Annular and figurate plaques due to central clearing and scarring with a verrucous surface on the arm (**A**) and a more granulomatous appearance on the leg (**B**). **C** Brown-colored sclerotic body (inset) within a mixed granulomatous and neutrophilic dermal infiltrate. *C, Courtesy C. Massone, MD.*

History and epidemiology

Dr. John Gill provided the first formal description of mycetoma in 1842, in Madura (India), hence the name "Madura foot"[47]. Mycetoma, now classified as an NTD, is endemic to tropical and subtropical climates. Actinomycotic mycetoma is more prevalent in Mexico, while eumycotic mycetoma is more common in other areas including Africa. The typical patient is a man between 20 and 50 years of age.

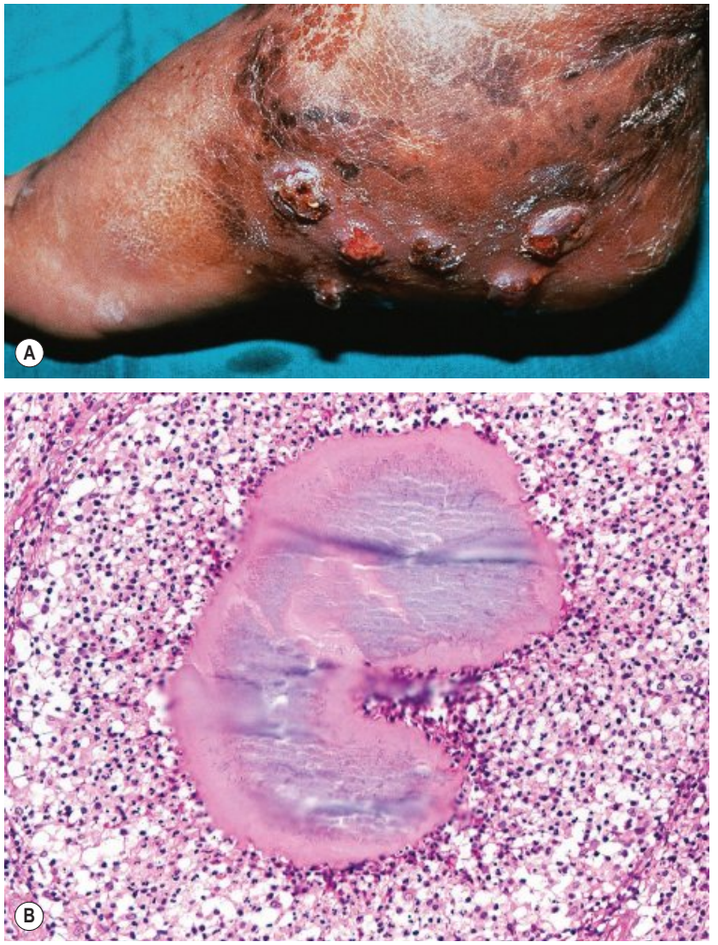

Fig. 77.25 Mycetoma (Madura foot). A Note the soft tissue swelling of the foot as well as multiple nodules with pustular discharge. **B** Histology of a grain, which represents tightly packed colonies of fungal organisms. *B, Courtesy Lorenzo Cerroni, MD.*

Pathogenesis

In most cases, causative organisms are acquired from the soil via direct inoculation into the skin, leading to a dermal and subcutaneous fungal infection. Deeper invasion to muscle or bone can subsequently occur. This process may occur rapidly or over many years. Sometimes, multiple sites of involvement appear in the vicinity of the original lesion, likely due to multiple injuries rather than contiguous spread of disease. Lack of protective footwear, malnutrition, and exposed cuts and abrasions are risk factors for infection.

Clinical features

The foot is the most common site of infection, followed by the hand, trunk, and scalp. Involvement is typically unilateral and begins as a painless papule. Once the subcutaneous tissues are infected, there is swelling and eventual formation of purulent draining sinuses (Fig. 77.25A). The drainage contains the characteristic grains, which represent compact masses of fungal colonies and vary in size from minute to half a centimeter in diameter. Invasion of deeper tissues then ensues, and sometimes cavities are formed within involved bone. Surprisingly, this disease is generally asymptomatic. All subtypes can have a similar clinical presentation.

Pathology

Pseudoepitheliomatous hyperplasia is a common histologic finding that accompanies suppurative and granulomatous inflammation of the dermis and subcutis as well as fibrosis. The characteristic grains represent tightly packed colonies of organisms (Fig. 77.25B). Estimation of the diameter of the filaments comprising the grain as compared to the size of the nuclei of surrounding inflammatory cells allows a distinction between eumycotic (thicker filaments) and actinomycotic (thin, fine filaments) mycetomas. Special stains, e.g. methenamine silver, Brown–Brenn, can aid in distinguishing the subtype (see Ch. 0).

Differential diagnosis

To establish the diagnosis of mycetoma, both the history and clinical appearance are important considerations followed by laboratory evaluation. In addition to noting the color of the grains (Table 77.16), KOH examination, Gram stain, and culture (bacterial and fungal) of exudate from a sinus tract and/or tissue should be performed. Molecular techniques such as PCR-based assays can also be utilized to identify organisms. Mycetoma has to be differentiated from botryomycosis and actinomycosis, which are also associated with grain formation (see Ch. 74).

COLORS OF GRAINS AND GEOGRAPHIC DISTRIBUTION OF EUMYCOTIC AND ACTINOMYCOTIC MYCETOMAS

Pathogen		Grain color	Geographic distribution
Eumycotic	*Madurella mycetomatis* also *M.sudanensis, M fahalii*	Black	Sudan, Africa, Central and South America; Caribbean, Middle East, Asia
	Trematosphaeria grisea	Black	North, Central and South America; Africa, Asia
	Plenodomus senegalensis	Black	Africa, Asia
	*Scedosporium apiospermum**	White	North, Central and South America; Africa, Oceania, Asia, Europe
	Acremonium and *Sarocladium* spp.	White	North, Central and South America; Asia, Europe, Oceania
Actinomycotic	*Nocardia brasiliensis*†	White	Worldwide (all *Nocardia* spp.)
	Nocardia asteroides‡	White	
	Nocardia caviae	Yellow–white	
	Actinomadura madurae	Yellow or white	Worldwide
	Actinomadura pelletieri	Red	North and South America, Africa, India
	Streptomyces somaliensis	Brown or yellow	Africa (arid regions)
	Actinomyces israelii¶	Yellow–white	Worldwide

*Most common cause in the US.
†Most common cause in Mexico.
‡Rare.
¶Very rare cause of mycetoma; usually causes actinomycosis (e.g. cervicofacial, thoracic and abdominal), which also has draining sinuses and grains.

Table 77.16 Colors of grains and geographic distribution of eumycotic and actinomycotic mycetomas. Grains can also be seen in botryomycosis and actinomycosis (see Ch. 74).

Treatment

For the best outcome, eumycotic mycetoma must be diagnosed early and surgically excised (including a large margin of normal surrounding tissue) before the underlying bone becomes involved. Systemic antifungal therapy is administered before and after excision. Depending upon the particular fungus, itraconazole, voriconazole, posaconazole, and terbinafine have been used to treat eumycotic mycetomas[48]. The medical treatment of actinomycotic mycetoma typically consists of streptomycin or amikacin plus either trimethoprim–sulfamethoxazole or dapsone; therapy is continued for months to years. Other useful drugs include moxifloxacin and imipenem.

Sporotrichosis

Synonym: ■ Rose gardener's disease

Introduction

Sporotrichosis is a subcutaneous mycosis caused by dimorphic organisms of the genus *Sporothrix* (e.g. *S. schenckii*, *S. braziliensis*, *S. globose*, *S. mexicana)*[49]. A gardener being pricked by a contaminated rose thorn is a classic vignette for the acquisition of sporotrichosis. Although various clinical presentations are possible, the most common one is a lymphocutaneous or "sporotrichoid" pattern, which refers to the primary inoculation site plus spread of the infection along the lymphatics in a nodular pattern.

Epidemiology

Sporothrix is present in the soil throughout the world. However, sporotrichosis is endemic to Mexico, Central America, and South America as well as other areas such as South Africa. In these locations, exposure to the organism typically occurs in individuals who work outdoors. In temperate climates, such as in the US and Canada, the disease most often develops in gardeners, especially those growing orchids and roses. All age groups can be affected, but it is more common in adults. In the past several decades, the incidence of sporotrichosis in the Rio de Janeiro region of Brazil has increased >100-fold due to transmission of *S. brasiliensis* by infected cats, which (in contrast to humans) harbor large numbers of organisms in cutaneous ulcers[50]. This epidemic has spread to other areas of Brazil and adjacent countries such as Argentina, with recent reports outside of South America (e.g. in the United Kingdom).

Pathogenesis

Sporotrichosis is most commonly acquired from cutaneous inoculation, especially by vegetation such as thorns and wood. With the exception of *S. brasiliensis* from cats, animal-to-human transmission is rare. Multiple inoculations may occur simultaneously, not to be confused with spread of a single primary lesion. The presentation and course of sporotrichosis depends on the host immune response as well as the size and virulence of the inoculum. In naive hosts, involvement of regional lymphatics ensues. However, in some patients, especially those with a prior history of exposure to *Sporothrix*, lymphatic spread does not occur and a "fixed" ulcer[51] or granulomatous plaque develops at the site of inoculation; the latter is often seen on the face, especially in children living in endemic areas.

Extensive cutaneous disease with or without systemic involvement is also possible, especially in an immunocompromised host. Cases of inhaled sporotrichosis have been reported with systemic and cutaneous dissemination, similar to disseminated histoplasmosis and other dimorphic fungal infections.

Clinical features

The initial presentation of sporotrichosis is a single papule at a site of injury, most commonly on the hand, appearing several weeks after inoculation. The lesion then becomes eroded or ulcerated with purulent drainage, but it is generally not painful. Additional lesions appear weeks later, typically developing as dermal and subcutaneous nodules and ulcers along the path of lymphatic drainage (often up the arm; Fig. 77.26). This is the well-known "sporotrichoid" pattern. The involved lymphatic vessels may become fibrosed[52]. Lesions of "fixed" cutaneous sporotrichosis can have a granulomatous appearance, often with ulceration, while disseminated lesions typically present as subcutaneous nodules. Reactive conditions such as erythema multiforme and erythema nodusum have been reported in patients with sporotrichosis, especially that due to *S. brasiliensis*.

Pathology

Histologically, suppurative and granulomatous inflammation is found in the dermis and subcutis. The causative organisms are rarely evident; staining with fluorescent-labeled antibodies may aid in recognition of the sparse cigar-shaped yeast forms. Asteroid bodies are often seen. When numerous fungi are present (e.g. in an immunocompromised host), budding yeast and cigar-shaped organisms can often be visualized with PAS (Fig. 77.26D) or silver stains.

Differential diagnosis

When there is a sporotrichoid pattern, the major entity to be excluded is an atypical mycobacterial infection, in particular with *M. marinum*; less common causes are outlined in Table 77.17. As organisms are not typically seen by KOH or histopathologic examination, culture (of pus or tissue) is often required to definitively diagnose sporotrichosis; a nested PCR assay can also be used to detect organisms in clinical samples[53]. *Sporothrix* spp. are dimorphic fungi (see below), and whether a hyphal or yeast form develops depends on the temperature. Growth is rapid at 25°C, revealing a glabrous white to brown mold that becomes firm, wrinkled, and more darkly pigmented over time. Microscopically, delicate conidia are clustered at the ends of conidiophores (specialized

Fig. 77.26 Lymphocutaneous (sporotrichoid) pattern. A An eroded nodule on the thumb representing the primary lesion with a secondary lesion along the lymphatics due to sporotrichosis. **B** Ulcerated nodule on the extensor forearm with multiple more proximal nodules due to nocardiosis in a patient with lymphoma who was receiving systemic corticosteroids. **C** Granulomatous plaques with evidence of upward spread along the lymphatics. **D** Multiple yeast forms of *Sporothrix schenckii* in the dermis; note that many of the organisms have the characteristic cigar shape. *B, Courtesy Jean L. Bolognia, MD; C, Courtesy Luis Requena, MD; D, Courtesy Ronald P. Rapini, MD.*

hyphae); single, thick-walled pigmented conidia can also arise from hyphae. At 37°C, on enriched glucose-containing media, there are slow-growing, whitish, pasty, yeast-like colonies. On microscopic examination of the latter, cigar-shaped budding yeasts are seen. Full speciation depends on molecular studies[49]. The differential diagnosis of fixed plaque sporotrichosis and disseminated lesions is broad and includes other granulomatous disorders, both infectious and inflammatory.

Treatment

Topical therapy is not effective. Oral saturated solution of potassium iodide (SSKI) has been used with success. Although neither fungistatic nor fungicidal, SSKI is thought to affect the host's immune reaction to the organism. Its cost is low, but it has a bitter taste as well as potential side effects including iododerma, gastrointestinal upset, and thyroid suppression (see Ch. 100). Based upon multicenter, non-randomized trials and case series, the Mycoses Study Group of the Infectious Diseases Society of America has recommended itraconazole (100–200 mg/day) for 3–6 months as the treatment of choice for lymphocutaneous or fixed cutaneous sporotrichosis[54]. The drug is generally safe and well tolerated, and the relapse rate is low. Amphotericin B may be indicated in severe or disseminated disease.

Lobomycosis

Synonyms: ■ Keloidal blastomycosis ■ Lacaziosis ■ Lobo's disease

Lobomycosis is a chronic fungal infection characterized by cutaneous nodules that resemble keloids. The causative organism, *Lacazia loboi* (previously known as *Loboa loboi*)[55], is closely related to *Paracoccidioides brasiliensis* and has never been cultured *in vitro*[56]. Lobomycosis occurs in Central and South America and has been linked to contact with dolphins and a marine environment as well as soil and vegetation in rural areas. Infection typically occurs after minor trauma and most often affects men[57].

Lobomycosis presents as firm, keloid-like nodules that may be pruritic or asymptomatic. It favors the distal extremities, ears (especially the helices), and face but can also affect the trunk (Fig. 77.27A,B). The lesions enlarge slowly over years, forming broad, multinodular plaques that may have a smooth surface or (occasionally) a verrucous appearance and ulceration. Histologic evaluation shows highly characteristic chains of thick-walled, yeast-like cells (known as "brass knuckles") with intercellular bridges (Fig. 77.27C); PAS or silver stains highlight these organisms, which can also be identified in scrapings from the surface of skin lesions[58]. Additional findings include a dermal granulomatous infiltrate and either atrophy or pseudoepitheliomatous hyperplasia of the epidermis. Treatment with surgical excision or cryosurgery is employed if feasible, since antifungal medications are typically ineffective. However, posaconazole or clofazimine plus itraconazole may be of benefit for patients with widespread disease[59,60].

INFECTIOUS CAUSES OF A LYMPHOCUTANEOUS ("SPOROTRICHOID") PATTERN
Most common
Atypical mycobacteria, especially *M. marinum*, but also other species (e.g. *M. chelonae*, *M. kansasii*)
Sporotrichosis (Fig. 77.26A)
Unusual
Nocardiosis (Fig. 77.26B)
Pyogenic bacteria (e.g. *Staphylococcus aureus*, *Streptococcus pyogenes*)
Pseudallescheria boydii/Scedosporium apiospermum
Rare (in high-income countries)
Leishmaniasis
Tularemia*
Tuberculosis*
Dimorphic fungi (other than *Sporothrix* spp.)
Opportunistic fungi in immunocompromised hosts (e.g. *Fusarium*, *Alternaria* spp.)
Glanders (*Burkholderia mallei*)*
Cat scratch disease*
Anthrax
Cowpox
Acanthamoeba spp.
*Often ulceroglandular.

Table 77.17 Infectious causes of a lymphocutaneous ("sporotrichoid") pattern. There are also non-infectious causes such as lymphoma, Langerhans cell histiocytosis, and in-transit metastases. In addition, perineural spread of leprosy can mimic a lymphocutaneous pattern.

SYSTEMIC MYCOSES

This section reviews systemic infections caused by opportunistic as well as true fungal pathogens. The true pathogens are generally dimorphic and cause infection in hosts with normal immune status, while opportunistic pathogens, which are generally less virulent, take advantage of the immunocompromised state.

True Pathogens

Introduction

The systemic mycoses due to true pathogens include histoplasmosis, blastomycosis, coccidioidomycosis, and paracoccidioidomycosis. They are caused by dimorphic fungi, meaning the organisms can exist in two forms – as molds (with septate hyphae and conidia) in nature and as other forms (usually yeasts) in living tissue and (with the exception of *Coccidioides* spp.) at 37°C. Each pathogen has certain geographic preferences (Fig. 77.28; see below). Acquisition of disease is typically through inhalation of the causative fungi, leading to pulmonary symptoms and pneumonitis. The vast majority of infections resolve spontaneously, and patients are left with strong, specific immunity. Disseminated histoplasmosis and coccidioidomycosis may occur in people living with HIV, as can disseminated infections with *S. schenckii* (dimorphic) and *Talaromyces (Penicillium) marneffei* (talaromycosis; dimorphic and opportunistic)[61]. *Emergomyces* spp. are dimorphic fungal pathogens that were initially described in South Africa (*E. africanus*; formerly *Emmonsia pasteuriana*) and subsequently reported in Europe, Asia, and the Americas (*E. canadensis, E. europaeus, R. orientalis, E. pasteurianus*)[62,63]. Disseminated infection in immunocompromised patients (e.g. those with HIV infection) can present with multiple crusted papules/nodules or ulcers, with parasitized macrophages similar to histoplasmosis and penicilliosis evident histologically[62,63] (Table 77.18).

Histoplasmosis

Synonyms: ■ Darling's disease ■ Cave disease ■ Ohio valley disease ■ Reticuloendotheliosis

Fig. 77.27 Lobomycosis. A, B Multinodular pinkish-brown plaques with a keloid-like appearance on the helix and back. **C** Spherical organisms with doubly refractile walls are seen within the dermis. Chain formation is commonly observed (inset; methenamine silver stain). *A, B, Courtesy Regina Carneiro, MD and Caroline Brandao, MD; C, Courtesy C. Massone, MD.*

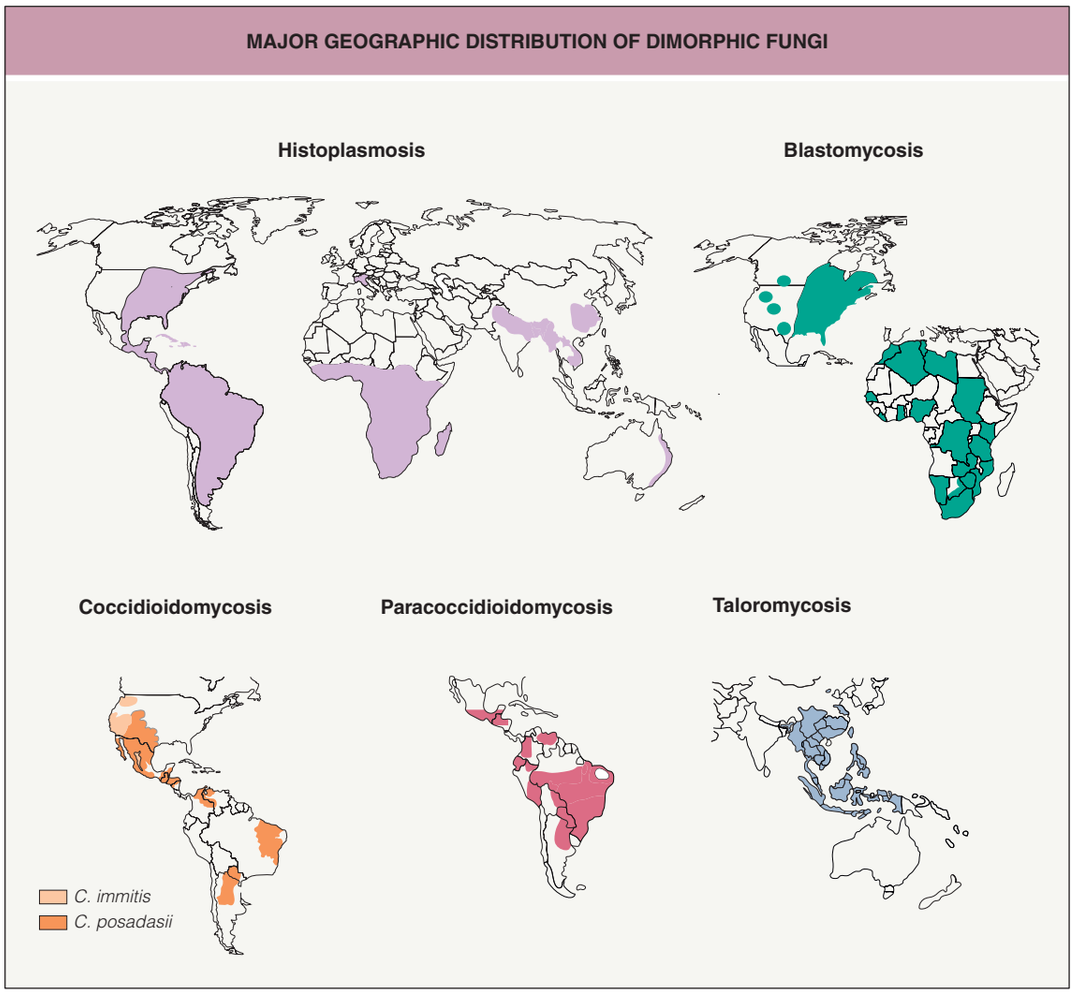

Fig. 77.28 Major geographic distribution of dimorphic fungi. Histoplasmosis has a worldwide distribution, with cases reported outside of these areas, and blastomycosis has also been reported in India and the Middle East. In addition, emergomycosis due to several dimorphic fungal species (*Emergomyces africanus, E. canadensis, E. europaeus, R. orientalis, E. pasteurianus*) has been reported in Africa, Europe, Asia, and the Americas.

DIFFERENTIAL DIAGNOSIS OF PARASITIZED MACROPHAGES		
Disease	**Organism**	**Key features**
Rhinoscleroma	*Klebsiella rhinoscleromatis*	Russell bodies (dilated endoplasmic reticulum cisternae containing aggregated immunoglobulins; form within plasma cells); Mikulicz cell (large histiocyte containing organisms)
Granuloma inguinale	*Calymmatobacterium granulomatis*	"Donovanosis"; Donovan bodies (vacuoles containing bacilli within macrophages)
Histoplasmosis	*Histoplasma capsulatum*	Yeast within cytoplasm of macrophages; surrounded by clear halo
Leishmaniasis	*Leishmania* spp.	Non-encapsulated organism; contains nucleus and paranucleus (kinetoplast)
Talaromycosis	*Talaromyces (Penicillium) marneffei*	Small yeast within macrophages; resembles histoplasmosis
Emergomycosis	*Emergomyces* spp. (include the former *Emmonsia pasteuriana*)	Small yeast within macrophages

Table 77.18 Differential diagnosis of parasitized macrophages. *Adapted from reference 2.*

Introduction

Histoplasmosis is caused by the dimorphic fungus *Histoplasma capsulatum* var. *capsulatum*[64].

Epidemiology

H. capsulatum is found in the soil in warm, moist climates, particularly the Mississippi, Ohio, and St Lawrence river valleys in the US and Canada. Between 80% and 90% of persons from endemic areas may exhibit positive histoplasmin skin testing[65]. Birds, fowl, and bats are significant reservoirs for histoplasmosis. Because the feces of these animals contain the organisms, the areas in which they live can harbor infectious fungal spores. Caves, schoolyards, construction sites, unoccupied buildings, and chicken coops tend to be high-risk areas. *H. capsulatum* var. *capsulatum* is also endemic along river basins in some areas of Africa, India, Southeast Asia, and Australia.

Pathogenesis

Histoplasmosis is caused either by inhalation of *H. capsulatum* or, rarely, by direct cutaneous inoculation of the fungus. Immunocompetent hosts can acquire the disease, but immunocompromised hosts have a higher risk of dissemination. Clinical presentations include acute and chronic pulmonary histoplasmosis, disseminated histoplasmosis, and primary cutaneous histoplasmosis. In disseminated histoplasmosis, the most common sites of involvement (after the lung) are the spleen, lymph nodes, bone marrow, and liver; calcifications within the lymph nodes, lungs, and spleen can serve as evidence of prior infection. Cutaneous manifestations most commonly result from disseminated disease. Severe disseminated histoplasmosis has been reported in individuals with impaired interferon-γ responses due to mutations in *IFNGR1* or *STAT1*, which encode interferon-γ receptor 1 and signal transducer and activator of transcription 1, respectively (see Ch. 60).

Clinical features
The skin lesions of histoplasmosis are nonspecific, making the diagnosis virtually impossible with physical examination alone. When chronic disseminated histoplasmosis occurs in immunocompetent hosts, the most common mucocutaneous finding is oral ulcers but occasionally nodules and vegetative plaques are also seen. Disseminated histoplasmosis in immunocompromised hosts (including people living with HIV) can present with mucocutaneous erosions or ulcers as well as multiple erythematous papules or nodules with scale or crust (Fig. 77.29A,B). In African histoplasmosis, a variant caused by *H. capsulatum* var. *duboisii*, most patients present with mucocutaneous, subcutaneous, and bone lesions.

Pathology
Microscopic examination of biopsy specimens demonstrates characteristic intracellular yeast forms surrounded by a rim of clearing (Fig. 77.29C). Histiocytes and giant cells are the host cells in histoplasmosis, which is in the differential diagnosis of "parasitized macrophages" (see Table 77.18). For easier identification of the fungi, tissue may be stained with PAS or methenamine silver (Fig. 77.29D).

Differential diagnosis
Because cutaneous histoplasmosis has a wide spectrum of clinical presentations, the diagnosis usually rests on histologic examination and culture of involved skin tissue. To evaluate for disseminated disease, bone marrow (sensitivity 70%–90%) and blood should be cultured at 25°C and 37°C, with plates held for up to a month. At 25°C, characteristic tuberculate macroconidia develop. Additional diagnostic tests include cultures of sputum and body fluids, polysaccharide antigen testing of blood and urine (useful in detecting disseminated disease), histoplasmin skin testing (indicated only in non-endemic areas), and serologic assays to measure antibody responses (complement fixation, immunodiffusion). Highly sensitive and specific PCR-based assays can be used to identify histoplasmosis in blood and tissue[66,67]. Diseases in the differential diagnosis include other dimorphic fungal infections (e.g. paracoccidioidomycosis), mucocutaneous tuberculosis, major aphthae, and oral squamous cell carcinoma. For primary cutaneous histoplasmosis, entities in Table 77.17 should be considered.

Treatment
In primary, self-limited, asymptomatic histoplasmosis, treatment may not be necessary. However, in symptomatic or disseminated disease, systemic antifungal therapy is required. Amphotericin B, given intravenously and titrated up to 1 mg/kg/day, is currently the most effective therapy and should be used initially for severe disease, followed by itraconazole. In immunocompetent hosts with mild to moderate, stable disease, itraconazole (200–400 mg/day) is the treatment of choice[68]. HIV-infected patients with disseminated histoplasmosis require lifelong maintenance therapy with itraconazole after initial treatment with amphotericin B (if required for severe disease). Successful treatment with voriconazole, posaconazole, and isavuconazole have also been described[69,70], but ketoconazole is no longer routinely used.

Blastomycosis

Synonyms: ■ North American blastomycosis ■ Gilchrist's disease

Introduction
Blastomyces dermatitidis is a dimorphic fungus and the most common causative agent of blastomycosis. Additional species that have more recently been associated with blastomycosis include *B. gilchristii*, *B. helicus* (formerly *Emmonsia helica*), *B. emzantsi*, and *B. percursus*[70–72].

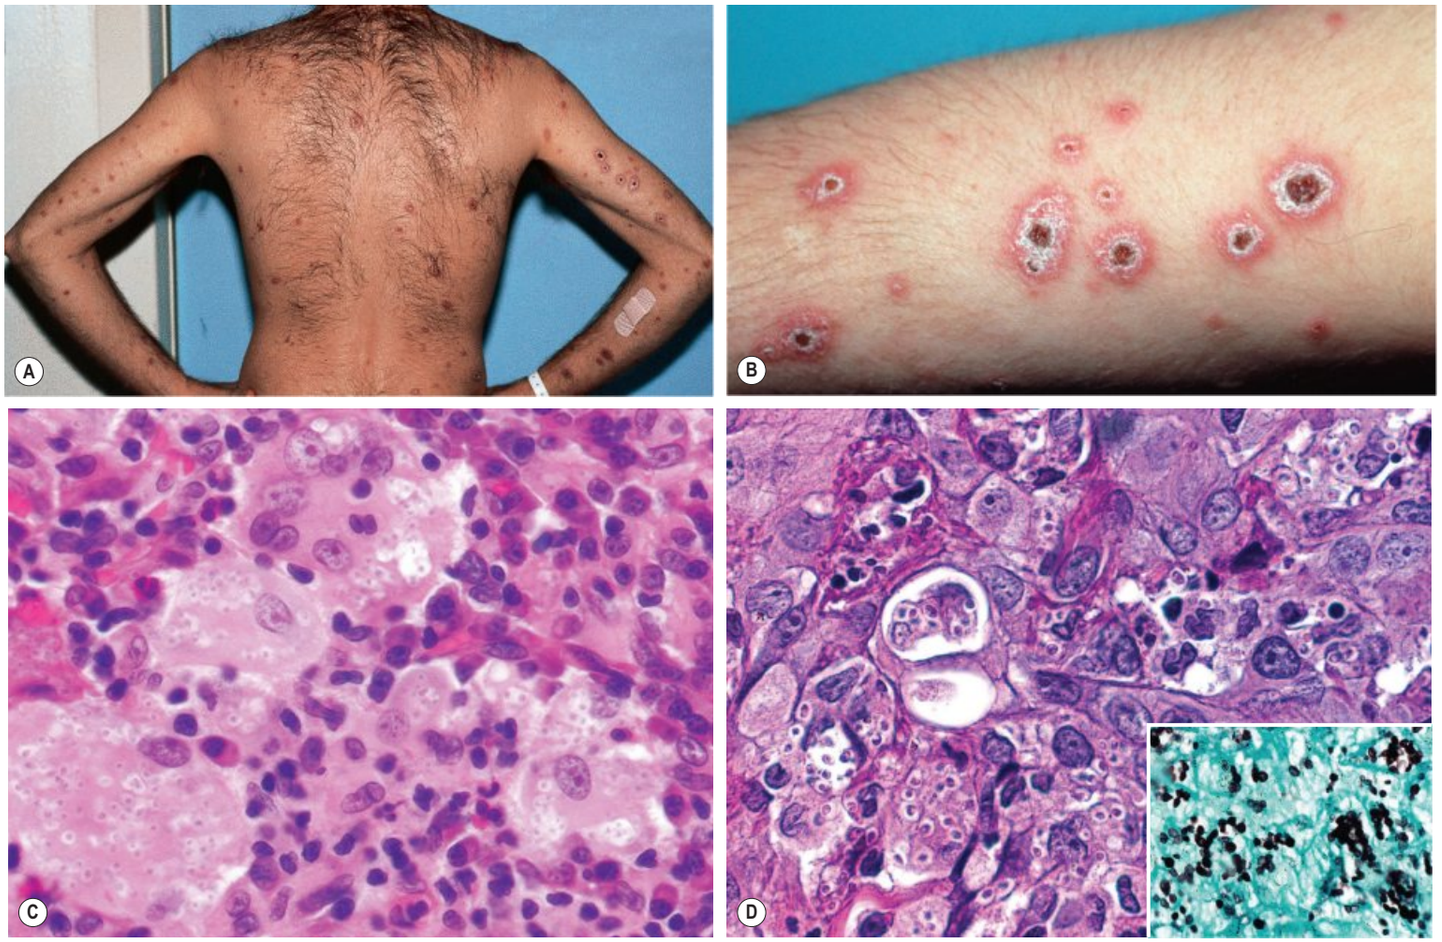

Fig. 77.29 Histoplasmosis. A, B Disseminated papules and nodules with scale-crust in a patient with AIDS. **C** Numerous yeasts within giant cells as well as dermal macrophages. **D** The organisms are highlighted with a methenamine silver stain (inset). *C, Courtesy Jennifer McNiff, MD; D, Courtesy C. Massone, MD.*

Epidemiology
Blastomycosis due to *B. dermatitidis* is endemic to North America, particularly the Mississippi and Ohio river valleys, Great Lakes region, and southeastern states; within this region, especially in the northern US and Canada, blastomycosis is also occasionally caused by *B. gilchristii*[72]. While all ages and sexes can be affected, adult men are most likely to develop systemic infection, and children are more likely to develop acute pulmonary blastomycosis rather than chronic or cutaneous disease. The soil is an important source of infection, making those who have occupations with frequent outdoor exposure at higher risk than the remainder of the population. Disseminated disease due to *B. helicus* in immunocompromised hosts has been reported in the Western US and Canada[72]. Blastomycosis also rarely occurs in other areas of the world, including Africa, India, and the Middle East; recent investigations suggest that *B. emzantsi* and *B. percusus* underlie most disease in these regions[69,72].

Pathogenesis
The lungs are typically the first site of infection, via inhalation of organisms. In contrast to infections with other dimorphic fungi, secondary cutaneous dissemination is a common occurrence and may even be the first sign of disease. Cutaneous manifestations are sometimes seen in the absence of overt pulmonary disease. Primary cutaneous blastomycosis is uncommon and results from direct inoculation of the skin from trauma, such as in the laboratory.

Clinical features
The most common cutaneous findings are papulopustules and well-demarcated verrucous plaques with scale-crust and pustules within their borders (Fig. 77.30A,B). Central ulceration can occur, and more advanced disease may have an appearance similar to pyoderma gangrenosum. The number of lesions can vary from one to several, and they tend to occur on exposed skin. Healing begins centrally and is followed by cribriform scarring. Mucous membrane involvement is occasionally observed.

Pulmonary infection is subclinical in up to 50% of patients with inhalation blastomycosis. Bone involvement may occur and presents as osteomyelitis with rare extension to muscle; genitourinary disease is uncommon.

Pathology
Histologic examination of skin lesions demonstrates pseudoepitheliomatous hyperplasia, suppurative and granulomatous inflammation, and round yeast forms with characteristic broad-based budding and thick, double-contoured walls. This budding pattern helps to differentiate blastomycosis from other fungal infections. Methenamine silver and PAS staining allow better visualization of the fungi within giant cells and neutrophilic abscesses (Fig. 77.30D). Similar budding yeast forms can be seen in sputum samples.

Differential diagnosis
Cutaneous blastomycosis must be differentiated from other cutaneous infections (e.g. verrucae, folliculitis, nocardiosis, tuberculosis, chromoblastomycosis, those due to other dimorphic fungi), inflammatory dermatoses (e.g. pyoderma gangrenosum, halogenoderma, sarcoidosis) and neoplasms (e.g. squamous cell carcinoma). Lesions of blastomycosis-like pyoderma, an exaggerated vegetative response to a prolonged primary or secondary bacterial infection, can also resemble cutaneous blastomycosis. Current or past residence in an area in which blastomycosis is endemic is a helpful clue.

Identification of characteristic broad-based budding yeast forms in pus by KOH or calcofluor examination is diagnostic of blastomycosis. Either skin tissue or pus should be cultured at both 37°C and 25°C. The former temperature allows identification of the budding yeast form, while the characteristic colonial morphology with white spikes (coremia) is observed at 25°C. Other tests such as blastomycin skin testing and complement fixation testing are not usually helpful, but PCR-based assays are available[73].

Treatment
Blastomycosis, like histoplasmosis, requires systemic treatment with amphotericin B (given at the same doses) when severe or progressive. In mild to moderate non-CNS disease, itraconazole (200–400 mg/day) is the treatment of choice[74]. Fluconazole (400–800 mg/day), voriconazole (especially following amphotericin B for CNS disease), posaconazole, and isavuconazole are alternative medications[69,75]; ketoconazole is no longer routinely used. Occasionally, surgical treatment is indicated.

Coccidioidomycosis

Synonyms: ■ Valley fever ■ Desert rheumatism ■ San Joaquin valley fever ■ California disease

Introduction
Coccidioidomycosis is caused by two dimorphic and highly virulent pathogens that are closely related, *Coccidioides immitis* and *C. posadasii*[76].

Epidemiology
Coccidioidomycosis occurs predominantly in the summer and fall in the southwestern US, northern Mexico, and Central and South America; *C. immitis* is found primarily in California and *C. posadasii* elsewhere within these regions. The arthroconidia of *Coccidioides* spp. are inhaled via dust particles. Primary infection of the respiratory tract shows no sex or age preference, but disseminated disease is more common in Mexicans (5×), African-Americans (25×) and Filipinos (175×). Immunosuppressed states (e.g. HIV infection) and pregnancy also predispose to dissemination; White women are most likely to have more limited disease.

Fig. 77.30 Blastomycosis. A Facial plaque with scale-crust and a border with a granulomatous appearance. **B** Well-demarcated plaques with erosions, central scarring, and black crusting. **C** Verrucous plaque with focal crusting on the medial thigh. **D** Budding yeast forms in the dermis, several of which are within a giant cell (PAS stain). Note the single, broad-based budding (arrow). *A, Courtesy Louis A. Fragola, Jr, MD; B, Courtesy Paul Lucky, MD; C, Courtesy Elizabeth Ergen, MD; D, Courtesy Mary Stone, MD.*

Pathogenesis

C. immitis and C. posadasii are thought to be the most virulent of all fungi[76]. Infectious arthroconidia are inhaled and cause pulmonary infection in the vast majority of people living in endemic areas. The infection is asymptomatic in ~60% of affected individuals, while the remainder develop flu-like symptoms several weeks after exposure[77]. Dissemination to the skin and other organs can occur and depends on host factors (see above). Of note, similar to histoplasmosis, severe disseminated disease has been associated with an impaired interferon-γ response due to mutations in *IFNGR1* or *STAT1* (see Ch. 60). Rarely, primary cutaneous coccidioidomycosis results from direct inoculation of the organism into the skin.

Clinical features

Symptomatic primary inhalation coccidioidomycosis typically presents as a flu-like syndrome with fatigue, anorexia, fever, cough, and pleuritic chest pain. The cutaneous manifestations can occur alone or in combination with the above symptoms and are grouped into four patterns:

- papules, pustules, plaques, abscesses, and sinus tracts favoring the face (Fig. 77.31A,B)
- ulcerations
- toxic erythema presenting as a diffuse macular eruption early in the disease course and sometimes mimicking contact dermatitis
- hypersensitivity reactions such as erythema multiforme and erythema nodosum.

In people living with HIV, the papules may resemble molluscum contagiosum. Bone and meningeal involvement can also occur, presenting as osteomyelitis and meningitis, respectively.

Pathology

Biopsy specimens of specific lesions (types 1 and 2 above) reveal characteristic endospore-containing spherules that measure 30–60 microns when mature (Fig. 77.31C). PAS and methenamine silver stains are helpful in identifying immature spherules. A suppurative granulomatous reaction with histiocytes, lymphocytes, and giant cells typically surrounds the spherules and released endospores.

Differential diagnosis

Coccidioidomycosis can be diagnosed via direct examination (with KOH or calcofluor) and culture of infected tissue, pus, or body fluids. Histologically, larger sporangia (up to 300 microns in diameter) containing numerous endospores can also be seen in mucosal polyps due to *Rhinosporidium seeberi*. When cultured at 25°C or 37°C, *Coccidioides* spp. proliferate quickly (within days) and yield white to tan-brown colonies with varying morphology. Microscopically, septate hyphae that form thick-walled, barrel-shaped arthroconidia are seen at both temperatures. These arthroconidia alternate with thin-walled, vacant cells, which rupture and release the infectious arthroconidia when mature (Fig. 77.32). The infectious hyphal forms produced in culture should be examined with extreme caution, as the examiner is at risk for contracting the disease.

Serologic testing and exoantigen testing are useful in making the diagnosis of coccidioidomycosis. PCR-based assays are also available and *in situ* hybridization has been described[73,78].

Treatment

As in the other dimorphic fungal infections, systemic antifungal therapy is required for severe or disseminated disease. Amphotericin B is the most effective medication, and the intravenous dose for severe disease is 1.0–1.5 mg/kg per day (higher dose for patients with AIDS). The chronic nature of disseminated disease requires prolonged therapy with itraconazole (400 mg/day) or, in the case of meningitis, fluconazole. Voriconazole, posaconazole, and isavuconazole, which have *in vitro* activity against coccidioidomycosis equal or superior to that of itraconazole, have been used successfully (alone or in combination with liposomal amphotericin B) to treat disseminated disease[69]. Ketoconazole is no longer routinely used. Successful use of targeted immunomodulation with dupilumab and interferon-γ in addition to antifungal therapy in a child with refractory disseminated coccidioidomycosis associated with increased interleukin-4 and reduced interferon-γ has been reported[79].

Paracoccidioidomycosis

Synonyms: ■ South American blastomycosis ■ Brazilian blastomycosis

Introduction and epidemiology

Paracoccidioidomycosis is caused by the dimorphic fungus *Paracoccidioides brasiliensis*. It is endemic to the Central and South American countries of Brazil, Argentina, Venezuela, Ecuador, and Colombia.

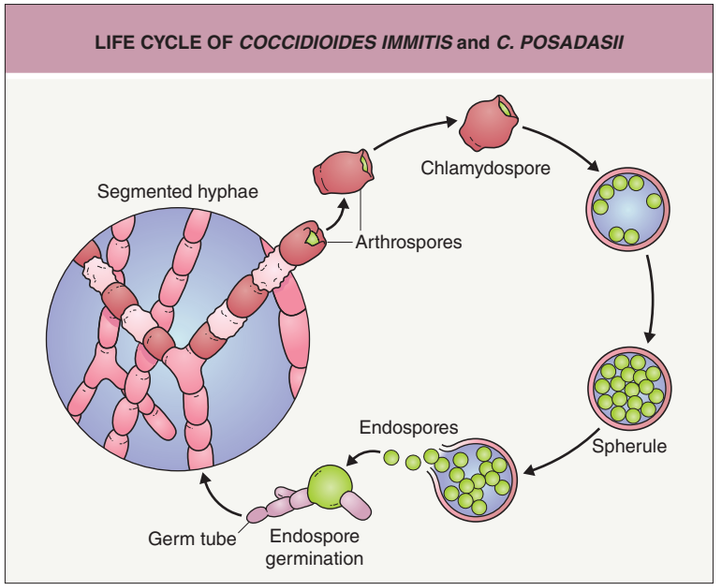

Fig. 77.32 Life cycle of *Coccidioides immitis* and *C. posadasii*.

Pathogenesis
P. brasiliensis is a dimorphic saprophyte that is found in the soil. In most cases, infection occurs via inhalation of the conidia from the environment. Pulmonary disease ensues and can be followed by dissemination to the skin, mucous membranes, gastrointestinal tract, spleen, adrenal glands, and lymph nodes.

Clinical features
Paracoccidioidomycosis has several different clinical presentations with varying prognoses. In many patients, the primary pulmonary disease is subclinical to mild. When progressive disseminated disease occurs, mucocutaneous involvement is commonly seen. Lesions are often painful and ulcerative or verrucous; they are typically found on the face and in the nasal and oral mucosae (Fig. 77.33A,B). The ulcerations are referred to as "moriform stomatitis". Lymphatic spread may occur, resulting in cervical lymphadenopathy.

Another clinical presentation is that of primary mucocutaneous paracoccidioidomycosis. This frequently has an intraoral and perioral distribution due to trauma from chewing contaminated sticks and leaves. Granulomatous lesions are typically seen. Primary cutaneous paracoccidioidomycosis can also occur via direct inoculation of the skin, resulting in the development of a verrucous papule or plaque or cutaneous ulceration.

Pathology
The histologic features of paracoccidioidomycosis resemble those of blastomycosis (see above). Pseudoepitheliomatous hyperplasia is accompanied by suppurative and granulomatous inflammation. Yeast forms are found within and outside of giant cells. Large, thick-walled organisms with multiple narrow-based buds may be seen, leading to an outline that resembles a "mariner's wheel" (Fig. 77.33C).

Differential diagnosis
The differential diagnosis includes mucocutaneous leishmaniasis, granulomatosis with polyangiitis, NK cell lymphoma, and syphilis (endemic and epidemic) (see Table 45.3). Microscopic examination and culture of the organism are essential for diagnosing paracoccidioidomycosis. KOH or calcofluor examination of an appropriate specimen (sputum, dermal scraping, or pus) may reveal round to ovoid cells with narrow-based buds, which are also seen when the organism is cultured at 37°C.

Treatment
There are several effective treatment options for paracoccidioidomycosis, including amphotericin B, systemic azoles, and sulfonamides. Prolonged therapy is generally required. In disseminated disease, systemic therapy with amphotericin B or an azole antifungal is indicated. Itraconazole is a preferred treatment because it provides reasonable efficacy and side-effect profile, as well as low potential for recurrent disease. Treatment with voriconazole or isavuconazole can also be effective. Attempts to modulate the immune system via peptides derived from the *P. brasiliensis* 43 kDa glycoprotein have been described[80].

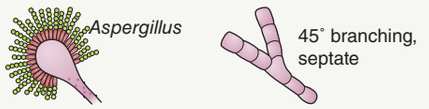
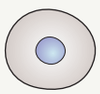
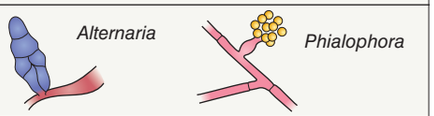
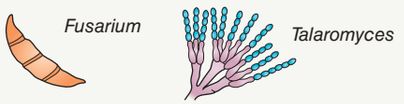
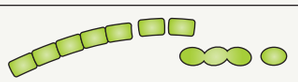
Opportunistic Pathogens











Introduction
Opportunistic mycotic infections may occur in individuals with primary or secondary immunodeficiencies. Worldwide, disseminated candidiasis and aspergillosis are the two most common systemic mycoses in neutropenic patients. Less commonly, mucormycosis, phaeohyphomycosis (due to pigmented fungi; see below), and hyalohyphomycosis (due to non-pigmented [hyaline] fungi; most often fusariosis) are seen (Fig. 77.34). Disseminated histoplasmosis, coccidioidomycosis, cryptococcosis, and talaromycosis are the systemic mycoses seen most commonly in the setting of HIV infection[61]. Opportunistic pathogens are less virulent than true pathogens and impart no specific protective immunity to those infected.

History
Aspergillosis was among the first mycoses recognized, with the initial report of a human case by Sluyter in 1847. In 1855, Kurchenmeister isolated *Mucor* from the lung and described zygomycosis. Benham distinguished cryptococcosis from blastomycosis in the 1930s. *Fusarium* emerged as an opportunistic pathogen in neutropenic oncology patients in the 1990s.

Epidemiology
With the exception of several dimorphic fungi, opportunistic fungal infections occur worldwide and have no geographic predilection. The causative pathogens are commonly found in the environment. For example, *Aspergillus* spp., *Fusarium* spp., and Mucormycetes are soil saprophytes found in decaying vegetation[81]. *Cryptococcus neoformans* can be isolated from avian (especially pigeon) droppings. *T. marneffei* is endemic to Southeast Asia and China, where the reservoir is thought to be in bamboo rats, but imported infections have been reported in the US. Lastly, *Candida* spp. commonly colonize the skin and gastrointestinal tract[1].

Overall, the incidence of opportunistic mycoses increased in conjunction with the greater use of immunosuppressive therapy and the HIV pandemic. In fact, some opportunistic mycoses are considered to be AIDS-defining diseases (see Ch. 78). Notably, the incidence of disseminated candidiasis and aspergillosis has fallen with the use of prophylactic voriconazole in high-risk oncology patients (e.g. neutropenic patients with hematologic malignancies, hematopoietic stem cell transplant

CUTANEOUS FEATURES OF COMMON OPPORTUNISTIC MYCOSES

Mycosis	Common cutaneous presentations	Microscopic appearance
Systemic candidiasis† • *Candida albicans* • *C. tropicalis* (frequent skin lesions) • *C. glabrata, C. krusei* (intrinsic fluconazole resistance)	Firm erythematous papules and nodules, often with a pale center (but possibly hemorrhagic); ecthyma gangrenosum-like lesions	
Aspergillosis† • *Aspergillus flavus* and *fumigatus*	Necrotic papulonodules, subcutaneous nodules (secondary cutaneous); may be associated with an intravenous catheter site (primary cutaneous); disseminated disease usually results from primary pulmonary involvement; galactomannan (more specific, lower sensitivity) and 1,3β-D-glucan (less specific for aspergillosis) serum assays can be used to screen high-risk patients	
Mucormycosis† • *Mucor* • *Rhizopus* • *Lichtheimia* (formerly *Absidia*)	Ecthyma gangrenosum-like lesions, cellulitis, facial edema (commonly unilateral due to contiguous spread of sino-orbital disease), necrotic papulonodules, plaques, large hemorrhagic crusts on the face; may be associated with an intravenous catheter site (primary cutaneous)	
Cryptococcosis** • *Cryptococcus*	Ulceration, cellulitis, molluscum contagiosum-like lesions; assays to detect cryptococcal antigens in blood or CSF are available	
Phaeohyphomycosis* • *Alternaria* • *Exophiala* • *Phialophora*	Subcutaneous cysts, ulcerated plaques, hemorrhagic pustules, necrotic papulonodules	
Hyalohyphomycosis* • *Fusarium* • *Talaromyces (Penicillium)*** • *Paecilomyces*	Umbilicated or necrotic papules, pustules, abscesses, cellulitis, subcutaneous nodules; *Fusarium* infection can be associated with a periungual focus	
Trichosporonosis • *Trichosporon* spp.	Papulovesicles, purpuric papules, necrotic papulonodules	

* Less common
** Especially in the setting of AIDS
† With the use of prophylactic voriconazole, posaconazole, and isavuconazole in high-risk oncology patients (e.g. neutropenic patients with hematologic malignancies, hematopoietic stem cell transplant recipients), the incidences of disseminated candidiasis, systemic aspergillosis, and mucormycosis (posaconazole and isavuconazole) have declined in these individuals

Fig. 77.34 Cutaneous features of common opportunistic mycoses. While the lesions of opportunistic fungal infections seem nonspecific, certain presentations may be more likely associated with a particular species.

recipients). However, voriconazole lacks activity against Mucormycetes, which are covered by newer antifungals (e.g. posaconazole, isavuconazole).

Pathogenesis

Aspergillosis is an opportunistic mycosis that is caused by fungi in the genus *Aspergillus*, most often *A. fumigatus* and *A. flavus*. Burns, sites of trauma, surgical wounds, intravenous catheters (Fig. 77.35A), and macerated skin underlying occlusive dressings typically serve as portals of entry in primary cutaneous aspergillosis[82]. The risk of dissemination is significant in immunocompromised individuals. In *secondary* cutaneous aspergillosis (a more common form), the conidia are inhaled, producing a primary lung infection that is followed by dissemination to the skin. Immunosuppression – particularly neutropenia plus chronic use of corticosteroids and sometimes late-stage AIDS – is a major risk factor for the development of invasive or disseminated aspergillosis.

Fungi in the subphylum Mucoromycotina, class Mucormycetes (also known as Mucoromycetes; formerly Zygomycetes), and order Mucorales cause mucormycosis, which was previously called zygomycosis. The genera most commonly responsible are *Rhizopus, Mucor, Rhizomucor*, and *Lichtheimia* (formerly *Absidia*)[83]. Risk factors include poorly controlled diabetes mellitus as well as other forms of immunosuppression, especially when associated with neutropenia. *Primary* infections can be rhino-orbito-cerebral, pulmonary, or gastrointestinal as well as cutaneous via direct inoculation of the skin in settings similar to those of primary cutaneous aspergillosis; hematogenous dissemination may occur in immunocompromised hosts. Skin lesions that arise from contiguous spread (e.g. from the sinuses) or hematogenous dissemination are referred to as *secondary* cutaneous mucormycosis. Aspergillosis and mucormycosis are both characterized by necrotic skin lesions due to the angioinvasive nature of these organisms. Rapidly progressive mucormycosis with a mortality rate of up to ~30% has been described in association with SARS-CoV-2 infection, most often rhino-orbital(-cerebral) disease in patients with diabetes mellitus who recently received systemic corticosteroids[84].

Cryptococcus neoformans represents the predominant pathogen in cryptococcosis, which is known for producing meningitis in immunocompromised patients. In contrast, symptomatic infections with the *C. gattii* complex more commonly develop in otherwise healthy individuals and have led to outbreaks of life-threatening pneumonia in the Pacific Northwest[85]. Both of these organisms, which are present in the soil and bird droppings (pigeons for *C. neoformans*), result in a primary pulmonary infection via inhalation. Subsequent dissemination to the CNS, bone, and skin may occur, especially with *C. neoformans* infections in people living with HIV and other immunocompromised hosts. Resultant skin disease is referred to as *secondary* cutaneous cryptococcosis. *Primary* cutaneous cryptococcosis can also occur, but the diagnosis is made after a systemic evaluation has been performed. The use of antiretroviral therapy (ART) in people living with HIV has led to a dramatic decrease in the incidence of cryptococcosis.

Yeasts belonging to the genus *Candida* are responsible for candidiasis, which can present as a mucocutaneous condition (see above) or, in immunocompromised hosts, a disseminated infection that often originates from the gastrointestinal tract. The ability of *Candida* to

Fig. 77.35 Clinical findings of opportunistic fungal infections in immunocompromised hosts. Primary cutaneous aspergillosis characterized by hyperpigmented plaques with brown–black scale-crusts at the site of intravenous catheters on the arm (**A**); firm pink papulonodule due to disseminated candidiasis (**B**); erythematous papulonodules with central purpura, vesiculation and/or crusting in a leukemic patient with disseminated fusariosis (**C**); hemorrhagic vesicle representing a *Fusarium solani* septic embolus in a patient with acute lymphoblastic leukemia (**D**); necrotic hemorrhagic bulla due to embolus of *Aspergillus flavus* (**E**); cellulitis with large areas of necrosis due to *Rhizopus* (**F**) and cryptococcosis (**G**); cryptococcal cellulitis mimicking bacterial cellulitis (**H**); disseminated cryptococcosis presenting with crusted lesion(s) resembling molluscum contagiosum (**I**) and a basal cell carcinoma (**J**); cryptococcal cellulitis (**K**); numerous papules and nodules with central umbilication and crusting in disseminated *Talaromyces (Penicillium) marneffei* infection (**L**). *D, Courtesy Edward Cowen, MD; H, Courtesy Catherine Baker, MD; L, Courtesy Evangeline Handog, MD and the Dermatology Department, Research Institute for Tropical Medicine.*

exist in the form of pseudohyphae in tissue and blastoconidia in the bloodstream allows for adaptation and evasion of host defenses[86]. Neutropenia, especially in patients who have received prolonged courses of corticosteroids, sets the stage for disseminated candidiasis; patients are usually also receiving broad-spectrum antibiotics. *C. albicans* is the most common species, but *C. tropicalis* is often implicated in fungemia in patients with leukemia. *C. auris* has been detected in ~50 countries, with increased frequency since the SARS-CoV-2 pandemic and a tendency to colonize the skin, medical equipment, and other surfaces. This organism presents a global health threat due to multidrug resistance, high transmissibility, and challenges in laboratory identification, with a mortality rate of ~20%–60% for invasive infection[87].

Hyalohyphomycosis includes infections with *Fusarium, Talaromyces*, and *Paecilomyces* spp. (see Fig. 77.34). These molds are found in the soil and throughout the environment and can cause disseminated infections in immunocompromised hosts. Disseminated infections with *Fusarium*, an angioinvasive organism, most often affect neutropenic oncology patients and may originate from a periungual focus (e.g. paronychia, onychomycosis). *Talaromyces marneffei* is a dimorphic fungus, and people living with HIV are particularly at risk.

Clinical features

All of the opportunistic mycoses can present with several different types of cutaneous lesions (see Fig. 77.34). Skin findings range from firm papules (Fig. 77. 35B) and purpuric or necrotic papulonodules (Fig. 77.35C) to hemorrhagic bullae (Fig. 77.35D,E) and ulcers. Subcutaneous nodules and cellulitis, often with areas of necrosis, can also be seen (Fig. 77.35F,G,H,K).

In disseminated aspergillosis, the CNS, kidneys, and heart (in addition to the lungs) are often involved in severe widespread disease. The prognosis is poor but improves when the patient is no longer neutropenic or corticosteroids are discontinued. Secondary cutaneous mucormycosis due to an underlying sinus infection may initially present with subtle unilateral facial swelling and mild erythema, while advanced disease is characterized by large areas of necrosis covered by a thick hemorrhagic crust.

Secondary cutaneous cryptococcosis is associated with a poor overall prognosis, with a mortality rate of up to 80% if left untreated[88]. Findings range from papulonodules to cellulitis and panniculitis to necrotic ulcers and abscesses (Fig. 77.35H,K); they may also resemble lesions of molluscum contagiosum, herpes viral infections, or basal cell carcinoma (Fig. 77.35I,J)[89]. Approximately 15% of patients with systemic cryptococcosis have skin lesions, and no predictable body distribution has been identified[90].

Cutaneous lesions of disseminated candidiasis frequently present as firm pink papules or nodules (see Fig. 77.35B) on the trunk and extremities. The lesions often have a pale center but may be purpuric in patients with thrombocytopenia. Other presentations include ecthyma gangrenosum-like lesions (hemorrhagic bulla followed by a necrotic eschar; see Fig. 77.22H), pustules, abscesses, and purpura (in thrombocytopenic patients). While *C. albicans* is the most commonly associated species, *C. tropicalis* is more likely to produce cutaneous lesions. Systemic sites of involvement include the liver, spleen, muscle, kidney, retina, and heart valves. A sepsis-like syndrome may occur, with tachycardia, hypotension, dyspnea, and high fevers.

Like histoplasmosis, *T. marneffei* typically infects the liver, spleen, and lymph nodes. The skin may be involved with umbilicated papules that resemble molluscum contagiosum, necrotic nodules, and acneiform lesions. The most common sites are the face (particularly the forehead), arms, and trunk (Fig. 77.35L). When mucosal surfaces are involved, ulcers and papules are seen; prominent lymphadenopathy is often present.

Skin lesions develop in ~75% of patients with disseminated fusariosis, typically presenting as targetoid erythematous, ecthyma gangrenosum-like, or purpuric nodular lesions in a widespread, scattered distribution (see Fig. 77.35C). Affected individuals often have high fevers and severe myalgias.

Pathology

Histologic examination of lesions of cutaneous aspergillosis demonstrates 45° dichotomous branching of hyaline, septate hyphae that are best demonstrated with methenamine silver or PAS staining (Fig. 77.36A). Suppurative and granulomatous inflammation and/or necrosis may be observed.

In mucormycosis, there are highly characteristic broad, non-septate hyphae that have 90° branching and have been likened to ribbons (Fig. 77.36B). PAS staining may be helpful. Suppuration and necrosis, as well as blood vessel invasion by the fungi, are often seen.

Histologic findings in cryptococcosis are described as either gelatinous with numerous organisms and little inflammation, or granulomatous with fewer organisms, more inflammation, and little necrosis. While a PAS stain highlights the central yeast forms (Fig. 77.36C), mucicarmine or Alcian blue is used to visualize the characteristic capsule. India ink preparations, e.g. of CSF or dermal scrapings, also demonstrate the presence of the capsule. The wider the capsule and the more severe the immunocompromised state, the less the inflammation. Of note, cryptococcoid Sweet syndrome can mimic cryptococcosis both clinically and histologically, with cytoplasmic vacuolization of inflammatory cells resembling the capsule of *Cryptococcus* organisms and acellular basophilic bodies mimicking the yeast itself.

In disseminated candidiasis, budding yeast and pseudohyphae are seen in the dermis, rather than in the stratum corneum as in mucocutaneous candidiasis.

T. marneffei has microscopic characteristics similar to histoplasmosis. The small organisms are numerous and found within macrophages and giant cells (see Table 77.18). The histologic findings of fusariosis are similar to those of aspergillosis, with acute-branching, septate hyphae, angioinvasion, necrosis, and a variable granulomatous infiltrate.

Differential diagnosis

Microscopic examination of dermal scrapings (using KOH or calcofluor), histologic analysis, and culture of skin tissue are used to diagnose opportunistic fungal infections. The former studies are important considering that many of these organisms can also represent culture contaminants[91]. The clinical differential diagnosis ranges from folliculitis and molluscum contagiosum to cellulitis and ecthyma gangrenosum due to a disseminated bacterial infection. When there are necrotic eschars, the possibility of herpes zoster or vasculitis may be raised (see Fig. 77.34).

Macroscopically, cultures of *Aspergillus flavus* and *A. fumigatus* have been likened to "south sea islands" because the central portion is khaki

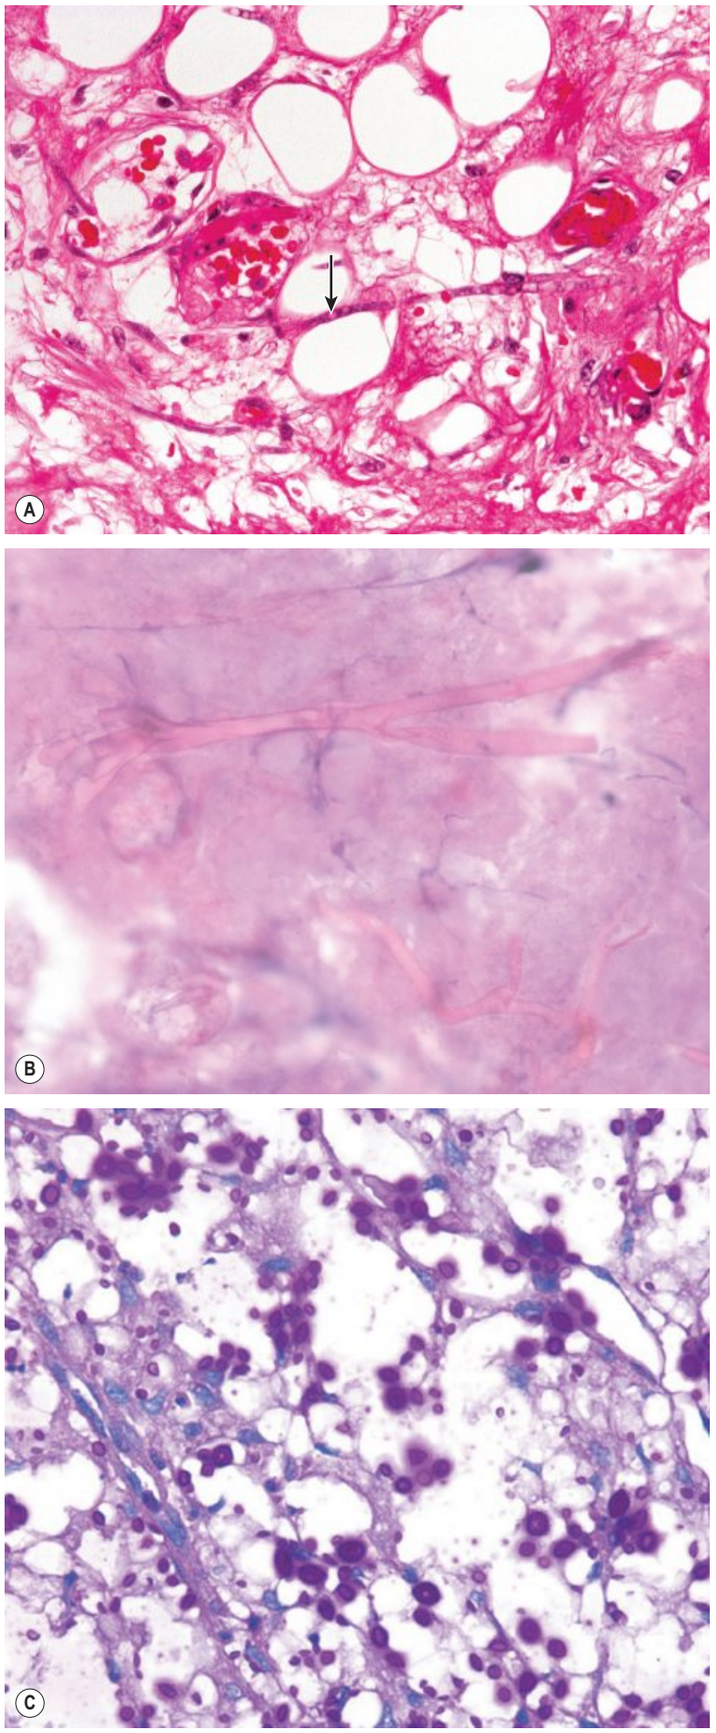


Fig. 77.36 Histologic findings of opportunistic fungal infections in immunocompromised hosts. A Septate hyphae (arrow) within necrotic skin from a patient with disseminated aspergillosis. **B** Ribbon-like, non-septate *Rhizopus* hyphae in a "touch" preparation of dermal scrapings from the base of a necrotic bulla. **C** Numerous dermal yeast forms with gelatinous capsules in secondary cutaneous cryptococcosis (PAS stain). *A, Courtesy Lorenzo Cerroni, MD; B, Courtesy Jean L. Bolognia, MD; C, Courtesy Athanasia Syrengelas, MD, PhD.*

green (*flavus*) or blue–green (*fumigatus*) with a rim of white to yellow color. Microscopically, spherical "heads" with conidia forming on the exterior are seen. In zygomycoses, culture reveals fast-growing "woolly" colonies in most instances. Microscopically, rhizoids, round sporangia, and sporangiospores (asexual spores formed within sporangia) are seen (see Fig. 77.34)[51]. Culture of *Cryptococcus neoformans* yields a cream-colored colony that is similar in appearance to *Candida* colonies. On birdseed agar, the *C. neoformans* colony becomes brown. Because *T. marneffei* is a dimorphic fungus, at 25°C the mold form is seen with a diffusible red pigment, and at 37°C the colony appears as a yeast.

Antibodies against the capsule can be detected in cryptococcosis, and high titers herald a poor prognosis. Serum assays for components of the fungal cell wall, such as 1,3 β-D-glucan (detects a variety of fungi, including *Aspergillus* and *Fusarium*) and galactomannan (relatively specific for *Aspergillus* but somewhat less sensitive), have been used to screen high-risk patients for early evidence of an invasive fungal infection. PCR-based assays have also become available for detection of many opportunistic fungi (especially *Aspergillus*)[92,93].

Treatment

Prevention of opportunistic mycoses in high-risk patients can be aided by reduced exposure to environments such as construction sites and the use of ventilation systems. Prophylaxis with systemic antifungals (e.g. fluconazole, posaconazole, voriconazole, isavuconazole) is commonly administered to patients receiving myelosuppressive chemotherapy and to hematopoietic stem cell transplant recipients, both before and during periods of neutropenia. Even in the absence of neutropenia, individuals on chronic high-dose systemic corticosteroids (e.g. with chronic GVHD) are at significant risk for opportunistic fungal infections and represent another group now receiving prophylaxis. In the past, a febrile neutropenic patient unresponsive to systemic broad-spectrum antibiotics was empirically begun on amphotericin B. Nowadays, that patient might receive voriconazole, posaconazole, isavuconazole, or one of the echinocandins (e.g. caspofungin; Table 77.19; see Ch. 127). Of note, voriconazole is a triazole that has activity against *Aspergillus* and *Fusarium* as well as *Candida* (but not Mucormycetes); it causes photosensitivity associated with an increased risk of squamous cell carcinoma and melanoma and, like itraconazole, drug–drug interactions due to inhibition of cytochrome P450. Posaconazole and isavuconazole, triazoles with a similar range of activity (except for less *Fusarium* coverage with isavuconazole) that also cover Mucormycetes, are used for both treatment and prophylaxis of opportunistic fungal infections.

Once an opportunistic mycosis is diagnosed, prompt treatment is essential. Primary cutaneous infections with opportunistic molds, if localized, can be surgically excised, followed by administration of oral antifungals. Disseminated infections carry a poor prognosis and are frequently fatal, particularly when treatment is delayed or ineffective. Amphotericin B (including lipid formulations) had been the standard treatment for several decades. However, voriconazole has proven superior for invasive fungal infections due to *Aspergillus*, and, in the case of disseminated candidiasis, caspofungin can also be administered[94] (see Ch. 127). For systemic infections due to other opportunistic fungi, amphotericin B is sometimes still employed, but voriconazole has activity against *Fusarium*, while posaconazole has activity against both *Fusarium* and Mucormycetes and isavuconazole is approved for the treatment of invasive mucormycosis.

In addition to amphotericin B and several triazoles, terbinafine may have activity against *T. marneffei*, which has a high mortality rate if inadequately treated. Unfortunately, recurrence is likely unless treatment is continued indefinitely[95].

Phaeohyphomycosis

Introduction and history

Phaeohyphomycosis refers to infections with a group of dematiaceous fungi (i.e. pigmented due to melanin in the cell wall) that produce distinct brown to black hyphae in tissue rather than Medlar bodies or grains (see chromoblastomycosis and eumycotic mycetoma above). Although systemic disease can occur, particularly spread to the CNS from a primary lung source, this section will focus on the other three forms of phaeohyphomycosis – superficial, cutaneous, and subcutaneous.

Ajello and colleagues coined the term "phaeohyphomycosis" in 1974. Initially, the list of causative pathogens was limited, but it is now extensive and continues to lengthen[11].

Epidemiology

Because phaeohyphomycosis encompasses infections caused by many fungi, the epidemiology is complex. All age groups and both sexes may be affected. There may be a slightly higher incidence in men due to increased environmental and occupational exposure. The culprit fungi in phaeohyphomycosis are found in plants and soil, making individuals with certain occupations, activities, and cultural habits (such as not wearing protective footwear) at higher risk of infection.

Pathogenesis

Superficial phaeohyphomycosis includes tinea nigra and black piedra (see above), while cutaneous phaeohyphomycosis includes infections of the hands, feet, and nails that mimic tinea infections in the same locations (e.g. *N. hyalinum*, *N. dimidiatum*; see Table 77.11). Trauma is typically the cause of subcutaneous phaeohyphomycosis. Both immunocompetent and immunocompromised hosts may acquire this disease. The immune status of the patient has a significant effect on the severity and the likelihood for disseminated disease; *Cladophialophora bantiana* is most commonly associated with CNS disease[88]. Secondary cutaneous phaeohyphomycosis occurs when dematiaceous fungi spread from other sites to the skin.

Clinical features

The clinical presentation of cutaneous phaeohyphomycosis is similar to that of dermatophyte infections of the hands, feet, or nails. Subcutaneous phaeohyphomycosis most commonly presents as a nodule or plaque in regions of the body that are prone to trauma (Fig. 77.37A). The course is usually chronic, with slowly progressive disease. Clinical manifestations of disseminated disease include nonspecific skin lesions (papules, plaques, nodules) and signs of cerebral involvement.

TREATMENT OF OPPORTUNISTIC MYCOSES

	Aspergillosis	Mucormycosis	Cryptococcosis	Candidiasis	*T. marneffei* infection	Fusariosis	Forms of administration
Amphotericin B	+	+	+	+	+	+	iv
Itraconazole (200–400 mg/day)	+	–	+	+	+	–	po, iv

Micafungin	+	–	–	+	–	–	iv
Anidulafungin	+	–	–	+	–	–	iv

Table 77.19 Treatment of opportunistic mycoses. Appropriate selection of therapy for opportunistic infections is essential, given the likelihood of rapid, widespread dissemination and high mortality rates[67]. iv, intravenously; po, orally.

Fig. 77.37 Phaeohyphomycosis – clinical and histopathologic findings. **A** Purpuric plaque with central necrosis and surrounding erythema in a patient with subcutaneous phaeohyphomycosis due to *Exerohilum rostratum*. **B** PAS-positive hyphae with focal pigmentation within a phaeohyphomycotic cyst. *B, Courtesy Luis Requena, MD.*

Pathology

Histologic examination of cutaneous and subcutaneous phaeohyphomycosis reveals pigmented hyphae in the stratum corneum and dermis/subcutis, respectively (Fig. 77.37B). In the latter, there are cyst-like abscesses that can have a fibrous capsule, hence the term "phaeomycotic cysts". Occasionally, implanted material (e.g. a splinter) may also be observed.

Differential diagnosis

For the subcutaneous and systemic forms, the differential diagnosis may include a foreign body granuloma, cutaneous leishmaniasis, chromoblastomycosis, and dimorphic fungal infections. KOH examination (superficial and cutaneous types), culture (all types), and histopathology (usually just subcutaneous and systemic types) allow the diagnosis to be made. Determination of genera and species requires fungal culture, but histopathology is useful in determining the extent of invasion and in differentiating causative pathogens from contaminants in culture specimens. *Exophiala jeanselmei* and *E. dermatitidis* are the organisms most commonly isolated from subcutaneous phaeohyphomycosis.

Treatment

Subcutaneous disease is surgically excised, if possible[96]; complete surgical excision is usually curative. Systemic disease due to dematiaceous fungi continues to be a therapeutic dilemma, as it is difficult to eliminate with oral antifungals alone. Nevertheless, itraconazole, given at a dose of 200 mg twice daily for a prolonged course (>12 months), has some efficacy for the non-surgical treatment of phaeohyphomycosis. Close follow-up is required and includes repeat cultures and histologic analyses of affected sites. Additional treatments for systemic disease include voriconazole, posaconazole, amphotericin B, and flucytosine.

Pneumocystis

In the past, *Pneumocystis jirovecii* (formerly referred to as *Pneumocystis carinii*) was classified as a protozoan. Currently, it is considered to be a fungus, based on genetic and biochemical analyses. This opportunistic infection occurs in individuals who are immunocompromised, including those with AIDS. The lungs are the most common site of infection (pneumonia), but, on occasion (<3% of patients), there is dissemination to other sites such as the liver, spleen, and lymph nodes.

Cutaneous involvement is rare and is characterized by erythematous or skin-colored, non-tender papules or nodules[97]; there may be associated ulceration. The external ear (including the auditory canal) represents the most commonly reported site of involvement. Histologically, a diffuse infiltrate of foamy cells is seen within the dermis. Special stains (e.g. methenamine silver, Giemsa, Steiner) can be used to highlight the organisms, as can monoclonal antibodies; detection of *P. jirovecii* is also possible via PCR.

The most common treatment for pneumocystosis is trimethoprim–sulfamethoxazole (TMP-SMX). Additional therapies include parenteral pentamidine and oral atovaquone. Prophylaxis in the setting of immunosuppression usually consists of oral TMP-SMX or, less often, aerosolized pentamidine, oral dapsone, or oral atovaquone. Prophylaxis is important for dermatologic patients receiving systemic corticosteroids combined with immunosuppressive agents such as azathioprine and cyclophosphamide.

78 Cutaneous Manifestations of HIV Infection

Roy K.W. Chan, Martin T.W. Chio and Hong Yi Koh

Key features

- A broad spectrum of infectious, inflammatory, and neoplastic skin conditions may occur in the setting of HIV-induced immune dysfunction
- The cutaneous findings often correlate with immune status, and knowing the viral load and $CD4^+$ T cell count can help to generate a more focused differential diagnosis
- The possibility of HIV infection should be considered when patients present with severe, unusual, and treatment-resistant skin conditions; examples include giant molluscum contagiosum, extensive seborrheic dermatitis, and refractory herpes simplex virus infection
- Following initiation of antiretroviral therapy (ART), skin disorders such as herpes zoster and *Mycobacterium avium* complex infection may become clinically apparent or worsen when the immune status improves, a phenomenon known as the immune reconstitution inflammatory syndrome (IRIS)
- Although ART has led to a reduction in the frequency of severe opportunistic infections and skin conditions associated with advanced HIV disease, e.g. Kaposi sarcoma, other dermatologic problems have become more common, e.g. lipodystrophy, neoplasia related to human papillomavirus infection
- The medications used in ART can lead to drug eruptions, and HLA testing prior to initiating therapy may help predict the likelihood of a severe cutaneous adverse reaction

INTRODUCTION

Mucocutaneous disorders not only provide important clues to the diagnosis of HIV disease and significantly impact quality of life, but they also serve as markers of progression and possible associated systemic disease. In addition, relapse of skin diseases can be associated with failure or discontinuation of antiretroviral therapy (ART). The World Health Organization (WHO) clinical staging of HIV-related disease is shown in Table 78.1, and conditions that typically develop at different $CD4^+$ T cell counts are presented in Table 78.2. Effective ART has transformed HIV disease from a progressive, fatal disorder to a chronic condition requiring maintenance therapy. As a result, cutaneous disorders associated with severe immunosuppression, such as Kaposi sarcoma and serious opportunistic infections, are observed less frequently. However, with longer survival, other diseases have become more common (e.g. anal intraepithelial neoplasia), and ART itself has led to dermatologic challenges, including drug reactions, lipodystrophy, and immune reconstitution inflammatory syndrome (IRIS). In low-income countries where ART may not be readily available, opportunistic infections are still a common cause of morbidity and mortality. Approximately 80%–95% of people living with HIV develop at least one skin disorder, and dermatologists worldwide continue to play important roles in their care.

HISTORY

In 1981, reports of *Pneumocystis jirovecii* (formerly *carinii*) pneumonia, Kaposi sarcoma, and chronic ulcerative herpes simplex virus (HSV) infections in homosexual men in association with reduced cell-mediated immunity were first published. Soon thereafter, the underlying condition was termed acquired immune deficiency syndrome (AIDS), with descriptions of other associated opportunistic infections as well as additional affected populations, including hemophiliacs/blood transfusion recipients, intravenous drug users, sexual partners of persons with the disease, infants, and heterosexual Haitians. The causative T-lymphotropic retrovirus was identified in 1983 and named the human immunodeficiency virus (HIV); homology to an African zoonosis originating from non-human primates was demonstrated.

Identification of blood-borne, sexual, and mother-to-child transmission of HIV led to universal precautions for the handling of blood and body fluids as well as specific protocols for delivery and breast-feeding. The first effective therapy against HIV, the nucleoside reverse transcriptase inhibitor zidovudine (AZT), was FDA-approved in 1987. Highly active antiretroviral therapy (HAART; now referred to as ART), which utilizes several agents to suppress viral replication and thereby delay clinical progression, was introduced in 1996. The latter has led to a substantial reduction in HIV-related morbidity and mortality.

EPIDEMIOLOGY

Approximately 85 million people have been diagnosed with HIV disease since the start of the pandemic, and HIV/AIDS continues to be a major worldwide public health challenge in the 21st century. HIV/AIDS disproportionately affects resource-poor countries and *key populations* which include sex workers, individuals who inject drugs, gay men, other men who have sex with men (MSM), transgender people, and prisoners. Globally in 2021, 38 million people were estimated to be living with HIV, with the majority (~21 million) in Eastern and Southern Africa (Fig. 78.1). The proportion of people with HIV who are receiving ART has risen dramatically, from <3% in 2000 to 75% in 2021[1], and the number of yearly AIDS-related deaths worldwide decreased from a peak of 2 million in 2005 to ~650 000 in 2021. Globally, ~1.5 million people were newly diagnosed with HIV in 2021, representing a decline of almost 50% from 2.9 million in 2000.

Although the annual number of new HIV diagnoses in sub-Saharan Africa has been decreasing since 2010, the HIV pandemic still most severely affects this region, which accounted for two-thirds of all people living with HIV and ~60% of new HIV diagnoses in 2021. Of note, the HIV transmission rate has recently increased in Eastern Europe, Central Asia, the Middle East, North Africa, and Latin America[1,2]. In 2021, key populations and their sexual partners accounted for 70% of new HIV disease globally, ranging from 46% in Eastern and Southern Africa to >95% in Europe, Asia, the Pacific, the Middle East, North Africa, and North America. Risk factors for HIV transmission include high viral load, condomless receptive anal intercourse, lack of circumcision, and the presence of other sexually transmitted infections.

PATHOGENESIS

AIDS is caused by HIV-1 and much less often HIV-2. Both are enveloped, single-stranded RNA lentiviruses in the Retroviridae family. They are zoonotic and originated from simian immunodeficiency viruses (SIVs) that infect African primates: HIV-1 from chimpanzees and HIV-2 from sooty mangabeys. HIV-1 has four distinct lineages, each resulting from an independent cross-species transmission event; group M is responsible for ~99% of pandemic HIV disease, while groups N, O, and P are restricted to West Africa. HIV-2 is also largely restricted to West Africa, where its overall prevalence is declining. Compared with HIV-1, HIV-2 is less transmissible and virulent, resulting in lower viral loads and infrequent progression to AIDS. HIV exhibits substantial genetic variability due to the error-prone nature of its reverse transcriptase as well as very rapid virus replication in infected individuals.

During HIV-1 infection, the viral envelope proteins gp120 and gp41 initially interact with the CD4 molecule followed by a second interaction with a chemokine receptor, usually CCR5 or CXCR4 (Fig. 78.2).

WHO CLINICAL STAGING OF HIV/AIDS IN THE SETTING OF CONFIRMED HIV INFECTION		
All ages	**Adults and adolescents**	**Children**
Clinical stage 1 – asymptomatic; immunologic correlate*: ≥500 CD4⁺ cells/mm³		
• Asymptomatic • Persistent generalized lymphadenopathy		
Clinical stage 2 – mild; immunologic correlate*: 350–499 CD4⁺ cells/mm³		
• **Herpes zoster** • **Fungal nail infection** • **Pruritic papular eruptions†** • **Angular cheilitis** • **Recurrent oral ulcerations** • Recurrent/chronic upper respiratory tract infections (sinusitis, otitis media/otorrhea, tonsillitis, pharyngitis)	• **Seborrheic dermatitis** • Moderate unexplained weight loss (<10% of body weight)	• **Extensive warts** • **Extensive molluscum contagiosum** • **Linear gingival erythema** • Unexplained persistent parotid enlargement • Unexplained persistent hepatosplenomegaly
Clinical stage 3 – advanced; immunologic correlate*: 200–349 CD4⁺ cells/mm³		
• **Persistent oral candidiasis (after first 6–8 weeks of life)** • **Oral hairy leukoplakia** • **Acute necrotizing ulcerative stomatitis, gingivitis, or periodontitis** • Unexplained chronic diarrhea (>1 month in adults, >2 weeks in children) • Unexplained persistent fever (≥37.6°C intermittent or constant, for >1 month) • Pulmonary tuberculosis (current) • Unexplained anemia (<8 g/dL), neutropenia (<0.5 × 10^9/L) or chronic thrombocytopenia (<50 × 10^9/L)	• Unexplained severe weight loss (>10% of body weight) • Severe bacterial infections such as pneumonia, empyema, pyomyositis, bone or joint infection, meningitis, bacteremia	• Unexplained moderate malnutrition or wasting not adequately responding to standard therapy • Recurrent severe bacterial pneumonia • Symptomatic lymphoid interstitial pneumonitis • Lymph node tuberculosis • Chronic HIV-associated lung disease including bronchiectasis
Clinical stage 4 – severe/AIDS-defining conditions; immunologic correlate*: <200 CD4⁺ cells/mm³		
• **Chronic herpes simplex infection (orolabial, genital, or anorectal of >1 month's duration or visceral at any site)** • **Kaposi sarcoma** • **Extrapulmonary cryptococcosis including meningitis** • **Disseminated endemic mycosis (coccidioidomycosis or histoplasmosis)** • **Disseminated non-tuberculous mycobacterial infection** • Unexplained severe wasting, stunting or severe malnutrition not responding to standard therapy (HIV wasting syndrome) • Cytomegalovirus infection (retinitis or infection of other organs; onset at age >1 month) • HIV encephalopathy • Progressive multifocal leukoencephalopathy • Extrapulmonary tuberculosis • Candidiasis of the esophagus, trachea, bronchi, or lungs • *Pneumocystis* pneumonia • Central nervous system toxoplasmosis (onset at age >1 month) • Chronic cryptosporidiosis (with diarrhea) • Chronic isosporiasis • Symptomatic HIV-associated nephropathy or symptomatic HIV-associated cardiomyopathy • Cerebral or B cell non-Hodgkin lymphoma, or other HIV-associated solid tumor	• **Atypical disseminated leishmaniasis** • Recurrent severe bacterial pneumonia • Recurrent non-typhoidal *Salmonella* bacteremia • Invasive cervical carcinoma	• Recurrent severe bacterial infections such as empyema, pyomyositis, bone or joint infection, or meningitis (but excluding pneumonia)

*In individuals ≥6 years of age; corresponding counts in children <6 years of age are available at https://www.cdc.gov/mmwr/preview/mmwrhtml/rr6303a1.htm?s_cid=rr6303a1_e.
†In the literature, <200 CD4⁺ cells/mm³.

Table 78.1 World Health Organization (WHO) Clinical Staging of HIV/AIDS in the setting of confirmed HIV infection. Conditions with mucocutaneous manifestations are in **bold**.

These receptors are found on activated CD4⁺ T cells, monocyte-macrophages, and dendritic cells. CXCR5 is the predominant fusion cofactor in most HIV transmissions; however, CD4-independent infection of renal cells and astrocytes gives rise to chronic renal disease and neurocognitive disorders. Following binding, changes in conformation induce fusion of the viral envelope with the plasma membrane, and the virus particle is thereby internalized. The RNA genome is transcribed by a reverse transcriptase enzyme that produces a DNA copy of the HIV RNA. This viral DNA copy is spliced into the host DNA through the action of an integrase enzyme. Transcription of viral DNA into RNA yields genomic material for new viral particles or it can be translated into viral proteins. Cleavage of the latter into structural components of the virus is accomplished by proteases. Intact viruses are then produced and host cells are destroyed.

Infection by the transmitted/founder virus is followed by a rapid increase in HIV replication (Fig. 78.3). After ~6 months, the viral load falls to a set point that is determined by the host's innate natural killer (NK) cell response plus an adaptive immune response by CD8⁺ cells and neutralizing antibodies. The initial antibody response develops within 1–3 months after transmission and is strain-specific. This antibody response drives viral escape, and virus mutants become resistant to neutralization in 80% of patients. However, in 20% of patients, variants of the transmitted/founder virus evolve and induce antibodies with considerable neutralization breadth. CD8⁺ cytotoxic T cells directed against HIV begin to function within 10 days of exposure, correlating with the reduction in viremia during the acute retroviral syndrome; these cells also help to control the HIV throughout the disease course.

Initial infection results in a reduction in circulating CD4⁺ T cells, which is followed by a recovery to nearly normal levels and a subsequent slow fall of about 50 to 100 cells/mm³ per year (see Fig. 78.3). In contrast, the CD4⁺ T cells residing within the gastrointestinal tract are rapidly depleted early on. The progressive depletion of CD4⁺ T cells is the result of killing by direct infection, bystander effects of syncytia formation, chronic immune activation, lymphoid tissue damage, and senescence.

The marked chronic immune activation that characterizes HIV disease is thought to be related to low-grade HIV replication, immune responses

GENERAL CORRELATIONS OF $CD4^+$ CELL COUNT WITH SPECIFIC HIV-ASSOCIATED DISORDERS				
System	**≥500 $CD4^+$ cells/mm^3**	**<500 $CD4^+$ cells/mm^3**	**<250 $CD4^+$ cells/mm^3**	**<50 $CD4^+$ cells/mm^3**

to HIV, reactivated infections, loss of mucosal integrity with consequent microbial translocation, and increased production of proinflammatory molecules. In patients receiving ART, increased levels of markers of inflammation have been associated with higher mortality rates and risk of cancer as well as cardiovascular, neurologic, and liver disease.

In a person living with HIV, AIDS is defined by a $CD4^+$ cell count of $<200/mm^3$ or <14% $CD4^+$ T cells and/or the presence of an AIDS-defining condition (see Table 78.1). The natural history of HIV disease varies considerably, with the rate of decline in $CD4^+$ T cells correlating with viral burden. In the absence of treatment, the median time for progression to AIDS is ~10 years. However, ~10%–15% of untreated patients, historically referred to as "long-term non-progressors", live with HIV for ≥8 years with no symptoms and $CD4^+$ T cell counts of $>500\,cells/mm^3$; in addition, <0.5% of patients are "elite controllers" with no evidence of viremia even without ART. The ability of ART to suppress viral replication and enable reconstitution of $CD4^+$ T cells has an immense impact on the disease course. Immune reactivation due to ART can result in a variety of inflammatory sequelae referred to as IRIS, ranging from unmasking or paradoxical "worsening" of infections or neoplasms to exacerbations of inflammatory disorders (see below).

HIV-RELATED INFECTIOUS SKIN CONDITIONS

In addition to the primary HIV exanthem, HIV-positive individuals often develop cutaneous viral, bacterial, and fungal infections as well as infestations. Patients who acquired HIV via sexual contact should also be tested for other sexually transmitted infections (see Ch. 82); the converse is also true. The presence of erosions and ulceration in the anogenital region due to conditions such as syphilis and herpes simplex virus infections can also increase the risk of HIV transmission.

Viral Infections

Primary HIV exanthem (acute retroviral syndrome)

Primary HIV infection refers to the initial disease phase, when HIV-1 RNA, DNA, and/or p24 antigen are present in the plasma prior to the development of HIV-1 antibodies. Initially, up to 80% of patients develop an "acute retroviral syndrome" resembling influenza or infectious mononucleosis. Symptoms develop 2–6 weeks after HIV exposure and often include fever, headache, myalgia/arthralgia, pharyngitis, lymphadenopathy, and night sweats. A morbilliform exanthem also occurs in 40%–80% of patients; it lasts 4–5 days and is typically generalized, with the most prominent involvement on the face and trunk. Oral and genital ulcers are occasionally present. Symptoms are self-limited and resolve in a few days to weeks, with a median duration of 14 days. The initial phase of rapid HIV-1 replication causes a temporary fall in $CD4^+$ cell counts, occasionally to an extent that gives rise to opportunistic infections.

Greater severity and longer duration of the acute retroviral syndrome is associated with a higher viral load set point and more rapid disease progression. Early initiation of ART during primary HIV infection may delay disease progression.

Herpes simplex virus (HSV) infection

Relatively immunocompetent people living with HIV usually have typical, self-limited HSV disease. As immunity wanes, the frequency of HSV recurrences increases and lesions take longer to heal, potentially evolving into chronic, extensive, deep, and painful ulcers that favor the perianal region, genitalia, and tongue (Fig. 78.4). Atypical presentations of HSV infection include folliculitis, verrucous plaques, and hypertrophic anogenital masses simulating neoplasia. Infection may become

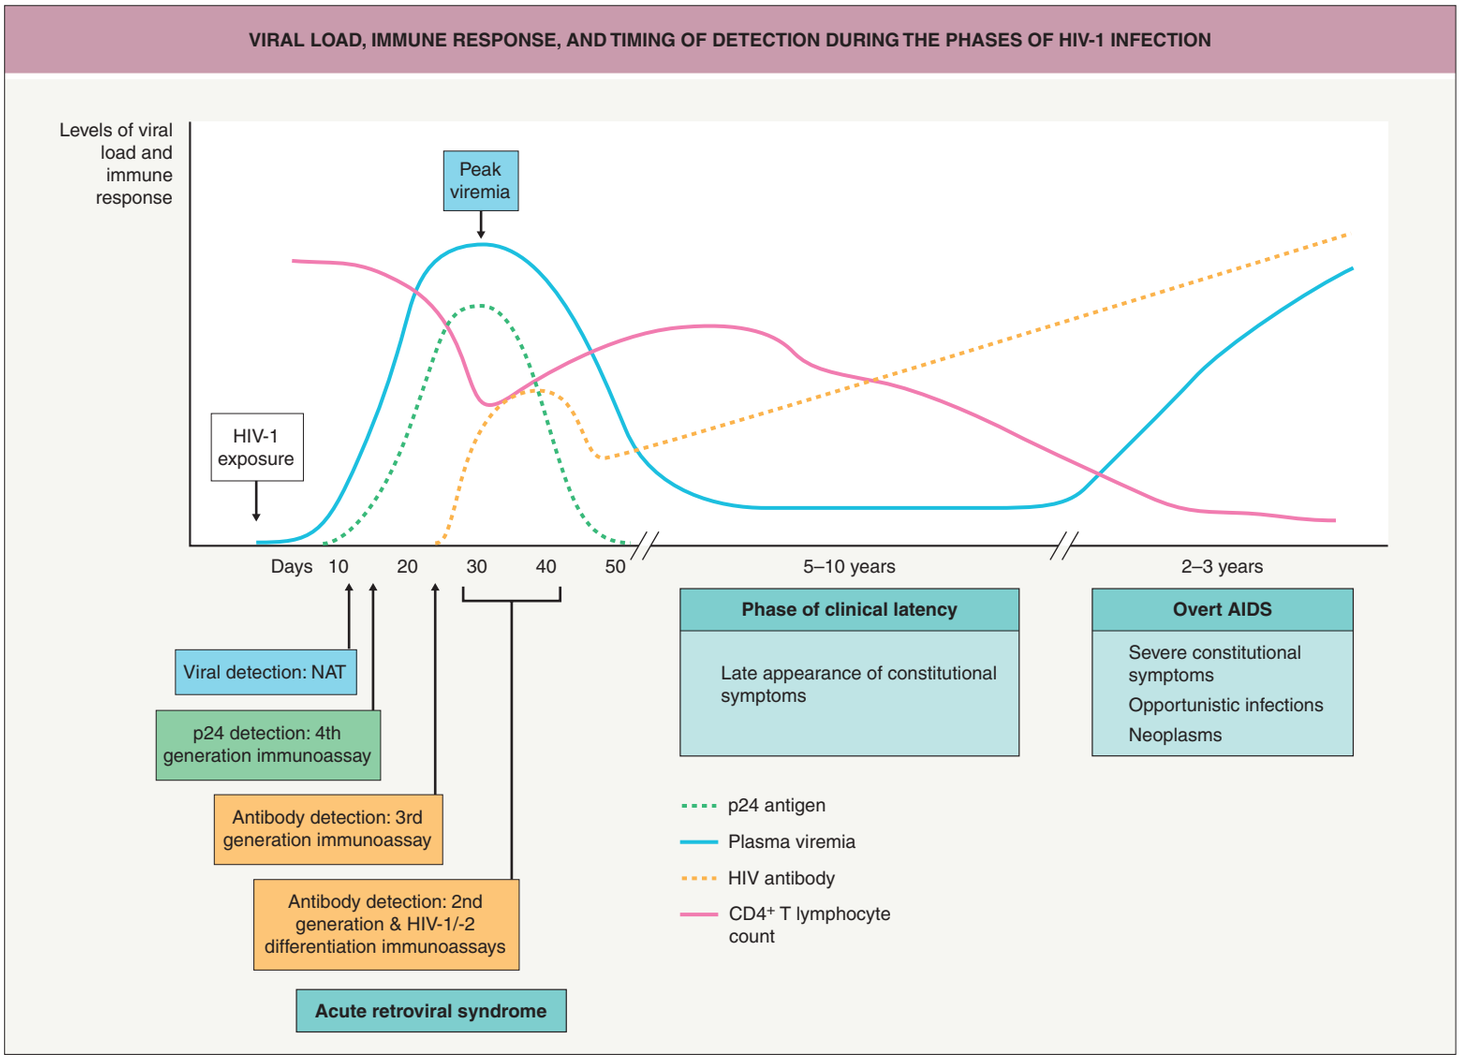

Fig. 78.3 Viral load, immune response, and timing of detection during the phases of HIV-1 infection. After HIV-1 exposure, initial virus replication and spread occur in the lymphoid organs, and systemic dissemination of HIV-1 is reflected by the peak of plasma viremia. A clinical syndrome of varying severity is associated with this phase of primary HIV-1 infection in up to 80% of HIV-1-infected persons. Downregulation of viremia during the transition from the primary to the early chronic phase coincides with the appearance of HIV-1-specific cytotoxic T lymphocytes and with the progressive resolution of the clinical syndrome. The long phase of clinical latency is associated with active virus replication, particularly in the lymphoid tissue. During the clinically latent period, $CD4^+$ T lymphocyte counts slowly decrease, as does the HIV-1-specific immune response. When $CD4^+$ T lymphocyte counts decrease below 200 cells/ml (i.e. when overt AIDS occurs), the clinical picture is characterized by severe constitutional symptoms and by the possible development of opportunistic infections and/or neoplasms. *Adapted from Bart PA, Pantaleo G. The immunopathogenesis of HIV-1 infection. In: Cohen J, Powderly WG. Infectious Diseases. Edinburgh: Mosby, 2004:1236.*

Fig. 78.4 Chronic ulcerative herpes simplex virus infection in a patient with HIV. Slowly enlarging ulcers on the buttocks and perianal area have a scalloped border.

disseminated or occur at unusual sites such as the non-keratinized (unattached) mucosa of the oropharynx (see Fig. 72.1) and the esophagus.

The ulcer edge should be scraped for HSV PCR (most sensitive), direct fluorescent antibody assay (DFA), and/or viral culture and, if negative, a skin biopsy performed; a Tzanck smear has low sensitivity. Higher doses and longer courses of antiviral medications are typically required, with continuation until all mucocutaneous lesions are healed. Resistance to acyclovir, usually due to reduced viral thymidine kinase activity, occurs more commonly in immunosuppressed (~5%) compared to immunocompetent (~1%) hosts. Alternative agents that do not rely on thymidine kinase include foscarnet, cidofovir, and imiquimod. Of note, HSV-2 infection increases the risk of HIV acquisition and promotes HIV-1 replication[3].

Varicella and herpes zoster

In people living with HIV, varicella tends to have new lesion formation over a longer period of time, a higher lesion count, and (particularly in adults) complications such as pneumonitis, hepatitis, and encephalitis. Lesions that persist as slowly healing ulcers have been reported.

People living with HIV have a 7- to 15-fold higher incidence of herpes zoster compared to the general population[4]. Of children living with HIV who develop varicella, herpes zoster or a disseminated eruption reminiscent of varicella occurs in ~50% within 2 years. In addition to classic dermatomal eruptions, HIV-associated herpes zoster can present

as chronic non-healing ulcers, hyperkeratotic verrucous plaques, and multidermatomal or disseminated skin lesions; potential complications include bacterial superinfection, systemic involvement, and multiple recurrences. The recombinant Shingrix® vaccine is recommended for the prevention of herpes zoster in immunocompromised adults, including those with HIV disease (see Ch. 80)[5].

People living with HIV who do not have VZV immunity should receive varicella–zoster immune globulin within 10 days of exposure to VZV. Antiviral treatment of VZV infection in patients should be continued until clinical resolution occurs (see Ch. 80); acyclovir resistance is possible. Of note, patients treated with ART may experience paradoxical worsening of herpes zoster when their CD4$^+$ T cell counts rise (see IRIS below).

Molluscum contagiosum

Molluscum contagiosum (MC) commonly occurs and tends to be more persistent in individuals with significantly reduced CD4$^+$ T cell counts. In addition to the typical presentation of small umbilicated papules (Fig. 78.5), people living with HIV can develop larger (>1 cm), coalescent, verrucous, and widespread lesions. The clinical differential diagnosis may include basal cell carcinoma (BCC) and cutaneous lesions of cryptococcosis, histoplasmosis, or other dimorphic fungal infections. Dermoscopic evaluation, microscopic examination following curettage of lesional contents, or biopsy can help to confirm the diagnosis. In addition to curettage and other destructive modalities, topical and intravenous cidofovir have been used successfully for refractory MC in patients with HIV disease. MC may resolve spontaneously after initiation of ART but can also present as a manifestation of IRIS.

Human papillomavirus (HPV) infections

The spectrum of mucocutaneous lesions due to HPV infection ranges from common warts and condylomata acuminata to squamous intraepithelial neoplasia and carcinoma. The prevalence of HPV infection is higher in people living with HIV than in the general population and correlates with decreasing CD4$^+$ T cell counts. People living with HIV have reduced HPV clearance, more treatment-resistant mucocutaneous lesions, and accelerated development of HPV-associated carcinoma. Skin lesions are often multiple, coalescent, and extensive (Fig. 78.6). There is evidence for synergistic interactions between HIV and HPV infections, suggesting that HPV vaccination may help control both infections at the population level in high prevalence settings[6].

Acquired epidermodysplasia verruciformis (AEDV) is characterized by hypopigmented to pink tinea versicolor-like lesions and numerous flat-topped papules that are due to HPV-5, -8, and other β HPV types. People living with HIV may develop squamous cell carcinomas (SCCs) in association with AEDV and other cutaneous warts, e.g. digital lesions due to high-risk HPV types, as well as anogenital warts.

Compared to the general population, women living with HIV have a 3-fold increase in the incidence of cervical intraepithelial neoplasia (CIN) as well as higher rates of high-grade CIN[7]. Anal HPV is present in >90% of MSM with HIV disease, and most have at least one high-risk HPV type. MSM with HIV disease also have an up to 50% prevalence of high-grade anal intraepithelial neoplasia (AIN) and a 30- to 50-fold higher risk of anal cancer than does the general population[8]; a 5-fold increased risk of penile cancer has also been documented[9]. Monitoring should include serial physical examinations of the anogenital area, colposcopy/proctoscopy, cervical/anal HPV determination and cytology, and histologic examination when indicated.

ART has not shown a demonstrable effect on the occurrence or clearance of cutaneous or anogenital warts. Enlargement or inflammation of pre-existing warts and an eruption of new warts can occur in the setting of IRIS. Some studies have shown a protective effect of ART on the development and progression of CIN and AIN. However, compared to the pre-ART era, incidence rates of cervical and anal cancers have not decreased[7]. This is likely due to the longer life expectancy afforded by ART.

The choice of therapy for anogenital warts depends upon their size, number, and location. Options include destructive modalities such as cryotherapy, electrosurgery, laser therapy and surgical excision, in addition to patient-applied topical therapies including imiquimod and podophyllotoxin (see Ch. 79). Immunosuppressed patients require more treatment sessions to achieve clearance and have frequent recurrences. The threshold for biopsy should be low, and several sites may need to be sampled to exclude SCC. HPV vaccines are immunogenic and well-tolerated in people with HIV disease.

Oral hairy leukoplakia due to Epstein–Barr virus (EBV) infection

Oral hairy leukoplakia (OHL) results from Epstein–Barr virus (EBV) infection of the oral mucosa and typically presents as hyperkeratotic, corrugated white plaques with hair-like projections on the lateral aspect of the tongue (Fig. 78.7). It can occur at any stage of HIV disease but is more prevalent in men and those with CD4$^+$ T cell counts below 200/mm^3. It represents a predictor of rapid disease progression if ART is not initiated[10]. OHL can also occur in patients with other forms of immunosuppression, such as organ transplant recipients. Although treatment is usually not necessary, topical or oral antiherpetic antiviral medications and topical podophyllin, tretinoin, or gentian violet may be of benefit; however, recurrence is common. OHL may also regress with ART.

Cytomegalovirus (CMV) infections

Reactivation of CMV is associated with CD4$^+$ T cell counts that are <100/mm^3, and it remains a significant cause of morbidity and mortality in patients with AIDS. Retinitis, esophagitis, and colitis represent common clinical manifestations, and mucosal ulcers may occur in the setting of disseminated disease. Cutaneous presentations are uncommon and include ulcers favoring the anogenital area (Fig. 78.8), verrucous or hyperpigmented plaques, prurigo nodularis-like lesions,

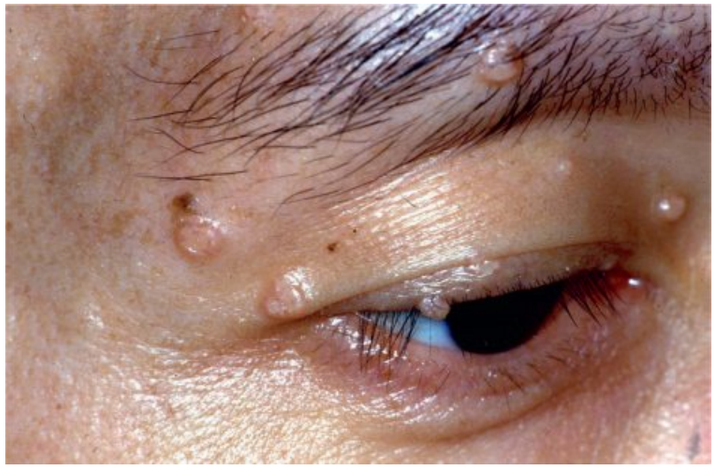

Fig. 78.5 Molluscum contagiosum. Multiple facial lesions are commonly seen in people living with HIV and less likely to resolve spontaneously. Disseminated fungal infections may present with molluscum contagiosum-like lesions and should be excluded.

Fig. 78.6 Extensive perianal condylomata acuminata. This 65-year-old man was receiving antiretroviral therapy and had a CD4$^+$ T cell count of 240/mm^3.

Fig. 78.7 Oral hairy leukoplakia. A Shaggy white keratotic plaques along the lateral aspect of the tongue. A corrugated pattern is often seen. **B** Histologic findings include irregular parakeratosis, acanthosis, and focal balloon cell change of the epithelium. The inset shows positive staining for Epstein–Barr virus-encoded RNA (EBER) in the nuclei of affected keratinocytes. *A, Courtesy Charles Camisa, MD; B, Courtesy Lorenzo Cerroni, MD; Inset, Courtesy Luis Requena, MD.*

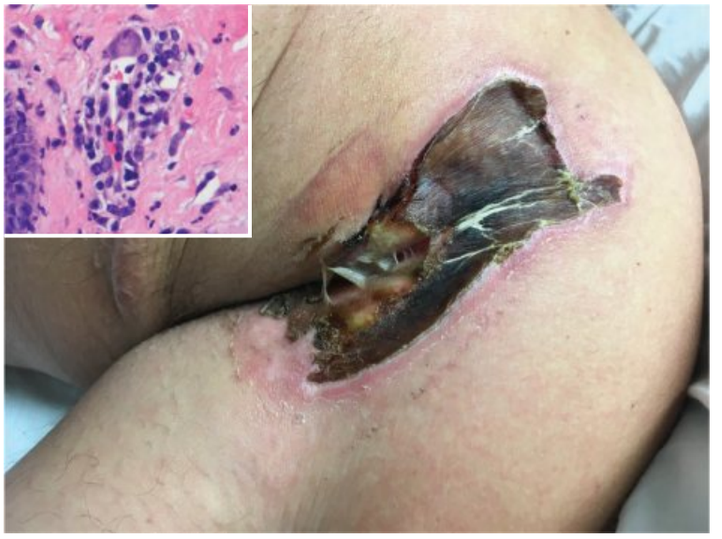

Fig. 78.8 Disseminated CMV infection with cutaneous involvement in a patient with newly diagnosed HIV infection. Well-demarcated ulceration with a thick eschar, pink rim, and associated brachial plexopathy. The HIV viral load was 6.6 million copies and CMV viral load was 14.5 million copies. Inset, histopathologic evaluation showed endothelial cell with "owl's eye" intracytoplasmic inclusions. *Courtesy Katherine Hunt, MD; Inset, Courtesy Peter Pavlidackey, MD.*

purpuric papules, vesicles, and morbilliform eruptions. Histologically, characteristic cytomegalic intranuclear inclusion bodies are seen within endothelial cells in the dermis of lesional skin (see Fig. 78.8 inset and Fig. 80.23). Ulcerative lesions are often co-infected with HSV or VZV, and because CMV can also be detected in non-lesional skin, its pathogenic role has been questioned. Specific treatments include oral valganciclovir and intravenous ganciclovir, foscarnet, and cidofovir.

Bacterial Infections

People living with HIV are at increased risk for the development of recurrent and potentially severe cutaneous bacterial infections, which can be localized or widespread and sometimes have unusual clinical appearances. In addition to diminished antibody- and cell-mediated immune responses, predisposing factors include skin barrier impairment from excoriations or other cutaneous infections, indwelling catheters, and malnutrition. In addition to the entities discussed below, cutaneous bacterial infections that can occur in association with HIV disease include necrotizing fasciitis, nocardiosis, malacoplakia, pseudomonal "hot tub" folliculitis, "malignant" otitis externa, and ecthyma gangrenosum.

Staphylococcus aureus *infections*

Staphylococcus aureus is the most common bacterial pathogen in individuals with HIV disease. Cutaneous presentations include impetigo, folliculitis, furunculosis, wound infections, cellulitis, and rarely botryomycosis. Compared with the general population, people living with HIV have a higher prevalence of methicillin-resistant *S. aureus* (MRSA) colonization of the skin and a 6- to 18-fold higher incidence of MRSA skin/soft tissue infections; they also have more frequent recurrences[11]. The lower extremities, buttocks, and scrotum are commonly affected, and risk factors include a low $CD4^+$ T cell count, prior MRSA infection, incarceration, illicit drug use, and recent antibiotic treatment or hospitalization. Use of intranasal mupirocin ointment and chlorhexidine washes can temporarily eradicate colonization but may not reduce infection rates.

Bacillary angiomatosis

Bacillary angiomatosis is a rare condition that is characterized by vascular proliferation and is due to the Gram-negative bacilli *Bartonella henselae* and *B. quintana*. It occurs in individuals with HIV disease who are severely immunocompromised, usually with $CD4^+$ T cell counts $<100/mm^3$. Bacillary angiomatosis favors the skin and subcutaneous tissues, although virtually any internal organ can be affected. Patients typically present with a single to numerous, firm, red or violaceous papules and nodules; these lesions may be painful, ulcerate, or bleed profusely after trauma. Large subcutaneous nodules of bacillary angiomatosis may also ulcerate. Disseminated infection is associated with systemic symptoms such as fever, night sweats, and weight loss.

The differential diagnosis may include Kaposi sarcoma, pyogenic granulomas, and non-tuberculous mycobacterial infections. Histologically, a lobular proliferation of capillaries and venules with large, protuberant endothelial cells is seen, surrounded by a neutrophilic infiltrate. Lesional bacilli can be visualized with a Warthin–Starry stain or identified via PCR-based assays; serologic testing for anti-*Bartonella* antibodies may assist in diagnosis. Treatment consists of doxycycline or macrolides. The median time to complete response is ~1 month, and 3–4 months of therapy is recommended to prevent relapse[12].

Mycobacterial infections

A diverse clinical spectrum of tuberculous and non-tuberculous mycobacterial skin infections can develop in people living with HIV. Cutaneous findings include erythematous to violaceous papules and nodules as well as ulcers, acneiform eruptions, abscesses, and verrucous plaques (Fig. 78.9); a sporotrichoid (lymphocutaneous) distribution pattern is sometimes seen. The risk of infection increases with progressive immunosuppression, and the classic histologic finding of caseating granulomas may be absent in patients with markedly diminished cell-mediated immunity.

Syphilis

Rates of syphilis have risen over the past decade, with possible factors including riskier sexual behaviors (due in part to the introduction of PrEP) as well as potential impediment of innate and acquired immunity to *Treponema pallidum* by ART[5,13]. In addition to classic papulosquamous lesions of secondary syphilis, people with HIV disease may

Fig. 78.9 *Mycobacterium haemophilum* infection. This 54-year-old man with HIV and a $CD4^+$ T cell count of 350/mm^3 presented with a 4-month history of slowly enlarging, thick plaques on his arms and legs. The lesions resolved over 6 months with treatment including ciprofloxacin, clarithromycin, and ethambutol.

Fig. 78.10 Secondary syphilis presenting as lues maligna. This man with HIV had a fever, headache, arthralgias, and myalgias together with this widespread eruption of pustules and crusted papulonodules.

present with multiple primary chancres, concomitant lesions of primary and secondary syphilis, palmoplantar keratoderma, annular plaques, and lues maligna. The latter, which is also known as malignant or ulceronodular syphilis, is a severe form of secondary syphilis (see Ch. 82). A prodrome of fever, arthralgia/myalgia, headache, and photophobia precedes the appearance of papules, pustules, and necrotic nodules with ulceration and crusting (Fig. 78.10); lesions are symmetrically distributed, with frequent involvement of the palms and sometimes the oral mucosa. Individuals with HIV disease have a higher likelihood, earlier onset, and greater severity of neurosyphilis. The standard stage-specific treatment regimens for syphilis are recommended, but with longer monitoring.

Fungal and Related Infections

In people living with HIV, clinical presentations of cutaneous fungal infections range from localized tinea corporis to widespread papulonodules due to disseminated dimorphic fungal infections.

Candidiasis

Candidiasis is the most common fungal disease in those living with HIV, and its incidence and severity are both increased in the setting of lower $CD4^+$ T cell counts. Oropharyngeal candidiasis is often the first clinical manifestation of HIV disease. Additional presentations include angular cheilitis, chronic paronychia, and onychodystrophy, as well as intertriginous, refractory vaginal, esophageal, and disseminated candidiasis. Continuous or intermittent use of systemic antifungal medications can prevent recurrences of candidiasis (see Ch. 127), but it increases the likelihood of infections with resistant *Candida albicans* as well as non-*C. albicans Candida* (NCAC) spp. that are intrinsically less sensitive to antifungal medications[14].

Dermatophytoses

Dermatophytosis in people living with HIV may be more widespread, atypical in appearance (e.g. less erythema, non-annular morphology), and refractory to treatment. Tinea pedis may extend onto the dorsum of the feet or give rise to chronic hyperkeratotic plaques, which may be bilateral on the palms and soles[15]. Nodular perifolliculitis (including Majocchi granuloma) can present with follicular papulopustules or deep granulomatous nodules. Proximal subungual onychomycosis is seen more frequently in immunocompromised patients and should prompt HIV testing. Of note, some azole antifungals (e.g. itraconazole) interact with antiretroviral medications (see Ch. 131). Use of absorbent powders and topical antifungal agents can help to prevent recurrences.

Systemic fungal infections

Individuals with HIV disease are predisposed to the development of disseminated cryptococcosis and dimorphic fungal infections, including histoplasmosis, blastomycosis, coccidioidomycosis, paracoccidioidomycosis, talaromycosis, emergomycosis, and sporotrichosis (see Ch. 77).

Cryptococcus neoformans is an encapsulated yeast that is found worldwide in bird droppings and contaminated soil. Patients with $CD4^+$ T cell counts $<100/mm^3$ are particularly susceptible, and pulmonary or central nervous system disease may be the initial presentation of AIDS. Cutaneous lesions occur in 10%–20% of patients with disseminated cryptococcosis and often appear as molluscum contagiosum-like umbilicated papules, nodules, and pustules that preferentially affect the head and neck (Fig. 78.11). Violaceous nodules and ulcerations may also be seen on the palate and tongue[16]. The yeast's polysaccharide capsule can be highlighted using the mucicarmine stain or India ink; detection of cryptococcal antigen in the serum or CSF can also be utilized for diagnosis.

Cutaneous findings in disseminated dimorphic fungal infections can include papulopustules, crusted or molluscum-like umbilicated papules, nodules, necrotic lesions, verrucous plaques, and ulcers. These may occur on the face, trunk, and extremities; oral or nasal ulcers can also be seen, especially with histoplasmosis and paracoccidioidomycosis. Intravenous amphotericin B is the first-line therapy for most of the severe, disseminated fungal infections, although azoles have a role as adjunctive and maintenance therapy. Treatment is often prolonged and difficult, with frequent relapses.

Because the differential diagnosis of widespread skin lesions in febrile patients with HIV disease includes disseminated bacterial, mycobacterial and fungal infections, a representative skin lesion should be biopsied and tissue sent for culture and/or PCR.

Pneumocystis jirovecii *infections*

P. jirovecii (formerly *P. carinii*) is currently categorized as a fungus rather than a protozoan. *Pneumocystis* pneumonia (PCP) is one of the most common opportunistic infections in those living with HIV. Extrapulmonary *P. jirovecii* infection is uncommon and most often involves the lymph nodes, liver, spleen, and bone marrow. Cutaneous involvement is very rare and may present as friable erythematous papulonodules of the external ear, molluscum contagiosum-like papules, and bluish or necrotic plaques. Treatment for extrapulmonary *P. jirovecii* infection includes intravenous trimethoprim–sulfamethoxazole (TMP-SMX), clindamycin–primaquine, or pentamidine. Patients with a previous *P. jirovecii* infection or $CD4^+$ T cell counts $<200/mm^3$ should receive prophylaxis with TMP-SMX, atovaquone, dapsone, or aerosolized pentamidine.

Other fungal and related infections

Cutaneous aspergillosis may be due to direct inoculation at sites of wounds and indwelling catheters, or arise from hematogenous dissemination. Clinical findings include fluctuant papulonodules, deep

Fig. 78.11 Disseminated cryptococcosis in the setting of AIDS. **A** Several ulcers with rolled borders. **B** Numerous molluscum contagiosum-like lesions. Microscopic examination and culture of either dermal scrapings or a biopsy specimen confirm the diagnosis.

Fig. 78.12 Crusted scabies in the setting of HIV infection. Crusted and keratotic plaque on the elbow that is teeming with mites.

abscesses, non-healing ulcers, and plaques with a purulent, verrucous or annular appearance[17]. Disseminated infections with *Fusarium*, *Pseudallescheria/Scedosporium*, and fungi in the order Mucorales (mucormycosis) can also occur. Protothecosis results from infection by the achlorophyllous algae *Prototheca*, usually after trauma or contact with contaminated water. Cutaneous lesions range from erythematous papulonodules and vesiculopustules to plaques and chronic ulcers.

Parasitic Infections

Leishmaniasis

Leishmaniasis is caused by at least 20 species of intracellular protozoans of the genus *Leishmania*. It is typically transmitted by sandflies with only occasional spread via contaminated needles. HIV-associated leishmaniasis occurs in both endemic and non-endemic regions of the world, with endemic areas including portions of the Mediterranean basin, Middle East, South Asia, East Africa, and Central/South America (see Fig. 83.1). HIV enhances the severity of leishmaniasis by inducing a shift from a protective Th1-type immune response to a Th2-type reaction pattern[18]. Cutaneous findings range from solitary ulcers in exposed areas to atypical diffuse induration of the skin, eroded erythematous plaques, extensive hyperpigmented macules and papules, and necrotic genital ulcers. Mucocutaneous leishmaniasis may result in disfiguring ulcerations of the lips, palate, and nose. The diagnosis of leishmaniasis can be established via microscopy, culture, or PCR of lesional tissue.

Leishmaniasis in people living with HIV has a higher rate of therapeutic failure, relapse, and associated mortality. Amphotericin B is recommended as first-line therapy, and lipid-based formulations are preferred due to their reduced systemic toxicity (particularly nephrotoxicity). Pentavalent antimonials do not represent first-line therapy in those co-infected with HIV and *Leishmania* due to a high incidence of side effects (e.g. pancreatitis, arrhythmias), treatment failure, and mortality[19]. Oral miltefosine is well-tolerated but less effective in the setting of HIV infection. Early initiation of ART is recommended, as it contributes to higher survival rates and lower relapse rates.

Strongyloidiasis

Strongyloides stercoralis is a soil-transmitted intestinal helminth with a worldwide distribution, although it most commonly leads to infection in tropical and subtropical regions. Autoinfection due to penetration of the intestinal mucosa can cause hyperinfection and disseminated strongyloidiasis, both of which are more common in patients with impaired cell-mediated immunity (see Ch. 83). People living with HIV have twice the risk of *S. stercoralis* infection compared to the general population, but not necessarily higher rates of hyperinfection or disseminated strongyloidiasis.

Cutaneous manifestations of strongyloidiasis include urticaria and larva currens – urticarial serpiginous tracks from larval penetration and migration through the dermis, often beginning in the perianal area. Disseminated strongyloidiasis produces rapidly progressing petechial and purpuric eruptions on the abdomen and proximal limbs ("thumbprint" purpura), and eosinophilia is common. Larvae are generally absent in skin biopsies of larva currens, but in disseminated disease they may be observed in the dermis in association with vascular damage. Ivermectin and albendazole have replaced thiabendazole as first-line treatment because of greater efficacy and tolerability. Mortality is high (up to 80%) with hyperinfection or disseminated disease.

Acanthamebiasis

Acanthamoeba are free-living amoebae present in the environment and secretions of healthy individuals. Infection occurs in people living with HIV who have CD4$^+$ T cell counts <250/mm^3[3,20]. The skin may be the initial portal of entry or a site of hematogenous dissemination. Cutaneous lesions include papules, pustules, ulcers, and indurated bluish or erythematous cellulitic plaques, which may or may not be painful. Trophozoites are scant and difficult to detect in routinely stained histologic sections. Optimal treatment is not well-defined and includes combinations of miltefosine with antifungal and antibacterial agents.

Ectoparasitic Infestations and Insect Bites

Scabies

The *Sarcoptes scabiei* var. *hominis* mite is the most common cause of ectoparasitic infestation in people living with HIV. In relatively immunocompetent hosts, scabies often has a classic presentation with extremely pruritic crusted papules, vesicles, and burrows favoring the interdigital web spaces of the hands, wrists, ankles, axillae, nipples/areolae (for women), waist, and groin (see Ch. 84). With progressive immunosuppression, especially when CD4$^+$ T cell counts fall below 200/mm^3, more severe forms develop, including generalized papules and crusted scabies. The latter presents with thick, hyperkeratotic, grayish-white plaques with characteristic granular, sand-like scales (Fig. 78.12). These lesions may be generalized or localized and can be surprisingly non-pruritic despite the high mite burden, numbering thousands per gram of skin. While the head and neck are usually spared in immunocompetent adults with scabies, these areas are commonly affected in those living with HIV, which may lead to the misdiagnosis of seborrheic dermatitis. Scabies can also resemble drug eruptions, eczema, and psoriasis. A high index of suspicion is necessary as delayed diagnosis may lead to major outbreaks in health care facilities.

Definitive diagnosis can be based on dermoscopy or identification of mites, eggs, or fecal pellets (scybala) on potassium hydroxide (KOH) or

mineral oil mounts of skin scrapings. PCR-based detection of *S. scabiei* DNA from skin scales has also been described[21]. Patients with classic scabies should receive standard therapy, such as topical permethrin 5% cream. Because treatment failure is more likely with crusted scabies, a combined regimen including topical permethrin and repeated doses of oral ivermectin is recommended; keratolytic agents can facilitate removal of scale. Scabies infestation may be complicated by bacterial superinfection and fatal septicemia in immunocompromised hosts.

Demodicosis

Demodicosis due to *Demodex folliculorum* and *D. brevis* can occur in the setting of HIV disease. Patients present with itchy or "burning" facial erythema in conjunction with papules, pustules, and scaling of the cheeks, perioral area, and neck. The differential diagnosis includes rosacea, acne vulgaris, eosinophilic folliculitis, and other pruritic papular eruptions associated with HIV disease (see below). Demodicosis can also flare as a manifestation of IRIS. Microscopic examination of skin scrapings placed in mineral oil or KOH solution demonstrates multiple *Demodex* mites. Treatment options include topical ivermectin, permethrin, or sulfur preparations as well as oral ivermectin or metronidazole[22].

Insect bite reactions

Exaggerated reactions to insect bites can occur in patients with HIV disease, attributable to immune dysregulation and hypereosinophilia[23]. Patients present with pruritic or painful erythematous, edematous papules and plaques that may blister (see Ch. 33). Occasionally, they are associated with constitutional symptoms such as fevers and malaise. The differential diagnosis often includes non-infectious papular pruritic disorders associated with HIV disease.

NON-INFECTIOUS HIV-RELATED DERMATOSES

While some non-infectious skin disorders specifically affect people living with HIV, others simply occur more frequently or have enhanced severity and unusual morphologies (Table 78.3). Such presentations should alert the clinician to consider the possibility of HIV as an underlying risk factor.

Papulosquamous and Eczematous Disorders

Seborrheic dermatitis

Seborrheic dermatitis affects ~30%–50% of people living with HIV, compared to <10% of the general population, and it can be seen in all stages of HIV disease. An acute onset or sudden flare of extensive or severe seborrheic dermatitis should raise the possibility of HIV infection. Atypical presentations include a papular component, exuberant facial plaques, involvement of non-seborrheic areas, and even erythroderma. Because particular histopathologic findings such as confluent parakeratosis, necrotic keratinocytes, plasma cells, and exocytosis can be seen, the term "seborrheic-like dermatitis of AIDS" has been proposed[24,25]. HIV-associated seborrheic dermatitis can prove more resistant to conventional therapies, including those targeting *Malassezia* spp.

Psoriasis

Although the prevalence of psoriasis is similar in people living with HIV as in the general population, HIV-associated psoriasis is characterized by greater disease severity, frequent exacerbations, atypical presentations, resistance to treatment, and a higher frequency of psoriatic arthritis[24]. While plaque psoriasis is still the most common subtype (Fig. 78.13), there is a greater likelihood of inverse, guttate, and erythrodermic psoriasis as well as rupioid lesions characterized by thick, lamellated, concentric scale-crust. A hallmark of HIV-associated psoriasis is multiple morphologic subtypes in the same patient. An acute change in the pattern of pre-existing psoriasis or new onset of psoriasis with atypical features should prompt consideration of HIV infection[26].

For HIV-associated psoriasis that is not responding to topical medications, therapeutic options include phototherapy (e.g. narrowband UVB), acitretin, and ART[27,28]. The latter has been reported to result in marked improvement or clearance of psoriasis, although worsening of psoriasis may occur as a manifestation of IRIS. Data on the use of targeted immune modulators is limited, and these agents should be reserved for individuals with refractory skin disease receiving concomitant ART, along with monitoring of the CD4$^+$ T cell count and viral load. Inhibitors of TNF, IL-(12/)23, and IL-17 as well as apremilast have been used successfully in this patient population, with less risk of opportunistic infections than traditional immunosuppressive agents (e.g. methotrexate, cyclosporine)[27].

MUCOCUTANEOUS DISORDERS ASSOCIATED WITH HIV INFECTION
Inflammatory disorders
When severe, recalcitrant, or of sudden onset, consider HIV infection
• Seborrheic dermatitis (e.g. face, scalp) • Psoriasis • Reactive arthritis
Alone raises the possibility of HIV infection
• Eosinophilic folliculitis* • Papular pruritic eruption • Pityriasis rubra pilaris type VI, with follicular spines ± acne conglobata
Infectious diseases and infestations*
When severe and/or recalcitrant, consider HIV infection
• Human papilloma virus infections (warts), including acquired epidermodysplasia verruciformis-like lesions • Molluscum contagiosum – numerous, coalescent, and/or giant-sized, especially in adults • Dermatophyte infections
Alone raises the possibility of HIV infection
• Syphilis and other sexually transmitted infections (e.g. chancroid) • Bacillary angiomatosis • Botryomycosis ("grains" within the dermis composed of *Staphylococcus*, *Pseudomonas*) • Disseminated mycobacterial infections (tuberculous and non-tuberculous) • Chronic oral and anogenital herpes simplex or disseminated HSV • Herpes zoster, especially if multi-dermatomal, disseminated, verrucous or chronic, but can have classic presentation • Oral hairy leukoplakia • Anogenital and oral ulcers, verrucous plaques, or morbilliform eruption due to CMV • Kaposi sarcoma • Oropharyngeal candidiasis • Proximal subungual onychomycosis • Disseminated cryptococcosis • Disseminated dimorphic fungal infections (e.g. coccidioidomycosis, histoplasmosis, talaromycosis) • Crusted scabies • *Demodex* folliculitis • Disseminated or necrotic cutaneous leishmaniasis
Other
• Xerosis and acquired ichthyosis • Major aphthae; acute necrotizing ulcerative stomatitis with gingivitis • Porphyria cutanea tarda (often in association with hepatitis C) • Facial hyperpigmentation, idiopathic or due to photolichenoid drug eruption • Linear telangiectasias of the chest • Trichomegaly of the eyelashes and change in texture of scalp hair (e.g. curly → fine and straight) • Cutaneous lesions of non-Hodgkin lymphoma • Anal intraepithelial neoplasia/anal carcinoma; keratinocyte carcinomas • Acral persistent papular mucinosis; atypical variants of granuloma annulare
*Particularly when there is no known cause of immunosuppression.

Table 78.3 Mucocutaneous disorders associated with HIV infection.

Reactive arthritis

In patients with HIV disease, the typical presentation of reactive arthritis is oligoarthritis involving lower extremity joints plus enthesitis and mucocutaneous features such as keratoderma blenorrhagicum and circinate balanitis. HLA-B27 is present in 80%–90% of White individuals but absent in nearly all Black individuals with HIV-associated reactive arthritis[29]. Acitretin, sulfasalazine, and institution of ART are preferred over immunosuppressive therapies. Reactive arthritis can also be a manifestation of IRIS.

Fig. 78.13 Severe psoriasis in a patient with AIDS. Both sudden acute exacerbations and treatment resistance can be observed.

Other eczematous and papulosquamous dermatoses

Xerosis, atopic dermatitis, prurigo nodularis, and pruritus are common in people living with HIV, with a prevalence of up to ~40%[5]. This may reflect an HIV-induced shift to a predominantly Th2 cytokine profile, which can lead to disruption of the skin barrier. Higher rates of pruritus and atopy are associated with lower $CD4^+$ T cell counts. Acquired ichthyosis can also be seen; it typically begins on the lower extremities and may become generalized. HIV-associated pityriasis rubra pilaris (type VI PRP) is characterized by a variable association with acne conglobata, hidradenitis suppurativa, and lichen spinulosus, which together are often referred to as the HIV-associated follicular syndrome[30]. Patients may progress to erythroderma, with ensuing secondary infection and death reported.

Non-Infectious Pruritic Papular Disorders

Pruritic papular disorders are among the most common cutaneous manifestations of HIV disease. The severe pruritus and stigmatizing appearance of these eruptions can result in significant morbidity. Possible explanations include: (1) a shift towards a Th2 cytokine profile, with associated eosinophilia and increased levels of IgE and interleukins 4 and 5; (2) hypersensitivity to drugs or parasites; (3) circulating pruritogens associated with systemic disorders such as hepatobiliary or renal disease and lymphoma; and (4) HIV-related neural irritation and autonomic dysfunction, with reduced sweat and sebaceous gland secretion.

The differential diagnosis for pruritic papules is extensive. An evaluation should include the patient's current immune status, use of prescribed or recreational drugs, travel history, and other exposures. Infections, infestations (e.g. scabies), drug reactions, and pruritus due to systemic disorders should be excluded. Because atypical presentations are common in this group of patients, laboratory investigations and histologic evaluation may be necessary.

Pruritic papular eruption

The pruritic papular eruption (PPE) of HIV is characterized by severe pruritus and skin-colored to erythematous, non-follicular papules that are distributed symmetrically on the extremities and trunk (Fig. 78.14A). Excoriations, prurigo simplex, prurigo nodularis, and postinflammatory hyperpigmentation are additional findings. PPE is thought to represent a hypersensitivity reaction to arthropod antigens, an explanation supported by the higher prevalence in tropical countries and a predilection for the extremities. Histologically, there is a wedge-shaped perivascular and interstitial infiltrate of lymphocytes and eosinophils, similar to the features found in an arthropod bite reaction. Of note, some authors believe that PPE represents a spectrum of pruritic disorders that also includes eosinophilic folliculitis. Multiple treatments have been tried with limited success, including topical corticosteroids, antihistamines, oral antibiotics, and antiscabetic regimens. UVB phototherapy (broadband or narrowband) and ART may be of benefit in ameliorating the pruritus[31].

Eosinophilic folliculitis

Eosinophilic folliculitis is characterized by intensely pruritic, erythematous, follicular-based papules that are often excoriated; rarely, intact pustules are present. Lesions favor the scalp, face, neck, and upper trunk (Fig. 78.14B; see Ch. 38). Eosinophilic folliculitis usually develops in patients with advanced HIV disease and $CD4^+$ T cell counts <250–300/mm^3. Cultures are negative and there may be peripheral eosinophilia. An exaggerated reaction to *Malassezia*, *Demodex*, or other organisms normally present within the follicular infundibula is the proposed pathomechanism.

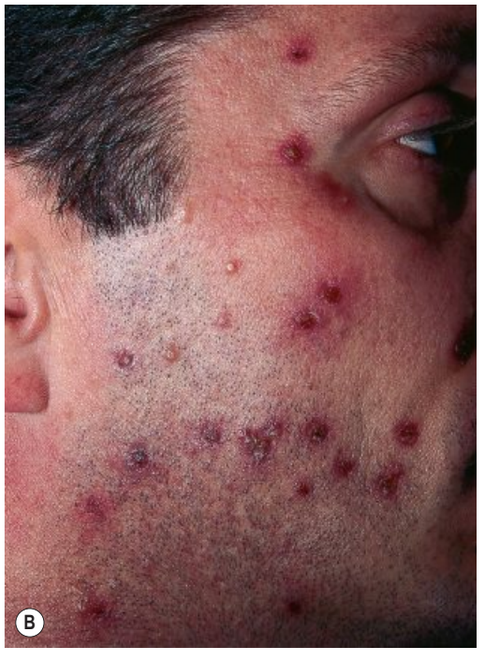

Fig. 78.14 Pruritic papular disorders. **A** The HIV-associated pruritic papular eruption is characterized by extremely itchy erythematous papules with a predilection for the limbs. This condition is thought to represent a hypersensitivity reaction to arthropod antigens. **B** Eosinophilic folliculitis with excoriated papules due to associated pruritus; lesions favor the head and upper trunk.

HIV-associated eosinophilic folliculitis, also referred to as immunosuppression-associated eosinophilic pustular folliculitis, can be distinguished from classic eosinophilic pustular folliculitis (Ofuji disease) by the intractable itch, lack of circinate lesions or palmoplantar involvement, and failure to respond to indomethacin. Although ART may lead to improvement of HIV-associated eosinophilic folliculitis, exacerbations can also occur as a manifestation of IRIS. Therapeutic options include: topical corticosteroids, tacrolimus and permethrin; oral antibiotics, itraconazole, dapsone and retinoids; and UVB phototherapy. However, the response is variable as HIV-associated eosinophilic folliculitis can prove difficult to treat.

Hair and Nail Disorders

A variety of hair and nail disorders can affect people living with HIV. Causes of hair loss range from telogen effluvium triggered by systemic infections to localized alopecia due to secondary syphilis or tinea capitis to side effects of antiretroviral drugs (e.g. emtricitabine/rilpivirine/tenofovir, indinavir, didanosine). Trichomegaly of the eyelashes, which reflects a prolonged anagen phase, has also been reported in association with HIV infection, including those treated with zidovudine and interferon-α[32,33]. Hair shaft alterations include straightening, curling, and becoming

softer/silkier or dull/lusterless. Sudden greying of the hair is thought to result from an autoimmune process targeting follicular melanocytes[34].

In one prospective study, nail changes were observed in two-thirds of individuals with HIV disease[35]. The most common finding was onychomycosis, with distal/lateral subungual and total dystrophic onychomycosis observed more frequently than the immunosuppression-associated proximal subungual variant. Additional reported nail changes include onychoschizia, onycholysis, leukonychia (including total leukonychia), Beau's lines, clubbing, koilonychia, and longitudinal melanonychia. Patients taking zidovudine may develop longitudinal and less often transverse or diffuse melanonychia (Fig. 78.15), and protease inhibitors (PIs) can cause paronychia or excessive periungual granulation tissue (see Ch. 71). Periungual erythema, fibromas, and SCC have also been reported.

Vasculitis

A broad spectrum of vasculitides, from cutaneous small vessel vasculitis to polyarteritis nodosa (PAN), has been observed in people living with HIV. Possible pathomechanisms include: (1) immune-complex deposition; (2) direct invasion of vessel walls by HIV; (3) co-infection with hepatitis B or C virus resulting in PAN or mixed cryoglobulinemia, respectively; and (4) opportunistic infections with cytomegalovirus, *Toxoplasma gondii*, *Pneumocystis jirovecii*, and mycobacteria[36]. Occasionally, a PAN-like vasculitis with peripheral neuropathy and digital ischemia occurs without concurrent hepatitis B virus infection. Erythema elevatum diutinum has been reported in patients with $CD4^+$ T cell counts $<300/mm^3$, and a Kawasaki-like syndrome has been described in both children and adults. Behçet disease has also been observed in the setting of acute HIV infection.

If corticosteroids and other immunosuppressive medications are required for HIV-associated vasculitis, they should be administered together with ART. ART alone may be beneficial but can also precipitate vasculitis as a manifestation of drug hypersensitivity or IRIS.

Photosensitivity Reactions

UV light hypersensitivity

People living with HIV may develop photosensitive dermatoses including chronic actinic dermatitis, porphyria cutanea tarda, photosensitive granuloma annulare, and photodistributed hyperpigmentation or depigmentation[37]. Photolichenoid eruptions can result from commonly prescribed medications such as TMP-SMX, dapsone, and NSAIDs (Fig. 78.16). Photosensitization is also a potential side effect of antiretroviral medications, e.g. efavirenz, tenofovir, saquinavir.

Porphyria cutanea tarda (PCT)

Acquired PCT can occur in patients with HIV disease, more often in men than women. This disruption in porphyrin metabolism could possibly be triggered by HIV-related impairment of cytochrome P450 enzymes, estrogen excess due to altered steroid hormone metabolism, co-infection with hepatitis B or C virus, alcohol intake, increased hepatic iron due to ineffective hematopoiesis, or direct hepatic damage by HIV[38].

Chronic actinic dermatitis

Chronic actinic dermatitis can be an initial manifestation of HIV disease. Pruritic eczematous lesions favor chronically sun-exposed areas (see Ch. 87). Most patients have a decreased minimal erythema dose (MED) to UVB ± UVA and visible light, and $CD4^+$ T cell counts are often $<200/mm^3$[3,39].

Metabolic Changes

HIV/ART-associated lipodystrophy and weight gain

In patients receiving ART, HIV/ART-associated lipodystrophy is a common finding. Patients may develop peripheral fat loss (lipoatrophy) or central fat gain (lipohypertrophy) or both (see Ch. 101). The underlying mechanisms of fat alteration are incompletely understood and involve a complex interplay between the virus, adipose immune system, and ART[40]. Lipodystrophy can be accompanied by metabolic abnormalities such as hyperlipidemia, insulin resistance, and diabetes mellitus. The reported prevalence ranges from 10% to 80%, with most patients developing the lipodystrophy within months to 2 years of ART initiation. Lipoatrophy and lipohypertrophy are recognized as distinct entities with separate pathogenic mechanisms.

Lipoatrophy is characterized by loss of subcutaneous fat, principally in the face, limbs and buttocks, without concomitant loss of lean muscle. The face looks "skeletal" due to loss of the buccal and/or temporal fat pads. Lipoatrophy is primarily a side effect of nucleoside reverse transcriptase inhibitors (NRTIs), especially earlier generation inhibitors such as stavudine. Proposed pathomechanisms include mitochondrial toxicity, impairment of adipogenesis and adipocyte differentiation, and increased lipolysis. Other risk factors include age >40–50 years, male sex, lower percentage of body fat, lower $CD4^+$ T cell count (<100 cells/mm^3), and higher plasma HIV-1 RNA levels ($>10^5$ copies/ml) at ART initiation.

Lipohypertrophy consists of fat accumulation in the abdominal visceral compartment, dorsocervical region ("buffalo hump"), and breasts. It has been attributed primarily to PIs and NRTIs. Hypothesized pathomechanisms include mitochondrial toxicity, dysregulation of fatty acid metabolism, changes in intra-abdominal glucocorticoid signaling, and alterations in growth hormone secretion. Additional risk factors include older age, female sex, elevated baseline triglycerides, higher percentage of baseline body fat, and longer duration of therapy. Lipohypertrophy represents one component of a broader condition of ectopic lipid deposition which can also involve the liver, epicardial tissue, and skeletal muscle.

Both weight and generalized fat gain are commonly observed following ART initiation, in part attributable to improved health and a concomitant gain in lean mass. However, weight gain is especially pronounced with

Fig. 78.15 Zidovudine-associated melanonychia. Patients receiving zidovudine may develop longitudinal streaks, horizontal bands, and diffuse hyperpigmentation.

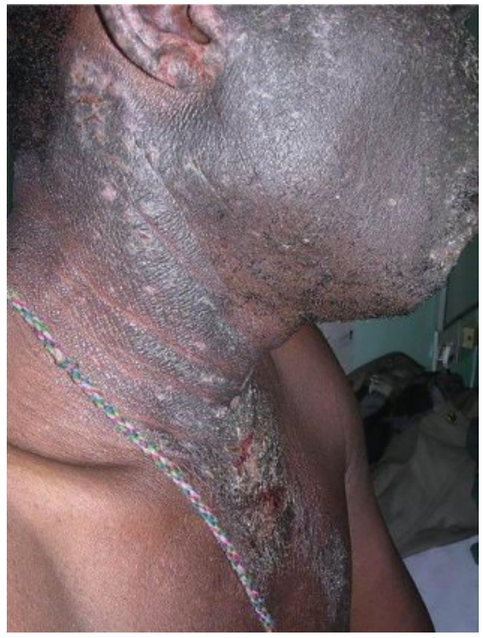

Fig. 78.16 Photolichenoid eruption in a patient with HIV. *Courtesy Ncoza Dlova, MD.*

integrase strand transfer inhibitors (INSTIs) and tenofovir alafenamide. The cause is unclear and may include effects on appetite or energy regulation.

The clinical implications of lipodystrophy include psychosocial distress, stigmatization, reduced adherence to ART, and increased risk for cardiovascular disease. Management includes a balanced diet with regular exercise and lipid- or glucose-lowering medications such as metformin[40]. Tesamorelin, an analogue of growth hormone-releasing hormone, is FDA-approved for treatment of abdominal obesity in individuals with HIV disease, but effects are not sustained after cessation of therapy and long-term safety data are lacking. Modest improvement in lipoatrophy and hyperlipidemia often occurs upon switching from thymidine analogue NRTIs to alternative agents, but substitution of other agents for PIs has had inconsistent effects in reversing lipohypertrophy.

Injectable fillers such as poly-L-lactic acid and calcium hydroxylapatite are FDA-approved for treatment of HIV/ART-associated lipoatrophy, and autologous fat transfer represents another option. Excess fat may be removed via surgery or liposuction, although reaccumulation typically occurs. In small series, bariatric surgery has been reported to lead to improvement. The incidence of lipodystrophy is expected to decrease further with the widespread use of newer ART regimens, although fat alterations can persist for years in patients who received older ART medications.

Malnutrition

The causes of malnutrition in people living with HIV include: (1) reduced food intake due to poor appetite, nausea, or dysphagia related to oral/esophageal candidiasis; (2) diarrhea secondary to infection, medications, or malignancy; (3) malabsorption; and (4) psychosocial issues[41]. Patients can develop the cutaneous manifestations of kwashiorkor, zinc deficiency, and other vitamin and mineral deficiencies. Nutritional replacement is critical, as malnutrition is associated with lower $CD4^+$ T cell counts and an increased risk of opportunistic infections.

Miscellaneous Dermatoses

Primary cutaneous mucinoses have been linked to HIV, especially localized papular variants of lichen myxedematosus in men with advanced HIV disease[42]. *Granuloma annulare* may present with generalized lesions or other atypical distribution patterns (e.g. a photodistribution). Both remission after ART and worsening as a manifestation of IRIS have been described[43]. *Major aphthae* presenting as large, painful, destructive oral lesions can also occur in people with HIV disease. Infective or neoplastic processes should be excluded, and severe cases may require treatment with systemic corticosteroids, thalidomide, or ART[44]. *Linear telangiectasias* on the chest have been reported in individuals with HIV infection, mostly in MSM[45].

HIV-RELATED CUTANEOUS NEOPLASMS

Factors that may contribute to the development of cutaneous malignancies in those with HIV disease include immunosuppression, co-infection with oncogenic viruses, and environmental exposures (e.g. UV radiation). In addition, HIV could potentially have direct effects such as activation of proto-oncogenes, alteration of cell cycle regulation, and inhibition of tumor suppressor genes[46].

Kaposi Sarcoma (KS)

HIV-associated KS is an aggressive vascular tumor that, like other types of KS (see Ch. 114), is caused by human herpesvirus type 8 (HHV-8). The latter can be transmitted by semen and saliva. Since the introduction of ART, there has been a marked decrease in the incidence, morbidity, and mortality of HIV-associated KS[47].

KS typically presents as red–purplish patches, papules, plaques, and nodules. The lesions can ulcerate and have a predilection for the face, upper body, oral cavity, and genitalia (Fig. 78.17). Oval lesions may align along the skin cleavage lines of the trunk (see Fig. 78.17D). Lymph node involvement can result in lymphedema, and the lungs and gastrointestinal tract are often affected.

The management of KS depends on the stage of HIV disease, the extent and sites of involvement, and medical comorbidities. ART is often an effective treatment for KS and represents a reasonable initial monotherapy for limited disease. However, flares of KS can also occur as a manifestation of IRIS following initiation of ART[48].

HIV-associated KS may respond to local destruction (e.g. cryotherapy), topical alitretinoin (9-cis-retinoic acid) gel, superficial radiotherapy/electron beam, photodynamic therapy, or intralesional vinblastine. Systemic therapies include liposomal doxorubicin or daunorubicin, paclitaxel, sirolimus, pomalidomide, interferon-α, and tyrosine kinase inhibitors (e.g. pazopanib) (see Ch. 114).

Keratinocyte Carcinomas and Melanoma

Compared to the general population, people living with HIV have a 2- to 3-fold increased risk of keratinocyte carcinomas[49]. The tumors tend to appear at a younger age and are more often multifocal and located on the trunk or extremities. In a Danish nationwide cohort study, the relative risks of BCC and SCC in people living with HIV compared to the general population were 1.8 and 5.4, respectively[50]. A low $CD4^+$ T cell count confers an increased risk of initial and subsequent primary SCCs[50,51]. These cutaneous SCCs also have a higher risk of recurrence and metastasis[48], but BCCs do not behave more aggressively. In general, BCCs and SCCs in patients with HIV disease should be managed in a traditional manner (see Ch. 108), with consideration of individual comorbidities.

Melanomas in people living with HIV are often multiple, frequently metastasize, and are associated with a poor prognosis[52]. Of note, HIV infection also increases the risk of developing Merkel cell carcinoma and sebaceous carcinoma[53].

Lymphomas

Cutaneous lymphomas may develop in people living with HIV[48,54], often in the setting of significant immune suppression. Clinically, pink to violaceous papules and nodules are seen; the lesions often ulcerate and may simulate panniculitis. HIV-associated lymphomas are most often B cell non-Hodgkin type and high or intermediate grade. They are typically in more advanced stages, and there is often involvement of the CNS, gastrointestinal tract, and/or skin at the time of presentation[55]. Approximately half of non-Hodgkin lymphomas in patients with HIV disease are associated with EBV infection.

Since the introduction of ART, a decrease in incidence and improved survival have been observed for all types of lymphoma. A prior diagnosis of AIDS and bone marrow involvement are associated with an unfavorable prognosis[56].

Cutaneous T cell lymphoma, in particular mycosis fungoides, as well as T cell lymphoproliferative disorders that may mimic mycosis fungoides clinically can also occur, albeit much less frequently than B cell lymphomas. The possibility of adult T cell leukemia/lymphoma caused by human T cell leukemia/lymphotropic virus type 1 (HTLV-1) should be considered and excluded.

Other Cutaneous Neoplasms

Eruptive atypical nevi have been described in people living with HIV. Cutaneous smooth muscle tumors, including leiomyomas and leiomyosarcoma, occur more frequently in children with HIV disease and may be associated with EBV infection.

DIFFERENTIAL DIAGNOSIS AND DIAGNOSIS

Differential Diagnosis of HIV-Associated Skin Conditions

The wide variety of infectious, inflammatory, and neoplastic disorders of the skin that may develop in the setting of HIV infection can have overlapping clinical features. Cutaneous eruptions range from classic forms to bizarre variants that present a diagnostic challenge. In particular, disseminated fungal infections and adverse drug reactions (see below) may be life-threatening and require early intervention with systemic antifungal agents or withdrawal of the offending medication.

The spectrum of cutaneous diseases tends to correlate with the immune status of the patient. An association between HIV-related disease incidence and the $CD4^+$ T cell count has been established (see Tables 78.1 & 78.2), and this allows for a more focused differential diagnosis. In general, disseminated and extensive disease occurs more frequently in the setting of lower $CD4^+$ T cell counts.

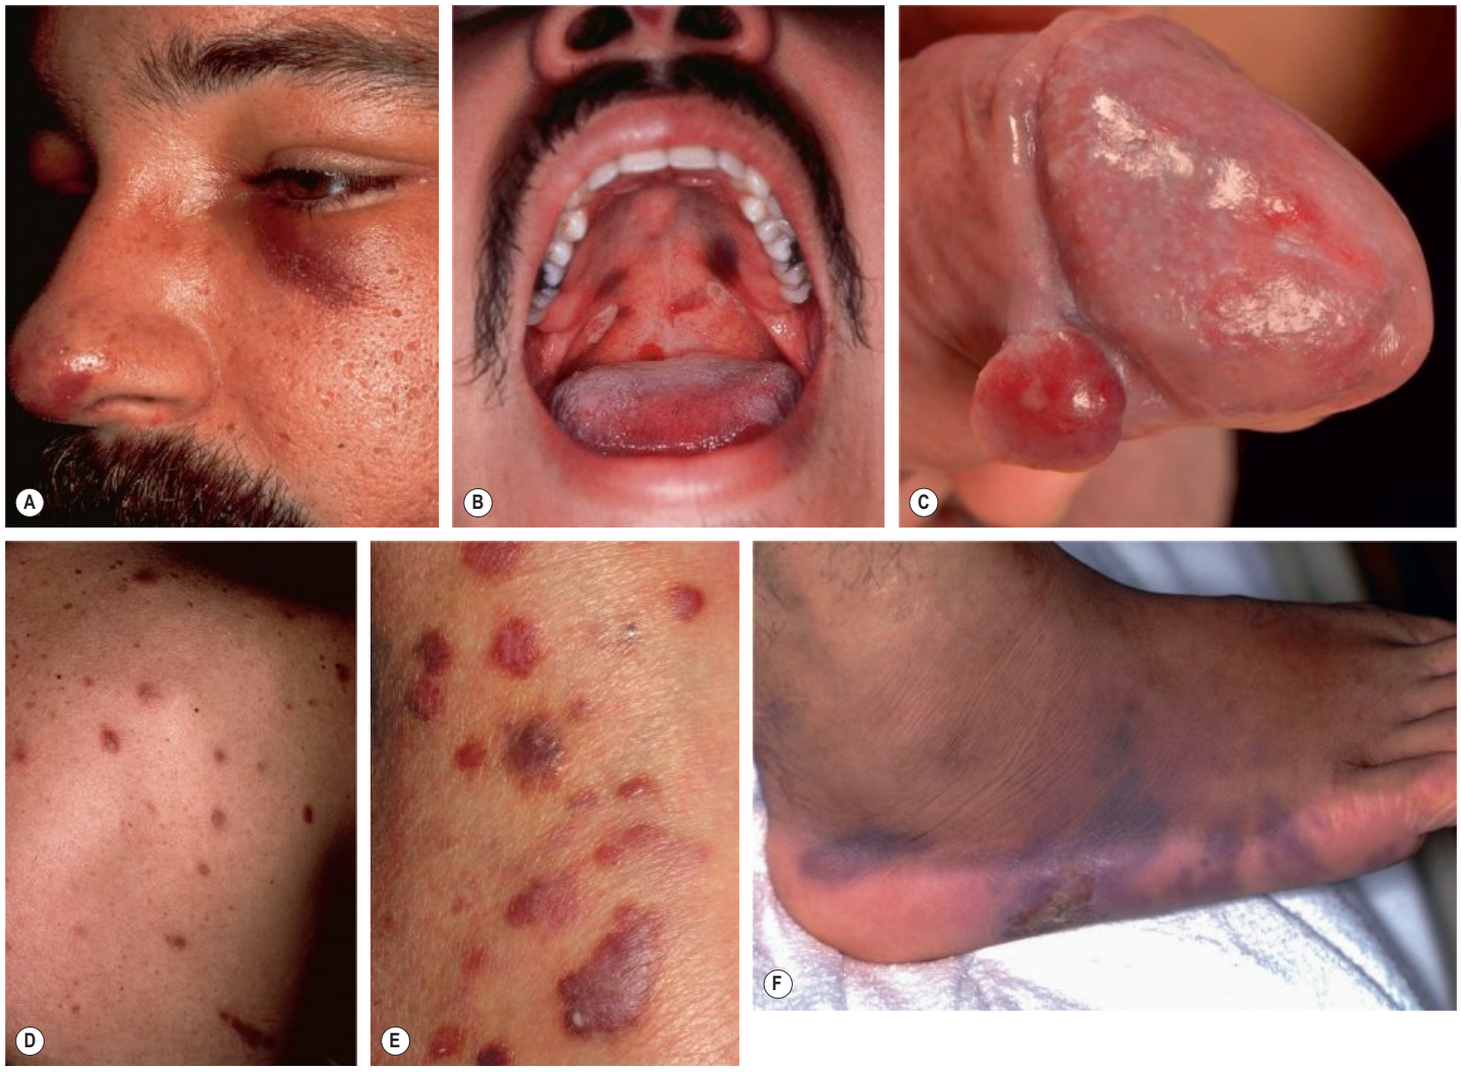

Fig. 78.17 HIV-associated Kaposi sarcoma. Violaceous to red–purple papules, nodules, and plaques on the face (**A**), palate (**B**), penis (**C**), back (**D**), leg (**E**), and foot (**F**). Oral candidiasis is also seen (**B**). Some of the elongated lesions on the trunk follow the skin cleavage lines (**D**), and early ulceration is evident on the foot (**F**). *F, Courtesy Thomas Horn, MD.*

Diagnosis of HIV-associated skin conditions

Diagnosis of cutaneous disorders in people living with HIV is based on the clinical appearance coupled with confirmatory studies such as scrapings, cultures, biopsies, and serologic or PCR-based assays. Patients often have mixed infections or combined infectious–neoplastic or inflammatory–neoplastic lesions (Fig. 78.18). Other factors such as age, sex, and anatomic distribution assist in narrowing the differential diagnosis (see Table 78.3).

Laboratory Diagnosis of HIV Infection

Since 1989, the diagnostic algorithm for HIV infection has included initial screening with a sensitive immunoassay, followed by confirmation with a more specific HIV antibody test, traditionally either a Western blot or indirect immunofluorescence assay (IFA). HIV seroconversion usually occurs ~4 weeks after initial infection, but the seronegative "window" period can last up to 3 months. Current fourth-generation HIV screening assays shorten this window via simultaneous assessment for anti-HIV IgM and IgG antibodies and the p24 capsid antigen, which can be detected as early as 15 days after infection (Table 78.4; see Fig. 78.3). The 2014 US Centers for Disease Control and Prevention (CDC) guidelines for the laboratory detection of HIV infection recommend fourth-generation screening with confirmation by an immunoassay that differentiates between HIV-1 and HIV-2 antibodies[57]. Although the screening tests have high sensitivities, the confirmatory tests are unable to detect recent infections; if the screening test is positive and the confirmatory test is negative or indeterminate, a nucleic acid test (NAT) for HIV-1 RNA can be performed[57].

Fig. 78.18 Oral herpes simplex virus infection and oral candidiasis. This combined infection was in an otherwise healthy young man who proved to be HIV-positive.

ANTIRETROVIRAL THERAPY (ART)

Antiretroviral Medications for Treatment and Prevention

There are >30 FDA-approved drugs in nine mechanistic classes that block HIV replication at various steps in its lifecycle (see Fig. 78.2). A list of FDA-approved antiretroviral medications is available at https://hivinfo.nih.gov/understanding-hiv/fact-sheets/fda-approved-hiv-medicines. Current ART regimens are more effective and better tolerated than those utilized in the past. Regimens that are less likely to lead to the emergence of HIV resistance, even when treatment adherence is not optimal, are favored.

LABORATORY TESTS FOR HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION		
Test	**Target of detection**	**Median "window" period from infection to positive test (days)**
Nucleic acid tests (NATs)		
Quantitative for HIV-1 viral load assessment	RNA (≥20–40 copies/ml)	6–10
Qualitative for HIV-1 diagnosis*	RNA (≥100 copies/ml)	10–12
Screening tests		
4th generation HIV-1/2 antigen/antibody EIA*	IgM, IgG, p24 antigen	16–18; 19–20 for rapid test†
3rd generation HIV-1/2 antibody EIA*	IgM, IgG	22–24; 26–32 for rapid test†
Supplemental/confirmatory tests		
HIV-1/2 antibody differentiation EIA*	IgG	32–36
HIV-1 Western blot	IgG	35–40
HIV-1 EIA	IgG	40+

*Currently recommended by the CDC for HIV diagnosis; the qualitative NAT is used when the screening test is positive but the confirmatory test is negative or indeterminate; tests that discriminate between HIV-1 and HIV-2 infection have been referred to as "5th generation".
†Results available in ≤30 minutes, so suitable for point-of-care use.

Table 78.4 Laboratory tests for human immunodeficiency virus (HIV) infection. The FDA-approved OraQuick® In-Home HIV Test provides results in 20 minutes from oral fluid, which has lower antibody levels than blood. Mail-in HIV tests that involve sending a finger-prick blood sample to a laboratory and receiving results as early as the next day are also available. EIA, enzyme-linked immunoassay; IFA, indirect immunofluorescence assay; NAT, nucleic acid test.
Data from Delaney KP, Hanson DL, Masciotra S, et al. Time until emergence of HIV test reactivity following infection with HIV-1: implications for interpreting test results and retesting after exposure. Clin Infect Dis 2017;64:53–9.

ART is recommended for all people with HIV who have a detectable viral load, regardless of the CD4+ T cell count[58]. Treatment should be initiated as soon as possible after HIV diagnosis in order to increase linkage to care and decrease time to viral suppression. The advantages of early HIV treatment include decreased morbidity and mortality as well as reduced HIV transmission.

The preferred first-line therapy in treatment-naive patients consists of an integrase strand transfer inhibitor (INSTI; also known as an integrase inhibitor) combined with dual nucleoside reverse transcriptase inhibitors (NRTIs); a two-drug regimen (INSTI + NRTI) is also an option in patients without hepatitis B co-infection[58–61]. Dual NRTIs plus either a non-nucleoside reverse transcriptase inhibitor (NNRTI) or a ritonavir-boosted protease inhibitor (PI) represent alternative regimens. Multiple antiretroviral drugs are often combined into a single pill in order to reduce pill burden, and intramuscular injection of two long-acting agents (INSTI + NNRTI) every 1–2 months is an option for adults who are virologically suppressed on a stable ART regimen with no resistance to these agents or history of treatment failure. In the setting of virologic failure, subsequent medication changes are guided by resistance testing[59–61].

Over the past decade, effective strategies for preventing HIV transmission and acquisition have been described. In randomized controlled trials, the use of antiretroviral medications was shown to reduce the risk of HIV transmission from an infected person by ≥96%[62,63]. Pre-exposure prophylaxis (PrEP) consists of antiretroviral medications taken daily or on demand by HIV-negative individuals who are at risk of acquiring HIV; intramuscular injection of a long-acting INSTI every 2 months is also available[64,64a]. In MSM and persons who inject drugs, PrEP has been shown to reduce the risk of HIV acquisition by 50%–85%[65–67]. Of course, central to the effectiveness of this strategy is compliance. In women at risk for acquiring HIV, consistent use of a vaginal ring that continuously releases dapivirine and is inserted monthly led to a 75% reduction in HIV transmission. In addition, male circumcision reduced the risk of men acquiring HIV via insertive vaginal sex by ~60%[68–70]. Lastly, consistent and correct use of condoms remains a cornerstone in the drive to prevent transmission and acquisition of HIV.

Fig. 78.19 Exacerbation of leprosy due to immune reconstitution inflammatory syndrome following institution of ART therapy. *Courtesy Beatriz Trope, MD, PhD.*

CUTANEOUS DISEASES THAT CAN "FLARE" DUE TO THE IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME
Infections
Mycobacterium tuberculosis
Mycobacterium leprae
Mycobacterium avium complex and other species
Herpes simplex virus 1 and 2
Varicella–zoster virus
EBV (e.g. oral hairy leukoplakia)
Cytomegalovirus
Human papillomavirus
Molluscum contagiosum virus
Candida spp.
Dermatophytes
Cryptococcus spp.
Histoplasma capsulatum, Talaromyces (Penicillium) marneffei
Demodex, Malassezia spp. (e.g. folliculitis)
Leishmania spp.
Inflammatory disorders
Psoriasis, seborrheic dermatitis
Pityriasis rubra pilaris
Granuloma annulare
Sarcoidosis
Foreign body reactions (granulomatous)
Eosinophilic folliculitis
Acne vulgaris, rosacea
Papular pruritic eruption
Lupus erythematosus (systemic, discoid, tumid), relapsing polychondritis
Alopecia areata
Dyshidrotic eczema
Mid-dermal elastolysis
Neoplasms
Kaposi sarcoma
Non-Hodgkin lymphoma
Multiple eruptive dermatofibromas

Table 78.5 Cutaneous diseases that can "flare" due to the immune reconstitution inflammatory syndrome (IRIS).

Immune Reconstitution Inflammatory Syndrome (IRIS)

The rapid improvement in immunologic status that follows institution of ART can paradoxically result in clinical exacerbations of infectious, neoplastic, and inflammatory diseases in a subgroup of patients with HIV (Fig. 78.19)[71,72]. This phenomenon is known as *immune reconstitution inflammatory syndrome* (IRIS). It occurs in ~15% of patients 1 week to 3 months after initiation of ART, with a higher risk in those with low CD4+ T cell counts (<50/mm^3) prior to therapy[73]. The overall mortality of IRIS is ~5%, but it is as high as 20% in patients with cryptococcal meningitis. Distinguishing IRIS-associated flares of inflammation from active opportunistic infections or drug reactions may be difficult. Cutaneous diseases that can be exacerbated in the setting of IRIS are listed in Table 78.5.

Drug–Drug Interactions

Knowledge of potential drug interactions is necessary to prevent adverse reactions and therapeutic failures. The human cytochrome P450 system metabolizes a number of drugs used to treat HIV disease and associated complications. Cytochrome P450 3A4 inhibitors, which include most of the PIs and delavirdine, impair drug metabolism, leading to accumulation of drugs that share the same metabolic pathway (see Ch. 131). Cytochrome P450 3A4 mixed inducers/inhibitors and inducers (e.g. efavirenz and nevirapine, respectively) may accelerate clearance of other medications, thereby necessitating dose adjustments. Cytochrome P450-independent interactions include: (1) an increase in intracellular drug levels and toxicity of didanosine when used in combination with ribavirin and/or tenofovir[74]; and (2) a decrease in atazanavir concentration when coadministered with tenofovir[75].

Drug Eruptions

Adverse drug reactions (ADR) are common in people living with HIV. Underlying risk factors include genetic predisposition as well as immune dysregulation and alterations in drug metabolism[76]. Because these patients typically take multiple medications, identification of the causal agent or combination of agents is often a complex and frustrating process (see Ch. 21). Morbilliform eruptions are the most common presentation of drug hypersensitivity, and the incidence is significantly higher in people with HIV disease than in the general population. Patients may also present with urticaria, pruritus, vasculitis, exfoliative erythroderma, drug reaction with eosinophilia and systemic symptoms (DRESS), Stevens–Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN). The major cutaneous side effects of antiretroviral medications are outlined in Table 78.6[77,78].

CUTANEOUS SIDE EFFECTS OF ANTIRETROVIRAL THERAPY (ART)

Type of skin reaction	NRTIs/NtRTIs	NNRTIs	Protease inhibitors	Integrase inhibitors	CCR5 inhibitors	Fusion inhibitors
Injection site reaction						
Morbilliform eruption	Emtricitabine*, Abacavir†	Nevirapine > etravirine, efavirenz	Atazanavir, fosamprenavir‡ > darunavir‡, tipranavir‡ > lopinavir			
DRESS (DIHS)	**Abacavir†**	**Etravirine, efavirenz**, **Nevirapine**	Atazanavir, darunavir‡, fosamprenavir‡, tipranavir‡, lopinavir	Raltegravir†	Rare	Rare
SJS/TEN	Rare	Rare, Nevirapine > efavirenz, etravirine	Rare	Rare		
Lipodystrophy (also insulin resistance and elevated TTGs)	d4T, ddI	Efavirenz				
Paronychia, excessive periungual granulation tissue	Lamivudine		Indinavir			
Xerosis			Indinavir			
Hyperpigmentation of skin and nails	AZT, emtricitabine (palmoplantar)					

*Palmoplantar eruption.
†Associated with HLA-B*5701 (abacavir) and HLA-B*5301 (raltegravir) alleles.
‡Sulfonamide-like structure and should be used cautiously in patients with sulfonamide allergy.

Table 78.6 Cutaneous side effects of antiretroviral therapy (ART). In general, patients with HIV infection have an increased risk of developing drug-induced morbilliform eruptions and toxic epidermal necrolysis, e.g. to sulfonamides. Rashes, including morbilliform eruptions, have also been described in patients treated with CD4 post-attachment and gp120 attachment inhibitors, and injection site reactions are common in patients receiving the capsid inhibitor lenacapavir. **Bold** = most common; dark-colored cells = common; light-colored cells = less common. A whole cell that lacks specific drug names refers to that class of drugs, whereas in subdivided cells, refers to the remainder of that class of drugs. AZT, zidovudine; CCR5, CC-chemokine receptor 5; DIHS, drug-induced hypersensitivity syndrome; DRESS, drug reaction with eosinophilia and systemic symptoms; NNRTIs, non-nucleoside reverse transcriptase inhibitors; NRTIs/NtRTIs, nucleoside/nucleotide reverse transcriptase inhibitors; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis; TTGs, triglycerides.

Fig. 78.20 Morbilliform drug eruption due to trimethoprim–sulfamethoxazole (TMP-SMX). This young man with HIV developed a widespread eruption of blanchable erythematous macules and papules 8 days after starting TMP-SMX. Note the coalescence on the upper trunk.

In people with HIV infection, trimethoprim–sulfamethoxazole (TMP-SMX) is the most common cause of a cutaneous drug reaction. Often taken for prophylaxis or treatment of *Pneumocystis jirovecii* pneumonia or toxoplasmosis, intravenously administered TMP-SMX leads to an exanthematous eruption and fever (typically 8–12 days after initiating therapy) in 50%–60% of patients (Fig. 78.20). This occurrence rate is 10 times that observed in the general population[79]. Additional side effects of TMP-SMX include fixed drug eruption, SJS, and TEN.

Close observation is often sufficient since most cutaneous drug eruptions spontaneously regress, especially the morbilliform type. However, if systemic signs such as fever develop or epidermal detachment is observed, the suspected offending agent(s) should be withdrawn immediately as this may herald a more serious, possibly life-threatening, complication. With some drugs such as zidovudine, sulfonamides, and dapsone, patients may be successfully desensitized after an adverse drug reaction. Drug rechallenge should be done under controlled circumstances. Rechallenge is contraindicated for abacavir and is not recommended for NNRTIs.

CONCLUSIONS

The number and variety of manifestations of HIV disease are greater in the skin than in any other organ. Cutaneous complications are a source of significant morbidity and may also be stigmatizing. Although ART has decreased the incidence of several HIV-associated skin conditions, other disorders such as IRIS, drug reactions, metabolic disturbances, HPV infections, and SCCs are still commonly observed. In fact, they may even be increasing in incidence due to prolonged survival of people living with HIV. By recognizing the spectrum of HIV-associated skin conditions and performing appropriate diagnostic tests, treatment can be administered in a timely fashion and outcomes optimized.

eFig. 78.11 Major aphthous ulcers in patients with HIV. Oral aphthous ulcers are often large, painful, and persistent in patients with HIV infection. Infectious and neoplastic processes should be excluded. Severe cases may require thalidomide.

79 Human Papillomaviruses

Reinhard Kirnbauer and Petra Lenz

Synonyms: ■ Verrucae vulgares (singular: verruca vulgaris) – common warts ■ Verrucae palmares et plantares – hand and foot warts ■ Verrucae planae – flat warts, plane warts ■ Condylomata acuminata (singular: condyloma acuminatum) – genital warts ■ Condylomata plana – flat cervical condylomas, plane condylomas ■ Squamous intraepithelial lesion (SIL) – cervical intraepithelial neoplasia (CIN); vulvar (VIN); vaginal (VaIN); penile (PIN or PeIN); anal (AIN) ■ Buschke–Löwenstein tumor – giant condylomata acuminata, condylomata acuminata gigantea ■ Florid oral papillomatosis – Ackerman tumor ■ Papillomatosis cutis carcinoides – Gottron tumor ■ Focal epithelial hyperplasia – Heck disease

Key features

- Human papillomaviruses (HPVs) comprise a large group of more than 200 genotypes that infect the epithelia of skin or mucosa and most commonly cause benign papillomas or warts
- Epidermodysplasia verruciformis (EV) is an inherited disease characterized by generalized flat warts or pityriasis versicolor-like macules, caused by chronic infection with HPV types in the genus β; patients often develop squamous cell carcinomas (SCCs) in sun-exposed areas
- EV-associated HPV types are also detected in skin cancers and normal skin. These viruses are activated by UV exposure, immunosuppression, and specific host genetic background (EV)
- Anogenital HPV is a highly prevalent, sexually transmitted infection (STI) seen predominantly in young adults. Condylomata acuminata or benign anogenital warts are typically caused by HPV-6 or -11, which are considered to be low-risk types
- Persistent infection with high-risk HPV types, predominantly HPV-16 and -18, is the major cause of cervical and anal cancers, a subset of vaginal, vulvar, penile, and oropharyngeal cancers, and rarely digital SCCs
- Patients with cellular immunodeficiencies are at higher risk for persistent HPV infection and progressive disease
- No effective specific antiviral treatment for warts exists, and most therapies focus on destruction of visible lesions or induction of a cellular immune response
- Highly effective prophylactic HPV vaccines based on virus-like particles (VLPs) have been licensed for the prevention of genital warts and/or HPV-associated anogenital cancers

INTRODUCTION

Papillomaviruses are a large group of DNA viruses that are widely distributed in animals and humans, most commonly inducing benign papillomas or warts[1]. Recurrent skin and anogenital warts may be disfiguring, impose a considerable psychological burden, and are a frequent cause of medical office visits. A subset of human papillomaviruses (HPVs) designated as high-risk types, most often HPV-16 and -18, is now recognized as the primary etiologic agent for: cervical cancer and its precursor lesions; a subset of malignancies at other anogenital sites and in the upper aerodigestive tract; and, rarely, squamous cell cancer (SCC) of the digits. In contrast, infection with the common cutaneous HPV types 1, 2, 4, 27, 57, etc. is not thought to have any oncogenic potential[1]. In immunocompromised patients, HPV infections tend to persist and result in an increased risk of anogenital neoplasias. The high prevalence of genital HPV infection in sexually active young adults is a major concern, as effective antiviral treatments do not exist. More than two decades ago, prophylactic vaccines based on virus-like particles (VLPs) that prevent transmission in animal models of papillomavirus infection were developed[2–4]. Human vaccine studies subsequently demonstrated safety and nearly complete (>90%) efficacy in preventing vaccine type-restricted genital HPV infection and the development of associated neoplasias[5–7].

History

An infectious etiology for human warts had long been suspected[1], and experimental transmission of common warts with a cell-free extract was demonstrated over 100 years ago[8]. The descriptions of cottontail rabbit papillomavirus (CRPV) in 1933 and the rare genodermatosis *epidermodysplasia verruciformis* (EV) demonstrated the oncogenic potential of papillomaviruses. Following the cloning of the first papillomavirus genome in the late 1970s, the plurality of human and animal papillomaviruses became evident[9]. Based on genome sequencing, HPV types can be grouped into phylogenetic trees with a remarkable relationship to biologic behavior, e.g. mucosal and cutaneous types, high-risk and low-risk genital HPV, and EV-associated HPV[9]. Today, the genomes of more than 200 HPV types have been fully characterized and additional partial DNA sequences have been obtained, indicating the existence of at least 200 HPV genotypes[10]. In 1976, zur Hausen proposed an association between papillomaviruses and cervical cancer[11], and subsequent molecular studies led to the recognition of a subset of HPV types in a high proportion of cervical carcinomas. The identification of biologic differences between "high-risk" and "low-risk" mucosal HPV confirmed that infection with oncogenic HPV was the main cause of cervical cancer and its precursor lesions[12].

EPIDEMIOLOGY

Cutaneous warts are caused by a small group of specific HPV types, with a prevalence of up to 30% in primary schoolchildren and a decline thereafter with increasing age[13–15]. Patients living in larger households often report an infected cohabitant, supporting the concept of person-to-person transmission. The majority of warts will regress spontaneously within 1–2 years. After clearance occurs, reinfection with the same HPV type appears to be uncommon, suggesting that protective type-restricted immunity may develop.

Genital infection with HPV occurs most commonly by intimate contact, while infection of non-genital skin may occur via direct skin-to-skin contact or indirectly through contaminated surfaces and objects (e.g. swimming pool, gymnasium). Basal keratinocytes, which serve as the primary targets for HPV infection, are exposed to the virus through minor abrasions, and infection is promoted by maceration. Autoinoculation of virus from the lesion to adjacent skin is observed frequently, especially for digital or flat warts. Using sensitive polymerase chain reaction (PCR)-based detection, normal-appearing skin surrounding HPV-associated lesions and even skin of healthy volunteers may contain HPV DNA. These observations help to explain the high recurrence rate of warts (e.g. 20%–50% for genital condylomata) and the observation that treatment may not prevent further transmission of the virus. Papillomaviruses are resistant to heat and desiccation due to the absence of a viral envelope, and even laser fumes may contain infectious virions[16].

Genital warts in prepubertal children are uncommon and their diagnosis raises special concerns. Although viral transmission may occur during delivery, from close family contacts, or by autoinoculation

from skin warts, the possibility that these lesions may have been caused by sexual abuse should always be carefully considered (see below)[17].

In the US, HPV infection of the lower anogenital tract was the most common sexually transmitted infection (STI)[18–21], with a historical overall prevalence of ~40% in those ages 19–59 years[18]. However, following the introduction of the quadrivalent HPV vaccine, the prevalence of HPV types 6, 11, 16, and 18 in cervicovaginal specimens decreased in women ages 14–19 years, declining from 11.5% in the prevaccine era (2003–2006) to 5% in the years 2007–2010[19]. Behavioral risk factors include sexual intercourse at an early age and the number of lifetime sexual partners[9]. Circumcised men are less likely to carry and transmit HPV infection. In men who have sex with men (MSM), anal HPV infection is very prevalent (up to 75%). The public health impact of genital HPV infection is evidenced by the high number of initial visits to physicians' offices for treatment of genital warts and the frequency of consequences such as abnormal Pap smears and cervical neoplasia. In the US, the estimated prevalence of sexually acquired HPV infection is 42 million people and the estimated annual cost burden of genital HPV infection is $6 billion, making it the second most costly STI after HIV infection[20].

Most genital papillomavirus infections resolve spontaneously, whereupon HPV DNA becomes undetectable by PCR. The median duration of high-risk HPV infections in women is 8 months and persistence is found in 30% after 1 year and in 9% after 2 years[9]. Persistent cervical infection with a high-risk HPV type is required for the development of cervical intraepithelial neoplasia (CIN) and carcinoma. HPV-16 is detected in ~50% of cervical cancers and high-grade CIN. Together, HPV-16, -18, -31, -33, -45, -52, and -58 have been identified in ~90% of cervical cancers[9], and all are targeted in the nine-valent HPV vaccine.

Worldwide, an estimated 570 000 cases of cervical cancer were diagnosed in 2018, resulting in about 310 000 deaths[22]. The disease occurs predominantly in low-income countries that lack effective cervical screening programs. In the US, prevention and early detection programs have reduced the incidence rate of cervical cancer by ~75%, to 8 per 100 000 women per year. According to the American Cancer Society, an estimated 14 500 new cases of cervical cancer occurred in 2021, resulting in ~4300 deaths. Although high-risk oncogenic HPV types account for most of the observed risk for developing cervical cancer, smoking, cervical inflammation, parity, and oral contraceptive use have been proposed as cofactors[9]. While there is little evidence for hematogenous spread of HPV, ~60% of patients with anogenital infections develop low-titer, type-restricted antibodies during the course of infection[23]. Titers tend to decrease slowly and may persist for years after viral clearance.

Immune suppression in HIV-infected patients and organ transplant recipients results in HPV infections that are more frequent, persistent, and likely to progress to intraepithelial neoplasia, with $CD4^+$ T cell depletion and HIV viral load being important risk factors. In studies analyzing anal swabs, up to 93% of HIV-seropositive MSM were positive for HPV DNA, compared to 60% of HIV-negative MSM[24]. HPV-associated anal intraepithelial neoplasia (AIN), a likely anal cancer precursor, is found in up to a third of HIV-infected MSM, compared to 20% of HIV-negative MSM. Antiretroviral therapy has shown no or only a modest beneficial effect on the incidence and progression of AIN or CIN. Similarly, organ transplant recipients are at an increased risk for developing warts and genital neoplasias[25]. They also have a higher incidence of premalignant and malignant skin neoplasias, e.g. actinic keratoses, Bowen disease, and SCCs, especially in sun-exposed areas.

Cutaneous tumors from organ transplant recipients as well as "healthy skin" and plucked hairs from immunocompetent patients often contain DNA from β HPV types (see below)[9,25]. Only in patients with EV and immunocompromised hosts do β HPV infections result in highly active viral replication with cytopathic effects and clinical lesions[25]. In skin swab samples, children from 1 month to 4 years of age have a high prevalence (from 50% to 70%) of HPV DNA[26], indicating that normal-appearing human skin is colonized with a multiplicity of β HPV types very early in life, most likely through close skin-to-skin contact. Beta HPV DNA has also been detected in psoriatic lesions[27] and skin cancers from PUVA-treated patients; however, highly sensitive PCR-based methods were required for detection and viral gene transcription has not been reported.

Recurrent respiratory papillomatosis (RRP) is characterized by exophytic lesions of the airways. It occurs in juvenile- and adult-onset forms and is usually caused by HPV-6 and -11. Despite its low incidence of 0.4–1.2 per 100 000[18], RRP is the most common benign tumor of the larynx. It is believed that in childhood-onset RRP, vertical HPV transmission from mother to child occurs by aspiration during delivery through an infected birth canal[28]. Although treatment should be considered in pregnant women with condylomata in order to reduce viral load, there is insufficient evidence to support cesarean section to prevent development of RRP in the offspring. Adult-onset RRP more likely results from genital-to-oral transmission.

PATHOGENESIS

Papillomavirus Evolution

Historically, papillomaviruses were grouped together with polyomaviruses, but their fundamentally different biology and genetic organization resulted in their reclassification as a separate family in 2000[10]. The National Center for Biotechnology Information (NCBI) nucleotide sequence database (www.ncbi.nlm.nih.gov) and the Karolinska Institutet International HPV Reference Center (www.hpvcenter.se) currently list more than 200 different HPV types as well as numerous incompletely characterized putative newer HPV types. By definition, a novel type has more than 10% dissimilarity from any previously characterized type in the DNA sequences of three HPV genes (E6, E7, and L1). Dissimilarity of 2%–10% is defined as a subtype, and <2% as a variant[10].

By comparing DNA sequences in conserved portions of the papillomavirus genomes across different types, a phylogenetic tree establishing the degree of relatedness among these types has been generated[10]. Two general, the α- and β-papillomaviruses, encompass almost all known HPV types, with the genus α containing mucosal and cutaneous HPV types that are pathogenic in normal hosts and the genus β containing the types associated with EV; γ, μ, and ν genera contain additional cutaneous types. Within each genus, HPV types are grouped according to sequence homology into species, which often share similar biologic and pathologic properties (e.g. HPV-16 and -31). Present models postulate that HPVs co-evolved with our human ancestors and novel HPV types or variants were generated through either genetic drift or natural selection via adoption of specialized ecologic niches. Genetic recombination between HPV types does not occur.

Virology

Papillomaviruses are non-enveloped, double-stranded DNA viruses ~55–60 nm in diameter[9]. The spherical capsid is composed of two virally encoded proteins: the major structural protein L1 and the minor structural protein L2. During virion assembly within cells, L1 proteins form pentamers called capsomeres, and 72 capsomeres multimerize to form the viral capsid with an icosahedral symmetry arranged on a $T = 7$ surface lattice. The capsid surrounds the viral DNA, thereby protecting it from degradation, and it also enables the virus to bind efficiently to target cells. Packaged viral DNA is associated with L2 and cellular histones, forming a mini chromosome. In contrast, the early (E) viral proteins are not incorporated into infectious virions.

When expressed in cell culture, the L1 major capsid proteins of papillomaviruses self-assemble into VLPs that are morphologically similar to native virions (Fig. 79.1)[3]. Papillomavirus VLPs display type-restricted and neutralization epitopes that are used to detect serum antibodies and as the basis for prophylactic vaccines (see below)[4,29].

The HPV genome, ~8 kilobases (kb) in length, is composed of three domains: the upstream regulatory region (URR), the early region, and the late region (Fig. 79.2). The URR, ~1 kb in length, lacks open reading frames (ORFs) and contains the origin of replication and many of the control elements for transcription and replication. The early region, ~4 kb in length, contains the ORFs for genes expressed early in the papillomavirus life cycle. The late region, ~3 kb in length, encodes the capsid proteins (see above)[9].

Papillomavirus Life Cycle

The papillomaviruses are highly species-specific, and productive infection has not been observed outside natural host tissue. The papillomavirus life cycle is completed only in fully differentiated squamous epithelia. This has impeded its study in monolayer tissue culture cells, where late gene expression and virion production do not occur. Only

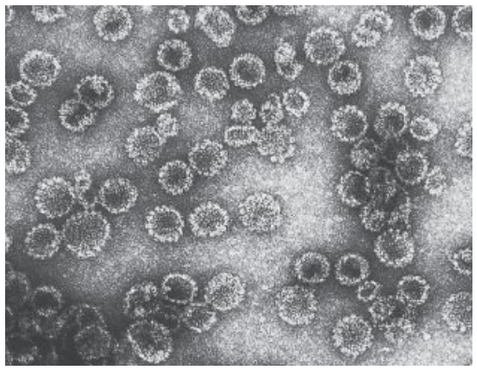

Fig. 79.1 Transmission electron photomicrograph of purified HPV-16 virus-like particles (VLPs). A prophylactic vaccine that contains HPV-6, -11, -16, -18, -31, -33, -45, -52, and -58 VLPs has been approved for the prevention of anogenital warts and cancers. Following expression in cell culture, the L1 capsid protein self-assembles into VLPs (empty capsids ~50 nm in diameter devoid of HPV DNA) that display type-restricted and neutralization surface epitopes similar to native virions. *Courtesy Saeed Shafti-Keramat.*

a small number of HPV types have been successfully propagated in mouse xenograft or raft culture systems, and limited amounts of infectious virions have been generated[9].

Productive infection and induction of hyperproliferation are initiated when the virus enters proliferating basal epithelial cells (Fig. 79.3). This layer of cells is not normally accessible to the virus because of the mechanical barrier provided by the overlying differentiated cell layers. Therefore, it is likely that infection requires an abrasion or other trauma to the epithelium to expose the basal cells to the virus. Our knowledge about early steps of infection such as viral entry and uncoating is limited. The receptor(s) that mediate virus binding to epithelial cells have not been definitively identified, but binding appears to depend on the L1 major capsid protein, and cell surface and/or basement membrane heparan sulfate is necessary for efficient infection *in vitro*[30,31]. The amino terminus of the L2 minor capsid protein is then cleaved by furin (a proprotein convertase), which exposes both a cross-neutralization epitope on L2 and a binding site (thought to be on L1) that facilitates viral entry via a putative secondary receptor on keratinocytes[31,32]. Upon infection, the covalently closed circular DNA genome becomes established as a low-copy autonomous replicon in the nuclei of basal cells, thereby creating a long-term reservoir of viral DNA.

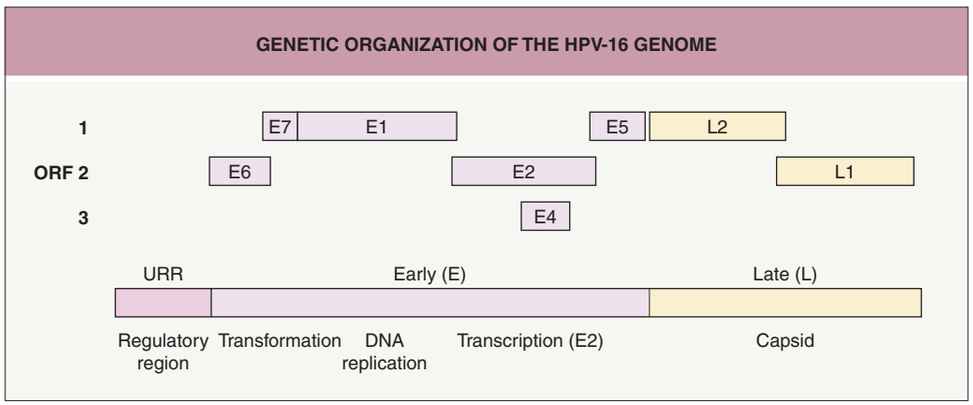

Fig. 79.2 Genetic organization of the HPV-16 genome. This is a linearized map of the 7.9 kb circular double-stranded genome. All open reading frames (ORFs) reside on one strand. Early (E) and late (L) regions are indicated. The upstream regulatory region (URR) contains the origin of replication and control elements for transcription and replication.

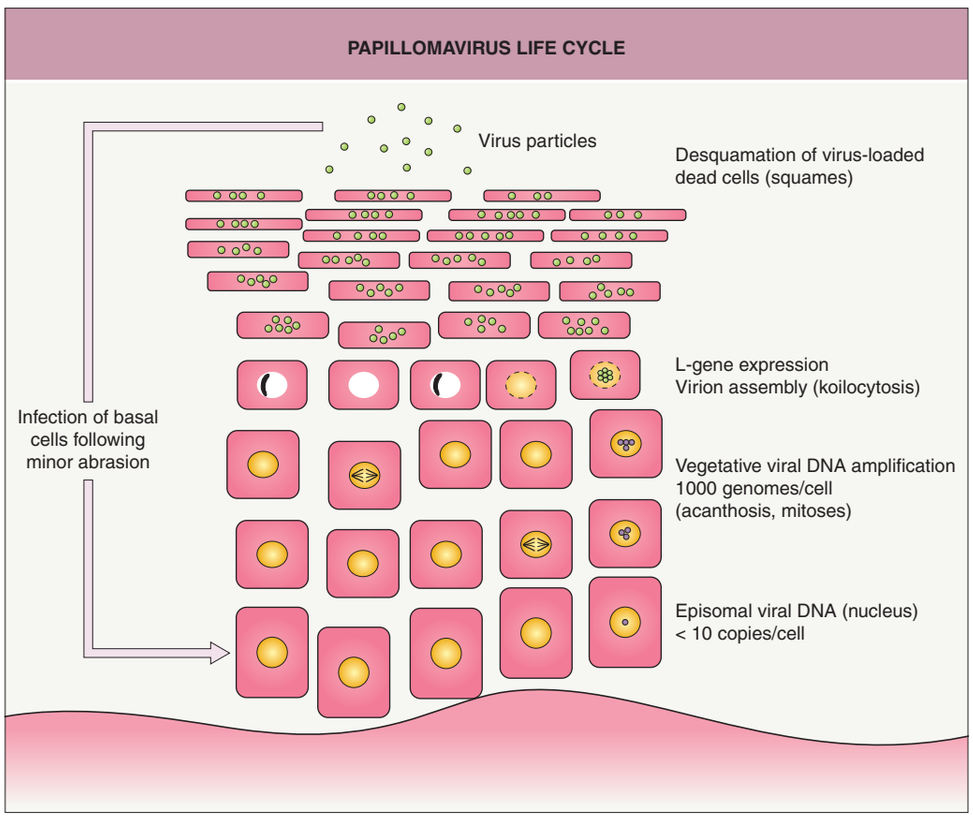

Fig. 79.3 The papillomavirus life cycle. The figure depicts a productive (virion-producing) benign wart. *Adapted from Orth G. Epidermodysplasia verruciformis. In: Salzman NP, Howley PM (eds). The Papovaviridae: Volume 2 The Papillomaviruses. New York: Plenum Press; 1987:199–243.*

The program of viral gene expression is intimately linked to the differentiation state of the infected cells. The E genes are transcribed at low levels in the basal cell layer and spinous layer. The first genes to be expressed following infection are the E1 and E2 genes, which are responsible for controlling the transcription of other viral genes and replication of the viral genome. HPVs do not encode the enzymes required for transcription or replication of viral DNA. Consequently, HPV is entirely dependent on the co-opting of cellular machinery for these functions. One major effect of HPV proteins E5, E6, and E7 is that the epidermal cell cycle, which is normally blocked for cells that are suprabasal, continues so that HPV genome copy number can be amplified to high levels during vegetative viral replication for assembly into virions (see Fig. 79.3). The E6 and E7 proteins of the high-risk mucosal HPV types act as viral oncoproteins, but no such functions are associated with the corresponding proteins of the low-risk mucosal and EV types[9]. There is limited understanding of possible differences between oncogenic (e.g. HPV-5, -8) and the non-oncogenic β HPV types.

In combination with other cellular proteins, E6 from high-risk mucosal HPV causes the ubiquitin-mediated degradation of the cellular protein p53. Elevated levels of p53 arrest cells in the G1 phase of the cell cycle or induce apoptotic cell death, so that E6-facilitated destruction of p53 removes a brake on suprabasal cell cycling. One of the principal effects of high-risk mucosal HPV E7 is to bind to the underphosphorylated form of RB (the retinoblastoma tumor suppressor protein). A physiologic role of underphosphorylated RB is to bind to and inhibit the function of the E2F transcription factor (see Fig. 107.4). When HPV E7 binds RB, E2F is liberated from this inhibition and is thereby able to induce the expression of genes required for DNA replication. Both E6 and E7 are multifunctional proteins, and while their effects on p53 and RB are critical ones, additional targets are also important to the oncogenic potential of the virus. These include activation of telomerase by E6, binding of histone deacetylases by E7, and synergistic effects of both proteins that lead to centrosome abnormalities and chromosomal instability[9].

The genes for the virion structural proteins, i.e. the late (or L) genes, are expressed in the terminally differentiated superficial layers of the epithelium. The more superficial epithelial layers also have higher levels of expression of E1 and E2 and amplification of viral DNA. The amplified genomes are encapsulated by the L1 and L2 capsid proteins to generate infectious virions, and virus particles are observed in the granular layer of the epithelium and above. Virus assembly is not believed to lyse the cells; instead, the virus is shed with the cornified layer as cells slough from the epithelial surface (see Fig. 79.3). E4 proteins are hypothesized to disrupt the intracellular filamentous network of keratinocytes, which may facilitate virus release from the corneocytes[9].

Host Immune Response

Persistent papillomavirus infections are common, indicating that HPVs have evolved mechanisms to evade immune surveillance. There is no viremic phase during the life cycle, so a systemic immune response is avoided. In addition, low levels of viral proteins are expressed in the basal and spinous cell layers of the epidermis, where they would be most likely to be recognized by Langerhans cells and infiltrating lymphocytes. Only in the more immunologically privileged terminally differentiated layers is there extensive production of virion proteins, with shedding of infectious virus exclusively from the external epithelial surface[9]. Despite the relative success of papillomaviruses in evading immune responses, up to two-thirds of cutaneous warts spontaneously regress within 2 years, and lesions of multifocal infections often regress concomitantly. There is also an increased prevalence of warts in patients with suppressed cell-mediated immunity. In contrast, patients with underlying defects in humoral immunity do not seem to be predisposed to HPV infections, suggesting a primary role of cell-mediated responses.

Although low amounts of virion capsid proteins are produced in the lower epidermal cell layers, serum antibodies specific to conformational virion epitopes of high-risk HPV-16 can be detected in more than half of women with low-grade or asymptomatic genital HPV-16 infections[33]. It is unknown if these antibodies play a role in limiting reinfection with the same type from autoinoculation or from an infected sexual partner.

Latent HPV infections are defined as persistence of HPV DNA in clinically and cytologically normal epithelium. However, it is difficult to distinguish true viral latency from persistent infection with a low level of DNA replication. The mechanisms by which HPV enters into and is activated out of latency are unknown[9].

Oncogenic Potential of HPV

Different HPV types have markedly different oncogenic potentials. The vast majority of cervical cancers, for example, contain the sequences of one of five HPV types: 16, 18, 31, 33, or 45[34]. In contrast, infection with HPV-6 or -11 occurs commonly in benign or low-grade intraepithelial lesions but is very rarely associated with the development of anogenital malignancies. HPV-5 and -8 DNA sequences are frequently detected in SCCs associated with EV.

Progression of HPV-associated cervical lesions to invasive cancer typically requires several decades. Both persistent HPV infection and the accumulation of additional genetic mutations are required in the current model of multistage carcinogenesis[9]. Integration of the viral genome randomly into the host DNA is a common event, invariably leading to loss of E1 and E2 expression. In HPV-16 and -18, E2 functions to repress the transcription of E6 and E7 genes. Therefore, integration is thought to increase expression of E6 and E7, which are selectively retained and expressed at elevated levels in carcinomas, suggesting a critical role for oncogenic progression (see above)[9].

Differences in the activities of E6 and E7 genes between oncogenic and non-oncogenic HPV types principally account for the different risk of progression. E6 and E7 proteins derived from high-risk HPV types (e.g. 16 and 18) degrade p53 and interact with RB (respectively) with greater efficiency than do E6 and E7 proteins from low-risk types (e.g. 6 and 11)[9]. Degradation of p53 by E6, which eliminates from infected cells the principal "guardian of the genome" (the protein responsible for cell cycle arrest in the presence of damage to cellular DNA), can lead to the accumulation of genetic mutations in infected cells. Thus, carcinogenic progression appears to be promoted or facilitated by increased E6 and E7 expression as well as by activity of external carcinogens, resulting in genomic instability[9].

CLINICAL FEATURES

Cutaneous and mucosal HPV types form two distinct groups that infect either skin or mucosa. However, viral tropism is not absolute, as DNA of skin types may be found in genital or oral warts, and in rare cases, mucosal types may be associated with skin lesions. Clinical manifestations depend on the HPV type involved, the anatomic location, and the immune status of the host (Table 79.1).

Cutaneous Infections

Cutaneous HPV types comprise a small group of viruses that infect the skin and induce common warts (Latin *verrucae vulgares*; singular *verruca vulgaris*), palmar and plantar warts (*verrucae palmares et plantares*), mosaic warts, flat warts (*verrucae planae*), and butcher's warts (see Table 79.1). In general, classification of warts is based on morphology, histology, and anatomic location.

Common warts are hyperkeratotic, exophytic, dome-shaped papules or plaques that are typically associated with HPV-1, -2, -4, -27, or -57. These warts are most frequently located on the fingers and dorsal surfaces of the hands (Fig. 79.4 & 79.5) or in other sites prone to trauma such as the knees or elbows, but they may occur anywhere on the skin surface. Involvement of the proximal nail fold and/or ablative therapy at that location may destroy the matrix, resulting in onychodystrophy (see Fig. 79.5). Characteristic features of common warts are punctate black dots representing hemorrhage into the stratum corneum (Fig. 79.6). Autoinoculation by scratching may cause a linear arrangement of warts. Slender, exophytic filiform warts can also develop, especially in periorificial locations on the face (Fig. 79.7). Numerous verrucae can be observed in immunocompromised patients and rarely they are eruptive when the immunosuppression is drug-induced.

Palmar and plantar warts appear as thick, endophytic papules on the palms, soles, and lateral aspects of the hands and feet, with gently sloping sides and a central depression resembling an anthill (hence the term *myrmecia*, meaning anthill). On the soles, these are often painful from pressure when walking, due to their deep inward growth (Fig. 79.8). Plantar warts that coalesce into large plaques are referred to as *mosaic warts* (see Fig. 79.8). Extensive chronic verrucosis that

is notoriously resistant to therapy has been observed in immunocompromised individuals, and, at times, in patients with no apparent immune dysfunction (Fig. 79.9). Inclusion warts of the sole are plantar cysts from which HPV types 4, 60, 63, and 65 have been isolated[35]. In studies from Europe, HPV-1 and the closely related types HPV-2, -27, and -57 caused the majority of palmoplantar warts, and they occurred most commonly in patients 6–10 years of age[36,37]. Although a higher incidence of HPV-2-related warts was reported in atopic children, other investigators have failed to find such an association.

Flat warts are skin-colored or pinkish to brown, relatively smooth-surfaced, slightly elevated, flat-topped papules that are most commonly located on the dorsal hands, arms, or face, often in a linear array (Fig. 79.10). They are usually caused by HPV-3 or -10, and less often by HPV-28 and -29.

Butcher's warts, which earn their name from their occurrence in meat- (or fish-) processing professionals, appear as extensive verrucous papules or cauliflower-like lesions on the dorsal, palmar, or periungual aspects of the hands and fingers. These warts are associated with HPV-7 not animal papillomaviruses.

Fig. 79.5 Periungual common warts. Destruction of the nail matrix and bed can lead to partial (**A**) or complete (**B**) absence of the nail plate. Bowen disease may be considered in the differential diagnosis, especially for a single, recalcitrant digital wart.

Fig. 79.6 Verrucae plantares (plantar warts). The photo was taken after shaving of the hyperkeratotic surface; the black dots represent hemorrhage into the stratum corneum.

Epidermodysplasia verruciformis (EV), first described in 1922 by Lewandowski and Lutz, is a rare genetic disease. It is characterized by a particular susceptibility to cutaneous infections with HPV types in the genus β (see above), which do not produce clinical lesions in immunocompetent individuals[38]. The disease usually manifests in childhood with highly polymorphic, widespread lesions. About two-dozen specific HPV types have been described in EV patients, a subset of which (mainly types 5 and 8) is also detected in EV-associated skin cancers. EV typically has an autosomal recessive pattern of inheritance and is caused by truncating mutations in two genes, *TMC6 (EVER1)* and

Fig. 79.7 Multiple filiform warts on the lower face.

Fig. 79.8 Myrmecial wart. The wart at the base of the distal phalanx of the hallux is painful due to deep endophytic growth; in addition, there are confluent plaques of superficial warts (mosaic warts).

Fig. 79.9 Extensive and chronic verrucosis of the soles in a patient with hepatic cirrhosis due to alcoholism. HPV-27 DNA was isolated from the lesions.

TMC8 (EVER2), that encode transmembrane proteins localized to the endoplasmic reticulum[39]. These proteins form a complex that interacts with the zinc transporter 1 (ZnT1) and affects intracellular zinc distribution, down-regulating zinc-associated transcription factors[40]. Inhibition of ZnT1-TMC6/8 function by the HPV E5 protein is thought to facilitate viral infection; β HPV types lack E5, but they become pathogenic in EV patients with TMC6/8 defects[40].

Patients with EV present with widespread, discrete, or confluent papules that resemble flat warts (Fig. 79.11A); scaly, pinkish, or hypopigmented guttate macules and thin plaques that resemble pityriasis versicolor represent another characteristic finding (Figs. 79.11B & 79.12). In an individual patient with EV, warts that appear clinically distinct often contain different HPV types, and each skin lesion usually contains several HPV types. Actinic keratoses usually arise after the age of 30 years and slowly transform into invasive SCCs in approximately half of EV patients. These tumors have low metastatic potential and develop primarily in sun-exposed areas such as the forehead, ears, and hands, implicating UV irradiation as an important co-carcinogen. Patients with EV should be educated about the importance of minimizing sun exposure, and family members should be screened for the presence of similar lesions.

It may be difficult to differentiate flat warts from EV-associated lesions based on histology alone (see below), but the presence of lesional β HPV DNA (e.g. HPV-5, -8, etc.) can establish the diagnosis in an otherwise healthy individual. Beta HPV types can also induce a sporadic EV-like eruption in immunosuppressed patients, including transplant recipients and those with AIDS or a lymphoma. Of note, efflorescence of HIV-associated acquired EV has been observed following the second dose of the quadrivalent HPV vaccine.

In addition, β HPV sequences have been isolated from the normal skin of healthy individuals by highly sensitive DNA detection methods, indicating that the general population acts as the reservoir for these HPV types. There is increasing epidemiologic and biologic evidence that β HPV types may play an adjunct role in the initiation, but not maintenance, of SCCs in immunosuppressed patients[41].

WHIM syndrome is a rare, autosomal dominant primary immunodeficiency disorder characterized by HPV-induced *w*arts (cutaneous and genital), *h*ypogammaglobulinemia, recurrent bacterial *i*nfections, and neutropenia due to *m*yelokathexis (retention of mature neutrophils in the bone marrow) (see Ch. 60). It is caused by mutations in the gene encoding the chemokine CXC receptor 4 (CXCR4), which result in impaired leukocyte trafficking and homing[42].

Several other primary immunodeficiencies are associated with severe HPV infection including DOCK8 deficiency, GATA2 deficiency (MonoMAC), hyper IgM syndrome, and idiopathic $CD4^+$ lymphopenia (see Table 60.1)[43].

Mucosal Infections

More than 40 HPV types preferentially infect the mucosa of the anogenital and upper aerodigestive tracts. Subclinical infections are much more common than visible warts. Application of 5% acetic acid (aceto-whitening) may aid in the identification of subclinical lesions as white areas.

Condylomata acuminata (singular: *condyloma acuminatum*), or anogenital warts, are found on the external genitalia and the perineum, perianally, or in adjacent areas such as the inguinal fold and mons pubis. Lesions may extend into the vagina, urethra, or anal canal (but rarely beyond the dentate line). Condylomata are typically discrete, sessile, smooth-surfaced exophytic papillomas or acuminate warts and may be skin-colored, brown, or whitish (especially when macerated in moist areas) (Fig. 79.13). They lack the thick cuirass of horny scale present on cutaneous warts and frequently measure one to several millimeters in diameter. Condylomata may also present as pedunculated or broad-based papillomas up to several centimeters in diameter or as large confluent plaques (Fig. 79.14). *Condylomata plana*, or flat cervical warts, may be difficult to recognize without aceto-whitening and the use of a (magnifying) colposcope. High-grade intraepithelial neoplasias are usually caused by high-risk types, mainly HPV-16, -18 and -31, whereas low-grade lesions may contain low-risk as well as high-risk HPV types.

Bowenoid papulosis manifests as multiple red–brown papules or confluent plaques on the external genitalia, on the perineum, or perianally (Fig. 79.15 & 79.16; see Fig. 73.13). These lesions primarily

Fig. 79.10 Verrucae planae (flat warts). Multiple skin-colored or pink (**A, B**) to brown (**C**) smooth-surfaced, flat-topped papules. (**D**) Thin pink papules and plaques that are well demarcated and have more scale than the patients in A-C. These lesions are typically caused by HPV-3 or -10. *B, Courtesy Kalman Watsky, MD; C, Courtesy Julie V. Schaffer, MD.*

Fig. 79.11 Epidermodysplasia verruciformis (EV). A Confluent scaly papules and plaques resembling flat warts. **B** Numerous hypopigmented and light pink, flat-topped papules, some of which are in a linear array, in acquired HIV-associated EV. *B, Courtesy Ncoza Dlova, MD.*

affect young adults and may clinically resemble genital warts, but histologically represent a high-grade squamous intraepithelial lesion (HSIL) or SCC *in situ*[44]. *Erythroplasia of Queyrat* is a distinct clinical entity, presenting as a well-demarcated, velvety erythematous plaque on the glabrous skin of the penis, vulva, or perianal region that histologically is an HSIL (Fig. 79.17). A biopsy is warranted for pigmented, erosive, bleeding, and/or therapy-resistant genital lesions to exclude malignancy. *Bowenoid papulosis* and *erythroplasia of Queyrat* contain high-risk HPV types, predominantly HPV-16, and may thus represent a precursor lesion of vulvar, penile, or perianal cancer. As noted above, these entities can represent variants of SCC *in situ*.

Buschke–Löwenstein tumor (giant condylomata acuminata), *oral florid papillomatosis of Ackerman* (oropharyngeal), *epithelioma cuniculatum* (plantar), and *papillomatosis cutis carcinoides of Gottron* (cutaneous) are types of "low-grade-malignant" verrucous carcinomas that have been associated with HPV infection. Verrucous carcinomas

Fig. 79.13 Condylomata acuminata. Verrucous lesions on the glans and in the sulcus, with a few small papules on the shaft of the penis and distal glans. Note the acuminate topography, i.e. the tapering to a point. *Courtesy Lorenzo Cerroni, MD.*

A depigmented scar is seen at the site of prior treatment with liquid nitrogen. **B** Large, exophytic, broad-based or pedunculated papillomas in a healthy 15-year-old boy. The differential diagnosis includes Buschke-Löwenstein tumor.

Fig. 79.15 Bowenoid papulosis of the vulva with histopathologic features of vulvar intraepithelial neoplasia (VIN). Extensive red–brown or whitish papules and plaques containing high-risk mucosal HPV in an HIV-positive patient. Analogous high-grade squamous intraepithelial lesions (HSIL) were present perianally (AIN) and on the cervix (CIN).

Fig. 79.16 Bowenoid papulosis of the anus positive for high-risk mucosal HPV in a man who had sex with men. Histology revealed high-grade anal intraepithelial neoplasia (AIN), not invasive SCC. However, continued monitoring is indicated.

are locally invasive and destructive but rarely metastasize[45] (see Ch. 108). Buschke–Löwenstein tumor is a rare neoplasm of the anorectal area and external genitalia associated with the low-risk HPV types 6 or 11 that usually cause condylomata acuminata. The basis for the difference in biologic behavior between these two entities has not been established. In rare cases, pre-existing anogenital condylomata may progress into large exophytic cauliflower-like tumor masses that infiltrate deeply into underlying tissues and form fistulas and abscesses (Fig. 79.18). The histology of the Buschke–Löwenstein tumor may appear remarkably benign and resemble that of condylomata acuminata (Fig. 79.19), but its architecture is more irregular, the epithelium is more hyperplastic, and the pattern of growth is at least focally infiltrative. Focal frank malignant transformation can occur spontaneously or following X-irradiation. High-resolution imaging and a large biopsy are essential for identifying the extent of the infiltration and foci of SCC. Radical surgery may cure the disease, but recurrences are frequent, resulting in a high morbidity rate.

Oral warts appear as small, soft, pink or white, slightly elevated papules and plaques on the buccal, gingival, or labial mucosa (Fig. 79.20),

the tongue, or the hard palate. Oral condylomata are associated with HPV types 6 and 11 and may result from digital or oral–genital sexual transmissions. In HIV-positive patients, oral papillomas are frequently detected and may contain unusual HPV types such as 7, 71, 72, and 73. In *focal epithelial hyperplasia*, or *Heck disease*, multiple circumscribed papules resembling flat warts or condylomata are found on the gingival, buccal, or labial mucosa. This disorder is rare in White individuals but relatively common in children who are native South Americans, native Greenlanders, or from South African communities. It is associated exclusively with HPV-13 or -32.

HPV (especially type 16) is a causative agent in about 25% of head and neck cancers, including the majority of oropharyngeal cancers that arise from the base of tongue and palatine tonsils. HPV-positive oropharyngeal cancers can develop irrespective of exposure to tobacco[46]. Although poorly differentiated histopathologically, they appear to have a better prognosis than HPV-negative oropharyngeal cancers whose primary risk factor is tobacco ± alcohol use[47].

In *oral florid papillomatosis*, multiple, confluent warty lesions are found in the oral cavity or the nasal sinuses. They are associated with HPV-6, -11, -16, and/or -18 in approximately half of cases. The development of these lesions is believed to be promoted by smoking, X-irradiation, and chronic inflammation. Patients with oral papillomas need frequent examinations and repeated biopsies for early diagnosis of progression to verrucous carcinoma.

