquired C1 inh deficiency, or drug reactions (e.g. ACE inhibitors, NSAIDs), and these are managed differently.

URTICARIA – CLINICAL CLASSIFICATION AND DIFFERENTIAL DIAGNOSIS
Clinical classification

• Spontaneous urticaria (all urticarias not classified below)
• Inducible urticarias (see Table 18.4)
  • Physical, non-physical (e.g. aquagenic), and cholinergic urticarias
  • Contact urticaria (induced by percutaneous or mucosal penetration)*

Differential diagnosis
• Urticarial drug eruption • Urticarial vasculitis (defined histologically by leukocytoclastic vasculitis) • Angioedema without wheals (e.g. hereditary angioedema, ACEi-induced angioedema) • Urticarial syndromes (e.g. autoinflammatory syndromes)
*Included within the inducible urticarias in the EAACI/GA²LEN/EDF/WAO Guideline[90].

Table 18.2 Urticaria – clinical classification and differential diagnosis. All clinical patterns of urticaria can be acute, episodic, or chronic. ACEi, angiotensin-converting enzyme (ACE) inhibitor.

Acute Versus Chronic Urticaria

All urticarias are acute initially. Some will become chronic after a period of time that is usually defined as 6 weeks or more. In a study from Korea, only a small proportion (7.8%) of patients with new-onset urticaria developed chronic urticaria during a 10-year follow-up period[49]. The term "chronic urticaria" should only be applied to continuous urticaria

TESTS EMPLOYED FOR AUTOIMMUNE URTICARIA				
Test		**Method**	**Strengths**	**Weaknesses**
Functional				
Basophil activation	Histamine release	Incubation of CSU sera with healthy donor basophils	• Test of CSU serum functionality – assumed IgG autoantibodies against FcεRI or IgE • Commercially available • May predict good response to cyclosporine	• Not specific for autoantibodies • May be present in patients with other illnesses and healthy individuals
	Basophil activation (CD203c or CD63)	Incubation of CSU sera with healthy donor basophils	• Test of CSU serum functionality – assumed IgG autoantibodies against FcεRI or IgE • Not commercially available outside the US	• No proven predictive value for treatment response
Autologous serum skin test (ASST)	Red wheal response to *autologous* serum	Intradermal *autologous* serum injection	• Visual demonstration of circulating serum factors and skin reactivity during CSU disease activity	• Not specific for functional antibodies or CSU • Not predictive of treatment response • No longer widely used due to concerns about safety of unregulated skin testing with blood products
Non-functional (and functional)				
Immunoassays	ELISA	IgG, IgM, and IgA autoantibodies against FcεRI and IgE	• Specific for autoantibody isotype and target antigens in CSU • Detects functional and non-functional antibodies	• Present in patients with other illnesses and healthy individuals • No proven utility for predicting treatment response • Not commercially available

Table 18.3 Tests employed for autoimmune urticaria. CSU, chronic spontaneous urticaria; ELISA, enzyme-linked immunosorbent assay.

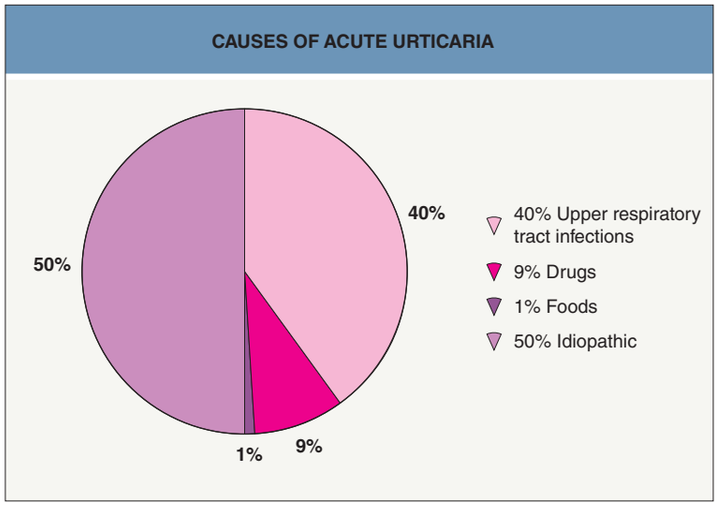


Fig. 18.7 Causes of acute urticaria. *Data from Zuberbier T, Iffländer J, Semmler C, Henz BM. Acute urticaria: clinical aspects and therapeutic responsiveness. Acta Derm Venereol 1996;76:295–7.*

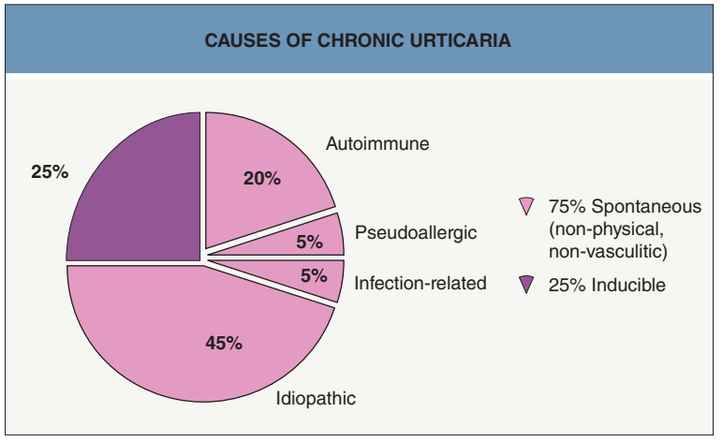

Fig. 18.8 Causes of chronic urticaria. Autoimmune represents those patients with functional autoantibodies against FcεRI or the Fc portion of IgE.

occurring at least twice a week off treatment. Urticaria occurring less frequently than this over a long period is better called episodic (or recurrent), because this presentation may be more likely to have an identifiable environmental cause.

The causes of *acute* urticaria in adults presenting to emergency dermatology clinics in one survey are shown in Fig. 18.7[50,51]. Most of these patients probably fall into the spontaneous category, because physical urticarias and urticarial vasculitis tend to persist beyond 6 weeks and contact urticarias would not normally present as an emergency. The high frequency of associated viral infections is notable, as is the lack of food allergy as a cause. The different clinical patterns of *chronic* urticaria and their causes (where known) are shown in Fig. 18.8. These data reflect the experience of specialist urticaria clinics in dermatology departments and may not represent the experience of other medical practitioners, such as those in general practice, internal medicine, pediatrics, or allergy.

Spontaneous Urticaria

The condition can present at any age. Acute urticaria is common in young atopic children but chronic urticaria peaks in the fourth decade. Multiple pruritic wheals of different sizes erupt anywhere on the body and then fade within 2–24 hours without bruising; angioedema may last up to 72 hours when severe. In literature reviews, isolated urticaria occurred in ~50% of patients, urticaria plus angioedema in ~40%, and angioedema alone in the remainder[52,53]. Wheals may occur at any time, but often appear in the evening or are present on waking. Irritation tends to be most intense at night and may disturb or prevent sleep. This, in turn, compounds the distress of the condition. Substantial impairment in quality-of-life measures, including self-image, sexual relationships, and social interactions, has been demonstrated. Women may describe premenstrual exacerbations. Systemic symptoms of fatigue, lassitude, sweats and chills, indigestion, myalgia, or arthralgia may occur with severe attacks[54], but the occurrence of pyrexia or arthritis should alert the clinician to another explanation, such as urticarial vasculitis or neutrophilic urticarial dermatosis due to Schnitzler syndrome, Still disease, or CAPS.

Associations and comorbidities

Chronic spontaneous urticaria has been associated with autoimmune thyroid disease[55] and other autoimmune conditions, including vitiligo, insulin-dependent diabetes, rheumatoid arthritis, and pernicious anemia[56]. Those chronic urticaria patients with demonstrable histamine-releasing autoantibodies have a very strong association with HLA DRB1*04 (DR4) and its associated allele DQB1*0302 (DQ8)[57]. A possible association between *Helicobacter pylori* gastritis and chronic urticaria was suggested by a systematic review of therapeutic studies,

which showed a higher frequency of urticaria remission when the infection was eradicated than when it was not[58]. Parasitic infections, in particular protozoa (e.g. *Blastocystis hominis*, *Giardia* spp.), are an uncommon cause of urticaria in high-income countries, but may be a significant problem where they are endemic. Acute urticaria due to gastric *Anisakis simplex* has been reported from Spain[59]. Possible associations between dental infections or gastrointestinal candidiasis and chronic urticaria have not been substantiated by large epidemiologic studies.

Although there have been anecdotal reports linking urticaria to malignancy[60], no statistically significant association was found in a Swedish survey[61]. However, an increased risk of hematologic malignancies, especially non-Hodgkin lymphoma, was noted in a large retrospective cohort study of a National Insurance database in Taiwan[62]. Atopic diseases[63], metabolic syndrome[64], and psychiatric disorders (especially anxiety and depression)[65] are reported comorbidities in chronic urticaria.

