The ANA titer may vary significantly, depending upon how the assay is performed and interpreted (see above). Major commercial laboratories typically report three ANA categories: (1) negative (titer <1:40); (2) equivocal (1:40 to 1:80); and (3) positive (>1:80). However, some laboratories will record an ANA titer of 1:40 as abnormal, presumably because accepting such low levels of ANA as being abnormal retains a high degree of *sensitivity* in detecting systemic AI-CTD. However, using such low ANA titer cut-offs can lead to positive, but clinically insignificant, ANA test results; i.e., it reduces specificity. Several studies that have compared ANA results in SLE populations with those in normal control populations have indicated that a titer of <1:160 has little clinical utility. For example, in one report based upon 15 international laboratories, the ANA positivity rate in a population of healthy individuals (ages 20–60 years) was 13% at 1:80, 5% at 1:160, and 3% at 1:320[8]. Elevated ANA titers can be observed in the elderly, relatives of those with SLE, and patients with other autoimmune disorders (e.g., autoimmune thyroid disease), as well as in healthy individuals. Potential pitfalls when interpreting the results of ANA assays are summarized in Table 40.5.

Immunofluorescence Patterns

Various patterns of nuclear immunofluorescence can be observed in the FANA test (Fig. 40.3): homogeneous (syn. diffuse), peripheral (syn. rim), speckled (syn. particulate), nucleolar, and centromeric (syn. discrete speckled). Except for the centromeric pattern, these patterns

AUTOANTIBODIES ASSOCIATED WITH LUPUS ERYTHEMATOSUS			
Target	**Median prevalence***	**Molecular specificity**	**Clinical associations**
High specificity for SLE			
dsDNA	60%–90%	Double-stranded (native) DNA	LE nephritis and monitoring activity of nephritis
Sm	10%–30% of White population 30%–40% of Asians and African-Americans	Spliceosome RNP – RNP particles involved in splicing pre-mRNA	Renal, neurologic, and hematologic involvement
rRNP	7%–15% 40% of Asians	Ribosomal P proteins – involved in ribosome function	Neuropsychiatric LE
Low specificity for SLE			
ANA (most common IF patterns: homogeneous, peripheral)	99%		
ssDNA	70%–95%	Denatured DNA	Possible risk for SLE in DLE patients; also seen in RA, DM/PM, MCTD, SSc, SjS, morphea
Histones	30%–70%	Histones	Drug-induced SLE; also occur in SLE, RA, and SSc with pulmonary fibrosis (in conjunction with other aAb)
C1q	20%–50% Nearly 100% of patients with active lupus nephritis	C1q component of complement	LE nephritis, severe SLE, hypocomplementemic urticarial vasculitis syndrome
U1RNP	30%–50%	Spliceosome RNP	Overlapping features with other AI-CTDs; MCTD (100%)
SSA/Ro	30%–50%†	Ro60 (60 kDa protein): hYRNP – quality control function for misfolded RNA molecules Ro52 (52 kDa protein): also known as TRIM21 – interferon-inducible protein with ubiquitin modifying function	SCLE (75%–90%), neonatal LE/congenital heart block (99%), SCLE–SjS overlap, primary SjS (70%); in SjS associated with vasculitis
SSB/La	10%–20%	hYRNP	SCLE (30%–40%), SCLE–SjS overlap, primary SjS (40%); occurs in conjunction with SSA/Ro
Cardiolipin	IgM: 20%–75% IgG: 15%–30%‡	Cardiolipin – a negatively charged phospholipid	Recurrent spontaneous abortions, thrombocytopenia, and hypercoagulable state in SLE (cutaneous manifestations include livedo reticularis, leg ulcers, acral infarction/ulceration, hemorrhagic cutaneous necrosis); similar associations in primary antiphospholipid antibody syndrome (APS); clinical manifestations have strongest association with IgG class of anti-cardiolipin aAb
β2 glycoprotein I	IgM: 10%–35% IgG: 8%–25%‡	An important cofactor for cardiolipin in cardiolipin aAb assays	Relatively high risk of thrombosis in SLE and primary APS
"Non-criteria" phospholipids	Phosphatidylserine IgG: 20% of SLE patients with thrombosis Phosphatidylinositol IgG: 20% of SLE patients with thrombosis Phosphatidylcholine: rare Phosphatidylethanolamine: rare Annexin V: rare	Negatively charged phospholipids	Clinical significance remains under investigation; not currently included in SLE or APS clinical criteria
Rheumatoid factor	25%	Fc portion of IgG	Nonspecific
Ku	10%	DNA end-binding repair protein complex	Overlap with other AI-CTDs such as DM/PM, SSc
Alpha-fodrin	10%	An actin-binding protein found at the periphery of chromaffin cells that may be involved in secretion	SjS

*Based on most common assay techniques currently employed in clinical immunology laboratories.
†Refers to SSA/Ro antigen detection as a whole and not Ro52 or Ro60 subsets; see text for specific Ro52 and Ro60 associations.
‡Range depending on 99th or 90th percentile assay cut-off.

Table 40.1 Autoantibodies associated with lupus erythematosus. aAb, autoantibody; AI-CTDs, autoimmune connective tissue diseases; ANA, anti-nuclear antibodies; DLE, discoid lupus erythematosus; DM/PM, dermatomyositis/polymyositis; IF, immunofluorescence; LE, lupus erythematosus; MCTD, mixed connective tissue disease; PCNA, proliferating cell nuclear antigen; RA, rheumatoid arthritis; RNP, ribonucleoprotein; SCLE, subacute cutaneous lupus erythematosus; SjS, Sjögren syndrome; SLE, systemic lupus erythematosus; SSc, systemic sclerosis. AUTOANTIBODIES ENCOUNTERED IN THE IDIOPATHIC INFLAMMATORY DERMATOMYOPATHIES			
Target	**Median prevalence***	**Molecular specificity**	**Clinical associations**
High specificity for DM/PM			
Mi-2	Classic DM: 10%–35% Juvenile DM: 4%–10%	Helicase nuclear protein	• Gottron papules/sign, shawl sign, cuticular telangiectasias, cuticular overgrowth/dystrophy • Favorable response to therapy and better prognosis
TIF1-γ (p155)	Classic DM: 10%–30% Clinically amyopathic: 20%–45% Classic DM in Japanese adults: 50% Juvenile DM: 20%–35%	p155: transcriptional intermediary factor 1 gamma (TIF1-γ) p140: TIF1-α	• Clinically amyopathic DM • In adult-onset classic DM, increased risk of malignancy • Extensive photosensitive cutaneous disease • Mucocutaneous findings include palatal erythema ("ovoid patches"), psoriasiform lesions, and hypopigmented and telangiectatic ("red on white") patches • In juvenile DM, associated with treatment-refractory disease, ulcerations, and chronic course
MDA5/CADM-140	Classic DM: 10%–15% In adult Japanese: • classic: 10%–45% • clinically amyopathic: 70%–85% • Juvenile DM: 5%–10%	Melanoma differentiation-associated protein 5 (MDA5)/clinically amyopathic DM-140 kDa molecule/IFN-induced with helicase C domain protein 1 (IFIH1)	• Clinically amyopathic DM • Rapidly progressive interstitial lung disease • Cutaneous ulcerations with associated vasculopathy, tender palmar papules, oral pain and ulceration • In juvenile DM, milder muscle disease, mucocutaneous ulcerations, and interstitial lung disease
ARS	Jo-1: 15%–30% PL-7: ≤5% PL-12: ≤5% OJ, EJ, KS, ZO, YRS: rare	Aminoacyl tRNA synthetases (ARS), e.g. Jo-1 targets histidyl tRNA synthetase	• Antisynthetase syndrome with fever, myositis, polyarthritis, Raynaud phenomenon, interstitial lung disease
NXP-2 (p140)	Adult DM: 5%–25% (varies by ethnicity, most common in White population) Juvenile DM: 20%–25%	Nuclear matrix protein 2 (MORC family CW-type zinc finger 3 [MORC3])	• In adult DM, associated with malignancy, subcutaneous edema, and calcinosis • In juvenile DM, more severe muscle disease and calcinosis
SAE	1%–8%	SUMO activation enzyme – posttranslational modification of proteins that are critical for subcellular localization	• Severe cutaneous disease, progressive muscle disease, dysphagia
SRP	1%–8%	Signal recognition particle – intracytoplasmic protein translocation	• Fulminant DM/PM • Cardiac involvement
Low specificity for DM/PM			
ANA (most common IF patterns: speckled, nucleolar)	40%		• Clinically amyopathic DM (65%)
ssDNA	40%	Single-stranded DNA	• SLE, SSc, morphea
PM-Scl (PM-1)	10%	Ribosomal RNA processing enzyme	• Overlap with SSc
SSA/Ro (especially Ro52)	15%	hYRNP	• Overlap with SjS, SCLE, neonatal LE/CHB, SLE
U1RNP	10%	Spliceosome RNP	• Overlap with other AI-CTDs
Ku	3%	DNA end-binding repair protein complex	• Overlap with SSc
U2RNP	1%	Spliceosome RNP	• Overlap with SSc
*Using current assay techniques.			

Table 40.2 Autoantibodies encountered in the idiopathic inflammatory dermatomyopathies (DM/PM). Rarely, patients develop specific aAb targeting Fer (elongation factor 1-α) and Mas (small RNA). ANA, anti-nuclear antibodies; ARS, aminoacyl tRNA synthetase; CADM, clinically amyopathic DM; CHB, congenital heart block; DM/PM, dermatomyositis/polymyositis; IF, immunofluorescence; IFN, interferon; LE, lupus erythematosus; RNP, ribonucleoprotein; SCLE, subacute cutaneous lupus erythematosus; SjS, Sjögren syndrome; SLE, systemic lupus erythematosus; SSc, systemic sclerosis. Adapted from references 2, 32, 36, 54–57.

have little disease specificity and are of little value in the management of patients. The centromeric pattern reflects the binding of aAb to the polypeptide components of chromosomal centromeres (e.g. CENP-B) and is associated primarily with the limited form of SSc (see Table 40.3). A peripheral pattern can be suggestive of aAb to DNA, including dsDNA. The nucleolar pattern is due to aAb binding to ribosomal RNA processing molecules such as fibrillarin and can be indicative of SSc. A speckled pattern is due to various antibodies, including those that recognize Sm, RNP, SSA/Ro, SSB/La, Sc1-70, and RNA polymerases (RNAP). Nowadays, commercial laboratories often report primarily homogeneous and speckled staining patterns because they commonly occur in healthy and older individuals. As a result, a higher threshold (e.g. ≥1 : 160) may need to be considered for determining whether a titer is clinically relevant. In general, ANA patterns have been replaced by specific tests for nuclear and cytoplasmic antigens.

Clinical Utility of the ANA Assay

Key concepts in laboratory testing – sensitivity, specificity, positive predictive value, and negative predictive value – are presented in Fig. 40.4[9]. These concepts should be kept in mind when considering the cost–benefit ratio of laboratory testing for AI-CTD. The ANA test is used most often for the diagnosis of SLE. In SLE patients, its sensitivity and specificity are 98% and 90%, respectively[10], but in unselected patients, the positive predictive value for SLE detection is 30%–40%, while the negative predictive value is 99%. Thus, about

AUTOANTIBODIES ASSOCIATED WITH SYSTEMIC SCLEROSIS (SSc)				
Target	**SSc, all***	**SSc with diffuse cutaneous scleroderma***	**SSc with limited cutaneous scleroderma (CREST syndrome)***	**Clinical features**
High specificity for SSc				
Centromere (CENP-B)	20%–40%	30%	80%	Better prognosis; pulmonary arterial hypertension
DNA topoisomerase I (formerly Scl-70; DNA-unwinding enzyme)	15%–40%	60%	15%	Worse prognosis; pulmonary fibrosis
RNA polymerase III	5%–30%	45%	6%	Worse prognosis; aAb levels correlate with extent of skin involvement and renal disease; malignancy association, especially breast cancer
Th/To RNP (mitochondrial enzyme)	1%–15%	10%	20%	Worse prognosis; limited pulmonary fibrosis
Fibrillarin (U3RNP, spliceosome RNP)	5%–10%			Worse prognosis; cardiac, renal involvement
RNPC-3 (U11/U12RNP, spliceosome RNP)	3%			Worse prognosis; pulmonary fibrosis, GI involvement, Raynaud phenomenon, malignancy association
Low specificity for SSc				
ANA	95%*			
Angiotensin type 1/Endothelin-1 type A receptors	80%			
PDGFR (expressed on fibroblasts)†	30%–100%			
Endothelial cells (activation and apoptosis)	45%–85%			
MMP-1 and 3 (degrade ECM proteins; aAb prevents degradation)	50%	70%	33%	
HMG (non-histone nucleosomal protein)		30%	40%	
Fibrillin-1 (component of ECM)	>50%			
Histones	40%			
ssDNA	10%–30%			
Rheumatoid factor	25%			
PM-Scl	5%–10%		More commonly associated with limited SSc	Better prognosis; overlap with DM/PM
U1RNP (spliceosome RNP)	2%–15%		More commonly associated with limited SSc	Better prognosis; overlap with MCTD

*Median prevalence using current assay techniques.
†Results vary, depending upon study; evidence that aAb do not activate the receptor; seen in up to 20% of controls.

Table 40.3 Autoantibodies associated with systemic sclerosis (SSc). The hallmark aAb of SSc are shaded in orange. ANA, anti-nuclear antibodies; ECM, extracellular matrix; HMG, high mobility group; IF, immunofluorescence; MCTD, mixed connective tissue disease; PDGFR, platelet-derived growth factor receptor; RNP, ribonucleoprotein; RNPC-3, RNA binding region (RNP1, RRM) containing 3. Adapted from references 2, 49, 50, and 58.

two-thirds of the positive ANA levels observed in a general medical population will be associated with disorders other than SLE, and only very rarely will a person with a negative ANA have SLE. Positive ANA tests are also seen in a large percentage of patients with other AI-CTDs: SSc – 90%; SjS – 70%; and idiopathic inflammatory dermatomyopathies – 40%–65%. There are numerous clinical associations for a positive ANA test[11], and it is noteworthy that clinically silent systemic autoimmune diseases (e.g. autoimmune thyroiditis, pernicious anemia, Addison disease) can contribute to a positive ANA in patients with autoimmune dermatologic disorders such as vitiligo and alopecia areata.

Clinical Value of aAb in Diagnosis, Prognosis, and Disease Activity Monitoring

In everyday practice, these laboratory tests can be used to: (1) establish the diagnosis of an AI-CTD; (2) provide prognostic information; and (3) in specific instances, monitor the level of activity of an AI-CTD[10]. For example, the Sm aAb is highly specific for SLE and thus has considerable diagnostic value. However, the absolute amounts of anti-Sm aAb present in a patient at different time points do not correlate strongly enough with SLE disease activity to have practical clinical value in patient management. Likewise, there is not much value in serial determinations of ANA titers when monitoring disease activity in SLE. However, a few aAb can be used for establishing the diagnosis and monitoring systemic activity, e.g. anti-dsDNA in LE nephritis and cytoplasmic anti-neutrophil cytoplasmic antibodies (c-ANCA) in granulomatosis with polyangiitis. Some aAb can even provide prognostic information, e.g. anti-RNAP aAb are a risk factor for developing renal crisis in patients with systemic sclerosis.

"Sontheimer's Corollary" to Greenwald's Law of Lupus

Robert A. Greenwald formulated a law stating that if a patient is diagnosed as having SLE, everything that happens to that patient afterward, rightly or wrongly, is attributed to SLE. Richard D. Sontheimer formulated a corollary to Greenwald's law, stating that anything happening to a patient with a positive ANA that is not immediately otherwise explicable will automatically be blamed on SLE[12]. This is especially true in patients presenting with non-lupus photosensitive facial eruptions (e.g. rosacea, polymorphic light eruption, photoallergic contact dermatitis) who might also have a positive ANA test for reasons other than SLE[13].

AUTOANTIBODIES ASSOCIATED WITH OTHER RHEUMATIC DISEASES HAVING CUTANEOUS MANIFESTATIONS			
Autoantibody	**Median prevalence***	**Molecular specificity**	**Clinical associations**
Rheumatoid arthritis			
Rheumatoid factor	80%	Fc portion of IgG	*Low levels*: very nonspecific (healthy elderly individuals, SLE, SSc, MCTD, neoplasia, chronic infections, chronic inflammatory lung diseases, chronic liver disease, sarcoidosis, systemic vasculitides) *High levels*: associated with erosive, crippling RA (25%–90%) and extra-articular manifestations of RA, e.g. systemic vasculitis (i.e. peripheral neuropathy, cutaneous vasculitis); mixed cryoglobulinemia secondary to hepatitis C infection (types II, III; 40%–100%); SjS
Anti-cyclic citrullinated protein (CCP) antibodies	70%	Citrullinated proteins in the skin (e.g., filaggrin) and joints	Increased severity of RA, including radiologic progression of erosive arthritic changes; predictor for the development of RA
Sjögren syndrome			
Alpha-fodrin	70%	An actin-binding protein found at the periphery of chromaffin cells that may be involved in secretion	More specific for SjS than anti-SSA/Ro aAb; also seen in SLE
SSA/Ro	60%	hYRNP	SLE, SCLE, neonatal LE/CHB
SSB/La	20%	hYRNP	SLE, SCLE, neonatal LE/CHB
Mixed connective tissue disease (MCTD, Sharp syndrome)			
U1RNP†	100%‡	Spliceosome RNP	Raynaud phenomenon, swollen hands with sausage-like swelling of digits, polyarthritis, myositis, inverse association with nephritis

*Using current assay techniques.
†In MCTD, associated with high-titer ANA and lack of other aAb.
‡By definition at time of diagnosis.

Table 40.4 Autoantibodies associated with other rheumatic diseases having cutaneous manifestations. More in-depth information concerning clinico-serologic associations can be found elsewhere[8,10,16,59]. aAb, autoantibodies; CHB, congenital heart block; LE, lupus erythematosus; MCTD, mixed connective tissue disease; RA, rheumatoid arthritis; RNP, ribonucleoprotein; SCLE, subacute cutaneous lupus erythematosus; SjS, Sjögren syndrome; SLE, systemic lupus erythematosus; SSc, systemic sclerosis.

Phototherapy and ANA

The question of ANA and anti-SSA/Ro antibody testing often arises in patients being considered for phototherapy, especially if there is any concern about an underlying photosensitive state. However, when screening patients for a multisystem autoimmune disease such as SLE, it is a good rule to remember that patients having any degree of clinically significant SLE are virtually never asymptomatic. Symptoms such as easy fatigability, malaise, and arthralgias are almost always present. In addition, studies have shown that phototherapy protocols such as PUVA or NB-UVB do not significantly induce the appearance of ANA and other aAb[14]. Consequently, while a thorough history, review of systems, and physical examination are indicated in all patients prior to phototherapy, ANA testing is not, unless there is a consistent history or suggestive physical findings.

How Does One Evaluate a Positive ANA Result in a Patient Suspected of Having SLE?

This question would likely be answered differently depending upon the specialist. Dermatologists usually see a highly selected population of LE patients by virtue of their having some form of cutaneous involvement that at times can be the only significant clinical manifestation of the autoimmune disease process (e.g. chronic or subacute cutaneous LE). Therefore, compared to rheumatologists evaluating a patient with suspected SLE, a more focused approach can be undertaken by dermatologists evaluating a positive ANA in a patient who has or is suspected of having cutaneous LE (Fig. 40.5).

AUTOANTIBODIES IN LUPUS ERYTHEMATOSUS

Over 180 LE-associated aAb have been described[15]. Table 40.1 summarizes aAb that are highly specific for SLE as well as less specific aAb that occur in both SLE and other AI-CTD[16]. For example, aAb to dsDNA and Sm are quite specific and the presence of either one represents six points in the EULAR/ACR classification criteria for SLE (see Table 41.5)[17]. The 2012 Systemic Lupus International Collaborating Clinics (SLICC) classification also includes both of these aAb in their immunologic criteria for SLE (see Table 41.4)[18]. Both the EULAR/ACR and SLICC classifications include antiphospholipid antibodies as a criterion, but these are not specific for SLE.

Anti-dsDNA Antibodies

Rising levels of anti-dsDNA aAb correlate positively with SLE disease activity, especially when associated with falling complement values. High levels can reflect an increased risk for LE nephritis. Unfortunately, the clinical value of anti-dsDNA aAb measurements is somewhat diluted by the characteristics of modern assay techniques. The popular ELISA assays preferentially detect *low-avidity* anti-dsDNA aAb that are also seen in patients who do not have SLE. It is recommended that all positive anti-dsDNA aAb ELISA results be confirmed by a second assay technique that detects *high-avidity* anti-dsDNA aAb, such as the Farr radioimmunoassay or the *Crithidia luciliae* indirect immunofluorescence test (CLIFT)[19,20].

Anti-SSA/Ro and Anti-SSB/La Antibodies

Anti-SSA/Ro and anti-SSB/La aAb were originally thought to react exclusively with cytoplasmic ribonucleoproteins (RNP) and were thus designated as cytoplasmic aAb. However, subsequent studies demonstrated that these aAb react with proteins present in human cytoplasmic RNP (hYRNP) that are found in both the cytoplasm and nucleus. Further investigations detected 52 kDa and 60 kDa Ro antigens (termed Ro52 and Ro60); Ro52 is localized within the cytoplasm, while Ro60 is in the nucleus. $Ro52^{-}Ro60^{+}$ serology has been associated with SLE, $Ro52^{+}Ro60^{+}$ with primary SjS, and $Ro52^{+}Ro60^{-}$ with several autoimmune diseases including inflammatory myositis[21]. Because the Ro and La antigens are present on the same RNP particles, an autoimmune response that develops against one of these autoantigens often spreads to the other. This explains the observation that when one aAb is present in an individual, the other is frequently present as well. However, while anti-SSA/Ro aAb can occur alone, this is extremely rare for anti-SSB/La aAb.

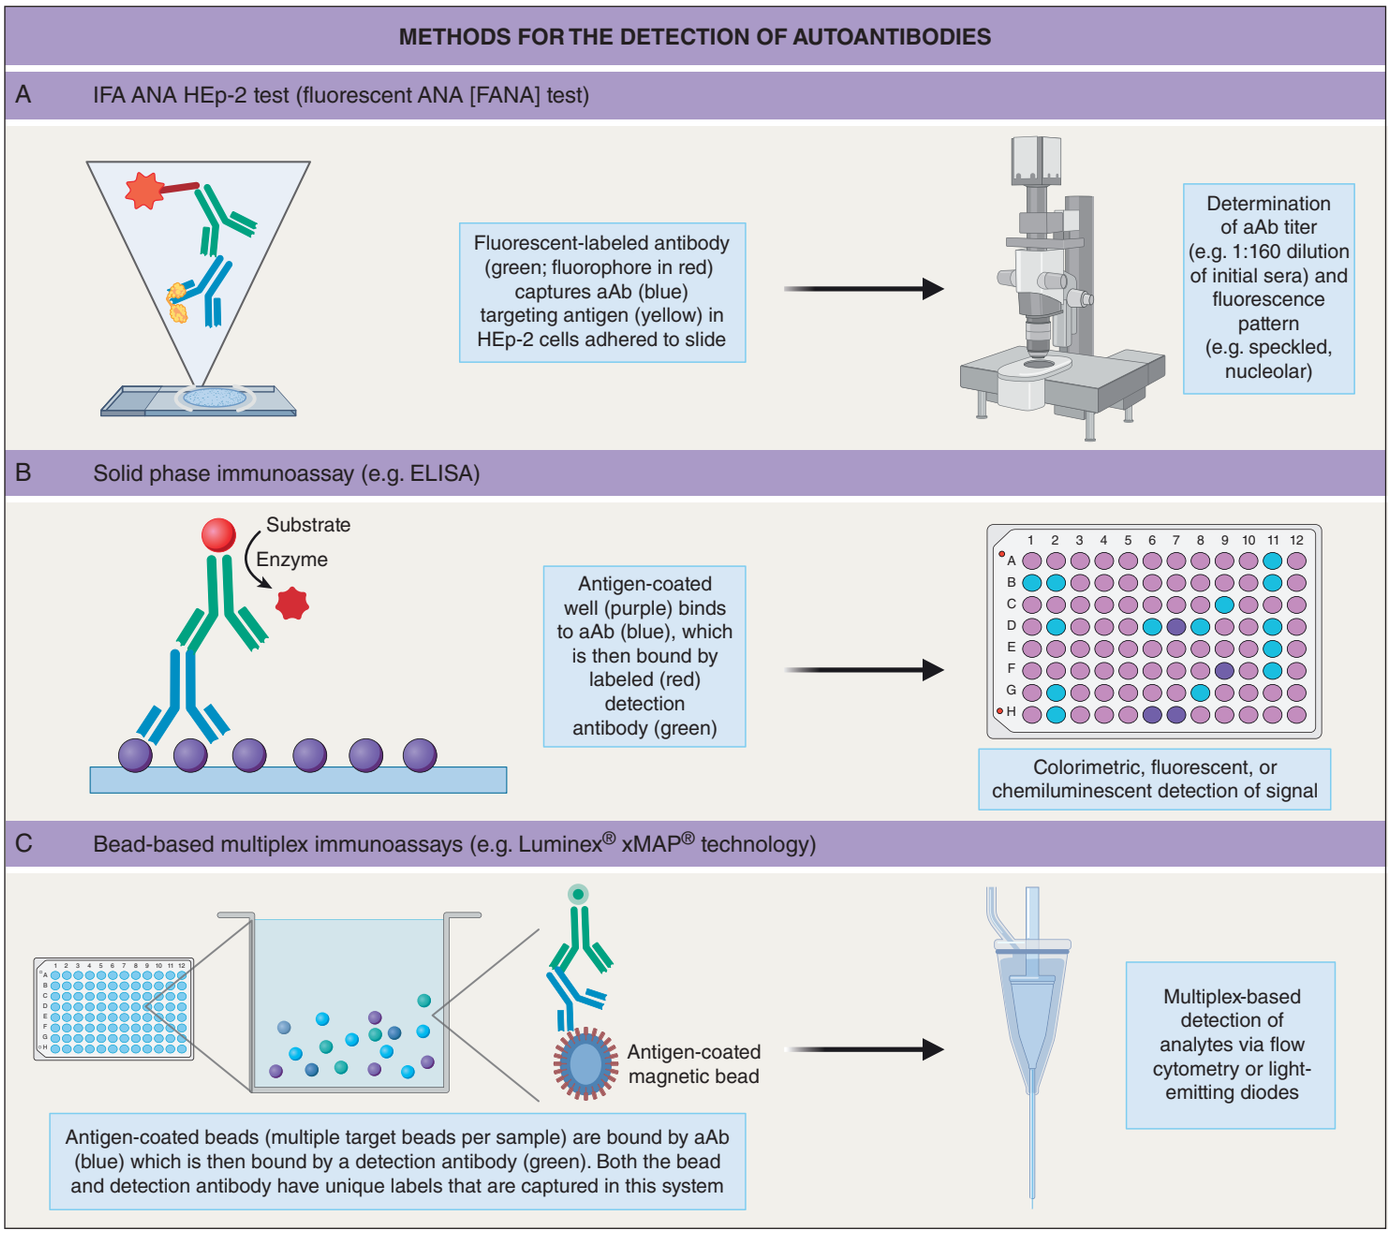

Fig. 40.2 Methods for the detection of ANA. A In the fluorescent ANA (FANA) test, serum samples are usually incubated on a slide with adherent HEp-2 cells. ANA that bind to autoantigens in HEp-2 cells are detected by fluorophore-labeled anti-immunoglobulin (detection) antibodies and visualized with a fluorescence microscope. **B** In a solid-phase immunoassay, a surface (e.g. polystyrene, nitrocellulose) is coated with autoantigens. Following binding of aAb to the autoantigens, they are detected by anti-immunoglobulin (detection) antibodies. By linking the detection antibody to an enzyme that produces one of the following – a colorimetric signal (enzyme-linked immunosorbent assay [ELISA]), a fluorescent signal (fluorometric enzyme-linked immunoassay [FEIA]), or a chemiluminescent signal (chemiluminescence immunoassay [CIA]) – the concentration of aAb is determined. **C** In bead-based multiplex immunoassays, autoantigens are coupled to beads. After the beads are incubated with the patient's serum, bound aAb are detected by fluorophore-labeled detection antibodies in a flow cytometry-based system using two lasers or light-emitting diodes. Both the beads and the detection antibodies have unique fluorescence signals, allowing simultaneous detection of multiple aAb.

MAJOR ISSUES RELATED TO THE INTERPRETATION OF RESULTS OF ANTI-NUCLEAR ANTIBODY (ANA) ASSAYS
• Methods of detecting and reporting ANA (e.g. use of a human tumor cell line substrate leads to increased sensitivity but decreased specificity)
• Subjective nature of FANA assay endpoint
• Requirement for predefined antigen combinations in ELISA or multiplex bead-based assays
• "Normal" versus "abnormal" ANA levels
• Patient age
• Drug-induced ANA
• ANA can be seen in disorders other than AI-CTDs
• Sontheimer's corollary to Greenwald's law of lupus

Table 40.5 Major issues related to the interpretation of results of anti-nuclear antibody (ANA) assays. AI-CTD, autoimmune connective tissue disease; ELISA, enzyme-linked immunosorbent assay.

As with anti-dsDNA aAb assays, it is important to understand certain technical considerations relating to anti-RNP aAb assays, such as those used to measure anti-SSA/Ro, anti-SSB/La, anti-U1RNP, and anti-Sm aAb (i.e. ENA). Nowadays, anti-RNP aAb are usually detected via solid-phase immunoassays such as ELISA (see Fig. 40.2B), which are more sensitive but less specific than the older double immunodiffusion (DID) assays. As a result, some of the original clinical correlations for anti-SSA/Ro, anti-SSB/La, anti-Sm, and anti-U1RNP aAb that were based upon the results of DID assays do not hold with regard to the results of modern ELISA. For example, Lee and colleagues[22] compared the sensitivity of DID assays and ELISA for the detection of aAb to SSA/Ro in patients with SCLE and discoid LE (DLE). High-titer anti-SSA/Ro aAb in the ELISA correlated with positive results in DID assays and the clinical diagnosis of SCLE. Low-titer anti-SSA/Ro aAb in the ELISA were observed in approximately two-thirds of DLE sera tested and correlated with negative results in DID assays. In conclusion, low

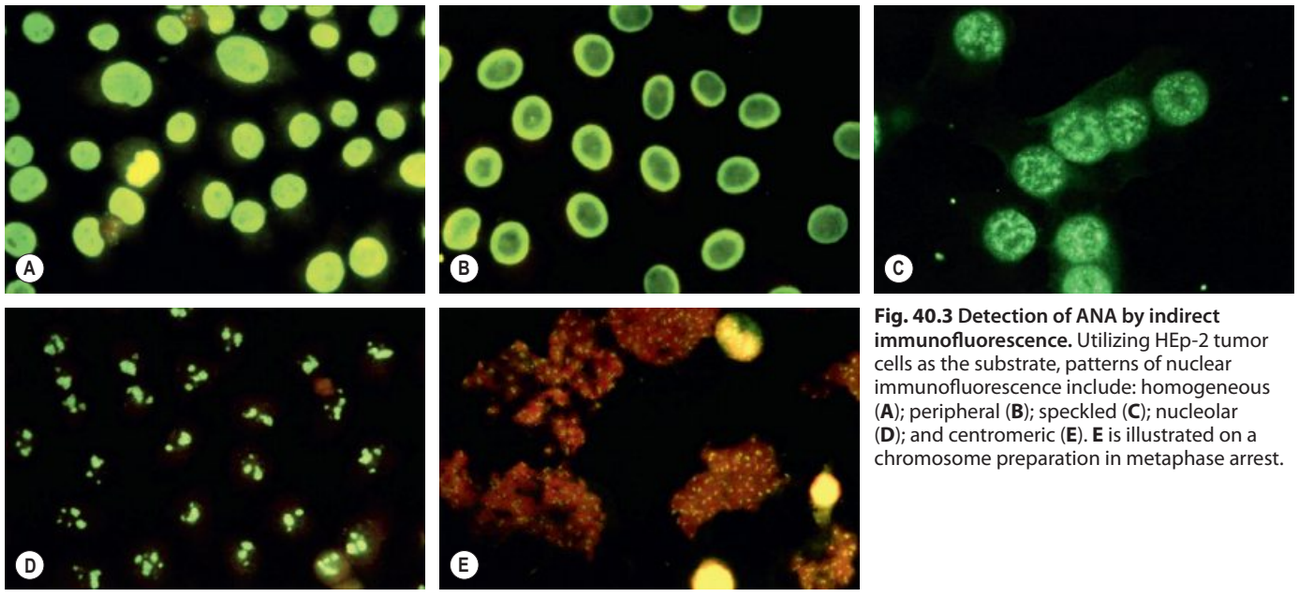

Fig. 40.3 Detection of ANA by indirect immunofluorescence. Utilizing HEp-2 tumor cells as the substrate, patterns of nuclear immunofluorescence include: homogeneous (**A**); peripheral (**B**); speckled (**C**); nucleolar (**D**); and centromeric (**E**). **E** is illustrated on a chromosome preparation in metaphase arrest.

CONCEPT OF CLINICAL UTILITY IN LABORATORY TESTING

	Disease present	Disease absent
Positive result	True positive (TP)	False positive (FP)
Negative result	False negative (FN)	True negative (TN)

Sensitivity=TP/(TP+FN)
Specificity=TN/(TN+FP)
Positive predictive value=TP/(TP+FP)
Negative predictive value=TN/(TN+FN)

Fig. 40.4 Concept of clinical utility in laboratory testing. *With permission from Ward MM. Laboratory testing for systemic rheumatic diseases. Postgrad Med 1998;103:93–100.*

anti-SSA/Ro titers are of uncertain clinical significance, may be found in normal sera, and should not be used as evidence to support diagnoses classically associated with anti-SSA/Ro aAb.

Drug-Induced ANA/SLE

Several drugs can trigger ANA or a drug-induced SLE syndrome, including minocycline, procainamide, hydralazine, isoniazid, chlorpromazine, phenytoin, quinidine, and methyldopa. The predominant clinical manifestations of drug-induced SLE are musculoskeletal symptoms (arthritis, arthralgia, myalgia) and serositis (pleuritis, pericarditis). Skin involvement is uncommon. In a comprehensive review[23], only 25% of hydralazine-induced SLE patients had "skin involvement", and fewer than 5% of procainamide-induced SLE patients experienced "skin changes", whereas 71% of idiopathic SLE patients had some type of skin change. Anti-histone aAb represent also a serologic marker of drug-induced ANA and drug-induced SLE (present in 95%), but can also be present in patients with idiopathic SLE.

A different set of drugs, including hydrochlorothiazide, terbinafine, proton pump inhibitors, griseofulvin, diltiazem and taxanes, can trigger anti-SSA/Ro aAb production and the cutaneous lesions of SCLE[24]. Anti-histone aAb are not a characteristic finding in drug-induced SCLE. Finally, SCLE, DLE, and SLE have occasionally been observed in patients receiving immune checkpoint inhibitors such as nivolumab and pembrolizumab[25].

Induction of ANA and anti-dsDNA antibodies by tumor necrosis factor inhibitors

Tumor necrosis factor (TNF) blockade by recombinant proteins is a common therapeutic intervention (see Ch. 128) and is associated with the induction of aAb, especially ANA and anti-dsDNA antibodies. However, the clinical significance of these aAb is not well defined and the incidence of clinically detectable autoimmune disease is low. In a study of 125 psoriasis patients treated with a TNF inhibitor, newly positive ANA titers developed after a mean of 8–20 months in ~20% of those who received etanercept (9/45) or adalimumab (9/47), compared with 48% of those who received infliximab (16/33); anti-dsDNA aAb developed in 6% of patients in each group (8/125 overall)[26]. However, clinical manifestations of LE were not evident in any of these patients. In a series of 22 patients who developed a lupus-like syndrome during therapy with either infliximab or etanercept, cutaneous features included: a butterfly rash (ACLE), SCLE, DLE, small vessel vasculitis, and chilblains[27]. Additional findings were arthritis, phlebitis (with anti-cardiolipin antibodies), leukopenia, thrombocytopenia, serositis, and general manifestations (e.g. fever, weight loss, asthenia); renal involvement was rare[28].

Notably, all the TNF inhibitors have the propensity to induce ANA and anti-dsDNA aAb as well as cutaneous LE, SLE, or a lupus-like syndrome. When a French pharmacovigilance database was analyzed for TNF inhibitor-induced LE or lupus-like syndrome, the estimated reporting odds ratios were 9–10 for infliximab and adalimumab, and 4 for etanercept[29]. Interestingly, in patients with rheumatoid arthritis and psoriasis, the production of lupus-associated antibodies was linked to both the formation of anti-drug antibodies (resulting in decreased therapeutic efficacy) and type 1 interferon production[30]. However, when over 1000 patients with rheumatoid arthritis underwent serial measurements of ANA and anti-dsDNA aAb, the serologic results failed to predict the onset of lupus or vasculitis[31].

In summary, although the development of aAb is relatively common during TNF inhibitor administration, they are only occasionally of clinical significance. In the absence of clinical signs or symptoms, we do not recommend screening for ANA prior to initiation of TNF inhibitors.

AUTOANTIBODIES IN IDIOPATHIC INFLAMMATORY DERMATOMYOPATHIES

The term "idiopathic inflammatory *dermato*myopathies" (syn. dermatomyositis [DM]/polymyositis [PM], idiopathic inflammatory myopathies; see Ch. 42) has been coined to include cutaneous-only or cutaneous-predominant subsets of DM, such as clinically amyopathic DM (i.e. amyopathic DM and hypomyopathic DM). Patients with adult-onset, clinically amyopathic DM (CADM) appear to have a somewhat higher prevalence of ANA (65%) than patients with classic DM and PM. Compared to LE, there are more highly specific aAb, and titers of some of these specific aAb are associated with disease severity[32]. Table 40.2

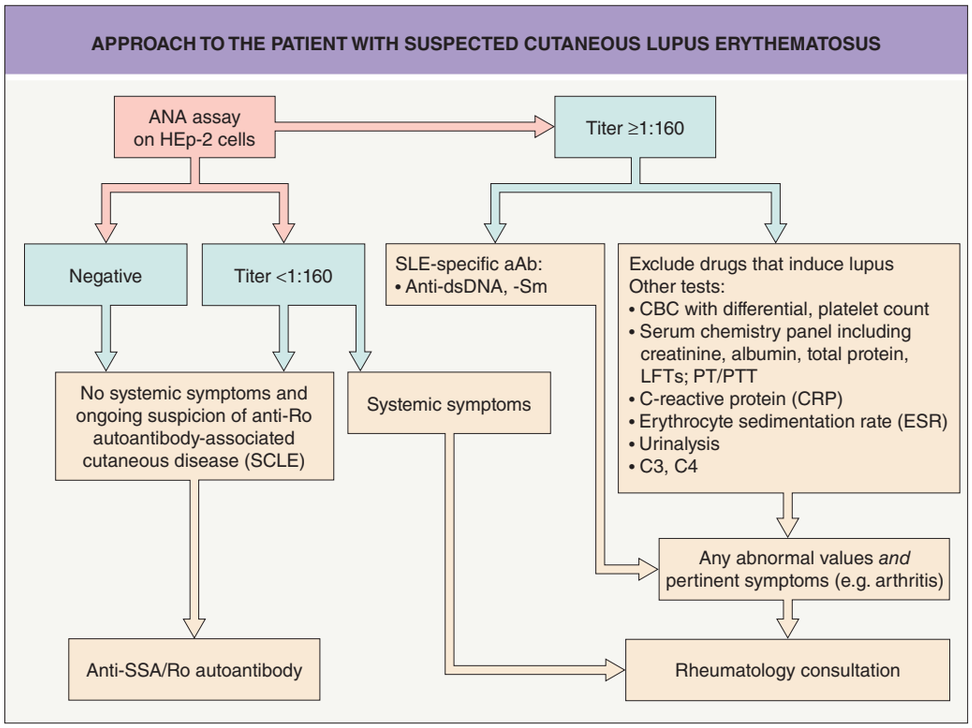

Fig. 40.5 Approach to the patient with suspected cutaneous lupus erythematosus. It should be noted that these recommendations are most relevant within the context of a dermatology practice setting. CBC, complete blood count; LFTs, liver function tests; PT, prothrombin time; PTT, partial thromboplastin time; SCLE, subacute cutaneous lupus erythematosus.

summarizes the aAb in patients with idiopathic inflammatory dermatomyopathies. Both high specificity and low specificity aAb are included, with the latter also seen in other AI-CTD.

Anti-TIF1-γ (p155), -TIF1-α (p140) Antibodies

aAb to a 155 kDa polypeptide was initially reported in 20%–30% of patients with the classic form of juvenile-onset or adult-onset DM[33] and was subsequently noted to bind to transcriptional intermediary factor 1 gamma (TIF1-γ). aAb to TIF1-α can also be observed in DM and are associated with TIF1-γ antibodies (see Table 40.2). In patients with adult-onset classic DM, the presence of anti-TIF1-γ aAb has been associated with an increased risk of internal malignancy[34]. Individuals with anti-TIF1-γ aAb often have diffuse erythema in a photodistribution, extensive inflammatory skin disease, and relatively mild muscle disease; calcinosis is uncommon[32]. They also have palatal erythema, a finding termed "ovoid patch"[35], in addition to keratotic palmar papules, psoriasiform lesions, and hypopigmented and telangiectatic ("red on white") patches[36].

Anti-MDA5/CADM-140 Antibodies

In adult Japanese patients with clinically amyopathic DM (CADM) and interstitial lung disease, aAb to a 140 kDa molecule (CADM-140) were first noted[37]. Subsequently these aAb were found to bind the interferon-induced with helicase C domain protein 1 (IFIH1), which is also known as melanoma differentiation-associated protein 5 (MDA5)[38]. In a retrospective series, plasma samples from 77 patients with DM were screened for anti-MDA5 aAb[39]. The ten patients (13%) with this aAb had a rather distinct clinical phenotype with cutaneous ulcerations that can overlie Gottron papules, tender palmar papules, oral pain and ulceration, arthritis/arthralgia, and diffuse hair loss. Recognition of this subset of patients is clinically important because of the association of anti-MDA5 aAb with rapidly progressive interstitial lung disease; the latter occurs more frequently in Asians[32]. The titer of anti-MDA5 aAb is used to monitor the associated interstitial lung disease and the risk of its relapse following therapy[40].

Anti-Jo-1 Antibodies

The anti-Jo-1 antibody is one of several myositis-specific aAb directed against the aminoacyl transfer RNA synthetases (ARS) that deliver amino acids to ribosomes during protein translation. The presence of one or more of these anti-ARS aAb correlates positively with a subset of mostly PM and some DM patients who have an increased risk of erosive arthritis, Raynaud phenomenon, and interstitial lung disease; this clinico-serologic constellation has been referred to as the "antisynthetase syndrome"[41]. The mechanic's hand skin lesion was originally described in these patients, but has subsequently been observed in other DM subsets, including CADM[42].

Anti-Mi-2, -SRP, -NXP-2, and –SAE Antibodies

Anti-Mi-2 aAb are found in patients with the hallmark skin lesions of DM (Gottron papules, Gottron sign, shawl sign). aAb to the signal recognition particle (SRP) are uncommon, but when present, they signal a risk for fulminant DM/PM with cardiac involvement and a high mortality rate. Anti-nuclear matrix protein 2 (NXP-2) aAb are associated with more severe muscle disease and calcinosis in children[32]; in adults, they are associated with subcutaneous edema, increased risk of cancer, and calcinosis[43,44]. aAb to SAE (SUMO activation enzyme) have been described in a rare subset of DM patients with severe cutaneous disease, progressive muscle involvement, and dysphagia[32].

AUTOANTIBODIES IN SYSTEMIC SCLEROSIS (SSc; SCLERODERMA) AND MORPHEA (LOCALIZED SCLERODERMA)

Table 40.3 summarizes aAb associated with SSc (see Ch. 43)[1,45,46]. The current classification criteria for SSc incorporate the following aAb: anti-centromere (CENP-B); anti-topoisomerase I (formerly Scl-70); and anti-RNA polymerases (RNAP), in particular anti-RNA polymerase III[47]. Anti-centromere aAb correlate with the limited cutaneous form of SSc (CREST syndrome), while aAb against DNA topoisomerase I and RNAP are seen more commonly in the diffuse cutaneous form of SSc. aAb that recognize RNAP are also associated with an increased risk of developing SSc-associated renal disease[48]. Anti-RNA polymerase III aAb have been associated with an increased risk of internal malignancies and may be indicative of paraneoplastic SSc[49,50], with triggering of cellular immunity by the malignancy also promoting sclerosis[50]. However, these aAb are not subset- or disease-specific; e.g. anti-CENP-B aAb can also be detected in ~10% of patients with diffuse cutaneous SSc as well as in disorders such as primary biliary cholangitis. Lastly, as with other AI-CTDs, some aAb encountered in SSc patients are nonspecific (e.g. anti-histone, anti-ssDNA, anti-PM/Scl).

While there is little clinical overlap between SSc and morphea (see Ch. 44), some degree of serologic overlap has been described (e.g.

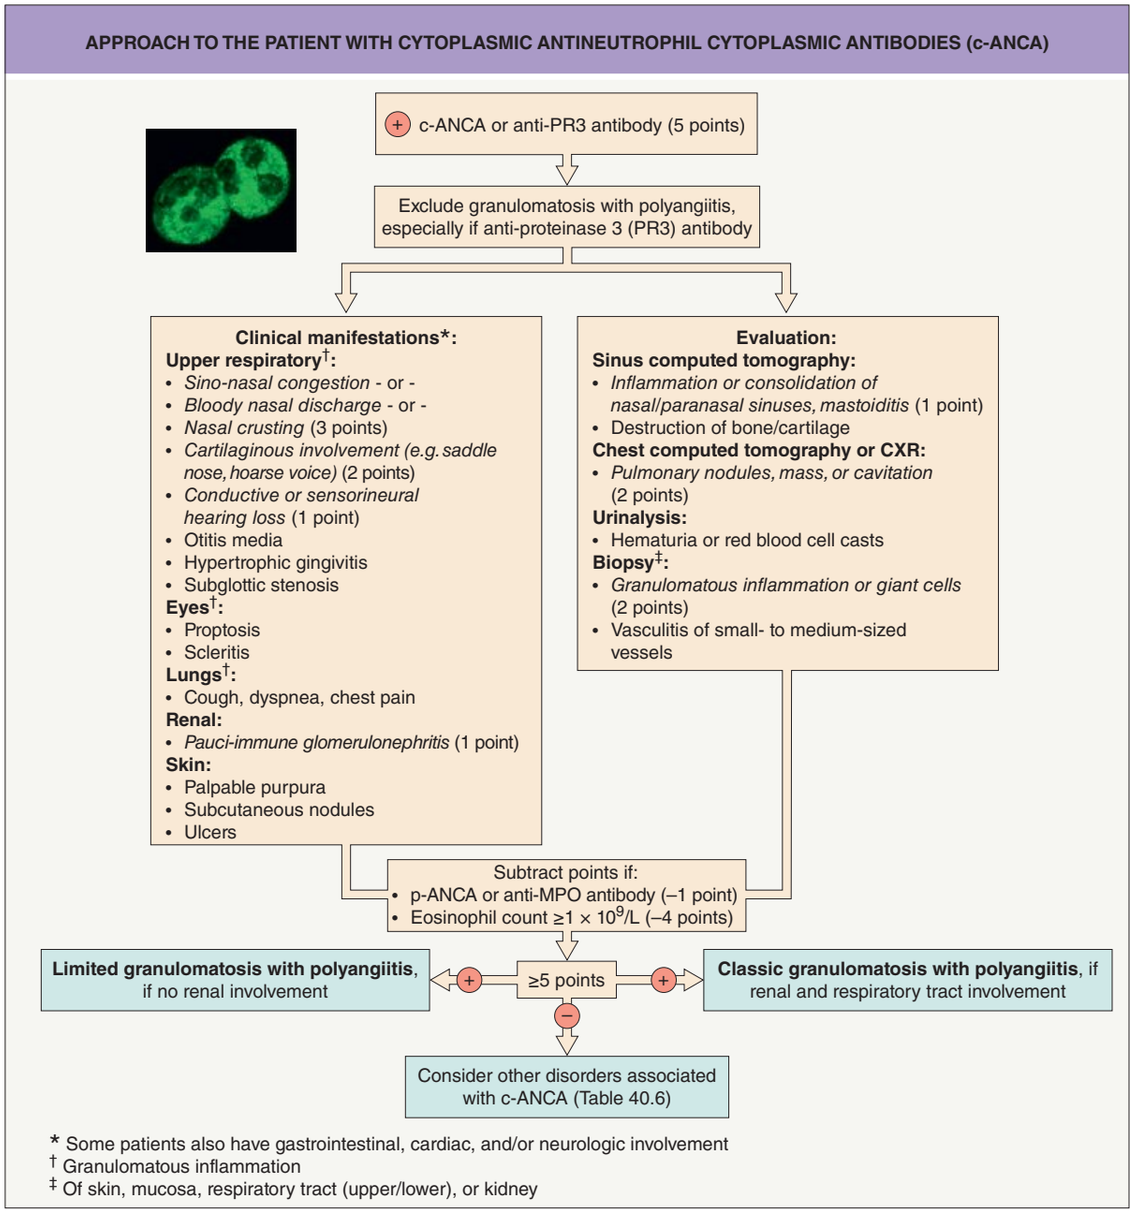

Fig. 40.6 Approach to the patient with cytoplasmic anti-neutrophil cytoplasmic antibodies (c-ANCA). The presence of ≥5 points yields a sensitivity of 93% and specificity of 94% for GPA per the ACR/EULAR 2022 classification criteria. *Photomicrograph from Wiik AS, Fritzler MJ. Laboratory tests in rheumatic disorders. In: Hochberg MC, Silman AJ, Smolen JS, et al. (eds). Rheumatology, 4th edn. London: Mosby Elsevier; 2008.*

anti-fibrillin-1 aAb). aAb to fibrillin-1 (as distinguished from fibrillarin [U3RNP]), histones, and ssDNA occur in 30%–50% of patients with morphea. As with classic ANA, these antibodies have been observed more often in patients with more widespread forms of morphea such as linear or generalized morphea. To date, morphea-specific aAb have not been identified nor have aAb that reflect disease activity or prognosis.

AUTOANTIBODIES IN OTHER RHEUMATIC DISORDERS AFFECTING THE SKIN

Table 40.4 summarizes aAb seen in patients with other rheumatic disorders that can have cutaneous manifestations (see Ch. 45)[1]. Anti-neutrophil cytoplasmic antibodies (ANCA) are a subgroup of neutrophil-specific aAb that are characteristic of systemic vasculitides (see Ch. 24). Figs. 40.6 and 40.7 present a clinical approach to patients with either cytoplasmic ANCA (c-ANCA) or perinuclear ANCA (p-ANCA) and Table 40.6 summarizes other disorders associated with ANCA.

Acknowledgment

The editors wish to thank Dr. Jan P. Dutz for his valuable contribution to this chapter in previous editions.

Additional figure available in our eBook (see inside front cover for access code).

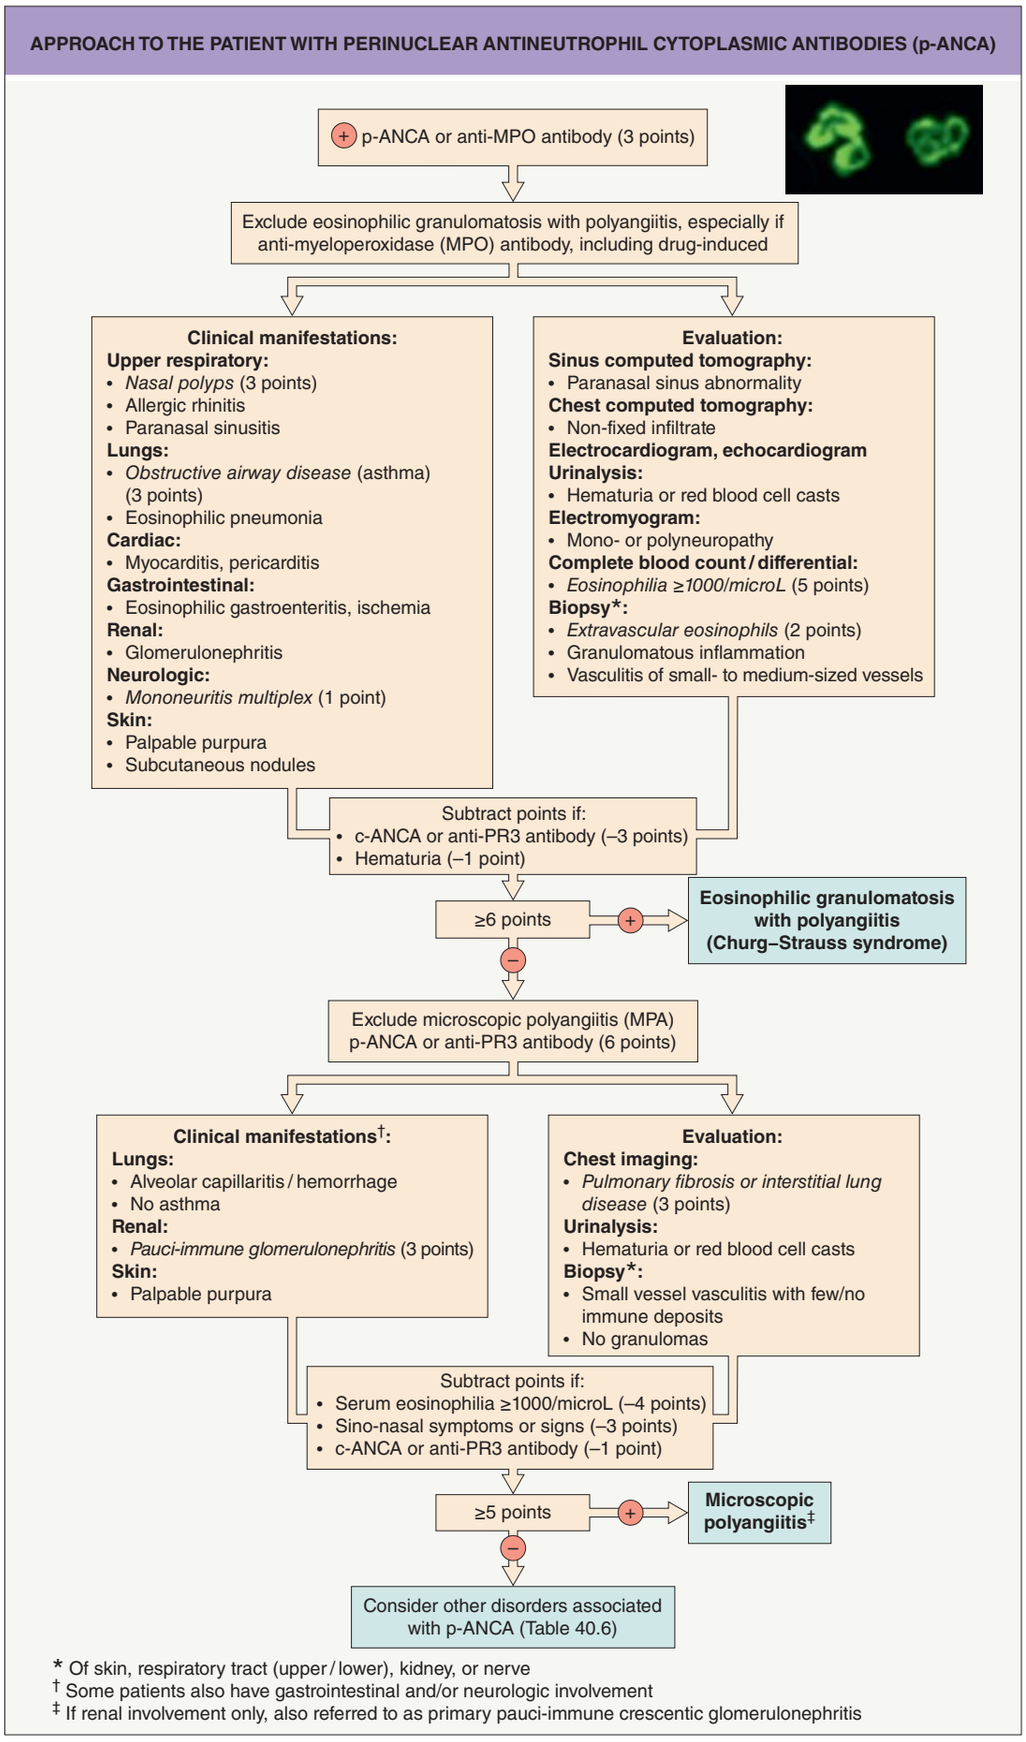

Fig. 40.7 Approach to the patient with perinuclear anti-neutrophil cytoplasmic antibodies (p-ANCA). Use of leukotriene inhibitors (see Ch. 130) has been associated with the onset of eosinophilic granulomatosis with polyangiitis (EGPA; Churg–Strauss syndrome). Whether this represents unmasking of previously undiagnosed EGPA is a subject of ongoing debate. The presence of ≥6 points yields a sensitivity of 85% and a specificity of 99% for EGPA while >5 points yields a sensitivity of 91% and a specificity of 94% for microscopic polyangiitis per the ACR/EULAR 2022 classification criteria. *Photomicrograph from Wiik AS, Fritzler MJ. Laboratory tests in rheumatic disorders. In: Hochberg MC, Silman AJ, Smolen JS, et al. (eds). Rheumatology, 4th edn. London: Mosby Elsevier; 2008.*

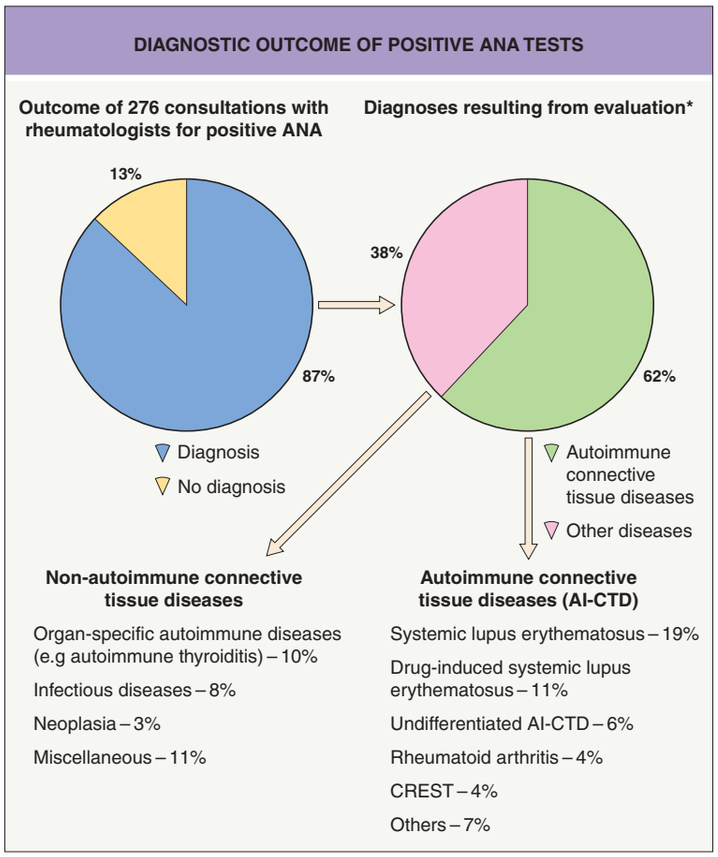
OTHER DISORDERS ASSOCIATED WITH ANTI-NEUTROPHIL CYTOPLASMIC ANTIBODIES (ANCA)			
	Type of ANCA*	**Major antigen(s)†**	**Evaluation**
Inflammatory bowel disease			
Ulcerative colitis (50%–70%) > Crohn disease (20%–40%)	p > c	Catalase, BPI, α-enolase, LF, CG, HMG1/2 > MPO, PR3	Colonoscopy
Autoimmune liver disease			
Autoimmune hepatitis (type 1; 80%), primary sclerosing cholangitis (70%) > primary biliary cirrhosis (30%)	p > c	Actin, HMG1/2	LFTs; ANA; anti-smooth muscle Ab; antimitochondrial Ab
Autoimmune connective tissue disease			
Systemic lupus erythematosus, rheumatoid arthritis, systemic sclerosis (20%–30%) > Sjögren syndrome, dermatomyositis, reactive arthritis, relapsing polychondritis, antiphospholipid syndrome	p > c	MPO, PR3, BPI, CG, LF, lysozyme, HMGI/2	ANA panel; RF; anti-cardiolipin and anti-β_2 glycoprotein I Ab
Drug-induced vasculitis/lupus/hepatitis			
Propylthiouracil (20%), minocycline, methimazole, carbimazole > levamisole, sulfasalazine	p > c	MPO > PR3, elastase	Skin biopsy; ANA panel; LFTs; discontinue drug
Hydralazine, penicillamine > allopurinol‡	p	MPO, elastase	
TNF inhibitors	p, c	MPO, PR3	
High-dose intravenous immunoglobulin	c	–	
Other cutaneous or systemic vasculitides¶			
Mixed cryoglobulinemia, Behçet disease, paraneoplastic	p > c	Variable	Skin biopsy; cryoglobulins; hepatitis B, C panels; exclude malignancy
Henoch–Schönlein purpura, Buerger disease	p	Variable	
Other glomerulonephritides			
Anti-GBM Ab-associated (30%) > immune complex (15%) > poststreptococcal	p	MPO	UA; BUN/creatinine; ASO; renal biopsy
Infections/Vaccines			
Respiratory tract infections (bacterial/mycobacterial/ fungal), enteritis, periodontitis, HIV, parvovirus B19, malaria, leprosy, SARS-CoV-2 infection, and SARS-CoV-2 mRNA vaccine	p, c	MPO, others	Cultures; serologies; echocardiogram
Onchocerciasis	p	Defensin	
Hepatitis C virus infection	p, c	CG, BPI, MPO	Serologies
Subacute bacterial endocarditis, chromomycosis, invasive amebiasis	c	PR3	
Miscellaneous			
Cystic fibrosis (80%)	c > p	BPI	Sweat test
Hypergammaglobulinemia	p, c	–	Serum protein electrophoresis



*c-ANCA are often atypical; in addition, immunofluorescence testing in some laboratories may not distinguish c-ANCA (atypical) from atypical ANCA.
†p-ANCA often have antigen specificity other than MPO, e.g., LF, elastase, CG, lysozyme, BPI, HMG1/2, α-enolase, catalase, actin, defensin; c-ANCA (atypical) have antigen specificity other than proteinase 3, e.g. BPI, lysozyme or multiple antigens.
‡Other drugs associated with p-ANCA in scattered case reports include cimetidine, cefotaxime, phenytoin, isotretinoin, clozapine, atorvastatin, indomethacin, isoniazid, and thioridazine.
¶Although primarily associated with c-ANCA, 5%–50% of patients with granulomatosis with polyangiitis have p-ANCA; likewise, although primarily associated with p-ANCA, 5%–30% of patients with eosinophilic granulomatosis with polyangiitis and ~25%–30% of those with microscopic polyangiitis have c-ANCA; ANCA have also been reported in leukocytoclastic vasculitis of unknown etiology and unclassified vasculitis.

Table 40.6 Other disorders associated with anti-neutrophil cytoplasmic antibodies (ANCA). Ab, antibodies; ANA, anti-nuclear antibodies; ASO, antistreptolysin O; BPI, bactericidal/permeability-increasing protein; c, cytoplasmic [c-ANCA or c-ANCA (atypical)]; CG, cathepsin G; GBM, glomerular basement membrane; HMG1/2, high mobility group non-histone chromosomal proteins; LF, lactoferrin; LFTs, liver function tests; MPO, myeloperoxidase; p, perinuclear (p-ANCA); RF, rheumatoid factor; UA, urinalysis. *Courtesy Julie V. Schaffer, MD.*

41 Lupus Erythematosus

Lela A. Lee and Victoria P. Werth

Synonyms/variants: ■ Discoid lupus erythematosus: a subset of chronic cutaneous lupus erythematosus ■ Lupus profundus: a variant of lupus panniculitis ■ Lupus erythematosus tumidus: tumid lupus

Key features

- There are several variants of cutaneous lupus, defined in part by the location and depth of the inflammatory infiltrate
- Acute cutaneous lupus involves primarily the epidermis and upper dermis and is usually associated with active systemic disease
- Subacute cutaneous lupus involves primarily the epidermis and upper dermis and most patients demonstrate or report photosensitivity and have anti-SSA/Ro autoantibodies sometime during the course of their disease; the majority do not have serious systemic involvement (renal, CNS, or cardiopulmonary)
- Discoid lesions of lupus involve the epidermis, upper and lower dermis, and adnexal structures, and they can develop atrophy and/or scarring; the majority of patients do not have clinically significant systemic disease
- Lupus erythematosus tumidus involves the dermis and adnexal structures, with sparing of the epidermis, and has a prominent infiltration of mucin; lesions are often photo-inducible
- Lupus panniculitis involves the subcutaneous tissue and may result in disfiguring depressed areas due to lipoatrophy

INTRODUCTION

Lupus erythematosus is a multisystem disorder that often affects the skin. Cutaneous lesions can be a source of disability and, on many occasions, indicate and correlate with internal disease.

HISTORY

The term "lupus erythemateaux" was first used by Cazenave in the mid-1800s[1]. Cazenave and others helped to articulate the difference between lupus erythematosus (LE) and lupus vulgaris, a clinical variant of cutaneous tuberculosis. Due in part to observations of Hutchinson, Osler, and Jadassohn, it was recognized that cutaneous lesions of LE may be associated with significant internal abnormalities, including arthritis, nephritis, serositis, cytopenias, and neurologic disease. In 1964 and during the following years, Dubois developed the concept of lupus as a spectrum of disease, ranging from isolated cutaneous lesions to life-threatening, multi-organ disease. Gilliam also developed the concept of a spectrum of cutaneous disease, and, in 1979, along with Sontheimer and Thomas, clearly separated and named the entity now known as subacute cutaneous lupus erythematosus (SCLE)[2]. The description was virtually identical to that of "ANA-negative" lupus, reported by Maddison, Provost, and Reichlin in 1981[3].

Important diagnostic advances included: discovery of the LE cell phenomenon by Hargraves, Richmond, and Morton in 1948; identification of ANA by Friou in 1957; description of the lupus band test by Burnham, Neblett, and Fine in 1963; and the association of specific clinical manifestations of lupus with specific autoantibodies by a variety of investigators[4–6]. With regard to skin disease, the associations of anti-Ro (also known as anti-SSA) autoantibodies with neonatal lupus by Weston et al.[7] in 1981 and with subacute cutaneous LE (SCLE) by Sontheimer et al.[8] in 1982 are noteworthy milestones.

Antimalarial therapy in the form of quinine was used for cutaneous lupus by Payne in 1894. By the late 1950s, synthetic antimalarials had become a mainstay of therapy. Systemic corticosteroids and other immunosuppressive agents came into use during the mid-twentieth century.

EPIDEMIOLOGY

Systemic lupus erythematosus (SLE) is a common disease with significant morbidity and mortality. The strongest factor affecting risk for lupus is *sex*: women with SLE outnumber men by at least 9 : 1[9]. Since SLE occurs most commonly in women during their childbearing years, it is likely that hormonal factors influence susceptibility. Consistent with the importance of sex steroids in the expression of disease, lupus is rare in prepubertal children. Those patients with "only" cutaneous lesions appear to have a somewhat lower female-to-male ratio (perhaps 3 : 1), but there is still a female predominance.

Ethnicity is also a major risk factor, and its effect in some populations is almost as strong as that of sex. In the US, the prevalence of SLE is fourfold higher in African-American women as compared to White women (211 in 100 000 versus 64 in 100 000)[9]. Additionally, African-Americans tend to develop disease at an earlier age and have a higher mortality rate. A long-term study of a multi-ethnic cohort of 587 SLE patients from Texas, Alabama, and Puerto Rico found that African-Americans and Hispanics from Texas had more severe disease than Whites or Hispanics from Puerto Rico[10]. It is likely that Asians, Latin Americans, and White populations in Europe have a similar prevalence of lupus as do White populations living in the US[9].

Highlighting the importance of skin disease in LE, population-based studies indicate that there are approximately as many patients who have cutaneous LE without concurrent SLE as there are patients who have SLE[11,12].

PATHOGENESIS

The pathogenesis of cutaneous LE is complex, and it involves an interaction between genetic and environmental factors. The latter include ultraviolet radiation (UVR), medications, cigarette smoking, and possibly viruses. This interplay triggers a complex inflammatory cascade of cytokine, chemokine, and inflammatory cell responses that include cells residing within as well as recruited to the skin. Overall, the lichenoid tissue reaction, defined as epidermal basal cell damage and a band-like lymphocytic infiltrate in the upper dermis, characterizes most subsets of cutaneous LE. It involves activation of keratinocytes, endothelial cells, and skin dendritic cells plus the production of type I interferons (IFNs), followed by the recruitment and activation of $CD4^+$ and $CD8^+$ cytotoxic T cells. The end result is cytotoxic keratinocyte damage.

Genes that can affect overall immunoreactivity include those whose protein products are involved in B and T cell function, innate immunity, immune complex clearance, apoptosis, ubiquitination, DNA methylation, or cellular adhesion[13]. Examples from all these gene classes, in addition to genes with unknown function, have been implicated in some way in human or animal models of SLE (Table 41.1; see Ch. 4).

Both genetic background based upon ancestry and mutations in specific genes contribute to the clinical heterogeneity in cutaneous LE. For example, the incidences of photosensitivity and discoid LE (DLE) differ in those of northern versus southern European ancestry[14], and SCLE is associated with the HLA-B8-DR3 extended haplotype (including *TNF2*), as well as C2 and C4 deficiencies (see Table 60.9)[15]. Genes previously associated with SLE, e.g. *TYK2*, *IRF5*, *CTLA4*, also confer

GENES ASSOCIATED WITH SYSTEMIC LUPUS ERYTHEMATOSUS	
B and T cell function	***HLA-DR*** – major histocompatibility complex, class II
	BLK – B lymphoid tyrosine kinase
	BANK1 – B cell scaffold protein (with ankyrin repeats) 1
	CTLA4 – cytotoxic T lymphocyte antigen-4
	FCGR2B – Fc fragment of IgG receptor IIb (low affinity; CD32)
	LYN v-yes-1 – Yamaguchi sarcoma viral related oncogene homolog
	IKZF1 – Ikaros family zinc finger 1
	PTPN22 – protein tyrosine phosphatase, non-receptor type 22 (lymphoid)
	STAT4 – signal transducer and activator of transcription 4
	PDCD1 – programmed cell death 1
	IRAK1 – interleukin-1 receptor-associated kinase 1
	ETS1 – v-ets erythroblastosis virus E26 oncogene homolog 1
	TNFSF4 – tumor necrosis factor (ligand) superfamily member 4
	IL21 – interleukin-21
Innate immunity	***IRF5*** – interferon regulatory factor 5
	TNFAIP3 – tumor necrosis factor, alpha-induced protein 3
	SPP1 – secreted phosphoprotein 1 (osteopontin)
	TREX1 – three prime repair exonuclease 1 (see text)
	TYK2 – tyrosine kinase 2
	TLR7 – Toll-like receptor 7
	IRAK1 – see above
	STAT4 – see above
	RASGRP3 – RAS guanyl releasing protein 3
	SLC15A4 – solute carrier family 15 member 4
Immune complex clearance	*FCGR3A* – Fc fragment of IgG, low affinity IIIa, receptor (CD16a)
	FCGR3B – Fc fragment of IgG, low affinity IIIb, receptor (CD16b)
	CRP – C-reactive protein, pentraxin-related
	ITGAM – integrin, alpha M (complement component 3 receptor 3 subunit; CD11b)
	C4A – complement component 4A
	C4B – complement component 4B
	C2 – complement component 2
	C1Q – complement component 1, Q subcomponent
Apoptosis	*ATG5* – autophagy related 5 homolog
	STAT4 – see above
Ubiquitination	*UBE2L3* – ubiquitin-conjugating enzyme E2L3
	TNFAIP3 – tumor necrosis factor, alpha-induced protein 3
	TNIP1 – TNFAIP3 interacting protein 1
DNA methylation	*MECP2* – methyl CpG binding protein 2 (Rett syndrome)
Cellular adhesion	*ITGAM* – see above
Other/unknown	*PXK* – PX domain containing serine/threonine kinase
	ICA1 – islet cell autoantigen 1
	SCUBE1 – signal peptide, CUB domain, EGF-like 1
	NMNAT2 – nicotinamide nucleotide adenylyltransferase 2
	XKR6 – XK, Kell blood group complex subunit-related family, member 6
	KIAA1542

Table 41.1 Genes associated with systemic lupus erythematosus. For detailed information on the function of these protein products, see www.genecards.org. The most strongly associated genes are in bold. *Adapted from Moser KL, Kelly JA, Lessard CJ, et al. Recent insights into the genetic basis of systemic lupus erythematosus. Genes Immun 2009;10:373–9.*

an increased risk for developing DLE and SCLE[16], while mutations in *TREX1*, which encodes a DNA exonuclease, are associated with familial chilblain lupus[17]. In the latter patients, dysfunction of the exonuclease leads to an accumulation of IFN-stimulatory nucleic acids.

Autoantibodies clearly play a role in SCLE and neonatal lupus, where anti-SSA/Ro (more specifically, anti-SSA/Ro60 and anti-SSA/Ro52) and anti-La autoantibodies are frequently observed (see Ch. 40); in the case of neonatal lupus, these antibodies are transmitted transplacentally. Blocking the function of either SSA/Ro60 or SSA/Ro52 presumably predisposes one to these diseases. Of note, SSA/Ro60 plays an important role in cell survival following UVR, possibly via binding to misfolded non-coding RNAs and targeting them for degradation, and mice which lack SSA/Ro60 develop a lupus-like syndrome[18]. SSA/Ro52 has a known regulatory role in inflammation, targeting both

interferon regulatory factor 3 (IRF3) and IRF8 for degradation[19]; thus, antibodies to SSA/Ro52 may be proinflammatory. Alternatively, or in addition, these autoantibodies could lead to disease via activation of proteins and cells of the immune system, following immune complex formation.

Both ultraviolet B (UVB) and ultraviolet A radiation have been implicated in exacerbation of cutaneous LE, although UVB is a more efficient cause of photo-induced changes in the skin[20]. UVR induces apoptosis, which leads to translocation of cellular and nuclear antigens[21], and there may also be a reduction in the clearance of apoptotic cells. In addition, UVR increases keratinocyte production of SSA/Ro52[22] and type I IFNs[23].

A number of proinflammatory cytokines, including tumor necrosis factor (TNF), interleukin (IL)-1, IFN-γ, HMGB1 (high-mobility group box 1), and IL-18 are induced by UVR[24,25]. There is also upregulation of antimicrobial peptides within the skin as well as a release of *e*xtracellular *t*raps (ETs) by dying *n*eutrophils (NETosis); these traps are composed of a lattice of DNA, histones, and cytoplasmic proteins (Fig. 41.1)[26,27]. Following UV irradiation of keratinocytes, a complex array of chemokines, including chemokine (C-C motif) ligand 5 (CCL5), CCL20, CCL22, and chemokine (C-X-C motif) ligand 8 (CXCL8), is produced (see Table 11.3). Of note, there is an increase in these chemokines within lesions of cutaneous LE, likely leading to leukocyte recruitment to the skin[28]. These effects require adhesion molecules, with activation of endothelial cells (increased expression of ICAM-1, VCAM-1, and E-selectin) and induction of ICAM-1 on basal keratinocytes[29,30].

IFN is another cytokine that plays a role in the pathogenesis of cutaneous LE. Increased secretion of IFN can result from: binding of apoptotic cells to Fcγ receptors on macrophages; binding of viral pathogens, DNA, RNA, or immune complexes to Toll-like receptors on plasmacytoid dendritic cells; and single nucleotide polymorphisms (SNPs) in genes that encode proteins in the IFN pathway[31]. Notably, an increase in proteins upregulated by IFN, including the chemokines CXCL9 and CXCL10, has been observed in the skin of patients with

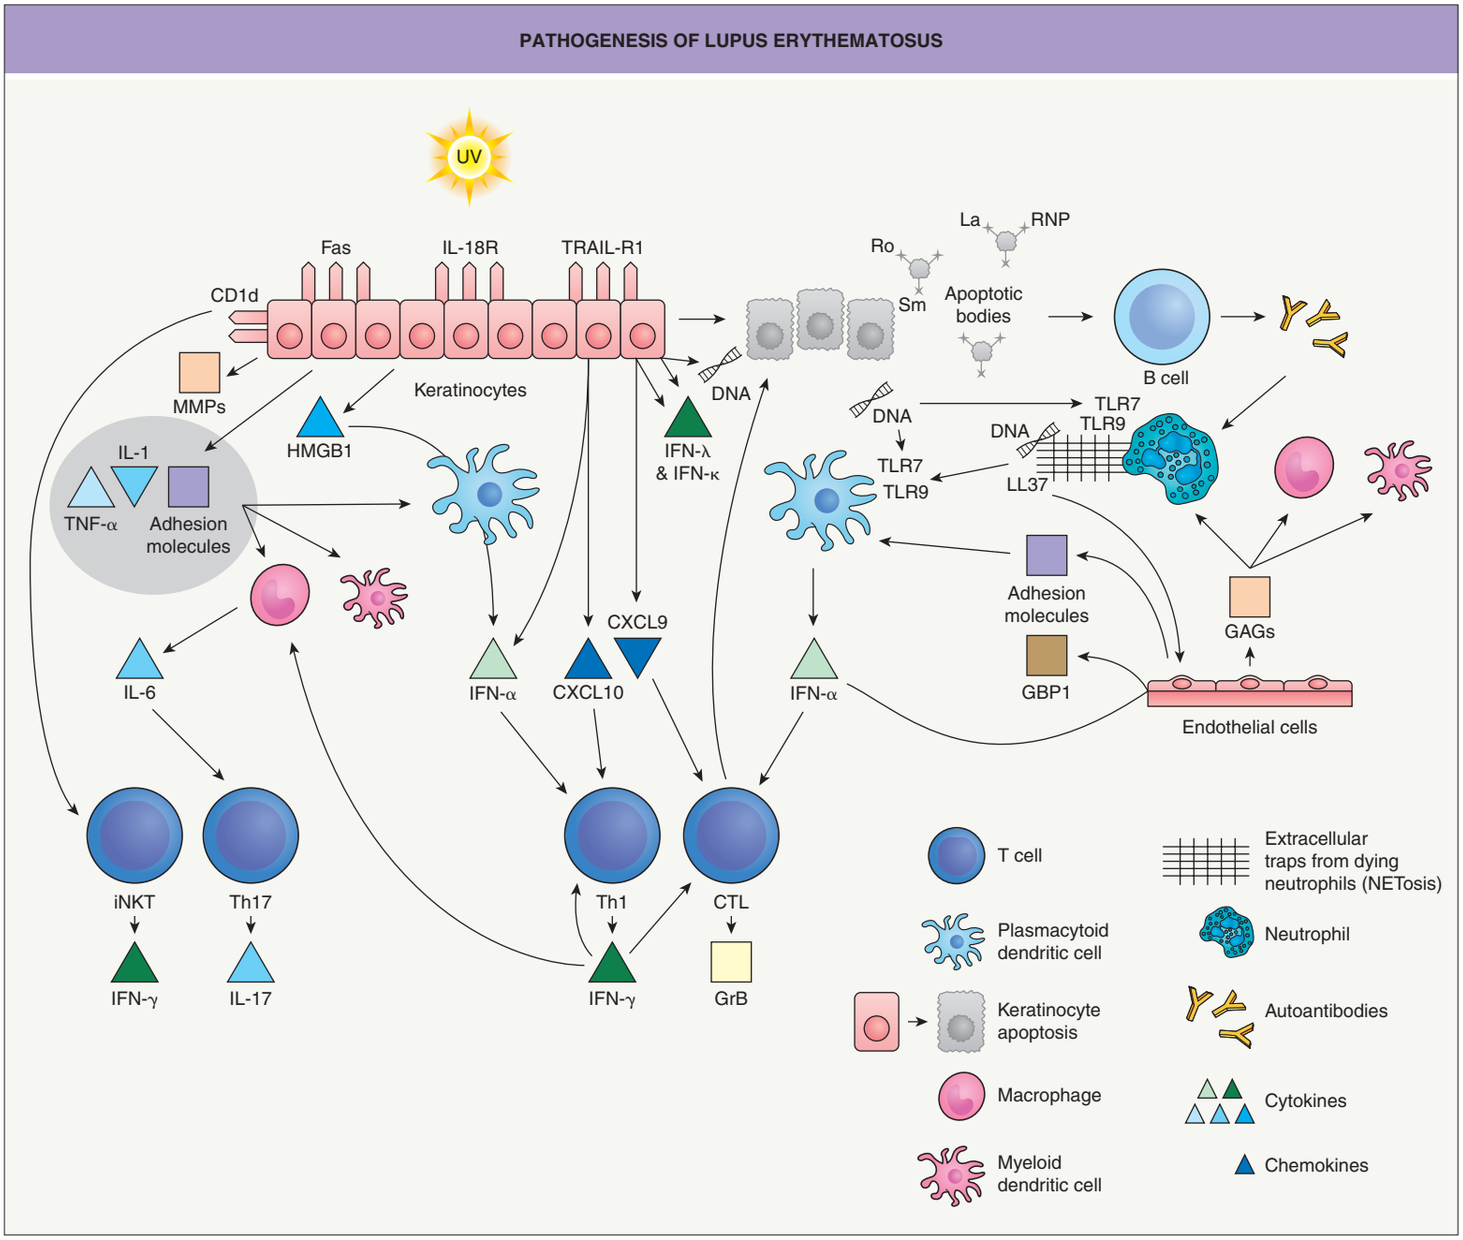

Fig. 41.1 Pathogenesis of lupus erythematosus. In photosensitive cutaneous LE, ultraviolet radiation triggers cytokine and chemokine production, innate immune proteins, NETosis of neutrophils, and apoptosis of cells leading to release of DNA. A lichenoid tissue reaction is the endpoint of a complex cascade that includes activation of dendritic cells, in part due to activation of the TLR7/MyD88 pathway, release of interferon (IFN), production of chemokines, and activation of T cells. CTL, cytotoxic T lymphocyte; CXCL, chemokine (C-X-C motif) ligand; GAGs, glycosaminoglycans; GBP1, guanylate binding protein-1; GrB, granzyme B; HMGB1, high-mobility group box 1; IL, interleukin; iNKT cells, invariant natural killer T cells; LL-37, cathelicidin; MMPs, matrix metalloproteinases; RNP, ribonucleoprotein; Th, T helper cell; TLR, Toll-like receptor; TNF, tumor necrosis factor; TRAIL-R1, tumor necrosis factor-related apoptosis-inducing ligand-receptor 1. *Adapted from Achtman JC, Werth VP. Pathophysiology of cutaneous lupus erythematosus. Arthritis Res Ther 2015;17:182.*

cutaneous LE (see Fig. 41.1)[28,32]. IFN-α further drives the differentiation of monocytes to plasmacytoid dendritic cells, which are potent producers of IFN-α/β, thus forming an amplification loop[33]. Increased numbers of plasmacytoid ($CD123^+$) and myeloid dendritic cells have been found within cutaneous LE lesions[32,34]. Epidermal and dermal dendritic cells can acquire keratinocyte-derived antigens and prime $CD8^+$ T cells to these antigens within the skin-draining lymph nodes[35]. Corroborating evidence for the role of IFN-α is provided by the induction of cutaneous LE in patients receiving IFN-α for other medical conditions. The increased IFN signature seen in SLE has also been detected in peripheral blood mononuclear cells from patients with DLE and SCLE, but not those with LE tumidus[36].

The IFN-upregulated chemokines can recruit CXCR3-positive $CD4^+$ and $CD8^+$ T cells to the skin, as well as immature plasmacytoid dendritic cells, contributing to the characteristic interface infiltrate of cutaneous LE[28,37]. In addition, via the production of IFN-α, plasmacytoid dendritic cells drive the activation and expansion of T cells. There is also evidence for the presence of granzyme B and TIA1 (poly(A)-binding protein), two cytotoxic granule-associated proteins involved in apoptosis, in the skin of all subsets of cutaneous LE, although somewhat less so in SCLE, suggesting that there are fewer $CD8^+$ T cells in SCLE[37]. In patients with disseminated, scarring DLE, high numbers of circulating $CCR4^+$ cytotoxic T cells were detected[38]. One study found *decreased* numbers of $Foxp3^+CD4^+CD25^+$ T regulatory cells in the skin, but not the blood, of cutaneous LE patients, and Treg cells are known to downregulate the immune response[39].

A scenario that integrates current theories regarding the pathogenesis of several subsets of cutaneous LE is shown in Fig. 41.1. In the proposed model, a response to UVR triggers cytokine, chemokine, and antimicrobial peptide production by keratinocytes as well as endothelial cell activation, thereby initiating the immune response. In the context of genetic and environmental risk factors, a complex cascade ensues that includes activation of dendritic cells, release of IFN, activation of T cells, and production of chemokines; a positive feedback loop ultimately results in a lichenoid tissue reaction. In some patients with hydroxychloroquine-refractory disease, myeloid dendritic cells play a role and are associated with a TNF signature[34].

CLINICAL FEATURES

Cutaneous Lupus – Three Major Forms

Classification

The most commonly used classification of cutaneous lesions in LE is that of Dr. James Gilliam[40]. He segregated skin lesions into those that are specific for cutaneous LE and those that are not specific based upon whether the histopathology demonstrated an interface dermatitis or not, respectively. Within the category of specific cutaneous lesions, he subdivided these into acute cutaneous LE, subacute cutaneous LE, and chronic cutaneous LE (Fig. 41.2). This choice of terms was based upon the observation that three distinct types of cutaneous LE are commonly seen: the often transient lesions of acute cutaneous LE (ACLE) typified by malar erythema; the frequently long-lived, intensely inflammatory discoid LE (DLE) lesions which can lead to permanent disfiguring scars; and a photosensitive eruption characteristically more long-lasting than ACLE but without the potential for atrophy or scarring, for which the term subacute cutaneous LE (SCLE) was coined. Typically grouped within the chronic cutaneous LE category are the less common disorders LE tumidus, lupus panniculitis, and chilblain lupus (see Fig. 41.2), despite the observation that characteristic lesions frequently lack an interface dermatitis, especially LE tumidus.

Formal studies have not been done comparing duration of disease activity for the various types of cutaneous LE, and there is a considerable range in the duration of activity within each subtype. Patients with SCLE lesions may have a chronic, relapsing course, while DLE or LE tumidus lesions may have a relatively short duration due to resolution or effective disease control. In fact, some authorities have proposed that LE tumidus should be removed from the chronic category and be given its own category, intermittent cutaneous LE[41]. These controversies aside, Gilliam's classification schema has proven utility in the organization of the various types of cutaneous LE and it is the basis for the classification herein, accompanied by a focus on the morphology and histopathology of lesions (Fig. 41.3). The three major forms of cutaneous LE will be discussed first, followed by the remaining entities outlined in Fig. 41.2.

Discoid lupus erythematosus (DLE)

Discoid lesions represent one of the most common skin manifestations of lupus and they are most frequently found on the face, scalp, and ears (Fig. 41.4), but may be present in a more widespread distribution (Fig. 41.5). It is unusual for discoid lesions to be present below the neck without lesions also being present above the neck[41a]. Occasionally, discoid lesions develop on mucosal surfaces, including the lips, nasal mucosa, conjunctivae, and genital mucosa.

Some patients with discoid lesions exhibit a photodistribution, and sun exposure appears to have a role in lesional development. However, many patients have discoid lesions on sun-protected skin, and there is no clear association between sun exposure and their development.

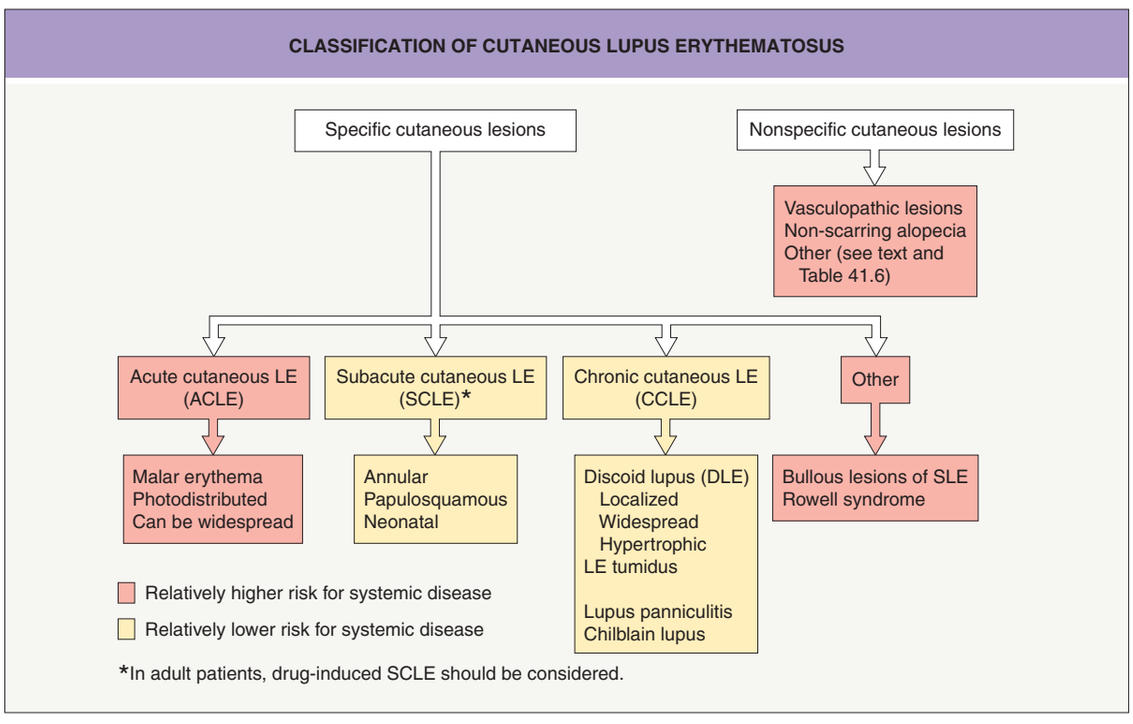

Fig. 41.2 Classification of cutaneous lupus erythematosus (LE). Based upon the classification system originally proposed by Gilliam and Sontheimer[40].

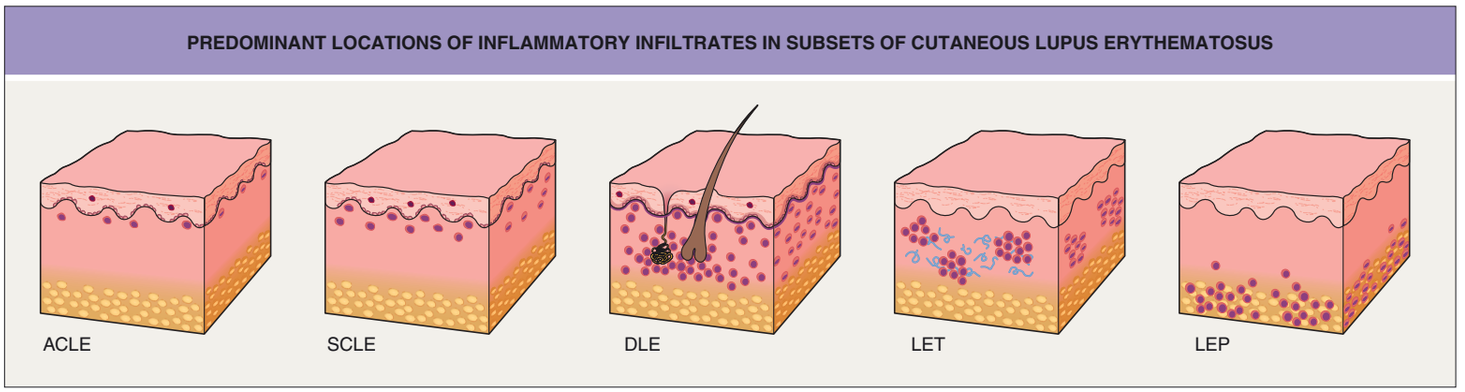

Fig. 41.3 Predominant locations of inflammatory infiltrates in subsets of cutaneous lupus erythematosus. The types of cutaneous lupus erythematosus are: acute cutaneous lupus erythematosus (ACLE), subacute cutaneous lupus erythematosus (SCLE), discoid lupus erythematosus (DLE), lupus erythematosus tumidus (LET), and lupus panniculitis (LEP); the latter three are forms of chronic cutaneous lupus erythematosus (see Fig. 41.2). The primary locations of the infiltrates are as follows: superficial dermis, ACLE and SCLE; superficial and deep dermis perivascular and periadnexal, DLE; superficial and deep dermis perivascular and periadnexal, LET; and subcutaneous fat, LEP. The final diagnosis requires clinicopathologic correlation.

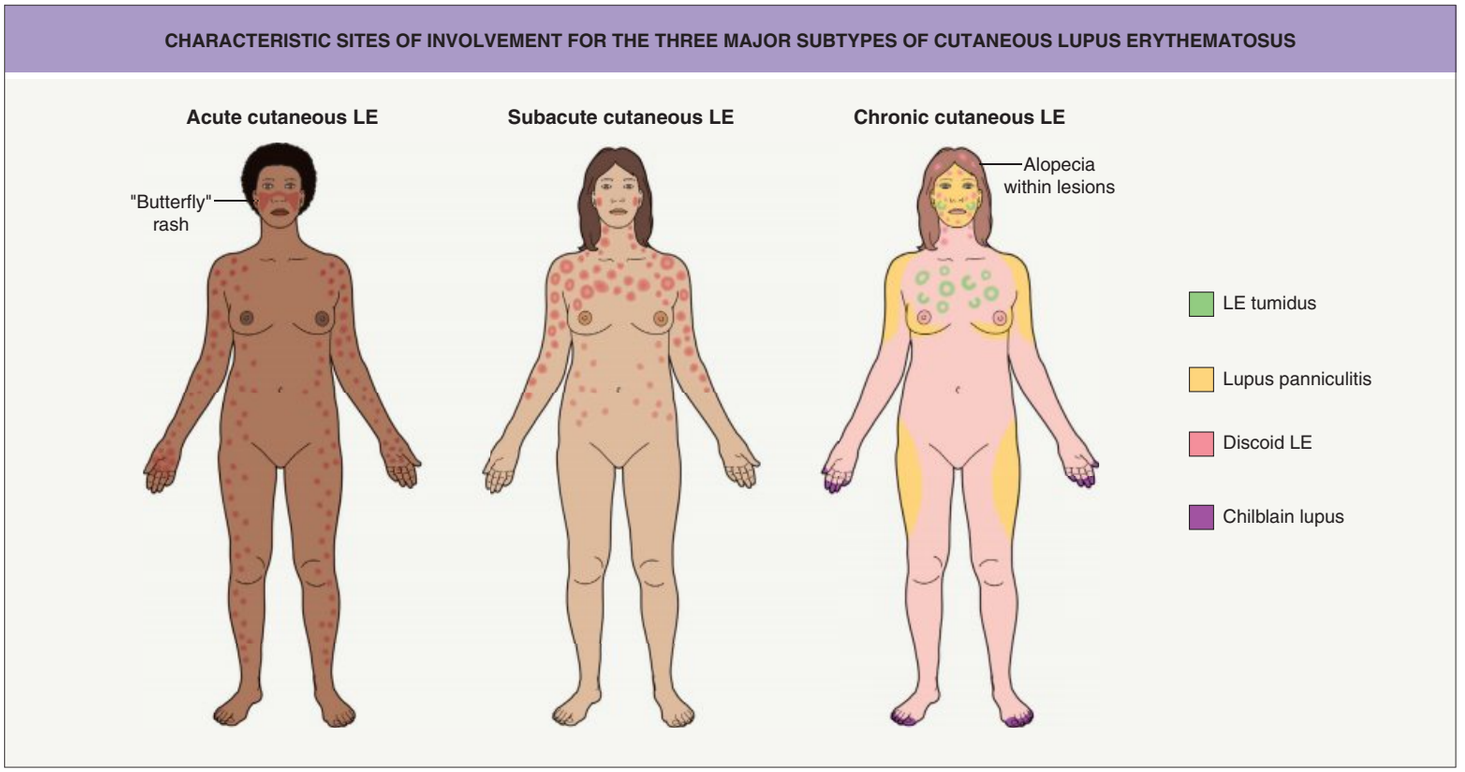

Fig. 41.4 Characteristic sites of involvement for the three major forms of cutaneous lupus erythematosus (LE).

Discoid lesions have the potential for scarring, and, over time, a substantial proportion of patients develop disfiguring scarring. Active lesions are intensely inflammatory, with a pronounced superficial and deep dermal inflammatory infiltrate. As a result, on palpation, active lesions typically feel thicker and firmer than surrounding uninvolved skin. The adnexa are prominently involved, with follicular plugging and scarring alopecia commonly observed. Dyspigmentation is a common sequela noted in longstanding lesions, typically with hypopigmentation in the central area and hyperpigmentation at the periphery (Fig. 41.6), but sometimes with vitiligo-like depigmentation. Rarely, squamous cell carcinoma develops in a longstanding discoid lesion.

Patients who present with discoid lesions may have associated arthralgias, but, over time, only ~10%–20% of these patients eventually meet the classification criteria for SLE (see below)[12,42–44]. Many of these patients meet criteria based primarily upon mucocutaneous disease and/or mild hematologic abnormalities (e.g. leukopenia) rather than serious internal disease[44], and the majority of those who progress do so within five years. The risk may be higher in patients with widespread (disseminated) discoid lesions, defined as having lesions below the neck[42,43], and in children[45].

An unusual variant of DLE is hypertrophic (verrucous) DLE, characterized by thick scaling overlying the discoid lesion or occurring at the periphery of the discoid lesion. The intensely hyperkeratotic lesions are often prominent on the extensor surface of the arms (see Fig. 41.5J), but the face and upper trunk may also be involved. Frequently, there are characteristic lesions of discoid LE present in other locations.

Subacute cutaneous lupus erythematosus (SCLE)

Patients with SCLE typically report photosensitivity and lesions of SCLE most frequently occur on sun-exposed skin. It is notable that the midface is usually spared, while the sides of the face, upper trunk, and extensor aspects of the upper extremities are commonly involved (Fig. 41.7; see Fig. 41.4)[46]. In some patients, the disease may be mild, with only a few small scaly patches appearing after sun exposure.

Lesions of SCLE may have an annular configuration, with raised pink–red borders and central clearing (Fig. 41.8), or a papulosquamous presentation with a chronic psoriasiform or eczematous appearance. SCLE

Fig. 41.5 Various presentations of discoid lesions of lupus erythematosus. A–C Lesions, which favor the head and neck region, may show erythema, scaling, atrophy, and dyspigmentation in addition to scarring (and alopecia). **D** Note the patulous follicular openings in addition to hyperpigmentation and scale. **E–G** The plaques are well-demarcated and both hypopigmentation and scarring can be seen in a range of skin phototypes. **H, I** Less common sites include the palms and soles, where lesions can be keratotic or ulcerative as in lichen planus. The patient with plantar involvement had systemic lupus erythematosus and responded well to isotretinoin. **J** Occasionally, hypertrophic lesions develop with significant hyperkeratosis. **K** The scarring process may be destructive. *C, Courtesy Kalman Watsky, MD; E–G, Courtesy Luis Requena, MD; J, Courtesy Julie V. Schaffer, MD.*

lesions characteristically have a relatively sparse, superficial inflammatory infiltrate, and, consequently, they are minimally palpable. Lesions often result in dyspigmentation, particularly hypopigmentation or even depigmentation, but rarely develop scarring or dermal atrophy as sequelae.

In about a third of patients with SCLE, the disease is linked to medications, either at its onset or as a drug-induced exacerbation of previously well-controlled disease (Table 41.2). The first drug associated with the development of SCLE was hydrochlorothiazide, but at least 100 agents have been reported subsequently to induce or exacerbate SCLE[47]. A population-based study from Sweden identified (in decreasing order) terbinafine, TNF inhibitors, anti-epileptics, and proton pump inhibitors as the most frequently associated medications[48]. More recently, immune checkpoint inhibitors, in particular pembrolizumab and nivolumab, have been linked to the development or exacerbation of SCLE[49,50]. The cutaneous lesions may or may not clear once the medication is discontinued.

Fig. 41.6 Discoid lupus erythematosus (DLE) lesions with dyspigmentation and scarring alopecia. Hypopigmentation often develops centrally with areas of hyperpigmentation at the periphery. Note the plugging of follicular openings at 12 o'clock. By trichoscopy, follicular red dots can be seen in addition to follicular keratotic plugs (see Ch. 69). *Courtesy Kalman Watsky, MD.*

Fig. 41.7 Subacute cutaneous lupus erythematosus (SCLE). Numerous erythematous annular plaques on the back, some of which have associated white scale. Note the photodistribution. *Courtesy Kathryn Schwarzenberger, MD.*

Fig. 41.8 Subacute cutaneous lupus erythematosus (SCLE). Lesions are most commonly seen on the upper trunk and sun-exposed aspects of the upper extremities. The margins of the annular lesions may have scale-crust (**A**) or be composed of multiple papules (**B**). **C** Note the peripheral scale and relative sparing of the proximal interphalangeal joints. **D** Numerous annular lesions with scale-crust in the inner borders in a patient with terbinafine-induced SCLE. *C, Courtesy Lorenzo Cerroni, MD; D, Courtesy Luis Requena, MD.*

Fig. 41.9 Acute cutaneous lupus erythematosus (ACLE). The facial erythema, often referred to as a "butterfly rash" may be variable (**A**), edematous (**B**), or have associated scale (**C**). The presence of small erosions can aid in the clinical differential diagnosis. *A, Courtesy Kalman Watsky, MD.*

MEDICATIONS ASSOCIATED WITH DRUG-INDUCED SUBACUTE CUTANEOUS LUPUS ERYTHEMATOSUS
More common/higher risk*
Terbinafine
Thiazide diuretics (e.g. hydrochlorothiazide)
TNF inhibitors (e.g. adalimumab, etanercept, golimumab, infliximab)
Proton pump inhibitors (e.g. lansoprazole, pantoprazole, omeprazole)
Calcium channel blockers (e.g. diltiazem, nifedipine, nitrendipine, verapamil)
Anti-epileptics (e.g. carbamazepine, phenytoin)
Chemotherapy (e.g. taxanes, capecitabine, gemcitabine > doxorubicin, 5-fluorouracil)
Immune checkpoint inhibitors (e.g. nivolumab, pembrolizumab, atezolizumab)
ACE inhibitors (e.g. enalapril, lisinopril)
Less common*
β-blockers
Imiquimod (topical)
Interferon-α and -β
Other immunomodulators (e.g. abatacept, leflunomide, secukinumab, ustekinumab)
Palbociclib, abemaciclib
Ranitidine
HMG-CoA reductase inhibitors ("statins")
Tamoxifen
Thrombocyte inhibitors (e.g. ticlopidine)
VEGF/VEGFR inhibitors (e.g. bevacizumab, pazopanib)
*Medications are classified as being more common or having a higher risk if there were >10 cases reported in the literature as of 2023 or the relative risk in reference 48 was ≥2.0. Medications are classified as being less common if there have been 3–10 cases reported and the relative risk was <2.0.

Table 41.2 Medications associated with drug-induced subacute cutaneous lupus erythematosus (SCLE). ACE, angiotensin converting enzyme; VEGF, vascular endothelial growth factor; VEGFR, VEGF receptor.

Approximately half of patients presenting with SCLE fulfill classification criteria for SLE[51]. However, most do so on the basis of laboratory and mucocutaneous findings. In a study of 85 SCLE patients, only six had renal and three had neurologic disease[51]. Since anti-SSA/Ro autoantibodies are associated with Sjögren syndrome as well as SCLE, it is not surprising that some patients have features of both conditions, and some may have serious internal manifestations of Sjögren syndrome such as pulmonary or neurologic disease.

An important feature of SCLE, from the standpoint of understanding the pathogenesis of lupus, is its regular association with anti-SSA/Ro autoantibodies (see Ch. 40). Although investigators differ in their opinions as to the prevalence of anti-SSA/Ro autoantibodies in SCLE, it is likely that a substantial majority of patients with this condition (~70% in a large series, reported range of 60%–100%) have anti-SSA/Ro antibodies[46,52].

Acute cutaneous lupus erythematosus (ACLE)

The lesions of ACLE are exemplified by the development of bilateral malar erythema ("butterfly rash"; Fig. 41.9). These lesions tend to be transient, follow sun exposure, and resolve without scarring (but sometimes with dyspigmentation). An association with anti-dsDNA antibodies and lupus nephritis has been proposed and is plausible, although some patients with a malar rash have neither anti-dsDNA antibodies nor lupus nephritis. Patients presenting with this type of eruption must be evaluated carefully for evidence of internal disease.

Fig. 41.10 Acute cutaneous lupus erythematosus (ACLE). This patient had ACLE lesions on the arms as well as the face.

The morphology of the lesions ranges from mild erythema to intense edema. The presence of telangiectasias, erosions, dyspigmentation and epidermal atrophy (i.e. poikiloderma) may help to distinguish the malar erythema of ACLE from that of common facial eruptions such as seborrheic dermatitis and the erythematotelangiectatic type of rosacea. Occasionally, there is a papular component, and occasionally lesions develop scaling (see Fig. 41.9C). The duration may range from a few hours to several weeks. The face, particularly the malar area, is most commonly affected, and there is often sparing of the nasolabial fold; sometimes lesions may be more widespread in distribution (Fig. 41.10; see Fig. 41.4). When lesions occur on the hands, the knuckles are typically spared. It is not unusual for patients with ACLE to also have oral ulcerations.

The presence of erythema multiforme-like lesions in lupus patients has been termed Rowell syndrome[53]. Rarely, patients develop an acute eruption clinically similar to toxic epidermal necrolysis or erythema multiforme major (see below). These lesions may represent a severe variant of ACLE or, in some cases, SCLE.

The three major types of cutaneous LE are not mutually exclusive. In a given patient, more than one type of cutaneous lesion may occur.

Cutaneous Lupus – Additional Variants (See Fig. 41.2)

Lupus erythematosus tumidus

Lesions are typically firm erythematous plaques that lack scale or follicular plugging. Although the epidermis appears to be uninvolved in the disease process, there is an intense perivascular and periadnexal inflammatory infiltrate within the dermis, as well as mucin deposition. LE tumidus lesions may be the same as the "urticarial plaques" described in lupus patients. However, these fixed plaques should not be confused with urticarial vasculitis (see Ch. 24). Some authors state that the lesions most commonly occur on the face, but they are often

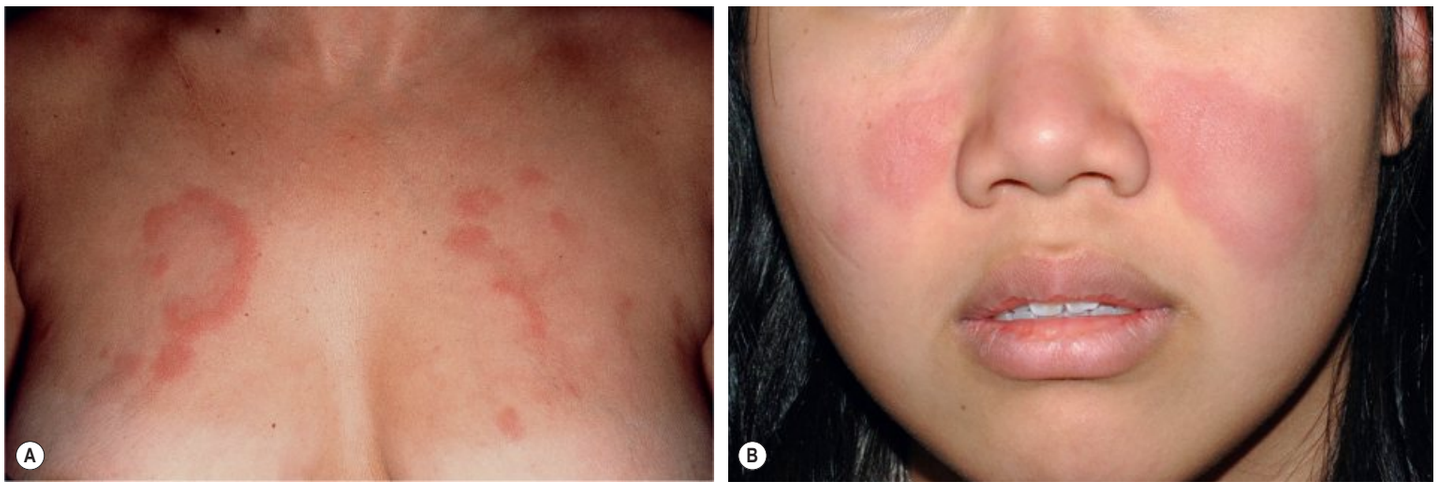

Fig. 41.11 Lupus erythematosus tumidus. Annular pink plaques on the chest (**A**) and pink–violet plaques on the face (**B**). None of the lesions have epidermal change. *B, Courtesy Julie V. Schaffer, MD.*

Fig. 41.12 Lupus panniculitis. Erythematous plaque on the upper arm. The lesions may resolve with lipoatrophy.

Fig. 41.13 Chilblain lupus. Violaceous plaques, some with scale, on toes. If there is a family history of this disorder, the possibility of mutations in *TREX1*, which encodes a DNA exonuclease, or *SAMHD1*, which encodes a host restriction nuclease that plays a role in the innate immune response, can be considered.

observed on the trunk as well (Fig. 41.11). Morphologically, the lesions are similar to those of lymphocytic infiltrate of Jessner and may have central clearing (see Ch. 121); some clinicians believe that lymphocytic infiltrate of Jessner and LE tumidus are either very closely related or exist along the same disease spectrum[54].

In patients reported to have LE tumidus, the very low prevalence of SLE, the relative lack of serologic abnormalities, and the very low prevalence of immunoglobulin deposition within the cutaneous lesions have made it difficult to determine whether LE tumidus is actually a variant of LE or an independent entity. However, the presence of LE tumidus lesions in patients with other specific types of cutaneous LE is evidence in favor of its being classified as a form of cutaneous LE. In the majority of patients, LE tumidus has been reported to be reproducible by phototesting[55]. The lesions tend to resolve without scarring, atrophy, or dyspigmentation.

Lupus panniculitis

Intense inflammation in the fat leads to indurated plaques that can evolve into disfiguring, depressed areas. Lesions of lupus panniculitis have a distinctive distribution, occurring predominantly on the upper arms (Fig. 41.12), face, scalp, upper trunk, thighs, buttocks, and breasts (see Fig. 41.4)[56]. Some patients may have discoid lesions overlying the panniculitis, and, in those cases, the condition is sometimes referred to as lupus profundus. For further discussion of lupus panniculitis, see Chapter 100.

Chilblain lupus

Chilblain lupus (SLE pernio; Fig. 41.13) consists of red or dusky purple papules and plaques on the toes, fingers, and sometimes the nose, elbows, knees, and lower legs. The lesions are brought on or exacerbated by cold, particularly moist cold climates. These lesions may represent the concurrence of ordinary chilblains in a patient with LE (see Ch. 88), although, with time, the lesions may develop a gross and microscopic appearance consistent with that of a discoid lesion.

Heterozygous mutations in *TREX1* (see above) or *SAMHD1* can lead to a familial form of chilblain lupus with an onset during childhood[57]. Affected individuals may have arthralgias and a positive ANA, but otherwise do not develop internal disease. Mutations in these same genes, as well as *ADAR1*, *IFIH1*, and *RNASEH2A/B/C*, can result in the Aicardi–Goutières syndrome, a primarily autosomal recessive autoinflammatory disorder characterized by recurrent sterile fevers, progressive developmental delay, and chilblains (see Table 45.7, Type I interferonopathies). Mutations in these seven genes lead to an accumulation of nucleic acids, e.g. dsDNA, RNA:DNA duplexes.

Discoid lupus erythematosus/lichen planus overlap syndrome

A discoid lupus erythematosus/lichen planus overlap syndrome has been described, in which lesions with features of both conditions are present (see Ch. 11).

Neonatal lupus erythematosus (NLE)

A neonatal form of SCLE may occur in infants whose mothers have anti-SSA/Ro autoantibodies. In babies who have neonatal lupus erythematosus (NLE), the SCLE-like lesions are histologically identical to

Fig. 41.14 Neonatal lupus erythematosus. Annular erythematous plaques on the forehead and scalp. Note the resemblance to the annular form of subacute cutaneous lupus erythematosus. *Courtesy Julie V. Schaffer, MD.*

SYSTEMIC EVALUATION OF AN INFANT WITH CUTANEOUS NEONATAL LUPUS ERYTHEMATOSUS
Initial and serial evaluations until 6–9 months of age
History, review of systems & physical examination: examination includes monitoring of growth and head circumference*; frequency depends upon degree of systemic involvement
Laboratory studies: electrocardiogram +/− echocardiogram, CBC with differential and platelet count, liver function tests; if tests are initially normal and infant without signs or symptoms, then tests repeated every 2–3 months × 2–3 (otherwise more frequently)
Family counseling and care coordination: risk for NLE in subsequent pregnancies, risk for development of AI-CTD in mother and, possibly, child
Preemptive treatment: for mothers of infants with cardiac NLE, consider hydroxychloroquine during subsequent pregnancies
Long-term considerations
History and physical examination: periodically per pediatrician
Laboratory studies: if normal or return to normal and the child remains healthy, further testing is not required
Risk of AI-CTD as adolescent/adult
*Macrocephaly/hydrocephalus and chondrodysplasia punctata (stippled epiphyses) have been reported as possible manifestations of NLE.

Table 41.3 Systemic evaluation of an infant with cutaneous neonatal lupus erythematosus (NLE). In the setting of characteristic skin lesions, the diagnosis is established via autoantibody testing in the mother (anti-SSA/Ro autoantibodies) +/− in the infant (anti-SSA/Ro, -RNP); if skin lesions are atypical, histologic examination may be required. AI-CTD, autoimmune connective tissue disease; CBC, complete blood count.

those of SCLE in adults, and there is a strong association with anti-SSA/Ro antibodies. Indeed, almost 100% of babies with NLE have anti-SSA/Ro antibodies[58], and less frequently anti-U_1RNP autoantibodies are present. Unlike SCLE in adults, lesions have a predilection for the face, especially the periorbital region and scalp (Fig. 41.14).

Photosensitivity is very common in NLE, but sun exposure is not required for lesions to form, as it is possible for lesions to be present at birth. Neonatal lupus skin lesions typically resolve completely, although perhaps one-fourth to one-third of children have cutaneous residua of telangiectasias, dyspigmentation, and/or atrophic scarring[59,60]. Atrophic scarring may be more likely in infants whose lesions began *in utero*[60].

Infants who have the cutaneous lesions of NLE may also exhibit internal manifestations. The major extracutaneous findings are congenital heart block (with or without cardiomyopathy), hepatobiliary disease, and cytopenias, in particular thrombocytopenia. The heart block is almost always present by birth, but on rare occasions has developed after birth. Clinically significant cardiomyopathy occurs concurrently in a small percentage of babies who have heart block. Usually, the cardiomyopathy is apparent during the neonatal period, but it is possible for it to become apparent only after several months have elapsed. Cardiac NLE has a mortality rate of approximately 20%, and approximately two-thirds of children require pacemakers[61].

Hepatobiliary disease and cytopenias, especially thrombocytopenia, may be present at birth, or they may develop within the first few months of life[62]. Hepatobiliary disease can vary in severity and may present as liver failure during gestation or in the neonatal period, conjugated hyperbilirubinemia during the first few weeks of life, or mild elevations of aminotransferases at 2–3 months of life. There are also reports of hydrocephalus, microangiopathic hemolysis, and disseminated intravascular coagulation.

Although most children with cutaneous NLE do not have significant internal involvement, a systemic evaluation and counseling is recommended (Table 41.3). Mothers who have had a baby with cutaneous NLE have an increased likelihood of having a subsequent pregnancy complicated by NLE, including cardiac involvement. When pregnant, these women should be cared for by a perinatologist who has specialized training in high-risk prenatal care.

Bullous lesions

In the clinical setting of lupus, bullous lesions may appear for several reasons. On occasion, bullous or crusted lesions occur simply as a result of the intensity of the basal cell damage in lesions of ACLE or SCLE (see Fig. 41.8A) or, possibly, DLE. Rarely, a dramatic, acute eruption similar to erythema multiforme major or toxic epidermal necrolysis (TEN) may occur in patients with preexisting ACLE or SCLE, or it may appear *de novo* (Fig. 41.15). Blisters occurring within ACLE and SCLE lesions and erythema multiforme-like and TEN-like cutaneous lupus fit within the category of lupus-specific skin lesions.

Fig. 41.15 Toxic epidermal necrolysis-like eruption of acute lupus erythematosus. This presentation has also been referred to as a form of *a*cute *s*yndrome of *a*poptotic *p*an-epidermolysis (ASAP).

The term bullous eruption of SLE, or bullous SLE, has been used to describe an acquired blistering eruption in patients who fulfill the criteria for SLE. It consists of vesicles and bullae whose histopathology often resembles dermatitis herpetiformis, with a primarily neutrophilic infiltrate and microabscesses within the dermal papillae (Fig. 41.16)[63]. In some patients, the clinical and histopathologic features may resemble neutrophil-rich bullous pemphigoid or epidermolysis bullosa acquisita. Immunoreactants are often found at the basement membrane zone and antibodies to type VII collagen have been detected in several patients[64]. This eruption may represent the concurrence of lupus with an autoimmune blistering disease due to autoantibodies to a component of the basement membrane zone. There are also a number of case reports of other autoimmune bullous diseases appearing in patients with lupus (reviewed in reference 65).

Fig. 41.16 Bullous eruption of systemic lupus erythematosus. A Vesicles and bullae due to autoantibodies against type VII collagen can develop in patients with systemic disease. **B** Multiple vesicles and bullae as well as erosions and hypopigmentation at sites of previous lesions in a woman with SLE. *B, Courtesy Edward Cowen, MD.*

Systemic Lupus Erythematosus

Lupus erythematosus is potentially a multi-organ disease, although in individual patients often only one or a few organs are significantly involved. Organ systems most commonly affected are joints, skin, hematologic, renal, and CNS as well as pleural and pericardial serosal surfaces. Nonspecific signs and symptoms such as fever, weight loss, fatigue, myalgias, and lymphadenopathy are also common in SLE. Additional less common manifestations are quite varied and include sensorineural hearing loss and vision loss. Although ACLE is the cutaneous phenotype with the strongest association with systemic disease, patients with any type of cutaneous LE may develop internal involvement.

Since SLE is complex and variable, classification criteria have been developed to ensure that patients in clinical studies have SLE rather than other conditions that may mimic it. Historically, the American College of Rheumatology (ACR) criteria, developed in 1982 and modified in 1997, have been most commonly used. In 2012, a new set of criteria from the Systemic Lupus International Collaborating Clinics (SLICC) aimed to improve the sensitivity of the ACR criteria[66] (Table 41.4). In 2019, the ACR, in concert with the European League Against Rheumatism (EULAR), released a new classification system[67] (Table 41.5). Some of its notable features are as follows:

1. Presence of ANA (titer ≥1 : 80) is an entry criterion. Patients with persistently negative ANA tests are excluded.
2. Individual criteria have different weights and need not occur simultaneously.
3. Within a particular domain (e.g. renal), only the highest weighted criterion counts.
4. A criterion is counted only if SLE is the most likely explanation for the finding.

Nonspecific Cutaneous Lesions

Vascular lesions are common in patients with LE, particularly in those who have systemic disease (Table 41.6). These lesions include Raynaud phenomenon (see Ch. 43), livedo reticularis, palmar erythema, and nail-fold telangiectasia. Purpura, urticarial papules, or ulcerations due to vasculitis may occur, as well as cutaneous infarctions resembling Degos disease or atrophie blanche. Patients with cutaneous LE who have any of these findings should be evaluated for systemic disease. Livedo reticularis, thromboses, ulcerations, and lesions resembling Degos disease have each been associated with antiphospholipid antibodies[68] (see Ch. 23). The association of livedo reticularis with ischemic CNS disease has been called Sneddon syndrome (see Ch. 23), and the phenotype of the antiphospholipid syndrome has been called Hughes syndrome[69].

Alopecia often occurs as a result of scarring discoid lesions. However, non-scarring diffuse alopecia can appear in patients with systemic disease. It has been reported that patients with lupus have an increased likelihood of alopecia areata compared with the general population.

Sclerodactyly, calcinosis, and rheumatoid nodules, findings more consistent with systemic sclerosis or rheumatoid arthritis, have been observed in some patients with lupus, although many of the patients with these findings may have overlap syndromes rather than classic lupus. Other skin findings reported to occur in patients who have lupus include erythromelalgia, papulonodular mucinosis (of Gold; see Ch. 46), and anetoderma (see Ch. 99). Of note, ~75% of the patients with papulonodular mucinosis have SLE. Rarely, significant periorbital edema can develop secondary to dermal mucin. A Sweet syndrome-like presentation can also be seen in patients with SLE and this has been given several names including neutrophilic dermatosis in conjunction with LE and non-bullous neutrophilic LE as well as simply Sweet syndrome in association with SLE.

Patients with SLE have more subtle nail-fold capillary abnormalities than do patients with systemic sclerosis or dermatomyositis. Prominent large, tortuous capillaries and areas of marked avascularity are not characteristic of SLE.

PATHOLOGY

Histopathology

Histologic findings in cutaneous LE depend in large part on the subtype (Fig. 41.17; see Fig. 41.3). Characteristic findings in ACLE, SCLE, discoid lesions, LE tumidus, and lupus panniculitis are outlined in Table 41.7. However, in practice, an overlap in histologic findings occurs among the various clinical phenotypes, particularly ACLE, SCLE, and discoid lesions. Some of the more distinctive histologic features of cutaneous LE are basal cell damage (also referred to as vacuolar degeneration, hydropic change, or interface dermatitis), lymphohistiocytic inflammatory infiltrates admixed with $CD123^+$ plasmacytoid dendritic cells, and, primarily in discoid lesions, periadnexal inflammation, follicular plugging, and scarring. In lesions of ACLE, dermal changes can be relatively subtle although basal cell damage may be pronounced. In SCLE, epidermal changes and a superficial lymphocytic infiltrate are common. In contrast to discoid lesions, SCLE lesions tend to have little or no hyperkeratosis, basement membrane thickening, periadnexal infiltrate, follicular plugging, deep dermal infiltrate, or scarring[70,71]. LE tumidus has prominent dermal mucin deposition and dermal perivascular and periadnexal lymphocytic infiltrates with a lack of epidermal change. While changes of lupus panniculitis are most prominent in the subcutis, there may be overlying changes of DLE[72]. Occasionally, cutaneous LE presents with a neutrophil-rich infiltrate mimicking that of a neutrophilic dermatosis.

The inflammatory infiltrates of cutaneous lupus typically contain plasmacytoid dendritic cells that produce interferons and may play a role in the induction of lesions. Immunohistochemical staining for CD123, a marker for plasmacytoid dendritic cells, has been explored as a means to distinguish cutaneous lupus from other inflammatory diseases (e.g. lichen planopilaris, polymorphous light eruption) and from cutaneous lymphoma. Although positive CD123-staining is not specific for lupus and its sensitivity and specificity remain to be definitively established[73], the pattern and intensity of staining may help to distinguish lupus from other conditions.

THE SYSTEMIC LUPUS INTERNATIONAL COLLABORATING CLINICS (SLICC) CLASSIFICATION SYSTEM – CLINICAL AND IMMUNOLOGIC CRITERIA
Clinical criteria
1. Acute cutaneous lupus, including: • Lupus malar rash (do not count if malar discoid) • Toxic epidermal necrolysis variant of SLE • Photosensitive lupus rash in the absence of dermatomyositis • Bullous lupus • Maculopapular lupus rash *OR* Subacute cutaneous lupus (non-indurated psoriasiform and/or annular polycyclic lesions that resolve without scarring, although occasionally with postinflammatory dyspigmentation or telangiectasias)
2. Chronic cutaneous lupus, including: • Classic discoid rash – Localized (above the neck) – Generalized (above and below the neck) • Hypertrophic (verrucous) lupus • Mucosal lupus • Lupus panniculitis (profundus) • Lupus erythematosus tumidus • Chilblain lupus • Discoid lupus erythematosus/lichen planus overlap
3. Oral ulcers*: palate, buccal, tongue, *or* nasal ulcers*
4. Non-scarring alopecia†
5. Synovitis involving 2 or more joints, characterized by swelling or effusion OR tenderness in 2 or more joints and at least 30 minutes of morning stiffness
6. Serositis • Typical pleurisy for more than 1 day *OR* pleural effusions *OR* pleural rub • Typical pericardial pain (pain with recumbency improved by sitting forward) for more than 1 day *OR* pericardial effusion *OR* pericardial rub *OR* pericarditis by electrocardiography‡
7. Renal Urine protein-to-creatinine ratio (or 24-hour urine protein) representing 500 mg protein/24 hours *OR* red blood cell casts
8. Neurologic • Seizures • Psychosis • Mononeuritis multiplex¶ • Myelitis • Peripheral or cranial neuropathy§ • Acute confusional state‖
9. Hemolytic anemia
10. Leukopenia (<4000/mm^3 at least once)# OR lymphopenia (<1000/mm^3 at least once)^
11. Thrombocytopenia (<100 000/mm^3 at least once)**
Immunologic criteria
1. ANA level above laboratory reference range
2. Anti-dsDNA antibody level above laboratory reference range (or >2-fold the reference range if tested by ELISA)
3. Anti-Sm: presence of antibody to Sm nuclear antigen
4. Antiphospholipid antibody positivity as determined by any of the following: • Positive test result for lupus anticoagulant • False-positive test result for rapid plasma reagin • Medium- or high-titer anti-cardiolipin antibody level (IgA, IgG, or IgM) • Positive test result for anti-β2-glycoprotein I (IgA, IgG, or IgM)
5. Low complement: low C3, low C4, low CH50
6. Direct Coombs test in the absence of hemolytic anemia
*In the absence of other causes, such as vasculitis, Behçet disease, infection (herpesvirus), inflammatory bowel disease, reactive arthritis, and acidic foods. †Diffuse thinning or hair fragility with visible broken hairs in the absence of other causes such as alopecia areata, drugs, iron deficiency, and androgenic alopecia. ‡In the absence of other causes, such as infection, uremia, and Dressler pericarditis. ¶In the absence of other known causes such as primary vasculitis. §In the absence of other known causes such as primary vasculitis, infection, and diabetes mellitus. ‖In the absence of other causes, including toxic/metabolic, uremia, drugs. #In the absence of other known causes, such as Felty syndrome, drugs, and portal hypertension. ^In the absence of other known causes, such as corticosteroids, drugs, and infection. **In the absence of other known causes, such as drugs, portal hypertension, and thrombotic thrombocytopenic purpura.

Table 41.4 The Systemic Lupus International Collaborating Clinics (SLICC) classification system – clinical and immunologic criteria[66]. Criteria are cumulative and need not be present concurrently. The diagnosis of systemic lupus is based upon having at least 4 of 17 criteria, including at least 1 clinical criterion and 1 immunologic criterion OR biopsy-proven lupus nephritis in the presence of ANAs or anti-dsDNA antibodies. anti-dsDNA, anti-double-stranded DNA; ANA, anti-nuclear antibody; ELISA, enzyme-linked immunosorbent assay; SLE, systemic lupus erythematosus.

Antibody Deposits in Lesional Skin

Examination of the skin for deposits of immunoreactants is called direct immunofluorescence (DIF). DIF of lesional skin does not replace routine histologic staining as the method of choice for establishing a diagnosis of cutaneous LE. However, in those cases where the routine histopathology is equivocal, DIF can be a valuable asset in establishing a diagnosis.

The most characteristic DIF finding in cutaneous LE is antibody deposition at the dermal–epidermal junction and around hair follicles. These deposits are typically granular, and they are composed primarily of IgG and/or IgM (Fig. 41.18), although IgA can also occasionally be seen. In addition, deposits of complement proteins are to be expected. Some investigators have reported that in SCLE, granular deposits of IgG and IgM are observed primarily within the epidermis rather than at the dermal–epidermal junction[71]. There is evidence that the epidermal deposits are due to anti-SSA/Ro autoantibodies depositing directly within the skin[74].

In active lesions of ACLE, SCLE, and DLE, DIF of lesional skin is positive in the majority of cases. In general, a positive DIF supports

EULAR/ACR classification for SLE

Entry criterion
Anti-nuclear antibodies (ANA) at a titer of ≥1:80 on HEp-2 cells or an equivalent positive test (ever)

If absent, do not classify as SLE; if present, apply additive criteria

Additive criteria
- Do not count a criterion if there is a more likely explanation than SLE
- Occurrence of a criterion on at least one occasion is sufficient
- SLE classification requires at least one clinical criterion and ≥10 points
- Criteria need not occur simultaneously
- Within each domain, only the highest weighted criterion is counted toward the total score*

Clinical domains and criteria	Weight	Immunology domains and criteria	Weight
Constitutional		**Antiphospholipid antibodies**	
Fever (>38.3°C)	2	Anti-cardiolipin antibodies† *OR*	
Hematologic		Anti-β2GP1 antibodies *OR*	
Leukopenia (WBC <4.0 x 10^9/L)	3	Lupus anticoagulant	2
Thrombocytopenia (plts <100 x 10^9/L)	4	**Complement proteins**	
Autoimmune hemolysis	4	Low C3 *OR* low C4	3
Neuropsychiatric		Low C3 *AND* low C4	4
Delirium	2	**SLE-specific antibodies**	
Psychosis	3	Anti-dsDNA antibody‡ *OR*	
Seizure	5	Anti-Sm antibody	6
Mucocutaneous¶			
Non-scarring alopecia§	2		
Oral ulcers§	2		
Subacute cutaneous§ *OR* discoid lupus§	4		
Acute cutaneous lupus	6

CUTANEOUS FINDINGS (NONSPECIFIC) THAT SUGGEST THE DIAGNOSIS OF SYSTEMIC LUPUS ERYTHEMATOSUS
Diffuse non-scarring alopecia
Raynaud phenomenon
Nail-fold (periungual) telangiectasias and erythema
Vasculitis
• Urticarial vasculitis
• Small vessel vasculitis (e.g. palpable purpura)
• Polyarteritis nodosa-like lesions
• Ulcerations
Cutaneous signs of antiphospholipid syndrome
• Livedo reticularis
• Ulcerations
• Acrocyanosis
• Atrophie blanche-like lesions
• Degos-like lesions
• Livedoid vasculopathy
Palmar erythema
Papular and nodular mucinosis
Sweet syndrome-like neutrophilic dermatosis and neutrophilic urticarial dermatosis

Table 41.6 Cutaneous findings (nonspecific) that suggest the diagnosis of systemic lupus erythematosus. These are in addition to skin signs of other autoimmune connective tissue diseases, which raise the possibility of an overlap syndrome.

the diagnosis of cutaneous LE, but a negative DIF does not exclude the diagnosis. It has been noted that DIF is most likely to be positive in well-established, active lesions. DIF is often negative or nonspecific in LE tumidus. In lupus panniculitis, DIF may show immunoreactants around dermal vessels, but granular deposits at the dermal–epidermal junction are not uniformly present.

Antibody Deposits Within Normal-Appearing Skin

In normal-appearing skin, the presence of antibody deposits at the dermal–epidermal junction correlates reasonably well with systemic disease. The antibody deposits are typically granular and are sometimes referred to as a "lupus band", with examination for the deposits referred to as the "lupus band test". The terminology is confusing, because some authors use the term "lupus band" to apply to the antibody deposits at the dermal–epidermal junction, whether the skin tested is normal-appearing or lesional, while other authors reserve the term "lupus band" to describe antibody deposits in normal-appearing skin. It has been proposed that, if this terminology is used, the investigator should modify the term "lupus band" by a preceding adjective of "lesional" or "non-lesional", so that the subject of discussion is clearly identified.

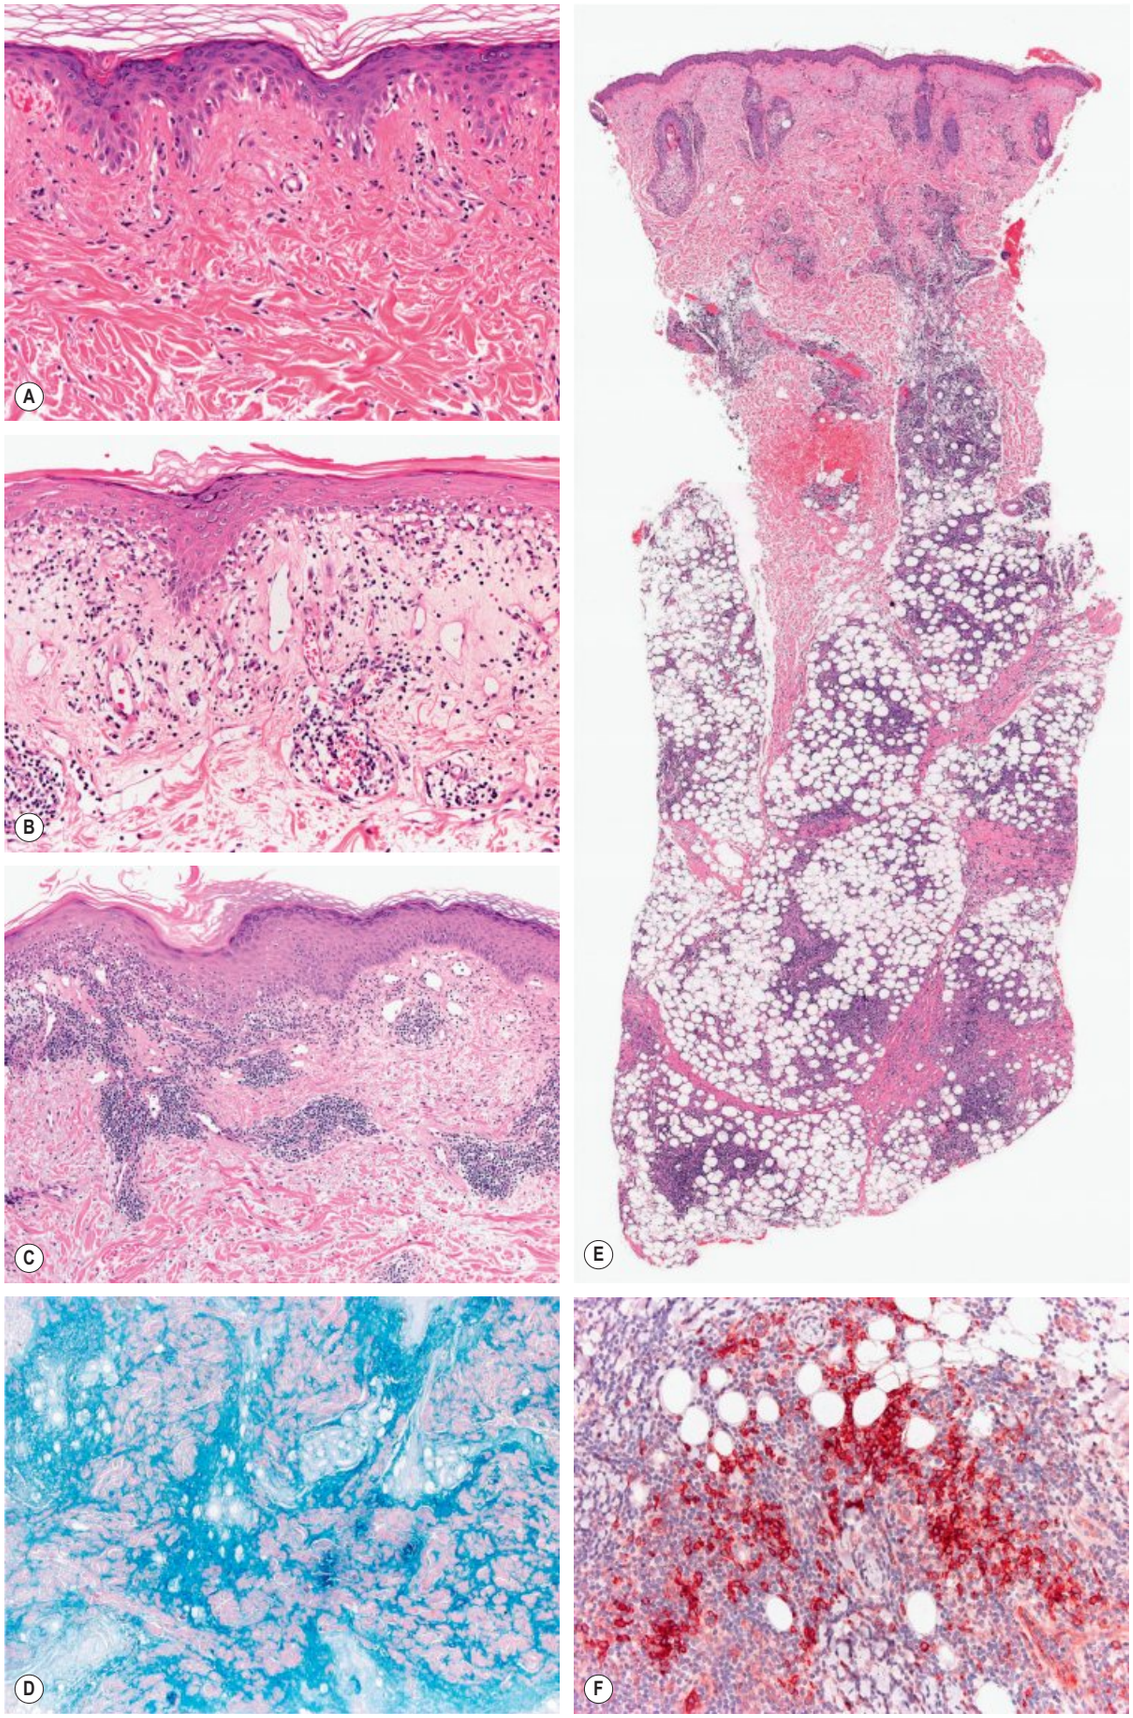

Fig. 41.17 Histopathologic features of cutaneous lupus erythematosus (LE). A Acute cutaneous LE showing mild interface dermatitis with vacuolization of basal keratinocytes and sparse superficial lymphoid infiltrates. **B** Subacute cutaneous LE with more obvious interface dermatitis and perivascular inflammation. **C** Discoid LE showing focal interface dermatitis and dense perivascular lymphoid infiltrates throughout the dermis. **D** Mucin deposition within the dermis highlighted by a colloidal iron stain. **E** Lupus panniculitis with prominent inflammatory infiltrates within the lobules of the subcutaneous fat. Perivascular and periadnexal lymphocytic infiltrates are also present in the dermis. **F** The pattern and intensity of immunohistochemical staining for CD123 (plasmacytoid dendritic cells) may help to distinguish cutaneous lupus, including lupus panniculitis, from other disorders. *Courtesy Lorenzo Cerroni, MD.*

Weak, discontinuous deposits may be seen in persons who do not have LE, including healthy adults, particularly when chronically sun-exposed skin is examined. For this reason, many investigators do not consider a non-lesional lupus band test to be positive unless the deposition of immunoreactants is strong and continuous. A true positive non-lesional lupus band test occurs in three-quarters or more of patients with SLE if sun-exposed skin is examined, and in about one-half of patients with SLE if sun-protected skin is examined[75]. A positive non-lesional lupus band test is unlikely to occur in patients who do not have SLE, but there are instances where the non-lesional lupus band test has been positive in patients with other autoimmune diseases.

Table 41.7 Characteristic histologic findings in cutaneous lupus erythematosus (LE). The table is intended as a broad overview only. Not every feature will be present in every lesion, some features may be present that are not indicated as characteristic, and overlap exists amongst subtypes. [–], not a defining feature; [+/–], a feature that may be present in some lesions; [+], a feature that is typically present; [++], a defining feature that may be prominent.

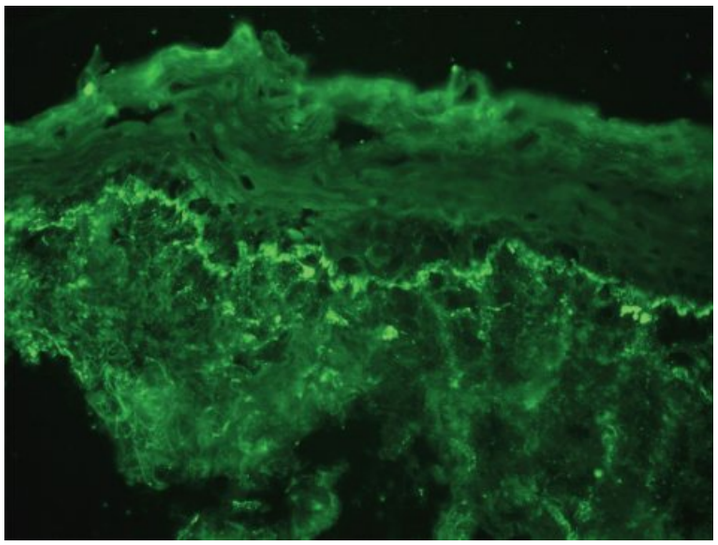

Fig. 41.18 Direct immunofluorescence of cutaneous lupus. Granular deposits of IgM are present at the dermal–epidermal junction within lesional skin. Antibody deposits at the dermal–epidermal junction are the most characteristic immunohistologic finding in lesions of cutaneous lupus and normal skin of patients with systemic lupus erythematosus. *Courtesy Janet Fairley, MD.*

In most cases, clinical evaluation and serologic testing for specific autoantibodies provide the required information, and the non-lesional lupus band test is superfluous. In cases where the clinical presentation or laboratory findings are atypical, the non-lesional lupus band test may have diagnostic value.

DIFFERENTIAL DIAGNOSIS AND EVALUATION

The differential diagnosis varies considerably with the subtype of cutaneous LE under consideration. Some of the major entities in each of the differential diagnoses are outlined in Table 41.8.

In evaluating a patient with cutaneous lesions, lesional biopsy for H&E is, in general, the most valuable diagnostic test. An approach to the diagnosis of cutaneous LE is shown in Fig. 41.19. In an occasional situation, such as that of a patient with known SLE who has transient facial lesions that appear to be ACLE, the clinician may forego a biopsy because of the high likelihood of obtaining nonspecific findings and the cosmetic sequela of a scar on the face. Thus, the diagnostic tree presented is not intended to be followed strictly for each situation, but

DIFFERENTIAL DIAGNOSES OF CUTANEOUS LUPUS SUBTYPES
Acute cutaneous lupus/malar rash
• Rosacea (including corticosteroid-induced) • Seborrheic dermatitis (especially photosensitive form) • Sunburn • Drug-induced photosensitivity (phototoxic and photoallergic) • Dermatomyositis • Erysipelas • Pemphigus erythematosus and foliaceus • Dermatitis – atopic, contact, and photocontact
Subacute cutaneous lupus
• Psoriasis • Dermatophytosis, including tinea incognito • Photolichenoid drug eruption • Polymorphous light eruption • Granuloma annulare • Figurate erythemas (e.g. erythema annulare centrifugum) • Dermatitis – atopic, contact and photocontact • Pemphigus foliaceus
Discoid lesions
• Facial discoid dermatosis • Tinea faciei, capitis or corporis, pityriasis (tinea) versicolor • Lichen planus and lichen planopilaris • Sarcoidosis • Granuloma faciale • Dimorphic fungal infections, lupus vulgaris • Follicular mucinosis (alopecia mucinosa) • When single lesion, non-melanoma skin cancer
Tumid lupus lesions
• Lymphocytic infiltrate of Jessner* • Polymorphous light eruption • Cutaneous lymphoid hyperplasia (pseudolymphoma of the skin) • Reticular erythematous mucinosis†
Lupus panniculitis
• Other panniculitides, in particular subcutaneous panniculitis-like T cell lymphoma (see Ch. 100)
*Some authorities believe that lymphocytic infiltrate of Jessner and LE tumidus are the same condition or along the same disease spectrum. †Some authorities believe that reticular erythematous mucinosis and LE tumidus are the same condition or along the same disease spectrum.

Table 41.8 Differential diagnoses of cutaneous lupus subtypes. Mothers of boys with X-linked chronic granulomatous disease and patients with Sjögren syndrome have an annular erythema similar to annular SCLE; patients with GVHD can develop SCLE-like lesions.

rather is meant as a general overview that is to be individualized for each patient.

In evaluating a patient with cutaneous lesions for the presence of systemic disease, the dermatologist can take a directed history, perform a cutaneous examination looking for signs of possible systemic disease (such as vasculitic lesions), and perform blood and urine testing for evidence of hematologic or renal disease, ANA, and SLE-specific autoantibodies (Table 41.9; see Fig. 40.5). Many clinicians also obtain an ESR and complement levels. Autoantibodies to dsDNA and Sm are relatively specific for SLE, and are, therefore, helpful indicators of a high likelihood of systemic disease (see Ch. 40). Autoantibodies to SSA/Ro, SSB/La, U1RNP, histones, and ssDNA are common in patients with SLE, but they are not disease-specific. An ANA test is helpful if negative, as it is quite unusual for patients with SLE to have a negative ANA test, particularly if the assay employed is the indirect immunofluorescent test. It is common for the ANA test to be positive in patients with cutaneous lesions, but a positive ANA is neither an indicator of systemic disease nor of LE. ANAs may be found in patients with many other diseases (see Ch. 40) and even in apparently normal individuals. Approximately a third of apparently normal individuals have a positive ANA at a dilution of 1:40, 13% at a dilution of 1:80, and 5% at a dilution of 1:160[76].

Clinical evaluation should also include consideration of drug-induced systemic or cutaneous lupus (Table 41.10). Drug-induced SLE typically presents as a systemic illness with arthralgias, myalgias, pleuritis, and fever, but lacking nephritis and CNS disease. SCLE is the most common form of drug-induced cutaneous LE and is clinically and serologically indistinguishable from the classic form; however, patients tend to be older.

In many cases, the decision to make a diagnosis of SLE is done on the basis of whether or not the patient's findings fulfill classification criteria (see Tables 41.4 & 41.5). However, there are limitations to making a diagnosis on the basis of criteria, which were developed primarily to improve reproducibility of research studies and clinical trials. Meeting criteria does not necessarily imply the presence or development of major organ involvement, nor does lack of meeting criteria ensure that an individual patient does not have SLE.

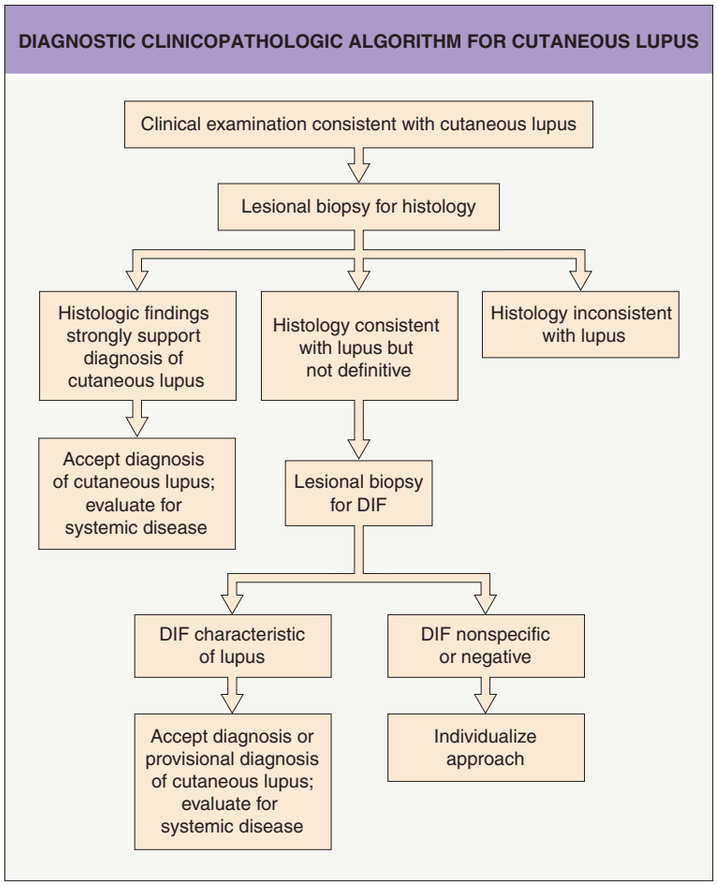

Fig. 41.19 Diagnostic clinicopathologic algorithm for cutaneous lupus. This algorithm is intended as a guide to diagnosis and should be individualized for each situation. For example, lesional biopsy for direct immunofluorescence (DIF) may be performed at the same time as a lesional biopsy for routine histology. Less definitive histologic findings might sometimes be acceptable if the patient is already known to have SLE. Whether a diagnosis is clear-cut or provisional may be, on occasion, a subjective determination.

TREATMENT

Topical Therapy

Topical or intralesional corticosteroids are a mainstay of therapy (Table 41.11). They offer a high degree of safety as well as the potential for a relatively rapid response. The systemic side effects of

EVALUATION FOR SYSTEMIC LUPUS ERYTHEMATOSUS

CLASSIC DISTINCTIONS BETWEEN DRUG-INDUCED SUBACUTE CUTANEOUS LUPUS ERYTHEMATOSUS (DI-SCLE) AND DRUG-INDUCED SYSTEMIC LUPUS ERYTHEMATOSUS (DI-SLE)				
Disease	**Most commonly associated medications**	**Cutaneous findings**	**Systemic findings**	**Associated autoantibodies**
DI-SCLE	See Table 41.2	SCLE	• Usually none • Sometimes arthralgias	Anti-SSA/Ro
DI-SLE	Hydralazine, procainamide, isoniazid, quinidine, methyldopa, chlorpromazine, minocycline, TNF inhibitors*	Usually absent May have malar or photodistributed erythema	• Serositis (arthralgia, pleuritis, pericarditis) • Fever, weight loss, myalgia • Nephritis and CNS disease usually absent	Anti-histone† Anti-dsDNA (reported with TNF inhibitors)
*TNF inhibitors have been associated with DI-SCLE and DI-SLE (as well as drug-induced discoid lupus erythematosus). †Anti-histone antibodies are not specific for DI-SLE as they are commonly found in patients with classic SLE, as well as in other autoimmune connective tissue diseases.				

Table 41.10 Classic distinctions between drug-induced subacute cutaneous lupus erythematosus (DI-SCLE) and drug-induced systemic lupus erythematosus (DI-SLE). CNS, central nervous system.

THERAPY OF CUTANEOUS LUPUS ERYTHEMATOSUS Rx
Local therapy
Sun protection (2)
Topical and intralesional corticosteroids (2)
Topical calcineurin inhibitors (2)
Topical retinoids (3)
Topical tofacitinib (3)
Systemic antimalarial therapy
Hydroxychloroquine (200 mg po daily–BID in adults; up to 6.5 mg/kg ideal body weight/day) (1)*
Chloroquine (125–250 po daily in adults; up to 3.5–4 mg/kg ideal body weight/day) (2)*
Quinacrine (100 mg po daily) (2)
Combination of hydroxychloroquine or chloroquine and quinacrine (2)
Systemic therapy for antimalarial-resistant cutaneous disease
Retinoids (e.g. acitretin, isotretinoin) (1,2)
Thalidomide (50–100 mg po daily for clearing and, if necessary, 25–50 mg po daily–twice weekly for maintenance)† (2)
Lenalidomide (5–10 mg po daily)† (2)
Dapsone (50–150 mg/day, primarily for bullous eruption of SLE) (2)
Methotrexate (10–25 mg/week, orally, IM, SC) (1)
Mycophenolate mofetil (1000–3000 mg/day) (2)
Azathioprine (100–150 mg/day) (3)
Anifrolumab (1, systemic; 2, cutaneous)
Litifilimab (1)
Daxdilimab (1)
JAK inhibitors (3)
Sulfasalazine (2)
Systemic corticosteroids (3)‡
IVIg (2 g/kg every 4–8 weeks, depending on response) (2)
Rituximab (3)
Belimumab (3)
*In 2016, the American Academy of Ophthalmology recommended a maximum dose of ≤5 mg/kg real weight/day of hydroxychloroquine and ≤2.3 mg/kg real weight/day for chloroquine[78]. In a patient weighing 140 pounds (63.6 kg), the dose would be 300 mg daily which could be administered as 200 mg tablets BID alternating with 200 mg daily versus 1.5 tablets daily.
†Concurrently with antimalarials as latter may reduce thrombosis risk.
‡Usually reserved for severe inflammatory cutaneous disease (e.g. Rowell syndrome).

Table 41.11 Therapy of cutaneous lupus erythematosus. General measures for all patients include avoiding photosensitizing medications and smoking cessation. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. BID, twice daily; IM, intramuscular; SC, subcutaneous.

corticosteroids are largely avoided, although the cutaneous side effects are not. It is frequently the case that topical corticosteroids need to be of high potency in order for a response to occur, and discoid lesions are one of the few instances where it may be appropriate to use high-potency corticosteroids on the face. Patients should be instructed about the risks and benefits of therapy, the need to limit the application to affected areas, and the need for monitoring for cutaneous side effects. Particularly in active discoid lesions and LE tumidus lesions, intralesional triamcinolone, often given in a concentration of 2.5–5 mg/ml, depending upon anatomic location, can be very effective. The injections may be repeated monthly while the lesions are active. There are also reports of the successful use of topical immunomodulators (e.g. tacrolimus, pimecrolimus) for cutaneous lesions.

Systemic Therapy

Antimalarial therapy has been used for more than a half-century for cutaneous LE, and it remains the gold standard for systemic therapy. Hydroxychloroquine sulfate is the most commonly chosen antimalarial, as it is usually well tolerated. Chloroquine and quinacrine (mepacrine) are alternatives, but quinacrine is currently not readily available in many parts of the world. In patients who are not responsive to hydroxychloroquine sulfate, quinacrine may be added to the regimen[77]. Quinacrine can turn the skin yellow, although it does not invariably do so. The dose of hydroxychloroquine sulfate chosen is usually 200 mg once or twice per day. It has been reported that if the dose does not exceed 5 mg/kg *actual body weight*/day, eye toxicity is quite unlikely[78]. For chloroquine, the usual dose is 125–250 mg/day, with the eye toxicity-minimizing dose being no more than 2.3 mg/kg *actual body weight*/day[78]. Quinacrine is thought by most not to cause eye toxicity. For patients on hydroxychloroquine sulfate or chloroquine, periodic eye examinations should be done by a physician knowledgeable in antimalarial eye toxicity.

The response to antimalarials is relatively slow. It may take 2 or 3 months for efficacy to be appreciated, and sometimes several more months to achieve maximal efficacy. Consequently, for patients who are beginning therapy for cutaneous LE, topical or intralesional therapy should usually be given along with antimalarial therapy. However, some patients do not respond either to single antimalarial therapy or to the combination of quinacrine with either hydroxychloroquine sulfate or chloroquine[78a].

Disease that is refractory to antimalarials is often refractory to other therapies as well. Nonetheless, it is reasonable to seek a therapy that will work well, if the risks of therapy are deemed to be worth the potential benefits. For antimalarial-resistant patients, therapeutic options include oral retinoids, dapsone, immunosuppressive agents such as mycophenolate mofetil, azathioprine or methotrexate, sulfasalazine, thalidomide or lenalidomide, and systemic corticosteroids[79]. Dapsone is used occasionally for cutaneous LE prior to advancing to immunosuppressive therapy, but it is most often employed for the rare bullous eruption of SLE[80]. Both retinoids and thalidomide are potent teratogens, making them difficult choices in women of childbearing potential. Thalidomide also frequently causes a peripheral neuropathy. For that reason, some clinicians have advocated giving thalidomide in low or intermittent dosing in an attempt to minimize toxicity. Lenalidomide, a second-generation thalidomide derivative, has led to improvement of refractory cutaneous LE and there may be a lower risk of developing peripheral neuropathy.

Responses to both belimumab and rituximab have been disappointing for patients with DLE and mixed for patients with SCLE, suggesting that the underlying pathogenesis, at least for DLE, is not dependent on B cells or that depletion of regulatory B cells by rituximab might be deleterious[81,82]. Of note, rituximab may be helpful for refractory bullous LE. In the future, other immune response modifiers such as anifrolumab (anti-IFN-α receptor antibody)[83], drugs that inactivate or deplete plasmacytoid dendritic cells (e.g. litifilimab, daxdilimab), iberdomide (promotes degradation of transcription factors Ikaros and Aiolos which regulate lymphocyte differentiation), anti-IL-33 antibody, or Janus kinase (JAK) inhibitors may play a role in the treatment of cutaneous LE.

In patients with systemic LE but no major organ involvement (i.e. potentially life-threatening involvement of visceral organs), treatment for mild disease includes NSAIDs, while corticosteroids and immunosuppressives (e.g. mycophenolate mofetil, azathioprine, methotrexate, leflunomide) are usually prescribed for moderate to severe disease. When there is a mild degree of major organ involvement, corticosteroids are the primary treatment, but for moderate to severe involvement, pulse cyclophosphamide or mycophenolate mofetil +/− pulse corticosteroids are often recommended. For a comprehensive review of future biologic therapies for refractory disease, see reference 79.

Adjunctive Therapy

Sun protection is a vital part of therapy for many patients because the sun exacerbates or initiates their skin lesions. For others, sun protection is important for cancer prevention, particularly in hypopigmented skin or in chronic discoid lesions, where the risk of skin cancer development may be higher. Cancer prevention is also essential for patients who are on immunosuppressive therapy. Lastly, it has been reported that sun exposure can exacerbate systemic disease in patients who have SLE. Therefore, there are a variety of reasons why sun protection should be emphasized, even in persons whose skin lesions are not induced or exacerbated by sun exposure.

Sunscreens should be applied to exposed skin daily, and more often if sun sensitivity is great or sun exposure is intense or prolonged. Broad-spectrum, high-SPF sunscreens are preferred (see Ch. 132). In some cases, the addition of a physical sunblock such as titanium dioxide or zinc oxide is useful. Protective clothing is important to emphasize, as the proper protective clothing is often significantly more effective

than sunscreens. Sun avoidance is even more effective than protective chemicals and clothing. Midday sun is particularly high in UVB, a spectrum of UV radiation to which many patients are susceptible. It is more difficult to minimize UVA exposure, as UVA is present in substantial quantities throughout the day and can penetrate some types of window glass. Education on the optimal use of sunscreens and protective clothing and effective approaches to sun avoidance is important for most patients with lupus. Careful attention should be given to vitamin D and calcium intake.

For some patients, cosmetic cover-up is the most helpful therapeutic intervention (see Ch. 153). Particularly in situations where the disease activity has subsided but dyspigmentation remains, cosmetic camouflage of the hyper- or hypopigmentation may be the best approach.

It has been observed that a larger-than-expected percentage of cigarette smokers are represented amongst patients who present with cutaneous lupus and that smokers may have more extensive cutaneous disease and may be more refractory to therapy. Thus, smoking cessation represents a useful adjunctive therapy in some individuals.

Additional figures and table, 1997 Update of the 1982 American College of Rheumatology revised criteria for classification of systemic lupus erythematosus, available in our eBook (see inside front cover for access code).

A thickened basement membrane is a characteristic finding and can be highlighted by PAS staining (inset). *Courtesy Lorenzo Cerroni, MD.*

1997 UPDATE OF THE 1982 AMERICAN COLLEGE OF RHEUMATOLOGY REVISED CRITERIA FOR CLASSIFICATION OF SYSTEMIC LUPUS ERYTHEMATOSUS*	
Criterion	**Definition**
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by physician
5. Arthritis	Non-erosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	a) **Pleuritis** – convincing history of pleuritic pain, rubbing heard by a physician, or evidence of pleural effusion
	OR
	b) **Pericarditis** – documented by ECG, rub or evidence of pericardial effusion
7. Renal disorder	a) Persistent **proteinuria** greater than 0.5 g/day or greater than 3+ if quantitation not performed
	OR
	b) **Cellular casts** – may be red cell, hemoglobin, granular, tubular or mixed
8. Neurologic disorder	a) **Seizures** – in the absence of offending drugs or known metabolic derangements, e.g. uremia, ketoacidosis or electrolyte imbalance
	OR
	b) **Psychosis** – in the absence of offending drugs or known metabolic derangements, e.g. uremia, ketoacidosis, or electrolyte imbalance
9. Hematologic disorder	a) **Hemolytic anemia** with reticulocytosis
	OR
	b) **Leukopenia** – less than 4000/mm^3 total WBC on two or more occasions
	OR
	c) **Lymphopenia** – less than 1500/mm^3 on two or more occasions
	OR
	d) **Thrombocytopenia** – less than 100 000/mm^3 in the absence of offending drugs
10. Immunologic disorder	a) **Anti-DNA antibody to native DNA** in abnormal titer
	OR
	b) **Anti-Sm** – presence of antibody to Sm nuclear antigen
	OR
	c) Positive finding of **antiphospholipid antibodies** based on: (1) an abnormal serum level of IgG or IgM anti-cardiolipin antibodies; (2) a positive test result for lupus anticoagulant using standard methods; or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test (FTA-ABS)
11. Anti-nuclear antibody	An abnormal titer of anti-nuclear antibody by immunofluorescence (or an equivalent assay) at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome
*The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.	

eTable 41.1 1997 Update of the 1982 American College of Rheumatology revised criteria for classification of systemic lupus erythematosus. 42 Dermatomyositis

Ruth Ann Vleugels and Joseph L. Jorizzo

Synonyms: ■ Dermatomyositis ■ Idiopathic inflammatory myopathies ■ Idiopathic inflammatory dermatomyopathies

Key features

- Autoimmune connective tissue disease of uncertain etiology with both juvenile and adult forms
- Clinical and laboratory signs of proximal extensor inflammatory myopathy
- Distinctive, photodistributed, pink–violet poikiloderma favoring the scalp, periocular region, and extensor surfaces, in addition to distinctive nail-fold changes and pink–violet papules overlying the knuckles
- Histopathologic evidence of interface dermatitis plus mucin deposition in skin biopsy specimens and lymphocytic myositis in biopsy specimens from affected muscle
- When myositis is present, therapy includes systemic corticosteroids and steroid-sparing immunosuppressive and immunomodulatory drugs, with the prognosis being very good, except for those individuals with refractory myositis, systemic involvement, or an associated advanced malignancy
- Management of cutaneous dermatomyositis via skin-directed therapies can be challenging and is directed by disease severity

INTRODUCTION

Along with polymyositis and inclusion body myositis, dermatomyositis is classified as one of the idiopathic inflammatory myopathies. Dermatomyositis is a disease of presumed autoimmune pathogenesis that presents with a symmetric, proximal, extensor inflammatory myopathy and a characteristic cutaneous eruption. Previously, polymyositis was thought to represent the same disease process but limited to the muscles; however, there is robust evidence that the pathogenetic mechanisms of polymyositis and dermatomyositis differ significantly. In polymyositis, clonally expanded, autoreactive $CD8^+$ T cells invade myocytes expressing MHC class I antigens and cause necrosis via the perforin pathway. In contrast, there are data to support the theory that autoantigens activate a humoral immune process in dermatomyositis, in which complement is deposited in capillaries causing capillary necrosis and ischemia[1]. Because an appreciation of these pathogenetic differences occurred relatively recently, previous studies often pooled cases of dermatomyositis and polymyositis, making interpretation of their data challenging.

Dermatomyositis is characterized by a bimodal age distribution, with both adult and juvenile forms, and up to one-quarter of patients in the adult group having an associated malignancy. Patients with juvenile dermatomyositis do not have an increased risk of malignancy, but do have an increased incidence of calcinosis cutis and associated small vessel vasculitis. There is a subset of patients in whom the cutaneous manifestations of dermatomyositis exist without objective evidence of muscle inflammation, referred to as amyopathic dermatomyositis, and formerly known as dermatomyositis sine myositis. For dermatologists, establishing the diagnosis of dermatomyositis is important because it is a serious, treatable, multisystem disease that has a different prognosis and treatment approach from lupus erythematosus (LE). The malignancy association in adults provides the dermatologist with an opportunity to assist medical colleagues in detecting the tumor at an early stage because the skin disease often precedes the onset of symptoms related to the malignancy.