In *recurrent respiratory papillomatosis* (RRP), there are benign exophytic laryngeal papillomas caused by HPV-6 and -11[28]. Patients classically present with a triad of hoarseness, stridor, and respiratory distress. Papillomas arise most often at the transition zones between the squamous and cilia-bearing epithelia of the larynx and subglottis, but they may rarely extend to the distal trachea, the bronchi, or even the bronchoalveoli. Malignant transformation of laryngeal papillomas into SCCs in patients with long-lasting disease has been reported, and exogenous factors such as X-irradiation, smoking, chemical toxins, or chemotherapy have been implicated as co-carcinogens.

PATHOLOGY

The histopathologic changes induced by HPV infection are variable, reflecting the myriad clinical presentations and different anatomic sites. In productive HPV infections, a common motif in epithelial cells

is the presence of cytoplasmic vacuoles isolating the nucleus from the cytoplasmic membrane. Cells with this distinctive vacuolization are referred to as koilocytotic (hollow) cells, and the presence of koilocytosis is a useful feature that distinguishes verrucae from other types of papillomas[48].

Common and Deep Palmoplantar Warts

Common warts are well circumscribed from the surrounding skin and characteristically have steeply sloping "church spire" papillomatosis heaped with ortho- and parakeratosis (Fig. 79.21). Parakeratosis is most commonly observed directly overlying the summits of the papillomatosis and is often accompanied by small intracorneal hemorrhages. There is also marked acanthosis and the rete ridges are elongated. In palmoplantar warts, the lateral edges of the wart bow inward to create a cup-shaped invagination below the papillomatosis. Higher-power examination reveals hypergranulosis and condensed coarse cytoplasmic keratohyalin-like granules of variable size and shape within the granular layer, along with vacuolization of cells on top of, or sometimes between, the papillae. Koilocytosis is typically observed in or immediately below the granular layer. The papillary dermis underlying the elongated rete ridges has minimal pathologic changes; increased vascularity can be observed.

Flat Warts

The characteristic features of flat warts include orthokeratosis alternating with parakeratosis, acanthosis, no or minimal papillomatosis, a uniformly thickened granular layer, and vacuolization of cells in the granular and upper spinous layers (termed "bird's eyes")[48].

Some patients with flat warts develop clinically evident inflammation around these warts, which may precede their spontaneous involution. Characteristic histologic features of regressing flat warts include parakeratosis, spongiosis, exocytosis of mononuclear cells into the lower epidermis, and (occasionally) satellite cell necrosis. By immunohistochemistry, T helper cells predominate and HLA-DR antigen, a marker of immune activation, is detected on the surface of the infiltrating lymphocytes and on some keratinocytes. Many of these changes can also be observed in regressing condylomata, suggesting that wart regression is mediated, at least in part, by a delayed-type hypersensitivity-like cellular immune response directed against keratinocytes expressing wart antigens[49].

Epidermodysplasia Verruciformis

In patients with EV, the flat warts and pityriasis versicolor-like lesions exhibit orthokeratosis with a basket-weave appearance, parakeratosis, and acanthosis. Under higher power, some cells within the hyperplastic spinous layer have characteristic cytopathic changes. These cells are large with perinuclear halos and a cytoplasm that has blue–gray pallor and contains keratohyaline granules of various sizes and shapes (Fig. 79.22). Keratinocytic dysplasia and actinic keratoses may be evident, especially in biopsies of lesions from sun-exposed areas[48]. Because the histologic picture is nonspecific, it may be difficult to differentiate typical flat warts from EV-associated lesions based on histology alone.

Anogenital Warts

The most consistent histologic features seen in condylomata include epidermal hyperplasia, parakeratosis, koilocytosis, and papillomatosis. The papillomatosis is more gently rounded than is seen in common warts. The upper portions of the epithelia of mucosal surfaces normally have some degree of cytoplasmic vacuolization, so its detection is specific for condylomata acuminata only if present within the deeper portions of the spinous layer[48]. Mitotic figures may be evident, and prior treatment with podophyllotoxin (which interferes with microtubule formation in cells undergoing mitosis) can induce the appearance of atypical mitoses that could potentially lead to misdiagnosis as SCC.

Giant Condylomata of Buschke–Löwenstein

The histology of the Buschke–Löwenstein tumor shares many features with condylomata acuminata, but there is more evident irregular epithelial hyperplasia, with marked downward extension of characteristically bulbous rete ridges, and less vacuolization of epidermal cells (see Fig. 79.19). Mitotic figures are rarely detectable, and, when present, are normal. While usually associated with extension into and destruction of local tissue, metastases to local lymph nodes from foci of SCC arising in these tumors have been reported[45].

Squamous Intraepithelial Neoplasias

Persistent infection with high-risk HPV types can lead to intraepithelial neoplasia that may progress to invasive carcinoma. The precancerous lesions represent a continuum of morphologic changes with indistinct boundaries. In CIN grade I, nuclear enlargement and hyperchromasia is observed in the lower epithelial layers; these changes may be accompanied by cytoplasmic halos (koilocytotic atypia). The next stage (CIN II) shows progressive atypia in all layers of the epithelium, with abnormal differentiation of the keratinizing cell layers. The atypical cells have an increased nuclear–cytoplasmic ratio, variability of nuclear size, and an increased number of mitotic figures, including abnormal mitoses and hyperchromasia. In CIN III, the epithelium is totally replaced by immature, atypical cells

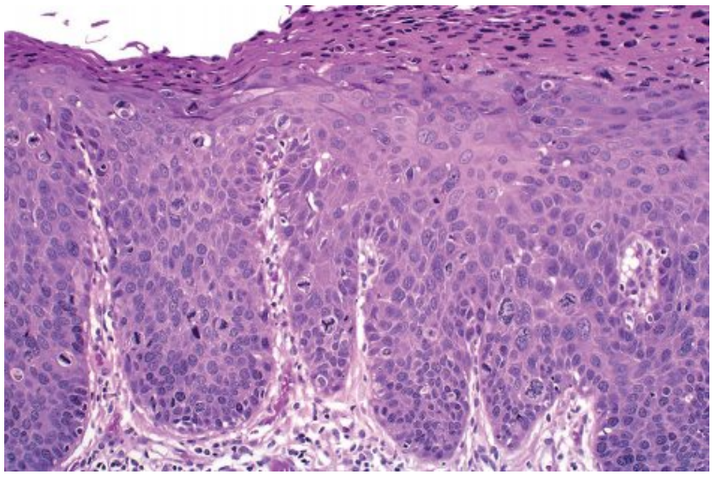

Fig. 79.23 Vulvar intraepithelial neoplasia (VIN) – histopathologic features. Note the characteristic features of abnormal keratinocyte maturation, nuclear pleomorphism, and dyskeratosis. Koilocytosis, due to cytoplasmic vacuoles that isolate the nucleus from the cytoplasmic membrane, can be observed in or immediately below the granular layer. Some pathologists refer to these intraepithelial neoplasias as SCC *in situ*. *Courtesy R. Tyler, MD.*

with a lack of surface differentiation. The analogous lesions of the vulva, vagina, penis, and anus are termed VIN (vulvar intraepithelial neoplasia; Fig. 79.23), VaIN (vaginal intraepithelial neoplasia), PIN or PeIN (penile intraepithelial neoplasia), and AIN (anal intraepithelial neoplasia), respectively. Clinically, these may appear as erythematous or whitish plaques (erythroplasia, leukoplakia) or red–brown papules (bowenoid papulosis) (see Figs. 79.15–79.17). Terminology of these lesions remains a matter of debate, and many pathologists refer to these "intraepithelial neoplasias" as "SCC *in situ*".

DIFFERENTIAL DIAGNOSIS

The diagnosis of cutaneous and genital warts is straightforward if typical clinical features are present. Occasionally, various other diagnoses have to be considered and a biopsy may be required for confirmation and to identify dysplastic lesions. Immunohistochemistry with antibodies directed against cross-reacting epitopes of papillomavirus capsid proteins allows the detection of virions in palmoplantar warts, which are highly productive infections, but has limited sensitivity in genital warts and dysplasias. There is no routine infectivity assay available to detect virions in clinical samples, and diagnostic tests are therefore based on the molecular detection of papillomavirus DNA. Commercially available tests that utilize nucleic acid hybridization (e.g. *digene* Hybrid Capture® 2 [HC2] HPV DNA Test; Amplicor® HPV and Linear Array® HPV Genotyping Test, Roche [not available in the US]) can identify low-risk versus high-risk mucosal HPV types in clinical samples with high sensitivity and specificity. In routinely processed histologic sections, RNA *in situ* hybridization can also be performed utilizing pooled high-risk versus low-risk HPV subtypes. In addition, PCR-based techniques can detect a broad range of genital and skin HPV types[50,51]. Development of circulating antibodies against the L1 major capsid protein is common following infection with genital HPV types, and ELISAs using L1 VLPs as the antigen have been useful in epidemiologic studies[33]. However, due to low antibody titers and variable intervals between infection and seroconversion, this assay is not used for diagnosis in individual patients.

Common, Flat, and Palmoplantar Warts

Seborrheic keratoses (SKs), actinic keratoses (AKs), cutaneous horns (which can arise from warts as well as AKs, SCCs, SKs, and other neoplasms; see Ch. 109), keratoacanthomas, other SCCs, tricholemmomas, Spitz nevi, and amelanotic melanomas may resemble *common warts*, and even tuberculosis verrucosa cutis or a plaque of psoriasis, hypertrophic lichen planus, hypertrophic lupus erythematosus, or pseudoepitheliomatous tattoo reaction can have a warty clinical appearance. On the distal or lateral finger or periungually, a wart-like or erythematous, well-demarcated plaque may occasionally represent Bowen disease and harbor high-risk HPV types, e.g. 16 or 18. Similarly, amelanotic melanoma can masquerade as a persistent periungual or plantar wart and should be clinically suspected if erosion or subtle pigmentation is present. The differential diagnosis of *flat warts* may include acrokeratosis verruciformis, Gottron papules of dermatomyositis (distinguished by their localization over the knuckles), lichen nitidus, lichen planus, and lichenoid keratoses. Although lesions of both lichen planus and flat warts can have a linear array, the presence of Wickham striae points to the former diagnosis. Plantar clavi (corns) are often misdiagnosed as warts, although verruca can be differentiated by the presence of punctate black dots rather than a glassy appearance; in addition, paring of the keratotic wart surface leads to capillary bleeding from the superficially located dermal papillae. Punctate palmoplantar keratoderma, punctate porokeratosis, arsenical keratoses, poromas, and eccrine poromatosis can mimic plantar warts.

In patients with cellular immunodeficiencies, including organ transplant recipients and those with AIDS or hematologic malignancies, the number as well as incidence of cutaneous and genital warts is increased. Warts that appear at less common sites such as the face and the neck need to be differentiated from mollusca contagiosa. In immunosuppressed patients, macular and flat warts may resemble EV, but the clinical setting and absence of a family history can aid in establishing the correct diagnosis. Other heritable immunodeficiencies that predispose affected individuals to the development of warts include WHIM syndrome (see above), idiopathic $CD4^+$ lymphopenia, DOCK8 deficiency, hyper IgM syndrome, PI3Kδ syndrome, and GATA2 deficiency (MonoMAC) (see Ch. 60 & Table 60.1)[43].

Anogenital Lesions

Condylomata acuminata are rarely confused with condylomata lata of secondary syphilis, but serologic testing for syphilis (and, as indicated, other STIs) is recommended in patients with genital warts, and dark-field examination for spirochetes may be considered. Mollusca contagiosa preferentially involve the mons pubis and can be distinguished by their umbilication, with dermoscopy revealing a multilobular, yellow–white central structure surrounded by a "crown" of vessels. In men, pearly penile papules are normal anatomic structures consisting of several rows of discrete, monomorphic, dome-shaped, 1 to 2 mm papules circumferentially around the corona and/or sulcus of the glans penis (see Ch. 116). An analogous picture exists in women, called vestibular papillomatosis, with tiny, uniformly shaped, finger-like projections at the introitus and on the labia minora. Sebaceous glands of the prepuce and labia majora appear as white–gray to yellow, small papules with a regular array. Epidermoid cysts, steatocystomas, or angiokeratomas of the scrotum seldom pose diagnostic problems. Occasionally, verrucous herpetic infections may mimic genital warts.

Detection of subclinical genital HPV infection is facilitated by soaking with 5% acetic acid for 3 to 5 minutes; this leads to whitening ("aceto-whitening") of lesions, and the use of a colposcope for magnification will further increase diagnostic accuracy. However, aceto-whitening is not specific for HPV-induced lesions and is also observed in infectious or inflammatory conditions such as *Candida* vulvitis or balanoposthitis, psoriasis, lichen planus, and eczematous dermatitis.

Bowenoid papulosis consists of red–brown papules or confluent, sometimes leukoplakia-like plaques that may be difficult to distinguish from condylomata (see Fig. 79.15 & 79.16 and Ch. 73). *Erythroplasia of Queyrat* is a well-defined, velvety, erythematous plaque of the glans or vulva that must be differentiated from erosive lichen planus and Zoon balanitis. *Bowen disease* can present as a solitary patch or plaque, sometimes scaly, of the vulva or penis, most often in older individuals. *Extramammary Paget disease* appears as a well-defined red plaque in the groin or pubic region or on the vulva, penile root, or perianal skin, with distinctive histopathologic features (see Ch. 73).

Vulvar carcinomas are etiologically heterogeneous. Carcinomas with basaloid or warty histology are related to HPV infection, whereas keratinizing squamous carcinomas are not[52]. Basaloid and warty vulvar carcinomas typically arise in younger women, are found adjacent to vulvar intraepithelial neoplasia (VIN; also referred to as high-grade squamous intraepithelial lesion [HSIL]), and are associated with risk factors related to sexual practices. Close to 90% of high-grade VIN/HSIL and basaloid and warty vulvar carcinomas contain high-risk HPV DNA

Fig. 79.24 Invasive squamous cell carcinoma of the penis. It developed over more than a decade from a papular lesion of the prepuce. HPV-16 and -51 DNAs were detected by RT-PCR.

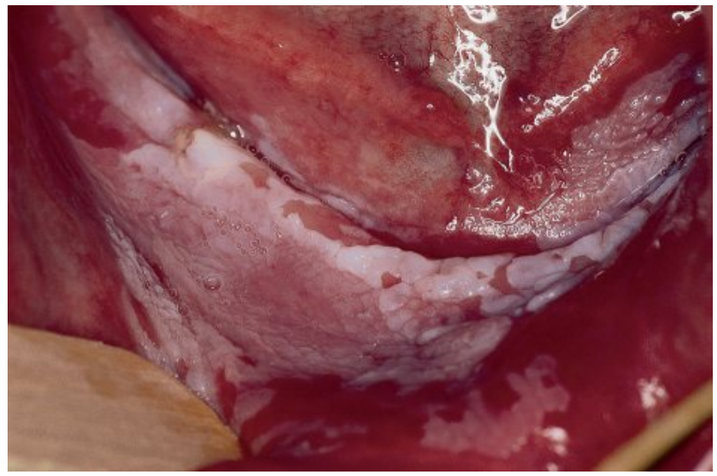

Fig. 79.25 Proliferative verrucous leukoplakia of the oral cavity. The lesions have focally progressed to invasive squamous cell carcinoma; HPV DNA was not detectable by PCR.

(most often HPV-16, but also HPV-31 and -33), suggesting a common etiology. In contrast, the more common keratinizing vulvar carcinomas in older women, which typically arise adjacent to lichen sclerosus and differentiated VIN, infrequently contain HPV DNA and thus are regarded as a distinct entity[53].

Although there is heterogeneity in anal SCC[53,54], in both sexes, the vast majority of anal cancers are attributable to HPV infection. Cancers of the anal canal that are positive for high-risk HPV (mostly HPV-16, but also HPV-18, -31, -33) tend to occur in younger men (especially MSM) and women with high-risk sexual behaviors, have basaloid histology, and arise adjacent to AIN. In contrast, HPV-negative anal cancers usually affect older men, are well keratinized, and arise from perianal skin without AIN. Heterogeneous etiology has also been described for penile cancer (Fig. 79.24), analogous to that observed for vulvar and anal SCCs[53]. Immunosuppression and a history of HPV-associated malignancy are notable risk factors for the development of a (second) anogenital cancer attributable to HPV.

Anogenital warts in children may give rise to suspicion of sexual abuse (see Ch. 90). Findings that make non-abusive transmission of HPV more likely include age <3 years, wart location somewhat distant from the anus or vulva, genital condylomata in the mother, and an absence of signs of physical abuse or of other sexually transmitted infections[17].

Giant condyloma acuminatum, or Buschke–Löwenstein tumor, is clinically suspected by its size and the presence of fistulas or abscesses (see Fig. 79.18). Histologic findings may be bland, and distinction from large benign genital warts can therefore be difficult at an early stage (see Fig. 79.19)[45,55]. However, high-resolution imaging reveals the extent of infiltration, and a large biopsy with serial sectioning may detect locally destructive growth and, rarely, transformed foci of SCC.

Oral Warts

Oral warts or condylomata may resemble the papules of focal epithelial hyperplasia (Heck disease); the latter is very rare in White individuals. A distinct oral condition with the descriptive name "proliferative verrucous leukoplakia" is clinically similar to oral florid papillomatosis but does not contain HPV DNA and has a high risk of progression to oral SCC (Fig. 79.25)[56]. Additional diagnostic considerations may include leukoedema (grayish-white translucent plaques, sometimes with a "moth-eaten" appearance, that favor the buccal mucosa and may become less evident upon stretching), white sponge nevus, and hereditary benign epithelial dyskeratosis.

MANAGEMENT OF ANOGENITAL WARTS WITH GRADING OF RECOMMENDATIONS
Patient-applied therapy (avoiding non-involved skin)
• Podophyllotoxin 0.5% solution, 0.5% gel, 0.15% cream* [BID for 3 days then discontinue for 4 days, up to 4 treatment cycles; ≤10 cm^2] (1) • Imiquimod 5% cream [6–10 hours 3 times/week, up to 16 weeks] (1) • Imiquimod 3.75% cream [once daily, up to 8 weeks] (1) • Sinecatechins 10%* or 15% ointment [TID, up to 16 weeks] (1)†
In-office therapies
• Cryotherapy (liquid nitrogen spray, cryoprobe) (1) • Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80%–90% solution (1) • Electrosurgery (1) • Scissor or shave excision, curettage (1) • Laser vaporization (CO_2, PDL, Nd:YAG) (2) • Surgical excision (3)
Other considerations
When external anal or perianal warts are present, the possibility of intra-anal warts should be excluded, e.g. by anoscopy
*Not FDA-approved; available outside the USA. †Might weaken condoms and vaginal diaphragms.

Table 79.2 Management of anogenital warts with grading of recommendations. Based upon cases series, additional therapies include 5-fluorouracil 5% cream, topical (1%–3%) or intralesional (15 mg/ml) cidofovir, and photodynamic therapy. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports[58,83]. PDL, pulsed dye laser. BID, twice daily; TID, three times daily.

THERAPY

General Considerations

There is currently no specific antiviral therapy available to cure HPV infection. Existing modalities focus primarily on the destruction or removal of visible lesions or induction of cytotoxicity against infected cells (Table 79.2). Because of the benign and self-limited nature of warts, treatments that cause scarring should be avoided. There is no evidence that aggressive treatment results in a better long-term outcome, and temporary interruption of therapy is an option. Common warts often regress spontaneously in children and therefore may not require treatment. A simplified algorithm for the approach to treatment of cutaneous warts is presented in Fig. 79.26.

Genital warts may be disfiguring and pose a significant psychological burden. HPV infection is typically widespread and multifocal throughout the anogenital tract, and subclinical lesions are often present. Thus, regardless of the applied therapeutic modality, reported recurrence rates are high (25%–65%) and it is unproven whether treatment reduces

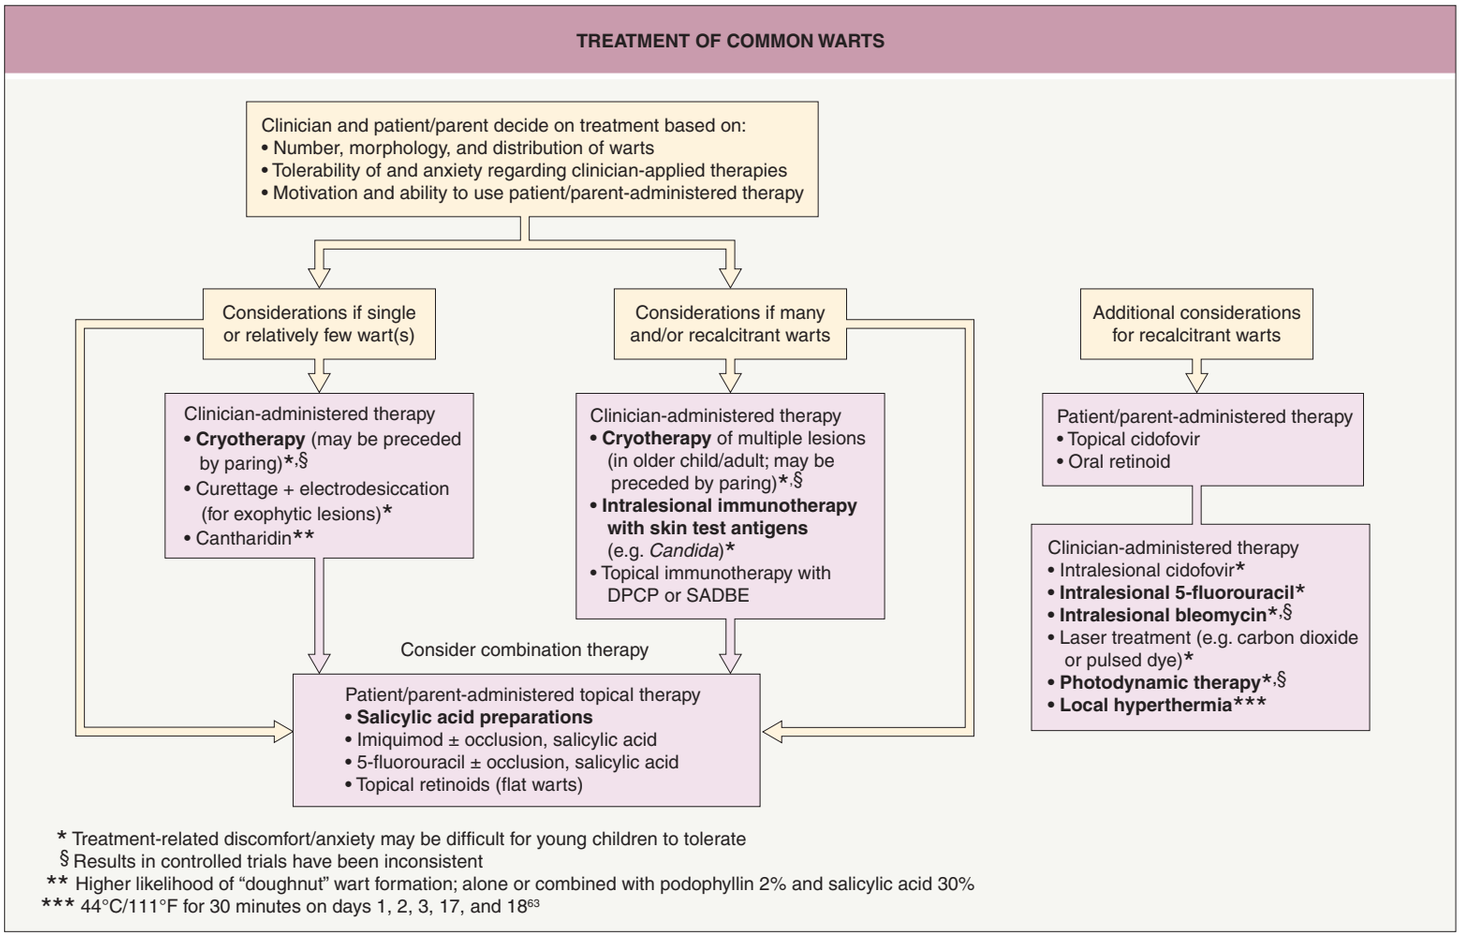

Fig. 79.26 Treatment of common warts. Therapies found to be effective in controlled trials are in **bold**. While still employed by some clinicians, three double-blind, placebo-controlled trials failed to confirm efficacy of cimetidine therapy for recalcitrant common warts. Topically, cidofovir is incorporated into an ointment, cream, or gel base at 1%–3% and intralesional cidofovir is diluted to 15 mg/ml saline. DPCP, diphenylcyclopropenone; SADBE, squaric acid dibutyl ester.

transmission rates to new sexual partners. Limiting the number of partners remains the mainstay of decreasing transmission. Condom use may also be helpful, and it has promoted regression of flat penile lesions and CIN as well as clearance of HPV in couples infected with the same HPV type[57]. Treatment is time-consuming, uncomfortable, and limited to visible warts and intraepithelial neoplasias with a high risk of progression. A simplified treatment algorithm is shown in Fig. 79.27. Current therapies for genital warts are summarized in Table 79.2 and include destructive, antiproliferative, and immunomodulatory modalities[58,59].

Local Destructive Therapy

Recommended destructive or ablative therapies for *genital warts* include cryotherapy, trichloroacetic acid (TCA) or bichloroacetic acid (BCA), electrosurgery, scissor or shave excision, curettage, laser vaporization, or excisional surgery. When anesthesia is required, topical application or injection of a local agent is usually sufficient (see Ch. 143), although general anesthesia may be indicated for surgical debulking of large lesions and occasionally in children. Ablative laser therapy is also useful for vaginal, vulvar, or anal intraepithelial neoplasias. Precautions should be taken to avoid inhalation of virus particles in the aerosol plume when laser or electrosurgical procedures are performed. Application of TCA 80%–90% solution is a commonly utilized office-applied therapy that results in local tissue destruction. Although scarring may occur following dermal injury, TCA has the advantage of a complete lack of systemic toxicity and it can be used during pregnancy.

Cryotherapy with liquid nitrogen is inexpensive, effective, safe during pregnancy, and usually does not require anesthesia; as a result, it is often used as a first-line in-office therapy for genital warts followed by patient-applied podophyllotoxin or imiquimod (see Table 79.2). Liquid nitrogen is applied with a cotton swab, spray gun, or closed system cryoprobe (see Ch. 138). Two freeze–thaw cycles, the extent of which is visually controlled, lead to wart necrosis and sometimes blistering. Multiple treatment sessions result in remission rates of 75% to 85%, with recurrences in 20%–40% of patients.

Cutaneous warts may be treated by daily application of salicylic acid/lactic acid/collodion (1:1:4), if possible with occlusion and after removing the thickened stratum corneum, or other salicylic acid preparations for 3–4 months; this results in regression in two-thirds of patients. Application of petrolatum to the surrounding normal skin protects against the corrosive effect of the concentrated acid. Weight pressure causes deep inward growth of plantar warts (myrmecia), and the resulting pain can be reduced by repeated shaving of the hyperkeratotic surface to a level at which capillary bleeding occurs. Cryotherapy with liquid nitrogen (see above) may be utilized for persistent or recurrent verrucae, including periungual lesions, with cure rates similar to or better than salicylic acid preparations in randomized controlled studies[60–64]. Other in-office or at-home freezing products (e.g. those containing dimethyl ether and propane) are less effective. Either cryotherapy that does not include a rim of surrounding skin or topical application of the blistering agent cantharidin (0.7% or 1%) may produce a "doughnut wart" due to clearance in the center but not at the periphery of the lesion. Additional destructive modalities include curettage or scissor excision (especially for filiform warts and other exophytic lesions), electrosurgery (see Ch. 140), and laser treatment (e.g. with CO_2, Nd:YAG, or pulsed dye lasers). Combination therapy with the application of topical agents following destruction may reduce the rate of recurrence.

Topical and Intralesional Cytotoxic Therapy

Podophyllin is a crude resin extract from the roots of the May apple *Podophyllum peltatum* (North America) or *Podophyllum emodi*

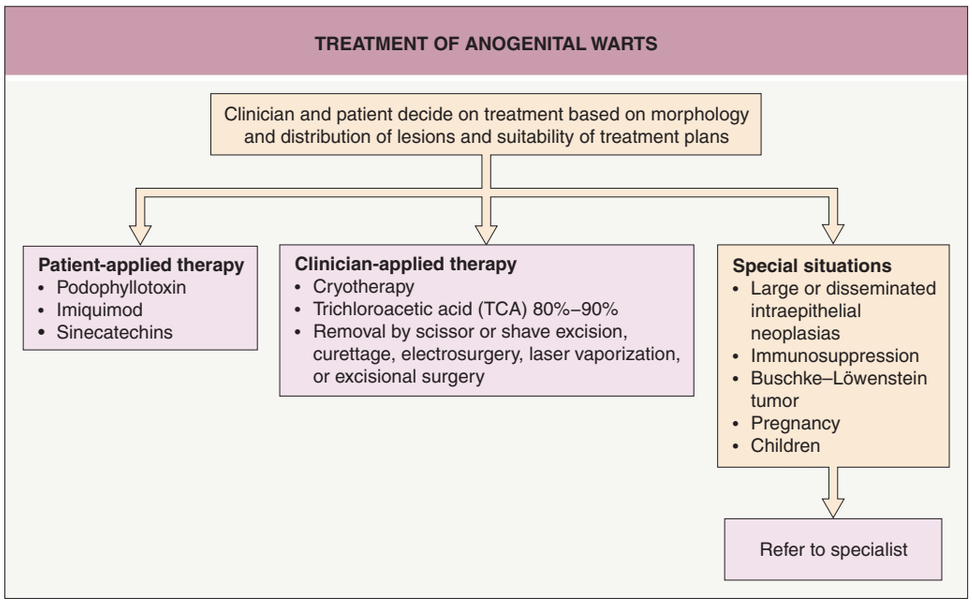

Fig. 79.27 Treatment of anogenital warts. See Table 79.2 for details of patient-applied therapies. TCA, trichloroacetic acid.

(Far East) that has been used since the early 1940s for the treatment of genital warts. Systemic toxicity can occur when applied in large volumes, and death, intrauterine demise, and teratogenicity have been reported. Because of low efficacy and potential toxicity, podophyllin use is no longer recommended[57]. Podophyllotoxin has been identified as the most active constituent of podophyllin. A regimen of patient self-applied podophyllotoxin 0.5% solution or gel twice a day for 3 days repeated in weekly cycles was shown to be effective and without evidence of systemic absorption and toxicity (see Table 79.2). Erythema and erosions are the most common side effects. In a recent network meta-analysis, podophyllotoxin 0.5% solution was significantly more efficacious than imiquimod 5% cream in clearing genital warts in non-immunocompromised patients, but the former had more adverse side effects[65]. Both podophyllin and podophyllotoxin are contraindicated during pregnancy.

Warts of the urethral meatus and urethra are difficult to manage, and stenosis and stricture due to therapy are potentially serious complications. 5-Fluorouracil (5-FU) 5% cream can be applied twice a week to treat intraurethral condylomata or, as an alternative to destructive treatments, intraepithelial neoplasias of the external genitalia. However, its use in the genital area is limited by inflammatory side effects. Successful treatment of cutaneous warts with 5-FU 5% cream applied daily under occlusion or together with salicylic acid has also been described in children and adults[66], and effective therapy with intralesional 5-FU has been reported.

Intralesional bleomycin is occasionally used to treat recalcitrant cutaneous warts, but injections are painful and may result in excessive cutaneous necrosis.

Topical Immunomodifiers

Imiquimod is an imidazoquinoline compound with immunomodulatory activities that has been approved by the US Food and Drug Administration (FDA) for the topical treatment of condylomata acuminata. Imiquimod has been shown to interact with Toll-like receptors 7 and (to a lesser degree) 8, resulting in activation of cytokine secretion from monocytes/macrophages (including interferon-α, interleukin-12, and tumor necrosis factor) as well as stimulation of antigen-presenting dendritic cells (see Ch. 128).

In an initial randomized, double-blind, placebo-controlled clinical trial, complete clearance of *genital warts* occurred in 50% of patients treated with imiquimod 5% cream compared to 11% of those treated with vehicle control; recurrence rates were low (<15%) in both groups[67]. Response rates were higher for warts on mucosal sites (i.e. female and uncircumcised male patients) than for lesions on the penile shaft or suprapubic area, suggesting the importance of crossing the stratum corneum barrier for effective treatment. Later studies confirmed the therapeutic effect of imiquimod for anogenital warts and documented that this treatment resulted in a reduction of viral load, presumably due to activation of cellular immune responses. A direct comparison of imiquimod and cryotherapy for genital warts found an earlier response with imiquimod, slightly higher efficacy with cryotherapy, and similar recurrence rates[68]. In clinical practice, destruction of genital warts by the physician, followed by patient-applied imiquimod (often requiring several cycles) is favorable over either modality alone[69]. Imiquimod has also been incorporated into suppositories and applied via anal tampons to prevent recurrence of anal condylomata following surgical ablation, or as primary treatment for anal condylomata and AIN in order to avoid the risk of scarring and stenosis of the anal canal associated with surgical procedures[70].

Therapeutic efficacy of imiquimod 5% cream has also been described for *persistent cutaneous warts*. In a controlled study (right versus left comparison) involving 14 immunosuppressed patients with recalcitrant warts on their hands and/or feet, a 36% response rate was observed for warts treated with imiquimod (three times weekly for 8 weeks, daily for 8 weeks, then daily with occlusion for 8 weeks) compared to 7% for untreated warts[71]. Improvement of common and flat warts with imiquimod therapy (daily application; ± occlusion for common warts) has also been reported in uncontrolled studies in immunocompetent patients[72]. Occlusion and/or concurrent use of salicylic acid or cryotherapy may increase imiquimod's penetration through the stratum corneum, which is especially important in acral sites.

Side effects of imiquimod include application site reactions (inflammation, erosion) that may require treatment-free periods. Imiquimod therapy is often more costly than other treatment options.

Sinecatechins 15% ointment, which contains green tea leaf-derived catechins thought to have immunostimulatory and antiproliferative properties, is approved as a topical treatment for anogenital warts. In randomized double-blind clinical studies, application of this product three times daily for up to 16 weeks led to complete clearance of anogenital warts in ~55% of patients (with frequent local irritation), compared to 35% of those treated with a vehicle control[73].

Systemic Immunomodifiers

Interferons have been used topically, intralesionally, and systemically for genital warts in controlled trials and have failed to demonstrate consistent efficacy. Systemic therapy, which is expensive and causes dose-related toxic side effects, is therefore not recommended for routine clinical use. However, interferons may be helpful as an adjunct or salvage therapy in selected patients[55]. More recently, low-dose pomalidomide was reported to clear or improve HPV-associated anal HSIL.

Immunotherapy

Increasing evidence that cellular immune responses play a critical role in wart clearance has inspired the development of topical and intralesional

immunotherapy regimens for patients with multiple and/or recalcitrant warts. In a large uncontrolled study[74], 154 children and adults with recalcitrant palmoplantar warts underwent successful topical sensitization with 2% diphenylcyclopropenone (DPCP) followed by at least six applications of 0.5%–4% DPCP to their warts at 3-week intervals. An 88% complete clearance rate was observed after an average of 6 months, with only local side effects (pruritus, blistering, eczematous reactions). Similar clearance rates have been reported for other contact sensitizers such as squaric acid dibutyl ester (SADBE), with application frequencies ranging from daily to monthly (often twice weekly), and regression of distant untreated warts has also been described.

Intralesional injection of *Candida*, *Trichophyton*, and/or mumps skin test antigens represents another approach to immunotherapy for warts in immunocompetent adults and children. In a randomized controlled clinical trial, a significantly higher clearance rate for treated as well as distant untreated common warts was observed in patients receiving intralesional antigen as compared to placebo at 3-week intervals for a total of up to five treatments (60% versus 22%, and 41% versus 19%, respectively)[75]. Effective treatment of flat warts and anogenital warts with topical and intralesional immunotherapy has also been described.

Antiviral Agents

Cidofovir is an acyclic nucleoside phosphonate with broad-spectrum activity against DNA viruses, including HSV and molluscum contagiosum, and it is approved for the systemic treatment of cytomegalovirus retinitis in AIDS patients. Although limited by the potential for renal toxicity, systemic treatment with cidofovir has shown efficacy in patients with HPV-associated lesions, including extensive cutaneous warts and severe RRP with pulmonary involvement. Intralesional injection of cidofovir (15 mg/ml saline) and topical application of 1%–3% cidofovir incorporated into an ointment, cream, or gel base have been successfully used in multiple case series of immunocompetent or immunosuppressed (e.g. HIV-infected) patients with cutaneous warts, condylomata acuminata, intraepithelial neoplasias, or RRP[76,77].

Retinoids

The effects of retinoids on keratinocyte differentiation and proliferation may lead to inhibition of HPV replication and assembly. Reduction in the bulk of extensive cutaneous or genital warts with oral retinoid therapy (e.g. acitretin, isotretinoin) has been reported in immunocompetent and immunosuppressed patients[78,79]. Successful treatment of flat warts with topical tretinoin or tazarotene has also been described.

Anti-PD-1/PD-L1 Antibodies

The aggressive nature of HPV-associated carcinomas is in part due to their ability to evade immunosurveillance via the expression of immune checkpoint molecules such as programmed cell death-ligand 1 (PD-L1), which interacts with its receptor (PD-1) on tumor-specific T cells and limits the latter's antitumor activity (Fig. 128.9)[80]. Increased levels of PD-L1 have been found in HPV-related cervical and head and neck SCCs and may play a critical role in the growth, progression, and metastases of these tumors. For example, expression of PD-L1 has been reported in 35%–95% of cervical carcinomas[81]. In several clinical trials of cervical or head and neck SCCs treated with anti-PD-1/PD-L1 antibodies, increased objective response rates and progression-free survival were observed when patients were stratified for HPV status and PD-L1 expression[82]. As a result, the FDA approved pembrolizumab in combination with chemotherapy for persistent, recurrent, or metastatic cervical cancer whose tumors express PD-L1. Pembrolizumab is also approved as a single agent for metastatic or unresectable recurrent head and neck SCCs that express PD-L1.

Special Considerations, Including Intraepithelial Neoplasias and Pregnancy

Early diagnosis of Buschke–Löwenstein tumor and other verrucous carcinomas is important to allow wide excision with clear resection margins. Surgery is the only established treatment that may cure the disease, although recurrence rates are high and the tumor can ultimately result in death. Cytotoxic chemotherapy and injections of interferon-α have led to remissions or cure in individual patients[45,55]. Whether anti-PD-1/PD-L1 antibodies could play a therapeutic role remains to be determined.

In transplant recipients and HIV-infected patients, skin and genital warts tend to resist standard treatment modalities. A surgical approach followed by non-invasive treatment of recurrent warts may be appropriate. In placebo-controlled studies, local application of imiquimod reduced genital wart area by more than 50% in 38% of HIV-infected patients. Imiquimod cream has also been used for VIN while imiquimod incorporated into suppositories or applied via anal tampons has been used for AIN, supporting a role for cellular immune enhancement for treatment of HPV-induced neoplasia.

During *pregnancy*, genital warts can increase in size and destructive procedures including surgery, cryotherapy, TCA application, and laser treatments are appropriate for removing lesions, which may theoretically reduce the risk for the newborn to acquire RRP[28]. However, this assumption is not proven and the presence of condylomata is not an indication for delivery by cesarean section. Podophyllin and podophyllotoxin are teratogenic and thus must not be used in pregnant women.

The treatment of intraepithelial neoplasias (bowenoid papulosis, erythroplasia of Queyrat, Bowen disease) is generally more aggressive than that of benign condylomata[83]. Prior to therapy, an aiming biopsy (e.g. colposcopically directed) is always required to exclude (micro) invasion histologically. For patients with bowenoid papulosis and erythroplasia who are younger than 45 years of age, superficial destruction of lesions (e.g. with cryotherapy or laser vaporization) may be appropriate to avoid mutilation[84]. In immunocompetent patients less than 35 years of age, bowenoid papulosis is regarded as a benign and self-limited disease[85]. Nevertheless, prolonged observation appears mandatory to detect recurrences.

HPV VACCINES

Three decades ago, recombinant DNA technology was used to generate a prophylactic subunit vaccine that consists of the L1 major capsid protein, which self-assembles into empty capsids designated as virus-like particles (VLPs) (see Fig. 79.1)[3]. VLPs resemble native virions morphologically and immunologically, and they carry neutralization epitopes on their surface. However, as a safety advantage, VLPs do not contain potentially oncogenic viral DNA and cannot replicate. Systemic immunizations with VLPs induce high-titer, long-lasting, and type-restricted neutralizing antibodies[4,86].

Prophylactic vaccinations in several animal models of papillomavirus infection were spectacularly successful in preventing natural or experimental infection of skin and mucosa[2,87]. In phase I/II human trials, systemic immunizations with VLP-based vaccines were non-toxic and highly immunogenic, inducing robust neutralizing antibody responses[86]. Based on these promising results, large-scale prophylactic vaccination trials were conducted to evaluate the safety and efficacy of two agents in preventing genital HPV infection and associated lesions in young women: (1) a quadrivalent vaccine of HPV-6, -11, -16, -18 VLPs (Gardasil®; Merck); and (2) a bivalent vaccine of HPV-16, -18 VLPs (Cervarix®; GlaxoSmithKline). Study endpoints were detection of HPV DNA and the development of dysplasias (squamous intraepithelial lesions) or (for the quadrivalent vaccine) anogenital warts. These studies showed near-complete protection (>90% vaccine efficacy) that was type-restricted against vaccine-type HPV infection. In addition, there was 100% protection in preventing genital warts as well as low- and high-grade CIN, VaIN, and VIN that were associated with the vaccine HPV types (for at least 10 years)[5–7,88,89]. The quadrivalent vaccine was also found to be nearly 90% effective in preventing both genital warts caused by HPV types 6 and 11 in young men and AIN. While post-marketing evaluation of the duration of efficacy of the vaccines is ongoing, trial results have demonstrated stabilized antibody titers for at least 10 years after vaccination, suggesting induction of a strong B cell memory response. Also, in studies where girls and boys between the ages of 10 and 15 years were vaccinated, more than 99% have seroconverted, and they developed antibody titers that were even higher than those in women 16 to 23 years of age[90].

Because these first two commercial HPV vaccines contain HPV-16 and -18 VLPs, they induce protection against the two high-risk HPV types that together account for ~70% of cervical cancers and high-grade CIN. Of note, they may offer limited cross-protection against closely related HPV-31, -33, and -45. More recently, the 9-valent vaccine

(Gardasil®9) was licensed which contains VLPs for HPV-6 and -11 as well as high-risk HPV types 16, 18, 31, 33, 45, 52, and 58[91]. Together, these seven high-risk HPV types have been identified in ~90% of cervical cancers[9,21]. Because it is not 100%, vaccinated women should continue to have Pap smears performed.

The three HPV vaccines that have been introduced worldwide over the past fifteen years are aimed at achieving universal vaccination of children and adolescents, ideally at 11 or 12 years of age. This would be prior to the onset of sexual activity and when the strongest immune response is generated, with the CDC recommending "catch-up" shots for those ages 13–26 years. Four years after implementing a national quadrivalent HPV vaccine program in Australia that was aimed at girls and young women and resulted in 70% coverage, genital warts nearly disappeared in women and heterosexual men <21 years of age[21]. In addition, high-grade cervical lesions significantly declined[92], with both outcomes demonstrating vaccine effectiveness at the population level.

The 9-valent vaccine is FDA-approved for females and males ages 9 to 45 years to prevent anogenital warts as well as cervical, vulvar and vaginal cancers, anal cancer, and HPV-related head and neck cancers. Of note, both the bivalent and quadrivalent vaccines have been removed from the US market due to low demand, but are available in other countries. The CDC views vaccination of inadequately vaccinated adults 27 to 45 years of age as optional as a greater percentage of these individuals have already been exposed to HPV.

Because the HPV vaccines have no therapeutic efficacy against preexisting infection or disease, the benefit of vaccinating older patients is considerably smaller. To date, there are no randomized, placebo-controlled trials demonstrating therapeutic efficacy of licensed HPV vaccines in the treatment of genital, cutaneous, or laryngeal warts. Although vaccinating males (e.g. with Gardasil®) is less cost-efficient than vaccinating females, this intervention likely increases vaccine efficiency in the population as a whole due to herd immunity[4,86]. Vaccination is also expected to lead to a drastic reduction in anal dysplasia and cancer (particularly in MSM) as well as an estimated one-third reduction in the incidence of oropharyngeal cancer. In 2020, the WHO launched a 90-70-90 strategy for the global elimination of cervical cancer via the vaccination of 90% of girls by age 15 years, screening 70% of women by 35 years of age and again by 45 years of age, and treating 90% of women with cervical precancer or cancer.

Currently, HPV vaccines are approved for use as either two- or three-dose regimens according to age. However, questions remain regarding the duration of vaccine efficacy and cross-protection with two doses (or even one dose) as compared to three doses. To date, several hundred million doses of HPV vaccines have been administered with retention of a good safety profile. There is also no indication of replacement by non-vaccine-targeted HPV types. The information gained from ongoing studies will aid in answering additional questions, including: duration of protection (when to boost if at all); possible longer-term benefit of preventing re-infection; utility of (pseudovirion) surrogate assays for neutralizing antibodies; and correlates of protection.

As an alternative approach for generating broader-spectrum vaccines, genetic engineering has been employed to develop L1 VLPs that also express type-common epitopes of the minor capsid protein L2 (e.g. the highly conserved "RG1" peptide of HPV-16 L2 that contains a cross-neutralization epitope), which can induce cross-protective immunity to a variety of mucosal and even cutaneous HPV types[93–95]. In a preclinical genital challenge animal model, vaccination with HPV16 RG1-VLP provided broad protection against virtually all high-risk mucosal HPVs, in addition to inducing cross-neutralization against low-risk mucosal types, common cutaneous types (HPV-2, -27, -57, -3), and oncogenic β types (HPV-5, -8)[96]. As part of the US National Cancer Institute PREVENT program, a phase I first-in-human trial of a RG1-VLP vaccine candidate is planned. Such monovalent VLP vaccines may become a cost-effective alternative strategy for implementing national HPV vaccination programs, especially in low-income countries that cannot afford multivalent HPV vaccines or cytology (Pap) screening, yet carry >80% of the worldwide burden of cervical cancer[97,98].

Successful experiments in animals have encouraged efforts to develop *therapeutic* vaccines against HPV infections. Most papillomavirus infections are self-limited, and it is generally agreed that a cellular immune response (albeit poorly understood) is required for clearance of infection. Cell-mediated immunity to L1 or L2 is unlikely to exhibit therapeutic efficacy, as capsid proteins are expressed neither in basal cells that harbor HPV DNA nor in progressed lesions that do not produce virions. Candidate rejection antigens are the E6 and E7 oncoproteins, which are selectively retained and expressed in cervical dysplasia and cancer, and E1 or E2 proteins, which are required to maintain the viral genome as an episome. Multiple strategies have been employed, including vaccinations with papillomavirus proteins fused to or combined with immunostimulants or dendritic cells in addition to attenuated viral or DNA expression vectors[99].

Chimeric VLPs have been engineered to incorporate an early protein such as E7 into an L1 or L1/L2 capsid. The induction of cytotoxic T-lymphocyte responses to the E7 oncoprotein, in addition to antibodies directed against the L1 capsid protein, provides both therapeutic and prophylactic benefit in mouse tumor models[100]. These strategies may prove effective in low-grade dysplasia or condylomata that have a high likelihood of spontaneous regression. However, mechanisms of immune evasion such as down-regulation of MHC type I expression may diminish the success of therapeutic vaccines and, thus, favor their application as an adjunct to established ablative therapies. Also, safety issues associated with live attenuated or DNA vectors and with vaccines containing E6 or E7 oncoproteins are complex[86,101].

Chapter Contents

Herpes Simplex Viruses (HSV-1 and HSV-2) *1412*
Varicella–Zoster Virus (VZV; HHV-3) *1418*
Epstein–Barr Virus (HHV-4). *1427*
Cytomegalovirus (HHV-5) *1429*
Human Herpesvirus Type 6 (HHV-6) *1431*
Human Herpesvirus Type 7 (HHV-7) *1433*
Human Herpesvirus Type 8 (HHV-8) *1433*

The human herpesviruses (HHVs) are categorized into three groups: alpha, beta, and gamma herpesvirinae (Table 80.1). Each virus contains a core of linear double-stranded DNA, an icosahedral capsid 100–110 nm in diameter, and an envelope with glycoprotein spikes on its surface. The pathogenesis of herpesvirus infections follows the sequence of primary infection, latency, and reactivation. The eight human herpesviruses are discussed in this chapter and include the following: herpes simplex virus types 1 and 2 (HSV-1, HSV-2), varicella–zoster virus (VZV), Epstein–Barr virus (EBV), cytomegalovirus (CMV), and human herpesvirus types 6–8 (HHV-6–8).

HERPES SIMPLEX VIRUSES (HSV-1 AND HSV-2)

Synonyms/clinical variants: ■ Herpes – herpes simplex ■ Herpes labialis – cold sore, fever blister, herpes febrilis ■ Herpes gladiatorum – scrum pox ■ Herpetic whitlow ■ Genital herpes – herpes progenitalis

Key features

- Herpes simplex viruses produce primary and recurrent vesicular eruptions that favor the orolabial and genital regions
- The use of sensitive and specific serologic markers has provided insights into the epidemiology of HSV infections
- Antiviral therapy significantly influences the course and spectrum of HSV disease

Introduction

HSV-1 and HSV-2 are ubiquitous pathogens that produce primarily orolabial and genital infections. Worldwide, genital herpes is one of the most common sexually transmitted infections. The use of sensitive and specific serologic markers has enabled the epidemiology of HSV infections to be deciphered, while antiviral therapy has allowed clinicians to control the course and extent of HSV disease. Prevention of HSV infections via molecularly derived vaccines remains an important goal.

History

Herpetic lesions have been described since antiquity, including by the noted physicians Hippocrates and Galen. The word "herpes" was first defined by Greek scholars as "to creep or crawl" in reference to the spreading nature of the skin lesions. The association between orolabial herpetic lesions and genital infection was first recognized during the late eighteenth century. However, better understanding of the pathogenesis of herpes infections did not occur until the twentieth century. Lipschitz was the first to suggest antigenic differences between the two HSV types, but it was not until 1968 that Nahmias and Dowdle demonstrated that HSV-1 was more frequently associated with orolabial and HSV-2 with genital infections[1]. In the past several decades, there have been critical insights into the pathogenesis of HSV infections as well as advances in their diagnosis, treatment, and prevention.

Epidemiology

Herpes simplex viruses have a worldwide distribution. Their interaction with human hosts has the following components: (1) *primary infection* – initial HSV infection, without pre-existing antibodies to HSV-1 or HSV-2; (2) *non-primary initial infection* – infection with one HSV type in an individual with pre-existing antibodies to the other HSV type; (3) *latency* – virus in sensory ganglia; and (4) *reactivation* – recurrent infection with asymptomatic viral shedding or clinical manifestations (recrudescence). Primary, non-primary initial, and recurrent infections can each be symptomatic or asymptomatic. It is estimated that approximately one-third of the world's population has experienced a symptomatic HSV infection.

In children <10 years of age, ~80%–90% of herpetic infections are caused by HSV-1. Analyses on a worldwide basis have demonstrated HSV-1 antibodies in 50%–90% of individuals 20–40 years old. Although HSV-2 remains the major cause of recurrent genital herpes infections (70%–90% overall)[2], the proportion due to HSV-1 has been increasing in the US, Canada, and the UK. In these countries, HSV-1 now accounts for the majority of genital herpes infections in young adults, especially college students[3,4]. Recurrences of genital herpes are less common with HSV-1, which lacks HSV-2's specific tropism for genital epithelium.

In the Centers for Disease Control and Prevention (CDC)'s 2015–2016 National Health and Nutrition Examination Survey (NHANES)[5], the seroprevalence of HSV-2 among individuals 14–49 years of age in the US was 12% overall, with higher rates in women (16%, versus 8% in men) and Black individuals (35%). Of note, ~80% of those with positive serology never had a previous diagnosis of genital HSV infection. Other factors associated with acquisition of genital herpes include an age of 15–30 years (period of greatest sexual activity), an increased number of sexual partners, lower levels of income and education, and HIV-positivity; conversely, genital HSV-2 infection also increases the risk of acquiring and transmitting HIV infection[3].

Pathogenesis

Transmission of HSV can occur during asymptomatic periods of viral shedding. HSV-1 is spread primarily through direct contact with contaminated saliva or other infected secretions, while HSV-2 is spread primarily by sexual contact. Virus replicates at the mucocutaneous site of infection and then travels by retrograde axonal flow to the dorsal root ganglia, where it establishes latency until reactivation. Latency enables the virus to exist in a relatively non-infectious state for varying periods of time in its host. HSV-1 can induce intracellular accumulation of CD1d molecules in antigen-presenting cells, providing a possible explanation for how the virus evades detection and establishes latency. Normally, CD1d molecules are transported to the cell surface, where they present lipids and stimulate natural killer T cells, thus promoting an immune response[6]. HSV's mechanisms to evade the immune system also include downregulation of various immunologic cells and cytokines (Table 80.2).

The goals of the early host immune response against HSV are to limit viral replication and recruit other inflammatory cells. Toll-like receptors are critical to the first line of innate immune defense against HSV, and their functions include priming $CD8^+$ T cells. HSV-specific memory $CD8^+$ T cells, which are selectively activated and retained in

THE EIGHT HUMAN HERPESVIRUSES, THEIR CLASSIFICATION AND DIFFERENTIAL DIAGNOSES				
Human herpesvirus	**Classification**	**Predominant cell type infected**		**Differential diagnosis**
		Lytic infection	**Latent infection**	
Herpes simplex virus type 1 (HSV-1) (HHV-1)	Alphaherpesvirinae	Epithelial cells	Neurons	Orolabial herpes: aphthous stomatitis, erythema multiforme major, Stevens–Johnson syndrome, herpangina, pharyngitis (e.g. due to EBV), oral candidiasis, mucositis secondary to chemotherapy
Herpes simplex virus type 2 (HSV-2) (HHV-2)	Alphaherpesvirinae	Epithelial cells	Neurons	Genital herpes: trauma, chancre (primary syphilis), aphthae, reactive non-sexually related acute genital ulcers associated with infection (e.g. EBV, CMV, *Mycoplasma*, influenza, SARS-CoV-2), CMV-related ulcers (AIDS), chancroid, granuloma inguinale, lymphogranuloma venereum
Varicella–zoster virus (VZV) (HHV-3)	Alphaherpesvirinae	Epithelial cells	Neurons	Varicella: vesicular viral exanthem (e.g. coxsackievirus A6), rickettsialpox, mpox, disseminated HSV, PLEVA, insect bites, drug eruption, scabies, smallpox
				Herpes zoster: zosteriform HSV, contact dermatitis, phytophotodermatitis, bullous impetigo, cellulitis
Epstein–Barr virus (EBV) (HHV-4)	Gammaherpesvirinae	B cells, epithelial cells	B cells	Group A streptococcal infection, acute viral hepatitis, drug reaction with eosinophilia and systemic symptoms (DRESS), toxoplasmosis, lymphoma; primary CMV, HHV-6, and HIV infections
				For genital ulcers: see genital herpes
Cytomegalovirus (CMV) (HHV-5)	Betaherpesvirinae	Lymphocytes, macrophages, endothelial cells	Lymphocytes, macrophages	EBV-induced infectious mononucleosis, toxoplasmosis, viral hepatitis, lymphoma
				For genital ulcers: see genital herpes
Human herpesvirus 6 (HHV-6)	Betaherpesvirinae	$CD4^+$ T cells	Lymphocytes, monocytes	Viral exanthems (e.g. measles, rubella; enterovirus, adenovirus, EBV, and parvovirus infections), scarlet fever, Rocky Mountain spotted fever, Kawasaki disease
Human herpesvirus 7 (HHV-7)	Betaherpesvirinae	T cells	T cells	Similar to HHV-6
Human herpesvirus 8 (HHV-8)	Gammaherpesvirinae	Lymphocytes	Lymphocytes, endothelial cells	Acroangiodermatitis (pseudo-KS), bacillary angiomatosis, ecchymosis, hemangioma, angiosarcoma, pyogenic granuloma, pseudolymphoma/lymphoma, dermatofibroma

Table 80.1 The eight human herpesviruses, their classification and differential diagnoses. KS, Kaposi sarcoma; PLEVA, pityriasis lichenoides et varioliformis acuta.

latently infected sensory ganglia, have important roles in controlling the infection and preventing symptomatic recurrences (see Table 80.2).

HSV can be reactivated either spontaneously or by a trigger such as emotional stress, ultraviolet light, fever, menstruation, immunosuppression, surgical or dental procedures, and other local tissue damage. Typically, reactivation produces vesicular lesions localized to the skin. However, viremia followed by widespread internal organ involvement can occur in immunocompromised hosts.

Clinical Features

HSV infections have a wide range of clinical presentations, and asymptomatic infection is very common. In primary infections, symptoms typically occur within 3 to 7 days after exposure. A prodrome of tender lymphadenopathy, malaise, anorexia, and fever often occurs before the onset of mucocutaneous lesions, which may be preceded by localized pain, tenderness, burning, and tingling. Painful, grouped vesicles appear on an erythematous base and may become umbilicated, followed by progression to pustules, erosions, and/or ulcerations with a characteristic scalloped border. Crusting of lesions and resolution of symptoms typically occurs within 2 to 6 weeks. A similar prodrome can precede recurrent lesions, but these are often fewer in number, with decreased severity and duration compared to those of a primary infection.

The majority of primary orolabial infections are asymptomatic. Symptomatic infections often present as gingivostomatitis in children or as pharyngitis and a mononucleosis-like syndrome in young adults. The mouth and lips are the most common sites of involvement (Fig. 80.1A,B), with oral lesions typically appearing on the buccal mucosa and gingivae. Edema and painful oropharyngeal ulcerations can lead to dysphagia and drooling.

Among individuals with latent HSV-1 infection, 20%–40% develop recurrent herpes labialis due to reactivation. Recurrent lesions appear most often on the vermilion border of the lip (Fig. 80.1C). Less common sites are perioral skin, nasal mucosa, cheek, and attached oral mucosa overlying bone (e.g. gingiva, hard palate) (Fig. 80.2). In immunocompromised hosts, recurrent herpes infections can involve intraoral movable mucosa not overlying bone (see Fig. 72.1).

Primary and non-primary initial genital herpes infections are frequently asymptomatic but (especially with the former) can also present as an excruciatingly painful, erosive balanitis, vulvitis, or vaginitis. In women, lesions often also involve the cervix, buttocks, and perineum and may be associated with inguinal adenopathy and dysuria (Fig. 80.3). Genital lesions in men typically occur on the glans or shaft of the penis, and the buttocks are occasionally affected. Systemic complaints and complications are more common in women. Extragenital lesions, urinary retention, and aseptic meningitis occur in 20%, 10%–15%, and 10% of affected women, respectively[7]. In contrast, aseptic meningitis is a rare complication of primary genital herpes infection in men. The presence of more extensive local involvement, regional lymphadenopathy, and fever generally distinguishes primary herpes infection from recurrent disease.

Genital HSV infections can result in both subclinical viral shedding and clinically evident recurrences, which are often relatively mild; recurrences occur more frequently with HSV-2 than HSV-1. Usually, a limited number of vesicles reappear on the genitalia or buttocks (Fig. 80.4), with resolution within 7–10 days, compared to ~20 days for primary infections[7]. Complications are uncommon. The frequency of recurrences correlates directly with the severity of the primary infection and tends to decrease over the next several years. The time interval between recurrences varies greatly, with individuals having an average of four to seven outbreaks annually. Surprisingly, although the majority of individuals with HSV-2 seropositivity report no history of genital herpes infection, symptomatic infection is eventually diagnosed in 50% of this group of patients.

Other Clinical Presentations of HSV Infection

HSV infection can occur anywhere on the skin or mucous membranes. The clinical settings and manifestations of other cutaneous and

INTERACTION OF HERPES SIMPLEX VIRUSES WITH THE IMMUNE SYSTEM: HOST RESPONSES AND VIRAL EVASION MECHANISMS
Host immune responses to HSV infection
Innate immunity

• HSV is detected by Toll-like receptors (TLRs; see Ch. 4) on epithelial cells, antigen-presenting cells (APCs), plasmacytoid dendritic cells (DCs), and NK cells
  • TLR2 on the cell surface interacts with a viral surface glycoprotein* and leads to proinflammatory cytokine production (via NF-κB activation), including IL-1β, IL-6, IL-8, IL-12, TNF, and MCP-1
  • TLR3 on endosomes interacts with double-stranded RNA (which accumulates in HSV-infected cells) and leads to IFN-β and IFN-λ production†
  • TLR9 on endosomes interacts with viral genomic DNA (unmethylated CpG sequences) and leads to IFN-α production via NF-κB activation
• HSV is also recognized by intracellular nucleic acid sensors (e.g. IFN-γ-inducible protein 16) that detect HSV DNA and stimulate type I IFN (IFN-α and -β) production
• Type I IFNs increase expression of IFN-stimulated genes; their effects include inhibiting translation/promoting degradation of viral mRNA, inducing DC maturation, and, in part through stimulation of IL-15 production, promoting NK cell survival and proliferation
• NK cells release IFN-γ and destroy virus-infected cells, e.g. via release of perforin and granzyme B
• $CD8^+$ T cells are primed in a process that requires TLR3 signaling by $CD8\alpha^+$ DCs
• Collectively, these responses limit HSV replication, promote host cell apoptosis, and recruit and activate DCs, other APCs, neutrophils, and other leukocytes of both innate and adaptive lineages
• Evidence is emerging that innate immune defenses also have a role in the control of latent HSV infections

Adaptive immunity
• $CD4^+$ T cells are recruited to the site of infection and activated by DCs • $CD4^+$ T cells release IFN-γ, which induces secretion of chemokines (e.g. CXCL9 and CXCL10 by epithelial cells) that recruit cytotoxic $CD8^+$ T cells • $CD8^+$ T cells, which also release IFN-γ, kill infected cells through perforin and Fas-mediated pathways, clearing the active infection • Following the priming and contraction phases of the T cell response, virus-specific $CD8^+$ T cells accumulate (referred to as memory inflation) and provide immunosurveillance; viral latency and periodic restimulation by subclinical HSV reactivation maintain this pool of cells • B cells are recruited to the site of infection and activated by $CD4^+$ T cells to produce antibodies • Regulatory T cells are present, but their exact role in preventing excessive immune responses versus diminishing the efficiency of viral clearance has not been determined
HSV's mechanisms of immune evasion
• HSV inhibits signaling through TLRs, e.g. the HSV-1 ICP0 protein reduces TLR2 signaling • The HSV *v*irion *h*ost *s*hut-off (VHS) protein degrades mRNA; it prevents DC activation by a TLR-independent pathway • HSV decreases cell surface expression of CD1d by APCs; this prevents presentation of lipid antigens that stimulate NK cells • HSV decreases langerin expression by and increases apoptosis of Langerhans cells • The HSV ICP47 protein binds to TAP and blocks loading of peptides onto MHC class I molecules; "empty" MHC class I molecules are degraded by the proteasome • The HSV-1 glycoprotein B manipulates the MHC class II processing pathway by hijacking HLA-DR from its normal transport route to the cell surface • The HSV-1 glycoprotein C blocks complement activation, and glycoprotein E functions as an IgG Fc receptor that can block host responses such as antibody-dependent cellular cytotoxicity • The HSV protein tristetraprolin destabilizes mRNA and can target proinflammatory cytokines such as TNF • HSV can block cytokine effects by other mechanisms, e.g. inducing expression of *s*uppressor *o*f *c*ytokine *s*ignaling-*1* (SOCS-1) in keratinocytes and thereby abrogating the effects of IFN-γ • HSV can induce expression of Fas ligand on the surface of monocytes/macrophages, causing apoptosis of interacting T cells and NK cells
*Viral envelope fusion with the host cell membrane during entry leaves viral proteins on the cell surface. †Mutations in the genes encoding TLR3 or proteins required for TLR3 signaling (e.g. *UNC-93B*, *TRAF3*) lead to particular susceptibility to HSV encephalitis, and polymorphisms in the gene encoding IFN-λ3 (IL-28b) have been associated with increased risk of recurrent orolabial herpes simplex.

Table 80.2 Interaction of herpes simplex viruses (HSV) with the immune system: host responses and viral evasion mechanisms. HLA, human leukocyte antigen; ICP, infected cell polypeptide; IFN, interferon; IL, interleukin; MCP-1, monocyte chemotactic peptide 1; MHC, major histocompatibility complex; NK, natural killer; TAP, transporter associated with antigen processing; TRAF3, tumor necrosis factor (TNF) receptor-associated factor 3.

extracutaneous presentations of HSV infection, including those in immunocompromised individuals and neonates[8–17], are summarized in Table 80.3 (Figs. 80.5–80.9).

Diagnosis and Pathology

Multiple laboratory tests are available to diagnose HSV infection, including viral culture, direct fluorescent antibody (DFA) assays, molecular techniques, and serology. Identification of HSV by viral culture usually requires 2–5 days. In addition to being the preferred method for identifying HSV in the cerebrospinal fluid, PCR is now commonly used as a more rapid, sensitive, and specific method for detecting HSV DNA in specimens from the skin and other organs.

For prevalence or incidence studies and to establish serostatus, the Western blot represents the gold standard for serologic assays; it is 99% sensitive and specific for HSV antibodies. In addition, several commercially available serologic tests can reliably identify patients who have been infected with HSV and are able to distinguish HSV-1 antibodies from HSV-2 antibodies by utilizing type-specific G-1 and G-2 glycoproteins, respectively. However, the sensitivity and specificity of these commercial assays do vary depending on the setting. The mean time to seroconversion following initial infection is 3–4 weeks[18].

A Tzanck smear of scrapings from early lesions, in particular the base/edges of a freshly unroofed vesicle, reveals multinucleated epithelial giant cells in ~60%–75% of HSV outbreaks (Fig. 80.10). In routinely stained biopsy specimens as well as Tzanck smears, HSV-1 cannot be differentiated from HSV-2. Enlarged, slate-gray keratinocyte nuclei with margination of chromatin represent an early histologic finding. This is followed by intraepidermal vesiculation associated with ballooning degeneration of keratinocytes, which is most prominent at the vesicle base (Fig. 80.11). These swollen, pale keratinocytes often fuse to form multinucleated giant cells and may contain eosinophilic intranuclear inclusion bodies surrounded by an artifactual cleft (Cowdry type A inclusions). Ballooning degeneration can affect adnexal structures as well as the interfollicular epidermis. A variably dense dermal infiltrate of lymphocytes, neutrophils, and eosinophils is observed, with a tendency to be milder in recurrent disease. Vascular changes may include areas of hemorrhagic necrosis and perivascular cuffing. Epidermal necrosis is sometimes extensive, especially in the setting of disseminated skin lesions.

Differential Diagnosis

Orolabial herpes can sometimes be confused with aphthous stomatitis, erythema multiforme major or Stevens–Johnson syndrome, herpangina

Fig. 80.1 Orolabial herpes simplex virus (HSV) infections. A Primary herpes gingivostomatitis due to HSV-1 in a child. Note the coalescing lesions with scalloped borders. **B** Primary versus non-primary initial HSV-2 infection in a teenager. and other coxsackievirus infections, pharyngitis (e.g. due to EBV), oral candidiasis, Behçet disease, and chemotherapy-induced mucositis (see Table 80.1). Oral aphthae typically present as a single or few lesion(s) on the buccal mucosa without associated vesicles. Erythema multiforme major (most often triggered by HSV) and Stevens–Johnson syndrome can usually be distinguished from HSV by the presence of characteristic cutaneous as well as other mucosal lesions. In herpangina, the posterior pharynx is more commonly involved, unlike in HSV infection, which favors the anterior portion of the mouth. Oral lesions of hand-foot-and-mouth disease are generally accompanied by vesicles that favor acral and (especially with coxsackievirus A6) perioral areas. Exudative tonsillitis,

The buttocks represent a common location in women. **D** Ulcers with subtly scalloped borders on the penis. *A, C, Courtesy Kalman Watsky, MD; B, Courtesy Louis A. Fragola, Jr, MD; D, Courtesy Edward Cowen, MD.*

diffuse hyperemia of the oropharynx, and petechiae on the hard and soft palate are common manifestations of EBV-induced mononucleosis. Although a white, curd-like coating of the tongue, buccal mucosa, and pharynx is the most common presentation of oral candidiasis, there is also an erythematous form of the disease. In Behçet disease, oral aphthae are recurrent and patients have additional manifestations such as genital aphthae, uveitis, and papulopustular or erythema nodosum-like skin lesions[19]. In immunocompromised hosts, the possibility of coexisting infections must be considered.

Trauma, syphilitic chancres, chancroid, mpox, and lymphogranuloma venereum are considerations in the differential diagnosis of genital herpes (see Ch. 82). The syphilitic chancre is usually a single lesion that is neither painful nor recurrent. Chancroid often manifests as several tender ulcers with a yellowish-gray exudate overlying a base of granulation tissue, while lymphogranuloma venereum presents with a transient papule, herpetiform vesicle, erosion, or ulcer; both conditions typically result in tender inguinal lymphadenopathy. Reactive non-sexually related acute genital ulcers (e.g. associated with EBV, CMV, or *Mycoplasma* infection) and other genital aphthae can be difficult to distinguish from herpetic lesions without viral culture, DFA, or PCR. Additional entities in the differential diagnosis of genital erosions are listed in Table 73.6.

Treatment and Prevention

FDA-approved antiviral agents for treatment of recurrent episodes of orolabial herpes in immunocompetent persons include valacyclovir 2 g twice daily for 1 day, a single 1.5-g dose of famciclovir, and the topical treatments listed in Table 80.4. Randomized controlled trials have shown that these therapies have modest benefits, decreasing the duration of mucocutaneous lesions, viral shedding, and pain[20–23]; efficacy is maximized when treatment is started at the first sign or symptom of a recurrence. Both valacyclovir and famciclovir have also been shown to reduce the frequency of orofacial herpes outbreaks after laser resurfacing.

For treatment of primary and recurrent genital herpes, oral antivirals are the agents of choice (see Table 80.4). With initiation within 24–48 hours of onset, acyclovir, famciclovir, and valacyclovir reduce the duration of viral shedding, pain, and time to healing for first-episode and recurrent genital herpes. Intravenous acyclovir is indicated for neonatal HSV infection, severe infections in immunocompromised hosts, severe eczema herpeticum, and patients with systemic complications. In immunocompromised patients, it is important to treat with oral or intravenous antivirals until the cutaneous lesions are completely healed. Systemic antiviral agents need to be dose-adjusted for patients with impaired renal function (Table 80.5).

Chronic suppressive therapy with oral antiviral agents is usually reserved for patients with six or more outbreaks per year (see Table 80.4), although clinicians often exercise more lenient criteria for initiation of therapy for individuals with severe or problematic outbreaks, an insufficient prodrome to benefit from episodic therapy, or immunosuppression. In addition to decreasing the frequency of symptomatic outbreaks or even eliminating them, suppressive therapy decreases asymptomatic viral shedding by 95% and can thereby reduce transmission of genital herpes to a susceptible partner[24]. Daily suppressive therapy, together with consistent condom use and avoidance of sexual activity during recurrences, is therefore also recommended for individuals with genital herpes who have a seronegative partner.

OTHER CLINICAL PRESENTATIONS OF HERPES SIMPLEX VIRUS INFECTIONS		
Form of infection	**Clinical settings and HSV type(s)**	**Cutaneous and/or extracutaneous findings**
Predominantly mucocutaneous		
Eczema herpeticum (Kaposi varicelliform eruption)	• Affects infants/children > adults with atopic dermatitis (Fig. 80.5); risk is associated with mutations in the gene encoding filaggrin • A similar presentation can occur in patients with an impaired skin barrier due to other conditions such as burns, irritant contact dermatitis, pemphigus (foliaceus, vulgaris), Darier disease, Hailey–Hailey disease, mycosis fungoides, Sézary syndrome, ichthyoses, and rarely Grover disease and pityriasis rubra pilaris with acantholysis, as well as following ablative laser procedures or application of topical 5-fluorouracil • Usually due to HSV-1	• Rapid, widespread cutaneous dissemination of HSV infection in areas of dermatitis/skin barrier disruption • Monomorphic, discrete, 2–3 mm punched-out erosions with hemorrhagic crusts (see Fig. 80.5) are evident more often than intact vesicles • May have fevers, malaise, and lymphadenopathy • Occasionally complicated by bacterial superinfections (e.g. *Staphylococcus aureus*, group A streptococci) or systemic dissemination of HSV infection • Differential diagnosis includes "eczema coxsackium" due to coxsackievirus A6 infection and streptococcal infection and eczema vaccinatum
Herpetic whitlow	• Often in young children, usually due to HSV-1 (Fig. 80.6A) • Increasing frequency in adolescents/adults (Fig. 80.6B,C) secondary to digital–genital contact, usually due to HSV-2 • Historically in dental and medical personnel who did not use gloves	• Pain, swelling, and clustered vesicles on a digit (Fig. 80.6); appearance of vesicles may be delayed • Recurrences in the same location can be a clue to the diagnosis • Often misdiagnosed as blistering dactylitis or paronychia
Herpes gladiatorum	• Participation in contact sports such as wrestling (Fig. 80.7) • Usually due to HSV-1	• Distribution reflects sites of contact with another athlete's skin lesions and is sometimes widespread
Herpes simplex folliculitis	• Shaving with a blade razor (e.g. *herpetic sycosis* in a man's beard area) • Usually due to HSV-1 • HIV-positive or otherwise immunocompromised individuals	• Rapid development of follicular vesicles and pustules • See Table 38.1
Severe/chronic HSV infections	• Immunocompromised patients, e.g. hematopoietic stem cell or solid organ transplant recipients, individuals with HIV infection or leukemia/lymphoma	• Most common presentation is chronic, enlarging ulcerations (Fig. 80.8A,B) • Cutaneous lesions may affect multiple sites or be disseminated • Skin findings are often atypical, i.e. verrucous, exophytic, or pustular lesions • Recurrences can involve oral mucosa, including the tongue (Fig. 80.8C) and movable areas that do not overlie bone • Involvement of the respiratory tract, esophagus, and remainder of the gastrointestinal tract may also occur
Predominantly extracutaneous		
Ocular HSV infection	• Often due to HSV-2 in newborns (see below) • Usually due to HSV-1 in children and adults	• Primary infection: unilateral or bilateral keratoconjunctivitis with eyelid edema, tearing, photophobia, chemosis, and preauricular lymphadenopathy • Branching dendritic lesions of the cornea represent a pathognomonic finding • Recurrent episodes are common and typically unilateral • Complications include corneal ulceration and scarring, globe rupture, and blindness
Herpes encephalitis	• Most common cause of fatal sporadic viral encephalitis in the US • Associated with mutations in the genes encoding Toll-like receptor 3 or UNC-93B, which impair interferon-based cellular antiviral responses (see Table 80.2) • Usually due to HSV-1 • Natalizumab, an anti-α4 integrin monoclonal antibody used for the treatment of multiple sclerosis and Crohn disease, increases the risk of encephalitis and meningitis due to HSV and VZV	• Manifestations can include fever, altered mental status, bizarre behavior, and localized neurologic findings • The temporal lobe is often involved • Mortality ≥70% without treatment; residual neurologic defects in most survivors • Herpes labialis may be a coincidental finding
Proctitis	• Most common in men who have sex with men	• Manifestations include diarrhea, anal pain, and a feeling of rectal fullness
Cutaneous and extracutaneous		
Neonatal HSV infection	• Occurs in ~1:10 000 newborns in the US[8,9], usually resulting from exposure to HSV during a vaginal delivery • Risk of transmission is highest (30%–50%) for women who acquire a genital HSV infection (which is often asymptomatic) near the time of delivery • Risk of transmission is low (<1%–3%) for women with recurrent genital herpes • Due to HSV-2 or HSV-1; the latter accounts for 30%–50% of cases	• Onset from birth to 2 weeks of age, but usually ≥5 days of age • Localized (favoring the scalp and trunk; Fig. 80.9) or disseminated cutaneous lesions; involvement of the oral mucosa, eye, CNS, and multiple internal organs can occur • Vesicles may progress to bullae and erosions (see Ch. 34) • Encephalitis can present with lethargy, irritability, poor feeding, temperature instability, seizures, and a bulging fontanelle • For CNS or disseminated disease, mortality is >50% without treatment and ~15% with treatment; many survivors have neurologic deficits

Table 80.3 Other clinical presentations of herpes simplex virus (HSV) infections.

A Coalescing vesicles and erosions on the distal finger of a child. **B** An edematous erythematous plaque with relatively subtle central vesicle formation on the thumb of a child. **C** Grouped vesicles on the toe of an adult. Herpetic whitlow is sometimes misdiagnosed as cellulitis or blistering distal dactylitis, or, depending on the distribution, paronychia. *C, Courtesy Louis A. Fragola, Jr, MD.*

The emergence of acyclovir-resistant HSV is an increasing concern for immunocompromised individuals. Foscarnet is the only antiviral drug approved by the FDA for treatment of acyclovir-resistant HSV (see Fig. 127.11). Cidofovir is another antiviral agent that has shown efficacy in the treatment of acyclovir-resistant HSV. The use of foscarnet or *systemic* cidofovir is limited by potentially severe renal toxicity and the requirement for intravenous administration. Although not FDA-approved, compounded *topical* cidofovir has been advocated by the CDC as a "user-friendly", albeit expensive, alternative treatment[25].

Individuals co-infected with HIV and HSV have more severe outbreaks and more frequent viral shedding than those without HIV infection. When added to the medical regimen of HIV-infected patients, antiherpetic suppressive therapy appears to allow the co-infected person to respond better to antiretroviral therapy and to reduce genital and plasma HIV-1 RNA levels, but it does not seem to decrease the risk of HIV-1 transmission[26]. Oral acyclovir, famciclovir, and valacyclovir can be used for genital and orolabial HSV in the setting of HIV infection if there is no evidence of acyclovir resistance.

There is significant interest in prevention of HSV disease. Between 70% and 80% of HSV is transmitted during periods of asymptomatic viral shedding. Sexual abstinence is the only method for absolute prevention of genital herpes, which can be transmitted even with the use of condoms[27]. In addition to antiviral therapy, patient education regarding prevention of genital herpes transmission is essential.

There is currently no licensed vaccine available for HSV, although several vaccines are under development and evaluation for prevention of HSV infection and recurrences. GEN-003, a therapeutic vaccine under investigation for genital HSV-2 infection, was found in phase I/II clinical trials to reduce the rates of outbreaks and asymptomatic viral shedding[28]. In randomized controlled studies, adults with a history of genital herpes due to HSV-2 who received the helicase-primase inhibitor pritelivir had significantly decreased HSV shedding and fewer days with genital lesions than those who received placebo or valacyclovir[29]. There is currently an ongoing trial of the use of oral pritelivir for acyclovir-resistant mucocutaneous HSV infections in immunocompromised hosts.

VARICELLA–ZOSTER VIRUS (VZV; HHV-3)

Synonyms/clinical forms: ■ Varicella – chickenpox ■ Herpes zoster – shingles

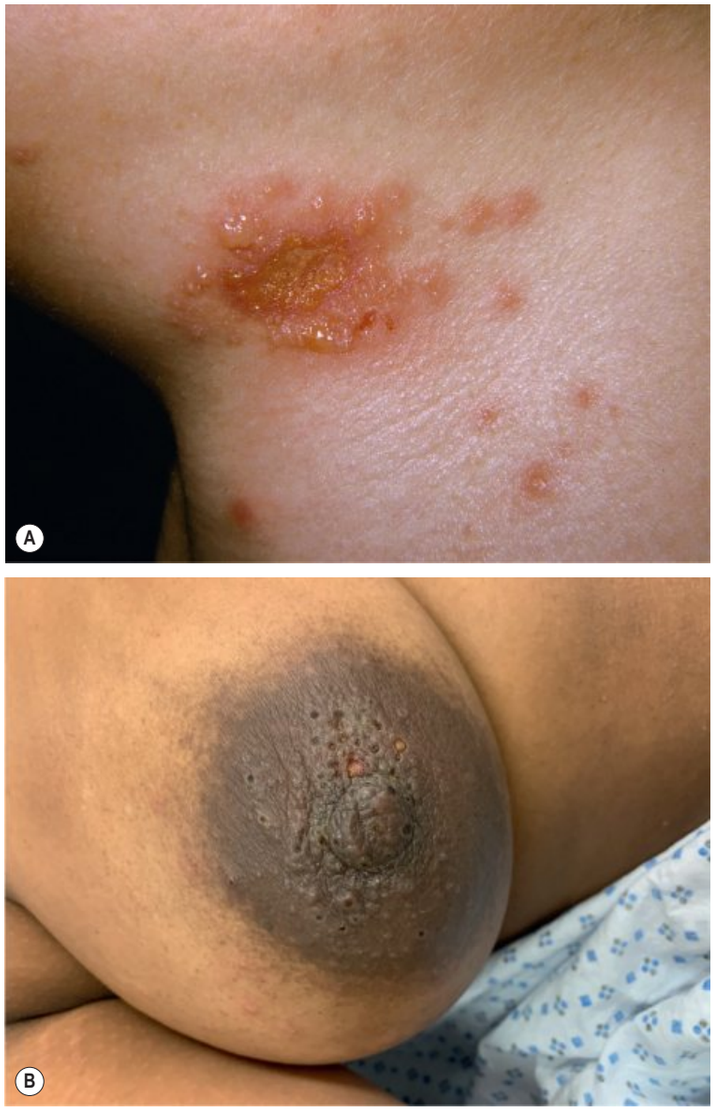

Fig. 80.7 Herpes simplex infections in less common locations. A Herpes gladiatorum presenting as grouped vesicles and erosions on the neck of a high-school wrestler. **B** Small vesicles and punched-out erosions clustered on the nipple and areola. *A, Courtesy Louis A. Fragola, Jr, MD; B, Courtesy Kalman Watsky, MD.*

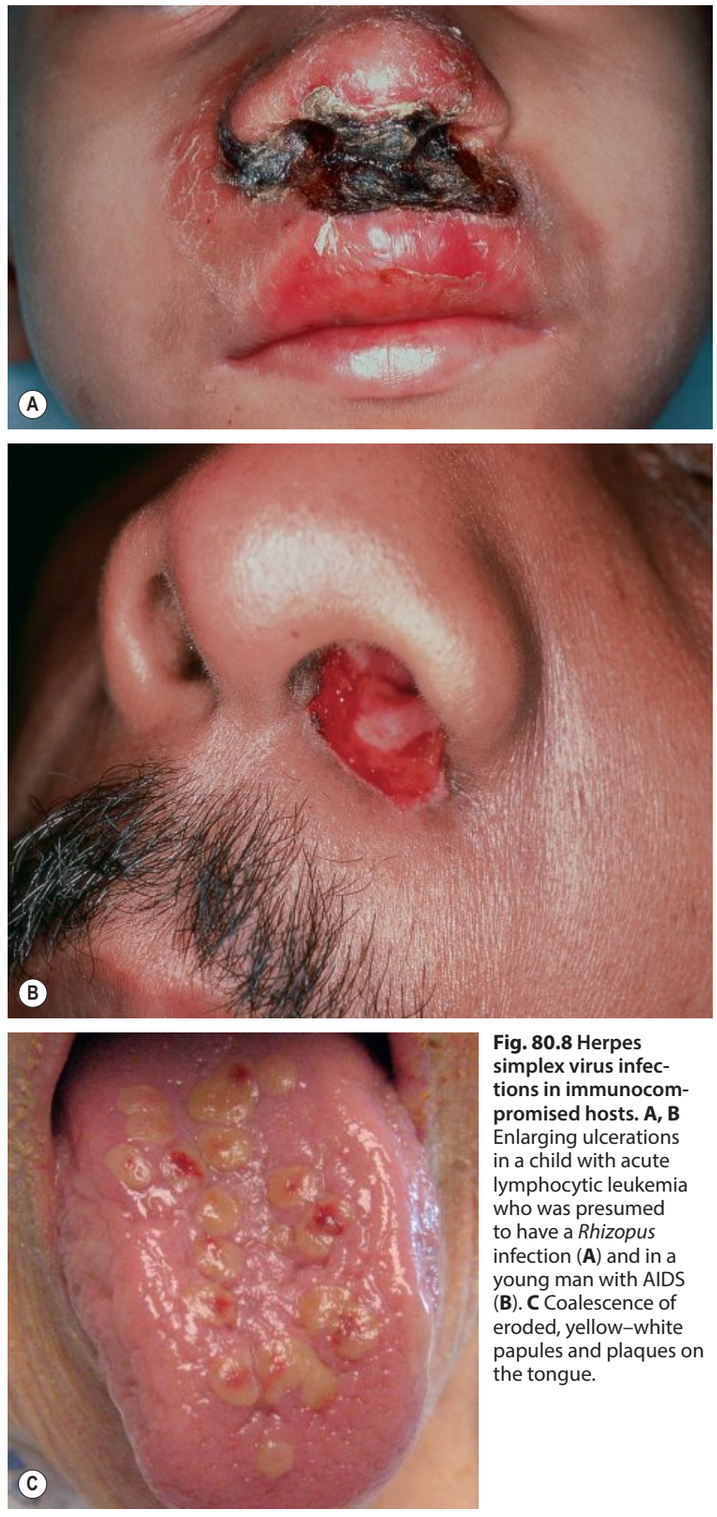

Fig. 80.8 Herpes simplex virus infections in immunocompromised hosts. A, B Enlarging ulcerations in a child with acute lymphocytic leukemia who was presumed to have a *Rhizopus* infection (**A**) and in a young man with AIDS (**B**). **C** Coalescence of eroded, yellow–white papules and plaques on the tongue.

Key features

- VZV is the etiologic agent of varicella (chickenpox) and herpes zoster (shingles)
- VZV has a high morbidity and mortality rate in immunocompromised hosts
- Antiviral treatment as well as vaccination can reduce or eliminate serious disease-associated sequelae and decrease the incidence of VZV infection

Introduction

VZV is the etiology of varicella (chickenpox) and herpes zoster (shingles). Varicella is usually symptomatic, and before the advent of the varicella vaccine, it occurred in 90% of children in the US by the time they reached 10 years of age. Herpes zoster represents reactivation of latent VZV infection and develops in ~20% of healthy adults and 50% of immunocompromised persons, with substantial morbidity and mortality in the latter group. Early initiation of antiviral treatment can reduce or eliminate serious sequelae of VZV infections.

History

Heberden first distinguished chickenpox from smallpox in 1767. The term "chickenpox" is thought to come from either the French word "chiche-pois" for chickpea (referring to the size of the vesicles) or the Old English word "gigan" meaning "to itch". The relationship between varicella and herpes zoster was first recognized in 1888, when von Bokay described the development of varicella in children following exposure to those with herpes zoster infection. Kundratitz (1922) and Bruusgaard (1932) more convincingly demonstrated the association between the two diseases by the development of varicella in susceptible children who had been inoculated with vesicle fluid from patients with herpes zoster. This was followed by the identification of the same virus in both diseases, confirming that their etiologies were identical.

Epidemiology

VZV has a worldwide distribution and 98% of the adult population is seropositive. In the pre-vaccine era, 90% of children <10 years of age developed varicella and ~4 million cases occurred annually in the US, with large outbreaks during the winter and spring. Since the introduction of the varicella vaccine in 1995, the overall incidence of varicella has decreased by ~85%, with evidence of herd immunity. The age of peak incidence also shifted from 5–9 years to 10–14 years, and a higher rate of breakthrough varicella among immunized children in the latter age group led to the addition of a second varicella vaccine dose to the routine childhood immunization schedule in 2006[30].

Although the incidence and severity of herpes zoster increase substantially in middle to late adulthood, it can occur at any age and is more common in younger persons who had a varicella infection within the first year of life. Overall, individuals with a history of varicella have a 20% lifetime chance of developing zoster. The annual incidence of herpes zoster in the US and Europe is classically 2.5/1000 persons between ages 20 and 50 years, 5/1000 between ages 51 and 79 years, and 10/1000 in those >80 years of age. However, there is evidence that exposure to varicella can protect seropositive adults from the development of zoster, and it has been postulated that widespread vaccination against varicella could reduce this immune boosting effect and increase the incidence of zoster. Whether this hypothetical increase will be counterbalanced by zoster vaccination remains to be determined. Other risk factors for herpes zoster include mental and physical stress, a family history of zoster, use of JAK inhibitors or proteasome inhibitors (e.g. bortezomib, carfilzomib), and an immunocompromised state, especially when due to HIV infection and allogeneic hematopoietic stem cell transplantation (HSCT)[31,32].

Pathogenesis

Airborne droplets are the usual route of transmission of varicella, although direct contact with vesicular fluid is another mode of spread, and the incubation period is 11–20 days. Varicella is extremely contagious, and 80%–90% of susceptible household contacts develop a clinically evident infection. The affected individual is infectious from 1–2 days before skin lesions appear until all the vesicles have crusted.

During varicella infection, primary viremia occurs after an initial 2–4 days of viral replication within regional lymph nodes. A cycle of viral replication in the liver, spleen, and other organs is then followed by a secondary viremia, which seeds the entire body 14–16 days postexposure. During this period, the virus enters the epidermis by invading capillary endothelial cells. VZV subsequently travels from mucocutaneous lesions to dorsal root ganglion cells, where it remains latent until reactivation at a later time.

Herpes zoster appears upon reactivation of latent VZV, which may occur spontaneously or be induced by stress, fever, radiation therapy, local trauma, or immunosuppression. During a herpes zoster outbreak, the virus continues to replicate in the affected dorsal root ganglion and produces a painful ganglionitis. Neuronal inflammation and necrosis can result in a severe neuralgia that intensifies as the virus spreads down the sensory nerve. Fluid from herpes zoster vesicles can transmit VZV to seronegative individuals, leading to varicella but not herpes zoster. The transmission rate to susceptible household contacts is ~15% for zoster, compared to 80%–90% for varicella.

Clinical Features

Varicella

A prodrome of mild fever, malaise, and myalgia may occur, especially in adults. This is followed by an eruption of pruritic, erythematous macules and papules, which starts on the scalp and face, and then spreads to the trunk and extremities (Fig. 80.12). Lesions rapidly evolve over ~12 hours into 1–3 mm clear vesicles surrounded by narrow red halos ("dew drops on a rose petal"). The number of vesicles varies from only a few to several hundred, and there is often involvement of the oral mucosa (see Fig. 80.12D). Sparing of the distal and lower extremities is common. Older vesicles evolve to form pustules and crusts, with individual lesions healing within 7–10 days. The presence of lesions in all stages of development is a hallmark of varicella.

The disease course is usually self-limited and benign in healthy children. However, prior to introduction of the varicella vaccine, complications resulted in 11 000 hospitalizations annually in the US. Secondary bacterial infection of the skin with subsequent scarring is the most common complication. CNS sequelae are uncommon (<1 per 1000 cases) and may include encephalitis and acute cerebellar ataxia; Reye syndrome which consists of encephalitis plus fatty liver is now

ANTIVIRAL THERAPY FOR HERPES SIMPLEX VIRUS AND VARICELLA–ZOSTER VIRUS	
Disease context	**Drug and dosage**
Herpes simplex infections	
Orolabial herpes* (recurrence)	*Topical* Docosanol: 5×/d until healed Penciclovir: 1% cream applied q2 h while awake × 4 days Acyclovir: 5% ointment applied q3 h or 6 times/day × 7–10 days Acyclovir + hydrocortisone: 5%/1% cream applied 5×/d × 5 days Acyclovir mucoadhesive tablet: 50 mg single application in the canine fossa on the side affected *Oral** Acyclovir†: 400 mg po TID × 7–10 days Famciclovir: 1.5 g po × 1 dose Valacyclovir: 2 g po BID × 1 day
Genital herpes (first episode)	Acyclovir: 200 mg po 5×/d × 10 days or 400 mg po TID × 10 days Famciclovir: 250 mg po TID × 10 days Valacyclovir: 1 g po BID × 10 days
Genital herpes (recurrence)	Acyclovir: 400 mg po TID × 5 days or 800 mg po BID × 5 days or 800 mg po TID × 2 days Famciclovir: 1 g po BID × 1 day or 500 mg po × 1 dose then 250 mg po BID × 2 days or 125 mg po BID × 5 days Valacyclovir: 500 mg po BID × 3 days or 1 g po daily × 5 days
Chronic suppression	Acyclovir: 400 mg po BID Famciclovir: 250 mg po BID Valacyclovir: 500 mg po daily for <10 outbreaks/year or 1 g po daily for ≥10 outbreaks/year
Neonatal	Acyclovir: 20 mg/kg iv q8 h × 14–21 days
Immunocompromised	*Recommend use until all mucocutaneous lesions are healed* Acyclovir: 400 mg po 5×/d or 5 mg/kg (if age ≥12 y) to 10 mg/kg (if age <12 y) iv q8 h Famciclovir†: 500 mg po BID Valacyclovir†: 1 g po BID
Eczema herpeticum/Kaposi varicelliform eruption†	*Recommend use for 10–14 days or (especially if immunocompromised) until all mucocutaneous lesions are healed* Acyclovir: 15 mg/kg (400 mg max) po 3–5×/d or, if severe, 5 mg/kg (if age ≥12 y) to 10 mg/kg (if age <12 y) iv q8 h Famciclovir: 500 mg po BID Valacyclovir: 1 g po BID
Genital herpes, recurrent in the setting of HIV infection	*Recommend use until all mucocutaneous lesions are healed* Acyclovir†: 400 mg po TID Famciclovir: 500 mg po BID Valacyclovir†: 1 g po BID
Chronic suppression in the setting of HIV infection	Acyclovir†: 400–800 mg po BID–TID Famciclovir†: 250–500 mg po BID Valacyclovir: 500 mg po BID
Acyclovir-resistant HSV in immunocompromised patients	Foscarnet: 40 mg/kg iv q8–12 h × 2–3 weeks (or until all lesions are healed) Cidofovir: 1% cream or gel daily × 2–3 weeks or (for severe disease) 5 mg/kg iv weekly × 2 weeks then every other week (together with probenecid)
Varicella–zoster virus infections	
Varicella	Acyclovir: 20 mg/kg (800 mg max) po 4×/d × 5 days Valacyclovir‡: 20 mg/kg (1 g max) po TID × 5 days
Herpes zoster	Acyclovir: 800 mg po 5×/d × 7–10 days Famciclovir: 500 mg po TID × 7 days Valacyclovir: 1 g po TID × 7 days
Immunocompromised patient or disseminated disease	Acyclovir: 10 mg/kg (500 mg/m^2) iv q8 h × 7–10 days *or until cropping has ceased* (depending on the setting, consider continuing until lesions are healed)

*Indications for and efficacy of antiviral treatment for initial episodes of orolabial herpes in immunocompetent adults have not been defined, but the regimens used for initial genital episodes can be considered in individuals with severe disease; acyclovir 15 mg/kg (200 mg max) po 5×/d × 7 days (initiated within 3 days of disease onset) has been shown to be beneficial in young children with primary herpes gingivostomatitis.
†Not specifically FDA-approved for this indication.
‡FDA-approved for ages 2–17 years; pharmacies can compound valacyclovir tablets into an oral suspension (25 or 50 mg/ml).

Table 80.4 Antiviral therapy for herpes simplex virus and varicella–zoster virus. Topical antiviral agents should be applied using a finger with intact skin. BID, twice daily; d, day; h, hours; iv, intravenously; po, orally; q, every; TID, three times daily.

rare due to avoidance of aspirin in children with varicella. Varicella in adolescents and adults is often more severe than in children, with an increased number of skin lesions (see Fig. 80.12A) and more frequent development of pneumonia, which has a 10%–30% mortality rate if untreated[33]. Occasional complications include thrombocytopenia, hepatitis, glomerulonephritis, optic neuritis, keratitis, arthritis, myocarditis, pancreatitis, orchitis, and vasculitis.

Maternal varicella during the first 20 weeks of pregnancy is associated with an ~2% risk of *congenital* varicella syndrome (varicella embryopathy). Possible congenital defects include a low birth weight, cutaneous scarring, ocular abnormalities, cortical atrophy, psychomotor retardation, and hypoplastic limbs. Children whose mothers had varicella during pregnancy may also develop zoster early in life without ever having extrauterine varicella. Severe *neonatal* varicella, in which amelioration by maternal antibodies is lacking, can occur when maternal varicella develops between 5 days before and 2 days after delivery.

In immunocompromised individuals, varicella may lead to severe complications and even death. These patients frequently have a more extensive and atypical cutaneous eruption, often with hemorrhagic or purpuric lesions[10]. Involvement of the lungs, liver, and CNS is common.

DOSE REDUCTIONS FOR ACYCLOVIR, VALACYCLOVIR, AND FAMCICLOVIR IN PATIENTS WITH RENAL DISEASE						
Indication	**Acyclovir**		**Valacyclovir**		**Famciclovir**	
	Creatinine clearance (ml/min)	**Adjusted dose**	**Creatinine clearance (ml/min)**	**Adjusted dose**	**Creatinine clearance (ml/min)**	**Adjusted dose**
Primary genital herpes simplex	<10	200 mg po BID	10–29	1 g daily	20–39	125 mg BID
			<10	500 mg daily	<20	125 mg daily
Recurrent genital herpes simplex			<30	500 mg daily	40–59	500 mg BID × 1 day
					20–39	500 mg once
					<20	250 mg once

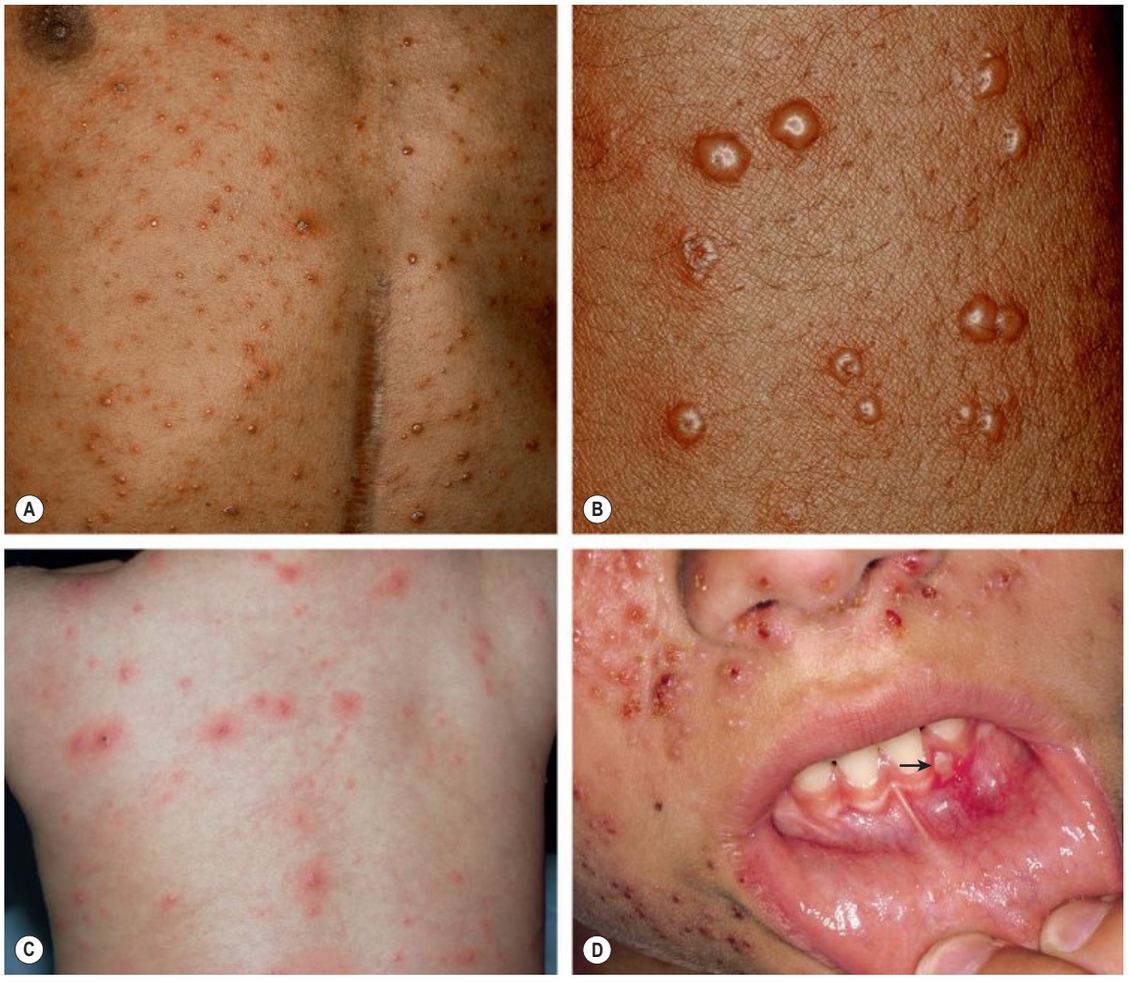

Fig. 80.12 Varicella. A–C Lesions in different stages of evolution, including vesicles, pustules, and hemorrhagic crusts. Vesicles often develop central umbilication. **D** Oral lesions can also occur (arrow). *A, B, Courtesy Robert Hartman, MD; C, Courtesy Julie V. Schaffer, MD; D, Courtesy Judit Stenn, MD.*

Herpes zoster

Reactivation of VZV may occur at any time after the development of varicella. In >90% of patients, herpes zoster begins with a prodrome of pruritus, tingling, tenderness, hyperesthesia, and/or intense pain, which can mimic a myocardial infarction, surgical abdomen, or toothache. These symptoms occasionally occur without subsequent skin lesions, a phenomenon referred to as "zoster sine herpete". However, most patients develop a painful eruption of grouped vesicles on an erythematous base in a dermatomal distribution (Figs. 80.13–80.15); the lesions can involve more than one contiguous dermatome and occasionally cross the midline. Edematous papules and plaques may precede the appearance of vesicles, and progression to pustules or bullae can occur (see Fig. 80.14). Any cutaneous site may be affected, with the trunk representing the most common location, followed by the face. VZV DNA can often be detected in the peripheral blood and saliva of patients with herpes zoster, even after initiation of antiviral treatment[34,35].

Herpes zoster usually resolves without sequelae in immunocompetent children and young adults. However, the pain, cutaneous lesions, and complications of herpes zoster become more severe with increasing age and immune compromise. The most common complication is postherpetic neuralgia, which is characterized by dysesthetic pain (e.g. burning or stabbing sensation, allodynia) that persists after the skin lesions have healed. This affects 10%–20% of all herpes zoster patients and increases in both incidence and severity with age[36]. Complications of herpes zoster related to the dermatome that is affected are presented in Table 80.6. Other complications can include secondary bacterial infection, scarring, meningoencephalitis, pneumonitis, and hepatitis. Cutaneous disorders that can develop within sites of previous herpes zoster, including granulomatous (Fig. 80.16) and pseudolymphomatous lesions, are listed in Table 80.7.

In immunocompromised individuals, herpes zoster may be more severe and can have unusual clinical presentations, e.g. persistent crusted, verrucous lesions in HIV-infected patients (Fig. 80.17) or postherpetic hyperhidrosis[10,37]. Disseminated cutaneous disease, defined as more than 20 vesicles outside the area of primary or adjacent dermatomes, and/or visceral involvement occurs in ~10% of immunocompromised persons with zoster (Fig. 80.18)[38].

Diagnosis and Pathology

A clinical diagnosis can usually be made based upon the history, including previous varicella or vaccine administration, and physical examination. A Tzanck smear, PCR, or DFA can assist in quickly confirming the diagnosis (see above and Fig. 80.10). The latter two (but not the Tzanck smear) can differentiate between HSV and VZV. Varicella and herpes zoster have the same histologic findings as HSV infections (see above and Fig. 80.11), but immunohistochemical staining can distinguish between the two viruses. Exclusive involvement of the hair follicles may be observed in herpes zoster, but not in HSV infection.

Additional laboratory tests include viral culture and serology. Viral culture is a very specific test; however, it is not very sensitive and results may not be available for >1 week. Serologic assays are diagnostic of VZV if the convalescent serum has at least a fourfold increase in the VZV titer relative to the acute serum. As a result, serology is only useful in retrospect.

Differential Diagnosis

The differential diagnosis of varicella may include vesicular viral exanthems (e.g. due to coxsackieviruses), disseminated HSV infection, pityriasis lichenoides et varioliformis acuta (PLEVA), rickettsialpox, drug eruptions, bullous insect bite reactions, and even scabies. Although no longer naturally occurring, smallpox also presents with a widespread vesicular eruption; its distinct clinical features are reviewed in Chapter 81. For herpes zoster, diagnostic considerations

Bolognia, MD; D, Courtesy Louis A. Fragola, Jr, MD.*

may include zosteriform HSV infections (which often recur in the same site), bacterial skin infections (e.g. cellulitis, bullous impetigo), contact dermatitis, and phytophotodermatitis. The entities listed above can usually be differentiated from VZV infections based on the history and clinical presentation, but laboratory studies and histologic evaluation are sometimes needed.

Treatment and Prevention

Varicella

Varicella in immunocompetent children can be treated symptomatically with antipyretics (e.g. acetaminophen), antihistamines, calamine lotion, and tepid baths. If started within 24–72 hours after the onset of the cutaneous eruption, acyclovir has been shown to decrease the duration and severity of varicella[39]. Oral acyclovir and valacyclovir are FDA-approved for the treatment of varicella in children (2–17 years of age) while acyclovir is approved for adults (see Table 80.4). These antiviral agents are recommended for varicella in healthy adolescents and adults as well as in children with chronic cutaneous or pulmonary disorders and in those receiving chronic salicylate therapy, inhaled corticosteroids, or intermittent oral corticosteroids. However, routine antiviral therapy is not recommended for otherwise healthy children with varicella due to the self-limited disease course and modest benefits of treatment[40]. Intravenous acyclovir is indicated for varicella in immunocompromised patients, including those receiving chronic systemic corticosteroids, due to their increased risk of more severe disease and complications[39].

Administration of varicella zoster immune globulin (125 U/10 kg, 625 U maximum) intramuscularly within 96 hours of varicella exposure is recommended to provide passive prophylaxis to nonimmune immunocompromised individuals and pregnant women as well as high-risk neonates (see above)[41]. Protection lasts for ~3 weeks. Another option for postexposure varicella prophylaxis in these patient groups is administration of intravenous immunoglobulin (IVIg; ≥400 mg/kg), which contains high levels of varicella-specific IgG[42]. Prophylactic oral acyclovir administration with usual varicella dosing (see Table 80.4) for 1 week, starting 7–10 days after exposure, can also be considered. Lastly, postexposure varicella vaccination (within 72–120 hours) may prevent or modify disease in nonimmune individuals who are ≥12 months of age, immunocompetent, and eligible to receive this live attenuated vaccine (see below).

Approved by the FDA in 1995, the live attenuated VZV vaccine (Oka strain; Varivax®) is highly efficacious, with seroprotection rates of ~85% after one dose and ≥99% after two doses in healthy children. Two doses of the vaccine, routinely given at ages 12–15 months and 4–6 years, are recommended to improve protection and counteract waning vaccine-induced immunity (see below). Studies indicate that one dose of the vaccine is 70%–90% effective in preventing infection and 95%–100% effective in preventing severe disease, and recipients of two doses are more than threefold less likely to develop breakthrough varicella than those who received one dose. The incidence and severity of both varicella (usually due to wild-type VZV) and zoster (most often due to the attenuated Oka strain) (Fig. 80.19) are decreased in vaccine recipients compared to unimmunized children. However, in a report based on surveillance of 350 000 subjects who received one vaccine

CLINICAL FINDINGS RELATED TO THE DERMATOME INVOLVED IN HERPES ZOSTER		
Dermatome/nerve involved	**Cutaneous findings**	**Extracutaneous findings**
Ophthalmic division of the trigeminal nerve (V_1; ~10%–15% of zoster patients)	*Hutchinson's sign* refers to increased risk of ocular involvement if skin lesions are in the distribution of the nasociliary branch, which supplies the nasal tip, dorsum, and root of the nose, and medial canthus as well as the cornea	• ~50% of patients have ocular involvement, which can include conjunctivitis, (epi)scleritis, keratitis, uveitis, acute retinal necrosis, and optic neuritis • May lead to ocular scarring and visual loss
Geniculate ganglion of the facial nerve – *Ramsay Hunt syndrome*	Lesions affecting the external auditory canal, tympanic membrane, anterior two-thirds of the tongue, and/or hard palate	• Ear pain • Facial nerve paralysis (peripheral) • Loss of taste in anterior two-thirds of the tongue • Dry mouth and eyes • If the vestibulocochlear nerve is also affected: tinnitus, hearing loss, and/or vertigo
Cervical dermatome	Lesions in cervical dermatome	• Peripheral motor neuropathy of the arm, which may result in muscle atrophy with gradual recovery of strength • Diaphragmatic weakness (C3–5)
Thoracic dermatome	Lesions in thoracic dermatome	• Abdominal muscle weakness or paralysis • Abdominal wall pseudohernia presenting as asymptomatic bulging of the anterolateral abdomen
Lumbar or sacral dermatome	Lesions in lumbar or sacral dermatome	• Peripheral motor neuropathy of the leg, which may result in muscle atrophy with gradual recovery of strength • Bowel or bladder dysfunction

Table 80.6 Clinical findings related to the dermatome involved in herpes zoster.

dose, loss of vaccine-induced immunity over time was observed, e.g. within 1 year of vaccination, there were 1.6 cases of varicella per 1000 person-years versus 58.2 per 1000 person-years at 9 years post-vaccination[43]. Because this is a live viral vaccine, administration is contraindicated during pregnancy and in individuals with immunosuppression due to hematologic malignancies, HIV infection (if $CD4^+$ T cells are <15% or <200 cells/mcl), other T cell immunodeficiencies, or systemic immunosuppressive therapy such as TNF inhibitors or prednisone (≥20 mg daily for ≥2 weeks, or ≥2 mg/kg daily when weight <10 kg).

Herpes zoster

For herpes zoster, beginning antiviral treatment within 72 hours of the development of skin lesions is optimal, but initiation up to 7 days after onset also appears to be beneficial. Acyclovir, famciclovir, and valacyclovir are all FDA-approved for the treatment of herpes zoster in immunocompetent individuals and result in decreased severity and duration of both skin lesions and pain (see Table 80.4). In controlled studies of immunocompetent individuals >50 years of age with acute herpes zoster, famciclovir and valacyclovir were equally effective (and

Fig. 80.16 Granulomatous dermatitis in the site of previous herpes zoster. Pink papules and plaques developed several weeks after an episode of herpes zoster in the same dermatomes. A sharp midline demarcation was observed on the back. Histologically, a granulomatous dermatitis was present within the dermis and focally a perineural distribution pattern was seen. *Courtesy Rebecca Vaughn, MD.*

CUTANEOUS DISORDERS THAT CAN DEVELOP WITHIN SITES OF HERPES ZOSTER
Acneiform – comedones, furunculosis, "acneiform eruption", rosacea (trigeminal distribution)
Dermatitis and urticaria – contact dermatitis (allergic and irritant), chronic localized urticaria
Granulomatous – granuloma annulare (including perforating variant), granulomatous dermatitis (sarcoidal, tuberculoid, unclassified, periadnexal, perineural; see Fig. 80.16), granulomatous vasculitis, lichenoid and granulomatous dermatitis*
Infiltrative – pseudolymphoma†, xanthomatous, Rosai–Dorfman disease
Malignancies, hematologic – leukemia (especially CLL), lymphoma cutis‡
Malignancies, other – Kaposi sarcoma (HIV-associated form), angiosarcoma, solid-organ metastases
Papulosquamous – psoriasis, lichen planus, lichenoid GVHD*
Sclerosing – lichen sclerosus, morphea, hypertrophic scars/keloids
Ulcerative – trophic syndrome (trigeminal, cervical)
Miscellaneous – acquired perforating disorder (acquired perforating collagenosis), nodular solar degeneration, tinea, bullous pemphigoid
*"Giant cell lichenoid dermatitis" has also been described within herpes zoster scars in an allogeneic bone marrow transplant recipient.
†In patients with chronic lymphocytic leukemia, a diagnosis of "pseudolymphoma" should be made only if leukemia cutis has been excluded.
‡Some solid organ metastases may show a zosteriform arrangement of the lesions without history of previous herpes zoster.

Table 80.7 Cutaneous disorders that can develop within sites of herpes zoster. The phenomenon of a new, unrelated disease appearing in the same location as a previously healed disease is referred to as the *Wolf isotopic response*. This list does not include routine scarring and acute complications such as bacterial infections. CLL, chronic lymphocytic leukemia.

similar or superior to acyclovir) at reducing the frequency and duration of postherpetic neuralgia[44]. Intravenous acyclovir is indicated for the treatment of zoster in immunocompromised patients as well as those with serious complications. Amenamevir, a helicase-primase inhibitor that is approved in Japan, was found to be non-inferior to valacyclovir in treatment of adults with zoster.

Multiple treatments are available for patients who develop postherpetic neuralgia. Low-dose tricyclic antidepressants have demonstrated considerable efficacy and appear to act by a mechanism independent from their antidepressant effects. In a randomized, controlled, multicenter trial, gabapentin (up to 3600 mg/day) was found to be effective in the treatment of pain and sleep interference associated with

Fig. 80.18 Disseminated varicella zoster viral infection. A Multiple violet–black papules on the feet. **B** Widely distributed necrotizing vesicles and bullae, some of which have formed large clusters, in a patient with lymphoma. Patients with disseminated cutaneous skin lesions should be evaluated for possible visceral involvement (e.g. hepatic, pulmonary, CNS), especially if they are immunocompromised. *B, Courtesy Edward Cowen, MD.*

Fig. 80.19 Herpes zoster following varicella vaccination. This healthy 3-year-old boy developed an eruption of erythematous papulovesicles in the C5 and C6 dermatomes of the right arm. He had received the varicella vaccine in the right shoulder at age 12 months, and several erythematous, edematous papulonodules had appeared in the region of the injection 2 weeks later. *Courtesy Julie V. Schaffer, MD.*

postherpetic neuralgia[45]. Combined treatment with nortriptyline and gabapentin reduced pain more than either agent alone in another randomized controlled trial[46]. In one open study, the use of gabapentin together with valacyclovir during acute herpes zoster was more effective in preventing postherpetic neuralgia than treatment with valacyclovir alone in historical controls; this regimen is recommended for patients with acute herpes zoster presenting with moderate to severe pain[47,48]. Although treatment with prednisone in addition to acyclovir can reduce acute pain in patients with herpes zoster, several controlled trials have failed to demonstrate a difference in the incidence or severity of postherpetic neuralgia with this combination compared to acyclovir monotherapy[49]. An 8% capsaicin patch was found to reduce the pain of postherpetic neuralgia for up to 12 weeks after a 1-hour application[50]. Other treatments used for postherpetic neuralgia include analgesics, EMLA cream, lidocaine patches, narcotic analgesics, pregabalin, nerve blocks, and biofeedback. Although some evidence suggests that patients receiving TNF inhibitors for various immune-mediated diseases may have a slightly higher incidence of herpes zoster, development of postherpetic neuralgia in these patients appears to be uncommon[51,52].

Because reactivation of VZV is linked with states of decreased cell-mediated immunity, the varicella vaccine was studied as a method of prophylaxis for herpes zoster. A large trial utilizing a 14-fold more concentrated version of the varicella vaccine in almost 40 000 adults ≥60 years of age showed a 51% reduction in the incidence of herpes zoster and 67% decrease in the likelihood of postherpetic neuralgia in vaccine recipients[53]. The FDA approved this live attenuated vaccine (Zostavax®) for immunocompetent adults ≥50 years of age in 2006, and the Advisory Committee on Immunization Practices (ACIP) recommended a single dose of Zostavax® for the prevention of herpes zoster in immunocompetent individuals ≥60 years of age[54]. However, multiple subsequent studies found that immunity induced against zoster by this vaccine was relatively short-lived, with a decrease in efficacy to <35% by year 6 after administration[55–58]. Considering its limited effectiveness as well as reports of necrotizing retinitis in immunocompromised vaccine recipients, Zostavax® is no longer available in the US.

In phase III studies, a recombinant subunit vaccine containing VZV glycoprotein E and the $AS01_B$ adjuvant system (HZ/su) administered in two doses two months apart reduced the likelihood of herpes zoster ~97% and postherpetic neuralgia ~90% in adults ≥50 years of age[59]. Efficacy of this vaccine was unaffected by advancing age and persisted for >3 years. In 2017, the FDA approved this recombinant zoster vaccine (Shingrix®) as a two-dose regimen, with the ACIP also recommending its use for the prevention of herpes zoster in immunocompetent adults ≥50 years of age (2–6 months between doses) and those ≥18 years of age who are or will be immunocompromised (1–6 months between doses)[60,61]. Vaccination is recommended regardless of whether or not the individual has a history of varicella, herpes zoster, or administration of a live attenuated VZV vaccine[60].

EPSTEIN–BARR VIRUS (HHV-4)

Synonym: ■ Infectious mononucleosis – glandular fever

Key features

- EBV is responsible for a variety of clinical diseases, most notably infectious mononucleosis; it is also associated with lymphoproliferative disorders and lymphomas
- Knowledge of EBV-specific serologies and other laboratory tests for EBV is essential for the clinician

Introduction and History

EBV is a ubiquitous human herpesvirus (HHV-4) that is responsible for a broad spectrum of clinical diseases, including infectious mononucleosis, oral hairy leukoplakia (see Ch. 78), hydroa vacciniforme (see Ch. 87), and a variety of lymphoproliferative disorders, lymphomas (B and T cell), and other malignancies (Table 80.8). It replicates well in B lymphocytes and can lead to their immortalization. EBV was named after its two discoverers, who found this herpesvirus in an African Burkitt lymphoma in 1964. In 1968, a link between infectious mononucleosis and EBV was established. Since then, various clinical disorders have been associated with EBV and are classified based on the type of cell infected and state of viral infection.

Epidemiology

In high-income countries, the prevalence of EBV infection in the general population approaches 95% by early adulthood. Peaks of incidence occur in individuals 1 to 6 and 14 to 20 years of age. Approximately 60%–80% of young children in low-income countries are seropositive for EBV, compared to ≤50% in the US. Most children with primary EBV infection have either no symptoms or a mild, nonspecific febrile illness. In contrast, ~50% of adolescents and young adults with primary EBV infection develop infectious mononucleosis. In the US, EBV is commonly associated with B cell lymphomas (~20%) and lymphoproliferative disorders (polyclonal and monoclonal) in immunocompromised patients. Worldwide, EBV is also implicated in Burkitt lymphoma (particularly the African-endemic form) and nasopharyngeal carcinoma (primarily in Asia) (see Table 80.8).

Pathogenesis

EBV is transmitted primarily through infectious saliva and occasionally via blood transfusion, although its presence in genital secretions and breast milk has been reported[62,63]. The virus preferentially infects human mucosal epithelial cells and B lymphocytes, with primary infection originating within the oropharyngeal epithelium. Infectious mononucleosis results from active viral replication, which is subsequently terminated by the host immune response.

After infectious mononucleosis resolves, circulating B lymphocytes can become latently infected with EBV as the virus enters cells by specifically binding to cell surface complement receptors CR2 or CD21. As the B lymphocyte divides, expression of the EBV nuclear antigen-1 gene (*EBNA-1*) is essential for replication of EBV DNA. Furthermore, the EBNA-1 protein and the virally encoded latent membrane protein-2 (LMP-2) are important in establishment of EBV latency within B lymphocytes and evasion from the cellular immune system[64]. In the presence

EBV-ASSOCIATED DISORDERS
Infectious mononucleosis
Gianotti–Crosti syndrome
Genital ulcers*
Periodontal disease
Oral hairy leukoplakia
Hydroa vacciniforme and related conditions due to chronic active EBV infection in childhood†
• Classic hydroa vacciniforme
• Hydroa vacciniforme-like lymphoproliferative disorder‡
• Severe hypersensitivity to mosquito bites‡
Lymphadenitis, including Kikuchi disease
Lymphoproliferative disorders and lymphomas
• Post-transplant lymphoproliferative disorder/lymphoma
• Methotrexate-associated lymphoproliferative disorder (usually in patients with rheumatoid arthritis)
• Systemic EBV$^+$ T cell lymphoma of childhood
• EBV$^+$ mucocutaneous ulcer
• X-linked lymphoproliferative syndrome
• EBV$^+$ hemophagocytic lymphohistiocytosis
• Lymphomatoid granulomatosis
• Burkitt lymphoma, endemic ≫ sporadic
• Extranodal NK/T cell lymphoma, nasal type
• EBV$^+$ diffuse large B cell lymphoma, NOS
• Angioimmunoblastic T cell lymphoma
• Other non-Hodgkin lymphomas (including T cell), particularly in HIV-infected patients
• Hodgkin lymphoma
Other malignancies
• Nasopharyngeal carcinoma
• Gastric carcinoma
• Leiomyosarcoma
Smooth muscle tumors

*There may or may not be evidence of EBV within the ulcer; reactive non-sexually related acute genital ulcers (Lipschütz ulcers) can be triggered by EBV and other infections (e.g. cytomegalovirus, influenza, *Mycoplasma pneumoniae*), most often in adolescent girls; this is thought to represent a form of aphthosis, which may be recurrent and associated with a history of oral aphthous ulcers.
†May progress to T or NK cell lymphoma or hemophagocytic lymphohistiocytosis; most often affects East Asian and Latin American children.
‡Present with bullous, necrotic, and ulcerative skin lesions together with fever, lymphadenopathy, hepatosplenomegaly and (with mosquito bite hypersensitivity) natural killer (NK)-cell lymphocytosis.

Table 80.8 EBV-associated disorders. Other skin conditions that are only occasionally associated with EBV include erythema nodosum, urticaria, erythema multiforme, erythema annulare centrifugum, drug reaction with eosinophilia and systemic symptoms (DRESS), small vessel vasculitis, granuloma annulare-like eruptions, and pityriasis lichenoides. NOS, not otherwise specified.

Fig. 80.20 Reactive non-sexually related acute genital ulceration associated with primary EBV infection. EBV-related genital ulcers, which are most common in adolescent girls, are often misdiagnosed as genital herpes simplex infection and in some patients represent a variant of aphthosis (see Table 80.8).

Fig. 80.21 Ampicillin-induced eruption in a patient with infectious mononucleosis due to EBV infection. Erythematous macules and papules have become confluent on the upper trunk.

of a normally functioning immune system, cell-mediated immune responses toward EBV antigens generally prevent the transformation and immortalization of B lymphocytes. However, in patients with deficient cell-mediated immunity, B lymphocytes can become immortalized and give rise to EBV-induced lymphoproliferative disorders.

Cell-mediated immunity to EBV infection is persistent and protects against developing infectious mononucleosis upon re-exposure to different types and strains of EBV later in life. The humoral immune response, although it generates antibodies to a variety of EBV antigens, does not appear to be protective. Latent virus in EBV-infected B lymphocytes can subsequently reinfect the oropharyngeal epithelium, resulting in periodic EBV reactivation and viral shedding for the lifetime of the host. However, reactivation of EBV is less common compared to other herpesviruses.

Clinical Features

EBV-induced infectious mononucleosis most commonly occurs in adolescents and young adults 15–25 years of age. After an incubation period of 30–50 days, the clinical triad of pharyngitis, fever lasting up to 10 days, and lymphadenopathy (especially cervical) occurs in >80% of patients. An initial prodrome of headache, malaise, and fatigue often precedes onset of the triad. The absence of cervical lymphadenopathy and fatigue makes the diagnosis unlikely. Splenomegaly is found in >50% of patients and can be accompanied by hepatomegaly. Other clinical findings may include exudative pharyngitis (often gray–white), anorexia, nausea, vomiting, cough, and arthralgias.

EBV infection can have a variety of dermatologic manifestations. A faint, nonspecific erythematous exanthem has been reported in up to 70% of hospitalized patients and ~10% of all patients with infectious mononucleosis[65]. The exanthem typically develops on day 4–6 of the illness and may last up to 1 week. It can be morbilliform, urticarial, scarlatiniform, vesicular, erythema multiforme-like, purpuric, or petechial in nature, usually beginning on the trunk and proximal upper extremities with later extension to the face and forearms. Eyelid petechiae, periorbital edema, and petechiae at the junction of the hard and soft palate may also be observed. Resolution of the illness usually occurs after 2 to 3 weeks, although symptoms of fatigue and malaise may last longer.

Painful genital ulcers, often measuring >1 cm, occasionally develop in patients (especially adolescent girls) with primary EBV infection (Fig. 80.20); PCR or *in situ* hybridization has confirmed the presence of lesional EBV in some cases[66]. Cutaneous conditions that are occasionally associated with primary EBV infection include Gianotti–Crosti syndrome (see Ch. 81), erythema nodosum, urticaria, acrocyanosis, erythema multiforme, erythema annulare centrifugum, and pityriasis lichenoides.

Administration of ampicillin or amoxicillin, and less commonly penicillin or cephalosporins, to patients with infectious mononucleosis, frequently (up to 90% with the former agents) leads to the development of a "hypersensitivity" skin reaction. This usually develops 7–10 days following institution of the antibiotic. Typically, a pruritic, pink to copper-colored, scarlatiniform or morbilliform eruption develops on extensor surfaces and pressure points and then becomes confluent as it spreads onto the trunk and extremities (Fig. 80.21). Desquamation

occurs 1 week later. The mechanism of this enhanced immune response to aminopenicillins in the setting of EBV infection is not well understood. In the absence of a pre-existing allergy, such reactions do not generally preclude the use of this class of antibiotics after the infectious mononucleosis resolves.

EBV-induced infectious mononucleosis can have serious complications. Splenic rupture occurs in 0.2% of affected adults, usually after trauma. Significant enlargement of oropharyngeal lymphoid tissue can lead to airway compromise. Other potential complications include hepatitis, thrombocytopenia, hemolytic anemia, glomerulonephritis, and CNS disturbances.

Diagnosis and Pathology

Laboratory findings in patients with infectious mononucleosis include mild to moderately elevated hepatic transaminase levels, mild thrombocytopenia, and an absolute and relative lymphocytosis (up to 50 000 cells/dl) with 20%–40% atypical lymphocytes. Atypical lymphocytosis is not pathognomonic for EBV infection, as a variety of infectious agents and drugs can also cause this phenomenon. Diagnosis is usually made by a positive monospot test, a simple slide test that detects IgM heterophile antibodies, or by increased titers of heterophile antibodies; the latter reach a titer of >1 : 40 in ~90% of young adults infected with EBV. Heterophile antibodies are capable of agglutinating sheep, horse, or bovine erythrocytes, and they typically become detectable 1 week to 1 month after the onset of symptoms and persist for 3 to 18 months.

Because heterophile antibody titers are positive in only a minority of young children with a primary EBV infection, EBV-specific serologies are often necessary to establish the diagnosis in this age group. Titers of at least three different antibodies should be assessed to determine the stage of EBV infection, allowing differentiation between an acute primary, past/latent, and reactivated infection (Table 80.9)[65].

PCR-based assays to detect EBV DNA in peripheral blood or tissue samples are also available. Markedly elevated peripheral blood levels are found in patients with infectious mononucleosis and in immunodeficient individuals with EBV-associated lymphoproliferative disorders. Of note, lower levels of EBV DNA can also be detected in the peripheral blood of healthy individuals with a latent EBV infection. *In situ* hybridization for EBV-encoded small RNA (EBER) represents a widely available, sensitive, and specific method to detect EBV-infected cells in the skin and other tissues. This assay can be performed on paraffin-embedded specimens, and EBER-positive cells are prominent in EBV-related dermatoses (e.g. T cells in hydroa vacciniforme; see Fig. 87.11) and malignancies, but absent in inflammatory dermatoses and lymphomas that are not related to EBV infection.

Primary EBV infection is not associated with any pathognomonic histologic findings. Features are similar to those observed with other viral exanthems, i.e. slight spongiosis, parakeratosis, and a perivascular lymphocytic infiltrate. Additional findings may include focal keratinocyte necrosis, mild ballooning degeneration, and, rarely, multinucleated keratinocytes, but less prominent than with HSV and VZV infection. Aminopenicillin-induced eruptions in the setting of infectious mononucleosis often demonstrate vacuolar interface changes and spongiosis in association with a denser dermal inflammatory infiltrate. Biopsies of involved lymph nodes typically show reactive lymphoid hyperplasia.

Differential Diagnosis

The differential diagnosis of EBV-induced infectious mononucleosis includes drug reaction with eosinophilia and systemic symptoms (DRESS, see Ch. 21 and HHV-6 section below), which is often associated by reactivation of herpesviruses including EBV as well as HHV-6. DRESS is distinguished by exposure to an implicated drug in addition to features such as eosinophilia and marked facial edema. Group A streptococcal infection, acute viral hepatitis, toxoplasmosis, lymphoma, and primary CMV, HHV-6, and HIV infections may represent additional diagnostic considerations. A combination of history, physical examination, and laboratory studies can differentiate among these diseases.

Treatment

In most cases of infectious mononucleosis, the disease is self-limited and treatment is supportive. Acyclovir can inhibit EBV replication; however, in controlled studies where primary EBV infection was treated with acyclovir or acyclovir combined with systemic corticosteroids, there was no effect on clinical outcome[67]. In one study of healthy individuals with a past/latent EBV infection, the administration of valacyclovir for 1 year reduced the number of EBV-infected B cells in the peripheral blood compared to an untreated control group[68]. Due to their multiple side effects, corticosteroids are reserved for only complicated cases of infectious mononucleosis associated with hemolytic anemia, severe thrombocytopenia, liver failure, or lymphadenopathy resulting in airway compromise[69]. In patients with EBV-associated lymphoproliferative disorders, reduction of immunosuppression can lead to spontaneous resolution, especially when the disorder is polyclonal.

CYTOMEGALOVIRUS (HHV-5)

Key features

- CMV is the leading infectious cause of congenital deafness and intellectual disability (TORCH syndrome) as well as the leading cause of blindness (due to retinitis) in AIDS patients
- Neonates and immunocompromised hosts are at risk for severe clinical infections

Introduction

CMV is endemic in all parts of the world, and it is the most common cause of intrauterine infection in humans. In immunocompetent hosts, 95% of infections are asymptomatic or subclinical. Neonates and immunocompromised individuals, especially individuals with AIDS, allogeneic HSCT recipients, and patients receiving alemtuzumab, are at risk for severe clinical manifestations of CMV infection.

History

In 1881, Ribbert first observed "protozoan-like cells" in the organs of a stillborn baby with presumed congenital syphilis. Before the discovery of a viral etiology, the disease was initially called "cytomegalic inclusion

EBV SEROLOGIES					
Antibody	**Timing of appearance**	**Timing of disappearance**	**Acute primary infection**	**Past/latent infection**	**Reactivated (RA)/chronic active (CA)* infection**
VCA IgM	Prior to onset of symptoms	Usually within 3 months	Positive	Negative	Negative in RA/variable in CA
VCA IgG	With onset of symptoms	Persists for life	Positive	Positive	Positive
EA IgG†	With onset of symptoms	Usually within 3–6 months; positive if active infection‡	Positive	Negative‡	Positive
EBNA IgG	1–6 months after onset of symptoms, upon establishment of latency	Persists for life	Negative	Positive	Positive in RA/variable in CA

*Associated with hemophagocytic lymphohistiocytosis, lymphoproliferative disorders, and lymphomas.
†Not usually included in routine serologic testing.
‡Persists following resolution of infection in ~20% of healthy individuals.

Table 80.9 EBV serologies. EA, early antigen; EBNA, EBV nuclear antigen; VCA, viral capsid antigen.

disease" based on the characteristic enlarged cells (cytomegalia) and intranuclear inclusions. In 1956, human CMV was independently isolated *in vitro* by three groups of investigators led by Weller, Rowe, and Smith. Originally known as the "salivary gland virus" or "salivary inclusion disease virus", CMV was given its current name by Weller and his colleagues in 1960[70].

Epidemiology

The prevalence of CMV infection is inversely proportional to socioeconomic status. For example, 80%–100% of the African population is CMV-seropositive compared with 60%–70% of the US and Western European populations. The increased seroprevalence in low-income countries is thought to be due to crowded living conditions, poor hygiene, and greater numbers of individuals caring for an infant. Age-related prevalence studies in the US have shown highest risks of CMV acquisition during early childhood, adolescence, and the reproductive years.

CMV seropositivity is especially high among toddlers in day care centers, and transmission from young children to their mothers has been described[71]. In adults, CMV infections are often contracted through sexual contact. Blood transfusions carry a 3%–4% risk of CMV infection per transfusion unit[72]. To decrease this risk, leukocyte-depleted blood can be used in immunosuppressed patients.

Solid organ transplant and HSCT recipients, other individuals receiving immunosuppressive agents, and those infected with HIV are at increased risk of disseminated CMV infection. More recently introduced treatments such as CAR-T cellular therapy and bispecific T cell engager therapy also put patients at risk for CMV infections. CMV represents a source of significant morbidity (e.g. retinitis, colitis) and mortality in patients with AIDS. In the US, congenital CMV infection occurs in ~0.5% of all neonates[73].

Pathogenesis

Transmission of CMV is via body fluids, including saliva, blood, urine, semen, breast milk, and cervical and vaginal secretions, as well as in transplanted organs and rarely hematopoietic stem cells. CMV can also be spread indirectly by contaminated fomites, such as toys. Transplacental transmission of CMV to the fetus is more likely in the setting of a primary infection in the mother, with 40% of fetuses becoming infected, compared to <1% in recurrent cases.

CMV has an estimated incubation period of 4–8 weeks, followed by viremia via infected blood leukocytes and spread to various organs. It is a cytotoxic virus that causes cell enlargement (cytomegaly) and nuclear condensation (inclusion). In immunocompetent hosts, the virus induces high levels of specific anti-CMV $CD4^+$ and $CD8^+$ T cells[74]. CMV infection may be either primary or recurrent, and the latter can result from either viral reactivation or reinfection with a different antigenic type.

Following primary infection, CMV persists in a latent state for the life of the host and rarely causes disease. In immunocompromised individuals, however, reactivation of latent virus can lead to recurrent infection characterized by persistent viral replication, viremia, and dissemination to distant organs. Cell injury and tissue destruction contribute to organ damage by directly altering cellular function and producing an inflammatory response.

The organ infected depends on the age of the host. Infection in healthy children and adults often involves the lymphoid tissues, while fetal and neonatal infection commonly affects the salivary glands and neurons. Infection in immunocompromised individuals frequently involves the retina and lungs as well as the liver and gastrointestinal tract.

Clinical Features

More than 90% of primary CMV infections are subclinical, although a "mononucleosis-like syndrome" similar to that seen with EBV occasionally develops in immunocompetent persons (Table 80.10). This syndrome has also been described in both immunocompetent and immunocompromised individuals after a blood transfusion. Infected patients develop non-exudative pharyngitis in addition to fever, malaise, myalgias, lymphadenopathy, and hepatosplenomegaly. Atypical lymphocytosis and elevated liver enzymes may also occur. An exanthem, which can be morbilliform, urticarial, petechial or purpuric, develops in a small percentage of patients. As with infectious mononucleosis, the administration of ampicillin or related drugs during this symptomatic period leads to a cutaneous eruption in 80%–100% of individuals. Although the clinical course of CMV-induced mononucleosis is self-limited, rare complications include hemolytic anemia, thrombocytopenia, granulomatous hepatitis, Guillain–Barré syndrome, meningoencephalitis, myocarditis, interstitial pneumonia, arthritis, and gastrointestinal and genitourinary manifestations.

Congenital CMV infection is the leading infectious cause of deafness and intellectual disability in the US. Approximately 5%–10% of infected neonates have symptoms at birth, presenting with jaundice, hepatosplenomegaly, intrauterine growth retardation, thrombocytopenia, chorioretinitis, seizures, and/or intracranial calcifications. Cutaneous manifestations include purpuric papules and nodules of dermal hematopoiesis which are sometimes referred to as "blueberry muffin" lesions (Fig. 80.22; see Ch. 121), in addition to petechiae, purpura, and vesicles. Another 10%–15% of children are born with asymptomatic CMV infection and later develop sequelae, most often sensorineural hearing loss. Perinatal CMV infection is often asymptomatic; however, a limited number of infected infants develop pneumonitis, lymphadenopathy, or hepatosplenomegaly[75].

CUTANEOUS MANIFESTATIONS OF CMV INFECTIONS
Immunocompetent host
Mononucleosis-like syndrome
• Maculopapular/morbilliform eruption • Petechiae and purpura • Ampicillin-induced eruption • Urticaria • Erythema nodosum
Congenital infections
• "Blueberry muffin" lesions (extramedullary hematopoiesis; see Ch. 121) • Petechiae and purpura • Vesicles
Immunocompromised host
Cutaneous vasculitis Maculopapular/morbilliform eruption Petechiae and purpura Ulcers (most often genital, perianal, or oral) Vesicles Verrucous plaques Nodules and hyperpigmented plaques

Table 80.10 Cutaneous manifestations of CMV infections. CMV infection can also trigger reactive non-sexually related acute genital ulcers (see Table 80.8).

Fig. 80.22 TORCH syndrome due to cytomegalovirus. Multiple purpuric papules of dermal hematopoiesis. *Courtesy Mary S. Stone, MD.*

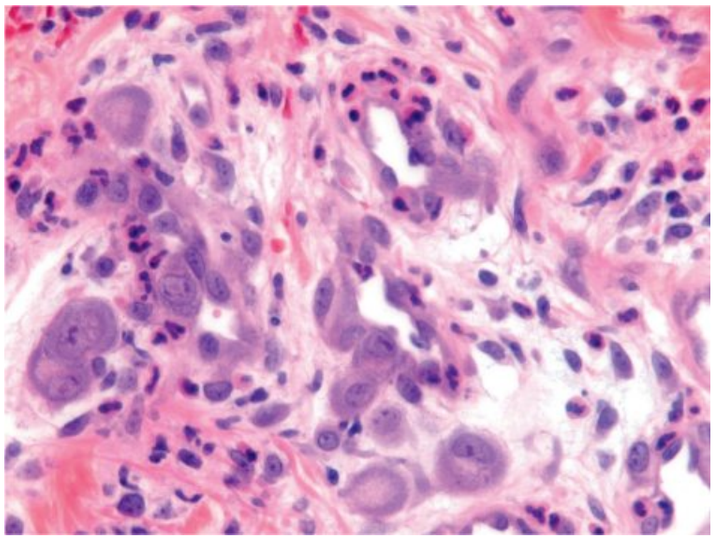

Fig. 80.23 Histology of cytomegalovirus (CMV) infection. Enlarged endothelial cells with a prominent intranuclear inclusion are typical of CMV infection. *Courtesy Angela Galan, MD.*

In AIDS patients, CMV may cause chronic ulcers of the perineum or extremities, chorioretinitis, esophagitis, colitis, and pneumonitis, as well as endocrine, bone marrow, CNS, and renal abnormalities. Cutaneous manifestations can range from vesicles to nodules to verrucous plaques. In recipients of solid organ transplants and HSCTs, gastrointestinal involvement and less often interstitial pneumonia are the most serious manifestations of CMV infection.

Diagnosis and Pathology

Culture of CMV in human fibroblasts is the traditional diagnostic "gold standard", but this takes several days to weeks. Detection of CMV in tissue cultures within 24–48 hours is possible with the shell vial assay, in which monoclonal antibodies specific for early CMV antigens are employed. In addition to CMV-specific serologies, assays that detect CMV antigens (e.g. pp65) within leukocytes or CMV DNA via PCR (necessary in neutropenic patients) are commonly employed to identify and monitor viremia and systemic infection[76]. CMV retinitis in patients with AIDS is diagnosed by ophthalmologic examination.

Like other viral exanthems, the histologic features of the acute exanthem of CMV infection include mild spongiosis and a sparse perivascular lymphocytic infiltrate in the upper dermis. Epidermal changes are minimal since CMV does not infect keratinocytes. However, it does infect endothelial cells, which can have an "owl's eye" appearance that is pathognomonic for CMV infection. The cells are enlarged two- to threefold and contain purplish, crystalline intranuclear inclusion bodies surrounded by a clear halo (Fig. 80.23). These cytomegalic cells are most likely to be evident in ulcers, and vascular dilatation is another common finding. CMV vasculitis, a manifestation of disseminated disease, is characterized by marked endothelial swelling and inflammation.

Differential Diagnosis

The clinical differential diagnosis of the mononucleosis-like syndrome of CMV infection includes EBV-induced infectious mononucleosis, which is generally more severe and often associated with exudative pharyngitis. Other diagnostic considerations may include DRESS, which may also be associated with reactivation of CMV (see HHV-6 section below), as well as toxoplasmosis, viral hepatitis, GVHD, and lymphoma. A high index of suspicion is necessary to diagnose CMV-induced ulcers and atypical cutaneous manifestations in immunocompromised patients.

Treatment and Prevention

Management is targeted at prevention plus prophylactic antiviral treatment in susceptible immunocompromised individuals as well as antiviral treatment in those who are symptomatic. Treatment of CMV-induced mononucleosis in immunocompetent individuals, however, is only supportive.

TREATMENT FOR CMV INFECTIONS IN IMMUNOCOMPROMISED PATIENTS		
Medication	**Route**	**Major side effects**
Ganciclovir	iv, intravitreal implant or injection	Bone marrow suppression, GI symptoms > renal insufficiency, neuropathy
Valganciclovir	po	
Maribavir	po	GI symptoms, taste disturbance, drug-drug interactions (e.g. cyclosporine, other CYP3A4 substrates/inducers)
Letermovir†	po, iv	GI symptoms, peripheral edema, cardiac adverse events, drug-drug interactions (e.g. cyclosporine, statins, pimozide, ergot alkaloids)
Cidofovir	iv*, intravitreal injection	Renal toxicity
Foscarnet	iv, intravitreal injection	Renal toxicity
Fomivirsen	Intravitreal injection	

*Initially given weekly for 2 weeks for AIDS-related CMV retinitis.
†FDA-approved for primary prophylaxis in CMV-seropositive adult allogeneic hematopoietic stem cell transplant recipients.

Table 80.11 Treatment options for CMV infections in immunocompromised patients. iv, intravenous; po, orally.

As a preventive measure, hematopoietic stem cells and other tissues from CMV-seronegative donors are used preferentially for transplantation in seronegative recipients. Letermovir, an inhibitor of the CMV terminase complex, is currently FDA-approved for prophylactic administration in adult CMV-seropositive allogeneic HSCT recipients. Usually administered for at least 100 days, letermovir reduces the risk of clinically significant CMV infection and non-relapse mortality in this patient population[77,78]. While letermovir lacks the myelosuppression associated with ganciclovir, it does not have activity against HSV-1 and -2. Pre-emptive management consisting of following blood CMV DNA levels and initiating first-line therapies if they increase represents another strategy in transplant recipients.

The first-line agents for treatment of CMV infections in immunocompromised patients are intravenous ganciclovir or oral valganciclovir; intravitreal injections/implants of ganciclovir are used for localized retinitis. When patients fail to respond to these medications or develop significant side effects, maribavir, foscarnet, and cidofovir are additional options[79] (Table 80.11). Maribavir, an inhibitor of the CMV UL97 protein kinase, was recently FDA-approved for post-transplant CMV infections that fail to respond to other medications. In general, relapse is common after discontinuation of antiviral agents. Treatment with CMV-specific T cell adoptive transfer is being studied in immunocompromised individuals but is not readily available.

There is ongoing investigation of several CMV vaccines, including those utilizing a replication defective whole-virus, adjuvanted subunits, virus-like particles, viral vectors, and mRNA encoding vaccine antigens.

HUMAN HERPESVIRUS TYPE 6 (HHV-6)

Synonym: ■ Roseola infantum – exanthem subitum, sixth disease

Key features

- HHV-6 is the cause of exanthem subitum (roseola infantum), a common febrile disease of early childhood
- Although HHV-6 infection is usually a benign condition without long-term consequences, it can be life-threatening if reactivated in the setting of immunosuppression
- HHV-6 and other herpesviruses (e.g. EBV, CMV, HHV-7) have been implicated in the pathogenesis of DRESS syndrome

Introduction

HHV-6 is the etiologic agent of exanthem subitum (roseola infantum), one of the most common viral exanthems in infants and young children. Although HHV-6 infection usually is a benign disease without long-term sequelae, the virus remains latent and can be life-threatening if reactivated in the setting of immunosuppression.

History

Zahorsky distinguished exanthem subitum from other exanthems in 1910 and is credited for its first description. In 1988, Yamanishi and colleagues used serologic methods to confirm that HHV-6 caused exanthem subitum[80]. A subsequent study discovered two distinct variants of the virus: HHV-6A and HHV-6B, each with different biologic, immunologic, and genetic characteristics. Variant B is primarily the cause of exanthem subitum, while the pathogenic role of variant A is unclear, except that it is identified more frequently in patients with Hashimoto disease.

Epidemiology

HHV-6 is found worldwide. Infection is most common in young children, occurring between the ages of 6 months and 3 years in 95% of cases, with a peak incidence between 6 and 12 months of age. Boys and girls are equally affected. Seroprevalence studies have shown that maternal IgG against HHV-6 is transferred to 70%–97% of fetuses. The level of these maternal antibodies in infants wanes by 6 months of age, and subsequent primary infections result in a peak HHV-6 seroprevalence of 90%–100% at 3 to 4 years of age. Antibody levels then decline again, with a prevalence of 65% to 95% in adults[81]. Despite the high seroprevalence, only 30% of children develop clinical manifestations of exanthem subitum. Infections occur throughout the year but are most common in the spring.

Pathogenesis

HHV-6 has a tropism for $CD4^+$ T lymphocytes, but it can infect a variety of other cells, including neurons. Transmission is typically through infected saliva, although HHV-6 DNA has been isolated from the cervix and may cause perinatal infection. After primary HHV-6 infection, the virus establishes lifelong latency in $CD4^+$ T lymphocytes, with the potential for reactivation. Immunosuppressed patients are at particular risk for HHV-6 reactivation, sometimes with severe consequences[82]. In HSCT recipients, asymptomatic HHV-6 reactivation is more common with alternative donors (e.g. cord blood, haploidentical) than with matched donors, but symptomatic disease (e.g. encephalitis) is unusual. HHV-6 also has the ability to integrate its genome into the telomeres of infected cells; as a result of this occurring in the germline, ~1% of the general population has inherited chromosomally-integrated HHV-6A/B present in all the cells of the body.

The effects of HHV-6 in HIV-infected individuals are unclear. *In vitro* studies have described both increased and decreased replication of HIV-1 in cells co-infected with HHV-6 and HIV-1. To date, there is no definitive evidence that HHV-6 influences HIV-1 disease progression[80,83].

Patients with acute myelogenous leukemia and lymphoproliferative malignancies including Hodgkin lymphoma, follicular large cell lymphoma, Burkitt lymphoma, and angioimmunoblastic T cell lymphoma have higher HHV-6 antibody titers than healthy individuals, as do patients with systemic lupus erythematosus, multiple sclerosis, and myalgic myoencephalitis/chronic fatigue syndrome. Of note, HHV-6 DNA has been demonstrated in lesions of Rosai–Dorfman disease[84], and HHV-6 has been postulated to have a possible role in the pathogenesis of pityriasis rosea (together with HHV-7; see below). HHV-6 and other herpesviruses (e.g. EBV, CMV, HHV-7) have been implicated in the pathogenesis of DRESS syndrome (see Ch. 21). It has been postulated that drug-related immunosuppression or induction of viral replication leads to viral reactivation, which stimulates a cellular immune response directed against herpesviruses and likely cross-reacting with the drug.

Clinical Features

The classic clinical manifestations of exanthem subitum occur in ~30% of those with primary HHV-6 infections. The incubation period ranges from 5 to 15 days, but it is most often 9–10 days. Typically, an otherwise well-appearing infant presents with a high fever (102–105°F; 38.9–40.6°C) that lasts for 3–5 days, followed by a cutaneous eruption as the fever begins to subside. The fever may be intermittent and tends to peak in the early evening. The cutaneous eruption usually lasts for 24–48 hours and may develop before the temperature returns to normal or up to 2 days afterwards. The lesions are discrete, circular or elliptical, "rose-red" macules and papules that are 2–5 mm in diameter and occasionally surrounded by a white halo. The cutaneous eruption commonly affects the trunk (Fig. 80.24), proximal extremities, neck, and less often the face; its appearance can be very similar to rubella or rubeola. An enanthem of red papules on the soft palate (Nagayama's spots) may also be seen, and ulcers on the uvula and at the palatoglossal junction represent a characteristic finding. Eyelid edema, mild upper respiratory symptoms, injection of the tympanic membranes, cervical or occipital lymphadenopathy, and a bulging anterior fontanelle may also be evident.

The most common complication of exanthem subitum is febrile seizures, which occur in 10%–15% of affected infants and children. Infection with or reactivation of HHV-6 in immunocompromised patients can lead to fever and a cutaneous eruption as well as more serious consequences such as hepatitis, pneumonitis, bone marrow suppression, encephalitis, and transplanted tissue rejection[80].

Diagnosis and Pathology

In healthy individuals, HHV-6 infection is typically diagnosed clinically. Serology may be helpful in ambiguous situations. The presence of IgM antibodies indicates primary infection, but this assay is not reliable for the detection of reactivation. A fourfold increase in IgG in paired samples from the acute and convalescent phases of the disease can give retrospective confirmation of HHV-6 reactivation.

Other diagnostic tools include PCR-based assays and viral culture. PCR detection of cell-free HHV-6 DNA in serum or plasma has diagnostic utility. However, qualitative PCR using cellular specimens (e.g. peripheral blood mononuclear cells) cannot reliably distinguish between latent and active infection.

Histopathologically, exanthem subitum shows nonspecific changes such as spongiosis of the epidermis with spongiform vesicles and exocytosis of lymphocytes. A sparse inflammatory infiltrate is found in the superficial dermis, and papillary dermal edema is often evident. Nuclear basophilic inclusions can be found within perivascular lymphocytes in the cutaneous eruptions that may occur in immunocompromised patients.

Differential Diagnosis

The differential diagnosis of exanthem subitum is primarily other viral exanthems such as rubeola, rubella, and enterovirus, adenovirus, EBV, and parvovirus infections. Other considerations may include scarlet fever, Rocky Mountain spotted fever, and Kawasaki disease (see Ch. 81).

Treatment

Although HHV-6 infection is usually self-limited, serious complications can occur in immunocompromised patients. At present, there are no approved compounds or vaccines exclusively for the treatment of HHV-6. However, some studies have shown that phosphonoacetic acid, foscarnet, ganciclovir, brincidofovir, and artesunate may inhibit HHV-6. There are reports of successful treatment of serious infections with foscarnet and ganciclovir, and *post hoc* analysis of a randomized, placebo-controlled trial found that brincidofovir reduced the frequency of HHV-6 reactivation in HSCT recipients. A multivirus specific T-cell therapy, posoleucel, has orphan drug designation for infections with HHV-6 as well as EBV, CMV, adenovirus, BK virus, and JC virus in allogeneic HSCT recipients.

HUMAN HERPESVIRUS TYPE 7 (HHV-7)

Key feature

- HHV-7 is a lymphotropic virus that has been linked to reactivation of HHV-6 in some patients with exanthem subitum

HHV-7 is a ubiquitous lymphotropic herpesvirus that was first isolated by Frenkel et al.[85] in 1990. More than 95% of adults are seropositive[86]. Infections with HHV-7 mainly occur during the first 5 years of life, with a peak at 1–2 years of age, and then typically remain latent. Transmission via saliva is most likely, since HHV-7 is only known to replicate in human salivary glands; however, HHV-7 has also been found in cervical secretions.

Little is understood about the pathogenesis of HHV-7, but it has been shown to utilize the CD4 receptor for entry into cells. HHV-7 downregulates the expression of CD4 molecules on lymphocytes and may downregulate the infectivity of HIV, since both viruses compete for the same receptor.

The virus grows best in cord blood lymphocytes and has a limited range of host tissues compared to that of HHV-6, although HHV-7 antigen has been found in human lungs, mammary glands, and skin. Compared to HHV-6, HHV-7 is less cytopathic, associates more with cells, and grows more slowly in culture. Significant homology exists between the two viruses and limited antigenic cross-reactivity has been demonstrated between HHV-7 and HHV-6A (but not HHV-6B)[82]. However, HHV-7 is serologically distinct from HHV-6, and immunity to HHV-7 is not conferred with HHV-6 antibodies (or vice versa).

HHV-7 has not been clearly established as a causative factor for clinical disease, although it has been linked to several conditions, including DRESS (see above and Ch. 21). A subset of exanthem subitum has been associated with reactivation of HHV-6 (particularly variant B) in conjunction with primary infection with HHV-7. The cutaneous eruption associated with HHV-7-induced exanthem subitum is lighter in color and presents later in the disease course than that of primary HHV-6 infection[87]. Neurologic complications, such as febrile seizures and acute hemiplegia, have also been reported with HHV-7-induced exanthem subitum. Several studies have suggested that HHV-7 may be a cofactor for symptomatic CMV infection in renal transplant recipients[88,89].

HHV-7 and pityriasis rosea (PR) were first associated when HHV-7 DNA was detected via PCR in blood monocytes, plasma, and lesional skin from 12 patients with PR, but not in the plasma or skin of controls[90]. Although some subsequent studies were unable to isolate HHV-7 DNA from PR lesions, others supported a role for HHV-7, and possibly HHV-6, in PR[91].

Methods to detect HHV-7 infection include serologic tests, PCR, viral culture, and immunohistochemical staining. The differential diagnosis is similar to that of exanthem subitum. Currently, there is no available treatment for HHV-7 infection.

HUMAN HERPESVIRUS TYPE 8 (HHV-8)

Synonyms: ■ Kaposi sarcoma-associated herpesvirus (KSHV) ■ Kaposi sarcoma herpesvirus (KSHV)

Key features

- HHV-8 is a latent virus found in virtually all lesions of all types of Kaposi sarcoma (KS) worldwide
- The seroprevalence of HHV-8 corresponds to the incidence rates of KS and varies by geographic location
- Clinical features of primary infection with HHV-8 have not yet been clearly identified, and its associated diseases are postulated to be a result of viral reactivation

Introduction

HHV-8, also called Kaposi sarcoma herpesvirus (KSHV), is a latent virus found in all types of Kaposi sarcoma (KS) worldwide. KS is discussed in more detail in Chapter 114.

History

In 1994, the association of KS and HHV-8 was recognized when herpes-like DNA sequences were identified in KS lesions from an AIDS patient. Associations of HHV-8 with Castleman disease, body cavity-based lymphomas, and other lymphoproliferative disorders were subsequently noted.

Epidemiology

HHV-8 is found in all types of KS worldwide, including: (1) *classic KS* – favors older men of Mediterranean or Ashkenazi Jewish descent; (2) *African-endemic KS* – affects primarily men and young children; (3) *iatrogenic immunosuppression-associated KS* – most often occurs in solid organ transplant recipients; (4) *AIDS-related epidemic KS* – occurs mainly in men who have sex with men (MSM); and (5) the recently described *nonepidemic KS in HIV-seronegative MSM* – favors middle-aged individuals[92–94] (see Table 114.3).

Seroprevalence of HHV-8 varies geographically, ranging from <5% in North America and Northern Europe to ~10%–20% in Southern Europe and 30%–80% in Africa[92]. In North America and Europe, HHV-8 antibodies are present in ~30% of HIV-1-infected MSM[95].

Pathogenesis

The mechanisms of HHV-8 transmission are not fully understood. Receptive anal intercourse appears to increase the likelihood of transmission, as the seroprevalence of HHV-8 is higher in MSM than in HIV-infected women. The number of same-sex male partners and the presence of HIV infection may be other risk factors[80]. There is evidence that exposure to saliva via close non-sexual contact or sexual practices represents another route of HHV-8 transmission. In areas in Africa where HHV-8 is endemic, seroprevalence is high in young children, and some but not all studies have found that this is associated with mother-to-child horizontal transmission; vertical transmission is uncommon[96,97]. HIV-infected infants have a significantly increased risk of HHV-8 infection[97]. HHV-8 transmission by blood transfusion has also been demonstrated[98].

HHV-8 can infect the endothelial cells of both lymphatic and blood vessels and induce transcriptional reprogramming, providing an explanation for the mixed lymphatic/blood vascular phenotype (see Ch. 114). In addition, HHV-8 is involved in the development of several lymphoproliferative disorders, including primary effusion lymphoma (also associated with EBV infection), multicentric Castleman disease, HHV-8-positive diffuse large B cell lymphoma, germinotropic lymphoproliferative disorder, and HHV-8 inflammatory cytokine syndrome[99,100].

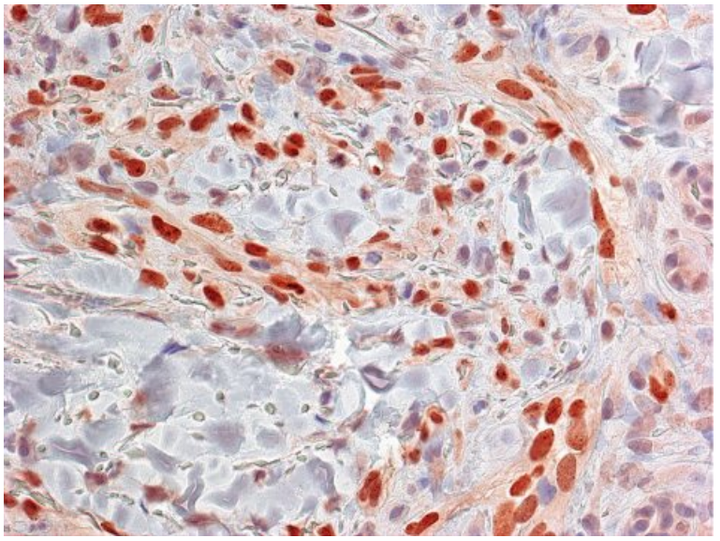

Fig. 80.26 Kaposi sarcoma. Immunohistochemical staining utilizing antibodies against a latency-associated nuclear antigen (LANA-1) demonstrates the presence of HHV-8. *Courtesy Shawn Cowper, MD.*

Clinical Features

Clinical manifestations of primary infection with HHV-8 have not yet been clearly identified. The five KS types have somewhat different presentations and clinical courses (see Ch. 114), although all typically feature red, brown, or violaceous papules, plaques, and nodules (Fig. 80.25). Edema is often present in all types, although less prominent in *nonepidemic KS in MSM*[92]. *Classic KS* favors the lower legs and can become hyperkeratotic or eczematous; it tends to be slowly progressive. *AIDS-related KS* typically presents as more widely distributed lesions, with frequent involvement of the trunk, central face, oral mucosa, and internal organs (e.g. lungs, gastrointestinal tract; see Ch. 78). Flares of KS may occur as a manifestation of IRIS (immune reconstitution inflammatory syndrome). *Immunosuppression-associated KS* can have an aggressive course but may improve or resolve upon reduction or removal of immunosuppressive therapy. Another option is substitution of sirolimus for calcineurin inhibitors as sirolimus inhibits the HHV-8 lytic replication cycle and has antineoplastic and antiangiogenic as well as immunosuppressive effects. The course of *African-endemic KS* ranges from indolent or locally aggressive disease to a fulminant lymphadenopathic pediatric variant. *Nonepidemic KS in MSM* typically has an indolent course similar to that of *classic KS*, although associated lymphoproliferative disease has been reported[101].

Diagnosis and Pathology

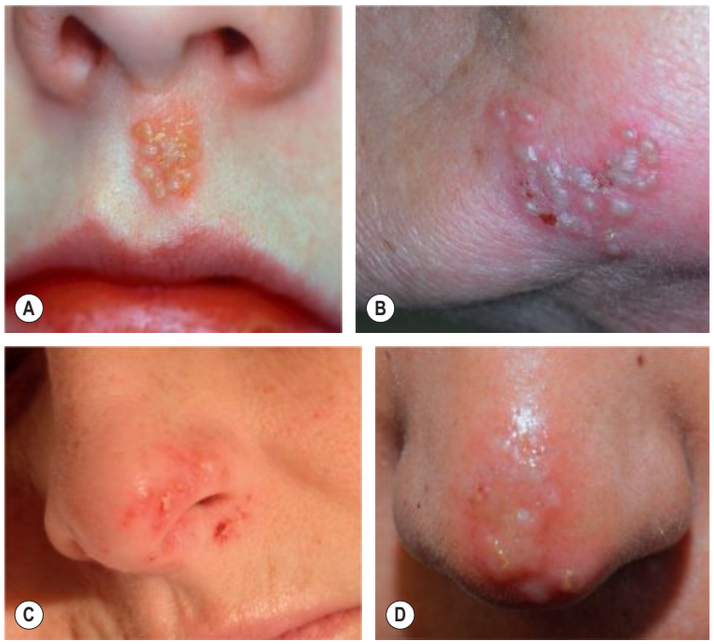
The diagnosis of KS is confirmed by a skin biopsy of a suspected lesion (see Ch. 114). Serology for HHV-8 is not required, but immunohistochemical staining for latency-associated nuclear antigen (LANA-1) can demonstrate the presence of HHV-8 within biopsy specimens of KS (Fig. 80.26).

Treatment

The treatment of KS is reviewed in Chapter 114.

CONCLUSION

The eight human herpesviruses are associated with a wide spectrum of clinical features. Expansion in the number of immunocompromised patients has led to significant increases in the diversity and severity of clinical presentations of human herpesvirus infections. Thus, it is imperative to be aware of the various manifestations of these viral infections and to perform appropriate diagnostic tests. The clinician must also be aware of the indications, contraindications, dosages, and limitations of antiviral agents. Currently, the only licensed vaccines that exist for human herpesvirus are the varicella and varicella zoster vaccines. Therefore, public health measures remain critical for controlling the spread of these viruses. It is anticipated that better diagnostic tests, antiviral drugs, and vaccines for human herpesviruses will become available in the future.



Additional figures and table on Recommendations of the Advisory Committee on Immunization Practices for administration of the varicella vaccine, available in our eBook (see inside front cover for access code).

A Well-demarcated ulceration with a thick eschar, pink rim, and associated brachial plexopathy. HIV viral load was 6.6 million copies and CMV viral load was 14.5 million copies. **B** Ulcerations in different stages of healing. *A, Courtesy Katherine Hunt, MD.*

RECOMMENDATIONS OF THE ADVISORY COMMITTEE ON IMMUNIZATION PRACTICES FOR ADMINISTRATION OF THE VARICELLA VACCINE

Category	Varicella vaccine administration

Routine childhood vaccination	• 2 doses
	  • First at age 12–15 months
	  • Second at age 4–6 years*

Individuals ≥13 years of age without evidence of varicella immunity, especially: • Students, teachers, residents/staff in institutional settings • Healthcare providers • If household contacts are immunocompromised or children • Postpartum/non-pregnant women of childbearing age • International travelers	• 2 doses, 4–8 weeks apart

Second dose catch-up vaccination for individuals >6 years of age who received 1 dose previously	• 1 additional dose
	  • ≥3 months after previous dose if <13 years old
	  • ≥4 weeks after previous dose if ≥13 years old

HIV-infected individuals: • 1–8 years of age with $CD4^+$ T cell percentage ≥15% • >8 years of age with $CD4^+$ T cell count ≥200 cells/mcl	• 2 doses, 3 months apart

Postexposure vaccination in individuals who received 1 dose previously	• 1 additional dose, ideally within 3–5 days, if:
	  • ≥3 months after previous dose for those <13 years old
	  • ≥4 weeks after previous dose for those ≥13 years old

Postexposure vaccination in individuals ≥1 year of age without evidence of varicella immunity	• Administer first dose within 3–5 days
Contraindications	
• Allergy to vaccine components • Immunocompromised states including: hematologic malignancies, HIV infection with $CD4^+$ T cell percentage <15% or count <200 cells/mcl, other T cell immunodeficiencies, systemic immunosuppressive therapy (e.g. tumor necrosis factor [TNF] inhibitors; prednisone ≥2 mg/kg/day or, if weight >10 kg, ≥20 mg/day for ≥2 weeks) • Pregnancy	

*May be given earlier provided that the interval between the two doses is ≥3 months.

eTable 80.1 Recommendations of the Advisory Committee on Immunization Practices for administration of the varicella vaccine. Varicella vaccination is generally required for entry to child care centers, schools, colleges, and other educational institutions. Skin lesions directly related to the attenuated virus (usually ≤5 papules or papulovesicles; localized to the area of injection in half of cases) develop in 5%–10% of vaccinated individuals, usually 5–25 days after immunization.

Other Viral Diseases 81

INTRODUCTION

Viral infections are frequently associated with cutaneous manifestations, especially in children, in whom they are the most common cause of exanthems. An exanthem is defined as a skin eruption occurring as a sign of a general disease. Viral exanthems may present with distinctive cutaneous features or in an entirely nonspecific fashion, and at times they may pose a significant diagnostic challenge, even to the most astute clinician[1]. While dermatologists are most likely to be consulted for atypical or less widely recognized exanthems, a solid working knowledge of the classic disorders, whether common (e.g. roseola) or rare in high-income countries (e.g. measles), is essential[2].

This chapter describes classic childhood and less common exanthems; eruptions associated with poxvirus and polyomavirus infections; and the cutaneous manifestations of hepatitis A, B, and C viral as well as SARS-CoV-2 infections. Kawasaki disease, which features a polymorphic exanthem together with other mucocutaneous findings and systemic manifestations that can mimic a viral syndrome, is also discussed. In contrast to the symptomatic management of most viral exanthems, prompt recognition and initiation of therapy for Kawasaki disease is necessary to prevent potentially life-threatening systemic complications. Herpesvirus infections, including infectious mononucleosis, are covered in Chapter 80. Structural features and sizes of major types of viruses that infect humans are shown in Fig. 81.1.

Nonspecific viral exanthems are the most common type of exanthem seen in children. These eruptions lack distinctive features such as specific lesional morphologies, distribution patterns, natural histories, or enanthems (eruption on the mucous membranes). They most often present with blanchable erythematous papules and macules in a widespread distribution on the trunk and extremities, and less often the face. Associated symptoms such as a low-grade fever, myalgias, headache, rhinorrhea, or gastrointestinal complaints may be present. Although multiple infectious agents can cause such exanthems, the most common etiologies in children are the non-polio enteroviruses (see below) in the summer/fall and respiratory viruses such as adenovirus and parainfluenza virus in the winter. Nonspecific exanthems tend to be self-limited, with spontaneous resolution within 1 week, and supportive therapy is usually sufficient. While identification of the exact etiologic agent would be desirable, in many instances it is neither necessary nor clinically feasible. Fig. 81.2 outlines the clinical features to be considered when evaluating the patient with a morbilliform ("maculopapular" or "measles-like") viral exanthem, highlighting similar and different aspects of various etiologies. Diagnostic considerations in patients presenting with fever and a "rash" are listed in Fig. 0.11.

ENTEROVIRUS INFECTIONS

Key features

- Most common in summer and fall
- Exanthems include erythematous, vesicular, and petechial types
- Meningitis and encephalitis possible

Introduction

The enteroviruses, a subgroup of the picornavirus family, cause a wide array of illnesses associated with exanthems. The non-polio enteroviruses include echoviruses and coxsackievirus types A and B, with >100 genetically distinct types that infect humans. These viruses consist of a single-stranded RNA genome with an unenveloped capsid.

Epidemiology

Enteroviral infections occur worldwide and are usually transmitted human-to-human via fecal–oral or respiratory routes, usually with a 3- to 6-day incubation period. They can also be spread from mother to infant in the peripartum period. Exposure to virus in fecally contaminated water in swimming pools or via ingestion of oysters may be responsible for some infections. Clinical attack rates are highest in young children, and infections occur more frequently in lower socioeconomic groups. In temperate climates, infections are most common in the summer and fall. However, coxsackievirus A6 outbreaks frequently affect adults and can occur in the winter.

Pathogenesis

Enteroviruses infect epithelial surfaces of the pharynx and lower alimentary tract. They then replicate in lymphoid tissues and disseminate via an initial minor viremia. Subsequently, replication may occur at multiple anatomic sites, including the CNS, heart, liver, adrenals, respiratory tract, skin, and mucous membranes[3]. This replication correlates with the appearance of clinical symptoms. A major viremia occurs during the period of viral multiplication in the secondary infection sites.

Clinical Features and Differential Diagnosis

Fig. 81.3 depicts the potential clinical manifestations of an enteroviral infection.

The most distinctive exanthematous illness due to enteroviruses is *hand-foot-and-mouth disease* (HFMD). This disorder is characterized by a vesicular eruption on the palms and soles (Fig. 81.4A) in conjunction with an erosive stomatitis. The dorsal aspect of the hands and feet may be involved as well as the buttocks and perineum; oral

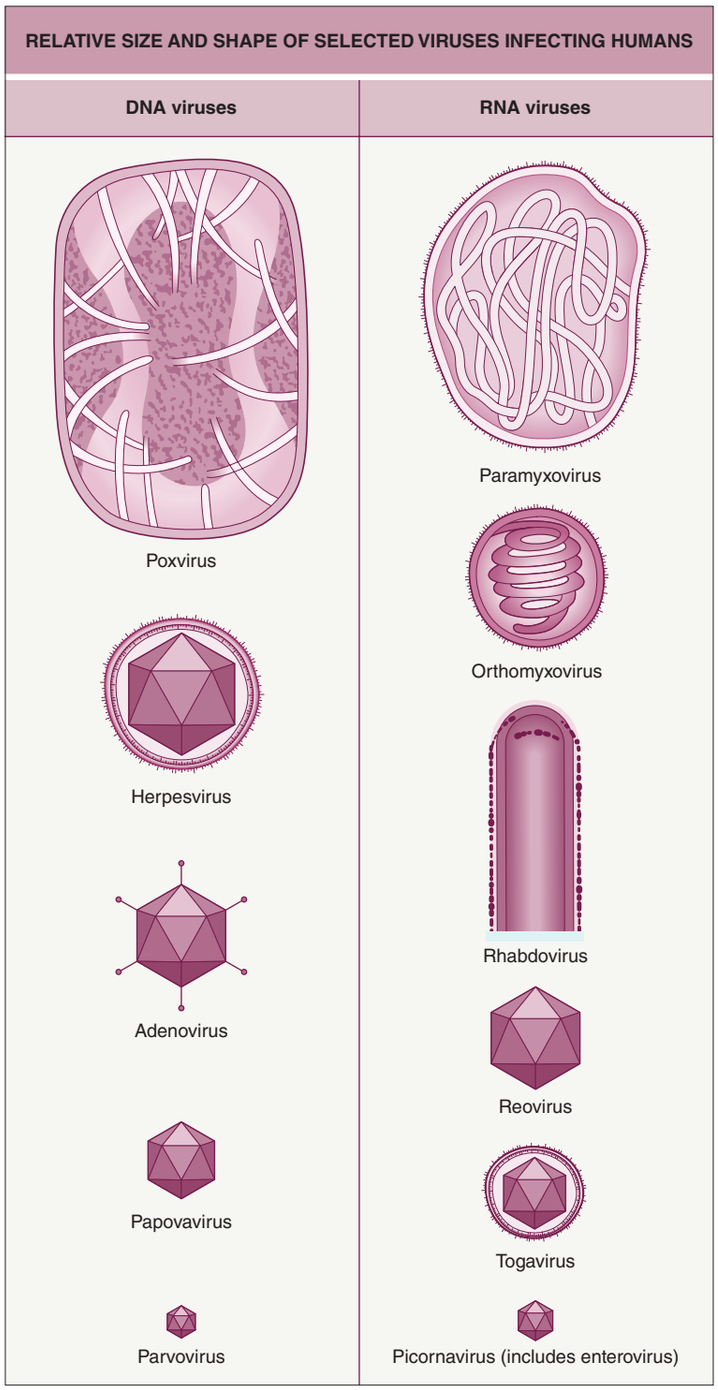

Fig. 81.1 Relative size and shape of selected viruses infecting humans. *Adapted from Hsiung's Diagnostic Virology, Yale University Press, 1994.*

lesions are most common on the tongue, buccal mucosa, palate, uvula, and anterior tonsillar pillars. Onychomadesis occasionally occurs 1–2 months after HFMD as a consequence of temporary nail matrix arrest related to the viral infection[4].

Patients with HFMD often present with fever and malaise, and they may have a mild prodrome prior to the onset of the exanthem. Numerous coxsackievirus serotypes have been implicated, most commonly type A16; in addition, type A10 represents a major cause of outbreaks in Europe and Asia. Although HFMD generally runs a benign and self-limited course, since 1998 there have been multiple epidemics of severe enterovirus 71 infection, primarily in the Asia-Pacific region, which have resulted in cardiopulmonary and neurologic complications and even deaths in affected young children[5].

Globally beginning in 2008 and since 2011 in the US, coxsackievirus A6 (CVA6) has emerged as a major cause of both outbreaks and sporadic cases of severe and atypical HFMD[6]. This variant is characterized by more widespread vesicular, papulovesicular, and sometimes bullous or petechial eruptions that frequently involve the perioral area, arms, legs, and trunk as well as the palms, soles, and buttocks (Fig. 81.4B–G). Oral lesions develop in approximately half of patients, and delayed acral desquamation and onychomadesis are common[7]. The eruption may be accentuated in areas of pre-existing skin injury or eczematous dermatitis, with the latter referred to as *"eczema coxsackium"* (see Fig. 81.4F). The differential diagnosis may include eczema herpeticum, varicella, disseminated zoster, Gianotti–Crosti syndrome, erythema multiforme, and autoimmune bullous diseases. In addition, patients with HFMD due to CVA6 are often febrile but do not usually have neurologic or other complications.

Herpangina is a febrile illness, primarily in children 3–10 years of age, characterized by painful vesicles and erosions on the soft palate, uvula, tonsils, pharynx, and buccal mucosa. An exanthem is usually absent. Coxsackievirus groups A and B, as well as echoviruses, are the usual pathogens. Coxsackievirus B5 infection has also been associated with conjunctival hyperemia.

In addition to HFMD and herpangina, enteroviruses cause a diverse spectrum of exanthems that may be morbilliform, rubelliform, roseola-like, urticarial, scarlatiniform, vesicular, pustular, and/or petechial. The majority of enteroviral exanthems feature erythematous macules and papules in a widespread distribution. Petechiae are fairly common, especially with echovirus 9 infection, and may lead to consideration of a more serious infection such as meningococcemia. Non-polio enteroviruses often infect newborns, producing a nonspecific erythematous exanthem and additional features such as fever, gastroenteritis, hepatitis, pneumonia, and meningoencephalitis[8,9].

In 1969, Cherry et al.[10] described four children with echovirus 25 or 32 infection who had fever and transient vascular papules; histologically, dilated blood vessels were seen. The term *eruptive pseudoangiomatosis* was subsequently proposed, and additional cases have been described in adults as well as children, with spontaneous resolution within a few weeks. Associated infections have included other enteroviruses, cytomegalovirus (CMV), Epstein–Barr virus (EBV), adenovirus, parvovirus B19, and SARS-CoV-2 (vaccination as well as infection) [11,12].

While classic HFMD and herpangina are fairly straightforward clinical diagnoses, other less specific exanthematous illnesses due to enteroviruses may have a broad differential diagnosis. Important factors that may point to the etiology include the season, exposure history, geographic location, and clinical signs and symptoms.

Confirmation of an *enteroviral* infection may be accomplished via viral culture, which has low sensitivity (especially for CVA6)[6], or polymerase chain reaction (PCR)-based assays; determination of the specific type of enterovirus via gene sequencing following RT-PCR is currently done only at research and public health laboratories (e.g. the US Centers for Disease Control [CDC]). Viral testing can be performed from vesicular fluid (preferred for HFMD), throat swabs, stool samples, and cerebrospinal fluid (CSF). Serologic diagnosis is difficult due to the large number of different serotypes and the time delay, which make it clinically less useful. Table 81.1 lists types of serologic assays.

Pathology

Skin biopsy is generally not a useful diagnostic procedure in enteroviral infections. Histopathologic features of the vesicular lesions of HFMD include epidermal necrosis with intraepidermal vesicles, a lack of inclusion bodies or multinucleation, and a nonspecific dermal inflammatory infiltrate.

Treatment

For most enteroviral exanthems, the course is self-limited, the prognosis is excellent, and supportive care suffices. However, in certain patient populations, e.g. immunosuppressed individuals or neonates, an enteroviral infection may be associated with potentially life-threatening complications. Pleconaril, a drug that interferes with enterovirus attachment and uncoating by binding to the protein capsid, has been demonstrated to be effective both *in vitro* and in clinical studies, including a randomized, placebo-controlled trial in neonates with enteroviral sepsis[13]; it therefore has potential as a specific antiviral therapy for serious enteroviral infections[14]. Three inactivated enterovirus-71 vaccines are licensed for clinical use in China, and other enteroviral vaccines are under development.

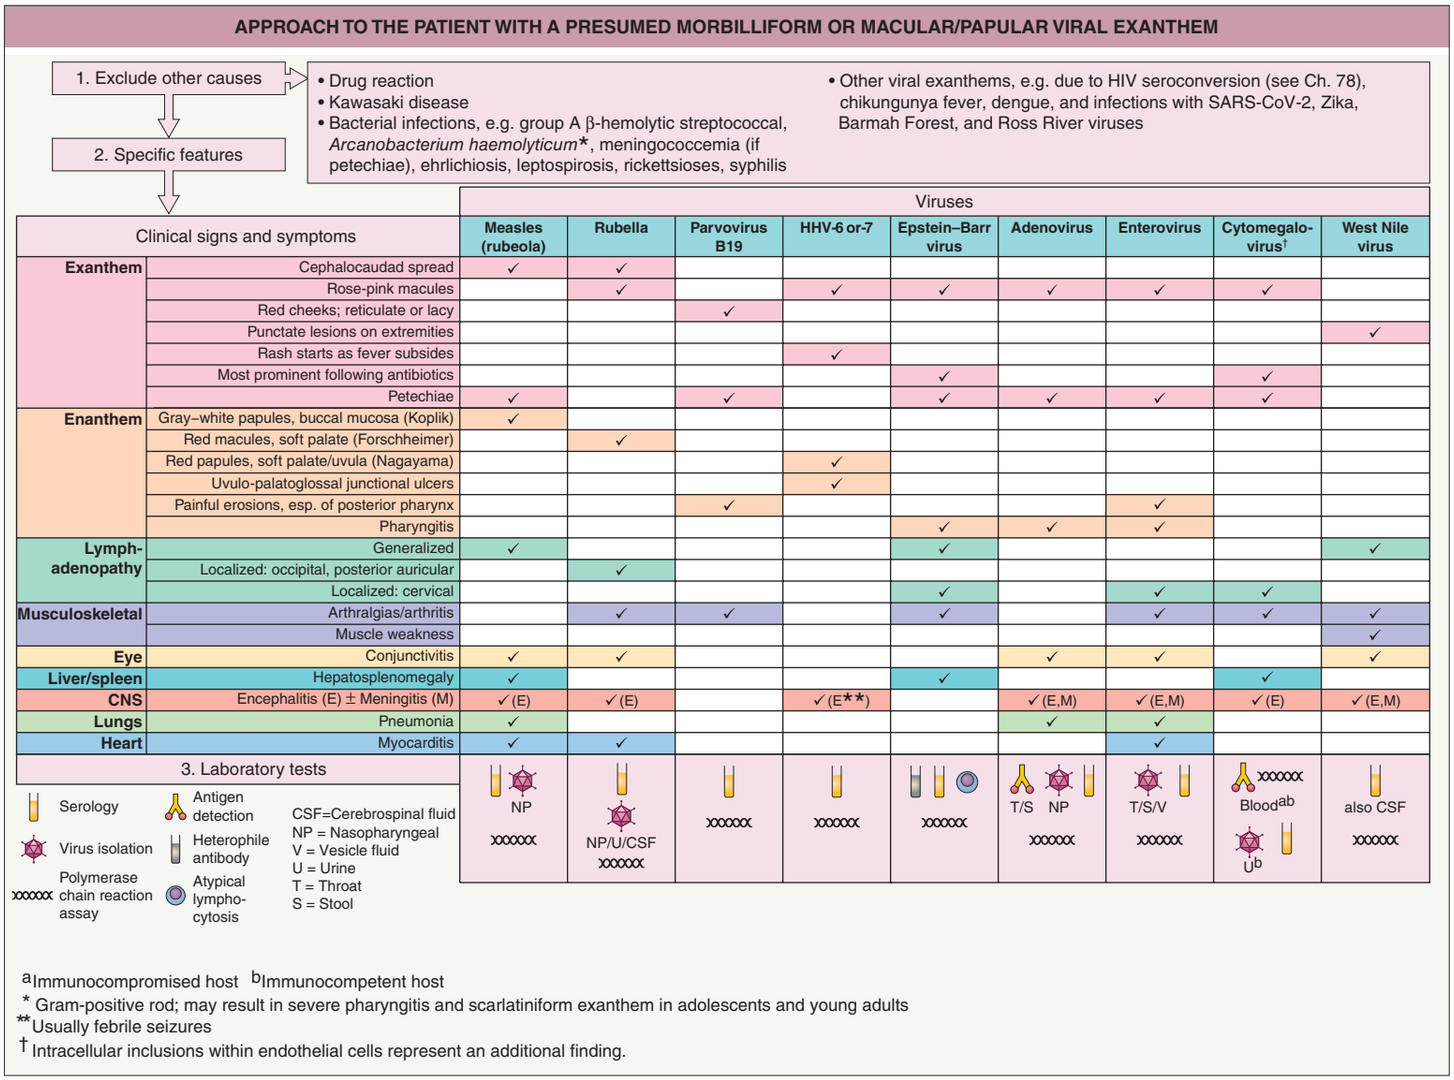

Fig. 81.2 Approach to the patient with a presumed morbilliform or macular/papular viral exanthem.

MEASLES

Synonym: ■ Rubeola

Key features

- Incidence greatly decreased with vaccination
- Prodrome of cough, coryza, conjunctivitis, and Koplik spots
- Cephalocaudad spread of exanthema

Introduction and History

The incidence of measles has markedly decreased since the introduction of the live vaccine in 1963. Despite high vaccination coverage, measles outbreaks continue to occur in both high-income and low-income countries, and the disease is still regarded as a major health burden. Use of the vaccine is estimated to have reduced global measles morbidity and mortality by 75% and 85%, respectively, compared with the prevaccine era[15].

Epidemiology

The incubation period of measles, which is highly contagious and spread via respiratory droplets, is 10–14 days. In the prevaccine era, measles was endemic throughout the year in heavily populated areas, without regard to age or sex. During the 1989–1990 epidemic, reported measles cases in the US increased six- to ninefold over the mean of 3000 cases diagnosed annually between 1985 and 1988. Target populations during that epidemic were unvaccinated children younger than 5 years of age and vaccinated school-aged children who failed to develop immunity against the virus. The latter highlighted the need for more than one dose of vaccine; as a result, a two-dose measles vaccine schedule was recommended in 1989, which greatly decreased the incidence of measles in the US[16]. Although the median number of cases of measles diagnosed annually in the US is now ~100, outbreaks still occur. For example, >1250 measles cases were confirmed in the US in 2019, ~75% of which occurred in Orthodox Jewish communities in New York with low vaccination rates[17]. Such observations underscore the importance of sustained efforts at universal vaccination against measles.

Pathogenesis

Measles is caused by an RNA virus in the Paramyxoviridae family, and humans are the natural host and reservoir of infection. The disease starts with replication of the virus within the epithelial cells of the respiratory tract, with subsequent spread to the lymphoid tissue and blood, resulting in viremia. The virus can then disseminate to internal organs, including the lungs, liver, and gastrointestinal tract.

Clinical Features and Differential Diagnosis

Measles classically presents with a prodrome of fever, cough, nasal congestion, and rhinoconjunctivitis. A pathognomonic enanthem, Koplik spots, appears during the prodrome and is composed of gray–white papules on the buccal mucosa. The exanthem develops over 2–4 days

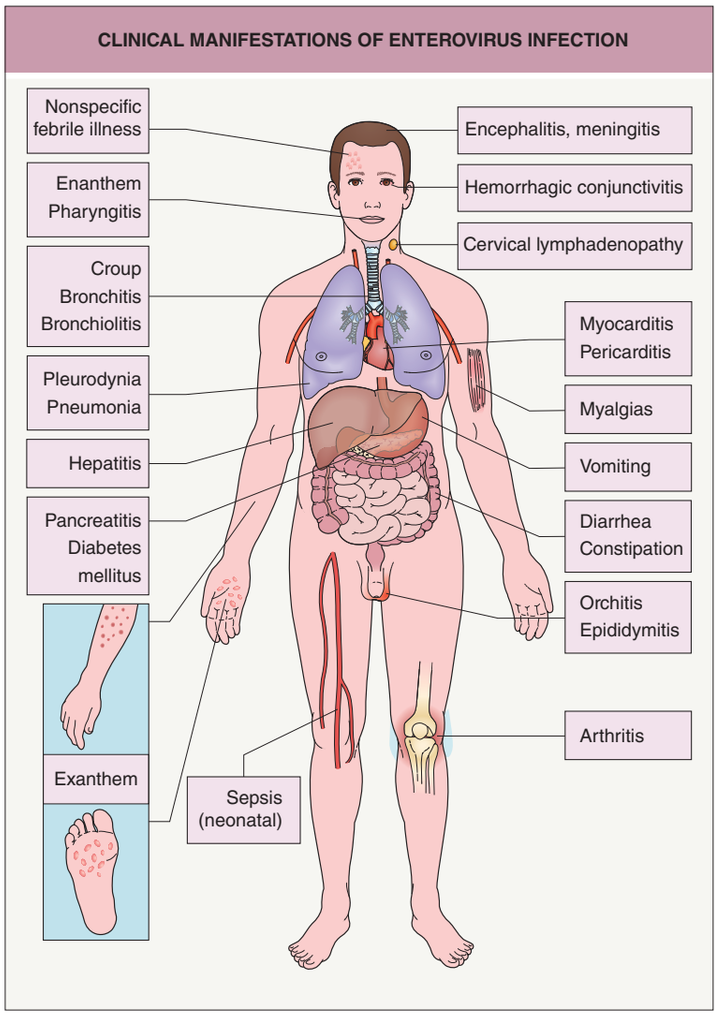

Fig. 81.3 Clinical manifestations of enterovirus infection.

and consists of erythematous macules and papules that begin on the forehead, hairline, and behind the ears and then spread in a cephalocaudad direction (Fig. 81.5). On the fifth day, the exanthem starts to fade in the same order as it appeared.

Morbilliform ("measles-like") eruptions can result from other viral infections, e.g. with enteroviruses, EBV, parvovirus B19, and human herpesvirus-6 (HHV-6)[18]. The differential diagnosis may also include a drug eruption and Kawasaki disease (see Fig. 81.2).

Atypical measles due to infection with wild-type virus in the setting of partial immunity has been reported in several groups, including recipients of killed measles vaccine (used from 1963 to 1968), those who failed vaccination, and immunocompromised individuals. It is characterized by high fevers, cough, and pulmonary infiltrates that reflect immune complex deposition related to non-protective, complement-fixing antibodies. Coryza and conjunctivitis are generally absent, and the exanthem is variable, potentially including vesicles, petechiae, purpura, and acral edema.

Complications of measles include otitis, pneumonia, encephalitis, and myocarditis. Subacute sclerosing panencephalitis is a delayed neurodegenerative disorder that can occur as a complication of measles many years after the acute disease. It is characterized by seizures, personality changes, coma, and death. Laboratory diagnosis of measles can be accomplished by virus isolation or detection via RT-PCR in nasopharyngeal secretions or urine, as well as serologic assays for measles-specific antibodies (IgM or IgG).

Pathology

The histopathologic findings are nonspecific, including a superficial perivascular lymphocytic infiltrate together with variable spongiosis and dyskeratosis.

Treatment

There is no specific antiviral therapy for measles. Because low serum vitamin A levels are associated with increased measles-related morbidity and mortality, the World Health Organization (WHO) recommends that all children with acute measles receive vitamin A once daily for 2 days at the following doses: 200 000 IU if age ≥12 months; 100 000 IU if age 6–11 months; or 50 000 IU if age <6 months.

Prevention of measles by vaccination is the most effective way to reduce measles morbidity and mortality. The current recommendation for measles immunization is an initial vaccine dose at 12–15 months of age and a second dose at 4–6 years of age[19]. For unvaccinated individuals exposed to measles, administration of the vaccine within 3 days or intramuscular or intravenous immunoglobulin (IM/IVIg) within 6 days of the exposure may provide some protection.

RUBELLA

Synonym: ■ German measles

Key features

- Exanthem of rose-pink macules with cephalocaudad spread
- Tender lymphadenopathy, especially occipital and posterior auricular
- Joint involvement common
- Fetal infection is associated with congenital anomalies

Introduction and History

Rubella is caused by an RNA virus in the Togaviridae family. Although usually a mild, self-limited disease in children and adults, it can cause major complications when transmitted to a fetus *in utero*, including miscarriage, stillbirth, and severe congenital malformations.

Epidemiology

The disease is spread via respiratory droplets, with an incubation period of 16–18 days. The incidence of rubella has markedly declined since the licensure of the MMR (measles, mumps, and rubella) vaccine in 1969. Rubella was declared as eliminated from the US in 2005 and from the Americas in 2014; currently all US cases reported since 2012 (<10 per year) were acquired in another country. Rubella has a worldwide distribution and occurs most often in the spring.

Pathogenesis

The primary site of infection is the nasopharynx, followed by spread to regional lymph nodes and a subsequent viremia.

Clinical Features and Differential Diagnosis

Rubella typically presents with a mild prodrome that includes fever, headache, and upper respiratory symptoms. In children, many cases are subclinical. One to 5 days following the prodrome, an eruption of erythematous macules and papules appears on the face, spreading in a cephalocaudad direction. Erythematous petechial macules may also be present on the soft palate (Forchheimer spots). The eruption is often accompanied by tender lymphadenopathy, especially of the occipital, posterior auricular, and cervical regions. The cutaneous eruption tends to fade in 2–3 days in the same order as it appeared.

Rubella may result in arthralgias and arthritis, especially in postpubertal girls and women; less frequent complications include hepatitis, myocarditis, pericarditis, hemolytic anemia, and thrombocytopenia. Encephalitis occurs in ~1 in 6000 infected individuals[20].

Rubella can be diagnosed by detection of anti-rubella IgM antibodies or a fourfold increase in specific IgG antibodies; virus isolation or detection via RT-PCR from a nasal wash, throat swab, or urine sample is also possible. The exanthem of rubella is nonspecific and the differential diagnosis includes other viral exanthems (e.g. adenovirus, enterovirus,

Fig. 81.4 Hand-foot-and-mouth disease. A Vesicle and erythematous macules on the sole in classic hand-foot-and-mouth disease. **B–G** Coxsackievirus A6 infection presenting as: multiple erythematous macules and papules with some targetoid lesions resembling early erythema multiforme on the palm (**B**); vesicles and papulovesicles on the dorsal hand (**C**) and thigh (**D**); perioral monomorphic crusted lesions resembling eczema herpeticum (**E**); more extensive "eczema coxsackium" in toddlers (**F** & **G**) and an infant (**H**) with atopic dermatitis. *A–G, Courtesy Julie V. Schaffer, MD. H, Courtesy Henry Heaton, MD.*

SEROLOGIC ASSAYS OF ANTIBODY RESPONSES	
Assay	**Principle**
Neutralization	Visual read of infected cell monolayers incubated with test sera, looking for CPE inhibition
Radioimmunoassay (RIA)	Ab and Ag bind, then radiolabeled antiglobulin added, *or* radiolabeled Ag added and it binds Ab; radioactivity measured
Enzyme-linked immunosorbent assay (ELISA)	Microplates coated with Ag, serum and enzyme-labeled antiglobulin added, then enzyme substrate added and color change measured
Western blot	Ag mixture separated by electrophoresis, transferred to membrane, serum added and then labeled antiglobulin; seen as colored bands
Latex agglutination	Ag-coated latex particles incubated with serum, Ab agglutinates particles
Hemagglutination inhibition (HI)	Serially diluted test sera mixed with viral Ag, then animal erythrocytes added; inhibition of agglutination measured
Complement fixation	Ag added to serially diluted test sera; Ag–Ab complex binds complement, so the latter is unavailable for lysis of sheep erythrocytes in the presence of Ab to erythrocytes
Immunodiffusion	Ab and soluble Ags combine to produce visible lines of precipitate in a gel
Immunofluorescence	Test sera added to infected cell monolayer, then fluorescein-labeled anti-IgG Ab added; examined with fluorescence microscope

Table 81.1 Serologic assays of antibody responses. Ab, antibody; Ag, antigen; CPE, cytopathic effect.

measles, EBV) and toxin-mediated eruptions such as scarlet fever. The occipital lymphadenopathy and the typical progression of the eruption can be helpful in diagnosing the disease.

Congenital rubella occurs when a nonimmune pregnant woman transfers the virus to the fetus. Birth defects are most commonly observed when infection is during the first 16 weeks of pregnancy. Congenital rubella syndrome is characterized by cataracts, deafness, congenital heart defects (patent ductus arteriosus, ventricular septal defects), and CNS abnormalities (microcephaly, developmental delay). A "blueberry muffin baby" presentation due to dermal hematopoiesis is occasionally observed (see Ch. 121).

Both wild type and vaccine-derived rubella virus have been identified and found to persist for years in macrophages within cutaneous granulomas in individuals with immunodeficiencies characterized by

Fig. 81.5 Measles. Pink macules and minimally elevated papules. *Courtesy Louis A. Fragola, Jr, MD.*

T cell lymphopenia and/or defective lymphocyte cytotoxicity. The latter include ataxia telangiectasia, Griscelli syndrome type 2, and a variety of combined immunodeficiency syndromes (see Ch. 60)[21]. Clinically, these patients present with pink–violet to red–brown papules, nodules, and plaques, often with crusting or ulceration, that favor the extremities and face but may be widespread[21]. Rubella virus has also been identified within cutaneous granulomas (palisaded and necrotizing type) involving the left upper arm (a typical vaccination site) in clinically immunocompetent adults; localized lesions associated with vaccine-derived rubella developed 2 to >10 years after the last MMR vaccine administration[22].

Pathology

Reported histopathologic findings of rubella include a superficial perivascular infiltrate with mild spongiosis. Atypical lymphocytes may be evident in the cutaneous infiltrate as well as in peripheral blood.

Treatment

Treatment of rubella is supportive. The current recommended immunization schedule for rubella vaccine, which is given in conjunction with the measles and mumps vaccines (MMR vaccine), is an initial dose at 12–15 months and a second dose at 4–6 years[19]. In a pregnant woman who has been exposed to rubella, serologic testing (IgG and IgM) should be performed. Prophylaxis via administration of IM/IVIg to rubella-susceptible women exposed to confirmed rubella early in pregnancy may be considered, but it does not reliably prevent fetal infection. If rubella-specific IgM antibodies or a diagnostic rise in IgG anti-rubella antibodies (the latter not useful following IM/IVIg administration) are detected, the patient should be offered prenatal counseling.

ERYTHEMA INFECTIOSUM

Synonyms: ■ Fifth disease ■ "Slapped cheek" disease ■ Parvovirus B19 infection

Key features

- "Slapped cheeks" followed by lacy extremity-predominant eruption, especially in children
- Eruptions in adolescents and adults may be petechial and/or have an acral or periflexural distribution
- Marked affinity of parvovirus B19 for erythrocyte precursors
- Fetal infection may result in anemia, fetal hydrops, or death

Introduction and History

Human parvovirus B19 (B19), the only parvovirus known to infect humans, was accidentally discovered in 1975 by Cossart and colleagues, who were screening blood samples for hepatitis B virus. The small, single-stranded DNA virus, which was named after the panel of sera in which it was found (number 19, row B), was identified as the etiology of erythema infectiosum in 1983. Subsequent elucidation of the pathogenesis of human B19 infections has led to its association with a wide variety of clinical findings (Table 81.2).

PARVOVIRUS B19 CLINICAL ASSOCIATIONS
Established associations
Mucocutaneous
• Erythema infectiosum • Papular-purpuric gloves and socks syndrome • Petechial/purpuric eruptions in a generalized, bathing trunk, periflexural, acral, and/or perioral distribution • Enanthem with erosions and petechiae • Degos-like lesions
Extracutaneous
• Arthropathy • Hydrops fetalis • Transient aplastic crises in at-risk individuals* • Chronic anemia • Thrombocytopenia, neutropenia, pancytopenia • Hepatitis
Possible associations
Vasculitides
• Small vessel vasculitis • Henoch–Schönlein purpura • Cryoglobulinemic vasculitis • Polyarteritis nodosa • Granulomatosis with polyangiitis
Additional exanthems
• Microvesicular eruption • Unilateral laterothoracic exanthem • Gianotti–Crosti syndrome
Other
• Neurologic disease • Chronic fatigue syndrome • Systemic lupus erythematosus-like illness • Hemophagocytic lymphohistiocytosis • Myositis
*Patients suffering from decreased red cell production (e.g. iron deficiency, thalassemias) or increased red cell destruction (e.g. sickle cell anemia, hereditary spherocytosis, pyruvate kinase deficiency, glucose-6-phosphate dehydrogenase deficiency), as well as patients with HIV infection and recipients of allogeneic hematopoietic stem cell or solid organ transplants.

Table 81.2 Parvovirus B19 clinical associations. Asymptomatic infection may also occur.

Epidemiology

Infection with B19 occurs in a seasonal pattern, with a peak incidence of erythema infectiosum during the winter and spring. Transmission is via respiratory secretions, blood products, and vertically from mother to fetus; the incubation period is between 4 and 14 days. B19 infection occurs worldwide and is most common in school-aged children. A cyclical pattern of epidemics seems to have peaks about every 6 years[23], and individual community epidemics last 3–6 months. The seroprevalence of B19 antibodies increases in direct proportion with age, with immunity in 2%–15% of children 1–5 years of age, 15%–60% of those 5–19 years of age, and 30%–80% of adults.

Pathogenesis

B19 has a strong tropism for erythroid progenitor cells, and the erythrocyte "P antigen" (globoside) is the cellular receptor to which the virus binds. In fact, individuals who lack the P antigen (blood group P_1^k or p phenotypes) seem to be naturally resistant to B19 infection[24].

After initial infection of the respiratory tract, a B19 viremia occurs, ending when the anti-B19 IgM antibody appears ~8–10 days post

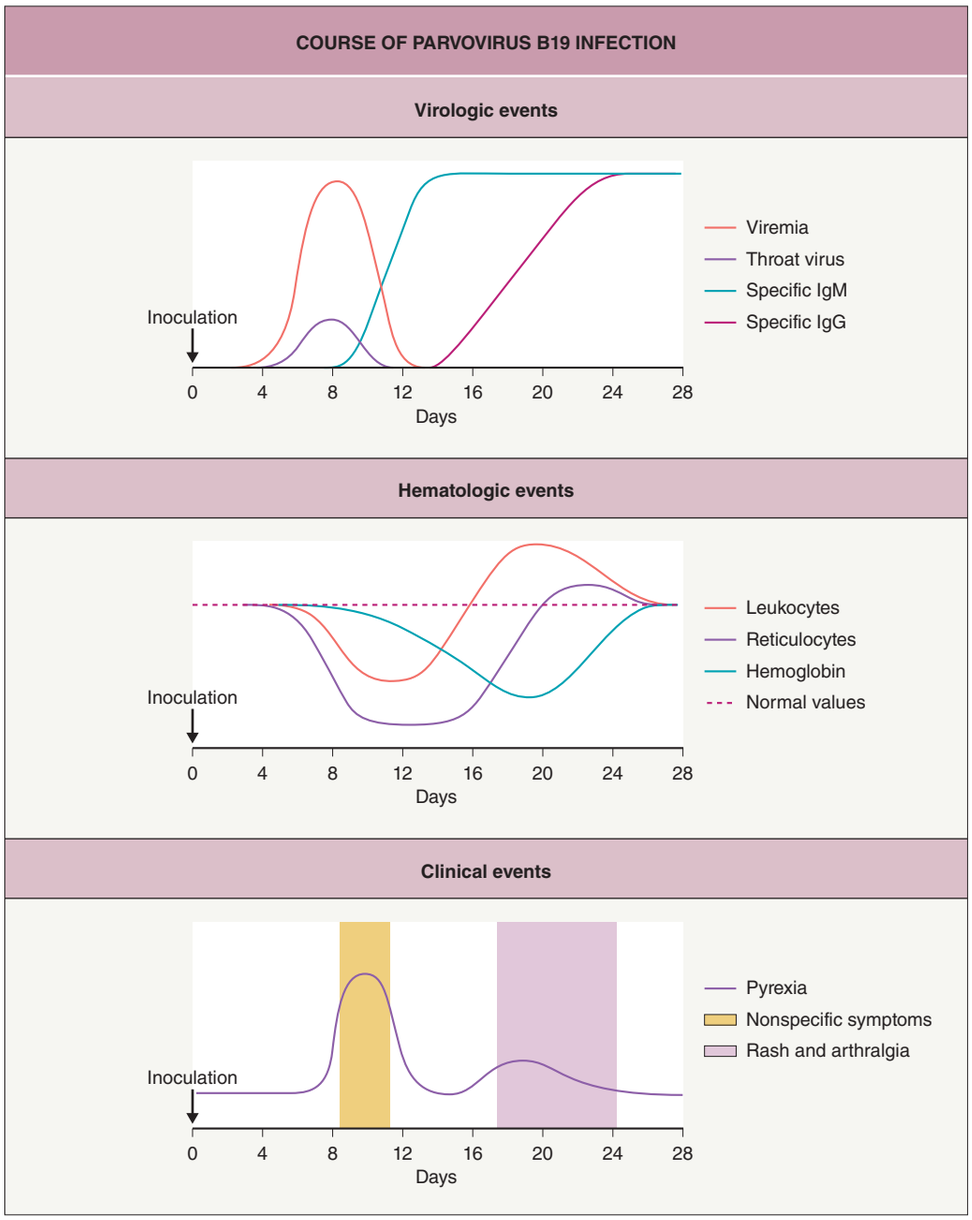

Fig. 81.6 Course of parvovirus B19 infection. Volunteers were infected with parvovirus B19 and the virologic, hematologic, and clinical events that followed were recorded. *Reprinted from Cohen J, Powderly WG. Infectious Diseases, 2nd edn. St Louis: Mosby, 2004.*

inoculation (Fig. 81.6). During the viremic period, reticulocytopenia occurs for 7–10 days[23]. One week after the appearance of IgM antibody, anti-B19 IgG appears and coincides with the appearance of the rash and arthralgia. An immune-mediated process is suggested by the temporal disconnect between the viremia and the clinical symptoms.

The anemia and reticulocytopenia tend to be inconsequential in the normal host but may result in transient aplastic crises in at-risk individuals, such as those with disorders resulting in enhanced red blood cell destruction or decreased production; thrombocytopenia, neutropenia, and pancytopenia may also occur (see Table 81.2). Fetal infection from intrauterine virus transmission causes fetal anemia of varying severity (see below).

Clinical Features and Differential Diagnosis

The most common illness caused by B19 infection is erythema infectiosum, which most often occurs in children 4–10 years of age. Mild prodromal symptoms such as a low-grade fever, myalgias, and headache may develop 7–10 days before the characteristic exanthem appears. The initial stage of the exanthem consists of bright red macular erythema of the cheeks, with sparing of the nasal bridge and circumoral regions (Fig. 81.7A). One to 4 days later, the second stage appears as erythematous macules and papules on the extremities and to a lesser extent the trunk, progressing to form a lacy, reticulated pattern (Fig. 81.7B,C). This exanthem typically lasts 1–3 weeks or occasionally longer; it fluctuates in intensity during this period, often with exacerbations upon exposure to sunlight or overheating. The differential diagnosis of erythema infectiosum may include scarlet fever, enteroviral infection, and rubella, but the diagnosis is usually straightforward when the characteristic eruption is present. Although the evanescent exanthem of systemic juvenile idiopathic arthritis (Still disease) is also accentuated by heat, it is accompanied by episodic high fevers, has a more chronic course, and often exhibits the Koebner phenomenon.

In adolescents and adults with B19 infection, the exanthems tend to be petechial and often have an acral or periflexural distribution (see Table 81.2)[25]. A distinctive *papular-purpuric gloves and socks syndrome* (PPGSS) was first described in 1990[26] and subsequently found to be associated with acute B19 infection, although other infectious etiologies have also been reported, e.g. coxsackievirus B6, HHV-6, and EBV. PPGSS most often develops in the spring, and although it has a predilection for young adults, PPGSS may occur at any age, including in children. The hallmark findings are edema and erythema of the hands and feet, especially the palms and soles, in association with petechiae and purpura (Fig. 81.8). Occasionally, there is extension onto the dorsal surfaces of the hands and feet, and patients may complain of burning and pruritus. Additional manifestations can include an enanthem of erosions and petechiae involving the palate, pharynx, and tongue, as well as fever and mild prodromal symptoms.

Fig. 81.7 Erythema infectiosum. A Bright red macular erythema on the cheeks. **B–D** Lacy, reticulated erythematous eruptions on the extremities during the second stage of the exanthem. *A, D, Courtesy Louis A. Fragola, Jr, MD; B, Courtesy Julie V. Schaffer, MD; C, Courtesy Kalman Watsky, MD.*

Fig. 81.8 Papular-purpuric gloves and socks syndrome. Erythema and edema with associated petechiae and small purpuric papules on the dorsal aspect of the fingers and hands. *Courtesy Luis Requena, MD.*

Therapy of PPGSS is symptomatic, and spontaneous resolution usually occurs over 1–2 weeks. Although few studies have addressed the immune response in PPGSS, based on limited data it appears that patients develop the mucocutaneous lesions while still viremic, which implies contagiousness and therefore has different epidemiologic implications than the classic eruption of erythema infectiosum.

Arthralgia or arthritis occurs in up to 10% of patients with erythema infectiosum and is usually self-limited, typically resolving in 1–3 weeks but sometimes lasting for months. It tends to affect the small joints of the hands as well as the wrists, knees, and ankles. Joint involvement related to B19 infection is more common in adults, especially women, occurring in up to 30%–60% of those with acute infection[27]. Arthropathy may be seen without an accompanying exanthem.

The manifestations of *fetal B19 infection* range from self-limited anemia to hydrops, spontaneous miscarriage, or stillbirth. The greatest susceptibility is associated with infections acquired before 20 weeks' gestation, and most fetal losses occur between 20 and 28 weeks' gestation. Third-trimester fetal demise may also occur, but it is less often associated with fetal hydrops[28]. The overall risk of fetal loss in the setting of acute B19 infection during pregnancy is only 2%–6%[29–31], and the majority of infants born to B19-infected mothers are delivered asymptomatic at term. There is no evidence for long-term neurodevelopmental sequelae for surviving infected infants, and congenital malformations have not been conclusively demonstrated.