Inducible Urticarias (syn. Physical Urticarias)

These urticarias represent a distinct subgroup of urticaria that is induced by an exogenous stimulus rather than occurring spontaneously. This section discusses physical triggers while the next section reviews other chemical and protein stimuli. Because cholinergic urticaria is triggered by factors that lead to sweating (e.g. a rise in core body temperature, stress, spicy foods), rather than an external physical stimulus, it is often classified separately from other inducible urticarias. The inducible urticarias are classified by the predominant stimulus that triggers whealing, angioedema, or anaphylaxis[66] (Table 18.4). Of all the urticarias, they may affect the quality of life most severely, particularly delayed pressure urticaria and cholinergic urticaria[67]. While the lesions of most physical urticarias occur within minutes of provocation and generally resolve within 2 hours, a few physical urticarias (e.g. delayed pressure urticaria, delayed dermographism) develop after a delay of several hours and persist for 24 hours or longer.

The wheals are usually localized to the stimulated area of skin. However, sometimes the physical stimuli need to produce a systemic effect, e.g. a rise or drop in core body temperature, to induce urticaria of a reflex type. Thus, generalized heating of the body can induce cholinergic urticaria (which is common), and generalized cooling, cold reflex urticaria (which is rare). Here, multiple small wheals occur on widespread areas of the body.

Angioedema may be seen with all the physical urticarias except with symptomatic dermographism. Vibratory angioedema manifests with subcutaneous swellings but not wheals. Also, several forms of physical urticaria can coexist in the same patient. Common combinations include: (1) symptomatic dermographism and cholinergic urticaria; and (2) cold and cholinergic urticaria. In addition, delayed pressure urticaria may coexist with CSU. Some rare forms of physical urticaria, such as familial delayed cold urticaria, are beyond the scope of this chapter.

CLASSIFICATION OF INDUCIBLE URTICARIAS
Urticaria due to mechanical stimuli

Dermographism
• Immediate
  • Simple
  • Symptomatic
• Delayed
Delayed pressure urticaria
Vibratory angioedema
• Inherited
• Acquired

Urticaria due to temperature changes

Heat
• Heat contact urticaria
Cold
• Cold contact urticaria
  • Primary
  • Secondary (cryoproteins)

Urticaria due to sweating or stress
Cholinergic urticaria Adrenergic urticaria Exercise-induced urticaria • Exercise-induced anaphylaxis • Food- and exercise-induced anaphylaxis
Contact urticaria
Solar urticaria
Aquagenic urticaria
Rare variants are not shown here for simplicity.

Table 18.4 Classification of inducible urticarias by the eliciting stimulus.

Urticaria due to mechanical stimuli

Dermographism (literally "skin writing") (syn. dermatographism, factitious urticaria)

Immediate dermographism

This is divided into simple or symptomatic. *Simple* immediate dermographism occurs in at least 5% of the normal population in response to moderate stroking of the skin and may be regarded as an exaggerated physiologic response and is typically not pruritic.

Symptomatic immediate dermographism is the most common type of physical urticaria (Fig. 18.9). It manifests as pruritic linear wheals at sites of scratching or sites of friction, such as collars and cuffs of clothes. Whealing occurs after gentle stroking of the skin in response to a shearing force. Patients, most frequently young adults, often complain of pruritus before the wheals appear and may not associate them with scratching. It is worst in the evening and often occurs in bouts. The lesions usually resolve within an hour. Oral mucosal involvement does not occur, but vulvodynia and swelling during sexual intercourse has been reported[68].

The general course is unpredictable, but usually there is a gradual tendency towards improvement over several years. Symptomatic dermographism occasionally follows scabies infestation and penicillin allergy reactions. There is no association with systemic disease, atopy, food allergy, or autoimmunity.

Rarer forms of dermographism

These include delayed dermographism, which appears at least 30 minutes after a stroking stimulus, red dermographism (in response to rubbing, not stroking, the skin), localized dermographism, cholinergic dermographism, and Darier's sign (a localized dermographic response after gentle rubbing of cutaneous mastocytosis lesions). The blanching response seen in patients with atopic and other forms of dermatitis, known as white dermographism, is not a form of urticaria nor is black dermographism in which there is dark discoloration of the skin due to surface deposition of metallic particles.

Delayed pressure urticaria

Delayed pressure urticaria (DPU) is important because it can interfere severely with quality of life; it may be underdiagnosed and its treatment is difficult[69]. DPU is characterized by the development of deep

Fig. 18.9 Symptomatic immediate dermographism. Itchy wheals appear very soon after scratching. *Courtesy Jean L. Bolognia, MD.*

Fig. 18.10 Delayed pressure urticaria.

Fig. 18.11 Cold urticaria. Wheals developed on the forearm after placement of an ice cube for 10 minutes, followed by rewarming. *Courtesy Thomas Schwarz, MD.*

erythematous swellings at sites of sustained pressure to the skin, after a delay of 30 minutes to 12 hours (Fig. 18.10); sometimes it resembles angioedema. The swellings are usually pruritic, painful, or both, and may persist for several days, unlike the spontaneous wheals of ordinary urticaria. Sites frequently involved are the waistline after wearing tight clothing, below the elastic of socks, the feet in tight shoes, the palms after manual work, the soles after walking or climbing ladders, and the genitalia after intercourse.

Rarely, systemic features such as malaise, "flu-like" symptoms, and arthralgia may occur. If the swellings develop over joints, the resulting restriction of motion may be mistaken for arthritis. The prognosis is variable, but the mean duration in different series was 6–9 years. Up to 35% of patients with CSU attending a hospital specialist clinic had associated DPU. Conversely, nearly all patients with DPU have associated spontaneous wheals. Because of this association and the delayed onset, patients may not be aware of any relationship to pressure unless specifically questioned.

Vibratory angioedema

This is a very rare form of urticaria, where a vibratory stimulus induces localized swelling and erythema within minutes, lasting 30 minutes. Stimuli include jogging, vigorous rubbing with a towel, and the use of vibrating machinery such as lawnmowers and motorcycles. Avoidance of vibratory stimuli enables patients to live a normal life. Vibratory angioedema may be acquired or familial. The acquired form is often milder, and it may be associated with other physical urticarias such as DPU and symptomatic immediate dermographism. The familial form is dominantly inherited, has its onset during infancy, and intense vibratory stimuli may induce generalized erythema and systemic symptoms such as headaches[70]. Pathogenic variants in *ADGRE2*, which encodes adhesion G protein-coupled receptor E2, have been detected (see Pathogenesis).

Urticaria due to temperature changes

Heat exposure

Heat contact urticaria

This is one of the rarest forms of urticaria. Within minutes of contact with heat from any source, itching and whealing occur at the site of contact, lasting up to 1 hour. This must be distinguished from cholinergic urticaria. Patients can present after contact with hot water (e.g. washing dishes), but also after contact with radiant heat or warm sunlight. Systemic symptoms of faintness, headache, nausea, and abdominal pain have occurred when the urticaria is extensive. There is an even rarer delayed form[71].

Cold exposure

Cold urticaria represents a heterogeneous group of conditions in which whealing occurs within minutes of rewarming after cold exposure[72]. There are both typical and atypical forms, with the latter group constituting ~30% of cases and being characterized by negative provocation tests. Typical forms are primary cold contact urticaria and secondary cold contact urticaria, while atypical forms are systemic atypical acquired cold urticaria, cold-dependent dermographism, cold-induced cholinergic urticaria, delayed cold urticaria, and localized cold reflex urticaria[73].

Primary cold contact urticaria

The most commonly encountered form is primary cold contact urticaria; it accounts for at least 95% of cases (Fig. 18.11). Although cold urticaria may follow respiratory infections, arthropod bites or stings, and perhaps HIV infection, the cause of most cases remains unknown (idiopathic). It may occur at any age, but is most frequently seen in young adults. Itching, burning, and whealing occur in cold-exposed areas minutes after rewarming the skin. Commonly, primary cold contact urticaria occurs in rainy, windy weather and after contact with cold objects or drinking cold liquids. Patients often relate symptoms to changes in temperature as much as to the absolute external temperature. Systemic symptoms of flushing, headache, syncope, and abdominal pain can develop if large areas are affected. Cold baths and swimming should usually be avoided as there is a potential risk of anaphylaxis. The mean duration was 6–9 years in one series, though primary cold contact urticaria may be more transient if it follows a viral infection.

Secondary cold contact urticaria

Cases due to cryoproteinemia are rare, and they are associated with other manifestations such as Raynaud phenomenon or purpura. The wheals are usually similar to those of primary cold contact urticaria, but may last longer. The presence of circulating cryoglobulins should be determined and if detected, underlying causes, such as hepatitis B or C viral infections, lymphoproliferative disease, or infectious mononucleosis, should be excluded.

Reflex cold urticaria

In this form, generalized cooling of the body induces widespread whealing. Patients with this disorder can experience life-threatening reactions from exposures such as diving into a cold lake. The ice cube test is negative, but placing the patient in a cold room at 4°C can reproduce lesions; however, one should exert caution because anaphylaxis could occur.