HISTORY

Dermatomyositis has been recognized as a clinical entity for more than 100 years. Although the first adult patients with dermatomyositis and malignancy were described early in the twentieth century, a causal association was not suggested until the 1940s. A major step forward in the understanding of this disorder occurred in 1975, when Bohan and Peter proposed generally accepted clinical diagnostic criteria[2,3]. Over the past two decades, it has become more widely accepted that a subset of patients has skin-limited disease (i.e. amyopathic dermatomyositis). For this reason, Sontheimer[4] proposed a revised classification of the idiopathic inflammatory myopathies that includes amyopathic forms of dermatomyositis, with muscle involvement no longer required for a definitive diagnosis (Table 42.1)[5]. Based upon epidemiologic studies, an estimated 20% of dermatomyositis patients have clinically amyopathic disease[6].

EPIDEMIOLOGY

Dermatomyositis is a relatively rare disease that occurs throughout the world. In adults, dermatomyositis affects women two to three times more often than men. The incidence of dermatomyositis ranges from 2 to 9 per million amongst various populations[6–8] and seems to be increasing, although this may simply be a result of increased detection, as well as better diagnosis and reporting. Table 42.2 summarizes the demographic findings from five series of patients with dermatomyositis[6,9–11,11a].

PATHOGENESIS

Dermatomyositis is believed to result from an immune-mediated process triggered by "outside" factors (e.g. malignancy, drugs, infectious agents)

REVISED CLASSIFICATION SYSTEM FOR THE IDIOPATHIC INFLAMMATORY DERMATOMYOPATHIES
Dermatomyositis (DM)
Adult-onset
Classic DM
Classic DM with malignancy
Classic DM as part of an overlapping connective tissue disorder
Clinically amyopathic DM*
Amyopathic DM
Hypomyopathic DM
Juvenile-onset
Classic DM
Clinically amyopathic DM*
Amyopathic DM
Hypomyopathic DM
Polymyositis
Isolated polymyositis
Polymyositis as part of an overlapping connective tissue disorder
Inclusion body myositis
*Both adult-onset and juvenile-onset amyopathic DM and hypomyopathic DM can be further subcategorized as "provisional" and "confirmed" when patients have biopsy-confirmed hallmark cutaneous manifestations of DM without muscle weakness and with normal muscle enzymes for ≥6 months (provisional) or 24 months (confirmed).

Table 42.1 Revised classification system for the idiopathic inflammatory dermatomyopathies. This classification scheme recognizes, with equal weighting, the cutaneous and muscle manifestations of this group of disorders. *Adapted from Sontheimer RD. Would a new name hasten the acceptance of amyopathic dermatomyositis (dermatomyositis sine myositis) as a distinctive subset within the idiopathic inflammatory dermatomyopathies spectrum of clinical illness? J Am Acad Dermatol 2002;46:626–36.*

CLINICAL SUBTYPES OF DERMATOMYOSITIS – DEMOGRAPHICS AND ASSOCIATED FINDINGS						
	Clinical subtype					
	Adult-onset classic dermatomyositis[6,11a]		Adult-onset clinically amyopathic dermatomyositis[9,11a]		Juvenile-onset classic dermatomyositis[10]	Juvenile-onset clinically amyopathic dermatomyositis[11]
No. of patients	20	142	291	59	120	38
Mean age (years)	51.9	51	50	53	7.7	10.5
Malignancy detected	6/20 (30%)	14/142 (9.9%)	41/291 (14%)	1/59 (1.7%)	0/120 (0%)	0/38 (0%)
Sex ratio (F:M)	3:1	4.9:1	3:1	28.5:1	2.2:1	3:2

Table 42.2 Clinical subtypes of dermatomyositis – demographics and associated findings.

in genetically predisposed individuals. Table 42.3 illustrates some of the evidence that supports this theory[12–37]. Serum anti-nuclear autoantibodies are often present, as are other myositis-specific or myositis-associated autoantibodies, as summarized in Table 42.4[29,37–39]. The anti-synthetase antibodies are directed against cytoplasmic antigens; therefore the anti-nuclear antibody test may be negative. Patients with anti-synthetase antibodies often have overlap syndromes. The term anti-synthetase syndrome has been coined to refer to patients with these autoantibodies, fever, erosive polyarthritis, "mechanic's hands", Raynaud phenomenon, and interstitial lung disease[43].

CLINICAL FEATURES

Cutaneous Disease

The features that are classically considered pathognomonic for dermatomyositis include the heliotrope sign and Gottron papules (Fig. 42.1). The former is characterized by a pink–violet color, primarily of the eyelids and periorbital skin, which may have associated edema (Fig. 42.2). The heliotrope sign can be quite subtle, with only mild erythema of the eyelid margins, and it may wax and wane in intensity. Some patients will have more widespread facial erythema (see Fig. 42.2B,C) or midfacial erythema that tends to involve the nasolabial folds (Fig. 42.3).

The cutaneous lesions of dermatomyositis are accentuated on extensor surfaces, including the elbows, knees, metacarpophalangeal joints, and both the proximal and distal interphalangeal joints (knuckles; Fig. 42.4A). When papules on the knuckles develop a secondary lichenoid quality, they are termed *Gottron papules* (Fig. 42.4B,C); involvement of the elbows and/or knees is known as *Gottron sign* (Fig. 42.5).

A critical diagnostic feature of the cutaneous eruption of dermatomyositis is poikiloderma. This feature may occur both in patients with dermatomyositis, where it is frequently characterized by a pink–violet color, and in patients with lupus erythematosus, where the poikiloderma is typically more red in color. However, in patients with skin phototypes I and II, the hue of the poikiloderma of dermatomyositis may be pink–red rather than truly violet (Fig. 42.6A). Photodistributed poikiloderma is very characteristic of dermatomyositis, often involving the upper chest (*V-neck sign*) and the upper back (*shawl sign*). Poikiloderma can also affect photoprotected areas, such as the lateral thigh, referred to as the *holster sign* (Fig. 42.6B,C). If the clinician misses the poikiloderma, the eruption of dermatomyositis may occasionally be misdiagnosed as psoriasis, especially when there are well-defined plaques on the elbows and knees with fine silvery scale.

The cutaneous lesions of dermatomyositis are often intensely pruritic (Fig. 42.7), and this can significantly affect patients' quality of life[44]. IL-31 may play a role as it does in other pruritic disorders. Of note, pruritus is a feature that can occasionally help to distinguish dermatomyositis from LE.

An additional clinical clue to the diagnosis of dermatomyositis is nail-fold changes. Cuticular dystrophy (i.e. "ragged" cuticles and cuticular hypertrophy) is quite characteristic, as are nail-fold telangiectasias in which dilated capillary loops alternate with capillary dropout (Fig. 42.8). If the photodistribution and nail-fold changes are missed, the eruption may be misdiagnosed as other conditions characterized by poikiloderma, such as cutaneous T cell lymphoma. Often, the dermatologist correctly notices the photodistribution but considers the diagnosis of photodrug eruption or lupus erythematosus rather than dermatomyositis.

Calcinosis cutis is more prevalent in juvenile dermatomyositis, affecting 25%–70% of pediatric patients[7,45], and it is usually associated

PATHOGENESIS OF DERMATOMYOSITIS
Genetics[12–14]

• Monozygotic twins affected
• Associated human leukocyte antigens (HLA)
  • HLA-DR3 and -B8 (juvenile dermatomyositis)
  • HLA-DR52 (patients with anti-Jo-1 antibodies)
  • HLA-DR7 and -DRw53 (patients with anti-Mi-2 antibodies)
  • HLA-B14 and -B40 (adults with dermatomyositis overlap)
  • HLA-DRB1*15021 (Japanese with juvenile dermatomyositis)
• TNF-α 308 A allele polymorphism

Cellular immunity/apoptosis[15–21]
• Histopathologic findings in skin and muscle ($CD8^+$ lymphocytes) • Lymphocyte-mediated experimental myositis in mice • Increased Ki-67 and p53 expression in keratinocytes after UVB irradiation • Increased CD40 expression on muscle cells • Decreased circulating CD54 (ICAM-1)-positive lymphocytes • Dysregulaion of type 1 interferons • Fas ligand on T cells and Fas receptor on muscle cells • MHC class I overexpressed in affected muscle tissues • Elevated expression of COX-1, COX-2, and 5-LOX mRNA in affected muscle tissues
Humoral immunity[22,24,31,34]
• Association with autoimmune diseases (Hashimoto thyroiditis, Graves disease, myasthenia gravis, type I diabetes mellitus, primary biliary cirrhosis, dermatitis herpetiformis, vitiligo, and other autoimmune connective tissue diseases) • Myositis-specific autoantibodies (see Table 42.4) • Upregulation of interferon pathway and complement activation • Endomysial deposition of activated complement fragments (C5b–C9)
Infectious precipitants[23,24]
• Seasonal variation • Picornavirus substrate for aminoacyl-tRNA synthetases • *Escherichia coli*, muscle protein, and a capsid protein of a picornavirus that induces mouse myositis all have some homology in amino acid sequences with Jo-1 • Echovirus infection in patients with hypogammaglobulinemia • Coxsackievirus-9 myositis
Drug and vaccine precipitants[25,26,35–37]
• Hydroxyurea, lipid-lowering drugs (statins > gemfibrozil), TNF inhibitors, checkpoint inhibitors (e.g. nivolumab, ipilimumab), nonsteroidal anti-inflammatory drugs, immunostimulatory herbal supplements (e.g. *Spirulina*, IsaLean®), MAP kinase inhibitors, trastuzumab, taxanes, capecitabine, cyclophosphamide, BCG and SARS-CoV-2 vaccines, D-penicillamine; to date single case reports of alfuzosin (α-antagonist for BPH), articaine, etoposide, interferon-α-2b, ipecac (repeated exposures), omeprazole, phenytoin, sulfacetamide sodium ophthalmic drops, tegafur, terbinafine, zoledronic acid
Malignancy association (adults)[27–30]
• Anti-transcription intermediary factor 1-γ (TIF1-γ) antibodies, e.g. risk ratio = 5 in Chinese • Anti-nuclear matrix protein (NXP-2) antibodies, particularly in men • In one study, at least 80% of patients with cancer-associated dermatomyositis had antibodies against either TIF1-γ or NXP-2

Table 42.3 Pathogenesis of dermatomyositis. Other environmental triggers such as ultraviolet radiation may play a role (e.g. correlation between rate of dermatomyositis with anti-Mi-2 antibodies and proximity to the equator). BCG, Bacillus Calmette–Guérin; BPH, benign prostatic hyperplasia; ICAM, intercellular adhesion molecule; MAP, mitogen-activated protein; TNF, tumor necrosis factor.

SERUM AUTOANTIBODIES IN ADULT AND JUVENILE DERMATOMYOSITIS				
Autoantibodies	**Target antigen function**	**Clinical phenotype**	**Autoantibody frequency, %**	
			Adult DM	**Juvenile DM**
Anti-aminoacyl-tRNA synthetases (e.g. anti-Jo-1 [histidyl], anti-PL-7 [threonyl]; see Ch. 40)	Intracytoplasmic protein synthesis	Anti-synthetase syndrome (myositis, mechanic's hands, erosive polyarthritis, fever, Raynaud phenomenon, high frequency of interstitial lung disease)	up to 20	1–3
Anti-SRP	Protein translocation	Acute-onset necrotizing myopathy (severe weakness, high CK); may be refractory to treatment	5	<1
Anti-Mi-2	Helicase – transcription	Adult DM and juvenile DM (hallmark is cutaneous disease, milder muscle disease with good response to treatment)	15	<10
Anti-TIF1-γ (p155)	Cell proliferation, apoptosis, innate immunity	Cancer-associated myositis in adult DM; extensive cutaneous disease in adult DM and juvenile DM; palmar hyperkeratotic papules, psoriasiform lesions, red-on-white telangiectatic patches, ovoid palatal patch	20–40	~25
Anti-NXP-2 (p140)	Nuclear transcription, RNA metabolism	Cancer-associated myositis in adult DM (particularly in men); adult and juvenile DM with calcinosis; prominent muscle involvement with myalgias, peripheral edema, dysphagia, mild skin disease	10–20	~25
Anti-SAE	Post-translational modification	Adult DM; may present with clinically amyopathic DM	5	NA
Anti-MDA5 (CADM-140)	Innate immunity	Cutaneous ulcerations – periungual region and overlying Gottron papules and/or Gottron sign, tender palmar macules and papules that favor palmar and fingertip creases, oral ulcerations, prominent non-scarring alopecia, arthritis; clinically amyopathic DM; interstitial lung disease including a rapidly progressive form (often considered a dermato-pulmonary syndrome)	5–20	NA

Table 42.4 Serum autoantibodies in adult and juvenile dermatomyositis (DM). The autoantigen CADM-140 was subsequently found to be identical to two previously identified gene products, interferon induced with helicase C domain protein 1 (IFIH1) and melanoma differentiation-associated gene 5 (MDA5). amyo, amyopathic; CADM-140, clinically amyopathic dermatomyositis antibody, 140 kD; CK, creatine kinase; NA, not applicable; NXP-2, nuclear matrix protein-2; SAE, small ubiquitin-like modifier activating enzyme; SRP, signal recognition particle; TIF1-γ (transcription intermediary factor 1-γ). Note: Autoantibody frequencies vary depending on the ethnicity/population in which the study was conducted. Adapted from references 29, 39–42.

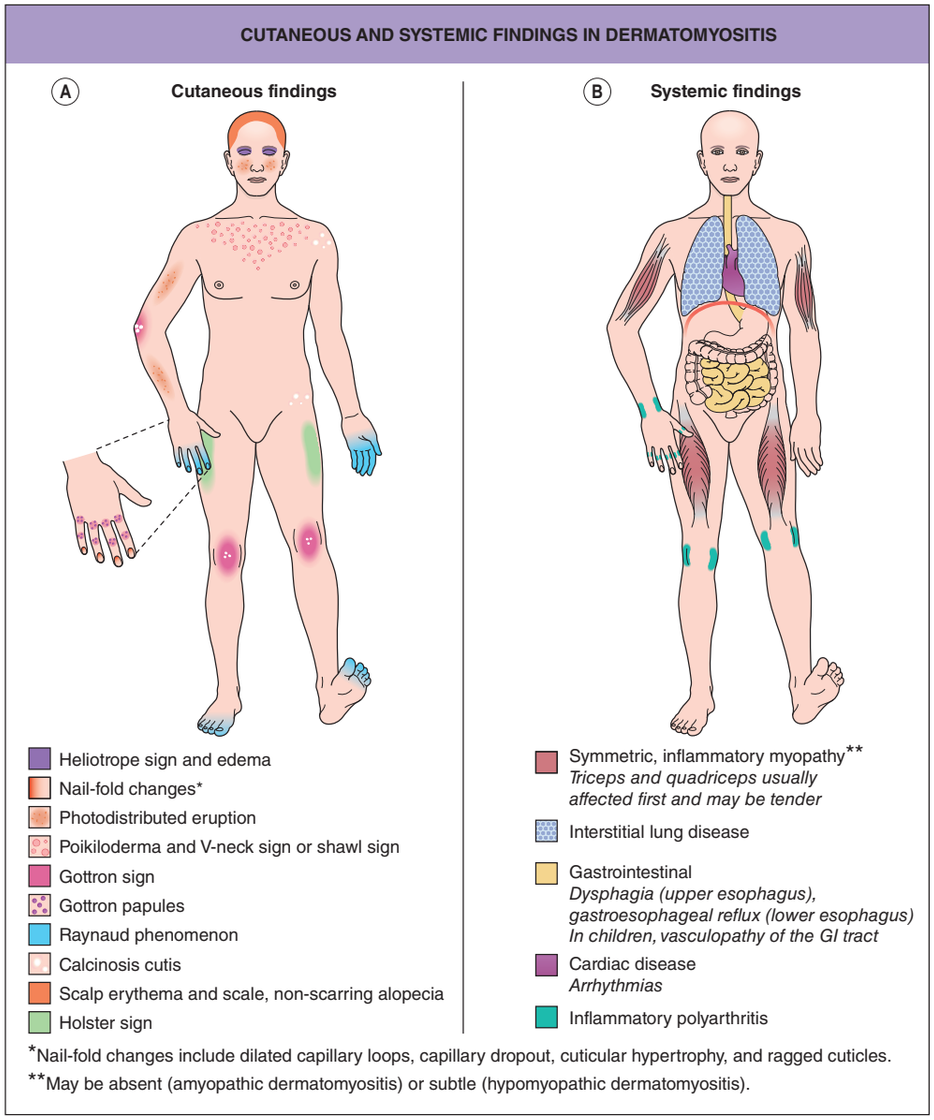

Fig. 42.1 Cutaneous and systemic findings in dermatomyositis. A Cutaneous. **B** Systemic.

Fig. 42.2 Dermatomyositis – eyelid edema and heliotrope sign. **A** Inflammation of the upper eyelid can be more subtle in darkly pigmented skin; note involvement of the lateral nasal root and the cheeks. The eyebrow alopecia is due to chemotherapy. **B** The characteristic pink–violet color is seen with involvement of the hairline, lower forehead, upper eyelids, and cheeks; the edema is striking, especially of the upper eyelids and nasal root. **C** Heliotrope with marked lower eyelid edema. *B, Courtesy Jean L. Bolognia, MD; C, Courtesy Kalman Watsky, MD.*

Fig. 42.3 Dermatomyositis – marked facial involvement. Note the violaceous hue. Misdiagnoses include psoriasis, contact dermatitis, and if there is significant facial involvement as in this patient, acute cutaneous lupus erythematosus.

with a delay in diagnosis, a delay in the institution of systemic corticosteroids, and/or advanced, therapy-resistant disease. In addition to the skin, calcium deposits may develop within the deep fascia and intramuscular connective tissue. Calcinosis cutis presents as hard, irregular papules, plaques, or nodules that occasionally drain a chalky material (Fig. 42.9A). Lesions favor sites of trauma, such as the elbows and knees (Fig. 42.9B), but can occur anywhere and may be painful and interfere with function.

Additional cutaneous manifestations range from poikiloderma and scaling of the scalp (often accompanied by non-scarring alopecia) to centripetal flagellate erythema (Fig. 42.10A) to erosions and ulcerations (Fig. 42.10B; Table 42.5)[46–48]. "Mechanic's hands" can also be seen, more commonly in patients with anti-synthetase syndrome (Fig. 42.10C). Occasionally, especially in the setting of more severe disease, there can be edema of the extremities or even anasarca. Wong-type dermatomyositis is a variant that occurs more commonly in Asians in which the cutaneous findings mimic pityriasis rubra pilaris[49]. Lastly, because of the frequency of overlap syndromes, it is important to look for the skin signs of other autoimmune connective tissue diseases in patients with dermatomyositis.

Patients may present with the classic cutaneous manifestations of dermatomyositis but no muscle disease. Upon careful patient evaluation and longitudinal assessment, some of these patients will be found to have skin disease alone (amyopathic dermatomyositis) while others eventually evolve into classic dermatomyositis (with muscle disease) or develop hypomyopathic dermatomyositis, i.e. no muscle weakness clinically but characteristic laboratory or radiographic abnormalities[50]. The clinical characteristics of patients with classic and amyopathic dermatomyositis have been compared[9], including an examination of differences in malignancy risk. Although it was generally thought that the malignancy risk was greater in the setting of classic dermatomyositis, there have been multiple studies that have observed associated malignancies in patients with amyopathic dermatomyositis. Fulminant lung disease has also been reported in patients with amyopathic dermatomyositis. Therefore, both malignancy screening and evaluation for pulmonary involvement are recommended, irrespective of muscle involvement.

Systemic Disease

In dermatomyositis, the dermatologic manifestations frequently precede the onset of *objective* muscle disease; however, when present, the muscle disease is clinically indistinguishable from that seen in polymyositis. The myopathy affects proximal muscle groups, especially the extensor groups (triceps and quadriceps), in a symmetric fashion. In advanced disease, all muscle groups can be affected. Patients may be unable to complete simple tasks such as combing their hair or rising to their feet from a sitting position. Muscle involvement is often accompanied by malaise and fatigue.

Muscle strength should be graded on sequential visits by muscle groups (e.g. right and left triceps 3/5, right and left quadriceps 4/5,

Fig. 42.4 Dermatomyositis – Gottron papules. A Only a few Gottron papules are present, but there is definite accentuation of the pink–violet inflammation over the metacarpophalangeal (MCP) joints and proximal and distal interphalangeal (PIP, DIP) joints as well as the proximal nail folds. Note the ragged cuticles. **B** The flat-topped (lichenoid) papules overlying the DIP, PIP, and MCP joints (knuckles) are subtle and were misdiagnosed as verrucae vulgares in this child. **C** More obvious disease in which the multiple pink–violet lichenoid papules are coalescing and there is some involvement of the interphalangeal skin. *A, Courtesy Kalman Watsky, MD; B, Courtesy Julie V. Schaffer, MD.*

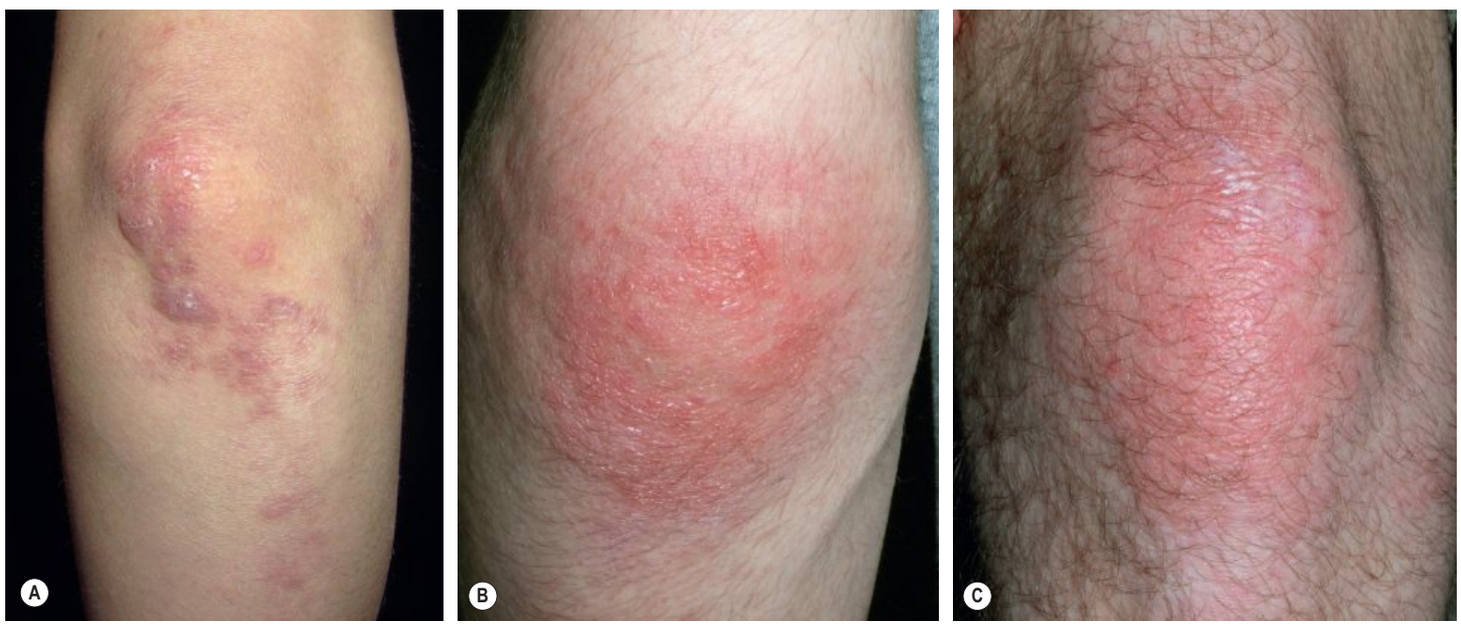

Fig. 42.5 Dermatomyositis – Gottron sign. Pink–violet papules (**A**) and thin pink plaques (**B**) of the elbows and knee (**C**). Some of the papules on the elbow are flat-topped (lichenoid) and others have white scale. The presence of plaques on the elbows and knees can lead to the misdiagnosis of psoriasis. *B,C, Courtesy Julie V. Schaffer, MD.*

etc.), although other more formal methods of quantification have been described. Assessment of neck flexor weakness can also be used to gauge muscle involvement. Symptoms of dysphagia should prompt investigation for overlap with systemic sclerosis, although patients with advanced muscle disease can have cricopharyngeal muscle dysfunction and consequently difficulty initiating swallowing. Distal esophageal involvement can present as gastroesophageal reflux disease.

Pulmonary disease occurs in ~15%–30% of patients with dermatomyositis, and generally presents as a diffuse interstitial fibrosis that is similar to that seen in patients with rheumatoid arthritis or systemic sclerosis[51]. Symptoms include a dry cough and progressive breathlessness. In one US-based study, there was no significant difference in the prevalence of interstitial lung disease when amyopathic dermatomyositis was compared to the classic form[52]. All adult patients should have screening pulmonary function tests (PFTs) that include diffusion capacity for carbon monoxide (DLCO)[52]. In those who have reduced DLCO, a high-resolution chest CT should then be performed. Patients with a high-risk phenotype for pulmonary involvement (e.g. anti-MDA5 dermatomyositis) often have a high-resolution chest CT performed at baseline as well as PFTs with DLCO.

In Eastern Asian populations, patients with anti-MDA5 (CADM) antibodies have a high risk of rapidly progressive lung disease and a poor prognosis despite a lack of muscle disease (see Table 42.4)[53,54]. Furthermore, a novel MDA5 antibody-associated dermato-pulmonary syndrome has been reported in non-Asian populations[55] in which patients develop tender palmar papules and cutaneous ulcerations, primarily on the elbows, dorsal hands, and periungual region (Fig. 42.11)[56]. Additional characteristic features of anti-MDA5 dermatomyositis include arthritis, oral ulcerations, and severe non-scarring alopecia. Recognition of this constellation of cutaneous findings alerts the clinician to the increased risk of associated and potentially fatal pulmonary disease.

Pulmonary involvement is also a notable feature of the antisynthetase syndrome[43]. For example, if anti-Jo-1 antibodies are present, there is a 70% likelihood that the patient will develop pulmonary disease. Because pulmonary disease associated with dermatomyositis is resistant to corticosteroid therapy, it follows a course independent from that of the muscle disease and can adversely affect prognosis.

Cardiac disease is usually not symptomatic. When it is, it commonly presents as arrhythmias or as conduction defects[57]. Patients with

Fig. 42.6 Dermatomyositis – poikiloderma and holster sign. A Photodistributed poikiloderma is very characteristic of dermatomyositis and often involves the upper chest (*V-neck sign*). In this patient with skin phototype I, the color is pink–red. **B** Broken-up pink–violet plaque on the upper lateral thigh (holster sign). **C** Holster sign with a pink–brown color in a patient with more darkly pigmented skin. *A, Courtesy Edward Cowen, MD; B, Courtesy Jonathan Leventhal, MD; C, Courtesy Sara Perkins, MD.*

Fig. 42.7 Dermatomyositis – involvement of the upper back. The pink–violet plaques, some with associated scale, were very pruritic, as evidenced by multiple excoriations. Linear streaks of erythema are also seen. *Courtesy Jean L. Bolognia, MD.*

Fig. 42.8 Dermatomyositis – cuticular dystrophy and nail-fold telangiectasias. The cuticles are "ragged" and within the proximal nail fold, dilated capillary loops alternate with vessel dropout (inset). Atrophy, telangiectasias, and hypopigmentation are present on the fingers. *Courtesy Julie V. Schaffer, MD.*

dermatomyositis are often not thoroughly evaluated for possible cardiac disease, and prompt treatment of the muscle disease may mask the true frequency of cardiac involvement. In one retrospective review, cardiac involvement was shown to be the major prognostic factor for death in patients with dermatomyositis, in the absence of an underlying malignancy[58]. Additional reported indicators of poor prognosis (other than malignancy) include older age, progressive disease, initiation of therapy after 24 months of muscle weakness, longer duration of symptoms before diagnosis, pulmonary disease, dysphagia, and extensive cutaneous involvement of the trunk[59].

For the patient with dermatomyositis, a thorough review of systems should include a discussion of arthritis, gastrointestinal disease, pulmonary disease, cardiac disease, and other manifestations such as Raynaud phenomenon. The presence of additional clinical findings and/or systemic symptoms may signify an overlap with other connective tissue diseases – in particular, systemic LE, rheumatoid arthritis, and systemic sclerosis. One dermatology-based case series observed a 19% overlap rate in adult patients with dermatomyositis[60].

Malignancy

The reported frequency of an internal malignancy in adults with dermatomyositis varies from <10% to >50%; however, the best data point to a probable risk of 15%–25%. The malignancy association occurs with adult dermatomyositis (both classic and amyopathic), but not with the juvenile form or with polymyositis. Genitourinary

A Rock-hard hyperpigmented plaques on the buttocks with multiple sites of drainage in an adult with longstanding dermatomyositis. **B** In this patient with juvenile dermatomyositis, the nodules favored the extensor surface of the knees and resulted in a decrease in joint mobility. *A, Courtesy Edward Cowen, MD.*

Fig. 42.10 Dermatomyositis – less common presentations. A Flagellate erythema of the posterior trunk. **B** Cutaneous erosions and ulcerations can also occur. **C** Hyperkeratosis and mild erythema of the lateral and palmar surfaces of the fingers in a patient with "mechanic's hands".

malignancies, especially ovarian cancer, and colon cancer may be overrepresented[61,62]; in some Southeast-Asian populations, nasopharyngeal carcinoma is overrepresented[63]. Other commonly detected malignancies include breast, lung, gastric, pancreatic, and lymphomas (including non-Hodgkin)[62]. The risk of malignancy may return to a relative baseline after 3 years[28,62,64].

Callen has suggested that the best approach to patient management in this setting is ongoing vigilance with frequent and thorough medical histories, repeated review of systems, complete physical examinations, and screening laboratory tests[65]. He has also advocated for additional cancer-screening investigations, including CT of the chest, abdomen, and pelvis as well as transvaginal pelvic ultrasound in women (Table 42.6)[64]. Patients should be up-to-date with regard to recommended screenings such as colonoscopy and mammography.

Several myositis-associated autoantibodies have been described (see Table 42.4), and presence of the anti-TIF1-γ (p155) autoantibody in particular has been associated with an increased risk of malignancy[30]. Indeed, in one study, at least 80% of patients with cancer-associated dermatomyositis had antibodies against either TIF1-γ (transcription intermediary factor 1-γ) or nuclear matrix protein NXP-2[29]. In a recent systematic review and meta-analysis, older age, male sex, dysphagia, cutaneous ulceration, anti-TIF1-γ antibodies, and classic dermatomyositis (i.e. without anti-synthetase syndrome or clinically amyopathic dermatomyositis) were associated with a significantly higher risk of an underlying malignancy[66]. This study also concluded that CT

MUCOCUTANEOUS MANIFESTATIONS OF DERMATOMYOSITIS	
Common	**Uncommon**
Heliotrope sign (Fig. 42.2) Eyelid edema (Fig. 42.2) Gottron papules (Fig. 42.4) Gottron sign (Fig. 42.5) Photodistributed poikiloderma (includes facial erythema, shawl sign, V-neck sign) (Figs. 42.3, 42.6A & 42.7) Scalp poikiloderma and scaling Non-scarring alopecia Nail-fold changes (includes ragged cuticles, cuticular hypertrophy, nail-fold telangiectasias*) (Fig. 42.8) Holster sign (poikiloderma of the lateral thighs) (Fig. 42.6B,C) Psoriasiform lesions Calcinosis cutis (especially in juvenile dermatomyositis) (Fig. 42.9)	Cutaneous erosions or ulcerations (Figs. 42.10B & 42.11A,B) Flagellate erythema (Fig. 42.10A) Tender palmar macules and papules (Fig. 42.11C) Hyperkeratotic palmar papules "Mechanic's hands" (Fig. 42.10C) Exfoliative erythroderma Cutaneous eruption that mimics PRP (Wong variant) Vesiculobullous lesions Oral ulcers† Ovoid palatal patch Gingival erythema & telangiectasias Panniculitis Lipoatrophy (especially in juvenile dermatomyositis) Small vessel vasculitis (especially in juvenile dermatomyositis)
*Dilated capillary loops alternating with vessel dropout. †Additional intraoral findings include xerostomia and lichen planus-like changes.

A, B Vasculopathic ulcerations favor the elbows, dorsal hands, and periungual region; they can be associated with Gottron sign and Gottron papules. **C** Painful violaceous macules and papules with an irregular outline that favor the digital creases.

EVALUATION OF THE PATIENT WITH DERMATOMYOSITIS	
History and physical examination	
• History, including potential triggers (see Table 42.3) and previous malignancies, and a review of systems • Physical examination – skin, muscle, and complete general examination, including, in adults, breast and pelvic (women), testicular and prostate (men), and rectal (both sexes) examinations; in Southeast-Asian patients, consider full ENT examination	
Laboratory evaluation	
Cutaneous	• Skin biopsy(ies)
Muscle	• Serum creatine kinase, serum aldolase, occasionally LDH (particularly in juvenile dermatomyositis) or urine creatine* • Electromyography (EMG); muscle biopsy; MRI or U/S (increasingly, MRI is being done in lieu of EMG and muscle biopsy if classic cutaneous findings are present)
Pulmonary	• Pulmonary function tests (PFTs) with CO diffusion • If PFTs abnormal, high-resolution chest CT; in patients with high-risk phenotypes (e.g. anti-MDA5 dermatomyositis), high-resolution chest CT performed at baseline as well as PFTs with DLCO
Cardiac	• Electrocardiogram (EKG) • If symptomatic, echocardiogram and/or Holter monitor
Esophageal	• If muscle involvement and symptoms, barium swallow or manometry
General	• Complete blood count, comprehensive metabolic panel with fasting levels of glucose and lipids†, comprehensive myositis antibody panel (in laboratories with reliable testing, e.g. Oklahoma Medical Research Foundation)
Malignancy screen (adults)‡,¶	• Urinalysis, stool occult blood testing • Serum prostate-specific antigen (PSA) [men] • Serum CA125 [women] • Serum CA19-9 [men and women] • Mammogram, Papanicolaou smear, and transvaginal pelvic U/S [women] • CT of chest, abdomen, and pelvis • Colonoscopy, if age-appropriate, iron deficiency anemia, occult blood in stool, or symptoms • Upper endoscopy – if colonoscopy negative in the setting of iron deficiency anemia, occult blood in stool, or symptoms
If planning chronic systemic corticosteroids	• DEXA bone density scan (see Ch. 125)
*Aspartate transaminase (AST), alanine transaminase (ALT), and lactic dehydrogenase (LDH) may also be elevated due to myositis; in children, serial examination of LDH is considered important. †Fasting levels of glucose and lipids are important in children. ‡Malignancy screening should be performed at the time of diagnosis and annually for a minimum of 3 years from disease onset; history and physical examination can be performed more frequently. ¶Can also consider serum protein and immunofixation electrophoreses.	

Table 42.6 Evaluation of the patient with dermatomyositis. CA125 screens primarily for ovarian carcinoma and CA19-9 for pancreatic and biliary tract carcinoma. Microscopic colitis can be seen in patients with chronic diarrhea. CO, carbon monoxide; CT, computed tomography; DEXA, dual energy X-ray absorptiometry; DLCO, diffusion capacity for carbon monoxide; ENT, ear, nose and throat; LDH, lactic dehydrogenase; MRI, magnetic resonance imaging; U/S, ultrasound.

of the chest, abdomen, and pelvis appeared to be effective in identifying otherwise asymptomatic malignancies, further supporting this screening strategy.

With regard to long-term survival, as expected, patients with cancer-associated dermatomyositis have an inferior survival curve when compared to patients with juvenile or non-cancer-associated adult myopathies[58].

PATHOLOGY

The characteristic changes seen in skin biopsy specimens from patients with dermatomyositis can be very subtle (Fig. 42.12) and include epidermal atrophy, signs of interface dermatitis with vacuolar alteration of basal keratinocytes and pigment incontinence, and dermal changes consisting of interstitial mucin deposition and a sparse lymphocytic infiltrate. In some cases, a colloidal iron stain may help to highlight

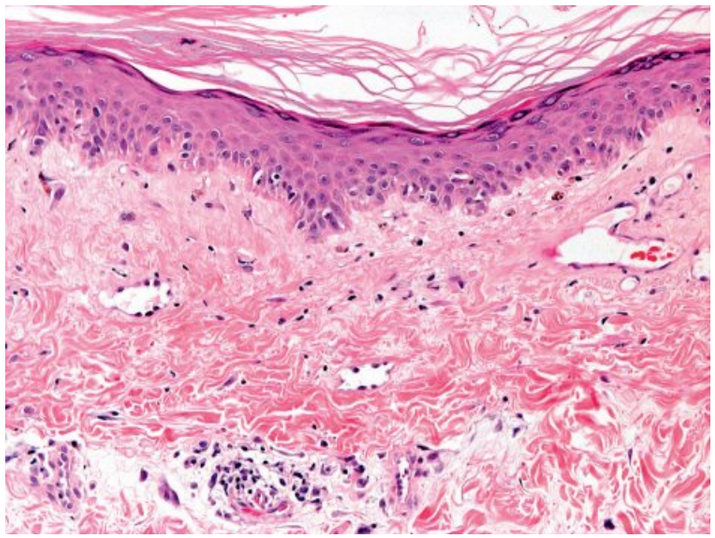

Fig. 42.12 Dermatomyositis – histopathologic features. The vacuolar changes within the basal layer can be subtle. In the dermis, dilated blood vessels and a sparse lymphocytic infiltrate are seen (poikilodermatous changes). *Courtesy Lorenzo Cerroni, MD.*

the presence of mucin. The histopathologic changes may be indistinguishable from those of cutaneous LE, in particular acute and subacute. Gottron papules show an interface dermatitis but have acanthosis and hyperkeratosis rather than epidermal atrophy[67]. A lobular panniculitis can also occur in patients with dermatomyositis and can resemble lupus panniculitis.

Muscle biopsy specimens also show characteristic changes. The combination of type II muscle fiber atrophy, necrosis, regeneration, and hypertrophy with centralized sarcolemmal nuclei, plus lymphocytes in both a perifascicular and a perivascular distribution, is classic[68]. It is best for the clinician to request that the surgeon sample triceps muscle rather than the usually biopsied deltoid muscle because the latter is often spared until late in the disease. Another option, especially for patients with mild involvement, is to choose the biopsy site based upon MRI findings (see below).

DIFFERENTIAL DIAGNOSIS AND EVALUATION

A detailed differential diagnosis of the patient who presents with proximal muscle weakness in the absence of skin lesions, i.e. the differential diagnosis of polymyositis, is beyond the scope of this dermatologic review. The patient with a characteristic cutaneous eruption should have a skin biopsy performed to confirm the clinical impression of dermatomyositis, keeping in mind that cutaneous LE can have similar histologic findings (Fig. 42.13). Table 42.7 summarizes the differential diagnosis of the dermatologic findings in dermatomyositis. Two validated instruments, the Dermatomyositis Skin Severity Index (DSSI) and the updated Cutaneous Dermatomyositis Disease Area and Severity Index (CDASI), can be used to determine the severity of cutaneous disease. These indices are helpful in assessing therapeutic responses in clinical trials[69,70].

Once the presumed diagnosis is confirmed histopathologically, a search for muscle and/or associated systemic disease must be undertaken (see Table 42.6), because it is their presence or absence that dictates therapeutic decisions. The evaluation for myositis can include: strength testing of proximal extensor muscles and other muscles including the neck flexors, serum levels of muscle enzymes, an electromyogram, and/or triceps muscle biopsy. However, increasingly, an MRI (Fig. 42.14) or ultrasound (Fig. 42.15) of proximal muscles is obtained prior to, or in lieu of, a muscle biopsy, especially in patients with classic cutaneous lesions. Individuals with normal muscle enzyme levels should be followed at regular intervals because these patients can have occult muscle disease, evolve into classic dermatomyositis, or remain as amyopathic dermatomyositis (see Fig. 42.13)[50].

Additional baseline investigations for pulmonary disease (predicted in part by autoantibody profile; see above and Table 42.4), for cardiac

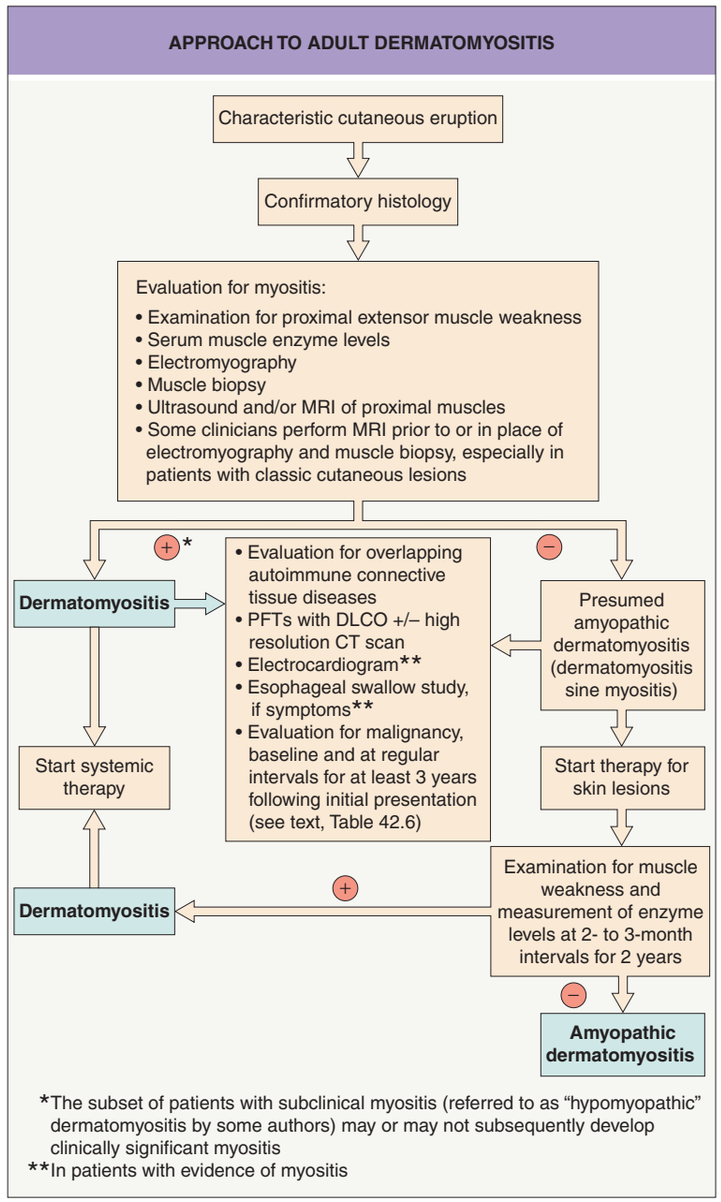

Fig. 42.13 Approach to adult dermatomyositis. The approach for children is similar but without the malignancy evaluation; in addition, pulmonary testing is not performed in children in the absence of symptoms given the low risk of interstitial lung disease. Table 42.1 outlines the definitions of "provisional" and "confirmed" amyopathic dermatomyositis but patients in the former group rarely go on to develop muscle disease. PFTs, pulmonary function tests.

disease, for symptomatic esophageal disease (barium swallow or manometry), and for features of overlap autoimmune connective tissue disease should be performed at this stage, prior to the institution of systemic therapy unless immediate therapy is warranted to halt rapidly progressive disease. Adult patients should have screening for malignancy annually for at least 3 years from disease onset (see Table 42.6), or more frequently based upon symptoms. A detailed history, review of symptoms, and complete physical examination should be performed at regular intervals of 4–6 months. Adult patients with amyopathic dermatomyositis should have similar evaluations for malignancy and associated pulmonary disease.

The classic muscle enzymes that should be assessed at baseline and at regular intervals throughout the treatment period are creatine kinase (CK) and aldolase. Aspartate and alanine transaminases and lactate dehydrogenase are often elevated as well, since they also are released from damaged muscle tissue. It has been estimated that 95% of patients with classic dermatomyositis have an elevated CK at some point during their illness[8]. Urine creatine is elevated in some patients who have a normal serum CK, but this test is not routinely performed.

DIFFERENTIAL DIAGNOSIS OF DERMATOMYOSITIS
Systemic lupus erythematosus*
Physician might notice nail-fold erythema and photodistributed poikiloderma but miss the muscle weakness, heliotrope, extensor distribution, pruritus, and the violaceous hue (Fig. 42.3) The malar rash of SLE classically spares the nasolabial folds, whereas the midfacial erythema of dermatomyositis involves the nasolabial folds Most commonly an issue when patient has amyopathic dermatomyositis and presents with a photosensitive eruption and no muscle weakness
Psoriasis
Involvement of elbows and knees with papulosquamous lesions can lead to misdiagnosis In addition, Gottron papules, extensor surfaces, and scalp can have psoriasiform scaling
Airborne or allergic contact dermatitis
Eyelid edema and lichenification secondary to pruritus can be marked in dermatomyositis; look for additional sites of contact dermatitis or dermatomyositis
Photodrug eruption
Photodistribution
Cutaneous T cell lymphoma
The poikiloderma often begins in intertriginous zones rather than on the scalp, face, and extensor surfaces
Atopic dermatitis
Usually in children, where the physician focuses on the pruritus and secondary lichenification
Systemic sclerosis*
The nail-fold telangiectasias may be similar in appearance, but the dyspigmentation is quite different; edema of the hands ("puffy hand sign") is an early sign of systemic sclerosis
Trichinosis
Patients have painful muscles and periorbital edema, but not other features
Photodistributed form of multicentric reticulohistiocytosis (MRH)
Firm papules have distinct histologic features and may occur along the nail fold Patients with MRH do not have the following nail-fold changes: dilated capillary loops, capillary dropout, cuticular hypertrophy, and ragged cuticles
Still disease
Persistent plaques may be linear Rarely, adults develop erythematous eyelid edema and flagellate erythema
*If the patient has an overlap syndrome, true lupus erythematosus or systemic sclerosis might be present.

Table 42.7 Differential diagnosis of dermatomyositis. SLE, systemic lupus erythematosus.

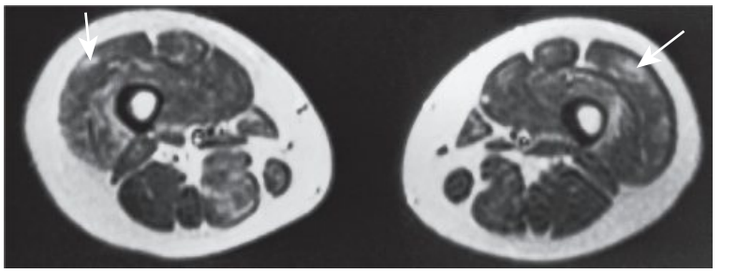

Fig. 42.14 T2-weighted MR images of the proximal thigh in a patient with dermatomyositis. Note the increased signal intensity, primarily in the extensor muscles (white color, arrows). The increased signal correlates with inflammation.

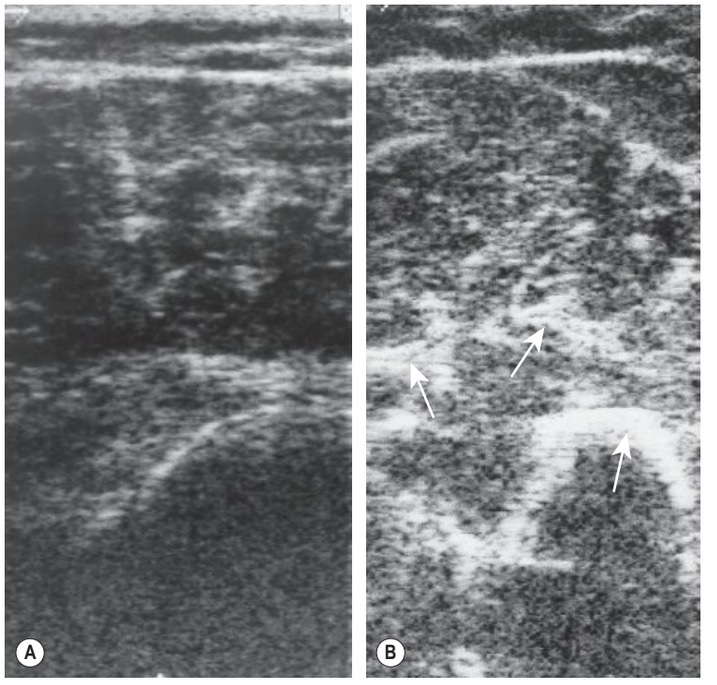

Fig. 42.15 Ultrasound images of the triceps muscle. A Cross-sectional ultrasound image from normal (control) triceps muscle. **B** Ultrasound image from affected triceps muscle in a patient with dermatomyositis. An increase in interstitial echoes is seen (arrows). This image highlights the triceps muscle, which is a higher yield biopsy site in dermatomyositis given that the deltoid muscle is often relatively spared until late in the disease.

Electromyography (EMG) is a sensitive but nonspecific test in patients with dermatomyositis. Over 90% of patients with classic dermatomyositis have abnormal EMG results. In the absence of classic cutaneous lesions, the muscle biopsy is a very important test for confirming the diagnosis and excluding other inflammatory myopathies. Surgeons will usually biopsy the deltoid muscle for convenience, but this muscle is relatively spared until late in the disease; therefore, the surgeon should be directed to perform a triceps muscle biopsy.

MRI (see Fig. 42.14) and ultrasound (see Fig. 42.15) of muscles are sensitive tests that can add greatly to patient evaluation. Both can be used to determine the appropriate site for a muscle biopsy[50]. Ultrasound is less expensive and easier to perform sequentially. MRI may be the most sensitive test for muscle disease, but it is more expensive[50,71]. In children with juvenile dermatomyositis, bilateral thigh MRI utilizing a myositis protocol is considered standard of care in many medical centers. MRI may also be useful in evaluating children for soft tissue changes that might precede calcinosis cutis[71].

TREATMENT

A therapeutic ladder for the treatment of patients with dermatomyositis is summarized in Table 42.8. As with many rare dermatologic diseases, there are few double-blind, placebo-controlled trials. However, a dermatology-based case series supported the belief that a number of patients (75%–85%) can become muscle disease-free, off treatment, after a period of 24–48 months, utilizing a slow corticosteroid taper[60]. Long-term follow-up of pediatric patients also confirmed this conclusion[45,72]. There is a clear discordance between response of the muscle disease to therapy and response of the skin disease[60]. Available therapy for the skin disease is clearly inadequate, with many patients experiencing persistent cutaneous disease and pruritus, especially of the scalp, which can become major complaints once the muscle disease is under control. Aggressive topical therapy and systemic therapy (e.g. antimalarials and/or weekly methotrexate) added specifically for the skin disease often do not provide adequate relief. However, it is clear that, except in adult patients with an advanced malignancy, the prognosis for corticosteroid-treated dermatomyositis in children and adults is excellent, especially when compared with a mortality rate of up to 50% in the pre-corticosteroid era[45].

The treatment of dermatomyositis must take into account the discordance between the response of the muscle disease and that of the dermatologic disease to systemic therapy. If *muscle disease* is confirmed, then

THERAPEUTIC LADDER FOR DERMATOMYOSITIS Rx
Systemic therapy
Oral prednisone: 1 mg/kg/day tapered to 50% over 6 months and to zero over 2–3 years (1)
Option to use pulse, split-dose, or alternate-day (2)
Methotrexate: 5–25 mg weekly po, sc, IM (2)
Azathioprine: 2–3 mg/kg/day po (1)
Others:
IVIg (2 g/kg/month) (1)
Mycophenolate mofetil (1–1.5 g po twice daily) (2)
Rituximab (375 mg/m^2 IV weekly × 4) (1)
Pulse cyclophosphamide (0.5–1.0 g/m^2 IV monthly) (2)
Cyclosporine (3–5 mg/kg/day po) (2)
Tacrolimus (0.12 mg/kg/day po) (3)
Sirolimus (5 mg/day × 2 weeks, 2 mg/day × 2 weeks, then 1 mg/day po) (3)
TNF inhibitors (e.g. infliximab, etanercept) (3)*
Fludarabine (3)
Hematopoietic stem cell transplantation (3)
Plasmapheresis (3)†
Cutaneous lesions
Photoprotection including sunscreens (high SPF including protection against UVA) and clothing (3)
Topical corticosteroids (3)
Topical tacrolimus (3)
Hydroxychloroquine (5 mg/kg divided over two doses daily [up to 200 mg po twice daily]; increased frequency of drug eruptions in patients with dermatomyositis) or chloroquine (250 mg po daily) (2)
Hydroxychloroquine (200 mg twice daily) or chloroquine (250 mg po daily) *plus* quinacrine (100 mg po daily) (3)
Low-dose weekly methotrexate (5–25 mg weekly po, sc, IM) (2)
Mycophenolate mofetil (3)
IVIg (2 g/kg/month) (1)
Lenabasum (cannabinoid receptor type 2 agonist) (1)
Tofacitinib (5–10 mg daily or 11 mg extended-release daily) (2)
Rituximab (750 mg/m^2 up to 1 g IV weekly × 2 – *or* – 1 g IV every other week × 2 doses – *or* – 375 mg/m^2 IV weekly × 4) (1)
Oral tacrolimus (3)
Retinoids (3)
Apremilast (3)
Dapsone (3)
Thalidomide (3)
Leflunomide (3)
Antiestrogens (e.g. tamoxifen, anastrazole) (3)
TNF inhibitors (e.g. infliximab, etanercept) (3)*
Low-dose naltrexone (4.5 mg nightly maximum dose) (3)
*Reported to cause drug-induced dermatomyositis and to induce disease flares in patients with pre-existing dermatomyositis; hence, most experts recommend avoiding these agents in patients with dermatomyositis.
†Double-blind trial showed no benefit.

Table 42.8 Therapeutic ladder for dermatomyositis. Dazukibart, which targets interferon beta 1, led to a reduction in cutaneous lesions in a phase II placebo-controlled trial. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. IM, intramuscular; IV, intravenous; IVIg, intravenous immunoglobulin; po, oral; sc, subcutaneous; SPF, sun protection factor.

systemic corticosteroid therapy is initiated in doses aimed at control of the myositis (i.e. generally prednisone 1 mg/kg/day). Patients with dermatologic manifestations alone can be treated as described below, with repeated clinical muscle examination and enzyme screening (generally CK and aldolase) at 2- to 3-month intervals.

If CK and aldolase serum levels are minimally elevated and corticosteroid therapy is initiated early, the disease generally comes under control rapidly over 2–4 weeks, with a taper to half the starting dose by 6 months. If the disease is advanced and enzyme levels are high (e.g. CK >1000 U/L), the disease can be much more difficult to control and often requires intravenous pulse corticosteroids plus early initiation of a steroid-sparing agent such as low-dose weekly methotrexate. Again, an attempt is made to taper the prednisone to 0.5 mg/kg/day in a single morning dose by 6–8 months.

Attention to general health maintenance principles and osteoporosis prevention is a key element of patient management (see Ch. 125). This can be accomplished by joint longitudinal care with an internist or pediatrician. Adults also need frequent (e.g. every 4–6 months for at least 3 years) complete physical examinations for malignancy.

Children with juvenile dermatomyositis should be followed at least twice yearly by a pediatrician comfortable with monitoring their developmental milestones while on immunosuppressive therapy. In addition, lipodystrophy and metabolic abnormalities, including hypertriglyceridemia and insulin resistance, have become increasingly recognized as potential complications of juvenile dermatomyositis[73,74].

When muscle disease is present, there is support for steroid-sparing therapies (especially in the setting of severe or recalcitrant disease), including IVIg[75–77], methotrexate[78], azathioprine[79], mycophenolate mofetil[80,81], rituximab[82,83], pulse cyclophosphamide[84,85], and cyclosporine (also for lung disease)[86]. Less often tacrolimus[87,88], sirolimus[89], infliximab[90], fludarabine[91], and hematopoietic stem cell transplantation[92] are used. Caution should be exercised if TNF inhibitors are being considered as cases of drug-induced and drug-exacerbated dermatomyositis have been reported. Consequently, many experts recommend avoiding these agents in patients with dermatomyositis.

Of the limited number of randomized, controlled trials performed to date, two assessed IVIg, with both demonstrating benefit in both muscle and skin disease[76,77], and one examined rituximab. The rituximab trial failed to reach its primary and secondary endpoints for muscle disease, but this was potentially related to study design – muscle disease improved in 83% of patients and a steroid-sparing effect was noted[83]. In this trial, none of the core measures of disease activity were skin-specific and no validated skin score was used; however, follow-up analysis utilizing a cutaneous visual analog scale demonstrated improvement of skin disease in both adult and juvenile dermatomyositis[93]. In contrast, a pilot trial of rituximab that used a validated skin score found no improvement in cutaneous disease activity[94]. A small, randomized pilot study that investigated abatacept for muscle disease in both dermatomyositis and polymyositis observed a reduction in disease activity in nearly 50% of treated patients[95]. Notably, a placebo-controlled study showed no benefit from plasmapheresis or leukapheresis in dermatomyositis[96]. In children with severe or refractory disease, IVIg is often administered[97].

Adjunctive physical therapy is also very important in improving muscle strength and endurance[98]. Benefits of exercise and rehabilitation have been demonstrated, even in the course of active disease, without inducing flares of the myositis[99].

Dermatologic disease can be particularly challenging therapeutically, and not all patients clear their cutaneous manifestations when their muscle disease remits. Patients with dermatologic disease without active muscle disease are generally not treated with systemic corticosteroids as a mainstay of their therapy, and they often present a unique therapeutic challenge. As a result, the treatment of amyopathic dermatomyositis often differs significantly from the treatment of classic dermatomyositis in that systemic corticosteroids are not traditionally utilized.

For cutaneous disease, anecdotal reports, case series, retrospective reviews, and limited prospective data support the use of topical corticosteroids, topical tacrolimus[100], antimalarial therapy[101,102] (either as monotherapy or in combination but with a less dramatic effect than in cutaneous LE), low-dose weekly methotrexate, mycophenolate mofetil[103], IVIg[76,104,105], dapsone[106], tofacitinib[107–109], and thalidomide[110], as well as additional agents listed in Table 42.8. Of note, there is an increased risk of a cutaneous drug reaction to hydroxychloroquine in patients with dermatomyositis as compared to those with LE[111]. This medication is still frequently used as first-line therapy, but a pre-treatment warning is recommended. Some patients who develop a cutaneous reaction to hydroxychloroquine may tolerate chloroquine[111].

Clinical studies to support a specific treatment algorithm for cutaneous dermatomyositis are lacking. A common therapeutic approach includes a trial of antimalarials for mild cutaneous disease, whereas patients with moderate to severe skin disease are often treated with methotrexate, mycophenolate mofetil, and/or IVIg[112]. As noted previously, antimalarials are considered less effective for cutaneous dermatomyositis as compared to cutaneous LE. In fact, one study

demonstrated that only 11% of patients with clinically amyopathic dermatomyositis achieved adequate control of their skin disease with antimalarial therapy[113].

Calcinosis cutis may respond to diltiazem and/or surgical excision[114]; other therapies include low-dose warfarin, bisphosphonates, probenecid, colchicine, TNF inhibitors, aluminum hydroxide, sodium thiosulfate, and electric shock wave lithotripsy (ESWL). Early and aggressive therapy of juvenile dermatomyositis does seem to reduce the risk of calcinosis cutis, which is often extremely challenging to treat[45].

SYSTEMIC SCLEROSIS

Synonyms: Systemic sclerosis: ■ Scleroderma ■ Progressive systemic sclerosis
Subtypes of cutaneous involvement: ■ Diffuse ■ Limited (includes CREST syndrome)

Key features

- An uncommon autoimmune connective tissue disease of unknown etiology
- Characterized by symmetric hardening of the skin of the fingers, hands, and face that may generalize
- Raynaud phenomenon is common, and digital ulcers may develop
- Internal organ involvement is frequent and affects the lungs, gastrointestinal tract, heart, and kidneys
- Important to monitor for lung involvement because pulmonary disease is the leading cause of death
- Treatment focuses on internal organ manifestations; effective therapy for cutaneous sclerosis remains inadequate

Introduction

Systemic sclerosis (SSc, scleroderma) is an autoimmune connective tissue disease (AI-CTD) of unknown etiology that affects the skin, blood vessels, and internal organs[1]. The name *systemic sclerosis* is meant to convey the systemic nature of the disease, which has two major clinical subtypes: *limited cutaneous SSc* (lcSSc) and *diffuse cutaneous SSc* (dcSSc). LcSSc is characterized by cutaneous sclerosis that is limited to the fingers, hands, and face. In dcSSc, generalized cutaneous sclerosis is seen that usually begins in the fingers and hands but eventually extends to the forearms, arms, face, trunk, and lower extremities. Other entities that can lead to symmetric and widespread cutaneous induration include generalized morphea, eosinophilic fasciitis, scleromyxedema, nephrogenic systemic fibrosis, scleredema, and chronic GVHD (Table 43.1).

History

The first reported case of SSc in 1754 was a young Italian woman who developed progressive skin induration[1]. From the clinical description, it is impossible to determine whether she had true SSc or another sclerodermoid disorder such as scleredema.

Epidemiology

SSc has a worldwide distribution and affects all races. The annual incidence and prevalence rates in the US are approximately 20 and 275 cases per million, respectively[2]. Women are affected three to four times as often as men. Although SSc can occur in children and the elderly, onset is typically between the ages of 35 and 50 years. Black individuals have an earlier mean age of onset and a higher likelihood of diffuse disease[2]. Approximately 1.5% of SSc patients have one or more affected first-degree relatives, representing a 10- to 15-fold higher risk of SSc in family members than in the general population[1]. SSc is associated with significant mortality, with an overall 10-year survival of ~70%[1]. Clinical features predicting a worse prognosis include male sex, older age at diagnosis, being African-American, internal organ involvement (especially pulmonary) at the time of diagnosis, cutaneous sclerosis affecting the trunk, and elevated ESR[1].

Pathogenesis

The pathogenesis of SSc is unknown. Key pathogenic abnormalities in the skin and internal organs are vascular dysfunction, immune activation with autoantibody production, and tissue sclerosis characterized by deposition of collagen and other extracellular matrix proteins (Fig. 43.1)[2a–5].

Vascular dysregulation

Impaired angiogenesis is an early event in the pathogenesis of SSc[5]. The blood vessels affected range from the smallest capillaries within the proximal nail fold to the large pulmonary arteries. Endothelial cell injury occurs early (before sclerosis is evident), based on changes seen by electron microscopy, such as perivascular leak and edema[6]. Endothelial cell activation leads to increased expression of adhesion molecules and binding of circulating inflammatory cells. Vascular endothelial growth factor (VEGF) and its receptors (VEGFR) are elevated in the dermis in SSc[5].

Surrounding smooth muscle cells are also affected and have altered production of and responsiveness to vasoconstrictive (e.g. cold, endothelin) and vasodilatory (e.g. nitric oxide) factors. Structural abnormalities such as intimal proliferation lead to luminal occlusion and hypoxia which then induces synthesis of profibrotic cytokines, fibroblast activation, and collagen production[7]. Raynaud phenomenon and digital ulcers are caused by reversible vasospasm as well as irreversible arterial damage with intimal proliferation and luminal obstruction. Scleroderma renal crisis and pulmonary artery hypertension are manifestations of large vessel dysregulation.

Immune dysregulation

Autoantibodies unique to SSc, in particular anti-centromere, anti-topoisomerase I, and anti-RNA polymerase III, are useful for diagnostic and prognostic purposes (see Ch. 40)[1,8]. These three autoantibodies bind tissues of interest in SSc, as do anti-U3RNP (antifibrillarin), anti-Th/To, anti-U1RNP, anti-PM-Scl, and anti-Ku autoantibodies[5,8]. The latter are rather rare and play a role in overlap syndromes.

Evidence of a direct pathogenic role for these autoantibodies includes complexes containing topoisomerase I autoantibody that, when bound to the surface of fibroblasts, have been found to stimulate monocyte adhesion and activation. In addition, anti-endothelial cell antibodies from SSc patient sera can trigger endothelial cell apoptosis. One group described stimulatory autoantibodies against the platelet-derived growth factor (PDGF) receptor in SSc sera, which induced reactive oxygen species and expression of type I collagen by normal human fibroblasts[9]. However, two subsequent studies were unable to confirm these findings[10].

Lymphocytic infiltrates, composed of both T and B cells, have been observed in the skin and lungs of SSc patients before the development of fibrosis. Oligoclonal T cell expansion has been identified in lesional skin, indicating an antigen-driven response, and T cells demonstrate

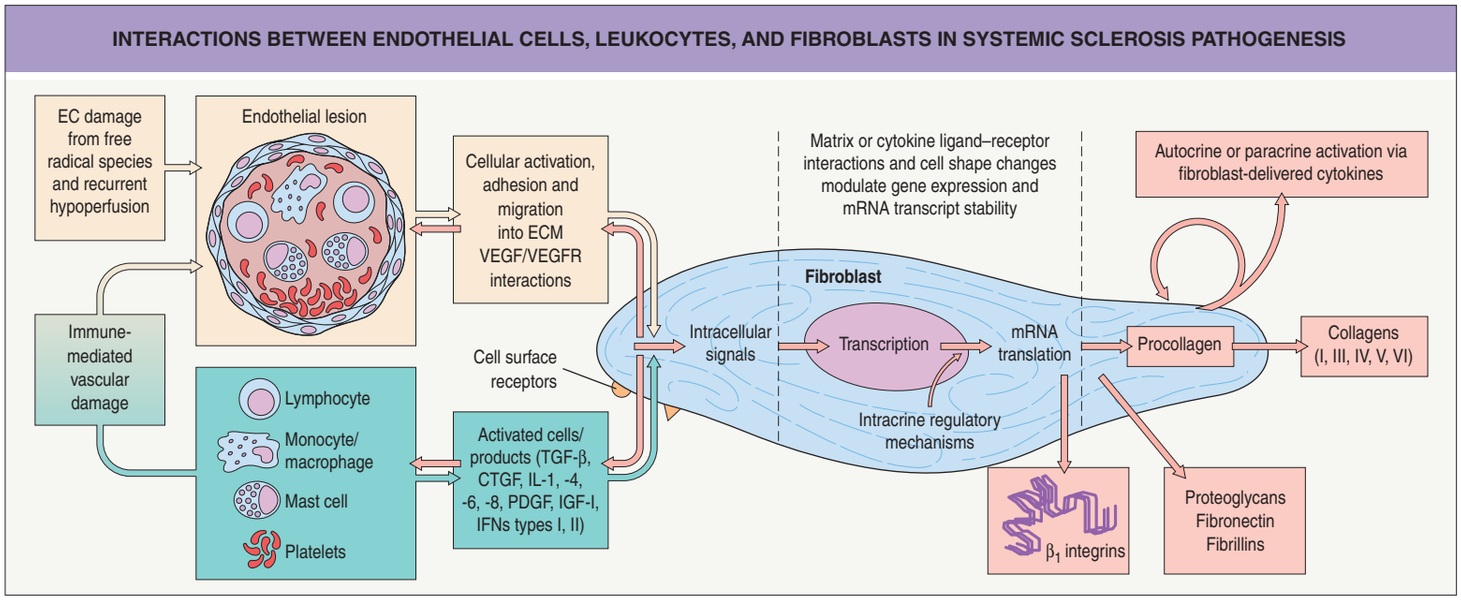

Fig. 43.1 Interactions between endothelial cells, leukocytes, and fibroblasts in systemic sclerosis pathogenesis. In patients with systemic sclerosis, variants in genes involved in innate immunity (e.g. *IRF5*), T cell activation (e.g. *STAT4*), and the TNF pathway (e.g. *TNFAIP3*) have been identified. Mutations in the gene that encodes fibrillin-1 (*FBN1*) lead to stiff skin syndrome. CTGF, connective tissue growth factor; EC, endothelial cell; ECM, extracellular matrix; IFN, interferon; IGF, insulin-like growth factor; PDGF, platelet-derived growth factor; TGF, transforming growth factor; VEGF, vascular endothelial growth factor; VEGFR, VEGF receptor. *Adapted from Hochberg MC, Silman AJ, Smolen JS, et al (eds). Rheumatology, 3rd edn. Edinburgh: Mosby, 2003.*

a Th2-predominant profile with up-regulation of profibrotic cytokines such as interleukin (IL)-4 and IL-13. SSc patients also have expansion of naive B cells and chronic activation, but a decreased number, of memory B cells.

More recently, Th17 cells and IL-17 have been implicated in SSc, as have the *innate* immune system and types I (α,β) and II (γ) interferons. For example, elevated numbers of plasmacytoid dendritic cells have been observed in the blood and skin of SSc patients[11]. In a proteome-wide analysis of five large cohorts, circulating levels of the chemokine CXCL4 were found to be significantly elevated (compared to controls), and the CXCL4 levels correlated with the presence and progression of pulmonary disease[11]. Prospective studies have shown changes in CXCL4 at 12 months predicted future progression[12].

Extracellular matrix dysregulation

Sclerosis represents the final common pathway for tissue damage in SSc. There is excessive deposition of collagens, proteoglycans, fibronectin, fibrillins, and adhesion molecules (e.g. β_1-integrins), which sequester cytokines and growth factors (see Fig. 43.1). Attention has focused on transforming growth factor β (TGF-β) and connective tissue growth factor (CTGF). The latter is induced by TGF-β and may be responsible for maintenance of collagen synthesis.

Given the complex extracellular matrix changes seen in SSc[13], both the fibroblast and the myofibroblast have been a focus of investigation. There is evidence suggesting an inherent defect, an autocrine loop, or a hypersensitivity to growth factors in SSc fibroblasts. Alternatively, SSc fibroblasts may have a normal phenotype but instead find themselves in an abnormal microenvironment with enhanced growth factors or ischemic mediators. The accumulation of collagen in SSc seems to be primarily the result of increased synthesis, rather than decreased degradation.

Clinical Features

Classification and diagnostic criteria

The American College of Rheumatology (ACR) updated the classification criteria for SSc in 2013 (Table 43.2)[14]. These classification criteria ensure the patient population being studied is well-defined and homogeneous, which is particularly important in rheumatic diseases where nonspecific and overlapping symptoms may lead to misclassification. As a result, *classification* criteria are stricter than the *diagnostic* criteria used for an individual patient. Nonetheless, for our purposes, they will be used interchangeably.

In the 2013 classification scheme for SSc, the sole major criterion – skin thickening of the fingers on both hands extending proximal to the metacarpophalangeal (MCP) joints – leads to a diagnosis of *definite* SSc (9 points)[14]. If the patient does not meet this criterion, seven other minor criteria may be used to reach a diagnosis of SSc (see Table 43.2). These 2013 criteria have greater sensitivity (91%) and specificity (92%) compared to older criteria[14].

Based upon the degree of skin involvement, there are two major clinical subtypes (Fig. 43.2): lcSSc and dcSSc[1]. When the skin disease involves the distal and proximal portions of the extremities, trunk and face, it is considered dcSSc, but when the induration is limited to the distal extremities and face, it is considered lcSSc[1]. Although both can have systemic manifestations, there are variable patterns and severity of internal organ involvement (Table 43.3). Typically, dcSSc is associated with early internal organ involvement (within 5 years of disease onset) and a worse prognosis[1], whereas patients with lcSSc tend to develop internal involvement later in the disease and have a better prognosis.

The acronym CREST describes clinical features in a subset of patients with lcSSc: *c*alcinosis, *R*aynaud phenomenon, *e*sophageal involvement, *s*clerodactyly and *t*elangiectasia. However, because not every patient has all five features, the term lcSSc is favored. Rarely, patients present with characteristic internal organ involvement, Raynaud phenomenon, abnormal nail-fold capillaries, and positive serologies, but no cutaneous sclerosis. This clinical presentation is referred to as *systemic sclerosis sine scleroderma* (ssSSc), and it behaves similarly to lcSSc.

Cutaneous features

Many patients with SSc experience an early edematous phase, which often features pitting edema of the digits (Fig. 43.3). Digital pits are also a characteristic finding (Fig. 43.4). The skin subsequently hardens and develops a taut, shiny appearance (indurated phase). Eventually,

ACR/EULAR CRITERIA FOR THE CLASSIFICATION OF SYSTEMIC SCLEROSIS

Item	Sub-item	Weight/score
Skin thickening of the fingers of both hands extending proximal to the MCP joints (*sufficient criterion*)	–	9
Skin thickening of the fingers	Puffy fingers - *or* - Sclerodactyly	2 4
Fingertip lesion	Digital tip ulcers - *or* - Pitting scars	2 3
Telangiectasias	–	2
Abnormal nail-fold capillaries	–	2
Pulmonary arterial hypertension - *or* - Interstitial lung disease		2 2
Raynaud phenomenon	–	3
SSc-related autoantibodies	Anti-centromere Anti-topoisomerase I Anti-RNA polymerase III	3

Table 43.2 2013 American College of Rheumatology (ACR)/European League Against Rheumatism (EULAR) criteria for the classification of systemic sclerosis (SSc). The total score is determined by adding the maximum weight (score) in each category. Patients with a total score of ≥9 are classified as having *definite* SSc. *From Van den Hoogen F, Khanna D, Fransen J, et al. 2013 classification criteria for systemic sclerosis. Arthritis Rheum. 2013;65:2737–47.*

COMPARISON OF CLINICAL AND LABORATORY FEATURES OF DIFFUSE AND LIMITED SYSTEMIC SCLEROSIS

Clinical feature	Diffuse SSc (%)	Limited SSc (%)
Raynaud phenomenon	90	99

there may be gradual thinning of the skin (late atrophic phase). The fingers can develop flexion contractures and ulcers (Fig. 43.5) while involvement of the face can lead to a beaked nose, microstomia, and a more youthful appearance.

There are a number of cutaneous changes other than sclerosis in patients with SSc. **Dyspigmentation** in areas of sclerosis is commonly observed. Some patients develop diffuse hyperpigmentation, with accentuation in sun-exposed areas and sites of pressure. The "leukoderma of scleroderma" is characterized by localized areas of depigmentation with sparing of the perifollicular skin; this helpful diagnostic finding is sometimes referred to as the "salt and pepper" sign (Fig. 43.6). Pigment may also be retained in the skin overlying superficial veins. This leukoderma favors the upper trunk and central face and may overlie uninvolved or sclerotic skin.

Telangiectasias are more common in patients with lcSSc but also occur in patients with dcSSc (see Table 43.3). The telangiectasias most often involve the face, lips, and palms. These telangiectatic macules are matted or squared-off (Fig. 43.7). Capillary abnormalities in the proximal nail fold are present in more than 90% of SSc patients and can be useful in supporting the diagnosis[15]. Use of magnification may enhance appreciation of these findings. In SSc, capillary loss ("drop out") alternating with dilated loops is characteristic, and density changes have been shown to have prognostic value for fingertip ulceration and lung disease progression.

Calcinosis cutis most commonly develops on the extremities, usually near joints and in distal locations (Fig. 43.8). In addition, the skin is often

Fig. 43.3 Early, edematous phase of systemic sclerosis. Note the demonstration of pitting edema on two of the digits. *Courtesy Jean L. Bolognia, MD.*

dry due to decreased sweating, and pruritus can be quite marked. Sclerotic skin may show diminished hair growth, but this is variable; hypertrichosis can also occur, particularly during the recovery phase. Overall, the cutaneous changes are extremely troublesome to patients with SSc. In a questionnaire-based study involving 300 patients with SSc, facial involvement and microstomia were the patients' greatest concerns[16].

Raynaud phenomenon is characterized by episodic vasospasm of the digital arteries resulting in white, blue, and red discoloration of the fingers secondary to cold exposure[17]. Raynaud phenomenon occurs in two settings (Table 43.4). *Primary Raynaud phenomenon* (Raynaud disease) typically develops in adolescent girls and young women and is not associated with any underlying medical problems[18]. Primary Raynaud phenomenon is common and estimated to affect 3% to 5% of the population. In contrast, *secondary Raynaud phenomenon* is uncommon and is associated with an underlying medical disorder, including SSc (Fig. 43.9; Table 43.5). An approach to differentiating primary from secondary Raynaud phenomenon is presented in Figure 43.10.

Cutaneous ulcers are common in patients with SSc (Fig. 43.11). Whereas ulcers on the tips of the digits are probably due to ischemia, those on the interphalangeal joints are more likely to persist because of continued trauma (see Fig. 43.5). They may also overlie sites of calcinosis cutis. Ulcers can lead to osteomyelitis and even amputation (autoamputation or surgical).

Extracutaneous features

The majority of SSc patients have internal organ involvement (Table 43.6), which is the major cause of morbidity and mortality in this disease[1,19]. Occasionally, a patient with SSc will present with internal organ involvement before skin involvement is evident. The most commonly affected organs are the gastrointestinal tract, lungs, heart, and kidneys. Of note, pulmonary disease has replaced renal crisis as the leading cause of death in SSc. There are two major forms of pulmonary involvement in SSc[1,19]: (1) interstitial lung disease (ILD); and (2) pulmonary arterial hypertension (PAH). Screening tests for both disorders are outlined in Table 43.6. Recently, a rare subtype of ILD referred to as pleuroparenchymal fibroelastosis (PPFE) was described. It is characterized by fibrotic thickening of the visceral pleura as well as the subadjacent parenchymal areas of the lungs' upper lobes. PPFE portends a poor prognosis and requires close monitoring with serial determinations of DLCO (*d*iffusing capacity of the *l*ungs for *c*arbon *m*onoxide) and high-resolution computed tomography scans.

Autoantibodies

Autoantibody testing is useful in confirming the diagnosis of SSc (see Ch. 40). Most SSc patients have elevated titers of anti-nuclear antibodies (ANA)[1,8], with the nucleolar or discrete speckled (centromere) patterns being relatively specific for SSc. Patients with anti-centromere antibodies are more likely to have lcSSc, digital gangrene, and PAH[1]. Patients with antibodies to topoisomerase I (Scl-70) are more likely to have dcSSc with an increased risk of ILD leading to pulmonary fibrosis[1]. Lastly, the subset of patients with anti-RNA polymerase III antibodies is more likely to have rapidly progressive, diffuse skin disease, and renal involvement[1]. This subset may also have an increased risk of an associated malignancy, most commonly breast cancer[20].

Pathology

Histologically, areas of cutaneous induration are characterized by compact or hyalinized collagen, excessive deposition of collagen, atrophic eccrine and pilosebaceous glands, "miniaturization" or loss of subcutaneous fat, and a sparse lymphocytic infiltrate in the dermis and subcutis (Fig. 43.12). Plasma cells may be present. Adnexal structures, especially eccrine glands, appear "trapped" by the excessive deposition of collagen. In some cases, there may be a

Fig. 43.8 Calcinosis cutis of the finger in a patient with systemic sclerosis.

perineural arrangement of the inflammatory infiltrate within the deep dermis. Of note, the different subsets of SSc cannot be distinguished histologically.

Direct immunofluorescence studies are usually negative in patients with SSc. While endothelial damage can occur in cutaneous blood vessels, this finding is only seen at the ultrastructural level[6]; reduplication of the basement membrane is also observed. It should be noted that, in its end stage, areas of sclerosis may be indistinguishable histologically from other diseases characterized by collagen deposition, such as morphea (which tends to have a more robust inflammatory infiltrate than SSc in its earlier stages).

Differential Diagnosis

The primary differential diagnosis of SSc is outlined in Table 43.1 while additional entities that may have a sclerodermoid presentation are

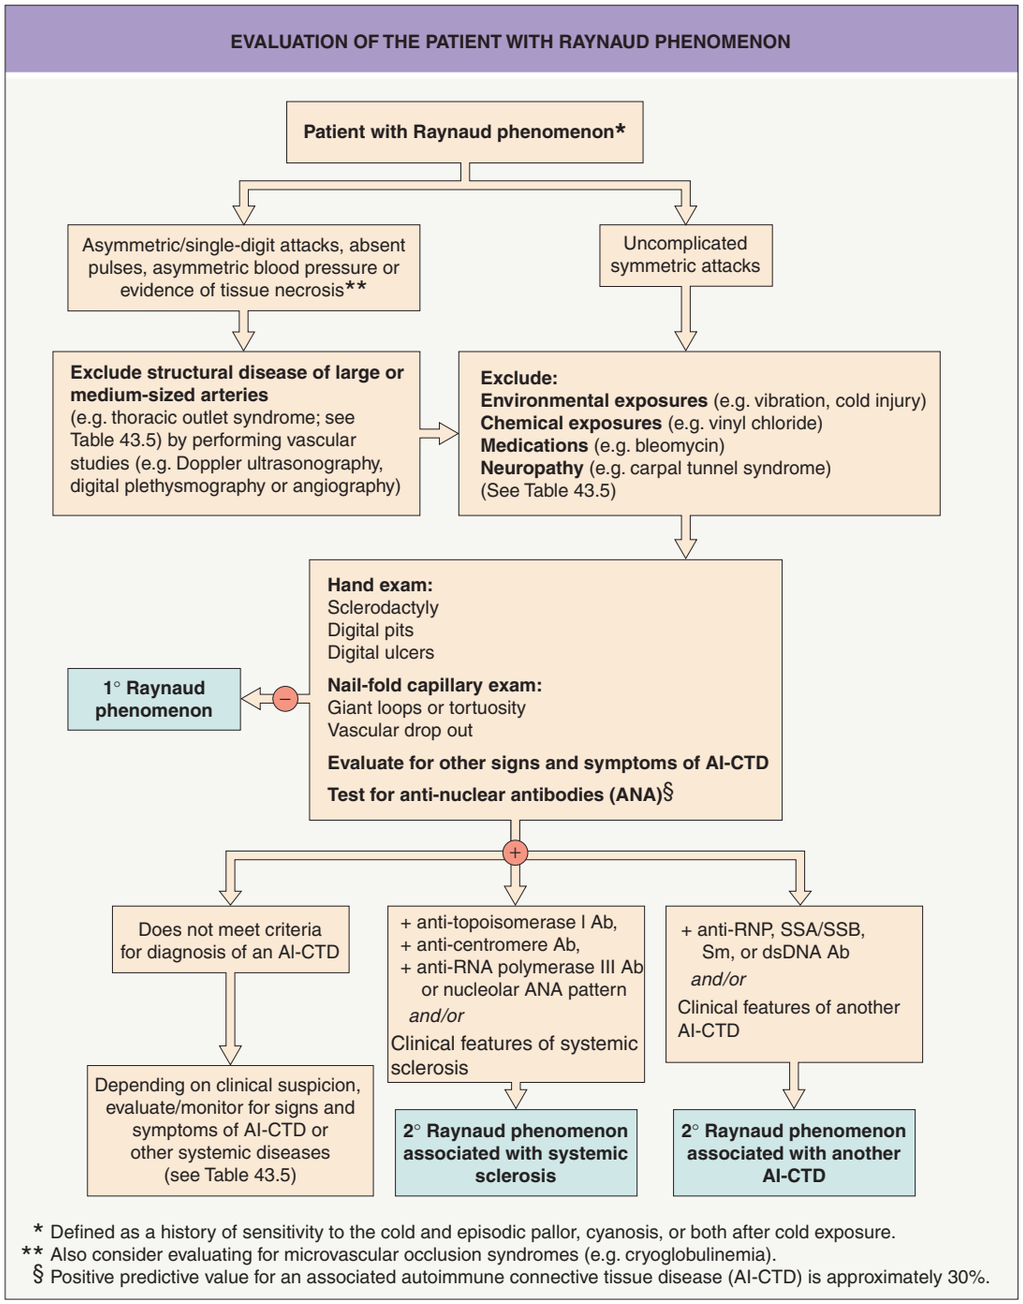

Fig. 43.10 Evaluation of the patient with Raynaud phenomenon. ds, double-stranded; RNP, ribonucleoprotein; Sm, Smith.

listed in Table 43.7[21]. Of note, chronic GVHD can have both pulmonary (e.g. bronchiolitis obliterans) and gastrointestinal manifestations. Some patients with SSc also have features of another AI-CTD, i.e. an overlap syndrome. Localized forms of scleroderma (morphea) are discussed in Chapter 44 as are morpheaform disorders.

Treatment

SSc is a challenging disease to treat[21a,21b]. Therapeutic interventions focus primarily on internal organ involvement (see Table 43.6), but unfortunately most of these treatments have minimal effect on cutaneous sclerosis and the other cutaneous manifestations (Table 43.8)[1,22].

Raynaud phenomenon

First-line therapy for Raynaud phenomenon is behavioral and involves educating patients to keep warm and avoid smoking to minimize the frequency and severity of attacks[23].

Second-line therapy is pharmacologic, starting with vasodilators[18]. Calcium channel blockers (e.g. nifedipine, amlodipine) have been the most widely used medications (see Table 43.8). Angiotensin II receptor blockers (e.g. losartan) may also be effective, and combination therapy can be tried. More recently, phosphodiesterase type 5 inhibitors (e.g. sildenafil, tadalafil) that target the nitric oxide-mediated vasodilation pathway have been employed[24]. Care must be taken so that the vasodilators do not excessively lower systemic blood pressure. In addition, calcium channel blockers may exacerbate gastroesophageal reflux disease and lead to peripheral edema. In patients who cannot tolerate these medications because of hypotension, a selective serotonin reuptake inhibitor (e.g. fluoxetine) may be an option[23]. Injections of botulinum toxin type A into the base of digits have also been reported as successful and their use has increased [24a], although outcomes in a prospective trial were disappointing[25].

Oral antiplatelet agents (e.g. low-dose aspirin, clopidogrel) and/or pentoxifylline may theoretically provide additional blood flow to compromised distal sites. Biofeedback can also be helpful. Use of HMG-CoA reductase inhibitors ("statins") as a vasoprotective treatment is under investigation and appears to be safe and well tolerated[26].

Cutaneous ulcers

Digital ulcers on the fingers are difficult to treat and a source of great morbidity. Management includes the treatments for Raynaud phenomenon outlined above. Detailed occupational and recreational histories are important to identify risk factors and sources of injury

DIFFERENTIAL DIAGNOSIS OF RAYNAUD PHENOMENON
Structural vasculopathies
Large and medium-sized arteries
Thoracic outlet syndrome
Brachiocephalic trunk disease (atherosclerosis, Takayasu arteritis)
Buerger disease (thromboangiitis obliterans)*
Crutch pressure
Small arteries and arterioles
Systemic sclerosis
Systemic lupus erythematosus
Dermatomyositis
Overlap syndromes
Cold injury
Vibration disease (hand–arm vibration syndrome, hypothenar hammer syndrome)
Chemotherapy (bleomycin, vinca alkaloids, cisplatin, carboplatin)
Vinyl chloride disease
Arsenic poisoning
Normal blood vessels – abnormal blood elements
Cryoglobulinemia (monoclonal or mixed)
Cryofibrinogenemia
Cold agglutinin disease
Myeloproliferative disorders (e.g. essential thrombocythemia)
Normal blood vessels – abnormal vasomotion
Primary (idiopathic) Raynaud phenomenon
Drug-induced (ergot alkaloids, bromocriptine, interferon, estrogen, cyclosporine, sympathomimetic agents, clonidine, cocaine, nicotine, calcitonin gene-related peptide (CGRP)-targeting drugs)
Carpal tunnel syndrome
Pheochromocytoma
Carcinoid syndrome
Complex regional pain syndrome
Other vasospastic disorders (migraine, Prinzmetal)
*Can also affect small arteries.

Table 43.5 Differential diagnosis of Raynaud phenomenon. Paraneoplastic acral vascular syndrome, which can present with Raynaud phenomenon as well as acrocyanosis and gangrene, has been observed in patients with various solid tumors (e.g. lung or ovarian carcinoma). In acute idiopathic blue finger (Achenbach syndrome), the digital blue discoloration represents ecchymosis.
Adapted from Hochberg MC, Silman AJ, Smolen JS, et al (eds). Rheumatology, 3rd edn. Edinburgh: Mosby, 2003. © Elsevier 2003.

and cold exposure. Based upon two randomized controlled trials, bosentan, an oral endothelin receptor antagonist, has been approved in Europe, but not the US, for the prevention of new digital ulcers in SSc patients[27]. While disappointing results were observed in a double-blind randomized trial of *oral* iloprost (a prostacyclin analogue)[28], when administered *intravenously*, it resulted in a reduction in digital ulcers and improved healing[29]. More limited studies of the subcutaneous prostacyclin analogue treprostinil suggest that it may also be effective. In refractory cases, nerve blocks and sympathectomies may be considered.

In patients with SSc, autolytic debridement of ulcers via occlusive dressings is thought to be safer than mechanical debridement. In general, moist hydrocolloid dressings provide a better wound healing environment than dry or wet-to-dry dressings. Skin equivalents or grafts can also be used to stimulate the wound bed and decrease wound pain. Topical vasodilators such as nitroglycerin are attractive because of ease of application and minimal systemic side effects; however, evidence-based data on their effectiveness are lacking[23].

Cutaneous sclerosis

In the early stage of SSc, cutaneous and subcutaneous edema develops rapidly, but during the indurated and atrophic stages, the cutaneous involvement progresses more slowly and tends to gradually improve, independent of treatment. Unfortunately, objective, quantitative measurements of cutaneous sclerosis that are sensitive to change over short periods of time are currently lacking for SSc. The traditional instrument for measuring skin involvement in SSc is the modified

Fig. 43.11 Cutaneous ulcerations in systemic sclerosis. Ulcers favor the digits (**A**) and sites of trauma such as the elbow (**B**). Note the calcinosis cutis at the base of the forefinger and the pterygium inversum unguis of the third finger.

There is a dense sclerosis of the dermis with decreased adnexal structures and "trapping" of remaining adnexal structures that are encased by collagen. Sparse perivascular infiltrates of lymphocytes are present. *Courtesy Ronald P. Rapini, MD.*

INTERNAL ORGAN INVOLVEMENT IN SYSTEMIC SCLEROSIS – SCREENING AND TREATMENT OPTIONS		
Internal organ	**Screening tools***	**Treatment options**
Lung*		
• Interstitial lung disease (ILD)	• **PFTs (DLCO, spirometry, and lung volumes)** • **High-resolution CT (HRCT)** • Bronchoalveolar lavage and lung biopsy	• Immunosuppression (e.g. mycophenolate mofetil, cyclophosphamide, rituximab) • Nintedanib†, tocilizumab† • Lung transplantation • Autologous HSCT in selected patients with rapidly progressive ILD
• Pulmonary arterial hypertension (PAH)	• **Transthoracic echocardiography** • **Serum *N*-Tpro-BNP level** • Right heart catheterization	• Oxygen • Anticoagulation • Endothelin receptor antagonists (e.g. bosentan) • Phosphodiesterase type 5 inhibitors (e.g. tadalafil) • Prostacyclin analogues (e.g. treprostinil) • Prostacyclin receptor agonists (e.g. selexipag) • Soluble guanylate cyclase stimulant (e.g. riociguat) • Lung transplantation
Kidney		
• Renal crisis • Hypertension	• **Close monitoring of blood pressure** • **BUN/Cr** • **Urinalysis**	• ACE inhibitors instituted early for treatment but not helpful for prevention
Heart		
• Fibrosis/restrictive cardiomyopathy • Heart failure secondary to PAH	• Echocardiography	• ACE inhibitors
Gastrointestinal tract		
• Esophageal dysmotility • Small bowel involvement	• Barium swallow with small bowel follow through • Manometry • Endoscopy	• Proton pump inhibitors • Promotility agents (e.g. ondansetron)

*Patients are typically asymptomatic during the early stages of ILD and PAH, which is when the diagnosis should be made and treatment instituted; cough, dyspnea on exertion, and shortness of breath are typical later-onset symptoms.
†FDA-approved for SSc-ILD.

Table 43.6 Internal organ involvement in systemic sclerosis – screening and treatment options. Initial screening tests for all patients are in **bold**. ACE, angiotensin-converting enzyme; BUN, blood urea nitrogen; Cr, creatinine; CT, computed tomography scan; DLCO, diffusing capacity of the lung for carbon monoxide; HSCT, hematopoietic stem cell transplant; *N*-Tpro-BNP, *N*-terminal pro b-type natriuretic peptide; PFTs, pulmonary function tests.

DIFFERENTIAL DIAGNOSIS OF SCLERODERMOID CONDITIONS	
Disorder	**Clinical features**
Mucinoses	
• Scleredema	Induration of the upper back, neck and face; occasional internal involvement (see Ch. 46)
• Scleromyxedema	Waxy papules (often in a linear array); diffuse induration favoring the face, upper trunk, arms, and thighs; monoclonal gammopathy; neurologic, gastrointestinal, and pulmonary involvement (see Ch. 46)
Immunologic	
• Sclerotic chronic GVHD*	Variable sclerosis that often resembles plaque-type or deep morphea initially and then may become generalized; eosinophilic fasciitis (see Ch. 52)
• Eosinophilic fasciitis	Symmetric induration with a “pseudo-cellulite” appearance on the extremities (sparing hands and feet) (see text)
• Generalized morphea*	Expansion and coalescence of morphea plaques to involve a large portion of the trunk and extremities (see Ch. 44)
• Fibroblastic rheumatism	Sclerodactyly; fibrotic nodules on the hands
• Overlap syndromes	Sclerodactyly; myositis; arthritis
Paraneoplastic	
• POEMS syndrome	Sclerotic skin on the extremities (see Ch. 114)
• Amyloidosis (primary systemic)†	Diffuse induration favoring the face, distal extremities, and trunk (see Ch. 47)
• Carcinoid syndrome	Sclerotic skin on the legs (see Table 53.2)
• Paraneoplastic scleroderma-like syndrome	Similar to systemic sclerosis, but older age at onset; seen in association with a monoclonal gammopathy, hairy cell leukemia, and solid tumors (e.g. breast, lung)
Neoplastic	
• Carcinoma *en cuirasse**	Sclerodermoid encasement of the chest by metastatic carcinoma (usually breast cancer) (see Ch. 122)

Table 43.7 Differential diagnosis of sclerodermoid conditions.

DIFFERENTIAL DIAGNOSIS OF SCLERODERMOID CONDITIONS	
Disorder	**Clinical features**
Metabolic	
• Diabetic cheiroarthropathy	Thickened skin and limited mobility of the hands (see Fig. 53.18)
• Porphyria cutanea tarda*,‡	Morpheaform plaques in sun-exposed areas (see Ch. 49)
Neurologic	
• Complex regional pain syndrome*	Painful, cold, swollen extremity eventually develops cutaneous sclerosis (see Ch. 6)
• Spinal cord injury	Sclerotic skin in affected areas
Toxin-mediated	
• Nephrogenic systemic fibrosis*	Associated with exposure to gadolinium-based contrast agents (new cases becoming rare) (see text)
• Eosinophilia–myalgia syndrome	Associated with L-tryptophan ingestion (US, 1989) (see text)
• Toxic oil syndrome*	Associated with toxic oil ingestion (Spain, 1981) (see text)
• Silicosis	Associated with occupations such as mining (see text)
Drug- or chemical-induced (see text)	
• Bleomycin*	Acrosclerosis; Raynaud phenomenon; pulmonary fibrosis (more common, usually no concurrent skin fibrosis)
• Taxanes*	Edema followed by sclerosis of the lower extremities; acrosclerosis; rarely, pulmonary fibrosis
• Vinyl chloride, chlorinated hydrocarbons*	Acrosclerosis; acral fibrotic papulonodules; Raynaud phenomenon; acro-osteolysis; pulmonary fibrosis
Venous insufficiency	
• Lipodermatosclerosis*	Woody induration and red–brown discoloration of the lower legs in the chronic phase; may also involve the pannus (see Ch. 100)
Genetic disorders	
• Restrictive dermopathy¶	Tight, thin skin over the entire body; joint contractures; *LMNA* or *ZMPSTE24* mutations
• Hutchinson–Gilford progeria syndrome	Sclerotic skin on the lower trunk, buttocks and thighs; *LMNA* mutations (see Ch. 63)
• Werner syndrome	Tight, sclerotic skin on the distal extremities; *WRN*/*RECQL2* mutations (see Ch. 63)
• Stiff skin syndrome*	Fibrosis of the skin/fascia of the buttocks and thighs with hip contractures; *FBN1* mutations (see text)
• Phenylketonuria	Sclerotic skin on the thighs and buttocks with hip contractures; *PAH* mutations (see Ch. 63)
• MONA (multicentric osteolysis, nodulosis, and arthropathy)	Areas of skin thickening with overlying hyperpigmentation and hypertrichosis; subcutaneous nodules favoring hands/feet; digital swelling; *MMP2* mutations
• Weill–Marchesani syndrome 2	Sclerosis of the back and extensor surfaces of the extremities, with sparing of the face; also referred to as GEMSS (glaucoma, lens ectopia, microspherophakia, stiffness of the joints, and shortness) syndrome; *FBN1* mutations
• Primary hypertrophic osteoarthropathy (pachydermoperiostosis)	Thickening of the skin of the distal extremities and face, with furrowing of the forehead; seborrhea; digital clubbing; *HPGD* and *SLCO2A1* mutations (see Ch. 98)
• Ataxia–telangiectasia	Tight, sclerotic facial skin; *ATM* mutations (see Ch. 60)
• Huriez syndrome	Congenital scleroatrophy of distal extremities, palmoplantar keratoderma, hypoplastic nails & development of aggressive SCC in affected areas; haploinsufficiency of *SMARCAD1* which encodes a DNA helicase (see Ch. 58)
• Geleophysic dysplasia	Thick skin, short stature, a "happy" face, and joint contractures; mutations in *ADAMTSL2*, *FBN1*, and *LTBP3*
• H syndrome (histiocytosis–lymphadenopathy plus syndrome)	*H*ypertrichosis in association with areas of *h*yperpigmentation and induration (primarily lower trunk and lower extremities), sensorineural *h*earing loss, short *h*eight, *h*eart anomalies, *h*epatosplenomegaly, scrotal masses, hypergonadotropic *h*ypogonadism, antibody-negative insulin-dependent diabetes mellitus, facial telangiectasias (see Fig. 55.2); mutations in *SLC29A3* which encodes nucleoside transporter hENT3

*Can overlap with morpheaform disorders, which are listed in Table 44.1.
†Primary cutaneous amyloidosis can also occur in patients with systemic sclerosis and generalized morphea.
‡May also be observed in patients with congenital erythropoietic porphyria and hepatoerythropoietic porphyria.
¶Sclerodermoid changes are typically present at birth.

Table 43.7 Differential diagnosis of sclerodermoid conditions. Disorders with a clinical presentation similar to systemic sclerosis are referred to as *sclerodermoid*, while those reminiscent of morphea are referred to as *morpheaform* (see Ch. 44).

Rodnan skin score (mRSS)[1]. Although this is a validated outcome measure, it is not ideal and is relatively insensitive to small changes over short periods of time. An adapted engineering tool, the durometer, may be more suitable for assessing cutaneous induration and hardness in patients with SSc[30]. Ultrasound and lasers have also been used to measure skin sclerosis.

In general, topical therapies and phototherapeutic regimens are those utilized for morphea (see Ch. 44)[31] and may help some SSc patients. With regard to systemic medications, in a trial of D-penicillamine for dcSSc, there was no difference between the low-dose and the high-dose treatment groups, and this drug is now rarely used[32]. Although minocycline looked promising in a pilot study, a larger follow-up study failed to show a benefit[33]. Methotrexate (MTX) can be helpful in SSc patients with overlapping myositis and inflammatory arthritis. However, in a randomized, placebo-controlled trial (involving 71 patients with early SSc) in which MTX was administered for 1 year, there was a trend in favor of MTX, but it did not reach statistical significance[34]. Nonetheless, based upon its usefulness in morphea[31], a 3- to 6-month trial of MTX is reasonable in patients *without* ILD (see Table 43.8).

Mycophenolate mofetil (MMF) is routinely used for SSc-ILD (see below) and in some patients, it may be of benefit for early cutaneous sclerosis[35]. However, there is no consensus regarding a 6- to 12-month empiric

CUTANEOUS FEATURES OF SYSTEMIC SCLEROSIS – POSSIBLE TREATMENTS	
Cutaneous feature	**Possible treatment options**
Cutaneous sclerosis	• Topical therapies (see Ch. 44) • UV phototherapy (see Ch. 44) • Mycophenolate mofetil • D-penicillamine* • Methotrexate (if no ILD)‡,¶ • IVIg • Rituxumab
Raynaud phenomenon (Figs. 43.9 and 43.10)	**First-line** • Cold avoidance • Hand and feet warming packets • Discontinue all tobacco products **Second-line** • Calcium channel blockers (for normotensive patients, starting doses: nifedipine SR 30 mg daily, increasing to BID after 2 weeks if tolerated; amlodipine 2.5 mg daily, with increments of 2.5 mg every 2 weeks as tolerated, up to 10 mg daily) **Third-line** (especially when accompanied by ulceration) • Phosphodiesterase type 5 inhibitors (sildenafil: initial dose as low as 5 mg PO TID, but most patients tolerate and require 50 mg PO BID; tadalafil: initially 20 mg PO every other day, then increased every 3–5 days as tolerated up to 40 mg PO daily) • α-Adrenergic blockers (e.g. prazosin) • Angiotensin II receptor blockers (e.g. losartan) • Endothelin receptor antagonists (e.g. bosentan) **Fourth-line** • Serotonin reuptake inhibitors (e.g. fluoxetine) • Botulinum toxin type A injections into base of digits
Cutaneous ulcers (Fig. 43.11)	• Avoid excessive debridement • Moist, non-adherent dressings • Therapies listed above for Raynaud phenomenon • Low-dose aspirin or clopidogrel • IV prostanoid (e.g. epoprostenol) • Surgical excision (recalcitrant and severe cases)
Calcinosis cutis (Fig. 43.8)	• Bisphosphonates • Calcium channel blockers (e.g. diltiazem) • Sodium thiosulfate (see Ch. 50)
Mat telangiectasias (Fig. 43.7)	• Lasers appropriate for vascular lesions

*Nowadays used infrequently.
‡Methotrexate-induced pneumonitis may complicate SSc-ILD picture.
¶Concern that concomitant administration of systemic corticosteroids may increase risk of developing renal crisis; low-dose corticosteroids (e.g. prednisone <10 mg daily) may be safe.

Table 43.8 Cutaneous features of systemic sclerosis – possible treatments. Therapeutic agents under investigation include romilkimab, a humanized antibody that neutralizes IL-4/IL-13, and in preclinical models, dersimelagon, an oral agonist of the melanocortin I receptor. BID, twice a day; ILD, interstitial lung disease; IV, intravenous; PO, per os (oral administration); SR, slow release; TID, three times a day; UV, ultraviolet.

trial of MMF (2–3 g daily) for early dcSSc. As expected, the dosage may need to be adjusted based upon side effects, in particular cytopenias and gastrointestinal symptoms (see Ch. 130). MMF may be used in junction with MTX for severe, rapidly progressive cutaneous sclerosis, but close monitoring is required. Sirolimus is an mTOR inhibitor that has been used for renal transplant rejection and may also be a candidate drug for SSc. It has an anti-fibrotic effect and has been used in GVHD. Some data exist to support the use of IVIg, even in recalcitrant cutaneous disease, but larger studies are needed[36]. In a phase II trial, the autotaxin inhibitor ziritaxestat led to an improvement in cutaneous sclerosis based upon mRSS.

A number of other systemic agents have been tried in SSc, but ultimately most have been shown to be ineffective[37]. A small study that examined anti-TGF-β1 antibodies did not show a benefit[1]. Histologically, a decrease in skin thickness was observed in dcSSc following 12 months of imatinib[38].

Other cutaneous complications

Calcinosis cutis represents a serious problem for which no effective medical therapy exists. While low-dose warfarin may decrease the inflammatory reaction associated with calcium deposits, it is no longer a recommended treatment[38a]. Although there were case reports of the effectiveness of calcium channel blockers for calcinosis, this was not observed in larger patient series. Topical and intralesional sodium thiosulfate has been used to treat calcinosis cutis[37], but the injections can be painful (see Table 50.2). In certain situations, surgical removal of the calcium deposits may be necessary. Treatment with extracorporeal shock wave lithotripsy has also been reported. Telangiectasias can be treated cosmetically with lasers appropriate for vascular lesions (e.g. pulsed dye).

Internal organ involvement

Treatment of specific internal organ involvement is outlined in Table 43.6. Detailed discussions of these therapeutic approaches are available in other texts[1,19]. Of note, the use of ACE inhibitors to treat scleroderma renal crisis represents a major therapeutic advance[1].

In a number of studies, treatment with either cyclophosphamide or MMF has been shown to benefit SSc-ILD[1]. For example, one prospective, randomized, controlled trial showed a modest benefit with oral cyclophosphamide (1 to 2 mg/kg/day for 1 year) compared to placebo[39]. However, there are significant potential side effects associated with cyclophosphamide, such as cytopenias, hemorrhagic cystitis, and an increased risk of bladder carcinoma (see Ch. 130). A large, multicenter, randomized, controlled trial showed that cyclophosphamide and MMF had an equivalent benefit on SSc-ILD, but MMF had a superior tolerability and safety profile[40].

Nintedanib blocks autophosphorylation-based activation of several growth factor receptors (GFRs) – fibroblast (FGFRs), platelet-derived (PDGFRs) and vascular endothelial (VEGFRs) – via binding to their intracellular ATP binding sites. It was FDA-approved for the treatment of SSc-ILD based upon less of a decline in forced vital capacity in a randomized, double-blind, controlled trial involving 576 patients[41]. The most common side effects include diarrhea, nausea, transaminitis, hypertension, and pneumonia. Tocilizumab, an interleukin 6 receptor inhibitor, is also FDA-approved for SSc-ILD but in a phase III randomized trial its effect on skin fibrosis did not differ from placebo[42].

Advances in the treatment of PAH have also occurred, in particular the use of oral vasoactive compounds, some of which are also used for Raynaud phenomenon and digital ulcers[1]. These include endothelin receptor antagonists (bosentan[43], ambrisentan, macitentan) and phosphodiesterase type 5 inhibitors (sildenafil, tadalafil). Prostacyclin analogues (iloprost [inhaled], epoprostenol [intravenous], treprostinil [inhaled, subcutaneous, or intravenous]) and the oral prostacyclin receptor agonist selexipag are approved for PAH in SSc patients but are no longer sole or first-line therapy[1]. Lung transplantation is an option, with survival rates as well as risks for developing acute rejection and bronchiolitis obliterans syndrome similar in SSc patients when compared to those without AI-CTDs[44].

A French nationwide cohort study found that IVIg led to an improvement in muscle and joint, but not skin, disease[45]. In a recent meta-analysis examining the efficacy of imatinib, cutaneous sclerosis improved based upon mRSS following a 6- to 12-month course, but there were insufficient data regarding its effect on lung involvement[46]. Rituximab has been investigated as a rescue therapy and in one trial was superior to cyclophosphamide for SSc-ILD[47].

Three randomized controlled trials comparing cyclophosphamide versus autologous hematopoietic stem cell transplantation (HSCT) demonstrated HSCT superiority, with greater improvement in lung and skin disease as well as quality-of-life[48]. Risks include transplant-related mortality and recurrence of disease. Therefore, autologous HSCT is considered for selected patients with rapidly progressive SSc at risk of organ failure or significant morbidity.

EOSINOPHILIC FASCIITIS

Synonyms: ■ Shulman syndrome ■ Diffuse fasciitis with eosinophilia

History

Eosinophilic fasciitis was first reported in 1975 by Shulman, who described a fibrosing disorder characterized by the rapid onset of woody induration of the extremities in association with peripheral eosinophilia[49].

Clinical Features

A history of strenuous physical activity precedes the clinical findings in about 30% of patients with eosinophilic fasciitis. Initial manifestations include edema and pain of the involved extremities, which quickly progress to sclerosis and a dimpled or "pseudo-cellulite" appearance (Fig. 43.13). The distribution is symmetric and usually spares the hands, feet and face. The "groove sign" refers to linear depressions where veins appear to be sunken within the indurated skin.

Laboratory findings include an elevated ESR, hypergammaglobulinemia, and peripheral eosinophilia[50]; the latter may not be present if the patient is already receiving corticosteroids. The ANA titer is typically not elevated, and complement levels are normal. Pancytopenia, anemia, thrombocytopenia, myeloproliferative disorders, and monoclonal gammopathy have been reported in association with this disease. Some authors have advocated that patients with eosinophilic fasciitis and unexplained anemia undergo bone marrow biopsy to evaluate for a hematologic malignancy. Patients with chronic GVHD can develop clinical manifestations resembling eosinophilic fasciitis (see Ch. 52), as can those receiving immune checkpoint inhibitors, in particular anti-PD-1 and -PD-L1 antibodies.

Pathology

Histologically, there is a thickening of the deep fascia, which may be 10 to 50 times the normal width (Fig. 43.14). Within the fascia and subfascial muscle, a patchy infiltrate composed of lymphocytes, plasma cells, and a variable number of eosinophils is seen. Dermal sclerosis is a feature in some cases[51].

Treatment

Once the diagnosis of eosinophilic fasciitis is established via fascial biopsy and/or MRI (see Fig. 52.9), prompt treatment is essential to preserve mobility and function and prevent joint contractures. Therapy is usually initiated with oral corticosteroids (e.g. prednisone 1–2 mg/kg daily). Response is typically noted within the first few weeks, and clinical improvement may be seen over several months. The dose of prednisone is tapered over 6–24 months as tolerated. Due to the need for a relatively prolonged course of corticosteroids, a concurrent immunosuppressive drug (e.g. methotrexate, MMF) is often administered[52]. If an inadequate response is observed, other options include pulse-dose corticosteroids, IVIg, hydroxychloroquine, JAK inhibitors, UVA-based phototherapy, and cyclosporine.

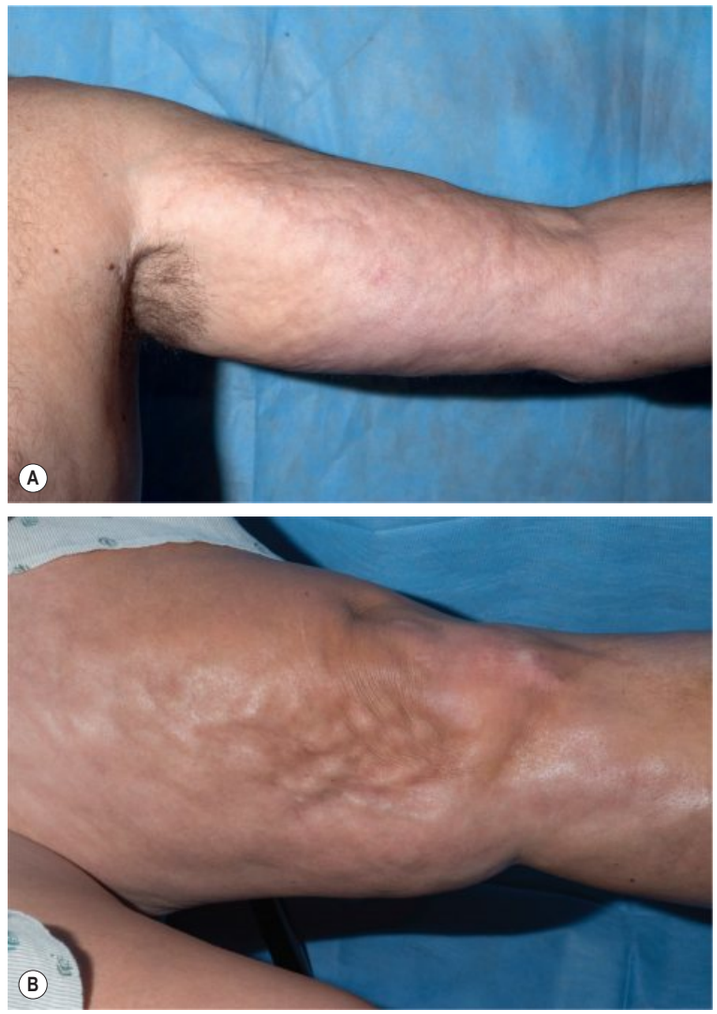

Fig. 43.13 Eosinophilic fasciitis – clinical features. A Induration of the arm with a dimpled or "pseudo-cellulite" appearance, also referred to as rippling or puckering. **B** Firm, irregular induration and nodularity of the medial thigh. The differential diagnosis includes deep morphea. *Courtesy Edward Cowen, MD.*

STIFF SKIN SYNDROME

Synonym: ■ Congenital fascial dystrophy

History

Stiff skin syndrome was first described by Esterly and McKusick in 1971[53].

Epidemiology

This condition may be congenital or develop during early childhood. Familial occurrences have been described.

Pathogenesis

Stiff skin syndrome is due to heterozygosity for a mutation in the gene that encodes fibrillin-1 (*FBN1*). The presence of giant "amianthoid-like" collagen fibrils in affected fascia had been postulated to reflect a disturbance in the organization of collagen and glycosaminoglycans within the extracellular matrix.

Clinical Features

Stiff skin syndrome is characterized by "rock hard" induration and thickening of the skin and subcutaneous tissues, which is most pronounced on the buttocks and thighs, with characteristic sparing of the inguinal folds[54]. The hands and feet are not involved. Mild hypertrichosis is often observed in affected areas. Restricted joint mobility leads to a characteristic posture of hip and knee flexion and prominent lumbar lordosis while standing, and patients may have short stature. The condition is stable or slowly progressive, and abnormalities of internal organs are not typically observed.

Patients with unilateral involvement have been reported, some with features that overlapped with scleredema, deep morphea, and linear melorheostotic scleroderma. In a patient with the segmental form of stiff skin syndrome, an interleukin(IL)-17C mutation was detected.

Pathology

Histopathologic examination demonstrates markedly thickened, hyalinized fascia without an associated inflammatory infiltrate. Thickened collagen bundles and mucin deposition may or may not be present in the overlying dermis.

Treatment

Stiff skin syndrome has a chronic course, and no effective treatments have been reported. Physical therapy can help to prevent progressive joint contractures. The segmental form with an associated IL-17 mutation (see above) was successfully treated with secukinumab.

SCLERODERMOID SYNDROMES INDUCED BY EXOGENOUS SUBSTANCES

Exposure to drugs, chemicals, and other exogenous substances can lead to cutaneous and extracutaneous sclerosis (see Table 43.7)[21].

Nephrogenic Systemic Fibrosis

Synonym: ▪ Nephrogenic fibrosing dermopathy

Fortunately, the incidence of nephrogenic systemic fibrosis (NSF) has steadily declined since nearly all patients had a history of exposure to gadolinium-based contrast agents with the vast majority having advanced chronic kidney disease or acute kidney injury at the time of exposure (see Table 43.1)[55–57]. Initial cases were described in the early 2000s and by 2010, the FDA had declared three gadolinium-based contrast agents (gadopentetate dimeglumine [Magnevist®], gadodiamide [Omniscan™], gadoversetamide [OptiMARK™]) as contraindicated in such patients.

NSF presents with thick, indurated plaques distributed symmetrically on the trunk and extremities, often resulting in joint contractures (Fig. 43.15). The plaques are erythematous to hyperpigmented and can have an irregular advancing edge with an "ameboid" appearance. In addition to yellow scleral plaques, fibrosis can develop within the heart, lungs, and skeletal muscle. Because the disease process typically extends along fibrous septa into the subcutis, a deep biopsy specimen is required for diagnosis. Histopathologic features include a haphazard arrangement of thickened collagen bundles and increased dermal fibroblast-like cells that stain positively for CD34 and procollagen I. Mucin deposition and osseous metaplasia may be seen and by energy dispersive spectroscopy, particles of gadolinium can be detected within involved tissue.

Fig. 43.15 Nephrogenic systemic fibrosis (NSF) – clinical features. Orange–brown indurated plaques. Note the "ameboid" outline of one of the plaques on the left foot. *Courtesy Edward Cowen, MD.*

NSF is generally refractory to treatment with corticosteroids and other immunosuppressive drugs; potential therapeutic options are outlined in Table 53.14. Improvement in renal function following renal transplantation has been reported to improve NSF.

Toxic Oil Syndrome

In 1981, the toxic oil syndrome affected more than 25 000 people in Spain; 600 died and ~300 remained permanently disabled. It resulted from the ingestion of aniline-degraded and reprocessed rapeseed oil, which led to a specific immune response in genetically susceptible individuals. In humans, toxic oil syndrome started with a morbilliform eruption and flu-like symptoms such as fever and headache; peripheral eosinophilia was observed in half of affected individuals. The inflammatory process subsequently affected the CNS, lungs, and salivary glands. Skin involvement either resolved, evolved into a lichen planus-like eruption, or progressed to a morpheaform or sclerodermoid picture.

Eosinophilia–Myalgia Syndrome

In 1989, a contaminated preparation of L-tryptophan led to an outbreak of "eosinophilia–myalgia syndrome", which affected more than 1500 people in the US and led to at least 30 fatalities. The acute phase of the condition was characterized by severe myalgias, fever, dyspnea, edema, a macular exanthem, and peripheral eosinophilia. Despite the discontinuation of L-tryptophan intake, approximately half of patients went on to a chronic phase that featured diffuse, deep sclerodermoid induration of the extremities (with acral sparing), progressive peripheral neuropathy, and myopathy.

Sclerodermoid Syndromes Induced by Other Chemicals

Exposure to certain organic chemicals can lead to a clinical picture that resembles SSc (see Table 43.7). In contrast to the acute onset of the toxic oil and eosinophilia–myalgia syndromes, exposure to vinyl chloride, organic solvents (e.g. trichloroethylene, trichloroethane, perchloroethylene), pesticides, or epoxy resins induces a slowly progressive process of sclerosis. It typically begins with insidious acrosclerosis and Raynaud phenomenon (especially with vinyl chloride exposure). Acral osteolysis, hepatic toxicity, and pulmonary involvement are often observed. In addition, patients experience fatigue, weight loss, arthralgias, and myalgias. Autoantibodies are absent, and cessation or reversal of the disease process follows removal of the exposure.

Silicosis

The incidence of SSc is approximately 20-fold higher in individuals with occupational exposure to silica, such as miners and foundry workers, than in the general population. In an epidemiologic study from Germany, three-quarters of men with typical SSc had been exposed to silica dust in the workplace. The mean duration of exposure was 14 years, with a mean delay in onset of the disease of 24 years from the first exposure. Once absorbed, silica cannot be removed from the body. Although silica has nonspecific proinflammatory and profibrotic effects, HLA and TNF allele associations suggest the need for a specific pre-existing immunophenotype for disease progression to occur. SSc associated with pulmonary silicosis is clinically, serologically, and immunologically indistinguishable from the idiopathic form of the disease.

Sclerodermoid Syndromes Induced by Drugs

Several drugs, particularly bleomycin and the taxanes (see Table 43.7), can induce cutaneous sclerosis and pulmonary fibrosis mimicking SSc. Additional medications that have been associated with sclerodermoid changes include other chemotherapeutic agents such as cisplatin, pemetrexed, carboplatin, topotecan, and gemcitabine (especially of the lower extremities) as well as ergot alkaloids, L-5-hydroxytryptophan +/− carbidopa, appetite suppressants, and cocaine.

Additional figures and table on Eosinophilic fasciitis - diagnostic criteria, available in our eBook (see inside front cover for access code).

EOSINOPHILIC FASCIITIS – DIAGNOSTIC CRITERIA
Major criterion
• Symmetric plate-like sclerotic lesions on four extremities*
Minor criteria
• Histopathology (biopsy specimen includes fascia) – fibrosis of subcutaneous connective tissue, with thickening of the fascia and inflammatory infiltrate of eosinophils and monocytes
• Diagnostic imaging, e.g. MRI – thickening of fascia
Definitive diagnosis: 1 major and 1 minor or 1 major and 2 minor criteria
*Absence of Raynaud phenomenon and systemic sclerosis excluded.

eTable 43.1 Eosinophilic fasciitis – diagnostic criteria.

Morphea and Lichen Sclerosus 44

Martin Röcken and Kamran Ghoreschi

Morphea and lichen sclerosus (LS) are inflammatory skin diseases that ultimately evolve into two distinct modes of cutaneous sclerosis. In morphea, there is inflammation of the dermis that may extend into subcutaneous structures. Lichen sclerosus is primarily a disease of the genital mucosa (and less often extragenital sites) that affects the epidermis and the dermis. Morphea may lead to joint contractures and atrophy of underlying muscle, but there is no involvement of internal organs. The exceptions are the ocular and neurologic symptoms seen in a small minority of patients with linear morphea of the head or Parry–Romberg syndrome, in which there is extension into underlying muscles, bones, and occasionally deeper structures. While some patients may develop both disorders simultaneously, they are addressed separately because of their distinct features and different but overlapping therapeutic approaches.

MORPHEA

Synonyms/subtypes: ■ Localized scleroderma ■ Circumscribed scleroderma ■ Plaque-type morphea ■ Linear morphea – linear scleroderma ■ Morphea *en coup de sabre* – scleroderma *en coup de sabre* ■ Deep morphea – morphea profunda

Key features

- Asymmetric sclerotic plaques, usually 2–15 cm in diameter
- Active lesions can have a lilac border with central hypo- or dyspigmentation, while inactive lesions often become hyperpigmented
- The sclerosis may extend deeply into the fat or underlying structures (e.g. fascia, muscle, bone), causing disability
- With the exception of ocular or neurologic symptoms in patients with linear morphea of the head, associated systemic disease is not observed
- Often progresses for several years, then regresses; the linear subtype is usually persistent

INTRODUCTION

Morphea is a clinically distinct inflammatory disease, primarily of the dermis and subcutaneous fat, which ultimately leads to a scar-like sclerosis. The small vessel changes, inflammatory infiltrate, and ultimate structural modifications are identical in morphea and systemic sclerosis (SSc), but the two diseases are distinct entities that can be distinguished clinically. In addition, their triggers presumably differ and coexistence of morphea and SSc is rare[1]. Morphea has an asymmetric patchy or linear distribution. In contrast, SSc begins either as symmetric tightening of the fingers and hands that extends progressively toward the forearms (*limited cutaneous* SSc [lcSSc]) or as symmetrically extending sclerosis of the trunk and proximal upper extremities (*diffuse cutaneous* SSc [dcSSc]). Rarely, generalized morphea may resemble early dcSSc. The presence of Raynaud phenomenon, digital sclerosis, and involvement of the gastrointestinal tract and the lung also allows differentiation of SSc from morphea. Distinguishing between deep morphea and eosinophilic fasciitis can prove more difficult – whether these two disorders represent distinct entities or simply the ends of a broad clinical spectrum remains debatable, e.g. eosinophils may be present at the inflammatory border of morphea[2].

Morphea can cause significant morbidity as a result of pain, skin tightness, and impaired joint mobility. In ~10% of patients with morphea, sclerosis leads to significant contractures, growth retardation, and even micromelia, resulting in long-term functional disability[3]. Disease activity correlates with reduced quality of life[4].

HISTORY

A disease with thickened skin was first mentioned by Hippocrates (400 BCE). The term "scleroderma" is derived from the Greek words *skleros* (hard or indurated) and *derma* (skin). The first description of a generalized "hardness" of the skin in a young woman was by an Italian physician, Carlo Curzio, in 1753; the French physician Gintrac coined the term "sclérodermie" in 1847. Thomas Addison has been credited with the first detailed description of morphea in 1854, which he referred to as Alibert's keloid syndrome. In 1924, Matsui described the typical histopathologic changes of scleroderma and in 1930 O'Leary and Nomland elaborated on the distinctive features of SSc versus morphea.

EPIDEMIOLOGY

Even though morphea has been long recognized as a well-defined entity, few population-based studies exist. A survey from Olmsted County, Minnesota attempted to register all patients with the disorder from 1960 to 1993[5]. During this period, the annual incidence rate was 27 per million. According to this study, 56% of patients had plaque-type, 20% linear, 13% generalized, and 11% deep morphea[5].

The prevalence of morphea increases with age, occurring in ~500 and 2200 per million at ages 18 and 80 years, respectively[3]. The disease is more prevalent in women than in men (2.6:1), with the exception of linear morphea, which has no sex preference. Data published on the incidence and prevalence of morphea probably reflect an underestimation, as they critically depend on clinical recognition and diagnosis.

Morphea is rarely life-threatening. In the Olmsted County study, the survival rate of patients with morphea was not significantly different from that of the general population[5]. However, in 11% of the patients, substantial disability occurred. This is of particular concern since disability occurs primarily with linear morphea, which has its onset before age 18 years in two-thirds of patients[3,4].

PATHOGENESIS

Autoantibodies are usually as prevalent in morphea as in the general population, with two exceptions: (1) an increased prevalence of anti-single strand DNA (ssDNA), -topoisomerase IIα, -phospholipid, -fibrillin-1, and -histone antibodies (AHA) in patients with morphea; and (2) high titers of anti-nuclear antibodies (ANA) in juvenile patients with linear morphea and individuals with generalized morphea. In patients with linear morphea, the presence of ssDNA antibodies or AHA seems to be associated with increased risk of functional impairment[6].

Neither histology nor immunohistology of a single lesion will distinguish between morphea and SSc. In most clinicopathologic reviews, it is assumed that the two diseases are triggered by distinct events. However, the development of sclerosis following the initiating event seems to follow a common pathway. It is therefore assumed that pathogenic steps leading to SSc also contribute to the development of morphea, so they will be included in this discussion.

Currently, sclerosis of the skin is thought to involve three major, closely connected components: vascular damage, activated T cells, and altered connective tissue production by fibroblasts (Fig. 44.1)[7].

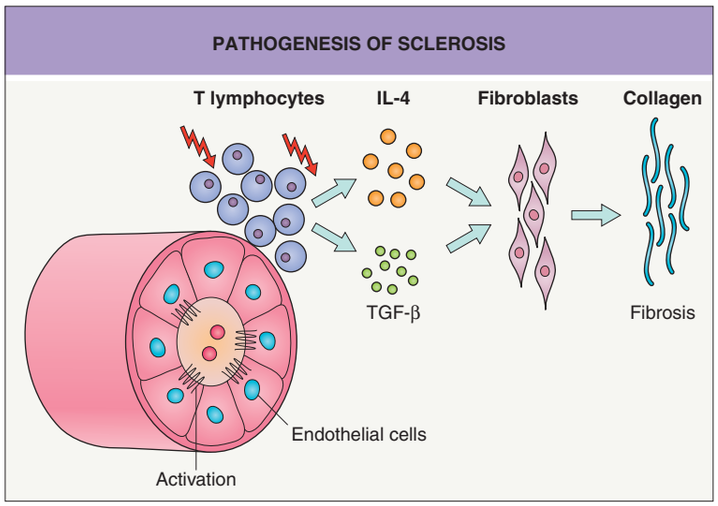

Fig. 44.1 Pathogenesis of sclerosis. Three components are involved during the formation of sclerosis: vascular damage, lymphocyte activation, and altered connective tissue production. IL, interleukin; TGF, transforming growth factor.

Vascular Changes

A prominent feature of advanced sclerosis is a reduction in the number of capillaries. Studies performed in SSc suggest that hypoxia resulting from microvascular injury is a very early, or even the primary, event. Endothelial cells respond to various stimuli, including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and transforming growth factor-β (TGF-β) (see Ch. 102). In the sera of patients with SSc, markers indicative of endothelial cell activation (e.g. soluble adhesion molecules, VEGF) are elevated. Morphologic changes principally affect capillaries and small arterioles, and the initial changes in SSc include expression of adhesion molecules and endothelial swelling, followed by thickening of the basement membrane and intimal hyperplasia. An extrapolation is that similar changes may occur early on in morphea.

Control of Fibroblast Function by T Cell-Derived Cytokines

Pioneering work by E. Carwile Leroy showed that *in vitro* cultured fibroblasts isolated from sclerotic tissue produce increased amounts of collagen (types I, II, and III) and other extracellular matrix proteins. These fibroblasts can maintain this phenotype for weeks over several passages. This raised the question as to whether SSc results from an inborn or acquired error in collagen metabolism within fibroblasts. Today, most data favor the concept that abnormal collagen production is directed by surrounding cells. T cells in particular have the capacity to modify collagen synthesis by fibroblasts, and T cells are regularly present, at least early on, in a perivascular location and especially at the leading edge of developing sclerosis (see Fig. 44.1).

Enhanced production of collagen and other extracellular matrix proteins is induced by T cell-derived cytokines, especially interleukin (IL)-4, IL-13, IL-17A, and TGF-β[8]. IL-4 is produced by $CD4^+$ T helper type 2 (Th2) lymphocytes (see Ch. 4) and can directly enhance TGF-β production[9]. Macrophages activated via the IL-4 receptor α (IL-4Rα) have been shown to influence collagen fibril assembly and promote fibrosis[10]. In contrast, production of collagen and other extracellular matrix proteins can be significantly suppressed by interferons that are associated with Th1 lymphocytes[9,10]. Th1 differentiation also implicates IL-12 signaling via the transcription factor STAT4. Of note, an association between *STAT4* polymorphisms (e.g. rs7574865) and susceptibility to SSc, especially the limited subtype, has been reported[11]. In a rare form of dominantly inherited pansclerotic morphea, gain-of-function variants in *STAT4* were detected, with JAK inhibition leading to reduction of the hyperinflammatory fibroblast phenotype *in vitro* and clinical improvement[11a]. Additional susceptibility loci associated with SSc include immune-related genes (e.g. *CD247*, *IRF5*, *HLA* region)[12] and the promoter region of the gene that encodes connective-tissue growth factor (CTGF)[13].

Circulating levels of the chemokine ligand CXCL4 (secreted by plasmacytoid dendritic cells) have been found to be significantly elevated in SSc[14]. Increased CXCL4 levels correlated with a higher prevalence of lung fibrosis and faster progression of skin fibrosis[14]. Interestingly, CXCL4 promotes the Th2 cytokines IL-4 and IL-13 and has anti-angiogenic properties.

IL-4 is the most potent force in driving differentiation of Th2 lymphocytes (see Fig. 4.9)[15]. Because IL-4 enhances pathologic collagen production by fibroblasts and induces recruitment of eosinophils, it is believed that immune responses dominated by IL-4- as well as IL-13- and TGF-β-producing cells are critical in the initiation of skin sclerosis[8,10]. This concept is supported by clinical and experimental data:

- *In situ* analysis of the advancing inflammatory margins of skin sclerosis revealed predominantly IL-4 expression.
- Th2-associated IL-13 and IL-33 have been shown to promote skin fibrosis in mice, and early treatment of scleroderma-developing mice with anti-IL-4 antibodies prevented scleroderma.
- Th2-like regulatory T (Treg) cells present in the skin of patients with SSc produce IL-4 and IL-13 and are responsive to IL-33[16].
- Systemic retinoids (which interact with TGF-β signaling) appear to reduce pathologic collagen synthesis by fibroblasts and may improve skin sclerosis in patients with chronic GVHD[17,18].
- Th2-promoting CXCL4 is so closely associated with SSc that it has been suggested as a biomarker for SSc[14].

One theoretical therapeutic approach for morphea would be to redirect Th2 responses into Th1 responses. Unfortunately, placebo-controlled clinical trials of the Th1-inducing cytokines IFN-γ or IFN-α in patients with morphea produced negative results[19]. The finding of elevated expression of IFN-related factors (e.g. CXCL9, CXCL10) in the skin and serum of cohorts with active morphea might provide an explanation[20], as it suggests that Th2 and Th1 cells may be activated simultaneously. Reports of the development of morphea and SSc during treatment with anti-PD-1 antibodies[21] also point to the importance of activated T cells in their pathogenesis. It remains to be determined whether highly effective, broader inhibitors of the Th2 cytokines IL-4 and IL-13 or other morphea-associated T cell responses could help prevent the inflammatory phase of morphea and attendant skin sclerosis. More recently, antibodies directed against type 1 IFN-triggered dendritic cell-derived epiregulin, which blocked activation of EGFR on fibroblasts and subsequent paracrine NOTCH activation, were shown to reverse fibrosis in skin explants[21a].

Lastly, when SSc fibroblasts are compared to control fibroblasts, there are differences in intracellular signaling proteins. Examples include activation of p38 mitogen-activated protein kinase and higher levels of Ha-Ras protein and reactive oxygen species. These findings plus data from animal studies demonstrating a link between skin fibrosis and pro-oxidative agents support hypoxia and oxidative stress as key factors in the pathogenesis of skin sclerosis.

Animal Model and Genetics

Currently, the best animal model for studying pathogenic events in SSc is the tight skin (TSK) mouse (Fig. 44.2). A partial duplication of the fibrillin-1 gene is thought to be responsible for the increased synthesis and accumulation of collagen in the skin and internal organs of TSK mice. TSK mice not only have increased collagen deposits, but also the collagen fibers are reduced in length and the quantity of hydroxyproline is increased in the dermis. Moreover, the mice have high antibody titers against topoisomerase I and fibrillin-1, similar to patients with SSc and morphea, respectively. One major difference is that blood vessels remain uninvolved in TSK mice, demonstrating that sclerosis of the skin can develop in the presence of apparently normal vessels[22]. The phenotype can be transferred from diseased animals to healthy syngeneic mice via bone marrow cells (see Fig. 44.2).

Fibroblasts from TSK mice have elevated IL-4Rα expression and back-crossing the TSK mice onto a genetic background that either cannot respond to IL-4 or is deficient in producing TGF-β prevents skin sclerosis. Moreover, this back-cross normalizes collagen length, skin thickness, and hydroxyproline content and prevents antibody formation to topoisomerase I (see Fig. 44.2)[22]. In this murine model of SSc, interventions that promoted Th1 responses or targeted PDGF receptor activity (e.g. imatinib) reduced dermal thickening and fibrosis[23]. More recent strategies for improving experimental skin fibrosis have focused on the role of platelet-derived serotonin[24], β-integrins, TGF-β[25], and

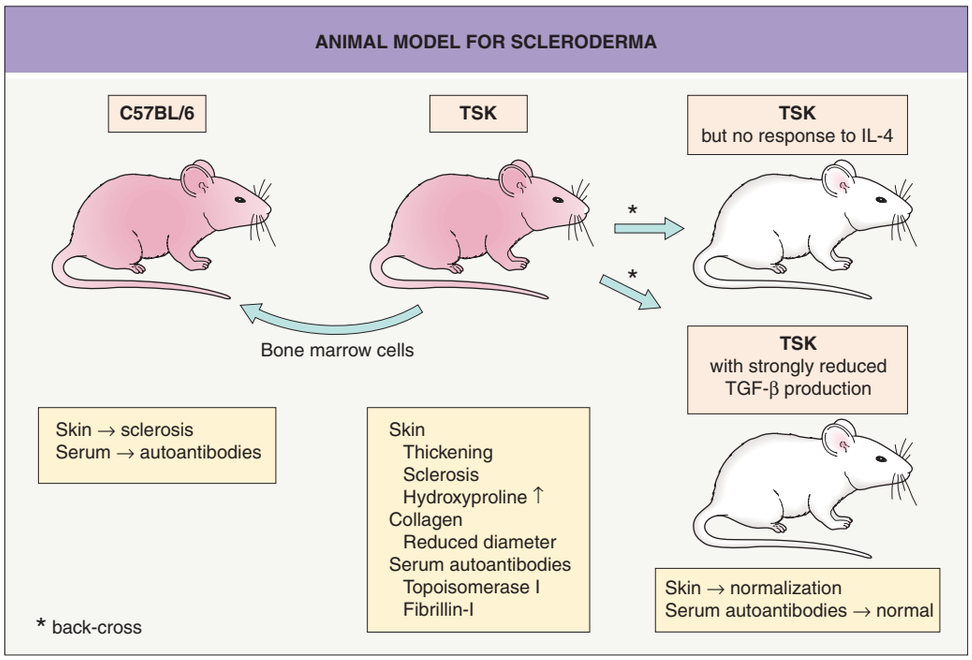

Fig. 44.2 Animal model for scleroderma. Transfer of scleroderma phenotype from diseased animals (TSK mice) to healthy syngeneic mice (C57BL/6) by bone marrow cells. Lack of tight skin and autoantibody production by back-crossing TSK mice with mice that cannot respond to IL-4 or mice that produce minimal amounts of TGF-β. IL, interleukin; TGF, transforming growth factor; TSK, tight skin strain of mice.

Janus kinases[26]. Of note, estrogen inhibition can exacerbate experimental dermal fibrosis driven by TGF-β[27].

In addition to the phenotypic similarities, the genetic locus associated with the TSK phenotype appears to be related to the risk of developing SSc. In humans, this susceptibility locus is on chromosome 15q in a region that contains the fibrillin-1 gene (*FBN1*); mutations in *FBN1* have been detected in patients with stiff skin syndrome (see Ch. 43)[28].

Triggering Events

Most immunologic and metabolic studies have been directed toward understanding SSc, and the question remains as to whether they can also explain focal, asymmetric inflammation and sclerosis of the skin. The major discriminating factor between morphea and SSc might be the triggering event, with morphea being caused by a local trigger within the skin and SSc initiated by a systemic insult. The putative local triggering events for morphea include mechanical trauma, injections, vaccinations[29], and X-irradiation.

These questions initiated the search for potential triggers and studies of diseases that share clinical features with morphea and SSc. One intensively investigated area was the potential role of infection with *Borrelia burgdorferi*. The isolation of *B. burgdorferi* from the skin of some selected patients with morphea originally supported this speculation. However, larger studies failed to confirm this initial observation[30]. Thus, this theory has been abandoned.

CLINICAL FEATURES

As outlined in Table 44.1, there are several classification schemes for morphea[31–34]. Major forms include plaque-type (circumscribed), linear, generalized, and other less common variants (e.g. nodular or keloidal). There are also inflammatory syndromes leading to superficial or deep sclerosis of the skin that resemble morphea (i.e. morpheaform; see below). Patients with morphea do not have Raynaud phenomenon or involvement of internal organs, except for underlying fascia, muscle, and bone in some patients with linear morphea and the occasional patient with linear morphea of the head who has ocular or neurologic symptoms. In rare patients with presumptive morphea, clinically insignificant fibrosis of the lung or slightly reduced esophageal motility has been detected radiographically or by scintigraphy. Clinically relevant involvement of internal organs is observed in certain types of pseudoscleroderma (see Ch. 43).

FOUR MORPHEA CLASSIFICATION SCHEMES

Peterson (1995)[31]	Padua (2006)[32]	European Dermatology Forum (2017)[33]	Dallas–Pittsburgh (proposed 2021)[34]
Subtypes	***Subtypes***	***Subtypes***	***Subtypes***

• Eosinophilic fasciitis			
• Panclerotic			

Table 44.1 Four morphea classification schemes. A recent cross-sectional study that included 944 adult and pediatric patients with morphea from two prospective cohorts compared three previously published morphea classification schemes. The Padua criteria performed best (95%) in classifying patients into groups with cohesive demographic and clinical features, compared with the Peterson (56%) and European Dermatology Forum (52%) criteria. Based on their findings, a modified morphea classification scheme was formulated[34].

Plaque-Type (Circumscribed) Morphea

Plaque-type (circumscribed) morphea, the most frequent variant, is characterized by the insidious onset of a slightly elevated, erythematous or violaceous, slightly edematous plaque that undergoes centrifugal expansion (Fig. 44.3). It is generally asymptomatic and therefore frequently goes unnoticed by the patient. The central portion of the progressing lesion starts to transform into sclerotic, scar-like tissue. Depending on the depth of the sclerosis, the skin becomes progressively indurated. Centrally, it can acquire a shiny white color and peripherally, a violaceous or "lilac" ring (Fig. 44.4A). Postinflammatory hyperpigmentation often dominates over the white sclerosis as the lesions mature (Fig. 44.4B).

Fig. 44.3 Early inflammatory plaque-type (circumscribed) morphea of the trunk. Early-stage lesion presenting as an erythematous edematous plaque.

Fig. 44.4 Plaque-type (circumscribed) morphea. A Sclerotic plaques with the characteristic lilac-colored rim. Histologic findings will differ depending upon whether the biopsy specimen is obtained from the inflammatory edge or the central area of sclerosis (see Fig. 44.12). **B** The predominant lesion is a large, well-demarcated, hyperpigmented plaque that is depressed centrally; the trunk is a common location for plaque-type morphea.

Skin structures such as hairs and sweat glands are frequently lost. Some patients complain of itch, perhaps due to associated xerosis. Once the "lilac" ring vanishes, the lesion's progression also halts. Although this inflammatory margin may be difficult to appreciate, especially in linear sclerosis, it is an important indicator of clinical activity.

The plaques of morphea most commonly develop on the trunk and in general are between 2 and 15 cm in diameter. They are usually multiple and asymmetric, but marked variation exists. Individual lesions may enlarge significantly or remain stable in size.

The course of morphea is also variable. In most patients, morphea progresses over 3–5 years, then arrests and eventually resolves spontaneously. However, residual atrophy and dyspigmentation are commonly observed. Patients rarely have relapsing disease for more than 5 years, but may have sequelae such as calcinosis cutis (see Fig. 50.2)[35].

Variants

Various manifestations of morphea have become associated with specific names. They do not really reflect unique entities, but rather different morphologic features, distribution patterns, or depth of involvement. In most patients, morphea seems to be randomly distributed. However, in some patients, the lesions are unilateral, and they may follow dermatomes or the lines of Blaschko.

- **Guttate morphea** presents primarily as multiple, rather superficial, nummular plaques. Even though relatively small, they may become deeply indurated.
- **Atrophoderma of Pasini and Pierini** is considered by some to be a very superficial variant of plaque-type morphea, while others consider it to be a separate entity in the differential diagnosis of "burnt-out" morphea (see Ch. 99). Hyperpigmented patches are seen most commonly on the posterior trunk; occasionally, lesions follow the lines of Blaschko (linear atrophoderma of Moulin).
- **Deep morphea** denotes inflammation and sclerosis that affects primarily the deep dermis and subcutaneous fat and may even involve underlying structures (e.g. the fascia) (Fig. 44.5A). Patients normally develop a small number of hard deep plaques that may impair motility of the skin; ultimately, lesions may calcify, leading to dystrophic calcinosis cutis. Because of the location of the sclerosis, individual lesions may resemble eosinophilic fasciitis (Fig. 44.5B and see Ch. 43).

Fig. 44.5 Comparison of deep morphea and eosinophilic fasciitis. A Note the "pseudo-cellulite" appearance of the involved skin of the thigh in deep morphea. **B** In eosinophilic fasciitis, the level of fibrosis is also deep, resulting in a similar rippled appearance. This patient had the eosinophilic fasciitis-like form of chronic GVHD, also referred to as chronic GVHD-related fasciitis. *B, Courtesy Edward Cowen, MD.*

Fig. 44.6 Nodular or keloidal morphea. Multiple firm, hyperpigmented nodules mimicking keloids in a 10-year-old girl. *Courtesy Julie V. Schaffer, MD.*

Fig. 44.7 Parry–Romberg syndrome. Unilateral sclerosis and loss of subcutaneous fat, leading to facial asymmetry. *Courtesy Lorenzo Cerroni, MD.*

- In **nodular or keloidal morphea**, inflammation within the dermis leads to thick, keloid-like nodules (Fig. 44.6) or bands. It can be clinically indistinguishable from indurated keloids.
- In rare patients, especially those where sclerosis of the skin is associated with diffuse, rapidly progressive edema, lymphoceles may result from stasis of lymphatic fluid. When the latter develop into bullae, this is referred to as **bullous morphea**. It is more frequently observed in generalized morphea and sclerodermoid or morpheaform GVHD and is rarely a feature of plaque-type morphea. Bullous morphea has to be distinguished from mechanical blisters that may occur centrally within plaques and are secondary to impaired mechanical stability of the dermal–epidermal junction.

Linear Morphea and Parry–Romberg Syndrome

Linear morphea is different from plaque-type morphea, with respect to age of onset, distribution, clinical outcome, and serologies. Morphea *en coup de sabre* (meaning stroke or blow with a single-edged sword) is a term used for linear morphea of the forehead and scalp. Hemifacial atrophy, or Parry–Romberg syndrome, is probably a very severe variant of linear morphea, but it may be a phenotype for more than one entity. There is a progressive loss of subcutaneous fat, but little or no sclerosis (Fig. 44.7). The entire distribution of the trigeminal nerve, including the eye and the tongue, may be affected.

Linear morphea may present initially as a linear, erythematous (inflammatory) streak, but more frequently begins as a harmless-appearing lesion of plaque-type morphea that extends longitudinally as a series of plaques that then join to form a scar-like band (Fig. 44.8). This band may severely impair the mobility of the affected limb. Linear morphea tends to involve the underlying fascia, muscle, and tendons. This leads not only to muscle weakness but also to shortening of the muscles and fascia which then impairs joint mobility. Linear morphea is especially problematic when it extends over joints, as this almost invariably results in a decrease in range of motion and functional impairment[36]. In some patients, involvement is circular rather than linear and results in progressive atrophy of the limb similar to the Parry–Romberg variant of facial morphea. The linear variant can have prolonged periods of quiescence followed by reactivation.

The *en coup de sabre* type of morphea represents linear morphea of the head (Fig. 44.9). It is typically unilateral and extends from the forehead into the frontal scalp. It may start either as a linear streak, which may initially mimic a port-wine birthmark, or as a row of small plaques that coalesce. A paramedian location is most common. Like plaque-type morphea, it may initially be surrounded by a discrete lilac ring that extends longitudinally and may reach the eyebrows, nose, and even the cheeks. As inflammation wanes, a linear, hairless crevice develops that in some patients is sclerotic, while in others appears more atrophic.

Fig. 44.8 Linear morphea of an extremity. A Linear sclerotic band of the arm with both hyper- and hypopigmentation. The majority of patients with linear morphea have unilateral involvement. **B** More inflammatory phase with ulceration in addition to induration. The differential diagnosis includes linear melorheostosis which is often associated with underlying candlewax-like linear hyperostosis. *A, Courtesy Julie V. Schaffer, MD.*

En coup de sabre morphea can also involve the underlying muscles and osseous structures. Rarely, the inflammation and sclerosis progress to involve the meninges and even the brain, creating a potential focus for seizures[37]. Ocular involvement has been reported in up to 15% of juvenile and 25% of adult patients.

Generalized Morphea

Generalized morphea normally begins insidiously on the trunk as plaque-type morphea. While individual lesions are indistinguishable in these two forms, in generalized morphea they do not stop expanding. Just as in the diffuse form of SSc, multiple plaques rapidly coalesce and can affect nearly the entire trunk, often only sparing the areolae and nipples (Fig. 44.10). The sclerosis may involve the extremities down to the hands (presenting initially as puffy edema). As the cutaneous sclerosis progresses, it may result in disabling constrictions that even cause difficulty in breathing due to impaired thorax mobility and inflammation of the intercostal muscles. Although an aggressive therapeutic approach is recommended, the disease is usually persistent given its often limited response to treatment.

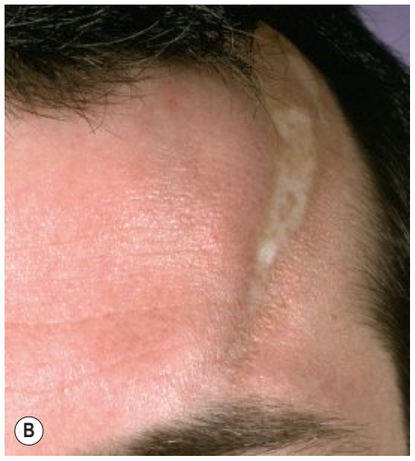

Fig. 44.9 Morphea *en coup de sabre*. On the forehead, the linear band(s) of sclerosis and atrophy are usually paramedian (rather than midline). **A** Both hyper- and hypopigmentation are present as well as subtle depression. **B** An obviously depressed, sclerotic, hypopigmented linear band. **C** Scarring alopecia develops when there is involvement of scalp; "lonely hairs" are also seen in other forms of scarring alopecia. **D** Note the prominent veins and loss of the medial eyebrow. Progression to Parry–Romberg syndrome would be a concern.

Fig. 44.10 Generalized morphea. A Multiple hyperpigmented plaques on the trunk that are becoming confluent. **B** Circumferential involvement with sparing of the central portion of the breast is a classic distribution pattern. *B, Courtesy Luis Requena, MD.*

Fig. 44.11 Extensive linear morphea of the right leg leading to hypoplasia. In addition to marked hypoplasia, there is induration and a flexion contracture of the knee.

Morphea in Childhood

Approximately 20% of individuals with morphea are children and teenagers. The female-to-male ratio for plaque-type morphea in this age group is about 2:1, with a mean age at disease onset of 7 years[38]. In two-thirds of patients with linear morphea, disease onset is prior to age 18 years, providing an explanation for the possibility of growth retardation of the affected limb. Thus, if left untreated, linear morphea may result not only in decreased range of motion of joints but also in permanent limb asymmetry from unilateral hypoplasia (Fig. 44.11).

Pansclerotic morphea, also referred to as disabling pansclerotic morphea of children, is similar to generalized morphea of the adult. It usually starts before 14 years of age and tends to cause lifelong severe disability due to persistent atrophy of the underlying muscles and contractures of the involved joints. The disease tends to extend from the trunk to the hands and feet. Periodontal atrophy may occur, but there is only slight involvement of the esophagus and lung. Distinction from SSc may prove challenging.

Importantly, in a large multicenter study of children with morphea, 22% had extracutaneous findings that were primarily articular (11%), neurologic (4%), and ocular (2%)[38]. The latter two findings were seen primarily in those with linear morphea of the head or Parry–Romberg syndrome, i.e., 85% of affected patients had these two variants.

LABORATORY FINDINGS

Laboratory abnormalities are not a prominent feature of morphea, except for generalized and linear morphea. The ESR and serum protein levels are usually normal, but eosinophilia may occur, especially during early active phases of the disease. High titers of ANA or antibodies to ssDNA and histones can be detected in 40%–80% of patients with linear and generalized morphea, but are uncommon in adults with plaque-type morphea (see above). Approximately 40% of children and adolescents with morphea have elevated ANA titers[38].

PATHOLOGY

The histopathology of morphea depends on two factors: the stage and area of the lesion sampled (inflammatory margin or central sclerosis) and the depth to which the disease extends. In most situations, morphologic changes are best seen at the border between the dermis and subcutaneous fat. Specimens for histopathology must include subcutaneous fat and it is important to note whether the biopsy specimen is taken from the inflammatory border or from the fibrotic center.

At the inflammatory border, vascular changes are relatively discrete by light microscopy. Vessel walls show endothelial swelling and edema. Capillaries and small arterioles are surrounded by an infiltrate that contains primarily $CD4^+$ T cells and sometimes eosinophils, plasma cells, and mast cells (Fig. 44.12A).

In later stages, the inflammatory infiltrate wanes and ultimately disappears completely, except in some areas of the subcutaneous fat. The epidermis is basically normal in appearance, but the rete ridges may be diminished, leaving a flattened dermal–epidermal junction. Edema is no longer visible in the dermis and upper subcutis. Capillaries and small vessels are significantly reduced in number, and homogeneous collagen bundles with decreased space between the bundles replace most structures. At this stage, collagen bundles in the reticular dermis appear densely packed, as evidenced by a more intense eosinophilic staining, and are aligned parallel to the dermal–epidermal junction (Fig. 44.12B). Eccrine glands appear atrophic and "trapped" within the thickened dermis. The underlying subcutis is homogenized and hyalinized.

Deep morphea affects primarily the deep subcutaneous tissue. Following the inflammatory phase, extensive sclerosis and hyalinization extend into the underlying fascia. Involvement of the underlying fascia is obligatory in deep morphea and is also frequently observed in linear and generalized types of morphea. In these patients, the fascia and even the underlying muscle (frequently vacuolated) are involved in the process of progressive sclerosis, characterized by replacement of the differentiated tissue by collagen bundles.

MORPHEAFORM (AND SCLERODERMOID) INFLAMMATORY SYNDROMES

Some disorders that are characterized by acrosclerosis and Raynaud phenomenon (e.g. sclerosis secondary to exposure to bleomycin, vinyl chloride, or epoxy resin) have a clinical presentation similar to lcSSc (i.e. sclerodermoid or pseudoscleroderma), while others present with circumscribed plaques similar to morphea (i.e. morpheaform). The former are discussed in Chapter 43 and the latter are discussed below and presented in Table 44.2. There are also clinical disorders that may have either type of clinical presentation, such as chronic GVHD.

While a variety of inflammatory diseases ultimately lead to superficial or deep sclerosis of the skin, their exact relationship to morphea is enigmatic. Some of these diseases are preceded by or associated with eosinophilia in blood or tissue. Infiltration by eosinophils may be of unknown etiology, as in eosinophilic fasciitis, or it may reflect an immune reaction to a defined toxic insult or antigenic stimulus, as in the L-tryptophan syndrome (eosinophilia–myalgia syndrome), toxic oil syndrome, or GVHD following hematopoietic stem cell transplantation (HSCT). Lastly, since certain exogenous drugs or chemicals, endogenous metabolites, or X-irradiation induce sclerosis at the site of tissue injury in only a subset of individuals, this suggests that unique metabolic events and innate or adaptive immune responses to these compounds determine the individual's susceptibility to develop sclerosis[2].

- **Lipodermatosclerosis**. Chronic venous insufficiency, along with chronic hypoxia, leads to sclerosis, most commonly on the lower extremities. This entity is discussed in Chapter 100.
- **Injections of vitamin K_1 (Texier disease)**. Rarely, injection of oil-soluble vitamin K_1 causes a strictly localized eosinophilic fasciitis that is indistinguishable from deep morphea. It may ultimately resolve with dermal and/or subcutaneous atrophy.
- **Vaccination-associated morphea**. Development of plaque-type or deep morphea has been described in children and adults at intramuscular vaccination sites. Given the limited number of case reports, it is uncertain whether the antigens, the adjuvants, or the injection trauma trigger the inflammatory fibrosis[39].
- **Paraffin and silicone injections or implants**. It is suspected that leakage of silicone implants and injection of silicone or liquid paraffin during reconstructive surgery and cosmetic soft tissue augmentation may cause chronic inflammation that results in localized morphea-like sclerosis. The belief that these substances

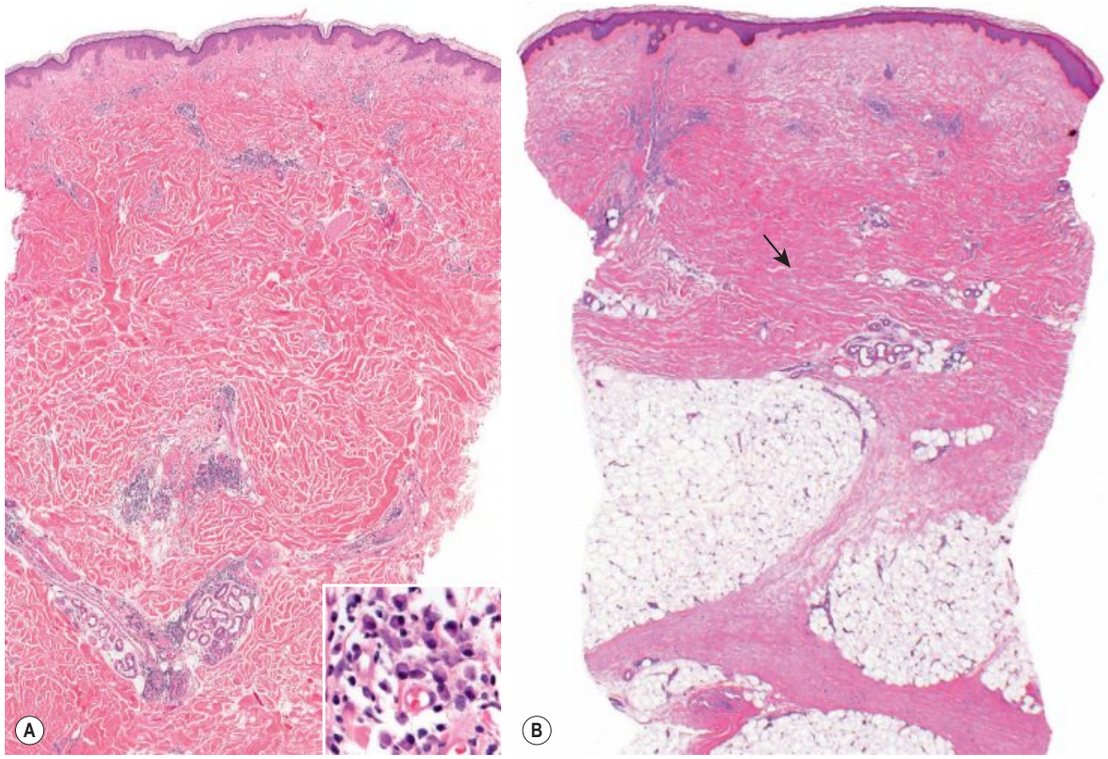

Fig. 44.12 Morphea – histopathologic features. A Overview with thickening of the dermis and perivascular and periecrine infiltrates of lymphocytes and plasma cells (inset). These changes can be seen in the inflammatory border. **B** Advanced sclerosis of the entire dermis extending into the fat with thickened collagen bundles and "trapped" eccrine glands (arrow). This corresponds to the areas of induration within the plaque. *A, Courtesy Lorenzo Cerroni, MD.*

can trigger systemic diseases such as SSc, eosinophilic fasciitis, or mixed connective tissue disease was not substantiated when meta-analyses were performed.

- **Porphyrias**. In adults, porphyria cutanea tarda can lead to morphea-like sclerosis in UV-exposed sites, such as the face, hairless scalp, dorsal aspects of the hands, and the upper chest. Histopathology and electron microscopy findings may resemble morphea except for the presence of PAS-positive deposits around dermal blood vessels. Other rare forms of porphyria can also lead to scarring in UV-exposed sites (see Ch. 49).
- **Radiation-induced morphea**. This disorder is characterized by marked sclerosis, erythema, and pigmentary changes occurring within the radiation field or even beyond it (Fig. 44.13). The incidence of radiation-induced morphea is about 1 in 500 patients and it is seen primarily in patients treated for breast carcinoma. Predictive risk factors for the development of radiation-induced morphea are unknown and it can present several years after radiation therapy. In addition to the changes of radiation dermatitis, histopathology demonstrates perivascular and subcutaneous inflammation together with dermal fibrosis and collagen deposition.
- **Nephrogenic systemic fibrosis**. This entity is discussed in detail in Chapter 43.
- **Chronic GVHD**. Patients with chronic GVHD may develop lesions that resemble morphea and lichen sclerosus as well as eosinophilic fasciitis (see Ch. 52).

DIFFERENTIAL DIAGNOSIS

In addition to the other morpheaform and sclerodermoid conditions discussed above, the most important entity in the differential diagnosis is SSc (see Ch. 43). Asymmetric skin involvement as well as the absence of Raynaud phenomenon and lung or esophageal involvement are characteristic features of morphea. The other common considerations are lichen sclerosus and keloids; however, the former can coexist with morphea. Dupuytren contracture and camptodactyly, a benign ulnar deviation of the fourth and fifth finger, can be clinically distinguished from linear morphea.

Scleredema leads to diffuse woody induration, primarily of the upper back and neck. Symmetric tightness and induration of acral skin can be seen in insulin-dependent diabetics with cheiroarthropathy, also referred to as waxy skin and stiff joints. In children, progeria and premature aging syndromes need to be distinguished from Parry–Romberg syndrome, but the latter is unilateral, as is silent sinus syndrome. Additional entities in the sclerodermoid differential diagnosis (e.g. scleromyxedema) are listed in Table 43.7.

TREATMENT

Various therapeutic modalities have been described for morphea, although quality evidence in support of many of these therapies has been limited[40]. In addition, there has been a lack of standardized outcome measures for assessing the efficacy of various therapies. However, the localized scleroderma cutaneous assessment tool (LoSCAT) is gaining recognition as a valid and reproducible index for disease activity and damage in morphea[41]. Radiologic imaging (e.g. ultrasound, MRI) may also provide useful information[41].

The major therapies for morphea include topical medications, phototherapy, systemic immunosuppressants, and physical/occupational therapy (Table 44.3). Several factors, including level of disease activity, subtype of morphea, depth of involvement, location and extent of disease, and degree of current or potential functional impairment or disfigurement, play a role in determining the most appropriate treatment.

Therapies are most effective when there is active disease (e.g. inflamed and expanding patches and plaques), whereas inactive disease (e.g. fixed sclerotic plaques) is less likely to respond. Plaque-type morphea

DIFFERENTIAL DIAGNOSIS OF MORPHEAFORM SKIN LESIONS
Morphea (plaque-type, linear, generalized* or deep*)
Chronic graft-versus-host disease*
Lichen sclerosus (may coexist with morphea)
Lipodermatosclerosis*
Sclerosis at injection sites
• Vitamin K_1 (Texier disease) or vitamin B_{12}
• Silicone or paraffin implants
• Interferon-β
• Glatiramer
• Enfuvirtide
• Bleomycin (intralesional therapy)
• Opioids (e.g. pentazocine, ketobemidone, methadone)
• Vaccinations
Medications and chemical/toxin exposures†
• Immune checkpoint inhibitors
• Aromatic/chlorinated hydrocarbons (e.g. benzene or toluene at sites of contact with skin)*
• Nephrogenic systemic fibrosis (induced by gadolinium-containing contrast media)*
• Toxic oil syndrome (historical)*
Radiation-induced morphea
Porphyria (porphyria cutanea tarda, hepatoerythropoietic porphyria, congenital erythropoietic porphyria)*
Muckle–Wells syndrome
Winchester syndrome*
Stiff skin syndrome*
Linear melorheostosis
Complex regional pain syndrome*
Morpheaform sarcoidosis
Sclerosing congenital melanocytic nevus
Paraneoplastic scleroderma-like syndrome*
Cutaneous metastases (e.g. carcinoma *en cuirasse*)
*Can overlap with sclerodermoid disorders, which are outlined in Table 43.7; in particular, deep morphea and eosinophilic fasciitis may have a similar appearance. †Systemic medications for which there have also been reports of an association with morpheaform lesions include bleomycin, taxanes (e.g. paclitaxel, docetaxel), bromocriptine, ethosuximide, valproic acid, appetite suppressants, and penicillamine.

APPROACH TO THE TREATMENT OF MORPHEA Rx	
Morphea variant	**Treatment**
Plaque–type (circumscribed)	*First-line** • Topical class I CS, daily–twice daily • Intradermal CS (e.g. triamcinolone acetonide 5–10 mg/mL) every 4–6 weeks into active rim • Tacrolimus 0.1% ointment, twice daily *Second-line* • Topical vitamin D analogue (calcipotriene [calcipotriol]) under occlusion ± class I topical CS • Lesion-limited phototherapy† *Third-line (or if lesions spreading, unstable)* • Generalized phototherapy† • Weekly methotrexate‡ • Topical crisaborole 2% ointment for steroid-refractory plaque *Refractory, rapidly progressive, or deep variant* • Weekly methotrexate‡ ± systemic CS¶ • CS-sparing agents (e.g. mycophenolate mofetil, JAK inhibitors [e.g. tofacitinib])
Linear	**Deep variant, facial involvement, crossing joints** *First-line** • Weekly methotrexate‡ ± systemic CS¶ *Second-line* • CS-sparing agents (e.g. mycophenolate mofetil, JAK inhibitors, tocalizumab) **Superficial variant, not involving face or crossing joints** • Phototherapy†
Generalized	*First-line** • Phototherapy† (if superficial and without joint contractures) • Weekly methotrexate‡ ± systemic CS¶ *Second-line* • CS-sparing agents (e.g. mycophenolate mofetil, JAK inhibitors [e.g. tofacitinib, baricitinib], tocalizumab)
Pansclerotic	See systemic therapies for generalized morphea
*If not improved after ~8 to 10 weeks, progress to next line of therapy. †Phototherapy choice based on local availability (UVA1, BB-UVA, PUVA), with preference for UVA1 if available; NB-UVB may be considered for limited, superficial plaque-type disease. ‡Weekly methotrexate doses, either orally or subcutaneously: adults, 15–25 mg/week; children, 0.3–0.5 mg/kg/week. ¶Especially for early/progressive lesions; pulsed dosing (e.g. intravenous methylprednisolone 1000 mg/day for three consecutive days per month, with a pediatric dose of 30 mg/kg/day in those ≤ 33 kg) favored over daily dosing (e.g. oral prednisone 1 mg/kg/day).	