When diagnostic confirmation of B19 infection is needed, detection of serum anti-B19 IgM antibody is the preferred method, and its presence indicates infection within the previous 2–4 months. PCR-based assays may be helpful in diagnosing infection in immunocompromised patients.

Pathology

Skin biopsy is generally not useful in the diagnosis of B19 infection. In patients with PPGSS, histologic evaluation demonstrates a lymphocytic dermal infiltrate with frequent extravasation of erythrocytes. Anti-B19 antibodies can highlight infected endothelial cells in superficial dermal blood vessels.

Treatment

No specific antiviral therapy is available for B19 infections. Children with erythema infectiosum usually feel well and often require no treatment. NSAIDs are useful if symptomatic arthropathy is present. Patients who develop an aplastic crisis may require red blood cell transfusions. Pregnant women with confirmed primary B19 infection during the first two trimesters should undergo serial fetal ultrasonography, and management of severely affected fetuses is possible with *in utero* transfusions and other interventions.

ROSEOLA INFANTUM

Synonyms: ■ Exanthem subitum ■ Sixth disease

Key features

- High fever followed by an exanthem at defervescence
- Affects primarily infants and toddlers
- Febrile seizures possible

Roseola infantum is a common febrile illness of infancy that is primarily caused by human herpesvirus-6 (HHV-6) infection and is occasionally associated with human herpesvirus-7 (HHV-7) infection (see Ch. 80). Most cases occur between age 6 months, when levels of protective maternal antibodies wane, and 3 years, with peak incidence at age 6–12 months. Between 40% and 80% of children are seropositive for HHV-6 by age 13 months[26,32], and most of the remainder by 3 years; however, less than a third of infections result in the classic clinical manifestations of roseola infantum. Roseola infantum occurs year-round but is most common in the spring; the incubation period is usually 9–10 days.

The characteristic presentation is a high fever (to 40–40.5°C; 104–105°F) for 3–5 days in an infant who otherwise appears well. Seizures occur during the febrile period in up to 10% of patients. Defervescence is accompanied by the appearance of rose-pink macules and papules on the trunk, neck, proximal extremities, and occasionally the face. Mild upper respiratory symptoms, injection of the tympanic membranes, cervical or occipital lymphadenopathy, edematous eyelids, and a bulging anterior fontanelle may also be present. An enanthem of red papules on the soft palate and uvula (Nagayama spots) can develop, and uvular and palatoglossal junctional ulcers represent a characteristic finding[33]. The skin eruption typically fades over a few days. Nonspecific fevers with or without otitis media in infants may also be due to HHV-6 infection.

Additional pathogenic features and clinical manifestations of HHV-6 infection, including reactivation in the settings of immunosuppression and drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome, are discussed in Chapter 80.

UNILATERAL LATEROTHORACIC EXANTHEM

Synonym: ■ Asymmetric periflexural exanthem of childhood

Key features

- Initial unilateral distribution, most often affecting the axilla and lateral trunk
- Subsequent generalization, but maintains unilateral predominance
- Spontaneous resolution over 3–6 weeks
- Presumed to be viral in etiology, although exact cause unknown

Introduction and History

This disorder was first described in 1962[34], and the term "unilateral laterothoracic exanthem" (ULTE) was introduced in 1992[35]. ULTE is initially characterized by a unilateral periflexural (often axillary) location, with spread in a centrifugal pattern to the contralateral side over time.

Epidemiology

ULTE occurs most commonly in toddlers and preschool-aged children, with an age range of 6 months to 10 years and a male : female ratio of 1 : 2. It has most often been reported in Europe and North America, and the majority of cases occur in the spring.

Fig. 81.9 Unilateral laterothoracic exanthem. Erythematous macules and papules involving the left axilla and upper flank (**A**) and a slightly more extensive distribution on the left lateral trunk (**B**).

Pathogenesis

The etiology of ULTE remains unknown despite multiple attempts to identify a causative infectious agent. The seasonal pattern, associated prodrome, reports of familial cases, and lack of response to systemic antibiotics suggest a viral etiology. In studies in which screening for multiple viruses (e.g. EBV, CMV, HHV-6, HHV-7) was performed, no etiologic agent has been consistently demonstrated. A relationship to infection with *Spiroplasma*, parvovirus B19, EBV, and SARS-CoV-2 has been noted in individual cases[36,37].

Clinical Features and Differential Diagnosis

The eruption typically begins with a unilateral distribution (Fig. 81.9), most commonly in the axillary region, followed in frequency by the trunk, arm, and thigh. It is usually morbilliform or eczematous in nature and tends to spread to contralateral areas while maintaining a unilateral predominance.

The exanthem may be preceded by a low-grade fever, diarrhea, and/or rhinitis in up to 60% of patients, and pruritus is common. Lymphadenopathy may also be present. The eruption typically lasts 3–6 weeks and then resolves spontaneously, usually without recurrence.

Contact dermatitis is often initially suspected, and the differential diagnosis also includes a nonspecific viral exanthem, a drug eruption, atypical pityriasis rosea, scabies, miliaria, and tinea corporis. If there is prominent involvement of the extremities, Gianotti–Crosti syndrome may also be considered. An eczematous eruption with a distribution pattern similar to ULTE can occur in association with mollusca contagiosa located in the same areas. Laboratory evaluation is generally unnecessary.

Pathology

Histologic features are nonspecific and include mild spongiosis, exocytosis of lymphocytes into the epidermis, and a superficial perivascular infiltrate that is predominantly lymphocytic. The dermal infiltrate may be accentuated around eccrine ducts.

Treatment

Supportive treatment is indicated in symptomatic patients, although topical corticosteroids tend to be of little help. Parents should be reassured that the exanthem will resolve spontaneously in about 3–6 weeks.

GIANOTTI–CROSTI SYNDROME

Synonyms: ■ Papular acrodermatitis of childhood ■ Papulovesicular acrolocated syndrome

Key features

- Symmetric papular eruption on the extremities, face, and buttocks
- EBV and globally hepatitis B virus represent the most common triggers

Introduction and History

Gianotti–Crosti syndrome (GCS) was first described by Gianotti and Crosti in the 1950s. This childhood condition is characterized by the acute onset of a symmetric papular eruption on the face, extremities, and buttocks. In 1964, Gianotti and Crosti reported coexistent anicteric hepatitis, and in the 1970s an association with hepatitis B virus was described. Subsequent reports demonstrated that GCS can result from a variety of viral triggers (Table 81.3).

The term "papulovesicular acrolocated syndrome" was used by Gianotti in 1985 to distinguish a more vesicular variant that is characterized by a lack of hepatitis, more pruritus, and a prolonged course[38]. However, differences in clinical manifestations are not generally related to the etiologic agent[39], and this variant is now included within the spectrum of GCS.

Epidemiology

GCS has a worldwide distribution and occurs most often in young children during the spring and early summer. In one large series, the age range was 6 months to 14 years, with a mean of 2 years[39].

Pathogenesis

GCS is regarded as a self-limited cutaneous response to various infections. Hepatitis B virus and EBV are the most frequently reported agents, with EBV representing the most commonly documented cause in the US. Other potential etiologic associations are summarized in Table 81.3. Although the pathogenic mechanisms in GCS are not clear, there is some suggestion that immunizations or immune imbalance may enhance the risk of developing the exanthem following certain infections.

Clinical Features and Differential Diagnosis

GCS is often preceded by an upper respiratory syndrome with mild constitutional symptoms. The exanthem begins abruptly, with monomorphic, skin-colored to pink–red, edematous papules that are

POTENTIAL ETIOLOGIES REPORTED IN ASSOCIATION WITH GIANOTTI–CROSTI SYNDROME	
Viral	
• **Hepatitis B virus***	• Rotavirus
• **Epstein–Barr virus†**	• Parvovirus B19
• Hepatitis A and C viruses	• Mumps virus
• Cytomegalovirus	• Human herpesvirus-6
• Coxsackievirus	• Herpes simplex virus 1
• Respiratory syncytial virus	• Influenza virus
• Adenovirus	• SARS-CoV-2
• Parainfluenza virus	• Human immunodeficiency virus
Non-viral	
• Group A β-hemolytic streptococci	• *Bartonella henselae*
• *Mycoplasma pneumoniae*	• *Neisseria meningitidis*
Vaccines	
• Polio	• Hepatitis B > A
• Diphtheria–pertussis–tetanus (DPT)	• Influenza
• Measles–mumps–rubella (MMR)	• SARS-CoV-2
*Reported most commonly in Europe. †Most common cause in US.	

Table 81.3 Potential etiologies reported in association with Gianotti–Crosti syndrome. A pruritic Gianotti–Crosti syndrome-like eruption can also occur in patients with molluscum contagiosum (see text). Most common viral etiologies are in bold.

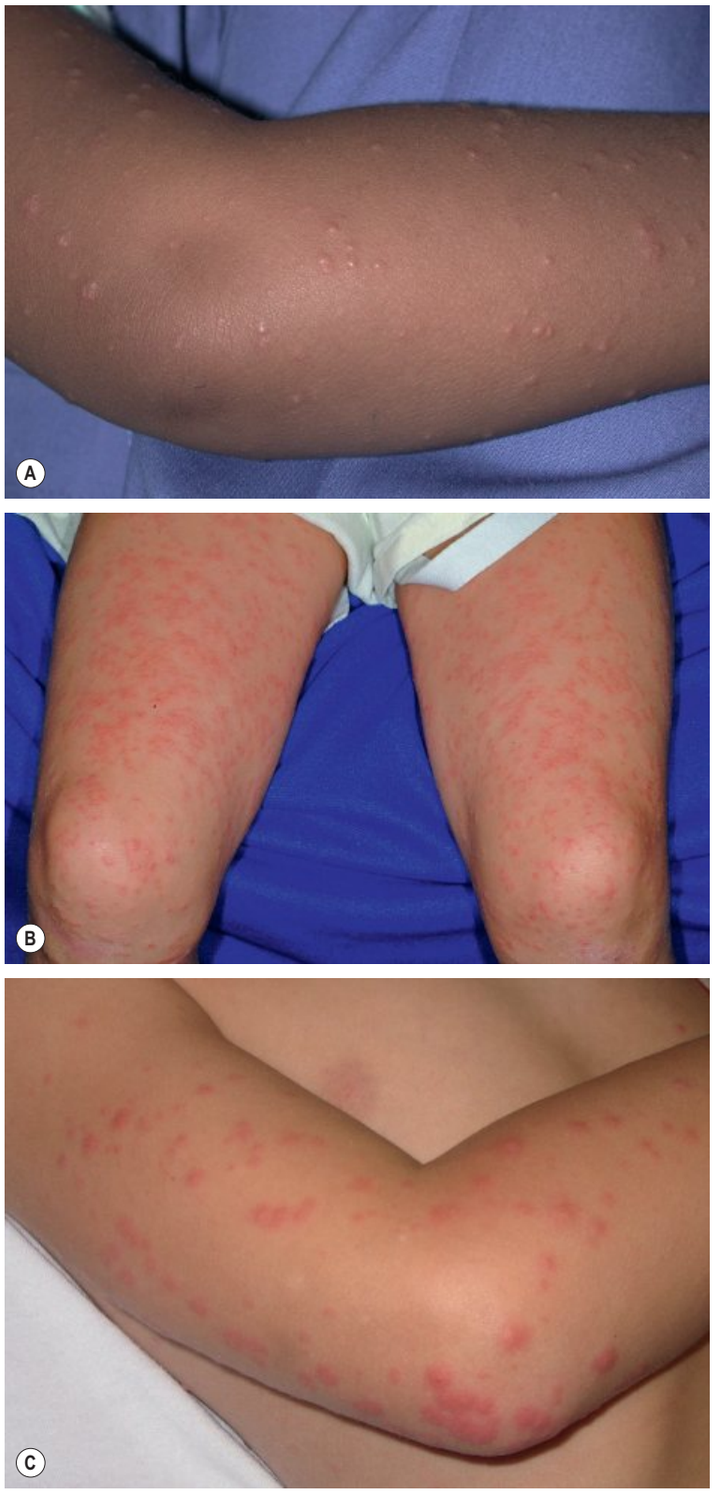

Fig. 81.10 Gianotti–Crosti syndrome. A Monomorphic, small erythematous papules on the elbow. **B** A more exuberant eruption of coalescing edematous, erythematous papules on the thighs and knees. **C** Larger edematous, erythematous papules on the elbow.

symmetrically distributed on the face, buttocks, and extensor surfaces of the extremities (Fig. 81.10). In some patients, lesions may be limited to the face[40]. The trunk is usually spared, although some extension onto the trunk does not exclude the diagnosis[41]. Lesions tend to be asymptomatic and may occasionally be vesicular or purpuric. Systemic manifestations include a low-grade fever and lymphadenopathy (mainly inguinal and axillary) that can persist for a few months; hepatomegaly and splenomegaly occur less often.

The differential diagnosis of GCS may include a drug eruption, papular urticaria, other viral exanthems, erythema multiforme, and molluscum contagiosum. An inflammatory response to molluscum contagiosum, which often heralds clearance of the lesions, can present with an eruption of monomorphic erythematous papules that favor the elbows and knees; this "id" reaction-like phenomenon can resemble GCS but tends to be extremely pruritic and to respond to treatment with topical corticosteroids[42].

Pathology

The histopathologic findings are nonspecific and can include spongiotic and lichenoid changes as well as a lymphocytic vasculitis. Exocytosis of lymphocytes within the lower epidermis and increased numbers of cytotoxic T lymphocytes in the infiltrate may be observed[43,44].

Treatment

The treatment for GCS is supportive, and topical corticosteroids are often of little benefit. A thorough history and physical examination should be performed, and laboratory tests for hepatitis or specific viral agents (e.g. hepatitis B virus, EBV) should only be obtained if clinically indicated. Spontaneous resolution usually occurs within 3–6 weeks, although the eruption may occasionally persist for 8 weeks or longer.

POXVIRUS INFECTIONS

Key features

- Although the last reported case of smallpox was in 1978, it is still considered a bioterrorism threat
- Molluscum contagiosum represents the most common poxvirus infection in humans

The family Poxviridae are large, brick- or ovoid-shaped, double-stranded DNA viruses that are characterized by cytoplasmic replication. Diseases caused by poxviruses include smallpox, vaccinia, cowpox, mpox (previously referred to as monkeypox), tanapox, orf, milker's nodules, and molluscum contagiosum (Table 81.4)[45–50]. The most historically significant of these was smallpox, which at one time was endemic throughout the world and responsible for millions of human deaths. The last epidemic of smallpox in the US was in 1949, and in 1980, the World Health Assembly declared the world free from smallpox. However, two reference collections remain in the US and Russia. The infection that has clinical features most similar to smallpox is varicella; a comparison of these two conditions is provided in Table 81.5.

Because of concerns regarding smallpox being used as a bioterrorism agent[51–53], extensive recommendations have been adopted for handling of a suspected outbreak (emergency.cdc.gov/agent/smallpox/). The current strategy of ring vaccination involves isolation of patients with suspected infection and immunization of all identified contacts as well as their contacts. If given within 3–4 days following exposure, smallpox vaccination may prevent or reduce the severity of disease. If possible, first responders and healthcare workers who come into contact with a suspected patient should have previously been vaccinated[54]. Tecovirimat and brincidofovir are both FDA-approved for the treatment of smallpox in adults and children (weighing ≥13 kg and including neonates, respectively). Recently, tecovirimat access was expanded to include patients with other orthopoxvirus infections, including mpox[55]. Both of these agents as well as the JYNNEOS™ (Modified Vaccinia Ankara) vaccine were utilized in the 2022 international mpox outbreak[45–47] (see Table 81.4).

With the eradication of smallpox, *molluscum contagiosum* (MC) became the only remaining poxvirus infection to specifically afflict humans. The MC virus (MCV) is a member of the *Molluscipox* genus of Poxviridae, and the MCV I and MCV II subtypes result in indistinguishable skin lesions[56]. MC is a common, self-limited condition in children. It also occurs in adults, usually as a sexually transmitted disease, and in immunocompromised hosts, most notably HIV-infected individuals. Transmission is via skin-to-skin contact and, less commonly, fomites.

MC lesions are firm, umbilicated, pearly papules with a waxy surface. They can occur anywhere on the skin surface but are most common in skin folds (e.g. axillae, neck); on the lateral trunk, thighs, and buttocks; and in the genital region (Fig. 81.13A). Facial lesions can also occur and are often especially distressing to the patient (Fig. 81.13B). Widespread, large, and occasionally deforming lesions may be seen in the setting of immunosuppression, particularly AIDS (see Ch. 78).

SELECTED POXVIRUS INFECTIONS

Disease	Virus/genus	Host	Clinical findings	Treatment	Comment
Smallpox	Variola/ Orthopoxvirus	Humans	*Major criteria** • Febrile prodrome (>101°F [38.3°C], 1–4 days prior to rash onset with headache, backache or abdominal pain) • Firm, deep-seated, well-circumscribed vesicles/pustules • Lesions in the same stage of development in any one area of the body *Minor criteria* • Centrifugal distribution† • First lesions in the pharynx, oral mucosa • Patient appears "toxic" • Slow evolution of rash (i.e. 1–2 days for each stage: macule, papule, vesicle) • Lesions on the palms and soles See Table 81.5 for additional findings	Tecovirimat (adults and children weighing ≥13 kg), brincidofovir (any age, including neonates); supportive; prophylaxis with vaccination – ACAM2000® (vaccinia; see below) or JYNNEOS™ (Modified Vaccinia Ankara; approved to prevent smallpox and mpox in adults at high risk of infection)	• Enters via respiratory tract • Incubation period – 7 to 17 days • Variola major = severe form with high mortality rate; variola minor (alastrim) = mild form • Complications: panophthalmitis, blindness, arthritis, encephalitis • Usual causes of death: toxemia, immune complex deposition, hypotension • High risk of smallpox – 3 major criteria; moderate risk – febrile prodrome + *either* 1 other major criterion *or* ≥4 minor criteria; low risk – no febrile prodrome or febrile prodrome + <4 minor criteria • Laboratory diagnosis: variola real-time PCR (+), orthopox real-time PCR (+), non-variola orthopoxvirus real-time PCR (–), EM (if available), viral culture; acceptable specimens: vesicular "touch prep", vesicle roof, vesicular swab, biopsy tissue • Theoretically eradicated; potential use as bioterrorism agent

Table 81.4 Selected poxvirus infections.

Continued

SELECTED POXVIRUS INFECTIONS					
Disease	**Virus/genus**	**Host**	**Clinical findings**	**Treatment**	**Comment**

Vaccinia	Vaccinia/ Orthopoxvirus	Humans	• Papule at the vaccination site (usually deltoid or thigh) develops into vesiculopustules, then crust (Fig. 81.11A)
			• Occasionally, satellite lesions
			• Lymphadenopathy, fever, malaise common
				Supportive; heals with pitted scar	• Used for smallpox vaccination; historically in the general population, currently in military and first responders, including healthcare workers
					• Live vaccine (ACAM2000®) from a single purified isolate of the previous vaccine (Dryvax®; last manufactured in 1978) that is aseptically propagated in cell culture began to be utilized in 2008, with >200 million doses in the US Strategic National Stockpile
					• Possible adverse events‡:
					  • superinfection of the vaccination site or regional lymph nodes
					  • inadvertent autoinoculation (non-ocular)
					  • contact transmission (non-ocular)
					  • ocular vaccinia
					  • generalized vaccinia (more severe in immunocompromised hosts)
					  • eczema vaccinatum (atopic dermatitis, Darier disease) (Fig. 81.11B)
					  • postvaccination non-viral pustulosis
					  • progressive vaccinia (immunocompromised hosts)
					  • erythema multiforme (Fig. 81.11C), Stevens–Johnson syndrome
					  • fetal vaccinia
					  • postvaccinial CNS disease
					  • myo/pericarditis
					  • dilated cardiomyopathy (controversial)
					• Additional cutaneous findings that can develop 1–3 weeks post vaccination include urticarial and exanthematous eruptions lasting 4–15 and 7–20 days, respectively
					• Laboratory diagnosis: variola real-time PCR (–), orthopox real-time PCR (+), non-variola orthopoxvirus real-time PCR (+), viral culture; acceptable specimens as for smallpox

Mpox (previously referred to as monkeypox)	Mpox/ Orthopoxvirus – clade I (Central African; more severe disease), clade IIa (West African), clade IIb (2022 outbreak)	Monkeys (especially captive), rodents, humans	• Malaise, fever, flu-like symptoms, and oral enanthem may precede eruption (more severe with clade I) • Number of lesions varies from a few to >100 (often <10 with clade IIb) • Papules progress to vesiculopustules then crust (Fig. 81.18); various stages may be present simultaneously • Clade I: centrifugal distribution†, often involving the palms and soles; clade IIb: favors genital, perianal, and oropharyngeal inoculation sites • Lymphadenopathy common • May be accentuated in areas of eczematous dermatitis ("eczema mpoxicum"); verrucous lesions or necrotic ulcers may develop in immunocompromised patients	Supportive; tecovirimat (first-line; expanded-access protocol¶), brincidofovir, or cidofovir for severe disease/risk of severe disease or strictures; usually self-limited course; deeper lesions heal with scarring and potentially anogenital strictures; prophylaxis with vaccination (JYNNEOS™) for adults at high risk; smallpox vaccination with ACAM2000® also protective	• Endemic in West and Central Africa • Global outbreak in 2022 (>100 countries, >85 000 cases) declared by WHO as a public health emergency of international concern[45–47]; person-to-person transmission primarily in MSM • US outbreak in 2003 due to contact with infected prairie dogs exposed to an infected imported Gambian giant rat[48] • Acquired from animal or human source via skin/mucosal contact, less often via fomites or inhalation • Incubation period – ~3–17 days • Laboratory diagnosis: variola real-time PCR (–), orthopox real-time PCR (+); acceptable specimens as for smallpox • Histologic findings include enlarged keratinocytes with pale cytoplasm and epidermal necrosis (Fig. 81.19)
Cowpox	Cowpox/ Orthopoxvirus	Cattle (now a rare host), cats, rodents, humans	• Painful papule at site of contact with lesions on infected animals (usually cats) • Hands and face most common sites of involvement • Erythematous, edematous papule rapidly becomes vesicular, pustular, then hemorrhagic • Progresses to ulcer with crust and eschar • Lymphadenopathy, fever and flu-like symptoms	Supportive; heals over 4 weeks with scarring; scars often large and depressed	• Primarily in Europe and Central Asia • Less common than orf or milker's nodule • May be transmitted by cats with subclinical infections • Incubation period – 7 days • Occasionally severe disease, including generalized eruptions in patients with atopic dermatitis

Table 81.4 Selected poxvirus infections.

SELECTED POXVIRUS INFECTIONS					
Disease	**Virus/genus**	**Host**	**Clinical findings**	**Treatment**	**Comment**

Orf (ecthyma contagiosum, sore mouth disease, scabby mouth disease, contagious pustular dermatosis, infectious pustular dermatitis)	Orf/Parapoxvirus	Sheep, goats, reindeer, humans	• Papules (1 to few) on hands (Fig. 81.12A) at sites of contact with infected animals (lesions favor perioral area and udders of ewes), carcasses, or fomites (e.g. fences, barn doors)
			• Progression through several stages:
			  • maculopapular
			  • targetoid
			  • weeping nodule
			  • regenerative dry stage with black dots
			  • papillomatosis
			  • regression with a dry crust
			• May be accompanied by lymphangitis, lymphadenopathy, malaise, fever
				Supportive; topical imiquimod may stimulate early regression; usually heals without scarring	• Endemic in sheep and goats
					• At-risk occupations: shepherds, butchers, veterinary surgeons, sheepshearers
					• Histologic findings depend on stage of the lesion and include epidermal necrosis, vacuolated keratinocytes, a dense mixed dermal infiltrate, and delicate finger-like projections of the epidermis into the dermis; eosinophilic inclusion bodies (intracytoplasmic > intranuclear) (Fig. 81.12B)
					• Laboratory diagnosis: histologic examination of skin lesion ± EM; parapox real-time PCR (+), orf real-time PCR (+)
					• Erythema multiforme occasionally occurs 10 to 14 days later

Milker's nodules (bovine papular stomatitis, pseudocowpox)	Paravaccinia/ Parapoxvirus	Cattle, humans	• Papule develops at site of contact with lesions on infected animals (e.g. muzzles of calves, teats of cows) • Often single lesions; favor hands and forearms • Cutaneous lesions virtually identical to orf	Supportive	• Endemic in cattle • At-risk occupations: dairy farmers, ranchers, butchers, veterinary surgeons • Laboratory diagnosis: histologic findings ± EM (see orf); parapox real-time PCR (+), paravaccinia real-time PCR (+)
Deer-associated parapoxvirus infection	Parapoxvirus	Deer, humans	• Friable violaceous nodule at site of non-healing cut obtained while field dressing a deer carcass • Single lesion on a finger • Fever following biopsy in one patient	Supportive	• Reported in deer hunters in the Eastern US[49] • Histologic findings include epidermal hyperplasia ± necrosis, intracytoplasmic eosinophilic inclusion bodies in keratinocytes, dilated vascular spaces with swollen endothelial cells, and variable lymphohistiocytic and neutrophilic infiltrates • Parapox real-time PCR (+)
Tanapox	Tanapox/ Yatapoxvirus	Non-human primates, humans	• Isolated skin lesion, usually on the leg • Macular, papular, pustular, ulcerative, and crusted stages • Local swelling and lymphadenopathy common • Associated fever and flu-like symptoms	Supportive; heals over 6–8 weeks with scarring	• Endemic in equatorial Africa • Transmission to humans probably occurs via an arthropod vector, although direct transmission also possible[50]

*Per the CDC (emergency.cdc.gov/agent/smallpox/).
†Concentrated on the face and extremities.
‡Case definitions are in ref. 51.
¶cdc.gov/poxvirus/monkeypox/clinicians/Tecovirimat.html

Table 81.4 Selected poxvirus infections. Human infection with a novel orthopoxvirus acquired from cows in the country of Georgia has also been reported to present with painful papules on the hands. CNS, central nervous system; EM, electron microscopy; MSM, men who have sex with men.

An associated molluscum dermatitis is common (Fig. 81.13C), especially in children with atopic dermatitis. Inflammation of MC lesions can occur, often with a pustular or furuncle-like component (Fig. 81.13D); this signals the development of a host immune response. As noted above, an id reaction-like eruption of pruritic erythematous papules that favor the elbows and knees occasionally develops in conjunction with an inflammatory response to MC.

The differential diagnosis of MC may include adnexal tumors, verrucae, condylomata acuminata, basal cell carcinoma, juvenile xanthogranuloma, melanocytic nevi (especially Spitz nevi), papular granuloma annulare, and pyogenic granuloma. In immunocompromised hosts, infectious processes such as cryptococcosis or histoplasmosis can mimic MC. Inflammatory reactions to mollusca may resemble nummular dermatitis, staphylococcal furunculosis, Gianotti–Crosti syndrome, or unilateral laterothoracic exanthem (ULTE). Histologic evaluation of an MC lesion reveals large, intracytoplasmic inclusion bodies (molluscum bodies, Henderson–Patterson bodies) within epidermal keratinocytes, which increase in size as they move toward the skin surface (Fig. 81.13E). A variably dense dermal infiltrate may occasionally have pseudolymphomatous features.

MC resolves spontaneously in immunocompetent children, with the time interval between onset and clearance of the lesions ranging from several months to several years. However, treatment may be requested when there are numerous or cosmetically significant lesions. Therapeutic options include curettage, manual expression, cryotherapy, topical chemovesicants, keratolytics, and cidofovir (Table 81.6). Although imiquimod has been used anecdotally for MC, efficacy was not demonstrated in large controlled studies[57]. In-office use of cantharidin was recently FDA-approved for the treatment of MC in individuals ≥2 years of age, with complete MC clearance in ~50% of patients after 4 applications at 3-week intervals[58] (see Ch. 129). Although cantharidin has the benefit of non-traumatic application, it may require more visits than curettage. Berdazimer 10.3% gel is a nitric oxide-releasing agent shown in randomized controlled studies to result in complete MC clearance in ~30% of patients treated daily for 12 weeks[59]. Treatment of molluscum dermatitis with a topical corticosteroid may help to reduce associated pruritus and prevent autoinoculation from scratching.

VIRAL HEMORRHAGIC FEVERS, INCLUDING DENGUE

The hemorrhagic fevers are a group of zoonotic viral infections that range in severity from a mild, self-limited febrile illness to a severe, life-threatening disease. Cutaneous manifestations of hemorrhagic fevers are nonspecific and include petechiae, purpura, and mucosal hemorrhage. Patients with serious infections suffer from shock, bleeding, and multi-organ failure, with a high mortality rate. Viral hemorrhagic fevers are most common in South America and Africa, although some agents have a worldwide distribution. Table 81.7 lists the epidemiologic characteristics of several viral hemorrhagic fevers.

Dengue, including severe disease classically referred to as *dengue hemorrhagic fever* (DHF) and *dengue shock syndrome* (DSS), is a febrile illness caused by the dengue virus, which has four serotypes, DENV1–4. These viruses are members of the Flaviviridae family, and infection is transmitted to humans by mosquitoes. In endemic areas (Fig. 81.14), the virus can be transmitted vertically from mother to fetus[60]. Epidemics may occur when the virus is introduced into a new geographic area by travelers.

Manifestations of dengue range from asymptomatic infection to potentially lethal disease[61]. After an incubation period of 3–8 days, affected individuals develop a biphasic fever, headaches, myalgias, nausea, vomiting, and retro-orbital pain. A cutaneous eruption develops in up to 50% of patients; it may be morbilliform or scarlatiniform, with areas of sparing referred to as "white islands in a sea of red". Minor hemorrhagic manifestations can occur, including petechiae, epistaxis, and gingival bleeding[62]. Severe dengue (including DHF/DSS), which is more common in children and following reinfection with a second virus serotype, is characterized by plasma leakage resulting in shock and respiratory distress as well as severe hemorrhage and organ impairment. Non-neutralizing, fucosylated IgG1 antibodies that bind the activating Fc receptor FcγRIIIA and appear to cross-react with platelet antigens were recently found to contribute to thrombocytopenia and severe disease[63].

The diagnosis of dengue can be confirmed by serologic assays, RT-PCR analysis, or detection of the viral nonstructural protein 1 (NS1) antigen. No specific therapy exists for dengue, but intensive supportive care can decrease the mortality rate to 1%[62]. CYD-TDV (Dengvaxia®) is a live attenuated vaccine that was FDA-approved in 2019 for individuals 9–16 years of age with a laboratory-confirmed previous dengue virus infection who are living in an endemic area; it should be avoided in seronegative individuals, as it can lead to more severe infection if they later contract natural dengue infection. TAK-003 (Qdenga®), a recombinant chimeric vaccine that has greater efficacy against DENV2 than other dengue virus subtypes, appears to be equally safe and effective in seropositive and seronegative individuals; it is currently approved in several countries, including the Euopean Union, Brazil, and Thailand.

COMPARISON OF VARICELLA/DISSEMINATED ZOSTER TO SMALLPOX		
	Varicella/disseminated zoster	**Smallpox**
Prodrome	None or mild fever and malaise	Fever ≥101°F (38.3°C) for 1 to 4 days prior to onset of eruption, plus prostration, headache, chills, backache, and/or gastrointestinal symptoms
Distribution of lesions	Face/scalp initially; trunk affected more than distal extremities May have an enanthem	Lesions concentrated on face and limbs; can progress to involve entire body surface Enanthem often precedes cutaneous eruption
Stage of lesions	Different stages (papules, vesicles, pustules) are seen simultaneously in any one area of the skin	Adjacent lesions are all at same stage of development (synchronous)
Type of lesions	Relatively superficial, with evolution from macules/papules to vesicles to pustules	Begin as papulovesicles and then become firm, deep-seated pustules with a tendency to confluence
Course	Lesions tend to appear in crops over a 3-day period	Lesions spread over 1–2 weeks, and crusting develops over 1 week
Scarring	Rare in uncomplicated cases	Common and marked

Table 81.5 Comparison of varicella/disseminated zoster to smallpox.

WEST NILE VIRUS INFECTION

West Nile virus (WNV), a single-stranded RNA virus in the Flaviviridae family, is an enzootic agent most commonly found in Africa, Europe, and Asia. It is transmitted among wild birds (e.g. crows, ravens, jays) by *Culex* mosquitos. Since 1999 there has been geographic expansion of the virus within the US, with human cases in all of the contiguous states and ~2700 deaths to date[64–66]. Although transmitted primarily by mosquito bites, transmission can also occur via blood transfusions, solid organ transplantation, and possibly breastfeeding[67–69].

WNV infection most commonly occurs between late spring and early fall, during periods of active mosquito feeding. Approximately 80% of infections are clinically asymptomatic. In symptomatic patients, manifestations include fever, headache, malaise, anorexia, nausea, vomiting, eye pain, lymphadenopathy, encephalitis, myalgias, and muscle weakness. Older patients have a higher risk of more severe neurologic disease.

An exanthem occurs in 25%–50% of symptomatic patients with WNV infection. It has been described as a macular, papular, psoriasiform, or erythematous eruption[67]. Both predominance on the extremities and small punctate lesions have been reported. Development of a rash may be associated with decreased risk of encephalitis and death from WNV[70]. The diagnosis is confirmed by serum or cerebrospinal fluid IgM ELISA or RT-PCR. Treatment is supportive; preventive measures include reducing the number of vector mosquitoes and avoidance of mosquito bites.

ZIKA VIRUS INFECTION

Zika virus is a member of the Flaviviridae family that was initially identified in 1947 in Uganda. It can be transmitted by *Aedes aegypti* and *A. albopictus* mosquitoes, through sexual contact, via blood transfusions, and from mother to fetus. Large Zika virus outbreaks began in 2007 in Micronesia, with subsequent transmissions in other Pacific Islands, Central and South America, Caribbean islands, Mexico, Florida, and Texas; however, since 2018 there have been no reports of Zika virus infections acquired in the US.

In 2016, Zika infection during pregnancy was linked to risk of fetal microcephaly. Approximately 20% of Zika viral infections are symptomatic, with manifestations including fever, arthralgias/arthritis, headache, and conjunctivitis. A morbilliform or scarlatiniform exanthem typically begins on the face and spreads to the trunk and extremities[71]; follicular accentuation and palmar involvement have been described. Zika-related Guillain–Barré syndrome has also been reported. Diagnosis can be confirmed by RT-PCR-based testing of serum or urine as well as serology. Vaccine development is ongoing.

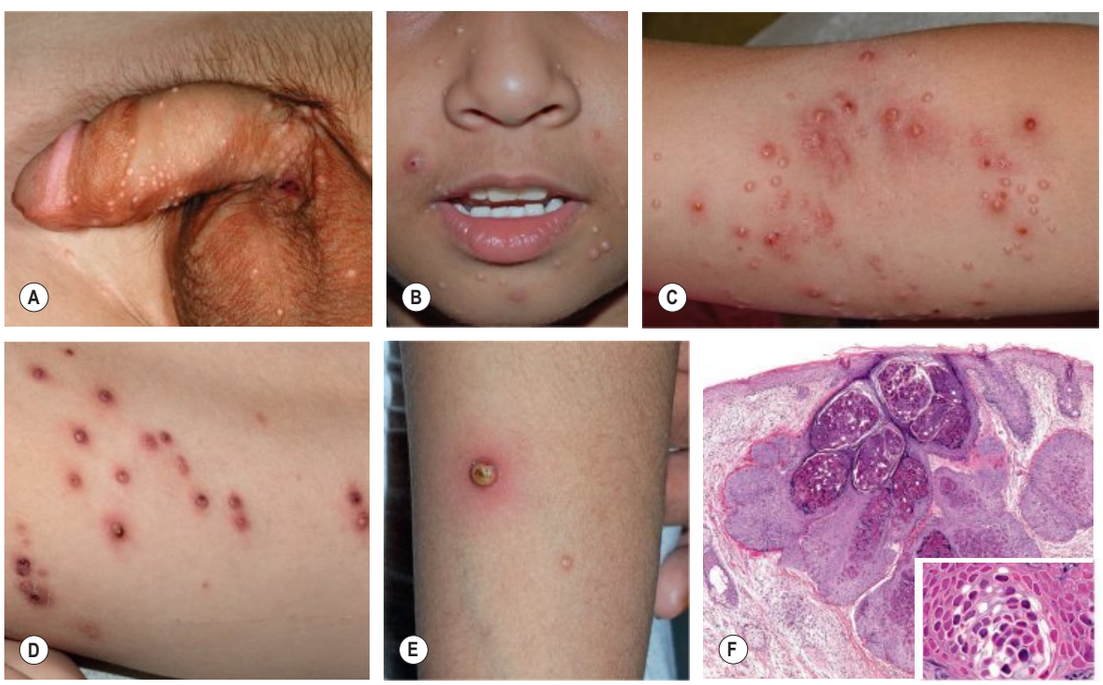

Fig. 81.13 Molluscum contagiosum. Multiple pearly, umbilicated papules in the genital area (**A**) and on the face (**B**); note the inflamed lesion on the right cheek. Inflammatory reactions are a sign of the host immune response to the virus. **C** Inflamed lesions surrounded by "molluscum dermatitis". **D, E** Pustular presentations of inflamed molluscum. Culture revealed only normal skin flora. **F** Histologic evaluation shows numerous molluscum bodies (inset). Demonstrating these bodies in a saline preparation of expressed lesional contents serves as a technique for bedside diagnosis. *B–E, Courtesy Julie V. Schaffer, MD; F, Courtesy Lorenzo Cerroni, MD.*

TREATMENT OF MOLLUSCUM CONTAGIOSUM Rx
No therapy
Eventual spontaneous involution in immunocompetent patients
Risks of spread (especially in atopic patients), associated dermatitis, and pruritus

Trichloroacetic acid (1)
Candida antigen, intralesional (2)
Interferon-α, intralesional (3)
Laser therapy
CO_2 (3)
Pulsed dye (2)
Systemic therapy
Cidofovir (in HIV-infected patients) (3)
Cimetidine (2)
Griseofulvin (3)
Antiretroviral therapy (in HIV-infected patients) (3)
Interferon-α, subcutaneous (3)
*A well-developed lesion is pierced with an insulin syringe via a lateral entry point, followed by repeated puncturing (5–7 times).

Table 81.6 Treatment of molluscum contagiosum. Large randomized, placebo-controlled trials showed no benefit of imiquimod. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

CHIKUNGUNYA FEVER

Chikungunya fever is due to the chikungunya virus, a member of the Togaviridae family, that is transmitted primarily by *A. aegypti* and *A. albopictus* mosquitoes. Initially, infections occurred primarily in India, Indian Ocean islands, Southeast Asia, and Africa, with subsequent outbreaks in Italy, France, Central and South America, Caribbean islands, Mexico, and Florida[72]. After a typical incubation period of 2–7 days, patients present with fever, headache, and myalgias.

Acute cutaneous manifestations include morbilliform eruptions; acral or facial erythema and edema (sometimes localized to the nose or ears); and genital, intertriginous, and oral ulcers[73]. Widespread vesiculobullous eruptions are common in infants and occasionally occur in older children and adults. Subsequently, prominent hyperpigmentation often develops on the face (especially the tip of the nose ["chik sign"]) and extremities. Freckle-like macules and flagellate streaks can be seen as well as diffuse or reticulated pigmentation[73]. Severe low back pain and debilitating arthralgias are characteristic and may last for weeks to months. Complications can include meningoencephalitis, Guillain–Barré syndrome, and myocarditis. No specific treatment is available, and several candidate vaccines are under investigation. VLA1553, a single-shot live-attenuated chikungunya vaccine, was found to be safe and immunogenic in a phase 3 clinical trial[73a].

BARMAH FOREST AND ROSS RIVER VIRUS INFECTIONS

Barmah Forest and Ross River viruses are Togaviridae family members that are endemic in Australia and transmitted to humans by *Aedes* mosquitoes[68,69]. Patients present with fever, lethargy, myalgias, and arthralgias/arthritis. An exanthem affects ~90% of patients with Barmah Forest virus infection, often with initial facial erythema and edema (especially of the nose and ears), followed by a widespread macular, maculopapular, vesicular, or purpuric eruption. Either infection can be diagnosed via serology or PCR.

CUTANEOUS MANIFESTATIONS OF HEPATITIS A, B, AND C INFECTION

Infections with hepatitis A, B, and C viruses (especially the latter two) are associated with a variety of cutaneous manifestations. Infections with hepatitis A, an RNA enterovirus, occasionally lead to cutaneous findings such as panniculitis, urticaria, and a scarlet fever-like exanthem[74], whereas infections with hepatitis B and C viruses have been linked to the entities listed in Table 81.8. Viral nucleic acid testing (NAT) for hepatitis B and C represents a sensitive means of screening donated blood for infection[75], monitoring response to antiviral treatment, and detecting viral reactivation in patients receiving immunosuppressive.

POLYOMAVIRUS INFECTIONS

Synonyms: Trichodysplasia spinulosa: ■ Viral-associated trichodysplasia (of immunosuppression) ■ "Cyclosporine-induced" folliculodystrophy ■ Follicular dystrophy of immunosuppression ■ Pilomatrix dysplasia ■ Trichodysplasia of immunosuppression

Human polyomaviruses (HPyVs) were initially described in 1971, when JC and BK viruses were identified in immunosuppressed patients with progressive neurodegenerative disease. HPyVs were subsequently linked to several skin disorders, beginning in 2008 with the discovery that most *Merkel cell carcinomas* are driven by the Merkel cell polyomavirus (see Ch. 115). *Trichodysplasia spinulosa* is an increasingly recognized entity that was first reported in 1999 and found in 2010 to be caused by the trichodysplasia spinulosa-associated polyomavirus (TSPyV)[75–77]. This condition occurs primarily in solid organ transplant recipients receiving immunosuppressive medications and patients undergoing chemotherapy for a leukemia or lymphoma. *Pruritic and dyskeratotic dermatoses* have also been linked to infections with HPyV6 and 7 in immunocompromised individuals (e.g. with solid organ transplantation or HIV infection)[78]. Most recently, *HPyV9 infection* was found to underlie widespread keratotic skin lesions and fatal pulmonary disease in solid organ transplant recipients[79].

Trichodysplasia spinulosa presents with numerous erythematous to skin-colored papules with a central spiny projection on the face (especially the mid portion), ears, and less often extremities and trunk (Fig. 81.15A). Associated alopecia of the eyebrows and eyelashes, or less often other facial and body hair, as well as thickening of the skin resulting in a leonine appearance may develop. Histologic evaluation is characterized by dilated anagen follicles with abnormal maturation and eosinophilic keratinocytes containing large trichohyaline granules[80]. Large eosinophilic inclusions within affected keratinocytes show positive immunohistochemical staining for the polyomavirus middle T antigen, and electron microscopy demonstrates intranuclear icosahedral viral particles. The diagnosis can be confirmed by PCR-based viral detection in skin scrapings or a biopsy specimen. Trichodysplasia spinulosa may improve following reduction or discontinuation of immunosuppressive medications, and successful treatment with topical cidofovir, oral valganciclovir, and leflunomide has been described[81]. Trichodysplasia spinulosa-like hyperkeratosis has also been described in a patient with basal cell nevus syndrome treated with vismodegib[82].

Pruritic and dyskeratotic dermatoses (PDDs) are characterized by scaly pink to gray–brown papules, patches, and/or plaques coalescing on the trunk and extremities, with associated pruritus and/or burning. Additional reported findings have included diffuse involvement with islands of sparing, alopecia, spiny perifollicular papules, and palmar pits or spicules (Fig. 81.15C)[83]. *HPyV9 infection-associated eruptions* presented with keratotic, pink–violet to brown papules and plaques that began acrally and spread to the proximal extremities and trunk;

Tyring, MD, PhD; C, Courtesy Jeffrey Callen, MD.*

keratotic spines and lesions resembling keratoacanthomas were noted in one patient[79]. Histopathologically, both of these disorders are characterized by a "peacock plumage" pattern of dyskeratotic cells and irregular columns of parakeratosis[78,79]. Successful treatment of PDDs with acitretin ± topical cidofovir has been described[81,83].

RABIES

While rabies is not accompanied by a cutaneous eruption, dermatologists may be asked to perform a biopsy of nuchal skin that can be assayed for rabies virus antigen or (via PCR) rabies virus RNA.

CUTANEOUS MANIFESTATIONS OF SARS-CoV-2 INFECTION

Since initially being reported in Wuhan, China in December 2019, the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) pandemic has caused >6.5 million deaths worldwide. While respiratory failure and hypercoagulability are associated with the highest morbidity and mortality, cutaneous findings occur in up to 20% of individuals with SARS-CoV-2 infection, ranging from morbilliform eruptions to retiform purpura[84–86] (Table 81.9). Although SARS-CoV-2 infection in pediatric patients usually has a milder course compared to adults, an exaggerated immune response can result in multisystem inflammatory syndrome in children (MIS-C), which presents with systemic and mucocutaneous manifestations similar to those of Kawasaki disease[87–89] (Table 81.10). In addition, a wide variety of local and widespread cutaneous reactions to SARS-CoV-2 vaccines have been described[85] (see Table 81.9).

KAWASAKI DISEASE

Synonym: ▪ Mucocutaneous lymph node syndrome

Key features

- Fever, conjunctival injection, oral mucosal changes, acral swelling, and cervical lymphadenopathy
- Polymorphous exanthem, often with early perineal involvement
- Represents the most common cause of acquired heart disease in children in the US

Introduction and History

Kawasaki disease (KD) is an acute febrile multisystem disease that primarily affects children ≤5 years of age. Initially described by Kawasaki in Japanese children[90], KD has subsequently been reported worldwide, and in the US it represents the leading cause of acquired heart disease in the pediatric population. Coronary artery aneurysms or ectasias develop in 15%–25% of untreated KD patients, resulting in substantial morbidity and mortality. The clinical manifestations of KD can mimic a variety of other diseases, in particular viral exanthems, and the need to promptly treat KD in order to prevent potentially life-threatening complications makes differentiation among these entities essential.

CUTANEOUS MANIFESTATIONS OF SARS-CoV-2 INFECTION AND VACCINATION	
Cutaneous finding	**Comments**
Manifestations associated with infection	
Morbilliform eruption (Papulo)vesicular eruption Urticaria/urticarial eruption	• Favor the trunk, often pruritic • Typically concurrent with or following other symptoms, often in adults with moderate or (for morbilliform and urticarial) severe disease
Livedo reticularis/racemosa, retiform purpura	• Favor buttocks and extremities • Usually following other symptoms in older adults with severe disease requiring intensive care, often with associated ARDS and other thromboembolic manifestations
Multisystem inflammatory syndrome in children (MIS-C)	• See Table 81.10
Pernio	• Following asymptomatic or mild disease in children and adolescents; likely associated with lifestyle changes during the early pandemic
Additional reported findings include: dengue-like petechiae, erythema multiforme-like and papulosquamous eruptions (e.g. pityriasis rosea-like, psoriasiform), Gianotti–Crosti syndrome, ULTE, Sweet syndrome, erythema nodosum	
Manifestations associated with vaccination	
Injection site reactions	• Swelling, erythema, and pain develop within 3 days of vaccine administration
Delayed large local reactions ("COVID arm")	• Induration and erythema develop >7 days after administration of an mRNA vaccine
Vaccine-related eruption of papules and plaques (V-REPP)	• Range from papulovesicular to pityriasis rosea-like clinically, with variable degrees of spongiosis and interface dermatitis histopathologically
Urticaria Morbilliform eruption Autoimmune bullous disease (bullous pemphigoid > pemphigus vulgaris > others) Erythema multiforme SJS/TEN, AGEP, DRESS (rare) Gianotti–Crosti syndrome, ULTE Small-vessel vasculitis Pernio, erythromelalgia Sweet syndrome, pyoderma gangrenosum	• Immediate hypersensitivity, which may include urticaria, is rare and develops within 4 hours of vaccine administration • Urticaria and morbilliform eruptions typically develop several days after vaccine administration
Flares of inflammatory skin disease, e.g. psoriasis, atopic dermatitis, dermatomyositis, SCLE, rosacea, vitiligo, alopecia areata	• Pre-existing > new onset
Reactions to hyaluronic acid dermal fillers Radiation recall dermatitis Herpes zoster and herpes simplex virus reactivation	• Filler reactions may be related to interaction of SARS-CoV-2 spike proteins with the ACE2 receptor, and treatment with ACE inhibitors has been reported

Table 81.9 Cutaneous manifestations of SARS-CoV-2 infection and vaccination. Telogen effluvium also commonly occurs following SARS-CoV-2 infection and less often vaccination. ACE, angiotensin-converting enzyme; AGEP, acute generalized exanthematous pustulosis; ARDS, acute respiratory distress syndrome; DRESS, drug reaction with eosinophil and systemic symptoms; SCLE, subacute cutaneous lupus erythematosus; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis; ULTE, unilateral laterothoracic exanthem.

MULTISYSTEM INFLAMMATORY SYNDROME IN CHILDREN (MIS-C): 2023 CASE DEFINITION AND COMPARISON WITH KAWASAKI DISEASE		
2023 CDC case definition of MIS-C		

An individual <21 years of age, in the absence of a more likely alternative diagnosis, meeting each of the following criteria:
• Subjective or documented fever (T ≥38.0°C)
• Clinical severity requiring hospitalization or resulting in death
• C-reactive protein (CRP) ≥3.0 mg/dl
• New onset manifestations in ≥2 of the following categories:
  • *Cardiac involvement:* coronary artery dilatation/aneurysm, left ventricular ejection fraction <55%, or troponin elevation above normal
  • *Shock*
  • *Mucocutaneous involvement:* exanthem, oral mucosal inflammation*, conjunctivitis/conjunctival injection, or extremity findings (erythema, edema)
  • *Gastrointestinal involvement:* abdominal pain, vomiting or diarrhea
  • *Hematologic involvement:* platelet count <150 000/mcl, absolute lymphocyte count <1000/mcl
• Detection of SARS-CoV-2 nucleic acid/antigen during or up to 60 days prior to hospitalization, or in a postmortem specimen (*for confirmed case*); **OR** detection of SARS-CoV-2 antibodies associated with current illness (*for confirmed case*); **OR** close contact with a confirmed/probable COVID-19 case in the 60 days prior to hospitalization (*for probable case*)		

Comparison between MIS-C and Kawasaki disease		
Typical demographics		
Age	6 months to 5 years	6 to 11 years
Sex	Male:female ~1.5:1	Male:female ~1:1
Racial/ethnic predilection	East Asian	Black, Hispanic
Pathogenesis		
Trigger	Unknown; possible preceding viral or bacterial infection	Onset ~3–6 weeks after SARS-CoV-2 infection
Immunologic similarities	Enhanced IL-1β+ neutrophils and immature neutrophils	
Immunologic differences	T cell activation by conventional antigen High levels of IL-17 Infrequent MAS-like cytokine profile Lymphopenia rare	SARS-CoV-2 spike protein acts as superantigen High levels of IL-15, IFN-γ ~50% with MAS-like cytokine profile Lymphopenia common
Clinical features		
Similarities	Fever, exanthem (see Kawasaki disease text), cervical lymphadenopathy, extremity changes, neurological symptoms	
Differences	More frequent conjunctival injection and oral mucosal changes*	More frequent GI symptoms, myocarditis, coagulopathy, and shock
Management		
Usual	IVIg, systemic corticosteroids, aspirin	
Less common	Infliximab, cyclosporine, anakinra	Anakinra, tocilizumab, cyclosporine
*Mucosal erythema/swelling, drying/fissuring of the lips, or strawberry tongue.		

Table 81.10 Multisystem inflammatory syndrome in children (MIS-C): 2023 case definition and comparison with Kawasaki disease. CDC, Centers for Disease Control and Prevention; IL, interleukin; IFN, interferon; MAS, macrophage activation syndrome. *Adapted from references 88 & 89.*

Epidemiology

The peak incidence of KD is in children ≤2 years of age, and 85% of patients with KD are ≤5 years of age; however, adults with KD have also been reported. The condition is 1.5 times more common in boys than in girls[90]. A peak incidence in late winter to early spring has been observed in North America. Epidemics have occurred in both Japan and the US and are characterized by a wave-like spread over a 2- to 4-year

period[91]. KD is more common in children of Asian descent. Male sex and an age of <1 year or >6 years appear to be risk factors for the development of cardiovascular sequelae, which may be related to delayed diagnosis in the latter group[92].

Pathogenesis

The etiology of KD remains unknown, but several observations suggest an infectious cause, including the clinical features, seasonal variation in incidence, community outbreaks, rarity in infants under 6 months of age with potentially protective maternal antibodies, and infrequent recurrences[90]. However, conventional microbial cultures and serologic studies have failed to identify a causative agent. A pathogenic role for a bacterial toxin that acts as a superantigen has been hypothesized; although this remains unproven, it is supported by the increased prevalence of superantigen-encoded genes in the stool of KD patients compared to other febrile or healthy children[93].

In fatal cases of KD, IgA-producing plasma cells have been found in the coronary arteries, pancreas, kidney, and upper respiratory tract; the latter finding is similar to that seen in children with fatal respiratory viral infections[94]. Oligoclonal KD antibodies synthesized *in vitro* have been shown to bind to cytoplasmic antigen in the proximal bronchial epithelium, coronary arteries, and macrophages of KD patients. Furthermore, electron microscopic studies have provided evidence of virus-like particles within intracellular inclusion bodies in the ciliated bronchial epithelium of patients with KD[95]. These findings are suggestive of a respiratory infectious agent with tropism for vascular tissue.

KD is characterized by marked activation of the immune system, with increased numbers of activated lymphocytes (both T and B) and mononuclear cells as well as increased levels of proinflammatory cytokines. A functional polymorphism in the inositol 1,4,5-trisphosphate 3-kinase C gene (*ITPKC*) has been shown to be significantly associated with KD susceptibility and an increased risk of coronary artery lesions in children from the US and Japan. ITPKC acts as a negative regulator of T cell activation through the nuclear factor of activated T cells (NFAT) signaling pathway; the polymorphism, which reduces the efficiency of ITPKC splicing, may contribute to immune hyperreactivity in Kawasaki disease[96].

Clinical Features and Differential Diagnosis

The diagnostic criteria for KD include fever lasting at least 5 days plus the presence of four of the five following criteria:

- bilateral non-purulent conjunctival injection
- oropharyngeal changes including diffuse hyperemia, strawberry tongue, and lip fissures
- cervical lymphadenopathy (usually unilateral)
- peripheral extremity changes including erythema, edema, and eventual desquamation of the hands and feet
- a polymorphous exanthem.

The diagnosis of KD should be strongly considered in any child presenting with prolonged, unexplained fever in association with skin findings. The fever in KD is usually high-spiking (>39°C; 102°F), and it may not respond to antipyretics[90].

A cutaneous eruption is seen in >80% of patients with KD. It is usually composed of macular and papular erythematous lesions, often in a morbilliform pattern, but may also be erythema multiforme-like, urticarial, scarlatiniform, or even pustular (Fig. 81.16A,E). Petechiae and crusting are unusual findings and vesiculobullous lesions are rarely if ever seen. In some patients, ulceration at the site of a bacillus Calmette–Guérin (BCG) vaccination has been observed during the disease course. A characteristic early cutaneous finding is erythema of the perineum, which often desquamates within 48 hours (Fig. 81.16A–C). Edema and brawny induration of the hands and feet are also common early in the disease course (Fig. 81.16D), with eventual desquamation that is prominent in the periungual regions. Gangrene of the peripheral extremities occasionally occurs. Subacute cutaneous manifestations of KD can include a psoriasiform eruption and transverse orange–brown (pseudo)chromonychia thought to result from nail bed splinter hemorrhages[97,98].

The conjunctival injection of KD is typically bulbar with sparing of the limbus (an avascular zone around the iris); it is not associated with increased tearing or an exudate. Keratitis and photophobia are uncommon and should suggest an alternative diagnosis. Oropharyngeal changes consist of dry, fissured lips, a "strawberry tongue" (Fig. 81.17), and in some patients diffuse hyperemia of the oral mucous membranes.

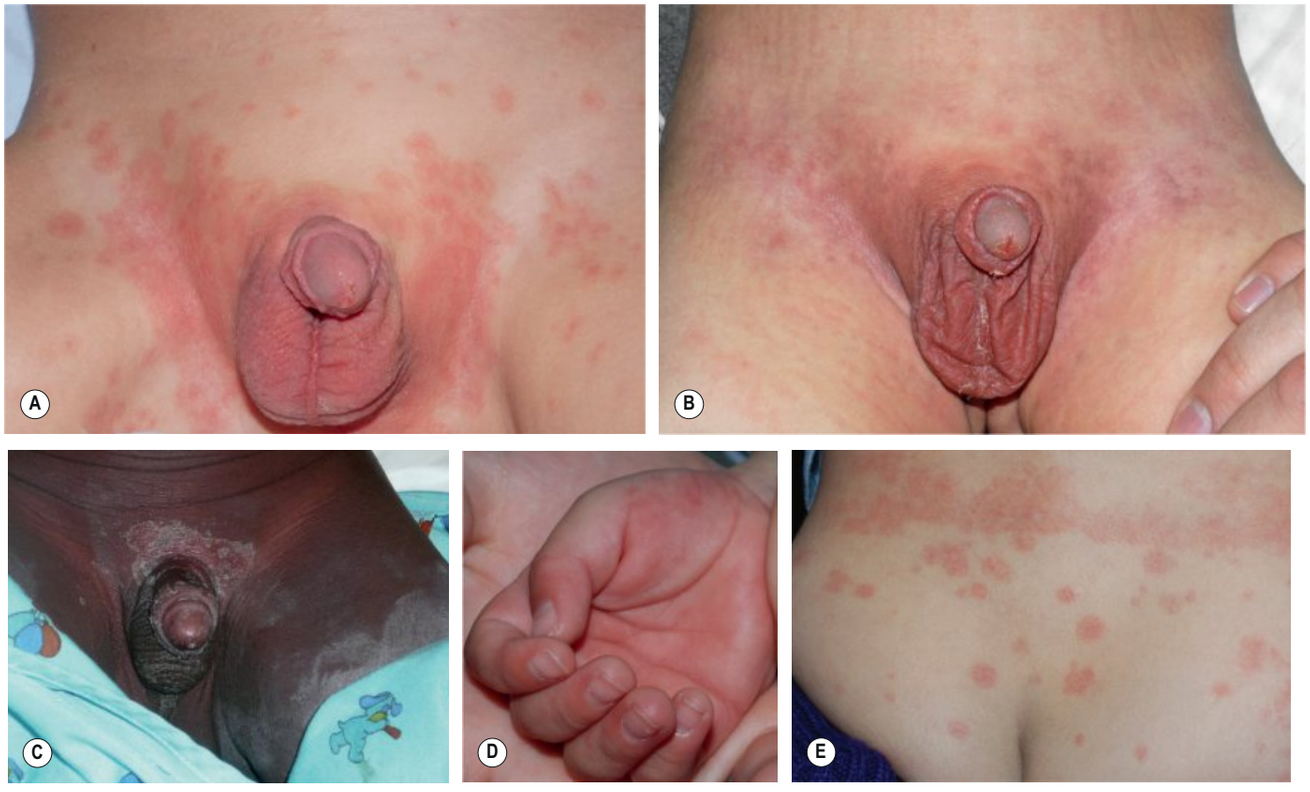

Fig. 81.16 Kawasaki disease. Erythema multiforme-like lesions becoming confluent in the perineal region on the second day of fever (**A**), followed by desquamation 2 days later (**B**). **C** Erythema (less evident due to the patient's darkly pigmented skin) and desquamation in the genital area. Involvement of the skin in this location is a characteristic early finding in Kawasaki disease. **D** Erythema and edema of the palm early in the disease course. **E** Pink papules coalescing along the waistline. *A, B, D, E, Courtesy Julie V. Schaffer, MD.*

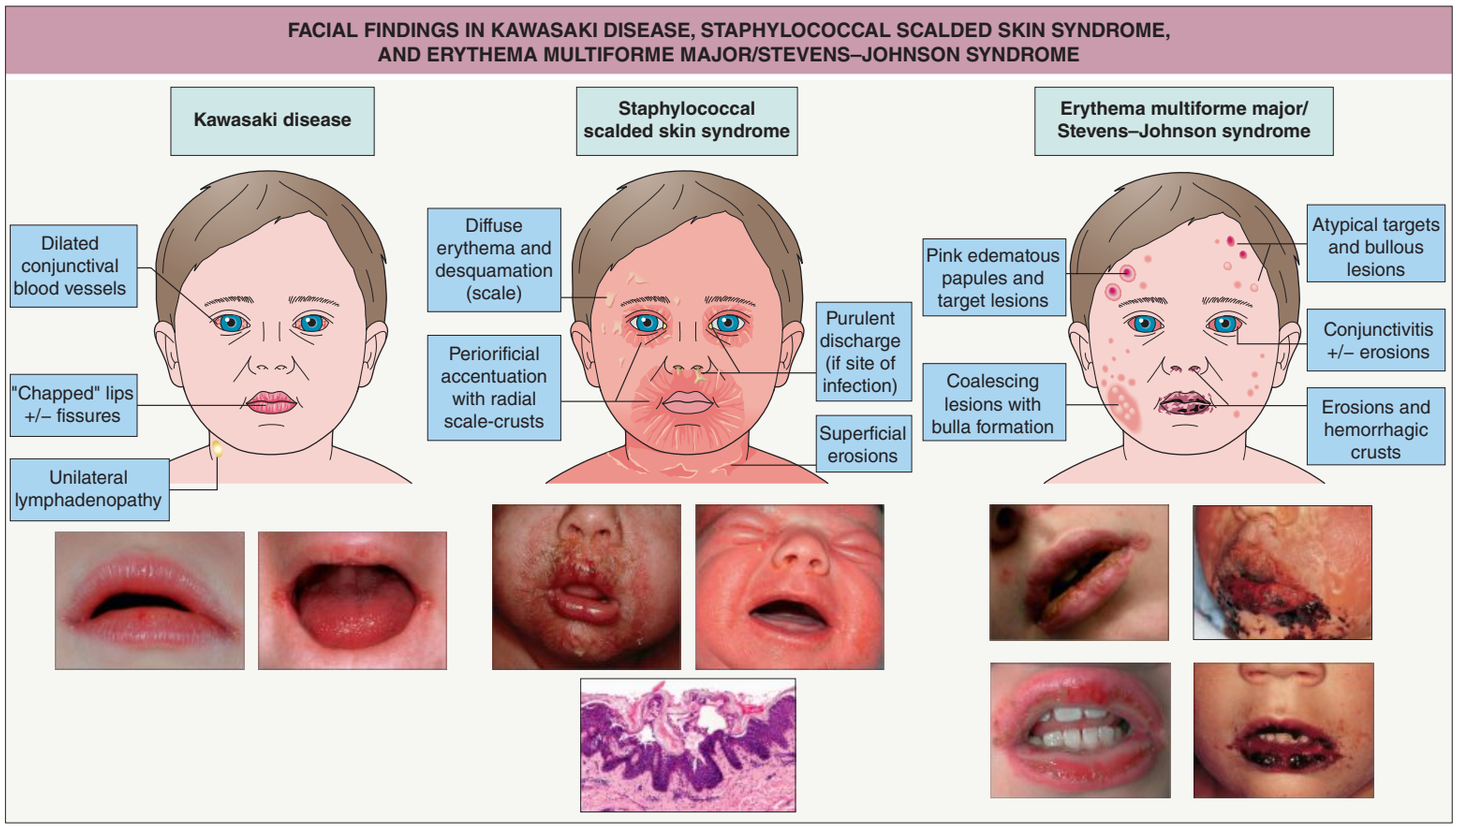

Fig. 81.17 Facial findings in Kawasaki disease, staphylococcal scalded skin syndrome, and erythema multiforme major/Stevens–Johnson syndrome. Hemorrhagic crusting and erosions of the vermilion portion of the lips can also be seen in primary gingivostomatitis due to herpes simplex virus, pemphigus vulgaris, and paraneoplastic pemphigus. Histologic examination of the flaccid sterile bullae of staphylococcal scalded skin syndrome shows cleavage at or below the stratum granulosum (see inset).

Cardiac involvement can include myocarditis, pericardial effusions, congestive heart failure, and coronary aneurysms; the latter represent the source of greatest morbidity in KD. Valvular disease, usually mitral or aortic, may also occur. Tachycardia, murmurs, gallops or distant heart sounds may be noted on cardiac examination. Other possible sites of involvement include the CNS (extreme irritability, aseptic meningitis, cranial nerve palsies, sensorineural hearing loss), gastrointestinal tract (abdominal pain, diarrhea, hepatic dysfunction, obstructive jaundice, gallbladder hydrops), musculoskeletal system (arthralgias, arthritis) and the genitourinary tract (urethritis, meatitis, sterile pyuria).

"Incomplete" ("atypical") KD may be diagnosed in patients with prolonged fever plus coronary artery disease detected by echocardiography or coronary angiography, but fewer than four additional criteria (see above)[91,99]. This presentation tends to be more common in infants, and the diagnosis may be difficult to establish. An algorithm for evaluation of suspected incomplete KD has been proposed and was updated in 2017[99,100]. For children with fever of unknown etiology for ≥5 days who meet 2–3 KD clinical criteria and have an elevated ESR (≥40 mm/hour) and/or CRP level (≥3.0 mg/dl), echocardiography should be performed and treatment initiated if there are signs of cardiac involvement. Both echocardiography and (regardless of the findings) treatment are recommended for those individuals with persistent fever, 2–3 KD clinical criteria, and elevated acute phase reactants who meet ≥3 supplemental laboratory criteria. The latter include hypoalbuminemia, anemia, elevated alanine aminotransferase, white blood cell count ≥15 000/mm^3 (often with neutrophilia), thrombocytosis after 7 days of illness, and sterile pyuria; thrombocytopenia is occasionally observed, although not included as a criterion. Because infants <6 months of age meet KD diagnostic criteria less often and have a greater risk of coronary artery disease, echocardiography is recommended for all patients in this age group with fever of unknown etiology for ≥7 days and an elevated ESR and/or CRP level[101].

Electrocardiographic findings associated with cardiac involvement in KD include decreased R-wave voltage, ST-segment depression, and T-wave flattening or inversion. Higher serum levels of N-terminal pro-brain natriuretic peptide (NT-proBNP) are associated with increased risk of coronary artery disease and IVIg resistance[102], and NT-proBNP may also have utility as a diagnostic marker in young infants[103]. Macrophage activation syndrome is a rare complication of recalcitrant KD that presents with hepatosplenomegaly, cytopenias, hypofibrinogenemia, and marked hyperferritinemia[104] (see Table 91.1).

Although ~25%–50% of patients diagnosed with multisystem inflammatory syndrome in children (MIS-C) also meet criteria for KD, the two entities have distinct epidemiological, immunological, and clinical features[87–89] (see Table 81.10). The differential diagnosis of KD also includes viral exanthems (e.g. adenoviral, enteroviral, EBV, measles), scarlet fever, toxic shock syndrome, staphylococcal scalded skin syndrome, erythema multiforme, drug eruptions, serum sickness-like reaction, recurrent toxin-mediated perineal erythema, systemic juvenile idiopathic arthritis, annular erythema of infancy, infantile polyarteritis nodosa (cutaneous arteritis), and periodic fever syndromes. Fig. 81.17 shows the facial findings that differentiate KD from staphylococcal scalded skin syndrome and erythema multiforme major.

Pathology

Histologic findings are nonspecific and include dermal edema and a perivascular mononuclear infiltrate[91].

Treatment

During its acute phase, the treatment for KD is aimed at decreasing inflammation, and the current first-line therapy is IVIg administered in a single infusion of 2 g/kg over 8–12 hours. This regimen was demonstrated to be more efficacious in preventing coronary aneurysms than the prior recommendation of multiple daily infusions[105]. However, the mechanism of action of IVIg in the treatment of KD is unknown. With the utilization of IVIg, the incidence of coronary aneurysms decreases from 25% to ≤5%–10%, and mortality from 2% to 0.3%. Aspirin is also recommended during the acute phase, with initial administration of 30–100 mg/kg daily (maximum 4 g/day) divided into four doses for 14

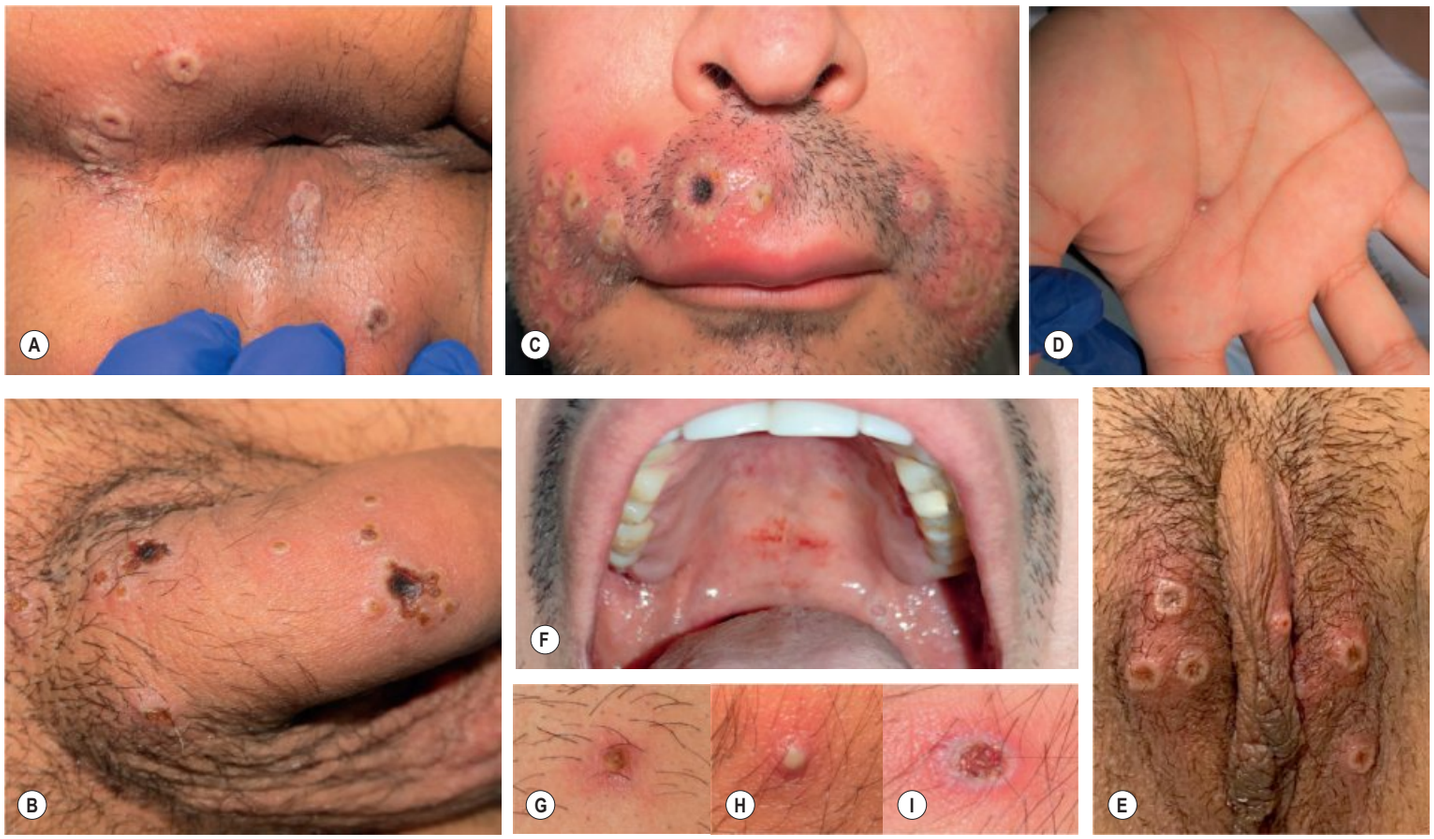

Fig. 81.18 Clinical spectrum of mpox. A-E Umbilicated vesicles, some of which have become necrotic with central hemorrhagic crusts, clustered in the oral and anogenital regions; lesions can also be randomly scattered. A scalloped border is occasionally seen as in herpes simplex viral infection (**B**). **F** Intraoral erosions. **G-I** Primary lesions vary from edematous erythematous papules to pustules to vesicles with a central hemorrhagic crust. *Courtesy, Luis Requena, MD.*

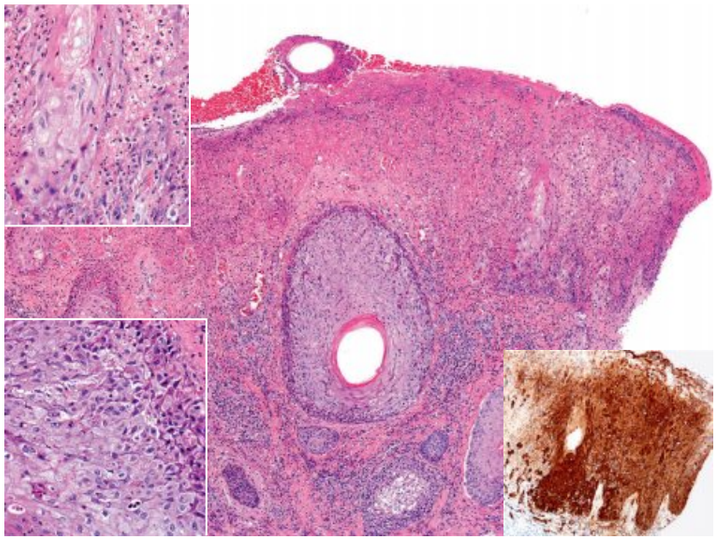

Fig. 81.19 Histopathologic findings in mpox. In addition to epidermal necrosis, hemorrhage, and erosion, there is a brisk lymphohistiocytic infiltrate in the dermis admixed with neutrophils. Note the viral changes (enlarged cells with pale cytoplasm and scattered apoptosis) in the keratinocytes of the epidermis (left upper inset) and hair follicle (left lower inset). Immunohistochemical staining for orthopox antigens can assist in diagnosis (right lower inset). *Courtesy, Luis Requena, MD.*

days or until afebrile for 48–72 hours, followed by a maintenance dosage of 3–5 mg/kg daily, usually for 6 to 8 weeks[99].

Approximately 10%–20% of children with KD have persistent or recrudescent fevers after receiving a single dose of IVIg, and these individuals have a greater risk of coronary artery disease. A second dose of IVIg may be given to patients who fail to become afebrile within 24–48 hours after completion of the first dose. Management options for high-risk or refractory KD include corticosteroids and infliximab administered along with or following failure of IVIg therapy, respectively. One large randomized, double-blind trial found that initial treatment with pulsed corticosteroids plus conventional therapy (IVIg and aspirin) showed no benefit over conventional therapy alone in terms of hospital days, days of fever, rates of retreatment with IVIg, or adverse events[106]. However, another randomized controlled study found that the addition of pulsed corticosteroids to initial IVIg therapy in patients at high risk of having refractory KD was associated with fewer days of fever and a lower likelihood of coronary artery dilation[107]. Randomized controlled studies have shown that infliximab is well tolerated and equally or more effective than a second dose of IVIg in pediatric patients with IVIg-resistant KD[108–110], although it did not decrease the likelihood of resistant disease when given as initial therapy together with IVIg and aspirin[111].

Long-term cardiac follow-up of KD patients is recommended, as adults with a history of KD may have vascular endothelial dysfunction and an increased risk for early-onset atherosclerosis.

Chapter Contents

Syphilis 1461
Gonorrhea 1473
Chancroid 1477
Lymphogranuloma Venereum 1480
Donovanosis (Granuloma Inguinale) 1481

INTRODUCTION

The term "venereal diseases" was historically used to refer to infections that are sexually transmitted, i.e. syphilis, gonorrhea, chancroid, lymphogranuloma venereum, and granuloma inguinale. These disorders are now referred to as "sexually transmitted diseases" (STDs) or "sexually transmitted infections" (STIs), terms that directly reflect recognition that they are caused predominantly by sexual contact with an infected person. For infections caused by pathogens for which non-sexual routes of transmission predominate, e.g. yeasts or cytomegalovirus, the term "sexually transmissible infections" is used. Table 82.1 lists the names of commonly encountered sexually transmitted or transmissible pathogens.

SEXUALLY TRANSMITTED AND TRANSMISSIBLE PATHOGENS	
Bacteria	*Neisseria gonorrhoeae* *Treponema pallidum* *Haemophilus ducreyi* *Chlamydia trachomatis* *Mycoplasma hominis, M. genitalium* *Ureaplasma urealyticum* *Gardnerella vaginalis* *Atopobium vaginae* *Mobiluncus curtisii, M. mulieris* *Klebsiella (Calymmatobacterium) granulomatis* *Shigella* spp. *Campylobacter* spp. *Helicobacter cinaedi, H. fennelliae*
Viruses	Human immunodeficiency virus, types 1 and 2 Herpes simplex virus, types 2 > 1 Human papillomavirus (several types) Hepatitis viruses, B > C and (via fecal–oral contact) A Cytomegalovirus Molluscum contagiosum virus Human T cell leukemia/lymphotrophic virus, types I and II Human herpesvirus, type 8 Mpox
Protozoa	*Trichomonas vaginalis* *Entamoeba histolytica* *Giardia lamblia*
Fungi	*Candida albicans*
Ectoparasites	*Phthirus pubis* *Sarcoptes scabiei*

Table 82.1 Sexually transmitted and transmissible pathogens.

SYPHILIS

Synonym: ■ Lues

Key features

- Sexually acquired, chronic infection caused by *Treponema pallidum* that is characterized by a variety of clinical manifestations and involvement of multiple organ systems
- Can also be transmitted before birth (congenital)
- Intermittently active disease with primary, secondary, and tertiary stages as well as a latent period of variable length that occurs before the onset of tertiary syphilis
- Mucocutaneous manifestations vary from genital ulcers to widespread papulosquamous eruptions to granulomatous nodules
- Syphilis facilitates the transmission of HIV, especially in countries with a high rate of both infections
- Overall, the incidence of syphilis and other STIs has increased substantially in high-income countries after the introduction of antiretroviral therapy and pre-exposure prophylaxis for HIV

History

Syphilis has been of great historical importance and has played a major role in medicine for centuries. The disease was named after an afflicted shepherd named Syphilus in 1530. Theories on the origin of the disease in the late fifteenth century are controversial. One theory proposes that Christopher Columbus and his crew acquired the disease from Native Americans living in the Caribbean islands and brought it back to a nonimmune population in Europe in 1493, as signs of syphilis have been found in skeletons of pre-Columbian Native Americans[1,2]. Another theory is that venereal syphilis may have already been endemic but became more widespread and severe as a consequence of the wars at that time in Europe. Lastly, the environmental theory claims that venereal syphilis is a variant of other diseases caused by *Treponema* spp. and became modified by environmental factors, especially temperature[3,4].

Information on the natural course of untreated syphilis has come primarily from two large studies (Fig. 82.1). The Oslo Study[5] was a prospective investigation of infected, but untreated, individuals conducted between 1890 and 1910, with a follow-up period of 50 years. Approximately one-quarter of infected persons had at least one additional relapse of secondary syphilis, often occurring during the first year (90%). Approximately 15% of infected persons developed benign tertiary syphilis with gummas of the skin (70%), bones (10%), and mucous membranes (10%). Cardiovascular syphilis was reported in ~14% of men and 8% of women, while neurosyphilis was observed in 10% of men and 5% of women. Altogether, the study concluded that 17% of men and 8% of women died as a result of untreated syphilis.

The Tuskegee Study was undertaken in 1932 in infected Black men, with regular examinations for short- and long-term consequences of untreated infection. This represented a highly unethical investigation, as penicillin treatment was withheld without written consent. The principal finding was an increased mortality rate in the syphilitic group compared to the controls, with an ~20% loss-of-life expectancy at an interval of 12 years. Specific lesions of late syphilis were found in about 14% of infected men at the 20-year evaluation, and 12% after 30 years, with cardiovascular syphilis and neurosyphilis representing the primary causes of death[6–8]. The unethical aspects of this study had serious social implications, contributing to mistrust in the healthcare system amongst African-Americans[9].

Epidemiology

Syphilis is distributed worldwide and is particularly problematic in low-income countries, where it is a leading cause of genital ulcer disease. Worldwide, the rates of primary and secondary syphilis decreased dramatically with the introduction of penicillin treatment after the Second World War. In contrast to Western European countries, an increase in the infection rate was observed during the late 1980s in rural southern and urban regions of the US. Although the number of syphilis cases per year in the US subsequently declined and in 2000 fell to its lowest point since reporting began in 1941, the number of primary and secondary syphilis cases diagnosed per year in men has subsequently increased more than sevenfold (Fig. 82.2). According to the Centers for Disease Control and Prevention (CDC), the incidence rate of primary and secondary syphilis in 2019 in the US was 20.1 cases per 100 000 population in men and 3.9 cases per 100 000 population in women. In the US, the incidence in Hispanic and Black individuals is 2- to 5-fold higher than in other population groups, but the highest risk group is men who have sex with men (MSM) as they accounted for nearly 60% of cases of primary and secondary syphilis in 2019[10].

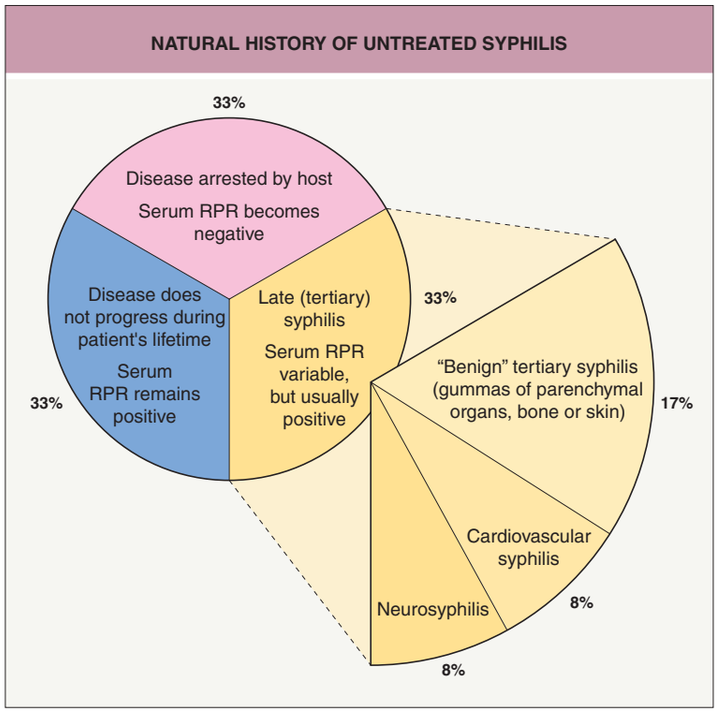

Fig. 82.1 Natural history of untreated syphilis. The data represent a composite of several studies. The specific antibody assays (e.g. MHA-TP, FTA-ABS) remain positive in at least 95% of all patients. RPR, rapid plasma reagin.

With the resurgence of syphilis in Eastern Europe in the 1990s and migration of sex workers from this region to Western Europe, syphilis has also been observed more frequently in Western European countries over the past few decades.

Biology of *T. pallidum*

T. pallidum is a member of the genus *Treponema* of the order Spirochaetales, and it was identified in 1905 by Schaudinn and Hoffmann (Table 82.2)[11]. The characteristics of this microorganism are outlined in Table 82.3. Fig. 82.3 represents a darkfield photomicrograph of *T. pallidum*.

Pathogenesis of Untreated Syphilis

Syphilis is a chronic systemic infection that progresses through active and latent stages (Fig. 82.4). Inoculation and penetration occur via mucosal surfaces and abraded skin, followed by attachment to host cells and multiplication of the microorganism. Within a few hours, treponemes disseminate to the regional lymph nodes and internal organs[12].

Primary stage

The primary lesion develops 10–90 days after infection (median of 3 weeks) as an indolent papule, followed by surface necrosis and the

CLASSIFICATION OF *TREPONEMA* SPECIES

Order Spirochaetales
Genus *Leptospira*
Genus *Borrelia*
Genus *Treponema*

	Disease	Distribution	Transmission
T. pallidum subsp. *pallidum*	Venereal syphilis	Worldwide	Sexual; maternal–fetal
T. pallidum subsp. *pertenue*	Yaws	Tropics	Non-venereal (all ages)
T. pallidum subsp. *endemicum*	Endemic syphilis (Bejel)	Desert	Non-venereal (all ages)
T. carateum	Pinta	Tropics	Non-venereal (all ages)
T. denticola, *T. socranskii*	Periodontal disease	Worldwide	Non-venereal

Common features shared by all spirochetes within the genus *Treponema*: morphology, antigenic properties, many DNA sequences, serologic detection, biochemical properties.
Variable features for spirochetes within the genus *Treponema*: transmission mode, geography, age of patients, appearance of clinical lesions.

Table 82.2 Classification of *Treponema* species.

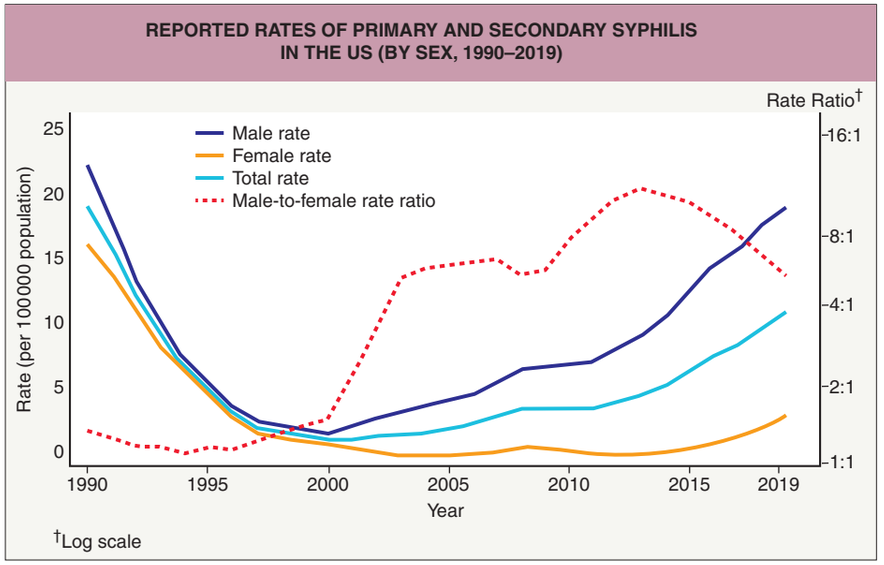

Fig. 82.2 Reported rates of primary and secondary syphilis in the US (by sex, 1990–2019). Note the elevated male : female ratio since 2000. Unfortunately, the use of pre-emptive antiretroviral therapy has been associated with a reduction in the use of condoms, including in men who have sex with men. *From the Centers for Disease Control and Prevention: Sexually Transmitted Disease Surveillance 2019. https://www.cdc.gov/std/statistics/2019/std-surveillance-2019.pdf.*

CHARACTERISTICS OF *TREPONEMA PALLIDUM*

• 6–20 microns in length, 0.1–0.18 microns in diameter
• Regular tight spirals
• Inability to survive outside an animal host
• Cannot be cultured *in vitro* for an extended time period
• Limited capacity for DNA repair
• Outer membrane:
  • lipid-rich
  • contains uniform-sized *t*ransmembrane *r*are *o*uter *m*embrane *p*roteins (TROMP)
  • lacks lipopolysaccharide
• Periplasmic flagella

Table 82.3 Characteristic features of *Treponema pallidum*.

Fig. 82.3 Positive darkfield examination. Treponemes are recognized by their characteristic corkscrew shape, and deliberate forward and backward movement with rotation about the longitudinal axis. *From Morse SA, et al. Atlas of Sexually Transmitted Diseases and AIDS, 3rd edn. London: Mosby, 2003.*

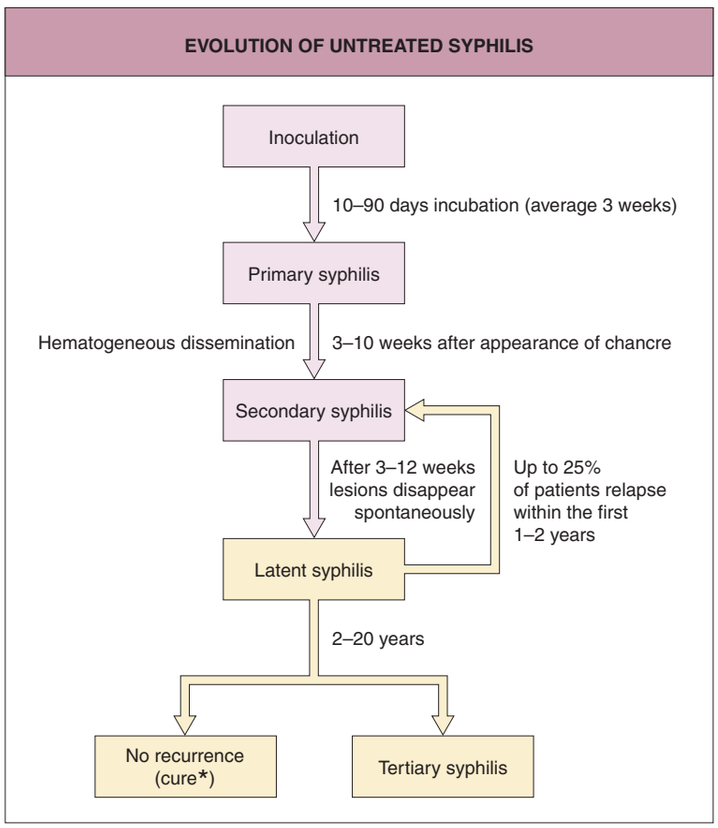

Fig. 82.4 Evolution of untreated syphilis. *Or clinically asymptomatic. *Adapted from Rein MF, Musher DM. Late syphilis. In: Rein MF (ed). Atlas of Infectious Diseases, Vol V: Sexually Transmitted Diseases. New York: Current Medicine, 1995:10.1–10.13.*

typical well-circumscribed ulceration that is firm to palpation (chancre). It is accompanied by enlarged regional lymph nodes. Histopathologically, the microorganism is observed among T cells that produce interferon-γ and interleukin-17[13], which lead to macrophage activation and destruction of a large number of treponemes. Several pathogenic mechanisms have been proposed, including an antigenically inert treponemal cell surface, resistance to phagocytosis, and premature down-regulation of the local host immune response[14].

Secondary stage

The secondary stage is characterized by dissemination and multiplication of the microorganism in different tissues, either simultaneously with the primary local lesion or up to 6 months after the primary lesion has healed. This stage follows primary syphilis in almost every patient who does not receive appropriate treatment. Circulating immune complexes (which contain treponemal outer membrane proteins), human anti-fibronectin antibodies, and complement are present during this stage of the disease and play a role in the pathogenesis of the different types of lesions[15].

Secondary syphilis is characterized by a broad spectrum of cutaneous manifestations as well as systemic signs such as malaise, fever, and generalized lymphadenopathy. It lasts several weeks or months, with relapses in ~25% of patients. Pregnant women can infect a fetus via transplacental passage of the microorganism.

Latency

Latency is the period between healing of the clinical lesions and appearance of late manifestations, and it can last for many years. About 70% of untreated individuals will remain in this stage for the rest of their lives and are immune to new primary infection (see Fig. 82.1). Latent syphilis is divided into early (1 year or less) and late (more than 1 year) subsets, and it is characterized by positive serologic tests for specific antibodies (see below) without clinical signs or symptoms. Infectivity may occur intermittently due to the presence of treponemes in the bloodstream, and pregnant women with latent syphilis may infect the fetus *in utero*.

Tertiary stage

The tertiary stage is also called late syphilis and is characterized by the presence of a small number of organisms and a high cellular immune reactivity against the organism. Signs of late syphilis can be recognized in approximately one-third of untreated individuals several months to years after being infected with treponemes (see Fig. 82.1). The microorganisms may invade the central nervous and cardiovascular systems as well as the skin and other organs (e.g. bones), leading to damage related to host delayed-type hypersensitivity responses, which produce local inflammation and gummas in affected tissues.

Syphilis and HIV

Syphilis and other STIs that produce genital ulcers further increase the risk of acquiring HIV. Reasons for the increased risk of HIV transmission include:

- lack of an epithelial barrier due to ulceration of the skin or mucous membranes
- large numbers of macrophages and T cells with receptors for HIV
- production of cytokines by macrophages stimulated by treponemal lipoproteins.

In addition, syphilitic manifestations are altered in HIV-positive patients[16,17], with a higher likelihood of neurologic findings and (in those with secondary syphilis) ulcerative lesions.

Clinical Features

Syphilis is usually sexually acquired, but maternal–fetal transmission also occurs and can result in congenital syphilis. Syphilis is an intermittent disease with primary, secondary, and tertiary stages as well as a latent period of variable length (divided into early and late subsets) that precedes the onset of tertiary syphilis (see Fig. 82.4)[18]. The definitions of early and late syphilis by the CDC and World Health Organization (WHO) differ slightly. *Early syphilis* includes the primary and secondary stages as well as early latency (CDC: acquired <1 year previously; WHO: acquired <2 years previously). *Late syphilis* extends from late latency (CDC: acquired >1 year previously; WHO: acquired >2 years previously) through the tertiary stage.

Primary syphilis

The chancre usually presents as a single, indolent, round or oval, indurated ulcer (Fig. 82.5) that is associated with regional adenopathy. Some patients report a preceding painless papule that enlarged and ulcerated a few days later. The time of onset ranges from 10 to 90 days (average 3 weeks) after *T. pallidum* exposure. Untreated, chancres heal within a few weeks (Fig. 82.6).

Asymptomatic infections are commonly due to unrecognized chancres, especially when located in the cervical region in women; in these cases, syphilis is more frequently diagnosed during the secondary stage. The same applies to chancres located in the anal, perianal, or rectal areas (see Fig. 82.5D), seen more commonly in MSM. The mechanism of spontaneous healing without treatment is not well understood and seems to depend on local immunity.

Laboratory diagnosis of *primary* syphilis includes the following:

- Detection of *T. pallidum* DNA via PCR from a swab of a chancre is the most sensitive and specific method.
- Darkfield microscopic examination of fluid from the surface of the chancre is also a sensitive, and for the genital region a specific, method for confirming the presence of *T. pallidum* (see Fig. 82.3).
- Immunohistochemical staining of biopsy specimens (or Warthin-Starry staining if immunohistology not available).

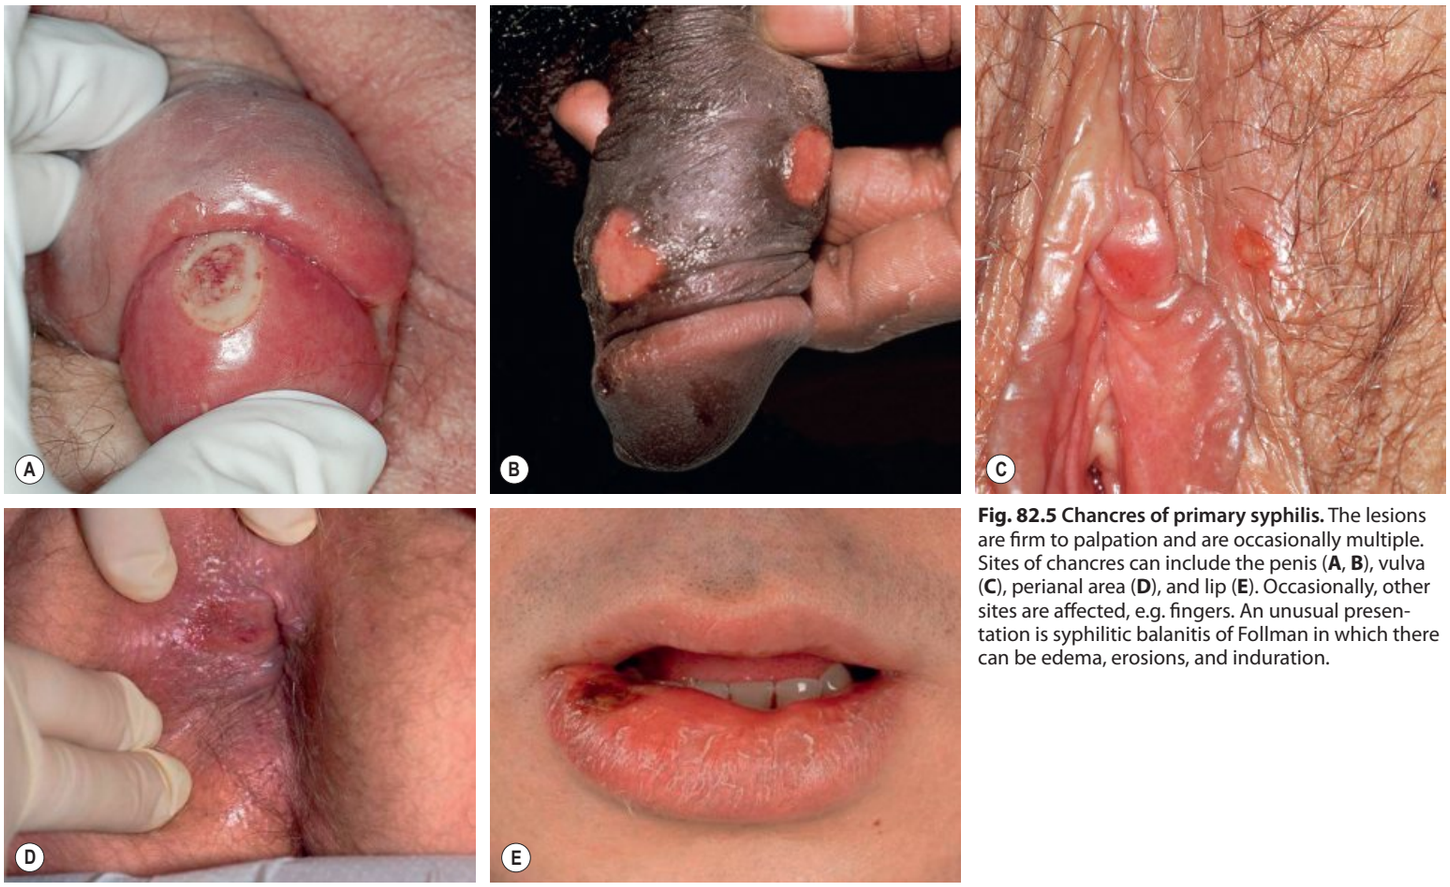

Fig. 82.5 Chancres of primary syphilis. The lesions are firm to palpation and are occasionally multiple. Sites of chancres can include the penis (**A**, **B**), vulva (**C**), perianal area (**D**), and lip (**E**). Occasionally, other sites are affected, e.g. fingers. An unusual presentation is syphilitic balanitis of Follman in which there can be edema, erosions, and induration.

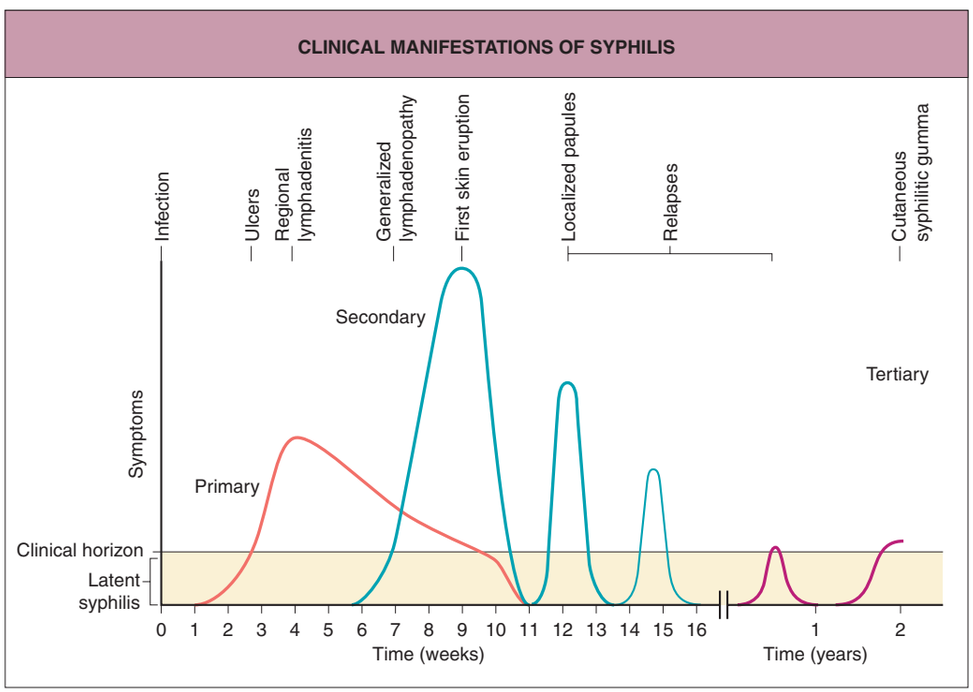

Fig. 82.6 Clinical manifestations of syphilis. *Adapted from Fritsch P, Zangerle R, Stary A. Venerologie. In: Fritsch P (ed). Dermatologie und Venerologie. Berlin: Springer, 2004:865–86.*

- Antibodies to cardiolipin are present in ~80% of individuals at the onset of clinical symptoms. Cardiolipin, a component of mammalian cells, seems to be modified by treponemes such that antibodies are produced by the infected person and can be measured by the rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL) assay.
- Antibodies to surface proteins of *T. pallidum* as detected by hemagglutination assays (*T. pallidum h*em*a*gglutination test [TPHA], *m*icro-*h*em*a*gglutination assay for antibodies to *T. pallidum* [MHA-TP]), or *f*luorescent *t*reponemal *a*ntibody *abs*orption (FTA-ABS) assay are present in 90% of patients with clinical symptoms of primary syphilis. Since antibodies usually remain positive for life, a differentiation between primary syphilis and a prior infection may not be possible and PCR or darkfield examination should be undertaken.

Secondary syphilis

The secondary stage of the disease results from the hematogenous and lymphatic dissemination of treponemes after a few weeks or months (3–10 weeks; Fig. 82.7). It is characterized by recurrent disease activity, with mucocutaneous as well as systemic manifestations. Prodromal symptoms include low-grade fever, malaise, sore throat, adenopathy, myalgias, weight loss, and sometimes a headache from meningeal irritation (Table 82.4).

During the second stage of syphilis, the most commonly observed clinical presentation (80%) is a generalized, non-pruritic papulosquamous eruption (Fig. 82.8). Lesions can range from 1–2 mm to 15–20 mm in diameter, and they vary in color from pink to violaceous to red–brown. Mucosal lesions range from small, superficial ulcers that resemble painless aphthae to large gray plaques (Fig. 82.9A,B). Condylomata lata are often observed in the moist regions of the anogenital area due to local spreading of the microorganisms (Fig. 82.9C,D). Lymph node enlargement is present in the majority of patients. Focal neurologic findings occasionally occur as does bone pain.

Additional cutaneous presentations of secondary syphilis include annular or figurate plaques with central hyperpigmentation on the face (Fig. 82.10A), non-scarring "moth-eaten" alopecia, split papules at the oral commissures (Fig. 82.10B), granulomatous nodules and plaques (Fig. 82.10C,D), and crusted necrotic lesions (Fig. 82.10E). Malignant syphilis (lues maligna) is extremely rare; the disseminated lesions resemble primary chancres (Fig. 82.10F).

Without treatment, the lesions resolve over several weeks to months. Relapse occurs in ~20% of patients within 1 year, often with mucosal or mucocutaneous manifestations in the anogenital area.

Laboratory diagnosis of *secondary* syphilis includes the following:

- Presence of treponemes by darkfield examination of serous exudates from localized lesions of the skin and mucous membranes (the exception being the oral cavity; see below).
- Serologic tests are more useful in secondary, as compared to primary, syphilis. Cardiolipin antibodies (e.g. RPR or VDRL tests) as well as specific antibodies are always positive in patients with secondary syphilis; a mistakenly or temporarily negative non-treponemal test rarely occurs due to the prozone phenomenon or HIV infection, respectively (see Table 82.8).
- Immunohistochemical staining of biopsy specimens (or Warthin-Starry staining if immunohistology not available).

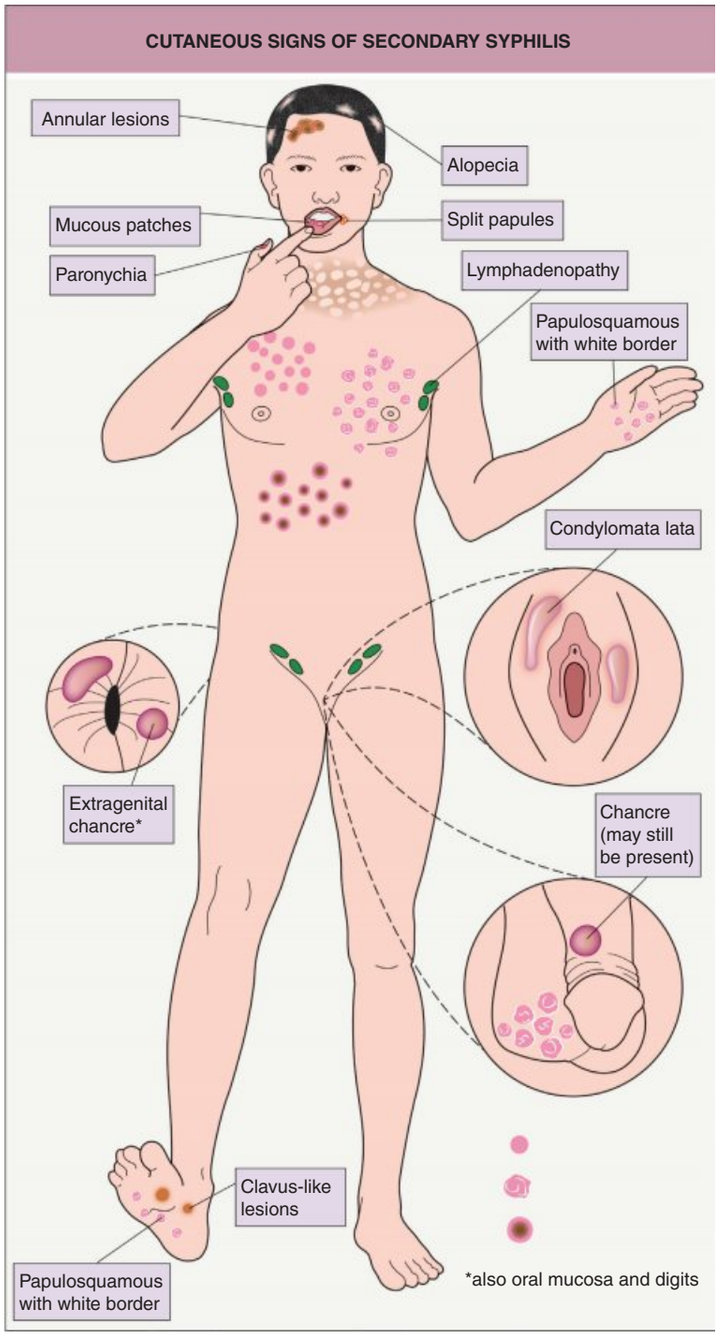

Fig. 82.7 Cutaneous features of secondary syphilis. Additional symptoms include low-grade fever, malaise, sore throat, myalgias, bone pain, and headaches.

CLINICAL FEATURES OF SECONDARY SYPHILIS

- **Prodromal symptoms and signs:**
  Weight loss
  Low-grade fever
  Malaise
  Headache (meningeal irritation)
  Sore throat
  Conjunctivitis (iridocyclitis)
  Arthralgia (periostitis)
  Myalgias
  Hepatosplenomegaly (mild hepatitis)
- **Generalized lymphadenopathy with indolent enlargement of lymph nodes** (50%–85%)
- **Skin manifestations:**
  Early (10%): generalized eruption; non-pruritic, roseola-like, discrete macules, initially distributed on the flanks and shoulders
  Late (70%): generalized maculopapular and papulosquamous eruptions; more infiltrated lesions, often copper-colored; annular plaques on the face; corymbose arrangement (satellite papules around a larger central lesion); occurs in successive waves and is polymorphic
  Localized syphilids (specific infiltrations of treponemes; positive darkfield examination):
  - palms and soles: symmetric papules and plaques with a collarette of scale (collarette of Biett)
  - anogenital area: condylomata lata
  - seborrheic area: "corona veneris" along the hairline

  Hypopigmented macules, mainly on the neck (postinflammatory; "necklace of Venus")
- **Manifestations involving mucous membranes (30%):**
  Syphilitic perlèche, split papules
  Mucous patches: "plaques muqueuses" in the oropharynx (equivalent to condylomata lata in the genital area)
  Syphilitic sore throat: inflammation of the whole pharynx
- **Patchy alopecia** (7%): "moth-eaten" localized areas of hair loss; toxic telogen effluvium

Table 82.4 Clinical features of secondary syphilis.

Fig. 82.8 Secondary syphilis. Widespread exanthem of pink papules (**A**), subtle minimally inflamed lesions localized to the arms in an HIV-positive man (**B**), and generalized papulosquamous lesions (**C**). Genital lesions can resemble psoriasis (**D**) while lesions on the palms and soles (**E, F**) often have a collarette of scale. *B,D, Courtesy Kalman Watsky, MD.*

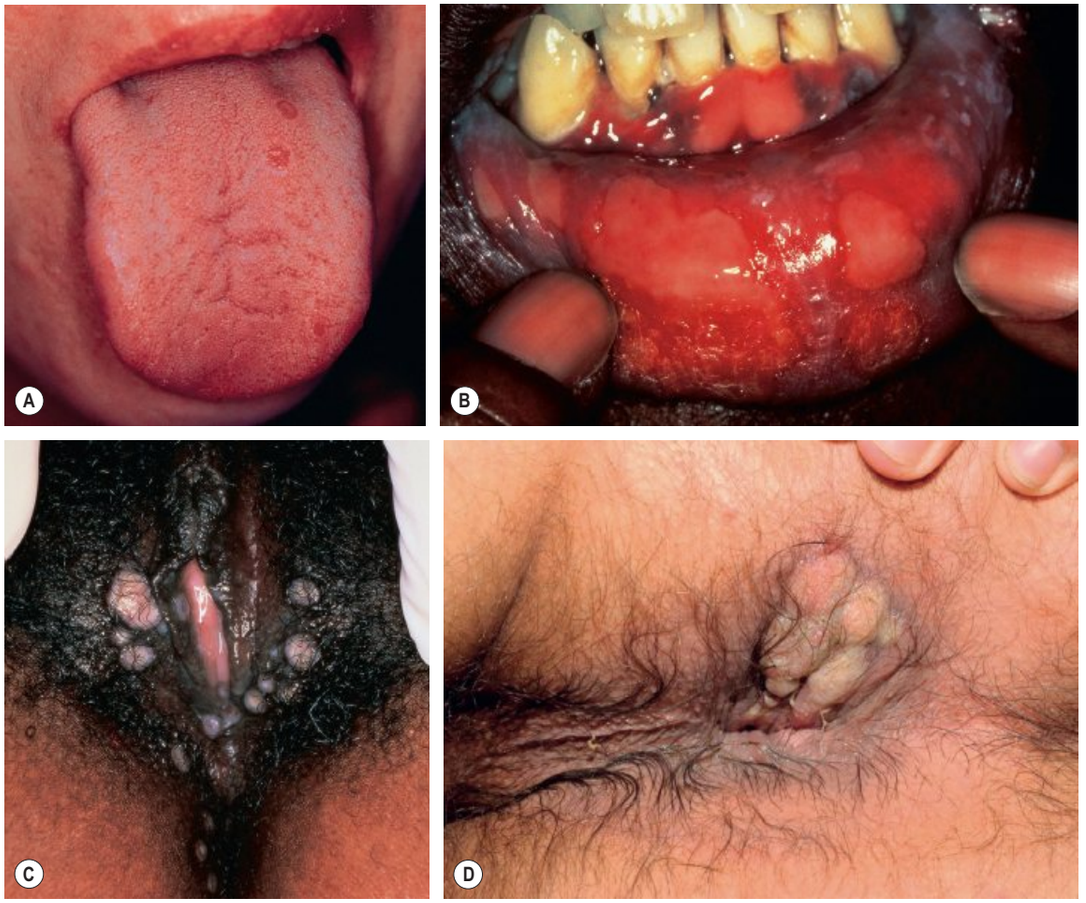

Fig. 82.9 Orogenital lesions of secondary syphilis. Oral lesions can vary from small superficial ulcers (**A**) to mucous patches (**B**). Occasionally, leukokeratosis or nodules are seen. Condylomata lata in the vulvar (**C**) and anal (**D**) areas may be misdiagnosed as HPV infection (i.e. condylomata acuminata).

Fig. 82.10 Less common manifestations of secondary syphilis. A Annular and polycyclic plaques with central hyperpigmentation on the forehead. **B** Split papule at the oral commissure. **C, D** Two elderly patients with granulomatous lesions, varying from numerous, monomorphic, dull pink papules to papulonodules and plaques of varying sizes. **E** Necrotic lesion with scale-crust in a patient with AIDS. **F** "Malignant" syphilis with multiple necrotic, ulcerated and crusted lesions associated with severe constitutional symptoms. *C, Courtesy Department of Dermatology, Medical University of Graz; E, Courtesy Judit Stenn, MD.*

- Spirochetes can be detected by immunohistochemistry in the majority of biopsy specimens (see Fig. 0.33).

Management considerations for patients diagnosed with secondary syphilis include the following:

- All patients should be tested for HIV infection, and testing should be repeated in those who fail to respond to treatment.
- Patients with ocular symptoms (e.g. photophobia, visual changes) should undergo ophthalmologic evaluation, including slit-lamp examination, to assess for uveitis/iritis, neuroretinitis, and optic neuritis.
- A lumbar puncture and cerebrospinal fluid (CSF) analysis should be performed in patients with ocular or neurologic (e.g. headache, hearing loss, cranial neuropathies) signs/symptoms and when treatment failure is suspected (e.g. persistent/recurrent signs/symptoms or failure of non-treponemal test titers to decline fourfold within 6–12 months).
- In patients with symptoms of otosyphilis (e.g. hearing loss, vertigo), an otologic examination is needed. However, CSF evaluation in patients with otosyphilis does not assist in clinical management, so lumbar puncture is not recommended.
- Patients with HIV disease are at increased risk for neurosyphilis, especially if they have a CD4 count <350 cells/ml and/or an RPR titer of ≥1 : 32; however, unless neurologic symptoms are present, CSF examination in HIV-positive patients has not been associated with improved clinical outcomes.

Latent syphilis

After a period of 3–12 weeks, untreated secondary syphilis typically resolves spontaneously, leaving the patient in an asymptomatic state. Diagnosis is based on a positive syphilis serology test result

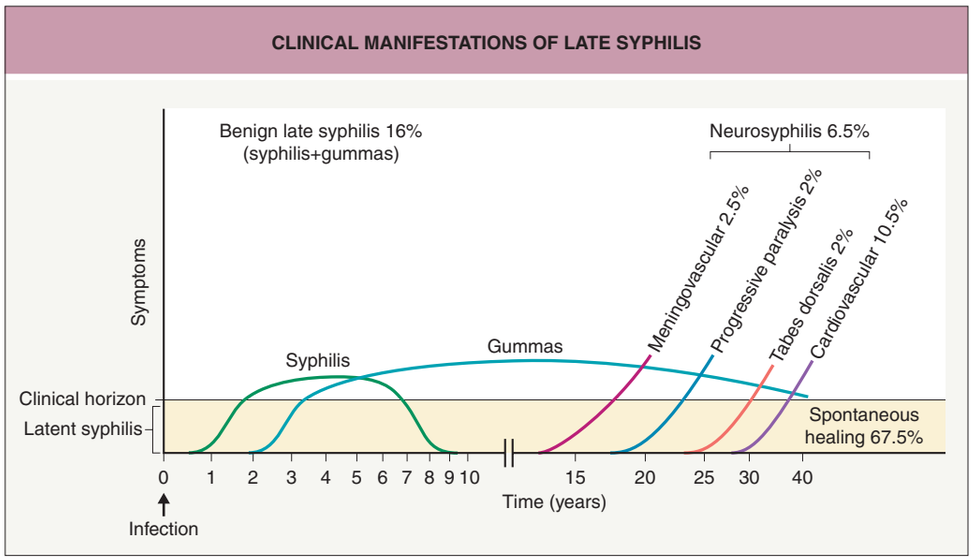

Fig. 82.11 Clinical manifestations of late syphilis.
Adapted from Fritsch P, Zangerle R, Stary A. Venerologie. In: Fritsch P (ed.). Dermatologie und Venerologie. Berlin: Springer, 2004:865–86.

in the setting of no clinical evidence of treponemal infection. The two stages are:

- Early latent stage: within 1 year of the onset of latency (CDC definition), with the possibility of recurrence of the disease. About 90% of secondary relapses occur within the first year.
- Late latent stage: after 1 year from the onset of the disease (CDC definition); relapses after 1 year are very infrequent. This disease state may last for many months or years.

Experience regarding the outcome of late latent syphilis in the absence of treatment is based upon several studies. About one-third of infected individuals have a non-reactive RPR test, no sign of reactivation during the remainder of their lives, and only the specific antibody assays (e.g. MHA-TP, FTA-ABS) remain positive (see Fig. 82.1). Another one-third of patients remain clinically asymptomatic for the rest of their lives, but antibodies against cardiolipin (e.g. RPR, VDRL) persist together with a positive MHA-TP or FTA-ABS assay. In the remaining one-third, clinical symptoms of tertiary syphilis occur.

Diagnosis of latent syphilis is established by reactivity in an RPR or VDRL assay, a positive MHA-TP or FTA-ABS test, and the absence of any clinical signs of the disease. The diagnosis is easy to establish, if there is a history of a chancre or skin manifestations that fit the clinical picture of syphilis. In many cases, however, the medical history provides no useful information regarding the presence of clinical symptoms in the previous weeks to months or whether the patient was previously treated. In such instances, differentiation between early and late latency is not possible and patients are regarded as having late latent syphilis from a management standpoint (see below). Response of latent syphilis to treatment is indicated by a decline in the RPR or VDRL titer. Persistently high (e.g. lack of a fourfold decline within 12–24 months) or rising titers are a sign of treatment failure, and examination of the CSF should be performed.

Tertiary (late) syphilis

Classic tertiary syphilis, as a consequence of untreated syphilis, is nowadays rare. It has a variable range of manifestations that appear months to years after initial infection (Fig. 82.11). In particular, these include involvement of the skin, bones, CNS, heart, and great vessels. Approximately one-half of patients with tertiary syphilis have "benign" late syphilis with the development of gummas, about one-quarter develop cardiovascular manifestations, and one-quarter develop neurologic symptoms (see Fig. 82.1).

In tertiary syphilis, non-treponemal serologic tests are usually positive with high titers. Patients with tertiary syphilis (or any symptoms related to late syphilis) should undergo lumbar puncture and CSF examination to determine if neurosyphilis is present before therapy is initiated.

"Benign" late syphilis

The most common feature of late syphilis is gummas, which are locally destructive lesions in the skin, bones, liver, and other organs. The gummas in the skin are nodular or noduloulcerative lesions, often with an arciform pattern (Fig. 82.12). They remain for weeks to months and then involute with scarring, but eventually new nodules reappear. With treatment, resolution of the lesions is prompt and complete. A solitary gumma that is located subcutaneously may become necrotic, similar to a "cold" abscess, resulting in ulceration of the skin or mucous membranes as well as destruction of underlying bones.

Fig. 82.12 Cutaneous gummas of tertiary syphilis. Arciform, erythematous eroded plaques with central scarring.

Bones are affected as frequently as the skin. Within the bone, a gumma is destructive and is typically accompanied by periostitis and osteitis. Clinical manifestations include pain, swelling, and limited range of motion. Other sites that can be affected by gummas include the tongue and oral cavity, upper respiratory tract, myocardium, and digestive as well as nervous systems.

Cardiovascular syphilis

Cardiovascular syphilis has a late onset, with a latent period of 15–30 years, and it occurs in about 8%–10% of individuals with untreated

infection. During the early stage of the disease, *T. pallidum* demonstrates a predilection for the vasa vasorum of the proximal aorta and produces transmural inflammatory lesions, which lead to endarteritis of the vessels. The organisms then remain there in a latent state for many years.

Neurosyphilis

Although classically a manifestation of tertiary syphilis, neurosyphilis can occur at any stage of the disease. Neurosyphilis is the reflection of a chronic (or sometimes acute) form of meningitis, with vascular and parenchymatous sequelae in the cerebrum and spinal cord (Table 82.5)[19]. Asymptomatic neurosyphilis is defined by the presence of abnormalities in the CSF (see below), but in the absence of any neurologic symptoms or clinical findings. While in some individuals the CSF abnormalities may resolve spontaneously or persist into advanced age, asymptomatic neurosyphilis can progress to late symptomatic neurosyphilis.

The basic pathomechanism for cerebrovascular syphilis is an infarction secondary to syphilitic endarteritis; this can result in hemiparesis or hemiplegia. Parenchymatous neurosyphilis, including general paresis, dementia paralytica, and paretic neurosyphilis, is due to direct invasion of the cerebrum by treponemes. It is a rare and late form of neurosyphilis, with dementia and neurologic symptoms such as paralysis progressing, if untreated, until death occurs.

Tabes dorsalis, which affects up to a third of patients with neurosyphilis after a long latent period, has a number of typical clinical signs and symptoms, including diplopia, lightning pains (painful paresthesias, especially of the extremities), loss of vibratory and position sense, reduced reflexes in the legs, ataxia, sphincter dysfunction, visceral crisis (abdominal, rectal, and laryngeal pain), and Argyll Robertson pupils (abnormal pupillary light reflexes: loss of direct and consensual; retention of accommodation). Tabes dorsalis may burn out even without treatment.

Neurosyphilis in HIV-infected individuals

In the mid 1970s, the first cases of so-called "atypical neurosyphilis" were described. With the subsequent recognition of co-infections with syphilis and HIV, it became apparent that neurosyphilis is common in HIV-infected individuals, and patients present with manifestations of early-onset neurosyphilis.

Laboratory diagnosis of neurosyphilis

In addition to the clinical findings, the diagnosis of neurosyphilis (including acute syphilitic meningitis, meningovascular syphilis, and parenchymatous neurosyphilis) is based upon reactive blood and CSF antibody testing, which are almost always positive. CSF abnormalities include elevation of pressure, protein concentration, and immunoglobulin level as well as a mononuclear pleocytosis. The presence of specific antitreponemal antibodies in the CSF is mandatory, but it is not proof of the diagnosis of neurosyphilis, since IgG antibodies can diffuse into the CSF or result from contamination of the CSF by blood. Establishment of local antibody synthesis is possible by using the CSF-IgG index, obtained by dividing the CSF to serum IgG ratio by the CSF to serum albumin ratio. A result >0.7 is indicative of IgG synthesis in the brain due to local inflammation. The intrathecal *T. pallidum* antibody index is calculated by dividing the TPHA titer in the CSF by the CSF to serum albumin ratio multiplied by a factor of 10^3, and an index >100 is indicative of the synthesis of treponemal-specific antibodies within the CNS. The presence of nonspecific antibodies, e.g. a positive VDRL test or RPR assay in CSF, is observed in most, but not all, cases, and a negative test does not exclude the presence of neurosyphilis.

Congenital syphilis

Congenital syphilis was initially described in 1497 and is therefore the oldest recognized congenital infection. In 1906, it was demonstrated via the Wassermann test that transmission of syphilis to the fetus required an infection in the pregnant woman.

There was an upsurge in congenital syphilis in Eastern Europe in the late 1990s, which paralleled the increased incidence of syphilis in adults and adolescents in this region. In the early 1990s, an increased frequency of congenital syphilis was also observed in some inner-city minority populations in the US[20]. From 2015–2019, the number of reported cases of congenital syphilis in the US nearly quadrupled[10]. The risk of mother-to-child transmission of untreated syphilis and its potential consequences are outlined in Table 82.6. Therefore, all women should be screened serologically for syphilis at the first prenatal care visit[21].

Early congenital syphilis

Infants generally present with symptoms during the neonatal period or within the first 3 months of life (Fig. 82.13). At the latest, they develop symptoms within the first 2 years of life. Typical manifestations are marasmic syphilis (i.e. cachexia) and skin lesions similar to those of acquired secondary syphilis (Fig. 82.14), except that they may be bullous (pemphigus syphiliticus) and tend to be more erosive. Additional clinical findings are "snuffles" (bloody or purulent mucinous nasal discharge), perioral and perianal fissures, lymphadenopathy, and hepatosplenomegaly. Skeletal involvement (i.e. osteochondritis) may result in pseudoparalysis of Parrot because of reduced movement of the extremities due to pain; other manifestations include anemia, thrombocytopenia, syphilitic pneumonitis (pneumonia alba), hepatitis, nephropathy, and congenital neurosyphilis.

Late congenital syphilis and stigmata

Late congenital syphilis in a child or adolescent corresponds to tertiary syphilis in an adult and is not infectious. The stigmata represent the delayed consequences of localized inflammation at the sites of treponemal infection (Table 82.7). In about one-third of children, an interstitial keratitis is seen; this finding together with typical dental abnormalities (Hutchinson teeth) and neural deafness forms the Hutchinson triad.

Laboratory diagnosis of congenital syphilis

A confirmed diagnosis of congenital syphilis requires laboratory demonstration of treponemes or child-specific antibodies. Serodiagnosis of congenital syphilis poses a difficult problem because IgG antibodies that are present may have been acquired transplacentally from the mother. A serum titer for a non-treponemal test that is fourfold higher than the mother's titer is suggestive of infection, but infected neonates

CLASSIFICATION OF NEUROSYPHILIS
• **Asymptomatic**
• Early
• Late
• **Meningeal**
• Acute syphilitic meningitis
• Meningovascular
• Cerebrovascular
• Spinal form
• **Parenchymatous**
• General paresis (dementia paralytica)
• Tabes dorsalis
• Taboparesis (mixed)
• Optic atrophy
• **Gummatous**
• Cerebral form
• Spinal form
• Both spinal and cerebral

Table 82.5 Classification of neurosyphilis.

MOTHER-TO-CHILD TRANSMISSION OF UNTREATED SYPHILIS AND ITS CONSEQUENCES
Risk
• Infection of the mother from conception to 7th month of pregnancy: risk of transmission is nearly 100% (often fetal demise or severe congenital syphilis)
• Infection at least 2 years before pregnancy: reduced risk of transmission to 50%
• Infection during 7th, 8th, or early 9th month: reduced risk of transmission
• Infection 3–6 weeks before labor: no placental transmission; risk of perinatal transmission
Consequences of infection
• Spontaneous abortion (second or third trimester) (10%)
• Stillbirth (10%)
• Infant death (20%)
• Congenital syphilis (20%)
• Healthy child (40%)

Table 82.6 Mother-to-child transmission of untreated syphilis and its consequences.

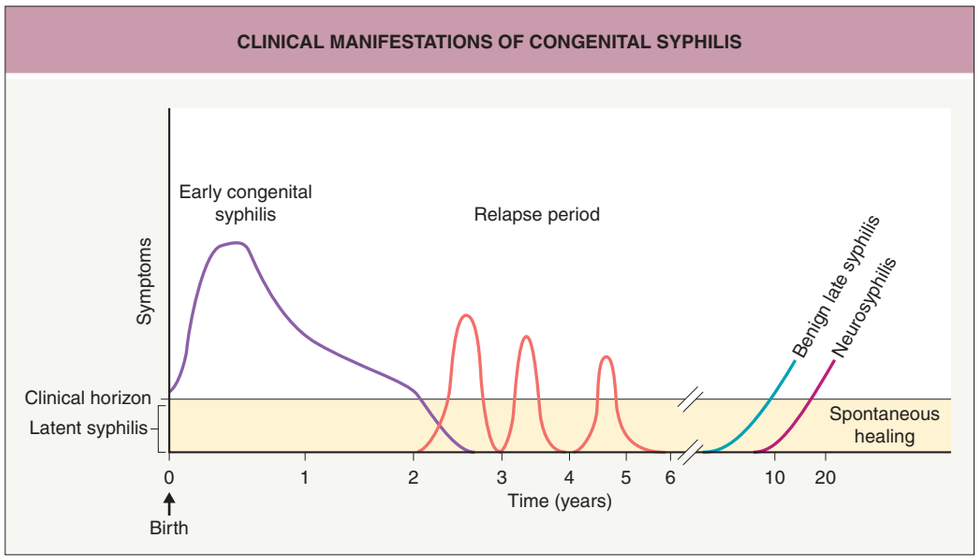

Fig. 82.13 Time course for clinical manifestations of congenital syphilis. *Adapted from Fritsch P, Zangerle R, Stary A. Venerologie. In: Fritsch P (ed). Dermatologie und Venerologie. Berlin: Springer, 2004:865–86.*

Fig. 82.14 Congenital syphilis. Red–brown plaques on the plantar surface.

STIGMATA OF CONGENITAL SYPHILIS
Cutaneous
• Rhagades – radial periorificial (mouth, nose, eyes, anus) scars at sites of previous fissures
Dental
• Hutchinson teeth – peg-shaped, notched permanent incisors*
• Mulberry molars – multiple rounded rudimentary cusps on the permanent first molars
• Caries due to defective enamel
Skeletal
• Saddle nose – depression of the nasal root due to destruction of cartilage/bone
• Frontal bossing of Parrot ("Olympian brow")
• Hypoplastic maxilla, relatively prominent mandible
• High palatal arch ± perforation
• Higouménakis' sign – thickening of the medial clavicle
• Scaphoid scapulae
• Saber shins – anterior tibial bowing
• Clutton's joints – painless synovitis and effusions of the knees
Other
• Eighth nerve deafness*
• Interstitial keratitis leading to corneal ulcers and opacities*
*Components of Hutchinson triad.

Table 82.7 Stigmata of congenital syphilis.

may have lower titers. The detection of chromatographically separated 19S-antibodies in the FTA-ABS-19S-IgM test has a sensitivity of about 90%, similar to the IgM-capture ELISA. More recently, it has been shown that the detection of spirochetemia by PCR can improve the sensitivity of the diagnosis of congenital syphilis in neonates.

In late congenital syphilis, diagnosis is based on clinical findings in association with reactive serologic tests.

Laboratory Diagnosis of Syphilis

The diagnosis of syphilis is based on the direct detection of treponemes or treponemal DNA by microscopy or molecular biologic techniques as well as various serologic tests that assess antibody responses to either cardiolipin (non-treponemal tests) or treponemal antigens (treponemal tests). Diagnosis of the different stages of syphilis depends on the interpretation of laboratory test results, the presence of clinical signs and symptoms, and their history. All patients who have syphilis should also be tested for HIV infection.

Identification of T. pallidum

The detection of the microorganism depends on microscopic examination and molecular assays, since *T. pallidum* cannot be routinely cultured *in vitro*. For propagation and experimental studies, growth in rabbit testicles is possible.

Microscopic examination

Darkfield microscopy permits the definite diagnosis of syphilis by visual detection of motile spirochetes from lesions of the skin (see Fig. 82.3). It requires careful specimen collection, ideally consisting of serous fluid free of red blood cells. Identification is easy for an experienced microbiologist because of the typical episodic movements of the microorganism. Due to the presence of saprophytic spirochetes in the oral cavity, there is limited utility for darkfield examination of serous exudate from lesions in this site. Immunologic detection of the microorganism by the indirect fluorescent antibody test, which utilizes fluorescein-labeled anti-*T. pallidum* antibodies, is especially useful for oral lesions.

In the case of a negative result from microscopic examination, repeat testing is recommended. Serologic tests are also indicated.

Polymerase chain reaction-based assays

PCR-based assays for detection of *T. pallidum* DNA can be useful in special circumstances, e.g. neurosyphilis, congenital syphilis, extragenital primary syphilis, and are increasingly being employed for more classic presentations.

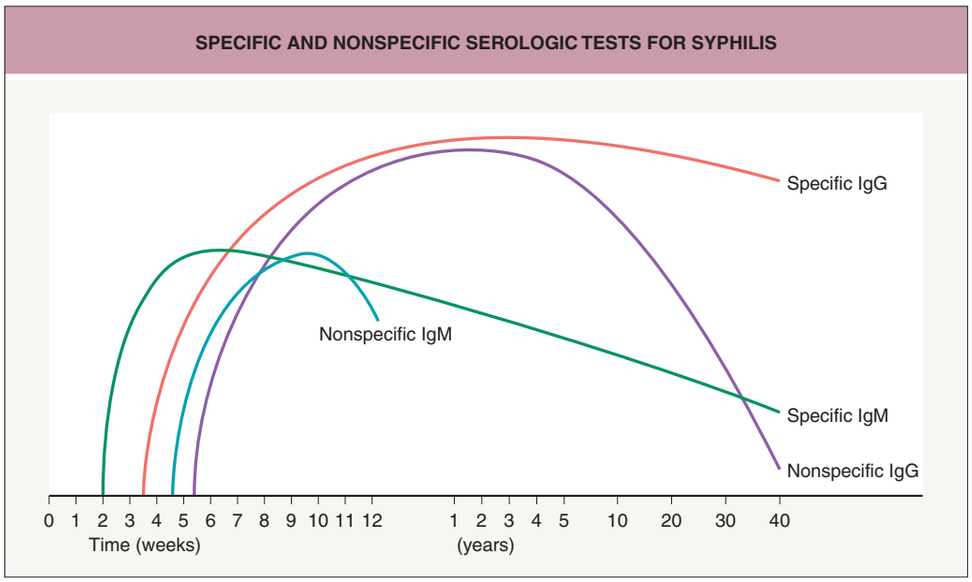

Fig. 82.15 Specific and nonspecific serologic tests for syphilis. These curves represent untreated patients. Non-treponemal tests are nonspecific and treponemal tests are specific. *Adapted from Fritsch P, Zangerle R, Stary A. Venerologie. In: Fritsch P (ed). Dermatologie und Venerologie. Berlin: Springer, 2004:865–86.*

Serologic tests for syphilis

Non-treponemal tests

The VDRL and RPR tests and related assays such as the unheated serum reagin (USR), reagin screen test (RST), and toluidine red unheated serum test (TRUST) detect antibodies to cardiolipin. The latter is a component of mammalian cells that is incorporated and modified by treponemes, which results in the development of host antibodies against it (comparable with autoantibodies directed against phospholipids; see Ch. 23). All these tests measure IgG and IgM antibodies against this lipoprotein-like material released from damaged host cells and from treponemes.

Titers of these antibodies correlate with disease activity and are useful in screening and monitoring treatment (Fig. 82.15). *Qualitative* non-treponemal tests are suitable for screening purposes, and reactive results have to be confirmed by antibody titer. The performance of a *quantitative* non-treponemal test is generally requested even with a positive darkfield examination or PCR assay, in order to provide a baseline for longitudinal evaluation after antibiotic therapy. A fourfold decrease in the antibody titer indicates successful treatment, while a fourfold increase indicates relapse or reinfection. In the case of early and efficacious treatment, non-treponemal assays usually become negative. Limitations of the tests are listed in Table 82.8.

Treponemal tests

The major indication for treponemal tests for syphilis is confirmation of reactive non-treponemal tests. IgM and IgG antibodies are usually detected in these assays by the end of the fourth week after infection. Accurate quantitative evaluation is not useful. The specific treponemal tests generally remain positive indefinitely, except in the case of treatment of very early syphilis where they do revert to negative. The specificity is very high and biologic false-positive reactions seldom occur. The sensitivity varies with the stage of syphilis: between 70% and 100% in primary syphilis, 100% in secondary and latent syphilis, and about 95% in late syphilis[22]. There is no differentiation between antibodies to *T. pallidum* and other treponemes and spirochetes.

Specific assays include the following:

- TPHA, MHA-TP, *T. pallidum p*article *a*gglutination test (TPPA): these assays measure antibodies directed against surface proteins of *T. pallidum* (sonicated fragments of treponemes) attached to rabbit erythrocytes as antigen carriers. Automatization is useful for large-scale testing and screening purposes. A positive result means that the patient had or still has active syphilis, but no assessment about the activity of the disease can be concluded from the qualitative result. Ninety percent of patients are positive at the time they seek medical care for a chancre.
- FTA-ABS assay: the serum reacts with the whole treponeme and forms antigen–antibody complexes visualized by fluorescein-isothiocyanate. To avoid nonspecific reactions with antibodies directed against saprophytic treponemes, a further step with Reiter treponemes is included to absorb nonspecific antibodies. The differentiation into IgM and IgG is possible by including selective anti-Ig antibodies.
- FTA-ABS-19S-IgM test: the isolated IgM antibody fraction is separately tested and provides a higher specificity than other tests. It is restricted to special situations, e.g. congenital syphilis or the differentiation of relapsing syphilis from reinfection.
- Solid *p*hase *hem*adsorption test (SPHA) or IgM ELISA: the SPHA test is used for the detection of specific IgM antibodies that attach to the solid phase of microtiter plates by reacting with the treponemal antigen on rabbit erythrocytes as antigen carriers. IgM antibodies can also be measured by ELISA technology. These tests are useful for the diagnosis of congenital syphilis, neurosyphilis (positive, but low-titer), and reinfection.

LIMITATIONS OF NON-TREPONEMAL AND TREPONEMAL TESTS

Non-treponemal tests

- Lack of reactivity in early darkfield- or PCR-positive primary syphilis
- Usually become negative with effective therapy (~15% of patients with early syphilis do not achieve a fourfold decline in titers 1 year after appropriate treatment, which is considered to represent a therapeutic failure)
- False-negative results
  - Prozone phenomenon: inhibition of flocculation in the setting of high titers of antibodies; requires serum dilution
  - Temporary negative result: secondary syphilis in the setting of HIV infection; reactive on subsequent testing
- Biologic false-positive results due to tissue damage
  - Pregnancy
  - Autoimmune diseases (e.g. lupus erythematosus)
  - Illicit drug abuse
  - Lymphomas
  - Infectious diseases (e.g. malaria)
  - Vaccinations
  - Hepatic cirrhosis
  - Antiphospholipid syndrome
  - Idiopathic, familial
- False-positive: endemic treponematoses and borreliosis

Treponemal tests

- Lack of reactivity in early darkfield- or PCR-positive primary syphilis
- Remain positive indefinitely, so not useful for monitoring response to treatment
- Biologic false-positive: autoimmune diseases, HIV infection, hypergammaglobulinemia
- False-positive: endemic treponematoses and borreliosis

Table 82.8 Limitations of non-treponemal and treponemal tests.

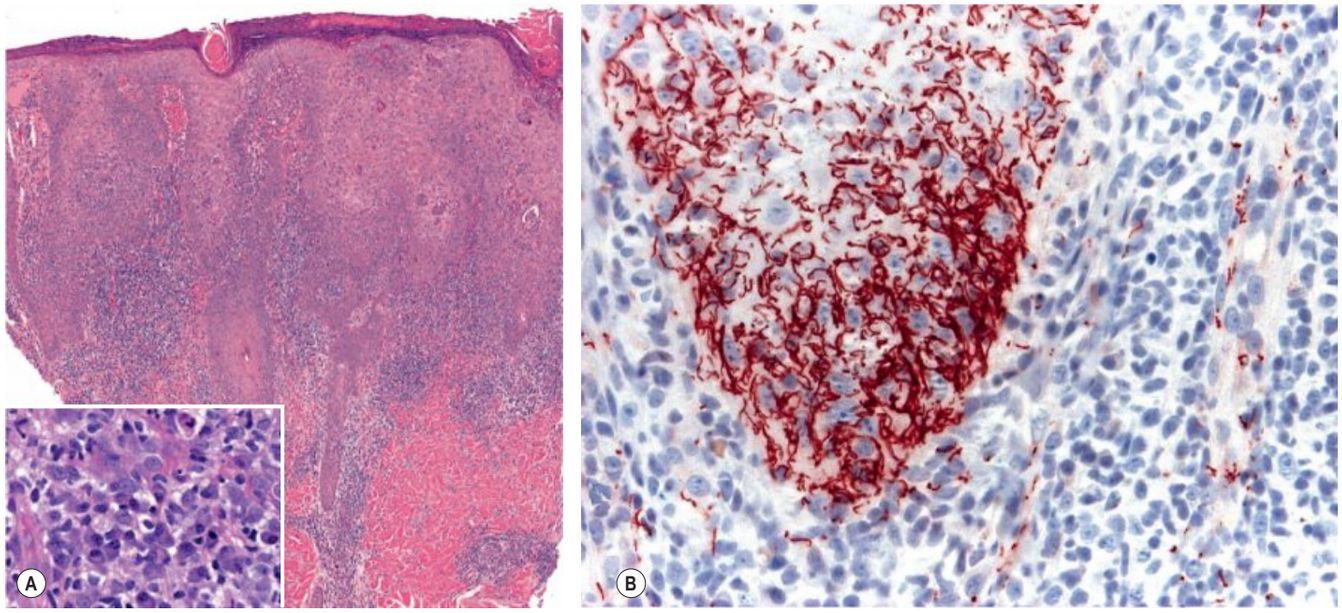

Fig. 82.16 Histology of secondary syphilis. A Psoriasiform epidermal hyperplasia and a dense dermal infiltrate of plasma cells (see inset), lymphocytes, and histiocytes are observed. **B** Positive immunohistochemical staining with an anti-*Treponema pallidum* antibody; note the characteristic elongated, twisted shape of the spirochetes. *Courtesy Lorenzo Cerroni, MD.*

DIFFERENTIAL DIAGNOSES FOR SYPHILIS
Primary syphilis
Other causes of genital ulcers should be considered: • Genital herpes • Genital trauma • Fixed drug eruption • Ulcerative genital carcinoma (e.g. squamous cell carcinoma) • Chancroid: jagged border, yellow exudate, painful • Lymphogranuloma venereum: transient, indurated, painless • Reactive non-sexually related acute genital ulcers (Lipschutz ulcers) • Behçet disease
Secondary syphilis
• Cutaneous: pityriasis rosea, guttate psoriasis, viral exanthems, lichen planus, pityriasis lichenoides, primary HIV infection, drug eruption, nummular eczema, folliculitis • Mucous membranes: lichen planus; chronic aphthae; hand, foot and mouth disease; herpangina; perlèche; pemphigus • Condylomata lata: warts due to HPV, bowenoid papulosis, squamous cell carcinoma
Tertiary syphilis
• Cutaneous: lupus vulgaris, chromoblastomycosis, dimorphic fungal infections, leishmaniasis, lupus erythematosus, mycosis fungoides, sarcoidosis, tumors, venous ulcer

Table 82.9 Differential diagnoses for syphilis.

Pathology

In *primary syphilis*, there is ulceration and a diffuse dermal infiltrate of plasma cells, lymphocytes, and histiocytes. Endothelial swelling is also present. Spirochetes may be detected with Warthin–Starry or immunohistochemical staining.

In *secondary syphilis*, there is great variability in the histopathological pattern, reflecting the variable clinical appearance of the disease. The epidermis may be normal, psoriasiform, necrotic, or ulcerated. Dermal infiltrates of plasma cells, lymphocytes, and histiocytes can be perivascular, lichenoid, nodular, or diffuse (Fig. 82.16A). Older lesions of secondary syphilis may be granulomatous and can resemble sarcoidosis or other granulomatous dermatoses, except for the presence of plasma cells. Endothelial swelling and vascular proliferation can also be seen in secondary syphilis. By immunohistochemistry, spirochetes are identified in the majority of cases (Fig. 82.16B). Lues maligna is characterized by vasculitis.

In *tertiary syphilis*, tuberculoid granulomas (with or without caseation) are present together with plasma cells. Endothelial swelling is evident, but organisms may be difficult to identify.

Differential Diagnosis

The differential diagnoses for the different stages of syphilis are listed in Table 82.9.

Treatment

Penicillin G is still the treatment of choice for all stages of syphilis, and recommended regimens are listed in Table 82.10. A treponemicidal level of the antimicrobial should be achieved in the serum and (for patients with neurosyphilis) in the CSF. A penicillin level of >0.018 mg/L is considered treponemicidal, but the maximally effective *in vitro* concentration is considerably higher (0.36 mg/L)[23,24]. No tendency toward penicillin resistance has been detected in *T. pallidum*. Tetracyclines are used as second-line therapy if penicillin cannot be given; although a single 2 g dose of azithromycin can be effective[25], treatment failures due to macrolide-resistant *T. pallidum* have been reported.

Recommended treatment regimens in the settings of pregnancy and congenital syphilis are summarized in Table 82.11. Although HIV-infected patients are at increased risk for neurologic complications and may have higher rates of treatment failure, prevention of these outcomes by altered therapeutic regimens has not been demonstrated. The CDC and International Union Against Sexually Transmitted Infections (IUSTI) currently recommend that HIV-infected individuals receive the same syphilis regimens as HIV-negative patients. Treatment guidelines and additional information are provided by the CDC (www.cdc.gov/std/treatment-guidelines/STI-guidelines-2021.pdf) and IUSTI (www.iusti.org)[26]. Of note, a Jarisch–Herxheimer reaction characterized by the acute onset of fever, headache, and myalgias can occur upon treatment of early syphilis.

The IUSTI recommends that non-treponemal tests (e.g. VDRL, RPR) be performed 1, 2, 3, and 6 months following antibiotic treatment of early syphilis, then every 6 months for up to 2 years post treatment[26]; the CDC suggests clinical and serologic evaluation at 6 and 12 months for uncomplicated cases, with more frequent and extended evaluation (e.g. at 3, 6, 9, 12, 24 months) for HIV-infected patients. Evaluation of late syphilis at 6-month intervals for up to 3 years is recommended. In the setting of abnormal CSF findings, a CSF examination is recommended at 6-month intervals until cell counts are normal and the CSF-VDRL is negative. Evaluation of sexual partners and reporting are mandatory in many countries.

TREATMENT RECOMMENDATIONS FOR SYPHILIS
Early syphilis (primary, secondary, and early latent [acquired <1 year previously])
Recommended:
• Benzathine penicillin, 2.4 million units* im as a single dose – *or* – • Procaine penicillin, 1.2 million units im daily for 10 days†
Alternative regimens for penicillin-allergic patients‡:
• Doxycycline, 200 mg daily (100 mg po BID preferred over a single 200 mg dose) for 14 days – *or* – • Tetracycline, 500 mg po four times daily for 14 days – *or* – • Ceftriaxone, 1–2 g im or iv daily for 10–14 days – *or* – • Azithromycin, 2 g po as a single dose¶
Late latent (acquired >1 year previously or of unknown duration), cardiovascular and gummatous syphilis; retreatment of primary, secondary or latent syphilis after failed initial treatment§
Recommended:
• Benzathine penicillin, 2.4 million units* im weekly for three doses – *or* – • Procaine penicillin, 1.2 million units im daily for 20 days†
Alternative regimens for penicillin-allergic patients‡:
• Doxycycline, 200 mg daily (100 mg po BID preferred over a single 200 mg dose) for 28 days – *or* – • Tetracycline, 500 mg po four times daily for 28 days
Neurosyphilis and ocular syphilis
Recommended:
• Aqueous penicillin G, 3–4 million units iv q4h (18–24 million units daily) for 10–14 days – *or* – • Procaine penicillin, 2.4 million units im daily plus probenecid, 500 mg po four times daily, both for 10–14 days
Alternative regimens for penicillin-allergic patients:
• Ceftriaxone, 2 g im or iv daily for 10–14 days – *or* – • Consider desensitization
*In children, 50 000 U/kg up to the adult dose. †Alternative treatment regimens in the World Health Organization (WHO) guidelines (http://apps.who.int/iris/bitstream/10665/249572/1/9789241549806-eng.pdf) and the guidelines of the International Union Against Sexually Transmitted Infections (http://www.iusti.org/sti-information/guidelines/). ‡Limited data. ¶Resistance reported. §E.g. If RPR/VDRL titers fail to decrease fourfold or symptoms persist/progress; must first examine the CSF to exclude neurosyphilis.

Table 82.10 Treatment recommendations for syphilis. BID, twice daily; h, hours; im, intramuscularly; iv, intravenously; po, orally; q, every. Also see CDC guidelines (https://www.cdc.gov/std/treatment-guidelines/STI-Guidelines-2021.pdf).

TREATMENT RECOMMENDATIONS FOR SYPHILIS IN SPECIAL SITUATIONS
Pregnancy
Recommended:
• Benzathine penicillin, 2.4 million units im weekly for two (early syphilis) or three (late syphilis) doses – *or* – • Procaine penicillin, regimen appropriate for the stage of syphilis (see Table 82.10)
In the case of penicillin allergy:

• Desensitization to penicillin – *or* –
• Alternative regimens*:
  • Ceftriaxone, 1 g im daily for 10–14 days – *or* –
  • Azithromycin, 2 gm po as single dose† – *or* –
  • Erythromycin, 500 mg po four times daily for 14 days†

Congenital
Neonate with proven or highly probable disease or born to mother with untreated early syphilis‡:
• Aqueous penicillin G, 50 000 U/kg iv q12h for the first 7 days of life, then q8h for 3 days (100 000–150 000 U/kg/day for a total of 10 days) – *or* – • Procaine penicillin, 50 000 U/kg im daily for 10–14 days
Neonate with no signs of disease born to mother with treated syphilis¶:
• Benzathine penicillin, 50 000 U/kg im in a single dose
*Limited data; not recommended by the Centers for Disease Control (CDC) or European guidelines but included in the World Health Organization (WHO) guidelines. †Do not completely cross placental barrier so infected fetus is not adequately treated; newborns need to be treated soon after delivery. ‡CSF analysis should be performed prior to therapy. ¶Neonate with a normal physical examination and serum non-treponemal antibody titer less than fourfold the maternal titer; treatment is optional if the mother was fully treated before pregnancy.

Table 82.11 Treatment recommendations for syphilis in special situations. h, hours; im, intramuscularly; iv, intravenously; po, orally; q, every.

GONORRHEA

Synonyms: ■ Gonorrhea: "clap" ■ Disseminated gonococcal infection: arthritis–dermatosis syndrome

Key features

- Gonorrhea is the most common reportable STI in high-income countries
- It is caused by *Neisseria gonorrhoeae*, which infects the mucosal surfaces of the human genital tract (as well as the anus, rectum, and oropharynx) after direct – usually sexual – contact with an infected person
- Cutaneous pustules as well as systemic symptoms such as arthritis and fever can result from hematogenous dissemination, which occurs in only a small percentage of infected individuals
- Overall, the incidence of gonorrhea declined during the latter portion of the 20th century as a result of safer sexual practices to avoid transmission of HIV, but afterwards the incidence has increased substantially in high-income countries following the introduction of antiretroviral therapy and pre-exposure prophylaxis for HIV
- Over the past several decades, resistance of *N. gonorrhoeae* to various antimicrobials has increased in frequency

History

Gonorrhea was mentioned in ancient literature from China, Egypt, the Roman Empire and Greece, as well as in the Old Testament[27]. Over the centuries, several names have been used to denote infection with *N. gonorrhoeae*, including: "strangury", as used by Hippocrates; "clap", derived from the district of prostitution called "Les Clapiers" in Paris; "gonorrhea", chosen by Galen (130 CE) to describe the urethral exudate as a "flow of seed"; and "M. Neisser", recognizing Albert Neisser, who discovered the microorganism in 1879 in stained smears from vaginal, urethral, and conjunctival exudates.

Culture of *N. gonorrhoeae* was first described by Leistikow and Lüffler in 1882, and it was improved in 1964 by Thayer and Martin, who devised selective growth conditions on special agar plates[28]. Understanding the differences in the virulence of gonococci and studies of its molecular biology have led to greater insight into the pathology of the organism[29]. Treatment of gonococcal infections was problematic until sulfonamides were introduced in 1936 and penicillin in 1943. For decades, gonorrhea was easily treated with just a single dose of one antibiotic. However, over the past several decades, an increase in antimicrobial resistance to penicillin and other antibiotics, such as tetracyclines and quinolones, has been observed and has become problematic. Declining *in vitro* susceptibility to cefixime led to a change in treatment guidelines, such that dual therapy with ceftriaxone and azithromycin became the recommended therapeutic regimen for uncomplicated gonorrhea. However, a more recent and worrisome development is elevated MICs (minimum inhibitory concentrations) to azithromycin[10,30] and scattered reports of ceftriaxone-resistant, multi-drug-resistant *N. gonorrhoeae*[30a].

Epidemiology

During the past century, the incidence of gonorrhea was influenced by politics, with peaks at the ends of the First and Second World Wars. A sudden decrease in reported cases occurred after the introduction of penicillin and other effective antimicrobials. Subsequently, the

sexual freedom of the 1970s led again to an increase in the incidence of gonorrhea. However, with the advent of the AIDS epidemic, sexual practices again changed due to concerns regarding transmission of HIV, and this had a remarkable impact on the incidence of gonorrhea. Total gonorrhea rates in the US peaked in the mid 1970s and remained relatively low and stable from the 1990s to the mid 2010s.

Political changes in Eastern Europe led to an increased rate of gonorrhea (as well as syphilis) in the 1990s, especially in sex workers and those with sexual exposure to them. Migration of sex workers with a high infection rate also increased the number of reported cases of gonorrhea in other regions of Europe, especially in urban areas and high-risk groups. This probably reflects an increase in unsafe sexual behavior, particularly among young people and in high-risk populations. At the same time, the incidence of gonorrhea decreased in many countries (see above) due to safer sexual practices to avoid transmission of HIV. However, following the introduction of antiretroviral therapy and especially pre-exposure prophylaxis (PrEP) for HIV, there has been a reemergence of infections with *N. gonorrhoeae* as well as other STIs, especially amongst MSM. Of note, the national lockdowns imposed to prevent spread of SARS-CoV2 were associated with a sudden reduction in reported cases. Nonetheless, the trend of an increasing number of reported cases of gonorrhea, driven primarily by MSM, is expected to continue; for example, in many European countries the number of cases among women has also been increasing continuously since 2009 (ECDC Surveillance report: Annual epidemiological report for 2018).

Similar to other venereal diseases, the incidence of gonorrhea varies with age and is highest in the 15- to 24-year-old age group, in which there is a higher rate in women than in men. In the US, African-Americans have a 10-fold higher rate of gonococcal infections than White individuals. This may reflect different sexual behavior patterns and exposures as well as a better reporting system in public health institutions, which are more often utilized by African-Americans.

Transmission

N. gonorrhoeae is a pathogen restricted to humans as its only host and transmitted primarily by sexual contact. The most efficient transmission occurs by vaginal or anal intercourse where there is physical contact with the mucosal surface of a sexual partner with an asymptomatic or mildly symptomatic infection. An exception is indirect contact among prepubescent girls sharing contaminated objects. There is no evidence that gonococci can be spread by air droplet transmission as occurs with meningococci. Vertical transmission can occur from an infected mother to the newborn during parturition, and this may lead to gonococcal conjunctivitis, pneumonia, or even vulvovaginal infection.

Biology of *N. gonorrhoeae*

Gonococci are Gram-negative diplococci that typically grow in pairs. They exhibit multiple colony types when grown on hemoglobin-containing media in a 3% CO_2 atmosphere. The outer membrane structure of *N. gonorrhoeae* is typical for Gram-negative bacteria but, in contrast to *N. meningitidis*, it lacks the polysaccharide capsule that is responsible for the virulence of meningococci. Surface molecules on the outer membrane are involved in attachment, invasion and host injury, and they also represent important antigenic structures, especially the fibrillar pili (composed of 18 kDa pilin subunits)[31].

Gonococci require iron to grow, with sources including transferrin, lactoferrin, and hemoglobin; acquisition of iron is mediated by binding to host proteins via specific receptors. The microorganism cannot tolerate drying or low temperatures, and its growth is optimal at 35–37°C in a 5% CO_2 atmosphere on a complex growth medium containing inorganic iron, glucose, vitamins, and cofactors as well as antibiotics.

Pathogenesis

Although there is increasing knowledge about the pathogenicity of this microorganism, the exact molecular mechanisms of invasion of gonococci into the host cell are still unknown. Several virulence factors are involved in the processes of adherence, inflammation, and mucosal invasion[32]. Because pili increase adhesion to the host cell and allow movement, they also play an important role in pathogenesis; this may explain why non-piliated gonococci have a reduced ability to cause infections in humans. The adherence of gonococci to the human epithelial host cell and to neutrophils is dependent not just on the pili but also on Opa ligands. Anti-pilus antibodies have been shown to block epithelial adherence and increase phagocytic killing. Expression of the transferrin receptor and full-length lipo-oligosaccharide (LOS) appear to increase infectivity. Gonococci are able to multiply and divide intracellularly, where they are immune to host defense mechanisms. Cellular invasion is favored by expression of certain Opa proteins and non-sialylated LOS.

Gonococci have the ability to cause tissue destruction by production of a variety of enzymes and lipids such as phospholipase, peptidases, and lipid A. This plays a role in their damage of fallopian tubes and the development of postinflammatory arthritis.

Clinical Features

Gonorrhea has a broad spectrum of clinical manifestations in both men and women, including asymptomatic infections, local symptomatic mucosal infections (with or without local complications), and systemic dissemination (Table 82.12). Symptoms vary according to the site of infection and strain of organism.

The incubation period for gonorrhea is relatively short; it only takes 2–5 days until signs and symptoms of an infection with *N. gonorrhoeae* appear. Up to 10% of infected men and 50% of infected women lack clinical symptoms, which is especially common in rectal and pharyngeal infections[33].

Gonococcal infection in men

The most common clinical presentation of gonococcal infection in men is an acute anterior urethritis with dysuria and a urethral discharge that is typically purulent and profuse (Fig. 82.17). In about one-quarter of infected men, the urethral symptoms are less pronounced, similar to those of non-gonococcal urethritis, and appear only after urethral manipulation ("stripping"). Without treatment, clinical symptoms disappear in most patients after about 6 months. Local complications can include inflammation of the Cowper and Tyson glands and gonococcal pyoderma; ascension of the infection may lead to epididymitis, prostatitis, and vesiculitis. Patients with gonococcal epididymitis present with unilateral testicular pain and swelling accompanied by urethritis.

Gonococcal infection in women

In about 50% of infected women, gonococcal infection is asymptomatic and therefore remains unnoticed. The primary site of gonococcal infection in women is the endocervical canal, with associated clinical

CLINICAL MANIFESTATIONS OF GONORRHEA
Disseminated infection
• Arthritis • Fever • Tenosynovitis • Acral cutaneous pustules • Scalp abscesses (in neonates at sites of fetal scalp monitor electrodes) • Endocarditis • Meningitis
Direct mucosal infection
• Urethritis • Cervicitis • Proctitis • Pharyngitis • Vulvovaginitis (children) • Ophthalmia neonatorum
Local extension
• Prostatitis • Vesiculitis • Epididymitis • Salpingitis • Oophoritis • Pelvic inflammatory disease

Table 82.12 Clinical manifestations of gonorrhea.

Fig. 82.17 Gonococcal urethritis with a purulent urethral discharge.

Fig. 82.18 Gonococcemia (arthritis–dermatosis syndrome). Pustule with surrounding erythema on the toe.

symptoms consisting of increased vaginal discharge, dysuria, intermenstrual bleeding, and menorrhagia. Clinical inspection shows purulent cervical discharge with erythema and edema; swabbing of the endocervical canal results in a highly characteristic yellow color. Urethral colonization is present in 70%–90% of infected women and is the usual site of infection in women who have had a hysterectomy. Occasionally, inflammation of the Bartholin glands is observed, with acute swelling of the labial folds and appearance of purulent discharge when pressure is applied to the gland.

The most common local complication in women is acute salpingitis or pelvic inflammatory disease (PID) due to ascension of the microorganisms. It occurs in ~10%–20% of infected women (often developing immediately after a menstrual period) and may result in the long-term consequences of infertility, chronic pelvic pain, and ectopic pregnancy. The clinical manifestations of PID vary and include lower abdominal pain, adnexal tenderness, elevation of the ESR, leukocytosis, and fever. Gonorrheic perihepatitis (Fitz-Hugh–Curtis syndrome), with inflammation of the adjacent peritoneal area, is an infrequent complication in which symptoms of PID are accompanied by pain in the right upper quadrant that mimics acute cholecystitis.

Extragenital gonorrhea

Pharyngeal gonorrhea

This can occur in both men and women after oral sexual exposure. Because it is usually asymptomatic, the infection typically goes undetected and spontaneously resolves within a few weeks[34]. Pharyngeal gonorrhea disproportionately affects MSM and may be an important source of urethral gonorrhea in MSM[35]. It is important to address this site of infection, especially in this high-risk group.

Rectal gonorrhea

Rectal gonorrhea is mainly seen in MSM and in heterosexual women who practice receptive anal intercourse. Rectal gonorrhea is asymptomatic in at least 50% of patients, but it may result in gonococcal proctitis that is accompanied by inflammation, rectal discharge, anal pruritus, bleeding, tenesmus, and constipation.

Gonococcal ophthalmia (including ophthalmia neonatorum)

Gonococcal ophthalmia is uncommon in adults but still represents a major cause of blindness in some low-income countries. Primarily due to self-inoculation and unusual sexual practices, it initially presents as purulent conjunctivitis and, if left untreated, can rapidly progress to severe keratitis followed by corneal opacification.

Gonococcal infection in newborns is caused by inoculation with *N. gonorrhoeae* during delivery through an infected birth canal, and most often it presents with purulent conjunctivitis (ophthalmia neonatorum). Due to preventive application of antimicrobial ointment (usually erythromycin) immediately after birth, the rate of this gonococcal infection is currently low.

Disseminated gonococcal infection

Arthritis–dermatosis syndrome (gonococcemia)

The most common clinical manifestation of gonococcal bacteremia is an acute arthritis–dermatosis syndrome, which occurs in ~0.5%–1% of patients with mucosal gonorrhea[36]. Risk factors for disseminated gonococcal infection include: (1) menstruation, with the majority of cases in women developing during or immediately following menses; (2) deficiencies in the late complement components C5–C9 (see Ch. 60); and (3) inhibitors of the cleavage of C5 to C5a and C5b, e.g. ravulizumab, eculizumab. The classic syndrome consists of fever, joint pain, and a paucilesional eruption of hemorrhagic pustules. Gonococcal tenosynovitis affects primarily larger joints (e.g. knees, elbows, wrists, ankles) and is sometimes visible as erythema overlying the tendons.

The cutaneous lesions consist of scattered pustules, often necrotic, due to an embolic septic vasculitis. They occur primarily on the distal portions of the extremities (Fig. 82.18). With a longer duration of symptoms, positive blood cultures become less common.

Laboratory Diagnosis

Laboratory diagnosis is based on the identification of *N. gonorrhoeae* in secretions from infected mucous membranes by using stained smears, molecular biologic techniques, and/or bacterial culture (Fig. 82.19). Samples are typically obtained from the endocervical canal in women (after wiping off exudate), the urethra in men and occasionally in women who have had a hysterectomy, and (when indicated) the posterior pharynx. For diagnosis by nucleic acid amplification methods (see below), a vaginal swab or urine sample can also be used. Anorectal specimens should be obtained via direct visualization using anoscopy if possible.

Staining methods

Direct detection of Gram-negative diplococci within neutrophils in Gram- or methylene blue-stained smears provides an immediate diagnosis (Fig. 82.20), which is especially helpful in symptomatic individuals. It also represents a recommended point-of-care test. Gram-stained urethral exudate detects between 95% and 98% of symptomatic infections in men, whereas Gram-stained cervical smears have a sensitivity of about 50%. The specificity of Gram-stained exudates depends on several factors including the experience of the microscopist, proper collection, the presence of acute symptoms, and bacterial load; specificity may approach 100% in an optimal setting. However, because of its lower sensitivity in asymptomatic individuals, a negative Gram stain should not be considered sufficient for excluding infection in such patients. Smears are not helpful for detection of rectal and pharyngeal gonorrhea due to the presence of a large number of other bacteria.

Culture techniques

Isolation of *N. gonorrhoeae* via culture is still recommended for cases with medicolegal implications. In addition, pustular skin lesions due to gonococcemia should be cultured. Although it does depend on the symptomatic status of the infected person, antibiotic-containing selective media (Thayer–Martin) or selective New York media can have a sensitivity of 80%–95% when *genital* swabs are directly plated at the time of collection. The specificity of bacterial culture is reported to be ~95% for genital samples. However, sensitivity is much lower for *extragenital* swabs such as those from the rectal area (<50%). Confirmation of a positive culture by *N. gonorrhoeae*-specific tests is recommended and is mandatory in cases of extragenital infection.

The advantage of isolating *N. gonorrhoeae* via culture is the ability to perform antimicrobial resistance (AMR) testing. This is particularly

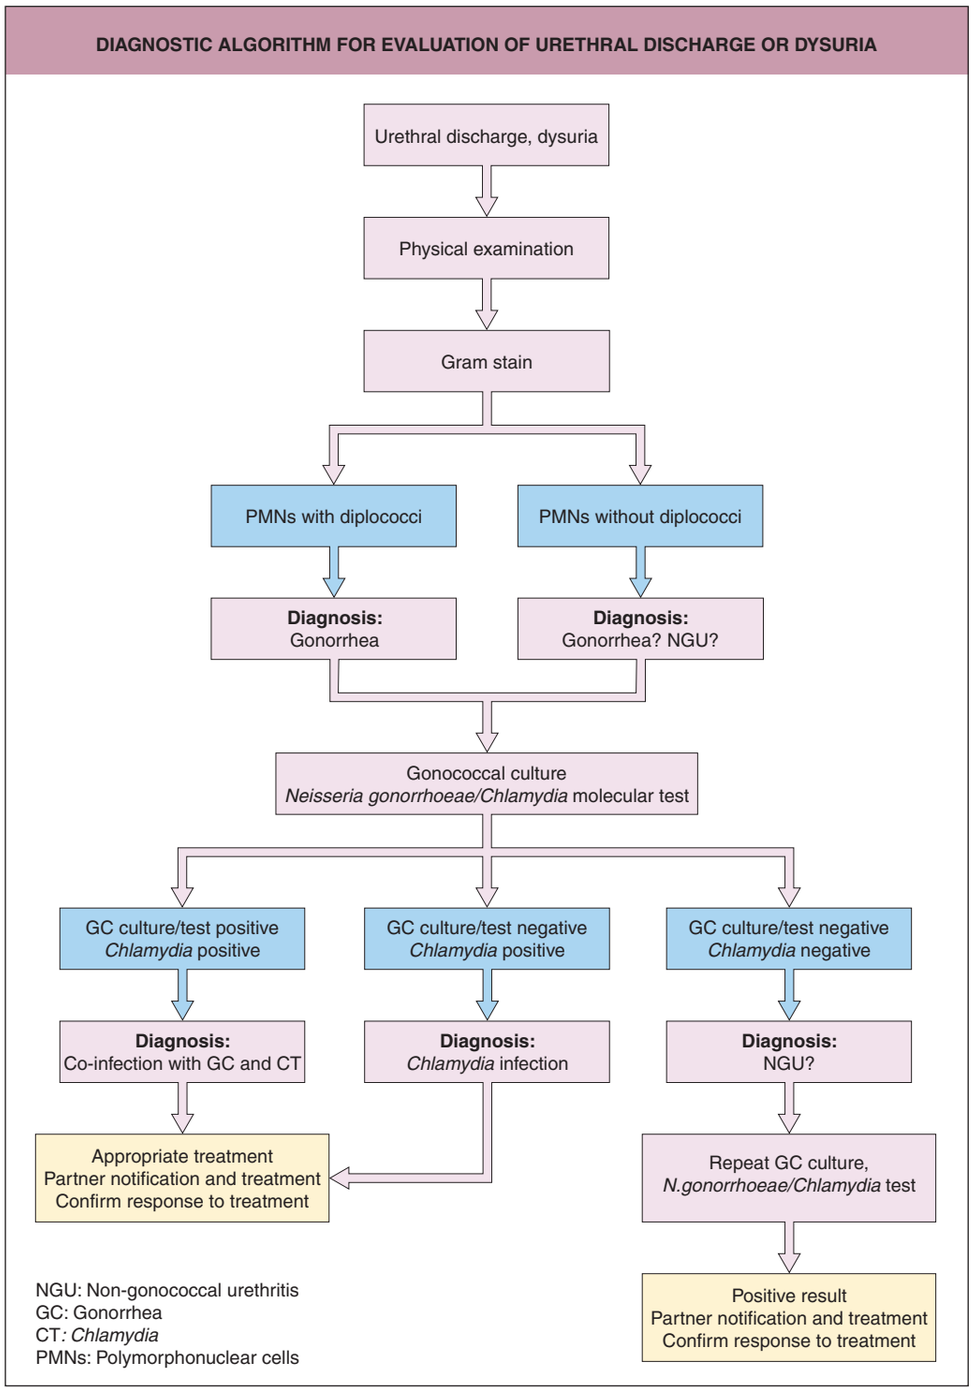

Fig. 82.19 Diagnostic algorithm for evaluation of urethral discharge or dysuria. If cultures are negative, but polymorphonuclear cells are seen on smear, some clinicians will still prescribe doxycycline.

important given the rising number of antibiotic-resistant isolates, and it also allows for regional AMR surveillance. Monitoring antibiotic susceptibility is crucial, especially with the increasingly routine use of non-culture techniques.

Non-culture techniques for gonococcal diagnosis

Molecular techniques for diagnosing gonococcal infections are widely employed and are advantageous over bacterial culture when specimen transport and storage are potential problems. The former are also more sensitive than culture for extragenital sites and when the infection is asymptomatic[37]. In addition, molecular tests can detect gonococci in easy-to-obtain specimens such as urine and are therefore the best test when screening asymptomatic individuals. Another advantage is that multiplex amplification assays can detect *Chlamydia trachomatis* (CT) and other sexually transmitted microbes such as *Mycoplasma genitalium*, in addition to *N. gonorrhoeae* (NG), without the need for an additional specimen (see Fig. 82.19). Their major disadvantage is the lack of antibiotic sensitivity testing (see above).

Nucleic acid amplification techniques (NAATs)

With respect to overall sensitivity, specificity, and ease of specimen transport, NAATs outperform other tests that are currently available for the diagnosis of gonococcal infections.

NAATs are used to detect gonococcal DNA or RNA, often in addition to chlamydial DNA or RNA. Methods include transcription-mediated amplification to detect rRNA (e.g. Aptima Combo 2® assay for CT/NG) and strand displacement amplification (e.g. BD ProbeTec™ ET System). The Xpert® CT/NG test kit can detect *N. gonorrhoeae* within 90 minutes and also co-amplifies CT and NG.

NAATs are continuously being enhanced, leading to faster turnaround times, more user-friendly features, and detection of an increasing number of pathogens from a single sample (e.g. *Trichomonas vaginalis* as well as *C. trachomatis* and *N. gonorrhoeae* via the BD MAX™ CT/GC/TV assay). As previously noted, in addition to physician-collected specimens, samples for NAATs can be obtained "non-invasively", using self-collected vaginal or introital swabs[38] or just urine.

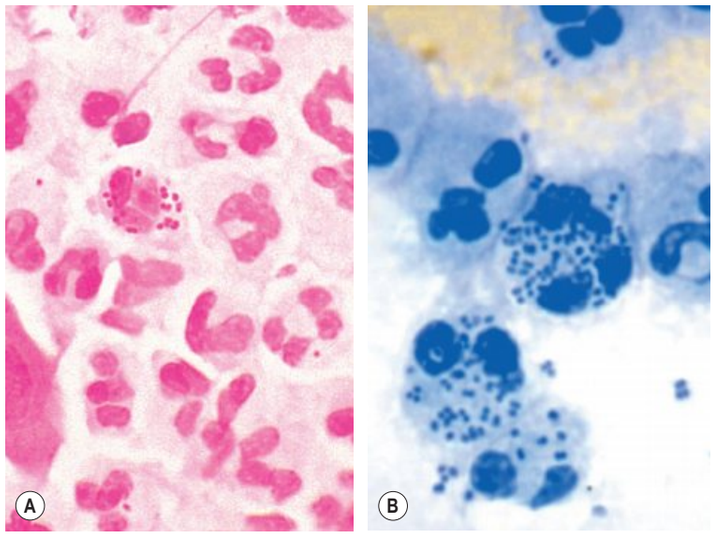

Fig. 82.20 Gonococci in Gram-stained (A) and methylene blue-stained (B) smears of urethral discharge. Neutrophils containing Gram-negative or methylene blue-positive diplococci, consistent with *Neisseria gonorrhoeae*, are evident. *B, Courtesy Harald Moi, MD.*

Pathology

Biopsies of skin lesions due to gonococcemia show a septic vasculitis with extravasated erythrocytes and thrombi. Organisms are usually not demonstrated.

Differential Diagnosis

Other causes of urethral and cervical discharge in men and women must be considered, including infections with *C. trachomatis*, *M. genitalium*, *T. vaginalis*, yeasts, and anaerobic bacteria. The skin lesions of disseminated gonococcemia may need to be distinguished from folliculitis (e.g. bacterial), another disseminated infection, a neutrophilic dermatosis, cutaneous vasculitis, or a pustular drug eruption.

Treatment

Although many antibiotics can be used for the treatment of gonorrhea, selection of therapy depends on the susceptibility of the organism that is isolated (or regional patterns), the anatomic site(s) of the infection, clinical symptoms, and the cost (especially in resource-poor settings) as well as potential side effects of the drug. Over the past several decades, strains of gonorrhea resistant to a number of antibiotics, including sulfonamides, penicillin, tetracyclines, erythromycin, spectinomycin, and more recently quinolones, azithromycin, and some cephalosporins, have emerged. Antibiotic resistance of *N. gonorrhoeae* clearly represents an urgent public health threat.

Over the years, the development of different types of resistance has led to regular revisions of gonococcal treatment recommendations. For example, in 2007, the CDC recommended that fluoroquinolones no longer be prescribed for the treatment of gonococcal infections in the US. Third-generation cephalosporins then became the antibiotics of choice for gonococcal infections (Table 82.13)[39]; however, treatment failures (especially with oral cephalosporins in Asian countries) and decreased *in vitro* sensitivity, e.g. to cefixime, began to appear[40]. In addition to the emergence of a small number of strains with decreased susceptibility to ceftriaxone[41], the first gonococcal strain with ceftriaxone resistance combined with high-level resistance to azithromycin was reported from England and Australia in 2018[42,43]. As a result, the WHO declared antimicrobial-resistant *N. gonorrhoeae* a priority global health issue[44].

The current CDC treatment guidelines recommend a single dose of 500 mg of intramuscular ceftriaxone for uncomplicated gonococcal infections. Alternative regimens are available when ceftriaxone cannot be used to treat urogenital or rectal gonorrhea[45]. Of note, there is a portable, rapid, on-cartridge magnetofluidic purification and testing (PROMPT) PCR test for determining susceptibility of *N. gonorrhoeae* to ciprofloxacin that allows for targeted therapy and leads to a reduction in the use of ceftriaxone[46]. Persons infected with *N. gonorrhoeae* are frequently co-infected with *C. trachomatis* and this co-infection is readily diagnosed by combined NAATs (see above). When confirmed or if *C. trachomatis* infection cannot be excluded, doxycycline is the recommended treatment (see Table 82.13).

For disseminated gonococcal infection, first-line therapy consists of intravenous ceftriaxone (1 g every 24 hours for at least 7 days). Lastly, confirmation of cure, compliance with therapy, and partner notification are legal recommendations for gonococcal treatment and prevention in some countries.

TREATMENT RECOMMENDATIONS FOR GONOCOCCAL INFECTIONS
Uncomplicated gonococcal infections of the urethra, cervix, rectum, or pharynx
Recommended regimens*:
• Ceftriaxone, 500 mg im as single dose† If not excluded, also treat for *Chlamydia trachomatis* with doxycycline 100 mg po BID for 7 days or during pregnancy, azithromycin 1 g po as single dose
Alternative regimen (except for pharynx)*:
• Gentamicin 240 mg im as a single dose PLUS azithromycin 2 g po as single dose – *or* – • Cefixime 800 mg po as single dose
Gonococcal conjunctivitis
• Ceftriaxone, 1 g im as single dose
Disseminated gonococcal infection
***Recommended regimen*:**
• Ceftriaxone, 1 g im or iv q24h • Ceftriaxone administered until 24–48 hours after improvement begins
Alternative regimens*:
• Cefotaxime 1 g iv every 8 hours – *or* – • Ceftizoxime 1 g iv every 8 hours
Neonatal infections
Disseminated gonococcal infection and gonococcal scalp abscesses in newborns
• Ceftriaxone, 25–50 mg/kg iv or im daily for 7 days (10–14 if meningitis) – *or* – • Cefotaxime, 25 mg/kg iv or im q12h for 7 days (10–14 if meningitis)
Ophthalmia neonatorum or asymptomatic neonate born to mother with untreated gonorrhea
• Ceftriaxone, 25–50 mg/kg iv or im as single dose, not to exceed 250 mg
*Alternative treatment regimens in the International Union Against Sexually Transmitted Infections (IUSTI) guidelines 2020 (https://iusti.org/wp-content/uploads/2020/10/IUSTI-Gonorrhoea-2020.pdf). †If patient weighs <150 kg; if ≥150 kg, 1 g is administered.

Table 82.13 Treatment recommendations for gonococcal infections. Based on CDC 2021 Guidelines (www.cdc.gov/std/treatment-guidelines/STI-Guidelines-2021.pdf). BID, twice daily; h, hours; im, intramuscularly; iv, intravenously; po, orally; q, every.

CHANCROID

Synonyms: ■ Soft chancre ■ Ulcus molle

Key features

- Chancroid is characterized by acute genital ulcers and inguinal adenitis
- It is caused by the sexually transmitted, Gram-negative, and facultatively anaerobic bacterium *Haemophilus ducreyi*
- It is a rare disease in high-income countries, and its occurrence is closely linked with commercial sex workers

History

In 1850, chancroid was first differentiated from syphilis. In 1889, Ducrey described the responsible organism as a streptobacillary rod, which he was able to subcultivate by serial autoinoculations into the forearm of a patient[47,48].

Epidemiology

The disease is common in parts of Africa, the Caribbean, and Southeast Asia and is endemic in many low-income countries (Fig. 82.21), with a worldwide annual incidence of about 7 million[49]. Outbreaks are occasionally reported in cities in high-income countries, predominantly within the US. In the US, the number of chancroid cases peaked in the early 1990s and has been very low for the past 25 years. In most of the disease settings, sex workers are the reservoir for the microorganism, and men are much more frequently affected than women (ratio 10:1). In some low-income countries, chancroid is the most common cause of infectious genital ulcer disease (Table 82.14), with frequencies even higher than those of genital herpes.

Transmission

The source of infection is almost always sexual contact with an infected person who has genital ulcers. The probability of transmitting chancroid after a single sexual contact is 35%, and untreated infected women are estimated to be infectious for up to 45 days (while the clinical lesions are present)[50]. Asymptomatic carriers seem to be rare and there is no evidence that infected individuals harbor the organism for a significantly long period of time without clinical findings.

Chancroid and HIV

Chancroid and other diseases that produce genital ulcers are important risk factors for transmission of HIV. Men infected with HIV more often have had a history of genital ulcers compared with HIV-negative men[51]. The risk of acquiring HIV after having sexual contact with HIV-positive women was highest for uncircumcised men with genital ulcer disease compared with circumcised men with and without genital ulcer disease (29% versus 6% versus 2%). In women, the risk of becoming infected with HIV also increases with the number of episodes of genital ulcer disease.

The presence of increased numbers of $CD4^+$ lymphocytes and macrophages in ulcers due to infection with *H. ducreyi* provides an ideal opportunity for a latent HIV infection to become productive, with excretion of the virus into ulcer secretions. Genital lesions therefore become both a portal of viral entry for non-infected individuals and viral exit for HIV-infected persons[52].

Biology of the Organism

H. ducreyi is a Gram-negative, facultatively anaerobic bacillus of small size that shows a typical chaining pattern on Gram stain (Fig. 82.22). It does not share many similarities with other members of the genus *Haemophilus*.

Pathogenesis

The penetration of the microorganism occurs via microscopic barrier defects in the epidermis. Signs of inflammation develop due to infiltration of lymphocytes, macrophages, and granulocytes in a primarily

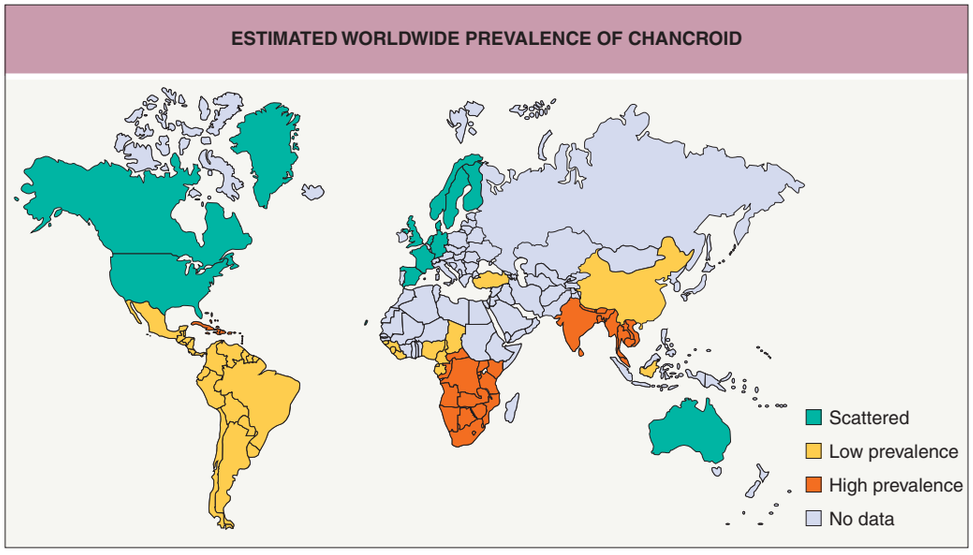

Fig. 82.21 Estimated worldwide prevalence of chancroid[48].

INFECTIOUS CAUSES OF GENITAL ULCER DISEASE				
Disease	**Incubation time**	**Clinical lesion**	**Diagnosis**	**Organism**
Genital herpes	3–7 days	Vesicles, erosions, ulcers; history of herpes viral infection; painful	PCR, culture, DFA, Tzanck (if vesicles)	HSV 2 > 1
Primary syphilis	10–90 days, average 3 weeks	Non-purulent; usually single ulcer; indurated; relatively painless	Darkfield microscopy, serology, PCR	*Treponema pallidum*
Chancroid	3–10 days	Purulent; often multiple ulcers; soft, undermined edges; painful	Culture, PCR	*Haemophilus ducreyi*
LGV	3–12 days	Transient ulcer; indurated; painless	PCR, culture, serology	*Chlamydia trachomatis* serovars L1–3
Donovanosis	2–12 weeks	Chronic ulcer; indurated, beefy red, friable	Smears, histology	*Klebsiella (Calymmatobacterium) granulomatis*

Table 82.14 Infectious causes of genital ulcer disease. DFA, direct fluorescent antibody assay; LGV, lymphogranuloma venereum.

Th1 cell-mediated immune response combined with pyogenic inflammation. Chancroid is associated with regional lymphadenitis due to the spread of the infection and resultant pyogenic inflammation.

Clinical Features

The incubation period is 3–10 days; usually, the onset of clinical symptoms occurs between days 4 and 7. In men, the lesion starts with a papule surrounded by erythema and soon progresses to a pustule and then a painful ulcer. The latter typically has a purulent base and soft, undermined edges and is sharply demarcated (Fig. 82.23A,B). In about one-half of infected men, several ulcers develop due to apposition with the initial lesion, and they can coalesce to form giant ulcers. Most lesions are located on the internal or external surface of the prepuce, in the coronal sulcus (particularly in uncircumcised men), or around the frenulum. They are often accompanied by edema of the prepuce.

Occasionally, a so-called "septic sore" can be observed on the shaft of the penis or prepuce, with pus trapped within the skin in the absence of an obvious ulcer. In this case, the pus that can be expressed is full of microorganisms[47]. In contrast to chlamydial infections, chancroid is symptomatic in almost all infected individuals.

Fig. 82.22 Gram-stained smear in chancroid. This smear of exudate from a genital ulcer shows the characteristic chaining pattern of *Haemophilus ducreyi*.

Co-infections with syphilis or herpes simplex virus (HSV) are possible. In Kenya, ~4% of men with genital ulcer disease have a co-infection with both *T. pallidum* and *H. ducreyi* (ulcus mixtum) and about the same percentage have HSV plus *H. ducreyi*, which makes etiologic diagnosis based on clinical findings impossible.

In women, the majority of lesions are within the introital area; they may also occur on the cervix or vaginal wall, or in the perianal area, but rarely occur in an extragenital location. Lesions in women are sometimes only mildly symptomatic and are more often multiple.

In both men and women, painful inguinal lymphadenitis may accompany the genital lesions. It is more often observed in men (about 40% of patients) and is usually unilateral (Fig. 82.23C). Inguinal buboes may rupture and lead to inguinal ulceration.

Pathology

Biopsies of chancroid classically have three zones of inflammation beneath the ulcers. The first zone has necrotic debris, fibrin, and neutrophils. The middle zone is an area of granulation tissue, and the deepest zone contains lymphocytes and plasma cells. Gram-negative coccobacilli are only rarely found with tissue Gram or Giemsa stains and are best seen with smears.

Diagnosis

Material is usually obtained with a cotton swab, on which the organism can only survive for a few hours without being refrigerated at 4°C. Gram stain of *H. ducreyi* in a smear of the exudate shows a "school-of-fish" or "railroad track" pattern of small Gram-negative bacilli (see Fig. 82.22). The finding is not specific because other bacteria may have a similar arrangement, and it is insensitive because the responsible bacteria are only seen in about a third to a half of infected persons.

Accurate diagnosis of chancroid requires isolation of *H. ducreyi* on special culture media; small, non-mucoid, semiopaque or translucent colonies appear after 24–72 hours if grown at 33–35°C in a 5%–10% CO_2 atmosphere. Further identification methods are needed, such as the porphyrin test, to prove the requirement of hemin (factor X) for growth. There are variations in media (which are not widely available from commercial sources) and the sensitivity of culture is between 60% and 80%, depending on the quality and handling of the specimen, culture conditions, and laboratory experience.

If culture is not possible or is inconclusive, diagnosis can be based on the clinical picture and the exclusion of other microorganisms

Fig. 82.23 Chancroid. A Well-demarcated painful ulcers on the penis. **B** Multiple purulent ulcers with undermined borders. **C** Unilateral lymphadenitis with overlying erythema. *B, Courtesy Joyce Rico, MD.*

TREATMENT REGIMENS FOR CHANCROID
• Azithromycin, 1 g po, single dose – *or* –
• Ceftriaxone, 250 mg im, single dose – *or* –
• Ciprofloxacin, 500 mg po twice daily for 3 days*,† – *or* –
• Erythromycin base, 500 mg po three times daily for 7 days†
*Contraindicated for pregnant or lactating women. †Worldwide, isolates with intermediate resistance.

Table 82.15 Treatment regimens for chancroid. Based on CDC 2021 Guidelines (www.cdc.gov/std/treatment-guidelines/STI-Guidelines-2021.pdf). im, intramuscularly; po, orally.

that cause genital ulcer disease, such as syphilis or genital herpes, as well as on the epidemiologic data and response to therapy. A genital ulcer disease panel that can detect HSV-1, HSV-2, *T. pallidum*, and *H. ducreyi* via real-time PCR is commercially available in some countries[53].

Other diagnostic procedures, such as antigen detection methods or serologic tests, are still under development and cannot yet be recommended for routine diagnosis.

Differential Diagnosis

Other infections that cause genital ulcers have to be considered (see Table 82.14), as well as trauma, a fixed drug eruption, and, occasionally, carcinoma.

Treatment

Successful treatment can be achieved using several antimicrobial drugs (Table 82.15); ulcers improve within 3 days and typically heal in 14 days or less, depending on the initial lesions. The different treatment regimens cure about 95% of infected individuals, with azithromycin and ceftriaxone requiring only a single dose. Ciprofloxacin is contraindicated in pregnant and lactating women. In patients with HIV infection, the treatment recommendations are the same, but with a longer treatment course; close monitoring may be necessary because of delayed healing and possible treatment failures.

Sexual partners from the 10 days preceding the onset of symptoms should be examined and treatment offered regardless of whether the microorganism can be cultured or clinical symptoms are present.

LYMPHOGRANULOMA VENEREUM

Synonyms: ■ Durand–Nicolas–Favre disease ■ Climatic bubo ■ Strumous bubo ■ Poradenitis inguinale ■ Lymphogranuloma inguinale

Key features

- Lymphogranuloma venereum (LGV) is an STI caused by *Chlamydia trachomatis* serovars L1–3 and can be associated with abscesses, fistulas, and involvement of lymphatic tissue
- LGV is endemic in some areas of Africa, Asia, and South America
- Outbreaks of LGV proctocolitis can occur in high-income countries amongst MSM who also have increased rates of HIV infection
- The disease progresses through three stages: (1) initial infection of the genital mucosa; (2) inguinal lymphadenopathy that is usually unilateral; and (3) a firm mass and bubo with spontaneous drainage and involution, often accompanied by proctocolitis and involvement of perirectal or perianal lymphatic tissue

History

Lymphogranuloma venereum (LGV) has been confused with other diseases that cause inguinal lymphadenopathy, especially syphilis, genital herpes, and chancroid. A major diagnostic advantage arose with the introduction of the Frei test, a specific skin test established in 1925[54]. The first isolation of *Chlamydia* was reported in 1930, enabled by intracerebral inoculation of monkeys, followed in 1935 by cultivation in fertilized eggs[55].

CLINICAL MANIFESTATIONS OF LYMPHOGRANULOMA VENEREUM
Initial manifestations: 3–12 days
• Papule • Erosion or ulcer • Herpetiform vesicle • Nonspecific urethritis or cervicitis
Inguinal syndrome: 10–30 days up to 6 months
• Regional lymphadenopathy (mostly inguinal and femoral; also perirectal, deep iliac) • Overlying erythema • Constitutional symptoms • Eruption of buboes • Pelvic inflammatory disease (PID), back pain
Ano-genito-rectal syndrome: months to years
• Proctocolitis • Hyperplasia of intestinal and perirectal lymphatic tissue • Perirectal abscesses • Ischiorectal and rectovaginal fistulas • Anal fistulas • Rectal strictures and stenoses
Other manifestations
• Urethro-genito-perineal syndrome • Peno-scrotal elephantiasis • Erythema nodosum • Submaxillary or cervical lymphadenopathy associated with oropharyngeal lesions

Table 82.16 Clinical manifestations of lymphogranuloma venereum.

Epidemiology

LGV is endemic in East and West Africa, Southeast Asia, India, South America, and the Caribbean basin. In some countries, it is a reportable disease. LGV classically affected sailors, soldiers, and travelers who acquire the disease in endemic regions. In the past, data regarding the prevalence of LGV have been based on the results of serologic tests and the Frei skin test, both of which are nonspecific and have cross-reactivity with other genito-ocular chlamydial infections.

LGV is reported more often in men than in women and the peak age correlates with the period of maximum sexual activity. However, the frequency of infection following sexual intercourse has not been well investigated. Since 2003, a series of outbreaks of LGV have been reported in Western Europe and the US[56]. The affected individuals are primarily MSM who live in large cities[57], many of whom have concurrent HIV infection. In these outbreaks, LGV can present as ulcerative proctitis or as an asymptomatic infection[58].

Pathogenesis

Caused by specific *Chlamydia trachomatis* serovars (L1–3), LGV affects mainly the lymphatic tissue in the genitorectal area. The organisms enter the body via microscopic defects in the mucosa or the skin. The microorganisms then enter the lymphatics, leading to lymphangitis, perilymphangitis, and infection of lymph nodes. Over a period of many weeks to months, the inflammatory process expands and results in periadenitis, involvement of a few neighboring lymph nodes, the development of abscesses (which can rupture), and the formation of fistulas and strictures. In the rectum, destruction and ulceration of the mucosa may occur. Local progression and systemic dissemination are both influenced by host immunity. Latent persistence of the microorganism within involved tissues may last for many years.

Clinical Features

The clinical manifestations of LGV can be separated into primary lesions, inguinal and ano-genito-rectal syndromes, and other manifestations (Table 82.16).

The initial clinical presentations vary, appearing after an incubation period of 3–12 days (see Table 82.16). In up to half of infected individuals, a herpetiform lesion develops at the site of exposure and heals rapidly without a scar. This transient lesion is most often located on the coronal sulcus in men and on the posterior vaginal wall in women, and it is usually accompanied by local lymphangitis. Cervicitis and urethritis are mild and often remain unrecognized. Rectal exposure might result in proctocolitis associated with rectal discharge, anal pain, and tenesmus. Co-infection with other pathogens can sometimes be observed.

The secondary stage is characterized by the *inguinal syndrome*, in which unilateral lymphadenopathy (depending on the site of the primary infection) is accompanied by overlying erythema. The bubo is initially firm and then undergoes rapid enlargement, becoming more painful. Eventually the overlying skin develops a bluish discoloration and the bubo finally ruptures through the skin; pus may drain through numerous sinus tracts (Fig. 82.24), followed by healing. If untreated, relapses occur in about 20% of patients. Constitutional symptoms such as meningeal irritation, hepatitis, and arthritis are rare and may occur due to systemic spread of the organism. Inguinal adenopathy is only observed in about one-third of infected women; proctitis and pain in the lower abdomen may be the only symptoms.

The manifestations of the *ano-genito-rectal syndrome* include proctocolitis and hyperplasia of the intestinal and perirectal lymphatic tissue. This leads to late manifestations dominated by local abscesses with anal fistulas as well as rectal strictures and stenoses[59].

Additional manifestations include urinary incontinence because of papillary growth of the mucosa of the urethral meatus in women. Extragenital lesions in the oropharynx, due to infection from oral sexual contact, are difficult to diagnose.

Pathology

Histologically, the skin may be ulcerated. A diffuse mixed infiltrate of neutrophils, histiocytes, plasma cells, and sometimes multinucleated giant cells is seen in the dermis. Although abscesses may occur in the skin, characteristic stellate abscesses are usually only observed in the lymph nodes. Organisms are rarely demonstrated within histiocytes (Gamna–Favre bodies) by Giemsa stain. An anti-*C. trachomatis* antibody has been used successfully to demonstrate microorganisms in skin biopsies.

Fig. 82.24 Lymphogranuloma venereum. Inguinal bubo that has ruptured and drained.

TREATMENT REGIMENS FOR LYMPHOGRANULOMA VENEREUM

• Recommended: doxycycline, 100 mg po twice daily
• Alternative and in case of pregnancy:
  • Erythromycin base, 500 mg po four times daily
  • Azithromycin 1 g po once weekly*

Duration for both regimens: 3 weeks
*Because not validated, a test of cure with *C. trachomatis* nucleic acid amplification technique (NAAT) 4 weeks after completion of treatment can be considered.

Table 82.17 Treatment regimens for lymphogranuloma venereum. po, orally. Based on CDC 2021 Guidelines (www.cdc.gov/std/treatment-guidelines/STI-Guidelines-2021.pdf).

Diagnosis

The diagnosis of LGV is based primarily on the detection of *Chlamydia*-specific DNA in lesional tissue by PCR or other nucleic acid amplification techniques (NAATs). This method is diagnostically more sensitive than is isolation of the organism via tissue culture. Typically, rectal specimens are tested for the presence of *C. trachomatis* and, if positive, are then genotyped in order to diagnose LGV. Serology testing is only recommended if it is performed in conjunction with DNA detection. In serologic assays, such as the complement fixation test or other assays that detect specific antibodies to the serovars L1–3 of *C. trachomatis*, the titer of antibodies is high. A differentiation of antibodies to L1–3 from those to other serovars is difficult but possible in the microimmunofluorescence test. A disadvantage of this diagnostic procedure is the lack of commercial availability.

Differential Diagnosis

Other causes of lymphadenopathy in the genital region (e.g. chancroid, lymphoma, cat scratch disease) or of genital ulcers or erosions should be excluded by additional diagnostic procedures (see Table 82.14). Pyogenic and mycobacterial infections also need to be considered, as well as Crohn disease, especially in the case of the ano-genito-rectal syndrome. Routine syphilis and HIV serologies are recommended and should be repeated after 3–6 months.

Treatment

Doxycycline is the treatment of choice, followed by macrolides (Table 82.17). Antibiotic treatment can cure the infection, but surgical intervention may be required in the case of large buboes.

Examination and treatment of sexual partners is required if contact occurred during the 30 days preceding the onset of symptoms. HIV-positive individuals may need prolonged treatment due to delayed resolution of symptoms.

DONOVANOSIS (GRANULOMA INGUINALE)

Synonyms: ■ Granuloma venereum ■ Granuloma inguinale tropicum ■ Granuloma venereum genitoinguinale ■ Granuloma genitoinguinale ■ Ulcerating sclerosing granuloma ■ Ulcerating granuloma of the pudendum ■ Serpiginous ulceration of the groin ■ Lupoid form of groin ulceration

Key features

- Donovanosis is a rare, chronic, progressive, ulcerative bacterial infection with *Klebsiella granulomatis* (previously known as *Calymmatobacterium granulomatis*), a Gram-negative bacillus
- Ulcers occur primarily in the genital region
- The responsible microorganisms are found within macrophages in smears or biopsy specimens (Donovan bodies)

History

The disease was initially described in India as ulcerations followed by elephantiasis of the genitalia. The microorganism was first identified in 1905 by Donovan, who noted the characteristic Donovan bodies in macrophages and epithelial cells of the stratum malpighii[60]. In 1950, Marmell and Santora proposed the name "donovanosis"[61]. Limited success in culturing the organism until the 1990s explains the slow progress in donovanosis research[62].

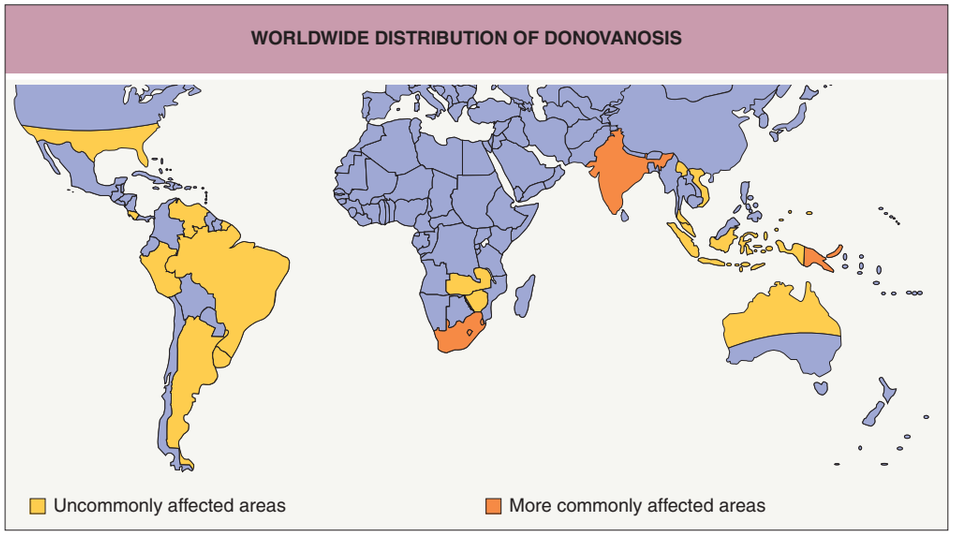

Fig. 82.25 Worldwide distribution of donovanosis.

Epidemiology

In the pre-antibiotic era, donovanosis was distributed in both hemispheres, but now it is restricted primarily to a few low-income countries. A large number of cases, the majority in the 20- to 40-year-old age group, are reported from South Africa, India, Papua New Guinea, and some parts of Australia (Fig. 82.25).

Although donovanosis is listed among the group of STIs, the disease can also occur in individuals who are not sexually active, and a wide variation in the prevalence of the infection (from 0.5% to 50%) is reported in sexual partners[63]. This is probably due to different diagnostic procedures and a long incubation period of up to 1 year. It is also not clear whether fecal contamination represents a route of non-sexual transmission.

Pathogenesis

Donovanosis is caused by *Klebsiella granulomatis* (previously known as *Calymmatobacterium granulomatis*), an intracellular Gram-negative bacillus. The primary lesion is a small cutaneous papule or nodule that contains mononuclear cells with cytoplasmic vacuoles that are filled with microorganisms. The cytoplasmic vacuoles can rupture and release bipolar Donovan bodies[64] of coccoid, coccobacillary, and bacillary morphology.

Clinical Features

The average incubation period is thought to be ~17 days, but a range from 1 day to 1 year has been reported. A small papule or nodule initially appears and eventually ulcerates. The lesions of donovanosis are usually painless or mildly painful and slowly expand over a period of weeks to months. They are often highly vascular, with a beefy red appearance and a tendency to bleed (Fig. 82.26). Extensive tissue destruction may result, and a foul-smelling exudate is characteristic of necrotic donovanosis. Inguinal lesions occur in up to 20% of patients and are often combined with genital involvement. The most frequent sites of lesions in men are the prepuce, glans penis, frenulum, and coronal sulcus. In women, the most common location is the vulvar area, where large ulcers as well as granulomatous or verrucous papules may be observed.

Extragenital lesions due to autoinoculation or secondary to dissemination have been observed in the skin, bones, abdominal cavity, and oral cavity; they can involve any organ, with the bones most commonly affected. In some patients, primary extragenital lesions are seen.

Pathology

Histologically, ulceration with exuberant granulation tissue is evident. Pseudoepitheliomatous hyperplasia may be present at the ulcer edge. A diffuse infiltrate of histiocytes, plasma cells, and a few lymphocytes is present in the dermis, sometimes with small neutrophilic abscesses. The organisms are easier to find in smears than in histologic sections.

Fig. 82.26 Donovanosis (granuloma inguinale). Large ulcers with a characteristic "beefy" appearance. *Courtesy Joyce Rico, MD.*

They are 1–2 microns in diameter and are within histiocytes, as is also characteristic of leishmaniasis, rhinoscleroma, and histoplasmosis (see Table 77.18). Bipolar staining is found at two ends of the organisms (Donovan bodies), giving them a "safety pin" appearance.

Diagnosis

The diagnosis of donovanosis is usually based on the demonstration of Donovan bodies in smears from active lesions by Giemsa, Wright, or Leishman stains. The smears are prepared from tissue scrapings or touch preparations of biopsies taken from the dermis or subcutis of lesions.

There are no serologic tests available for the diagnosis of donovanosis. Nucleic acid amplification assays such as PCR are under investigation, but they are not yet commercially available. Although successful culture of *K. granulomatis* has been reported in human peripheral blood mononuclear cells and Hep2 cells, attempts to grow this organism in fertilized eggs or on routinely available artificial media have been unsuccessful.

Differential Diagnosis

Donovanosis is frequently confused with other diseases of the anogenital region. Other infectious causes of genital ulcer disease have to be considered (see Table 82.14); early lesions of secondary syphilis, especially condylomata lata, often have a clinical appearance similar to donovanosis. Carcinoma, amebiasis, tuberculosis, dimorphic fungal infections, blastomycosis-like pyoderma, Crohn disease, and pyoderma gangrenosum may represent additional diagnostic possibilities.

TREATMENT REGIMENS FOR DONOVANOSIS
Recommended:
• Azithromycin, 1 g po once weekly – *or* – 500 mg po daily
Alternative:
• Doxycycline, 100 mg po BID – *or* – • Trimethoprim–sulfamethoxazole, 1 double-strength (160 mg/800 mg) tablet po BID – *or* – • Erythromycin base, 500 mg po four times daily
Duration for all regimens: until all lesions completely healed (at least 3 weeks)

Table 82.18 Treatment regimens for donovanosis. For any of the regimens, the addition of another antibiotic (e.g. gentamicin 1 mg/kg iv q8h) can be considered if lesions do not respond within the first few days of therapy. Based on CDC 2021 Guidelines (www.cdc.gov/std/treatment-guidelines/STI-Guidelines-2021.pdf). BID, twice daily; po, orally.

Treatment

The recommended treatment is azithromycin, but treatment regimens in different geographic areas reflect the availability of antibiotics; for example, in Papua New Guinea, chloramphenicol is used. Doxycycline, trimethoprim–sulfamethoxazole, quinolones, and erythromycin (recommended during pregnancy) have also been shown to be effective in the treatment of donovanosis (Table 82.18). For azithromycin, successful treatment with a daily dose of 500 mg for 1 week has been reported[65]. However, the CDC 2021 guidelines recommend 1 g weekly or 500 mg daily for at least 3 weeks and until all lesions have completely healed.

Examination of sexual partners is recommended if there has been sexual contact during the previous 60 days or if the partner is symptomatic. Relapses can occur 6–18 months later, despite effective initial treatment.

Chapter Contents

Protozoa 1485
Leishmaniasis 1485
Cutaneous Diseases Caused by Amebas 1492
Trypanosomiasis 1494
Toxoplasmosis 1499
Worms (Helminths) 1500
Cutaneous Larva Migrans 1500
Gnathostomiasis 1503
Onchocerciasis 1507
Filariasis 1512
Schistosomiasis and Swimmer's Itch 1513
Cysticercosis and Echinococcosis 1515

Key features

- Protozoa are responsible for many tropical diseases that not only affect large regions of the world but also can have different clinical presentations in the Old World versus the New World (e.g. leishmaniasis)
- Protozoal infections can lead to significant morbidity in both immunocompromised hosts (e.g. toxoplasmosis) and immunocompetent individuals (e.g. *Balamuthia* spp.)
- Worms (helminths) are common parasites with a worldwide distribution; cutaneous manifestations vary considerably, from pruritus ani to elephantiasis
- Even helminthic diseases with a restricted geographic distribution, such as onchocerciasis and echinococcosis, may be observed in individuals from non-endemic areas due to immigration, tourism, disaster relief efforts, or military service

PROTOZOA

LEISHMANIASIS

Synonyms: ■ Old World cutaneous leishmaniasis: oriental sore, Delhi boil, Baghdad boil ■ New World cutaneous and mucocutaneous leishmaniasis: American tegumentary leishmaniasis, chiclero ulcer (Mexico), uta and espundia (Peru), ulcera de Bauru (Brazil), bush or forest yaws, pian boi (Guyanas) ■ Diffuse cutaneous leishmaniasis: anergic, lepromatous, or pseudolepromatous leishmaniasis ■ Visceral leishmaniasis: kala-azar, Dumdum fever

Key features

- Chronic parasitic (protozoan) disease in which organisms are found within phagolysosomes of mononuclear phagocytes
- The clinical manifestations of leishmaniasis depend on the host's cell-mediated immune response and the species of *Leishmania* involved; clinical subtypes include cutaneous, disseminated cutaneous, diffuse cutaneous, mucocutaneous/mucosal, and visceral leishmaniasis
- The most common cutaneous finding is a papule at the site of inoculation that classically evolves into an ulcer
- The vector is a sandfly infected with promastigotes
- The disease has a worldwide distribution but is endemic in Latin America, the Mediterranean basin, and parts of Asia and Africa

Introduction

Leishmaniasis encompasses a spectrum of chronic infections in humans and several animal species. It is caused by over 20 species of *Leishmania* (Table 83.1), flagellated protozoans belonging to the order Kinetoplastidae. Transmission is via the bite of infected female sandflies from the genera *Phlebotomus* and *Lutzomyia*.