Familial cold urticaria

Familial cold urticaria, also referred to as familial cold autoinflammatory syndrome (FCAS), belongs to the group of disorders known as cryopyrin-associated periodic syndromes (CAPS) (see Table 45.2). The patients with FCAS1 have mutations in *NLRP3*, which encodes the inflammasome protein cryopyrin, and they develop cold-induced urticaria wheals. FCAS2 and FCAS3 are due to mutations in *NLRP12* and *PLCG2*, respectively; the latter encodes a phospholipase (see Table 45.7). Lastly, *gain-of-function* mutations in *F12* have been detected in families with either HAE3 or cold-induced urticarial lesions and systemic symptoms[35].

Urticaria due to sweating or stress

Cholinergic urticaria

Cholinergic urticaria is characterized by multiple, transient, papular wheals that are 2–3 mm in diameter and surrounded by an obvious flare. They occur within 15 minutes of sweat-inducing stimuli, such as any form of physical exertion, hot baths, or sudden emotional stress (Fig. 18.12). Other eliciting stimuli include moving from a cold to a hot room, drinking alcohol, and eating spicy food. It occurs more frequently in young adults with an atopic diathesis and is unusual in the elderly. It may be associated with acquired generalized hypohidrosis (see Table 39.11)[74].

After the appropriate stimulus, pruritus is followed by the development of small, monomorphic wheals that are symmetrically distributed. They are most prominent on the upper half of the body, but can also affect the lower legs and forearms and even become generalized. Angioedema and systemic manifestations consisting of faintness, headache, palpitations, abdominal pain, and wheezing may occur. Reduced forced expiratory volumes (in the absence of respiratory symptoms) have been recorded by spirometry. In more severely affected individuals, cholinergic urticaria can cause severe personal and occupational disability.

Cold urticaria, symptomatic dermographism, or aquagenic urticaria may be associated with cholinergic urticaria. There is usually a gradual tendency towards improvement, but the condition may last for years. Rarer forms include cholinergic pruritus, cholinergic erythema (in which pruritic, symmetric, small erythematous macules appear to be persistent, but individual lesions actually last for up to 1 hour), and cholinergic dermographism. Severe exercise-induced cholinergic urticaria may sometimes progress to anaphylaxis.

Exercise-induced anaphylaxis (EIA)

This can occur without the typical wheals of cholinergic urticaria and appears to be a syndrome in its own right. Food- and exercise-induced anaphylaxis (FEIA) is an increasingly recognized syndrome[75]. In FEIA, angioedema and/or anaphylaxis occur within minutes of exercise if it follows either prior ingestion of a specific food (e.g. α-gliadin in wheat), or sometimes within 4 hours of a heavy meal. FEIA may be due to priming of the mast cell by either prior exposure to an allergen or an unknown mechanism. EIA is produced by exercise, but not by an increase in core temperature induced by other means capable of provoking cholinergic urticaria (e.g. passive overheating in a hot bath), and this distinction can be used to differentiate between the two conditions.

Adrenergic urticaria

Adrenergic urticaria can be distinguished from cholinergic urticaria by the presence of blanched vasoconstricted skin surrounding small pink wheals induced by sudden stress, as opposed to pale wheals surrounded by a pink halo. The lesions can be reproduced by intradermal injections of norepinephrine (noradrenaline).

Urticaria due to other exposures

Solar urticaria

Itching and whealing occur within minutes of exposure to ultraviolet or visible wavelengths of solar radiation specific to the patient (see Ch. 87).

Fig. 18.12 Cholinergic urticaria on the trunk after hot bath provocation.

Aquagenic urticaria

In aquagenic urticaria, contact with water of any temperature induces an urticarial eruption resembling a sparse form of cholinergic urticaria, with large flares around papular wheals. Lesions occur most frequently on the upper part of the body and last for less than an hour. Other physical urticarias must be excluded and the condition must be differentiated from aquagenic pruritus (see Ch. 6).

Contact Urticaria (see Ch. 16)

Contact urticaria is defined by the development of urticaria at the site(s) of contact with skin or mucosa but contact erythema and even burning and stinging without erythema are sometimes embraced in the definition[44]. Percutaneous or mucosal penetration of the urticant may have distant effects, including acute urticaria or even anaphylaxis. Contact urticaria may be more common than reported, as patients often do not present to the hospital or tertiary care clinics, because the diagnosis is usually self-evident.

Immunologic and non-immunologic forms are recognized, depending on whether the contact urticaria is due to allergen interaction with specific IgE or is IgE-independent. *Immunologic* (i.e. allergic) contact urticaria can be seen in children with atopic dermatitis who become sensitized to environmental allergens, such as grass, animals and foods, or in glove-wearers who are allergic to latex. In those individuals repeatedly exposed to latex via mucosal surfaces (e.g. urinary catheterization in spina bifida patients), allergic contact urticaria can be complicated by anaphylaxis. *Non-immunologic* (i.e. non-allergic) contact urticaria is due to direct effects of urticants on blood vessels, such as from exposure to either sorbic acid and benzoic acid in eye solutions and foods or cinnamic aldehyde in cosmetics; it may be mediated by PGD_2 and can be inhibited by NSAIDs. Percutaneous microinjection of histamine, acetylcholine, and/or serotonin by nettle stings as well as contact with histamine liberators that degranulate mast cells (e.g. dimethylsulfoxide, cobalt chloride) can result in contact urticaria.

Food contact hypersensitivity syndrome

The oral allergy syndrome, also referred to as pollen–food allergy syndrome, presents with itching and mild swelling of the mouth, tongue, and soft palate within minutes of eating fresh fruits such as apples, pears, peaches, and cherries, but not cooked fruit. It usually occurs in hay fever sufferers and represents a cross-reaction between fruit proteins and panallergens in grass (profilin) or birch pollen allergens, in particular Bet v 1, a member of the PR-10 family. Angioedema and anaphylaxis are fortunately very rare. The term "food contact hypersensitivity syndrome" was proposed to include all forms of immediate mucosal food contact reactions, including oral allergy syndrome[76].

Angioedema Without Wheals

Recurrent angioedema without wheals is in most instances idiopathic, but it is important to exclude a drug reaction and to consider the possibility of C1 inhibitor (inh) deficiency. The latter can be inherited or acquired (e.g. B cell lymphoproliferative disorders, plasma cell dyscrasias, autoantibodies against C1 inh).

Drug reactions

A number of drugs can cause angioedema without wheals. The most common are NSAIDs[77] and ACE inhibitors (see Fig. 18.6)[78]. Aspirin intolerance may present with angioedema alone, or with urticaria or anaphylaxis; cross-reactions with other NSAIDs can occur. A causative link to ACE inhibitors may be overlooked because angioedema can present over a year after starting the medication and occasionally even years later. An increased risk of ACE inhibitor-induced angioedema has been observed when the latter is coadministered with dipeptidyl peptidase-4 inhibitors ("gliptins") and mTOR inhibitors[79,80]. ACE inhibitors are contraindicated in patients with HAE and acquired C1 inh deficiency, and for practical purposes, ACE inhibitors should be discontinued in favor of other antihypertensive medications if angioedema occurs without wheals.

Angiotensin receptor blockers (ARBs) such as valsartan and losartan are also associated with development of angioedema. Depending upon the study, the risk of ARB-induced angioedema in patients with ACE inhibitor-induced angioedema varies from 0–15%. As a result, ARBs are

avoided in such patients. As with other drug eruptions, it is important to consider exposure via combination drugs, in this case sacubitril–valsartan, which is increasingly being used to treat congestive heart failure. Of note, an increased incidence has been reported in Black patients[81].

Hereditary angioedema (HAE), types I and II (inherited C1 inh deficiency)

The likelihood of inherited C1 inh deficiency as a cause of recurrent angioedema is increased if there is a family history or previous laryngeal edema or colicky abdominal pain (sometimes presenting as a surgical emergency). Trauma (emotional or physical) and estrogens can trigger attacks. The usual duration is 48–72 hours, and episodes are often followed by a refractory period. Some families with HAE describe a transient, prodromal erythematous eruption, but urticaria wheeling does not occur and so a history of recurrent wheals effectively excludes the disorder.

Hereditary angioedema (HAE) with normal C1 inh activity (nC1-INH-HAE; previously type III)

This form of HAE currently has seven subgroups, six of which are associated with mutations in the genes that encode factor XII, plasminogen, angiopoietin-1, kininogen 1, myoferlin, and heparan sulfate 3-O-sulfotransferase 6 (see above). The seventh group includes those whose genetic basis is unknown. Compared to patients with an inherited deficiency of C1 inh, the age of onset is later (usually in or after the second decade) and there is a higher frequency of facial angioedema.

Distinctive Syndromes with Urticarial Lesions

Hereditary periodic fever syndromes

Cryopyrin-associated periodic syndromes (CAPS)

The allelic disorders Muckle–Wells syndrome, familial cold autoinflammatory syndrome (familial cold urticaria), and neonatal-onset multisystem inflammatory disease (NOMID/CINCA) are all now known to be due to mutations in *NLRP3*, which encodes the protein cryopyrin (see Table 45.2)[82]. These patients can develop wheals from an early age that are resistant to antihistamines.