Table 44.3 Approach to the treatment of morphea. Treatment is most effective in active, inflammatory lesions. Systemic therapy should be instituted if: (1) progression or risk of functional impairment (e.g. decreased range of motion of joints, involvement across joints) or significant disfigurement (e.g. linear facial morphea); (2) deep morphea (e.g. subcutaneous, fascia, muscles). Systemic retinoids (e.g. acitretin 10–50 mg/day), apremilast (30 mg twice daily), abatacept, and hydroxychloroquine (200–400 mg/day) are additional therapies. CS, corticosteroids.

Fig 44.13 Radiation-induced morphea. Erythema and induration of the left breast. *Courtesy Department of Dermatology, Medical University of Graz.*

with limited body surface area involvement can often be managed with topical therapies while generalized or extensive disease responds best to phototherapy or systemic medications. Active deep morphea with involvement of the subcutaneous tissue, fascia, or muscles as well as morphea with the potential for functional impairment (e.g. linear morphea overlying joints) or significant disfigurement (e.g. facial involvement) should be managed aggressively with systemic immunosuppressants. In addition, patients at risk for functional impairment (e.g. joint contractures, loss of mobility) should be referred to physical and occupational therapists before the onset of such complications.

If persistent contractures do develop, reconstructive surgery may be required. Surgical revision can be offered for inactive linear or *en coup de sabre* morphea. Autologous fat transplantation has been used successfully for Parry–Romberg syndrome and injection of hyaluronic acid fillers, with or without fractional laser ablation, to correct facial morphea has been reported[42]. Finally, patients with extracutaneous involvement may require additional evaluation and management, such as rheumatologic referral for arthritis or synovitis. Patients with

morphea that involves the head are at risk for ocular and/or neurologic complications and, when indicated, referred to ophthalmology and neurology, respectively.

Phototherapy

Phototherapy for morphea was first described in 1994[43], and since then, efficacy has been confirmed by more than 30 publications[44,45] and was recently supported by an open label controlled study[46]. Various phototherapy modalities have been used, including UVA1, broadband UVA (BB-UVA), PUVA, and narrowband UVB (NB-UVB). When available, UVA1 has become the phototherapy of choice, followed by BB-UVA and PUVA. NB-UVB, because of its shallower depth of penetration, may be beneficial for superficial morphea but is less effective for deeper morphea. Treatment can be lesion-directed when there is a limited number of plaques or administered to the majority of the skin surface. The efficacy of phototherapy is thought to be due to immunomodulatory effects as well as upregulation of matrix metalloproteinases that stimulate collagen breakdown. Patients may also benefit from phototherapy plus low-dose systemic retinoids as this combination has led to improvement of sclerodermoid GVHD and plaque-type morphea[18,47].

Due to the nature of phototherapy, placebo-controlled studies have not been performed. Nonetheless, little doubt exists as to the efficacy of this therapy, as untreated morphea normally progresses over 3–5 years and then regresses very slowly over several years. More rapid spontaneous improvement only occurs in a small minority of patients[3]. The clinical course is definitely different in patients receiving phototherapy. Following 30–36 treatments of bath PUVA therapy (at slightly suberythematous doses) or UVA1 (30–60 J/cm^2), morphea resolves or markedly improves in at least 60% of patients[48,49] (Fig. 44.14). Further advantages of phototherapy, and especially UVA1, include clinical improvement in all skin types[50] and sustained remissions. Recurrence of morphea plaques after successful phototherapy has been reported, but primarily in patients with a prolonged period of disease prior to initiation of phototherapy. The dose of UVA1 phototherapy (medium versus high) does not appear to correlate with risk of recurrence[51].

The ideal dose for UVA1 therapy has been debated. Most initial studies were performed with either low (20–30 J/cm^2) or medium doses (40–70 J/cm^2) of UVA1 and reported similar efficacy. A study that utilized 20 MHz ultrasound rather than clinical assessment of morphea lesions reported a better response with medium-dose (70 J/cm^2) than with low-dose (20 J/cm^2) UVA1[52]. In agreement with these reports, we have observed that 36 treatments with either 30 J/cm^2 or 50–60 J/cm^2 of UVA1 markedly improves morphea in the majority of patients[48]. Importantly, in responding patients, lesions of morphea continue to improve beyond the end of the therapy. Thus, therapy can be terminated after 36 treatments, even if the sclerosis has not yet completely resolved. The only exception appears to be linear morphea, which may require up to 60 treatments.

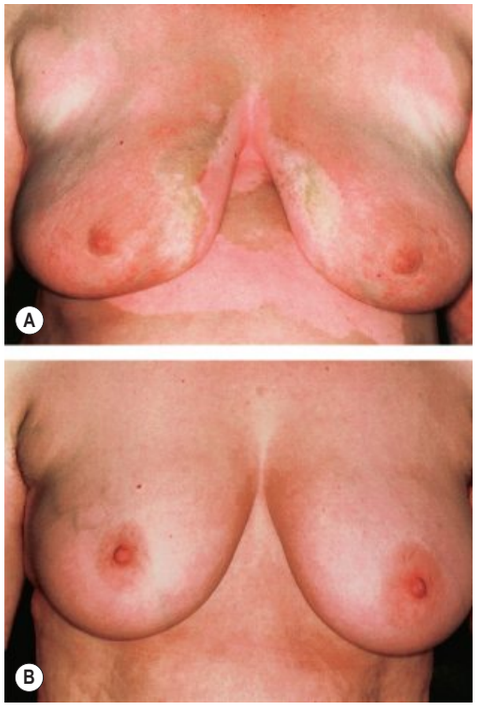

Fig. 44.14 Phototherapy for morphea. Disseminated morphea on the trunk, with sparing of the central portions of the breasts. Before (**A**) and after (**B**) PUVA bath photochemotherapy.

Systemic Therapies

Indications for systemic therapies are outlined above and in Table 44.3. For decades, methotrexate, either alone or in combination with systemic corticosteroids, has represented a first-line treatment[53–55]. Systemic corticosteroids are often added for severe involvement or when more rapid control of the disease is desired[56–58]. Typically, the methotrexate is continued for at least 12 months and tapering is not begun until at least 6–12 months after the disease is inactive. Tapering of systemic corticosteroids (over several months) usually occurs sooner, once the disease is no longer active.

Recent data from retrospective cohort and longitudinal studies suggest that mycophenolate mofetil (MMF) is also beneficial and well tolerated in patients with severe morphea, even in those with a history of previously ineffective treatments[59,60]. MMF is usually the next line of treatment should methotrexate +/– corticosteroids fail or be contraindicated. Efficacy data for other systemic agents are even more limited. In small case series, JAK inhibitors (e.g. tofacitinib, baricitinib) led to improvement in patients with recalcitrant morphea or eosinophilic fasciitis[61]. Additional reported therapies include hydroxychloroquine[62] and systemic retinoids (acitretin, isotretinoin)[17,18,63,64]. Of note, vitamin A derivatives have antifibrotic effects and can modulate collagen metabolism[65].

In case series and reports, improvement has been observed with tocilizumab, which blocks the IL-6R, including for pansclerotic morphea in children[66], as well as abatacept, a CTLA4 fusion protein that inhibits T cell activation[67]. A placebo-controlled, multi-center trial with dupilumab, which blocks the interaction of the profibrotic cytokines IL-4 and IL-13 with IL-4Rα, is currently underway. Lastly, a novel approach based upon genetically modified autologous fibroblasts that express metalloproteinase-1 (MMP-1) has not progressed beyond phase I/II trial status.

LICHEN SCLEROSUS

Synonyms/site-specific names: ■ Lichen sclerosus et atrophicus ■ Kraurosis vulvae ■ Balanitis xerotica obliterans (lichen sclerosus of the penis)

Key features

- Sclerotic, ivory-white, flat papules and plaques with epidermal atrophy and, in extramucosal sites, follicular plugging
- Most commonly affects female or male genitalia, less often extragenital skin
- May cause scarring of the vaginal introitus or phimosis
- Severe pruritus may occur
- No systemic manifestations

INTRODUCTION

Lichen sclerosus (LS) is a clinically distinct inflammatory disease, primarily of the superficial dermis or submucosa, that leads to ivory-white scar-like atrophy. Extragenital LS may itch and be cosmetically disturbing whereas genital LS causes both dryness and severe, persistent pruritus, and it often leads to progressive atrophy and functional impairment. Phimosis or scarring of the vaginal introitus are the most frequent complications. If left untreated, ~4% of patients with vulvar LS may develop differentiated vulvar intraepithelial neoplasia (VIN) or squamous cell carcinoma (SCC)[68].

HISTORY

François Henri Hallopeau's report on a "lichen plan atrophique" in 1887 is considered to be the first description of LS. The typical histopathologic changes of lichen sclerosus et atrophicus were published by Ferdinand Jean Darier in 1892. Unna, Westberg, von Zumbusch, and others elucidated the clinical features of LS in various case reports[69]. This contributed to the panoply of terms, such as white spot disease or lichen albus, an aspect that complicates any literature survey. Lichen sclerosus in the genital area was first described in women by August Breisky as kraurosis vulvae and 40 years later in men by Alfred Stühmer as balanitis xerotica obliterans. Today, lichen sclerosus, the term proposed by the International Society for the Study of Vulvar Disease, is used most frequently[70,71].

EPIDEMIOLOGY

Lichen sclerosus is relatively uncommon, although the exact prevalence is unknown. It occurs at all ages with a similar incidence in all races; the reported female-to-male ratio varies widely, depending upon the study, from 10:1 to 1:1[70,71]. In both sexes, the anogenital area is affected in ~85% of patients, but the best epidemiologic studies concentrate on vulvar disease.

Studies in adult patients suggest that LS is one of the most common causes of symptomatic vulvar disease. In two large series, LS was diagnosed in 13% to 19% of patients presenting with symptomatic vulvar disease. In women, the peak incidence is during the fifth and sixth decades, and a second peak occurs in girls between 8 and 13 years of age. Among prepubertal girls with vulvar disease, the relative frequency of LS is similar to that in adults. Extragenital LS is rare in children. In boys and men, LS frequently leads to phimosis (seen in 14 of 100 prepubertal boys undergoing circumcision for phimosis). Of 357 male patients attending a dermatology clinic because of genital skin disease, 14% had LS[72].

A recent retrospective analysis demonstrated a high prevalence of LS in patients with plaque-type morphea and generalized morphea[73]. This coexistence suggests either a common trigger or a common susceptibility factor for both diseases.

PATHOGENESIS

As in most inflammatory diseases, genetic predisposition contributes to the development of LS, as it may be found in monozygotic and fraternal twins. In addition, association with the MHC class II antigen HLA-DQ7 was observed in a relatively large study. The existence of a relevant susceptibility gene for sclerosis within this region of the MHC is underlined by the finding that the same region is associated with a greater risk of organ-specific autoimmune diseases. Even though inflammation seems essential for initiation and progression of LS, the mechanisms leading to subsequent sclerosis remain speculative. Increased production of IL-6, TNF, and collagen (types I, III, and V) is thought to promote the sclerosis[74].

Perhaps with the exception of autoantibodies against extracellular matrix protein 1 (ECM-1), no specific immunologic parameters have been identified in patients' sera that clearly correlate with either risk of disease or disease activity. IgG autoantibodies against ECM-1 are found in 80% of patients with LS[75]. Moreover, in female patients with LS, there is a higher prevalence of autoimmune diseases (especially autoimmune thyroid disease) and ANA positivity than in male patients with LS[76].

Oxidative stress may also play a role in the pathogenesis of LS, based upon analysis of lesional skin that showed lipid peroxidation of epidermal basal cell layers, oxidative DNA damage, and oxidative protein damage.

CLINICAL FEATURES

Lichen sclerosus most frequently affects the anogenital region, and less often extragenital skin. Lichen sclerosus of the oral cavity, palms, or soles is rare. Intraorally, bluish-white papules up to 5 mm in diameter may occur on the buccal mucosa or under the tongue. They can lead to superficial scar-like atrophy or erosions.

Extragenital LS normally does not cause symptoms except for dryness and associated pruritus. Lesions favor the trunk (Fig. 44.15) and the proximal extremities. More specific predilection sites include the neck, shoulders, flexor surfaces of the wrists, and sites of physical trauma or continuous pressure (e.g. the shoulder or hip). The periorbital area and scalp are rarely affected.

It is unusual to see extragenital disease during its early phases when single lesions begin as polygonal, bluish-white, shiny, slightly elevated, interfollicular papules. Over time, these papules often enlarge or coalesce into larger plaques. Most patients present with slightly sclerotic, scar-like papules and plaques that are usually ivory in color and have a shiny and/or wrinkled surface. Occasionally, lesions have a pink or light violet hue. At sites of continuous pressure, the surface may acquire a parchment-like appearance.

In more advanced stages, telangiectasias or follicular plugging can be seen (Fig. 44.16A). The flattened interface between the epidermis and dermis results in fragility of the dermal–epidermal junction. As a result, LS is occasionally complicated by the development of bullae that tend to become hemorrhagic (Fig. 44.16B).

In women, the vulva and the perianal region are commonly involved, often in a figure-of-eight configuration (see Ch. 73). Although the disease may be symptom-free, it frequently causes severe pruritus and soreness. These symptoms may be considerable and lead to dysuria, dyspareunia, or pain upon defecation (often manifesting as constipation in children). As a result, quality of life can be adversely affected, including in children and adolescents[77,78].

Vulvar LS often begins as a slightly elevated, sharply demarcated area of erythema, which can be slightly eroded. Over time, the involved skin becomes shiny, hypopigmented, and sclerotic, and fissures may develop, especially in the perineum (Fig. 44.17). When progressive, associated scarring can lead to burying of the clitoris and fusion of the

Fig. 44.15 Lichen sclerosus. Symmetric ivory-colored, shiny plaques with a thin pink peripheral rim are seen; a perianal pyramidal protrusion is also present. **B** Perianal lichen sclerosus in which the hypopigmented plaques are accompanied by a linear erosion (skin tear) at 6 o'clock and central fissuring of the perineum. **C** Involvement of the clitoral hood and clitoris as well as fusion of the left labia minora and labia majora. *A, Courtesy A. Hernández-Martín, MD; C, Courtesy Louis A. Fragola, Jr, MD.*

Fig. 44.18 Lichen sclerosus of the penis (balanitis xerotica obliterans). Note the ivory color, erosion, and scarring.

labia minora to the labia majora, and when untreated, an increased risk of malignancy[68]. With severe disease, loss of the labia minora and significant narrowing of the introitus can occur. Sexual intercourse may become impossible. In general, LS does not worsen during pregnancy and when treated successfully, vaginal delivery is possible without an increased incidence of perineal tears and episiotomies (compared with healthy control populations)[79].

Areas of purpura often develop within lesions of anogenital LS and can actually aid in the clinical diagnosis (see Fig. 73.3). However, the hemorrhage combined with erosions may be misdiagnosed as sexual abuse (see Ch. 90). A careful history and clinical examination, along with histologic confirmation when needed, can assist in establishing the diagnosis.

In boys and men, acquired phimosis or recurrent balanitis are the primary presenting features, and perianal involvement is rare. Itching and soreness are common. On the glans and the inner aspect of the foreskin, LS starts as sharply demarcated, sometimes slightly blue–red lesions, occasionally with erosions. This inflammation tends to evolve into an atrophic white sclerotic scar (Fig. 44.18). The constriction may cause pain on erection and, at advanced stages, dysuria and urinary obstruction. If the foreskin is affected in uncircumcised male patients, LS invariably leads to phimosis (difficulty in retracting the foreskin to uncover the glans), with the additional risk of paraphimosis (when a foreskin is retracted behind the glans and cannot be returned to its original position); the latter represents a urologic emergency. Many boys and men first present when the phimosis impairs repositioning of the foreskin;

in these situations, diagnosis depends on histology. With progression, poorly healing ulcers of the glans can develop. While circumcision is clearly a first-line therapy, LS may recur at the site of a circumcision.

A continuing debate is whether genital LS is a precancerous condition. Interpretation and comparison of the data are complicated by at least two factors: some of the patients reported as developing cancer had previously received X-ray therapy for the disease or had previous dysplasia due to human papillomavirus (HPV) infection. It is therefore very difficult to perform a useful meta-analysis based on existing data. Some data suggest that genital LS is not intrinsically precancerous, but a recent prospective cohort study of 507 women with vulvar LS noted the development of SCC or VIN in 5% of patients partially compliant with topical corticosteroid treatment and in none of the compliant patients, with a mean follow-up of 4.7 years[68,70,71,80]. Whether the microRNA signature will assist in identifying those patients at increased risk of SCC remains to be determined[80a].

Lentigines and melanocytic nevi can arise within areas of LS, primarily genital LS; histologically they may resemble persistent (recurrent) melanocytic nevi and therefore be confused with melanoma[81].

PATHOLOGY

Lichen sclerosus has a specific histologic pattern that is seen in all age groups[82]. Initially, superficial dermal edema is associated with a band-like lymphocytic infiltrate (Fig. 44.19A). The epidermis is thinned, with orthohyperkeratosis and vacuolar degeneration of the basal layer. Hyperkeratosis is especially pronounced at follicular openings and may lead to plugging. Vacuolar degeneration of the basal layer and flattening of the rete ridges predispose to the development of blisters, which may become hemorrhagic. The most important changes are found in the superficial dermis, where the pale staining reflects edema initially and then homogenized dermal collagen (Fig. 44.19B). Loss of elastic fibers is typical for LS and is not observed in morphea. Subepidermal clefting and hemorrhage within the homogenized papillary dermis is frequently observed.

During the early phases, the inflammatory infiltrate is especially pronounced along the zone of hyalinization and consists of lymphocytes ($CD3^+$, $CD4^+$, $CD8^+$), macrophages, and mast cells. In older lesions, the mononuclear infiltrate is reduced and sparse, and patchy islands of mononuclear cells are dispersed within the hyalinized dermis. Ultrastructural studies reveal shortened collagen fibers.

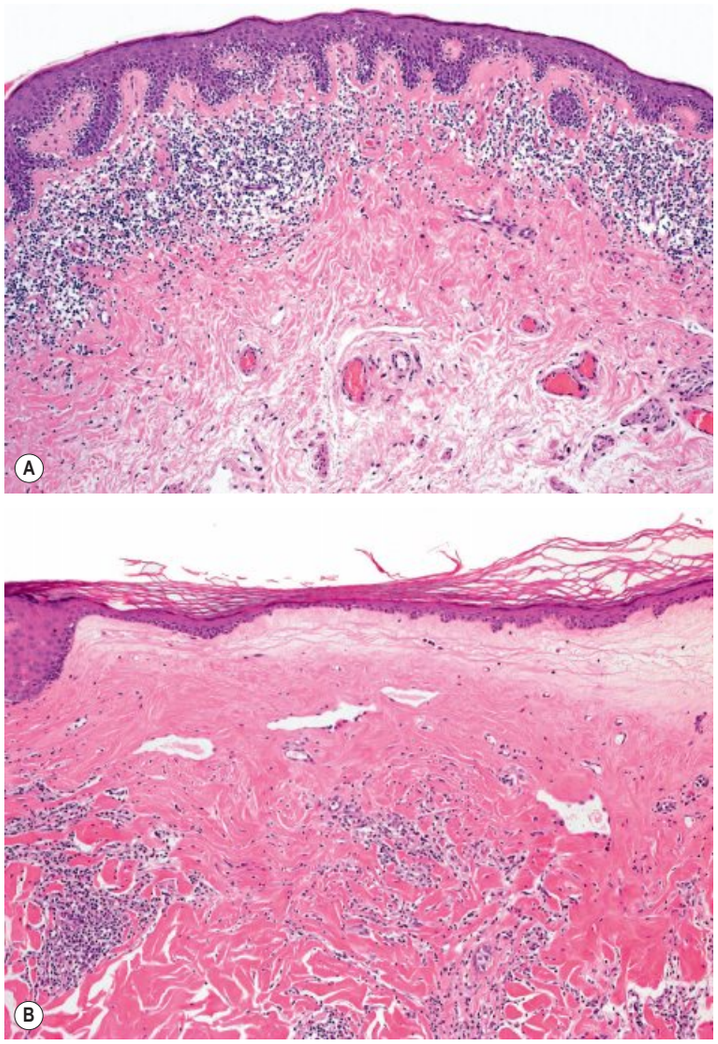

Fig. 44.19 Lichen sclerosus – histopathologic features. A Early lesion with band-like infiltrate of lymphocytes in the upper dermis and vacuolar change at the dermal–epidermal junction. Mild homogenization of the papillary dermis is present. **B** Late lesion with orthohyperkeratosis, thinning of the epidermis, and homogenization of the upper dermis. There is also hyalinization and sclerosis of the papillary dermis, telangiectasias, and an interstitial lymphocytic infiltrate. *Courtesy Lorenzo Cerroni, MD.*

DIFFERENTIAL DIAGNOSIS

The most important entity in the differential diagnosis of extragenital LS is morphea, and in the case of genital LS in girls and boys, sexual abuse. However, morphea and LS may coexist in the same patient. In adults, genital LS may mimic erosive lichen planus, mucous membrane pemphigoid, or erythroplasia of Queyrat (see Ch. 73). Distinction often requires histologic examination. Biopsies may also be needed to exclude associated differentiated VIN or invasive SCC. Histologically, LS-associated pseudoepitheliomatous hyperplasia has to be distinguished from SCC. A past history of allogeneic HSCT points to chronic GVHD that may be clinically and histologically indistinguishable from morphea or LS (see Fig. 44.16A).

TREATMENT

Genital Lichen Sclerosus

Identification, early treatment, and ongoing maintenance therapy of *genital* LS is recommended, with the goals of relieving symptoms (e.g. pruritus), reversing skin changes (e.g. hyperkeratosis), and preventing the development of scarring, adhesions, and SCC[68,83]. Table 73.1 outlines a detailed approach to anogenital LS.

Topical corticosteroids are the gold standard for treatment of genital LS in both adults and children and intralesional corticosteroids are also useful for treating areas of hyperkeratosis. Both retrospective and prospective studies have shown that ultrapotent topical corticosteroids (e.g. clobetasol propionate 0.05%) are highly effective in the treatment of *genital* LS[84–86]. In boys with genital LS, topical corticosteroids can avoid circumcision in one-third of patients[87].Topical calcineurin inhibitors, although less potent than the recommended class I corticosteroids, also have a role in topical therapy[84,85]. Ointments are preferred over creams because they are better tolerated, and frequent use of emollients (e.g. petrolatum) is also recommended. Topical JAK inhibitors (e.g. ruxolitinib 1.5% cream) are currently under investigation for anogenital LS.

Failure to respond to ultrapotent local corticosteroids should prompt evaluation for contributing factors, such as improper use of the corticosteroids, secondary infection (e.g. candidiasis), menopause-related vulvovaginal atrophy, and development of SCC. Second-line therapeutic options for *genital LS* have more limited efficacy data but include systemic agents (e.g. acitretin, abrocitinib)[88,89,89a].

Importantly, because symptoms often recur upon discontinuation of initial therapy and because of the long-term risk of malignancy (i.e. SCC), it is now recommended that patients follow a long-term maintenance regimen upon resolution of signs (e.g. hyperkeratosis, ecchymoses, fissures) and symptoms (e.g. pruritus) after ~6–12 weeks of induction therapy. Follow-up at regular intervals until a stable maintenance regimen is in place is advised, as is annual genital examination to exclude the development of malignancy.

Phototherapy

Phototherapy, primarily UVA1, has shown efficacy in some patients with genital LS and can be considered if topical/intralesional corticosteroids have failed. The long-term safety of UVA1 therapy in the genital region is unknown[90,91]. The successful use of photodynamic therapy (PDT) for vulvar LS has been reported in small case series and reports. Additional studies are needed to evaluate the role of PDT in treating genital LS.

Surgery

Circumcision is the treatment of choice for genital LS complicated by phimosis or paraphimosis. Excellent results have been reported[92]. Surgery in vulvar LS is indicated for the treatment of coexistent vulvar intraepithelial neoplasia, SCC, or fusion. LS will frequently recur around the scarring in females[93]. Lastly, fractional laser ablation has been used for treatment of hyperkeratotic LS plaques.

Extragenital Lichen Sclerosus

Fewer studies exist for the treatment of *extragenital* LS. Phototherapy and weekly methotrexate +/− systemic corticosteroids are potential treatment options for widespread disease, while potent topical corticosteroids and topical vitamin D analogues (e.g. calcipotriene [calcipotriol]) +/− under occlusion as well as topical calcineurin inhibitors are options for more limited disease[86,93]. When available, UVA1 phototherapy is preferred for widespread extragenital LS, followed by NB-UVB and then PUVA. The largest study to date of successful phototherapy for treating extragenital LS involved 10 patients who received 40 UVA1 sessions at a dose of 20 J/cm^2 four times/week[94]. Case reports exist for successful use of NB-UVB and PUVA[95–97].

Systemic immunosuppressive therapy is typically reserved for widespread cases that are refractory to phototherapy or in those patients who cannot undergo phototherapy. Weekly methotrexate alone (10–20 mg/week) or in combination with systemic corticosteroids (either pulsed [e.g. intravenous methylprednisolone 1000 mg/day for 3 consecutive days/month] or daily dosing [e.g. prednisone 1 mg/kg/day]) has shown efficacy in case reports and small case series[98–100]. In a case report, dupilumab led to improvement.

Chapter Contents

Systemic-Onset Juvenile Idiopathic Arthritis (Still Disease) *732*
Adult-Onset Still Disease *736*
Relapsing Polychondritis *737*
Sjögren Syndrome *738*
Mixed Connective Tissue Disease *742*
Extra-Articular Manifestations of Rheumatoid Arthritis *743*
Autoinflammatory Diseases *746*

Although all the disorders in this chapter represent inflammatory systemic diseases, there are two major groups based upon underlying pathomechanisms. Disorders such as systemic-onset juvenile idiopathic arthritis (Still disease) and inherited autoinflammatory diseases are related to abnormalities in the innate immune system whereas other disorders, including rheumatoid arthritis and Sjögren syndrome, are characterized by autoimmune-mediated tissue damage via autoreactive antigen-specific T cells and the presence of characteristic autoantibodies.

SYSTEMIC-ONSET JUVENILE IDIOPATHIC ARTHRITIS (STILL DISEASE)

Synonym: ■ Juvenile idiopathic arthritis: juvenile rheumatoid arthritis (JRA); juvenile chronic arthritis

Key features

- There are several types of juvenile idiopathic arthritis, including systemic-onset, polyarticular (either rheumatoid factor [RF]-positive or RF-negative), and oligoarticular
- Systemic-onset juvenile idiopathic arthritis, also known as Still disease, is characterized by high spiking fevers, lymphadenopathy, hepatosplenomegaly, and arthritis
- Most commonly, transient cutaneous eruptions of erythematous macules and papules, often accompanying the fevers and associated with Koebner phenomena, are seen; less often there are persistent, sometimes linear, plaques

Introduction

Juvenile idiopathic arthritis (JIA) is classified into seven major types (Table 45.1)[1], including systemic-onset, rheumatoid factor (RF)-positive polyarticular, RF-negative polyarticular, and oligoarticular. Systemic-onset JIA (sJIA), also known as Still disease, is characterized by an evanescent, erythematous eruption that typically accompanies spiking fevers. Cutaneous manifestations are less common in the other types, although the RF-positive subgroup of polyarticular JIA can present with rheumatoid nodules and other skin findings similar to those seen in adults with rheumatoid arthritis (see below), and nearly all patients with psoriatic arthritis have cutaneous and/or nail psoriasis (see Ch. 8).

History

In 1897, George Still, an English pediatrician, first described a chronic arthritis in children that was associated with fever, lymphadenopathy, and organomegaly.

Epidemiology

JIA is the most common rheumatic disease in childhood, and its overall prevalence is estimated to be 0.2–1 per 1000 children (≤16 years of age)[2]. sJIA comprises 15%–20% of all cases of JIA and can occur at any time from infancy through adolescence, with a mean age at onset of 6 years. Whereas most other types of JIA have a female predominance, sJIA affects both sexes equally. A monogenic autosomal recessive form of sJIA with an underlying mutation in *LACC1* has been described; its protein product regulates metabolism within macrophages[3].

Pathogenesis

More recent insight into the pathogenesis of sJIA suggests that it is better classified as an *autoinflammatory* rather than an autoimmune disease. The inflammation characteristic of this disease appears to result from activation of *innate* immune responses, in contrast to adaptive immune responses that are antigen-specific and lymphocyte-driven (see Ch. 4). Dysregulated production of interleukin (IL)-1 appears to play a critical role in the pathogenesis of sJIA, as exemplified by the ability of IL-1 antagonists (e.g. anakinra, rilonacept, canakinumab) to dramatically reduce disease activity in a subset of patients with sJIA (see below)[4]. The dysregulated IL-1 production may be due to inflammasome activation (see Fig. 4.2)[5] and/or dysregulation of the alternative secretory pathway downstream of caspase-1 that exerts proinflammatory effects on endothelial cells and leukocytes.

At the onset and during flares of sJIA, vascular endothelial cells express leukocyte adhesion molecules, leading to a perivascular infiltrate of neutrophils and activated monocytes that secrete proinflammatory cytokines including tumor necrosis factor (TNF), IL-1, and IL-6[6]. Many clinical features of sJIA can be explained by the effects of these cytokines. For example, IL-1 stimulates granulopoiesis in the bone marrow and activates thermoregulatory functions of the hypothalamus to cause fever. The chronic overexpression of IL-6 observed in sJIA increases osteoclastogenesis while reducing osteoblast activity and it stimulates hepatocytes to produce acute phase reactants such as C-reactive protein[7]. The association of polymorphisms in the genes that encode IL-6 and MIF with increased susceptibility to sJIA and the successful treatment of sJIA with anti-IL6R antibodies provide further support for the role of IL-6.

Clinical Features

Daily high fevers (usually above 38.9°C) that typically occur in the late afternoon or early evening are characteristic of sJIA. The arthritis is frequently polyarticular, and the joints most commonly affected are the wrists, knees, ankles and hips, followed by the small joints of the hands. A subgroup of patients may develop destructive joint disease similar to that seen in RF-positive polyarticular arthritis (see Table 45.1).

CLASSIFICATION OF JUVENILE IDIOPATHIC ARTHRITIS	
Systemic onset (15%–20%) (Still disease)	**Features required for diagnosis** • High episodic fevers – daily for ≥2 weeks and documented to be quotidian for ≥3 days • At least one of the following: *evanescent eruption*, generalized lymphadenopathy, hepatomegaly and/or splenomegaly, serositis • Symmetric polyarticular arthritis > oligoarticular arthritis (erosive in 20%)* ***Other features*** • Leukocytosis with neutrophilia, anemia (often severe), thrombocytosis, elevated ESR, elevated ferritin and C-reactive protein levels • Occasionally myocarditis, pneumonitis, anterior uveitis (<1%), CNS involvement, macrophage activation syndrome (~10%); rarely amyloidosis or interstitial lung disease due to pulmonary alveolar proteinosis and/or endogenous lipoid pneumonia (PAP/ELP) • RF- and ANA-negative in >95% of patients; absence of IBD or acute anterior uveitis
RF-negative polyarticular arthritis (15%)	• 3–9 years of age • ≥5 joints in the first 6 months • Small joints of the hands & feet > knees, wrists, ankles; erosive arthritis (15%) • RF-negative; ANA-negative
RF-positive polyarticular arthritis (5%)	• 10–16 years of age • ≥5 joints in the first 6 months • Small joints of the hands & feet > knees, wrists, ankles; erosive arthritis (>50%) • *Rheumatoid nodules*, low-grade fever, mild anemia, weight loss • RF-positive (100%): ≥2 tests at least 3 months apart during first 6 months; ANA-positive (70%)
Oligo/pauciarticular arthritis (50%): • type I – majority • type II – minority	• ≤4 joints in the first 6 months† • Knees > ankles, wrists; often asymmetric • Type I: 1–8 years of age; uveitis 30%–50%; ANA-positive 60%; RF-negative • Type II: 9–16 years of age; HLA-B27; RF-negative; ANA-negative
Enthesitis-related arthritis (5%–10%)	• Arthritis *and* enthesitis - or - • Arthritis *or* enthesitis plus ≥2 of the following: sacroiliac joint tenderness/inflammatory lumbosacral pain, HLA-B27, family history of HLA-B27-associated disease in first- or second-degree relative, acute anterior uveitis, onset of arthritis in a boy after age 6 years
Psoriatic arthritis (~5%)	• Arthritis and *psoriasis* - or - • Arthritis and ≥2 of the following: dactylitis, *nail pitting, onycholysis*, family history of psoriasis in ≥1 first-degree relative • Other features: anterior uveitis, ANA-negative
Other arthritis	• Children with arthritis of unknown cause persisting ≥6 weeks that does not fulfill criteria for any other categories or fulfills criteria for more than one category

*Onset may be delayed for months to years.
†The **persistent** oligoarticular arthritis subtype does not affect more than 4 joints, whereas the **extended** oligoarticular arthritis subtype affects a cumulative total of ≥5 joints after the first 6 months of disease.

Table 45.1 Classification of juvenile idiopathic arthritis. The previous term was juvenile rheumatoid arthritis. Enthesitis is inflammation at the site of insertion of muscles. For all the types, diagnosis requires onset before 16 years of age and duration of arthritis for ≥6 weeks in at least one joint. Reactive arthritis (formerly Reiter syndrome) should be excluded. ANA, anti-nuclear antibody; ESR, erythrocyte sedimentation rate; IBD, inflammatory bowel disease; RF, rheumatoid factor.

An exanthem is present in up to 90% of patients with the acute febrile presentation of sJIA, and it is often preceded by or accompanied by arthralgias. Although arthritis usually develops during the first few months of the disease course, in approximately one-quarter of patients the exanthem begins prior to the onset of arthritis, occasionally by several years. The eruption is typically transient, non-pruritic, and erythematous, and it coincides with fevers (Fig. 45.1A). There is a predilection for the axillae and waist, and linear lesions secondary to the Koebner phenomenon are often observed. Other less common cutaneous features include persistent plaques, which also may be linear (Fig. 45.1B,C), and periorbital erythematous edema[8]. Rheumatoid nodule-like lesions that favor extensor surfaces have been described in the setting of methotrexate therapy for sJIA[9]. Additional systemic features are outlined in Table 45.1. Although there are no laboratory findings specific for sJIA, leukocytosis, granulocytosis, thrombocytosis, elevated hepatic enzymes, an elevated ESR, and a polyclonal gammopathy are commonly observed; ANA and RF are rarely present. Serum ferritin levels are elevated.

Up to 10% of children may develop a serious and potentially lethal complication, the macrophage activation syndrome (MAS), characterized by fever, cytopenias, liver dysfunction, coagulopathy, hypofibrinogenemia, hypertriglyceridemia, and very high serum levels of ferritin (see Table 91.1). Increased serum IL-18 levels and depressed NK cell cytolytic function are also observed in patients with sJIA who develop MAS. Another serious, albeit rare, complication is severe interstitial lung disease due to pulmonary alveolar proteinosis and/or endogenous lipoid pneumonia (PAP/ELP). Acute clubbing accompanied by digital erythema may be an early sign. Lymphopenia and elevated serum levels of ferritin are seen in children with PAP/ELP as is an increased incidence of drug hypersensitivity to IL-1 and IL-6 inhibitors[10].

Pathology

The evanescent exanthem is characterized by a perivascular and interstitial neutrophil-dominant mixed infiltrate, a reaction pattern also seen in autoinflammatory diseases (see below) and referred to as a "neutrophilic urticarial dermatosis"[11]. A variable number of dyskeratotic keratinocytes, located primarily in the upper epidermal layers, is also a typical finding, especially in linear and/or persistent lesions.

Fig. 45.1 Systemic-onset juvenile idiopathic arthritis (Still disease). **A** Evanescent pink papules and figurate plaques in a child. **B, C** Persistent linear plaques on the upper back that are pink-brown in lightly pigmented skin versus violet-brown in more darkly pigmented skin. *B,C, Courtesy Julie V. Schaffer, MD.*

Differential Diagnosis

The differential diagnosis of a transient exanthem associated with fever and arthritis/arthralgias includes rheumatic fever, hypocomplementemic urticarial vasculitis, serum sickness-like reaction, and hereditary periodic fever syndromes (Table 45.2). The characteristic cutaneous findings in rheumatic fever are erythema marginatum (see Ch. 19) and urticarial lesions; rheumatic fever nodules are unusual. Patients with urticarial vasculitis may have arthralgias and fever; however, the urticarial lesions persist >24 hours and often resolve with purpura or postinflammatory hyperpigmentation. Histologic examination of recent-onset lesions demonstrates leukocytoclastic vasculitis.

Additional disorders to consider include other autoimmune connective tissue diseases; leukemia (which may present with fevers and musculoskeletal complaints prior to the development of diagnostic abnormalities in the peripheral blood) as well as other malignancies (e.g. lymphoma); and infections such as parvovirus B19, malaria, chronic meningococcemia, and rat bite fever. In children with known cystic fibrosis, relapsing-remitting episodes of arthralgias plus evanescent, slightly pruritic, salmon-pink macules have been described, typically without fever or elevated inflammation markers (cystic fibrosis-associated episodic arthritis)[12].

Treatment

The course and prognosis of sJIA is variable. In ~40%–50% of patients, the arthritis resolves completely. However, approximately one-half of the children have a chronic course that includes persistent arthritis and systemic complications such as macrophage activation syndrome (see above), hepatitis, pericarditis, and rarely amyloidosis or PAP/ELP (see Table 45.1). Patients with symptoms that persist for longer than 6 months carry a worse prognosis.

Mild articular or extra-articular disease can be treated with nonsteroidal anti-inflammatory drugs (NSAIDs). In the past, moderate or severe disease was often treated with systemic corticosteroids with or without adjuvant drugs such as methotrexate; however immunomodulators that target IL-1/IL-1R (e.g. anakinra, canakinumab) or IL-6R (e.g. tocilizumab) are increasingly employed as first-line therapy. This is due to superior effectiveness and more favorable side effect profiles, especially if used early during the course of the disease[13–18]. Inhibitors of TNF are less effective in patients with sJIA than in those with other

Schaffer, MD.*

types of JIA but they may play a role as a second-line therapy, especially for chronic polyarthritis or in combination with other steroid-sparing or immunomodulating agents (e.g. methotrexate, abatacept, azathioprine, leflunomide)[13]. Thalidomide is also a therapeutic option for children with sJIA if access to first-line therapies is limited. Hematopoietic stem cell transplantation has been successfully performed in children who have failed to respond to combinations of medications[13].

ADULT-ONSET STILL DISEASE

Synonyms: ■ Still disease in the adult ■ Adult Still disease

Key features

- A characteristic feature is recurrent episodes of high spiking fevers that often occur in the late afternoon
- An asymptomatic macular exanthem accompanies the fevers, is salmon-pink in color, and frequently demonstrates the Koebner phenomenon
- Arthritis with subsequent carpal ankylosis is a distinctive feature

Introduction

Adult-onset Still disease can be a severe debilitating systemic illness that is often difficult to diagnose. The vast majority of these patients have an exanthem, and this can be the most distinctive sign of the disorder.

Epidemiology

Adult-onset Still disease primarily affects young adults, with an onset before the age of 30 years in the majority of patients. Rarely, it occurs in individuals over the age of 60 years. Women are affected slightly more often than men.

Pathogenesis

Although the etiology of adult-onset Still disease is unknown, the underlying pathogenesis likely overlaps with that of sJIA (see above). The disease has been linked with a number of HLA antigens, suggesting a genetic component[19]; nonetheless, familial cases are uncommon. It has been hypothesized to occur in a susceptible individual as a reactive condition triggered by a variety of infectious agents, including a wide range of viruses, from enteroviruses to herpesviruses, as well as bacteria, in particular those that cause pneumonia and enterocolitis[19]. To date, however, no infectious agent has been implicated consistently.

Serum levels of IL-2, IL-6, IL-18, TNF, and IFN-γ are elevated in patients with the disease[19].

Clinical Features

The onset of the disease is frequently heralded by a sore throat and constitutional symptoms including arthralgias and myalgias. Fever is a prominent feature; it is usually above 39°C and has a spiking pattern, often occurring in the late afternoon or early evening and resolving within several hours. The skin eruption is asymptomatic and transient, occurring in association with the fever spikes. It is most often macular with a characteristic salmon-pink color (Fig. 45.2A), favors sites of pressure, and can exhibit the Koebner phenomenon. Although the trunk is most commonly involved, lesions can appear on the extremities, including the palms and soles.

Violaceous to reddish brown, scaly, persistent papules and plaques can also occur, and were observed in more than half of patients with adult-onset Still disease in a Taiwanese series[20]. Persistent erythematous eyelid edema and flagellate erythema are rare manifestations[21], both of which can mimic dermatomyositis. Persistent lesions, also categorized as "atypical", have been associated with a worse prognosis[22].

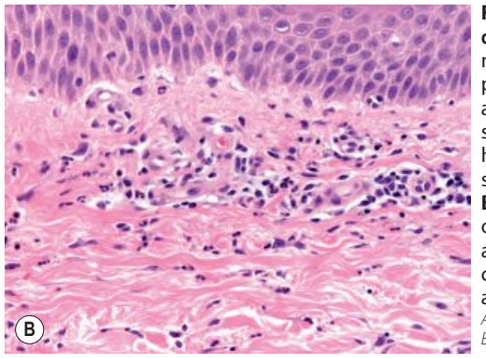

Fig. 45.2 Adult-onset Still disease. A Multiple pink macules and urticarial papules that were accompanied by a fever spike. The patient also had markedly elevated serum ferritin levels. **B** Histologic features of a mixed perivascular and interstitial infiltrate composed of neutrophils and lymphocytes. *A, Courtesy Diane Davidson, MD. B, Courtesy Lorenzo Cerroni, MD.*

Depending upon the series, arthritis occurs in 65%–100% of patients and most often affects the knees, wrists, and ankles, although other joints may also be involved. The pattern is usually symmetric, and most patients ultimately develop joint pain associated with the fever spikes. A distinctive feature of the arthritis of adult-onset Still disease is carpal ankylosis, which results in minimal pain but a limited range of motion in the carpal joints. Similar ankylosis may occur in the proximal and distal interphalangeal joints as well as the cervical spine. The metacarpophalangeal (MCP) joints are usually spared.

There may be hepatomegaly, but splenomegaly is less common. Involvement of the lungs (pleuritis, pleural effusions, pulmonary fibrosis, pulmonary arterial hypertension), heart (pericarditis, myocarditis, cardiac tamponade), and kidneys (nephritis) is rare.

Laboratory findings in adult-onset Still disease are similar to those of sJIA and include elevations in the C-reactive protein level, ESR, and platelet count. Leukocytosis and anemia are common, as are abnormalities in liver function tests. There are often significant elevations in serum ferritin levels, sometimes >4000 mg/ml, and ferritin levels may correlate with disease activity[19]; a low circulating level of glycosylated ferritin (fraction <20%) is characteristic. ANA and RF are either negative or, if present, low titer.

Pathology

Histopathologic changes of evanescent lesions are indistinguishable from those of the juvenile form of the disease (see above) and include an interstitial and perivascular neutrophil-dominant mixed infiltrate (Fig. 45.2B)[11]. Epidermal involvement is frequently seen in persistent lesions, including acanthosis, spongiosis, and/or necrotic keratinocytes within the spinous layer.

Differential Diagnosis

Adult-onset Still disease should always be considered in an adult with fever of unknown origin (defined as fever >101°F [38.3°C]

on several occasions over a period of at least 3 weeks or uncertain diagnosis after 1 week of hospitalization). The differential diagnosis is similar to that of sJIA (see above). Additionally, Schnitzler syndrome should be considered in an adult patient with recurrent fevers, arthralgia, and an urticarial eruption (see Ch. 18). In addition to non-pruritic urticaria, patients with Schnitzler syndrome have recurrent fevers, bone pain (lower extremity, iliac, and vertebral due to hyperostosis), and a monoclonal IgM gammopathy. Angioedema is observed in about 15% of these patients and lymphoplasmacytic malignancies in 10%–15%[23]. Histopathologic features are similar to those of adult-onset Still disease, i.e. a neutrophilic urticarial dermatosis[11], but the neutrophilic infiltrate may be more dense.

In patients with eyelid edema and/or persistent and linear lesions, dermatomyositis may be considered. Additional overlap occurs when there is involvement of the dorsal hands and face. Myositis, dermatomyositis-specific autoantibodies, and histopathologic features (e.g. interface dermatitis with vacuolar degeneration of the basal keratinocytes) are findings that point to the diagnosis of dermatomyositis.

Treatment

Although some patients respond to high-dose aspirin or NSAIDs, the majority require oral corticosteroids (e.g. 40–60 mg prednisone daily) to control acute systemic features. When corticosteroids cannot be tapered because of persistent arthritis, methotrexate is the most commonly employed second-line therapy. As in sJIA, biologic agents that inhibit IL-1/IL-1R (e.g. canakinumab) or IL-6R (e.g. tocilizumab) are increasingly utilized as first-line therapy for moderate to severe disease characterized by systemic inflammation without predominant joint disease[24,25]. A therapeutic response to TNF inhibitors has also been reported, especially in those patients with severe chronic polyarticular disease. Rituximab has been used effectively for refractory disease[26].

RELAPSING POLYCHONDRITIS

Synonyms: ■ Atrophic polychondritis ■ Systemic chondromalacia

Key features

- A prominent clinical feature is erythema, swelling and pain of the cartilaginous portion of the ear, followed by destruction of the cartilage
- Additional findings include nasal chondritis, which may result in a saddle nose deformity, as well as arthritis of the joints of the central chest
- The most serious complications result from ocular, renal, and respiratory tract involvement; some of the patients develop myelodysplastic syndrome

Introduction

Relapsing polychondritis is an uncommon inflammatory disorder with a suspected autoimmune origin that primarily affects cartilaginous structures. The diagnosis is usually established based upon the presence of: (1) histologically confirmed chondritis in *two* of the following three sites: auricular, nasal, or laryngotracheal cartilage; or (2) chondritis in *one* of the aforementioned sites plus at least *two* other features including: ocular inflammation, vestibular dysfunction, hearing loss, and seronegative inflammatory arthritis. Relapsing polychondritis has been associated with other autoimmune disorders (25%–30% of patients) as well as myelodysplastic syndromes, with the latter occurring primarily in the context of VEXAS (vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic) syndrome (see Ch. 53). Dermatologic manifestations may be the initial presenting sign and early diagnosis and treatment can prevent later complications, e.g. ascending aortitis, glomerulonephritis.

History

The disease was first described in 1923 by Jaksch-Wartenhorst and was called "polychondropathia". It was later renamed "relapsing polychondritis" due to its episodic nature.

Epidemiology

Relapsing polychondritis is most common in the White population, but has been reported in other races. In 80% of cases, the onset is between the ages of 20 and 60 years. Men and women are equally affected.

Pathogenesis

Although the etiology of relapsing polychondritis is unknown, the pathogenesis appears to involve an immunologic reaction, both cellular and antibody-mediated, against various extracellular matrix components of cartilage[27]. Circulating antibodies against type II collagen are present in fewer than half of affected individuals, and antibodies against types IX and XI collagen or matrilin-1 have also been described[27]; however, their clinical usefulness is unclear. That said, transmission of relapsing polychondritis to a neonate from an affected mother has been reported (with subsequent recovery of the infant), lending support to an antibody-mediated pathogenesis. Additionally, there may be a positive association with HLA-DR4.

Clinical Features

The most prominent clinical feature is erythema, swelling, and pain of the cartilaginous portion of the *auricle*, sparing the earlobe (Fig. 45.3). Symptoms can persist for several days to weeks and may encroach on the external auditory meatus, compromising hearing. Chronic inflammation leads to destruction of the cartilage, leaving the ear unsupported and scarred. During the course of the disease, 90% of patients will develop auricular involvement, and in at least 25% it is a presenting sign.

Nasal chondritis eventually develops in up to 70% of patients and may result in a saddle nose deformity. Symptoms include pain, stuffiness, crusting, rhinorrhea, epistaxis, and compromise of olfaction. Nasal chondritis is typically less recurrent than the auricular chondritis, and the saddle nose deformity is more common in men[28].

Involvement of the cartilage of the *respiratory tract* (larynx, trachea, bronchi) and/or *costochondral joints* occurs in ~50% of patients and can be the most serious complication. Signs and symptoms include

Fig. 45.3 Relapsing polychondritis. Erythema and swelling of the ear with sparing of the earlobe. *Courtesy Kalman Watsky, MD.*

cough, hoarseness, choking, dyspnea, wheezing, or tenderness to palpation of the anterior neck in sites overlying the larynx or trachea. Complications include airway obstruction or collapse, flail chest, and secondary pulmonary infections.

Arthritis is common (50%–80% of patients) and it is the presenting symptom in one-third of patients. An episodic, migratory, asymmetric, non-erosive oligo- or polyarticular arthritis can affect any joint, although the knees and MCP and proximal interphalangeal joints are those most commonly affected. There may also be involvement of the sternoclavicular and sternomanubrial joints. *Ocular* inflammation develops in ~65% of patients. It can involve virtually any component of the eye, leading to conjunctivitis, scleritis, corneal ulcerations, uveitis, or optic neuritis[28].

A variety of reactive *cutaneous* lesions are seen in patients with relapsing polychondritis[29], including aphthae, small vessel vasculitis, annular urticarial plaques, Sweet syndrome (including the lymphocytic variant), erythema elevatum diutinum, livedo reticularis, superficial thrombophlebitis, and erythema nodosum. Although none is pathognomonic and some may be coincidental or due to a coexisting disease, the presence of Sweet syndrome or vasculitis, especially in an older man, points to the diagnosis of VEXAS syndrome. In addition to cutaneous small vessel vasculitis, the presence of aphthae have been reported to increase the likelihood of an associated myelodysplastic syndrome (see Ch. 24). Also an overlap between relapsing polychondritis and Behçet disease, termed *m*outh *a*nd *g*enital ulcers and *i*nflamed *c*artilage (MAGIC) syndrome, has been reported[30].

Less common systemic features include *audiovestibular* damage, *cardiovascular* disease (aortitis, valvular dysfunction, pericarditis, conduction system abnormalities, myocarditis), *renal* dysfunction (glomerulonephritis, glomerulosclerosis, tubulointerstitial disease), *neurologic* sequelae (cranial nerve palsies, vasculitis of the central or peripheral nervous system), and deep aseptic abscesses that are responsive to corticosteroids.

Pathology

Histologically, there is breakdown of the normal lacunar structure of the cartilage, with neutrophilic infiltrates initially, followed by lymphoplasmacytic infiltrates. In late stages, there is replacement of cartilage by granulation tissue and fibrosis.

Differential Diagnosis

During the early inflammatory phase, the erythema and pain may be misdiagnosed as erysipelas or cellulitis. Red ear syndrome is a rare disorder in which there are recurrent episodes of unilateral or bilateral erythema and pain of the ears. The attacks can last from seconds to hours and possible triggers include rubbing, heat, and cold; associated disorders include migraines, neuralgias, and cervical spine disease. In Europe and Asia, borrelial lymphocytoma involving the helix may also be considered, but this location is less common than the earlobe and there is no accompanying pain. Infectious or traumatic chondritis, granulomatosis with polyangiitis, small vessel vasculitis, and congenital syphilis may mimic the cartilage destruction seen in relapsing polychondritis (Table 45.3).

DIFFERENTIAL DIAGNOSIS OF NASAL DEFORMITY OR DESTRUCTION
Neoplastic disorders
Extranodal natural killer/T cell lymphoma, nasal-type*
Squamous cell and basal cell carcinomas
Olfactory neuroblastoma, salivary gland tumors
Rhabdomyosarcoma, chondrosarcoma, other sarcomas
Inflammatory disorders
Relapsing polychondritis, including VEXAS syndrome
Granulomatosis with polyangiitis
Sarcoidosis
SAVI (STING [*st*imulator of *in*terferon *g*enes]-associated vasculopathy with onset in infancy) (see Table 45.7)
PLAID (PLCG2-associated antibody deficiency and immune dysregulation) (see Table 45.7)
Infectious disorders
Bacterial
Rhinoscleroma
Glanders
Noma
Syphilis (late congenital and tertiary)
Yaws (gangosa)
Mycobacterial
Leprosy
Tuberculosis (lupus vulgaris)
Fungal
Paracoccidioidomycosis > other dimorphic fungal infections
Zygomycosis (mucormycosis and entomophthoramycosis)
Aspergillosis
Parasitic
Mucocutaneous leishmaniasis (espundia)
Amebiasis due to free-living organisms†
Rhinosporidiosis‡
Other etiologies
Substance abuse (e.g. cocaine)
Nasal myiasis
Factitious/traumatic, including trigeminal trophic syndrome
*Previously referred to as angiocentric T cell lymphoma and lethal midline granuloma.
†Include *Acanthamoeba* spp. and *Balamuthia mandrillaris*; granulomatous centrofacial skin lesions may lead to fatal amebic encephalitis.
‡Characterized by nasal polyps; recent molecular studies have classified the causative organism, *Rhinosporidium seeberi*, as an aquatic protistan parasite, phylogenetically at the animal–fungus boundary.

Table 45.3 Differential diagnosis of nasal deformity or destruction. VEXAS, vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic[31] (see Ch. 53).

Treatment

Although relapsing polychondritis has traditionally been associated with significant morbidity and mortality, it is a treatable disease, with a survival rate of ~95% at 8 years. A comprehensive evaluation for systemic involvement, including a PET scan, should be performed prior to initiation of therapy, as systemic disease requires more aggressive treatment. The most common causes of death are pneumonia, systemic vasculitis, airway collapse, and renal failure[28]. Patients who lack tracheobronchial involvement or associated myelodysplastic syndrome have a more favorable prognosis[32].

The initial treatment is with prednisone (0.5–1 mg/kg/day; higher range doses are given if there is visceral involvement), which improves acute flares and decreases the number and severity of recurrences. NSAIDs and colchicine may decrease fever, auricular chondritis, and arthralgias; dapsone (50–150 mg/day) can also be used. Hydroxychloroquine and immunosuppressive agents (e.g. methotrexate, cyclosporine, azathioprine, cyclophosphamide, mycophenolate mofetil) have been tried alone or in conjunction with corticosteroids, with variable responses. More recently, successful results were reported with anti-IL-6R antibodies (tocilizumab), TNF inhibitors (adalimumab, infliximab), and rituximab, while abatacept and the IL-1R antagonist anakinra were less effective[33]. Tocilizumab appears to be beneficial in patients with aortic involvement[34,35]. Surgery is sometimes performed to repair damage to cartilaginous structures after the inflammation has been controlled. Patients with myelodysplastic syndrome, often in the context of VEXAS syndrome, can be particularly treatment-resistant to therapies other than moderate- to high-dose corticosteroids[33].

SJÖGREN SYNDROME

Synonym: ■ Sicca syndrome

Key features

- This autoimmune disorder primarily affects secretory glands
- The most common features are xerostomia, xerophthalmia, and arthritis
- Cutaneous manifestations include xerosis, petechiae, purpura (palpable and non-palpable), urticarial vasculitis, and annular erythema
- Serious complications include B cell lymphomas, in particular extranodal marginal zone lymphomas of the MALT (mucosa-associated lymphoid tissue) type, peripheral neuropathy, interstitial pulmonary fibrosis, and systemic vasculitis
- Patients often have an additional autoimmune disorder, in particular rheumatoid arthritis and lupus erythematosus
- Factors associated with a poorer prognosis include vasculitis, hypocomplementemia, cryoglobulinemia, and/or parotid enlargement

Introduction

Sjögren syndrome (SjS) is an autoimmune disorder that affects secretory glands, in particular the lacrimal and salivary glands. In addition to exocrine gland dysfunction, patients may develop a range of systemic manifestations due to autoimmune-mediated insults to multiple organ systems. This disease can be difficult to diagnose due to its insidious onset and initially nonspecific symptomatology. Mucocutaneous manifestations are prominent and may be the initial presenting signs. SjS may exist as a primary disorder or in association with other autoimmune diseases (secondary SjS), including rheumatoid arthritis, systemic lupus erythematosus (LE), and systemic sclerosis.

History

The first description of SjS was by Hadden in 1888. However, it was not until 1933 that Henrik Sjögren described the triad of keratoconjunctivitis sicca, xerostomia, and arthritis. Over the past several decades, the diagnostic criteria for SjS have been debated and revised, and currently the American College of Rheumatology (ACR)/European League Against Rheumatism (EULAR) 2016 Classification Criteria for Primary Sjögren's Syndrome are most often employed (Table 45.4)[36].

Epidemiology

Although SjS most commonly presents during the fourth and fifth decades, pediatric cases have been reported. The female:male ratio is 9:1 and men with this syndrome tend to have a less aggressive disease course with fewer extraglandular manifestations. SjS is one of the most common autoimmune disorders, affecting ~0.3%–0.6% of the total population[41]. The overall mortality rate in primary SjS is comparable to that in the normal population[41].

Pathogenesis

As in other autoimmune diseases, environmental factors likely trigger inflammatory events in a genetically susceptible host, resulting in the autoimmune phenomena characteristic of the disease. In SjS, it has been proposed that viral infection of the salivary glands (e.g. by EBV, HTLV-1, HCV) may stimulate the innate immune system, leading to autoimmune destruction of glandular cells due to molecular mimicry[42,43]. Upregulation of type I and II interferon gene expression, initiated by the viral infection and perpetuated by immune complexes such as anti-SSA/Ro or anti-SSB/La antibodies complexed with hYRNA, promotes activation of the adaptive immune system. The latter includes B cell activating factor (BAFF)-mediated B cell activation and proliferation as well as T cells with Th1 and Th17 phenotypes playing a leading role in glandular damage[44].

Patients with SjS frequently have hypergammaglobulinemia and autoantibodies that recognize SSA/Ro and/or SSB/La; presence of these autoantibodies increases the risk of developing subacute cutaneous lupus-like drug reactions and cutaneous small vessel vasculitis, both in patients with SjS and in those with systemic LE. Chronic antigen-driven B cell stimulation and clonal expansion may result in lymphomagenesis with development of marginal zone B cell lymphoma in salivary or lacrimal glands.

AMERICAN COLLEGE OF RHEUMATOLOGY (ACR)/EUROPEAN LEAGUE AGAINST RHEUMATISM (EULAR) 2016 CLASSIFICATION CRITERIA FOR PRIMARY SJÖGREN'S SYNDROME (SjS)

The classification of primary SjS applies to any individual who meets the inclusion criteria*, does not have any of the conditions listed as exclusion criteria†, and has a score of ≥4 when the weights from the five criteria items below are summed

Criterion	Weight/score
Labial salivary gland with focal lymphocytic sialadenitis and focus score of ≥1 foci/4 mm²‡	3
Anti-SSA/Ro-positive	3
Ocular staining score ≥5 (or van Bijsterveld score ≥4) in at least one eye¶,§	1
Schirmer's test ≤5 mm/5 min in at least one eye¶	1
Unstimulated whole saliva flow rate ≤0.1 mL/min¶,¶¶	1

*Inclusion criteria apply to any patient with at least one symptom of ocular or oral dryness, defined as a positive response to at least 1 of the following questions: (1) Have you had daily, persistent, troublesome dry eyes for more than 3 months? (2) Do you have a recurrent sensation of sand or gravel in the eyes? (3) Do you use tear substitutes more than 3 times a day? (4) Have you had a daily feeling of dry mouth for more than 3 months? (5) Do you frequently drink liquids to aid in swallowing dry food? *or* in whom there is suspicion of SjS from the EULAR SjS Disease Activity Questionnaire (at least 1 domain with a positive item).
†Exclusion criteria include prior diagnosis of any of the following conditions: (1) history of head and neck radiation treatment; (2) active hepatitis C viral infection (with confirmation by PCR); (3) AIDS; (4) sarcoidosis; (5) amyloidosis; (6) GVHD; (7) IgG4-related disease.
‡Per Daniels et al. protocol[37] and performed by an experienced pathologist.
¶Patients taking anticholinergic drugs should be evaluated after a sufficient interval without these medications for tests to be valid.
§Per Witcher et al. scoring system[38] and van Bijsterveld scoring system[39].
¶¶Per Navazesh and Kumar protocol[40].

GVHD, graft-versus-host disease. *From Shiboski CH, Shiboski SC, Seror R, et al; International Sjögren's Syndrome Criteria Working Group. 2016 American College of Rheumatology/European League Against Rheumatism classification criteria for primary Sjögren's syndrome: A consensus and data-driven methodology involving three international patient cohorts. Ann Rheum Dis. 2017;76:9–16.*

Clinical Features

The most prominent feature of SjS is xerosis of the mucous membranes, particularly of the eyes, mouth, and vagina. Keratoconjunctivitis sicca occurs as a result of destruction of the lacrimal gland, and patients may experience ocular dryness, a foreign body sensation, pain, or photophobia. Objective tests to verify decreased tear production (e.g. Schirmer test) and to assess the integrity of the corneal surface (e.g. lissamine green stain, fluorescein stain, Rose Bengal dye) should be performed by an ophthalmologist (see Table 45.4)[42]. In the Schirmer test, a piece of Whatman paper wick is folded over the lower eyelid for 5 minutes. Tear film migration that is ≤5 mm is indicative of lacrimal gland dysfunction. Complications of xerophthalmia include keratitis, corneal thinning and ulceration, and recurrent infections[42].

Xerostomia due to destruction of the major and minor salivary glands may present as dryness, soreness, or burning of the mouth and lips. Patients may have difficulty swallowing or require frequent ingestion of fluids during conversations. On examination, the infralingual salivary pool may be absent and the saliva cloudy and stringy. Although the major salivary glands (parotid and submandibular) may become transiently enlarged (~20% of patients), persistent swelling of these salivary glands or lymphadenopathy should prompt an evaluation for lymphoma. Of note, patients with SjS have an incidence rate of lymphoma that is nearly 20× that of the general population[45]; these B cell lymphomas are often extranodal and can originate in salivary as well as lacrimal glands.

Xerostomia may be assessed functionally by salivary gland scintigraphy, sialometry, or parotid sialography, but these tests are not commonly

employed. On the other hand, salivary gland biopsy is a readily available procedure and represents an important component of the diagnosis of SjS (see Table 45.4). Perlèche or thrush can result from candidal overgrowth and should be suspected when patients report a sudden increase in pain. Dental caries are common, particularly along the gingival margin, and scrupulous dental hygiene with frequent dental examinations is crucial. Because saliva has an elevated pH that neutralizes gastric acid, patients with SjS may experience more severe gastroesophageal reflux disease or gastrotracheal reflux (which can mimic upper respiratory tract infections), and aggressive reflux treatment is warranted[42].

Vaginal xerosis is common, and since many patients are perimenopausal or postmenopausal, it may be multifactorial. Symptoms include dryness, burning, and/or dyspareunia. Candidal and bacterial overgrowth are common complications.

The most common skin finding is xerosis, usually presenting as pruritus. Other cutaneous manifestations include palpable and non-palpable purpura (Fig. 45.4), urticarial vasculitis, erythema nodosum, nodular amyloidosis, and Sweet syndrome. Lesions of annular erythema, clinically reminiscent of subacute cutaneous LE or LE tumidus, have been reported primarily in Japanese patients with SjS. Whether or not these patients have an LE/SjS overlap is a matter of debate. Raynaud phenomenon has been reported in 30% of patients with primary SjS and may precede sicca symptoms by years.

Vasculitis is the most important cutaneous finding in SjS and is associated with an increased risk of morbidity and mortality[46]. Patients with cutaneous small vessel vasculitis may present with palpable purpura or with urticarial lesions and may have hypo- or normocomplementemia (see Ch. 24). Some patients develop lesions of pigmented purpura (capillaritis) or macular hemorrhage, which can be identical to the lesions seen in patients with hypergammaglobulinemic purpura of Waldenström (see Ch. 22). Of note, many of the patients with the latter disorder have evidence of autoimmune connective tissue disease, including SjS. The presence of purpura should prompt an evaluation for cryoglobulinemia. Patients found to have vasculitis, cryoglobulinemia, and/or hypocomplementemia have an increased mortality rate and an increased risk of developing B cell lymphomas[45].

Extraglandular and extracutaneous involvement may present with a diverse array of symptoms due to involvement of a variety of tissues including the lungs (interstitial pneumonitis, often subclinical), kidneys (interstitial nephritis, tubular dysfunction), bone marrow, and peripheral and central nervous systems (peripheral neuropathy, short-term memory loss, depression, immune-mediated hearing loss, multiple sclerosis-like presentation)[42]. Arthritis is a common finding; it is usually polyarticular, non-erosive, chronic and progressive, and it can be asymmetric. The most frequently involved joints are the knees and ankles. This should be distinguished from fibromyalgia, which may develop in up to 40% of patients with SjS.

As discussed above, the risk of developing B cell lymphomas is increased in patients with SjS[45]. The lymphomas are often extranodal in origin (e.g. salivary glands, lacrimal glands) and usually marginal zone lymphomas of the MALT type[47].

Fig. 45.4 Cutaneous small vessel vasculitis in a patient with Sjögren syndrome. Patients can also develop lesions of pigmented purpura (capillaritis).
Courtesy Penn State Department of Dermatology.

Laboratory Findings

Primary SjS is associated with anti-SSA/Ro (~60%–80%), and anti-SSB/La (~40%–60%) autoantibodies. Patients with secondary SjS may have additional autoantibodies, depending upon the specific autoimmune connective tissue disease (see Ch. 40).

Other laboratory abnormalities often observed in patients with SjS include an elevated ESR, hypergammaglobulinemia, and a positive RF.

Pathology

In order to establish the diagnosis of SjS, a biopsy of the minor salivary glands is often performed. The presence of one or more foci of inflammatory cells (50 or more lymphocytes) in 4 mm^2 of salivary gland tissue fulfills one of the classification criteria for SjS (see Table 45.4). A mixture of B and T cells (with a normal CD4:CD8 ratio) is usually seen.

The typical histopathologic features of pigmented purpuric eruptions, cutaneous small vessel vasculitis, cryoglobulinemic vasculitis, and urticarial vasculitis are seen in the vasculopathies associated with SjS; however, none of the histologic findings is specific for SjS.

Differential Diagnosis

Sicca symptoms are common in the elderly in part due to age-related atrophy of secretory glands. Xerostomia is a common side effect of drugs with anticholinergic properties and it may also result from previous irradiation, salivary gland stones, and chronic viral infections. Xerophthalmia can be a symptom of ocular rosacea (see Ch. 37), infiltration of the lacrimal glands (e.g. sarcoidosis, amyloidosis), irradiation, and hypovitaminosis A. It may reflect impaired blinking (e.g. Parkinson disease) or herald the onset of mucous membrane (cicatricial) pemphigoid. In addition, patients with chronic GVHD can have both xerophthalmia and xerostomia.

Early in the disease course, it may be difficult to distinguish SjS from other autoimmune connective tissue diseases. Complaints such as arthralgias and myalgias are often nonspecific. Because 50% of the salivary glands must be destroyed before symptoms arise, sicca symptoms may not be a prominent complaint initially. Patients with SjS/LE overlap can pose a diagnostic challenge. They are often anti-Ro-positive and may have prominent cutaneous disease or they may be asymptomatic but give birth to a child with neonatal LE (anti-Ro antibodies are associated with subacute cutaneous LE as well as with neonatal LE; see Ch. 41).

Treatment

Therapy for most manifestations of SjS is symptomatic. Xerophthalmia may be treated with preservative-free artificial tears and lubricating ointments. The placement of punctal plugs that occlude the nasolacrimal ducts may increase accumulation of tear film. Home humidifiers may help relieve symptoms of xerophthalmia. Cyclosporine (0.05%) eye drops may prove helpful, but can cause eye irritation and take several months to achieve a therapeutic effect; autologous serum tears may be helpful. Treatment of xerostomia is outlined in Table 45.5.

Dryness of the skin can be treated with emollients. Vaginal dryness may be improved with artificial lubricants. Frequent monitoring for and treatment of candidal and bacterial overgrowth is recommended; prophylactic use of vaginal antifungal agents is an option. In postmenopausal women, intravaginal or systemic estrogen replacement therapy can reduce compounding of symptoms.

In general, immunosuppressive agents should be reserved for patients with cutaneous vasculitis or involvement of the nervous system and internal organs. Systemic corticosteroids, hydroxychloroquine, and steroid-sparing immunosuppressants (e.g. methotrexate, azathioprine,

XEROSTOMIA – PATIENT INSTRUCTIONS	
General measures	
Avoid smoking cigarettes, cigars	• Smoking exacerbates dryness
Reduce intake of salty, spicy and acidic foods	• These foods can exacerbate dryness and cause irritation
Limit carbohydrate intake, including sugars	• These foods or drinks increase risk of dental caries
Avoid acidic (low pH) drinks	• Examples: cola (pH 2.6), herbal tea (pH varies, but can be as low as 2.5–3), coffee (pH 5) • Acceptable drinks: black tea (pH 5.7–7), tap water (pH 7)
Reduce alcohol and caffeine consumption	• They can worsen dryness
Avoid excessive sipping	• Can reduce mucous film
Avoid OTC antihistamines and decongestants	• Further decrease saliva production
Use sodium bicarbonate mouth rinse* twice daily	• Analgesic effects via its buffer action • May improve taste disturbance • Can reduce tendency for oral candidiasis
Use a humidifier in bedroom overnight	• Adds moisture to the ambient air
Saliva substitutes (oral moisturizers)	
• Contain various combinations of xylitol, hydroxyethyl cellulose, glycerin, and sorbitol; should be alcohol-free and contain fluoride or calcium phosphate • Try different products as they vary in taste, viscosity, feel of lubrication, duration of efficacy; choice based upon patient preference	
Spray, e.g. Biotene® Moisturizing Mouth Spray, Oasis® Dry Mouth Moisturizing Spray	• Use prior to speaking and during the day to assist in talking
Solution, e.g. Salivart® Oral Moisturizer, Saliva Substitute™ (Roxane)	• Use prior to eating to assist in swallowing and to form food bolus
Gel, e.g. Biotene® Oral Balance Gel	• At bedtime
Lozenges, e.g. Xylimelts®, ACT® Dry Mouth Lozenges	• Use overnight
Saliva stimulants – sialagogues	
Local	
Sugar-free†, acid-free gum or candy that contains xylitol	• Should not contain lemon, orange or citric acid • Acceptable examples: Biotene® Dry Mouth Gum • Recaldent®-containing gum may also enhance remineralization, e.g. Trident Xtra Care®
Dried fruit slices	• Example: dried peaches
Systemic‡	
• Approximately 50% of patients respond • Judge response at 8–12 weeks; at that time point, dosage can be increased • Contraindicated in patients with pulmonary disease (e.g. asthma, bronchiolitis obliterans due to GVHD), narrow angle glaucoma	
Pilocarpine (Salagen®)	• 5 mg three times daily
Cevimeline (Evoxac®)	• 30 mg three times daily
Dental care	
Avoid toothpastes that contain detergent (e.g. SLS), whiteners, or flavorings if this causes burning	• Whitening toothpastes have abrasives that can be irritating • Acceptable toothpastes: Biotene® PBF Dry Mouth Fluoride Toothpaste
Avoid commercial mouthwashes that contain alcohol or peroxide	• Acceptable mouthwashes: Biotene® Dry Mouth Oral Rinse; supersaturated calcium phosphate rinses, e.g. NeutraSal®, Caphosol®
Avoid anti-bacterial mouthwashes that contain alcohol or phenol	• Acceptable anti-bacterial mouthwashes: alcohol-free chlorhexidine gluconate mouth rinse USP 0.12% (GUM®)
Professional dental cleaning	• 3 to 4 times per year
Topical fluorides	• Fluoride rinses, e.g. ACT® Total Care Dry Mouth Rinse • Brush-on fluoride gel (can also be applied in mouth tray 5 minutes/day), e.g. PreviDent® 5000
Remineralizing agents, e.g. Seal-Rite™	• Can be applied by dentist

*Half teaspoon of sodium bicarbonate in glass of tap water.
†Not sugarless, as these products may contain fructose.
‡Also helpful for xerophthalmia.

Table 45.5 Xerostomia – patient instructions. GVHD, graft-versus-host disease; OTC, over-the-counter; SLS, sodium lauryl sulfate. *Courtesy Alison Bruce, MD.*

mycophenolate mofetil) are used in patients with serious internal manifestations. Overall, therapy with TNF inhibitors has not proven to be very useful[42]. B cell depletion with rituximab has led to conflicting results[48], with no consistent effect on fatigue or xerostomia[49]. Rituximab is probably most useful in the treatment of symptoms related to cryoglobulinemic-associated vasculitis[50]. Belimumab (anti-BAFF antibody) may play a role as a rescue therapy in refractory cases[50].

MIXED CONNECTIVE TISSUE DISEASE

Synonyms: ■ Undifferentiated connective tissue disease ■ Sharp syndrome

Key features

- The existence of mixed connective tissue disease (MCTD) as a distinct entity is controversial, as patients often have overlapping clinical and serologic features of various combinations of systemic sclerosis, polymyositis, rheumatoid arthritis, and systemic LE
- Major disease features include: high-titer IgG anti-U1 ribonuclear protein (U1RNP) antibodies, Raynaud phenomenon, swollen hands or sclerodactyly, myositis, esophageal dysmotility, and arthritis
- Compared with systemic LE, there is a lower incidence of renal disease and a higher incidence of pulmonary disease
- Pulmonary hypertension is the most serious complication

Introduction

The designation of mixed connective tissue disease (MCTD) as a distinct disease entity continues to be debated. However, there is little argument that there exists a group of patients with a constellation of serologic and clinical manifestations for whom MCTD is a useful label. These patients have high titers of antibodies to U1RNP and certain clinical features observed in other autoimmune connective tissue diseases, including arthritis, pulmonary hypertension, esophageal dysmotility, myopathy, digital swelling, and constitutional symptoms. Over time, some patients with MCTD develop manifestations more consistent with the diagnosis of systemic LE or systemic sclerosis.

History

MCTD was first described by Sharp et al.[51] in 1972, including its clinical features and the presence of an antibody to an extractable nuclear antigen.

Epidemiology

MCTD is much more common in women than in men (9:1), with most patients presenting during the second or third decade of life. The exact incidence of MCTD is unclear, especially since some authors do not consider it to be a separate entity. It is believed that "classic" MCTD is the least common of the autoimmune connective tissue diseases. In the past, the prognosis of MCTD was thought to be better than that of systemic LE; however, long-term evaluation of patients with MCTD has found their prognosis to be poorer than that expected in patients with systemic LE. The majority of deaths in MCTD have been attributable to pulmonary hypertension[52,53].

Pathogenesis

Although the pathogenesis is not clear, there appears to be an immune response to U1RNP[54]. U1RNP plays an essential role in the splicing of pre-mRNA into mRNA. Although anti-U1RNP IgG antibodies may be seen in LE, systemic sclerosis and polymyositis, titers of anti-U1RNP tend to be higher in MCTD. Of note, antibodies to EBV and cytomegalovirus cross-react with components of U1RNP, suggesting that molecular mimicry related to prior exposure to these viruses may be involved in the development of anti-U1RNP autoimmunity. Genetic studies have demonstrated an association of HLA-DR4, -DR1 and -DR2 and MHC class I polypeptide-related sequence A (MICA) in patients with MCTD[55].

Clinical Features

MCTD often presents with prominent cutaneous symptoms, including Raynaud phenomenon and edematous erythematous digits. Raynaud phenomenon is often an early manifestation, and it eventually develops in almost all patients; "ice-pick" digital infarcts or even gangrenous digits can be observed. The patients often have nailfold telangiectasias with dropout areas, and the hands and fingers may feel sclerodermatous and tight due to increased dermal collagen deposition as well as edema. Calcinosis cutis can also occur.

Poikilodermatous areas on the upper trunk and proximal extremities are common, in addition to the sclerodermoid changes of the distal extremities. However, the diffuse involvement of the face, upper trunk or extremities observed in patients with systemic sclerosis is usually not seen. Photosensitivity and lesions indistinguishable clinically and histologically from acute systemic LE (e.g. malar rash) or subacute cutaneous LE may also occur. Cutaneous small vessel vasculitis and livedoid vasculopathy may develop as well[56]. Cutaneous mucinosis, rheumatoid nodules, and orogenital mucosal lesions such as buccal ulcers and nasal septal perforation have been described[56].

An inflammatory myopathy is common in patients with MCTD. However, dermatomyositis-specific findings such as Gottron papules, a periorbital heliotrope rash, and erythema and scaling of the scalp are not usually seen. Arthralgias or polyarticular arthritis occur in 50%–70% of patients with MCTD, often early in the disease course[56]. The arthritis ranges from mild to erosive.

Pulmonary hypertension is the most serious complication of MCTD (occurring in up to 25% of patients), and it may be associated with the presence of antiphospholipid antibodies and elevated serum levels of NT-proBNP (N-terminal pro-brain natriuretic peptide)[57]. Pulmonary fibrosis, often mild, may also occur and, like pulmonary hypertension, is frequently asymptomatic early during its course. Pleurisy and pericarditis occur in ~60% of patients[58]. Periodic pulmonary examinations, chest radiographs, high-resolution CT scans, echocardiography, and pulmonary function tests are warranted. Esophageal dysmotility is common, occurring in up to 85% of patients; it can be asymptomatic, but most commonly manifests as reflux esophagitis and dysphagia.

Pathology

There are no histopathologic features pathognomonic for MCTD. The histologic findings vary depending upon the type of skin lesion examined. In general, cutaneous manifestations clinically resembling acute or subacute cutaneous LE, leukocytoclastic vasculitis, or livedoid vasculopathy will have the histopathologic features characteristic of these entities.

Differential Diagnosis

The differential diagnosis of MCTD consists primarily of systemic sclerosis, systemic LE, dermatomyositis/polymyositis, and overlap syndromes. Some patients initially diagnosed with MCTD may over time develop a preponderance of clinical and serologic features of one of these diseases, requiring a change in diagnosis. The absence of hypocomplementemia or anti-dsDNA and anti-Sm antibodies helps to distinguish MCTD from systemic LE, while myositis and more severe arthritis help distinguish MCTD from systemic sclerosis. The inflammatory myopathies usually manifest with more severe myositis than is encountered in MCTD, and the former do not usually feature the lower esophageal dysmotility common in MCTD.

Treatment

The goal of therapy in MCTD is to control symptoms and maintain function. Therapy should be tailored to the specific organ involvement and disease severity. Patients with pulmonary hypertension require longitudinal care with a pulmonologist or rheumatologist experienced in managing pulmonary complications (see Ch. 43).

In general, manifestations of MCTD that often overlap with LE or polymyositis, such as serositis, cutaneous lesions, arthritis and myositis, usually respond to corticosteroids, while scleroderma-like features such as Raynaud phenomenon and pulmonary hypertension generally do not[59]. Topical corticosteroids and systemic antimalarials are often helpful for LE-like dermatoses. Raynaud phenomenon can be treated with vasodilators in addition to non-pharmacologic measures (avoidance of cold, gloves; see Ch. 43). For severe systemic disease, a variety of therapies have been evaluated, including immunosuppressive agents (e.g. methotrexate, cyclosporine, azathioprine, mycophenolate mofetil, cyclophosphamide), plasmapheresis, and autologous hematopoietic stem cell transplantation. It is difficult to evaluate the efficacy of these treatments since there are no prospective large-scale studies, and most are based on single cases or small case series.

EXTRA-ARTICULAR MANIFESTATIONS OF RHEUMATOID ARTHRITIS

Key features

- In addition to deforming arthritis, patients can develop rheumatoid nodules, pyoderma gangrenosum, and small and medium-sized vessel vasculitis
- Other cutaneous manifestations include rheumatoid neutrophilic dermatitis and palisaded neutrophilic and granulomatous dermatitis

Introduction

Rheumatoid arthritis (RA) is a systemic disease in which the primary manifestation is inflammatory arthritis, but there can be a variety of cutaneous manifestations (see Table 53.1). Several of these can serve as helpful diagnostic clues or, in the case of rheumatoid vasculitis, point to serious illness.

Epidemiology

RA is common, affecting 1%–3% of the adult population in the US. Women are affected two to three times more often than men, and although it may develop in any age group, the peak onset is between 30 and 55 years of age.

Pathogenesis

As with other autoimmune diseases, a complex interplay between innate and acquired immune responses appears to be involved. One hypothesis is that the preclinical stage, i.e. before joint symptoms develop, involves mucosal inflammation[60]. Initiating events in the joints include the binding of extracellular matrix constituents in the synovium to Toll-like receptors, leading to the subsequent induction of inflammatory responses (increased TNF, IL-6, chemokines, and angiogenic factors) and maturation of antigen-presenting cells. A gain-of-function polymorphism in *PTPN22*, which encodes a lymphoid-specific protein tyrosine phosphatase that serves as a negative regulator of T cell activation, confers susceptibility to RA and JIA as well as other autoimmune disorders (perhaps by impairing thymic negative selection or regulatory T cells). Of note, there is a reduction in the number of regulatory T cells in RA; Th17 lymphocytes are also thought to play a pathogenic role[61].

RA is also associated with HLA-DR1 and -DR4. The HLA-DRB1 shared epitope allele, a highly significant genetic risk factor for RA, contributes to its pathogenesis primarily by increasing the propensity to develop antibodies that target citrullinated proteins (which are found in the skin and joints). Such antibodies represent specific and predictive serologic markers for RA, and they have been shown to bind the synovium and enhance tissue injury in animal models of autoimmune arthritis. A variety of infectious agents, including particular proteins produced by EBV and *Escherichia coli*, have been thought to play a role due to molecular mimicry of the hypervariable domain of HLA-DRB1*0401 or induction of anti-citrullinated protein antibody production (detected by anti-cyclic citrullinated peptide [anti-CCP] antibody assays).

Clinical Features

Rheumatoid nodules

Rheumatoid nodules are present in 20% of patients with RA, and they occur in patients with moderate to high titers of RF (IgG, IgM, or IgA). Most, if not all, of the cases of seronegative RA with "rheumatoid nodule"-like lesions were proven to be subcutaneous granuloma annulare or other entities with palisading granulomas histologically (see Ch. 93). Rheumatoid nodules are firm, semi-mobile papulonodules that occur most commonly in periarticular locations over extensor surfaces (Fig. 45.5), and in areas subject to pressure or trauma. They range from several millimeters to as large as 5 cm in diameter and are typically asymptomatic. Occasionally the nodules are tender or painful, especially if there is associated trauma or ulceration. Rheumatoid nodules may also occur in visceral organs.

Accelerated rheumatoid nodulosis is characterized by the sudden appearance of multiple rheumatoid nodules (Fig. 45.6). Lesions usually appear following the initiation of methotrexate therapy, but rarely can occur after the initial administration of TNF inhibitors, leflunomide, or tocilizumab. In some of these patients, there had also been a tapering of systemic corticosteroids. Methotrexate can also induce a papular eruption whose histologic features overlap with those of interstitial granuloma annulare and reactive granulomatous dermatitis (see Ch. 93)[62].

Fig. 45.6 Methotrexate-induced nodulosis in a patient with rheumatoid arthritis. *Courtesy Jean L. Bolognia, MD.*

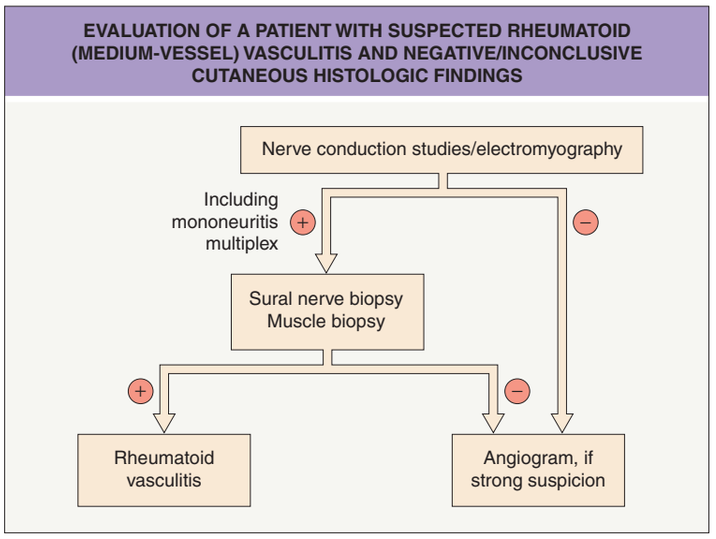

Fig. 45.7 Evaluation of a patient with suspected rheumatoid vasculitis (involving medium-sized vessels) in whom cutaneous histologic findings are negative or inconclusive.

Rheumatoid vasculitis

Rheumatoid vasculitis is a rare and typically late complication of RA. It is thought to occur in only 2%–5% of those with RA, but, at autopsy, vasculitis has been found in up to a third of patients. Rheumatoid vasculitis typically occurs in the context of high-titer RF, rheumatoid nodules, and a history of severe erosive arthritis. The vasculitis may affect vessels of any size, and the clinical presentations reflect this, with palpable and non-palpable purpura in small vessel disease versus nodules, ulcerations, necrotizing livedo reticularis, and/or digital infarcts in medium-sized vessel disease[63]. Systemic manifestations of rheumatoid vasculitis can include neuropathies, cerebral infarction, scleritis, alveolitis, carditis, intestinal ulcers, and proteinuria.

Clinicopathologic correlation and serologic assessment should be performed when rheumatoid vasculitis is suspected. For example, if an ulcer is biopsied, a wedge perpendicular to the edge of the ulcer which includes both surrounding non-ulcerated skin as well as the ulcer base should be obtained. In up to 40% of patients with RA and medium-sized vessel vasculitis, there is evidence of a peripheral neuropathy (subclinical or clinical) that often presents as mononeuritis multiplex. This incidence seems to be even higher in patients with extensive cutaneous disease. Therefore, if vasculitis cannot be identified after multiple deep skin biopsies but the diagnosis is still suspected, nerve conduction studies followed by sural nerve biopsy (or a muscle biopsy) can be performed (Fig. 45.7). Mortality may be as high as 40%[64], and, therefore, aggressive intervention is warranted.

Bywaters lesions

Bywaters lesions include nailfold thromboses and purpuric papules on the distal digits, especially the digital pulp (see Fig. 53.4). Histologically, there is a small vessel leukocytoclastic vasculitis. Typically these lesions are not associated with systemic vasculitis.

Felty syndrome

Felty syndrome represents an uncommon but severe subset of seropositive RA that is characterized by granulocytopenia, splenomegaly, and therapy-resistant leg ulcers (often pretibial). These patients are predisposed to cutaneous and systemic infections that can be refractory to standard treatment, and they are at increased risk of lymphomas and leukemias. The ulcers are likely multifactorial and may be secondary to pyoderma gangrenosum, medium-sized vessel vasculitis (although vasculitis is often not confirmed histologically), venous hypertension, immobilization (ankle ankyloses), neuropathy, or perhaps an ulcerating form of palisaded neutrophilic and granulomatous dermatitis (PNGD)[65].

Neutrophilic dermatoses

Sterile infiltration of the skin by neutrophils can occur in patients with RA. The primary disorders are pyoderma gangrenosum (PG), Sweet syndrome, and rheumatoid neutrophilic dermatitis (see Chs. 25 & 53), but there may be overlap and the term "neutrophilic dermatosis" is often used. Pyoderma gangrenosum occurs at a higher frequency in patients with RA than in the general population. Lesions can develop on the lower extremities (Fig. 45.8), as well as less common locations such as the abdomen and face.

Fig. 45.8 Pyoderma gangrenosum in a patient with rheumatoid arthritis. The chronic relapsing ulcerations involved the lower extremities.
Courtesy Carlos H. Nousari, MD.

Rheumatoid neutrophilic dermatitis (also referred to as rheumatoid neutrophilic dermatosis) resembles Sweet syndrome, both clinically and histologically. It occurs in patients with severe and usually seropositive RA, and it is characterized by erythematous urticarial papules and plaques that are persistent and asymptomatic, but occasionally ulcerate. Lesions are symmetrically distributed, most commonly on the extensor forearms and hands, but they can occur elsewhere.

Other

Patients with RA may also develop erythema elevatum diutinum (EED; see Ch. 24), PNGD (see Ch. 93), and intralymphatic histiocytosis (see Fig. 121.6) as well as a number of cutaneous side effects from medications used to treat the arthritis (see Table 53.1). In RA patients receiving methotrexate, EBV-associated lymphoproliferative disease may involve the skin.

Pathology

Rheumatoid nodules are typically located in the deep dermis or subcutis and are composed of a central zone of brightly eosinophilic fibrin surrounded by a palisaded layer of histiocytes and granulation tissue (Fig. 45.9). Acute or early lesions may show leukocytoclastic vasculitis and/or an interstitial neutrophilic infiltrate.

The histopathologic findings of PG, Sweet syndrome, and small, medium-sized and large vessel vasculitis are discussed in Chapters 24 and 25. When rheumatoid vasculitis affects medium-sized vessels, it can be histologically indistinguishable from polyarteritis nodosa. Direct immunofluorescence in rheumatoid vasculitis shows prominent deposition of IgM as well as C3 in small and medium-sized vessels, whereas in polyarteritis nodosa the IgM and C3 vascular deposits are weaker and sparse and limited to medium-sized vessels.

Differential Diagnosis

Although rheumatoid nodules share several histologic features with PNGD, in the latter the clinical lesions are more polymorphous, with papules and plaques rather than periarticular skin-colored nodules. Because both the clinical and histologic findings can be similar, subcutaneous granuloma annulare may be misdiagnosed as rheumatoid nodules. However, individuals with subcutaneous granuloma annulare are otherwise healthy and are usually children. Occasionally, gouty tophi, tuberous xanthomas, and late-stage EED may be mistaken clinically for rheumatoid nodules.

The differential diagnosis of cutaneous vasculitis is discussed in detail in Chapter 24. Specifically, rheumatoid vasculitis may be confused with mixed cryoglobulinemia given the presence of arthritis, RF, and complement activation in both entities. However, in the former the titer of RF is significantly higher and levels of both C3 and C4 are decreased,

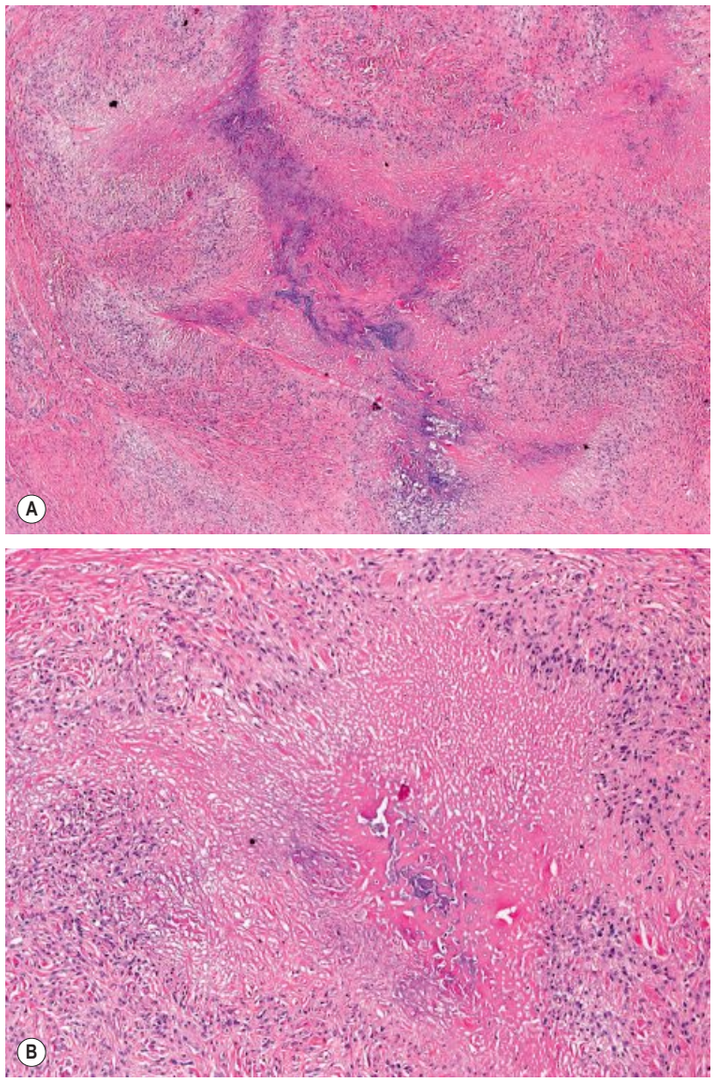

Fig. 45.9 Rheumatoid nodule – histopathologic features. A Large, irregular area of necrobiosis surrounded by a palisade of histiocytes. **B** Details of necrobiosis and palisade of histiocytes with elongated nuclei.

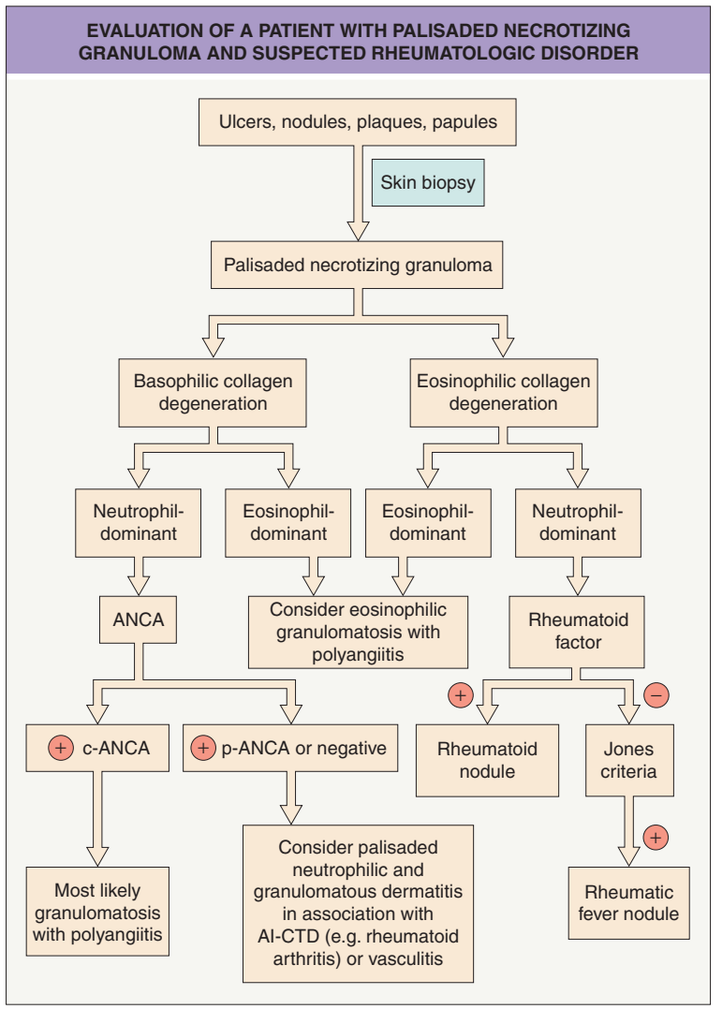

Fig. 45.10 Evaluation of a patient with palisaded necrotizing granuloma and suspected rheumatologic disorder. Jones criteria for rheumatic fever are reviewed in Chapter 19. AI-CTD, autoimmune connective tissue disease.

whereas in cryoglobulinemia C4 levels are low with relatively normal levels of C3. Bywaters lesions may resemble septic emboli, traumatic lesions and, less often, pernio.

As previously mentioned, rheumatoid neutrophilic dermatitis resembles Sweet syndrome, but could also be mistaken for urticaria or urticarial vasculitis. Ulcerations in RA and Felty syndrome may have a variety of causes, including PG, rheumatoid vasculitis, superficial ulcerating rheumatoid necrobiosis (see Fig. 53.3) and secondary antiphospholipid syndrome, as well as infections (especially in patients receiving immunosuppressives), lymphoma (particularly angiocentric variants), and thromboembolic disorders.

The evaluation of a patient with the histologic finding of palisaded necrotizing granulomas and a suspected rheumatologic disorder is outlined in Fig. 45.10.

Treatment

RA therapy is aimed at improving symptoms and preventing end-organ damage. Some of the cutaneous manifestations may improve with treatment of the joint disease, while others (e.g. rheumatoid nodules) often persist. Rheumatoid nodules can be excised, but recurrence is common. Intralesional corticosteroid injections may decrease the size of the nodules, but do not lead to complete resolution. Rheumatoid neutrophilic dermatitis is treated with oral corticosteroids or antineutrophilic agents such as dapsone or colchicine, while Felty syndrome may be treated with recombinant granulocyte colony-stimulating factor (G-CSF) and/or splenectomy.

Rheumatoid vasculitis involving medium-sized and large vessels requires aggressive treatment as it can be rapidly progressive and life-threatening. Intravenous methylprednisolone (500–1500 mg/day for 3 days) followed by prednisone (1 mg/kg/day) plus cyclophosphamide (daily or monthly) and plasmapheresis should be considered.

In less severe cases, including the small vessel variant of rheumatoid vasculitis, azathioprine and mycophenolate mofetil may be considered; methotrexate does not have a consistent effect in this complication of RA. Although there are reports of vasculitis developing in patients with RA after the initiation of TNF inhibitors, there are also multiple reports documenting their beneficial effects in the treatment of rheumatoid vasculitis[63,65]. Several reports have also documented improvement in rheumatoid vasculitis after rituximab therapy[63,65]. Recurrences of rheumatoid vasculitis are less likely to occur when a stable, long-term regimen re-establishes control of the underlying RA.

For the treatment of RA-associated PG, systemic corticosteroids and cyclosporine are highly effective. Excellent results have also been reported with TNF inhibitors. Additional treatments are reviewed in Chapter 25.

Treatment of the inflammatory arthritis consists of NSAIDs, low-dose systemic corticosteroids, disease-modifying antirheumatic drugs (e.g. hydroxychloroquine, leflunomide, methotrexate, sulfasalazine), biologic immunomodulators (e.g. TNF inhibitors, abatacept, tocilizumab, rituximab), and JAK inhibitors.

AUTOINFLAMMATORY DISEASES

RANGE OF CUTANEOUS FINDINGS IN INHERITED AUTOINFLAMMATORY DISEASES					
		Treatment*			
		Inhibition of:			
Cutaneous and histologic features	Inherited autoinflammatory disease(s)	IL-1	TNF	Other	Sporadic or complex disorders with similar findings
Evanescent maculopapular/urticarial eruption (often a neutrophilic infiltrate within the dermis [neutrophilic urticarial dermatosis])	Cryopyrin-associated periodic syndrome	√			• Schnitzler syndrome (Ch. 18) • *Adult-onset Still disease* • *Systemic-onset juvenile idiopathic arthritis (sJIA; Still disease)*
Ulcerations (a sterile neutrophilic infiltrate within the dermis† as in pyoderma gangrenosum)	PAPA spectrum disorders‡ PAAND	√	√		Pyoderma gangrenosum – idiopathic and in the setting of associated disorders (e.g. ulcerative colitis) (Ch. 25)
Pustules (sterile)	DIRA	√			• Generalized pustular psoriasis • Impetigo herpetiformis • SAPHO syndrome (Ch. 25) • Acne fulminans
	DITRA		√	√ [IL-17, IL-12/23 inhibitors]	
	PAPA syndrome‡	√	√		
	CAMPS			IL-12/-23 inhibitors	
Edematous papules, plaques, and nodules (a mainly neutrophilic infiltrate within the dermis and/or panniculus)	Majeed syndrome	√		√ [CS]	Sweet syndrome – idiopathic or occurring in the setting of associated disorders (e.g. acute myelogenous leukemia) (Ch. 25)
Also folliculitis and pathergy	Haploinsufficiency of A20	√	√	√ [colchicine]	• Behçet disease
	OTULIN-related autoinflammatory syndrome (ORAS)		√		
Livedo racemosa with nodules, digital necrosis (medium-sized vessel vasculitis or thrombotic vasculopathy)	ADA2 deficiency		√		• Sneddon syndrome • Sporadic polyarteritis nodosa
Periorificial violaceous erythema, lipodystrophy, and recurrent plaques that resemble cutaneous LE or dermatomyositis (atypical myeloid infiltrate)	Proteasome-associated autoinflammatory syndrome/ CANDLE syndrome/Nakajo–Nishimura syndrome			√ [JAK inhibitors]	• Lupus erythematosus • Dermatomyositis
Acral violaceous erythema with telangiectasia and sometimes ulcerations, often exacerbated by cold exposure (inflammatory and/or thrombotic microangiopathy)	STING-associated vasculopathy of infancy Aicardi– Goutières syndrome			√ [JAK inhibitors]	• Pernio • Lupus erythematosus • Dermatomyositis • Antiphospholipid syndrome
Small papules > plaques (granulomatous infiltrate)	Blau syndrome		√	√ [CS]	• Sarcoidosis • Crohn disease
Follicular papules and spines, coalescing keratosis (acanthosis and dyskeratosis)	*NLRP1*-associated autoinflammation with arthritis and dyskeratosis			√ [acitretin]	• Pityriasis rubra pilaris • Keratosis lichenoides chronica
Psoriasiform lesions	CAMPS (spectrum includes CAPE)			√ [IL-12/23 inhibitors]	• Psoriasis • Pityriasis rubra pilaris

*Given the rarity of many of the disorders, may be based on case reports or small series.
†Untreated lesion.
‡PAPA spectrum disorders are a group of diseases sharing two main clinical features, pyoderma gangrenosum (P) and propensity to severe acne (A), which may be associated with: pyogenic arthritis (PA) in PAPA syndrome; hidradenitis suppurativa (SH) in PASH syndrome; pyogenic arthritis and hidradenitis suppurativa in PAPASH syndrome; psoriatic arthritis (PsA) and hidradenitis suppurativa in PsAPASH syndrome; ankylosing spondylitis and hidradenitis suppurativa in PASS syndrome; ulcerative colitis (C) in PAC syndrome; or hepatosplenomegaly and pancytopenia in PSTPIP1-associated myeloid-related proteinemia inflammatory (PAMI) syndrome. Most of them have been linked to mutations in *PSTPIP1*, except for PsAPASH and PASS that still lack genetic characterization.

Table 45.6 Range of cutaneous findings in inherited autoinflammatory diseases. Disorders discussed in this chapter are in *italics*. Cutaneous vasculitis and neutrophilic dermatosis can also be seen in VEXAS (vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic) syndrome[31], but the mutations in *UBA1* on the X chromosome are somatic (see Ch. 53). See Tables 45.2 and 45.7 for details of inherited autoinflammatory diseases. ADA, adenosine deaminase; CAMPS, CARD14-mediated psoriasis; CANDLE, chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature; CAPE, CARD14-associated papulosquamous eruption; CS, corticosteroids; DIRA, deficiency of interleukin-1 receptor antagonist; DITRA, deficiency of interleukin-36 receptor antagonist; PAAND, pyrin-associated autoinflammation with neutrophilic dermatosis; SAPHO, synovitis, acne, pustulosis, hyperostosis, osteitis.

Key features

- Monogenic diseases related to aberrant activation of the innate immune system that are characterized by recurrent fevers and flares of multi-organ inflammation; the skin is frequently involved as are the joints, eyes, and serosae
- This group includes the hereditary periodic fever syndromes, deficiency of the interleukin (IL)-1 receptor antagonist (DIRA), pustular psoriasis due to abnormal IL-36 signaling, and interferonopathies
- The cutaneous lesions reflect their pathomechanism and nosographic context:
  - aseptic neutrophilic dermatoses presenting as evanescent urticarial papules, sterile pustules, pyoderma gangrenosum, and Sweet syndrome
  - acne and hidradenitis suppurativa
  - cold-induced dermatoses presenting as pernio-like lesions and acral necrosis
  - panniculitis and lipoatrophy
  - vasculitis and livedo reticularis
  - granulomatous dermatoses and disorders of keratinization
- Increased production of IL-1 via inflammasomes can be seen and several of these entities respond to IL-1/IL-1R antagonists, e.g. anakinra, rilonacept, canakinumab
- Complex disorders such as Schnitzler syndrome, systemic-onset juvenile idiopathic arthritis (Still disease), and lupus erythematosus share mechanistic and clinical features

EXAMPLES OF INHERITED AUTOINFLAMMATORY DISEASES WITH CUTANEOUS MANIFESTATIONS

Disease	Proposed mechanism	Protein product of mutated gene (gene)	Mode of inheritance	Predominant ethnic group(s)	Age of onset	Clinical features	Treatment
Inflammasomopathies and other IL-1 family-related conditions (see Table 45.2 for additional entities)							
AIFEC (autoinflammation with infantile enterocolitis)*	NLRC4 activation	NLRC4 *(NLRC4)*	AD	Caucasian	Early infancy	Urticarial eruption with dermographism Enterocolitis Macrophage activation syndrome	IL-1 antagonists, e.g. anakinra, rilonacept, canakinumab IL-18 antagonists
DIRA (deficiency of interleukin-1 receptor antagonist)	Receptor antagonist deficiency	Interleukin [IL]-1 receptor antagonist *(IL1RN)*	AR	Puerto Rican, Brazilian, Lebanese, Newfoundlanders, Dutch	Neonatal	Pustules within areas of erythema – appearance similar to pustular psoriasis (Fig. 45.11A) Sterile osteolytic bone lesions Neonatal distress	IL-1 antagonists – often a dramatic response
DITRA (deficiency of IL-36 receptor antagonist)*	Receptor antagonist deficiency	Interleukin [IL]-36 receptor antagonist *(IL36RN)*	AR	Tunisian, Lebanese	Childhood to adulthood; can flare with pregnancy	Pustules within areas of erythema – resembles generalized pustular psoriasis (Fig. 45.11B)	Oral retinoids IL-1 antagonists – pustules may respond better than papulosquamous lesions IL-17 inhibitors IL-12/23 or IL-23 inhibitors
NAIAD (*NLRP1*-associated autoinflammation with arthritis and dyskeratosis)	NLRP1 activation	NLRP1 *(NLRP1)*	AD	Algerian Dutch	Early infancy	Follicular hyperkeratosis Arthritis Corneal and laryngeal dyskeratosis	IL-1 antagonists TNF inhibitors
PAAND (pyrin-associated autoinflammation with neutrophilic dermatosis)	Pyrin activation	Pyrin *(MEFV)*	AD	Spanish	Puberty	Recurrent pyoderma gangrenosum, severe pustular acne, neutrophilic panniculitis Arthritis	TNF inhibitors
PAPA spectrum disorders (see footnote Table 45.6)	Pyrin activation Cytoskeletal dysregulation	Proline-serine-threonine phosphatase-interacting protein 1 *(PSTPIP1)* To date, genetic bases unknown for PsAPASH and PASS	AD	Northern European	Childhood	See footnote Table 45.6; Fig. 45.11H	TNF inhibitors IL-1 antagonists Corticosteroids
NOCARH (neonatal onset cytopenias with dyshematopoiesis, autoinflammation, rash, and episodes of HLH)	Pyrin activation Cytoskeleton dysregulation	Cell divison cycle 42 *(CDC42)* Mutations in C-terminal domain	AD	Ethnically diverse	Neonatal	Urticarial plaques, some annular Fever, diarrhea, pancytopenia, death due to HLH	Corticosteroids Emapalumab IL-1 antagonists HSCT

Table 45.7 Examples of inherited autoinflammatory diseases with cutaneous manifestations. (cont'd)

EXAMPLES OF INHERITED AUTOINFLAMMATORY DISEASES WITH CUTANEOUS MANIFESTATIONS							
Disease	**Proposed mechanism**	**Protein product of mutated gene (gene)**	**Mode of inheritance**	**Predominant ethnic group(s)**	**Age of onset**	**Clinical features**	**Treatment**
Aberrant NF-κB and/or TNF activity							
ADA2 deficiency	Dysregulation of TNF	Adenosine deaminase 2 *(CECR1)*	AR	Georgian Jewish, German, Turkish	Infancy to adulthood	Childhood-onset polyarteritis nodosa Livedo racemosa (Fig. 45.11G) Early-onset strokes Hepatosplenomegaly Hypogammaglobulinemia, severe cytopenia	TNF inhibitors Allogeneic HSCT
ADAM17 deletion/ neonatal-onset inflammatory skin and bowel disease	Dysregulation of TNF	ADAM metallopeptidase domain 17 *(ADAM17)*	AR	Not known	Neonatal	Psoriasiform erythroderma and widespread pustules Short hair, wiry eyelashes & eyebrows Onychauxis, paronychia Diarrhea, often bloody; malabsorption	TNF inhibitors plus IL-12/23 inhibitors
Blau syndrome (familial juvenile systemic granulomatosis)	Dysregulation of NF-κB signalling	Nucleotide-binding oligomerization domain [NOD] containing 2 *(NOD2)*	AD	Not known	Childhood	Numerous tiny papules (Fig. 45.11C) Granulomatous infiltrate in dermis Uveitis Early-onset, symmetric, granulomatous polyarticular arthritis	Corticosteroids TNF inhibitors (e.g. infliximab) MTX, CSA IL-1 antagonists JAK inhibitors
Type I interferonopathies (increased IFN signaling)							
Aicardi–Goutières syndrome (AGS)/ familial chilblain lupus (FCL)	Nucleic acid processing and degradation	3′ repair exonuclease 1 (*TREX1*), SAM- and HD-domain containing protein 1 (*SAMHD1*) for AGS or FCL; adenosine deaminase, RNAspecific (*ADAR1*), interferon induced with helicase C domain 1 (*IFIH1*), and ribonuclease H2, subunits A, B or C (*RNASEH2A/B/C*) for AGS	AR >> AD (AGS) AD (FCL)	Ethnically diverse	Neonatal or infancy (AGS) to childhood (FCL)	Pernio-like lesions on hands, feet and ears (Fig. 45.11E) Arthritis (FCL) Encephalopathy with white matter changes and progressive developmental delay (AGS)	Difficult to treat JAK inhibitors
PRAAS (proteosome associated autoinflammatory syndrome)/ CANDLE (chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature) syndrome/ Nakajo–Nishimura syndrome	Proteasome dysfunction disturbing intracellular protein homeostasis	Proteasome subunit, beta type, 8 (*PSMB8*), 4 (*PSMB4*), 9 (*PSMB9*) or 10 (*PSMB10*) Proteasome subunit, alpha type, 3 (*PSMA3*) Proteasome subunit, gamma type, 2 (*PSMG2*) Proteasome maturing protein (*POMP*)	AR (except for *POMP* mutations, AD) Can be digenic, e.g. *PSMB8* & *PSMA3*	Japanese, Spanish, Ashkenazi Jewish	Infancy	Violaceous plaques that can be annular, pernio-like lesions, eyelid edema and erythema Myeloid infiltrate in dermis – varies from immature to mature cells Partial lipomuscular atrophy, joint contractures Basal ganglia calcification (Fig. 45.11F)	JAK inhibitors Corticosteroids MTX

Table 45.7 Examples of inherited autoinflammatory diseases with cutaneous manifestations.

EXAMPLES OF INHERITED AUTOINFLAMMATORY DISEASES WITH CUTANEOUS MANIFESTATIONS							
Disease	Proposed mechanism	Protein product of mutated gene (gene)	Mode of inheritance	Predominant ethnic group(s)	Age of onset	Clinical features	Treatment
SAVI (STING [*st*imulator of *in*terferon *g*enes]-associated vasculopathy with onset in infancy)	Nucleic acid sensing	Stimulator of interferon genes (*STING1*)	AD (rarely, AR)	European, Turkish	Early infancy	Acral (digits, ears, nose) infarcts, ulcerations, and gangrene Bone resorption with loss of digits, including nails (Fig. 45.11D) Acral violaceous plaques Nasal septum perforation Interstitial lung disease	JAK inhibitors
Disorders of ubiquitination							
Haploinsufficieny of A20	Dysregulation of NF-κB signaling	NF-κB regulatory protein A20 (*TNFAIP3*)	AD	Ethnically diverse	Childhood	Recurrent oral and genital ulcers, pathergy, erythema nodosum-like lesions Scarring chorioretinitis Gastrointestinal ulcers Arthralgias/arthritis	JAK inhibitors IL-1 antagonists TNF inhibitors Colchicine
***OTULIN*-related autoinflammatory syndrome (ORAS)**	Dysregulation of NF-κB signaling	OTU deubiquitinase with linear linkage specificity (*OTULIN*)	AR	Consanguinity	Infancy	Panniculitis, lipodystrophy, large urticarial plaques Arthralgias	TNF inhibitors IL-1 antagonists
Other mechanisms							
APLAID (autoinflammation and PLCG2-associated antibody deficiency and immune dysregulation)	Intracellular calcium signaling	Phospholipase C, γ2 (*PLCG2*)	AD	Caucasian	Early childhood	Variable presentation, from vesicles that resemble epidermolysis bullosa to erythematous plaques that resemble cellulitis, sometimes evolving to cutis laxa Ocular inflammation Interstitial pneumonitis Enterocolitis Mild to severe immunodeficiency	Not known
PLAID (PLCG2-associated antibody deficiency and immune dysregulation)	Intracellular calcium signalling	Phospholipase C, γ2 (*PLCG2*)	AD	Ethnically diverse	Childhood	Familial cold autoinflammatory syndrome (FCAS)-3 Cold air-induced/evaporative cooling-induced urticaria and angioedema, neonatal nasal ulcers Non-infectious cutaneous granulomas in a subset of patients Recurrent infections, antibody deficiency, autoimmunity	Protection from cooling H1 anti-histamines Antibiotic prophylaxis and/or IVIg based upon frequency of infections
IL-10/IL-10R deficiency	Cytokine dysregulation	Interleukin [IL]-10 (*IL10*) Interleukin [IL]-10 receptor α & β (*IL10RA*, *IL10RB*)	AR	Turkish, Lebanese	Neonatal	Folliculitis, primarily with IL-10R deficiency Severe infantile (very early-onset) enterocolitis	Allogeneic HSCT (case reports)

*Spectrum includes familial cold autoinflammatory syndrome-4 (FCAS4) which presents with fever, urticarial eruption, arthralgias, conjunctivitis, and panniculitis (adults).

Table 45.7 Examples of inherited autoinflammatory diseases with cutaneous manifestations. The classic hereditary periodic fever syndromes are outlined in Table 45.2. *Most of these disorders are also characterized by recurrent fevers and elevations in acute phase reactants.* AD, autosomal dominant; AR, autosomal recessive; CSA, cyclosporine; HLH, hemophagocytic lymphohistiocytosis; HSCT, hematopoietic stem cell transplant; IFN, interferon; JAK, Janus kinase; MTX, methotrexate; NLRC4, NLR family CARD domain containing 4; NLRP1, NLR family pyrin domain containing 1; TNF, tumor necrosis factor.

Autoinflammatory diseases encompass the monogenic inflammatory diseases that reflect aberrant activation of the *innate* immune system[66], in contrast to autoimmune diseases where there is dysregulation of the adaptive immune system with formation of autoantibodies and T cell-mediated tissue damage. That said, some degree of autoimmunity or immune deficiency can be seen in autoinflammatory diseases[67].

As a group, autoinflammatory diseases are characterized by recurrent fevers and flares of multi-organ inflammation. These episodes are seemingly unprovoked and frequently involve the skin as well as the joints, eyes, and serosae. Oftentimes, these tissues contain sterile infiltrates of neutrophils. The cutaneous findings vary and include sterile pustules, transient urticarial papules, ulcerations, livedo reticularis, and pernio-like lesions (Table 45.6; see Table 45.2)[66]. It is important to appreciate the significant overlap these rare disorders have with more common polygenic disorders such as pustular psoriasis and chilblains. Their inclusion in the differential diagnosis, especially in early-onset or treatment-resistant disease, often allows for more specific therapy to be instituted.

Table 45.7 outlines the key features, in particular dermatologic, of several monogenic autoinflammatory diseases. The genetic basis of a number of these entities has only been described in the past several years so these diseases may not yet be that familiar to dermatologists. Of note, the pathophysiology of a significant percentage of the disorders in Table 45.6, as well as the cryopyrin-associated periodic syndromes (CAPS; see Table 45.2), involves interleukin (IL)-1 overactivity. There can be excessive production (e.g. CAPS) or defective inhibition (e.g. DIRA) of IL-1 (Fig. 45.12). This provides an explanation for the therapeutic efficacy of IL-1/IL-1R antagonists, including anakinra, rilonacept, and canakinumab (Fig. 45.13).

Histologically, the cutaneous infiltrates in patients can vary from granulomas within the dermis (Blau syndrome) to pustules within the epidermis (DIRA, CARD14-induced pustular psoriasis). A characteristic finding in patients with the hereditary periodic fever syndromes (see Table 45.2) has been termed "neutrophilic urticarial dermatosis"; biopsy specimens of transient urticarial papules demonstrate perivascular and interstitial infiltrates of neutrophils within the dermis[11].

Fig. 45.11 Cutaneous manifestations of inherited autoinflammatory disorders. A Annular erythematous plaques studded with pustules in an infant with deficiency of the interleukin-1 receptor antagonist (DIRA); note the similarity to pustular psoriasis. **B** Child with deficiency of interleukin-36 receptor antagonist (DITRA) – widespread psoriasiform plaques whose edges contain pustules. **C** Blau syndrome with numerous, small, pink-tan, flat papules in a generalized distribution in a 1-year-old boy; histologically, a granulomatous infiltrate is seen. **D** STING (*st*imulator of *in*terferon *g*enes)-associated vasculopathy with onset in infancy (SAVI) is characterized by acral violaceous plaques and resorption of digits and loss of nails; patients may be diagnosed as having Aicardi–Goutières syndrome, antiphospholipid antibody syndrome, or vasculitis. **E** Aicardi–Goutières syndrome with pernio-like lesions. **F** Chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE) syndrome with deforming arthritis (e.g. swan neck deformity) and thin pink plaques overlying the metacarpophalangeal joints that resemble dermatomyositis. **G** Livedo racemosa in a patient with adenosine deaminase 2 (ADA2) deficiency. **H** Cystic acne and extensive scarring in a pediatric patient with pyogenic arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome. *A, Courtesy Gillian Clarke, MD. B, Courtesy Antonio Torrelo, MD. C,E, Courtesy Julie V. Schaffer, MD. D,F–H, Courtesy Edward Cowen, MD.*

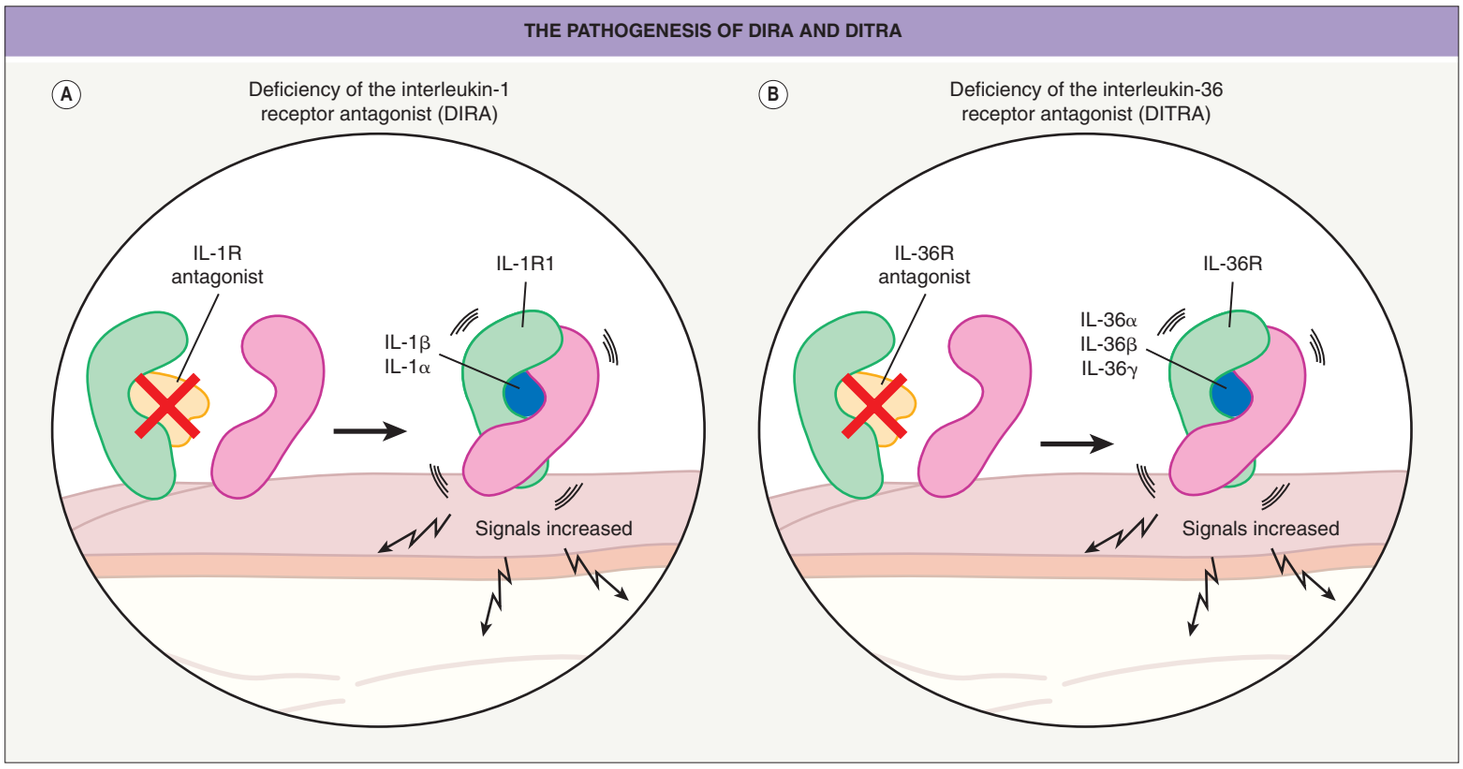

Fig. 45.12 The pathogenesis of DIRA (deficiency of interleukin-1 receptor [IL-1R] antagonist) and DITRA (deficiency of interleukin-36 receptor [IL-36R] antagonist). A Loss of the IL-1R antagonist leads to unopposed proinflammatory signaling by IL-1α and IL-1β in patients with DIRA. **B** In DITRA, loss of the IL-36R antagonist results in analogous unchecked signaling by IL-36α, IL-36β, and IL-36γ at the IL-36R. *Reproduced from Cowen EW, Goldbach-Mansky R. DIRA, DITRA, and new insights into pathways of skin inflammation. What's in a name? Arch Dermatol 2012;148:381–4.*

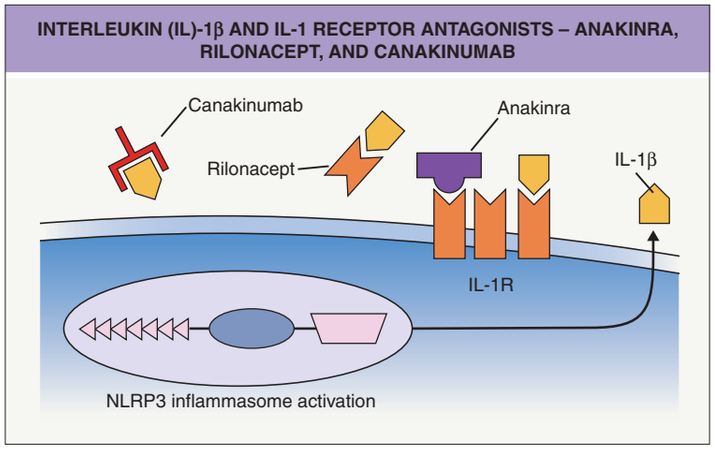

Fig. 45.13 Interleukin (IL)-1β and IL-1 receptor antagonists – anakinra, rilonacept, and canakinumab. Anakinra is an antagonist of the IL-1 receptor (IL-1R). Rilonacept is an IL-1 Trap. Canakinumab is an anti-IL-1β monoclonal antibody. See Fig. 4.2 for details of NLRP3 inflammasome. NLRP3, *NOD-like receptor pyrin* domain-containing protein 3.

Leukocytoclasia can be present, but not fibrinoid degeneration of vessel walls. As outlined in Table 45.6, neutrophilic urticarial dermatosis is also observed in patients with complex disorders such as Schnitzler syndrome (see Ch. 18), sJIA or adult-onset Still disease (see above), as well as some patients with SLE[68,69].

The group of autoinflammatory diseases continues to expand and some of the disorders classically categorized as neutrophilic dermatoses, e.g. Behçet disease, are beginning to be viewed as having a similar pathophysiology.

46 Mucinoses

Franco Rongioletti

Key features

- The cutaneous mucinoses are a heterogeneous group of disorders in which an abnormal amount of mucin accumulates in the skin
- The etiopathogenesis of cutaneous mucinoses is unknown
- The cutaneous mucinoses are divided into two groups: (1) primary cutaneous mucinoses, in which the mucin deposition leads to clinically distinctive lesions and is the major histologic feature; and (2) secondary mucinoses, in which the mucin deposition is simply an associated finding
- Primary cutaneous mucinoses are further divided into degenerative–inflammatory forms (which may be dermal or follicular) and hamartomatous–neoplastic forms
- Associated disorders include paraproteinemia (scleromyxedema, scleredema), diabetes mellitus (scleredema), thyroid disease (pretibial myxedema, myxedema), and autoimmune connective tissue disease (lupus erythematosus, dermatomyositis)

INTRODUCTION

The cutaneous mucinoses are a heterogeneous group of disorders in which an abnormal amount of mucin accumulates in the skin, either diffusely or focally[1].

Mucin is a component of the dermal extracellular matrix and is normally produced in small amounts by fibroblasts. It is a jelly-like, amorphous mixture of acid glycosaminoglycans (formerly referred to as acid mucopolysaccharides), which are complex carbohydrates composed of multiple repeating polysaccharide units (see Ch. 95). The acid glycosaminoglycans may be attached to both sides of a protein core (proteoglycan monomer), as in the case of dermatan sulfate and chondroitin sulfate, or they may be free, as in the case of hyaluronic acid, which is the most important component of dermal mucin.

Mucin is capable of absorbing 1000 times its own weight in water, playing a major role in maintaining the salt and water balance of the dermis. In routinely stained sections, the presence of either a blue-staining material between separated collagen bundles or empty spaces within the dermis are good clues that there is mucin deposition. For confirmation, special stains can be used, such as Alcian blue, colloidal iron, or toluidine blue (Table 46.1). Furthermore, dermal mucin is PAS-negative and, if composed of hyaluronic acid, hyaluronidase-sensitive. Fixation of biopsy specimens in absolute alcohol, rather than formalin, may improve dermal mucin detection. In addition, monoclonal antibodies have been used to detect sulfated acid glycosaminoglycans[2]. An alternative approach is to utilize biotinylated hyaluronan (HA)-binding proteins coupled to an avidin–peroxidase reaction[3].

Why mucin abnormally accumulates within the skin of some individuals is unclear. Certain "serum factors", e.g. immunoglobulins and/or cytokines, could promote the upregulation of glycosaminoglycan synthesis[4]. For example, elevated serum immunoglobulin levels (monoclonal or polyclonal) and circulating autoantibodies can be found in association with cutaneous mucinoses such as scleromyxedema, Graves disease-associated pretibial myxedema, and papulonodular mucinosis of lupus erythematosus. However, the serum from these patients stimulates mucin production even *after* the elution of either the IgG paraprotein in those with scleromyxedema or the autoantibodies in those with Graves disease-associated pretibial myxedema. Circulating cytokines such as interleukin (IL)-1, tumor necrosis factor (TNF), and TGF-β, which are known to stimulate glycosaminoglycan synthesis within the skin, could play a role in excess mucin deposition. A reduction in the normal catabolic degradation of mucin could also be a factor.

This chapter focuses on the disorders characterized by abnormal dermal deposits of mucin, composed primarily of hyaluronic acid (Fig. 46.1). The mucopolysaccharidoses, in which the predominant dermal mucin is dermatan sulfate or heparan sulfate (e.g. Hunter syndrome), are discussed in Chapter 48.

STAINING CHARACTERISTICS OF ACID GLYCOSAMINOGLYCANS (MUCOPOLYSACCHARIDES)

Histologic stain	Acid glycosaminoglycans (mucopolysaccharides)	
	Non-sulfated (hyaluronic acid*)	Sulfated (heparan sulfate, dermatan sulfate, chondroitin sulfate†)
Colloidal iron	+	+
Alcian blue		
pH 2.5	+	+
pH 0.5	–	+
Metachromasia with toluidine blue		
pH 4.0	+	+
pH <2.0	–	+
PAS‡	–	–
Hyaluronidase-sensitive	+	–

*Major GAG in the disorders discussed in this chapter; not bound to a protein core.
†Major GAGs in the mucopolysaccharidoses, e.g., Hunter syndrome, Hurler syndrome; bound to a protein core (proteoglycan).
‡Stains neutral mucopolysaccharides.

Table 46.1 Staining characteristics of acid glycosaminoglycans (mucopolysaccharides). GAG, glycosaminoglycan.

CLASSIFICATION

The cutaneous mucinoses may be classified as *primary*, in which mucin deposition is the major histologic feature resulting in clinically distinctive lesions (Table 46.2), or *secondary*, in which mucin simply represents an associated histologic finding (Table 46.3). Primary mucinoses can then be divided into *degenerative–inflammatory* forms and *hamartomatous–neoplastic* types. The former are further subdivided into dermal and follicular forms, based upon the location of the mucin (see Table 46.2).

PRIMARY DEGENERATIVE–INFLAMMATORY MUCINOSES

Dermal Mucinoses

Scleromyxedema

Synonyms: ■ Papular mucinosis ■ Diffuse/generalized and sclerodermoid lichen myxedematosus ■ Arndt–Gottron syndrome

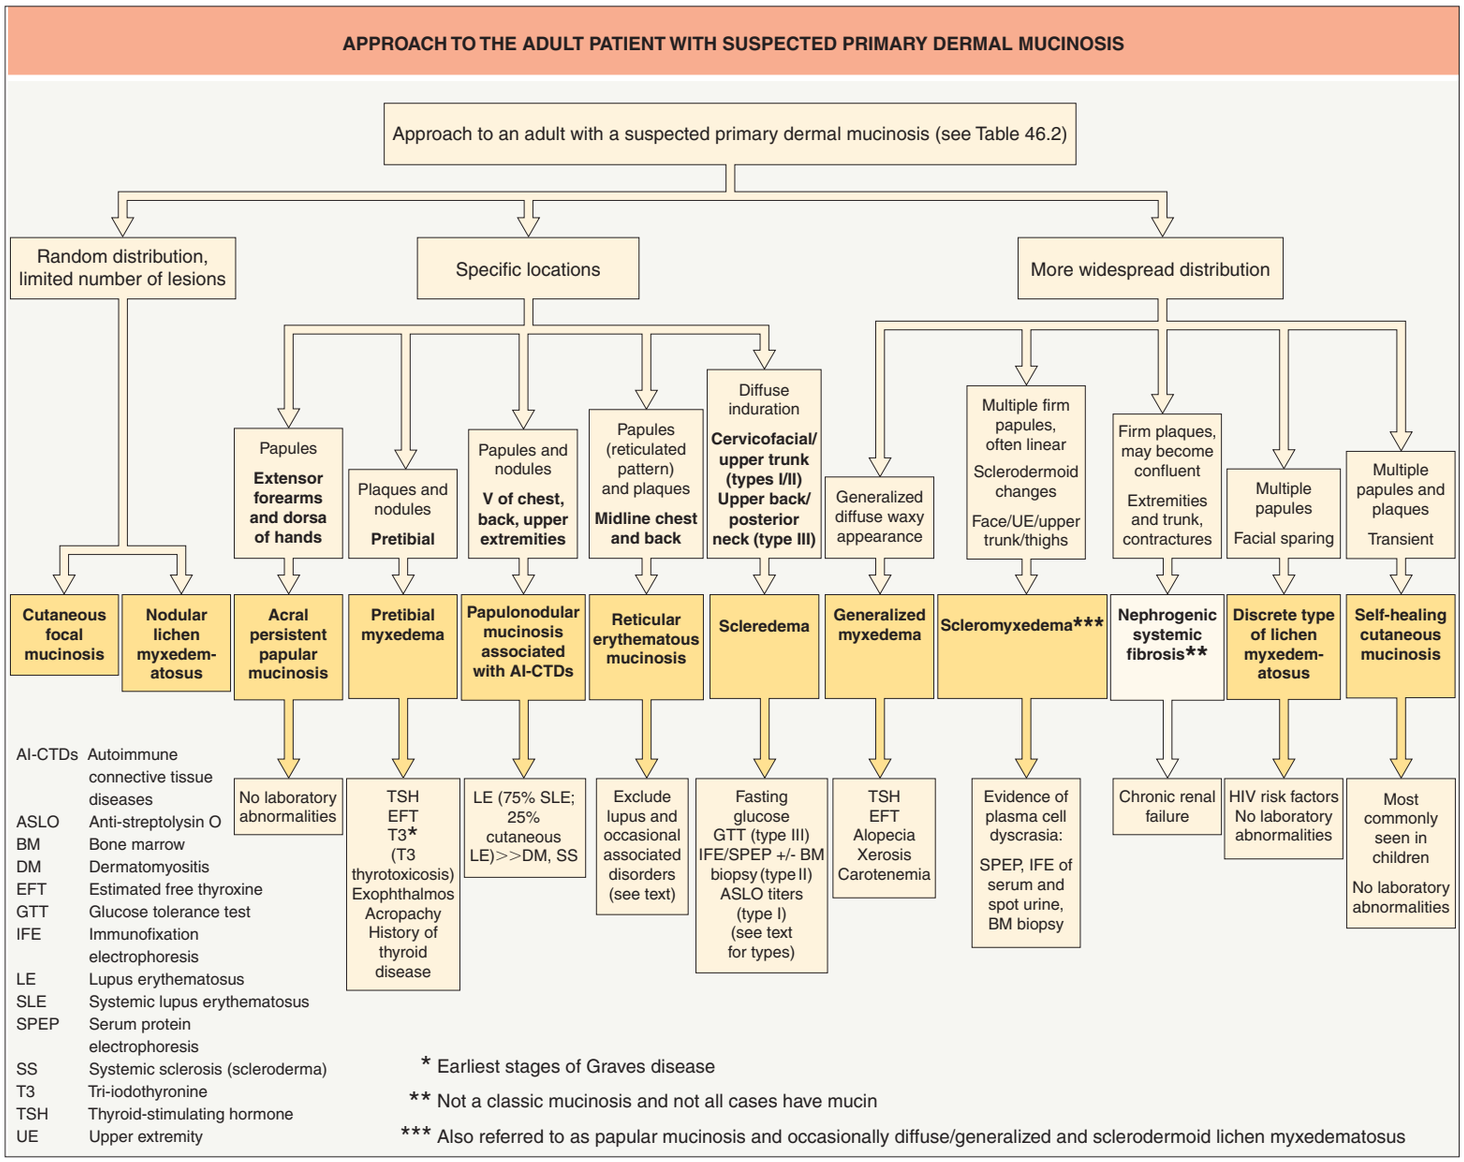

Fig. 46.1 Approach to the patient with suspected primary dermal mucinosis. Pretibial myxedema must be distinguished from obesity-associated lymphedematous mucinosis.

Introduction and definition

Scleromyxedema is a chronic idiopathic disorder characterized by numerous firm papules and areas of induration that are due to dermal mucin deposition in association with an increase in dermal collagen[4]. Nearly all patients also have a monoclonal gammopathy, and some may have systemic, even lethal, manifestations[5]. This entity must be distinguished from localized variants of lichen myxedematosus where the skin is the sole site of involvement (Table 46.4). There are, however, occasional patients who have an atypical constellation of findings and fall between scleromyxedema and localized lichen myxedematosus (see "atypical forms" below).

History

Although the first descriptions of scleromyxedema were attributed to Dubreuilh in 1906 and Reitman in 1908, it was not until the review of Montgomery and Underwood in 1953 that the disease was distinguished from scleroderma and generalized myxedema. A year later, Gottron and his colleagues gave the name "scleromyxedema" to the generalized and sclerotic form. The association of a monoclonal gammopathy with scleromyxedema was first described in 1963.

Epidemiology and pathogenesis

Scleromyxedema is a fairly uncommon disease, affecting middle-aged adults of both sexes equally. The pathogenesis of scleromyxedema is unknown. The role of the associated monoclonal gammopathy remains a matter of debate. While most patients have a plasma cell dyscrasia, paraprotein levels do not correlate with either the extent or the progression of the disease. In addition, sera from patients with scleromyxedema enhanced fibroblast proliferation *in vitro*, but an immunoglobulin purified from paraprotein-containing sera failed to do so, suggesting a pathogenetic role for circulating factors other than the paraprotein. Clinical remission of scleromyxedema, along with a reduction in the M-protein, that follows autologous hematopoietic stem cell transplantation (HSCT) points to the bone marrow as a source of these circulating factors.

In addition to circulating cytokines, such as IL-1 and TNF, which are known to stimulate glycosaminoglycan synthesis and fibroblast proliferation in the skin, analysis of RNA in involved skin tissue also confirmed a promoting role for TGF-β[6]. Abnormally high secretion of IL-4, a profibrotic cytokine, was recently detected in the serum of scleromyxedema patients, suggesting a chronic Th2-skewed response against an unknown target antigen[7]. Lastly, the development of scleromyxedema following a cutaneous granulomatous reaction to intradermal injections of hyaluronic gel or silicone breast implants suggests autoimmune phenomena[5].

Clinical features

In scleromyxedema, numerous, 2–3 mm, firm, waxy, closely aligned papules develop in a relatively widespread symmetrical pattern. The most common sites of involvement are the head and neck region, upper trunk,

CLASSIFICATION OF THE PRIMARY CUTANEOUS MUCINOSES
Degenerative–inflammatory mucinoses
Dermal
Scleromyxedema or papular mucinosis*
Lichen myxedematosus (localized variants)
• Discrete papular form†
• Acral persistent papular mucinosis
• Cutaneous mucinosis of infancy
• Nodular form
Self-healing cutaneous mucinosis
• Juvenile type
• Adult type
Scleredema
• Non-diabetic type (types I and II)
• Diabetic type (type III)
Mucinoses associated with altered thyroid function
• Localized (pretibial) myxedema
• Generalized myxedema
Reticular erythematous mucinosis
Papulonodular mucinosis associated with autoimmune connective tissue diseases (most commonly LE)
Cutaneous focal mucinosis
Digital mucous cyst (myxoid cyst)
Miscellaneous mucinoses
Follicular
Follicular mucinosis (Pinkus)
Urticaria-like follicular mucinosis
Hamartomatous–neoplastic mucinoses
Mucinous nevus
(Angio)myxoma
*Has been referred to as diffuse/generalized and sclerodermoid lichen myxedematosus. †Also seen in HIV-infected individuals.

Table 46.2 Classification of the primary cutaneous mucinoses. LE, lupus erythematosus.

MAJOR DISORDERS ASSOCIATED WITH HISTOLOGIC DEPOSITION OF MUCIN (SECONDARY MUCINOSES)
Epithelial mucinosis
• Basal cell carcinoma
• Rare – squamous cell carcinoma, keratoacanthoma, verruca, seborrheic keratosis, mycosis fungoides
Dermal mucinosis
• Granuloma annulare
• Lupus erythematosus, dermatomyositis > morphea, systemic sclerosis
• Obesity-associated lymphedema
• Rosacea, phymatous and granulomatous
• Mesenchymal tumors (e.g. myxosarcoma, myxoid lipoblastoma, DFSP)
• Neural tumors (e.g. neurofibroma, lobular neuromyxoma)
• Epithelial tumors (e.g. basal cell carcinoma, eccrine carcinoma)
• Other tumors (e.g. cutaneous metastases, mucinous carcinoma of the eyelid)
• Hypertrophic scar
• Rare – chronic GVHD, cutaneous reactions to interferon, herpes zoster, venous insufficiency, hereditary progressive mucinous histiocytosis
Follicular mucinosis
• Mycosis fungoides (rarely other T cell lymphomas)
• Eczematous dermatoses
• Rare – lupus erythematosus, insect bites (including so-called exaggerated insect bite-like reactions in the setting of CLL), rosacea, side effect of imatinib, familial reticuloendotheliosis

Table 46.3 Major disorders associated with histologic deposition of mucin (secondary mucinoses). A limited amount of dermal mucin can occasionally be observed in virtually all cutaneous disorders. CLL, chronic lymphocytic leukemia; DFSP, dermatofibrosarcoma protuberans; GVHD, graft-versus-host disease.

hands, forearms, and thighs (Fig. 46.2). Papules are often arranged in a strikingly linear array. The surrounding skin is shiny and indurated, i.e. sclerodermoid in appearance, and the glabella is typically involved with deep longitudinal furrowing. Severe involvement of the face can result in a leonine facies (Fig. 46.3A). Deep furrowing can also occur on the trunk and extremities and is referred to as the "Shar-Pei sign" (Fig. 46.3B).

Erythema, edema, and a brownish discoloration may also be seen in the involved areas, and pruritus is not uncommon. The mucous membranes and scalp are spared. As the condition progresses, erythematous and infiltrated plaques may appear with skin stiffening, sclerodactyly, and decreased motility of the mouth and joints. Overlying the proximal interphalangeal joints, a central depression surrounded by an elevated rim (due to skin thickening) can be seen and is referred to as

DIAGNOSTIC CRITERIA OF SCLEROMYXEDEMA VERSUS LOCALIZED VARIANTS OF LICHEN MYXEDEMATOSUS	
Scleromyxedema	**Localized variants of lichen myxedematosus**
Diffuse/generalized papular eruption and sclerodermoid features	Papular eruption (or nodules and/or plaques due to confluence of papules)
Microscopic triad (mucin deposition, fibroblast proliferation, fibrosis), or occasionally interstitial granulomatous pattern	Mucin deposition with variable fibroblast proliferation
Monoclonal gammopathy	Absence of monoclonal gammopathy
Absence of thyroid disorder	Absence of thyroid disorder

Table 46.4 Diagnostic criteria of scleromyxedema versus localized variants of lichen myxedematosus.

Fig. 46.2 Scleromyxedema. A, B Numerous monomorphic, firm, skin-colored to tan papules which can have a strikingly linear arrangement. This is most obvious on the posterior neck. **C** The skin can also become shiny and indurated, leading to a sclerodermoid appearance, but the small firm papules in a linear array are a clue to the diagnosis. *A, B, Courtesy Edward Cowen, MD; C, Courtesy Lorenzo Cerroni, MD.*

the "doughnut sign". Mat and cuticular telangiectasias and calcinosis, as seen in systemic sclerosis, are absent.

Scleromyxedema is almost always associated with paraproteinemia. The monoclonal gammopathy is usually IgG and the light chains are more commonly lambda. Although a mild plasmacytosis may be observed in bone marrow biopsies, <10% of patients with scleromyxedema progress to symptomatic myeloma. Patients with scleromyxedema can have a number of internal manifestations, in particular muscular, neurologic, rheumatologic, pulmonary, renal, and cardiovascular. Dysphagia, proximal muscle weakness due to myositis, disturbances of the CNS leading to unexplained coma, peripheral neuropathy, arthropathies, carpal tunnel syndrome, restrictive or obstructive lung disease, and scleroderma-like renal disease may accompany or follow the cutaneous manifestations[5]. While the predominantly sensory peripheral neuropathy typically affects older men and has an insidious onset, the dermato-neuro syndrome is a potentially life-threatening encephalopathy. This syndrome begins abruptly with a worsening of skin lesions, a flu-like prodrome, fever, and seizures, and it can eventuate in an unexplained coma. Possible triggers include viral infections and vaccines (e.g. SARS-CoV-2)[7a].

Pathology

Scleromyxedema is characterized by a triad of microscopic features[8]:

- a diffuse deposit of mucin in the upper and mid reticular dermis
- an increase in collagen deposition
- a marked proliferation of irregularly arranged fibroblasts (Fig. 46.4).

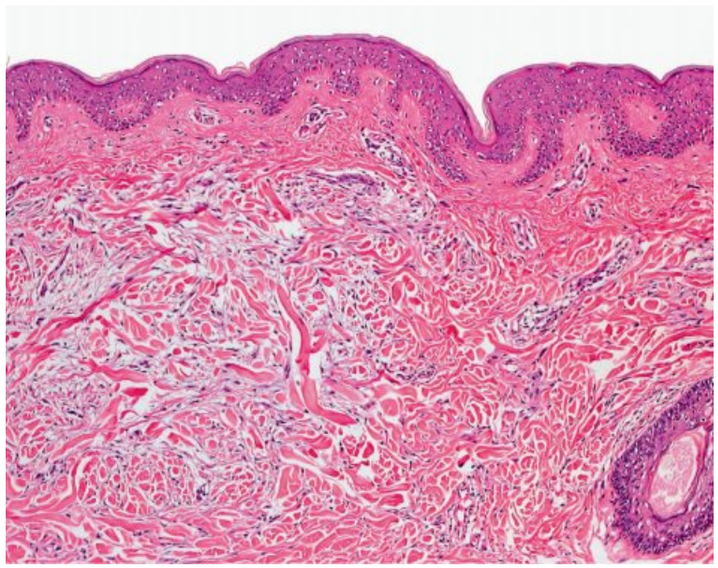

Fig. 46.4 Scleromyxedema – histopathologic features. Typical triad of fibrosis, an increased number of irregularly arranged fibroblasts, and interstitial deposits of mucin in the upper and mid reticular dermis. *Courtesy Lorenzo Cerroni, MD.*

The epidermis may be normal or thinned by the pressure of the underlying mucin and fibrosis; the hair follicles may be atrophic. A slight superficial, perivascular, lymphoplasmacytic infiltrate is often present. The elastic fibers are fragmented and decreased in number. More recently, an interstitial granuloma annulare-like pattern was described[9]. Mucin may fill the walls of myocardial blood vessels as well as the parenchyma of the kidney, pancreas, adrenal glands, nerves, and lymph nodes. In the dermato-neuro syndrome, autopsy findings have not proved helpful in elucidating an underlying pathogenesis.

Differential diagnosis

The primary differential diagnosis for scleromyxedema is systemic sclerosis (scleroderma) and scleredema. The presence of papules, especially in linear arrays, is a very helpful clinical sign in distinguishing scleromyxedema. In the occasional patient with systemic sclerosis who develops primary cutaneous amyloidosis (see Fig. 47.6), histologic findings allow distinction. Additional entities in the scleredermoid differential diagnosis should be excluded (see Ch. 43). For example, nephrogenic systemic fibrosis, which develops in individuals with renal impairment exposed to gadolinium-containing contrast media, may show mucin in biopsy specimens, but patients lack both facial involvement (commonly seen in scleromyxedema) and paraproteinemia. Criteria for diagnosing scleromyxedema versus localized variants of lichen myxedematosus are summarized in Table 46.4, and the dermatologic disorders in which leonine facies can develop are outlined in Table 46.5.

Treatment

Recommendations are still based on case reports and open-label small case series. In the past, monthly courses of melphalan were often the therapy of choice, targeting the plasma cell dyscrasia. However, while this alkylating agent can result in some clinical improvement, it has also been implicated in 30% of the deaths secondary to its induction of hematologic malignancies and septic complications[10]. Other chemotherapeutic agents (e.g. cyclophosphamide, methotrexate, chlorambucil, 2-chlorodeoxyadenosine) have been tried, but with no better results and the risk of significant side effects.

IVIg, alone or in combination with systemic medications (see below), has gained widespread acceptance as first-line therapy for both cutaneous involvement and associated systemic manifestations, including the dermato-neuro syndrome[11,12]. Although long-lasting remissions after cessation of IVIg therapy have been reported, the response is usually not permanent and maintenance infusions are required[5]. Either thalidomide or lenalidomide or a combination of lenalidomide, a proteasome inhibitor (e.g. bortezomib) and dexamethasone, standard therapy for multiple myeloma, is considered second-line treatment and is often

LEONINE FACIES – ASSOCIATED DERMATOLOGIC DISEASES
Scleromyxedema
Lepromatous leprosy
Leishmaniasis
Cutaneous lymphoma (T cell, rarely B cell)
Actinic reticuloid form of chronic actinic dermatitis
Leukemia cutis (specific cutaneous manifestation of B-CLL)
Phymatous rosacea
Viral-associated trichodysplasia
Systemic amyloidosis
Lipoid proteinosis
Mastocytosis (nodular)
Sarcoidosis
Multicentric reticulohistiocytosis
Progressive nodular histiocytosis
Other non-Langerhans cell histiocytoses (e.g. indeterminate cell histiocytosis)
Pachydermoperiostosis
Late-stage onchocerciasis
Trichoepitheliomas, cylindromas, and/or spiradenomas

Table 46.5 Leonine facies – associated dermatologic diseases. Leonine facies can also be seen in patients with Paget disease of the bone and rarely secondary syphilis. B-CLL, B cell chronic lymphocytic leukemia. *Inset, Courtesy Joyce Rico, MD.*

administered in combination with IVIg[11–13]. This multi-drug regimen may represent first-line therapy for individuals with severe disease including CNS or cardiac involvement[12]. Autologous HSCT represents third-line therapy, especially for individuals with disabling or potentially life-threatening disease[13]. Due to the excellent response observed in patients with myeloma, the anti-CD38 monoclonal antibodies daratumumab and isatuximab may represent future therapies.

Additional therapies, including PUVA, UVA1, systemic retinoids, cyclosporine, electron beam radiation, plasmapheresis, and extracorporeal photochemotherapy, have all produced variable results. Dysarthria and a flu-like illness may herald life-threatening coma, and the patient should be promptly admitted to the hospital for close observation and consideration of treatment with a multi-drug regimen (see above) plus IVIg and plasmapheresis[12].

Lichen myxedematosus (localized variants)

Introduction

In the localized variants of lichen myxedematosus, patients develop small, firm, waxy papules (or nodules and plaques produced by the confluence of papules) that are limited to only a few sites – usually the upper and lower extremities and/or trunk. The *skin is the only site of involvement* and these variants, in contrast to scleromyxedema, are not associated with sclerosis, paraproteinemia, or systemic involvement nor are they associated with thyroid disease (see Fig. 46.1)[4]. While most dermatologists equate lichen myxedematosus with localized, skin-limited disease, a source of potential confusion is the uncommon and more historical use of the term "diffuse/generalized and sclerodermoid lichen myxedematosus" to describe scleromyxedema.

The localized variants of lichen myxedematosus are subdivided into four subtypes:

- a discrete papular form
- acral persistent papular mucinosis
- cutaneous mucinosis of infancy
- a pure nodular form.

Localized variants of lichen myxedematosus may be observed in association with HIV infection, exposure to toxic oil or L-tryptophan (historical), and hepatitis C viral (HCV) infection.

Epidemiology

Exact incidence and prevalence rates for the localized variants of lichen myxedematosus are not known.

Clinical features

Discrete papular lichen myxedematosus is characterized by 2–5 mm papules, numbering from just a few to hundreds and involving the limbs and trunk in a symmetrical pattern[14] (Fig. 46.5). The affected skin is not indurated and the face is spared. Lesions progress slowly without systemic involvement. However, they rarely resolve spontaneously. To date, progression to scleromyxedema has never been definitively proven.

Fig. 46.5 Localized lichen myxedematosus – discrete papular type. Persistent whitish papules on the arms.

Fig. 46.6 Acral persistent papular mucinosis. Skin-colored papules on the dorsal aspect of the hands.

In **acral persistent papular mucinosis**, first described in 1986 by Rongioletti et al.[15], multiple ivory to skin-colored papules develop exclusively on the dorsal aspect of the hands and extensor surface of the distal forearms (Fig. 46.6). A female : male ratio of 3 : 1 has been noted. The lesions persist, but without systemic manifestations[16].

In **cutaneous mucinosis of infancy** (syn. papular mucinosis of infancy), first described by Lum in 1980, firm opalescent papules appear on the neck (Fig. 46.7), upper arms (especially the elbows), and trunk[17]. In contrast to self-healing mucinosis, neither systemic symptoms nor spontaneous resolution are observed. Of the handful of patients described to date, at least two have had a congenital linear variant, which might be better categorized as an example of a mucinous nevus[17].

Nodular lichen myxedematosus is characterized by multiple nodules on the limbs and trunk, with a mild or absent papular component. **Atypical tuberous myxedema** (Jadassohn–Dosseker) probably represents a pure nodular variant of lichen myxedematosus[1,17a].

Localized lichen myxedematosus in HIV-infected patients. The majority of patients developed either the discrete papular form or the nodular variant of lichen myxedematosus, with lesions on the limbs and trunk. All became infected with HIV before the onset of the lichen myxedematosus. Most had hypergammaglobulinemia, a well-recognized manifestation of HIV infection, and to date only two had paraproteinemia. Of note, up to 10% of HIV-infected individuals may have monoclonal gammopathy of undetermined significance (MGUS) and how this relates to the mucinosis remains to be determined. None of the patients had visceral involvement due to mucin deposition[18].

Localized lichen myxedematosus in "toxic" syndromes. Multiple papules due to mucin deposition with a clinical appearance similar to the discrete form of lichen myxedematosus have also been described

Fig. 46.7 Cutaneous mucinosis of infancy. Skin-colored papules on the back of the neck in a young girl.

Fig. 46.8 Self-healing cutaneous mucinosis. Pink to skin-colored dermal and subcutaneous nodules as well as periorbital swelling. *Courtesy Drs Hansgeorg Müller and Heinz Kofler.*

in the setting of toxic oil syndrome and L-tryptophan-associated eosinophilia–myalgia syndrome. Although unrelated epidemiologically and both of historical interest, toxic oil syndrome (due to the ingestion of adulterated rapeseed oil in Spain in the early 1980s) and L-tryptophan-associated eosinophilia–myalgia (related to a contaminant in L-tryptophan-containing products used as sedatives during the late 1980s) share several clinical features, including constitutional symptoms, peripheral eosinophilia, hyperpigmentation, and a sclerodermoid appearance[19], in addition to this mucinous papular eruption. Usually 1–5 months after the onset of the illness, 1–5 mm, white or skin-colored papules appeared, primarily on the limbs. The lesions resolved slowly after exposure to the toxic substance ceased.

Localized lichen myxedematosus and HCV infection. An association of lichen myxedematosus with chronic hepatitis due to HCV infection has been reported, especially from Japan[20], but this relationship needs to be confirmed by more extensive studies.

Cutaneous mucinosis consistent with **localized lichen myxedematosus** has been associated with several **medications** including targeted immunomodulators ("biologics"), inhibitors of CSF-1R (colony-stimulating factor-1 receptor), and interferons (including at injection sites) in addition to **trauma** (e.g. mechanical, following total knee replacement)[21].

Atypical forms of lichen myxedematosus. Occasionally patients with lichen myxedematosus have atypical features or features intermediate between scleromyxedema and localized lichen myxedematosus[22]. This group includes patients with scleromyxedema who lack a monoclonal gammopathy as well as individuals with localized forms of lichen myxedematosus who also have a monoclonal gammopathy and/or systemic symptoms. One possible explanation for the former group is performance of just a serum protein electrophoresis (SPEP), rather than an SPEP plus an immunofixation electrophoresis (IFE) of serum and urine, as IFE is a more sensitive assay.

Pathology

In the localized forms of lichen myxedematosus, the histologic changes are less characteristic than in scleromyxedema. Mucin accumulates in the upper and mid reticular dermis and fibroblast proliferation is variable; fibrosis is not marked and may even be absent. In acral persistent papular mucinosis, mucin accumulates focally in the upper reticular dermis (sparing a subepidermal zone) and fibroblasts are not increased in number. In cutaneous mucinosis of infancy, the mucin may be so superficial as to look as if it were "enclosed" by epidermis, although mucin may also deposit in the reticular dermis[17].

Differential diagnosis

Histologic examination of the skin helps to distinguish localized variants of lichen myxedematosus from several papular eruptions that can have a similar appearance, such as papular granuloma annulare, amyloidosis, colloid milium, molluscum contagiosum, papular elastorrhexis, and eruptive collagenomas. It is also important to differentiate these entities from scleromyxedema and the cutaneous mucinosis that can occur in the setting of autoimmune connective tissue diseases (see below).

Treatment

Localized lichen myxedematosus does not require therapy, and a wait-and-see approach is recommended. Topical application of corticosteroids, pimecrolimus, or tacrolimus may be of some benefit[14]. One patient with associated HIV infection had a complete remission after treatment with oral isotretinoin. Spontaneous resolution may occur, even in the setting of HIV infection[18].

Self-healing cutaneous mucinosis

Although previously considered a subtype of localized lichen myxedematosus, self-healing cutaneous mucinosis is best regarded as a distinct rare form of primary dermal mucinosis[23]. It was initially described in children, with ages of reported patients ranging from 1 to 15 years[17]. The same disorder was subsequently observed in a few adults, but in the author's opinion, some of the adult patients were actually examples of localized lichen myxedematosus with spontaneous resolution[24].

Self-healing cutaneous mucinosis is characterized by the following clinical presentations: (1) an acute eruption of multiple papules, sometimes coalescing into linear infiltrated plaques, on the face, neck, scalp, abdomen, and thighs; and (2) mucinous subcutaneous nodules in periarticular areas and on the face, with periorbital swelling (Fig. 46.8). In addition, systemic symptoms (e.g. fever, arthralgias, and muscle tenderness) may accompany the cutaneous lesions, but paraproteinemia, bone marrow plasmacytosis, and thyroid dysfunction are not observed. Spontaneous resolution over a period of 1–8 months is characteristic, hence the name. Histologically, papular lesions show dermal mucin deposition with mild inflammation and a small increase in the number of fibroblasts, whereas nodules have deep mucinous deposits associated with bands of fibrosis and a prominent proliferation of fibroblast-like cells and gangliocyte-like cells mimicking proliferative fasciitis[17,23]. While spontaneous complete regression is the expectation, longitudinal evaluation is recommended due to the possible development of dermato-rheumatologic disorders such as fibroblastic rheumatism[23].

Scleredema

Synonyms: ■ Scleredema adultorum of Buschke ■ Scleredema diabeticorum

Introduction

Scleredema is a symmetrical diffuse induration of the upper part of the body due to a thickened dermis and deposition of mucin.

History

Although Buschke has been credited with first describing scleredema, the original description dates back to Pitford in 1876. A relationship with diabetes mellitus was only established in 1970.

Epidemiology and pathogenesis

Scleredema is an unusual disease that affects all races. The form that is associated with diabetes mellitus is more prevalent in men, while other forms are seen more commonly in women. Irreversible glycosylation of collagen and resistance to degradation by collagenase may lead to an accumulation of collagen. Alternatively, enhanced stimulation by insulin, microvascular damage, and hypoxia may increase the synthesis of collagen and mucin. Streptococcal hypersensitivity (type I), injury to lymphatics, and paraproteinemia (type II) may also play a role.

Clinical features

Classically, there are three types of scleredema, although a simpler division into those with and those without diabetes has been suggested[25,26]. The *first type* affects primarily children and middle-aged women. It is preceded by fever, malaise, and an infection (usually streptococcal) of the upper or lower respiratory tract. The skin of the cervicofacial region suddenly hardens with extension to the trunk and proximal upper limbs. The face is expressionless and opening of the mouth and swallowing are difficult because of the involvement of the tongue and pharynx. This type usually resolves spontaneously.

The *second type* shares the same clinical features as the first but has a more subtle onset, without a preceding illness. It persists for years. This type is more frequently associated with a monoclonal gammopathy[25].

The *third type* occurs primarily in obese middle-aged men with insulin-dependent diabetes *(scleredema diabeticorum)*. The onset is subtle and the involvement persistent. Erythema and induration of the posterior neck and the back are commonly observed (Fig. 46.9), as is a *peau d'orange* appearance of the skin. In those patients who also have cheiroarthropathy, the skin of the distal extremities may appear waxy, presumably due to increased amounts of glycosylated collagen.

Occasionally, patients with limited site involvement (e.g. periorbital skin) have also been reported. In all three forms, systemic manifestations such as serositis, myositis, dysarthria, dysphagia, parotitis, and ocular and cardiac abnormalities (e.g. ophthalmoplegia, congestive heart failure) may occur, but are unusual. Scleredema may be idiopathic and anecdotal associations with autoimmune diseases (e.g. rheumatoid arthritis, Sjögren syndrome, primary biliary cholangitis, dermatomyositis, lichen sclerosus), internal neoplasms (malignant insulinoma, gallbladder carcinoma, carcinoid, pituitary–adrenocortical neoplasm), and HIV infection have been described[18,27]. Except for limitation of movement, scleredema usually causes little morbidity. While postinfectious scleredema may clear within 6–24 months, scleredema associated with diabetes or a monoclonal gammopathy has a chronic unremitting course. Rarely, death may occur when internal organs are involved.

Pathology

The principal alteration in scleredema is the thickening of the reticular dermis, with large collagen bundles separated from one another by clear spaces filled with mucin, resulting in fenestration of the dermis (Fig. 46.10). There is no increase in the number of fibroblasts, but the elastic fibers are reduced in number. At times, the mucin deposition can be so slight that multiple biopsies or staining of unfixed frozen sections are required to detect it. There is sometimes a sparse perivascular lymphocytic infiltrate. Direct immunofluorescence is usually negative, but deposits of IgG and C3 have been observed at the dermal–epidermal junction. Mucin also accumulates within skeletal muscle and the heart.

Differential diagnosis

Scleredema may be confused with systemic sclerosis, but the absence of Raynaud phenomenon and cuticular and mat telangiectasias points to scleredema. Histologically, mucin deposition may be observed in systemic sclerosis, but adnexal structures are atrophic or absent and the dermis is diffusely sclerotic, as opposed to the "fenestration" observed in scleredema. Patients with scleromyxedema also have firm papules (often in a linear array) in addition to dermal induration as well as a proliferation of fibroblasts histologically. The other types of cutaneous mucinoses are usually distinguished on the basis of clinical findings[26]. Additional entities in the sclerodermoid differential diagnosis should be excluded (see Ch. 43). Occasionally, because of associated erythema, diabetes-associated scleredema is sometimes misdiagnosed as cellulitis (usually by non-dermatologists).

Treatment

Therapy is unnecessary for scleredema associated with streptococcal infections because it is self-limited. Management of scleredema associated with diabetes or a monoclonal gammopathy is more difficult and no specific treatment is available. Phototherapy, in particular UVA1 and narrowband UVB, is considered first-line therapy as it can stimulate fibroblasts to synthesize collagenase, thereby enhancing degradation of sclerotic tissue[25,28]. For scleredema associated with a plasma cell dyscrasia, systemic medications used to treat myeloma (see above), may be effective. Some, but not all, patients with diabetes-associated scleredema improve with strict glycemic control.

Systemic and intralesional corticosteroids, intralesional hyaluronidase, antibiotics, methotrexate, cyclosporine, pulse therapy with cyclophosphamide plus oral corticosteroids, tamoxifen, and allopurinol have all been tried, with variable results. Electron beam radiotherapy, IVIg[29], and extracorporeal photopheresis are additional reported therapies. In patients with limited mobility or respiratory difficulty, ultrasonic massage and physical therapy can be employed. Aggressive therapies should be limited to individuals with disabling disease or systemic manifestations.

Mucinoses associated with altered thyroid function

Localized (pretibial) myxedema

Definition

Localized or pretibial myxedema is characterized by cutaneous induration of the shins due to mucin deposition. It is often associated with hyperthyroidism (most commonly due to Graves disease), but may appear following treatment of the thyroid disease.

Epidemiology and pathogenesis

Graves disease is seven times more common in women than in men and onset is usually during the third or fourth decade. Pretibial myxedema is one sign of Graves disease, along with goiter, exophthalmos, thyroid acropachy, and thyroid-stimulating immunoglobulins that recognize the thyroid-stimulating hormone (TSH) receptor. Overall, pretibial myxedema is found in 1%–5% of patients with Graves disease, but in up to 25% of those with exophthalmos[30]. It can also appear in the setting of hypothyroidism following the treatment of Graves disease. Rarely, localized myxedema occurs in the setting of Hashimoto thyroiditis without thyrotoxicosis, and even in euthyroid patients.