The disease has a worldwide distribution, affecting millions of people in South America, the Mediterranean basin, and parts of Asia and Africa[1] (Figs. 83.1 & 83.2). There are four major clinical patterns: (1) cutaneous, which is restricted to the skin and is seen more often in the Old World; (2) mucocutaneous, which affects both the skin and mucosal surfaces and occurs almost exclusively in the New World; (3) diffuse cutaneous, which occurs mainly in the New World; and (4) visceral, which affects the organs of the mononuclear phagocyte system, e.g. liver, spleen[2,3].

Epidemiology

According to the World Health Organization, more than a million new cases of cutaneous leishmaniasis and ~30 000 new cases of visceral leishmaniasis occur annually[4]. Over 90% of cutaneous infections with *Leishmania* occur in the Middle East (Afghanistan, Algeria, Iran, Iraq, Saudi Arabia, Syria) and South America (Brazil, Peru, Colombia) (Table 83.2), but the disease is also found in the Mediterranean basin, sub-Saharan Africa, Central Asia, and India (see Fig. 83.1). In the US, climate change has led to the expansion of sandfly vectors to northern Texas. One study found that 59% (41/69) of novel cases of cutaneous leishmaniasis reported to laboratories in Texas from 2007–2017 were autochthonous (occurring in patients with no history of travel outside the US), and all 22 of such cases that were confirmed by PCR were due to *L. mexicana*[5].

Mucocutaneous leishmaniasis is endemic in several countries in Central and South America. Although the visceral form of leishmaniasis has a worldwide distribution, it is seen most frequently in Africa and Asia (see Fig. 83.2)[1,2,6].

Old World cutaneous leishmaniasis is usually due to *L. major* or *L. tropica*, and less often *L. infantum* (Mediterranean basin) or *L. aethiopica* (Ethiopia and Kenya) (see Table 83.1 & Fig. 83.1). In the New World, cutaneous leishmaniasis is caused primarily by subspecies of *L. mexicana* and the *L. braziliensis* complex, whereas mucocutaneous/mucosal disease is associated with the latter organisms. Diffuse cutaneous leishmaniasis is most closely associated with *L. amazonensis*[3]. Infections with *L. donovani* (e.g. India, Bangladesh, Sudan) and *L. infantum* (especially in the setting of HIV infection) as well as the subspecies *L. infantum chagasi* (e.g. Central and South America; previously known as *L. chagasi*) are the major causes of visceral leishmaniasis (Table 83.3 & Fig. 83.2).

The species of *Leishmania* can also vary within a particular geographic region. For example, in the Middle East, *L. major* is found in rural areas where the primary animal reservoirs are desert rodents, whereas *L. tropica* is endemic in urban areas[6].

EPIDEMIOLOGIC AND CLINICAL PATTERNS OF INFECTIONS WITH *LEISHMANIA* SPECIES					
Complex	**Major species**	**Major reservoirs**	**Major geographic distribution**	**Clinical patterns (in addition to cutaneous)**	**Clinical forms of the cutaneous pattern**
Leishmania donovani	*L. donovani*	Humans	Sudan, South Sudan, Ethiopia, Kenya, Somalia; India, Nepal, Bangladesh; China	**Visceral, PKD**, mucosal (rare)	(Uncommon)
	L. infantum	Dogs, foxes	Mediterranean region	**Visceral (favors children)**, PKD*, mucosal† (rare)	Favors children (uncommon)
	L. infantum chagasi‡	Dogs, foxes, opossums	Central and South America (mainly Brazil)		
Leishmania tropica	*L. major*	Rodents	Arid areas of Africa (north and south of the Sahara), Middle East and Central Asia	Mucosal (rare)	**Old World zoonotic/rural** (moist, early ulcerative with rapid course), recidivans (rare), lupoid (rare)
	L. tropica	Humans, dogs	Eastern Mediterranean region, Middle East, Central Asia	Visceral (rare), mucosal (rare)	**Old World anthroponotic/ urban** (dry, late ulcerative with chronic course), recidivans, lupoid
	L. aethiopica	Hyraxes	Ethiopia, Kenya, Yemen	Diffuse cutaneous, mucocutaneous	Dry/late ulcerative or moist/early ulcerative
Leishmania mexicana	*L. mexicana*	Forest rodents	Mexico, Central America	Diffuse cutaneous (rare)	**New World** Variants include ulcerative, plaque-like, pustular, impetigo-like, erysipeloid, sarcoidosis-like, papulotuberous, verrucous, sporotrichoid, eczematous
	L. amazonensis	Forest rodents	South America	**Diffuse cutaneous**, mucocutaneous, visceral (rare), PKD (rare)	
	L. venezuelensis, pifanoi, garnhami	Unknown	Venezuela	Diffuse cutaneous (rare)	
Leishmania (Viannia) braziliensis	*L. braziliensis*	Forest rodents	Central and South America	**Mucocutaneous**, visceral†	
	L. guyanensis	Sloths, anteaters	Guyana, Brazil	Mucocutaneous	
	L. panamensis	Sloths	Panama, Costa Rica, Colombia	Mucocutaneous	
	L. peruviana	Dogs	Peru, Argentina		

*Rare/controversial; reported in children and in HIV-infected adults following antiretroviral therapy.
†Especially in immunocompromised hosts.
‡*L. infantum* subspecies in the New World; previously known as *L. chagasi*.

Table 83.1 Epidemiologic and clinical patterns of infections with *Leishmania* species. Common clinical patterns for particular species are in **bold**. Additional minor species include *L. garnhami*, *naiffi*, *lainsoni*, *colombiensis*, *shawi*, *archibaldi*, and *martiniquensis*. *Viannia* is a subgenus of *Leishmania*. Mucosal leishmaniasis refers to oronasal lesions not preceded or accompanied by cutaneous involvement. PKD, post-kala-azar dermal leishmaniasis. *Modified from Lupi O, Barlett BL, Haugen RN, et al. Tropical dermatology: tropical diseases caused by protozoa. J Am Acad Dermatol 2009;60:897–925 and Peters W, Pasvol G. Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

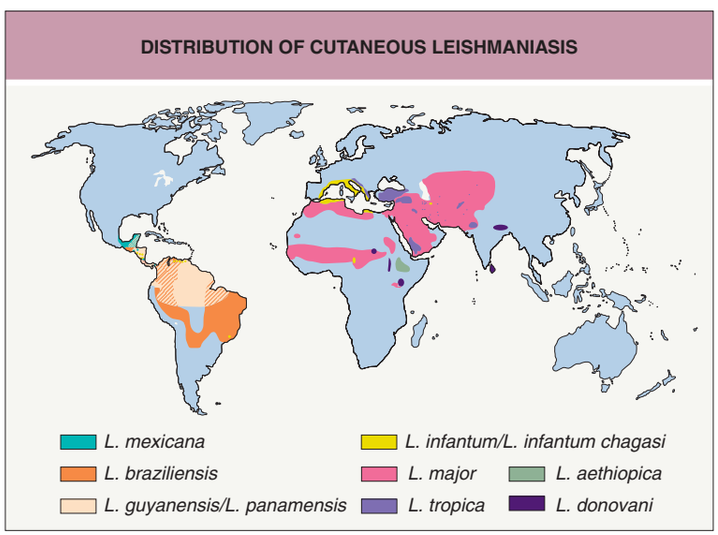

Fig. 83.1 Distribution of cutaneous leishmaniasis. Climate change is expected to lead to expansion of these distributions. For example, autochthonous cases of cutaneous leishmaniasis due to *L. mexicana* have reported as far north as Texas. *Modified from Aronson N, Herwaldt BL, Libman M, et al. Diagnosis and Treatment of Leishmaniasis: Clinical practice guidelines by the Infectious Diseases Society of America (IDSA) and the American Society of Tropical Medicine and Hygiene (ASTMH). Clin Infect Dis 2016;63:1539–57 and Cohen J, Powderly WG, Opal SM (eds). Infectious Diseases, 4th edition. Edinburgh: Elsevier, 2016.*

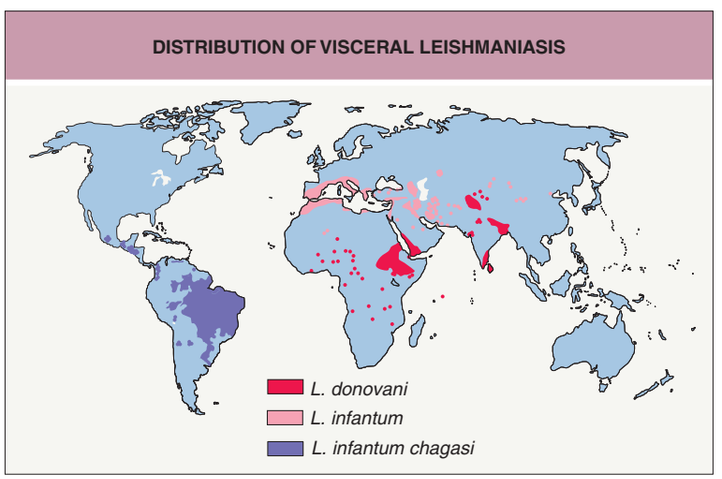

Fig. 83.2 Distribution of visceral leishmaniasis. These organisms, in particular *L. infantum* and *L. donovani*, can also cause cutaneous disease. *Modified from Aronson N, Herwaldt BL, Libman M, et al. Diagnosis and Treatment of Leishmaniasis: Clinical practice guidelines by the Infectious Diseases Society of America (IDSA) and the American Society of Tropical Medicine and Hygiene (ASTMH). Clin Infect Dis 2016;63:1539–57 and Cohen J, Powderly WG, Opal SM (eds). Infectious Diseases, 4th edition. Edinburgh: Elsevier, 2016.*

Canine and rodent species act as the main reservoirs for *Leishmania* (see Table 83.1). Transmission between these species (as well as to humans) is via sandflies, primarily of the genera *Phlebotomus* (Old World) and *Lutzomyia* (New World). Human-to-human spread of *L. tropica* can also occur. In general, humans contract leishmaniasis as accidental hosts when they intrude into the sandfly's habitat. Overall, the disease is most common in men between 20 and 40 years of age, but Old World cutaneous leishmaniasis occurs more often in children[2].

Epidemics of cutaneous leishmaniasis have occurred in populations affected by natural disasters, forced migration, and civil unrest as well as in foreign military personnel serving in endemic areas of the Middle East (e.g. Iran, Afghanistan, Syria, Iraq). Whereas the incidence of visceral leishmaniasis seems to be decreasing in endemic countries such as India, Bangladesh, and Nepal, new areas of epidemic visceral leishmaniasis are appearing in Sudan and South Sudan. Migration from rural areas to peri-urban centers has also contributed to an increasing incidence of visceral leishmaniasis in Brazil. Solid organ and hematopoietic stem cell transplant recipients and other individuals receiving immunosuppressive medications (e.g. tumor necrosis factor [TNF] inhibitors) represent additional groups at increased risk for visceral leishmaniasis[7].

Pathogenesis

Leishmania spp. are obligate intracellular parasites that exist in two forms: promastigote and amastigote. In the gut of the sandfly, the organisms multiply as extracellular flagellated promastigotes. Following migration to the proboscis, the parasites are inoculated (in the promastigote form) via the sandfly bite. Once inoculated into the skin, the parasites are rapidly engulfed by the host's mononuclear phagocytes, where they transform into amastigotes and multiply via binary fission (Fig. 83.3). The incubation time from infection until the first clinical manifestation can vary from ≤2 weeks for cutaneous lesions (typically several weeks to 2 months) to >2 years for mucocutaneous lesions or visceral involvement (typically 3 to 9 months)[8].

COUNTRIES WITH THE HIGHEST INCIDENCE OF LEISHMANIASIS	
Old World cutaneous leishmaniasis	Afghanistan, Algeria, Iran, Iraq, Saudi Arabia, Syria
New World cutaneous leishmaniasis	Brazil, Peru, Colombia
Mucocutaneous/mucosal leishmaniasis	Bolivia, Brazil, Peru
Visceral leishmaniasis	Brazil, Ethiopia, India, Kenya, Somalia, South Sudan, Sudan, Nepal, China

Table 83.2 Countries with the highest incidence of leishmaniasis. The incidence of visceral leishmaniasis has been decreasing in Bangladesh, Nepal, and India. Further information is provided at http://www.who.int/mediacentre/factsheets/fs375/en/ and https://paho.org/en/topics/leishmaniasis.

The clinical manifestations of leishmaniasis depend on the species of *Leishmania* (see Table 83.1), the host's cell-mediated response, and the ability of the parasite to evade host defense mechanisms[9]. A robust Th1 response with production of interleukin-2 (IL-2) and interferon-γ (IFN-γ) is associated with quicker resolution, whereas a lack of a Th1 response and/or the development of a Th2-type response with production of IL-4 and IL-10 is associated with disease progression[10–12]. Depending on the type of immune response, L-arginine metabolism within infected macrophages occurs via two alternative pathways: (1) Th2 cytokines promote its catabolism by arginase to produce L-ornithine, which favors *parasitic* growth; or (2) Th1 cytokines promote nitric oxide synthase-induced generation of L-citrulline plus nitric oxide, and the latter increases host resistance via NLRP3 (NLR family pyrin domain-containing-3) inflammasome-derived IL-1β[13]. Resistance of *L. amazonensis* and *L. braziliensis* promastigotes to nitric oxide *in vitro* correlates with poorer clinical outcomes.

Mucocutaneous disease is associated with the infection of *Leishmania* organisms with *Leishmania* RNA virus-1 (LRV1); this virus is recognized by human Toll-like receptor 3, leading to a proinflammatory cascade that subverts the immune response to *Leishmania*, and allows disease progression[14]. *L. donovani* has been shown to induce epigenetic changes via macrophage DNA methylation that downregulate host defense mechanisms, allowing parasitic replication and survival[15]. Human genetic factors include HLA variants that contribute to leishmaniasis risk and *IL2RA* variants that reduce IL-2-dependent responses and thereby increase susceptibility to cutaneous and visceral leishmaniasis[16].

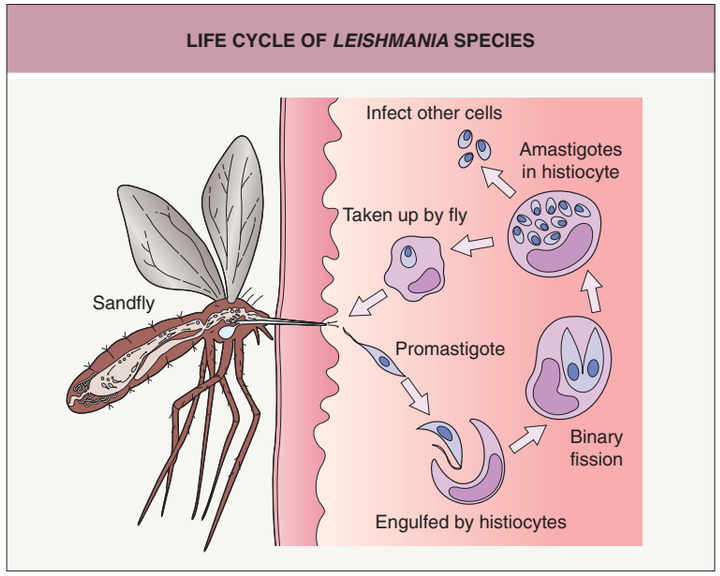

Fig. 83.3 Life cycle of *Leishmania* species. Promastigotes develop within the gut of the sandfly and then migrate to the proboscis.

EPIDEMIOLOGY AND CLINICAL PATTERNS OF VISCERAL LEISHMANIASIS		
Type of disease	**Major species**	**Major geographic distribution**
Kala-azar (60% 10–20 years of age)	*Leishmania donovani*	India, China (north of Yangtze River), Kenya, Sudan
Infantile kala-azar (90% <10 years of age)	*L. infantum*	Central Asia, China, Iraq, France, Italy, Egypt, elsewhere in the Mediterranean basin, Saudi Arabia
	L. infantum chagasi	Brazil, Colombia, Venezuela, Central America, Mexico
Oronasal kala-azar	*L. infantum**	France
Post-kala-azar dermal leishmaniasis	*L. donovani* *L. infantum*† *L. amazonensis*	India, China, Kenya Mediterranean basin, South America
Atypical kala-azar complex (typically in adults)	*L. tropica* *L. amazonensis* *L. braziliensis**	Northeast Saudi Arabia South America South and Central America

*Especially in immunocompromised hosts.
†Controversial (see Table 83.1).

Cutaneous leishmaniasis is sometimes mistaken for a basal cell carcinoma. *A, C, Courtesy Julie V. Schaffer, MD; D, Courtesy Kalman Watsky, MD.*

IFN-γ is the most potent cytokine involved in the induction of activity against organisms residing within macrophage phagolysosomes. It is produced by Th1 cells and leads to the production of oxygen species. The differentiation of naive $CD4^+$ cells into Th1 cells is aided by IL-12 (see Fig. 4.9), which also stimulates natural killer (NK) cells to produce IFN-γ[10,12,17]. TNF produced by macrophages and NK cells amplifies the IFN-γ-driven macrophage activation[11,18]. Consequently, use of TNF inhibitors increases the risk of developing leishmaniasis, especially the visceral form. More recent studies have also highlighted the role of TNF-dependent IL-32γ in stimulating the production of proinflammatory cytokines and microbicidal molecules in human macrophages infected with New World *Leishmania* spp.[19]. In addition, Th17 cells can potentially contribute to both host resistance and tissue damage in patients with leishmaniasis.

Animals that have recovered from *L. tropica* or *L. donovani* infections acquire immunity against reinfection from the same species of *Leishmania*, but not against other species. Similarly, humans with New World cutaneous leishmaniasis have been inoculated successfully with *L. tropica*. However, it has been reported that surviving an episode of visceral leishmaniasis confers lifelong immunity against all types of leishmaniasis.

Clinical Features

Cutaneous leishmaniasis

Cutaneous leishmaniasis is divided into two subsets based on the geographic region where the infection is acquired: Old World and New World. These two groups differ with regard to the causative organisms, vectors, reservoirs, clinical presentation, and prognosis[3]. Both Old World and New World cutaneous leishmaniasis usually begin as a small, well-circumscribed papule at the inoculation site. This lesion may slowly enlarge over several weeks into a nodule or plaque and then become ulcerated or verrucous (Figs. 83.4–83.6). Exposed sites such as the face, neck, arms, and legs are most commonly involved. For example, the chiclero ulcer results from infection on the ear in forest workers who collect gum from the chicle tree in Mexico and Central America (see Fig. 83.4D). The lesions of leishmaniasis are often solitary but may be multiple, with the formation of satellites or lymphatic spread (sporotrichoid pattern; Fig. 83.7). Unusual clinical presentations include erysipeloid, zosteriform, psoriasiform, and eczematous. Most acute cutaneous infections resolve spontaneously within several months, often with scarring (cicatricial stage)[20]. A minority of patients develop chronic or disseminated disease.

Several clinical forms of ***Old World*** cutaneous leishmaniasis have been described, including zoonotic, anthroponotic, recidivans, and lupoid leishmaniasis. Zoonotic cutaneous leishmaniasis (rural, moist, or early ulcerative form) usually has a mild, rapid course and is caused by *L. major*. Anthroponotic cutaneous leishmaniasis (urban, dry, or late ulcerative form), has a more chronic course and is caused by *L. tropica*[3]. Leishmaniasis recidivans is a chronic, destructive form that is characterized by recurrence at the site of an original ulcer, generally within 2 years and often at the edge of the scar[20]. Anthroponotic or, less frequently, zoonotic cutaneous leishmaniasis occasionally develops into chronic lupoid leishmaniasis, which clinically and histologically (epithelioid granulomas surrounded by lymphocytes) resembles the lupus vulgaris form of cutaneous tuberculosis. Amastigotes are scarce and difficult to find in lupoid leishmaniasis, making the diagnosis more challenging.

Fig. 83.5 Cutaneous leishmaniasis of the nose due to *Leishmania aethiopica*. This patient presented with an infiltrated hyperpigmented plaque with papules at its periphery. Cutaneous leishmaniasis due to *L. aethiopica* often affects the face and can evolve to mucocutaneous disease. *Courtesy Edward Cowen, MD.*

New World cutaneous leishmaniasis has a wide clinical spectrum, including plaque-type, sporotrichoid, pustular, impetigo-like,

eczematoid, sarcoid-like, lupoid, erysipeloid, papulotuberous, verrucous, disseminated, and diffuse presentations. There is also the potential for developing leishmaniasis recidivans[20].

Disseminated cutaneous leishmaniasis, which most often results from *L. braziliensis* or *L. amazonensis* infection, is characterized by multiple (10 to >300) secondary lesions, either in proximity to or distant from the primary site. The lesions resemble those of classic cutaneous leishmaniasis, including papules and small nodules that may have an acneiform appearance, and ulceration is common (Fig. 83.8A). Up to 25% of affected individuals have concomitant mucosal disease, and patients may have systemic symptoms such as fever and malaise. Disseminated skin disease most likely results from early hematologic spread, and it is associated with decreased production of IFN-γ and TNF[21].

Diffuse cutaneous leishmaniasis is a rare presentation that develops in the setting of reduced cell-mediated immunity, analogous to the lepromatous form of Hansen disease. *L. aethiopica* (in Africa) and *L. amazonensis* (in the Americas) are the most common pathogens (see Table 83.1). Multiple nodular and keloid-like lesions on the face and limbs are usually observed[3] (Fig. 83.8B); ulceration is uncommon but occasionally occurs secondary to trauma. Nasal infiltration and mucosal ulceration may develop due to spread from nearby skin lesions, but destruction of the nasal septum is rare. There may also be laryngeal and pharyngeal involvement[20].

Mucocutaneous/mucosal leishmaniasis

After a variable time period ranging from a few months to more than 20 years, mucocutaneous/mucosal disease develops in some patients infected with *Leishmania* spp. in the *Viannia* subgenus (known as the *L. braziliensis* complex), most commonly *L. braziliensis* and occasionally *L. panamensis*, *L. guyanensis*, or hybrid genotypes[22]. Mucosal lesions range from edema of the lips and nose to perforation of the nasal septum or (less often) the laryngeal cartilage or palate. Infiltration and/or ulceration of the mucosal surfaces of the nose, lips, and oropharynx are typical features (Figs. 83.9 & 83.10); ocular or genital involvement is rare. In some patients, there is extensive loss of tissue in both the mouth and nose, causing a characteristic "tapir face" known as espundia. Hoarseness may result from vocal cord involvement[20–22].

Fig. 83.11 Post-kala-azar dermal leishmaniasis. Nodules of various sizes, some pedunculated, are seen in this patient who had been treated for kala-azar over a period of 6 months, 20 years previously. *With permission from Peters W, Pasvol G. Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

SYSTEMIC FEATURES OF VISCERAL LEISHMANIASIS (*L. DONOVANI*)			
Clinical features	**Proportion affected (%)**	**Clinical features**	**Proportion affected (%)**
Age <9 years	20 (*L. infantum* and *L. infantum chagasi* more commonly affect children and infants)	Age <15 years	45
Fever	85–100	Wasting	70–100
Loss of appetite	60–75	Cough	70–85
Epistaxis	45–55	Diarrhea	25–55
Vomiting	2–35	Jaundice	2–7
Splenomegaly	90 (adults); >95 (children)	Hepatomegaly	55–65
Lymphadenopathy	55–85 (uncommon outside of Africa)	Edema	2–7
Laboratory findings			
Globulin >30 g/l	95	Albumin <30 g/l	90
Anemia	60–90	Leukopenia	85
Thrombocytopenia	75	Elevated bilirubin	15
Elevated liver transaminases	20	Elevated alkaline phosphatase	40
Positive *Leishmania* serology	95	Parasitologically proven	95

Table 83.4 Systemic features of visceral leishmaniasis *(L. donovani)*. The duration of symptoms is usually 2 to 4 months, but it is typically shorter in children. *With permission from Davidson RN. Leishmaniasis. In: Cohen J, Powderly WG (eds). Infectious Diseases. Edinburgh: Mosby, 2004.*

Visceral leishmaniasis (kala-azar)

Visceral leishmaniasis, or kala-azar, occurs when the parasite spreads to the bone marrow, spleen, and liver[3]. It is primarily caused by *L. donovani* in adults and *L. infantum* or *L. infantum chagasi* in children (see Fig. 83.2). The incubation period ranges from 1 to 36 months. Fever, wasting, cough, lymphadenopathy, and hepatosplenomegaly are the most common systemic findings (Table 83.4). There may be an abrupt onset or slow progression, and fever may be continuous or intermittent. Additional complications include enteritis, oronasal or gastrointestinal hemorrhage, pneumonia, and nephritis, which may lead to death[20]. Cutaneous manifestations may be disease-specific papules, nodules, or ulcers at infected sites as well as nonspecific findings such as purpura, hyperpigmentation, xerosis, and kwashiorkor-like hair discoloration.

Post-kala-azar dermal leishmaniasis develops as a sequela of untreated or treated visceral leishmaniasis (Fig. 83.11)[3]. This form of cutaneous leishmaniasis is most commonly seen in Sudan and India, where it occurs in 50% and 10% of patients cured of visceral leishmaniasis, respectively[23]. Onset may be up to 20 years after treatment[23]. Skin findings include hypopigmented macules, malar erythema, skin-colored nodules, and verrucous papules[24].

Leishmaniasis and HIV

Co-infection of HIV and leishmaniasis can alter the progression and presentation of leishmaniasis, especially the visceral form (see Ch. 78)[25]. HIV infection increases the risk of developing visceral leishmaniasis 100- to over 2000-fold, with the prevalence of visceral leishmaniasis ranging from 4% to >15% among HIV-infected patients who live in *Leishmania*-endemic areas[25]. Co-infection often results in an atypical clinical presentation, reduced therapeutic response, and increased mortality. Chronic immune activation from the *Leishmania* infection may lead to increased HIV load and accelerated progression of AIDS, while the immunosuppressed state from the HIV infection creates an ideal environment for parasitic growth[24].

Pathology

Histologically, cutaneous lesions typically show ulceration, pseudoepitheliomatous hyperplasia, and a mixed inflammatory infiltrate composed of histiocytes, lymphocytes, plasma cells, and neutrophils. Amastigotes present within dermal macrophages, especially those in the papillary dermis (Fig. 83.12), are evident in ~50% of skin biopsies. Over time, lesions develop an increasing number of giant cells and fewer parasites; in longstanding cutaneous leishmaniasis, tuberculoid granulomas with caseation necrosis may be observed. In the cicatricial stage, the epidermis becomes flattened and hyperpigmented in areas with dermal fibrosis. Identical changes are seen in mucosal lesions. In diffuse cutaneous leishmaniasis, numerous amastigotes are present within foamy histiocytes; in contrast, the disseminated form features a primarily lymphoplasmacytic infiltrate with few amastigotes. The parasite can be detected in the lymph nodes, bone marrow, and spleen in patients with visceral leishmaniasis.

Diagnosis

The diagnosis of cutaneous leishmaniasis can be confirmed by demonstrating the presence of amastigotes in dermal macrophages within skin biopsy specimens, tissue impression smears (touch preparations), and smears obtained by dermal scraping or needle aspiration of skin lesions[2,20,26]. Although routine hematoxylin and eosin staining allows the visualization of the amastigotes, Giemsa, Wright, or Feulgen stains can help to identify the organisms in smears and tissue: the cytoplasm appears blue, the nucleus pink, and the kinetoplast a deep red[20]. CD1a immunostaining can also highlight the amastigotes, but its positivity may vary depending on the species (Fig. 83.12, inset)[27]. The edge of a relatively new ulcer is the location of choice for obtaining dermal scrapings, a biopsy specimen, or a needle aspirate; the latter two types of samples may be used for culture and all three types for polymerase chain reaction (PCR)-based assays (see below)[3,26].

In longer-standing lesions of leishmaniasis, parasites may be scarce. In this context, the delayed skin reaction test (Montenegro skin test or

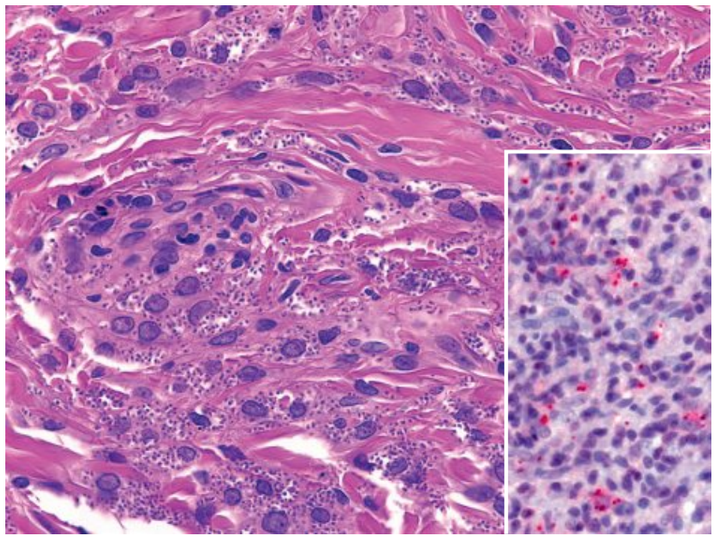

Fig. 83.12 Histopathology of leishmaniasis. Parasitized macrophages that contain amastigotes are seen in the dermis and highlighted by CD1a immunostaining (inset). Each amastigote has a nucleus and kinetoplast (not always visible) at opposite poles. *Courtesy Luis Requena, MD; inset, courtesy Lorenzo Cerroni, MD.*

Leishman reaction), which uses leishmanial antigens to induce a cell-mediated response, has traditionally been an important diagnostic tool. A phenolated suspension of killed promastigotes is injected intradermally, usually on the volar aspect of the forearm. The test is considered positive if a papule >5 mm in diameter forms at the site of inoculation after 48–72 hours (see Fig. 83.6)[20]. It is positive in up to 90% of patients with cutaneous and mucocutaneous leishmaniasis of over 3 months duration[3] and is invariably negative in patients with diffuse cutaneous (anergic) leishmaniasis[20]. However, this test (which is not approved by the US Food and Drug Administration [FDA]) cannot distinguish between past and present infection, so it is most useful in patients who do not reside in areas where leishmaniasis is endemic; positivity develops while the skin lesions are still active, and the test remains positive long after spontaneous cure. The test is usually negative during the febrile phase of visceral leishmaniasis, but it often becomes positive after cure.

For culturing *Leishmania*, specialized media are required, e.g. Nicolle–Novy–MacNeal (NNM) media or chick embryo media. Cultures are positive in ~40% of cases. Serologic and immunologic tests are also available, e.g. indirect immunofluorescence, ELISA, immunoprecipitation, and isoenzyme electrophoresis. Serologic testing is most useful for visceral and occasionally mucocutaneous disease, although it is not specific due to cross-reactivity (e.g. with Chagas disease antibodies)[28]. PCR-based methods represent the most sensitive and specific diagnostic tests, and their availability is increasing[2,20]. The combination of PCR (heat shock protein 70, mini-exon) with histopathology increases sensitivity to >90%. Of note, an FDA-approved real-time PCR assay for the diagnosis of leishmaniasis is available through the Centers for Disease Control and Prevention (CDC)[26].

Differential Diagnosis

The differential diagnosis of *cutaneous* leishmaniasis includes persistent arthropod bite reaction, basal cell carcinoma, tuberculosis, non-tuberculous mycobacterial infections, and subcutaneous mycoses; other infectious causes of lesions in a lymphocutaneous pattern are listed in Table 77.17. *Mucocutaneous* leishmaniasis can resemble paracoccidioidomycosis and tertiary syphilis. In addition, granulomatosis with polyangiitis and angiocentric NK/T cell lymphoma should be considered when ulcerative mucocutaneous lesions affect the central part of the face. Cocaine-induced nasal ulcerations can also mimic the mucosal involvement of leishmaniasis. Histologic examination allows distinction among these diseases[22]. The histologic differential diagnosis includes other infections characterized by parasitized macrophages (see Table 77.18) and neoplasms such as squamous cell carcinoma when pseudoepitheliomatous hyperplasia is present. The morphology and distribution of *diffuse cutaneous* leishmaniasis can mimic the lepromatous form of Hansen disease; however, in leishmaniasis the eyebrows are spared and the lesions are usually less infiltrative[20].

CLINICAL CHARACTERISTICS DIFFERENTIATING SIMPLE AND COMPLEX FORMS OF CUTANEOUS LEISHMANIASIS (CL)

Simple CL	Complex CL or mucocutaneous leishmaniasis
Caused by *Leishmania* species not associated with mucosal leishmaniasis (ML)	Caused by *Leishmania* species with increased risk for ML* or acquired in an increased ML-risk region, especially the "mucosal belt" of Bolivia, Brazil, and Peru†
No mucosal involvement	Mucosal involvement
Lack of subcutaneous nodules or lymphadenopathy	Subcutaneous nodules‡ or regional lymphadenopathy
One or a few small (<1 cm diameter) lesions	≥5 lesions >1 cm in diameter, or an individual lesion ≥5 cm in diameter
Location feasible for local treatment	Location where local treatment is not feasible
Lesions in areas that are not cosmetically or functionally important	Lesions on face (especially eyelids or lips), ears, genitalia, fingers, toes, and skin overlying joints
Immunocompetent host	Immunocompromised host, especially if affecting cell-mediated immunity
Lesion(s) resolving without therapy	Clinical failure of local therapy

*High-risk species for ML in the *Viannia* subgenus (*L. braziliensis* complex): *L. braziliensis, L. guyanensis and L. panamensis.* In general, systemic treatment is offered for infections with these species.
†The highest risk region for ML is south of the Amazon basin in Bolivia, Brazil, and Peru; moderate risk regions extend south of Nicaragua to the Amazon basin, and low risk regions are endemic areas north of Costa Rica. Areas of the Amazonian basin up to an altitude of 2000 meters are considered as increased ML-risk regions.
‡There is ongoing controversy regarding whether systemic therapy is necessary for Old World CL presenting with a few small subcutaneous nodules.

Table 83.5 Clinical characteristics differentiating simple and complex forms of cutaneous leishmaniasis (CL). Patients at risk for mucosal leishmaniasis (ML) based on the geographic region where the infection was acquired or the organism identified should be questioned about mucosal symptoms and undergo examination of the nasal and oropharyngeal mucosa; referral for otorhinolaryngologic evaluation is indicated for those with signs or symptoms of mucosal disease. Systemic treatment is generally required for complex CL, whereas local therapy or, if the lesions are healing spontaneously within 6 months, observation are options for patients with simple CL. Systemic therapy is also necessary for disseminated or diffuse cutaneous leishmaniasis as well as leishmaniasis recidivans. *Modified from Aronson N, Herwaldt BL, Libman M, et al. Diagnosis and Treatment of Leishmaniasis: Clinical practice guidelines by the Infectious Diseases Society of America (IDSA) and the American Society of Tropical Medicine and Hygiene (ASTMH). Clin Infect Dis 2016;63:1539–57.*

Treatment

Factors to consider in the treatment of leishmaniasis include the region of the world in which the infection was acquired, the species of *Leishmania*, the site(s) and severity of the infection, and host factors such as immune status and age (Table 83.5). The benefits of therapy need to be balanced with the goal of minimizing drug toxicity. Without treatment, Old World cutaneous leishmaniasis typically resolves within 2–4 months (*L. major*) or 6–15 months (*L. tropica*). Indications for systemic treatment of Old World cutaneous leishmaniasis include: (1) an immunocompromised host; (2) ≥5 lesions of substantial size (e.g. >1 cm) or individual lesion(s) measuring ≥5 cm; (3) enlarged regional lymph nodes; and (4) involvement of the mucosa, face, ears, genitalia, fingers, toes, or skin overlying a joint[29–31]. For patients who do not meet these criteria, either observation, if the lesions are healing spontaneously within 6 months, or local therapy are options.

New World cutaneous leishmaniasis caused by *L. mexicana* resolves within 3 months in >75% of cases. In contrast, cutaneous disease caused by *L. braziliensis* and *L. panamensis* spontaneously heals in less

than 10% and 35% of cases, respectively. Therefore, systemic treatment is indicated when *L. braziliensis* complex infection is suspected in order to accelerate healing, decrease scarring (especially in cosmetically sensitive sites), and prevent dissemination, relapse, or the development of mucosal or diffuse disease (see Table 83.5)[31].

Both parenteral pentavalent antimonials and miltefosine are first-line systemic treatments for cutaneous and mucocutaneous/mucosal leishmaniasis. While miltefosine is a less toxic therapy, its use can be limited by cost. Liposomal amphotericin B is the treatment of choice for visceral leishmaniasis[29,31]. Table 83.6 summarizes treatment regimens for cutaneous and mucocutaneous/mucosal leishmaniasis[31–37]. Table 83.7 lists frequent adverse reactions to drugs used for the treatment of leishmaniasis. The addition of oral pentoxifylline to antimonial therapy has been utilized for refractory mucocutaneous leishmaniasis and is included as an alternative treatment by the Pan American Health Organization, although RCTs have not consistently shown a benefit[38,39]. Additional interventions that have demonstrated some efficacy for cutaneous or mucocutaneous/mucosal leishmaniasis (in combination with other agents) include thermotherapy, cryotherapy, photodynamic therapy, and allopurinol[40].

Drugs or vaccines that completely prevent leishmanial infection have not yet been developed. The best form of protection is to avoid the bite of the sandfly and eliminate animal reservoirs. Personal protection includes applying DEET-based repellants, bed netting, permethrin-treated clothing, and sleeping in minimal-risk areas. People are at increased risk of bites in the early morning and late evening[32].

CUTANEOUS DISEASES CAUSED BY AMEBAS

Amebas (ameboid protozoa) are single-celled eukaryotes characterized by movement via pseudopodia (temporary cytoplasmic extensions). Organisms in this group that can produce cutaneous disease include enteric pathogens (e.g. *Entamoeba histolytica*) and free-living amebas such as *Acanthamoeba* spp. and *Balamuthia mandrillaris*. *E. histolytica* has a worldwide distribution and may infect the skin via inoculation or extension from the gastrointestinal tract. *B. mandrillaris* and *Acanthamoeba* spp. can cause skin infections and granulomatous encephalitis in immunocompromised and (for *B. mandrillaris*) immunocompetent patients. Acanthamebiasis may present with papules, nodules, and ulcers in the setting of profound immunosuppression, including those with advanced HIV infection (see Ch. 78).

Amebiasis Due to *Entamoeba histolytica*

Key features

- Amebiasis due to *Entamoeba histolytica* usually affects the gastrointestinal tract and rarely spreads to the skin
- The skin can become involved by extension of rectal amebiasis to the anus, perianal skin or vulva, as well as by a fistula from a liver abscess to the skin of the abdominal wall
- Cutaneous lesions are usually painful ulcers or verrucous plaques

Introduction

Amebiasis in humans is primarily a gastrointestinal infection caused by *Entamoeba histolytica*. However, there can be extraintestinal manifestations, including cutaneous involvement[41].

Epidemiology

E. histolytica infection results in ~50 million cases of invasive disease worldwide each year, causing 100 000 deaths annually[3]. Infection is associated with poor sanitation, crowded living conditions, and lower socio-economic status. In high-income countries, risk factors include a history of travel to or residence in high-prevalence areas, institutionalization, immunosuppression, and sexual behavior (especially men having sex with men). Humans are the reservoir for the disease, and an asymptomatic carrier may excrete up to 45 million cysts a day in the stool. Transmission of amebiasis is fecal–oral via contaminated hands, water, or food, and oral–anal sex.

TREATMENT RECOMMENDATIONS FOR LEISHMANIASIS		
Cutaneous leishmaniasis		
First-line systemic drugs	Miltefosine*	50 mg BID if weight is 30–44 kg and TID if weight is ≥45 kg × 28 days
	Sodium stibogluconate†	20 mg/kg/day IV or IM × 20 days Various intralesional regimens, e.g. 0.2–5 ml (5 sites/lesion intradermally for 0.1 ml/cm^2 until blanched) every 3–21 days for 5–8 sessions or until healing
	Meglumine antimonate†	
Alternatives	Paromomycin 15% plus MBCL 12% ointment	Topically BID × 10 days, wait 10 days, then repeat
	Paromomycin 15% plus gentamicin 0.5% cream	Topically daily for 20 days
	Pentamidine	3–4 mg/kg IV or IM every other day × 3–4 doses
	Fluconazole‡	200 mg/day or 6–8 mg/kg/day PO × 6 weeks
	Liposomal amphotericin B‡	3 mg/kg/day IV for a total dose of 20–40 mg/kg
	Amphotericin B deoxycholate	0.5–1 mg/kg IV daily or every other day for a total dose of 15–30 mg/kg
Mucocutaneous leishmaniasis		
First-line systemic drugs¶	Sodium stibogluconate†	20 mg/kg/day IV or IM × 28–30 days
	Meglumine antimonate†	
	Liposomal amphotericin B	<3 mg/kg/day IV for a total dose of 20–40 mg/kg
	Amphotericin B deoxycholate	0.5–1 mg/kg IV daily or every other day for a total dose of <20–45 mg/kg
	Miltefosine*	50 mg BID if weight is 30–44 kg and TID if weight is ≥45 kg × 28 days
Alternative	Pentamidine	2–4 mg/kg IV or IM every other day or 3 times per week for ≥15 doses; 4–7 mg/kg IV or IM every 72 hours x 3 doses

*FDA-approved for the treatment of cutaneous and mucosal leishmaniasis due to *L. braziliensis*, *L. guyanensis*, and *L. panamensis* in patients ≥12 years of age.
†Doses refer to mg of pentavalent antimony – 100 mg/ml for sodium stibogluconate (Pentostam®), 85 mg/ml for meglumine antimonate (Glucantime®).
‡Limited evidence of efficacy; other azole antifungals that have been utilized (with variable results) include itraconazole (7 mg/kg/day PO × 3 weeks).
¶In patients with severe mucosal disease or HIV co-infection, liposomal amphotericin B or amphotericin B deoxycholate are considered first-line therapy.

Table 83.6 Treatment recommendations for leishmaniasis. The treatment regimen (drug, dose, duration) that is chosen depends upon the geographic region, species of *Leishmania*, location and severity (e.g. number and size of lesions) of disease, and host factors. The Centers for Disease Control and Prevention (CDC), World Health Organization (WHO), and Pan-American Health Organization (PAHO) represent resources for up-to-date information. Sodium stibogluconate is not approved by the US Food and Drug Administration (FDA), but it is available from the CDC; meglumine antimonate and paromomycin are not readily available in the US. The use of pentoxifylline in addition to stibogluconate is included as an alternative treatment regimen for mucocutaneous disease by the PAHO. Inpatient monitoring and prophylactic corticosteroid administration are typically required for patients with laryngeal/pharyngeal disease. BID, twice daily; IM, intramuscular; IV, intravenous; MBCL, methylbenzethonium chloride; PO, orally; TID, three times daily.

Pathogenesis

Once the cyst is ingested, it travels to the colon, where it becomes a trophozoite. Although trophozoites can be excreted, cysts represent the primary excreted form[41,42]. Infection of intestinal mucosa depends upon interaction of lectins on the surface of the ameba with mucin glycoproteins on the intestinal epithelium[43]. The main mechanism

ADVERSE EFFECTS OF THE MOST COMMONLY USED DRUGS FOR LEISHMANIASIS		
Drug	**Side effect**	**Incidence**
Intralesional pentavalent antimony	Localized pain, erythema, edema	25%–50%
Parenteral pentavalent antimony	Elevated amylase/lipase and/or LFTs (interrupt therapy if clinical pancreatitis)	>50%
	Myalgia, arthralgia, headaches, fatigue	25%–50%
	Abdominal pain/nausea	25%–50%
	Thrombocytopenia/leukopenia	<25%
	ECG changes (e.g. QT prolongation, ST-T wave changes) or cardiotoxicity	<25%
Miltefosine	Motion sickness	>50%
	Nausea (administer with high fat food to reduce), vomiting, and diarrhea	25%–50%
	Elevated serum creatinine	25%–50%
	Mildly elevated LFTs	<25%
	Teratogenicity*	>50%
Pentamidine	Nausea, vomiting, abdominal pain, and dysgeusia	>50%
	Hyperglycemia, hepatotoxicity, nephrotoxicity, cytopenias	<25%
	Cardiotoxicity (QT prolongation); infuse slowly to avoid hypotension	<25%

*Contraindicated during pregnancy. Contraception is required during administration and for 2 months after the drug is discontinued.

Table 83.7 Adverse effects of the most commonly used drugs for leishmaniasis. Side effects of amphotericin B can include fevers/chills, nausea/vomiting, nephrotoxicity, electrolyte abnormalities, and cytopenias (see Ch. 127). ECG, electrocardiogram; LFTs, liver function tests.

by which *E. histolytica* produces disease is through tissue lysis[42]. The trophozoites kill target cells upon direct contact, due in part to the release of proteolytic enzymes, e.g. cathepsin B and collagenase. The trophozoites also have the capacity to destroy neutrophils, resulting in release of their intracellular contents, which further contribute to the destruction of host tissues. The mechanisms of defense against *E. histolytica* include mucosal immune responses (e.g. antiamebic IgA antibodies), cell-mediated immune defense (e.g. cytotoxic T lymphocytes and production of lymphokines such as IFN-γ, which activate macrophages to kill the trophozoites), and non-immune defenses (e.g. production of mucus by colonic mucosa, inhibiting amebic adherence to and lysis of the mucosa).

Clinical features

Patients with symptomatic amebiasis due to *E. histolytica* typically develop colitis and present with abdominal pain, tenesmus, bloody diarrhea, and mucosal ulcerations[41]. Extraintestinal complications, which can occur from hematogenous spread via invasion through the gastrointestinal epithelium, include hepatic abscesses, empyema, and pericardial effusions[41,43]. The skin is affected in <1% of patients with amebiasis. Skin involvement occurs as a result of extension of rectal amebiasis to the anus, perianal skin, or vulva; spread to the abdominal wall from a colostomy or after surgical drainage of a liver abscess; or inoculation of the penis during anal intercourse. Primary cutaneous amebiasis via external inoculation is exceedingly rare but has been reported on the face[44,45].

Cutaneous lesions can present as verrucous plaques or ulcers with a gray–white necrotic base (Fig. 83.13). Ulcerative lesions are usually painful and somewhat oval in shape, with irregular borders and intervening areas of unaffected skin. Extensive tissue destruction is characteristic.

Pathology and diagnosis

Histologically, ulcerated lesions have central necrosis with adjacent pseudoepitheliomatous hyperplasia. Mixed inflammatory infiltrates are present in the dermis and can extend into the subcutaneous tissue.

Fig. 83.13 Cutaneous amebiasis. Multiple large ulcers on the leg of a patient with amebiasis. Note the extensive tissue destruction and resemblance to pyoderma gangrenosum. *Courtesy Omar P. Sangüeza, MD.*

Within the ulcerated and necrotic areas, it is possible to identify the trophozoites of *E. histolytica*. They have ample, finely granular eosinophilic cytoplasm, eccentric nuclei, and prominent nucleoli, and some may contain phagocytized red cells. Chronic lesions show prominent irregular epidermal hyperplasia and inflammatory infiltrates, with few organisms present. Touch and wet drop preparations from the pus may also be utilized to identify the trophozoite[3]. Examination of fresh stool has a low yield for demonstrating the trophozoite, and multiple stool samples must be obtained[41]. Where available, PCR may be used for detection. Once the diagnosis is established, evaluation of other body sites for involvement is recommended.

Differential diagnosis

A diagnosis of amebiasis should be considered in patients with painful anogenital ulcers. In high-income countries, a patient with colitis and necrotic cutaneous ulcers is more likely to have inflammatory bowel disease-associated pyoderma gangrenosum. Other infectious causes of skin ulcers, e.g. streptococci, dimorphic or opportunistic fungi, tuberculosis and mixed bacterial flora (phagedenic or tropical ulcer), should be excluded. Verrucous lesions in the anogenital region may be confused with condylomata acuminata and squamous cell carcinoma.

Treatment

Oral metronidazole is the drug of choice for amebiasis due to *E. histolytica*: for adults, 500–750 mg three times daily for 7–10 days and for children, 35–50 mg/kg/day divided into three doses for 10 days. Other medications that have been used include diloxanide, tinidazole, pentamidine, and iodoquinol[30,43].

Balamuthia mandrillaris Infection

Key features

- *B. mandrillaris* is a free-living ameba that causes a rare, usually fatal encephalitis in immunocompetent individuals
- Skin infection presents weeks to months prior to hematogenous spread to the central nervous system (CNS)
- Slowly growing, indurated plaques favor the central face and occur less often on the extremities

Introduction

B. mandrillaris is a free-living ameba that can infect the skin and subsequently lead to fatal encephalitis.

Epidemiology

At least three genera of free-living amebas cause disease in humans, including *Naegleria*, *Acanthamoeba*, and *Balamuthia*[46]. These amebas

are found worldwide in the soil and (especially for the former two organisms) fresh water. Cutaneous infection with *B. mandrillaris* or *Acanthamoeba* spp. may precede development of granulomatous encephalitis. Such infections may be acquired from exposure of microabrasions or open wounds in the skin to soil and water sources; encephalitis can also result from infection of the nasal/respiratory mucosa via inhalation. *Naegleria fowleri* infection can cause acute, fatal encephalitis but is not known to have skin manifestations.

Although uncommon, *B. mandrillaris* has increasingly been recognized as a cause of encephalitis, with >100 cases reported in the US[47]. Most affected individuals reside in warmer regions, including Latin America and the southern US[48]. Unlike *Acanthamoeba* infections, which only affect immunocompromised patients, most *B. mandrillaris* infections occur in immunocompetent individuals, favoring children as well as the elderly; the male : female ratio is <2–3 : 1[48,49]. In addition, nearly 50% of the *B. mandrillaris* infections identified in the US have been in individuals of Hispanic ethnicity[50,51]. Transmission of *B. mandrillaris* via solid organ transplantation has also been described[52].

Pathogenesis

B. mandrillaris is a free-living ameba that can exist both as a dormant cyst and as an infectious trophozoite. Because *B. mandrillaris* can cause disease in immunocompetent hosts, it is thought to be more virulent than *Acanthamoeba*. However, clinically unaffected individuals have been shown to have antibodies against *B. mandrillaris*[53]. The presence of predisposing factors such as local disruption of the skin or mucosal barrier is likely required for infection. The trophozoites feed on human cells and can spread to the CNS hematogenously[54].

Clinical features

B. mandrillaris causes a subacute to chronic granulomatous encephalitis that has a mortality rate of >80%[49,55]. In a subset of patients, CNS involvement is preceded by the development of a slowly expanding, indurated, asymptomatic plaque on the central face or less often other sites such as an extremity (especially around the knee), the gluteal area, or the oral mucosa (Fig. 83.14)[46]. A skin lesion may be present for 5–8 months before the organism disseminates to the CNS[3]. As the plaque enlarges, it may become infiltrative (Fig. 83.14B) and occasionally ulcerates. Although there is usually a single skin lesion, local "satellite" lesions or involvement of multiple sites can occur. Neurologic manifestations are similar to those in other forms of meningoencephalitis and include headache, altered mental status, cranial nerve dysfunction, and seizures; however, the symptoms may have an insidious onset and chronic course.

Pathology and diagnosis

The diagnosis of *B. mandrillaris* infection is often made at autopsy or by skin biopsy[3]. In the dermis of affected skin, there is a mixed granulomatous infiltrate with many giant cells, but usually few identifiable trophozoites[56]. Immunohistochemical staining or PCR-based analysis of skin specimens can provide definitive diagnosis[57]. Culture and isolation of *B. mandrillaris* requires a complex medium containing fetal bovine serum or a specialized cell type (e.g. monkey kidney cells, human lung fibroblasts)[57]. Examination of the cerebrospinal fluid (CSF) may show motile amebic trophozoites with pseudopodia formation. Brain imaging in patients with advanced disease reveals calcified, mass-like lesions[58].

Treatment

Considering the poor prognosis of *B. mandrillaris* encephalitis, early diagnosis when the disease is limited to the skin is critical. Multiagent therapy for a prolonged period (e.g. 12 months) is recommended, with reported regimens including miltefosine with various combinations (2–5 drugs) of pentamidine, sulfadiazine, flucytosine, an azole antifungal, liposomal amphotericin B, a macrolide antibiotic (clarithromycin or azithromycin), and albendazole[55,58,59]. However, controlled trials are lacking. Surgical excision of cutaneous lesions should also be considered when possible[59].

TRYPANOSOMIASIS

Synonyms: ■ Chagas disease: American trypanosomiasis, Chagas–Mazza disease ■ African trypanosomiasis: African sleeping sickness

Although the genus *Trypanosoma* consists of at least 20 species of protozoa, only two are known to cause human disease. Chagas disease (American trypanosomiasis) is caused by *T. cruzi* infection and transmitted by reduviid bugs, while African trypanosomiasis is caused by *T. brucei* infection and transmitted by tsetse flies.

Chagas Disease

Key features

- An endemic disease in many areas of Central and South America
- Transmission of *T. cruzi* is via infected reduviid bugs and occasionally by contaminated blood
- A serious systemic disease with three phases (acute, indeterminate, and chronic). The chronic phase primarily affects the heart and gastrointestinal tract
- Following inoculation of the parasite into the skin, localized erythema and edema (chagoma) can develop in conjunction with regional lymphadenopathy
- When the conjunctiva is the portal of entry, edema of the palpebral and periocular tissue is seen (Romaña sign)

Epidemiology

T. cruzi and its arthropod vectors (reduviid or kissing bugs) are found in the Americas, from the southern US to southern Argentina (Fig. 83.15)[60]. Reduviid bugs feed mainly on human, animal, or avian blood, but they sometimes engage in cannibalism or coprophagia, which may result in vector-to-vector transmission of *T. cruzi*. A favorite habitat for these bugs is cracks in the walls of mud huts in poor rural areas, and they are known as kissing bugs because of their habit of biting the face of humans. Direct transmission of *T. cruzi* via transfusion of contaminated blood can occur; since 2007, blood donated in the US has been screened for this organism[61]. In addition, transplacental transmission can result in congenital infection.

Fig. 83.14 ***Balamuthia mandrillaris* infection. Fig. 83.16 Life cycle of *Trypanosoma cruzi*. *Adapted with permission from Keusch GT. Host response to infection. In: Cohen J, Powderly W (eds). Infectious Diseases, 2nd edition. London: Mosby, 2004.*

It is estimated that ~6 million people in the Americas are infected with *T. cruzi*, including <300 000 individuals in the US, especially immigrants from Latin America living in Texas and California[62,63]. Chagas disease kills ~10 000 people per year[64], mostly in rural areas of Latin America; it represents the leading cause of parasitic death in Latin America and the third leading cause in the world. The acute form of the disease (see below) is seen more commonly in children, and, in some areas, 85% of children under the age of 10 years are infected.

Pathogenesis

Blood-sucking reduviid bugs ingest trypomastigotes from the peripheral blood of vertebrate hosts (Fig. 83.16). Once the bug has become infected, it remains so for the rest of its life. The parasites transform into epimastigotes and multiply in the bug's midgut, later becoming metacyclic trypomastigotes in its hindgut. When the infected bug takes a subsequent blood meal, it usually defecates during or after feeding, depositing infective metacyclic trypomastigotes on the skin. The parasites penetrate the skin (generally via the bite wound) or mucosa (usually the conjunctiva). Following invasion of the host's cells, amastigotes multiply within the cytoplasm and then develop into trypomastigotes. The latter are released when the cells rupture and then can either infect other cells or enter the bloodstream, where they become the source of infection for new vectors. *T. cruzi* can also be transmitted transplacentally as well as through blood transfusions, organ transplantation, laboratory accidents, and occasionally contaminated food.

The autonomic nervous system that innervates the heart and gastrointestinal tract appears to be a primary target of *T. cruzi* infection. The visceral involvement seen in the chronic stage (see below) is thought to reflect neuronal damage during the acute phase. A role for autoimmunity in the chronic phase of the disease has also been hypothesized. In addition, trypomastigotes have the ability to penetrate the smooth muscle of the heart and the wall of the gastrointestinal tract[65].

Clinical features

Chagas disease has acute and chronic phases with distinct clinical manifestations. Although the acute phase can affect individuals of any age, it is usually observed in children and tends to be more severe in those ≤2 years of age[66]. At the cutaneous site of parasitic entry (see Fig. 83.16), some patients develop a chagoma, which is a localized area of erythema and swelling that is often accompanied by regional lymphadenopathy. When the conjunctiva is the portal of entry, the painless edema of the palpebral and periocular tissues that appears is referred to as the Romaña sign or ophthalmoganglionar complex (Fig. 83.17)[3]. The Romaña sign occurs in ~80% of individuals infected by this route. In some patients, the swelling is accompanied by preauricular lymphadenopathy (Parinaud sign)[60].

Fig. 83.17 Chagas disease. Young child with unilateral periorbital edema characteristic of this disease (Romaña sign) when the conjunctiva is the portal of entry. *Courtesy Omar P. Sangüeza, MD.*

These initial clinical findings can be accompanied by fever, malaise, anorexia, and edema of the face and lower extremities. Some patients develop erythematous macules, hepatosplenomegaly, thrombocytosis, leukocytosis, and/or eosinophilia. The acute phase may last for up to 2 months but usually resolves spontaneously. In addition, inflammation at the sites of parasite entry can persist for several weeks[60]. Occasionally, patients develop life-threatening myocarditis or meningoencephalitis[65].

After resolution of the acute phase, patients enter the indeterminate phase of Chagas disease. This stage is characterized by asymptomatic parasitemia and positive serology. Then, many years or even decades after the initial infection, 30% of patients develop symptoms of chronic Chagas disease[66]. The heart is the organ most commonly affected and the clinical manifestations include congestive heart failure, arrhythmias,

and heart block[65]. The gastrointestinal tract is also frequently involved, leading to megacolon and megaesophagus.

If patients who chronically harbor *T. cruzi* become immunosuppressed, reactivation of the disease can occur. When this happens, the disease is often more severe than in typical cases of Chagas disease, and patients may develop nodules and plaques that favor the lower extremities[60,66].

Pathology

Histologically, at the site of parasite entry (chagoma), there is interstitial edema and a mononuclear cell infiltrate. Within cells in the subcutaneous tissue and muscle, aggregates of amastigotes may be seen. Enlarged lymph nodes are hyperplastic and intracellular amastigotes can be observed. In the chronic stage, trypanosomes are rare in affected organs.

Diagnosis and differential diagnosis

The diagnosis of *acute* Chagas disease is typically based upon the microscopic identification of either trypomastigotes in the blood (or CSF) or amastigotes within tissue. Because the concentration of parasites is low even in the acute stage, hemoconcentration techniques are used to enhance the yield. PCR currently represents the most sensitive diagnostic method for acute disease, with positive results days to weeks earlier than microscopy; PCR is especially useful for the diagnosis of infections acquired vertically, via organ transplantation, or after laboratory exposure[67,68]. Cultures of blood, CSF, or tissue are less sensitive for detection of acute *T. cruzi* infection.

Serologic tests such as ELISAs and immunofluorescent antibody assays (IFAs) are used to establish the diagnosis of *chronic* Chagas disease. PCR-based detection has variable sensitivity and limited utility for chronic Chagas disease, although it may serve as an indicator of treatment failure or disease reactivation[63]. Xenodiagnosis represents a specific and fairly sensitive (≤50%) method, and it can be used to confirm a serologic diagnosis[60]; however, this technique is expensive and is only available in large laboratories in endemic areas. For xenodiagnosis, trypanosome-free reduviid bugs are allowed to feed on patients and the feces or hindgut contents of the bugs are examined for epimastigotes 10 to 30 days later.

The nonspecific symptoms that may occur during the acute phase of Chagas disease, such as a macular eruption and influenza-like symptoms, make the differential diagnosis broad. When the site of inoculation is the eye, other entities to consider include a reaction to a bite from another type of insect, angioedema, and bacterial cellulitis.

Treatment

Treatment is most effective early in the course of Chagas disease[67]. Benznidazole and nifurtimox (both available through the CDC) can reduce the severity and duration of symptoms associated with the *acute* phase, with a parasitologic cure in 60%–90% of patients[63,69]. Because benznidazole is better tolerated, it is favored by most experts[63]. The side effects of these two medications are reviewed in Table 83.8.

Benznidazole, allopurinol, itraconazole, and posaconazole have also been evaluated for the treatment of *chronic* Chagas disease[70–72].

ANTIHELMINTHIC DRUGS: THERAPEUTIC USES, SIDE EFFECTS, AND CONTRAINDICATIONS

Drug	Therapeutic use	Toxicity and side effects		Precautions and contraindications
		Direct drug effects	"Allergic" reactions	
Thiabendazole	Strongyloidiasis, cutaneous larva migrans (second-line therapy), dracunculiasis	• GI: nausea, vomiting, anorexia > diarrhea, abdominal pain > elevated transaminases, cholestasis • Neurologic: dizziness, drowsiness > headache, paresthesias, weakness > tinnitus, seizures, hallucinations • Ocular: irritation, blurred vision, xerophthalmia • Other: crystalluria without hematuria, transient leukopenia, xerostomia	• Cutaneous: urticaria (3%), exanthem (<5%) > fixed drug eruption, pruritus, perianal rash, flushing, angioedema, contact dermatitis, Jarisch–Herxheimer reaction, Stevens–Johnson syndrome • Fever, anaphylaxis	• Use in pregnancy if benefits outweigh risks • Discontinue during lactation • Use with caution if hepatic disease
Mebendazole	GI nematode infections (e.g. enterobiasis, ascariasis, ancylostomiasis), toxocariasis, trichinosis, sparganosis	• GI: nausea, vomiting, diarrhea, abdominal pain > elevated transaminases • Neurologic: dizziness, drowsiness > tinnitus, seizures • Hematologic: anemia, thrombocytopenia, leukopenia > agranulocytosis • Other: alopecia, oligospermia	• Cutaneous: exanthem, urticaria, angioedema, pruritus, flushing	• Use in pregnancy if benefits outweigh risks • Use with caution in children <2 years of age
Albendazole	Cutaneous larva migrans, GI nematode infections (as above), gnathostomiasis, echinococcosis, neurocysticercosis, toxocariasis	• GI: nausea, vomiting, diarrhea, abdominal pain, elevated transaminases > cholestasis • Neurologic: headache, dizziness > increased intracranial pressure (with treatment of neurocysticercosis), seizures • Hematologic: leukopenia > thrombocytopenia, agranulocytosis, pancytopenia • Other: alopecia	• Cutaneous: exanthem, urticaria > angioedema, Stevens–Johnson syndrome • Fever, anaphylaxis	• Use in pregnancy if benefits outweigh risks; avoid during first trimester • Avoid during lactation • Use with caution if hepatic disease
Diethylcarbamazine	Filariasis, dirofilariasis, loiasis, toxocariasis (second-line therapy)	• GI: nausea, vomiting, anorexia • Neurologic: headache	• Mazzotti reaction: pruritus, lymphadenopathy > papular exanthem, fever, tachycardia, arthralgias, headache • Nodular swellings along the lymphatics • Leukocytosis, eosinophilia • Ocular: limbitis, punctate keratitis > uveitis, atrophy of the retinal pigment epithelium > retinal hemorrhage (*L. loa*) • Encephalitis (*L. loa*) • Proteinuria	• Appears to be safe for use during pregnancy (controlled studies show no fetal risk) • Avoid population-based administration in regions where onchocerciasis or loiasis is endemic

Table 83.8 Antihelminthic drugs: therapeutic uses, side effects, and contraindications.

ANTIHELMINTHIC DRUGS: THERAPEUTIC USES, SIDE EFFECTS, AND CONTRAINDICATIONS				
Drug	**Therapeutic use**	**Toxicity and side effects**		**Precautions and contraindications**
		Direct drug effects	**"Allergic" reactions**	
Ivermectin	Onchocerciasis, filariasis (second-line therapy), cutaneous larva migrans, gnathostomiasis, ascariasis, strongyloidiasis	• GI: nausea, vomiting, diarrhea, elevated transaminases > cholestasis • Neurologic: dizziness > drowsiness, headache, tremor • Other: leukopenia	• Mazzotti-like reaction and ocular side effects (*O. volvulus*; see above) • Pruritus, urticaria, peripheral edema • Orthostatic hypotension	• Use in pregnancy if benefits outweigh risks • Considered safe during lactation
Moxidectin	Onchocerciasis	• GI: nausea, vomiting, diarrhea • Neurologic: dizziness, headache • Other: musculoskeletal pain, leukopenia	• Mazzotti-like reaction and ocular side effects (see above) • Pruritus, urticaria, peripheral edema • Orthostatic hypotension • Encephalitis (*L. loa*)	• Limited data on use in pregnancy and lactation
Praziquantel	Schistosomiasis; liver fluke and tapeworm infections (e.g. cysticercosis, sparganosis)	• GI: nausea, vomiting, abdominal discomfort > bloody diarrhea, elevated transaminases • Neurologic: headache, dizziness > drowsiness • Other: arrhythmias	• Cutaneous: pruritus > urticaria, exanthem • Arthralgias, myalgias • Fever • Meningismus, CSF pleocytosis, seizures (in neurocysticercosis)	• Controlled studies in pregnant women have not shown adverse outcomes • Considered safe during lactation • Contraindicated for ocular cysticercosis
Levamisole	GI nematode infections (e.g. ascariasis, ancylostomiasis; second-line therapy)	• GI: nausea, vomiting, diarrhea, abdominal discomfort • Neurologic: headache > dizziness, insomnia, paresthesias > multifocal leukoencephalopathy • Hematologic: leukopenia, anemia, thrombocytopenia > agranulocytosis • Other: dysgeusia, xerosis, alopecia, arthralgias	• Cutaneous: exanthem (5%–10%) > pruritus, urticaria, angioedema, fixed drug eruption, lichenoid eruption, vasculitis/vasculopathy (favors the ears), Stevens–Johnson syndrome • Stomatitis (5%) • Fever, anaphylaxis	• Use in pregnancy if benefits outweigh risks • Considered safe during lactation
Nifurtimox	Chagas disease	• GI: nausea, vomiting, anorexia > abdominal pain, diarrhea • Neurologic: paresthesias, weakness, headache, insomnia > psychiatric disturbances, seizures • Other: myalgias > leukopenia, oligospermia	• Cutaneous: exanthem, urticaria, angioedema • Fever, anaphylaxis	• Use in pregnancy if benefits outweigh risks
Benznidazole	Chagas disease	• GI: nausea, vomiting, anorexia • Neurologic: paresthesias, weakness • Hematologic: leukopenia > thrombocytopenia, agranulocytosis • Other: myalgias	• Cutaneous (more common than with nifurtimox): exanthem, urticaria, angioedema, generalized peripheral edema • Fever, lymphadenopathy, anaphylaxis	• Use in pregnancy if benefits outweigh risks
Suramin	African trypanosomiasis	• GI: nausea, vomiting > diarrhea, abdominal pain, elevated transaminases, cholestasis • Neurologic: palmoplantar hyperesthesia/paresthesias, weakness, headache > seizures • Ocular: blepharitis, conjunctivitis, photophobia, excessive lacrimation • Hematologic: leukopenia > agranulocytosis, hemolytic anemia, thrombocytopenia • Other: malaise, dysgeusia, proteinuria > renal or adrenal insufficiency	• Cutaneous: exanthem, urticaria > exfoliative dermatitis, generalized peripheral edema • Stomatitis • Fever, anaphylaxis (1 : 2000)	• Use in pregnancy if benefits outweigh risks • Use with caution if renal disease
Eflornithine	African trypanosomiasis (*T. brucei gambiense*)	• GI: diarrhea (40%) > nausea, vomiting, abdominal pain • Neurologic: dizziness, headache, seizures (~5%) • Hematologic: anemia (50%) > leukopenia (25%) > thrombocytopenia • Other: alopecia > hearing loss	• Cutaneous: exanthem • Fever	• Use in pregnancy if benefits outweigh risks

Table 83.8 Antihelminthic drugs: therapeutic uses, side effects, and contraindications. Emodepside is currently in veterinary use and represents a candidate for onchocerciasis and infections with *Trichuris trichiura* and hookworms in humans. CSF, cerebrospinal fluid; GI, gastrointestinal.

Although these agents can decrease serum parasite load, to date, there is no evidence that pathologic changes or progression of the chronic phase of this disease can be reversed or stopped by any therapy. Thus, chronic disease is managed primarily by supportive care (e.g. antiarrhythmics)[65].

Prevention of the infection involves education about sanitation and the use of residual insecticides in domestic areas. Vaccines are being investigated but are not currently available. Cyanotriazoles, a new class of antiparasitic drugs that inhibit topoisomerase II, may be of utility for the treatment of trypanosomiasis and leishmaniasis.

African Trypanosomiasis

Key features

- In West Africa, the disorder is due to *Trypanosoma brucei gambiense* infection, and in East Africa it is caused by *Trypanosoma brucei rhodesiense* infection
- The vectors are several species of tsetse flies
- Cutaneous manifestations include a localized bite reaction ("trypanosomal chancre") and an annular erythematous eruption that coincides with fever spikes

Epidemiology

The incidence of African trypanosomiasis decreased from <10 000 cases in 2009 to ~750 in 2021[73]. This disease is almost invariably fatal if left untreated and occurs in two forms that are named based on their separate geographic distributions in Africa (see Fig. 83.15). The West African form, which is due to *Trypanosoma brucei gambiense* and accounts for >95% of cases, is a chronic anthroponotic disease with primarily neurologic features. Since 2020, elimination of West African trypanosomiasis has been achieved in several countries, including Togo, Côte d'Ivoire, Benin, Uganda, and Equatorial Guinea[73]. The East African form, caused by *Trypanosoma brucei rhodesiense*, is an acute zoonotic disease (with antelopes as a reservoir) that is often fatal even with treatment. Fortunately, *T. b. rhodesiense* only occasionally infects humans, mainly farmers, hunters, and tourists[74,75].

Both types of *T. brucei* are transmitted to humans by blood-sucking tsetse flies (genus *Glossina*), which are found in Africa. The flies become infected by ingesting blood from infected mammalian hosts (Fig. 83.18). Transmission transplacentally or via blood products may also potentially occur.

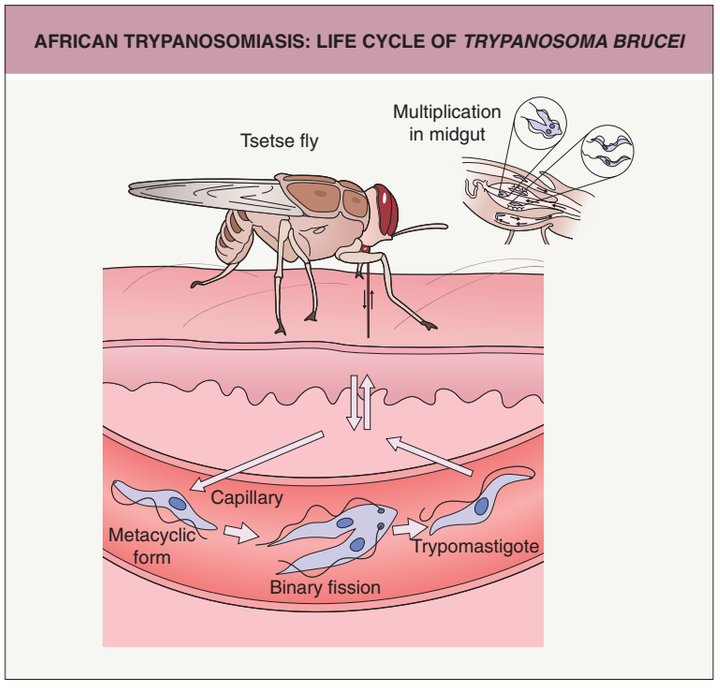

Fig. 83.18 African trypanosomiasis: life cycle of *Trypanosoma brucei*.

Pathogenesis

After inoculation, trypanosomes may produce a local chancre before spreading via the lymphatics to regional (and then distant) lymph nodes. The organisms disseminate to the bloodstream and eventually to the CNS, and they multiply by binary fission[76]. They escape significant immunologic response by continuously changing their surface glycoproteins[74,75].

Clinical features

An indurated, painful reaction develops at the portal of entry of the organisms, referred to as a "trypanosomal chancre" (Fig. 83.19). This is seen more commonly (70%–80% of cases) in the East African form due to *T. b. rhodesiense*[60]. The lesion appears 1–2 weeks after the tsetse fly bite and heals spontaneously over several weeks.

The *first (hemolymphatic) stage* occurs when the trypanosomes enter the lymphatic system and bloodstream 1–3 weeks after infection. Patients develop spiking fevers, malaise, and symmetrical lymphadenopathy. Enlargement of the lymph nodes of the posterior cervical triangle, referred to as the Winterbottom sign, is a classic finding in the West African form due to *T. b. gambiense*. Patients may have peripheral or facial edema, hepatosplenomegaly, and ascites[3]. A transient eruption (referred to as "trypanids") of annular and targetoid erythematous patches or urticarial plaques may occur in concert with fever spikes 6–8 weeks after onset of the illness. The eruption favors the trunk and while reported to occur in ~50% of patients is more easily noted in those with lighter skin phototypes[3,77].

The *second (meningoencephalitic) stage* of the disease is characterized by neurologic manifestations, including irritability, changes in personality, inability to concentrate, and daytime somnolence alternating with nighttime restlessness and insomnia, hence the term sleeping sickness[78]. Deep delayed hyperesthesia after a brisk tap or pinch (Kerandel sign) reflects CNS involvement[77]. CSF examination demonstrates lymphocytic pleocytosis and increased protein content; in some patients, trypanosomes are evident when the fluid is centrifuged.

East African trypanosomiasis tends to follow a more acute course with earlier onset of CNS symptoms, which are often delayed months to years in the West African variant, and the stages are not as well defined. In addition, East African trypanosomiasis may result in heart failure due to myocardial damage, even preceding CNS symptoms[79].

Pathology and diagnosis

Definitive diagnosis requires identification of the parasites in the skin, blood (especially the buffy coat), lymph node, or CSF. Routine histologic sections from skin lesions demonstrate a superficial perivascular lymphocytic infiltrate and mild spongiosis; trypanosomes are usually

Fig. 83.19 Trypanosomal chancre. The bite reaction, the earliest clinical lesion, is known as a "trypanosomal chancre". It resembles a boil but is usually painless. Fluid aspirated from the nodule contains actively dividing trypanosomes. This reaction is seen more commonly in *T. b. rhodesiense* than in *T. b. gambiense* infection. *With permission from Peters W, Pasvol G. Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

not seen. Serologic tests become positive about 2 weeks after the onset of infection[3]. PCR represents the most sensitive test[60], and a CRISPR-based assay suitable for point-of-care diagnosis has been developed.

Differential diagnosis

The differential diagnosis of the chancre includes infectious disorders such as extragenital primary syphilis and primary inoculation tuberculosis; entities that lead to an annular erythema are discussed in Chapter 19.

Treatment

According to current WHO guidelines, oral fexinidazole represents the treatment of choice for first and non-severe second (<100 leukocytes/mcl in CSF) stages of *T.b. gambiense* infection in patients ≥6 years of age weighing ≥20 kg[80]. In children <6 years of age or weighing <20 kg, pentamidine is recommended for the first stage and nifurtimox-eflornithine combination therapy (NECT) for the second stage. NECT is also indicated for severe second-stage disease (≥100 leukocytes/mcl in CSF) in older children and adults. For *T.b. rhodesiense* infections, suramin is utilized for the first stage and melarsoprol for the second stage[80].

TOXOPLASMOSIS

Key features

- A common, worldwide disease caused by the protozoan *Toxoplasma gondii*
- Cutaneous involvement is unusual but occasionally occurs in immunocompromised individuals, pregnant women, and neonates
- In congenital infections, the skin lesions are usually necrotic or hemorrhagic papules

Toxoplasma gondii is an intestinal coccidian parasite of domestic cats and other mammals (Fig. 83.20). *Toxoplasma* infections in humans can be acquired or congenital. In immunocompetent hosts, most infections are asymptomatic or produce only flu-like symptoms, with occasional development of lymphadenopathy or chorioretinitis. In immunosuppressed patients, more severe disease can occur[81]. Cutaneous manifestations are rare and may be seen in both congenital

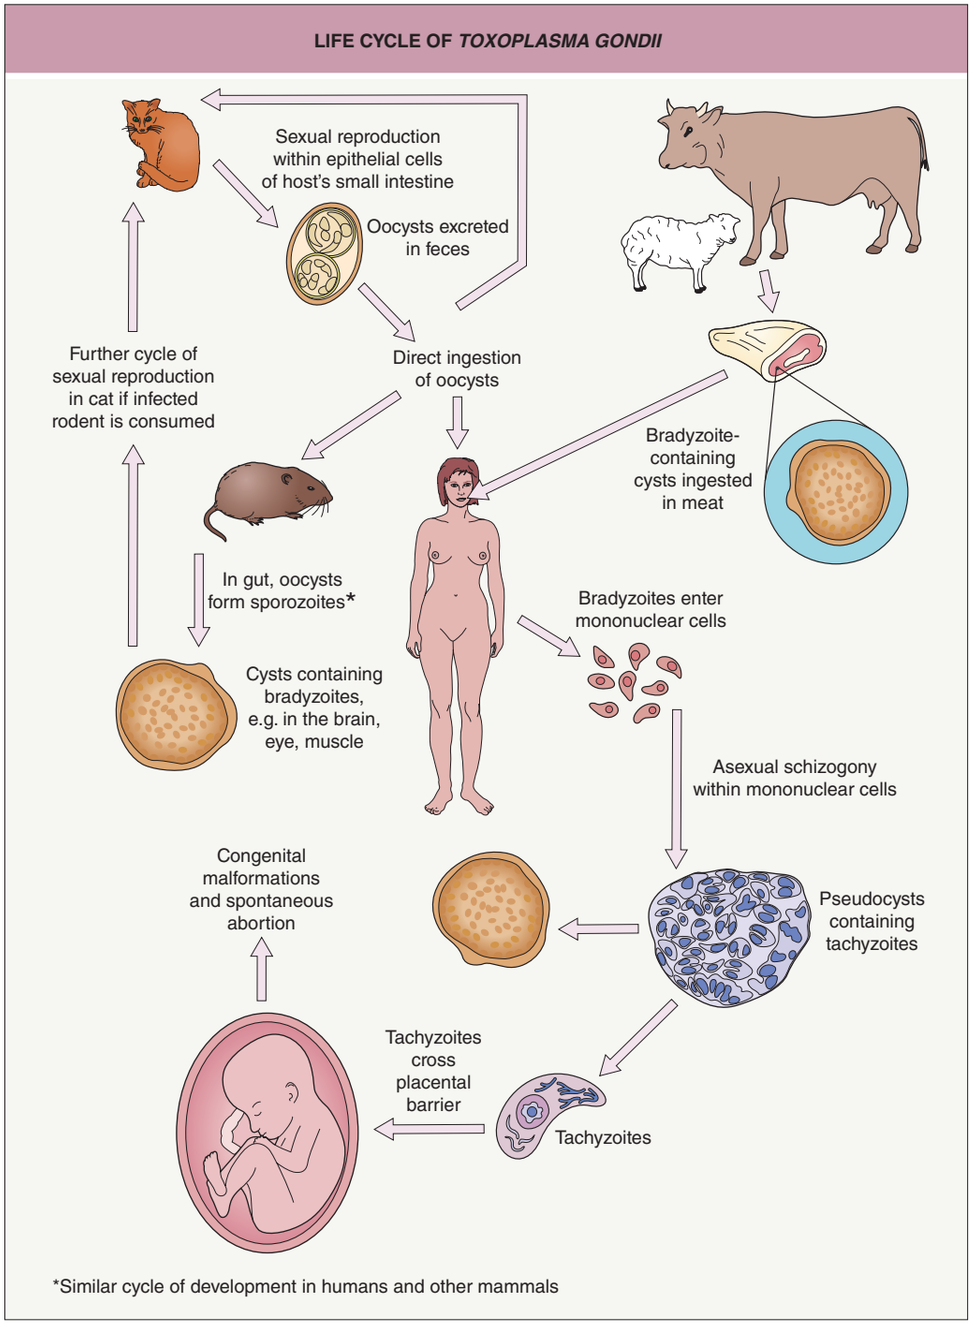

Fig. 83.20 Life cycle of *Toxoplasma gondii*. There is a wide range of mammalian hosts, the most important being the domestic cat. *Adapted from Peters W, Pasvol G. Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

TOXOPLASMOSIS	
Epidemiology	• *Toxoplasma gondii* is found worldwide • In the US, ~10%–15% of the population has antibodies against *T. gondii* • Congenital toxoplasmosis: 1 in 1000 (in Latin America) to <1 in 10 000 (in US) live births
Main definitive host	• Cats and wild felines
Route of infection	• Ingestion of bradyzoite-containing cysts within raw/undercooked meat (especially pork, lamb, and venison) • Ingestion of oocysts from cat feces (e.g. via contaminated soil or water) • Transplacental: more likely in the third trimester, more severe disease if in the first trimester • Organ transplantation or blood transfusion from an infected donor
Extracutaneous clinical features	• Acute acquired infection: asymptomatic (~90% of immunocompetent individuals) or lymphadenopathy and flu-like symptoms (e.g. fever, malaise, myalgias) • In immunocompromised individuals: encephalitis, pneumonitis, pericarditis, myositis, hepatitis • Chronic acquired infection: occasionally chorioretinitis • Congenital infection: asymptomatic (70%–90%) or variable chorioretinitis, deafness, microcephaly, hydrocephalus, seizures, developmental delay, hepatosplenomegaly, pneumonitis, fever, thrombocytopenia
Cutaneous manifestations	• Acquired infection: roseola-like exanthem, erythema multiforme-like eruption, papular urticaria; rarely erythroderma, sclerodermatous, dermatomyositis-like • Congenital: hemorrhagic or necrotic papules favoring the trunk
Skin histopathology	• Superficial and deep perivascular dermal infiltrates of lymphocytes, macrophages, plasma cells, and eosinophils; also dilated capillaries, foci of dermal hemorrhage, and occasionally small vessel vasculitis • Tissue forms of *T. gondii* – trophozoites within macrophage cytoplasm (singly or inside pseudocysts) – evident in <50% of biopsy specimens from lesional skin • Immunoperoxidase staining is very specific
Diagnosis	• *T. gondii* IgM and Ig in acute and convalescent sera • PCR-based assays can detect parasite DNA in blood, CSF, aqueous humor, and bronchoalveolar lavage fluid
Differential diagnosis	• Acquired infection: mononucleosis, other viral exanthems, meningococcemia, syphilis, erythema multiforme, autoimmune connective tissue diseases, urticarial vasculitis • Congenital infection: other TORCH infections (see Chs. 80 & 121)
Treatment for severe acute, active chronic, or congenital disease and in immunocompromised patients	• Pyrimethamine: in adults, a loading dose of 200 mg followed by 50–75 mg daily; in children, a loading dose of 2 mg/kg followed by 1 mg/kg/day Plus • Folinic acid Plus • Sulfadiazine (1–1.5 g q6h daily in adults and 100 mg/kg in two divided doses daily in children) • If sulfonamide allergic, can substitute clindamycin for sulfadiazine

Table 83.9 Toxoplasmosis.

and acquired forms of the disease[82]. The epidemiology, clinical features, diagnosis, and treatment of toxoplasmosis are presented in Table 83.9.

WORMS (HELMINTHS)

Medically important worms, or helminths, belong to two different phyla: Nematoda (roundworms) and Platyhelminthes (flatworms). The roundworms include free-living species as well as parasitic ones; they are unsegmented, and each species has two different sexes, a body cavity, and a digestive tract. The flatworms are primarily parasitic worms that do not have a body cavity; they can be segmented or unsegmented, and most species are hermaphroditic. Flatworms can be further subdivided into two different classes: trematodes or flukes (the cause of schistosomiasis) and cestodes or tapeworms (the cause of cysticercosis and echinococcosis). Several helminthic infections have been chosen for more detailed discussion in the remainder of the chapter, and additional disorders are outlined in Table 83.10.

Of note, an alternative way of classifying worms is by their life cycle[83]. This schema divides associated infections into four classes: (1) soil-transmitted infections, including those due to hookworms (e.g. ancylostomiasis, cutaneous larva migrans) and other nematodes (e.g. strongyloidiasis; Figs. 83.21 & 83.22); (2) infections transmitted mainly by insects, including onchocerciasis, filariasis, and loiasis (Fig. 83.23); (3) infections due to trematodes (flukes) whose life cycle involves snails, such as fascioliasis and schistosomiasis (Fig. 83.24); and (4) infections acquired via ingestion, such as gnathostomiasis, cysticercosis, and echinococcosis, enterobiasis, trichinosis, and toxocariasis (Figs. 83.25 & 83.26).

CUTANEOUS LARVA MIGRANS

Synonym: ▪ Creeping eruption

Key features

- Due to larvae of animal hookworms (intestinal nematodes)
- Skin lesions are serpiginous and pruritic, representing the paths of migration of organisms within the epidermis
- The rate of migration is 1–2 cm per day
- Self-limited disease

Cutaneous larva migrans is a serpiginous cutaneous eruption caused by the accidental penetration and migration of animal hookworm larvae through the epidermis. The infection has a worldwide distribution and occurs most frequently in warmer climates. The skin lesions are usually self-limited[83].

Epidemiology and Pathogenesis

Cutaneous larva migrans is caused by the larvae of hookworms that infect domestic dogs and cats, most often *Ancylostoma braziliense* or *A. caninum* and occasionally *Uncinaria stenocephala* or *Bunostomum phlebotomum*. Although cutaneous larva migrans has a worldwide distribution[84], it is most commonly seen in warm climates, such as the southeastern US, Central and South America, Africa, and other tropical areas[83]. The infection is usually acquired by walking barefoot on ground contaminated with animal feces, but the buttock or other body sites can become infected via contact with contaminated soil or sand. The larvae enter the skin and begin a prolonged process of migration within the epidermis. With rare exceptions, the parasite remains confined to the epidermis, producing visible tracts and intense pruritus. The parasite lacks collagenase, which is necessary to disrupt the basement membrane and enter the dermis.

Clinical Features

Patients have intense localized pruritus that begins shortly after the hookworm penetrates the skin. Several days later, the pruritus is associated with small vesicles and/or one or more edematous, serpiginous

MAJOR PARASITIC WORMS THAT CAUSE DISEASES AND CUTANEOUS MANIFESTATIONS IN HUMANS								
Disease	**Organism**	**Distribution**	**Mode of spread**	**Skin findings**	**Systemic findings**	**Diagnosis**	**Therapy***	**Figure**
Ascariasis (roundworms), intestinal nematode	*Ascaris lumbricoides*	Widespread and high prevalence, esp. in tropical countries	Ingestion of eggs	None	Abdominal pain, diarrhea, intestinal obstruction, nutritional deficiencies, Loeffler syndrome	Detection of eggs in the stools	Mebendazole Albendazole Pyrantel pamoate Ivermectin	83.22
Enterobiasis (pinworms), intestinal nematode	*Enterobius vermicularis*	Widespread and high prevalence, esp. in countries within temperate zones	Ingestion of eggs	Perianal and perineal pruritus	Restlessness Asymptomatic in most patients	Detection of eggs via adhesive cellophane tape pressed against perianal skin	Mebendazole Albendazole Pyrantel pamoate	83.22
Ancylostomiasis (hookworms), intestinal nematode	*Ancylostoma duodenale, Necator americanus*	Tropical and subtropical distribution	Percutaneous via contact with infective larvae in soil	Dermatitis (via contact with infective larvae in soil)	Iron deficiency anemia, GI symptoms, Loeffler syndrome, eosinophilia	Direct fecal smear examination for eggs	Mebendazole Albendazole Pyrantel pamoate	83.22
Strongyloidiasis, intestinal nematode	*Strongyloides stercoralis*	Occurs worldwide, esp. in tropical areas; in cooler climates found in warm humid mines	Percutaneous via contact with infective larvae; occasionally ingestion of larvae Autoinfection via penetration of perianal skin Hyperinfection in immunocompromised patients, due to penetration of intestinal mucosa	Generalized or localized urticarial eruption beginning perianally and extending to the buttocks, thighs, and abdomen (larva currens) "Thumbprint" purpura in hyperinfection (see Fig. 83.21)	Diarrhea, duodenitis, eosinophilia, pulmonary symptoms Symptoms more severe in immunocompromised patients	Examination of stool for larvae; rarely, diagnosis is made by lung biopsy or pulmonary cytology	Ivermectin Albendazole Thiabendazole	83.22
Loiasis, tissue nematode	*Loa*	West and Central Africa	Transmitted by bite of tabanid flies of the genus *Chrysops* (mango flies) carrying infective larvae Mature in connective tissue	Transient localized subcutaneous edema (Calabar swellings), often of the hands, wrists and forearms; represent tracts of migrating adult worms; associated with pruritus and pain	Conjunctivitis (due to movement of adult worms under conjunctiva), eosinophilia, renal disease	Detection of microfilariae in blood during the daytime Occasionally, adult worms can be extracted from the eye	Diethylcarbamazine Albendazole	83.23
Dirofilariasis, tissue nematodes of animals	*Dirofilaria immitis* (dog heartworms); *D. tunuis* (filaria of raccoons); *D. repens* (filaria of dogs and cats); *D. ursi* (filaria of bears)	*D. immitis* occurs worldwide; *D. tunuis* in Southeast US; *D. repens* in Europe and Asia; *D. ursi* in North America and Japan	Transmitted by mosquitoes carrying infective larvae Do not mature in humans	*D. tunuis, D. repens* and *D. ursi* cause small painful subcutaneous nodules with or without inflammation	*D. immitis* causes nodules in the lung	Detection of larvae by biopsy	Surgical excision Ivermectin	

Table 83.10 Major parasitic worms that cause diseases and cutaneous manifestations in humans.

Continued

MAJOR PARASITIC WORMS THAT CAUSE DISEASES AND CUTANEOUS MANIFESTATIONS IN HUMANS								
Disease	**Organism**	**Distribution**	**Mode of spread**	**Skin findings**	**Systemic findings**	**Diagnosis**	**Therapy***	**Figure**
Dracunculiasis (guinea worm), tissue nematode	*Dracunculus medinensis*	Africa, particularly Ghana and Sudan	Ingestion of infected water fleas of the genus *Cyclops* in drinking water migrate from intestine to subcutaneous tissue, usually of the legs	Papulonodule then blister and/or ulceration, usually of the lower extremity; calcified nodules	Anaphylactic shock, rheumatic symptoms	Confirmation of worms in the subcutaneous tissue Immunodiagnosis, e.g. ELISA Sequence analysis of 18 S RNA	Gradual extraction of the worm (e.g. on a stick)	83.23
Trichinosis (Trichinellosis), tissue nematode	*Trichinella spiralis*	Widespread in temperate zones	Ingestion of encysted larvae from raw/undercooked animal meat, usually pork	Periorbital edema in severe infection, splinter hemorrhages	Most infections are subclinical Heavy infection also leads to fever, enteritis, myositis, and eosinophilia; occasionally myocarditis and encephalitis	Confirmation of encysted larvae in the skeletal muscle; fluorescent antibody testing; ELISA	No satisfactory treatment Corticosteroids for severe symptoms plus mebendazole or albendazole	
Toxocariasis (visceral larva migrans), larval stage of dog roundworm, larval nematode	*Toxocara canis*	Worldwide distribution	Ingestion of eggs excreted by dogs Larvae migrate through the viscera as they are unable to mature into adults	Urticaria, cutaneous nodules	Cough, fever, hepatomegaly, eosinophilia; ocular and hepatic granulomas	Diagnosis is usually suggested clinically Confirmation by histologic examination is uncommon Serologic assay (Western blot)	Mebendazole Albendazole Diethylcarbamazine (second-line) Corticosteroids for severe ocular larva migrans	
Sparganosis, larval stage of tapeworms of dogs and cats, cestode	*Spirometra*	Sporadic in most countries, seen most frequently in the Far East	Ingestion of larvae in intermediate hosts (e.g. snakes, frogs, fish) Occasionally application of frogs to eyes as poultice	Painless small subcutaneous nodules at sites of larval proliferation Edema if periorbital involvement	Rarely pulmonary or CNS involvement	Biopsy to identify larvae	Surgical excision Praziquantel	83.26
Fascioliasis (liver fluke), trematode	*Fasciola hepatica*	South America, Europe, Africa, China, Australia	Ingestion of metacercariae on aquatic plants, e.g. wild watercress	Ectopic fascioliasis is occasionally reported; cutaneous cysts	Fever, hepatomegaly, obstruction of bile duct (rare), eosinophilia	Detection of ova in feces or bile Abdominal CT	Triclabendazole Nitazoxanide Bithionol	83.24
Paragonimiasis (lung flukes), trematode	*Paragonimus westermani*	*Paragonimus westermani* in Far East; other species in West Africa, Central and South America	Consumption of flesh of freshwater crustaceans containing living metacercariae	Cutaneous paragonimiasis rare, but has been reported	Productive cough, hemoptysis, bronchitis, lung abscess, pleural effusion Symptoms related to ectopic worms in abdomen, brain, etc.	Examination of sputum or feces for eggs ELISA	Praziquantel Triclabendazole	83.24

*Details regarding the majority of these medications are provided in Table 83.9.

Table 83.10 Major parasitic worms that cause diseases and cutaneous manifestations in humans. Cutaneous larva migrans, gnathostomiasis, onchocerciasis, filariasis, schistosomiasis, cysticercosis and echinococcosis are covered in the text.

tracts (Fig. 83.27). Each larva produces one tract and migrates at a rate of 1 to 2 cm per day ("creeping eruption"). The most frequent location is the distal lower extremities or buttocks. Additional sites of involvement include the hands, thighs, and rarely perianal area[83–85]. In severe infections, hundreds of such lesions may develop. If untreated, a single larval tract may progress, disappear for a few days, reappear, advance further, and so on, for weeks or months; spontaneous resolution occurs after a mean of 2 to 4 weeks.

Unlike human hookworm disease and strongyloidiasis, the larvae rarely progress beyond the skin, and systemic manifestations such as migratory pulmonary infiltrates and peripheral eosinophilia (Loeffler syndrome) are rarely seen. The only common systemic finding is a

Fig. 83.21 Strongyloidiasis hyperinfection. Multiple purpuric lesions (sometimes referred to as "thumbprint" purpura) on the abdomen of an immunocompromised patient. *Courtesy Jean L. Bolognia, MD.*

moderate peripheral blood eosinophilia. Due to intense pruritus and scratching, superimposed bacterial infections may complicate the clinical picture. Vesicles and bullae may develop in previously sensitized patients (see Fig. 83.27)[83,86].

Pathology

Although the diagnosis is usually made clinically, based on the characteristic lesions and history of recent exposure (e.g. walking barefoot), biopsies are sometimes performed. It is unusual to see the parasite in biopsy specimens, but occasionally the larva can be identified within the epidermis. More commonly, cavities left by the parasite are located within the upper epidermis and are associated with spongiosis. In the dermis, there is a mixed inflammatory infiltrate composed of lymphocytes, histiocytes, and numerous eosinophils. Occasionally, collections of eosinophils may be present in the epidermis and within hair follicles[83].

Differential Diagnosis

The cutaneous eruption is characteristic, and the diagnosis is usually straightforward. The human species of intestinal hookworms (*A. duodenale* and *Necator americanus*) penetrate the skin prior to possible migration into venules (see Fig. 83.22), causing a nonspecific pruritic localized rash lasting 1–2 weeks that is referred to as "ground itch"[83,87]. Unlike cutaneous larva migrans, *A. duodenale* and *N. americanus* infections can progress to systemic hookworm disease, which manifests with anemia, malnutrition, and pulmonary and gastrointestinal symptoms (see Table 83.10). With these human species, autoinfection from larvae in the feces can occur, sometimes years after the initial infection.

The differential diagnosis may also include allergic contact dermatitis, impetigo, inflammatory tinea, scabies, myiasis, and other nematode infections such as the superficial form of gnathostomiasis and strongyloidiasis. Larva currens is a localized or occasionally more widespread urticarial eruption that is caused by autoinfection with *Strongyloides stercoralis* in immunocompetent individuals (see Table 83.10); it typically begins in the perianal area and then rapidly extends, as quickly as 5–10 cm per day, onto the buttocks, thighs, and abdomen[88]. The lesions are relatively short-lived, lasting hours to days, but often recur[89].

Treatment

Although cutaneous larva migrans is self-limited, the intense pruritus and prolonged course often necessitate treatment. A single ivermectin dose of 12 mg in adults or 150–200 mcg/kg in children has 80%–100% efficacy. Administration of a single 400 mg oral dose of albendazole to adults and children >2 years of age produces cure rates of 45%–100%, but a dose of 400–800 mg/day in adults or 10–15 mg/kg/day (maximum of 800 mg/day) in children for 3–5 days results in more consistent cure rates of 80%–100%[86]. In the largest series to date, application of ivermectin 1% cream daily for two weeks led to improvement in only 1 of 12 patients with larva migrans involving primarily the feet/ankles[90]; however, a few case reports have described benefit when lesions involved the genitals or thighs, where cutaneous penetration may be higher. Topical 10%–15% thiabendazole solution or ointment (not available in the US) may have benefit for localized disease, but it requires application three times daily for at least 15 days. Oral thiabendazole is also effective but is less well tolerated than either ivermectin or albendazole[86].

GNATHOSTOMIASIS

Synonyms: ■ Nodular migratory eosinophilic panniculitis ■ Shanghai rheumatism ■ Tuao chid ■ Yangtze edema

Key features

- Typically acquired via consumption of raw freshwater fish
- Clinical presentations include nodular migratory panniculitis, a superficial type that mimics cutaneous larva migrans, and furuncular lesions; peripheral eosinophilia is often present

Introduction

Gnathostomiasis is caused by the larvae of nematodes of the genus *Gnathostoma* and the usual definitive hosts are cats, dogs, and pigs. However, humans can become infected by eating raw freshwater fish, which represent an intermediate host during the parasite's life cycle (see Fig. 83.25). The most common clinical presentation is a migratory panniculitis, associated with tissue and peripheral eosinophilia.

Epidemiology

Gnathostomiasis is endemic in Southeast Asia and Japan; it also occurs elsewhere in Asia as well as in Mexico, Central and South America, and South Africa[91]. At least two cases of autochthonous gnathostomiasis have been reported in the US[92]. Local and imported dishes containing raw freshwater fish, eels (e.g. Asian swamp), frogs, birds, and reptiles are the source of infection, and travelers may develop the disease after returning home[93].

Pathogenesis

G. spinigerum is the most common cause of human gnathostomiasis. Other pathogenic species include *G. hispidum*, *G. doloresi*, *G. nipponicum*, *G. malaysiae*, and *G. binucleatum*[94].

The adult worms are enteric parasites of cats, dogs, pigs, wild felines, weasels, and rats (see Fig. 83.25). *Gnathostoma* eggs are passed in the feces of these infected hosts and hatch when they reach the water, e.g. in a nearby river. The first-stage larva is ingested by a copepod (*Cyclops*) and develops into a second-stage larva. The copepod is then ingested by a fish or other aquatic intermediate host, and the larva reaches a third stage in its flesh, which is eaten either by a definitive host or human. The larva penetrates the human gastrointestinal mucosa and starts to migrate, first to the peritoneal cavity and subsequently to the subcutaneous tissues and internal organs.

Clinical Features

Abdominal pain, other gastrointestinal symptoms, and fever may occur during early infection. Cutaneous manifestations typically develop 2–4 weeks after ingestion of the larva. The classic presentation is migratory panniculitis characterized by a single, deep-seated, pruritic or tender inflammatory nodule that disappears spontaneously after a few days to weeks and then reappears a few centimeters away or in a different body region. Sites of involvement may develop a *peau d'orange* appearance. Occasionally, the parasite's migratory pattern becomes more superficial

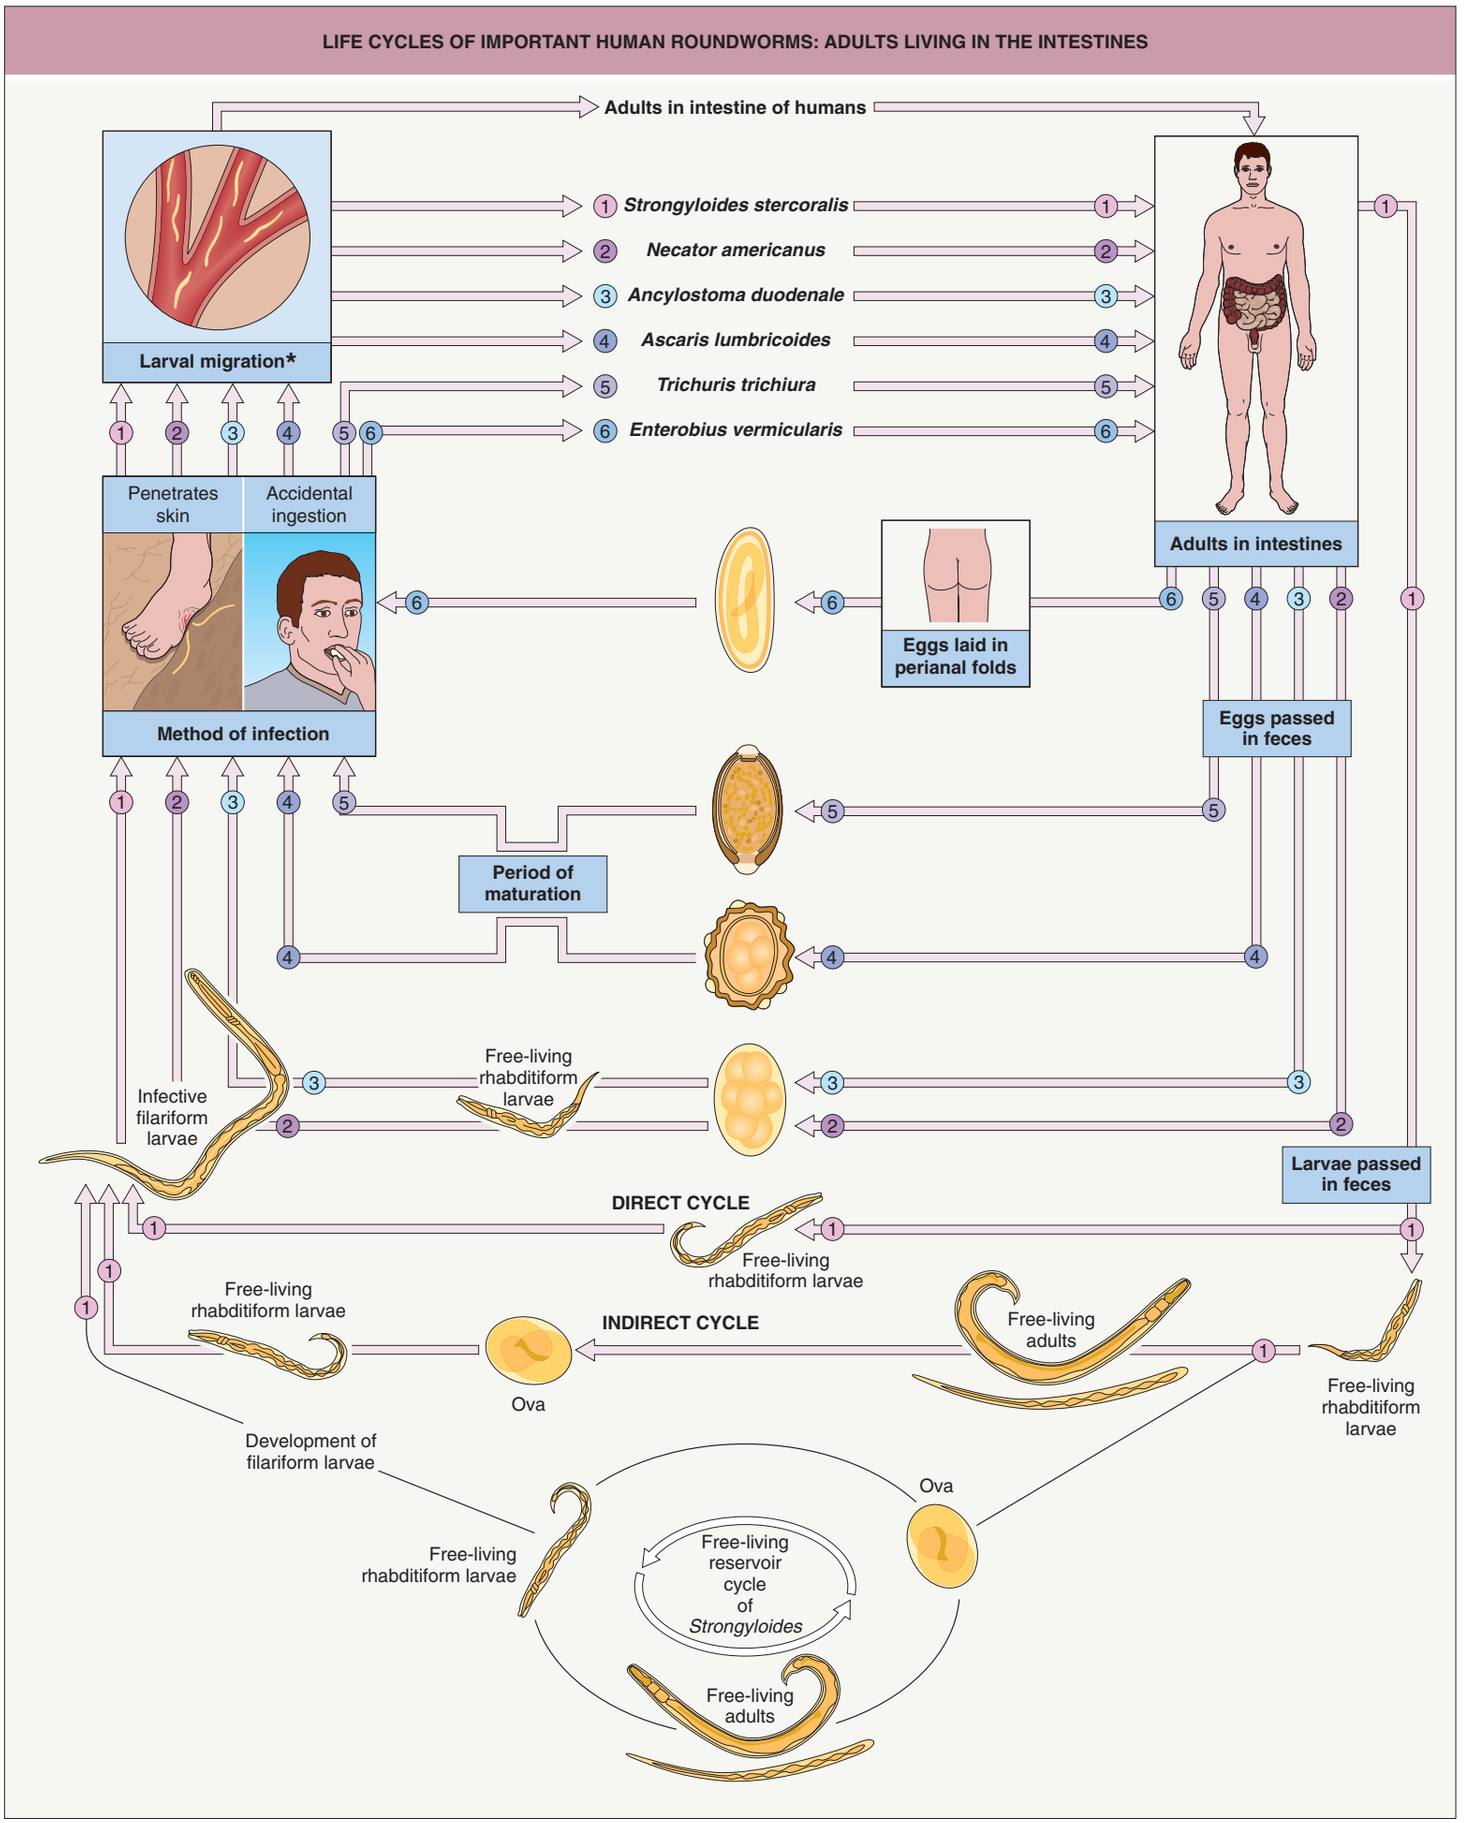

Fig. 83.22 Life cycles of important human roundworms: adults living in the intestines. *Larvae can migrate from venules into the right heart and lungs, then via alveoli into the trachea; eventually they are swallowed. *With permission from Cross JH. Helminths. In Cohen J, Powderly W (eds). Infectious Diseases, 2nd edition. London: Mosby, 2004.*

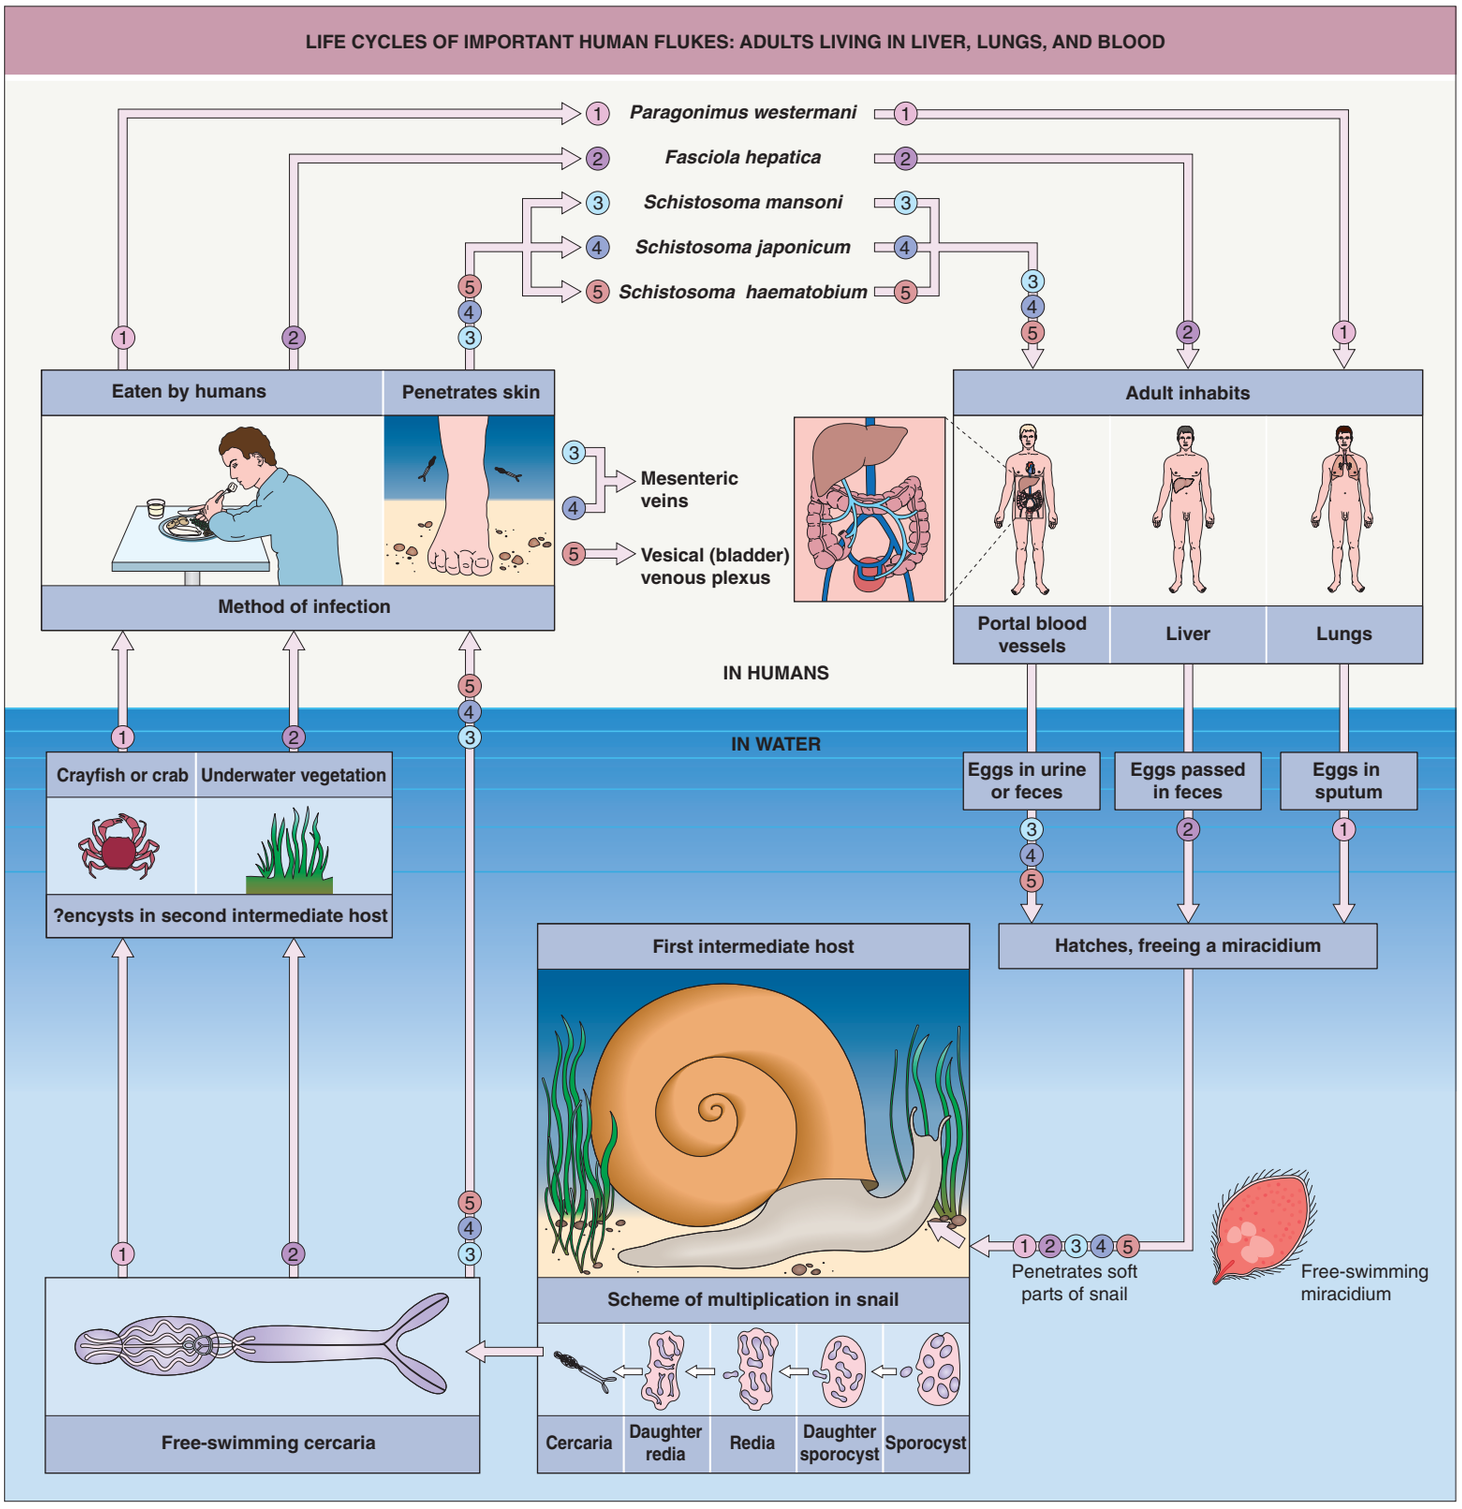

Fig. 83.24 Life cycles of important human flukes: adults living in the liver, lungs, and blood. *Adapted with permission from Cross JH. Helminths. In Cohen J, Powderly W (eds). Infectious Diseases, 2nd edition. London: Mosby, 2004.*

and mimics that of cutaneous larva migrans. Both patterns may be seen simultaneously in the mixed form (Fig. 83.28A). Following treatment, the parasite tends to be located near the skin surface, inducing the formation of a vesicle or pustule overlying a papulonodule; this has been called furuncular gnathostomiasis. Rarely, the parasite reaches the surface and becomes visible[95].

Migration of the larva into deeper tissues can result in pulmonary, gastrointestinal, renal, or ocular involvement. Invasion of the CNS is associated with a mortality rate of up to 25% and may lead to radiculomyelitis, eosinophilic meningitis, and subarachnoid hemorrhage. Neurologic symptoms often wax and wane, reflecting the migratory pattern of infection, and an altered state of consciousness or coma can occur with cerebral involvement.

Pathology

Nodular lesions demonstrate an eosinophilic lobular panniculitis with linear hemorrhage. In superficial lesions, an eosinophilic infiltrate is present in the mid and deep dermis. The parasite itself may be seen, especially in the furuncular type. The worm has a cylindrical shape, measuring 0.2–0.4 mm in diameter, with an external cuticle and central intestine (Fig. 83.28B).

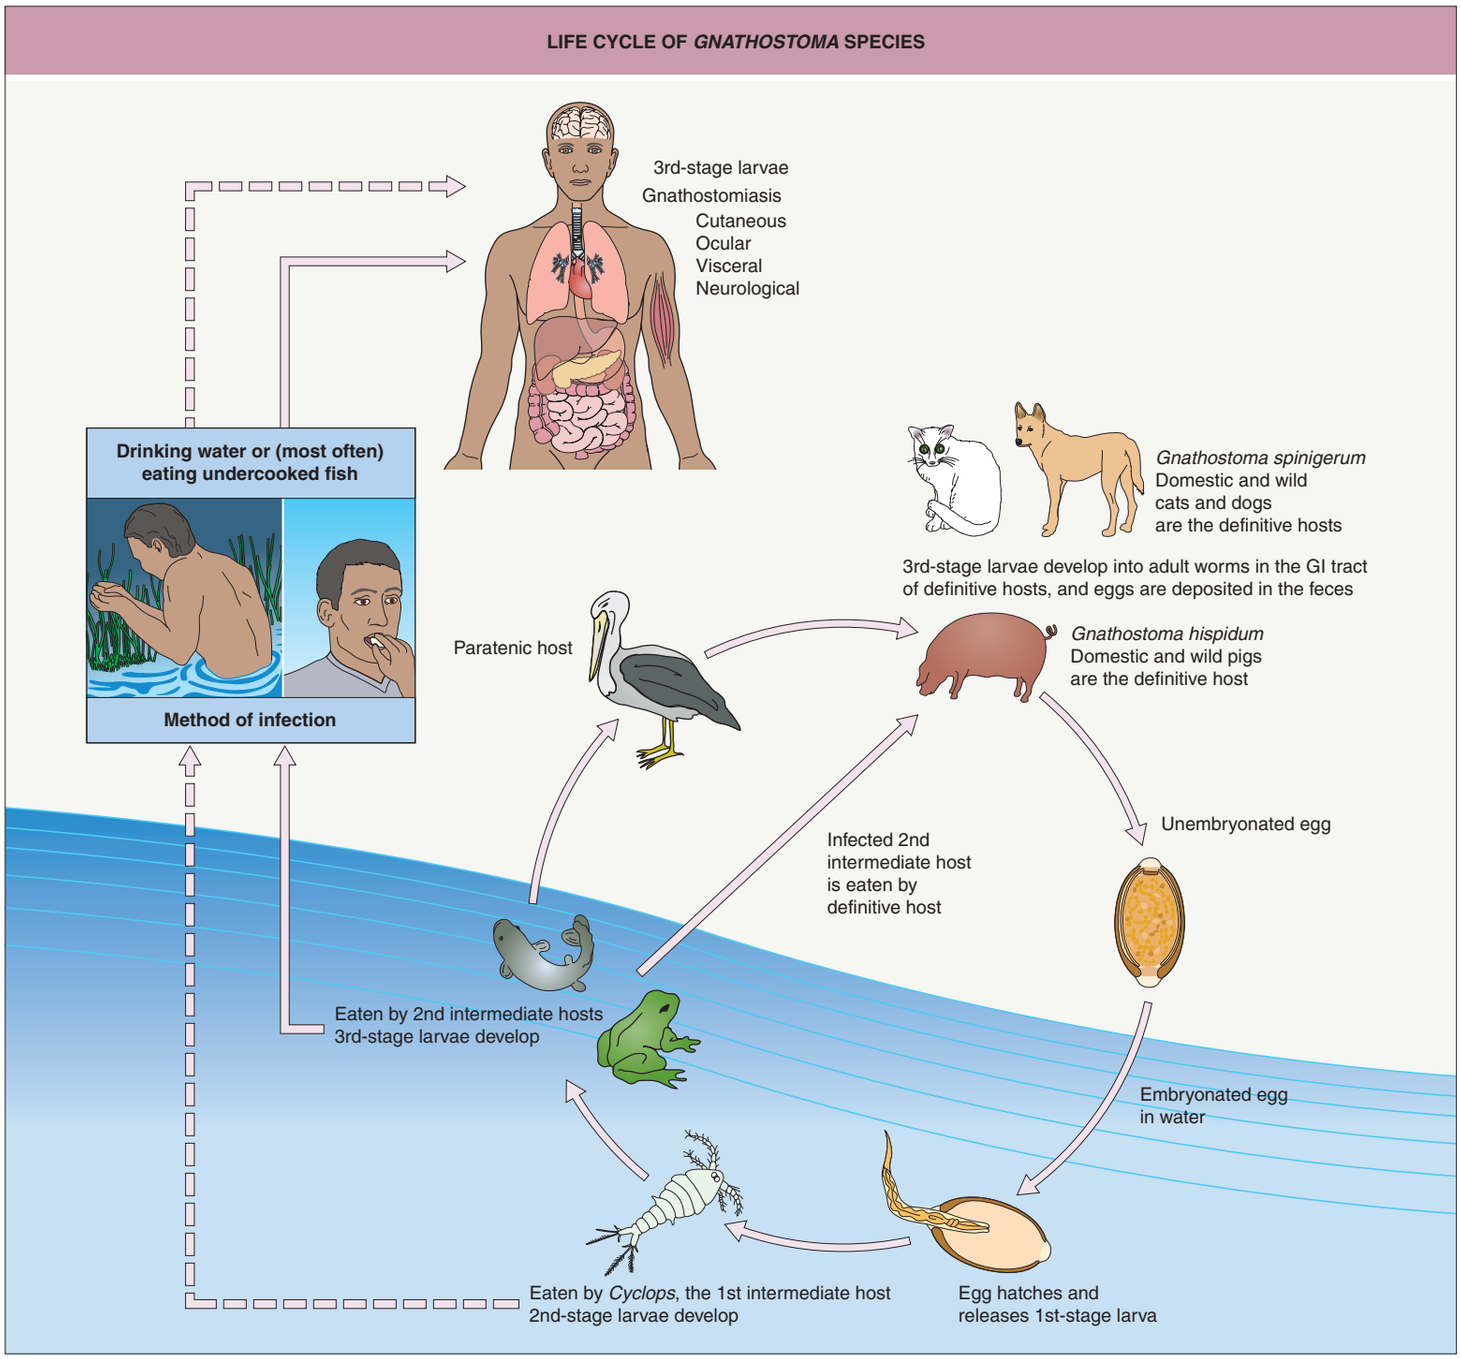

Fig. 83.25 Life cycle of *Gnathostoma* species. Transmission to humans via copepods in drinking water has been postulated but not confirmed. *Modified from www.cdc.gov/parasites/gnathostoma/biology.html.*

Diagnosis and Differential Diagnosis

Gnathostomiasis should be suspected in patients with a migratory panniculitis or dermatitis plus recent consumption of raw fish or another potentially contaminated raw food. The diagnosis is supported by the presence of peripheral eosinophilia (≤50% of cases) as well as tissue eosinophilia. Worldwide serologic testing via immunoblot based on a specific L3 antigen is available in specialized research centers. Development of a rapid filtration-based immunoassay is currently under investigation.

The differential diagnosis includes other nematode infections with migratory skin lesions, including cutaneous larva migrans, strongyloidiasis, and toxocariasis. Similar inflammatory nodules may also be seen in sparganosis, fascioliasis, and myiasis.

Treatment

Recommended therapy is either albendazole 400–800 mg/day for 21 days or ivermectin 200 mcg/kg/day for 1–2 days. Relapses often occur[96].

ONCHOCERCIASIS

Synonyms: ■ River blindness ■ Enfermedad de Robles ■ Erysipelas (erisipela) de la costa ■ Craw-craw

Key features

- *Onchocerca volvulus* is a tissue-dwelling nematode that is mainly found in Africa and transmitted by black flies
- Most clinical manifestations are caused by microfilariae in the skin and eyes
- Cutaneous manifestations include subcutaneous nodules that contain adult worms, a pruritic papular dermatitis, lichenification, and leukoderma
- The diagnosis can be established by identification of microfilariae via microscopic examination of a skin sample (skin snip) or slit-lamp examination of the eyes

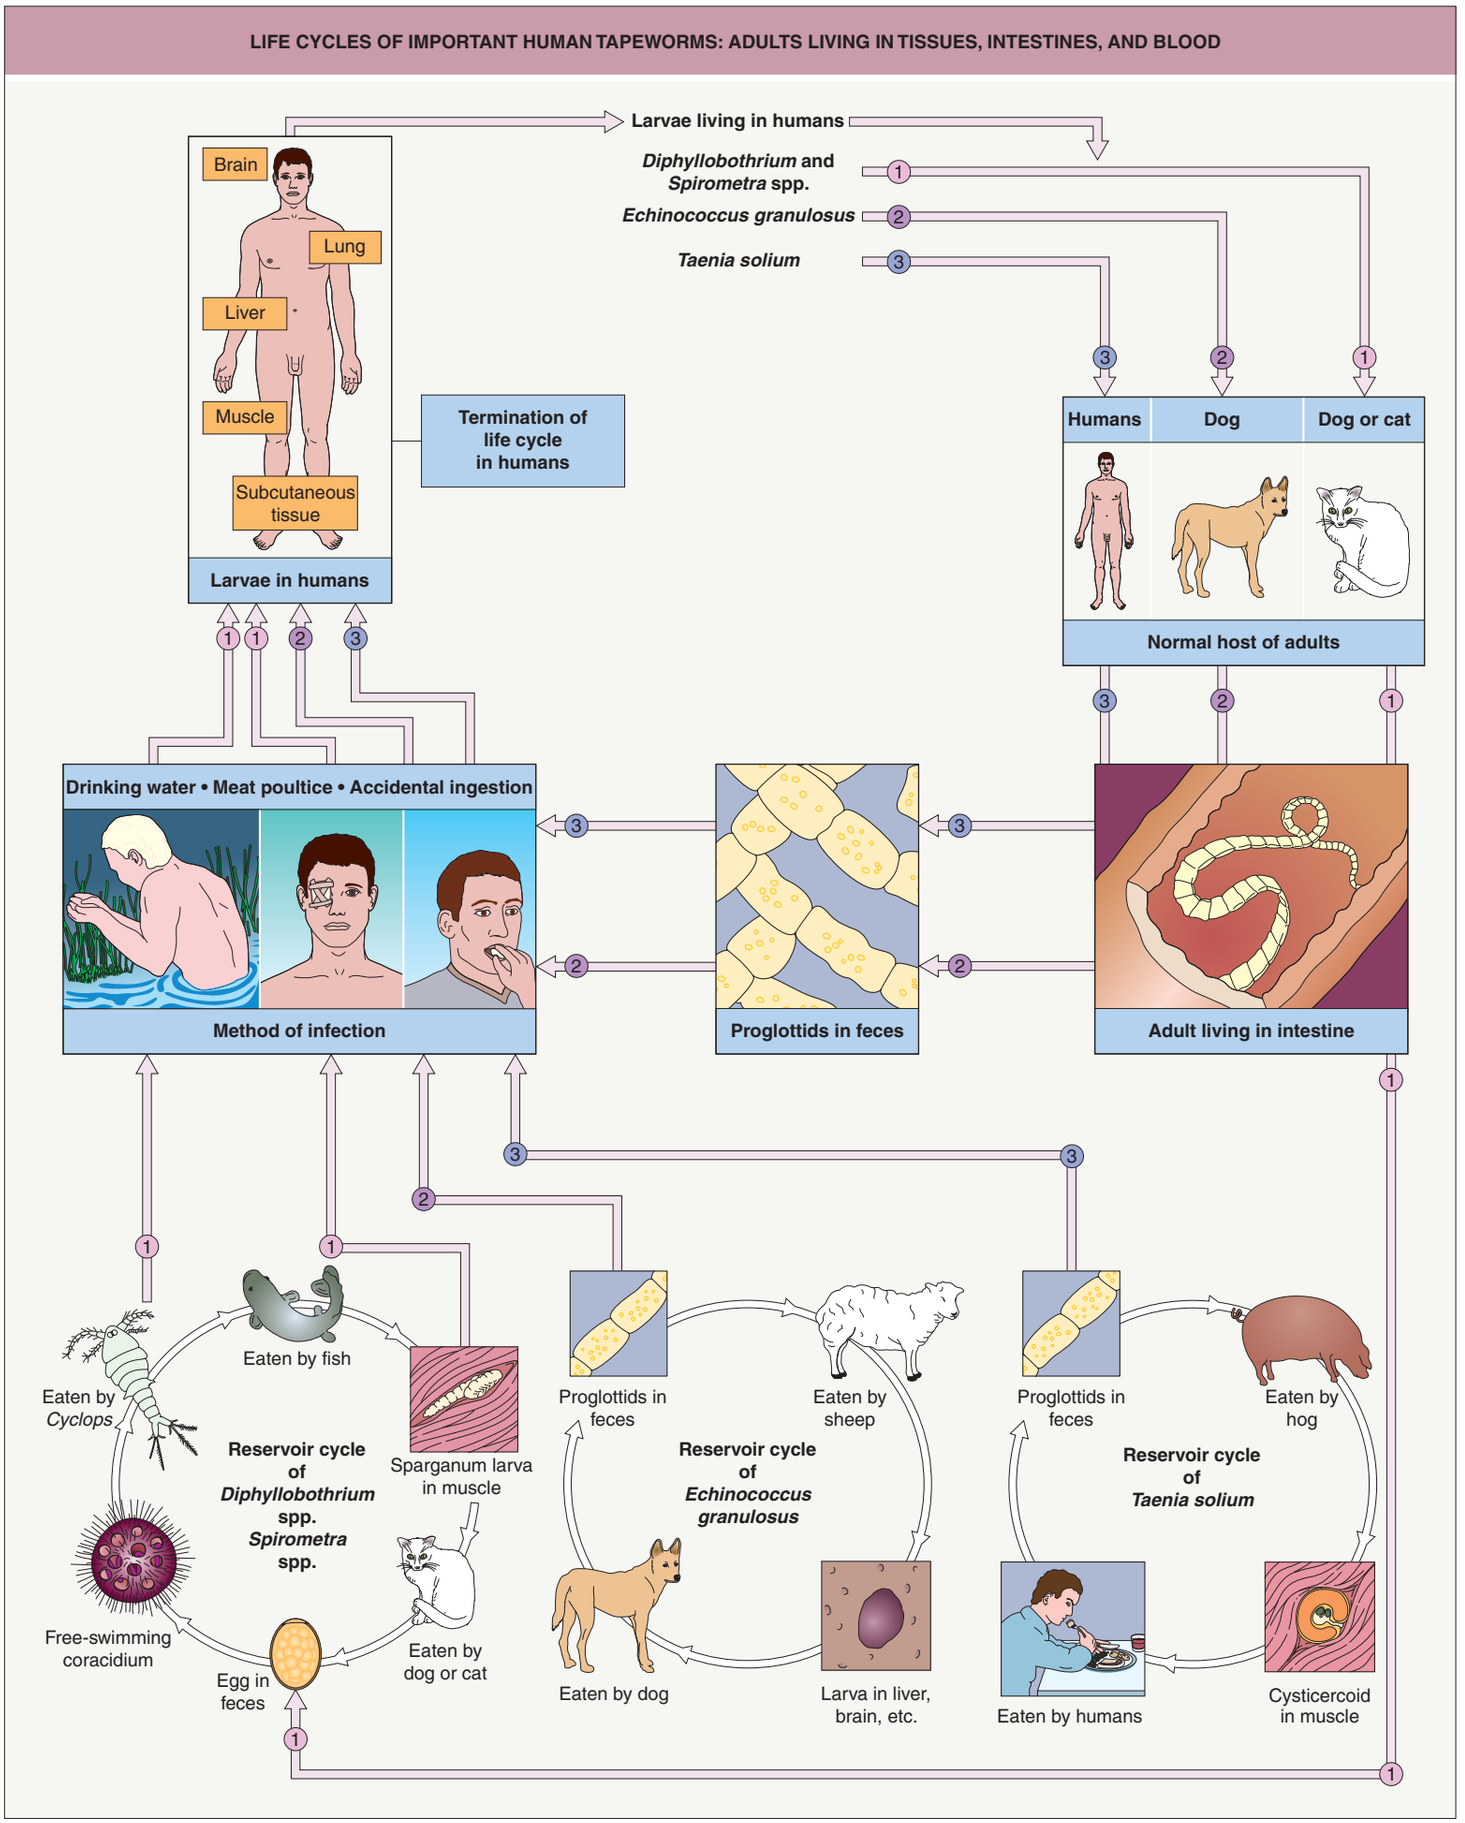

Fig. 83.26 Life cycles of important human tapeworms: adults living in tissues, intestines, and blood. *Adapted with permission from Cross JH. Helminths. In Cohen J, Powderly W (eds). Infectious Diseases, 2nd edition. London: Mosby, 2004.*

Introduction

Onchocerciasis, or river blindness, predominantly affects cutaneous and ocular tissue and is caused by *Onchocerca volvulus*, a filarial nematode[97]. Onchocerciasis most commonly occurs in inhabitants of tropical Africa and occasionally develops in residents of tropical areas in South America and the Middle East. In the early stage of the disease, cutaneous manifestations include subcutaneous nodules and pruritic papular dermatitis, while skin thickening and leukoderma are later findings. Progressive sclerosing keratitis can lead to blindness.

Epidemiology

Onchocerciasis is a debilitating disease that worldwide affects ~16 million people, in particular those living for prolonged periods of time near fast-flowing rivers in endemic areas[98]. The larvae of *O. volvulus* have an obligatory aquatic stage during which they require high oxygen tension, thus explaining the significant role well-oxygenated water plays in this disease[97,99]. Severe disease requires repeated exposures over many years. Approximately 99% of all cases are acquired in equatorial Africa, but some endemic foci remain in the Middle East, Venezuela, and Brazil (Fig. 83.29). As of 2016, onchocerciasis was considered eradicated in Colombia, Ecuador, Mexico, and Guatemala[100]; in addition, Niger is currently undergoing verification to become the first African nation to eliminate onchocerciasis.

Pathogenesis

Onchocerciasis is transmitted by the bite of an infected black fly (*Simulium* spp.). Because these flies often assume a "hump-backed" stance, they are sometimes referred to as "buffalo gnats". Black flies feed by "rasping" (abrading) the surface of the skin until a pool of blood forms, which they lap up. Microfilariae previously residing in the dermis are present in this blood, and they penetrate the gut wall of the insect and migrate to its thoracic muscles, where they develop into larvae. The larvae then migrate to the proboscis, from which they will be transmitted to another human host during a blood meal (see Fig. 83.23)[99]. *Wolbachia* bacterial endosymbionts are required for normal development of *O. volvulus* larvae and embryos, are thought to support the survival of adult worms, and drive immune responses that contribute to disease pathogenesis[101].

Once in their human host, larvae take almost a year to reach maturity. The adult worms are large, measuring up to 50 cm in length. They are encapsulated within fibrous tissue and reside in nodules close to the surface of the skin or near joints. These nodules are known as onchocercomas (Fig. 83.30). Each female worm produces hundreds of microfilariae, which live for 1–2 years and migrate into the skin, connective tissue, eyes, and lymph nodes. It is the microfilariae that cause most of the serious clinical features of onchocerciasis[102]. There is little inflammation until the microfilariae degenerate, which triggers a hypersensitivity reaction. In the skin, this results in intense pruritus and dermatitis.

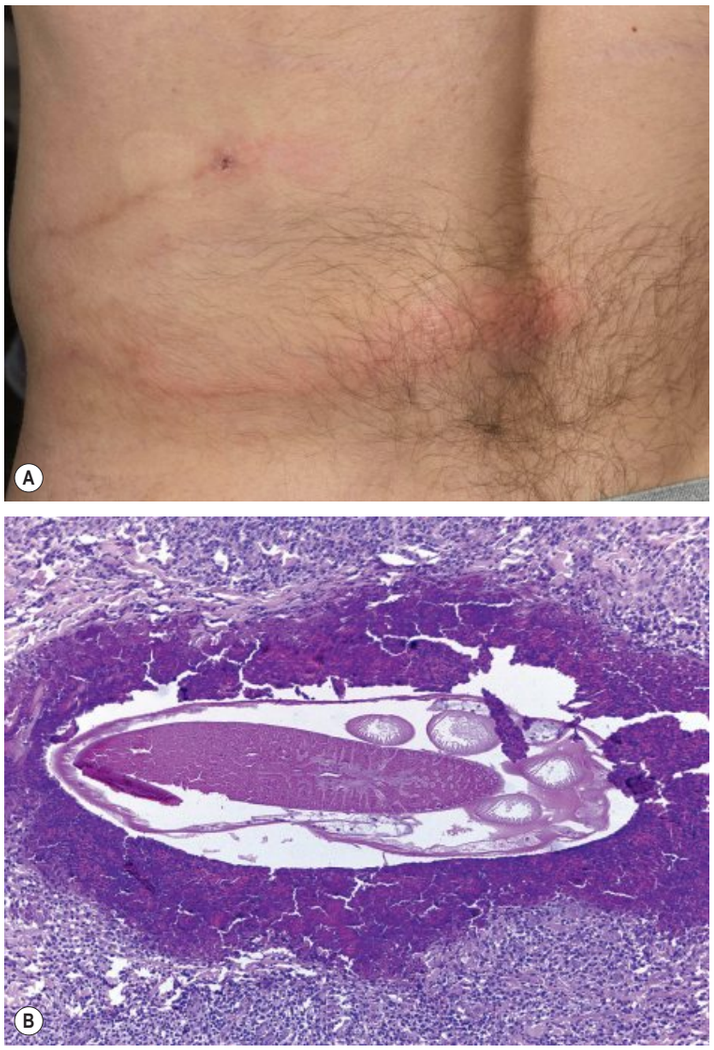

Fig. 83.28 Gnathostomiasis. A In addition to a serpiginous pattern on the lower back that is similar to larva migrans, there is an indurated pink plaque with a peau d'orange appearance. **B** A skin biopsy specimen occasionally reveals the *Gnathostoma* third-stage larva. *A, Courtesy Edward Cowen, MD.*

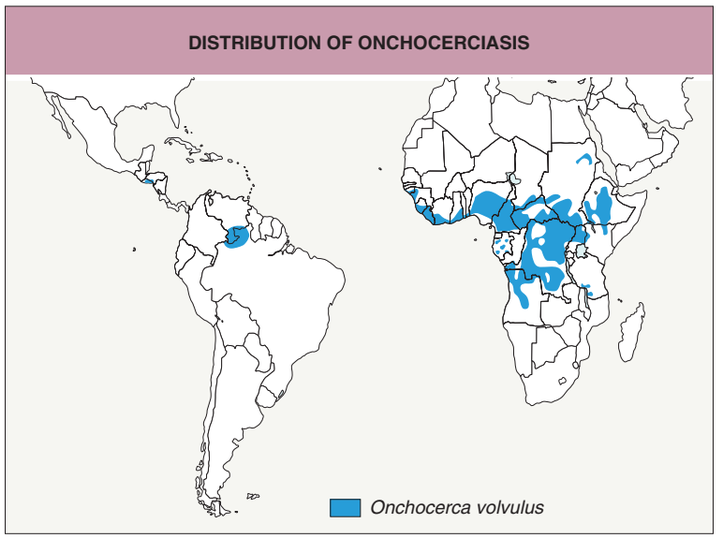

Fig. 83.29 Distribution of onchocerciasis. The disease is found primarily in Africa and focal areas of the Amazon region in South America.

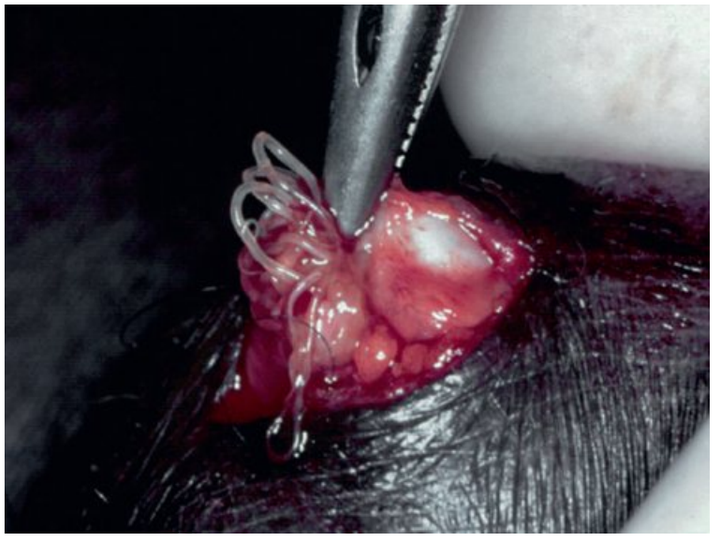

Fig. 83.30 Onchocerciasis. Extraction of adult worms from an onchocercal nodule on the buttocks.

Clinical Features

The primary manifestations of onchocerciasis involve the eye and the skin. Cutaneous findings are classified into the following groups: acute papular onchodermatitis, chronic papular onchodermatitis, lichenified onchodermatitis, onchocercal atrophy, and depigmentation (Fig. 83.31)[103]. Patients first present with subcutaneous nodules that are usually located over bony prominences; they favor the upper part of the body in patients living in South America and the lower part of the body in those from Africa. The subcutaneous nodules represent fibrous tissue surrounding adult worms. An intermittent, intensely pruritic acute papular onchodermatitis follows, in which small papules form around the microfilariae (called "craw-craw" in Africa).

In chronic onchocerciasis, the skin becomes thickened and wrinkled; this is accompanied by lichenification and hyperpigmentation and is sometimes referred to as "lizard" or "elephant" skin or "sowda". The back, thighs, and lower trunk are frequently affected, and hyperpigmentation may develop on one lower extremity in association with inguinal lymphadenopathy (see Fig. 83.31). Atrophy and a loss of pigment with sparing of perifollicular skin are also seen in late stage onchocerciasis. The latter changes, sometimes referred to as "leopard" skin, are most often evident on the shins (see Fig. 83.31 and Ch. 66)[104]. Chronic lymphatic obstruction and involvement of the inguinal lymph nodes can lead to hanging groin or elephantiasis of the genitalia (see Fig. 83.31).

In Central America, young patients who are heavily infested may develop erythema on the face or upper trunk (erisipela de la costa). Older patients may have violaceous papules or plaques (mal morado), which can lead to leonine facies.

In addition to skin lesions, microfilariae can also be found in the conjunctivae; from there they can move through the cornea into the anterior and posterior chambers of the eye, leading to conjunctivitis, sclerosing keratitis, uveitis, chorioretinal lesions, optic atrophy, and glaucoma[97]. Blindness occurs in the most severe cases. Dead microfilariae in the cornea can induce a tissue reaction that produces characteristic "snowflake" opacities.

Pathology

In onchodermatitis, microfilariae are present in all levels of the skin but are most concentrated in the dermal papillae, where they can infect black flies during feeding. Microfilariae are ~250 microns long with two or three pairs of anterior nuclei. Initially, they are surrounded by an infiltrate with numerous eosinophils. Lymphocytes, macrophages, plasma cells, and mast cells may become more prominent at later stages, and epidermal hyperplasia (secondary to rubbing) may develop. The final outcome is fibrosis surrounding the microfilariae with minimal inflammation[105].

The adult female worms are found in a subcutaneous nodule. They are initially surrounded by an infiltrate containing many eosinophils, with progressive development of fibrosis.

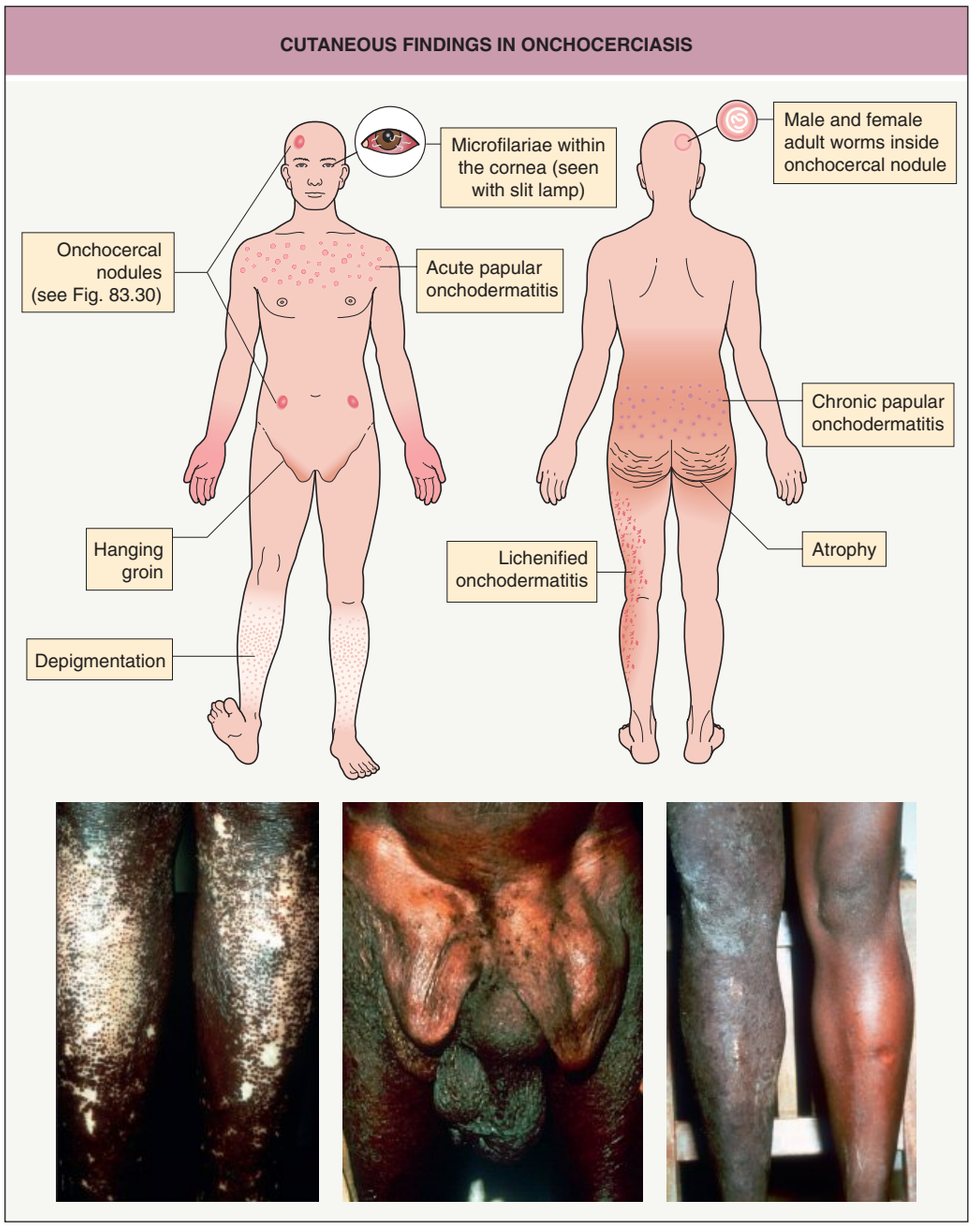

Fig. 83.31 Cutaneous findings in onchocerciasis. Photos: left, depigmentation with perifollicular sparing ("leopard" skin); middle, hanging groin due to chronic lymphatic obstruction and lymph node involvement; right, lichenified onchodermatitis ("sowda"). *Insets, courtesy David O. Freeman, MD.*

Diagnosis

The clinical diagnosis of onchocerciasis is usually not difficult in endemic areas. It is confirmed by microscopic visualization of microfilariae as they emerge from multiple skin snips placed in saline; these small, thin discs (including superficial dermis) are taken from skin near a nodule and over the shins, iliac crests, and/or scapulae[106]. Onchocerciasis can also be diagnosed by the identification of the adult worm in an excised nodule. In heavily infected individuals, microfilariae can be found in the blood, sputum, and urine. By slit-lamp examination, microfilariae (when present) are easily visualized within the anterior chamber of the eye.

When skin snips are negative, the "Mazzotti test" may be helpful in diagnosing onchocerciasis: 50 mg of diethylcarbamazine (DEC) is administered orally, and a pruritic eruption develops within 15 minutes (as the microfilariae die) if the patient is infected. In the "Mazzotti patch test", DEC is applied topically (e.g. in a 10% lotion under occlusion) to a small area of skin, which is examined 24 hours later for the development of papules and edema; this diagnostic method is not as sensitive as oral administration of DEC but less likely to produce a systemic reaction. A dipstick test to detect *Onchocerca volvulus* antigen in the urine or tears has a sensitivity of >90% and a specificity of 100%[107]. Highly sensitive and specific PCR-based tests have also been developed. Tests based on antibody detection cannot distinguish between active and past infections.

Differential Diagnosis

Early lesions of onchocercal dermatitis must be distinguished from insect bites, scabies, and atopic or allergic contact dermatitis. The chronic skin lesions may be mistaken for chronic eczema with postinflammatory pigmentary changes, Hansen disease (leprosy), or the leukoderma of scleroderma. The differential diagnosis of elephantiasis includes other types of filarial infestation (see Fig. 83.23), and a false-positive skin snip can occur if the tissue is contaminated with blood filariae, especially *Mansonella perstans* or *Loa loa*.

Treatment

Therapy for onchocerciasis has drastically improved as a result of the widespread use of oral ivermectin since 1987[108]. This drug is effective in rapidly killing microfilariae and preventing their escape from gravid females. Ivermectin causes few or no adverse reactions and no Mazzotti reaction, whereas older drugs, e.g. diethylcarbamazine and suramin, are associated with severe hypersensitivity or dangerous toxic reactions. Ivermectin is administered as a single dose of 150 mcg/kg every 3 to 12 months. After treatment, microfilariae usually disappear from the skin within 1 week and from the eye within 3 months. Although multiple doses of oral ivermectin can kill adult worms, treatment is typically continued for the worm's lifetime (10–15 years).

Moxidectin is a macrocyclic lactone in the milbemycin family that was recently FDA-approved for the treatment of onchocerciasis. Compared to ivermectin (a macrocyclic lactone in the avermectin family), moxidectin has a longer half-life and greater potency against microfilariae of *O. volvulus* as well as other nematodes such as *Dirofilaria immitis*[109,110]. In addition, moxidectin has potential as an alternative treatment for scabies[109,110]. Administration of doxycycline (100–200 mg/day for 6 weeks) to target *Wolbachia* endosymbionts represents another potential therapeutic approach that can markedly reduce or eliminate *O. volvulus* microfilariae for >18 months[111,112]. Nodulectomy is also a popular treatment in countries where nodules on the head are common (see Fig. 83.31); their removal reduces the chance of ocular disease.

Preventive measures such as spraying black fly breeding sites with larvicides have not significantly changed the epidemiology of the disease. In contrast, mass treatment of endemic populations with ivermectin once or twice yearly has resulted in significant progress toward elimination of the disease in both the Americas and Africa[113]. In addition to onchocerciasis and scabies, mass drug administration of ivermectin or moxidectin targets strongyloidiasis, pediculosis, and cutaneous larva migrans.

FILARIASIS

Synonyms: ■ Lymphatic filariasis, elephantiasis ■ Elephantiasis

Key features

- Filariasis is an infection of the lymphatic system by tissue nematodes (roundworms) acquired via mosquito vectors
- There are acute, chronic, and asymptomatic forms of filariasis
- Manifestations of the acute phase include lymphangitis and orchitis
- Chronic disease is characterized by the sequelae of lymphatic obstruction, e.g. lymphedema, elephantiasis, hydroceles, and chyluria; associated skin findings include hyperkeratosis, verrucous changes, soft tissue hypertrophy, and fibrosis

Introduction

Lymphatic filariasis is an infection of the lymphatic system by two genera of filarial nematodes (roundworms). Several species of mosquitoes act as vectors (see below). Cutaneous findings during the acute and chronic stages include lymphangitis and lymphedema accompanied by changes of elephantiasis.

Epidemiology

There are two major forms of filariasis, Bancroftian (due to *Wuchereria bancrofti*), causing 90% of infections, and Malayan (due to *Brugia malayi* and *B. timori*). The disease affects ~120 million people living in ~50 countries located primarily within the tropical and subtropical regions of South America, Africa, Asia, and the Pacific Islands. *W. bancrofti* is found worldwide, whereas *B. malayi* is restricted to South and East Asia. The distribution of *B. timori* is limited to islands in the Indonesian archipelago[114].

A number of mosquito species act as vectors for filarial nematodes. The most important ones for *W. bancrofti* are *Culex quinquefasciatus*, *Anopheles gambiae*, *Anopheles funestus*, *Aedes polynesiensis*, *Aedes scapularis*, and *Aedes pseudoscutellaris*. Both *B. malayi* and *B. timori* are transmitted by *Anopheles barbirostris*. *B. malayi* can also be transmitted by several species of *Aedes* and *Mansonia* mosquitoes[114,115].

Pathogenesis

Multiple bites from infected mosquitoes seem to be required to produce symptomatic infections, and the incubation period varies from 2 to 18 months. Larvae enter lymphatic vessels and then, once mature, the adult worms mate within the lymphatics or lymph nodes and release sheathed microfilariae into the bloodstream[114]. The mosquito then acquires microfilariae during a blood meal. Over several days, the microfilariae develop into larvae within the mosquito, which can then transmit infection to other humans during subsequent blood meals (see Fig. 83.23).

The clinical manifestations of lymphatic filariasis reflect a complex interplay of the pathogenic potential of the parasite, the immune response of the host, and secondary bacterial and fungal infections. Maturing adult worms provoke an eosinophilic and chronic inflammatory cell infiltrate around lymphatic vessels, leading to dilation and valvular damage with eventual scarring and obstruction of lymphatic flow. The death of worms within lymphatic vessels and lymph nodes results in an intense inflammatory reaction with granulomatous changes and necrosis[114]. *Wolbachia* bacterial endosymbionts are required for the worms' development, embryogenesis, and survival; *Wolbachia* also stimulates an innate and adaptive immune response that leads to expression of vascular endothelial growth factors (VEGFs) that promote lymphangiogenesis, lymphatic endothelial proliferation, and dilation of lymphatic vessels[111].

Clinical Features

There are acute, chronic, and asymptomatic forms of filariasis. Acute episodes of *retrograde adenolymphangitis* typically last up to one week and usually recur 1 to 10 times per year; the inguinal lymph nodes are most often involved. Early on, the affected body part appears clinically normal in between these episodes. Men with *W. bancrofti* infection often present with orchitis and epididymitis. Another disease manifestation is *acute dermatolymphangioadenitis* characterized by cutaneous or subcutaneous inflammatory plaques associated with ascending lymphangitis, regional lymphadenitis, and fever; this may result from a bacterial or fungal superinfection, often with an interdigital entry point[116]. Acute symptoms, which are thought to reflect a lack of tolerance to filarial antigens, are most common in recently infected young adults and older patients. Children residing in endemic areas are often asymptomatic until they reach puberty, when they typically develop chronic manifestations[117].

After 10 to 15 years of infection, the clinical features of chronic disease, i.e. the sequelae of lymphatic obstruction due to both adult worms and granulomatous inflammation, are noted[116]. These include lymphedema, elephantiasis, hydroceles, and chyluria. In some communities in endemic regions, 40%–60% of adult men have hydroceles. In sites of lymphedema and elephantiasis, the skin can be hyperkeratotic, verrucous, and fibrotic with soft tissue hypertrophy and redundant folds. Fissures, ulceration, and gangrene may also develop. Secondary bacterial and fungal infections are common.

There are two major reasons for the predilection of filariasis for the lower extremities and genitalia: (1) the female mosquito flies near the ground, thus it is more likely to bite the lower limbs, which is followed by retrograde involvement of the inguinal region; and (2) due to gravitational forces, the legs are at greater risk for venous hypertension and valvular incompetency and therefore more susceptible to the development of chronic lymphedema[114].

Tropical pulmonary eosinophilia occurs in some patients with filarial infections. Clinical findings include cough, wheezing, dyspnea, chest pain, and fever accompanied by marked eosinophilia and pulmonary infiltrates. This may progress to restrictive pulmonary disease[118].

Travelers to endemic areas who become infected do not manifest the classic findings of filariasis. Instead, they have a hyperresponsive clinical presentation, known as "expatriate syndrome", with more intense inflammatory reactions to the filarial parasites. Clinical findings include lymphangitis, lymphadenitis, and genital pain from the associated lymphatic inflammation, as well as urticaria, nonspecific cutaneous eruptions, and peripheral eosinophilia[97].

Diagnosis

Detection of circulating filarial antigen is now the preferred method for diagnosis of Bancroftian filariasis; immunochromatographic card tests or test strips are typically utilized[111]. Similar tests are not currently available for Malayan filariasis, which can be diagnosed using a dipstick test for IgG4 antibody specific for the *Brugia* antigen BmR1. Alternatively, the diagnosis can be established by the demonstration of microfilariae in the blood, urine, or other body fluids and tissues, or by the identification of adult worms (Fig. 83.32)[119,120]. Visualization

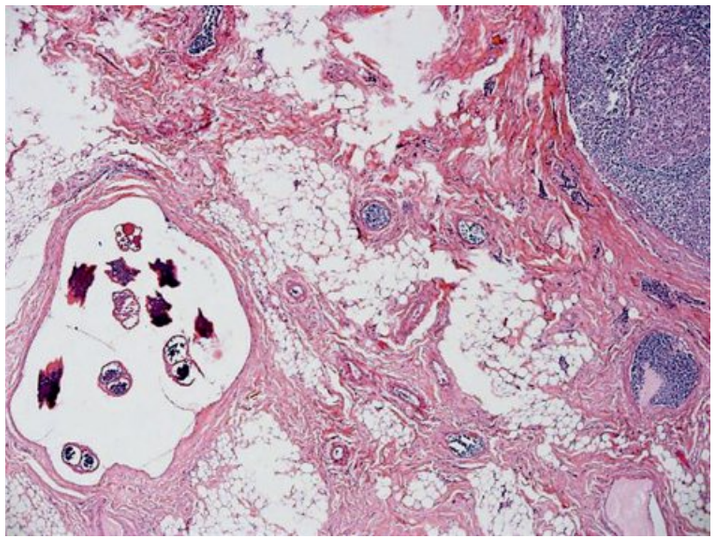

Fig. 83.32 Histopathology of filariasis. Dilated lymphatic with a mature adult worm and surrounding enlarged inguinal lymph nodes.

of motile adult worms may be possible using ultrasound to evaluate the infected lymphatics. As the parasite exhibits a nocturnal periodicity in humans, 10 p.m. to 2 a.m. is the optimal time period for collection and direct smear of blood or other fluids. The use of filters with a pore size of 3 microns has improved the rate of detection of microfilariae in the blood and urine. However, parasite detection is not a particularly reliable method because many symptomatic patients are amicrofilaremic. Species-specific PCR-based assays have been developed and are utilized in research studies on filariasis[121].

Peripheral eosinophilia and elevated serum IgE are very common laboratory findings. In addition, more than 50% of microfilaremic patients with *W. bancrofti* infections have hematuria and/or proteinuria[117].

Differential Diagnosis

The differential diagnosis depends upon the stage of the infection. Acute infection may be misdiagnosed as a bacterial lymphangitis. Lymphedema and elephantiasis have multiple possible etiologies, including recurrent bacterial lymphangitis, severe venous hypertension, lymph node dissections, podoconiosis, Milroy disease, and Klippel–Trenaunay syndrome (see Ch. 105)[122].

Treatment

The drug of choice is diethylcarbamazine, which is active against microfilariae but has a limited effect on adult worms. Filariasis is usually treated with a single 6 mg/kg dose of diethylcarbamazine; a 14–21-day course is recommended for patients with tropical pulmonary eosinophilia[111].

Mass drug administration programs with the goal of eradicating filariasis from endemic countries initially provided at-risk individuals yearly single doses of diethylcarbamazine. Current programs utilize annual administration of a triple-drug regimen including albendazole, ivermectin, and diethylcarbamazine, which has resulted in increased microfilarial clearance[123]. In areas co-endemic for loiasis or onchocerciasis, diethylcarbamzine is held (see below), with albendazole administered alone or together with ivermectin, respectively.

Doxycycline (200 mg/day for 4–8 weeks) targeting the *Wolbachia* endosymbiont can also eliminate microfilariae, kill adult worms, and improve lymphatic drainage. During the treatment period, antihistamines and corticosteroids may be useful in decreasing the allergic reaction that may result from massive disintegration of microfilariae. Because severe reactions may follow the administration of diethylcarbamazine in patients who have loiasis or onchocerciasis, it is important to exclude other helminthic diseases before instituting therapy[122]. Other management strategies include elevation of the affected body part, compression stockings, other anti-inflammatory drugs, treatment of secondary infections, and protection of the affected area from trauma[122].

SCHISTOSOMIASIS AND SWIMMER'S ITCH

Synonyms: ■ Schistosomiasis: bilharziasis ■ Swimmer's itch: clam digger's itch

Key features

- Schistosomiasis is a trematode (fluke) infection caused by five species of anthropophilic schistosomes, each with a specific geographic distribution and distinct intermediate host (snails)
- The disease is most commonly seen in Africa, the Far and Middle East, and South America
- Clinical manifestations include cercarial dermatitis, Katayama fever, and chronic fibro-occlusive disease involving the liver, intestine, and urinary tract
- The cercariae of more than 20 species of animal schistosomes may penetrate human skin and cause a transient dermatitis called swimmer's itch

Introduction

Schistosomiasis is a trematode (fluke) infection endemic to the tropics and subtropics caused by members of the superfamily Schistosomatidea[124]. The disease has a worldwide distribution, affecting more than 200 million people in over 75 countries. Human disease can be caused by five schistosome species, most often *Schistosoma haematobium*, which infects the urinary system, and *S. japonicum* and *S. mansoni*, which infect the gastrointestinal tract[124]. In addition, when the cercariae of other species that usually infect birds and mammals penetrate human skin, they can evoke "swimmer's itch", a local inflammatory response associated with marked pruritus.

Epidemiology

Schistosomes have a two-host life cycle (see Fig. 83.24). Snails serve as the intermediate host, while the definitive host is species-dependent. Humans are the major definitive host for five schistosome species[124], each of which has a specific geographic distribution (Fig. 83.33): *S. mansoni* occurs in Africa, South America, and the Caribbean; *S. japonicum* in Japan, China, and the Philippines; *S. haematobium* in Africa and the Middle East; *S. mekongi* in Southeast Asia; and *S. intercalatum* in West and Central Africa.

The geographic distribution of schistosomiasis has changed significantly in recent decades. It has been nearly eradicated from Japan and the Caribbean islands, and the transmission cycle has been interrupted in North Africa, the Philippines, Saudi Arabia, and Venezuela. However, environmental changes related to water resource development and population movement have led to spread of the disease to previously non-endemic areas such as sub-Saharan Africa. Schistosomiasis is now present in and around several major cities in northeastern Brazil and is a major public health problem in certain regions of China.

Swimmer's itch (a form of cercarial dermatitis) is due to over 20 species of schistosomes that usually infect birds and mammals (e.g. *Trichobilharzia*, *Gigantobilharzia*, *Ornithobilharzia* spp.). It is a cutaneous disease with distribution on every continent except Antarctica. In the US, it occurs most often in the north central states. Outbreaks of swimmer's itch are episodic.

Pathogenesis

Adult worms live in the venous system of the liver, rectum, or urinary bladder of their definitive host. The eggs penetrate the rectum or bladder and are passed into the feces or urine (see Fig. 83.24). In freshwater environments, the eggs hatch and release miracidia that penetrate the body of a snail, which acts as an intermediate host. For each schistosome species, a specific snail species acts as an intermediate host. In the snail, the miracidia develop into cercariae, the infective forms that can penetrate human skin on contact[125].

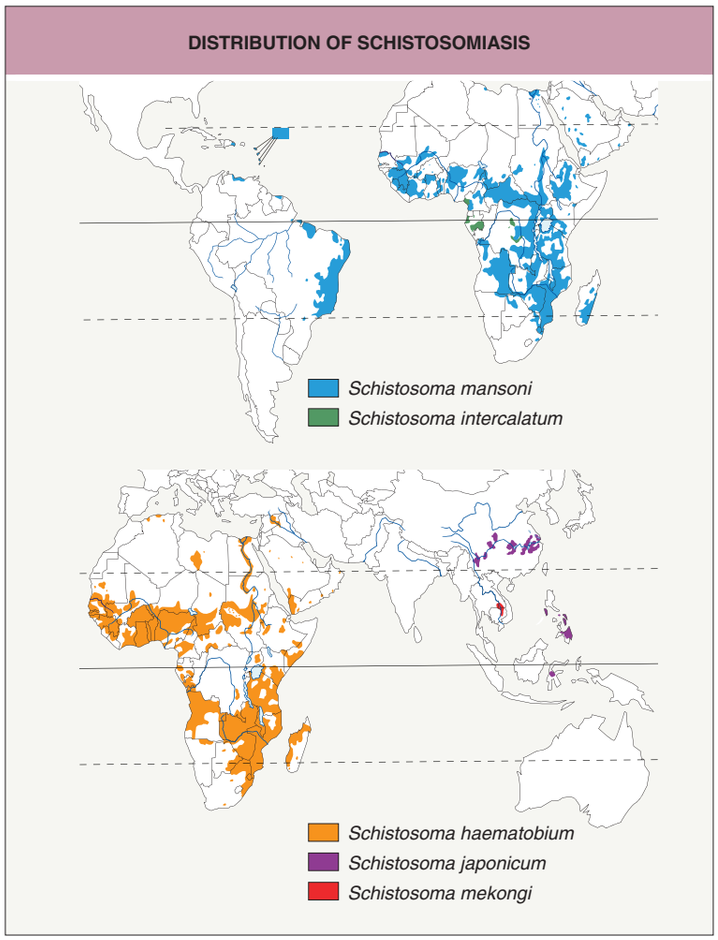

Fig. 83.33 Distribution of schistosomiasis. *Adapted from Gryseels B, Polman K, Clerinx J, Kestens L: Human schistosomiasis. Lancet 2006;368:1106–18.*

The species responsible for swimmer's itch complete their life cycle in birds and animals, including ducks, cows, sheep, and rodents. In contrast to human schistosomes, which cause systemic disease, the cercariae of animal schistosomes die after penetration into human skin, inducing only a local inflammatory reaction. Because humans cannot support the development of these schistosomes, they represent incidental, "dead-end" hosts[124–126].

Clinical Features

The cutaneous manifestations produced by the anthropophilic species of schistosomes can be classified into five categories: cercarial dermatitis, Katayama fever, late nonspecific allergic dermatitis, perigenital papulonodules (bilharziasis cutanea tarda), and extragenital ("ectopic") papules and plaques[127–129]. Lesions in the latter two categories can have an infiltrative granulomatous appearance. *Cercarial dermatitis* is associated with cutaneous penetration by the cercariae. Though fairly common, patients rarely present with this transient, erythematous, pruritic papular or urticarial eruption at the site of inoculation. The reaction is relatively nonspecific and is more severe with *S. japonicum* and *S. mansoni* infections. Within hours of contact, macules develop and then either disappear or, more commonly, are replaced by small pruritic papules that may persist for a few days[125].

In some patients, a systemic allergic reaction (*Katayama fever*) occurs during the acute phase of a moderate or heavy infection. Affected individuals have an acute onset of fever, chills, sweats and headaches, in association with peripheral blood eosinophilia and urticaria. Katayama fever is seen most commonly with *S. japonicum* infections and is due to circulating immune complexes. Approximately 4 to 6 weeks later, some patients experience another *transient cutaneous reaction with nonspecific findings* ranging from urticarial or purpuric lesions to periorbital edema[126,127,129].

Fig. 83.34 Swimmer's itch. Numerous edematous dark red papules on the feet and ankles. *Courtesy Kalman Watsky, MD.*

Bilharziasis cutanea tarda is characterized by papular, granulomatous, or verrucous lesions on genital and perineal skin secondary to the deposition of ova within dermal vessels in this area[126,129]. Occasionally, *"ectopic" cutaneous lesions* have been observed due to inflammatory reactions to deposited ova. They have been described as red–brown to brown papules and plaques and may have a zosteriform distribution on the trunk[127].

Systemically, chronic infections with *S. mansoni* and *S. japonicum* are associated with hepatic fibrosis and cirrhosis as a reaction to the ova; portal hypertension, including ascites and esophageal varices; and splenomegaly. Additional findings include colonic polyps (which contain ova) and granulomas around ova in the liver, lung, and colon (Hoeppli reaction). Urogenital infections with *S. haematobium* can lead to polypoid lesions composed of numerous ova, fibrosis, and calcification. Calcified ova may be seen through the atrophic epithelium, leading to "sandy patches" that are pathognomonic of schistosomiasis on cystoscopy[130]. Additionally, the presence of numerous ova can lead to obstruction of the urinary tract and hydronephrosis. Carcinoma of the bladder is a life-threatening complication.

Lesions of swimmer's itch have an appearance similar to that of cercarial dermatitis, i.e. pruritic papules at sites of inoculation (Fig. 83.34). As a result, areas of skin covered by clothing are spared[131]. The eruption may last for days but is self-limited.

Pathology

Histologically, cercarial dermatitis is characterized by spongiosis and a mixed inflammatory infiltrate composed of histiocytes, lymphocytes, neutrophils, and eosinophils. Edema is present in the dermis. Genital and perineal lesions of bilharziasis cutanea tarda show hyperkeratosis and acanthosis and occasionally prominent pseudoepitheliomatous hyperplasia. The dermis may contain numerous ova, which can be associated with a granulomatous reaction. "Ectopic" extragenital lesions contain ova in the superficial dermis and can also be associated with granuloma formation.

Diagnosis

The diagnosis is usually established by microscopic detection of eggs in the urine or feces. In the case of *S. japonicum* and *S. mansoni* infections, microscopic evaluation of mucosal biopsy specimens may point to the diagnosis. Serologic tests (e.g. ELISA) can detect IgG, IgM, and IgE against worm and egg antigens. Monoclonal antibody-based assays that detect circulating antigens, such as the urine circulating cathodic

antigen (CCA) dipstick, also represent sensitive and specific methods for establishing the diagnosis as well as assessing response to therapy and cure[132]. In addition, sensitive and specific PCR-based tests have been developed for the detection of schistosome DNA in feces, urine, and serum[133].

Differential Diagnosis

The diagnosis of cercarial dermatitis, including swimmer's itch, requires a history of exposure to contaminated water. The lesions may be confused with arthropod bites, but the distribution is clearly distinct from that of seabather's eruption, which affects areas under the swimsuit (see Fig. 85.20). The differential diagnosis of anogenital and ectopic cutaneous ova deposition includes secondary syphilis (in particular the granulomatous form), condylomata acuminata, cutaneous Crohn disease, granuloma inguinale, and sarcoidosis.

Treatment

Praziquantel is an antihelminthic agent that is safe and effective against all five human schistosomal species[134]. The recommended regimen is 40 mg/kg (for *S. mansoni*, *S. haematobium*, and *S. intercalatum*) or 60 mg/kg (for *S. japonicum* and *S. mekongi*) divided into 2–3 oral doses administered over one day[133]. A single 40 mg/kg dose is used in massive population control programs, with an efficacy of 65%–95%. Retreatment in 4 to 6 weeks can improve the cure rate[133]. Side effects are mild and include abdominal discomfort, fever, and headache.

Although topical remedies (e.g. phenolized calamine) and antihistamines have been recommended for swimmer's itch, no controlled studies have defined the most effective therapy[131,135]. If left untreated, the acute episode resolves spontaneously within 7–10 days.

The most effective way to prevent swimmer's itch is to avoid lakes and bodies of fresh water known to be infested, especially those periods of the year when cercariae are most plentiful, i.e. the early and mid summer in temperate regions.

CYSTICERCOSIS AND ECHINOCOCCOSIS

Synonyms: ■ Echinococcosis: hydatidosis, hydatid disease

Key features

- Cestodes (tapeworms) that commonly affect animals (e.g. *Taenia solium*, *Echinococcus granulosus*) can also infect humans
- Cutaneous cysticercosis is characterized by papules and nodules that are usually multiple and asymptomatic; the brain (neurocysticercosis), eye, heart, other muscles, and peritoneal cavity may also be affected
- In echinococcosis, the liver and lungs are the major sites of involvement, with development of one or more hydatid cysts. Allergic symptoms, such as urticaria, asthma and anaphylaxis, are uncommon

Introduction

In the two stages of their life cycle (adult and larval), cestodes (tapeworms) can cause disease in humans. The adult worms reside in the *definitive* host's intestines (including humans) and are often associated with minimal clinical manifestations (see Fig. 83.26). In *intermediate* hosts, the larval stage can lead to clinical disease, e.g. cysticercosis or echinococcosis in humans[136].

Epidemiology

The four most common human cestodes (tapeworms) are *Taenia solium* (pork tapeworm), *Taenia saginata* (beef tapeworm), *Diphyllobothrium latum* (fish tapeworm), and *Hymenolepis nana*. In humans, they cause primarily gastrointestinal symptoms, but the larval stage of *T. solium* also causes cysticercosis. Larvae of *T. solium* and *T. saginata*, respectively, can cause cysticercosis in pigs and cattle. Cysticercosis has a worldwide distribution, affecting more than 50 million people, and it is more common in rural areas. Endemic regions include Central and South America, sub-Saharan Africa, India, and East Asia[137,138].

Echinococcosis is a zoonosis caused by *Echinococcus* species, the definitive hosts of which are dogs and other members of the family Canidae. Humans are only infected by the larval stage, i.e. they are intermediate hosts, and develop cysts within viscera. Most human disease is due to larval stages of *E. granulosus* and *E. multilocularis*. Echinococcosis occurs in tropical and subtropical countries worldwide, primarily in sheep- and cattle-raising areas. Endemic regions include the southern province of Brazil, the Middle East, parts of Asia, and Northern and East Africa. It is particularly common in Lebanon and Greece[136,137].

Pathogenesis

The adult tapeworm can reach a length of up to 30 feet in the intestinal tract of its definitive host. Its body has two main parts: a single head (scolex) for attachment to the host and many proglottids, each of which has male and female reproductive organs. Fertilized eggs accumulate in large numbers inside the uterine horns of the proglottids; the eggs can be released directly into the host's intestine or the entire gravid terminal proglottid can be excreted by the host[136]. Both eggs and proglottids are found in the host's stool (see Fig. 83.26).

When eggs or proglottids are ingested by a susceptible intermediate host, they develop into larvae called oncospheres. In humans, oncospheres can develop into encysted forms (cysticerci in cysticercosis) or generate germinal tissue with a cyst (hydatid in echinococcosis). Subsequent ingestion of cyst-containing tissues by a susceptible definitive host allows the development of the larvae into adults and completion of the life cycle[139].

Humans are the only definitive host for *T. saginata* (beef tapeworm) and *T. solium* (pork tapeworm), becoming infected with the adult form after eating poorly cooked muscle of a diseased animal (see Fig. 83.26). Humans are also intermediate hosts of *T. solium*, developing cysticercosis as a result of ingestion of food or water contaminated with infected human feces or via autoinfection from anus to mouth. In contrast, humans are only intermediate hosts of *E. granulosus* (as are sheep and cattle) as a result of ingesting contaminated dog feces. Dogs are the definitive host of *E. granulosus*, becoming infected with adult tapeworms after eating infected beef or lamb.

When humans are infected by the adult stage of *T. solium* (i.e. are the definitive host), the tapeworms within the intestine usually cause no morphologically identifiable change in the mucosa or submucosa. Some patients may develop moderate peripheral eosinophilia. Immunity plays only a limited role during infections with the adult stage and has little effect on the duration of infection or on the susceptibility to reinfection. However, immunity plays an important role when humans are the intermediate host, i.e. develop cysticercosis. After penetrating the host's intestinal wall and disseminating, the oncosphere matures rapidly and by 10 weeks is fully developed. The cyst that forms is usually 0.5–1.0 cm in diameter and remains viable for 3 to 5 years before degenerating. At this time, the inflammatory response is markedly intensified, and calcification also often takes place[137,140,141]. The signs and symptoms triggered by these reactions depend on the location of the cysts. For example, if there are cysts at the base of the brain, a cysticercic meningitis may ensue. In brain tissue itself, cysts that calcify may cause seizures.

When humans ingest the eggs of *E. granulosus*, oncospheres penetrate the mesenteric vessels. While the majority are trapped by the liver sinusoids, some bypass the liver and are carried in the bloodstream to other organs and tissues. Within hours, an inflammatory response may be seen. If the larvae survive, they develop into hydatid cysts within 5 days. Cell-mediated immunity controls dissemination during the early phase of infection.

Clinical Features

In *cysticercosis*, cysts can develop in almost any organ or tissue in the body. Skin involvement presents as subcutaneous papulonodules that are more often palpable than visible[140,142,143]. They are usually multiple and asymptomatic. The brain, eye, heart, other muscles, and peritoneal cavity may also be affected. Subcutaneous involvement is recognized in <1%–20% of patients[142,143], and it is said to be more common in Asia and Africa than in Latin America[144]. However, in a Brazilian study of 30 patients with

cysticercosis, 90% had cysts in the subcutaneous tissue, skeletal muscle, or mucous membranes, while the CNS was affected in <10%[137].

In *echinococcosis*, the cysts may be single or multiple and they affect primarily the liver (50%–75%) and lungs (20%). The skin is involved in fewer than 2% of the patients. Cysts increase in size at the rate of ~1 cm/year. The clinical features are highly variable and reflect the location and size of the cysts. Most symptoms are due to mechanical pressure by the cyst mass or an allergic reaction (urticaria, wheezing, anaphylaxis) to foreign antigens in leaking cyst fluid[137].

Soft tissue cysts may present as firm subcutaneous nodules or as masses that are fluctuant and nontender. *E. multilocularis* has been noted to cause multiple supraumbilical dermal and subcutaneous nodules with associated ulceration, local inflammation, and painless cutaneous fistulas[137].

Diagnosis

The diagnosis of *cysticercosis* is often made by X-ray examination of the head or extremities, which reveals the calcified cysts. CT or MRI can also demonstrate lesions. ELISA and hemagglutination tests utilizing cyst vesicular fluid as antigen are 80%–95% sensitive and specific. An enzyme-linked immunoblot assay is the serologic test of choice, as its specificity and sensitivity approach 100% and 94%, respectively[137]. Tests that detect circulating cysticercal antigens and PCR-based assays have also been developed.

The diagnosis of *echinococcosis* is based on detection of cysts via ultrasound, CT, or MRI. Examination of the contents of the cyst and identification of the parasite provides confirmation. Peripheral eosinophilia is present in one-third of patients. Western blot and enzyme immunoassays are also available, which have a high degree of cross-reactivity with assays for cysticercosis. The assays have decreased sensitivity when the lesions are calcified, only one cyst is present, or the echinococcal cysts are not located in the liver[106].

Treatment

"Old", inactive lesions of cutaneous cysticercosis are treated surgically. Patients with active disease may be treated with albendazole (15 mg/kg/day with a maximum of 800 mg, for ≥8 days) or praziquantel (50–100 mg/kg/day in three divided doses for 2 weeks). Albendazole is cheaper and has 20% more cysticidal activity than praziquantel[145]. Evaluation for neurocysticercosis is mandatory in patients with cutaneous cysticercosis. Antiparasitic treatment in individuals with multiple CNS cysts may induce cerebral inflammation and edema that can exacerbate neurologic symptoms; concurrent administration of a systemic corticosteroid and close inpatient monitoring are recommended[144].

Surgical removal of the intact cyst is the preferred form of therapy for echinococcosis. Albendazole has been used in doses of 10 mg/kg/day for 8 weeks for the treatment of inoperable disease and as preoperative therapy for 4 days[145].

Control of the deposition of human feces is important for the prevention of cysticercosis. In addition, meat inspection for *T. solium* decreases its transmission[137]. Proper disposal of the carcasses and entrails of sheep, cattle, and hogs can help to prevent infection of dogs and thereby break the cycle of *Echinococcus* spp. transmission.

eFig. 83.11 Life cycle of *Trichinella spiralis*. This nematode is a zoonotic infection that circulates between rats and various carnivores. Trichinosis in humans commonly results from eating raw or inadequately cooked pork products such as sausages. Infection is acquired by eating muscle containing encysted larvae which excyst in the small intestine and develop into adults. Mature females deposit larvae which migrate from the gastrointestinal tract through tissues to reach skeletal muscles in which they then encyst. *With permission from Nabarro L, Morris-Jones S, Moore DAJ: Peters' Atlas of Tropical Medicine and Parasitology, 7th edition. London: Elsevier, 2019.*

GUIDELINES FOR CUTANEOUS AND MUCOCUTANEOUS LEISHMANIASIS
Epidemiology
Areas endemic for leishmaniasis include: • Asia – Middle East, Central Asia, India • Europe – Mediterranean countries, from Spain through the Balkans • Africa – Mediterranean countries, sub-Saharan countries, Sudan, Ethiopia • Americas – From Texas through Mexico, Central and South America, except Chile and Uruguay *In each country, the endemicity of areas a patient has visited should be assessed*.
Risk factors
Disease can be acquired by residents and visitors to endemic areas, which include rural as well as urban settings. For transmission, close contact is required between vector sandflies (*Phlebotomus* [Old World] and *Lutzomyia* [New World]) and natural reservoirs such as dogs, rodents, and humans.
Clinical
• Incubation period: weeks to months • Classical cutaneous leishmaniasis (CL) presents as an ulcerated or verrucous papule, nodule, or plaque in an exposed area of the body. Multiple lesions may develop, sometimes with satellites or sporotrichoid spread; additional presentations include erysipeloid and zosteriform patterns. • Disseminated and diffuse forms can also occur. • Patients should be assessed for scars suggestive of previous disease. • Mucosal leishmaniasis (ML) often starts as an ulceration of the nasal septum (with eventual perforation) but may involve the mouth, pharynx, and larynx. The nasal and oral mucosa should be examined in those at risk for ML, and otorhinolaryngology evaluation is recommended for those with signs/symptoms of mucosal involvement.
Diagnosis
Diagnosis is definitive with visualization of the amastigote. No test is 100% sensitive, so it is helpful to use multiple forms of assessment, depending on availability. • Clinically compatible morphology • Direct examination smear of fluid from the lesion stained with Giemsa, Wright, or Feulgen • Full-thickness skin biopsy for histopathological assessment and culture (in Nicolle–Novy–MacNeal–Nicolle [NNN] medium). Amastigotes can be seen in 50% of cases on H&E, but less often in long-standing lesions or if well-formed granulomas are present. Immunostaining has been developed but is not available commercially, and the utility of CD1a staining utility remains to be defined. • Delayed skin reaction test via intradermal injection of leishmania antigens; most useful in patients who do not reside in an area where leishmaniasis is endemic. • PCR-based assays on fluids, fresh tissue, or formalin-fixed paraffin-embedded tissue
Therapy
Cutaneous disease
• In *simple* CL(see Table 83.6) – e.g. an immunocompetent patient with ≤4 skin lesions <1 cm in diameter, thought to be infected with a *Leishmania* species not associated with ML – waiting for the lesion(s) to resolve spontaneously or local therapy may be appropriate. • Local therapies include heat, cryotherapy, topical paromomycin, intralesional pentavalent antimonials, and photodynamic or laser therapy. • In patients with CL at risk for ML based on the species or area acquired, even if lesions are healing/recently healed, systemic treatment should be considered; however, watchful waiting with monitoring for signs of ML may be a reasonable approach in some patients. • Systemic treatment with a parenteral pentavalent antimonial or miltefosine is recommended for patients with *complex* CL (see Table 83.6), defined as: disease caused by the *Viannia* subgenus or acquired in Brazil, Bolivia, or Peru; lesions with subcutaneous component, ≥4 in number, ≥5 cm in diameter, or located on the face, ears, fingers, toes, joints, or genitalia; CL occurring in an immunocompromised patient; or clinical failure of local therapy. • Leishmaniasis recidivans, disseminated cutaneous leishmaniasis, and diffuse cutaneous leishmaniasis should receive systemic therapy. • Patients with CL should be monitored for 6 to 12 months to rule out treatment failure.
Mucocutaneous disease
• All patients with mucocutaneous leishmaniasis should undergo otolaryngologic assessment and receive systemic therapy. • Impatient monitoring and prophylactic corticosteroids are recommended for patients with laryngeal/pharyngeal disease. • Systemic treatment options include a pentavalent antimonial, amphotericin B deoxycholate, liposomal amphotericin B, and oral miltefosine. • In patients with severe mucosal disease or HIV co-infection, the first line therapy is liposomal amphotericin B or amphotericin B deoxycolate.

eTable 83.1 Guidelines for cutaneous and mucocutaneous leishmaniasis.

COMPARISON BETWEEN WEST AFRICAN AND EAST AFRICAN TRYPANOSOMIASIS		
	West African trypanosomiasis	**East African trypanosomiasis**
Causative agent	*T. brucei gambiense*	*T. brucei rhodesiense*
Vector	Tsetse fly	Tsetse fly
Main host	Humans	Wild game > humans
Reservoir	Humans	Antelope, cattle
Location	West/central regions of sub-Saharan Africa	Ethiopia, Uganda, Zambia, Botswana, Tanzania, Mozambique
Clinical presentation	• Slow progression (3 years) • Chancre uncommon • Chronic neurologic symptoms • Posterior cervical (Winterbottom sign) and supraclavicular lymphadenopathy • Trypanids (10%–50% of patients, easier to detect in lighter skin phototypes)	• Quick progression (weeks to months) • Chancre common (75% of patients) • Acute neurologic symptoms • Axillary and epitrochlear lymphadenopathy • Trypanids common (easier to detect in lighter skin phototypes) • Myocarditis/heart failure
Treatment		
Hemolymphatic (first stage)	• Oral fexinidazole • IM pentamidine (children <6 years of age or <20 kg)	• Suramin
CNS involvement (second stage)	• Oral fexindazole (non-severe disease) • Nifurtimox + eflornithine (severe disease; children <6 years of age or <20 kg)	• IV melarsoprol

eTable 83.2 Comparison between West African and East African trypanosomiasis. Non-severe second stage: <100 leukocytes/mcl in CSF; severe second-stage: ≥100 leukocytes/mcl in CSF. IM, intramuscular; IV, intravascular.

SCABIES

Synonyms: ■ Itch mite infestation ■ "Seven-year itch"

Key features

- Human scabies is a pruritic condition caused by infestation with the host-specific mite *Sarcoptes scabiei* var. *hominis*, which lives its entire life within the epidermis
- Although the scabies mite is not a known vector for any systemic disease, secondary bacterial infections with *Streptococcus pyogenes* or *Staphylococcus aureus* may develop
- Transmission typically occurs via direct close contact with an infested person; fomite transmission is also possible, especially with the crusted variant
- Permethrin 5% cream is generally the first-line treatment for classic scabies

Introduction

The scabies mite continues to plague all countries of the world[1]. An estimated 150–200 million individuals are affected globally, with an overall worldwide prevalence of ~2.5%[2,3]. In 2017, the World Health Organization (WHO) designated scabies as a neglected tropical disease to highlight the need for global control strategies. Pruritus associated with this infestation is usually severe, especially at night, and treatment typically requires prescription scabicidal therapy.

History

Scabies has been a common companion of the human species for over 2500 years[1].

Epidemiology

Scabies is a worldwide problem and all ages, races, and socioeconomic groups are susceptible. Environmental factors that promote its spread include overcrowding, institutional settings, delayed treatment, and lack of public awareness of the condition. There is considerable variation in the prevalence of scabies, with rates in low-income countries ranging from 4% to 70%[1–3]. Higher incidences occur in tropical regions, and outbreaks may occur in the setting of natural disasters, wars, economic depression, and refugee displacement[1,4]. Scabies can be transmitted directly by close personal contact, sexual or otherwise, or indirectly via fomites. Prevalence is higher in children and people who are sexually active, and spread of the infestation among family members and other close contacts is common[4]. The scabies mite is not a known vector for systemic disease.

Crusted scabies (formerly called Norwegian scabies) is found in individuals with compromised immune systems, such as the elderly, people infected with HIV or human T cell lymphotropic virus type 1 (HTLV-1), and solid organ transplant recipients; it can also occur in those with decreased sensory functions and/or ability to scratch (e.g. patients with leprosy or paraplegia). These patients may experience minimal pruritus despite their infestation with a large number of mites and are highly contagious[4].

Pathogenesis

The species-specific, eight-legged mite *Sarcoptes scabiei* var. *hominis* causes human scabies (Fig. 84.1). The *Sarcoptes* mites that cause infestations in animals (e.g. *S. scabiei* var. *canis* in dogs) are not a source of human infestation, but they can produce bite reactions (see Ch. 85). The scabies mite is 0.35 × 0.3 mm in size and too small to be seen by the naked eye. The entire 30-day life cycle of these mites is completed within the epidermis (Fig. 84.2). Each day a female mite lays 2–3 eggs, which require approximately 10 days to mature. The number of mites living on an infested host can vary greatly, although there are usually fewer than a hundred and often no more than 10–15. However, patients with crusted scabies may have thousands of mites on their skin surface, and live mites can be recovered in debris from sheets, the floor, curtains, and chairs in the environment of affected individuals[5]. Scabies mites usually live 3 days or fewer off a human host, but those from patients with crusted scabies may live up to 7 days by feeding on sloughed skin.

The incubation period before symptoms develop can range from days to months. In first-time infestations, it usually takes 2–6 weeks before the host's immune system becomes sensitized to the mite or its by-products, resulting in pruritus and cutaneous lesions. In contrast, a subsequent infestation often becomes symptomatic within 24–48 hours. Asymptomatic scabies-infested individuals are not uncommon, and they can be considered "carriers"[5].

Clinical Features

The epidemiologic history (e.g. pruritus in household members or other close personal contacts), the distribution and types of lesions, and pruritus form the basis of the clinical diagnosis. The intense pruritus is classically accentuated at night and by a hot bath or shower. Pruritus may be present before any overt physical signs appear and is thought to be mediated by nonhistaminergic mechanisms[6]. Cutaneous lesions are symmetrical, typically involving the interdigital web spaces of the hands, flexural aspect of the wrists, axillae, posterior auricular area, waist (including the umbilicus), ankles, feet, and buttocks. In men, penile and scrotal lesions are common, while in women, the areolae, nipples, and vulvar area are often affected. In infants, the elderly and immunocompromised hosts, all skin surfaces are susceptible, including the scalp and face[1,5].

Typically, small erythematous papules are present in association with a variable degree of excoriation (Fig. 84.3A–C). Vesicles, indurated nodules, and eczematous dermatitis are also common (Fig. 84.3B–F). The pathognomonic sign is the burrow, representing the tunnel that a female mite excavates while laying eggs. Clinically, the burrow is wavy, thread-like, grayish-white, and 1–10 mm in length (Fig. 84.3G). Many patients, however, do not have obvious burrows on inspection, especially in warm climates.

Acral vesiculopustules can represent a clue to the diagnosis of scabies in infants (see Fig. 84.3D). Crusted scabies often manifests with marked hyperkeratosis that favors acral sites including subungual areas,

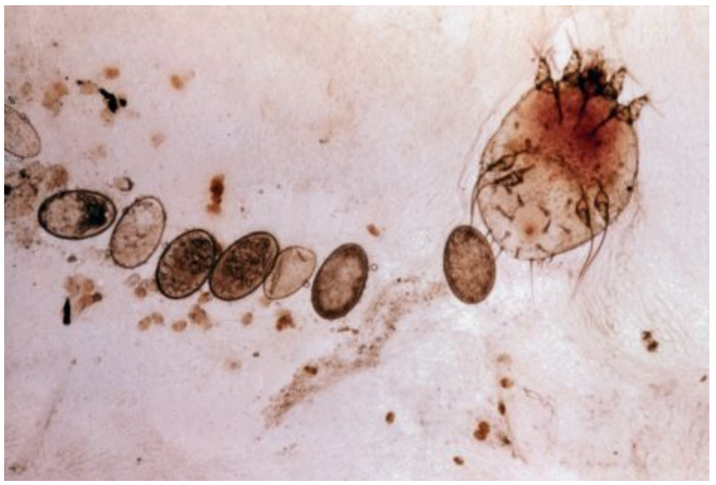

Fig. 84.1 Female scabies mite with eggs and scybala in skin scrapings. Note the mite's flattened, oval body and eight legs.

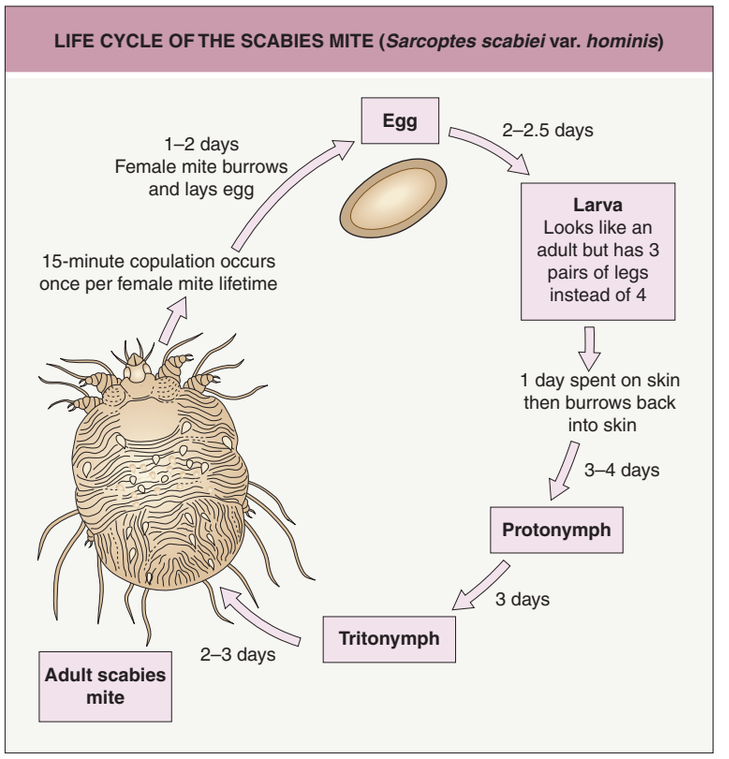

Fig. 84.2 Life cycle of the scabies mite (*Sarcoptes scabiei* var. *hominis*).

Fig. 84.3 Scabies. A–C Erythematous papules and oozing dermatitic plaques in infants with scabies. **D** Vesiculopustules on an infant's foot. Similar findings are seen in acropustulosis of infancy, which can occur following successful scabies treatment. **E** Penile involvement with erythematous papules and nodules. **F** Nodular scabies in an infant. **G** Classic scabetic burrows. Burrows are of high yield for visualizing mites via dermoscopy and isolating mites via skin scraping. *A–D, Courtesy Julie V. Schaffer, MD; F, Courtesy Kalman Watsky, MD.*

Fig. 84.4 Crusted scabies. Scabies incognito presenting as an asymptomatic hyperkeratotic "rash" on the hand in a patient with impaired sensory function (**A**) and on the abdomen of a hospitalized man (**B**). *A, Courtesy Joyce Rico, MD; B, Courtesy Kalman Watsky, MD.*

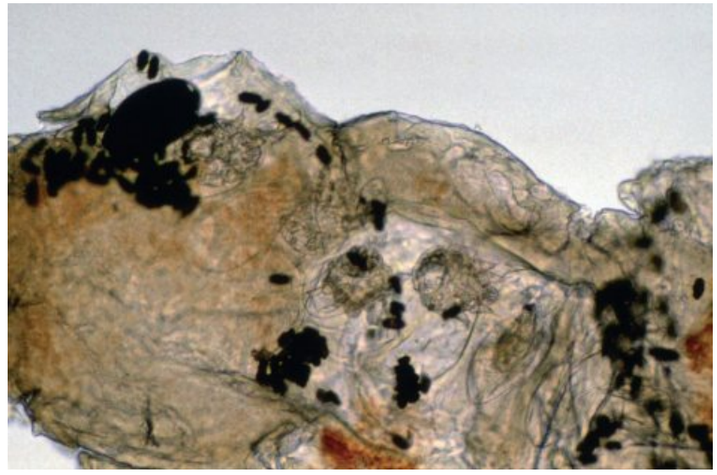

Fig. 84.5 Microscopy of a skin scraping from a patient with scabies. Four mites, eggs, and scybala are present. The mites blend in with the background scale, making them difficult to see.

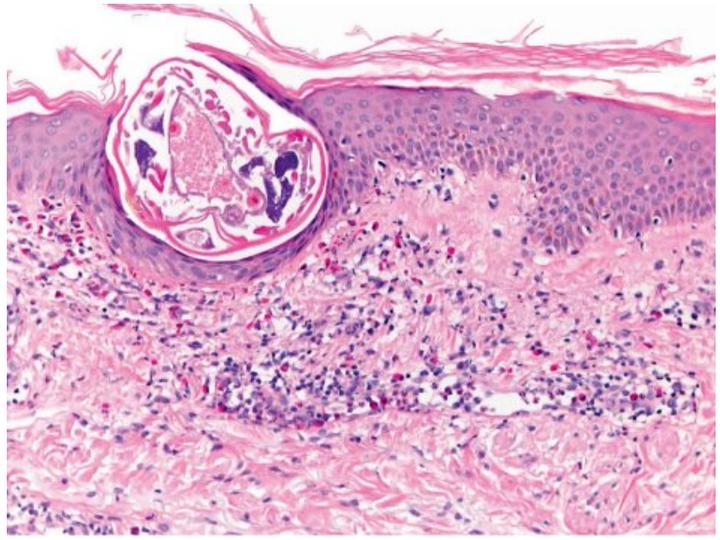

Fig. 84.6 Scabies – histologic features. A mite is evident in the stratum corneum and an eosinophil-rich dermal infiltrate is present. *Courtesy Lorenzo Cerroni, MD.*

but involvement may be widespread (Fig. 84.4). Areas of affected skin have been referred to as pachyderma.

Secondary bacterial infections with *Staphylococcus aureus* or *Streptococcus pyogenes* sometimes complicate scabies. In resource-poor countries with endemic scabies, post-streptococcal glomerulonephritis is a significant issue. Peripheral eosinophilia can be the primary sign of scabies in patients with disorders of keratinization.

Confirmation of the diagnosis can be achieved by light microscopic examination of mineral oil preparations of skin scrapings (from infested areas) for adult mites, eggs, and/or fecal pellets (scybala; Fig. 84.5). A scalpel or curette may be used to obtain the skin sample[7]. Microscopic examination of transparent adhesive tape following its application to infested areas of skin represents another diagnostic technique. Dermoscopy and confocal microscopy can prove useful for direct *in vivo* visualization of mites and eggs (see Fig. 84.5). Recent consensus criteria for a *confirmed* scabies diagnosis require visualization of mites, eggs, or feces either by light microscopy of skin samples or on an individual by a high-powered imaging device or dermoscopy[8]. A skin biopsy may confirm the clinical diagnosis, but only if the specimen obtained happens to contain the mite or its eggs. Often, however, the diagnosis is a clinical one, resting on history and physical findings (e.g. burrows, genital lesions)[8] as well as response to treatment. The diagnostic potential of PCR-based analysis of skin scrapings or swabs and serologic testing to detect IgE specific for a recombinant *S. scabiei* antigen are under investigation[9,10].

Pathology

A patchy to diffuse infiltrate with prominent eosinophils as well as lymphocytes and histiocytes is noted in the reticular dermis. A transected scabies mite may occasionally be seen within the epidermis (Fig. 84.6). Pink "pigtail"-like structures attached to the stratum corneum, which represent fragments of the adult mite exoskeleton, can serve as a clue to the diagnosis of scabies when entire mites, scybala, and eggs are not identified[11].

Differential Diagnosis

Unless burrows or (via dermoscopy) mites and eggs are noted clinically, a wide variety of pruritic skin diseases should be considered in the differential diagnosis. These include atopic, allergic contact, autosensitization ("id" reaction), and nummular dermatitis as well as arthropod bites, pyoderma, dermatitis herpetiformis, and bullous pemphigoid. Occasionally, scabies can mimic Langerhans cell histiocytosis clinically and histologically, as a dense infiltrate of Langerhans cells may be present. The clinical and histologic features of infantile scabies may also resemble findings in the inflammatory stage of incontinentia pigmenti. Acropustulosis of infancy can both mimic scabies and follow scabies as a hypersensitivity phenomenon.

TOPICAL AND ORAL TREATMENTS FOR SCABIES					
Therapy	**Administration**	**Concerns**	**Efficacy & resistance**	**Use in infants**	**Use in pregnancy**
Permethrin cream (5%)	Topically overnight (8–12 hours) on days 1 and 8*	Allergic contact dermatitis in individuals with sensitivity to formaldehyde	Excellent, but some signs of tolerance developing	FDA approved for infants ≥2 months of age	Considered safe
Spinosad suspension (0.9%)	Topically for ≥6 hours on day 1	Skin irritation, dry skin	Good	FDA approved for children ≥4 years of age	Considered safe
Lindane lotion or cream (1%)	Topically overnight on days 1 and 8	Potential CNS toxicity, especially in individuals weighing <110 pounds (50 kg), the elderly and those with crusted scabies, other skin conditions or a history of seizures	Poor, resistance very common	Not recommended for infants, children or breastfeeding mothers; contraindicated in premature infants	Not recommended
Crotamiton lotion or cream (10%)	Topically overnight for 2–5 consecutive days	Irritant contact dermatitis, especially in areas of denuded skin	Very poor; has antipruritic properties and may be used for postscabetic pruritus	Considered safe	Not established
Sulfur ointment (5%–10%)	Topically overnight for 3 successive days	Toxicity studies not performed	Good	Considered safe	Considered safe
Benzyl benzoate lotion or emulsion (10%–25%)	Topically (left on for 24 hours) on days 1 and 8	Irritant contact dermatitis	Good	Not well established	Not established
Ivermectin	Oral dose of 200 mcg/kg on day 1 and repeated on day 8 or 14*,† (available as 3 mg tablets)	Potential risk of CNS toxicity in infants and young children	Excellent	Not well-established, although recent studies suggest safety in children (age ≥1–2 months) weighing <33 pounds (15 kg)	Generally not recommended for scabies in pregnant women
	0.5%–1% lotion/cream topically overnight on days 1 ± 8	Potential skin and eye irritation	Not established	Not established	

*For crusted scabies, the CDC recommends: (1) topical permethrin 5% every 2–3 days for 1 to 2 weeks; (2) oral ivermectin (200 mcg/kg/dose) administered as three doses (days 1, 2 and 8), five doses (days 1, 2, 8, 9, and 15), or seven doses (days 1, 2, 8, 9, 15, 22, and 29), depending upon the severity of the infection; and (3) application of a topical keratolytic (e.g. salicylic or lactic acid) in areas of hyperkeratosis (www.cdc.gov).
†Administration of second dose at 1 week is recommended by the CDC (www.cdc.gov).

Table 84.1 Topical and oral treatments for scabies. Topical therapies for scabies require careful instructions to ensure correct application by patients.

Treatment

Two treatments 1 week apart with an antiscabetic medication are typically recommended, with permethrin 5% cream a standard first-line therapy (Table 84.1)[4,12]. Topical preparations are applied to the entire body surface, from head to toe, in infants and the elderly. In other age groups, the face and scalp can be excluded from treatment. Special attention should be paid to the interdigital spaces, intergluteal cleft, umbilicus, and subungual areas. To reduce the potential for reinfestation by fomite transmission, at the time of each treatment, clothing, linens, and towels used within the previous week can be either washed in hot water and dried on high heat or stored in a bag for 7–10 days[13]. The relatively common occurrence of asymptomatic mite carriers in households necessitates that all family members and other close contacts be treated simultaneously, even if they have not developed any pruritus or clinical signs. Pets cannot harbor human mites and do not have to be treated. Secondary bacterial infections should be treated with appropriate antibiotics.

Following successful treatment, pruritus and skin lesions can persist for 2–4 weeks or longer, especially for acral vesiculopustules in infants and nodules. This is referred to as "postscabetic" pruritus or dermatitis. Patients should be informed that such reactions do not imply treatment failure, but rather represent the body's response to dead mites that are eventually sloughed off (within 2 weeks) along with normal epidermal exfoliation. Many patients, however, experience relief from pruritus within 3 days. The second treatment is performed in order to reduce the potential for reinfestation from fomites as well as to ensure killing of any nymphs that may have survived within the semi-protective environment of the egg and subsequently hatched (see Fig. 84.2).

Permethrin

Permethrin is a synthetic pyrethroid formulated in a 5% cream that is currently the standard topical scabicide[4,12,14a]. Like other pyrethroids, it inhibits sodium transport in arthropod neurons, thereby causing paralysis. Adverse reactions are rare and are usually related to brief stinging on application. Prolonged *in vitro* survival of *S. scabiei* var. *hominis* following permethrin exposure has been noted, but clinical resistance has not been documented.

Spinosad

In 2021, 0.9% spinosad suspension was FDA-approved for the treatment of scabies in patients ≥4 years of age. In a randomized clinical study (n=206), a single application of 0.9% spinosad suspension to the entire body (neck to toes; left on for ≥6 hours) led to a complete cure on day 28 in 78% of patients with scabies, compared to 40% for placebo ($p<0.001$)[14b].

Lindane

Lindane (gamma-hexachlorocyclohexane), an organochlorine agent, is marketed in a 1% lotion and cream. CNS side effects may occur from increased percutaneous absorption through damaged skin, misuse, overuse, or accidental ingestion. Because of the potential for CNS toxicity, lindane is contraindicated in premature infants, individuals with crusted scabies or pre-existing skin conditions (e.g. extensive atopic dermatitis) that may increase its systemic absorption, as well as patients with an uncontrolled seizure disorder. Potential toxicity, relatively poor efficacy, widespread resistance, and issues related to environmental contamination make lindane an inferior treatment choice compared to permethrin or oral ivermectin. In 2003, the US Food and Drug Administration (FDA) issued a "black box" warning for lindane products, stating that they should be used with caution in infants, children, other individuals who weigh <110 pounds (50 kg), and the elderly due to an increased risk of neurotoxicity[4].

Crotamiton

An alternative scabicide is crotamiton, which is formulated in a 10% lotion and cream. Although it has an antipruritic effect, crotamiton

can cause irritation of denuded skin and is less effective than the other prescription options[15].

Sulfur ointment

Another alternative therapy for scabies is three consecutive overnight applications of 5%–10% sulfur in a petrolatum base. A pharmacist must compound the medication, and toxicity studies have not been performed. Sulfur is messy, malodorous, and irritating to the skin and can stain clothing. However, its efficacy has been reported to be as high as 60%–96% with three consecutive 24-hour applications[16a].