Other syndromes

In hyperimmunoglobulinemia D with periodic fever syndrome (HIDS) due to partial mevalonate kinase deficiency as well as TNF receptor-associated periodic syndrome (TRAPS), erythematous and edematous urticarial plaques can occur in addition to periorbital edema (in TRAPS). The cutaneous lesions in familial Mediterranean fever are more erysipelas-like in appearance (see Table 45.2).

Acquired autoinflammatory syndromes

Schnitzler syndrome

Schnitzler and colleagues in 1974 described an unusual variant of chronic urticaria characterized by recurrent, non-pruritic wheals plus intermittent fevers, bone pain, arthralgia or arthritis, an increased ESR, and an IgM monoclonal gammopathy[83]. Occasionally, there is an IgG paraprotein. The Strasbourg validated diagnostic criteria for Schnitzler syndrome consist of two major criteria – urticarial rash and IgM or IgG monoclonal gammopathy – and four minor criteria – recurrent fever >38°C without any other cause, changes in bone structure visible in imaging ± bone remodelling, neutrophilic dermal infiltrate, and leukocytosis and/or elevated CRP. Confirming the diagnosis requires both major and at least two minor criteria (if IgM) or at least three minor criteria (if IgG). If the two major criteria are accompanied by only one minor criterion (if IgM) or two minor criteria (if IgG), the diagnosis is considered probable[84]. Some of the patients with Schnitzler syndrome will have an MYD88 L265P variant.

The clinical presentation overlaps with that of the CAPS group of inherited autoinflammatory disorders. While skin biopsy specimens usually show a neutrophil-predominant dermal infiltrate without edema, fully developed small vessel vasculitis is not seen. Some clinicians believe that these patients are best considered as having a variant of neutrophilic urticaria while others prefer the term neutrophilic urticarial dermatosis (see Table 45.6). Schnitzler syndrome responds very well to IL-1 blockade, e.g. anakinra, canakinumab, rilonacept.

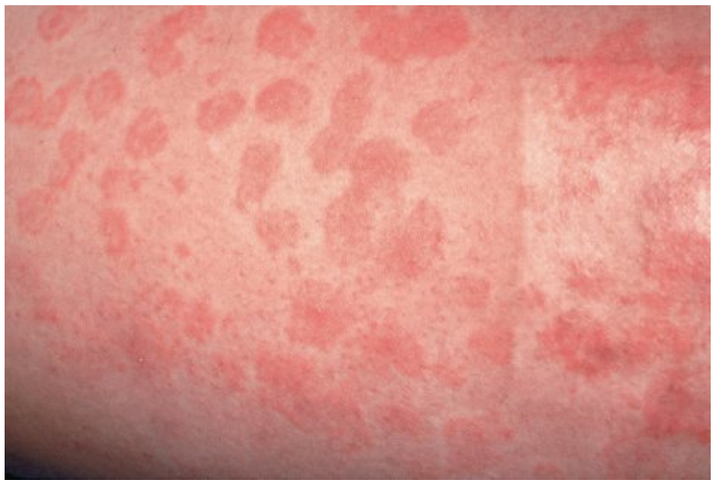

Fig. 18.13 Urticarial vasculitis. Lesions look like spontaneous urticaria but last longer and may bruise. An incidental finding is a skin graft donor site.

Adult-onset Still disease

This is a rare acquired autoinflammatory disorder in which patients present with fever, a sore throat, an often evanescent urticarial eruption, arthritis, lymphadenopathy, and hyperferritinemia (see Ch. 45).

Episodic angioedema with eosinophilia (Gleich syndrome)

A syndrome of episodic angioedema with hypereosinophilia, weight gain, and fever has been described. The cause is uncertain, but increased serum levels of IL-5 have been noted[85].

Systemic capillary leak syndrome

Also known as Clarkson syndrome, this rare acquired disorder is characterized by episodic massive plasma exudation from blood vessels, leading to potentially life-threatening hypotension, analogous to anaphylaxis. Angioedema may be a feature. It is associated with an IgG paraproteinemia. Medications, in particular IL-2, can also produce a systemic capillary leak syndrome.

Urticarial vasculitis (see Ch. 24)

Urticarial vasculitis is a clinicopathologic entity in which cutaneous lesions resemble urticaria clinically, but last longer than 24 hours and may resolve with postinflammatory hyperpigmentation or purpura (Fig. 18.13). Histologically, there is evidence of leukocytoclastic vasculitis. Extracutaneous manifestations, especially in the setting of hypocomplementemia, may include arthralgias, abdominal pain, obstructive pulmonary disease, glomerulonephritis, and uveitis or episcleritis.

PATHOLOGY

The histopathology of urticaria is characterized by upper dermal edema with a mild mixed perivascular infiltrate of lymphocytes, eosinophils, basophils, and some neutrophils (Fig. 18.14). A predominantly neutrophilic pattern has been described in a minority of patients (see below)[86]. Previous reviews of biopsy specimens from large series of patients with chronic urticaria have emphasized a spectrum of changes, ranging from mild lymphocytic infiltrates with rare neutrophils to occasionally showing fully developed leukocytoclastic vasculitis[87], pointing to some histopathologic overlap between chronic urticaria and urticarial vasculitis. Features of the latter include endothelial cell damage, a perivenular cellular infiltrate rich in neutrophils, swelling of vessel walls, and leukocytoclasis. Extravasation of erythrocytes and fibrinoid deposits in and around blood vessels may also be seen.

The term *neutrophilic urticaria* is sometimes used when biopsy specimens of urticaria contain predominantly neutrophilic dermal infiltrates but lack features of vasculitis[88]. Although this pattern did not appear to have clinical or etiologic significance[68], neutrophilic urticaria overlaps with *neutrophilic urticarial dermatosis*. This term is used to describe an aseptic, interstitial, perivascular, and peri-appendageal neutrophilic infiltrate with nuclear dust and neutrophils within dilated dermal blood vessels, but without vasculitis. The latter occurs

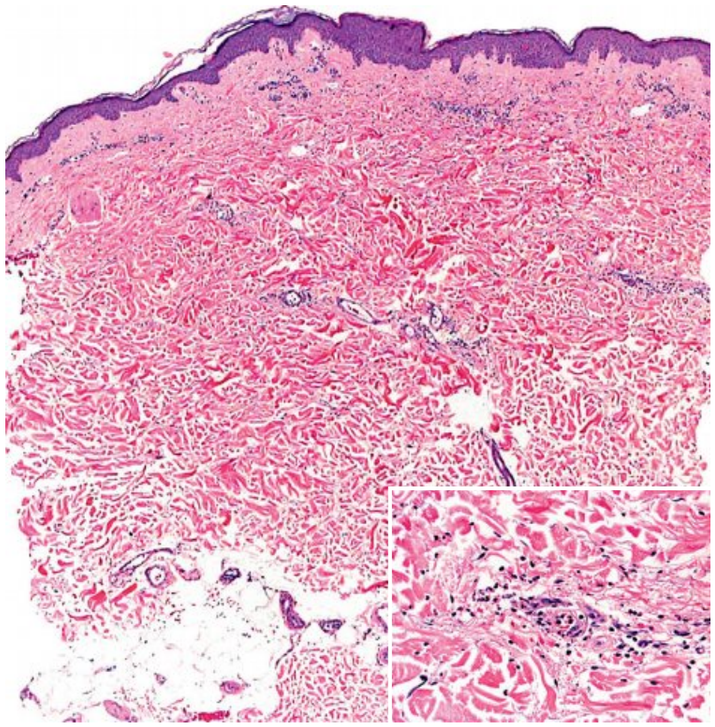

Fig. 18.14 Spontaneous urticaria – histologic findings. A sparse, mainly perivascular inflammatory infiltrate and scant edema within the superficial and mid dermis. Note several neutrophils and a few eosinophils (inset). *Courtesy Lorenzo Cerroni, MD.*

Fig. 18.15 Urticaria in a young child. This clinical presentation of urticaria is sometimes misdiagnosed as erythema multiforme because of the dusky centers, with some clinicians referring to it as urticaria multiforme. As lesions expand, central clearing can occur, which is not seen in erythema multiforme. *Courtesy Luis Requena, MD.*

in the setting of inherited acquired and inherited autoinflammatory syndromes (e.g. CAPS, Schnitzler syndrome, Still disease; see Table 45.6) as well as occasionally in systemic lupus erythematosus.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The differential diagnosis of urticaria includes all dermatologic conditions with an urticarial component, including insect bite reactions (papular urticaria), urticarial drug reactions, pre-bullous phase of pemphigoid (i.e. urticarial pemphigoid), urticarial vasculitis, autoinflammatory syndromes, eosinophilic cellulitis (Wells syndrome), polymorphic eruption of pregnancy, acute eyelid contact dermatitis (versus angioedema), and the urtication that may occur when lesions of urticaria pigmentosa are rubbed. In all these conditions, the urticarial component is part of a more prolonged inflammatory process (or mast cell proliferation in the case of mastocytosis) than in true urticaria and should be readily distinguishable by the prolonged duration of individual lesions or associated systemic findings. Especially in young children, urticaria may develop a dusky center (urticaria multiforme; Fig. 18.15; see Table 20.3) and be confused with erythema multiforme, serum sickness-like reaction, or hemorrhagic edema of infancy.