A serum factor (unrelated to thyroid-stimulating immunoglobulins) may incite fibroblasts to produce mucin. Fibroblasts from the dermis of the lower extremities have been found to be more sensitive to such a factor than are fibroblasts from other areas of the body. An insulin-like growth factor, trauma, and lymphatic obstruction due to mucin may also play a role.

Clinical features

Localized myxedema presents as erythematous to skin-colored, but sometimes purple–brown or yellowish, waxy indurated nodules or plaques. A *peau d'orange* appearance is a characteristic finding (Fig. 46.11). The lesions are usually located on the anterolateral aspect of the lower legs or the feet. Localized myxedema can also present as a diffuse non-pitting edema of the shins or feet that evolves into elephantiasis. Even more rarely, localized myxedema affects the face, shoulders, upper extremities, lower abdomen, scars, or donor graft sites. Large plaques are often painful and pruritic. When present, hypertrichosis and hyperhidrosis are confined to pretibial myxedematous skin.

Apart from appearance and possible pain, associated morbidity is usually minimal. Entrapment of peroneal nerves by mucinous connective tissue may cause foot drop or faulty dorsiflexion.

Pathology

Large quantities of mucin are deposited within the reticular dermis, causing collagen bundles to separate and the dermis to thicken[6]. A subepidermal grenz zone of normal collagen is also observed. A perivascular and periadnexal lymphocytic infiltrate with mast cells is seen, as well as large stellate fibroblasts. Elastic fibers are reduced in number. There is often hyperkeratosis in addition to papillomatosis and hyperplasia of the epidermis.

Differential diagnosis

In addition to lichen simplex chronicus and hypertrophic lichen planus, pretibial myxedema should be distinguished from lymphedema, lipedema, and obesity-associated lymphedematous mucinosis[31]. In the latter disorder, semi-translucent papules, plaques with woody induration, and occasionally vesicles develop on the shins of euthyroid, morbidly obese individuals with significant lower extremity edema. Histologically, mucin deposition is found within the superficial papillary dermis and around vessels, in addition to epidermal atrophy (with effacement of the rete ridge pattern), vertically oriented capillaries, and deposits of hemosiderin[31].

Treatment

Corticosteroids, either applied under occlusive dressings or delivered by intralesional injection (e.g. triamcinolone 10–40 mg/cc), are considered first-line therapy[32]. Intralesional hyaluronidase, alone or in combination with intralesional corticosteroids, may also be tried[33]. More recently, teprotumumab, an IGF-1R inhibitor that is FDA-approved for the treatment of thyroid-associated ophthalmopathy, was reported to lead to improvement[33a]. For the severe elephantiasis form, medical treatments, including IVIg, rituximab, plasmapheresis and octreotide, have been of benefit and are sometimes combined with surgery[32,33]. Unfortunately, skin grafting is usually followed by recurrence. Compression stockings and gradient pneumatic compression are useful for the associated lymphedema. Addressing risk factors such as obesity and smoking is recommended. Therapy for hyperthyroidism does not improve the cutaneous lesions and, often, localized myxedema develops after treatment has been instituted or completed. Localized myxedema may clear spontaneously after an average of 3.5 years.

Generalized myxedema

Definition

Generalized myxedema is a manifestation of severe hypothyroidism in which mucin is deposited in the dermis, leading to waxiness of the skin.

Pathogenesis

Generalized myxedema is due to a quantitative or functional deficiency of thyroxine. Impaired degradation of mucin, rather than increased synthesis, has been suggested as the cause.

Clinical features

Hypothyroidism may be congenital, with sequelae formerly referred to as cretinism, or of juvenile or adult onset.

Congenital hypothyroidism affects 1 in 5000 neonates and may cause a distinctive syndrome of dwarfism, intellectual disability, and systemic and cutaneous findings. Somnolence, constipation, poor feeding, poor muscle tone, persistence of jaundice, and respiratory distress all suggest the diagnosis. However, more than a third of infants have no symptoms. Periorbital tissues and the tongue, lips, hands, and genitals are puffy. The skin is dry, cold, and pale. Nails and hairs are dry and brittle, and there can be patchy alopecia. The presence of a clavicular pad is diagnostic.

Fig. 46.11 Pretibial myxedema in patients with Graves disease. A Skin-colored to pink thick plaques on the shins. **B** Purple–brown nodules and plaques on the shins of a patient with a darker skin phototype. A *peau d'orange* appearance is present in both patients. **C, D** Induration and violaceous erythema of the legs with disfiguring soft tissue overgrowth of the dorsal feet and toes. *C, D, Courtesy Edward Cowen, MD.*

Juvenile hypothyroidism develops in a previously euthyroid child. Clinical features include short stature, abnormal physical and mental development, retardation of sexual maturity, and poor performance at school. Hypertrichosis may develop on the shoulders and upper back.

Adult hypothyroidism is the most common form of the disease. It is seen primarily in women 40–60 years of age, often as a result of autoimmune disease (usually Hashimoto thyroiditis), therapy of hyperthyroidism (usually Graves disease) or, rarely, pituitary or hypothalamic failure. Rarely, the ingestion of large quantities of foodstuffs that contain inhibitors of iodine uptake by the thyroid gland, e.g. raw bok choy, can lead to myxedema.

The initial symptoms are subtle and include mental and physical sluggishness, weight gain, constipation, leg cramps, loss of appetite, and cold intolerance. The face has a dull expression. The eyelids, lips, tongue, and hands are puffy, the nose is broad (Fig. 46.12), and the speech becomes hoarse and slurred. The skin is pale, cool, waxy, and dry; an absence of sweating can lead to acquired ichthyosis or eczema craquelé. A yellowish discoloration of the palms and soles due to carotenoderma may appear. Hair and nails are dry and brittle, and a diffuse non-scarring alopecia is common; alopecia of the lateral third of the eyebrows can also be seen. Purpura involving the extremities, blue telangiectatic fingertips, delayed wound healing, and xanthomas may be observed. Systemic manifestations include cardiomegaly, megacolon or bowel obstruction, psychiatric symptoms mimicking Alzheimer disease, serositis, carpal tunnel syndrome, and seventh nerve paralysis[34].

Pathology

Mucin deposits, mainly perivascular and perifollicular, splay collagen bundles and may extend into the subcutaneous fat and nerves. Fibroblasts are not increased in number, but elastic fibers are reduced. Mucin deposits in the brain probably cause the psychiatric symptoms.

Diagnosis and differential diagnosis

The diagnosis is suspected clinically. Low levels of circulating free T_4 confirm the diagnosis. Serum TSH level is high in primary hypothyroidism and low in secondary hypothyroidism. Myxedema does not seem to occur in secondary hypothyroidism.

Treatment

Early treatment is crucial for proper mental development of neonates with hypothyroidism, but it is also critical for the juvenile and adult forms. Measurement of serum levels of T_4 and/or TSH is performed between 2 and 4 days of age in newborn screening panels, and treatment should be initiated within the first 2 weeks of life. Usually, symptoms subside with thyroxine administration and recur if it is discontinued. Even areas of hair loss regrow with proper treatment. If untreated, patients can die as a result of "myxedema coma".

Fig. 46.12 Generalized myxedema in an adult with hypothyroidism. The face is puffy with a dull expression and the hair is dry.

Reticular erythematous mucinosis

Synonyms: ■ Plaque-like cutaneous mucinosis ■ Reticular erythematous mucinosis syndrome ■ Midline mucinosis

Introduction and definition

Reticular erythematous mucinosis (REM) is a disorder in which persistent, erythematous papules or plaques develop in the midline of the back or chest. The papules often have a reticular or net-like configuration. This disorder has some overlap with lupus erythematosus (LE) tumidus[35,36].

History

Steigleder and colleagues coined the term "reticular erythematous mucinosis" in 1974. However, in 1960, Perry and colleagues described three similar patients with plaque-like cutaneous mucinosis. Some authors regard these two entities as identical, while others view them as being on a continuum[36].

Epidemiology and pathogenesis

REM is a rare disorder that occurs most often in middle-aged women, although men and children are not spared. It is seen worldwide and can be provoked or exacerbated by a wide range of factors, from heat and perspiration to oral contraceptives and pregnancy to radiation therapy. There is debate as to whether REM is a photoaggravated disorder. Familial cases suggest a genetic predisposition.

Within endothelial cells and pericytes of lesional skin, tubuloreticular inclusions have been detected. Although these inclusions occur in viral infections, they can also be produced by high levels of interferon and are also found within endothelial cells in LE. Lastly, the fibroblasts of REM patients exhibit an abnormal overstimulation when exposed to exogenous IL-1.

Clinical features

Plaque-like cutaneous mucinosis and REM are probably different clinical presentations of the same rare syndrome. On the mid back or chest, pink to red macules and papules merge into reticulated and annular patterns (Fig. 46.13) or plaque-like lesions. They may be slightly pruritic and sometimes lesions spread to the abdomen. While sun exposure may worsen the eruption, it has also been reported to be beneficial. Provocative phototests (UVA and/or UVB) can sometimes reproduce REM lesions. In general, REM is not associated with systemic diseases or abnormal laboratory tests. However, there are reports of autoimmune diseases (e.g. SLE), hypothyroidism, and more common internal malignancies in patients with REM[35].

Pathology

The epidermis is normal. Interstitial deposits of small amounts of mucin are seen in the upper dermis, along with a perivascular and, at times, perifollicular T cell infiltrate[6]. Vascular dilation is present. Usually, direct immunofluorescence is negative, but, rarely, granular deposits of IgM, IgA, and C3 have been seen at the dermal–epidermal junction[36].

Differential diagnosis

In biopsy specimens of discoid lesions of LE there is involvement of the epidermis and deposits of IgG and C3 are found at the dermal–epidermal junction, and in lymphocytic infiltrate of Jessner, there is minimal, if any, dermal mucin. LE tumidus is very difficult to distinguish microscopically from REM. Both diseases have perivascular dermal infiltrates of T lymphocytes, primarily $CD4^+$, plus increased dermal mucin. In REM, the mucin and the lymphocytes tend to be more superficial and the lymphocytes more scattered. In LE tumidus, plasmacytoid dendritic cells were found to be clustered whereas in REM they were fewer in number and appeared as single cells[36]. These findings aside, some authors view REM and LE tumidus as variants of the same disease and along a continuum with cutaneous LE. It would be unusual for polymorphous light eruption to be restricted to the chest and histologically there is less abundant mucin and sometimes pronounced edema of the superficial dermis. Seborrheic dermatitis and tinea versicolor may involve the central chest, but they have associated scale and can be diagnosed clinically, as can confluent and reticulated papillomatosis.

Treatment

Hydroxychloroquine or chloroquine (+/− quinacrine) are usually effective in clearing the lesions within 4–8 weeks. Results from other treatments such as topical and systemic corticosteroids, topical calcineurin inhibitors, oral antihistamines, tetracyclines, cyclosporine, UVB irradiation, and pulsed dye laser are quite variable. Despite the potential for an exacerbation, improvement following UVA1 or UVB irradiation has been reported[35]. The lesions may clear spontaneously, even after 15 years.

Papulonodular mucinosis associated with autoimmune connective tissue diseases

Synonyms (when associated with LE): ■ Cutaneous lupus mucinosis ■ Papulonodular mucinosis in (systemic) lupus erythematosus ■ Papular and nodular mucinosis of Gold

Papules, nodules, and plaques secondary to mucin deposition may accompany or even antedate an autoimmune connective tissue disease, most commonly LE, and rarely dermatomyositis or systemic sclerosis. Cutaneous lupus mucinosis occurs in ~1%–2% of patients with LE[37]. Only in Japan has a male predominance been observed. The lesions present as asymptomatic, skin-colored, at times erythematous, 0.5–2 cm papules and nodules (Fig. 46.14); rarely, they merge into large plaques. Tangential illumination can be used to enhance detection of the lesions. A central depression and pigmentation may be additional features. The back, V of the chest, and the upper extremities are the most common sites of involvement. In only a few reported patients was there a flare of the papulonodules after sun exposure.

Fig. 46.14 Papulonodular mucinosis in a patient with lupus erythematosus. Skin-colored papules and nodules leading to a "lumpy" appearance of the chest.

Cutaneous lupus mucinosis can antedate LE or begin concurrently. The clinical course may correlate, in some patients, with underlying disease activity. Approximately 75% of patients with LE who develop papular and nodular mucinosis have systemic involvement, primarily renal and articular. The minority have only skin involvement, usually discoid or subacute cutaneous LE lesions.

Histologically, mucin abounds in the upper and mid dermis but may involve the subcutaneous fat as well. Sometimes, it is accompanied by a slight perivascular lymphocytic infiltrate. The epidermal changes of LE are absent, but linear or granular deposits of immunoglobulin and/or C3 are detected at the dermal–epidermal junction.

Cutaneous lesions of dermatomyositis often have dermal mucin histologically; rarely, patients develop erythematous nodules and plaques due to mucin deposition. The latter appear primarily on the trunk[38] and usually follow the myositis. Papular and nodular mucinosis can also occur in association with systemic sclerosis[39].

Treatment

Therapies for papular and nodular mucinosis are similar to those used for LE and dermatomyositis, i.e. sunscreens, topical corticosteroids, and oral antimalarials. For unresponsive cases, systemic corticosteroids can be prescribed. Intralesional corticosteroids may prove useful for reducing the size of large nodules and plaques.

Cutaneous focal mucinosis

Cutaneous focal mucinosis presents as an asymptomatic, skin-colored papule or nodule, <1 cm in diameter[40]. The lesion can occur anywhere on the body or in the oral cavity. Cutaneous focal mucinosis favors adults and only rarely has it been linked to thyroid disorders (without myxedema), REM, or scleromyxedema. Trauma can be an inciting factor[41]. The diagnosis is based upon histologic findings.

Histologically, mucin is dispersed throughout the upper and mid dermis, sparing the subcutaneous fat. Cleft-like spaces, but no cysts, are seen. Spindle-shaped or stellate, vimentin-positive fibroblasts are present[41]. There is also a minor population of dermal dendrocytes that are partially factor XIIIa-positive and partially CD34-positive. The elastic and reticulum fibers are absent, but capillaries are normal in number[40].

Cutaneous focal mucinosis results from a "muciparous" reaction of the connective tissue to nonspecific stimuli and should be distinguished from digital mucous cyst or from angiomyxoma, which represents a true neoplasm. Cutaneous focal mucinosis can be surgically excised, and relapses are uncommon.

Digital mucous cyst (myxoid cyst) is discussed in Chapter 110.

Primary Follicular Mucinoses

Mucin accumulates within the follicular epithelium in two distinctive primary disorders: Pinkus follicular mucinosis and urticaria-like follicular mucinosis. Otherwise, follicular mucinosis is considered a histologic epiphenomenon (i.e. secondary mucinosis), most often associated with cutaneous T cell lymphoma, in particular mycosis fungoides and Sézary syndrome, or other skin diseases (e.g. atopic dermatitis; see Table 46.3).

Follicular mucinosis

Synonyms: ■ Alopecia mucinosa ■ Mucinosis follicularis ■ Pinkus follicular mucinosis – benign primary form

History, epidemiology, and pathogenesis

This uncommon inflammatory disorder, described in 1957 by Pinkus, has a predilection for children and for adults in the third and fourth decades of life. It is unclear why dermal-type mucin is deposited selectively within an epithelial structure. Although follicular keratinocytes have been considered to be the source of the mucin, an etiologic role for cell-mediated immune mechanisms has been proposed[42], including a reaction to persistent antigens such as *Staphylococcus aureus*.

Clinical features

Primary follicular mucinosis is an idiopathic benign form of the disease, apparently not linked to lymphoma[42]. Clinically, it presents as an acute or

subacute eruption in children and young adults and is characterized by one or several pink plaques, often composed of grouped follicular papules. There may be associated scale, and lesions are limited to the face (Fig. 46.15A) and scalp and are associated with alopecia. Papulonodules (Fig. 46.15B), annular plaques, folliculitis, follicular spines, and acneiform eruptions have also been described[42,43]. A second type of follicular mucinosis, characterized by: (1) a more generalized distribution (extremities, trunk and face; Fig. 46.15C); (2) larger and more numerous plaques; (3) a chronic clinical course; and (4) occurrence in a slightly older age group[41], is probably best regarded as a secondary follicular mucinosis associated with atopic dermatitis or cutaneous T cell lymphoma, rather than a primary condition. Follicular mucinosis has occasionally been observed in patients with hematologic malignancies other than mycosis fungoides.

Pathology

Mucin accumulates within the follicular epithelium and sebaceous glands, causing keratinocytes to disconnect (Fig. 46.15D). In more advanced lesions, the follicles are converted into cystic spaces containing mucin, inflammatory cells, and altered keratinocytes. A perifollicular and intrafollicular infiltrate of lymphocytes, histiocytes, and eosinophils is seen[6].

Differential diagnosis

The differentiation between primary follicular mucinosis and mycosis fungoides-associated follicular mucinosis is very difficult[6], and there is no single reliable criterion. Although the existence of a primary form of follicular mucinosis has been questioned by some authors (who consider it as an "indolent" localized form of cutaneous T cell lymphoma[44]), features in favor of a primary form are the young age of the patient, a solitary plaque or limited number of lesions in the head and neck region, spontaneous resolution, and the absence histologically of epidermotropism and atypical lymphocytes. Detection of clonal T cell gene rearrangements does not seem to help differentiate the two types[42,42a].

Treatment

There is no specific treatment. A wait-and-see approach is recommended for primary follicular mucinosis as many cases resolve spontaneously within 2–24 months. Topical, intralesional, and systemic corticosteroids, antimalarials[44], phototherapy (PUVA, UVA1), minocycline, dapsone, indomethacin, oral isotretinoin, interferon-α-2b, and orthovoltage irradiation have been reported to be beneficial. For secondary forms, treatment of the underlying disease is indicated. Longitudinal evaluation and assessment for cutaneous T cell lymphoma is recommended for patients with presumed primary follicular mucinosis that is persistent or becomes more extensive.

Urticaria-like follicular mucinosis

Urticaria-like follicular mucinosis is a very rare disorder that occurs primarily in middle-aged men. Pruritic urticarial papules or plaques appear on the head and neck within an erythematous "seborrheic" background. As lesions resolve, red macules persist for a few weeks. Hair-bearing regions may be involved, but neither follicular plugging nor alopecia is seen. Urticaria-like follicular mucinosis waxes and wanes irregularly over a period that can vary from a few months to 15 years. There are no associated systemic diseases. Response to natural sunlight has been inconsistent, but it has been beneficial in a small number of cases.

As in primary follicular mucinosis, mucin-filled cystic spaces occupy hair follicles. In the upper dermis, lymphocytes and eosinophils are seen around blood vessels and hair follicles. In only a single patient to date were vascular C3 deposits seen by direct immunofluorescence. The prognosis is good, and based upon a limited number of case reports, antimalarials and dapsone were reportedly beneficial[45].

PRIMARY HAMARTOMATOUS–NEOPLASTIC MUCINOSES

Although stromal mucin deposition may be found in a variety of cutaneous tumors as an additional finding (e.g. basal cell carcinomas, neurofibromas), only in mucinous nevus and (angio)myxoma is the mucin deposition a distinctive feature.

Mucinous Nevus

A mucinous nevus (nevus mucinosus) is a benign hamartoma that can be congenital or acquired. It consists of a plaque that usually has a unilateral linear nevoid pattern[46]. Histologically, a diffuse deposit of mucin is seen in the upper dermis, and collagen and elastic fibers are absent within the mucinous area. The epidermis can be normal or it may be acanthotic with elongation of the rete ridges and hyperkeratosis, as in an epidermal nevus. The latter set of findings points to a combined hamartoma, in which features of an epidermal nevus are associated with those of a connective nevus of the proteoglycan type. The cellular component of a mucinous nevus consists of $CD34^+$ fibroblasts and scarce factor XIIIa-positive dendritic cells.

Superficial (Angio)Myxoma

Superficial (angio)myxoma, also known as cutaneous myxoma, is an acquired benign neoplasm that is usually nodular and measures 1–5 cm in diameter. It favors the trunk, head and neck, and genital region; rarely, cutaneous myxomas have an acral location[47]. These tumors can be solitary, without any systemic abnormalities, or multiple. When multiple and involving the external ears, eyelids, or nipples, they may be a manifestation of Carney complex (cutaneous myxomas, cardiac myxomas, numerous lentigines, multiple blue nevi, endocrinopathies)[48].

Histologically, a cutaneous myxoma is a lobulated, well-defined lesion characterized by a mucinous matrix within the dermis and the subcutis, with variably shaped fibroblasts, mast cells, and a few collagen and reticulin fibers. Bizarre multinucleated cells and regular mitotic figures can be seen. The stromal cells are positive for vimentin and smooth muscle α-actin (SMA), with variable positivity for CD34, S-100, factor XIIIa, and CD68[47].

Myxomas must be distinguished from cutaneous focal mucinosis, a reactive lesion which is usually <1 cm and ill-defined histologically; the latter does not have an epithelial component and the mucin deposits are in the dermis but not the subcutis. This differentiation is important as (angio)myxomas are true neoplasms, although benign, which can recur after incomplete excision. When an (angio)myxoma is located in the genital region, it needs to be distinguished from an aggressive angiomyxoma, a rare neoplasm with potential for local recurrence and very rarely for distant metastases. Aggressive angiomyxomas usually stain positively for estrogen and progesterone receptors and are characterized by a different vascular component with variable thickness of vessel walls.

SECONDARY CUTANEOUS MUCINOSES

Secondary cutaneous mucinoses include all those diseases in which mucin deposition represents only an additional histologic finding and not the main feature[1]. As an epiphenomenon, a wide range of inflammatory disorders and neoplasms may have mucin deposition in the epidermis and/or dermis or within the follicular unit. Secondary mucinoses are outlined in Table 46.3.

Amyloidosis 47

Richard W. Groves

INTRODUCTION

Amyloidosis is not a single disease; rather, the term is used to refer to several diseases that share the common feature of abnormal extracellular deposition of amyloid, a fibrillar proteinaceous material, within tissues. Deposits of amyloid can be seen in a range of clinical disorders, from plasma cell dyscrasias and Alzheimer disease to familial polyneuropathies and primary cutaneous lichen amyloidosis.

Amyloid itself is not a single chemically distinct substance, and several types of amyloid have been described. However, regardless of the source, pathogenetic mechanisms, or underlying disease, amyloid material shares certain common tinctorial and physico-chemical properties, e.g. the cross-β-pleated sheet configuration[1].

The two clinical settings in which dermatologists are likely to encounter amyloidoses are: (1) the more common primary cutaneous forms of amyloidosis; and (2) the less common systemic amyloidosis with cutaneous manifestations (Fig. 47.1).

History

Virchow, in 1854, introduced the term "amyloid"[2]. He believed that the substance resembled starch or cellulose because, like starch, it turned blue when stained with iodine followed by dilute sulfuric acid. In 1928, Gutmann first described a patient with clinical features of lichen amyloidosis, while Freudenthal, in 1930, introduced the term "lichen amyloidosus"[3].

Epidemiology

The precise epidemiology of systemic amyloidosis is not known, as the disease is often underdiagnosed or misdiagnosed[4]. In the US, the incidence of primary systemic amyloidosis is estimated to be ~1300 to 3200 new cases per year[4]; an increase in detection will likely accompany more widespread use of the assay for serum free light chains. Since 1980, there has been a marked decline in the incidence of symptomatic rheumatoid arthritis-associated secondary systemic amyloidosis due to better control of the inflammatory response[5,6].

Primary cutaneous amyloidosis is commonly observed in Southeast Asian countries, including Singapore, Taiwan, and Thailand[7]. Lichen amyloidosis in particular appears to be more prevalent in those of Chinese descent. Macular amyloidosis is frequently seen in Central and South American countries, especially those close to the equator[8]. In general, macular and lichen amyloidosis occur more often in individuals with skin phototypes III and IV.

Classification

Amyloidosis can be classified clinically into systemic (generalized) forms, with involvement of several organ systems, and organ-limited (localized) forms, in which deposits are limited to a single organ such as the skin (Table 47.1). In the localized forms, amyloid deposition occurs at or near the site of synthesis, while in the systemic forms the precursors are secreted into the circulation, followed by amyloid deposition at distant sites[9]. Amyloidosis can also be classified according to its constituent precursor protein (Table 47.2; see next section).

Pathogenesis

The major component of amyloid is the fibril protein; the minor components are amyloid P component, glycosaminoglycans, and apoE lipoprotein. Amyloid P is a glycoprotein derived from serum amyloid P protein (SAP) and it has a specific calcium-dependent binding affinity for amyloid. Over 40 distinct forms of amyloid fibril proteins and their precursors have been identified[9a], including: AL (amyloid light chains), containing immunoglobulin light chains; AA (amyloid-associated), composed of an acute phase protein synthesized by the liver; Aβ amyloid, found in cerebral lesions of Alzheimer disease; and ATTR (transthyretin-associated), found in some forms of familial amyloidosis (mutated) and senile systemic amyloidosis (wild-type)[9]. Each condition is associated with a specific precursor protein (see Table 47.2)[10]; these amyloid precursors are initially soluble proteins that undergo changes leading to aggregation, polymerization, fibril formation, and, finally, extracellular tissue deposition as insoluble amyloid.

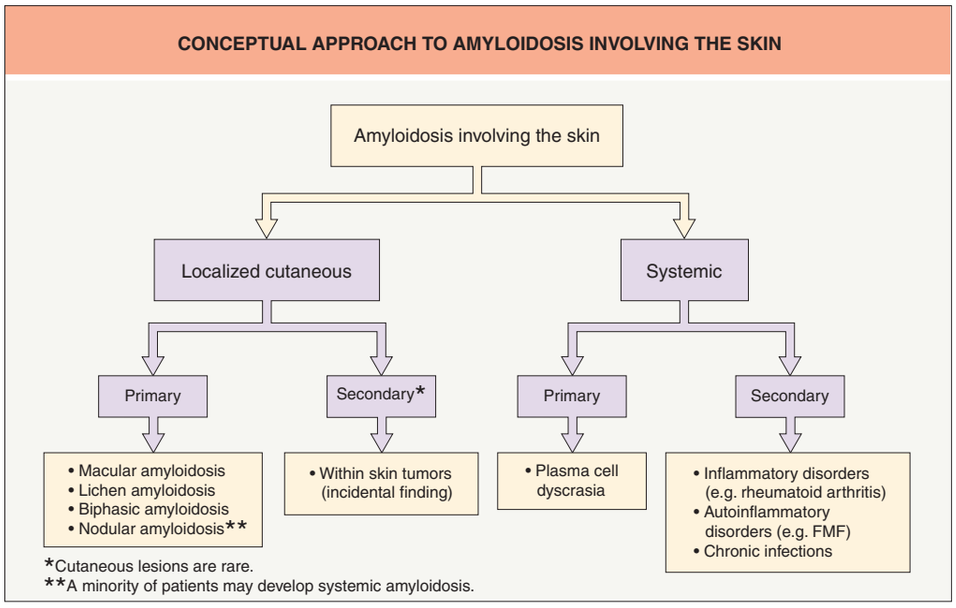

Fig. 47.1 Conceptual approach to amyloidosis involving the skin. FMF, familial Mediterranean fever.

CLINICAL CLASSIFICATION OF AMYLOIDOSIS
Organ-limited (localized) amyloidosis
Cutaneous • Primary: macular, lichen, biphasic, dyschromic, nodular • Secondary: incidental finding within various skin tumors (e.g. seborrheic keratoses, basal cell carcinomas, dermatofibromas, intradermal melanocytic nevi, adnexal tumors, Bowen disease, porokeratosis); following PUVA therapy Endocrine • Medullary carcinoma of the thyroid, insulinoma, type 2 diabetes Cerebral • Alzheimer disease
Systemic amyloidosis
Primary systemic amyloidosis (AL ≫ AH amyloid protein) • Plasma cell dyscrasias (more common) • Multiple myeloma-associated Secondary systemic amyloidosis (reactive; AA amyloid protein) • Chronic inflammation (e.g. rheumatoid arthritis, hidradenitis suppurativa) • Chronic infection (e.g. tuberculosis, Hansen disease [leprosy]) ATTR amyloidosis (transthyretin amyloid protein*) • Familial amyloid polyneuropathy (*TTR* mutations) • Familial amyloid cardiomyopathy/ATTR-CM (*TTR* mutations) • Wild-type ATTR amyloidosis (ATTRwt)/senile systemic amyloidosis/senile cardiac amyloidosis • ALect2 amyloidosis (leukocyte chemotactic factor 2) See Table 47.2 for additional forms
*Transthyretin is a serum transport protein for thyroxine and retinol-binding protein that is produced in the liver, choroid plexus and eye[9].

Table 47.1 Clinical classification of amyloidosis.

The process by which this transformation takes place differs amongst the various types of amyloidoses. In primary systemic amyloidosis, substitution of amino acids at specific positions within the variable region of the immunoglobulin light chain potentially destabilizes these chains thereby increasing the likelihood of their conversion to amyloid fibrils. Similarly, mutations in the transthyretin gene have been shown to alter the stability of the transthyretin protein and increase its baseline mild amyloidogenicity[1,4]. The accumulation of these relatively inert amyloid fibrils within vital organs leads to functional impairment.

The precise pathogenesis of primary cutaneous amyloidosis is not yet fully understood. Prolonged friction, genetic predisposition (e.g. *OSMR*, *IL31RA*), and environmental factors have all been implicated as possible etiologies. The precursor protein involved has not been fully characterized; however, for the macular and lichenoid variants of primary cutaneous amyloidosis it is thought to be keratinocyte-derived. This has been supported by ultrastructural studies demonstrating transitional forms between viable keratinocytes and amyloid, as well as by positive reactions with monoclonal antibodies directed against basal layer keratins[11]. The fibrillar theory proposes that keratinocyte tonofilaments undergo degeneration and pass into the dermis, where they are presumably modified by histiocytes and fibroblasts into amyloid material. An alternative theory suggests that the material is produced at the epidermo-dermal interface, with precursor proteins being secreted by basal keratinocytes. This hypothesis has been supported by ultrastructural findings and demonstration of basement membrane antigens such as type IV collagen and laminin within amyloid deposits[11]. Although these cutaneous amyloid deposits stain positively with anti-human antibodies directed against IgG, IgM and IgA, this staining is thought to be the result of nonspecific immunoglobulin absorption as opposed to an immunoglobulin being the putative precursor protein. Apolipoprotein E4, galectin-7, and actin have also been shown to be associated with primary cutaneous amyloid deposits and may be synthesized locally by keratinocytes[12,13]. Small fiber neuropathy has been observed in primary cutaneous amyloidosis and may be related to the associated pruritus[14].

In nodular amyloidosis there is no specific staining with antikeratin antibodies, but rather the amyloid deposits are composed of immunoglobulin light chains, suggesting plasma cell derivation akin to the cutaneous lesions of primary systemic amyloidosis. Thus, its origin is very different from that of either macular or lichen amyloidosis[11]. Presumably, there is local cutaneous production of light chains in nodular amyloidosis, whereas in primary systemic amyloidosis with skin involvement, the light chains are derived from the systemic circulation.

CHEMICAL CLASSIFICATION OF AMYLOIDOSES		
Precursor protein	**Amyloid protein**	**Clinical syndrome**
Aβ precursor protein (AβPP)	Aβ	Alzheimer disease, aging
(Apo) serum AA*	AA	Secondary systemic amyloidosis (see Table 47.1), autoinflammatory syndromes (e.g. familial Mediterranean fever, Muckle–Wells syndrome, TRAPS; see Table 45.2)
Apolipoprotein AI	AApoAI	Hereditary apolipoprotein AI-associated amyloidosis; distribution of organ involvement, including skin, related to location of mutation
Apolipoprotein AII	AApoAII	Familial renal amyloidosis
β_2-microglobulin	Aβ_2M	Chronic hemodialysis
Calcitonin	ACal	Medullary carcinoma of the thyroid
Cystatin C	ACys	Hereditary cystatin C amyloid angiopathy†
Gelsolin	AGel	Familial amyloidosis, Finnish type
Immunoglobulin heavy chain (very rare)‡	AH	Primary systemic amyloidosis
Keratin	AKer	Primary (localized) cutaneous amyloidosis
Immunoglobulin light chain	AL	Primary systemic amyloidosis (associated with plasma cell dyscrasia¶ ≫ multiple myeloma), primary cutaneous nodular amyloidosis
Medications: insulin enfurvitide anakinra GLP-1 receptor agonist	AIns AEnf AIL1RAP AGLP1	At sites of injections, firm nodules or in abdominal fat of normally appearing skin (AGLP1)
Leukocyte chemotactic factor 2	ALect2	Progressive renal insufficiency and hepatic involvement; favors Mexican-Americans
Transthyretin	ATTR	ATTR amyloidosis: (1) familial amyloid polyneuropathy (*TTR* mutations); (2) familial amyloid cardiomyopathy (*TTR* mutations); and (3) wild-type ATTR amyloidosis/senile systemic amyloidosis/senile cardiac amyloidosis
Corneodesmosin	ACor	Hypotrichosis simplex of the scalp

*Amyloid-associated protein synthesized by the liver.
†Detection of deposits within clinically normal skin allows diagnosis prior to clinical symptoms (cerebral hemorrhage).
‡More commonly, heavy chains produce a non-amyloid type deposit termed heavy chain deposition disease which is sometimes associated with acquired cutis laxa.
¶Monoclonal gammopathy; progression depends upon risk factors (e.g. non-IgG paraprotein).

Table 47.2 Chemical classification of amyloidoses. Except for Aβ, AApoAII, ACal and ALect2 (light shade), there are reports of amyloid deposits in involved or clinically uninvolved skin and/or oral mucosa. Although >40 types of amyloid have been characterized[9a], to date there are no reports of associated cutaneous lesions in types not listed in the table. GLP, glucagon-like peptide; IL1RAP, interleukin-1 receptor antagonist protein; TRAPS, TNF receptor-associated periodic syndrome. *Adapted from Sipe JD, Benson MD, Buxbaum JN, et al. Amyloid fibril protein nomenclature: 2010 recommendations from the nomenclature committee of the International Society of Amyloidosis. Amyloid 2010;17:101–4.*

Amyloid Properties

In H&E-stained sections, amyloid appears as amorphous, eosinophilic fissured masses (Figs. 47.2, 47.3A & Table 47.3). With a Congo red stain, amyloid has an orange–red color on routine light microscopy, whereas under polarized light it exhibits green birefringence (Fig. 47.3B). Other special stains that can be used to detect amyloid deposits include crystal violet, methyl violet, periodic acid Schiff (PAS), Sirius red, pagoda red, Dylon stain, and Thioflavin T (Fig. 47.3C)[15]. AA (but not AL) amyloid loses its affinity for Congo red after exposure to potassium permanganate.

By electron microscopy, amyloid appears as 7 to 10 nm wide, non-branching, non-anastomosing fibrils (see Fig. 47.2). X-ray crystallography and infrared spectroscopy reveal a characteristic cross-β-pleated sheet conformation. These findings are identical in all types of amyloid, regardless of clinical setting or chemical composition[15]. The cross-β-pleated sheet structure of amyloid is believed to be responsible for its staining and birefringence with Congo red stain.

Immunohistochemical stains utilizing antibodies directed against the amyloid fibril proteins (e.g. immunoglobulin γ light chain, transthyretin, keratin, AA protein) can help to differentiate between the types of amyloid (Fig. 47.3D). However, these immunohistochemical stains have limitations. For precise protein identification, including AL, ATTR and Alect2, liquid chromatography–tandem mass spectrometry (LC-MS/MS) is performed on formalin-fixed, paraffin-embedded sections or subcutaneous fat fine needle aspirates (see Table 47.2)[16,17]. Laser capture technology can be used to obtain the sample for testing.

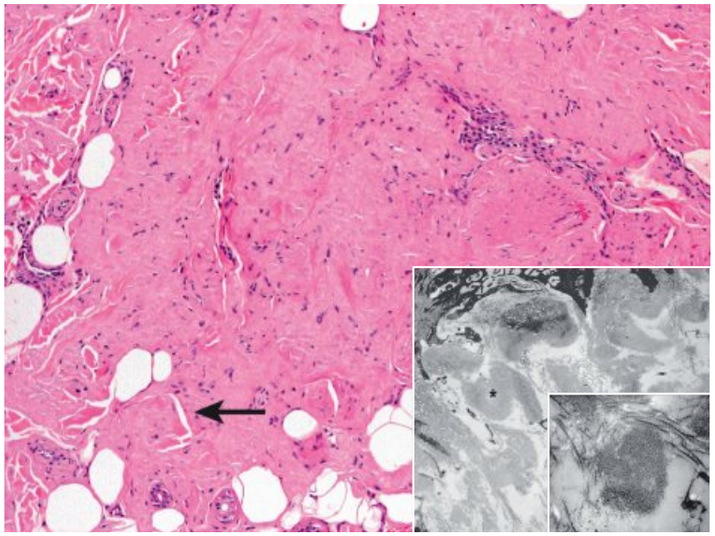

Fig. 47.2 Histologic features of amyloid deposits within the skin. In this example of nodular amyloidosis, the dermal deposits are eosinophilic, amorphous and contain fissures (arrow). By electron microscopy, there are clusters of filamentous deposits (*) and 7–10 nm non-branching fibrils (inset). *Courtesy Lorenzo Cerroni, MD and St John's Institute of Dermatology.*

HISTOPATHOLOGIC FEATURES OF AMYLOID DEPOSITS
• Homogeneous, hyaline, eosinophilic deposits in H&E-stained sections (Figs. 47.2 & 47.3A)
• Crystal violet metachromasia
• Positive staining with alkaline Congo red
• Apple-green birefringence under polarized light after Congo red staining; also dichroic (Fig. 47.3B)
• Fibrillar structure on electron microscopy (Fig. 47.2)
• Stains brightly by ultraviolet fluorescence microscopy after Thioflavin T staining (Fig. 47.3C)
• Staining with antibodies to amyloid P component
• Staining with antibodies directed against specific precursors (e.g. keratin [Fig. 47.3D])

Table 47.3 Histopathologic features of amyloid deposits[2].

PRIMARY LOCALIZED CUTANEOUS AMYLOIDOSIS

Primary cutaneous amyloidosis is associated with the deposition of amyloid in the skin but not internal organs (see Table 47.1). The most common variants are macular amyloidosis, lichen amyloidosis, and biphasic amyloidosis.

Clinical Features – Macular, Lichenoid, Biphasic, and Dyschromic Amyloidosis

Although primary cutaneous amyloidosis is classically divided into macular (macular amyloidosis), papular (lichen amyloidosis), and nodular (nodular amyloidosis) forms, the first two entities actually represent the ends of a clinical spectrum. In some patients and even some lesions both macular and papular forms can be present, termed "biphasic amyloidosis"[18,19]. Primary cutaneous amyloidosis can have a profound effect on quality of life due to the associated pruritus and visual appearance of the skin lesions[20].

Macular amyloidosis is often pruritic but it may be asymptomatic. The lesions of macular amyloidosis are hyperpigmented, either in a confluent or rippled pattern (Fig. 47.4A). The latter can be best appreciated by stretching the skin. The most common site of involvement is the upper back, especially over the scapular area, followed by the extensor surfaces of the extremities. A linear or even nevoid pattern may be seen (Fig. 47.4B). Macular amyloidosis usually presents in early adulthood, and women may be affected more often than men[15,21]. In biphasic amyloidosis, fine papular lesions are superimposed upon a background of hyperpigmentation.

The term "friction amyloidosis" has been used to describe a subgroup of patients in whom local friction from nylon brushes, towels, and other rough materials contributes to the production of macular and lichenoid lesions. There is also significant clinical overlap between macular amyloidosis and the pigmented form of notalgia paresthetica, where pruritus of the scapular areas leads to rubbing and scratching (see Ch. 6).

Lichen amyloidosis is the most common form of primary cutaneous amyloidosis and usually presents as persistent, pruritic plaques on the shins or other extensor surfaces, e.g. anterior thighs or forearms (Fig. 47.5)[10,18]. Initial lesions are discrete, firm, scaly, skin-colored or hyperpigmented papules, which later coalesce into plaques that often have a rippled or ridged pattern. At the onset, lesions are usually unilateral, but over time a bilateral symmetric distribution pattern can develop[18].

Primary cutaneous amyloidosis manifesting as pigmentation and lichenification of the anal and sacral regions has been described as an ano-sacral variant, but these patients often have lichen amyloidosis

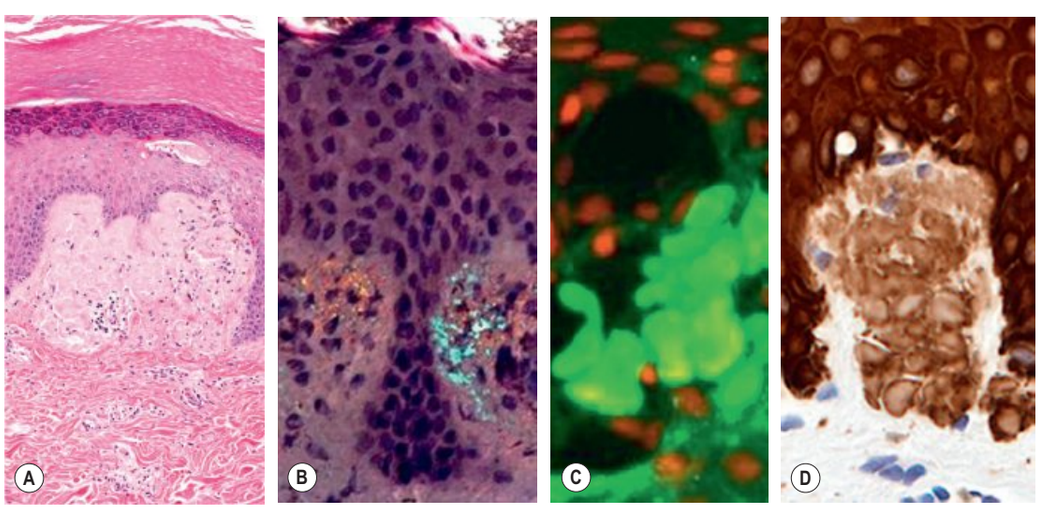

Fig. 47.3 Use of special stains to identify amyloid deposits within the papillary dermis in lichen amyloidosis. A In hematoxylin & eosin-stained sections, amyloid deposits, admixed with melanophages, are seen within the papillary dermis in addition to compact orthohyperkeratosis and acanthosis. **B** With Congo red stain, there is characteristic green birefringence with polarized light; the color can vary from yellow–green to blue–green. **C** With Thioflavin T stain, amyloid deposits stain brightly with ultraviolet fluorescence microscopy. **D** Positive immunohistochemical stain for keratin (MNF 116, broad-spectrum anti-keratin antibody). *A, Courtesy Lorenzo Cerroni, MD; B,C, Courtesy St John's Institute of Dermatology; D, Courtesy Jennifer McNiff, MD.*

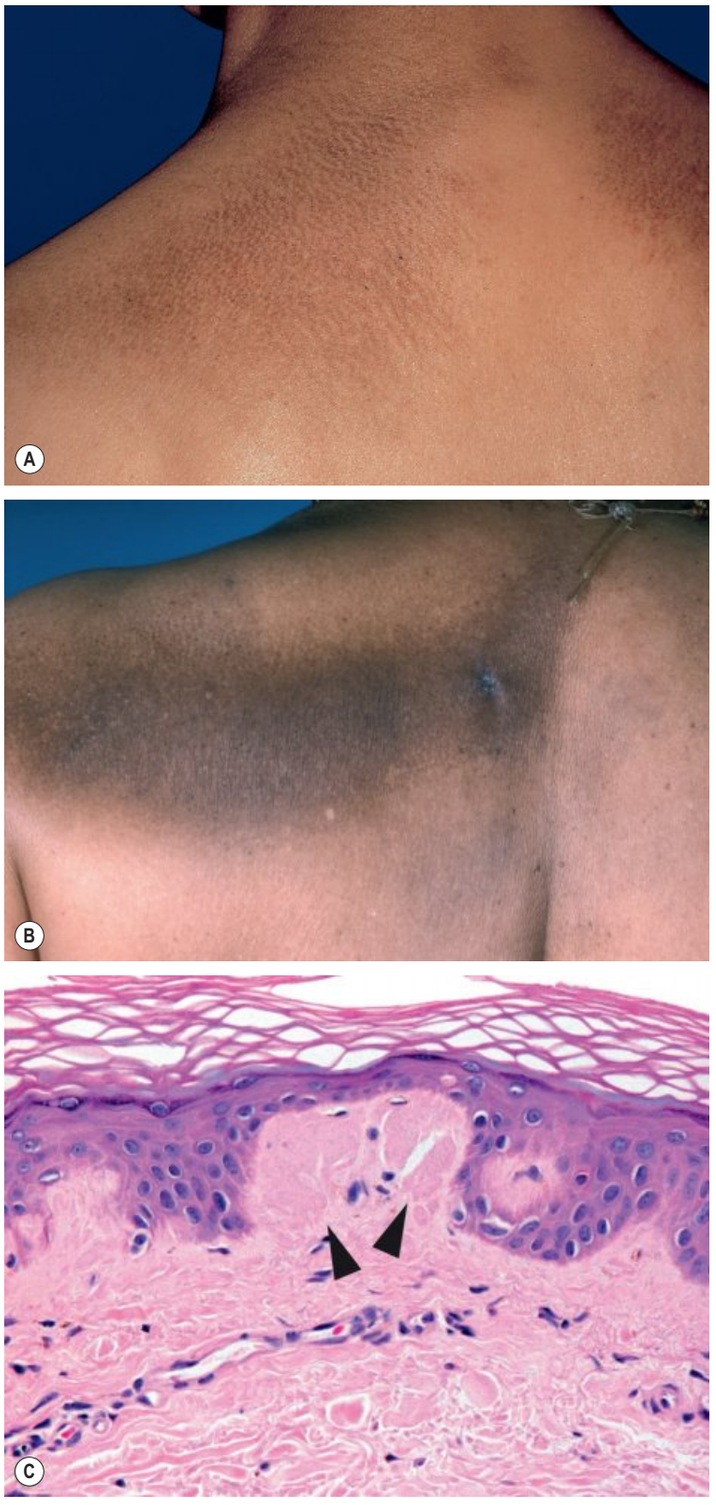

Fig. 47.4 Macular amyloidosis. A Characteristic rippled hyperpigmentation of macular amyloidosis. **B** Occasionally a linear accentuation is seen. Scattered papules can also be seen in both patients. **C** Histologically, deposits of amyloid within the dermal papillae (arrowheads) as well as melanophages within the papillary dermis; note the characteristic fissure in the amyloid deposit. These deposits may be subtle. *C, Courtesy Lorenzo Cerroni, MD.*

Fig. 47.5 Lichen amyloidosis. A Multiple monomorphous papules on the shin; the rippled appearance is most obvious laterally. **B** Numerous small monomorphous papules on the calves admixed with focal hemorrhagic crusts from scratching and hypopigmented scars. *B, Courtesy Lorenzo Cerroni, MD.*

Fig. 47.6 Primary cutaneous amyloidosis in a patient with systemic sclerosis. Note the numerous papules, some of which are in a grid-like array.

or biphasic amyloidosis elsewhere[18,19]. Bullous lesions have also been described in the setting of lichen amyloidosis, but they are more commonly associated with systemic amyloidosis.

Macular and/or lichen amyloidosis has also been described in association with autoimmune connective tissue disorders (e.g. systemic sclerosis [Fig. 47.6], systemic lupus erythematosus, dermatomyositis), and primary biliary cirrhosis[15]. One patient was observed to have sparing of lichen amyloidosis lesions in areas with higher cutaneous temperatures (such as along the course of large superficial veins), suggesting that amyloid fibril formation may be a temperature-dependent process *in vivo*[22].

Familial primary cutaneous amyloidosis syndromes

A number of genetic disorders have been identified that predispose to the development of primary localized cutaneous amyloidosis (PLCA).

IL-31 receptor-associated amyloidosis (PLCA1 and PLCA2)

Several families with primary localized cutaneous amyloidosis have been shown to have pathogenic variants in the genes that encode either the β subunit of the oncostatin M receptor (OSMR; PLCA1)[23] or the α subunit of the interleukin (IL)-31 receptor (IL-31RA; PLCA2)[24]. However, the protein product of *OSMR* serves as the β subunit of two receptors – not just OSMR but also IL-31R; this subunit then combines with IL-31RA to form the IL-31 receptor[25]. Of note, IL-31 has been shown to be of importance in pruritic skin conditions (e.g. dermatitis, prurigo nodularis), and nemolizumab, an anti-IL-31RA antibody, reduced pruritus in patients with atopic dermatitis[26]. In these families with primary localized cutaneous amyloidosis, IL-31 signalling may also be influenced by monocyte chemoattractant protein 1 (MCP-1)[27].

Dyschromic amyloidosis (PLCA3)

Dyschromic amyloidosis, also referred to as primary localized cutaneous amyloidosis 3 (PLCA3), is an unusual variant in which a guttate leukoderma is superimposed upon a background of hyperpigmentation and admixed with characteristic lesions of macular and lichen amyloidosis (see Fig. 67.27). Homozygous and compound heterozygous mutations in *GPNMB*, which encodes glycoprotein nonmetastatic melanoma protein b, have been detected in patients with dyschromic amyloidosis[28].

Sipple syndrome or multiple endocrine neoplasia (MEN) type 2A

Sipple syndrome is an autosomal dominant disorder with the triad of medullary carcinoma of the thyroid, pheochromocytomas, and hyperparathyroidism (see Ch. 63). Increased serum levels of calcitonin are a reflection of hyperplasia or carcinoma of the parafollicular calcitonin-producing C cells of the thyroid. Multiple endocrine neoplasia (MEN) type 2A is associated with pruritic areas of hyperpigmentation on the upper back. The lesions have been described as notalgia paresthetica, macular amyloidosis, and lichen amyloidosis. The unusual aspect is the early age of onset, often before the age of 10 years. Recognition of this skin sign of systemic disease can lead to prophylactic thyroidectomy once the diagnosis is established[29]. A study of 10 families with MEN 2A found an incidence of lichen amyloidosis of 36%; moreover, all those with cutaneous amyloidosis had a specific pathogenic variant in codon 634 of the *RET* proto-oncogene[30].

X-linked reticulate pigmentary disorder (Partington amyloidosis)

Partington and colleagues described a family with an X-linked disease in which adult women had linear streaks of hyperpigmentation and male patients manifested reticulated, mottled brown skin pigmentation, which on biopsy demonstrated dermal deposits of amyloid (in adults but not children). In women, involvement was limited to the skin, but in male patients, recurrent respiratory infections, corneal dystrophy, and photophobia were seen (see Ch. 67). As in macular amyloidosis, the amyloid deposits are keratin-positive and absent in other tissues[31].

Pathogenic variants in *POLA1* on chromosome Xp22, which encodes the catalytic subunit of DNA polymerase α1, have been detected in several families. This was associated with an activation of proinflammatory genes (e.g. NF-κB) and an increased type I interferon profile.

Other associated disorders

Primary cutaneous amyloidosis has also been reported in association with pachyonychia congenita, dyskeratosis congenita, and familial palmoplantar keratoderma[15]. At sites of injection of several medications, e.g. insulin, cutaneous amyloid deposits can develop (see Table 47.2)

Clinical Features – Nodular Amyloidosis

Nodular amyloidosis is rare, and presents as single or multiple waxy nodules or infiltrated plaques, most commonly on the trunk or extremities (Fig. 47.7A,B). Immunoglobulin γ light chains as well as β_2-microglobulin have been demonstrated within the deposits, and both are thought to be produced by plasma cells in the vicinity (Fig. 47.7D)[32]. In several patients with nodular amyloidosis, the cutaneous plasma cells had monoclonal restriction of their immunoglobulin light chains as determined by immunohistochemistry or *in situ* hybridization; examination of the bone marrow in one patient showed no evidence of a clonal plasma cell proliferation[33,34]. Of note, there may be an association between Sjögren syndrome and nodular amyloidosis of the skin or lung[35]. It has been suggested that at least some cases of cutaneous nodular amyloidosis could represent a variant of primary cutaneous marginal zone lymphoproliferative disorder (lymphoma) with unusual histopathologic features, but a similar excellent prognosis (see Ch. 119)[36,37].

There are reports of the nodular variant progressing to systemic involvement, hence longitudinal evaluation is appropriate. However, recent observations suggest that this risk is ~7%, much less than the previously quoted 50%. Although 40% of patients in this long-term study had a paraproteinemia at presentation, the gammopathy remained static during the follow-up period and progression to systemic involvement was

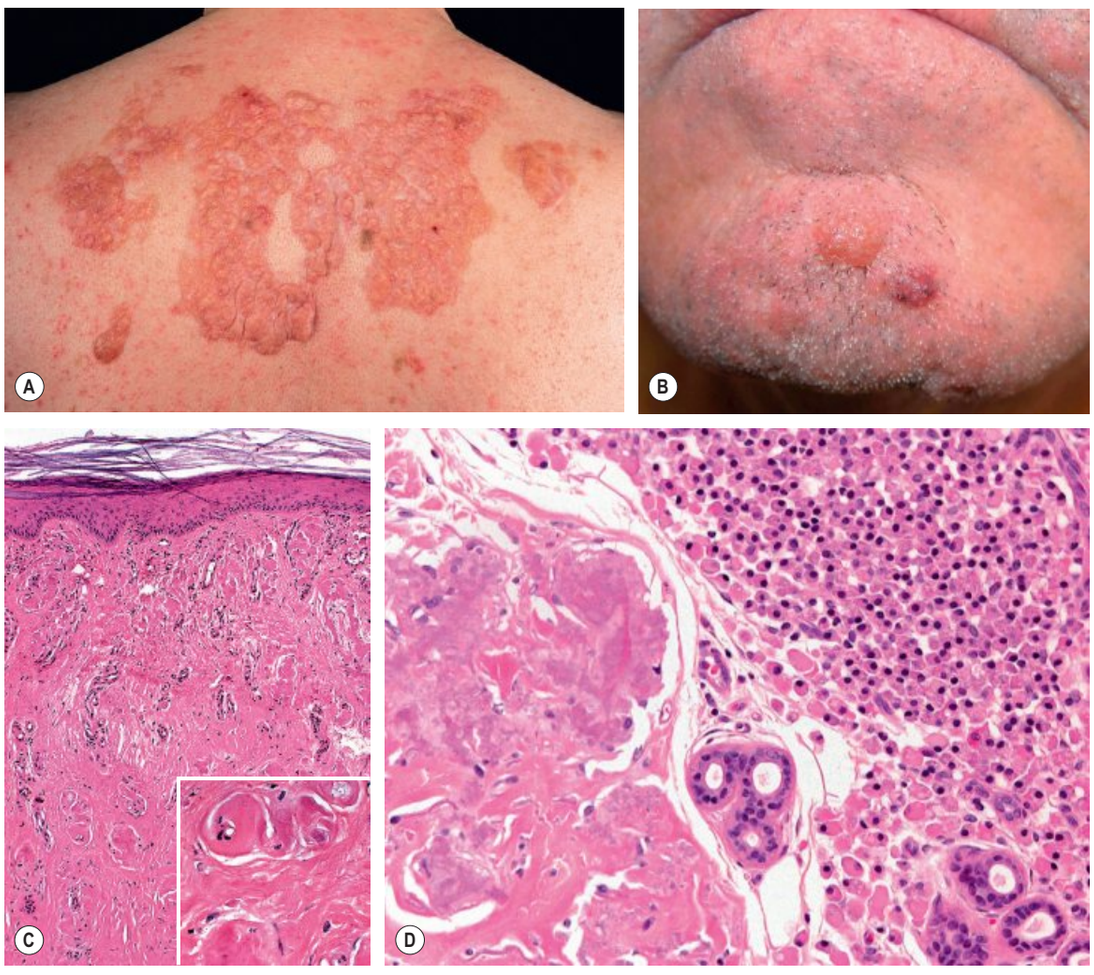

Fig. 47.7 Nodular amyloidosis. A, B Firm waxy plaques and nodules on the back and chin. The color can vary from skin-colored to pink–yellow to violaceous. **C** Histologically, there are extensive amyloid deposits within the dermis and around blood vessels. **D** An infiltrate of plasma cells can be seen in association with the amyloid deposits. *D, Courtesy Lorenzo Cerroni, MD.*

observed in only 1 of 15 patients, 23 years after the initial presentation[38]. A similar study of 16 patients with nodular amyloidosis found a near equal sex distribution, with a tendency for an acral distribution. There was one patient who subsequently died from systemic amyloidosis[34].

Pathology

In macular and lichen amyloidosis, amyloid deposits are restricted to the upper dermis, particularly the papillary dermis (Fig. 47.4C). In lichen amyloidosis, the deposits may expand the papillae and displace the elongated rete ridges laterally. The overlying epidermis often has features of chronic rubbing, e.g. acanthosis, compact orthohyperkeratosis (see Fig. 47.3A). Melanophages and a sparse perivascular lymphohistiocytic infiltrate can be seen in both forms. Although antikeratin antibodies (e.g. MNF 116) may be useful in confirming the keratin origin of the amyloid deposits in these two forms of primary cutaneous amyloidosis, they are seldom required (see Fig. 47.3D).

In contrast, in the nodular variant, the dermis, subcutis, and blood vessel walls are diffusely infiltrated with amyloid (Fig. 47.7C). A perivascular infiltrate of plasma cells is nearly universally present, but in most cases is inconspicuous (see Fig. 47.7D)[38]. Immunostaining for light chain deposition can aid in the diagnosis of nodular amyloidosis. As noted previously, these plasma cells are usually monoclonal, and it has been recently suggested that a number of cases of primary cutaneous nodular amyloidosis ("nodular amyloidoma") may represent a peculiar variant of cutaneous marginal zone lymphoproliferative disorder (lymphoma)[36,37].

Differential Diagnosis

The diagnosis of primary cutaneous amyloidosis is based on clinical morphology and histologic demonstration of amyloid deposits within the skin (see Table 47.3).

There is significant overlap in the appearance of *macular amyloidosis* and notalgia paresthetica. The latter is also seen on the upper back and can have rippled hyperpigmentation. Histologically, the early stages of notalgia paresthetica contain scattered necrotic keratinocytes and a few melanophages but no amyloid deposits. However, later on, even within the same lesion, deposits can appear. When macular amyloidosis is more diffuse or confluent, it must be distinguished from postinflammatory hyperpigmentation. Other entities in the differential diagnosis may include pityriasis versicolor, atrophic lichen planus (LP), erythema dyschromicum perstans (ashy dermatosis), and drug-induced pigmentation.

The primary differential diagnosis for *lichen amyloidosis* includes lichen simplex chronicus (LSC) and hypertrophic LP. Both are characterized by chronic pruritic plaques, often on the shins and, histologically, exhibit hyperkeratosis, acanthosis, and a mild to moderate lymphohistiocytic inflammatory infiltrate but no amyloid deposits. In LSC, lichenification is often prominent, while hypertrophic LP lesions may have a violaceous hue and, on histologic examination, a lichenoid infiltrate with vacuolar degeneration. Other entities that may be considered in the clinical differential diagnosis include papular mucinosis, pretibial myxedema, prurigo simplex/nodularis, pemphigoid nodularis, lichen ruber moniliformis, and epidermolysis bullosa pruriginosa.

Nodular amyloidosis may resemble the cutaneous lesions of primary systemic amyloidosis and the latter should be excluded. The clinical differential diagnosis also includes other nodular lesions (e.g. cutaneous lymphoid hyperplasia, sarcoidosis, colloid milium), all of which have rather distinctive histopathologic features and therefore can be easily differentiated.

Treatment

No treatment modalities described to date have proven to be curative or uniformly effective in patients with *macular or lichen amyloidosis* (Table 47.4)[39]. Treatment must be directed at breaking the itch–scratch–itch cycle usually present in these patients. Chronic friction, scratching, and rubbing can serve as possible precipitating or aggravating factors and patients should be advised of this. Potent topical corticosteroids are useful to some extent, especially in mild cases, and application under occlusion or in combination with a mild keratolytic agent such as salicylic acid (particularly in lichen amyloidosis) may have added benefit. The involved sites can be protected from scratching by applying occlusive dressings such as hydrocolloids or gauze wraps impregnated with zinc oxide for a period of weeks to months, but recurrence rates may be high. Based upon case reports, topical calcineurin inhibitors may play an adjunctive role, and more recently, dupilumab was observed to be an effective treatment for lichen amyloidosis[40]. Whether nemolizumab, the anti-IL-31RA antibody, will lead to improvement remains to be determined.

TREATMENT OF MACULAR AND LICHEN AMYLOIDOSIS
Potent topical corticosteroids, including under occlusion (2)
Topical calcineurin inhibitors (3)
Intralesional corticosteroids (3)
Occlusive dressings (e.g. hydrocolloid) or wraps (e.g. zinc oxide-impregnated) (3)
UVB phototherapy (2)
PUVA phototherapy (2)
Systemic retinoids (2)
Dermabrasion (2)
CO_2 laser therapy (2)
Low-dose cyclophosphamide (3)
Cyclosporin (3)
Dupilumab (3)
Thalidomide (3)

Table 47.4 Treatment of macular and lichen amyloidosis. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. PUVA, psoralen plus UVA; UVB, ultraviolet B.

In a study that compared the efficacy of topical corticosteroids versus either UVB or topical PUVA phototherapy for the treatment of lichen amyloidosis, there was greater improvement in the pruritus and roughness scores on the sides treated with either form of phototherapy, with PUVA being marginally better in reducing pruritus[41]. Dermabrasion was shown to be beneficial in lichen amyloidosis involving the limbs with the effects lasting at least five years: the epidermis and part of the papillary dermis along with some of the amyloid was removed, permitting re-epithelialization to occur from the adnexal structures[42]. CO_2 or erbium:YAG laser therapy may also be of benefit in some patients with macular and lichen amyloidosis[43,44].

Retinoids including acitretin[45] and alitretinoin[46] have been reported to improve pruritus and result in flattening of lesions, with some clearance of the associated hyperpigmentation[45]. In a preliminary study, low-dose cyclophosphamide (50 mg daily) was effective in reducing pruritus and papules in lichen amyloidosis[47]. However, the side effects of these systemic medications (see Chs. 126 & 130) must be weighed against the possible benefits.

Surgical excision, cryotherapy, electrodesiccation, and CO_2 laser can be used to treat *nodular amyloidosis*, but local recurrences are common[42]. Rarely, the local recurrence lacks amyloid deposits and has the histopathologic features of a conventional primary cutaneous marginal zone lymphoma[36]. There are scattered reports of the use of cyclophosphamide (see above)[47].

SECONDARY CUTANEOUS AMYLOIDOSIS

Secondary cutaneous amyloidosis refers to amyloid deposits that are inapparent clinically but can be detected histopathologically within skin lesions, most commonly in seborrheic keratoses and basal cell carcinomas and occasionally in dermatofibromas, intradermal melanocytic nevi, pilomatricomas, trichoepitheliomas, sweat gland tumors, Bowen disease, and porokeratosis[15]. In these settings, the amyloid deposits represent a histologic epiphenomenon without obvious clinical implications. Secondary cutaneous amyloidosis has also been reported following PUVA therapy.

Hypotrichosis simplex of the scalp 1/hypotrichosis 2 (HYPT2) is an uncommon autosomal dominant disorder and is perhaps best regarded as a particular form of secondary cutaneous amyloidosis. Patients have normal hair at birth, but progressively lose most scalp hair by the third decade. Eyebrows, beard and axillary hair, nails, and teeth develop normally. Pathogenic variants in the gene that encodes corneodesmosin, a glycoprotein expressed in the epidermis and inner root sheath, lead to truncated corneodesmosin proteins. The latter accumulate as amorphous amyloid deposits around hair follicles and in the papillary dermis[48].

SYSTEMIC AMYLOIDOSIS

Primary Systemic Amyloidosis

Multiple forms of systemic amyloidosis have been identified, but skin involvement is variable[49]. The following discussion focuses on those in which the skin is a major target.

AL amyloidosis

AL amyloidosis is a life-threatening manifestation of an underlying plasma cell dyscrasia, although patients usually do not fulfill the criteria for multiple myeloma (e.g. hypercalcemia, osteolytic lesions; see Ch. 119). The fibrils are composed of AL protein, which consists of immunoglobulin light chains, usually λ-type (75%–80%).

Clinical features

AL amyloidosis is associated with a wide spectrum of organ involvement. The presenting symptoms are varied and nonspecific, such as fatigue, weight loss, paresthesias, dyspnea, and syncopal attacks due to orthostatic hypotension[4,50]. As a result, there is often difficulty and delay in diagnosis.

In the oral cavity, amyloid deposits appear as rubbery swellings or an infiltration of the mucosa (Fig. 47.8A). An associated hemorrhagic component is frequently seen. The tongue can be uniformly enlarged and firm (Fig. 47.8B), or it may have hemorrhagic papules, plaques, and blisters on its surface; the latter may vary from translucent to yellow–brown in color. Xerostomia can result from infiltration of the salivary glands.

Following minor trauma, petechiae, purpura, and ecchymoses are often observed, especially on the eyelids and neck and in the axillae and anogenital region (due to amyloid infiltration of vessel walls; Fig. 47.9). Characteristically, periorbital purpura (the "raccoon eyes" sign) may be precipitated by coughing, the Valsalva maneuver, or proctoscopy for a rectal biopsy, as well as after pinching or rubbing the skin (pinch purpura). Even removal of adhesive tape can lead to purpura.

Clinically evident skin involvement occurs in ~25% of individuals with AL amyloidosis. Skin infiltration by amyloid presents as waxy, translucent, or purpuric papules (Fig. 47.8D,E & 47.10), nodules, and plaques that resemble nodular amyloidosis. A smooth, erythematous, waxy infiltration with scattered superimposed papules can appear on the palms and volar aspect of the fingertips (Fig. 47.8C). Smooth, skin-colored papules, a few millimeters in diameter, may be seen on the face, neck, and scalp and in the anogenital region.

Fig. 47.10 Primary systemic AL amyloidosis. A Numerous waxy translucent facial papules. Some have a yellow to yellow–brown color. **B** Some of the waxy papules have become purpuric, but this can be more difficult to appreciate because of the pigmentation of the skin (compare to Fig. 47.9). The periorbital region is a characteristic site of involvement. *A, Courtesy Jean L. Bolognia, MD; B, Courtesy Judit Stenn, MD.*

Less often, diffuse cutaneous infiltration can result in an infiltrated sclerodermoid appearance or cause the scalp skin to be thrown into folds resembling cutis verticis gyrata with associated alopecia. Bullous lesions, especially hemorrhagic blisters resembling those of porphyria cutanea tarda and epidermolysis bullosa acquisita, may be the initial sign of the disease. In addition, nail dystrophy can occur and may resemble lichen planus, with longitudinal ridging and thinning; histologically, amyloid deposits are found around blood vessels and in the dermis of the nail bed and matrix. Rarely, patients also have evidence of acquired acral cutis laxa. The presence of macroglossia together with carpal tunnel syndrome is a classic presentation and should trigger an investigation for amyloidosis.

Other signs and symptoms of AL amyloidosis depend upon the organs involved. Renal involvement manifests as proteinuria (albuminuria) which leads to hypoalbuminemia and edema, i.e. nephrotic syndrome. Cardiac involvement may eventually lead to a restrictive cardiomyopathy and congestive heart failure, but with a preserved ejection fraction. This results in dyspnea, hepatomegaly, and bilateral lower extremity as well as presacral edema. Autonomic and sensory neuropathies are common. Sensory involvement is usually bilateral and symmetrical, while autonomic involvement can result in postural hypotension, impotence, and disturbances in gastrointestinal motility (e.g. gastroparesis). Hepatomegaly due to amyloid infiltration or congestive heart failure may be present.

In up to 80%–90% of patients with AL amyloidosis, amyloid deposits can be demonstrated in random rectal mucosal biopsies or in abdominal subcutaneous fat aspirates; the latter is preferred because of the potential risk for bleeding with the former. Gingival or tongue biopsies may also be obtained to demonstrate the presence of amyloid, but in the absence of involvement clinically, they are less sensitive. In addition, bone marrow biopsies are examined for the presence of amyloid deposits. Based upon the finding that all of these amyloid deposits contain amyloid P (which is derived from serum amyloid protein [SAP]), SAP scintigraphy is also employed, primarily outside the US. It utilizes radioiodine-labeled SAP and is a sensitive, non-invasive method for locating amyloid deposits and monitoring disease. A more practical method for assessing response to therapy is measurement of serum free light chains.

The approach to a patient with suspected or confirmed AL amyloidosis is outlined in Fig. 47.11.

Pathology

In AL amyloidosis, cutaneous lesions are characterized by amyloid deposits in the dermis and subcutis. Amyloid is also often found around sweat glands and within blood vessel walls (Fig. 47.12). Rarely, an infiltrate of amyloid-producing monoclonal plasma cells can be found adjacent to the amyloid deposits. An unusual pattern of amyloid deposition around elastic fibers, in which the fibers appear coated with a thick mantle of amyloid-staining material, is occasionally seen and has been termed *amyloid elastosis*. The latter is rarely observed in primary cutaneous amyloidosis.

Differential diagnosis

The differential diagnosis of the waxy papules includes papular mucinosis, nodular amyloidosis, and lipoid proteinosis, and when the lesions are primarily on the face, they can be confused with adnexal tumors (see Ch. 111). Conditions in the sclerodermoid differential diagnosis (see Table 43.7) need to be considered when there is diffuse infiltration of the skin.

Treatment

Without therapy, the prognosis for AL amyloidosis is poor: median survival is ~13 months[50], especially if there is cardiac involvement. Treatment strategies have paralleled those for multiple myeloma, including melphalan and systemic corticosteroids[4,51,52]. The current FDA-approved treatment regimen for AL amyloidosis is the combination of cyclophosphamide, bortezomib, and dexamethasone (CyborD) plus daratumumab (anti-CD38 antibody). If the patient is younger and has minimal cardiac involvement, high-dose melphalan followed by autologous hematopoietic stem cell transplantation is a potentially curative therapeutic option. In one study with an 8-year follow-up period, a complete hematologic response was observed in 40% of transplanted patients and was associated with a prolonged survival. A survival benefit and clinical improvement in organ function was also seen in those who did not achieve a complete hematologic response[53].

Supportive measures are administered according to the organs affected and the consequent manifestations. Nephrotic syndrome and congestive heart failure require diuretic therapy and treatment of associated arrhythmias. Neuropathy and gastrointestinal involvement are treated symptomatically.

Secondary Systemic Amyloidosis (AA Amyloidosis)

Secondary systemic amyloidosis occurs as a complication of severe chronic inflammatory diseases of an infectious or non-infectious nature, such as tuberculosis, lepromatous leprosy, rheumatoid arthritis, and ankylosing spondylitis. It has also been observed in patients with hidradenitis suppurativa, dystrophic epidermolysis bullosa, generalized psoriasis, chronic pustular psoriasis, systemic sclerosis, dermatomyositis, autoinflammatory syndromes such as familial Mediterranean fever and Muckle–Wells syndrome, and systemic lupus erythematosus. Secondary systemic amyloidosis is characterized by the deposition of a distinctive non-immunoglobulin protein designated AA (amyloid A protein). The precursor is an acute phase protein which is synthesized by the liver and appears to have a regulatory function in lipoprotein metabolism during inflammation. AA amyloidosis usually affects the kidneys, liver, spleen, adrenals, and heart. Cutaneous lesions due to amyloid deposits are rarely seen in this type of amyloidosis, although amyloid can be detected within aspirates of subcutaneous fat[15].

Successful treatment of the underlying infectious or inflammatory disease may halt the progression of the reactive amyloidosis. For example, the use of systemic immunomodulators ("biologic agents") such as TNF inhibitors in patients with rheumatoid arthritis or ankylosing spondylitis and secondary amyloidosis has been shown to be clinically beneficial, resulting in a significant reduction in acute phase reactants and proteinuria[54]. A controlled clinical study found

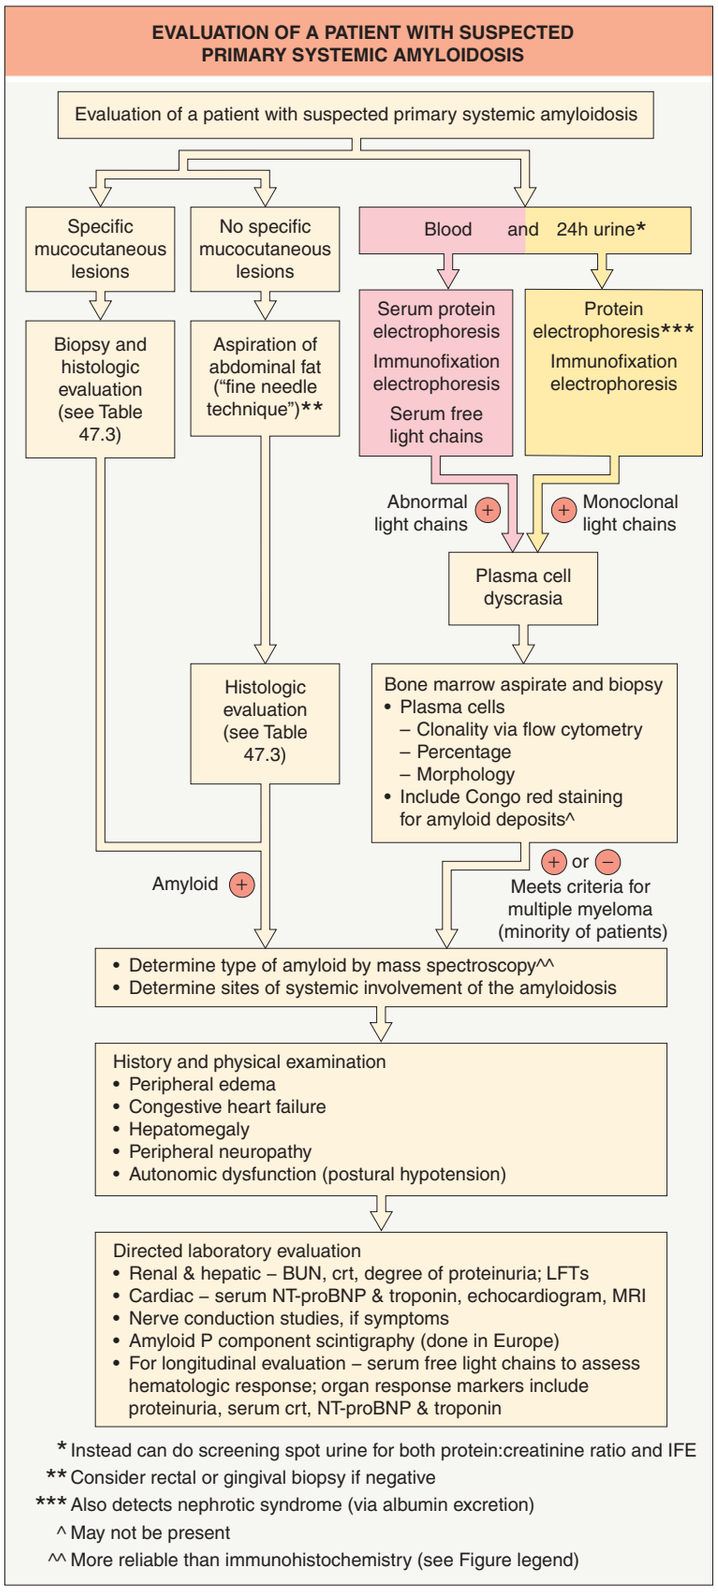

Fig. 47.11 Evaluation of a patient with suspected primary systemic AL amyloidosis. Because the amyloid is formed from immunoglobulin light chains, an abnormality of free light chains in the blood or urine (e.g. increased concentration or abnormal ratio in the blood, positive immunofixation electrophoresis [IFE] of the urine) is required for diagnosis. Mass spectroscopy has become more routine given the potential for misdiagnosis of older patients with wild-type ATTR deposits in the heart or ALect2 deposits in the kidney and liver in the setting of a monoclonal gammopathy of unknown significance. A positive cardiac pyrophosphate scan points to the diagnosis of ATTR amyloidosis. BUN, blood urea nitrogen; crt, creatinine; LFTs, liver function tests; NT-proBNP, N-terminal pro-brain natriuretic peptide.

that eprodisate may slow the loss of renal function in AA amyloidosis. Interestingly, this oral drug acts by changing the conformational configuration of the amyloid protein, rather than by affecting its production[55].

Hemodialysis-Associated Amyloidosis ($A\beta_2M$ Amyloidosis)

Hemodialysis-associated amyloidosis results from decreased excretion of β_2-microglobulin and is seen in patients receiving long-term hemodialysis for renal failure. Because β_2-microglobulin is not readily filtered through dialysis membranes, it is retained within the circulation and has a tendency to deposit in synovial membranes. Thus, the predominant manifestations are musculoskeletal, including carpal tunnel syndrome, bone cysts, and a destructive spondylo-arthropathy[4]. Occasionally, skin lesions have been observed, usually as subcutaneous nodules[56,57]. With improvement in dialysis membranes, the incidence has declined.

INHERITED AMYLOIDOSES

The genetic bases of primary localized cutaneous amyloidosis have been previously discussed (see above). Additional inherited forms of amyloidosis are listed in Tables 47.1 and 47.2, including those associated with autoinflammatory disorders (see Ch. 45).

Familial Amyloidosis, Finnish Type (AGel Amyloidosis)

Patients with the rare Finnish type of familial amyloidosis, which is due to variants in the gene that encodes gelsolin[58], present with a characteristic triad of corneal lattice dystrophy, cranial neuropathies, and skin findings including cutis laxa-like changes and skin fragility[59]. Interestingly, despite the multisystem nature of the condition, life expectancy does not seem to be affected[60].

Transthyretin Amyloidosis (ATTRwt/ATTRv Amyloidosis)

There are two forms of transthyretin amyloidosis: (1) ATTRwt which results from deposition of wild-type transthyretin in cardiac tissue and predominantly affects the elderly; and (2) ATTRv (variant transthyretin amyloidosis) that is due to mutations in the transthyretin gene and presents with either neurologic or cardiac dysfunction. The latter represents the commonest inherited form of systemic amyloidosis. The skin is only rarely involved[61], although cutaneous amyloid deposition occurs early in the disease and thus abdominal fat pad biopsy can be helpful in diagnosis.

Orthotopic liver transplantation represents a therapeutic option for hereditary ATTR amyloidosis[38] and tafamidis meglumine is FDA-approved for treatment of wild-type or hereditary ATTR cardiomyopathy[62]. Tafamidis binds selectively to transthyretin and slows monomer formation, misfolding, and amyloidogenesis. Patisiran, a small interfering RNA (siRNA), and inotersen, an antisense oligonucleotide, are approved therapies for hereditary ATTR polyneuropathy. A preliminary clinical trial utilized gene-editing CRISPR-Cas9 technology to target and significantly reduce production of misshapen transthyretin by the liver.

APPENDIX

Mucopolysaccharidoses 781

INTRODUCTION

The cutaneous deposition disorders are a heterogeneous group of conditions characterized by the presence of primarily endogenous substances within the dermis or the subcutis. Deposition disorders can be associated with localized or generalized cutaneous findings, and skin involvement is sometimes the earliest sign of a deposition disease. Histologic examination of cutaneous lesions, along with the use of special stains including immunohistochemistry, is a very helpful diagnostic tool (Table 48.1). In addition, specific enzymatic assays or genetic mutational analysis can then be performed to establish the precise diagnosis.

This chapter will focus on gout, pseudogout, lipoid proteinosis, colloid milium, and the mucopolysaccharidoses. Additional deposition disorders such as mucinoses, amyloidosis, porphyria, and calcinosis cutis are reviewed in Chapters 46–50.

GOUT

Synonyms ■ Urate crystal arthropathy ■ Podagra (first MTP joint) ■ Urate deposition disease

Key features

- Gout is a metabolic disease in which the underlying abnormality is hyperuricemia
- Deposits of needle-like crystals of monosodium urate are found in several sites, most commonly the skin (as tophi) and the joints
- In fresh preparations of synovial fluid and expressed material from tophi, the crystals exhibit negative birefringence when examined by polarized light
- In routinely fixed histologic sections, amorphous deposits that contain needle-like clefts are seen in the dermis and subcutis

Introduction

Gout is a metabolic disease in which needle-like crystals of monosodium urate (the ionized form of uric acid) from supersaturated fluids are deposited within tissue. Clinical manifestations include gouty arthritis, accumulation of crystals in connective tissue (tophi), uric acid nephrolithiasis, and renal impairment[1,2].

Epidemiology

Gout is the most common form of crystal-induced arthritis, and its prevalence seems to have increased over the past several decades. Men 40–50 years of age are most commonly affected. The male-to-female ratio is 9:1, and most women with gout are postmenopausal. Gout is found in up to 4% of adults and ~20% of patients have a family history of gout[2,3].

Pathogenesis

Gout is a consequence of deposits of urate crystals that have precipitated from supersaturated body fluids. Uric acid is the end product of the catabolism of purines. When the body increases its production of uric acid or if the kidneys do not excrete sufficient amounts, the result is hyperuricemia (Table 48.2). Migration and activation of neutrophils that are attempting to phagocytize urate crystals lead to the generation of neutrophil extracellular traps (NETs). The latter activate the NLRP3 inflammasome (see Fig. 4.2) via RIPK3-MLKL signaling, with subsequent production of proinflammatory cytokines. RIPK3 and MLKL represent two core proteins of the necroptosis pathway. Of note, NETs can also promote auto-resolution of the inflammatory phase of gout[4].

Clinical Features

The typical patient with gout is a middle-aged or older man, who may have a family history of the disease. Risk factors include obesity, excessive alcohol intake, renal insufficiency, and certain medications, most commonly diuretics. The natural history of gout involves four clinical stages[1]: (1) asymptomatic hyperuricemia; (2) acute gouty arthritis; (3) intercritical gout (the intervals between attacks, which progressively become shorter in duration); and (4) chronic tophaceous gout.

Acute gouty arthritis

The most common symptom of gout is the development of severe joint pain over a period of 6–12 hours, accompanied by tenderness, erythema, warmth, and swelling. Initial attacks are often monoarticular, but in up to 40% of patients they may be polyarticular[5]. In 75% of patients, the first metatarsophalangeal joint is involved (referred to as podagra); additional sites include the knee, ankle, and foot, and less commonly, the hand, wrist, and elbow. Fever and systemic symptoms may accompany an acute attack of gout. As the swelling subsides, the skin acquires a violaceous hue often followed by desquamation as edema subsides.

Chronic tophaceous gout

Cutaneous deposits of monosodium urate, known as "tophi", usually appear an average of 10 years after the onset of gout. These tophi present as firm dermal or subcutaneous papules and nodules or as a fusiform swelling. Their contours may be smooth or multilobulated (Fig. 48.1) and they vary from skin-colored to white–yellow to red (Fig. 48.2). The surface may be ulcerated and there may be associated drainage of material, which varies from clear fluid with white flecks to a thick chalky material.

The most common locations for tophi are the skin overlying joints and the helix of the ear. Unusual sites include the eyes, nose, larynx, breast, and heart valves. However, tophi develop in fewer than 10% of patients with gout. Depending upon the size and location of the tophi, complete, partial, or minimal resolution can occur when the serum uric acid level is normalized[2,6].

Elevated levels of uric acid in the urine are associated with uric acid nephrolithiasis and may cause acute renal failure when uric acid precipitates in the renal tubules and collecting ducts. The most common setting for the latter is tumor lysis syndrome following chemotherapy for a rapidly dividing chemosensitive malignancy, e.g. leukemias, lymphomas.

The initial diagnosis of gout is usually made in the setting of acute arthritis, based upon the presence of urate crystals in an aspirate of joint fluid. Hyperuricemia is usually present, but alone it is insufficient for establishing a definitive diagnosis of gout. Additional laboratory abnormalities during an acute attack include elevated white blood cell count (in the joint fluid and blood) and ESR.

DISORDERS WITH DERMAL DEPOSITS – HISTOLOGIC FEATURES			
Disease	**Microscopic findings**	**Histochemical stains**	**Special processing**
Gout	In formalin-fixed specimens, dermal deposits of amorphous material with needle-like clefts surrounded by a granulomatous infiltrate with giant cells Polarizing light/fresh preparation – fine, needle-like crystals; negative birefringence	20% silver nitrate solution: urate crystals appear black and the surrounding tissue yellow De Galantha stain: crystals brown–black	Best fixative to preserve crystals: ethanol-based (Carnoy's fluid)
Lipoid proteinosis	Masses of amorphous or laminated hyalin-like material Also surrounds capillaries in the papillary dermis and appendages	Contains type IV collagen and laminin PAS-positive and diastase-resistant ⊕ Alcian blue, hyaluronidase-sensitive Sudan III (+/–) Congo red (usually –)	Direct immunofluorescence with anti-ECM1 antibodies to assess protein expression
Colloid milium (adult form)	Nodules of amorphous eosinophilic material Artifactual clefts Solar elastosis	Stains similarly to amyloid (especially in frozen sections): ⊕ Congo red ⊕ Thioflavin T ⊕ Crystal violet	
Mucopolysaccharidoses	Metachromatic granules within fibroblasts Large vacuolated cells in sweat glands and the external root sheath of hair follicles (gargoyle cells)	Granules within fibroblasts: ⊕ Metachromasia with toluidine blue and Giemsa ⊕ Alcian blue ⊕ Colloidal iron (see Table 46.1)	Fixation in absolute alcohol better than in formalin (consider when clinical diagnosis not supported by histologic findings)
Mucinoses, e.g. papular mucinosis, scleredema, pretibial myxedema (Ch. 46)	Mucin between collagen and variable fibroblast proliferation	⊕ Metachromasia with toluidine blue ⊕ Alcian blue ⊕ Colloidal iron (see Table 46.1)	Fixation in absolute alcohol better than in formalin
Amyloidosis (Ch. 47)	Fractured, amorphous, faintly eosinophilic material in dermis	⊕ Congo red ⊕ Thioflavin T ⊕ Crystal violet	In glutaraldehyde for electron microscopy
Ochronosis (Chs. 63 & 67)	Sausage- or banana-shaped brown/yellow/orange structures	Black staining with methylene blue or cresyl violet	
Calcinosis cutis (Ch. 50)	Irregular masses of deeply basophilic materialVariable granulomatous inflammation (may be absent)	⊕ von Kossa ⊕ Alizarin red (more specific)	May fracture microtome blade May need decalcification solution first
Porphyrias, in particular EPP (Ch. 49)	Perivascular rim of delicate eosinophilic fibrillar material In chronic lesions, also dense homogeneous deposits	PAS-positive and diastase-resistant Immunohistochemistry for BMZ components (type IV collagen)	

Table 48.1 Disorders with dermal deposits – histologic features. BMZ, basement membrane zone; ECM1, extracellular matrix protein 1; EPP, erythropoietic protoporphyria.

CLASSIFICATION OF HYPERURICEMIA	
Overproduction of uric acid	• Primary/idiopathic • Excessive dietary purine intake and obesity • Increased nucleotide turnover • High-grade lymphomas (e.g. Burkitt) and myeloma • Myeloproliferative disorders, esp. acute myelogenous leukemia • Tumor lysis syndrome • Hemolysis • Psoriasis (severe) • Accelerated ATP degradation • Alcohol abuse • Severe muscle exertion • Hypoxanthine–guanine phosphoribosyl transferase deficiency (Lesch–Nyhan syndrome) • Glucose-6-phosphatase deficiency (glycogen storage disease type 1; von Gierke disease) • Phosphoribosyl pyrophosphatase synthetase overactivity
Decreased excretion of uric acid	• Primary/idiopathic • Chronic kidney disease • Enhanced tubular urate reabsorption (e.g. diuretics, dehydration) • Drug ingestion (e.g. cyclosporine > tacrolimus, pyrazinamide, low-dose salicylates) • Toxins (e.g. lead-induced nephropathy) • Miscellaneous – lactic acidosis, ketoacidosis, hypertension, hyperparathyroidism, hypothyroidism

Table 48.2 Classification of hyperuricemia. ATP, adenosine triphosphate.

Fig. 48.1 Tophaceous gout of a digit. The deposits create a multilobulated appearance and there is evidence of transepidermal elimination. A small incision over the yellow–white papules followed by microscopic examination of the expressed material would allow for a bedside diagnosis. *Courtesy Lorenzo Cerroni, MD.*

Fig. 48.2 Tophaceous gout of the tragus. The erythema reflects surrounding inflammation.

When examined by polarized light microscopy, the needle-shaped urate crystals change color from yellow to blue based upon their alignment relative to the axis of the "red plate" compensator, i.e. they exhibit negative birefringence. In patients with recurrent attacks, radiographs of involved joints often show "punched-out" erosions with sclerotic "overhanging" margins, but no osteophytes. A 24-hour urine collection for uric acid allows the identification of patients at risk for nephrolithiasis (see Table 48.2).

Pathology

The key histologic feature of formalin-fixed gouty tophi is the presence of deposits of amorphous material within the dermis and subcutis, corresponding to sites of crystal deposition. These deposits contain needle-like clefts (which represent dissolved urate crystals) surrounded by a granulomatous infiltrate with multinucleated giant cells (Fig. 48.3). Secondary calcification or even ossification can occasionally be seen in older lesions.

In order to preserve the crystals, the biopsy specimen needs to be placed in an ethanol-based fixative, such as Carnoy's fluid. Then, under regular or polarized light, brightly refractile brown sheaths of fine needle-like crystals can be seen. Upon staining with 20% silver nitrate solution, the crystals appear black and the surrounding tissue yellow, whereas with the De Galantha stain, the crystals appear brown to black[7].

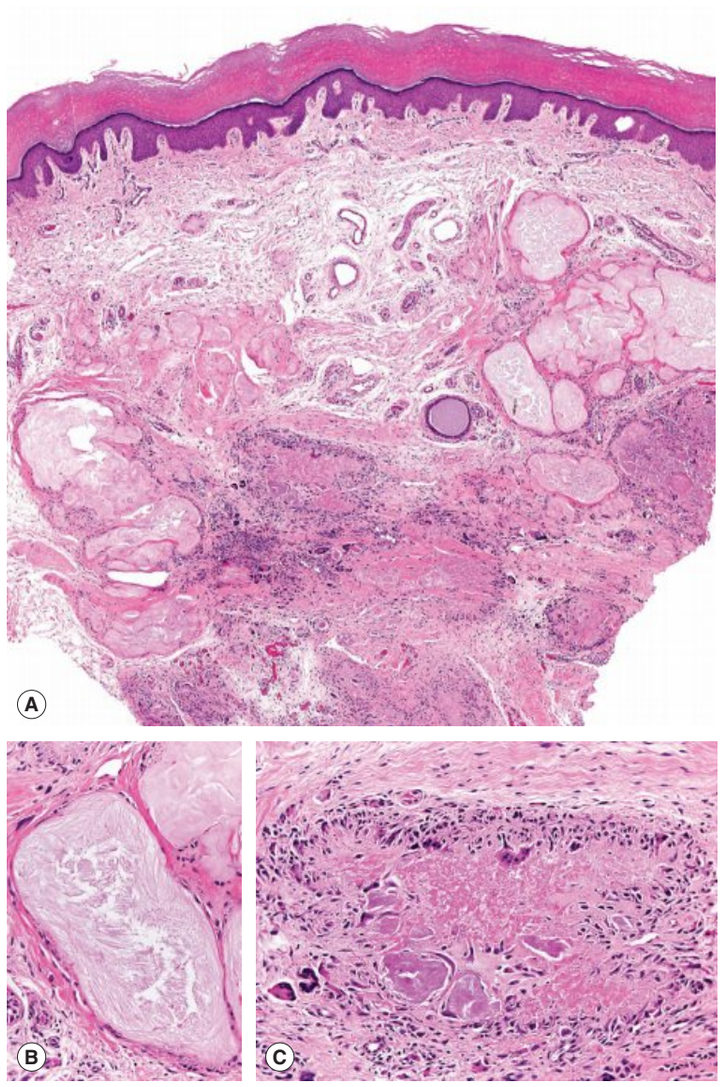

Fig. 48.3 Tophaceous gout – histopathologic features. A Within the dermis and subcutis, there are deposits of amorphous, acellular material. These deposits contain needle-like clefts (**B**). Histiocytes and multinucleated giant cells surround some of the deposits (**C**). *Courtesy Lorenzo Cerroni, MD.*

Differential Diagnosis

The differential diagnosis of acute gouty arthritis includes pseudogout (see below), osteoarthritis, psoriatic arthritis, reactive arthritis (previously referred to as Reiter disease), and septic arthritis. Given its destructive nature, septic arthritis needs to be considered even in patients in whom the diagnosis of gout has been previously established. The presence of needle-shaped crystals with negative birefringence in an aspirate of joint fluid is diagnostic of gout, while Gram stain and culture exclude septic arthritis. Occasionally, patients are misdiagnosed as having cellulitis.

The differential diagnosis of cutaneous gouty tophi includes xanthomas, rheumatoid nodules, and calcinosis cutis. Examination of expressed fluid or chalky material by polarized light can provide a "bedside" diagnosis. By ultrasonography, central clear spaces are seen within tophi whereas rheumatoid nodules contain central echodense areas[6].

Treatment

For acute gout, short-acting oral nonsteroidal anti-inflammatory drugs (NSAIDs) are taken within 24 hours of onset at the highest safe dosage as long as symptoms persist, e.g. indomethacin 50 mg three times daily for several days. Contraindications include peptic ulceration, renal insufficiency, and anticoagulation[6–8].

Colchicine, a derivative of the autumn crocus, inhibits the transport of phagocytized urate crystals to lysosomes within neutrophils via its binding to microtubules. Colchicine also interferes with leukocyte migration, chemotaxis, and adhesion. For patients with normal renal function who are not receiving strong CYP3A4 inhibitors, the recommended dosage for acute gout flares is 1.2 mg orally followed by 0.6 mg 1 hour later. Low-dose NSAIDs and colchicine (0.6 mg twice daily) are both utilized for prophylaxis. Outside of the US, colchicine tablets often contain 0.5 mg. Side effects of colchicine are outlined in Table 130.9. Intra-articular or systemic *corticosteroids* may be used for a period of 1–3 weeks if NSAIDs and colchicine are ineffective or contraindicated[6–8].

Urate-lowering therapy (ULT) consists of the xanthine oxidase inhibitors *allopurinol* and *febuxostat* which block uric acid production. Allopurinol is the preferred first-line ULT, but low starting doses (≤100 mg/day or lower if chronic kidney disease) are recommended[7]. ULT is indicated for patients with tophaceous gout, radiographic damage due to gout, or frequent gout flares. Concomitant anti-inflammatory prophylaxis therapy for 3–6 months is also recommended when initiating ULT[7].

Side effects of allopurinol include diarrhea, thrombocytopenia, hepatitis, and skin eruptions that can range from morbilliform to erythroderma to Stevens–Johnson syndrome/toxic epidermal necrolysis (SJS/TEN). HLA-B*58:01-positive individuals are at markedly increased risk of developing severe cutaneous adverse reactions, including both SJS/TEN and DRESS. Of note, this allele

is most common in those of Han Chinese, Korean, or Thai descent. Major side effects of febuxostat are liver enzyme elevations and cardiovascular thromboembolic events[9]. Drug–drug interactions, e.g. with azathioprine, can occur with both of these medications (see Fig. 130.5). Uricosuric agents such as oral *probenecid* can be added or used as second-line therapy for patients with normal renal function and no renal stones. Overall, maintenance of a serum uric acid level of ≤6 mg/dl is recommended. A newer agent, *lesinurad*, is a selective inhibitor of reabsorption of uric acid.

Some patients may benefit from a reduction in purine-rich foods (e.g. organ meats [liver, heart], fish), alcohol consumption, and body weight[6]. In the setting of potential tumor lysis syndrome, intravenous *rasburicase* can be administered, which rapidly converts uric acid to the more soluble allantoin. Bimonthly intravenous *pegloticase*, which has the same mechanism of action, can be used for patients with chronic gout refractory to conventional therapy. IL-1 blocking agents (e.g. *anakinra, canakinumab*) have been used for recurrent acute gout unresponsive to other therapies, but are not currently approved for this indication (see Fig. 45.13).

PSEUDOGOUT

Synonyms: ■ Chondrocalcinosis ■ Calcium pyrophosphate disease ■ Calcium gout

Key features

- Pseudogout is a form of arthritis that is due to deposits of calcium pyrophosphate dihydrate (CPPD) crystals within the joint
- It most commonly affects the knee and other large joints of older persons with osteoarthritis
- In aspirates of joint fluid, there are rhomboid CPPD crystals that exhibit weakly positive birefringence under polarized light

Pseudogout, which may be clinically indistinguishable from gout, was recognized as a distinct disease entity in 1962[10]. It results when CPPD crystals (produced by nucleoside triphosphate pyrophosphohydrolase, a catalytic enzyme found in osteoarthritic cartilage) form within joint fluid and then lead to lysis of neutrophils that have ingested the crystals. As in gout, the formation of NETs plays a role in the inflammatory cascade. Although pseudogout is most commonly related to osteoarthritis, it has also been associated with metabolic abnormalities such as hyperparathyroidism and hemochromatosis.

Symptoms of pseudogout include intermittent attacks of pain and swelling of affected joints, most commonly the knee, wrist, and shoulder. The onset of symptoms in pseudogout is usually more insidious than in gout. Occasionally, extra-articular CPPD deposition (tophaceous pseudogout) may present as a hard subcutaneous nodule overlying joints, primarily of the head (especially the temporomandibular joint), neck, or distal extremities[11].

Microscopically, CPPD crystals appear shorter than urate crystals and are often rhomboidal in shape. In tophaceous pseudogout, rhomboid crystals as well as foci of calcification can be seen within the dermis. Polarizing microscopy of sections stained with a non-aqueous alcoholic eosin stain (NAES) allows the demonstration of CPPD crystals with positive birefringence[12]. This is in contrast to the negative birefringence of urate crystals in gout and the lack of birefringence of calcium hydroxyapatite crystals in tumoral calcinosis. Treatment of the acute phase of pseudogout is identical to that of gout[11]. In patients with chronic renal failure, the anti-IL-1β antibody *canakinumab* may be considered (see Fig. 45.13)[13].

LIPOID PROTEINOSIS

Synonyms: ■ Hyalinosis cutis et mucosae ■ Urbach–Wiethe disease

Key features

- A rare autosomal recessive deposition disorder due to mutations in *ECM1*, which encodes extracellular matrix protein 1
- Hyalin-like material is deposited within multiple organs, including the skin, oral mucosa, larynx, and brain
- Papules and nodules favor the face, as do pitted scars; diffuse waxy thickening of the skin can be associated with verrucous changes, especially on the elbows, knees, and hands

History

Lipoid proteinosis was first described by Siebenmann in 1908. Twenty years later, it was established as a distinct entity by two Viennese physicians, Erich Urbach, a dermatologist, and Camillo Wiethe, an otorhinolaryngologist.

Epidemiology

Most patients are of European ancestry, including descendants of Dutch immigrants who settled in South Africa in the middle of the 17th century[14]. Not only do Afrikaners have the highest incidence of this genetic disease, they also exhibit a founder effect, i.e. the population shares a common mutation.

Pathogenesis

In 2002, lipoid proteinosis was shown to be due to loss-of-function mutations in *ECM1*, which encodes extracellular matrix protein 1[15]. ECM1 is a secretory glycoprotein that can act as a negative regulator of endochondral bone formation, a promoter of angiogenesis, and an inhibitor of matrix metalloproteinase 9. In addition, ECM1a (see below) is found within the basement membrane zone and can enhance the binding of collagen IV to laminin 332. It also interacts with components of the extracellular matrix such as fibronectin and glycosaminoglycans (e.g. hyaluronic acid, chondroitin sulfate)[16].

ECM1 has three major splice variants that result in different isoforms: (1) ECM1a, a protein of 540 amino acids encoded by a 10-exon gene; (2) ECM1b, a protein of 415 amino acids reflecting a lack of exon 7; and (3) ECM1c, a protein of 559 amino acids due to an additional exon 5a within intron 5. Patients with mutations in exon 7 still express the ECM1b isoform and tend to have milder disease as compared to those with mutations in exon 6, who tend to have more severe disease and reduced expression of all three isoforms. A majority of pathogenic mutations occur within exon 6 or 7[15]; occasionally, they occur in exon 2, 4, or 9[17]. The degree of dermal immunofluorescent staining (utilizing an anti-ECM1 antibody) points to the location; reduced staining suggests mutations in exon 7 and an absence of staining mutations in exon 6[16].

Clinical Features

The first clinical sign of lipoid proteinosis is often a weak cry or hoarseness due to infiltration of the laryngeal mucosa. Hoarseness remains throughout life. Cutaneous lesions usually appear during the first 2 years of life, in two overlapping stages. In the first stage, vesicles and hemorrhagic crusts develop within the mouth and on the skin of the face and extremities, often in association with trauma. The cutaneous lesions may resolve with scarring, including "ice-pick"-like scars.

During the second stage, there is an increase in the hyalin deposits within the dermis (Fig. 48.4). The skin becomes diffusely thickened and waxy and develops a yellow color. Papules, plaques, and nodules appear on the face (including the eyelid margin) as well as in the axillae and on the scrotum. Verrucous lesions may develop on the extensor surfaces, especially the elbows (see Fig. 48.4C), knees, and hands. Generalized scaling has also been observed as has alopecia of the eyebrows and eyelashes. Corneal ulcers may occur due to infiltration of the eyelids.

Fig. 48.4 Lipoid proteinosis – clinical features. A Beaded eyelid papules (moniliform blepharosis), hemorrhagic crusts, and confluent waxy papules of the glabella leading to an early leonine facies. **B** Skin-colored papulonodules of the elbow as well as irregular hypopigmented scars of the extensor forearm. **C** Characteristic verrucous changes of the elbow. **D** A firm tongue with numerous tiny papules on the dorsal surface. **E** Multiple, round hypopigmented and depressed scars on the shoulder. **F** Waxy, yellowish plaque on the back. *B, D, E, Courtesy Julie V. Schaffer, MD; C, Courtesy Judit Stenn, MD.*

In addition to involvement of the tongue (diffuse infiltration), the frenulum (restricted motion of the tongue), and the oropharynx, recurrent parotitis can occur due to occlusion of the salivary duct. Dental anomalies include hyperplasia or aplasia of the upper incisors, premolars or molars; patients usually lose their teeth at an early age. Neurologic manifestations are common and consist of behavioral and learning difficulties, seizures, and, less often, intracerebral hemorrhage. A pathognomonic radiographic finding is bilateral, intracranial, sickle-shaped calcification within the amygdalae[18]. More recently, an increased prevalence of renal cysts has been described.

In general, the disease has a stable or slowly progressive course that is compatible with a normal lifespan, except for the risk of respiratory obstruction in infancy. An elevated ESR may be seen due to increased α- or γ-globulins.

Pathology

The major clinical manifestations are related to the deposition of an amorphous or laminated material around blood vessels and within the connective tissues. The amorphous deposits consist primarily of non-collagen proteins, while the concentric layers of basement membrane-like material contain collagen (types II and IV) and laminin. In addition, the deposits are PAS-positive and diastase-resistant, indicating the presence of neutral glycosaminoglycans (GAGs; mucopolysaccharides).

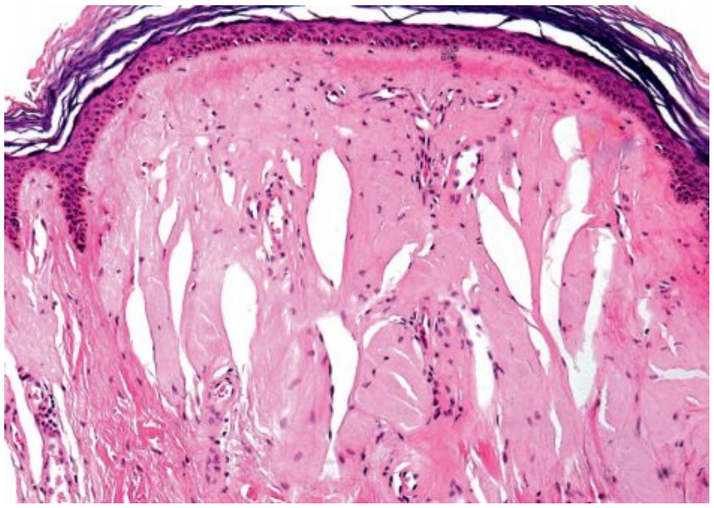

Fig. 48.5 Lipoid proteinosis – histopathologic features. Hyperkeratosis, a flattened epidermis, and vertically oriented eosinophilic deposits in the dermis. Note the cleft formation. *Courtesy Lorenzo Cerroni, MD.*

H&E-stained sections of early lesions reveal pink, hyalin-like deposits around the capillaries within the papillary dermis and at the periphery of eccrine sweat glands. Older lesions are characterized by hyperkeratosis, occasionally papillomatosis, and a thickened dermis in which bundles of pink hyalin deposits are found in a diffuse pattern (Fig. 48.5); the bundles are often oriented perpendicularly to the dermal–epidermal junction. There are smaller scattered deposits of hyalin in the lower dermis. Hyalin deposits also surround the hair follicles, sebaceous glands, and arrector pili muscles as well as the eccrine glands.

In addition to type IV collagen, laminin, and neutral GAGs, hyaluronic acid is present in the dermis, as demonstrated by Alcian blue and hyaluronidase staining (see Ch. 46). Fat stains (e.g. Sudan III) give inconsistent results when the tissue is formalin-fixed, and rarely the deposits stain with Congo red. Ultrastructurally, reduplication of the basement membrane of vessels and occasionally the dermal–epidermal junction is seen; the deposits appear to be composed of small granules and short filaments of low electron density that measure 3–5 nm in diameter.

There are few reports of the histopathologic features of the vesicular first phase and they vary from intraepidermal acantholysis to cell-poor subepidermal blisters.

Differential Diagnosis

The clinical differential diagnosis includes erythropoietic protoporphyria (EPP), amyloidosis, papular mucinosis (scleromyxedema), colloid milium, and non-Langerhans cell histiocytoses. During the initial phase, hydroa vacciniforme may be considered. In infants, the possibility of hyaline fibromatosis syndrome (juvenile hyaline fibromatosis and infantile systemic hyalinosis) needs to be considered, which is due to mutations in the gene that encodes capillary morphogenesis protein 2 (see Ch. 98). Histologically, the differential diagnosis includes EPP and colloid milium. In cutaneous lesions of EPP, colloid milium, and amyloidosis (see Table 48.1), the hyalinization is milder, more focal and superficial, and it rarely involves the eccrine glands. The deposits in colloid milium do not have the striking perivascular pattern seen in lipoid proteinosis.

Treatment

Currently, there is no known cure or effective treatment for lipoid proteinosis. Oral, intralesional (including submucosal), and topical corticosteroids have been used with some beneficial effect, as have humectants. Plastic surgery, dermabrasion, and laser resurfacing have been successfully performed[19], and there are limited reports of the use of systemic retinoids (e.g. acitretin 0.5 mg/kg/day for 6 months)[20], D-penicillamine, and oral dimethyl sulfoxide (DMSO)[21].

COLLOID MILIUM

Synonyms: ■ Colloid degeneration of the skin ■ Elastosis colloidalis conglomerata ■ Miliary colloidoma

Key features

- A rare disorder in which dome-shaped, translucent papules develop in sun-exposed skin
- Four variants are recognized: adult, juvenile, and pigmented colloid milium and nodular colloid degeneration
- Histologically, amorphous, eosinophilic, granular deposits are found within the superficial dermis

Introduction and Epidemiology

Adult colloid milium is the most common form of the disease. It usually occurs in middle-aged, fair-skinned individuals who have had significant cumulative sun exposure, with a male-to-female ratio of 4:1. The adult form has also been observed in outdoor oil refinery workers, suggesting an additional effect of petrochemicals. In general, *juvenile* colloid milium develops before puberty and both an autosomal recessive and an autosomal dominant inheritance pattern have been reported[22].

Pathogenesis

Although excessive sun exposure clearly plays a role in *adult* colloid milium, the precise pathogenesis is not known. Photoinduced damage to dermal elastic fibers, as in solar elastosis, has been suggested. In *juvenile* colloid milium, ultraviolet light-induced damage to epidermal keratinocytes has been observed and this may reflect an inherited susceptibility. *Pigmented* colloid milium is a variant of the adult form in which there is a combination of excessive sun exposure plus topical application of hydroquinone or phenols[23].

Clinical Features

In both the *adult and juvenile* forms, multiple, dome-shaped, translucent to yellow or yellow–brown papules are seen in areas of chronic sun exposure (Fig. 48.6), e.g. the face (especially periorbitally), ears, posterolateral neck, and the dorsal aspect of the hands and forearms. With minor trauma, lesions can become hemorrhagic. By dermoscopy, a diffuse orange background is seen along with linear-curved blurred telangiectasias and a few milia-like cysts. In *pigmented* colloid milium, grouped to confluent gray–brown papules are present on the face, whereas in *nodular colloid degeneration*, skin-colored to yellowish nodules or plaques develop, often on the face[22,23].

Pathology

In *adult* colloid milium, nodules composed of homogeneous eosinophilic colloid material are seen in the papillary dermis (Fig. 48.7). Within the nodules, there may be clefts and fissures. A grenz zone is often present, as is evidence of solar elastosis beneath the nodules. Although the colloid masses contain degenerated elastic fibers, they often exhibit a staining profile similar to amyloidosis, i.e. positive staining with crystal violet, Congo red, and thioflavin T stains; such staining is more consistent in frozen sections. In addition, PAS staining is positive. A negative pan-cytokeratin stain is helpful in distinguishing adult colloid milium from primary cutaneous amyloidosis (amyloid K).

In *juvenile* colloid milium, amorphous eosinophilic deposits are also found within the papillary dermis, but when compared to the adult form, there is less clefting and no grenz zone. As with colloid bodies (which are also keratinocyte-derived), nonspecific staining for immunoglobulins, complement, and fibrin is seen. Similar to primary cutaneous amyloidosis, staining for keratin is positive due to the presence of amyloid K.

In *pigmented* colloid milium, lightly pigmented islands of colloid material are found in the upper dermis. In *nodular colloid degeneration*,

Fig. 48.6 Juvenile and adult colloid milium. A Coalescing brown papules in sun-exposed sites of the face. Note the sparing of the philtrum. **B** Yellowish, translucent papules and multi-lobulated plaques are present on the nose, admixed with telangiectasias. *A, Courtesy Lorenzo Cerroni, MD, and Sergio Chimenti, MD; B, Courtesy Luis Requena, MD.*

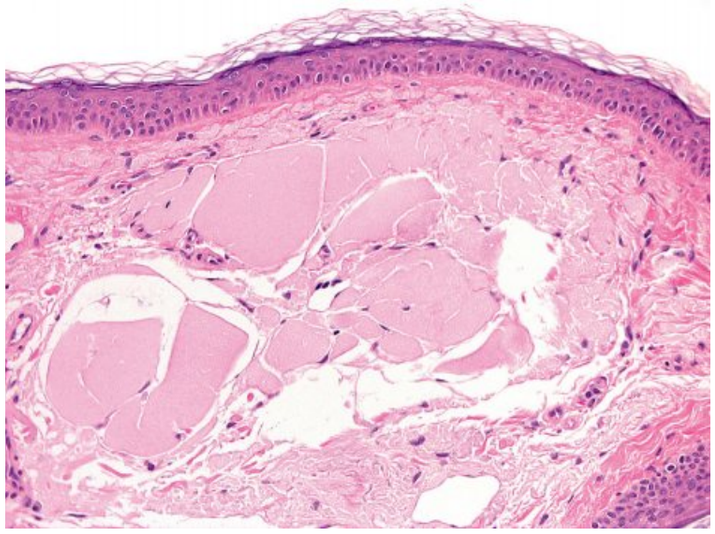

Fig. 48.7 Adult colloid milium – histopathologic features. Nodular mass of eosinophilic, homogeneous material within the upper dermis with a thin subepidermal grenz zone. Note fissures and clefts within the mass with a few fibroblasts along some of the clefts. *Courtesy Lorenzo Cerroni, MD.*

homogenized amorphous dermal collagen with small fissures and clefts is seen. Whether this entity is a variant of nodular amyloidosis is still under debate. Ultrastructurally, colloid milium is characterized by amorphous and granular material which lacks the straight, non-branching filaments seen in amyloidosis.

Differential Diagnosis

Clinically, the differential diagnosis of juvenile and adult forms of colloid milium includes erythropoietic protoporphyria (EPP), mucinoses (e.g. papular, self-healing), lipoid proteinosis, adnexal tumors, and primary systemic amyloidosis (adults). Pigmented colloid milium needs to be distinguished from exogenous ochronosis. Histologically, colloid milium must be distinguished from EPP, lipoid proteinosis, and primary cutaneous amyloidosis. In cutaneous lesions of EPP, there are hyalin deposits around and within the superficial blood vessel walls, whereas the dermal deposits of lipoid proteinosis are accentuated around the blood vessels. Primary cutaneous amyloidosis may be indistinguishable from the juvenile type of colloid milium, as both stain positively for keratin; some authors consider juvenile colloid milium to be a variant of lichen amyloidosis. Unlike lipoid proteinosis and lichen amyloidosis, the dermal deposits of adult colloid milium do not stain positively for laminin and type IV collagen or cytokeratin, respectively.

Treatment

Treatment modalities are limited and include laser therapy (e.g. long-pulsed Er:YAG, fractional photothermolysis), dermabrasion, intense pulsed light, photodynamic therapy, cryotherapy, and chemical peels[24].

MUCOPOLYSACCHARIDOSES

Key features

- A group of inherited disorders, primarily autosomal recessive, characterized by deficiencies of specific lysosomal enzymes involved in the catabolism of glycosaminoglycans (GAGs), also referred to as mucopolysaccharides
- Excessive amounts of the GAGs are found in various tissues and lead to coarse facies, intellectual disability, hepatosplenomegaly, skeletal abnormalities, and corneal clouding
- Hunter syndrome (X-linked recessive) has distinctive skin-colored to white papules over the scapulae (pebbling)
- Screening tests include examination of the urine, peripheral leukocytes, and dermal fibroblasts for the presence of excessive GAGs followed by genetic mutational analysis

Clinical Features and Pathology

The mucopolysaccharidoses are due to mutations in several genes that encode enzymes involved in the catabolism of glycosaminoglycans (GAGs)[25]. Examples of these GAGs include dermatan sulfate, heparan sulfate, and chondroitin sulfate. The storage of excessive amounts of GAGs in various tissues can lead to coarse facies, intellectual disability, hepatosplenomegaly, skeletal abnormalities (dysostosis multiplex), joint stiffness, cardiovascular disease, and corneal clouding (Table 48.3).

Cutaneous manifestations are nonspecific (e.g. hypertrichosis, thickening of the skin), except for the presence of skin-colored to white papules or nodules over the scapulae ("pebbling") in patients with Hunter syndrome[26], which is inherited in an X-linked recessive fashion. The lesions measure 1–10 mm in diameter and may become confluent; they can extend from the posterior axillary line to the midline. Less common sites are the arms, the lateral upper chest, and the buttocks. Extensive dermal melanocytosis (i.e. Mongolian spots) can occur on the trunk and extremities in patients with Hunter or Hurler syndrome.

Screening tests include examination of the urine for excessive amounts of GAGs and examination of circulating leukocytes or dermal fibroblasts for vacuoles or granules that can be demonstrated via special stains (see Table 46.1). The peripheral blood smear should be fixed in absolute methanol and fixation of the skin biopsy specimen in absolute alcohol is preferred. Specific enzyme assays or genetic mutational analysis can then be performed; prenatal diagnosis is possible.

THE MUCOPOLYSACCHARIDOSES				
Disorder	**Enzyme deficiency**	**Stored material**	**Clinical types (onset)**	**Inheritance**
MPS 1 H, Hurler	α-L-Iduronidase	Dermatan sulfate Heparan sulfate	Infancy	AR
MPS I H/S, Hurler/Scheie	α-L-Iduronidase	Dermatan sulfate Heparan sulfate	Childhood	AR
MPS I S, Scheie	α-L-Iduronidase	Dermatan sulfate Heparan sulfate	Late childhood/early adulthood	AR
MPS II, Hunter	Iduronate 2-sulfatase	Dermatan sulfate Heparan sulfate	Severe – infancy Mild – late childhood	X-linked recessive
MPS III A–D, Sanfilippo A–D	A: Heparan-*N*-sulfatase B: *N*-acetyl-α-glucosaminidase C: Acetyl-CoA: α-glucosaminide *N*-acetyltransferase D: *N*-acetyl-glucosamine-6-sulfatase	Heparan sulfate	Early childhood	AR
MPS IV A, Morquio A	*N*-acetylgalactosamine-6-sulfatase	Keratan sulfate Chondroitin-6 sulfate	Childhood	AR
MPS IV B, Morquio B	β-Galactosidase†	Keratan sulfate Chondroitin-6 sulfate	Childhood	AR
MPS VI, Maroteaux–Lamy	Arylsulfatase B (*N*-acetylgalactosamine-4-sulfatase)	Dermatan sulfate	Late infancy/childhood	AR
MPS VII, Sly	β-Glucuronidase	Dermatan sulfate Heparan sulfate Chondroitin-4 and -6 sulfate	Wide range Severe – neonatal Mild – adolescence	AR

*Persistent and extensive, often involving the anterior as well as posterior trunk; has also been described in patients with GM1 gangliosidosis (see Ch. 63).
†Allelic with GM1 gangliosidosis.

Table 48.3 The mucopolysaccharidoses. AR, autosomal recessive; MPS, mucopolysaccharidosis. *Adapted with permission from Hopkin RJ, Grabowski GA. Lysosomal storage diseases. In: Kasper DL, Fauci AS, Hauser SL, et al (eds). Harrison's Principles of Internal Medicine, 19th edn. New York: McGraw-Hill, 2015.*

In biopsy specimens from all types of mucopolysaccharidosis (MPS), metachromatic granules are seen within the cytoplasm of fibroblasts and in some cases in sweat glands, the external root sheath of hair follicles, and epidermal keratinocytes. The latter may have a pale distended cytoplasm which displaces the nucleus to one side. Biopsy specimens of diffusely thickened skin demonstrate fragmentation and hyalinization of collagen and increased mucin. Extracellular deposits of metachromatic material and mucin deposition are seen in the papulonodular lesions of Hunter syndrome[26]. By electron microscopy, fibrillogranular material is seen within lysosomes in all types of MPS.

Treatment

Although supportive interventions (e.g. home oxygen, physical therapy for joint stiffness, cardiac valve replacement) play an important role in the treatment of MPSs, additional therapeutic options – in particular, enzyme replacement therapy (ERT) and hematopoietic stem cell transplantation (HSCT) offer long-term hope for affected individuals[27,28]. Currently available ERT includes α-L-iduronidase (laronidase; Aldurazyme™) for MPS I, iduronate-2-sulfatase (idursulfase; Elaprase™) for MPS II, *N*-acetylgalactosamine 4-sulfatase (galsulfase; Naglazyme™) for MPS VI, and β-glucuronidase (vestronidase-α; Mepsevii™) for MPS VII. ERT is effective in controlling pulmonary insufficiency, decreased joint mobility and hepatosplenomegaly, but does not improve bone or valvular heart disease. Nor does it affect the intellectual disability, as the enzymes cannot pass the blood–brain barrier[27].

Allogeneic HSCT has been used successfully in patients with MPS I, II, IVA, VI, and VII[28]. Results vary depending upon the age of the patient and the disease stage at the time of the procedure, with better results when performed at an early age. Joint mobility, cardiopulmonary function, hearing, vision, and coarse facies can be improved with allogeneic HSCT, in addition to improvement of CNS impairment in MPS I, II, and VII[28]. Substrate reduction therapy and gene therapy represent future treatment options[25,29]. An example of the latter is administration of hematopoietic stem and progenitor cells transduced *ex vivo* with an α-L-iduronidase-encoding lentiviral vector after myeloablative conditioning[29a].

49 Porphyria

Jorge Frank

Key features

- The porphyrias result from dysfunction of enzymes involved in heme biosynthesis
- The different types can be classified into either acute versus non-acute or cutaneous versus non-cutaneous forms
- Cutaneous symptoms exclusively involve sun-exposed areas of the body
- Life-threatening neurologic attacks can occur in the acute porphyrias
- Diagnosis of specific types of porphyria may at times be difficult because clinical symptoms are often nonspecific and biochemical findings can overlap
- The genetic bases of the porphyrias have been well characterized, facilitating accurate molecular diagnosis and genetic counseling

INTRODUCTION

The porphyrias are metabolic disorders, each arising from a predominantly hereditary deficiency of one of the eight enzymes of the porphyrin–heme biosynthetic pathway (Fig. 49.1)[1]. Traditionally, these disorders are subdivided into erythropoietic and hepatic forms, according to the major site of expression of the enzyme deficiency. From a dermatologist's perspective, the porphyrias can be classified into cutaneous and non-cutaneous forms (Table 49.1), whereas from a general clinician's point of view, it is more appropriate to classify the porphyrias into acute and non-acute forms, thereby emphasizing the presence or absence of potentially life-threatening acute neurologic attacks (Table 49.2)[2]. Therefore, we will adhere to the latter classification throughout this chapter.

The porphyrias are of particular dermatologic interest because most forms have characteristic cutaneous manifestations that often allow a presumptive diagnosis. Laboratory tests are then used to confirm the suspected diagnosis. The genetic defects underlying the porphyrias have been well characterized (Table 49.3), facilitating molecular diagnosis and genetic counseling for affected families.

HISTORY

In 1874, Schultz described a man with a history of cutaneous photosensitivity, accompanied by the excretion of wine-red urine[3]. Subsequently, Baumstark detected urinary pigments, which he named "urorubrohaematin" and "urofuscohaematin"[4]. Günther established the first classification of the porphyrias in 1911, recognizing them as hereditary metabolic disorders characterized by increased porphyrin excretion. He distinguished between two different forms: (1) haematoporphyria acuta, characterized by acute neurovisceral attacks without skin lesions; and (2) haematoporphyria congenita and chronica, both disorders having cutaneous findings in sun-exposed areas of the body[5]. In 1937, the terms "acute intermittent porphyria" and "porphyria cutanea tarda" were introduced. Over the next four decades, variegate porphyria (in 1953), hereditary coproporphyria (in 1955), erythropoietic protoporphyria (in 1961), hepatoerythropoietic porphyria (in 1969), and δ-aminolevulinic acid (ALA) dehydratase deficiency porphyria (in 1979) were described[6]. Most recently, X-linked dominant protoporphyria was recognized[7].

EPIDEMIOLOGY

The porphyrias are rare disorders, occurring in all races and both sexes. Whereas some forms appear during infancy, other variants usually do not present until puberty or adulthood. Prevalence rates vary from 0.1 to 10 per 100 000 individuals (see Table 49.2)[1,8]. However, the precise prevalence of the various porphyrias is not known, due primarily to geographic differences, the likelihood of underdiagnosis, and the incomplete penetrance of the dominantly inherited porphyrias.

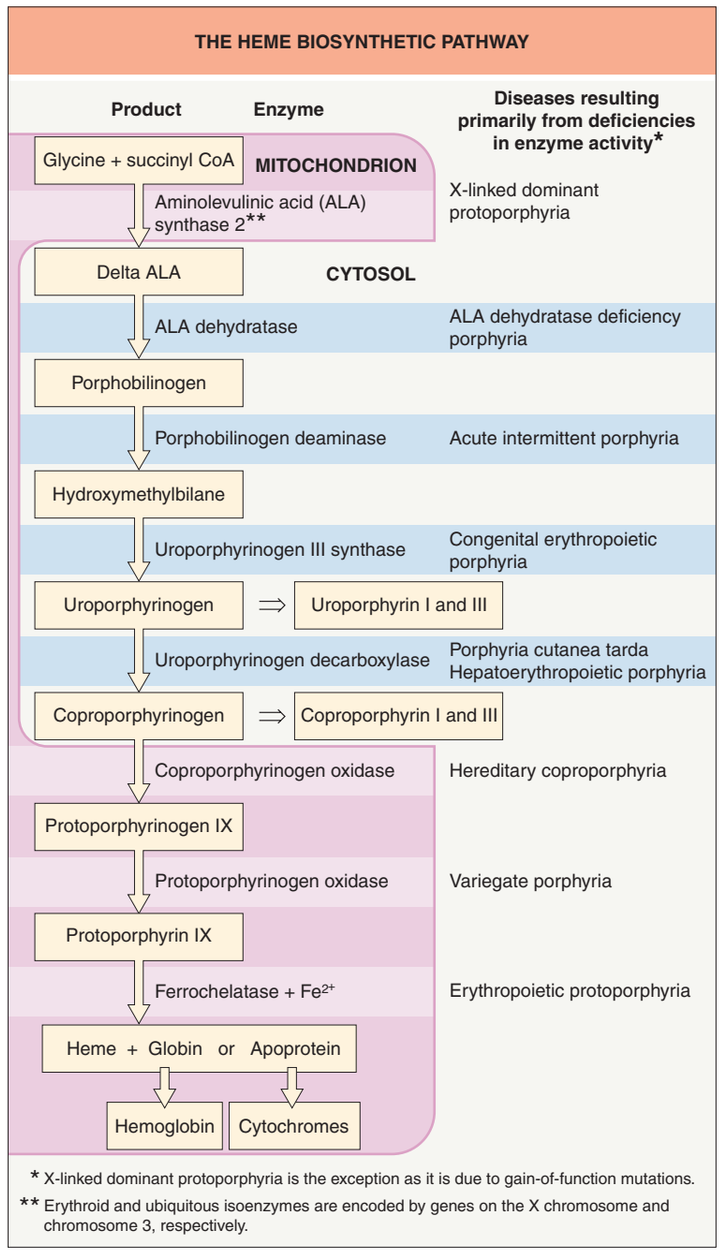

Fig. 49.1 The heme biosynthetic pathway. ALA, aminolevulinic acid, also referred to as δ-aminolevulinic acid or 5-aminolevulinic acid.

PATHOGENESIS

Mutations in any of the genes encoding the enzymes in the heme biosynthetic pathway can lead to a pathologic accumulation and excess excretion of porphyrins and/or porphyrin precursors, as a result of enzyme dysfunction[1]. Except for patients with acquired porphyria cutanea tarda, all forms of porphyria are inherited as monogenetic traits (see Table 49.3).

CLASSIFICATION OF THE PORPHYRIAS INTO CUTANEOUS AND NON-CUTANEOUS FORMS	
Cutaneous	**Non-cutaneous**
Porphyria cutanea tarda Erythropoietic protoporphyria Variegate porphyria Hereditary coproporphyria Congenital erythropoietic porphyria Hepatoerythropoietic porphyria X-linked dominant protoporphyria	Acute intermittent porphyria ALA dehydratase deficiency porphyria

Table 49.1 Classification of the porphyrias into cutaneous and non-cutaneous forms. ALA, aminolevulinic acid.

Cutaneous Findings

To date, no single factor can explain the various photosensitivity patterns evoked by porphyrins plus visible and UV radiation. Nonetheless, a number of cellular and soluble factors are thought to be involved, including reactive oxygen species, certain cell types (e.g. erythrocytes, mast cells, polymorphonuclear cells, fibroblasts), and soluble mediators (e.g. components of the complement system or factor XII-dependent pathways, eicosanoids), as well as matrix metalloproteinases[6]. Most likely, interactions between these factors contribute to the development of cutaneous lesions.

Within the Soret band (400 to 410 nm), porphyrins absorb light energy most efficiently and enter into an excited molecular state. There is also less prominent absorption of adjacent UV wavelengths and other minor visible bands. These light-excited porphyrins can then in turn transfer this absorbed energy to oxygen molecules thereby generating highly reactive oxygen species. Cellular and tissue damage induced by photoactivated porphyrins is believed to result primarily from the formation of reactive singlet oxygen and free radicals, with subsequent lipid peroxidation and protein cross-linking[9,10].

The type of cellular damage depends on the solubility and tissue distribution of the porphyrins. Accumulation of water-soluble uro- and coproporphyrins leads to blistering, as is seen in most of the cutaneous porphyrias (e.g. porphyria cutanea tarda, variegate porphyria). In contrast, accumulation of lipophilic protoporphyrins leads to an immediate cutaneous burning sensation after exposure to

CLASSIFICATION OF THE PORPHYRIAS INTO ACUTE AND NON-ACUTE FORMS			
Disorder	**Incidence**	**Age of onset**	**Important aspects**
Acute porphyrias			
Acute intermittent porphyria	0.5–1 per 100 000	Second to fourth decade of life; rarely before puberty	Most common acute porphyria worldwide; acute neurologic attacks but no photosensitivity/cutaneous manifestations
Variegate porphyria	~1 per 300 in South Africa; relatively rare elsewhere	Second to third decade of life; usually not before puberty	*Cutaneous manifestations similar to porphyria cutanea tarda*, and acute attacks similar to acute intermittent porphyria can occur (neurocutaneous porphyria); founder mutations identified in South Africa and Chile
Hereditary coproporphyria	Very rare (<75 cases reported)	Usually not before puberty	Acute attacks similar to acute intermittent porphyria; *cutaneous manifestations, including erythema and blistering in sun-exposed areas, can occur* (neurocutaneous porphyria)
ALA-D deficiency porphyria	Extremely rare (<10 cases reported)	Early and late onset have been described	Neurologic symptoms similar to acute intermittent porphyria can occur; no photosensitivity/cutaneous manifestations
Non-acute porphyrias (all can have cutaneous features)			
Porphyria cutanea tarda	Most common porphyria worldwide	Third to fourth decade of life; usually not before puberty	Acquired and hereditary variants exist; moderate to severe photosensitivity; cutaneous findings in sun-exposed areas include skin fragility, erosions, crusts, vesicles and bullae, milia, scarring, hyperpigmentation and hypertrichosis; indistinguishable from variegate porphyria
Erythropoietic protoporphyria	Second-highest incidence of the cutaneous porphyrias	Early childhood (1 to 4 years); late onset extremely rare	Cutaneous manifestations include erythema, edema, crusts, purpura, skin thickening, and waxy scars, primarily on the dorsal hands and face; usually no blistering; in ~5% of patients, severe liver disease can occur; cholelithiasis; palmar keratoderma in rare AR form; adult-onset form associated with underlying MPD or MDS
Congenital erythropoietic porphyria	Very rare (~170 cases reported)	Infancy/first decade of life	Very severe clinical course; in sun-exposed sites, vesicles and bullae, erosions, ulcerations, crusts, milia, scarring, hyperpigmentation, and hypertrichosis; mutilation; hemolytic anemia; hepatosplenomegaly; porphyrin deposition in bones and teeth (erythrodontia); pink, red, or violet staining of diapers
Hepatoerythropoietic porphyria	Extremely rare (~35 cases reported)	Early infancy	Homozygotic or compound heterozygotic variant of porphyria cutanea tarda; markedly increased photosensitivity and severe clinical course possible; in sun-exposed sites, vesicles and bullae, skin fragility, erosions, crusts, milia, scarring, and hypertrichosis; mutilation can occur; diapers stained by darkly colored urine
X-linked dominant protoporphyria	Very rare	Early childhood	Skin symptoms indistinguishable from erythropoietic protoporphyria; most recent type of porphyria to be recognized; liver disease appears to occur more frequently than in erythropoietic protoporphyria

Table 49.2 Classification of the porphyrias into acute and non-acute forms. Important clinical and epidemiological aspects are highlighted. ALA-D, aminolevulinic acid dehydratase; AR, autosomal recessive; MDS, myelodysplastic syndrome; MPD, myeloproliferative disorder.

GENETIC ASPECTS OF THE PORPHYRIAS			
Disorder	**Gene locus**	**Protein product and gene symbol**	**Mode of inheritance**
Acute porphyrias			
Acute intermittent porphyria	11q23.3	Porphobilinogen deaminase; *PBGD*	AD
Variegate porphyria	1q22–23	Protoporphyrinogen oxidase; *PPOX*	AD
Hereditary coproporphyria	3q12	Coproporphyrinogen oxidase; *CPO*	AD
ALA-D deficiency porphyria	9q34	δ-Aminolevulinic acid dehydratase; *ALAD*	AR
Non-acute porphyrias			
Porphyria cutanea tarda	1p34	Uroporphyrinogen decarboxylase; *UROD*	AD (up to 25% of cases); otherwise acquired
Erythropoietic protoporphyria	18q21.3	Ferrochelatase; *FECH*	AD*; rarely, AR
Congenital erythropoietic porphyria	10q25.2–q26.3	Uroporphyrinogen III synthase; *UROS*	AR
Hepatoerythropoietic porphyria	1p34	Uroporphyrinogen decarboxylase; *UROD*	AR
X-linked dominant protoporphyria	Xp11.21	δ-Aminolevulinic acid synthase 2; *ALAS2* (gain-of-function mutations)	XLD

*Actually semi-dominant inheritance with a mutation in one allele and a specific intronic polymorphism in the second allele ("hypomorphic" allele; see text).

Table 49.3 Genetic aspects of the porphyrias. ALA-D, aminolevulinic acid dehydratase; AD, autosomal dominant; AR, autosomal recessive; XLD, X-linked dominant.

the appropriate wavelengths of light, accompanied by erythema and edema, as seen in erythropoietic protoporphyria[10].

Acute Porphyric Attack

Two porphyria variants, ALA dehydratase deficiency porphyria and acute intermittent porphyria, are not associated with cutaneous findings (see Table 49.1). The dysfunctional enzymes in these two porphyrias are involved in early steps of heme biosynthesis, and their substrates, ALA and porphobilinogen (PBG), respectively, are non-phototoxic porphyrin precursors (see Fig. 49.1). However, both acute intermittent porphyria and ALA dehydratase deficiency porphyria can manifest with life-threatening acute neurologic attacks (see Table 49.2). It appears that ALA and PBG, which are excreted in massive amounts from the liver during an acute attack, are extremely neurotoxic. Lacking appropriate barrier protection, the autonomic and peripheral nervous systems are particularly susceptible to the toxic effects[11].

Of note, porphyrin abnormalities are also observed in the setting of lead poisoning, sideroblastic and hemolytic anemia, iron deficiency, renal failure, cholestasis, liver disease, and gastrointestinal hemorrhage. However, associated photosensitivity has only been documented in rare cases of sideroblastic anemia[6].

CLINICAL AND LABORATORY INVESTIGATION

In establishing the diagnosis of a specific type of porphyria, the medical evaluation involves up to four steps:

- a thorough clinical assessment that includes a family history and physical examination, with particular reference to sun-exposed sites
- biochemical measurement of porphyrins and porphyrin precursors in urine, feces, blood, and/or plasma (Table 49.4)
- determination of the activity of specific enzymes (specialized laboratories)
- DNA mutational analysis (specialized laboratories).

Difficulties in obtaining a definitive diagnosis are primarily a result of the different types of porphyria having overlapping clinical and/or biochemical features (Fig. 49.2). This is especially true of variegate porphyria and hereditary coproporphyria, which may present with cutaneous lesions similar to those observed in porphyria cutanea tarda and/or neurologic and visceral findings resembling those encountered in acute intermittent porphyria.

With regard to biochemical analyses, markedly elevated urinary levels of the porphyrin precursors ALA and PBG can be found during an acute attack. However, asymptomatic "carriers" (who harbor mutations) are rarely detected via measurement of urinary porphyrin precursors because the latter can exhibit significant variability and levels may be only slightly elevated or even normal during the intervals between acute attacks (see Table 49.4 [shaded areas]). In addition, diagnoses based upon measurements of enzymatic activity in fibroblasts or lymphocytes are not always conclusive. This is because an overlap exists between the values obtained in patients, asymptomatic carriers, and normal control individuals[12].

Therefore, the ability to detect specific genetic mutations has made a significant impact on the precise diagnosis of porphyrias and the ability to provide accurate genetic counseling[6,11].

THE NON-ACUTE PORPHYRIAS

The non-acute porphyrias consist of porphyria cutanea tarda (PCT), erythropoietic protoporphyria (EPP), congenital erythropoietic porphyria (CEP), hepatoerythropoietic porphyria (HEP), and X-linked dominant protoporphyria (XLDPP). All these porphyrias present primarily with cutaneous findings (see Tables 49.1 & 49.2)[1,6]. While histologic examination of involved skin is not required to confirm a presumptive diagnosis of any of the cutaneous porphyrias, a biopsy specimen may have been obtained to exclude other entities in the differential diagnosis. Occasionally, the pathologist may identify histologic features that support the diagnosis of cutaneous porphyria even though the clinician suspected another disorder, e.g. epidermolysis bullosa acquisita.

Porphyria Cutanea Tarda (PCT)

Worldwide, PCT is the most common type of porphyria. It results from decreased activity of uroporphyrinogen decarboxylase, the fifth enzyme in heme biosynthesis (see Fig. 49.1)[1,6].

At least two types of PCT can be distinguished: (1) a sporadic (acquired) variant, designated **type I PCT**, in which the dysfunctional enzyme is exclusively expressed in the *liver*; and (2) an autosomal dominant familial (hereditary) variant, designated **type II PCT**, in which the catalytic enzymatic defect is detected in *all tissues* (see Table 49.3). In most countries, the ratio of type I to type II PCT is currently estimated to be approximately 3 : 1 to 4 : 1[13]. Interestingly, Elder[14] reported several families with typical clinical and biochemical features of overt PCT but with normal uroporphyrinogen decarboxylase activity in their red blood cells. This variant of the disease has been designated **type III PCT**. Indeed, there is increasing evidence that some facets of the etiology of PCT have yet to be completely elucidated.

The cutaneous manifestations of PCT include increased photosensitivity and skin fragility as well as blistering, erosions, crusts, milia, and scars in sun-exposed sites (Fig. 49.3; see Table 49.2). Additionally, postinflammatory hyperpigmentation, hypertrichosis (Fig. 49.4), scarring alopecia, and morpheaform and sclerodermoid changes (Fig. 49.5) can be observed.

Histologic examination of vesiculobullae commonly reveals subepidermal cell-poor blisters with a characteristic festooning of dermal papillae; the latter is most likely due to the deposition of PAS-positive

CHARACTERISTIC BIOCHEMICAL FINDINGS IN THE PORPHYRIAS											
	Urine				Feces			Erythrocytes

Callen, MD.*

glycoproteins in and around the wall of vessels localized in the upper dermis (Fig. 49.6). Direct immunofluorescence microscopy often demonstrates immunoglobulins (mainly IgG; less commonly IgM), complement, and fibrinogen at the dermal–epidermal junction and around blood vessels of the papillary dermis. As opposed to autoimmune bullous diseases, these immunoglobulin deposits are presumed to be non-antigen-specific. In sclerotic lesions, there is dermal fibrosis as well as PAS-positive deposits around blood vessels.

Biochemically, increased urinary excretion of uroporphyrin (type I isomers > type III isomers), hepta-carboxylated porphyrins (type III isomers > type I isomers), and coproporphyrin can be detected, as well as increased excretion of isocoproporphyrin in the feces; the latter finding is exclusive to PCT and hepatoerythropoietic porphyria (see Table 49.4). Historically, a presumptive clinical diagnosis of PCT was followed by an examination of the patient's urine, both under Wood's lamp illumination (in the dark) and after exposure to natural light. Due to the excessive excretion of porphyrins, the urine of PCT patients turns red to brown after several hours of exposure to natural light and it has a pink to red fluorescence when exposed to a UVA light source. However, it has to be borne in mind that these bedside observations are neither sensitive nor specific diagnostic tests.

A wide variety of triggering factors (including hepatotoxins) have been reported to precipitate the clinical manifestations of PCT, among them alcohol (most common), estrogens, polychlorinated hydrocarbons, dialysis in patients with renal failure, iron, inheritance of specific mutations in *HFE* which underlie classic hemochromatosis, and viral infections such as hepatitis C and HIV. Interestingly, homozygosity for *HFE* mutation C282Y has been found to be associated with an earlier onset of disease in both sporadic and familial PCT, with the effect being more marked in familial PCT[15].

Erythropoietic Protoporphyria (EPP)

EPP is due to a semi-dominantly inherited deficiency of ferrochelatase, the last enzyme in the heme biosynthetic pathway (see Fig. 49.1)[1,6].

Clinically, EPP is characterized by cutaneous photosensitivity that typically manifests early in life, i.e. during early childhood. Acute photosensitivity episodes are characterized by intense burning,

Fig. 49.8 Erythropoietic protoporphyria. A Subtle scarring on the nose and linear scars on the upper cutaneous lip in a 6-year-old child. **B** Extensive scarring of the cheeks and linear scars on the upper cutaneous lip and chin in an adult. *A, Courtesy Gillian Murphy, MD; B, Courtesy Luis Requena, MD.*

stinging, and pruritus of sun-exposed skin, particularly on the nose, cheeks and dorsal hands, followed by erythema, edema, crusts, petechiae, and then wax-like scarring (Fig. 49.7 & 49.8; see Table 49.2); blistering usually does not occur. Skin symptoms can develop within minutes of sun exposure, often starting early in the springtime, continuing throughout the summer, and diminishing during fall and winter. Window glass does not protect the patient. Patients suffering from EPP often report that the only way to relieve the burning and stinging sensations is to cool the affected skin under cold water. In patients with EPP who have not had recent sun exposure, the only detectable cutaneous findings may be scars on the nose and lips (see Fig. 49.8). In rare patients with recessively inherited EPP, palmar keratoderma can be seen[16].

Adult-onset EPP, also referred to as late-onset EPP, is very unusual, and the atypical age of onset often delays the diagnosis. To date, all reported individuals with late-onset EPP have had a history of either a myeloproliferative disorder or myelodysplastic syndrome[17]. Interestingly, in these patients the hematologic disease is thought to possibly give rise to somatic hematopoietic mutations or clones that result in abnormal porphyrin metabolism and systemic protoporphyrin accumulation. Thus, this disorder should be considered in adults with new-onset, otherwise unexplained photosensitivity, especially if they have an underlying hematologic disorder.

Histologically, vacuolization of epidermal cells is seen in acute lesions. Intercellular edema may also be present, as well as vacuolization and

lysis of endothelial cells within superficial dermal blood vessels. In older lesions (e.g. areas of waxy scarring), eosinophilic PAS-positive deposits are observed around blood vessels (Fig. 49.9). There can be a resemblance to the amorphous protein depositions seen in lipoid proteinosis. Ultrastructurally, thickening and degeneration of capillary basement membranes is seen.

Biochemically, EPP is characterized by an increase in *free* protoporphyrin levels in erythrocytes, plasma, feces, and other tissues such as the liver (see Table 49.4)[1,6]. Historically, microscopic examination of a blood smear via UV illumination was performed to detect erythrocyte fluorescence. However, this test is not particularly sensitive or specific. The greatest concern in patients with EPP is a rapid accumulation of protoporphyrin within the liver and biliary system, with the development of cholestasis. This can lead to hepatic damage and progressive (even fatal) liver failure. Of note, liver function tests may remain normal until late in the course of the disease[18].

The genetic basis for the development of cutaneous symptoms in EPP has been elucidated. Only those individuals who inherit a heterozygous ferrochelatase gene mutation involving one parental allele (allele A) *and* a specific intronic polymorphism (IVS3–48 T/C) of the other parental allele (allele B) develop skin symptoms. This latter specific polymorphism *in trans* constitutes a "hypomorphic" allele and leads to abnormal modulation of splicing. As a result, the aberrantly spliced mRNA is degraded by a nonsense-mediated decay mechanism, producing a decreased steady-state level of mRNA. Combined, a mutation in allele A plus the polymorphism in allele B lead to a marked reduction in ferrochelatase activity that is ~15%–25% of normal[19].

Certainly, the identification of the molecular mechanisms underlying the photosensitivity observed in EPP has to be considered a milestone in porphyria research. Still, the development of protoporphyrin-induced hepatic disease and the molecular mechanisms underlying the phenotype associated with severe liver injury are not yet well understood.

X-linked Dominant Protoporphyria (XLDPP)

XLDPP is characterized by gain-of-function mutations in *ALAS2* on the X chromosome. This gene encodes the erythroid tissue-specific isoform of the first enzyme in the heme biosynthetic pathway, δ-aminolevulinic acid synthase 2. The resultant increase in synthetase activity eventually leads to an overproduction of protoporphyrin IX and a clinical phenotype that is indistinguishable from EPP. However, the percentage of patients at risk for potentially fatal liver disease appears to be higher than in classic EPP. Biochemical profiling demonstrates higher total protoporphyrin levels in erythrocytes (as compared to EPP due to ferrochelatase deficiency), with ~40% being zinc protoporphyrin[7].

Congenital Erythropoietic Porphyria (CEP)

Synonym: ■ Günther disease

With ~170 cases reported to date, CEP is a very rare, autosomal recessively inherited disorder that results from markedly decreased catalytic activity of uroporphyrinogen III synthase, the fourth enzyme in heme biosynthesis (see Fig. 49.1). CEP manifests shortly after birth with severe cutaneous photosensitivity, blistering, erosions, crusts, and ulcerations, followed by extensive scarring and deformation, primarily of the hands (Fig. 49.10A; see Table 49.2). On the face, a loss of eyebrows and eyelashes, as well as severe mutilation of cartilaginous structures (e.g. the nose), are frequently observed. Furthermore, erythrodontia (Fig. 49.10B), acro-osteolysis, and skeletal abnormalities (e.g. demineralization) are common clinical features. In addition, a variable degree of hematologic involvement, ranging from mild forms of hemolytic anemia to intrauterine hydrops fetalis and hepatosplenomegaly, can be observed. Pink, red, or violet staining of diapers can serve as an early clue to the diagnosis. Biochemically, there is increased urinary excretion of uroporphyrin I and coproporphyrin I plus elevated levels of coproporphyrin I in the stool (see Table 49.4)[20].

Hepatoerythropoietic Porphyria (HEP)

HEP, the homozygous (or compound heterozygous) variant of hereditary PCT, is an extremely rare disease that is due to a pronounced decrease in uroporphyrinogen decarboxylase activity (see Table 49.3). Clinically, HEP usually presents during early childhood, with dark urine in the diapers often the initial clinical finding. Subsequently, severe cutaneous photosensitivity develops, associated with blistering, pruritus, hypertrichosis, hyperpigmentation, and scleroderma-like scarring (Fig. 49.11; see Table 49.2). If the clinical course is severe, the symptoms closely resemble those observed in CEP. However, unlike the latter, HEP is not usually associated with hematologic abnormalities (e.g. severe anemia).

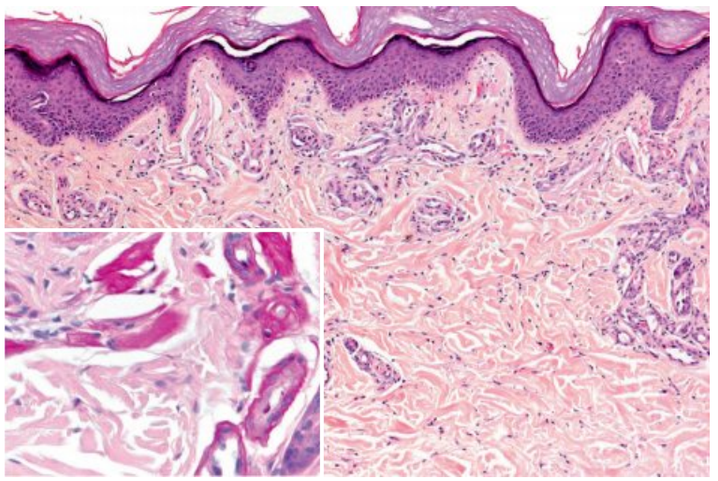

Fig. 49.9 Erythropoietic protoporphyria – histologic features. Eosinophilic deposits around blood vessels are more pronounced than in porphyria cutanea tarda. These deposits are highlighted by a PAS stain (inset). *Courtesy Lorenzo Cerroni, MD.*

5-Fluorouracil (intravenous)	Sunitinib
Flutamide	**Voriconazole**
*When caused by NSAIDs, consider prescribing indomethacin, meloxicam, or sulindac.	

Table 49.5 Drug-induced pseudoporphyria. The most common causes are in **bold**. In addition to discontinuation of the offending agent, antioxidants such as N-acetylcysteine have had a beneficial effect in some case series. NSAID, nonsteroidal anti-inflammatory drug. *Courtesy Misty Sharp, MD.*

Urinary levels of uroporphyrin and hepta-carboxylated porphyrins are elevated, as are fecal levels of coproporphyrin and isocoproporphyrin. Increased levels of zinc-chelated protoporphyrin within erythrocytes can also be seen (see Table 49.4)[1,21].

Pseudoporphyria

Pseudoporphyria (also referred to as pseudoporphyria cutanea tarda, bullous dermatosis of dialysis, or therapy-induced bullous photosensitivity) encompasses those conditions that clinically resemble PCT. However, in contrast to PCT, no biochemical abnormalities in porphyrin metabolism are detected (see Fig. 49.2). Skin fragility, erosions, blisters, and scarring have a predilection for the dorsal aspect of the hands (Fig. 49.12), the face, and the extensor surfaces of the legs. Pseudoporphyria is commonly encountered in patients suffering from stage 4 or 5 chronic kidney disease or in those undergoing renal dialysis (hemodialysis more often than peritoneal dialysis). It is also seen in association with the ingestion of specific drugs, including nonsteroidal anti-inflammatory drugs (e.g. naproxen, nabumetone, ketoprofen), furosemide, antibiotics (e.g. nalidixic acid, tetracycline), and retinoids (Table 49.5), and it can occur in association with the use of tanning beds. In the latter situation, vesicles may be seen on the palms.

Histologic findings are indistinguishable from those found in lesions of PCT. Patients who require renal dialysis may develop PCT or pseudoporphyria. Even if they are anuric, it is important to remember that the diagnosis of PCT can be established via plasma or stool studies (see Table 49.4). Treatment is easier for drug-induced pseudoporphyria, as the major recommendation is discontinuation of exposure to the suspected precipitant[22]. Sun protection is advised for all patients.

Differential Diagnosis

PCT must be distinguished from other types of cutaneous porphyria that manifest with blistering. These include mild variants of CEP and HEP and importantly (since they can be associated with life-threatening acute attacks), variegate porphyria (VP) and hereditary coproporphyria (HCP). Furthermore, pseudoporphyria (see above), epidermolysis bullosa acquisita, polymorphous light eruption, and phototoxic and bullous drug eruptions have to be excluded. These latter diseases can easily be differentiated from PCT by porphyrin analysis[1,6,15,23]. If no porphyrin abnormalities are detected, histologic examination of lesional skin (routine and immunofluorescence) can aid in establishing the diagnosis.

In ***EPP***, the differential diagnosis consists of solar urticaria, phototoxic or photoallergic contact dermatitis and drug reactions, polymorphous light eruption, hydroa vacciniforme, and lipoid proteinosis[1,6,16,23].

CEP has to be differentiated from HEP and the rare homozygous (or compound heterozygous) variants of VP and HCP as well as STING-associated vasculopathy with onset in infancy (SAVI; see Table 45.7). Mild variants can sometimes mimic PCT. Likewise, the most important entities in the differential diagnosis of ***HEP*** are CEP and the rare aforementioned homozygous or compound heterozygous variants of VP and HCP.

Treatment

A causal therapeutic strategy would consist of either specific enzyme replacement therapy or gene therapy. However, such therapeutic modalities are not currently available.

THERAPEUTIC APPROACHES TO THE ACUTE AND NON-ACUTE PORPHYRIAS	
Acute porphyrias	**Therapy strategies**
Acute intermittent porphyria; variegate porphyria; hereditary coproporphyria; ALA-dehydratase deficiency porphyria	**Acute attacks** 1. Identification and elimination of precipitating factors (porphyrinogenic drugs; alcohol; hormones) 2. Monitoring in intensive care unit and input from porphyria specialists 3. Adequate pain therapy, e.g. with opioid analgesics 4. Adequate therapy of nausea and vomiting, e.g. with ondansetron, promethazine 5. Intravenous administration of either: (1) heme arginate (Normosang®; Europe only), 3 mg/kg once daily for 4 consecutive days; or (2) hemin (Panhematin®; FDA-approved), usually 1–4 mg/kg/day (over 10–15 min) for 3–14 days *versus* 3–4 mg/kg once daily for 4 days with more extended treatment for severe cases 6. If necessary, until heme preparations become available, intravenous glucose infusions 7. Once monthly subcutaneous givosiran (Givlaari®), aminolevulinic acid synthase 1-directed small interfering RNAs (siRNAs) 8. Measurement of urinary porphyrin excretion during the acute attack (daily, if possible) **Cutaneous symptoms (variegate porphyria; hereditary coproporphyria)** 1. Photoprotection, e.g. broad-spectrum sunscreens*, protective clothing, window films 2. Avoidance of sunlight exposure and trauma
Non-acute porphyrias	**Therapy strategies**
Porphyria cutanea tarda	1. Photoprotection, e.g. broad-spectrum sunscreens*, protective clothing, window films 2. Avoidance of sunlight exposure and trauma 3. Cease alcohol ingestion; stop estrogen therapy 4. Phlebotomy: 400–500 ml every 2 weeks over ~3–6 months 5. *Low-dose* hydroxychloroquine: 100 mg twice weekly (e.g. on Monday and Thursday) over 6–12 months, until porphyrin excretion is within normal range 6. Measurement of urinary porphyrin excretion to monitor therapeutic outcome
Erythropoietic protoporphyria/ X-linked dominant protoporphyria	1. Photoprotection, e.g. broad-spectrum sunscreens*, protective clothing, window films 2. Avoidance of sunlight exposure (common window glass does not provide protection) 3. Oral β-carotene: 30–90 mg/day in children; 60–180 mg/day in adults. Desirable maximum plasma level: 600–800 mcg/dl. Administration during the spring, summer, and fall, with a hiatus during the winter in higher latitudes 4. Afamelanotide ([Nle^4, D-Phe^7]-α-MSH; 16 mg every 60 days as a resorbable implant) may increase tolerance to light exposure 5. Consider cholestyramine or charcoal to reduce enterohepatic recirculation of porphyrins and bile acids in order to enhance hepatic porphyrin excretion; results vary
Congenital erythropoietic porphyria	1. Photoprotection, e.g. broad-spectrum sunscreens*, protective clothing, window films 2. Strict avoidance of sunlight exposure 3. Change day–night rhythm 4. Splenectomy (reduces hemolysis and platelet consumption) 5. Bone marrow or hematopoietic stem cell transplantation
Hepatoerythropoietic porphyria	1. Photoprotection, e.g. broad-spectrum sunscreens*, protective clothing, window films 2. Strict avoidance of sunlight exposure and trauma 3. Change day–night rhythm 4. Of note, therapeutic approaches used in porphyria cutanea tarda (e.g. phlebotomy, antimalarials) are not effective
*Sunscreens that contain the physical blockers zinc oxide, titanium dioxide, and iron oxide are most effective.	

Table 49.6 Therapeutic approaches to the acute and non-acute porphyrias. While the therapeutic measures for an acute porphyric attack are the same for each of the acute porphyrias, different treatment strategies are recommended for each of the non-acute porphyrias, depending upon the prevailing manifestations and the respective form of porphyria. ALA, aminolevulinic acid; MSH, melanocyte stimulating hormone.

The avoidance of UV light exposure, sun-protective clothing, window films, and regular application of broad-spectrum sunscreens are crucial, both prophylactically and therapeutically. However, because the primary wavelengths that induce the porphyrias are in the visible 400–410 nm range, sunscreens are limited in their photoprotective efficacy, with the exception of titanium dioxide and zinc oxide (see Ch. 132). Tinted sunscreens containing iron oxide are also protective against visible light exposure.

Patients with ***PCT*** should be encouraged to eliminate triggering factors such as alcohol ingestion and estrogen therapy. In patients with iron overload, successful treatment can be achieved by repeated phlebotomy (venesection) of ~500 ml blood every 2 weeks, as tolerated by the patient; some authors recommend weekly venesections of 300 ml blood. When required, maintenance phlebotomy is performed at less frequent intervals.

Therapeutic phlebotomy reduces iron stores, thereby improving heme synthesis by reducing iron-induced inhibition of uroporphyrinogen decarboxylase activity. While the therapeutic goal is to reduce serum ferritin levels to the lower limit of the reference range, care should be taken to avoid inducing anemia. Phlebotomy usually leads to resolution of skin fragility and blistering within 2–4 months. However, normalization of urinary porphyrin concentrations will usually take longer (about 12 months).

Another therapeutic option is *low-dose* hydroxychloroquine. This antimalarial is thought to work by accelerating hepatic elimination and urinary excretion of porphyrins, and it may also inhibit porphyrin synthesis. Standard therapy consists of 100 mg of hydroxychloroquine *twice weekly*, and complete remission can be expected within 6–9 months (Table 49.6); scored tablets should be prescribed. Administration of higher doses (as are used in cutaneous lupus erythematosus) can lead to hepatotoxicity. Hydroxychloroquine can be combined with phlebotomy to induce a remission more rapidly[1,6,16]. The genetic background of PCT patients, with respect to the presence of *HFE* mutations, appears to play a critical role in the outcome of hydroxychloroquine treatment. Whereas heterozygosity for mutation *C282Y* and compound heterozygosity for *HFE* mutations did not compromise the therapeutic response, PCT patients homozygous for *C282Y* failed to respond to antimalarial therapy and retained high serum iron and ferritin levels as well as transferrin saturation[24].

In a pilot trial, deferasirox led to improvement of cutaneous findings in 8 of 10 patients with PCT who completed 6 months of treatment[25]. Treatment of underlying HCV infection with direct-acting antivirals also leads to improvement.

In some patients with ***EPP***, β-carotene minimizes burning, stinging, and photosensitivity reactions. Although β-carotene has no effect on the protoporphyrin levels in erythrocytes, it reduces photosensitivity

by quenching the formation of free radicals that occurs during the cutaneous photoreaction. The administered doses range from 30 to 90 mg/day in children and from 60 to 180 mg/day in adults, with desired maximum plasma levels of 600–800 mcg/dl. Afamelanotide, an analogue of melanocyte stimulating hormone ([Nle^4, D-Phe^7]-α-MSH), was FDA-approved for the prevention of EPP phototoxicity in 2019, and it received regulatory approval in Europe in 2016. In a multicenter, randomized, placebo-controlled trial involving 168 patients with EPP, those treated with afamelanotide (16 mg every 60 days as a resorbable implant) experienced increased tolerance to sun exposure and improved quality of life[26]. In a case series, narrowband UVB phototherapy, including home phototherapy, was shown to be of benefit after 15–20 treatments[27]. Cholestyramine or charcoal can be considered in order to reduce enterohepatic recirculation of porphyrins and bile acids. Overall, current therapeutic options for EPP are more limited than for PCT[1,6,10,11,16,28,29].

Patients with ***CEP*** require surveillance for anemia and skin infections. Frequent blood transfusions can suppress erythropoiesis, thereby decreasing porphyrin production and photosensitivity. Concomitant administration of deferoxamine or deferasirox can reduce the resulting iron overload. Bone marrow or hematopoietic stem cell transplantation leads to marked reduction of porphyrin levels and photosensitivity and has been reported to be curative[1,11,20].

No specific treatment options are currently available for patients with HEP and XLDPP. Careful patient education regarding sun protection is very important.

THE ACUTE PORPHYRIAS

The acute porphyrias consist of acute intermittent porphyria (AIP), variegate porphyria (VP), hereditary coproporphyria (HCP), and δ-aminolevulinic acid dehydratase (ALA-D) deficiency porphyria (see Tables 49.1 & 49.2)[2,6].

Patients with acute porphyrias can present with a broad range of clinical findings, including persistent colicky abdominal pain, nausea and vomiting, obstipation, tachycardia, hypertension, seizures, paresthesias, para- and tetraplegia, and acute psychosis (Table 49.7). Unfortunately, this spectrum of fairly nonspecific symptoms can mimic a number of other diseases and the porphyrias are often not included in the differential diagnosis, especially if neurologic symptoms prevail[2,30]. Acute attacks can be precipitated by a variety of factors, including porphyrinogenic drugs (e.g. antimalarials, tetracyclines, sulfonamides), alcohol, hormonal changes, recurrent or chronic infections, and reduced caloric intake due to fasting or diets. The latter may be a result of enhanced expression of the transcriptional coactivator PGC-1α[31].

In addition to the manifestations outlined in Table 49.7, patients with VP and HCP may have cutaneous findings that are clinically indistinguishable from those of PCT. As a result, VP and HCP are also referred to as neurocutaneous porphyrias[1,2].

A consortium of porphyria specialists from several European porphyria centers has established the European Porphyria Network (EPNET). The goals of the EPNET are to set standards and provide guidelines for the diagnosis and treatment of porphyrias. On the EPNET (porphyria.eu) and the American Porphyria Foundation (porphyriafoundation.com) websites, important information is available for both patients and physicians.

POSSIBLE MANIFESTATIONS OF AN ACUTE PORPHYRIC ATTACK		
Gastrointestinal and metabolic	**Neurologic**	**Cardiac and pulmonary**
Colicky abdominal pain	**Paresthesias**	**Tachycardia**
Nausea and vomiting	**Motor and sensory peripheral neuropathy (para- and tetraplegia)**	Hypertension
Constipation	Seizures	Respiratory paralysis
Obstipation	Muscle pain, back pain	
Hyponatremia	Encephalopathy	
	Paralysis	
	Anxiety	
	Acute psychosis	
	Coma	

Table 49.7 Possible manifestations of an acute porphyric attack. The more prevalent symptoms are in **bold**.

Acute Intermittent Porphyria (AIP)

Worldwide, AIP is the most common type of acute porphyria. This autosomal dominantly inherited disorder is characterized by a deficiency of porphobilinogen deaminase, the third enzyme in heme biosynthesis (see Fig. 49.1).

AIP will not be discussed in detail here because patients do not have skin manifestations. It usually presents after puberty with acute porphyric attacks (see Table 49.7) that may be precipitated by the various trigger factors outlined above. Elevated urinary levels of the porphyrin precursors ALA and PBG can be detected during an acute attack: ALA levels range from 5 to 20 times normal and PBG levels are increased to as high as 20- to 50-fold normal[1,32].

Variegate Porphyria (VP)

Synonyms: ■ South African porphyria ■ Mixed porphyria

VP is characterized by an autosomal dominantly inherited deficiency of protoporphyrinogen oxidase, the seventh enzyme in the pathway of heme biosynthesis (see Fig. 49.1).

Cutaneous and neuropsychiatric symptoms can occur separately or simultaneously in affected individuals. Clinically, the skin findings in VP cannot be differentiated from those observed in PCT. Likewise, the acute attacks observed in VP are identical to those encountered in AIP.

During acute attacks, elevated urinary levels of ALA and PBG are encountered. However, during periods of remission, urinary ALA and PBG levels may be within normal range (see Table 49.4 [shaded areas]). Therefore, additional biochemical analyses of fecal porphyrins are mandatory in order to establish the diagnosis of VP. Elevated levels of stool protoporphyrin and coproporphyrin can be detected, with the concentration of protoporphyrin usually being higher than that of coproporphyrin. It is noteworthy that this abnormal biochemical stool profile can also be detected during periods of remission between attacks[1,33]. On the other hand, a plasma fluorescence emission peak of 624–626 nm is seen only in symptomatic patients, including those with cutaneous involvement.

Hereditary Coproporphyria (HCP)

HCP is a very rare autosomal dominantly inherited disease, characterized by a deficiency of coproporphyrinogen oxidase, the sixth enzyme in the porphyrin–heme biosynthetic pathway (see Fig. 49.1). The clinical symptoms are similar to those encountered in VP. However, in contrast to the latter, the concentrations of coproporphyrin in the stool are usually higher than those of protoporphyrin (see above)[1,34].

δ-Aminolevulinic Acid Dehydratase (ALA-D) Deficiency Porphyria

Synonyms: ■ Plumboporphyria ■ Doss porphyria

This autosomal recessively inherited porphyria variant is extremely rare. As fewer than 10 cases have been reported worldwide, ALA-D deficiency porphyria does not have an important clinical presence. The disease can present during early childhood (as well as in adulthood) with acute neurologic symptoms that resemble those encountered in AIP[1,7].