Benzyl benzoate

Benzyl benzoate is an ester of benzoic acid and benzyl alcohol that is neurotoxic to mites. It is available over-the-counter (OTC) in a 10%–25% lotion or emulsion (not directly sold in US pharmacies; lower concentrations used in children) that is left on for 24 hours. Regimens include: 2-3 applications over a 24-hour period; applications on 3 consecutive days; and applications on day 1 and day 8. Cure rates of ~90% have been reported, and the main side effect is skin irritation[16b].

Ivermectin

Ivermectin is a macrocyclic lactone produced by *Streptomyces avermitilis*. Although not FDA-approved for scabies, ivermectin represents an effective treatment for this and other ectoparasitic infestations[1,17]. By blocking transmission across nerve synapses that utilize glutamate or γ-aminobutyric acid (GABA), ivermectin causes paralysis of peripheral motor function in insects and acarines[1,17]. Although GABA and glutamate are neurotransmitters within the human cerebral cortex, after early infancy, the blood–brain barrier prevents CNS penetration of the drug. However, neurotoxicity can occur in rare individuals with biallelic nonsense mutations in the *ABCB1* (ATP-binding cassette subfamily B member 1) gene encoding the P-glycoprotein that functions in the blood–brain barrier[18]. Ivermectin is not recommended for pregnant women or breastfeeding mothers because of the lack of safety data in these groups[1]. Oral ivermectin treatment for scabies in infants and children weighing <33 pounds (15 kg) was well-tolerated in a recent large series,[19] although traditionally not recommended in this group.

In clinical studies, oral ivermectin has proven to be extremely safe. Over 18 million people >5 years of age have been treated annually with ivermectin in the WHO Onchocerciasis Eradication Program. An increased death rate in elderly patients who received ivermectin in a single retrospective study[20] was determined to be causally unrelated to the medication by the WHO, medical examiners, and the scientific community. A related medication with a longer half-life, moxidectin, was recently FDA-approved for onchocerciasis and is under investigation as a potential scabies treatment[4].

For treatment of scabies, an oral ivermectin dose of 200 mcg/kg is usually administered twice, 1–2 weeks apart[1,17]. Although there is only one report to date of clinical resistance to this agent by the scabies mite, increased *in vitro* survival times of mites exposed to ivermectin have been described in communities with a high prevalence of scabies[21]. In areas with endemic disease, mass administration of oral ivermectin or topical permethrin (± coadministration of azithromycin) can help to control scabies and reduce the prevalence of impetigo[22].

Topical ivermectin in a 1% concentration (FDA-approved for the treatment of rosacea) also appears to be effective for scabies, but further study is warranted before recommending its routine use for this indication[23]. In patients with subungual disease, addition of a topical scabicide is recommended because a systemic medication will not penetrate into thickened keratotic debris. A combination of oral ivermectin and topical permethrin is often required to treat patients with crusted scabies (see Table 84.1), and use of a topical keratolytic agent (e.g. salicylic or lactic acid) can help to decrease the associated hyperkeratosis.

HEAD LICE

Synonyms: ■ Pediculosis capitis ■ "Cooties"

Key features

- This worldwide infestation is caused by bloodsucking, wingless, six-legged insects that live only on the hairs of the scalp
- Diagnosis is usually confirmed by the presence of 0.8 mm eggs ("nits") firmly attached to scalp hairs
- Head lice are spread by head-to-head contact as well as by fomite transmission
- Resistance to traditional over-the-counter preparations (pyrethrins, permethrin) is growing
- Newer treatments, including topical ivermectin, are now available

Introduction

Lice are bloodsucking, wingless insects belonging to the suborder Anoplura. Twelve million cases per year occur in the US alone, and resistance to traditional treatments is increasing. Prescription products (e.g. topical malathion, topical or oral ivermectin) are often needed to treat resistant cases, requiring greater physician involvement.

History

Head lice have infested mankind for thousands of years. Nits have been found on the hair of Egyptian and Peruvian mummies[1].

Epidemiology

Head lice are found worldwide with no strict limitations based upon age, sex, race, or socioeconomic class. Children 3–11 years of age have the highest incidence. The worldwide prevalence in school-aged children was estimated to be 19% in a recent meta-analysis, with prevalences as high as 60% in some countries[1,24]. Infestation with head lice is more frequent in girls, probably due to their tendency to have longer hair as well as to exchange brushes, barrettes, and other hair accessories. Head lice are distinctly uncommon in African-Americans, as head lice in the US are unable to properly position themselves to lay eggs on coarse curly hair[20].

Pathogenesis

The head louse, *Pediculus capitis*, is a highly host-specific insect approximately the size of a sesame seed (2–3 mm; Fig. 84.7). These obligate human parasites feed on the blood of the host approximately every 4–6 hours. The female louse lives for 30 days, during which time she lays between 5 and 10 eggs a day on hair shafts (Fig. 84.8). The

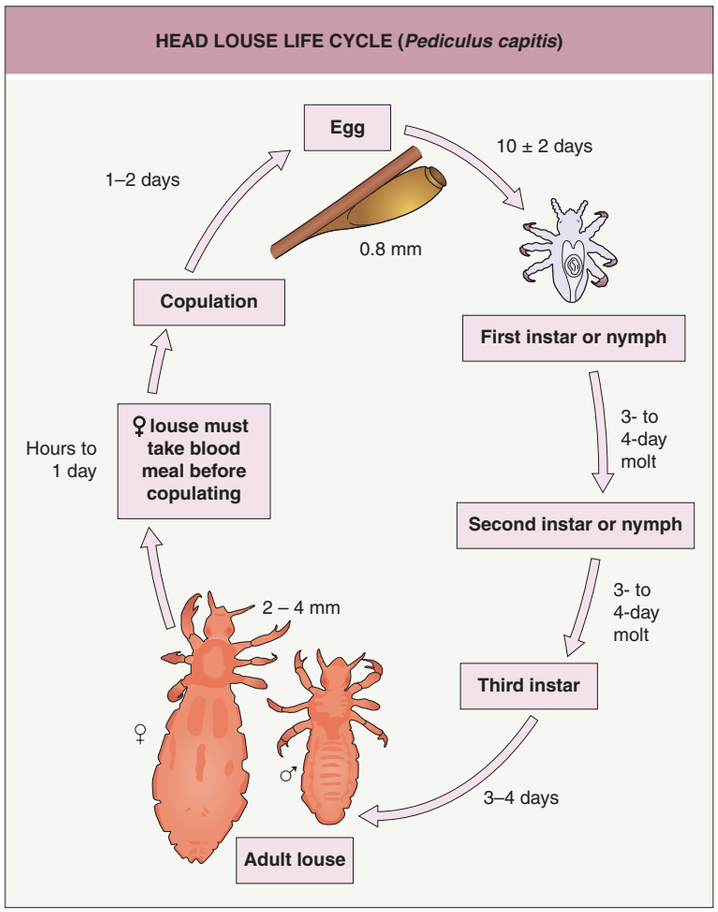

Fig. 84.8 Head louse life cycle (*Pediculus capitis*).

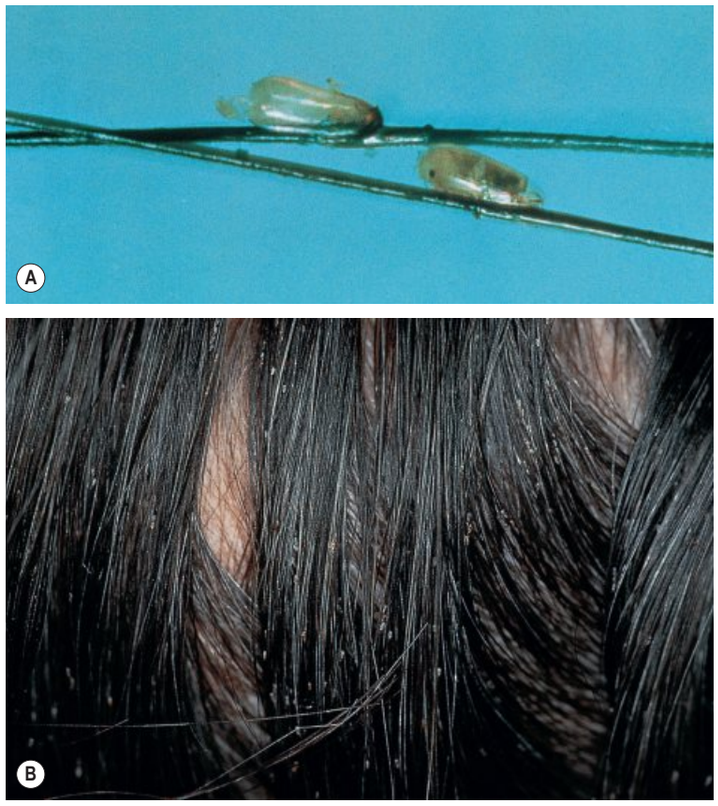

Fig. 84.9 Head lice. A The head louse egg or nit is 0.8 mm in length. **B** Head lice nits on hair. *With permission from Taplin D, Meinking TL. Infestations. In: Schachner LA, Hansen RC (eds). Pediatric Dermatology, 4th edn. Edinburgh: Mosby, 2011:1141–80.*

oval egg capsules (nits) measure 0.8 mm in length and are usually laid close to the scalp for warmth; in general, eggs located within 1 cm of the scalp are unhatched. In warm climates, however, viable nits may be found 15 cm or more from the scalp, especially in the area above the nape of the neck. The nits are cemented to individual hairs by a proteinaceous matrix that closely resembles the amino acid constituents of the human hair shaft itself[25,26]. Head lice rarely live for more than 36 hours away from the host without a blood meal; however, given an appropriate temperature (82–90°F/28–32°C) and level of humidity (70%–90%), nits can survive and hatch after 10 days away from the host. Transmission occurs via direct head-to-head contact or by fomites such as combs, brushes, blow-dryers, hair accessories, bedding, helmets, and other headgear[27].

Clinical Features

Skin findings of head lice infestation are limited to the scalp, behind the ears, and the nape of the neck. The classic symptom of intense pruritus varies among patients. It may take 2–6 weeks following an initial infestation before pruritus is evident, reflecting a delayed immunologic response to components of the lice saliva or excreta. In repeat infestations, pruritus develops within the first 24–48 hours. However, some individuals are asymptomatic "carriers". Although excoriations, erythema, pyoderma, and scaliness of the scalp and posterior neck are common findings, definitive diagnosis is made by the identification of nits and/or adult lice on the scalp hair. Viable eggs are usually tan to brown in color, whereas hatched eggs are clear to white (Fig. 84.9).

Patients occasionally present with a low-grade fever and lymphadenopathy due to a secondary bacterial infection. Head lice can carry *S. aureus* and *Str. pyogenes* on their surfaces and are a common cause of pyoderma of the scalp[1]. There is increasing evidence that head lice may harbor other pathogens such as *Bartonella recurrentis*, *B. quintana*, *Coxiella burnetii*, and *Acinetobacter* spp.; however, it is unclear whether this is associated with disease transmission[28,29].

Pathology

The epidermis and dermis may display nonspecific inflammation.

Differential Diagnosis

Although several dermatoses, such as seborrheic dermatitis and psoriasis, can cause pruritus of the scalp, the finding of nits or adult lice is diagnostic. Nits are more firmly adherent to the hair shaft than dandruff, dried hair products (e.g. sprays, gels) or hair casts, and they must be differentiated from other causes of hair shaft nodules such as piedra (white or black) and trichorrhexis nodosa (see Fig. 77.1).

Treatment

The choice of treatment is based on the efficacy and potential toxicity of different agents, insecticide resistance patterns in the geographic area, and ease of access to prescription remedies[30]. Pediculicides remain the mainstay of therapy (Table 84.2). With all topical preparations (regardless of package instructions), two applications, 1 week apart, are advisable in order to: (1) kill any nits that survived treatment; (2) better defend against the growing resistance to many pediculicides; and (3) reduce the risk of reinfestation by means of fomites. Conditioner should not be applied prior to topical medications, and the hair should not be rewashed for 1–2 days[30].

Unsubstantiated claims of successful treatment with alternative, non-pesticidal products, including petroleum jelly, hair pomade, olive oil, mayonnaise, vegetable oil and mineral oil, persist. Such products may slow the movements of adult lice and allow them to be more easily combed out of the scalp, but these substances are not lethal to lice. Several essential oils (e.g. combinations of tea tree, lavender, and eucalyptus oils) have been reported to be effective as lice therapy,[30,31] and they have been incorporated into various products that are typically found in health food stores. However, additional clinical studies are needed to confirm their safety and efficacy. Oral trimethoprim–sulfamethoxazole may potentially improve the efficacy of topical agents, but its routine use is not recommended[32].

Many school authorities enforce a "no-nit" policy and do not allow children to return to school if they have nits, regardless of whether they

TREATMENTS FOR HEAD LICE				
Treatment	**Group**	**Administration on days 1 and 8**	**Concerns**	**Efficacy & resistance**
Over-the-counter products				
Ivermectin lotion (0.5%)‡	Avermectin	Topical application for 10 minutes to dry hair	Potential skin and eye irritation	Good; single report of resistance to date
Dimethicone liquid gel, lotion, or spray (4%–100%)	Silicone oil	Topical application for 10–15 minutes or overnight	None	Good (varies with different formulations)
Pyrethrins (0.33%) synergized with piperonyl butoxide (4%), various formulations	Natural botanicals	Topical application for 10 minutes to dry hair	Allergic reactions in individuals with sensitivity to chrysanthemums, ragweed and related plants	Poor–fair; resistance common
Permethrin cream rinse or lotion (1%)	Synthetic pyrethroid	Topical application for 10 minutes to clean, dry hair	None	Poor–fair; resistance common
Prescription products (order based upon efficacy, but those ranked as Good are often used as first-line therapies)				
Malathion lotion or gel (0.5%)†	Organophosphate cholinesterase inhibitor	Topical application for 8–12 hours to dry hair (Ovide® and gel products with isopropyl alcohol base are effective at 20 minutes)	Flammable isopropyl alcohol base; burning or stinging at sites of eroded skin	Excellent (in US); resistance noted in Europe and Australia, but to date not in US
Oral ivermectin (available as 3 mg tablets)	Avermectin	Oral dose of 200–400 mcg/kg	Potential risk of CNS toxicity; not recommended for breastfeeding mothers or pregnant women (category C); recent studies suggest safety in children ≥1–2 months of age weighing <33 pounds (15 kg), but use is not well-established in this group	Excellent; single report of resistance to date
Spinosad suspension (0.9%)‡	Bacterial fermentation product	Topical application for 10 minutes to dry hair	Potential skin and eye irritation	Good; no resistance noted to date
Abametapir lotion (0.74%)‡	Metalloproteinase inhibitor	Topical application for 10 minutes to dry hair	Potential skin irritation	Good; no resistance noted to date
Benzyl alcohol lotion (5%)‡	Alcohol	Topical application for 10 minutes to dry hair	Potential skin irritation	Good; no resistance noted to date
Permethrin cream (5%)*	Synthetic pyrethroid	Topical overnight application to clean, dry hair	Allergic contact dermatitis in individuals with sensitivity to formaldehyde	Poor–fair; resistance common
Lindane shampoo (1%)	Organochlorine	Topical application for 4 minutes to clean, dry hair, then add water to lather and rinse	Potential CNS toxicity; not recommended for infants, children, breastfeeding mothers or pregnant women (category C)	Poor; resistance common
Carbaryl shampoo (0.5%)	Carbamate cholinesterase inhibitor	Topical application for 8–12 hours	Possible carcinogen	Poor–fair; resistance common (not approved in the US)

*Approved for individuals ≥2 months of age; considered safe during pregnancy.
†Approved for individuals ≥6 years of age; considered safe during pregnancy.
‡Approved for individuals ≥6 months of age; spinosad cream rinse, abametapir lotion, and benzyl alcohol lotion are considered safe during pregnancy.

Table 84.2 Treatments for head lice. In general, treatments should be given on two separate occasions, 1 week apart. However, the FDA-approved regimen for treatment of head lice with 0.5% ivermectin solution and abametapir 0.74% lotion is a single application. Airallé® is an FDA-cleared medical device that uses hot air to treat head lice via dehydration of their eggs and, to a lesser degree, hatched lice. Isopropyl myristate 50% in cyclomethicone solution (Resultz®) was FDA-approved as an over-the-counter treatment for head lice in 2017; it is available in Canada and Europe but has not yet been marketed in the US. Benzyl benzoate 10%–25% lotion or emulsion (over-the counter; not directly sold in US pharmacies) may be used for head lice, although there are few investigational studies; it is applied to the hair for 12–24 hours on days 1 and 8.

are viable or not. As a result, the tedious task of physically removing all nits via combs with closely spaced metal teeth is required. Currently there are no products that easily aid in nit removal[33]. Flexibility and understanding by school boards would be more welcomed than a straight adherence to a "no-nit" policy.

Pyrethrins

In the US, pyrethrins, 1% permethrin, and 0.5% ivermectin are FDA-approved, OTC topical pediculicides. Pyrethrin insecticides are derived from a natural extract of flower heads of *Chrysanthemum cinerariaefolium*. Patients allergic to chrysanthemums, ragweed, or related plants have experienced wheezing and dyspnea with use of the crude extract. Pyrethrins are presently formulated into lotions, shampoos, foam mousse, and cream rinses. The addition of piperonyl butoxide slows the biotransformation of pyrethrins by partially inhibiting the insects' cytochrome P450 enzymes, thereby initially improving effectiveness. Pyrethrin products are applied to the head for 10 minutes and then rinsed off. Due to growing resistance to this insecticide, treatment failures are now commonplace[1].

Permethrin

Permethrin is the only synthetic pyrethroid that is used worldwide for head lice. The OTC 1% permethrin cream rinses and lotions are applied for 10 minutes; however, an 8–12-hour application of the 5% cream used for scabies is an alternative therapy. Unfortunately, resistance to even the higher-concentration products has developed in head lice and other insects. Point mutations in the gene encoding the α-subunit of the insects' voltage-sensitive sodium channels commonly lead to a reduction

in the binding affinity of permethrin and other pyrethroids. However, some studies have found >85%–90% success rates for treatment with permethrin in children whose lice had these mutations, suggesting that other factors play a role in pyrethroid resistance[34].

Malathion

The prescription organophosphate malathion is a cholinesterase inhibitor. Although the recommended application time for topical malathion is 8 to 12 hours, with repeated treatment in 7 days if live lice are present, high efficacy has also been reported when the duration of application is reduced to 20 minutes[35]. The existing US product (Ovide® lotion) contains 78% isopropyl alcohol, which enhances its effectiveness but raises the issue of flammability. Some resistance to malathion products has been reported, especially in Europe and Australia[36].

Ivermectin

A 0.5% *topical* ivermectin preparation (Sklice® lotion) was FDA-approved in 2012 for the treatment of head lice in patients ≥6 months of age and is now available OTC. Topical ivermectin has been shown to kill permethrin-resistant head lice,[37] and the viability of lice hatched from treated eggs is severely compromised[38]. In two randomized controlled studies (total n = 765), 74% of patients treated with a single 10-minute application of 0.5% ivermectin lotion to dry hair were lice-free after 15 days, compared to 18% of those who received a vehicle control ($p<0.001$)[39].

Oral ivermectin represents another therapeutic option for resistant head lice infestations. In a large multicenter clinical trial, 95% of patients with head lice that previously failed topical therapy (pyrethrin or malathion) who received 400 mcg/kg of ivermectin on days 1 and 8 were lice-free on day 15, compared to 85% of those treated with two applications of topical malathion[40]. In several other controlled studies, >90% of children treated with 200 mcg/kg of ivermectin on days 1 and 8 were lice-free at 2-week follow-up[41]. Because lice are only exposed to the drug while feeding, oral ivermectin has no ovicidal activity and (unlike topical ivermectin) two treatments are required. Of note, clinical ivermectin resistance associated with a mutation in the ivermectin target site was documented in head lice from two children from rural Senegal following a second oral ivermectin treatment[42].

Dimethicone

Dimethicone is a silicone oil that is used as an emollient in skin care products. Dimethicone-containing products may suffocate lice or block their ability to excrete water and result in death due to osmotic stress[43]. In several randomized controlled studies, 10-minute to overnight application of 4%–100% dimethicone liquid gel, lotion, or spray (e.g. LiceMD®, Hedrin®, NYDA®) on day 1 ± day 8 resulted in 70%–97% of patients being lice-free on day 14, representing significantly higher efficacy than treatment with 1% permethrin cream rinse or 0.5% malathion liquid in some reports[44,45].

Spinosad

In 2011, 0.9% spinosad topical suspension (Natroba™) was approved by the FDA as a therapy for head lice, and it is currently indicated for children ≥6 months of age. Spinosad is a fermentation product of the bacterium *Saccharopolyspora spinosa* that induces muscle spasms and paralysis in lice when applied topically. A clinical trial (n = 1038) showed that 0.9% spinosad suspension left on for 10 minutes without nit combing on day 1 ± day 7 had superior efficacy to 1% permethrin cream with nit combing (~86% vs ~44%; $p<0.001$), and spinosad therapy led to no significant adverse effects[46].

Abametapir

In 2020, 0.74% abametapir lotion (Xeglyze™) was FDA-approved for the treatment of head lice in children ≥6 months of age. This metalloproteinase inhibitor targets metalloproteinases critical to the development of lice and their eggs. In two clinical trials (n = 704), 86% of patients treated with a single 10-minute application of 0.74% abametapir lotion to dry hair were lice-free through day 14, compared to 63% of those treated with the vehicle ($p<0.001$)[47].

Benzyl alcohol

In 2009, the FDA approved 5% benzyl alcohol lotion (Ulesfia®) as a prescription treatment for head lice in children ≥6 months of age; benzyl alcohol is thought to act via asphyxiation by preventing lice from closing their respiratory spiracles, which become blocked by the lotion; it is not ovicidal. In two randomized, double-blind, controlled clinical studies (total n = 250), 75% of patients were lice-free 14 days after the last of two 10-minute applications of benzyl alcohol (administered 1 week apart), compared to 5%–25% of those treated with a vehicle control[48]. Ulesfia has been discontinued; however generic benzyl alcohol may be commercially available.

Lindane

Lindane, a chlorinated hydrocarbon, is available as a 1% prescription shampoo that is applied for 4 minutes. Because of possible CNS side effects, especially after prolonged applications beyond the recommended time interval, the FDA has issued a "black box" warning that lindane is reserved for patients who fail to respond to other approved lice therapies. However, resistance to lindane is commonly observed.

Carbaryl

Like malathion, carbaryl is a cholinesterase inhibitor. It is available in a 0.5% lotion and shampoo in the UK and other countries. This product is not presently available in the US. In comparison to malathion, carbaryl is potentially more toxic to patients, while being less lethal to lice.

CRAB LICE

Synonyms: ■ *Pthirus pubis* or *Phthirus pubis* ■ Pubic lice ■ Pediculosis pubis ■ "Crabs"

Key features

- More properly designated "crab lice" (rather than "pubic lice") because infestations may involve other hair-bearing sites such as the beard, eyelashes, axillae, and perianal region
- Transmitted by sexual or close contact and to a lesser extent via contaminated clothing, towels, and bedding

Introduction

Infestation with *Pthirus pubis*, the crab louse, causes discomfort, pruritus, and embarrassment and may coexist with other sexually transmitted infections.

History

The parasitic relationship between humans and crab lice dates back to prehistoric times.

Epidemiology

The incidence rate may be slightly higher in men, probably because they have a greater amount of coarse body hair. Infestations with crab lice can be found in all socioeconomic and ethnic groups, although those of Asian descent or with minimal pubic hair are rarely affected. The incidence of crab lice has decreased with current cultural practices of hair removal from the pubic region[49]. Infestation is most frequently observed in those 15 to 40 years of age, correlating with increased promiscuous sexual activity. The highest prevalence is in men who have sex with men. Although infestation is often considered a sexually transmitted disease, individuals who have had no sexual exposures are occasionally infested via fomite transmission from contaminated clothing, towels, or bedding[1].

Pathogenesis

Crab lice, *Pthirus pubis*, are approximately 1 mm in length and resemble tiny crabs, with a wider, shorter body than head lice (Fig. 84.10). Crab lice eggs, which are found attached to human hairs, are viable for up to 10 days; the adult crab louse can live for at least 36 hours away from the host. Crab lice have serrated edges on their first claw that enable them to ambulate on the entire body surface. Thus, infestation occurs not only in pubic hair, but also in hair of the scalp, eyebrows, eyelashes,

Fig. 84.10 Adult crab louse. Respiratory spiracles and circulatory system are easily seen (45×). *Courtesy Tony Burns, MD.*

moustache, beard, axillae, and perianal area. Indeed, 60% of patients with pubic lice are infested in at least two hair-bearing sites. When the pubic area is shaved or treated, surviving crab lice can travel to other hairy areas of the body, including the scalp.

Clinical Features

Crab lice infestations typically present with pruritus in the pubic region. Crab lice cling to the base of hairs (Fig. 84.11A) and can be brown to skin-colored or mimic hemorrhagic crusts. Other findings may include nits at the base of hair shafts, erythema around hair follicles, excoriations, evidence of a secondary bacterial infection, and lymphadenopathy. When the eyelashes are affected (Fig. 84.11B), feces that accumulate can resemble flecks of mascara. Macula caerulea are asymptomatic, slate-gray to bluish, irregularly shaped macules that measure 0.5–1 cm in diameter and favor the trunk and thighs. These lesions, which typically develop in chronic crab lice infestations, are thought to result from the breakdown of bilirubin to biliverdin by enzymes in louse saliva.

In individuals with crab lice, the possibility of additional sexually transmitted infections should be considered and the original source of the infestation sought in order to reduce the risk of recurrence.

Pathology

Crab lice cause nonspecific inflammatory changes in the epidermis and dermis. Because lice live on the surface of the skin, they are not evident histologically.

Differential Diagnosis

The identification of crab lice and/or their nits is diagnostic (see Fig. 84.10). Skin diseases associated with pruritus that may be considered in the differential diagnosis include other infestations (e.g. scabies) and arthropod bites. Nits on pubic or axillary hairs must be distinguished from white piedra and trichomycosis pubis or axillaris.

Treatment

Topical insecticides are the standard therapy for crab lice. Sexual partners should be treated simultaneously. Most commonly, permethrin (1% or 5%) and synergized pyrethrin products are utilized (Table 84.3). As with head lice, the topical insecticide should be applied on two occasions, 1 week apart, to ensure complete eradication of hatched eggs. Moreover, all hairy areas of the body must be inspected for the existence of lice and treated if there is a possibility of infestation. A single application of topical products to only pubic hair may limit success rates to as low as 55%[50].

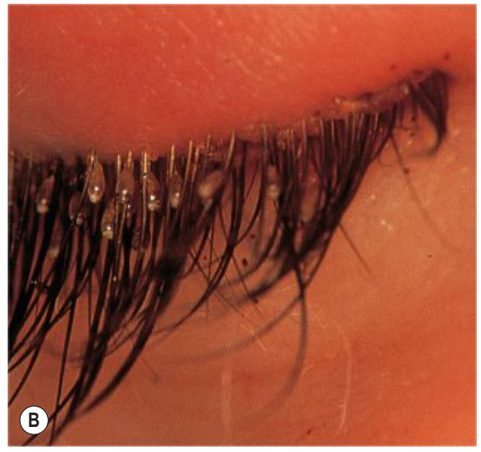

Fig. 84.11 Crab lice. **A** Both adult crab lice and nits are evident on pubic hairs. **B** Crab lice nits and feces on the eyelashes. *A, Courtesy Louis A. Fragola, Jr, MD; B, With permission from Taplin D, Meinking TL. Infestations. In: Schachner LA, Hansen RC (eds). Pediatric Dermatology, 4th edn. Edinburgh: Mosby, 2011:1141–80.*

Currently, the safest and most effective topical treatment is 5% permethrin cream applied generously overnight to all potentially infested hairy areas, and then repeated 1 week later[40]. Lindane has poor efficacy and higher toxicity, and the shampoo is not approved for extensive body application. Oral ivermectin on days 1 and 8 can be used for patients with perianal or eyelash involvement or when topical therapy is unsuccessful (see Table 84.3)[30,51].

BODY LICE

Synonyms: ■ Pediculosis corporis ■ Clothing lice

Key features

- An infestation of humans and their clothing, body lice most commonly affect the homeless, refugees, and victims of war and natural disasters
- Body lice do not live or lay eggs on people but in their clothing
- Infections transmitted by body lice include epidemic typhus, trench fever, and relapsing fever

Introduction

Body lice infestations are associated with overcrowding, poor hygiene, poverty, war, and natural disasters. These insects are the primary vectors for diseases caused by *Rickettsia*, *Borrelia* and *Bartonella* spp. (see Chs. 74 & 76). Body lice resemble head lice but are larger in size.

TREATMENTS FOR CRAB LICE			
Treatment	**Administration on days 1 and 8**	**Concerns**	**Efficacy**
Permethrin (1%) cream rinse or synergized pyrethrin shampoo*	Topical application for 10 minutes to clean, dry hair	None	Fair
Permethrin cream (5%)	Topical application for 8–12 hours	Allergic contact dermatitis in individuals with sensitivity to formaldehyde	Good
Lindane shampoo (1%)	Topical application for 4 minutes to dry hair, then add water to lather and rinse	Potential CNS toxicity; not recommended for infants, children, breastfeeding mothers or pregnant women (category C)	Poor
Ivermectin	0.5%–1% lotion/cream topically overnight	Potential skin and eye irritation	Not established
	Oral dose of 250 mcg/kg (available as 3 mg tablets)	Potential CNS toxicity; not recommended for breastfeeding mothers or pregnant women (category C)†	Excellent

*Over-the-counter products.
†Recent studies suggest safety for children ≥1–2 months of age weighing <33 pounds (15 kg), but use is not well-established in this group.

Table 84.3 Treatments for crab lice. All crab lice treatments should be given on two separate occasions, 1 week apart, i.e. days 1 and 8. Benzyl benzoate 10%–25% lotion or emulsion (over-the counter; not directly sold in US pharmacies) may be used for crab lice, although there are few investigational studies; it is applied three times over a 24-hour period without an intervening bath.

Epidemiology

Body lice are found worldwide. Increased prevalence rates of body lice are tied to poor hygiene, poverty, and homelessness. There are no racial, age, or sex restrictions.

Pathogenesis

Pediculosis corporis is caused by an infestation of humans and their clothing by *Pediculus humanus* var. *corporis*. In addition to exposure to conditions conducive to obtaining body lice, infestation requires an inability to wash and change clothes.

Several important human diseases are transmitted by the body louse. These include epidemic typhus (*Rickettsia prowazekii*) and relapsing fever (*Borrelia recurrentis*) as well as several diseases caused by *Bartonella quintana* – trench fever, bacillary angiomatosis, and endocarditis[30,52]. Whether this louse has a role in transmission of *Acinetobacter baumannii* or *Yersinia pestis* to humans remains to be determined[52]. Transmission of microorganisms from body lice to humans occurs not from louse bites, but rather from inoculation of louse feces into the skin via scratching or by inhalation of dry, powdery louse feces from infested bedding or clothing.

Clinical Features

P. humanus var. *corporis* measures between 2.5 and 4.0 mm in length. Unlike head and crab lice, the nits and lice are rarely found on the patients' skin, save for feeding, as they reside primarily on the clothing of their hosts. This infestation leads to severe pruritus. The back, neck, shoulders, and waist areas are commonly involved. Clinical findings include pinpoint red macules, small erythematous papules, crusts and excoriations, occasionally complicated by impetigo and lymphadenopathy. Blood and fecal pellets often stain clothing and bedding. On inspection, nits and adult lice are found along clothing seams that are in contact with the neck, axillae, and waistline (Fig. 84.12).

Pathology

The epidermis has minimal spongiosis with nonspecific infiltrates of eosinophils and neutrophils in the dermis.

Differential Diagnosis

Other causes of widespread pruritus and excoriations that may be considered in the differential diagnosis of body lice include systemic diseases (e.g. hepatic or renal impairment), drug reactions, atopic dermatitis, contact dermatitis (irritant or allergic), and other infestations (e.g. scabies).

Treatment

Preferably, the clothing and bedding of infested individuals should be discarded in tightly sealed, plastic biohazard bags and incinerated.

Fig. 84.12 Body lice eggs in the seams of clothing.

Only if the latter is not possible should disinfection be attempted. This involves fumigating the clothing or laundering it using hot water (temperature of ≥130°F/55°C), followed by machine drying with high heat. Hot ironing of the seams of upholstered furniture can also be performed, and exposure to untreated infested items should be strictly avoided for 2 weeks. Topical insecticide regimens similar to those used for scabies can eradicate concurrent scabies or crab lice infestations as well as kill any body lice adherent to hairs.

Mass delousing in crowded, large populations due to natural disaster, war, or famine is accomplished by dusting powders. These powders may contain DDT, malathion, dieldrin, lindane, or permethrin.

TUNGIASIS

Synonyms: ■ *Tunga penetrans*: chigoe flea, jigger flea, burrowing flea, sand flea ■ Pique ■ Nigua ■ Pio and bicho de pie

Key features

- This infestation is caused by the burrowing flea, *Tunga penetrans*
- It is endemic in the Caribbean islands and parts of Central and South America, Africa, Pakistan, and India
- The female flea burrows into the skin and then enlarges to create a nodule with a central punctum through which eggs are ejected

Introduction

The burrowing flea, *Tunga penetrans*, is the causative agent of tungiasis. A female flea burrows into the upper dermis and enlarges to approximately 1 cm in diameter, creating a nodule with a central punctum through which eggs (fertilized or unfertilized) are eventually discharged.

Fig. 84.13 Tungiasis in a child.

History

Tungiasis was first reported in crew members on Christopher Columbus' original trip to the New World in 1492.

Epidemiology

Tungiasis can occur in anyone exposed to the flea, regardless of sex, race, or age. Areas of high incidence include the Caribbean islands, parts of Central and South America, and sub-Saharan Africa. In endemic areas, risk factors include walking barefoot, wearing open-toed shoes, and living in homes with dirt or unclean floors[30].

Pathogenesis

Tunga penetrans is a wingless flea that is 1 mm in size and usually lives in warm, dry soil. Both sexes of this flea require an occasional blood meal from a warm-blooded animal for maturation[53]. Due to the fleas' limited jumping ability, the most common location for bites is the foot. Female fleas, rather than simply obtaining a blood meal, burrow headfirst into mammalian skin. They subsequently undergo marked abdominal hypertrophy, growing to 1 cm in diameter. The flea protrudes its rear cone through a central punctum that is always maintained; whether or not fertilization occurs via mating of the embedded female flea with a free-roaming male flea, over a hundred eggs are discharged within 3 weeks[53]. After expelling the eggs, the female dies and its remains are eventually sloughed from the skin.

Clinical Features

Bites of immature fleas cause no symptoms; however, burrowing of the female flea into the skin can cause significant clinical morbidity. The burrowing is initially asymptomatic, but varying degrees of pain or pruritus usually develop. The first sign of disease is a small black dot, which evolves into a pearl-like whitish papule and then a larger nodule that is said to resemble a watch glass, with a clearly demarcated white halo surrounding the black central punctum. A peripheral zone of erythema is frequently evident. When the flea dies, a black crust covers the involuting lesion. The Fortaleza classification scheme divides tungiasis into stages based upon symptoms, lesion size and the clinical appearance[53].

The most common site of disease is the periungual area of the toes, followed by the soles and toe webs (Fig. 84.13). Ulceration, secondary infection, and lymphangitis can occur; less frequent complications include tetanus, gangrene, and amputation of a digit[53]. Over half of periungual infections lead to deformation or loss of the nail, and heavy infestations produce substantial morbidity in resource-poor communities within endemic areas[54,55].

Pathology

A nonspecific inflammatory infiltrate surrounds the flea within the dermis.

Differential Diagnosis

The differential diagnosis may include myiasis, tick bite reactions, cercarial dermatitis, pyoderma, plantar warts, verruga peruana, and squamous cell carcinoma.

Treatment

Spontaneous recovery does occur; however, most clinicians and patients prefer to treat the infestation by removal of the female flea. In an early infestation, a sterile needle can be used to pry the insect from the skin. Covering the punctum with dimethicone, liquid paraffin, or a mixture of neem and coconut oils may prevent flea growth and expedite removal[54–56]. If treatment is delayed, curettage, electrodesiccation, or surgical excision may be required. Careful cleaning of the cystic cavity speeds clinical resolution, and antibiotic therapy may be needed for secondary infections. Tetanus prophylaxis should be strongly considered. Topical application of ivermectin, metrifonate, or thiabendazole may lead to more rapid demise of embedded fleas, but this has limited clinical benefit[54,55]. In a randomized controlled study, oral ivermectin was not found to have significant efficacy compared to placebo.

Preventative measures include wearing closed shoes or boots and avoiding ground contact in endemic areas. A plant-based insect repellent containing coconut and jojoba oils has also been shown to prevent sand flea infestation[55].

CUTANEOUS MYIASIS

Synonym: ■ Names for the various flies associated with this entity include human botflies, screwworms, blowflies, fleshflies, and tumbu flies

Key features

- Infestation of the skin by fly larvae (maggots)
- The larvae inhabit cutaneous wounds (wound myiasis) or burrow into the dermis causing boil-like lesions (furuncular myiasis)
- Although they usually cause minimal morbidity, larvae can cause problems when they involve the nasal cavity and sinuses

Introduction

Cutaneous myiasis is an infestation of the skin by developing larvae (maggots) of a variety of fly species within the arthropod order Diptera. The two main clinical types are wound and furuncular myiasis.

History

Maggots were central to Francesco Redi's experiment rejecting the theory of spontaneous generation. Wound debridement by maggots has been used for centuries, including during the American Civil War and by Napoleon's troops.

Epidemiology

Myiasis is a worldwide infestation with seasonal variation whose prevalence is related to latitude and the life cycle of the various species of flies. Its incidence is higher in the tropics and subtropics of Africa and the Americas. The flies responsible prefer a warm and humid environment, thus they are restricted to the summer months in temperate zones, while living year-round in the tropics.

Pathogenesis

Myiasis is the infestation of living humans (or other vertebrates) with dipterous larvae that feed on the host's tissues, liquid body substances, or ingested food. Myiasis can be caused by several species of arthropods

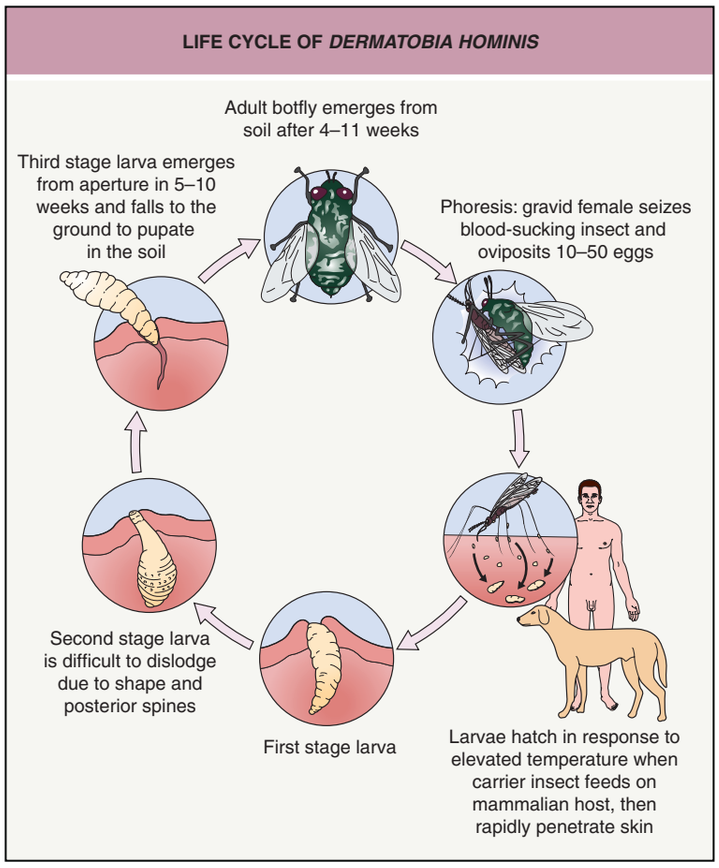

Fig. 84.14 Life cycle of *Dermatobia hominis* in cutaneous myiasis.

within the order Diptera, the two-winged true fly. The causative flies can be classified by: (1) taxonomic family; and (2) differences in pathogenic behavior of the fly species.

Worldwide, the most common flies that cause human infestation are *Dermatobia hominis* (human botfly) and *Cordylobia anthropophaga* (tumbu fly). The routes of transmission of fly larvae to human hosts differ among the fly species. For example, *D. hominis* lays its eggs on mosquitoes, which in turn deposit them on a warm-blooded mammal (Fig. 84.14). *C. anthropophaga* deposits its eggs on moist clothing and soiled blankets and in sand. The larva can live 15 days without feeding, but once it makes contact with a host, it penetrates the skin, which initiates further maturation. In endemic areas, people often iron their clothes after hanging them out to dry to kill the fly eggs. In wound myiasis, an open wound or orifice attracts flies to deposit their eggs. Any body area can be infested, and the most serious sequelae occur when the nasal cavity, sinuses, or scalp are involved. The incubation period for larvae to mature into adulthood depends on the fly and can range from 1 to 12 weeks.

Clinical Features

Furuncular cutaneous myiasis, which is caused by the human botfly and tumbu fly, causes boil-like lesions. Whereas myiasis from the tumbu fly typically occurs on the trunk, thighs and buttocks, botfly lesions are usually on exposed areas of the body, including the scalp, face, forearms and legs. A pruritic papule develops within 24 hours of penetration, enlarging to a 1–3 cm nodule with a 2–3 mm central punctum (Fig. 84.15A–C). These lesions can be painful or tender and may become crusted and purulent; there may be a sensation of movement.

In *wound* myiasis, the larvae are deposited in a suppurating wound or on decomposing flesh. *Cochliomyia hominivorax*, a screwworm, is the most common cause of this form of myiasis in the Americas, while *Chrysomya bezziana* is typically seen in Africa, Australia, and Asia. The diagnosis is obvious when larvae are visible on the surface of the wound (Fig. 84.15D) and more difficult when they have burrowed beneath the surface.

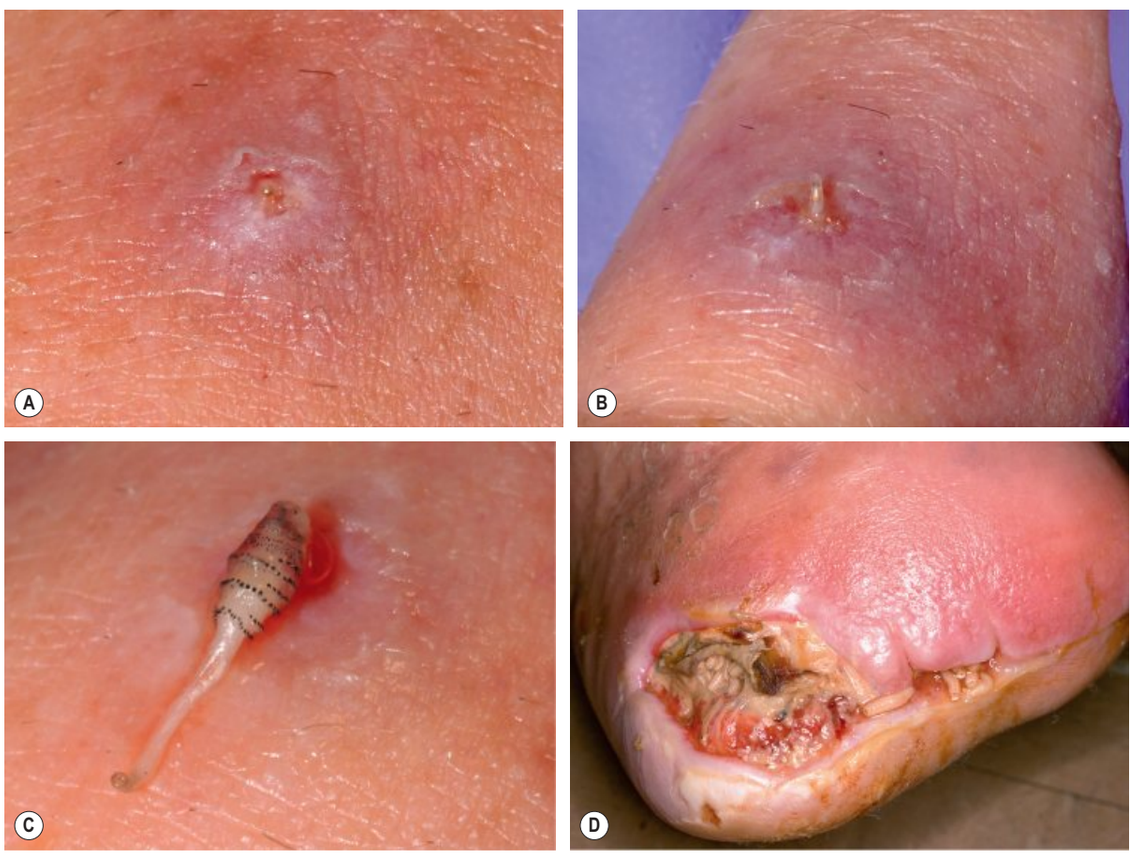

Fig. 84.15 Cutaneous myiasis. **A–C** Furuncular myiasis on the forearm presenting as a papulonodule with a central punctum (**A**) through which the larva's posterior end, which contains respiratory spiracles, may protrude (**B**). Note the characteristic appearance of the extracted botfly larva, with parallel rows of dark spines and hooks (**C**). **D** Wound myiasis in an amputation stump. *A–C, Courtesy Edward W. Cowen, MD; D, Courtesy Louis A. Fragola, Jr, MD.*

Creeping (or migratory) cutaneous myiasis may be caused by *Hypoderma bovis* if there is exposure to infested cattle, or by *Gasterophilus intestinalis* in those who work with horses. This form of myiasis resembles cutaneous larva migrans, but the fly larvae migrate more slowly, persist for longer (often months), and are larger than helminth larvae.

Myiasis is a self-limiting infestation with minimal morbidity in the vast majority of cases. The major reasons for treatment are reduction of pain, cosmesis, and psychological relief. However, larvae such as *C. hominivorax* can infest around orifices of the head and may burrow into brain tissue.

Pathology

Histologically, an inflammatory response occurs in stages in which lymphocytes, giant cells, neutrophils, eosinophils, mast cells, and plasma cells participate. The larvae can be seen in cross-section.

Differential Diagnosis

Furuncular cutaneous myiasis should be differentiated from a ruptured epidermoid cyst, an abscess, furunculosis, a foreign body reaction, onchocerciasis, tungiasis, an exaggerated arthropod bite reaction, and lymphadenopathy.

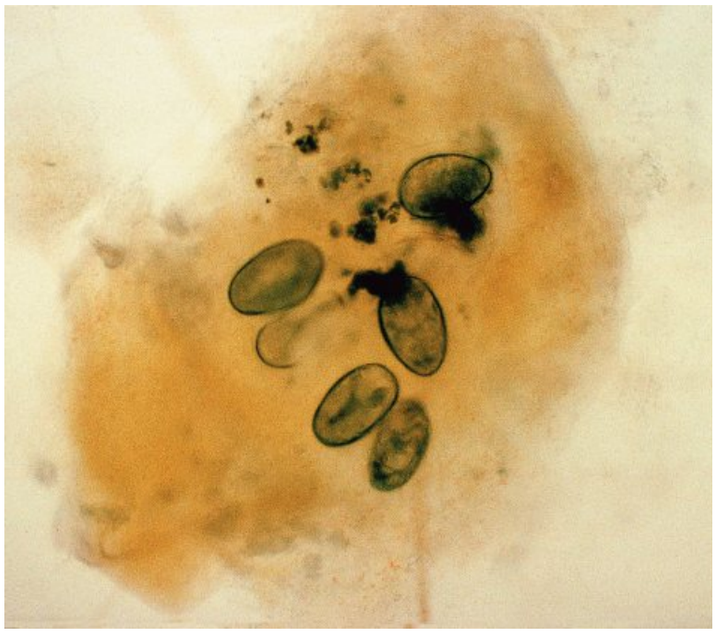
Treatment

The larva in furuncular cutaneous myiasis should not be forcibly removed through the central punctum because its tapered shape with rows of spines and hooks prevents simple extrusion (see Fig. 84.15C). Surgical debridement under local anesthesia is curative, although a foreign body reaction can occur if parts of the larva remain[56]. Occlusion/suffocation approaches involve placement of petroleum jelly, liquid paraffin, beeswax, nail polish, heavy oil, lard, or strips of bacon over the central punctum[56,57]. Such blockage forces the aerobic larva to surface for air over the course of several hours – at which time, forceps aid in their capture. Alternatively, ethyl chloride sprays, liquid nitrogen, chloroform in vegetable oil, or insecticides have been used alone or in combination. In addition, the larva can be forced to the surface by injecting lidocaine into the base of the tissue cavity or by using a suction-based venom extractor[57,58]. After removal of larvae, antiseptic dressings are indicated, as are antibiotics if secondary infection is present.

Wound myiasis requires debridement with irrigation to eliminate the larvae from the wound, or surgical removal. If burrowing has occurred, the method of extraction is identical to that for furuncular cutaneous myiasis.

An alternative treatment for all types of myiasis is oral ivermectin, which has proven especially helpful with oral and orbital involvement[56]. Surgical removal is not required unless requested by the patient, as the larvae are naturally sloughed within 2 weeks. Myiasis can be a portal of entry for *Clostridium tetani*, and vaccination of affected individuals should be considered.

Preventative Measures



In endemic areas, it is important to avoid activities that increase the risk of myiasis, such as wearing damp clothing or resting in sandy areas. The use of insect repellents (including on the scalp) can be useful in preventing mosquitoes that are harboring the larvae of the human botfly from depositing their living cargo.

SUMMARY OF THE 2020 INTERNATIONAL ALLIANCE FOR THE CONTROL OF SCABIES CONSENSUS CRITERIA FOR THE DIAGNOSIS OF SCABIES
A. Confirmed scabies
At least one of: A1: Mites, eggs or feces on light microscopy of skin samples A2: Mites, eggs or feces visualized on an individual using a high-powered imaging device A3: Mite visualized on an individual using dermoscopy
B. Clinical scabies
At least one of: B1: Scabies burrows B2: Typical lesions affecting male genitalia B3: Typical lesions in a typical distribution and two history features
C. Suspected scabies
One of: C1: Typical lesions in a typical distribution and one history feature C2: Atypical lesions or atypical distribution and two history features
History features
H1: Itch H2: Positive contact history
Diagnosis can be made at one of the three levels (A, B, or C). A diagnosis of clinical or suspected scabies should only be made if other differential diagnoses are considered less likely than scabies.

eTable 84.1 Summary of the 2020 International Alliance for the Control of Scabies Consensus Criteria for the Diagnosis of Scabies. *From Engelman D, Yoshizumi J, Hay RJ, et al. INPATIENT MANAGEMENT OF CLASSIC SCABIES & CRUSTED SCABIES

Background

- Both classic and crusted scabies present challenges in management and infection control in the institutional setting
- In individuals with crusted scabies, live mites can be recovered from the debris in the environment (e.g. bedding, clothes)
- Mites typically live no more than 3 days off of human hosts; however, in crusted scabies they can live up to 7 days on sloughed skin
- Crusted scabies is most commonly found in the elderly and HIV+ or other immunosuppressed populations

Management of classic scabies

- Debrief the medical team immediately – all teams following the patient should be notified
- Initiate contact precautions, which can be discontinued 24 hours after beginning treatment
- Initiate medical treatment:
  - Head to toe permethrin cream once then repeated again at 7 or 14 days **OR**
  - Ivermectin 0.2 mg/kg/dose (14 mg for 70 kg individual) once then repeated again at 7 or 14 days
- Machine wash and dry all bedding/clothes items using hot water and high heat cycles (temperatures in excess of 50 degrees C for 10 minutes will kill mites and eggs)
  - Includes bedding/clothing 3 days before treatment
- Contact the institutional Department of Infection Prevention to determine their role in management
- Thoroughly clean and vacuum the room when the patient leaves the facility or moves to a new room

Management of crusted scabies

- Debrief the medical team immediately – all teams following the patient should be notified
- Initiate contact precautions and isolate the affected individual from other patients
- Initiate medical treatment (note that this is far more intensive than a standard scabies regimen described above):
  - Head to toe permethrin cream daily × 7 days **AND**
  - Ivermectin 0.2 mg/kg/dose (14 mg for 70 kg individual) on days 1, 2, 8, 9, and 15
- Trim nails and use a nail brush to remove mites
- Contact the institutional Department of Infection Prevention
- Machine wash and dry all bedding/clothes items using hot water and high heat cycles (temperatures in excess of 50 degrees C for 10 minutes will kill mites and eggs)
  - Includes bedding/clothing 3 days before treatment
- Clean the room regularly to remove contaminating skin crusts and scales
- Thoroughly clean and vacuum the room when the patient leaves the facility or moves to a new room
- Tasks completed in coordination with the Infection Prevention team:
  - Maintain records of all staff who provided hands-on care to the patient before implementation of infection control measures
  - Identify and treat all patients, staff, and visitors who may have been exposed to a patient with crusted scabies or to clothing, bedding, furniture or other items used by such a patient
  - Contact family and/or skilled nursing facility to determine additional contacts prior to admission
- Maintain contact precautions until skin scrapings from a patient with crusted scabies are negative
  - Reasonable target would be repeat scraping after two weeks after initiation of treatment
- Staff generally can return to work the day after receiving a dose of treatment with permethrin or ivermectin (if felt indicated by the Infection Prevention team)

INSECTS

Insect Bites and Stings (Class Insecta)

Key features

- Pruritic papules sometimes progress to vesiculobullae or persistent prurigo nodularis-like lesions
- Papular urticaria may be localized to sites of bites or generalized
- Pseudolymphomatous reactions occasionally occur
- Anaphylaxis is mainly related to hymenopterid stings
- Secondary infection is most often staphylococcal

Introduction

Insect bites and stings are prevalent throughout the world. In temperate climates they are primarily a seasonal phenomenon, although indoor infestations can persist year-round. Insects are important disease vectors worldwide, and many emerging infectious diseases are linked to arthropod vectors. Personal protection against bites plays a major role in disease prevention.

Arthropods produce a wide spectrum of clinical lesions. Bullous arthropod reactions may suggest a diagnosis of immunobullous disease, and positive direct immunofluorescence has been reported, especially in the setting of scabies infestation. Pseudolymphomatous reactions can also occur (see Ch. 121).

Epidemiology

While some diseases have a single arthropod vector, others have multiple vectors and/or additional means of transmission. For example, bites from ticks and handling of infected animals are the most common modes of tularemia transmission in the US, but the disease can also be acquired through bites by deerflies and other horseflies. The vector has an important influence on the patient population affected by a particular disease. For example, cat ownership is a risk factor for cat scratch disease, which is associated with *Bartonella henselae* transmission by fleas, while homelessness is a risk factor for trench fever, which is caused by *Bartonella quintana* transmission by lice; however, either organism–vector pair can cause *Bartonella* endocarditis and bacillary angiomatosis, explaining why these diseases affect both patient populations. Vector-borne diseases often become epidemic during war or following natural disasters, and poverty and homelessness contribute to the spread of vector-borne disease.

Pathogenesis

Insect venoms and saliva are complex. Immediate reactions are commonly related to histamine, serotonin, formic acid, or kinins. Delayed reactions are typically manifestations of the host's immune response to proteinaceous allergens. Patients with large local reactions to insect stings, defined as a swelling measuring >10 cm and lasting >24 hours, often have elevated serum levels of venom-specific IgE[1].

Roughly one-quarter of reported cases of anaphylaxis are due to stings from insects in the order Hymenoptera (meaning membranous wings), which includes bees, wasps, hornets, and ants. These insects can possess specialized stingers and produce complex venoms that contain substances such as formic acid, kinins, and proteinaceous allergens. Insect sting hypersensitivity is more common in individuals with an atopic diathesis, and patients with mastocytosis may develop more severe reactions.

Clinical features

Characteristic insect bite reactions are grouped or disseminated, 2 to 8 mm, erythematous urticarial papules that are markedly pruritic and often excoriated (Fig. 85.1); they typically resolve over 5–10 days. Occasionally, bite reactions present as evanescent wheals or longer-lasting disseminated "papular urticaria" that persists for weeks or even months, sometimes reactivating when new bites occur in different locations. Edematous plaques, targetoid lesions, purpuric papules, nodules, and vesiculobullous reactions can also occur (Fig. 85.2; see Ch. 33). Chronic or resolving lesions are often hyperpigmented (see Figs. 67.2B & 85.6B), and prurigo nodularis-like lesions may develop, especially on the extremities. Secondary infection is common; although staphylococcal infections are seen most frequently, streptococcal infections also occur.

Insect bite reactions are most frequent in children 2–10 years of age and tend to involve exposed areas of the head, neck, and extremities. Commonly, only one member of a family is affected, as most clinical manifestations relate to the individual's immune response rather than the bite itself.

Fig. 85.1 Mosquito bite reactions. This patient has excoriated edematous papules and papulovesicles. *Courtesy Julie V. Schaffer, MD.*

Fig. 85.2 Spectrum of insect bite reactions. Sometimes patients develop large, erythematous, edematous plaques (**A**), frank bullae (**B**), or purpuric lesions that may be mistaken for leukocytoclastic vasculitis (**C**). *A, B, Courtesy Julie V. Schaffer, MD; C, Courtesy Jean L. Bolognia, MD.*

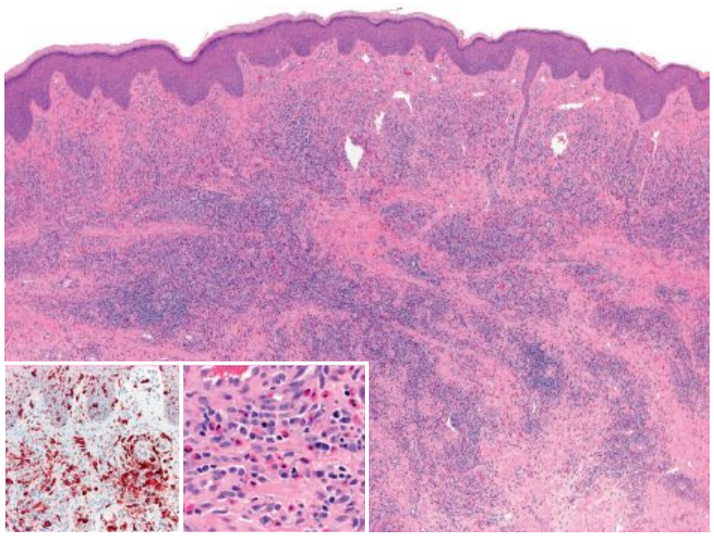

Fig. 85.3 Insect bite reaction with Langerhans cell hyperplasia. Note the dense superficial and deep lymphohistiocytic infiltrate with prominent eosinophils (right inset) and CD1a-positive, dendritic Langerhans cells (left inset). *Courtesy Lorenzo Cerroni, MD.*

Exaggerated insect bite reactions (e.g. papulovesicular, nodular) can represent a manifestation of chronic lymphocytic leukemia and less often other hematologic malignancies (see Ch. 33). In addition, hypersensitivity to mosquito bites with bullous and necrotic skin lesions may occur in individuals (typically Asian or Hispanic children and adolescents) with chronic EBV infection and proliferation of EBV-carrying natural killer (NK) cells; this may overlap with severe hydroa vacciniforme (HV)-like eruptions or HV-like lymphoproliferative disorder (see Ch. 87)[2]. Screening for hematologic malignancies and latent EBV infection, including *in situ* hybridization to detect EBV RNA in biopsy specimens of lesional skin if positive serology, should be considered in patients with unusual arthropod bite reactions.

Bee and wasp stings typically produce immediate burning pain, which is followed by the development of local erythema and swelling that usually subsides within a few hours to days but can be more severe and persistent in sensitized individuals. Atrial arrhythmias have been reported after bee stings in the absence of anaphylaxis. Killer bee and wasp attacks may be associated with myoglobinuria or hemoglobinuria and acute tubular necrosis. Although bee stings have been utilized as an alternative therapy for inflammatory arthritis, beekeepers may develop a chronic arthropathy related to stings.

Pathology

Histologic features suggestive of a bite or sting include the presence of a wedge-shaped perivascular lymphocytic infiltrate with eosinophils, endothelial prominence, and overlying spongiosis or focal epidermal necrosis. Marked spongiosis can result in blister formation, and Langerhans cell hyperplasia may be evident (Fig. 85.3).

Differential diagnosis

Arthropod reactions account for many "cryptic" chronic skin eruptions. Features that should suggest an arthropod reaction include grouping of papules, patterns of eruption that correlate with exposure, and the histologic features noted above. When an arthropod reaction is suspected, a detailed history of outdoor exposures, pets, work environment, and hobbies may prove helpful.

Treatment

Camphor and menthol lotion and gel formulations may be useful in the control of pruritus. Topical anesthetic preparations can also be helpful, and those containing pramoxine are readily available and present a low risk of contact dermatitis. For more persistent bite reactions, topical corticosteroids are often required. In young children, mid-strength corticosteroid preparations may suffice, while in older children and adults, class 1 or 2 corticosteroids are preferable. These agents can be applied under occlusion to enhance efficacy, but for a predetermined time period to avoid potential side effects of cutaneous atrophy and striae.

When topical agents fail, intralesional corticosteroid injection (e.g. triamcinolone 5–10 mg/ml) or excision of the pruritic nodule may be necessary. Occasionally, pseudolymphomatous nodules may require higher triamcinolone concentrations (e.g. 20–40 mg/ml). Cutaneous atrophy can occur, especially if a higher concentration of corticosteroid is injected superficially or into uninvolved surrounding skin. Atrophy may also be noted in a distribution corresponding to lymphatic drainage.

COMMONLY USED INSECT REPELLENTS	
Conventional skin-applied repellents in EPA classification	
DEET (N,N-diethyl-3-methylbenzamide)*	Effective against a wide range of arthropods Long history of use
Picaridin (KBR 3023)	Good evidence for mosquitoes Fewer studies support repellent effect against ticks
Biopesticide skin-applied repellents in EPA classification	
IR 3535 (3-[N-butyl-N-acetyl]-aminopropionic acid, ethyl ester)	Good evidence for mosquitoes in some, but not all, studies Fewer studies support repellent effect against ticks
Oil of lemon eucalyptus/p-menthane-3,8-diol†	Good evidence for mosquitoes Fewer studies support repellent effect against ticks
2-undecanone	Limited data available; may have strong odor
Botanicals (e.g. soybean oil, oil of citronella, neem oil, fennel oil, geraniol, catnip oil)	Have consumer appeal as "natural" repellents Best published evidence is for neem oil Lack of evidence does not necessarily equate to lack of efficacy, but available evidence to date suggests they are inferior to the synthetic repellents listed above
Repellent-treated clothing	
Permethrin	Can be sprayed on or impregnated in clothing, nets, tents, and sleeping bags Repels and kills mosquitoes, ticks, and chiggers

*There is a plateau of efficacy at 30% with long-acting products, and higher concentrations should generally be avoided. Because sunscreens require frequent reapplication and DEET does not, combination products with these ingredients are not recommended.
†The active ingredient of oil of lemon eucalyptus; use on children less than 3 years of age is not recommended.

Table 85.1 Commonly used insect repellents. Agents are listed in order of decreasing evidence of efficacy. EPA, Environmental Protection Agency.

Prevention of bites is best accomplished through the use of protective clothing and repellents. The most commonly used repellents are listed in Table 85.1. Factors that can influence the choice of a repellent include its efficacy, cost, convenience, odor and potential for irritation, as well as common arthropod pests in the area and the time of day, duration and environment of the exposure. DEET (N,N-diethyl-3-methylbenzamide, previously called N,N-diethyl-m-toluamide) remains the most widely used repellent for the prevention of bites from mosquitoes and most other insects. DEET can be applied to exposed skin or clothing. While mosquitoes that carry dengue virus tend to bite during the day, the anopheline mosquitoes that carry malaria tend to bite at night, and pyrethroid-impregnated mosquito netting represents an additional preventative measure. Treatment of clothing and other fabrics with permethrin can also be helpful.

The duration of efficacy of DEET depends primarily upon the dose applied. It provides less protection in women than in men, an observation that appears to be independent of serum estradiol levels. Efficacy may be reduced by the presence of skin abrasions. Rare toxic reactions include anaphylaxis and encephalopathy, and high concentrations of DEET can occasionally produce bullous eruptions.

Because of the potential for toxicity, the lowest effective DEET dose should be selected, especially in children. Many products with 10% or lower concentrations are available, although the American Academy of Pediatrics has stated that concentrations as high as 30% can be used safely in children 2 months of age or older (see Table 85.1). Sunscreen application over DEET may enhance DEET absorption, so sunscreen should be applied first when they are used concurrently[3].

Picaridin, IR3535, and p-menthane-3,8-diol perform reasonably well against a variety of mosquitoes and generally outperform soybean oil, citronella, neem oil, fennel oil, and geraniol (see Table 85.1)[4]. For protection against the common mosquitoes *Aedes aegypti* and *Culex quinquefasciatus*, IR3535 may be comparable to DEET. The Mediterranean monk's pepper plant (*Vitex agnus-castus*) has demonstrated efficacy in repelling *Ixodes ricinus* and *Rhipicephalus sanguineus* ticks as well as some mosquitoes, biting flies and fleas, and pyrethroid acids show promise as mosquito repellents[5]. Transfluthrin-treated sandals were shown to confer protection against mosquito bites in areas endemic for malaria[6].

Because insect stings are often unexpected, individuals with known hypersensitivity to stinging insects should always have an epinephrine (adrenaline) autoinjector (e.g. EpiPen®, AUVI-Q®) readily available in a dose appropriate for their body weight: 0.3 mg if >66 pounds (30 kg), 0.15 mg if 33–66 pounds (15–30 kg), and 0.1 mg if 16.5–33 pounds (7.5–15 kg). Patients must receive instructions regarding the use of the autoinjector, which needs to be protected from heat and light as well as inspected periodically for brown discoloration of the contents. Bee stingers should be removed as rapidly as possible.

Venom immunotherapy has been shown to improve quality of life for patients allergic to stings[7], reducing anxiety as well as the incidence and severity of local and systemic reactions. Desensitization protocols vary and should be discussed with an allergist. Rush (accelerated) immunotherapy can be performed for those with severe reactions, and it has a reasonable safety profile[8]. In the setting of mastocytosis, immunotherapy may need to be continued indefinitely, frequently induces immediate hypersensitivity reactions, and is only partially effective. Omalizumab has been used in conjunction with immunotherapy for patients refractory to standard regimens, and this may help prevent immunotherapy-related anaphylaxis[9].

Fire Ants

Key features

- Imported fire ants are red–brown in color and 1–2 mm in length
- When their mounds are disturbed, the ants swarm and sting in great numbers
- Immediate burning pain is followed by intensely pruritic, grouped vesicles and pustules
- Fire ant allergy is an important cause of anaphylaxis in endemic areas

Introduction

The range of *Solenopsis invicta*, the red imported fire ant (originally from South America), has spread to encompass much of the southern and southwestern US, and its territory continues to expand. The size of fire ant mounds varies in proportion to the amount of rainfall. The mounds may be inconspicuous during periods of drought, but they can reach more than a foot (30 cm) in height after heavy rains. When the mound is disturbed, the ants swarm. Because of their small size, they are not felt until they all begin to sting simultaneously in response to a chemical signal. Fire ants are attracted to electrical boxes and therefore present a hazard to electricians. Indoor attacks by swarms of fire ants can be particularly dangerous to infants and elderly individuals with impaired mobility[10].

Fig. 85.4 Fire ant bites presenting as clusters of sterile pustules on the foot.

Fig. 85.5 Bedbugs. Red–brown in color with a segmented abdomen and vestigial wings.

Pathogenesis

Fire ant venom is complex and acts by increasing membrane permeability and allowing release of histamine from mast cells. Allergic responses are directed at proteins within the venom. The venom is less concentrated in winter months, so winter sting reactions may be milder.

Clinical features

Fire ant stings begin as extremely painful wheals and evolve into intensely pruritic vesicles and sterile pustules (Fig. 85.4). The fire ant first grasps the skin with its mandibles; it then pivots and delivers a series of stings in a circular fashion, which may produce a rosette pattern. Scattered individual lesions are also common, especially when the victim is able to remove the ants before they have a chance to sting again. Secondary staphylococcal infections sometimes occur after fire ant stings. The absence of persistent tenderness can help differentiate sterile pustular reactions from secondary infections. Life-threatening anaphylactic reactions to fire ant stings have become a significant problem in the southern US[11].

Treatment

Patients with a life-threatening fire ant allergy should carry an epinephrine autoinjector with them at all times. Immunotherapy improves quality of life for individuals with severe fire ant allergies, and rush immunization protocols can be successful for those at high risk of stings[12,13]. Unfortunately, it is often impossible to avoid stings in endemic areas. Local reactions may be treated with potent topical or intralesional corticosteroids. A variety of methods of fire ant control are available, including bait insecticides that have a low environmental impact and are reasonably effective, as well as insecticide treatments for individual mounds.

Bedbugs

Key features

- Flattened oval body that is red–brown in color and 5–7 mm long in adults
- Segmented abdomen and vestigial wings
- Blood-sucking insects that feed at night and produce rows of pruritic, edematous papules

Introduction

In the past two decades, there has been a worldwide resurgence of bedbugs, which are now frequently found in homes, hotels, and dormitories[14–16]. Increased international travel, expanded immigration, changes in pest control practices, and the development of insecticide resistance have likely contributed to this trend.

Bedbugs belong to the family Cimicidae (order Hemiptera) and are blood-sucking mammalian and avian ectoparasites. They have a flattened oval body, a segmented abdomen, a retroverted labium (sucking mouthpiece), a semicircular to triangular scutellum (dorsal sclerotic plate), and antennae with four segments (Fig. 85.5). *Cimex lectularius* (the common bedbug) and *C. hemipterus* (found in warmer climates) affect humans most frequently; *C. lectularius* also parasitizes bats, chickens, and other domestic animals. *C. lectularius* ranges in size from 5 to 7 mm, with females slightly longer than males. *C. hemipterus* is roughly 25% longer than *C. lectularius*. Interspecies mating occurs in nature.

Bedbugs are nocturnal. They hide in mattress seams and crevices (e.g. within the bed frame and other furniture, behind baseboards, under peeling paint) during the day and feed at night, especially just before dawn. Red–brown fecal staining and nit-like ova are commonly visible in mattress seams.

Pathogenesis

Bedbug bite reactions result from an immune response to salivary proteins (e.g. nitrophorin) injected by the insect while feeding. Bedbugs digest their blood meal very slowly. The blood in the bug's gut remains relatively unclotted and is not membrane-bound.

Clinical features

Bedbug bites typically present as pruritic, erythematous, edematous papules, sometimes with a visible central hemorrhagic punctum (Fig. 85.6). As with other insect bites, the clinical appearance and duration of lesions vary depending on the individual's degree of sensitization. Some individuals have little or no reaction to bedbug bites, and it is common for only one or a few family members (even among those sleeping in the same bed) to report lesions. Most bites occur in exposed areas. Three lesions in a row (referred to as "breakfast, lunch, and dinner"; see Fig. 85.6B) are characteristic of, but not specific to, bedbug bites. Although affected individuals classically awake with new lesions, bite reactions can take several days to appear, and the latency tends to decrease with exposure to additional bites[14,16].

To date, transmission of infectious diseases to humans by bedbugs has not been documented[17]. Although hepatitis B virus has been detected within wild bedbugs, laboratory studies have failed to demonstrate viral multiplication or transmission to chimpanzees[17]. However, the possibility of bedbugs serving as vectors of American trypanosomiasis has been raised, and a recent laboratory study found that *Trypanosoma cruzi* could be transmitted among mice by bedbugs[18]. Bedbug dung may play a role in asthma. In a recent study in patients presenting to the emergency department, having bedbug bites was associated with an increased risk of anemia, with chronic blood loss and inflammation hypothesized as possible mechanisms[19].

Treatment

Bedbug bites can be treated as described above for other insect bites (e.g. with topical corticosteroids). Eradication of bedbugs from infested homes is difficult and usually requires the assistance of professional exterminators. Integrated pest management strategies utilizing both

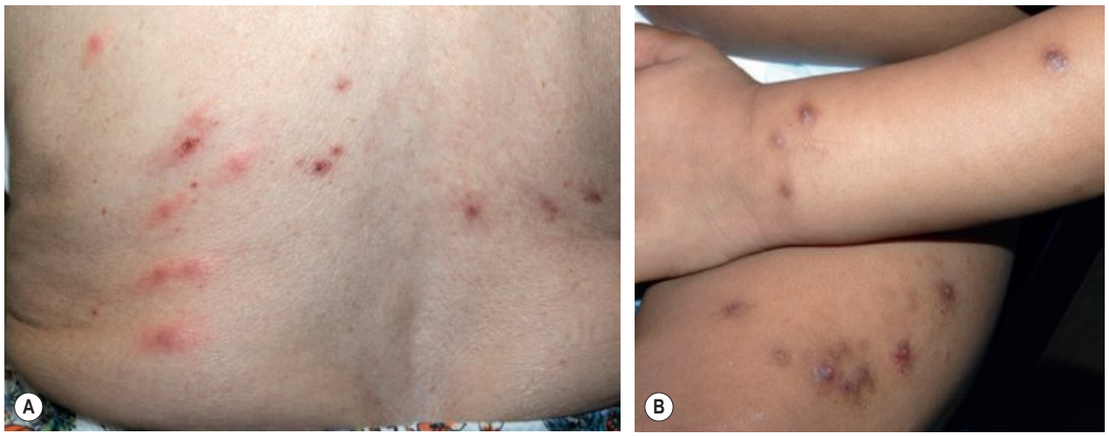

Fig. 85.6 Bedbug bite reactions. A Multiple pink edematous papules with either a central punctum or excoriation. **B** Excoriated hyperpigmented papules in an arcuate array ("breakfast, lunch, and dinner") in a young child with Fitzpatrick phototype IV. Residual hyperpigmentation following bug bite reactions is common in individuals with darker skin types and can persist for months. *A, Courtesy Kalman Watsky, MD; B, Courtesy Julie V. Schaffer, MD.*

insecticides and non-chemical methods (e.g. heating/steaming, freezing, elimination of cracks and crevices) are most effective.

Triatomine (Reduviid) Bug

Synonym: ■ Kissing bug

Key features

- Half-membranous wings (hard proximally and membranous distally) whose tips overlap
- Tan and dark "tiger stripes" on the abdomen
- Vector for American trypanosomiasis (Chagas disease)
- Bites can produce large, persistent edematous plaques

Introduction

Triatomine bugs are a type of reduviid bug that feeds on the blood of mammals and other vertebrates. Like bedbugs, they are true bugs of the order Hemiptera. Triatomine bugs are typically 1.5–3 cm in size as adults and have half-membranous wings that overlap. Characteristically, the wings fail to cover the lateral portions of their "tiger-striped" abdomen (Fig. 85.7). The antennae are long, thin and composed of four segments; the position of the antennae is used to classify the bugs. The labium (sucking mouthpiece) is straight and composed of three segments. Behind the head is a triangular pronotum (first segment of the thorax) with a broad posterior base.

Triatomine bugs are vectors for American trypanosomiasis (Chagas disease; see Ch. 83). The bugs have a pronounced gastrocolic reflex, resulting in defecation as they eat. Infectious feces are then inoculated into the bite site or conjunctiva by scratching or rubbing.

Triatomine bugs are primarily nocturnal and live in peri-domestic sites in Central and South America and the southern US, especially cracked stone walls and piles of tiles or bricks. They commonly feed on domestic animals, and trypanosome transmission may cross over between domestic and sylvatic (wild animal) life cycles. Control of this vector has been difficult, and insecticide spraying in affected communities is often followed by reinfestation originating from nearby livestock enclosures or wild populations of triatomine bugs.

Clinical features

Triatomine bug bites are typically painless, and the first sign is delayed erythema, swelling, and pruritus at the site. Exaggerated responses in the form of large urticarial plaques or vesiculobullous lesions occasionally develop. These insects are known as "kissing bugs" because of their tendency to bite the face, especially around the lips. Unilateral eyelid and periorbital swelling 1–2 weeks after conjunctival exposure to infected triatomine feces is referred to as Romaña sign and represents a chagoma. Trypanosomes subsequently infect the autonomic nervous system, resulting in chronic complications that include cardiomegaly and megacolon (see Ch. 83). Triatomine bugs and cockroaches share antigens that are strongly immunogenic in atopic patients.

Fig. 85.7 Triatomine bug. Note that the wings fail to cover the lateral portions of the abdomen and the tan and dark "tiger stripes" on the abdomen.

Blister Beetles

Synonym: ■ Spanish fly

Key features

- Oblong bodies (1–2 cm long) and antennae composed of multiple short segments
- Wide variety of colors and patterns
- Contact with beetles results in vesicles and bullae due to their production of cantharidin

Introduction

Blister beetles (order Coleoptera) belong to the family Meloidae. These insects produce the blistering agent cantharidin, which serves to protect them from predators. Members of the family Oedemeridae are classified as "false" blister beetles but also produce cantharidin, whereas rove beetles of the family Staphylinidae make another vesicant, pederin (see below).

Much of what is known about blister beetles is extrapolated from studies of a few species. In *Epicauta funebris*, cantharidin has been identified in all ten life stages of the beetle, and it accumulates during the first five larval stages. When threatened, larvae protect themselves by exuding cantharidin in a milky oral fluid, rather than in the hemolymph that adult beetles discharge from leg joints. Adult male beetles contain up to 10% cantharidin by weight. If kept in isolation, females lose their larval reserves and must mate to preserve their stores of cantharidin. During mating, the female acquires cantharidin from her mate as a copulatory gift. She then transfers the cantharidin to her eggs, rendering them resistant to predation.

Clinical features

Contact with blister beetles typically results in the development of vesicles and bullae within 12–24 hours. Topical application of cantharidin has been used for the treatment of molluscum contagiosum and warts since the 1950s (see Chs. 79 & 81).

Pathology

Histologic sections of the blisters demonstrate acantholysis in suprabasal keratinocytes. Disruption of cell outlines and cellular necrosis may be noted. The profile of adhesion molecule loss in cantharidin blisters is similar to that seen in Darier disease.

Treatment

Avoidance is the best measure, but immediate washing with soap and water may be of some benefit.

Rove Beetles

Synonym: ■ Nairobi fly

Key features

- Narrow bodies (0.5–1.5 cm long), a red–orange abdomen, and short forewings
- A vesiculopustular eruption can result from contact with pederin-containing beetle hemolymph

Introduction

Rove beetles belong to the Staphylinidae family. The hemolymph of some rove beetles in the *Paederus* genus contains the vesicant pederin, which is thought to be produced by endosymbiotic bacteria. *Paederus* dermatitis (dermatitis linearis) is a streaky vesiculopustular eruption that results from release of pederin when a rove beetle is crushed or injured on the skin. Outbreaks of *Paederus* dermatitis have been reported in warm climates worldwide, typically occurring when beetle populations increase during the rainy season. *Paederus* dermatitis has also been described in returning travelers[20]. Epidemics of vesiculobullous skin lesions in military units and hospital wards with open windows have been attributed to the rove beetle's attraction to ultraviolet light (e.g. from fluorescent bulbs).

Clinical features

Contact with pederin leads to inflamed skin with erythema and often pustules as well as vesicles (Fig. 85.8), in contrast to the relatively non-inflammatory vesicles produced by cantharidin. These changes usually begin to develop 24–36 hours after exposure, and "kissing lesions" may be seen on adjacent flexural surfaces. "Nairobi eye" represents periocular dermatitis and keratoconjunctivitis caused by *Paederus eximius*, a rove beetle found in Northern Kenya.

Pathology

Histologic features include suprabasal acantholysis, reticular degeneration, and necrosis of the epidermis together with an inflammatory infiltrate containing neutrophils.

Treatment

Immediate washing with soap and water is recommended. Preventative measures include use of insect-proof netting at night, changing to light sources without ultraviolet emission, and removing beetles from the skin without crushing them.

Carpet Beetles

Synonyms: ■ Khapra beetle ■ Hide beetle

Key features

- Adults have rounded bodies (1.5–3.5 mm long) with three bright bands; larvae measure 4–5 mm with stripes and dense hairs
- A pruritic papulovesicular eruption can result from contact with hastae (specialized hairs) on carpet beetle larvae

Fig. 85.8 *Paederus* dermatitis. Erythematous plaque with multiple small vesicles and vesiculopustules. *Courtesy Vidal Haddad, Jr, MD.*

Introduction

Carpet beetle dermatitis represents a hypersensitivity reaction to the hastae (larval hairs) or hemolymph of beetles in the Dermestidae family, including *Attagenus*, *Dermestes*, *Anthrenus*, and *Trogaderma* spp. The larvae feed on household organic materials such as wool and hide, e.g. in rugs and furniture.

Clinical features

Contact with hastae typically results in a pruritic papulovesicular eruption[21]. Other reactions that have been described include superficial bullae, erosions, urticarial papules, and vasculitis[22]. Lymphadenopathy and inflammation of the eyes and upper respiratory tract can also occur.

Treatment

Skin lesions respond to topical corticosteroids. The infestation should be eliminated via cleaning, removal of contaminated items, and extermination as needed.

Fleas

Key features

- Laterally compressed bodies and large hind legs
- The most common flea on dogs is *Ctenocephalides felis*, the cat flea
- Produce intensely pruritic papules, vesicles and bullae, often grouped on the lower extremities
- Serve as vectors for endemic (murine) typhus, flea-borne spotted fever, and plague

Introduction

Fleas (order Siphonaptera) are ubiquitous pests and show little host specificity. The most common flea on dogs is *Ctenocephalides felis*, the cat flea. *Pulex irritans*, the human flea (Fig. 85.9), is a common dog flea in some locations. It is also found on wild animals with no human contact. *Ctenocephalides* fleas have two ctenidia (combs) that resemble a mane of hair (pronotal comb) and mustache (genal comb) (Table 85.2).

Clinical features

Flea bites present as intensely pruritic papulovesicles, usually located on the lower legs. Other parts of the body may also be affected, especially when an infested pet has been groomed or held. Flea allergy is common, and allergic patients tend to react to a wide range of fleas. Flea pupae can lie dormant for many months then hatch rapidly in response to

Fig. 85.9 *Pulex irritans*, the human flea. The body is laterally compressed and no combs are present.

CHARACTERISTIC ANATOMIC FEATURES OF SEVERAL COMMON TYPES OF FLEAS	
Flea	**Characteristics**
Pulex	Round frons (forehead); single pair of hairs behind antennae
Xenopsylla	Round frons; several pairs of hairs behind the antennae; pleural rod (vertical thickening in mesothorax)
Ctenocephalides felis	Two ctenidia (combs) on the head*; sloped frons; six hair-bearing notches on dorsal hind tibia
Ctenocephalides canis	Two ctenidia (combs) on the head*; round frons; eight hair-bearing notches on dorsal hind tibia
Sticktight flea	Flat frons; broad lacinia (serrated piercing lance-like mouthpart)
*Resemble a mane of hair and a mustache.	

Table 85.2 Characteristic anatomic features of several common types of fleas.

vibration. Individuals who enter a vacant house can find that fleas rapidly besiege them.

Fleas serve as vectors for endemic (murine) typhus, flea-borne spotted fever, plague, and (primarily among cats) *Bartonella henselae* infection (see Chs. 74 & 76). Endemic typhus is common in southern Texas and California, where the cat flea and *Xenopsylla cheopis* (the oriental rat flea) are the primary vectors, respectively. The disease has also emerged with a worldwide distribution. Feeding alone can transmit endemic typhus, although fleas also defecate infectious bloody feces when feeding.

Tungiasis (caused by the jigger or sand flea, *Tunga penetrans*) usually presents with papular necrotic lesions on the feet, often located adjacent to the great toenail (see Ch. 84). The incidence peaks during dry weather. A gravid female flea is typically found within the upper dermis of the lesions. Infestation most often occurs in beach areas and urban slums, and the flea is common on dogs, cats, and rats.

Treatment

Options for treatment and prevention of flea infestation in animals include *topical* fipronil, neonicotinoids (e.g. imidacloprid), selamectin, flumethrin, and indoxacarb as well as *oral* spinosad, isoxazolines (e.g. afoxilaner), nitenpyram, and lufenuron. Boric acid, growth regulators such as pyriproxyfen, and insecticides may be helpful adjunctive treatments for the infested environment. The best source of information is a knowledgeable veterinarian.

Tungiasis is usually treated surgically. A double-blinded randomized controlled trial of oral ivermectin (300 mcg/kg on two consecutive days) showed it to be ineffective in treating patients with multiple lesions. Wearing protective footwear is preventative.

Fig. 85.10 Characteristic train-track hemorrhage from exposure to *Megalopyge opercularis* (puss caterpillar) .

Lepidopterism

Key features

- Caterpillar dermatitis is caused by the larval form of a butterfly or moth
- Dermatitis may also result from the hairs or scales of adult lepidopterids
- Severe systemic reactions may occur with some species
- Important cause of ophthalmia nodosa

Introduction

Lepidopterism refers to the broad spectrum of adverse reactions to caterpillars, cocoons, butterflies, and moths. Some authors use the term erucism for solely cutaneous reactions to these organisms or specifically for reactions to caterpillars[23,24]. A wide variety of species has been implicated[23].

Pathogenesis

Much of the irritation due to contact with the hairs of lepidopterids is purely mechanical in nature. Toxin-mediated reactions may be related to histamine, kinins, plasminogen activators and other proteinaceous toxins associated with hairs (setae), spines, or hemolymph. Allergy usually does not play a significant role in the reactions.

Clinical features

Cutaneous manifestations include pain, pruritus, erythema, swelling, hemorrhage (Fig. 85.10), papules, and urticaria. Cutaneous reactions may be accompanied by systemic reactions, e.g. respiratory distress or a bleeding diathesis with intracranial hemorrhage (Table 85.3). Contact with Australia's white-stemmed gum moth (*Chelepteryx collesi*) produces yellow discoloration of the skin.

Dermatitis due to gypsy moth caterpillars may result from direct contact with the caterpillar or from hairs on clothesline-dried clothing. Erythematous urticarial papules and macular erythema with pruritus are commonly localized to the flanks, feet, inner aspects of the arms and legs, and collar region.

Ocular lesions caused by caterpillar hairs (ophthalmia nodosa) are similar to those caused by tarantula hairs. Ocular reactions to hairs include acute "toxic" conjunctivitis, chronic mechanical keratoconjunctivitis, subconjunctival granulomatous nodules, iritis, and vitreoretinal involvement. The hairs tend to migrate inward in the direction of the sharp tip.

Children who ingest caterpillars may develop focal or diffuse erythema and edema of the lips, tongue, and buccal mucosa. Esophageal and tracheobronchial involvement can also occur. Removal of hairs and spines may require endoscopy.

CUTANEOUS AND SYSTEMIC REACTIONS ASSOCIATED WITH LEPIDOPTERISM			
Moth/caterpillar common name	**Scientific name**	**Region**	**Clinical findings**
Gypsy moth caterpillar	*Lymantria dispar*	Northeastern US	"Dermatitis" from direct contact or from hairs on clothesline-dried clothing
Io moth caterpillar	*Automeris io*	US	Immediate stinging sensation, "dermatitis" (often transient urticarial papules)
Saddleback caterpillar	*Acharia stimulea* (formerly *Sibine stimulea*)	US	Immediate stinging sensation, "dermatitis" (often transient urticarial papules)
Buck moth caterpillar	*Hemileuca maia*	Eastern US	Immediate stinging sensation, "dermatitis"
Puss caterpillar	*Lagoa crispata* (also known as *Megalopyge crispata*)	Oklahoma and eastern US	Immediate burning sensation, "dermatitis"; in Oklahoma, spines contain high concentrations of tannins (ingested from oak trees)
Southern flannel caterpillar, puss caterpillar, wooly asp	*Megalopyge opercularis*	Southern US, Mexico, Central America	Immediate intense radiating pain; characteristic "railroad track" pattern of hemorrhage (Fig. 85.10); edema, hives, and systemic symptoms
Saturniid moth caterpillar, giant silkworm moth	*Lonomia achelous, L. oblique*	Latin America	Local reactions, bleeding diathesis, renal failure
Processionary caterpillars: pine, Cyprus, and oak (characteristically travel single-file)	*Thaumetopoea pityocampa*, *T. wilkinsoni*, *T. processionea*	Mediterranean region, central Europe, Britain	Urticaria (often immunologic), angioedema, conjunctivitis, respiratory distress, abdominal pain, phalangeal osteolysis; widespread reactions from airborne urticating hairs
Pine moth caterpillar and cocoon	*Dendrolimus punctatus*	China, imported elsewhere	"Dermatitis", arthritis (usually monoarticular), chondritis, ophthalmia nodosa
Tussock moth caterpillar	*Orgyia pseudotsugata*	Western US, especially Pacific Northwest	"Dermatitis", pruritus of the skin and eyes, respiratory symptoms (irritant and allergic mechanisms); forestry workers
Yellowtail moth (adult female)	*Hylesia metabus*, *H. alinda*	Mexico and South America (including Venezuelan port of Caripito)	Papular urticaria (Caripito itch in ship crew)

Table 85.3 Cutaneous and systemic reactions associated with lepidopterism. "Dermatitis" can include pruritic urticarial papules as well as eczematous reactions. Tape stripping of skin has been used to identify caterpillar hairs (setae). Caterpillars can have short spines projecting from a long slender shaft or short tapered shafts with ball-in-socket structures resembling trichorrhexis invaginata.

ARACHNIDS

Tick Bites (Class Arachnida: Subclass Acarina)

Key features

- Hard ticks are common disease vectors
- *Ornithodoros* soft ticks transmit borrelial relapsing fever
- *Dermacentor* ticks hidden in the scalp can cause fatal tick paralysis
- Tick bites may lead to galactose-α-1,3-galactose sensitization and red meat allergy
- Tick control measures are important in preventing disease

Introduction

Patients with tick bites often present with the tick still attached[25]. Scalp attachment is particularly common for *Dermacentor* ticks, and the patient may be unaware of a tick that is hidden by hair. This is of concern considering that *Dermacentor* ticks produce a neurotoxin that can cause paralysis when the tick is attached for ≥4 days[26,27]. Symptoms resolve rapidly upon tick removal, and any child presenting with rapidly progressive ascending flaccid paralysis should be examined for ticks. In Australia, *Ixodes* ticks can cause paralysis, but this occurs primarily in dogs. Tick bites (especially *Amblyomma* spp.; see below) can result in sensitization to the carbohydrate antigen galactose-α-1,3-galactose associated with red meat allergy[8].

Correct identification of an attached tick (see Fig. 76.1) provides the physician with an opportunity to discuss tick control measures and symptoms of tick-borne disease[28,29]. Most hard ticks have a three-host life cycle. Larval (seed) ticks have six legs and feed on small animals in nature. The nymphs and adults feed on larger animals. Nymphs resemble small adult ticks, with eight legs, but are sexually immature. Because they attach for one long blood meal during each phase of their life cycle and search for a new host for each blood meal, ticks are efficient disease vectors. Hard ticks have a hard dorsal plate (scutum) and account for most medically important ticks, transmitting human diseases including Lyme borreliosis, ehrlichiosis, human granulocytic anaplasmosis, babesiosis, and a variety of rickettsial infections (including Rocky Mountain spotted fever [RMSF]) (see Table 76.1). Soft ticks such as *Ornithodoros* (the vector of borrelial relapsing fever) lack a scutum and have retroverted mouthparts. These ticks tend to live in close association with a single host.

Clinical features

Once the tick has been removed, hypersensitivity reactions at the site are common. Papular, nodular, and vesiculobullous lesions can occur and are typically pruritic. Hypersensitivity reactions presenting as erythematous plaques are commonly misinterpreted as erythema migrans. Nodules with pseudolymphomatous histology can also develop.

Treatment

Milder tick bite reactions may respond to application of a potent (class 1 or 2) topical corticosteroid; occlusion of these agents can increase efficacy. More intense reactions may require intralesional corticosteroid injection or surgical excision.

Most tick-borne diseases respond readily to tetracyclines. Suspected RMSF requires empiric therapy, which should not be delayed until confirmatory tests are available (see Ch. 76). Delayed treatment of RMSF has led to deaths in children[30]. Doxycycline is the drug of choice for children as well as adults with RMSF. Staining of teeth is unlikely with a short course of doxycycline, and chloramphenicol is less effective for RMSF.

TICK CONTROL MEASURES	
Personal	**Environmental**
Protective clothing tightly laced, snapped or tied	Removal of leaf debris
Clothing treated with permethrin	Area acaricide application
Clothing treated with repellents such as DEET	Exclusion of animal hosts
Regular tick inspections	Acaricide-treated feed corn

Table 85.4 Tick control measures. DEET, N,N-diethyl-3-methylbenzamide.

Environmental measures

Exclusion of animal hosts from communities and recreational areas can be helpful in control of tick-borne illness (Table 85.4), although this may be difficult to achieve for small animal hosts (e.g. mice, rabbits). There is evidence that communities located close to wildlife reserves have higher rates of tick-borne illnesses. Oral agents, such as the avermectins, can be placed in corn eaten by deer to kill ticks that feed on the deer. Injectable ivermectin is helpful in reducing tick infestation of livestock. Removal of leaf debris is a critical part of tick control efforts because it: (1) enables acaricides to reach the ticks; and (2) leads to a reduction in tick numbers via dehydration of adults (which require leaf debris to maintain hydration) and eggs (which require sufficient humidity to hatch).

Repellents

Permethrin has been marketed as a tick repellent. The spray formulation is most widely available. Once applied to clothing, permethrin is stable through several wash cycles. It is also suitable for treating sleeping bags, tents, and fabric used for insect screening. A liquid concentrate can be used to impregnate fabric for the life of the garment. Permethrin is particularly helpful in the prevention of tick and chigger bites, since these crawling arthropods must travel across the treated fabric, whereas flying insects tend to be attracted directly to exposed skin. The combination of a DEET-containing repellent and permethrin-treated clothing is generally highly effective against a wide range of biting arthropods.

Some North African camel ticks have demonstrated high-level resistance to permethrin. Instead of killing the tick, permethrin may produce a pheromone-like attachment response. This attachment phenomenon has not yet been described in North American ticks, but permethrin resistance does occur. High-level permethrin resistance in cattle ticks has been linked to outbreaks of bovine babesiosis and anaplasmosis in Mexico[31].

Methods to eliminate and prevent tick infestations in dogs include: *topical* application of products containing fipronil, permethrin, or fluralaner every month; *oral* administration of an isoxazoline (e.g. afoxolaner) every 1–3 months; and collars impregnated with imidacloprid/flumethrin, deltamethrin, or amitraz[32].

Tick removal

Ticks should be removed as completely as possible, and care should be taken not to squeeze the abdomen. Gentle traction is generally preferred, but a twisting motion can also be used; the latter technique may leave a small mouthpart. Inexpensive plastic tick removal devices (e.g. Tick Nipper™, Tick Twister®) can be utilized to grasp the tick just behind the mouthparts without severing them. A tick removal device can also be made by cutting a V-shaped notch in a plastic spoon or credit card with a sharp pair of scissors or hot blade. Petroleum jelly, fingernail polish, isopropyl alcohol, and hot matches are generally ineffective. Hands should be washed if they were in contact with the tick.

Antibiotic prophylaxis after tick bites

Antibiotic prophylaxis after tick bites remains controversial, and most authorities do not recommend its routine use, including for prevention of Lyme disease (see Ch. 19). In endemic areas (>20% of ticks infected), if a nymphal or adult *I. scapularis* has been attached for >36 hours and prophylaxis can be started within 72 hours of tick removal, a single 200 mg dose of doxycycline may decrease the risk of developing Lyme disease (from 3.2% in the placebo group to 0.4% in the treatment group in one study)[33,34]. A meta-analysis of antibiotic prophylaxis concluded that in order to prevent one case of Lyme disease, 50 people bitten by an *Ixodes* tick would need to be treated – the risk in the placebo group was 2.2% compared with 0.2% in the antibiotic-treated group[35]. Routine serologic testing for Lyme disease in individuals bitten by *Ixodes* ticks is not useful, and there is no evidence that molecular testing for *Borrelia burgdorferi* in a tick is helpful in predicting the risk of Lyme disease in a human bitten by that tick[36]. Treatment regimens for erythema migrans are outlined in Table 19.4.

The utility of antibiotic prophylaxis in preventing other tick-borne illnesses has not been established. For example, in a guinea pig model of RMSF, a single dose of oxytetracycline was found to prevent disease if given shortly before the expected onset of illness. However, administration any earlier merely delayed the development of clinical symptoms, making correct timing of administration of a single dose difficult. Single-dose doxycycline for Lyme disease prophylaxis should be avoided in RMSF-endemic areas, since changing the course of RMSF could potentially delay definitive treatment.

Amblyomma Ticks

Synonym: ■ Lone star tick

Key features

- Ornate scutum (hard dorsal plate)
- Single white dorsal spot on female *Amblyomma americanum*
- Papular, nodular, and bullous lesions at attachment sites
- *Amblyomma* ticks are vectors of ehrlichiosis, several rickettsial infections, southern tick-associated rash illness (STARI), and tularemia
- *Amblyomma* tick bites have been associated with the development of red meat allergy

Introduction

Amblyomma ticks are particularly common in the southern US. This, plus the characteristic white dorsal spot of the female *A. americanum* (Fig. 85.11; see Fig. 76.1), has given rise to the common name "lone star tick". Males have ornate markings that often form pale "inverted horseshoes" on the posterior portion of their dark scutum. *Amblyomma* ticks have prominent eyes, festoons (grooves in the posterior edge of the scutum), and long anterior mouthparts.

A. americanum has a wide distribution, now ranging from Texas to Iowa and Maine (see Fig. 76.12), that is continuing to expand due to the explosion in the white-tailed deer population[37]. Other species of *Amblyomma* ticks are common in Africa, the Caribbean, and Central and South America. Some *Amblyomma* ticks attach to birds, and migration of avian hosts has been implicated in dissemination of tick-borne diseases.

Fig. 85.11 *Amblyomma americanum* (lone star tick). Note the characteristic white dorsal spot on the female ticks. The female's scutum often covers only a portion of the body to allow room for engorgement.

Clinical features

Amblyomma tick attachments favor the legs, buttocks, and groin and often affect people who work outdoors or take part in outdoor recreation (e.g. construction workers, fishermen, hunters, hikers), especially when new development displaces the tick's usual hosts. Patients usually become aware of *Amblyomma* tick bites while the tick is still attached. This is partly because the ticks often attach in large numbers. Once the tick has been removed, delayed-type hypersensitivity to tick antigens can lead to a reaction at the attachment site. Papular, nodular, and bullous lesions are common.

A. americanum is the major vector of *Ehrlichia chaffeensis*, the agent of human monocytic ehrlichiosis[38]. This disease has been documented in more than 30 states, with systemic symptoms similar to those of RMSF (e.g. fever and headache) and variable cutaneous manifestations (see Ch. 76). *A. americanum* is also the primary vector for *Ehrlichia ewingii* infection.

Southern tick-associated rash illness (STARI; "Missouri Lyme disease") was originally described in Missouri but can also occur in other southern and southeastern states. It presents with an expanding erythematous annular plaque 3–14 days after *A. americanum* attachment, often in association with fever, headache, myalgias, and arthralgias. *Borrelia lonestari* has been implicated as a potential cause.

Amblyomma ticks have been implicated in the transmission of RMSF (*Rickettsia rickettsii*; primarily in Central and South America, where it may be referred to as Brazilian spotted fever), American tick bite fever (*Rickettsia parkeri*), African tick bite fever (*Rickettsia africae*), and tularemia (see Chs. 74 & 76). In the midwestern and southern US, *A. americanum* is also the vector of Heartland virus disease and likely Bourbon virus infection, which are due to a phlebovirus and thogotovirus, respectively. A related phlebovirus causes severe fever with thrombocytopenia syndrome, an emerging infection in Asia transmitted by *Haemaphysalis* ticks, which have recently been identified in the eastern US.

Bites from *Amblyomma* ticks have been most strongly associated with allergy to beef, pork, and lamb via development of IgE antibodies specific to galactose-α-1,3-galactose, a blood group substance of non-primate mammals[39]. Urticaria, angioedema, or anaphylaxis typically develops 3–5 hours after eating red meat[40]. Of note, IgE against galactose-α-1,3-galactose has also been implicated in cetuximab-induced anaphylaxis.

Dermacentor Ticks

Synonyms: ■ *D. andersoni:* Rocky Mountain wood tick ■ *D. variabilis*: American dog tick

Key features

- Large ticks
- Ornate scutum (hard dorsal plate) with deep punctuations
- The adult tick prefers to attach to the head, neck, and shoulder
- *D. variabilis* is the major vector for RMSF in the United States, while *D. andersoni* can transmit Colorado tick fever as well as RMSF

Introduction

Dermacentor ticks are commonly found in open areas with low bushy vegetation, but they are scarce in heavily wooded areas. Peak abundance of the tick is in April and May, declining by July. *Dermacentor* ticks have an ornate scutum, prominent eyes and festoons (grooves in the posterior scutum), small anterior mouthparts, and a rectangular basis capituli. Both *D. variabilis* (Fig. 85.12; see Fig. 76.1) and *D. andersoni* have brown legs, and coxa 1 (the attachment base for the first pair of legs) is bifid. Coxa 4 is greatly enlarged in the male, and males have no ventral plates. As in most hard ticks, the scutum in the female is smaller, leaving a portion of the abdomen exposed.

D. variabilis is found throughout the US, except for the Rocky Mountain states. In parts of Canada, its range overlaps with that of *D. andersoni*, which is generally confined to the Rocky Mountains. In Georgia and South Carolina, *D. variabilis* is the second most common tick found on humans (*A. americanum* being the most common).

Fig. 85.12 ***Dermacentor variabilis*** **tick (engorged female) with an ornate scutum.** This species is the major vector for Rocky Mountain spotted fever in the US.

Pathogenesis

During the course of engorgement, *D. andersoni* saliva downregulates local cell-mediated immunity. This phenomenon may explain the delayed onset of many nodular tick bite reactions. It might represent an adaptive mechanism, allowing the tick to feed unnoticed.

Clinical features

Dermacentor ticks preferentially attach to the head and neck region; in contrast, *Amblyomma americanum* prefers the lower legs, buttocks, and groin, and *Ixodes scapularis* shows less site preference but most often attaches to the trunk. Prolonged attachment of a *Dermacentor* tick is the most frequent cause of tick paralysis in the US (see above).

D. variabilis is the major vector for RMSF in the US[41]. The highest incidence of RMSF is in the eastern states, especially in North Carolina (see Fig. 76.2). RMSF typically presents with fever and headache. An acral eruption of erythematous macules and/or petechiae may be evident but is commonly absent early in the disease process. As many as 40% of patients with RMSF are not aware of a recent tick bite. As the mortality rate in RMSF is heavily dependent on the interval between onset of symptoms and initiation of antibiotic therapy, the disease should be considered in every patient with fever and a headache in endemic areas.

D. andersoni is the major vector for RMSF in the Rocky Mountain states, and it is also the vector for the viral illness Colorado tick fever. Because the symptoms of Colorado tick fever overlap with those of RMSF, specific diagnostic tests such as paired serologic studies (acute and convalescent) and immunohistochemical staining, direct immunofluorescence, or PCR-based analysis of lesional skin biopsy specimens can help to confirm the diagnosis of RMSF; however, empiric treatment should not be delayed until the results are available. Additional diseases that can be transmitted by *Dermacentor* ticks include tularemia, rickettsial infections in Europe and Asia, Pacific Coast tick fever in California (*Dermacentor occidentalis*), and occasionally, human monocytic ehrlichiosis and Q fever.

Rhipicephalus Ticks

Synonym: ■ Brown dog tick

Key features

- Common dog ticks
- Most are brown with brown legs, a teardrop shape and inornate scutum (hard dorsal plate)
- Vectors for boutonneuse fever and (occasionally) RMSF in the southwestern US

Fig. 85.13 *Rhipicephalus* ticks. Common brown dog ticks; the lower tick is engorged with blood.

Fig. 85.14 *Ixodes scapularis* tick. The inornate brown scutum is overshadowed by the large, cream-colored, engorged abdomen.

Introduction

Rhipicephalus ticks (Fig. 85.13) are common dog ticks that are typically brown in color with an inornate scutum. They have prominent eyes and festoons (grooves in the posterior scutum), but small mouthparts attached at a hexagonal basis capituli.

Clinical features

Rhipicephalus ticks carry RMSF (primarily in the southwestern US and Mexico) and boutonneuse fever (see Ch. 76). They may also be vectors for Congo–Crimean hemorrhagic fever virus, although *Hyalomma* ticks usually transmit this condition.

Ixodes Ticks

Synonyms: ■ Blacklegged tick ■ Deer tick

Key features

- Teardrop shape, often with dark legs
- Inornate brown scutum (dorsal hard plate) that is small relative to the large abdomen in females
- Vectors for Lyme disease, human granulocytic anaplasmosis, babesiosis, viral encephalitis (e.g. due to Powassan virus), and other borrelial and rickettsial infections

Introduction

Ixodes scapularis (formerly also known as *I. dammini*), the eastern blacklegged tick, is the best known of the *Ixodes* ticks. Adult females are typically found attached to the host in late fall and spring. Their small, inornate brown scutum is often overshadowed by a large, soft, cream-colored engorged abdomen (Fig. 85.14; see Fycks have short anterior mouthparts, prominent broad "antennae", and an upside-down U-shaped ventral groove with its apex anterior to the anus.

Clinical features

Ixodes ticks are vectors for Lyme disease, babesiosis, and human granulocytic anaplasmosis (HGA)[42,43]. Babesiosis is a malaria-like illness, whereas HGA is an acute febrile illness characterized by leukopenia, thrombocytopenia, and increased serum hepatic transaminases. In the western US, *I. pacificus* (the western blacklegged tick) is the major vector for Lyme disease (see Fig. 76.12). In the Great Lakes region and eastern US, *I. scapularis* is the major vector. *I. ricinus* and *I. persulcatus* are important vectors for Lyme disease in Europe and Eurasia, respectively. Because the larval and nymph stages of the tick often attach to birds in the spring and summer, avian migration (particularly of robins) may be responsible for the broad geographic distribution of the tick and of Lyme disease.

A single *Ixodes* tick may transmit more than one disease. In one study of a rural New Jersey county, 55% of adult *I. scapularis* ticks carried at least one disease (Lyme disease, 43%; babesiosis, 5%; HGA, 17%) and 10% carried more than one of the three diseases. Co-infection with more than one of these three diseases is also common in Wisconsin and Minnesota, and *I. scapularis* has been reported to carry both Lyme disease and HGA in New York City parks.

Ixodes ticks carry viral encephalitis in Europe and transmit rickettsial infections in Europe and Australia (see Table 76.1). Emerging infectious diseases that are transmitted by *Ixodes* ticks include a viral-like illness or relapsing fever due to the spirochete *Borrelia miyamotoi* (Asia, Europe, North America), Powassan encephalitis due to a flavivirus (northeastern US, Great Lakes region), ehrlichiosis due to *E. muris eauclairensis* (Minnesota and Wisconsin), and neoehrlichiosis due to *Candidatus* Neoehrlichia mikurensis (Europe and Asia).

Mites (Class Arachnida: Subclass Acarina)

Key features

- Mites are identified by their mouthparts and legs; the shape of their body, dorsal plates, and shields (sternal, anal, and genitoventral); and the setae (bristles or hairs) on the latter structures
- Trombiculid mites are typically larval (chiggers; six-legged) when attached to a host; they are vectors for scrub typhus
- *Cheyletiella* mites are commonly found on pets and may produce papular or vesiculobullous lesions in the owner
- Species that parasitize birds, mammals, and grains can produce dermatoses; the house mouse mite is a vector for rickettsialpox

Introduction

Mites are small arachnids that range from 0.1 to 2 mm in length. Tens of thousands of species exist worldwide (Table 85.5). The majority of mites

MITE FAMILIES	
Acaridae	Food mites
Demodicidae	Follicle mites
Dermanyssidae	Bird, rodent mites
Glycyphagidae	Food mites
Haemoganasidae	Straw mites
Psoroptidae	Mange, scab mites
Pyemotidae	Grain mites, straw mites
Sarcoptidae	Scabies mites
Trombiculidae	Chigger, harvest mites

Table 85.5 Mite families.

MITES OF MEDICAL IMPORTANCE	
Acarus siro	Grain mite: hay, grain, house dust; **baker's itch**
Cheyletiella spp.	**Walking dandruff on pets**
Cheyletus malaccensis	Wheat mite; **wheat warehouse itch** (Japan)
Demodex spp.	**Folliculitis;** possibly **rosacea, blepharitis; demodectic mange** in dogs and cats
Dermanyssus gallinae, D. avium	Fowl mite: chickens, wild birds, rodents, rabbits
Dermatophagoides farinae, D. pteronyssinus	Dust mite (**allergy**): dust, blankets, mattresses, pillows, pets, stored foods and grains
Euroglyphus maynei	Dust mite; **allergy, cross-reactions with other dust mites**
Glycyphagus domesticus	Cheese mite, barn mite, grocer's mite: cheese, grains, hay, mattresses; **grocer's itch**
Laelaps spp., *Androlaelaps* spp., *Eulaelaps* spp.	Rodent mites
Lepidoglyphus destructor	Dust mite, hay mite
Liponyssoides (Allodermanyssus) sanguineus	House mouse mite; **rickettsialpox**
Neotrombicula autumnalis	Harvest mite (Northern Europe)
Ophionyssus natricus	Snake mite
Ornithonyssus sylviarum, O. bacoti, O. bursa	Tropical rat mite, fowl mite, tropical fowl mite, northern fowl mite: rodents, chickens, wild birds, carnivores
Pyemotes ventricosus, P. tritici	Straw itch mite, grain mite: parasites of insects in grains and straw; **Pyemotes dermatitis**
Trombicula (Eutrombicula) alfreddugesi	Chigger mite, red bug, harvest mite (US)
Trombicula (Leptotrombidium) akamushi, L. deliense, L. fletcheri, L. arenicola, L. pallidum, L. pavlovskyi, L. scutellare	Scrub mite; **scrub typhus**
Tyrophagus putrescentiae	Mold mite, grain storage mite; **copra itch**

Table 85.6 Mites of medical importance. Scientific names, common names and associated diseases (in bold) are listed. With the exception of *Demodex* and dust mites, mite bites typically lead to pruritic papular eruptions in humans.

Fig. 85.15 Avian mite bites. Multiple erythematous pruritic papules, several of which have hemorrhagic crusts. The exposure was birds nesting on the patient's house. *Courtesy Jean L. Bolognia, MD.*

are free-living, but thousands of species parasitize animals or plants. Like fleas, most mites lack host specificity. Mites of medical importance may cause skin lesions, incite allergic reactions (especially in atopic individuals), or spread disease (Table 85.6). Like ticks, mites mature through larval, nymph, and adult stages. Typically, there is a single larval stage (referred to as chiggers in trombiculid mites) and several nymphal stages. Most mites lay eggs, but some, such as the spiny rat mite (*Laelaps echidninus*), are viviparous, producing non-motile larvae. The straw itch mite (*Pyemotes tritici*) retains its young until they emerge as sexually mature mites. Sarcoptic mites are relatively species-specific and complete their entire life cycle on the host (see Ch. 84).

Clinical features

Cutaneous reactions to mites are common and include papular, papulovesicular, bullous, urticarial, and morbilliform eruptions (Fig. 85.15). Chigger bites most often affect the lower legs, skin at the edges of underwear, and the genital region. Larvae of trombiculid mites in Asia are vectors for scrub typhus, while house mouse mites transmit rickettsialpox (see Ch. 76). Eschars at the site of the bite are a clue to rickettsial disease, and serologic testing can be helpful. As with tick-borne rickettsial diseases, biopsy of the eschar can be sent for immunohistochemical staining or PCR to distinguish typhus group organisms from the spotted fever group.

Differential diagnosis

Mite-induced dermatoses are often misdiagnosed. Bullous lesions are especially common, and false-positive direct immunofluorescence has been described. Histologic features resembling those of an insect bite may suggest the correct diagnosis, as may a clinical pattern of skin lesions corresponding to areas of exposure. However, eosinophil-rich subepidermal bullae occur in both mite infestation and bullous pemphigoid, so a careful history is essential.

Mite-induced dermatitis can be associated with pets, rodents, straw bedding, bird nests, grains, and even onion bulbs (see Table 85.6). Avian mite dermatitis may also be associated with pet rodents, such as gerbils. Pets should be examined by a knowledgeable veterinarian; skin scraping, adhesive tape stripping, or biopsy may reveal the mite(s) on the animal. Vacuum cleaners can also be fitted with filters to collect mites (Table 85.7). Another helpful technique is to spray areas of dandruff or crust on a pet with an acaricidal agent recommended by a veterinarian. A fine-toothed comb or toothbrush is then used to remove the scale-crust, which is placed in a sealed bag. When alcohol is added to the bag, scale-crust and hair will sink, whereas mites will float.

Treatment

Some types of mites inflict a "bite and run" injury, while others remain attached for a prolonged meal. Scraping, tape stripping, or vigorous washing with soap and water are all effective in removing or killing attached mites. Scrapings, tape strippings, and biopsy specimens may be helpful diagnostically as well as therapeutically.

PREPARATION OF COLLECTED MITES FOR MICROSCOPIC EXAMINATION
Preferred method
• Clear with either lactic acid or lactophenol (may take hours to days) • Wash with water • Mount in Hoyer's medium*
Rapid method
• Mount live or alcohol-fixed mites directly in Hoyer's medium* • Mount live mites in Permount™ (details of mites less obvious)
*Prepared by adding 30 g of gum arabic to 50 ml distilled water, then adding 200 g chloral hydrate followed by 20 g glycerin; filter through cheesecloth.

Table 85.7 Preparation of collected mites for microscopic examination. If mites are collected onto filters inside a vacuum cleaner, the filter samples are treated with potassium hydroxide (KOH) and then floated in concentrated sugar solution to collect the mites.

Definitive treatment requires avoidance or treatment of the infested source. Mite identification can be helpful in establishing the likely source. Management strategies differ for free-living, zoonotic, and grocery mites. An acarologist can be of immeasurable value in this setting, and the *Medical and Veterinary Entomology* text by Gary Mullen and Lance Durden is an excellent resource. As noted above, animals should be examined and treated by a veterinarian. In public parks and training areas, animal exclusion and acaricides may be helpful measures. Personal protection with permethrin-treated clothing is also of value.

Skin lesions in humans may be treated with topical antipruritics such as camphor and menthol, or with topical anesthetics such as pramoxine. Potent topical corticosteroid preparations can be helpful, especially when occluded. Intralesional corticosteroid injections and excision of pruritic nodules may be necessary. Bullous and excoriated lesions can develop secondary infections, and appropriate wound care is important. Home remedies typically attempt to remove or kill attached mites and reduce itch with counterirritants (e.g. propylene glycol-containing deodorant sticks). Patients may present with irritant and allergic contact dermatitis to antiseptics, nail polish, or even battery acid.

Chiggers

Introduction

Trombiculid mites are oviparous, depositing their eggs on the ground, leaves, or blades of grass. After several days, the egg cracks, but the mite remains in a quiescent prelarval stage. Following the prelarval stage, the six-legged larvae (chiggers) actively search for a suitable host. It is the larval mite that is found attached to the host. After a prolonged meal, the larvae drop off and mature through the eight-legged free-living nymph and adult stages.

Clinical features

Chigger bites are intensely pruritic, especially in highly sensitized individuals. Grouped papules, vesicles, or bullae are typically found on the lower extremities, or where elastic meets the skin. Seasonal penile swelling associated with pruritus and dysuria in children, referred to as "summer penile syndrome", appears to represent a hypersensitivity response to chigger bites.

Treatment

The topical antipruritics and anesthetics discussed above may be helpful. Most patients presenting to a dermatologist require potent topical or intralesional corticosteroid therapy. Vigorous washing with soap and water immediately after the exposure is helpful. Treatment of clothing with permethrin is a useful strategy for prevention.

Cheyletiella

Introduction

Cheyletiella are non-burrowing mites that are commonly found on cats (*C. blakei*), rabbits (*C. parasitovorax*), and dogs (*C. yasguri*). In humans, they are a frequent cause of cryptic mite-induced dermatitis. Infestations in animals are variably pruritic and produce a subtle dermatitis that presents with dry white scales, which is sometimes termed "walking dandruff". The animal should be evaluated by a veterinarian, and it is important to note that a single negative scraping does not exclude cheyletiellosis. In a study of dogs with *Cheyletiella*, samples collected by using a vacuum cleaner on the dog were shown to be significantly more sensitive than tape stripping, hair plucking, or skin scraping.

Fig. 85.16 *Cheyletiella* bites. These mites are non-burrowing and are found on cats, rabbits, and dogs.

Clinical features

The typical patient with *Cheyletiella* dermatitis is a young or middle-aged woman who presents with grouped pruritic papules (Fig. 85.16). Bullous eruptions have also been described. It is uncommon to find the mite on the patient.

Treatment

Skin reactions in humans should be treated as described above. Treatment of the animal should be directed by a veterinarian.

Spider Bites (Class Arachnida: Order Araneae)

Spiders are arachnids related to scorpions, ticks, and mites. Many species of toxic spiders are found worldwide. The bite of *Phoneutria* wandering spiders in Brazil can be fatal in children, but most spider bites result only in a local cutaneous reaction. Toxic spiders are often regional in distribution, and many are poorly characterized. The most clinically significant spiders are discussed below. It is noteworthy that many important species in the US were not native to North America, but were imported in recent years as a result of worldwide travel and commerce. Examples are the hobo spider and *Loxosceles laeta* spider.

Widow Spiders (*Latrodectus*)

Key features

- Black widows are large, shiny black spiders with a round abdomen
- A variety of black, brown and red widow spiders exist worldwide
- In *Latrodectus mactans*, a red hourglass shape is seen on the ventral abdomen
- Acute pain and edema occur at the bite site
- Systemic symptoms mimic acute abdomen and may include rhabdomyolysis

Introduction

Widow spiders (*Latrodectus* spp.) are found worldwide, with five species including black, brown, and red variants in North America alone. *Latrodectus mactans* is the most common black widow spider in

North America, with a range that extends to the Caribbean islands. *L. tredecimguttatus*, *L. curacaviensis*, and *L. indistinctus* are black widow spiders found in Europe, South America, and Africa (referred to as a button spider), respectively. Female black widow spiders from North American species have a red hourglass-shaped mark on the ventral abdomen, while species from other areas of the world have different red patterns. Brown (*L. geometricus*) widow spiders characterized by an orange ventral hourglass shape have a widespread distribution that includes the US, South America, and Africa. Australia has the red-back spider (*L. hasselti*) and New Zealand the red katipo spider (*L. katipo*).

Widow spiders are typically found in woodpiles, in shoes, and under outhouse seats. Human envenomation usually occurs when the spider's environment is disturbed, and the spider is inadvertently trapped or pressed against the skin. Widow spiders are more aggressive when protecting an egg sack.

Pathogenesis

Black widow venom contains latrotoxins that act by depolarizing neurons, increasing intracellular calcium, and stimulating uncontrolled exocytosis of neurotransmitters. Divalent cation-dependent tetramers related to α-latrotoxin can insert into lipid bilayers, forming membrane pores. Calcium-independent receptors for latrotoxin have also been identified.

Clinical features

The degree of morbidity caused by widow spider bites varies depending upon the amount of venom injected and the site of the bite as well as the species, age, and sex of the spider, with only adult females capable of envenomation. Local skin reactions are usually limited to transient erythema, edema, sweating, and piloerection. Extracutaneous manifestations are often prominent and can include painful muscle spasms (initially around the bite site, then more widespread), symptoms suggestive of an acute surgical abdomen, headache, and nausea; generalized diaphoresis may also occur. The symptoms of brown widow bites tend to be milder and restricted to the tissues near the bite.

Treatment

Benzodiazepines and intravenous calcium gluconate can be helpful for associated tetany. In one study, calcium gluconate was shown to be superior to methocarbamol (Robaxin®). Antivenin can produce rapid relief of tetany and complications such as priapism that are unresponsive to other agents. Purified equine Fab fragment-based antivenin is associated with a lower risk of hypersensitivity reactions than classic antivenin.

Loxosceles Spiders

Key features

- Brown recluse spider (*Loxosceles reclusa*) has a small body and long legs
- Dark brown fiddle pattern present on cephalothorax
- Dermonecrotic bite reactions
- Systemic reactions include shock, hemolysis, renal insufficiency, and disseminated intravascular coagulation
- Other *Loxosceles* spiders can produce similar reactions

Introduction

Loxosceles spiders are found throughout the world and classically have a dark brown, violin-shaped marking on the dorsal cephalothorax (Fig. 85.17). In the US, bites from *L. reclusa* (the brown recluse spider), *L. laeta*, *L. rufescens*, *L. deserta*, and *L. arizonica* can cause skin necrosis, although reactions to the latter three species are generally mild. Many other spiders are capable of producing dermonecrotic or systemic reactions, and bites of these spiders are often erroneously attributed to the brown recluse spider. Brown recluse spiders are most common in the south central US, from Tennessee and Missouri to Oklahoma and Texas (Fig. 85.18). They are often found in woodpiles, in attics, and under radiators.

Most bites occur when the spider has been disturbed. *Loxosceles* spiders are non-aggressive, and there are reports of families living in houses infested by thousands of brown recluse spiders without a single bite. This suggests that brown recluse bites are overdiagnosed, especially in regions where the spider is rare. The diagnosis can be confirmed by an enzyme immunoassay to detect *Loxosceles* venom in a skin biopsy specimen or plucked hairs (obtained up to 4 days after the bite) or by a passive hemagglutination inhibition test (up to 3 days after the bite); in addition, reduced glycophorin A on the erythrocyte surface may represent a marker of venom exposure.

Fig. 85.17 Brown recluse spider (*Loxosceles reclusa*). This spider has a small body, long legs, three pairs of eyes, and a dorsal violin pattern on the cephalothorax.

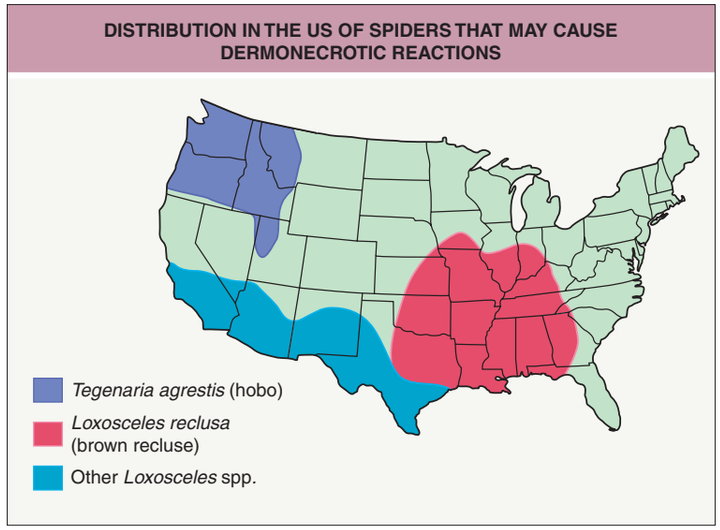

Fig. 85.18 Distribution in the US of spiders that may cause dermonecrotic reactions. The potential for hobo spider bites to result in dermonecrosis is debated in the literature. *Adapted from: Sams HH, Dunnick CA, Smith ML, et al. Necrotic arachnidism. J Am Acad Dermatol. 2001;44:561–73.*

Pathogenesis

Sphingomyelinase D is the major toxin in brown recluse venom, and it interacts with serum amyloid protein. Hyaluronidase allows eschars to spread in a gravity-dependent fashion. Neutrophils are not directly activated by the venom, and neutrophil activation may be dependent upon the interaction between the venom and endothelial cells. The venoms of geographically diverse spiders such as *L. reclusa*, *L. laeta*, *L. deserta*, *L. gaucho*, and *L. intermedia* have similar sphingomyelinase activity and electrophoretic profiles, with a major protein band at 32–35 kDa. All contain hyaluronidase as well as metalloproteinases

Fig. 85.19 Dermonecrotic spider bite. Note the central dusky necrosis. The patient was initially misdiagnosed with cellulitis and hospitalized after failure to respond to oral antibiotic therapy.

with fibrinogenolytic activity. The similarity of these venom components and documented cross-reactivity suggests the potential for a single global *Loxosceles* antivenin[44].

Clinical features

The majority of bites by *Loxosceles* spiders, including the brown recluse, do not cause serious reactions. Local pain is frequently delayed until several hours after the bite, which most often occurs on an extremity (Fig. 85.19). Cutaneous reactions typically begin with erythema and then develop central vesiculation or duskiness with a blanched halo, which may evolve into hemorrhagic bullae and necrosis[45]. Dermonecrotic reactions can eventuate in dry, necrotic eschars or ulceration. Upper airway obstruction caused by envenomation of the neck by brown recluse spiders has been reported. Systemic reactions include thrombocytopenia and Coombs-positive hemolytic anemia[46,47]. *L. arizonica*, a spider found in the southwestern US, causes less severe necrosis but has been implicated as a cause of shock.

Pathology

Histologic findings have been best described in laboratory models of brown recluse spider envenomation in rabbits[48]. The findings are time-dependent, with early biopsy specimens demonstrating a neutrophilic infiltrate. Later changes include "mummified" coagulative necrosis of the epidermis, adnexal epithelium, and superficial dermis. A neutrophilic band-like infiltrate may still mark the border between viable skin and eschar. Small vessel vasculitis and thrombosis are often evident adjacent to the neutrophilic band, and larger vessel vasculitis resembling polyarteritis nodosa may account for the extent of tissue necrosis seen after some bites. Arterial thrombosis leading to gangrene of the foot has been reported[49].

Treatment

Optimal treatment to prevent dermonecrotic reactions remains elusive. Most bites can be treated with rest, ice, and elevation. Intradermal injection of polyclonal anti-*Loxosceles* Fab fragments can attenuate necrosis in an animal model up to 4 hours after envenomation, and antivenin may reduce the ultimate size of the necrotic area even when administered up to 48 hours after envenomation[50]. Hyperbaric oxygen therapy may decrease the final size of ulceration, although results have varied. Studies with more widely available agents such as dapsone, colchicine, and prednisone have been inconsistent and often disappointing[51]. Dapsone therapy is complicated by the risk for hemolysis, especially in individuals who have a glucose-6-phosphatase dehydrogenase (G6PD) deficiency. Current recommendations for systemic therapy are limited to antivenin (if available) and prednisone (for systemic reactions). Anecdotal reports and some animal data also suggest that intralesional triamcinolone may have some efficacy for dermonecrotic reactions[51]. The complement inhibitor eculizumab was shown to prevent brown recluse venom-induced hemolysis *in vitro*, and clinical studies are needed to determine the drug's therapeutic potential for brown recluse bite reactions.

Funnel Web Spiders

Key features

- Large, hairy, aggressive spiders found in dark, moist areas such as basements
- Funnel-shaped webs
- *Tegenaria agrestis* (hobo spider, aggressive house spider), found in the northwestern US, Canada and Europe, is 4–5 cm in diameter and may occasionally cause dermonecrotic reactions
- Other funnel web spiders can produce local and systemic reactions

Introduction

When *Tegenaria agrestis* (hobo spider) was imported to North America from Europe, this spider found few major competitors and became common in human dwellings in the northwestern US (see Fig. 85.18), usually in basement webs at soil level in contact with concrete or stone. In Europe, the hobo spider has a largely rural habitat while the less aggressive *T. gigantea* (also known as *T. duellica*; giant house spider) and *T. domestica* (domestic house spider) are more likely to be found in human dwellings. The sternum of the hobo spider has a lightly colored center and dark vertical bands on the sides.

The most medically important funnel web spiders, *Hadronyche* and *Atrax*, are endemic to eastern Australia. These spiders produce potent neurotoxins, and their bites can result in severe systemic symptoms (see below). Similar reactions may occur following bites from *Phoneutria*, spiders in South America (especially Brazil) and Costa Rica.

Pathogenesis

Australian funnel web spider robustoxin contains small peptide neurotoxins (δ-atracotoxins) that slow tetrodotoxin-sensitive, voltage-gated sodium channel inactivation, resulting in catecholaminergic and cholinergic excess when severe envenomation occurs in humans. In contrast, agatoxins from the native American funnel web spider (*Agelenopsis aperta*) target ion channels and paralyze insect prey but are not medically significant to humans.

Clinical features

Whether *T. agrestis* bites can potentially produce dermonecrosis or systemic symptoms represents a subject of controversy[52]. There are very few documented reactions to bites from this spider in the literature, and studies have failed to demonstrate induction of cutaneous necrosis or hemolysis by *T. agrestis* venom in animal and laboratory models[53]. Bites of Australian funnel web spiders of the genera *Hadronyche* and *Atrax* are often associated with extreme pain, puncture marks, local redness, and bleeding. For these spiders, severe envenomation is characterized by autonomic excitation (e.g. diaphoresis, hypersalivation, brady- or tachycardia, hypertension) and neuromuscular symptoms (e.g. paresthesias, fasciculations, muscle spasms), which may culminate in myocardial injury and shock without antivenin therapy.

Tarantulas (Family Theraphosidae)

Key features

- Typically large hairy spiders, up to 15 cm in diameter
- Normally non-aggressive
- Urticating hairs are thrown at skin and eyes
- Important cause of ophthalmia nodosa

Introduction

Tarantulas are large hairy spiders common in the southwestern US, and related species are found throughout the world. They are often sold in pet stores. Most tarantula bites do not produce severe systemic toxicity.

Many species of tarantulas possess urticating hairs in a characteristic patch on the dorsal abdomen. These hairs are used in a defensive

fashion to drive predators from the spider's burrow. Vibrations of the hind legs are used to flick hairs at the perceived attacker. Urticating hairs are absent on most African and Asian species.

Clinical features

Itching at the site of urticating hair penetration may persist for several weeks after exposure. Hairs that penetrate the cornea can result in ophthalmia nodosa, a chronic granulomatous reaction that can lead to loss of vision.

Pathology

Urticating tarantula hairs penetrate the stratum corneum and epidermis and may extend as deep as the reticular dermis.

Scorpions (Class Arachnida: Order Scorpiones)

Key features

- Large anterior claws
- When threatened, the long tail is curved upward to sting
- Blunt thorn on the tail of *Centruroides* spp.

Introduction

Many toxic scorpions exist worldwide[54]. Scorpions are typically found under tabletops, in woodpiles, and in shoes. They sting when disturbed and accidentally trapped by a hand or foot. Several clinically relevant species are listed in Table 85.8.

Clinical features

Local and systemic symptoms (e.g. pain, paresthesia) are typically out of proportion to cutaneous signs such as erythema and edema, which are not usually prominent at the site of the sting. Most fatalities are related to cardiorespiratory manifestations, including cardiogenic shock and pulmonary edema, in children younger than 10 years of age. Pancreatitis is also an important cause of morbidity after scorpion envenomation.

Treatment

Antivenin is available in endemic areas and, along with supportive care, has been shown to reduce morbidity and mortality from severe scorpion envenomation[55,56]. However, application of ice is sufficient for most minor scorpion envenomations. Prazosin reverses the autonomic storm characteristic of Indian red scorpion (*Hottentotta tamulus*) envenomation, resulting in accelerated recovery and preserved myocardial function. Tacrolimus was also found to have protective effects against systemic toxicity from scorpion envenomation in an animal model[57].

SELECTED CLINICALLY IMPORTANT SCORPION SPECIES

Region	Species	Comments
Africa, Asia	*Parabuthus granulatus, P. transvaalicus, Androctonus australis, A. crassicauda, Leiurus* spp., *Hemiscorpius lepturus*	*Parabuthus* (Africa) and *Androctonus* (North Africa, Middle East) spp. have fat tails; highly toxic
North Africa, Europe	*Buthus* spp.	Less toxic
South Asia	*Hottentotta (Mesobuthus) tamulus*	Red color; toxic
Brazil	*Tityus serrulatus*	Yellow color; implicated as a cause of death in children
Southwestern US, especially Arizona	*Centruroides exilicauda*	Very rarely associated with deaths; public health risk has been overestimated
Central US, especially Texas	*Centruroides vittatus*	Painful sting
US, Mexico, Central America	*Centruroides sculpturontus, C. noxius*	More toxic; some deaths attributed to *C. exilicauda* may be due to these species

Table 85.8 Selected clinically important scorpion species.

CENTIPEDES (CLASS CHILOPODA) AND MILLIPEDES (CLASS DIPLOPODA)

Key features

Centipedes

- Long, worm-like bodies that are flattened dorsoventrally
- 17 or more segments; up to 20 cm in length
- Each segment, except the last one, has one pair of legs
- Pain, edema and erythema at bite sites

Millipedes

- Long, cylindrical, worm-like bodies with many segments
- Each segment has two pairs of legs and two pairs of respiratory spiracles
- Do not bite (biting jaws are absent), but can cause chemical irritant contact dermatitis

Introduction

Centipedes are fierce hunters. They inject a neurotoxic venom through ducts in their jaws. Millipedes do not bite but can cause burn-like reactions.

Clinical features

Centipede bites may produce pain, erythema, and edema. The bites can bleed profusely and are frequently associated with paresthesia. Centipede ingestion by children can result in systemic toxicity. Rarely, bites lead to severe systemic manifestations such as myocardial ischemia, rhabdomyolysis, proteinuria, and renal failure. The Vietnamese centipede, *Scolopendra subspinipes*, is a large, aggressive tropical centipede that has recently become popular as a pet, and local bite reactions can be severe.

Millipedes do not bite, but they can secrete noxious substances that result in chemical irritant contact dermatitis. Millipede burns frequently involve the eyes, and millipedes in line-dried clothing can produce widespread dermatitis. Of note, millipede burns and associated brownish skin discoloration (which can persist for months) may be misdiagnosed as child abuse.

Treatment

Centipede bites seldom require more than symptomatic treatment, although systemic symptoms may be very frightening to the patient. Children bitten by a centipede often report they have been bitten by a snake. The minor degree of edema compared to that associated with snake bites as well as the characteristic chevron shape of the centipede bite can be helpful distinguishing features. Ice packs, analgesics, and hot water immersion provide similar improvements in pain after centipede envenomation[58].

SNAKE BITES

Key features

- Rapid onset of pain and swelling
- Symptoms depend on the species and amount of venom injected
- Antivenin may be life-saving, but it does not prevent all complications and may cause anaphylaxis

Introduction

Snake bites occur primarily in individuals who engage in outdoor activities, especially camping and hiking. Occupational bite injuries may

also affect those who raise snakes and are particularly common in those who extract venom. Death from a snake bite is rare in the US but more common in Africa and Asia[59].

Clinical features

Snake bites are typically associated with marked edema within an hour of the envenomation. Hemorrhage and necrosis are common. The presence of paired bite marks is often noted.

Treatment

Antivenin therapy is an important part of management and may be of benefit even when administration is delayed. Adverse reactions to antivenin include serum sickness and anaphylaxis. Preparations to treat anaphylaxis should be made before initiating antivenin therapy. Hypersensitivity to antivenin is a particular problem for those who have been previously treated. The evaluation of antivenin reactions is complicated because serum sickness and snake bites share some signs and symptoms, and repeated snake bites can be independently associated with IgE-mediated anaphylaxis. Even in individuals who have never received previous treatment, snake antivenin can result in anaphylactoid reactions.

Thrombocytopenia induced by rattlesnake venom is only partially reversed by antivenin (Crotalidae) administration, and disseminated intravascular coagulation caused by North American crotalid snakebites can occur even after antivenin treatment. The risk of severe bleeding is higher in patients who take antiplatelet drugs[60].

Tourniquets to limit systemic toxicity from the venom may lead to tissue ischemia if improperly applied. Studies have not been performed for all snakes, but tourniquet application appears to be of little benefit.

DOG AND CAT BITES

Key features

- Bites may be unprovoked, especially with dogs
- Infection is common and pathogens include *Pasteurella* spp. and *Capnocytophaga canimorsus*
- Antibiotic treatment is generally considered mandatory

Introduction

Cat bites are commonly provoked, whereas dog bites are often unprovoked. Dog bites are particularly common in children, and the dog is usually a family pet or a neighbor's dog.

Rabies still occurs almost everywhere in the world, with exceptions including New Zealand, parts of Europe, parts of South America, and isolated Pacific islands. Rabies associated with dog bites remains a problem in low-income countries. Fortunately, because of vaccination programs, rabies related to dog bites is rare in high-income countries, where most human rabies is associated with bat exposure. In the US, rabies is carried primarily by bats, raccoons, and skunks. Although unvaccinated dogs occasionally acquire rabies from wild animals, the canine rabies virus variant that is responsible for dog-to-dog transmission has not been detected in the US since 2004. Oral rabies vaccination programs using bait to target gray foxes and coyotes in Texas and raccoons in the eastern US have helped to decrease the spread of rabies.

Local health authorities should be contacted to report a dog or cat bite and (if necessary) to arrange for quarantine. Latex agglutination testing of dog saliva for rabies antigen is 95% sensitive compared to fluorescent antibody testing on brain smears. A scalp biopsy from the hairy area on the nape of the neck can be sent for PCR or fluorescent antibody testing.

Clinical features

Common pathogens associated with bite wounds include streptococci, staphylococci, *Pasteurella* spp., *Capnocytophaga canimorsus*, and anaerobes. Breast implant infection and lung abscesses due to *Pasteurella multocida* have been linked to cat exposure, and staphylococcal endocarditis has been reported after a cat bite (without a preceding local infection); brain abscess formation has been observed following a dog bite. In immunocompromised patients, there is a significant risk of *Pasteurella* or *Capnocytophaga* sepsis. *Capnocytophaga canimorsus* sepsis has a high mortality rate and has been associated with purpura fulminans. Human bites have a higher likelihood of infections with *Staphylococcus aureus* and *Eikenella corrodens*. The most common pathogens associated with bite wound infections are listed in Table 85.9.

Treatment

A combination of a β-lactam antibiotic and a β-lactamase inhibitor (e.g. amoxicillin/clavulanic acid) provides good coverage for most organisms associated with dog and cat bites[61,62]. Alternatives include: (1) second-generation cephalosporins with anaerobic activity (e.g. cefoxitin, cefotetan); (2) penicillin plus a first-generation cephalosporin; or (3) clindamycin plus a fluoroquinolone. The need for hospitalization of patients with *Pasteurella*-infected animal bite wounds is strongly associated with initial use of suboptimal antibiotic therapy. A 3- to 5-day course of preemptive antimicrobial therapy is recommended for patients with immunocompromise, asplenia, advanced liver disease, or edema of the affected area (preexisting or resultant) as well as for injuries that are moderate to severe (especially of the hand or face) or penetrate the periosteum or joint capsule[63]. In addition to appropriate antibiotic therapy, early primary repair is typically indicated for dog bites to the face but is generally not recommended for other body sites[64].

LEECHES

Key features

- Found in fresh water
- Purpura and bleeding

Introduction

Leech attachments occur after contact with bodies of fresh water such as ponds or rivers.

PATHOGENS ASSOCIATED WITH HUMAN AND ANIMAL BITE WOUND INFECTIONS

Bite	Pathogens
Human bites	• *Staphylococcus aureus* • *Streptococcus pyogenes* • *Eikenella corrodens* • Various anaerobes†
Cat bites	• *Pasteurella multocida* (~75%)* • *Moraxella* spp. • *Neisseria weaveri* • *Bergeyella zoohelcum* • Various anaerobes†
Dog bites	• *Pasteurella* spp. (*canis* > *multocida*) (~50%)* • *S. aureus* (~20%) • *Str. pyogenes* • *N. weaveri* • *Capnocytophaga canimorsus* • *B. zoohelcum* • Various anaerobes†
Horse and sheep bites	• *Actinobacillus* spp. • *Pasteurella* spp. • Various anaerobes†
Marine animal bites	• *Vibrio* spp. • *Aeromonas hydrophila* • *Pseudomonas* spp. • *Plesiomonas shigelloides*

*Relatively short incubation period of 12–24 hours.
†May include *Fusobacterium*, *Bacteroides*, *Porphyromonas*, and *Prevotella* spp.

Table 85.9 Pathogens associated with human and animal bite wound infections. Most infections are polymicrobial and include aerobic and anaerobic bacteria (median of 4–5 isolates), which can originate from the skin of the patient as well as the oral flora of the biting animal or human.

Pathogenesis

Leeches prevent blood coagulation, partly through interference with platelet aggregation. Medical leeches have been associated with *Aeromonas hydrophila* wound infection[65].

Clinical features

Leech attachment sites often become purpuric and may bleed freely when the leech is removed. Leeches can attach to the tonsils (resulting in hemoptysis) or inside the nose (causing epistaxis). Disordered coagulation associated with massive bleeding and anemia has been reported after a leech bite.

Treatment

Leech removal is often complicated by bleeding or infection. Saturated salt solutions have been used to facilitate leech removal.

Leech therapy

Medical leeches and hyperbaric oxygen have been used together to enhance the survival of skin flaps subjected to venous occlusion. Sated leeches can be induced to continue feeding from the flap by posterior crop (stomach) incision and immersion in a serotonin solution.

MARINE INJURIES

Key features

- Marine organisms contain some of the most potent toxins known
- Drowning can occur after loss of consciousness following envenomation
- Penetrating injuries are prone to secondary infection
- Marine *Vibrio* infections are more common in patients with liver disease
- First aid for most marine venoms includes immersion in hot, but not scalding, water

Introduction

Penetrating marine injuries may be complicated by secondary bacterial infection. *S. aureus* is the most common organism, but *Vibrio* infections also occur. *Vibrio vulnificus* sepsis is strongly associated with liver disease, especially cirrhosis (see Ch. 74). Although most infections are related to ingestion of oysters or injuries in brackish water, the organism can survive on the skin for more than 24 hours, and infection has been reported after a penetrating injury on dry land. With warming of the oceans, there has been a northward extension of the geographic range of *Vibrio*. Seal finger, resulting from seal bites to the hand, is caused by *Mycoplasma* infection. Cutaneous infections with *Erysipelothrix rhusiopathiae* (see Ch. 74), *Aeromonas hydrophila*, and *Mycobacterium marinum* (see Ch. 75) can also be acquired from trauma in an aquatic environment.

Pathogenesis

Cnidarians (including jellyfish, corals, and sea anemones) are aquatic animals that produce specialized epidermal cells called cnidocytes with organelles referred to as nematocysts or stinging capsules. A physical (e.g. contact with a foreign body) or osmotic trigger causes a coiled, inverted, hollow filament within the nematocyst to be ejected externally and discharge its toxic contents.

Clinical features

Sea urchins are echinoderms with fragile spines that break easily in the skin. Pigment from the spine often diffuses into the wound, making it difficult to find and remove the spine. Only about 80 of the roughly 600 species of sea urchin described are known to be hazardous to humans. Long-spined urchins such as the black sea urchin (*Diadema setosum*) are often a problem, and spines embedded near joints have been associated with synovitis and arthritis. Sea cucumbers, another type of echinoderm, can eject an irritating visceral liquid.

Seabather's eruption (sea lice) is characterized by pruritic papules located under the bathing suit (Fig. 85.20) and in intertriginous areas. It may be caused by a variety of stinging larvae, including those of the thimble jellyfish (*Linuche unguiculata, L. aquila*), common in southern waters (e.g. the Florida coast and Caribbean). Seabather's eruption acquired off the coast of Long Island, New York, is typically caused by larvae of a sea anemone (*Edwardsiella lineata*). Swimmer's itch, in contrast, affects exposed skin after wading or swimming in bodies of fresh water; this condition is related to cercariae (free-swimming larvae) of avian schistosomes (see Ch. 83).

Jellyfish stings result in immediate pain as well as delayed and occasionally recurrent cutaneous reactions. Erythematous, urticarial, or hemorrhagic streaks may be observed (Fig. 85.21), and they tend to be longer and fewer in number following contact with larger jellyfish. A lichen planus-like eruption and inflammation distant from the site of envenomation have also been reported. *Chironex fleckeri*, the Pacific box jellyfish or sea wasp, is generally considered the most dangerous of the jellies, and stings often result in shock. Confirmation of envenomation can be obtained by tape stripping of nematocysts from skin. *Physalia physalis*, the Portuguese man of war, is found in southern waters of the Atlantic while *Physalia utriculus*, the blue bottle jellyfish, is seen in the Pacific. These *Physalia* spp. contain nematocysts but are actually siphonophores, not true jellyfish. *Cyanea* and *Chrysaora* sea nettles are common causes of jellyfish dermatitis. Storms frequently drive jellies into shallow water in great numbers.

Haloclava producta, the "ghost anemone", is a burrowing sea anemone found off the east coast of the US and in the Gulf of Mexico.

Fig. 85.21 Jellyfish sting. Painful red papules and papulovesicles in multiple linear streaks. *Courtesy Joyce Rico, MD.*

It is responsible for summer outbreaks of dermatitis off the coast of Long Island, New York. Corals are another group of stinging cnidarians in the same class (Anthozoa) as sea anemones. Coral cuts can be slow to heal and should be washed vigorously. Fire corals are false corals that produce intense stinging and a papular eruption that can last for several days. Cnidarian nematocysts found in seaweed and in the dorsal papillae of nudibranch sea slugs can also cause dermatitis. Exposure to algae alone can lead to dermatitis as well, referred to as seaweed dermatitis (see Ch. 17).

Red sponges and fire sponges (members of the phylum Porifera) both cause dermatitis. Sponge dermatitis is related to spicules embedded in the skin, but sponge diver's disease is caused by the stings of sea anemones attached to the base of sponges. Local itching and burning progress to erythema and vesiculation. Systemic symptoms such as nausea, vomiting, and headache are common.

Two classes of the phylum Mollusca, cephalopods and gastropods, have been linked to human envenomation. The blue-ringed octopus contains a potent venom. This small cephalopod is often only 10 cm long and is found in waters off the coast of Australia. Envenomation from cone shells (marine gastropods) may be associated with a 20% mortality rate. The shells are about 10 cm in length and tend to be found in shallow water, mainly in tropical and subtropical climates.

Encounters with stingrays can result in soft tissue injury and embedded spines. Death has been reported after a penetrating chest injury from a stingray barb resulting in venom-induced myocardial necrosis. Injuries inflicted by stingrays occur in both fresh and salt water, and pain is the major manifestation.

Lionfish are common in subtropical and tropical waters. Since August 2000, lionfish have been reported along the eastern coast of the US, from Florida to New York. Lionfish belong to the family of scorpionfish (Scorpaenidae). The family includes the genera *Pterois* (lionfish), *Scorpaena* ("true scorpionfish", bullrout and sculpin), and *Synanceia* (stonefish). Stonefish are the most toxic members of the family, although all produce local pain as well as systemic symptoms. Catfish spine injuries occur in both salt and fresh water. They may be associated with local pain, bleeding, and systemic symptoms.

Pathology

Marine *Vibrio* infections cause intense cellulitis affecting the subcutis and dermis. The superficial dermis is devitalized and lacks an inflammatory infiltrate. Bullae are subepidermal in location and non-inflammatory. Many organisms are present, especially around vessels.

Sea urchin spines examined by polarized light microscopy exhibit an ornate symmetric structure produced by calcite crystals. Cutaneous granulomatous reactions may occur.

Histologic sections from sites of jellyfish stings may demonstrate nematocysts penetrating the epidermis and papillary dermis.

Treatment

Avoidance is the best means of preventing injury, which can result from specimens in salt water fish tanks as well as in the ocean. When envenomation occurs in a swimmer, the individual should immediately be removed from the water to prevent drowning. Initial treatment for all marine envenomations includes soaking the site in hot, but not scalding, water to denature some of the venom proteins[66].

Antivenin is available for some of the more toxic species such as *C. fleckeri*, and it was shown to neutralize cardiovascular effects of *C. fleckeri* envenomation in an animal model. In contrast, verapamil did not improve cardiovascular status and increased mortality in the same animal model. In an animal model of envenomation by the *Chiropsalmus* species of box jellyfish, pretreatment with *C. fleckeri* antivenin or $MgSO_4$ did not have any effect on the venom-induced hypertensive response or subsequent cardiovascular collapse. This highlights the importance of species identification following box jellyfish envenomation.

In a study of acute *Carybdea alata* box jellyfish stings, hot water immersion (40–41°C) was more effective than papain meat tenderizer or vinegar. Topical jellyfish sting inhibitors, including lotions in which they are combined with sunscreens, are available. Sea water can be used to remove jellyfish tentacles. Inactivation with acidic or alkaline solutions can be risky, as it may also lead to unexpected discharge of nematocysts. Treatment with topical corticosteroids and calcineurin inhibitors may be helpful for delayed reactions.

Most fish envenomations should be treated with hot water immersion. In a study of fresh water ray envenomation, hot water immersion controlled acute pain, but it did not prevent skin necrosis.

Additional figures and a table on Approach to the Evaluation and Management of Bedbug Infestations, available in our eBook (see inside front cover for access code).

APPROACH TO THE EVALUATION AND MANAGEMENT OF BEDBUG INFESTATIONS
Diagnosis
• Evaluation begins with assessment for clinical symptoms and environmental findings suggestive of insect bites, which can result in a wide range of skin manifestations depending on the degree of sensitization. Some individuals have little or no reaction, and it is common for only one or a few family members (even those sleeping in the same bed) to report lesions. • Bites usually occur at night on exposed areas of skin, most often the face, neck, arms, and legs. Although patients classically awake with new lesions, the reaction can take several days to appear. • Patients typically present with pruritic, erythematous, edematous papules, sometimes with a visible central hemorrhagic punctum. • The size, degree of itching, and propensity toward vesiculation all increase with repeated exposure. • Patient may observe a linear series often consisting of three bites (“breakfast, lunch, and dinner”). • The psychological consequences of bedbug bites should be considered, including sleep deprivation and phobias.
Management of Infestations
• Patients should carefully scrutinize the bedroom for signs of bedbug infestation. One may encounter fecal smears or flecks of blood on bed linens, inside furniture cracks and crevices, and behind peeling wallpaper. Bedbugs may travel as far as 20 feet for a meal. Densely infested rooms may also have a distinctive, pungent, soda syrup–like odor. • Vacuuming is effective in removing bedbugs but does not remove the eggs. Wash bedsheets and clothing in hot water with detergent with at least 20 minutes in a dryer. Bedbugs have a high thermal death point of 45° C (113° F) and also may survive at temperatures as low as 7° C (44.6° F). Some companies perform a treatment in which the room is heated above 50° C (122° F), which is a lethal temperature for all stages of a bedbug’s life cycle. Coating bedposts with antifriction or adhesive substances such as petrolatum or duct tape may hinder bedbugs from gaining access to the bed. • A combination of chemical and physical intervention is often necessary for complete eradication. All hiding areas must be carefully inspected and cleaned. Treatment may include pesticides, laundering, heat, freezing, vacuuming, and hiring a professional service to eradicate bedbugs. • A pest control professional should be consulted for safe eradication.

86 Ultraviolet Radiation

Peter Wolf and Thomas M. Rünger

Key features

- Exposure of the skin to UV light has acute, short-term effects and chronic, long-term effects, both of which are wavelength-dependent and occur even at non-erythemogenic doses
- UV light is sensed via absorption by chromophores; these include urocanic acid, nucleotide bases, membrane lipids, tryptophan, and 7-dehydrocholesterol (provitamin D_3)
- UV light induces several types of DNA damage in a wavelength-dependent manner, including 6-4 photoproducts, pyrimidine dimers, and oxidative guanine base modifications; pyrimidine dimers are the most important pre-mutagenic DNA lesions
- UV light-induced mutations play a pivotal role in photocarcinogenesis; some base substitution mutations (e.g. C→T, CC→TT) are so typical for UV light that they have been termed signature or fingerprint mutations
- UV light triggers both pro- and anti-inflammatory responses, primarily via innate immunity and adaptive immunity, respectively
- UV-induced immunosuppression contributes to skin carcinogenesis by induction of regulatory T cells and immunosuppressive cytokines such as IL-10
- The proapoptotic, immunomodulatory, antipruritic, antifibrotic, and propigmentary properties of UV light are employed to treat various inflammatory and neoplastic skin disorders

INTRODUCTION

Dermatologists are confronted daily with the effects of UV light on the skin and often deal with them in a seemingly contradictory way. On the one hand, they have the responsibility of warning their patients against the deleterious effects of sunlight, such as sunburn, photoaging, and sun-induced skin cancers, and on the other hand, they use UV irradiation to treat skin disease[1]. As with all medical interventions, dermatologists are weighing the risks versus the benefits when they use UV light for therapeutic purposes.

SPECTRUM OF UV LIGHT AND ABSORPTION SPECTRA

The sun emits UV radiation as part of an electromagnetic spectrum (see Fig. 134.1). It is usually subdivided, rather arbitrarily, into UVC (200–290 nm), UVB (290–315 nm), and UVA (315–400 nm). UVA has been further subdivided into UVA1 (340–400 nm) and UVA2 (315–340 nm). Of note, some authors use 320 nm as the demarcation between UVA and UVB. More than 95% of the sun's UV radiation that reaches the Earth's surface is UVA. Practically all UVC, and much of the UVB, are absorbed by the oxygen and ozone in the Earth's atmosphere so that UV radiation below 290 nm is virtually undetectable at ground level. However, the remaining UV radiation can still be absorbed by biologic molecules (DNA, protein, lipids) and can damage cells.

In order to survive in our environment, all living organisms have had to develop protective mechanisms to prevent UV-induced lethality and to maintain the stability of their genome. These protective mechanisms include the development of UV-absorbing and -reflecting surface layers, enzymatic and non-enzymatic anti-oxidative defenses, repair processes, and removal of damaged cells. Via evolution, humans have lost most of their UV-protective fur, which remains an effective UV-protector only on the scalp. Nonetheless, the human skin is quite effective in protecting the rest of the organism from the harmful effects of solar UV irradiation, since UV radiation does not penetrate any deeper than the skin.

Within the skin, the penetration depth of UV light is wavelength-dependent[2,3] – i.e. the longer the wavelength, the deeper the penetration (Fig. 86.1). While UVA readily reaches the dermis, including its deeper portions, most of the UVB is absorbed in the epidermis such that only a small proportion reaches the upper dermis. UVC is absorbed or reflected predominantly by the stratum corneum and the upper layers of the epidermis. However, when considering the biologic effects of different wavelengths in the different layers of the skin, it is necessary to keep in mind that a particular wavelength can even have a biologic effect in a layer that it does not reach. One mechanism is secretion of proinflammatory mediators in the epidermis that can produce subsequent effects in the dermis[4] and subcutaneous fat[5]. For example, keratinocyte-produced soluble IL-6 appears to gain access to the circulation and may function, via its pyrogenic as well as acute phase-inducing effects, as an important mediator of a systemic sunburn reaction with symptoms including malaise, somnolence, fever, and chills[5a].

Some of the UV light reaching the skin is absorbed by biomolecules, with light-absorbing molecules referred to as chromophores. Upon absorption of the radiation's energy, the chromophore is elevated to an excited state. The resulting photochemical reactions can either directly alter the chromophore or indirectly alter a molecule other than the chromophore by energy transfer in a so-called photosensitized reaction. Absorption is wavelength-dependent and if a photon is not absorbed due to its wavelength, a photochemical reaction cannot occur. For UVB, the most important chromophore is DNA, while a typical UVA- and visible light-absorbing chromophore is porphyrin. Other important chromophores/their mediators include *trans*-urocanic acid/*cis*-UCA, membrane lipids/platelet-activating factor, tryptophan/aryl hydrocarbon receptor ligands, and

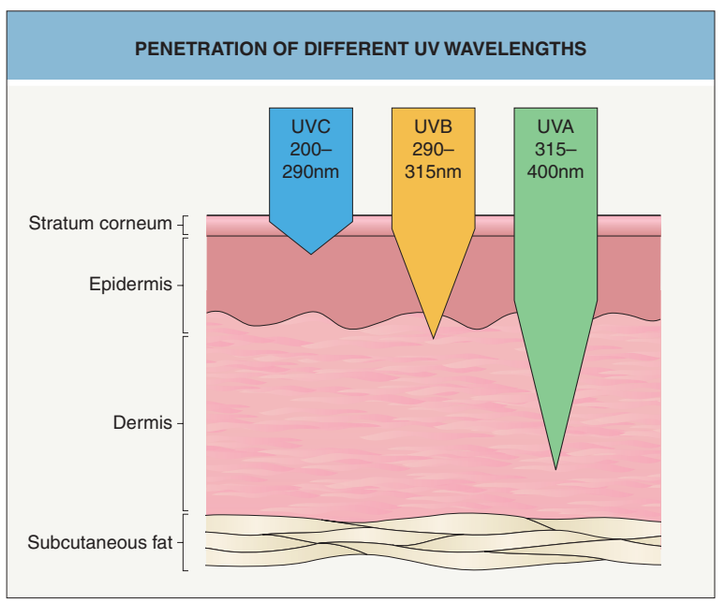

Fig. 86.1 Depth of penetration of different wavelengths of UV light into human skin. Depth of penetration varies greatly with the thickness of the different skin layers and their composition (e.g. melanin content). The beginning of the wedge-shaped portion of the penetration symbol represents a decrease to approximately one-third of the incident energy density, and the tip of the symbol represents a decrease to approximately 1%. Of note, some authors use 320 nm as the demarcation between UVA and UVB. Figure not drawn to scale.

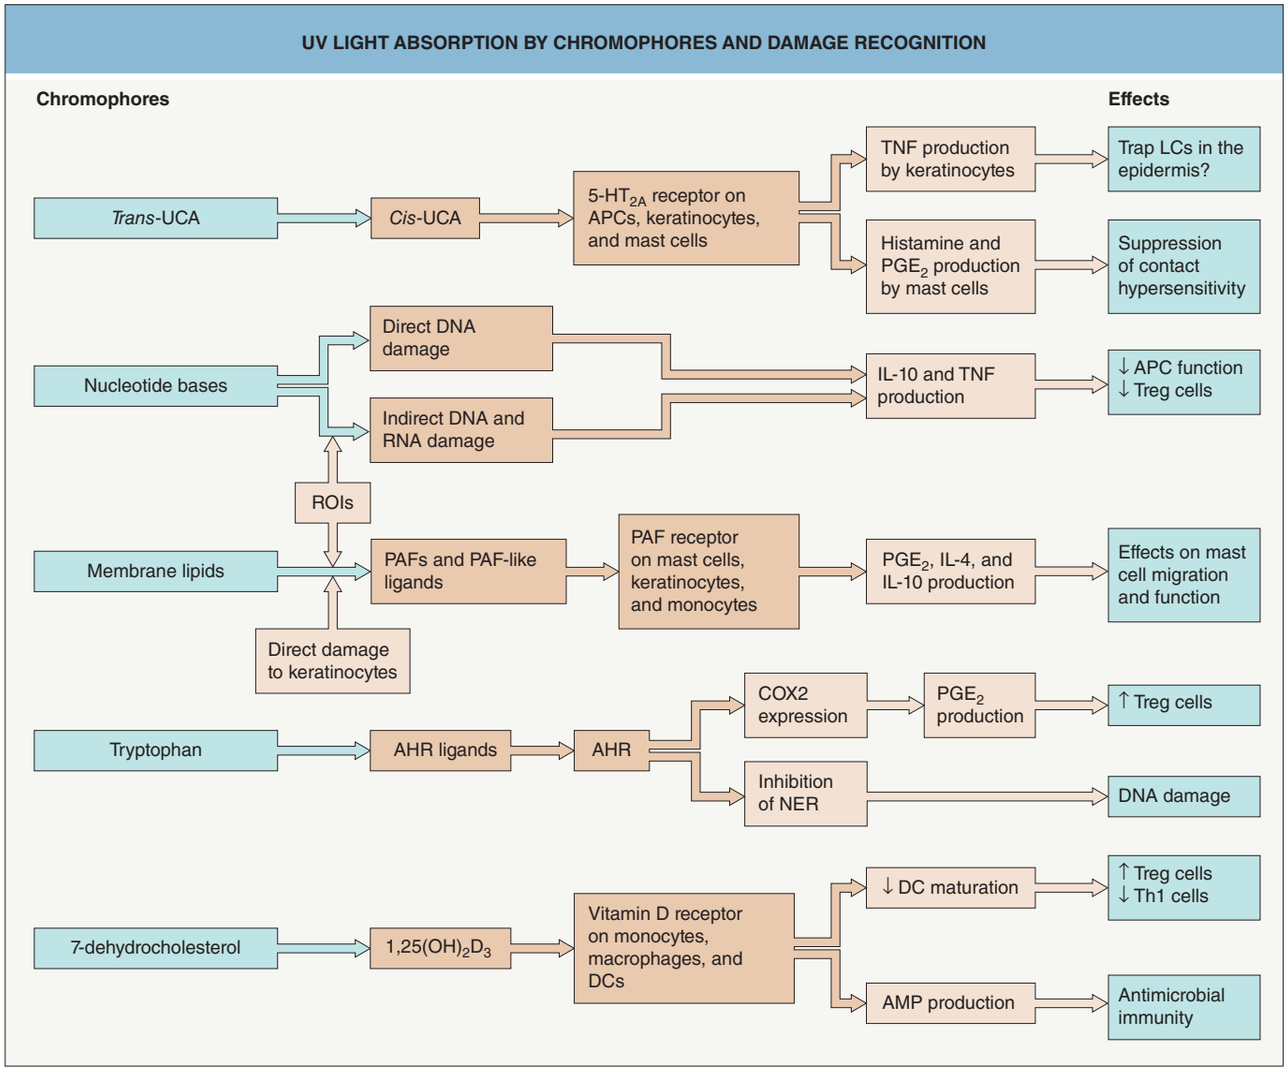

Fig. 86.2 UV light absorption by chromophores and damage recognition. *Cis*-urocanic acid (*cis*-UCA), an imidazole derivative produced by the isomerization of *trans*-UCA following absorption of UV light, initiates many of the immunomodulatory effects of UV by binding to the serotonin receptor (5-HT_{2A}) on antigen-presenting cells (APCs), keratinocytes, and mast cells. *Cis*-UCA stimulates the release of tumor necrosis factor (TNF) from keratinocytes, which might trap Langerhans cells (LCs) in the epidermis and prevent the presentation of antigen to T cells in the draining lymph node. *Cis*-UCA also stimulates histamine and prostaglandin E_2 (PGE_2) production by mast cells. UV causes direct damage to DNA, which induces the release of IL-10 and TNF and also impairs the function of APCs, resulting in impaired induction of regulatory T (Treg) cells. In addition to direct UV-induced DNA damage, the generation of reactive oxygen intermediates (ROIs) by UV causes indirect damage to both DNA and RNA. The oxidation of phosphatidylcholine by ROIs results in the production of platelet-activating factor (PAF)-like molecules at the cell membrane. PAF (produced by direct damage to keratinocytes) and PAF-like ligands induce immunosuppression by binding to the PAF receptor on mast cells, keratinocytes, and monocytes and stimulating the release of PGE_2, IL-4, and IL-10. The absorption of UVB by cytosolic tryptophan results in the formation of high-affinity aryl hydrocarbon receptor (AHR) ligands. AHR signaling results in increased expression of cyclooxygenase 2 (COX2), which can contribute to UV-induced immunosuppression through PGE_2 production and the induction of Treg cells. Also, AHR signaling inhibits nucleotide excision repair (NER) by inducing the proteasomal degradation of the $p27^{KIP1}$ tumor suppressor protein. 7-Dehydrocholesterol absorbs UV and converts to pre-vitamin D_3, which then isomerases to the active metabolite 1,25-dihydroxyvitamin D_3 (1,25$(OH)_2D_3$). 1,25$(OH)_2D_3$ modulates immunity by directly stimulating antimicrobial peptide (AMP) production and by inhibiting dendritic cell (DC) maturation. 1,25$(OH)_2D_3$-modulated DCs have suboptimal APC function, thereby inducing the expansion of Treg cell populations and suppressing T helper 1 (Th1) cell responses.

7-dehydrocholesterol/1,25$(OH)_2D_3$. Activation of various receptors and pathways following absorption of UV light by chromophores results in numerous downstream effects (Fig. 86.2).

Knowledge of absorption spectra of molecules is critical for understanding the photobiologic consequences of UV absorption, including photomutagenesis of DNA by UVB, the efficacy of UV filters in sunscreens, and the elicitation of photodermatoses by specific wavelengths of UV light. An absorption spectrum defines the probability that a molecule will be excited by a particular wavelength. While the absorption maximum indicates the wavelength at which absorption is most likely, other wavelengths can still be absorbed. For example, the absorption maximum of DNA is 260 nm, which is within the UVC range. However, UVB still effectively excites DNA, and even UVA and visible light can do so. This explains why DNA photoproducts, a type of DNA damage induced by a photochemical reaction following direct excitation of the DNA molecule, are not only induced by UVB, but also by UVA or visible light, albeit at a much lower efficacy.

Both short- and long-term effects of exposure to UV light are wavelength-dependent. However, when comparing the photobiologic properties of UVB with those of UVA, it should be noted that the division between UVA and UVB is somewhat arbitrary and there is a continuum of wavelengths whose properties change gradually.

SHORT-TERM EFFECTS OF ULTRAVIOLET LIGHT: SUNBURN AND TANNING

Visible, short-term, cutaneous effects of UV irradiation include sunburn (solar erythema and possibly blister formation, followed by desquamation) and tanning. Microscopically, short-term effects include epidermal edema with spongiosis, acanthosis, hyperkeratosis, formation of sunburn cells (apoptotic keratinocytes), depletion of Langerhans cells, an increase in epidermal melanin, vasodilation, and an inflammatory infiltrate of lymphocytes and neutrophils. On a cellular and molecular

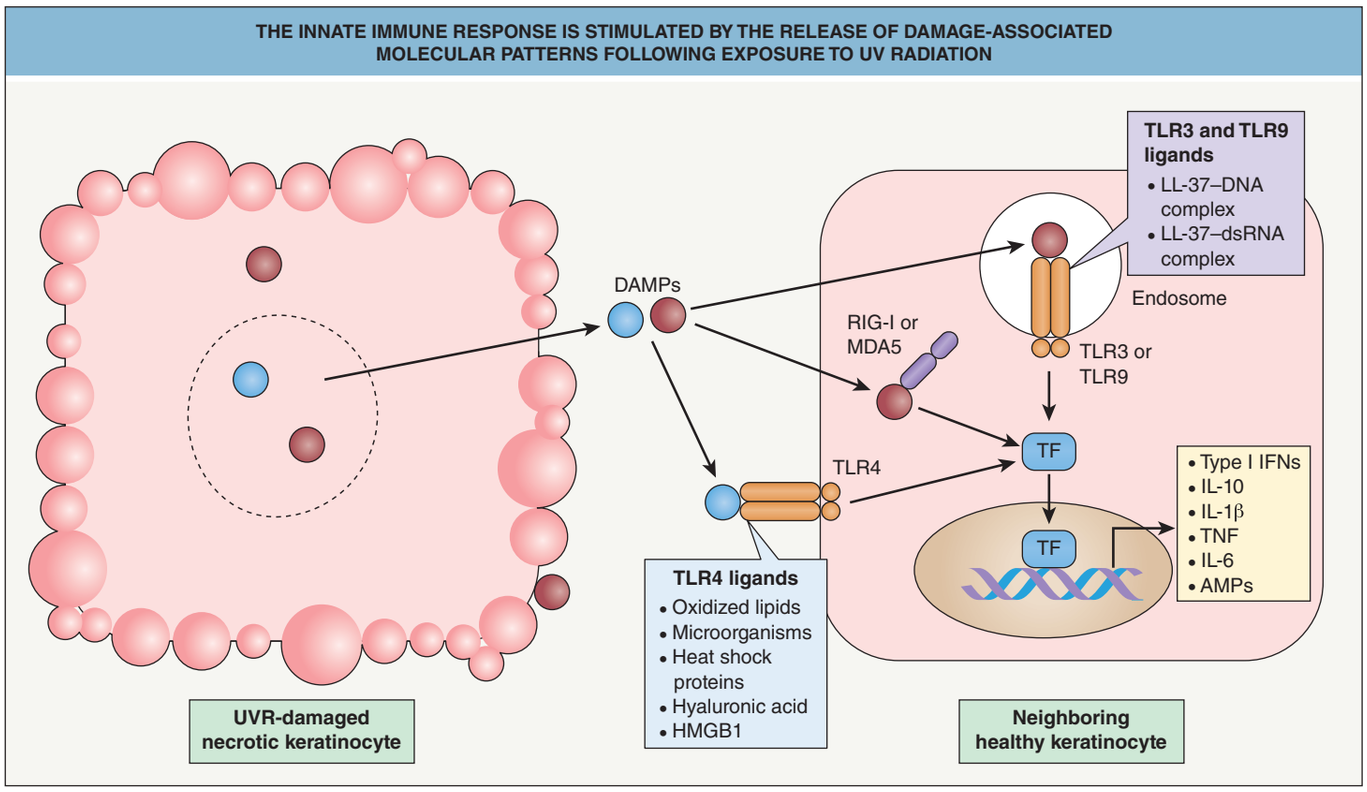

Fig. 86.3 The innate immune response is stimulated by the release of damage-associated molecular patterns following exposure to UV radiation (UVR). UVR induces the formation and release of damage-associated molecular patterns (DAMPs) from necrotic keratinocytes that activate Toll-like receptor (TLR) signaling. UVR can induce the formation and/or release of DAMPs that are recognized by the innate immune system as non-self, such as LL-37–DNA complex, LL-37–double-stranded RNA (dsRNA) complex, oxidized lipids, microorganisms, heat shock proteins, hyaluronic acid, and high-mobility group box 1 protein (HMGB1). TLR signaling in neighboring healthy keratinocytes leads to a type I interferon (IFN) response and the release of tumor necrosis factor (TNF), IL-10, IL-1β, IL-6, and antimicrobial peptides (AMPs). Cell responses to DNA and dsRNA are also mediated by the cytosolic receptors retinoic acid-inducible gene I (RIG-I) and melanoma differentiation-associated protein 5 (MDA5), which trigger the release of the above-mentioned cytokines and AMPs. TF, transcription factor. *Reproduced with permission from Bernard JJ, Gallo RL, Krutmann J. Photoimmunology: how ultraviolet radiation affects the immune system. Nat Rev Immunol 2019;19:688–701.*

level, UV exposure induces a multitude of damage responses, including the induction of stress proteins and repair processes as well as production of cytokines (e.g. IL-1, -6, -10, TNF) and antimicrobial peptides (AMPs; Fig. 86.3). In a dose-dependent manner, exposed cells can either undergo apoptosis (visible histologically as sunburn cells) or cease proliferating (cell cycle arrest) to allow time for repair. However, this initial growth arrest may be followed by hyperproliferation, visible histologically as epidermal thickening. The inflammatory response in the sunburn reaction is likely due to activation of innate immunity. Lastly, UVB-induced activation of transient receptor potential ion channels in keratinocytes with subsequent calcium influx has been shown to mediate sunburn pain[6].

The ability to induce sunburn rapidly declines with increasing wavelength. For example, UV light with a wavelength of 360 nm is ~1000-fold less erythemogenic than UV light with a wavelength of 300 nm. UVB-induced sunburn reaches its peak between 6 and 24 hours after exposure; an immediate erythema reaction is rarely observed. In contrast, after exposure to a high dose of UVA, an immediate erythema reaction can occur, followed by a distinct delayed erythema after 6 to 24 hours. However, the doses of UVA present in natural sunlight are not sufficient to cause sunburn unless patients have increased UV sensitivity (see Ch. 134).

The tanning response of human skin to sun exposure is biphasic and wavelength-dependent. *Immediate* pigment darkening occurs primarily with UVA and develops during and immediately after exposure. It is due to alteration (e.g. oxidation) and redistribution of existing melanin. *Delayed* tanning is primarily due to UVB and peaks ~3 days after sun exposure. Fair skin (phototype II) usually tans only with UVB doses greater than the erythema threshold, i.e. only after a sunburn. Darker skin (phototypes III and higher) tans following suberythemogenic doses, i.e. without a sunburn. A UVB-induced tan is characterized by an increased number of melanocytes, increased melanin synthesis, increased arborization of melanocytes, and increased transfer of melanosomes to keratinocytes (see Ch. 65). A UVA-induced tan, such as from the use of a tanning bed (Fig. 86.4), provides 5–10 times

Fig. 86.4 Sequelae of exposure to UV light. A UVA-induced tan with reduced pigmentation within an area of relative ischemia (due to pressure while lying on a tanning bed); this leads to reduced UVA-induced, oxygen-dependent melanin oxidation within this area. Excessive sun exposure plus long-term use of tanning beds has led to a leather-like appearance to the skin. **B** Sharp demarcation on the thigh of solar lentigines and the dyspigmentation of photodamaged skin. The patient consistently wore Spandex shorts. *Courtesy Jean L. Bolognia, MD.*

less protection against sunburn from subsequent UV exposure than a UVB-induced tan, probably because a UVA-induced tan is characterized by less pronounced epidermal thickening and hyperkeratosis.

An individual's tendency to develop sunburn and tanning after sun exposure has been used to categorize skin phototypes (see Table 134.4).

These categories of an individual's susceptibility to short-term effects also correlate with the individual's susceptibility to long-term effects following sunlight exposure. In general, individuals with higher acute sun sensitivity also have a higher risk of developing skin cancer after chronic UV exposure.

EFFECTS ON THE CUTANEOUS IMMUNE SYSTEM

While sunburn represents a proinflammatory state, UV light also has anti-inflammatory properties as demonstrated by the efficacy of UV phototherapy in the treatment of inflammatory skin disorders. Currently, the *immunostimulatory* effects of UV light are thought to be primarily due to activation of innate immunity (see Fig. 86.3), whereas its *immunosuppressive* effects are mainly due to inhibition of adaptive, antigen-specific immunity (Fig. 86.5)[7]. However, a simple dichotomy is unlikely, as there are multiple factors that influence these immune effects, including dose- and wavelength-dependent differences that go beyond variations in skin phototype. An example of individual factors is the observation that the majority of patients with psoriasis improve with UV phototherapy, but a small minority flares. Another example is polymorphic light eruption in which inhibition of contact hypersensitivity by UV light is *reduced*, presumably predisposing patients to reactions to photo-induced allergens or toxins[8]. In individuals with both psoriasis and polymorphic light eruption, exposure to UV light often leads to psoriatic Koebner phenomena that involve induction of AMPs such as LL-37[9]. The ability of UVB to promote both double-stranded RNA and LL-37 may also be responsible for increased photosensitivity in patients with rosacea[10].

UV light-induced effects on the immune system involve not only the cutaneous sites directly exposed to UV light, but also non-irradiated areas. An example of systemic immunosuppression is the development in non-exposed skin of antigen-specific immune tolerance to antigens that were initially applied to UV-exposed skin. This effect is known to be mediated by the release of immunosuppressive cytokines such as interleukin (IL)-10 and then ultimately by UV-induced regulatory T cells.

The downside of photo-induced immunosuppression and immune tolerance is that they inhibit the recognition of tumor antigens and thereby contribute to photocarcinogenesis. The upside is the prevention of autoimmune reactions, e.g. diseases such as lupus erythematosus (LE) would likely be more prevalent without effective suppression of immune reactions against self-antigens unmasked by UV-induced cell damage. Another example of this equilibrium is polymorphic light eruption, in which less efficient UV-induced immunosuppression is balanced by a lower risk of UV-induced skin cancer[11].

Cellular photoreceptors that mediate signaling which leads to UV-induced immune responses include: DNA (via formation of DNA damage), urocanic acid in the stratum corneum (via UV-induced isomerization from the *trans*- to the *cis*-isoform)[12], membrane lipids (via UV-induced alteration of the membrane redox potential), and activation of the NLRP1 inflammasome (see Fig. 4.2). The latter acts as a sensor within keratinocytes whose activation was found to be a consequence of a UVB-induced ribotoxic stress response[12a]. While the immunosuppressive effects of UVB are well established, the relative contribution of UVA is still controversial[13].

While both acute and chronic UV exposure can lead to a selective loss of fibroblasts within the papillary dermis, repair consisting of local fibroblast proliferation can follow acute UV irradiation (UVR) whereas a permanent reduction in fibroblast number follows chronic UVR. Recruited T cells and neutrophils were found to promote fibroblast survival[13a].

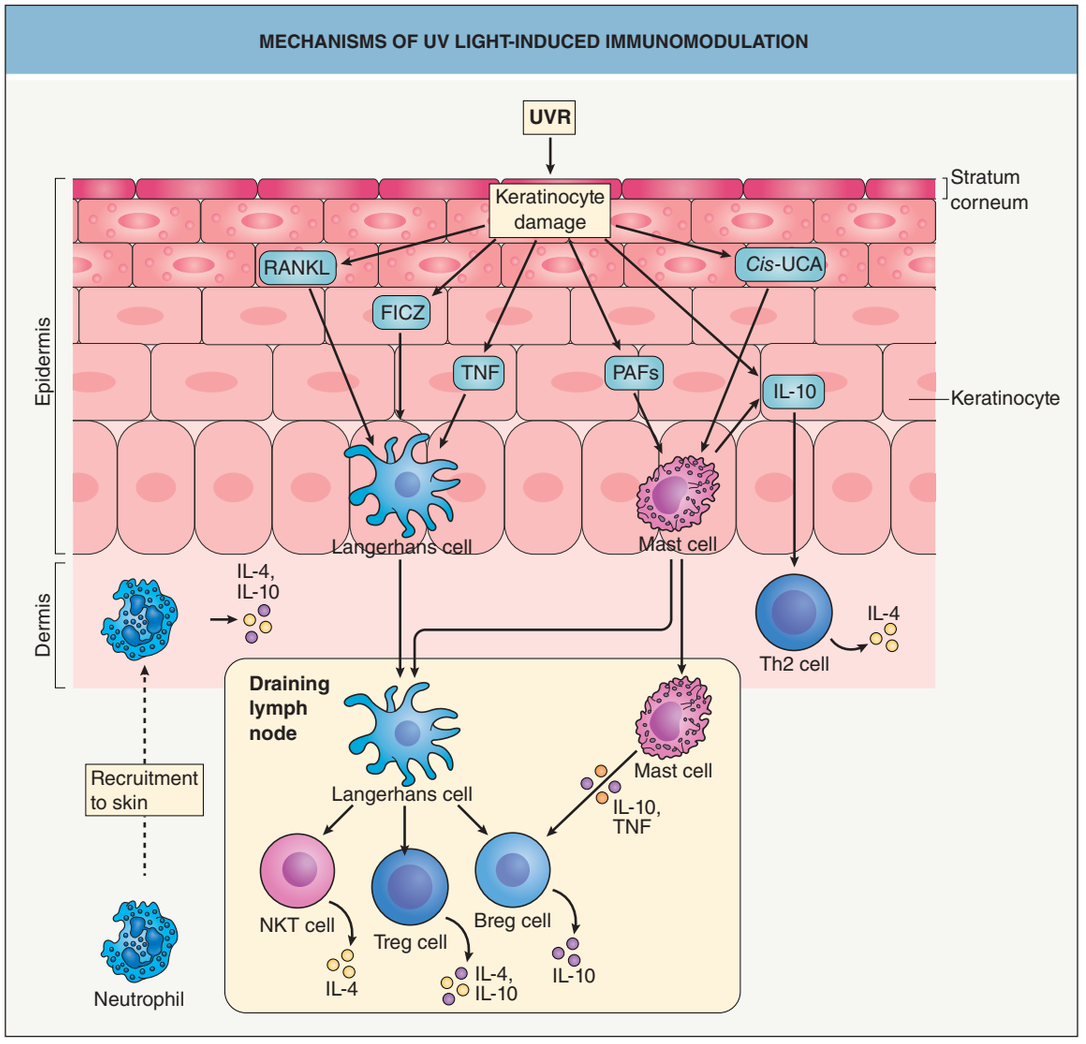

Fig. 86.5 Mechanisms of UV light-induced immunomodulation. As a direct result of ultraviolet light (UV)-induced epidermal damage, keratinocytes produce and release immunomodulators, including, but not limited to, *cis*-urocanic acid (*cis*-UCA), platelet-activating factors (PAFs) and PAF-like ligands, IL-10, 6-formylindolo[3,2-*b*] carbazole (FICZ), epidermal-derived receptor activator of nuclear factor-κB ligand (RANKL), and tumor necrosis factor (TNF). TNF, FICZ, and RANKL stimulate Langerhans cells; PAFs and *cis*-UCA stimulate mast cells. From these reactions, multiple signaling pathways and cells are activated and more soluble mediators are produced. For example, IL-10 released from UV-exposed keratinocytes and mast cells promotes a T helper 2 (Th2) cell response. PAFs stimulate the migration of mast cells to the draining lymph node, where they produce IL-10 and TNF and promote the formation of IL-10-producing regulatory B (Breg) cells. Collectively, the signaling pathways induced by UV exposure lead to an immunosuppressive environment, with high levels of TNF, IL-4, and IL-10 being associated with Langerhans cell migration to the lymph node and neutrophil recruitment to the skin. This leads to the induction of IL-4-producing natural killer T (NKT) cells, as well as regulatory T (Treg) cells and Breg cells, which promote cell-mediated and humoral immunosuppression. *Reproduced with permission from Bernard JJ, Gallo RL, Krutmann J. Photoimmunology: how ultraviolet radiation affects the immune system. Nat Rev Immunol 2019;19:688–701.*

LONG-TERM EFFECTS OF ULTRAVIOLET LIGHT: PHOTOAGING AND PHOTOCARCINOGENESIS

The long-term effects of chronic sun exposure include photoaging and photocarcinogenesis. In photocarcinogenesis, UV exposure provides a one-two punch: (1) it generates DNA damage, leading to mutations and malignant transformation; and (2) it has immunosuppressive properties. The latter include the induction of specific tolerance to antigens from UV-induced skin tumors which reduces the ability of the host immune-defense system to recognize and remove malignant cells. UV irradiation also impairs immune surveillance against cells infected with viruses (e.g. certain HPV types) and thereby promotes skin cancer formation.

The advantage of reduced immune reactivity following exposure to UV light is the prevention of illicit (auto)-immune reactions to transiently UV-altered cells (see above). Any shift in the balance between pro- and anti-inflammatory responses toward a more immunosuppressed state increases the risk of UV-induced tumor formation, as occurs in chronically immunosuppressed patients. Shifting this balance toward proinflammatory responses and autoimmunity increases the risk of developing photodermatoses or photoaggravated skin diseases such as LE. The critical nature of this equilibrium is also illustrated by the observation that effective photoprotection often leads to spontaneous resolution of actinic keratoses, even though these precursor lesions have identifiable genetic changes that provide growth advantage over non-mutated cells (see Ch. 107).

Photoaging

Photoaging encompasses the clinical, histologic, and physiologic changes present in chronically sun-exposed skin. This extrinsic skin aging is classically distinguished from intrinsic aging, which refers to age-dependent changes in sun-protected skin. Photoaging affects all components of the skin, including the epithelium, the pigmentary system, the vasculature, the dermal connective tissue, and possibly even the subcutaneous fat[14].

Due to its ability to penetrate deeper into the dermis, UVA is thought to play an important role in inducing the dermal changes of photoaging. Since UVA, but not UVB, penetrates through window glass, the patient in Fig. 86.6 illustrates the ability of UVA to induce photoaging[15]. However, wavelengths of UV light that do not reach the dermis, particularly UVB, could still contribute to photoaging of the dermis via signals originating from the epidermis[4]. In addition to differences in their depths of penetration, UVA and UVB also produce different cellular effects that likely influence their effects on photoaging.

In contrast to photocarcinogenesis, in which the immunosuppressive effects of UV light play a pivotal role, photoaging is thought to be the result of chronic and repetitive inflammatory responses to UV light. This results in upregulation of extracellular matrix-degrading proteases and downregulation of collagen synthesis, resulting over time in loss of collagen and deposition of abnormal degenerative elastotic material within the dermis (actinic elastosis). However, if photoaging were merely due to UV-induced inflammation, wrinkling and other features should be reversible with complete photoprotection, but of course this is not the case[16].

UV-Induced Tumor Formation

Exposure to UV light is a major risk factor for developing skin cancer[17]. UV-induced cutaneous carcinomas may evolve via the photocarcinogenesis cascade outlined in Fig. 86.7. Carcinogenesis often entails the stepwise accumulation of genomic aberrations in a single cell, with subsequent clonal expansion. Usually, it takes decades until a tumor arises and in one study, over 25% of epidermal cells in aged chronically sun-exposed skin were found to contain cancer-causing mutations[18]. However, cancer can also arise from a single catastrophic cellular event, termed chromothripsis, in which there are hundreds of clustered mutations and chromosomal rearrangements (see Ch. 107). Chromothripsis provides a mechanism for the rapid accumulation of numerous genomic aberrations within a few cell divisions, thus challenging the conventional tumor progression model consisting of the gradual acquisition of somatic mutations over time[19,20].

While the carcinogenic properties of short-wavelength UV light, in particular UVB, are well established, UVA was originally thought to be harmless due to its relative inability to induce sunburn. More recently, however, it was shown that UVA can induce cutaneous SCC in mice and is now recognized as an independent class I carcinogen[17]. Natural sunlight contains much more UVA than UVB (depending on the time of day and weather: 20- to 100-fold more), which offsets the weaker effects of UVA. Because UVA is less filtered by window glass and clothing and it penetrates more effectively to the basal layer of the epidermis, these properties may further increase the relative contribution of UVA to the carcinogenic properties of sunlight.

Although less is known about the action spectrum for the induction of melanoma, it is known that the burden of UV-signature mutations varies from low in acral and mucosal melanomas to high in lentigo maligna melanoma[21]. There are several lines of evidence for a role for

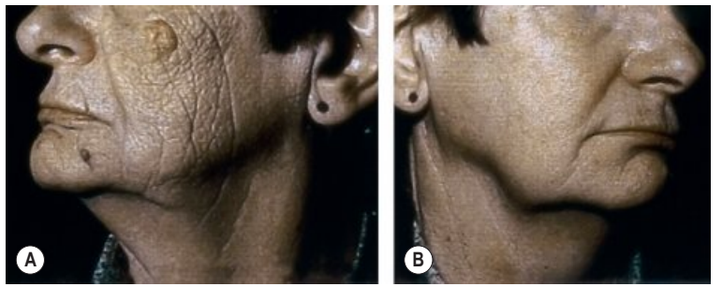

Fig. 86.6 Unilateral photoaging following 15 years of unilateral sun exposure through window glass. A Exposed side of face. **B** Nonexposed side of face. This individual had been working in the same office for 15 years, close to a window, with the left cheek always facing the window. Biopsy confirmed the diagnosis of nodular cutaneous elastosis with cysts and comedones (Favre–Racouchot disease). Since UVB does not penetrate window glass, this observation identifies UVA as an effective promoter of photoaging. *Reproduced with permission from Moulin G, Thomas L, Vigneau M, Fiere A. Fig. 86.7 Photocarcinogenesis cascade. UV-induced DNA damage generates mutations and after accumulation of a sufficient number of mutations in critical genes, this may finally result in malignant transformation of single keratinocytes or melanocytes and subsequent formation of skin cancer.

UVA, including increased melanoma risk with tanning bed use[22]. For example, a case–control study found adjusted overall melanoma risks of 2.86 and 4.44 for users of UVB-enhanced and primarily UVA-emitting indoor tanning units, respectively[23]. In a mouse melanoma model, both UVB and UVA were shown to induce melanoma[24].

One hypothesis to explain why melanomas commonly arise in intermittently sun-exposed skin rather than in chronically sun-exposed areas is that because of their relative inability to undergo apoptosis, melanocytes might be more prone to UV-induced mutagenesis following a single high dose of UV light[25]. Melanocytes contain high levels of anti-apoptotic proteins such as Bcl-2, providing a possible explanation for why sunburn-induced apoptosis has not been described in melanocytes. As a result, melanocytes with a high amount of DNA damage are more likely to survive than are keratinocytes, which readily undergo apoptosis.

In chronically sun-exposed skin, adaptive responses that follow repeated exposures to low-dose UV radiation (e.g. increased pigmentation, upregulation of DNA repair) may help to protect cells from mutagenic assaults. However, keratinocytes are more prone to UV-induced mutagenesis because they proliferate more rapidly and are more likely to replicate unrepaired DNA. This may explain why keratinocytes are more vulnerable than melanocytes to the mutagenic effects of low-dose UV irradiation observed in chronically sun-exposed skin.

UV INDUCTION OF DNA DAMAGE

Different wavelengths of UV light induce different types of DNA damage. UVC and UVB, but much less so UVA, are capable of exciting the DNA molecule directly and subsequently generating DNA photoproducts[26]. Indeed, DNA is regarded as the chromophore for most of the biologic effects of UVB and UVC, including erythema, tanning, immunosuppression, and mutagenesis. DNA photoproducts are dimers, formed by covalently binding two adjacent pyrimidines in the same polynucleotide chain. The two major types of pyrimidine dimers are cyclobutane–pyrimidine dimers and 6,4-photoproducts.

Cyclobutane–pyrimidine dimers (CPDs) are the most common DNA photoproducts formed by UV irradiation. They are generated upon saturation of the 5,6 double bonds and formation of a four-membered cyclobutyl ring (Fig. 86.8). CPDs are observed at all possible dipyrimidine sites, with the thymine–thymine dimer (T–T) being the most common, followed by C–T and T–C dimers. C–C dimers are the least common. The formation of CPDs is not a random phenomenon: it is influenced by the sequence and conformational context of the affected DNA sequence. More recently, an additional molecular mechanism for the formation of CPDs was described, consisting of photoexcitation of melanin and formation of peroxynitrite. Due to the long half-life of these reactive molecules, this mechanism adds to CPD formation for hours after UV irradiation, but only in melanin-containing cells. These CPDs have been termed "dark CPDs"[27].

The *6,4-photoproduct* is a non-cyclobutane dipyrimidine photoproduct, which is formed upon covalent linkage between the C-6 position of one pyrimidine and the C-4 position of the 3′ adjacent pyrimidine (Fig. 86.9). The T–C (6–4) dimer is the most common dimer of this type, but C–C and T–T dimers are also observed after UV irradiation. Upon further irradiation with UV wavelengths between 280 and 360 nm, the normal isomers of 6,4-photoproducts can be converted to their Dewar valence isomers, which are less mutagenic than the normal isomers but may still contribute to solar mutagenesis[28]. Although eightfold fewer in number than CPDs, 6,4-photoproducts can activate the ATR-CHK1 DNA damage response pathway and may be the major trigger for UV-induced DNA damage responses[29]. A few other rare DNA photoproducts have been described, such as complex purine lesions and pyrimidine hydrates, but their physiologic significance in cutaneous photobiology is unknown.

The absorption maximum of DNA is at 260 nm. This makes UVC the most effective wavelength for the induction of DNA photoproducts in naked DNA. However, *in vivo*, due to the absorption of shorter wavelengths in upper layers of the epidermis, 300 nm (UVB) is the most effective wavelength for inducing DNA photoproducts in the basal layer of the epidermis (Fig. 86.10)[30]. It is now well recognized that when solar-available doses are compared, UVA can also generate pyrimidine dimers, albeit at a lower frequency than UVB[31].

While formation of UVB-induced pyrimidine dimers results from the direct absorption of photons by bases of DNA, UV irradiation can also damage DNA indirectly. After absorption of photons by chromophores other than DNA, energy can be transferred either to DNA (type I photosensitized reaction) or to molecular oxygen, with reactive oxygen species in turn being able to damage DNA (type II photosensitized reaction). Many of the biologic properties of UVA, including its toxicity to cells, are dependent upon the presence of molecular oxygen, which points to a prominent role for reactive oxygen species. Although these reactive

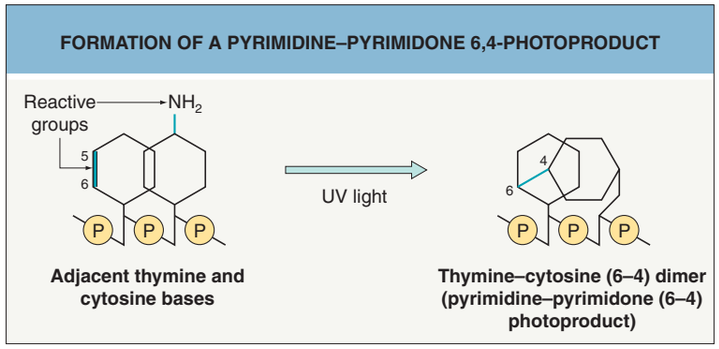

Fig. 86.9 Formation of a pyrimidine–pyrimidone 6,4-photoproduct. A pyrimidine–pyrimidone (6–4) photoproduct is formed by covalent linkage between C-6 and C-4 of two adjacent pyrimidines (here a thymine and a cytosine base), following excitation of the bases by UV light.

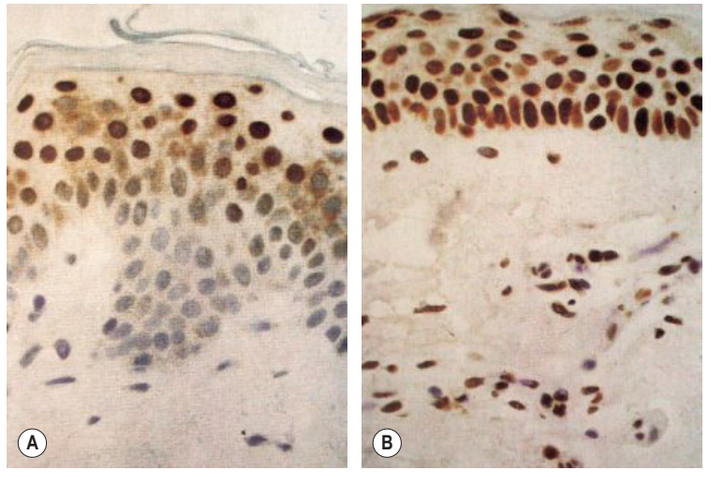

Fig. 86.10 A wavelength of 300 nm is more effective than one of 290 nm in inducing thymine dimers in the basal layer of the human epidermis. A After irradiation of human skin with monochromatic 290 nm UVB (2 MED) and staining with anti-thymine dimer antibodies, most cells in the basal layer show only blue counterstaining, while suprabasal layers demonstrate pronounced reactivity. **B** In contrast, with 2 MED of monochromatic 300 nm UVB, a pronounced immunostaining is also evident in the basal layer of the epidermis (as well as in cells within the dermis). *Reproduced with permission from Young AR, Chadwick CA, Harrison GI, et al. The similarity of action spectra for thymine dimers in human epidermis and erythema suggests that DNA is the chromophore for erythema. J Invest Dermatol 1998;111:982–8.*

oxygen species are also formed by UVB, UVA is responsible for almost all oxidative DNA damage after exposure of cells to natural sunlight[32].

UV-induced reactive oxygen species include singlet oxygen and probably others such as hydrogen peroxide and the superoxide radical[33]. Even the highly reactive hydroxyl radical may be formed by a reaction of hydrogen peroxide with nuclear metals through a Fenton reaction. This oxidative stress affects not only DNA, but also membranes and proteins. Singlet oxygen and other reactive oxygen species react predominantly with guanine and generate several DNA changes, including the mutagenic and well-studied 7,8-dihydro-8-oxoguanosine (8-oxoG; Fig. 86.11).

Kielbassa et al.[34] published a UV action spectrum for the formation of dimers and oxidative guanine base modifications in mammalian cells (Fig. 86.12). Differences between the DNA-damaging properties of UVA, UVB, and UVC are gradual, and, as noted previously, only a few pyrimidine dimers are generated by UVA. There is mounting evidence that pyrimidine dimers are the most important pre-mutagenic DNA lesions, not only in UVB-induced, but also in UVA-induced, mutation formation, with oxidative DNA damage playing only a minor role in mutagenesis[35]. Lastly, DNA double-strand breaks are probably not formed by either UVB or UVA[36].

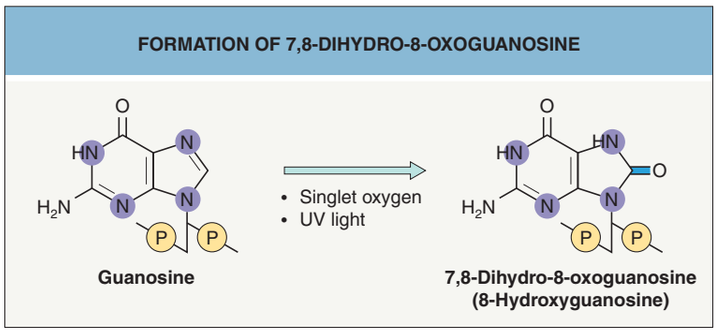

Fig. 86.11 Formation of 7,8-dihydro-8-oxoguanosine. 7,8-Dihydro-8-oxoguanosine (tautomer: 8-hydroxyguanosine) is an oxidation product of guanosine. It is formed by singlet oxygen, which is generated through a photosensitized reaction after excitation of a cellular chromophore by UV light.

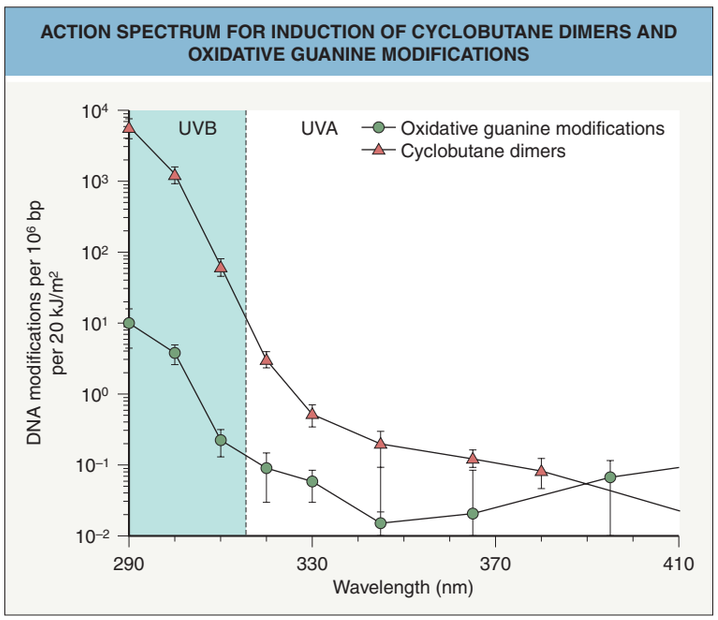

Fig. 86.12 Action spectrum for the induction of cyclobutane dimers and oxidative guanine modifications in Chinese hamster ovary cells. The number of DNA lesions was assessed by the ability of repair enzymes to incise DNA from cells irradiated with different wavelengths from a monochromator. The ability of UV light to induce cyclobutane dimers and oxidative DNA damage rapidly declines with increasing wavelengths, e.g. 320 nm UV light is approximately 1000-fold less capable of inducing cyclobutane dimers than is 290 nm UV light. This decline parallels well with the decline of skin cancer formation in mice from 300 to 340 nm (Utrecht–Philadelphia skin cancer action spectrum[75]). This decline does not mean that longer wavelengths do not contribute to photocarcinogenesis, because longer-wavelength UVA is much more abundant in natural sunlight than is UVB, which offsets at least some of the weaker effects of UVA. The second peak of oxidative base damage formation in the UVA range parallels with a second peak of skin cancer formation at 380 nm. Since there is no second peak of cyclobutane dimer formation with UVA, this has been interpreted as evidence that oxidative base damage contributes to mutagenesis and skin cancer formation. However, more recent data indicate that pyrimidine dimers are the most important pre-mutagenic DNA lesion not only for UVB, but also for UVA.

REPAIR OF UV-INDUCED DNA DAMAGE

The bulky DNA photoproducts (pyrimidine dimers) are usually repaired via the nucleotide excision repair (NER) pathway. In patients with xeroderma pigmentosum (XP), defects in the NER pathway increase UV mutagenesis and this leads to a higher incidence of melanoma and keratinocyte carcinomas (Fig. 86.13). XP includes seven genetic complementation groups (XPA through XPG), which represent different proteins in the NER pathway (Fig. 86.14), in addition to a separate form, XP variant. The latter is due to dysfunction of DNA polymerase-η which normally bypasses T–T dimers with correct insertion of two A residues (see below).

NER involves recognition of DNA damage, incision of the DNA strand containing a lesion, and DNA synthesis and ligation to replace an excised oligonucleotide (see Fig. 86.14). In active genes, the transcribed strand is corrected up to 10 times faster than the non-transcribed strand. Here, recognition of DNA damage is mediated via the RNA polymerase stalled at the site of a pyrimidine dimer plus recruitment of CSA and CSB (protein products of *C*ockayne *s*yndrome complementation group *A* and group *B* genes); this initiates *transcription-coupled repair*. In non-transcribed genes and non-coding regions, the XPC and XPE proteins bind to UV-damaged DNA, marking it for further processing; this initiates *global genome repair*. After either form of DNA damage recognition, all subsequent steps of NER are identical. A key intermediate is an open, unwound structure formed around a DNA lesion in a reaction that uses the helicase activities of XPB and XPD. This creates sites for cutting by the endonucleases XPG on the 3′ side of the lesion and the XPF–ERCC1 complex on the 5′ side. A 24- to 32-residue oligonucleotide is released, and the gap is filled by DNA polymerase δ or ε and then sealed by DNA ligase 1.

Defects in NER are found not only in XP, but also in two other photosensitive disorders, Cockayne syndrome and the photosensitive form of the brittle hair syndrome trichothiodystrophy (see Table 87.4). These disorders are not cancer-prone, but sometimes have features that overlap with those of XP. It is remarkable how different mutations in *XPB/ERCC3*, *XPD/ERCC2*, and *XPG/ERCC5* are associated with dissimilar clinical phenotypes. The transcription/repair syndrome hypothesis has been put forward to explain these various discrepancies. According to this hypothesis, mutations in XPD or XPB could affect

the *repair function* of transcription factor IIH (TFIIH; see Fig. 86.14), resulting in photosensitivity and cancer development, and/or affect the *transcription function* of TFIIH, accounting for the typical phenotypes of trichothiodystrophy and Cockayne syndrome.

Cells from patients with XP variant have an intact NER, yet a phenotype that is indistinguishable from the other XP complementation groups. These patients have a deficiency in what they do with unrepaired DNA photoproducts during replication within the S phase of the cell cycle[37]. Replicative DNA polymerases usually stall at unrepaired DNA lesions and detach from the DNA strand. For this situation, cells have several specialized DNA polymerases that are able to bypass different kinds of DNA damage and extend replication forks through damaged sites. Due to a mutation in *POLH*, patients with XP variant lack the ability of DNA polymerase-η to bypass T–T dimers and correctly insert two A residues[38]. This indicates that NER does not always repair all DNA lesions and that the function of a high-fidelity translesional DNA polymerase is crucial for maintaining genomic stability. In XP variant patients, NER can remove most of the T–T dimers, but because polymerase-η is deficient, any remaining dimers are more likely to be bypassed by translesional DNA polymerases (other than DNA polymerase-η) that insert incorrect residues. This causes a UV-mutator phenotype. If DNA polymerase-η, or any other specialized translesional DNA polymerase, fails to bypass DNA damage during S phase, the cell is faced with a stalled replication fork. In these instances, DNA recombination repair, which utilizes strand invasion from the sister chromatid, can resolve the stalled replication fork[39].

In contrast to the bulky pyrimidine dimers, which can only be repaired by NER, the non-bulky oxidative DNA base modifications can be processed via base excision repair[40]. As the name implies, the initial step in base excision repair is the removal of a base rather than a nucleotide. This step is carried out by a DNA glycosylase, which removes the damaged DNA base by hydrolytically cleaving the base–deoxyribose glycosyl bond, leaving an apyrimidinic/apurinic site for further processing. This DNA glycosylase has substrate specificity for a particular kind of DNA base damage. The human DNA glycosylase, 8-oxoG DNA glycosylase 1, has specificity for oxidized guanine bases such as 8-oxoG (see Fig. 86.11), and it initiates processing of these lesions via base excision repair.

Lastly, the cytokines IL-12 or -23 can interfere with DNA repair. They are capable of effectively rescuing UV-irradiated cells from apoptosis by triggering DNA repair mechanisms that inhibit immune suppression, most likely due in part to abrogation of induction of regulatory T cells (Tregs). In particular, IL-23 may counteract photocarcinogenesis[41–43].

UV-INDUCED MUTATIONS

Many of the previously discussed forms of UV-induced DNA damage can result in mutations. The principal mechanism by which DNA damage results in a base substitution mutation is via mispairing during DNA replication in the S phase of the cell cycle. Because mutations in several specific genes are usually required for a normal cell to undergo malignant transformation and these mutations are quite unlikely to occur in a single cell, genetic instability (a mutator phenotype) is thought to be required for the development of cancer, including skin cancer[44]. XP serves as an example of an inherited genetic instability. While the amount of DNA damage formed in the skin following UV exposure is the same as in normal individuals, deficient repair of this damage results in many more mutations at sites of DNA damage as compared to repair-intact individuals.

Most of the *TP53* mutations in cutaneous SCCs and their precursors are C→T single base transition mutations at dipyrimidine sites[45]. Tandem CC→TT transition mutations are found in 10% of cutaneous SCCs. This spectrum of *TP53* mutations is very different from *TP53* mutations found in malignancies of internal organs; the latter do not have the preponderance of C→T mutations nor do they have any CC→TT mutations. This, together with the fact that pyrimidine dimers most commonly cause C→T and some CC→TT mutations, provides convincing evidence for a crucial role of pyrimidine dimers in photocarcinogenesis. Therefore, C→T, and especially CC→TT mutations, have been termed "signature mutations" for UV-induced mutagenesis (Fig. 86.15). However, to date, studies have not found an increased risk of skin cancer in patients with skin disorders treated with standard regimens of UVA1, UVB, or NB-UVB[46,47].

MECHANISMS OF UV-BASED PHOTOTHERAPY

UV irradiation is an effective treatment for a variety of skin diseases, from psoriasis, atopic dermatitis, prurigo, and vitiligo to lichenoid dermatoses (e.g. lichen planus, pityriasis lichenoides, graft-versus-host disease), morphea, and cutaneous T cell lymphoma (CTCL; see Ch. 134)[1,48]. The therapeutic mechanisms are complex and depend upon the particular disease and the administered wavelengths, e.g. NB-UVB versus UVA1. UV radiation has proapoptotic, immunomodulatory, antipruritic, antifibrotic, propigmentary, and proprebiotic properties, which alone or in combination lead to clinical improvement. Despite having diverse etiologies, most photoresponsive disorders have disturbances in the cutaneous immune microenvironment.