Diagnosis

A comprehensive history is essential in every patient with urticaria. It should cover the duration of disease, frequency of attacks, duration of individual lesions, medications, known allergies, past and family history including comorbidities, previous treatments and responses, occupation and leisure activities, and an assessment of the impact of the disease on the patient's quality of life. The use of a detailed questionnaire in conjunction with a complete blood count and ESR was found to be almost as good as a complete diagnostic evaluation[89]. A full physical examination looking for the morphology and duration (by circling individual lesions) of wheals, bruising, livedo reticularis, and signs of systemic disease should always be undertaken, but it is often normal. The patient's own photographs can often be useful because it is common for urticaria to have cleared by the time of consultation. Investigation should be targeted at specific features identified in the clinical assessment, as outlined below, and may include blood tests, skin biopsy (obtained in all patients with lesions consistently lasting more than 24 hours), challenges for physical urticarias, food additives, and drugs, and, infrequently as an extended investigation, skin tests for allergy and measurement of histamine-releasing autoantibodies[90]. Most patients with antihistamine-responsive urticaria do not need an extensive investigation. A diagnostic algorithm is given in Fig. 18.16.

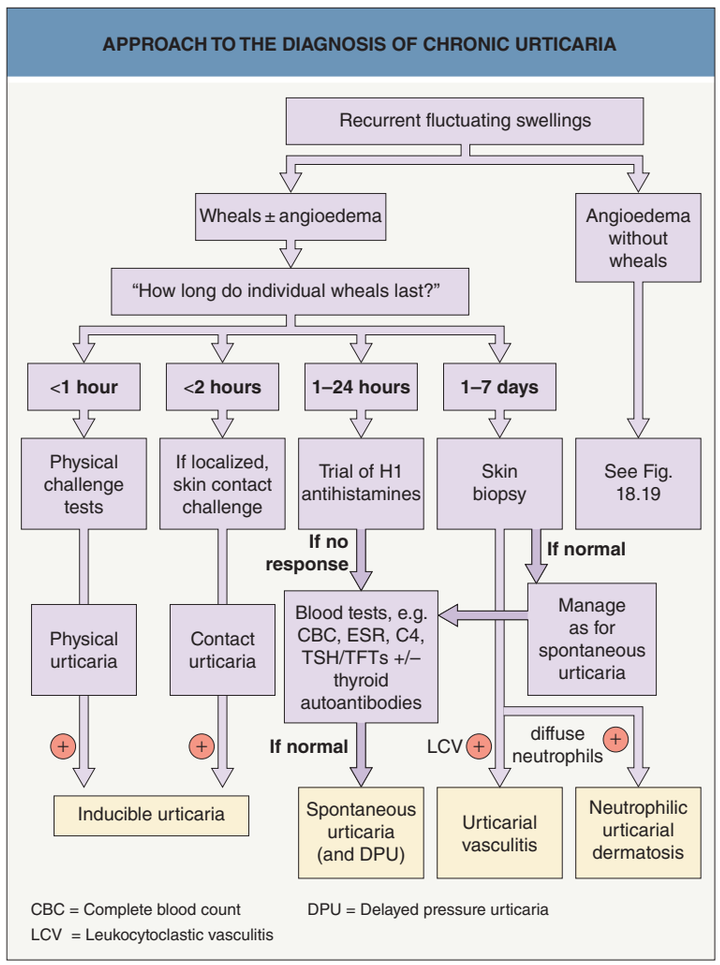

Fig. 18.16 Approach to the diagnosis of chronic urticaria.

Acute urticaria

No routine laboratory tests are recommended for acute urticaria but when a type 1 allergic reaction to environmental allergens is suspected as the cause of acute urticaria or contact urticaria, skin prick testing and measurement of specific IgE antibodies (e.g. ImmunoCAP®) can be performed.

Chronic urticaria

No investigations are routinely required for the majority of patients with mild disease that responds to antihistamines. A useful screening profile for non-responders with more severe disease could include a complete blood count with differential (for instance, to detect the eosinophilia of intestinal parasitosis) and ESR (usually normal in CSU). The ESR may be elevated in urticarial vasculitis, and it is consistently high in symptomatic acquired and genetic autoinflammatory syndromes in which patients also have an elevated C-reactive protein level (usually >30 mg/l). Measurement of thyroid autoantibodies and thyroid function tests should be performed if indicated clinically. The prevalence of thyroid autoantibodies is higher in patients with chronic urticaria than in controls and may be an indicator of autoimmune urticaria. Tests for helminths may be considered in the appropriate clinical setting. Although evidence is equivocal that *Helicobacter pylori* infection can be associated with CSU, patients with hyperacidity should be tested since eradication therapies may lead to urticaria remission.

Although the term "autoimmune" urticaria is increasingly being used for patients with evidence of functional serum autoantibodies (see Fig. 18.3 & Table 18.3), there is still a lack of agreement with regard to definitively establishing such a diagnosis. Demonstration of autoreactivity in the form of a localized wheal and flare response to intradermal injection of autologous serum (autologous serum skin test [ASST]) provides useful evidence of functional factors in the blood but is not specifically a test for functional autoantibodies[91] (Fig. 18.17). A negative test, however, has very good negative predictive value for the absence of functional autoantibodies[92]. However, stricter regulatory guidelines regarding the handling of blood products will increasingly limit performance of this assay.

Immunoassays for anti-FcεRI and anti-IgE antibodies do not necessarily correlate with basophil and mast cell histamine-releasing assays because non-functional as well as functional autoantibodies have been detected by Western blot and ELISA (see Table 18.3). Fig. 18.18 illustrates the overlap between: (1) autoreactivity by ASST; (2) functional autoantibodies as detected via basophil or mast cell activation assays; and (3) immunoassays ("immunoreactivity"). The most convincing evidence for an autoimmune etiology of urticaria is provided by demonstrating all three features, but some clinicians would accept a positive functional assay as providing sufficient proof of autoimmunity to guide therapies and prognosis. Because CSU patients can have increased rates of IgE sensitization to autoantigens such as thyroid peroxidase[18,93] and interleukin-24[94] and some have a very rapid response to anti-IgE antibody (e.g. omalizumab), the concept of autoallergic urticaria has been proposed.

Physical urticarias

International standards for the diagnosis of physical urticarias and definitions of challenge testing have been proposed[66]. *Symptomatic dermographism* can be tested for by stroking the skin of the back lightly with the rounded edge of a wooden spatula or a plastic device with round pegs that have different lengths (FricTest®). A calibrated instrument called a dermographometer, which is a spring-loaded stylus, the pressure of which can be adjusted to a predetermined setting, can be used to confirm the diagnosis of symptomatic dermographism (if ≤36 g/mm^2). *Delayed pressure urticaria* is confirmed if applying either a 2.5-kg weight to the thigh or back for 15 minutes (using a rod with a diameter of 1.5 cm) or a dermographometer set at 100 g/mm^2 for 70 seconds results in a palpable wheal at 30 minutes to 8 hours (usually at 6 hours).

Provocation tests for *cholinergic urticaria* include exercise to the point of sweating in an overheated environment, preferably on a treadmill or exercise bicycle, or partial immersion in a hot bath at 42°C for

Fig. 18.17 Autologous serum skin test (ASST). At 30 minutes, a red wheal response is present at the site of an intradermal injection of autologous serum, but not at that of a normal saline control. For the test to be positive, the wheal response at the serum injection site must be at least 1.5 mm greater in diameter than the control site. This criterion is a reasonably sensitive and specific screening test for functional autoantibodies as detected by the basophil release assay. Spontaneous wheals are also present at the venipuncture site and above the serum skin test.

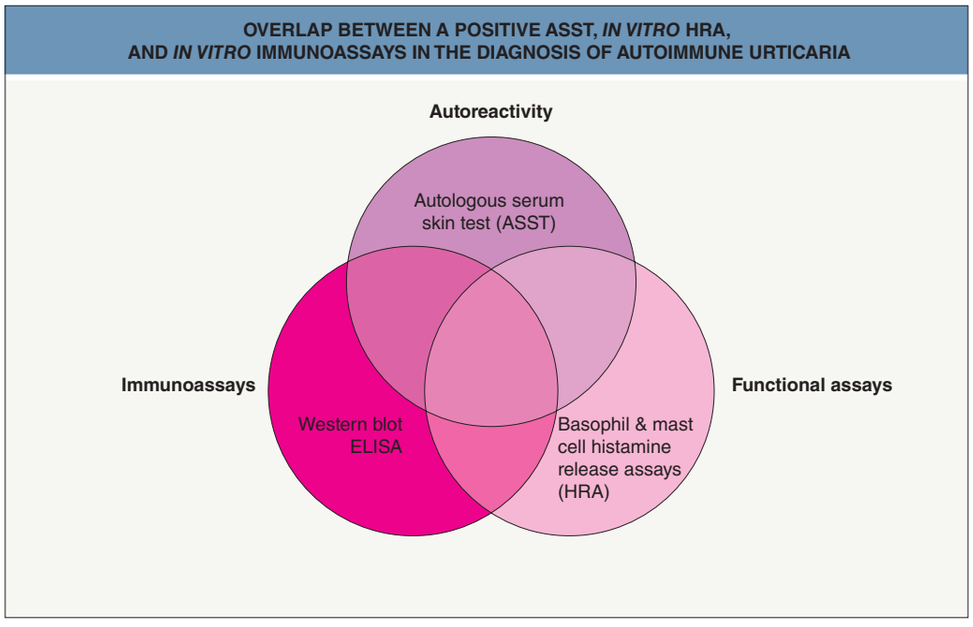

Fig. 18.18 Overlap between a positive autologous serum skin test (ASST), *in vitro* histamine release assays (HRA), and *in vitro* immunoassays in the diagnosis of autoimmune urticaria. The ASST will become increasingly difficult to perform in the future as regulations regarding blood products become more restrictive.