Differential Diagnosis

When patients with VP or HCP present with cutaneous manifestations, the differential diagnosis is identical to that of PCT (see above). If acute neurologic attacks prevail, a broad range of gastrointestinal, neurologic, and psychiatric diseases have to be excluded, including an "acute

abdomen", peripheral neuropathies, and viral infections[1,2,6]. A more detailed discussion can be found in textbooks of internal medicine.

Treatment

Cutaneous symptoms

Patients with VP or HCP must minimize outdoor light exposure by wearing sun-protective clothing and applying broad-spectrum sunscreens. In contrast to PCT, phlebotomy seems to be of no benefit as are chloroquine and hydroxychloroquine. Furthermore, the latter antimalarials belong to the group of drugs considered to be potential inducers of acute porphyric attacks. Thus, their use is not recommended.

Acute porphyric attack

An acute porphyric attack is a potentially life-threatening event associated with a significant mortality rate (up to 5%). It requires rapid therapeutic intervention to prevent complications such as paralysis, respiratory failure, and coma. Treatment should consist of the following consecutive measures (see Table 49.6)[2,29]:

1. Precipitating factors, e.g. porphyrinogenic drugs, must be identified and eliminated. If necessary, patients should be initially monitored in an intensive care unit.
2. Systemic symptoms such as abdominal pain, nausea, and vomiting should be treated symptomatically, e.g. by administration of opioid analgesics and ondansetron or promethazine, respectively.
3. The most important therapeutic step for a patient with an acute attack is prompt intravenous administration of heme preparations such as heme arginate (Normosang® [Orphan Europe/Recordati Rare Diseases]) or hemin (FDA-approved; Panhematin® [Recordati Rare Diseases])[35]. Heme arginate reduces the overproduction of porphyrin precursors via a negative feedback mechanism in which the increased activity of ALA synthase, the rate-limiting enzyme in heme biosynthesis, is repressed. Of note, heme preparations have the disadvantage of being unstable, and thrombophlebitis is a fairly common side effect[36–38].

Historically, acute attacks were treated primarily with glucose infusions. However, given the availability of effective heme preparations (see above), glucose should only be administered adjunctively or as a temporary measure if heme arginate or hematin are not immediately available.

In 2019 and 2020, the FDA and European Medicines Agency approved givosiran (Givlaari® [Alnylam Pharmaceuticals]) for the treatment of adults with acute (hepatic) porphyria. Givosiran is a solution of small interfering RNAs (siRNAs) that are injected subcutaneously once monthly. These siRNAs promote the degradation of aminolevulinic acid synthase 1 (ALAS1) mRNA within liver cells, thereby reducing circulating levels of neurotoxic metabolites[39]. The most common side effects are injection site reactions and nausea, and both liver function tests and serum creatinine need to be monitored. Givosiran can lead to severe hyperhomocysteinemia, probably due to inhibition of the heme-dependent enzyme cystathionine-β-synthase which is important for homocysteine metabolism, with subsequent protein-N-homocysteinylation[40].

APPENDIX

Laboratories that measure porphyrin level (serum, plasma, erythrocytes, urine and feces):

USA

- ARUP Laboratories (www.arupconsult.com)
- Mayo Medical Laboratories (www.mayocliniclabs.com) – also do enzyme assays and genetic analyses
- University of Texas Medical Branch – Porphyria Center (https://www.utmb.edu/internalmedicine/divisions/gastroenterology/research/research-programs/porphyria-program/porphyria-center)

Europe

- Porphyrin Laboratory, Free University of Brussels (frederic.cotton@lhub-ulb.be)
- Porphyria Research Centre Finland (raili.kauppinen@hus.fi)
- French Porphyria Center Paris (www.porphyrie.net)
- French Porphyria Center Bordeaux (emmanuel.richard@u-bordeaux.fr)
- European Porphyria Specialist Center, Düsseldorf (porphyriaspecialistcenter@med.uni-duesseldorf.de)

50 Calcifying and Ossifying Disorders of the Skin

Daniela Kroshinsky and Janet A. Fairley

Chapter Contents

Cutaneous Calcification 796
Cutaneous Ossification (Osteoma Cutis) 802
Laboratory Evaluation of Patients with Cutaneous Calcification and Ossification 804

Synonyms: ■ Calcinosis cutis: cutaneous calcification ■ Osteoma cutis: cutaneous ossification ■ Calciphylaxis: calcific uremic arteriolopathy; calcifying panniculitis; uremic gangrene syndrome ■ Subepidermal calcified nodule: solitary congenital nodular calcification; Winer's nodular calcinosis

Key features

- Calcium regulates several key physiologic events in the skin, including epidermal proliferation, differentiation, and cell–cell adhesion
- Disruption of normal calcium regulatory pathways can lead to calcification and/or ossification of the skin
- Five major types of cutaneous calcification are seen: *dystrophic*, in which pre-existing damage to the skin results in calcium deposits; *metastatic*, where systemic metabolic disorders lead to calcium deposits in the skin and often other tissues; *iatrogenic*, as a result of medical therapy or testing; *idiopathic*, in which no cause can be identified; and *mixed*, a combination of metastatic and dystrophic
- In cutaneous ossification, there is deposition of calcium and phosphorus as hydroxyapatite crystals within a protein matrix; it can occur in conjunction with calcification or primarily in a number of genetic syndromes
- Correct classification of calcifying disorders requires an evaluation of calcium-phosphate metabolism and examination for associated systemic abnormalities
- Treatment of calcifying disorders is difficult with removal of triggers and correction of any associated disorder, such as hyperparathyroidism, essential for preventing progression. Surgical excision may be useful in circumscribed disease that interferes with function while efficacy of agents that modify calcium metabolism is based primarily upon case series

INTRODUCTION

Calcium plays a vital role in regulating key physiologic events in many tissues, including the skin. In the epidermis, calcium assists in regulating major functions, including proliferation, differentiation, and cell–cell adhesion. Control of intra- and extracellular calcium concentrations and maintenance of gradients are essential for its regulatory role. When factors that regulate calcium in the skin are disrupted, either by local or systemic events, cutaneous calcification or ossification as well as acantholysis and dyskeratosis can develop.

Calcification arises from the deposition of amorphous, insoluble calcium salts, while ossification results from deposition of calcium and phosphorus in a proteinaceous matrix as hydroxyapatite crystals. Ossification may follow pre-existing calcification in the skin, but in most disorders one form of calcium deposition predominates. While each of the calcifying and ossifying disorders of the skin is rare, as an aggregate finding calcium deposition within the skin is not uncommon.

CUTANEOUS CALCIFICATION

Calcifying disorders of the skin are generally divided into five broad categories: dystrophic, metastatic, idiopathic, iatrogenic, and mixed calcification (Table 50.1)[1,2]. *Dystrophic* calcification occurs in the setting of localized tissue damage, without an underlying metabolic abnormality in calcium regulation. Theoretically, dystrophic calcification occurs because the underlying disease process damages cell membranes, allowing calcium influx and subsequent intracellular crystallization. Alternatively, the acidity that accompanies cell damage may disrupt normal processes that inhibit calcification. In contrast, *metastatic* calcification occurs in normal tissue when there is dysfunction of calcium regulatory systems. When no known local or systemic factors can be identified, the calcification is categorized as *idiopathic*, and that related to medical therapy or testing is *iatrogenic*. *Mixed* calcification arises when metastatic calcification due to an underlying metabolic abnormality acts as a trigger for dystrophic calcification.

Dystrophic Calcification

Autoimmune connective tissue disease

Dystrophic calcification may be seen in any of the autoimmune connective tissue diseases (AI-CTDs), but it is most common in childhood dermatomyositis and in the localized form of systemic sclerosis, also known as CREST (*c*alcification, *R*aynaud phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia) syndrome. As a comparison, cutaneous calcification develops in 10%–20% of patients with adult dermatomyositis, whereas it occurs in up to 50% of children with the disease[3–5]. The presence of dermatomyositis-associated calcinosis correlates with longer disease duration, fingertip ulceration, and anti-NXP-2 autoantibodies, while a negative correlation exists with anti-transcriptional intermediary factor 1-γ antibodies[3]. Small deposits may occur in the skin or larger firm masses may begin in the muscle groups most severely affected by the disease. The most frequently involved sites are the elbows, knees, buttocks, and shoulders (see Fig. 42.9). Extrusion of calcium through the skin causes significant morbidity with pain and secondary infection.

In calcinosis universalis, the most severe form of dystrophic calcification, there is diffuse involvement with sheet-like masses of calcium. Calcification occurs along fascial planes, often leading to severe functional impairment. Aggressive treatment of dermatomyositis with immunosuppressive agents and/or IVIg may be warranted to try to limit this serious complication (see Ch. 42). However, once calcification has developed, the effectiveness of these therapies is quite variable.

The localized (CREST) variant of systemic sclerosis is the other AI-CTD in which cutaneous calcification is frequently seen. Calcification is usually less severe than in dermatomyositis and is usually restricted to the hands and upper extremities (Fig. 50.1); it is also seen over bony prominences and tendons. Extrusion of white chalky material is sometimes followed by localized ulceration, often at sites of trauma such as the digits. Calcinosis universalis can occur in systemic sclerosis, but much less frequently than in dermatomyositis.

Dystrophic calcification has occasionally been reported in chronic cutaneous, acute systemic, and subacute cutaneous lupus erythematosus as well as generalized morphea (Fig. 50.2)[6,7]. Calcification may also occur within lesions of lupus panniculitis. In systemic lupus erythematosus, calcification is most often an asymptomatic radiologic finding.

DISORDERS OF CUTANEOUS CALCIFICATION
Dystrophic
• Autoimmune connective tissue diseases, especially dermatomyositis, CREST • Panniculitis • Cutaneous tumors or cysts, e.g. pilomatricomas, pilar cysts • Infections, especially parasitic • Trauma, including "heel sticks" in neonates, injection sites, surgical scars • Chronic graft-versus-host disease • Genetic disorders, e.g. pseudoxanthoma elasticum, Ehlers–Danlos syndrome
Metastatic

• Advanced chronic kidney disease
  • Calciphylaxis*
  • Benign nodular calcification of renal disease
  • Tumoral calcinosis
• Hypervitaminosis D
• Milk–alkali syndrome
• Sarcoidosis
• Tumoral calcinosis (familial)
• Hyperparathyroidism
• Neoplasms (e.g. multiple myeloma, adult T cell leukemia/lymphoma, SCC of the lung or head and neck)

Idiopathic
• Idiopathic calcified nodules of the scrotum • Subepidermal calcified nodule • Tumoral calcinosis (sporadic) • Milia-like calcinosis
Iatrogenic
• Extravasation of intravenous solutions containing calcium or phosphate • Application of calcium-containing electrode paste for EMGs and EEGs • Application of calcium alginate dressings to denuded skin • Fibroblast growth factor receptor inhibitors† • Organ transplantation, especially liver • Gadolinium (nephrogenic systemic fibrosis)
*Can occasionally occur in the setting of severe primary hyperparathyroidism and, less often, in the absence of a clearly identifiable trigger. †Calcinosis cutis and calciphylaxis due to hyperphosphatemia.

Table 50.1 Disorders of cutaneous calcification. CREST, *c*alcification, *R*aynaud phenomenon, *e*sophageal dysmotility, *s*clerodactyly and *t*elangiectasia; EEG, electroencephalogram; EMG, electromyography; SCC, squamous cell carcinoma.

Treatment of dystrophic calcification

The management of dystrophic calcification can be challenging. Therapies include a low calcium and phosphate diet, aluminum hydroxide, and bisphosphonates, as well as management of the underlying disorder, although no controlled trials have convincingly shown consistent clinical improvement. While long-term treatment with diltiazem has been reported to decrease the size of calcium deposits, presumably through its effect on calcium transport into cells, its efficacy is variable and months to years of treatment may be required for extensive calcification[8,9]. In case reports and series, minocycline, colchicine, probenecid, IVIg, and JAK inhibitors have demonstrated some efficacy. Application of topical sodium thiosulfate 250 mg/ml [12.5 gm/50 ml] compounded 1 : 1 with petrolatum applied daily) can lead to resolution, while larger lesions may variably respond to intralesional injections (Table 50.2)[10–13].

Surgical excision is appropriate in selected patients with localized masses that are painful or interfere with function, but recurrences can occur. Laser therapy and extracorporeal shock wave lithotripsy represent additional localized therapeutic options[13].

Panniculitis

Any lobular panniculitis may develop focal dystrophic calcification, including pancreatic panniculitis, lupus profundus, and subcutaneous fat necrosis of the newborn (see Ch. 100). In the latter, calcium deposits are small and are most easily noted radiologically; occasionally, more widespread deposits may be seen[14].

Genetic disorders

A number of genetic disorders may be accompanied by cutaneous calcification, including *pseudoxanthoma elasticum* (PXE; see Ch. 97). The coexistence of typical elastic fiber calcification along with small discrete foci of cutaneous calcification or ossification has been reported[15,16]. PXE most frequently results from inactivating mutations in *ABCC6* which encodes a membrane transporter system[17]. ABCC6 directly mediates the sinusoidal release of ATP from the liver, which is then converted to AMP and inorganic pyrophosphate (PPi) within the liver vasculature[18,19]. PPi normally prevents the matrix calcification that is thought to create the findings in PXE[19]. In addition, serum levels of fetuin-A, another major anti-mineralization protein, are significantly reduced in PXE patients[18,20]. These factors, combined with impaired carboxylation of the inhibitor matrix Gla protein, may allow for increased responsiveness to pro-calcifying stimuli and unchecked calcification of elastic fibers in affected tissues[20,21].

SODIUM THIOSULFATE – INTRALESIONAL AND INTRAVENOUS ADMINISTRATION	
Intralesional	
• 250 mg/ml solution • Interventions to address significant associated pain include: (1) premedication (e.g. acetaminophen, oxycodone, hydromorphone); (2) 1 : 1 dilution with 2% lidocaine without epinephrine (adrenaline); and (3) use of small gauge needles and low volume syringes • Inject solution into the skin surrounding the ulceration (not the ulcer) every 1 cm* not to exceed 25 g • Injected weekly until resolution of active erythema and purpura then as needed for new lesions	
Intravenous	
• If receiving hemodialysis, 12.5 g three times per week during the last hour of hemodialysis (first 3 doses) then can increase to 25 g three times per week as tolerated • If receiving peritoneal dialysis, 25 g weekly • If not receiving hemodialysis, can be dosed up to 25 g daily • Continue until resolution of active erythema and purpura	
Side effects†	
• Nausea, vomiting • Volume overload due to sodium load (intravenous)‡ • Hypotension • QT prolongation	• Anion gap metabolic acidosis (thiosulfuric acid) • Reduced bone density • Headache
*Injected in a manner similar to the injection of lidocaine for local anesthesia. †May be reduced by decreasing the dosage, increasing the interval (nonuremic patients), and/or changing the intravenous solution from saline-based to 5% dextrose in water. ‡Cardiology consultation for those with cardiovascular disease.	

Table 50.2 Sodium thiosulfate – intralesional and intravenous administration. The risk:benefit ratio must be considered before injecting lesions overlying bone. For injections into large dense calcium deposits, larger bore needles (e.g. 14g) are sometimes employed. g, gram. From references 37, 45, 55, 59, 62–65.

Ehlers–Danlos syndrome encompasses multiple disorders in which genetic mutations lead to abnormal collagen synthesis, metabolism, or function (see Ch. 95). Patients develop hard subcutaneous nodules known as spheroids or spherules over bony prominences, which are thought to represent herniated fat lobules that have calcified (see Ch. 97). It is also possible that minor trauma results in scar tissue which then becomes a focus for dystrophic calcification[22]. Of note, similar calcifications can occur within the breast in these patients and their detection by mammography may lead to false-positive radiographic findings for breast carcinoma.

Dystrophic calcification may also be seen in patients with *porphyria cutanea tarda* (PCT; see Ch. 49). It occurs most often in patients with longstanding disease who develop sclerodermoid changes and secondary calcification within these areas[23]. As with the other lesions of PCT, calcification appears most often in the head and neck region or on the dorsal surface of the hands. Ulceration has also been reported, although rarely, in association with these lesions.

Other rare genetic syndromes in which cutaneous calcification may be seen include *Werner syndrome* and *Rothmund–Thomson syndrome* (see Ch. 63). *Cerebral amyloid angiopathy*, an autosomal dominant condition due to mutations in the gene encoding the amyloid precursor protein, can present with dementia, patchy leukoencephalopathy, hemorrhagic stroke, external carotid artery dysplasia, and occipital calcifications[24]. Microcalcification of the dermal blood vessels may also be seen, and while the latter is asymptomatic, dermatologists might be called upon to biopsy the skin as a diagnostic measure.

Infections

Infections, particularly parasitic, can lead to dystrophic calcification. Calcified cysts form around larvae or worms, including *Onchocerca volvulus* and the tapeworm *Taenia solium*. Intrauterine herpes simplex viral infections may cause annular plaques of calcinosis cutis in newborns.

Neoplasms

Incidental calcification has been noted in a large number of benign and malignant tumors of the skin. Up to 75% of pilomatricomas develop calcification and in 15%–20% there is evidence of ossification. A chalky, calcium-containing material may drain from the surface of these tumors. Activating mutations in the β-catenin gene have been demonstrated in sporadic pilomatricomas[25]. Other calcifying adnexal tumors or cysts include basal cell carcinomas, pilar cysts, epidermoid cysts, and chondroid syringomas[26]. Rarely, melanocytic nevi, atypical fibroxanthomas, pyogenic granulomas, trichoepitheliomas, and seborrheic keratoses have been reported to calcify.

Fig. 50.3 Dystrophic calcification in an infant at the site of a previous "heel stick" for obtaining blood. *Courtesy Julie V. Schaffer, MD.*

Other

Trauma, "heel sticks" (for obtaining blood in neonates; Fig. 50.3), subcutaneous or intramuscular injection sites, surgical and burn scars, and keloids have also been reported as triggers of dystrophic calcification. Localized or widespread cutaneous calcification may also be seen in chronic graft-versus-host disease[27].

Metastatic Calcification

Renal disease

The most common cause of metastatic calcification is advanced chronic kidney disease (Fig. 50.4). In patients with renal failure, there is an impaired ability to clear phosphate and impaired activation of vitamin D_3, as 1-α hydroxylation occurs in the kidney. Impaired production of 1,25-dihydroxyvitamin D_3 leads to decreased absorption of calcium from the intestine and hypocalcemia. Hypocalcemia, in turn, induces increased secretion of parathyroid hormone (PTH) and subsequent mobilization of calcium and phosphate. The serum calcium concentration is normalized, but significant hyperphosphatemia may develop, leading to elevation of the calcium × phosphate solubility product and resultant metastatic calcification.

Benign nodular calcification usually develops in the setting of prolonged secondary hyperparathyroidism due to advanced chronic kidney disease. Clinically, there are large deposits of calcium in the skin and subcutaneous tissue, often in periarticular sites. The number and size correlate with the severity of the hyperphosphatemia. Lesions are usually asymptomatic except for pain from pressure placed on surrounding structures. Normalization of serum calcium and phosphate levels may result in resorption of the lesions; however, if larger deposits interfere with function, surgical removal is recommended.

In renal transplant recipients, deposition of calcium within the skin has been reported following subcutaneous administration of low-molecular-weight heparin (nadroparin). Nodules with secondary ulceration developed at the sites of the heparin injections, but the process was self-limited and resolved following discontinuation of the nadroparin. The calcium content of the heparin in combination with hyperphosphatemia due to renal dysfunction was hypothesized as the underlying pathogenic mechanism[28].

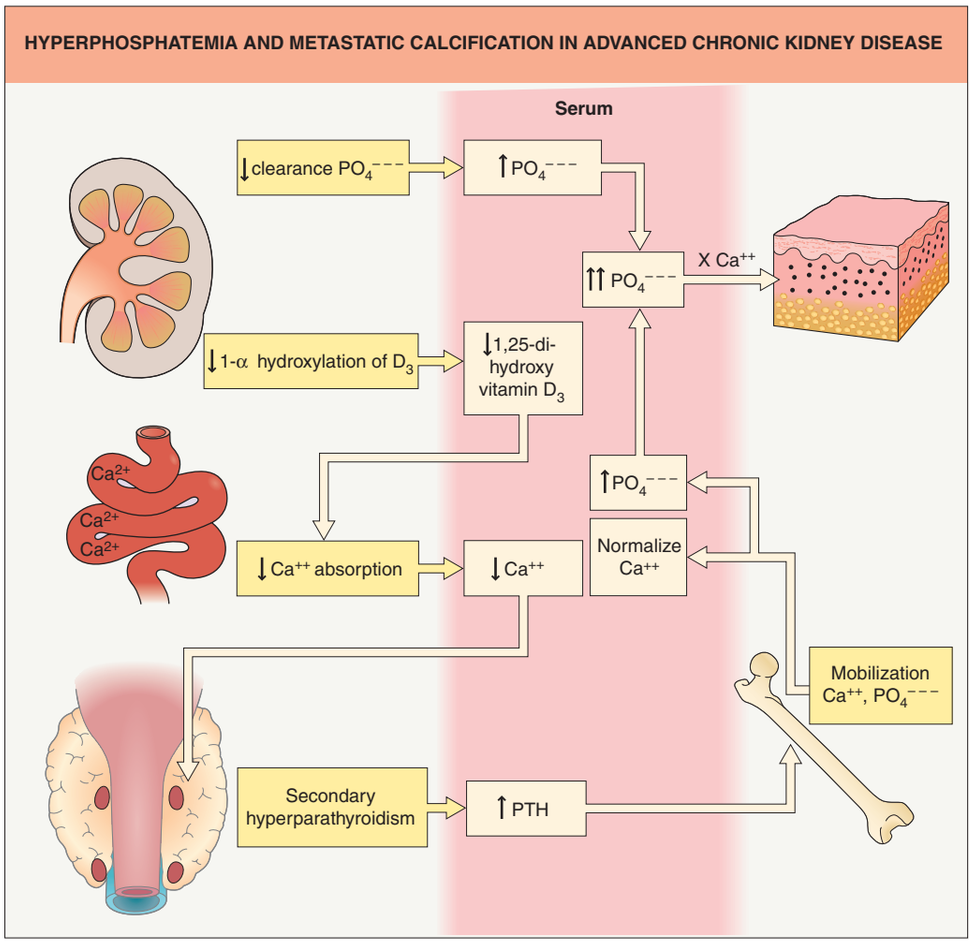

Fig. 50.4 Mechanisms of hyperphosphatemia and metastatic calcification in patients with advanced chronic kidney disease. PTH, parathyroid hormone.

Milk–alkali syndrome

Ingestion of excessive amounts of calcium-containing foods or antacids can lead to hypercalcemia and the milk–alkali syndrome. Patients with milk–alkali syndrome have acute manifestations including nephrocalcinosis, irreversible renal failure, and diffuse subcutaneous calcification.

Hypervitaminosis D

Chronic ingestion of supraphysiologic doses of vitamin D can lead to hypercalcemia and hypercalciuria. Clinical signs include weakness and lethargy, nausea, headache, and polyuria. Nephrolithiasis and calcinosis cutis may occur. Hypercalcemia is also seen in patients with sarcoidosis secondary to increased calcium absorption due to 1,25-dihydroxyvitamin D production by the granulomas. For other causes of metastatic cutaneous calcification, see Table 50.1.

Mixed Calcification

In mixed calcification, there is a combination of metastatic and dystrophic calcification, which is initiated by calcium dysregulation and then propagated by trauma.

Calciphylaxis

Calciphylaxis is a thrombotic vasculopathy that is characterized by microvascular deposition of calcium and subsequent thrombosis that results in ischemic necrosis of the skin and soft tissues[29,30]. While the majority of patients have severe or end-stage chronic kidney disease (CKD) requiring dialysis, nonuremic calciphylaxis can occur and has a better prognosis.

Early lesions usually present as poorly demarcated, often symmetric, extremely painful patches of erythema or livedo reticularis that progress to retiform purpura. Lesions favor areas with abundant adipose tissue such as the breasts and girdle area or sites of trauma, but they can also involve the distal extremities and penis (Fig. 50.5A,B)[29]. Bullae or a dusky gray color may then develop, signifying imminent tissue necrosis and the appearance of ulcerations with black, leathery eschars (Fig. 50.5C). Often, there is surrounding subcutaneous induration that extends beyond the margins of the visibly active lesions and may have a peau d'orange appearance; this can be helpful in distinguishing calciphylaxis from other forms of retiform purpura.

Early recognition and treatment is imperative because secondary infection and sepsis can develop as well as internal organ involvement. One-year mortality rates range from 30%–80%, with proximal lesion location and ulceration associated with a higher risk of death[29–32]. Nonuremic calciphylaxis is associated with lower one-year mortality rates which range from ~25% (all causes) to ~10% (when limited to calciphylaxis-related complications)[32].

The causes of calciphylaxis have not been fully elucidated. Selye, who coined the term calciphylaxis in 1961, suggested a "sensitizer plus challenger" model in which an underlying metabolic dysfunction involving serum levels of calcium and phosphate (e.g. secondary hyperparathyroidism) predisposed an individual to calciphylaxis. However, a second incident, or challenger, such as trauma or increased calcium load, ultimately resulted in calcium deposition and lesion formation[29,33,34]. In fact, new lesion formation has been reported following subcutaneous insulin or heparin injections and at sites of biopsies or aggressive debridement.

Additional contributing factors include thrombophilia (e.g. protein C or S deficiency, antiphospholipid antibodies) and alterations of vitamin K-dependent anti-calcification proteins such as fetuin-A and matrix Gla protein (see above)[35–38]. For vascular calcification to occur, an important step is the transdifferentiation of vascular smooth muscle cells into osteoblast-like cells. Phosphates, inflammatory mediators within the vessel wall, and bone morphogenic protein (BMP)-2 have all been proposed as potential stimuli for this conversion. In addition to matrix Gla protein and fetuin-A, BMP-7, osteoprotegerin, and phosphatonins are possible positive or negative regulators of this process[39]. Of note, patients who develop calciphylaxis have lower levels of anti-calcification proteins. Vitamin K is necessary to produce the active carboxylated forms of these proteins and a reduced level or inhibition of vitamin K is a known risk factor for calciphylaxis (see Ch. 23).

Fig. 50.5 Calciphylaxis in three patients with advanced chronic kidney disease. A Large reticulated violaceous plaques in an obese woman. Centrally, there is retiform purpura (inset) which precedes the ulcerations that are also present. **B** Irregular violaceous plaques on the leg with retiform purpura and hemorrhagic crusts overlying ulcerations. **C** Large ulceration with leathery black eschar. Retiform purpura and scarring are seen in the surrounding skin. *A, B, Courtesy Lorenzo Cerroni, MD.*

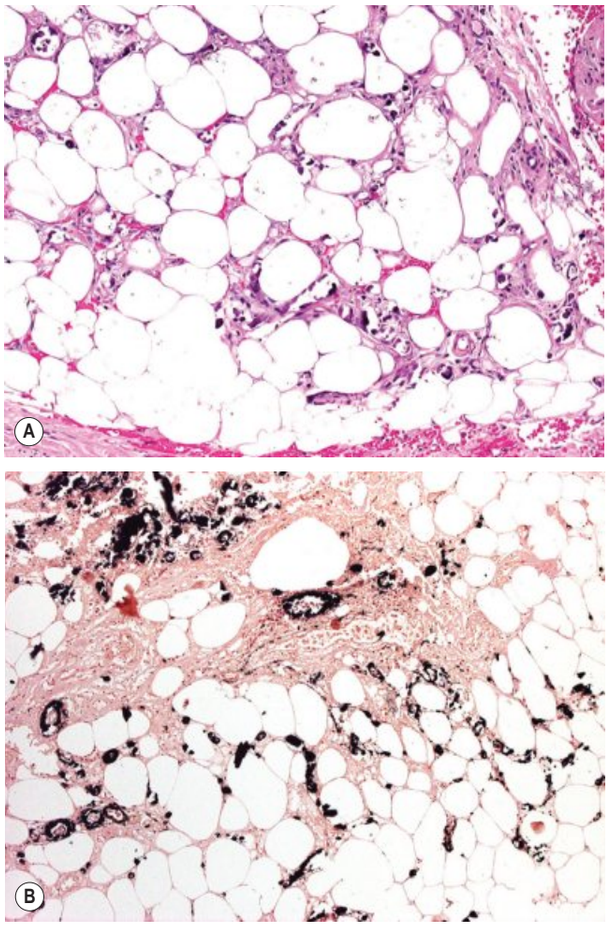

Fig. 50.6 Calciphylaxis – histopathologic features. A Perivascular deposition of calcium is seen within the walls of blood vessels in the subcutaneous fat. **B** Staining for calcium (von Kossa) highlights calcium deposition within blood vessel walls (black circular deposits) as well as focal, irregular calcification of connective tissue. Of note, even when the clinical lesions are impressive, the degree of calcification seen histologically may be subtle and clinical suspicion should remain high despite the absence of overt calcium deposits. *Courtesy Lorenzo Cerroni, MD.*

Additional risk factors include severe or end-stage CKD, dialysis, obesity, diabetes mellitus, AI-CTDs, and female sex as well as warfarin exposure, corticosteroids, and liver disease[29]. Hyperparathyroidism, calcium supplementation, and vitamin D intake are also risk factors, with the latter possibly related to stimulation from the conversion of vascular smooth muscle cells into osteoblast-like cells[40]. In nonuremic calciphylaxis, rapid weight loss, as seen in gastric bypass surgery, has emerged as a risk factor[41,42].

Diagnosis of calciphylaxis

Originally, calciphylaxis was thought to arise primarily in the setting of an elevated calcium × phosphate product. However, more recent studies have shown no statistical differences in the serum levels of calcium, phosphate, and PTH or the calcium × phosphate product in those with calciphylaxis compared to control dialysis patients at the time of presentation. The possible exception is elevations in time-averaged calcium × phosphate products or phosphate levels in affected individuals[43]. Nonetheless, initial evaluation should include a comprehensive metabolic panel, calcium, phosphorus, and PTH levels, and a complete coagulation profile.

While skin biopsy is currently considered the gold standard for diagnosing calciphylaxis, its role is controversial given the associated low sensitivity and specificity and risk of complications (e.g. ulceration). Classic findings are microvascular intimal calcium deposition and fibrin thrombi, often accompanied by ischemic changes and/or necrosis of the fat as well as the overlying epidermis and dermis. A calcifying lobular panniculitis is also a common finding (Fig. 50.6A). Because calcium

deposits may be subtle in H&E-stained sections, von Kossa and Alizarin red stains are used to increase detection (Fig. 50.6B)[44]. The presence of both media calcification and thrombosis increases the specificity of skin biopsies[45].

Clinicopathologic correlation is required as vascular calcium deposits +/− thrombosis can be seen in patients with and without CKD in the absence of calciphylaxis[45,46]. Some clinicians have therefore proposed that just clinical features, alone or aided by radiographic findings, be utilized to establish the diagnosis due to the potential shortcomings of histopathology[47,48]. That said, to increase sensitivity, biopsy specimens should be obtained from the most active margin rather than ulcerated or necrotic areas. In the authors' opinion, when biopsies are performed, "double-punch" or telescoping techniques with adequate fat sampling are preferred over thin wedge biopsies[45], but this is still debated. The key is obtaining an adequate depth. Image-guided biopsy (e.g. by xeroradiography or ultrasound) may increase diagnostic yield. When penile calciphylaxis is suspected, diagnostic imaging with Doppler ultrasonography and a CT scan is recommended rather than performing a biopsy[49,50].

The differential diagnosis of calciphylaxis is outlined in Table 50.3.

Treatment of calciphylaxis including wound care

A multimodal approach is essential for the management of calciphylaxis. Contributing factors (e.g. calcium and iron supplementation, vitamin D intake) should be identified and addressed. For patients with end-stage CKD, potential interventions include increased frequency or duration of dialysis, low calcium dialysate, low phosphate diet, and phosphate binders[33]. While the value of altering dialysis parameters or types requires additional investigation, at least temporary conversion from peritoneal dialysis to hemodialysis may allow for treatment optimization[47,51,52].

When possible, warfarin should be discontinued and can be replaced by direct factor Xa inhibitors as this has been associated with improved survival[32]. Given the thrombotic component of calciphylaxis, institution of direct-acting oral anticoagulants (DOACs) or low-molecular-weight heparin should be considered in general, especially in those with thrombophilic conditions[53,54]. Calcimimetics (e.g. cinacalcet, etelcalcetide) that reduce PTH secretion via activation of calcium-sensing receptors can be administered for hyperparathyroidism, with parathyroidectomy reserved for those who fail to respond to medical management[47,55,56].

There are multiple reports of the successful use of sodium thiosulfate, but larger controlled studies are needed[37,57–61]. The proposed mechanisms of action include reduction of reactive oxygen species, vasodilation via hydrogen sulfide and nitric oxide production, solubilization of calcium, inhibition of calcium deposition[37], and improvement in vascular endothelial function[37,55]. Table 50.2 outlines the dosing regimens and side effects for both intralesional and intravenous sodium thiosulfate. In some patients, there may be a role for topical sodium thiosulfate.

There are additional therapies that may be considered. Bisphosphonates such as pamidronate and etidronate may be helpful in patients who fail to improve with sodium thiosulfate[66–69]. Vitamin K supplementation may help restore the functionality of vitamin K-dependent anti-calcification proteins (see above)[70–72]. Renal transplantation may be curative but calciphylaxis has also been reported following transplantation and transplantation carries additional risks in patients with large, open wounds[73,74].

In patients with ulcerations, intensive wound care, including autolytic or chemical debridement (see Ch. 105) and appropriate dressings (see Ch. 145), is required to maximize healing and minimize infection and pain. While some analyses have shown that overall survival is improved by surgical debridement, patients were not controlled for extent of disease[75,76]. Given the concern for Koebner phenomena in patients with active calciphylaxis, i.e. trauma leading to new lesions or worsening of disease, it has been suggested that wounds with clean bases or non-infected dry eschars not undergo surgical debridement[59,77–80]. When debridement is indicated to remove deeply necrotic or infected tissue, conservative removal of devitalized tissue, often feasible at the bedside, is preferred over larger excisional surgical procedures[32,47,76,79].

Hyperbaric oxygen therapy may promote more rapid wound healing and has a precedent in other ischemic diseases. Via delivery of highly concentrated pressurized oxygen, there is stimulation of fibroblast proliferation, collagen production, angiogenesis, and phagocytosis as well as reduction in anaerobic colonization[81–83]. A multidisciplinary team approach that includes the pain service, nutritionists, and physical therapists can optimize recovery.

CALCIPHYLAXIS AND ITS DIFFERENTIAL DIAGNOSIS

Disorder	Most common locations for purpuric lesions* +/or ulcerations	Risk factors
Calciphylaxis	• Sites of greater adipose tissue, e.g. breasts, thighs, abdomen, buttocks • Sites of trauma, including lower extremities	• End-stage chronic kidney disease, dialysis, obesity, diabetes mellitus, AI-CTDs, female sex, thrombophilia/hypercoagulability, use of warfarin or corticosteroids, liver disease, hyperparathyroidism, excess calcium/vitamin D ingestion, rapid weight loss
Warfarin (Coumadin®) necrosis	• Sites of greater adipose tissue, e.g. breasts, thighs, abdomen, buttocks	• Starting warfarin with a large loading dose or without concomitant heparin; appears 2–5 days after initiating treatment • Female sex, age >50 years
Cholesterol emboli	• Lower extremities, especially distally	• Recent catheterization, introduction of anticoagulants 1–2 months prior
Infectious emboli	• Distal extremities or more widespread	• Immunosuppression, endocarditis (including prosthetic heart valves), intravenous drug use, implanted intravascular devices
Vasculitis of medium-sized blood vessels	• Primarily lower extremities†	See Ch. 24
Diffuse dermal angiomatosis (DDA)	• Lower extremities, including thighs • Breasts • Abdomen	• Peripheral artery disease, usually severe • Macromastia • Obesity • Changes of DDA can overlie calciphylaxis
Vasculopathy/vasculitis due to levamisole-adulterated cocaine	• Lower extremities, ears • Can be widespread	• Use of cocaine via smoking, snorting, or injection (see Ch. 89)
Thrombophilia (hypercoagulability)	• Depends on underlying cause, e.g. more widespread in DIC versus more acral in type I cryoglobulinemia	See Tables 22.5 and 105.9
Oxalosis	• Acral	See Ch. 23

*Macular, plaques
†Also subcutaneous nodules.

Table 50.3 Calciphylaxis and its differential diagnosis. Especially when on the lower extremities, additional causes of ulceration (e.g. venous ulcer, hypertensive ulcer, pyoderma gangrenosum) need to be excluded before establishing a definitive diagnosis of calciphylaxis (see Ch. 105). AI-CTDs, autoimmune connective tissue diseases; DIC, disseminated intravascular coagulation.

Idiopathic Calcification

Idiopathic calcified nodules of the scrotum

The term "idiopathic calcified nodules of the scrotum" is used to describe firm, skin-colored to yellow–white nodules that develop on the scrotum, typically in men 20 to 40 years of age[84]. Scrotal calcinosis occurs more often in individuals with darker skin phototypes. There can be multiple lesions and they may be asymptomatic, pruritic, or ulcerated. Histologically, a calcified epidermoid cyst or eccrine duct cyst may be seen; however, often only dermal calcinosis, with or without a surrounding granulomatous foreign-body type reaction, is present. This has led to a debate as to whether these nodules represent idiopathic or dystrophic calcification[85–87]. A female equivalent, idiopathic calcinosis of the vulva, has also been described[84,88]. Surgical excision is performed for symptomatic lesions and for cosmetic concerns. CO_2 laser has emerged as an alternative therapeutic option[89].

Subepidermal calcified nodule

Subepidermal calcified nodules are smooth to verrucous, firm, yellow–white to erythematous papules or nodules that can be solitary or multiple. They favor the head and neck region, but also occur on the extremities[90]. Subepidermal calcified nodules usually develop in children but have been observed in all age groups. Trauma, perhaps *in utero*, or calcification of a pre-existing milium, eccrine duct hamartoma, or hair follicle nevus has been hypothesized as the cause. Histologically, focal amorphous masses of calcium with a surrounding inflammatory infiltrate are seen. Epidermal ulceration and transepidermal elimination of the calcium deposits occur frequently. Surgical removal is recommended for symptomatic lesions that do not self-resolve.

Tumoral calcinosis

Tumoral calcinosis may be either sporadic or familial. In both forms, patients develop large, often painful, deposits of calcium phosphate in the dermis and subcutaneous tissues around large joints (Fig. 50.7). Ulceration of the overlying skin may occur in larger lesions. The *sporadic* form is most often associated with secondary hyperparathyroidism due to advanced CKD[91].

Familial tumoral calcinosis is inherited in an autosomal recessive pattern and has both hyperphosphatemic and normophosphatemic forms[92]. The hyperphosphatemic form is most commonly due to mutations in *GALNT3*, which encodes N-acetylgalactosaminyltransferase 3 (ppGalNAc-T3), an enzyme that initiates mucin-type O-glycosylation[93]. It is hypothesized that this glycosylation regulates "phosphatonins" that in turn modulate circulating phosphate levels. Hyperphosphatemic familial tumoral calcinosis can also be caused by loss-of-function mutations in either *FGF23* or *KL*; the former encodes fibroblastic growth factor 23, a phosphaturic protein that is glycosylated by ppGalNAc-T3, while the latter encodes Klotho, a co-receptor for FGF23. Homozygous mutations in *SAMD9* (*s*terile *a*lpha *m*otif *d*omain containing 9), which encodes a protein involved in the regulation of extraosseous calcification, has been found to underlie normophosphatemic familial tumoral calcinosis in families of Jewish Yemenite origin[94].

Dietary phosphate restriction and antacids that inhibit phosphate absorption may be of some benefit, but surgical excision of symptomatic lesions remains the treatment of choice.

Milia-like calcinosis

Idiopathic calcinosis may sometimes take the form of small, milia-like lesions that develop on the dorsal surface of the hands and the face. Most commonly, these lesions appear in the setting of Down syndrome, although rarely they have been reported in patients without other medical issues[95,96]. In some patients, the calcinosis appears to result from calcification of pre-existing syringomas, but usually no precursor lesions can be found.

Iatrogenic Calcification

Iatrogenic calcification is due to the rapid precipitation of calcium salts within the skin. When the tissue concentration of calcium rises and exceeds the solubility product, calcium precipitates within the tissue, resulting in firm nodules within the dermis and/or subcutaneous tissue. A secondary inflammatory response is elicited and, over a period of weeks to months, the calcium is either absorbed or is transepidermally eliminated, depending on the depth of the deposit.

Iatrogenic calcification most commonly occurs with extravasation of calcium gluconate, calcium chloride, or calcium phosphate-containing intravenous solutions[97]. In a rabbit model of iatrogenic calcification, intralesional injections of triamcinolone into sites of extravasation decreased inflammation and ulceration. This treatment appeared to be most helpful when given immediately after the initial extravasation. Iatrogenic calcification has also been reported following prolonged electroencephalograms, electromyography, and brainstem auditory evoked potential testing when a high-calcium electrode paste is employed[98]. Several patients were noted to develop calcification in split-thickness skin graft donor sites following the use of calcium alginate dressings[99].

Transient cutaneous calcifications have been observed in patients following liver or lung transplantation[100]. They are generally small deposits in the skin that appear shortly after the transplant. They are hypothesized to arise as a consequence of the large amounts of calcium and blood products containing citrate required during surgery, combined with metabolic abnormalities during the perioperative period[101].

CUTANEOUS OSSIFICATION (OSTEOMA CUTIS)

There are four genetic disorders that often have cutaneous or subcutaneous ossification: fibrodysplasia ossificans progressiva, progressive osseous heteroplasia, plate-like osteoma cutis, and Albright hereditary osteodystrophy (Fig. 50.8). Of these disorders, *fibrodysplasia ossificans progressiva* differs from the others in that the bone formation is endochondral and involvement of the skin and subcutaneous tissue

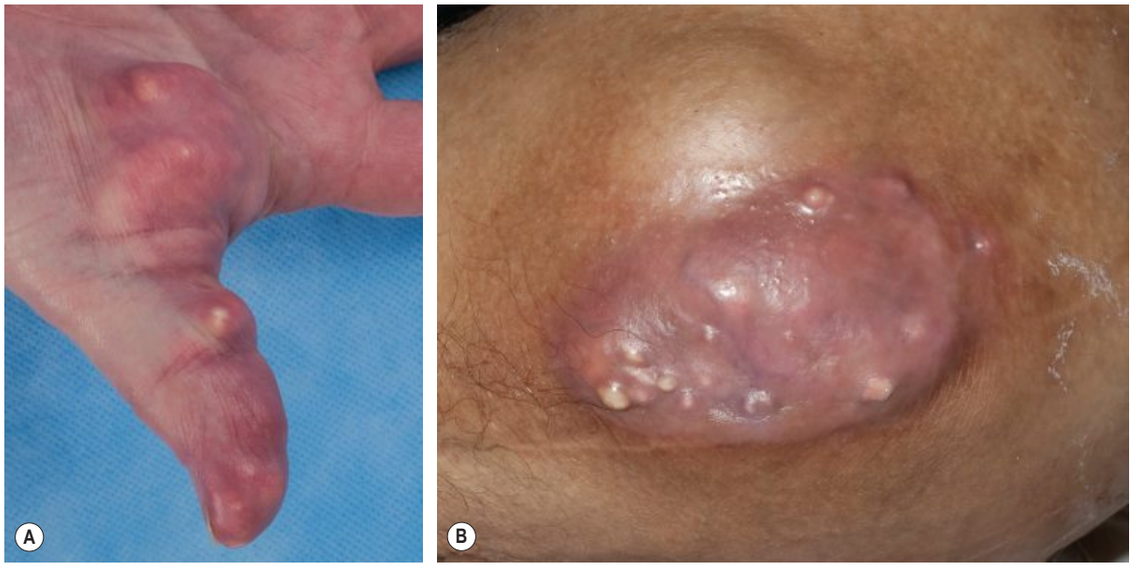

Fig. 50.7 Familial tumoral calcinosis. A, B There are large, frequently painful, deposits of calcium phosphate within the dermis and subcutaneous tissues, often around large joints. *Courtesy Edward Cowen, MD.*

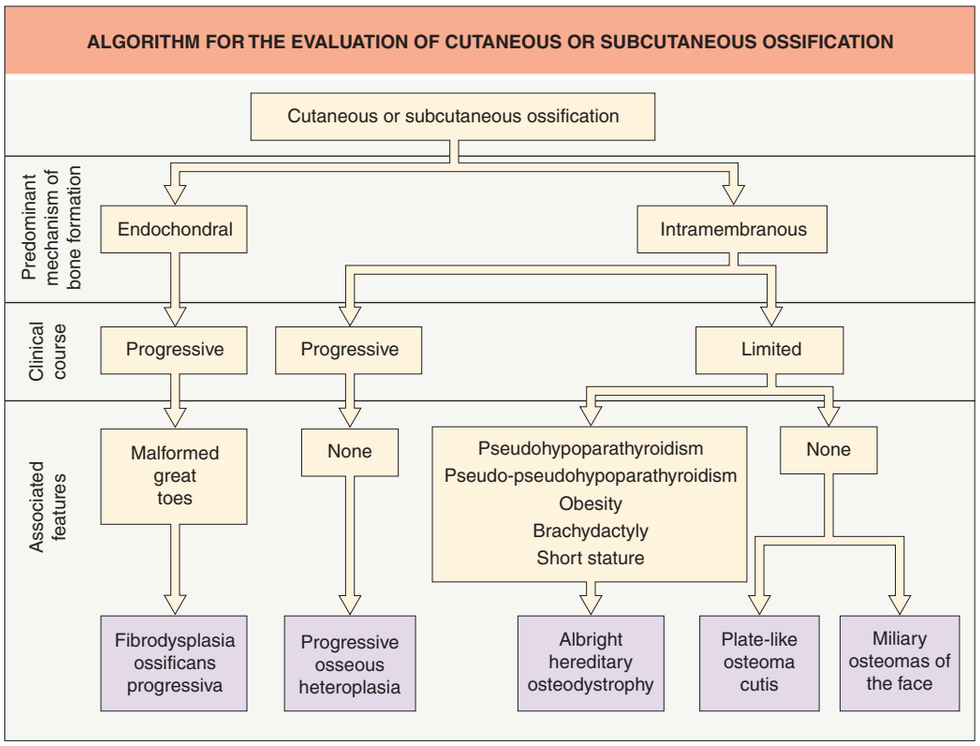

Fig. 50.8 Algorithm for the evaluation of cutaneous or subcutaneous ossification.

occurs only via extension from deeper tissues. These patients have extreme morbidity and often die at an early age due to restriction in movement of the chest. Fibrodysplasia ossificans progressiva is an autosomal dominant disorder with dysregulation of the bone morphogenic protein (BMP) signaling pathway. Heterozygosity for mutations in *ACVR1*, which encodes the activin A receptor (a BMP type I receptor), has been identified in both the inherited and sporadic forms of the disease. Of note, an arginine (R) to histidine (H) substitution at position 206 (R206H) was found not only in affected family members (i.e. the inherited form of the disease), but also in 30 of 32 *de novo* cases of fibrodysplasia ossificans progressiva, leading the authors to suggest that the R206H-associated mutation may represent one of the most specific codons in the human genome to be associated with a disease phenotype[102,103]. These patients are unlikely to present to a dermatologist due to their limited and late skin involvement.

Progressive osseous heteroplasia, plate-like osteoma cutis, and Albright hereditary osteodystrophy are all characterized by intramembranous ossification that begins in the dermis (Fig. 50.9). While distinctive features are seen in each of these entities, there is also considerable clinical overlap. The cutaneous lesions in *progressive osseous heteroplasia* are asymptomatic papules and nodules. Some are more plaque-like and studded with papules that give rise to a "rice-grain" texture. The lesions generally appear shortly after birth and may be rapidly progressive[104,105]. The location and extent of the ossification determines the associated morbidity; in general, there are no associated developmental or endocrine abnormalities. Unilateral involvement has also been described.

Plate-like osteoma cutis is considered to be a localized, non-progressive form of progressive osseous heteroplasia, with a single or limited number of sites of involvement[106]. *Albright hereditary osteodystrophy* is distinguished from these two entities by the presence of associated findings, including pseudohypoparathyroidism or pseudo-pseudohypoparathyroidism plus brachydactyly, obesity, short stature, and round facies. Fig. 50.8 demonstrates how clinical features may be used to classify these genetic disorders of cutaneous ossification.

Patients with progressive osseous heteroplasia, plate-like osteoma cutis, and Albright hereditary osteodystrophy all have mutations in the gene (*GNAS1*) that encodes the α-subunit of the stimulatory G protein which regulates adenyl cyclase activity[107,108]. The latter is believed to be a negative regulator of bone formation. Patients with progressive osseous heteroplasia have loss-of-function of the Gs-alpha isoform encoded by the **paternal** allele of *GNAS*, while those with Albright hereditary osteodystrophy have loss-of-function of the isoform encoded by the **maternal** allele of *GNAS*[109]. In other words, this locus is subject to imprinting (see Ch. 54), and different splice variants are expressed solely by maternal or paternal alleles[110].

Fig. 50.9 Osteoma cutis in Albright hereditary osteodystrophy. Hard pink–violet plaque studded with yellowish-white papules on the arm of an infant. *Courtesy Julie V. Schaffer, MD.*

Therapy for cutaneous ossification is difficult. Underlying abnormalities in calcium and/or phosphorus should be addressed; however, when complete ossification develops, the only therapeutic intervention is excision of neoformed bone. Even with surgical removal, recurrence of the bony deposits is common in this group of genetic disorders.

Miliary osteomas of the face is a fairly common entity characterized by multiple, scattered foci of cutaneous ossification. Small, firm papules appear on the face of adults and they can be skin-colored, white, or bluish (Fig. 50.10)[111]. Although these osteomas are often observed in the setting of chronic acne vulgaris, patients without a history of acne have also been reported. The unusual appearance of these osteomas on CT scan is shown in Fig. 50.10B. Histologically, islands of bone formation are seen in the dermis (Fig. 50.11).

Treatment of miliary osteoma cutis is primarily surgical. An incision over each lesion followed by gentle curettage of the bony

Fig. 50.10 Miliary osteoma cutis. A Multiple discrete white papules on the face of a patient with no previous history of acne. **B** The foci of ossification are readily apparent on the CT scan (arrow). **C, D** In contrast, many of the papules in these patients with a history of acne are skin-colored or blue.

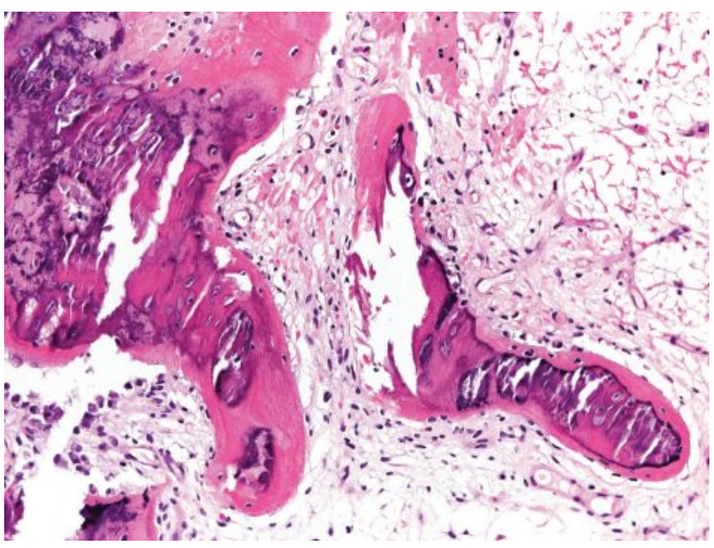

Fig. 50.11 Osteoma cutis – histologic features. Islands of bone formation are present within the dermis. Occasionally, osteoblasts and bone marrow elements can also be seen. *Courtesy Lorenzo Cerroni, MD.*

material with the edge of a surgical blade and then suture closure has been recommended. When lesions are numerous, however, this may not be practical. The use of lasers to expose osseous fragments has been reported[112,113]. Topical tretinoin gel may also be of some benefit[114].

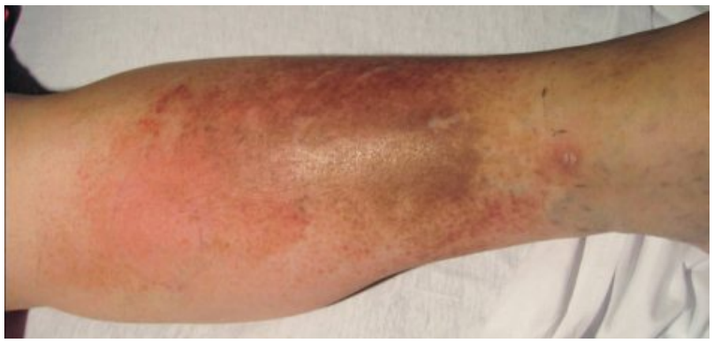
"Secondary" Cutaneous Ossification

Ossification may develop as a secondary event. Most disorders in which calcification can be seen have also been reported to ossify. Ossification occurs as a result of inflammatory or neoplastic processes and is often preceded by calcification. Secondary ossification has been described in melanocytic nevi, pilomatricomas, pilar and epidermoid cysts, basal cell carcinomas, nephrogenic systemic fibrosis, and chronic calciphylaxis.

LABORATORY EVALUATION OF PATIENTS WITH CUTANEOUS CALCIFICATION/OSSIFICATION
Serum levels of: • Calcium • Phosphate • Parathyroid hormone (PTH) • Vitamin D_3
24-hour urinary calcium excretion
Protein C activity and function (if calciphylaxis suspected)
Genetic analysis (if hereditary disorder suspected)

Table 50.4 Laboratory evaluation of patients with cutaneous calcification/ossification.

LABORATORY EVALUATION OF PATIENTS WITH CUTANEOUS CALCIFICATION AND OSSIFICATION



In addition to a thorough history and physical examination focusing on the associated features that have been described, selected laboratory investigations may be helpful in the evaluation of calcifying and ossifying disorders. A summary of this evaluation is outlined in Table 50.4. Abnormalities are expected most often in association with metastatic causes of calcification (see Table 50.1). Serum calcium and phosphate levels should be obtained in order to calculate the calcium × phosphate product. While this may give a general clue regarding the patient's metabolic status with regard to calcium and phosphate, a normal value does not necessarily exclude these disorders. There are rare reports of patients with calcinosis cutis and a normal serum calcium level, but abnormally low urinary excretion of calcium; thus, an assessment of the 24-hour urinary calcium excretion may be warranted in some patients.

Nutritional Diseases 51

Bernice Y. Kwong, Lucero Noguera-Morel, Stephanie Ann McLeish and Chad M. Hivnor

Key features

- Deficiencies in macronutrients (carbohydrates, fats, proteins) and micronutrients (vitamins, essential trace minerals) can affect any organ system, including the skin, which may provide clues to the diagnosis
- Severe acute malnutrition manifests as two classic protein–energy malnutrition syndromes: kwashiorkor and marasmus
- In addition to inadequate oral intake, there are secondary causes of nutritional deficiencies including intestinal malabsorption due to medical conditions, medications, and surgical procedures as well as increased nutritional demand due to severe illnesses (e.g. late-stage metastatic carcinoma, systemic infection)
- Vitamin and trace element deficiencies can lead to a wide range of mucocutaneous findings, from follicular keratoses to periorificial erosions to poor wound healing
- Obesity can be associated with high-calorie malnutrition and multiple skin changes ranging from acanthosis nigricans to lipodermatosclerosis

INTRODUCTION

Proper nutrition is fundamental to human life. From fetal development to adulthood, proper nutrition is essential for survival, physical growth, mental development, productivity, and overall health[1]. Deficiency of one isolated nutrient is rare, as individuals are usually deficient in multiple nutrients at the same time. In general, nutrients are categorized as macronutrients (carbohydrates, proteins, and fats) or micronutrients (vitamins and minerals). Most people who suffer from nutritional deficiencies live in low-income countries. However, there are certain conditions that predispose individuals from high-income countries to develop nutritional deficiencies, such as alcohol use disorder, intestinal malabsorption, anorexia nervosa or bulimia, restrictive diets, medications, and chronic or severe acute illnesses.

Nutrients require a process of ingestion, digestion, absorption, and circulation plus subsequent metabolism in order to be beneficial. When any one of these steps is disrupted, or if energy expenditure is increased, clinical manifestations may appear due to insufficient nutrition.

EPIDEMIOLOGY AND PATHOGENESIS

In low-income countries, malnutrition stems primarily from inadequate ingestion of all macronutrients as well as many micronutrients (Fig. 51.1). The World Health Organization (WHO) has estimated that worldwide, ~45% of deaths in children <5 years of age are due directly or indirectly to the multisystem ramifications of undernutrition. In industrialized regions of the world, malnutrition is directly linked to the per capita gross national product; if a country has a per capita income that is less than US$300 per year, endemic malnutrition is likely, especially in infants and young children.

At the same time, a global epidemic of obesity has emerged within industrialized countries, with increasing rates of death due to cardiovascular disease and diabetes mellitus[1]. Excessive consumption of foods high in calories but low in nutrients can lead to obese patients who lack essential vitamins and minerals. This is supported by a study in which 57% of morbidly obese patients undergoing preoperative assessment for bariatric surgery were found to have a deficiency in at least one micronutrient[2].

Restrictive diets, including those based upon real or perceived need (e.g. food allergies, weight loss, health benefit), psychiatric illness (e.g. anorexia nervosa) or mental impairment (e.g. substance use disorder), also disrupt the intake of appropriate nutrients and can result in malnutrition.

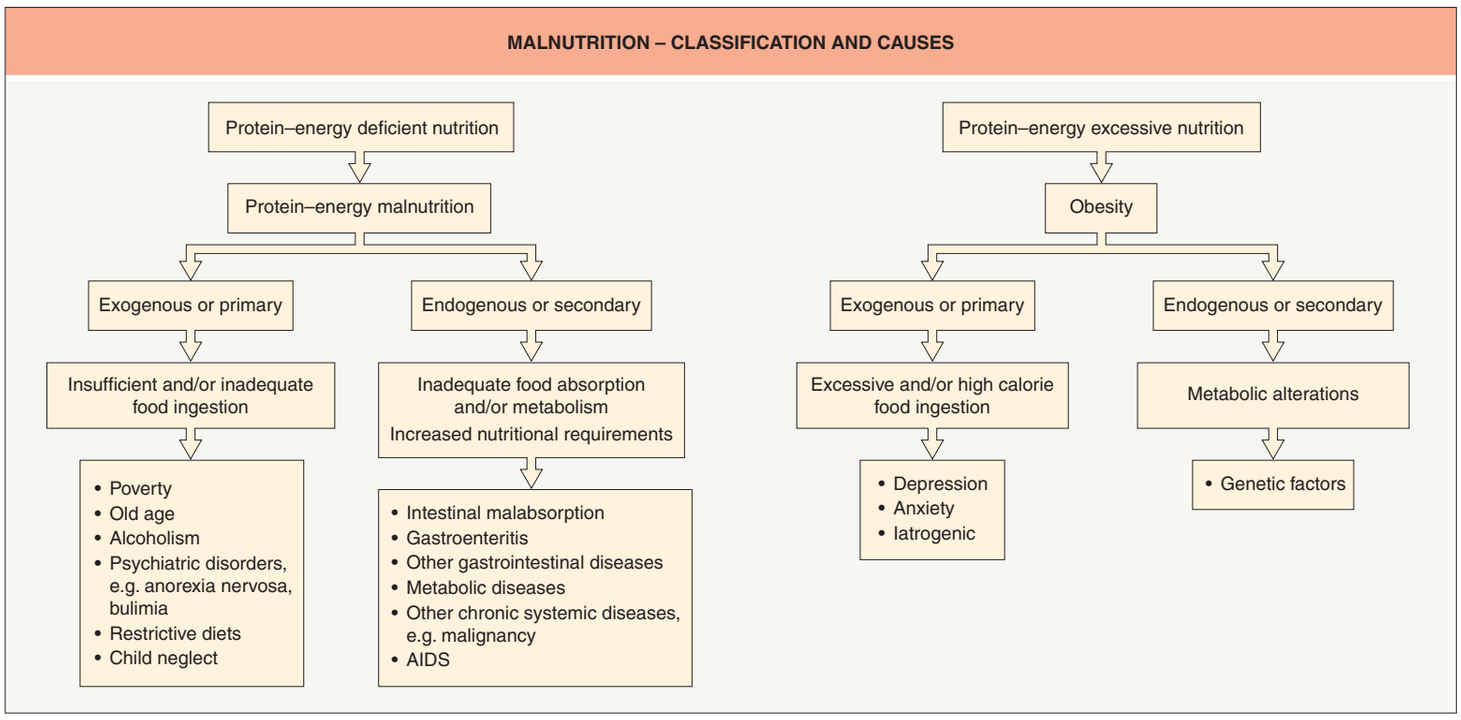

Fig. 51.1 Malnutrition – classification and causes. *Courtesy Ramón Ruiz-Maldonado, MD.*

In addition to a diet inadequate in the quantity and/or quality of macro- and micronutrients (i.e. primary causes), there are medical conditions that can lead to a functional malnutrition, i.e. secondary causes. The latter include an increase in metabolic requirements (e.g. severe infections, prolonged hospitalization) and/or a decrease in the transport and utilization of nutrients (e.g. intestinal malabsorption, bariatric surgery, medications). Malnutrition is also seen in individuals with late-stage internal malignancies and advanced AIDS as well as following allogeneic hematopoietic stem cell transplantation as a result of conditioning and/or gastrointestinal graft-versus-host disease (Table 51.1)[3].

CLINICAL FEATURES

Weight-for-height scores and height-for-age scores are utilized to evaluate malnutrition; scores are compared to the standard deviations (SD) from the median value for the reference population. An individual is considered to have moderate malnutrition if the scores are between the 2nd to 3rd (lower) SD and severe malnutrition if below the 3rd SD, with or without symmetrical edema[4]. Cutaneous manifestations in part reflect the fact that epidermal maturation (from basal cell layer to stratum corneum) occurs over a period of 10–14 days. Deficiencies,

CHARACTERISTICS OF SEVERE ACUTE MALNUTRITION (PROTEIN–ENERGY MALNUTRITION) AND ESSENTIAL FATTY ACID DEFICIENCY

	Severe acute malnutrition (protein–energy malnutrition)		
	Marasmus	**Kwashiorkor**	**Essential fatty acid deficiency[45,46]**
Causes	• Prolonged insufficient energy (caloric) intake • Develops over months to years • Primary causes: reduced caloric intake (poverty, alcoholism, substance use disorder, other psychiatric disorders, restrictive diets, child or elderly neglect/abuse) • Secondary causes: reduced absorption (intestinal malabsorption, chronic diarrhea), increased caloric demand (malignancies), chronic systemic diseases (e.g. hepatic failure, end-stage renal disease), AIDS*, metabolic disorders)	• Insufficient nutritional intake with adequate caloric intake during periods of stress lasting a few weeks or more • Diets consisting primarily of rice or rice-based beverages (e.g. "rice milk") for perceived milk intolerance, restrictive low-protein fad diets • Other causes: protein-losing enteropathies, malabsorption (e.g. cystic fibrosis), extensive gastrointestinal surgeries, HIV disease*, severe illnesses/prolonged hospitalizations	• Protein–energy malnutrition • Gastrointestinal disorders/surgeries causing severe fat malabsorption • Long-term parenteral nutrition without lipid supplementation • Diets extremely low in fat • Nephrotic syndrome • Inborn errors of metabolism, e.g. deficiency of fatty acid desaturase 2 (FADS2; also referred to as delta (6) desaturase)
Cutaneous features	• Dry, thin, pale, lax and wrinkled skin • Occasionally, fine scaling and hyperpigmentation (Fig. 51.3) • Follicular hyperkeratosis and folliculitis in adults • Ulcerations • Excess of lanugo-like hair • Thin hair that grows slowly and falls out readily • Impaired growth of nails and fissured nails • Purpura (Fig. 51.4)	• Dyschromia is a common finding • Pallor due to distention of the skin and loss of pigment • Hypopigmentation following abrasions; ulcerations and hyperpigmentation in areas subject to trauma • Superficial desquamation in mild cases ("enamel paint spots"), but in severe cases large areas of erosion ("flaky paint") (Fig. 51.6) • Other cutaneous signs include erythema, thinning, petechiae, ecchymoses, and purpura • Hair is sparse, dry, lusterless and brittle with a reddish tinge; bands of light and dark coloration ("flag sign") reflect intermittent periods of malnutrition; positive gentle hair pull test • Nails are soft and thin • Mucosal lesions: cheilitis, xerophthalmia, and vulvovaginitis	• Dry, scaly, and leathery skin with underlying erythema • Intertriginous erosions • Alopecia and more lightly pigmented hair • Increase in transepidermal water loss • Petechiae
Systemic features	• Starved appearance but alert • Reasonably preserved responsiveness to short-term stress • Bradycardia, hypotension, and hypothermia • Loss of subcutaneous fat and muscle (Fig. 51.3) • "Monkey facies" or an aged appearance (due to loss of buccal fat pads) • Suppression of growth	• Relatively well-nourished appearance • Edema or even anasarca (Fig. 51.5) • Apathy, anorexia, irritability • Failure to thrive (retardation of growth and mental development) • Superimposed bacterial and fungal (e.g. candidal) infections • Bilateral parotitis, hepatomegaly, diarrhea, loss of muscle mass	• Growth failure • Poor wound healing • Impaired reproduction • Abnormal liver and kidney function tests • Capillary fragility • Increased susceptibility to infections • Neurologic damage
Lab findings and diagnostic criteria	• Triceps skin-fold <3 mm • Mid-arm muscle circumference <15 cm • Creatinine–height index <60% of standard • Low plasma zinc levels • Epidermal acanthosis, confluent hyperkeratosis, pallor of upper layers of the epidermis (missing in later lesions) • Most hair bulbs are in the telogen phase • Abundant broken hairs	• At least one of the following: poor wound healing, decubitus ulcers, or skin breakdown • Anergy • Hypoalbuminemia (<2.5 g/dl) • Total iron-binding capacity <200 mcg/dl • Peripheral lymphocyte count <1500/mcl • Steatohepatitis • Decreased number of anagen hair follicles and increased number of telogen follicles • Structural abnormalities in anagen follicles – severe atrophy, shaft constriction, depletion of pigment • Exclude nephrotic syndrome	• Low plasma levels of linoleic and linolenic acids • Accumulation of 5,8,11-eicosatrienoic acid • Triene (eicosatrienoic acid) : tetraene (arachidonic acid) ratio >0.4 • Elevated levels of palmitoleic and oleic acids • Anemia, thrombocytopenia • Orthokeratotic hyperkeratosis, acanthosis with hypergranulosis, atrophic sebaceous glands, and papillary dermal vasodilation with a mixed cell infiltrate (in rat models) • Steatohepatitis

Table 51.1 Characteristics of severe acute malnutrition (protein–energy malnutrition) and essential fatty acid deficiency.

CHARACTERISTICS OF SEVERE ACUTE MALNUTRITION (PROTEIN–ENERGY MALNUTRITION) AND ESSENTIAL FATTY ACID DEFICIENCY			
	Severe acute malnutrition (protein–energy malnutrition)		
	Marasmus	**Kwashiorkor**	**Essential fatty acid deficiency**[45,46]
Treatment	• Treat or prevent hypothermia, dehydration, hypoglycemia, and electrolyte imbalances • Treat infections • *Slowly* replace proteins and calories, allowing for readaptation of metabolic and intestinal functions • Supplementation with linoleic acid and zinc • Monitor for hypophosphatemia and cardio-respiratory failure (associated with overly aggressive nutritional replacement) • Address underlying diseases, social issues	• Aggressive nutritional support is indicated to rapidly restore metabolic balance; correction of any electrolyte disturbances or hypoglycemia • Institute diet with adequate protein and caloric intake; supplementation with minerals and vitamins is required as patients often have multiple nutritional deficiencies • Identify and attempt to treat underlying cause(s), including bacterial and parasitic diseases • Topical moisturizers as needed	• Essential fatty acid replacement, depending upon severity • Correction of coexisting nutritional deficiencies
Prognosis	• 10% mortality, often secondary to diarrhea or pneumonia • Mortality rate related to underlying disease(s)	• Prognosis in adult patients is poor, even with aggressive nutritional support • In children, a lesser degree of stress is required to precipitate the disorder, so it is less foreboding • Severe, relapsing cases and those with coexistent HIV disease have a high mortality rate • Death usually occurs due to overwhelming infection despite antibiotic treatment	• Prognosis depends on the severity and coexistence of other nutritional deficiencies • Depends on awareness of this entity
*HIV disease is more often associated with marasmus than with kwashiorkor.			

Table 51.1 Characteristics of severe acute malnutrition (protein–energy malnutrition) and essential fatty acid deficiency. AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

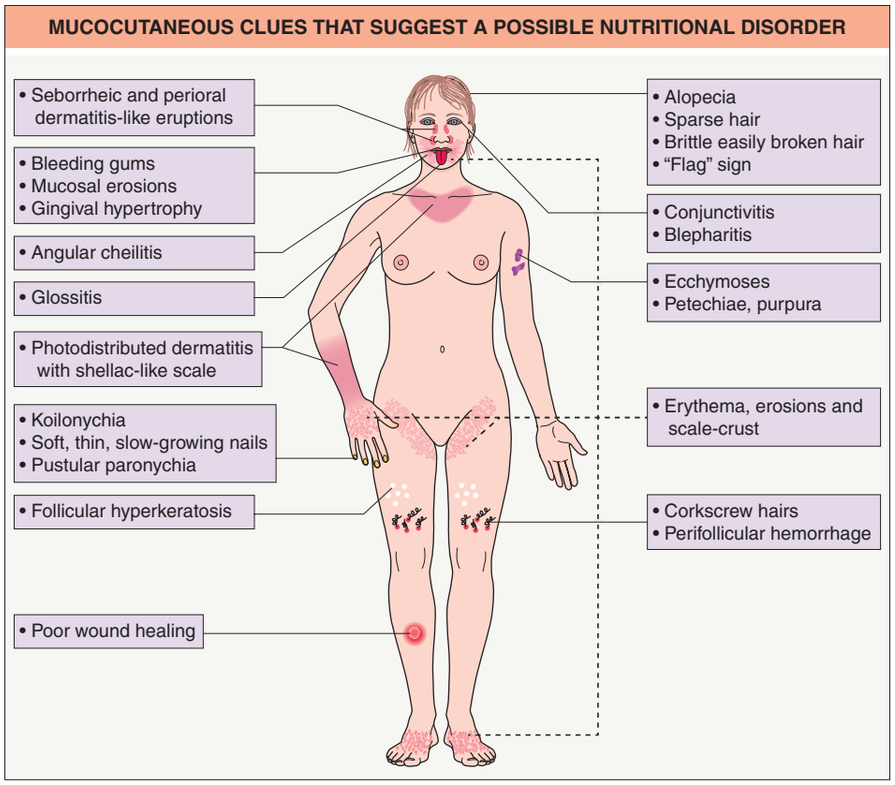

Fig. 51.2 Mucocutaneous clues that suggest a possible nutritional disorder. Risk factors are similar to those outlined for marasmus in Table 51.1. *Courtesy Karynne O. Duncan, MD.*

especially of macronutrients, can interfere with this process, resulting in skin that is dry and thin in appearance with associated epidermal atrophy. Prolonged deficiency can reduce both protein production, including that of dermal collagen and muscle, and the amount of subcutaneous fat. As a result, patients may develop dermal atrophy, muscle wasting, and/or lax skin.

Additional clinical findings of marasmus and kwashiorkor, such as dyschromia (hypo- and hyperpigmentation), desquamation, and erosions, are reviewed in Table 51.1. Patients may also have cutaneous manifestations from a deficiency in one or more micronutrients, and these are outlined in Table 51.2[5–10]. Mucocutaneous clues to the possibility of a nutritional deficiency are summarized in Fig. 51.2.

Protein–Energy Malnutrition

Worldwide, protein–energy malnutrition (or undernutrition) is the most prevalent nutritional deficiency. The two major forms of severe acute malnutrition (SAM) are: (1) marasmus, also referred to as wasting or malnutrition without edema (Figs. 51.3 & 51.4); and (2) kwashiorkor, also referred to as edematous malnutrition. Patients with marasmic kwashiorkor have features of both wasting and edema. According to the WHO, on a global basis, SAM affects almost 20 million young children (<5 years of age).

Marasmus (SAM *without* edema) can occur in individuals of all ages and results from a prolonged inadequate intake of total calories (energy).

These patients frequently develop recurrent infections due to their inability to mount a normal immune response.

Kwashiorkor (SAM *with* edema) is a more acute form of childhood and adult protein–energy malnutrition (see Table 51.1). A characteristic finding is peripheral edema or even anasarca in association with hypoalbuminemia (Fig. 51.5). One consequence of this edema is a body weight that is higher than is seen with marasmus, and it may be 60%–80% of expected weight (rather than <40%). Some patients will have overlapping features of both disorders and this is referred to as marasmic kwashiorkor[11]. In at-risk populations, kwashiorkor can develop after a child is weaned from breast milk and begins a diet rich in carbohydrates but deficient in protein. In addition to peripheral edema, patients with kwashiorkor also develop desquamation and erosions that have been likened to "enamel paint" and "flaky paint" (Fig. 51.6).

Based upon clinical observations, it was thought that kwashiorkor was due to a relative deficiency in protein *intake*. However, more recently, this proposed pathogenesis has been questioned based upon several findings. For example, protein intake was found to be similar in a group of children, irrespective of whether they had marasmus or kwashiorkor[12]. In addition, kwashiorkor can develop within just a few weeks of an acute, life-threatening illness. A current theory is that kwashiorkor is related to physiologic stresses secondary to an acute or chronic illness (including infections), with the stress leading to an increase in protein and energy requirements at a time when intake is frequently limited[13]. This would help to explain why kwashiorkor often occurs in the setting of an acute illness superimposed upon a chronic state of milder malnutrition. It is hypothesized that the stress of the acute illness blocks the protein-sparing response that is normally in effect during states of starvation. There is also increasing evidence for a relationship between the gut microbiome and the development of malnutrition, including kwashiorkor. A deficiency of anti-inflammatory taxa and an increase in inflammogenic bacteria were noted in the gut microbiome of affected children[14,15].

Both kwashiorkor and marasmus can have secondary causes such as "rice milk" diets or chronic diarrhea (see Table 51.1). The cutaneous and systemic abnormalities associated with primary protein–energy malnutrition are often reversible following nutritional therapy. However, if the malnutrition is prolonged, this may preclude normal physical and/or mental development[11].

Severe acute malnutrition is less common in adults, but can occur in the setting of critical illnesses requiring hospitalization, where catabolism exceeds anabolism. Protein loss and hypoalbuminemia may also develop in patients with exfoliative erythroderma (see Ch. 10). Delayed wound healing is one of the important consequences of protein deficiency.

Fig. 51.3 Marasmus. This child is emaciated and has obvious hyperpigmentation. Both erosions and desquamation are present on the scalp. *Courtesy Ramón Ruiz-Maldonado, MD.*

Essential Fatty Acid Deficiency

Essential fatty acids (EFAs) are unsaturated fatty acids that must be obtained from an exogenous source because they cannot be synthesized by the human body. Linoleic acid and alpha-linolenic acid, which

Fig. 51.5 Kwashiorkor. There is intense edema of the buttocks and lower extremities in addition to areas of erythema with erosions and desquamation. The edema is a reflection of hypoalbuminemia. *Courtesy Ramón Ruiz-Maldonado, MD.*

Fig. 51.4 Marasmus. Multiple sites of purpura are seen. *Courtesy Ramón Ruiz-Maldonado, MD.*

Fig. 51.6 Kwashiorkor. Edema, ulceration, and shellac-like scale that resembles peeling paint.

represent omega-6 and omega-3 fatty acids, respectively, are major types of EFAs. These fatty acids are present in plant oils (e.g. canola, flaxseed, soybean) and in fish oils. EFAs have multiple functions, both structural and synthetic, including prostaglandin formation, phospholipid membrane integrity, energy storage, and proper lamellar granule formation. Humans can convert linoleic acid into arachidonic acid. From 15% to 30% of the skin's fatty acids are EFAs and cutaneous as well as systemic manifestations of EFA deficiency are outlined in Table 51.1.

While an isolated deficiency of EFAs is uncommon, it may occur following parenteral nutrition without lipid supplementation and with overly aggressive low-fat diets. In most instances, however, EFA deficiency is associated with other nutritional deficiencies. The presence of decreased plasma levels of linoleic and linolenic acids plus increased levels of eicosatrienoic acid (normally undetectable) establishes the diagnosis of EFA deficiency (see Table 51.1).

Data from the American Heart Association suggest that obtaining 5%–10% of energy from omega-6 fatty acids (e.g. linoleic acid) reduces the risk of cardiovascular disease. However, there is still controversy regarding the recommended upper limit of consumption of EFAs, as epidemiologic studies suggest that an excess of linoleic acid may contribute to cardiovascular disease, cancer, and inflammation[16].

Vitamins and Trace Elements

Micronutrients represent a diverse array of dietary components that are necessary to sustain health. The physiologic roles of micronutrients are as varied as their composition. Several micronutrients function as cofactors for enzymes, while others act as biochemical substrates or hormones; in addition, there are some whose function has not been well defined[5]. Under normal circumstances, the recommended average daily dietary intake for each micronutrient is measured in milligrams or even smaller quantities. This distinguishes micronutrients from macronutrients (carbohydrates, fats, proteins) as well as the macrominerals (calcium, magnesium, phosphorus)[5].

Vitamins

Vitamins are required constituents of the human diet as they are essential for development and maintenance of bodily functions. However, they do not have a direct role as an energy source. Vitamins are categorized as either fat-soluble (A, D, E, K) or water-soluble (all others) (see Table 51.2). While none of the fat-soluble vitamins appear to serve as cofactors for enzymes, most of the water-soluble vitamins have this function[5]. In addition, symptomatic vitamin excess is more likely with fat-soluble vitamins (see below). Lastly, the use of vitamins

VITAMIN DEFICIENCIES IN ADULTS AND CHILDREN

Vitamin	Clinical manifestations			Reference values	Replacement therapy
	Mucocutaneous	Systemic	Other		
Fat-soluble vitamins – can easily accumulate and lead to toxicity if replaced in high doses for prolonged periods					
A (retinol)	• Phrynoderma – follicular papules with central keratotic plug; favors extensor surfaces of extremities (Fig. 51.7) & buttocks • Generalized xerosis • Sparse, fragile hair	• Night blindness • Xerophthalmia (dryness of the cornea & conjunctivae) • Bitot spots (gray–white patches on the conjunctivae) • Keratomalacia (softness of the cornea, sometimes with ulceration)[47] • Stunted growth	• Increase in measles-related mortality (see Ch. 81) • Increased susceptibility to and mortality from respiratory and diarrheal illnesses[47]	• Serum: LC–MS/MS for vitamin A levels • Reference values (fasting): 0–6 yrs: 11–65 mcg/dl 7–12 yrs: 13–80 mcg/dl 13–17 yrs: 14–98 mcg/dl ≥18 yrs: 32–78 mcg/dl • Supplementation recommended when <20 mcg/dl • Severe deficiency when <10 mcg/dl	• Based on severity of ophthalmologic impairment • Infants (<6 mos): 50 000 IU PO × 3 on days 1, 2, and at least 14 • Infants (6–12 mos): 100 000 IU PO × 3 doses (see above) • Children >1 yr, men, postmenopausal women: 200 000 IU PO × 3 doses (see above)* • Higher doses given if keratomalacia
D **D_2:** ergocalciferol **D_3:** cholecalciferol	None	• Muscle weakness • Rickets in children • Osteomalacia in adults	• Possible decrease in innate immunity (see Table 51.3) • Possible increase in internal malignancies (e.g. colon, prostate)	• Total serum or plasma 25(OH) vitamin D is measured (D_2 plus D_3) • Deficiency: <12 ng/ml (IU: <30 nmol/l) • Insufficiency: 12–20 ng/ml (IU: 30–50 nmol/l)[20]	• For deficiency, 50 000 IU of vitamin D_2 or D_3 (preferred) PO once weekly × 6–8 weeks • Maintenance dose is age-dependent (see text) • For insufficiency, vitamin D_3 800–1000 IU/day PO • Plus 1 g/day of oral calcium if deficient
E (tocopherol)	None	• Ophthalmoplegia, ptosis • Muscle weakness, ataxia, areflexia • Pigmentary retinopathy		• Serum: LC–MS/MS for vitamin E levels • Reference values (fasting): 0–17 yrs: 3.8–18.4 mg/l ≥18 yrs: 5.5–17.0 mg/l • Significant deficiency: <3.0 mg/l	• Children 200–300 mg/day PO • Adults 800–1000 mg/day PO
K **K_1:** phytonadione (source = diet) **K_2:** menaquinone (source = gut bacteria)	Petechiae, purpura, ecchymoses, mucosal bleeding	• If severe hypoprothrombinemia, extensive hemorrhage at any body site • Hemorrhagic disease of the newborn – infants not given vitamin K at birth plus inadequate diet or mother on medications which inhibit vitamin K function†,[47]		• Elevated prothrombin time & INR • Serum or plasma vitamin K_1 level is measured • ≥18 yrs: 0.10–2.20 ng/ml versus 0.2–3.2 ng/ml	• Newborns: 0.5–1 mg sc or IM • Children: 2 mg PO • Adults: 5–10 mg PO • IV or SC administration if emergency • Intravenously in emergencies (risk of anaphylaxis) • Fresh frozen plasma • Doses for K_1 and K_2 similar

Table 51.2 Vitamin deficiencies in adults and children.

Continued

VITAMIN DEFICIENCIES IN ADULTS AND CHILDREN					
Vitamin	**Clinical manifestations**			**Reference values**	**Replacement therapy**
	Mucocutaneous	**Systemic**	**Other**		
Water-soluble vitamins – less likely to accumulate & lead to toxicity, but in high doses can lead to side effects, e.g. nephrolithiasis (vitamin C), hepatitis (niacin)					
C (ascorbic acid)	• Spongy gingivae with bleeding & erosions • Petechiae, ecchymoses • Follicular hyperkeratosis, especially forearms, abdomen, & legs • Corkscrew hairs (flattened & curled) with perifollicular erythema or hemorrhage (Fig. 51.8) • Splinter hemorrhages • Poor wound healing	• Subperiosteal hemorrhage with "pseudoparalysis", especially in children • Arthralgias, joint swelling, edema • Loose teeth • Weakness, malaise, depression • Vasomotor instability[47] • In infants, hemorrhage into GI and GU tracts • Anemia • Impeded growth • Cerebral & femoral sheath hemorrhages	• Many of the signs of *scurvy* are related to impaired collagen synthesis • Fractures of cartilaginous matrix • Positive Rumpel–Leede capillary fragility test (>20 petechiae/inch^2)‡	• Plasma: HPLC for ascorbic acid levels • Conventional (fasting): 0.6–2.0 mg/dl • <0.2 mg/dl = scurvy • Absence of vitamin C in urine • Leukocyte vitamin C is more accurate, but less accessible, assay; 0 mg/dL = scurvy; up to 7 mg/dL = deficiency	• Adults: 200–1000 mg/day PO (in divided doses) • Children: 100–300 mg/day PO (in divided doses), then 100 mg PO once weekly • Higher dosage (1–2 g/day) may decrease symptom duration • IM or IV administration if required
B_1 (thiamin; thiamine)	• Peripheral edema with possible secondary skin breakdown in "wet" beriberi • Glossitis and glossodynia • Angular cheilitis	• Early – fatigue, apathy, irritability, depression, drowsiness, anorexia, nausea, abdominal pain • Late – peripheral neuropathy, weakness, cardiac failure, mental alterations, growth retardation • Prolonged deprivation – meningismus, coma	• *Beriberi* is divided into "wet" and "dry" forms¶ • Korsakoff syndrome – amnesia, confabulation & peripheral neuropathy • Wernicke encephalopathy – ophthalmoplegia, horizontal nystagmus, ataxia, confusion	• Whole blood thiamine diphosphate (TDP) level to assess active form of vitamin B_1 within erythrocytes • TDP reference values (fasting): 70–180 nmol/l • TDP level <70 nmol/l suggests deficiency	• 100 mg TID IV × several days, followed by 100 mg/day PO until complete recovery[41] • Infantile beriberi: 5–20 mg IV[41]
B_2 (riboflavin, lactoflavin)	• Angular cheilitis and dry fissured lips • Glossitis – pebbly appearance, then atrophic with irregular denudation of papillae • Pharyngitis • In periorificial sites (head & neck, anogenital region) – painless scaly papules, ulcers, indolent fissures & seborrheic dermatitis-like lesions • Conjunctivitis	• Superficial keratitis • Photophobia • Changes in iris (pigment clumping) • Anemia due to bone marrow hypoplasia • Intellectual disability in newborns	• In adults, *oro-oculo-genital syndrome* can occur, especially if there are additional B vitamin deficiencies	• Plasma: LC–MS/MS for riboflavin levels • Reference values (fasting): 1–19 mcg/l • Riboflavin level <1 mcg/l = deficiency; marginally low levels should also be corrected	• Riboflavin 3–10 mg/day PO • In refractory cases, 2 mg IM TID
B_3 (niacin, nicotinic acid)	• Photodistributed, well-demarcated erythema that becomes scarlet or hyperpigmented, with scale-crust; surface has shellac-like appearance (Fig. 51.9) • "Casal necklace" – well-demarcated band around the neck • Painful fissures of the palms & soles • Peri-anal & oral inflammation & erosions • Cheilitis and glossitis (atrophic, red) • Vaginitis with ulceration	• Peripheral neuropathy with dysesthesias, including burning • Esophagitis • Anorexia • Lassitude • Dizziness • Irritability, disorientation • Abdominal pain • Late – irritability, anxiety, apathy, diarrhea, nausea, dementia	• The classic triad of *pellagra* is dermatitis, diarrhea, and dementia, with the fourth "d" possibly death • Because of large tissue stores, symptoms develop after months of niacin or tryptophan deficiency • Other causes of pellagra include carcinoid syndrome, Hartnup disease, and medications, e.g. isoniazid	• Plasma; HPLC for niacin levels • Reference values (fasting; mcg/ml): Children <10 yrs 0.50–8.91 (normal) <0.50 (low) Adults & children >10 yrs: 0.50–8.45 (normal) <0.50 (low)	• Nicotinamide (niacinamide) is the amide/water-soluble form of niacin • Adults: nicotinamide 300 mg/day PO (in divided doses) × 3–4 weeks, then maintenance of niacin 15–20 mg/day PO • Children: 10–50 mg every 6 hours PO until resolution of all signs and symptoms, then maintenance of 15–20 mg/day of niacin • *For severe cases*, in adults: 50–100 mg five times/day IM or 25–100 mg twice daily IV (slow infusion); in children: up to 300 mg/day IV (slow infusion)

Table 51.2 Vitamin deficiencies in adults and children.

VITAMIN DEFICIENCIES IN ADULTS AND CHILDREN					
Vitamin	**Clinical manifestations**			**Reference values**	**Replacement therapy**
	Mucocutaneous	**Systemic**	**Other**		
B_5 (pantothenic acid)	• None	• Fatigue, headache & vomiting • Hypoglycemia • Paresthesias ("burning feet" syndrome)	• Rare	• Serum: microbiological assay • Reference values (mcg/l): ≤1 yr: 3.45–845 1–10 yrs: 3.45–229.2 >10 yrs: 37–147	Vitamin B_5 is ubiquitous in the food supply and deficiency rare
B_6 (pyridoxine, pyridoxamine, pyridoxal)	• Periorificial seborrheic dermatitis-like lesions • Angular cheilitis, stomatitis • Glossitis – atrophic with ulceration • Conjunctivitis • Intertrigo	• Anorexia, nausea, vomiting • Neurologic symptoms including peripheral neuropathy, somnolence, confusion, & seizures • Sideroblastic anemia, eosinophilia, lymphopenia		• LC–MS/MS for pyridoxal 5-phosphate levels • Reference value (fasting): 5–50 mcg/l	• Pyridoxine 50–100 mg/day PO to prevent neuropathy[41] • 100 mg/day IV in those with seizures[41]
B_7 (biotin)	• Alopecia • Seborrheic dermatitis of the scalp, face, and flexures • Periorificial dermatitis (ocular, nasal, oral, anal) • Cutaneous candidiasis • Nummular eczema[47] • Blepharitis, conjunctivitis • Brittle nails • Erythroderma in neonatal form • Juvenile form may resemble acrodermatitis enteropathica	• Depression, lassitude • Anorexia, nausea, & vomiting • Paresthesias & hyperesthesias • Hypotonia, muscle pain • Developmental delay, hearing loss • Seizures, ataxia • Both forms fatal if not treated	• Neonatal form – holocarboxylase synthetase deficiency (see Fig. 51.13) • Juvenile form – biotinidase deficiency • Two forms have overlap; both autosomal recessive • Metabolic acidosis, lactic acidosis, hyperammonemia	• White blood cells: levels of biotinylated carboxylases, e.g. 3-methylcrotonyl-CoA or propionyl-CoA carboxylases • Serum: microbiological assay • Reference values (pg/ml) for microbiologic assay: <12 yrs: 100–2460 ≥12 yrs: 221–3004 • Increased urinary excretion of organic acids (e.g. 3-hydroxy-isovaleric acid, 3-hydroxyisovalerylcarnitine) • Genetic analysis (see Fig. 51.13)	• Infants & children: 5–20 mg/day PO or IM • Adults: 10–40 mg/day PO or IM
B_9 (folic acid; folate)	• Cheilitis, glossitis, mucosal erosions and ulcerations • Diffuse hyperpigmentation, with accentuation in sun-exposed sites	• Megaloblastic anemia (macrocytosis plus hypersegmented neutrophils is pathognomonic)[47] • Weakness secondary to anemia • Neuropsychiatric symptoms due to impaired synthesis of myelin	• While folate can reverse the megaloblastic anemia of B_{12} deficiency, it cannot reverse the neurologic degeneration	• *Serum* folate levels: <4 mcg/l suggests folate deficiency • *RBC* folate levels: 140–628 ng/ml in packed RBCs • IU: 317–1422 nmol/l in packed RBCs	• Replace folate and exclude B_{12} deficiency • Folate 1 mg TID PO, followed by 1 mg/day • Folate 1–5 mg/day IV if acutely ill[41]
B_{12} (cyanocobalamin [CNCbl])	• Diffuse or patchy hyperpigmentation, including flexural areas, dorsal hands and feet, palmar creases, soles, nails, oral cavity • Glossitis with fissures of the oral mucosa (early sign prior to anemia)[48] • Painful, red, swollen tongue • Increased incidence of vitiligo, poliosis, and alopecia areata in patients with pernicious anemia	• Megaloblastic anemia due to altered folic acid metabolism • Peripheral neuropathy, ataxia	• Pernicious anemia – decrease in gastric intrinsic factor • Juvenile form – normal gastric acid secretion (in contrast to adult form) • Use of Schilling test has been supplanted by serologic testing for anti-parietal cell and anti-intrinsic factor antibodies • Associated autoimmune endocrinopathies	• Megaloblastic anemia with decreased serum B_{12} levels • Conventional: 200–835 pg/ml • IU: 148–616 pmol/l • More sensitive assay is serum levels of methylmalonic acid and homocysteine[§]	• Pernicious anemia: CNCbl 1000 mcg IM weekly × 4 weeks, then 1000 mcg PO, SL, or IM monthly • If neurologic symptoms or severe anemia: CNCbl 1000 mcg IM twice weekly × 2 weeks then weekly × 2 months then monthly[41]

*For women of reproductive age, 5000–10 000 IU/day × 4 weeks or 25 000 IU/week × 4 weeks unless severe keratomalacia.
†Medications that inhibit hepatic vitamin K epoxide reductase: warfarin, anticonvulsants, certain cephalosporins (containing side chains of N-methylthiotetrazole or methylthiadiazole), high-dose salicylates, and rifampin.
‡Following inflation of blood pressure cuff to a point between systolic and diastolic blood pressure for 5 minutes.
¶"Wet" beriberi derives its name from the edema that occurs secondary to cardiac failure, which can be high-output. In "dry" beriberi, neurologic manifestations predominate, e.g. peripheral neuropathy (sensory and motor), confusion, and nystagmus.
§Levels of both are increased early in vitamin B_{12} deficiency; in folate deficiency, homocysteine levels are elevated but methylmalonic acid levels are normal.

Table 51.2 Vitamin deficiencies in adults and children. HPLC, high performance liquid chromatography; IM, intramuscularly; INR, international normalized ratio; IV, intravenously; LC–MS/MS, liquid chromatography–tandem mass spectrometry; mos, months; PO, orally; SC, subcutaneously; SL, sublingual; TID, three times per day; yrs, years. Adapted in part from refs 5–10.

VITAMINS – SOURCES, FUNCTIONS AND RECOMMENDED PROPHYLACTIC DOSES				
Vitamin	**Natural sources**	**Functions**	**Underlying etiologies/risk factors**	**Recommended daily intake (RDA in bold and *AI in italics*)**
A (retinol)	• Dietary pro-vitamin A (e.g. beta-carotene) from plant sources: leafy green vegetables, sweet potatoes, carrots • Dietary preformed vitamin A (e.g. retinol) from animal sources: liver, milk, animal fats	• Normal vision • Embryogenic development • Physical growth • Immune function • Keratinocyte proliferation and differentiation • If deficiency, squamous metaplasia of sebaceous and eccrine glands	• Minimal, if any, animal fats in diet • Poverty • Alcohol use disorder • Anorexia nervosa • Fad diets • Fat malabsorption (e.g. gastric bypass, pancreatic insufficiency, inflammatory bowel disease, liver disease, cystic fibrosis)	• Measured in mcg of retinol activity equivalents (RAE)/day* • Infants & children: 0–12 mos: *400–500 mcg* 1–8 yrs: **300–400 mcg** 9–13 yrs: **600 mcg** • ≥14 yrs: **700–900 mcg** • Pregnant women: **750–770 mcg** • Lactating women: **1200–1300 mcg**
D **D_2:** ergocalciferol **D_3:** cholecalciferol	• Estimates of sources – 90% from UVB irradiation of the skin; 10% from food • Plant sources (D_2; e.g. spinach, mushrooms exposed to UVR) • Animal sources (e.g. cod liver oil, fatty fish such as salmon, herring, mackerel or tuna, fortified milk or yogurt)	• Induces antimicrobial peptide gene expression in keratinocytes, monocytes, NK cells, T cells, B cells, & neutrophils[17] • Induces cathelicidins via the vitamin D receptor • Helps absorption of ~85% of calcium and 40% of phosphorus via the gut • Decreases proliferation of malignant cells & induces terminal differentiation[17]	• Risk factors include: breastfed infants, individuals with highly pigmented skin or limited sun exposure, advanced age, BMI >30 (fat sequesters vitamin D), living at extreme degrees of latitude[17] • Generalized disorders of cornification • Impaired absorption (e.g. gastrointestinal disease, gastric bypass, medications including phenytoin, corticosteroids, and stimulant laxatives) • Organoid nevi	• Institute of Medicine recommendations: 0–12 mos: 400 IU 1–70 yrs: 600 IU >71 yrs: 800 IU • Many countries and institutions have their own recommendations regarding the appropriate dose of oral vitamin D per day
E (tocopherol)	• Ubiquitous in foods, so deficiency is rare	• Possible role in cellular homeostasis • Antioxidant • Interferes with vitamin K-dependent coagulation via unknown mechanism	• Long-term fat malabsorption (chronic cholestasis, small bowel resection, pancreatic insufficiency [absorption requires biliary and pancreatic secretions])[41] • Genetic disorders (e.g. *TTPA* [alpha tocopherol transfer protein] pathogenic variants)	• Infants & children: 0–12 mos: *4–5 mcg* 1–8 yrs: **6–7 mcg** 9–13 yrs: **11 mcg** • ≥14 yrs: **15 mcg** • Pregnant women: **15 mcg** • Lactating women: **19 mcg**
K **K_1:** phytonadione (source = diet) **K_2:** menaquinone (source = gut bacteria)	• K_1: green leafy vegetables & meat • K_2: fermented foods & grass-fed animals • Diet: ~50% • Bacteria within large bowel: ~50%	• K_1: hepatic synthesis of coagulation factors II, VII, IX & X and proteins C & S • K_2: regulates mineral localization (e.g. calcium)[49]	• Broad-spectrum antibiotics (reduce intestinal bacteria) • Malabsorption syndromes • Low-birthweight infants (inadequate intake, non-colonized colon, low hepatic stores, maternal medications†) • Liver diseases, biliary atresia, cystic fibrosis • Medications: cholestyramine, colestipol, colesevelam, orlistat, vitamin E, and inhibitors of vitamin K epoxide reductase† • Total parenteral nutrition (TPN)	• Infants & children: 0–12 mos: *2–2.5 mcg* 1–8 yrs: *30–55 mcg* 9–13 yrs: *60 mcg* 14–18 yrs: *75 mcg* • ≥19 yrs: *90–120 mcg* • Pregnant & lactating women: *75–90 mcg*
C (ascorbic acid)	• Fresh fruits & vegetables	• Collagen formation • Cofactor for several enzymes, e.g. lysyl hydroxylase • Antioxidant • Iron absorption • Folate metabolism (folic acid to active form folinic acid)	• Alcohol and substance use disorders • Fad diets • Deficient intake for as few as 3 months can lead to scurvy[47] • Increased requirements in the setting of febrile illnesses, malabsorption, iron deficiency, hemodialysis	• Infants & children: 0–12 mos: *40–50 mg* 1–8 yrs: **15–25 mg** 9–13 yrs: **45 mg** 14–18 yrs: **65–75 mg** • ≥19 yrs: **75–90 mg** • Pregnant women: **80–85 mg** • Lactating women: **115–120 mg**
B_1 (thiamine; thiamin)	• Yeast, cereals, liver, meat (pork), eggs, brown rice, vegetables including legumes	• Role in pyruvate metabolism (a source of energy generation) • Cofactor in metabolism of carbohydrates, lipids, branched-chain amino acids[41]	• Starvation, alcohol use disorder • Polished rice diet • Hyperemesis gravidarum • B_1-deficient diet (IV hyperalimentation or TPN) followed by high-carbohydrate diet exacerbates symptoms[41,‡] • Hemodialysis, leukemia, rapidly growing carcinoma • Urinary loss due to diuretics	• Infants & children: 0–12 mos: *0.2–0.3 mg* 1–8 yrs: **0.5–0.6 mg** 9–13 yrs: **0.9 mg** 14–18 yrs: **1–1.2 mg** • ≥19 yrs: **1.1–1.2 mg** • Pregnant & lactating women: **1.4 mg**

Table 51.3 Vitamins – sources, functions and recommended prophylactic doses.

VITAMINS – SOURCES, FUNCTIONS AND RECOMMENDED PROPHYLACTIC DOSES				
Vitamin	**Natural sources**	**Functions**	**Underlying etiologies/risk factors**	**Recommended daily intake (RDA in bold and *AI in italics*)**
B_2 (riboflavin; lactoflavin)	• Milk, cheese, eggs, fortified bread and cereals, yeast, lean meat, green vegetables	• Intracellular oxidation–reduction reactions	• Achlorhydria & GI malabsorption • Alcohol use disorder • Hypothyroidism • Neonatal phototherapy for hyperbilirubinemia • Low milk intake (e.g. due to lactose intolerance) • Medications: chlorpromazine, probenecid, tricyclic antidepressants • Exacerbated by respiratory infections	• Infants & children: 0–12 mos: *0.3–0.4 mg* 1–8 yrs: **0.5–0.6 mg** 9–13 yrs: **0.9 mg** 14–18 yrs: **1–1.3 mg** • ≥19 yrs: **1.1–1.3 mg** • Pregnant women: **1.4 mg** • Lactating women: **1.6 mg**
B_3 (niacin; nicotinic acid)	• Liver, lean pork, salmon, poultry, red meat, beans, milk, eggs • Humans are able to synthesize niacin from tryptophan (an essential amino acid)	• Vital oxidation–reduction reactions • Biosynthesis of epidermal lipids, e.g. ceramides	• Malnutrition • Intestinal malabsorption • Alcohol use disorder • Diet limited to tryptophan-deficient corn (maize)[¶] • Carcinoid syndrome[¶] • Hartnup disease[¶] • HIV infection, including those receiving isoniazid preventive therapy • Medications: isoniazid > 6-mercaptopurine, azathioprine, 5-fluorouracil and drugs that inhibit conversion from tryptophan (e.g. phenobarbital, ethionamide) • Deficiency of micronutrients (e.g. iron, riboflavin, pyridoxine) required for conversion from tryptophan	• Infants & children: 0–12 mos: *2–4 mg* 1–8 yrs: **6–8 mg** 9–13 yrs: **12 mg** • ≥14 yrs: **14–16 mg** • Pregnant women: **18 mg** • Lactating women: **17 mg**
B_5 (pantothenic acid)	• Synthesized in gut by bacterial flora	• Component of coenzyme A which plays major role in metabolism	• Protein–energy malnutrition	• Infants & children: 0–12 mos: *1.7–1.8 mg* 1–8 yrs: *2–3 mg* 9–13 yrs: *4 mg* • ≥14 yrs: *5 mg* • Pregnant women: *6 mg* • Lactating women: *7 mg*
B_6 (pyridoxine, pyridoxamine, pyridoxal)	• Widely distributed in nature • Pyridoxine in plant food • Pyridoxal and pyridoxamine in animal products • All forms convert to the active form pyridoxal phosphate	• Cofactor for multiple enzymes involved in amino acid metabolism and conversion of linoleic acid to arachidonic acid • Ceramide synthesis • Gluconeogenesis & heme biosynthesis[41]	• Other vitamin or trace element deficiencies (metabolism of B_6 is dependent on riboflavin, niacin, & zinc) • Medications: isoniazid, anticonvulsants, penicillamine, hydralazine, oral contraceptives, corticosteroids[41] • Inflammatory bowel disease, uremia, & cirrhosis	• Infants & children: 0–12 mos: *0.1–0.3 mg* 1–8 yrs: **0.5–0.6 mg** 9–13 yrs: **1 mg** 14–18 yrs: **1.2–1.3 mg** • ≥19 yrs: **1.3–1.7 mg** • Pregnant women: **1.9 mg** • Lactating women: **2 mg**
B_7 (biotin)	• Liver is best source • Other meats, egg yolks, yeast, soybeans, tomatoes • Probably synthesized in gut by bacterial flora	• Essential cofactor for several carboxylases involved in cellular metabolism, e.g. of fatty acids • Plays role in gluconeogenesis[47]	• Inborn error of metabolism (e.g. deficiencies of biotinidase or holocarboxylase synthetase) • Inadequate diet • Excessive raw egg white consumption[§] • Chronic anticonvulsant therapy • Pregnancy • Chronic alcohol use disorder	• Infants & children: 0–12 mos: *5–6 mcg* 1–8 yrs: *8–12 mcg* 9–13 yrs: *20 mcg* 14–18 yrs: *25 mcg* • ≥19 yrs: *25–30 mcg* • Pregnant women: *30 mcg* • Lactating women: *35 mcg*
B_9 (folate; folic acid)	• Liver, green leaves, meat, milk, yeast, fortified foods • Easily destroyed with cooking[47] • Body stores are limited, so anemia can result after 4–5 months of deficient intake	• DNA synthesis	• Deficient diets • *MTHFR* pathogenic variants • Alcohol use disorder • Intestinal malabsorption (inflammatory bowel disease, gastric bypass) • Medications (which interfere with folate metabolism): methotrexate, sulfasalazine, pyrimethamine, phenytoin, trimethoprim	• Measured in mcg of dietary folate equivalents (DFEs)[‖] • Infants & children: 0–12 mos: *65–80 mcg* 1–8 yrs: **150–200 mcg** 9–13 yrs: **300 mcg** • ≥14 yrs: **400 mcg** • Pregnant women: **600 mcg** • Lactating women: **500 mcg**

Table 51.3 Vitamins – sources, functions and recommended prophylactic doses.

Continued

VITAMINS – SOURCES, FUNCTIONS AND RECOMMENDED PROPHYLACTIC DOSES				
Vitamin	**Natural sources**	**Functions**	**Underlying etiologies/risk factors**	**Recommended daily intake (RDA in bold and *AI in italics*)**
B_{12} (cyanocobalamin)	• Fish, shellfish, meat, dairy products, fortified foods • Body stores are large, so development of deficiency requires 3–6 years of a deficient state	• DNA synthesis	• Strict vegetarianism/veganism • Decrease in gastric intrinsic factor (pernicious anemia) • Atrophic gastritis • Intestinal malabsorption (e.g. celiac disease, inflammatory bowel disease) • Gastrectomy, surgical resection of terminal ileum • Overgrowth of intestinal bacteria • Medications: metformin, H2 receptor antagonists, proton pump inhibitors, nitrous oxide • Alcohol use disorder	• Infants & children: 0–12 mos: 0.4–0.5 mcg 1–8 yrs: **0.9–1.2 mcg** 9–13 yrs: **1.8 mcg** • ≥14 yrs: **2.4 mcg** • Pregnant women: **2.6 mcg** • Lactating women: **2.8 mcg**

*1 IU retinol = 0.3 mcg RAE; 1 IU β-carotene (dietary supplements) = 0.15 mcg RAE; 1 IU β-carotene (food) = 0.05 mcg RAE; 1 IU α-carotene or β-cryptoxanthin = 0.025 mcg RAE.
†Medications which inhibit vitamin K epoxide reductase in the liver: warfarin, anticonvulsants, certain cephalosporins (containing side chains of N-methylthiotetrazole or methylthiadiazole), high-dose salicylates, isoniazid, and rifampin.
‡Pyruvate and lactate, which interfere with carbohydrate metabolism, accumulate in a B_1-deficient state. A high-carbohydrate diet accentuates the pre-existing vitamin-deficient state, often precipitating a Wernicke or Korsakoff syndrome.
¶Tryptophan (an essential fatty acid) is a precursor of niacin. Tryptophan is deficient in maize, and millet interferes with tryptophan metabolism as it is high in leucine. In carcinoid syndrome, tryptophan is preferentially converted to serotonin instead of niacin, and in Hartnup disease, niacin deficiency is due to decreased intestinal absorption of tryptophan.
§Excessive consumption of raw egg whites (>20 eggs/day) leads to high levels of the protein avidin, which binds to biotin, rendering it biologically unavailable. Avidin is deactivated by cooking, while biotin remains intact.
‖1 mcg DFE = 1 mcg food folate; 1 mcg DFE = 0.6 mcg folic acid from fortified foods or dietary supplements consumed with foods; 1 mcg DFE = 0.5 mcg from dietary supplements taken on an empty stomach.

Table 51.3 Vitamins – sources, functions and recommended prophylactic doses. Recommended Dietary Allowance (RDA) is the average daily dietary intake that is sufficient for 97%–98% of healthy individuals in a group while the Adequate Intake (AI) is an approximation when an RDA cannot be determined. mos, months; MTHFR, methylenetetrahydrofolate reductase; UVB, ultraviolet B radiation; UVR, ultraviolet irradiation; yrs, years. Adapted in part from refs 5–7,9,10.

Fig. 51.7 Phrynoderma of vitamin A deficiency. Multiple clusters of follicular papules with central keratotic plugs. Histologically, keratinous plugs within follicles, hyperkeratosis, and atrophy of sebaceous glands are seen. It must be differentiated from pityriasis rubra pilaris and keratosis pilaris.

as therapeutic interventions in dermatology includes topical vitamin D analogues for psoriasis[17] (see Ch. 129), oral nicotinamide for autoimmune blistering diseases and non-melanoma skin cancer prevention, oral or topical retinoids to treat acne and disorders of cornification (see Ch. 126), and topical vitamin C to try to reverse photodamage[18].

Tables 51.2 and 51.3 review the major fat- and water-soluble vitamins, including their functions and recommended daily dosages, as well as the risk factors for vitamin deficiencies and associated signs and symptoms[5–7,9,10].

Vitamin excess

Excessive ingestion of vitamins most commonly occurs in individuals seeking potential (and often unproven) "anti-aging" or antineoplastic effects. High doses of fat-soluble vitamins may lead to harmful side effects, including hepatic toxicity, nephrolithiasis, and peripheral neuropathy (Table 51.4)[5–7]. They may also have unanticipated effects at high doses in certain populations. For example, in the β-Carotene and Retinol Efficacy Trial (CARET), a large cancer prevention trial, patients at high risk for lung cancer were given supplements containing β-carotene and vitamin A. Not only did these supplements fail to prevent lung cancer, they were actually associated with increased rates

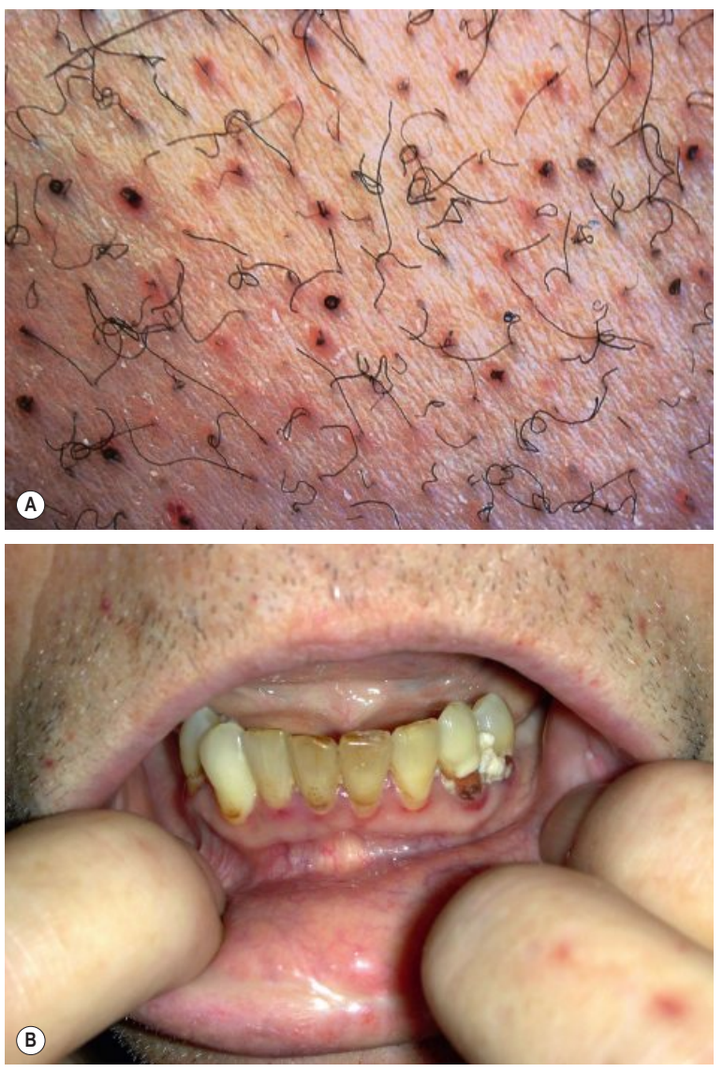

Fig. 51.8 Scurvy. A Corkscrew hairs and perifollicular hemorrhage on the lower extremities. **B** Gingivitis and gingival erosions. *B, Courtesy Jeffrey P. Callen, MD.*

Fig. 51.9 Pellagra. A Hyperpigmentation and desquamation of the dorsal aspects of the hands and forearms. The shellac-like scale is seen best on the forearms. **B** Striking hypopigmentation with peripheral desquamation of the sun-exposed area of the chest in a man from sub-Saharan Africa. *B, Courtesy Rosemarie Moser, MD.*

of lung cancer[19]. The reported association of oral isotretinoin and topical tretinoin with increased mortality in smokers remains controversial[20].

Toxicity due to high doses of water-soluble vitamins (i.e. B vitamins, vitamin C) is rarely seen, as these compounds are rapidly excreted via the urine. While not an excess issue, ingestion of biotin to possibly improve hair and nails can interfere with biotin-streptavidin-based cardiac troponin, β-hCG, parathyroid, and thyroid (TSH, T3, T4) immunoassays.

Vitamin D

Vitamin D plays a role in the absorption of calcium and phosphorus, helping to maintain normal serum levels of these minerals (Fig. 51.11). Vitamin D also functions as an antiproliferation and prodifferentiation hormone, but its exact role is not known[10]. Although a possible association of vitamin D deficiency with cutaneous disorders such as alopecia areata, atopic dermatitis, and psoriasis has been suggested, to date there are no known cutaneous signs of vitamin D deficiency. In addition, the Institute of Medicine (IOM) found no strong evidence to support a role for vitamin D supplementation for any medical condition other than bone health[21].

With the exception of individuals with sarcoidosis, the preferred method for assessing vitamin D status is measurement of total serum levels of 25-hydroxyvitamin D. While secondary hyperparathyroidism can influence the 1,25-dihydroxyvitamin D assay, this is not the case with the 25-hydroxyvitamin D assay. In addition, 25-hydroxyvitamin D has a longer half-life (2 weeks) and therefore is thought to better reflect body stores[18,22]. Currently, although a consensus is lacking, vitamin D *deficiency* is defined by most experts as a serum level of 25-hydroxyvitamin D that is <12 ng/ml (30 nmol/l), and vitamin D *insufficiency* as circulating levels of 12–20 ng/ml (30–50 nmol/l) (see Table 51.2).

Based upon these levels, it is estimated that one billion people worldwide have either deficient or insufficient levels of vitamin D[23]. Depending upon the study, ~50%–60% of nursing home residents, the elderly, and hospitalized patients in the US are deficient in vitamin D[23]. Decreased levels of 25-hydroxyvitamin D (<20 ng/ml) were also observed in half of US Hispanic or Black adolescents and White preadolescent girls[22]. In addition, ~50% of Black and 55% of White infants have vitamin D deficiency, while over 90% of infants in Iran, Turkey, and India have vitamin D deficiency.

While the IOM recommends a daily intake of vitamin D_3 of 400 IU/day (0–12 months of age), 600 IU/day (1–70 years of age), and 800 IU/day (>70 years of age), some experts have advocated 1000 IU/day for children or adolescents and 1500–2000 IU/day for adults (unless there are contraindications)[18,21,23]. All of these doses are below the age-dependent, tolerable, upper daily limits of 1000–4000 IU for infants and children (up to 18 years old) and 4000 IU for adults[23], with the range reflecting the current lack of a consensus regarding the upper daily limit. Vitamin D_3 (cholecalciferol; animal diet source) is viewed as nutritionally superior to vitamin D_2 (ergocalciferol; plant source) and therefore is regarded as the preferred form for supplementation and for fortifying foods. Although it is difficult to obtain enough vitamin D_3 from dietary sources alone, patients should be made aware of vitamin D-rich foods such as fatty fish, beef liver, cheese, egg yolks, mushrooms that have been exposed to ultraviolet light, and fortified foods[23].

An endogenous source of vitamin D production also exists, initiated with the conversion of 7-dehydrocholesterol to provitamin D_3 when skin is exposed to ultraviolet B radiation (see Fig. 51.11). It is thought that typically over 90% of vitamin D is produced via UVB exposure; however, the skin's ability to synthesize vitamin D diminishes with age and it is reduced in individuals with darker skin phototypes. The balance between sun protection (to prevent photodamage and cutaneous malignancies) and the risk of vitamin D deficiency has become a matter of debate. As effects of vitamin D, beyond calcium homeostasis and bone mineralization, have become increasingly recognized, the debate has intensified. For example, immunomodulatory effects via the innate immune system have been reported, as has an association between vitamin D deficiency and an increased risk of several internal malignancies[21]. While there are studies that refute the latter as well as no direct evidence linking sunscreen use with vitamin D deficiency[20,24], it is prudent to recommend that patients who are limiting sun exposure and/or have risk factors for the development of vitamin D deficiency ingest the daily recommended amount of vitamin D_3 (see Tables 51.2 & 51.3).

Trace elements

Trace elements and minerals constitute ~3% of body weight at birth and 4% in adults. Based upon animal studies, 15 trace elements have been identified as essential for health: *iron*, *zinc*, *copper*, *chromium*, *selenium*, *iodine*, *fluoride*, *manganese*, *molybdenum*, *cobalt*, nickel, tin, silicon, vanadium, and arsenic (in very small doses). There is compelling evidence that the first 10 (in italics) are essential nutrients in humans. They serve multiple cellular functions including as cofactors for enzymes and as prosthetic groups in metalloproteins. An example of the latter is the complexing of iron and protoporphyrin IX via ferrochelatase to form heme[4]. Deficiency syndromes related to essential trace elements, other than iron, zinc, copper, iodine or cobalt, were not recognized until more recently. Explanations include the exceedingly small requirements for these trace elements, their ubiquitous nature in foodstuffs[4], and the lack of routine laboratory assays. Only trace elements of dermatologic importance will be discussed in this chapter.

Zinc

Zinc is one of the most important trace elements in humans, playing a critical role in the function of more than 200 zinc-dependent metalloenzymes that regulate lipid, protein, and nucleic acid synthesis and degradation. Zinc can be found in human breast milk, animal-based foods, shellfish, legumes, and green leafy vegetables. There is evidence to suggest that zinc plays a role in enhancing wound healing as well as immune function[25] and this may explain the poor wound healing and

VITAMIN EXCESS IN ADULTS AND CHILDREN				
		Clinical manifestations		
Vitamin	**Mechanism of toxicity**	**Cutaneous**	**Systemic**	**Comments**
A	• Chronic intake of >25 000 IU vitamin A per day • Ingestion of polar bear liver • Coadministration with other retinoids	• Cheilitis • Xerosis with pruritus • Exfoliative dermatitis • Alopecia	• Painful swelling of the long bones in young children • Elevated hepatic enzymes • Skeletal hyperostosis • Calcification of extraspinal tendons and ligaments • Pseudotumor cerebri • Lethargy, anorexia	• Assessment by serum concentrations – unreliable • Similar side effects as oral retinoids (see Ch. 126) • Treatment – immediate discontinuation
Beta-carotene (natural provitamin of vitamin A)	• Carotenemia – high intake of carrots & yellow squash, including as baby food • Lycopenia – high intake of tomatoes, gac, papaya, pink guava, & other fruits • Inability to convert β-carotene to vitamin A (e.g. hypothyroidism, diabetes, anorexia nervosa)	• Yellow–orange discoloration (Fig. 51.10) due to deposition of carotenes/lycopenes in areas with: – the thickest layer of stratum corneum (palms & soles) – abundant sebaceous glands (nasolabial folds, forehead) • Carotenoderma usually appears when carotene levels are 3–4× normal	• None	• Skin discoloration slowly disappears after altering diet • Measurement of serum carotenoids (normal range: 0.4–1.5 mg/l) differentiates this disorder from jaundice, in which mucous membranes have a yellow color (most apparent in sclerae)
D	• >50 000 IU/day of oral supplementation	• None	• Nausea, vomiting • Poor appetite • Diarrhea, constipation • Weakness • Nephrolithiasis, nephrocalcinosis • Hypercalcemia, hypercalciuria, hyperphosphatemia	• NOT caused by excessive exposure to UVR (previtamin D_3 and vitamin D_3 inactivated by sustained exposure of skin to heat) • Tolerable upper limit for adults is 2000–4000 IU/day[6]
E	• High supplement doses	• Petechiae, ecchymoses	• May reduce platelet aggregation • Interferes with function of vitamin K	• Drug–drug interactions with warfarin (increased anticoagulant effect) and antiplatelet agents (enhanced effect) (see Ch. 133) • High doses of vitamin E (>400 IU/day) may reduce platelet aggregation
K	• None	• None	• None	• Side effects at sc injection sites: – early: erythematous plaque, often annular (see Ch. 21) – late: morpheaform plaque (Texier disease)
C	• Excessively high doses of oral supplements	• None	• GI upset • Osmotic diarrhea • Nephrolithiasis (oxalate renal calculi)	• Abrupt discontinuation of excessive vitamin C intake can also lead to scurvy
B_3 (niacin, nicotinic acid)	• Excessively high doses of oral supplements	• Flushing, pruritus, xerosis • Acanthosis nigricans	• Dyspepsia • Hepatic failure • Hyper- or hypoglycemia • Hyperuricemia • Hypothyroidism	
B_6	• Long-term oral doses of >200 mg/day	• Photosensitivity	• Loss of proprioception • Painful sensory neuropathy	
B_7 (biotin)				High levels of biotin may interfere with biotin-streptavidin-based cardiac troponin, β-hCG, parathyroid, and thyroid (TSH, T3, T4) immunoassays

Table 51.4 Vitamin excess in adults and children. GI, gastrointestinal; SC, subcutaneous; UVR, ultraviolet radiation. Adapted in part from refs 5–7.

increased susceptibility to cutaneous infections observed in patients with chronic zinc deficiency. Due to its antioxidant properties, zinc might protect the skin against UV-induced damage[26].

Patients with zinc deficiency can develop erythema, scale-crusts and erosions, especially periorally, acrally, and in the anogenital region (Fig. 51.12); occasionally, vesicles or bullae are seen as well as psoriasiform plaques. Zinc deficiency may also lead to alopecia, paronychia, onychodystrophy, blepharitis, conjunctivitis, stomatitis, and angular cheilitis. Diarrhea, depression (apathy), and dermatitis (erosive) are sometimes considered the triad of zinc deficiency, but the complete triad is seen in only 20% of patients. Superimposed cutaneous infections with *Candida* spp. and staphylococci are very common. Patients are typically irritable and sleep poorly; children with chronic zinc deficiency may experience growth retardation and/or develop hypogonadism. If treatment is not initiated, death may ensue.

Zinc deficiency can be either acquired or inherited as an autosomal recessive disorder, known as acrodermatitis enteropathica (AE). The latter is due to mutations in the gene that encodes the transmembrane

Fig. 51.10 Carotenoderma. The patient's legs are noticeably orange when compared to the photographer's hand.

zinc transporter SLC39A4 which is expressed in the intestine and kidney. Clinical manifestations usually appear within 1 to 2 weeks after weaning from breast milk, or at 4 to 10 weeks of age if bottle-fed. Of note, transient neonatal zinc deficiency can develop in breastfed babies when breast milk contains low levels of zinc due to dysfunction of SLC30A2, the zinc transporter in the breast (in the mother). In addition, infants and children with cystic fibrosis can develop zinc deficiency (Fig. 51.13). This deficiency should be considered in children who have treatment-resistant seborrheic dermatitis or anogenital dermatitis.

There are several risk factors for developing acquired zinc deficiency, including alcohol use disorder, anorexia nervosa, diets high in mineral-binding phytate (Middle Eastern diets), and vegan diets. Of note, vegan diets can also lead to low levels of long-chain n-3 (omega-3) fatty acids, calcium, vitamin D, and vitamin B_{12}[27]. Intestinal malabsorption often results in multiple deficiencies, including zinc. In addition, zinc deficiency can be seen in association with pregnancy, HIV disease, chronic renal failure, sickle cell disease, and drugs (e.g. penicillamine). Especially when combined with other risk factors, drugs such as diuretics and antacids can result in zinc deficiency while quinolones and tetracyclines can reduce absorption of zinc supplements.

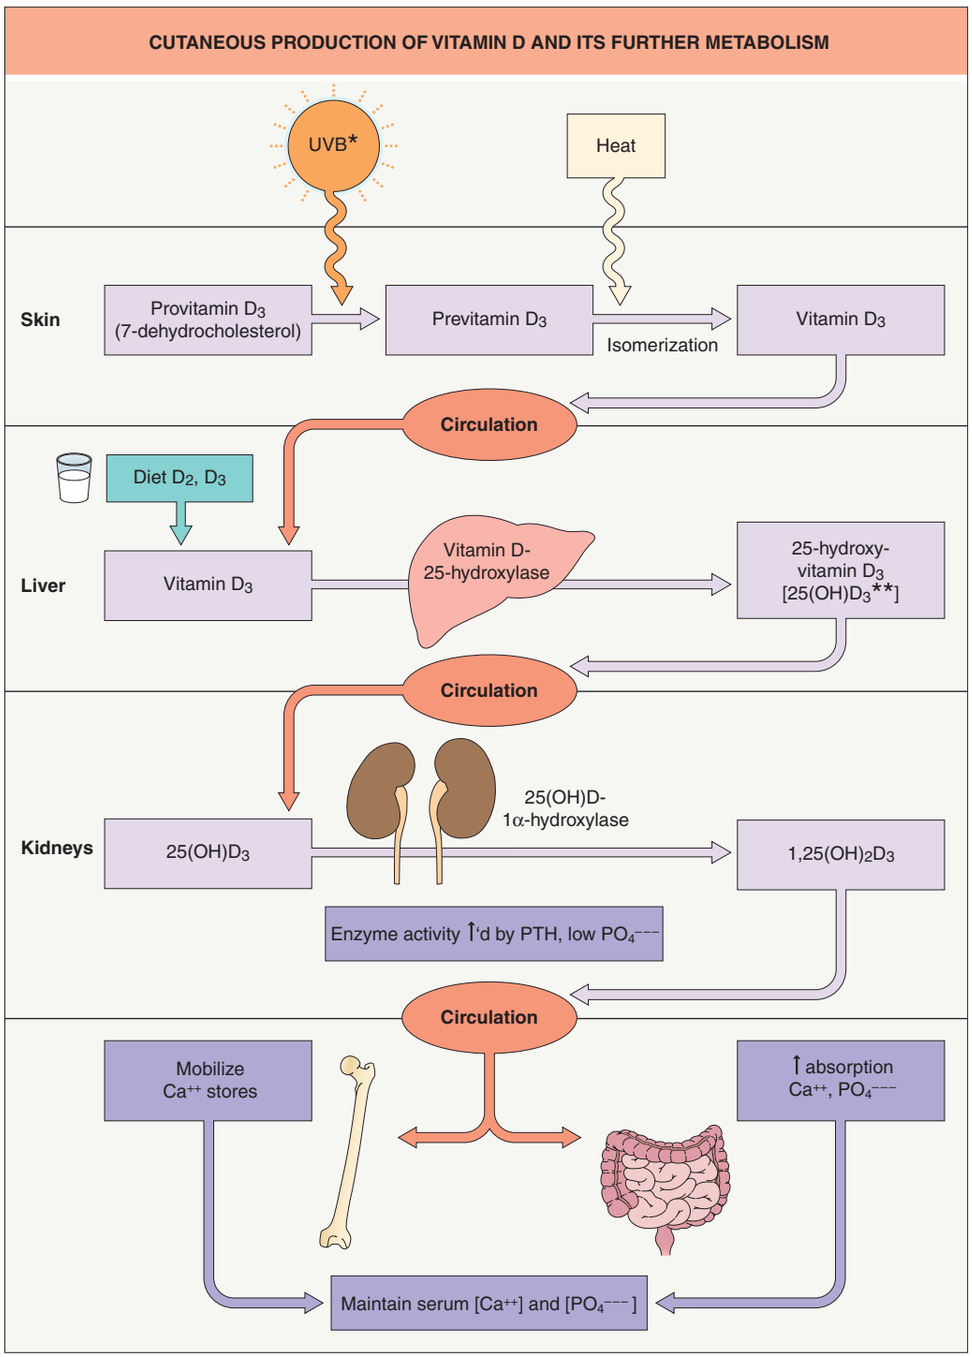

Fig. 51.11 Cutaneous production of vitamin D and its further metabolism. During exposure to ultraviolet B radiation, 7-dehydrocholesterol within the skin is converted to previtamin D_3, which is then immediately converted to vitamin D_3 in a heat-dependent process[22]. Of note, the heat from excessive sunlight exposure can degrade previtamin D_3 and vitamin D_3 into inactive photoproducts. Both forms of vitamin D (D_3 and D_2) are biologically inactive and they require activation in the liver and then the kidney. After binding to carrier proteins, vitamin D is transported to the liver, where it is enzymatically hydroxylated to 25-hydroxyvitamin D [25(OH)D], the major circulating form of vitamin D. 25-hydroxyvitamin D is then converted into its active form, 1,25-dihydroxyvitamin D [$1,25(OH)_2D$], within the kidney by the enzyme 1α-hydroxylase. Of interest, this final hydroxylation step can also occur in keratinocytes when the enzyme CYP27B1 is upregulated in response to wounding or by Toll-like receptor (TLR) activation from microbial-derived ligands[17]. Serum levels of phosphorus, calcium, and fibroblast growth factor 23 can either increase or decrease renal production of $1,25(OH)_2D$. $1,25(OH)_2D$ decreases its own synthesis via feedback inhibition and decreases the synthesis and secretion of parathyroid hormone by the parathyroid glands. $1,25(OH)_2D$ also enhances intestinal calcium absorption in the small intestine by interacting with the vitamin D receptor–retinoic acid X receptor complex (VDR-RXR) to enhance the expression of the epithelial calcium channel and calbindin-D 9 K, a calcium-binding protein. In addition, $1,25(OH)_2D$ is recognized by its receptor in osteoblasts, leading to a series of events that maintain calcium and phosphorus levels in the blood which in turn promotes mineralization of the skeleton. *Most effective wavelength = 300 ± 5 nm. **Measurement of this form most commonly done to assess vitamin D status.

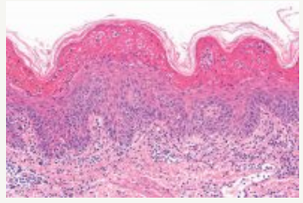
Fig. 51.12 Zinc deficiency – inherited and acquired forms. Erythema with erosions and scale-crust that is often shellac-like favors the perioral (**A**), acral (**B–D**), and anogenital (**E**, **F**) regions. Pustular paronychia can also be seen (**B**). The degree of involvement can vary from subtle to striking and may mimic other types of "nutritional dermatitis" (see Fig. 51.13), necrolytic migratory erythema, and more common disorders such as seborrheic dermatitis and psoriasis. The superficial erosions are a reflection of necrosis of the upper portion of the epidermis (**G**). *A–C,F, Courtesy Julie V. Schaffer, MD; G, Courtesy Lorenzo Cerrroni, MD.*

The histologic finding of epidermal necrosis (see below) plus low serum alkaline phosphatase (a zinc-dependent enzyme) and zinc levels suggest zinc deficiency; the normal reference range for zinc is 70–150 mcg/dl (10.7–22.9 mcmol/l). Reduced zinc levels can occasionally lag behind cutaneous manifestations. Some patients with necrolytic acral erythema also have reduced zinc levels (and improve with zinc supplementation) while others have associated hepatitis C viral infections[28]. Likewise, zinc levels can be normal or reduced in patients with necrolytic migratory erythema (NME) as well as EGFR inhibitor-induced NME-like eruptions.

Cutaneous and systemic manifestations respond dramatically to supplementation with elemental zinc (1–2 mg/kg/day in the acquired forms and 3 mg/kg/day for AE). There are several forms of commercially available zinc supplements including zinc sulfate, zinc gluconate, and zinc acetate, and they contain variable amounts of elemental zinc, e.g. 220 mg zinc sulfate tablets contain 50 mg of elemental zinc. Patients with persistent malabsorption syndromes and AE require lifelong zinc supplementation, along with regular serum zinc determinations. Of note, ingestion of excessive amounts of zinc can decrease copper absorption and lead to copper deficiency.

Copper

Copper is an essential trace element that is required for the function of a number of enzymes, e.g. tyrosinase, lysyl oxidase. In the bloodstream, 90% of copper is associated with ceruloplasmin, and the remainder is bound to other plasma proteins, primarily albumin. Acquired copper deficiency is rare, but it has been reported in infants receiving milk low in copper, in protein–energy malnutrition, and as a consequence of excessive zinc intake. Symptoms include anemia, neutropenia, and failure to thrive. Cutaneous findings are limited to rare reports of pigmentary dilution of the skin and hair.



Menkes disease, also known as kinky hair disease, is an X-linked recessive condition characterized by defective copper absorption with low copper levels in the blood, liver, and hair. Affected infants may appear normal and develop normally until 2 to 3 months of age, when they gradually manifest failure to thrive, lethargy, hypothermia, and hypotonia. In addition to seizures and developmental delay, patients may also have anemia and bony abnormalities (similar to those in scurvy). Arteriography demonstrates tortuosity and elongation of arteries, a reflection of immature elastin[29]. Decreased activity of several enzymes, including cytochrome C oxidase (in the brain), lysyl oxidase (in connective tissues and blood vessels), and ascorbic acid oxidase (in bones), may account for the associated clinical findings.

Pudgy cheeks, a cupid's bow of the upper lip, and horizontal eyebrows comprise the typical facies in Menkes disease[30]. However, a more obvious and characteristic finding is alopecia with abnormal hair shafts. There are 180° twists of the hair (pili torti), segmental shaft narrowing (monilethrix), and brush-like swellings of the hair shaft (trichorrhexis nodosa). Hairs are light in color, sparse (Fig. 51.14), fragile, and kinky. Patients may also have diffuse cutaneous pigmentary dilution due to decreased activity of tyrosinase, a copper-dependent enzyme. In addition, obligate female carriers may have patches of swirled

DIFFERENTIAL DIAGNOSIS OF "NUTRITIONAL DERMATITIS"

Evaluation of the infant/child* with periorificial and acral erythema and erosions

Zinc deficiency	Essential fatty acid deficiency	Biotin deficiency	Organic acidurias**	Cystic fibrosis
Acrodermatitis enteropathica (genetic form): • Onset days to weeks after birth if bottle-fed, or after weaning if breastfed **Acquired forms:** • Low zinc level in maternal milk (transient neonatal) • Parenteral nutrition without zinc supplementation • Gastrointestinal disorders/ surgeries or high-fiber diets (high phytate content) causing poor absorption • HIV infection	• Parenteral nutrition without lipid supplementation • Gastrointestinal disorders/ surgeries causing severe fat malabsorption • Nephrotic syndrome	**Biotinidase deficiency:** onset age 3 months to 2 years (juvenile form) **Holocarboxylase synthetase deficiency:** onset days to months after birth (neonatal form) **Acquired forms:** • Parenteral nutrition without biotin supplementation • Gastrointestinal disorders/ surgeries causing severe malabsorption • Excessive intake of raw egg whites • Chronic anticonvulsant therapy (e.g. phenytoin, carbamazepine, valproic acid)	**Propionic acidemia** (propionyl CoA carboxylase deficiency) **Methylmalonic acidemia** (methylmalonyl CoA mutase deficiency or lack of vitamin B_{12} activity) **Maple syrup urine disease** (branched-chain α-ketoacid dehydrogenase deficiency) **Citrullinemia** (argininosuccinic acid synthetase deficiency)	Onset typically at age 3–5 months (precedes respiratory symptoms)
Signs: • Stomatitis, glossitis • Alopecia • Secondary infections (e.g. candidiasis) • Photophobia • Diarrhea • Irritability • Failure to thrive	**Signs:** • Diffusely xerotic skin • Alopecia and lightly pigmented hair • Failure to thrive • Thrombocytopenia	**Signs:** • Alopecia • Blepharitis, conjunctivitis • Secondary infections (e.g. candidiasis) • Vomiting • Metabolic acidosis • Hypotonia, lethargy, seizures, developmental delay • Optic atrophy, hearing loss, ataxia (with biotinidase deficiency)	**Signs:** • Alopecia • Secondary infections (e.g. candidiasis) • Vomiting • Metabolic acidosis • Hypotonia, lethargy, developmental delay • Failure to thrive • Pancytopenia	**Signs:** • Eruption often involves the trunk • +/– Alopecia • No mucous membrane involvement • Diarrhea • Edema • Irritability • Failure to thrive • Palmoplantar aquagenic wrinkling
Laboratory: • Plasma zinc level • Serum alkaline phosphatase level (low) • +/– Zinc level of maternal milk • Genetic analysis	**Laboratory:** • Plasma linoleic, arachidonic and eicosatrienoic acid levels; triene (eicosatrienoic acid): tetraene (arachidonic acid) ratio > 0.4	**Laboratory:** • Plasma ammonia and lactate levels • Urine organic acid analysis • Biotinidase activity in serum • Holocarboxylase synthetase activity in skin fibroblasts or peripheral blood lymphocytes • Genetic analysis	**Laboratory:** • Plasma ammonia and glycine levels • Urine organic acid analysis • Plasma isoleucine level (if on low branched-chain amino acid diet)	**Laboratory:** • Serum albumin level • Plasma zinc level • Sweat test • Genetic analysis

* In older patients, the differential diagnosis includes necrolytic migratory erythema (as seen in glucagonoma syndrome) and necrolytic acral erythema (in association with hepatitis C infection); periorificial (oral and perineal) erythema and erosions can also be seen in niacin (pellagra) and riboflavin deficiencies, with a characteristic photodistributed eruption found in the former; severe infantile seborrheic dermatitis typically involves other intertriginous sites such as the neck as well as the diaper area, scalp, and face

** Cutaneous eruptions may be associated with adherence to a therapeutic diet low in branched-chain amino acids (e.g. isoleucine deficiency)

Fig. 51.13 Differential diagnosis of "nutritional dermatitis" (in addition to exogenous protein–energy malnutrition). *Courtesy Julie V. Schaffer, MD; Photomicrograph Courtesy Luis Requena, MD.*

hypopigmentation or pili torti along the lines of Blaschko, as a result of lyonization.

The clinical features, low serum levels of copper and ceruloplasmin, and microscopic hair shaft findings establish the diagnosis. Infants with Menkes disease have a poor prognosis, with a life expectancy of 3 to 5 years and progressive deterioration leading to death. Treatment with copper histidine is unsuccessful in the majority of patients, but those with mutations leading to reduced, but not absent, copper transport may be more likely to respond to early intervention. Mutations in *ATP7A*, which encodes a copper-transporting ATPase, lead to Menkes

Fig. 51.14 Menkes disease. This child has the characteristic pale skin and sparse kinky hair. *Courtesy Ramón Ruiz-Maldonado, MD.*

disease (as well as occipital horn syndrome; see Ch. 97); therefore, prenatal diagnosis is possible.

Copper toxicity can be acquired or inherited. The acquired form usually results from the ingestion of excessive amounts of copper (e.g. milk boiled in eroded copper pots) and this leads to gastrointestinal symptoms and, occasionally (in predisposed individuals), childhood cirrhosis. The inherited form is Wilson disease, an autosomal recessive disorder characterized by an accumulation of copper within internal organs, in particular the liver, cornea, and brain. Affected individuals have mutations in *ATP7B* which also encodes a copper-transporting P-type ATPase. Dysfunction of this protein leads to an impairment of both intrahepatic trafficking and biliary excretion of copper[30].

Because daily copper intake exceeds the body's requirements, an effective means of excreting excess copper is crucial. This is accomplished by ATP7B, which mediates both copper secretion into plasma (coupled with ceruloplasmin synthesis) and its excretion into bile. When ATP7B is dysfunctional, the presence of excess copper within tissues induces free-radical reactions and lipid peroxidation. Resultant hepatic damage leads to steatosis, inflammation, cirrhosis, and eventually liver failure[31].

The diagnosis of Wilson disease is established by the detection of low serum ceruloplasmin, increased urinary copper excretion, increased hepatic copper content, and/or genetic testing. The clinical hallmarks of Wilson disease are hepatomegaly, cirrhosis, Kayser–Fleischer corneal rings, and neurologic symptoms (dysarthria, dyspraxia, ataxia, and parkinsonian-like extrapyramidal signs).

The chelating agents penicillamine and trientine, which facilitate excretion of copper, are approved for the treatment of Wilson disease. Oral zinc acetate can be prescribed for pre-symptomatic patients or as maintenance therapy, as it blocks intestinal absorption via induction of copper-binding metallothionein within enterocytes, thereby preventing serosal transfer.

Selenium

Selenium, in the form of selenocysteine, is an essential component of several enzymes, including those involved in thyroid hormone metabolism and protection against oxidative damage (e.g. glutathione peroxidase). Deficiency of selenium typically results in a cardiomyopathy as well as muscle pain and weakness due to muscle degeneration; there may also be signs and symptoms of hypothyroidism. Cutaneous manifestations include hypopigmentation of the skin and hair (considered early signs), leukonychia, and xerosis, all of which respond to selenium replacement[32]. There was also a report of erythematous scaly papules and plaques involving the cheeks, hips, thighs, and popliteal fossae, along with erosions in the diaper area[33]. Elevated serum levels of creatine kinase and transaminases are often present in selenium deficiency as well.

Selenium deficiency has been reported in patients receiving total parenteral nutrition and in those who live in areas where the soil content of selenium is poor[34]. Low serum levels of selenium and glutathione peroxidase activity are indicative of selenium deficiency. The recommended replacement dosage in selenium-deficient patients is a maximum of 100–200 mcg/day, and the Recommended Dietary Allowance (RDA) is 55 mcg/day for adults and 15 mcg/day for infants.

Although controversial, over-supplementation can occur due to reported beneficial cardiovascular and anticancer effects of selenium[35]. If supplements are taken, they should not exceed 200 mcg/day. Excessive selenium ingestion (e.g. supplements, Brazil nuts, selenium-enriched green tea) can produce selenosis in humans, leading to a peripheral neuropathy, dermatitis, facial flushing, alopecia, discolored or brittle nails, nausea and vomiting as well as a garlic-like breath odor. The use of selenium sulfide shampoo in large areas of eroded or ulcerated skin may lead to excessive absorption, with loss of appetite and tremor.

Anorexia Nervosa and Bulimia (Nervosa)

Anorexia nervosa and bulimia nervosa are eating disorders characterized by starvation, excessive exercise, self-induced vomiting, and/or abuse of medications (e.g. laxatives, diuretics). Both can result in primary and secondary nutritional deficiencies. Anorexia nervosa is a persistent unwillingness or inability to maintain adequate body weight, whereas patients with bulimia typically binge-eat then purge or fast. These disorders occur most commonly in adolescent girls and young adult women, but can affect both sexes and all age groups. Skin disorders, either real or perceived, are common in these patients and women in particular report a greater dissatisfaction with the appearance of their skin when compared to a similar cohort[36].

The dietary changes and starvation associated with anorexia nervosa and bulimia can lead to telogen effluvium, lanugo-like hair, xerosis, generalized pruritus, carotenoderma (see Fig. 51.10), and hyperpigmentation. In addition, patients can develop acrocyanosis, perniosis, and livedo reticularis. Signs of specific nutritional deficiencies (e.g. pellagra, scurvy) may be present, as well as poor wound healing, seborrheic dermatitis, and edema[37]. Additional clues to the diagnosis include petechiae, interdigital intertrigo, paronychia, and particularly calluses or scars on the knuckles or dorsal surface of the hand (Russell's sign) due to repeated self-induced vomiting over prolonged periods of time (Fig. 51.15). Patients with bulimia may also have enlarged salivary glands and erosion of their tooth enamel. Psychiatric and nutritional support must be instituted as severe malnutrition is common.

Obesity

Obesity, whether acquired or inherited, is defined as a body mass index (BMI; measured in kg/m^2), that is >30; the latter has been found to correlate with high levels of the adipokine leptin[38]. Genetic disorders such as Prader–Willi, Bardet–Biedl, Alström, and Wilson–Turner syndromes have been associated with childhood-onset obesity. In addition, endocrine disorders such as Cushing disease, Cushing syndrome, and insulin resistance include obesity amongst their clinical manifestations.

Acquired obesity is at epidemic proportions in both adults and children in industrialized nations. Although paradoxical, it is a functional malnutrition due to the consumption of high-caloric foods that are low in nutrients. Obesity is a systemic disease, as evidenced by an increased incidence of hypertension, hyperglycemia and hyperlipidemia, components of the metabolic syndrome (see Table 53.5), as well as atherosclerotic cardiovascular disease and premature death. Cutaneous manifestations are nonspecific, but some of the more common findings, such as acanthosis nigricans, appear to be related to insulin resistance (see Fig. 51.15)[39].

Bariatric Surgery and Gastrointestinal Malabsorption

The increase in acquired obesity has led to an increase in the number and types of bariatric surgery performed. Due to subsequent alterations in gastrointestinal absorption, post-bariatric surgery patients are at risk for developing nutritional deficiencies. Two of the more commonly performed surgeries are laparoscopic adjustable gastric banding and the Roux-en-Y gastric bypass. Because the normal absorptive surface is left intact with the former, nutrient deficiencies in these patients are rare. On the other hand, the Roux-en-Y gastric bypass procedure reduces stomach size and, as a result, there are lower levels of intrinsic factor, gastrin, hydrochloric acid, and pepsinogen, which lead to a reduction in protein digestion. The Roux-en-Y procedure also decreases the physical grinding of food that typically helps to release vitamins and minerals. Abnormally low levels of micronutrients, such as iron, zinc, copper, and vitamins A, E, B_9 (folate), and B_{12}, may be seen in these patients, and long-term monitoring is required, as it may take months or years for signs and symptoms to appear[40,41].

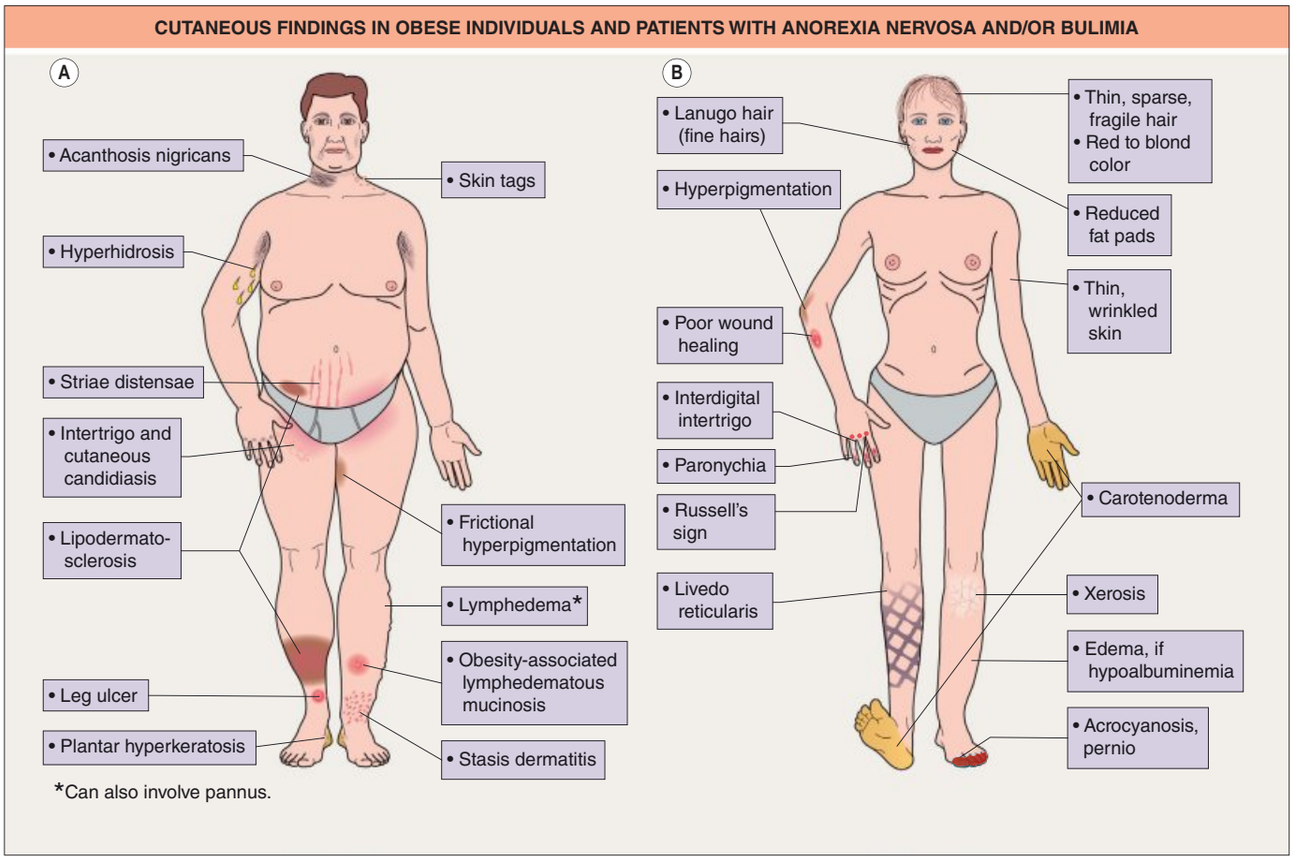


Fig. 51.15 Cutaneous findings in obese individuals (A) and patients with anorexia nervosa and/or bulimia (B). Russell's sign consists of calluses or scars on the knuckles or dorsal surface of the hand due to repeated self-induced vomiting over prolonged periods of time. See Fig. 51.2 for signs of nutritional deficiencies.

In disorders such as Crohn disease that are associated with gastrointestinal malabsorption, at least 50% of patients may have low plasma concentrations of vitamin C, copper, niacin, and zinc[42].

PATHOLOGY

Nutritional deficiencies generally occur in combination; therefore, the resultant pathologic changes are often very variable. Although nutritional diseases have been better studied biochemically than structurally, there are several helpful histologic clues, including necrosis of the upper one-third of the epidermis (see Fig. 51.12G). This distinctive reaction pattern has been reported in pellagra, acrodermatitis enteropathica, acquired zinc deficiency, and necrolytic migratory erythema. In the early stages, there is pallor and ballooning of the upper half of the epidermis. This stage is followed by the development of acanthosis, with confluent hyperkeratosis and degenerative features of the upper epidermal layers. In the late stages, the pallor of the upper epidermis is usually missing[43]. In protein–energy malnutrition, nonspecific histologic features are seen, such as epidermal atrophy and hyperkeratosis.

Hair is a superb model of growth and differentiation. In some patients, histologic study of the hair matrix and hair shaft may provide evidence of moderate to severe degrees of protein–energy malnutrition[44].

DIFFERENTIAL DIAGNOSIS

Nutritional dermatoses rarely result from the deficiency of a single nutrient, element, or vitamin as multiple deficiencies often coexist. A high index of suspicion is required in that clinical manifestations are often nonspecific and, in mild to moderate deficiencies, somewhat subtle. A few specific deficiencies do have characteristic mucocutaneous and systemic features that can be accurately recognized by the experienced clinician. Suspected deficiencies can usually be confirmed via laboratory analysis (see Table 51.2), and they readily respond to the administration of the deficient nutrient, element, and/or vitamin.

TREATMENT

The treatment of nutritional diseases must be individualized, taking into account the likelihood of multiple deficiencies of both macro- and micronutrients. The recommended treatment for specific nutritional diseases is reviewed in this chapter, but management frequently requires a multidisciplinary approach.

Graft-versus-Host Disease 52

Jennifer T. Huang and Edward W. Cowen

Key features

- Currently, over 35 000 allogeneic hematopoietic stem cell transplants (HSCTs) are performed worldwide each year
- An HLA-matched sibling donor is the ideal donor source
- Nowadays nearly all eligible patients can receive an allogeneic HSCT due to the increased use of alternative stem cell sources including matched unrelated donors, haploidentical donors, and umbilical cord blood
- Reduced intensity conditioning regimens allow older patients and those with comorbidities to receive allogeneic HSCTs
- Donor lymphocyte infusions as well as withdrawal of immunosuppression may impact the incidence, timing, and presentation of graft-versus-host disease (GVHD)
- Acute GVHD is a major complication of allogeneic HSCT; severe skin involvement, although uncommon, is associated with a high mortality rate
- Chronic cutaneous GVHD is a polymorphous condition with features that can resemble lichen planus, lichen sclerosus, morphea, and eosinophilic fasciitis
- Chronic cutaneous GVHD is difficult to treat and the aggressiveness of treatment must be balanced against the complications of chronic immunosuppression

INTRODUCTION

Graft-versus-host disease (GVHD) is a multi-organ disorder most commonly due to the transfer of foreign donor hematopoietic stem cells into a host recipient via an allogeneic hematopoietic stem cell transplant (HSCT). GVHD may also occur following transfusion of non-irradiated blood products (to immunocompromised hosts) or rarely in the setting of solid organ transplantation. Despite decades of experience with HSCT for a broadening array of disorders (Table 52.1), GVHD remains a significant cause of non-relapse-related morbidity and mortality.

HISTORY

The first successful allogeneic bone marrow transplant was performed in 1968. Subsequent advances in histocompatibility antigen testing increased safety, while establishment of bone marrow donor registries made HSCT accessible to thousands of patients each year who lacked a matched related donor. The introduction of alternative stem cell sources, including matched unrelated donors and especially haploidentical family donors, has led to a further increase in the number of transplants. In addition, when neither of these donor sources is available, umbilical cord stem cells represent a more universal option because a greater degree of mismatch is better tolerated. The evolution of reduced intensity conditioning regimens has permitted older patients and those with comorbidities to receive HSCTs. Post-transplant cyclophosphamide, initially introduced for haploidentical HSCTs, is increasingly being used for matched sibling and matched unrelated donor (MUD) HSCTs where it has significantly reduced the incidence and severity of acute and chronic GVHD.

EPIDEMIOLOGY

Currently, over 35 000 allogeneic HSCTs are performed worldwide each year. Although a variety of donor and recipient factors ultimately impact GVHD incidence (e.g. older age, T cell-replete graft), the most important predictor of GVHD remains HLA compatibility between donor and recipient. With traditional immunosuppression consisting of a calcineurin inhibitor plus either methotrexate or mycophenolate mofetil, ~40% of HLA-identical HSCT recipients and 60%–70% of HLA-mismatched HSCT recipients will develop GVHD. Of note, post-transplant cyclophosphamide (given on days +3 and +4) significantly reduces the incidence and severity of acute and chronic GVHD via enrichment of regulatory T cells. In addition, abatacept has recently been approved for prophylaxis against acute GVHD.

Because of ease of acquisition and more rapid engraftment, peripheral blood has surpassed bone marrow as the predominant source of stem cells. The one disadvantage is that peripheral blood has been associated with an increased risk of chronic GVHD (cGVHD)[1]. Cord blood stem cells are used primarily in children because of higher rates of non-engraftment in adults. The two major advantages of cord blood transplantation are: (1) decreased incidence of GVHD; and (2) nearly universal availability of donors for patients who lack matched related or unrelated donors.

Several other trends in HSCT are affecting the natural history of GVHD. Removal of donor T cells ("T cell depletion") prior to transplantation through *ex vivo* graft manipulation (e.g. cell separation), or *in vivo* treatment of the recipient (e.g. antithymocyte globulin, alemtuzumab), significantly decreases the risk of GVHD, but at the expense of increased infection rates. The advent of reduced intensity conditioning regimens has decreased conditioning-related toxicities (e.g. mucositis) and allowed for HSCT in older patients and those with comorbidities. While these regimens appear to decrease the risk of acute GVHD (aGVHD), they may also delay the appearance of "classic" aGVHD manifestations. The use of total body irradiation for conditioning (in place of or in conjunction with chemotherapy) may confer an increased risk for the later development of cGVHD[2]. Finally, donor lymphocyte infusions (DLI), administered to the recipient post-HSCT to augment the graft-versus-tumor effect or to attempt to reverse falling donor chimerism, can alter the traditional timing of both "acute" and "chronic" disease. For instance, DLI may induce classic aGVHD manifestations even when administered after the 100-day time period.

PRIMARY DISORDERS TREATED WITH ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION
• Leukemias (e.g. acute myelogenous, acute lymphoblastic > chronic myelogenous, chronic lymphocytic)
• Lymphomas (e.g. non-Hodgkin)
• Bone marrow failure (e.g. aplastic anemia, dyskeratosis congenita, Fanconi anemia)
• High-risk myelodysplasia
• Immunodeficiencies (e.g. severe combined immunodeficiency, Griscelli syndrome [type 2], Chédiak–Higashi syndrome, Wiskott–Aldrich syndrome, ataxia–telangiectasia syndrome, chronic granulomatous disease, DiGeorge syndrome, familial hemophagocytic lymphohistiocytosis, GATA2 deficiency, DOCK8 immunodeficiency syndrome)
• Other myeloproliferative disorders (e.g. myelofibrosis)
• Other hematologic disorders (e.g. plasma cell dyscrasias including myeloma, hypereosinophilic syndrome, paroxysmal nocturnal hemoglobinuria, sickle cell disease, thalassemia)
• Metabolic disorders (e.g. fucosidosis, Gaucher disease, mucopolysaccharidoses)
• Autoimmune diseases (e.g. ALPS, IPEX syndrome)
• Miscellaneous (e.g. congenital erythropoietic porphyria [Günther disease], histiocytoses, epidermolysis bullosa)

Table 52.1 Primary disorders treated with allogeneic hematopoietic stem cell transplantation. ALPS, autoimmune lymphoproliferative syndrome; IPEX, immune dysregulation, polyendocrinopathy, X-linked.

The skin is the most frequently affected organ in both aGVHD and cGVHD. Approximately 80% of patients who develop aGVHD have skin involvement at the time of diagnosis[3]. The incidence of skin involvement in patients with cGVHD ranges from 30%–40%[4]. In one institutional review of 270 consecutive patients following HLA-identical HSCT, only 7 (13%) of 53 patients with cGVHD manifested sclerotic features[5]. In contrast, in a cross-sectional cohort of 206 NIH cGVHD patients enriched for refractory disease, sclerotic features were detected in 109 (53%)[2].

PATHOGENESIS

The current model for aGVHD pathogenesis can be summarized in a three-step process. First, HSCT conditioning and consequent damage to host tissues leads to activation of *host* antigen-presenting cells (APCs). Second, *donor* T cells proliferate in response to contact with activated APCs. Finally, destruction of target tissues (skin, liver, gastrointestinal tract) occurs via cytotoxic T lymphocytes, natural killer cells, and soluble factors (TNF, IFN-γ, IL-1, nitric oxide)[6]. Recently, humanized mouse models have demonstrated that *donor* APC activation of *host* resident T cells can also elicit a graft-versus-host response. These two proposed mechanisms may not contradict, but rather complement, one another and suggests multiple pathways of disease pathogenesis.

A clear understanding of cGVHD is still lacking and available murine models recapitulate only select features of human disease (e.g. sclerotic skin involvement, autoantibodies). Alloreactive T cells are again thought to play a central role, but a number of other immune mediators have been increasingly implicated. Many cGVHD manifestations resemble autoimmune disease, suggesting a role for B cells in the disease process. Indeed, rituximab (anti-CD20 antibody) is a beneficial salvage therapy in some patients. B cells appear to prime T cells to minor histocompatibility antigens, and serum levels of *B* cell *a*ctivating *f*actor of the TNF *f*amily (BAFF), a marker of B cell activation, correlate with cGVHD. Multiple autoantibodies are often present in patients with cGVHD, including anti-nuclear, anti-dsDNA, and anti-smooth muscle antibodies, although, to date, they have not been shown to correlate with specific disease manifestations. Activating antibodies against the platelet-derived growth factor receptor (PDGFR) were observed in patients with cGVHD, suggesting that targeting this receptor and its profibrotic pathway with agents such as imatinib mesylate could improve cGVHD[7]. However, the functional significance of these antibodies remains uncertain[8].

HSCT recipients have also been shown to have a deficiency of regulatory T cells (Tregs) due to decreased thymic differentiation. Tregs are integral to the development and maintenance of self-tolerance, and impairment of Treg function is associated with autoimmunity. In mouse models of allogeneic HSCT, adoptive transfer of Tregs has been shown to ameliorate signs and symptoms of cGVHD[9]. A possible role for Th17 cells was suggested by elevated levels of IL-17 and -22 in tissue and plasma in patients and mouse models of cutaneous cGVHD[10,11] and IL-17 inhibitors have been investigated as treatment for cGVHD[12]. Of note, different mechanisms may underlie cGVHD based on duration and phenotype of disease[13].

CLINICAL FEATURES

Acute GVHD

Acute GVHD presents in the skin as a morbilliform exanthem (Fig. 52.1), with an initial predilection for acral areas (e.g. dorsal hands and feet, palms, soles, forearms, ears), as well as the upper trunk. Lesions most commonly appear 4–6 weeks following HSCT despite prophylactic immunosuppressive therapy. Pruritus is variable and a folliculocentric pattern may be observed. Patients may be thrombocytopenic, which can give the eruption a hemorrhagic appearance. The gastrointestinal tract (nausea, voluminous diarrhea, abdominal pain) and the liver (cholestasis > transaminitis) are the two other primary organ systems affected by aGVHD. Together with body surface area of skin involvement, these manifestations are used for staging and grading of disease severity (Table 52.2). Stage IV acute skin disease consists of generalized involvement with bullae formation which may lead to skin sloughing resembling toxic epidermal necrolysis and portends a very low likelihood of survival. Fortunately, this degree of severity is nowadays rarely seen.

Chronic GVHD

In contrast to aGVHD, cGVHD may manifest in nearly any organ system (Fig. 52.2). Skin and mucosal involvement are exceedingly common, but there is remarkable variability in both presentation and severity. Other common sites of involvement include the eyes (keratoconjunctivitis sicca, blepharitis, corneal erosions), salivary glands (sicca syndrome), and lungs (bronchiolitis obliterans); less commonly, the esophagus (strictures, webs), liver, and pancreas (exocrine insufficiency) are affected.

Fig. 52.1 Clinical spectrum of acute cutaneous graft-versus-host disease. A *Stage I* – discrete and coalescing small pink papules on the upper chest and neck of a woman 6 weeks following allogeneic bone marrow transplant. **B, C** *Stage II* – pink macules and papules on the dorsal aspect of the hands that are becoming confluent 4 weeks post allogeneic bone marrow transplant, and widespread pink–violet macules and papules on the abdomen in a liver transplant recipient. **D** *Stage III* – diffuse erythema with desquamation, but without bullae formation. **E** *Stage IV* – widespread bullae and epidermal necrosis in a patient who had received a donor lymphocyte infusion (DLI) following allogeneic bone marrow transplant; note the resemblance to toxic epidermal necrolysis. *C, Courtesy Julie V. Schaffer, MD.*

CLINICAL STAGING OF ACUTE GRAFT-VERSUS-HOST DISEASE (aGVHD)			
Stage	**Skin**	**Liver**	**Gut**
1	Erythematous macules and papules, <25% BSA	Bilirubin 2 to <3 mg/dl	Diarrhea, 500–1000 ml/day, or persistent nausea
2	Erythematous macules and papules, 25%–50% BSA	Bilirubin 3–6 mg/dl	Diarrhea, 1000–1500 ml/day
3	Erythematous macules and papules (>50% BSA) to generalized erythroderma	Bilirubin 6–15 mg/dl	Diarrhea, >1500 ml/day
4	Generalized erythroderma with bulla formation	Bilirubin >15 mg/dl	Severe abdominal pain with or without ileus

Table 52.2 Clinical staging of acute graft-versus-host disease (aGVHD). Grade I aGVHD represents stage 1 or 2 cutaneous aGVHD while grade II aGVHD represents stage 3 cutaneous aGVHD; neither grade I nor II have significant liver or gut involvement. Grades III and IV aGVHD require internal involvement. BSA, body surface area.

DIAGNOSTIC MUCOCUTANEOUS MANIFESTATIONS OF CHRONIC GRAFT-VERSUS-HOST DISEASE
Skin
Lichen planus-like (Fig. 52.3A)
Lichen sclerosus-like (Fig. 52.3B)
Morphea-like (Fig. 52.3C,D)
Scleroderma-like (Fig. 52.3F)
Fasciitis (Fig. 52.4)
Poikiloderma
Oral mucosa
Keratotic plaques
Lichen planus-like (Fig. 52.6B)
Restriction of oral opening from sclerosis
Genital mucosa
Lichen planus-like (Fig. 52.6A)
Vaginal scarring and/or stenosis

Table 52.3 Diagnostic mucocutaneous manifestations of chronic graft-versus-host disease (based on NIH Consensus Criteria[14]). For involvement of other organs, see Fig. 52.2.