As depicted in Figs. 86.3 and 86.5, UV irradiation induces various mediators including cytokines, chemokines, AMPs, *cis*-urocanic acid, platelet activating factor (PAF), and PAF-like molecules that simultaneously influence the cutaneous micromilieu and its interplay with the microbiota of the skin. In particular, the induction of regulatory

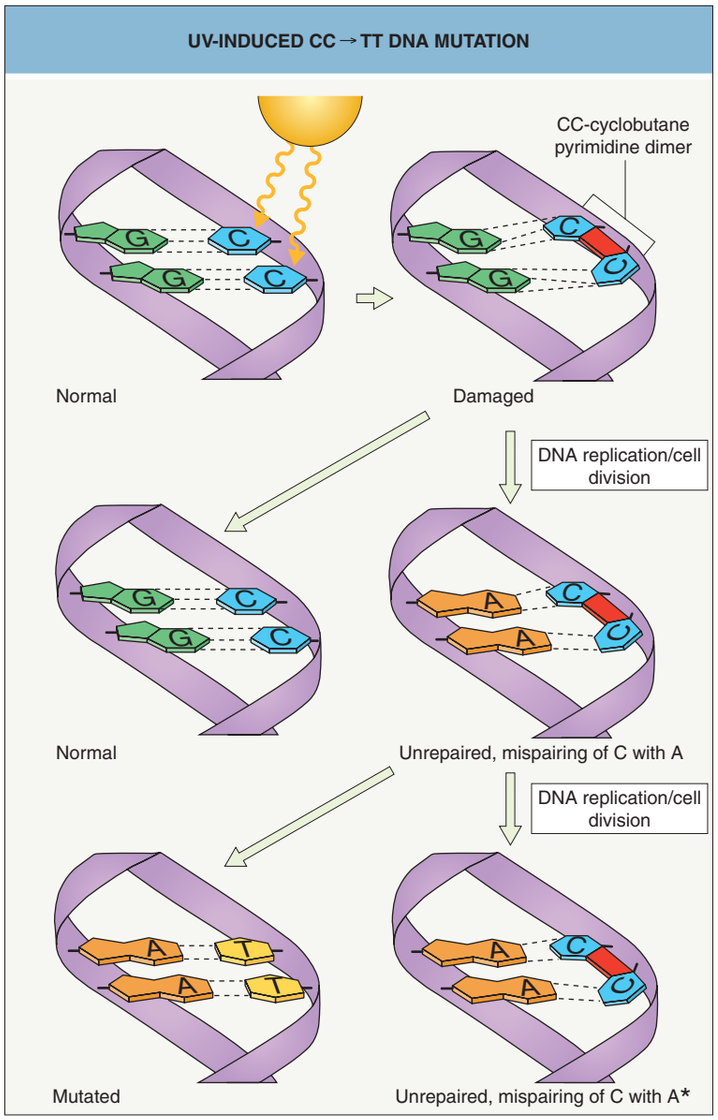

Fig. 86.15 UV-induced CC→TT DNA mutation. Following formation of a pyrimidine dimer between two adjacent cytosines and subsequent cell division, a CC→TT mutation results. This represents a UV-signature mutation. *May give rise to more C→T mutations.

T cells, along with downregulation of the Th17/IL-23 axis, may be crucial for months-long disease remission in disorders such as psoriasis even after treatment is discontinued[1,48,49]. In mycosis fungoides, phototherapy can disrupt the cutaneous proinflammatory microenvironment, along with diminishing the growth of T cells via suppression of the production and secretion of IL-9[50,51]. In both atopic dermatitis and CTCL, UV irradiation affects the cutaneous microbiota (e.g. inhibits the growth of *Staphylococcus aureus*) which suppresses the proinflammatory microenvironment of the skin[1,52]. In fibrotic skin diseases such as morphea, phototherapy (UVA1) induces matrix metalloproteinase and Smad7 expression as well as downregulation of IL-6, leading to increased collagenase activity and effectively reducing tissue fibrosis[1].

UV irradiation can also lead to vitamin-dependent and -independent systemic effects that may affect gut microbiota[53,54], thereby playing a potential role in a variety of skin disorders[1]. In patients with psoriasis, phototherapy decreases systemic inflammation as measured by serum levels of C-reactive protein (CRP) and IL-6; it can also increase levels of high-density lipoprotein (HDL)-P and restore HDL composition and function which may reduce aortic inflammation[55] and cardiovascular risk[56,57], respectively. Lastly, exposure to UV light may benefit multiple sclerosis[58,59] as well as alter mood, behavior and cognition, possibly due to increased synaptic release of glutamate and enhanced motor learning and memory[60].

PHOTOPROTECTION BY UV FILTERS AND OTHER MODALITIES

To ensure that most of the damage inflicted by sun exposure will not lead to the formation of skin cancer, UV-exposed cells have several lines of defense against the photocarcinogenesis cascade (Fig. 86.16). For example, the epidermis can increase its thickness, which reduces UV exposure in the basal layer. Anti-oxidative enzymes quench reactive oxygen species and reduce the formation of oxidative DNA damage. Cellular melanin is a mixture of different polymerized pigments that absorb UV radiation (see Ch. 65). Illumination of the brown to black eumelanin generates the superoxide radical within the molecule, but it is very rapidly scavenged. However, red or yellow pheomelanin is a less effective radical scavenger, and upon UV exposure, pheomelanin is degraded, with a net formation of superoxide. Therefore, pheomelanin is regarded as a photosensitizer, rather than a photoprotector like eumelanin.

To prevent mutation formation after UV-induced DNA damage, cells have several different DNA repair systems (see above) as well as the ability to bypass DNA damage without inducing mutations. Cells can also halt proliferation (cell cycle arrest via increased expression of p53) to allow more time for repair and to reduce the chance of replicating a damaged template. Some of these protective mechanisms can be upregulated, facilitating an adaptive response to repeated UV "attacks". They include pigmentation, skin thickening, antioxidant enzymes, and DNA excision repair. In contrast, immune surveillance is downregulated following UV exposures (see above), likely contributing significantly to photocarcinogenesis.

Exposure to UVA cannot be regarded as harmless, and dermatologists must warn not only against UVB but also UVA exposure. Because broad-spectrum sunscreens do not filter UVA as efficiently as UVB, the use of sunscreens may actually increase UVA exposure[61]. The use of high-dose UVA emitters for cosmetic purposes in tanning parlors also continues to be popular, and an increase in melanoma incidence has already been linked to tanning parlors in Iceland[22].

In order to prevent or reduce UV irradiation of the skin, one can limit outdoor activities, especially around midday, stay in the shade, wear protective clothing, and/or wear sunscreens. Sunscreens are topical preparations that attenuate UV radiation before it enters the skin, by reflection, absorption, or both (see Ch. 132). They not only protect against the acute skin injury of sunburn, but also against UV-induced immune suppression, photoaging, and skin cancer[62,63]. The sun protection factor (SPF) of sunscreens, which indicates by what factor *sunburn* is prevented by sunscreen use (see Table 132.2), does not correlate well with protection factors for other non-erythema endpoints[64]. Therefore, the SPF cannot be regarded as a reliable guide to non-erythema and chronic endpoints.

A good sunscreen should provide broad-spectrum protection against UVB and UVA, ideally in a balanced way with equal protection against both UVA and UVB. Additionally, it should be photostable and have a comfortable vehicle to ensure its regular use. Filters that degrade with UV exposure lose their effectiveness and need reapplication. In addition, degradation products may induce further reactions, providing an explanation for why unstable sunscreen filters are more likely to cause photoallergic reactions[65]. Lastly, sunscreens should not be used to prolong sun exposure, because this would offset any protective effect and might even increase exposure to unfiltered or less-well-filtered wavelengths, such as UVA.

In order to prevent oxidative damage – in particular, oxidative DNA damage – the addition of antioxidants to sunscreens has been advocated. However, their protective effects against any of the above-mentioned endpoints have not been well established, or are marginal at best[66]. In addition, the finding that oxidative DNA damage might not contribute significantly to UVA-induced mutagenesis (as was previously thought) brings into question whether antioxidants provide any protection against skin cancer. Reactive oxygen species are not only damaging to cells, but also induce cellular responses that can protect against photocarcinogenesis, including induction of senescence via generation of the aging-associated protein progerin[67]. Thus, in theory, antioxidants could actually promote photocarcinogenesis.

Topical application of immunoprotective DNA repair enzymes has been shown to increase DNA repair in skin cells and to accelerate removal of DNA photoproducts[68]. In patients with XP, such applications

Pigmentation Epidermal thickening and hyperkeratosis Anti-oxidative enzymes	Oculocutaneous albinism	Broad-spectrum sunscreens Antioxidants
DNA damage		
DNA repair High-fidelity translesional DNA synthesis Cell cycle arrest/apoptosis	Xeroderma pigmentosum Xeroderma pigmentosum variant Familial melanoma Basal cell nevus syndrome	Antioxidants DNA repair liposomes Nicotinamide
Mutations		
Removal of mutated cells (immune surveillance)	Immunosuppression, e.g. solid organ transplant patients	Improve immune surveillance (e.g. PD-1 inhibitors)
Skin cancer		

Fig. 86.16 Mechanisms that protect against or prevent the photocarcinogenesis cascade and disorders that predispose to skin cancer because of impaired intrinsic protective mechanisms. Several intrinsic mechanisms protect against the formation of skin cancer following UV exposure at different points of the photocarcinogenesis cascade of events. These mechanisms are impaired in disorders with increased risk for UV-induced skin cancer. Each step of the photocarcinogenesis cascade can be targeted for therapeutic modification and reduction of skin cancer risk.

have been reported to reduce the occurrence of actinic keratoses[69]. Similarly, oral nicotinamide may have the capacity to reduce the rates of keratinocyte carcinomas and actinic keratoses[70]. Its mechanism of action has yet to be determined, but it is a substrate and inhibitor of the nuclear enzyme poly-ADP-ribose polymerase, which plays a central role in DNA repair. This indicates that it may be possible to prevent the formation of mutations after the introduction of DNA photoproducts with the use of enzymatic sunscreens or other modalities. Interestingly, the cutaneous microbiome has recently been found to have immunoprotective properties[71], with UV exposure not only capable of inducing AMPs but also shifting the microbiota of the skin[72,73]. It remains to be determined how application of sunscreens interferes with the cutaneous microbiome in humans[74].

DEFICIENT DNA REPAIR GENES IN XERODERMA PIGMENTOSUM (XP) COMPLEMENTATION GROUPS XPA TO XPG, TRICHOTHIODYSTROPHY (TTD), COCKAYNE SYNDROME (CS), AND XP VARIANT

Complementation group or inherited disorder	Function of affected gene product in DNA repair	Also associated with
Nucleotide excision repair		
XPA	High affinity for injured DNA (single strands)	
	Has many interactions with other NER proteins	
	Might have a role in assembling the DNA repair machinery around the DNA lesion	
XPB	Subunit of the transcription factor TFIIH	
	Unwinds the DNA helix around the DNA lesion with its 3′→5′ helicase function	XP/CS*, TTD
XPC	DNA damage recognition	
	Only required for global genome repair, not for transcription-coupled repair	
XPD	Subunit of the transcription factor TFIIH like XPB	
	Unwinds the DNA helix around the DNA lesion with its 5′→3′ helicase function	TTD
XPE	Affinity for UV-damaged DNA	
	Might have an auxiliary role in DNA damage recognition	
XPF	5′-repair endonuclease	
	The ERCC1/XPF complex cuts at the single-strand to double-strand transition 5′ of the DNA lesion	XP/CS*
XPG	3′-repair endonuclease	
	Cuts at the single-strand to double-strand transition 3′ of the DNA lesion	
	Stabilizes TFIIH	XP/CS*
TTDA	Subunit of TFIIH (TFB5)	
	See XPB and XPD	
CSA	Only required for transcription-coupled repair	
	Regulates recruitment of repair factors and chromatin remodelers upon stalling of RNA polymerase at the DNA lesion	
CSB	Only required for transcription-coupled repair	
	Regulates recruitment of repair factors and chromatin remodelers upon stalling of RNA polymerase at the DNA lesion	
Translesional DNA synthesis		
XP variant	DNA polymerase-η	
	Bypasses T–T dimers with correct insertion of two A residues	

*Xeroderma pigmentosum/Cockayne syndrome overlap syndrome.

eTable 86.1 Deficient DNA repair genes in xeroderma pigmentosum (XP) complementation groups XPA to XPG, trichothiodystrophy (TTD), Cockayne syndrome (CS), and XP variant. In addition, mutations in the gene that encodes TTDN1, a protein that may have a role in maintaining cell cycle integrity, can lead to a non-photosensitive form of TTD. ERCC1, excision repair cross complementing gene 1; NER, nucleotide excision repair; TFIIH, transcription factor IIH.

TYPES OF IMPAIRED FUNCTION IN INHERITED DISORDERS WITH ABNORMAL DNA REPAIR				
	Global genome NER	**Transcription-coupled NER**	**Translesional DNA synthesis**	**Mismatch DNA repair**
Xeroderma pigmentosum (XP)	+	+	+ (XP variant)	
Cockayne syndrome (CS)		+		
XP–CS overlap	+	+		
Trichothiodystrophy		+		
Muir–Torre syndrome				+

eTable 86.2 Types of impaired function in inherited disorders with abnormal DNA repair. Patients with Cockayne syndrome and trichothiodystrophy are not at increased risk of developing skin cancer. NER, nucleotide excision repair.

87 Photodermatologic Disorders

Henry W. Lim and Cheryl F. Rosen

INTRODUCTION

All skin phototypes react to sunlight because the skin contains molecules (chromophores) capable of absorbing ultraviolet radiation (UVR) or visible light. This absorbed energy is then either re-emitted harmlessly as biologically inactive radiation or diverted to driving thermochemical reactions, leading to molecular, cellular, tissue, and clinical changes. These alterations are either subsequently repaired or result in permanent changes. Nucleic acids are the most ubiquitous chromophores and can initiate UVR-induced changes. In melanocytes, opsin-3 may play a role as a sensor for visible light[1] although opsin-3 appears to be a negative regulator of melanin production[2].

Photodermatoses result from either *abnormal* tissue responses following absorption of photons by endogenous molecules or *expected* responses to absorption by porphyrins or photosensitizing drugs or chemicals (Table 87.1). Clues to the diagnosis of specific photodermatoses are provided in Fig. 87.1.

ABNORMAL CUTANEOUS RESPONSES TO LIGHT

Worldwide, polymorphous light eruption is the most common photodermatosis. Photoaggravated dermatoses, drug-induced photosensitivity, and chronic actinic dermatitis are also commonly observed photodermatoses, depending upon the population, while solar urticaria is relatively uncommon[3]. All have a significant negative effect on patients' quality of life[4].

Immunologically-Mediated Photodermatoses

This group of disorders is outlined in Table 87.2.

Polymorphous light eruption

Synonyms: ■ Polymorphic light eruption ■ Benign summer light eruption (clinical variant) ■ Juvenile spring eruption (clinical variant)

Key features

- The most common photodermatosis
- Papules, vesicles, or plaques appear within hours following sun exposure; lasts for a few days
- In patients with darker skin phototypes, the most common primary lesion is a pinhead-sized papule
- Action spectra: UVB, UVA, and rarely visible light
- Management: photoprotection and narrowband (NB)-UVB hardening

Introduction and history

Polymorphous light eruption (PMLE) is a common, sunlight-induced eruption affecting individuals of all races and skin colors[3,5]. Within minutes to hours of sun exposure, pruritic, erythematous papules, papulovesicles, or rarely vesicles develop. In patients with darker skin phototypes, pinhead-sized papules represent the most common morphology. Lesions resolve within a few days without scarring. The eruption is generally most severe in the spring and early summer, especially in temperate climates. As summer progresses, PMLE becomes milder, a phenomenon known as "hardening".

PMLE was first described by Carl Rasch in 1900 and mentioned again by Haxthausen in 1918.

Epidemiology

The prevalence of PMLE in the general population is inversely related to latitude, being highest in Scandinavia (22%), high in the UK and northern US (10%–15%), and low in Australia (5%) and equatorial Singapore (~1%)[5]. This is probably due to the development of UVR-induced immunologic tolerance ("hardening") due to constant year-round solar exposure in sunny climates. Women are affected slightly more often than men, with the second and third decades being the most common times of onset.

Pathogenesis

Attacks of PMLE are triggered by exposure to UVR (and occasionally visible light) from sunlight or other sources such as tanning beds and phototherapy units. Spring and summer sunlight in temperate regions is most likely to induce outbreaks. The action spectrum ranges from UVB to UVA and rarely to visible light. Patients typically have normal minimal erythema doses (MEDs) to UVB, UVA, and visible light,[5] although severely abnormal phototesting results have been reported in some patients[6].

PMLE is considered to be a delayed-type hypersensitivity (DTH) response to as-yet-undefined, *photoinduced* endogenous cutaneous antigens[5]. Timed biopsy specimens, following solar-simulated irradiation (~0.6 MED), have shown perivascular infiltrates of lymphocytes, primarily $CD4^+$ (within hours) and $CD8^+$ (within days), in association with an increased number of dermal and epidermal antigen-presenting cells[7]. Following UV exposure, reductions in IL-4 and IL-10 production as well as in infiltrates of neutrophils and mast cells have been observed[5].

Susceptibility to PMLE appears to be genetic, with up to 70% of the population having a propensity for developing this condition, but not all expressing it because of variations in disease penetrance[8]. There appears to be a *resistance* to the normal UVR-induced suppression of the induction,[9] but not the elicitation,[10] of cutaneous DTH responses. As a result, in PMLE, a lesser degree of cutaneous immunosuppression following UVR exposure (compared to normal individuals) likely results in a persistent ability to mount a DTH response against UVR-altered endogenous cutaneous molecules, leading to the development of clinical lesions. Possible underlying mechanisms include: (1) an under-expression of apoptotic-cell clearance genes in keratinocytes, thus prolonging antigen presence; and/or (2) inefficient free radical removal, thereby increasing photoantigen production. UVR-induced cutaneous immunosuppression may protect against developing disruptive PMLE, but it can also increase the risk of skin cancer. Indeed, PMLE patients have been reported to have a reduced tendency to develop such cancers[11].

Clinical features

In temperate climates, PMLE usually occurs during the spring and early summer, following minutes to hours of sun exposure[5]. Outbreaks may also occur after exposure to snow-reflected sunlight, tanning beds, or UV phototherapy. The eruption fades over one to several days, but may recur. PMLE tends to improve over the summer or a lengthy sunny vacation, presumably due to the development of immunologic tolerance, also known as "hardening"[5].

Typically, some, but virtually never all, of the exposed skin is affected. Lesions are usually symmetrically distributed in a patchy fashion. Areas that are normally continuously exposed to sunlight (e.g. face) are often spared (Fig. 87.2). The distribution pattern and morphology of lesions in a given patient are usually consistent over time. Areas commonly affected are the neck, outer aspects of the arms, and dorsal hands (Fig. 87.3), but there may be more widespread involvement of sun-exposed sites (Fig. 87.4).

Clinically, mildly to markedly pruritic, grouped, erythematous or skin-colored papules of varying sizes, sometimes coalescing into large, smooth or unevenly surfaced plaques, are seen. In darkly pigmented individuals, the most common morphology is grouped, pinhead-sized papules in sun-exposed areas (see Fig. 87.3D); upon resolution, shiny pinhead-sized macules may be observed. Vesicles, bullae, papulovesicles, and confluent edematous swelling are additional manifestations; rarely, only pruritus occurs. Occasionally, particularly in boys, the helices of the ears may be principally affected in a form of PMLE referred to as juvenile spring eruption. Vesicles are commonly observed in this variant. In a 32-year follow-up of 94 patients, the disease improved or resolved in 58% over a period of 16 years, and in 75% over a period of 32 years.

CLASSIFICATION OF PHOTODERMATOSES

• Immunologically mediated (see Table 87.2)
• Defective DNA repair and chromosomal instability disorders
• Photoaggravated dermatoses
• Chemical- and drug-induced photosensitivity
  • Exogenous: ingested or externally applied drugs or chemicals
  • Endogenous: cutaneous porphyrias, pellagra, Smith–Lemli–Opitz syndrome

Table 87.1 Classification of photodermatoses.

IMMUNOLOGICALLY MEDIATED PHOTODERMATOSES
• Polymorphous light eruption • Actinic prurigo • Hydroa vacciniforme • Chronic actinic dermatitis • Solar urticaria

Table 87.2 Immunologically mediated photodermatoses.

Fig. 87.2 Polymorphous light eruption of the face. A Larger erythematous patch on the nose as well as erythematous plaques on the malar eminence and chin. **B** Edematous erythematous plaques on the cheek in a young child.

Pathology

There is variable epidermal spongiosis and a superficial and deep, perivascular and periappendageal, lymphohistiocytic dermal infiltrate, often with scattered eosinophils and neutrophils. Significant papillary dermal edema occurs commonly (Fig. 87.5). Occasionally, difficulty in distinction from cutaneous lupus may occur if interface changes are significant. $CD123^+$ cells are usually present in lupus erythematosus (LE) but absent in PMLE.

Differential diagnosis

PMLE can often be distinguished from LE, photoaggravated dermatoses (e.g. atopic dermatitis, seborrheic dermatitis), solar urticaria, and rarely, erythropoietic protoporphyria (EPP) by the natural history and clinical appearance of the cutaneous lesions. Occasionally, clinicopathologic correlation and laboratory evaluation are required (Table 87.3; see Fig. 87.1). For photoaggravated dermatoses, the characteristic clinical features of the primary disorder usually allow for distinction.

Treatment

PMLE in its milder forms can be managed by photoprotection, including the use of broad-spectrum, high SPF sunscreens and physical barriers. In patients with more severe disease, two-to-three times per week sessions of NB-UVB, usually for 15 sessions in the spring, can produce hardening and be effective for several months[12]. An initial starting dose of 30%–50% of the MED for NB-UVB is recommended, with the dose then increased by 10%–15% per treatment. Oral prednisone (0.5–1 mg/kg) may be used during the initial seven to ten days of phototherapy to minimize photoexacerbation. Once hardening is achieved, it may be possible to maintain the effect by having patients expose themselves weekly to sunlight between 10 AM and 2 PM for 15–20 minutes (without sunscreen) for the remainder of the sunny season.

Other therapeutic options for prevention of PMLE include oral prednisone (<0.5 mg/kg, usually given for 5–7 days during vacations to a sunny climate)[13] and less commonly, hydroxychloroquine[14,15].

Actinic prurigo

Synonyms: ■ Hutchinson's summer prurigo ■ Familial (or hereditary) polymorphous light eruption of American Indians ■ Hydroa aestivale

Key features

- Severe form common in Native Americans, often with cheilitis and conjunctivitis
- Can occur in all races
- Childhood onset; often resolution by adolescence, but can persist indefinitely
- Intensely pruritic, crusted papules or nodules in sun-exposed sites
- Strong association with HLA-DR4 (DRB1*0401) and subtype DRB1*0407
- Primary management: photoprotection, NB-UVB, topical calcineurin inhibitors, and thalidomide

Introduction and history

Actinic prurigo is a fairly uncommon, sunlight-induced, pruritic and crusted, papular or nodular eruption involving uncovered and, to a lesser extent, covered skin[16]. It was first described in the 1960s and 1970s, and was noted to affect North, Central, and South Americans of indigenous or mixed race.

Hutchinson first described this disorder in 1879, followed in 1918 by Haxthausen, who described it as a PMLE variant. In 1968, Londoño coined the term "actinic prurigo".

Epidemiology

Actinic prurigo is particularly common in Native Americans, especially Mestizos (mixed American Indian and European ancestry) living at high altitudes. It also occurs, but much less commonly, in Europe and Asia. A familial form is relatively common.

Pathogenesis

Actinic prurigo is triggered by UVR exposure and therefore typically flares during the spring and summer, especially in temperate climates. Phototesting results are abnormal in approximately two-thirds of patients and cutaneous lesions can be provoked by UVB or UVA.

The immunologic nature of actinic prurigo is supported by a study of Mexican Mestizo patients, where the remarkable therapeutic efficacy of thalidomide has been shown to be associated with an inhibition of TNF synthesis and the modulation of interferon-γ-producing $CD3^+$ cells. The presence of a dense lymphocytic infiltrate and lymphoid follicles in lesional biopsy specimens from the lips provides further support for this concept[16].

Actinic prurigo may represent a persistent variant of PMLE, as clinical conversion between actinic prurigo and PMLE has been observed, and in family studies, the two disorders are closely linked[17]. There is also a strong association of actinic prurigo with HLA-DR4 (DRB1*0401) and subtype DRB1*0407[17], and this may be the genetic factor that transforms PMLE into actinic prurigo. Indeed, the presence of this HLA subtype is strongly suggestive of the diagnosis.

Clinical features

Actinic prurigo usually appears during childhood and is more frequently seen in girls. It often resolves by adolescence, but may persist indefinitely[16]. The eruption is usually worse during the summer in temperate

climates, but may not always be clearly related to sun exposure. In tropical regions of Latin America, it can persist year-round.

Erythematous papules or nodules, sometimes with hemorrhagic crusts due to excoriation, are present in sun-exposed sites, especially the face (including the nose) and the distal limbs (Fig. 87.6). Lesions may be scattered or densely distributed, and there are sometimes eczematous features or lichenification. Fine linear or pitted scars may appear as facial papules heal. In patients from the UK, involvement of covered sites, particularly the buttocks, has been well described (Fig. 87.7).

EVALUATION OF PHOTOSENSITIVITY WITH SUGGESTED LABORATORY INVESTIGATIONS
• Routine histology • Antinuclear antibodies • Anti-SSA/Ro, -SSB/La antibodies • Plasma porphyrins, followed by complete porphyrin profile if positive (see Ch. 49) • Phototesting to UVA, UVB, and visible light • Photopatch testing (see Fig. 87.19)

Table 87.3 Evaluation of photosensitivity with suggested laboratory investigations.

Fig. 87.6 Actinic prurigo. Multiple papules on the upper cheek, several of which have central crusts. A linear excoriation is seen on the lower portion of the upper eyelid.

Fig. 87.7 Actinic prurigo. More severe actinic prurigo with involvement of the buttocks as well as sun-exposed sites. *Courtesy John L. M. Hawk, MD.*

Cheilitis and conjunctivitis are common, with cheilitis often being the only clinical manifestation (Fig. 87.8)[16].

Pathology

In early lesions, there is epidermal spongiosis, acanthosis, and a dermal perivascular mononuclear cell infiltrate with occasional eosinophils, but, unlike in PMLE, papillary edema is usually absent[16]. Later, crusts, more pronounced acanthosis, variable lichenification, excoriations, focal dermal papillary fibrosis, and a heavier mononuclear cell infiltrate can be seen. These latter features are nonspecific and may resemble those of chronic dermatitis, prurigo nodularis, or, very rarely, cutaneous B cell lymphoma. Dermal lymphoid follicles have been observed in biopsy specimens taken from the lips[16]. Direct immunofluorescence microscopy is negative.

Fig. 87.8 Actinic prurigo. The cheilitis is more severe on the lower vermilion lip. On the upper lip, chronic inflammation has led to blurring of the border between vermilion lip and the cutaneous lip. *Courtesy Jean L. Bolognia, MD.*

Differential diagnosis

The history and clinical features often suggest the diagnosis. Clinicopathologic correlation and laboratory evaluation aid in excluding LE and childhood porphyrias (see Table 87.3). Lesions of prurigo nodularis are not accentuated in sun-exposed skin. Patients with CARMIL2-related immunodeficiency can develop an actinic prurigo-like photosensitivity in addition to Epstein–Barr virus (EBV)-associated smooth muscle tumors and impaired T cell function[18].

Treatment

Rigorous photoprotection is helpful. For milder disease, topical corticosteroids and topical calcineurin inhibitors may be used. NB-UVB should be considered next, with protocols similar to those for PMLE (see above). Resistant disease is best treated with oral thalidomide (50–100 mg nightly)[16], administered for several weeks until remission is achieved and then tapered to as low a maintenance dose as possible (e.g. 50 mg every second or third night). However, the risks of teratogenicity and peripheral neuropathy require very careful patient selection and supervision (see Ch. 130). Other possible systemic therapies include corticosteroids, azathioprine, cyclosporine, dupilumab, and lenalidomide or pomalidomide. In comparison to thalidomide, the latter have significantly less neuropathy, fatigue, and constipation.

Hydroa vacciniforme

Synonym: ■ Bazin's hydroa vacciniforme

Key features

- Very rare, childhood-onset photodermatosis
- Two types: classic hydroa vacciniforme (HV) and HV-like lymphoproliferative disorder (LPD)
  - Classic HV: photodistributed papules and plaques develop umbilicated vesiculation, followed by hemorrhagic crusting (often severe) and varioliform scarring
  - HV-like LPD: papulovesicles in sun-exposed and sun-protected sites, facial edema, lymphadenopathy, and systemic symptoms; may progress to systemic EBV^+ T cell or natural killer (NK) cell lymphoma
- Inclusion of classic HV as a subtype of HV-like LPD has been proposed
- Management requires rigorous photoprotection

Introduction and history

Classic hydroa vacciniforme (HV) is a rare, sunlight-induced, childhood-onset, intermittent but permanently scarring disorder. The condition was first reported by Bazin in 1862.

Epidemiology

HV is well recognized globally, including in the US, UK, Europe, Korea and Japan, and in these countries has been reported to have a predilection for lightly pigmented individuals. The condition typically has its onset during childhood, affecting boys slightly more often than girls and with more severe disease in boys. The disorder can resolve during adolescence or early adulthood[19]; rare familial cases have been noted.

The 2018 update of the WHO-EORTC classification of primary cutaneous lymphomas contains a new category in which patients have chronic active EBV infection. Of particular interest to dermatologists, this category includes HV-like LPD (usually $CD8^+$ T cell phenotype) and severe mosquito bite allergy (usually NK cell phenotype)[20]. Per this classification scheme, the term HV-like LPD encompasses patients previously referred to as having HV as well as HV-like T cell or NK cell lymphoma. However, inclusion of classic HV remains controversial. In patients with HV-like lesions, the development of facial edema, lymphadenopathy, and hepatosplenomegaly points to the diagnosis of HV-like LPD or even lymphoma. The latter disorders have been observed primarily in Asians and indigenous populations of Latin America[21,22].

Pathogenesis

Although tropical sunlight or summer sunlight in temperate regions is generally required to provoke the eruption, abnormal erythematous, or rarely vesicular, phototest responses to repeated monochromatic or broad-spectrum UVR exposure can be induced. The exact pathophysiology of the cutaneous reaction in HV is unknown.

In a study from Japan, T cells positive for EBV RNA were detected in lesional skin infiltrates from 94% of children with clinically typical HV (17/18) and 11/11 patients with severe HV-like eruptions associated with systemic symptoms, but 0/32 skin biopsy samples from patients with various other dermatoses, including photodermatoses[21]. While the relationship between EBV infection and classic HV remains a matter of debate, it is likely that classic HV and HV-like LPD reside along a clinical spectrum[22].

Clinical features

Within hours of summer sun exposure, symmetric, clustered, pruritic or stinging, erythematous macules develop in a photodistribution, especially on the face and dorsal aspects of the hands. Over the next several hours, the macules become tender papules or plaques surmounted by vesicles or bullae (often hemorrhagic), before umbilicating and condensing into hemorrhagic crusts over a span of several days (Fig. 87.9A,B). Healing then occurs over a period of weeks, leaving individual or confluent, sometimes telangiectatic, varioliform scars (Fig. 87.9C). Generalized malaise with fever or headache rarely accompanies the attacks. However, quality of life in affected children is negatively impacted by their inability to play outdoors[19].

In addition to fevers, lymphadenopathy, hepatosplenomegaly, and facial edema, the development of more severe HV-like papulonodules (including in sun-protected sites), oral and labial ulcerations, and panniculitis point to HV-like LPD (Fig. 87.10). These patients may also have exaggerated reactions to mosquito bites, increased NK lymphocytes, hemophagocytic lymphohistiocytosis with leukopenia and thrombocytopenia, and elevated hepatic transaminases. A high circulating EBV DNA load is generally detected by PCR.

Pathology

Progressive epidermal spongiosis precedes findings that are almost pathognomonic: prominent, reticular keratinocyte degeneration; the formation of intraepidermal vesicles containing fibrin and acute inflammatory cells; and confluent epidermal and occasionally focal upper dermal necrosis (Fig. 87.11). Early on, a variably dense perivascular lymphohistiocytic infiltrate admixed with neutrophils and occasionally a few eosinophils is seen; this is followed by epidermal necrosis. Direct immunofluorescence microscopy findings are nonspecific. *In situ* hybridization for EBV RNA shows positivity within the lymphoid infiltrate.

A Papulovesicles with crusting of the nose, cheeks, and lips appeared a few days after sun exposure. **B** Hemorrhagic crusts are admixed with varioliform scars; the latter are the sequelae of repeated acute attacks. Note the scaling and erosions of the lower vermilion lip. **C** Varioliform scars and postinflammatory hyperpigmentation on the cheek. *A,C, Courtesy Tor Shwayder, MD; B, Courtesy Jean L. Bolognia, MD.*

Fig. 87.10 Hydroa vacciniforme-like lymphoproliferative disorder. Extensive involvement of the face by erythematous edematous and infiltrated plaques with hemorrhagic crusts at sites of vesiculation.

Differential diagnosis

LE and childhood porphyrias can be excluded by clinicopathologic correlation and laboratory evaluation (see Table 87.3), while herpes simplex is excluded by a negative PCR, DFA assay, or viral culture. Occasionally, other photodermatoses such as the vesicular form of PMLE and actinic prurigo may be considered.

Treatment

HV is almost always refractory to treatment. Rigorous photoprotection can be useful in mild to moderate disease. Anecdotally, the following have been reported to be helpful: broadband (BB)-UVB, NB-UVB, PUVA, β-carotene, antimalarials, azathioprine, thalidomide, cyclosporine, and dietary fish oil. Systemic therapies such as thalidomide and interferon are also used for HV-like LPD while treatment of EBV^+ T cell lymphoma includes systemic chemotherapy and allogeneic hematopoietic stem cell transplant.

Chronic actinic dermatitis

Key features

- In sun-exposed areas, chronic eczematous eruption (acute, subacute or chronic lichenified) or pseudolymphomatous lesions
- Most common in men over 50 years of age
- Positive phototests to varying combinations of UVB, UVA, and visible light
- Positive patch or photopatch tests common
- Management includes photoprotection, avoidance of (photo) contact sensitizers, intermittent oral and topical corticosteroids, topical calcineurin inhibitors, low-dose PUVA, cyclosporine, azathioprine, mycophenolate mofetil, and/or dupilumab
- Probability of spontaneous resolution is 10% over 5 years, 20% over 10 years

Introduction and history

Chronic actinic dermatitis (CAD) is a persistent, often disabling dermatosis of uncovered (and to a lesser extent, covered) skin, generally affecting older men, particularly in the summer[3,23]. It is evoked by UVR and occasionally also visible light exposure. CAD probably represents a contact allergy-like DTH response against endogenous photoinduced antigen(s).

Reference to a condition suggestive of CAD was first made in 1933 by Haxthausen, then in the 1960s by Wilkinson in the UK and Jillson and Baughman in the US, with the latter authors terming it "*persistent light reaction*". In 1969, its severe form, *actinic reticuloid*, was described, followed shortly thereafter by reports of two milder variants, *photosensitive eczema* and *photosensitivity dermatitis*. In 1979, the current encompassing term, CAD, was introduced by Hawk and Magnus[24].

Epidemiology

CAD has been regularly observed throughout the world. It occurs primarily in temperate zones and more commonly affects older men[2,23]. However, CAD has been increasingly recognized in younger women as well as in patients with darker skin phototypes.[3,25] Familial incidence has not been noted.

Pathogenesis

The action spectra for CAD include UVB, UVA and/or visible light, with UVB plus UVA being the most common. The eczematous clinical and histologic appearances of CAD, its dermal infiltrate of primarily $CD8^+$ T lymphocytes, and its pattern of adhesion molecule activation all closely mimic the DTH response of allergic contact dermatitis. This strongly suggests that CAD is presumably a reaction against endogenous, photoinduced, cutaneous antigen(s).

Fig. 87.12 Chronic actinic dermatitis. Chronic eczematous changes of the posterior neck with lichenification and a sharp cut-off at the collar in a patient with phototype V skin.

CAD was initially described as most common among individuals who spent a lot of time outdoors. However, a significant number of patients, especially those with darker skin phototypes, do not have a history of frequent outdoor activities[23,25]. It is possible that in CAD chronic photodamage leads to a partial abrogation of normal cutaneous immunosuppression, thereby permitting enhanced cutaneous immune responsiveness against an otherwise weak endogenous photoantigen. It should be noted that positive patch testing to *Compositae*, commonly observed in the UK, has not been confirmed in the US and Japan.

It is likely that nucleic acids may be involved as chromophores in the pathogenesis of CAD, in that the shape of the CAD induction spectrum resembles that of sunburn inflammation, for which UVR absorption by nucleic acids is known to be responsible[23].

Clinical features

CAD may develop in previously normal skin, in patients with a prior history of dermatitis (in particular, photoallergic contact dermatitis, allergic contact dermatitis, and atopic dermatitis), or rarely following longstanding oral drug photosensitivity or PMLE. Coexistent allergic contact sensitivity to plant antigens, fragrances, or topical medications is common. The eruption consists of pruritic papules and lichenified plaques in sun-exposed areas (Fig. 87.12); during disease flares, involvement of sun-protected sites, albeit less severe, can be seen. Scattered or widespread, erythematous, shiny, infiltrated, pseudolymphomatous papules or plaques may be present in severely affected individuals.

Lesions develop primarily within sun-exposed sites, frequently with a sharp cut-off at the lines of clothing, and often with sparing in the depths of skin furrows, upper eyelids, finger webs, nasolabial folds, or postauricular areas (Figs. 87.13–87.15). Occasionally, palmoplantar eczematous changes may also be present, while eyebrow or scalp hairs may be stubbly or sparse from rubbing or scratching. Rarely, erythroderma develops in severely affected patients. The probability of resolution has been estimated to be 10% over 5 years, 20% over 10 years, and 50% over 15 years[26].

A rather uncommon photodermatosis, *broad-spectrum abnormal localized photosensitivity syndrome*, also known as *fixed sunlight sensitivity*, is probably a variant of CAD. It is characterized by localized erythema, edema, and blistering that is induced by broad-spectrum UV radiation and occurs most commonly on the extremities[26a].

Pathology

There is epidermal spongiosis and acanthosis, lymphocytic exocytosis, and a superficial and deep, frequently dense, perivascular lymphohistiocytic dermal cellular infiltrate, often containing eosinophils and plasma cells[23]. In more severely affected skin, erosions, focal epidermal necrosis, Pautrier microabscess-like epidermal cellular collections, dermal–epidermal junction fibrin deposition, dermal neutrophils with nuclear dust, vertically streaked papillary dermal collagen, and/or small, multinucleated dermal giant cells are often seen. In addition, the dense infiltrate, epidermal lymphocyte exocytosis, and frequent nuclear polymorphism may on occasion suggest a histologic diagnosis of cutaneous T cell lymphoma (CTCL).

Fig. 87.13 Chronic actinic dermatitis. Lichenification and hyperpigmentation in sun-exposed sites with areas of depigmentation. Note the sparing of sun-protected areas (e.g. nasolabial fold).

Fig. 87.14 Chronic actinic dermatitis. Chronic eczematous changes of the dorsal hand and wrist with associated hyperpigmentation and scaling. Note the sharp cut-off on the distal forearm.

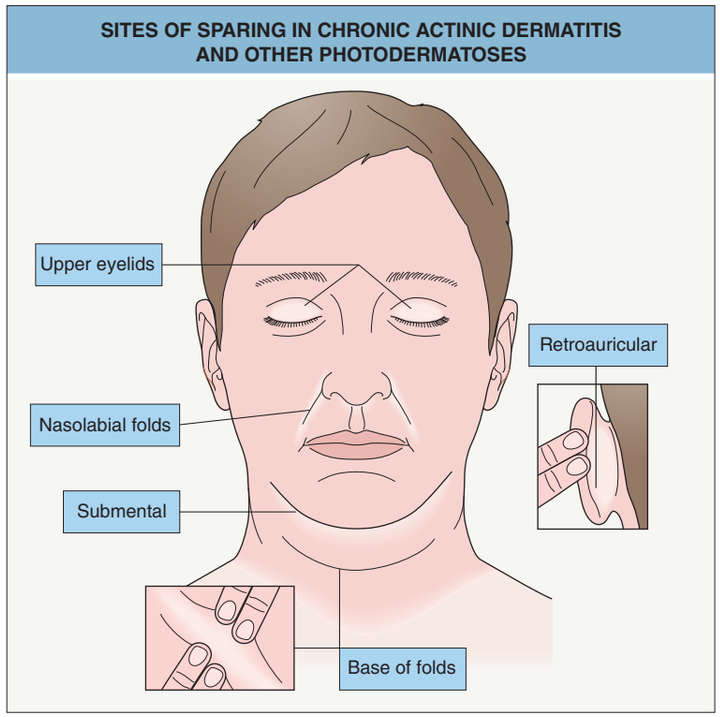

Fig. 87.15 Sites of sparing in chronic actinic dermatitis and other photodermatoses. Relatively sun-protected sites include the upper eyelids, the nasolabial folds, the retroauricular areas, the submental region and the deepest portion of skin furrows. In airborne contact dermatitis these areas are usually involved.

Differential diagnosis

Photoaggravated dermatoses are differentiated by the characteristic clinical features of the underlying primary disorder and normal cutaneous irradiation responses. In drug- and chemical-induced photosensitivity, there is usually a history of exposure to a relevant drug or allergen or clinical evidence (e.g. positive photopatch testing results; see below).

In contrast to CTCL, CAD infiltrates are predominantly $CD8^+$ cells[23] and T cell receptor gene rearrangement studies are negative. Very rarely, primary CTCL may present with severe CAD features and should therefore be considered if apparent CAD is totally refractory to treatment[27]. Erythrodermic CAD must be differentiated from other causes of erythroderma (see Ch. 10), but histologic features may not allow discrimination so phototesting after the erythroderma has been controlled can assist in establishing the diagnosis.

Treatment

Strict photoprotection and the avoidance of relevant contact allergens are of primary importance. Of note, computer and video screens are safe. Commercially available films that block UVR can be placed on home and car windows. Topical or intermittent oral corticosteroids, along with emollients, are generally needed, and topical calcineurin inhibitors may also be helpful[23]. Therapy for refractory disease includes mycophenolate mofetil (1–2 g/day) cyclosporine (3.5–5 mg/kg/day), or azathioprine (1–2.5 mg/kg/day). Dupilumab has recently been reported to improve recalcitrant CAD[27].

Solar urticaria

Key features

- A physical urticaria induced by sun exposure; lesions appear within 5 to 10 minutes and resolve over 1 to 2 hours
- The action spectrum generally includes both UVA and visible light, but rarely UVB
- There is a slight female predominance, often with an onset during the third decade of life
- Estimated probability of resolution is 15% at 5 years, 25% at 10 years
- Management: photoprotection; high-dose, non-sedating antihistamines; omalizumab; cyclosporine; low-dose UVA; PUVA; plasmapheresis; and IVIg

Introduction and history

In solar urticaria, transient wheals appear within 5 to 10 minutes of exposure to UV or visible radiation. Lesions then resolve over 1 to 2 hours. Solar urticaria was first reported in 1905.

Epidemiology

Solar urticaria is a form of inducible urticaria; one study from Scotland reported a prevalence of ~3.1 per 100 000[28]. There is a slight female predominance, and the onset is most frequently during the third decade of life. Solar urticaria may occasionally coexist with PMLE, CAD, and very rarely, EPP[28].

Pathogenesis

As in other forms of urticaria (see Ch. 18), mast cells play a major role. Although factors triggering their degranulation have not been fully elucidated, an IgE-mediated response against photoinduced, endogenous cutaneous antigen(s) is a likely mechanism. This is supported by observations that omalizumab, which blocks the binding of IgE to its receptor, is effective in many patients.

Clinical features

Patients present with whealing limited to sun-exposed areas, particularly the upper chest and extensor arms, within 5 to 10 minutes of sun exposure. Occasionally, erythema without urtication may occur. The lesions then resolve over 1 to 2 hours. Patients almost invariably note an accompanying pruritus, burning sensation, or rarely pain, while severe attacks are rarely associated with malaise, light-headedness, nausea, bronchospasm and/or syncope.

Although solar urticaria is oftentimes classified by its action spectrum, in an individual patient, the spectrum may gradually change over time[29]. Most commonly, visible light is responsible, but usually with extension into the UVA waveband. In some patients, the action spectrum may include UVB[30].

Occasionally, continued regular skin exposure to UVR may decrease the likelihood of attacks of solar urticaria, a phenomenon referred to as "hardening". The probability of spontaneous resolution has been estimated as being 15% at 5 years and 25% at 10 years after onset[28].

There are several uncommon manifestations of this disorder. Fixed solar urticaria is limited to specific areas, presumably due to mast cell alterations just at those sites[30]. "Drug-induced" solar urticaria has been reported following exposure to chlorpromazine, tetracycline, or tar. Solar angioedema occurs 2-10 hours after exposure and takes days to resolve.

Pathology

The histologic findings are similar to those of other urticarias. There is mild dermal edema with a sparse perivascular mixed neutrophilic and eosinophilic infiltrate; mononuclear cells may also be seen. In addition, eosinophil major basic protein has been demonstrated within the dermis by immunofluorescence.

Differential diagnosis

The differential diagnosis includes other forms of urticaria, particularly heat urticaria, PMLE, and very rarely, EPP. A detailed history should differentiate solar urticaria from idiopathic urticaria and other physical urticarias. Phototesting of affected patients generally results in typical whealing within minutes (Fig. 87.16), while the use of a water filter in front of the light source eliminates heat to exclude heat urticaria. Patients with EPP complain of a more deep-seated pain following sun exposure, and they have elevated free RBC protoporphyrin levels (see Ch. 49). The time course of PMLE is distinct from that of solar urticaria, and LE can be excluded via laboratory evaluation (see Fig 87.1 and Ch. 41).

Treatment

Oral non-sedating antihistamines, often in high doses and taken regularly or about an hour or so before expected sun exposure, are effective in ~50% of patients. Those with very mild disease may occasionally require only photoprotective measures; however, sunscreens do not generally provide sufficient protection against long-wavelength UVA and visible light to be effective[31]. Omalizumab is often effective[32]. Graduated exposures to UVA, UVA1 or PUVA are occasionally helpful[33]. Other treatment options, including methotrexate, cyclosporine, plasmapheresis, or IVIg,[34] have been reported to be successful.

Photosensitivity Due to Hereditary Defects in DNA Repair

The major disorders characterized by both defective DNA repair and photosensitivity are discussed below and outlined in Table 87.4.

Fig. 87.16 Solar urticaria. Wheal and flare responses within minutes of exposure to UVB radiation in a patient undergoing phototesting.

The underlying pathogenesis is reviewed in greater detail in Chapter 86. Five of the disorders are associated with defects in one of the nucleotide excision repair (NER) proteins: xeroderma pigmentosum, Cockayne syndrome, cerebro-oculo-facio-skeletal (COFS) syndrome, UV-sensitive syndrome, and the photosensitive form of trichothiodystrophy[35,36].

Xeroderma pigmentosum

Introduction and history

Xeroderma pigmentosum (XP) is an autosomal recessive condition associated with a marked increase in the development of malignancies, especially cutaneous. Eight complementation groups, corresponding to eight genotypes, have been identified. XP was first described by Hebra and Kaposi in 1874.

Epidemiology

XP has an estimated incidence of 2.3 per million live births in Western Europe, 1 in 20 000 in Japan, and 1 in 250 000 in the US[37].

Pathogenesis

XP can result from defects in one of eight genes. The seven complementation groups A through G are each associated with a different site of impairment in global genomic nucleotide excision repair (GG-NER), i.e. impairment in the removal of DNA damage from any part of the genome[37]; the damaged DNA then accumulates, leading to mutations and cancer. XP-A through XP-G represent different proteins in the NER pathway (see Fig. 86.14). It should be noted that different mutations in *ERCC3* (*XPB*), *ERCC4* (*XPF*), and *ERCC5* (*XPG*) can be associated with different phenotypes – either XP or XP/Cockayne syndrome – and mutations in *ERCC3* (*XPB*) and *ERCC2* (*XPD*) can also be associated with photosensitive forms of trichothiodystrophy (see below). Mutations in an eighth gene, which encodes DNA polymerase-η, lead to the XP variant phenotype. This enzyme is responsible for bypassing unrepaired DNA photoproducts during DNA replication; mutations thus result in the insertion of erroneous residues during replication.

Phototesting in XP patients has shown the action spectrum for inflammatory erythema of the skin to be in the 290 to 340 nm range. The MEDs corresponding to those wavelengths are generally quite reduced, with the peak responses often vesicular and delayed by a day or two.

Clinical features

Fifty percent of patients have marked photosensitivity in addition to an early onset for all major types of skin cancer (see Table 87.4)[37]. From an early age, many patients easily develop sunburns with erythema, edema and vesicles following minimal sun exposure. By the age of 2 years, practically all patients have developed solar lentigines (Fig. 87.17). With continued sun exposure, the skin gradually becomes xerotic, accounting for the term "xeroderma pigmentosum".

Actinic keratoses, basal cell carcinomas (BCCs), squamous cell carcinomas (SCCs), and less frequently, melanomas then develop in sun-exposed sites, also prematurely. In addition to the lips, SCCs of the distal tongue can also develop. Individuals with severe photosensitivity are less likely to develop skin cancers than those who are less photosensitive, presumably due to more rigorous photoprotective behaviors in the former group[38].

Ocular abnormalities are observed in ~40% of patients. Severe photophobia, keratitis, corneal opacification, and vascularization are common manifestations, while loss of eyelashes, ectropion, and SCC and melanoma of the UVR-exposed parts of the eyes are also frequently reported[38].

Approximately 20%–30% of XP patients develop neurologic degeneration, especially those in the XP-D group. The most severe presentation is the DeSanctis–Cacchione syndrome, in which microcephaly, a progressive decline in intellectual capacity, delayed growth and sexual development, deafness, choreoathetosis, ataxia, and quadriparesis may all occur. However, some XP patients develop a limited number of clinical manifestations, such as isolated hyporeflexia and progressive deafness. XP variant patients usually have no neurologic problems. Deep tendon reflex testing and audiometry are good screening tests for the presence of neurologic involvement. It has been postulated that these neurologic abnormalities are due to defective DNA repair in nerve cells, resulting in neuronal death. Patients with XP have an ~10- to 20-fold increase in the incidence of internal malignancies, including tumors of the brain, lung, oral cavity, gastrointestinal tract, kidney, and hematopoietic system.

INHERITED PHOTOSENSITIVITY DISORDERS ASSOCIATED WITH DEFECTIVE DNA NUCLEOTIDE EXCISION REPAIR OR CHROMOSOME INSTABILITY					
Disorder	**Clinical features**	**Inheritance**	**Photosensitivity**	**Action spectrum**	**Laboratory findings**
Xeroderma pigmentosum (XP)	• 1 in 20 000 in Japan; 1 in 250 000 in US; 2.3 per million in Western Europe • Photosensitivity (50%), early-onset lentigines (typically by 2 years of age) • Basal cell carcinomas, squamous cell carcinomas, and melanomas in sun-exposed areas • Median age for development of first non-melanoma skin cancers: 9 years & for melanoma, 22 years • Photophobia, keratitis, corneal opacification, and vascularization • Neurologic abnormalities: hyporeflexia, deafness, seizures (most common in groups A and D) • Median lifespan: 37 years (29 years in those with neurodegenerative disease) • Death most commonly due to: skin cancer, neurologic degeneration, internal malignancies • Support group: www.xps.org	AR	Yes	290–340 nm	• Complementation groups A to G: defective global genomic nucleotide excision repair (GG-NER) of UVR-induced DNA damage (e.g. pyrimidine dimers) from any part of the genome • XP variant: defective DNA polymerase-η, resulting in insertion of incorrect nucleotides during replication of DNA with UVR-induced damage • Defective genes for all the XP groups have been identified* • Cells are hypersensitive to killing by UVR
Cockayne syndrome (CS)	• Prevalence: 2.5 per million • Photosensitivity, pigmented macules, thinned skin, alopecia, clubbing of nails, acral edema, sunken eyes due to loss of adipose tissue, prominent ears, dental caries • Hypogonadism, stooped posture, joint contractures, short stature with extremely thin body habitus ("cachectic dwarfism"), microcephaly, intellectual impairment, deafness • Calcification of basal ganglia, demyelination, pigmentary retinal degeneration, osteoporosis • No increase in malignancies in "pure" CS • CS type I: 80% of patients; onset at birth to 2 years of age, progressive; life expectancy: second to third decades • CS type II: symptoms at birth, life span = 6–7 years • CS type III: late onset, normal growth and development • Combined XP/CS: solar lentigines, skin cancers, pigmentary retinal degeneration, basal ganglion calcification • Support group: http://cockaynesyndrome.org/	AR	Yes	UVB, UVA	• Defective transcription-coupled nucleotide excision repair (TC-NER), which targets transcriptionally active regions of the genome • CS cells are defective in the repair of pyrimidine dimer photoproducts and oxidative DNA base modifications typically induced by UVB and UVA, respectively • To date, ~30 mutations in *ERCC8* (*CSA*) and ~80 mutations in *ERCC6* (*CSB*) identified
Cerebro-oculo-facio-skeletal (COFS) syndrome	• Microcephaly, congenital cataracts and/or microphthalmia, arthrogryposis, severe developmental delay, postnatal growth retardation • Facial dysmorphism with prominent nasal root and/or overhanging upper lip	AR	Yes	UVB, UVA	• Mutations in *ERCC6 (CSB), ERCC2 (XPD), ERCC5 (XPG), ERCC1*

UV-sensitive syndrome (UV^sS)	• Fewer than 20 patients reported to date
	• Milder phenotype than CS
	• Clinical overlap with CS (types I and II) UV^sS due to mutations in same genes as CS
	• Photosensitivity, solar lentigines; otherwise normal
		AR	Yes	Unclear	• Similar to CS: defective TC-NER, normal GG-NER; however, unlike CS, patients with UV^sS only have a defect in repair of UVB-induced photoproducts (not in the repair of oxidative damage)
					• Mutations:
					  • Type 1 – *ERCC6* (*CSB*)
					  • Type 2 – *ERCC8* (*CSA*)
					  • Type 3 – *UVSSA*

Trichothiodystrophy (TTD)	• Over 110 patients reported to date
	• PIBIDS: *p*hotosensitivity, *i*chthyosis, *b*rittle hair, *i*ntellectual impairment, *d*ecreased fertility, *s*hort stature
	• Other features: microcephaly, receding chin, protruding ears
	• No increase in malignancies
	• 9 types: types 1–3 are photosensitive while types 4–9 are non-photosensitive†
		AR	Yes (in ~50% of patients) TTD1, 2, 3	Unclear	• Hair shaft: alternating light and dark bands ("tiger tail banding"), trichoschisis, trichorrhexis nodosa-like changes, "ribboning"
					• Reduction of cysteine-rich matrix proteins and low sulfur content in hair shafts
					• Mutations in photosensitive forms:
					  • TTD1 – *ERCC2* (*XPD*)
					  • TTD2 – *ERCC3* (*XPB*)
					  • TTD3 – *GTF2H5*

Table 87.4 Inherited photosensitivity disorders associated with defective DNA nucleotide excision repair or chromosome instability.

INHERITED PHOTOSENSITIVITY DISORDERS ASSOCIATED WITH DEFECTIVE DNA NUCLEOTIDE EXCISION REPAIR OR CHROMOSOME INSTABILITY					
Disorder	**Clinical features**	**Inheritance**	**Photosensitivity**	**Action spectrum**	**Laboratory findings**
Bloom syndrome	• 265 patients currently listed in Registry; one-quarter are of Jewish ancestry • Carrier rate in Ashkenazi Jewish population: 1 in 100 • Malar erythema and telangiectasias, café-au-lait macules and areas of hypopigmentation, elongated facies with malar hypoplasia and prominent nose, short stature • Normal intelligence • Recurrent infections, especially otic and pulmonary • Additional internal manifestations: lymphoma, leukemia, carcinomas (e.g. GI) in up to half of patients; diabetes and chronic lung disease less common • Men: sterile due to defective sperm; women: reduced fertility • Average lifespan: 26 years • Patient registry: https://pediatrics.weill.cornell.edu/research/bloom-syndrome-registry	AR	Yes	Unclear	• Decreased IgA, IgM, sometimes IgG • Mutations in *BLM*, resulting in increased sister chromatid exchanges, chromosomal breakage and rearrangement • Quadriradial configurations in lymphocytes and fibroblasts are diagnostic
Rothmund–Thomson syndrome	• Over 300 patients reported to date • Erythema, edema and vesicles on the cheeks and face during the first few months of life, followed by poikiloderma that typically affects the dorsal aspect of the hands/forearms and the buttocks • Sparse hair (scalp, eyebrows, eyelashes), hypoplastic nails, acral keratoses (in adolescents and adults), short stature, skeletal (e.g. radial ray defects, osteoporosis) and dental abnormalities, juvenile cataracts, chronic diarrhea/vomiting during infancy, pituitary hypogonadism (may be associated with midface hypoplasia/ "saddle nose") • Osteosarcoma (10%–30% in type 2), squamous cell carcinoma (<5%; often acral) • Normal immune function, intelligence and lifespan (in the absence of malignancy)	AR	Transient (early childhood)	UVA	• Mutations in *ANAPC1* (type 1) or *RECQL4* (type 2), resulting in dysfunctional DNA helicase • Genomic instability accounts for propensity for malignancies

* *XPA, ERCC3 (XPB), XPC, ERCC2 (XPD), DDB2 (XPE), ERCC4 (XPF), ERCC5 (XPG).*
† Non-photosensitive forms due to mutations in *MPLKIP* (TTD4; AR), *RNF113A* (TTD5; XLD), *GTF2E2* (TTD6; AR), and *TARS1* (TTD7; AR).

Table 87.4 Inherited photosensitivity disorders associated with defective DNA nucleotide excision repair or chromosome instability. Kindler syndrome also has photosensitivity (UVA, UVB), along with early-onset blistering, mucosal involvement, skin atrophy, and progressive poikiloderma and it is due to mutations in *FERMT1* (*KIND1*) with dysfunction of kindlin-1 resulting in abnormal cell adhesion and proliferation. ERCC, excision repair cross-complementation; UVR, ultraviolet radiation.

Fig. 87.17 Xeroderma pigmentosum. Multiple solar lentigines of the face and a history of photosensitivity in this four-year-old child. *Courtesy Antonio Torrelo, MD.*

Treatment

Management consists of extremely rigorous photoprotection. Oral calcium and vitamin D supplementation should also be recommended for these patients. Cryotherapy, topical 5-fluorouracil and imiquimod, electrodesiccation and curettage, surgical excision, and Mohs micrographic surgery are used to manage the premalignant and malignant skin tumors. Oral retinoids can be used as chemopreventive agents. Topical application of the DNA repair enzymes – T4 endonuclease V/T4N5 or photolyase (incorporated into sunscreen) – have been successful in decreasing the development of actinic keratoses and keratinocyte carcinomas[39].

Cockayne syndrome

Introduction and history

Cockayne syndrome is a rare, progressive, multisystem disease with photosensitivity that is transmitted in an autosomal recessive fashion (see Table 87.4).[40,41] This entity was first described by Cockayne in 1936.

Epidemiology

Cockayne syndrome has been reported from the US, Europe and Japan, with over 120 genetically confirmed patients from Western Europe[39].

Pathogenesis

The fundamental defect in NER in Cockayne syndrome is different from that of XP (see Fig. 86.14). In the former, there is defective transcription-coupled NER (TC-NER), a repair that specifically removes transcription-blocking lesions from the genome. This defect results in the inability to recover mRNA synthesis after exposure to UVR. In contrast, XP cells have defective global genomic NER (GG-NER; see above).

In contrast to XP, skin cancers on sun-exposed areas are not observed in patients with Cockayne syndrome, whose average lifespan is only 12 years (although there is considerable variation)[40]. One explanation is that cells with low-level damage due to defective TC-NER are eliminated, protecting the body from carcinogenesis, but at the expense of accelerated aging. Rigorous photoprotection may also play a role in reducing the formation of skin cancers[41].

Two-thirds of the patients have mutations in *ERCC6* (also known as *CSB*) while one-third have mutations in *ERCC8* (also known as *CSA*) (see Table 87.4)[41].

Clinical features

Patients with Cockayne syndrome have been classified into three types based upon severity of symptoms and age of onset[41]. In the most severely affected individuals, there is a congenital onset and the clinical manifestations overlap with those of cerebro-oculo-facial-skeletal (COFS) syndrome (see Table 87.4). In a more recent series of 16 patients with Cockayne syndrome and COFS, patients were noted to have sensitivity to UVB and UVA, pigmented macules, stellate scars, clubbing of the nails, and acral edema[40].

Treatment

This consists of photoprotection and symptomatic treatment only.

UV-sensitive syndrome

UV-sensitive syndrome (UV^{s}S) is a rare, photosensitive, autosomal recessive disease. To date, fewer than 20 patients have been reported (Japan, France, Israel, Iran and Pakistan)[42,43]. Although it shares defective TC-NER with Cockayne syndrome (see above), clinically patients only have UV photosensitivity (see Table 87.4). However, the action spectrum is unknown. In addition to mutations in *ERCC8* (*CSA*) and *ERCC6* (*CSB*), mutations in a gene that encodes a UV-stimulated scaffold protein A (*UVSSA*) have been identified in these patients.

Trichothiodystrophy

Introduction and history

Trichothiodystrophy (TTD) is an autosomal recessive disorder with over 110 patients reported to date (see Table 87.4)[44]. The term "trichothiodystrophy" was coined by Price in the late 1970s.

Epidemiology

The disorder appears to occur worldwide and affects men and women.

Pathogenesis

To date, mutations in three genes have been identified in patients with photosensitive TTD – *ERCC3* (*XPB*), *ERCC2* (*XPD*), and *GTF2H5* (*TTDA*) – with mutations in an additional six genes detected in those with non-photosensitive TTD (see Table 87.4). While mutations in *ERCC3* (*XPB*) and *ERCC2* (*XPD*) are also found in patients with XP, dysfunction of *g*eneral *t*ranscription *f*actor *IIH* subunit *5* has only been observed in TTD (see Fig. 86.14).

Clinical features

TTD has a broad range of phenotypes, from individuals with just brittle hair and scaly skin to those with severe neurodevelopmental defects and death at an early age[44,45]. Unlike XP, TTD is not associated with skin cancers, and pigmentary alterations are uncommon.

The clinical features of TTD are frequently described by the acronym PIBIDS[44,45]:

Photosensitivity: Photosensitivity has been reported in up to 50% of affected patients, but the action spectrum is not known.

Ichthyosis: A non-bullous congenital ichthyosiform erythro (*TTDA*) derma phenotype is commonly observed during infancy, and patients occasionally present with a collodion membrane. The erythema tends to fade over time, eventuating in ichthyosis of variable severity (see Ch. 57).

Brittle hair: This is the hallmark of TTD and is present in most, but not all, patients[45,46]. By polarizing microscopy, hair shafts demonstrate alternating bright and dark bands ("tiger tail banding") (see Fig. 69.24). Light microscopic findings include an irregular contour, trichoschisis (transverse fractures through the shafts) and, sometimes, trichorrhexis nodosa-like features. Hair shafts are flattened and may fold like a ribbon. There is also a reduction in cysteine-rich matrix proteins, resulting in defective cross-linking of the intermediate keratin filaments and a low sulfur content within the hair shaft. This defect may also account for the brittle nails and the ichthyosis seen in TTD.

Intellectual impairment: This ranges from mild to severe.

Decreased fertility: This has been reported in patients of both sexes, but is not a prominent feature.

Short stature: Growth retardation is present to a varying degree.

Other manifestations include a characteristic facies with a receding chin and protruding ears, sideroblastic anemia, eosinophilia, and hepatic angioendotheliomas.

Treatment

No specific treatment is available.

Photosensitivity Due to Chromosomal Instability

Bloom syndrome

Synonym: ■ Congenital telangiectatic erythema

Introduction and history

Bloom syndrome is a rare autosomal recessive genetic disorder (see Table 87.4). The Bloom Syndrome Registry maintains a database and provides clinical information for patients with this syndrome[47]. The condition was first reported by David Bloom, an American dermatologist, in 1954.

Epidemiology

Bloom syndrome was initially described as occurring most frequently amongst Ashkenazi Jews. However, when 265 patients in the Bloom Syndrome Registry were reviewed, three-quarters were not Jewish[47].

Pathogenesis

Bloom syndrome is due to mutations in *BLM*, a gene that encodes for the DNA helicase RECQL3[47,48]. The RECQ family consists of five DNA helicases. They are highly conserved throughout evolution and are critical for maintenance of genomic stability. Mutations in *BLM* result in an increased susceptibility to cancer development[49].

Clinical features

Beginning within the first few weeks of life, patients typically develop erythema and telangiectasias of the malar areas and occasionally the dorsal aspects of the hands and forearms. Blisters on the lower lip may also occur. In addition, café-au-lait macules with adjacent areas of hypopigmentation are commonly seen. The action spectrum for the photoexacerbated erythema remains unclear. Growth delay and short stature with a disproportionately small head are usually the most common reasons parents seek medical care (see Table 87.4)[47].

Treatment

Symptomatic management and photoprotection are the only treatment strategies.

Rothmund–Thomson syndrome

Synonym: ■ Poikiloderma congenitale

Introduction and history

Rothmund–Thomson syndrome is a rare entity with autosomal recessive inheritance. To date, over 300 cases have been reported in the English literature[50] (see Table 87.4). In 1868, the disorder was first recognized by Auguste Rothmund, a German ophthalmologist. Sydney Thomson, a British dermatologist, then described a similar entity in 1923. In 1957, William Taylor proposed the eponym Rothmund–Thomson syndrome.

Epidemiology

Patients have been reported worldwide.

Pathogenesis
Rothmund–Thomson syndrome is due to mutations in *ANAPC1* (type 1), whose protein product mediates ubiquitination and controls progression through mitosis and G1 of the cell cycle, or *RECQL4* (type 2), which encodes a DNA helicase. As in Bloom syndrome, helicase dysfunction in type 2 Rothmund–Thomson syndrome results in an increased susceptibility to cancer[51].

Clinical features
Patients typically present during the first few months of life with photodistributed erythema, edema, and vesicles of the cheeks and face, which may extend to involve the buttocks and extremities. Over months to years, poikiloderma develops (see Fig. 63.12)[50,51]. Other features are summarized in Table 87.4 and Table 63.9.

Differential diagnosis
In addition to the entities listed in Table 87.4, the differential diagnosis includes hereditary benign telangiectasia and poikiloderma with neutropenia. The latter is a rare autosomal recessive disorder (~30 patients reported to date) due to mutations in *USB1*. Its protein product, U6 SnRNA biogenesis phosphodiesterase 1, is thought to interact with RECQL4 via SMAD4 proteins, thereby accounting for the clinical overlap with Rothmund–Thomson syndrome[52].

Treatment
Management includes regular surveillance for cancer and symptomatic treatment.

Chemical- and Drug-Induced Photosensitivity

Key features
- *Phototoxicity* is characterized by an exaggerated sunburn-like reaction, usually caused by medications
- *Photoallergy* presents with eczematous lesions, most commonly related to topical photoallergens
- The cutaneous porphyrias are an example of phototoxicity induced by endogenous agents
- Management includes identification and avoidance of the offending agent, in addition to photoprotection.

Exogenous photosensitivity
Introduction and history
Photosensitivity induced by exogenous agents can be divided into phototoxicity and photoallergy (Table 87.5). *Phototoxicity* is the result of direct tissue and cellular injury following UVR-induced activation of a phototoxic agent; theoretically, phototoxicity can be induced in any individual. In contrast, *photoallergy* is a delayed-type hypersensitivity response consisting of a sensitization phase, an incubation period of 7 to 10 days (following the first exposure), and a clinical elicitation reaction with any subsequent challenge; only immunologically sensitized individuals can develop photoallergy.

Phototoxic agents have been used as medications from as early as 4000 BCE, with the inhabitants of Mesopotamia (and later the Indians and Egyptians) employing plant-derived psoralens for the treatment of leukoderma. In 1913, Meyer-Betz demonstrated hematoporphyrin-induced phototoxicity on himself, while the current method of PUVA therapy was introduced in the 1970s. Photoallergy was first recognized in 1939 based on a classic study of sulfanilamide by Epstein.

Epidemiology
While the exact prevalences of phototoxicity and photoallergy in the general population are unknown, their frequency in photodermatology referral centers has ranged from 3% to 16% for phototoxicity and 1% to 8% for photoallergy. Both are more common in White as compared to Black individuals[3,53,54].

Pathogenesis
The pathogenesis of phototoxicity involves the generation of free oxygen radicals, superoxide anions, hydroxyl radicals and singlet oxygen, which leads to a host of cytotoxic tissue effects. Other mechanisms of damage include the generation of stable photoproducts (e.g. chlorpromazine, tetracyclines), the formation of photoadducts (e.g. psoralens), and the recruitment of inflammatory mediators (e.g. porphyrins, demeclocycline)[55].

The pathogenesis of photoallergy is identical to that of allergic contact dermatitis, with the exception of the requirement for the presence of UVR to induce photoallergen formation.

COMMON PHOTOTOXIC AND PHOTOALLERGIC AGENTS

Common phototoxic agents	Common photoallergic agents

• Antiarrhythmics
  • Amiodarone
  • Quinidine
• Anti-fibrotic agents
  • Pirfenidone
• Calcium channel blockers
  • Diltiazem
• Diuretics
  • Furosemide
  • Thiazides
• Nonsteroidal anti-inflammatory drugs
  • Nabumetone
  • Naproxen
  • Piroxicam
• Phenothiazines
  • Chlorpromazine
  • Prochlorperazine
• Photodynamic therapy agents
  • Aminolevulinic acid
  • Methyl aminolevulinate
• Psoralens (oral or topical)
  • 5-Methoxypsoralen
  • 8-Methoxypsoralen
  • 4,5′,8-Trimethylpsoralen
• Quinolones
  • Ciprofloxacin
  • Lomefloxacin
  • Nalidixic acid
  • Sparfloxacin
• St. John's wort
  • Hypericin
• Sulfonamides
• Sulfonylureas
• Tar (topical)
• Targeted therapies
  • BRAF inhibitors (e.g. vemurafenib)
  • Anti-CCR4 antibody (mogamulizumab)
  • EGFR inhibitors
  • Avapritinib
  • Enzalutamide
• Tetracyclines
  • Doxycycline
  • Demeclocycline
• Triazole antifungals
  • Voriconazole
	Topical agents:
	• Sunscreens: active UV absorbers (e.g. oxybenzone [benzophenone-3], octocrylene)
	• Fragrances
	  • 6-Methylcoumarin
	  • Musk ambrette
	  • Sandalwood oil
	• Antimicrobial agents
	  • Bithionol
	  • Chlorhexidine
	  • Fenticlor
	  • Hexachlorophene
	• Nonsteroidal anti-inflammatory drugs
	  • Diclofenac
	  • Etofenamate (outside US)
	  • Ketoprofen
	• Phenothiazines
	  • Chlorpromazine
	  • Promethazine
	• **Systemic agents:**
	• Antiarrhythmics
	  • Quinidine
	• Antimalarials
	  • Quinine
	• Antifungals
	  • Griseofulvin
	• Antimicrobials
	  • Quinolones (e.g. enoxacin, lomefloxacin)
	  • Sulfonamides
	• Nonsteroidal anti-inflammatory drugs
	  • Ketoprofen
	  • Piroxicam*

*Often have positive patch test to thimerosal.	

Table 87.5 Common phototoxic and photoallergic agents. EGFR, epidermal growth factor receptor; UV, ultraviolet.

Clinical features
Phototoxicity
Following cutaneous or systemic exposure to a phototoxic agent *and* appropriate UVR, phototoxicity develops within hours. For the vast majority of such agents, the action spectrum falls within UVA[56]. Erythema and edema as well as burning and stinging sensations characterize the initial presentation, with vesicles and bullae seen in severely affected patients. Phototoxic reactions due to oral medications resemble an exaggerated sunburn. These reactions then resolve spontaneously with desquamation and hyperpigmentation once the photosensitizer or UVR is avoided[56].

Other less common manifestations of phototoxicity include pseudoporphyria (frequently caused by nonsteroidal anti-inflammatory drugs [NSAIDs], especially naproxen), photo-onycholysis (reported with

Fig. 87.18 Exogenous drug-induced photosensitivity and hyperpigmentation. Gray–brown patches involving the sun-exposed skin of a patient receiving diltiazem.

tetracyclines and psoralens), slate-gray hyperpigmentation (reported with amiodarone, tricyclic antidepressants, and diltiazem) (Fig. 87.18), lichenoid eruptions (seen with quinine and quinidine), and sensations of burning or pain (amiodarone). In a systematic review of phototoxicity due to oral agents, evidence was strongest for vemurafenib, NSAIDs, and antibiotics (fluoroquinolones and tetracylines)[57]. The medications most commonly associated with phototoxicity are listed in Table 87.5.

5-Fluorouracil (5-FU), methotrexate, and retinoids, three commonly used medications in dermatology, have also been associated with photosensitivity reactions; however, none is typically associated with classic phototoxicity or photoallergy. Exacerbation of 5-FU-induced inflammation by UVR usually occurs in sites with actinic keratoses. The administration of methotrexate can cause a recurrence ("recall") of previous UVR-induced erythema. However, phototesting in patients taking methotrexate has been normal, and the mechanism for this "recall" reaction remains unclear. Phototesting in patients taking isotretinoin or acitretin, or who apply topical tretinoin, is also usually normal. The propensity for these patients to develop UVR-induced erythema is most likely due to retinoid-induced thinning of the stratum corneum.

Phytophotodermatitis is another phototoxic reaction, with linear streaks of erythema occurring a day or so after skin contact with plants containing furocoumarins plus subsequent exposure to UVA in sunlight. Linear postinflammatory hyperpigmentation is a classic finding. Plants capable of inducing phytophotodermatitis include yarrow, parsley, celery, lime, and fig (see Ch. 17). Therefore, this condition most commonly occurs in individuals whose outdoor activities expose them to such plants, such as vegetable harvesters and bartenders who mix drinks outdoors. Roofers and road workers occasionally develop phototoxicity secondary to exposure to tar and concomitant UVA from sunlight.

St John's wort (*Hypericum perforatum*), used in non-traditional medicine to treat a variety of ailments including depression, contains hypericin, another known phototoxic agent. Voriconazole is often prescribed for months or even years in immunocompromised hosts as a prophylactic systemic antifungal agent. This can cause phototoxic reactions, actinic cheilitis, and lentigines, as well as an increased risk for developing large hypertrophic actinic keratoses, aggressive cutaneous squamous cell carcinomas, and cutaneous melanoma. There are alternatives for voriconazole, e.g. posaconazole, that are not associated with phototoxicity. Vemurafenib, a selective BRAF inhibitor, has been shown to be phototoxic with an action spectrum in the UVA range[58].

Photoallergy

In previously sensitized individuals, exposure to photoallergens and sunlight results in the development of a pruritic eczematous eruption. In more severely affected patients, vesicles and bullae may develop, though less commonly than in phototoxic reactions. While phototoxic reactions usually resemble sunburns and photoallergic reactions often resemble allergic contact dermatitis, these two reaction patterns may not always be easily distinguishable by morphology alone[56].

In the UK and the US, sunscreen agents (especially benzophenone-3 [oxybenzone]) were the most common causes of photoallergy[59]. However, the overall prevalence of photoallergy amongst sunscreen users is very low. In Europe, topical NSAIDs, especially ketoprofen and etofenamate, were the most common cause (see Table 87.5)[60]. Photoallergy can generally be confirmed by photopatch testing, where duplicate sets of photoallergens are placed on the patient's back and only one set is irradiated with UVA (Table 87.6). The interpretation of results from such testing is shown in Fig. 87.19.

Pathology

Phototoxicity is characterized by scattered necrotic keratinocytes ("sunburn cells") and a superficial dermal infiltrate of primarily lymphocytes and neutrophils. In contrast, photoallergy is characterized by epidermal spongiosis plus a superficial dermal lymphohistiocytic infiltrate, indistinguishable from other causes of spongiotic dermatitis.

Differential diagnosis

Inflammatory phototoxic reactions should be distinguished from ordinary sunburn, which requires more UVR exposure, and LE (see Table 87.3). The differential diagnosis of photoallergic reactions includes all other forms of dermatitis that can involve sun-exposed areas, particularly airborne contact dermatitis and atopic dermatitis. In airborne contact dermatitis, all exposed sites can be involved, including the upper eyelids, submental region, and postauricular areas; these sites are frequently spared in photoallergic contact dermatitis (see Fig. 87.15).

Treatment

The identification and avoidance of the offending agent are of prime importance. Sometimes it is not possible to discontinue the culprit medication and strict photoprotection (UVB and UVA) is required. For phototoxic and photoallergic reactions, analgesia may be helpful. Topical corticosteroids, and, for severe flares, short courses of systemic corticosteroids, can be used for photoallergic dermatitis. Occasionally, evening dosing of a phototoxic drug can be implemented so that peak systemic levels occur during the night.

Endogenous photosensitivity

The cutaneous porphyrias, discussed in Chapter 49, represent the most obvious examples of photosensitivity induced by endogenous agents. The mechanism of porphyrin-induced phototoxicity involves reactive oxygen species, the complement system, mast cells, and neutrophils (Fig. 87.20).

Smith–Lemli–Opitz syndrome is an autosomal recessive disorder with an early onset of photosensitivity to UVA in 55% to 75% of patients[61]. Its frequency is 1 in 40 000 conceptions. Mutations in *DHCR7*, which encodes 7-dehydrocholesterol reductase, result in an accumulation of 7-dehydrocholesterol. The mechanism of the photosensitivity is unknown. Pellagra, which is due to niacin deficiency, is also associated with photosensitivity but its pathogenesis remains unclear as well[62].

Photoaggravated Dermatoses

Key features

- The primary underlying disease is not caused, but rather exacerbated, by sun exposure, sometimes severely
- Phototesting is usually normal, with lupus erythematosus being the exception
- Therapy focuses on treatment of the underlying disease

Introduction and history

A number of skin diseases that are not directly caused by UVR exposure may, in some patients, be worsened by it (Table 87.7). The reasons for

COMMONLY EMPLOYED PHOTOPATCH TEST SERIES			
Class of photoallergen	**Photoallergen**	**North American photopatch series**	**European photopatch baseline series**
		Conc/vehicle	
Sunscreen ingredients	Ethylhexyl methoxycinnamate (octinoxate, Parsol MCX)	7.5% pet	10% pet

such aggravation, however, have been poorly studied, with the exception of lupus erythematosus (LE) (see Ch. 41)[63].

Epidemiology

Photoaggravated dermatoses occur worldwide[63]. In photodermatology referral centers, as a group, the prevalence ranges from 15% to 25%[3,54].

Clinical features

The primary dermatosis may be mildly or severely exacerbated by UVR exposure (Fig. 87.21), usually within minutes to hours, but sometimes a day or more later. The UVR-exacerbated eruption is usually limited to sites characteristically involved by the underlying condition. Less often the flare involves all sun-exposed skin.

Pathology

The histology is that of the underlying dermatosis.

Differential diagnosis

In general, photoaggravated dermatoses are recognized by the features of the underlying skin disease (see Table 87.7). The differential diagnosis often includes PMLE, although PMLE is typically papular and mildly pruritic, has negative lupus serology, and can be induced by

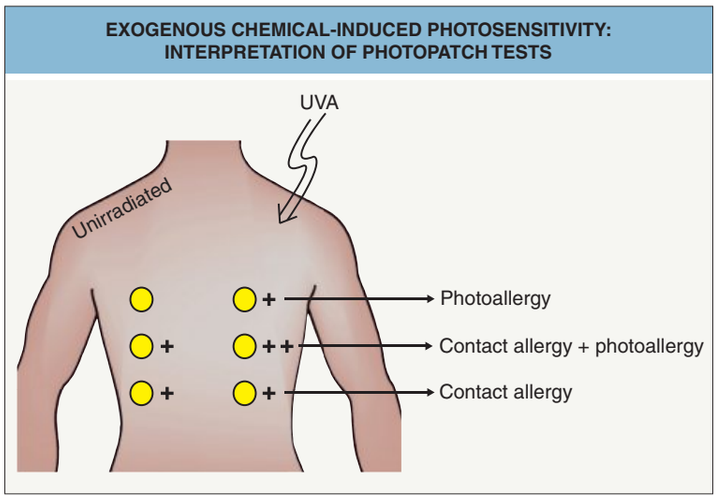

Fig. 87.19 Exogenous chemical-induced photosensitivity: interpretation of photopatch tests. This schematic demonstrates the interpretation of photopatch tests. The UVA dose is usually the lower of: 5 J/cm^2 or 50% of the MED to UVA.

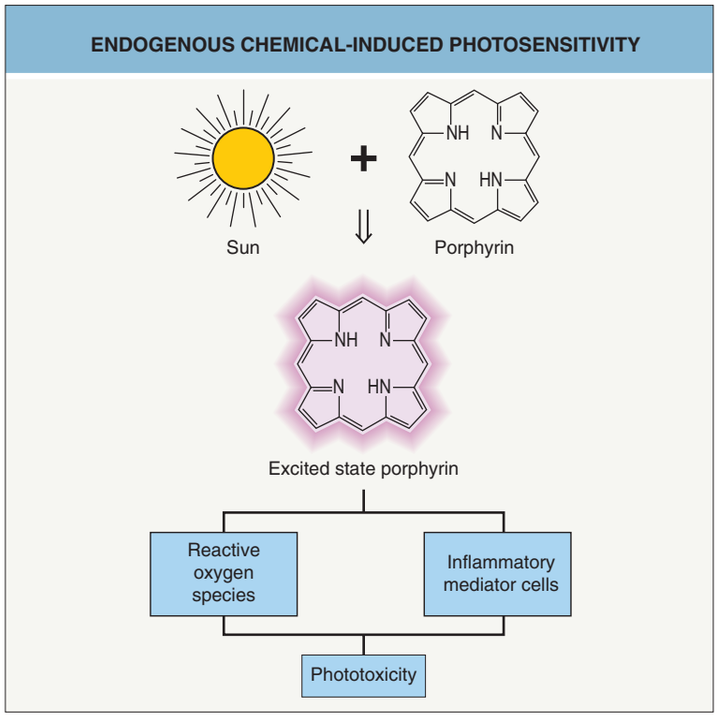

Fig. 87.20 Endogenous chemical-induced photosensitivity. The pathophysiology of phototoxicity as seen in the cutaneous porphyrias is shown.

PHOTOAGGRAVATED DERMATOSES
• Acne vulgaris
• Atopic dermatitis
• Bullous pemphigoid
• Carcinoid syndrome
• Cutaneous T cell lymphoma (Sézary syndrome)
• Darier disease (keratosis follicularis)
• Dermatomyositis
• Disseminated superficial actinic porokeratosis
• Erythema multiforme
• Hailey–Hailey disease (familial benign chronic pemphigus)
• Hartnup syndrome
• Lichen planus and lichenoid drug eruptions
• Lupus erythematosus
• Pellagra
• Pemphigus, including pemphigus foliaceus (erythematosus)
• Pityriasis rubra pilaris
• Psoriasis (in some patients)
• Reticular erythematous mucinosis (REM)
• Rosacea
• Seborrheic dermatitis
• Grover disease (transient acantholytic dermatosis)
• Viral infections, including herpes simplex, exanthems

Table 87.7 Photoaggravated dermatoses. This often applies to a subset of patients.

Fig. 87.21 Photoaggravated atopic dermatitis induced by the solar simulator. This was the appearance 24 hours after irradiation. *Courtesy John L.M. Hawk, MD.*

photoprovocation tests (~80% of patients). However, the latter requires repeated daily UVR exposures and is therefore not commonly done. It is important to note that PMLE may sometimes coexist with photoaggravated dermatoses, in particular LE. Photoaggravated atopic dermatitis is characterized by a confirmed history of atopic dermatitis plus photosensivity and positive phototest results.

Treatment

Treatment should focus on the underlying disorder and photoprotection. Topical corticosteroids and low-dose NB-UVB may sometimes lead to improvement. Rarely, short courses of oral corticosteroids are required.

Grover Disease

Grover disease, also known as transient (and later persistent) acantholytic dermatosis, most commonly occurs in White men over 40 years of age who have significant photodamage. Some patients flare in the summer while others flare during the winter. Pruritic, often crusted, skin-colored to pink papules and papulovesicles appear on the trunk, primarily in sun-exposed sites (Fig. 87.22). In addition to UV exposure, exacerbating factors include sweating, heat, and occasionally, friction and ionizing radiation. While lesions may resolve over weeks to months, they commonly recur.

Histologically, four major patterns are seen (sometimes in combination): Darier disease-like, Hailey–Hailey disease-like, pemphigus vulgaris- or foliaceus-like, and spongiosis with acantholysis (Fig. 87.23). Rarely, there may be acantholytic cells that appear multinucleated and this pattern has been referred to as pseudoherpetic. The differential diagnosis of Grover disease includes folliculitis, miliaria rubra, arthropod bites, multiple lichenoid keratoses, early pemphigus foliaceus, and when chronic, Darier disease (see Fig. 59.4). Except for the latter two entities, histologic examination allows distinction; the focal nature of the histologic findings, negative immunofluorescent microscopy, and lack of additional clinical features (e.g. palmar keratoses, longitudinal erythronychia with notching) point to the diagnosis of Grover disease. Therapy includes topical agents (e.g. corticosteroids, pramoxine, calcineurin inhibitors, vitamin D analogues) and oral antihistamines, in addition to avoidance of exacerbating factors. Oral retinoids, PUVA, and UVA1 have also been tried with some success, and most recently, dupilumab.

Bolognia, MD; C, Courtesy Kalman Watsky, MD.*

NORMAL CUTANEOUS EFFECTS OF UVR AND VISIBLE LIGHT EXPOSURE

Key features

- Acute and subacute effects of UVR exposure include acute inflammatory erythema (sunburn), pigment darkening, delayed pigmentation, epidermal hyperplasia, immunologic changes, and vitamin D_3 synthesis
- Visible light can induce pigmentation in individuals with darker skin phototypes and immediate erythema in fair-skinned individuals
- Chronic effects include photoaging and photocarcinogenesis (keratinocyte carcinomas and melanoma)

This discussion is limited to the clinical aspects of UVR and visible light as the underlying mechanisms are reviewed in Chapter 86.

Acute and Subacute Effects

These effects are primarily the result of UVR absorption by DNA and RNA and the possible interaction of visible light with opsin-3 on melanocytes in darkly pigmented individuals.

Acute inflammatory erythema (sunburn)

Excessive UVR exposure leads to the acute inflammatory reaction of sunburn. In terrestrial sunlight, wavelengths around 300 nm are the most erythemogenic. The lowest dose capable of inducing erythema (MED) in individuals with skin phototype I is about 30 mJ/cm^2 (300 J/m^2) for broadband UVB (280–320 nm), and 30 J/cm^2 (300 kJ/m^2) for broadband UVA (320–400 nm). UVB-induced sunburn pain is thought to result from activation of epidermal TRPV4 ion channels.

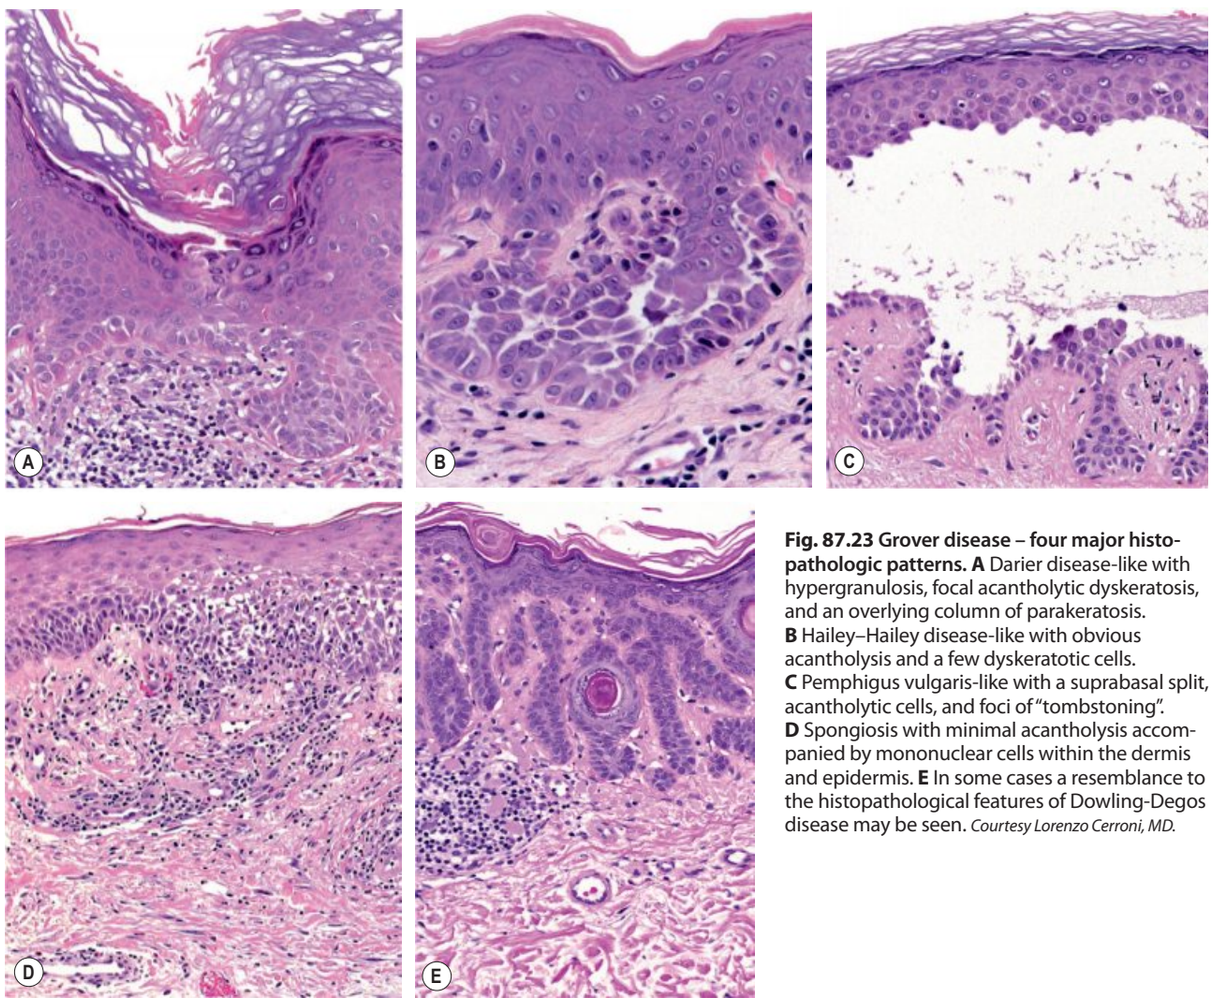

Fig. 87.23 Grover disease – four major histopathologic patterns. A Darier disease-like with hypergranulosis, focal acantholytic dyskeratosis, and an overlying column of parakeratosis. **B** Hailey–Hailey disease-like with obvious acantholysis and a few dyskeratotic cells. **C** Pemphigus vulgaris-like with a suprabasal split, acantholytic cells, and foci of "tombstoning". **D** Spongiosis with minimal acantholysis accompanied by mononuclear cells within the dermis and epidermis. **E** In some cases a resemblance to the histopathological features of Dowling-Degos disease may be seen. *Courtesy Lorenzo Cerroni, MD.*

In a few individuals, brief immediate erythema occurs within seconds of UVR exposure and lasts for minutes. Otherwise, the typical delayed bright red appearance of a sunburn develops confluently on all sufficiently exposed skin, beginning within 30 minutes to 8 hours, peaking at 12 to 24 hours and diminishing over hours to days in the case of UVB exposure. With exposure to UVA alone, however, the reaction is deeper red in color and is usually more persistent. After excessive exposure, edema and blistering may occur, which if widespread, may lead to systemic symptoms such as chills and malaise. Such reactions are generally followed by pruritus and desquamation over a period of days to weeks. In individuals with lighter skin phototypes, visible light has been shown to produce immediate erythema[64].

Photoprotection is the best preventive measure. In the case of excessive UVR exposure, symptomatic treatment is instituted as soon as possible after exposure. This includes increased fluid intake, emollient creams or lotions, topical corticosteroids, and oral nonsteroidal or steroidal anti-inflammatory agents. Of note, in a placebo-controlled trial involving 20 healthy adults, 200 000 IU of vitamin D_3 administered one hour after an experimental sunburn led to a reduced expression of pro-inflammatory mediators (e.g. TNF), reduced skin redness, and increased expression of the anti-inflammatory mediator arginase-1 in those with higher serum vitamin D_3 levels[65].

Pigment darkening and delayed tanning

Immediate, often grayish, darkening of irradiated skin that lasts for 10–20 minutes may occur within seconds of ~2–12 J/cm^2 of UVA irradiation; however, this response can last for up to 3 months[1]. In darkly pigmented individuals, the blue spectrum of visible light induces similar changes, possibly due to absorption of the blue light by opsin-3, a receptor on the surface of their melanocytes (see above)[66]. Transient pigmentary changes, known as *immediate pigment darkening*, result from photo-oxidative darkening and the cellular redistribution of melanin within epidermal melanocytes. Pigmentation that persists for more than 2 hours after irradiation is referred to as *persistent pigment darkening*; it is brownish in color, lasts for up to 24 hours, and is also due to oxidation of pre-existing melanin. Persistent pigment darkening then blends with *delayed pigmentation*, or *tanning*, which develops in genetically competent individuals over hours to days and persists for weeks to months following ~40 mJ/cm^2 of broadband UVB (slightly higher than the MED, particularly in fair-skinned persons), and 15–20 J/cm^2 of broadband UVA (a little less than the MED). As a result of delayed tanning, further sunburning sensitivity is mildly decreased by a factor of two to four.

Epidermal hyperplasia

Hyperplasia lasting a month or so occurs over a period of hours to days following UVB, but generally not UVA, exposure. This results from a markedly increased cellular mitotic rate and DNA, RNA and protein synthesis, following several initial hours of inactivity. Hyperplasia of the viable epidermis and thickening of the stratum corneum result in several-fold protection against later sunburning; this adds to, and may exceed, that simultaneously provided by delayed tanning, particularly in fair-skinned individuals. UV-induced epidermal hyperplasia is generally neither visible nor apparent by palpation.

Immunologic changes

Exposure to UVB and UVA radiation alters epidermal Langerhans cell function, generates suppressor T lymphocytes, and changes the cutaneous cytokine profile. This topic is discussed in greater detail in Chapter 86.

Vitamin D_3 synthesis

UVB (maximum: 300 ± 5 nm) irradiation quickly converts epidermal 7-dehydrocholesterol into previtamin D_3 (see Fig. 51.11)[67]; the latter then isomerizes to vitamin D_3 (cholecalciferol), which is then converted in the liver to 25-hydroxyvitamin D and subsequently in the kidneys to 1,25-dihydroxyvitamin D, its active form. UVR-induced vitamin D_3 synthesis is maximal at suberythemogenic doses. The action spectrum for vitamin D synthesis is similar to that for DNA damage. Ideally, vitamin D homeostasis is achieved by a combination of incidental outdoor daylight exposure and dietary sources rather than through intentional exposure to sunlight or tanning beds.

Other changes

Occasionally, otherwise healthy individuals who are not on any medications may develop *photo-onycholysis* and increased skin fragility with blistering (*pseudoporphyria*) following intense exposure to sunlight or tanning beds. *Mid-dermal elastolysis* is characterized by patches of finely wrinkled skin and loss of elastic fibers in the mid-reticular dermis (see Ch. 99); its onset is frequently associated with intense UVR exposure. *Brachioradial pruritus*, characterized by primary pruritus of the outer arm, is associated with cervical radiculopathy; however, in many patients, UVR may act as a trigger of the symptoms (see Ch. 6).

Chronic Effects

Photoaging in fair-skinned patients

Photoaging refers to cutaneous changes secondary to long-term exposure to sunlight (Table 87.8). Characteristic clinical manifestations are outlined below.

Solar (actinic) elastosis develops in chronically sun-exposed areas and presents as thickened skin with a yellow hue. It is most commonly seen on the face, neck, and extensor aspect of the mid arms (Fig. 87.24A). More widespread involvement can be seen in those from tropical climates, especially when there is minimal constitutive pigmentation (Fig. 87.24B). Histologically, a marked increase in abnormal, altered dermal elastic fibers is seen. *Cutis rhomboidalis nuchae* refers to similar changes occurring on the posterior neck (Fig. 87.24C); it is characterized by deep furrowing associated with a leathery texture.

A *solar lentigo* is a light brown to dark brown, even-colored or reticulated macule or patch that occurs in sun-exposed areas, most often as multiple lentigines. The dorsal aspects of the hands, extensor forearms, upper trunk, and face are the most commonly affected sites (see Ch. 109). An *ephelide*, also known as a freckle, presents as a light red–brown to medium brown macule, usually <6 mm in diameter. Such lesions occur primarily in sun-exposed areas, are usually clustered, and are more apparent after sun exposure (see Ch. 112). Histologically, a solar lentigo is associated with elongation and hyperpigmentation of the rete ridges and a mild increase in the number of melanocytes, while

CUTANEOUS SIGNS OF SIGNIFICANT PHOTODAMAGE
Common
• Solar elastosis (Fig. 87.24A,B) • Cutis rhomboidalis nuchae (Fig. 87.24C) • Wrinkling (coarse > fine) • Favre–Racouchot syndrome (nodular elastosis with cysts and comedones) (Fig. 87.24E) • Poikiloderma of Civatte ("red neck"; Fig. 87.24D) • Solar purpura and hemosiderin deposition (Fig. 87.24F,G) • Fragility and skin tears* (Fig. 87.24H) • Pseudoscars (Fig. 87.24H) • Erosive pustular dermatosis (Fig. 87.24I; see Ch. 25) • Dyschromia, including idiopathic guttate hypomelanosis • Solar lentigines, ephelides • Weathering nodules
Uncommon
• Acquired elastotic hemangioma • Adult colloid milium • Elastoma of Dubreuilh • Elastotic nodules of the ear • Keratoelastoidosis marginalis (Fig. 87.24J) • Solar elastotic bands
Neoplasms
• Actinic keratoses • Squamous cell carcinoma • Basal cell carcinoma • Cutaneous melanoma, including lentigo maligna • Merkel cell carcinoma
*Classification scheme – tear can (1a) or cannot (2a) be realigned to the normal anatomic location and flap color is *not* pale, dusky, or darkened; tear can (1b) or cannot (2b) be realigned to the normal anatomic location and flap color is pale, dusky or darkened; skin flap is absent (3).

Table 87.8 Cutaneous signs of significant photodamage.

Fig. 87.24 Cutaneous signs of significant photoaging. A Solar elastosis of the neck and V of the chest; note the thickening and furrowing of the skin. **B** Solar elastosis of the neck extending onto the back in a patient with oculocutaneous albinism from sub-Saharan Africa. **C** Cutis rhomboidalis nuchae with deep furrowing of the posterior neck. **D** Poikiloderma of Civatte with sparing of the submental region and follicular skin. **E** Multiple open comedones of the periorbital region in Favre–Racouchot syndrome. **F, G** Solar (actinic) purpura and residual discoloration due to hemosiderin. There is also evidence of skin fragility. **H** Skin tear due to fragility of atrophic photodamaged skin (dermatoporosis) and pseudoscars from previous tears. **I** Erosive pustular dermatosis of the bald scalp. **J** Keratoelastoidosis marginalis with keratotic papules in a marginal distribution on the medial aspects of the forefingers. **K** Given her age, this 93-year-old woman has relatively fine wrinkling of her face, in addition to scattered seborrheic keratoses. *A, Courtesy Kalman Watsky, MD; B, Courtesy Rosemarie Moser, MD; D, G, H, Courtesy Jean L. Bolognia, MD; I, Courtesy Harvey Lui, MD; J, Courtesy Karynne O. Duncan, MD.*

hyperpigmentation of the basal layer without elongation of the rete ridges is observed in an ephelide.

Idiopathic guttate hypomelanosis favors chronically sun-exposed sites of the extremities, especially the forearms and shins, but typically spares the face. Well-demarcated hypopigmented macules are typically 3–10 mm in diameter (see Ch. 66).

Poikiloderma of Civatte refers to reticulated red to red–brown patches composed of telangiectasias that spare perifollicular skin. It is most commonly observed on the lateral aspects of the neck in fair-skinned individuals with significant cumulative sun exposure (Fig. 87.24D). Characteristically, there is sparing of the central submental region. Mild atrophy and hyperpigmentation are sometimes present.

Histologically, telangiectasias, mild epidermal atrophy, melanophages, and dermal solar elastosis are observed.

In *Favre–Racouchot syndrome*, multiple large open comedones develop on the lateral and inferior aspects of the periorbital area (Fig. 87.24E), in association with marked solar elastosis of the surrounding skin. In some patients, cigarette smoking may be a cofactor. Histologically, there are dilated pilosebaceous openings and cyst-like spaces filled with horny material in addition to marked solar elastosis.

Solar purpura occurs in areas of cumulative photodamage that are subject to trauma, e.g. dorsal hands, extensor forearms, shins (Fig. 87.24F,G). As lesions resolve over weeks, a brown discoloration due to hemosiderin may appear. It is often accompanied by skin fragility (Fig. 87.24H).

Adult colloid milium is characterized by translucent yellow papules that measure 1–3 mm in diameter. There are usually numerous, closely spaced lesions in chronically sun-exposed sites, especially the neck, face and dorsal hands. Histologically, homogeneous masses of PAS-positive, diastase-resistant colloid are present in the papillary dermis; positive staining with thioflavin T and Congo red has been reported in some cases. The exact nature of the colloid deposits is still debated, but it has been suggested that, at least in some forms, they may represent elastin degeneration.

Erosive pustular dermatosis of the scalp classically presents as sterile pustules, keratotic crusts, erosions, and mild inflammation arising within the atrophic, photodamaged skin of a bald scalp[68] (Fig. 87.24I). However, similar clinical findings can occur in other sites with atrophic or fragile skin, e.g. the lower extremities of older patients with venous hypertension, sites of injury in neonates (see Ch. 25).

Acquired elastotic hemangiomas present as erythematous plaques within actinically damaged skin, usually on the neck or upper extremities. Histologically, there is a horizontal proliferation of capillaries in the upper reticular dermis and prominent solar elastosis.

Photoaging in patients with dark skin phototypes

Photoaging is much less pronounced and has a delayed onset in individuals with more darkly pigmented skin[69] (Fig. 87.24K). Small seborrheic keratoses, melasma, and mottled hyperpigmentation are common signs of photoaging in East Asians, such as Chinese, Japanese, Koreans, and Filipinas; in addition, any wrinkles are fine and do not usually appear before 50 years of age. South Asians, such as Indians, Pakistanis, Sri Lankans and Bangladeshis, often have darker skin than East Asians and dyspigmentation and fine wrinkles are the primary signs of photoaging. Lightly pigmented Latinos have changes similar to those seen in White individuals, while those with brown skin photoage in a manner similar to that seen in South Asians. Black-skinned individuals, including African-Americans, Afro-Caribbeans and people from Africa, have a wide range of skin phototypes, from III to VI. Dyspigmentation is common and fine wrinkles appear late in life.

Photocarcinogenesis

Chronic sun exposure has been associated with the development of actinic keratoses (AKs), SCC, BCC and melanoma, in particular lentigo maligna. Epidemiologic studies have shown that SCCs tend to develop within chronically sun-exposed areas in fair-skinned individuals; e.g. people who migrate to Australia early in life have a higher risk of developing SCC than immigrants who arrive when older. Furthermore, the incidence of BCC is higher in native-born Australians than immigrants, and a statistically significant association between *intermittent* sun exposure and the risk of BCC has also been reported. These findings are supported by the observation that the use of sunscreens led to a decrease in the development of AKs, SCC, melanoma, and to a lesser extent, BCC[70]. Exposure to tanning beds is associated with an increased risk for developing cutaneous melanoma as well as SCC and BCC.

In studies of populations in which there was a greater proportion of individuals with darkly pigmented skin, a higher melanoma incidence associated with an increased UV index and lower latitude was only seen in non-Latino White populations, but not in Black or Latino populations[69,71].

The skin is our primary interface with the environment. Amongst Earth's creatures, humans are unique in their ability to manipulate the environment by manufacturing clothing, shelter, and heating or cooling devices to allow them to live in a variety of environmental extremes. Despite technologic advances that have allowed humans to live, work and play in most of the environments on this planet, deliberate or inadvertent exposure to those environments may subject individuals to injury. The following discussion will focus upon chemical, frictional, traumatic, and water immersion skin injuries, temperature-related skin diseases, electrical burns, cutaneous diseases due to heavy metals, sports-related dermatoses, and skin issues in amputees and instrumental musicians.

INJURY DUE TO HEAT EXPOSURE

Heat-Related Illnesses and Thermal Burns

Synonyms/variants: ■ Heat-related illnesses: heat cramps, heat syncope, heat edema, heat exhaustion, heat stroke ■ Thermal burns: burns

Key features

- Heat-related illnesses occur when the body's thermoregulatory mechanisms fail; correction of fluid and electrolyte balance is critical in their treatment
- Management of thermal burns requires assessment of burn depth (i.e. first, second, or third degree) and body surface area involved
- Burn treatment includes prevention of infection, serial excisions, and skin substitutes

Introduction

Humans, like all other mammals and all birds, are homeothermic organisms that maintain their core body temperature within a narrow range by varying cutaneous and visceral blood flow. Normal core body temperatures vary between 36°C and 37.5°C (96.8°F and 99.5°F). At normal core temperature, cutaneous blood flow is about 4% of cardiac output or 250 ml/min. Modulation of cutaneous blood flow is performed by the hypothalamus via a delicate balancing act between heat retention and loss. Cutaneous, muscle, and spinal cord temperature sensors send signals to the preoptic area of the anterior hypothalamus. Communication with the posterior hypothalamus sets up the subconscious thermoregulatory mechanisms of vasomotor control, sweating, and shivering.

When prolonged exposure to a hot environment leads to an increase in core temperature, the subsequent decrease in sympathetic output results in peripheral vasodilation, allowing an increase in cutaneous blood flow of up to 6–8 L/min. Cholinergic output stimulates sweating. These changes allow radiant, conductive, convective, and evaporative heat loss. In contrast, cold temperature exposure leads to increased sympathetic output with peripheral vasoconstriction. Countercurrent heat exchange between parallel arteries and veins further reduces heat loss to the skin, thereby conserving core heat. The behavioral response of shivering generates heat through muscular activity[1].

Pathologic conditions arise when the normal hypothalamic regulatory set point is overcome by extremes of temperature (Table 88.1). The following discussion will explore heat-related illnesses and thermal burns. Heat-induced urticaria is covered in Chapter 18.

History

It has been speculated that King Edward and his armored crusaders lost the final battle of the Holy Land because the Arab horsemen were adapted and dressed appropriately for the severe heat.

Epidemiology

The frequency of heat-related illnesses is unknown, since milder forms resolve with simple measures. Heat-related illness accounted for more than 8000 deaths in the US between 1979 and 1999, and is responsible for ~7% of wilderness deaths. The European heat wave of 2003 contributed to the deaths of about 14 800 individuals in France[1]. In US high school athletes, the incidence of heat-related illness is ~9000 cases annually, with the highest rates during football season and representing the third leading cause of death in this cohort. From 2006 to 2010, five in 10 000 visits to the emergency department were for heat-related illnesses: 75% with heat exhaustion and 5% with heat stroke[2]. Risk factors are listed in Table 88.2.

Burn injuries are far more commonly reported, with more than half a million Americans presenting for medical treatment each year, resulting in 40 000 hospitalizations and >3000 deaths, half of which occur in children[3–5]. The male to female ratio is ~2:1, and the major sources of burns in children are scald, flame, and electrical. Abuse or neglect may account for up to 20% of pediatric burns. Mortality rates have steadily declined due to improved resuscitative and surgical management. In the 1940s, burns in children involving 50% body surface area (BSA) had a 50% survival rate, whereas today, 50% of children with 90% BSA burns survive[4,5].

A unique form of burn injury is that due to fireworks. In the US alone, there were at least 25 000 emergency department visits for injuries due to fireworks between 2006 and 2010. Half of the visits were by individuals <20 years of age, with a predominance of male patients (~75%). The most common injuries were distal extremity burns, followed by ocular injury, open wounds of distal extremities, and ocular burns[6].

Pathogenesis

Athletic activity can generate 800 to 1000 kcal/h of heat for prolonged periods. This results in a 1°C rise in core body temperature every 5 to 8 minutes. The normal thermoregulatory mechanisms dissipate this heat as it is generated. When these regulatory mechanisms fail, heat injury occurs. Heat illnesses are not defined by a specific temperature, but by the abnormal response to heat. Table 88.1 outlines the pathogenesis of heat-related disorders.

HEAT-RELATED ILLNESSES				
Condition	**Core temperature**	**Clinical features**	**Treatment**	**Pathogenesis**
Heat cramps	Normal	Painful spasm in large muscle groups, weakness, fatigue, N/V, **marked sweating**, tachycardia, ↑BP	Fluid and salt replacement	Dilutional hyponatremia due to free water (but not electrolytes) being replaced
Heat syncope	Normal	Nausea, sighing, yawning, restlessness, fainting (brief)	Avoid standing still in heat, flex legs, lie down if prodrome, cool off, replace fluid	Decreased cerebral blood flow due to volume depletion, peripheral vasodilation, and decreased vasomotor tone in poorly acclimatized or elderly individuals
Heat edema	Normal	**Dependent edema** from vasodilatory pooling	None needed (self-limited)	Vasodilatory pooling
Heat exhaustion	Normal to 39°C (102.2°F)	Weakness, dizziness, headache, N/V, irritability, dyspnea/hyperventilation, malaise, myalgias/muscle cramps, tachycardia, orthostatic hypotension, **profuse sweating, piloerection**, impaired judgment, syncope *Hypernatremic* form: thirst, rare cramps *Hyponatremic* form: fatigue, cramps, history of excessive free water intake, altered mental status	Intravenous fluids and electrolytes, sprinkle water and fan or use ice packs, rest, cool environment	Volume and/or salt depletion
Heat stroke	>40°C (104°F)	**Anhidrosis to profuse sweating**, ↓BP, N/V, diarrhea, altered mental status (profound), seizures, coma, cardiac arrhythmias, ↑transaminases, rhabdomyolysis, acute kidney injury, DIC, respiratory alkalosis Poor prognostic indicators: T >42.2°C (108°F); coma >2 h; AST >1000 (day 1)	Rapid lowering of core temperature to 38°C (100.4°F), intravenous hydration, intensive care unit	End result of thermoregulatory failure; volume depletion leads to peripheral vasoconstriction and reduced transfer of heat peripherally; resultant core heating leads to organ failure

Table 88.1 Heat-related illnesses[1,2]. Cutaneous features are indicated in **bold**. AST, aspartate transaminase; BP, blood pressure; DIC, disseminated intravascular coagulation; N/V, nausea and vomiting; T, temperature.

RISK FACTORS FOR HEAT-RELATED ILLNESS	
• Occupational exposure	• Age (elderly, young child)
• Poverty	• Insufficient acclimatization
• Drug and alcohol use, mental illness, dementia	• Obesity, deconditioning, or sedentary lifestyle
• Medications (anticholinergics, phenothiazines, diuretics; see Table 39.9)	
Environmental factors (absence of shelter or shade, high temperatures and/or humidity, lack of access to water)	
Medical conditions	
• Excessive fluid loss (e.g. diarrhea, uncontrolled diabetes mellitus) • Suboptimal sweating (e.g. ectodermal dysplasias; see Tables 39.8 & 39.10) • Excessive sweating (see Tables 39.2, 39.3 and 39.4) • Inadequate fluid intake (see above) • Decreased thirst (e.g. cystic fibrosis) • Abnormal thermoregulation (prior heat illness, malnutrition)	

Table 88.2 Risk factors for heat-related illness[1,2].

Thermal burns occur when skin is exposed to infrared radiation (800 to 170 000 nm) from an external heat source with a temperature exceeding 44°C (111°F). Time and temperature curves have been developed to determine maximum threshold thermal exposure times. Necrosis of the epidermis occurs in about 45 minutes at 47°C (117°F) but in only 1 second at 70°C (158°F). Denaturation and coagulation of cellular proteins occur in thermal injury. Interstitial edema develops from altered osmotic pressure and capillary permeability. Several chemical mediators with vasoactive and tissue-destructive properties are released, including prostaglandins, bradykinin, serotonin, histamine, lipid peroxides, and oxygen radicals[5].

Clinical features

Although heat-related illnesses are not primary skin diseases, they can present with cutaneous findings. Their clinical features are summarized in Table 88.1.

Thermal burns of the skin differ in their clinical presentation, depending upon the depth of injury (Table 88.3)[5,7,8]. Conventional nomenclature categorizes cutaneous burn wounds as *first degree* (superficial; limited to epidermis), *second degree* (partial-thickness), and *third degree* (full-thickness). Second-degree burns are further subdivided into superficial (Fig. 88.1) and deep variants. Burns involving deeper structures such as muscle are sometimes referred to as fourth-degree burns. However, a definitive determination of wound depth may not be possible for the first 24 to 72 hours because of vascular occlusive changes.

At sites where the dermis is thinner (ears, volar forearms, medial thighs, perineum), burns may be deeper than the initial presentation might suggest; this is also the case in the comparatively thinner skin of children and the elderly. Wounds that appear dull red from entrapment of clot (denatured hemoglobin) imply full-thickness injury[7].

The severity of burn injuries is based upon depth and BSA involvement. BSA is estimated in adults by the "rule of nines" (Fig. 88.2). This formula cannot be applied to children, since the head accounts for ~19% BSA in a 2-year-old, 15% in a 7-year-old, and 13% in a 12-year-old. Lund & Browder charts are useful for more accurate assessment of BSA involvement[5,7]. Initial evaluation should address airway and circulatory status; associated inhalation injury is seen in up to 25% of burn patients. Cardiovascular evaluation must address the issue of hypovolemic shock, regardless of burn severity. Urine output must be monitored because of the significant fluid loss and rhabdomyolysis that may compromise renal function[4,5,7].

Pathology

Pathologic features of thermal burns are summarized in Table 88.3.

Differential diagnosis

The differential diagnosis of heat injury is listed in Table 88.1. Although there is considerable overlap in clinical features, an important distinction is the degree of neurologic compromise. The most important diagnostic issue with thermal burns is the depth of the injury (see Table 88.3).

Treatment

Management of heat-related injuries involves removal from the hot environment, rest, rehydration, restoration of electrolyte balance, and evaluation of involved systems (Table 88.1; see Atha[1] for more details).

Initial management of burn victims includes assessment of cardiopulmonary status as well as the extent and depth of the burn. Information regarding resuscitation of burn victims is beyond the scope of this text, but can be found in references 4, 5, and 7. For first- and second-degree burns, the burn wound itself should initially be rinsed with room temperature/cool running water for 20 minutes in order to ease pain, reduce heat, and reduce burn depth[5]. Then the wound should be gently cleansed to remove any foreign material. The next step is prevention of infection, followed by creation of a proper healing environment. Topical

CLINICAL AND PATHOLOGIC FEATURES OF THERMAL BURNS			
Type	**Depth**	**Clinical features**	**Pathology**
First degree	Epidermis only	Pain, tenderness, erythema No blistering Heals without scar	Upper epidermal necrosis
Second degree – superficial	Epidermis and superficial dermis	Severe pain, tenderness, serous or hemorrhagic bullae, deep rubor, erosion, and exudation Heals in 10–21 days with mild but variable scarring	More extensive epidermal necrosis with vertical elongation of keratinocytes Necrotic areas may have serous crust with neutrophils, fibrin, and cellular debris Subepidermal bullae possible
Second degree – deep	Epidermis and most of dermis destroyed, including deep follicular structures	Intense pain but reduced sensation, deep red to pale and speckled in color Serosanguineous bullae and erosions May appear devitalized initially Prolonged healing time Hypertrophic scars and marked wound contracture	Destruction of entire epidermis, dermal collagen, and most of adnexal structures Collagen bundles may be fused, with eosinophilic appearance Thrombosis of deep vessels common Granulation tissue present at junction of normal and injured tissue
Third degree	Full-thickness epidermal and dermal destruction	Dry, hard, charred, non-blanching, hypo- or anesthetic areas of coagulation necrosis Small lesions heal with significant scarring Most require surgical correction	Necrosis of entire epidermis and dermis, with extension into subcutis Inflammatory infiltrate at interface between burned and normal skin When scar forms, it exhibits hyalinized collagen, decreased elastic tissue, and loss of arrector pili muscles

Table 88.3 Clinical and pathologic features of thermal burns[5,7,8].

Fig. 88.1 Thermal burn. This superficial second-degree burn is characterized by bullae that contain serous fluid. *Courtesy Kalman Watsky, MD.*

antimicrobial agents shown to be effective in burn wound care include silver sulfadiazine, mafenide acetate, and silver nitrate. Silver sulfadiazine has gained wide acceptance for both pediatric and adult burn treatment, but it is known to be cytotoxic and percutaneous absorption can lead to leukopenia. Silver sulfadiazine also produces a pseudoeschar that may interfere with burn depth assessment and prolonged application may lead to localized argyria. Some experts therefore prefer mafenide acetate.

While superficial wounds may require minimal additional therapy[4,5,7], deeper burn wounds need more aggressive therapy, with the standard approach being serial excision and autografting (if there are sufficient donor sites). Third-degree burns are excised early, with indeterminate and deep second-degree wounds delayed until maximum depth and extent are known. Biologic dressings (e.g. pig skin, human allograft) were popular for several years, but have been largely displaced due to higher infection risk and poorer healing. Skin substitutes such as acellular human dermal matrix (Alloderm®), bilaminar bovine collagen–shark chondroitin sulfate (Integra® Dermal Regeneration Template), and cultured epithelial autografts are increasingly being utilized[7] (see Ch. 145).

Erythema Ab Igne

Synonyms: ■ Toasted skin syndrome ■ Fire stains

ASSESSING THE EXTENT OF BODY SURFACE AREA (BSA) INVOLVEMENT IN BURN INJURUES: RULE OF NINES

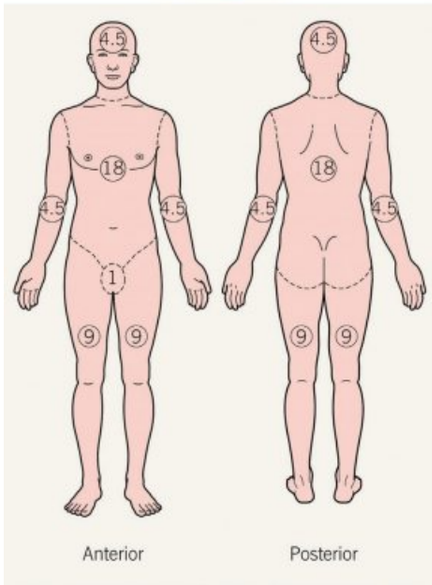

Fig. 88.2 Assessing the extent of body surface area (BSA) involvement in burn injuries: rule of nines. In adults, an estimate of burn extent is often based on this surface area distribution chart. Infants and children have a relatively increased head:trunk surface area ratio and this chart is ineffective for them. Note that the palm is ~1% of BSA and can be used for estimating patchy areas. These estimates are also used for primary cutaneous disorders. Only partial- and full-thickness burns are considered in BSA measurements. The most accurate method of estimating the BSA involvement of burn injury in adults and children is with the Lund–Browder chart (www.ncbi.nlm.nih.gov/pmc/articles/PMC449823/).

Key features

- Localized areas of reticulated erythema and hyperpigmentation
- Chronic exposure to heat below the threshold for a thermal burn
- Commonly in lumbosacral region (heat applied to relieve pain) and shins (in regions without central heating in homes)
- Squamous atypia histologically (in later lesions)
- Risk of cutaneous malignancy, particularly squamous cell carcinoma

Introduction

Chronic exposure to low levels of infrared heat can lead to the characteristic reticulated cutaneous pattern of erythema ab igne (EAI), with subsequent risk of malignant degeneration.

History

EAI, once a very common entity, was first described in the UK as a result of standing near stoves fired with peat. In the southern US, the custom

HEAT SOURCES REPORTED TO CAUSE ERYTHEMA AB IGNE	
• Heating pads	• Steam radiators
• Hot water bottles	• Heated car seats
• Electric stove/heater	• Heated reclining chairs
• Open fires	• Heating blanket
• Peat fires	• Hot bricks
• Coal stoves	• Infrared lamps
• Wood stoves	• Microwave popcorn
• Sauna belt	• Laptop computer*
• Prolonged hot bathing	• Motorcycle muffler/silencer
*Anterior thighs >> abdomen; heat originates from the battery, optical drive, or ventilation fan.	

Table 88.4 Heat sources reported to cause erythema ab igne[9–12].

of sitting around pot-bellied stoves to keep warm while socializing also led to its development. Although the advent of central heating in much of the industrialized world has led to a dramatic decline in incidence, creative cultural and therapeutic applications of various heating devices continue to induce EAI[9–11].

Epidemiology

In the past, EAI was seen up to 10 times more frequently in women than in men. The vast majority of those affected were middle-aged or older. Risk factors include lack of central heating, occupations with close heat exposure, and medical conditions with symptoms relieved by heating or associated with decreased sensation. More recently, EAI has been associated with technologic advances such as heated car seats and recliners as well as laptop computers. The latter lead to EAI in a wide range of age groups and characteristically lead to an asymmetric distribution pattern[10,11].

Pathogenesis

Long-term exposure to heat below the threshold for thermal burn is the primary etiologic factor in EAI. The precise pathophysiology is unknown, but the clinical pattern corresponds with the dermal venous plexus. Repeated exposure to heat below 47°C (116.6°F) produces reticulated erythema followed by hyperpigmentation in the same pattern[9]. Heat sources reported to cause EAI are found in Table 88.4[9–12].

Clinical features

The initial presentation is transient macular erythema in a broad reticulated pattern that easily blanches. The overall size and shape often approximates that of the heat source. With recurrent heat exposure, the erythema evolves into a dusky hyperpigmentation; lesions become fixed and are no longer blanchable (Fig. 88.3). Epidermal atrophy may overlie the reticulated pigmentation. Later-stage lesions can become somewhat keratotic and bullae may appear. Lesions are characteristically asymptomatic, although a slight burning sensation is sometimes noted[9].

Once the heat source is identified, it is important to determine if it is being used to relieve pain and, if so, the cause of the pain. A lumbosacral location usually points to musculoskeletal disease or, less often, bone metastases. EAI of the abdomen, flank, or mid back may reflect an attempt to relieve pain from inflammation (e.g. pancreatitis, peptic ulcer disease) or malignancy (e.g. pancreatic, gastric). Symptoms of pain should prompt a thorough review of systems and consideration of a search for occult disease. An inquiry into occupation and hobbies is also important, as EAI can develop in exposed areas, e.g. the forearms of bakers, the face or arms of glass blowers and foundry workers, and the anterior thighs or abdomen in those with prolonged use of laptop computers[10,11,13].

The possible development of cutaneous squamous cell carcinoma (SCC) or Merkel cell carcinoma represents the major long-term risk. The latent period may be 30 years or more. The risk of developing SCC is reportedly highest with hydrocarbon-fueled heat exposure, e.g. "peat fire cancers" on the shins of women, Japanese "Kairo cancers" and "Kangri ulcers" in Kashmir due to coal-fired clothing warmers, and Chinese and Tibetan "Kang cancers" from sleeping on coal fire-heated bricks ("Kang beds")[9,10]. Basal cell carcinoma and cutaneous marginal zone B cell lymphoproliferative disorder have also been reported in association with EAI[10,13].

Callen, MD; B, Courtesy Kalman Watsky, MD; C, Courtesy Peter Klein, MD.*

Pathology

The earliest histopathologic changes include epidermal atrophy, vasodilation, and dermal pigmentation (both melanin and hemosiderin) (Fig. 88.4). As lesions progress, the epidermal atrophy becomes more pronounced, with flattening of the rete ridges. Basal cell vacuolization has been reported and the dermal–epidermal junction may exhibit interface dermatitis. The dermis appears thinned and sometimes edematous, with accumulation of abnormal elastic tissue and pigment as well as ectatic capillaries. Dermal capillaries may exhibit enlarged endothelial cells with hyperchromatic nuclei. Later lesions may also show basophilic degeneration of connective tissue. Hemosiderin deposition and prominent telangiectasias are seen most often in leg lesions. Focal hyperkeratosis and dyskeratosis may be noted, along with squamous atypia, in long-standing lesions. Ultrastructural evaluation also shows increased melanocyte dendritic processes, suggesting melanocyte activation[9].

Differential diagnosis

EAI needs to be distinguished from livedo reticularis, which is a temperature-sensitive vasculopathy that favors the extremities and only occasionally develops associated hyperpigmentation (see Ch. 106). Cutis marmorata and cutis marmorata telangiectatica congenita are less commonly considered in the differential diagnosis of EAI. The presence of telangiectasias along with atrophy and hyperpigmentation raises the possibility of poikiloderma and its various causes, e.g. cutaneous T cell lymphoma (see Ch. 120), dermatomyositis (see Ch. 42), several genodermatoses (see Ch. 63).

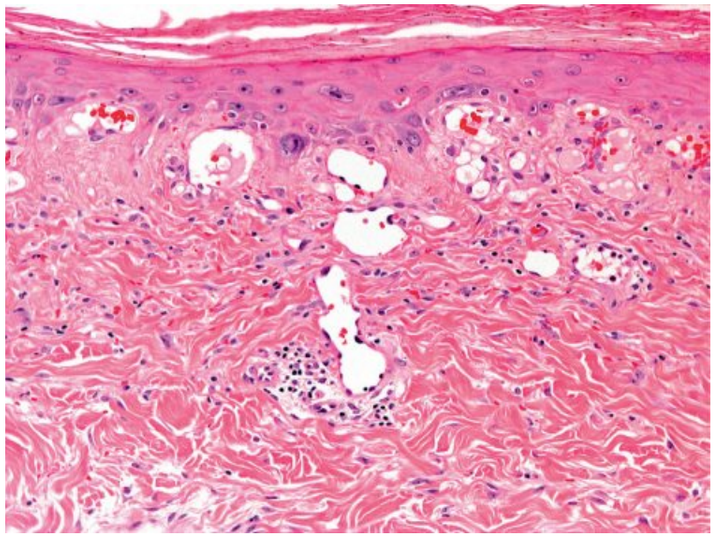

Fig. 88.4 Erythema ab igne – histologic features. The blood vessels within the superficial dermis are markedly dilated. There is hyperkeratosis and a sparse inflammatory infiltrate. Note also thinning of the epidermis with some apoptotic keratinocytes and atypical cells. *Courtesy Lorenzo Cerroni, MD.*

Treatment

Management consists primarily of removal of the offending heat source. The epidermal atypia is comparable to that of actinic keratoses, and anecdotally it has been treated successfully with topical 5-fluorouracil. As mentioned above, the use of heat to treat symptoms of pain should prompt an evaluation to determine its etiology[9–14].

Burns and Cutaneous Radiation Injury Associated With Magnetic Resonance Imaging (MRI) and Fluoroscopy

Key features

- MRI may produce first-, second-, or third-degree burns due to metal or wire contact with skin, creating a closed-loop conduction system
- Fluoroscopy, particularly when repeatedly performed in patients with cardiovascular disease, may result in radiation-induced injury

Introduction

The radiologic literature is replete with reports of superficial to full-thickness thermal or electrical burns occurring during MRI. Risk factors for MRI burns are listed in Table 88.5[15]. In addition, there are reports in the radiologic and dermatologic literature of ulcerations, most commonly on the back, following repeated fluoroscopy[16–18].

Pathogenesis

Although the precise cause of MRI burns is unknown, the presence of both pulsed radiofrequency and pulsed magnetic gradient fields is thought to play a role. If an electrically conductive loop is formed between the patient and an electrode, patient and wiring, or even small areas of skin–skin contact, current can be produced by the changing magnetic flux, causing a thermal or electrical burn. Resistance at the skin surface may create a thermal injury, while contact with wiring may create electrical injury via current induction. Alternatively, the burn may result from formation of a resonant conducting loop with an extended wire creating a resonant antenna, heating maximally at the antenna tip[15,19].

In addition to thermal burns, cutaneous complications of fluoroscopy include allergic drug reactions, irritant and allergic contact dermatitis, non-target embolization to the skin, intravascular catheter-related infections, and radiation dermatitis[17]. The mechanism behind fluoroscopy-induced radiodermatitis is related to the dose of radiation that is delivered, the interval between radiation exposures (dose fractionation), and the size of the irradiated area[16]. Repeated procedures are notorious for increasing the risk[18]. Additional potential risk factors include smoking, diabetes mellitus, obesity with overlapping skin folds, autoimmune connective tissue diseases (e.g. systemic sclerosis), genetic DNA repair defects, and various drugs including chemotherapeutic agents[16,17]. Radiation recall, which can occur days to years after fluoroscopy, has been observed following the administration of drugs such as methotrexate[16].

RISK FACTORS FOR BURNS DURING MAGNETIC RESONANCE IMAGING	
• ECG leads	• Metallic body piercing jewelry
• Monitoring cables	• Tattoos
• Pulse oximeter	• Extremity skin-to-skin contact
• Pins in halo fixation device	• Clothing with metal threads
• Transdermal patches	

Table 88.5 Risk factors for burns during magnetic resonance imaging[15–17]. ECG, electrocardiogram.

Fig. 88.5 Fluoroscopy-induced radiation dermatitis. The left upper back is a characteristic location for patients who have undergone attempts at coronary artery revascularization (e.g. angioplasty, stent placement). *Courtesy Jeffrey P. Callen, MD.*

Clinical features

Thermal burns appear soon after MRI, and may be partial- to full-thickness (see Table 88.3). The shape and size of the burns are determined by the conductor causing the injury (e.g. circular burns under ECG electrodes; figurate burns conforming to the shape of metallic wires or tattoo pigment deposition)[15,19].

Fluoroscopy-induced radiation dermatitis may be acute, but, as time passes and the acute injury resolves, the patient may continue to develop further changes, including epilation of hair, desquamation, telangiectasias, permanent erythema, and eventual ulceration due to dermal necrosis (Fig. 88.5). The left upper back is a characteristic location for patients with cardiovascular disease who have had cardiac catheterizations with attempts at revascularization (e.g. angioplasty, stent placement)[18]. Although often referred to as cutaneous complications, severe radiation injuries can extend into the subcutaneous fat and muscle[16]. Rarely, skin burns develop at the site of an indifferent electrode in those undergoing radiofrequency catheter ablation of cardiac arrhythmias[18a].

Differential diagnosis

Because of the proximity of the MRI event to the detection of a burn injury, the diagnosis is generally straightforward. However, in the case of a tattoo burn, allergic contact dermatitis or foreign body granuloma formation within the tattoo may be considered. Timing of the event plus the sensation of a burn rather than pruritus should allow a distinction.

The differential diagnosis of fluoroscopy-induced disease includes fixed drug eruptions, contact dermatitis, herpes virus infection, impetigo, and spider bites.

Treatment

Prevention of this injury by avoiding risk factors is ideal (see Table 88.5). However, when burns occur, they should be managed as any other thermal burn, or, in the case of fluoroscopy-induced injury, by limiting the dose delivered.

Airbag Burns

Key features

- Deployment of airbags causes numerous cutaneous injuries, including frictional and blunt trauma, thermal burns, and possibly chemical burns
- Friction due to contact with the bag, thermal burning from the bag and its released gases, and exposure to corrosive aerosol produce the injuries

Introduction

Automobile airbags provide additional crash protection, reducing driver and passenger fatalities by up to 30%. Although patented in 1953, US manufacturers only began installation of airbags in the mid-1970s. European airbag installation began in 1981. The US Federal Motor Vehicle Safety Standard 208 was amended in 1984, requiring that all vehicles made after 1989 have passive restraints. Further revisions in 1998 made dual front seat airbags mandatory. Despite the beneficial effect, numerous injuries have resulted from airbag deployment, including burns, abrasions, and lacerations[20,21].

Pathogenesis

Airbag activation consists of detection, inflation, and deflation phases. The sudden deceleration caused by impact triggers sensors in the front bumper to fire a sodium azide canister inside the nylon rubber bag. The sodium azide ignites with an explosive release of hot nitrogen gas which inflates the bag in about 10 milliseconds at speeds exceeding 160 km/h. The hot nitrogen gas and other by-products are then vented out the upper sides of the bag away from the occupant, thus deflating the bag. Vented aerosol contains nitrogen, carbon mono- and dioxides, sodium hydroxide, ammonia, nitric oxide, metallic oxides and other trace gases, creating a corrosive environment. Friction and pressure from the bag, heat from the bag and gases, and contact with the corrosive aerosol may produce injury[20–22].

Clinical features

The cutaneous injuries produced by airbag deployment are summarized in Table 88.6. Chemical burns occur rarely, but appear to be a result of skin exposure to small amounts of the corrosive alkaline aerosol. The aerosolized particles need to dissolve in a water layer such as tears or sweat before creating a corrosive injury. Of note, alkali burns of the skin may continue to deepen and extend over time, unless all the corrosive chemical is washed away[20–22].

Differential diagnosis

The pattern of injury and history of airbag deployment makes the diagnosis obvious. However, it is important to determine whether a burn injury is purely thermal or if it has a chemical component. Assessment of tissue pH and monitoring for continued extension of the burn help determine whether an alkali injury exists.

Treatment

Prevention is, of course, the most effective approach. Newer airbag designs include repositioning the exhaust vents in order to direct the escape of hot gases away from areas of potential skin contact. Seats should be positioned as far back from the airbag module as possible. Children too small to benefit from the adult three-point restraint should not be in the front passenger area. Children in any type of car seat or booster should never be put in the front seat. When a thermal or frictional injury occurs, local wound care and protection from secondary infection usually suffice.

Alkali burns require copious irrigation to dilute the corrosive substance. Acidic neutralization is contraindicated because of possible extension of injury by the resulting exothermic reaction. When the tissue pH is normal, local wound care is adequate.

AIRBAG INJURIES TO SKIN		
Type	**Frequency**	**Clinical features**
Abrasions/ friction burns	65%	Patches of erythema or ecchymosis, typically with superficial erosion
Contusion	40%	Ecchymosis
Lacerations	20%	Variable severity
Thermal burns	8%	First- and second-degree most common (see Table 88.3)
		Localized full-thickness burn may result from metallic accessories or melted clothing
		Face and forearms, followed by hands and chest
Chemical burns	?	Painful, superficial, violaceous erythema and edema
		Partial- to full-thickness, often in splash pattern
Irritant dermatitis	?	Erythema and edema of upper chest, arms, and face
		Burning or stinging sensation
		Desquamation and postinflammatory hyperpigmentation common

Table 88.6 Airbag injuries to skin[20–22].

INJURY DUE TO COLD EXPOSURE

Frostbite

Synonym: ■ First-degree frostbite – frost-nip

Key features

- Frostbite can occur when the skin temperature drops below about −2°C (28°F)
- Erythema, edema, and numbness are followed by marked hyperemia and pain
- Tissue freezing, vasoconstriction, and inflammatory mediator release are central to the pathophysiology of frostbite
- Rapid rewarming in a warm water bath is the cornerstone of therapy

Introduction

Exposure to cold environments, whether during occupational or recreational activities, poses a risk of cold-related injury. Prolonged exposure may lead to hypothermia, frost-nip, or frostbite. Hypothermia, i.e. a decline in core temperature below 35°C (95°F), is a systemic process with minor cutaneous features and therefore will not be discussed in detail.

History

Cold injury predates recorded history – the quest for clothing, shelter, and fire as protection from the elements must have preoccupied prehistoric humans. Mass casualties from cold injury have historically been seen most often in military conflicts. However, as interest in outdoor activities and the number of homeless individuals have risen, there has been increased exposure to cold among the general population[23–25].

Epidemiology

Environmental risk factors for the development of frostbite include prolonged duration of exposure, higher wind chill, and immersion. A history of psychiatric illness, alcohol and illicit drug use, or smoking are additional risk factors as are previous cold injury, peripheral arterial disease, and dehydration[23,25].

Pathogenesis

The underlying pathophysiology of frostbite is a combination of freezing, vascular insufficiency (constriction and occlusion), and damage due to

FOUR STAGES OF FROSTBITE		
Phase	**Physiologic events**	**Clinical findings**
I (cooling)	• Cyclic vasoconstriction and vasodilation • Extracellular ice formation (–2°C, 28°F) • Intracellular ice crystal formation (if rapid freeze of >10°C or 18°F/min) • Intravascular ice formation leads to erythrocyte sludging and vessel occlusion	Cool extremity Blanched appearance Numbness Hard, woody texture
II (thawing and rewarming)	• Ice melts • Dehydrated cells start to swell • Loss of integrity of vessel walls, creating edema • Vascular tone is compromised, leading to vasodilation • Inflammatory mediator release leads to aggregation of platelets and leukocytes, causing thrombosis	Erythematous to violaceous color Intense pain Blisters form
III (extension of injury)	• Thromboxane A2 levels increase • Platelet and leukocyte aggregation extends into bordering tissue, creating vascular compromise	Blisters rupture
IV (resolution)	• Tissue either re-epithelializes or desiccates and mummifies • Vasomotor instability may persist indefinitely	Healing or amputation

Table 88.7 Four stages of frostbite[23,24].

Fig. 88.6 Frostbite. **A** Erythema, edema, and hemorrhage are seen on the fingertips in first-degree frostbite. **B** Bullae filled with clear fluid on the distal plantar surfaces in second-degree frostbite. *B, Courtesy Timothy Givens, MD.*

inflammatory mediators. As extremities cool, the "hunting response of Lewis" (alternating vasoconstriction and vasodilation) occurs, ending with vasoconstriction. This tends to conserve the core temperature at the expense of the extremity, which shifts toward ambient temperature. The head does not exhibit a vasoconstrictor response, except for the nose and ears. The trunk surface may cool slightly, but the core temperature is maintained. Frostbite is therefore unusual on the trunk or head (except the nose and ears), unless there is direct contact with ice or a refrigerant. The pathophysiologic stages of frostbite are summarized in Table 88.7, along with key clinical features[23,24].

Clinical features

Frostbite has been divided into four categories of severity, analogous to burn injuries. These are only recognizable upon rewarming. *Frostnip* (first-degree frostbite) presents with erythema, edema, cutaneous anesthesia, and transient pain (Fig. 88.6A). Full recovery is expected, with only mild desquamation. *Second-degree frostbite* is characterized by marked hyperemia, edema and blistering, with clear fluid in the bullae (Fig. 88.6B). Healing occurs, but many patients have long-term sensory neuropathy, often with significant cold sensitivity.

Third-degree frostbite consists of full-thickness dermal loss, with hemorrhagic bulla formation or development of waxy, dry, mummified skin. The latter features are poor prognostic indicators for tissue loss. In *fourth-degree frostbite*, there is full-thickness necrosis leading to skin, muscle, tendon, and bone damage and tissue loss. Injuries of this severity lead to amputation[23,24]. Some authors advocate a simpler classification consisting of superficial or deep injury, citing better prognostic accuracy.

Pathology

Superficial dermal edema and subepidermal bulla formation are typical findings in early frostbite. Vascular permeability leads to hemorrhage that is most pronounced in deep injury. The epidermis and involved dermis become necrotic, with an inflammatory infiltrate and granulation tissue at the junction with normal tissue[8].

Differential diagnosis

Frostbite injuries should be readily recognizable, given an exposure history and typical presentation. A greater diagnostic challenge is determining the depth of the injury (see above). One possible diagnosis in the differential is cold water immersion foot (see Table 88.9).

Treatment

Fundamental therapeutic goals in frostbite are rapid rewarming, prevention of further cold exposure, and restoration of circulation. Once the patient is in a setting in which re-freezing cannot occur, rapid water bath rewarming is indicated. The water bath temperature should be about 37–39°C (99–102°F), ideally a whirlpool is utilized so a steady temperature can be maintained. This process of rewarming may be painful, so appropriate analgesia should be provided. Rubbing the frozen extremity with ice, using dry heat, and slow rewarming are all contraindicated. In the hypothermic patient with frostbite injury, it is important to complete fluid resuscitation and core rewarming before limb rewarming, to prevent sudden hypotension and shock. Accurate clinical assessment of the degree of injury, routine wound care, protective dressings, monitoring for infection, and consideration of tetanus prophylaxis should then follow. Radiologic evaluation (e.g. MRI, bone scan, plain films) may help determine extent of injury and prognosis. Nowadays, angiography and triple-phase bone scans are considered the standard of care for assessing tissue viability and guiding care during the initial days following injury[23].

Additional therapeutic suggestions have been based on animal studies, case reports, or small series. Because of increased blood viscosity and sludging, thrombolytic therapy (e.g. heparin, tissue plasminogen activator, streptokinase) ± a vasodilator (e.g. iloprost, limaprost) has been suggested. Superficial non-hemorrhagic bullae may be aspirated or debrided to avoid prolonged exposure to prostaglandins and thromboxanes within blister fluid. Aloe vera, a thromboxane inhibitor, has been shown to be useful as a topical agent in superficial frostbite. The problem of vasoconstriction has been addressed by sympathectomy, with the most impressive effect being prevention of re-injury with repeat exposure to cold conditions. Pentoxifylline has been found to be useful, as have anti-inflammatory agents such as methylprednisolone, methimazole, and aspirin. Hyperbaric oxygen therapy reduces edema in post-ischemic tissues, but its delivery requires adequate blood flow. Increased viscosity and thrombosis in sites of frostbite injury may explain the variable results with this therapy[23,24,26].

Pernio

Synonyms: ■ Chilblains ■ Perniosis

Key features

- Cold-sensitive inflammatory disorder in which erythrocyanotic discoloration of acral skin is accompanied by a sensation of itching, burning, or pain
- Common trigger is exposure to cold, wet, non-freezing conditions
- Must be distinguished from chilblain lupus and cold-sensitive blood dyscrasias
- Nifedipine can be used to treat moderate to severe pernio

Introduction

Pernio is an abnormal inflammatory response to cold, damp, non-freezing conditions[27]. It is most common in areas without central heating.

History

Over a hundred years ago, pernio/chilblains was apparently common enough in Europe and the UK that the condition was well recognized. In 1881, Piffard[28] described it quite well:

"This affection, so common in cold climates, affects, by preference, the face, hands, nose, and ears. It is characterized by redness, usually with a purplish tinge, together with more or less pain of a burning character giving little or no trouble during the summer, but causing inconvenience and suffering as cold weather sets in."

Epidemiology

Exposure to cold, wet conditions is the major risk factor for pernio. This disorder has been reported most frequently in the UK and northwestern Europe, particularly in those whose homes lack central heating. It also occurs more often in individuals whose work and leisure activities are outdoors. Young women, children, and the elderly are most commonly affected, as well as those with a lower body mass index. Elderly patients may have a prolonged course, while younger patients improve spontaneously[29–31].

Pathogenesis

Pernio can be either primary (idiopathic) or secondary, i.e. due to an underlying condition. The precise pathogenesis of idiopathic pernio is unknown, but it is thought to represent an abnormal inflammatory response to vascular ischemia caused by prolonged vasoconstriction in the setting of extended exposure to cold, damp environments[27]. In children and adults, it may be associated with cryoglobulins or cold agglutinins[31,32].

Clinical features

Pernio presents with single or multiple, erythematous to blue–violet macules, papules or nodules (Fig. 88.7A–C). In severe cases, blistering and ulceration may be seen (Fig. 88.7D). Lesions are often symmetrically distributed on the distal toes and fingers, and less often on the heels, nose, and ears. Overlying scale can also develop (see Fig. 88.7B). Deep pernio may be seen on the thighs, calves, and buttocks as blue–erythrocyanotic plaques. Patients describe itching, burning or pain. Onset is often within 24 hours of exposure to cold, and lesions typically resolve within 1 to 3 weeks. Elderly patients with venous insufficiency are the exception, as lesions can become chronic[30,31].

Fig. 88.7 Pernio (chilblains) – clinical and histologic features. A Distal erythema of multiple toes with some edema in a symmetric pattern. **B** Violaceous patches and thin plaques, primarily on the toes; note the associated scaling on the hallux. **C** Erythematous papules and plaques of the distal fingers with scaling and an erosion. **D** Recurrent, more severe disease with thin violaceous papules and plaques, hemorrhage, desquamation, scarring, and postinflammatory dyspigmentation. **E** A dense perivascular and peri-eccrine lymphocytic infiltrate. Detail of predominantly lymphocytic perivascular infiltrate without atypical features (inset). Note the thickened stratum corneum characteristic of an acral site. *A,C,D, Courtesy Kalman Watsky, MD; B, Courtesy Jean L. Bolognia, MD; E, Courtesy Lorenzo Cerroni, MD.*

Pathology

There are variable degrees of dermal edema plus a superficial and deep lymphohistiocytic infiltrate with peri-eccrine accentuation (Fig. 88.7E). The infiltrate is composed predominantly of T lymphocytes. Necrotic keratinocytes and lymphocytic vasculitis have been noted[30].

Differential diagnosis

Idiopathic pernio needs to be distinguished from several other cold-induced syndromes (Table 88.8)[29–32]. In addition to clinical features, e.g. retiform purpura, these entities can be further assessed by laboratory evaluation including: (1) complete blood count to exclude hemolytic anemia, myelogenous leukemia, or myelodysplastic syndrome; (2) cryoglobulin, cold agglutinin, and cryofibrinogen levels to eliminate cold-sensitive dysproteinemia; and (3) serum protein electrophoresis and immunofixation electrophoresis to exclude a monoclonal gammopathy.

Chilblain lupus (Hutchinson), whose clinical features are similar to pernio, may also be indistinguishable from pernio histologically.

DIFFERENTIAL DIAGNOSIS OF SKIN LESIONS INDUCED BY NON-FREEZING COLD EXPOSURE

Disorder	Features	Possible associated conditions	Chapter reference
Acrocyanosis	Red to purple discoloration Hands and feet Painless	Erythromelalgia	106
		Cryoproteins	23
		Anorexia nervosa	51
Pernio	Erythrocyanotic Symmetric distribution Painful	Secondary pernio: AI-CTD Interferonopathies (Table 45.7). Cold agglutinins* Cryoglobulins Hematologic disorders (e.g. acute myelogenous leukemia, myelodysplastic syndrome, paraproteinemia) Possibly SARS-CoV-2 infection	88, 45
Raynaud phenomenon	Clearly demarcated pallor, followed by blue then red discoloration Idiopathic form usually does not ulcerate	AI-CTD Blood dyscrasias Drugs Trauma	43 (Tables 43.4 & 43.5)
Livedo reticularis	Bluish, broad reticulated patches May be idiopathic	Peripheral arterial disease AI-CTD Hematologic disorders Vasculopathies & thrombophilia (e.g. antiphospholipid syndrome) Infections Medications	105, 106 (Tables 105.9 & 106.1)
Cold panniculitis	Erythematous indurated plaques, most often on cheeks Children more commonly affected Upper lateral thighs in equestrians† Can resolve in 2 weeks		100
Cold urticaria	Cold-induced wheals May be idiopathic	Cryoproteins (see below) Infections Familial cold autoinflammatory syndrome	18
Chilblain lupus	Cold-induced acral lesions Histologic features may be indistinguishable from pernio, but features of interface dermatitis are usually more marked Coexistent lupus erythematosus		41
"Pulling boat hands"	Rowing in cold, wet conditions Papules to vesicles Itching, burning, tenderness		
Retiform purpura due to cryoproteins‡	Favors acral sites		23
Cryoglobulins	Cold *serum* protein precipitate	Plasma cell dyscrasias Lymphoproliferative disorders	
Cryofibrinogen¶	Cold *plasma* protein precipitate	AI-CTD Infections Malignancies	
Cold agglutinins¶	RBCs agglutinate in cold Occasional RBC lysis in cold	Infections (e.g. with *Mycoplasma*, EBV, CMV) Lymphoproliferative disorders	
Cold hemolysins¶	RBC lysis in cold Paroxysmal hemoglobinuria	Infections (e.g. viral, syphilis)	

*Clinical significance oftentimes unclear.
†Because inflammation is primarily in the dermis, use of the term panniculitis has been challenged.
‡Acrocyanosis, Raynaud phenomenon, livedo reticularis, and cold urticaria can also be observed in association with cryoproteins.
¶Rarely cause cold-related occlusion syndromes.

Table 88.8 Differential diagnosis of skin lesions induced by non-freezing cold exposure[29,30,33]. AI-CTD, autoimmune connective tissue disease; CMV, cytomegalovirus; EBV, Epstein–Barr virus; RBC, red blood cell.

However, features of interface dermatitis are usually more marked in chilblain lupus and patients have serologic evidence of autoimmunity (e.g. positive antinuclear antibody screen). Patients with type I interferonopathies, such as Aicardi–Goutières syndrome/familial chilblain lupus and proteosome-associated autoinflammatory syndrome/CANDLE syndrome, also develop pernio-like lesions (see Table 45.7). Symmetric lividity of the palms and soles (pressure points) can involve the distal fingers and toes but is due to occlusive footwear, usually in association with hyperhidrosis. Diagnosis of the lupus pernio form of sarcoidosis, which favors the nose, is confirmed by the presence of the histologic features of sarcoidosis[29,33].

During the SARS-CoV-2 pandemic, an increased incidence of pernio has been reported ("COVID toes"), most often in children and teenagers. The vast majority of patients have been SARS-CoV-2 PCR-negative and did not develop anti-SARS-CoV-2 antibodies. As a result, there is an ongoing debate as to the relationship of pernio to SARS-CoV-2 infection. Nonetheless, patients with pernio should be questioned regarding symptoms of SARS-CoV-2 infection and possible contacts[34,35]. In general, those individuals who were infected had a mild clinical course.

Treatment

Adequate clothing and avoidance of cold, damp conditions are important preventive measures, as are keeping feet dry and avoidance of smoking. In a double-blind, placebo-controlled trial, nifedipine (20 to 60 mg daily) was found to be efficacious for the treatment of pernio. None of the nifedipine-treated patients relapsed, while all of the placebo-treated patients developed new lesions[36]. It is effective in about 70% of patients with pernio. Medium- to high-potency topical corticosteroids are often prescribed, but supportive evidence is lacking. Other anecdotal remedies include topical 0.2% nitroglycerin, topical minoxidil, oral nicotinamide, pentoxifylline, phenoxybenzamine, sympathectomy, and erythemogenic UVB phototherapy[29].

INJURY DUE TO WATER EXPOSURE

Immersion Foot

Synonyms: ■ Trench foot ■ Tropical jungle foot ■ Shelter foot ■ Paddy-field foot ■ Swamp foot ■ Jungle rot ■ Foxhole foot ■ Peripheral vasoneuropathy ■ Nonfreezing cold injury

Key features

- Injury occurs after continuous exposure of feet to moist, occluded conditions
- Cold water, warm water, and tropical variants exist
- The underlying pathologic process is overhydration of the stratum corneum
- Nonfreezing cold injury can lead to peripheral vasoneuropathy
- Neuropathy may persist indefinitely
- Feet exposed to immersion injury are more sensitive to re-injury

Introduction

Immersion injury occurs in either cold or warm environments when the feet are exposed to continuous moisture with no opportunity for intermittent drying. Severe injury may produce permanent peripheral neuropathy and long-term morbidity.

History

Soldiers on the Western Front in World War I spent extended periods of time in the cold, wet, muddy conditions of trench warfare, leading to the death of ~75 000 British soldiers and the term *trench foot*. *Immersion foot* emerged during World War II, with shipwrecked troops spending days in partially submerged lifeboats. The Korean conflict and the Vietnam War led to more variations and tremendous numbers of casualties. Immersion foot also occurs outside armed conflicts, including in persons experiencing homelessness, fishermen, skiers, and revelers at music festivals[37–39].

Epidemiology

Susceptibility to immersion foot is widely variable. Use of sandals or open shoes, constant activity, thinner plantar stratum corneum, and intermittent air drying seem somewhat protective. Risk factors for immersion foot include: prolonged occupational or recreational exposure to wet conditions, constrictive clothing, immobility or prolonged dependency of feet, dehydration, poor nutritional status, altered mental status, smoking, peripheral vascular disease, uncontrolled diabetes, tinea pedis, trauma, and experiencing homelessness[37,39].

Pathogenesis

The underlying pathophysiology of all forms of immersion foot is overhydration of the stratum corneum. The permeability coefficient of plantar skin is ~10 times that of the dorsal foot skin, leading to increased water absorption. The plantar stratum corneum can absorb ~200% of its dry weight in water, with a proportionately higher absorption of fresh water than saline.

Warm water immersion foot (WWIF) results from severe hyperhydration of the stratum corneum, with subsequent maceration. Plantar skin temperature reaches body core temperature after about an hour in an impervious boot with 19°C (66°F) water. As the injury continues, inflammatory changes develop and may progress to a lymphocytic vasculitis with vascular compromise and erythrocyte extravasation (*tropical immersion foot* [TIF]). Eventual involvement of the dorsal foot skin develops with striking inflammation. Secondary infection may develop in the compromised tissue after 3–4 days, further complicating management and worsening morbidity[24,40].

Cold water immersion foot (CWIF), also referred to as nonfreezing cold injury, is more severe due to the addition of cold-induced vasospasm. Because water conducts heat 23 times faster than air, the cold water immersion invokes "thermo-protective" peripheral vasoconstriction. This creates hypoxic injury to nerves (initially large myelinated axons, but eventually all types) and muscle, with later injury to subcutaneous fat and blood vessels. With reperfusion, there can be additional injury superimposed on ischemic tissue damage[38,41].

Clinical features

The clinical syndromes of immersion foot are divided into the three variants previously discussed: WWIF, TIF, and CWIF (Table 88.9)[24,37]. Although TIF is sometimes viewed simply as a prolonged and more severe variant of WWIF, it is discussed separately because prolonged warm water exposure leads to different clinical features.

Pathology

All forms of immersion foot demonstrate edema, thickening, and fragmentation of the stratum corneum. Variable superficial dermal edema is noted. In more severe forms (TIF, CWIF), superficial dermal capillaries are narrowed due to edema or even frank lymphocytic vasculitis. Immunohistochemical staining for nerve fibers was shown to be reduced, perhaps playing a role in the vasoneuropathy[41]. CWIF leads to damage of much deeper blood vessels (narrowing and fibrosis), muscle, nerves, and bone.

Differential diagnosis

The differential diagnosis of immersion foot includes dermatophyte infection, cellulitis, contact dermatitis, pitted keratolysis, Gram-negative or complex toe web infections, erythrasma, and (occasionally in diabetics) candidiasis. The latter three conditions are usually predominantly within the toe web spaces, and dermatophytosis is usually more patchy, with fine scale and no significant maceration outside the web spaces. Pitted keratolysis can be distinguished by history and by the presence of punched-out tiny pits in the plantar surface of the forefoot and heel. Cellulitis is not limited at the immersion water mark, and it can progress proximally. Maceration due to occlusive footwear, usually in association with hyperhidrosis, is seen in symmetric lividity of the palms and soles.

Treatment

Prevention is the best treatment. Once the condition develops, thorough and rapid drying is essential to restore function. CWIF patients must remain some distance from a heat source because the neuropathic insensitivity poses further risk of inadvertent thermal injury. WWIF can be prevented by frequent drying breaks and the use of silicone grease.

IMMERSION FOOT: WARM WATER, TROPICAL, AND COLD WATER VARIANTS					
Variant	**Exposure temperature**	**Exposure time**	**Clinical features**	**Complications**	**Duration**
Warm water	15.5–32°C (60–90°F)	1–3 days	Thickening, softening, and exaggerated wrinkling of soles (thicker soles worse) Ambulation painful ("walking on rope")		3 days
Tropical	21–32°C (70–90°F)	3–7 days	Prolonged warm water exposure In addition to plantar hyperhydration, dorsal foot becomes inflamed and edematous Pruritus, erythema, and scattered vesicles Later purpura, brawny edema, maceration, and scaling Fever, lymphadenopathy		>5 days
Cold water	15.5–21°C (60–70°F)	>7 days	Feet cold, heavy, stiff, and numb May appear swollen Waxy white to mildly cyanotic	Infection Muscle atrophy Chronic venous stasis Joint contractures Trophic ulcers Myonecrosis Permanent axonal damage Bony changes such as hammer toe	
			Three phases after rewarming: 1. Pre-hyperemic – feet cold, edematous and numb, with stocking anesthesia; purpura, blisters, and necrosis possible; pulses not palpable 2. Hyperemic – return of vascular and nerve function; tingling, pain, and throbbing; increasing erythema and edema; skin anhidrotic, hot, and painful to touch; ambulation difficult; vasomotor instability; dependent rubor, pallor upon elevation; bullae, intermittent cyanosis; infection risk high 3. Post-hyperemic – cold sensitivity with digital blanching, intermittent edema, hyperhidrosis, persistent peripheral neuropathy		Hours to days
					Up to 10 weeks
					Years

Table 88.9 Immersion foot: warm water, tropical, and cold water variants[24,37,38].

The silicone has minimal value in TIF and is of no use in CWIF[38,40]. Although evidence is lacking, possible treatment options include vasodilators (e.g. iloprost, papaverine), nicotine tartrate, sympathectomy, and medications that address neuropathic pain (e.g. gabapentin, amitriptyline, pregabalin). Co-existing tinea pedis and cellulitis should be treated[38].

INJURY DUE TO ELECTRICITY

Electrical Burns

Key features

- The extent of an electrical burn injury may be much worse than the cutaneous contact burns suggest
- Contact point burns may be partial- to full-thickness
- Neurovascular, muscular, and skeletal tissue may be damaged
- Lightning strikes can result in an erythematous, transient fern-like pattern on the skin

Introduction

Although electricity and lightning claim hundreds of lives each year, many more non-fatal injuries occur. The majority of electrical burns are work-related, particularly among electricians, linesmen, and construction workers. Children are also a major risk group, with low-voltage (<1000 V) injury more common under 6 years of age and high-voltage injury in older children and adolescents. A survey of 700 electrical injury admissions to Parkland Memorial Hospital over a 20-year period showed electric arc (flash burn, no current) injury to be the most common (40%), followed by high voltage (38%), low voltage (20%), and lightning strikes (2%). Mortality was highest with lightning strikes[42].

Lightning is the second leading cause of weather-induced death in most of the world, with the incidence peaking during the summer months. Most lightning strike victims are men (usually between 15 and 45 years of age) involved in outdoor activities[42,43]. Worldwide, lightning strikes lead to an estimated 0.2–1.7 deaths/1 million people/year. Death occurs in 10%–30% of lightning strike victims and about three-quarters of survivors will have permanent sequelae[43].

Pathogenesis

The severity of an electrical injury depends upon the strength and frequency of the electrical field, the duration of exposure, path of current, and relative resistance of the tissue. Acute tissue damage by strong (high-voltage) low-frequency fields is due to holes punched in cell membranes (electroporation), Joule heating of the extracellular fluid, and cell membrane protein denaturation through electroconformational coupling. The thermal effects (i.e. Joule and dielectric) depend upon tissue resistance to the flow of current. For example, bone has the most resistance of any body tissue and therefore generates the most heat. The order of resistance then decreases through fat, tendon, skin, muscle, blood vessels, and, finally, nerves (least resistance). An additional indirect effect is field-generated formation of free radicals with subsequent lipid peroxidation and membrane disruption[44,45].

Lightning injury follows similar electrothermal principles, but with three important differences: (1) current and voltage are massive, e.g. 30 000 to 50 000 amperes (A), and a difference between clouds and object of 2 million V/m; (2) the superheating of air through which the current passes to 30 000°K, creating a high-pressure thermoacoustic shock wave (thunder) that may generate 100 atm of air pressure locally; and (3) the creation of internal conduction loops as the large magnetic field passes through the body. Injury can occur from a radial spread of current after lightning strikes the ground, from a direct hit, from flashover (current around body), or from blast effect[43].

Clinical features

Electrical burns usually range from partial- to full-thickness, and high-tension burns often involve deep tissue, with the current damaging muscle, nerves, and vessels. Erythema, edema, and blisters (partial-thickness damage) may result from a current of 20 to 35 mA/mm^2 with an exposure time of 20 seconds (heats skin to 50°C). At a higher current of 75 mA/mm^2 with the same exposure time, the temperature could rise to 90°C, causing skin perforation and charring.

Identification of so-called "entrance" and "exit" wounds is of no value, since 60 Hz alternating current (AC) has current changing directions 120 times per second. More important is determination of the extent of skin and internal injury. In some cases, current may arc between body parts, creating "kissing" wounds. High-voltage injuries may result in electroplating of skin with black metallic debris that leaves charred craters when removed. Additional thermal injury may occur when clothing or nearby items are ignited by an electrical arc[43,45].

Deep tissue injury can be considerably more severe than the cutaneous wounds might suggest. Muscle injury may be deceptively deep, since bone (with higher electrical resistance) retains heat more readily than other tissues. Edema in deep burns may result in compartment syndromes. Additional complications include cardiac

arrhythmias, which may become chronic and recurrent; myoglobinuria due to muscle injury; and solid organ injuries such as bowel perforation. Patients can also develop cataracts as well as cognitive and neuropsychologic impairment[43–46].

Lightning burns generally are more superficial due to the very brief contact. A unique pattern of skin lesions after a lightning strike is the "lightning print", "feathering", or Lichtenberg figures. These markings are transient, erythematous, linear fern-like patterns that resolve in hours to days. While not a true burn, they are pathognomonic of lightning strike injury. Other cutaneous changes may include patchy mottling, erythema, blistering, full-thickness punctate skin loss, flash burns, thermal burns from ignited clothing, and contact burns from grounding. Although internal burn injuries are uncommon in lightning strikes because of the very brief duration, the internal electrical currents that are created are strong enough to cause cardiac arrest or seizures. Additional sequelae include profound neuromuscular shutdown (keraunoparalysis), confusion, temporary amnesia, deafness and blindness, and prolonged or permanent neurologic disturbances such as peripheral sensory neuropathy[43,45].

Pathology

Electrical burns are characterized by epidermal necrosis, with cytoplasmic strands extending into the cavity between damaged and normal skin. Keratinocytes may be elongated vertically, and collagen appears homogenized. Severe electrical burns destroy the entire skin, including the subcutis, often with accompanying necrosis of deeper blood vessel walls. The Lichtenberg figures after lightning injury usually display no pathological changes or variable degrees of hemorrhage[8].

Treatment

Electrical injuries are very complex, often involving multiple organ systems, since any organ in the path of current can be damaged, and initial assessment may underestimate the extent of injury. Although full management of electrical burns should be carried out in level one trauma centers, initial management includes isolation of the patient from the power source, assessment of vital signs, cervical spine immobilization, determination of contact points on the skin, and, if possible, venous access. For more details, see the section above on thermal burns.

One special circumstance should be noted. Toddlers who sustain oral commissure burns from biting into electrical cords are at risk for delayed bleeding. About 10–14 days after the burn, the eschar comes off, often exposing a damaged labial artery. Direct pressure will control the bleeding, pending definitive care[43–45].

Chemical Burns and Exposures

These entities are discussed in several chapters, including those on irritant contact dermatitis (Ch. 15), occupational dermatoses (Ch. 16), plant dermatoses (Ch. 17), and child abuse (Ch. 90).

INJURY DUE TO CHEMICAL EXPOSURE

Chemical Hair Discoloration

Synonym: ■ Green hair – chlorotrichosis

Key features

- Hair discoloration may be an intentional cosmetic change or the result of a chemical or metal exposure
- Green hair may result from exposure to copper or selenium
- Most hair discoloration normalizes spontaneously over time

Introduction

Decorative hair coloring has risen to new heights with the flamboyant artistry of the past several decades. Brilliant pink, green, purple, blue and orange and myriad styles, from a buzz cut to dramatic multicolored spikes, adorn many of today's youths. Much of this is deliberate decoration, but hair discoloration at any age may be inadvertent and sometimes unwanted.

History

Green hair among copper workers was noted as early as 1654. More recently, such discoloration has been attributed to swimming pools[47].

Epidemiology

Most patients with unwanted hair discoloration have blond or white hair, although brunette and black hair may become discolored as well. Risk factors include exposure to the substances in Table 88.10[47–50], in addition to frequent contact with chlorinated water (especially swimmers), use of an alkaline shampoo, coloring or peroxide bleaching of hair, and mechanical or sun-induced hair damage[47–50].

Pathogenesis

When due to exposure to copper-containing water in swimming pools or domestic supplies, green hair discoloration results from binding of the copper to proteins within the hair shaft[49]. Damage to the hair cuticle from bleaching, permanent wave treatments, frequent water exposure, and sunlight allows the copper to penetrate the hair more readily. The copper content of discolored green hair (or golden hair in Asian patients) is considerably higher than in non-discolored hair in the same individual. Of note, increased systemic copper (e.g. Wilson disease) is not associated with green hair color[47–50].

Nanko et al.[48] speculated that the golden color of Japanese swimmers' hair was due to water friction injury of the cuticle, allowing hypochlorous acid from the chlorination process to invade the cortex and degrade melanosomes. Copper appeared to play a role as well, but the mechanism was unclear.

Clinical features

The presenting concern is a progressive yellow to green discoloration of the hair. Scalp hair is the only hair involved, and the surface hair is more noticeably discolored than underlying hair.

Pathology

By electron microscopy, loss of the hair cuticle and wearing of the cortex layers were seen in discolored, golden hairs in Japanese swimmers (see above)[48]. In addition, there was a reduced number and density of melanosomes in the discolored hair relative to controls. X-ray spectrography demonstrated an increased chlorine content in both the discolored and normal hair of swimmers relative to controls, and a reduced sulfur content in only the discolored hairs. Atomic absorption spectroscopy can be used to detect copper within hair shafts as can staining with rhodanine[49].

Differential diagnosis

Hair discoloration is readily visible. The specific etiology and subsequent therapy needed may be determined by ascertaining the type of exposure that led to the color change (see Table 88.10). For example, copper from cosmetic plant extracts and metallic eyeglass frames can produce green hair.

Treatment

Discontinuation of the offending exposure and avoidance of risk factors is recommended. Penicillamine- and EDTA-containing shampoos can

CAUSES OF UNINTENTIONAL HAIR DISCOLORATION		
Green	**Yellow to orange to golden**	**Purple**
• Copper* • Selenium sulfide • Tar shampoo • Cobalt • Chromium • Nickel • Yellow mercuric oxide • Phenylketonuria†	• Tar shampoo • Anthralin • Minoxidil • Copper*	• Alkalinized anthralin

be used to chelate copper molecules, followed by rinsing to remove complexes. Numerous anecdotal remedies have been described, including hot vegetable oil, hydrogen peroxide, alkaline shampoos, lemon juice, commercial hair decolorizers, and hydroxyethyl diphosphonic acid[47,50].

Arsenical, Elemental and Heavy Metal Dermatoses

Key features

- Chronic arsenic exposure may occur via contaminated drinking water or occupational exposure
- Chronic arsenicism is characterized by mottled hyperpigmentation with areas of hypopigmentation, keratoses on the palms and soles (and other sites), and multiple non-melanoma skin cancers, particularly Bowen disease
- Histologically, arsenical neoplasia is almost identical to actinic neoplasia

Introduction

Arsenic is a ubiquitous metalloid, ranking 20th in abundance among all the elements. Exposure occurs via drinking water, agricultural uses, ore mining, and medicinal applications. Chronic exposure poses significant health risks, including development of benign and malignant tumors (Table 88.11)[51,52,55,56]. Additional toxic elements and heavy metals, along with their cutaneous impact, are outlined in Table 88.12[51,52,55–69]. Allergic contact dermatitis due to metals is covered in Chapter 14.

History

Medicinal effects of arsenic have been known since the days of Hippocrates and Galen. Early applications of arsenic included the treatment of inflammatory dermatoses (e.g. psoriasis, eczema, lupus, urticaria), infections (e.g. furuncles, syphilis, leprosy, warts, molluscum contagiosum), epitheliomas, and lichen rubor[28]. Even in the late 1800s, cutaneous side effects of arsenic exposure were noted, including pruritus, papulosquamous eruptions, and palmoplantar keratoses.

Chemical forms of therapeutic arsenic include Fowler's solution (liquor potassii arsenitis), arsenici bromidum, arsenici iodidum, Salvarsan (arsphenamine), Pearson's solution (liquor sodii arseniatis), arsenicum hydrogenisatum, Donovan's solution (liquor arseni et hydrargyri iodidi), and Asiatic pills (arsenic with opium or pepper)[28]. Apparently, Fowler's solution and Asiatic pills were the most widely used, with the latter still available in India and the Far East. Traditional Chinese medicine may continue to use inorganic arsenic. Most of the Western world has abandoned arsenicals, although treatment of asthma with Fowler's solution continued until the 1960s in parts of the US. Arsenic trioxide is now used therapeutically for acute promyelocytic leukemia[51,55].

Metallic arsenic has been consumed in large quantities by the arsenic eaters of the Swiss and Austrian Alps, believing that such consumption improved physical strength. Inorganic arsenic (the toxic form) is believed to have caused Napoleon's death during his second exile at St Helena[51].

Treatment of acute arsenic poisoning was developed during World War I to decrease the toxicity of the vesicant lewisite (2-chlorovinyldichloroarsine). British anti-Lewisite (BAL; dimercaprol) binds to the arsenic in lewisite[55].

Epidemiology

Accidental exposure to arsenic still occurs via contaminated drinking water in more than 30 countries, including India, Bangladesh, China, Taiwan, the Philippines, Thailand, Chile, Argentina, and western states in the US. Careless contamination of drinking water has resulted from mining of ores containing silver, gold, tin, copper, lead, tungsten, zinc, and cobalt. Arsenic is also present in foods and supplements such as seaweed, shellfish, tuna, and cod liver oil. Occupational exposure to arsenic occurs with pesticides, herbicides, and chromated copper arsenate-treated wood, as well as during electroplating, mining or smelting, wine making, and the manufacture of glass and gallium arsenide computer microchips[51,57].

The current World Health Organization provisional guideline value and the US Environmental Protection Agency limit of arsenic concentration in drinking water is 0.01 mg/L. In 2006, it was decreased from the previous limit of 0.05 mg/L, since cutaneous and internal cancers may develop with the latter level of exposure. However, no chronic skin changes have been noted with arsenic concentrations <0.017 mg/L in drinking water. It is estimated that globally more than 200 million people are exposed to arsenic levels in drinking water that are >0.01 mg/L[51,52,55–57].

An estimated cumulative dose of arsenic capable of producing arsenical keratoses or skin cancer is about 0.5 to 1 g. As noted previously, adverse effects have been noted when arsenic is in drinking water at a concentration as low as 0.05 mg/L. Despite this, a number

CLINICAL FEATURES OF ACUTE AND CHRONIC ARSENIC POISONING
Acute
Skin
• Flushing, erythema, facial edema, acrodynia, urticaria • Loss of hair and nails • Remaining nails show Mees' lines after 8 weeks
Gastrointestinal
• Nausea, vomiting, severe abdominal pain, profuse watery diarrhea, malabsorption
Neurologic
• Acute peripheral neuropathy • May progress to Guillain–Barré-like ascending paralysis
Other
• Pancytopenia, metallic breath odor, cardiac arrhythmias, renal failure, respiratory failure
Chronic
Skin

• Hyperpigmentation of axillae, groin, nipples, palms, soles and pressure points, with superimposed guttate hypopigmentation ("raindrops on a dusty road")
• Alopecia
• Arsenical keratoses – precancerous papules on palms and soles (Fig. 88.8)
  • Symmetric, yellow, punctate, corn-like papules measuring 2–10 mm
  • Favor thenar and hypothenar eminences, distal palms, lateral fingers, dorsal aspect of IP joints, weight-bearing plantar surfaces
  • Rarely on trunk, proximal extremities, eyelids, genitalia
  • May coalesce to plaques
• Blackfoot disease (vascular occlusive disease with blackening of skin)

Other
• Nasal septum perforation • Peripheral neuropathy • Bone marrow hypoplasia • Diarrhea • Hepatomegaly, hepatic fibrosis • Obstructive or restrictive lung disease • Diabetes mellitus
Malignancies

• Bowen disease
• Any skin surface
  • If no HPV, occurrence on sun-protected skin might suggest arsenic exposure
  • Skin-colored to erythematous papules and plaques that become keratotic
  • Scale-crust removal leaves red, moist, papillomatous base
  • Multiple lesions common
  • Invasive squamous cell carcinoma develops in 5%–20%
• Squamous cell carcinoma
  • Arising in arsenical keratosis or Bowen disease, has more aggressive behavior
  • Metastasis in one-third
• Basal cell carcinoma
  • Multiple, superficial, may resemble Bowen disease
• Extracutaneous malignancies
  • Genitourinary, especially bladder, prostate
  • Lung
  • Liver

Table 88.11 Clinical features of acute and chronic arsenic poisoning[51–54].
HPV, human papillomavirus; IP, interphalangeal.

MUCOCUTANEOUS FINDINGS ASSOCIATED WITH EXPOSURE TO TOXIC ELEMENTS AND HEAVY METALS					
Metal/ element	**Form**	**Cutaneous health hazards**	**Treatment and protection**	**IDLH***	**Cancer risk**
Aluminum	Alum, sulfates	Irritant contact dermatitis, vaccine hypersensitivity	Wash off	–	–
Antimony	Metal	Irritant contact dermatitis	Soap wash immediately	50 mg/m^3	–
Arsenic	Inorganic	See Table 88.11	Avoidance, chelation Soap and water wash immediately	Cancer: 5 mg/m^3	Lung, bladder, and skin cancer
	Arsine	Cold injury with arsine gas, including frostbite	See text	Cancer: 3 ppm	Lung cancer, lymphoma
Barium	Chloride, nitrate	Irritant contact dermatitis, burns	Water flush immediately	50 mg/m^3	–
Beryllium	Metal	Dermatitis, granulomas in skin, lung and liver	–	Cancer: 4 mg/m^3	Lung cancer
Bismuth	Telluride	Irritant contact dermatitis, black tongue	Soap wash immediately	–	–
Boron	Borates, oxide, tribromide, trifluoride	Erythema, irritant contact dermatitis, burns, anagen effluvium, loss of eyelashes	Soap wash, water flush promptly	25 ppm as trifluoride; 2000 mg/m^3 as oxide	–
Cesium	Hydrate, hydroxide	Irritant contact dermatitis, burns	Water flush immediately	–	–
Chromium	Hexavalent	Allergic and irritant contact dermatitis, skin ulceration, burns; systemic absorption can lead to renal failure, hepatic failure, anemia, coagulopathy	Water flush promptly	Cancer: 15 mg/m^3 as Cr VI	Lung, nasopharyngeal, liver, GU, and GI cancers Possibly skin cancer
Cobalt	Metal dust	Dermatitis, diffuse nodular fibrosis, cobalt-related asthma due to inhalation	Soap wash	20 mg/m^3	–
Copper	Metal dust	Dermatitis	Soap wash promptly	100 mg/m^3	–
Gold	Elemental salts	Most common: lichen planus, lichenoid drug eruption, allergic contact dermatitis, eczematous dermatitis, PR-like eruption, pruritus, flushing, erosive stomatitis Less common: chrysiasis, erythema nodosum, erythema multiforme, TEN, exfoliative dermatitis	Avoid gold-laden liquor	–	–
Indium	Metal	Irritant and allergic contact dermatitis	Soap wash	–	–
Iron	Salts	Irritant contact dermatitis, mucosal irritation	Soap wash	2500 mg/m^3 (iron oxide dust, fume)	–
Lead	Metal	Irritant contact dermatitis, gingival lead line	Soap wash promptly	100 mg/m^3	–
Lithium	Hydride	Irritant contact dermatitis, burns	Brush off gently, DO NOT WASH	0.5 mg/m^3	–
Magnesium	Carbonate	Irritant contact dermatitis	–	500 mg/m^3	–
Manganese	Cyclopentadienyl tricarbonyl	Irritant contact dermatitis	Soap wash	–	–
Mercury	Elemental, inorganic, organic	Acrodynia, tattoo reaction (cinnabar), granulomas, exanthem, slate-gray discoloration, allergic and irritant contact dermatitis, baboon syndrome, alopecia, stomatitis	Soap wash promptly Avoid mercury-laden cosmetics	10 mg/m^3 (elemental) 2 mg/m^3 (organic)	–
Nickel	Metal	Allergic contact dermatitis, systemic contact dermatitis	Water wash immediately	10 mg/m^3	Lung and nasal cancer
Osmium	Tetroxide	Irritant contact dermatitis	Soap wash immediately	1 mg/m^3	–
Platinum	Metal	Irritant contact dermatitis	Soap wash	4 mg/m^3	–
Polonium	^{210}Po radionuclide	Erythema, alopecia; ulceration in higher doses Triad of early emesis, hair loss, and bone marrow failure is characteristic of acute radiation sickness	Avoid ingestion; wash off	0.1–0.3 GBq (fatal in 3–4 weeks)	
Selenium	Elemental, alloy	Irritant contact dermatitis, conjunctivitis, skin burns, alopecia, Mees' lines	Soap wash immediately	1 mg/m^3	–
Silver	Metal, nanocrystalline	Argyria, irritant contact dermatitis, skin ulceration	Water flush	10 mg/m^3	–
Tantalum	Metal	Irritant contact dermatitis		2500 mg/m^3	
Tellurium		Dermatitis, garlic smell of sweat	Soap wash promptly	25 mg/m^3	–

Table 88.12 Mucocutaneous findings associated with exposure to toxic elements and heavy metals[51–69].

MUCOCUTANEOUS FINDINGS ASSOCIATED WITH EXPOSURE TO TOXIC ELEMENTS AND HEAVY METALS					
Metal/ element	**Form**	**Cutaneous health hazards**	**Treatment and protection**	**IDLH***	**Cancer risk**
Thallium	Soluble	Alopecia, acneiform papules, keratotic plaques on hands and feet, Mees' lines, hyperpigmentation Systemic absorption may lead to GI symptoms, followed by polyneuropathy	Water wash promptly Prussian blue, dialysis	15 mg/m^3	–
Tin	Metal, organic	Irritant contact dermatitis, skin burns, pruritus	Water flush immediately	100 mg/m^3 (metal) 25 mg/m^3 (organic)	–
Tungsten		Irritant contact dermatitis	Soap/water wash immediately	–	–
Uranium		Irritant contact dermatitis, skin burns	Soap/water wash immediately	10 mg/m^3	Lung cancer
Vanadium	Dust, fume	Irritant contact dermatitis, green tongue	Soap wash promptly	35 mg/m^3	–
Zinc	Chloride	Irritant contact dermatitis, skin burns (fixes tissue *in situ*), mucocutaneous hyperpigmentation, oral lichen planus (dental fillings)	–	50 mg/m^3	–
Zirconium		Irritant contact dermatitis, granulomas, blue–gray skin discoloration	Soap wash	25 mg/m^3	

*Concentration posing immediate danger to life and health (IDLH). Since 1979, the National Institute for Occupational Safety and Health (NIOSH) has not allowed detectable levels of known carcinogens.

Table 88.12 Mucocutaneous findings associated with exposure to toxic elements and heavy metals[51–69]. Additional information is included in Table 15.4. GBq, gigabecquerel; GI, gastrointestinal; GU, genitourinary; PR, pityriasis rosea; TEN, toxic epidermal necrolysis.

of authors have suggested that higher concentrations of 0.4 to 0.6 mg/L are actually required[53].

Chronic exposure to inorganic arsenic poses an increased risk for developing several types of cancer (see Table 88.11). Trivalent inorganic arsenic is the most toxic form, with a latent period for chronic manifestations of 30 to 50 years[51].

Pathogenesis

Many of the toxic effects of arsenic are through interference with cellular respiration and uncoupling of oxidative phosphorylation. Arsenic can cause chromosomal alterations and gene amplification, induce sister chromatid exchanges, inhibit DNA repair, and transform mammalian cells *in vitro*. The precise mechanism of tumor promotion is unknown, but arsenic has been shown to modulate expression of several key transcription factors, including p53, NF-κB, and activating protein-1 (AP-1)[51,52,55–57]. In addition, epigenetic modifications of *CDK2NA* and *DAPK* via hypermethylation of their promoter regions was found to be associated with a higher risk of developing arsenic-induced skin lesions[52].

Clinical features

Arsenic exposure can be divided into acute and chronic forms. Acute exposure (medicinal, homicidal, suicidal) produces myriad cutaneous and systemic features (see Table 88.11). Chronic arsenic exposure (drinking water, occupational) produces altered pigmentation, keratoses, and substantial malignancy risk (Fig. 88.8). The presence of arsenic-induced keratoses and skin cancers may serve as biomarkers of internal malignancy. Hazard ratios for the development of lung and urinary tract carcinomas are significantly higher (4.64 and 2.02, respectively) for patients with cutaneous features of arsenicism, as compared to those having similar arsenic exposure but no cutaneous manifestations[53].

Arsenic may be detected in blood, urine, hair and nails, with quantitative measurements via inductively coupled plasma–mass spectroscopy usually performed on blood or urine samples[57]. Patient preparation prior to sampling of blood or urine should include avoidance of vitamins, minerals, nutritional supplements, seafood, and shellfish for 48–72 hours. In addition, for urine arsenic quantitation, the patient should not have had iodinated contrast media for one month prior to testing (see chapter appendix). The normal reference interval for blood arsenic is 0–13 mcg/L and a potentially toxic level is >600 mcg/L; the normal range for urine is 0–35 mcg/L.

Pathology

Arsenical keratoses exhibit marked hyperkeratosis with scattered parakeratosis and mild to moderate keratinocyte atypia. There are no features that clearly distinguish arsenical keratoses from actinic keratoses. Lesions with only minimal atypia may resemble hyperkeratotic seborrheic keratoses.

Arsenical Bowen disease exhibits the same epidermal histologic features as common Bowen disease (see Ch. 108). Although the superficial type is most commonly observed, the basal cell carcinomas (BCCs) associated with arsenic can be any of the clinicopathologic subtypes (see Ch. 108)[51,54].

Differential diagnosis

Arsenical keratoses may resemble punctate palmoplantar keratoderma (including the porokeratotic variant) and verruca vulgaris. Small pits are often noted when central keratotic plugs are removed from the papules in the inherited keratodermas, but not with arsenical keratoses. Family history and early onset are helpful in distinguishing palmoplantar keratodermas. In the basal cell nevus syndrome, there are persistent pits due to the localized absence of stratum corneum; additional clues are the characteristic facial features, odontogenic jaw cysts, and typical basaloid proliferative histology in the palmar pits (see Ch. 108).

Treatment

Chelation therapy is the mainstay of treatment for *acute* arsenicism. Dimercaprol is the most widely used agent. Other chelating agents reported as being efficacious include dimercaptosuccinic acid (DMSA) and dimercaptopropane sulfonate (DMPS). DMPS is the treatment of choice and can improve the neuropathy and respiratory symptoms. For *chronic* arsenicism, chelation is controversial, but may reduce arsenic stores. Oral retinoids have been reported to reduce arsenical keratoses and decrease formation of arsenical BCCs. Surgical extirpation, curettage, cryosurgery, topical imiquimod or 5-fluorouracil, and photodynamic therapy have been reported with some success. These treatments are all anecdotal or based upon small series[51,54].

Illness due to Aquatic Toxin Ingestion

Introduction

Ingesting pufferfish (fugu) can result in neurotoxicity due to tetrodotoxin, while eating predatory fish that contain toxins produced by dinoflagellates leads to the gastrointestinal and neurologic symptoms of ciguatera. However, neither is associated with cutaneous manifestations. In contrast, scombroid poisoning presents with generalized flushing and sweating, facial swelling, and urticaria following consumption of scombroid fish that has not been properly refrigerated.

Fig. 88.8 Cutaneous manifestations of exposure to arsenic. A Guttate hypopigmentation superimposed on hyperpigmentation resembles "raindrops on a dusty road". **B, C** Arsenical keratoses on the plantar and palmar surface. *A, Courtesy John Steinbaugh, MD; C, Courtesy Jeffrey P. Callen, MD.*

Epidemiology

In the 1990s, scombroid poisoning accounted for 38% of all seafood-related outbreaks in the US and 32% in England and Wales[70]. Based upon analyses of data from the Foodborne Disease Outbreak Surveillance System (2000–2007) and the National Poison Data System (2005–2009), plus taking into account underreporting, it was estimated that ~15 900 cases of ciguatera and 35 000 cases of scombroid poisoning occur annually in the US[71].

Pathogenesis

Fish of the family Scombridae (including tuna and mackerel) have high levels of free histidine in their muscle tissue. While these fish were among the first reported causes of scombroid poisoning, many other fish species have subsequently been implicated, including mahi mahi, bluefish, marlin, bonito, amberjack, sardines, anchovies, herring, swordfish and salmon, with all but the last two also having high levels of muscle histidine[70].

When any of these fish are kept improperly refrigerated, bacterial histidine decarboxylase converts the histidine to histamine. Upon ingestion, the victim receives a very large dose of histamine, with prompt deleterious effects due to its binding to histamine receptors. However, some of the myriad effects cannot be explained by histamine content alone. Proposed contributing factors include potentiation of histamine absorption and inhibition of its catabolism, an as-yet-unidentified "scombrotoxin" that degranulates mast cells, and the possibility of histamine intolerance, particularly by those individuals more severely affected[70–72].

Clinical features

Symptoms of scombroid poisoning typically appear 10 minutes to 1 hour after consumption of the fish. They may include a metallic taste, headache, dizziness, tachycardia, and dysphagia. The most obvious cutaneous findings are generalized flushing, urticaria, and facial swelling. Some patients also develop nausea, vomiting, and diarrhea. Recovery can take several days. Rare cases of serious illness, including anaphylaxis, have been reported[70]. The various causes of generalized flushing are found in Tables 106.2 & 106.3.

Treatment

Antihistamines are the mainstay of treatment[70].

FRICTIONAL AND TRAUMATIC INJURY TO THE SKIN

Mechanical injuries due to plant parts (e.g. spines, glochids) are discussed in Chapter 17 and marine injuries (e.g. from sea urchins, corals) are reviewed in Chapter 85.

Corns and Calluses

Synonyms: ■ Corn – clavus, heloma ■ Hard corn – heloma durum ■ Soft corn – heloma molle ■ Callus – callosity, tyloma, intractable plantar keratosis

Key features

- Corns and calluses are keratotic lesions resulting from repeated trauma
- Ill-fitting footwear, bony protuberances, and specific activities are contributing factors
- Hard corns are found on the dorsal aspects of the toes, while soft corns are in the interdigital web spaces
- Proper footwear and medical management usually suffice

Introduction

Repeated mechanical trauma to the feet, whether from poorly fitting footwear, anatomic deformities, or work or leisure activities, produces hyperkeratosis. This otherwise natural protective response to injury may result in the formation of uncomfortable thickened areas of skin known as corns or calluses. Corns are more narrowly based and sharply defined, whereas calluses are broad-based. Calluses also form on the hands from repeated trauma, but are usually asymptomatic[73].

Epidemiology

Risk factors for the development of corns and calluses on the feet include bony protuberances, abnormal biomechanical foot function, poorly fitted shoes, and repetitive trauma due to athletic activity[73].

Pathogenesis

Bony protuberances such as the condyles of metatarsal and phalangeal bones create outward pressure on the skin. Footwear and activities (walking, running) create counterpressure at these sites.

The repeated friction and pressure leads to hyperkeratosis. The latter further compromises the site by increasing pressure. The cycle of friction, pressure, and thickening continues until a corn or callus develops[73].

Clinical features

Hard corns (heloma durum) are firm, small, dome-shaped papules with translucent central cores, most commonly found on the dorsolateral fifth toes and dorsal aspects of other toes as well as within plantar calluses overlying the second and third metatarsal heads (Fig. 88.9). Soft corns (heloma molle) are painful keratoses in the interdigital web spaces; they often become macerated. Opposing toes may exhibit "kissing lesions". Broad keratotic plaques, often under the metatarsal heads, are calluses.

A unique callus is seen on the tip of the second (and sometimes third) toe, with associated transverse ridging, thickening, and splinter hemorrhages in the nail. This is known as tennis toe (see Fig. 88.17) or center's callus. Also seen in gymnasts, soccer players, runners, football players and dancers, it results from sudden stops with repeated collision between toe tip and shoe. In many cases, the second toe is found to project further forward than the hallux[73,74]. Distal tips of hammer toes can also develop calluses (Fig. 88.10).

Differential diagnosis

These common lesions seldomly elude diagnosis, but must be distinguished from verruca vulgaris. Warts and corns interrupt dermatoglyphics, while calluses often demonstrate accentuated lines. Paring of a corn reveals a central translucent whitish yellow core, as opposed to the intracorneal hemorrhages and multiple bleeding points seen in a wart. Paring of a callus reveals layers of yellowish keratin, without the multiple punctate intracorneal hemorrhages of a mosaic plantar wart.

Fig. 88.9 Callus plus hard corns. Calluses are broad-based and have accentuated skin markings while corns are round, more sharply defined papules with a central translucency and an interruption in dermatoglyphics. The skin overlying the second and third metatarsal heads is a common location for such lesions. *Courtesy Jean L. Bolognia, MD.*

Fig. 88.10 Toe tip callus due to a hammer toe deformity. There is also a small central hemorrhagic crust and subungual hyperkeratosis of the third toe. *Courtesy Kalman Watsky, MD.*

Treatment

Treatment should be directed toward both symptomatic relief and correction of the biomechanical conflict. Paring of the callosity, with removal of the corn's central core, provides prompt relief. Filing after warm water soaking can be performed periodically by the patient. Topical agents such as salicylic acid or urea can also be used to soften the callosity. Some clinicians employ curettage or cryotherapy.

Soft cushions (silicone sheet, sheepskin) reduce friction and improve comfort. Properly fitted footwear and the use of appropriate orthotics are also recommended. If all of these maneuvers fail, a radiograph to look for exostoses and referral to orthopedic surgery may be indicated[73,74].

Black Heel and Palm

Synonyms: ■ Talon noir ■ Tache noir ■ Intracorneal hemorrhage (of the skin) ■ Post-traumatic cutaneous intracorneal blood ■ Calcaneal petechiae ■ Post-traumatic punctate intraepidermal hemorrhage

Key features

- Black macules on the palms or soles due to hemoglobin within the thickened stratum corneum
- Lesions are secondary to impact trauma and resolve with paring or time

Introduction

Black heel (or palm) is a post-traumatic intraepidermal hemorrhage seen most often in athletes. This harmless and self-healing process is a potential source of concern because of its dark black color.

History

Black heel was first described in 1961 by Crissey and Peachey[75] as calcaneal petechiae. A variety of subsequent reports under different monikers (see above) has led to confusion and debate over the proper nomenclature. The association with sports has been recognized since the beginning, with basketball being the prototypical sport.

Epidemiology

Adolescents and young adults comprise the majority of patients with this entity. Sports participation is of paramount importance, particularly basketball, lacrosse, tennis, football, gymnastics, and marching. Elderly patients with unusual palm and sole trauma may also be predisposed. Self-inflicted hammer injury can produce a similar clinical finding[75–77].

Pathogenesis

Black heel is a traumatic phenomenon thought to be due to shearing forces, often produced by sudden stopping or landing on the floor or ground. These shearing forces rupture papillary dermal blood vessels, with subsequent leakage of blood into the epidermis[77]. Hemoglobin resides in the stratum corneum for a longer transit time, and because the blood is out of reach of phagocytic cells in this location, the molecular structure of hemoglobin remains intact[76,77].

Clinical features

The black or violet–black macules are asymptomatic and may be isolated or clustered. They can form linear or horizontal arrays on the posterior or posterolateral aspect of the heel (Fig. 88.11A). Lesions are usually unilateral and favor the edge of the thick plantar keratin. Forefoot, toe, and palmar lesions have also been observed (Fig. 88.11B,C); in patients with thickened stratum corneum due to disorders of cornification, extra-palmoplantar lesions can be seen. Paring of the stratum corneum reveals red–brown to red–violet specks of dried blood, and dermoscopy can also prove useful.

Pathology

Hyperkeratosis with "lakes of hemorrhage" within the stratum corneum form the characteristic histopathology[77]. Iron stains may be negative (especially Prussian blue). Both the benzidine and Patent Blue V stains for hemoglobin are positive, perhaps because the intracorneal location has no phagocytic or proteolytic activity to allow formation of hemosiderin[76,77].

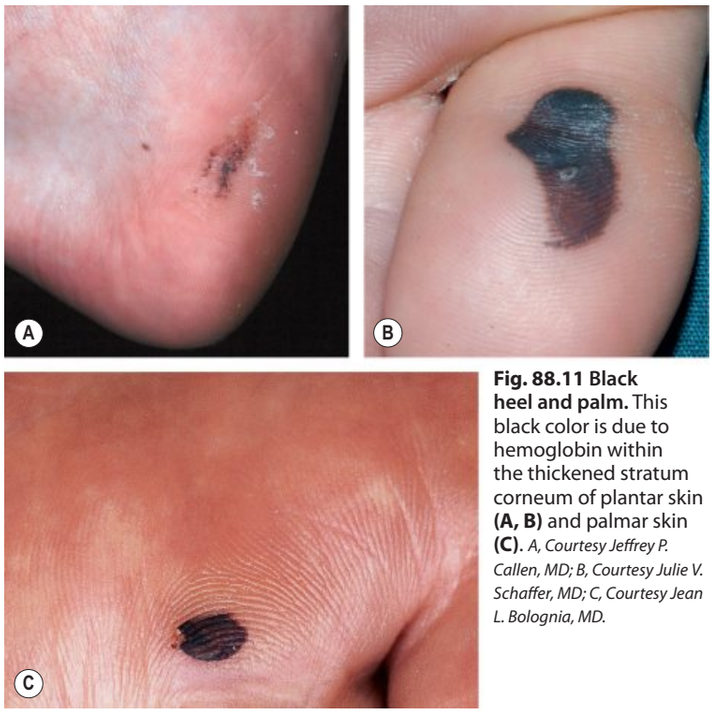

Fig. 88.11 Black heel and palm. This black color is due to hemoglobin within the thickened stratum corneum of plantar skin **(A, B)** and palmar skin **(C).** *A, Courtesy Jeffrey P. Callen, MD; B, Courtesy Julie V. Schaffer, MD; C, Courtesy Jean L. Bolognia, MD.*

Fig. 88.12 Senile gluteal dermatosis (sitter's sign). Symmetric plaques with horizontal ridging in a triangular pattern on the mid to upper buttocks. There are also areas of hyperkeratosis and irritant contact dermatitis. *Courtesy Jean L. Bolognia, MD.*

SENILE GLUTEAL DERMATOSIS
• Synonyms: sitter's sign, hyperkeratotic lichenified skin lesion of the gluteal region, grandfather's disease • Risk factors: elderly, low body mass, prolonged sitting, men > women • Etiology: pressure and friction • Clinical features: gradual appearance of poorly defined, ridged brown plaques; ridges are horizontal and can be keratotic (Fig. 88.12) • Locations: medial aspects of the mid to upper buttocks, upper gluteal cleft, over ischial tuberosities • Distribution pattern: usually bilateral and there may be a triangular distribution pattern • Symptoms: asymptomatic (~60%), pruritic (~35%), painful (<10%) • DDx: anosacral amyloidosis, lichen simplex chronicus due to scratching or rubbing by patient • Treatment: relieve pressure via cushions

Table 88.13 Senile gluteal dermatosis. See reference 78 regarding symptoms.

Differential diagnosis

The major entities in the differential diagnosis are cutaneous melanoma and verruca vulgaris. The ability to remove the lesion with gentle paring allows one to exclude a melanocytic lesion; positive staining for hemoglobin provides additional evidence. One author found the standard stool guaiac test (e.g. Hemoccult®) to be useful for confirming the presence of hemoglobin in parings[77].

Treatment

Once the diagnosis is ascertained, treatment is unnecessary.

Senile Gluteal Dermatosis

The details of this disorder are outlined in Table 88.13.

ENVIRONMENTAL DERMATOSES OF THE EXTERNAL EAR

The external ear is uniquely vulnerable to environmental stresses and trauma, given its protuberance and the thin skin overlying cartilage (Table 88.14). It is particularly susceptible to cold injuries (see above) and chronic photodamage, especially in men. Unique environmental exposure-induced conditions of the ear due to trauma, pressure, friction, or UVR include chondrodermatitis nodularis helicis (Fig. 88.13), acanthoma fissuratum (Fig. 88.14), weathering nodules (Fig. 88.15), and auricular hematoma (Fig. 88.16)[73–77,79,80].

SPORTS-RELATED DERMATOSES

Variants: ■ Tennis toe ■ Jogger's toe ■ Turf toe ■ Surfer's nodules ■ Surfer's knots ■ Jogger's nipple

Key features

- Cutaneous trauma produces abrasions, blistering, ecchymoses, callosities, and unique sport-specific stigmata
- Allergic contact dermatitis in athletes is often due to rubber antioxidants and adhesives
- Cutaneous bacterial, viral, and fungal infections occur more often in those engaged in sports with close physical contact
- Existing dermatoses may be exacerbated by sports participation

Introduction

Participation in sports may be associated with many types of cutaneous injuries or infections. Most of these problems are minor inconveniences. The following discussion will be organized into: mechanical trauma (acute, chronic); exposure-related dermatoses; infections; and exacerbation of existing conditions.

History

Cutaneous injury has been an accepted consequence of athletic activity at least since ancient Greece. Stigmata such as the wrestler's "ear-mark" have been viewed as marks of athletic prowess.

Epidemiology

Sports participation has shown a steady increase over the past several decades. Along with the gain in popularity of athletic activity has come an increase in sports-related dermatoses and infections. For example, herpes simplex viral infections among wrestlers are becoming increasingly common, with prevalence rates of herpes gladiatorum ranging from 2% to 40%. Similarly, the prevalence of tinea gladiatorum among wrestlers has been reported in up to 60%, along with multiple

ENVIRONMENT-RELATED CUTANEOUS DISORDERS OF THE EXTERNAL EAR				
Disorder	**Chondrodermatitis nodularis helicis (and antihelicis)**	**Acanthoma fissuratum**	**Weathering nodules**	**Auricular hematoma**
Synonyms	Chondrodermatitis nodularis chronica helicis, ear corn, chondrodermatitis nodularis chronica helicis et antihelicis	Granuloma fissuratum, spectacle frame acanthoma, eyeglass frame acanthoma		Wrestler's ear, cauliflower ear
Pathogenesis	Precise etiology unknown, but contributing factors include local ischemia due to pressure (often affects most protruding portion of the ear), actinic damage, cold exposure, and trauma, leading to inflammation	Ill-fitting eyeglass frames create a frictional injury	Precise pathogenesis unknown, but presence of chronic photodamage suggests a role for UV light	A glancing blow or twisting movement against the anterolateral pinna avulses the anterior perichondrium from the underlying cartilage Shearing forces rupture vessels that then bleed into the subperichondrial or intracartilaginous space
Clinical features	Usually seen in older adults Men tend to develop lesions on the helix at an earlier age, while women often develop antihelix lesions Skin-colored to erythematous, dome-shaped papules with central crusts or occasionally keratin-filled craters (Fig. 88.13A) Can be painful and tender	Firm, skin-colored to erythematous plaque or nodule on the upper portion of the postauricular sulcus or upper lateral nose, with a central vertical groove or fissure (Fig. 88.14) Tenderness, a serous discharge, slight hyperkeratosis, or an inflammatory halo may be present	Occur primarily in men with skin phototypes I and II and evidence of chronic photodamage Asymptomatic, 1–3 mm, white to skin-colored papules along the free margin of the helix (Fig. 88.15) Usually bilateral and create a scalloped appearance to the helical rim	Most commonly occurs in wrestlers, boxers, rugby players, and piano movers Painless to slightly tender swelling appears on the upper anterior aspect of the pinna in the scaphoid or triangular fossa; swelling can persist, especially if left untreated, becoming either firmer due to fibroneocartilage production or soft and cystic Color varies from skin-colored to slightly bluish Repeated injury produces the multinodular deformity known as cauliflower ear (Fig. 88.16)
Pathology	Well-circumscribed area of acanthosis, parakeratosis, and hypergranulosis; a central crater with epidermal disruption may be filled with a keratotic plug or dermal debris (Fig. 88.13B) The underlying dermis shows degenerative changes with fibrosis and variable lymphohistiocytic inflammation; the infiltrate extends into a thickened perichondrium	Irregular acanthosis, most marked at the lesion's periphery, with occasional pseudoepitheliomatous hyperplasia The central depression may show epidermal thinning with compact orthohyperkeratosis and patchy areas of parakeratosis near the central groove Dermal papillae exhibit dilated vessels and a moderately dense perivascular inflammatory infiltrate comprised of lymphocytes, histiocytes and plasma cells, with occasional neutrophils; slight fibrosis may be noted in the superficial and mid dermis	Fibrous tissue spur with cartilage metaplasia extending upward from disrupted perichondrium No inflammation or epidermal disruption are noted	Hematoma plus fibrosis and foci of new cartilage formation Older lesions may exhibit calcification and even ossification within the hematoma
Differential diagnosis	AK, SCC, BCC, cutaneous horn, verruca > KA, weathering nodule, calcinosis cutis, gouty tophi, reactive perforating collagenosis	BCC, SCC *in situ*, lichen simplex chronicus superimposed on seborrheic or allergic contact dermatitis > keloid	Gouty tophi, calcinosis cutis, CNH, elastotic nodules, amyloidosis, granuloma annulare	Auricular pseudocyst, relapsing polychondritis, epidermoid cyst
Treatment	Padding to relieve pressure, surgical excision, cryotherapy, corticosteroid injections, topical corticosteroids, laser ablation, soft tissue fillers, nitroglycerin gel and patches	Lesions usually clear within a few months of discontinuation, replacement, or proper adjustment of the offending spectacles Excision can be considered for persistent lesions Intralesional corticosteroids (case reports)	Treatment rarely required Cryosurgery (case reports)	Evacuation of the hematoma and prevention of fluid reaccumulation via aspiration or incision and drainage (with or without cartilage removal) then splinting

Table 88.14 Environment-related cutaneous disorders of the external ear[79–85]. Elastotic nodules of the ears are due to chronic photodamage and favor the antihelix. AK, actinic keratosis; BCC, basal cell carcinoma; CNH, chondrodermatitis nodularis helicis; KA, keratoacanthoma; SCC, squamous cell carcinoma.

epidemics[86,87]. Cutaneous infections with community-acquired MRSA have also been observed among athletes, with nasal colonization rates in team athletes higher than in the general population (4%–23% vs 1.3%, respectively)[88,89]. Risk factors include frictional injuries, weight, poor hygiene, and sharing clothing and towels with team members.

Pathogenesis

The types of frictional and mechanical trauma that can lead to dermatoses in athletes are summarized in Table 88.15. For example, acne mechanica is thought to occur when the local microenvironment of the skin is altered by a combination of pressure, heat, moisture (perspiration), friction, and occlusion[90].

Exposure to heat and cold are discussed in other sections of this chapter.

Clinical features

Acute or chronic mechanical trauma during sports activity creates unique cutaneous lesions summarized in Table 88.15.

In some patients, chronic friction on extensor extremities during the summer is thought to produce frictional lichenoid dermatitis

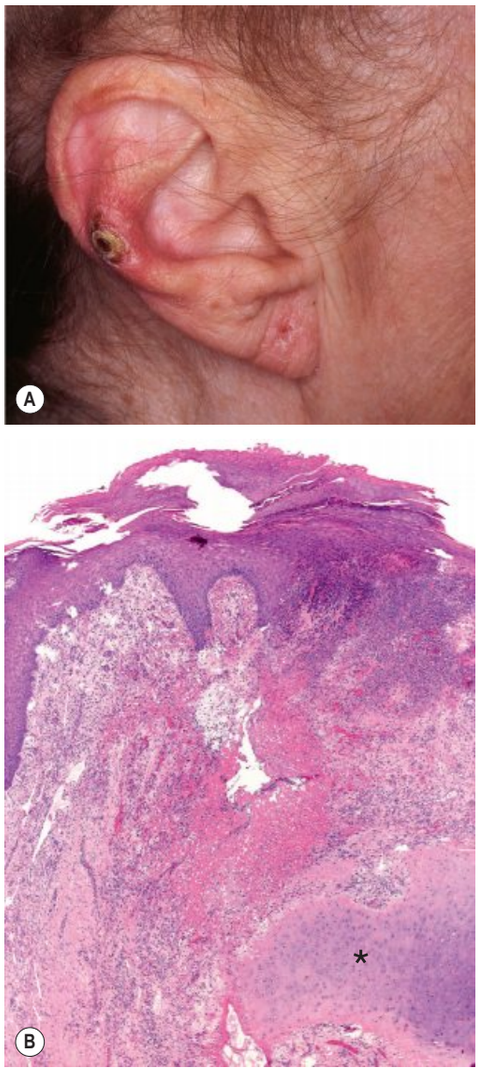

Fig. 88.13 Chondrodermatitis nodularis (anti)helicis. **A** Tender, erythematous papulonodule with central scale-crust on the mid antihelix of an older woman. This represented the site most susceptible to pressure-induced ischemia. **B** Central hyperkeratosis with scale-crust, epithelial hyperplasia, chronic inflammation, hemorrhage, fibrosis, granulation tissue, and degenerated cartilage (*) are seen on histologic examination. *A, Courtesy Kalman Watsky, MD; B, Courtesy Lorenzo Cerroni, MD.*

(summertime pityriasis). This malady affects prepubertal children (mostly boys) and is characterized by irregular clusters of pale to skin-colored, flat-topped, lichenoid papules on the elbows, knees, and dorsal metacarpophalangeal and interphalangeal joints, as well as extensor shins and forearms. Mild pruritus may develop, although most children are asymptomatic[91].

Another common finding in athletes is the presence of striae distensae, or stretch marks (see Fig. 99.6). Although striae appear in non-athletic settings (e.g. Cushing syndrome, obesity, pregnancy, overuse of corticosteroids) and they are thought to occur in 70% of adolescent girls and 40% of adolescent boys[90], weightlifting has been identified as a risk factor. Striae are therefore commonly observed in football players, wrestlers, gymnasts, and body builders[86,87] and favor the anterior shoulders, lower back, and thighs.

Environmental exposure creates additional challenges for sports enthusiasts, especially with activity during temperature extremes. Summer heat poses risks such as heat exhaustion and heat stroke (see above). Mountain climbers, skiers (downhill and Nordic), biathletes, winter hikers, and others are at risk for cold injury (see above). Water exposure in swimming, diving, snorkeling, and scuba diving has intrinsic risks as well. Overhydration of the stratum corneum increases susceptibility to blisters, skin breakdown, and cutaneous infection.