10 minutes. A positive hot bath test excludes exercise-induced anaphylaxis. *Cold contact urticaria* is confirmed either by the development of whealing at the site of application of a melting ice cube in a thin polyethylene bag or glove for 5 minutes (the most sensitive individuals may react after 30 seconds, with the least sensitive requiring up to 20 minutes of ice application; see Fig. 18.11) or by assessment of the critical temperature threshold by an instrument such as TempTest®.

Phototesting confirms the diagnosis of *solar urticaria*, with the development of wheals within minutes of exposure to natural or artificial radiation. The action spectra of the inducing wavelengths can be determined by narrowband monochromators (see Ch. 87). The diagnosis of *aquagenic urticaria* is made by inducing a limited number of small pruritic wheals with a large flare after a bath or shower at body temperature, or under wet gauze applied at body temperature for 20 minutes. *Heat contact urticaria* is confirmed by applying a heated cylinder (temperature increments up to 44°C) to the skin for 30 seconds to 5 minutes or assessment of the critical temperature threshold by an instrument such as TempTest®.

Urticarial vasculitis

Lesional skin biopsy is essential and should be undertaken if circled lesions consistently last >24 hours, in order to confirm the presence or absence of leukocytoclastic vasculitis histologically. The sampled lesion should have been present for 12–24 hours. Direct immunofluorescence microscopy for C3 and immunoglobulin deposits in blood vessels is generally uninformative and does not need to be performed routinely. Patients with urticarial vasculitis need a full vasculitis screen (see Ch. 24).

Angioedema without wheals

Detection of a low serum level of C4 is a very sensitive, but nonspecific, screening test for types I and II HAE and acquired C1 inh deficiency (the level is normal in nC1-INH-HAE). Measurement of the *amount* of C1 inh by immunochemical assay for type I HAE and C1 inh *function* to detect type II HAE should be performed if indicated by the history and supported by a low serum C4 level. Serum C1q levels are also reduced in acquired C1 inh deficiency (Fig. 18.19).

TREATMENT

Patients should be given advice and information on common precipitants, treatments, and prognosis. Antipruritic lotions and the avoidance of aggravating factors, including NSAIDs, may be sufficient for some, but many will need additional interventions, including systemic medications. These can be stratified into first-, second-, and third-line therapies (Fig. 18.20). The management of urticarial vasculitis is discussed in Chapter 24 and treatment of C1 inh deficiency is considered separately because its pathogenesis and therapeutic interventions differ. Patients must understand that although systemic corticosteroids may completely eliminate their lesions, recurrences often occur with tapering of the dosage and long-term use is unacceptable. In addition, H1 antihistamines and other drug combinations can nearly always control symptoms and significantly improve quality of life.

Acute, Chronic Spontaneous, and Inducible Urticarias

First-line therapies

H1 antihistamines are the mainstay of management for most patients with urticaria, although not all patients will respond and only about 40% of those attending tertiary care clinics will clear or almost clear at licensed doses. Antihistamines reduce pruritus, flatten wheals, shorten wheal duration, and reduce wheal numbers, even though they may not clear urticaria completely. It is worth discussing the relative benefit with patients who feel that "they haven't worked".

Antihistamines should be taken on a daily basis, the frequency depending on their half-life. In other words, they should not be taken only when the patient is symptomatic. As a general rule, antihistamines

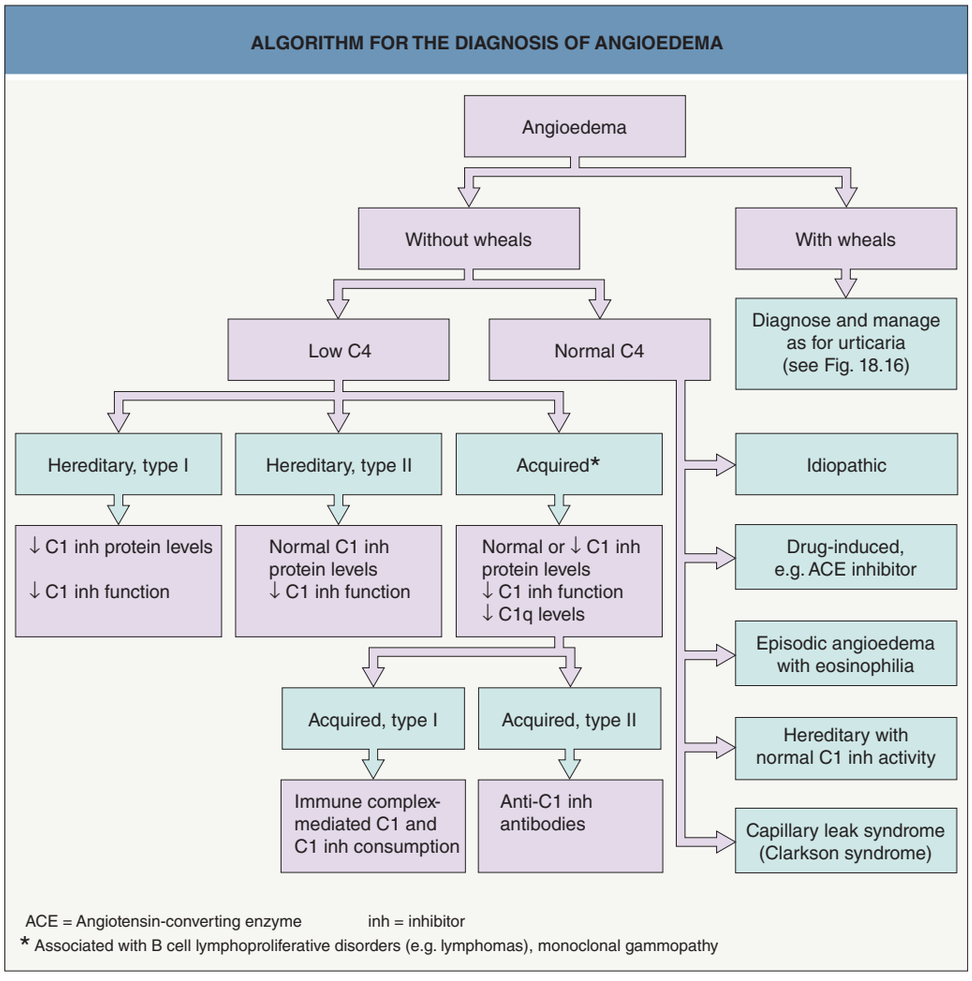

Fig. 18.19 Algorithm for the diagnosis of angioedema. Episodic angioedema with hypereosinophilia, along with weight gain and fever, is known as Gleich syndrome. There are currently 7 subgroups of HAE with normal C1 inh activity (nC1-INH-HAE, previously referred to as type III HAE); the six subgroups that have a known underlying genetic mutation are termed HAE3 to HAE8 (see Fig. 18.6), while the seventh subgroup includes those whose genetic basis is unknown.

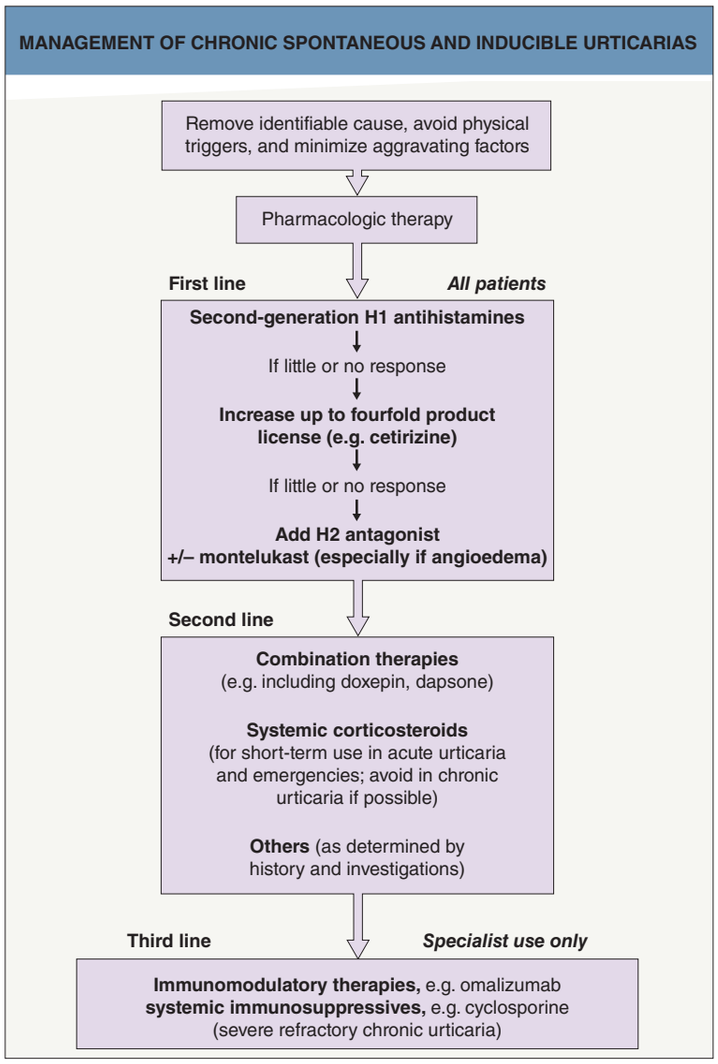

Fig. 18.20 Management of chronic spontaneous and inducible urticarias.