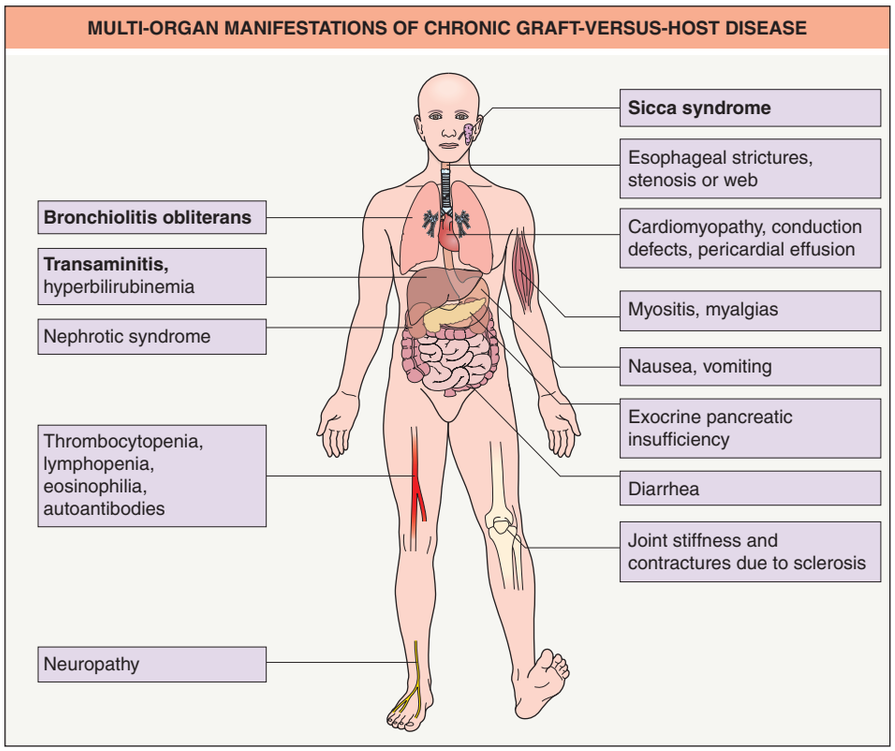

Fig. 52.2 Protean multi-organ manifestations of chronic graft-versus-host disease. The most common manifestations are in **bold**.

In the past, differentiation of aGVHD and cGVHD was linked to time of onset following HSCT (≤ or >100 days); however, this is a somewhat arbitrary distinction and newer HSCT regimens have altered the onset of classic aGVHD and cGVHD manifestations. As a result, acute features may first present after day 100 (delayed acute GVHD). In addition, features of aGVHD can be seen in patients who also meet the diagnostic criteria for cGVHD and is referred to as overlap cGVHD. The NIH Consensus Project proposed a classification of cGVHD using organ-specific criteria[14]. "Diagnostic" criteria, i.e. those skin manifestations sufficient to make a clinical diagnosis of cGVHD, are provided in Table 52.3. "Distinctive" cGVHD criteria (e.g. papulosquamous lesions, vitiligo, alopecia) require exclusion of other possible etiologies.

The most characteristic manifestation of epidermal cGVHD involvement is reticulate pink to violaceous papules and plaques with overlying scale, which in some patients resembles lichen planus (LP; Fig. 52.3A). Lesions often initially involve the dorsal aspects of the hands and feet, the forearms and trunk, but they can become widespread. In the past, the term "lichenoid" was used as a broad term which encompassed this presentation as well as all other non-sclerotic cGVHD skin eruptions. In light of the greater appreciation for the breadth of clinical presentations of cutaneous cGVHD and to utilize more precise diagnostic terminology, the term "lichenoid" should be reserved for histologic description rather than as designation of a GVHD phenotype. In addition to LP-like lesions, psoriasiform plaques, keratosis pilaris-like follicular erythema, a subacute cutaneous LE-like eruption, or poikiloderma may develop (Table 52.4). Epidermal cGVHD involvement often leaves a remarkable patterned hyperpigmentation which is often reticulated and resolves very slowly over several months.

Similar to the use of "lichenoid", the single designation "sclerodermoid" cGVHD is inadequate to describe the spectrum of sclerotic skin and subcutaneous tissue presentations. Sclerotic involvement includes superficial lichen sclerosus-like plaques, localized or widespread morphea-like involvement, and subcutaneous rippling of the skin with joint contractures resembling eosinophilic fasciitis[15]. Lichen sclerosus-like involvement commonly presents as shiny, wrinkled, gray–white plaques on the upper back (Fig. 52.3B); there may be associated follicular plugging. Morphea-like (morpheaform) areas of sclerosis may occur anywhere on the body, but frequently localize to sites of previous

Fig. 52.3 Clinical spectrum of chronic cutaneous graft-versus-host disease. A Lichen planus-like: thin pink–violet papules and plaques with scale, admixed with postinflammatory hyperpigmentation. **B** Lichen sclerosus-like: multiple gray–white thin plaques with obvious wrinkling are present on the mid back. **C, D** Morphea-like: shiny, hyperpigmented, sclerotic plaques extending from the breasts to the lateral torso and in the girdle area; the latter is a common site of involvement for this form of cGVHD. **E** Morphea-like: sclerotic hyperpigmented plaque on the upper arm, with shiny bound-down skin of the forearm and dorsal hand; note the joint contractures. **F** Scleroderma-like: the skin is shiny and bound-down with dyspigmentation, hair loss, multiple erosions and ulceration; angiomatous nodules and marked reduction in range of motion of the ankles are also present.

ADDITIONAL CUTANEOUS MANIFESTATIONS OF CHRONIC GRAFT-VERSUS-HOST DISEASE (cGVHD)
Skin lesions
• Psoriasiform, eczematous/dyshidrotic, SCLE-like, pityriasis rosea-like • Eczema craquelé, ichthyosis-like, keratosis pilaris-like follicular erythema • Hypo- or hyperpigmentation, vitiligo (Fig. 52.5A) • Angiomatous nodules (Fig. 52.3F) • Calcinosis cutis
Hair
• New-onset alopecia (patchy > diffuse; scarring or non-scarring; Fig. 52.5B), alopecia areata • Premature graying
Nails
• Ridging, thinning, splitting, brittleness, onycholysis, dorsal pterygium, anonychia (Fig. 52.5C)
Oral mucosa
• Gingivitis, mucositis, pseudomembranes, ulcers (Fig. 52.6B) • Xerostomia*, mucosal atrophy, mucocele
Genital mucosa
• Fissures, erosions, ulcers, balanitis, phimosis (Fig. 52.6C)
*For xerostomia treatment regimen, see Table 45.5.

Table 52.4 Additional cutaneous manifestations of chronic graft-versus-host disease (cGVHD). These clinical findings are considered non-diagnostic, i.e. insufficient to establish a diagnosis of chronic GVHD without further testing or evidence of other organ system involvement. SCLE, subacute cutaneous lupus erythematosus.

Fig. 52.4 Eosinophilic fasciitis-like presentation of chronic cutaneous graft-versus-host disease. A rippled appearance and irregular nodular texture to the skin is indicative of involvement of subcutaneous tissues. Especially in the earlier, edematous phase, the presence of hypereosinophilia may be a clue to the diagnosis.

skin injury (e.g. port placement sites) as well as areas of friction (e.g. the waistband) (Fig. 52.3C–E). In young children, the diaper area can be the initial area of involvement. In contrast to systemic sclerosis, cGVHD is rarely associated with sclerodactyly, pinched facies, or Raynaud phenomenon[15]. Deep-seated fibrosis of the subcutaneous tissue and fascia may present with insidious loss of joint range-of-motion or as nonspecific myalgias and cramping. Subtle rippling of the overlying skin may be present with a firm, nodular texture noted with deep palpation (Fig. 52.4). Linear depressions within sites of fascial involvement (groove sign) demarcate the path of vascular structures or fascial bundles. Longstanding fibrosis may result in skin ulceration, particularly of the legs and frictional surfaces, and the proliferation of benign angiomatous nodules[16] (Fig. 52.3F).

Vitiligo can develop within skin affected by cGVHD as well as uninvolved skin. It occurs in 1%–2% of patients who have had an HSCT and ~5% of patients with cGVHD[17,18]. The presence of vitiligo should alert the clinician to examine for additional evidence of cGVHD (Fig. 52.5A,B).

Mucosal surfaces are frequently affected by cGVHD (Fig. 52.6). Oral involvement resembles LP with lacy white plaques on the non-attached mucosa, ulceration, and gingivitis. Cheilitis is also a common manifestation (see Figs. 72.15 & 72.16F) and the development of mucoceles is an additional clinical finding. Genital involvement, ranging from

Fig. 52.5 Additional cutaneous findings in chronic graft-versus-host disease. **A** Vitiligo with patches of amelanosis; note the nail dystrophy. **B** Scarring alopecia and vitiligo in the setting of extensive sclerotic cGVHD. **C** Nail thinning, splitting, and dorsal pterygium formation.

erythema and fissuring to labial resorption and fusion, can occur in as many as 50% of female patients[19]. Symptoms of burning, pruritus, and dyspareunia are common. Scarring of the vagina may lead to shortening and narrowing of the vaginal canal and risk of hematocolpos in menstruating women. Male genital involvement is less common, but includes balanoposthitis and lichen planus-like lesions, and phimosis may develop in some patients.

Nail changes in cGVHD range from thin, brittle nails with distal splitting to dorsal pterygium and anonychia (Fig. 52.5C). In children, nail dystrophy, particularly dorsal pyterygium, has been associated with pulmonary cGVHD[20]. Additional cutaneous findings include facial milia, alopecia areata, angiomatous nodules, scarring alopecia, and calcinosis cutis. The latter three entities are seen in patients with sclerotic disease and calcinosis cutis may contribute to decreased range of motion[21].

PATHOLOGY

Histologically, aGVHD is characterized by widespread keratinocyte necrosis, basal layer hydropic degeneration, and a band-like lymphohistiocytic infiltrate in the upper dermis (Fig. 52.7). However, skin biopsies obtained shortly after disease onset may display more subtle findings, e.g. only focal vacuolar change of basal keratinocytes, and histologic features of aGVHD may be limited to the hair follicle. In addition, these histologic features overlap with those of viral exanthems and drug eruptions, making a definitive diagnosis difficult to render in some patients. With increasing severity of aGVHD, basilar vacuoles can fuse to form clefts and microvesicles and even complete separation of epidermis from dermis.

The histology of cGVHD reflects the variable skin manifestations of the condition[22]. cGVHD with epidermal involvement may resemble aGVHD, but with a more robust lichenoid infiltrate and additional features of epidermal orthohyperkeratosis, hypergranulosis, and variable (usually mild) acanthosis. The sclerotic subtypes of cGVHD may have concurrent epidermal features or may only demonstrate sclerosis of the dermis (Fig. 52.8), subcutaneous tissue, and/or fascia. Thickening of subcutaneous fat septae indicates a deep-seated sclerosis and magnetic resonance imaging may be helpful to identify fascial involvement (Fig. 52.9).

DIFFERENTIAL DIAGNOSIS

The primary differential diagnosis of aGVHD is morbilliform drug eruption, viral exanthem, and engraftment syndrome (Table 52.5). If there is prominent acral involvement, particularly involvement of the palms and soles, toxic erythema of chemotherapy should be considered, especially if there is flexural involvement and in men, scrotal burning and erythema. The possibility of a viral exanthem is more likely in children and is favored if conjunctivitis, rhinorrhea, or cough are present. Engraftment syndrome often presents with fever and fluid overload, including pulmonary edema, at the time of neutrophil engraftment (see Table 52.5).

Because of its clinical variability, the differential diagnosis of cGVHD is much broader, and includes lichenoid drug eruptions, autoimmune connective tissue diseases (lupus, dermatomyositis, morphea, systemic sclerosis), and papulosquamous disorders. Reports of transient acantholytic dermatosis[23] and voriconazole-associated photosensitivity[24] misdiagnosed as cGVHD emphasize the value of biopsy confirmation when non-diagnostic clinical features are encountered.

TREATMENT

Acute GVHD

Limited cutaneous aGVHD (without other organ involvement) may initially be managed with topical corticosteroids while patients with more extensive skin involvement or internal manifestations require systemic treatment. First-line therapy consists of adding oral prednisone or IV methylprednisolone (0.5–1 mg/kg twice daily) to ongoing prophylactic GVHD therapy (usually a systemic calcineurin inhibitor plus either methotrexate or mycophenolate mofetil). This treatment approach results in disease control in ~50% of patients. Recently, the JAK inhibitor ruxolitinib was FDA-approved for steroid-refractory aGVHD and represents the preferred second-line therapy[25]. Increasingly it is being used as a steroid-sparing agent earlier after the diagnosis of aGVHD. Third-line therapies include other immunomodulatory agents such as TNF antagonists, but they are associated with an increased risk of infections. Unfortunately, until the recent introduction of ruxolitinib, patients who did not respond well to corticosteroid therapy were at high risk of mortality.

Fig. 52.6 Orogenital involvement in chronic cutaneous graft-versus-host disease. A, B Lichen planus-like: flat-topped violet papules on the penis and several ulcers on the tongue with a lacy white pattern on the upper vermilion lip and the distal dorsal tongue. **C** Severe erosive disease of the vulva, with nearly total resorption of the labia minora and agglutination of the lips of the clitoral hood. The vulvar introitus is also markedly narrowed. *B, Courtesy Jean L. Bolognia, MD.*

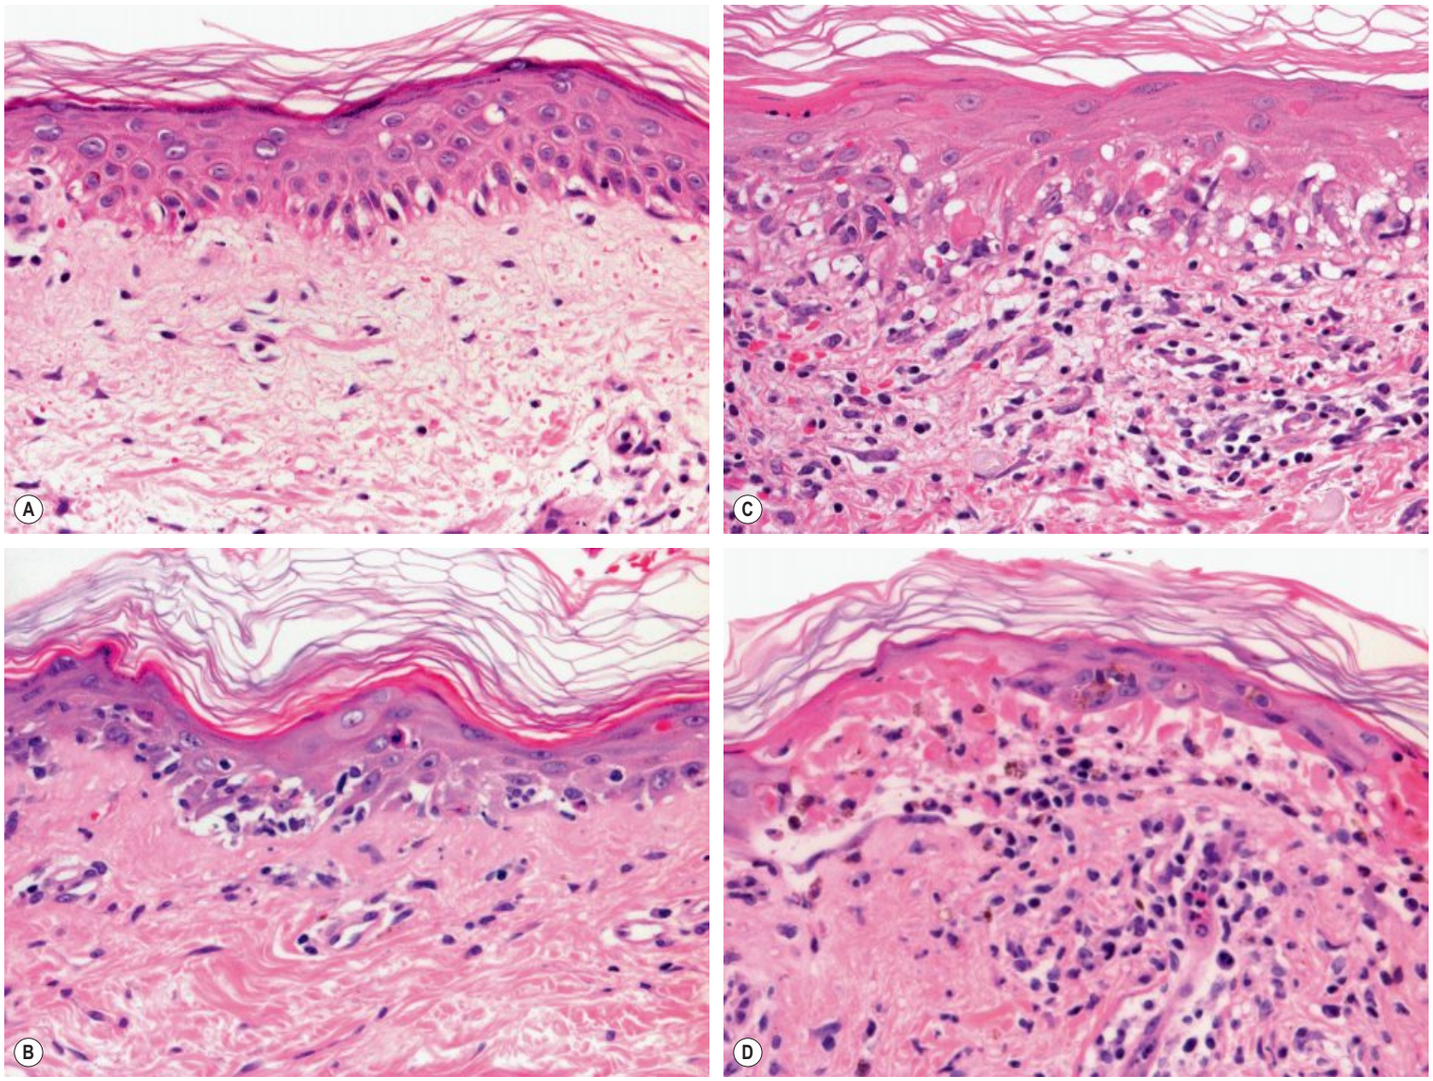

Fig. 52.7 Acute cutaneous graft-versus-host disease – histopathologic grades. A Grade I: focal vacuolar changes of the basal layer of the epidermis and sparse lymphocytic infiltrate. **B** Grade II: necrosis of keratinocytes and more obvious vacuolar degeneration of the basal layer. **C** Grade III: apoptosis of keratinocytes and blurring of the dermal–epidermal junction due to marked vacuolar degeneration and a lichenoid infiltrate of lymphocytes. **D** Grade IV: full-thickness necrosis of the epidermis with separation of the epidermis from the dermis. Of note, grade I changes are rather nonspecific and are also seen with autoimmune disorders showing the histopathologic pattern of an interface dermatitis (e.g. lupus erythematosus). *Courtesy Lorenzo Cerroni, MD.*

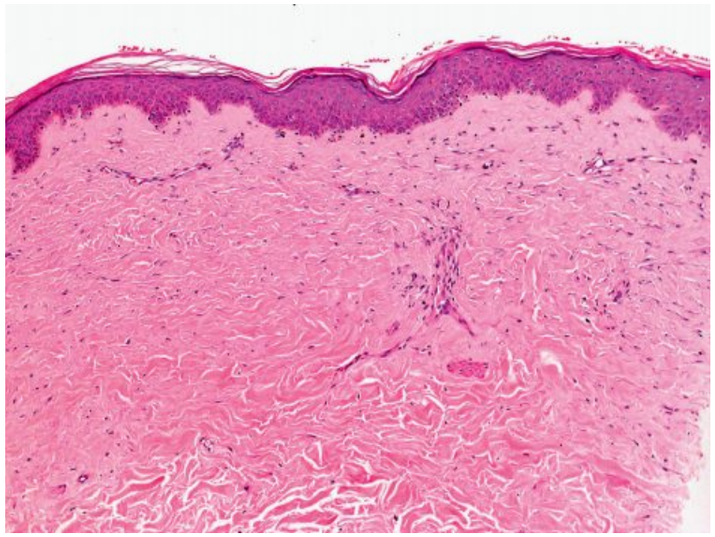

Fig. 52.8 Chronic cutaneous graft-versus-host disease (morphea-like) – histologic features. There is sclerosis of the dermis with thickening of collagen bundles. These same histologic features can be seen in morphea and systemic sclerosis (scleroderma). Pigmentary incontinence, with a few melanophages within the papillary dermis can also be seen in this form of chronic GVHD. *Courtesy Lorenzo Cerroni, MD.*

CLINICAL FEATURES OF ENGRAFTMENT SYNDROME VERSUS ACUTE GRAFT-VERSUS-HOST DISEASE (GVHD)

Clinical feature	Engraftment syndrome	Acute GVHD
Type of transplant	Autologous or allogeneic	Allogeneic
Exanthem	Yes	Yes
Pruritus	Variable	Variable
Fever	Yes	Uncommon
Peripheral eosinophilia	Variable	Variable
Diarrhea	No	Yes
Transaminitis/cholestasis	Uncommon	Yes
Pulmonary edema	Yes	No
Weight gain	Yes	No
Renal insufficiency	Variable	No
Encephalopathy	Uncommon	No
Rapid response to corticosteroids	Yes	Variable to yes
Timing post-transplant	~10–12 days (coinciding with myeloid recovery)	Peak incidence at 30–40 days

Table 52.5 Clinical features of engraftment syndrome versus acute graft-versus-host disease (GVHD).

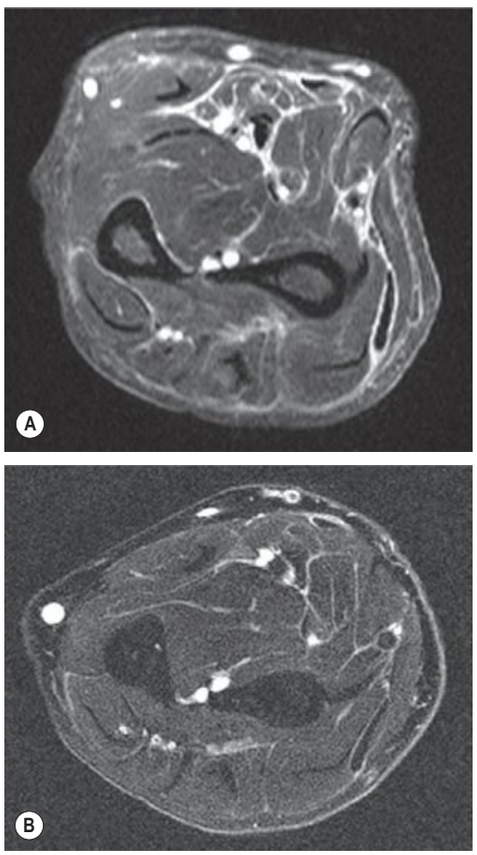

Fig. 52.9 Magnetic resonance imaging of the eosinophilic fasciitis-like presentation of chronic cutaneous graft-versus-host disease. A Prior to treatment (systemic corticosteroids), with a lace-like white pattern representing edema of the fascia. **B** After treatment, with marked diminution of edema. The round white circles represent blood vessels. *Courtesy Dennis Cooper, MD.*

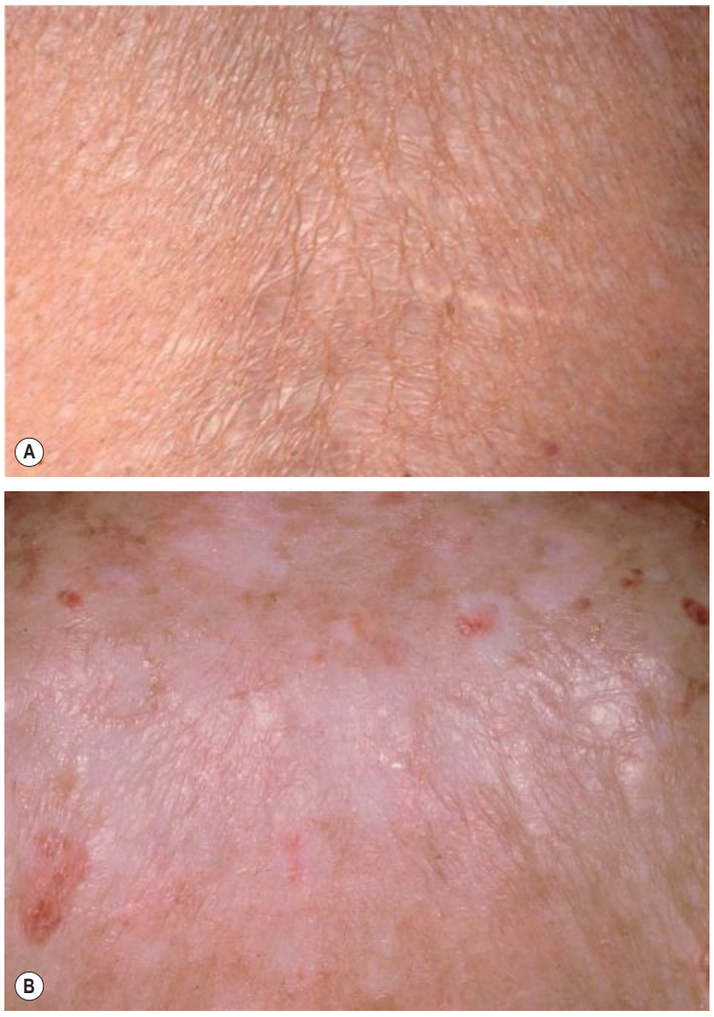
Chronic GVHD

Chronic GVHD continues to be a major therapeutic challenge, but the consistent observation that post-transplant cyclophosphamide has reduced its incidence without an increase in relapse or opportunistic infections is encouraging. With respect to cutaneous cGVHD, skin-directed therapies can play an important adjunctive role. For an LP-like eruption or pruritus, medium- to high-potency topical corticosteroids and topical calcineurin inhibitors (pimecrolimus, tacrolimus) are effective. Of note, use of topical tacrolimus under occlusion may lead to toxic drug levels in patients on concurrent systemic tacrolimus[26]. Various forms of phototherapy have shown some benefit in small series, however controlled trial data are needed. The potential for increased skin cutaneous malignancies in the setting of concurrent immunosuppressive therapy or prophylactic voriconazole must also be weighed against the benefit of UV therapy.

As with aGVHD, first-line systemic therapy of cGVHD is systemic corticosteroids, but while the dose is less (maximum dose of prednisone is 1 mg/kg/day), the duration of treatment is often prolonged. This extended corticosteroid therapy is a major cause of non-relapse morbidity and mortality, especially from opportunistic infections. Approximately 50% of cGVHD patients will not respond adequately to corticosteroid therapy, and better treatment for this group remains a critical unmet need. Ibrutinib[27] is FDA-approved for steroid-refractory cGVHD, but since the approval of ruxolitinib[28] for the same indication, the use of ibrutinib has declined. For patients who have failed ≥2 lines of therapy, belumosudil, a well-tolerated oral inhibitor of rho-associated coil kinase 2 (ROCK2), has recently been FDA-approved given a response rate of >70%. There are also ongoing trials of the use of axatilimab, an anti-CSF-1R antibody, for cGVHD[28a]. Other options include extracorporeal photophoresis[29], sirolimus, imatinib mesylate[30], and rituxumab[31].

Patients with mucocutaneous cGVHD should undergo ocular, oral, and genital examinations. Site-specific therapies, including scleral contact lenses, oral rinses (e.g. dexamethasone elixir), and vaginal dilators can prove very helpful. Referral to physical therapy is strongly recommended in patients with sclerotic involvement to improve any decreased joint range-of-motion.

Long term, the importance of sun protection should be emphasized, as patients are typically prescribed one or more photosensitizing agents, including trimethoprim–sulfamethoxazole, levofloxacin, and voriconazole. In addition, the latter drug can increase the risk of developing cutaneous malignancies. Patients, especially those with significant photodamage and/or a previous history of cutaneous carcinomas, should be educated regarding skin cancer risk in the setting of immunosuppression, and they should receive regular surveillance for skin cancer. Ideally, patients with chronic mucocutaneous GVHD should be managed in a coordinated multidisciplinary manner by specialists in ophthalmology, gynecology, oral medicine, physiatry, and dermatology in order to optimize care.



Additional figures and tables on Risk factors associated with the development of graft-versus-host disease, and Comparison of clinical and laboratory features of sclerotic-type chronic GVHD and systemic sclerosis, available in our eBook (see inside front cover for access code).

RISK FACTORS ASSOCIATED WITH THE DEVELOPMENT OF GRAFT-VERSUS-HOST DISEASE
Donor
HLA incompatibility with recipient Unrelated to recipient Female (especially multiparous) with male recipient
Recipient
Age (older-aged > middle-aged > pediatric)
Stem cell source
Peripheral blood > bone marrow > cord blood T cell-replete graft
Other
Myeloablative conditioning regimen*
*Associated with higher rate of acute GVHD compared with non-myeloablative HSCT, but does not affect incidence of chronic GVHD.

eTable 52.1 Risk factors associated with the development of graft-versus-host disease (GVHD). HSCT, hematopoietic stem cell transplant.

COMPARISON OF CLINICAL AND LABORATORY FEATURES OF SCLEROTIC-TYPE CHRONIC GVHD (cGVHD) AND SYSTEMIC SCLEROSIS		
	Sclerotic-type cGVHD	**Systemic sclerosis**
Autoantibodies	Variable, nonspecific	Yes, associated with specific clinical subtypes
Cardiac involvement	Rare	Yes, conduction system abnormalities
GI dysmotility/ strictures	Yes	Yes
Pulmonary hypertension	No	Yes
Pulmonary fibrosis	Yes*	Yes
Renal disease	Rare, nephrotic syndrome	Yes, scleroderma renal crises (in diffuse subtype)
Raynaud disease	Rare	Yes
Sclerodactyly	Rare	Yes
Skin manifestations		
Fibrosis	Dermis, subcutaneous tissue, and/or fascia	Dermis
Natural history	Patchy involvement, variable course	Symmetric, acral to proximal progression
Facial involvement	Rare, usually patchy involvement	Common, diffuse skin tightening (scleroderma facies)
*In setting of bronchiolitis obliterans.		

eTable 52.2 Comparison of clinical and laboratory features of sclerotic-type chronic GVHD (cGVHD) and systemic sclerosis.

PATIENT HANDOUT – GENERAL DERMATOLOGIC RECOMMENDATIONS FOR PATIENTS WITH CUTANEOUS GRAFT-VERSUS-HOST DISEASE (GVHD)
Dry skin and pruritus
Use soapless, fragrance-free cleansers
Apply emollients frequently, in particular ointments and thicker creams
Avoid tight-fitting or abrasive clothing; wear cool, breathable fabrics
Avoid antihistamines if there is dryness of the eyes or mouth (sicca syndrome)
Nail dystrophy
Keep nails trimmed or filed to prevent breakage and pain
A clear nail lacquer can be used as a nail hardener
Signs of skin sclerosis (hardening)
Early signs of skin sclerosis (hardening) include darkening or tightening of the skin at the waistband or bra line, rippling or dimpling of the skin, and decreased joint range-of-motion
Skin ulcers
Areas of skin breakdown serve as potential sites where bacteria can enter the body; these areas should be kept clean and covered
Recommendations regarding sun exposure and skin cancer
The risk of skin cancer is increased in patients with GVHD, especially those who are chronically immunosuppressed and/or receive phototherapy (e.g. UVB, PUVA)
Exposure to sunlight can trigger a flare of GVHD or photodrug eruption
Several frequently prescribed medications can increase sun sensitivity; they include trimethoprim–sulfamethoxazole (Septra®, Bactrim®) and voriconazole (Vfend®)
If possible, avoid outdoor activities during peak hours of UVR (10 am–4 pm)
Apply broad-spectrum sunblock on sun-exposed sites on a regular basis
Use a broad-brimmed hat and protective clothing; consider using a laundry additive that increases the UV protective factor of clothing (e.g. SunGuard™)
Perform skin self-examination on a regular basis

eTable 52.3 Patient handout – general dermatologic recommendations for patients with cutaneous graft-versus-host disease (GVHD).

Dermatologic Manifestations in Patients with Systemic Disease

Other Systemic Diseases with Cutaneous Manifestations 848

Key features

- Because of the frequency of skin involvement in systemic diseases, cutaneous manifestations often prove helpful in establishing the correct diagnosis
- Skin signs of systemic disease can be specific, e.g. cutaneous lupus erythematosus, cutaneous sarcoidosis, in part because of associated histologic features, while others are best described as suggestive, e.g. pyoderma gangrenosum, acquired ichthyosis
- Cutaneous disease can serve as the initial manifestation of a systemic disorder, including an internal malignancy

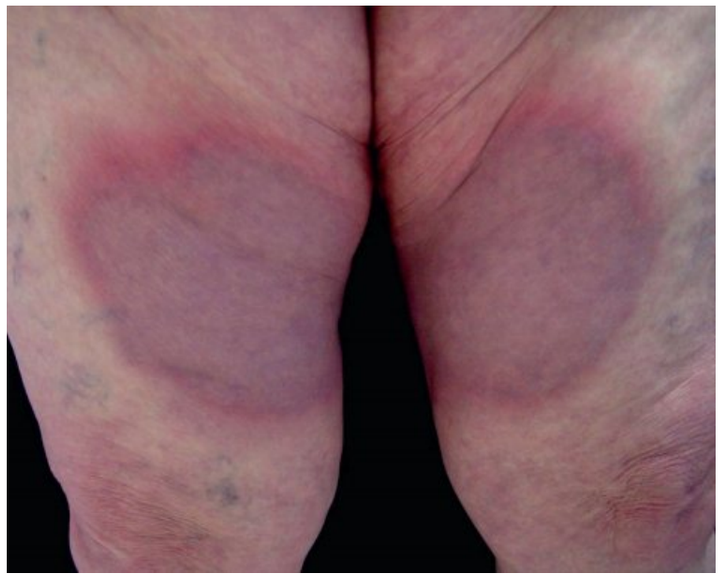

Fig. 53.1 Interstitial granulomatous dermatitis (IGD) – annular variant. This clinical presentation with annular plaques on the medial thighs is often seen in the setting of rheumatoid arthritis. Of note, IGD has also been implicated as a side effect of medications, including TNF inhibitors, HMG-CoA reductase inhibitors ("statins"), and calcium channel blockers.

Skin disease is often associated with internal manifestations[1], e.g. psoriatic arthritis, and there are many cutaneous disorders that are traditionally associated with systemic disease. For example, rheumatologic disorders frequently have skin manifestations, as do infectious diseases and endocrinopathies. When one examines many of the disorders that are discussed elsewhere in this text, it becomes clear that isolated dermatologic disease is relatively uncommon. A detailed review of all dermatologic signs of internal disease is beyond the scope of this chapter. Rather, representative disorders are discussed individually, while the remainder are reviewed via tables that contain information relevant to dermatologists. Disorders are grouped on the basis of affected organ systems.

CUTANEOUS RHEUMATOLOGY

The spectrum of disorders traditionally considered to be cutaneous rheumatology[2] includes: lupus erythematosus (Ch. 41); dermatomyositis (Ch. 42); systemic sclerosis (Ch. 43); Sjögren syndrome (see below and Ch. 45); vasculitides (Ch. 24); and miscellaneous disorders. Miscellaneous disorders usually include: rheumatoid arthritis (Ch. 45), reactive arthritis (formerly Reiter disease) (Ch. 8), psoriatic arthritis (Ch. 8), neutrophilic dermatoses including Behçet disease (Ch. 25), Kawasaki disease (Ch. 81), relapsing polychondritis (Ch. 45), and several of the autoinflammatory disorders (see Table 45.7).

Cutaneous conditions reported in patients with rheumatoid arthritis are summarized in Table 53.1 (Figs. 53.1–53.5)[3,4]. Dermatologists should be particularly careful in this group of patients to couple laboratory evaluation with a comprehensive cutaneous examination, including all mucosal surfaces, nails, nail folds, and hair. Clinical criteria are published for the diagnosis of many of these rheumatologic disorders; dermatologists should be familiar with the criteria and incorporate them into a focused, thorough history, which includes relevant negatives. It is very helpful to consider the clinicopathologic basis and pathogenesis of cutaneous lesions. For example, patients with systemic lupus erythematosus can have different types of photodistributed

Fig. 53.2 Rheumatoid papules. Multiple red–brown papules, some with scale-crust, on the lower extremity. This entity is within the spectrum of palisaded neutrophilic and granulomatous dermatitis (see Table 53.1).

CUTANEOUS MANIFESTATIONS OF RHEUMATOID ARTHRITIS	
Condition	**Features**
Palisading granulomas	
Rheumatoid nodules	• Seen in ~20% of RA patients, often associated with high-titer rheumatoid factor (RF) • Firm, semi-mobile papulonodules favoring periarticular locations (e.g. elbows; see Figs. 24.6B & 45.5) and other sites of repetitive trauma or pressure (e.g. the sacral region if bedridden) • Histologically, central zone of necrobiosis surrounded by palisaded histiocytes (see Fig. 45.9) • DDx: subcutaneous granuloma annulare, gouty tophi, synovial hyperplasia/cysts (softer, painful)
Reactive granulomatous dermatitis (includes interstitial granulomatous dermatitis [IGD] and palisaded neutrophilic & granulomatous dermatitis [PNGD])	• The clinical spectrum includes the annular variant of IGD (Fig. 53.1), rheumatoid papules (Fig. 53.2), and superficial ulcerating rheumatoid necrobiosis (Fig. 53.3) • See Ch. 93 for details
Neutrophilic dermatoses	
Rheumatoid neutrophilic dermatitis (rheumatoid neutrophilic dermatosis)	• Erythematous papules and plaques that may be vesiculated or crusted; favors extensor extremities • Unlike Sweet syndrome, usually not tender or associated with fevers and malaise
Sweet syndrome and pyoderma gangrenosum (PG)*	• See Chapter 25
Neutrophilic lobular panniculitis	• Tender red nodules favoring the lower legs; may ulcerate with purulent drainage • Overlap with subcutaneous Sweet syndrome; infectious etiologies need to be excluded
Vasculitis and vascular reactions	
Bywaters lesions	• Punctate purpuric papules on the distal digits due to cutaneous small vessel vasculitis (Fig. 53.4) • Often has a more benign course

Rheumatoid vasculitis	• Associated with long-standing (often "burnt out") joint disease, high-titer RF, and mononeuritis multiplex; may also affect the eyes and internal organs
	• Cutaneous involvement is usually the first manifestation
	  • *Small vessel vasculitis*: purpuric macules and papules (see Fig. 24.6B)
	  • *Medium-sized vessel vasculitis*: nodules, ulcers, digital gangrene, livedo reticularis, atrophie blanche-like scars
	• Systemic disease requires aggressive immunosuppressive therapy

Intralymphatic histiocytosis	• Erythema, induration, and plaques with a reticular pattern; co-localizes with involved joints or metallic orthopedic implants (see Fig. 121.6)
Erythema elevatum diutinum	• Firm, red to yellow–brown papulonodules and plaques, usually symmetrically distributed over joints and on extensor surfaces • Chronic cutaneous vasculitis occasionally associated with RA (exclude IgA monoclonal gammopathy)
Complications of therapy for RA	
NSAIDs	• Pseudoporphyria (particularly naproxen) (Fig. 53.5), phototoxicity, toxic epidermal necrolysis
Methotrexate	• EBV-associated lymphoproliferative disease that may involve the skin
Methotrexate >> TNF inhibitors, leflunomide, tocilizumab	• Accelerated rheumatoid nodulosis – sudden appearance of multiple papulonodules, especially on the hands (see Fig. 45.6)
TNF inhibitors	• Local injection site reactions, urticaria, urticarial eruptions; eczematous and psoriasiform eruptions, sometimes admixed, palmoplantar pustulosis; RGD, vasculitis, cutaneous LE, dermatomyositis (see Table 128.7)
IL-17 inhibitors	• Local injection site reactions, urticaria (see Table 128.7)
IL-12/23 & IL-23 inhibitors	• Local injection site reactions, urticaria (see Table 128.7)
*"PG-like" leg ulcers are a feature of Felty syndrome, which is characterized by the triad of neutropenia, splenomegaly, and RA; Felty syndrome is associated with a higher incidence of rheumatoid nodules and may be associated with T cell large granular lymphocyte leukemia.	

Table 53.1 Cutaneous manifestations of rheumatoid arthritis (RA). DDx, differential diagnosis; EBV, Epstein–Barr virus; LE, lupus erythematosus; RGD, reactive granulomatous dermatitis; TNF, tumor necrosis factor.

Fig. 53.3 Superficial ulcerating rheumatoid necrobiosis. Shiny, yellow plaques with red–brown edges and areas of ulceration that clinically resemble necrobiosis lipoidica. This patient had active rheumatoid vasculitis.

Fig. 53.4 Bywaters lesions. Tender, purpuric papules on the distal fingers in a patient with rheumatoid vasculitis. Histologically, leukocytoclastic vasculitis is seen.

lesions with an interface histopathology, e.g. discoid, subacute, poikilodermatous, and they have different implications with regard to systemic disease. Such lesions are also treated differently than those caused by vessel-based pathology, e.g. small or larger vessel vasculitis.

Sjögren syndrome is an autoimmune disorder characterized by keratoconjunctivitis sicca and xerostomia (see Table 45.4). In primary Sjögren syndrome, vascular inflammation within the skin (e.g. small vessel vasculitis, hypergammaglobulinemic purpura) can occur even before the clinical diagnosis has been established and may have prognostic implications. Some patients from the Far East, including Japan and the Philippines, have been described with "annular erythema of Sjögren syndrome". There is ongoing debate as to whether this disorder is unique to Sjögren syndrome or if it is, in fact, a form of subacute cutaneous lupus erythematosus[5]. Secondary Sjögren syndrome occurs in patients with other rheumatologic diseases, including rheumatoid arthritis, dermatomyositis, and systemic sclerosis. It is important to remember that the diagnosis of Sjögren syndrome is one of exclusion, and that other conditions can cause xerostomia/xerophthalmia, including chronic GVHD, sarcoidosis, primary systemic amyloidosis, hepatitis C viral infection, IgG4-related disease, and HIV disease.

Fig. 53.5 Pseudoporphyria in a patient with rheumatoid arthritis. The cause was a nonsteroidal anti-inflammatory drug. *Courtesy Kalman Watsky, MD.*

CUTANEOUS HEMATOLOGY AND ONCOLOGY

Disorders of mutual interest to the dermatologist and hematologist/oncologist are well covered in the following chapters of this textbook: metastatic disease (Ch. 122), leukemia/lymphoma (Chs. 119–121), dysproteinemias (Ch. 119), histiocytoses (Ch. 91), vascular neoplasms (Ch. 114), cutaneous T cell lymphoma (Ch. 120), melanoma (Ch. 113), and cutaneous reactions to chemotherapeutic agents, targeted therapies, and immune checkpoint inhibitors (Ch. 21). Skin signs of internal malignancy are summarized in Tables 53.2 and 53.3.

Both disease-specific and nonspecific skin lesions have been reported in association with *myelodysplastic syndrome* (MDS)[14]. The former include leukemia cutis and "cutaneous myelodysplasia"; the latter is characterized by an infiltrate of atypical myeloid cells in a patient who does not fulfill criteria for leukemia. Patients with MDS can also develop cutaneous small vessel vasculitis (CSVV; see Fig. 24.6), as well as Sweet syndrome, including the subcutaneous, histiocytoid, and lymphocytic variants[15–17]. The latter variant may portend a poorer prognosis[17]. In the VEXAS (*v*acuoles, *E*1 enzyme, *X*-linked, *a*utoinflammatory, *s*omatic) syndrome due to *somatic* mutations in *UBA1*, chondritis, Sweet syndrome, and vasculitis (CSVV > polyarteritis nodosa or giant cell arteritis) can accompany MDS; a clue to the diagnosis is vacuolated myeloid and erythroid precursors in the bone marrow[18].

PARANEOPLASTIC DERMATOSES		
Dermatoses	**Cutaneous findings**	**Comments**
Disorders that are associated with cancer in most or all cases		
Acquired hypertrichosis lanuginosa (malignant down)	Growth of fine lanugo hairs in a generalized distribution or localized to the face. With time, these hairs may become coarser (see Ch. 70)	Associated with a variety of internal malignancies, most often carcinoma of the lung, colon, or breast
AESOP syndrome	Large red to violet–brown patch	Patch overlies a plasmacytoma
Bazex syndrome (acrokeratosis paraneoplastica)	Acral psoriasiform plaques, typically with involvement of the nose and helices; often the lesions are violaceous (Fig. 53.6) Longitudinal and horizontal ridging of the nails occurs in 75% of patients	By definition, this condition is linked to malignancy, occurring most commonly in the upper aerodigestive tract (oropharynx, larynx, or esophagus)
Carcinoid syndrome	Rosacea-like flushing and erythema of the head and neck Pellagra-like dermatitis and sclerodermoid changes may develop in advanced disease	Flushing associated with ~10% of mid-gut tumors (small intestine, appendix, proximal colon) and liver metastases are required; type III gastric and bronchial carcinoid tumors are also associated with flushing (liver metastases are not required)
Ectopic adrenocorticotropic hormone (ACTH) syndrome	Generalized hyperpigmentation that may be accentuated in sun-exposed sites	Production of ACTH by a tumor (often a small cell carcinoma of the lung) may result in hyperpigmentation and features of Cushing syndrome
Erythema gyratum repens	Concentric erythematous lesions, often giving rise to a wood-grain appearance (Fig. 53.7; see Ch. 19)	Variable sites and types of malignancy
Glucagonoma syndrome	Necrolytic migratory erythema, angular cheilitis, glossitis	Due to a glucagon-secreting tumor of the pancreas and associated with weight loss and diabetes mellitus Patients often treated for intertrigo prior to diagnosis
Paraneoplastic pemphigus	Erosive disease of the mucous membranes and erythema multiforme-like, bullous pemphigoid-like or lichenoid skin lesions (see Fig. 29.10)	Most often associated with non-Hodgkin lymphoma, chronic lymphocytic leukemia or Castleman disease (with the latter accounting for the majority of cases in children and Asian populations) Castleman tumors have been shown to produce the autoantibodies responsible for paraneoplastic pemphigus, and their resection can lead to remission of mucocutaneous lesions Bronchiolitis obliterans is a common complication
Tripe palms	Ridged velvety lesions on the palms	May or may not be accompanied by acanthosis nigricans

Table 53.2 Paraneoplastic dermatoses[6–8].

Continued

PARANEOPLASTIC DERMATOSES		
Dermatoses	**Cutaneous findings**	**Comments**
Disorders that are strongly associated with cancer in a subset of cases		
Acanthosis nigricans	Rapid onset of hyperpigmented velvety changes in multiple flexural sites (e.g. neck, axillae, groin) May also involve extensor surfaces (e.g. elbows, knees, knuckles) and, in malignancy-associated cases, lips, oral mucosa, and palms (see above, tripe palms)	Association with adenocarcinomas (e.g. stomach, other sites within the GI or GU tracts) and often accompanied by weight loss More commonly associated with endocrinologic disorders, in particular insulin resistance (see Fig. 53.14); such patients are typically overweight, and the onset of the condition is usually insidious
Anti-laminin 332 mucous membrane pemphigoid/ anti-epiligrin cicatricial pemphigoid*	Oral ulcerations, conjunctival erosions, and scarring Tense blisters and erosions of the skin may also develop (see Ch. 30)	Roughly one-third of patients have or develop cancer within the first year following diagnosis Most often an adenocarcinoma and frequently diagnosed at an advanced stage
Dermatomyositis (adult)	Diffuse scaling and pruritus of the scalp, heliotrope, photodistributed poikiloderma, Gottron papules of the hands, thin plaques of the elbows, knees, lateral hips/thighs (holster sign) and upper back (shawl sign), nail-fold overgrowth with dilated capillary loops (see Ch. 42)	Population-based studies demonstrate an over-representation of ovarian, lung, colorectal, and pancreatic carcinomas and non-Hodgkin lymphoma in White individuals Nasopharyngeal carcinoma is over-represented in patients of Asian descent
Eosinophilic dermatosis of hematologic malignancy	Severe insect bite reactions and insect bite-like reactions with pruritic papulonodules and vesiculobullous lesions	Chronic lymphocytic leukemia, NK/T cell lymphoma, and ALK-positive anaplastic large cell lymphoma, in addition to other hematologic malignancies
Neutrophilic dermatoses	Sweet syndrome (Fig. 53.8) or pyoderma gangrenosum (particularly the atypical bullous form) (see Ch. 25)	~10%–20% of cases are associated with hematologic disorders such as acute myelogenous leukemia, myelodysplasia, or plasma cell dyscrasia (IgA) Underlying solid tumors are rare
Disorders associated with a monoclonal gammopathy†		
Acquired angioedema due to C1 esterase inhibitor dysfunction	Acquired angioedema without associated wheals (see Ch. 18)	Associated with B cell lymphoproliferative disorders, including lymphomas, as well as monoclonal gammopathy of undetermined significance (MGUS)
Amyloidosis, primary systemic	Waxy, translucent, or purpuric papules; periorbital and pinch purpura; macroglossia (see Ch. 47)	Monoclonal gammopathy due to plasma cell dyscrasia ≫ multiple myeloma; deposits composed of immunoglobulin light chain (AL)
Cryoglobulinemia, type I	Retiform purpura and necrosis that favors cooler acral sites; acral cyanosis; livedo reticularis (see Ch. 23)	Monoclonal gammopathy due to plasma cell dyscrasia or lymphoproliferative disorder
Necrobiotic xanthogranuloma	Indurated xanthomatous plaques with necrosis and ulceration, usually in a periorbital location (see Ch. 91)	Paraproteinemia (>80% of cases, most often IgG with κ light chains) due to plasma cell dyscrasia or lymphoproliferative disorder; multiple myeloma develops in a minority of patients
Normolipemic plane xanthoma	Yellowish patches and thin plaques that favor the skin folds, upper trunk, and periorbital area (see Ch. 92)	Paraproteinemia due to plasma cell dyscrasia or lymphoproliferative disorder
POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-protein and *s*kin changes)	Although the glomeruloid hemangioma (Fig. 53.10) is considered to be pathognomonic, it is present in a minority of patients Additional skin findings include cherry angiomas and other vascular tumors, hyperpigmentation, hypertrichosis, sclerodermoid induration, acrocyanosis, acquired facial lipoatrophy, hyperhidrosis, digital clubbing, plethora, and leukonychia	Monoclonal gammopathy due to plasma cell dyscrasia including multiple myeloma (osteosclerotic > osteolytic) and plasmacytomas or Castleman disease Patients may also have peripheral edema, ascites, pulmonary effusions, papilledema, thrombocytosis, polycythemia, and increased serum levels of VEGF
Schnitzler syndrome	Chronic urticarial lesions Histologically, a neutrophil-rich dermal infiltrate is often seen (see Ch. 18)	Associated with an IgM, usually κ, paraproteinemia, with lymphoma or multiple myeloma developing in ~15% of patients Additional manifestations include fevers, arthralgias, and bone pain[9] and treatment includes anti-IL-1 agents[10] (see Fig. 45.13)
Scleromyxedema	Sclerodermoid induration plus firm, waxy papules arranged in linear arrays (see Ch. 46)	Almost always associated with paraproteinemia (usually IgG with λ light chains); multiple myeloma develops in <10% of patients
Dermatoses that may be associated with cancer in a subset of patients		
Acquired ichthyosis	Resembles ichthyosis vulgaris; most often located on the legs	Most commonly associated with lymphoma, which typically predates the diagnosis of the ichthyosis
Cutaneous small vessel vasculitis	Palpable purpura; may be widespread and/or in unusual locations (see Ch. 24)	Less than 5% of patients with vasculitis have an associated malignancy, most commonly plasma cell dyscrasia, myelodysplasia, myeloproliferative or lymphoproliferative disorder, and hairy cell leukemia IgA vasculitis in adults may be associated with solid organ malignancies[10a]
Dermatitis herpetiformis (DH)	Pruritic blisters and erosions on extensor surfaces, scalp and/or buttocks (see Ch. 31)	Through the association of DH with gluten-sensitive enteropathy, enteropathy-associated T cell lymphoma can occur Possible association with B cell non-Hodgkin lymphoma[10b]

Table 53.2 Paraneoplastic dermatoses[6–8].

PARANEOPLASTIC DERMATOSES		
Dermatoses	**Cutaneous findings**	**Comments**
Eruptive disseminated porokeratosis	Abrupt onset of numerous, widespread, inflamed keratoses with histologic features of porokeratosis	In a literature review of 35 patients, ~30% of patients had an associated malignancy, most commonly involving the GI tract[11]
Exfoliative erythroderma	Widespread, diffuse, scaly erythematous skin (see Ch. 10)	May be associated with cutaneous T cell lymphoma or, occasionally, with a systemic lymphoma or leukemia
Juvenile xanthogranulomas (JXGs) in the setting of neurofibromatosis 1 (NF1)	Pink–yellow to red–brown, dome-shaped papules and nodules, most often located on the head and neck (see Ch. 91)	A triple association between JXGs, NF1, and juvenile myelomonocytic leukemia has been described
Multicentric reticulohistiocytosis	Papulonodular lesions, most often on the dorsal aspects of the hands, elbows, and face (Fig. 53.11)	Often accompanied by destructive arthritis Variety of associated malignancies reported, developing in ~25%–30% of adult patients[11a]
Mycosis fungoides	Patch, plaque, or nodular disease (see Ch. 120)	Increased risk of second malignancies: other lymphomas >> leukemia or solid organ malignancies
Pancreatic panniculitis	Subcutaneous nodules, most commonly on the legs, which may ulcerate and drain oily liquid (see Ch. 100)	Underlying pancreatic carcinoma or pancreatitis May herald metastatic disease Additional findings include polyarthritis (PPP syndrome), abdominal pain, and eosinophilia
Porphyria cutanea tarda (PCT)	Fragility, erosions, blisters, milia and scars on the dorsal aspect of the hands, facial hypertrichosis, sclerotic plaques (see Ch. 49)	Through its association with hepatitis C virus, PCT may also be associated with primary hepatocellular carcinoma (hepatoma)
Reactive granulomatous dermatitis (disseminated cutaneous granulomatosis)	Granulomatous papules and plaques, sometimes with an annular configuration Overlap with IGD, PNGD, & granuloma annulare	More commonly associated with myelodysplastic syndrome and lymphoproliferative disorders than with solid organ malignancies
Disorders whose association with cancer is controversial		
Sign of Leser–Trélat	Rapid appearance or growth of multiple seborrheic keratoses which may be inflamed	There is ongoing controversy as to whether this represents a paraneoplastic phenomenon, as many adults have numerous seborrheic keratoses and it can be difficult to determine if the keratoses are truly eruptive The rapid onset of numerous lesions, particularly if inflamed and associated with diffuse pruritus and/or acanthosis nigricans, may warrant evaluation Eruptive seborrheic keratoses can also develop in erythrodermic patients who do not have an underlying malignancy

*Evidence for this association is limited by the small number of affected individuals.
†Patients can also develop follicular spicules (Fig. 53.9); for complete list, see Table 119.5.

Table 53.2 Paraneoplastic dermatoses[6–8]. Other signs include pruritus (most commonly with lymphomas or carcinomas that lead to cholestasis) and pityriasis rotunda. AESOP, *a*denopathy, *e*xtensive *s*kin patch *o*verlying (a) *p*lasmacytoma; IGD, interstitial granulomatous dermatitis; GI, gastrointestinal; GU, genitourinary; PNGD, palisaded neutrophilic and granulomatous dermatitis; PPP, pancreatitis, polyarthritis, and panniculitis; VEGF, vascular endothelial growth factor.

INTERNAL MALIGNANCIES IN FAMILIAL CANCER SYNDROMES WITH CUTANEOUS MANIFESTATIONS
• Cowden disease (breast, thyroid and GU carcinomas), Muir–Torre syndrome (GI and GU carcinomas), Gardner syndrome (GI carcinoma), Peutz–Jeghers syndrome (various malignancies) – see Table 53.10
• Costello syndrome (rhabdomyosarcoma, neuroblastoma, bladder carcinoma), Werner syndrome (thyroid carcinoma, osteosarcoma) – see Table 53.12
• Birt–Hogg–Dubé syndrome, hereditary leiomyomatosis and renal cell cancer – see Tables 111.1 & 117.2
• Howel–Evans syndrome (esophageal carcinoma) – see Ch. 58
• Ataxia–telangiectasia (leukemia, lymphoma, breast cancer) – see Ch. 60
• Neurofibromatosis (malignant peripheral nerve sheath tumors, JMML, rhabdomyosarcoma, pheochromocytoma, carcinoid), tuberous sclerosis (renal cell carcinoma) – see Ch. 61 and Table 61.1
• Multiple endocrine neoplasia syndromes – see Table 63.2
• Dyskeratosis congenita (acute myelogenous leukemia, oral and anogenital SCC) – see Ch. 67
• Basal cell nevus syndrome (medulloblastoma, ovarian fibrosarcoma) – see Table 108.3
• Bloom syndrome (lymphoma, acute leukemias, GI malignancies), Rothmund–Thomson syndrome (osteosarcoma), xeroderma pigmentosum (brain tumors [e.g. medulloblastoma, glioblastoma], oral SCC [not just anterior tongue]) – see Table 87.4
• Familial melanoma (pancreatic carcinoma, neural tumors, renal cell carcinoma, and gliomas, when mutations in *CDKN2A* (p16), *CDKN2A* (p14), *MITF*, and *POT1*, respectively; uveal melanoma, mesothelioma, clear cell renal cell carcinoma, and cholangiocarcinoma with *BAP1* mutations)

Table 53.3 Internal malignancies in familial cancer syndromes with cutaneous manifestations[12,13]. GI, gastrointestinal; GU, genitourinary; JMML, juvenile myelomonocytic leukemia; SCC, squamous cell carcinoma.

Generalized granulomatous dermatitis, panniculitis, and a variety of autoimmune disorders including Behçet disease, and bullous pemphigoid have also been reported in patients with MDS. These cutaneous disorders may precede the diagnosis of MDS, serving as its harbinger. Recurrence of skin lesions, or their lack of response to therapy, may herald progression to leukemia.

An eczematous or psoriasiform plaque of the nipple and surrounding skin can be seen in *Paget disease* due to epidermal extension of an underlying ductal adenocarcinoma of the breast (Fig. 53.12). While extramammary Paget disease (EMPD) most commonly represents a primary intraepithelial or invasive adenocarcinoma (>75% of patients; Fig. 53.13), secondary EMPD can be due to an underlying visceral malignancy, e.g. colorectal, urothelial (see Fig. 73.16).

Acanthosis nigricans is characterized by velvety hyperpigmentation of intertriginous areas and, less often, extensor surfaces (Fig. 53.14 & 53.15). Although this disorder may be associated with an internal malignancy (e.g. gastric adenocarcinoma), it is most often associated with insulin resistance[19]. The sites most frequently affected are the neck and axillae, but can include any skin fold, including that of the lower lip and chin. Malignancy-associated acanthosis nigricans is usually rapid in onset and may be accompanied by skin tags, multiple seborrheic keratosis, tripe palms, or florid cutaneous papillomatosis. Verrucous changes of the lips may also develop, and weight loss is common. In contrast, acanthosis nigricans associated with endocrine dysfunction is more insidious in onset and less widespread, and the patients are often overweight or obese. In either instance, there are probably one or more circulating factors that stimulate the epidermal proliferation (i.e. papillomatosis) that is observed histopathologically. An approach to the patient with acanthosis nigricans in outlined in Fig. 53.16. Treatment of the underlying malignancy, or effective treatment of

Fig. 53.6 Bazex syndrome (acrokeratosis paraneoplastica). A Acral psoriasiform lesions that have a violaceous hue, accompanied by nail dystrophy. The patient had a squamous cell carcinoma (SCC) of the tonsillar pillar. **B** Thin hyperpigmented plaques of the helix and antihelix in a patient with SCC of the pharynx. *B, Courtesy Jean L. Bolognia, MD.*

Fig. 53.7 Erythema gyratum repens. This patient had cancer of the breast.

Fig. 53.8 Acute febrile neutrophilic dermatosis (Sweet syndrome). Vesicopustules with surrounding erythema on the dorsal hand in a patient with myelodysplastic syndrome.

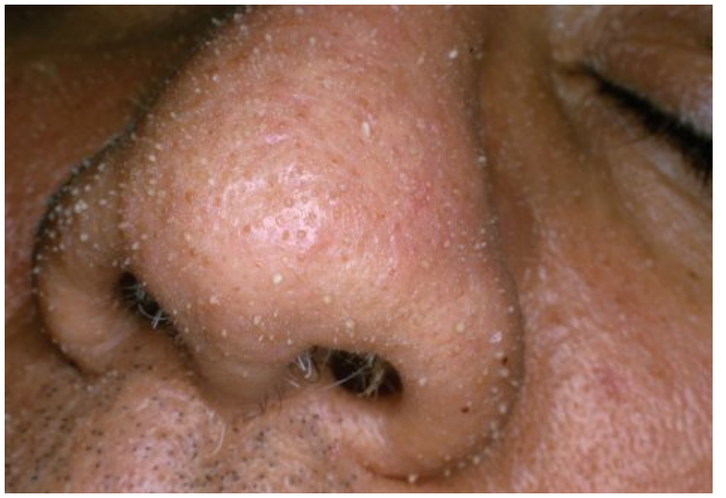

Fig. 53.9 Follicular spicules in a patient with multiple myeloma. *Courtesy Irwin Braverman, MD.*

the endocrinopathy, including weight loss and use of insulin sensitizers, may result in improvement or disappearance of the acanthosis nigricans. Recurrence of malignancy-associated acanthosis nigricans requires a search for recurrent cancer.

The glucagonoma syndrome is characterized by the development of *necrolytic migratory erythema* (NME), adult-onset diabetes mellitus, weight loss, and glossitis. These patients are also frequently anemic, and personality changes may occur. Skin lesions of NME are eroded, erythematous patches and plaques that characteristically involve the intertriginous areas, face (especially around the mouth), and distal extremities. Blisters may occur and lead to erythematous erosions. The eruption, which can be painful or pruritic, remits and recurs over the course of several weeks to months. It is frequently misdiagnosed as intertrigo or as seborrheic dermatitis. Histologically, pallor of the upper epidermis is highly suggestive of NME or a "nutritional" dermatosis (see Ch. 51). However, psoriasiform hyperplasia of the epidermis is often seen in NME and therefore clinicopathologic correlation is required.

Most, but not all, patients with NME have a glucagon-secreting tumor of the pancreas, and effective treatment of the tumor will result in a disappearance of the disease. Rarely, NME develops in the setting of severe liver disease or chronic pancreatitis. Similar skin lesions occur in patients with deficiencies of zinc, fatty acids or biotin (see Fig. 51.13) and replacement therapy leads to resolution of the cutaneous findings. The differential diagnosis of NME also includes necrolytic acral erythema (see below).

Fig. 53.10 POEMS syndrome. This patient had multiple angiomas on his trunk as well as his face and scalp. All the angiomas that were examined histologically were glomeruloid hemangiomas. In addition, he reported a recent 10 lb (4.5 kg) weight loss, impotence and fatigue, and was found to have a neuropathy, adult-onset diabetes, hypothyroidism, and peripheral edema. His underlying disorder was an osteosclerotic myeloma.

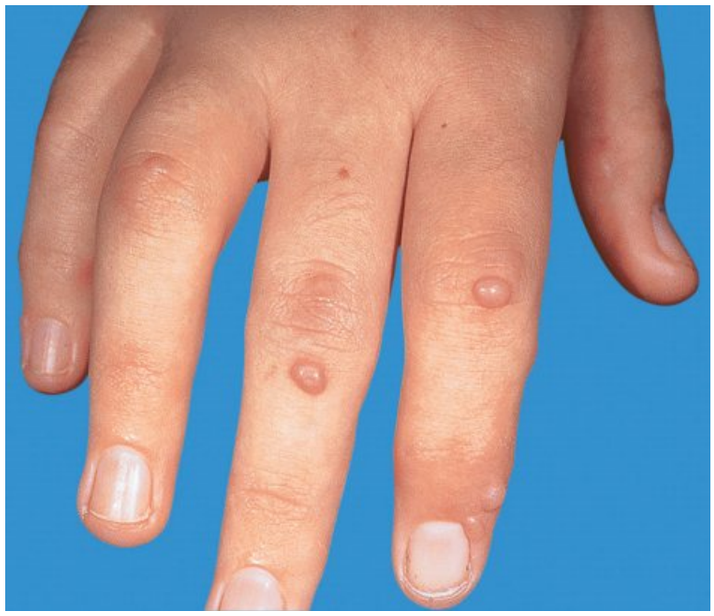

Fig. 53.11 Multicentric reticulohistiocytosis. Multiple nodules are present on the dorsal hands in this adolescent. This patient did not have a malignancy.

There is growing recognition of the role both inherited and acquired disorders of hypercoagulability or thrombophilia play in various skin disorders[20] (see Chs. 23 and 105). Some associations, such as those between protein C deficiency and neonatal purpura fulminans or prothrombin gene mutations and livedoid vasculopathy, are fairly well understood. However, there are other disorders in which cutaneous thromboses have been identified (e.g. calciphylaxis) where the precise role remains less well defined. Evaluation for hypercoagulability is warranted in patients with unexplained cutaneous thrombosis (see Table 105.9).

Fig. 53.12 Paget disease of the breast. A chronic, erythematous plaque surrounds the nipple. *Courtesy Robert Hartman, MD.*

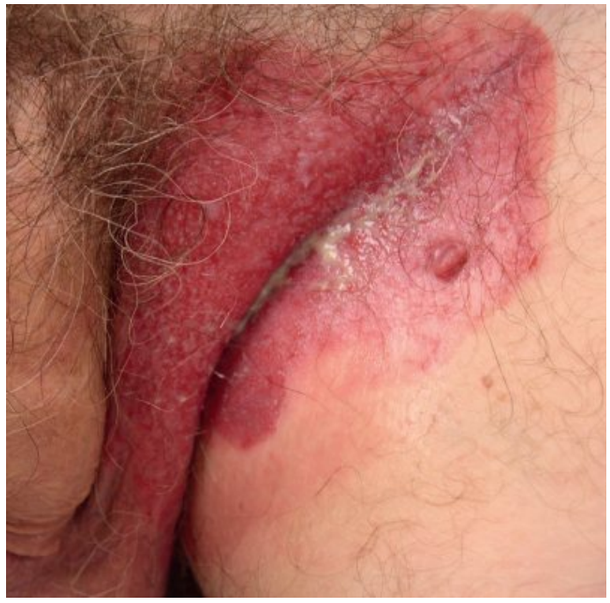

Fig. 53.13 Extramammary Paget disease. Eroded erythematous plaque with exudate, especially in the inguinal crease. The patient refused any further evaluation and had never undergone colonoscopy or cystoscopy.

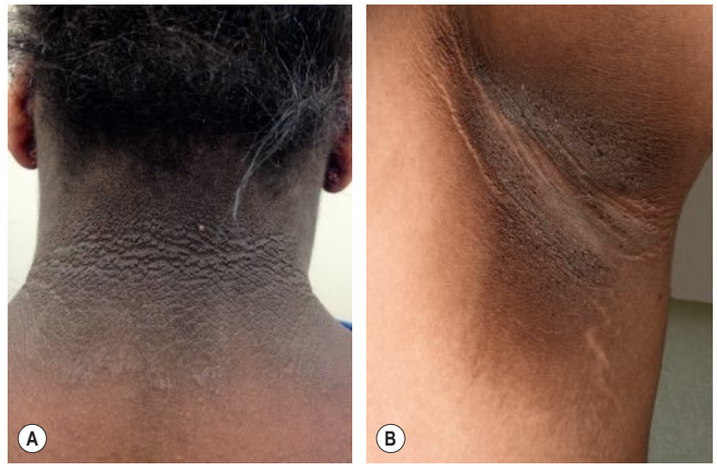

Fig. 53.14 Acanthosis nigricans. A Involvement of the posterior neck in a young woman with obesity and insulin resistance. There is also an acrochordon. **B** Axillary involvement in an obese 10-year-old Filipino boy with insulin resistance and a strong family history of type 2 diabetes mellitus. *B, Courtesy Julie V. Schaffer, MD.*

Fig. 53.15 Acanthosis nigricans (AN) of the hands. A Changes of AN overlie the knuckles in a patient with insulin resistance and obesity; acanthosis nigricans can involve extensor surfaces as well as flexural areas. **B** Diffuse involvement of the dorsal aspect of the fingers. Evaluation for an internal malignancy is recommended in patients with this type of clinical presentation. *A, Courtesy Jean L. Bolognia, MD; B, Courtesy Joyce Rico, MD.*

EVALUATION OF THE PATIENT WITH ACANTHOSIS NIGRICANS

Was AN apparent at birth or during early childhood and associated with skeletal abnormalities and/or short stature?	Consider autosomal dominant disorders due to FGFR defects, especially if AN is extensive: • Crouzon syndrome with AN (features craniosynostosis), SADDAN, and thanatophoric dysplasia (*FGFR3* mutations) • Beare–Stevenson cutis gyrata syndrome (features craniosynostosis; *FGFR2* mutations) Consider: • Costello syndrome (see Table 53.12) • Rabson–Mendenhall syndrome (features dental dysplasia, insulin-resistant diabetes mellitus; compound heterozygote for *INSR* mutation)
Was AN apparent during childhood or adolescence and associated with loss/absence of subcutaneous fat?	Consider generalized lipodystrophy (more extensive AN with congenital variant) or partial lipodystrophy (familial > acquired (see Ch. 101))
Was the onset sudden and accompanied by constitutional symptoms or weight loss?	Consider underlying malignancy, particularly if AN is extensive and involves sites such as the palms and soles. Restaging is required if AN recurs in a patient with a known malignancy
Is the patient overweight or obese?	Evaluate for associated insulin resistance states, especially diabetes mellitus. Consider evaluation for other underlying endocrinopathies, including thyroid disease
Does the patient have striae, hypertension, central obesity and/or a buffalo hump?	Evaluate for Cushing syndrome
If female, does the patient have acne, hirsutism and/or irregular menses?	Evaluate for polycystic ovary syndrome and HAIR-AN syndrome (see Fig. 70.17)
Is the patient on medications such as niacin, human growth hormone, oral contraceptives, corticosteroids or protease inhibitors?	AN may be drug-induced

Fig. 53.16 Evaluation of the patient with acanthosis nigricans (AN). Severe acanthosis nigricans may also be associated with epidermal growth factor receptor (EGFR) variants. FGFR, fibroblast growth factor receptor; HAIR-AN, hyperandrogenemia, insulin resistance, acanthosis nigricans; INSR, insulin receptor; SADDAN, severe achrondroplasia with developmental delay and AN.

CUTANEOUS DISEASES IN PATIENTS WITH ENDOCRINOLOGIC AND/OR METABOLIC DISORDERS

Cutaneous manifestations may provide important clues to the diagnosis of endocrine disorders, including diabetes mellitus[21]. Patients with endocrine diseases are especially susceptible to a number of associated mucocutaneous disorders.

Diabetes mellitus is a very common medical condition that affects almost every organ system. Table 53.4 summarizes cutaneous manifestations of diabetes mellitus (Figs. 53.17–53.22). Further details are available in reviews on the subject[19,21].

The primary characteristics of *metabolic syndrome* are central obesity, hypertension, dyslipidemia, and type 2 diabetes. Almost all patients have insulin resistance, and it is associated with a high risk of cardiovascular disease. Clinical criteria for the diagnosis of metabolic syndrome are outlined in Table 53.5. Women with polycystic ovary syndrome have a greater frequency of metabolic syndrome and often present with acanthosis nigricans, acne vulgaris, and hirsutism[22]. An association between psoriasis vulgaris and metabolic syndrome has also been identified, which may account for why patients with moderate to severe psoriasis have an increased risk of atherosclerotic cardiovascular disease[23].

Thyroid disease is also associated with a significant number of dermatologic disorders. Several reviews have highlighted these

SELECTED DERMATOLOGIC ASSOCIATIONS OF DIABETES MELLITUS

Dermatosis	Clinical description	Comments
Acanthosis nigricans (AN)	Velvety hyperpigmentation of the intertriginous/flexural areas (Fig. 53.14) and, less often, extensor surfaces (Fig. 53.15A)	Commonly associated with insulin resistance in both adults and children Most patients are obese More common in Hispanics and African-Americans
Acral dry gangrene	Necrosis of the toes > fingertips	Ischemia due to peripheral arterial disease
Acral erythema	Erysipelas-like erythema of the hands and/or feet	May be due to small vessel occlusive disease with compensatory hyperemia or autonomic dysfunction
Carotenoderma	Diffuse orange–yellow skin color	Related to an increase in serum carotene level
Charcot foot (neuropathic osteoarthropathy)	Erythema, warmth, swelling (early) Rocker bottom foot (later)	May be misdiagnosed as cellulitis, acute gout, or osteomyelitis
Diabetic bullae (bullous diabeticorum)	Tense non-inflammatory bullae on the lower extremities (Fig. 53.17)	Uncertain pathogenesis; microangiopathy possible contributor
Diabetic cheiroarthropathy	Thickened skin and limited joint mobility of the hands and fingers, leading to flexion contractures (starting with the fifth digit and progressing radially) and an inability to approximate the palmar surfaces of the hands and fingers (prayer sign; Fig. 53.18)	Postulated to result from increased glycosylation of collagen in the skin Associated with retinopathy, nephropathy, and duration (but not control) of the DM
Diabetic dermopathy	Brown atrophic macules and patches on the legs (Fig. 53.19)	Possibly due to trauma with altered healing due to microangiopathy
Disseminated granuloma annulare	Erythematous annular lesions composed of papules	There is controversy about the exact relationship of disseminated granuloma annulare and DM (see Ch. 93)
Eruptive xanthomas	Red–yellow papules that appear over a period of weeks to months (Fig. 53.20)	Associated with elevated serum triglycerides in patients with poorly controlled diabetes Control of the DM results in resolution of the xanthomas (see Ch. 92)
Hemochromatosis	Generalized bronzing of the skin due primarily to an increase in melanin	Excess iron stores associated with cirrhosis and cardiac dysfunction as well as DM Due to mutations in *HFE* (most commonly C282Y) and a risk factor for porphyria cutanea tarda
Necrobiosis lipoidica	Yellow atrophic patches, most often on the shins; a red–brown rim may indicate activity at the border (Fig. 53.21) Ulceration can occur and is often slow to heal	Develops in <1% of patients with DM (see Ch. 93) Not always associated with DM
Neuropathic ulcers	Non-painful ulcerations at sites of pressure, most commonly on the foot (Fig. 53.22) When the ulcer is on the plantar surface, a characteristic keratotic rim is seen	Associated with sensory neuropathy (see Ch. 105) Distinguish purely neuropathic ulcers from neuroischemic ulcers which also require vascular evaluation
Perforating disorders (e.g. acquired perforating dermatosis)	Keratotic papules, primarily on the extremities	Diabetic patients with chronic kidney disease on dialysis (see Ch. 96)
Rubeosis	Chronic, flushed appearance of the face, neck and upper extremities	Improves with dietary diabetic control and flares with vasodilator therapies
Scleredema (adultorum of Buschke)	Induration of the upper back and nape due to glycosaminoglycan deposition May have overlying erythema	No relationship to control of DM Also referred to as type III scleredema (see Ch. 46)

Table 53.4 Selected dermatologic associations of diabetes mellitus (DM). Additional cutaneous conditions associated with DM include hirsutism (e.g. related to polycystic ovary syndrome or HAIR-AN – *h*yperandrogenemia, *i*nsulin *r*esistance, *a*canthosis *n*igricans; see Ch. 70), necrolytic migratory erythema (in the setting of DM due to a glucagon-secreting pancreatic tumor; see Table 53.2), compensatory and gustatory hyperhidrosis (see Ch. 39), vitiligo, and infections such as mucocutaneous candidiasis, furuncles, abscesses, cellulitis, necrotizing fasciitis, malignant otitis externa, and erythrasma (especially the disciform variant). *Adapted from Jorizzo JL, Callen JP. Dermatologic manifestations of internal disease. In: Arndt KA, Robinson JK, LeBoit PE, et al (eds). Cutaneous Medicine and Surgery. Philadelphia: WB Saunders, 1996:1863–89.*

Fig. 53.17 Bullosis diabeticorum (diabetic bullae). Non-inflammatory bullae on the lower extremity in a patient with diabetes mellitus.

Fig. 53.19 Diabetic dermopathy. Note the brown macules and patches on the shins. *Courtesy Jean L. Bolognia, MD.*

Fig. 53.21 Necrobiosis lipoidica. This plaque on the shin has an inflammatory border and a yellow color with atrophy and telangiectasias centrally. Controversy exists about the exact risk of diabetes mellitus in such patients, but it is much more strongly associated with diabetes than is granuloma annulare.

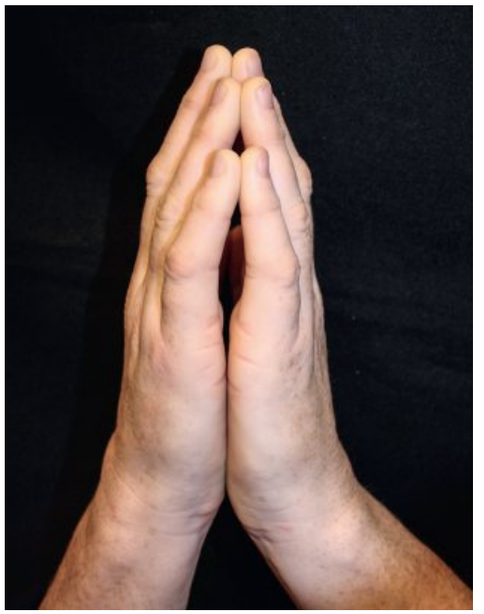

Fig. 53.18 Diabetic cheiroarthropathy (diabetic stiff hand syndrome). Because of limited joint mobility and thickening of the skin of the hand, the patient is unable to appose the palms ("prayer sign"). *Courtesy Jean L. Bolognia, MD.*

Fig. 53.20 Eruptive xanthomas in association with poorly controlled diabetes mellitus. This patient was first discovered to have diabetes following the appearance of these yellow–red papules.

Fig. 53.22 Neuropathic ulcers on the toes of a patient with diabetic sensory neuropathy.

CRITERIA FOR THE CLINICAL DIAGNOSIS OF METABOLIC SYNDROME
• Elevated waist circumference (population- and country-specific definitions)
• Elevated triglycerides (≥150 mg/dl)
• Reduced HDL (<40 mg/dl in males; <50 mg/dl in females)
• Elevated blood pressure (systolic ≥130 and/or diastolic ≥85 mm/Hg)
• Elevated fasting blood glucose (≥100 mg/dl)

Table 53.5 Criteria for the clinical diagnosis of metabolic syndrome. Metabolic syndrome is identified by the presence of three of these five criteria. Drug treatment for dyslipidemia, hypertension or hyperglycemia also fulfills the corresponding criterion. Most patients with type 2 diabetes mellitus meet criteria for metabolic syndrome. *Adapted from Alberti KGMM, Eckel RH, Grundy SM, et al. Harmonizing the metabolic syndrome: a Joint Interim Statement of the International Diabetes Federation Task Force on Epidemiology and Prevention; National Heart, Lung, and Blood Institute; American Heart Association; World Heart Federation; International Atherosclerosis Society; and International Association for the Study of Obesity. Circulation. 2009;120:1640–5.*

DERMATOLOGIC MANIFESTATIONS OF THYROID DISEASE		
	Hyperthyroidism	**Hypothyroidism**
Cutaneous changes	Fine, velvety, smooth skin Warm and moist due to increased sweating Hyperpigmentation – localized or generalized Pruritus	Dry, rough, coarse skin Cold and pale Boggy and edematous skin (myxedema) Yellow discoloration as a result of carotenoderma Easy bruising (capillary fragility)
Cutaneous diseases	Pretibial myxedema*, thyroid acropachy (acral soft tissue swelling, periostitis, and clubbing of the digits) Urticaria, dermographism Increased incidence of vitiligo	Acquired ichthyosis and palmoplantar keratoderma Eruptive and/or tuberous xanthomas Increased incidence of vitiligo
Hair changes/ diseases	Fine, thin Mild, diffuse alopecia Increased incidence of alopecia areata	Dull, coarse, brittle Slow growth (increase in telogen hair phase) Alopecia of the lateral third of the eyebrows Increased incidence of alopecia areata
Nail changes	Onycholysis	Thin, brittle, striated
	Koilonychia	Slow growth
	Clubbing from thyroid acropachy	Onycholysis (rare)

*Can persist when patient is treated and becomes euthyroid or can be associated with euthyroid Graves disease.

Table 53.6 Dermatologic manifestations of thyroid disease. Serum thyroid-stimulating hormone (TSH) level is the most reliable test of thyroid function; it is usually markedly suppressed in patients with hyperthyroidism. Additional laboratory findings in hyperthyroid patients include elevated free T_3 and/or free T_4 levels. Patients with primary hypothyroidism have elevated TSH levels and decreased free T_4 levels. The detection of anti-thyroid peroxidase and/or anti-thyroglobulin antibodies suggests autoimmune thyroid disease (Hashimoto thyroiditis, Graves disease) while the presence of anti-TSH receptor antibodies points to Graves disease. Ascher syndrome consists of blepharochalasis, double lip, and goiter.

dermatologic manifestations and associations[24], and they are summarized in Table 53.6.

Adrenal disease classically manifests as excessive (Cushing syndrome) (Fig. 53.23 & 53. 24) or insufficient (Addison disease) corticosteroid activity (Fig. 53.25); this can include gluco- and mineralocorticoids. Excessive production of adrenal androgens may also occur (see Ch. 70). Features of these syndromes are outlined in Table 53.7 (see Ch. 125).

Fig. 53.23 "Buffalo hump" of Cushing syndrome due to fat redistribution. The patient also has evidence of hirsutism. *Courtesy Judit Stenn, MD.*

Fig. 53.24 Cushing syndrome with multiple striae. *Courtesy Judit Stenn, MD.*

CUTANEOUS GASTROENTEROLOGY

With the exception of Table 25.13, cutaneous aspects of gastroenterologic or hepatic disease are not specifically discussed elsewhere in this text[25–27]. Table 53.8 is a list of selected cutaneous associations of Crohn disease and ulcerative colitis (Figs. 53.26–53.28). Patients with ostomies, particularly those with an ileostomy, may develop peristomal dermatoses, the most common of which are listed in Table 53.9. Table 53.10 lists dermatologic conditions associated with gastrointestinal bleeding or hemorrhage (Figs. 53.29–53.32)[26].

Table 53.11 lists selected dermatologic aspects of liver disease[27]. Necrolytic acral erythema has been described in association with hepatitis C viral infection. This entity is histologically similar to necrolytic migratory erythema (see above), but is clinically distinct in that it primarily involves acral sites. The lesions present as painful or pruritic, pink to violet–brown plaques with hyperkeratosis (Fig. 53.33).

Fig. 53.25 Diffuse hyperpigmentation of Addison disease. The hyperpigmentation (shown in contrast to the physician's hand) is accentuated in sun-exposed skin and can also involve sites of trauma, skin creases, and mucosae.

DERMATOLOGIC MANIFESTATIONS OF ADRENAL DISORDERS	
Cushing disease*	**Addison disease**
Altered subcutaneous fat distribution • Rounded "moon" facies • Dorsal cervical fat deposition "buffalo hump" (Fig. 53.23) • Pelvic girdle fat deposition • Reduced fat in the arms and legs	Hyperpigmentation (MSH-like effect of ACTH) • Diffuse with accentuation in sun-exposed skin (Fig. 53.25) • Prominent at sites of trauma • Axillae, perineum, nipples • Palmar creases • Mucous membranes • Hair • Nails (longitudinal melanonychia) • Melanocytic nevi and lentigines
Skin atrophy • Multiple striae (Fig. 53.24) • Fragile skin • Prolonged wound healing • Purpura from minor trauma	Loss of androgen-stimulated (axillary, pubic) hair in postpubertal women
Cutaneous infections • Tinea (pityriasis) versicolor • Dermatophytosis and onychomycosis • Candidiasis	Fibrosis and calcification of cartilage, including ear (rare)
Acne	Vitiligo, alopecia areata, mucocutaneous candidiasis (in patients with APECED syndrome)
Hirsutism	
*Screening tests include urine free cortisol (24-hour), late-night salivary cortisol, 1-mg overnight low-dose dexamethasone suppression test (DST), and 8-mg overnight high-dose DST.	

Table 53.7 Dermatologic manifestations of adrenal disorders. Both over- and underproduction of adrenal hormones lead to characteristic skin findings. The plasma adrenocorticotropic hormone (ACTH) level is elevated in Cushing disease (pituitary overproduction) and ectopic ACTH syndrome, whereas it is suppressed in patients with adrenal tumors. Plasma ACTH levels are also elevated in patients with primary adrenocortical insufficiency (Addison disease) and suppressed in secondary adrenocortical insufficiency due to exogenous corticosteroid administration. When adrenal insufficiency is suspected, including in patients receiving a prolonged course of corticosteroids, an ACTH stimulation test can provide useful information. APECED, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; MSH, melanocyte stimulating hormone.

Fig. 53.26 Pyoderma gangrenosum in a patient with ulcerative colitis and relapsing polychondritis. Central ulceration preceded by a violaceous bulla with an inflammatory border. *Courtesy Frank Samarin, MD.*

Fig. 53.27 Peristomal pyoderma gangrenosum in the setting of inflammatory bowel disease. Patients with ostomies, particularly ileostomies, are at risk for peristomal dermatoses, including pyoderma gangrenosum.

SKIN FINDINGS IN CROHN DISEASE AND ULCERATIVE COLITIS

• Erythema nodosum – often reflective of active bowel disease
• Urticaria
• Cutaneous small vessel vasculitis, cutaneous polyarteritis nodosa
• Thrombotic vasculopathy
• "Pustular" vasculitis or bowel-associated dermatosis–arthritis syndrome-like lesions
• Pyoderma gangrenosum – primarily the classic (typical) ulcerative form (Fig. 53.26) or peristomal lesions (Fig. 53.27); a vegetative pustular variant (pyoderma vegetans) occasionally occurs. These lesions may or may not reflect activity of the bowel disease
• Other neutrophilic dermatoses, ranging from acneiform lesions to Sweet syndrome to neutrophilic panniculitis
• Oral lesions (see Chs. 25 & 72)
  • Granulomatous infiltrates (with Crohn disease only)
  • Aphthosis
  • Angular cheilitis, including in children
  • Pyostomatitis vegetans (mucosal variant of pyoderma gangrenosum)
• Contiguous (anogenital) and noncontiguous ("metastatic") Crohn disease (Fig. 53.28)
• Fistulae (perianal and abdominal)
• Genital lymphedema
• Perianal skin tags
• Acquired acrodermatitis enteropathica-like lesions (patients with zinc deficiency and/or essential fatty acid deficiency)
• Epidermolysis bullosa acquisita
• Psoriasis
• Hidradenitis suppurativa

Table 53.8 Skin findings in Crohn disease and ulcerative colitis. See Ch. 93 for discussion of mucocutaneous manifestations of Crohn disease.

Fig. 53.28 "Metastatic" Crohn disease. Noncontiguous granulomatous inflammation of the skin is often manifested by deep inflammatory fissures in the inguinal folds. These have been described as "knife-like" fissures.

Fig. 53.29 Hereditary hemorrhagic telangiectasia. Several small red macules and papules on the lips. *Courtesy Irwin Braverman, MD.*

Fig. 53.30 Blue rubber bleb nevus syndrome. Several venous malformations are evident on this patient's tongue.

PERISTOMAL SKIN DISORDERS	
Skin disorder	**Comments**
Irritant contact dermatitis	Most common cause of peristomal dermatitis, especially in patients with an ileostomy Primarily attributed to exposure to feces or urine
Pre-existing skin disease (e.g. psoriasis, seborrheic dermatitis, atopic dermatitis)	May reflect Koebner phenomenon Exclude primary contact dermatitis or infection or superimposed contact dermatitis
Cutaneous infection (*Candida* spp., dermatophyte, herpes virus [primarily simplex], bacteria [especially *Staphylococcus aureus*])	Colonization with bacteria and/or yeast is common Recent treatment with antibiotics predisposes to candidiasis May initially improve then worsen if treated inappropriately with topical corticosteroids
Allergic contact dermatitis	Relatively uncommon; potential allergens include: adhesive pastes, adhesive ring or wafer of stoma bag, ostomy bag, epoxy resin, rubber, lanolin, and fragrances Patch test with both standardized allergens and patient's own products
Pyoderma gangrenosum	Infrequent cause of peristomal dermatitis Most common in patients with inflammatory bowel disease (Fig. 53.27)
Pseudoverrucous papules and nodules	Seen more commonly in association with urostomies; may be misdiagnosed as verrucae vulgares or condylomata acuminata
Bullous pemphigoid	Localized to stoma site but may precede generalized disease Exclude bullous contact dermatitis

Table 53.9 Peristomal skin disorders. Peristomal skin disorders are common and may limit use and efficacy of the stoma appliance. When the etiology **is uncertain, evaluation can include KOH examination, microbial cultures, patch testing, and histologic examination.** *Adapted from Lyon CC, Smith AJ, Griffiths CE, Back MH. The spectrum of skin disorders in abdominal stoma patients. Br J Dermatol 2000;143:1248–60.*

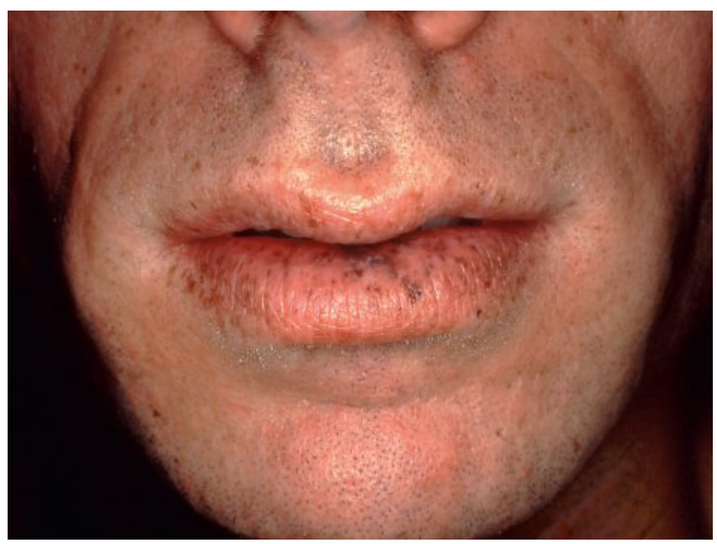

Fig. 53.31 Peutz–Jeghers syndrome. Multiple brown macules on the vermilion lips and a few on the lower cutaneous lip.

CUTANEOUS DISEASES ASSOCIATED WITH GASTROINTESTINAL BLEEDING OR HEMORRHAGE				
Disorder	**Cutaneous findings**	**Gastrointestinal features**	**Other pertinent findings**	**Treatment and comments**
Genetic (especially those associated with vascular malformations and GI polyps)				
Hereditary hemorrhagic telangiectasia (HHT)	Macular and papular telangiectasias on facial and acral skin as well as the oral mucosa (Fig. 53.29) Telangiectasias actually represent arteriovenous malformations (AVMs)	Recurrent hemorrhage in the upper GI tract due to AVMs Subset of patients have both juvenile GI polyposis and HHT, most commonly due to mutations in *SMAD4*; associated risk of early-onset colorectal cancer	Epistaxis is often the initial manifestation AVMs of the lungs, liver, and CNS	AD; ~80% of patients have mutations in *ENG* or *ACVRL1*, which encode endoglin and ALK1, both of which are TGF-β receptors Evaluation outlined in Table 104.6 Treatment consists of surgical resection, embolization or laser therapy of AVM causing hemorrhage
Blue rubber bleb nevus syndrome	Subcutaneous blue to purple venous malformations (Fig. 53.30)	GI vascular malformations	Possible vascular malformations in other organs (e.g. CNS, lungs, heart)	Mosaic due to double (cis) somatic *TEK* mutations in lesional tissue
Pseudoxanthoma elasticum	Yellow papules and plaques on neck and in intertriginous zones, redundant lax skin	Upper or lower GI hemorrhage	Angioid streaks in the eye, hypertension, premature atherosclerosis, uterine hemorrhage, vascular calcification	AR; due to mutations in *ABCC6*; PXE-like skin findings when mutations in *ENPP1* and *GGCX* Diet high in magnesium may be helpful
Ehlers–Danlos syndrome, vascular type	Translucent fragile skin with extensive bruising	GI hemorrhage due to arterial rupture or intestinal perforation	Minimal joint hyperextensibility (limited to digits), rupture of other arteries or the uterus, acrogeric facies	AD; deficiency of type III collagen
Gardner syndrome	Epidermoid cysts, pilomatricomas, lipomas, fibromas, and desmoid tumors	Hemorrhage from adenomatous colonic polyps Adenocarcinoma of the colon is universal if the colon is not removed	Mandibular and maxillary osteomas and cysts, *c*ongenital *h*ypertrophy of the *r*etinal *p*igment *e*pithelium (CHRPE)	AD; due to mutations in *APC* Colectomy must be appropriately timed
Peutz–Jeghers syndrome	Melanotic macules on mucosal surfaces (Fig. 53.31) and, less often, on acral or perioral skin	Hamartomatous polyps throughout the GI tract Intussusception or hemorrhage may occur	Increased incidence of breast, GI (colorectal, stomach, pancreatic, small intestine), lung, and GU (ovarian, uterine, cervical, testicular) carcinomas	AD; due to mutations in *STK11*, which encodes a serine/threonine kinase Screening includes upper endoscopy, video capsule endoscopy or MRE, and colonoscopy, beginning at age 8 years See www.cancer.net for additional screening recommendations
Cowden syndrome (PTEN hamartoma syndrome; multiple hamartoma syndrome)	Multiple facial or periorificial papules (tricholemmomas), perioral lentigines, cobblestoning of the oral mucosal surface (Fig. 53.32), acral keratotic papules, sclerotic fibromas, lipomas	Hamartomatous polyps throughout the GI tract Bleeding is rare as is colorectal carcinoma	Fibrocystic breast disease along with frequent cancers of the breast, often bilateral Thyroid tumors, including cancer GU carcinomas	AD; due to mutations in the *PTEN* tumor suppressor gene Screening recommendations are outlined in Table 63.3
Muir–Torre syndrome	Benign and malignant sebaceous neoplasms and multiple keratoacanthomas	Colorectal >> gastric carcinoma, carcinoma of the small bowel, hepatobiliary tract or pancreas	GU carcinomas (endometrial, ovarian, urinary tract) carcinomas second most common type after colorectal	AD; due to mutations in one of several mismatch repair genes, including *MSH2* (70%–90%), *MLH1* and *MSH6* Screening recommendations are outlined in Table 63.6
Inflammatory/autoimmune				
Cronkhite–Canada syndrome	Lentigines of buccal mucosa, face and hands/feet, alopecia, generalized nail thinning	Adenomatous GI polyps, diarrhea, abdominal pain	Weight loss due to malabsorption	Malignant degeneration is unusual, but 5-year mortality rate ~55%
Vasculitis	Palpable purpura, necrotizing livedo reticularis, nodules, or ulcers	Ulcerations secondary to vasculitis of the blood vessels in the bowel May be more common in IgA-associated vasculitis (Henoch–Schönlein purpura)	Arthritis and nephritis are two additional features of Henoch–Schönlein purpura	Corticosteroids and/or immunosuppressive agents may lead to improvement
Malignant atrophic papulosis (Degos disease)	Early lesions – pale red papules with central necrosis Late lesions – atrophic ivory scars	Small infarctions in the GI mucosa Hemorrhage and intestinal perforation may result in death	CNS involvement, pleuritis, pericarditis	No standard effective therapy Eculizumab and treprostinil may be beneficial in some patients Prognosis depends on systemic involvement

Table 53.10 Cutaneous diseases associated with gastrointestinal bleeding or hemorrhage.

CUTANEOUS DISEASES ASSOCIATED WITH GASTROINTESTINAL BLEEDING OR HEMORRHAGE				
Disorder	**Cutaneous findings**	**Gastrointestinal features**	**Other pertinent findings**	**Treatment and comments**
Ulcerative colitis	Erythema nodosum, vasculitis, pyoderma gangrenosum, aphthous stomatitis (see Table 53.8)	Uniform and continuous inflammation of the colon Rectal involvement is present in majority (>95%) of patients Toxic megacolon may develop	Colorectal carcinoma frequently occurs in uncontrolled, longstanding disease	Treatment options include 5-aminosalicylates, immunosuppressives (e.g. azathioprine, TNF inhibitors, vedolizumab), corticosteroids, and total colectomy
Crohn disease	Erythema nodosum, vasculitis, pyoderma gangrenosum, perianal fistulae, and noncontiguous Crohn disease (see Table 53.8)	Chronic inflammation, often granulomatous, of the bowel Skip areas occur	Aphthous stomatitis, arthritis, chronic blood loss	Treatment options include corticosteroids and other immunosuppressives, including azathioprine, TNF inhibitors, vedolizumab, ustekinumab, natalizumab
Nutritional				
Scurvy	Perifollicular purpura, corkscrew hairs	Collagen degeneration in the vasculature due to vitamin C deficiency GI blood loss results in anemia	Gingivitis with friable gums and easy bleeding, conjunctival hemorrhage, difficulty walking	Vitamin C replacement (see Table 51.2)
Neoplastic				
Kaposi sarcoma (KS)	Violaceous macules, papules, and nodules of the skin and oral mucosa	Similar tumors may occur in the GI tract Possible complications include ulceration, bleeding, perforation and ileus, which are more common in AIDS-related than in classic type	Includes AIDS-related (epidemic), African endemic, iatrogenic (immunosuppression-related), and classic subtypes (see Table 114.3) Caused by HHV-8 infection	Antiretroviral therapy or reduction of exogenous immunosuppression (if indicated), chemotherapy (e.g. liposomal anthracyclines, taxanes), and/or radiation therapy may be helpful for GI KS See Ch. 114 for treatment options for cutaneous KS
Adapted from refs 26 & 27.				

Table 53.10 Cutaneous diseases associated with gastrointestinal bleeding or hemorrhage. AD, autosomal dominant; AR, autosomal recessive; CNS, central nervous system; ENPP1, ectonucleotide pyrophosphatase/phosphodiesterase 1; GGCX, γ-glutamyl carboxylase; GI, gastrointestinal; GU, genitourinary; HHV, human herpesvirus; MRE, magnetic resonance enterography; SMAD, *s*mall (body size) plus *m*others *a*gainst *d*ecapentaplegic [involved in TGF-β signaling]; TGF, transforming growth factor.

Fig. 53.32 Gingival cobblestoning in Cowden disease. This patient also had trichilemmomas and a "Cowden nodule" or sclerotic fibroma on the neck.

Fig. 53.33 Necrolytic acral erythema. This is a manifestation of hepatitis C viral infection.

DERMATOLOGIC ASPECTS OF LIVER DISEASE		
Liver disease	**Dermatologic manifestations/associations**	**Other features, treatment, and comments**
Cirrhosis	• Spider angiomas and other telangiectasias • Palmar erythema • Dilated abdominal wall veins • Terry nails (white nail bed) • Muehrcke nails (transverse white bands) • Sparse axillary, pubic, and pectoral hair • Pruritus • Jaundice	• Gynecomastia • Parotid enlargement
Primary biliary cholangitis (PBC)	• Jaundice • Diffuse hyperpigmentation • Xanthomas – eruptive, planar and, occasionally, tuberous • Pruritus • May coexist with systemic sclerosis	Cholestyramine, rifampin, ursodiol, SSRIs, phototherapy, and opioid receptor antagonists may help to relieve pruritus (see Table 6.7) Treatment options for PBC include ursodiol, obeticholic acid, fibrates, colchicine, methotrexate, and liver transplantation
Hemochromatosis ("bronze diabetes")	• Generalized bronzing of the skin due primarily to an increase in melanin	See Table 53.4
Wilson disease (hepatolenticular degeneration)	• Kayser–Fleischer ring – golden brown or greenish circle of pigment in Descemet membrane at the periphery of the cornea • Blue lunulae • Pretibial hyperpigmentation	AR; due to mutations in *ATP7B* which encodes a copper-transporting ATPase Neuropsychiatric symptoms and jaundice are additional findings Treatment with copper-chelating drugs (trientine, penicillamine) or metallothionein-inducer drugs (zinc acetate); liver transplantation for hepatic failure
Hepatitis B and C viruses	• Cutaneous small vessel vasculitis (B,C) • Cryoglobulinemic vasculitis (C≫B) • Urticarial vasculitis (B,C) • Polyarteritis nodosa (classic – B, cutaneous – C) • Necrotizing livedo reticularis (C) • Urticaria (B,C) • Porphyria cutanea tarda (C>B) • Pruritus (B,C) • Lichen planus – particularly erosive oral disease (C) • Necrolytic acral erythema (Fig. 53.33) (C) • Gianotti–Crosti syndrome (B>C) • Erythema multiforme (B,C) • Erythema nodosum (B>C) • Sarcoidosis (following therapy with interferon and/or ribavirin) (C>B)	Treatment of hepatitis viral infections vary based on disease stage, patient comorbidities, and hepatitis C virus genotypes Hepatitis B Rx options include: entecavir, tenofovir, lamivudine, adefovir, telbivudine, and interferon Hepatitis C Rx options include: direct-acting antivirals (DAAs), which include hepatitis C protease and polymerase inhibitors (e.g. sofosbuvir + velpatasvir, glecaprevir + pibrentasvir); nowadays pegylated interferon + ribavirin is used less commonly

Table 53.11 Dermatologic aspects of liver disease. AR, autosomal recessive; Rx, treatment; SSRIs, selective serotonin reuptake inhibitors.

Blisters and erosions are common, and disease activity tends to wax and wane. Most reported cases have been associated with hepatitis C viral infection, and there has been variable success following treatment with oral zinc supplementation and/or treatment of the underlying hepatitis C viral infection. Occasionally, patients with hypothyroidism develop similar lesions[28].

OTHER SYSTEMIC DISEASES WITH CUTANEOUS MANIFESTATIONS

Sarcoidosis is an example of a multisystem disease with a range of cutaneous manifestations (see Ch. 93)[29]. Table 53.12 reviews the cardiac and dermatologic features of multisystem disorders (Fig. 53.34 & 53.35)[31,32]. Skin changes associated with pulmonary and renal disorders are summarized in Tables 53.13 and 53.14, respectively (Figs. 53.36–53.38)[33–38].

Pruritus is a feature of uremia, but can also occur in non-uremic patients on hemodialysis. It is still unclear why patients with chronic kidney disease on dialysis experience itching, and it may be localized or generalized (see Ch. 6).

Solid organ transplant recipients receive immunosuppressive agents, including cyclosporine, tacrolimus, sirolimus, azathioprine, and/or corticosteroids, in order to prevent rejection. The combination of these drugs predisposes the patient to two significant cutaneous problems: infection (e.g. HPV, CMV) and malignancy (e.g. squamous cell carcinoma, Kaposi sarcoma, Merkel cell carcinoma).

Pregnancy is an important physiologic state that is associated with its own specific dermatoses and with modification of other skin disorders (see Ch. 27)[39]. Mast cell disease is covered in Chapter 118. Internal diseases can have a range of effects on the nails, hair, and mucous membranes, and the reader is referred to the chapters that review these structures in detail. Leg ulcers are also potential clues to underlying disease and are discussed in Chapter 105.

Additional figures available in our eBook (see inside front cover for access code).

CARDIOCUTANEOUS ABNORMALITIES IN MULTISYSTEM DISORDERS			
Disease	**Cutaneous features**	**Cardiovascular findings**	**Comments**
Genetic			
Connective tissue disorders			
Cutis laxa	Lax redundant skin with reduced elasticity	Aortic dilation and rupture, pulmonary artery stenosis, right-sided heart failure	AD and AR forms due to mutations in several genes including those that encode elastin, EFEMP2/fibulin-4, fibulin-5, and V-type H^+ ATPase subunit (see Table 95.5); systemic involvement is more common in the AR form
Ehlers–Danlos syndrome (EDS)	Variable degree of skin hyperelasticity and fragility (e.g. "cigarette" paper scars, ecchymoses)	Classic and hypermobility types: aortic root dilation, mitral and tricuspid valve regurgitation or prolapse	Due to mutations in the genes encoding collagen V (classic type), tenascin X and adipocyte enhancer-binding protein 1 (classical-like types), collagen III (vascular type), and collagen I (cardiac valvular type)
		Vascular type: arterial aneurysms, dissection and rupture	
		Cardiac valvular type: valvular abnormalities	
Loeys–Dietz syndrome	Translucent skin, easy bruising, atrophic scarring, milia, atrophic scarring	Aortic aneurysms, arterial tortuosity; significant risk of aortic dissection and rupture, even at an early age	AD; mutations in the genes that encode TGF-β receptor 1 and 2, TGF-β 2 and 3, SMAD family member 2 and 3 Overlapping clinical features with Marfan syndrome and vascular type EDS, with variable craniofacial anomalies
Enzyme deficiencies			
Fabry disease	Angiokeratoma corporis diffusum, hypohidrosis	Hypertrophic cardiomyopathy, valvular abnormalities, conduction defects, progressive atherosclerotic disease of the coronary and cerebral arteries	α-Galactosidase A deficiency, X-linked recessive disorder Cardiac and cerebrovascular disease and renal failure are the usual causes of death
Homocystinuria	Livedo reticularis, malar rash, tissue-paper scars, diffuse pigmentary dilution	Atherosclerosis, arterial and venous thrombosis	AR; most commonly due to homozygous cystathionine β-synthase (CBS) deficiency; rarely due to deficiency of MTHFR or other enzymes listed in Table 97.1 Patients also exhibit marfanoid characteristics and ectopia lentis Hyperhomocysteinemia (due to homozygous MTHFR deficiency ≫ heterozygous CBS deficiency) also increases risk of arterial and venous thrombosis
Palmoplantar keratodermas			
Carvajal syndrome	Striate epidermolytic palmoplantar keratoderma, woolly scalp hair	Dilated left ventricular cardiomyopathy	AR; due to desmoplakin mutations
Naxos disease	Diffuse non-epidermolytic palmoplantar keratoderma, woolly scalp hair	Arrhythmogenic right ventricular cardiomyopathy	AR; due to mutations in the gene that encodes plakoglobin
Premature aging syndromes			
Hutchinson–Gilford progeria syndrome	Sclerodermoid changes, mottled hyperpigmentation, loss of subcutaneous fat, alopecia	Premature atherosclerosis	AD; premature aging syndrome due to mutations in the gene encoding lamins A and C
Werner syndrome	Premature graying, alopecia, sclerodermoid changes, loss of subcutaneous fat, ankle ulcerations	Premature atherosclerosis	Myocardial infarction is usually responsible for death by the fifth decade AR; due to mutations in *WRN*/*RECQL2*, which encodes a helicase Other features include cataracts and sarcomas
RASopathies (see NF1 below)			
Cardio-facio-cutaneous syndrome	Keratosis pilaris, keratosis pilaris atrophicans, focal palmoplantar keratoderma, numerous melanocytic nevi, café-au-lait macules, sparse curly hair, sparse or absent eyebrows and eyelashes	Pulmonic stenosis, atrial septal defects, hypertrophic cardiomyopathy	AD "RASopathy" due to mutations in four genes that encode proteins in the RAS/MAPK (mitogen-activated protein kinase) pathway (see Fig. 55.4): *BRAF* > *MAP2K1, MAP2K2* > *KRAS* Patients have characteristic facies, short stature, and developmental delay
Costello syndrome	Lax skin on the hands and feet, deep palmoplantar creases, periorificial papillomas, acanthosis nigricans, curly hair	Pulmonic stenosis, hypertrophic cardiomyopathy, arrhythmias	AD "RASopathy" due to mutations in two genes that encode proteins in the RAS/MAPK pathway: *HRAS* > *KRAS* Patients have mental and growth retardation and an increased risk of rhabdomyosarcoma and bladder carcinoma
Noonan syndrome with multiple lentigines/ LEOPARD syndrome	Multiple lentigines, café-au-lait and café-noir macules	ECG abnormalities, pulmonary artery stenosis	*L* – lentigines, *E* – ECG abnormality, *O* – ocular hypertelorism, *P* – pulmonary stenosis, *A* – abnormalities of the genitalia, *R* – retardation of growth, *D* – deafness AD "RASopathy" due to mutations in *PTPN11*, *RAF1*, and *BRAF* (see Fig. 55.4)

Table 53.12 Cardiocutaneous abnormalities in multisystem disorders.

Continued

CARDIOCUTANEOUS ABNORMALITIES IN MULTISYSTEM DISORDERS			
Disease	**Cutaneous features**	**Cardiovascular findings**	**Comments**
Tumor predisposition syndromes			
Carney complex (NAME and LAMB syndromes)	Cutaneous myxomas, blue nevi, lentigines, café-au-lait and café-noir macules	Atrial myxoma	Endocrine neoplasia of the adrenal glands, pituitary gland, and/or testes AD – due to mutations in *PRKAR1A*; 2nd genetic locus on chromosome 2p16
Multiple endocrine neoplasia (MEN) types 2A (Sipple syndrome) and 2B (multiple mucosal neuroma syndrome)	MEN 2A – notalgia paresthetica, macular or lichen amyloidosis, often with childhood onset MEN 2B – neuromas of the eyelids, lips, tongue and other mucosal sites	Hypertensive crises due to pheochromocytomas (often bilateral)	AD; due to mutations in the *RET* proto-oncogene Also manifest with medullary cell carcinoma of the thyroid (MEN 2A and 2B), parathyroid adenomas (MEN 2A), and a marfanoid habitus (MEN 2B)
Neurofibromatosis 1 (NF1)	Café-au-lait macules, neurofibromas, intertriginous freckling (lentigines)	Hypertension, essential or due to pheochromocytoma or renal artery stenosis	AD; due to mutations in *NF1*, which encodes neurofibromin; the latter interacts with the RAS/MAPK pathway (see Fig. 55.4)
Tuberous sclerosis complex (TSC)	Facial angiofibromas, ungual fibromas, ash leaf macules, shagreen patch	Cardiac rhabdomyomas, arrhythmias	Developmental delay, seizures, renal angiomyolipomas, CNS tumors, lymphangioleiomyomatosis (women) Due to mutations in *TSC1* or *TSC2*, which encode hamartin and tuberin, respectively
Other			
Hemochromatosis	Generalized bronzing of the skin due primarily to an increase in melanin	Congestive heart failure, supraventricular arrhythmias	See Table 53.4
Inflammatory/autoimmune			
Behçet disease	Oral and genital aphthae, pathergy, pustular vasculitis, pyoderma gangrenosum-like lesions, erythema nodosum-like lesions	Pericarditis, coronary arteritis, myocarditis, arrhythmias, valvular disease; vasculitis of the vasa vasorum, primarily of large blood vessels	Ocular and CNS involvement Inflammatory bowel disease should be excluded
Dermatomyositis	Gottron papules, heliotrope rash, photodistributed poikiloderma (see Table 53.2)	Usually asymptomatic; arrhythmias, conduction defects; pericarditis and congestive heart failure are rare	Cardiac involvement is a poor prognostic sign
DRESS/DIHS (drug hypersensitivity with eosinophilia and systemic symptoms/drug-induced hypersensitivity syndrome)	Widespread morbilliform, urticarial or EM-like eruption and erythroderma; facial edema and lymphadenopathy often present	Myocarditis due to infiltrates of eosinophils Can occur during initial presentation or be delayed, including following corticosteroid taper Elevated cardiac enzymes, ECG changes, systolic dysfunction on echocardiography	Myocarditis associated with mortality rate up to 50%–55% Fever, hepatitis, and peripheral eosinophilia common (see Table 21.9) Treatment consists of discontinuation of offending drug and corticosteroids +/– other immunosuppressives Long-term consequences include persistent cardiac and thyroid dysfunction[30]
Kawasaki disease (mucocutaneous lymph node syndrome)	Glossitis, cheilitis, acral erythema, edema and desquamation, polymorphous eruption, conjunctival injection	Coronary arteritis, coronary artery aneurysms	High fever, lymphadenopathy Treatment with IVIg and aspirin significantly decreases risk of coronary artery disease
Neonatal lupus erythematosus (NLE)	Transient, non-scarring annular lesions of LE (SCLE-like) that favor the periorbital region	Congenital heart block (CHB)	Presumed to be due to transplacental passage of autoantibodies, most commonly anti-SSA/Ro, but anti-RNP also detected May have transient cytopenias and hepatitis Mothers may have a known AI-CTD (~50%) and in those without a known AI-CTD, a significant percentage will develop one over time; for mothers with anti-SSA/Ro antibodies, there is <1% chance of having a baby with NLE, but once have baby with NLE, chance in subsequent pregnancies is 25% Hydroxychloroquine may reduce recurrence rate
Systemic lupus erythematosus	Malar erythema, photosensitivity, range of lupus skin lesions Patients with antiphospholipid antibodies may have necrotizing livedo reticularis, leg ulcers or widespread cutaneous necrosis (Fig. 53.34)	Pericarditis, verrucous endocarditis (Libman–Sacks), coronary artery disease	Anti-cardiolipin antibody may play a role Treatment of LE with systemic corticosteroids may predispose to coronary artery disease
Multicentric reticulohistiocytosis	Erythematous nodules of the hands and, less often, the extremities and the face (Fig. 53.11)	Pericarditis, congestive heart failure, coronary artery disease, cardiomegaly	Deforming arthritis is frequent

Table 53.12 Cardiocutaneous abnormalities in multisystem disorders.

CARDIOCUTANEOUS ABNORMALITIES IN MULTISYSTEM DISORDERS			
Disease	**Cutaneous features**	**Cardiovascular findings**	**Comments**
Psoriasis	Well-demarcated, pink-to-red plaques with silvery scale on the elbows, knees and scalp, around the umbilicus, and in the gluteal cleft	Increased risk of cardiovascular disease, including cerebrovascular and peripheral artery disease In patients with moderate to severe psoriasis, possible increased risk of death from atherosclerotic cardiovascular disease	High incidence of metabolic syndrome in patients with moderate to severe psoriasis (see Table 53.5) Systemic therapy may reduce mortality from cardiovascular disease
Relapsing polychondritis	Beefy, red ears (sparing the lobes); inflammation in other tissues with cartilage (e.g. nose, larynx, trachea) Late findings include floppy ears and weakness in other areas where the cartilage was affected (Fig. 53.35)	Aortic and mitral regurgitation, aortic root dilation, aortic aneurysms (thoracic, abdominal) > heart block, pericarditis, coronary artery vasculitis	Arthritis, scleritis, eyelid edema and chemosis, tracheal collapse, MDS; for latter consider VEXAS syndrome Rx: dapsone, corticosteroids, and/or other immunosuppressive agents
Rheumatic fever	Erythema marginatum, subcutaneous nodules	Pancarditis in the acute phase Late manifestations include mitral and/or aortic valve dysfunction	Rare in US Follows pharyngitis due to group A β-hemolytic streptococcal infection Polyarthritis, chorea, fever
Sarcoidosis	Papules, nodules, plaques and/or lesions in scars (Fig. 53.36)	Conduction defects, congestive heart failure	Pulmonary disease, lymphadenopathy, hepatic involvement, hypercalcemia Cardiac involvement denotes a poor prognosis
Systemic sclerosis (scleroderma)	Cutaneous sclerosis, Raynaud phenomenon	Pulmonary artery hypertension, conduction defects, pericarditis, visceral Raynaud phenomenon	Cardiac involvement denotes a poor prognosis May also have interstitial lung disease
Vasculitis	Palpable purpura, nodules, livedo reticularis, ulcerations	Coronary artery vasculitis	Arthritis, GI colic, or bleeding Cardiac involvement is uncommon
Neoplastic			
Primary systemic amyloidosis (AL)	Pinch purpura, waxy skin, translucent papules, macroglossia	Restrictive cardiomyopathy, conduction disturbances	Proteinuria, urinary light chains, association with plasma cell dyscrasia ≫ multiple myeloma
Carcinoid syndrome	Flushing, telangiectasias, pellagra-like dermatitis, and occasionally sclerodermoid features	Endocardial plaques – tricuspid insufficiency, conduction defects	Flushing associated with ~10% of mid-gut tumors (small intestine, appendix, proximal colon) and liver metastases are required; type III gastric and bronchial carcinoid tumors are also associated with flushing (liver metastases are not required)
Infectious			
Endocarditis – bacterial or fungal	Purpura, nail-fold infarction, Janeway lesions, Osler's nodes In subacute bacterial endocarditis, vasculitis, digital clubbing	Vegetations and dysfunction of the valves	Fever often present
Metabolic/endocrine			
Diabetes mellitus	See Table 53.4	Coronary artery and peripheral artery disease	Occurs with both type 1 and type 2; insulin resistance may contribute
Hyperlipidemia	Xanthomas of multiple types	Coronary artery disease	See Ch. 92
Other			
Exfoliative erythroderma	Exfoliative dermatitis	High-output cardiac failure	The eruption may be idiopathic or due to a drug, primary skin disease (e.g. dermatitis, psoriasis), or neoplasm (e.g. cutaneous T cell lymphoma)
PHACE(S) syndrome	Segmental infantile hemangioma, most often of the face and neck	Coarctation of the aorta, atrial and ventricular septal defects, anomalous cervical and cerebral arteries	*P* – posterior fossa malformations, *H* – hemangioma, *A* – arterial anomalies, *C* – cardiac defects and coarctation of the aorta, *E* – eye anomalies, *S* – sternal defects and supraumbilical raphe

Table 53.12 Cardiocutaneous abnormalities in multisystem disorders. AD, autosomal dominant; AI-CTD, autoimmune connective tissue disease; AR, autosomal recessive; CNS, central nervous system; ECG, electrocardiogram; GI, gastrointestinal; EFEMP2, epidermal growth factor (EGF)-containing fibulin-like extracellular matrix protein 2; IVIg, intravenous immunoglobulin; LAMB, lentigines, atrial myxoma, mucocutaneous myxoma, blue nevi; LE, lupus erythematosus; MDS, myelodysplasia syndrome; MTHFR, methylenetetrahydrofolate reductase; NAME, nevi, atrial myxoma, myxoma of the skin, ephelides; TGF, transforming growth factor; VEXAS, vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic. *Adapted from Jorizzo JL, Callen JP. Dermatologic manifestations of internal disease. In: Arndt KA, Robinson JK, LeBoit PE, et al (eds). Cutaneous Medicine and Surgery, Philadelphia: WB Saunders, 1996:1863–89.*

Fig. 53.34 Antiphospholipid antibody syndrome. In addition to bland thromboses, these patients may have cardiac valvular vegetations.

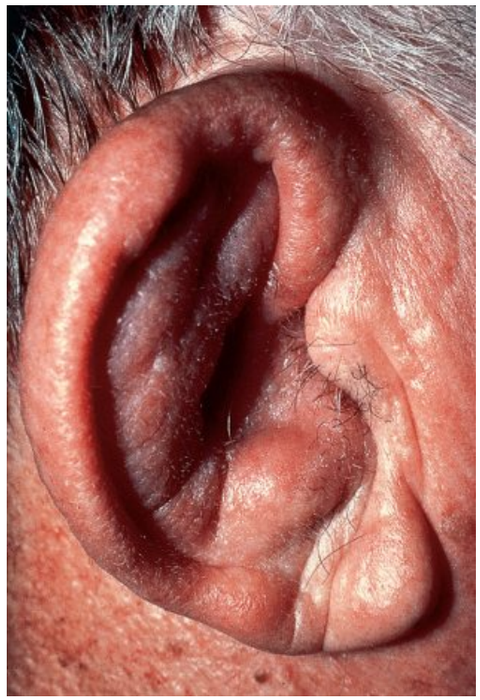

Fig. 53.35 Relapsing polychondritis. The inflammation spares the earlobes, which lack cartilage.

PULMONARY DISEASE AND THE SKIN				
Disorder	**Cutaneous findings**	**Pulmonary disease**	**Other features**	**Treatment and comments**
Genetic				
Birt–Hogg–Dubé syndrome	Classic triad of fibrofolliculomas, trichodiscomas and acrochordons	Lung cysts, spontaneous pneumothoraces	Increased risk of renal carcinoma Due to mutations in the gene encoding folliculin	High-resolution CT scan of the chest and renal MRI scan (preferred) or abdominal/pelvic CT scan* See Table 111.1 for recommendations regarding frequency of screening exams
Hereditary hemorrhagic telangiectasia	Macular and papular telangiectasias on facial and acral skin as well as the oral mucosa (Fig. 53.29) Telangiectasias represent AVMs	Pulmonary AVMs that can lead to hypoxia, hemorrhage, and paradoxical emboli	Epistaxis, recurrent GI bleeding, AVMs in other organs including the CNS	Transcatheter embolotherapy; antibiotic prophylaxis for procedures with risk of bacteremia and avoiding air bubbles during IV access (see Table 104.6)
Yellow nail syndrome	Thickened, slow-growing, excessively curved, yellow-to-green nails with onycholysis, transverse ridging, onychomadesis, and absent cuticles and lunulae	Pleural effusions, bronchiectasis, chronic bronchitis	Lymphedema, sinusitis	Complete triad of yellow nails, lymphedema and respiratory tract involvement seen in only one-third of patients; 2 of 3 findings needed for diagnosis Treatment options outlined in Ch. 71
Tuberous sclerosis complex	See Table 53.12	Lymphangioleiomyomatosis (women)	See Table 53.12	Outlined in Ch. 61
Inflammatory/autoimmune				
Sarcoidosis – chronic	Papules, nodules, plaques (Fig. 53.36), lupus pernio, lesions in scars and tattoos; acquired ichthyosis	Fibrosis secondary to granulomatous inflammation can lead to “honeycombing” of the lung parenchyma	Hypercalcemia, lymphadenopathy, hepatosplenomegaly, uveitis, CNS disease, bone cysts	Rx of skin lesions includes hydroxychloroquine, MTX, prednisone, other immunosuppressive agents (e.g. oral tacrolimus, TNF inhibitors, JAK inhibitors)
Sarcoidosis – acute	Erythema nodosum	Bilateral hilar lymphadenopathy	Arthritis, anterior uveitis	Self-limiting NSAIDs or potassium iodide may provide symptomatic relief

Table 53.13 Pulmonary disease and the skin.

PULMONARY DISEASE AND THE SKIN				
Disorder	**Cutaneous findings**	**Pulmonary disease**	**Other features**	**Treatment and comments**
Granulomatosis with polyangiitis (formerly Wegener granulomatosis)	Vasculitic lesions (e.g. palpable purpura, nodules), crusted papules due to RGD, pyoderma gangrenosum-like ulcers (see Table 24.7)	Dyspnea, cough, hemoptysis, and/or pleuritis; irregular pulmonary infiltrates or nodules that may cavitate	Glomerulonephritis, upper respiratory tract inflammation, mucosal ulceration, friable hypertrophic gingiva ("strawberry gums")	Presence of antineutrophil cytoplasmic antibodies (ANCA) may aid in diagnosis Rx (usually combination): corticosteroids, rituximab, cyclophosphamide, methotrexate, sulfonamides
Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome)	Palpable purpura, urticarial plaques, nodules, crusted papules of the elbows due to RGD, ulcers (see Table 24.7)	Asthma, eosinophilic pneumonia	Paranasal sinusitis, allergic rhinitis, nasal polyps, peripheral eosinophilia, mononeuritis multiplex, systemic vasculitis	Presence of antineutrophil cytoplasmic antibodies (ANCA) may aid in diagnosis Rx: corticosteroids, cyclophosphamide, mepolizumab, and/or rituximab
Dermatomyositis	Diffuse scaling and pruritus of the scalp, heliotrope, Gottron papules and sign, photodistributed poikiloderma, nail-fold overgrowth with dilated capillary loops	Interstitial lung disease (ILD), aspiration pneumonitis, hypoventilation	Proximal, symmetric muscle weakness	If PFTs demonstrate reduced DLCO, high-resolution chest CT should be performed Higher risk with anti-MDA5 (CADM-140) antibodies and antisynthetase syndrome Rx: corticosteroids, immunosuppressive agents (e.g. MTX, mycophenolate mofetil, JAK inhibitors), and/or IVIg
Systemic sclerosis (scleroderma)	DcSSc: Raynaud disease (sudden onset), more widespread sclerosis LcSSc: Raynaud disease (preceding long duration), limited, acrofacial sclerosis	DcSSc: Interstitial lung disease (ILD) > pulmonary artery hypertension (PAH) LcSSc: PAH > ILD	Esophageal dysmotility, hypertension, renal crisis, cardiomyopathy	Evaluation of ILD: PFTs, high-resolution chest CT Evaluation of PAH: transthoracic echocardiography, serum N-Tpro-BNP level Rx: mycophenolate mofetil, cyclophosphamide for ILD; endothelin receptor antagonists, prostacyclin analogues, phosphodiesterase-5 inhibitors for PAH
Urticarial vasculitis	Urticarial papules and plaques, often with a subtle purpuric component, angioedema	Chronic obstructive pulmonary disease	Hypocomplementemic variant may involve the joints, GI tract, kidneys and eyes as well as the lungs; patients may have SLE or Sjögren syndrome	Oral corticosteroids, hydroxychloroquine, dapsone, colchicine (see Table 24.10)
Neoplastic/paraneoplastic				
Kaposi sarcoma	Red–violet to dark purple plaques and/or nodules of the skin and oral mucosa; in the classic form, most commonly seen on the lower extremities	Multifocal involvement can be asymptomatic or lead to dyspnea, cough, hemoptysis and/or chest pain (especially in AIDS-related type)	Lymphedema of the lower extremities Gastrointestinal involvement common	See Table 53.10 for systemic therapies
Lymphomatoid granulomatosis	Papulonodules, plaques, ulcers	Cough, dyspnea, and chest pain due to angiocentric, angiodestructive infiltrate of atypical lymphocytes	Fever, arthralgias, myalgias; associated with EBV infection and diffuse large B cell lymphoma	Multi-drug chemotherapy and/or rituximab. If present, reversal of exogenous immunosuppression
Paraneoplastic pemphigus	Erosive disease of the mucous membranes and erythema multiforme-like, bullous pemphigoid-like or lichenoid skin lesions	Bronchiolitis obliterans	Most often associated with non-Hodgkin lymphoma, chronic lymphocytic leukemia or Castleman disease	Abnormal PFTs Rx: rituximab, immunosuppressive/cytotoxic medications, and/or plasmapheresis, IVIg Resection of Castleman disease can lead to remission of mucocutaneous lesions
Infectious				
Tuberculosis	Lupus vulgaris, orificial, acute miliary, tuberculous gumma, scrofuloderma (see Table 75.7)	Apical infiltrates, cavitating infiltrates; non-productive or productive cough	Fever, weight loss	Multi-drug regimens based on patient and antibiotic sensitivities (see Ch. 75)
Blastomycosis†	Verrucous, ulcerated plaques or nodules; may be studded with pustules, especially at the periphery	Patchy infiltrates, nodules, interstitial or miliary disease Chest X-ray may be normal	Bone and GU involvement, including testes	Inhalation followed by dissemination, including to skin; treatment includes itraconazole, amphotericin B

Table 53.13 Pulmonary disease and the skin.

Continued

PULMONARY DISEASE AND THE SKIN				
Disorder	**Cutaneous findings**	**Pulmonary disease**	**Other features**	**Treatment and comments**
Cryptococcosis	Variable cutaneous findings, from papulonodules and plaques to molluscum contagiosum-like lesions and cellulitis	Varies from asymptomatic infection to severe pneumonia and acute respiratory distress syndrome	Meningeal involvement (needs to be excluded via lumbar puncture)	Severe infections favor immunocompromised hosts Depending upon severity, amphotericin B ± flucytosine and/or fluconazole
Aspergillosis	Angioinvasive *Primary* cutaneous lesions – violaceous or necrotic papules, plaques, or nodules *Secondary* cutaneous emboli – necrotic papules and plaques, often with ulceration and rapidly progressive	In those with disseminated cutaneous emboli, cavitating infiltrates and nodules	In immunocompromised hosts, can disseminate widely	Disseminated disease affects primarily patients who are neutropenic and immunosuppressed (e.g. chronic corticosteroids) Rx: voriconazole or posaconazole + echinocandin, voriconazole, posaconazole, isavuconazonium sulfate, or amphotericin B May require surgical debridement
Varicella	Lesions in various stages of development, including papules, papulovesicles, pustules, and hemorrhagic crusts; cephalocaudal progression	Pulmonary involvement correlates with severity of skin involvement Interstitial infiltrates or patchy airway disease leads to cough and dyspnea	Liver and CNS additional sites of infection Reye syndrome associated with use of aspirin	Adults, pregnant or postpartum women, and immunocompromised individuals at highest risk for pulmonary disease Systemic antiviral medications recommended (see Table 127.23)
Other				
Toxic epidermal necrolysis	Widespread necrosis and detachment	When there is involvement of bronchial epithelium Acute respiratory distress syndrome, secondary bacterial pneumonia Chronic sequelae	Erosions of the oropharyngeal, nasal, conjunctival, esophageal, and GU mucosa	Prompt discontinuation of all potential culprit drugs; treatment options include etanercept, cyclosporine, corticosteroids, and IVIg; management in intensive care or burn unit

*Renal surveillance begins at age 20 years.
†Primary pulmonary infection also occurs in other systemic mycoses due to dimorphic pathogens, including coccidioidomycosis, histoplasmosis, and paracoccidioidomycosis.

Table 53.13 Pulmonary disease and the skin. Bronchiolitis obliterans can occur in the setting of graft-versus-host disease and thrombophilia with retiform purpura can be seen with severe SARS-CoV-2 infection. AVMs, arteriovenous malformations; CNS, central nervous system; CT, computed tomography; DcSSc, diffuse cutaneous systemic sclerosis; DLCO, diffusion of carbon monoxide; EBV, Epstein–Barr virus; GI, gastrointestinal; GU, genitourinary; HHV, human herpesvirus; IV, intravenous; IVIg, intravenous immunoglobulin; LcSSc, limited cutaneous systemic sclerosis; MRI, magnetic resonance imaging; MTX, methotrexate; NSAIDs, nonsteroidal anti-inflammatory drugs; *N*-Tpro-BNP, N-terminal pro b-type natriuretic peptide; PFTs, pulmonary function tests; RGD, reactive granulomatous dermatitis; Rx, treatment; SLE, systemic lupus erythematosus; TNF, tumor necrosis factor.

RENAL DISEASE AND THE SKIN				
Disorder	**Cutaneous findings**	**Renal abnormality**	**Other findings**	**Treatment and comments**
Genetic				
Tuberous sclerosis complex (TSC)	Facial angiofibromas, ash leaf macules, shagreen patch, ungual fibromas	Renal hamartomas (angiomyolipomas) Polycystic kidney disease may occur in a contiguous gene syndrome with TSC2	See Table 53.12	See Table 53.12
Fabry disease	Angiokeratoma corporis diffusum	Proteinuria, renal failure due to accumulation of globotriaosylceramide (Gb3) and related glycosphingolipids	Acral pain and paresthesias, hypohidrosis, corneal and lenticular opacities Hypertrophic cardiomyopathy, coronary artery disease, CVAs	X-linked recessive disorder Replacement therapy with the deficient enzyme, α-galactosidase A, migalastat (oral chaperone), renal transplantation
Nail–patella syndrome	Hypoplasia of the nails, with greatest involvement of medial digits; triangular lunulae	Congenital nephrosis, glomerulonephritis	Absence or hypoplasia of the patella, iliac horns	AD; due to mutations in *LMX1B*
Birt–Hogg–Dubé syndrome	Classic triad of fibrofolliculomas, trichodiscomas and acrochordons	Renal tumors, in particular chromophobe, oncocytic, and/or hybrid	Spontaneous pneumothoraces, lung cysts	See Table 53.13 & Table 111.1
Hereditary leiomyomatosis and renal cell cancer (Reed syndrome)	Multiple cutaneous leiomyomas	Type 2 papillary renal cell carcinoma (early-onset, aggressive) > collecting duct renal cell carcinoma Benign cysts	Uterine leiomyomas	AD; due to mutations in the gene encoding fumarate hydratase. See Table 117.2 for screening recommendations
BAP1 tumor predisposition syndrome	Epithelioid atypical Spitz tumors, cutaneous melanoma	Clear cell renal cell carcinoma	Uveal melanoma, mesothelioma, cholangiocarcinoma	AD; due to mutations in *BAP1*

Table 53.14 Renal disease and the skin.

RENAL DISEASE AND THE SKIN				
Disorder	**Cutaneous findings**	**Renal abnormality**	**Other findings**	**Treatment and comments**
Inflammatory/autoimmune				
Systemic lupus erythematosus (SLE)	Malar erythema, cutaneous LE lesions, photosensitivity, diffuse alopecia, vasculitis	Glomerulonephritis – focal, membranous or proliferative	Arthritis, serositis, cytopenias, multiple autoantibodies, hypocomplementemia	Varies, depending upon the organ system involved and the severity or type of involvement
Systemic sclerosis (scleroderma)	Raynaud phenomenon, diffuse or limited cutaneous sclerosis, CREST syndrome	Hypertension, renal crisis	Esophageal dysmotility, arthritis, interstitial lung disease, pulmonary artery hypertension (see Table 53.13)	Angiotensin-converting enzyme inhibitors, avoidance of high-dose corticosteroids if possible to reduce risk of renal crisis, dialysis, renal transplantation
Henoch–Schönlein purpura	Palpable purpura	IgA-associated glomerulonephritis which may be chronic	Arthritis, GI vasculitis with abdominal pain, GI bleeding, and/or vomiting	Supportive care; systemic corticosteroids may be beneficial for nephritis
Systemic (classic) polyarteritis nodosa (PAN)	Palpable purpura, retiform purpura, livedo reticularis/racemosa, ulcers > subcutaneous nodules	Renal artery aneurysms, renovascular hypertension, renal failure	Arthritis, mononeuritis multiplex, abdominal pain, orchitis, fever	For systemic PAN, corticosteroids +/– cytotoxic agents (e.g. cyclophosphamide) If present, treat HBV infection
Granulomatosis with polyangiitis (formerly Wegener granulomatosis)	Vasculitic lesions (e.g. palpable purpura, nodules), crusted papules due to PNGD, pyoderma gangrenosum-like ulcers (see Table 24.7)	Glomerulonephritis	See Table 53.13	See Table 53.13
Cutaneous small vessel vasculitis	Palpable purpura, urticarial lesions, hemorrhagic vesicles, and occasionally pustules or ulcerations	Glomerulonephritis may occur	Arthritis	Basic evaluation includes urinalysis Symptomatic therapy or corticosteroids, with or without immunosuppressive agents
Sarcoidosis	Papules, nodules, plaques (Fig. 53.36)	Hypercalciuria, nephrolithiasis	Lymphadenopathy, uveitis, pulmonary fibrosis, hepatosplenomegaly, CNS disease, hypercalcemia	Corticosteroids, immunosuppressive agents
Nephrogenic systemic fibrosis (NSF)	Woody indurated plaques on the extremities > trunk, often becoming confluent and limiting motion of the joints Peau d'orange appearance is common (Fig. 53.38)	Occurs primarily in patients with chronic renal failure on dialysis, but also described in renal transplant recipients and patients with acute renal failure	Systemic fibrosis (e.g. heart, lungs, skeletal muscle) has been observed Caused by gadolinium-containing contrast media Hypercoagulable state also a risk factor	Prevention via assessment of renal function pre-MRI Hemodialysis, renal transplantation, and, based upon case series, imatinib, rapamycin, UVA1 phototherapy, ECP
Neoplastic				
Primary systemic amyloidosis (AL)	Pinch purpura, hemorrhagic bullae, translucent papules, macroglossia	Proteinuria, including nephrotic syndrome, and renal insufficiency	Restrictive cardiomyopathy, paraproteinemia due to plasma cell dyscrasia	First line: daratumumab + dexamethasone + bortezomib + cyclophosphamide; lena-/pomalidomide, melphalan, isatuximab, hematopoietic stem cell transplant
Other				
Cutaneous changes of end-stage renal disease	1. Pale color, sallowness 2. Xerosis or acquired ichthyosis 3. Pruritus 4. Acquired perforating dermatosis 5. Pseudoporphyria 6. Calciphylaxis (Fig. 53.37) 7. Uremic frost	End-stage renal disease of various causes 1–6 are more common in dialysis patients; 7 is rarely observed	1. Anemia of chronic disease 2. – 3. Possible increase in tissue mast cells 4. Related to pruritus 5. Porphyrins may be borderline elevated or within normal limits 6. Risk factors include obesity, systemic corticosteroids, warfarin; calcium and phosphorus dysregulation, increased PTH level; calcification of the vessel walls and microthrombi lead to tissue necrosis	1. Erythropoietin, transplantation 2. Emollients, lactic acid or urea preparations 3. UV light 4. See Table 96.4 5. Erythropoietin, N-acetylcysteine 6. Dialysis optimization, phosphate binders (non-calcium), sodium thiosulfate, consider DOAC, wound care/hyperbaric oxygen; parathyroidectomy may be helpful 7. Dialysis
Cutaneous diseases associated with long-term immunosuppression	1. Infections – mycobacterial, viral, bacterial, fungal 2. Neoplasia – porokeratosis, squamous cell carcinoma, Kaposi sarcoma, Merkel cell carcinoma, melanoma	Transplant recipients with end-stage renal disease from various causes	–	Reduction in level of immune suppression Treat infections with appropriate antimicrobials Treat carcinomas with removal of lesions and reduce number with oral acitretin; consider sirolimus rather than calcineurin inhibitor

Table 53.14 Renal disease and the skin. AD, autosomal dominant; CNS, central nervous system; CREST, *c*alcinosis, *R*aynaud, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasias; CVA, cerebrovascular accident; DOAC, direct oral anticoagulant; ECP, extracorporeal photophoresis; GI, gastrointestinal; HBV, hepatitis B virus; MRI, magnetic resonance imaging; PTH, parathyroid hormone.

Fig. 53.36 Periorificial and facial papules of sarcoidosis. The presence of lesions on the nasal rim is often associated with granulomatous inflammation of the upper respiratory tract.

Fig. 53.37 Calciphylaxis. This patient presented with these necrotic skin lesions and was found to have severe end-stage renal disease due to renal amyloidosis.

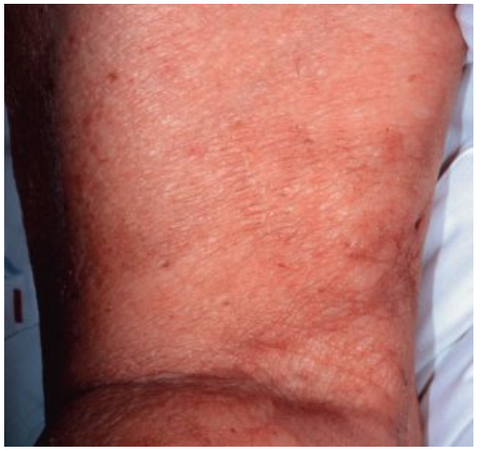

Fig. 53.38 Nephrogenic systemic fibrosis. This sclerosing disorder is seen almost exclusively in patients with renal failure who have received gadolinium-containing contrast media. In addition to the peau d'orange appearance of the skin, this patient had severe restriction of the movement of his hands, wrists, and feet.

54 Basic Principles of Genetics

Jennifer L. Hand and Angela M. Christiano

INTRODUCTION

The complete sequencing of the human genome, with an estimated size of 3.2 gigabases (Gb) containing ~20 000–25 000 genes[1], represented a major scientific accomplishment. Detailed information on human sequence variation and advanced technologies for its detection continue to broaden our knowledge of the genetic basis of human disease. The pathogenesis of many disorders also involves epigenetics, which represent heritable changes in phenotype and/or gene expression that do not result from changes in the DNA sequence.

A wide variety of molecular biology techniques (see Ch. 3) and information-based tools provide direct access to clinically relevant genetic information. Consequently, it is important for physicians in general, and dermatologists in particular, to understand basic concepts of genetics (Table 54.1). Familiarity with new techniques and approaches to identifying disease-causing genes is essential in order to appropriately utilize and interpret the results of genetic studies in the patient care setting. The wealth of new information emphasizes the need to bridge the gap between the bench and the bedside, bringing together efforts from the clinical and research arms of dermatology.

Access to patients with genetic disorders and accurate clinical descriptions are essential for laboratory investigations aimed at the identification of disease-causing genes. Combined with functional studies and translational approaches, these findings can in turn provide benefits to affected individuals. Such insights have importance in genetic counseling and prenatal diagnosis, and they can also contribute to the identification of at-risk individuals/families, prediction of disease course and possible complications, determination of response to therapeutic interventions, and even the development of targeted treatments.

Since the early 1980s, the molecular bases of numerous cutaneous genetic disorders have been elucidated, including multiple forms of epidermolysis bullosa (EB; see Ch. 32), ectodermal dysplasia (ED; see Ch. 63), and ichthyosis (see Ch. 57). The gene-identification strategies employed for these relatively uncommon Mendelian (single-gene) disorders have provided a foundation for the study of common complex disorders such as atopic dermatitis, psoriasis, and alopecia areata. Advances in mapping and detecting human sequence variation have led to more sophisticated approaches, including genome-wide association studies (GWAS) and whole-exome or whole-genome sequencing. Functional genomic studies, e.g. comparison of the transcriptome (expressed genes) in samples from patients and unaffected individuals, have also helped to identify candidate genes for further investigation. The clinician plays a key role in enabling such research, which requires a well-characterized collection of patient samples.

GENETIC DISEASES

Key features

- Accurate information about phenotype and family history is essential in identifying the pattern of inheritance of a genetic disease
- Genetic diseases include Mendelian (monogenic) disorders caused by defects in one gene as well as polygenic disorders due to defects in more than one gene; complex (multifactorial) disorders result from the interaction of environmental and genetic factors
- The major Mendelian patterns of inheritance are autosomal recessive (e.g. oculocutaneous albinism), autosomal dominant (e.g. Darier disease), X-linked recessive (e.g. hypohidrotic ectodermal dysplasia), and X-linked dominant (e.g. incontinentia pigmenti)
- Factors modifying the basic Mendelian pattern of inheritance include incomplete penetrance, age-dependent penetrance, variable expression, *de novo* mutations, pseudodominant inheritance, genomic imprinting, and mitochondrial inheritance
- Chromosomal anomalies can consist of abnormalities in the number (e.g. polyploidy, aneuploidy) or structure (e.g. translocations, inversions) of the chromosomes
- Heterogeneity at the locus or allelic level can make identification of the genetic defects responsible for cutaneous disorders challenging

Genetic diseases can manifest in multiple members of a family. However, not every disease presenting in more than one family member is genetic. Pedigrees of families in which a genetic disease is transmitted (i.e. segregates or is inherited) can range from a single affected member to many affected members in several generations.

Mendelian (monogenic) diseases are caused by defects in one gene, while *polygenic* diseases result from defects in more than one gene and *complex (multifactorial)* diseases result from the interaction of environmental and genetic factors. In addition to mutations within particular genes, abnormalities in the structure, number, or parental contribution of chromosomes can cause disease.

In the following sections, we provide an overview of the different types of genetic diseases. While this chapter focuses on genodermatoses, the explanations of Mendelian and complex traits also apply to extracutaneous diseases.

MENDELIAN PATTERNS OF INHERITANCE

A key initial step in the assessment of reproductive risk for a particular inherited disease is determination of its mode of inheritance. For this purpose, it is essential to collect accurate information on the clinical phenotype and to examine as many family members as possible to classify their status – affected or unaffected. The family is usually ascertained through one affected family member, the *proband*, around whom the pedigree is built with information on the phenotypes and relationships between different individuals.

Even when a single-gene defect is enough to cause a disease phenotype (monogenic disorders), the clinical expression can be affected by variable expression and incomplete penetrance (see below). Genes are expressed on a particular genetic background, which is different in every individual, and genes and their products interact with other genes and proteins. One can therefore expect that monogenic disorders will show some degree of variability.

Allelic heterogeneity refers to mildly or even considerably different clinical entities due to different mutations in the same gene[2–11] (Table 54.2). In contrast, *locus (genetic) heterogeneity* refers to mutations in different genes that result in the same phenotype[12–18] (Table 54.3). Of note, there are some diseases, such as EB simplex, that display both allelic and locus heterogeneity. Thus, diagnosis based purely on either clinical signs/symptoms or the results of genetic testing can lead to misclassification, underscoring the importance of integrating clinical and molecular findings.

Once a phenotype and its range of clinical findings are defined, the trait can be followed within a pedigree. The transmission of the trait in the pedigree defines the pattern of inheritance of the disease. The genes responsible for monogenic traits can be located either on autosomes, resulting in an autosomal pattern of inheritance, or on the X chromosome in the case of an X-linked pattern of inheritance. Irrespective of the gene location, when a mutation in one of two alleles

BASIC CONCEPTS IN GENETICS	
Nuclear DNA	• Deoxyribonucleic acid (DNA) contained within nuclei of eukaryotic organisms • Packed into chromosomes during cell division • Selectively folded and unfolded to allow the expression of appropriate genes at different times and in different cell types • Each somatic cell contains approximately 2 meters of DNA
Chromosome	• Organized structures of DNA and proteins that are found within a eukaryotic nucleus • Each diploid organism (including humans) has two sets of chromosomes, one from its father and one from its mother • Each pair of chromosomes contains two homologous chromosomes, one from each parent • Humans normally have 23 pairs of chromosomes: 22 pairs of autosomes and one pair of sex chromosomes (XX in females and XY in males) • Chromosomes X and Y share only two small homologous regions, known as pseudoautosomal regions
Karyotype	• Describes the full chromosomal constitution of an individual (e.g. 46, XY or 46, XX)
Haploid cell	• Contains only one chromosome complement or "n" (for humans, n = 23) • Gametes (paternal and maternal) are haploid cells
Diploid cell	• Contains two chromosome complements or "2n" (for humans, 2n = 46) • Human cells (other than gametes) are diploid

Centromere	• A site of constriction in a chromosome that is essential for correct cell division
	• Depending on the position of the centromere, chromosomes can be:
	  • *Metacentric*: centromere near the middle, two "arms" of similar length
	  • *Submetacentric*: centromere between the center and end, two "arms" of somewhat different lengths
	  • *Acrocentric*: centromere near the end, two "arms" of very different lengths
	• Composed of a series of histone proteins and repetitive DNA sequences (several thousand kilobases)
	• Divides the chromosome into two arms: the short (petite) arm or ***p***, and the long arm or ***q***

Telomere	• A region of repetitive DNA (TTAGGG sequence) and proteins at the ends of each chromosome • Plays a key role in the maintenance of chromosomal integrity and ensuring correct replication
Meiosis	• The process of cell division by which a diploid cell from the germline gives rise to haploid gametes via segregation and random assortment of homologous chromosomes • Results in combinations of chromosomes in the daughter cells that are different than that in the parental cell
Mitosis	• The process of somatic cell division of proliferating cells by which the genetic material of a cell is duplicated and equally distributed between the two resulting daughter cells • To achieve this duplication of genetic material, the chromosome replicates itself and forms two *sister chromatids*, which will each become the chromosome of a daughter cell
Locus	• The location of a particular sequence of DNA (e.g. a gene or DNA fragment) on a chromosome • Since we have two copies of each chromosome, we also have two copies of each locus, which can be identical or different
Gene	• A segment of DNA that encodes a protein (or occasionally an RNA chain) that serves a function

Allele	• Alternative forms of a particular gene or DNA sequence at a given locus
	• An individual has two alleles at each autosomal locus (one from each parent), and the locus/individual is referred to as:
	  • *Homozygous* if the alleles are identical
	  • *Heterozygous* if the alleles are different
	• Since males have only one copy of the X and Y chromosomes, they are *hemizygous* for loci on these two chromosomes

Polymorphic locus	• Exhibits at least two alleles with a frequency in the general population of >1% • Can be located within or outside of a gene
Single nucleotide polymorphism (SNP)	• A single nucleotide in a particular location within the genome that has at least two different forms with a frequency of >1% in the general population • Occurs on average every 1000 nucleotides
Mutation	• A change in the DNA sequence • Refers to variation resulting in a disease phenotype • Although any change in the DNA is technically a mutation, the term is often used to refer to a pathogenic variant that results in a disease phenotype
Genotype	• The alleles present at a specific locus (or in the whole genome) of an individual
Phenotype	• The manifestation of a particular genotype (in the context of the environment in which it is expressed) • Different genotypes are not always recognizable as distinct phenotypes • A change in a phenotype can be caused by variant alleles that are present in the general population (normal variation) or by pathogenetic variation that leads to a disease

Table 54.1 Basic concepts in genetics.

is sufficient to produce the phenotype, the trait is considered *dominant*. In contrast, when both alleles of a gene (or one allele in hemizygotes) must be altered in order to produce the phenotype, the condition is considered *recessive*. Hence, Mendelian inheritance patterns include autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive (Table 54.4). There are also Y-linked genes that primarily affect male fertility[19], although their relevance in more general diseases is possible.

Autosomal Dominant Inheritance

In a pedigree of an autosomal dominant disease, each affected person other than the first affected family member, who has a *de novo* mutation, has an affected parent. Both sexes are equally affected and can transmit the trait, and there is vertical transmission from generation to generation (Fig. 54.1A)[20–22]. Since a single mutant allele is enough to produce the phenotype, each offspring of an affected individual has a 50% risk of inheriting the mutant allele and therefore the disorder. Examples of

EXAMPLES OF ALLELIC HETEROGENEITY IN GENODERMATOSES	
Mutated gene	**Phenotypes**
GJB3	Erythrokeratodermia variabilis et progressiva AR and AD nonsyndromic hearing impairment AD peripheral sensory neuropathy and hearing impairment
Desmoplakin (*DSP*)	Striate palmoplantar keratoderma Carvajal syndrome (dilated cardiomyopathy with woolly hair and keratoderma) Severe dermatitis, multiple allergies, and metabolic wasting (SAM) syndrome Skin fragility–woolly hair syndrome Acantholytic erosive disorder Arrhythmogenic right ventricular cardiomyopathy
ABCA12	Harlequin ichthyosis Lamellar ichthyosis
Plectin (*PLEC*)	EBS and limb-girdle muscular dystrophy EBS of the Ogna type EBS with pyloric atresia

EXAMPLES OF GENODERMATOSES WITH LOCUS (GENETIC) HETEROGENEITY	
Phenotype	**Gene**
Striate palmoplantar keratoderma	*DSG1* *DSP* *KRT1*
Epidermolytic ichthyosis	*KRT1* *KRT10*
Epidermolysis bullosa simplex (localized and generalized variants)	*KRT5* *KRT14*
Hermansky–Pudlak syndrome (HPS)	*HPS1, HPS3, HPS4, HPS5, HPS6* *AP3B1, AP3D1* *DTNBP1, BLOC1S3, BLOC1S5, BLOC1S6*
Tuberous sclerosis complex (TSC)	*TSC1* *TSC2*
Hypohidrotic ectodermal dysplasia*	*EDA* (ectodysplasin A) *EDAR* (ectodysplasin A receptor) *EDARADD* (EDAR-associated death domain)

*Mutations in different genes result in X-linked recessive (EDA), autosomal recessive (EDAR, EDARADD), and autosomal dominant (EDAR, EDARADD) forms of the disorder (see Fig. 63.15).

Table 54.3 Examples of genodermatoses with locus (genetic) heterogeneity[12–18]. *AP3B1/D1*, adaptor related protein complex 3, β1/δ1 subunit gene; *BLOC1S3/5/6*, biogenesis of lysosome-related organelles complex-1, subunit 3/5/6 gene; *DSG1*, desmoglein 1 gene; *DSP*, desmoplakin gene; *DTNBP1*, dystrobrevin binding protein 1 gene; *KRT*, keratin gene.

PATTERNS OF INHERITANCE					
Pattern	**Parents affected**	**Sex affected**	**Transmission**	**Recurrence risk**	**Risk factors**
Autosomal recessive	No (carriers)	Both equally	Disease seen in siblings of proband, not in parents or offspring Usually only in one generation	1 in 4	Consanguinity, isolated population (e.g. geographically, linguistically)
Autosomal dominant	Yes*	Both equally	Disease seen in successive generations	1 in 2	*De novo* mutations
X-linked recessive	Mother a "carrier"*	Males have the "complete" disease Female "carriers" may have mild manifestations (e.g. in a mosaic pattern)†	No male-to-male transmission (but all daughters of an affected male are "carriers")	1 in 2 male children born to a female "carrier" will be affected (and 1 in 2 of her female children will be carriers)	*De novo* mutations
X-linked dominant	Yes*	Predominantly females if lethal in males during embryonic development; otherwise milder in females (often with a mosaic pattern of skin lesions) and more severe in males	Affected males have: (1) no affected sons; and (2) all daughters affected No male-to-male transmission	1 in 2 children born to affected female; may spontaneously abort male fetuses if "male-lethal" condition	*De novo* mutations

*Unless the proband has a *de novo* mutation and is therefore the first generation affected.
†Does not represent a "pure" X-linked recessive disorder if there are manifestations in female "carriers".

Table 54.4 Patterns of inheritance.

autosomal dominant genodermatoses include EB simplex, Darier and Hailey–Hailey diseases, and nail–patella syndrome.

A patient with an autosomal dominant disease is usually heterozygous for the disease-causing mutation. Homozygosity for autosomal dominant traits occasionally occurs, and this usually results in a more severe phenotype. For example, a mutation in the keratin 14 gene (*KRT14*) may give rise to localized EB simplex when heterozygous but generalized EB simplex when homozygous[23]. Exceptions to the expected autosomal dominant inheritance pattern may also be due to incomplete penetrance or variable expression (see below).

Dominant mutations can give rise to a phenotype by: (1) *haploinsufficiency*, in which the protein produced from one wild-type (non-mutant) allele is not sufficient to sustain normal function; or (2) a *dominant negative effect*, where the mutated proteins physically interfere with wild-type proteins and prevent them from functioning properly. The latter mechanism often occurs when the mutated protein forms dimers or polymers; examples include keratins (e.g. *KRT14* in EB simplex) and tyrosine kinase receptors (e.g. *KIT* in piebaldism).

Autosomal Recessive Inheritance

In a pedigree of an autosomal recessive disease, an affected individual has clinically unaffected parents, both sexes are equally affected, and there is no transmission from generation to generation (Fig. 54.1B). Both alleles of a given gene must be mutated for the disease to develop. When both parents are heterozygous carriers of a pathogenic allele, the chance of inheriting the disorder is 25% for each of their offspring. Oculocutaneous albinism type 1 and atrichia with papular lesions are examples of autosomal recessive genodermatoses.

There is often an increased frequency of *consanguinity* (sharing a common ancestor) in families with rare recessive conditions. Consanguineous matings (inbreeding) increase the probability that a mutated allele present in the common ancestor will become homozygous in the offspring (homozygosity by descent); these individuals are typically also homozygous for the region surrounding this mutated gene. When more than one affected family member with an autosomal recessive disease is present in a single pedigree, they are usually part

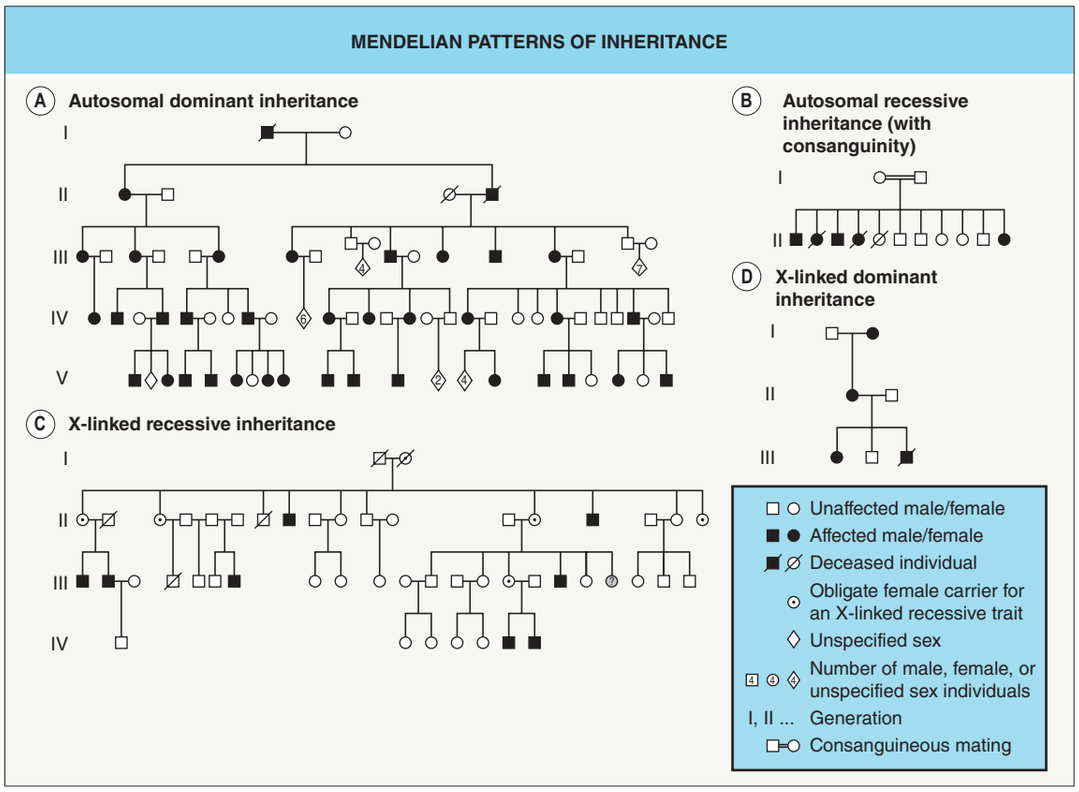

Fig. 54.1 Mendelian patterns of inheritance. A Autosomal dominant. Note the involvement of both sexes in multiple generations. **B** Autosomal recessive. **C** X-linked recessive. **D** X-linked dominant lethal, e.g incontinentia pigmenti.
A, Adapted from ref. 22; B, Adapted from ref. 21; C, Adapted from ref. 46; D, Adapted from ref. 20.

of the same generation. However, the presence of consanguinity can also explain some pedigrees in which an autosomal recessive trait is observed in more than one generation. For example, matings between unaffected carriers and affected patients can give rise to affected family members in two consecutive generations (pseudodominant inheritance; see below).

Patients with an autosomal recessive disease have two mutant alleles (biallelic mutations), while both of their parents are typically heterozygous carriers of one mutant allele and one wild-type allele. If both parents carry the same mutation, their affected offspring will be homozygous for the disease-causing mutation; this is the usual mechanism in consanguineous families. However, the parents may carry two different mutations in the same gene, and their affected offspring will be *compound heterozygous*.

X-Linked Recessive Inheritance

Patients with an X-linked recessive disease are typically male, and they classically have unaffected parents. However, in several X-linked "recessive" disorders, patients' mothers have some clinical evidence of the condition due to functional mosaicism (see Ch. 62). These mosaic manifestations in female "carriers" blur the distinction between recessive and dominant forms of X-linked inheritance, thereby removing such conditions from the "pure" X-linked recessive category. With variable skewing of X-inactivation (see below), the spectrum of disease in female "carriers" can range from absent to severe.

There is no male-to-male transmission, since an affected male will transmit his Y chromosome and not the mutated X chromosome to each son, and the complete (non-mosaic) trait does not appear in successive generations (Fig. 54.1C). However, one rare exception is the offspring of an affected male and a female carrier.

The inheritance risk for the offspring depends on the parent transmitting the disease allele. An affected father will transmit his mutated X chromosome (but not the complete disease) to all his daughters, but to none of his sons. Thus, his daughters become obligate carriers and will transmit the mutated allele to 50% of their children. As a result, the sons and daughters of a carrier mother will have a 50% chance of being affected or carriers, respectively.

Examples of recessive X-linked diseases in dermatology include hypohidrotic ectodermal dysplasia and X-linked recessive ichthyosis (steroid sulfatase [STS] deficiency; see Ch. 57). Because the *STS* gene is located on a region of the X chromosome that partially escapes inactivation, female carriers do not show any features of the disorder.

X-Linked Dominant Inheritance

In a pedigree of an X-linked dominant disease, affected individuals have an affected parent, with the exception of the first affected family member. Unless male-lethal, these disorders occur in both males and females. However, because females are heterozygous rather than hemizygous, they generally have a milder and/or mosaic phenotype (see below). There is no male-to-male transmission, and the trait appears in successive generations (Fig. 54.1D). The risk of the offspring inheriting the disease depends on the transmitting parent. An affected father will transmit the trait to all his daughters, but to none of his sons. An affected mother, on the other hand, will transmit the trait to 50% of her children, regardless of the sex of the offspring.

Some X-linked dominant diseases are lethal in males during early intrauterine development. In this situation, the disorder almost exclusively affects females, and when these women become pregnant they may have an increased frequency of spontaneous abortions. Occasional male patients can be explained by mosaicism, either functional in the setting of Klinefelter syndrome (47, XXY karyotype) or genomic due to mosaicism secondary to a *de novo* half-chromatid or postzygotic mutation (see Ch. 62).

Because female embryos undergo lyonization, i.e. the random epigenetic inactivation of one of the two X chromosomes in each cell, female patients with X-linked dominant skin diseases typically have a mosaic pattern of cutaneous lesions (see Ch. 62). Non-random patterns of X-inactivation in these patients may reflect preferential survival of cells expressing the normal X chromosome. Examples of X-linked dominant, male-lethal diseases in which girls present with a mosaic pattern of skin findings are focal dermal hypoplasia (Goltz syndrome)[24] and incontinentia pigmenti[25].

EXCEPTIONS TO BASIC MENDELIAN PATTERNS OF HERITANCE

Although the genotype at a single locus is responsible for the development of a Mendelian disease, other factors can affect the phenotypic manifestations and pattern of inheritance. Exceptions to basic Mendelian inheritance patterns are presented in Table 54.5 and Fig. 54.2.