As in the general population, irritant contact dermatitis is more prevalent than allergic contact dermatitis (ACD), and while the latter is likely to be as common among athletes as the general population, specific presentations reflect the use of specialized equipment. Erythema in the distribution of a swimmer's goggles or scuba mask ("mask burn") may be seen, and individuals with more severe reactions can also develop vesiculation, weeping, crusting, pruritus, and pain. Rubber antioxidant allergy is known to occur in this setting, with mercaptobenzothiazole, tetramethylthiuram, and paraphenylenediamine derivatives being the major allergens. Rubber compounds in athletic shoes pose risks to individuals with contact sensitivity, particularly with thiourea, mercaptobenzothiazole, and thiuram antioxidants. The resulting erythema, desquamation, vesiculation, fissuring, pain, and pruritus of the feet can prove quite disabling for the athlete, particularly when alternative footwear

FRICTIONAL AND MECHANICAL DERMATOSES IN ATHLETES				
Condition	**Clinical features**	**Sports**	**Etiology/pathogenesis**	**Prevention/treatment**
Friction blisters (see Ch. 33)	Bullae and superficial erosions	Any	Friction or tangential impact to foot while in warm moist shoes	Frequent drying of feet, lubrication, proper shoe fit, drain blisters/ leave roof
Contusion	Ecchymosis	Any	Perpendicular mechanical trauma producing vascular damage	Padding
Subungual hematoma		Running, tennis, basketball	Sudden impact of toe tip with end of shoe	Enlarged shoe toe box with proper arch and metatarsal support, drainage of hematoma may be needed
Black heel/talon noir	See text			
Turf toe	Painful, erythematous, edematous hallux	Football, soccer	Acute dorsal and plantar tendonitis	Rest
Jogger's nipple	Pain, erythema, fissuring, occasional bleeding	Running	Repeated friction of rough shirt fabric	Woman: jogging bra Man: taping, lubrication, semisynthetic or silk shirt
Callosities	See text	Many		
Tennis toe	Toe tip callus, nail thickening, subungual hyperkeratosis (Fig. 88.17)	Tennis, running, ice hockey, skating	Repeated trauma of longest toe against inside of toe box	Proper shoe fit, enlarged toe box, improved arch support
Nail dystrophy	Onycholysis, hematoma, subungual hyperkeratosis, paronychia, onychocryptosis (ingrown nail)	Many	Repeated trauma to nails	Keeping nails trimmed with a straight edge, proper shoe fit
Fibrotic nodules (e.g. surfer's knots)	Thick fibrotic nodules on knees, knuckles, dorsal feet	Surfing, boxing, football, marbles, cricket, baseball, ice hockey, skating	Chronic pressure over bony prominences	Padding, position change, prone rather than kneeling on surfboard
Skate bite	Painful inflammatory plaques or pseudonodules under the tongue of the skate	Ice hockey, figure skating	Pressure from a rigid skate tongue over the anterior ankle or dorsal foot	Padding under the skate tongue or improve pliability of the tongue
Piezogenic papules	Multiple asymptomatic to tender yellowish outpouchings on the medial and lateral aspects of the heels when standing (Fig. 88.18)	Distance running, high-impact sports, figure skating	Herniation of subcutaneous fat through small tears in plantar fascia	None known
Runner's rump	Small ecchymoses in upper gluteal cleft	Running	Constant friction with each stride	Lubrication
Rower's rump	Well-demarcated, lichenified plaques of the buttocks	Rowing	Repeated friction and trauma between buttocks and unpadded seat of a rower	Padded seat or shorts Potent topical or intralesional steroids
Swimmer's shoulder	Erythematous plaque on shoulder	Swimming	Friction of unshaven beard against the shoulder during the swim stroke	More frequent shaving
Alopecia and hypertrichosis	Transient alopecia on forearms followed by hypertrichosis	Gymnastics	Frictional alopecia, compensatory regrowth	

Table 88.15 Frictional and mechanical dermatoses in athletes[86–98]. Acne mechanica and auricular hematoma are discussed in the text and Table 88.14, respectively. Auricular pseudocyst, which is seen most commonly in rugby players, is reviewed in Ch. 110.

Fig. 88.17 Chronic "tennis toe". Chronic and repeated trauma of the longer second toe against the end of the tennis shoe toe box during sudden stops creates the distal callus formation and nail plate thickening known as tennis toe.

Fig. 88.18 Piezogenic papules. Yellowish outpouchings on the heel represent herniation of subcutaneous fat through the plantar fascia in this sometimes painful condition.

without rubber (e.g. soccer cleats, baseball cleats) is not readily available. However, the development of polyurethane shoes by a few manufacturers offers an alternative for runners allergic to rubber components.

Acetophenone azine is an emerging allergen that has been identified in ethyl vinyl acetate-containing foam that is used in shin guards, shoe soles, and flip-flops. The resultant ACD has been referred to as shin guard dermatitis[99]. Adhesives in tape, benzoin, topical antiseptics and antibiotics, dyes, and leather tanning agents also may be problematic in athletes[89,90,96]. For excellent reviews of contact allergens in sports equipment, see references 89 and 92.

Acne mechanica occurs commonly in athletes in whom occlusive uniforms or protective gear create the right microenvironment. Football players flare during the August pre-season practice with follicular papules, pustules and nodules on the forehead, preauricular areas, chin and shoulders, corresponding to forehead and ear pads of the helmet, chin strap, and shoulder pads, respectively. Acne keloidalis of the lower occiput may be aggravated by the helmet as well. Other sports in which protective headgear may create acne mechanica include hockey, lacrosse, and wrestling. Occlusive synthetic clothing of dancers and gymnasts, plastic benches of weight lifters, golf bag shoulder straps, and the cradling of the shot against the neck in shot putters may also produce acne mechanica[87,90,96].

Heat, moisture, friction, and contact with other athletes or various surfaces increase the risk of several cutaneous infections (Table 88.16). Common monikers attest to these associations, such as "jock itch", "herpes gladiatorum", "athlete's foot", and "swimmer's ear". A report that evaluated the risk of staphylococcal infections in football players within a professional team noted that weight and turf injuries were risk factors and, therefore, linemen were more prone to developing this infection. However, habits of the trainers and the use of whirlpool equipment also pointed to risks associated with poor hygienic practices[88].

The final issue of sports-related skin disease is aggravation of pre-existing conditions. Psoriasis, vitiligo, and lichen planus may exhibit a Koebner phenomenon, flaring in areas of skin injury such as abrasions. Epidermolysis bullosa simplex, localized (formerly Weber–Cockayne) is worsened by friction on the feet and hands, particularly in warm summer months (see Ch. 32). Photosensitive dermatoses may be exacerbated by outdoor sun exposure (see Ch. 87). Both cholinergic and exercise-induced urticaria may worsen with heavy physical exertion[89] (see Ch. 18). Vibratory angioedema has also been reported with bicycling, walking, and jogging[93]. The reader is referred to the American Academy of Pediatrics guide for further information on medical conditions affecting sports participation[94].

CUTANEOUS INFECTIONS IN ATHLETES

Condition	Common name	Clinical features	Organisms	Typical sport
Impetigo		Small vesicles to large bullae on glistening erythematous bases; honey-colored crusts	*Staphylococcus aureus*, β-hemolytic streptococci	Most sports, especially close contact
Folliculitis		Erythematous follicular papules and pustules	*S. aureus*	Most sports
Hot tub folliculitis		Markedly erythematous, edematous follicular papulopustules, few in number, often involving axillae, breasts, pubic area, and buttocks	*Pseudomonas aeruginosa*	Swimming; use of whirlpool, hot tub, or Jacuzzi
Pseudomonas hot-foot syndrome		Tender nodules on soles	*P. aeruginosa*	Use of wading pool
Furuncles	Boils	Tender, warm, red nodules or abscesses on trunk or extremities	*S. aureus*, including MRSA	Football, wrestling, basketball, swimming
Erythrasma		Reddish-brown dry patches in axillae, groin, or toe webs	*Corynebacterium minutissimum*	Most sports, especially with occlusive clothing
Pitted keratolysis	Toxic sock syndrome	Malodorous feet with 1–3 mm, punched-out, plantar erosions extending only through the stratum corneum of overhydrated skin	*Corynebacterium* spp., *Kytococcus* (*Micrococcus*) *sedentarius*, *Dermatophilus congolensis*	Running, tennis, basketball, ice hockey, skating
Otitis externa	Swimmer's ear	Pruritus may be followed by pain, discharge, tenderness of the pinna, sensation of fullness, and reduced hearing	*P. aeruginosa* most common; also streptococci, diphtheroids, and staphylococci	Swimming, diving (those with an atopic diathesis at risk)
Swimming pool granuloma		Firm, acral, red papules	*Mycobacterium marinum*	Swimming
Verruca vulgaris	Warts	Verrucous, keratotic papules and plaques	Human papillomavirus	Any that use locker-room showers or public pools
Herpes simplex viral infection	Herpes gladiatorum	Clustered vesicles on erythematous bases at point of skin-to-skin contact	Herpes simplex virus	Wrestling
Molluscum contagiosum		Shiny, umbilicated 2–3 mm papules at the skin contact site	Parapoxvirus	Wrestling, swimming
Tinea pedis	Athlete's foot	Maceration, scaling, pruritus in toe webs; diffuse plantar erythema and scale	*Trichophyton rubrum, T. interdigitale, Epidermophyton floccosum*	Any sport
Tinea cruris	Jock itch	Annular to polycyclic erythema with scaly, active borders; perifollicular papules or pustules; favors upper inner thighs	Same as tinea pedis	Any sport
Tinea corporis	Tinea gladiatorum	Except for location, the same as tinea cruris	*Trichophyton* spp.	Wrestling
Seabather's eruption	Sea lice	Pruritic papules on areas covered by bathing suit	*Edwardsiella lineata, Linuche unguiculata*	Salt water swimming
Swimmer's itch	Cercarial dermatitis	Pruritic erythematous papules on exposed skin	Avian schistosome cercaria	Fresh water pond and lake swimming and wading

Table 88.16 Cutaneous infections in athletes[86–91,97,100].

DERMATOLOGIC CONDITIONS IN LIMB AMPUTEES AND TREATMENT STRATEGIES				
Physical/mechanical effects	**Allergic contact dermatitis (most common allergens)**	**Infections**	**Exacerbation of pre-existing condition**	**Other**

• Irritant contact dermatitis
• Pruritus
• Sensitive and/or painful skin
• Altered temperature sensation
• Hyperhidrosis
• Erythema
• Callus and verrucous hyperplasia
• Hypertrichosis
• Edema
• Blisters
• Abrasions
• Ulceration
• Folliculitis (normal flora), pseudofolliculitis, follicular hyperkeratosis
• Epidermoid inclusion cyst, milia
	• Para-phenylenediamine (PPD)
	• Formaldehyde
	• Epoxy resin
	• Mercapto mix
	• Fragrance mix
		• Group A β-hemolytic *Streptococcus*
		  • impetigo, cellulitis
		• *Staphylococcus aureus*
		  • impetigo, cellulitis, folliculitis
		• *S. epidermidis*
		• Dermatophytes
		• *Candida* spp.
			• Psoriasis
			• Eczema/atopic dermatitis
			• Pyoderma gangrenosum
				• Stasis dermatitis
				• Acroangiodermatitis
				• Localized bullous pemphigoid
				• Marjolin ulcer (SCC)
				• Verrucous carcinoma
				• Angiosarcoma

Treatment strategies				
Folliculitis	• Clipping of hairs rather than shaving • Laser hair removal of pigmented hairs, avoiding hairs within tattoos as this can lead to ulceration			
Hyperhidrosis	• Topical aluminum chloride (see Table 39.7) • Topical and oral anticholinergics • Botulinum toxin injections • Microwave thermoablation			

Table 88.17 Dermatologic conditions in limb amputees and treatment strategies[102–104]. SCC, squamous cell carcinoma. *Courtesy Tim Durso, MD.*

Pathology

Many of the friction-induced conditions discussed here have histologic features similar to callosities (see above). Surfer's nodules show hyperkeratosis and mild acanthosis of the epidermis with increased numbers of normal-appearing collagen bundles. The overall histologic appearance is similar to that of a collagenoma[95]. The infectious processes are covered in detail in their respective chapters, as are the existing dermatoses aggravated by sports participation.

Treatment

Therapy for the non-infectious conditions discussed in this section is based primarily upon anecdotal reports and small series, and it is summarized in Table 88.15. Frictional lichenoid dermatitis responds to friction avoidance, the use of clothing to protect extensor surfaces, and moderate-potency topical corticosteroids[89–91,96]. Education and changes in practice behavior may aid in the prevention of infections in athletes. Therapeutic regimens for cutaneous infections are discussed elsewhere in the text.

AMPUTEE-RELATED DERMATOSES

Whether amputation is due to traumatic injuries (vehicular accidents, war-related, sports-related), environmental exposure, or a chronic medical condition (e.g. diabetes mellitus, peripheral artery disease, congenital abnormality, tumor), skin disorders are a frequent complication, with reported incidences ranging from 35% to 75%. For example, a survey of lower limb amputees found that 63% reported at least one skin problem during the preceding month, with the most common being severe sweating (50%), persistent redness after prosthesis removal (46%), and skin sensitivity (36%)[101]. In a clinical study of 124 lower limb amputees attending an orthopedic clinic, the prevalence of skin problems was 36%, and the latter led to reduced prosthetic use and decreased walking time without taking a break[102].

Table 88.17 lists dermatologic conditions observed in amputees. Implicated risk factors include higher level of amputation, higher activity level, and soft socket (as opposed to silicone) prostheses[103]. A meta-analysis of 27 studies (3105 patients) also found that traumatic below-knee and through-knee amputations were associated with a better quality of life in almost all their measures, when compared to above-knee amputations[103,104].

Treatment

While a detailed discussion of the management of these multisystem injuries is beyond the scope of this text, there are noteworthy studies. In a randomized controlled study involving 20 transtibial amputees with residual cutaneous ulcers or delayed wound healing, a vacuum-assisted active suction socket system led to a faster recovery and significant improvement in early ambulation (median 62 hours/week vs 5 hours/week); by 6 months there was no difference between the groups[105].

Battlefield injuries due to improvised explosive devices (IEDs) can lead to large BSA damage, contaminated wounds, and multiple amputations. As a result, there may be minimal healthy skin to serve as donor tissue, and the associated severe physiologic compromise makes grafting difficult. Therefore, alternative wound coverings are being utilized, e.g. a dermal bovine collagen regenerative matrix[106].

MUSICAL INSTRUMENT-RELATED DERMATOSES

Variants: ■ Cellist's chest or knee ■ Clarinetist's cheilitis ■ Drummer's digit ■ Fiddler's neck ■ Flautist's chin ■ Garrod's pads ■ Guitar nipple ■ Harpist's fingers

Key features

- Cutaneous disorders in musicians include frictional injury, irritant and allergic contact dermatitis, hyperhidrosis, acne mechanica, and vascular compromise
- Dermatoses tend to be recurrent unless the posture, use, or contact can be avoided
- Identification of the mechanism of injury is critical for successful therapy

Introduction

Musicians have unique cutaneous reactions related to countless hours of practice and performance required to master their art. Skin and associated soft tissue and musculoskeletal changes are therefore not uncommon. The major categories of injury in musicians are contact dermatitis, repetitive motion injury, and dysautonomia.

History

One of the first reports of an occupational dermatosis is reputed to be the recognition of fiddler's neck in 1713. About the same time, Italian physician Bernadino Ramazzini noted the peculiar distension and soft tissue laxity of the cheeks in horn players, and summarized the occupational problems of musicians[107].

DERMATOSES CAUSED BY MUSICAL INSTRUMENTS			
Condition (synonym)	**Clinical features**	**Pathogenesis**	**Associated instruments**
Acne mechanica and/or LSC (fiddler's neck, clarinetist's cheilitis, flautist's chin)	Follicular papules and pustules, lichenification, hyperpigmentation	Repetitive friction and pressure, coupled with occlusion and moisture (sweat, saliva)	Violin, viola, clarinet, saxophone, flute
Cellist's chest	Sternal skin tenderness, erythema, edema, hyperpigmentation	Pressure and friction	Cello
Cellist's knee	Erythema, scale, callus, and hyperpigmentation of left medial knee	Friction callus	Cello
Finger calluses	Hyperkeratotic callosities on fingertip pads	Repetitive friction	All strings
Drummer's digit	Vesicle or erosion on the radial aspect of the left ring finger distal and middle phalanx, followed by callus formation	Friction from holding left drumstick in classical position	Drums
Garrod's pads (violinist's pads)	Calluses on dorsal aspect of proximal interphalangeal joints of left index and middle fingers	Repeated extension and flexion of extensor tendon over tightly flexed joint	Violin, viola
Guitar nipple	Unilateral mastitis with erythema, edema, pain	Pressure and friction of guitar sound box pressed against chest	Guitar
Paronychia, onycholysis, subungual hemorrhage		Repeated trauma to nail apparatus	Piano, strings (especially playing pizzicato), harp, guitar

Table 88.18 Dermatoses caused by musical instruments[107–109]. LSC, lichen simplex chronicus.

Epidemiology

The injuries discussed below all require considerable devotion of time to practice and performance of the chosen instruments. Some of these conditions are considered marks of virtuosity, such as cellist's thumb. The impact of these conditions is greatest on professional musicians, although amateurs, and even beginners, may be afflicted[108].

Pathogenesis and clinical features

The clinical features and pathogenesis of dermatoses caused by musical instruments are summarized in Table 88.18.

Another common dermatosis that may occur in musicians is "lip licker's" dermatitis, characterized by erythema, fissuring, and scaling in wind instrument players. Intraoral hyperkeratosis of the lip or shallow erosions may develop in patients with dental irregularities or orthodontic appliances. Salivary abnormalities may interfere with performance with wind instruments. Xerostomia is devastating to the wind player (especially brass), while increased salivation is problematic for the recorder player. Sialolithiasis has been seen in association with fiddler's neck.

Sharing of mouthpieces may increase the risk of transmission of infections such as herpes simplex virus, EBV, cytomegalovirus, and hepatitis A and B viruses. Latent herpes simplex may be reactivated by the frictional trauma of wind instruments, with brass players tending to have upper lip lesions and woodwind players having lower lip lesions[109].

Hyperhidrosis of the palms may lead to corrosion of metal instruments or the inability to maintain proper contact with instrument keys or strings[110].

Allergic contact dermatitis associated with musical instruments is summarized in Table 88.19.

Pathology

Diagnosis of most of these conditions does not require histologic evaluation. However, fiddler's neck has been shown to exhibit epidermal hyperplasia with elongation of the rete ridges, follicular plugging, folliculitis and perifolliculitis, and epidermoid cyst formation[109].

Differential diagnosis

Fiddler's neck needs to be distinguished from localized cervical lymphadenitis, an inflamed epidermoid cyst, draining dental abscess, and acne mechanica from other causes (e.g. telephone, headset). Clinical history should suffice, along with the characteristic location and clinical features. For example, a dental abscess, scrofuloderma, or cervical actinomycosis with fistula formation often leaves the area indented and bound to underlying structures.

ALLERGIC CONTACT DERMATITIS ASSOCIATED WITH MUSICAL INSTRUMENTS		
Sensitizer/contactant	**Skin distribution**	**Instrument**
Rosin/colophony (abietic acid)	Hands, face, neck	Violin, viola, cello, double bass
Rosewood	Lips, chin, cheek	Strings, reeds
Makassar ebony	Chin	Violin
Cocobolo wood	Lips	Recorder
African blackwood	Lips	Recorder, oboe
Nickel	Chin	Violin
	Fingers, hands	Cello, sitar
	Lips, chin	Flute, brass
Reed (perhaps only irritant)	Lips	Saxophone, clarinet
Propolis (bee glue)	Hands	Violin
Chromium	Hands	Harp, violin
Paraphenylenediamine	Chin	Violin, viola

Table 88.19 Allergic contact dermatitis associated with musical instruments[107–111].

Treatment

Discontinuation of the instrument is curative in almost all cases, but usually quite impractical. Professional musicians, in particular, need other options. Frictional injuries may be addressed with padding, or change in position of the instrument. Fiddler's neck, for example, seems less common if the dropping neck position is avoided. Anecdotal remedies for the treatment of fiddler's neck include astringents, benzoyl peroxide, keratolytics, tretinoin, topical antibiotics, and application of French brandy.

Treatment of excess salivation with a transdermal scopolamine patch has been reported. Remedies for hyperhidrosis include topical aluminum-based drying agents, iontophoresis, β-adrenergic blocking agents (especially if the hyperhidrosis is due to "stage fright"), calcium channel blockers, botulinum toxin A, and ganglionectomy (see Ch. 39). Anticholinergic therapy is not useful for many musicians because of the frequent side effects of dry mouth and blurred vision[107–109]. If allergic contact dermatitis is suspected, patch testing can be performed (see Ch. 14).

APPENDIX

ARUP Laboratories at the University of Utah – measurements of blood (http://ltd.aruplab.com/tests/pub/0099045) and urine (http://ltd.aruplab.com/tests/pub/0025000) arsenic levels

Mayo Clinic Laboratories – measurements of blood (Test ID: ASB) and urine (Test ID: ASU) arsenic levels

Signs of Substance Use Disorder 89

Yul W. Yang and Mark R. Pittelkow

INTRODUCTION

The 2013 Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5) defines substance use disorder as "a cluster of cognitive, behavioral, and physiological symptoms indicating that the individual continues using the substance despite significant substance-related problems" (Table 89.1). The disorder encompasses ten classes of drugs: alcohol; caffeine; cannabis; hallucinogens; inhalants; opioids; sedatives, hypnotics or anxiolytics; stimulants; tobacco, and other (or unknown) substances[1,2]. Any one of these drugs can result in changes in brain physiology and pathologic behavior. Prior to DSM-5, substance use disorder was subdivided into substance abuse and substance dependence. While this distinction may still be used clinically, *substance use disorder* represents the overarching and currently preferred term[2].

A wide range of cutaneous findings are associated with substance use disorders and they can serve as a clue to the diagnosis. The skin is reportedly the tissue most evidently affected by intravenous drug addiction[3]. Complications may be local or systemic and can be due to the drug itself, adulterants, or contaminants including infectious agents.

SUBSTANCE USE DISORDER AS DEFINED BY DSM-5
A problematic pattern of use leading to clinically significant impairment or distress is manifested by two or more of the following within a 12-month period:
1. Often taken in larger amounts or over a longer period than was intended
2. There is a persistent desire or unsuccessful efforts to cut down or control use
3. A great deal of time is spent in activities necessary to obtain, use, or recover from the substance's effects
4. Craving or a strong desire or urge to use the substance
5. Recurrent use resulting in a failure to fulfill major role obligations at work, school, or home
6. Continued use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance
7. Important social, occupational, or recreational activities are given up or reduced because of use
8. Recurrent use in situations in which it is physically hazardous
9. Continued use despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance
10. Tolerance, as defined by either of the following: a. A need for markedly increased amounts of the substance to achieve intoxication or desired effect b. A markedly diminished effect with continued use of the same amount of the substance
11. Withdrawal, as manifested by either of the following: a. The characteristic withdrawal symptoms for the substance (refer to DSM-5) b. The substance (or a closely related substance) is taken to relieve or avoid withdrawal symptoms

Table 89.1 Substance use disorder as defined by DSM-5. Grading: mild (2–3), moderate (4–5), and severe (6 or more). *Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (Copyright ©2013). American Psychiatric Association. All Rights Reserved.*

Alcohol

Drinking alcohol can lead to euphoria and a lowering of inhibitions as well as impaired functioning. In the US, alcohol use disorder has a 12-month prevalence of 8.5% amongst adults[1]. Acutely, ingestion of alcohol may lead to transient flushing, especially in individuals (e.g. East Asians) with variants in alcohol metabolizing enzymes[4]. Trauma-induced ecchymoses secondary to falls due to ataxia or vehicular accidents may point to alcohol-induced impairment. Cutaneous findings such as spider telangiectasias, palmar erythema, and jaundice can develop in patients with alcoholic hepatitis and cirrhosis (see Ch. 53)[5–7]. Porphyria cutanea tarda and rosacea are examples of disorders that may be exacerbated by alcohol.

Stimulants

Stimulants include amphetamines (e.g. dextroamphetamine), cocaine ("coke", "blow" [powder form]; "crack" [freebase crystallized form]), methamphetamine ("meth"), methylphenidate, and cathinones (e.g. khat, mephedrone, "bath salts"). Routes of administration include oral ingestion, snorting, inhalation via smoking, and intravenous injection. While many of these stimulants represent illicit drugs, dextroamphetamine and methylphenidate are prescribed for narcolepsy and attention deficit hyperactivity disorder. Stimulants lead to a feeling of euphoria and confidence, with reduced appetite, restlessness, insomnia, and increased or distorted sensations. Patients can also develop tachycardia and hypertension, as well as flushing, sweating, uncontrollable movements, and seizures.

Stimulants, in particular crystallized methamphetamine ("crystal meth"), are highly addictive and high-intensity or chronic abusers can develop xerostomia, xerosis, pruritus, acne excoriée and formication, along with dental caries and loss of teeth ("meth mouth"). Cocaine use has also been associated with Raynaud phenomenon, cutaneous small vessel vasculitis, necrotizing granulomatous vasculitis, acute generalized exanthematous pustulosis, and Stevens–Johnson syndrome[8]. Ventricular arrhythmias and myocardial or cerebrovascular infarctions are additional side effects. When cocaine is adulterated with levamisole, neutropenia, pyoderma gangrenosum, and ischemic vasculopathy with necrotizing purpura and ulcerations may develop (see below).

Hallucinogens

Hallucinogens include phencyclidine (PCP; "angel dust"), ergolines (e.g. lysergic acid diethylamide [LSD; "acid"], lysergic acid amide from morning glory seeds), and phenylalkylamines (e.g. mescaline). Ketamine is a dissociative anesthetic that also has some hallucinogenic effects while 3,4-methylenedioxy-methamphetamine (MDMA; "ecstasy", "molly", "E", "X") is both a stimulant and hallucinogen. Psilocybin-containing mushrooms ("magic mushrooms"), dimethyltryptamine-containing Amazonian plants, *Salvia divinorum*, and *Datura stramonium* (jimsonweed) are additional natural sources of hallucinogens.

Hallucinogens may be ingested orally, smoked, snorted, or injected. They can produce alterations in mood, cognition, and perception, including visual pseudohallucinations. Side effects of PCP include sweating, sialorrhea, combative behavior, tachycardia, and hypertension; higher doses can lead to seizures, hypotension, and coma. Hyperthermia with rhabdomyolysis and renal failure can result from high doses of MDMA.

Opioids (Includes Opiates)

Opioids may be synthesized or extracted from opium poppies (*Papaver somniferum L.*). They are prescribed primarily for pain control, including morphine, hydrocodone, oxycodone, oxymorphone, and fentanyl. Methadone is also used to treat chronic pain in addition to opioid use disorder related to heroin (diacetylmorphine) and prescription opioids. In opioid use disorder, there is compulsive, prolonged, self-administration of opioids either without a legitimate medical purpose or in doses that exceed those required for a particular medical condition[1].

Opioids may be taken orally, snorted, smoked, or injected intravenously or subcutaneously. With lipid-soluble opioids such as heroin that quickly cross the blood–brain barrier, there can be a "rush" of euphoria immediately. Associated side effects include dry mouth/nose, flushing, decreased gastrointestinal motility, pupillary constriction, pruritus, and altered mental function. Overdose-related respiratory depression can be fatal and the exponential increase in the use of fentanyl as well as fentanyl- and carfentanil-laced drugs has led to an epidemic of overdose deaths.

Opioids may also contain additives that result in significant cutaneous disease. For example, desomorphine ("krokodil") is a fast-acting morphine derivative that is ten times more potent than morphine[9]. The drug can be synthesized by combining red phosphorus from match strikers with codeine and iodine derived from over-the-counter medications; unfortunately, it is frequently contaminated with these and other agents[10]. Injection of this "flesh-eating drug" can cause serious damage to the skin, blood vessels, bone, and muscles, leading to limb amputation in long-term users[10,11]. Of note, the tissue injury is due to iodine, phosphorus, and other toxic substances that remain after synthesis, not the opioid itself[10].

Gamma-Hydroxybutyrate

Gamma-hydroxybutyrate (GHB; "liquid X", "liquid ecstasy", "liquid G") and its precursors, gamma-butyrolactone (GBL) and 1.4-butanediol (BDO), are rapid-acting CNS depressants popular among revelers for its relaxant, euphoric, and purported aphrodisiac properties. GHB can lead to a loss of consciousness as well as induce amnesia, and like flunitrazepam (Rohypnol® ["roofie"]), it is used as a "rape drug". Because it reportedly promotes muscle mass and has been shown to elevate human growth hormone *in vivo*, GHB is also misused by bodybuilders.

Benzodiazepines

Benzodiazepines are among the most frequently prescribed medications in the US and the UK, where surveys indicate that ~10% of the population uses benzodiazepine sedatives/anxiolytics regularly. Although they are only mild euphoriants, benzodiazepines, in particular flunitrazepam (Rohypnol®; "roofies"), are commonly misused by polydrug addicts, alcoholics, and recreational drug users. Benzodiazepines are ingested (often with alcohol), snorted, or occasionally injected. They can lead to a decrease in alertness and a lack of coordination. Other side effects of benzodiazepines include disinhibition, anterograde amnesia, depression, and confusion, and with an overdose or intravenous use, hypotension and hypoventilation.

Cannabis

Cannabis ("marijuana", "pot", "grass", "herb", "weed") is a mixture of dried shredded leaves and flowers of the *Cannabis sativa* plant, which contains the chemical delta-9-tetrahydrocannabinol (THC). Medical marijuana is currently legal in over 39 states in the US and recreational use is legal in 21 states. It is usually smoked as a cigarette or through a pipe or bong. Marijuana cigarettes may be laced with other drugs, such as crack or heroin. The minimal amount of THC required to produce a perceptible psychoactive effect is ~10 mcg/kg body weight. Altered perception may be accompanied by an impairment of concentration, psychomotor coordination, and/or short-term memory. Arteritis has also been reported, and it may represent a particular form of Buerger disease, with cannabis acting as a cofactor in young smokers.

In many countries, including the US, there has been an increase in the use of synthetic cannabinoids ("K2", "Spice", "Black Mamba"), which also bind the THC receptor, but may have increased vasoactive and psychoactive effects, including psychosis. Cannabinoids can be sprayed onto dried plants or inhaled via vaporizer electronic cigarettes.

Anabolic Steroids

Anabolic steroids promote the growth of skeletal muscle and the development of male sexual characteristics. They are ingested (e.g. oxandrolone, oxymetholone, stanozolol) or injected intramuscularly (e.g. nandrolone, testosterone, boldenone) to increase muscle mass and boost physical performance. Their use can lead to androgenetic alopecia and acne (Table 89.2). Complications of anabolic steroid misuse include cardiovascular disease, hepatic disorders (e.g. peliosis hepatis, hepatic adenomas), acute and potentially chronic kidney injury, and mood disorders.

PATHOPHYSIOLOGY OF SUBSTANCE USE DISORDERS

Administration of addictive drugs, directly or indirectly, leads to direct activation of the brain reward system, resulting in feelings of pleasure and what is commonly referred to as a "high". Dopamine, opioid peptides, gamma-aminobutyric acid, and endocannabinoids play an important role in stimulation of the mesolimbic reward circuit[12].

EPIDEMIOLOGY

In 2020, the United Nations Office on Drugs and Crime estimated that globally 36 million people suffered from drug use disorders[13], but only a minority had received necessary treatment. According to the 2019 National Survey on Drug Use and Health (NSDUH), 20.4 million Americans age 12 years or older experienced a substance use disorder during that year (Fig. 89.1)[14]. The statistics were as follows: 71% had an alcohol use disorder, 41% had an illicit drug use disorder, and 12% had both. Drug abuse and addiction has cost American society more than $740 billion annually in lost workplace productivity, healthcare expenses, and crime-related costs.

CLINICAL FEATURES

Scars, Ulcerations, and Skin Necrosis

Intravenous drug users have a number of recognizable stigmata, identifying their habit to anyone with experience in illicit drug use. The most prominent of these are "skin tracks", which represent scarred veins with overlying hyperpigmentation (Fig. 89.2); inflammation from repeated non-sterile injections as well as injections of irritating drugs and adulterants lead to scarring. Intravenous drug users also have trails of punctures, hemorrhagic crusts, and ecchymoses along the veins of their extremities. The veins of the arms are often used initially for injections, and when these become scarred, drug is injected into the vessels of the hands, feet, legs, and neck. After years or decades of injecting drugs, more unusual locations such as the groin and digits become sites for injections[15]. Multiple injections into the distal extremities can lead to chronic, non-pitting edema, also known as puffy hand syndrome[16].

When attempting to inject veins, accidental extravasation can occur, leading to local tissue injury. In addition, as patent vessels become scarce, drugs are injected intradermally or subcutaneously. The resulting "skin popping" scars are depressed, irregular or circular, and often dyschromic (Fig. 89.3)[17]. Another method employed by individuals with no intact veins is to rub powdered drugs into self-inflicted lacerations or to inject drugs into the granulation tissue of self-perpetuated ulcerations (Fig. 89.4). These chronic non-healing ulcers have been referred to as "shooter's patches"[18,19].

Powdered drugs, such as cocaine and heroin, may be mixed or "cut" with other powdered substances[20]. *Diluents* (e.g. glucose, sucrose, lactose, mannitol) are pharmacologically inactive and serve to increase quantity and profits whereas *adulterants* are pharmacologically active. The latter include phenacetin, levamisole, caffeine, diltiazem, hydroxyzine, and lidocaine. Several adulterants, in particular quinine and dextrose, are highly sclerosing. Quinine was a popular adulterant

CUTANEOUS SIGNS OF DRUG ABUSE		
Lesion type	**Route(s)/associated drug(s)**	**Other associated signs**
Skin tracks	IV	Lymphedema
Skin popping scars	sc or dermal	Lymphedema
Ulcerations	IV/cocaine IV/propoxyphene sc/barbiturates sc, IM/pentazocine (± tripelennamine) IV, IM/xylazine	Circumferential pigmented bands (IV administration)
Retiform purpura with ulceration	Snorting, IV/cocaine adulterated with levamisole Smoking/crack cocaine adulterated with levamisole	Neutropenia, leukopenia Arthralgias, pulmonary hemorrhage, seizures, glomerulonephritis Autoantibodies: ANA, ANCAs (including anti-PR3, elastase), anti-dsDNA, lupus anticoagulant
Sclerosis	sc, IM/pentazocine sc/barbiturates sc/cocaine	
Palmar and digital hyperkeratosis	Smoking/crack cocaine	Madarosis Linear and circular black plaques on the fingers and palms Cuts and blisters on the lips
Nasal verrucae	Snorting/cocaine or heroin	Nasal irritation Septal perforation
Pseudoaneurysm	Arterial injection	Petechiae/purpura Local suppuration Reduced peripheral pulses
Thrombophlebitis (aseptic or septic)	IV, sc	Tender cord (if superficial) or deep vein thrombosis Extremity edema
Cellulitis	IV, sc, intradermal	Osteomyelitis and septic arthritis Infective endocarditis
Cutaneous *Pseudomonas* infection	IV, sc, intradermal/heroin sc/pentazocine ± tripelennamine	Folliculitis
Wound botulism (*Clostridium botulinum*, especially type A)	IM, sc/black tar heroin or quinine-adulterated heroin	Lymphedema Skin popping scars
Excoriations & self-induced ulcers	Methamphetamine	Dry leathery skin Red dry nose Dental caries/loss of teeth Weight loss Paranoia
Formication or delusions of parasitosis	Cocaine (chronic) Methamphetamine	
Pruritus	Opioids, including heroin Cocaine (chronic) Methamphetamine	With heroin: Flushing Pseudoacanthosis nigricans
Papulopustular acneiform eruption	MDMA (ecstasy)	
Acne vulgaris	Anabolic steroids	Coarse skin Hirsutism Male and female pattern alopecia Gynecomastia (in men) Testicular atrophy Clitoral enlargement Striae
	Methamphetamine Marijuana	Excoriations
Perinasal and perioral irritant dermatitis	Sniffing of volatile solvents and inhalants	

Table 89.2 Cutaneous signs of drug abuse. Additional signs include foreign body granulomas, hyperhidrosis (amphetamines, LSD), and parrot-beaked clawing of the nails (cocaine). ANA, anti-nuclear antibody, ANCA, anti-neutrophil cytoplasmic antibody; ds, double-stranded; IM, intramuscular; IV, intravenous; MDMA, methylenedioxymethamphetamine; PR3, proteinase 3; sc, subcutaneous.

because it has a bitter taste similar to heroin and it may accentuate the narcotic euphoria[21]. Levamisole-adulterated cocaine is associated with the development of retiform purpura, cutaneous necrosis, and pyoderma gangrenosum (see below).

Cocaine is highly vasoconstrictive and even inhaled freebase cocaine has induced skin and muscle infarction[22]. Injection of pentazocine, which may be combined with tripelennamine, can cause brawny, sclerodermatous skin thickening and large, irregularly shaped, deeply penetrating ulcers that may extend to muscle and then heal with significant atrophy[23] (Fig. 89.5). Fibrous myopathy, joint restriction, muscle contractures, brachial plexus neuropathy, inflexible ankylosis, and suppurative tenosynovitis are musculoskeletal and neurologic complications from intracutaneous and intravenous injections[3].

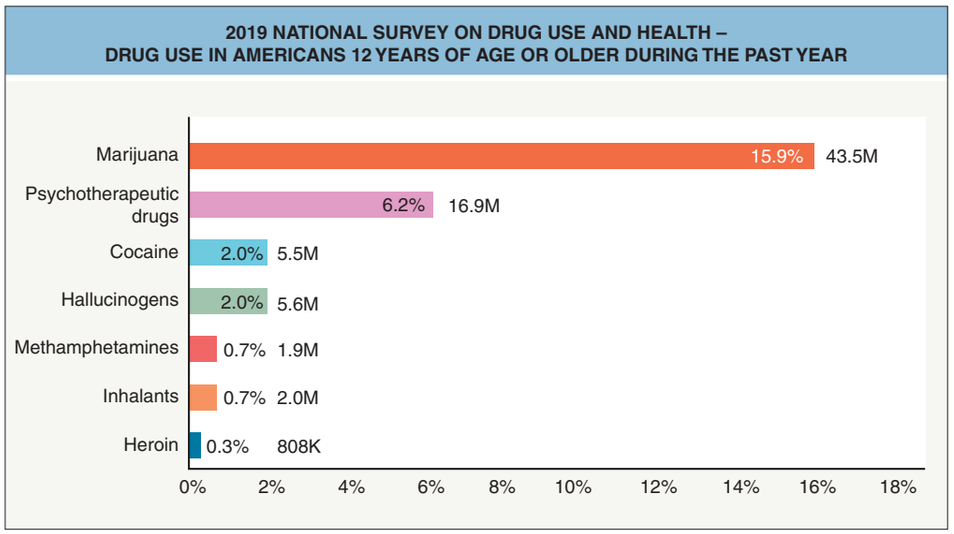

Fig. 89.1 2019 National Survey on Drug Use and Health – drug use in Americans 12 years of age or older during the past year. An estimated 10.8 million individuals experienced illicit drug use disorder +/- alcohol use disorder. Hallucinogens include MDMA (ecstasy), lysergic acid (LSD), and phencyclidine (PCP). *From Substance Abuse and Mental Health Services Administration. Key substance use and mental health indicators in the United States: Results from the 2019 National Survey on Drug Use and Health (HHS Publication No. PEP20-07-01-001, NSDUH Series H-55). Bacterial Infections

Unless they participate in needle exchange programs, parenteral drug users rarely use sterile technique and may share needles, predisposing them to infections (Table 89.3). Skin and soft tissue infections are the most common disorders for which drug addicts seek healthcare or are hospitalized[24]. In one study, 32% of injection drug users had active abscesses, cellulitis, or both[25]. The most common presentation of cellulitis is an erythematous, tender, warm, edematous, indurated plaque (Fig. 89.6); however, only tenderness and edema may be apparent initially, and in darkly pigmented skin, erythema may be difficult to appreciate. In contrast to the general population, cellulitis more frequently involves the upper extremity.

Lymphangitis is commonly associated with these skin infections. In addition, underlying osteomyelitis or septic arthritis should be considered in cutaneous infections associated with injections. Although cellulitis is most frequently caused by *Staphylococcus aureus* followed by streptococci[24], bacterial cultures and sensitivity testing are required to identify organisms such as Gram-negative bacilli and anaerobes, which occur more commonly in this setting, as well as polymicrobial infections.

Black tar heroin, whose name reflects its dark and sticky consistency, is notably associated with *Clostridium* infections[26], perhaps due to its high water content which supports bacterial growth. Wound botulism due to *Clostridium botulinum* type A occurs almost exclusively in drug addicts, especially those who skin pop black tar heroin[27,28]. The spores of *C. botulinum* are not destroyed by heating the contaminated heroin and are inoculated into the subcutaneous tissue, where they germinate and produce toxin[26]. In the early stages, there is usually pain, tenderness and swelling, but a cellulitis or abscess may not be apparent. Botulism causes acute, usually descending and symmetric, flaccid paralysis with ophthalmoplegia, ptosis, or other cranial nerve dysfunction. Culture of the wound and detection of the toxin are confirmatory tests. Treatment consists of high-dose penicillin, antitoxin, and respiratory support.

There are other clostridial species that may lead to disease in those who inject drugs. *C. sordelli* infection can present as toxic shock syndrome, and an outbreak of *C. novyi* type A with a high mortality rate was linked to drug users who injected heroin extravascularly[29,30]. Tetanus has also been linked to injection drug use[26].

In addition to frequent injections and non-sterile technique (e.g. dirty needles), additional risk factors for the development of cutaneous abscesses include "skin popping", injecting speedballs (a mixture of cocaine and heroin that can induce ischemia within soft tissues), HIV infection, and "booting" (refilling the syringe with blood then reinjecting to ensure no drug left in the syringe)[25,31,32]. Abscesses from subcutaneous drug injection are often deep and multilobulated with extensive necrosis, requiring exploration and debridement. Those that are superficial may rupture spontaneously, leaving punched-out ulcers.

Abscesses may be contiguous with underlying bone in the setting of associated osteomyelitis. In intravenous drug users, acute or chronic osteomyelitis develops from an infection in surrounding soft tissue, hematogenous seeding of bacteria, or direct penetrating trauma from needles. The presence of osteomyelitis should be considered in anyone with continued pain after treatment of a soft tissue infection or when the infection recurs or responds slowly to appropriate treatment with antibiotics. Occasionally, septic arthritis can develop via these same mechanisms and may involve more unusual sites, e.g. the sternoclavicular joint in those who "shoot the pocket" (jugular vein)[24].

Cervical abscesses usually occur in the anterior cervical triangle and may cause life-threatening complications such as mediastinitis, pneumomediastinum, airway obstruction, internal jugular vein thrombosis, and extension into the carotid sheath. Abscesses in the groin may present with only tenderness and edema. These abscesses can be deep and extensive, especially if they originate in the femoral triangle. In general, the degree of pain usually exceeds that anticipated from the clinical findings.

MRI is superior to CT imaging in detecting the presence of fluid and purulent collections in skin, joints, or tendon sheaths, but both are valuable in confirming the presence of deep and groin abscesses[33]. Sinography can be employed to delineate the extent of an abscess cavity or fistula. In those who inject illicit drugs, it is crucial to recognize that necrotizing fasciitis with or without myositis can present as erythema (77%), fluctuance (20%), edema (20%), or induration (43%), clinically resembling a non-fluctuant abscess yet requiring extensive subfascial debridement[34].

Fig. 89.3 "Skin popping" scars. A–C Multiple circular depressed scars, some with rims of postinflammatory hyperpigmentation, admixed with circular hemorrhagic crusts overlying ulcerations. Cocaine was injected into the thighs.

Fever and leukocytosis are often present. In some cases, only swelling or subtle cellulitis is apparent. However, severe pain, disproportionate to the physical findings, is typically present (85% of patients with necrotizing fasciitis in one series)[35]. If this complaint is disregarded or misinterpreted as a request for narcotics, the outcome can be devastating.

Notably, the classic cutaneous findings of necrotizing fasciitis, such as bullae (noted in 3% of patients), tissue crepitus (3%), and skin necrosis (10%), are only present in a small minority of those who inject illicit drugs[34]. For this reason, surgical exploration is mandatory in any parenteral drug user with cellulitis and unexplained severe pain. Any necrotic tissue should be debrided surgically and cultured (Fig. 89.7).

Fungal Infections

Dermatophytosis is very common in addicts. Disseminated candidiasis associated with injections of brown heroin was reported in the 1980s and found to be caused by an overgrowth of yeast in the lemon juice used to dissolve the heroin[36]. These patients developed high fevers, rigors, headaches, myalgias, and occasionally jaundice, but, at this stage, blood and urine cultures rarely demonstrated organisms. Most patients eventually developed pustular folliculitis and painful nodules in hair-bearing areas (scalp, moustache, and beard)[36]. The lesions resembled bacterial folliculitis but potassium hydroxide examination and lesional biopsy specimens demonstrated the presence of yeast[36].

In 2017, 10% of patients with candidemia were found to have a history of recent intravenous drug use, increasing to ~35% in individuals ages 19–44 years[37]. Of note, injection drug use is also a predisposing factor for zygomycosis. The characteristic cutaneous lesion is a cellulitic plaque or abscess with extensive necrotic tissue.

Granulomas

Injection of hydrous magnesium silicate (talc) or starch can produce granulomatous responses in the walls of veins as well as in the deep dermis and subcutaneous tissue, resulting in the formation of firm, movable cutaneous nodules[38] (Fig. 89.8; see Ch. 94). Talc can be found in tablets that have been crushed, diluted in liquid, and then injected. Talc granulomas may also develop in the lungs, liver, lymph nodes, spleen, and bone marrow. Granulomas may not appear for up to 50 years after subcutaneous injection and results from the conversion of larger silica particles to smaller particles in colloidal form[38]. When the inflammatory nodules ulcerate, they can heal with epidermal pigmentary changes, woody induration of the dermis and subcutaneous tissue, and retracted cicatrices.

Mucous Membrane Lesions

Snorting cocaine causes erythema of the nasal mucosa, nasal irritation, anosmia, and rhinitis, and it may lead to epistaxis, perforation of the nasal septum, and osteolytic sinusitis. Nasal verrucae (snorters' warts) can also develop. Less often, sniffing heroin causes these findings. A complex consisting of nasal collapse, septal perforation, palatal retraction, and pharyngeal wall ulceration has been described in cocaine snorters. Cuts and blisters on the lips from glass or metal smoking pipes have been noted in addicts who smoke crack cocaine, while ageusia, halitosis, and repeated lip smacking are additional signs of cocaine abuse. The labial mucosa may become dry in heroin or amphetamine users, and amphetamine use may also cause dysgeusia and xerostomia. There are reports of men and women applying cocaine

Fig. 89.4 Chronic, self-perpetuated, non-healing ulceration of the hand ("shooter's patch"). The patient injected heroin into the granulation tissue. *Courtesy Jake Wang, MD, and Jean L. Bolognia, MD.*

Fig. 89.5 Atrophic depressions of the thighs and extensive calcification from multiple pentazocine injections.

powder to their genitalia, including the glans penis[39]. These practices can lead to priapism, irritant dermatitis, and ulceration. Penile ulcers have also developed after injections of heroin into the shaft veins[40].

Chronic drug users frequently have marked dental and gingival disease due to poor hygiene (Fig. 89.9). Areca palm seeds (betel nuts) contain the stimulant arecoline and habitual chewing of these nuts, a practice in some areas of Asia, stains the teeth and is associated with the development of oral leukoplakia and oral submucous fibrosis[41]. The addictive habit of chewing *Catha edulis* tree leaves (also referred to as khat or qat), which contain the alkaloid stimulant cathinone, is popular in several African and Middle Eastern countries and can lead to oral keratotic white plaques[42].

Red or "bloodshot" eyes due to conjunctival vascular injection can occur with marijuana, cocaine, or phencyclidine (PCP) use. Repeated sniffing of volatile solvents and inhalants, such as glues, lighter fluid, butane gas, spray paints, gasoline, cleaning fluids, and aerosol sprays, can cause nasal, labial, perioral, and perinasal irritant dermatitis (sniffer's rash). The skin lesions may be discrete papules or erosions that are often confused with acne.

INFECTIOUS COMPLICATIONS OF DRUG ABUSE	
Type of infection	**Organisms and/or associated features**
Bacterial	
Abscesses and cellulitis	• *Staphylococcus aureus* > *Streptococcus* spp. > Gram-negative bacilli, anaerobes • Often polymicrobial • Lymphangitis is common • *Clostridium* infection (e.g. *C. botulinum* type A) with adulterated heroin (e.g. black tar skin popping), *C. tetani* • *Pseudomonas aeruginosa* with pentazocine ± tripelennamine or heroin injections • *Eikenella corrodens* with methylphenidate injections (esp. into the femoral triangle)
Necrotizing fasciitis	• Polymicrobial in 60%–85% of cases • Includes anaerobes in ~10%
Pyomyositis	• *S. aureus* most common, but can be polymicrobial • AIDS is an additional risk factor
Septic thrombophlebitis	• Associated with endocarditis or pulmonary emboli
Septic arthritis	• Increased likelihood of Gram-negative bacilli (esp. *Pseudomonas* spp.)
Osteomyelitis	• In *Pott's puffy tumor*, frontal sinusitis leads to frontal bone osteomyelitis and a subgaleal abscess; may be complicated by an epidural abscess
Endocarditis	• *S. aureus* > *Streptococcus viridans* > Gram-negative (esp. *Pseudomonas* spp.), polymicrobial • Often right-sided (e.g. tricuspid valve)
Fungal	
Candidiasis	• Disseminated candidiasis with pustular folliculitis; historically associated with injections of brown heroin • Septic arthritis, osteomyelitis, endocarditis (*C. parapsilosis, C. tropicalis*), septicemia ("fungemia syndrome")
Aspergillosis	• Pulmonary infections from contaminated marijuana • Dissemination and endocarditis may occur
Zygomycosis	• Cellulitic plaques or necrotic abscesses
Viral	
Hepatitis	• Hepatitis B viral infection may be associated with immune complex disease (e.g. arthritis, urticarial vasculitis) during the period of antigenemia • Syringe/needle sharing accounts for more than half of new cases of hepatitis C in the US
HIV	• Adults and adolescents who inject drugs account for 10% of new HIV infections in the US

Table 89.3 Infectious complications of drug abuse.

Burns

Burns are common in addicts with an altered state of mind, including burns from lit matches, cigarettes, paraphernalia, and contact with fire during cooking. Cigarette burns typically occur on the digits and sternum as the cigarette was being held or smoked prior to loss of

Fig. 89.6 Cellulitis of the lower extremity in an intravenous drug user.

Fig. 89.7 Necrotizing fasciitis of the upper extremity with extensive tissue necrosis in an intravenous drug user. Surgical debridement has been performed.

consciousness. Singeing of the eyelashes and eyebrows, resulting in madarosis, may be caused by rising hot vapors during the smoking of crack cocaine. Crack addicts may also have linear or circular black plaques on the fingers and palms.

Formication

Prolonged use of cocaine may lead to the development of formication, i.e. tactile hallucinations of insects crawling on or under their skin ("coke bugs"). Repetitive, stereotypical skin picking leading to

Fig. 89.8 Foreign body granuloma formation leading to papules at the sites of injection of adulterated heroin.

Fig. 89.9 Tooth decay is a common physical finding in hardcore drug addicts (arrow). The term "meth mouth" is applied to those who abuse methamphetamines.

excoriations and disfiguring skin ulcers on the face and extremities is a common finding in methamphetamine abusers. Not uncommonly, these individuals also feel that bugs are crawling under their skin, and cocaine or crystal methamphetamine use should be considered in anyone who presents with delusions of parasitosis as well as neurotic excoriations (Fig. 89.10). In addition to "meth mites", other cutaneous signs of methamphetamine abuse are dry skin, pruritus with lichenification, acne excoriée, a red dry nose, sweating, an unpleasant body odor, and premature aging. Patients may also have tooth decay, aggressive behavior, and paranoia.

Additional Cutaneous Findings

Circumferential, pigmented bands due to pressure from tourniquets are common in intravenous drug users with darkly pigmented skin. "Soot tattoos" are produced by injections of residual carbon on the needle after flaming[43]. Hyperkeratosis of the fingers and palms is common in heavy users of crack cocaine. Traumatic bullae at the site of injection are occasionally observed. Pressure erythema, bullae, and ulcers may develop in comatose patients after an overdose with barbiturates or other sedative drugs (Fig. 89.11; see Ch. 33).

As noted previously, use of both cocaine and crystal methamphetamine can lead to pruritus. The feeling of euphoria induced by heroin is frequently accompanied by skin flushing and itching, as well as a dry mouth, watery eyes, and rhinorrhea. Generalized or focal, especially genital, itching during the euphoric stage following heroin administration has been named "high pruritus"[44].

Hyperhidrosis is a common adverse effect of amphetamines and LSD. Within 30 to 90 minutes of LSD ingestion, the user feels a wide range

Fig. 89.10 Multiple excoriations in a cocaine addict. A, B The patient felt "crawling" sensations of his skin.

of emotions, accompanied by sweating, increased body temperature, dry mouth, tremors, and dilated pupils. Piloerection, paresthesias, and flushing are manifestations of the somatic phase of LSD intoxication, while pseudohallucinations and synesthesias occur during the perceptual phase. Hypoesthesia is a common manifestation of low-dose exposure to PCP.

There have been scattered reports in habitual MDMA (ecstasy) users of a papulopustular (acneiform) facial eruption, which may indicate a higher risk of severe adverse effects, such as hepatic damage. In some cases, the eruption responded to topical metronidazole[45]. Acne ranging from mild to cystic, especially on the trunk, is common among users of anabolic steroids. Other cutaneous effects of anabolic steroid abuse include oily hair and skin, male and female pattern alopecia, hirsutism in women, and coarse skin (see Table 89.2). Most are reversible if the abuser stops taking the drugs, but some are permanent.

Drug-Induced Reactions

Drug hypersensitivity reactions (especially morbilliform eruptions), urticaria (opioids, barbiturates, amphetamines), bullous eruptions, fixed drug reactions, small vessel vasculitis, Stevens–Johnson syndrome, and toxic epidermal necrolysis occur more frequently in illicit drug users than in the general population (Table 89.4). Pigmented circular patches on the skin and mucous membranes of addicts may reflect a fixed drug eruption.

Fig. 89.11 Coma bulla. Large bulla with subsequent erosion on the medial ankle due to prolonged coma from barbiturate overdose.

DRUG-INDUCED CUTANEOUS REACTIONS					
	Opioids	**Barbiturates**	**Amphetamines**	**Cocaine**	**Marijuana**

*Isolated case reports.
†Also polyarteritis nodosa with heroin.
‡Also eosinophilic granulomatosis with polyangiitis.
¶Levamisole-adulterated; can be accompanied by small vessel vasculitis.

Table 89.4 Drug-induced cutaneous reactions. Pemphigus (vulgaris, vegetans) has been reported with intranasal cocaine use. In patients with a morbilliform eruption, consider the possibility of DRESS (drug reaction with eosinophilia and systemic symptoms) syndrome.

Vascular Lesions

The most common vascular lesions are ecchymoses and even hematomas over injected vessels. Petechiae may form distal to the placement of a tourniquet. Vascular compromise of the hands is characterized by discoloration, edema, and a cold temperature. Intense burning pain is often experienced after intra-arterial injection of drugs[46]. This is followed within hours by edema of the affected limb. Although the peripheral pulses usually remain strong, cyanosis and patches of livedo reticularis can develop followed by distal ischemia and even necrosis and ulceration. Other manifestations reported after accidental or intentional drug injections into an artery include distal purpuric and pustular nodules, presumably as a result of embolization (Fig. 89.12).

Septic thrombophlebitis results in tender, swollen extremities with or without erythema. A tender cord may be present when the affected vein is superficial, but deep vein thrombophlebitis is easily misdiagnosed as cellulitis or an abscess, either of which may be an associated complication. Deep vein thromboses are diagnosed via Doppler ultrasonography.

Infected pseudoaneurysms result from non-sterile injuries to arteries (arterial wall or perivascular tissue) during intra-arterial injection of drugs. They are most commonly seen in the groin, followed by the extremities, with the close proximity of the femoral artery to the femoral vein one possible explanation for inadvertent arterial injections[47,48]. The typical lesion is a tender, diffusely indurated mass in the setting of intravascular drug use. In some patients, the mass may be pulsatile, suppurative, or purpuric; a bruit and decreased peripheral pulses may be present. Imaging assists in distinguishing infected pseudoaneuryms from abscesses[47,48], and treatment options include parenteral antibiotics, ligation, and reconstruction.

Fig. 89.12 Purpuric papules of the palm due to emboli of pill fragments following an intra-arterial injection. *Courtesy Jean L. Bolognia, MD.*

Bacteremia should be excluded in all injection drug users with skin and soft tissue infections and, if present, *infective endocarditis* should then be excluded. The latter is most commonly due to staphylococci and less often streptococci, and the tricuspid valve is involved in up to 80% of patients. In contrast, ~15% of all cases of infective endocarditis have right-sided cardiac involvement. Although symptoms of right-sided endocarditis include fever, cough, dyspnea, and pleuritic chest pain, there may be a delay in diagnosis. In patients with paradoxical emboli or left-sided endocarditis, brain and splenic abscesses from septic emboli can develop as well as several cutaneous signs: conjunctival hemorrhages, splinter hemorrhages, Janeway lesions, Osler nodes, and purpuric, ischemic, or necrotic lesions due to septic emboli. Infective endocarditis associated with injection drug use is also one of the rare settings in which polymicrobial endocarditis is encountered[24,49,50]. Of note, mycotic aneurysms occur in 15%–25% of patients with infective endocarditis, most frequently in the femoral artery.

Levamisole-adulterated cocaine is associated with neutropenia and retiform purpura that can become necrotic (Fig. 89.13)[51–54]. Histologic examination demonstrates microvascular thromboses within the dermis, sometimes accompanied by leukocytoclastic vasculitis (Fig. 89.14). Patients may also have anti-neutrophil cytoplasmic antibodies or anti-phospholipid antibodies and decreased levels of protein C and S. Pyoderma gangrenosum has also been associated with levamisole-contaminated cocaine[55]. While levamisole can be identified in the urine, it may not be detectable at the time of evaluation due to its half-life of 4 hours[56]. However, drug paraphernalia can still be tested for levamisole[57]. Cocaine-induced hypercoagulability (thrombophilia) can lead to superficial and deep venous thromboses, arterial thromboses, and cutaneous infarctions, and cocaine use may unmask subclinical systemic sclerosis. Illicit use of xylazine ("tranq", "zombie drug"), a veterinary sedative, can lead to multiple cutaneous ulcerations, possibly due to vasoconstriction.

Systemic Complications

In addition to infective endocarditis, parenteral drug users are at high risk for contracting bloodborne viruses, with a recent multistage systematic review estimating the worldwide prevalence of HIV to be ~18%, HCV ~50%, and HBV ~9%[58]. Globally, up to 40%–45% of new HCV infections are thought to be due to injection drug use[59].

Fig. 89.13 Retiform purpura due to levamisole-adulterated cocaine – clinical features. A, B Multiple sites of retiform purpura on the legs and arm in two patients. **C** The earlobe is a common site of involvement and purpuric lesions of the earlobe had been described previously as a side effect of levamisole. Up to 70% of the cocaine in the US at the time of writing contained levamisole but <3% of the heroin supply. *A, Courtesy Boni Elewski, MD and India Hill, MD; B,C, Courtesy Jeffrey P. Callen, MD.*

TREATMENT OF DRUG ADDICTION	
Drug	**Treatments**

Opioids	• Drug detoxification
	  • Buprenorphine + naloxone
	  • Clonidine + naltrexone
	• Maintenance therapy
	  • Agonist (methadone, levomethadyl*)
	  • Partial agonist (long-acting buprenorphine)
	  • Antagonist (naltrexone, including long-acting form)
	• Additional measures (counseling, psychotherapy, acupuncture)

Cocaine	• Drug rehabilitation, psychosocial interventions • Desipramine, bupropion, or citalopram may be used
Amphetamines	• Drug rehabilitation, psychosocial interventions • Stimulant agonists (e.g. dextroamphetamine, methylphenidate), naltrexone, or topiramate may be used • Antidepressants (e.g. bupropion, mirtazapine), riluzole, and pexacerfont are less effective
*Withdrawn from the US market due to risk of cardiac arrhythmias.	

Table 89.5 Treatment of drug addiction. Buprenorphine appears to act as a partial agonist of μ and κ opioid receptors; tolerance with chronic use may not develop, presumably due to the lack of δ-agonist activity. Buprenorphine is available as a sublingual tablet, subcutaneous depot, or subdermal implant as well as in combination with naloxone as a sublingual tablet or transmucosal film. Injection of the transmucosal formulations has been associated with soft tissue infections. GABA, gamma-aminobutyric acid.

Cutaneous manifestations of these viral infections may also be present (see Table 81.8 & Ch. 78).

Drug users also have a high prevalence of sexually transmitted diseases, due to multiple partners, the sex trade, and failure to use condoms[60]. However, narcotic abuse is a cause of false-positive non-treponemal syphilis screening tests (e.g. VDRL, RPR). In these cases, treponemal tests (e.g. MHA-TP, FTA-ABS) will be non-reactive. In addicts who have had syphilis, both types of tests will be positive, and the titers of the non-treponemal test may not decrease rapidly after treatment.

Nephrotic syndrome from amyloidosis has been reported in heroin skin poppers and intravenous drug users with chronically draining skin lesions.

TREATMENT

A detailed discussion of the management of drug addiction is beyond the scope of this chapter. When providing care to persons suspected of drug use disorder, it should be remembered that even admission of drug use is difficult, as patients risk disapproval and overt or concealed rejection even from medical professionals.

The selection of antibiotics to treat skin infections should be guided by antibiotic sensitivities of the cultured organisms (Table 89.5). With the emergence of community-acquired MRSA and the increased risk of polymicrobial infections, broad-spectrum coverage is recommended until culture results and antibiotic sensitivities are determined. However, even with aggressive surgical and medical treatment, the mortality rate of necrotizing fasciitis in drug addicts is ~20% and limb amputation is necessary in another 18%[34], necessitating prompt recognition and surgical consultation.

Skin grafting of large ulcers may be necessary when healing does not occur with compression and appropriate dressings. Some substance abusers may deliberately sabotage the skin graft by injecting through it or into the vacuum (VAC) dressing tubing[19]. Recovered parenteral drug users often wear long-sleeved shirts and other garments to hide the stigmata of their past addiction and may seek help in diminishing the appearance of these signs. Hypertrophic scars improve with intralesional injections of corticosteroids and pulsed dye laser treatments (see Ch. 98). Hyperpigmented scars require the use of pigment-specific lasers and bleaching agents, including hydroquinone. Tissue augmentation with hyaluronic acid or fat can improve the appearance of depressed scars. Such scars may also respond to low-fluency treatments with visible light lasers.

Child Abuse *1622*
Elder Abuse *1626*

CHILD ABUSE

Synonym: ■ Battered child syndrome

Key features

- Signs of physical abuse include: unexplained bruises; injuries of the thorax, abdomen, buttocks, genitals, chin, ears, or neck; curvilinear marks; and cigarette burns or other well-demarcated burns
- Signs of sexual abuse include laceration or bruising of genital or perianal tissue, complete transection of the posterior hymen, and scars of the perianal area or posterior fourchette

Introduction

Child abuse encompasses the broad spectrum of non-accidental maltreatment of children, including physical, emotional, and sexual abuse as well as neglect. Physical abuse is defined as non-accidental injury of a child; the injury may be the result of a single abusive episode or occur over a longer period of time. In the US, ~2.5 in 100 infants <1 year of age and one in 100 children 1–3 years of age are victims of abuse or neglect[1]. Because they are demanding, less verbal, and defenseless, infants and children <3 years of age are at greatest risk, accounting for almost 30% of child abuse victims. In 2016, 8.5% of childhood injuries reported to the National Trauma Data Bank were due to intentional assault, and 6% of assault-related injuries resulted in the child's death[2]. Abused children are more likely to sustain serious intracranial, thoracic, and abdominal injuries than children who are injured accidentally[3].

Parents may describe abused children as "difficult", which in fact may be true; however, the parents' attempts to intervene in an excessive and inappropriate manner constitute abuse. Premature infants, disabled children, and children with behavioral problems are at increased risk of abuse. Parents who abuse their children were often themselves abused as children. They are frequently immature, dependent, socially isolated individuals. Often, they do not handle stress well, and a personal or family crisis may trigger an abusive episode. It is important that all physicians recognize signs of physical abuse in children, as it tends to be repeated, and an intentionally injured child is at high risk for severe physical injury in the future.

Physical neglect is a failure to provide the necessities of life for a child, including nutrition, clothing, housing, medical care, and a safe, supervised environment. Emotional abuse or neglect results when parents fail to provide a nurturing environment that permits the child to grow and reach his or her full potential.

Sexual abuse can be defined as engaging a child in a sexual activity that the child cannot comprehend, for which the child is developmentally unprepared and cannot give informed consent, and/or that violates the social and legal taboos of society[4]. The child's involvement may be coerced with physical threats, rewarded through bribes, or induced via misrepresentation of moral values. Sexual abuse can be assaultive or non-assaultive. Non-assaultive sexual abuse often goes unreported since there is usually little or no physical injury to the child. In contrast, assaultive sexual abuse is characterized by physical injury and violence. Both types of sexual abuse may result in severe emotional trauma to the child.

History

Maltreatment of children has always existed, but in 1946, Dr John Caffey, a pediatric radiologist, initiated medical concern about child abuse by reporting six children who presented with skeletal fractures and subdural hematomas that were clearly related to trauma[5]. The immense importance of this problem was not generally recognized until 1962, when Kempe et al.[6] coined the term *battered child syndrome*, the findings of which include inadequately explained signs of trauma, multiple fractures at different stages of healing, and/or failure to thrive that responds to nutritional therapy or placing the child in an emotionally supportive environment.

Epidemiology

Child abuse is a worldwide problem that occurs among all ethnic and racial groups and in families of all socioeconomic and educational levels. In the US, single-parent families with incomes below 200% of the poverty threshold have much higher probabilities of violence[7]. Child abuse occurs more frequently when other problems such as unemployment, substance abuse, unplanned pregnancies, or discord between parents increase the stress on individuals within the family. Boys are at greater risk for serious injury than are girls, and infant boys have the highest fatality rate[1].

The perpetrator of sexual abuse is often a person well known to the child, most often the natural father, followed in frequency by a stepfather or another close relative. Although reports of abuse are about three times more likely in girls than in boys[8], sexual abuse in boys may be more likely to go undetected and/or unreported. The risk for sexual abuse rises during preadolescence and in family situations with a stepfather in the household, children living without one or both of their natural parents, and children whose mothers are disabled, ill, or extensively out of the home[8]. Overcrowded living conditions may also be associated with an increased risk of child sexual abuse[9].

Sexual abuse occurring during sex trafficking of minors, which involves the engagement of youth in sexual acts in exchange for money or items of value, is an increasingly recognized global health crisis[10]. The United Nations Children's Fund estimates that 1.2 million children are trafficked for sexual exploitation worldwide annually, including 200 000 children in the US. The average age of child sex trafficking victims is 12–14 years[11]. While many domestically trafficked children are homeless, runaways from abusive homes, or vulnerable due to unmet needs, others from stable homes are recruited via social media or lured away from public places such as malls and bus stops[11].

Clinical Features

Physical abuse

Physical abuse is frequently identified by *bruises* (ecchymoses) (Fig. 90.1) that may be located in areas not normally prone to accidental injury, most commonly the head and neck (particularly the face) followed by the buttocks, trunk, and arms[12]. They are often large, multiple, and in clusters. The shape of the bruises may help to identify the object with which the child was struck. Linear bruising is produced when an object such as a rod, stick, or strap is used to strike a child. Hematomas and traumatic fractures of underlying bone may be present.

Loop marks are perhaps the single most characteristic finding in child abuse. Such curvilinear marks are produced by small ropes, electrical cords, or belts and appear randomly over the body as a result of striking a struggling child[13].

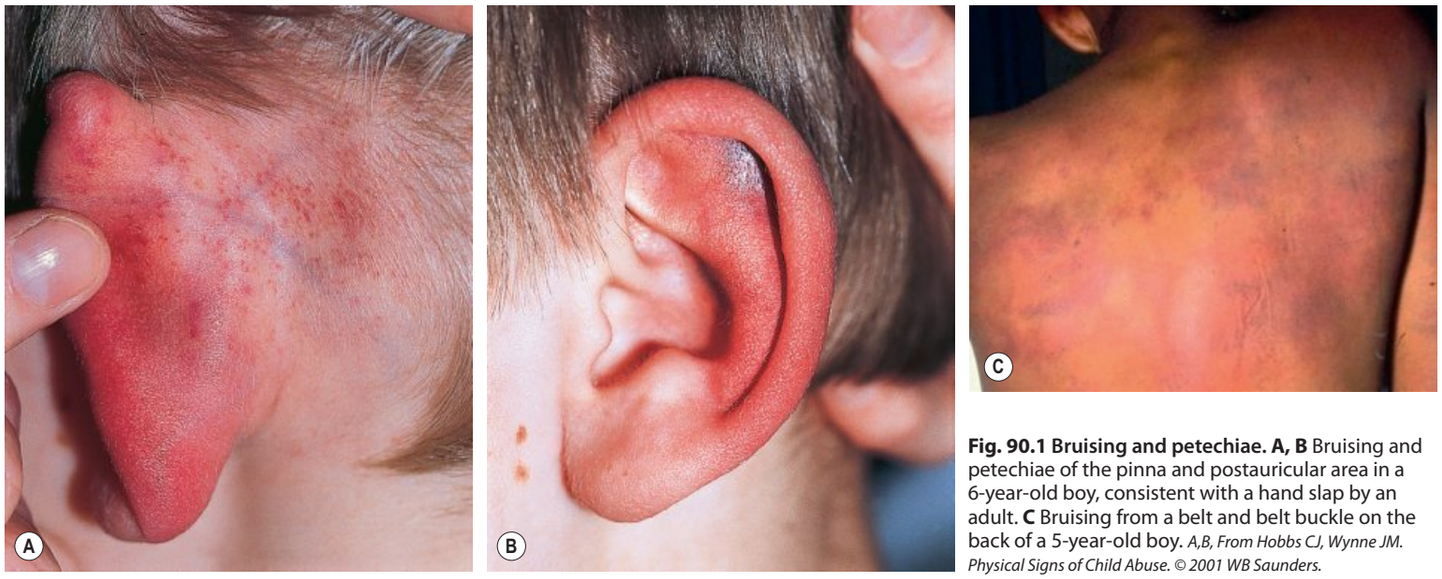

Fig. 90.1 Bruising and petechiae. A, B Bruising and petechiae of the pinna and postauricular area in a 6-year-old boy, consistent with a hand slap by an adult. **C** Bruising from a belt and belt buckle on the back of a 5-year-old boy. *A,B, From Hobbs CJ, Wynne JM. Physical Signs of Child Abuse. © 2001 WB Saunders.*

Fig. 90.2 Healing injury due to binding around the ankles.

Fig. 90.3 Injury produced by a cigarette burn.

Buckle imprints from belts can often be matched to the particular belt buckle used to strike the child. Buckles produce deep ecchymoses (see Fig. 90.1C) and can result in injury to underlying organs and bones.

Pinch marks, particularly on the ears or in the genital region of boys, should alert the examining physician to the possibility of abuse. Male toddlers rarely sustain bruises on the genitalia secondary to a fall.

Blunt trauma can be a very severe form of abuse that may or may not result in cutaneous lesions. Blunt trauma to the abdomen can lead to severe injury or even death of a child. Soft intra-abdominal organs are injured when they are slammed against the vertebral column by a kick or severe blow delivered to the abdomen. Blunt trauma in the form of slapping injury causes capillaries to break between the digits, producing linear bruises that outline the fingers. This often leaves the imprint of a hand on the child's skin, which can frequently be matched to the perpetrator.

Binding injuries are more likely to occur when the perpetrator is emotionally disturbed or psychotic. Acute binding injuries cause edema of the soft tissue around the wrists and ankles that may resemble rope burns with redness and warmth or abrasions (Fig. 90.2). Chronic binding injuries may result in bands of postinflammatory hyperpigmentation.

Traumatic alopecia results from forcefully pulling out the scalp hair. The occipital region is the most common location. When a large tuft of hair is abruptly pulled out, the underlying scalp may hemorrhage with subsequent hematoma formation.

Human bite marks leave the indelible mark of the perpetrator and may serve to identify the abuser. Adult human bite marks, which can be identified by the width of the dental arch (>4 cm), must be distinguished from those of a child, since toddlers may be bitten by their peers. Human bites produce a crushing type of injury, whereas animal bites typically result in puncture wounds.

Fig. 90.4 Branding injury on the thigh from a fork.

Thermal burns constitute an especially traumatic form of injury to the young child, and the abuser in such cases is likely to be suffering from a psychiatric disorder. Cigarette burns represent a frequent form of thermal injury and tend to be randomly distributed (Fig. 90.3). Branding injuries take the shape of the heated object (Fig. 90.4). Dunking scald injuries occur most often in infants and toddlers, and scalds on the

Fig. 90.5 Burn injury due to dunking in hot water. Note the sharp, symmetric lines of demarcation on the lower legs. *Courtesy Leo Litter, MD.*

buttocks may be associated with attempts to toilet train an infant. "Donut-type sparing" on the child's buttocks may be apparent when the buttocks are held against the cooler tub or basin while the surrounding hot water scalds the remaining immersed skin. Dunking scalds of the extremities leave a characteristic "stocking and glove" distribution with a very sharp demarcation of the burn (Fig. 90.5). In non-accidental burns, the adults responsible for the child (and possibly the burn) frequently claim not to have witnessed the burning incident, and other relatives commonly bring the child to the hospital. A delay between the injury and seeking medical care often occurs with inflicted burns.

A child may present with skin signs of multiple types of physical abuse. Such a child is at high risk for severe injury concurrently or in the future. Both acute and healing injuries are frequently present in chronically abused children.

Factitious disorder imposed on another, also known as *Munchausen syndrome by proxy*, is an uncommon form of abuse that typically affects children. In this condition, a parent or caregiver induces or feigns illness in a child for psychological gain. The perpetrator is often the mother, and the father is classically absent or uninvolved in care of the child. Cutaneous manifestations occur in ~9% of cases[14].

Physical neglect

Physical neglect usually results in a constellation of relatively obvious findings, including signs of poor nutrition, hygiene, and general health. Children may have old untreated injuries, dermatitis, and infestations of the skin and hair, and they typically have not received required childhood immunizations.

Emotional deprivation

Emotional neglect or deprivation accounts for at least half of the children in high-income countries diagnosed with *failure to thrive*. These children fail to grow and develop in their home environment despite adequate caloric intake, while they thrive with food and stimulation in a hospital setting or foster home. There are no characteristic physical findings or diagnostic laboratory tests for these children. The diagnosis can be rendered only after other potential causes of failure to thrive have been excluded, and it is usually confirmed when the child demonstrates "catch-up" growth and development outside the disturbed home environment.

Sexual abuse

The diagnosis of child sexual abuse is based on a combination of findings in the patient's history, physical examination and, when indicated, laboratory evaluation. Children rarely fabricate reports of sexual abuse, and any such description by a child should be thoroughly investigated. Unfortunately, false accusations by parents involved in custody disputes do occasionally occur and are a burden to the medical and legal systems.

Physical signs that are suggestive of childhood sexual abuse are described in Table 90.1. However, physical findings are present in a small minority of sexually abused children. Many types of sexual molestation, such as fondling and oral sodomy, usually do not leave physical signs. Even when mild or moderate injuries occur (e.g. petechiae, ecchymoses, abrasions, superficial lacerations), healing in the anogenital area often takes place within days, resulting in very subtle or undetectable physical findings[15,16]. In a large study of sexually abused girls, physical findings were present in 21% (73/340) of those examined acutely (within 72 hours) but only 2% (26/1160) of those examined nonacutely[17]. In the absence of a plausible history of accidental injury, findings that should alert the physician to the possibility of abuse include laceration or bruising of genital or perianal tissues, complete transection of the posterior hymen, and scars of the perianal area or posterior fourchette[18,19] (Fig. 90.6; see Table 90.1).

It is important to be aware of normal physical findings in the genital area of female children. Studies of newborn girls have noted that a hymen is invariably present and anterior hymenal clefts are common, but posterior clefts are not normally seen[15]. A complete hymenal cleft located between 4 and 8 o'clock is suggestive of penetration[16,17]. The presence of semen, detected via testing for prostatic acid phosphatase, or sperm is indicative of abuse; non-perinatally acquired syphilis, gonorrhea, or (if other modes of acquisition are excluded) HIV infection confirms mucosal contact (most likely sexual) with infective bodily

PHYSICAL FINDINGS SUGGESTIVE OF CHILD SEXUAL ABUSE
Findings from trauma to genital/perianal tissue *highly suggestive of abuse**
• Laceration or bruising of the labia, posterior fourchette, hymen, vagina, penis, scrotum, perineum, or perianal area • Petechiae or abrasions of the hymen • Scar of the posterior fourchette or perianal area • *Complete* hymenal transection/cleft *below* the 3–9 o'clock location, extending to or through the base of the hymen • Signs of female genital mutilation, such as loss of part or all of the clitoral hood, clitoris, labia minora or labia majora, or a vertical linear scar adjacent to the clitoris
Genital/perianal findings associated with abuse in some studies
• Complete anal dilation with relaxation of internal and external anal sphincters, in the absence of predisposing factors such as constipation, encopresis, sedation, and neuromuscular conditions • *Incomplete* hymenal notch/cleft *below* the 3–9 o'clock location, extending *nearly* to the base of the hymen† • *Complete* hymenal transection *at* the 3–9 o'clock location, extending to or through the base of the hymen†
Sexually transmitted infections‡
• Genital, rectal, or pharyngeal *Neisseria gonorrhea* or *Chlamydia trachomatis* infection • Syphilis • *Trichomonas vaginalis* infection • HIV, if transmission by blood products or contaminated needles is excluded
*Unless the child and/or caregiver provides a timely and plausible description of accidental anogenital straddle, crush, or impalement injury, or there is a history of past surgical interventions confirmed by review of medical records. †Should be confirmed using additional examination positions and/or techniques, to ensure that not normal variants. ‡Confirmed using appropriate testing, with perinatal transmission excluded.

Table 90.1 Physical findings suggestive of child sexual abuse. Perianal lacerations must be distinguished from anal fissures, which may be seen in children with constipation. *Adapted from Adams JA, Farst KJ, Kellogg ND. Interpretation of medical findings in suspected child sexual abuse: an update for 2018. J Pediatr Adolesc Gynecol 2018;31:225–31.*

Fig. 90.6 Bruising of the buttocks and perianal area of a sexually abused 2-year-old child.

secretions[15]. Perinatally acquired infections with *Chlamydia trachomatis* have been documented to persist as long as 28 months; therefore, infections with this organism in children younger than 3 years of age are not as suggestive of abuse.

Anogenital warts in children (see Ch. 79) may be perinatally acquired, transmitted during the routine care of children, autoinoculated from other sites of infection, or (especially for genital warts) acquired as a result of sexual abuse. In most studies, proven abuse is uncommon in children with anogenital warts who are younger than 3 years of age[20].

Human trafficking

Victims of human trafficking may demonstrate signs of physical, emotional, or sexual abuse as noted above. In addition, tattoos in locations ranging from highly visible (e.g. hands, face) to discrete (e.g. lower back, genitals) have been used by some traffickers to brand their victims[21], with common motifs depicting a male name, hearts, symbols of wealth, and profanity. Recognition of these tattoos, which are often low-quality, may help to identify victims of human trafficking[21].

Differential Diagnosis

Although it may be difficult to differentiate abuse from accidental injury in a child, the distribution of injuries is often helpful. Abused children have significantly more soft tissue injuries on the cheeks, trunk, genitalia, and upper legs than accidentally injured children[12]. Labbe and Caouette[22] performed over 2000 skin examinations in 1467 normal children to determine the type and location of recent skin injuries. The majority of children over 9 months of age had at least one injury, usually a bruise, but 15 or more injuries was rare. The lower limbs were the most commonly involved sites. Less than 2% of the children had injuries to the thorax, abdomen, pelvis, or buttocks, and less than 1% to the chin, ears, or neck. Bruises were rare in infants who were not yet independently mobile. Therefore, injury in infants or in the locations mentioned above should arouse suspicion of the possibility of abuse.

There are several cutaneous disorders that can mimic child abuse (Table 90.2; Fig. 90.7 & 90.8). In addition, normal anatomic variants are sometimes mistaken for signs of childhood sexual abuse. For example, 25% of newborn girls have a white line (linea vestibularis) in the posterior vestibule that could be confused with scar tissue produced by sexual abuse. Other conditions that are occasionally misdiagnosed as sexual abuse are listed in Table 90.3.

CONDITIONS THAT CAN MIMIC CHILD ABUSE

Condition	Comments
Bleeding into the skin (ecchymoses, purpura)	
Multiple bruises due to platelet or clotting disorders	• Areas most commonly traumatized by children (e.g. shins, knees)
Ehlers–Danlos syndrome, especially the vascular type	• Common sites of trauma, especially shins
Bruising due to "cupping" or cao gio (coin rubbing)	• Primarily children from SE Asia (see Ch. 133)
Vasculitis, particularly Henoch–Schönlein purpura (HSP) and acute hemorrhagic edema of infancy	• Favors lower extremities as well as the buttocks in HSP and the face in acute hemorrhagic edema; associated edema and arthritis
Blue discoloration of skin mistaken as bruising	
Dermal melanocytosis	• Lack of progression of color to green or yellow; favors presacrum and back
Infantile hemangioma (deep) or vascular malformation	
Linear hyperpigmentation	
Phytophotodermatitis (see Fig. 90.8A)	
Sock-line or mitten-line hyperpigmentation	
Vesicles, bullae, or erosions mistaken as non-accidental burns or other intentional injuries	
Impetigo, ecthyma, blistering distal dactylitis	
Erythema multiforme, fixed drug eruption	
Bullous mastocytosis	
Irritant contact dermatitis	• e.g. laxative-induced irritant contact dermatitis mimicking an immersion burn, chemical burns from topical application of garlic or apple cider vinegar (see Fig. 90.7)
Arthropod bite reaction	
Moxibustion Maquas	• Primarily children from SE Asia (see Ch. 133) • Small burns produced by hot metal spits or coals in areas of illness or pain; Bedouin, other Arabic, and Russian cultures
Burn from a hot car seat or seat-belt buckle	
Genetic disorders of skin fragility, e.g. forms of epidermolysis bullosa (see Ch. 32) or porphyria (see Ch. 49)	
Other	
Osteogenesis imperfecta	• Multiple fractures, blue sclerae
Hair tourniquet	
Self-inflicted injury	

Table 90.2 Conditions that can mimic child abuse.

Evaluation and Management

When any lesion suspicious for abuse is present, the entire cutaneous surface of the child as well as the oral, anal, and genital mucosae should be examined. Child abuse should be suspected if parents lack an explanation for a child's injuries, relate circumstances not compatible with the physical findings, describe activities for which a child is developmentally incapable, give differing accounts, or change their stories. A summary of recommended steps in the evaluation and management of suspected child abuse is provided in Table 90.4. Most countries (including the US) require physicians to report suspected physical abuse, neglect, and sexual abuse of children. Legal protection is generally given to healthcare providers who make such reports in good faith.

When a child gives a history of sexual abuse or has physical findings highly suggestive of abuse, an immediate referral should be made to a child protective services agency. If the history and physical findings are less certain, it may be most appropriate for experienced medical personnel to make the decision of whether sexual abuse is likely and referral to child protective services is warranted, since the potential negative impact of misdiagnosis on the family structure is substantial. Whenever feasible, any child suspected of being sexually abused should be examined by a pediatrician or gynecologist experienced in evaluating children for signs of abuse. Anogenital examination by multiple physicians should be avoided if possible, given the potential trauma this may impose on the child. Lastly, because physical signs of sexual abuse may resolve within a few days, children should be evaluated by an experienced provider as soon as possible[15].

When the history and/or physical findings suggest the possibility of oral, genital, or rectal contact, cultures and serologic tests to evaluate for sexually transmitted diseases are indicated. If the abuse occurred within 24 hours of the examination, samples should also be collected for forensic evidence[15].

Victims of all types of abuse may suffer long-term psychologic consequences. Some children withdraw and develop feelings of worthlessness, helplessness, hopelessness, and depression. Others exhibit aggressive and impulsive behavior and are at risk for delinquency, substance abuse, absenteeism from school or work, adolescent pregnancy, sexual promiscuity, and prostitution. Abused children are more likely as adults to abuse their own children and spouses. Thus, long-term psychologic support for abused children is desirable.

Fig. 90.7 Chemical burn from topical application of apple cider vinegar mimicking child abuse in an infant. Note the sharply demarcated erythema with angular borders and sparing of the skin folds, as well as the superficial blistering and desquamation.

In summary, the dermatologist may be the first physician to encounter the abused child, so it is important to be alert for signs of abuse, perform the appropriate documentation and testing, and report it to the proper authorities. It is often necessary to enlist the help of a primary care physician or gynecologist experienced in the evaluation of abuse. An atlas by Hobbs and Wynne[23] provides additional information and color illustrations.

ELDER ABUSE

Key features

- An intentional action by a caregiver or trusted person that causes harm or creates a serious risk of harm to an older adult constitutes elder abuse
- Failure by a caretaker to satisfy the basic needs of an elder or to protect the elder from harm also represents elder abuse

Introduction

In 1997, the International Network for the Prevention of Elder Abuse was established to address elder abuse around the world[24]. In most countries, both the healthcare system and legal statutes recognize the types of elder abuse listed in Table 90.5. Approximately one in four elders is at risk of abuse, and ~6% have experienced significant abuse in the past month[24,25].

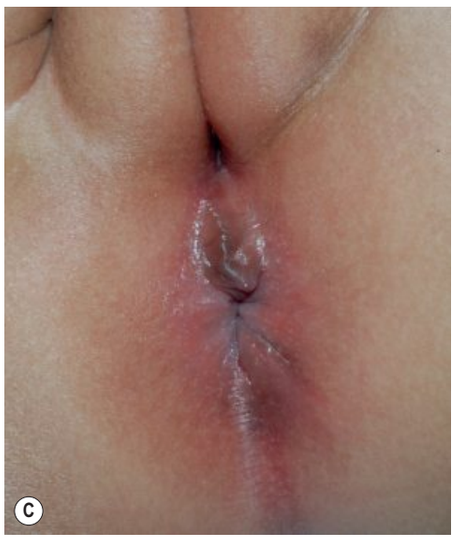

Fig. 90.8 Cutaneous disorders that may be misdiagnosed as physical or sexual abuse. **A** Hyperpigmented streaks on the back of a 2-year-old girl due to phytophotodermatitis; the mother had lime juice on her hand when she touched the child. **B** Genital lichen sclerosus may have associated purpura or hemorrhagic bullae. **C** A perianal pyramidal protrusion in the typical location, just anterior to the anus in the midline. This finding is most common in infant girls. **D** Self-induced suction purpura from a drinking glass on the upper lip of a young girl.
A, Courtesy Anthony J. Mancini, MD; B–D, Courtesy Julie V. Schaffer, MD.

CONDITIONS OCCASIONALLY MISDIAGNOSED AS CHILD SEXUAL ABUSE
• Accidental injury • Anal fissure or dilation due to constipation • Perianal streptococcal infection (see Fig. 74.11D) • Lichen sclerosus (may be associated with purpura or hemorrhagic bullae; see Fig. 90.8B) • Genital vitiligo • Localized vulvar bullous pemphigoid or other bullous diseases • Crohn disease (see Fig. 93.17) • Infantile hemangioma (especially if ulcerated; see Fig. 103.11) or vascular malformation in the genital area • Entities misdiagnosed as genital or perianal warts – Perianal pyramidal protrusion (see Fig. 90.8C) – Molluscum contagiosum – Pseudoverrucous papules and nodules due to fecal or urinary incontinence – Verrucous herpetic infections in immunocompromised hosts – Perianal papillomatous lesions of Goltz syndrome • Anatomic variants, e.g. anterior hymenal cleft, enlarged hymenal opening, linea vestibularis

Table 90.3 Conditions occasionally misdiagnosed as child sexual abuse.

EVALUATION AND MANAGEMENT OF SUSPECTED CHILD ABUSE
• Examine the entire cutaneous surface as well as oral, anal, and genital mucosae; estimate the ages of individual traumatic lesions and identify any associated injuries • Detail all traumatic lesions in the medical record • Photograph injuries whenever possible • Funduscopic examination to assess for retinal hemorrhages* • Otoscopic examination to exclude hemotympanum • Skeletal survey to assess for unsuspected fractures, especially in children under 5 years of age • Treat acute injuries or infections • Report suspected abuse, initially by telephone and subsequently in writing, to the local child protective services agency • Protect the child from further injury while suspected abuse is being investigated • Long-term counseling for proven abuse
*Can occur secondary to head trauma or severe shaking; the presence of extensive, bilateral retinal hemorrhages in a child <3 years of age is strongly suggestive of abuse.

Table 90.4 Evaluation and management of suspected child abuse.

TYPES OF ELDER ABUSE	
Physical abuse	• Use of physical force that results in pain, injury, or impairment • Inappropriate use of drugs, restraints, or confinement
Psychological abuse	• Use of verbal or nonverbal means to cause emotional pain or distress
Sexual abuse	• Nonconsensual sexual contact with an older adult
Material exploitation	• Unauthorized use of funds, assets, or property • Authorization for use of resources gained through intimidation of an elder
Neglect*	• Failure of a caretaker to satisfy the basic needs of an elder or to protect the elder from harm
*Elder self-neglect is more common than elder abuse or neglect by others.	

Table 90.5 Types of elder abuse.

POTENTIAL FINDINGS IN ELDER ABUSE OR NEGLECT	
Behavior observations	• Withdrawal • Absence of eye contact with interviewer • Infantilizing of patient by caregiver • Functionally impaired patient who presents without designated caregiver
General appearance	• Hygiene, cleanliness, and appropriateness of dress
Skin and mucous membranes	• Skin turgor, other signs of dehydration • Multiple abrasions in various stages of evolution • Wrist or ankle lesions suggestive of restraint use • Bruises (shape may suggest implement used) • Decubitus ulcers • Lack of care provided for established skin lesions • Infestations • Immersion (stocking/glove distribution) or cigarette burns
Head and neck	• Traumatic alopecia (distinguishable from androgenetic alopecia on basis of distribution) • Scalp hematomas, lacerations, abrasions
Genitourinary	• Rectal or vaginal bleeding could indicate sexual abuse
Musculoskeletal	• Examination for occult fracture, pain • Observe gait • Fractures that are not explained by mechanisms of reported injury

Table 90.6 Potential findings in elder abuse or neglect. *Adapted from Lachs MS, Pillemen K. Elder abuse. Lancet 2004;364:1263–72.*

Risk Factors for Elder Abuse

Because of increased opportunities for contact and thus for conflict and tension, a shared living arrangement is a major risk factor for elder abuse. Abuse also occurs in residential and nursing care facilities. Elderly individuals living alone are more likely to be victims of financial abuse, but they are at lower risk for other forms of abuse[26]. Physical abuse is reported to occur more frequently in elders with dementia, especially those with a history of aggressive behavior. Social isolation has also been identified as a risk factor, with victims more likely to be isolated from friends and family other than the person with whom they are living than are non-victims[24]. Pathologic characteristics of perpetrators of elder abuse include mental illness, particularly depression, and alcohol abuse. Additionally, people who abuse elders may actually be dependent (e.g. financially) on the person they are abusing. In some cases, abuse stems from attempts by relatives (particularly adult offspring) to obtain the victim's resources[26,27].

Clinical Features and Assessment

Potential findings in abused or neglected elders are listed in Table 90.6. Tools such as the Elder Abuse Suspicion Index have also been developed to improve physician identification of elder abuse[28,29]. Unfortunately, abused elders may not always have findings clearly attributable to abuse. Conversely, older individuals may have findings that mimic abuse but which are actually a result of accidental injuries or chronic disease[24,30,31].

When elder abuse is suspected, the clinical findings should be photographed and documented in the medical record. The patient should not be interviewed in the presence of the suspected abuser. The presence of other healthcare staff should also be minimized, since many patients are ashamed to admit that they are victims of elder abuse[24]. The patient may also hesitate to disclose abuse due to fears of being placed in a long-term care facility, perpetrator retaliation, severing family relationships, and legal implications for the perpetrator[32]. Although direct questions about abuse are appropriate, the interviewer may prefer to begin with general questions about safety issues and the home environment. The physician must use considerable caution in interacting with a suspected abuser. One of the risks of confronting an alleged abuser is that access to the elderly person may be lost. If the physician deems it necessary to interview a suspected abuser, an empathetic non-judgmental approach may be helpful[24].

Elder self-neglect is a related entity that occurs three times more commonly than abuse by others and is associated with a 16-fold increase in risk of death during the first year after diagnosis[33]. The CDC describes it as vulnerable elders who fail or refuse to address their own basic physical, emotional, or social needs in a way that threatens their health and safety. Elder self-neglect typically reflects impaired coping and decision making because of cognitive and/or functional impairments[33].

Management

Because elder abuse is multifactorial, potential interventions are based on the context of abuse. A multidisciplinary team involving physicians, nurses, social workers, elder care attorneys, adult protection agencies and, when appropriate, law enforcement officials is helpful when dealing with elder abuse. If the abused person is competent to make medical decisions and willing to accept intervention, education regarding elder abuse can be provided, a safety plan implemented, and the patient as well as family members referred to appropriate services. Reporting by healthcare providers of suspected cases of elder abuse or self-neglect to adult protective services is mandated by law in most states in the US, even if the elder is unwilling to accept intervention. The National Center on Elder Abuse website (https://ncea.acl.gov) provides additional information.

In summary, dermatologists should remain vigilant in looking for physical signs of abuse in elderly patients, especially those who are dependent on caregivers. Dermatologists who encounter signs of elder abuse are responsible for initiating the evaluation process that protects these fragile members of society.

Additional figures and a table on Interventions for elder abuse available in our eBook (see inside front cover for access code).

INTERVENTIONS FOR ELDER ABUSE	
Context of elder abuse	**Potential interventions**
Abuse potentially related to stress from caring for impaired family member	Respite services
	Adult daycare
	Caregiver education programs (e.g. on what constitutes abuse)
	Recruitment of other family, informal, or paid caregivers to share burden of care
	Psychotherapy for caregiver
	Treatment for depression
	Social integration of caregiver to reduce isolation
Violence related to substance or alcohol misuse	Referral to alcohol or drug misuse rehabilitation programs as appropriate
Violence related to behavioral problems associated with mental health	Treatment referral
Spousal violence (often longstanding)	Marital counseling
	Support groups
	Shelter
	Orders of protection
	Victim advocacy
Abuse by aggressive dementia patient	Geriatric medical assessment of causes of underlying behavior
Financial exploitation by family members	Guardianship proceeding, power of attorney (transfer of legal authority)
	Protective services
Financial exploitation by paid caregiver	Referral to legal services
	Involvement of law enforcement
	Protective services

Histiocytoses 91

Sylvie Fraitag and Stéphane Barete

OVERVIEW

The histiocytoses represent a group of proliferative disorders that share a common CD34$^+$ progenitor cell in the bone marrow. Three "histiocytic cells" of cutaneous importance are: (1) the *Langerhans cell*, which initially migrates from the embryonic yolk sac to the epidermis[1] and functions as a potent antigen-presenting cell (APC); (2) the *mononuclear cell/macrophage*, which migrates to and from the dermis and has both phagocytic and APC properties; and (3) the *dermal dendrocyte/dendritic cell*, of which there are two subtypes. Type 1 dermal dendrocytes are factor XIIIa-positive and generally reside within the papillary dermis, whereas type 2 dermal dendrocytes are CD34-positive and are generally found within the reticular dermis. Type 1 dermal dendrocytes may be involved in phagocytosis, antigen presentation, inflammation, collagen production, and wound healing, while the function of type 2 dermal dendrocytes is less certain. These two types represent myeloid dendritic cells and are distinct from plasmacytoid dendritic cells.

Dysfunction of these various histiocytes has led to a group of well-known, but poorly understood, disorders. For years, many of the histiocytoses were known by numerous names, reflecting the lack of understanding and agreement regarding their origin. Initially electron microscopy, then immunohistochemical stains, and most recently molecular pathology have provided insights into these conditions. Over the past decade, multiple types of histiocytoses were shown to be neoplasms of myeloid origin driven by somatic gain-of-function mutations that lead to activation of the mitogen-activated protein kinase (MAPK) signaling pathway. *BRAF* was found to be the most frequently altered gene. However, genes encoding membrane receptors (e.g. *CSF-1R, NTRK1, RET, ALK*) and components of the RAS-RAF-MEK-ERK (MAPK) pathway, both upstream (e.g. *NRAS, KRAS*) and downstream (e.g. *MAP2K1/MEK1*) of BRAF may also be involved (see Fig. 113.1). Less commonly, there is activation of the PI3K-AKT signaling pathway. In patients with disseminated disease, the mutation found in an affected organ can also be detected in blood cells and/or hematopoietic progenitors.

In the new classification scheme from the Histiocyte Society, histiocytoses are classified into five main groups based upon their clinical, histologic, and molecular characteristics: (1) Langerhans-related histiocytoses (L group); (2) cutaneous and mucocutaneous histiocytoses (C group); (3) malignant histiocytoses (M group); (4) Rosai–Dorfman disease (R group); and (5) hemophagocytic lymphohistiocytosis and macrophage activation syndrome (H group)[2].

This chapter covers the most common histiocytic disorders as well as several rare forms (Table 91.1).

"L" GROUP: LANGERHANS-RELATED HISTIOCYTOSES

Langerhans Cell Histiocytosis

Synonyms:

- Langerhans cell histiocytosis (LCH): class I histiocytosis, histiocytosis X
- Subtypes (historical names):
  - Acute (Letterer–Siwe disease)
  - Chronic (Hand–Schüller–Christian disease)
  - Localized (eosinophilic granuloma)
  - Congenital self-healing Langerhans cell histiocytosis (congenital self-healing reticulohistiocytosis; Hashimoto–Pritzker disease)

Key features

- A clonal proliferation of Langerhans cells, CD1a$^+$/CD207$^+$ dendritic cells derived from the bone marrow
- Somatic gain-of-function mutations, most commonly *BRAF* V600E, lead to activation of the mitogen-activated protein kinase (MAPK) signaling pathway; as a result, ERK phosphorylation is a consistent finding
- Histopathologic diagnosis is aided by immunohistochemistry, e.g. anti-VEI antibody, and DNA sequencing to detect associated mutations
- Systemic manifestations include osteolytic bone lesions and diabetes insipidus
- Targeted therapy consists of selective BRAF inhibitors (e.g. vemurafenib) and/or MEK inhibitors

Introduction

Langerhans cell histiocytosis (LCH) is a clonal proliferative disorder in which Langerhans cells, CD1a$^+$/CD207$^+$ dendritic cells, accumulate within a variety of organs. It is characterized by a broad spectrum of clinical presentations and outcomes, ranging from localized and self-healing to generalized and fatal.

History

Letterer–Siwe disease, Hand–Schüller–Christian disease, and eosinophilic granuloma were described in the early twentieth century. In 1953, Lichtenstein[3] grouped these three disorders into a single entity which he called *histiocytosis X*. Twenty years later, Hashimoto and Pritzker[4] described the entity *congenital self-healing reticulohistiocytosis*. Immunologic and ultrastructural studies confirmed the relationship of the pathologic cells in histiocytosis X and congenital self-healing reticulohistiocytosis to Langerhans cells, providing a basis for the Writing Group of the Histiocyte Society, in 1987, to reclassify them as "Langerhans cell histiocytoses"[5].

Epidemiology

LCH occurs worldwide and most commonly develops in children ages 1–3 years, although disease can occur at any age. The reported incidence of LCH varies widely. However, an annual incidence of at least five per million children is often quoted, with the adult incidence suspected to be less than one-third that of children. LCH is more common in boys, with a male : female ratio of nearly 2 : 1. In adults, there may be a slight female predominance.

Some cases of LCH appear to be familial. One study described simultaneous development of LCH in four of five monozygotic twin pairs and in one of three dizygotic pairs[6]. Additionally, in two families with affected non-twin siblings, parental consanguinity was known in one and possible in the other.

Pathogenesis

Until recently, the pathogenesis of LCH was unknown. In 2010, a significant percentage (55%–60%) of LCH specimens were shown to harbor the *BRAF* V600E mutation[4,7]. This strongly suggested that LCH was a clonal neoplasm, a finding supported by further studies in which clonality of CD1a$^+$ histiocytes was uniformly demonstrated[8–10]. In high-risk patients, *BRAF* V600E mutations were also detected in CD34$^+$ hematopoietic progenitor cells within the bone marrow as well as circulating CD11c$^+$/CD14$^+$ monocytic cells. As a result, LCH is now regarded to be a myeloid neoplasm[11,12].

As in melanoma, somatic gain-of-function mutations in *BRAF* point to activation of the mitogen-activated protein kinase (MAPK) signaling pathway (see Fig. 113.1). Of note, *BRAF* V600E mutations have been more commonly observed in patients with multisystem LCH than in those with isolated disease[13]. Mutations in genes that encode other kinases in the RAS-RAF-MEK-ERK (MAPK) pathway (e.g. *MAP2K1* [also referred to as *MEK1*]) as well as membrane receptors were subsequently detected (see Overview). The end result is phosphorylation of ERK. *BRAF* and *MEK1* mutations are mutually exclusive, and ~50% of LCH patients with wild-type *BRAF* have *MEK1* mutations[14].

Clinical features

Clinical manifestations of LCH vary from unifocal or single-system (S-S) disease to multifocal involvement to *multisystem (M-S) Letterer–Siwe-type disease*. The latter nearly always develops prior to age 2 years, and commonly presents in children less than 1 year of age. Cutaneous involvement occurs in most patients as 1–2 mm pink to skin-colored or purpuric papules, pustules, and/or vesicles in the scalp, flexural areas of the neck, axilla and perineum, and on the trunk (Fig. 91.1A–C). Rarely, the lesions resemble mollusca contagiosa (Fig. 91.1D)[7]. Scale and crust with secondary impetiginization are common findings, as is the development of petechiae and purpura (Fig. 91.1E). The lesions tend to

CLINICAL FEATURES OF THE HISTIOCYTOSES

Histiocytosis	Usual age	Most common mucocutaneous sites	Other findings
Langerhans cell histiocytoses			
Acute form	0–2 years	Scalp, flexural areas, trunk	Visceral and bone lesions
Chronic form	2–6 years	Scalp, flexural areas, trunk, gingival	Diabetes insipidus, bone lesions, exophthalmos
Localized form (eosinophilic granuloma)	7–12 years	Skin lesions rare	Bone lesions primarily
Congenital self-healing Langerhans cell histiocytosis	Congenital	Widespread, localized, or single lesion	Spontaneous resolution, but children should be followed longitudinally
Indeterminate cell histiocytosis	Any	Solitary or generalized Trunk & extremities > head & neck, genitalia	Uncommon visceral and bone lesions; possible association with B cell lymphoma and acute myelogenous leukemia
Erdheim–Chester disease	Any, but primarily adults	Eyelids, trunk, extremities, head and neck	Fever, bone pain (osteosclerosis of long bones); involvement of the lungs, kidneys, adrenals, heart (up to 50%), CNS, retroperitoneum (fibrosis), and testes
Non-Langerhans cell histiocytoses			
Primarily cutaneous, usually self-resolving			
Juvenile xanthogranuloma	0–2 years (adult form exists)	One to a few lesions ≫ numerous & widespread Head and neck > upper trunk > extremities	Rare eye and visceral lesions; spontaneous resolution; association with CALM, NF1, and/or juvenile myelomonocytic leukemia
Benign cephalic histiocytosis	0–3 years	Face and neck > trunk and extremities	Usually none (diabetes insipidus rare); spontaneous resolution
Generalized eruptive histiocytosis	<4 and 20–50 years	Widespread (axial)	Recurrent crops; spontaneous resolution > persistent; may relapse
Primarily cutaneous, often persistent/progressive			
Papular xanthoma*	Any	Generalized (discrete yellow papules and papulonodules with relative sparing of flexural sites)	Mucous membrane involvement can occur occasionally
Progressive nodular histiocytosis	Any	Generalized (discrete yellow papules and nodules, sometimes with prominent facial involvement)	May represent same entity as the progressive form of papular xanthoma[85]; mucous membrane involvement can occur
Hereditary or sporadic progressive mucinous histiocytosis	Childhood/ adolescence	Generalized (skin-colored to erythematous papules and nodules)	Usually occurs in female patients; histologically, abundant dermal mucin in addition to histiocytes
Cutaneous, with frequent systemic involvement			
Necrobiotic xanthogranuloma	17–60 years	Periorbital > other face, trunk, extremities	Paraproteinemia due to plasma cell dyscrasia or lymphoproliferative disorder, hepatosplenomegaly
Multicentric reticulohistiocytosis	30–50 years	Head; hands, elbows (over joints); mucosa (oral, nasopharyngeal)	Arthritis (often destructive); up to 30% with internal malignancy
Rosai–Dorfman disease	10–30 years	Eyelids and malar area	Massive lymphadenopathy in a subset of patients, fever, hypergammaglobulinemia; skin-limited form increasingly recognized
Xanthoma disseminatum	Any	Flexural areas to widespread > mucosa (oral, nasopharyngeal)	Diabetes insipidus
Systemic, with skin involvement rare to unusual			
Sea-blue histiocyte syndrome (sea-blue histiocytosis)* • Inherited • Acquired	Usually adolescence/ young adulthood (inherited form)	Skin involvement rare (inherited form): facial (macular hyperpigmentation and nodules)	Histiocytes contain cytoplasmic granules that stain azure blue with May–Gruenwald stain; multiple organs involved; can be fatal

Table 91.1 Clinical features of the histiocytoses.

CLINICAL FEATURES OF THE HISTIOCYTOSES			
Histiocytosis	**Usual age**	**Most common mucocutaneous sites**	**Other findings**

Hemophagocytic lymphohistiocytosis (HLH; hemophagocytic syndrome)*
• Primary (genetic; see Table 60.6)
  • Familial HLH†; Chédiak–Higashi syndrome, Griscelli syndrome type 2 > Hermansky–Pudlak type 2; X-linked lymphoproliferative syndrome;
• Secondary (acquired)
  • Infection-associated (e.g. EBV, CMV, dengue)
  • Malignancy-associated (e.g. NK/T cell lymphoma, B cell lymphoma)
  • Macrophage activation syndrome (MAS) associated with autoimmune connective tissue disease (e.g. sJIA, Still disease, systemic lupus erythematosus)
	Primary: 0–2 years
	Secondary: any
		Generalized (purpuric macules and papules, morbilliform eruptions, erythroderma, keratotic nodules) or acral (erythematous macules); malignancy-associated forms may present with lesions of cutaneous/subcutaneous cytotoxic NK/T cell lymphomas; skin biopsy specimens rarely demonstrate hemophagocytosis	• HLH diagnosed if genetic mutation detected or if at least 5 of the following 8 criteria: (1) fever for >7 days; (2) splenomegaly; (3) cytopenias; (4) hypertriglyceridemia or hypofibrinogenemia; (5) histologic evidence of hemophagocytosis (in the bone marrow, lymph nodes or spleen); (6) low or absent natural killer cell activity; (7) hyperferritinemia‡; and (8) elevated soluble CD25, plus evidence of infectious agent, malignancy, autoinflammatory disorder, or autoimmune connective tissue disease in secondary forms
			• Some of the patients with secondary forms may be heterozygous for genetic mutations that cause primary HLH
			• MAS in the setting of sJIA requires fever and ferritin >684 ng/ml *plus* any 2 of the following: thrombocytopenia, transaminitis, hypertriglyceridemia, hypofibrinogenemia
			• CNS dysfunction, hemorrhages, hepatomegaly, arthritis, and elevated levels of S100A12 may be present
			• Treatments include corticosteroids, cyclosporine, JAK inhibitors, emapalumab, etoposide, allogeneic hematopoietic stem cell transplant

*Not covered in the body of the text.
†In the US, most commonly due to mutations in the gene that encodes perforin (*PRF1*), referred to as subtype 2; additional genes include *UNC13D* (subtype 3), *STX11* (subtype 4), and *STXBP2* (subtype 5). Their protein products play a role in the cytotoxic activity of lymphocytes, including the exocytosis of cytotoxic granules by NK cells.
‡The primary differential diagnosis is iron overload, Still disease, HLH or MAS, infection, and malignancy.

Table 91.1 Clinical features of the histiocytoses. CALM, café-au-lait macule; CD25, interleukin-2 receptor alpha; CMV, cytomegalovirus; EBV, Epstein–Barr virus; NF, neurofibromatosis; sJIA, systemic juvenile idiopathic arthritis.

coalesce and become tender, especially when fissures develop in intertriginous zones (Fig. 91.1B,F). Palmoplantar and nail involvement can occur, as can soft tissue nodules (Fig. 91.1G). In patients with darkly pigmented skin, the lesions may appear relatively hypopigmented (Fig. 91.1H). The eruption is most often confused with seborrheic dermatitis, various forms of diaper dermatitis or intertrigo (see Figs. 13.4 and 13.12), and arthropod bites (including scabies) when pruritic.

During the course of the disease, many organs can become infiltrated by clonal LCH cells. However, only if the key functions of the organ are affected is such involvement of prognostic significance. Lung, liver, lymph node, and bone involvement commonly occur at some point during the illness. Osteolytic bone lesions are painful, usually multiple, and most frequently involve the cranium. Occasionally, the hematopoietic system can be affected, with thrombocytopenia and anemia portending a poor prognosis.

Another early-onset form of cutaneous LCH is known as *congenital self-healing Langerhans cell histiocytosis* or *Hashimoto–Pritzker disease*. It is present at birth or develops during the first few days of life. Clinical features include vesicles and/or pustules that can be mistaken for varicella as well as red–brown, crusted papulonodular lesions that often have central necrosis (Fig. 91.2). Some newborns may have a "blueberry muffin baby" presentation (see Table 121.4)[15]. Rarely, there is a single neonatal nodule, referred to as a *Langerhans cell histiocytoma*[16]. While congenital self-healing LCH is usually a benign, self-resolving disorder, its relationship to other LCH variants suggests a cautious approach with respect to prognosis, and longitudinal evaluation is recommended.

The triad of diabetes insipidus, bone lesions, and exophthalmos (*formerly called Hand–Schüller–Christian disease*) typically begins between the ages of 2 and 6 years. These patients tend to have a chronic, progressive course and often do not have the complete triad. Approximately 30% of patients develop skin or mucous membrane lesions (Fig. 91.1I). While early cutaneous lesions are similar to those seen in the M-S form, older lesions can become xanthomatous. Ulcerative nodules may develop in the oral and genital areas, with premature loss of teeth possible secondary to gingival lesions.

At least 80% of patients develop bone lesions, the cranium being preferentially involved. Chronic otitis media occurs commonly in these patients and in patients with all forms of LCH. Diabetes insipidus, secondary to infiltration of the posterior pituitary by LCH cells, develops in ~30% of patients and is more common in those individuals with cranial bone involvement.

A localized variant of LCH, formerly called *eosinophilic granuloma* generally affects older children, boys more than girls. The cranium is most frequently affected, though lesions can also develop within the ribs, vertebrae, pelvis, scapulae, and long bones. A spontaneous fracture or otitis media may be the first sign of disease. Skin and mucous membrane lesions are rare.

Adults rarely develop LCH, but when they do, the most commonly involved sites are the skin, lung, and bone (see Fig. 91.1F). Diabetes insipidus can also develop and, as in children, is more likely when bony involvement of the skull is present. Severe multisystem disease is rare in adults. However, LCH can be a progressive disease in adults, especially when both bone and extra-skeletal sites are involved. Pulmonary involvement can be isolated or be a component of multisystem disease and it favors men who smoke cigarettes[17].

There are two patterns of associations between LCH and malignancy[18]. The first is the development of acute leukemias and solid tumors in patients with a history of LCH who have been treated with chemotherapy, radiotherapy, or both, and the malignancies are likely to be treatment-related. There are reports of a few patients who developed skin or solid tumors (e.g. basal cell carcinoma, osteosarcoma) within the fields of radiotherapy for their LCH.

A second more interesting association is an apparent increased incidence of LCH in patients with hematologic malignancies, including acute myelogenous leukemia, acute lymphocytic leukemia, chronic myelomonocytic leukemia, and lymphomas of both T and B cell origin. These malignancies can occur prior to, concurrently, or following the diagnosis of LCH[19]. In contrast to treatment-related (often referred to as secondary) hematologic malignancies, it has been demonstrated in several patients that the LCH and the hematologic malignancy are clonally related, suggesting origin from a common neoplastic stem cell[20].

Fig. 91.1 Langerhans cell histiocytosis – clinical spectrum. A Scalp involvement may initially be diagnosed as seborrheic dermatitis; however, there are usually more discrete papules and crusting. **B** Pink, thin plaques with fissuring along the inguinal creases can also resemble seborrheic dermatitis. **C** Advanced disease with coalescence of papules into large plaques and prominent inguinal lymphadenopathy. **D** Pale pink to skin-colored papules, several of which have central umbilication and resemble mollusca contagiosa. **E** The presence of petechiae and purpuric papules is a clue to the diagnosis. **F** In an adult, the clinical presentation of inguinal involvement is similar to that of infants. **G** This subcutaneous nodule on the scalp involved the skull and represented the initial manifestation of multisystem Langerhans cell histiocytosis in an infant. **H** In patients with highly pigmented skin, the papules can be hypopigmented. **I** Eroded erythematous plaque of the labial mucosa. *B, Courtesy Richard Antaya, MD; D, Courtesy Kristen Hook, MD; E, G, H, Courtesy Julie V. Schaffer, MD.*

The prognosis of patients with LCH varies dramatically. Involvement of "risk organs" – hematopoietic system, liver, lungs, and/or spleen – substantially increases the risk of disease-related mortality. However, in individuals with single-system disease or multisystem disease that does not involve risk organs, mortality rates are very low (e.g. <5% in the latter group). As with hematologic malignancies, the response to initial systemic treatment is an important prognostic indicator in LCH. Of note, in one study patients with high-risk LCH had *BRAF* V600E mutations in their CD34$^+$ hematopoietic progenitor cells, while the mutation was limited to lesional CD207$^+$ (Langerin$^+$) dendritic cells in low-risk LCH patients[21].

Pathology

In a typical papule of LCH, a proliferation of neoplastic cells is present in the papillary dermis (Fig. 91.3A). They are medium-sized cells, 10–15 microns in diameter, with a reniform (kidney-shaped) nucleus and a pink, non-xanthomatous (non-foamy) cytoplasm. The LCH cells are often admixed with eosinophils, lymphocytes, and red blood cells. Epidermotropism is commonly observed, resulting into a spongiform pattern and focal parakeratosis (Fig. 91.3B). In nodular lesions of congenital self-healing LCH, including LC histiocytoma, epidermotropism is not a feature and the dermal infiltrate can extend into the deep dermis. Some of the histiocytes within the infiltrate have abundant eosinophilic cytoplasm and are intermixed with LCH cells and giant cells[16].

Like Langerhans cells, LCH cells are characterized by a CD1a$^+$, CD207$^+$ (Langerin$^+$) phenotype (Fig. 91.3C,D); CD207 is the major protein of Birbeck granules. Both CD207 and CD1a have important roles in the uptake, processing, and presentation of non-peptide (e.g. lipid) antigens by Langerhans cells (Table 91.2) In addition, LCH cells commonly stain positive for CD68, while they are negative for CD163 (macrophage/monocyte marker) and FXIIIa (Fig. 91.4). Electron microscopy demonstrates Birbeck granules, which are rod- or racquet-shaped cytoplasmic structures pathognomonic for Langerhans cells and LCH cells (Fig. 91.5). However, electron microscopy is no longer routinely performed.

Fig. 91.2 Congenital self-healing Langerhans cell histiocytosis (Hashimoto–Pritzker disease). Cluster of crusted red–brown papules as well as a large hemorrhagic crust on the posterior ankle of a neonate. *Courtesy Kristen Hook, MD.*

Molecular analysis and immunohistochemistry are increasingly being utilized as diagnostic tools in that up to 60% of cases of LCH harbor a clonal *BRAF* V600E mutation. The VE1 mutant-specific antibody is useful in detecting this mutation[22]. In addition, pERK expression as well as cyclin D1 nuclear positivity are always observed in LCH, irrespective of the *BRAF* V600E mutational status[22], since mutations other than *BRAF* V600E can lead to activation of the MAPK pathway (see Fig. 113.1)[23].

Differential diagnosis

The clinical differential diagnosis is vast and includes seborrheic dermatitis, various forms of diaper dermatitis or intertrigo (see Figs. 13.4 and 13.12), and arthropod bites (including scabies), as well as leukemia, B and T cell lymphomas, multiple myeloma (bony lesions), maculopapular cutaneous mastocytosis, and the non-Langerhans cell histiocytoses (see Table 91.1). However, the characteristic histologic features of LCH will lead one to suspect the diagnosis, which is confirmed by the combination of positive immunostaining for CD1a and CD207 (Fig. 91.6). Occasionally, dense dermal infiltrates of $CD1a^+$ dendritic cells can be seen in insect bite reactions, including scabies, and lead to misdiagnosis (see Fig. 85.3)[24]. However, these cells do not express CD207.

Treatment

All patients diagnosed with LCH should undergo evaluation of the hematologic, pulmonary, hepatosplenic, renal, and skeletal systems to determine the extent of disease. Depending on age and extent of involvement, some patients may not require specific treatment, while others will require systemic therapy. The latter include corticosteroids, vinblastine, cladribine, and/or interferon alpha-2a as well as targeted therapies such as selective BRAF and MEK inhibitors[25].

For mild, single-system *skin disease* (if treatment is required), topical agents, including corticosteroids, antimicrobials, mechlorethamine (nitrogen mustard) and imiquimod, as well as phototherapy (narrowband UVB, PUVA) have been reported to be effective in case series. For more extensive cutaneous disease, based upon case reports, thalidomide, azathioprine, or methotrexate may be effective[17,24]. Other chemotherapeutic treatments such as cladribine and cytarabine have been used for refractory disease[26,27] as have autologous hematopoietic stem cell transplants.

Targeted therapy in the form of selective BRAF and MEK inhibitors has revolutionized treatment strategies for patients with aggressive, resistant disease; however, aspects of their use such as duration are still under debate[28,29]. Updated information regarding ongoing clinical trials is available at www.clinicaltrials.gov and www.histiocytesociety.org.

Indeterminate Cell Histiocytosis

Key features

- Currently classified within the L group (Langerhans-related histiocytoses) due to mutations in *BRAF* V600E in nearly all patients
- Occurs in adults and children with both generalized and solitary variants
- Cells display the phenotype of dendritic cells: CD1a$^+$, S100$^+$, CD207$^-$
- Primarily a cutaneous disorder, but occasionally there is visceral involvement and associated hematologic malignancies

Introduction

Indeterminate cell histiocytosis (ICH) is a very rare proliferative disorder comprised of histiocytes that have both LCH and non-LCH immunophenotypic features. There are two clinical variants – solitary and generalized.

History

Indeterminate cells were described in 1963, and a patient with features first recognized as ICH was reported by Wood et al.[24] in 1985. To date, ~60 cases have been reported in the literature. ICH is thought to be closely related to LCH because the pathologic cells are positive for CD1a, although they do not express CD207.

Epidemiology

ICH is quite rare and has no apparent sex predominance. It can occur at any age, from infancy to adulthood, and a congenital form has been reported.

Pathogenesis

Most cases of ICH harbor a gain-of-function mutation in *BRAF* V600E. Translocations involving *NCOA2* (nuclear receptor co-activator 2) and *ETV3* (Ets variant 3) have also been reported[30].

Clinical features

While the majority of patients with ICH have involvement of the trunk and extremities, lesions have also been observed on the genitalia and in the head and neck region, including the eyelids and ears. Both a generalized form and a solitary form have been described. In the generalized form, cutaneous lesions usually begin as firm red to brown papules or nodules (Fig. 91.7). The solitary form presents as a single, often soft, erythematous nodule that is usually ~1 cm in diameter. Ulceration can occur and as lesions age, they become brown to yellow. The clinical course is variable, with some patients experiencing a partial or complete regression of lesions (which may wax and wane), while others have a progressive course.

Although mucous membrane involvement is rare, both corneal and conjunctival lesions have been reported. Patients are usually in good health, but because visceral involvement and death can occasionally occur, periodic evaluation is warranted. There is a report of an infant who developed an aggressive form of ICH with a fatal outcome; the disease initially presented in the bone and then eventually spread to visceral organs and the skin[31]. Several cases have been associated with hematologic malignancies including mast cell leukemia, acute myelogenous leukemia, and low-grade B cell lymphoma.

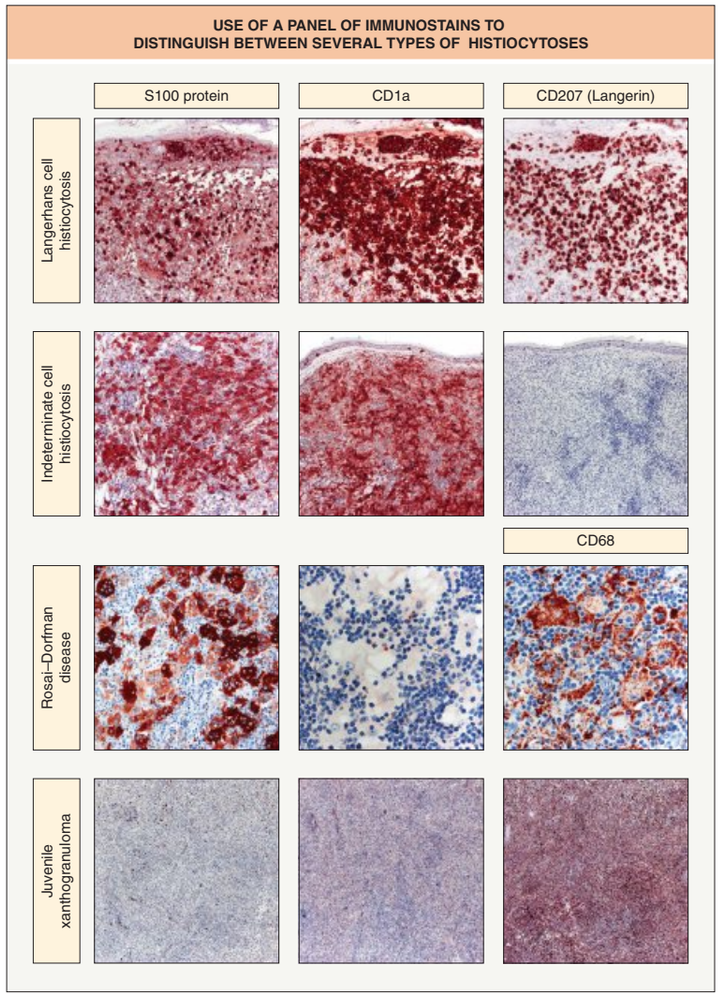

Fig. 91.6 Use of a panel of four immunostains to distinguish between Langerhans cell histiocytosis and several types of non-Langerhans cell histiocytosis. *Courtesy Lorenzo Cerroni, MD.*

Pathology

There is usually a predominantly monomorphous infiltrate of histiocytes, either well-circumscribed or more diffusely distributed within the dermis. Epidermotropism is less common than in LCH. Histiocytes often have an oncocytic appearance, with occasional spindled, scalloped, or vacuolated cell variants. Touton giant cells can be present. Lymphocytes are commonly present and eosinophils are occasionally observed.

The immunophenotype of ICH consists of positivity for CD68 and CD1a, but negativity for CD207. S100 may be either positive or negative, making this marker less helpful in establishing the diagnosis (see Fig. 91.4 & Table 91.2)[32–34].

Differential diagnosis

The clinical appearance of the cutaneous lesions of ICH is not unique. Similar-appearing papules in the same distribution can be found in generalized eruptive histiocytoma, juvenile xanthogranuloma, and congenital self-healing LCH (see Table 91.1). When lesions are limited to the head and neck region, benign cephalic histiocytosis should be considered as well. The clinical differential diagnosis also includes eruptive syringomas, maculopapular cutaneous mastocytosis, and lymphomatoid papulosis. While the diagnosis of ICH can be suspected based upon histopathology, confirmation requires demonstration of the characteristic CD1a$^+$, CD207$^-$ immunophenotype.

Treatment

Treatment of cutaneous lesions is usually not required as the lesions are asymptomatic and ICH is often either self-limited or non-progressive. A

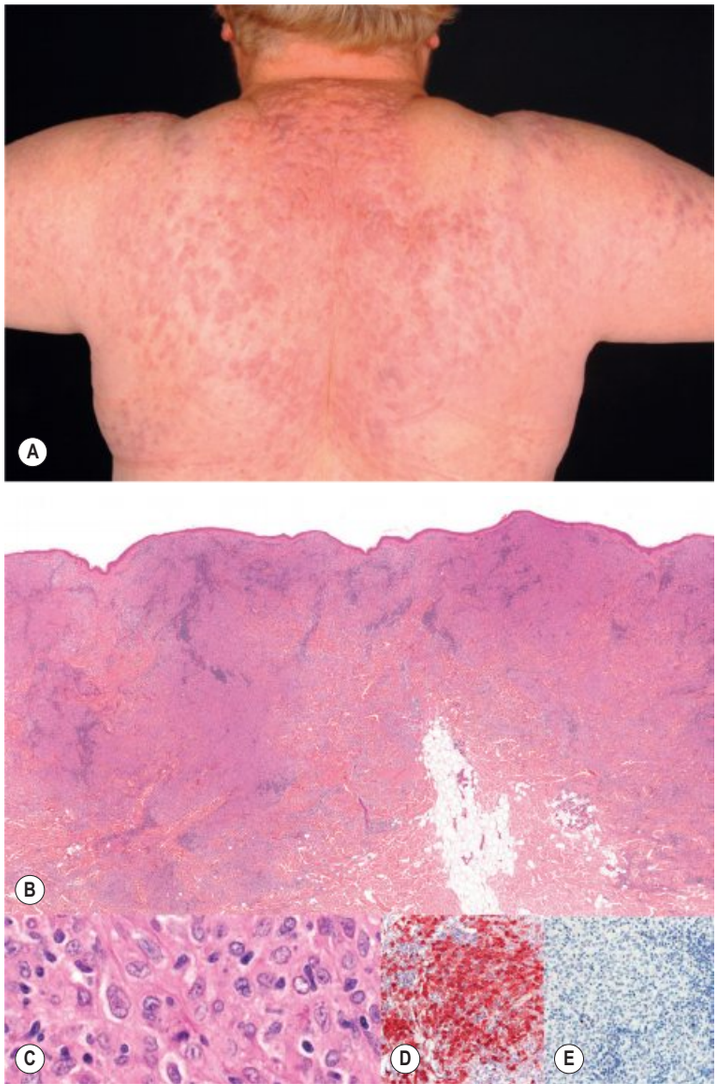

Fig. 91.7 Indeterminate cell histiocytosis. A Multiple pink-violet papules, plaques, and small nodules on the back. **B** Histologically, dense infiltrates were seen throughout the entire dermis and superficial subcutaneous fat. These infiltrates were composed of medium-to-large histiocytic cells (**C**) that were positive for S100 (**D**) and negative for CD1a (**E**). *Courtesy Lorenzo Cerroni, MD.*

single lesion can be removed surgically. Patients with extensive, disfiguring cutaneous disease have been treated with systemic chemotherapy (e.g. vinblastine, 2-chlorodeoxyadenosine, cyclophosphamide, and/or etoposide). There are also reports of the use of thalidomide, isotretinoin, methotrexate, NB-UVB, PUVA, or total skin electron beam therapy. As with LCH, selective BRAF and MEK inhibitors can be considered. Because visceral involvement and leukemia can occur, longitudinal evaluation of all patients with indeterminate cell histiocytosis is recommended[35].

Erdheim–Chester Disease

Key features

- Erdheim–Chester disease (ECD) is a severe form of histiocytosis which usually affects adults
- As in LCH, gain-of-function mutations in *BRAF* V600E are observed in >50% of patients; mutations in other genes that lead to activation of the MAPK pathway (e.g. *MAP2K1/MEK1*) also occur
- Cutaneous lesions occur in ~25% of patients and are accompanied by symmetric diaphyseal and metaphyseal osteosclerosis of the long bones as well as periaortic, retroperitoneal, and perirenal fibrosis
- Histologically, there are dermal infiltrates of histiocytes
- Treatment primarily consists of a selective BRAF inhibitor (e.g. vemurafenib) and/or a MEK inhibitor (e.g. cobimetinib)

Introduction

Erdheim–Chester disease (ECD) is a severe form of histiocytosis with visceral involvement characterized by xanthomatous or xanthogranulomatous infiltrates within tissues. It is a rare histiocytosis classified in the "L" group of histiocytoses[2].

History

ECD was first described in 1930 by the American physician Dr. William Chester while he was doing a postdoctoral fellowship with the Viennese pathologist Dr. Jakob Erdheim[36]. Although originally considered an aggressive histiocytosis of unclear origin, ECD is now regarded as a clonal hematopoietic disorder characterized in nearly all patients by an underlying *BRAF* V600E mutation or mutations in other genes that lead to activation of the RAS-RAF-MEK-ERK (MAPK) signaling pathway (see Fig. 113.1). More rarely, there is activation of the PI3K-AKT signaling pathway.

Epidemiology

The exact incidence of ECD is not known. Although it is considered an extremely rare disease, the incidence appears to be increasing. It occurs during adulthood (mean age = 55 years), with exceptional cases in children.

Pathogenesis

Originally classified as a non-Langerhans cell histiocytosis, it is now included with LCH in the "L" group[2] in light of the detection of *BRAF* V600E mutations in ~55%–60% of patients. Mutations in other genes that lead to activation of the MAPK pathway (e.g. *NRAS*, *KRAS*, *MAP2K1/MEK1*, *ALK*) have also been described[37,38]. Nearly 20% of patients with ECD have concomitant features of LCH, sometimes with cellular infiltrates of both entities within the same biopsy, further supporting placing ECD and LCH within the same group of histiocytoses[2].

Clinical features

Facial sinus osteosclerosis is suggestive of ECD, although it is often asymptomatic and discovered incidentally by CT or MRI. Bilateral hypermetabolic and sclerotic metaphyseal–diaphyseal involvement of long bones is highly suggestive of ECD, and this is usually associated with bone pain[39]. Plain radiography (skeletal survey) may not detect these lesions, but whole body low-dose CT, MRI, skeletal scintigraphy (bone scan), or ^{18}F-FDG PET scan represent more sensitive imaging tests. Diabetes insipidus may be an initial clinical manifestation. Patients can also develop respiratory symptoms, with pleural and pericardial (as well as peritoneal) thickening seen by CT or MRI. Approximately half of patients have periaortic fibrosis, described radiographically as a "coated aorta". Retroperitoneal fibrosis is a hallmark sign of ECD, with ~60% of patients having perirenal fibrosis ("hairy kidney") on CT scans[39].

Cutaneous involvement is present in 25% of patients, typically presenting as bilateral, symmetric, periocular xanthelasma-like lesions. Multiple yellow papules or plaques favor the medial upper eyelids and may precede other symptoms by several years. Yellow to brown plaques and papulonodules can also develop on the trunk, extremities, and head and neck region (Fig. 91.8), but mucosal involvement is rare[40,41]. Recently described cutaneous manifestations include panniculitis-like nodules and granuloma annulare-like lesions.

Pathology

Within the dermis, there is a granulomatous infiltrate with foamy histiocytes, a few multinucleated histiocytes or Touton giant cells, lymphocytes, and occasional plasma cells and eosinophils. Fibrosis may be prominent. The histiocytes express CD68, CD163, and focally FXIIIa, but are CD1a- and CD207-negative. However, pERK is consistently positive due to activation of the MAPK pathway, and VE1 mutant-specific antibody staining is positive in ~55%–60% of cases, reflecting the presence of the *BRAF* V600E mutation.

Differential diagnosis

The primary differential diagnosis includes xanthelasma and the yellow periocular plaques seen in patients with necrobiotic xanthogranuloma. When there is involvement of the trunk and extremities, other histiocytoses or granulomatous disorders need to be considered. An associated

Fig. 91.8 Erdheim–Chester disease. Red–brown papules and large confluent yellow–brown and brown plaques. The patient had concomitant features of LCH (mixed histiocytosis).

myeloid malignancy may develop in 20%–30% of patients and clonal hematopoiesis has been detected in almost half of patients with ECD; the most frequently mutated genes in the bone marrow are *TET2, ASXL1, DNMT3A,* and *NRAS*[42].

Treatment

Selective BRAF inhibitors such as vemurafenib are an effective treatment for patients who harbor the *BRAF* V600E mutation[39]. MEK inhibitors (e.g. cobimetinib) are very effective in patients with other mutations that activate the MAPK pathway[43]. For this reason, it is important to determine the mutational status of patients[44].

"C" GROUP: CUTANEOUS AND MUCOCUTANEOUS HISTIOCYTOSES

Synonym: ■ Histiocytoses of mononuclear phagocytes other than Langerhans cells

Benign Cephalic Histiocytosis

Synonym: ■ Infantile histiocytosis with intracytoplasmic worm-like bodies

Key features

- Infants <1 year of age are most commonly affected
- Red to brown macules and papules on the face and neck
- Self-limiting disease

Introduction

Benign cephalic histiocytosis (BCH) is a rare, self-limited histiocytic proliferative disorder of young children, primarily affecting the face.

History

Gianotti et al.[45] in 1971 described the condition as "infantile histiocytosis with intracytoplasmic worm-like bodies", based upon findings of comma-shaped structures by ultrastructural studies. When it became clear that several histiocytic disorders (e.g. LCH, juvenile xanthogranuloma) had similar ultrastructural findings, the disorder was renamed "benign cephalic histiocytosis", based upon typical clinical findings.

Epidemiology

BCH is a rare disorder but is probably under-reported. It typically begins by the age of 1 year and nearly always within the first 3 years of life. There may be a male predominance[46].

Pathogenesis

The pathogenesis of BCH is not known. However, due to the histopathologic and immunohistochemical features it shares with juvenile xanthogranuloma and generalized eruptive histiocytoma, several investigators have suggested that these three non-Langerhans cell histiocytoses should be viewed as a single disease with a spectrum of clinical presentations[47].

Clinical features

The eruption of BCH is characterized by the evolution of 2–5 mm, pink–red to red–brown macules and papules, initially on the face (Fig. 91.9A,B), with subsequent appearance on the ears and neck. Occasionally, lesions may develop on the trunk and arms, with infrequent involvement of the buttocks and thighs. The papules eventually flatten, often leaving residual hyperpigmentation that fades over time. Spontaneous resolution occurs over a period of months to years. Most children are otherwise healthy without involvement of the mucous membranes or internal organs. However, diabetes insipidus has been reported in a young girl with BCH[48]. The clinical course can be marked by exacerbations or evolution into generalized eruptive histiocytosis.

Pathology

The most typical finding is a well-circumscribed infiltrate of histiocytes that is confined to the upper dermis. Occasionally, a diffuse dermal infiltrate has been described. The histiocytes have regularly shaped nuclei and slightly vacuolated eosinophilic cytoplasm (Fig. 91.9C). Foamy cells and eosinophils are rarer than in juvenile xanthogranuloma. While multinucleated histiocytes and Touton giant cells were previously said to be absent, their presence has been described.

The histiocytes in BCH express typical (non-Langerhans) histiocytic markers including CD11b, CD11c, CD14b, CD68, CD163, HAM56, and factor XIIIa (see Fig. 91.4, Table 91.2)[2,49]. However, usually only immunostains for CD68 or CD163 and occasionally factor XIIIa are routinely performed.

Differential diagnosis

The differential diagnosis includes LCH, urticaria pigmentosa, and other non-LCH disorders (see Table 91.1). BCH overlaps with generalized eruptive histiocytoma and multiple juvenile xanthogranulomas in addition to sharing some features with progressive nodular histiocytosis and papular xanthoma. However, the clinical appearance and number of lesions as well as the distribution pattern usually allows for distinction of BCH from other non-LCH disorders while the immunophenotype of the histiocytic cells assists in excluding LCH (see Fig. 91.4).

Treatment

BCH is a self-limiting disorder and no treatment is usually needed. However, longitudinal evaluation of all patients is recommended, as both exacerbations of the disease and diabetes insipidus can occur.

Generalized Eruptive Histiocytoma

Synonyms: ■ Eruptive histiocytoma ■ Generalized eruptive histiocytosis

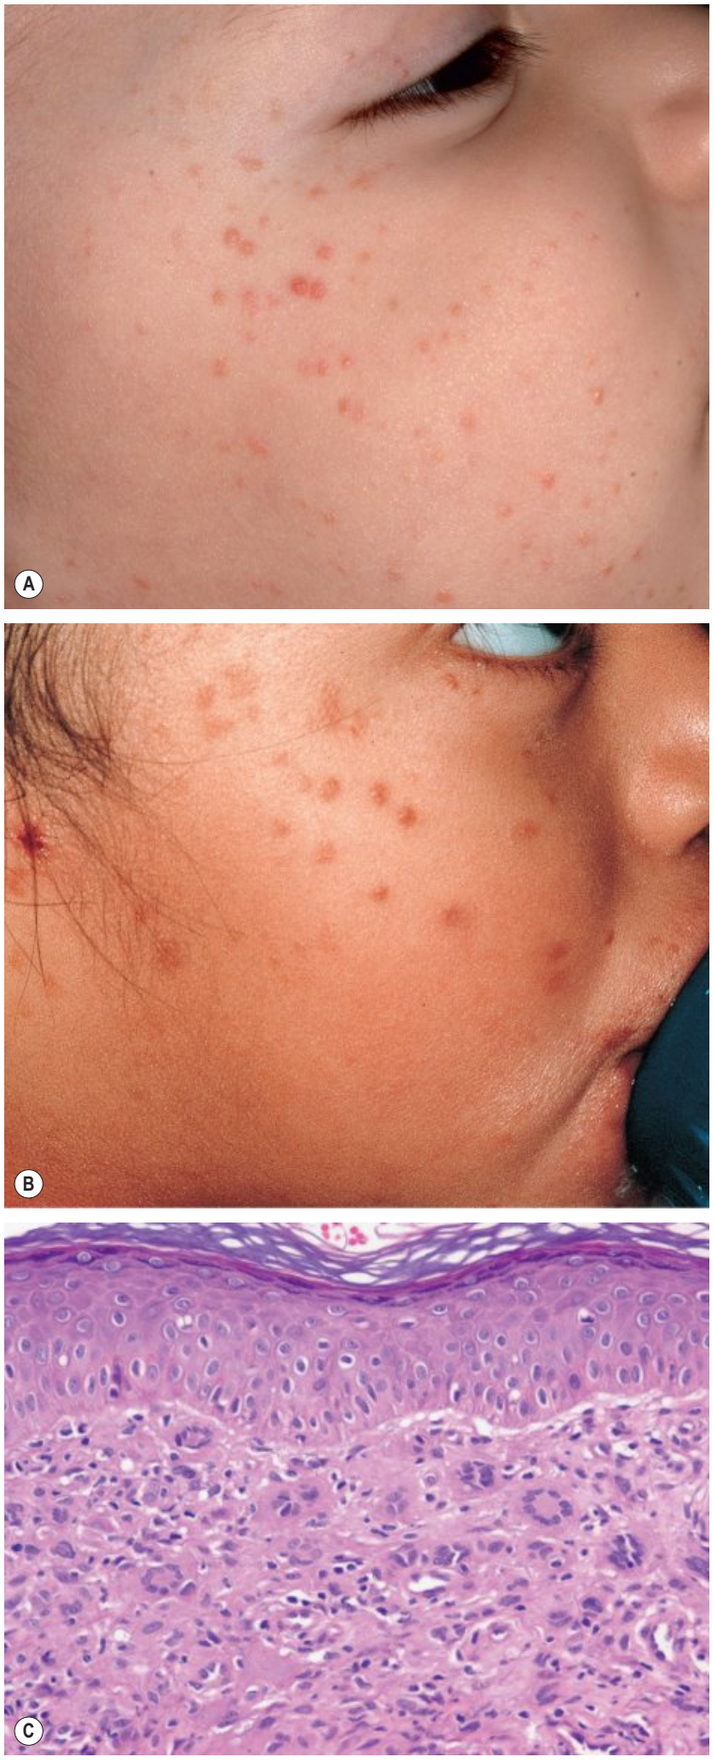

Fig. 91.9 Benign cephalic histiocytosis. Multiple papules that vary in color from light pink–brown (**A**) to brown (**B**) on the face of two young children with different skin phototypes. **C** Photomicrograph of the upper dermal infiltrate of histiocytes admixed with occasional Touton-like giant cells. *A, Courtesy Julie V. Schaffer, MD.*

Key features

- Adults affected more commonly than children
- Recurrent crops of numerous, small, red to brown papules
- Widespread axial distribution
- Self-limiting disease
- Rarely associated with leukemia (primarily acute or chronic myelomonocytic)

Introduction

Generalized eruptive histiocytoma is a rare disorder characterized by recurrent crops of small papules that are axially distributed and heal with hyperpigmented macules.

History

In 1963, Winkelmann and Muller first described three adult patients with generalized eruptive histiocytoma[50]. The disorder has since been reported in children.

Epidemiology

Generalized eruptive histiocytoma is a rare disease that is probably under-reported. Approximately one-quarter of the cases in the literature have been in children. There may be a male predilection. Onset in adults is from the third to sixth decade while in children, it is usually before the age of 4 years.

Pathogenesis

The cause of generalized eruptive histiocytoma is unknown, but there was a case report of a novel *LMNA-NTRK1* fusion. As discussed in the section on BCH, several authors have suggested that generalized eruptive histiocytoma, BCH, and juvenile xanthogranuloma represent different expressions of the same disorder. Generalized eruptive histiocytoma-like presentations have been seen early in the course of other non-LCH disorders, leading some investigators to suggest that generalized eruptive histiocytoma may be an early, indeterminate stage of non-LCHs (e.g. xanthoma disseminatum, progressive nodular histiocytosis)[51,52]. There are a few case reports of generalized eruptive histiocytoma in patients with leukemia, in particular acute or chronic myelomonocytic leukemia. In one patient, interphase FISH analysis showed that the cutaneous lesions of generalized eruptive histiocytoma were clonally linked to the hematologic malignancy[52].

Clinical features

The eruption is characterized by recurrent crops of red to brown papules. At each occurrence, hundreds of papules, less than 1 cm in diameter, are distributed on the trunk, proximal extremities, and occasionally the face (Fig. 91.10). The papules are usually arranged symmetrically, and mucosal surfaces are occasionally involved. Complete resolution may occur within several months or lesions may persist; recurrences have been observed. In some children, there may be a less symmetric distribution pattern and papules can become xanthomatous. Internal involvement has not been described and the affected individuals are otherwise healthy.

Pathology

The superficial and mid dermis typically contain a nearly uniform infiltrate of slightly vacuolated histiocytes with a few lymphocytes. Xanthomatous cells are rare as are multinucleated cells[53]. The histiocytes stain for mature histiocytic markers such as CD68, CD163, and factor XIIIa (see Fig. 91.4, Table 91.2)[54].

Differential diagnosis

The differential diagnosis includes LCH, urticaria pigmentosa, eruptive syringomas, widespread papular granuloma annulare, and other non-LCH disorders. Of the latter, juvenile xanthogranuloma, xanthoma disseminatum, BCH, indeterminate cell histiocytosis, and papular xanthoma (see Table 91.1) can be the most difficult to differentiate from generalized eruptive histiocytoma. However, the clinical features plus the histologic and immunohistochemical findings usually allow for distinction. Occasionally

Fig. 91.10 Generalized eruptive histiocytoma. Multiple firm red to red–brown papules on the trunk.

infections that lead to granulomatous inflammation (e.g. leishmaniasis, leprosy, atypical mycobacterial infections) need to be excluded.

Treatment

No treatment is usually required as the disorder lacks systemic involvement and is often self-limited. There are, however, scattered reports of the use of isotretinoin, cryotherapy, and PUVA. Longitudinal evaluation is recommended, as more serious forms of non-LCH (e.g. xanthoma disseminatum) and rare cases of leukemia have been reported to develop in patients with generalized eruptive histiocytoma[54].

Juvenile Xanthogranuloma

Key features

- Most common histiocytosis
- Usually occurs in infants and young children, with involvement of the head and neck region and upper body
- There are both small and large nodular forms, and lesions acquire a yellow color as they mature
- In patients with multiple lesions, a very small minority also have ocular involvement
- Rare association with both neurofibromatosis type 1 and juvenile myelomonocytic leukemia

Introduction

Juvenile xanthogranuloma (JXG) is a fairly common non-LCH, most often affecting infants and young children. Cutaneous lesions usually resolve and most patients have an otherwise unremarkable course. Although ocular JXG can lead to blindness and there is an association of JXG with neurofibromatosis type 1 (NF1) and juvenile myelomonocytic leukemia, these are unusual occurrences.

History

The term "juvenile xanthogranuloma" was suggested by Helwig and Hackney[55] in 1954 based upon histologic findings of xanthomatous histiocytes and giant cells. However, multiple cases of JXG, under different names, had previously been reported during the first half of the twentieth century. The first case of JXG was actually reported in 1905 by Adamson[56], who named the disorder "congenital xanthoma multiplex".

Epidemiology

JXG is a fairly common disorder and the most common histiocytic disease of childhood[57]. However, the true incidence may be underestimated, as many lesions, especially those which are solitary and small, may go unrecognized. In children, there is a male predominance of approximately 1.5 : 1; no sex predilection is noted in adults. A significant majority of those reported are White individuals. In almost 75% of cases lesions appear during the first year of life, with >15% of patients having them at birth. JXG is rare in adults, with a peak incidence during the late twenties to early thirties, although lesions have also been reported in the elderly. Most adult patients have solitary lesions.

Pathogenesis

The cause of JXG is not known; it is often suggested that the condition is reactive, with histiocytes possibly responding to a traumatic or infectious stimulus. However, in a recent series of 55 patients with both cutaneous and extracutaneous JXG, ~75% had a genetic mutation that would lead to activation of the MAPK pathway[58]. The reason for the progressive lipidation of histiocytes in the absence of hyperlipidemia is not clear. However, it has been shown that in adult patients with xanthogranulomas, the uptake of low-density lipoprotein and the synthesis of cholesterol within macrophages is increased[59]. As discussed in the section on BCH, several authors have suggested that generalized eruptive histiocytoma, BCH, and JXG may represent different expressions of the same disorder.

Clinical features

Gianotti and Caputo[60] described two common clinical variants of JXG: a small nodular form and a large nodular form. Patients with the small nodular form, also known as the micronodular form, present with multiple pink to red–brown, dome-shaped papules, 2–5 mm in diameter. The lesions are widely scattered on the upper part of the body and rapidly become yellow. In contrast, the more common large nodular form is characterized by one or a few nodules 1–2 cm in diameter. The two forms may coexist.

The most common location for JXG is the head and neck (Fig. 91.11), followed by the upper torso, the upper extremities, and then the lower extremities. Oral JXG is rare and usually presents as a solitary yellow nodule on the lateral aspect of the tongue or the midline of the hard palate. Unusual morphologic presentations include keratotic, pedunculated, subcutaneous, clustered, plaque-like, and giant lesions.

Extracutaneous lesions have been reported in many organs, with the eye being most commonly affected. The lung represents the second most frequent extracutaneous site of disease. Other visceral, bone, and CNS involvement is unusual and disease-related deaths are rare[61]. Ocular JXG is almost always unilateral and develops in <0.5% of patients with cutaneous lesions. However, ~40% of patients with ocular JXG have cutaneous lesions, always multiple, at the time of diagnosis[62]. Ocular involvement usually occurs before 2 years of age and often affects the iris. Hyphema (hemorrhage into the anterior chamber) and glaucoma are serious complications which can result in blindness. Early referral to an ophthalmologist for evaluation and possible treatment is important.

A well-recognized association exists between JXG and café-au-lait macules. Some of these patients have a family history of NF1, while others fulfill the clinical criteria for NF1 (see Table 61.3). Another well-known association is that of JXG and juvenile myelomonocytic leukemia; patients with NF1 also have an increased risk of developing juvenile myelomonocytic leukemia. A so-called "triple association" consisting of JXG, NF1, and juvenile myelomonocytic leukemia has been observed in several patients, and patients with JXG and NF1 have at least a 20× increased risk of developing juvenile myelomonocytic leukemia[63]. Other hematologic malignancies have been reported in association with JXG, e.g. chronic lymphocytic leukemia or B cell lymphoma in adults with multiple lesions.

In the majority of patients with disease limited to the skin, the course is self-limited and benign. These patients are otherwise in good health and lesions usually regress within 3–6 years. Hyperpigmentation, mild atrophy, or anetoderma may remain. However, in adults, the xanthogranulomas are usually solitary and persistent[2].

Pathology

In small lesions, there is a well-demarcated, dense infiltrate of histiocytes within the superficial dermis, which extends into the subcutis in larger

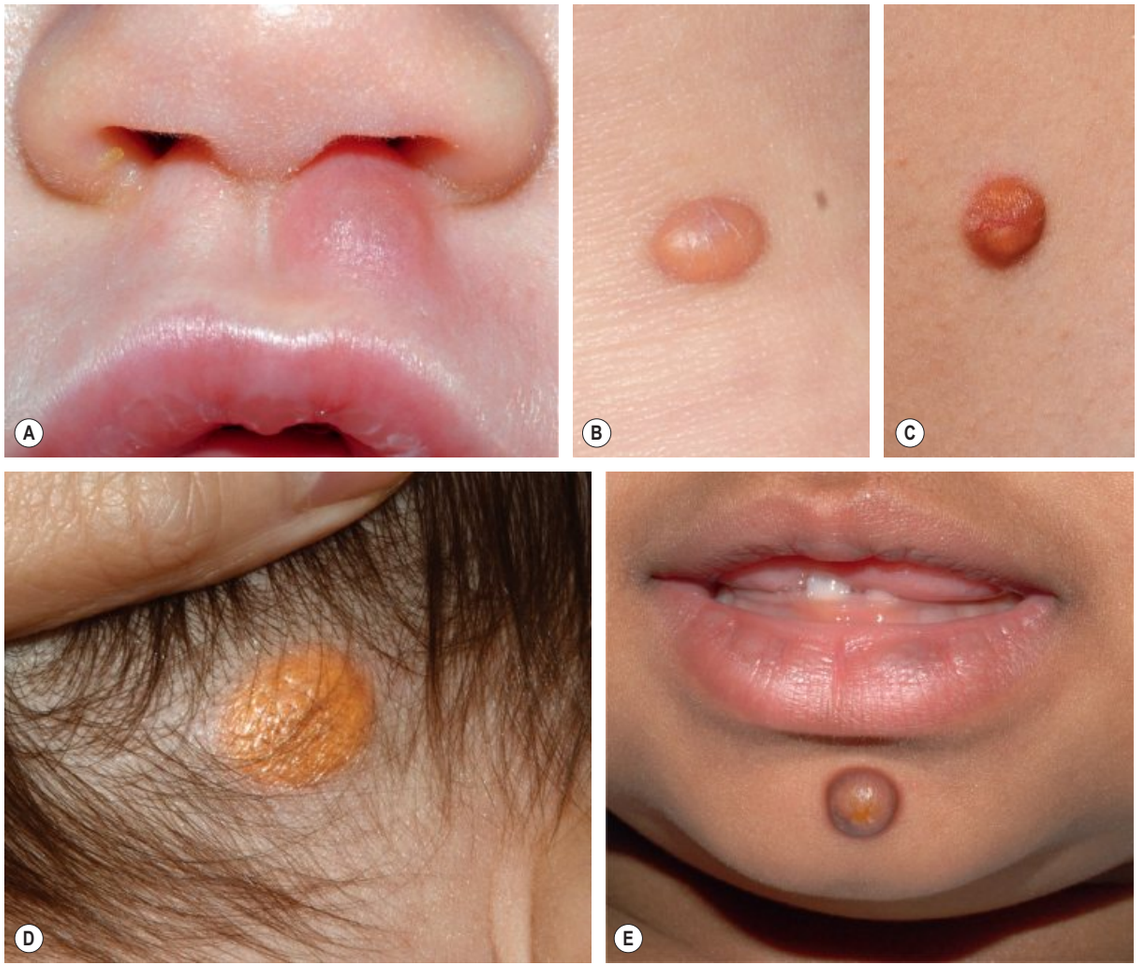

Fig. 91.11 Juvenile xanthogranuloma. A Pink nodule with a few telangiectasias representing an early lesion. Well-developed lesions that vary in color from pale yellow (**B**) to red–yellow (**C**) to yellow–orange (**D**) to yellow–brown (**E**), with the yellow hue reflecting the accumulation of lipid within histiocytes. *Courtesy Julie V. Schaffer, MD.*

lesions. A loss of the rete ridges is often seen, and ulceration occurs in some cases. Early lesions usually have monomorphous histiocytes with abundant eosinophilic cytoplasm (Fig. 91.12A). In mature lesions, the histiocytes develop lipid in their cytoplasm, creating a foamy "xanthomatous" appearance. Touton giant cells are a characteristic finding, but they may be absent in early lesions (Fig. 91.12B). Lymphocytes, eosinophils, plasma cells, and even neutrophils are also scattered throughout the infiltrate. Variants with spindle cells have been reported, which may be misinterpreted as another spindle cell tumor[37]. Other morphologic variants include mononuclear cells with an oncocytic appearance, vacuolated cells, and cells with a polygonal or spiculated cytoplasm[64,65].

The cells in JXG stain positively for mature histiocyte markers such as CD68, CD163, and factor XIIIa (see Table 91.2). In some cases there is expression of S100 protein on the large-sized cells, whereas CD1a and CD207 (Langerin) are always negative.

Differential diagnosis

The major entities to consider when there are multiple lesions are other histiocytic disorders including LCH. In a child with a single JXG, the initial clinical differential diagnosis can be broad (e.g. molluscum contagiosum, Spitz nevus, mastocytoma). A solitary lesion in an adult may be diagnosed clinically as a more common melanocytic nevus or dermatofibroma. The so-called "solitary reticulohistiocytoma" is simply a xanthogranuloma in which oncocytic macrophages and giant cells with ground-glass cytoplasm dominate[2].

In general, the constellation of clinical and histopathologic features allows for distinction between JXG and either BCH or generalized eruptive histiocytoma, although some cases of BCH can have giant cells (see Fig. 91.9C), and these three disorders may indeed exist within a spectrum. LCH can be differentiated from JXG via immunophenotyping (see Fig. 91.6).

Treatment

Due to the self-limiting nature of JXG, no treatment is usually required. Occasionally, lesions are removed for cosmetic concerns, despite the anticipated spontaneous resolution. While ocular lesions often require intervention (e.g. topical corticosteroids for iris lesions, excision for limbal lesions), sites of systemic involvement can be followed without treatment unless their location interferes with normal function. For these patients, various chemotherapeutic regimens, radiotherapy, high-dose systemic corticosteroids, and cyclosporine have been administered. Given the possibility of spontaneous involution, however, it is sometimes difficult to evaluate the response to treatment in a given patient.

Progressive Nodular Histiocytosis

Key features

- Affects primarily the elderly of either sex
- Hundreds of lesions of two types: small superficial papules and nodules or deep nodules and tumors
- Mucosal lesions may be seen
- Chronic without spontaneous regression

Introduction, epidemiology, and pathogenesis

Progressive nodular histiocytosis (PNH) is an extremely rare, clinically distinct disorder affecting primarily the elderly. It has a chronic course and an unknown etiology and pathogenesis. However, an *IRF2BP2-NTRK1* fusion was detected in a patient with PNH/xanthogranulomatosis.

Clinical features

Patients typically develop multiple lesions that progressively become widespread, but usually spare the flexural areas. Two distinct types of lesions have been described: (1) superficial xanthomatous papules and nodules that are 2–10 mm in diameter; and (2) deep fibrous nodules and tumors, 1–3 cm in diameter, that are primarily on the trunk. The face is

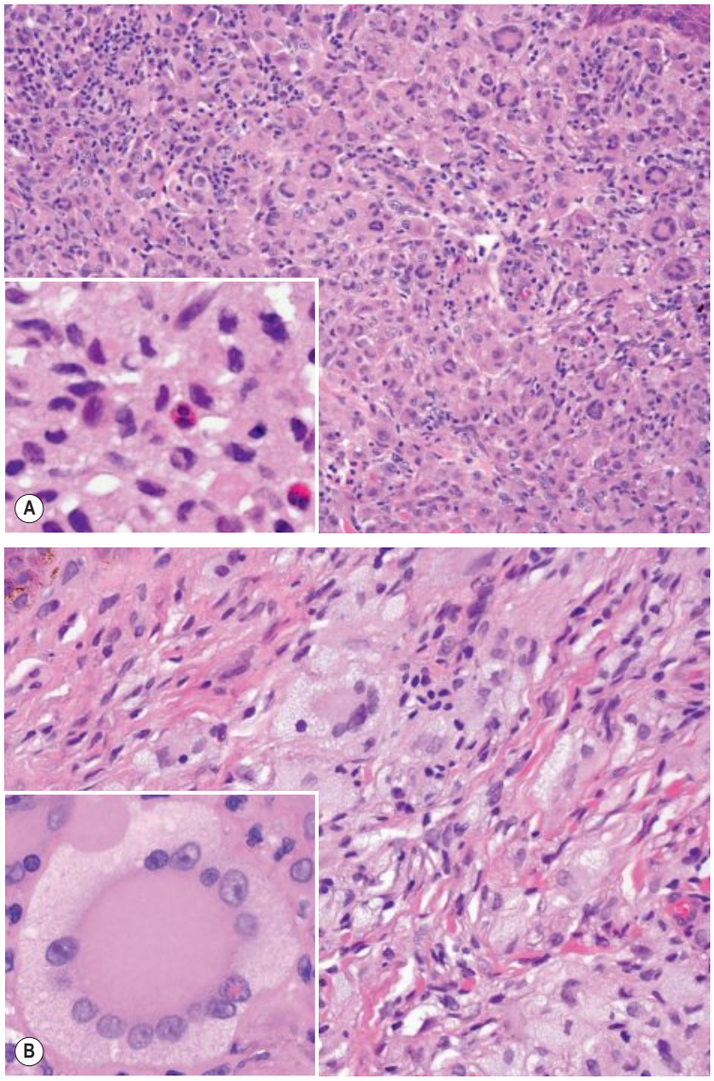

Fig. 91.12 Juvenile xanthogranuloma. A Earlier lesion – the dermal histiocytic infiltrate contains relatively few Touton giant cells. Lymphocytes and eosinophils are also present (inset). **B** Older lesion – multiple foamy (xanthomatous) histiocytes and giant cells as well a classic Touton giant cell with a "wreath-like" arrangement of nuclei (inset).

often involved and confluent nodules can lead to a "leonine facies" (see Table 46.5). A key to the diagnosis is the presence of these two distinct types of lesions. There may be conjunctival, oral, and laryngeal involvement.

In patients followed over a course of many years, the lesions have rarely regressed[66,67]. Visceral involvement has not been observed nor have consistent associations with other diseases. The significance of a report of a patient with PNH and chronic myeloid leukemia, hepatosplenomegaly, hyperuricemia, and hypocholesterolemia is unclear[68].

Pathology

The smaller papules contain foamy xanthomatous cells and occasional Touton giant cells, mimicking papular xanthomas. The larger nodules are distinctive and show features of spindle-cell xanthogranulomas. The cells express markers of mature dendritic histiocytes such as CD68, CD163, and FXIIIa.

Differential diagnosis

Other non-LCHs, especially those that do not regress spontaneously such as progressive mucinous histiocytosis, as well as sarcoidosis and leprosy represent the primary entities in the clinical differential diagnosis.

Treatment

The natural history is chronic and progressive, with an increase in the number of lesions. Treatment consists of removal of nodules via surgical excision or CO_2 laser.

Fig. 91.13 Xanthoma disseminatum. Symmetric involvement of the major flexures is a characteristic finding. Note the yellow discoloration of some of the coalescing papulonodules. *Courtesy David Wetter, MD.*

Xanthoma Disseminatum

Synonym: ■ Xanthoma disseminatum of Montgomery

Key features

- Classic triad of cutaneous xanthomas, mucous membrane xanthomas, and diabetes insipidus
- Symmetric distribution of lesions
- Favors flexural areas and intertriginous zones
- Corneal and conjunctival lesions can threaten vision

Introduction

Xanthoma disseminatum is a rare, normolipemic, histiocytic proliferative disorder that affects the skin, mucous membranes, and frequently, the hypothalamus and pituitary gland, leading to transient diabetes insipidus.

History

Four cases of "xanthomatosis disseminata" were described by Montgomery and Osterberg[69] in 1938. A review and characterization of the disorder was provided by Altman and Winkelmann[70] in 1962.

Epidemiology

Xanthoma disseminatum is a rare condition, with ~100 cases reported to date. Men are more commonly affected than women. Age of onset ranges from 8 months to 85 years, with >60% of patients developing the disease before the age of 25.

Pathogenesis

The etiology is unknown. As most patients have normal lipid levels, it has been suggested that xanthoma disseminatum represents a reactive proliferative disorder of histiocytes with secondary accumulation of lipid.

Clinical features

Patients may have the classic triad of cutaneous xanthomas, xanthomas of mucous membranes, and diabetes insipidus. The primary xanthomatous lesion is a yellow, red, or brown papule. Disease onset is marked by an eruption of hundreds of papules, symmetrically arranged on the face and in the major body folds and flexural areas of the trunk and proximal extremities (Fig. 91.13). The lesions tend to cluster into well-formed, potentially disfiguring plaques (Fig. 91.14). Older lesions may become atrophic.

Mucous membrane lesions are found in 40%–60% of patients, with the upper airway and oral mucosa being commonly involved. Corneal

Fig. 91.14 Xanthoma disseminatum. Sclerotic form of xanthoma disseminatum in a patient who developed multiple myeloma. Note the associated scarring.

and conjunctival lesions can threaten vision. CNS involvement of the hypothalamus and pituitary stalk results in diabetes insipidus in ~40% of patients. The latter is usually mild, transient, and sensitive to vasopressin. Rarer associations include monoclonal gammopathies due to plasma cell dyscrasias and thyroid disorders.

Caputo et al.[71] suggested that patients follow one of three clinical courses: (1) a rare, self-healing form with spontaneous resolution of lesions; (2) the common persistent form in which lesions may never resolve; and (3) the very rare progressive form with organ dysfunction and CNS involvement. A few disease-related deaths have been reported, including one patient with CNS involvement outside the pituitary gland and hypothalamus[72].

Pathology

In the early stages, there is a dense dermal infiltrate of scalloped macrophages in addition to a few foamy cells or other inflammatory cells. Well-developed lesions contain a mixture of scalloped cells, foamy cells and other inflammatory cells, as well as Touton and foreign body giant cells. The histiocytes express typical non-LCH markers such as CD68, CD163, CD11b, CD14, CD11c, and factor XIIIa (see Fig. 91.4, Table 91.2)[71].

Differential diagnosis

The disorders most likely to be confused with xanthoma disseminatum include generalized eruptive histiocytoma, papular xanthomas, eruptive and plane xanthomas (see Ch. 92), ECD, multiple JXGs, progressive nodular histiocytosis, and multicentric reticulohistiocytosis. In general, these can be fairly easily differentiated based on clinical and histopathologic features.

Treatment

As xanthoma disseminatum is a rare disease, there are no controlled trials of systemic therapies. Radiotherapy has been used to control obstructive airway disease. No significant improvement in cutaneous and mucosal lesions has been observed with oral corticosteroids. Physical modalities including surgery, radiotherapy, cryosurgery, and laser therapy have all been tried, as have systemic medications such as cyclophosphamide, cyclosporine, and 2-chlorodeoxyadenosine (2-CdA). In a case series, all five patients who received 2-CdA experienced a remission and long-term control of cutaneous lesions[72].

Progressive Mucinous Histiocytosis

Key features

- Affects primarily women
- Usually an autosomal dominant disorder but can be sporadic
- Involvement, which is limited to the skin, is chronic and unremitting

Introduction and pathogenesis

Progressive mucinous histiocytosis is an extremely rare form of non-LCH. Most cases are inherited in an autosomal dominant pattern, but rare sporadic cases have also been observed[73]. A germline gain-of-function missense mutation in *PDGFRB* (platelet-derived growth factor receptor beta) was recently detected in the original pedigree[73a].

Epidemiology

Most affected patients are women, but an explanation for this skewing is lacking. To date, eight families with the hereditary form have been described[74].

Clinical features

Cutaneous lesions appear during childhood or adolescence and persist indefinitely. They consist of multiple, discrete, skin-colored to red–brown papules or nodules that favor the face, hands, forearms, and legs in a symmetric distribution pattern. There is neither mucosal nor visceral involvement and no associated diseases have been described[67,73,74]. The clinical course is chronic with no spontaneous remissions.

Pathology

Progressive mucinous histiocytosis is characterized by an accumulation of spindled or epithelioid histiocytes in the upper and mid dermis that is accompanied by mucin deposition. The histiocytes express the phenotype of mature macrophages with positivity for CD68 and CD163.

Differential diagnosis

The differential diagnosis includes other non-LCHs, multinucleated cell angiohistiocytoma, and multiple dermatofibromas. These entities can be distinguished by clinical, histopathologic, and immunohistochemical features.

Treatment

There are no specific treatments. Lesions may be removed by surgery, CO_2 laser, or cryotherapy. Use of PDGFR inhibitors (e.g. imatinib) may represent an additional therapy.

Necrobiotic Xanthogranuloma

Synonym: ■ Necrobiotic xanthogranuloma with paraproteinemia

Key features

- Multisystem histiocytic disease that can present with hepatosplenomegaly as well as ocular and skin involvement
- In at least 70% of patients, there is an IgG monoclonal gammopathy due to a plasma cell dyscrasia or lymphoproliferative disorder (e.g. B cell chronic lymphocytic leukemia)
- Average age of onset is the sixth decade
- Firm nodules and plaques with a yellow hue are seen and they may develop ulceration
- Most common site of involvement is the periorbital region

Introduction

Necrobiotic xanthogranuloma (NXG) is a rare, progressive multisystem histiocytic disease in which characteristic cutaneous lesions point to the diagnosis. The majority (~80%) of patients have a monoclonal gammopathy due to either a plasma cell dyscrasia or a B cell lymphoproliferative disorder (see Ch. 119)[75].

History

Necrobiotic xanthogranuloma was codified in 1980 by Kossard and Winkelmann[76]. Their original eight patients demonstrated yellowish plaques, subcutaneous nodules, and an associated dysproteinemia. These authors also noted several reports published prior to 1980 representing unrecognized cases of NXG.

Epidemiology

Necrobiotic xanthogranuloma is a rare disorder with over 200 cases reported to date. In 1992, Mehregan and Winkelmann[77] described 32 patients with NXG and reviewed the 16 reported cases from the world literature. Men and women are generally equally affected. The average age of onset is the sixth decade.

Pathogenesis

While the pathogenesis of NXG is as yet unknown, its strong association with monoclonal gammopathies has led to several hypotheses. The M protein may act either as a primary inciting agent or as a cofactor in eliciting a giant cell granulomatous reaction. In a review of 17 cases, there was no evidence of a monoclonal proliferation of plasma cells within the inflammatory infiltrate of skin lesions[78]. It has been suggested that NXG and normolipemic plane xanthoma exist within a spectrum, given their shared relationship to monoclonal gammopathies[79].

Clinical features

Cutaneous lesions, typically multiple, develop in all patients with NXG. The classic skin lesion is an asymptomatic indurated papule, nodule, or plaque with a yellow, "xanthomatous" hue (Fig. 91.15). Other reported features include telangiectasias, atrophy, ulceration and scarring, with scars being common sites for the development of new lesions.

The periorbital region is the most common site of involvement. The trunk, remainder of the face, and proximal extremities are also frequently involved. From 15% to 50% of patients have ophthalmic manifestations, which include orbital masses, ectropion, ptosis, conjunctival lesions, keratitis and scleritis, episcleritis, anterior uveitis, and proptosis[75,80].

A hallmark feature of NXG is the associated IgG monoclonal gammopathy, which is found in ~80% of patients[75]. The M protein can be detected by serum protein electrophoresis and/or the more sensitive immunofixation electrophoresis. Other common findings include hepatomegaly, splenomegaly, an increased ESR/CRP, leukopenia, hypocomplementemia, and an underlying plasma cell dyscrasia (including multiple myeloma). Less commonly, cryoglobulinemia and/or an underlying B cell lymphoproliferative disorder are observed. Of the 48 patients described by Mehregan and Winkelmann[77], a plasma cell dyscrasia was found in 17 patients (with 8 fulfilling the criteria for multiple myeloma) and a lymphoproliferative disorder in 2 patients. In a more recent retrospective study from the same institution, a higher percentage of patients (12 of 17 [71%]) had a monoclonal gammopathy, with 3 patients fulfilling the criteria for multiple myeloma[78]. Postmortem examination has demonstrated involvement of multiple organ systems, with endocardial NXG found in most cases.

In one series, when patients with NXG developed a plasma cell dyscrasia or a lymphoproliferative disorder (10 of 26 patients), these disorders often arose after the onset of cutaneous manifestations and did not tend to be aggressive[79]. Overall survival was 100% at 10 years and 90% at 15 years.

Pathology

Classic, non-ulcerated lesions have a normal epidermis and superficial dermis. A palisading xanthogranuloma is found in the mid dermis extending into the panniculus (Fig. 91.16). The granulomas consist of histiocytes, foam cells, lymphoid follicles, plasma cells, and giant cells with zones of collagen degeneration ("necrobiosis"). Cholesterol clefts are found in areas of necrobiosis. A prominent feature is the presence of both Touton giant cells and large, bizarre foreign body giant cells. These cells are found scattered within the granuloma and often at the margins of areas of necrobiosis. Lymphoid or lymphoplasmacytic nodules are also common, and clonal infiltrates can be seen in patients with B cell chronic lymphocytic leukemia (CLL)[78]. Histiocytic cells stain positively for non-LCH markers such as CD68 and CD163, but are negative for FXIIIa (see Fig. 91.4, Table 91.2)[77,80,81].

Differential diagnosis

The clinical differential diagnosis includes necrobiosis lipoidica, normolipemic plane xanthomas, xanthelasma, non-LCH disorders (xanthoma disseminatum, ECD, multicentric reticulohistiocytosis, JXG), adult-onset asthma and periocular xanthogranuloma (AAPOX), foreign body granulomas, and sarcoidosis. However, most of these disorders can be excluded on the basis of morphology, distribution pattern, histologic features, and associated systemic manifestations (if any).

Treatment

No controlled clinical studies are available regarding the treatment of NXG. In the past, alkylating agents (e.g. chlorambucil, melphalan) were often tried but due to the availability of other therapeutic options and the risk of myelodysplastic syndrome and acute myelogenous leukemia, their use has declined[78]. In a multicenter cohort of 34 patients, IVIg was found to be the most effective therapy (9/9 patients), followed by antimalarial drugs (4/5) and intralesional triamcinolone (6/8)[75]. When the patient meets the criteria for multiple myeloma, combination therapy that can include an immunomodulatory drug (e.g. lenalidomide), proteosome inhibitor (e.g. bortezomib, carfilzomib), anti-CD38 antibody (e.g. daratumumab), and dexamethasone consistently leads to disappearance of the M protein. These medications can also be considered for patients with severe recalcitrant disease, even if they do meet the criteria for symptomatic

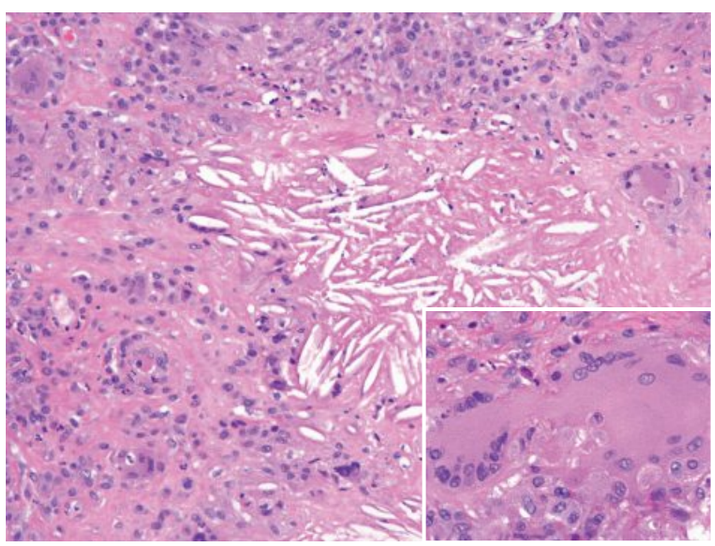

Fig. 91.16 Necrobiotic xanthogranuloma. A necrobiotic area contains cholesterol clefts. The presence of bizarre, large multinucleated giant cells is a typical feature (inset).

myeloma. For B cell CLL, current treatments include BTK inhibitors (e.g. ibrutinib, acalabrutinib, zanabrutinib), bcl-2 inhibitors (e.g. venetoclax), and anti-CD20 antibodies (e.g. obinutuzumab, rituximab).

Topical JAK inhibitors (e.g. tofacitinib 2% cream) may lead to improvement of cutaneous lesions. A recurrence rate of ~40% was observed in one series following surgical excision of lesions[80].

Multicentric Reticulohistiocytosis

Key features

- Occurs primarily in adults
- Papules and nodules favor the head, hands, and elbows; periungual papules have been likened to "coral beads"
- 50% of patients develop mucous membrane lesions (oral and nasopharyngeal)
- Multicentric reticulohistiocytosis is associated with a destructive arthritis and, in some patients, solid organ malignancies
- Histiocytes have a characteristic "ground glass" appearance

Introduction

Multicentric reticulohistiocytosis (MRH) is a rare form of non-LCH which most commonly affects adults. This disorder is characterized by both cutaneous and systemic features. Well-developed lesions demonstrate a classic histopathology consisting of mononucleated and multinucleated giant cells with a "ground glass" appearance.

History

The term *multicentric reticulohistiocytosis* was introduced in 1954 by Goltz and Laymon[81] to define cases with both cutaneous and systemic manifestations. Familial histiocytic dermatoarthritis, described in 1973, is a very rare variant of MRH, characterized by a familial occurrence and associated glaucoma, uveitis, and cataracts[82].

Epidemiology

MRH is uncommon, occurring most frequently in women during their fifth or sixth decade of life.

Pathogenesis

The pathogenesis of MRH is unknown. In one study from the 1960s, 56% of patients had a positive tuberculin skin test[83], leading to the suggestion that mycobacteria could be a possible trigger. In addition, MRH has been reported to respond to antituberculosis treatment. However, confirmation of mycobacteria within skin nodules is lacking. Others have proposed that the histiocytic response in MRH is an immunologic process related to an underlying neoplastic or autoimmune disorder. There is evidence that TNF, which can promote osteoclast formation, may play a role in its pathogenesis[84].

Clinical features

Patients with MRH usually have cutaneous and mucous membrane involvement in addition to a severe arthropathy, although histiocytic infiltrates can be found in multiple organs (see below). There is an association with hyperlipidemia, a positive tuberculin skin test, systemic vasculitis, and autoimmune disease (e.g. systemic lupus erythematosus, Sjögren syndrome). Up to 25%–30% of patients have reportedly had an associated malignancy, with a range of solid and hematologic malignancies[85]. An elevated ESR and anemia have been noted in approximately half of patients, and one-third demonstrate hypercholesterolemia. Rarely, monoclonal gammopathies or cryoglobulinemia have been observed. Fever and weight loss can also occur.

Cutaneous lesions range from a few millimeters to 2 cm and are skin-colored to pink, red–brown, or yellow. Lesions tend to have an acral distribution. Favored sites include the head, hands, fingers, ears, and articular regions of the limbs (Fig. 91.17). Small papules aligned

Fig. 91.17 Multicentric reticulohistiocytosis. A Grouped, firm, red–brown papules on the dorsal surface of the fingers, hand, and wrist in this 73-year-old African-American woman. **B** Grouped pink papulonodules on the elbow in a second patient. **C** A more subtle presentation in a third patient, with small pink papules and thin plaques that favor the skin overlying the small joints of the hands; this is the form that can initially be confused with dermatomyositis. **D** Telescoping of fingers due to arthritis mutilans. *A, Courtesy Susan D. Laman, MD; B, Courtesy Jean L. Bolognia, MD; C,D, Courtesy Kalman Watsky, MD.*

along the proximal and lateral nail folds result in a characteristic "coral bead" appearance. Approximately one-half of patients develop papules and nodules of the oral, pharyngeal, and/or nasal mucosae. Less common findings include a "leonine facies" secondary to severe facial involvement, periarticular rheumatoid-like nodules, an initial photodistribution, and secondary nail changes.

A 6- to 8-year course of symmetric, erosive arthritis of multiple joints is common, and there is progression to arthritis mutilans in ~45% of patients. The joints of the fingers and hands, as well as the knees and wrists, are most commonly involved, although any joint may be affected. Cartilaginous destruction of the nose and ears can lead to facial disfigurement. Rarely, there is histiocytic infiltration of the heart, eye, lungs, thyroid, liver, kidney, muscle, salivary gland, and/or bone marrow. In most patients the disease resolves spontaneously within 5–10 years, although patients are often left with significant disability. Fatal disease has been rarely reported in patients with widespread systemic involvement.

Pathology

In well-developed lesions there are numerous multinucleated giant cells and oncocytic macrophages that have eosinophilic, finely granular cytoplasm, often with a "ground glass" appearance (Fig. 91.18). The abundant eosinophilic granular cytoplasm (oncocytic change) is a reflection of accumulated mitochondria and lysosomes, which is evident by electron microscopy. The multinucleated cells have nuclei arranged haphazardly, aligned at the periphery, or clustered in the center.

Histiocytes in MRH express CD68, CD163, CD11b, CD14, and HAM56 (see Fig. 91.4, Table 91.2)[86]; S100 protein is usually negative as is FXIIIa.

Differential diagnosis

MRH must be differentiated from rheumatoid arthritis, dermatomyositis (especially when lesions are photodistributed), paraneoplastic reactive granulomatous dermatitis, and other non-LCH histiocytoses such as JXG, generalized eruptive histiocytosis, and cutaneous Rosai–Dorfman disease. The entity that may prove the most challenging to exclude is fibroblastic rheumatism; some authors consider fibroblastic rheumatism to be a type of histiocytosis while others view it as a fibromatosis[87].

Treatment

Systemic therapies for MRH often focus on treating the symptoms, and frequently they are not effective in achieving remission or in altering the course of the disease. Based upon case reports or case series, various combinations of NSAIDs, oral corticosteroids, JAK inhibitors, methotrexate, tocilizumab, cyclophosphamide, TNF inhibitors, and anakinra (an interleukin-1 antagonist) have been employed[84,88]. Other immunosuppressive drugs (e.g. azathioprine, leflunomide, cyclosporine) have also been tried, as well as hydroxychloroquine and isoniazid.

"R" GROUP: ROSAI–DORFMAN DISEASE

Synonyms: ■ Sinus histiocytosis with massive lymphadenopathy ■ Destombes–Rosai–Dorfman syndrome

Key features

- Children and young adults are most commonly affected
- Massive, painless, bilateral cervical lymphadenopathy is characteristic
- Involvement of extranodal sites can be the sole manifestation of the disease, with a skin-limited form increasingly being recognized
- In the systemic form, cutaneous lesions occur in a minority of patients (~10%), are usually multiple, and are clinically nonspecific
- Fever and polyclonal hypergammaglobulinemia are often seen
- In the lymph nodes and the skin, emperipolesis is a common histologic feature
- A rare familial form due to mutations in *SLC29A3* falls within the histiocytosis–lymphadenopathy plus syndrome

Introduction

Rosai–Dorfman disease (RDD) is an uncommon, often protracted, histiocytic proliferative disorder. It is characterized by massive, but painless, bilateral cervical lymphadenopathy, fever, anemia, elevated ESR/CRP, neutrophilia, and polyclonal hypergammaglobulinemia. Cutaneous lesions occur in a minority of patients with systemic disease, are usually multiple, and are clinically nonspecific. However, there is a form of RDD with only cutaneous involvement, and this skin-only form is currently classified within histiocytosis group C not group R.

History

Sinus histiocytosis with massive lymphadenopathy was described as a distinct entity by Rosai and Dorfman in 1969[89]. However, the eponymous designation "Rosai–Dorfman disease" is more appropriate as some patients have extranodal lesions as the sole manifestation of the condition[90].

Epidemiology

A repository for cases of RDD, rather than a true registry, was available during 1980s–1990s. In 1990, the repository contained 423 patients, and by 1995, almost 600 cases had been reported[91,92]. RDD has a widespread geographic distribution, although there is a higher incidence in the West Indies. The systemic form occurs most commonly in children and young adults and is more frequently seen in male patients. In 1990, an equal percentage of White and Black patients, 44% of each, were in the repository[91]. On the other hand, the skin-limited form occurs primarily in adults and favors women.

Pathogenesis

Somatic genetic mutations that lead to activation of the MAPK pathway have been detected in patients with RDD (see Fig. 113.1)[93]. These genes include *MAP2K1/MEK1* and *NRAS*, as well as *MET, KRAS*, and *ARAF* but rarely *BRAF*[94,95]. Heterozygous germline mutations in *FAS*, which lead to defects in Fas-mediated apoptosis, lead to type IA autoimmune lymphoproliferative syndrome and may be associated with RDD (see Table 60.6)[96]. There is also a familial form of RDD due to germline mutations in *SLC29A3*, which encodes an equilibrative nucleoside transporter hENT3[97]. These latter patients fall within the histiocytosis–lymphadenopathy plus syndrome which includes the H syndrome (see Table 70.2), pigmented hypertrichosis with insulin-dependent diabetes mellitus syndrome, and Faisalabad histiocytosis.

In addition, a viral pathogenesis has been postulated, including an association with HHV-6, cytomegalovirus, and Epstein–Barr virus. While HHV-6 sequences have been detected in involved lymph nodes[98], this finding is nonspecific given the presence of HHV-6 in many reactive

and infectious disorders of lymphoid tissue[99]. To date, no clear link has been proven[93].

Clinical features

While RDD is often an indolent, self-limited disease, a protracted course marked by remissions and exacerbations occurs in a number of patients. The characteristic clinical feature is massive, painless, bilateral cervical lymphadenopathy. However, any nodal site may be involved, unilateral involvement may occur, and an absence of lymph node involvement has also been reported. Fever is a frequent occurrence and most individuals have an elevated ESR/CRP and polyclonal hypergammaglobulinemia. A common finding is mild anemia, although severe anemia has been observed. Neutrophilia is occasionally seen. There are multiple reports of Hodgkin and non-Hodgkin lymphomas occurring in association with, or prior to, development of RDD. Of note, there was a report of a histiocytic sarcoma arising in a patient with autoimmune lymphoproliferative syndrome and associated RDD[100].

Immune disorders occur in ~15% of patients with RDD. Anti-red blood cell autoantibodies and joint disease are the most common findings. Patients with immunologic abnormalities have an unfavorable prognosis. In one analysis, 10 of 14 fatal cases were noted to have some form of immune dysfunction[101]. Other unfavorable prognostic signs include disseminated nodal disease or involvement of the liver, kidney, or lower respiratory tract.

Over 40% of patients with RDD have at least one extranodal site of involvement. The most common extranodal sites are the skin and soft tissue, the eyelid and orbit, the upper respiratory tract, major salivary glands, CNS, and bone. However, virtually any organ can be involved. In patients with hearing loss, there is overlap with H syndrome (see above)[97].

Cutaneous involvement occurs in ~10% of patients with the systemic form. The skin may be the only organ involved, with skin-limited disease increasingly being recognized. Cutaneous lesions are often multiple and appear as nonspecific red to red–brown or xanthomatous macules, papules, nodules, or plaques (Fig. 91.19); in the skin-limited form, there may be a single lesion. Panniculitis has also been reported. The eyelids and malar regions are frequent sites of involvement.

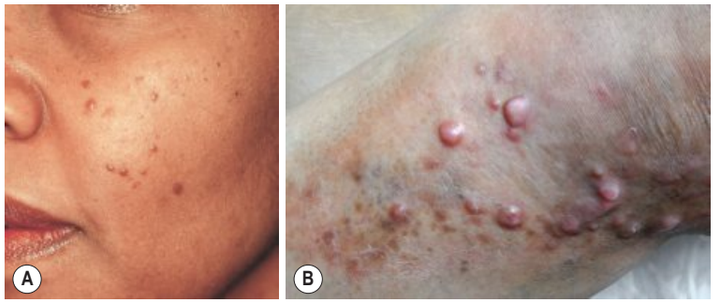

Fig. 91.19 Cutaneous Rosai–Dorfman disease. A Discrete, dome-shaped, brown papules on the cheek. **B** Multiple firm pink papulonodules arising within a yellow–brown plaque. *B, Courtesy Boni Elewski, MD.*

Pathology

The diagnosis requires the presence of histiocytic cells with abundant emperipolesis, i.e. engulfment of erythrocytes, plasma cells, and lymphocytes. The histiocytic cells stain positively for S100, CD68, CD14, and CD163; they are negative for CD1a and CD207 (Fig. 91.20; see Table 91.2). In addition, involved tissues usually contain abundant polyclonal plasma cells. Most cases demonstrate cyclin D1 and pERK expression, indicating activation of the MAPK pathway[102]. Recently, OCT2-positive nuclear staining was observed in all cases of RDD (51/51), but this finding is nonspecific as a variable number of neoplastic cells show positive staining in other histiocytoses[102a]. Although IgG4-positive plasma cells are found within the infiltrate of RDD, the relationship between RDD and IgG4-related disease, if any, is yet unclear.

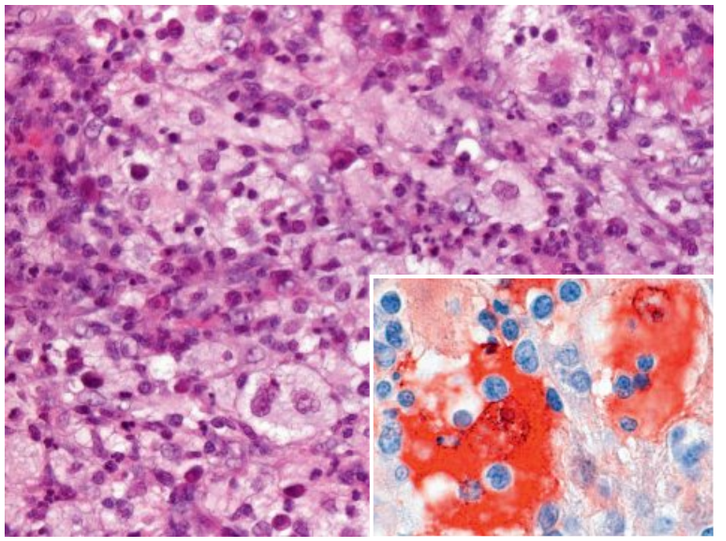

Fig. 91.20 Rosai–Dorfman disease. Large histiocytes with clear cytoplasm admixed with small lymphocytes and plasma cells. The large cells stain positively for S100 (inset), and the immunostain highlights lymphoid cells within the cytoplasm of large histiocytes (emperipolesis). *Courtesy Lorenzo Cerroni, MD.*

Differential diagnosis

Given the clinically nonspecific cutaneous lesions found in RDD, the differential diagnosis includes the other histiocytoses, sarcoidosis, granulomatous infectious diseases, and adnexal tumors. Of the histiocytoses, JXG in particular may resemble RDD as the former can also have large $S100^+$ macrophages and, rarely, emperipolesis. The diagnosis of cutaneous RDD is based upon the combination of characteristic histologic and immunohistochemical findings.

The differential diagnosis of massive lymphadenopathy includes Hodgkin and non-Hodgkin lymphoma, chronic lymphocytic leukemia, metastases, infectious lymphadenopathies, and Kikuchi disease (a histiocytic necrotizing lymphadenitis that often affects young Asian women). RDD is differentiated by a typical combination of clinical and laboratory findings plus confirmatory histology and immunohistochemistry.

Treatment

Many lesions are asymptomatic and heal spontaneously, thus not requiring treatment. When treatment is indicated due to destructive lesions, disseminated disease or lesions causing physical compromise, radiotherapy, surgical excision, and/or systemic corticosteroids are usually employed, but there are no controlled trials to date. Based upon case reports, improvement has been observed with thalidomide, imatinib, 2-chlorodeoxyadenosine, and clofarabine[103].

"M" GROUP: MALIGNANT HISTIOCYTOSES

Synonym: ■ Histiocytic, interdigitating cell, Langerhans cell or indeterminate cell sarcomas

The malignant histiocytoses represent a group of very rare undifferentiated tumors with an anaplastic histology. Diagnosis is mainly one of exclusion and is based on extensive immunohistochemical analysis and expression of at least two of the following histiocyte/dendritic cell markers: CD68, CD163, CD4, and lysozyme[2]. These tumors develop primarily in adults and are often aggressive, with the most common sites being the lymph nodes, skin, soft tissue, and GI tract.

Miscellaneous

ALK^+ histiocytosis

A few cases of histiocytoses, including cutaneous histiocytoses, have been noted to express anaplastic lymphoma kinase (ALK)[104]. ALK^+ histiocytosis affects primarily young children and there is usually systemic involvement including hepatosplenomegaly and dramatic hematologic abnormalities. However, lesions may be restricted to the skin.

In ALK^+ histiocytosis, the histiocytes are very large with irregularly folded nuclei and abundant eosinophilic cytoplasm, sometimes with

emperipolesis. Over time, there may an increase in the number of foamy histiocytes and Touton giant cells, thereby resembling a JXG. By immunohistochemistry, the histiocytes are positive for ALK, histiocytic markers (CD68, CD163) and variably S100; they are negative for CD1a, CD207, and BRAF V600E. Gene fusions can be present, in particular *KIF5B–ALK* and *COL1A2–ALK*[90]. In unresectable or disseminated disease, ALK inhibitors may be tried[105].

Acknowledgment

The authors wish to thank Drs. Warren T. Goodman and Terry L. Barrett for their valuable contributions to this chapter in the previous editions.

Xanthomas 92

William Trent Massengale

Key features

- Cutaneous xanthomas can signal the presence of an underlying hyperlipidemia or monoclonal gammopathy
- An understanding of basic lipid metabolism provides insight into the underlying hyperlipoproteinemias as well as the formation of xanthomas
- The major forms of xanthomas associated with hyperlipidemia are: eruptive, tuberous, tendinous, and plane (including xanthelasma)
- Normolipemic plane xanthomas occur in association with monoclonal gammopathies
- Histologically, lipid-laden macrophages (foam cells) are seen in the dermis
- Prompt recognition and proper treatment can lead to xanthoma resolution as well as prevention of potentially life-threatening complications

INTRODUCTION

Cutaneous xanthomas develop as a result of deposition of lipid in the dermis, primarily within macrophages (foam cells) but also extracellularly. One of their major distinguishing clinical features is a characteristic yellow to orange hue. Xanthomas may present with a variety of morphologies, from macules and papules to plaques and nodules. As discussed below, the morphology and anatomic location of the lesions often suggest the type of underlying lipid disorder or the presence of a paraproteinemia.

Xanthomas can develop in the setting of primary or secondary disorders of lipid metabolism. Thus, early recognition of these lesions can make a significant impact on the diagnosis, management, and prognosis of patients who suffer from an underlying disease. It is therefore important for dermatologists to become familiar with the basic concepts of lipid metabolism and the associated disease states, as well as to be able to recognize the often pathognomonic cutaneous findings.

EPIDEMIOLOGY

Hyperlipidemia is quite common in the general population. In North America alone, it is estimated that over 100 million people currently have an elevated serum cholesterol level >200 mg/dl. Despite the large number of people who suffer from hyperlipidemia, only a minority will develop cutaneous xanthomas. Also, because the exact mechanism by which xanthomas form is not yet fully understood, it is not always possible to predict who will develop them. Xanthomas are thought to result from the permeation of circulating plasma lipoproteins through dermal capillary blood vessels followed by phagocytosis of the lipoproteins by macrophages, forming lipid-laden cells known as foam cells[1]. However, the precise steps and their regulation are still an area of investigation.

PATHOGENESIS

There is strong evidence to support the theory that the lipids found in the various xanthomas are the same as those in the circulation[2]. The majority of plasma lipids are transported in complex structures known as lipoproteins. The basic structure of the lipoprotein allows the delivery of triglycerides and cholesterol to peripheral cells for their metabolic needs. This structure consists of a hydrophilic outer shell and a hydrophobic core. The outer shell consists of phospholipids, free cholesterol, and non-covalently linked specialized proteins known as apolipoproteins or apoproteins (apo). The inner core contains triglycerides and cholesterol esters.

Lipoproteins differ in their core lipid content. Triglycerides are the major core lipids in chylomicrons and very-low-density lipoproteins (VLDLs), while cholesterol esters dominate the core of low-density lipoproteins (LDLs), high-density lipoproteins (HDLs), and remnants of chylomicrons and VLDLs. The apoproteins found in the outer shell can also differ amongst the various lipoproteins (Table 92.1). These apoproteins serve several important functions, such as mediating the binding of lipoproteins to their respective receptors in target organs and activating enzymes involved in their metabolism.

There are two major pathways of lipoprotein synthesis (Fig. 92.1A). The *exogenous* pathway begins with dietary fat intake. Through the action of pancreatic lipase and bile acids, dietary triglycerides are degraded to fatty acids and monoglycerides. After absorption by the intestinal epithelium, the triglycerides are reformed and packaged with a small amount of cholesterol esters into the central core of a chylomicron. The outer shell of the chylomicron consists of phospholipids, free cholesterol, and several apoproteins, including B-48, E, A-I, A-II, and C-II.

Chylomicrons then enter the lymphatics and eventually the systemic circulation via the thoracic duct. Once in the circulation, hydrolysis of the core triglycerides occurs, releasing free fatty acids to the peripheral tissues. This is mediated through the action of the enzyme lipoprotein lipase that is bound to capillary endothelium. The activation of the lipoprotein lipase system is complex and involves not only hormones such as insulin, but also apoproteins such as C-II, located on the lipoprotein outer surface, and GPIHBP1, a protein expressed on endothelial cells that binds lipoprotein lipase and shuttles it to its site of action in the capillary lumen.

After hydrolysis of ~70% of the original triglyceride content, a chylomicron "remnant" exists. The central core now contains predominantly cholesterol ester that has been acquired from circulating HDL molecules. The chylomicron remnant is taken up by the liver via specialized high-affinity apo B-100/E receptors that recognize the apoproteins E_3 or E_4 on the remnant's outer shell. Once in the liver, the remaining lipids enter hepatic storage and apoproteins such as B-48 are degraded.

IMPORTANT APOPROTEINS		
Apoprotein	**Lipoprotein association**	**Function and comments**
A-I	Chylomicrons, HDLs	Major protein of HDL; activates *l*ecithin:cholesterol *acyl*transferase (LCAT)
B-48	Chylomicrons, chylomicron remnants	Unique marker for chylomicrons
B-100	VLDLs, IDLs, and LDLs	Major protein of LDL; binds to LDL receptor
C-II	Chylomicrons, VLDLs, IDLs, and HDLs	Activates lipoprotein lipase
E (at least 3 alleles [E_2, E_3, E_4])	Chylomicrons, chylomicron remnants, VLDLs, IDLs, and HDLs	Binds to LDL receptor (B-100/E receptor)

Table 92.1 Important apoproteins. See Fig. 92.1. Lipoprotein X appears in the sera of patients with severe cholestatic liver diseases. HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

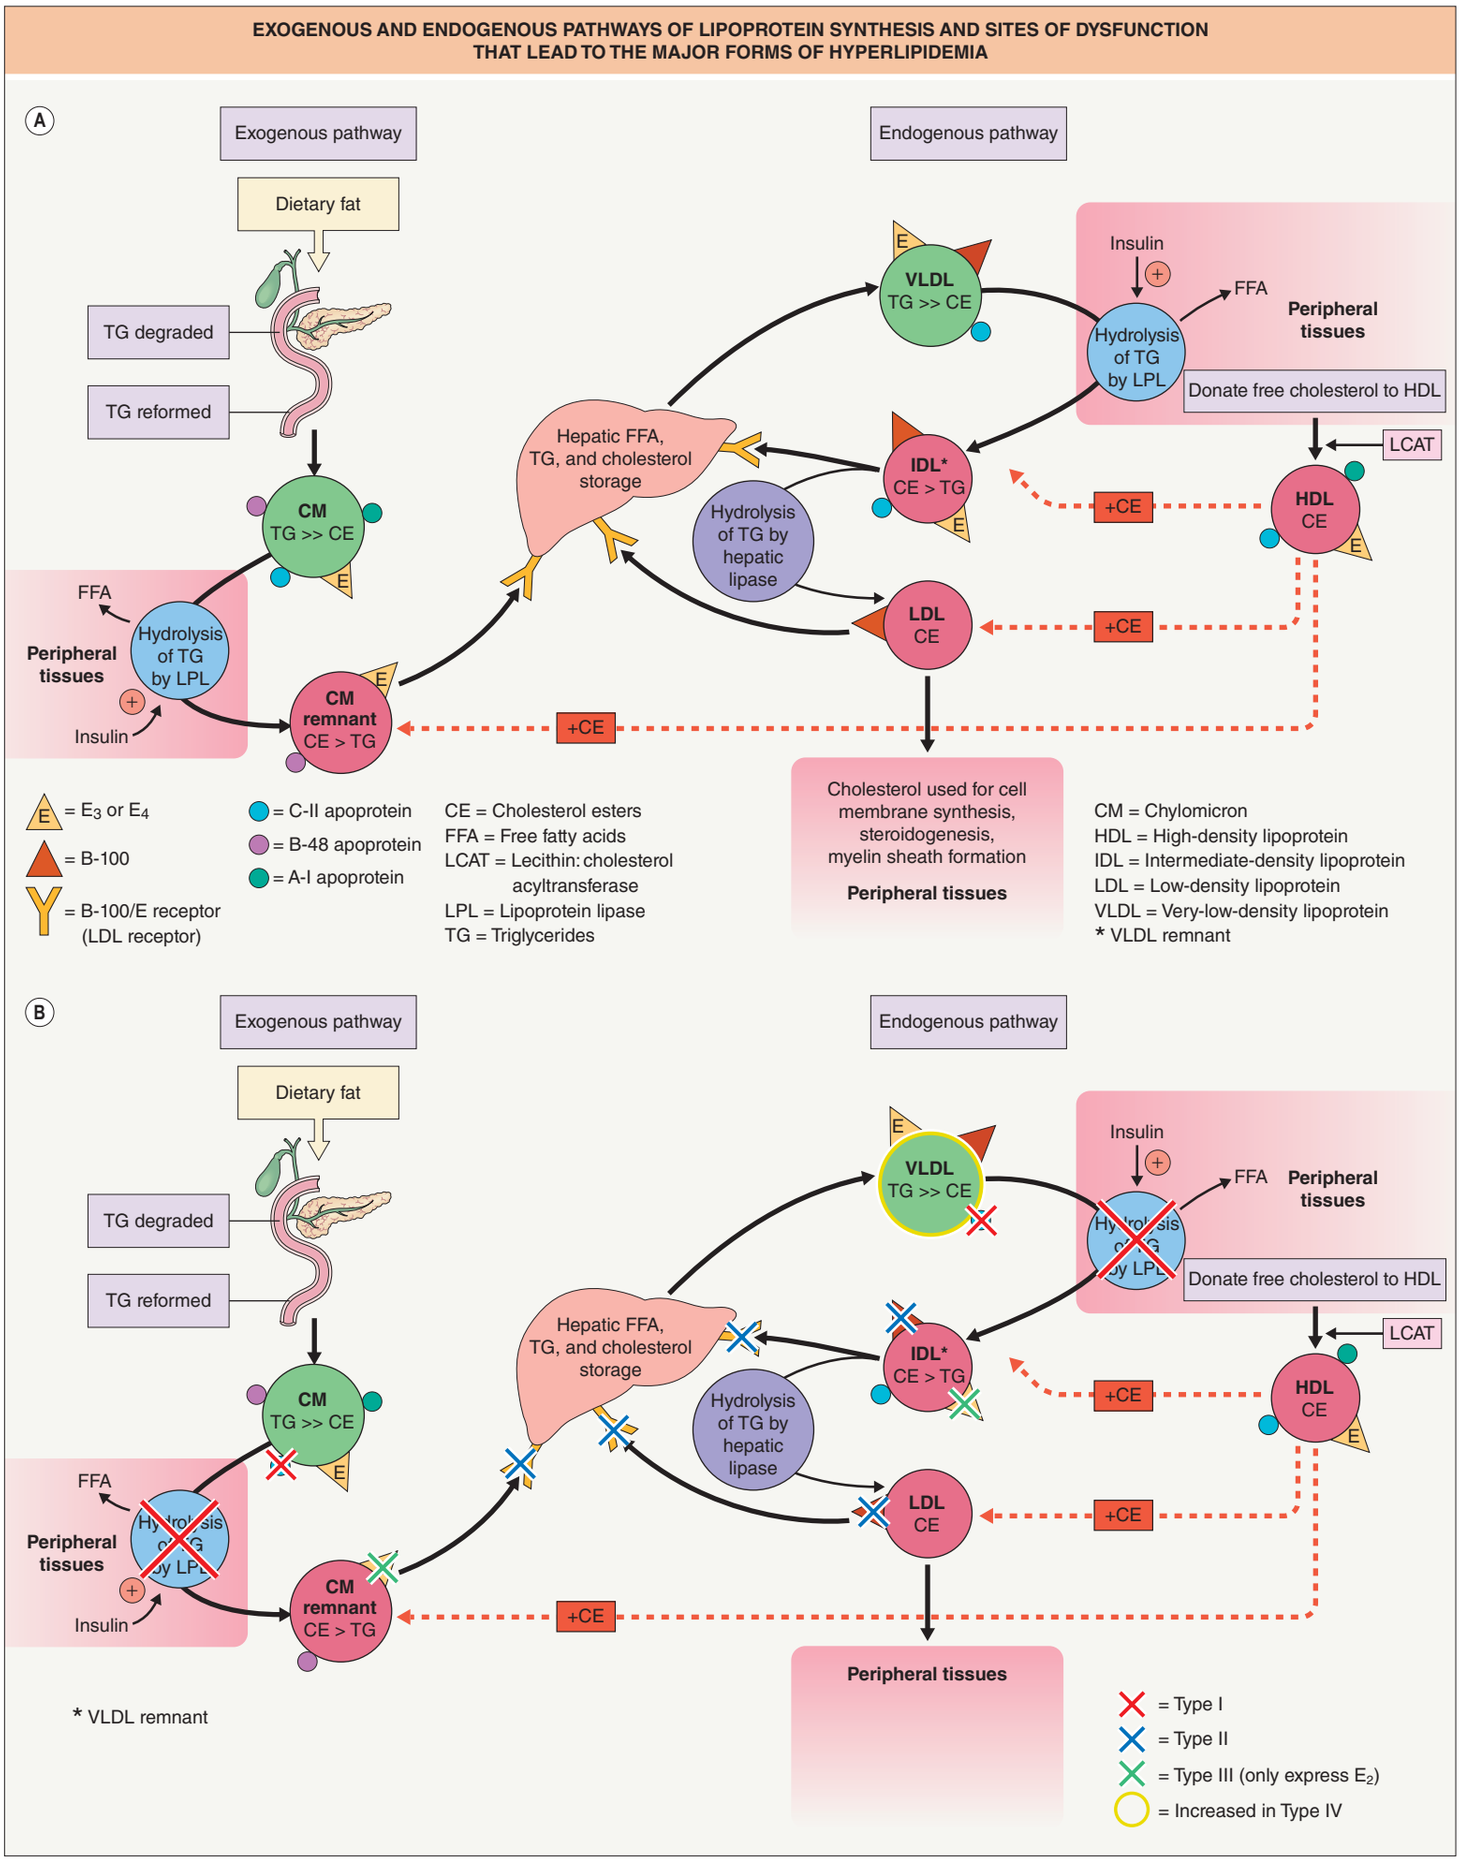

Fig. 92.1 Exogenous and endogenous pathways of lipoprotein synthesis (A) and sites of dysfunction that lead to the major forms of hyperlipidemia (B). Lipoprotein lipase (LPL) is activated by the C-II apoprotein.

The *endogenous* pathway begins with the hepatic formation of VLDL particles. The central core of the VLDL consists primarily of triglycerides, which are derived from circulating free fatty acids and hepatic triglyceride stores. Important apoproteins found on the outer shell include B-100, E, and C-II. In a fashion similar to the chylomicron, lipoprotein lipase mediates hydrolysis of the VLDL molecule, removing the majority of its triglyceride content, and its cholesterol esters are acquired from HDL molecules. Lipoprotein lipase activation requires the presence of apo C-II on the VLDL outer shell. After removal of the majority of the triglyceride content, the VLDL "remnant", also known as an intermediate-density lipoprotein (IDL), can then be taken up by the liver via apo B-100/E receptors and degraded. IDLs that escape uptake by the hepatocyte are stripped of their remaining core triglycerides by extracellular hepatic lipases and enter the circulation as LDLs.

The LDL contains predominantly cholesterol ester in its central core and expresses B-100 on its surface. LDL delivers cholesterol ester to peripheral tissues, where it can be converted to free cholesterol. Cholesterol has several important functions within the body, including being an essential component of cell membrane bilayers. It is also important in the production of the myelin sheath of nerves, adrenal and gonadal steroidogenesis, and the production of bile acids. Hepatocytes play the major role in the catabolism of LDLs. Their uptake is mediated through the high-affinity apo B-100/E receptor found on the cell surface of the hepatocytes. Of note, the LDL receptors on hepatocytes are catabolized by PCSK9 (proprotein convertase subtilisin/kexin type 9). Free cholesterol in excess of metabolic needs is re-esterified for storage.

HDLs serve several important functions in cholesterol metabolism (see Fig. 92.1A). One of the primary functions of HDLs is the removal of cholesterol from the peripheral tissues. During this process, free cholesterol and phospholipids are transferred from the cell membranes of peripheral cells to the HDL molecules. The free cholesterol is then esterified by the enzyme *l*ecithin:*c*holesterol *a*cyl*t*ransferase, or LCAT. This enzyme requires the presence of the HDL apoprotein A-I. HDL molecules then transfer the cholesterol esters to other lipoproteins such as LDLs and remnants of chylomicrons or VLDLs for transportation back to the liver.

The liver plays the central role in the overall cholesterol economy. Hepatic intracellular cholesterol levels have a direct impact on the activity of HMG-CoA reductase, the rate-limiting enzyme of cholesterol synthesis, and on the expression of the high-affinity apo B-100/E receptor. When intracellular cholesterol levels are low, HMG-CoA reductase becomes activated and high-affinity apo B-100/E receptor expression increases. The increase in high-affinity receptors leads to increased uptake of cholesterol-containing lipoproteins such as chylomicron remnants, IDLs, and LDLs. This is followed by the lowering of plasma cholesterol levels. As discussed later, this mechanism will be the basis for many of the pharmacologic interventions aimed at lowering cholesterol levels.