are safe and have few significant adverse effects. They can be grouped into first-generation (classic, sedating) antihistamines, second-generation (new generation, non- or minimally sedating) antihistamines and their derivatives, and the H2 antagonists (Table 18.5). The EAACI/GA^{2}LEN/EDF/WAO consensus guidelines on chronic urticaria strongly recommend *against* using sedating H1 antihistamines as monotherapy[90].

Classic antihistamines

Classic antihistamines are problematic because sedation and anticholinergic side effects are often dose-limiting. However, in combination with a daytime non-sedating antihistamine, they can be taken at night if sleep is disturbed by urticaria, but the following day they may interfere with skilled tasks (e.g. operating machinery and driving) or reduce the ability to concentrate at work or school.

Second-generation antihistamines

Second-generation antihistamines are usually well tolerated, with the majority of patients requiring only once-daily oral dosing (see Table 18.5). For chronic urticaria, there is probably little distinction between the second-generation antihistamines when they are taken at the licensed dosages. A consensus paper has recommended increasing the daily dose of second-generation H1 antihistamines up to fourfold for difficult urticaria[90]. It is possible that their additional anti-allergic and anti-inflammatory properties may be clinically beneficial at these higher doses, but direct evidence for this is lacking and they do represent unlicensed dosages.

Fexofenadine is licensed for urticaria at 180 mg daily. It is the active metabolite of terfenadine but does not appear to have the potential for ventricular arrhythmias as of its parent drug. Desloratadine (an active metabolite of loratadine) and levocetirizine (the active enantiomer of cetirizine) probably offer no clinical advantage over their parent drugs at equivalent doses.

Clinically important drug interactions are infrequent, but coadministration of mizolastine with systemic erythromycin and ketoconazole is contraindicated because of concern about possible cardiac arrhythmias. Caution is also recommended with regard to other hepatic cytochrome P450 3A4 inhibitors (e.g. cimetidine) or substrates (e.g. cyclosporine; see Ch. 131), which may be used for urticaria in special circumstances.

Addition of H2 antagonists to conventional H1 antihistamines

The addition of H2 antagonists to conventional H1 antihistamines may be helpful in some patients with chronic urticaria, although clinical trial evidence for combining H1 antihistamines and H2 antagonists is poor and not all authorities recommend this therapeutic approach. H2 antagonists have no effect on histamine-induced pruritus and should not be used as monotherapy. Nizatidine and famotidine have similar properties to ranitidine (currently unavailable) but have not been evaluated in clinical trials for chronic urticaria. They are preferable to cimetidine, which may interfere with hepatic metabolism of other drugs and is weakly anti-androgenic.

Antihistamines in pregnancy

No H1 antihistamine can be advertised as being safe during pregnancy, but recent urticaria guidelines suggest loratadine and cetirizine (previously FDA category B drugs) as preferred medications, especially in the second and third trimesters. Both drugs are also compatible with breastfeeding, but hydroxyzine is contraindicated because of reports of seizures in breastfed infants (see Ch. 27). Because of its lengthy prescription record, chlorphenamine has also been used, but it should be avoided close to parturition and during breastfeeding due to potential sedative effects in the child.

Second-line therapies (targeted interventions)

Second-line therapies may be considered when urticaria does not respond well to antihistamines, but high-quality evidence to support their use is lacking. They should usually be prescribed as additive therapies (to antihistamines) rather than as alternatives. The choice of second-line drugs should be guided by specific indications, summarized in Table 18.6. Here, the management of urticaria can be influenced considerably by a full clinical assessment and the experience of the clinician. It is unusual for children to need second-line therapies, except the occasional use of prednisolone for very severe acute exacerbations of chronic urticaria. Second-line drugs should be used with considerable care in pregnancy, and only after the risks have been carefully considered against the likely benefits. Non-drug interventions include diets (e.g. salicylate-free), phototherapy, and cold desensitization.

Drug therapies

Prednisone or *prednisolone* is effective for nearly all presentations of chronic urticaria, but often needs to be used at reasonably high doses (e.g. 30–50 mg daily in adults) to achieve good initial control of severe disease. It should be considered primarily for the short-term management of "crisis" urticaria and serious angioedema of the throat as a rescue medication, when, often, a single dose or several daily doses will be sufficient to re-establish control with regular full-dose antihistamines. Regular treatment with oral corticosteroids should be avoided because of the usually prolonged duration of chronic urticaria and because of their predictable long-term side effects (e.g. hypertension, weight gain, glucose intolerance, osteoporosis). Rebound is also a common problem and the long-term course of the urticaria is often not altered.

Epinephrine (adrenaline) by subcutaneous or intramuscular injection is the treatment of choice for anaphylactic shock or severe anaphylactoid reactions, whether due to an allergy, pseudoallergy, or inducible urticaria. Epinephrine may also be necessary for angioedema of the oropharynx in severe acute allergic urticaria and idiopathic angioedema, but it is rarely required for chronic urticaria and is not effective for HAE. Directing epinephrine mist from an aerosol inhaler onto mucosal angioedema may be helpful for minor episodes, but it is usually better to administer the drug intramuscularly or subcutaneously, if it is required. Side effects of epinephrine include tachycardia, anxiety, and headache. It should be used with caution in patients with hypertension, ischemic heart disease,

ANTIHISTAMINES FOR URTICARIA			
Class	**Examples**	**Plasma half-life (hours)**	**Daily adult dose***
Classic (sedating) H1 antihistamines	Chlorphenamine (1)	12–15	4 mg three times daily (up to 12 mg at night)
	Hydroxyzine (1)	7–20	10–25 mg three times daily (up to 75 mg at night)
	Diphenhydramine (2)	2.5–9	10–25 mg at night
	Doxepin† (1)	8–24	10–50 mg at night
Second-generation H1 antihistamines	Acrivastine‡ (1)	1.5	8 mg three times daily
	Cetirizine§ (1)	7–11	10 mg once daily
	Loratadine (1)	8–11	10 mg once daily
	Mizolastine¶ (1)	13	10 mg once daily
Newer second-generation H1 antihistamines	Bilastine¶	14.5	20 mg once daily
	Desloratadine (1)	27	5 mg once daily
	Fexofenadine (1)	11–15	180 mg once daily
	Levocetirizine (1)	7–10	5 mg once daily
	Rupatadine¶ (1)	6	10 mg once daily
H2 antagonists‖	Cimetidine (1)	2–3	400 mg twice daily
	Famotidine (3)	3	20 mg twice daily

*Current prescribing manuals should be consulted for details on doses in children; off-label, up to fourfold the approved doses of cetirizine and levocetirizine have been prescribed.
†Possesses potent H1 antihistaminic and H2 antagonist properties.
‡Only available in the US as a combination product with pseudoephedrine for seasonal allergic rhinitis.
¶Not available in the US.
§The active metabolite of hydroxyzine.
‖Used in combination with H1 antihistamines.

Table 18.5 Antihistamines for urticaria. A short-acting classic antihistamine may be added at night to a daily second-generation antihistamine, with or without the addition of an H2 antagonist for maximal antihistamine blockade. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

SECOND-LINE MEDICATIONS FOR CHRONIC SPONTANEOUS OR PHYSICAL URTICARIA				
Generic name	**Drug class**	**Route**	**Dose**	**Special indication/associated diseases**
Prednisone or prednisolone (2)	Corticosteroid	Oral	0.5 mg/kg daily	Severe exacerbations (days only) – "rescue" treatment
Epinephrine (2)	Sympathomimetic	Subcutaneous, IM (self-administered)	300–500 mcg	Idiopathic or allergic angioedema of throat/ anaphylaxis
Montelukast (3)	Leukotriene receptor antagonist	Oral	10 mg daily	Aspirin-sensitive urticaria, delayed pressure urticaria
Colchicine (3)	Neutrophil inhibitor	Oral	0.5/0.6–1.5/1.8 mg* daily	Neutrophilic infiltrates in lesional biopsy specimens or urticarial vasculitis
Dapsone (2)	Aminosalicylates	Oral	50–100 mg daily	Neutrophilic infiltrates in lesional biopsy specimens or urticarial vasculitis
Sulfasalazine (2)	Aminosalicylates	Oral	2–4 g daily	Delayed pressure urticaria

*Available in doses of 0.5 mg or 0.6 mg, depending upon the country.