EXCEPTIONS TO BASIC MENDELIAN INHERITANCE PATTERNS			
Type of exception	**Impact on phenotype and inheritance**	**Examples in dermatology**	**Impact on genetic counseling**
Variable expression	• Different degrees of phenotypic manifestation of a particular genotype, either between or within families • *Genetic anticipation* refers to the tendency of certain traits (primarily neuromuscular conditions) to increase in severity through successive generations	Broad ranges of severity in Darier disease and neurofibromatosis type 1	• Difficult to predict the severity of the phenotype
Incomplete/reduced penetrance	• Not all individuals with the disease genotype manifest with the condition • An AD trait may appear to skip a generation (see Fig. 54.2A)	Hereditary leiomyomatosis and renal cell cancer syndrome	• With incomplete penetrance, the phenotype may not correlate with the genotype
Age-dependent penetrance	• In *late-onset diseases*, some individuals are too young to exhibit manifestations	Late onset in Darier and Hailey–Hailey diseases	• Younger individuals in a pedigree may falsely appear to be unaffected
X-inactivation (lyonization; see Ch. 62)*	• The phenotype of an X-L condition in a female patient depends on the proportion of cells expressing the mutant allele in a particular tissue • Skewed/non-random X-inactivation can result from negative selection against cells with an active mutant allele • X-L skin disorders typically have a mosaic distribution	Skewed X-inactivation favoring the wild-type allele in the skin of girls with incontinentia pigmenti and the hematopoietic cells of female carriers of X-L dyskeratosis congenita	• In general, X-L dominant traits are milder in females than in males, and female "carriers" of X-L "recessive" conditions can exhibit some symptoms
De novo mutations	• A *de novo* (new) mutation (e.g. during meiosis) can produce an AD disease in a child who has no family history of that condition • *De novo* mutations account for a higher proportion of affected individuals in AD diseases that are severe or otherwise decrease reproductive fitness	*De novo* mutations account for ~30%–50% of patients with NF1 and >60% of those with tuberous sclerosis complex	• Future offspring of the unaffected parents of a child with an AD disease due to a *de novo* mutation are not at increased risk of the condition
Genomic mosaicism: somatic and gonadal (see Ch. 62)	• Genomic mosaicism results from a postzygotic alteration in the DNA sequence that gives rise to a genetically heterogeneous organism • The timing of the mutational event and the cell type(s) affected influence the extent, distribution, and type of clinical findings • Although a postzygotic mutation in somatic cells is not transmitted to the offspring, a mosaic mutation affecting the gonads may transmit *generalized* disease to the offspring	Transmission via gonadal mosaicism has been documented in NF1, dominant dystrophic EB, and epidermolytic ichthyosis (± an epidermolytic epidermal nevus reflecting somatic mosaicism in the parent)	• The proportion of gonadal cells that carry the dominant mutation determines the risk for generalized disease in the offspring; affected children are born to clinically unaffected or mosaic parents in the first generation, with an AD inheritance pattern in subsequent generations
Type 1 and 2 mosaicism/segmental manifestations in AD disorders (see Ch. 62)	• Cutaneous mosaicism can result in skin changes following the lines of Blaschko or in other segmental patterns (e.g. a block-like distribution) • In *type 1 mosaicism*, segmental affected skin is heterozygous for a dominant mutation, with a wild-type, unaffected background • In *type 2 mosaicism*, the genetic background is heterozygous for a mutation that causes an AD disorder, and a postzygotic mutation in the other allele ("second hit" resulting in loss of heterozygosity; see below) leads to a segmental region of skin with two mutations and often more severe disease	Type 1: epidermal nevi, linear Darier disease Type 2: linear porokeratosis superimposed on disseminated superficial actinic porokeratosis, segmental Hailey–Hailey disease in the setting of milder classic symmetric disease	• In patients with type 1 segmental skin disease, the potential presence of gonadal (in addition to somatic) mosaicism may result in some risk for generalized disease in offspring • In type 2 segmental diseases, the "background" condition has an AD inheritance pattern, with a 50% chance of the mutant allele being transmitted to each offspring
Loss of heterozygosity in AD tumor predisposition syndromes	• Affected individuals have a constitutional heterozygous loss-of-function mutation in a tumor suppressor gene that is involved in the regulation of cell growth • These individuals are at high risk of tumor formation, which can result from a single somatic mutation ("second hit") inactivating the second (normal) allele of the same gene; this process often involves *loss of heterozygosity (LOH)* resulting from deletion of the normal allele or gene conversion leading to two copies of the mutant allele	Skin tumors in hereditary leiomyomatosis and renal cell cancer and basal cell nevus (Gorlin) syndrome	• Affected individuals often develop multiple tumors
Revertant mosaicism† (see Ch. 62)	• A postzygotic mutation leads to partial or complete recovery of the wild-type phenotype in segment(s) of skin	Several types of EB, ichthyosis with confetti	• These somatic mutations are not transmitted to offspring
Consanguineous mating (inbreeding)	• In inbred populations, the probability that two carriers of a mutation originating from a common ancestor will mate and have a child with an AR disease is significantly higher than in the general population • Conversely, consanguinity is relatively common in families with AR diseases when the mutant alleles are rare within the general population	A founder effect due to ancestors (Dutch settlers) carrying a recessive mutation explains the high incidence of porphyria variegata in White South Africans	• When analyzing a pedigree, the possibility of consanguinity/over-representation of recessive mutations should be considered, especially for individuals in geographically, linguistically, and/or socially isolated populations where the probability of mating with related individuals is higher

Table 54.5 Exceptions to basic Mendelian inheritance patterns.

EXCEPTIONS TO BASIC MENDELIAN INHERITANCE PATTERNS			
Type of exception	**Impact on phenotype and inheritance**	**Examples in dermatology**	**Impact on genetic counseling**
Quasidominant (pseudodominant) inheritance	• Inheritance of an AR trait can mimic an AD pattern when an individual with an AR disorder mates with a carrier of a recessive mutation in the same gene (see Fig. 54.2C) • This parent-to-child transmission does not usually occur in successive generations	Consanguineous families with atrichia with papular lesions or pseudoxanthoma elasticum	• Mating between a homozygous affected individual and heterozygous carrier of an AR disorder produces a 50% risk of the disease in each offspring
Mitochondrial inheritance	• Inheritance of a mutation in the mitochondrial genome, with all (*homoplasmy*) or some (*heteroplasmy*) of the mitochondria affected • Women transmit the disease, but both male and female offspring may be affected • The phenotype depends on proportion of mutant versus normal mitochondria in a particular tissue	Mutation in the mitochondrial serine tRNA gene underlying palmoplantar keratoderma with or without associated sensorineural deafness	• Mitochondrial diseases have variable expression and incomplete penetrance
Phenocopy	• Clinical findings caused by environmental factors sometimes mimic the phenotype of a genetic disorder	A clinical presentation similar to porphyria cutanea tarda (PCT; an AD disorder) can result from exposure to certain hydrocarbons and pesticides	• Possible environmental as well as genetic etiologies for a condition should be considered
Imprinting and uniparental disomy (UPD)	• Imprinting is an epigenetic phenomenon in which the sex of the transmitting parent determines which allele of a given gene is expressed in the offspring (see Fig. 54.3A) • UPD represents inheritance of both homologous chromosomes from one parent due to errors in meiosis, either as *heterodisomy* with two different homologs from the same parent or *isodisomy* with a duplicated chromosome	Prader–Willi and Angelman syndromes (see Fig. 54.3B); uniparental isodisomy involving a recessive mutant allele has been reported in junctional EB, recessive dystrophic EB, and Harlequin ichthyosis	• Rare event with low risk for subsequent offspring • Prenatal screening can detect UPD by analysis of copy number variants and SNP/microsatellite markers

*For dosage compensation in females, one of the two X chromosomes in each cell is randomly inactivated via epigenetic mechanisms during embryonic development; this inactivation represents functional mosaicism that is passed on to all the "daughter" cells derived from each progenitor. However, genes in the pseudoautosomal region of the X chromosome escape inactivation.
†Genomic mechanisms include back mutations, mitotic recombination, gene conversion, and second-site mutations.

Table 54.5 Exceptions to basic Mendelian inheritance patterns. AD, autosomal dominant; AR, autosomal recessive, EB, epidermolysis bullosa; NF1, neurofibromatosis type 1; SNP, single nucleotide polymorphism; X-L, X-linked.

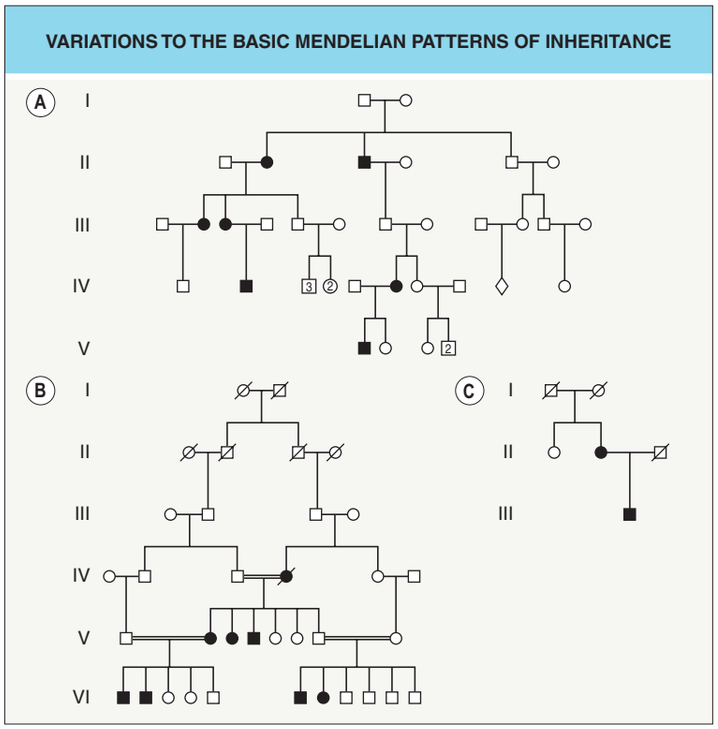

Fig. 54.2 Variations to the basic Mendelian patterns of inheritance. A Reduced penetrance in a pedigree with autosomal dominant retinitis pigmentosa. **B** High degree of consanguinity in a family with affected family members in several generations. **C** Pseudodominant inheritance in autosomal recessive disorder. The inheritance in this pedigree mimics an autosomal dominant resulting from the mating between a patient homozygous for the causative genetic mutation (II:2) and an unaffected carrier. The key for symbols commonly used for pedigree drawing is indicated at the bottom of Fig. 54.1. *A, Adapted from ref. 46; C, Adapted from ref. 47.*

EPIGENETICS AND IMPRINTING

Epigenetics refers to heritable changes affecting gene expression that do not result from alterations in the DNA sequence[26]. Epigenetic changes can involve DNA methylation or modification of histones (e.g. acetylation and deacetylation) and chromatin. RNA-dependent gene silencing can also occur under the influence of small and large RNA species, including small interfering RNAs (siRNAs)[27], microRNAs (miRNAs)[28], and large intervening non-coding RNAs (lincRNAs)[29].

Imprinting is an epigenetic phenomenon in which the sex of the transmitting parent determines whether particular genes are expressed in the offspring (Fig. 54.3A). For example, mating of a male lion with a female tiger results in the giant "liger" (due to inheritance of a growth gene from the lion father that is "turned on"), whereas a male tiger and female lion produce a considerably smaller "tigon" (due to inheritance of a growth gene from the lion mother that is "turned off").

The effect of imprinting is especially apparent in the case of *uniparental disomy (UPD)*, where both homologous chromosomes are derived from the same parent, instead of one from each parent. UPD can go undetected for some chromosomes, while it results in a disease phenotype for others. A classic example of the latter is UPD for chromosome 15 in Prader–Willi and Angelman syndromes (Fig. 54.3B). UPD that results in inheritance of a duplicated maternal or paternal recessive mutant allele can also produce various autosomal recessive disorders (see Table 54.5).

In addition to their roles in monogenic diseases, epigenetic changes are involved in cancer. Cancer is typically characterized by global hypomethylation and site-specific hypermethylation. The hypomethylation activates growth-promoting genes such as *HRAS*, cyclin D1 (*CCND1*), and those in the melanoma antigen family (*MAGE*)[26]. In contrast, hypermethylation silences tumor suppressor genes such as retinoblastoma 1 (*RB1*), von Hippel–Lindau (*VHL*), and adenomatosis polyposis coli (*APC*)[26]. Epigenetic alterations can also contribute to inflammatory disorders such as systemic lupus erythematosus.

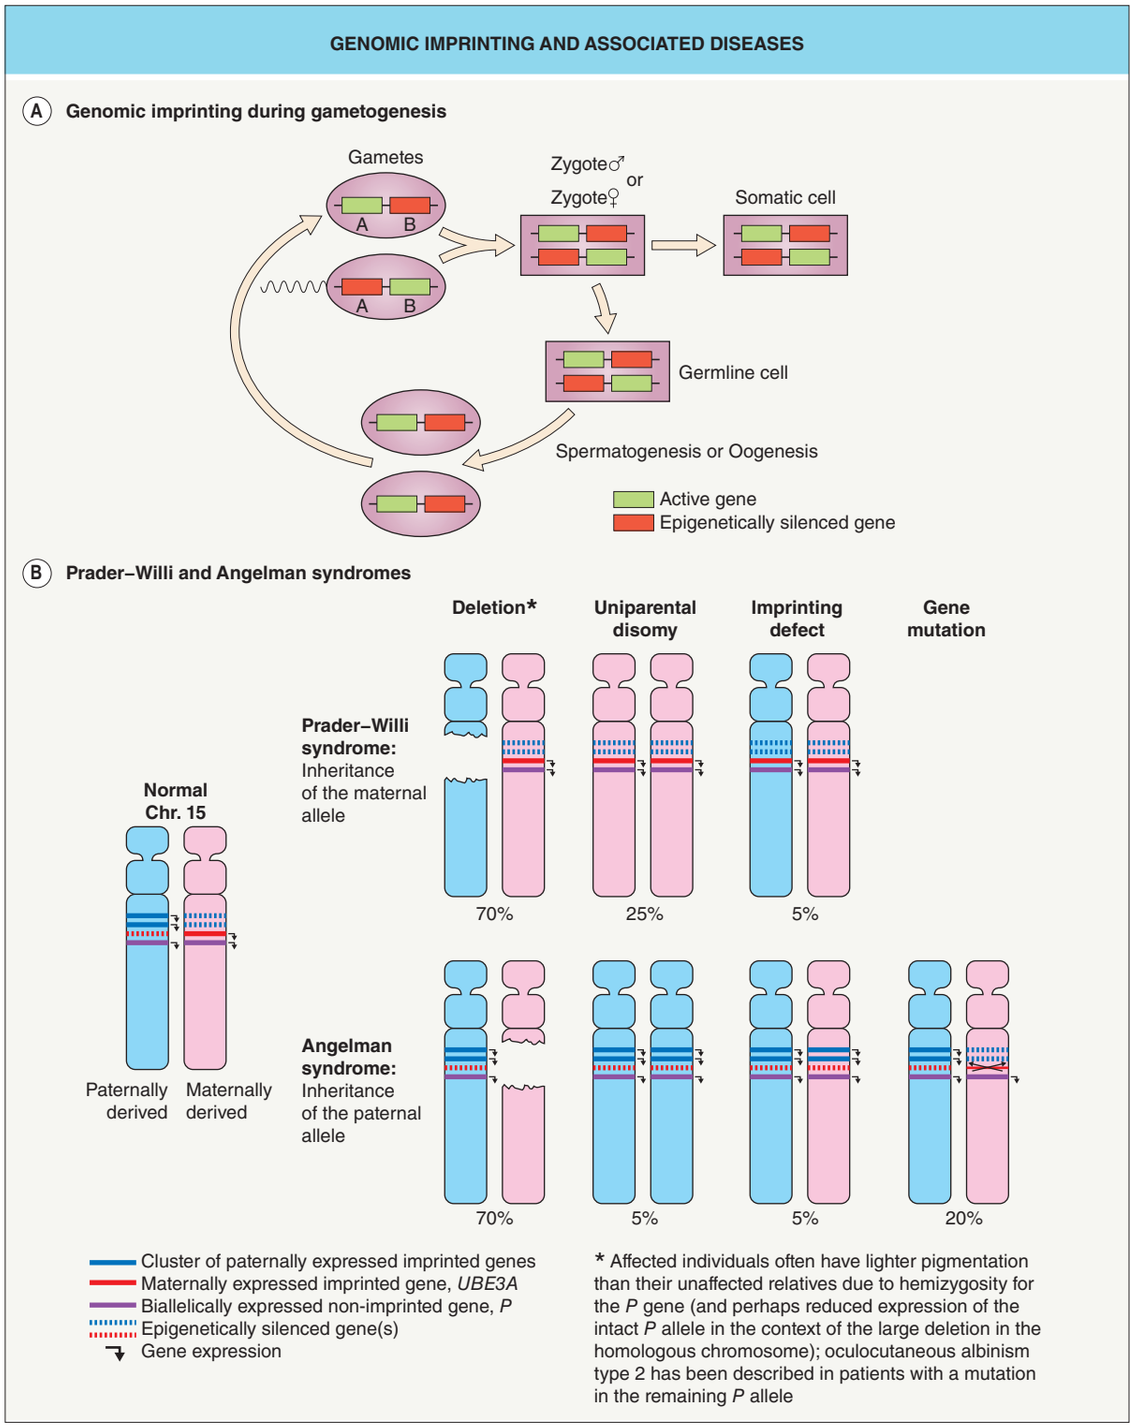

Fig. 54.3 Genomic imprinting and associated diseases. A Genomic imprinting occurs during gametogenesis. Genes A and B are epigenetically silenced in male and female gametes, respectively. Somatic cells in males and females maintain the imprinting pattern present in the gametes. In the germline, on the contrary, the imprinting is erased and the corresponding sex-specific imprint established. **B** Prader–Willi and Angelman syndromes represent diseases shaped by genomic imprinting.

CHROMOSOMAL DISORDERS

The above sections discussed disease-causing mutations that affect a single gene. However, other disorders can result from larger aberrations at the chromosomal level, and these anomalies may produce severe phenotypes due to the involvement of multiple genes and regulatory regions. For example, the majority of spontaneous abortuses exhibit chromosomal anomalies[30].

Chromosomal anomalies can affect the number or structure of chromosomal segments or the entire chromosome. Numeric chromosomal abnormalities may involve the whole genome (polyploidy) or just one pair of homologs (aneuploidy). The forms of *polyploidy* observed in humans are triploidy with three complete sets of chromosomes ($3n$), and tetraploidy with four chromosome complements ($4n$). However, unless mosaic, polyploidy results in a spontaneous abortion or death soon after birth. *Aneuploidy* refers to extra or missing chromosome(s), such as trisomies with three copies of a single chromosome or monosomies with only one copy. Trisomies for a whole chromosome that are compatible with extrauterine life (outside the setting of mosaicism) involve chromosomes 21 (Down syndrome), 18 (Edwards syndrome), 13 (Patau syndrome), and 23 (XXY, Klinefelter syndrome; XYY). Monosomy for the X chromosome (Turner syndrome) can also occur. Other trisomies and monosomies may be observed in mosaic or partial (e.g. due to translocations) forms.

Structural abnormalities involve breakage of chromosomes. They are *balanced* if there is no net gain or loss of genetic material, or *unbalanced* when they are accompanied by additional or missing genetic information. The stability of the resulting rearranged chromosome through cell division will depend on the presence of a centromere and two telomeres, the necessary elements for the correct segregation of chromosomes.

Balanced chromosomal abnormalities include some types of translocations and inversions. In a reciprocal translocation, two breaks in two non-homologous chromosomes occur and the chromosomal segments distal to the breaks are exchanged. The total number of chromosomes

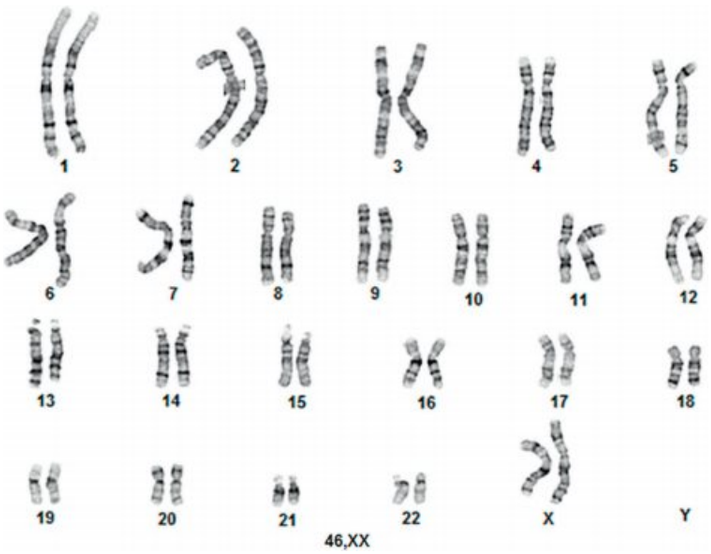

Fig. 54.4 Normal female karyotype. Metaphase chromosomes are photographed, cut out and placed in pairs from largest to smallest, including 22 autosomal pairs and 2 sex chromosomes.

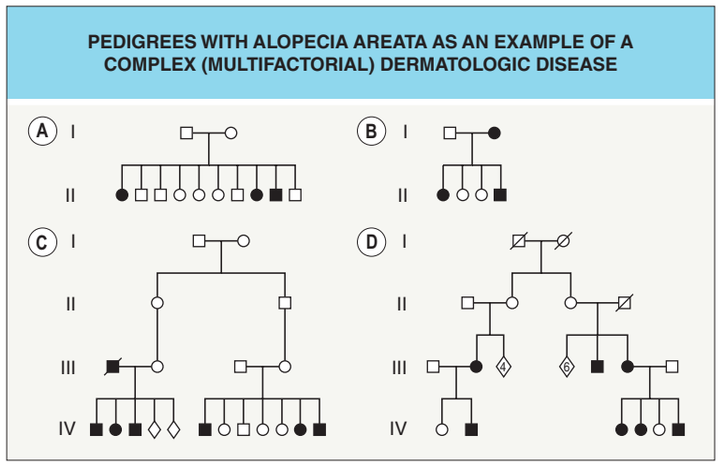

Fig. 54.5 Pedigrees with alopecia areata as an example of a complex (multifactorial) dermatologic disease. Although some of the pedigrees individually can mimic Mendelian patterns of inheritance (**A, B**), others show a more complex pattern (**C, D**). In some cases, the disease can be inherited through two unrelated branches of the family (**C**). A single mode of inheritance cannot be established for the disease as a group. The key for symbols commonly used for pedigree drawing is indicated at the bottom of Fig. 54.1.

remains the same. If the translocation breakpoint affects a gene or its regulatory sequence, or otherwise places a gene under the control of novel regulatory elements (e.g. the Philadelphia chromosome), it can result in an observable phenotype (e.g. chronic myelogenous leukemia). In addition, clinical manifestations related to reciprocal translocations can occur in the offspring of the carriers. Depending on the combination of parental chromosomes inherited, the offspring may have partial trisomy or monosomy for the chromosomal regions involved in the translocation, i.e. an *unbalanced* chromosomal anomaly.

Inversions are balanced rearrangements in which two breaks occur in the same chromosome and the intervening segment is inverted before the chromosome is reconstituted. In a *pericentric inversion*, the inverted segment includes the centromere, whereas in a *paracentric inversion*, the two breaks occur in the same chromosome arm, without involvement of the centromere.

Numerical and structural chromosomal aberrations can be detected using karyotypes, which allow visualization of banding patterns in stained metaphase chromosomes (Fig. 54.4). Fluorescence *in situ* hybridization (FISH) can identify much smaller changes in the chromosomal constitution that are not visible with conventional banding techniques but requires the use of preselected probes (see Table 3.5 and Fig. 3.8). More recently, advances in microarray technology have enabled the use of array-based comparative genomic hybridization (CGH) for detection of copy number variations (CNVs) at a considerably higher level of resolution than can be accomplished via karyotypes. Conventional CGH identifies chromosomal gains and losses and all CNVs in a single hybridization procedure[31]. While this method has improved resolution (5–10 Mb) compared to chromosomal banding, it still requires metaphase chromosomal preparations and is unable to identify balanced chromosomal rearrangements. However, array-based CGH (aCGH) that incorporates DNA microarray technologies has an improved resolution of ~100 Kb. Currently, single nucleotide polymorphism (SNP) oligonucleotide microarray analysis (SOMA), which combines SNP data with the detection of CNVs, yields the highest resolution (~6 Kb)[32] and detects both visible and submicroscopic imbalances, including cryptic insertions/deletions in apparently balanced chromosomes. It also provides SNP genotype information for additional studies, such as assessment of uniparental disomy (UPD) and zygosity.

Classic examples of skin conditions associated with chromosomal anomalies are linear nevoid hypo- or hyperpigmentation (including "hypomelanosis of Ito" and "linear and whorled nevoid hypomelanosis"), where streaks and swirls of hypo- or hyperpigmentation following the lines of Blaschko reflect mosaicism. In a subset of such patients, especially those with associated extracutaneous manifestations, a mosaic chromosomal anomaly can be identified in affected skin via culture of lesional fibroblasts[33]. Other genodermatoses are occasionally caused by chromosomal abnormalities. For example, hypohidrotic ectodermal dysplasia can result from X;autosome translocations or genomic deletions involving *EDA*[34].

COMPLEX GENETIC TRAITS

Classic Mendelian disorders represent only a small proportion of genetic diseases. Many common conditions develop as a consequence of multiple genetic factors that confer disease susceptibility, interacting with each other and the environment. Such complex (multifactorial) traits tend to cluster or aggregate in families (Fig. 54.5). In contrast to the predictable recurrence risks for Mendelian traits, the risks for complex traits are estimated based on epidemiologic data. Examples of complex traits in dermatology include atopic dermatitis, psoriasis, vitiligo, and alopecia areata.

Attempts to define the genetic basis of complex disorders have included twin studies, parametric linkage analysis, and genome-wide association studies (GWAS). The comparison of concordance rates in monozygotic (identical) and dizygotic (fraternal) twins represents a powerful technique for determining the genetic and epigenetic components of human diseases[35]. For psoriasis and alopecia areata, concordance rates of ~50%–70% in monozygotic twins compared to ~10%–20% in dizygotic twins demonstrate a strong genetic basis[36,37]. In investigations utilizing GWAS, several hundred thousand SNPs can be analyzed in thousands of individuals to help determine the genetic architecture of complex diseases.

Our understanding of the complex genetic and epigenetic architecture underlying polygenic diseases has been greatly facilitated by endeavors such as the Human Genome Project that mapped all human genes (completed in 2003), the Encyclopedia of DNA Elements (ENCODE) that catalogs all the functional regulatory elements in the human genome[38], and the Roadmap Epigenomics Project. The field of functional genomics is also playing a key role in the mission to decode the genetic architecture of complex traits. This progress will continue to elucidate disease mechanisms and facilitate the development of targeted therapies.

IDENTIFICATION OF DISEASE GENES

Key features

- Targeted multi-gene panels represent an efficient testing strategy for disorders with overlapping clinical features
- Whole-exome sequencing (WES) and whole-genome sequencing (WGS) are increasingly being utilized in clinical practice as a diagnostic tool
- Testing for somatic mutations and chromosomal aberrations in tumor tissue can help provide prognostic input and direct therapy
- Recognition of hereditary cancer syndromes caused by germline mutations is essential in order to facilitate appropriate evaluation and surveillance of patients and their families

INTERPRETATION OF SEQUENCE VARIANTS

A *mutation* is defined as a permanent change in the nucleotide sequence of DNA. There are several different types of mutations. Point mutations consist of the substitution of a single nucleotide position. This change can lead to an amino acid substitution (missense mutation), the generation of a termination codon (nonsense mutation), or no change in the protein sequence (silent mutation). There can also be small duplications, insertions, or deletions. If they affect a piece of the protein-coding sequence in a manner that is not a multiple of three nucleotides (a codon), this will lead to a frameshift in the protein sequence and often the generation of a premature termination codon. These types of mutations can affect both coding and non-coding sequences, e.g. the promoter region, consensus splicing signals, other key intronic positions. Large rearrangements, such as partial or complete deletions of the entire gene, can also occur.

It is important to recognize that some "mutations" as described above actually represent non-pathogenic variants present in the general population as "polymorphisms"; the latter are defined as having a population frequency of >1%. To avoid potential confusion regarding the consequences of a particular sequence variant, the American College of Medical Genetics and Genomics (ACMG) developed guidelines for the use of standard terminology in clinical genetic testing[39]. These guidelines recommend avoiding the terms "mutation" and "polymorphism" to describe genetic alterations relevant to Mendelian disease, and instead using "variant" with one of the following modifiers: pathogenic, likely pathogenic, uncertain significance, likely benign, or benign. However, the simple term "mutation" is embedded in the medical lexicon and appears in this textbook.

For the detection of mutations, traditional Sanger sequencing of genes, based upon the incorporation of fluorescent chain-terminating nucleotide analogues (see Ch. 3), can be performed; next-generation sequencing is described below. Additional methods that assess copy number and can detect larger deletions or duplications include multiplex ligation-dependent probe amplification (MLPA), quantitative PCR, targeted aCGH, and FISH (see above & Ch. 3).

Following the identification of genetic variants in both Mendelian and complex diseases, the next step is often determination of their downstream consequences, e.g. on gene expression and protein function. Methods to evaluate gene expression include microarray analysis, quantitative reverse transcription PCR, RNA sequencing, and immunohistochemical characterization of patient samples. Quantitative assays can be performed to determine whether the mutation leads to a loss or gain of protein function, and functional experiments may employ *in vitro* cell culture systems and mouse models.

NEXT-GENERATION (MASSIVELY PARALLEL) SEQUENCING

In recent years, high-throughput technology has revolutionized genetic testing via "next-generation" techniques that allow much faster and less expensive DNA and RNA sequencing than does the traditional Sanger method. Also referred to as massively parallel sequencing, this process involves amplification of fragmented sequences of DNA to produce thousands of copies, which are then sequenced as a group (see Table 3.2 and Fig. 3.5).

Multi-gene panels utilizing next-generation sequencing enable a large group of genes associated with a particular phenotype (e.g. epidermolysis bullosa, ichthyosis, vascular malformation) to be evaluated in a cost-effective manner. When testing of a single gene or panel of genes based on the clinical findings in a patient suspected of having a genetic disorder fails to provide an answer, WES or WGS can be the next step (Tables 54.6 and 54.7). For example, in a patient with sparse hair, hypohidrosis, and absent teeth, the initial step toward establishing a molecular diagnosis is targeted testing utilizing a panel of genes known to be associated with ectodermal dysplasia. An advantage of targeting specific genes is that coding regions and some non-coding regions can be analyzed in fine detail for both sequence aberrations and deletions or duplications. In contrast, WES uses an array to specifically capture the protein-coding (expressed) regions of the human genome, which account for only 1%–2% of genetic material but contain >85% of disease-causing mutations[40]. If a patient with ectodermal dysplasia has no pathogenic changes identified via targeted testing, WES enables examination of the coding regions of many additional genes. Currently, for identifying disease-causing mutations in both recessively and dominantly inherited conditions, WES followed by bioinformatics analysis of the data generated represents a more efficient and cost-effective approach than WGS (see Table 54.6)[41]. However, genetic technology is advancing rapidly, and further optimization of WGS is expected to lead to its increased use in the future.

COMPARISON OF NEXT-GENERATION SEQUENCING (NGS) OPTIONS

	Targeted testing (e.g. multi-gene panel)	WES	WGS
Optimized for genes/ mutations associated with a particular phenotype	Yes	No	No
Exons evaluated	Yes	Yes	Yes
Introns evaluated	Varies	No	Yes
Duplications evaluated	Better than WES & WGS	Larger errors may not be detected	Better than WES
Mitochondrial DNA evaluated	Varies	No	Yes
Mosaic mutation <20% in blood sample*	No	No	No
Cost	$	$$	$$$$

*NGS with deep sequence coverage can enhance sensitivity for lower-level mosaicism (e.g. <20%) that would be undetectable by conventional Sanger sequencing.

Table 54.6 Comparison of next-generation sequencing (NGS) options. All of these modalities can be performed on DNA extracted from a variety of sample types (e.g. blood, saliva, tissue), and none is able to completely exclude the possibility of a particular disorder. Whole-exome sequencing (WES) analyzes only expressed regions, which account for ~2% of the genome. Whole-genome sequencing (WGS) covers more non-coding regions, but at a lower depth of coverage compared to WES. For WES and WGS, samples from a parent–child trio can help to determine which variants are pathogenic and increase the diagnostic yield, and bioinformatics analysis is required to filter and prioritize variants identified based on function, zygosity, and population frequency.

GENETIC COUNSELING

Geneticists and genetic counselors can assist in educating patients and families about genetic diseases and testing, provide psychological support, and aid in decision-making processes. A typical visit includes a three-generation family history and drawn pedigree (see Fig. 54.1). Prior to proceeding with genetic analysis, its potential impact on the patient's diagnosis, prognosis, and medical care as well as implications for family members and reproductive planning are discussed. The limitations of genetic testing and possibility of equivocal or non-informative results are also reviewed. For example, a mutation in the protein kinase, cAMP-dependent, regulatory type Iα gene (*PRKAR1A*) that is known to cause Carney complex (myxoma, spotty pigmentation, and endocrine overactivity) is identifiable in ~70% of patients who meet clinical criteria for this condition. Possible explanations for false-negative findings include genetic alterations not detectable by the methods utilized, mosaicism (see Ch. 62), locus heterogeneity (see above), and laboratory error.

Other topics to address with patients and families undergoing genetic testing may include confidentiality, detection of non-paternity, and (for WES or WGS) incidental findings in a gene unrelated to the disease being investigated. In the US, the Genetic Information Nondiscrimination Act (GINA) of 2008 provides protection against access to genetic information and genetic discrimination in health insurance and employment settings. However, GINA does not include all possible forms of genetic discrimination (e.g. life or disability insurance). Many state governments require documentation of consent for performance of genetic testing and disclosure of genetic information.

GENETIC TESTING STRATEGIES		
Clinical findings	**Appropriate test**	**Example result**
Severe anomalies: e.g. recognizable trisomy with major neurologic abnormalities and aplasia cutis congenita	Karyotype	Trisomy 13 with associated aplasia cutis congenita
Multiple congenital anomalies: e.g. developmental delay, ichthyosis, anosmia	Chromosomal microarray	X-linked ichthyosis due to *STS* and contiguous gene deletion
Mendelian (single-gene) syndrome suspected: e.g. congenital erythroderma with erosions and epidermolytic hyperkeratosis histopathologically e.g. congenital ichthyosiform erythroderma without syndromic features	 Sequencing of most likely genes (*KRT1* & *KRT10*) Targeted panel of genes known to cause ichthyosis	 Epidermolytic ichthyosis with heterozygous *KRT1* pathogenic variant Autosomal recessive congenital ichthyosis due to biallelic *ALOX12B* pathogenic variants
If uninformative targeted testing results		
Unknown single gene disorder suspected: e.g. congenital ichthyosis, developmental delay, short stature, renal dysfunction	WES or WGS	Identification of a pathogenic variant in a novel gene expressed in the skin, brain, bones, and kidneys

Table 54.7 Genetic testing strategies. A genetic test should match the size of the error it is aiming to detect. A karyotype is a "big picture" genome-wide snapshot. Since approximately one-third of genes control brain function, errors seen by karyotype usually include cognitive deficits. Chromosomal microarray or "molecular karyotyping" has a finer resolution and detects errors too small to be seen at the chromosomal banding level. Multi-gene panels are useful for assessing related disorders with overlapping phenotypes and detect alterations as small as a single base pair. Finally, whole-exome sequencing (WES) and whole-genome sequencing (WGS) utilizing next-generation technology offer a broader, un-targeted approach. *ALOX12B*, arachidonate 12-lipoxygenase, 12 R type; *KRT1/10*, keratin 1/10; *STS*, steroid sulfatase.

TUMOR GENETICS FOR THE DERMATOLOGIST

Somatic Versus Germline Mutations

Analysis of the genetic alterations underlying cancer has revolutionized our understanding of the multiple intersecting signaling pathways involved in tumorigenesis (see Ch. 107) and provided tumor-specific therapeutic targets. *Somatic* mutations occur after conception and can result in mosaic skin conditions as well as cutaneous neoplasms. Mosaicism reflects a disease-causing somatic mutation that arises *in utero* (postzygotic) and presents with skin findings in developmental patterns (e.g. following the lines of Blaschko or segmental; see Ch. 62). The clinical manifestations of mosaic diseases depend upon the timing of the genetic change and cell type(s) affected, ranging from birthmarks such as congenital melanocytic and epidermal nevi to segmental forms of neurofibromatosis type 1 and Darier disease.

Examples of somatic mutations that commonly underlie cutaneous neoplasms include *BRAF* mutations in melanocytic nevi and melanomas, *PTCH1* (patched) mutations in basal cell carcinomas (BCCs), and UV-signature *TP53* mutations in BCCs and cutaneous squamous cell carcinomas (cSCCs) (see Chs. 107 and 113). Although somatic mutations typically result in focal lesions, exceptions with widespread skin involvement and systemic manifestations include maculopapular and diffuse cutaneous mastocytosis due to somatic activating *KIT* mutations and VEXAS (vacuoles, E1 ubiquitin activating enzyme, X-linked, autoinflammatory, somatic) syndrome due to somatic *UBA1* mutations.

Germline (constitutional) mutations can result in hereditary cancer predisposition syndromes that are associated with cutaneous malignancies (e.g. basal cell nevus syndrome) or benign cutaneous neoplasms (e.g. Cowden syndrome). These syndromes may be divided into three general categories: (1) defective "caretaker" genes involved in DNA repair and protection of genomic integrity (e.g. nucleotide excision repair genes in xeroderma pigmentosum; see Ch. 87); (2) defective tumor suppressor ("gatekeeper") genes (e.g. *PTEN* in Cowden syndrome; see Ch. 63); and (3) activated oncogenes (e.g. *RET* in multiple endocrine neoplasia 2 A/B; see Ch. 63). Increased risk of melanoma can result from germline mutations in high-penetrance genes such as *CDKN2A* (found in ~2% of melanoma patients overall and ~20%–40% of melanoma kindreds) as well as pigmentation genes such as *MC1R* responsible for the lightly pigmented skin that increases propensity for melanoma development (see Ch. 113).

Testing of Cutaneous Tumors for Somatic Mutations

In contrast to use of a blood or saliva sample to test for germline mutations, testing for somatic mutations typically requires lesional tissue. However, next-generation technology can potentially be employed to analyze circulating tumor DNA.

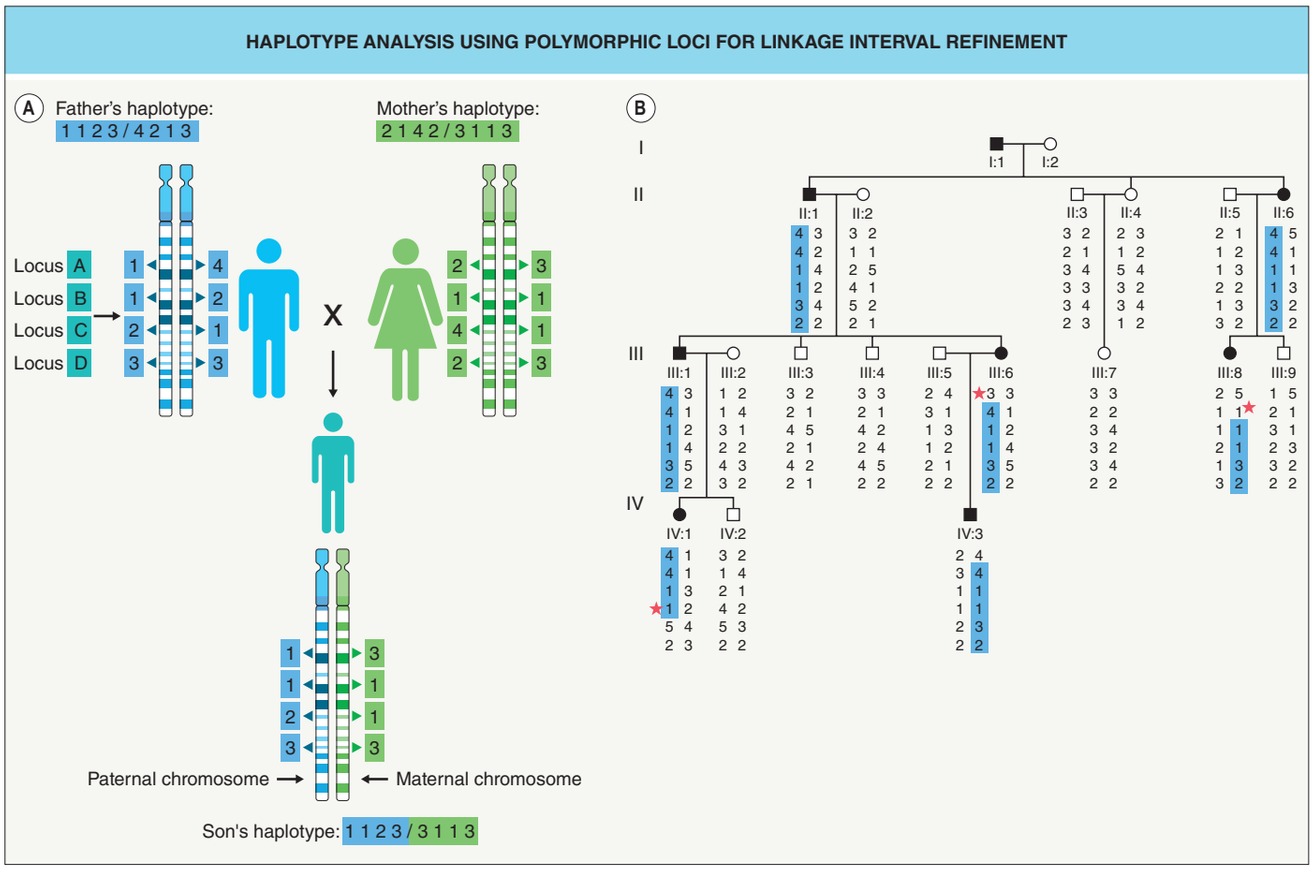
Carcinomas are characterized by a wide variety of mutations as well as other genetic abnormalities such as structural rearrangements, copy number aberrations, and gains and losses of partial or whole chromosomes (see Ch. 107). FISH utilizes fluorescent probes to target specific genes or chromosomes in order to assess DNA copy number changes (see Fig. 3.8). Array CGH uses different technology for a similar purpose, with applications such as helping to distinguish proliferating nodules from melanoma within congenital melanocytic nevi (see Ch. 112). The presence of a larger number of genetic errors is often (but not always) suggestive of a more malignant process. Various gene-expression profile assays are commercially available for pre-biopsy (via epidermal tape stripping) and post-biopsy assessment of pigmented lesions, but their use in clinical decision-making has limitations[42] (see Ch. 113).

Of note, evidence of certain somatic mutations in tumor tissue can raise the possibility of a hereditary cancer predisposition syndrome. Sebaceous neoplasms in the setting of Muir–Torre syndrome (MTS; a subset of Lynch syndrome) due to a heterozygous germline mutation in a mismatch repair gene represent an example relevant to dermatologists. Evidence of microsatellite instability and loss of expression of mismatch repair proteins (e.g. MLH1, MSH2, MSH6, and/or PMS2) via immunohistochemical staining are each more frequently present in MTS-associated than in sporadic sebaceous neoplasms[43]; testing for a germline mutation in mismatch repair genes should be considered in these patients, especially when there is clinical suspicion of MTS (see Table 63.5). Likewise, identification of BAP1-inactivated melanocytic tumors can prompt genetic testing to diagnose *BAP1* tumor predisposition syndrome due to a germline *BAP1* mutation[44].

The ability to test tumor tissue for somatic mutations enables molecularly targeted cancer therapy. For example, in advanced melanomas with an activating *BRAF* mutation, a marked tumor response is seen with the combination of a selective BRAF inhibitor plus a MEK inhibitor (see Ch. 113). Testing for other somatic mutations continues to evolve in an effort to better characterize tumors and direct therapy.

Testing for Hereditary Cancer Predisposition Syndromes

It is important for dermatologists to recognize the cutaneous manifestations of hereditary cancer syndromes in order to facilitate appropriate patient evaluation (see Table 55.5). General features that suggest the possibility of a cancer predisposition syndrome include younger age at cancer onset, multifocal tumors, multiple primary cancers (synchronous or asynchronous), certain characteristic tumor types (alone or in combination), multiple affected family members, and the absence of environmental risk factors. For example, pancreatic cancer and cutaneous



melanoma in the same individual raises suspicion for a *CDKN2A* mutation. Genetic testing should be considered in melanoma patients with risk factors such as ≥3 primary invasive melanomas or ≥2 first-degree relatives with a primary invasive melanoma and/or pancreatic cancer (see Table 113.4). Targeted multi-gene panels represent an efficient testing strategy when the features of different cancer predisposition syndromes overlap, and this represents the recommended approach when familial melanoma is suspected[45].

Of note, current technology does not confirm the molecular etiology in every patient with clinical findings suggestive of a genetic cancer predisposition syndrome. For example, in a patient strongly suspected to have hereditary leiomyomatosis and renal cell cancer (HLRCC [Reed syndrome]; see Table 117.2) based on clinical criteria, the fumarate hydratase (*FH*) pathogenic variant detection rate is ~70%–90%. It is recommended that individuals who meet clinical criteria but do not have an identifiable *FH* mutation still undergo annual surveillance for renal cancer. Conversely, it is important to recognize that many patients and families with multiple skin cancers have a multifactorial pathogenesis, with interactions between genetic susceptibility (e.g. pigmentary and nevus phenotypes) and environmental exposures (e.g. ultraviolet light, immunosuppression) (see Chs. 108 and 113).

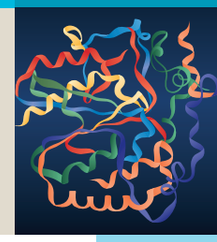
eFig. 54.1 Haplotype analysis using polymorphic loci for linkage interval refinement. A Haplotypes for a chromosomal region containing four polymorphic loci, A, B, C and D. Loci very close together will rarely be separated by recombination. **B** Haplotype analysis for the refinement of a linkage interval. The disease-associated haplotype, 4 4 1 1 3 2 (shaded in blue), has been broken by genetic recombination in three family members (stars). The two key recombinant individuals, III:8 and IV:1, have allowed the narrowing of the disease interval. The key for symbols commonly used for pedigree drawing is indicated at the bottom of Fig. 54.1.

eFig. 54.2 Types of polymorphisms: single nucleotide polymorphisms (SNPs) and microsatellites. SNPs consist of single base substitutions and can be detected via DNA sequencing (**A**) and restriction enzyme cleavage (**B**). **A** Point substitution (arrows) replacing a cytosine (C) with a thymidine (T) identified by DNA sequencing. **B** The sequence *ggAtcc* is the target site for the restriction enzyme *BamH1*. In the presence of this particular sequence, the enzyme will cut the DNA into two fragments, detected as two bands in an agarose gel (allele 2). If this sequence is altered by a base substitution and, therefore, not recognized by the enzyme, no cleavage occurs (allele 1). A polymorphism that affects the recognition site for a restriction enzyme is referred to as an RFLP (restriction fragment length polymorphism). **C** Example of microsatellites. The repeat unit of the microsatellites shown here is the dinucleotide (CA). The number of tandem repeats of the (CA) unit can vary in each allele. The figure shows two individuals heterozygous for the number of repeats of this dinucleotide. The differences in length between these three alleles appear as bands of DNA of different sizes in a polyacrylamide gel.



eFig. 54.3 Genome-wide association study (GWAS). A In a GWAS with a case–control design, single nucleotide polymorphisms (SNPs; markers of genetic variation) across the human genome are genotyped using DNA microarrays in a large group of individuals with a certain disease and compared to controls from the general population. **B** A small locus on chromosome 9 (representing a tiny fragment of the genome) containing two SNPs is depicted as an example. **C** The strength of the association between each SNP and the disease is calculated based on that SNP's prevalence in cases versus controls. Because of the large number of statistical tests that are performed and the resulting high false-positive rate, statistical significance is typically set a P value of 10^{-8}. In this example, SNPs 1 and 2 on chromosome 9 are associated with the disease, with P values of 10^{-12} and 10^{-8}, respectively. **D** For all genotyped SNPs that have survived a quality-control screen, the chromosomal location is plotted on the *x*-axis and the negative logarithm of the P value on the *y*-axis (a Manhattan plot). Each chromosome is shown in a different color. The results implicate a locus on chromosome 9, marked by SNPs 1 and 2, which are adjacent to each other (graph at right), and other neighboring SNPs. *Adapted with permission from Manolio TA. Genomewide association studies and assessment of the risk of disease. N Engl J Med 2010;363:166–76.*

Genetic Basis of Cutaneous Diseases

55

Vered Molho-Pessach and Julie V. Schaffer

Key features

- Advances in molecular technology have led to elucidation of the genetic bases of many single-gene inherited and mosaic skin disorders, greatly improving our understanding of these conditions
- McKusick's Online Mendelian Inheritance in Man (OMIM) database provides easily accessible, up-to-date information on human genes and genetic diseases; each gene or phenotype entry is assigned a specific six-digit MIM number
- Genotype–phenotype correlations in genodermatoses are often complex, with multiple examples of allelic heterogeneity (mutations in a single gene causing more than one disorder) and locus heterogeneity (mutations in different genes causing the same disorder)
- Molecular classification of genodermatoses into categories such as keratin defects and RASopathies complements traditional morphologic classification, highlighting pathomechanisms and relationships between conditions
- Certain syndromic associations actually represent contiguous gene syndromes caused by large deletions that affect two or more neighboring genes
- Types 1 and 2 mosaicism in autosomal dominant disorders have been confirmed on a molecular level, and functional X-chromosome mosaicism can lead to a mosaic distribution of skin lesions in female patients heterozygous for X-linked disorders
- Determining the molecular basis of monogenic skin disorders can enable the development of targeted therapies and provide insights into the pathogenesis of acquired skin diseases
- Molecular research has paved the way to the goal of gene therapy for severe inherited skin disorders such as epidermolysis bullosa

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; XD, X-linked dominant; XR, X-linked recessive.

INTRODUCTION

In 1987, deletions in the steroid sulfatase gene were found to underlie X-linked recessive ichthyosis[1]. This heralded an era of tremendous progress in the elucidation of the genetic bases of inherited skin disorders, made possible by rapid advances in molecular technology (including the development of next-generation massively parallel sequencing; see Fig. 3.5), utilization of animal models, and sequencing of the human genome[2–4]. Better understanding of signaling pathways, molecules involved in cell–cell communication and adhesion, and mechanisms of cutaneous differentiation have also contributed to the momentum.

As a result of this explosion in research, more than 1000 genes were recognized to be responsible for a particular human phenotype by the year 2000, with approximately 300 of these conditions including cutaneous abnormalities[5]; by 2023, these numbers had increased to nearly 5000 and 1700, respectively[6–8]. Currently, the molecular genetic bases of the majority of single-gene inherited skin disorders have been established[9,10]. Multigene panels as well as whole-exome (the transcribed portion of the genome) and whole-genome sequencing utilizing next-generation technology are clinically available to assist in the identification of disease-causing genes[10].

In the past, diagnosis of genodermatoses was complicated by the existence of multiple complex classification systems based on various combinations of clinical, histologic, radiographic, and biochemical criteria. Inconsistent nomenclature laden with descriptive terms, eponyms, and synonyms added to the confusion and potential for misdiagnosis[11]. As the genetic bases of genodermatoses have been determined, integration of molecular and clinical data has helped to simplify disease categorization and eliminate redundant terminology. This has been successfully accomplished for disorders such as epidermolysis bullosa (EB) and ichthyoses, but it represents a work in progress, to be continually refined as additional genotype–phenotype correlations are established[12,13]. In addition, grouping hereditary skin disorders according to their molecular bases (Table 55.1) can supplement traditional morphologic classification, clarifying pathomechanisms and the relationships between conditions. Groups of monogenic conditions listed in tables elsewhere in the book are noted in Table 55.2.

As the "morbid anatomy of the dermatologic genome" continues to be established, new challenges will arise and additional questions will be answered[14]. Because of the rarity of many genodermatoses, their full clinical spectra have yet to be elucidated. However, with the increasing availability of genetic testing, dermatologists can establish the diagnosis in patients with mild or atypical presentations, thereby expanding the range of phenotypes. Continuing to decipher heritable skin disorders will require close interactions between basic scientists and clinicians[15]. Hopefully, such research will continue to lead to better understanding of cutaneous structure and function; insights into the pathogenesis of common multifactorial disorders; and effective therapies as well as diagnostic and prognostic information, improved genetic counseling, and DNA-based prenatal/preimplantation testing for patients with genodermatoses.

McKUSICK'S MENDELIAN INHERITANCE IN MAN

McKusick's Mendelian Inheritance in Man (MIM) database was first published in 1966 as "Catalogs of Autosomal Dominant, Autosomal Recessive and X-linked Phenotypes". In the 1994 edition, the subtitle was changed to "A Catalog of Human Genes and Genetic Disorders", reflecting the progress that had been made in the field. Online MIM (OMIM; https://omim.org/) has been widely available on the Internet for almost 40 years, providing immediate access to current information on human genes and genetic diseases[6,7]. This database is updated continuously and can be searched by entering a constellation of clinical features as well as the name of a gene or syndrome.

A particular six-digit number (MIM number) is assigned to each OMIM entry. The first digit of the MIM number indicates the mode of inheritance of the corresponding genetic defect: 1 for autosomal dominant (entries before May 1994); 2 for autosomal recessive (entries before May 1994); 3 for X-linked; 4 for Y-linked; 5 for mitochondrial; and 6 for autosomal dominant or recessive (entries after May 1994). *Phenotype entries* describe the clinical and biochemical features, inheritance, mapping, and molecular genetics of a given disease or trait; a "#" is used to designate those for which the molecular basis is known (e.g. #162200). *Gene entries* are marked by a "*" (e.g. *613113), while *gene plus phenotype* entries are indicated with a "+" (e.g. +107670); both are appended with important disease-causing allelic variants (each of which is given a four-digit extension, beginning with .0001).

GENOTYPE–PHENOTYPE CORRELATIONS

Genotype–phenotype correlations in genodermatoses are often complex. Mutations in a single gene can cause more than one clinical disorder, a phenomenon referred to as *allelic heterogeneity* (see Table 54.2). This usually results from different mutations in a particular gene. However, it occasionally reflects the same mutation

MOLECULAR CLASSIFICATION OF GENETIC SKIN DISORDERS	
Molecular defect	**Examples of skin disorders that result**
Keratin defects	See Table 56.4 and Fig. 56.5
Defects in structural proteins of the cornified cell envelope	Ichthyosis vulgaris, loricrin keratoderma (variant Vohwinkel syndrome)
Lipid metabolism defects	Various ichthyoses, including CHILD syndrome, Conradi–Hünermann–Happle syndrome, neutral lipid storage disease, lamellar ichthyosis/congenital ichthyosiform erythroderma spectrum (e.g. defective lipoxygenase 3 or 12R, cytochrome p450 4F22), self-healing collodion baby (defective lipoxygenase 3 or 12R), late-onset autosomal recessive congenital ichthyosis, Refsum disease, rhizomelic chondrodysplasia punctata, Sjögren–Larsson syndrome, X-linked recessive ichthyosis and ichthyosis, intellectual disability and spastic quadriplegia; various hyperlipidemias; Farber lipogranulomatosis, Gaucher disease type 2, hyperimmunoglobulinemia D syndrome, localized autosomal recessive hypotrichosis II/autosomal recessive woolly hair, Niemann–Pick disease, psoriasiform dermatitis–microcephaly–developmental delay syndrome
Transglutaminase defects	Congenital ichthyosiform erythroderma spectrum (transglutaminase 1), acral peeling skin syndrome
Protease/proteasome defects	Dermatosparaxis, familial hidradenitis suppurativa, hereditary angioedema (type III), Howel–Evans syndrome, ichthyosis–hypotrichosis syndrome, IFAP (*i*chthyosis *f*ollicularis–*a*trichia–*p*hotophobia) syndrome, KLICK (*k*eratosis *l*inearis–*i*chthyosis *c*ongenita–sclerosing *k*eratoderma) syndrome, Olmsted syndrome, Papillon–Lefèvre and Haim–Munk syndromes, prolidase deficiency, restrictive dermopathy (defective zinc metallopeptidase), hereditary thrombotic thrombocytopenic purpura, MONA (*m*ulticentric *o*steolysis, *n*odulosis, and *a*rthropathy), proteasome-associated autoinflammatory/CANDLE/Nakajo–Nishimura syndrome)
Protease inhibitor defects	Antithrombin III deficiency, autosomal recessive exfoliative ichthyosis, hereditary angioedema (types I & II), Netherton syndrome
Desmosomal defects (see Fig. 56.8)	Acantholytic erosive disorder, arrhythmogenic right ventricular dysplasia/cardiomyopathy + palmoplantar keratoderma + woolly hair; Carvajal syndrome, erythrokeratodermia–cardiomyopathy syndrome, generalized inflammatory peeling skin syndrome, hypotrichosis and skin lesions, hypotrichosis simplex of the scalp, localized autosomal recessive hypotrichosis, monilethrix (autosomal recessive), Naxos disease, SAM (severe dermatitis, *a*llergies, and *m*etabolic wasting), skin fragility–ectodermal dysplasia syndrome, skin fragility/woolly hair syndrome, striate palmoplantar keratoderma
Connexin defects (see Table 58.5)	Bart–Pumphrey syndrome, Clouston syndrome, erythrokeratodermia variabilis et progressiva, lymphatic malformation 3, ILVEN, keratoderma–hypotrichosis–leukonychia totalis, KID (*k*eratitis–*i*chthyosis–*d*eafness) syndrome, oculodentodigital dysplasia, palmoplantar keratoderma with deafness, porokeratotic adnexal ostial nevus, Vohwinkel syndrome (classic)
Other defects in cell-to-cell adhesion	Ichthyosis–hypotrichosis–sclerosing cholangitis syndrome, cleft lip/palate–ectodermal dysplasia syndrome, ectodermal dysplasia–syndactyly syndrome, ectodermal dysplasia–ectrodactyly–macular dystrophy, hypotrichosis with juvenile macular dystrophy, leukocyte adhesion deficiency type I
Defects in keratinocyte–extracellular matrix (ECM) adhesion	Various forms of epidermolysis bullosa (EB) simplex, junctional EB, and dystrophic EB (keratin–ECM linkage); Kindler EB (actin–ECM linkage)
ATP-binding cassette (ABC) transporter defects	Harlequin ichthyosis, lamellar ichthyosis/congenital ichthyosiform erythroderma spectrum (defective ABCA12), pseudoxanthoma elasticum, sitosterolemia, Tangier disease/familial hypoalphaproteinemia
Calcium pump defects	Darier disease, Hailey–Hailey disease
Copper transporter defects	Menkes disease, occipital horn syndrome, Wilson disease
Defects in other transporters	Acrodermatitis enteropathica (zinc transporter), arterial tortuosity syndrome (glucose transporter), autosomal dominant hemochromatosis (iron-regulated transporter), spondylodysplastic Ehlers–Danlos syndrome (zinc transporter), H syndrome (nucleoside transporter), Hartnup disease (neutral amino acid transporter), ichthyosis–prematurity syndrome (fatty acid transporter), oculocutaneous albinism (transporters on lysosome-related organelles)
Collagen defects	Various types of dystrophic EB, various types of Ehlers–Danlos syndrome, Ullrich muscular dystrophy, lysyl hydroxylase 3 deficiency
Defects in other ECM proteins	Autosomal dominant cutis laxa, autosomal recessive cutis laxa type I, cutis laxa with severe pulmonary/gastrointestinal/urinary abnormalities, classic-like and hypermobile Ehlers–Danlos syndrome, juvenile hyaline fibromatosis/infantile systemic hyalinosis, lipoid proteinosis, Marfan syndrome, stiff skin syndrome
Nuclear membrane defects (see Table 63.10)	Buschke–Ollendorff syndrome/melorheostosis, Néstor–Guillermo progeria syndrome, Hutchinson–Gilford progeria syndrome, mandibuloacral dysplasia, partial > generalized lipodystrophy (familial and "acquired" forms), restrictive dermopathy
Defects in pyrin/NOD-family members and related proteins (see Fig. 4.2)	Blau syndrome, Yao syndrome, NOMID syndrome, familial cold autoinflammatory syndrome, familial Mediterranean fever, Muckle–Wells syndrome, PAPA syndrome
Interferonopathies (see Ch. 45)	Aicardi–Goutières syndrome, familial chilblain lupus, proteasome-associated autoinflammatory/CANDLE/Nakajo–Nishimura syndrome, SAVI (*STING*-*a*ssociated *v*asculopathy with onset in *i*nfancy), X-linked reticulate pigmentary disorder
RecQ DNA helicase defects	Bloom syndrome, Rothmund–Thomson syndrome, Werner syndrome
Classic DNA repair defects	Various subtypes of xeroderma pigmentosum, trichothiodystrophy and Cockayne syndrome; Muir–Torre syndrome, constitutional mismatch repair deficiency syndrome
Cell cycle checkpoint defects	Ataxia telangiectasia, familial atypical mole and melanoma (FAMM) syndrome, multiple endocrine neoplasia (MEN) 4
Defects in telomere maintenance	Dyskeratosis congenita (see Table 67.8; 11 genes implicated to date)
RAS–MAPK pathway activation (RASopathies; see Fig. 55.4)	Capillary malformation–arteriovenous malformation, cerebral capillary malformations (familial), cardio-facio-cutaneous syndrome, congenital melanocytic nevi, Costello syndrome, Legius syndrome, neurofibromatosis type 1, Noonan syndrome (with multiple lentigines), Noonan-like disorder with loose anagen hair, verrucous epidermal nevi, nevus sebaceus, woolly hair nevi

Table 55.1 Molecular classification of genetic skin disorders.

MOLECULAR CLASSIFICATION OF GENETIC SKIN DISORDERS	
Molecular defect	**Examples of skin disorders that result**
Phosphatidylinositol 3-kinase (PI3K)/AKT pathway activation	Epidermal nevi, lymphatic malformations, PIK3CA-related overgrowth spectrum (see Table 104.5), Proteus syndrome, PTEN hamartoma tumor syndrome, tuberous sclerosis complex, venous malformations
G protein activation	Diffuse capillary malformation with overgrowth (some patients), extensive dermal melanocytosis, McCune–Albright syndrome (versus loss-of-function in Albright hereditary osteodystrophy), phakomatosis pigmentovascularis, port-wine birthmarks, Sturge–Weber syndrome
cAMP and AMP-activated protein kinase pathway defects (see Fig. 55.3)	Albright hereditary osteodystrophy, Carney complex, McCune–Albright syndrome, Peutz–Jeghers syndrome, tuberous sclerosis complex
Defects in WNT/β-catenin signaling (see Fig. 55.6)	Anonychia congenita, ectodermal dysplasia–neoplastic syndrome, Gardner syndrome, Goltz syndrome (focal dermal hypoplasia), hereditary hypotrichosis simplex, palmoplantar keratoderma with cutaneous SCC and sex reversal, WNT10A-related ectodermal dysplasias (including odonto-onycho-dermal dysplasia and Schöpf–Schulz–Passarge syndrome)
Defects in transforming growth factor (TGF)-β signaling	Buschke–Ollendorff syndrome/melorheostosis, Ferguson–Smith multiple self-healing squamous epitheliomas, hereditary hemorrhagic telangiectasia, Loeys–Dietz syndrome, Marfan syndrome, stiff skin syndrome
Defective vesicle assembly/ protein sorting to vesicles	ARC (*a*rthrogryposis–*r*enal *d*ysfunction–cholestasis) syndrome, Hermansky–Pudlak syndrome, MEDNIK (*m*ental disability, *e*nteropathy, *d*eafness, *n*europathy, *i*chthyosis, *k*eratodermia) syndrome
Defective vesicle trafficking or transport	Autosomal recessive cutis laxa type IIA, CEDNIK (*c*erebral *d*ysgenesis, *n*europathy, *i*chthyosis and *k*eratoderma) syndrome, Chédiak–Higashi syndrome, gerodermia osteodysplastica, Griscelli syndrome, ocular albinism type 1, wrinkly skin syndrome, MACS (*m*acrocephaly, *a*lopecia, *c*utis laxa and *s*coliosis) syndrome

Table 55.1 Molecular classification of genetic skin disorders. cAMP, cyclic adenosine monophosphate; CANDLE, chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature; CHILD, congenital hemidysplasia with ichthyosiform nevus and limb defects; JAK, Janus kinase; MAPK, mitogen-activated protein kinase; NF-κB, nuclear factor-κB; NOD, nucleotide-binding oligomerization domain; NOMID, neonatal-onset multisystem inflammatory disease; PAPA, pyogenic arthritis, pyoderma gangrenosum, and acne; SCC, squamous cell carcinoma; STAT, signal transduction and activation of transcription; STING, stimulator of interferon genes; WNT, wingless-type integration site.

in patients with different ages at presentation, e.g. Cowden syndrome and Bannayan–Riley–Ruvalcaba syndrome (*PTEN*), or the same *mosaic* mutation affecting different cell types, e.g. nevus spilus and nevus sebaceus (*HRAS*). Mutations that affect different domains of a protein can produce divergent phenotypes; for example, mutations in the sterile alpha motif (SAM) domain of the p63 protein typically cause AEC (*a*nkyloblepharon, *e*ctodermal dysplasia, and *c*left lip/palate) syndrome, while those in the DNA-binding domain give rise to EEC (*e*ctrodactyly, *e*ctodermal dysplasia, and *c*left lip/palate) syndrome. Different mutations in a gene can also lead to disorders with distinct modes of inheritance, such as X-linked dominant incontinentia pigmenti and X-linked recessive hypohidrotic ectodermal dysplasia with immunodeficiency due to a partial deletion and milder, "hypomorphic" mutations in *IKBKG* (inhibitor of nuclear factor κB kinase regulatory subunit γ; *NEMO*), respectively. Lastly, mutations with opposite effects on a gene can produce disorders with completely disparate phenotypes, such as Ferguson–Smith multiple self-healing squamous epithelioma and Loeys–Dietz syndrome due to loss-of-function versus gain-of-function mutations in *TGFBR1* (TGF-β receptor 1), respectively.

The type of mutation can also affect the severity of a genodermatosis. The oftentimes lethal severe form of junctional EB (JEB), an *autosomal recessive* disorder, is typically caused by *LAMB3* mutations that produce a premature termination codon and absence of the LAMB3 protein. In contrast, milder forms of JEB result from missense mutations that result in decreased LAMB3 function. Conversely, in *autosomal dominant* conditions such as piebaldism (*KIT*) where the mutated protein forms a dimer, *dominant negative* missense mutations often result in more severe disease (via abnormal proteins disrupting normal proteins) than do premature termination codons that produce *haploinsufficiency* (absence of half of the proteins).

In other instances, mutations in different genes produce the same clinical disorder. This *locus heterogeneity* typically occurs when the mutated proteins serve a similar function. Examples include proteins interacting: (1) in a *complex*, e.g. components of various BLOCs (*b*iogenesis of *l*ysosome-related *o*rganelle *c*omplexes) in Hermansky–Pudlak syndrome (see Fig. 65.8A); (2) as a *ligand and receptor*, e.g. endothelin-3 and the endothelin-B receptor in type 4 Waardenburg syndrome (see Fig. 65.3); or (3) in a *signaling pathway*, e.g. RAS/mitogen-activated protein kinase [MAPK] pathway proteins in cardio-facio-cutaneous syndrome (see below). However, some phenotypic differences can arise when these proteins also have distinct functions and/or tissue distributions. For example, the neurologic abnormalities in Griscelli syndrome 1 result from myosin Va expression in neurons, and the immunodeficiency and hemophagocytic syndrome that characterize Griscelli syndrome 2 reflect RAB27A expression in hematopoietic cells.

MOLECULAR CLASSIFICATION OF HEREDITARY SKIN DISORDERS

Molecular classification (see Table 55.1) represents a useful approach to the categorization of genodermatoses. Based on the pathogenetic defect rather than the clinical presentation, it can facilitate better understanding of important cellular pathways such as phosphatidylinositol 3-kinase (PI3K)/AKT or RAS/MAPK signaling (see Fig. 113.1). Several groups of genodermatoses for which molecular classification has been instructive are discussed below.

Keratin Defects

In 1991, EB simplex became the first human disease shown to be caused by intermediate filament mutations. Molecular defects in keratins have subsequently been identified in a diverse group of hereditary skin disorders, with manifestations including mechanical fragility (EB simplex), scaling/hyperkeratosis (keratinopathic ichthyoses, palmoplantar keratodermas [PPKs]), hyperpigmentation (Dowling–Degos disease), nail dystrophy (pachyonychia congenita), hair abnormalities (monilethrix), oral mucosal changes (white sponge nevus), and ectodermal dysplasia (Naegeli–Franceschetti–Jadassohn syndrome) (see Table 56.4)[16].

Keratin intermediate filaments are expressed in a tissue- and differentiation-specific fashion. They are composed of heterodimeric subunits formed by the specific pairing of a type I (acidic) and type II (basic–neutral) keratin (see Ch. 56). Many keratin disorders can be caused by mutations (often dominant negative) in either the type I or type II component of a particular keratin pair, thus exhibiting locus heterogeneity (e.g. KRT10 or KRT1 for epidermolytic ichthyosis; KRT14 or KRT5 for EB simplex). Allelic heterogeneity is also observed, with mutations in the highly conserved helix initiation and termination motifs leading to more severe phenotypes (e.g. severe EBS) than those in other regions (e.g. localized EBS) (see Fig. 56.5).

GROUPS OF MONOGENIC SKIN DISORDERS LISTED IN TABLES ELSEWHERE IN THE BOOK	
Category	**Table(s)**
Congenital insensitivity to pain and related neuropathies	Table 6.10
Epidermolysis bullosa and other blistering disorders	Tables 32.1 & 32.3
Sclerodermoid disorders	Table 43.7
Autoinflammatory diseases	Tables 45.2 & 45.7
Porphyrias	Table 49.3
Keratinopathies and desmosomal disorders	Table 56.4; Figs. 56.5 & 56.8
Ichthyoses	Tables 57.1, 57.2, 57.6, 57.7 & 57.8
Connexin disorders and keratodermas	Tables 58.5 & 58.6
Primary immunodeficiencies	Tables 60.4, 60.6, 60.8, 60.10, 60.13, 60.15 & 60.16
Disorders associated with multiple café-au-lait macules	Table 61.3
Epidermal nevi and other mosaic disorders	Tables 62.3 & 62.6
Progeroid syndromes/inherited poikilodermas and nuclear membrane disorders	Tables 63.9 & 63.10
Ectodermal dysplasias	Tables 63.11–63.13
Aplasia cutis congenita, cleft lip/palate, and digital anomalies	Tables 64.3–64.6
Disorders of hypopigmentation (diffuse or circumscribed)	Tables 65.1 & 66.4
Disorders with reticulated hyperpigmentation, dyskeratosis congenita, and dyschromatoses	Tables 67.8, 67.9 & 67.11
Hypotrichosis, hair shaft disorders, and hypertrichosis	Tables 69.7; 70.1 & 70.2
Xeroderma pigmentosa and other photosensitivity disorders	Table 87.4
Hyperlipidemias	Table 92.2
Ehlers–Danlos syndrome, cutis laxa, and other extracellular matrix disorders	Tables 95.5; 97.1, 97.2 & 97.7
Lipodystrophy syndromes	Table 101.1
Vascular anomalies and overgrowth syndromes	Tables 104.2 & 104.5
Lymphatic malformations/lymphedema	Table 105.7
Disorders with multiple lentigines	Table 112.2

Table 55.2 Groups of monogenic skin disorders listed in tables elsewhere in the book. In addition, other chapters (especially in the genodermatosis section) have tables that present more detailed information on monogenic skin disorders.

Defects in Intercellular Junctions

Mutations in genes encoding components of desmosomes and gap junctions underlie a variety of genodermatoses, several of which have prominent extracutaneous manifestations.

Desmosomal defects

Desmosomes are intercellular junctions that provide mechanical integrity to tissues by anchoring intermediate filaments to the cell surface and mediating strong cell–cell adhesion (see Fig. 29.3B). They are particularly important in stratified squamous epithelia and the myocardium, tissues that are subjected to substantial mechanical stress[17]. It is therefore not surprising that impaired keratinization (especially PPK), skin fragility, and cardiomyopathy represent features of disorders caused by defects in desmosomal proteins such as desmoplakin, plakoglobin, and plakophilin 1 (see Fig. 56.8). Abnormal hair (oftentimes woolly in nature) can also result from abnormalities in these proteins, and defects in other desmosomal components such as desmoglein 4 and corneodesmosin (which are highly expressed within the hair follicle) can lead to hypotrichosis and (for desmoglein 4) an autosomal recessive form of monilethrix (Fig. 55.1). Additional consequences of desmosomal defects include inflammatory peeling skin (corneodesmosin) and *s*evere dermatitis, *a*llergies, and *m*etabolic wasting (SAM; desmoglein 1, desmoplakin).

Fig. 55.1 Autosomal recessive monilethrix due to desmoglein 4 mutations. Sparse short hairs, stubble, and follicular papules on the scalp. Inset: Trichogram showing alternating elliptical nodes and constrictions.

Connexin defects

Gap junctions are intercellular channels that connect the cytoplasm of neighboring cells, facilitating communication that coordinates cellular growth, differentiation and responses to stimuli as well as tissue morphogenesis and homeostasis (see Ch. 58). Transmembrane connexin proteins undergo oligomerization to form the connexons that compose gap junctions. Connexin proteins such as Cx26, Cx30, Cx31, and Cx43 are preferentially expressed in ectoderm-derived epithelia of the inner ear and cornea as well as in the epidermis and its appendages[18]. This accounts for the sensorineural deafness, keratitis, and cutaneous abnormalities ranging from keratoderma to erythrokeratoderma to ectodermal dysplasias affecting the hair and nails that are observed in various connexin disorders (see Table 55.1). Several connexins are expressed in lymphatic cells, and mutations in the gene encoding Cx47 (*GJC2*) cause a hereditary type of lymphedema[19].

Defects in Keratinocyte–Extracellular Matrix Adhesion

The hemidesmosome links keratin intermediate filaments (KRT5, KRT14) within basal keratinocytes to proteins within the lamina densa (basement membrane proper) and sublamina densa regions of the epidermal basement membrane zone (see Ch. 28). Defects in protein components of these structures lead to various forms of EB (simplex, junctional, and dystrophic; see Ch. 32)[20]. The basement membranes of epithelia in other sites such as the eye, oral cavity, gastrointestinal tract, and genitourinary tract may also be affected in patients with EB. Additional clinical manifestations can result when the abnormal protein has important functions in extraepithelial tissues, such as the skeletal muscle for plectin (leading to EBS with muscular dystrophy).

Focal adhesions are structurally defined sites of linkage between the intracellular actin cytoskeleton and the extracellular matrix (ECM; see

Fig. 28.3B). Mutations in the gene encoding the focal adhesion protein kindlin-1 cause Kindler EB, an autosomal recessive disorder characterized by acral blistering and photosensitivity early in life, progressive poikiloderma, and erosive periodontal disease (see Ch. 32). Kindlin-1 is found within basal keratinocytes along the cell surface that faces the basement membrane, and it has roles in keratinocyte adhesion, polarity, proliferation, and motility. To date, Kindler EB represents the only skin fragility disorder known to be caused by disruption of linkage between actin microfilaments (rather than keratin intermediate filaments) and the ECM[20].

Transmembrane Transporter Defects

Abnormalities in transmembrane transporters underlie a variety of genodermatoses, ranging from oculocutaneous albinism due to defective transporters on lysosome-related organelles to metabolic disorders such as acrodermatitis enteropathica. This list also includes defects in a fatty acid transporter in ichthyosis prematurity syndrome[21] and an intracellular nucleoside transporter in H syndrome (Fig. 55.2)[22]. Disorders of calcium pumps and ATP-binding cassette (ABC) transporters, which underscore the important roles of transmembrane transporters in cutaneous homeostasis, are discussed below.

Calcium pump defects

Darier disease and Hailey–Hailey disease are distinct autosomal dominant disorders that share the histologic feature of epidermal acantholysis leading to suprabasal cleft formation; on an ultrastructural level, this corresponds to disruption of the desmosome–keratin intermediate filament complex. The two conditions also have some clinical similarities, including intertriginous involvement, vesiculobullous lesions (relatively uncommon in Darier disease), nail changes, exacerbation with heat, and frequent superinfections. As a result of these overlapping features, it was initially postulated that Darier disease and Hailey–Hailey disease were allelic disorders caused by defects in a gene encoding a structural component of the epidermis. In 1999, pathogenetic mutations in *ATP2A2*, which encodes a sarcoplasmic/endoplasmic reticulum Ca^{2+} ATPase, were identified in patients with Darier disease. Subsequently, mutations in *ATP2C1*, which encodes a Ca^{2+} ATPase localized to the Golgi apparatus, were shown to cause Hailey–Hailey disease (see Fig. 59.1). Determining the molecular bases of these genodermatoses thus demonstrated the pivotal role of calcium homeostasis in epidermal differentiation and cell–cell adhesion[23].

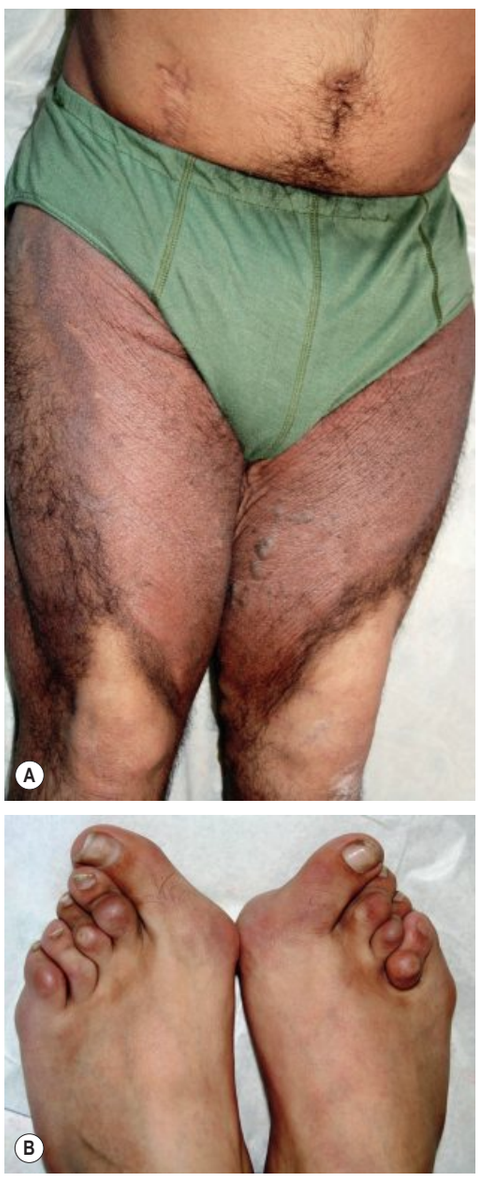


Fig. 55.2 H syndrome (histiocytosis-lymphadenopathy plus syndrome). This autosomal recessive disorder due to mutations in the *SLC29A3* gene (which encodes a nucleoside transporter) presents with *h*yperpigmentation, *h*ypertrichosis, induration, and varicose veins in a characteristic distribution pattern on the thighs with sparing of the knees (**A**). Additional features include *h*allux valgus and flexion contractures of the toes (**B**), *h*epatosplenomegaly, *h*eart anomalies, *h*earing loss, *h*ypogonadism, low *h*eight and *h*yperglycemia/diabetes mellitus.

ATP-binding cassette transporter defects

Members of the ABC transporter superfamily bind and hydrolyze adenosine triphosphate (ATP) in order to transport various molecules across a cell membrane or into a vesicle. Well-known examples include the CFTR (cystic fibrosis transmembrane conductance regulator) chloride ion channel that is defective in patients with cystic fibrosis and the P glycoprotein that mediates multidrug resistance. Several phenotypically diverse genodermatoses are also caused by mutations in ABC transporters (see Table 55.1)[24].

Because pseudoxanthoma elasticum (PXE) features fragmentation and calcification of elastic fibers, this autosomal recessive disorder was initially postulated to result from mutations in an extracellular matrix protein with roles in the skin, eyes, and cardiovascular system. Surprisingly, PXE was instead found to be caused by mutations in *ABCC6*, which encodes a hepatocyte efflux pump that transports ATP to the extracellular space. Extracellular ATP is rapidly converted to AMP and inorganic pyrophosphate (PPi), with the latter representing a physiologic anti-mineralization factor. PXE therefore actually represents a metabolic disorder with secondary connective tissue manifestations.

Biallelic mutations in *ABCA12*, which encodes a transporter that secretes lipids into lamellar granules, cause both harlequin ichthyosis and a form of lamellar ichthyosis[25] (see Fig. 56.2). Patients with harlequin ichthyosis tend to have nonsense mutations, whereas those with lamellar ichthyosis typically have missense mutations. This represents one of the most clearcut genotype–phenotype correlations observed to date for nonsyndromic autosomal recessive ichthyoses. Defective formation of intercellular lipid layers, which are essential for epidermal barrier function, due to genetic defects in lipid metabolism also represents the pathomechanism of an expanding list of other ichthyosiform disorders (see Table 55.1 and Fig. 56.2)[25].

Nuclear Envelope Defects

"Nuclear envelopathies" represent a clinically heterogeneous group of inherited disorders caused by defects in structural components of the nuclear envelope (see Table 63.10). In addition to a variety of extracutaneous findings – e.g. skeletal dysplasia, muscular dystrophy, cardiomyopathy, and neuropathy – dermatologic manifestations include: premature aging of the skin, e.g. in progeria and "atypical Werner syndrome" due to *LMNA* mutations; cutaneous fibrosis, e.g. in restrictive dermopathy and Buschke–Ollendorff syndrome/melorheostosis due to *LMNA* and *LEMD3* mutations, respectively; and partial lipodystrophy, e.g. familial Dunnigan and "acquired" Barraquer–Simons types due to *LMNA* and *LMNB2* mutations, respectively.

"Laminopathies" represent the largest subgroup of envelopathies and result from mutations in the genes that encode the lamin A/C and lamin B2 proteins of the nuclear membrane lamina, which lies just inside the inner nuclear membrane[26]. *LEMD3* encodes MAN1, an inner nuclear membrane protein that associates with lamin A. In addition to "true" envelopathies, mutations in *ZMPSTE24*, which encodes a zinc metallopeptidase involved in the processing of prelamin A into mature lamin A, can result in restrictive dermopathy and mandibuloacral dysplasia characterized by lipodystrophy, premature aging, and skeletal defects. The study of patients with envelopathies has provided insight into the importance of lamins and other nuclear envelope proteins to the structural integrity of the nucleus, chromatin organization, transcriptional regulation, control of differentiation, and mechanisms of aging[26].

Defects in Pyrin/NOD Family Members and Related Proteins

The molecular bases of several hereditary periodic fever syndromes and other autoinflammatory disorders have been found to be due to defects in proteins containing *n*ucleotide-binding *o*ligomerization *d*omains (NODs) and/or pyrin domains (see Table 45.2)[27]. This has drawn attention to the NOD and pyrin families and related proteins (see Fig. 4.2), helping to uncover their importance in innate immune responses and acquired inflammatory disorders. Defects in such proteins lead to diverse cutaneous phenotypes, ranging from urticarial papules in cryopyrin-related disorders and erysipeloid erythema in familial Mediterranean fever to nodulocystic acne and pyoderma gangrenosum in PAPA syndrome to granulomatous dermatitis (together with arthritis and uveitis) in Blau syndrome (see Fig. 45.11C). Upon uncovering *NOD2* mutations as the defect in Blau syndrome, it was also established that this autosomal dominant disorder and sporadic "early-onset sarcoidosis" are identical on a genetic as well as phenotypic level (with the latter resulting from *de novo NOD2* mutations), thus representing a single disease entity. However, other *NOD2* variants have been implicated in Crohn disease and susceptibility to leprosy.

Defects in DNA Repair Genes, Tumor Suppressor Genes, and Oncogenes

Hereditary tumor syndromes that affect the skin can be divided into groups based upon whether the associated neoplasms are primarily benign skin tumors (Table 55.3), skin cancers (Table 55.4), or extracutaneous malignancies (Table 55.5); individuals in the latter group may have either benign cutaneous neoplasms (e.g. Cowden syndrome) or non-neoplastic skin lesions (e.g. ataxia–telangiectasia)[28]. To complement this clinical approach, molecular classification of such syndromes can help to explain relationships among disorders, understand the

SELECTED HEREDITARY DISORDERS CHARACTERIZED BY BENIGN SKIN TUMORS			
Disorder	**Mode of inheritance**	**Gene or gene product**	**Gene symbol**
Familial cylindromatosis; Brooke–Spiegler syndrome; multiple familial trichoepitheliomas	AD	CYLD (deubiquitinating enzyme)	*CYLD*
Familial mastocytosis ± gastrointestinal stromal tumors*	AD	KIT proto-oncogene (stem cell factor receptor)	*KIT*
Lipomatosis, familial multiple	AD		
Lipomatosis, benign symmetric (Madelung disease)†	mt	Mitochondrial tRNA-lysine	*MT-TK*
	AR	Mitofusin 2	*MFN2*
	AR	Lipase E, hormone sensitive	*LIPE*
Ferguson–Smith multiple self-healing squamous epitheliomas	AD	Transforming growth factor-β receptor 1 (loss-of-function mutations)	*TGFBR1*
Neurofibromatosis type 1‡	AD	Neurofibromin 1 (GTPase activating protein)	*NF1*
Neurofibromatosis type 2	AD	Neurofibromin 2 (merlin)	*NF2*
Tuberous sclerosis complex	AD	Hamartin	*TSC1*
	AD	Tuberin	*TSC2*

*Occasionally malignant.
†Associated with myoclonic epilepsy with ragged red fibers (MT-TK mutations), neuropathy (MFN2 mutations), or partial lipodystrophy and myopathy (LIPE mutations).
‡Also associated with malignant peripheral nerve sheath tumors.

Table 55.3 Selected hereditary skin disorders characterized by benign skin tumors. Disorders associated with extracutaneous cancer as well as benign skin tumors are listed in Table 55.5. These conditions are discussed in Chapters 61, 62, 104, 117, and 118. mt, mitochondrial inheritance.

SELECTED HEREDITARY DISORDERS ASSOCIATED WITH SKIN CANCER			
Disorder	**Mode of inheritance**	**Gene or gene product**	**Gene symbol**
Bazex–Dupré–Christol syndrome	XD	Actin-related protein T1	*ACTRT1*
Epidermodysplasia verruciformis	AR	Transmembrane channel-like 6	*TMC6*
	AR	Transmembrane channel-like 8	*TMC8*
BAP1 tumor predisposition syndrome*	AD	BRCA-associated protein 1	*BAP1*
Familial atypical mole and melanoma (FAMM) syndrome*	AD	Cyclin-dependent kinase inhibitor 2A†	*CDKN2A*
	AD	Cyclin-dependent kinase 4	*CDK4*
Basal cell nevus syndrome	AD	Patched 1	*PTCH1*
	AD	Patched 2	*PTCH2*
	AD	Suppressor of fused homolog (Drosophila)	*SUFU*
Huriez syndrome (sclerotylosis)	AD		
Palmoplantar keratoderma with cutaneous SCC and sex reversal	AR	R-spondin 1	*RSPO1*
Pigmentation defects, palmoplantar keratoderma, and cutaneous SCC	AR	SAM and SH3 domain-containing 1	*SASH1*
Xeroderma pigmentosum (see Table 87.4)			

*Also associated with melanocytic nevi.
†Also associated with increased risk of developing pancreatic cancer.

Table 55.4 Selected hereditary disorders associated with skin cancer. These conditions are discussed in Chapters 79, 87, 99, 108, and 112. SCC, squamous cell carcinoma.

SELECTED HEREDITARY SKIN DISORDERS ASSOCIATED WITH EXTRACUTANEOUS CANCER				
Disorder	**Mode of inheritance**		**Gene or gene product**	**Gene symbol**
Ataxia–telangiectasia	AR		Ataxia–telangiectasia mutated (phosphatidylinositol 3-kinase-like serine/threonine protein kinase)	*ATM*
Birt–Hogg–Dubé syndrome	AD		Folliculin	*FLCN*
Bloom syndrome	AR		RecQ protein-like 3 (DNA helicase)	*BLM (RECQL3)*
Costello syndrome (see text)	AD		v-Ha-ras Harvey rat sarcoma viral oncogene homolog	*HRAS*
	AD		v-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog	*KRAS*
Dyskeratosis congenita (see Table 67.9)				
Ectodermal dysplasia–neoplastic syndrome	AD		Axis inhibitor 2	*AXIN2*
Gardner syndrome (variant of familial adenomatous polyposis)	AD		Adenomatous polyposis coli	*APC*
Howel–Evans syndrome (tylosis–esophageal carcinoma)	AD		Rhomboid 5 homolog 2	*RHBDF2*
Leiomyomatosis, cutaneous and uterine (Reed syndrome)	AD		Fumarate hydratase	*FH*
Muir–Torre syndrome (variant of Lynch syndrome)	AD		MutS homolog 2 (mismatch repair enzyme)	*MSH2*
	AD		MutS homolog 6 (mismatch repair enzyme)	*MSH6*
	AD		MutL homolog 1 (mismatch repair enzyme)	*MLH1*
MUTYH-associated polyposis	AR		MutY homolog	*MUTYH*
Constitutional mismatch repair deficiency syndrome (childhood tumor syndrome with neurofibromatosis type 1 phenotype)	AR		MutS homolog 2 (mismatch repair enzyme)	*MSH2*
	AR		MutS homolog 6 (mismatch repair enzyme)	*MSH6*
	AR		MutL homolog 1 (mismatch repair enzyme)	*MLH1*
	AR		Postmeiotic segregation increased 2 (mismatch repair enzyme)	*PMS2*
Multiple endocrine neoplasia (MEN)	MEN 1	AD	Menin	*MEN1*
	MEN 2A	AD	Ret proto-oncogene (cysteine-rich extracellular domain)	*RET*
	MEN 2B	AD	Ret proto-oncogene (particularly Met918Thr in substrate recognition pocket)	*RET*
	MEN 4	AD	Cyclin-dependent kinase inhibitor 1B (p27, Kip1)	*CDKN1B*
PTEN hamartoma tumor syndrome (including Cowden and Bannayan–Riley–Ruvalcaba syndromes)	AD		Phosphatase and tensin homolog	*PTEN*
Rothmund–Thomson syndrome	AR		RecQ protein-like 4 (DNA helicase)	*RECQ4*

Table 55.5 Selected hereditary skin disorders associated with extracutaneous cancer. These conditions are discussed in Chapters 60, 63, 67, 87, and 117.

disrupted pathway or process, and suggest candidate genes for patients with similar phenotypes for which the underlying molecular defect has not yet been identified. In addition to characterization based on the specific pathomechanism (e.g. RAS–MAPK pathway activation[29]; see below), hereditary cancer syndromes can be separated into three general categories: (1) defective DNA repair and protection of genomic integrity ("caretaker" genes); (2) defective tumor suppressor ("gatekeeper") genes; and (3) activated oncogenes.

Defective DNA repair and protection of genomic integrity

Inactivation of caretaker genes causes an increased mutation rate in all genes, including gatekeeper genes with critical roles in controlling tumor growth (see below). Classic examples of caretaker dysfunction include defects in the nucleotide excision repair of UV-induced DNA damage in xeroderma pigmentosum and abnormal mismatch repair in the Muir–Torre syndrome subtype of the hereditary non-polyposis colorectal cancer syndrome. Defects in RecQ helicases, which function in DNA replication, recombination, and repair, underlie Bloom, Rothmund–Thomson, and Werner syndromes. This leads to genomic instability, as evidenced by findings such as accumulation of chromosomal aberrations, increased sister chromatid exchange (Bloom syndrome), and shortened telomeres (Werner syndrome). The compromised telomere maintenance observed in dyskeratosis congenita can result from defects in telomerase subunits (RNA and reverse transcriptase) or associated proteins (e.g. dyskerin, a Cajal body protein, ribonucleoprotein homologs, shelterin complex components; see Table 67.9).

Defective tumor suppressor genes

In hereditary cancer syndromes caused by a defective tumor suppressor gene, there is classically a heterozygous germline loss-of-function mutation followed by a somatic "second hit" that leads to loss of heterozygosity and abrogation of protein function in affected tissues. Examples include *PTCH* (encoding patched) in basal cell nevus syndrome, *CDKN2A* (encoding $p16^{INK4a}$ and $p14^{ARF}$, which maintain activity of the retinoblastoma [Rb] and p53 tumor suppressor proteins, respectively) in the familial atypical mole and melanoma syndrome (see Fig. 107.4), and *PTEN* in the PTEN hamartoma tumor syndrome (see Table 63.3). The PTEN protein negatively regulates the PI3K/AKT cascade, which is positively regulated by the RET oncogene (Fig. 55.3; see below). The *PIK3CA*-related overgrowth spectrum and Proteus syndrome are caused by mosaicism for an activating mutation in *PIK3CA* and *AKT1* oncogenes, respectively. The roles of these proteins in the same pathway explains these conditions' clinical similarity to one another as well as to mosaic forms of PTEN hamartoma tumor syndrome (see Table 104.5 and below).

Activated oncogenes

Germline *gain*-of-function mutations in oncogenes have been identified in some autosomal dominant hereditary tumor syndromes, including *RET* in multiple endocrine neoplasia (MEN) 2A/2B (see Fig. 55.3), *KIT* in familial mastocytosis plus gastrointestinal stromal tumors, and those encoding RAS–MAPK pathway components in some "RASopathies" (Fig. 55.4). The latter include Costello (Fig. 55.5), Noonan, and

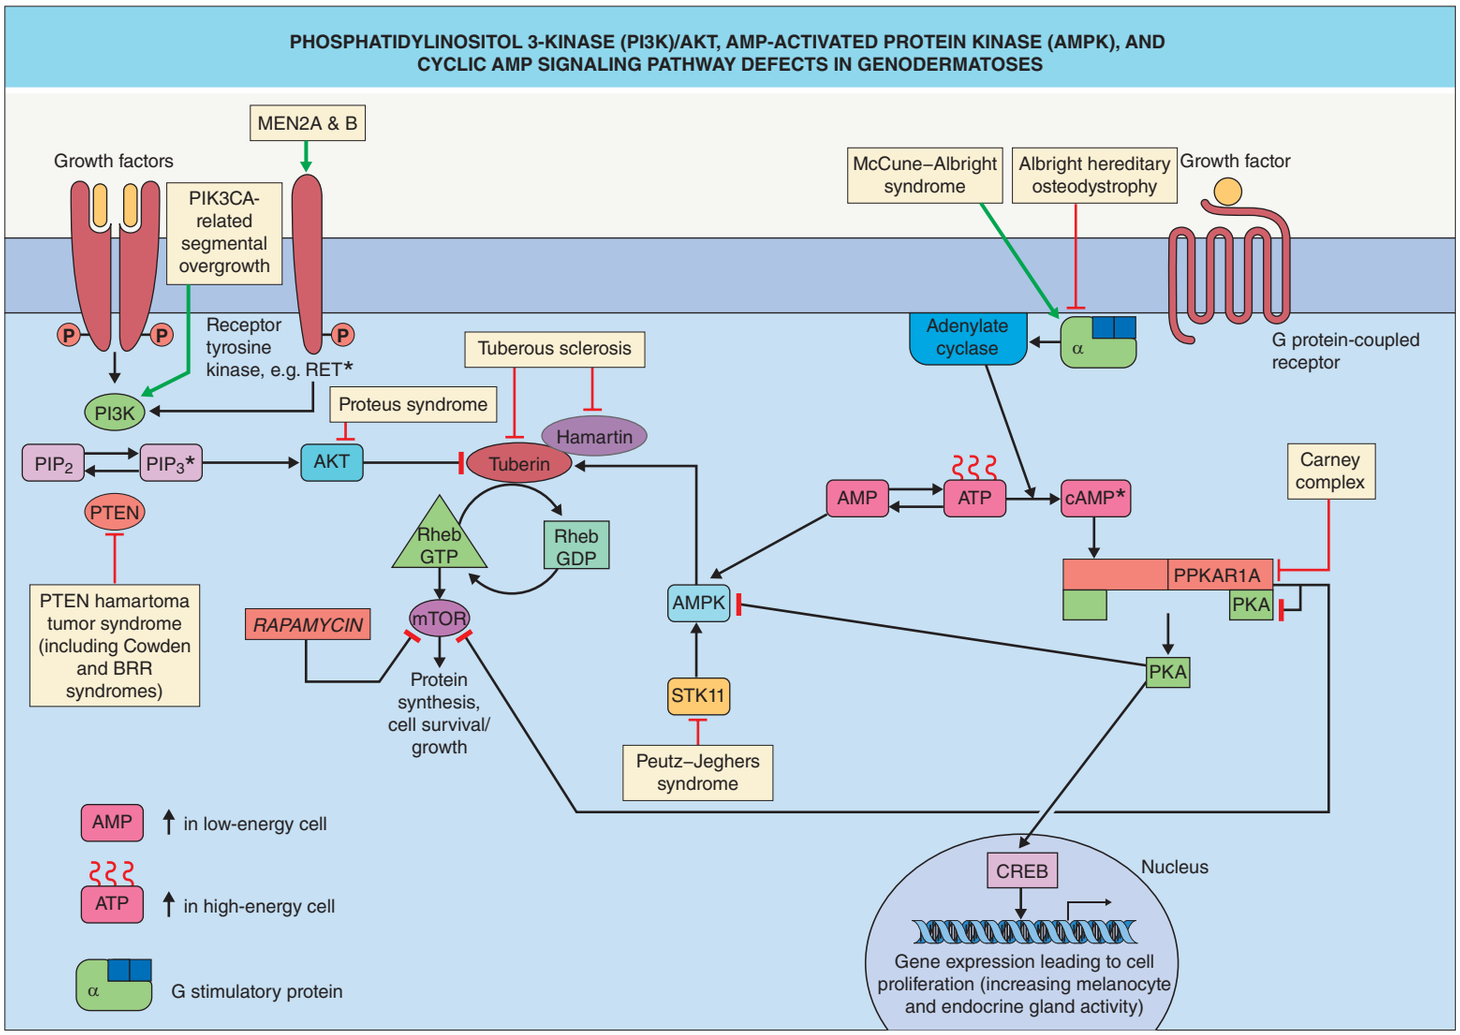

Fig. 55.3 Phosphatidylinositol 3-kinase (PI3K)/AKT, AMP-activated protein kinase (AMPK), and cyclic AMP signaling pathway defects in genodermatoses. The PI3K/AKT pathway is negatively regulated by the PTEN tumor suppressor protein and can be stimulated by a variety of receptor tyrosine kinases as well as by RAS (via cross-talk with the RAS–ERK pathway; see Fig. 55.4). AKT (protein kinase B) inhibits the GTPase activating-protein tuberin, which leads to increased *m*ammalian *t*arget *o*f *r*apamycin (mTOR) activity and resultant cell growth. During periods of nutrient depletion (high AMP/low ATP), serine–threonine kinase 11 (STK11) promotes AMPK-mediated activation of tuberin, which results in decreased mTOR activity and less protein synthesis. Ligand binding to G protein-coupled receptors activates adenylate cyclase, producing increased intracellular cAMP and activation of protein kinase A catalytic subunits (PKA; via release from *p*rotein *k*inase *A* regulatory subunit 1α [PRKAR1A]); this leads to transcription of *c*AMP *r*esponse *e*lement *b*inding protein (CREB)-controlled genes as well as inhibition of AMPK (which is also negatively regulated by AKT). *Other effector pathways include activation of RAS–ERK (see Fig. 55.4). AMP, adenosine monophosphate; ATP, adenosine triphosphate; BRR, Bannayan–Riley–Ruvalcaba; ERK, *e*xtracellular signal-*r*egulated *k*inase; GDP, guanosine diphosphate; GTP, guanosine triphosphate; PIP_2, phosphatidylinositol diphosphate; PIP_3, phosphatidylinositol triphosphate; PTEN, phosphatase and tensin homolog deleted on chromosome 10.

cardio-facio-cutaneous (CFC) syndromes as well as Noonan with multiple lentigines (LEOPARD) syndrome[29,30]. In addition, neurofibromatosis type 1 (NF1), Legius syndrome (previously referred to as NF1-like syndrome), and capillary malformation–arteriovenous malformation (CM-AVM) represent RASopathies due to germline *loss*-of-function mutations in tumor suppressor genes that normally downregulate RAS–MAPK signaling[29].

RASopathies share extracutaneous features such as ocular hypertelorism, macrocephaly, cardiac defects (especially pulmonary stenosis), and developmental delay, as well as a spectrum of skin findings that includes hair abnormalities (e.g. curly, woolly, loose anagen), pigmented lesions (e.g. lentigines, melanocytic nevi, café-au-lait macules)[31], keratosis pilaris, acanthosis nigricans, and distal phalangeal transverse creases (see Fig. 55.5B&C). Some RASopathies also have more specific cutaneous manifestations, such as neurofibromas in NF1, lax acral skin in Costello syndrome (see Fig. 55.5B), and capillary and arteriovenous malformations in CM-AVM. Different RASopathies are associated with variably increased risks for the development of benign (e.g. neurofibromas in NF1) and malignant (e.g. rhabdomyosarcoma in Costello syndrome) tumors. Targeted drugs aimed at proteins in the RAS–MAPK pathway hold promise for the treatment of sporadic cancers (e.g. BRAF inhibitors for melanoma) as well as RASopathies themselves (e.g. MEK inhibitors for plexiform neurofibromas)[32].

Defects in WNT/β-Catenin Signaling

WNT (*w*ingless-type *int*egration site) family members are lipid-modified, secreted signaling proteins that play important roles in numerous physiologic and pathologic processes, ranging from stem cell differentiation, cell polarity/adhesion, and tissue morphogenesis/maintenance (including hair follicle development) to wound repair, inflammation, oncogenesis, and aging. WNT signaling can be divided into canonical (β-catenin-dependent) and non-canonical (β-catenin-independent) pathways. Several genodermatoses result from defects in proteins that function in the WNT/β-catenin pathway (Fig. 55.6). Goltz syndrome (focal dermal hypoplasia; Fig. 55.7) is caused by mutations in *PORCN*, which encodes an O-acyltransferase in the endoplasmic reticulum that palmitoylates and thereby facilitates secretion of WNT proteins. Mutations in *WNT10A* produce several relatively common forms of ectodermal dysplasia as well as Schöpf–Schulz–Passarge syndrome (featuring hidrocystomas and palmoplantar keratoderma with eccrine syringofibroadenomatosis). Gardner syndrome (a variant

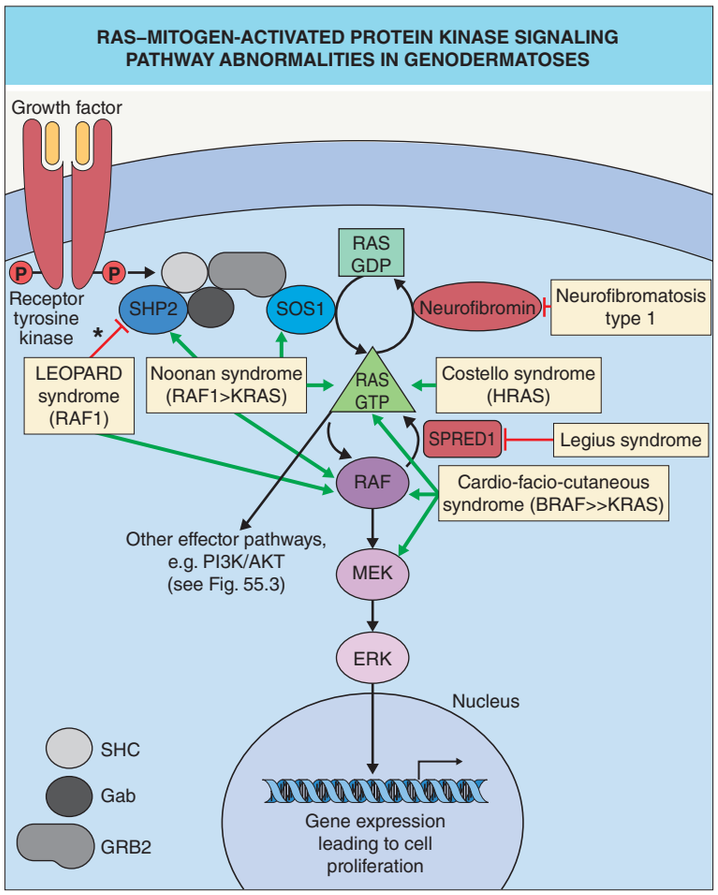

Fig. 55.4 RAS–mitogen-activated protein kinase (MAPK) signaling pathway abnormalities in genodermatoses. The phenotypic overlap among neurofibromatosis type 1 and Legius, Noonan, cardio-facio-cutaneous, Costello, and Noonan with multiple lentigines (also referred to as LEOPARD) syndromes is explained by underlying germline mutations in different components of the RAS–MAPK pathway that lead to activation of this signaling cascade. Of note, similar *somatic* activating mutations are found in a variety of benign and malignant tumors (e.g. *BRAF* or *NRAS* mutations in the majority of melanocytic nevi and melanomas; see Ch. 113) as well as epidermal/sebaceous nevi (see Ch. 62). Growth factor binding to receptor tyrosine kinases results in activated receptor complexes containing adapters such as Src *h*omology 2 domain-*c*ontaining (SHC), *g*rowth factor *r*eceptor-*b*ound 2 (GRB2), and GRB2-*a*ssociated *b*inding (Gab) proteins as well as SH2 domain-containing protein tyrosine phosphatase 2 (SHP2; encoded by *PTPN11*), which relays signals from activated receptors to RAS and deactivates negative regulators of RAS (e.g. Sprouty). The activated receptor complex recruits son of sevenless homolog 1 (SOS1), a guanine nucleotide exchange factor that increases levels of active RAS–guanosine triphosphate (GTP). In contrast, neurofibromin is a GTPase activating protein that promotes hydrolysis of RAS–GTP to RAS–guanosine diphosphate (GDP), which terminates signaling. **In vitro* studies suggest a dominant negative effect, but the consequences could vary depending on the substrate, cell type, or developmental stage.

Fig. 55.5 Costello syndrome due to a heterozygous activating *HRAS* mutation in a 3-year-old girl. **A** Verrucous periorificial (periocular, perinasal) plaques. **B** Loose acral skin with deep palmoplantar creases. Note the distal phalangeal transverse crease on the thumb. **C** Acanthosis nigricans.

of *a*denomatous *p*olyposis *c*oli) is due to mutations in the *APC* tumor suppressor gene that encodes an inhibitor of WNT/β-catenin signaling[33], and mutations in the APC downregulated 1 gene (*APCDD1*) underlie hereditary hypotrichosis simplex. Lastly, anonychia congenita and "palmoplantar keratoderma with cutaneous SCC and sex reversal" are caused by mutations in genes encoding R-spondins that activate WNT/β-catenin signaling.

CONTIGUOUS GENE SYNDROMES

Certain syndromic associations actually represent contiguous gene syndromes caused by large deletions that affect two or more neighboring genes. For example, deletions in the Xp22.3 region can give rise to X-linked recessive ichthyosis, X-linked recessive chondrodysplasia punctata, Kallmann syndrome (hypogonadotrophic hypogonadism with anosmia), ocular albinism type 1, short stature, and intellectual disability. Of note, more than 90% of patients with X-linked recessive ichthyosis have complete deletion of the *STS* gene and flanking sequences, which represents one of the highest incidences of chromosomal deletions among all genetic disorders. Additional genodermatoses that can present as contiguous gene syndromes include Ehlers–Danlos syndrome (due to tenascin-X deficiency) plus congenital adrenal hyperplasia (due to 21-hydroxylase deficiency), tricho-rhino-phalangeal syndrome plus multiple cartilaginous exostoses (together referred to as Langer–Giedion syndrome), and MIDAS (*mi*crophthalmia, *d*ermal *a*plasia, and *s*clerocornea) syndrome plus Aicardi syndrome (agenesis of the corpus callosum with a chorioretinal abnormality).

CUTANEOUS MOSAICISM

The current medical definition of a mosaic is: the coexistence of at least two genotypes in an individual derived from a single zygote, by the time

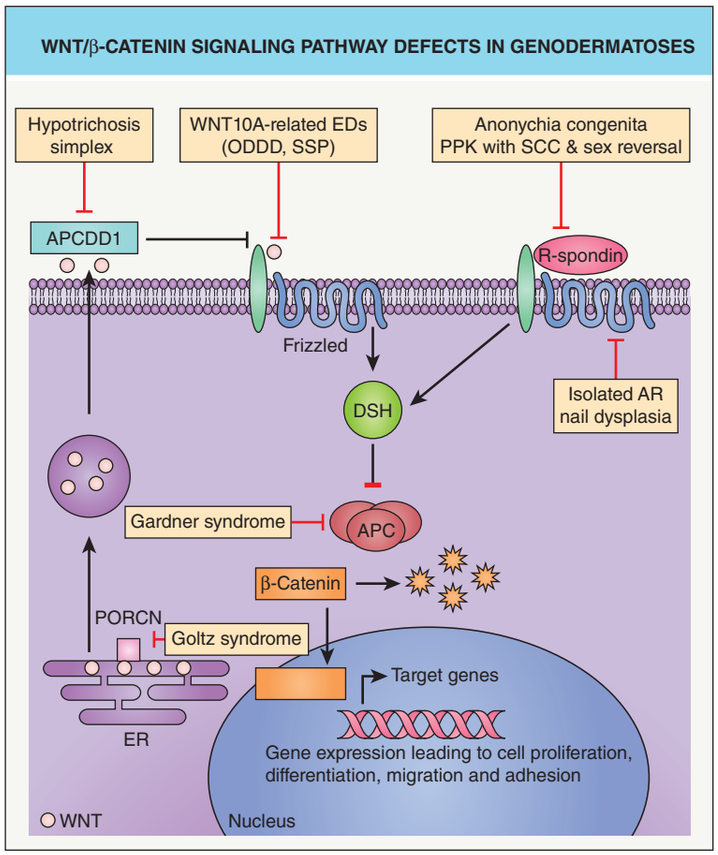

Fig. 55.6 WNT/β-catenin signaling pathway defects in genodermatoses. The porcupine homolog (PORCN) O-acyltransferase in the endoplasmic reticulum (ER) palmitoylates WNT proteins, facilitating their secretion. Extracellular WNT binds to the frizzled transmembrane receptor, which activates dishevelled (DSH), a cytosolic protein that inhibits the "destruction complex" (containing the adenomatous polyposis coli [APC] tumor suppressor protein) that mediates proteasomal degradation of β-catenin. As a result, β-catenin accumulates and is translocated to the nucleus, where it induces the transcription of genes that lead to cell proliferation, differentiation, migration, and adhesion. APC downregulated 1 (APCDD1) can inhibit WNT signaling. R-spondins are other secreted proteins that bind to frizzled and activate the WNT/β-catenin pathway. AR, autosomal recessive; EDs, ectodermal dysplasias; ODDD, odonto-onycho-dermal dysplasia; PPK, palmoplantar keratoderma; SCC, squamous cell carcinoma; SSP, Schöpf–Schulz–Passarge syndrome.

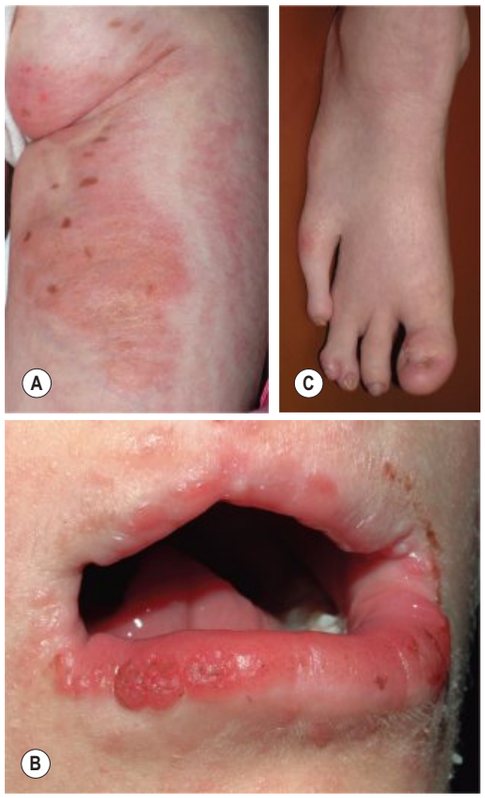

Fig. 55.7 Goltz syndrome (focal dermal hypoplasia). **A** Hyperpigmented macules and dermal atrophy with fat "herniation" on the posterior thigh. **B** Raspberry-like papillomas on the lower lip. **C** Ectrodactyly.

of birth, and which gives rise to a disease phenotype[34] (see Ch. 62). As a uniquely accessible organ, the skin provides an excellent opportunity to visualize and study mosaicism[35]. Patterns on the skin due to mosaicism include the lines of Blaschko, phylloid (see below), segmental with quadrilateral shapes, and non-segmental with circular shapes (see Fig. 62.1). Mosaicism for activating mutations affecting RAS-MAPK signaling or G protein α-subunits have been found to underlie a variety of birthmarks, including congenital melanocytic, epidermal, and sebaceous nevi as well as port-wine birthmarks and dermal melanocytosis. A single heterozygous mutation in a multipotent progenitor cell can lead to multiple types of birthmarks involving different skin lineages, such as nevus spilus (melanocytic) plus nevus sebaceus in phakomatosis pigmentokeratotica (*HRAS*) or port-wine birthmarks (vascular) plus dermal melanocytosis in phakomatosis pigmentovascularis (*GNAQ* or *GNA11*)[36,37]. Extracutaneous manifestations may occur if the mutation involves other organs such as the brain, eye, or bones.

Mosaic forms of autosomal dominant genodermatoses include: (1) a heterozygous postzygotic mutation occurring on a wild-type ("normal") background (type 1); and (2) a postzygotic "second hit" leading to loss-of-heterozygosity in the setting of a heterozygous constitutional mutation (type 2). The latter manifests clinically as a superimposed area of earlier onset or more severe disease than the background of generalized disease, e.g. linear porokeratosis in a patient with disseminated superficial actinic porokeratosis. Examples of type 1 mosaicism that have been confirmed on a molecular level include epidermolytic (*K1* or *K10*) and non-epidermolytic (fibroblast growth factor receptor 3 *[FGFR3]*) epidermal nevi; constitutional mutations in these genes produce epidermolytic ichthyosis and craniosynostosis syndromes associated with severe acanthosis nigricans (Fig. 55.8), respectively. Both type 1 and type 2 mosaicism have been documented for Darier disease (*ATP2A2*) and Hailey–Hailey disease (*ATP2C1*) (Fig. 55.9), while type 2 mosaicism has been confirmed for several genodermatoses due to a defective tumor suppressor gene, such as NF1, basal cell nevus syndrome (*PTCH1*), and PTEN hamartoma tumor syndrome.

All women and girls are *functional* mosaics due to the random, irreversible, stably inherited inactivation of one of the two X chromosomes that occurs in each cell during early embryonic development (lyonization). However, 15% of genes on the human X chromosome escape lyonization and 10% are variably inactivated. In women heterozygous for X-linked disorders, functional mosaicism can result in skin lesions that follow the lines of Blaschko or have other mosaic distribution patterns. This occurs in female patients with X-linked dominant, male-lethal disorders such as incontinentia pigmenti (*IKBKG/NEMO*), CHILD (*c*ongenital *h*emidysplasia with *i*chthyosiform nevus and *l*imb *d*efects) syndrome (*NSDHL*), Conradi–Hünermann–Happle syndrome (*EBP*), and Goltz syndrome (*PORCN*; see Fig. 55.7) as well as in female "carriers" of X-linked dermatoses such as hypohidrotic ectodermal dysplasia (*EDA*; Fig. 55.10) and *i*chthyosis *f*ollicularis–*a*trichia–*p*hotophobia (IFAP) syndrome (*MBTPS2*; Fig. 55.11). The gene encoding steroid sulfatase escapes lyonization, explaining why skin lesions in a mosaic pattern are not observed in female carriers of X-linked recessive ichthyosis.

REVERTANT MOSAICISM

Revertant mosaicism is a means of "natural gene therapy" in which a spontaneous secondary genetic phenomenon leads to rescue of a disease-causing mutation, allowing a mosaic clone of heterozygous cells to regain wild-type ("normal") function[38]. It has been described most often in patients with EB (see Ch. 32), potentially explaining the tendency of some forms of this condition to improve with age. A growth advantage and selective pressures (e.g. blistering) may help to increase the number of revertant cells over time. Revertant mosaicism via mitotic recombination accounts for the numerous small "islands" of normal skin in a

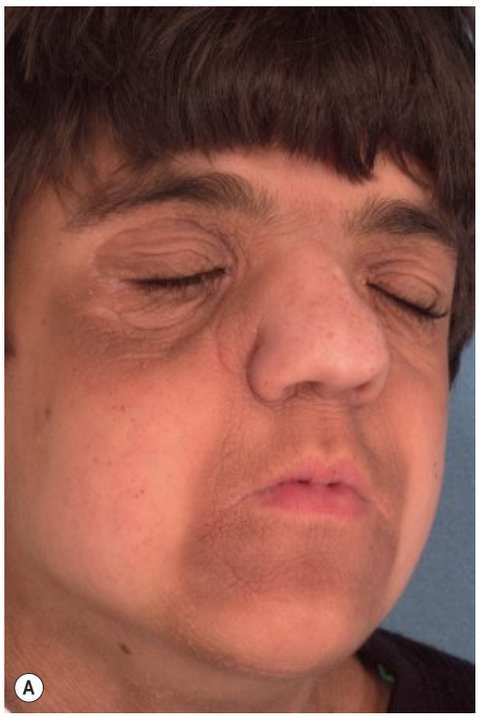

Fig. 55.8 Skin disease due to fibroblast growth factor receptor 3 (FGFR3) defects. **A** Severe acanthosis nigricans in a patient with the Crouzon craniosynostosis syndrome. **B** Systematized epidermal nevus in a young boy who had developmental delay. These conditions can be caused by germline and mosaic *FGFR3* mutations, respectively. *A, Courtesy Seth J. Orlow, MD, PhD.*

background of ichthyosiform erythroderma that characterize ichthyosis en confetti[39]. Affected individuals have specific frameshift mutations in *KRT10* or *KRT1*, which produce mutant proteins with an arginine-rich C-terminus that redirects them to the nucleolus; this mislocalization may have a role in promoting the reversion.

CHROMOSOMAL DISORDERS

Chromosomal disorders represent abnormalities in the number or structure of chromosomes. Aneuploidy refers to having an additional or missing chromosome; examples that are compatible with postnatal survival include complete trisomies for chromosomes 21 (Down syndrome; Fig. 55.12), 18 (Edwards syndrome), and 13 (Patau syndrome) as well as monosomy for the X chromosome (Turner syndrome) and XXY (Klinefelter syndrome) or XYY karyotypes. Mosaic aneuploidies or partial trisomies and monosomies due to duplications, deletions, or translocations of portions of chromosomes can also occur. The cutaneous and extracutaneous features of several relatively common chromosomal disorders are presented in Table 55.6.

Phylloid hypomelanosis, characterized by leaf-like hypopigmented patches (Fig. 55.13), usually results from mosaic trisomy 13. In contrast, hypo- or hypermelanotic streaks and swirls that follow the lines of Blaschko, occasionally with associated extracutaneous findings, can be caused by mosaicism for a variety of chromosomal aberrations (see Ch. 62).

Fig. 55.9 Type 2 segmental Hailey–Hailey disease. This 7-year-old girl had a history of recurrent blistering on the right abdomen, groin, and thigh since infancy.

Fig. 55.10 Female "carriers" of X-linked hypohidrotic ectodermal dysplasia. **A** The skin within hyperpigmented streaks and swirls following the lines of Blaschko is slightly depressed and very smooth, in contrast to follicular prominence in the surrounding areas. Starch-iodine testing on the back disclosed a patchy distribution of active sweat glands. This 2-year-old girl also had whorled areas of sparse hair on the posterior scalp and several cone-shaped teeth. **B** A color thermogram demonstrates an asymmetric distribution of skin temperature on the anterior trunk. *B, From Clark RP, Goff MR, MacDermot KD. Identification of functioning sweat pores and visualization of skin temperature patterns in X-linked hypohidrotic ectodermal dysplasia by whole body thermography. Hum Genet 1990;86:7–13.*

INSIGHT INTO ACQUIRED SKIN DISORDERS PROVIDED BY THE STUDY OF GENODERMATOSES

Inherited monogenic skin disorders can serve as models to improve our understanding of the pathogenesis of more common acquired skin diseases. For example, basement membrane proteins that are defective in JEB (e.g. type XVII collagen [bullous pemphigoid antigen 2], laminin 332 subunits) and dystrophic EB (type VII collagen) are also targeted in autoimmune blistering diseases such as bullous pemphigoid, mucous membrane (cicatricial) pemphigoid, and EB acquisita (see Fig. 28.7). The excessive granulation tissue that develops due to a truncated laminin α3 subunit in patients with laryngo-onycho-cutaneous syndrome has also provided clues to the role of this protein in regulating angiogenesis and granulation tissue formation during normal wound healing. Likewise, observation of similar dermal hyalinization in lichen sclerosus and the rare genodermatosis lipoid proteinosis led to the discovery of autoantibodies against extracellular matrix protein 1, the protein that is defective in the latter disorder, in the majority of patients with lichen sclerosus[40]. In addition, investigation of monogenic type I interferonopathies such as Aicardi–Goutières syndrome, familial chilblain lupus, and STING-associated vasculopathy with onset in infancy (SAVI; see Ch. 45) that are caused by abnormal processing of and immune responses to nucleic acids has provided pathogenic insights and potential targeted therapeutic approaches for lupus erythematosus and dermatomyositis[41,42].

Loss-of-function variants in the gene that encodes filaggrin, the protein that aggregates keratin filaments during keratinocyte terminal differentiation (see Ch. 56), not only cause ichthyosis vulgaris but also represent a major predisposing factor for atopic dermatitis, with a significantly higher prevalence (20%–50%) in individuals with atopic dermatitis compared to the general population (<5%–10%). Defective filaggrin also represents a predisposing factor for asthma, but specifically that occurring in individuals with pre-existing atopic dermatitis. Barrier dysfunction due to abnormalities in the serine protease inhibitor (SPINK5) involved in Netherton syndrome may also play a role in the pathogenesis of atopic dermatitis, and polymorphisms in *SPINK5* have been shown to be associated with this common acquired skin disease.

PRENATAL AND PREIMPLANTATION GENETIC DIAGNOSIS

In the past, prenatal diagnosis was based on techniques such as ultrastructural and immunohistochemical analysis of fetal skin biopsy specimens obtained between 18 and 22 weeks' gestational age (GA). Today, such methods have been largely replaced by DNA-based testing that is less invasive and more reliable. The diagnosis of genodermatoses for which the molecular basis is known can be established prenatally by performing chorionic villus sampling (at 10–12 weeks' GA) or amniocentesis (at 14–16 weeks' GA) and analyzing fetal DNA (after determining the underlying genetic defect in family members)[43]. Non-invasive prenatal diagnostic techniques that utilize fetal cells or cell-free DNA in the maternal circulation have also been developed[44,45]. Preimplantation genetic diagnosis is another option for severe genetic skin diseases. This involves analysis of DNA from single cells (blastomeres) extracted from late cleavage stage embryos following *in vitro* fertilization[46]. In this way, knowing the genetic bases of heritable skin conditions may be of tremendous value to affected families.

TREATMENT FOR HEREDITARY SKIN DISORDERS

Gene Therapy

The accessibility of the skin makes it an excellent target for gene therapy. In recent years, particular progress has been made in developing approaches to gene therapy for EB. For example, *ex vivo* gene therapy has led to functional correction of the skin fragility phenotype in patients with JEB due to *LAMB3* mutations and dystrophic EB due to *COL7A1* mutations, demonstrating for the first time successful

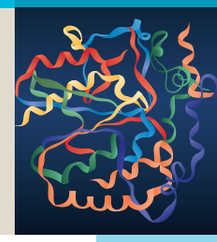
SKIN FINDINGS ASSOCIATED WITH CHROMOSOMAL ABERRATIONS				
Disorder	**Chromosomal aberration**	**Mucocutaneous anomalies**	**Extracutaneous anomalies**	**Comments**
Turner syndrome	45, XO	Congenital lymphedema (usually resolves by age 2 years), low posterior hairline, numerous melanocytic nevi, small hyperconvex nails, tendency to form keloids	Short stature, webbed neck, "shield-like" chest with widely spaced nipples, absence of sexual development, cardiovascular defects, renal malformations, sensorineural hearing loss, autoimmune hypothyroidism	Mosaicism (e.g. 45, XO/46, XX or 45, XO/46, XY) in ~40% of patients
Klinefelter syndrome	47, XXY	Varicose veins, leg ulcers	Tall stature, gynecomastia, small testes, infertility	Mosaicism 46, XY/47, XXY in ~20% of patients; uncommon variants include 48, XXXY and 48, XXYY
Trisomy 21 (Down syndrome)	47, XY, +21 47, XX, +21	Single palmar crease, protruding scrotal tongue, cheilitis (see Fig. 55.12A), multiple syringomas (often with calcification; see Fig. 55.12B), alopecia areata, ichthyosiform hyperkeratosis, keratosis pilaris, milia-like calcinosis cutis, elastosis perforans serpiginosa, multiple collagenomas, cutis marmorata/acrocyanosis; a predisposition to developing folliculitis, dermatophyte infections and Norwegian scabies; vesiculopustular eruptions associated with neonatal transient myeloproliferative disorder	Brachycephaly, characteristic facial appearance (e.g. epicanthal folds, flat nasal bridge), Brushfield spots (speckled irides), broad hands, brachydactyly, atlantoaxial instability, mental disability, immunodeficiency, congenital heart defects, duodenal atresia, leukemia (especially acute myeloid leukemia), hearing loss, autoimmune hypothyroidism	
Phylloid hypomelanosis (see Fig. 55.13)	Mosaic trisomy 13	Round, oval, or oblong hypopigmented macules resembling floral ornaments	Absence of corpus callosum, retinal coloboma, craniofacial defects, brachydactyly, clinodactyly, camptodactyly, conductive hearing loss	
Pallister–Killian syndrome	Mosaic tetrasomy 12p (isochromosome 12p)	Hypopigmented and/or hyperpigmented streaks; fine, sparse hair during infancy	Postnatal growth deficiency, characteristic facies (anteverted nostrils, down-turned mouth with thin upper lip), mental disability	

Table 55.6 Skin findings associated with chromosomal aberrations.

Fig. 55.13 Phylloid hypomelanosis due to mosaic trisomy 13. This condition is characterized by leaf-like and oblong patches of hypopigmentation in a pattern reminiscent of a floral ornament. *Courtesy Arne König, MD and Rudolf Happle, MD.*

gene therapy for a disease of solid tissue[47]. The technique involves retroviral-mediated transduction of autologous epidermal cells with a wild-type copy of the *LAMB3* or *COL71A* gene, followed by grafting of epidermal sheets grown from the genetically corrected cells. *In vivo* topical gene therapy with beremagene geperpavec (B-VEC), a non-replicating *COL7A1*-containing herpes simplex virus type 1 vector, was recently FDA-approved as a treatment to promote wound healing in patients with dystrophic EB[48]. Gene editing using technologies such as CRISPR-Cas9 and base editing to restore expression of functional proteins in EB is also under investigation[49] (see Fig. 3.13). Additional strategies include the use of drugs such as aminoglycoside antibiotics (e.g. topical or intravenous gentamicin) to induce read-through of nonsense mutations in recessive forms of EB as well as utilization of small interfering RNA to specifically "knock down" expression of the mutant protein in dominant-negative disorders such as EB simplex and pachyonychia congenita.

Therapy Targeting Affected Molecular Pathways



Understanding the molecular pathway that is affected in genodermatoses can translate into effective therapy. For example, loss-of-function mutations in tumor suppressor genes that negatively regulate the growth-promoting mTOR (*m*echanistic *t*arget *o*f *r*apamycin) signaling pathway underlie several hamartoma syndromes, including tuberous sclerosis complex, the PTEN hamartoma tumor syndrome, and Peutz–Jeghers syndrome (see Fig. 55.3). Recognition of the mTOR overactivation common to these disorders has led to successful treatment of affected individuals with the mTOR inhibitors sirolimus (rapamycin) and everolimus. For example, use of these agents in patients with tuberous sclerosis complex has resulted in regression of subependymal giant cell astrocytomas, renal angiomyolipomas, pulmonary lymphangioleiomyomatosis and (with topical as well as oral therapy) facial angiofibromas[50]. Additional examples of molecular advances resulting in successful targeted therapy include the use of the MEK inhibitor selumetinib for NF1-associated plexiform neurofibromas, the PI3K inhibitor alpelisib for the PIK3CA-related overgrowth spectrum, and the AKT inhibitor miransertib for Proteus syndrome[51,52].

56 Biology of Keratinocytes

Peter J. Koch, Anna L. Bruckner and Maranke I. Koster

Chapter Contents

The Epidermis: Structure and Function 883
Keratin Intermediate Filaments 885
Epidermal Differentiation 888
Keratinocyte Adhesion 889
Keratinocyte–Matrix Interactions 890
Related Diseases 890

Key features

- The epidermis functions as a barrier that provides protection against harmful substances, ultraviolet radiation, and water loss
- Through a complex terminal differentiation program, the progeny of epidermal stem cells undergo molecular and biochemical changes that generate the morphologically and functionally distinct layers of the epidermis
- Keratinocyte terminal differentiation culminates in the replacement of the plasma membrane with the cornified cell envelope
- Keratin intermediate filaments, which are expressed by keratinocytes in a differentiation-specific manner, are required to maintain epidermal integrity and have additional roles in the regulation of basic cell functions
- Desmosomes, which integrate the keratin cytoskeleton into the cell membrane and establish adhesive points between adjacent cells, are necessary for epidermal stability and stress resistance; these cell–cell junctions also function as signaling centers in epidermal morphogenesis and homeostasis
- Other cell–cell junctions that are found in keratinocytes include adherens junctions, tight junctions, and gap junctions
- A variety of inherited skin diseases are caused by a failure of normal epidermal differentiation and function

INTRODUCTION

The main function of the epidermis is to provide a barrier between the organism and the environment. This barrier is the result of a complex terminal differentiation program in which the progeny of epidermal stem cells undergo a series of molecular and biochemical changes that lead to the generation of the morphologically distinct layers of the epidermis (Fig. 56.1). This chapter reviews the molecular and cellular mechanisms that control this terminal differentiation program. It also discusses inherited skin diseases that are caused by a failure of normal epidermal differentiation.

THE EPIDERMIS: STRUCTURE AND FUNCTION

The epidermis, the outermost layer of the skin, functions as a barrier that protects the organism against harmful substances and water loss. The barrier function is established during embryogenesis and maintained in the mature epidermis through a continuous program of self-renewal[1]. Under homeostatic conditions, this self-renewal is mediated by epidermal stem cells located in the basal layer of the interfollicular epidermis. Another population of stem cells, located in the bulge region of the hair follicles, contributes to the interfollicular epidermis; however, this occurs in response to injury but not under homeostatic conditions. Like other types of stem cells, epidermal stem cells can generate daughter stem cells as well as transit-amplifying cells destined for differentiation. Transit-amplifying cells undergo several cell divisions before beginning a terminal differentiation program, which is associated with irreversible withdrawal from the cell cycle.

Terminally differentiating keratinocytes detach from the basement membrane and move suprabasally, a process that is facilitated by the inactivation of integrins, which are extracellular matrix receptors that anchor basal cells to the basement membrane (see Ch. 28). The cells are termed *spinous* keratinocytes when they reach the first suprabasal cell layer. As they continue to move upward, further differentiation leads to the formation of *granular* keratinocytes. These cells contribute to barrier function via their tight junctions which create a seal between neighboring keratinocytes[2]. Further differentiation culminates in the development of *corneocytes* that have lost their nuclei and cytoplasmic organelles as well as having their plasma membranes replaced by cornified cell envelopes.

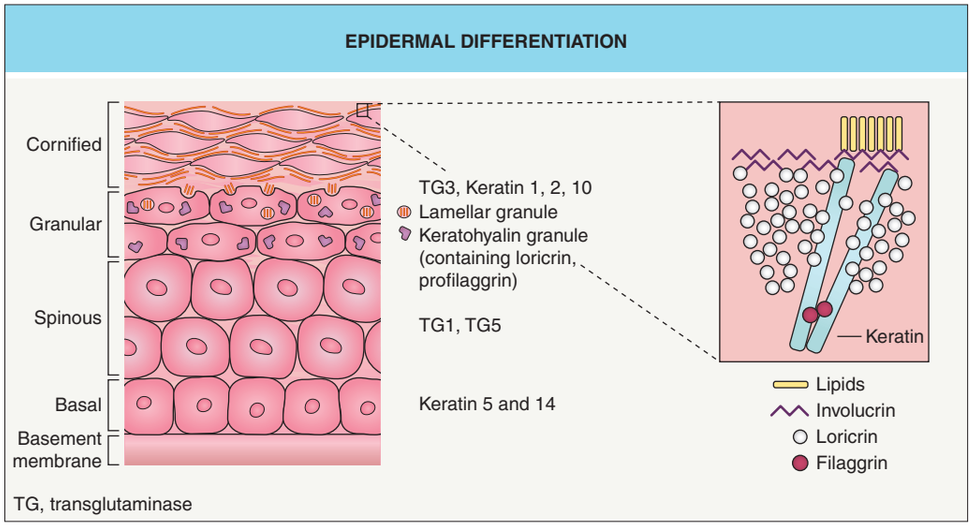

Fig. 56.1 Epidermal differentiation. As keratinocytes are transformed from mitotically active cells in the basal layer to fully differentiated, anucleated squames in the cornified layer, specific proteins are expressed at particular locations within the epidermis. Keratohyalin (profilaggrin- and loricrin-containing) and lamellar (lipid-containing) granules extrude their contents in the granular layer, leading to bundling of keratin filaments and replacement of the plasma membrane with the highly cross-linked, lipid-covered cornified cell envelope (see inset and Fig. 56.2).
Courtesy Julie V. Schaffer, MD.

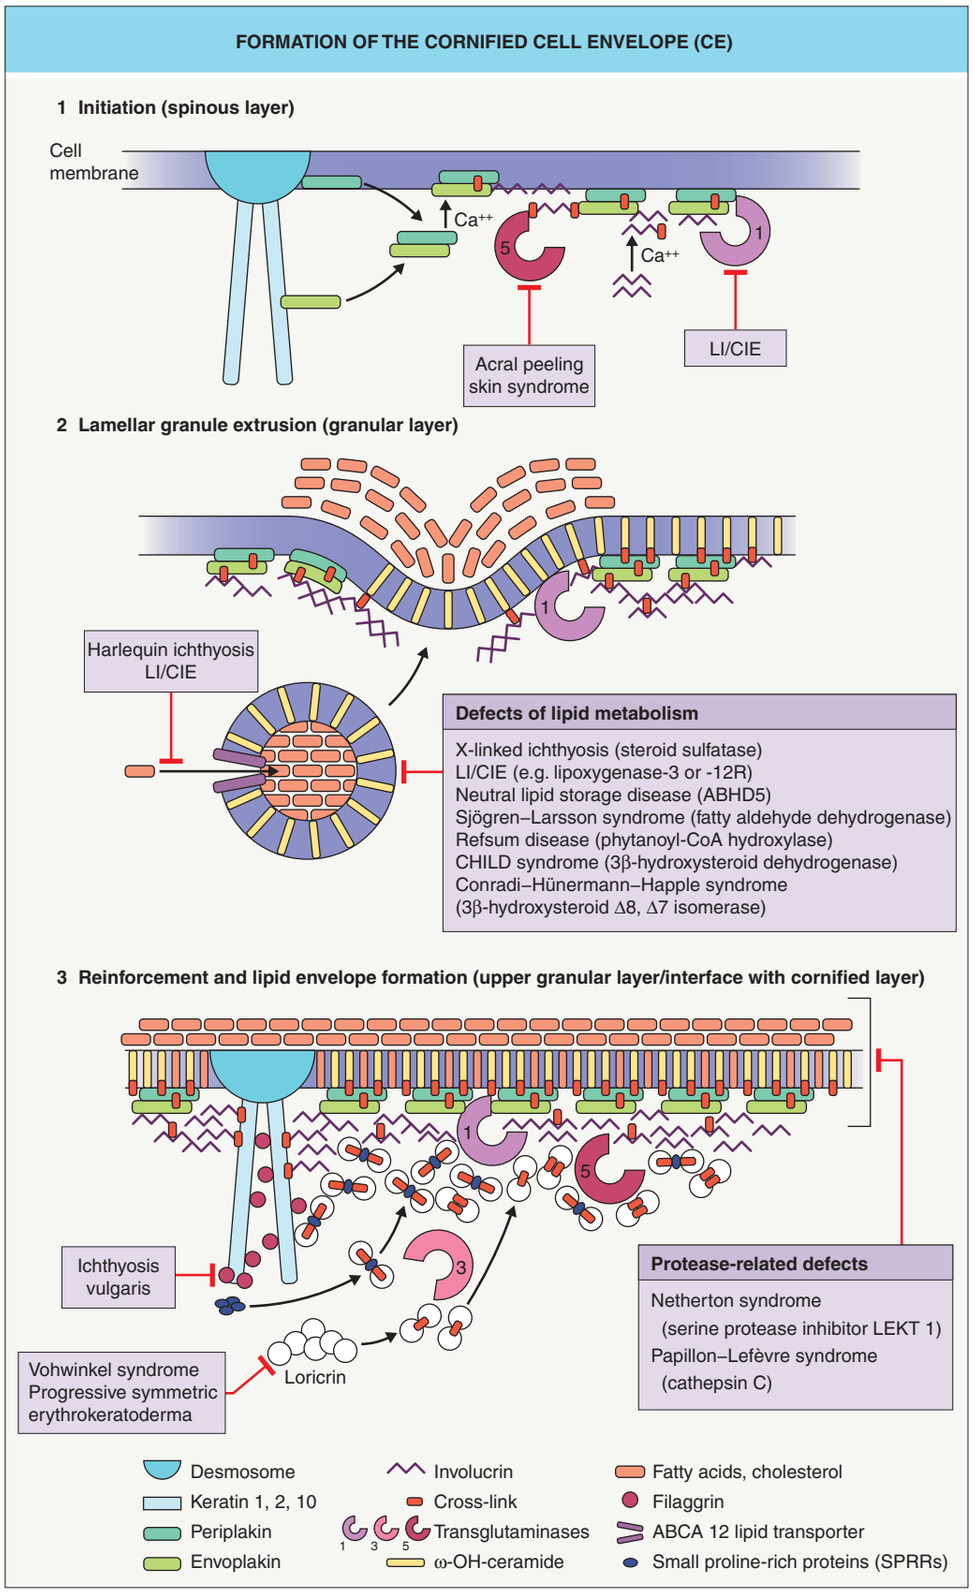

Fig. 56.2 Formation of the cornified cell envelope (CE). Terminal differentiation of keratinocytes is triggered by an increase in the intracellular Ca^{2+} concentration of the suprabasal epidermis. CE assembly is initiated in the upper spinous layer via formation of a cross-linked scaffold composed of envoplakin, periplakin, and involucrin along the inner surface of the cell membrane (**1**). This is followed by (or perhaps coincident with) extrusion of lamellar granules into the extracellular space (**2**). Specialized ω-hydroxyceramides are delivered to and eventually replace the cell membrane, where they become linked to scaffold proteins. Reinforcement occurs via cross-linking and translocation to the cell periphery of loricrin (which accounts for >80% of the mass of the CE) and small proline-rich proteins (SPRRs) (**3**). Complexes of keratin and filaggrin also become cross-linked to the CE. In addition, proteases play important roles in processing of CE proteins and the proteolysis of corneodesmosomes that is required for desquamation. A mature, terminally differentiated cornified cell thus consists of keratin filaments covalently attached to the CE, which is composed of protein and lipid envelope components and imbedded in extracellular lipid lamellae. Defects in transglutaminases, lipid metabolism, CE structural proteins and proteases lead to a variety of diseases characterized by ichthyosis and/or keratoderma (**1–3**). ABHD5, abhydrolase domain containing 5, lysophosphatidic acid acyltransferase; CHILD, congenital hemidysplasia with ichthyosiform erythroderma and limb defects; CIE, congenital ichthyosiform erythroderma; LI, lamellar ichthyosis. *Courtesy Julie V. Schaffer, MD.*

The *cornified cell envelope* (CE) is a composite of several covalently cross-linked proteins, most of which are encoded by genes located in the epidermal differentiation cluster on human chromosome 1. Examples of CE components include involucrin, small proline-rich proteins (SPRR), XP-5/late envelope proteins (LEP), loricrin, cystatin, envoplakin, periplakin, elafin, repetin, filaggrin, and S100 proteins, in addition to keratins and desmosomal proteins (Fig. 56.2)[3]. Mutations in some of the genes that encode these proteins can lead to skin disorders (see below). The extracellular surface of the CE is covered by lipids, which form the *cornified lipid envelope* (CLE) (see Ch. 124).

The stratum corneum, which serves to cover the body surface of terrestrial mammals, is composed of corneocytes. The CE and CLE of corneocytes are major contributors to the cutaneous water barrier. Failure or impairment of the water barrier leads to increased transcutaneous water loss and susceptibility to infections, a major problem in premature infants and in genetic disorders such as Netherton syndrome[4].

CE assembly begins within the upper spinous and granular cell layers, where proteins are chemically cross-linked, primarily by ε-(γ-glutamyl) lysine isopeptide bonds (Fig. 56.3). This reaction is catalyzed by a

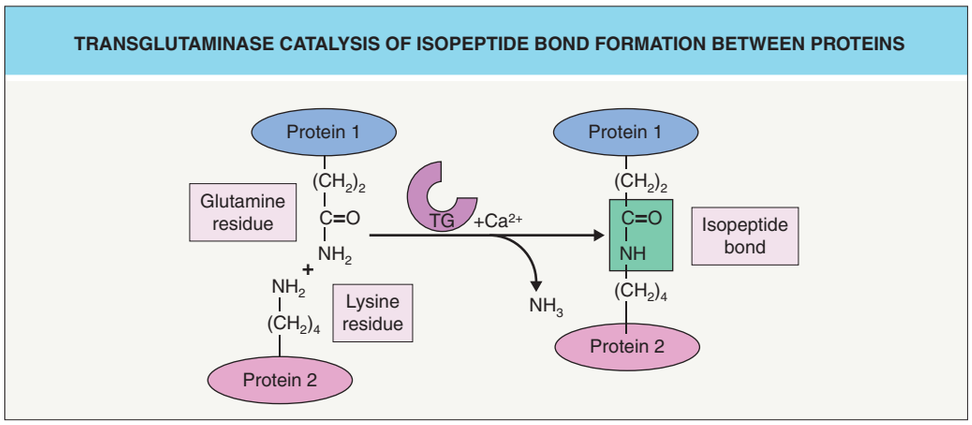

Fig. 56.3 Transglutaminase catalysis of isopeptide bond formation between proteins. Transglutaminases (TGs) are calcium-dependent enzymes that catalyze the formation of γ-glutamyl lysine isopeptide bonds between proteins. TGs also have a role in the creation of ester bonds between proteins and ω-hydroxyceramides. Such cross-linking is essential for assembly of the CE. Four TGs are expressed in the epidermis: TG1 (keratinocyte TG; membrane-bound), TG2 (tissue TG; basal layer), TG3 (epidermal TG; hair follicle and terminally differentiating keratinocytes) and TG5 (upper epidermis). *Courtesy Julie V. Schaffer, MD.*

class of enzymes termed transglutaminases (TGases). Loss-of-function mutations in the gene that encodes TGase 1 lead to lamellar ichthyosis and congenital ichthyosiform erythroderma, both of which are generalized forms of autosomal recessive congenital ichthyosis that result from a failure to form proper CEs.

Because the CE is highly resistant to chemical attack, very harsh conditions (e.g. boiling the epidermal cells in buffers containing high concentrations of detergents) are required to isolate and purify CE proteins. One surprising finding is that a loss of *individual* CE components in knockout mice does not necessarily have a major impact on barrier function. One possible explanation is the presence of compensatory gene regulatory pathways that maintain barrier function even in the absence of major CE components. Further investigations of these regulatory pathways will hopefully provide additional insights into how the barrier is established and maintained, thereby leading to the development of new strategies for the treatment of diseases caused by impaired barrier function.

KERATIN INTERMEDIATE FILAMENTS

Keratin intermediate filaments provide resilience to keratinocytes and represent the largest group of intermediate filament proteins (Table 56.1). Compared to microfilaments and microtubules, the other two major classes of filaments, intermediate filaments lack intrinsic polarity. The current classification system includes 54 human keratin genes which can be divided into three categories: (1) epithelial keratin genes; (2) hair keratin genes; and (3) keratin pseudogenes[5]. Based upon their biochemical properties, keratins are classified as either type I (KRT9–KRT28, KRT31–KRT40) or type II (KRT1–KRT8, KRT71–KRT86) (Table 56.2). Type I and type II keratins form obligatory heteropolymers, i.e. pairs composed of one keratin from each group. These heteropolymers represent the basic building blocks of epithelial intermediate filaments (Fig. 56.4).

Similar to other intermediate filament proteins, keratins have a structure composed of domains[6]. The central α-helical *rod domain* consists of 310 amino acid residues and is divided into four segments (1A, 1B, 2A, 2B), which are interrupted by three non-helical segments of variable lengths, termed linkers (Fig. 56.5). The rod domain is composed of seven-residue amino acid sequence repeats $(a\text{-}b\text{-}c\text{-}d\text{-}e\text{-}f\text{-}g)_n$ termed "heptad repeats", where positions "a" and "d" represent hydrophobic residues that are considered crucial for stabilization of the heterodimer. In the middle of the 2B domain, the heptad pattern is interrupted, giving rise to the "stutter". This helical segment is highly conserved among intermediate filaments and does not participate in the formation of the coiled-coil dimer (see Fig. 56.4).

The beginning and end of the α-helical rod domain, referred to as the *helix initiation* and *helix termination* motifs, are highly conserved within different keratins and play a pivotal role in keratin intermediate filament assembly (e.g. filament elongation). These helix boundary peptides represent genetic "hot spots" for mutations in many of the hereditary keratin disorders (see Fig. 56.5). The severity and other phenotypic features of genodermatoses caused by keratin defects often correlate with the position of the underlying mutation, with more severe disease resulting from mutations in the helix initiation and termination motifs (see Table 56.4).

The head and tail regions that flank the rod domain are subdivided into extreme end (E), variable (V), and (in type II keratins) homologous (H) domains. Epithelial keratins possess glycine- and serine-rich head and tail domains, whereas these regions in hair keratins have a high content of cysteine and proline. Variations in the head and tail domains account for much of the diversity among different keratin proteins, suggesting that these domains play an important role in cell type-specific functions such as interactions with cytosolic proteins.

Keratins and Signaling

Keratins are markers of keratinocyte differentiation and are required to maintain epidermal integrity. However, keratins may also influence other basic cell functions, such as cell cycle progression, metabolic activity, apoptosis, and migration[7]. The mechanisms by which keratins regulate these processes are not well understood, but accumulating evidence suggests that intermediate filaments directly interact with several cell signaling pathways including TNF receptor 2-induced apoptosis, Src-mediated migration, and Akt/mTOR-related growth. Interestingly, deletion of the entire murine type II keratin gene cluster, which completely prevented the assembly of keratin intermediate filaments, resulted in an early embryonic lethal phenotype with growth retardation and defects in yolk sac hematopoiesis and vasculogenesis. This underscores the importance of keratins in cellular signaling and differentiation of non-epithelial cell lineages.

PREVIOUS AND CURRENT HUMAN KERATIN NOMENCLATURE

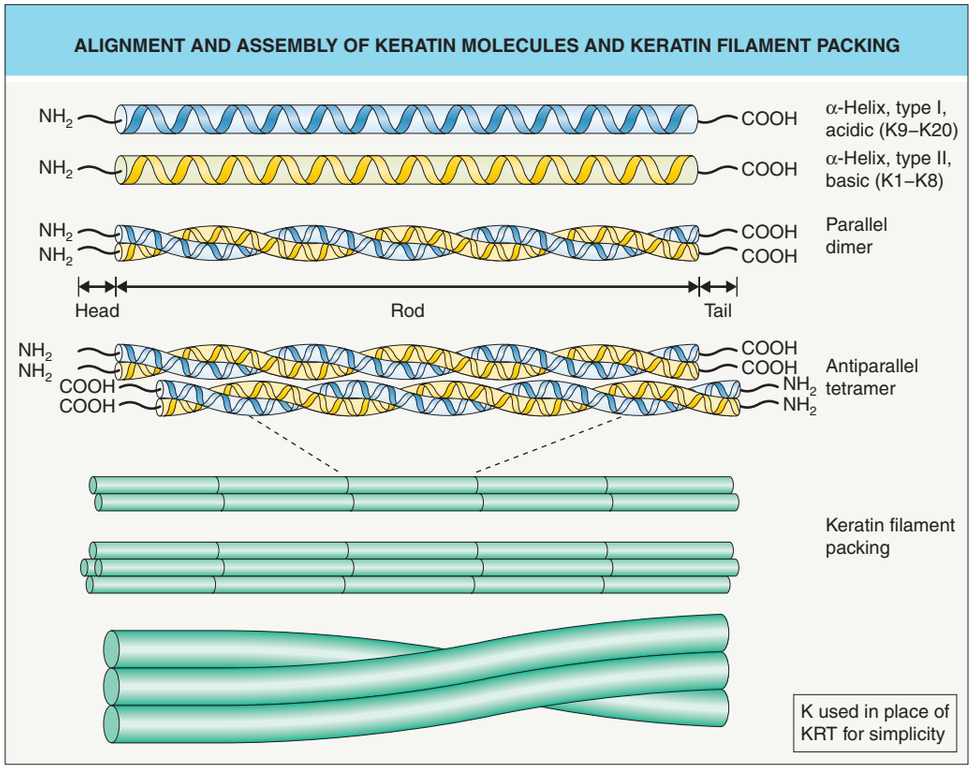

Fig. 56.4 Alignment and assembly of keratin molecules and keratin filament packing. Intermediate filament assembly takes place in several stages and begins with the heterodimerization of one type I and one type II keratin protein in a coiled-coil fashion. Two heterodimers then associate to form a tetramer. Lateral aggregation of tetramers yields higher-order polymers which eventually make up the filament network of the keratinocyte. *Courtesy Julie V. Schaffer, MD.*

Hair Keratins

The mature hair is the differentiation product of trichocytes and is found within the central core of the hair follicle. The anagen (growing) follicle is a complex structure consisting of eight distinct, concentrically arranged cell layers (see Fig. 68.5). The innermost compartment is the hair shaft, which is composed of a medulla, cortex, and one-layered cuticle; the latter serves as a protective coat for the hair shaft. The innermost living cell layer of the hair follicle is the inner root sheath (IRS). It surrounds the growing hair shaft and consists of the IRS cuticle as well as Huxley and Henle layers. The outermost compartment is the outer root sheath (ORS), which is continuous with the interfollicular epidermis. The companion layer is located between the IRS and the ORS.

The medulla contains a mixture of epithelial keratins (KRT17, KRT75) and hair keratins (KRT33, KRT34, KRT36, KRT37, KRT81), whereas the cortex contains type I hair keratins (KRT31–KRT38) and type II hair keratins (KRT81, KRT83, KRT85, and KRT86) (Fig. 56.6, see Fig. 68.6). The cuticle expresses hair keratins KRT32 and KRT35 (type I) and their partners KRT82 and KRT85 (type II). KRT71, KRT74, and KRT73 can be detected in the three IRS layers. The epithelial keratins KRT5 and KRT14 are found throughout the full thickness of the ORS, while expression of KRT6, KRT16, and KRT17 is limited to the isthmus and the lower ORS. Additional keratins expressed in the ORS are KRT15 and KRT19.

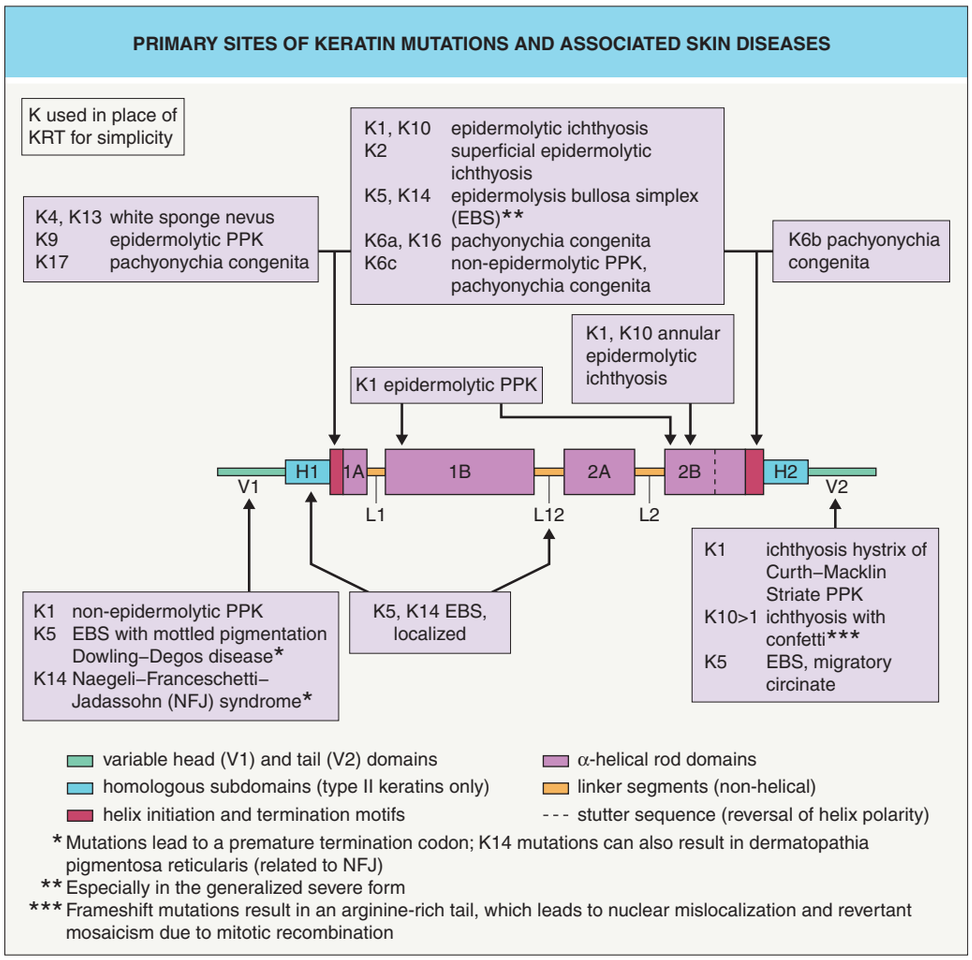

Fig. 56.5 Primary sites of keratin mutations and associated skin diseases. Over 90% of pathogenic alterations in keratins are missense mutations. Genotype–phenotype correlations are particularly well established for EBS. In the *severe* form of EBS, many patients have a "hot spot" mutation in a highly conserved arginine (Arg125) located within the helix initiation motif of KRT14. The corresponding arginine (Arg156) in KRT10 is also a mutational "hot spot" in epidermolytic ichthyosis. In the *intermediate* EBS subtype, mutations are more centrally located in the rod domains of KRT5 and KRT14. In contrast, mutations in the *localized* form of EBS are often outside the rod domain, e.g. in the L12 linker motifs of KRT5 and KRT14 or the H1 homologous subdomain of KRT5. Mutations in the variable head (V1) and tail (V2) domains of KRT1 can lead to non-epidermolytic PPK and ichthyosis hystrix Curth–Macklin. Rather than interfering with keratin intermediate filament assembly, mutations in these domains may cause intracellular maldistribution of loricrin. K or KRT, keratin; PPK, palmoplantar keratoderma. *Courtesy Julie V. Schaffer, MD.*

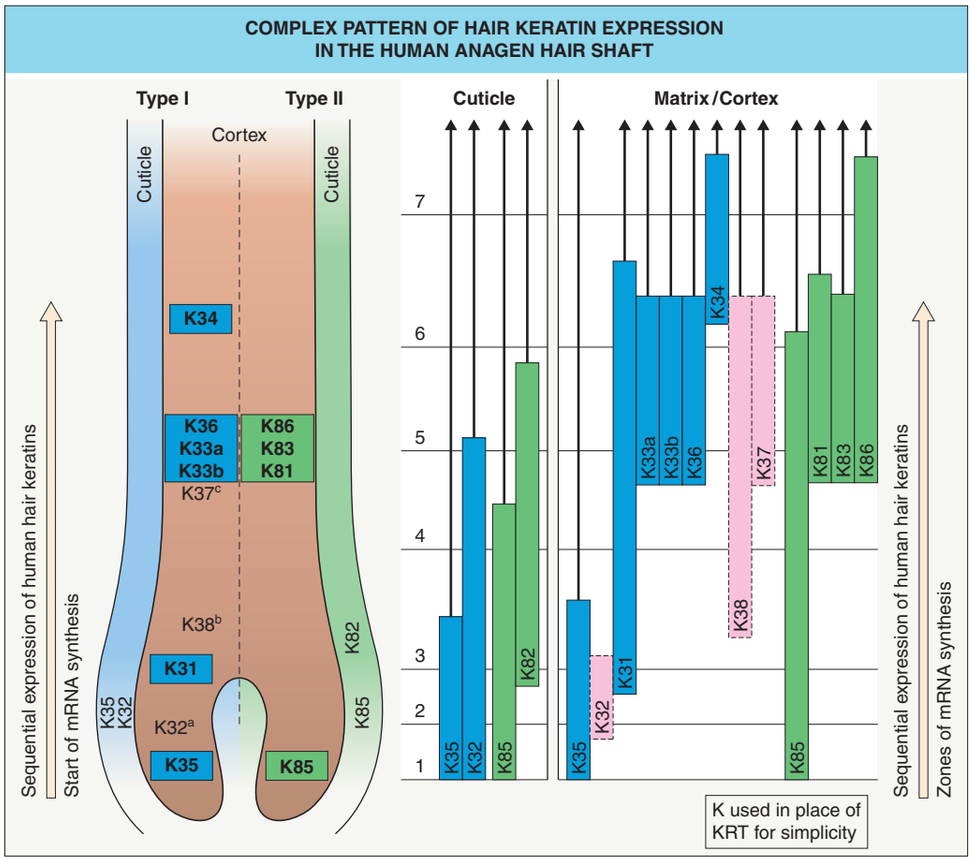

Fig. 56.6 Complex pattern of hair keratin expression in the human anagen hair shaft. Major type I hair keratins are in blue, and major type II hair keratins are in green. Minor hair keratins are in pink. [a]This protein is weakly expressed at this site. [b]To date, expression of this protein has only been detected in single cortex cells. [c]To date, this protein has only been detected in vellus hairs. Autosomal dominant monilethrix is caused by mutations in *KRT81*, *KRT83*, and *KRT86*. *Redrawn from Langbein L, et al. The catalog of human hair keratins. J Biol Chem 2001;276:35123–32.*

EPIDERMAL DIFFERENTIATION

Epidermal differentiation is a tightly regulated process that involves the transformation of proliferating cells in the basal layer into the dead corneocytes of the stratum corneum. During this process, the keratins and junctional proteins (see below) that are expressed are highly specific for the state of differentiation (Fig. 56.7). The mitotically active keratinocytes in the basal layer primarily express the keratin pair KRT5 and KRT14, with less abundant expression of KRT15. KRT15 is also able to assemble with KRT5, thereby providing mechanical stability to the keratinocyte in the absence of K14.

As keratinocytes move suprabasally to the spinous layer, they withdraw from the cell cycle. This process is associated with a downregulation of KRT5 and KRT14 and an induction of the differentiation-specific keratins, KRT1 and KRT10. Further maturation of spinous keratinocytes into granular keratinocytes results in expression of KRT2, a reinforcement keratin. With further maturation, filaments containing the suprabasal keratins are bundled parallel to the surface and, eventually, keratinocytes lose their cytoplasmic organelles and differentiate into lifeless corneocytes that are shed into the environment.

Interestingly, a number of epidermal keratins have a more restricted anatomic distribution pattern. For example, KRT9 is specifically expressed in the suprabasal cells of palmoplantar skin. KRT6, KRT16, and KRT17 are expressed in the palmoplantar epidermis as well as in the keratinocytes of the nail bed, hair follicle, and sebaceous and sweat glands. In addition, this group of keratins is rapidly induced by injury and ultraviolet radiation and appears in hyperproliferative conditions.

Regulatory Pathways Involved in Epidermal Development and Differentiation

The regulatory pathways necessary for normal epidermal differentiation include those that: (1) establish and maintain basal keratinocytes; (2) initiate and execute keratinocyte terminal differentiation; and (3) form the embryonic epidermis. Examples of these pathways are discussed below.

Genes required for establishing and maintaining basal keratinocytes

The importance of *TP63* in epidermal and adnexal development became apparent with the generation of knockout mouse models[8]. The p63 protein encoded by this gene has at least six different isoforms that activate or repress transcription, depending on the cellular context. p63 is essential for epidermal morphogenesis, as highlighted by the failure of *Trp63*-null mice to develop a stratified epidermis. After birth, exposure of these mice to the environment leads to rapid death due to dehydration. The failure of p63-deficient epithelial cells to adopt an epidermal fate underscores the critical role of p63 in specifying an epidermal lineage.

The p63 protein regulates the transcription of multiple genes in basal keratinocytes[9]. For example, p63 induces expression of epidermal keratins KRT5 and KRT14 while simultaneously repressing expression of KRT18, a keratin expressed in single-layered epithelia. Another key function of p63 is to maintain the proliferative state of basal keratinocytes by repressing cell cycle inhibitors.

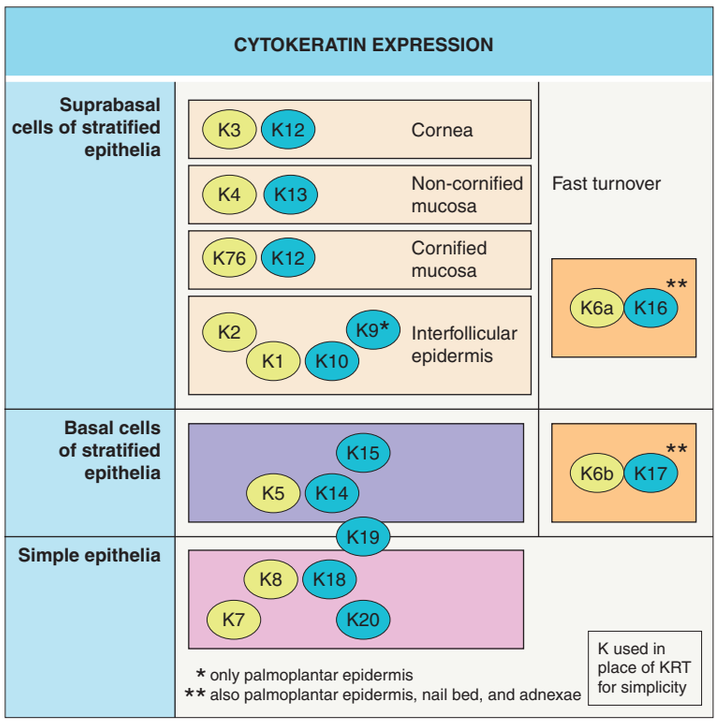

Fig. 56.7 Cytokeratin expression. Type II (basic) keratins are in yellow (KRT1–KRT8; KRT76) and type I (acidic) keratins are in blue (KRT9–KRT20). Keratin disorders are presented in Fig. 56.5 and Table 56.4.

Genes required for differentiation in mature epidermis

After basal keratinocytes have undergone a few rounds of cell division, they irreversibly withdraw from the cell cycle, move suprabasally, and become spinous keratinocytes. This process is also regulated by p63, in particular its ΔNp63α isoform[8]. In this context, p63 mediates cell cycle exit and induces expression of KRT1. The importance of p63 for normal epidermal development and differentiation is further underscored by the finding that p63 mutations underlie a subset of ectodermal dysplasias characterized by abnormalities in the skin and its adnexae (see Ch. 63).

Notch signaling is also required for the formation of the spinous layer[10]. In mouse models, ablation of Notch signaling resulted in the development of an extremely thin spinous layer, whereas constitutively active Notch signaling resulted in an expanded spinous layer. Notch signaling is essential for controlling the balance between proliferation and differentiation in the developing and postnatal epidermis.

Roles of Ca^{2+} in epidermal differentiation

The extracellular concentration of Ca^{2+} also plays an important role in keratinocyte differentiation[11]. In a mature epidermis, there is a gradient of increasing extracellular Ca^{2+} concentration from the basal layer to the cornified layer. Increasing the Ca^{2+} concentration in the media of cultured keratinocytes can induce a differentiation program similar to that of keratinocytes *in vivo*, with successive expression of markers of keratinocyte terminal differentiation.

Several Ca^{2+}-responsive proteins in the epidermis have key roles in the formation of the granular cell layer[12]. For example, the protein kinase C (PKC) family is activated by Ca^{2+} signaling and functions specifically in the transition from spinous to granular cells. PKC proteins have a dual role, contributing to the downregulation of KRT1 and KRT10 expression while also inducing markers of granular keratinocytes such as loricrin, filaggrin, and transglutaminases.

In addition to the PKC family, other proteins that undergo conformational changes upon binding to Ca^{2+} are expressed in mouse and human epidermis. Of these, the calcium-sensing receptor is specifically expressed in granular keratinocytes. Mice lacking a functional calcium-sensing receptor fail to properly form a granular layer, while overexpression of the calcium-sensing receptor in basal keratinocytes leads to expansion of the spinous and granular cell layers[13].