CLINICAL FEATURES

Due to the complexity of cholesterol homeostasis, there are several possible ways in which hyperlipidemia may occur, from inherited disorders to metabolic diseases such as diabetes mellitus. Genetic mutations can affect important enzymes, receptors, or receptor ligands, with such defects leading to the overproduction of lipoproteins or the inhibition of their clearance (Fig. 92.1B). Each possible defect would lead to a different abnormal lipid profile.

In 1965, Lees and Frederickson[3] published a system for classifying various disorders of lipid metabolism based upon the electrophoretic migration of the serum lipoproteins present. This system for phenotyping hyperlipoproteinemias is used today in a modified form (Table 92.2). In the next section, descriptions of underlying lipid disorders will reference not only the Frederickson classification system, but also the specific molecular defects when possible.

With the exception of the homozygous form of familial hypercholesterolemia (type II) and rare disorders such as sitosterolemia and biliary atresia, most cutaneous xanthomas do not appear until adulthood. Once the diagnosis is established, treatment of associated disorders (e.g. metabolic syndrome [see Table 53.5]) should reduce the incidence of potential systemic sequelae such as myocardial infarctions, cerebrovascular accidents, and hepatic steatosis[4].

Eruptive Xanthomas

Eruptive xanthomas appear as erythematous to yellow papules, approximately 1 to 5 mm in diameter (Fig. 92.2 & 92.3). They are usually distributed on the extensor surfaces of the extremities, buttocks, and hands. Early in their development, lesions may have an inflammatory halo (likely due to their triglyceride component), which may be accompanied by tenderness and pruritus. The Koebner phenomenon has been reported to occur with eruptive xanthomas[5].

Eruptive xanthomas can be seen in the setting of primary or secondary *hypertriglyceridemia*. Triglyceride levels in patients with eruptive xanthomas often exceed 3000 to 4000 mg/dl. In the Frederickson classification of hyperlipidemias, hypertriglyceridemia can be seen in type I (elevated chylomicrons), type IV (elevated VLDLs), and type V (elevated chylomicrons and VLDLs).

One reason for elevated triglyceride levels is failure to remove such lipids from the circulation (Fig. 92.4). Deficient activity of lipoprotein lipase will lead to accumulation of triglyceride-rich chylomicrons and VLDLs (see Fig. 92.1B). This can be related to either abnormalities in the enzyme itself, as in *lipoprotein lipase deficiency* (*chylomicronemia syndrome*), or in other controlling factors such as *dysfunctional apoprotein C-II* or *impaired insulin activity*[6,7]. In addition to *deficiency of GPIHBP1*, autoantibodies against GPIHBP1 can also lead to hypertriglyceridemia[8].

Another reason for increased triglyceride levels is hepatic overproduction of triglyceride-rich lipoproteins via the endogenous pathway. In *endogenous familial hypertriglyceridemia*, a genetic defect exists that causes the liver to respond abnormally to dietary carbohydrates and insulin, with overproduction of hepatic VLDLs. The result is a Frederickson type IV pattern of hypertriglyceridemia. Secondary acquired defects in lipoprotein lipase activity, such as those due to diabetes mellitus, are not uncommon in these patients. With this second insult, the lipoprotein lipase system can become saturated and, as a result, no longer handles dietary lipids, leading to chylomicron elevations as well. This pattern is classified as a Frederickson type V phenotype.

Environmental factors and underlying diseases commonly exacerbate genetic defects of triglyceride metabolism, leading to worsening of the hypertriglyceridemia with eruptive xanthoma formation (see Fig. 92.4). Such factors include obesity, high caloric intake, diabetes mellitus, alcohol abuse, oral estrogen replacement, and systemic medications that can lead to hypertriglyceridemia (e.g. retinoids, protease inhibitors, olanzapine). The resultant pattern usually leads to a Frederickson type IV phenotype. Oral retinoid therapy, especially bexarotene, can elevate triglyceride levels through an elevation in hepatic VLDL secretion. With isotretinoin, this elevation seems to be more prevalent in genetically predisposed individuals and may signal an increased risk for future metabolic syndrome[9]. Two of the five criteria for the clinical diagnosis of metabolic syndrome are lipid abnormalities – elevated triglycerides and reduced HDLs (see Table 53.5).

The treatment of eruptive xanthomas involves the identification and treatment of the underlying causes of the hypertriglyceridemia (see Fig. 92.4). Failure to recognize and treat the patient with hypertriglyceridemia could lead to complications such as acute pancreatitis. Pharmacologic and dietary lowering of the circulating triglycerides to reasonable levels will result in the prompt resolution of the eruptive lesions.

Tuberous/Tuberoeruptive Xanthomas

Tuberoeruptive and tuberous xanthomas are clinically and pathologically related and often described as being on a continuum. Tuberoeruptive xanthomas present as pink–yellow papules or nodules on extensor surfaces, especially the elbows and knees (Fig. 92.5). Tuberous lesions are noted to be larger than tuberoeruptive lesions and may exceed 3 cm in diameter (Fig. 92.6). Together, these lesions can be seen in hypercholesterolemic states such as *dysbetalipoproteinemia* (Frederickson type III) and *familial hypercholesterolemia* (Frederickson type II; see below). In contrast to eruptive xanthomas, tuberous xanthomas are usually slow to regress following institution of appropriate therapy.

Dysbetalipoproteinemia, or broad beta disease, is a genetic disorder of lipid metabolism that is usually inherited in an autosomal recessive fashion. It is caused by the presence of an isoform of apo E, primarily

IMPORTANT HYPERLIPOPROTEINEMIAS				
Type	**Pathogenesis**	**Laboratory findings**	**Clinical findings**	
			Skin (types of xanthoma)	**Systemic**
Type I (familial LPL deficiency, familial hyperchylomicronemia)	(a) Deficient or abnormal LPL (AR) (b) Apo C-II deficiency (AR) (c) Deficient glycosyl-phosphatidylinositol-anchored HDL-binding protein 1 [GPIHBP1] (AR) (d) Apo A-V* deficiency (AR)	Slow chylomicron clearance Reduced LDL and HDL levels **Hypertriglyceridemia**	Eruptive	No increased risk of coronary artery disease Recurrent pancreatitis
Type II (familial hypercholesterolemia)	(a) LDL receptor defect (AD)† (b) Reduced affinity of LDL for LDL receptor due to dysfunction of apo B-100 (ligand) (AD) (c) Accelerated degradation of LDL receptor due to missense *PCSK9* mutations (AD‡) (d) Defective LDL receptor adaptor protein 1 (required for receptor internalization) (AR)	Reduced LDL clearance **Hypercholesterolemia**	Tendinous, tuberoeruptive, tuberous, plane (xanthelasma, intertriginous areas, interdigital web spaces¶)	Atherosclerosis of peripheral and coronary arteries
Type III (familial dysbetalipoproteinemia, remnant removal disease, broad beta disease, apo E deficiency)	Hepatic remnant clearance impaired due to apo E abnormality; vast majority of patients only express the apo E_2 isoform that interacts poorly with the apo E receptor (AR >> AD)	Elevated levels of chylomicron remnants and IDLs **Hypercholesterolemia** **Hypertriglyceridemia**	Tuberoeruptive, tuberous, plane (palmar creases) – most characteristic Tendinous	Atherosclerosis of peripheral and coronary arteries
Type IV (endogenous familial hypertriglyceridemia)	Elevated production of VLDL associated with glucose intolerance and hyperinsulinemia; may be associated with heterozygous variants, e.g. in apo A-V*, LPL, or the glucokinase regulator protein	Increased VLDLs **Hypertriglyceridemia**	Eruptive	Frequently associated with type 2 non-insulin-dependent diabetes mellitus, obesity, alcoholism (see Fig. 92.4)
Type V	Elevated chylomicrons and VLDLs; may be associated with heterozygous variants, e.g. in apo A-V*, LPL, or the glucokinase regulator protein	Decreased LDLs and HDLs **Hypertriglyceridemia**	Eruptive	Diabetes mellitus

*Apolipoprotein A-V (apo A-V) interacts with the LDL receptor and activates lipoprotein lipase, inhibiting VLDL-TG production and modulating HDL maturation and cholesterol metabolism.
†In patients with the *LDLR* IVS14+1G-A mutation, the phenotype can be altered by SNPs in the genes that encode apo A-II, cytoplasmic epoxide hydrolase 2, or growth hormone receptor.
‡Gain-of-function mutations cause autosomal dominant hypercholesterolemia[28], whereas loss-of-function mutations (most prevalent in African-Americans) result in low LDL levels[29].
¶Said to be pathognomonic for homozygous state.

Table 92.2 Important hyperlipoproteinemias. Autoantibodies against GPIHBP1 can also lead to hypertriglyceridemia. In **bold** are the major lipid abnormalities found on routine screening. AD, autosomal dominant; Apo, apolipoprotein; AR, autosomal recessive; HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LPL, lipoprotein lipase; PCSK9, proprotein convertase subtilisin/kexin type 9; VLDL, very-low-density lipoprotein.

Fig. 92.2 Eruptive xanthomas due to hypertriglyceridemia. In this patient the lesions favored the extensor surface of the lower extremities, in particular the knees.

apo E_2, that is a poor ligand for the high-affinity apo B-100/E receptor (see Fig. 92.1B). This results in the poor hepatic uptake of chylomicron and VLDL remnants. As a result, the serum levels of both triglycerides and cholesterol are elevated. The cutaneous lesions that are most characteristic of this disease are tuberous or tuberoeruptive xanthomas (present in 80% of patients) and plane xanthomas of the palmar creases (*xanthoma striatum palmare*), which are present in two-thirds of patients (see below)[10].

Tendinous Xanthomas

Tendinous xanthomas are firm, smooth, nodular lipid deposits that can affect the Achilles tendons (Fig. 92.7) or the extensor tendons of the hands (Fig. 92.8), knees, or elbows. The overlying skin is normal in appearance. Ultrasound can aid in the diagnosis of subtle lesions of the Achilles tendon by demonstrating hypoechoic nodules or an increase in the anteroposterior diameter of the tendon[11]. The presence of tendinous xanthomas is almost always a clue to an underlying disorder of lipid metabolism. Lipid disorders that have been associated with this type of xanthoma include familial hypercholesterolemia, dysbetalipoproteinemia, and hyperlipidemia secondary to hypothyroidism (Table 92.3).

Tendinous xanthomas are most frequently seen in the setting of *familial hypercholesterolemia*. This disorder results from a deficiency of normal LDL receptors on cell membranes, which leads to the poor hepatic clearance of circulating LDLs and, therefore, elevated LDL cholesterol levels (Frederickson type II). This condition is inherited in an autosomal dominant fashion with a high degree of penetrance. Homozygotes can have LDL cholesterol levels of 800 to 1000 mg/dl with widespread atherosclerosis and the appearance of xanthomas during the first decade of life. Heterozygosity for the disorder is more common and is estimated to occur in 1 in 500 individuals in the US. The types of xanthomas seen in this disorder include tendinous, tuberous, tuberoeruptive, and plane (including xanthelasma). Because of its relatively

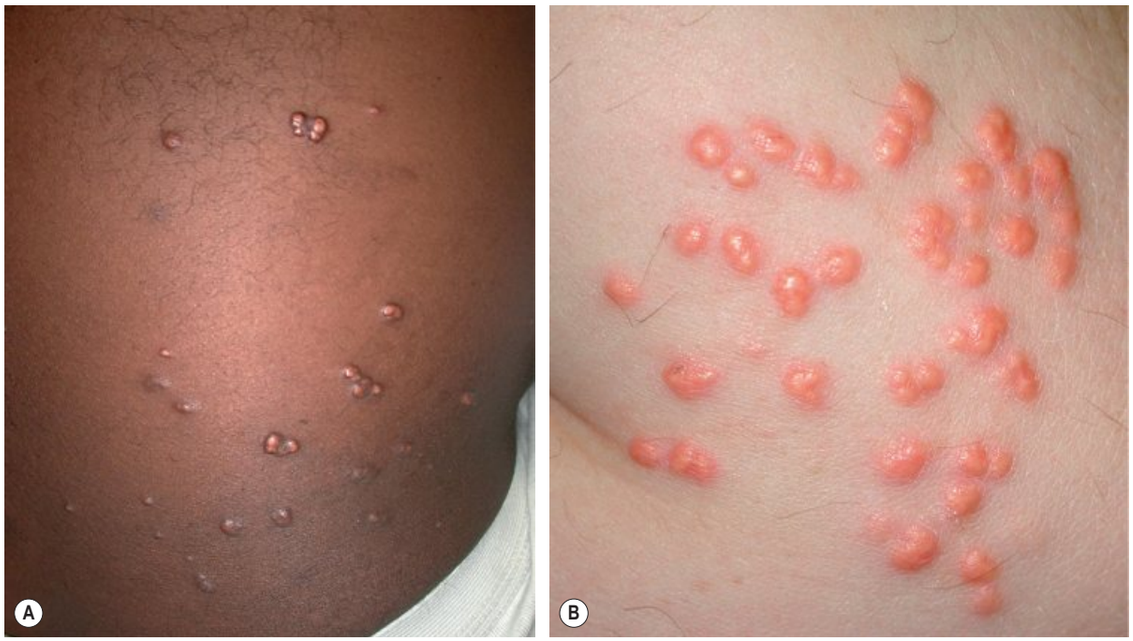

Fig. 92.3 Eruptive xanthomas. A, B The yellowish hue is influenced by the degree of pigmentation of the skin. Note the clustering of some of the lesions.

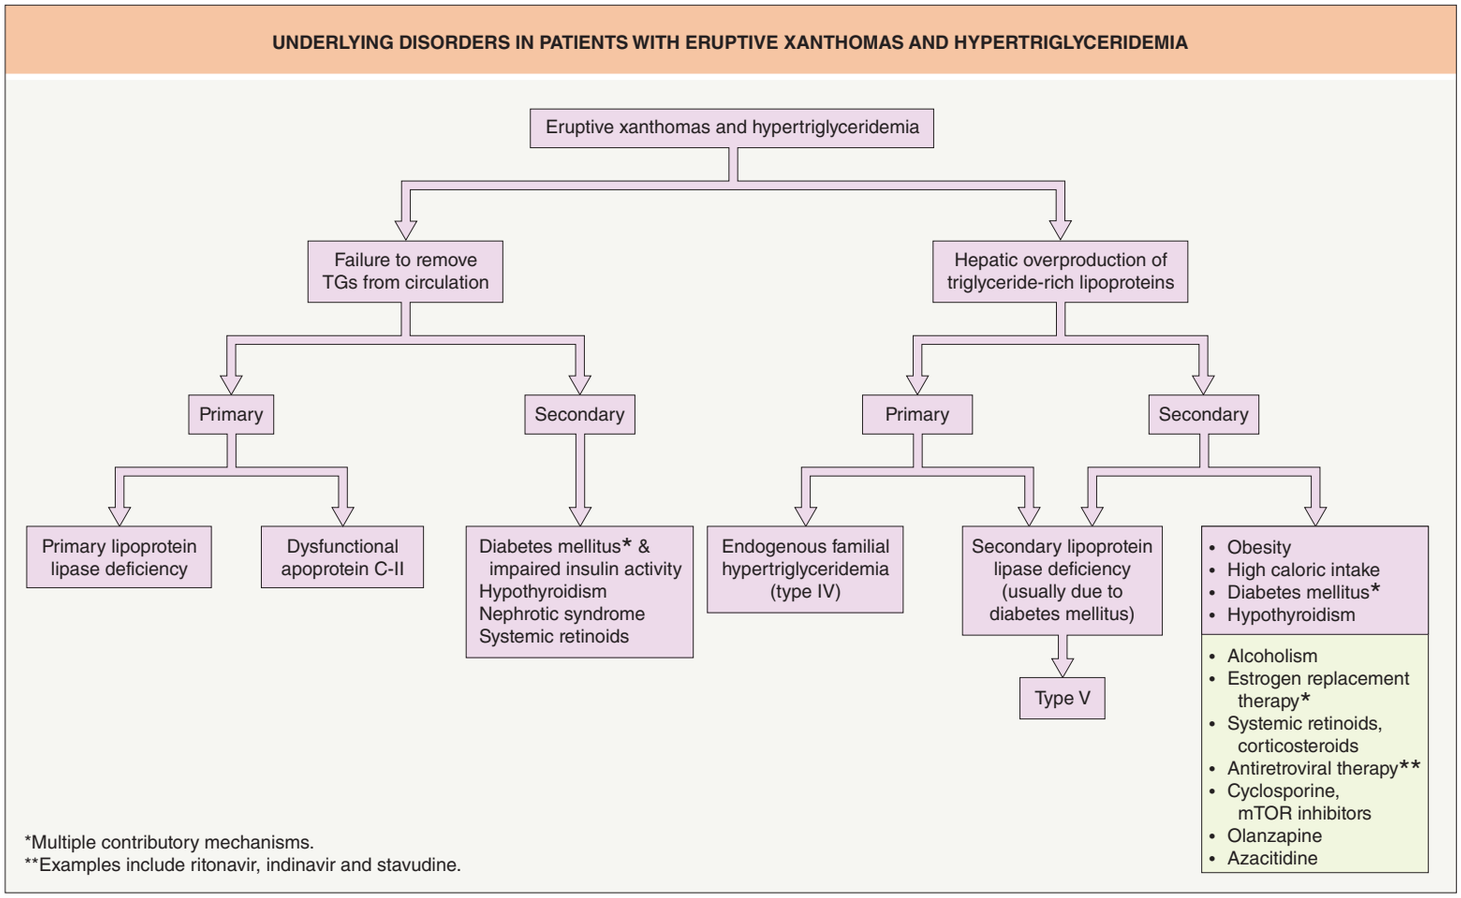

Fig. 92.4 Underlying disorders in patients with eruptive xanthomas and hypertriglyceridemia. mTOR, mammalian target of rapamycin; TGs, triglycerides.

common occurrence, patients with tendinous xanthomas are more likely to have the heterozygous form of the disease than the rare homozygous state. Plane xanthomas of the intertriginous web spaces of the fingers are thought to be pathognomonic for the homozygous condition (see Fig. 92.8)[12].

There is a closely related disorder, known as *familial defective apolipoprotein B-100*. In this dominantly inherited genetic disorder, the LDL receptor is normal. However, there is decreased affinity of LDL for the LDL receptor because the mutation affects its ligand, apo B-100 (see Fig. 92.1B). Patients may present with identical clinical findings as in familial hypercholesterolemia, although usually not as severe[13]. From a therapeutic standpoint, distinguishing this disorder from dysfunction or accelerated degradation of the LDL receptor (see Table 92.2) will become more important in the future as treatments aimed at correcting LDL receptor function become commercially available (e.g. evinacumab)[13a].

Rarely, tendinous xanthomas can develop in the absence of a lipoprotein disorder. Two examples are *cerebrotendinous xanthomatosis* and *sitosterolemia*. In cerebrotendinous xanthomatosis, an enzymatic

SECONDARY HYPERLIPIDEMIA – SELECTED UNDERLYING DISORDERS

- Diabetes mellitus*
- Cholestasis
  - Primary biliary cholangitis (often plane xanthomas, including palmar)
  - Alagille syndrome (elbows/knees, flexures, fingers, palms, helices)*,†
- Biliary atresia*
- Hypothyroidism*
- Nephrotic syndrome*
- Type I glycogen storage disease (von Gierke)*
- Lipodystrophy syndromes (see Fig. 101.1)

*Xanthomas can develop during childhood.
†Autosomal dominant disorder due to mutations in *JAG1*, which encodes the Notch signaling pathway ligand Jagged-1, or (in ~5% of patients) *NOTCH2*. Patients have cholestasis due to a paucity of intrahepatic bile ducts, elevated LDL (cholesterol) levels, cardiac defects, peculiar facies, growth retardation, and posterior embryotoxon; xanthomas within body folds may become very firm[30–32].

Table 92.3 Secondary hyperlipidemia – selected underlying disorders. In addition to a fasting lipid panel, screening blood tests include fasting glucose, liver function tests, TSH, and albumin. Other rare causes include pregnancy, multiple myeloma, and autoimmune connective tissue diseases (e.g. systemic lupus erythematosus, juvenile dermatomyositis)

defect exists in the bile acid synthetic pathway, leading to the abnormal accumulation of an intermediate known as cholestanol. This intermediate is deposited in most tissues, including the brain, and can also form tendinous xanthomas[14]. In sitosterolemia-1 and -2, an abnormal accumulation of plant sterols occurs, leading to tendinous and tuberous xanthoma formation.

Plane Xanthomas and Xanthelasma

Plane xanthomas appear as yellow to orange, non-inflammatory macules, papules, patches, and plaques. They can be circumscribed or diffuse. While anatomic locations vary, the site often serves as a clue to the particular underlying disease state. For example, intertriginous plane xanthomas may occur in body folds including the antecubital fossae (Fig. 92.9 & 92.10) or the web spaces of the fingers (see Fig. 92.8), where they are almost pathognomonic for homozygous familial hypercholesterolemia[12]. Plane xanthomas of the palmar creases, or *xanthoma striatum palmare*, are nearly diagnostic for dysbetalipoproteinemia, especially when accompanied by tuberous xanthomas[15].

Xanthelasma, or *xanthelasma palpebrarum*, are commonly observed plane xanthomas of the eyelids (Fig. 92.11). Although the presence of xanthelasma warrants investigation for hyperlipidemia, the latter is present in only about one-half of the patients with these lesions. Younger patients or those with a strong family history of hyperlipidemia are more likely to have an underlying lipid disorder and should be appropriately screened.

Plane xanthomas of cholestasis may occur as a complication of diseases such as biliary atresia or primary biliary cholangitis (previously primary biliary cirrhosis). In these conditions, unesterified cholesterol

begins to accumulate in the blood, leading to plane xanthoma formation. The lesions often begin as localized plaques on the hands and feet, but can become generalized.

Plane xanthomas can also occur in a normolipemic patient, where they may signal the presence of an underlying monoclonal gammopathy (Fig. 92.12), usually due to a plasma cell dyscrasia, but occasionally secondary to a lymphoproliferative disorder such as B cell lymphoma or Castleman disease (see Ch. 119). This type of xanthoma can also be seen in patients with chronic myelomonocytic leukemia. In gammopathy-associated plane xanthomas, monoclonal IgG is thought to bind to circulating LDL, rendering the antibody–LDL complex more susceptible to phagocytosis by macrophages[16]. Favored locations include the neck, upper trunk, flexural folds, and periorbital region. In the setting of a monoclonal gammopathy, the coexistence of plane xanthomas and necrobiotic xanthogranuloma has been observed, suggesting a disease overlap[17]. Of note, there is an entity known as hyperlipidemic myeloma in which xanthomas appear on the elbows and knees as well as within the palmar creases.

Verruciform Xanthomas

Verruciform xanthomas are asymptomatic, planar or verrucous, solitary plaques that are usually 1 to 2 cm in diameter. They occur primarily in the mouth (Fig. 92.13), but sometimes in periorificial, anogenital (including the scrotum), and acral sites. The latter are sometimes referred to as Vegas (verruciform genital-associated) and Vacas (verruciform acral-associated) xanthomas. These lesions may persist for years and there is usually no associated hyperlipidemia.

Single or multiple lesions are also seen in the setting of lymphedema, epidermolysis bullosa, pemphigus, discoid lupus erythematosus, lichen planus, and GVHD as well as within dermatofibromas and cutaneous lesions of the X-linked dominant disorder CHILD (*c*ongenital *h*emidysplasia with *i*chthyosiform erythroderma and *l*imb *d*efects) syndrome. The latter is due to mutations in *NSDHL*, which encodes 3β-hydroxysteroid dehydrogenase, an enzyme involved in cholesterol biosynthesis (see Ch. 57). In a molecular study of sporadic verruciform xanthomas, two of nine lesions were found to have a missense somatic mutation in exon 6 of *NSDHL* (only exons 4 and 6 were examined) which differed from the mutations seen in CHILD syndrome[18].

One proposal is that enzymatic dysfunction leads to an excess formation and accumulation of lipid storage droplets, followed by formation of lipid-laden dermal macrophages. Another hypothesis suggests that the foam cells result from damage to the epithelium

Fig. 92.11 Xanthelasma palpebrarum with typical yellowish hue.

Fig. 92.9 Plane xanthomas of the antecubital fossae. This young patient had dysbetalipoproteinemia.

(e.g. from lichenoid dermatoses) and subsequent engulfing of lipids by macrophages within the dermal papillae, analogous to the amyloid deposits within the dermal papillae in lichen amyloidosis. The few foam cells beneath the epithelium may be subtle and easy to miss, in which case verruciform xanthomas may be confused histologically with warts and other papillomatous disorders. Surgery is generally curative.

PATHOLOGY

The characteristic histologic finding in xanthomas is the foam cell. Foam cells consist of macrophages that contain imbibed lipid within their cytoplasm (Fig. 92.14). All xanthomas contain dermal infiltrates of lipid, but they may vary in the degree of lipid content, the inflammatory infiltrate, the amount and location of the infiltrate, and the presence of extracellular lipid. The histologic appearance of xanthomas is somewhat altered by routine processing, as formalin fixation can remove deposits of lipid and leave artifactual clefting. Immunohistochemical staining for adipophilin can be performed to detect lipid accumulation[19]. Adipophilin, also known as adipose differentiation-related protein, is a lipid droplet-associated protein.

Eruptive xanthomas contain lipid deposits in the reticular dermis. Of note, early in lesion development, foam cells are relatively small in number and size. The initial inflammatory infiltrate is mixed, containing both neutrophils and lymphocytes. As an increase in lipidization occurs, the appearance of the lesion becomes more typical of a xanthoma, but foam cells remain fewer in number compared with other types of xanthomas. Extracellular lipids are present in the dermis, which are seen as artifactual clefts filled with a wispy faint blue–gray material.

Tuberous xanthomas demonstrate large aggregates of foam cells in the dermis, often accompanied by fibrosis, but without a large number of inflammatory cells. *Tendinous xanthomas* have a similar histology, with foam cells that are even larger in size. Cholesterol esters are present in these lesions and can be seen with polarized microscopy.

DIFFERENTIAL DIAGNOSIS OF XANTHOMAS

- Eruptive xanthomas
  - Non-Langerhans cell histiocytoses
    - Xanthoma disseminatum
    - Papular xanthoma
    - Generalized eruptive histiocytoma
    - Indeterminate cell histiocytosis
    - Rosai–Dorfman disease
    - Juvenile xanthogranuloma (micronodular form)
  - Xanthomatous lesions of Langerhans cell histiocytosis
  - Disseminated granuloma annulare
- Tuberous xanthomas
  - Erythema elevatum diutinum
  - Multicentric reticulohistiocytosis
  - Juxta-articular fibroid nodules of *Borrelia* infection
- Tendinous xanthomas
  - Giant cell tumor of the tendon sheath
  - Rheumatoid nodule
  - Subcutaneous granuloma annulare
  - Erythema elevatum diutinum
- Xanthelasma
  - Syringomas
  - Necrobiotic xanthogranuloma
  - *A*dult-onset *a*sthma and *p*erio*c*ular *x*anthogranuloma (AAPOX)
  - Sebaceous hyperplasia
  - Palpebral sarcoidosis

Table 92.4 Differential diagnosis of xanthomas. Occasionally, xanthomatous cells may be observed histologically in some cutaneous tumors (e.g. dermatofibroma), unrelated to xanthomas.

Plane xanthomas such as xanthelasma can have a unique histologic appearance. The foam cells in this type of xanthoma are more superficial than in other types of xanthomas. Small aggregates of foam cells are often present in the superficial dermis. The lesions are non-inflammatory and have minimal fibrosis. With xanthelasma, there are often clues as to the location of the lesion, such as a thin epidermis, fine vellus hair follicles, and striated muscle fibers that are characteristic of the eyelid. In *verruciform xanthomas*, there is usually hyperkeratosis, acanthosis and papillomatosis, with foamy macrophages limited to the submucosa or dermal papillae.

A distinctive *papular neutrophilic xanthoma*, in which dermal foam cells are intermingled with neutrophils and prominent nuclear dust, has been described in HIV-infected patients with an IgA gammopathy. *Xanthomatized neutrophilic dermatosis* in the setting of myelodysplastic syndrome may represent a similar condition[20]. Lastly, dermal xanthomatous cells observed in biopsies of cutaneous GVHD may be indicative of hepatic GVHD[21].

DIFFERENTIAL DIAGNOSIS

A selection of the diseases included in the differential diagnosis of xanthomas is listed in Table 92.4.

TREATMENT

The treatment of xanthomas associated with hyperlipidemia requires the identification of the underlying lipoprotein disorder and other possible exacerbating factors. In addition to dietary measures, there are several medications available for lowering lipid levels in patients with primary and secondary hyperlipidemia. Table 92.5 outlines their mechanisms of action, clinical effects, and side effects. Correction of the underlying lipid disorder leads to the eventual resolution of the xanthomas in many patients. Xanthomas that have grown slowly over years, such as tendinous and tuberous xanthomas, are often slow to regress, whereas eruptive xanthomas may disappear within weeks of aggressive therapy.

Dietary measures are an important component of lipid-lowering therapy, in addition to oral medications (see Table 92.5). Decreasing total caloric intake and the achievement of ideal body weight alone can make a significant impact on lipid levels in some patients. Dietary fat restriction to <30% of total caloric intake should be attempted. Mono-unsaturated fats such as olive oil should comprise the majority of the fat intake. Alcohol avoidance is essential, especially in patients with hypertriglyceridemia.

LIPID-LOWERING MEDICATIONS				
Class of drug	**Mechanism of action**	**Clinical effects**	**Side effects/ interactions**	**Comments**
HMG-CoA reductase inhibitors ("statins")	• Competitive inhibition of the rate-limiting enzyme of hepatic cholesterol synthesis, with depletion of hepatocellular stores of cholesterol • Upregulation of hepatic LDL receptors (bind LDL & IDL; see Fig. 92.1) • Decreased endogenous VLDL production	• 25%–45% decrease in LDL levels • 25% decrease in VLDL levels • 10% increase in HDL levels	• Elevations in hepatic transaminases • Myopathy (risk may be increased with coadministration of other medications, e.g. cyclosporine, nicotinic acid, fibrates) • Drug-induced dermatomyositis • Interstitial granulomatous drug reaction • May increase warfarin levels	• Useful for many lipid disorders, including *heterozygous* familial hypercholesterolemia, hypercholesterolemia due to diabetes • Not effective in *homozygous* familial hypercholesterolemia (LDL receptor function is lacking)
Bile acid-binding resins (e.g. cholestyramine, colestipol, colesevelam)	• Bind to bile acids in the small intestine, preventing their reabsorption in the terminal ileum • Because of enhanced bile acid secretion, the liver must increase its synthesis of bile acids from cholesterol • Decrease in hepatic cholesterol stores leads to upregulation of hepatic LDL receptors (also increased HMG-CoA reductase activity)	• 10%–35% decrease in LDL levels (even with increase in hepatic cholesterol synthesis)	• Elevation of triglyceride levels, especially if dysbetalipoproteinemia or pre-existing hypertriglyceridemia • GI upset & gritty texture of resin • Affect absorption of medications such as digoxin, thyroxine, warfarin	• Lowering of LDL levels can be further enhanced by the addition of an HMG-CoA reductase inhibitor or nicotinic acid • Effective in *heterozygous* familial hypercholesterolemia • Not effective in *homozygous* familial hypercholesterolemia
Nicotinic acid (niacin)	• Lowers VLDL synthesis (and subsequently lowers LDL levels) • Enhances lipoprotein lipase activity (and subsequently lowers triglyceride levels)	• 20%–80% decrease in triglyceride levels (rapid) • 10%–15% decrease in LDL levels (slower) • 20–30 mg/dl increase in HDL	• Intense flushing and pruritus are common • Hepatitis • Worsening of glucose intolerance • Acanthosis nigricans, hyperpigmentation, xerosis • Increased risk of myopathy & rhabdomyolysis when coadministered with HMG-CoA reductase inhibitors	• Can be used in combination with HMG-CoA reductase inhibitors or bile acid-binding resins • Combination therapy for familial hypercholesterolemia • Treatment of severe hypertriglyceridemia refractory to fibric acid derivatives (to prevent pancreatitis)
Fibric acid derivatives (e.g. gemfibrozil, fenofibrate, clofibrate)	• Activation of lipoprotein lipase in peripheral tissues (e.g. muscle) • Decreases VLDL synthesis by suppression of the endogenous lipid pathway	• Dramatic improvement in lipid levels, with resolution of tuberous & palmar xanthomas (patients with dysbetalipoproteinemia) • Lowers triglyceride levels; prevents pancreatitis & eruptive xanthoma formation (patients with severe hypertriglyceridemia & chylomicronemia syndrome) • Increases levels of HDL	• Because of inhibition of the cytochrome P450 3A4 system, possibility of dermatologic drug–drug interactions (e.g. increased plasma levels of bexarotene or cyclosporine) • Increased risk of myopathy when administered with HMG-CoA reductase inhibitors	• Treatment of hypertriglyceridemia
Ezetimibe	• Inhibits intestinal absorption of dietary and biliary-excreted cholesterol	• ~15% reduction in LDL-C • Increases HDL by 3%	• Diarrhea • Rarely, elevated hepatic transaminases when coadministered with HMG-CoA reductase inhibitors	• Can be used in combination with HMG-CoA reductase inhibitors
PCSK9 inhibitors (e.g. alirocumab, evolocumab)	• Decreases LDL receptor degradation • Increases recirculation of the LDL receptor to the hepatocyte cell surface	• Lowers LDL cholesterol levels by 40%–60%	• Injection site reactions • Pruritus, urticaria, exanthem, cutaneous small vessel vasculitis • Transaminitis • Nasopharyngitis	• Effectively reduces LDL-C in patients with hypercholesterolemia except for those with *homozygous* familial hypercholesterolemia who lack the LDL receptor (receptor negative) • Administered subcutaneously or intravenously • No myopathy
Adenosine triphosphate-citrate lyase (ACL) inhibitors (e.g. bempedoic acid)	• ACL is an enzyme that functions upstream of HMG-CoA reductase • ACL catalyzes the formation of acetyl-CoA, a precursor of fatty acids and cholesterol • Inhibition of ACL yields similar results as HMG-CoA reductase inhibitors • Inhibits cholesterol synthesis	• 15%–25% reduction in LDL-C levels	• Upper respiratory tract infections, bronchitis • Muscle spasms • Hyperuricemia • Back, abdominal, or extremity pain • Anemia • Concomitant use with HMG-CoA reductase inhibitors may increase risk of statin-induced myopathy	• May be associated with reduced risk of cardiovascular events and diabetes • May be alternative for patients intolerant of statins or with statin-induced myopathy

Table 92.5 Lipid-lowering medications.

Continued

LIPID-LOWERING MEDICATIONS				
Class of drug	**Mechanism of action**	**Clinical effects**	**Side effects/ interactions**	**Comments**
Angiopoietin-like 3 (ANGPTL3) inhibitors (e.g. evinacumab)	• Binds to ANGPTL3 which is expressed primarily in the liver • ANGPTL3 inhibits lipoprotein lipase and endothelial lipase; inhibitors rescue enzyme activity • Promotes VLDL processing and clearance upstream of LDL formation	• Lowers levels of LDL-C (independent of the presence of LDL receptors), HDL-C, and triglycerides	• Injection site reaction • Cough, cold-like symptoms • Dizziness	• Treatment of *homozygous* familial hypercholesterolemia • Administered intravenously in combination with other lipid-lowering drugs (e.g. "statin", PCSK9 inhibitor)
Small interfering RNAs (siRNAs)	• Inclisiran inhibits translation of PCSK9	• 50% reduction in LDL-C levels	• Injection site reactions • Arthralgia, bronchitis	• Effective in *heterozygous* familial hypercholesterolemia • Administered subcutaneously in combination with a "statin"
Lipoprotein apheresis	• Physical removal of circulating lipoprotein(a)	• Lowers levels of circulating lipoprotein(a) by >60% per treatment and by ~30% long-term	• Venipuncture and anticoagulation required for procedure • Hypotension during procedure	• Treatment of *homozygous* familial hypercholesterolemia • Could be considered in patients with very high risk hyperlipidemia/cardiovascular disease • Lifelong therapy

Table 92.5 Lipid-lowering medications. Metreleptin is indicated for patients with congenital or acquired generalized lipodystrophy to address their leptin deficiency and hypertriglyceridemia. Additional treatments, e.g. apolipoprotein C-II mimetic peptides, are under investigation. C, cholesterol; GI, gastrointestinal; HDL, high-density lipoprotein; HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LDL-C, low-density lipoprotein-cholesterol; PCSK9, proprotein convertase subtilisin/kexin type 9; VLDL, very low-density lipoprotein. Based on references 4,33–44.

Xanthomas, particularly xanthelasma, can be treated surgically by excision or destructive methods. When xanthelasma excision is performed, it may be followed by suture or second intention healing[22]. Reported destructive methods for xanthelasma include laser surgery (e.g. CO_2, pulsed dye, erbium:YAG), chemical agents such as trichloroacetic acid, and cryosurgery[23–26]. Despite the initial success of the chosen method, the lesions often recur. Surgical excision has also been employed in the management of tendinous xanthomas. This can be technically difficult, however, as the lipid deposits may be intertwined with the involved tendon[27]. Application of topical lovastatin/cholesterol ointment has led to improvement of the cutaneous lesions in CHILD syndrome (see Ch. 57).

Acknowledgment

The author wishes to acknowledge the late Lee T. Nesbitt Jr, MD, for his valuable contribution to this chapter in the previous editions, and Erica Ann Grilletta, MD, and Caroline Savoie, MD, for their help in researching and editing this chapter.

Sarcoidosis *1660*
Granuloma Annulare *1667*
Necrobiosis Lipoidica *1671*
Cutaneous Crohn Disease *1674*
Foreign Body Granulomas (See Ch. 94) *1675*
Orofacial Granulomatosis (OFG; See Ch. 72) *1676*
Reactive Granulomatous Dermatitis – Includes Interstitial Granulomatous Dermatitis, Palisaded Neutrophilic and Granulomatous Dermatitis, and Interstitial Granulomatous Drug Reaction *1676*

INTRODUCTION

The granulomatous diseases discussed in this chapter may be defined as having an inflammatory cutaneous infiltrate in which histiocytes are the preponderant inflammatory cells. While cutaneous sarcoidosis is the prototype of non-infectious (sterile) granulomatous dermatitides, there are a number of other entities in this group (Fig. 93.1 & Table 93.1). Additional non-infectious granulomatous disorders are covered in other chapters, including rheumatoid nodules in Chapter 45, cheilitis granulomatosa in Chapter 72, foreign body granulomas in Chapter 94, necrobiotic xanthogranuloma in Chapter 91, and primary immunodeficiency-associated granulomatous dermatitis in Chapter 60.

SARCOIDOSIS

Synonyms/subsets: ■ Löfgren syndrome – erythema nodosum, hilar adenopathy, fever, arthritis ■ Heerfordt syndrome – parotid gland enlargement, uveitis, fever, cranial nerve palsy ■ Darier–Roussy disease – subcutaneous sarcoidosis

Key features

- A systemic granulomatous disorder of unknown origin that most commonly involves the lungs
- Cutaneous manifestations of sarcoidosis are seen in up to one-third of patients and may be the first clinical sign of the disease
- Red–brown to violaceous papules and plaques appear most often on the face, in particular the nose, as well as the neck, upper back, extremities, and within scars and tattoos
- Erythema nodosum is a nonspecific inflammatory skin finding that may be associated with an acute form of sarcoidosis which tends to remit
- Histologically, sarcoidosis is characterized by non-caseating epithelioid granulomas, usually with a sparse or absent surrounding lymphocytic inflammation (i.e. "naked" granulomas)

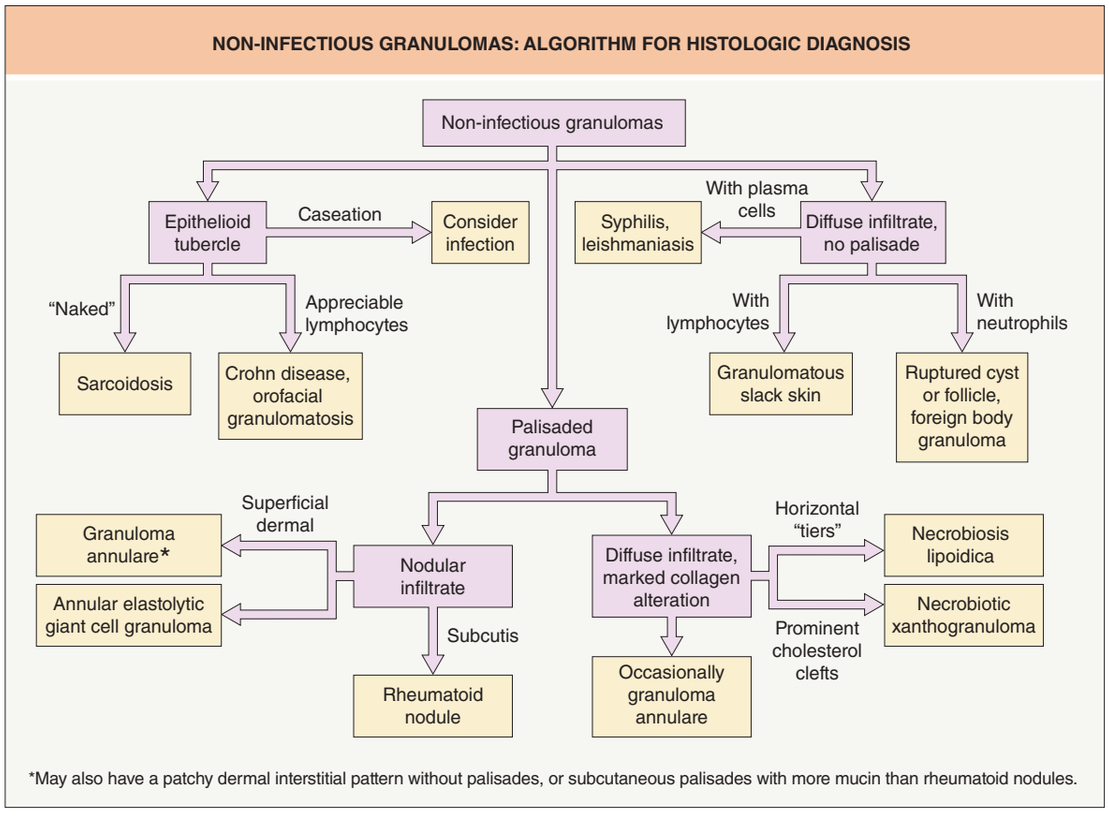

Fig. 93.1 Non-infectious granulomas: algorithm for histologic diagnosis. Reactive granulomatous dermatitis (interstitial granulomatous dermatitis, palisaded neutrophilic and granulomatous dermatitis, and interstitial granulomatous drug eruption) represents an additional diagnostic consideration (see Table 93.4).

CLINICAL FEATURES OF THE MAJOR NON-INFECTIOUS GRANULOMATOUS DERMATITIDES						
	Sarcoidosis*	**Classic granuloma annulare†**	**AEGCG**	**Necrobiosis lipoidica**	**Cutaneous Crohn disease**	**Rheumatoid nodule**
Average age (years)	25–35, 45–65	<30	50–70	30	35	40–50
Sex predilection	Female	Female	Female	Female	Female	Male‡
Racial/ethnic predilection in US	African-American	None	White	None	Ashkenazi Jews	None
Sites	Symmetric on face, neck, upper trunk, extremities	Hands, feet, extensor aspects of extremities	Face, neck, forearms (sites of chronic sun exposure)	Anterior and lateral aspects of shins	Anogenital region, buttocks, lower > upper extremities	Juxta-articular areas, especially elbows and hands
Appearance	Protean; most commonly red–brown or violaceous papules and plaques	Papules coalescing into annular plaques	Annular plaques	Plaques with elevated borders, telangiectasias centrally	Dusky erythema, lymphedema, ulceration, vegetating plaques	Skin-colored, firm, mobile subcutaneous nodules
Size of lesions	0.2 to >5 cm	1–3 mm papules, annular plaques usually <6 cm	2 to >10 cm	3 to >10 cm	Variable	1–3 cm
No. of lesions	Variable	1–10	1–10	1–10	1–5	1–10
Associations	Systemic manifestations of sarcoidosis (see Table 93.3); can be drug-induced (e.g. IFN, TNF inhibitors) or reaction pattern to underlying lymphoma	Possible diabetes mellitus, thyroid disease, or hyperlipidemia; rare reports of HIV infection, drugs, malignancy	Actinic damage	Diabetes mellitus, thyroid disease	Intestinal Crohn disease	Rheumatoid arthritis
Special clinical characteristics	Develop within sites of trauma including scars and tattoos	Central hyperpigmentation	Central atrophy and hypopigmentation	Yellow–brown atrophic centers, ulceration	Draining sinuses and fistulas	Occasional ulceration, especially at sites of trauma

*Clinical variants include lupus pernio and subcutaneous (Darier–Roussy), psoriasiform, ichthyosiform, angiolupoid, and ulcerative sarcoidosis.
†Clinical variants include generalized/disseminated, micropapular, nodular, perforating, subcutaneous, and patch granuloma annulare.
‡Although rheumatoid arthritis has a female : male ratio of 2–3 : 1.

Table 93.1 Clinical features of the major non-infectious granulomatous dermatitides. AEGCG, annular elastolytic giant cell granuloma; HIV, human immunodeficiency virus.

History

Sarcoidosis was described initially by Sir Jonathan Hutchinson in 1875 and cutaneous sarcoidosis (lupus pernio) by Besnier in 1889. Ten years later, Caesar Boeck coined the term "multiple benign sarkoid", noting that the lesions resembled benign sarcomas.

Epidemiology

Sarcoidosis, which occurs in patients of all races and ages as well as both sexes, is characterized by a bimodal age distribution, with peaks between 25 and 35 years and then between 45 and 65 years in women. In the US, there is an increased incidence of sarcoidosis in African-Americans, ranging from 18 to 70 per 100 000. Middle-aged African-American women have the highest incidence (107 per 100 000), with African-American women having a lifetime risk of developing the disease of 2.7%[1]. In comparison, the incidence in White individuals in the US ranges from 10 to 14 per 100 000. Sarcoidosis in African-Americans also tends to be more chronic and severe with a higher mortality rate than in other populations[2]. Worldwide, the incidence of sarcoidosis is highest in Sweden (64 per 100 000) and the UK (20 per 100 000) and lowest in Spain and Japan (both 1.4 per 100 000). A greater number of patients with new-onset sarcoidosis are reported in the winter and spring[3].

Pathogenesis

Immune mechanisms

Sarcoidosis is a multisystem granulomatous disease characterized by hyperactivity of the cell-mediated immune system. Patients with a genetic susceptibility are exposed to a triggering antigen, leading to activation of macrophages and T cells, with subsequent granuloma formation. While classically considered a Th1-predominant immune response, the inflammatory cascade in sarcoidosis likely spans multiple pathways, including the innate immune system (via activation of pattern recognition receptors such as Toll-like receptors or NOD-like receptors) and the Th17 arm of the immune system[4,5]. Specifically, $CD4^+$ T helper cells differentiate into Th1 and Th17 effector cells that produce IFN-γ as well as Th17 cells that produce IL-17[1]. This is triggered by antigen presentation by monocytes bearing MHC class II molecules, which initiates formation of epithelioid granulomas in a variety of tissue types[6]. In the lung, an oligoclonal α/β T cell population has been described, suggesting that antigenic triggers of sarcoidosis favor a progressive accumulation and activation of specific T cell clones[7].

Increased production of Th1 cytokines, including interleukin (IL)-2, IL-12, IL-18, and interferon (IFN)-γ, as well as release of tumor necrosis factor (TNF) by macrophages and some $CD8^+$ T cells, leads to persistent Th1 activity and persistent IFN-γ elevation. There is macrophage accumulation and hyperactivity, along with B cell stimulation and hypergammaglobulinemia. TNF and GM-CSF promote fusion of activated macrophages into the multinucleated cells seen within the granuloma[5].

Monocyte chemotactic factor (MCF), produced by activated T helper cells, attracts monocytes from the circulation into peripheral tissues. Compartmentalization of granuloma-forming T lymphocytes and monocytes within peripheral tissues leads to lymphopenia and decreased delayed-type hypersensitivity to common antigens (anergy), most pronounced during the initial stages of sarcoidosis. In addition, T regulatory cells may play a role in this anergic state. However, in some patients, there actually may be inadequate regulatory T cell function such that production of TNF or IFN-γ is not suppressed[8].

As macrophages differentiate into epithelioid cells and antigen-presenting cells, the phagolysosomal pathway plays an important role in sarcoidosis granuloma formation via promotion of mTORc1 (mechanistic target of rapamycin complex 1)/STAT3 signal transduction. In addition, IFN-γ stimulates the JAK (Janus kinase)/STAT pathway (see Fig. 128.11). With the discovery that this pathway plays a key role in

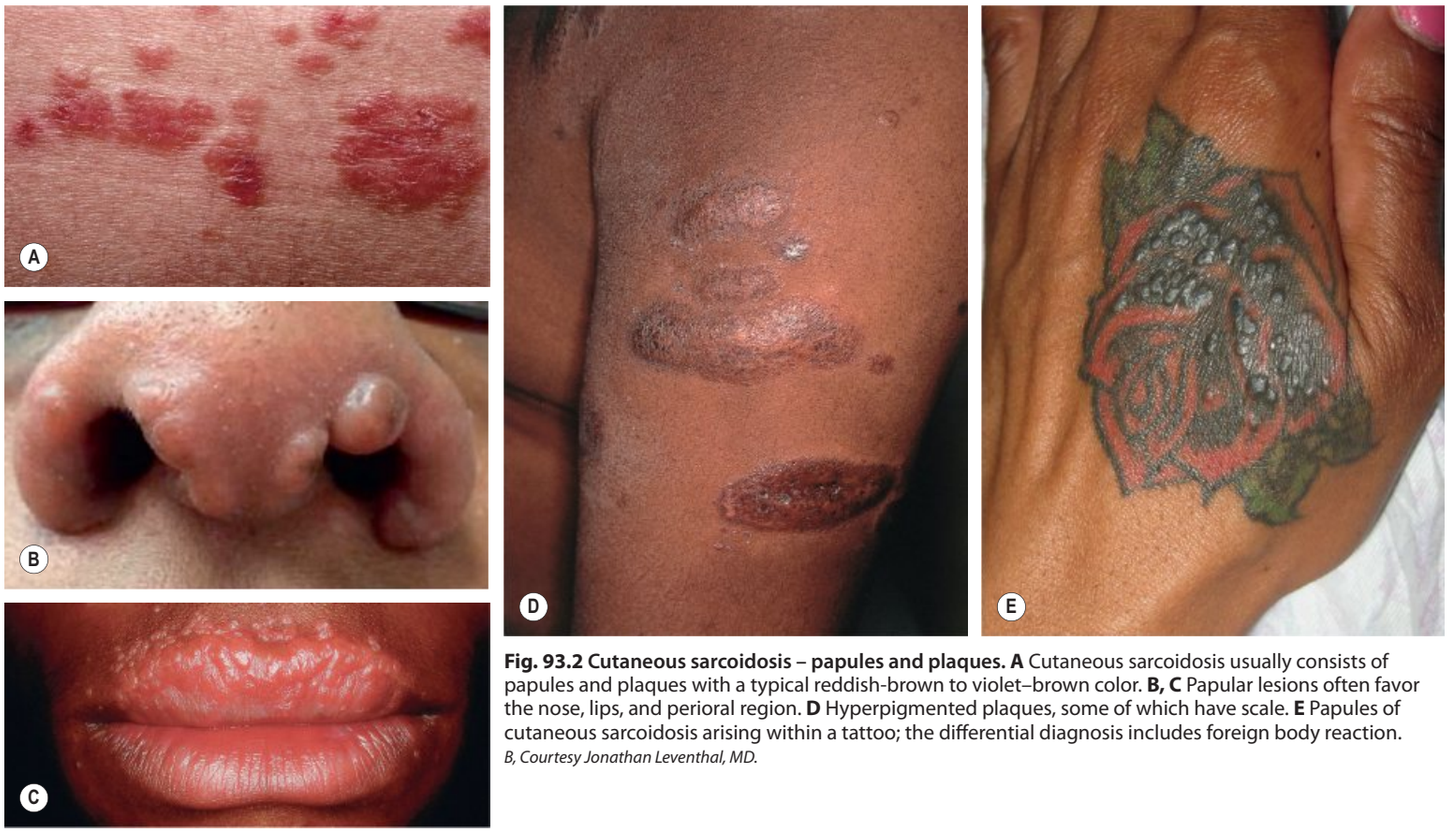

Fig. 93.2 Cutaneous sarcoidosis – papules and plaques. A Cutaneous sarcoidosis usually consists of papules and plaques with a typical reddish-brown to violet–brown color. **B, C** Papular lesions often favor the nose, lips, and perioral region. **D** Hyperpigmented plaques, some of which have scale. **E** Papules of cutaneous sarcoidosis arising within a tattoo; the differential diagnosis includes foreign body reaction. *B, Courtesy Jonathan Leventhal, MD.*

SPECTRUM OF CUTANEOUS MANIFESTATIONS OF SARCOIDOSIS	
Common	
• *Papules* – favor periorificial sites on face	• *Plaques* – favor trunk and extremities
• *Lupus pernio* – favors nose and central face	• Scar-associated – initial insult weeks to decades prior
• *Tattoo-associated* – favors sites of red and yellow pigments	
Uncommon	
• *Annular*	• Atrophic – favors head and neck region
• Lichenoid	• *Psoriasiform*
• Subcutaneous (Darier–Roussy) – favors extremities	
Rare	
• Alopecia – scarring or nonscarring	• *Angiolupoid* – favors face and can mimic rosacea
• Erythrodermic	• *Hypopigmented*
• *Ichthyosiform*	• Micropapular
• Nail dystrophy – subungual hyperkeratosis, onycholysis	• Photodistributed/photo-exacerbated
• Ulcerative	• Verrucous
Nonspecific and common	
• *Erythema nodosum*	

Table 93.2 Spectrum of cutaneous manifestations of sarcoidosis. Photographs of entities in chapter or online in *italics*. *Adapted from Haimovic A, et al. Sarcoidosis: a comprehensive review and update for the dermatologist: part I. Cutaneous disease. J Am Acad Dermatol 2012;66:699.e1–18.*

granuloma formation in a range of disorders including sarcoidosis, JAK inhibitors have become a therapeutic option[9].

Triggers

The identity of the antigen responsible for the cascade of events leading to granuloma formation in patients with sarcoidosis remains uncertain. Some investigators have proposed an autoimmune etiology, while others have searched for exposures to inorganic dusts and particles (e.g. zirconium, talc)[10] or an infectious cause. The latter is suggested by several observations, including the identification of microbial components such as mycobacterial DNA sequences in different sarcoidal tissues[11], the transmissibility of sarcoidal lesions via the Kveim reagent, and the observation that sarcoidal granulomas have developed in patients receiving organ transplants from donors with sarcoidosis. In a meta-analysis, mycobacterial nucleic acids were identified in ~25% of sarcoidal tissues[12]. Also, the catalase-peroxidase (mKatG) protein from *Mycobacterium tuberculosis* has been proposed as a potential triggering antigen for granulomatous inflammation.

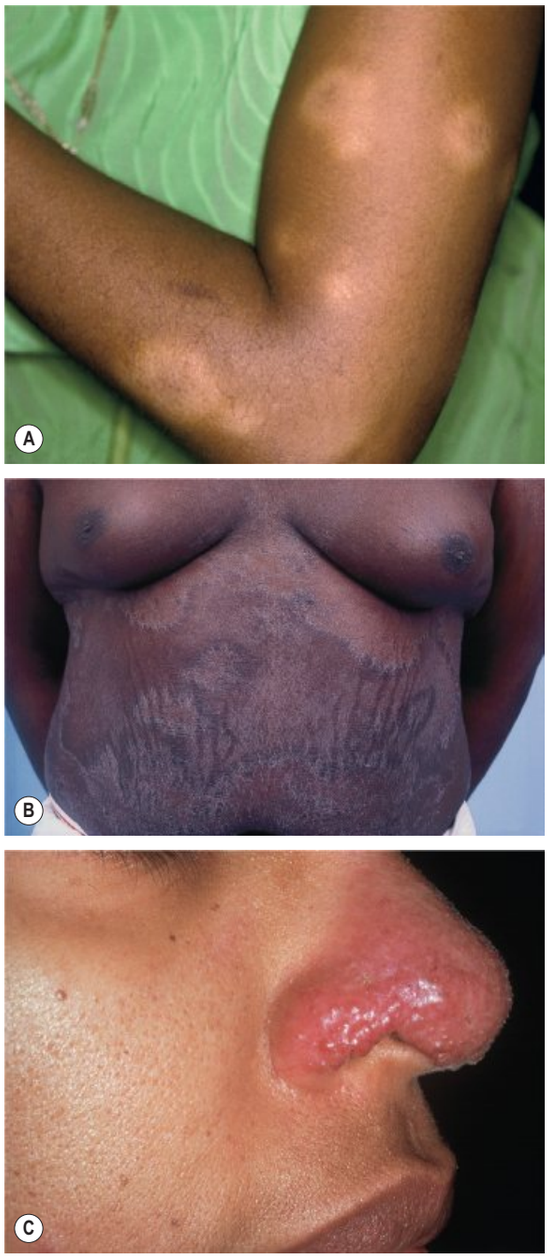

Fig. 93.3 Cutaneous sarcoidosis – clinical variants. A The hypopigmented variant is more noticeable in individuals with darkly pigmented skin. **B** Ichthyosiform presentation with obvious scale. **C** Coalescing violaceous papules on the nose in lupus pernio; note the notching of the nasal rim. *A, Courtesy Louis A. Fragola, Jr, MD; B, Courtesy Jean L. Bolognia, MD.*

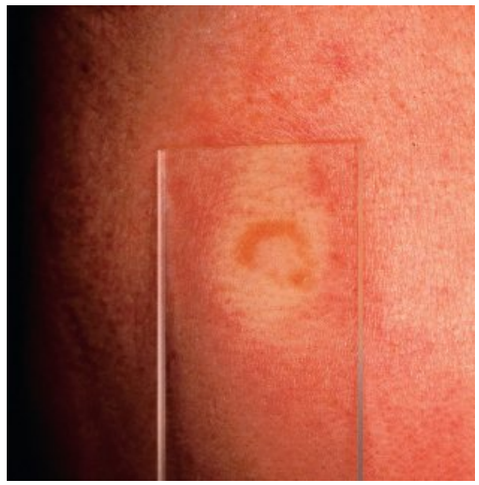

Fig. 93.4 Cutaneous sarcoidosis – diascopy. With diascopy, a yellow–brown, "apple jelly" color is seen.

Fig. 93.5 Erythema nodosum in a patient with sarcoidosis. These patients often have hilar lymphadenopathy. Löfgren syndrome consists of erythema nodosum, hilar lymphadenopathy, fever, and arthritis. *Courtesy Louis A. Fragola, Jr, MD.*

However, arguments against a purely infectious etiology include the observation that sarcoidosis patients do not develop fulminant infectious symptoms when placed on immunosuppressive agents. In addition, mycobacteria have not been cultured from sarcoidal tissues or from the sarcoid-like lesions that develop during antiretroviral-induced immune reconstitution[13]. Occupational associations have been noted in healthcare workers, navy personnel on aircraft carriers, and firemen[11], with a marked increase in sarcoidosis-like illnesses in the first responders to the 9/11 World Trade Center terrorist attacks. In addition, exposure to beryllium can lead to berylliosis, a granulomatous disease that can closely mimic pulmonary sarcoidosis. Additional proposed triggers of sarcoidosis include viruses[14], *Cutibacterium acnes*, and an abnormal accumulation of serum amyloid A (SAA).

Over the past two decades, an increasing number of medications have been reported to induce cutaneous sarcoidosis and sarcoid-like granulomatous eruptions, including IFN, other systemic immunomodulators (e.g. TNF inhibitors > IL-17 inhibitors, IL-1 receptor antagonists), immune checkpoint inhibitors (e.g. ipilimumab, nivolumab, pembrolizumab), and targeted kinase inhibitors (e.g. vemurafenib), as has administration of the SARS-CoV-2 vaccine. Patients with lymphoma may also develop secondary sarcoidal reactions, most commonly in lymph nodes but occasionally in the skin.

Genetics

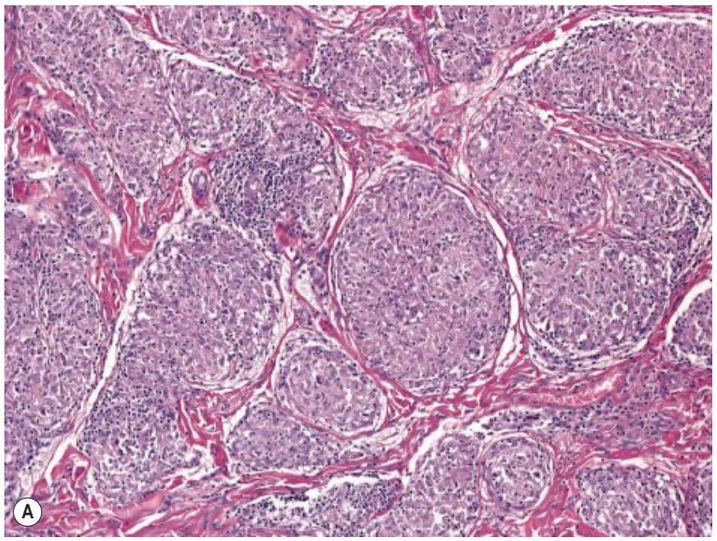
Sarcoidosis is a polygenic not a monogenic disease. A genetic component is supported by a twin study in which the monozygotic twins of patients with sarcoidosis had an 80-fold increased risk of having sarcoidosis[15]. The largest case–control study to date demonstrated a familial relative risk of 4.7[16]. The heritability of sarcoidosis has been estimated to range from 40% to 70%[1]. The impact of HLA alleles varies significantly, depending upon disease subtype and racial group. Overall, HLA-DRB1*01 and DRB1*04 protect against sarcoidosis in some populations, while DRB1*03, DRB1*11, DRB1*12, DRB1*14, and DRB1*15 appear to confer risk[17]; HLA-B8/DR3 may be associated with the development of Löfgren syndrome (see below). In African-Americans, HLA-DQB1 alleles may play a role[17], and patients with DRB1*03 may have a better prognosis. Specific susceptibility genes include *TNF* (variants associated with Löfgren syndrome) and *IL23R* (variants confer risk for Crohn disease and sarcoidosis)[17]. Whole genome sequencing of 41 members of a family with a high rate of sarcoidosis found variants within 34 candidate genes, one of which was *JAK2* (see above)[18].

While the etiologic agent clearly remains elusive, investigation of the immunopathogenesis of the disease (see above) has been aided by examining the cutaneous reaction produced by injection of a tissue suspension prepared from sarcoidal spleen. The suspension (Kveim–Siltzbach antigen) causes characteristic non-caseating granuloma formation in the skin of patients with sarcoidosis[6]. Nowadays, however, this skin test is rarely performed.

Clinical Features

Up to a third of patients with systemic sarcoidosis develop skin lesions, which may be the first or only clinical manifestation of the disease.

Although cutaneous sarcoidosis most commonly presents as papules and plaques, often red–brown to violaceous in color (Figs. 93.2A–D), the skin manifestations are protean (Table 93.2). Sarcoidal lesions are fairly symmetric in distribution and favor the nose, especially the alae, and the periocular and perioral regions of the face, followed by the neck, upper trunk, and extremities. Involvement at sites of prior injuries, e.g. scars, tattoos, is a characteristic finding (Fig. 93.2E). Unusual variants include hypopigmented, ichthyosiform, micropapular, psoriasiform, and ulcerative (Fig. 93.3A,B; see Table 93.2).



Although many lesions are red–brown to violaceous in color, they can vary from yellow–brown to erythematous, especially in lightly pigmented skin. Upon diascopy, in which pressure induces blanching, the lesions are said to have the color of "apple jelly" (Fig. 93.4); this finding is usually easier to appreciate in lightly pigmented skin. Individual plaques can develop central clearing leading to an annular configuration or they can contain prominent telangiectasias (angiolupoid sarcoidosis). Dermoscopic features include small translucent yellow to orange globules, linear vessels, and central scar-like areas.

Additional variants of sarcoidosis of relevance to dermatologists include Löfgren syndrome, Darier–Roussy disease, and lupus pernio. Patients with *Löfgren syndrome* present acutely with fever, arthritis, hilar adenopathy, and erythema nodosum. They often require supportive measures and occasionally systemic corticosteroids, with spontaneous resolution occurring over 1–2 years. Patients with *Darier–Roussy sarcoidosis* present with painless, firm, subcutaneous nodules or plaques without epidermal changes. This variant represents sarcoidosis limited to the panniculus and, like other forms of cutaneous sarcoidosis, is often associated with systemic sarcoidosis. *Lupus pernio* is characterized by papulonodules and plaques, which are often on the nose and cheeks and have a violaceous color, sometimes along with scale;

SYSTEMIC MANIFESTATIONS OF SARCOIDOSIS			
Organ	**% of patients affected**	**Clinical manifestations/radiographic and laboratory findings**	**Evaluation**
Lungs	90–95	Dyspnea, non-productive cough/pulmonary infiltrates, fibrosis, restrictive lung disease (↓VC, ↓RV, ↓TLC, ↓DLCO)	CXR, high resolution chest CT scan (more sensitive than CXR), PFTs that include DLCO
Lymph nodes (LN)	30–40*	Lymphadenopathy/enlarged hilar and/or paratracheal LN	CXR, high resolution chest CT scan (more sensitive than CXR)
Eyes	25	Uveitis (can be asymptomatic despite being severe), conjunctivitis, sicca symptoms	Yearly ophthalmologic examination; more frequently if ocular disease
Liver/spleen	10–20	Hepatomegaly and/or splenomegaly (rarely clinically relevant), cirrhosis, consequences of splenic enlargement (e.g. thrombocytopenia)/↑LFTs, ↓plts	• LFTs, physical examination • If clinically relevant hypersplenism suspected, abdominal/pelvic CT scan (lymphadenopathy common finding)
Heart	25 (10–15 clinically relevant)	Palpitations, sudden death, CHF/arrhythmias, cardiomegaly	• EKG, baseline and if history of palpitations • If any abnormalities, referral to cardiologist as patients may require echocardiogram, Holter monitor, cardiac MRI, or cardiac PET scan
CNS and peripheral nervous system	10–20	Neuropathies – cranial, spinal cord, peripheral, small fiber	• Dictated by symptoms (e.g. MRI, nerve conduction studies) • Referral to neurologist
Upper respiratory tract, including sinuses	5–10	Sinusitus, nasal congestion, stridor, parotiditis	• Referral to otolaryngologist and/or dedicated imaging • Also prompted by presence of lupus pernio
Bones	5–10	Usually asymptomatic/lytic bone lesions	• Radiography • Bone mineral density, especially in the setting of systemic corticosteroid use
Joints/muscles	5–10	Arthritis, weakness (up to a third of patients have severe fatigue), myopathy	• Referral to rheumatologist • EMG
Bone marrow	50	• Lymphopenia (↓$CD4^+$:$CD8^+$ ratio), leukopenia, eosinophilia, hypergammaglobulinemia, nonhemolytic anemia (5%) • Elevated risk of developing lymphoma is debatable†	CBC, SPEP, quantitative immunoglobulins
Kidneys	10–40	Nephrolithiasis/hypercalciuria, ↓renal function	• BUN, crt, serum calcium, spot urine calcium : crt ratio, 24-hour urine for calcium excretion • Referral to nephrologist
Endocrine	5–10	• Pituitary or thyroid dysfunction • Hypercalcemia (increased calcitriol synthesis by sarcoidal histiocytes)	• Thyroid function tests • Expanded hormonal testing when clinically indicated • Serum calcium levels • Measure both 1,25-dihydroxyvitamin D_3 (calcitriol) and 25-hydroxyvitamin D_3 (the latter is the routinely ordered test)
Other	<1 (rare)	• "Masses" – GI tract (luminal), ovarian, testicular – often asymptomatic • Granulomatous breast infiltration that can lead to ulceration	Site-specific imaging

*Pertains to peripheral lymphadenopathy; up to 90% have hilar lymphadenopathy.
†An association is based primarily on two studies, one of which found two cases of lymphoma in 2544 patients with sarcoidosis and the other had a standardized incidence ratio of 1.52 with a CI of 1.12–2.02. Multiple other studies have failed to find an association.

Table 93.3 Systemic manifestations of sarcoidosis. CHF, congestive heart failure; CT, computed tomography; CXR, chest X-ray; DLCO, diffusion lung capacity for carbon monoxide; EMG, electromyography; LFTs, liver function tests; MRI, magnetic resonance imaging; PET, positive emission tomography; PFTs, pulmonary function tests; plts, platelets; RV, residual volume; SPEP, serum protein electrophoresis; TLC, total lung capacity; VC, vital capacity. *Adapted from Chen ES, Moller DR. Sarcoidosis – scientific progress and clinical challenges. Nat Rev Rheumatol 2011;7:457–67 and Haimovic A, Sanchez M, Judson MA, Prystowsky S. there may be a beaded appearance along the nasal rim (see Fig. 93.3C). Recognition of lupus pernio is important because of its association with chronic sarcoidosis of the lungs (~75% of patients) and of the upper respiratory tract (~50% of patients), as well as its recalcitrant nature that often requires more aggressive therapy[19].

The most common and important nonspecific cutaneous manifestation of sarcoidosis is erythema nodosum (Fig. 93.5). In addition to its association with Löfgren syndrome, the presence of erythema nodosum portends a subacute, transient course of sarcoidosis that usually resolves spontaneously and typically does not require chronic immunosuppressive therapy. In general, there are no additional cutaneous manifestations.

Nail changes can be seen in sarcoidosis, including clubbing, subungual hyperkeratosis, and onycholysis. Oral sarcoidosis may affect the soft mucosa, gingival tissue, tongue, hard palate, and major salivary glands. Heerfordt syndrome (uveoparotid fever) includes parotid gland enlargement, uveitis, fever, and cranial nerve palsies, usually of the facial nerve.

Systemic manifestations of sarcoidosis are also protean. Lung disease occurs in ~90% of patients, ranging from alveolitis to granulomatous infiltration of the alveoli, blood vessels, bronchioles, pleura, and fibrous septa[20]. The end stage of pulmonary sarcoidosis is fibrosis with bronchiolectasis and "honeycombing" of the lung parenchyma. Hilar and/or paratracheal lymphadenopathy, which is usually asymptomatic, occurs in 90% of patients. Additional systemic manifestations are outlined in Table 93.3.

Childhood sarcoidosis is rare, and it usually presents with a triad of arthritis, uveitis, and cutaneous lesions, along with constitutional symptoms. Peripheral lymphadenopathy is frequently present. If sarcoidosis is being considered in a child, it is important to exclude Blau syndrome (see Ch. 45).

Pathology

The histopathologic hallmark of sarcoidosis is the presence of superficial and deep dermal epithelioid cell granulomas devoid of prominent infiltrates of lymphocytes or plasma cells ("naked tubercles") (Fig. 93.6). Central caseation is usually absent, although fibrinoid deposition may be observed in up to 10% of cases. Multinucleated histiocytes ("giant cells") are usually of the Langhans type, with nuclei arranged in a peripheral arc or circular fashion. The giant cells may contain eosinophilic stellate inclusions known as asteroid bodies (Fig. 93.7) or rounded laminated basophilic inclusions known as Schaumann bodies, although neither is specific or required for the diagnosis. Asteroid

bodies represent engulfed collagen, whereas Schaumann bodies likely represent degenerating lysosomes. Notably, up to 25% of biopsies of sarcoidosis contain polarizable material; therefore its presence does not exclude the diagnosis. Rarely, the granulomatous infiltrate is arranged in a superficial ("lichenoid") band. In vulvar sarcoidosis, transepidermal elimination of the granulomas may be seen.

A range exists within the histologic spectrum of sarcoidosis, from the characteristic tubercles with minimal or no surrounding lymphocytic inflammation to unusual cases with dense lymphocytic and plasmacytic infiltrates around and within the nodular histiocytic aggregates. Occasionally, these aggregates may extend into the subcutaneous fat, producing the clinical features of Darier–Roussy sarcoidosis.

Diagnosis and Differential Diagnosis

Sarcoidosis is a diagnosis of exclusion, both clinically and histologically. In order to establish the diagnosis, a supportive clinical history must be accompanied by the histologic presence of non-caseating granulomas in at least one organ system. Details of systemic manifestations are outlined in Table 93.3. An algorithm for initial and longitudinal evaluation has been proposed[21].

Serologically, elevated anti-nuclear antibody titers occur in ~30% of patients. The serum angiotensin-converting enzyme (ACE) level is elevated in ~60% of patients but is nonspecific for sarcoidosis; it has a false-positive incidence of 10%, making it a more useful test for monitoring disease progression in select patients where it is elevated, rather than for establishing the diagnosis. An ACE level >2–3 times the upper limit of normal is more suggestive of sarcoidosis but its clinical utility may still be limited. In sum, most sarcoidosis experts do not routinely order ACE levels.

Like syphilis, sarcoidosis is a great mimicker, and the clinical differential diagnosis depends upon the type of presenting clinical lesions. For example, a list of other disorders, in addition to sarcoidosis, that can present with annular lesions is provided in Table 19.1. Papules, nodules, and plaques may be nonspecific clinically, dictating a biopsy, and then the differential diagnosis rests upon the histopathologic findings. It is important to exclude the possibility of drug-induced cutaneous sarcoidosis (e.g. IFN-α for hepatitis C viral infection [use declining], TNF inhibitors, immune checkpoint inhibitors) (Fig. 93.8).

The histologic differential diagnosis is broad, and includes multiple infections that lead to granulomatous inflammation. Special stains for acid-fast and fungal organisms should be obtained. When clinically appropriate, tissue culture should be performed. Increasingly, PCR is being utilized to exclude infections, including mycobacterial. Both tuberculoid leprosy and lupus vulgaris are in the differential diagnosis and for the latter, a QuantiFERON®-TB Gold test may provide additional information. It is especially important to exclude infectious etiologies before initiating immunosuppressive agents.

Other histologic mimics include foreign body reactions to zirconium, beryllium, silica, tattoo ink, or soft tissue fillers. Special laboratory techniques, including histochemical, microincineration or spectrophotometric examinations, may be required to identify the causative agents (see Table 94.3). Specimens should be polarized to exclude birefringent foreign material as a causative agent, although up to 25% of known sarcoidal granulomas will have foreign material present within them. This finding is particularly common in lesions from the elbows and knees. Therefore, the dermatologic diagnoses of foreign body granuloma and sarcoidosis are not mutually exclusive[22].

In addition, granulomatous mycosis fungoides, Hodgkin disease, granulomatous rosacea, cutaneous Crohn disease, Blau syndrome (see Ch. 45), cheilitis granulomatosa, and the sarcoidal reaction to an underlying lymphoma can have histologic appearances similar to sarcoidosis. The histologic differences between sarcoidosis, granuloma annulare, annular elastolytic giant cell granuloma (AEGCG), necrobiosis lipoidica, rheumatoid nodule, and the reactive granulomatous dermatitides are outlined in Table 93.4.

HISTOLOGIC FEATURES OF THE MAJOR NON-INFECTIOUS GRANULOMATOUS DERMATITIDES

	Sarcoidosis	Granuloma annulare	AEGCG	Necrobiosis lipoidica	Cutaneous Crohn disease	Reactive granulomatous dermatitis		Rheumatoid nodule*
						Interstitial granulomatous dermatitis	Palisading neutrophilic and granulomatous dermatitis	
Typical location	Superficial and deep dermis†	Superficial and mid dermis†	Superficial and mid dermis	Entire dermis, subcutis	Superficial and deep dermis	Mid and deep dermis	Entire dermis	Deep dermis, subcutis
Granuloma pattern	Tubercle with few peripheral lymphocytes ("naked")	Palisading or interstitial; patchy with discrete foci	Palisading, irregular	Diffuse palisading and interstitial‡; horizontal "tiers"	Tubercle with surrounding lymphocytes	Interstitial and small "rosettes" around single collagen fibers	Palisading and interstitial; prominent neutrophils and leukocytoclasia	Palisading
Necrobiosis (altered collagen)	No	Yes ("blue")	No	Yes ("red")	No	Yes ("blue")	Yes ("blue")	Yes ("red")
Giant cells	Yes	Variable	Yes	Yes	Yes	Variable	Variable	Yes
Elastolysis	No	Variable	Yes	Variable	No	Variable	Variable	No
Elastophagocytosis	No	Variable	Yes	No	No	No	No	No

Vascular changes	No	Rare	No	Yes	No	No	Yes	Yes

*See Ch. 45.
†Subcutaneous variant can also occur.
‡Rare sarcoidal variants seen.
¶Even amid areas of uninvolved dermis.

Table 93.4 Histologic features of the major non-infectious granulomatous dermatitides. Interstitial granulomatous dermatitis and palisading neutrophilic and granulomatous dermatitis are thought to fall within the spectrum of reactive granulomatous dermatitis. Tan-shaded column is not covered in this chapter. AEGCG, annular elastolytic giant cell granuloma.

TREATMENT OF CUTANEOUS SARCOIDOSIS
Topical or intralesional corticosteroids (2)
Topical calcineurin inhibitors (3)
Oral tetracyclines (e.g. minocycline, doxycycline) (2)
Oral hydroxychloroquine or chloroquine (2)
Methotrexate (2)
TNF inhibitors (adalimumab, infliximab)* (1)
Systemic corticosteroids (2)
Thalidomide (2)
Phosphodiesterase inhibitors (pentoxifylline, apremilast) (2)
Leflunomide (2)
JAK inhibitors (2)
Azathioprine (3)
Intralesional chloroquine (3)
Allopurinol (3)
Isotretinoin (3)
PUVA (psoralen plus UVA) (3)
Mycophenolate mofetil (3)
Antimycobacterial therapy (levofloxacin, ethambutol, azithromycin, and rifampin) (1)
Pulsed dye or CO_2 laser (3)
Photodynamic therapy (3)
Surgical excision (3)
*Can rarely trigger sarcoidosis, particularly etanercept.

Table 93.5 Treatment of cutaneous sarcoidosis. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. TNF, tumor necrosis factor.
Adapted from Wanat KA, Rosenbach M. A practical approach to cutaneous sarcoidosis. Am J Clin Dermatol 2014;15:283–97.

Treatment

Corticosteroids, in either topical, intralesional, or systemic form, are the mainstay of therapy for systemic sarcoidosis (Table 93.5). Therapy is guided by organ involvement, disease severity and progression, and impact on patient quality of life. The typical oral prednisone dose for systemic disease is 0.5–1 mg/kg/day for 4–6 weeks, followed by a slow taper over months to years as dictated by the pulmonary disease, sarcoidosis of the upper respiratory tract, ocular disease, or other internal manifestations. The goal is alternate-day prednisone at the lowest possible dose that will maintain a remission. Cutaneous sarcoidosis may respond from the onset to lower doses of prednisone as well as every-other-day regimens. For limited cutaneous disease, topical or intralesional corticosteroids may suffice.

For treatment of more widespread cutaneous disease, alternative nonsteroidal systemic medications include hydroxychloroquine (200–400 mg/day), chloroquine (250–500 mg/day), minocycline or doxycycline (200 mg/day), and methotrexate (10–25 mg weekly). The use of thalidomide has declined, given recent negative studies, associated toxicities, and more effective alternative therapies. Improvement of both systemic and cutaneous sarcoidosis has been observed with TNF inhibitors, including infliximab and adalimumab[23]. These agents may be particularly effective for chronic, recalcitrant sarcoidosis (e.g. lupus pernio), but notably TNF inhibitors occasionally can trigger sarcoidosis (most commonly etanercept)[24,25]. In selected patients, pentoxifylline, retinoids, and apremilast have been reported to be helpful. While additional immunosuppressives (e.g. leflunomide, mycophenolate mofetil, azathioprine) are more often used for extracutaneous sarcoidosis, they may have a role in some patients. A treatment algorithm, based upon evidence-based methodology, has been proposed[21]. More recently, sustained responses have been observed with oral JAK inhibitors such as tofacitinib[9].

GRANULOMA ANNULARE

Synonyms: ■ Pseudorheumatoid nodule – subcutaneous granuloma annulare variant ■ Generalized granuloma annulare – disseminated granuloma annulare

Key features

- Small grouped papules assuming an annular configuration, often in a symmetrical and acral distribution
- Seen primarily in children and young adults
- Clinical variants include localized, generalized, and subcutaneous forms
- Possible associations with systemic diseases, including diabetes mellitus, hyperlipidemia, thyroid disease, and rarely HIV infection, remain controversial
- Histologically, there is an infiltrative or palisading granulomatous dermatitis with focal degeneration of collagen and elastin and deposition of mucin

History

Calcott Fox first described "ringed eruption of the fingers" in 1895. Radcliffe-Crocker called this entity granuloma annulare (GA) in 1902. Some authors consider annular elastolytic giant cell granuloma (AEGCG) to be a variant of GA; in 1975, O'Brien first referred to this entity as actinic granuloma and then it was renamed AEGCG by Hanke et al.[26] in 1979. Previous names included atypical (annular) necrobiosis lipoidica of the face and scalp[27], Miescher's granuloma of the face[28], and possibly granuloma multiforme[29]. Although controversy continues regarding the role of actinic damage in AEGCG and whether it is simply a variant of GA[30], in this chapter it will be considered a variant.

Epidemiology

Granuloma annulare typically presents during the first three to five decades of life. Subcutaneous GA occurs more commonly in children, whereas generalized GA is more often observed in older patients. While uncommon it is not a rare disease, representing 0.1%–0.4% of visits to dermatologists in several single-center studies. The female-to-male ratio is over 2 : 1, and GA is diagnosed more frequently in White patients. Compared to GA, AEGCG tends to occur in an older population.

Pathogenesis

The etiology of GA is unknown. Trauma, insect bite reactions, tuberculin skin testing, vaccination, UV exposure, *Borrelia*, and a number of viral infections have all been proposed as inciting factors[31,32]. Based on the T cell subpopulations identified in GA lesions, a delayed-type hypersensitivity reaction to an unknown antigen has been postulated as the precipitating event[33]. Morphologic similarities to other granulomatous processes suggest that GA is caused by a Th1 inflammatory reaction, with elevations in IL-2R-positive lymphocytes, IFN-γ-producing lymphocytes, and TNF production by macrophages[34,35]. These lymphocytes release cytokines, including macrophage inhibitory factor, that cause monocytes to accumulate within the dermis and release lysosomal enzymes that can degrade connective tissue[36]. In addition to inflammatory gene signatures associated with Th1 and innate immunity, when lesional skin was compared to non-lesional skin, there was upregulation of Th2 cytokines (IL-4, IL-31) and the JAK/STAT pathway (see Fig. 128.11)[37]. As with sarcoidosis (see above), this latter pathway is thought to play an important role in granuloma formation. As with other granulomatous disorders, elastophagocytosis may be observed in GA, but this most likely represents a secondary phenomenon.

Familial cases of GA have been reported, including cases in identical twins, and one small study suggested that an association may exist between generalized GA and HLA-Bw35[38]. Vessel-based mixed inflammatory cell infiltrates with endothelial swelling are sometimes detected in routine histopathologic specimens, and direct immunofluorescence studies of GA may show vessel-based deposits of immunoreactants, but a role for these findings in the pathogenesis of this disease has not been established.

Granuloma annulare has also been described in association with various medications including systemic immunomodulators (e.g. TNF

inhibitors, secukinimab, tocilizumab)[39], antiepileptics (levetiracetam, topiramate), amlodipine, thalidomide, allopurinol, and paroxetine[40]; the latter was in a photodistribution. The granulomatous eruptions seen with increasing frequency following administration of immune checkpoint inhibitors include GA as well as sarcoidosis[41].

With regard to AEGCG, its pathogenesis is not well understood but may be related to inflammation precipitated by actinic damage. Specifically, O'Brien postulated that "a state of auto-aggression develops in relation to the damaged [elastic] fibers", in an attempt to repair or remodel damaged skin. Infiltrating T lymphocytes are predominantly of the helper subset, suggesting that the pathogenesis may involve a cell-mediated immunologic response to a weakly antigenic determinant on altered elastotic fibers[30]. However, destruction of elastic tissue has also been observed in classic GA and necrobiosis lipoidica, leading to the argument that this finding may represent a secondary event caused by the granulomatous inflammation rather than a precipitating one, and occasionally, a patient may have both AEGCG and necrobiosis lipoidica or sarcoidosis[26].

Clinical Features

GA is a benign, usually self-limited, cutaneous disease that presents as arciform to annular plaques on the dorsal hands or feet of young people (Fig. 93.9)[32]. However, there is a wide array of clinical presentations, from a papular form to lesions that are subcutaneous, macular (patch form), or have central perforation (Fig. 93.10). Distribution patterns also vary, from localized to occasionally photodistributed or generalized/disseminated (see Fig. 93.10C)[40,42]. In general, the distribution of GA is: 60% isolated to the hands and arms, 20% on the legs and feet, 7% on both upper and lower extremities, 5% on the trunk, and 5% on the trunk plus other areas[43]. Facial lesions are rare. The plaques may be skin-colored, pink, or violaceous in color, and, upon close inspection, are found to be composed of individual small papules measuring a few millimeters in diameter. The lesions are usually asymptomatic.

In *generalized/disseminated* GA, the widespread, symmetrically distributed lesions can be annular plaques or discrete papules and they favor the trunk and/or extremities. This form is uncommon and has a later age of onset, poorer response to therapy, and an increased prevalence of the HLA-Bw35 allele. In one study of 100 patients with generalized GA, 45% had lipid abnormalities, including hypercholesterolemia, hypertriglyceridemia or both, while ~20% had diabetes mellitus[42]. Thyroid disease has been reported in ~25% of patients with GA.

Deep dermal or *subcutaneous* GA manifests as large, painless, skin-colored nodules which may be mistaken for rheumatoid nodules, leading to the term pseudorheumatoid nodule (see Fig. 93.10E). It has a predilection for children <6 years of age. Typical locations include the palms, hands, anterior tibial surfaces and feet, as well as the buttocks, scalp, and rarely the eyelids[32]. As many as 50% of individuals with deep GA lesions also have associated classic lesions.

In *perforating* GA, the small papules have central umbilication, scale-crust or focal ulceration, and they occur primarily on the dorsal hands and fingers (see Fig. 93.10A). This variant occurs in up to 5% of patients with GA, and histologically transepidermal elimination of degenerating collagen is seen[44]. While umbilicated GA has been described, it probably represents a variant of perforating GA.

Patch GA is a distinct, unusual variant that is characterized by patches of erythema on the extremities and trunk. Symmetrical lesions on the dorsum of the feet often present as macular (i.e. "patch") disease. Although an annular configuration may be absent, presence of the classic histopathologic findings of interstitial GA (see below) allow for the diagnosis to be made microscopically.

Patients with *AEGCG* have medium-sized to large annular plaques with a raised erythematous border (3–5 mm) and a slightly atrophic, hypopigmented center, distributed primarily in chronically sun-exposed areas (Fig. 93.11). The sites of predilection include the neck, face, upper trunk, and arms. Early on, skin-colored or pink papules may appear, either singly or in small groups, which then coalesce into annular plaques. Scale is rarely observed. In contrast to necrobiosis lipoidica, there is an absence of yellow color, telangiectasias, or associated alopecia. Individual lesions measure 1–10 cm in diameter, and the total number of lesions is generally fewer than 10. Patients are usually asymptomatic, although pruritus has been reported. A single plaque lasts for months to years, after which spontaneous remission may occur, leaving mottled dyspigmentation or normal-appearing skin. Conjunctival lesions with similar clinical and histologic features have also been described[45].

Rarely, GA has been reported as a possible paraneoplastic granulomatous reaction to solid organ tumors, Hodgkin disease, non-Hodgkin lymphoma, or granulomatous mycosis fungoides[46–49]. In these patients, the clinical pattern is frequently atypical, with painful lesions in unusual locations, including the palms and soles. In a literature review and in a case–control study, a relationship between GA and malignancy was not identified; however, patients with atypical presentations may warrant a complete physical exam with focused, age-appropriate screening[50,51]. While *photodistributed* GA has been reported, some of these patients may have had AEGCG.

Many reports either supporting or refuting the association of GA with diabetes mellitus have been published, but to date there have been no large-scale epidemiologic studies. In a retrospective study of 84 patients, 12% were found to have diabetes mellitus, and these patients were more likely to suffer from chronic relapsing GA than were non-diabetic patients[52]. In a larger retrospective study of 1383 patients, diabetes mellitus was diagnosed in ~20% of patients with generalized GA, compared with ~10% of patients with localized GA[42]. However, in a case–control study of 126 patients, an association was not identified[53].

Fig. 93.9 Granuloma annulare – clinical features. A–D Annular pink to pink–brown plaques. The dorsal aspects of the hands and feet are a common location. Lesions can be skin-colored as well as pink (**C**). Grouped discrete papules may also be seen, with a more subtle annular or arciform configuration (**A,C**). *C, Courtesy Julie V. Schaffer, MD; D, Courtesy Kalman Watsky, MD.*

Fig. 93.10 Granuloma annulare (GA) – less common variants. Rapini, MD; B, Courtesy Joyce Rico, MD; C, Courtesy Luis Requena, MD; D, Courtesy Kalman Watsky, MD; E, Courtesy Department of Dermatology, Medical University of Graz.*

An increased incidence of thyroid disease, in up to 25% of patients, has been described.

Classic GA and perforating GA may develop within herpes zoster scars (see Table 80.7)[54] and following BCG vaccinations. Atypical variants of GA, including photodistributed, have been associated with HIV infection[55]. Additional reported associations, based upon small studies, include hepatitis, post-vaccination, and post-SARS-CoV-2 infection[40]. Rarely, based upon case reports, AEGCG has been observed in patients with lymphoma or leukemia[56,57].

Pathology

GA is a granulomatous dermatitis characterized by focal degeneration of collagen and elastic fibers, mucin deposition, and a perivascular and interstitial lymphohistiocytic infiltrate in the upper and mid dermis. The key to the histopathologic diagnosis of GA is the presence of mucin plus the identification of histiocytes in one of two patterns. The most common is the interstitial or infiltrative pattern, in which scattered histiocytes are distributed between collagen fibers (Fig. 93.12). Degeneration of collagen fibers is minimal, but granular, basophilic mucin deposition between collagen bundles can be highlighted with Alcian blue and colloidal iron stains[36]. The second pattern is more obvious and is easier to diagnose. It consists of one to several palisading granulomas characterized by central connective tissue degeneration surrounded by a rim ("palisade") of histiocytes and lymphocytes (Fig. 93.13). Mucin is abundant in the center of the palisaded granuloma, and fibrin, neutrophils, and nuclear dust may also be present. Rarely, a prominent ("pseudolymphomatous") lymphoid infiltrate is seen.

Increased mucin can be detected in ~90% of biopsy specimens from GA lesions. The sensitivity of detection is increased by using at least two different mucin stains, such as colloidal iron and Alcian blue. Elastic tissue is reduced or absent within the histiocytic aggregates in ~20% of generalized GA and 35% of localized GA cases[58]. Collagen degeneration is more common in localized GA than in generalized GA[58], and elastophagocytosis is occasionally noted, but not as often as in AEGCG.

As noted previously, vascular changes in GA are variable, but include fibrin, C3, and IgM deposition in vessel walls (detected by direct immunofluorescence) and occlusion of vascular lumina[59]. One study found that the presence of leukocytoclastic or granulomatous vasculitis or a thrombotic vasculopathy within the lesions of GA was predictive of associated systemic disease[60], and the possibility of palisading neutrophilic and granulomatous dermatitis as a reflection of disorders such as rheumatoid arthritis needs to be considered.

Subcutaneous GA is characteristically a septal panniculitis with palisaded granulomatous inflammation and it can closely mimic a rheumatoid nodule histologically. An interstitial pattern is not observed in this form of GA. In *perforating* GA, there is a superficial histiocytic infiltrate with transfollicular and/or transepidermal elimination of granulomatous inflammation and degenerated collagen.

In *AEGCG*, a non-palisading granulomatous infiltrate composed of histiocytes, foreign body-type multinucleated giant cells (with haphazardly arranged nuclei), and lymphocytes is present within the mid to upper dermis; there is an absence of altered collagen or mucin or lipid deposition[61]. Elastic fibers are identified adjacent to and within the giant cells (elastophagocytosis; Fig. 93.14). Elastophagocytosis and asteroid bodies can be seen less frequently in other granulomatous disorders such as GA and necrobiosis lipoidica and therefore they are not specific for AEGCG. Elastic tissue stains, such as Verhoeff–van Gieson, show a characteristic complete absence of elastic fibers in the areas affected (or previously affected) by granulomatous inflammation. There is a sparse perivascular lymphocytic infiltrate, but no vascular changes.

Differential Diagnosis

GA is diagnosed based on its clinical and histopathologic features – there are no laboratory tests which aid in confirming the diagnosis.

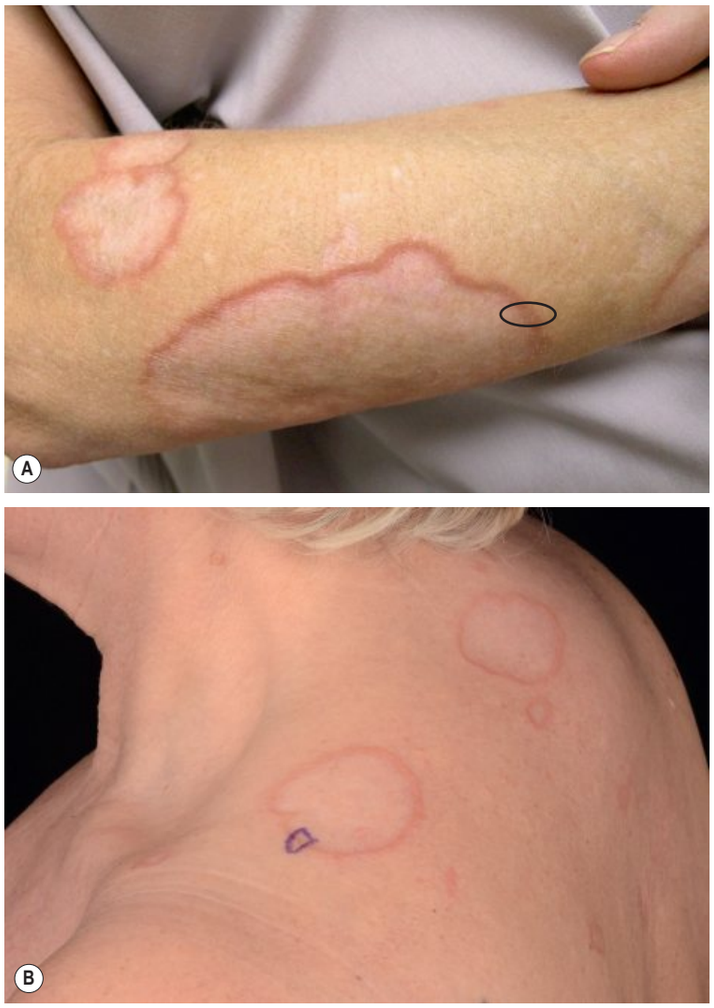

Fig. 93.11 Annular elastolytic giant cell granuloma – clinical features. A, B The inflammatory border resembles granuloma annulare but the central portion is hypopigmented and/or atrophic. A biopsy specimen that includes the areas outlined would contain the three characteristic histologic zones: absence of elastic fibers, granulomatous inflammation, and normal skin. Longitudinal sectioning of the surgical specimen is preferred. *B, Courtesy Department of Dermatology, Medical University of Graz.*

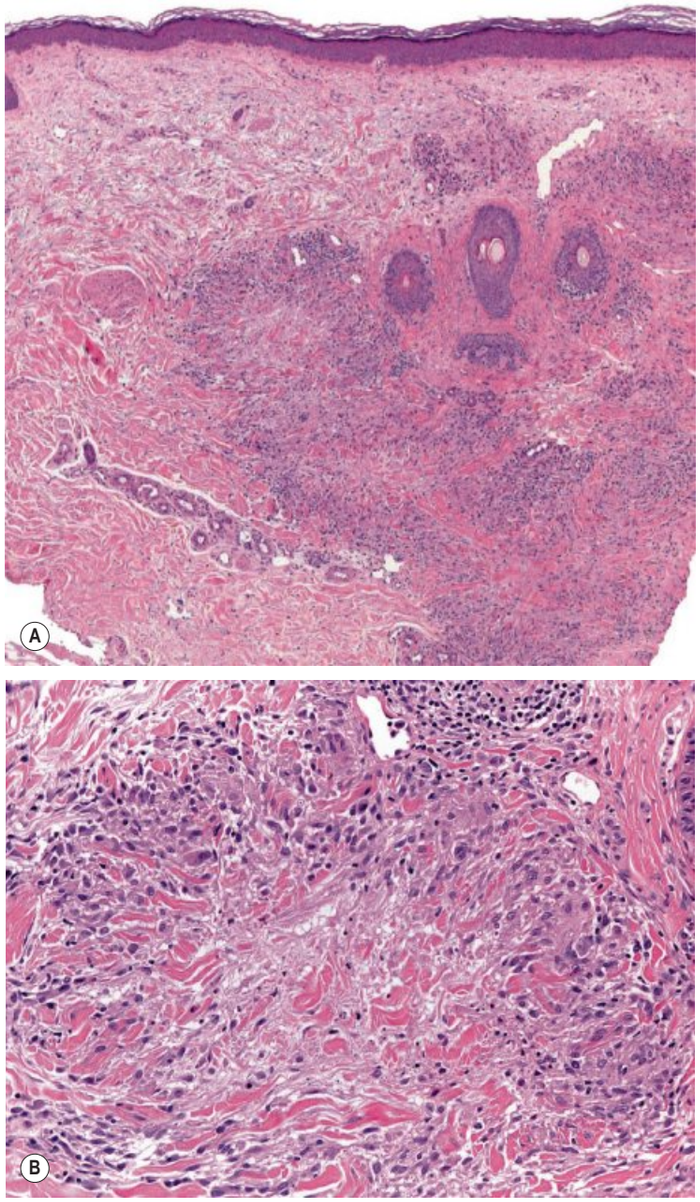

Fig. 93.13 Granuloma annulare – palisading granuloma pattern. A Multiple palisaded granulomas within the dermis. Degenerative collagen and mucin deposition are present in the central portion of the granulomas. **B** A palisaded granuloma with epithelioid histiocytes surrounding an anuclear dermis characterized by altered collagen and pallor due to deposition of acid mucopolysaccharides/glycosaminoglycans (mucin). *Courtesy Lorenzo Cerroni, MD.*

When the diagnosis of deep GA versus rheumatoid nodule is in question, rheumatoid factor and anti-cyclic citrullinated peptide antibody levels can aid in identifying patients at risk for the latter. Rheumatoid nodules also demonstrate fibrin rather than mucin histologically.

The clinical differential diagnosis for conventional GA includes the annular entities listed in Table 19.1, including annular sarcoidosis and AEGCG. A clue to the latter is central hypopigmentation and/or atrophy. Arcuate and annular plaques of mycosis fungoides or borderline leprosy may also simulate GA, requiring biopsy for definitive diagnosis.

Papular GA can simulate flat warts, secondary syphilis, early eruptive xanthomas, and the non-X-histiocytoses (see Ch. 91). *Subcutaneous* GA can be clinically similar to rheumatoid nodules, the nodules of rheumatic fever, tendinous xanthomas, epithelioid sarcoma, subcutaneous sarcoidosis, idiopathic granulomatous mastitis, and deep granulomatous infections. *Perforating* GA must be differentiated from primary perforating disorders (see Ch. 96) and, occasionally, perforating calcinosis cutis, perforating gout, or molluscum contagiosum[32].

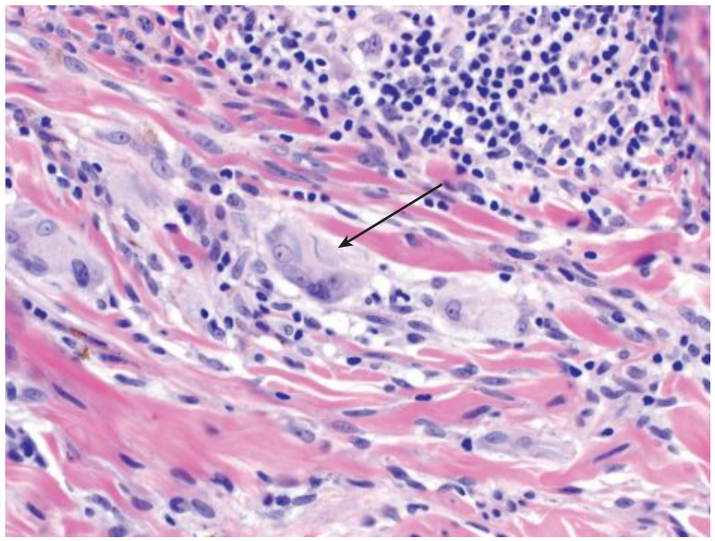

Fig. 93.14 Annular elastolytic giant cell granuloma – histopathological features. A dermal inflammatory infiltrate with several histiocytic giant cells. The presence of a fragmented elastic fiber within a giant cell (elastophagocytosis) is a characteristic finding (arrow).

TREATMENT OF GRANULOMA ANNULARE
Local therapy
Topical corticosteroids (2)
Intralesional corticosteroids (2)
Cryosurgery (2)
Topical calcineurin inhibitors (3)
Topical imiquimod (3)
Topical JAK inhibitors (3)
Phototherapy (NB UVB, PUVA, UVA1) (2)
Photodynamic therapy with topical 5-aminolevulinic acid (2)
Lasers: CO_2, pulsed dye (585 nm), excimer (308 nm) (3)
Electrodesiccation (3)
Surgical excision (3)
Intralesional interferon-γ (3)
Systemic therapy
Hydroxychloroquine or chloroquine (2)
Dapsone (2)
Niacinamide (nicotinamide) (3)
TNF inhibitors (adalimumab, infliximab) (2)
Pentoxifylline (2)
Methotrexate (2)
JAK inhibitors (3)
Retinoids (isotretinoin, acitretin) (3)
Apremilast (3)
Minocycline + ofloxacin + rifampin* (3)
Prednisone (3)
Dupilumab (3)
5-lipoxygenase inhibitor (zileuton) plus vitamin E† (3)
Cyclosporine (3)
Fumaric acid esters (3)
*Administered monthly: minocycline (100 mg), ofloxacin (400 mg) and rifampin (600 mg) × 3 months; improvement not observed in subsequent studies.
†Doses of 2400 mg po daily (zileuton) and 400 IU po daily (vitamin E).

Table 93.6 Treatment of granuloma annulare. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. NB UVB, narrowband ultraviolet B; PUVA, psoralens plus ultraviolet A; UVA, ultraviolet A. From references 40, 42, 63, 64, 66, 69a, 69b, and 69c.

The clinical and histologic differences between GA, sarcoidosis, AEGCG, necrobiosis lipoidica, rheumatoid nodule, and reactive granulomatous dermatitides are outlined in Tables 93.1 and 93.4. The histopathologic differential diagnosis of GA also includes morphea, cutaneous T cell lymphoma, xanthomas, epithelioid sarcoma and, rarely, scleromyxedema. Lastly, the possibility of drug-induced GA needs to be considered.

Treatment

Given the self-limited and benign nature of GA, reassurance and clinical observation may be the treatment of choice for localized, asymptomatic disease. High-potency topical corticosteroids with or without occlusion and intralesional corticosteroid injections are the usual first-line local therapies. Cryosurgery, photodynamic therapy, pulsed dye laser, and topical tacrolimus may also be effective. For more extensive disease, systemic medications can be considered including: (1) anti-inflammatory drugs or immunomodulators (e.g. antimalarials, tetracycline-class antibiotics, pentoxifylline, niacinamide, dapsone, apremilast, retinoids); (2) phototherapy – PUVA, NB-UVB, or UVA1 (especially patch variant[62]); and (3) immunosuppressants (TNF inhibitors, with adalimumab most often reported), while weighing the risk:benefit ratio (Table 93.6)[40,42,63–69]. In patients with photodistributed GA, oral medications such as dapsone are preferred over phototherapy. More recently, topical JAK inhibitors (e.g. compounded tofacitinib 2% ointment) have been used to treat GA as have oral JAK inhibitors.

Spontaneous resolution of GA occurs within 2 years in 50% of patients, but there is a 40% recurrence rate. The recurrent lesions tend to occur at the original sites, but clear more rapidly (80% within 2 years). The duration of untreated lesions has been reported to range from a few weeks to several decades[70].

NECROBIOSIS LIPOIDICA

Synonym: ■ Necrobiosis lipoidica diabeticorum (NLD)

Key features

- Plaques with violaceous to red–brown, palpable peripheral rims and yellow–brown atrophic centers with telangiectasias
- The most common site is the shins
- Ulceration can occur following trauma
- The proportion of patients with diabetes mellitus varies from 15% to 65%, but there is a strong association
- Pathogenesis is unknown
- Pathology shows a palisading granulomatous dermatitis with histiocytes and altered collagen that has a "layered" appearance and is often accompanied by perivascular plasma cells

History

First called "dermatitis atrophicans diabetica" by Oppenheim in 1929, the condition was renamed necrobiosis lipoidica diabeticorum by Urbach in 1932. The first non-diabetic patient with this condition was described in 1935 by Goldsmith, generating the more general term necrobiosis lipoidica (NL), which is currently the preferred term.

Epidemiology

NL typically occurs in young to middle-aged adults, with a female:male ratio that ranges from 3:1 to 8:1, depending on the study[71–73]. Diabetic patients present at a younger age than those without diabetes, e.g. in a multicenter study, the mean ages were 45 years and 52 years, respectively[71]. In a study of 171 patients with NL, diabetes mellitus, usually type 1, was present in ~65%; an additional 12%–15% had abnormal

glucose tolerance tests[72]. Also, over half of the patients with no evidence of diabetes and a normal glucose tolerance test reported a positive family history of glucose intolerance[72,73]. However, a more recent retrospective study of 65 patients with NL seen in a dermatology outpatient clinic found that only 11% had type 1 or type 2 diabetes mellitus at the time of presentation. An additional 11% were later diagnosed with impaired glucose tolerance or diabetes[74].

Only 0.3% of patients with diabetes develop NL. However, there is no proven connection between a patient's level of glycemic control and the likelihood of developing NL lesions. Diabetic patients with NL may or may not have a higher rate of diabetes-related complications such as peripheral neuropathy, retinopathy, and limited joint mobility, again depending upon the study[75]. In retrospective reviews, thyroid dysfunction was noted in 15%–25% of patients with NL[71,76].

Pathogenesis

The cause of NL remains unknown. Immunologically mediated vascular disease has been suggested as the primary cause of the altered collagen seen in NL. This hypothesis is supported by the presence of immunoreactants deposited in vessel walls of lesional and uninvolved skin in patients with NL[77]. Previous immunofluorescence studies had also found evidence for immune complex vasculitis in NL[78]. In addition, it has been postulated that the microangiopathic vessel changes seen in diabetic patients could contribute to the development of collagen degeneration and subsequent dermal inflammation. A shared pathogenesis would provide an explanation for the high rate of complications such as retinopathy observed in some series of patients with NL.

When lesions favor the lower extremities of adults, venous hypertension as a contributing factor needs to be considered. Both venous insufficiency and hyperlipidemia have been proposed as triggers that incite an inflammatory cascade in some patients[79]. Elevated plasma levels of fibronectin, factor VIII-related antigen, and α_2-macroglobulin have been detected in patients with NL, but the significance of these findings has not been determined[80]. Theories regarding abnormally elevated platelet adhesion, increased thromboxane A_2 production, and increased blood viscosity within NL lesions remain speculative.

Some investigators consider NL to be primarily a disease of collagen, with inflammation occurring as a secondary event. Anti-collagen antibodies have been detected in patients with both NL and GA, but no significant increase in antibody levels as compared with control patients has been demonstrated[81]. The concentration of collagen is decreased in NL lesions, and electron microscopy reveals a loss of the cross-striations of collagen fibrils and significant variation in the diameter of individual fibrils. Fibroblasts cultured from NL lesions synthesize less collagen than their counterparts from unaffected skin[82]. Although there are fewer collagen fibers overall, areas of fibrosis are seen. Overhydration of collagen due to hyperglycemia can lead to increased collagen cross-linking and stiffness, but it is unclear if this phenomenon occurs in NL.

From central Europe, there was a report of the detection of *Borrelia* spp. via focal floating microscopy in NL[83], but these findings need to be confirmed.

Clinical Features

Necrobiosis lipoidica is characterized by yellow–brown, atrophic, telangiectatic plaques with an elevated violaceous rim, most often in the pretibial region (Fig. 93.15). The plaques are usually multiple and bilateral. Lesions start as small, firm, red–brown papules that gradually enlarge and then develop central epidermal atrophy. Ulceration has been reported in 15%–35% of patients (see Fig. 105.20D), usually following minor trauma. Development of lesions secondary to Koebner phenomenon has also been reported[84]. Less typical anatomic locations for NL include the upper extremities, face, and scalp, where the lesions may be more annular or serpiginous in configuration and are often less atrophic. As a result, they may resemble AEGCG clinically.

Decreased sensation to pinprick and fine touch, hypohidrosis, and partial alopecia can be observed within NL plaques. Decreased S100 staining within the cutaneous nerves of inflammatory plaques has been described, with degenerative neural changes possibly accounting for the loss of sensation[75]. Of note, the cutaneous nerves in GA demonstrate normal S100 staining patterns. Although the lesions of NL are typically asymptomatic, some patients report pruritus, dysesthesia, or pain. Lesions that ulcerate after trauma or from transepidermal elimination of altered collagen and elastic fibers can be very painful. Rarely, squamous cell carcinoma has been reported to develop within lesions of NL[85]. By dermoscopy, comma-shaped vessels and an irregular pattern of arborizing vessels are observed in early and more advanced lesions, respectively; whitish areas correspond to degenerated collagen and yellow to orange patches to granulomatous inflammation[86,87].

There are reports of patients with NL who also had GA or sarcoidosis[88–90]. Possible versus random associations include systemic sclerosis, rheumatoid arthritis, and previous jejunoileal bypass surgery. The association of NL with diabetes mellitus and thyroid dysfunction are discussed in the Epidemiology section[91–93].

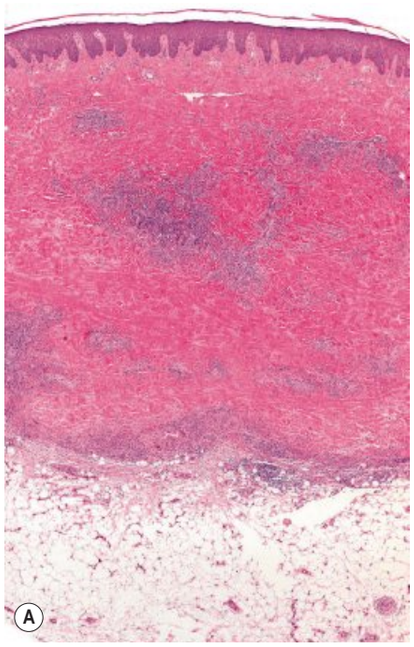
Pathology

In the palpable inflammatory border, a diffuse palisaded and interstitial granulomatous dermatitis that involves the entire dermis and extends into the subcutaneous fat septae is usually seen (Fig. 93.16). "Layered" tiers of granulomatous inflammation are composed of histiocytes surrounding horizontal tiers of degenerated collagen. The histiocytes are often multinucleated and the collagen fibers have irregular sizes and shapes. In areas of sclerosis, focal loss of elastic tissue may be seen. Extracellular lipid deposition can be demonstrated via adipophilin staining of routinely processed tissue sections or via oil red O staining of frozen tissue sections (latter rarely done nowadays). There is an associated superficial and deep perivascular infiltrate that is predominantly lymphocytic but often contains plasma cells and occasionally eosinophils. The epidermis is normal or atrophic.

In contrast to GA, there is no significant mucin deposition within the center of the palisading granulomas. Although early lesions of both NL and GA may have foci of leukocytoclasia, NL shows more prominent endothelial cell swelling, fibrosis, and hyalinization; the latter can lead to blood vessel wall thickening or even endarteritis obliterans. The vessel walls often contain a PAS-positive, diastase-resistant material suggesting neutral glycosaminoglycans[80].

Occasionally, NL lesions have less sclerotic collagen and more typical epithelioid cell granulomas rather than the horizontally tiered pattern of altered collagen and palisaded granulomatous inflammation described above. Vascular changes are rare, and this form of NL is felt to have a weaker association with diabetes mellitus than the classic lesions[80].

Differential Diagnosis



Clinically, the differential diagnosis of NL includes primarily GA, necrobiotic xanthogranuloma (NXG; see Ch. 91), sarcoidosis, diabetic dermopathy (see Ch. 53), and lipodermatosclerosis. Other entities in the differential diagnosis include additional forms of panniculitis (see Ch. 100), granulomatous infections (e.g. leprosy, dimorphic fungal infections, tertiary syphilis), morphea, lichen sclerosus, and sclerosing lipogranuloma.

Lesions of GA and sarcoidosis generally do not exhibit the same degree of atrophy, telangiectasias, or yellow–brown color as NL lesions, although prominent telangiectasias can be present in angiolupoid sarcoidosis and can occur following injections of triamcinolone. Ulcerated NL may be difficult to distinguish from ulcerative sarcoidosis or NXG[94].

Histopathologically, NL most commonly has to be distinguished from GA (see Table 93.4). NXG is also in the differential diagnosis, but there are abundant cholesterol clefts and larger zones of degenerated collagen. However, one case report did describe NL with prominent cholesterol clefts and transepithelial elimination of cholesterol crystals via hair follicles[95].

Treatment

No treatment for NL has proven to be effective in large, double-blind, placebo-controlled studies. In patients with diabetes mellitus, control of blood glucose levels may not have a significant effect on the course of NL. Spontaneous remission after an average of 8 to 12 years was observed in only 17% of 171 patients with NLD in one study[72].

First-line therapy consists of potent topical corticosteroids (including under occlusion) for early lesions and intralesional corticosteroids injected into the active borders of established lesions. Because the histologic changes can extend well into normal-appearing skin in clinically active NL lesions[75], some authors advocate the injection of intradermal corticosteroids into a rim of clinically normal skin around expanding plaques in an effort to halt disease progression. Careful monitoring for steroid-induced atrophy is important. Topical tacrolimus 0.1% ointment led to improvement of NL in uncontrolled case series[96–98]. Topical GM-CSF or bovine collagen[99] has been applied to ulcerations and tretinoin gel (0.025% BID) has been used to decrease lesional atrophy[100].

In addition to avoidance of trauma and local care of ulcers (see Ch. 145), therapies directed at increasing fibrinolysis, decreasing platelet aggregation, and/or decreasing thromboxane A_2 synthesis have been employed in order to decrease the microangiopathy and vascular thrombosis. Pentoxifylline, stanozolol, inositol niacinate (inositol nicotinate), nicofuranose, and ticlopidine hydrochloride are all agents that have been tried in anecdotal reports or uncontrolled case series. The use of stanozolol is limited by its potential hepatotoxicity and ticlopidine can cause agranulocytosis. Controlled trials of aspirin versus placebo or aspirin plus dipyridamole versus placebo showed no significant differences compared to placebo[101,102]. Perilesional injections of heparin have been reported in the Russian literature[103].

Based upon case series of patients, several systemic anti-inflammatory medications have been described as beneficial – antimalarials[104], niacinamide[80], mycophenolate mofetil[105], doxycycline, colchicine, methotrexate, thalidomide[106], TNF inhibitors, IL-12/23 inhibitors[107], and cyclosporine (severe ulcerations)[108,109]. As with sarcoidosis and GA, JAK inhibitors have emerged as a promising therapeutic option for selected patients[110]. In addition, 5-week courses of systemic corticosteroids were found to be effective in a series of six patients with an average follow-up period of 7 months, but this can be associated with side effects such as elevation of serum glucose levels[111].

Multiple prospective, uncontrolled studies have demonstrated improvement in ~50% of patients with topical PUVA therapy[112,113]. Lastly, there are case reports of beneficial effects from UVA1 phototherapy[114], pulse-dyed laser, fractional CO_2 laser, or photodynamic therapy.

Surgical therapy may be necessary in patients with severe, refractory ulcerations. Excision to deep fascia or periosteum must be performed to minimize the chance of recurrence. Split-thickness skin grafting is performed following excision.

CUTANEOUS CROHN DISEASE

Variants: ■ Contiguous Crohn disease ■ Distant/non-contiguous ("metastatic") Crohn disease

Key features

- Erythematous plaques, lymphedema, and knife-like ulcerations most commonly occur in the anogenital region
- Cutaneous non-caseating granulomatous lesions that are not contiguous with intestinal Crohn disease have been referred to as "metastatic"
- Approximately 20% of patients with cutaneous lesions have no preceding diagnosis of gastrointestinal Crohn disease

History

Crohn disease, first described in 1932, is characterized by segmental granulomatous inflammation of the intestinal tract and frequently involves cutaneous tissues as well. In 1965, cutaneous involvement was first described.

Epidemiology

Crohn disease usually begins between the second and fourth decades of life. Mucocutaneous findings occur in 20%–45% of patients (see Table 53.8)[115]. They can be subdivided into: (1) specific lesions including distant/non-contiguous cutaneous ("metastatic") Crohn disease, contiguous perianal Crohn disease, and oral Crohn disease; (2) nonspecific or reactive dermatologic disorders, e.g. erythema nodosum, Sweet syndrome, pyoderma gangrenosum; (3) nutritional skin changes secondary to malabsorption; and (4) treatment-related side effects[116–120].

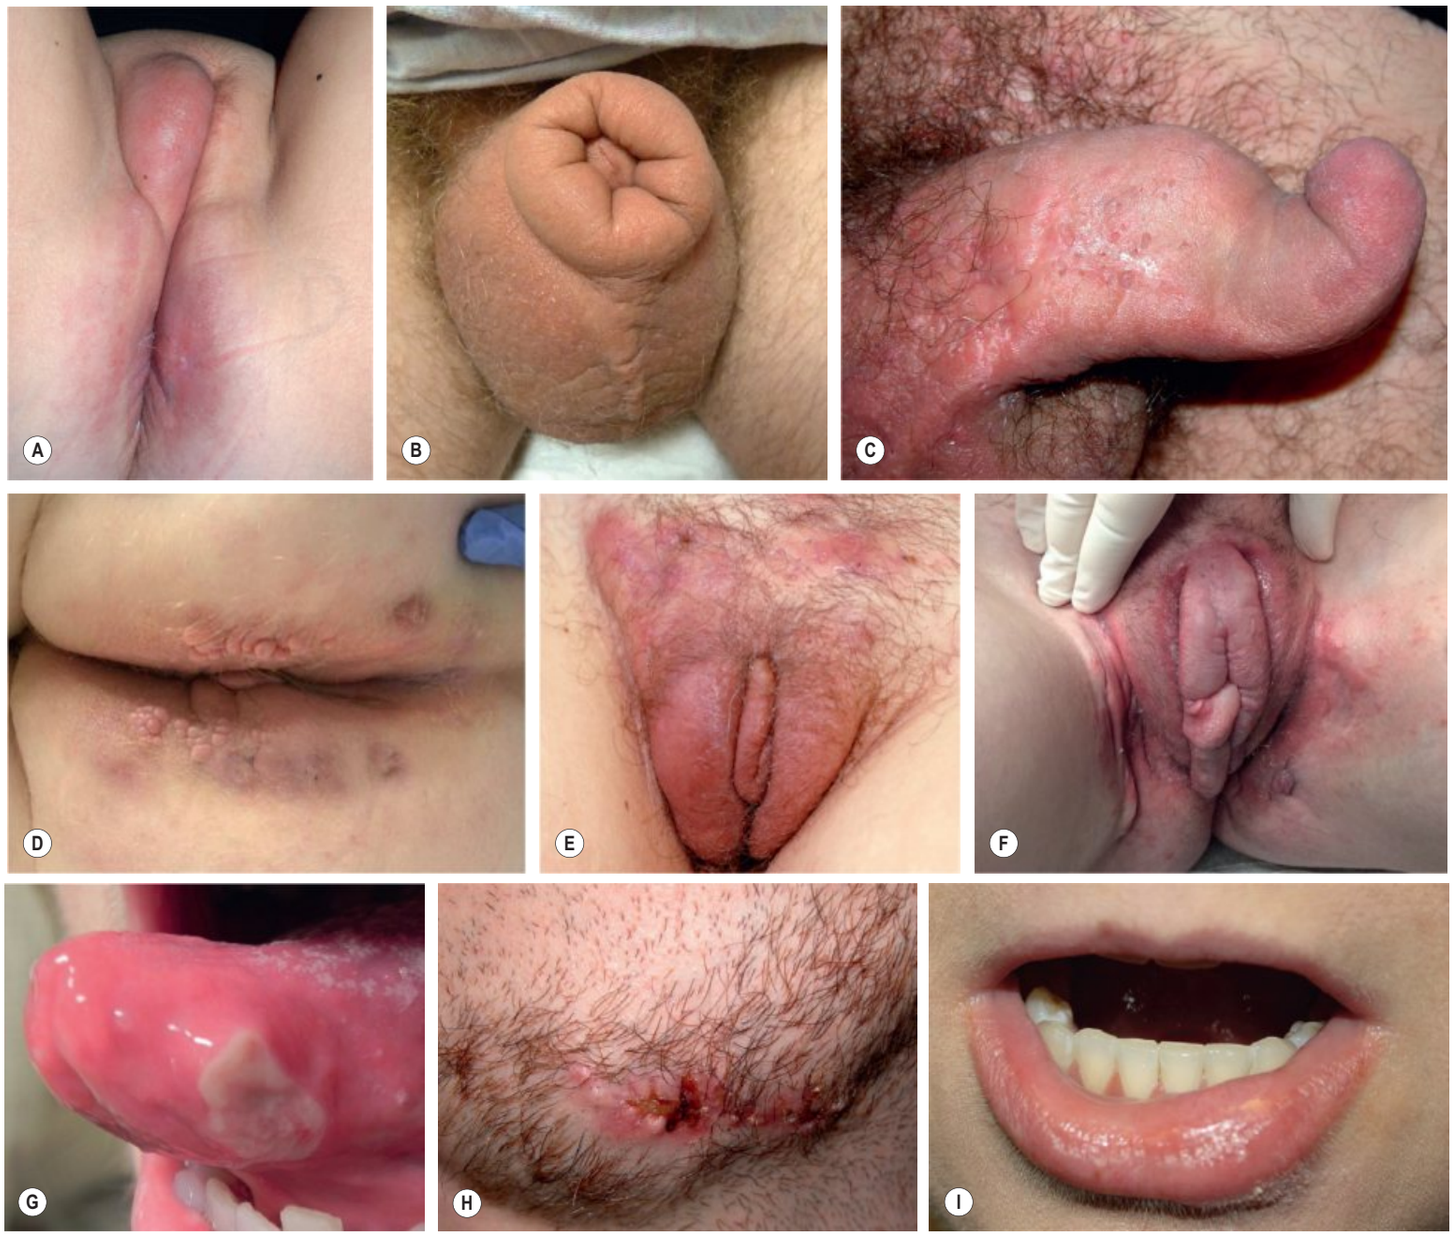

Fig. 93.17 Mucocutaneous Crohn disease. A Vulvar and perianal erythema and induration. Note the marked asymmetric vulvar swelling and perianal erosions. **B** Marked lymphedema of the prepuce with lymphedema and induration of the scrotum. **C** Inflammation and lymphedema leading to twisting of the penis along its long axis, referred to as a "saxophone penis". **D** Perianal tags and indurated plaques. **E** Firm erythematous plaques of the mons pubis and labia majora and minora. There are also draining sinuses. **F** Symmetric erythematous plaques, lymphedema, and a "skin tag"; note the marked swelling of the labia minora. **G** Intraoral ulcer that resembles a major aphthous ulcer. **H** Ulcerated erythematous plaque of the mandible with draining sinuses. **I** Asymmetric enlargement of the lower vermilion lip due to granulomatous inflammation. *A, Courtesy Julie V. Schaffer, MD; C, E, H, Courtesy Luis Requena, MD; D, Courtesy Mary Stone, MD; F, I, Courtesy Jeffrey P. Callen, MD, and Courtney R. Schadt, MD.*

Cutaneous Crohn disease is relatively rare with <300 cases reported in the literature to date and <100 cases in children. Two-thirds of the patients are women, and the mean age of onset is 35 years. Approximately 20% of the reported cases had skin disease that preceded the diagnosis of intestinal Crohn disease by 3 months to 8 years.

Pathogenesis

Cutaneous Crohn disease occurs in association with or precedes intestinal Crohn disease, reflecting a multisystem disease. A number of genetic abnormalities which can lead to an exaggerated T cell response to certain commensal enteric bacteria and defective microbial clearance, including after breaks in the mucosal barrier or an alteration in the balance in gut flora (dysbiosis), have been linked to Crohn disease. The protein products of these genes have several functions, including regulation of NF-κB function (e.g. *NOD2* [*CARD15*]) and autophagy (*ATG16L1*, *IRGM*). Patients with variants in *TRAF3IP2*, a psoriasis susceptibility gene, may have a greater risk of cutaneous involvement[121]. Like psoriasis, Crohn disease is a predominantly Th1- and Th17-mediated disease, with elevated levels of IL-23 and IL-17 within involved tissues[122].

Clinical Features

Cutaneous Crohn disease may be either genital or extragenital, with genital involvement found in approximately two-thirds of children and one-half of adults. Labial, penile, or scrotal erythema and/or lymphedema are common presenting signs and can be dramatic[123] (Fig. 93.17A–C,F). Linear or "knife-like" ulcerations that are within body folds (e.g. inguinal creases, perianal region, axillae) or involve the oral mucosa are relatively specific for mucocutaneous Crohn disease (see Figs. 53.28 and 72.25)[121].

Perianal involvement, which may extend to the adjacent perineum, buttocks or abdomen, consists of sinus tracts, fissures, ulcers, and vegetating plaques (Fig. 93.17D,E)[124]. These findings occur in approximately one-third of patients with intestinal Crohn disease. Perianal skin tags, thought to be secondary to lymphedema, are observed in up to 40% of patients; as with other sites of lymphedema, granulomatous inflammation may be present as well. Sites of abdominal surgery, e.g. laparotomies, colostomies, ileostomies, may also develop granulomatous inflammation. For semantic purposes, the latter is considered to be "contiguous" rather than non-contiguous ("metastatic") Crohn disease.

Oral lesions occur in 5%–20% of patients with Crohn disease, and these may consist of cobblestoning of the buccal mucosa, tiny gingival nodules, gingival hyperplasia, aphthae-like ulcers (Fig. 93.17G), linear, knife-like ulcerations, pyostomatitis vegetans (see Fig. 25.9A), angular cheilitis and ulceration, secondary orofacial granulomatosis (Fig. 93.17I), diffuse oral swelling, or indurated fissuring of the lower lip. Histologically, 90% of oral lesions associated with Crohn disease contain granulomas[124].

Non-genital disease presents with dusky erythematous plaques, often followed by the development of ulceration with undermined edges, draining sinuses and fistulas, and scarring (Fig. 93.17H). These lesions have been observed on the lower extremities and soles (40%), abdomen and trunk (25%), upper extremities and palms (15%), face and lips (10%), flexural areas (8%), and in a generalized distribution (4%)[116,125]. Other reactive cutaneous manifestations of Crohn disease include cutaneous arteritis (cutaneous polyarteritis nodosa), erythema nodosum, erythema multiforme, finger clubbing, cutaneous small vessel vasculitis, epidermolysis bullosa acquisita, vitiligo, palmar erythema, a pustular response to trauma (pathergy), Sweet syndrome, and pyoderma gangrenosum (see Ch. 53). Zinc deficiency may cause an acrodermatitis enteropathica-like syndrome in patients with severe Crohn disease[116].

Based upon a large retrospective series, cutaneous involvement may be indicative of colonic, rather than ileal, involvement[117,118]. No consistent correlation exists between mucocutaneous disease activity and degree of gastrointestinal involvement. However, levels of fecal calprotectin can reflect the degree of intestinal inflammation.

Pathology

In both cutaneous and oral lesions of Crohn disease, small, nodular, non-caseating, epithelioid granulomas with surrounding lymphocytes are found in the superficial and deep dermis, sometimes extending into the subcutaneous fat. There are a few scattered multinucleated Langhans-type giant cells and a sparse perivascular lymphohistiocytic infiltrate; overlying ulceration may be present. Of note, the combination of lichenoid and granulomatous inflammation plus granulomatous perivasculitis can serve as a histopathologic clue[126]. The walls of perianal sinuses and fistulas have similar granulomatous inflammation. However, the granulomatous foci may be subtle, requiring multiple sections to identify the granulomas, and clinicopathologic correlation as well as additional biopsies may be required.

Differential Diagnosis

Clinically, the differential diagnosis of cutaneous Crohn disease includes other granulomatous disorders such as cutaneous sarcoidosis, mycobacterial infections, deep fungal infections, and foreign body reactions. Other infections, such as actinomycosis or cellulitis, may mimic cutaneous Crohn disease. Ulcerated lesions may be misdiagnosed as pyoderma gangrenosum. In the case of genital swelling and ulcerations, one must consider granuloma inguinale, schistosomiasis, hidradenitis suppurativa, and chronic lymphedema due to obstruction[125].

The histopathologic picture of cutaneous Crohn disease can be indistinguishable from other granulomatous diseases with tuberculoid features, including lupus vulgaris. In the latter, central necrosis within tubercles is a helpful distinguishing clue. Differentiating cutaneous Crohn disease from sarcoidosis can also be challenging, although Crohn disease usually has denser collections of lymphocytes and granulomatous perivasculitis as well as the features described above. Foreign body granulomas and infectious granulomas should be considered in the histologic differential diagnosis. Special stains for acid-fast bacilli and fungal organisms should be obtained, and all skin biopsies should be polarized to look for foreign bodies. Pyoderma gangrenosum and cutaneous Crohn disease can sometimes have overlapping clinical and histopathologic features as neutrophilic inflammation may be present in both, but granulomas are absent in pyoderma gangrenosum.

Treatment

Cutaneous Crohn disease tends to be chronic, and its severity does not always correlate with the activity of the patient's intestinal disease. For localized disease, topical or intralesional corticosteroids and/or topical calcineurin inhibitors may be utilized[127]. Oral metronidazole (250 mg TID for at least 4 months) can be an effective treatment. For more extensive disease, use of systemic medications including corticosteroids, sulfasalazine, azathioprine, 6-mercaptopurine, and thalidomide may lead to improvement. By targeting the underlying immunopathogenesis, TNF inhibitors (e.g. infliximab, adalimumab)[128] and ustekinumab have been reported to improve cutaneous disease. IL-17 inhibitors have been reported to exacerbate Crohn disease. Surgical excision of lesions is often complicated by wound dehiscence and disease recurrence, but can be considered for refractory disease.

FOREIGN BODY GRANULOMAS (SEE CH. 94)

Key features

- The most common cause of a foreign body granuloma is rupture of a follicle or cyst
- Inflammation may be suppurative, granulomatous, or more commonly mixed suppurative and granulomatous
- Clues to the inciting foreign body should be sought by polarizing the specimen as well as by searching for cornified cells, tattoo pigment, suture remnants, splinter material, etc.

OROFACIAL GRANULOMATOSIS (OFG; SEE CH. 72)

Key features

- Persistent non-tender swelling of the lip and/or face
- Histologically, non-caseating granulomatous inflammation; biopsy of mucosal (inner) lip preferred
- Both primary (idiopathic) and secondary subtypes
- Primary OFG includes cheilitis granulomatosa and Melkersson–Rosenthal syndrome while secondary OFG includes sarcoidosis, foreign body reactions, and Crohn disease

REACTIVE GRANULOMATOUS DERMATITIS – INCLUDES INTERSTITIAL GRANULOMATOUS DERMATITIS, PALISADED NEUTROPHILIC AND GRANULOMATOUS DERMATITIS, AND INTERSTITIAL GRANULOMATOUS DRUG REACTION

Synonyms: ■ Interstitial granulomatous dermatitis (IGD) with arthritis – IGD with plaques and arthritis, IGD with plaques, IGD with cutaneous cords and arthritis ■ Palisaded neutrophilic and granulomatous dermatitis (PNGD) – rheumatoid papules, Churg–Strauss granuloma, cutaneous extravascular necrotizing granuloma, superficial ulcerating rheumatoid necrobiosis ■ Entire spectrum – reactive granulomatous dermatitis, reactive interstitial granulomatous dermatitis

Key features

- The overlap of interstitial granulomatous dermatitis with both palisaded neutrophilic granulomatous dermatitis and interstitial granulomatous drug reaction has led to the concept of *reactive granulomatous dermatitis* as a unifying term
- Clinical findings vary from erythematous crusted papules on extensor surfaces or linear cords to annular plaques and large thin plaques that resemble granuloma annulare
- Underlying disorders include autoimmune connective tissue diseases (rheumatoid arthritis, seronegative inflammatory arthritis, systemic lupus erythematous [SLE]), granulomatosis with polyangiitis, and occasionally a myelodysplastic syndrome or malignancy
- Histologically, there are palisaded or interstitial histiocytes with tiny foci of degenerated collagen, scant mucin deposits, and variable amounts of neutrophils and eosinophils; small foci of vasculitis also may be present

Introduction

Palisaded neutrophilic and granulomatous dermatitis (PNGD) and interstitial granulomatous dermatitis (IGD) with arthritis represent two patterns of granulomatous dermatitis that occur in patients with RA and other autoimmune disorders. Since these entities exhibit overlapping clinicopathologic features and may represent a disease spectrum, the overarching term *reactive granulomatous dermatitis* has been proposed[129].

History

In 1994, Chu and colleagues[130] proposed the term "palisaded neutrophilic and granulomatous dermatitis" for the histologic reaction pattern that characterizes papular eruptions on the extensor extremities that present in the context of autoimmune connective tissue disease and other conditions characterized by immune complex generation. Such skin lesions were originally described in the setting of eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome), and their association with a broad spectrum of autoimmune and inflammatory disorders was first recognized by Winkelmann in 1978 (cutaneous extravascular necrotizing granuloma). Some authors include "interstitial granulomatous dermatitis with arthritis", a term coined by Ackerman in 1993, within the PNGD spectrum. Others argue that the former represents a separate entity with distinct clinical (annular plaques and cords favoring the lateral trunk and skin folds) and histologic (histiocytic rosettes without evidence of vasculitis) features. More recently, the term *reactive granulomatous dermatitis* was introduced as an overarching term[129,131].

Pathogenesis

It is thought that the initiating insult in reactive granulomatous dermatitis is immune complex deposition on or around the walls of small dermal blood vessels as a result of the underlying disease, which leads to a subacute or chronic neutrophil-rich small vessel vasculitis. This then impairs blood flow to the area in a smoldering fashion, as opposed to the abrupt vascular occlusion of classic vasculitis; consequently, there is degeneration of the local collagen rather than acute necrosis. The degenerated collagen incites an immune response resulting in a palisading lymphohistiocytic infiltrate. This cascade of events is likely aggravated or precipitated by exogenous trauma, which explains the predilection of lesions for the extensor surfaces. Variable sizes, amounts, and sites of immune complex deposition (e.g. dermal venules versus the interstitial dermis), chronicity of the process, and different triggers and underlying systemic inflammatory disorders may account for the spectrum of clinical and histologic features.

Clinical Features

In classic descriptions of PNGD, skin-colored to erythematous papules develop symmetrically on extensor surfaces, particularly the elbows and

Fig. 93.18 Reactive granulomatous dermatitis, encompassing IGD and PNDG – clinical features. A Multiple violet–brown plaques, some of which are annular, on the lower extremities of a young woman with mixed connective tissue disease. **B** Firm, linear subcutaneous cord along the axillary line (arrows) in a patient with rheumatoid arthritis. **C** Violaceous plaques on the back in a patient with Hodgkin lymphoma. *A, Courtesy Lorenzo Cerroni, MD; B, Courtesy Kathryn Schwarzenberger, MD; C, Courtesy Department of Dermatology, Medical University of Graz.*

INTERSTITIAL GRANULOMATOUS DRUG REACTION – ASSOCIATED MEDICATIONS AND SUPPLEMENTS	
Common	
• **Calcium channel blockers**: diltiazem, verapamil, nifedipine • **Angiotensin-converting enzyme inhibitors**: enalapril, lisinopril • β-blockers: labetalol, metoprolol, atenolol, propranolol • Furosemide • **HMG-CoA reductase inhibitors**: simvastatin, pravastatin, lovastatin • Antihistamines (H1 or H2 blockers): famotidine, cimetidine, ranitidine, brompheniramine • **TNF inhibitors**: infliximab, etanercept, adalimumab; lenalidomide, thalidomide • Anakinra	
Uncommon	
• Allopurinol • Bosutinib • Bupropion • Carbamazepine • Chinese herbal medications • Darifenacin • Diazepam • Hydrochlorothiazide (HCTZ) • Febuxostat	• Ganciclovir • Gemfibrozil • Methotrexate • Nivolumab • Sennoside • Sorafenib • Soy • Strontium ranelate • Topiramate • Trastuzumab

Table 93.7 Interstitial granulomatous drug reaction – associated medications and supplements. It is also referred to drug-induced interstitial granulomatous dermatitis and can fall within the spectrum of reactive granulomatous dermatitis. Most common classes of drugs are in bold. HMG, β-hydroxy-β-methylglutaryl; TNF, tissue necrosis factor.

fingers. Central umbilication with crusts or perforation (with extrusion of necrobiotic collagen) may be present (see Fig. 53.2), and ulceration occasionally occurs. Such papular lesions have been observed most commonly in patients with SLE, rheumatoid arthritis, or systemic vasculitis, particularly granulomatosis with polyangiitis.

IGD with arthritis has been described as erythematous plaques, often with an annular configuration (Fig. 93.18A), or linear cords (the "rope sign"; Fig. 93.18B) that favor the lateral trunk, axillae, and girdle area (see Fig. 53.1). Extensive areas of involvement can be seen (Fig. 93.18C). This presentation has been described most often in women with rheumatoid arthritis, seronegative arthritis, or polyarthralgias and it may be associated with autoimmune thyroiditis. However, in a large retrospective series, the rope sign was noted in only two patients with autoimmune disease-associated IGD[131].

When viewed as a disease spectrum, the skin findings in reactive granulomatous dermatitis consisted of plaques, often annular, as well as macules, papules, or nodules located primarily on the extremities and trunk[131]. Associated conditions were observed in 75% of patients, irrespective of whether they were classified histologically as having IGD versus PNGD; the majority of these underlying disorders were autoimmune diseases (54%), followed by malignancies (12%). In addition to myelodysplasia, PNGD can develop in patients with chronic myelomonocytic leukemia, including those with *SRSF2* mutations.

Reactive granulomatous dermatitis also encompasses interstitial granulomatous drug reactions. The most likely culprits are calcium channel blockers and HMG-CoA reductase inhibitors ("statins"; Table 93.7), but the list of incriminated medications continues to expand. Cutaneous lesions typically appear after months to years of exposure to the drug. Of note, in patients with rheumatoid arthritis and psoriatic arthritis, TNF inhibitors have led to the development of IGD- and PNGD-like lesions[132].

Pathology

In that PNGD and IGD have overlapping clinical features, it follows that the histopathologic features of PNGD and IGD also constitute a spectrum, with features depending on the stage of evolution of the lesion that is biopsied. One series demonstrated overlapping histopathologic findings in 25% of cases, lending support for use of the overarching term reactive granulomatous dermatitis[131].

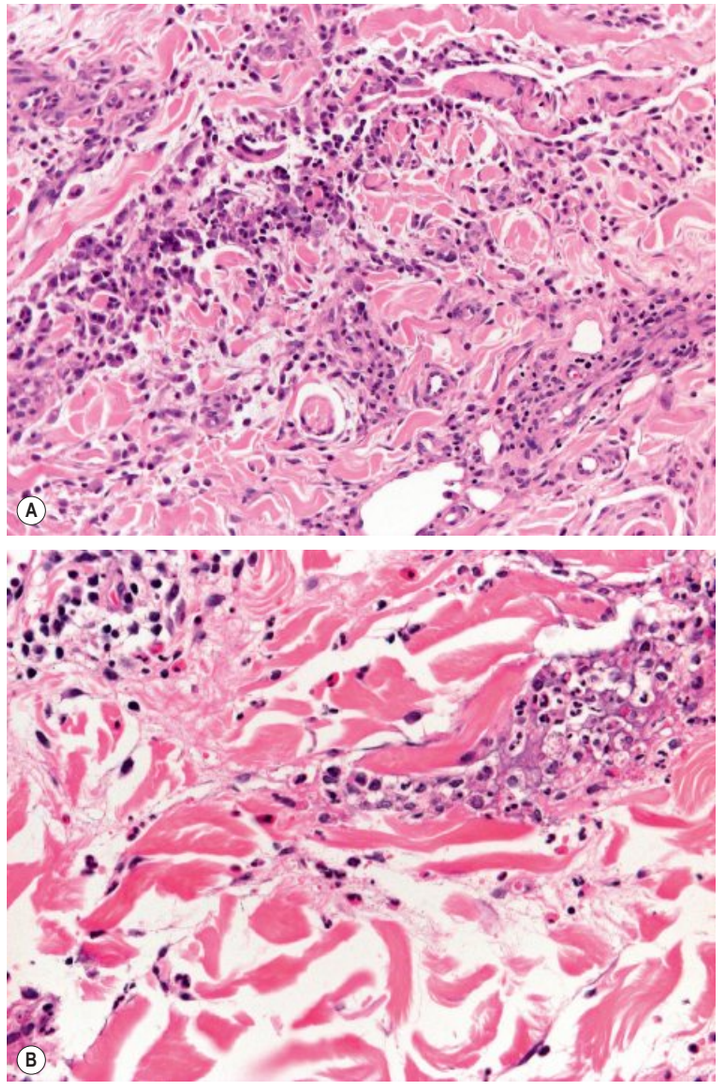

Fig. 93.19 Reactive granulomatous dermatitis, encompassing IGD and PNDG – histopathologic features. A Fully developed lesions usually demonstrate neutrophils and histiocytes in association with basophilic degenerating collagen bundles; some eosinophils may be present as well. **B** Details of histiocytes admixed with lymphocytes, neutrophils and eosinophils. *Courtesy Lorenzo Cerroni, MD.*

Early lesions of PNGD often show a pandermal infiltrate of neutrophils, sometimes with focal leukocytoclastic vasculitis. Classic, fully developed lesions are characterized by zones of basophilic degenerated collagen surrounded by palisades of histiocytes, neutrophils, and nuclear debris (Fig. 93.19). "Incomplete" early lesions may display focal basophilic collagen necrosis and histiocytes without orderly palisading in association with prominent neutrophils. On the other hand, late lesions can exhibit well-developed palisading granulomas with only a sparse complement of neutrophils. Mucin is rare to absent.

The histologic pattern of IGD features smaller "rosettes" of palisading histiocytes surrounding tiny, discrete foci of degenerated collagen (piecemeal fragmentation) within a dense, "bottom-heavy" dermal interstitial infiltrate that contains variable numbers of neutrophils and sometimes eosinophils. There is no evidence of vasculitis, and dermal mucin is usually absent.

In interstitial granulomatous drug eruptions, histopathologic features overlap with both PNGD and IGD, but there may be more tissue eosinophilia, lymphocyte atypia, and interface vacuolar changes.

Differential Diagnosis

The clinical differential diagnosis is broad. For classic PNGD lesions, it includes perforating disorders, early rheumatoid nodules, accelerated

SPECTRUM OF GRANULOMATOUS, NEUTROPHILIC, AND VASCULITIC DERMATOSES IN PATIENTS WITH RHEUMATOLOGIC DISORDERS		
Prevalent vasculitic changes	**Prevalent histiocytic infiltrates**	**Prevalent neutrophilic infiltrates**
Erythema elevatum diutinum	Interstitial granulomatous dermatitis	Palisaded neutrophilic and granulomatous dermatitis
Rheumatoid or other AI-CTD-associated vasculitis	Rheumatoid nodule	Sweet syndrome*
ANCA-associated vasculitis		Rheumatoid neutrophilic dermatitis
*Histiocytoid cells, rather than neutrophils, may be the prevalent population in some cases of Sweet syndrome (histiocytoid Sweet syndrome).		

Table 93.8 Spectrum of granulomatous, neutrophilic, and vasculitic dermatoses in patients with rheumatologic disorders. AI-CTD, autoimmune connective tissue disease; ANCA, anti-neutrophil cytoplasmic antibodies.

rheumatoid nodulosis, and papular granuloma annulare (GA). The clinical presentation of IGD with plaques may resemble patch-type GA, the inflammatory stage of morphea, erythema migrans, or mycosis fungoides.

The histologic differential diagnosis includes other palisaded granulomatous dermatitides such as GA, necrobiosis lipoidica, and rheumatoid nodules. GA is more likely to have a patchy infiltrate concentrated in the upper dermis ("top heavy") and mucin deposition. A paucity of neutrophils and leukocytoclasis distinguishes GA from PNGD, whereas the presence of either larger palisades or a lack of palisades (e.g. in the interstitial pattern seen in patch-type GA) differentiates GA from IGD. Rheumatoid nodules can be recognized by their central eosinophilia (rather than basophilia) and predominantly subcutaneous location (see Fig. 45.10). All of these entities may show transepidermal elimination of degenerated collagen. Additional diagnostic considerations for an interstitial granulomatous infiltrate with variable neutrophils may include dimorphic fungal or atypical mycobacterial infections, borreliosis, and leprosy. Histologic features that favor an interstitial granulomatous drug reaction over IGD include a vacuolar interface dermatitis, atypical lymphocytes, prominent eosinophils, a paucity of neutrophils, and minimal collagen degeneration.

The relationship of PNGD and IGD with other dermatoses that have granulomatous, neutrophilic, or vasculitic components and affect this patient population are shown in Table 93.8. Lastly, neonates with primary immunodeficiencies can develop perforating neutrophilic and granulomatous dermatitis associated with immunodeficiency in which papules develop into vesicles, pustules, crusts, and ulcers; histologically there is evidence of transepidermal elimination via hair follicles.

Treatment

Treatment of the underlying disorder or removal of the inciting medication can lead to resolution of existing lesions and prevent recurrences. For recalcitrant skin disease, improvement has been reported with the use of high-potency topical or intralesional corticosteroids, dapsone, hydroxychloroquine, and nonsteroidal immunosuppressants, guided by any underlying etiology.

Acknowledgment

The authors wish to thank Amy Reisenauer, MD, Kevin P. White, MD, Veselina Korcheva, MD, and Clifton R. White Jr, MD, for their valuable contributions to this chapter in the previous editions.

Foreign Body Reactions 94

M. Abdel Rahim Abdallah, Mahmoud M.A. Abdallah and Marwa Abdallah

Chapter Contents

General Considerations 1681
Foreign Body Reactions to Inorganic and Metallic Compounds. 1683
Reactions to Organic and Biologic Products 1688
Injectable Soft Tissue Fillers 1689
Miscellaneous. 1690

Key features

- Foreign body reactions represent inflammatory responses to inorganic and high-molecular-weight organic materials that have been introduced into the skin and are variably resistant to degradation
- Routes of introduction can vary from accidental or self-inflicted to surgical and cosmetic procedures to topical application of various compounds
- The most common clinical presentation is red to red–brown papules, nodules, or plaques (with or without ulceration) that are due to granulomatous inflammation
- Less common clinical presentations include lichenoid and pseudolymphomatous lesions, or the development of a fistula or draining wound
- Histopathologic findings vary from granulomas (foreign body, sarcoidal, palisading) to lichenoid, eczematous, or pseudolymphomatous patterns
- Diagnosis of foreign body reactions requires a high index of suspicion, thorough history, recognition of distinctive distribution patterns, and histologic examination (including polarized microscopy)

GENERAL CONSIDERATIONS

Definition

Literally, any material – living or non-living – introduced into the body is a "foreign body" and is treated by our immune system as "non-self" in order to elicit an appropriate response. Such a broad definition also includes infectious agents, but they are covered elsewhere (see Chs. 74–85). This chapter will focus on non-living materials that have been introduced into the dermis or subcutis[1–3]. They represent inorganic compounds or organic material of high molecular weight (or their products) that resist degradation by the body's inflammatory cells. Although granulomatous reaction patterns are most commonly observed, there is a broad range of clinicopathologic presentations. Foreign bodies reported to elicit skin reactions are listed in Table 94.1.

Routes of Entry

Accidental

Inoculation with foreign bodies may occur unintentionally during various activities such as gardening (wood splinters, cactus spines) or swimming and diving (coelenterate envenomation, sea urchin spines), or it may result accidentally, such as in a blast injury (silica particles) or motor vehicle accident.

Surgical procedures

Contamination of wounds by talc or starch powders used for lubrication of surgical gloves may incite a foreign body reaction. Surgical sutures also cause a foreign body response and this is routinely seen in surgical re-excisions (see Fig. 151.19). In addition, foreign body reactions have been observed in association with 2-octyl cyanoacrylate, a tissue adhesive used for small superficial wounds and lacerations, as well as a copolymer-containing lubricating agent used for liposuction[4].

Iatrogenic

Foreign material implanted into the skin for the purpose of tissue augmentation, e.g. injectable soft tissue fillers, can induce reactions in some individuals (Fig. 94.1). Paraffin is still being used illegally for tissue augmentation (see below), and a paraffin foreign body reaction can also occur after the application of paraffin-containing materials such as nasal packs[5].

Tattooing

Tattooing is the introduction of an exogenous pigment into the dermis, either deliberately or accidentally, resulting in permanent discoloration of the skin.

Topical application

When applied to the skin surface, antiperspirant and antipruritic preparations that contain zirconium oxide or zirconium lactate were noted to cause foreign body reactions. As a result, zirconium lactate was generally banned in 1978 (see below). These zirconium compounds have subsequently been replaced by aluminum–zirconium complexes and while the latter are less sensitizing, they may occasionally lead to foreign body reactions[6].

Self-inflicted

Self-administered intravenous and subcutaneous injections, a common practice among individuals with substance use disorder, may lead to the introduction of foreign material into the skin. An example is the injection of crushed talc-containing tablets.

Pathogenesis

The initial tissue response to most foreign substances involves an accumulation of neutrophils, which usually fail to properly deal with the foreign body. Its persistence attracts monocytes and local tissue macrophages that engulf the foreign material and become activated. Engulfed material may resist degradation and remain sequestered within the macrophages. Activated macrophages secrete a variety of specific biologically active substances, e.g. cytokines and chemokines, that attract additional macrophages and blood monocytes. The formation of a chronic granuloma represents an attempt by the body to sequester a persistent indigestible material. Individual macrophages may become larger (epithelioid histiocytes) or fuse to form multinucleated foreign body giant cells (Fig. 94.2)[7]. The infiltrate also contains T lymphocytes and fibroblasts. The pathogenesis of other patterns of reactions, e.g. lichenoid, pyogenic granuloma-like, pseudolymphomatous, remains speculative.

Clinical Features

The host response and, consequently, the clinical presentations of foreign body implantation are variable (Table 94.2 & 94.3). An acute inflammatory response occurs shortly after the entry of the foreign material. This may resolve, to be followed weeks, months, or even years later by a chronic inflammatory response. Although the latter may have a variety of clinical presentations, red to red–brown papules, nodules, and plaques (with or without ulceration) are most commonly observed. Over time, the lesions may become firmer due to fibrosis. The pattern

CLASSIFICATION OF FOREIGN BODIES ACCORDING TO THEIR ORIGINS AND ROUTES OF ENTRY		
Origin		**Route of entry**
Non-biologic (inorganic/metallic compounds)		
	Tattoo inks	Decoration Cosmetic Accidental Iatrogenic
	Ferrous subsulfate (Monsel's solution)	Hemostasis (iatrogenic)
	Paraffin	Tissue augmentation Iatrogenic
	Silicone (polydimethyl siloxane) liquid or gel	Tissue augmentation
	Silica	Wound contamination Blast injuries
	Talc	Surgical procedures Wound contamination Umbilical stump contamination Intravenous injection of self-prepared drugs
	Zirconium	Topical application: antiperspirants
	Beryllium	*Local cutaneous:* Laceration by broken fluorescent lamps (historical) *Systemic:* Penetration of intact skin by fine particles (<1 micron) Inhalation
	Aluminum	Subcutaneous injection of aluminum-containing vaccines
	Zinc	Subcutaneous injection of insulin–zinc preparations
	Other synthetic fillers, e.g. poly-L-lactic acid, calcium hydroxylapatite, polymethylmethacrylate	Tissue augmentation
Biologic		
Produced in the skin but normally isolated from body's immune surveillance	Hair keratin (see Ch. 38)	Ruptured follicle or cyst* Ingrown hair Pilonidal sinus Interdigital pilonidal sinus (hairdressers, barbers, dog groomers)
	Nail keratin	Ingrown nail
Produced by other living organisms	Starch	Surgical procedures, plasma expander
	Cactus spines	Accidental Occupational
	Jellyfish and corals	Accidental Swimming or diving
	Sea urchin spines (see Ch. 85)	Accidental Swimming or diving
	Silk sutures	Surgical procedures
	Hyaluronic acid	Tissue augmentation
	Bovine collagen†	Tissue augmentation
Miscellaneous	Corticosteroids	Intralesional injection
	Sutures, primarily absorbable (rarely nylon or polypropylene)	Surgical procedures
	Polyamide synthetic "hair" fibers	Scalp "hair" restoration
	2-octyl cyanoacrylate	Tissue adhesive for small, superficial wounds and lacerations
	Hydrophilic polymer and potassium ferrate (WoundSeal® powder)	Hemostasis
	Vitamin C serum	Via microneedling for rejuvenation

*Most common cause of a foreign body reaction in the skin.
†The only commercially available filler in the US that contains collagen also contains polymethylmethacrylate (PMMA) microspheres (Bellafill®).

Table 94.1 Classification of foreign bodies according to their origins and routes of entry.

and arrangement of the cutaneous lesions will correspond to the route of inoculation, and observation of this patterning, in association with a relevant patient history, is crucial.

In addition to nodules and plaques, other forms of foreign body reaction include pyogenic granuloma-like lesions[8], lichenoid lesions[9,10], and a chronic draining fistula or wound[11,12].

Pathology

Apart from the acute reaction to the trauma that accompanies the introduction of the foreign body, a chronic reaction is the usual response. Although different patterns of chronic local tissue reactions have been described, including lichenoid[9], eczematous, and pseudolymphomatous[13], the most common is the granulomatous type of reaction[7,14]

Fig. 94.1 Foreign body reaction at site of bovine collagen injection. Formation of granulomas at bovine collagen injection sites occurs in ~1% of patients who have had two negative skin tests.

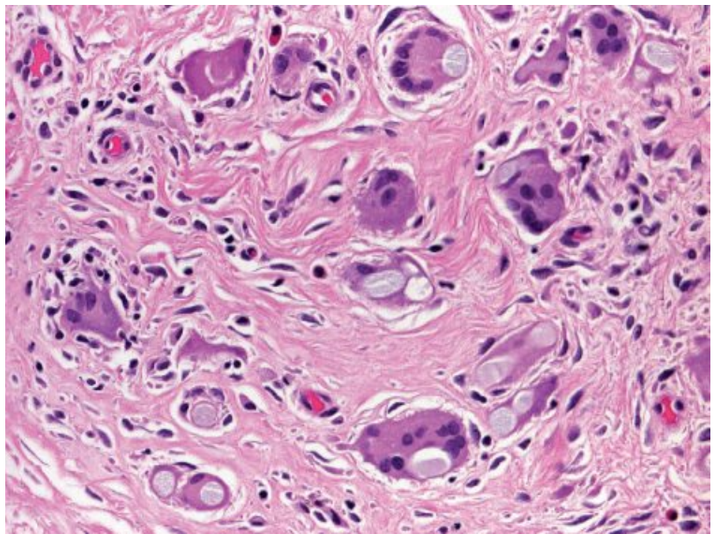

Fig. 94.2 Foreign body reaction to sutures. The foreign bodies have been engulfed primarily by foreign body-type giant cells; one Langhans-type giant cell is present at 12 o'clock. *Courtesy Lorenzo Cerroni, MD.*

(see Table 94.3). Granulomas that develop as a reaction to foreign bodies are of two major types:

- allergic (immunologic)
- non-allergic ("foreign body").

The allergic type is characterized by the presence of collections of individual epithelioid histiocytes associated with variable numbers of lymphocytes and fewer multinucleated Langhans-type giant cells[7]. In the non-immunologic type, the foreign body giant cell is the most conspicuous component of the infiltrate (see Fig. 94.2), which also contains histiocytes, lymphocytes, and other inflammatory cells[14].

A histologic decision as to whether a granuloma is of the foreign body type or of the allergic type is not always possible and different patterns may be seen in the same section. The foreign material inciting a reaction may be detected in conventional H&E-stained sections or may require special procedures for its identification (see Table 94.3).

Diagnosis

Foreign body reactions should be considered in the differential diagnosis of localized inflammatory nodules and plaques, especially when there is a persistent draining wound or sinus. Occasionally, these reactions present as pyogenic granulomas or localized lichenoid papules. Clinical morphology is usually not distinctive, but there may be a suggestive distribution pattern, and a thorough history is indispensable for arriving at the correct diagnosis.

Histopathologic examination can confirm the granulomatous nature of a lesion and occasionally foreign bodies may show distinctive microscopic features in H&E-stained sections (Fig. 94.3)[14]. Because some foreign bodies are better visualized via polarized microscopy, this is routinely performed (Fig. 94.4). In addition to detecting radiolucent foreign bodies, high frequency ultrasound has been employed to assess the severity and depth of inflammatory reactions to tattoos and soft tissue fillers[14]. CT, MRI, and PET-CT have also been used to evaluate foreign body reactions but can have limitations with regard to detection of small cutaneous foreign bodies.

Identification of the chemical nature of the foreign body requires sophisticated physicochemical procedures (e.g. energy-dispersive X-ray analysis, laser-induced breakdown spectroscopy) that are available in only a few research centers[15].

To summarize, accurate identification of a foreign body reaction depends on a high index of suspicion, thorough history-taking, and histologic examination, including polarized microscopy.

CLINICAL PRESENTATIONS OF FOREIGN BODY REACTIONS

Clinical presentation	Foreign substance
Erythema, induration, papules, nodules, plaques (with or without ulceration)	Tattoo inks, paraffin, silicone*, silica*, beryllium (local), starch, soft tissue fillers (e.g. hyaluronic acid)
Sarcoidosis-like granulomatous papules	Tattoo inks, talc, zirconium, beryllium (systemic), soft tissue fillers (e.g. hyaluronic acid, bovine collagen)
Pyogenic granuloma-like lesions	Talc, keratin (ingrown nail)
Pseudofolliculitis barbae, "ingrown" hairs of the pubic region and upper thighs	Keratin
Pruritic lichenoid papules and plaques (often in an irregular linear pattern)	Tattoo inks, jellyfish and coral stings
Abscess	Keratin (e.g. pilonidal sinus), zinc, paraffin, soft tissue fillers
Sinus tract/fistula	Suture, keratin (pilonidal sinus, interdigital pilonidal sinus [barbers, hairdressers])
Persistent subcutaneous nodules at injection site	Aluminum, soft tissue fillers (see Table 94.5)
Pseudolymphomatous reaction	Aluminum, tattoo inks
Photoallergic eczematous reaction	Tattoo ink containing cadmium sulfide (yellow), cadmium selenide (red), or azo dyes (yellow, red)

*Often a delayed onset (years).

Table 94.2 Clinical presentations of foreign body reactions.

FOREIGN BODY REACTIONS TO INORGANIC AND METALLIC COMPOUNDS

Tattoo

A tattoo may occur accidentally or deliberately for cosmetic and decorative purposes. Accidental tattooing results from unintentional deposition of exogenous pigmented substances such as asphalt, carbon, or graphite (pencils) within injured skin (Fig. 94.5). Automobile, bicycle, and skating accidents as well as puncture wounds are the most common causes of traumatic tattoos. In decorative tattooing, the pigment is introduced into the dermis via needles or a tattoo gun to create various designs, group-identity symbols, or writings. Cosmetic tattoos are also done to define the contours of lips and eyebrows, permanently replace eyeliner, make eyebrows appear fuller (via microblading), or camouflage an abnormality in skin color. An iatrogenic tattoo may remain after the use of ferrous subsulfate (Monsel's solution) for hemostasis. Other hemostatic agents, e.g. aluminum chloride, may cause a foreign body reaction histologically (see below), but do not lead to discoloration of the skin.

Decorative tattoos often contain a number of pigments that are combined to create different hues, but the composition of tattoo inks has not been standardized. The pigments may be inorganic salts of metals, such as mercury in cinnabar (red, becoming historical), cobalt

CLINICAL AND HISTOPATHOLOGIC FEATURES OF FOREIGN BODY REACTIONS				
Foreign body	**Clinical presentations**	**Histologic reaction patterns**	**Other distinctive features**	**Birefringent**
Tattoo inks	Erythema, induration, papules, nodules	Foreign body or (with certain dyes) sarcoidal granulomas‡ Pseudolymphoma	Pigment granules scattered throughout the infiltrate, extra- and intracellular (macrophages)	
	Lichenoid papules and plaques	Lichenoid dermatitis		
	Eczematous dermatitis (includes allergic* and photoallergic reactions†)‡	Spongiotic dermatitis		
	Verrucous papules and plaques	Pseudoepitheliomatous hyperplasia		
Silica	Nodules, indurated plaques within scar Disseminated papules (blast injuries) Prolonged incubation period	Granulomas (sarcoidal > foreign body)	Colorless crystals, extra- and intracellular	√
Talc	Sarcoid-like papules Thickening and erythema of an old scar Involvement of intertriginous zones, iv injection sites Umbilical stumps	Sarcoidal or foreign body granulomas	Needle-shaped or round talc crystals: clear, blue–green, or yellow–brown	√
	Pyogenic granuloma-like	Pyogenic granuloma-like		
Zirconium	Persistent, soft, brownish papules Involvement of axillary vault	Sarcoidal granulomas		
Beryllium, local cutaneous reaction	Nodule, ulcer (historical)	Caseating granulomas		
Beryllium, systemic	Widely scattered papules (<1% of cases)	Sarcoidal granulomas		
Aluminum	Persistent subcutaneous nodules at injection site	Granulomas with peripheral lymphocytes and eosinophils Pseudolymphoma	Basophilic granular material within the cytoplasm of histiocytes	
Zinc	Furuncles at injection sites	Early: dense neutrophilic infiltrate Late: granulomas and fibrosis	Rhomboidal crystals	√
Starch	Papules, nodules	Foreign body granulomas	Ovoid basophilic starch granules PAS-positive	√ ("Maltese cross"-like appearance)
Cactus spines	Dome-shaped, skin-colored papules with a central black dot	Early: neutrophils Late: sarcoidal or foreign body granulomas	Spines, extra- and intracellular (giant cells) PAS-positive	√
Jellyfish, corals, sea urchin spines	Pruritic lichenoid papules and plaques (onset 2–3 weeks after exposure) Linear, zig-zag and whip-like (flagellate) patterns of erythema/edema (early), hyperpigmentation or lichenoid papules (late)	Lichenoid dermatitis	Calcite crystals (sea urchin spines)	√ (sea urchin spines)
Keratin	Pseudofolliculitis/acne keloidalis	Foreign body granulomas	Other inflammatory cells	√
	Pyogenic granuloma-like lesions (ingrown nails) Pilonidal sinus	Pyogenic granuloma-like		
Intralesional corticosteroids	Skin-colored to yellow–white papules or nodules develop at the site of a previous intralesional injection of corticosteroid The incubation period varies between weeks to months	Foreign body granulomas	Pale bluish material in H&E-stained sections	
Suture	Wound appears inflamed, red, edematous (or develops papules or nodules) and opens to form a fistula	Foreign body granulomas		√

*May also be due to nickel contained in the tattoo gun or preservatives within the tattoo mixture.
†May be associated with a change in the original tattoo color.
‡Allergic reactions most commonly develop within areas of red color and sarcoidal reactions within areas of black color; Rush phenomenon represents the sudden appearance of sarcoidal reactions in multiple tattoos following a reaction in one of them.

Table 94.3 Clinical and histopathologic features of foreign body reactions. The order of the entities in this table corresponds to that in the text. Injectable soft tissue fillers are reviewed in Table 94.5. Energy-dispersive X-ray analysis (EDXA) or laser-induced breakdown spectroscopy can be used to detect tattoo inks, silica, talc, zirconium, aluminum, and zinc. iv, intravenous; PAS, periodic acid Schiff.

(blue), chromium (green), cadmium (yellow, red), ferric hydrate (sienna) and manganese (purple), or organic preparations.

Clinical features

Foreign body reactions may occur within a few weeks of the tattoo placement, but have been reported decades later[16]. Most commonly, erythematous papules, nodules, or plaques are seen (Fig. 94.6), but lesions may be verrucous, lichenoid, pseudolymphomatous, or eczematous. The reactions are usually confined to the site of the tattoo, with the degree of tenderness and erythema reflecting the intensity of the associated inflammation. "Allergic" reactions most frequently occur within the red-colored areas of the tattoo (Fig. 94.7)[13], while sarcoidal

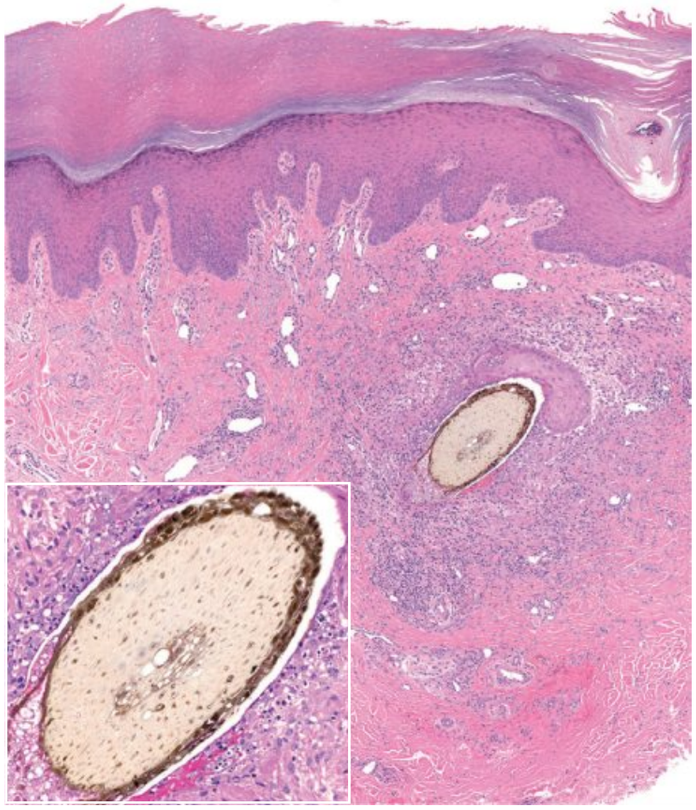

Fig. 94.3 Granulomatous foreign body reaction to implanted organic material in acral volar skin. A plant is the source of the foreign body and the latter is surrounded by a granulomatous reaction as well as neutrophils, lymphocytes, and cellular debris (inset). Superior to the foreign body is a portion of an epidermal cyst due to implantation of epidermal fragments into the dermis. *Courtesy Lorenzo Cerroni, MD.*

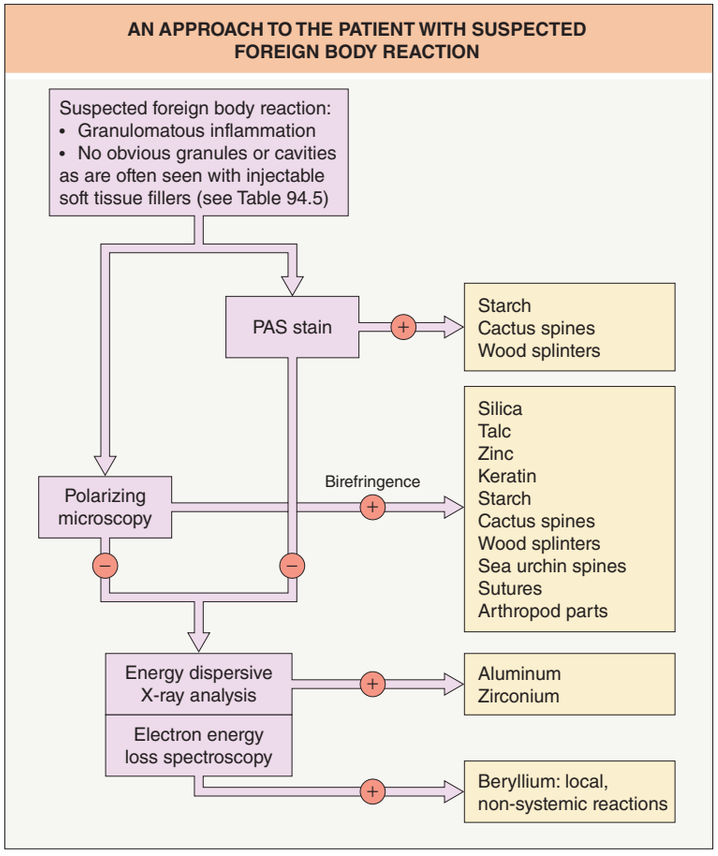

Fig. 94.4 An approach to the patient with suspected foreign body reaction. PAS, periodic acid Schiff.

Fig. 94.5 Traumatic tattoo of the eyelid due to asphalt following a motor vehicle accident. This type of tattoo responds favorably to Q-switched laser therapy.

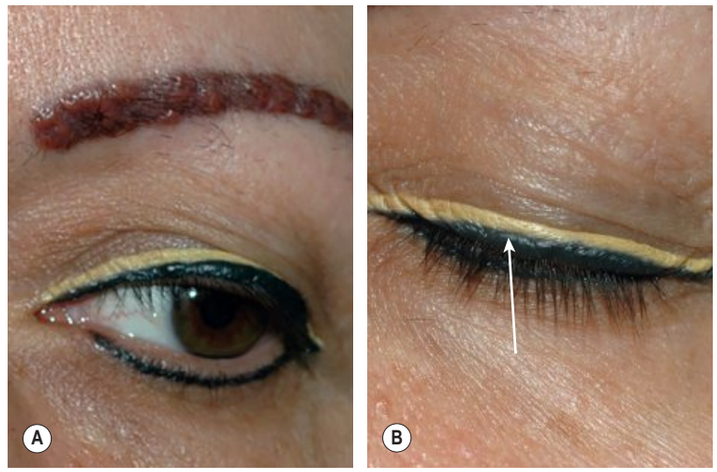

Fig. 94.6 Foreign body reaction to cosmetic tattoos. A Multiple erythematous papules within the eyebrow. **B** Small papules within black eyeliner (arrow). *Courtesy Luis Requena, MD.*

Fig. 94.7 Granulomatous reaction within the red portions of a tattoo. Over the past several years, cinnabar (mercuric sulfide) has been gradually replaced by cadmium selenide (cadmium red), ferric hydrate (sienna), and organic compounds. *Courtesy Lorenzo Cerroni, MD.*

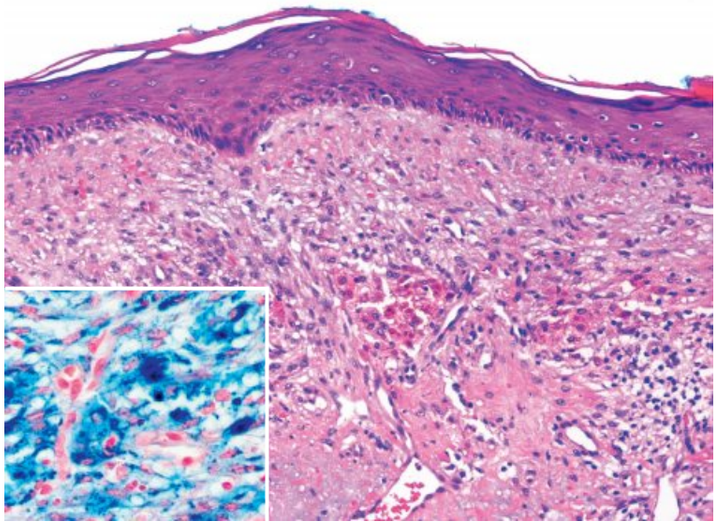

Fig. 94.8 Ferrous subsulfate (Monsel's solution) – iatrogenic tattoo and granulomatous reaction. Coarse granular brown pigment is seen within macrophages and between collagen fibers. The pigment is positive with Perls' stain (inset).
Courtesy Luis Requena, MD.

reactions favor sites of black color. In some patients, granulomatous papulonodules within a tattoo can be a manifestation of cutaneous or systemic sarcoidosis[17]. Rarely, a photoallergic reaction, presenting as pruritic, inflamed nodules, occurs in red or yellow tattoos containing cadmium sulfide following exposure to UV light[16].

Verrucous lesions and pseudoepitheliomatous hyperplasia can also develop within tattoos and may be misdiagnosed as human papillomavirus (HPV) infection or squamous cell carcinoma (SCC). The development of keratoacanthomas or SCCs within tattoos is rare. Tattoo pigments may migrate to the regional lymph nodes and at the time of lymph node sampling may clinically mimic metastatic melanoma[13,18].

Development of inflammation within older tattoos is occasionally triggered by a new tattoo that contains the same pigments. In the Rush phenomenon, granulomatous papulonodules initially develop in the new tattoo then within older tattoos, with sarcoidosis representing a risk factor[17].

Pathology

Different patterns of an inflammatory response can be elicited, including sarcoidal, foreign body granulomatous, lichenoid, eczematous, and pseudolymphomatous[13]. The majority of tattoo pigments appear black in H&E-stained sections, regardless of the color of the pigment (see Fig. 72.23B). Occasionally, colors other than black are seen (see below)[19]. The pigment is deposited in the upper and mid dermis, both extracellularly between collagen bundles and around blood vessels as well as a smaller amount within the cytoplasm of macrophages.

The pigment deposits in professional tattoos are relatively small and homogeneous in size and shape, while in traumatic tattoos they are larger and vary in size and shape[14]. Coarse, granular brown pigment within macrophages and between collagen fibers are seen in iatrogenic tattoos due to ferrous subsulfate (Monsel's solution; Fig. 94.8).

Diagnosis and differential diagnosis

The presence of inflammatory lesions confined to the site of a tattoo suggests the diagnosis. Inoculation of certain infectious agents (e.g. atypical mycobacteria) may mimic pigment-induced inflammation within a tattoo (Table 94.4). In addition to hypertrophic scars and keloids, unrelated benign and malignant tumors can also develop within tattoos.

Identification of the causative pigment is generally unnecessary unless further tattooing is anticipated. Other causes of dermal pigmentation include melanin, hemosiderin, lipofuscin, exogenous ochronosis, silver, gold, minocycline, amiodarone, and chlorpromazine. Special stains to identify melanin and iron (hemosiderin) may be useful (see Ch. 0).

INFECTIONS AND INFLAMMATORY DERMATOSES WITHIN TATTOOS	
Disorder	**Examples**
Infections (reflecting inoculation)	Streptococcal, staphylococcal; atypical mycobacteria (mycobacteria other than tuberculosis); HPV, molluscum contagiosum, HSV
Reactions to pigments	Eczematous, lichenoid, granulomatous foreign body reaction, sarcoidal*, pseudolymphomatous, pseudoepitheliomatous, photoallergic
Koebner phenomenon	Psoriasis, lichen planus, sarcoidosis
Thermal burn induced by MRI	Favors pigments that contain iron oxide
*Evaluate patient for sarcoidosis.	

Table 94.4 Infections and inflammatory dermatoses within tattoos. Systemic infections (e.g. hepatitis C virus, hepatitis B virus, tetanus) have also been reported following tattoo placement. HPV, human papillomavirus; HSV, herpes simplex virus; MRI, magnetic resonance imaging.

Treatment

Topical or intralesional corticosteroids can be used to treat inflamed tattoos. If injections do not lead to significant improvement, surgical excision, if feasible, to remove the inciting pigment is an option. Q-switched and picosecond lasers are commonly employed to remove the various pigments in tattoos (see Fig. 137.16 & Table 137.4)[18], but it is recommended that laser therapy be limited to non-inflamed tattoos[20]. There are reports of systemic reactions, presumably due to the release of pigment from macrophages, following laser therapy[21] and inflamed tattoos may be at greater risk for this side effect. Anecdotally, hydroxychloroquine, tetracyclines, and allopurinol as well as systemic corticosteroids have been used to treat resistant cases.

Paraffin

Paraffin, being a mineral oil, is not hydrolyzed by tissue lipases and is treated by the body as a foreign substance. Augmentation of body contour by local injection of paraffin, although banned in most countries, is still performed in some regions of the world and is mostly done by non-medical personnel. Accidental paraffinoma of the orbit and palpebra has been reported following intraoperative placement of paraffin-impregnated gauze packs within the nasal cavity[5].

Clinical features

In those cases due to injected paraffin, the genitalia, buttocks, and breast are the most common sites of involvement. Penile paraffinomas, also referred to as sclerosing lipogranulomas of the penis, can lead to significant deformity (Fig. 94.9A). Clinically, non-tender firm nodules and indurated plaques are seen, sometimes with ulceration or abscess formation and involvement of subcutaneous tissue (see Ch. 100). The interval between the time of injection and the development of lesions varies from weeks to decades.

Pathology

The dermis shows a characteristic "Swiss cheese" appearance due to the presence of numerous ovoid or round cavities where the paraffin resided prior to processing (Fig. 94.9B). Between the cavities, there is fibrotic connective tissue and a cellular infiltrate composed of macrophages, variable numbers of multinucleated foreign body giant cells, and lymphocytes. Some of the macrophages have foamy cytoplasm. In specially processed tissue, the foreign material stains with fat stains[22], although less intensely than neutral fats, helping to differentiate paraffinoma from reactions to silicone, which also have numerous cavities but negative fat stains.

Treatment

Excision with appropriate tissue reconstruction is the only means of therapy.

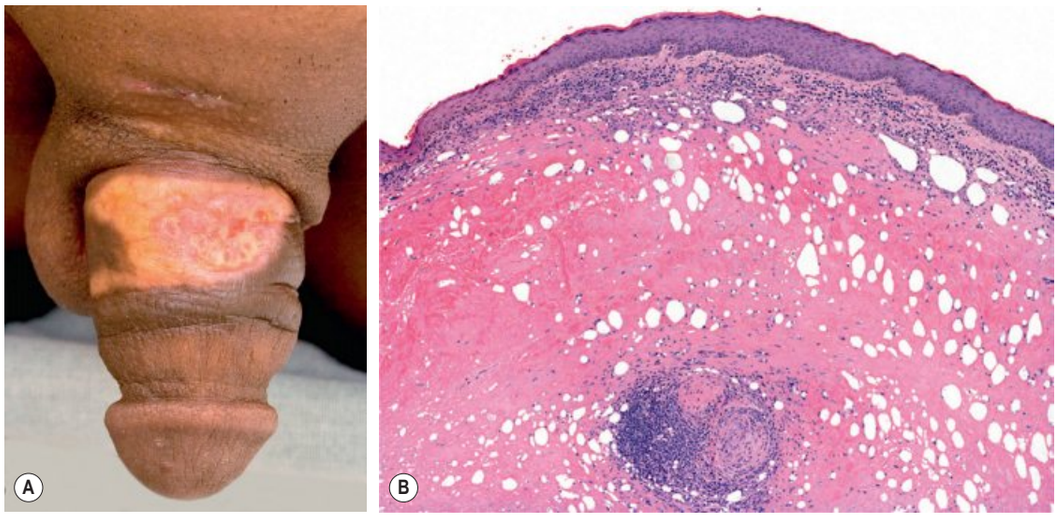

Fig. 94.9 Sclerosing lipogranuloma of the penis. A The penis was injected with paraffin in order to relieve urinary retention following a motorbike accident, and an ulcerated, indurated yellow plaque with telangiectasias developed at the site. **B** Histologic examination showed sclerosis as well as multiple circular and oval empty spaces within the dermis. *Courtesy Glen Foxton, MD and Clare Tait, MD.*

Silicone

Silicone (polydimethyl siloxane), in a liquid, gel, or solid form, is used for tissue augmentation. While silicone is generally regarded as an inert substance, in some patients its use has been followed by foreign body reactions.

Clinical features

Silicone gel-filled implants are widely used for breast augmentation as well as reconstruction after mastectomy and leakage due to permeability loss or rupture can occur. Silicone injections and implants have also been employed for body and facial contour augmentation, including correcting HIV-related lipoatrophy. When a cutaneous foreign body reaction occurs, nodules and plaques develop at the site of injection or placement after a period of months to years. Skin lesions also appear at distant sites, reflecting the tendency for silicone to migrate, including in a dependent, gravity-driven direction. With progression, sclerosis and ulcerations can be seen. Whether the immune system is recognizing the silicone itself versus additives or contaminants including microbes remains speculative[23].

In a recent systematic review, hypercalcemia with renal failure was noted in association with silicone-induced foreign body granulomas and, to lesser extent, polymethylmethacrylate-, paraffin-, and mineral oil-induced foreign body granulomas[24]. An increased risk of autoimmune connective tissue diseases (e.g. Sjögren syndrome, systemic sclerosis, rheumatoid arthritis) in patients with silicone breast implants has been observed in some, but not most, studies[25]. Agreement does exist that textured breast implants, both saline and silicone, are associated with anaplastic large cell lymphoma of the breast.

Pathology

A biopsy specimen is critical to establishing the diagnosis. Histologic sections have a multivacuolated appearance due to the presence of silicone-filled cavities surrounded by histiocytes, lymphocytes, and eosinophils. The histiocytes may be foamy or multinucleated. Fibrous tissue within the areas separating the cavities is also seen. In contrast to paraffinomas, the cavity contents do not stain with lipid stains. Occasionally, silicone granulomas can mimic a low-grade liposarcoma.

Treatment

Excision of persistent symptomatic lesions is recommended.

Silica

Wounds or penetrating injuries accidentally contaminated with silica (silicon dioxide) contained in sand, soil, rocks, and glass may be followed some years later by the formation of a foreign body reaction. The period between inoculation and development of a reaction may be as long as 25 years. This extended "incubation" period is due to the very slow release of colloidal silica (the only form capable of inciting a reaction) from the large particles of silica introduced into the body[26]. Reactions to silica are thought to be due to a delayed-type hypersensitivity response.

Clinical features

At first, the wound heals, but then papules, nodules, or indurated plaques develop within the scar years later. Multiple disseminated lesions may follow trauma produced by the explosion of land mines and bombs[26]. Patients with sarcoidosis may be at increased risk for immunologic responses to silica[27].

Pathology

The dermis contains multiple nodular aggregates of granulomas, usually sarcoidal and less often foreign body, separated by strands of connective tissue. Langhans- and foreign body-type giant cells are usually numerous in both types of granuloma. Colorless crystals may be observed within the cytoplasm of the giant cells or lying free in the interstitium. These bodies are birefringent when examined with polarized microscopy.

Differential diagnosis

Granulomatous lesions occurring at the site of an old scar may mimic cutaneous sarcoidosis clinically and histologically[28]. However, the presence of foreign material within a sarcoidal granuloma does not exclude sarcoidosis, given the attraction of sarcoidosis to existing scars. Examination under polarized light will identify silica crystals.

Treatment

Excision of persistent symptomatic lesions is recommended. Spontaneous resolution of silica granulomas, although reported, is exceptional.

Talc

Talc (hydrous magnesium silicate) is a common cause of foreign body granulomas given its presence in dusting, antifungal, and antibiotic powders. In addition, it is still preferred by some surgeons as a lubricant for surgical gloves. Talc can therefore contaminate wounds, erosions, and umbilical stumps, or it may enter the skin via abrasions and fissures, particularly in intertriginous zones in obese individuals who apply talc powder liberally[29].

Individuals with substance use disorder who inject solutions intravenously or subcutaneously that contain crushed tablets may also develop foreign body reactions to talc as talc is a common filler in tablets. The foreign body reactions may arise at injection sites or at distant sites (e.g. pulmonary intravascular talcosis)[30].

Clinical features

As with reactions to other forms of silica, the lesions usually take a long time to appear. The clinical appearance is varied: it may take the form of erythematous papules and nodules or simply thickening and erythema of an old scar, similar to the range of findings in sarcoidosis. Rarely lesions may resemble a pyogenic granuloma. Despite the long latency period, the diagnosis should be considered, especially when lesions appear in certain sites, e.g. the umbilicus in infants, inguinal area in patients with a history of intertrigo, injection sites in those with a history of intravenous drug use.

Pathology

The histologic features may be similar to those of sarcoidosis or non-caseating tuberculosis. Alternatively, there may be granulomatous inflammation consisting of histiocytes and foreign body giant cells. A few of these cells may contain clear, blue–green, or yellow–brown, needle-shaped or round crystals. Under polarized light, talc crystals are birefringent. A picture simulating a pyogenic granuloma plus giant cells has also been described[5].

Treatment

Excision of persistent symptomatic lesions is recommended.

Zirconium

Some zirconium salts were once components of antiperspirant preparations as well as over-the-counter preparations used in the treatment of allergic contact dermatitis. Sodium zirconium lactate was the first salt incriminated as a cause of foreign body reactions and while banned in the late 1970s, it was replaced by aluminum–zirconium complexes. Subsequently, zirconium oxide and aluminum–zirconium complex were shown to be capable of producing the same reaction. Development of foreign body granulomas represents a delayed-type hypersensitivity reaction to zirconium[6].

In sensitized individuals, persistent, soft, red–brown papules appear in areas to which zirconium-containing preparations were applied. The axillary skin is the most frequently affected site.

Histologically, non-caseating granulomas resembling a sarcoidal reaction are seen[6]. The small size of the zirconium particles does not allow their detection with polarized light microscopy; however, energy-dispersive X-ray analysis can prove their presence.

Beryllium

Chronic beryllium disease is an immunologically mediated occupational disease, primarily affecting workers exposed to beryllium during its manufacture and recycling or in alloy production. Inhalation of beryllium particles was thought to be the source of exposure, but more recent evidence points to both penetration of fine particles (<1 micron) through intact skin, as well as inhalation, as possible routes[31]. In systemic berylliosis, the primary pathology is in the lung and skin involvement is rare (<1%). The cutaneous granulomas of systemic berylliosis consist of widely scattered papules with no secondary changes.

Histologically, cutaneous lesions of systemic berylliosis are indistinguishable from sarcoidosis. In the past, when beryllium was used in the manufacture of fluorescent light bulbs, local cutaneous berylliosis was noted to have a caseating tuberculoid pattern. In systemic berylliosis, bronchioalveolar lavage is recommended for diagnosis.

Aluminum

Rare hypersensitivity reactions to the aluminum adjuvant in vaccines and hyposensitization immunotherapy do occur. Persistent subcutaneous granulomatous nodules can appear at the sites of injection several months after vaccination[32]. Histologically, a central zone of degenerated collagen is surrounded by a rim of both histiocytes, whose cytoplasm contains bluish-grey granules, and lymphoid aggregates, some of which form germinal centers[32,33]. There are also abundant eosinophils. Special stains (e.g. staining for aluminon in which the aluminum appears red) may make aluminum particles more evident. Of note, application of *topical* aluminum chloride for hemostasis can result in the presence of basophilic granules of varying size and shape within the cytoplasm of macrophages[34].

Zinc

A zinc-induced granuloma at the site of an injection is a rare complication of zinc-containing insulin[35]. Sterile furuncles develop at the injection sites and eventually heal with atrophic scars. Histologically, an initial stage characterized by a dense neutrophilic infiltrate is followed by granuloma formation that ends in fibrosis. By polarizing microscopy, birefringent rhomboid crystals are seen.

Treatment

Zirconium, beryllium, aluminum, and zinc granulomas may be surgically excised if they are symptomatic.

REACTIONS TO ORGANIC AND BIOLOGIC PRODUCTS

Starch

Granulomas may result from the contamination of wounds with starch used as a lubricant for surgical gloves.

Pathology

Foreign body granulomas with multinucleated giant cells are seen. Starch granules appear as ovoid basophilic structures. They stain positively with periodic acid Schiff (PAS) and with polarized light are birefringent with a characteristic "Maltese cross"-like appearance[36].

Cactus Spines

Accidental implantation of cactus spines into the skin results from contact with cacti in gardens and fields. Occupational exposure occurs in persons peeling and selling prickly pear fruit, especially in the Middle East and Latin America. Most of the reported cases are due to contact with the genus *Opuntia*[37].

At the time of injury, acute inflammation occurs and then, in some patients, eventually evolves into a typical foreign body reaction. The lesions occur primarily on the hands and fingers as clusters of dome-shaped, skin-colored papules with a central black dot, sometimes called "Sabra dermatitis" (see Ch. 17). This may resemble scabies or fiberglass dermatitis.

Pathology

Foreign body granulomas occupy the entire dermis and surround the spine fragments, which stain intensely red with PAS stain[14,37]. Wood splinters and thorns of other plant origin have a similar suppurative or granulomatous reaction. However, most splinters appear brown with a geometric pattern of cell walls. Fungal hyphae may be present within the plant material, but they seldom invade the surrounding dermis in a healthy host.

Cnidaria (Coelenterata) – Jellyfish, Corals

Members of the phylum Cnidaria (Coelenterata) include jellyfish, corals, and sea anemones (see Ch. 85). Almost all cnidarians possess nematocysts which contain highly coiled, hollow harpoon-like structures that inject a toxin into the skin upon contact.

Clinical features

Jellyfish and coral stings elicit similar cutaneous reactions: an early primary irritant toxic reaction in all exposed persons, and a delayed-type hypersensitivity reaction in a small percentage. A sharp burning pain is felt and, within minutes, the affected area becomes erythematous and edematous and may form blisters (see Fig. 85.20). The acute response may be accompanied by an immediate-type hypersensitivity reaction including urticaria, angioedema, and even anaphylaxis. The lesions resolve, leaving postinflammatory hyperpigmentation in a streaky flagellate fashion corresponding to where the coral or jellyfish brushed the skin. In some individuals, new lesions appear a

few weeks later at previously involved sites (average 3 weeks)[8]. The latter are severely pruritic, shiny, lichenoid papules and plaques and are arranged in a number of patterns, including linear, zig-zag, and whip-like.

Pathology

The lesions that comprise the delayed response have a lichenoid tissue reaction.

Treatment

First aid includes soaking the site in hot, but not scalding, water (denatures proteins). Subsequent use of topical potent corticosteroids, antihistamines, and systemic corticosteroids is controversial. Treatment of acute reactions is reviewed in Chapter 85. Intralesional corticosteroids are the most effective therapy for delayed-type hypersensitivity reactions.

Keratin

Keratin, normally sequestered from the body's immune surveillance by the surrounding epithelium, is treated as foreign if it directly contacts the dermis. This may occur as a result of the rupture of hair follicles, epidermoid cysts, or acne lesions as well as from external keratin sources such as ingrown nails or ingrown hairs; the latter occur in pseudofolliculitis and in pilonidal sinuses. Another source is accidental entry of hairs into interdigital skin, especially in barbers, hairdressers, and dog groomers.

Pseudofolliculitis barbae

In pseudofolliculitis barbae, there is a foreign body inflammatory reaction surrounding a hair that has been previously shaved or plucked (see Ch. 38). This condition affects mainly those with curly hair, with an incidence of more than 50% amongst Black individuals. Certain inherent properties of the hairs in affected individuals, in particular a curled flattened elliptical shape, play an important pathogenic role. Because the shaft is curved, it grows back toward the skin surface. When shaved, the flattened elliptical hair shaft develops a pointed tip, which facilitates re-entry of the hair into the skin (extrafollicular penetration). Transfollicular penetration can also occur (see Fig. 38.10). A foreign body reaction to keratin results in the development of inflammatory papules and pustules that are often followed by hyperpigmentation or small keloidal scars (see Fig. 38.11)[11].

Pseudofolliculitis also affects women or men who regularly remove hair from the pubic region, axillae, and legs by plucking or shaving. Papules containing embedded hairs, pustules, and crusted papules develop in affected areas, often resolving with significant postinflammatory hyperpigmentation.

Treatment

Apart from cessation of shaving or laser epilation of the affected areas, nearly all therapeutic modalities are unrewarding. For further details, see Chapters 38 and 137.

Pilonidal sinus

Most cases of pilonidal sinus occur in the sacrococcygeal region (see Ch. 38). Much less often, it is seen in the umbilical region[38], and, rarely, interdigitally in barbers[39].

Sacrococcygeal pilonidal sinuses may be asymptomatic (debris-filled pit) or present as a draining sinus or an acute abscess. The condition is more common in young men. There is often an underlying cyst with associated granulation tissue, fibrosis, and frequently tufts of hairs. Excisional specimens reveal a sinus tract extending into the dermis and subcutaneous tissue, surrounded by chronic inflammation. Hairs are found in the sinuses in three-quarters of the cases[40].

Small, asymptomatic or slightly tender, openings in the interdigital web spaces of the hands have been observed in barbers, hairdressers, and dog groomers. When these individuals cut hair while wearing sandals, lesions can develop in the web spaces of the feet as well. Penetration of short hairs into the interdigital spaces incites an inflammatory foreign body granuloma. The clinical course is usually self-limited but can be complicated by repeated infections, which may require surgical excision of the involved area[39]. Histologically, a sinus tract lined by epidermis and containing one or several hairs is seen. Hairs extending deeper than the sinus tract incite a foreign body reaction.

INJECTABLE SOFT TISSUE FILLERS

With the exception of autologous fat, all injectable soft tissue fillers, resorbable or non-resorbable, represent foreign bodies and therefore have the potential to cause foreign body reactions (Figs. 94.10 & 94.11; see Ch. 158). Two types of reactions have been reported: non-immunogenic and immunogenic. The former is characterized by localized tissue necrosis, which occurs shortly after implantation, and such reactions are probably the result of local vascular interruption; two-thirds of local necrotic events occur in the glabellar area[41]. Depending upon the particular filler, associated foreign body reactions can range from relatively common (e.g. paraffin) to rare (e.g. hyaluronic acid)[42]. Paraffin and silicone are discussed above and the histopathologic features of inflammatory reactions to various fillers are outlined in Table 94.5[41]. Foreign body reactions usually appear within 1–2 years after injection, and spontaneous resolution occurs in the majority of cases within a year, while the remainder have lesions that wax and wane[43,44].

Hyaluronic Acid

Currently, hyaluronic acid is the most commonly utilized injectable soft tissue filler, in part because the incidence of foreign body reactions is much lower (0.4%) than that reported for bovine collagen (3%–4%)[42]. When a reaction does occur, the injected site becomes firm, tender, edematous, and erythematous, and an abscess may form. This reaction responds to intralesional injections of corticosteroid or hyaluronidase (see Ch. 158)[44], although some patients may be willing to wait for spontaneous resolution which can occur over several months.

Bovine Collagen

In general, bovine collagen alone has been replaced by other less antigenic soft tissue fillers, especially hyaluronic acid. However, there are fillers in which bovine collagen is combined with polymethyl methacrylate microspheres, e.g. Bellafill® (formerly Artefill®). Despite negative skin testing (which is required prior to treatment), a small proportion of patients injected with bovine collagen still develop a local reaction (see Fig. 94.1)[44].

Fig. 94.10 Granulomatous reaction due to silicone injections. The procedure was performed in a beauty salon for cosmetic purposes.

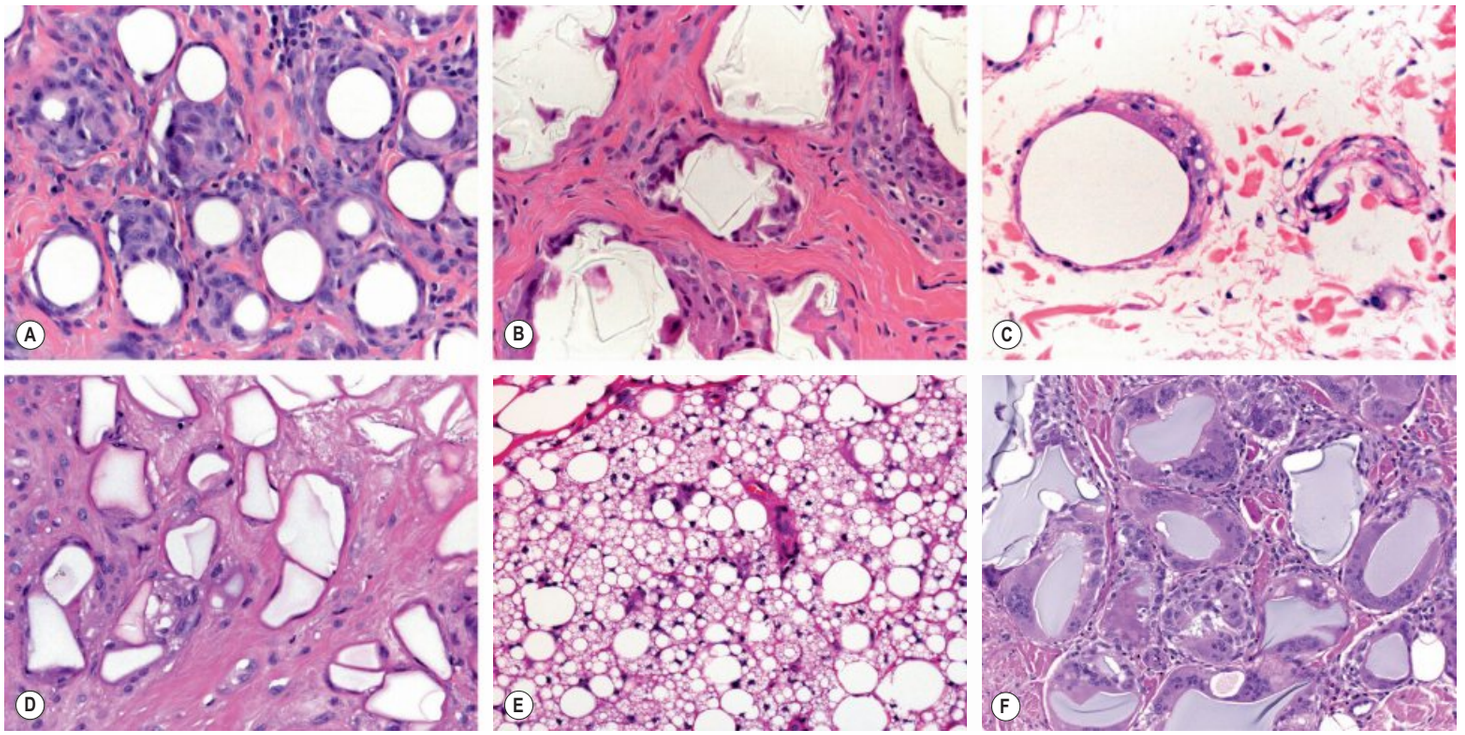

Fig. 94.11 Histopathologic features of granulomatous reactions to different injectable soft tissue fillers. A Multiple uniform vacuoles within an area of granulomatous inflammation due to polymethylmethacrylate microspheres suspended in bovine collagen (Bellafill®, previously known as ArteFill®). **B** Translucent, polygonal and irregularly shaped deposits plus fibrosis and granulomatous inflammation due to silicone elastomer particles and polyvinylpyrrolidone (Bioplastique®). **C** Rounded deposits of silicone surrounded by histiocytic giant cells in a granulomatous reaction to silicone that leaked from a breast implant. **D** Light pink to translucent deposits with a prominent rim in addition to fibrosis due to fragments of hydroxyethylmethacrylate/ethylmethacrylate fragments and hyaluronic acid (Dermalive®). **E** In this granulomatous reaction to silicone injected into the lip, the histiocytes have a foamy appearance due to engulfed silicone. **F** Homogeneous blue-gray deposits of hyaluronic acid within multiple foreign body giant cells. *A–D, F, Courtesy Lorenzo Cerroni, MD; E, Courtesy Luis Requena, MD.*

MISCELLANEOUS

Intralesional Corticosteroids

Foreign body reactions to intralesional corticosteroids are quite rare despite the widespread use of this treatment modality. Reactions result from failure of the injected material to disperse in the usual manner or from incomplete absorption, leaving a small residuum that evokes a foreign body reaction[45].

Histologically, pools of granular, lightly stained material surrounded by a histiocytic and foreign body granulomatous infiltrate are seen in the dermis. Cellular reactions are absent around sites of recent injections[45].

Sutures

Nylon and polypropylene sutures used in contemporary surgery are relatively inert (see Ch. 144), but most other materials regularly produce chronic inflammation and granuloma formation (see Fig. 151.19). The incubation period varies from weeks[46] to years[47].

The incision site may appear inflamed, red, and edematous. A sinus tract may develop, through which the suture material is extruded. Inflammation persists until the suture material is totally removed.

Histologically, granulomatous inflammation of various types is seen surrounding suture material: foreign body, histiocytic, palisading, or a combination thereof (see Fig. 94.2)[46,47]. Transepidermal elimination of the suture material occurs[46].

Polyamide "Hair" Implants

In patients with androgenetic alopecia in whom autologous hair transplantation is not feasible (e.g. inadequate donor sites), polyamide "hair" fibers have been used for synthetic scalp hair restoration. Although some authors have reported complications in only ~1% of patients, foreign body reactions are a real risk (Fig. 94.12)[48]. Polyamide fiber hair restoration is not approved in the US.

Fig. 94.12 Foreign body reactions to polyamide synthetic "hair" implantation. In addition to multiple perifollicular granulomas, there is evidence of chronic folliculitis.

Mesotherapy

Mesotherapy involves placement of a pharmacologic substance into the "mesoderm" (dermis and subcutis). For example, injections of deoxycholic acid (Kybella®) have been approved for the reduction of submental fat and may lead to a temporary chemical panniculitis. However, non-standardized combinations such as phosphatidylcholine plus a detergent solvent (e.g. deoxycholic acid) are also used for lipolysis. With

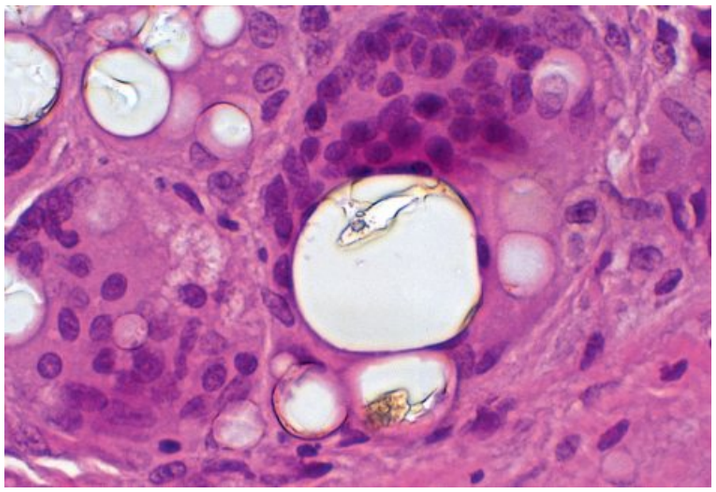
HISTOPATHOLOGIC FEATURES OF INJECTABLE SOFT TISSUE FILLERS		
Category	**Chemical composition**	**Histopathologic features**
Resorbable within months	Hyaluronic acid	• Irregular clusters of basophilic material surrounded by histiocytes and giant cells • Alcian blue stain positive
	Bovine collagen	• Palisading granulomas with foreign body giant cells and eosinophilic bovine collagen in the center of the granulomas • Appearance with polarization differs from human collagen* • IHC – positive staining with anti-bovine collagen type I antibodies
	Human collagen – bioengineered, cadaveric, autologous	• Granulomatous reaction • Appearance with polarization differs from bovine collagen*
Resorbable within years	Hyaluronic acid plus dextranomer microparticles	• Suppurative granulomas surround bluish-grey filamentous material and round, bluish, spherical particles
	Poly-L-lactic acid microspheres plus sodium carboxymethyl-cellulose	• Foreign body granulomas surround fusiform or oval translucent particles • Birefringent under polarized light
	Calcium hydroxylapatite plus carboxymethylcellulose	• Foreign body granulomas surround bluish, rounded particles
Permanent	Paraffin†	• Foreign body granulomas with "Swiss cheese" appearance (Fig. 94.9B) • Positive fat stains (e.g. oil red O) • Detected by IRS
	Silicone oil or silicone gel	• Foreign body granuloma with a multivacuolated appearance (also referred to as "Swiss cheese"; Fig. 94.11C) and histiocytes may be foamy (Fig. 94.11E) • Negative fat stains • Detected by EDXA and in an X-ray, appears radio-opaque
	Silicone particles (100–600 microns) suspended in polyvinylpyrrolidone	• Foreign body reaction with translucent, irregular, non-birefringent particles dispersed in a sclerotic stroma (Fig. 94.11B)
	Polymethylmethacrylate microspheres plus bovine collagen	• Granulomatous infiltrates around vacuolar structures of homogeneous shape and size (Fig. 94.11A)
	Hydroxyethylmethacrylate/ethylmethacrylate fragments in hyaluronic acid	• Foreign body granulomas surround polygonal, irregular, translucent pink structures (Fig. 94.11D)
	Polyacrylamide hydrogel	• Foreign body granulomas surround basophilic, multi-vacuolated material
	Polyalkylimide gel	• Basophilic, amorphous, granular material surrounded by inflammatory infiltrates
	Polyvinylhydroxide microspheres suspended in polyacrylamide gel	• No reports of cutaneous side effects to date; limited local reactions at test sites in volunteers
	Alginates	• Severe granulomatous reaction • Filler material may not be visible or may appear as large, basophilic, oval particles

*Human collagen is birefringent under polarized light and stains green with Masson trichrome stain, whereas bovine collagen is not birefringent with polarized light and stains pale gray–violet with Masson trichrome stain.
†Banned in most countries; also seen after application of paraffin-impregnated gauze packs.

Table 94.5 Histopathologic features of injectable soft tissue fillers. For trade names of the various fillers, see Ch. 158. EDXA, energy dispersive X-ray analysis; IHC, immunohistochemical; IRS, infrared spectrophotometry (non-processed tissue). *Adapted from references 42 & 44.*

these latter combinations, irritant cutaneous necrosis and atypical mycobacterial infections have been observed as well as granulomatous reactions[49]. Lastly, application of moisturizers prior to microneedling for facial rejuvenation can lead to granulomatous reactions[50].

Gouty tophi



Gouty tophi consisting of urate crystals form multiple lobules separated by fibrous septa surrounded by histiocytes and multinucleated foreign body giant cells, resembling a foreign body reaction (see Fig. 48.3). In long-standing tophi, calcium pyrophosphate dehydrate crystals have been detected and they may be dispersed or condensed and present at the edge or inside the tophus lobules. These calcium crystals appear to be a late event and may contribute to the persistence of gout tophi despite success in lowering serum urate levels[51].