Table 18.6 Some second-line medications for chronic or physical urticaria. Current prescribing manuals should be consulted for details on dose, drug interactions, and contraindications for individual patients. The stated doses represent guidelines only. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. IM, intramuscular.

cerebrovascular disease, and diabetes mellitus. Coadministration of epinephrine with tricyclic antidepressants (including doxepin) and β-blockers should be avoided. For reassurance, patients who are prone to severe acute allergic urticaria and idiopathic angioedema may carry a self-administered epinephrine pen and they need to be aware of side effects, drug interactions, and potential rebound phenomenon.

Doxepin is a tricyclic antidepressant with very potent H1 antihistaminic and H2 antagonistic properties. Although it has significant sedative and anticholinergic properties, it may be valuable, especially when dosed at night in adult patients with chronic urticaria. Monitoring of serum drug levels can prove helpful as clinical studies have frequently observed subtherapeutic levels (therapeutic range for doxepin plus *N*-desmethyldoxepin = 150–250 ng/mL)[95].

Montelukast, a leukotriene receptor antagonist (see Table 130.11), may be beneficial for aspirin-sensitive chronic urticaria due to the likely involvement of leukotrienes in its pathogenesis[96]. There have been anecdotal reports of responses in refractory chronic urticaria associated with delayed pressure urticaria, but clinical experience to date has been less encouraging. It may be useful in combination with H1 antihistamines for CSU patients with angioedema[97]. Side effects are uncommon, but urticaria, angioedema, and anaphylaxis have been reported when it has been given for other indications.

Dapsone has been shown in two randomized clinical trials as well as a larger retrospective medical record review to be an effective and well-tolerated second-line therapy for patients with refractory CSU, including the idiopathic and autoimmune subtypes[98]. Its precise mechanism of action in treating CSU is unknown but is thought to be related to its inhibition of prostaglandin and leukotriene activity, disruption of neutrophil adhesion molecules, suppression of neutrophil recruitment and activation, and interference with the release or functioning of neutrophil lysosomal enzymes (see Ch. 130). Dapsone can also be considered in DPU patients who are sensitive to NSAIDs.

Sulfasalazine may be helpful for chronic urticaria when delayed pressure urticaria (DPU) symptoms predominate, providing it is tolerated. Otherwise, these patients often require systemic corticosteroids. The drug should be avoided in patients with aspirin sensitivity and as with dapsone, glucose-6-phosphate dehydrogenase (G6PD) deficiency. For both medications, a complete blood count should be monitored every 2 weeks for the first 2 months and then regularly thereafter, along with hepatic enzymes. Side effects are reviewed in Chapters 31 and 130.

Colchicine may be beneficial for chronic urticaria when predominantly neutrophilic infiltrates are seen histologically ("neutrophilic urticaria") and it is also used for urticarial vasculitis. Potential side effects are outlined in Table 130.9. Patients receiving colchicine should avoid P-glycoprotein or strong CYP3A4 inhibitors.

Anabolic steroids, such as danazol and oxandrolone, may be useful for severe cholinergic urticaria, especially in male patients, but virilizing side effects and long-term concern regarding liver toxicity are disadvantages.

Miscellaneous drug therapies described for chronic urticaria include tranexamic acid, heparin, and warfarin, but convincing evidence for their use is lacking and there are no specific situations where they appear to be better than other treatments.

Non-drug therapies

Exclusion of food additives and natural salicylates from the diet has been advocated in a number of reports. The high success rates in some series may have been due in part to the natural history of remission in chronic urticaria, as <20% of patients responding to low-pseudoallergen diets flare after double-blind, placebo-controlled challenge with individual additives[99]. Diets nevertheless remain popular with CSU patients and are worth considering when antihistamines have failed and second-line drugs are inappropriate. There is general agreement that food allergy as a cause of adult chronic urticaria is exceptional, and that investigation for relevant immediate hypersensitivity reactions should not be undertaken without a strong lead from the history.

Induction of tolerance by repeated, frequent, graduated exposures to the precipitating physical factor can be helpful for cold urticaria, solar urticaria, and heat contact urticaria. The schedule is time consuming, not all patients can be rendered tolerant, and repeated daily exposures may be necessary to maintain tolerance.

Ultraviolet therapy and photochemotherapy (PUVA) have been used for chronic urticaria, but the reported results have been inconclusive. A retrospective survey suggested that narrowband UVB (NB-UVB) phototherapy might be effective. There is limited evidence that PUVA and NB-UVB are helpful for highly symptomatic dermographism at doses usually administered for psoriasis.

Autohemotherapy with whole blood or serum has been used in ASST-positive patients but strong evidence for this intervention is lacking[100].

Third-line therapies

Omalizumab (humanized anti-IgE monoclonal antibody) has been shown to be effective for chronic spontaneous/idiopathic urticaria in large phase III studies[101,102], as well as for associated angioedema[103] and H1 antihistamine-refractory CSU[104]. The most common dosage in adults is 300 mg monthly via subcutaneous injection. High baseline IgE levels appear to be a marker for early response[105] and early relapse[106]. In retrospective studies, patients with inducible urticarias also had a high rate of complete response of symptoms[107]. After six months of therapy, omalizumab is usually discontinued, while remaining on H1 antihistamines. Recurrences do occur and longer courses may be required.

Cyclosporine (3–4 mg/kg/day for 4–8 weeks) clears or substantially benefits approximately two-thirds of patients with chronic autoimmune urticaria refractory to antihistamines[21]. However, only 25% of responders remained clear or almost clear 4–5 months after discontinuing therapy. As a result, the risk of maintaining the "impossible to wean" patient on long-term cyclosporine is potentially considerable.

Other *immunosuppressive therapies*, including methotrexate, mycophenolate mofetil, and azathioprine, may be effective in some patients with severe CSU, if cyclosporine fails. For example, *methotrexate* has been beneficial in corticosteroid-dependent chronic urticaria patients with and without evidence of functional autoantibodies[108]. *Plasmapheresis* was used successfully in some patients with chronic autoimmune urticaria in a small, open, proof-of-concept study, but it is not recommended as monotherapy because of its expense and an early relapse of the urticaria[20]. *IVIg* infusions (total of 2 g/kg over 5 days) were beneficial in the majority of chronic autoimmune urticaria patients in another small open study, with remissions in some lasting at least three years; expense and potential side effects are concerns. Potential future therapies include other anti-IgE antibodies, Bruton tyrosine kinase inhibitors, anti-KIT monoclonal antibody, and eosinophil inhibitors.

C1 Esterase Inhibitor (C1 inh) Deficiency

The treatment of C1 inh deficiency differs from that of other types of angioedema. Intravenous C1 inh concentrate or recombinant C1 inh, subcutaneous icatibant (a specific bradykinin B_2 receptor antagonist), or subcutaneous ecallantide (a kallikrein inhibitor) should be given in an emergency, as this may prove to be life-saving (see Fig. 18.6). Fresh frozen plasma may be given as an alternative to C1 inh concentrate if the latter is unavailable. Antihistamines, corticosteroids, and epinephrine are not effective in patients with C1 inh deficiency[109]. To treat an acute life-threatening attack, patients with the acquired form of C1 inh deficiency often require much higher doses of C1 inh concentrate than the 20 units/kg recommended for HAE.

C1 inh concentrate may also be given intravenously for short-term prophylaxis 1 hour before elective surgery, especially when intubation or tooth extraction is necessary. For minor surgical procedures, oral tranexamic acid (1 g four times daily in adults or 500 mg four times daily in children) for 48 hours before and after the procedure, or an increase in established maintenance doses of tranexamic acid or danazol, can be effective prophylaxis.

Longer-term prophylaxis may be necessary for patients with symptomatic recurrent angioedema or abdominal colic due to bowel edema. Subcutaneous or intravenous C1 inh (every 3–4 days), the subcutaneous kallikrein inhibitor lanadelumab (every 2 weeks), and the oral kallikrein inhibitor berotralstat (150 mg daily) are therapeutic options. As a result, the use of anabolic steroids (see above) and tranexamic acid have declined. The latter is an inhibitor of the activation of plasminogen to plasmin and is contraindicated if there is a history of thrombosis; with chronic administration, regular eye examinations and liver function tests are recommended. Because HAE may be induced or exacerbated by estrogens in oral contraceptive pills or hormone replacement therapy, they should be avoided if possible.

PROGNOSIS

Most patients with chronic urticaria can expect to benefit symptomatically from treatment, but the prognosis for complete remission has probably changed little from that in a survey done over 50 years ago, which identified that 50% of patients attending a tertiary referral center with wheals alone were clear within a year, but that 20% with wheals and angioedema continued to have symptoms 20 years from the time of onset[110]. A mean duration of disease of slightly over six years has been reported[111].

Additional figures and table on Urticarial vasculitis, available in our eBook (see inside front cover for access code).