Genes required for development of the embryonic epidermis

During epidermal morphogenesis, basal keratinocytes do not directly differentiate into spinous keratinocytes as they do in postnatal skin[14]. Instead, basal keratinocytes initially differentiate into *intermediate* keratinocytes that, like spinous cells, express KRT1. However, unlike spinous keratinocytes, intermediate keratinocytes still undergo proliferation. The intermediate cell layer exists only transiently during epidermal morphogenesis, and intermediate keratinocytes ultimately differentiate into spinous and granular keratinocytes, which then undergo further terminal differentiation.

The importance of the intermediate cell layer for normal epidermal development has been demonstrated by mouse models in which intermediate cells fail to mature into spinous and granular cells. Such a block in differentiation occurs in mice lacking expression of inhibitor of κB kinase-α (IKKα), interferon regulatory factor 6 (IRF6), or ovo-like 1 (Ovol1), as well as in mice expressing a mutant form of the 14–3–3σ protein[14]. In all instances, an expanded intermediate cell layer develops, terminal differentiation is disrupted, and the consequent failure to establish barrier function results in neonatal lethality.

KERATINOCYTE ADHESION

Desmosomes

Desmosomes are multi-protein complexes that function as cell–cell adhesion structures (junctions) in epidermal cells (Fig. 56.8)[15]. They form within areas of specialized plasma membrane, termed *lipid raft domains*, that are enriched with sphingolipids and cholesterol[16]. Desmosomes also provide attachment sites for the keratin intermediate filament cytoskeleton of keratinocytes. Consequently, these junctions are critical components of a supracellular keratin network that traverses the interfollicular epidermis and epithelia of cutaneous adnexae, such as hair follicles.

Although the biochemical composition of desmosomes varies from tissue to tissue, the core of the desmosome is formed mainly by transmembrane glycoproteins that belong to the desmoglein (Dsg) and desmocollin (Dsc) subfamilies of Ca^{2+}-dependent cell adhesion proteins (cadherins). Heterophilic and homophilic interactions between Dsg and Dsc proteins are required to establish cell–cell coupling (see Ch. 29)[17]. Another protein, termed Perp, is also crucial for this process[18]. The transmembrane proteins are linked to the keratin intermediate filament network via a complex of several proteins, including desmoplakin, plakoglobin, one of several plakophilin (PKP) isoforms, and additional accessory proteins (see Fig. 29.3B)[19].

To complicate matters, several desmosomal components are encoded by multigene families. In humans, for example, there are four *DSG* genes, three *DSC* genes, and three *PKP* genes. In the epidermis, several Dsg and Dsc isoforms can be present in the same cell and even in the same desmosome[20]. The specific composition of the desmosome is thought to affect its adhesive properties. Similar to the epidermis, a differential expression pattern of desmosomal proteins is observed in the living layers of the hair follicle[21].

Regulating adhesiveness of junctions via changes in the protein composition or through protein modifications is also a crucial prerequisite for regulating cell migration, cell sorting, and the formation of the proper tissue histoarchitecture during embryonic development. An example of differential regulation of desmosomes during tissue/organ development is the formation of adnexae (e.g. hair follicles) and mammary glands. Regardless of the type of adnexal structure that is being formed, the initial steps are very similar. First, keratinocytes from the basal cell layer change their polarity and downregulate desmosomal proteins[22]. Next, these cells migrate into the underlying dermal tissue. Eventually, the cells begin to differentiate in order to form the various cell layers that constitute the new adnexal structure. During this process, desmosomal adhesion is re-established.

The molecular pathways that control differential expression of desmosomal genes during such developmental processes are not well understood. However, based on work focusing on the regulation of classical cadherins (e.g. E-cadherin), it is likely that major epidermal signaling pathways, such as the Wnt and NF-κB, are involved (see Figs. 55.6 and 130.4). Of note, the phenomenon of local proliferation of keratinocytes followed by invasion into dermal tissue also occurs in cutaneous wound healing and the initial stages of cancer progression. It is therefore likely that the same gene regulatory pathways that govern adnexal development also control these biological processes.

Desmosomes act as signaling centers that affect the basic characteristics of epithelial cells. For example, induction of epidermal Dsg1 expression is thought to counteract epidermal growth factor (EGF) signaling, triggering cell cycle withdrawal, expression of differentiation-associated proteins, and delamination of keratinocytes from the basal layer[20]. Desmosomal proteins are also involved in nuclear signaling. Plakoglobin (also known as junction plakoglobin) is associated with both desmosomes (see Fig. 56.8) and adherens junctions (see below) and is involved in relaying signals to the nucleus. Plakoglobin belongs to the armadillo protein family, the prototype of which is β-catenin. In addition to binding desmosomal cadherins (Dsg, Dsg) at the plasma membrane, plakoglobin forms complexes with Tcf/Lef transcription factors to control gene expression, thereby influencing cell proliferation, migration, and apoptosis[15]. Plakophilins can also affect cytoplasmic signaling pathways, and at least two isoforms (PKP1, PKP2) have nuclear functions[23].

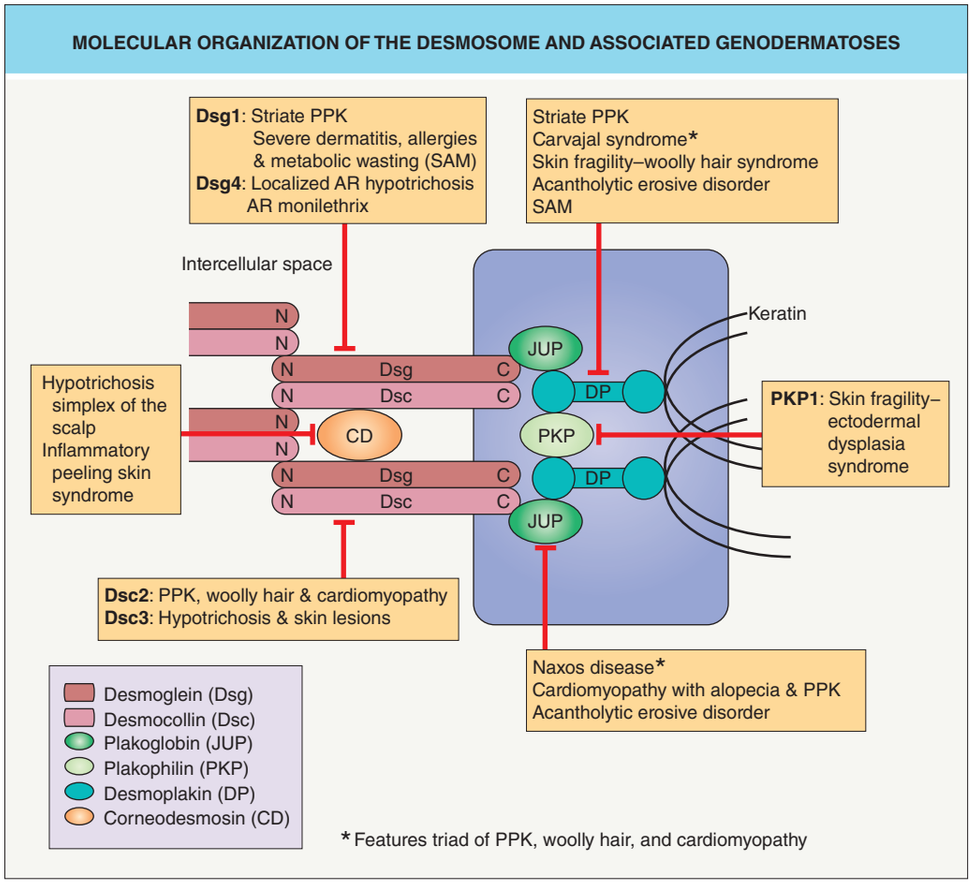

Fig. 56.8 Molecular organization of the desmosome and associated genodermatoses. Type 1 transmembrane glycoproteins from the cadherin family (desmogleins and desmocollins) are linked to intermediate filaments via a complex that contains catenins (plakoglobin, plakophilins) and plakin proteins (desmoplakin). Both homophilic and heterophilic interactions have been postulated to participate in establishing desmosomal adhesion. Examples of inherited skin diseases affecting the components of desmosomes are shown. AR, autosomal recessive; PPK, palmoplantar keratoderma.

What happens when desmosomes do not function properly?

Tissues that are subjected to mechanical stress, such as the skin and its adnexae, mucous membranes (e.g. oral cavity), and the heart, are often affected by desmosomal defects. The clinical symptoms of desmosomal diseases typically reflect tissue fragility, with mucocutaneous blistering and cardiomyopathy representing major manifestations[15,22]. In fact, skin and/or heart diseases have been linked to dysfunction of at least 12 desmosomal proteins, including Dsc1–3, Dsg1–4, desmoplakin, plakoglobin, plakophilin 1–2, and corneodesmosin (see Fig. 56.8). These disorders include genodermatoses, autoantibody-mediated diseases such as pemphigus vulgaris (PV) and pemphigus foliaceus (PF), and bacterial toxin-induced staphylococcal scalded skin syndrome.

The first mucocutaneous disorders linked to a desmosomal defect were PV and PF (see Ch. 29). In these diseases, autoantibodies bind to Dsg and induce epidermal and/or mucous membrane blistering via acantholysis, a process thought to be caused by loss of Dsg. In contrast to the blisters observed in patients with epidermolysis bullosa simplex due to keratin mutations, PV and PF blisters are caused by cell–cell separation, not cytolysis. Nevertheless, both groups of diseases illustrate the point that desmosomes and the associated keratin intermediate filaments must function properly to maintain tissue integrity.

The decreased function of desmosomal proteins may also lead to abnormal distribution of gap junction proteins, contributing to the development of cardiomyopathy in patients with mutations in desmosomal genes[24]. These findings support the emerging picture that desmosomes are part of a highly dynamic network of cellular junctions that interact with each other and the keratinocyte cytoskeleton in signal transduction and regulation of cell properties such as mechanical stress resistance, proliferation, migration, and differentiation[25].

Adherens Junctions

Adherens junctions consist of classical cadherins, in particular, E- and P-cadherin, as well as a complex of cytoplasmic plaque proteins (α-catenin, β-catenin, γ-catenin [also known as plakoglobin]) that connect the transmembrane proteins to the actin microfilament cytoskeleton (see Fig. 29.3A). Note that the armadillo protein plakoglobin can bind to both desmosomal and classical cadherins (see above).

P-cadherin is expressed primarily in the basal layer of mouse epidermis, whereas E-cadherin is expressed throughout the interfollicular epidermis. Genetically engineered loss of P-cadherin in mice has little effect on the interfollicular epidermis, whereas loss of E-cadherin can lead to severe defects in the homeostasis and function of the epidermis. Interestingly, it appears that loss of E-cadherin can affect tight junctions and thus the skin barrier function of the epidermis. Based on an analysis of genetically engineered mice, it has become evident that normal expression of the plaque proteins α-catenin, β-catenin, and plakoglobin is also required for normal epidermal function.

Similar to desmosomal cadherins, classical cadherins are differentially regulated during the development of adnexae within the skin[26]. For example, E-cadherin is downregulated in keratinocytes that invade the underlying dermis. A failure to downregulate cadherin-based adhesion suppresses invasive growth of keratinocytes and thus formation of adnexal structures.

As indicated above, armadillo proteins (e.g. β-catenin, plakoglobin) are involved in signaling from cell junctions to the nucleus. While β-catenin is a downstream effector of the classical (canonical) Wnt pathway, plakoglobin appears to be able to signal either via Wnt components or independently. Interestingly plakoglobin also counteracts classical Wnt signaling[27].

Tight Junctions

Tight junctions *(zonula occludens)* "seal" the intercellular space, thus preventing the free diffusion of macromolecules. The seal formed by tight junctions in the granular layer is required for maintaining the water barrier function of the epidermis (see Fig. 124.1)[28]. Together, tight junctions, adherens junctions, and desmosomes form the apical junctional complex in polarized epithelial cells.

KERATINOCYTE INTEGRIN RECEPTORS	
Integrin	**Ligand**
β1 family	
$\alpha_1\beta_1$	Fibrillar collagen, laminin
$\alpha_2\beta_1$	Fibrillar collagen, laminin
$\alpha_3\beta_1$	Fibronectin, laminin 332 (formerly laminin 5), denatured collagen
$\alpha_5\beta_1$	Fibronectin
$\alpha_6\beta_1$	Laminin

KERATINOCYTE–MATRIX INTERACTIONS

The epidermis is separated from the underlying dermis by a basement membrane (see Ch. 28), which consists of proteins secreted by epidermal keratinocytes and dermal fibroblasts[29]. The main components of the skin basement membrane are glycoproteins, including laminins, collagens, proteoglycans, and fibronectin. Keratinocytes are anchored to the basement membrane through integrins, transmembrane receptors for extracellular matrix proteins (Table 56.3). In addition to their structural role, integrins function by transducing signals from the extracellular matrix to the epidermal keratinocytes.

Another family of proteins required for basement membrane integrity during embryogenesis consists of Fras1, Frem1, and Frem2, three proteins that form a complex within the basement membrane. Loss-of-function mutations in any of these three genes destabilize this protein complex, causing aberrant basement membrane formation and skin blistering in mouse models. In humans, loss-of-function mutations in *FRAS1* or *FREM2* underlie Fraser syndrome, a multisystem autosomal recessive disorder characterized by embryonic (but not postnatal) blistering of the skin, cutaneous syndactyly, cryptophthalmos, and renal defects[30].

RELATED DISEASES

Keratin Disorders

Mutations in keratin genes cause a variety of disorders of the skin and other epithelia, usually with an autosomal dominant pattern of inheritance. The underlying mutations typically act in a dominant-negative fashion, interfering with normal intermediate filament assembly. This causes aggregation of disorganized keratin bundles, which often leads to clinically evident cell fragility. Mutations in the helix initiation and termination motifs are generally associated with relatively severe disease phenotypes, whereas mutations affecting other keratin domains usually cause milder disease (see Fig. 56.5). The location of mutations and genetic "hot spots" in skin disorders caused by mutations in keratin genes are presented in Table 56.4.

Epidermolysis bullosa simplex

Epidermolysis bullosa (EB) comprises a group of heritable skin fragility disorders characterized by skin and sometimes mucosal blistering following minor mechanical trauma[31] (see Ch. 32). Mutations in genes encoding desmosomal components can lead to several disorders associated with skin fragility (see Fig. 56.8). Genotype–phenotype correlations are well established for EB simplex due to *KRT5* and *KRT14* mutations (see Table 56.4). The clinical severity is related to the location of the mutations and the degree to which they perturb keratin

TYPES OF KERATIN MUTATIONS IN MUCOCUTANEOUS DISORDERS			
Disorder	**Inheritance**	**Gene(s)**	**Type/location of mutation(s)**
EBS, localized	AD	*KRT5, KRT14*	L12; H1 of *KRT5*
EBS, intermediate	AD		L12, L2; central portions of 1A & 2B
EBS, severe	AD		Helix initiation & termination motifs; "hot spot" Arg125Cys/His in *KRT14*
EBS, AR-KRT14	AR		Truncating or splice-site mutations
EBS with mottled pigmentation	AD	*KRT5* ≫ *KRT14*	Pro25Leu in V1 of *KRT5*
EBS, migratory circinate	AD	*KRT5*	Frameshift mutation leading to extended V2 region
Dowling–Degos disease	AD		V1 – truncating (leading to haploinsufficiency)
Naegeli–Franceschetti–Jadassohn syndrome & dermatopathia pigmentosa reticularis	AD	*KRT14*	V1 – truncating (leading to haploinsufficiency)
Epidermolytic ichthyosis	AD	*KRT1, KRT10*	Helix initiation & termination motifs; "hot spot" Arg156 in KRT10
	AR	*KRT10*	2B – truncating
Annular/cyclic epidermolytic ichthyosis	AD	*KRT1, KRT10*	2B
Ichthyosis hystrix Curth–Macklin	AD	*KRT1*	V2 – truncated tail
Ichthyosis with confetti	AD	*KRT10* ≫ *KRT1*	Frameshift mutations leading to arginine-rich tail; revertant clones via mitotic recombination
Superficial epidermolytic ichthyosis	AD	*KRT2*	Helix termination > initiation motifs
Epidermolytic PPK	AD	*KRT1*	1B (diffuse with "tonotubular" keratin), 2B (mild diffuse/focal)
		KRT9	Helix initiation > termination motifs, with "hot spot" Arg163
Non-epidermolytic PPK	AD	*KRT1*	V1 (diffuse), V2 (striate)
Pachyonychia congenita-6a & 16	AD	*KRT6A, KRT16*	Helix initiation > termination motifs
Pachyonychia congenita-6b & 17	AD	*KRT6B, KRT17*	Helix termination motif of *KRT6B*; helix initiation motif with "hot spots" Asn92 & Arg94 in *KRT17*
Pachyonychia congenita-6c & non-epidermolytic PPK (focal > diffuse)	AD	*KRT6C*	Helix termination > initiation motifs
Pseudofolliculitis barbae	Risk factor	*KRT75*	1A
Monilethrix	AD	*KRT81, KRT83, KRT86*	Helix termination (*KRT86* > *KRT81* > *KRT83*) & initiation (*KRT86*) motifs
"Pure" hair–nail type ectodermal dysplasia	AR	*KRT85*	V1 (more severe phenotype), V2
White sponge nevus	AD	*KRT4, KRT13*	Helix initiation > termination motifs

Table 56.4 Types of keratin mutations in mucocutaneous disorders. Also see Fig. 56.5. AD, autosomal dominant; AR, autosomal recessive; EBS, epidermolysis bullosa simplex; H1, homologous subdomain 1; KRT, keratin; L12/L2, linker segments (non-helical); PPK, palmoplantar keratoderma; V1, variable head domain; V2, variable tail domain; 1A/1B/2A/2B, α-helical rod domain segments.

structure[32]. Interestingly, hyperpigmentation is a major feature of Dowling–Degos disease, Naegeli–Franceschetti–Jadassohn syndrome, and dermatopathia pigmentosa reticularis (disorders that do not feature prominent blistering; see Ch. 67) as well as EBS with mottled pigmentation, demonstrating that mutations in keratin genes expressed in the basal epidermis can lead to pigmentary changes in addition to skin fragility (see Fig. 56.5).

Epidermolytic ichthyosis and palmoplantar keratoderma

Epidermolytic ichthyosis (EI) is a disorder of keratinization caused by mutations in *KRT1* or *KRT10* (see Ch. 57)[33]. It is usually inherited in an autosomal dominant fashion due to heterozygous missense mutations (typically involving the helix initiation and termination motifs) that lead to clumping of keratin filaments in the suprabasal layers of the epidermis and subsequent cytolysis. EI associated with PPK is mainly due to *KRT1* mutations, while EI without palmoplantar involvement is primarily due to *KRT10* mutations. *KRT1* mutations (outside of the critical helix initiation and termination regions) have also been identified in non-epidermolytic and epidermolytic variants of isolated PPK, which is more commonly caused by mutations in *KRT9*[34]. A recessive form of EI characterized by a complete absence of the KRT10 protein has also been described. Somatic mutations in *KRT1* or *KRT10* that occur during embryogenesis can present as an epidermolytic epidermal nevus (see Ch. 62), representing a mosaic form of EI. Vertical transmission of the mutation is possible if the gonads are involved, causing generalized disease in affected offspring. The types of mutations in keratin disorders are outlined in Table 56.4.

White sponge nevus

White sponge nevus is characterized by white plaques involving the oral mucosa, with occasional involvement of other mucosal surfaces such as the esophagus, vagina, rectum, and nasal cavity. The plaques may wax and wane over time, and suprabasal cytolysis and keratin clumping are observed histologically. Mutations in the genes encoding KRT4 and KRT13, which are specifically expressed in mucosal keratinocytes, cause this condition.

Gastrointestinal disorders

KRT8 and KRT18 are the major keratins that are expressed in gastrointestinal epithelia, including the liver, pancreas, and gut. Mutations in these simple keratins are typically located within the head and tail domains and do not involve the highly conserved helix boundary regions. KRT8 and KRT18 mutations are considered as risk factors for developing liver and gastrointestinal disorders (e.g. cirrhosis, inflammatory bowel disease) with additional genetic and environmental alterations likely required for disease development[35]. The

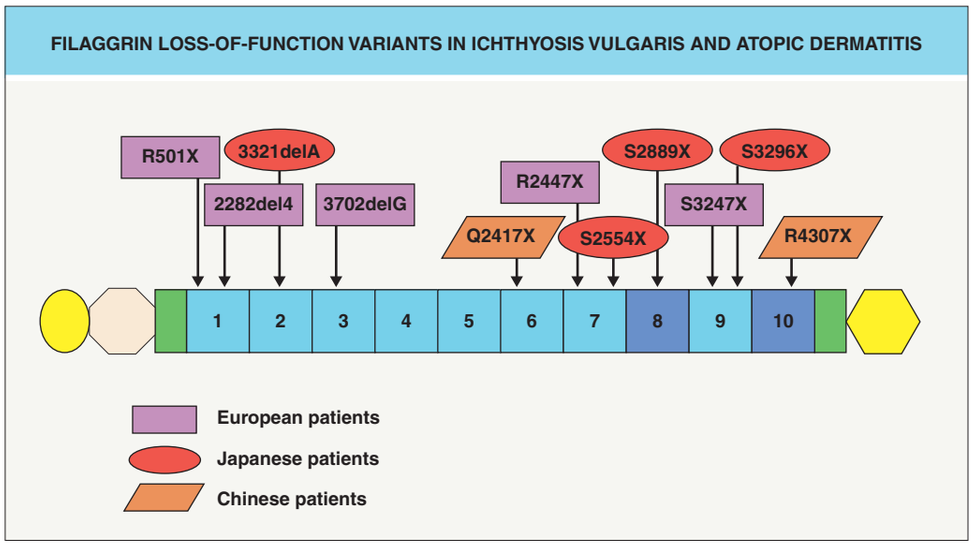

Fig. 56.9 Filaggrin loss-of-function variants in ichthyosis vulgaris and atopic dermatitis. The filaggrin protein consists of several domains: an S100 Ca^{2+}-binding domain (yellow oval), a B-domain (beige octagon), two imperfect filaggrin repeats (green rectangles), 10 filaggrin repeats (blue numbered rectangles; some individuals have two copies of repeat 8 and/or 10), and a C-terminal domain (yellow hexagon). Mutations in filaggrin that have been identified in patients with ichthyosis vulgaris and atopic dermatitis are indicated.

mutation-associated predisposition to tissue injury is likely related to mechanical and non-mechanical keratin functions, including maintenance of cell integrity and protection from oxidative injury and apoptosis.

Filaggrin Deficiency Disorders

Filaggrin is a component of the cornified cell envelope and is responsible for aggregating keratins. It represents the processed product of profilaggrin, which is cleaved into individual filaggrin polypeptides by caspase 14. Loss-of-function mutations in filaggrin underlie ichthyosis vulgaris (Fig. 56.9), a semidominant condition with incomplete penetrance (~90% in homozygotes and ~60% in heterozygotes; see Ch. 57)[36]. Whereas patients with a heterozygous filaggrin mutation display mild scaling or no phenotype, those with homozygous or compound heterozygous mutations have more severe ichthyosis vulgaris with dry, scaly skin and a substantially altered cutaneous barrier.

In addition to causing ichthyosis vulgaris, loss-of-function mutations in filaggrin also predispose to atopic dermatitis (see Ch. 12). Approximately 20%–50% of patients with atopic dermatitis have at least one filaggrin null allele. Furthermore, individuals who carry filaggrin mutations and develop atopic dermatitis are also predisposed to the subsequent onset of asthma, suggesting that epicutaneous sensitization and inflammation of the skin in the context of an abnormal epidermal barrier may play a role in the development of airway hyperreactivity.

Mouse Models for Structural and Desmosomal Proteins

The generation of mouse models has significantly increased our understanding of skin biology and the pathophysiology of genodermatoses. Animals harboring mutational "hot spots" that have been identified in humans are important for testing novel disease-targeted treatments and can help to bring new technologies closer to clinical use[37]. For example, a reporter mouse model was developed to assess topical formulations that deliver short interfering RNAs (siRNAs) into the skin to silence dominant-negative mutant alleles[38].

CONCLUSION

We have made great progress in understanding the structure and function of the epidermis. Another challenge is to better elucidate the gene regulatory mechanisms and cell signaling pathways required for the development and maintenance of the skin. Identification of epigenetic factors and modifier genes will help to explain phenotypic variations and establish more precise genotype–phenotype correlations. This knowledge will form the foundation for the development of new therapeutic strategies for acquired and inherited skin diseases.

Additional table on Mouse models for human skin diseases due to abnormalities in structural and desmosomal proteins, available in our eBook (see inside front cover for access code).

MOUSE MODELS FOR HUMAN SKIN DISEASES DUE TO ABNORMALITIES IN STRUCTURAL AND DESMOSOMAL PROTEINS		
Gene/protein	**Human diseases**	**Genotype and phenotype of mouse models**
Structural proteins		
Keratin 14	Epidermolysis bullosa simplex	R125C: blistering due to collapse of keratin network in basal keratinocytes
Keratin 1	Epidermolytic ichthyosis (See also Fig. 56.5)	KO: perinatal lethality
Keratin 10	Epidermolytic ichthyosis (See also Fig. 56.5)	R156C: blistering at birth, hyperkeratosis later in life KO: severe blistering and hyperkeratosis
Keratin 2	Superficial epidermolytic ichthyosis	KO: localized hyperkeratosis (ear, tail)
Keratin 9	Epidermolytic PPK	KO: footpad calluses
Keratin 6a	Pachyonychia congenita-6a	KO: delayed wound healing N172del: nail dystrophy
Keratin 6b	Pachyonychia congenita-6b	KO: starvation due to upper GI constriction
Keratin 16	Pachyonychia congenita-16	KO: oral leukokeratosis, footpad calluses
Keratin 17	Pachyonychia congenita-17 Steatocystoma multiplex	KO: alopecia
Loricrin	Vohwinkel syndrome Progressive symmetric erythrokeratoderma	KO: transient neonatal erythroderma 372insC: neonatal erythrokeratoderma, tail constriction bands, footpad hyperkeratosis
Filaggrin	Ichthyosis vulgaris Atopic dermatitis	KO*: impaired epidermal barrier, enhanced contact hypersensitivity
Desmosomal proteins		
Desmocollin 1	Subcorneal pustular dermatosis	KO: skin fragility with acantholysis, localized hair loss
Desmocollin 3	Hypotrichosis and skin lesions	Conditional KO: skin blistering with acantholysis, telogen hair loss
Desmoglein 3	Pemphigus vulgaris (PV)	KO or PV model (anti-Dsg3 Ab in Rag2 KO): mucous membrane blistering and hair loss
Desmoglein 4	Localized autosomal recessive hypotrichosis Autosomal recessive monilethrix	Y196S (biallelic): hair defects ("lanceolate hair")
Desmoplakin	Striate PPK Carvajal syndrome Skin fragility/woolly hair syndrome Acantholytic erosive disorder	KO: embryonic lethality; heart defects in tetraploid rescued mice
Plakoglobin	Naxos disease Cardiomyopathy with alopecia & PPK Acantholytic erosive disorder	KO: embryonic lethality, heart defects
Corneodesmosin	Hypotrichosis simplex of the scalp Inflammatory peeling skin syndrome	Conditional KO: loss of adhesion between granular and cornified cell layers, skin water barrier defects, hair loss
Plakophilin 1	Skin fragility–ectodermal dysplasia syndrome	KO: fragile skin, sparse and small desmosomes, abnormal tight junctions

*Similar findings in the "flaky tail" mouse with a biallelic single nucleotide deletion (5303delA) that results in a frameshift mutation and truncated protein.

Key features

- Ichthyoses and erythrokeratodermas are heterogeneous groups of disorders of cornification
- Ichthyoses are characterized by scaling of the skin in a widespread distribution
- Erythrokeratodermas feature discrete areas of erythema and hyperkeratosis, usually without substantial scale
- Most inherited ichthyoses and erythrokeratodermas are evident at birth or manifest in infancy
- Clinical features and pattern of inheritance as well as the underlying structural, biochemical, and molecular abnormalities help to differentiate these disorders
- Therapy is symptomatic and primarily aimed at reducing hyperkeratosis. Topical management consists of emollients, keratolytics, and retinoids
- Many, but not all, disorders respond well to oral retinoids. Treatment is initiated at low doses and titrated to response. Benefits and side effects must be carefully considered because of the chronic nature of these conditions

INTRODUCTION

Ichthyoses and erythrokeratodermas are disorders of cornification in which abnormal differentiation and desquamation of the epidermis result in a defective cutaneous barrier. Ichthyoses represent a large clinically and etiologically heterogeneous group of conditions that feature generalized scaling of the skin (Tables 57.1 and 57.2). Erythrokeratodermas are characterized by circumscribed areas of erythema and hyperkeratosis without obvious scaling. Willan introduced the term "ichthyosis", derived from the Greek root "*ichthy*" meaning fish, in his textbook of dermatology in 1808[1]. Since then, nomenclature and nosology of ichthyoses have continuously evolved, including a variety of descriptive names, eponyms, and synonyms.

Milestones in recognizing distinct entities include the description of harlequin ichthyosis in the nineteenth century, separation of the bullous and non-bullous types of ichthyosis by Brocq (who also coined the name "congenital ichthyosiform erythroderma") in the early 20th century[2], and differentiation between autosomal dominant "epidermolytic hyperkeratosis" and autosomal recessive "lamellar ichthyosis" by Frost and Van Scott in 1966[3]. Alibert mentioned the autosomal dominant inheritance of ichthyosis vulgaris as early as 1806[4]. X-linked ichthyosis, despite several earlier reports, was only fully recognized in Wells and Kerr's study in 1966[5], followed by the identification of steroid sulfatase deficiency in the 1970s[6]. Advances in the molecular etiology and biology of ichthyoses and erythrokeratodermas have provided tools to categorize these disorders of cornification, at least in part, based on their underlying genetic defects. In 2009, an international group of clinical and research experts developed a revised nomenclature and classification system for ichthyoses and other disorders of cornification, incorporating molecular causes as well as functional aspects of disease pathogenesis[7].

Establishing the correct diagnosis in a patient with ichthyosis is a prerequisite for making prognostic predictions, planning therapy, and offering genetic counseling. This may pose a considerable challenge, as these disorders are uncommon and have overlapping clinical spectra. However, a systematic approach utilizing clinical and laboratory-based clues in conjunction with genetic testing can aid in making the diagnosis (Fig. 57.1).

In general, it is helpful to determine whether an ichthyosis presented at birth (e.g. as a collodion baby) or later in life and whether manifestations are limited to the skin or are part of a multisystem disorder. The quality and distribution of the scale as well as the presence or absence of erythroderma, blistering, and abnormalities of cutaneous adnexa are other useful clinical features. A thorough family history is essential for recognizing the inheritance pattern, and examination of both parents (even in a seemingly sporadic case) may reveal valuable diagnostic hints such as an epidermal nevus representing a mosaic presentation of epidermolytic ichthyosis. Patients whose parents are clinically unaffected may have: (1) a recessive ichthyosis, especially in the setting of consanguinity and/or affected siblings; (2) a dominant ichthyosis due to a "new" mutation; or (3) for a male patient, an X-linked recessive ichthyosis where the mother may be an asymptomatic carrier but her male relatives could be affected. A few disorders are recognizable by characteristic histopathologic and ultrastructural features, such as epidermolytic ichthyosis and ichthyosis hystrix Curth–Macklin. Laboratory studies suggest the diagnosis in other conditions, including enzyme analysis in steroid sulfatase deficiency and observation of lipid vacuoles in circulating leukocytes in neutral lipid storage disease (see Fig. 57.1).

This strategy allows the clinician to identify some ichthyoses based on their key features. Genetic testing can confirm the diagnosis in ~90% of patients with ichthyosis[8,9], allowing for more precise genetic counseling and providing the basis for prenatal testing.

FEATURES OF SELECTED NONSYNDROMIC ICHTHYOSES AND ERYTHROKERATODERMAS							
Diagnosis	**Gene (protein)**	**Mode of inheritance**	**Incidence**	**Onset**	**Primary cutaneous features**	**Associated features**	**Diagnosis (in addition to molecular testing*)**
Common ichthyoses							
Ichthyosis vulgaris	*FLG* (filaggrin)	Autosomal semi-dominant; more severe with biallelic variants	1:100–1:250	Infancy/ childhood	Fine, adherent, grayish scales on extremities and trunk with sparing of flexures; larger scales on lower legs; hyperlinear palms/soles, furrowed heels	Keratosis pilaris; atopic dermatitis (in ~50%)/ atopic diathesis	Clinical; diminished/absent stratum granulosum; absent/ reduced filaggrin immunostaining
Steroid sulfatase deficiency (X-linked recessive ichthyosis)	*STS* (steroid sulfatase) Deletion in ~90% of patients	XL recessive	1:2000–1:9500 boys/men	Infancy	Fine to large, dark, rhomboidal, adherent scales on extremities, trunk, neck, and lateral face; sparing of skin folds, palms/soles	Corneal opacities; cryptorchidism; ADHD or autism spectrum *Female carriers*: corneal opacities; prolonged labor with affected child	FISH or chromosomal microarray to identify gene deletion; increased plasma (hydroxy) cholesterol sulfate; lipoprotein electrophoresis (increased mobility of β-fraction); decreased steroid sulfatase activity in leukocytes
Nonsyndromic autosomal recessive congenital ichthyoses (ARCI)							
ARCI phenotypic continuum ranges from lamellar ichthyosis (LI) to congenital ichthyosiform erythroderma (CIE), with intermediate phenotypes[8,9,36,39,52]	**Often LI phenotype:** *TGM1* (transglutaminase-1) *ABCA12* (ABC lipid transporter); also CIE, harlequin ichthyosis *NIPAL4* (transporter protein involved in lipid processing) *CYP4F22* (cytochrome P450 enzyme that forms acylceramides) *PNPLA1* (patatin-like phospholipase directing acylceramide synthesis) *SULT2B1* (cholesterol sulfotransferase) *CERS3* (ceramide synthase) **Often CIE phenotype:** *ALOX12B* and *ALOXE3* (lipoxygenases) *ABCA12* *NIPAL4* *PNPLA1* (synthesis of omega-O-acylceramides) *SDR9C7* (short chain dehydrogenase/ reductase) **Childhood-onset:** *LIPN* (lipase N)	AR†	1:100 000–1:200 000 (up to 1:60 000 in some European countries)	Birth	Frequently CM at birth‡, then a generalized distribution; variable PPK (esp. *ABCA12, NIPAL4, LOX, SDR9C7*) or hyperlinear palms (esp. *CYP4F22, CERS3, PNPLA1*) **LI**: large, thick, plate-like brown scales; absent or mild erythroderma **CIE**: fine, white scales; prominent erythroderma Prematurely aged skin appearance (*CERS3*) Sparing of skin folds and central face (*SULT2B1*) Occasional EKV-like lesions (*ABCA12, PNPLA1*)	Heat intolerance; frequent (LI) or variable (CIE) scarring alopecia and ectropion (esp. *TGM1*), eclabium; secondary hearing or eye problems; ear malformations (*ABCA12, LOX*); nails hyperconvex (*ABCA12*) or ridged (*LOX*); tapered fingers (*ABCA12);* frequent fungal infections of skin and nails (*SDR9C7*)	Clinical; LI: transglutaminase-1 immunostaining or *in situ* assay in skin biopsy specimen

Table 57.1 Features of selected nonsyndromic ichthyoses and erythrokeratodermas.

Continued

FEATURES OF SELECTED NONSYNDROMIC ICHTHYOSES AND ERYTHROKERATODERMAS							
Diagnosis	**Gene (protein)**	**Mode of inheritance**	**Incidence**	**Onset**	**Primary cutaneous features**	**Associated features**	**Diagnosis (in addition to molecular testing*)**
Harlequin ichthyosis	*ABCA12* *KDSR* (3-ketodihydrosphingosine reductase)	AR	Rare	Birth	Very thick, yellow–brown plates of scale that tightly encase the neonate; large, deep, bright red fissures; survivors develop severe CIE-like phenotype with PPK	Premature delivery; often neonatal death due to sepsis or respiratory insufficiency; extreme ectropion, eclabium, and ear deformities; later heat intolerance, skin infections, growth delay, joint contractures and arthritis; thrombocytopenia (*KDSR*)	Clinical
Ichthyosis prematurity syndrome[60,61]	*SLC27A4* (solute carrier family 27 member 4, encoding fatty acid transport protein 4 [FATP4]) Common founder mutation Asn176Asp in Scandinavian families	AR	Rare	Birth	Erythroderma; thick, yellow–white, spongy hyperkeratosis (resembling vernix caseosa) with cobblestone-like appearance favoring scalp, forehead, and trunk; neonatal findings resolve within a few months, leaving variable mild, fine scaling and follicular keratoses	Polyhydramnios; premature birth, neonatal asphyxia and respiratory distress; later peripheral eosinophilia and atopy	Clinical
AD lamellar ichthyosis[71]	*ASPRV1* (skin aspartic protease responsible for cleaving profilaggrin)	AD	Very rare	Birth to first few months	Generalized, large, plate-like scales; absent or mild erythema; PPK	Hypohidrosis	Clinical
Keratosis linearis with ichthyosis congenita and sclerosing keratoderma (KLICK) syndrome[165]	*POMP* (proteasome maturation protein)	AR	Very rare	Birth	Mild generalized fine scaling; linear distribution of keratotic papules in flexural sites; hyperkeratotic plaques on knees, PPK with digital constriction bands	Digital flexion contractures	Clinical
Keratinopathic ichthyoses							
Epidermolytic ichthyosis[9]	*KRT10* (keratin 10; ~75%); *KRT1* (keratin 1; ~25%)	AD (very rarely AR)	1:200 000–1:350 000	Birth	*At birth:* erythroderma, blistering, erosions *Later:* hyperkeratosis with cobblestone pattern (most prominent over joints), ridging of the flexures; generalized or localized; thick PPK (*KRT1*)	Frequent skin infections; malodor; contractures; gait and posture abnormalities	Clinical; histopathology showing epidermolytic hyperkeratosis

Table 57.1 Features of selected nonsyndromic ichthyoses and erythrokeratodermas.

FEATURES OF SELECTED NONSYNDROMIC ICHTHYOSES AND ERYTHROKERATODERMAS							
Diagnosis	**Gene (protein)**	**Mode of inheritance**	**Incidence**	**Onset**	**Primary cutaneous features**	**Associated features**	**Diagnosis (in addition to molecular testing*)**
Superficial epidermolytic ichthyosis	*KRT2* (keratin 2 intermediate filaments)	AD	Rare	Birth	Erythroderma and blistering at birth; later, hyperkeratosis with flexural accentuation, "molting" of the skin; palms and soles spared	Hypertrichosis	Clinical; histopathology
Ichthyosis with confetti	*KRT10* or *KRT1* splice or frameshift mutations altering keratin tail; revertant mosaicism	AD	Very rare	Birth	Ichthyosiform erythroderma; PPK; during childhood, development of small spots of normal-appearing skin, which increase in number/size over time	Micropinnae, alopecia universalis, ectropion (MAUIE variant); increased risk of melanoma and keratinocyte carcinomas	Clinical
Ichthyosis hystrix Curth–Macklin	*KRT1*	AD	Rare	Birth	Mild to severe, mutilating PPK; hyperkeratosis with verrucous, cobblestone, or hystrix-like pattern on extremities and trunk	Pseudoainhum; digital contractures	Clinical; electron microscopy
Nonsyndromic erythrokeratodermas							
Erythrokeratodermia variabilis et progressiva	*GJB3* (connexin 31) *GJB4* (connexin 30.3) *GJA1* (connexin 43; rare)	AD (very rarely AR) AR	Rare	Birth/infancy	Transient, variable erythematous patches (esp. during childhood); more stable, geographic, hyperkeratotic plaques over knees, elbows, Achilles tendons, extremities, buttocks, lateral trunk; face and scalp often spared; less common generalized hyperkeratosis; PPK in ~50% of patients	Burning or stinging sensation preceding or accompanying erythema	Clinical, particularly history or presence of transient, migratory erythema
Progressive symmetric erythrokeratoderma (encompasses multiple entities)	*KRT83*, keratin 83 *TRPM4* (transient receptor potential cation channel) *LOR* (loricrin)	AD	Rare	Infancy/childhood	Fixed, slowly progressive, erythematous, hyperkeratotic plaques with sharp, figurate borders; favor cheeks, knees, elbows; periorificial distribution (*TRPM4*); PPK (transgredient with *TRPM4*, mutilating/pseudoainhum with *LOR*)		Clinical

*Genetic testing is available for all types of ichthyosis with a known molecular basis; multigene panels are preferable over single gene testing if the diagnosis is not evident based on clinical and laboratory findings.
†There are also rare reports of autosomal dominant inheritance of LI or CIE phenotypes (occasionally with a collodion membrane at birth) with unknown genetic bases. Biallelic small deletions in the caspase 14 gene (*CASP14*) were identified in patients from two Algerian families who presented with generalized fine whitish scales with no erythema and no collodion membrane.
‡A CM presentation is common in patients with underlying mutations in *TGM1*, *ALOX12B* (>*ALOXE3*), *CERS3*, *PNPLA1*, and *SULT2B1*; a CM presentation occurs less often with *NIPAL4* and *CYP4F22* mutations.

The latter can potentially utilize circulating fetal cells as well as samples of chorionic villi or amniotic fluid[10]. However, despite advances in our understanding of the pathomechanisms underlying ichthyoses, effective therapies are available for only a subset of these conditions, and safety concerns may limit long-term use of treatments such as oral retinoids[11]. Hopefully, ongoing research will lead to the development of targeted treatments that will be of greater benefit to ichthyosis patients. Patient organizations such as the Foundation for Ichthyosis and Related Skin Types (FIRST; www.firstskinfoundation.org) can provide valuable support to affected individuals and their families.

COMMON ICHTHYOSES

ICHTHYOSIS VULGARIS

Synonyms: ■ Ichthyosis simplex ■ Autosomal dominant ichthyosis

History

In 1806, Alibert[4] described "ichthyose nacrée", which represented the first well-documented report of ichthyosis vulgaris. In 1966, Wells and Kerr[5] separated autosomal dominant and X-linked recessive forms of ichthyosis and delineated their clinical and epidemiological features.

Epidemiology

Ichthyosis vulgaris represents the most common disorder of cornification and is estimated to affect ~1 in 100 to 1 in 250 individuals[12]. It is inherited in an autosomal semi-dominant manner, with minimal to mild ichthyosis in individuals with heterozygous filaggrin mutations and more severe ichthyosis in those with complete filaggrin deficiency due to mutations on both alleles[13]. The overall penetrance in heterozygotes is ~80%–95% for ichthyosis vulgaris and/or associated findings (e.g. hyperlinear palms, keratosis pilaris, atopic dermatitis)[12–14], although there is variable phenotypic expression between and within families.

Pathogenesis

Ichthyosis vulgaris is caused by loss-of-function mutations in the filaggrin gene (*FLG*) (see Fig. 56.9) that result in haploinsufficiency[15]. Approximately 8% of European and 3% of East Asian individuals harbor at least one *FLG* mutation, compared to <1% among those of Mediterranean or African descent[13]. R501X and c.2282del4 account for up to 80% of mutations in Northern Europeans, while different null mutations are common in other population groups.

Profilaggrin represents a major component of the keratohyalin granules located in the granular layer of the epidermis. During keratinocyte differentiation, profilaggrin is cleaved into filaggrin peptides, which aggregate keratin intermediate filaments. These complexes are cross-linked to the cornified cell envelope and are responsible for proper formation of compact squamous cells (see Figs. 56.1 & 56.2). Filaggrin is eventually degraded into water-retaining amino acids, in particular histidine, that serve as a natural moisturizer.

Filaggrin deficiency results in impaired cornification, increased transepidermal water loss, enhanced penetration of allergens and irritants, and a propensity to develop inflammatory responses upon exposure to the latter. This explains the association of *FLG* mutations with atopic dermatitis (see Ch. 12) as well as hand eczema, irritant contact dermatitis, and nickel contact sensitization[13]. In addition, an association between *FLG* mutations and elevated serum vitamin D levels may result from increased UVB-induced vitamin D production in the skin, perhaps related to a paucity of urocanic acid, a photoprotective histidine metabolite. The flaky-tail mouse with biallelic loss-of-function mutations in *Flg* represents an animal model that serves as a tool for the study of ichthyosis vulgaris and other filaggrin-deficient conditions.

Clinical Features

Ichthyosis vulgaris in *FLG* heterozygotes is usually not evident at birth. Dry skin and mild to moderate scaling appear during infancy or early childhood. Fine, white, flaky scales typically develop on the extremities, especially the extensor surfaces (Fig. 57.2). The groin and flexural areas are spared because of increased humidity in those regions. On the lower legs, the scales are often larger with an adherent center and detached, outward-turning edges. Mild hyperkeratosis of the palms and soles leading to accentuated skin markings (hyperlinearity) is common (Fig. 57.3).

In more severe disease due to a complete lack of filaggrin, ichthyosis vulgaris may present at birth with mild erythema and generalized scaling or peeling. Later, large scales reminiscent of lamellar ichthyosis may develop and the trunk, scalp, forehead, and cheeks can be affected in addition to the extremities. Palmoplantar involvement is also more pronounced with furrows or painful fissures of the heels.

Severity and symptoms such as pruritus depend on the season and climate, improving during the summer and with higher humidity, and worsening in a dry, cold environment. Although the ichthyosis may be progressive during childhood, it usually improves with age. Ichthyosis vulgaris is frequently associated with keratosis pilaris and the atopic triad of asthma, hay fever, and atopic dermatitis. The latter is encountered in at least 25%–50% of patients with ichthyosis vulgaris and can obscure the characteristic sparing of the flexures. Conversely, 10%–15% of all individuals with atopic dermatitis and up to 50% of those of Northern European descent with atopic dermatitis also have moderate to severe ichthyosis vulgaris[15].

Pathology

Mild orthokeratotic hyperkeratosis is seen and a diminished granular layer is often but not always observed (Fig. 57.4). Approximately 30%–50% of affected individuals have no detectable granular layer and no keratohyalin granules by electron microscopy, while others have structural abnormalities in keratohyalin granules[13]. Immunohistochemistry demonstrates diminished or absent filaggrin staining in most patients.

Differential Diagnosis

The boundary between dry skin (xerosis) and mild ichthyosis vulgaris is not always clear-cut. In male patients, X-linked ichthyosis may be differentiated by larger, darker scales and involvement of the neck and other flexures; cryptorchidism, a maternal history of delayed or prolonged labor, and the inheritance pattern can represent additional clues. Chromosomal microarray or fluorescence *in situ* hybridization (FISH) testing can exclude steroid sulfatase deficiency. A rare mild form of autosomal recessive congenital ichthyosis that presents with generalized fine, whitish scaling similar to ichthyosis vulgaris results from mutations in *CASP14* (caspase 14), which is involved in the proteolytic degradation of profilaggrin. Acquired ichthyosis is distinguished by its development later in life and association with conditions such as malnutrition, infections (e.g. leprosy), neoplasms (e.g. lymphoma), inflammatory disorders (e.g. sarcoidosis), and medications (e.g. statins, ponatinib, immune checkpoint inhibitors)[15a]. Some individuals with other heritable forms of ichthyosis also have a partial or complete filaggrin deficiency, which may result in a more severe phenotype than is usually observed for those ichthyoses.

Treatment

The mainstay of treatment is application of emollients, humectants, and keratolytic agents to reduce scaling. Preparations that contain urea and/or glycolic, lactic, or salicylic acid are usually beneficial; with the latter, care must be taken to prevent salicylate toxicity (see Ch. 129). Skin irritation from topical retinoids limits their use for ichthyosis vulgaris, and vitamin D analogues are typically ineffective. Systemic treatment with acitretin or isotretinoin is rarely indicated. The use of moisturizing cleansers and humidifiers may also be helpful. Research is underway to identify compounds that could upregulate filaggrin expression and, for those patients with nonsense mutations, modify protein translation[13].

STEROID SULFATASE DEFICIENCY

Synonym: ■ X-linked recessive ichthyosis

History

A type of ichthyosis occurring only in boys and men was first reported in the early nineteenth century, and its X-linked recessive inheritance was clearly recognized in the 1920s. In 1966, the clinical features of this entity were distinguished from those of ichthyosis vulgaris[5]. The underlying steroid sulfatase deficiency was identified in the late 1970s[6].

Epidemiology

The worldwide incidence is between 1 in 2000 and 1 in 9500 male births. It is an X-linked recessive disorder that is transmitted by asymptomatic female carriers and almost exclusively affects boys and men.

Pathogenesis

Diminution or complete absence of steroid sulfatase activity is caused by a deletion of the entire *STS* gene on chromosome Xp22.31 in ~90% of patients and inactivating mutations in others[16]. Steroid sulfatase deficiency results in impaired hydrolysis of cholesterol sulfate and dehydroepiandrosterone sulfate (DHEAS), with subsequent accumulation of cholesterol 3-sulfate in the epidermis. High levels of this metabolite can inhibit transglutaminase-1, explaining the partial overlap with lamellar ichthyosis.

In women pregnant with an affected fetus, steroid sulfatase deficiency in the fetal placenta causes low or absent levels of estrogen in the urine and amniotic fluid because of inadequate deconjugation of DHEAS, which is necessary for estrogen synthesis. As a result, labor often fails to initiate spontaneously or progress, due to insufficient dilation of the cervix. This can only be partially overcome by oxytocin administration, often necessitating cesarean delivery.

Clinical Features

In ~90% of affected boys, steroid sulfatase deficiency presents during the neonatal period with mild erythroderma and generalized peeling, often with exfoliation of large, translucent scales. The typical polygonal, dark-brown, adherent scales develop later during infancy or childhood and are distributed symmetrically on the extremities, trunk, and neck (Fig. 57.5). The scales are occasionally grayish or white, and they tend to be larger on the lower extremities. Involvement of the preauricular area and neck is highly characteristic, which has resulted in the descriptive term "dirty neck disease" (see Fig. 57.5D); however, other skin folds are often not affected. The palms, soles, and remainder of the face are typically spared. Fine scaling of the scalp is frequently seen during early childhood but diminishes over time. The ichthyosis tends to improve in the summer; however, in contrast to ichthyosis vulgaris, it does not significantly subside with age.

Asymptomatic corneal opacities occur in 10%–50% of male patients and in some female carriers, but other ocular abnormalities such as deuteranopia (green color-blindness) are rare. Male patients have a 20-fold increased incidence of cryptorchidism[12]. A higher prevalence of attention deficit hyperactivity and mood disorders has also been reported as has an increased risk of atrial fibrillation/flutter in men[12,17]. Approximately 5% of patients with steroid sulfatase deficiency have a larger contiguous gene deletion, which may include the genes that underlie Kallmann syndrome (hypogonadotropic hypogonadism with anosmia), X-linked chondrodysplasia punctata, ocular albinism, intellectual disability/autism, and short stature.

Steroid sulfatase activity is measurably reduced in 85% of female carriers, but the remaining activity is sufficient to prevent skin manifestations. Because the *STS* gene at least partially escapes X-chromosome inactivation, mosaic ichthyotic changes are not seen.

Pathology

Histopathologic findings include hyperkeratosis or parakeratosis overlying a normal or slightly thickened granular layer. Follicular hyperkeratosis may be present. Electron microscopy shows an increased size and number of keratohyalin granules. In the stratum corneum,

APPROACH TO THE NEONATE OR INFANT WITH SIGNS OF ICHTHYOSIS AND DIAGNOSTIC CLUES

History
- Prenatal/birth history: prenatal diagnoses (e.g. heart defects), prolonged labor (suggestive of steroid sulfatase deficiency), prematurity (characteristic of harlequin ichthyosis, ichthyosis with prematurity)
- Consanguinity makes an autosomal recessive ichthyosis more likely
- Family history of epidermal nevi, ichthyosis, or erythrokeratoderma

Physical examination
- Types of skin findings (see Table 57.3): collodion membrane, bullae/erosions, erythroderma, peeling, diffuse scaling, circumscribed areas of erythema/hyperkeratosis
- Distribution of skin findings: generalized, unilateral, following lines of Blaschko, regional
- Evaluate the scalp hair, eyebrows, and eyelashes (including with trichoscopy); nails; and mucous membranes
- Evaluate for microcephaly, dysmorphic facies, asymmetry, contractures, hepatosplenomegaly, and other extracutaneous abnormalities

↓

Basic laboratory evaluation and additional assessment
- Complete blood count, electrolytes, hepatic panel, immunoglobulin levels (including IgE)
- Peripheral blood smear to evaluate for vacuoles in leukocytes
- Hearing screen (e.g. via the auditory brainstem response or oto-acoustic emission test)
- Ophthalmologic examination
- Consider X-rays to evaluate epiphyses, especially if ichthyosiform lesions are unilateral or in a mosaic distribution pattern
- Consider a skin biopsy, in particular if bullae/erosions (to assess for epidermolysis), if suspect ichthyosis vulgaris (to assess for a diminished granular layer; more evident in severe forms), or if genetic testing is not possible

↓

Consider genetic testing
- A multigene panel is preferable over single gene testing if the diagnosis is not evident based on clinical and laboratory findings
- FISH and microarray are alternatives if suspect steroid sulfatase deficiency

Other possible diagnostic testing (see Tables 57.1, 57.2, & 57.6–8)
- Following resolution of the collodion membrane if present, immunohistochemical staining of a skin biopsy specimen for transglutaminase-1, LEKTI, or filaggrin
- Lipid antibodies (e.g. adipophilin) or stains (e.g. oil red O, Sudan III) to detect cytoplasmic lipid droplets in paraffin-embedded or fresh frozen skin sections, respectively, if suspect neutral lipid storage disease
- Fibroblast or keratinocyte cultures of skin biopsy specimen to measure FALDH activity or check for elevated free fatty alcohols if suspect Sjögren–Larsson syndrome
- Electron microscopy of a skin biopsy specimen using ruthenium tetroxide fixation, to assess for abnormalities in the epidermal lipid system

Ⓐ

Fig. 57.1 Approach to the neonate or infant with signs of ichthyosis and diagnostic clues.

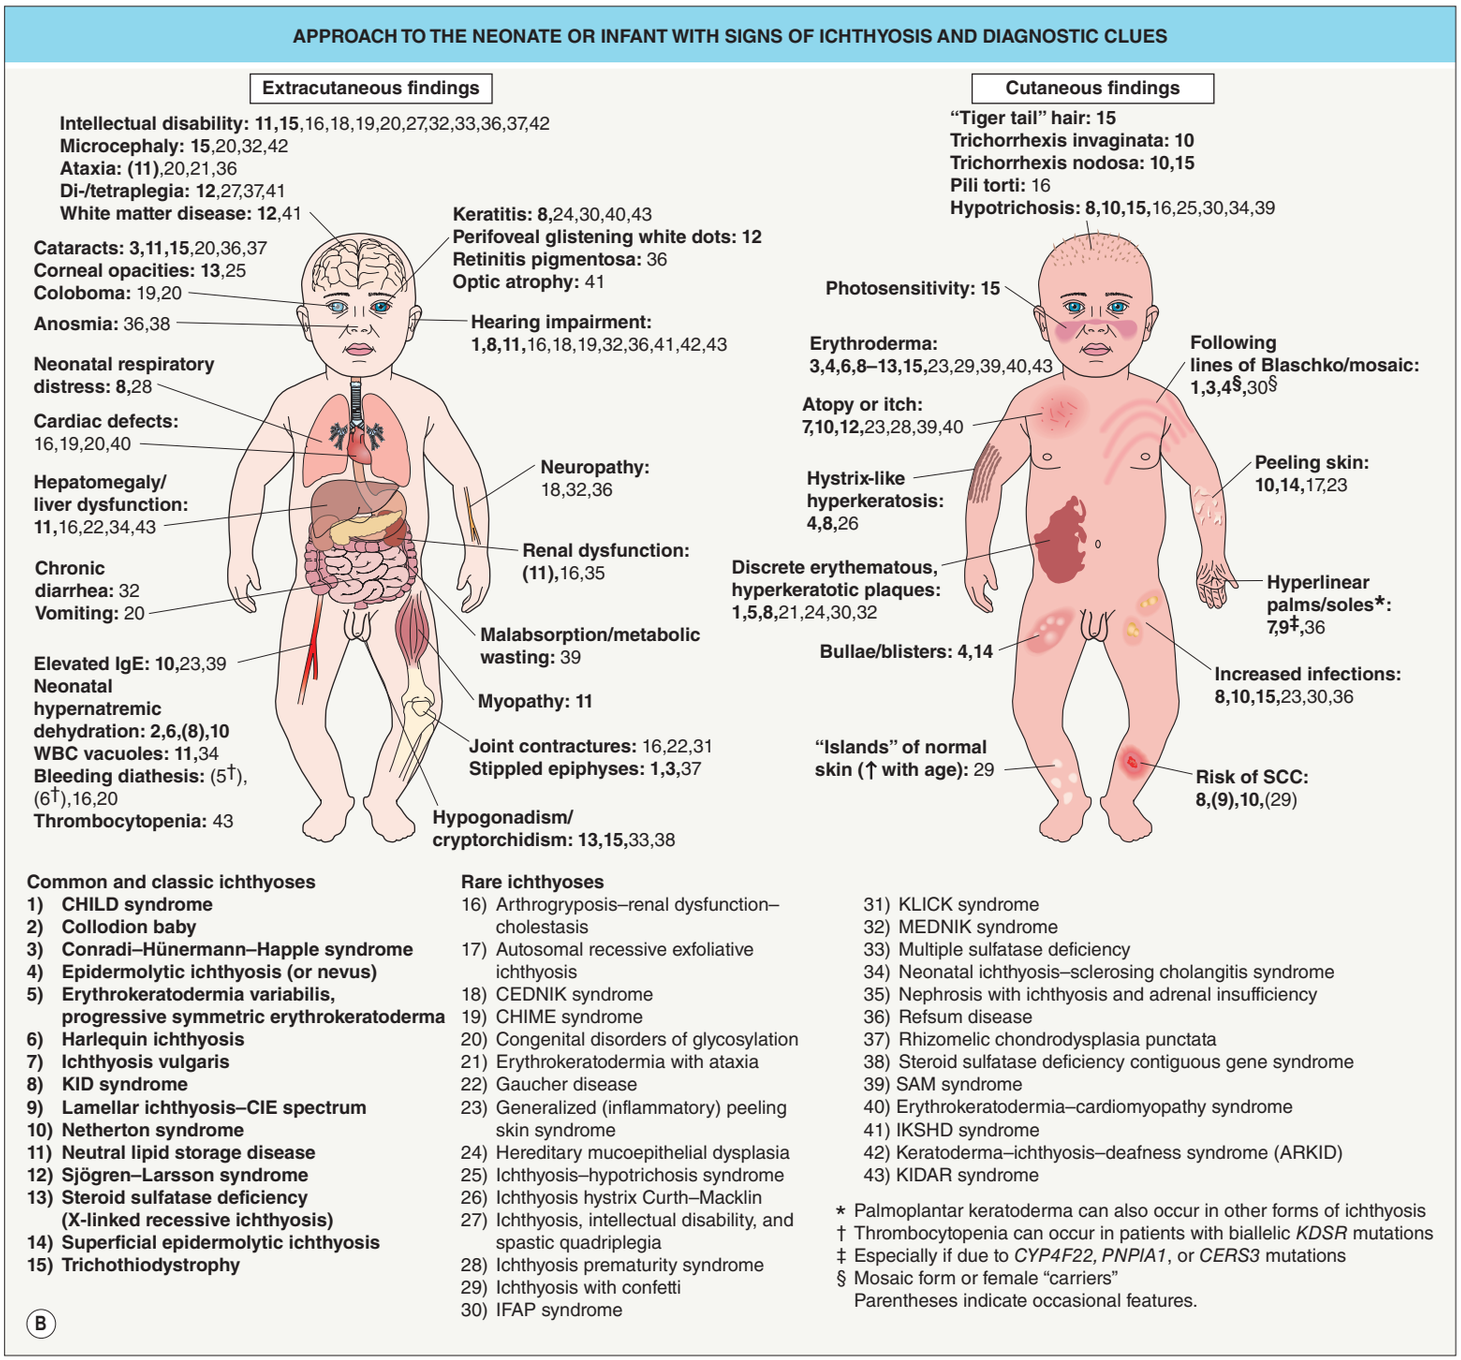

Fig. 57.1 Approach to the neonate or infant with signs of ichthyosis and diagnostic clues. IKSHD, ichthyotic keratoderma, spasticity, hypomyelination, and dysmorphic features; SAM, severe dermatitis, multiple allergies, metabolic wasting.

desmosomes are retained and cells contain a large number of melanosomes. Biochemical and cell kinetic studies show normal epidermal cell turnover and water homeostasis.

Other diagnostic tests

Underlying deletions can be identified by chromosomal microarray analysis or FISH, and molecular testing of *STS* is available. Prenatal diagnosis can also be performed (see Introduction)[10]. However, non-invasive prenatal diagnosis may be accomplished by identifying decreased maternal serum estriol levels or the presence of non-hydrolyzed sulfated steroids in maternal urine. Accumulation of (hydroxy) cholesterol sulfate can be detected indirectly by increased migration of the β-fraction in serum lipoprotein electrophoresis, or measured directly by liquid chromatography-mass spectrometry (LC-MS) of serum, epidermal scale, placental tissue, or amniotic fluid. In addition, steroid sulfatase enzymatic activity can be measured in leukocytes, fibroblasts, keratinocytes, or placental tissue.

Differential Diagnosis

Clinically, ichthyosis vulgaris is distinguished by its sparing of the neck and other flexural areas as well as the presence of hyperlinear palms and keratosis pilaris. As discussed above, an identical ichthyosis phenotype can be associated with extracutaneous findings in patients with larger contiguous gene deletions. Chromosomal microarray analysis, refined karyotyping, or FISH can be utilized to detect Xp deletions and X;Y translocations in patients who present with these additional findings. Autosomal recessive congenital ichthyosis due to defective cholesterol sulfotransferase (*SULT2B1* mutations) has a phenotype similar to that of steroid sulfatase deficiency, with lamellar scaling that spares the central face and skin folds[18].

Treatment

Topical humectants (especially propylene glycol), keratolytics, and retinoids are helpful alone or in combination. In contrast, vitamin D

analogues are less effective and cause significant irritation. Systemic retinoids are rarely necessary.

KERATINOPATHIC ICHTHYOSES

EPIDERMOLYTIC ICHTHYOSIS

Synonyms: ■ Bullous congenital ichthyosiform erythroderma (Brocq) ■ Epidermolytic hyperkeratosis ■ Bullous ichthyosis
Superficial epidermolytic ichthyosis subtype: ■ Ichthyosis bullosa of Siemens ■ Ichthyosis exfoliativa

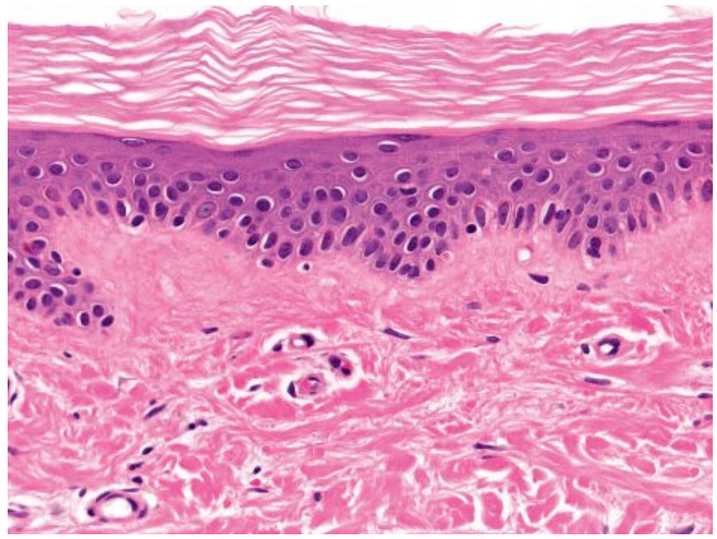

Fig. 57.4 Histologic features of ichthyosis vulgaris. Orthokeratotic hyperkeratosis and a diminished granular layer are evident. *Courtesy Lorenzo Cerroni, MD.*

History

Nikolsky first recognized the characteristic histopathology of the bullous form of congenital ichthyosis in 1897, and Brocq differentiated the dry (non-bullous) form from the wet (bullous) form of congenital ichthyosiform erythroderma in 1902[2]. Based on the distinctive histopathologic features of the epidermis, Frost and Van Scott[3] introduced the name "epidermolytic hyperkeratosis" for this autosomal dominant blistering form of congenital ichthyosis in 1966. In 1937, Siemens[19] first recognized a superficial form of epidermolytic ichthyosis as a distinct entity ("ichthyosis bullosa of Siemens").

Epidemiology

Epidermolytic ichthyosis (EI), which includes the superficial subtype (SEI), has an estimated worldwide prevalence of 1 in 200 000[20]. It is generally an autosomal dominant disorder with complete penetrance, with rare reports of autosomal recessive inheritance. Both sexes are affected equally. At least 50% of all cases occur sporadically due to new mutations.

Pathogenesis

EI is caused by heterozygous mutations in the genes encoding keratin 1 *(KRT1)*, keratin 10 *(KRT10)*, and (for SEI) keratin 2 (*KRT2*)[21]. There are rare reports in consanguineous families of a severe autosomal recessive form of EI due to biallelic loss-of-function mutations[22]. Keratins 1 and 10 are coexpressed in the differentiated spinous and granular layers of the epidermis, whereas keratin 2 is found in the uppermost spinous and granular layers; these represent the sites of disease pathology in classic EI and SEI, respectively. *KRT1* mutations are usually associated with palmoplantar keratoderma (PPK), which may be severe, while most *KRT10* mutations result in sparing of the palms and soles because there is less expression of *KRT10* in these locations[23]. Pathogenic mutations alter highly conserved amino acid residues located at the boundaries of the α-helical rod region; these sites represent mutational "hot spots" that impact the helix initiation and termination motifs (see Fig. 56.5)[21]. Mutations in other sites are uncommon and generally associated with a milder or unusual phenotype[21].

Mutations perturb keratin alignment, oligomerization, and filament assembly. This weakens the cytoskeleton, compromises the mechanical strength and cellular integrity of the epidermis, and leads to cytolysis and blistering. Epidermal acanthosis and hyperkeratosis result from hyperproliferation, decreased desquamation, and other factors. The barrier function of the skin is markedly disturbed, leading to increased transepidermal water loss and bacterial colonization of the stratum corneum.

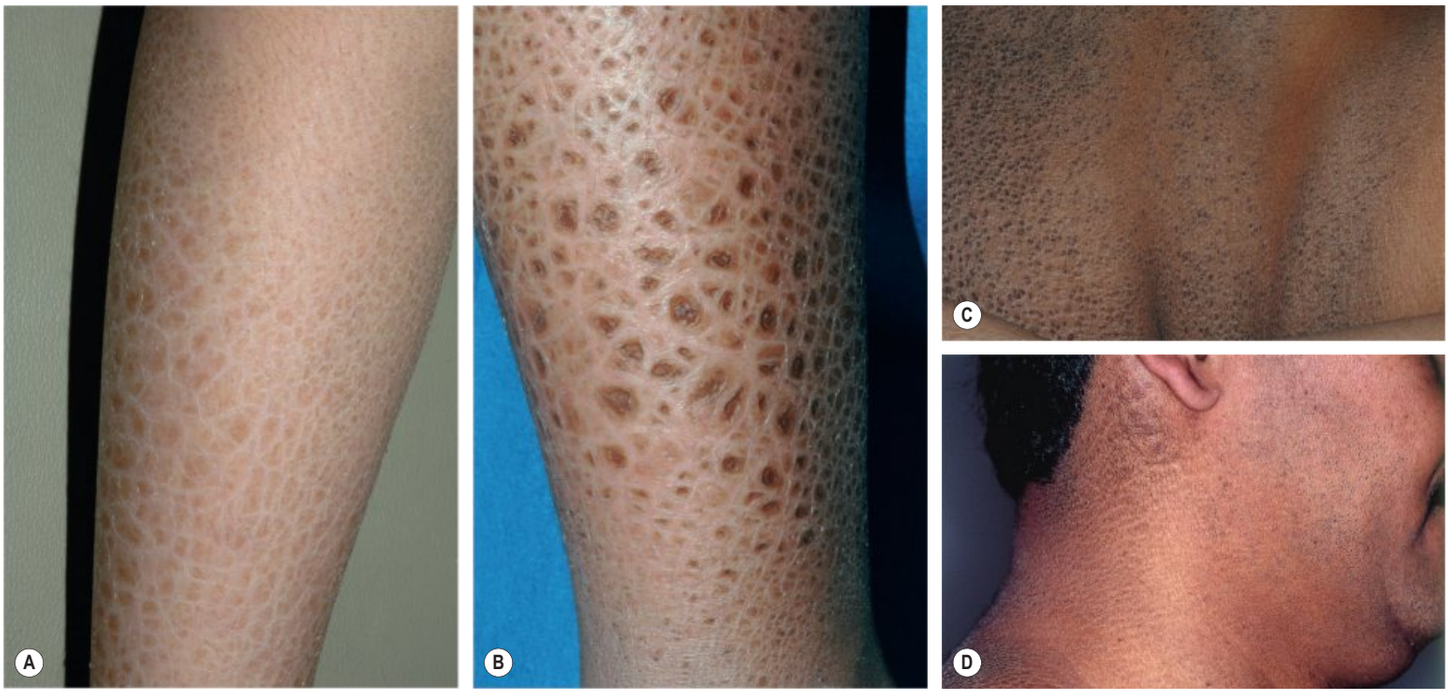

Fig. 57.5 Steroid sulfatase deficiency. Large light-brown (**A**) and more prominent dark-brown (**B**) scales on the lower legs. **C** Smaller dark-brown scales on the trunk, with sparing of the skin folds. **D** Dark scales on the neck, sometimes referred to as a "dirty neck". *A–C, Courtesy Julie V. Schaffer, MD.*

Clinical Features

Classic epidermolytic ichthyosis and variants

Classic EI presents at birth with erythroderma (Fig. 57.6A), peeling, erosions, and often widespread areas of denuded skin (see Fig. 34.16). Hyperkeratosis may be present, but it usually develops later during infancy. Skin fragility, blistering, and erythema decrease over time, and severe hyperkeratosis prevails (Fig. 57.6B–E). However, patients may still periodically shed large plates of superficial epidermis, revealing a tender, erythematous base. Ridges along skin lines are common in flexures (see Fig. 57.6C,D), while hyperkeratosis over the extensor surfaces of the joints often forms a cobblestone pattern (see Fig. 57.6E). When present, PPK may be severe and associated with digital contractures (Fig. 57.6F).

The clinical presentation of EI varies considerably, and six characteristic clinical patterns with or without PPK have been described[23]. Unusual clinical variants of EI include "cyclic ichthyosis with epidermolytic hyperkeratosis" and "annular epidermolytic ichthyosis", which are caused by distinct mutations outside the helix boundaries of *KRT1* and *KRT10*, respectively[21].

EI is disfiguring and has tremendous impact on patients' quality of life and social interactions. Sepsis as well as fluid and electrolyte imbalances can be life threatening in the neonatal period. Episodes of blistering and secondary skin infections are also problematic later in life. The disorder is accompanied by a pungent body odor, and it is occasionally associated with posture and gait abnormalities. Angular cheilitis and severe scalp involvement leading to encasement of hair shafts and hair loss are additional associated findings.

Superficial epidermolytic ichthyosis (SEI)

SEI is less severe than classic EI. At birth, the skin may appear normal or have mild blistering. Trauma-induced vesicles on the extremities occur during infancy but usually subside by early childhood, as hyperkeratosis develops. The skin overlying the joints, the flexures, and the dorsa of the hands and feet (Fig. 57.7) are sites of predilection, whereas the palms and soles are spared. Involved skin may appear ridged, shiny, or lichenified. A characteristic feature is superficially denuded areas with collarette-like borders, described as "molting" or "Mauserung", which develop due to superficial blistering and shedding of the stratum corneum[21].

Epidermolytic epidermal nevi (mosaic epidermolytic ichthyosis)

The mosaic form of EI is characterized by unilateral or bilateral streaks of hyperkeratosis that follow the lines of Blaschko[24]. Extensive involvement with marked hyperkeratosis leading to protruding, porcupine-like spines has been referred to as "ichthyosis hystrix", but this is a descriptive term rather than the name of a distinct disorder. Epidermolytic epidermal nevi are caused by a postzygotic mutation in *KRT1, KRT10*, or rarely *KRT2* that arises during embryogenesis. If this mutation involves gonadal cells, it can potentially be transmitted to the patient's offspring, resulting in full-blown, generalized disease[24]. Examination of both parents of a child with sporadic EI and genetic counseling are therefore recommended.

Pathology

Highly characteristic structural and ultrastructural abnormalities described as "epidermolytic hyperkeratosis" allow EI and SEI to be distinguished from other congenital ichthyoses. Key features of EI on routine histologic examination are dense orthokeratotic hyperkeratosis, prominent acanthosis, hypergranulosis, and cytolysis of the suprabasal and granular layers leading to small intraepidermal blisters (Fig. 57.8). In SEI, cytolysis is limited to the granular cell layers and can occasionally lead to superficial intraepidermal separation. Keratinocytes within the affected cell layers exhibit marked intracellular vacuolization and dense clumps of keratin intermediate filaments (KIFs). A mild perivascular lymphohistiocytic infiltrate is usually present in the upper dermis. Ultrastructural analysis of EI reveals fragmented, clumped KIFs in the lower epidermis and perinuclear KIF shells in the upper epidermis, while SEI has tonofilament clumping in the upper spinous and granular cell layers.

Other diagnostic tests

Mutation screening and complete sequencing of *KRT1, KRT10*, and *KRT2* are available. Prenatal diagnosis can be performed when the underlying mutation has been identified in affected family members.

Differential Diagnosis

In the neonatal period, the presence of blisters and erosions differentiates EI from non-bullous congenital ichthyoses (Table 57.3). Clinical distinction from the various forms of epidermolysis bullosa,

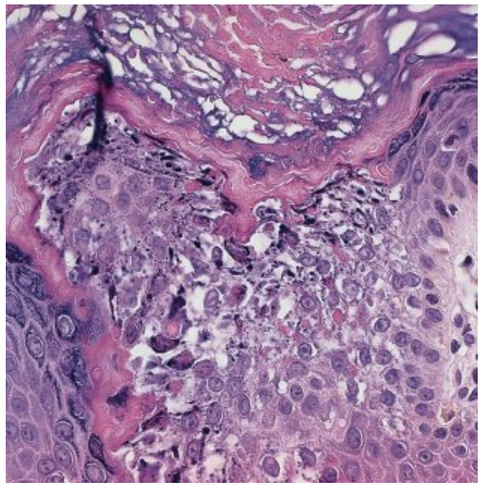

Fig. 57.8 Histology of epidermolytic ichthyosis. Striking ortho-hyperkeratosis, intracellular vacuolization of keratinocytes, and a prominent granular layer with clumped keratin filaments are seen.

staphylococcal scalded skin syndrome, and other vesiculobullous and erosive disorders that can present in neonates may require skin biopsy specimens and cultures (see Chs. 32 and 34).

Later in life, EI can be distinguished from other congenital ichthyoses by the history of blistering at birth with focal recurrences, frequent superinfections, characteristic clinical appearance, and distinctive histologic features. The latter may also be seen in epidermolytic PPK (see Ch. 58), but it is limited to the palms and soles. Ichthyosis hystrix Curth–Macklin sometimes resembles EI, with ridged, verrucous hyperkeratosis over joints and in flexures. In contrast to EI, there is neither blister formation nor histologic evidence of epidermolysis, and the KIFs have specific ultrastructural abnormalities (see below).

Infants with SEI usually do not present with the marked erythroderma and widespread blistering seen in classic EI. Later in life, SEI is differentiated by the lack of erythema and milder course with "molting" of the superficial epidermis. Peeling skin syndromes can have a clinical appearance similar to that of SEI but do not feature vacuolization of the granular layer.

NEONATAL PRESENTATION OF SELECTED ICHTHYOSES AND RELATED DISORDERS

Table 57.3 Neonatal presentation of selected ichthyoses and related disorders. Parentheses indicate less frequent or occasional findings.

Treatment

Treatment is symptomatic and depends on the age of the patient, disease severity, and clinical issues. In the neonatal period, infants with classic EI typically require management in an intensive care nursery to provide protective isolation and prevent or treat dehydration, electrolyte imbalance, and cutaneous superinfection. Sepsis should be treated with broad-spectrum antibiotics. When the neonate is handled carefully and protective padding and lubricants are used, erosions and denuded skin usually heal rapidly.

In children and adults with classic EI, therapy is aimed at reducing hyperkeratosis, removing scale, and softening the skin. Topical products containing urea, salicylic acid, α-hydroxy acids, and N-acetylcysteine can be effective but are often not well tolerated, especially in children, because of burning and stinging. Widespread topical application of higher-concentration salicylic acid preparations should be avoided because of the risk of systemic salicylism. Topical tretinoin and vitamin D may be beneficial but often cause skin irritation. Frequent use of emollients and humectants can be combined with hydration (e.g. soaking of the skin during bathing) and mechanical abrasion of keratotic skin via gentle scrubbing with a soft brush or sponge.

Bacterial skin infections are common in patients with classic EI and often trigger blistering; they require topical or systemic antibiotic treatment. Use of antiseptics such as antibacterial soaps, chlorhexidine, or dilute sodium hypochlorite baths may help to control bacterial colonization. Continuous use of oral or topical antibiotics should be avoided due to the risk of developing antibiotic resistance. Because of the increased skin fragility, it is also important to prevent mechanical trauma, e.g. by wearing comfortable clothing and shoes.

Oral retinoids may drastically reduce hyperkeratosis and the frequency of infections in patients with generalized EI, but they also increase epidermal fragility and blistering. Low initial doses with gradual increase and careful monitoring are advisable, with use of the lowest effective maintenance dose[11,25]. Responses to topical and systemic retinoids tend to be better in patients with EI due to *KRT10* mutations than in those with *KRT1* mutations; the latter individuals are vulnerable to retinoid-related down-regulated expression of KRT2, which can function as a substitute for KRT1[20]. Promising therapeutic approaches utilizing gene editing technologies to inactivate keratin genes with dominant-negative mutations are under development (e.g. *ex vivo* use of a transcription activator-like effector nuclease [TALEN])[26].

ICHTHYOSIS WITH CONFETTI

Synonyms: ■ Ichthyosis en confetti ■ Confetti ichthyosis ■ Congenital reticular ichthyosiform erythroderma (CRIE) ■ Ichthyosis variegata ■ MAUIE (*m*icropinnae, *a*lopecia *u*niversalis, congenital *i*chthyosis, and *e*ctropion) syndrome

Ichthyosis with confetti is a rare autosomal dominant disorder in which affected individuals are born with an ichthyosiform erythroderma and PPK[27]. During childhood, hundreds to thousands of small, confetti-like "islands" of normal skin appear in a widespread distribution (Fig. 57.9), increasing in size and number over time. The MAUIE – *m*icropinnae,

*a*lopecia *u*niversalis, congenital *i*chthyosis, and *e*ctropion – variant is associated with an increased risk of melanoma and keratinocyte carcinomas, which have also been reported in other ichthyosis with confetti patients[28].

Histologic findings in ichthyotic skin include acanthosis, perinuclear vacuolization of keratinocytes in the upper epidermis, and parakeratotic hyperkeratosis, while the white macules lack epidermal abnormalities by light microscopy.

This ichthyosis is caused by heterozygous splice or frameshift mutations in *KRT10* or less often *KRT1*[27]. The resulting mutant keratin protein is often extended and has an arginine-rich carboxy terminus. This leads to varying degrees of mislocalization of KIFs to the nucleus instead of the cytoplasm. Each island of normal skin represents a revertant clone that arises via loss-of-heterozygosity due to mitotic homologous recombination, i.e. a "crossing-over" process that leads to homozygous mutant and homozygous normal daughter cells. The exact role of the frameshift mutations in the markedly elevated rate of mitotic recombination remains to be determined.

ICHTHYOSIS HYSTRIX CURTH–MACKLIN

Synonyms: ■ Ichthyosis hystrix ■ "Porcupine man" ■ Ichthyosis hystrix gravior type Lambert ■ Systematized verrucous nevus

Introduction

Ichthyosis hystrix is a descriptive term for massive hyperkeratosis that leads to a verrucous surface or protruding porcupine-like spines. Of note, it does not represent a distinct clinical entity. This phenotype is most commonly observed in patients with EI, but can also be seen in clinically and genetically heterogeneous disorders ranging from ichthyosis hystrix Curth–Macklin to verrucous epidermolytic nevi to hystrix-like ichthyosis with deafness (HID) syndrome. The latter is a variant of keratitis–ichthyosis–deafness (KID) syndrome and is due to mutations in *GJB2*[29].

History

In 1954, Ollendorff-Curth and Macklin[30] described a family with hystrix-like spiky hyperkeratosis and PPK. Electron microscopic examinations by Anton-Lamprecht et al.[31] revealed binucleated keratinocytes and peculiar ultrastructural abnormalities of the cytoskeleton. Since the initial description, several large families with autosomal dominant inheritance have been reported as have sporadic cases. A well-known example of the ichthyosis hystrix phenotype is the "porcupine men" of the Lambert family from Suffolk, England[32]. Since no blister formation was mentioned in the records of this kindred, it remains unclear if they had ichthyosis hystrix Curth–Macklin or a form of EI.

Pathogenesis

In several unrelated patients with ichthyosis hystrix Curth–Macklin, heterozygous mutations in the keratin 1 (*KRT1*) or keratin 10 (*KRT10*) genes have been demonstrated. In contrast to EI, the mutations were small nucleotide deletions/insertions that mostly led to a frameshift and produced a keratin protein with an aberrant tail. Because the latter lacks the usual glycine loop motifs, protein–protein interactions are altered[33].

Clinical Features

The hyperkeratotic areas in ichthyosis hystrix Curth–Macklin can clinically mimic EI, but there is no skin fragility. Clinical expression varies even within families, ranging from isolated PPK (which may be severe and mutilating) to localized keratotic verrucous plaques to generalized hystrix-like hyperkeratosis with horny rigid spikes. Hyperkeratosis is present at birth or develops during early childhood. It has a cobblestone-like or ridged surface over large joints and in skin folds. Circular constriction bands (pseudoainhum), starfish-like keratoses, knuckle pads, digital flexion contractures, and secondary bacterial infections have been described.

Pathology

Most histopathologic features, including orthokeratotic hyperkeratosis, hypergranulosis, acanthosis, and church spire-like papillomatosis, are nonspecific. Cells in the differentiated cell layers may be vacuolated or binucleated. Ultrastructural abnormalities in the upper epidermis are diagnostic, with a shell-like, interspersed network of tangled KIFs, often associated with perinuclear vacuolization and formation of binucleated cells. In contrast to EI, there is no epidermolysis or keratin clumping.

Differential Diagnosis

Ichthyosis hystrix Curth–Macklin can be differentiated from EI by the absence of blistering and skin fragility as well as by electron microscopic findings.

Treatment

The most effective treatments are systemic retinoids and topical keratolytic agents (see EI above).

AUTOSOMAL RECESSIVE CONGENITAL ICHTHYOSES

AUTOSOMAL RECESSIVE CONGENITAL ICHTHYOSIS (ARCI): CLINICAL AND GENETIC SPECTRUM

Synonyms: ■ Nonsyndromic ARCI ■ Ichthyosis congenita

Introduction

Autosomal recessive congenital ichthyosis (ARCI) encompasses a clinically and genetically heterogenous group of nonsyndromic ichthyoses that are present at birth or shortly thereafter and feature generalized scaling with variable erythema. Approximately one-third of patients with ARCI are born preterm, and the most common presentation at birth is a collodion membrane (~70%; see below)[7,34]. Ectropion (eversion of the eyelids) occurs in ~50% of neonates and may persist, while eclabium (eversion of the lips), observed in ~25% of neonates, often resolves[34].

The spectrum of fully developed ARCI phenotypes ranges from large, dark, plate-like scales with no or minimal erythema in lamellar ichthyosis (LI) to fine white scales and pronounced erythroderma in congenital ichthyosiform erythroderma (CIE). In addition, there are many intermediate phenotypes with variable degrees of erythema as well as size and quality of the scales. Other frequent accompanying features include PPK, hypohidrosis, heat intolerance, scarring alopecia, and conductive hearing loss. Patients may also develop recurrent infections, arthritis or arthralgia, anemia, and vitamin D deficiency.

ARCI is caused by pathogenic variants in at least 13 genes which encode proteins that contribute to the structure and function of lipid and cornified cell envelopes, in particular via their roles in epidermal lipid processing and transport (see Chs. 56 and 124). As a result, affected individuals have perturbed homeostasis of the stratum corneum and abnormal skin barrier function.

History

In 1966, Frost and Van Scott[3] coined the term "lamellar ichthyosis" for all autosomal recessive forms of non-bullous congenital ichthyosis. Williams and Elias[35] further separated this group into two distinct phenotypes, lamellar ichthyosis (LI) and (non-bullous) congenital ichthyosiform erythroderma (CIE), which now have been recognized to reside along a continuum with intermediate phenotypes. In the current classification system, the LI–CIE spectrum as well as harlequin ichthyosis (HI) and ichthyosis–prematurity syndrome (IPS) fall within the nonsyndromic ARCI category[7,36].

Epidemiology

ARCI occurs worldwide with an estimated overall prevalence of 1 in 100 000 to 200 000 live births. It is more common in certain regions such as Norway (1 in 90 000) and Spain (1 in 60 000) as well as in highly consanguineous populations[12]. The various forms of ARCI are inherited as autosomal recessive traits.

Pathogenesis and Clinical Features

Approximately 85%–90% of patients with ARCI have identifiable mutations in one of the ≥13 genes currently known to underlie this group of ichthyoses (see Table 57.1)[9,34]. Most common is *transglutaminase-1* deficiency due to deleterious mutations in both copies of ***TGM1***, accounting for ~30%–70% of all patients with ARCI and 70%–90% of those with classic LI[37–39]. Transglutaminase-1 (TGM1) catalyzes the calcium-dependent cross-linking of proteins through the formation of ε-(γ-glutamyl) lysine isopeptide bonds; it also creates ester bonds between proteins and ω-hydroxyceramides (see Fig. 56.3). This enzyme is expressed in the upper differentiated layers of the epidermis, where it facilitates the formation of the cornified cell envelope via cross-linking of multiple structural proteins (e.g. involucrin, small proline-rich proteins, loricrin, keratins, desmosomal proteins) to one another as well as to the lipid envelope.

Many patients of northern European descent share a German founder mutation that leads to alternative splicing of *TGM1* mRNA[40]. Certain *TGM1* variants can also result in self-improving collodion ichthyosis with very mild residual scaling after the collodion membrane has been shed (see below). In addition, mutations that result in temperature-sensitive TGM1 cause an LI variant known as "bathing suit ichthyosis" that primarily affects warmer body sites such as the trunk and scalp.

Biallelic loss-of-function mutations in *ATP-binding cassette subfamily A member 12* (***ABCA12***) that lead to complete absence of this transporter protein in the skin underlie the most severe form of ARCI, harlequin ichthyosis (HI). The presence of at least one *ABCA12* splice site or missense variant that permits residual protein function may result in a CIE or LI phenotype. Overall, this gene plays a role in ~5%–10% of all ARCI patients[41]. A germline missense *ABCA12* mutation plus mosaicism for a postzygotic frameshift *ABCA12* mutation ("recessive mosaicism") has been reported in a patient with erythematous, scaly lesions following the lines of Blaschko[42]. Rarely, *ABCA12* mutations may result in a phenotype resembling erythrokeratodermia variabilis et progressiva (see Table 57.1)[9].

ABCA12 is responsible for the energy-dependent transmembrane transport of glucosylceramides and proteolytic enzymes (e.g. kallikrein 5 and 7) required for normal epidermal desquamation. This transporter is found in lamellar bodies, which are absent, reduced, or improperly formed in patients with HI[43,44]. A lack of functional ABCA12 prevents the formation of lipid bilayers in the stratum corneum and results in compensatory massive hyperkeratosis and a severe breakdown of the permeability barrier with increased transepidermal water loss. Rarely, individuals with biallelic mutations in *3-ketodihydrosphingosine reductase* gene (***KDSR***), which encodes an enzyme involved in *de novo* ceramide synthesis, may have a HI presentation associated with thrombocytopenia[45].

Depending on their ethnic background, 10%–30% of ARCI patients without *TGM1* mutations harbor biallelic inactivating mutations in one of two *lipoxygenase (LOX)* genes, either ***ALOX12B*** or ***ALOXE3***, with *ALOX12B* accounting for approximately two-thirds of cases[34,36,39,46,47]. Up to 70% of these individuals (most with *ALOX12B* variants) are born with a collodion membrane and subsequently develop mild to moderate CIE that may improve with age. Additional clinical features can include mild PPK, ridged nails, and an anteriorly overfolded outer rim of the ears[34]. As noted for *TGM1*, certain *ALOX12B* and *ALOXE3* variants (and rarely *NIPAL4* or *CYP4F22*) result in self-improving collodion ichthyosis. The lipoxygenase enzymes encoded by these genes are involved in the arachidonic acid degradation pathway and are preferentially synthesized in the epidermis, where their successive actions play a role in the creation of protein-bound ceramides in the corneocyte lipid envelope[48].

Mutations in ***NIPAL4***, which encodes *NIPA-like domain containing 4 (ichthyin)*, account for 5%–25% of ARCI, with a higher frequency in Northern Europe[49,50]. In a Scandinavian study, 16 of 18 ARCI families with ultrastructurally abnormal lamellar bodies in the granular layer (elongated perinuclear membranes [ARCI EM type III]) had mutations in this gene[34,50,51]. Affected individuals have variable patchy erythema and widespread coarse, gray–white scales with a predilection for the neck and skin folds but sparing of the face. Diffuse yellowish PPK and hypohidrosis are common manifestations while a collodion membrane at birth (<30%), ectropion, eclabium, nail abnormalities, cataracts, and keratoconus occur less frequently[34,50,51].

NIPAL4 is a Mg^{2+} transporter protein that associates with FATP4, an acyl-CoA synthetase critical for epidermal lipid processing that is implicated in ichthyosis prematurity syndrome (see below)[52]. Ichthyosis may result from disrupted lipid envelope formation due to a lack of sphingolipid end products. Cytotoxic events due to accumulation of long-chain free fatty acids that disrupt processing and transport of intracellular membrane components may also play a role.

Approximately 5%–10% of individuals with ARCI harbor mutations in ***CYP4F22***, which encodes a *cytochrome P450 enzyme* involved in the ω-hydroxylation of ultra-long-chain fatty acids to form acylceramides. The latter are important to skin barrier function[34,52,53]. Affected individuals have a mild form of LI or CIE, with a variable collodion membrane at birth and palmoplantar hyperlinearity[54]. Ultrastructurally, the stratum corneum shows fragmented and disorganized lamellar lipid bilayers and entombment of lipids and lamellar bodies[55].

ARCI is occasionally caused by mutations in ***CERS3*** which encodes *ceramide synthase 3*. This enzyme is involved in the synthesis of ultra-long-chain, epidermis-specific ceramides. Affected individuals often present with a collodion membrane and develop a prematurely aged appearance of the skin, generalized gray–brown scales, mild erythema, and palmoplantar hyperlinearity[9,56].

Mutations in the gene that encodes *patatin-like phospholipase domain-containing 1* (***PNPLA1***), an enzyme involved in acylceramide biosynthesis, account for ~5% of ARCI overall. This form of ARCI is more common in northern Africa, Spain, and Iran, where common founder mutations or consanguinity may result in pseudo-dominant inheritance[57,58]. Affected individuals have relatively mild generalized scaling, along with scalp involvement and variable erythema; approximately half are born with a collodion membrane. Occasional manifestations include a cyclic course, palmoplantar hyperlinearity, and sharply demarcated erythrokeratodermic plaques.

Loss-of-function variants in *cholesterol sulfotransferase* (***SULT2B1***), which encodes a cytosolic enzyme involved in the sulfoconjugation, synthesis and metabolism of steroids, may lead to LI with variable mild erythema and often a collodion presentation. Sparing of the skin folds and face (reminiscent of steroid sulfatase deficiency) and thickened, scaly gray plaques over large joints and in areas of friction distinguish this form of ARCI[18].

Mutations in *short chain dehydrogenase/reductase family 9C member 7* (***SDR9C7***), which contributes to skin barrier function via the covalent binding of acylceramides to the cornified cell envelope, can underlie a mild form of ARCI. Affected individuals present with generalized scaling with variable erythema and PPK; recurrent fungal infections of the skin and nails have been reported[59]. This ichthyosis tends to spare face and scalp, and it lessens in severity with age.

Pathogenic variants in *lipase N* (***LIPN***) can result in childhood-onset ichthyosis with generalized fine white scales but minimal erythema. This gene accounts for ~5% of Israeli families with nonsyndromic ARCI[47].

Lastly, *ichthyosis prematurity syndrome* (IPS), a clinically distinct form of ARCI first described in Scandinavia, results from mutations in *solute carrier family 27 member 4* (***SLC27A4***; see Table 57.1)[60–62]. The protein product of *SLC27A4* is FATP4 (fatty acid transport protein 4), which acts as an acyl-CoA synthetase and functions in the formation of very-long- and ultra-long-chain fatty acids. Its dysfunction leads to disruption of acylceramide production and skin barrier defects. Of note, FATP4 interacts with NIPAL4 and TGM1 in lipid metabolism and processing[63].

FATP4 is preferentially expressed in fetal murine epidermis, while the related FATP1 predominates in adult murine epidermis. If this pattern is also true for human skin, rescue of FATP4 deficiency by upregulation of another fatty acid transport protein after birth could explain the distinct clinical features and course of IPS. Clinically, hallmarks of IPS are premature birth, neonatal asphyxia, and massive verrucous or spiky hyperkeratosis favoring the scalp, forehead, and trunk. The hyperkeratosis resolves during the neonatal period, transitioning to mild generalized scaling and follicular keratoses[60].

COLLODION BABY

Synonyms: ■ Collodion fetus
Self-improving collodion ichthyosis/baby: ■ Self-healing collodion baby ■ Lamellar exfoliation of the newborn

Epidemiology

The collodion baby is a shared presentation of several congenital ichthyoses, most with autosomal recessive inheritance. It is not a distinct disorder.

Pathogenesis

The pathomechanisms leading to formation of a collodion membrane are not completely understood, but this presentation points to disturbed adaptation of the fetal epidermis to postnatal life. The most common causes of collodion ichthyosis are deficiencies of the crucial cross-linking enzyme TGM1[64] or various lipid-processing enzymes and lipid transporters. This includes *ALOX12B* (>*ALOXE3*), *CERS3*, *PNPLA1*, and *SULT2B1* (see ARCI). Less common etiologies are fatty aldehyde dehydrogenase deficiency in Sjögren–Larsson syndrome, deficiency of an activator of the adipose triglyceride lipase in neutral lipid storage disease, and β-glucocerebrosidase deficiency in Gaucher disease (see Fig. 56.2).

In ~10% of collodion babies[12], a milder "self-healing" phenotype known as *self-improving collodion ichthyosis* occurs. This has been reported in association with *TGM1, ALOX12B, ALOXE3*, *NIPAL4*, or *CYP4F22* mutations that fully inactivate the encoded protein *in utero* but not after birth[46,65]. It has been postulated that this "dynamic" phenotype is dependent on environmental conditions, which influence the stability of the mutant protein. A form of self-improving collodion ichthyosis in which membranes are localized to acral areas due to compound heterozygous *TGM1* mutations has also been described[66].

Clinical Features

Collodion babies are often born prematurely and small for gestational age, and they have increased perinatal morbidity and mortality. At birth, the neonate is covered with a taut, shiny, transparent membrane formed by the thickened stratum corneum, which resembles a plastic wrap (Fig. 57.10). Its tautness often leads to ectropion, eclabium, and hypoplasia of nasal and auricular cartilage. Sucking and pulmonary ventilation may also be impaired, resulting in dehydration, malnutrition, hypoxia, and pneumonia. After birth, the parchment-like membrane gradually dries, cracks, and breaks up. In the process, fissures develop that impair epidermal barrier function, which can lead to percutaneous loss of water and permit the entry of microorganisms; fluid and electrolyte imbalances, skin infections, and sepsis may follow. In addition, circular bands of hardened skin can lead to vascular constriction, ischemia, and distal edema. Growth hormone resistance and an increased prevalence of hypothyroidism have also been described.

Within two to four weeks after birth, the membrane peels off in sheets and a transition to the underlying disease phenotype takes place. Most commonly, CIE or LI ensues. Other ichthyoses may rarely present as a collodion baby (Table 57.4). In self-improving collodion ichthyosis, desquamation of the collodion membrane leaves normal skin or variable clinical findings including xerosis, fine or focal scaling, palmar hyperlinearity, mild PPK, red cheeks, and hypohidrosis[65].

Pathology

Light and electron microscopic abnormalities of the collodion membrane are nonspecific and reveal mostly an excessively thickened,

DIFFERENTIAL DIAGNOSIS OF A COLLODION BABY	
Disorder	**Frequency**
Self-improving collodion ichthyosis	Always
Lamellar ichthyosis	Common
Congenital ichthyosiform erythroderma	Common
Trichothiodystrophy	Fairly common
Sjögren–Larsson syndrome	Rare
Infantile Gaucher disease	Rare
Ichthyosis, intellectual disability, and spastic quadriplegia	Rare
Ichthyosis with confetti	Very rare
Autosomal dominant lamellar ichthyosis	Very rare
Neutral lipid storage disease	Very rare
Male *EBP* disorder with neurologic defects (MEND) syndrome	Very rare
Ectodermal dysplasias (EDs)*	Very rare
*e.g. hypohidrotic ED or ankyloblepharon–ED–clefting (AEC) syndrome.	

Table 57.4 Differential diagnosis of a collodion baby. A collodion membrane has also been described in a patient with neonatal inflammatory skin and bowel disease due to a homozygous ADAM17 mutation.

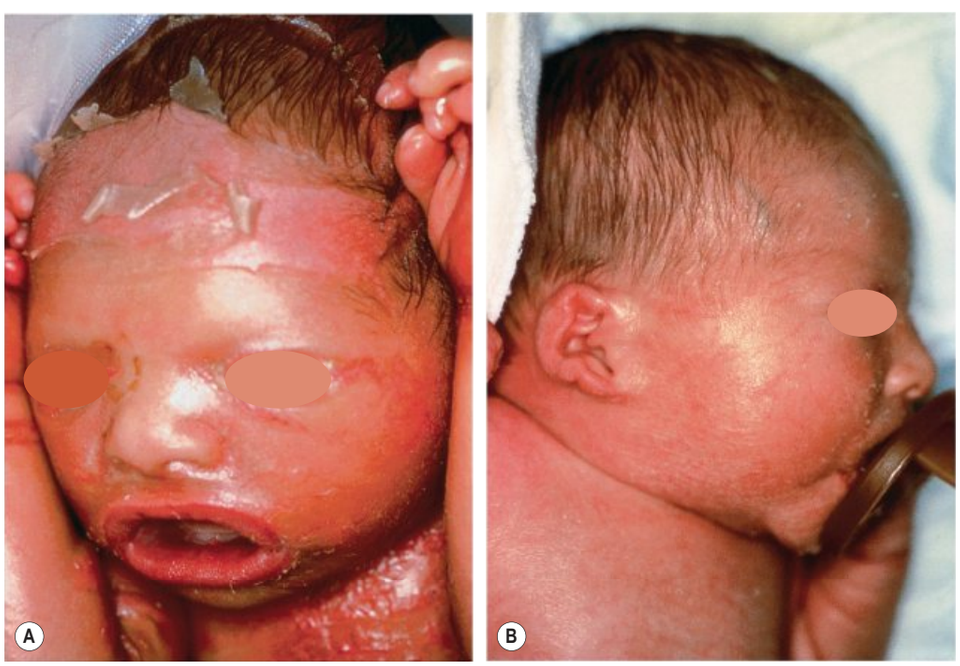

Fig. 57.10 Collodion baby. A Day 1 with eclabium. **B** Day 8 with erythema and diffuse mild scaling and misshapen ears.

orthokeratotic stratum corneum. Therefore, it is usually preferable to perform multigene molecular testing or to defer a skin biopsy until transition to the underlying disease phenotype occurs. At that time, immunostaining can demonstrate the presence or absence of TGM1 protein in the upper epidermis[67]. *In situ* assays of transglutaminase activity can also be performed on skin biopsy sections and allow rapid identification of patients with TGM1 deficiency, even as a collodion baby[67]. However, interpretation of the transglutaminase activity assay requires experience, and this test is not widely available.

Differential Diagnosis

The phenotype of harlequin ichthyosis is much more severe and so striking that a clinical distinction between the two disorders is, in most circumstances, not difficult.

Treatment

Collodion babies are at risk for thermoinstability, hypernatremic dehydration, skin infections, and sepsis. It is therefore essential to keep them in a controlled environment and to carefully monitor for fluid and electrolyte imbalances. Collodion babies are also at risk for pneumonia secondary to restricted ventilation and aspiration of amniotic fluid containing scales. To facilitate gradual desquamation of the collodion membrane, it is generally recommended that infants be placed in a humidified incubator and the skin treated with wet compresses and light emollients to increase its elasticity and pliability. Manual removal of the collodion membrane and use of topical keratolytic agents are not advisable because of the increased risk of infections and percutaneous absorption. Distal constriction bands occasionally require surgical release. Systemic retinoid therapy is rarely necessary but may be of benefit in selected cases of delayed membrane shedding or severe underlying ichthyosis[11].

LAMELLAR ICHTHYOSIS

Synonyms: ■ Non-erythrodermic autosomal recessive lamellar ichthyosis ■ Ichthyosis congenita type 2

Clinical Features

Classic LI is typically a severe disorder that is apparent at birth and persists throughout life, although milder variants also occur. Most affected neonates are encased in a collodion membrane that is gradually replaced over the first few weeks of life by large scales in a generalized distribution. These large, brown, plate-like scales form a mosaic or bark-like pattern, and there is minimal to no associated erythroderma (Fig. 57.11A,B). The scales are centrally attached and have raised borders, often leading to superficial fissures. "Bathing suit ichthyosis", which is caused by temperature-sensitive *TGM1* mutations, affects primarily the trunk and scalp; it was first reported in South Africans and subsequently described in individuals from around the world[68].

Tautness of facial skin commonly results in ectropion (Fig. 57.11C), eclabium, and hypoplasia of nasal and auricular cartilage. Severe ectropion may lead to lagophthalmos, madarosis, conjunctivitis, and ensuing corneal exposure and keratitis. Traction and compression exerted by the taut skin can cause scarring alopecia, especially at the periphery of the scalp. Although hair shafts are normal, they are often encased by the thickened stratum corneum. At least half of individuals with LI have PPK, which can range from accentuated skin markings to severe thickening with cracking and fissuring. Secondary nail dystrophy with thickened nail plates and ridging sometimes develops. Intraepidermal constriction of sweat ducts often results in severe heat intolerance, while accumulation of scale in the external ear canals can lead to occlusion, bacterial colonization, and recurrent infections.

Pathology

The histologic abnormalities are not diagnostic. Massive orthokeratotic hyperkeratosis covers an acanthotic epidermis, sometimes with psoriasiform or papillomatous hyperplasia. In contrast to CIE, the epidermal proliferation rate is normal or only slightly elevated. Elongated cholesterol clefts, variable numbers of translucent lipid droplets in the stratum corneum, and a thin or absent cornified cell envelope have been observed by electron microscopy, although these findings overlap with those of CIE[69].

Other diagnostic tests

In addition to measuring TGM1 activity in cultured keratinocytes, procedures to detect TGM1 deficiency in skin biopsy specimens include immunostaining with anti-TGM1 antibodies, *in situ* measurement of TGM1 activity (via covalent incorporation of biotinylated substrate peptides into skin cryostat sections)[67], and testing for the presence of cross-linked cell envelopes[70]. However, these assays are not widely available for diagnostic purposes.

Massively parallel (next-generation) sequencing panels that include the genes associated with ARCI have a diagnostic yield of >85%[9,34,39]. Alternatively, single-gene testing starting with *TGM1* can be considered, especially in patients with classic LI. ARCI patients with a collodion membrane at birth, plate-like scale, ectropion, and/or alopecia are approximately four times more likely to have *TGM1* mutations than those without at least one of these features[37]. Establishing a molecular diagnosis not only enables genetic counseling and family planning but can also provide prognostic information and help direct therapy. In families with known mutations, molecular prenatal diagnosis may be performed utilizing samples of chorionic villi, amniotic fluid, or circulating fetal cells obtained at an early gestational age[10].

Fig. 57.11 Lamellar ichthyosis. **A** Large, plate-like scales on the lower extremities forming a tile-like pattern. **B** Brown scales of various sizes with accentuation on the neck and in the axilla. **C** Obvious ectropion as well as plate-like scales. *B, Courtesy Julie V. Schaffer, MD.*

Differential Diagnosis

In the neonatal period, there is considerable clinical overlap of LI with other congenital ichthyoses that present with a collodion membrane, especially CIE and self-improving collodion ichthyosis (see Tables 57.3 and 57.4). Later in life, the large, dark, plate-like scales, ectropion, and no discernible erythroderma of LI can be readily distinguished from most other ichthyoses. Of note, a rare autosomal dominant form of LI with prominent PPK can occur due to heterozygous mutations in *ASPRVI* (aspartic peptidase retroviral-like 1), which encodes a protease important for profilaggrin processing[71]. Although classic CIE is differentiated by marked erythroderma and small white scales, some patients exhibit intermediate LI/CIE phenotypes with variable degrees of erythroderma as well as quality and size of scales.

Treatment

Neonatal care is detailed in the collodion baby section. Severe disease often necessitates oral retinoids from early childhood. Treatment is usually initiated at a low dose and then titrated to the minimal effective dose, which is dictated by the course and severity of the disease[11,25]. In addition to alleviating hyperkeratosis and scaling, there may be improvement of the ectropion, thus avoiding eye complications and reconstructive eyelid surgery. However, the benefits of long-term systemic retinoid therapy must be weighed against the potential toxicities. Of note, liarozole, a retinoic acid metabolism blocking agent that is not available in the US, had a similar efficacy to acitretin but with a more favorable tolerability profile[72]. In a randomized controlled study of 64 patients with moderate-to-severe LI, a 40%–50% response rate was observed in patients receiving liarozole, compared to 11% with placebo (p=0.056)[73].

Topical management strategies should take into consideration the severely impaired desquamation and barrier function of the skin as well as the patient's age and preferences. Addition of sodium bicarbonate to bath water (e.g. 2 handfuls of baking soda in a half-full standard tub) to raise the pH to ~7.9 one to three times weekly may facilitate scale removal. The use of keratolytics is often limited due to skin irritation and an increased risk of systemic absorption, especially in children; systemic absorption of topical tacrolimus and vitamin D_3 derivatives can also occur. Topical calcipotriene (calcipotriol), tazarotene, and formulations combining either lactic acid with propylene glycol or urea with N-acetylcysteine may be of benefit[52,74]. A topical isotretinoin formulation is currently under investigation in patients with LI.

Systemic therapies targeting interleukin (IL)-17 (e.g. secukinumab) or IL-12/23 (e.g. ustekinumab) may suppress the Th2-associated inflammation that has been documented in patients with ARCI. Because these antibodies have little impact on scaling, their potential benefit is greater for CIE than for LI[75]. Notably, in a small randomized controlled study of adults with several types of erythrodermic ichthyosis (ARCI, EI, Netherton syndrome), treatment with secukinumab for 16 weeks did not significantly decrease Th2-related biomarkers or disease severity[75]. Topical enzyme replacement (e.g. recombinant human TGM1) and acylceramide supplementation are being investigated as treatment strategies for ARCI, and a clinical trial of topical gene therapy utilizing a replication-defective herpes simplex virus type 1 vector encoding human TGM1 is underway in patients with TGM1-deficient ARCI[52,76].

Heat intolerance can be ameliorated by frequent moistening of the skin with water or the use of air conditioning and humidifiers. Severe ectropion requires longitudinal ophthalmologic evaluation. Surgical repair and/or topical retinoids (e.g. tazorotene) can be used to prevent irreversible corneal damage.

Because LI and other severe forms of ARCI are often disfiguring, they may hinder the psychosocial development of affected children and adolescents. An increased risk of depression and reduced quality of life scores have been reported. Families and patients need to be supported, and patient advocacy groups such as FIRST (www.firstskinfoundation.org) are excellent resources.

CONGENITAL ICHTHYOSIFORM ERYTHRODERMA

Synonyms: ■ Non-bullous congenital ichthyosiform erythroderma ■ Erythrodermic autosomal recessive lamellar ichthyosis ■ Ichthyosis congenita type 1

Clinical Features

CIE usually presents at birth with either erythroderma or a collodion membrane, followed by generalized erythroderma and scaling that remain throughout life. The clinical features of CIE tend to be milder than those of classic LI, but there is variability in the intensity of erythema as well as the size and type of scale. In severely affected patients, CIE is characterized by an intense, bright red erythroderma; generalized white, small scales with a "powdery" consistency (Fig. 57.12); and additional findings such as ectropion and scarring alopecia. Scales may become larger, darker, or plate-like, especially on the extensor surface of the lower extremities. The palms and soles

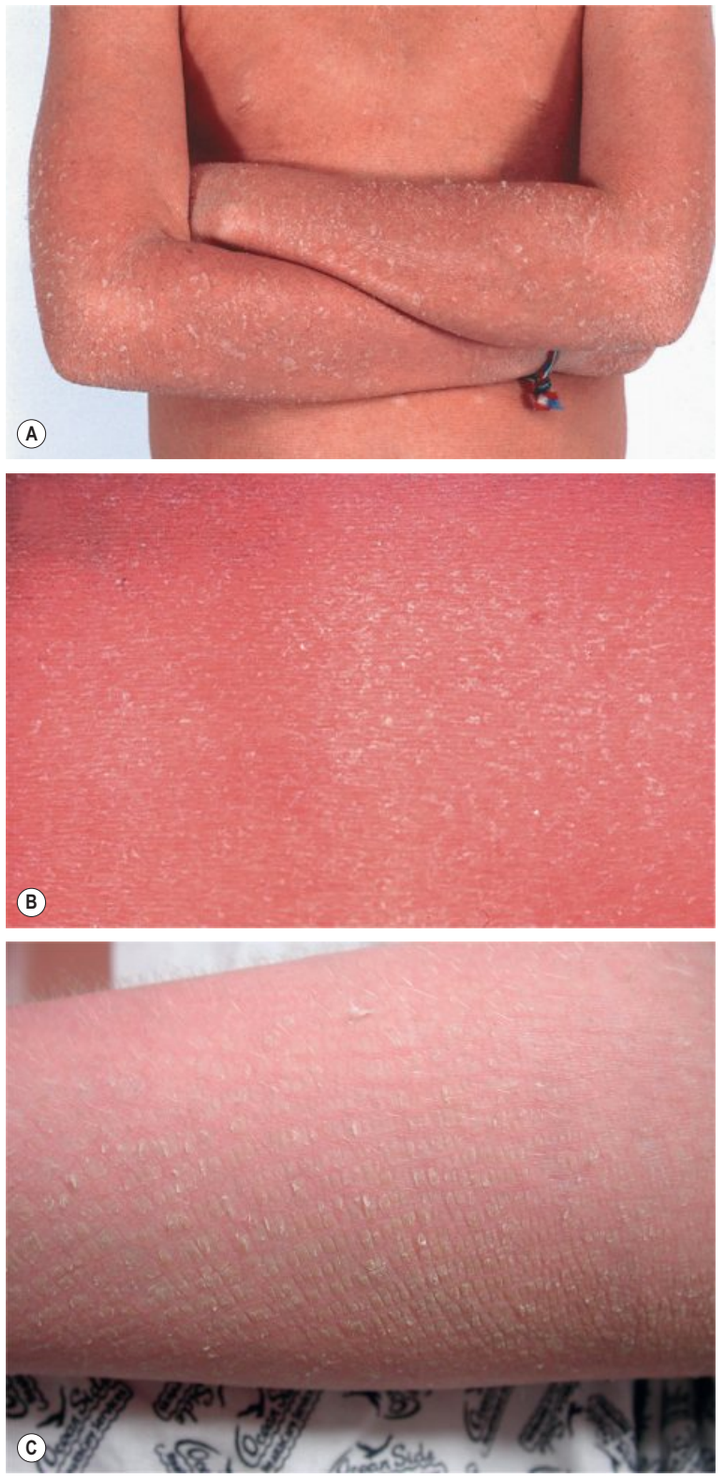

Fig. 57.12 Congenital ichthyosiform erythroderma. A Intense redness and fine, flaky, white scale on the trunk and arms. Close-up of fine white (**B**) and coarser yellowish (**C**) scale in a background of prominent erythema. *A, Courtesy S.J. Bale, PhD and J.J. DiGiovanna, MD.*

are often severely affected with a diffuse, fissuring keratoderma that contrasts with the fine, translucent scales elsewhere on the body; palmoplantar hyperlinearity is observed in some subtypes. Patients with milder disease exhibit less intense erythroderma and scaling, although the latter still tends to be generalized, and they have variable palmoplantar involvement.

Obstruction of sweat ducts and pores often results in hypohidrosis and heat intolerance. Secondary nail dystrophy, onychomycosis, and digital flexion contractures are not uncommon. Severe exfoliative erythroderma can cause metabolic stress in growing children, and failure to meet their high caloric needs can lead to growth retardation[77]. However, most children with CIE have normal growth and development. Adults with CIE may have an increased risk of developing cutaneous squamous cell carcinoma (SCC) and basal cell carcinoma (BCC), so longitudinal skin surveillance should be considered[78].

Pathology

The histopathologic and ultrastructural features of CIE are non-diagnostic. Compared to LI, there is more parakeratosis (focal or extensive) and the acanthosis is typically more pronounced and accompanied by hypergranulosis. Unlike LI, the epidermal cell turnover rate in CIE is markedly increased. Ultrastructural abnormalities in CIE include an increased number of lamellar bodies, an accumulation of lipid droplets in the stratum corneum (often more prominent than in LI), and disorganized intercellular lipid lamellae. While characteristic of CIE, these findings overlap with those seen in LI and other hyperproliferative epidermal disorders[79].

Other diagnostic tests

As in LI, TGM1 deficiency can be detected by immunostaining or assessing the activity of this enzyme in skin biopsy specimens. Genetic testing utilizing multigene panels is the only reliable method for distinguishing the different forms of CIE. Prenatal molecular diagnosis is possible when disease-causing mutations have been identified in family members.

Differential Diagnosis

A collodion membrane at birth requires consideration of LI, self-improving collodion ichthyosis, and other forms of ichthyosis (see Tables 57.3 and 57.4). After transition to the ichthyosis phenotype, pronounced erythroderma and fine white scales in classic CIE differentiate it from classic LI, which is characterized by less erythema, large dark scales, and more frequent ectropion, eclabium, and scarring alopecia. However, many intermediate phenotypes with variable degrees of erythema and size and quality of scale exist. As noted below, harlequin ichthyosis survivors typically develop an extremely severe CIE-like phenotype. A variety of clinical, histologic, and laboratory findings differentiate CIE from other erythrodermic forms of ichthyosis, including syndromic as well as nonsyndromic conditions (see Tables 57.1 and 57.2 and Fig. 57.1).

Treatment

A summary of therapeutic strategies is provided above in the section on LI. Erythrodermic patients have a special need for increased intake of fluids, calories, iron, and protein to balance substantial loss through the skin, which can be 3–10 times higher than normal[77]. Therapy with oral retinoids can reduce scaling, but it is less beneficial in suppressing the erythroderma.

HARLEQUIN ICHTHYOSIS

Synonyms: ■ Harlequin baby ■ Harlequin fetus ■ Ichthyosis congenita gravior

History

This most extreme and distinct form of ARCI was described as early as 1750 by the Reverend Oliver Hart. In 1900, Riecke recognized the histopathologic features of dramatic thickening of the stratum corneum and follicular hyperkeratosis, and he distinguished this disorder from other types of congenital ichthyosis. "Harlequin" refers to the resemblance of the facial features and diamond-shaped scales in affected neonates to the costume of the comic servant character with this name. Initially called a "harlequin fetus" because of the premature delivery and fatal outcome, increasing survival rates due to improved neonatal care and systemic retinoid treatment have resulted in evolution to the terms "harlequin baby" and (currently) "harlequin ichthyosis" (HI).

Epidemiology

This rare disorder has an estimated incidence of 1 in 300 000 births and is inherited in an autosomal recessive manner. HI has been reported in patients with a wide variety of ethnic backgrounds[80].

Clinical Features

Individuals with HI are usually born prematurely (mean gestational age, 35 weeks) and may die within a few days or weeks because of respiratory insufficiency or sepsis[80]. Affected neonates are encased in a hard, armor-like, tremendously thickened stratum corneum that results in severe immobilization and restricts ventilation. Shortly after birth, the hyperkeratotic cast cracks and forms large, yellow, adherent plates separated by broad, deep, intensely red fissures (Fig. 57.13). Increased transcutaneous loss of water and heat results in dehydration, electrolyte imbalances (e.g. hypernatremia), and temperature instability. The latter may impede recognition of skin infections or sepsis, which are promoted by the large fissures.

The tautness of the skin results in marked eversion of the eyelids (ectropion) and lips (eclabium), rudimentary development of ear and nasal cartilage, and sometimes microcephaly, giving the face an extremely distorted appearance. The hands and feet are edematous and swollen, often covered by a mitten-like casing. Although the digits are well developed, autoamputation due to constricting skin bands occasionally occurs. Eyelashes and eyebrows are usually missing, while scalp hair may be present. Eclabium and taut facial skin prohibit effective suckling by the infant.

Over the past two decades, improved postnatal care and oral retinoid therapy have led to prolonged survival in an increasing number of HI patients. More than half of affected individuals now live beyond the neonatal period, with the oldest HI patient to date being >25 years of age[80]. All survivors develop a severe, exfoliative ichthyosiform erythroderma, and half have a painful PPK; dystrophic nails (e.g. small, thickened) and poor hair growth are also common. Complications in these patients include recurrent skin infections, reduced sweating with heat intolerance, ocular problems related to persistent ectropion, chronic constipation, vitamin D deficiency, anemia, arthralgias, arthritis, and joint contractures[80]. Affected children often have delayed growth and development of motor skills, while intelligence is normal[34].

Fig. 57.13 Harlequin ichthyosis. Severe hyperkeratosis with fissuring as well as eclabium and ectropion. *Reproduced from Morillo M, Novo R, Torrelo A, et al. Feto arlequin. Actas Dermosifiliogr 1999;90:185–7.*

Pathology

The histologic hallmark is an extraordinarily thickened and compact orthokeratotic stratum corneum, although parakeratosis is occasionally observed. Hair follicles and sweat ducts have prominent hyperkeratotic plugging. Ultrastructural features include abnormal or missing lamellar bodies in the granular layer, absent extracellular lipid lamellae, and the presence of lipid inclusions or remnant organelles in the stratum corneum[44]. However, similar findings may be found in other forms of ARCI. Hair follicles show concentric accumulation of keratotic material around hair shafts, a highly characteristic feature that was historically used to establish the diagnosis based on prenatal skin biopsy specimens obtained in the second trimester[81].

Other diagnostic tests

Molecular diagnosis and prenatal testing are available for HI families. Ultrasonography can establish the diagnosis in affected fetuses during the last trimester of pregnancy based on facial features, acral edema, intrauterine growth retardation, polyhydramnios, and the "snowflake sign" due to floating scales in the amniotic fluid[80,82].

Differential Diagnosis

The clinical presentation of HI at birth is striking and highly characteristic. Hyperkeratosis and associated abnormalities, such as ectropion and eclabium, are usually much milder in collodion babies. However, the clinical findings in children and adults with HI overlap with severe forms of CIE. The facial features and taut, scaling skin in Neu–Laxova syndrome may be reminiscent of HI, but this rare autosomal recessive disorder also features microcephaly, lissencephaly (few and shallow convolutions of the brain), syndactyly, and other congenital malformations.

Treatment

HI remains a life-threatening and often fatal disorder, and survivors require long-term multidisciplinary management[80,82]. During the neonatal period, intensive care is needed to provide sufficient nutrition; monitor and manage body temperature and pain; correct fluid and electrolyte imbalances; and prevent and treat respiratory dysfunction, pneumonia, or sepsis. Severe ectropion necessitates ophthalmologic care. Infants should be kept in humidified incubators and treated with wet wraps and light emollients. Early administration of systemic retinoids, in particular acitretin, usually with an initial dose of 0.5–1 mg/kg once daily, has been shown to result in shedding of the large, keratotic plates within weeks as well as improvement of the ectropion and eclabium[80,82]. Subsequent titration to the lowest effective dose is recommended. It is important to discuss the overall prognosis, therapeutic options, and potential medication side effects with each family before beginning treatment.

SYNDROMIC ICHTHYOSES

NETHERTON SYNDROME

Synonyms: ■ Comèl–Netherton syndrome ■ Ichthyosis linearis circumflexa ■ Trichorrhexis invaginata

History

Comèl, an Italian dermatologist, first described the clinical features of ichthyosis linearis circumflexa in 1949. Netherton, an American dermatologist, subsequently discovered a hair shaft abnormality that he termed "bamboo hair" in a child with a CIE phenotype. Wilkinson et al.[83] delineated the triad of congenital ichthyosis, trichorrhexis invaginata, and atopy as "Netherton syndrome" in 1964. It was later recognized that this disorder encompasses different cutaneous presentations including ichthyosiform erythroderma, localized ichthyosis linearis circumflexa, and continuous skin peeling[84].

Epidemiology

Netherton syndrome (NTS) is an autosomal recessive disorder that occurs worldwide, with a higher prevalence in inbred populations. Considering the phenotypic variability and clinical overlap with atopic dermatitis as well as other forms of ichthyosis, it has been estimated that the incidence of NTS might be as high as 1 in 50 000[84]. In one series, 18% of patients who presented with erythroderma during the neonatal period had NTS[85].

Pathogenesis

NTS is caused by biallelic mutations in the serine protease inhibitor Kazal type 5 gene (*SPINK5*)[86,87]. Approximately 100 *SPINK5* mutations have been identified to date, with functional null alleles in ~65% of cases and missense mutations that compromise enzyme function in the remainder.

SPINK5 encodes the multi-domain serine protease inhibitor LEKTI that is expressed in the lamellar granules of epithelia and lymphoid tissues. A lack of functional LEKTI leads to uncontrolled activity of serine proteases, and NTS patients have an up to five-fold increase of trypsin-like proteolytic activity in their stratum corneum[88]. This disturbs the regulation of lipid-processing enzymes, which are critical to proper formation of the lamellar lipid bilayer system in the stratum corneum. Hastened degradation of desmoglein 1 results in disintegration and shedding of horny cells, ultimately producing superficial clefts within the stratum corneum and severely disrupted skin barrier function[89]. In addition, LEKTI deficiency leads to a loss of crucial anti-inflammatory and antimicrobial mechanisms in the skin.

Histochemical analysis of hair shafts in NTS demonstrates a reduced number of disulfide bonds, which is suggestive of diminished cross-linkage of hair keratin structures and a weaker coherence of cortical cells. Such focal softening of the hair shaft may allow intussusception of the distal shaft into the dilated proximal cup.

Clinical Features

NTS presents in most (but not all) patients at or soon after birth with CIE-like generalized erythroderma and scaling or with continuous peeling of the skin (Fig. 57.14A). A collodion membrane is not a feature of NTS. Approximately 20% of neonates develop potentially fatal complications such as hypernatremic dehydration, electrolyte imbalances, perturbed thermoregulation, failure to thrive, pneumonia, and sepsis. In patients with severe disease, generalized ichthyosis and erythroderma persist throughout life (Fig. 57.14B–D). However, in the majority of patients, the ichthyosis gradually evolves into serpiginous or circinate scaling and erythematous plaques, which are bordered by a peculiar double-edged scale and descriptively named "ichthyosis linearis circumflexa" (ILC; Fig. 57.15). The plaques are usually distributed on the trunk and extremities and change over time in size, shape, and location, reflecting the undulating course of NTS. The lesions are pruritic, and many patients develop eczematous plaques and/or lichenification in flexural sites, especially the wrists and antecubital and popliteal fossae. Scalp involvement with thick scale is common.

Hair shaft abnormalities usually develop during infancy and early childhood and improve with age, but they vary tremendously in the age of onset, extent, severity, and type. While in some patients the scalp hair grows slowly and is sparse, thin, and fragile, it has a normal appearance in others. Light microscopic examination of clipped hair from the scalp and (of particularly high yield) the eyebrows often reveals trichorrhexis invaginata (bamboo hair) with a ball-and-socket appearance (Fig. 57.16) or nodular thickening of the distal end of broken hair shafts ("golf tee", "matchstick"). Multiple additional abnormalities may be observed, including pili torti, trichorrhexis nodosa, and "helical" hair. Eyelashes and secondary sexual hair can also be affected.

The third characteristic feature of NTS is immune dysregulation that involves memory B, T, and NK cells, resulting in atopic manifestations as well as susceptibility to infections. There is increased secretion of both interferon-γ and tumor necrosis factor by T and NK cells, and the proportion of activated B cells correlates with frequency of bacterial skin infections. Serum levels of IgE are usually markedly elevated, ranging from 100 to >10 000 IU/ml. Eosinophilia and allergic

reactions to foods and other antigens are common, with clinical manifestations ranging from urticaria and angioedema to anaphylactic shock. Increased IL-17 signaling has been described in NTS and other ichthyoses (e.g. EI, LI, CIE), and clinical studies of IL-17 or IL-12/23 blockade are underway[90].

Patients with NTS often develop recurrent respiratory tract and staphylococcal skin infections, and they are at increased risk of sepsis[91]. Human papilloma virus (HPV) infections are frequent and can result from epidermodysplasia verruciformis-associated HPV types. HPV infections may increase the incidence of SCC of the anogenital area or other cutaneous sites in these patients. Development of multiple SCCs and BCCs in the third decade of life has been described[92].

During infancy and early childhood, patients with generalized skin involvement often continue to experience failure to thrive, which may be related to an enteropathy with villus atrophy as well as the increased caloric needs associated with erythroderma; this often results in short stature[93]. Intermittent aminoaciduria can occur, and a few patients with substantial developmental delay have been reported[94].

Pathology

On light microscopic examination, the epidermis shows pronounced parakeratotic hyperkeratosis with a diminished or absent granular layer, acanthosis, and papillomatosis. There are often dense, almost band-like, lymphohistiocytic perivascular infiltrates in the papillary dermis. Subcorneal clefting, spongiosis, exocytosis, and Munro microabscesses can occur. Trichorrhexis invaginata, in which the distal hair shaft is telescoped into the proximal segment, is a highly characteristic light microscopic finding in clipped hairs; other hair shaft abnormalities may also be evident (see above). A band-like pattern in hairs with polarized microscopy has also been described[95]. Trichoscopy of eyelashes and eyebrow hair may also reveal a "matchstick" or "golf tee" appearance.

Ultrastructural abnormalities in the epidermal lipid system that are not present in other erythrodermic disorders have historically assisted in differentiating NTS from CIE and erythrodermic psoriasis. Premature secretion of lamellar body contents in the upper epidermis as well as the presence of intercellular electron-dense accumulations and abnormal splitting in the superficial stratum corneum are specific for NTS and represent indicators of accelerated desquamation[89,96]. Other variable ultrastructural abnormalities include round cytoplasmic inclusion bodies in the upper cell layers, a decreased tonofilament–desmosome system, and a lack of lamellar bodies.

Other diagnostic tests

Molecular testing of *SPINK5* can facilitate diagnosis of NTS, and prenatal diagnosis may be performed in families with known *SPINK5* mutations[87]. In addition, immunostaining of skin biopsy specimens with anti-LEKTI antibodies can be used to determine absence or aberrant distribution of LEKTI protein in the epidermis[97].

Differential Diagnosis

During infancy, NTS often presents a diagnostic challenge due to its clinical overlap with CIE, erythrodermic psoriasis, and other primary immunodeficiencies. Although the presence of trichorrhexis invaginata and other hair shaft abnormalities can distinguish NTS from these conditions, characteristic hair shaft abnormalities may not be present at birth or in early infancy, and their detection requires repeated analysis of many hairs from different locations (e.g. scalp, eyebrows). Elevated serum IgE levels can also help to differentiate NTS from CIE and psoriasis.

Autosomal dominant hyper-IgE syndrome (AD-HIES) also features elevated serum IgE levels in association with atopic-like dermatitis and recurrent skin and respiratory tract infections. However, AD-HIES presents with a neonatal papulopustular eruption rather than erythroderma, and eventually characteristic facial, dental, and skeletal anomalies that are not seen in NTS develop. Other primary immunodeficiencies characterized by erythematous, scaly skin and elevated IgE levels include Wiskott–Aldrich, Omenn, and IPEX (*i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked) syndromes (see Ch. 60). Infants with failure to thrive and generalized eczematous or scaling skin require a comprehensive immunologic evaluation.

In acrodermatitis enteropathica, erythematous, sometimes figurate plaques with scale-crust are usually restricted to periorificial areas and the distal extremities (see Ch. 51). If zinc deficiency cannot be excluded with certainty, an empirical trial of zinc treatment is indicated. The migratory, serpiginous plaques of ichthyosis linearis circumflexa can also resemble those seen in erythrokeratodermia variabilis. Prominent borders with a double-edged scale and associated hair shaft abnormalities are specific for NTS, while transient, variable erythematous patches are characteristic of erythrokeratodermia variabilis.

Peeling skin syndromes (PSSs) are clinically and genetically heterogeneous disorders characterized by perpetual peeling and desquamation of the skin with variable associated erythema (see Table 57.8). They share many features with NTS, including pruritus, congenital erythroderma in the generalized inflammatory subtype of PSS, and histologic and ultrastructural abnormalities. Although mutations in the corneodesmosin gene (*CDSN*) cause generalized inflammatory PSS[98], *SPINK5* mutations have been identified in some patients with erythroderma and generalized skin peeling[94].

Treatment

Treatment is symptomatic and should be adjusted to the patient's specific needs. Neonates with exfoliative erythroderma and severe impairment of skin barrier function often require management in an intensive care nursery. Patients who develop failure to thrive and enteropathy need nutritional support to ensure sufficient intake of calories and protein.

Topical emollients, keratolytics, retinoids, calcipotriene, and corticosteroids alone or in combination are variably effective. Although the skin lesions of NTS may respond to topical tacrolimus, dramatically increased percutaneous absorption of this medication has been described in NTS patients, due to their severe skin barrier dysfunction[99]. Use of topical tacrolimus therefore requires monitoring of plasma drug levels. Topical pimecrolimus has also been successfully used, with considerably less systemic absorption[100]. Topical or systemic antimicrobial agents are often required to treat bacterial and fungal skin infections, but continuous preventive antibiotic therapy (oral or topical) should be avoided because of the risk of developing antibiotic resistance. In NTS patients receiving intravenous immunoglobulin (IVIg) therapy, fewer infections, reduced skin inflammation, growth, weight gain, and improvement in some immune imbalances have been observed[91].

Sedating oral antihistamines may be helpful in decreasing pruritus. Systemic retinoids have variable efficacy, leading to dramatic improvement in some patients and exacerbation in others. Benefit from treatment with narrowband UVB, psoralen plus UVA (PUVA), UVA1, and balneophototherapy (broadband UVB plus saltwater baths) has been reported. Treatment with anti-IL-17 or IL-12/23 agents (e.g. secukinumab, ixekizumab, ustekinumab) have been reported to decrease skin inflammation, reduce flares of ILC, and improve pruritus in patients with NTS[101,102], although significant benefit was not observed in a small clinical trial that included patients with NTS (see above)[75]. Additional treatment approaches that are under investigation include TNF and IL-4/13 inhibitors, topical protein replacement, and kallikrein-related peptidase inhibitors. Exploration of gene therapy strategies utilizing *ex vivo* gene transfer and *in vivo* viral vectors is also in progress.

SJÖGREN–LARSSON SYNDROME

History

In 1957, Sjögren and Larsson[103] defined the clinical triad of congenital ichthyosis, gradually developing di- or tetraplegia, and intellectual disability as a distinct disorder in 28 Swedish patients. In 1988, Rizzo et al.[104] discovered an underlying deficiency in the oxidation of long-chain fatty acids due to malfunction of the fatty alcohol dehydrogenase : fatty aldehyde dehydrogenase enzyme complex. Subsequently, De Laurenzi et al.[105] identified the underlying defect in the fatty aldehyde dehydrogenase gene (*ALDH3A2/FALDH*).

Epidemiology

Sjögren–Larsson syndrome (SLS) is an autosomal recessive neurocutaneous disorder. It occurs worldwide with an estimated prevalence of ~1 in 250 000. It is most common in northern Sweden, where the carrier frequency is estimated to be 1.3%[103].

Pathogenesis

SLS is caused by a deficiency of the microsomal fatty aldehyde dehydrogenase enzyme (FALDH) due to mutations in *ALDH3A2*[105]. More than 140 distinct mutations, including whole gene deletions, have been identified to date. Mutation analysis of *ALDH3A2* has an almost 100% sensitivity in patients with a clinical diagnosis of SLS. A few mutations have a high allelic frequency in northern European and Middle Eastern populations due to a founder effect[106].

FALDH catalyzes NAD-dependent oxidation of long-chain aliphatic aldehydes into fatty acids. This pathway is important for the recycling of epidermal ceramides as well as the catabolism of ether glycerolipids and sphingolipids in the brain[107]. The symptoms of SLS result from membrane alterations due to accumulation of fatty alcohol- or fatty aldehyde-modified lipids and proteins. In addition, FALDH catalyzes steps that are downstream of the lipoxygenases (12R-LOX and eLOX)

in the hepoxilin pathway of arachidonic acid metabolism, which is modulated by NIPAL4. FALDH also degrades leukotriene B_4, and the accumulation of leukotrienes may contribute to pruritus in SLS patients.

Clinical Features

SLS presents at birth with varying degrees of erythema, hyperkeratosis, and scaling. Preterm birth is common, while collodion membrane and ectropion are rare. After infancy, the erythema tends to fade, while hyperkeratosis and scaling become more prominent and darker in color. The ichthyosis varies from fine, white scales to larger, plate-like scales to non-scaling, yellowish hyperkeratosis (Fig. 57.17). Predilection sites include the lower abdomen (especially around the umbilicus), the neck (especially the sides and nape), and flexural areas. Approximately 70% of patients develop PPK. Accentuated skin markings and lichenification of flexural areas are common. Almost half of SLS patients experience persistent pruritus, which often leads to excoriations.

An important diagnostic and almost pathognomonic finding in SLS is the presence of perifoveal glistening white dots in the ocular fundus, which represents a form of juvenile macular dystrophy (Fig. 57.18)[108]. These dots can be detected in many, but not all, patients during the first year of life, and they increase in number over time. Involvement of the CNS usually manifests at the end of the first year of life with delayed motor development, an abnormal gait, pyramidal signs, spasticity, and contractures. The lower extremities are usually more severely affected than the arms. The di- or tetraplegia is gradually progressive and accompanied by speech defects and mild to severe intellectual disability. Seizures are present in almost 40% of affected individuals, and MRI of the brain shows white matter disease in most patients. Other variable clinical features of SLS include superficial corneal defects and photophobia, dental and/or osseous dysplasia, and hypertelorism. Despite the multisystem manifestations, most patients have a normal life expectancy.

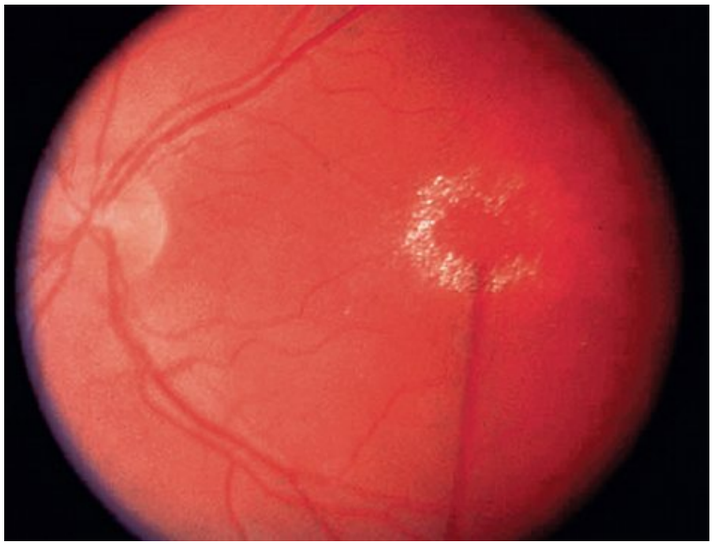

Fig. 57.18 Sjögren–Larsson syndrome. Perifoveal glistening white dots of the ocular fundus. *Courtesy William B. Rizzo, MD.*

Pathology

The histopathologic features are nonspecific and include primarily orthokeratotic hyperkeratosis, papillomatosis, and moderate acanthosis with a well-developed granular layer. Similarly, the ultrastructural abnormalities are not diagnostic. Keratinocytes may show mitochondrial proliferation and a prominent Golgi apparatus, with lamellar membranous inclusions and clefts in corneocytes.

Other diagnostic tests

Cultured skin fibroblasts, keratinocytes, and leukocytes have drastically reduced or absent FALDH activity. This assay also allows detection of unaffected carriers, who exhibit half of the normal levels. Another sensitive marker in SLS is the detection of elevated free fatty alcohols in cultured fibroblasts and plasma. However, these specialized tests are not widely available and the preferred method for confirming the diagnosis of SLS is DNA-based molecular testing. Prenatal molecular diagnosis can also be performed.

Differential Diagnosis

The combination of congenital ichthyosis with spasticity and retinal glistening dots is diagnostic for SLS, although ichthyosis, intellectual disability, and spastic quadriplegia can also result from biallelic *ELOVL4* mutations (see Table 57.2). The skin findings of SLS can overlap with those of steroid sulfatase deficiency, severe ichthyosis vulgaris, and mild forms of CIE or lamellar ichthyosis. In contrast to the latter two disorders, ectropion, eclabium, and alopecia are usually absent in SLS.

Treatment

Management of SLS requires a multidisciplinary approach, including dermatologic, neurologic, ophthalmologic, and orthopedic care as well as developmental support. Topical keratolytics and vitamin D preparations in combination with hydration of the skin are helpful in reducing hyperkeratosis and scaling. Systemic retinoids, especially acitretin, are effective and relatively safe even in children when a minimal effective dose is maintained and patients are monitored for side effects. Administration of a 5-lipoxygenase inhibitor (e.g. zileuton) to block the synthesis of leukotriene B_4 may decrease pruritus in some SLS patients (1 of 10 in a randomized controlled study) but does not improve the ichthyosis or CNS manifestations[109]. Topical application of the reactive aldehyde species inhibitor reproxalap is under investigation. Unfortunately, various forms of a fat-reduced diet have yet to provide consistent and reproducible results.

NEUTRAL LIPID STORAGE DISEASE WITH ICHTHYOSIS

Synonym: ▪ Chanarin–Dorfman syndrome

History

This disorder of lipid metabolism was first recognized as a distinct entity by Dorfman et al.[110] in 1974, and Chanarin et al.[111] coined the name in 1975.

Epidemiology

This is a rare autosomal recessive disorder. Most cases have been observed in consanguineous families from the Middle East and Mediterranean basin.

Pathogenesis

Neutral lipid storage disease with ichthyosis (NLSDI) is an inborn error of lipid metabolism with accumulation of triglycerides in the skin and

other organs. The disorder is caused by deleterious germline mutations in *ABHD5*, which encodes an activator of adipose triglyceride lipase (ATGL); this enzyme catalyzes the first step in triacylglycerol hydrolysis[112]. In patients with NLSDI, decreased ATGL activity results in cytoplasmic accumulation of triglyceride droplets. A profound decrease in the PNPLA1-dependent synthesis of acylceramides has been identified *in vitro* and in mice with Abhd5 deficiency[113].

Clinical Features

The disorder presents at birth with generalized, fine, white scaling of the skin and a variable degree of erythema, thus resembling CIE[111,112,114]. At least one patient with a collodion membrane has been reported and several patients have had ectropion, eclabium, and alopecia[114]. On the lower extremities and scalp, the scales may be grayish, larger, and plate-like with detached borders. Erythrokeratodermia variabilis et progressiva-like presentations have also been reported.

The widespread tissue deposition of neutral lipids results in a broad array of systemic manifestations during childhood. Serum liver enzymes and muscle phosphocreatine kinase are usually elevated, although the myopathy may be mild and detectable only by neurologic examination. Hepatomegaly is common, and liver biopsy often reveals severe fatty degeneration and fibrosis, which may not be reflected in liver function studies.

Cataracts, sensorineural deafness, and developmental delay are frequent features, while growth retardation, ataxia, microcephaly, renal insufficiency, splenomegaly, thyroid dysfunction, and intestinal malabsorption have only been occasionally observed. The prognosis of NLSDI depends primarily on the course of the liver disease and extent of hepatic fibrosis.

Pathology

A highly characteristic feature is the presence of numerous lipid-containing vacuoles in circulating granulocytes (Jordan anomaly) and monocytes, a finding detectable on a fresh peripheral blood smear but not by automated blood-counting methods (Fig. 57.19). Similar findings (but to a lesser extent) may be seen in heterozygous carriers. Lipid stains (e.g. oil red O, Sudan III) or antibodies (e.g. adipophilin) can detect cytoplasmic lipid droplets in fresh frozen or paraffin-embedded skin sections, respectively, particularly in the epithelium of eccrine sweat glands and ducts but also in fibroblasts and basal and sometimes suprabasal keratinocytes. Ultrastructural abnormalities of the epidermis include globular electron-lucent inclusions, which disrupt the normal structure of lamellar bodies in the cells of the granular layer and change the conformation of intercellular lipid lamellae throughout the stratum corneum[115].

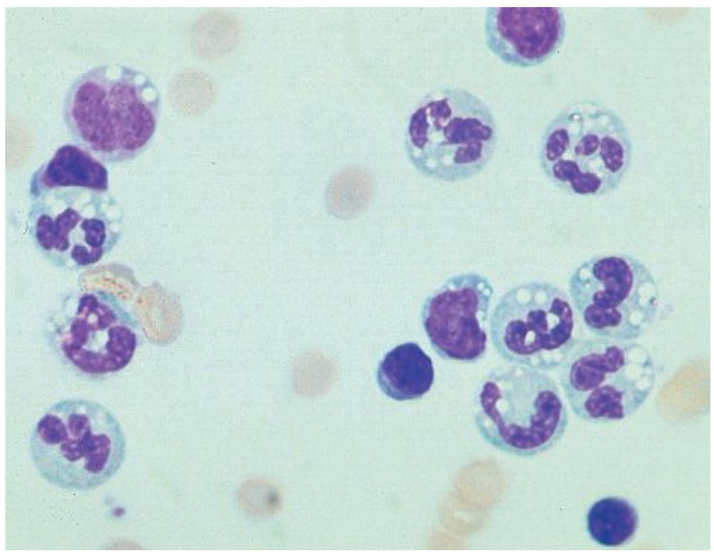

Fig. 57.19 Neutral lipid storage disease. Lipid droplets in circulating granulocytes and monocytes but not lymphocytes or erythrocytes. *Courtesy Mary L. Williams, MD.*

Differential Diagnosis

The associated ichthyosis is clinically similar to CIE, but the microscopic detection of lipid vacuoles in circulating white blood cells points to the diagnosis of NLSDI. In Refsum disease, a peroxisomal disorder characterized by accumulation of phytanic acid, the ichthyosis is not congenital and is more reminiscent of ichthyosis vulgaris (see Table 57.7). Although cytoplasmic lipid accumulations in basal keratinocytes may be found in both disorders, lipid droplets on a peripheral blood smear are not seen in Refsum disease. Neonatal ichthyosis–sclerosing cholangitis (NISCH) syndrome features vacuoles within circulating eosinophils but not neutrophils (see Table 57.7).

Treatment

Therapy is symptomatic. Topical emollients and keratolytics as well as systemic retinoids have been shown to improve the ichthyosis. A diet low in long-chain but enriched in medium-chain fatty acids has been reported to be beneficial in a few patients, but data are too limited to determine if systemic complications can be prevented.

TRICHOTHIODYSTROPHY WITH ICHTHYOSIS

Synonyms: ■ IBIDS: ichthyosis, brittle hair, infertility, developmental delay, short stature ■ Tay syndrome ■ PIBIDS: photosensitivity + IBIDS ■ Sulfur-deficient brittle hair syndrome

History

The first description of this disorder was in 1968, when Pollitt et al.[116] reported siblings with brittle hair, trichorrhexis nodosa, short stature, and intellectual disability. In 1971, Tay[117] described three siblings with similar features and additional skin involvement resembling CIE. Several years later, the term "trichothiodystrophy" was proposed to encompass a heterogeneous group of neuroectodermal disorders that share the finding of sulfur-deficient, short, brittle hair.

Epidemiology

With the exception of a few reported cases with X-linked transmission, the disorder is inherited in an autosomal recessive fashion, affecting both sexes equally.

Pathogenesis

Trichothiodystrophy (TTD) is a heterogeneous group of neuroectodermal disorders. Types of TTD that are associated with clinical and cellular photosensitivity result from severe instability and reduced amounts of general transcription factor IIH (TFIIH; see Ch. 86). This leads to reductions in the basal transcription of multiple genes expressed in the skin and CNS as well as defective transcription-coupled nucleotide excision repair (NER). Photosensitive trichothiodystrophy (PS-TTD) is due primarily to recessive mutations in two genes that encode helicase subunits of TFIIH, *ERCC2*/XPD and, less frequently, *ERCC3*/XPB. These genes are also mutated in patients with xeroderma pigmentosum (XP) and combined Cockayne syndrome–XP. Mutations in *GTF2H5*, which encodes the TFIIH subunit p8/TTD-A, have also been implicated in a small subset of patients with PS-TTD[118]. Non-photosensitive forms of trichothiodystrophy (NPS-TTD) with proficient NER typically *lack* ichthyosis and are caused by genetic defects that result in impaired transcription initiation or altered mRNA processing. Genes implicated in NPS-TTD include: (1) *MPLKIP (TTDN1)* – encodes the M-phase specific PLK1 interacting protein; (2) *GTF2E2* – β-subunit of TFIIE; (3) X-linked *RNF113A* – a ring finger protein; (4) *AARS1* – alanyl-tRNA synthetase; and (5) *TARS1* – threonyl-tRNA synthetase.

The TFIIH deficiency in patients with TTD due to abnormal XPD or XPB results in two major consequences: (1) impaired *transcription-coupled* NER, which leads to photosensitivity; and (2) repression of the basal transcription of genes that are highly expressed in differentiated cells of various tissues. The latter mechanism is thought to underlie

the defective synthesis of high-sulfur matrix proteins in hair and nails, growth retardation, short stature, and neurologic abnormalities seen in TTD, and this is supported by findings in transgenic animals[119]. In addition, the ichthyosis of TTD has been linked to decreased transcription of LXR (liver X receptor)-responsive genes that encode lipid transporters such as ABCA12 (see ARCI)[120].

In contrast, the TFIIH defect in XP profoundly impairs *global genome* NER, which is particularly important for UV-induced DNA damage, thereby leading to cancer formation as well as photosensitivity. Residual NER function of TFIIH in TTD explains the lack of increased carcinogenesis in affected individuals. In Cockayne syndrome, abnormal transcription-coupled NER results in apoptosis of metabolically active cells (e.g. neurons) rather than carcinogenesis.

Clinical Features

TTD is characterized primarily by hair, skin, and neurologic abnormalities. The obligatory finding in all types is short, unruly, fragile hair of the scalp, eyebrows, and eyelashes due to an abnormally low sulfur content, i.e. deficient cysteine and/or methionine. Body, axillary, and pubic hair may also be affected. Nail changes are common and can include thinning, longitudinal ridging, yellow discoloration, splitting, and onychogryphosis.

Patients with TTD are often born prematurely and small for their gestational age, and approximately one-third have a collodion membrane presentation that is not associated with ectropion or eclabium. Erythroderma and generalized fine scaling similar to that seen in CIE may be evident at birth or develop in the neonatal period[121]. The erythema usually resolves during infancy. The size and color of the associated scale is variable, ranging from fine and translucent to large and dark.

Photosensitivity occurs in half of patients; however, as in Cockayne syndrome, there is no propensity to develop cutaneous malignancies[119]. Additional cutaneous findings that have been described in TTD patients include follicular keratoses, folliculitis, erythema, atopic-like dermatitis, cheilitis, hypohidrosis, pruritus, hyperpigmentation of the eyelids, lentigines, hypopigmented macules, telangiectasias, poikiloderma, "hemangiomas", lipoatrophy, pyoderma, and palmar pustules.

Neurologic manifestations include intellectual disability, microcephaly, ataxia, and spastic paralysis; brain MRI may show dysmyelination, cerebellar atrophy, and dilated ventricles. Patients often fail to thrive and have short stature. Other potential associated abnormalities depend upon the type of TTD and include recurrent infections, gonadal abnormalities, progeria-like features (e.g. decreased subcutaneous fat), cataracts, joint contractures, and (very rarely) osteosclerosis.

Pathology

By light microscopy, hair shafts show transverse fractures (trichoschisis) in conjunction with an irregular surface and diameter. Occasionally, a nodal appearance similar to trichorrhexis nodosa or 180° twists as in pili torti may be evident. Polarizing light microscopy is the gold standard for detecting the characteristic light and dark bands, the so-called "tiger-tail" or "zigzag" pattern (see Ch. 69), which has been incorrectly referred to as alternating birefringence[119]. Transmission electron microscopy reveals an abnormal arrangement of microfibers and absence of the exocuticle and cuticular A-layer. If ichthyosis is present, histopathologic changes are typically similar to those found in ichthyosis vulgaris (see above), occasionally with perinuclear vacuoles.

Other diagnostic tests

Molecular genetic testing panels are available. Hair sulfur content can be semi-quantitatively analyzed by scanning electron microscopy. Determination of cysteine content via amino acid analysis of hydrolyzed hair is also possible.

Differential Diagnosis

Although Cockayne syndrome shares several features with the photosensitive form of TTD, the former lacks ichthyosis and tiger-tail hairs. Likewise, the characteristic microscopic hair findings distinguish TTD from other conditions with congenital alopecia or hypotrichosis, including Menkes disease. Polarized hairs can also have a tiger-tail pattern in healthy infants, but this is usually not prominent in all hairs as it is in TTD. Hair shaft abnormalities (including trichorrhexis nodosa and a band-like pattern with polarized microscopy), ichthyosiform erythroderma, and failure to thrive are also seen in NTS; although differentiation from TTD can be difficult in the neonatal period, elevated serum IgE levels are suggestive of NTS. Patients with SLS and ARCI have no hair shaft abnormalities.

Treatment

If photosensitivity is present, sun protection is essential. Treatment of the ichthyosis should be tailored to its severity. Symptomatic relief is best achieved with humectants, keratolytics, and in more severe cases, systemic retinoids. Multidisciplinary care is necessary to address neurologic issues and other manifestations.

ERYTHROKERATODERMAS

Erythrokeratodermas are disorders of cornification characterized by sharply demarcated keratotic plaques that are symmetrically distributed on the extremities, trunk, and/or face. The plaques tend to slowly expand over time and may be accompanied by migratory erythematous patches with circinate borders, as observed in erythrokeratodermia variabilis et progressiva. In addition to the conditions described below and in Tables 57.1 and 57.2 in which erythrokeratoderma (syndromic or nonsyndromic) represents the primary cutaneous finding, patients with other ichthyoses and PPKs occasionally present with erythrokeratoderma-like well-circumscribed keratotic plaques and/or circinate erythematous patches.

ERYTHROKERATODERMIA VARIABILIS ET PROGRESSIVA

Synonyms: ■ Erythrokeratoderma variabilis ■ Erythrokeratodermia figurata variabilis ■ Mendes da Costa disease ■ Progressive symmetric erythrokeratoderma

History

De Buy Wenninger published the first description of this entity in 1907. Mendes da Costa subsequently presented detailed clinical descriptions of patients with keratotic plaques plus migratory erythematous patches, and he coined the name "erythro-et keratodermia variabilis" (EKV)[122]. Darier provided the original description of progressive symmetric erythrokeratoderma (PSEK) in 1911, and Gottron coined the name in 1922. Although PSEK does not share the fleeting erythematous patches that characterize EKV[123,124], these two disorders otherwise have indistinguishable clinical characteristics and have been observed within the same family. Moreover, identical underlying *GJB4* mutations have been reported in patients with EKV and PSEK. Therefore, the unifying term erythrokeratodermia variabilis et progressiva (EKVP) was proposed by van Steensel et al.[125] in 2009.

Epidemiology

EKVP is a rare disorder that is predominantly inherited in an autosomal dominant pattern, with nearly complete penetrance but considerable intra- and interfamilial variability. In a few families, EKVP with autosomal recessive inheritance has been documented. It has been reported in individuals from a variety of ethnic backgrounds.

Pathogenesis

EKVP is caused by heterozygous mutations in *GJB3*, *GJB4*, or occasionally *GJA1* (see Table 57.1)[126–128]. These genes encode the gap junction proteins β3 (connexin 31), β4 (connexin 30.3), and α1 (connexin 43), which belong to a large family of transmembrane proteins that form intercellular channels (see Ch. 58). All reported mutations result in amino acid substitutions of conserved residues, thereby altering

the structure/activity of gap junction channels, impairing cytoplasmic trafficking of the mutant gap junction proteins to the cell membrane, and/or inducing cell death. The end result is impaired epidermal differentiation[125,129].

Clinical Features

The hallmark of classic EKV is the coexistence of transient erythematous patches and more stable keratotic plaques, with one of these features frequently predominating. The erythematous component is most prevalent during childhood, but it later slowly subsides and can be absent in adults. More than 50% of patients present at birth or in the neonatal period, and 90% within the first year of life, with transient erythematous patches that have a random distribution. These lesions are well demarcated with a geographic, circinate, or target-like appearance, and they can coalesce into large figurate patches (Fig. 57.20A). Circinate or gyrate erythematous patches have been associated primarily with mutations in *GJB4*, and this variant might be identical to the previously described "erythrokeratodermia en cocarde". The erythema is of variable intensity and is sometimes surrounded by a blanched halo. Individual lesions usually persist for only minutes to hours, although they may last for days. In about 35% of patients, the erythema is preceded or accompanied by a burning sensation, which may cause discomfort. The remarkable variability in number, size, shape, location, and duration of erythematous patches is reflected in the name of the disease.

Hyperkeratosis evolves simultaneously with or following the appearance of transient erythematous lesions. Sharply demarcated, yellow–brown to pink–brown thickened plaques with geographic borders progressively develop on the limbs, buttocks, and trunk in an almost symmetric distribution, descriptively termed progressive symmetric erythrokeratoderma (PSEK) (Figs. 57.20B–D & 57.21). In approximately half of all patients, the thickening of the skin extends onto the palms and soles, while the flexures, face, and scalp tend to be spared. The surface can be ridged, verrucous, or velvety, and it may have collarette-like peeling or fine, adherent scales. Lesions on the elbows, knees, Achilles tendons, dorsal aspect of the feet, and waistline are particularly common and tend to persist for months to years. In a subset of patients with severe disease, hyperkeratosis is generalized and persistent, with a yellow–brown–gray thickening of the skin and accentuated skin markings. Hypertrichosis may be observed. Some patients develop thick, dark plates of hyperkeratosis with a spiny, hystrix-like appearance, especially on the lower extremities.

After gradual progression throughout infancy and childhood, EKVP tends to stabilize after puberty. Improvement over time and periodic clearing of the skin are not unusual. Skin lesions may be triggered by factors such as emotional stress, sudden temperature changes, mechanical friction, and sun exposure.

Pathology

Histopathologic features are orthokeratotic, basket-weave hyperkeratosis, moderate to severe acanthosis with a prominent granular layer, and papillomatosis. There are dilated, elongated capillaries with minimal perivascular inflammation in the papillary dermis. Severe papillomatosis with suprapapillary thinning may result in a "church spire" configuration of the epidermis. Ultrastructural studies have had variable results, including a reduced number of lamellar bodies in the granular layer.

Other diagnostic tests

Molecular testing is available for the associated genes.

Differential Diagnosis

Not all published cases clinically categorized as PSEK fit into the EKVP clinical spectrum. For example, in a Japanese family with PSEK-like features plus mutilating PPK that included pseudoainhum, a heterozygous frameshift mutation in the loricrin gene was detected[130]. In addition, a homozygous loss-of-function mutation in *KRT83* (also implicated in autosomal dominant monilethrix) was found to underlie PSEK in a Pakistani kindred[131]. The lack of pathogenic variants in either connexin or loricrin genes in six unrelated patients with clinical findings of PSEK also pointed to a role for additional genes[125,126].

Autosomal recessive *periorificial and ptychotropic erythrokeratoderma* (*PERIOPTER*) *syndrome* due to *KDSR* mutations is distinguished by predilection of the hyperkeratotic plaques for periorificial sites and skin folds as well as associated transgredient PPK and thrombocytopenia (see Table 57.2)[45,132]. Nonsyndromic autosomal dominant *TRPM4* (transient receptor potential cation channel subfamily M

member 4)-*related PSEK* also features a periorificial distribution and transgredient PPK[133], and *Olmsted syndrome* presents with periorificial and intertriginous hyperkeratotic plaques plus mutilating PPK (see Ch. 58). Whereas heterozygous mutations in *PERP* (p53 effector related to PMP22), a component of desmosomes, underlie a form of Olmsted syndrome, biallelic *PERP* mutations have been associated with variable cutaneous manifestations including ichthyosis, erythrokeratoderma, PPK, psoriasiform plaques, and recalcitrant dermatophyte infections. In *erythrokeratodermia with spinocerebellar ataxia* due to mutations in *ELOVL4* (elongase-1 for very long-chain fatty acids), an autosomal dominant disorder that was first described in a French-Canadian family, EKVP-like findings during childhood are followed by the development of progressive ataxia due to cerebellar atrophy during adulthood. *MEDNIK syndrome* (mental disability, enteropathy, deafness, peripheral neuropathy, ichthyosis, keratoderma) features erythematous patches and hyperkeratotic plaques similar to EKVP (see Table 57.2). Lastly, generalized erythrokeratoderma, severe PPK, and ectodermal dysplasia as well as cardiac involvement distinguish *erythrokeratoderma–cardiomyopathy syndrome* due to *DSP* (desmoplakin) mutations.

The migratory, serpiginous erythematous plaques of ichthyosis linearis circumflexa in NTS are typically bordered by a double-edged scale, and patients have additional manifestations such as hair shaft abnormalities, eczematous lesions, and pruritus. Patients with erythrokeratolysis hiemalis develop erythematous circinate plaques with centrifugal peeling that primarily affect the palms and soles but occasionally extend to the arms and legs (see Table 57.8). Sharply demarcated hyperkeratotic plaques that wax and wane may also be seen in rare cyclic and annular subtypes of epidermolytic ichthyosis due to *KRT1* and *KRT10* mutations, respectively (see above). Greither syndrome, a heterogeneous condition that may also be due to *KRT1* mutations, features a transgredient PPK as well as erythrokeratoderma-like hyperkeratotic plaques (see Ch. 58). The presence of perifollicular papules, islands of sparing, and a salmon color distinguish pityriasis rubra pilaris and CARD14-associated papulosquamous eruption, while psoriasis has micaceous scale and a characteristic distribution pattern.

Treatment

Therapy is symptomatic and depends on the severity and extent of the hyperkeratosis, which varies over time. Topical management with keratolytic agents (e.g. α-hydroxy acids, salicylic acid), urea, and/or retinoids (e.g. tretinoin, tazarotene) may be sufficient for mild disease. Systemic retinoids such as acitretin and isotretinoin are the treatment of choice for more extensive or severe EKVP. These agents often produce dramatic improvement or complete clearing of hyperkeratosis and significant reduction in the development of erythematous lesions, although the latter cannot be completely suppressed. The minimal maintenance dose for patients with EKVP is usually considerably lower than that required for other disorders of cornification[134]. Nevertheless, the use of retinoids should always be considered carefully, since chronic therapy is necessary to avoid relapse and long-term side effects, especially in children, may ensue. Of note, other forms of PSEK do not tend to respond as well to systemic retinoids. The red patches in EKVP often result in cosmetic concerns, which can be limited by using camouflaging makeup. Avoidance of sudden temperature changes, friction, and irritation may be beneficial.

KERATITIS–ICHTHYOSIS–DEAFNESS SYNDROME

Synonyms: ■ KID syndrome ■ Erythrokeratodermia progressiva Burns Subtype: Hystrix-like ichthyosis with deafness [HID] syndrome ■ Ichthyosis hystrix gravior type Rheydt

History

In 1915, Frederick Burns provided a detailed clinical description delineating all the key features of this syndrome. Subsequently, several case reports emerged in the literature using different names to describe the skin involvement, such as "atypical erythrokeratodermia with deafness", "atypical ichthyosiform erythroderma", and "ichthyosiform dermatosis". In 1981, Skinner summarized the previous reports and coined the acronym "KID" (keratitis–ichthyosis–deafness) syndrome[135]. Although several authors argued that the skin findings represent erythrokeratoderma rather than ichthyosis[84,136], the widely-used acronym prevailed. KID syndrome presents an overlap between disorders of cornification and ectodermal dysplasias. Hystrix-like ichthyosis with deafness (HID) syndrome, which was first described as ichthyosis hystrix gravior type Rheydt, was originally considered to represent a distinct entity but is now classified as a clinical subtype of KID syndrome with more severe skin findings but less severe keratitis[29].

Epidemiology

KID syndrome is a rare disorder, with ~300 published cases. Although it is primarily inherited in an autosomal dominant manner, >90% of reported cases have been sporadic.

Pathogenesis

The vast majority of KID syndrome patients harbor mutations in *GJB2*, which encodes connexin 26 (Cx26), a β-type gap junction protein[137]. In a single patient with features of KID syndrome and congenital atrichia, a causative mutation was identified in *GJB6* (encoding connexin 30)[138]. All pathogenic *GJB2* variants identified to date have been heterozygous missense substitutions; D50N is particularly common and is detected in >80% of KID patients[137,139]. This latter mutation can also underlie KID syndrome associated with the follicular occlusion triad and hystrix-like-ichthyosis–deafness (HID) syndrome[29,139a]. Other *GJB2* mutations affecting the amino terminus or transmembrane domains of Cx26 have been associated with atypical clinical features such as a lack of PPK or corneal involvement, generalized spiny or verrucous keratoses, mucosal involvement, and the follicular occlusion triad. Two *GJB2* mutations, G45E and A88V, cause a very severe neonatal form of KID syndrome that is typically fatal during infancy or early childhood[140].

In vivo and *in vitro* functional studies have shown that *GJB2* mutations increase connexin hemichannel permeability, leading to ATP release, Ca^{2+} overload, and cell death. Mutations altering the Cx26 amino terminus may also allow the formation of constitutively active heteromeric Cx43/Cx26 hemichannels, whereas gap junction channels are not functional[141]. Cx26 hemichannels containing the substitutions N14K, N14Y, A40V, and A88V were shown *in vitro* to abolish the sensitivity of Cx26 to CO_2, providing a possible explanation for breathing abnormalities in patients with fatal KID syndrome[142].

Of note, somatic heterozygous *GJB2* mutations have been identified in porokeratotic eccrine ostial and dermal duct nevi (PEODDN), nevoid spiny hyperkeratosis, and other epidermal nevus variants, which could be considered to represent mosaic forms of KID syndrome. If these mutations involve the gonads, their transmission to the offspring of such individuals can result in KID syndrome[143]. Revertant mosaicism has also been documented in a KID syndrome patient with progressive development of normal-appearing spots within erythrokeratodermic lesions[144].

Clinical Features

There is considerable variability in the type, extent, and severity of cutaneous features in patients with KID syndrome (Table 57.5). The first manifestation is often transient erythroderma at birth or during infancy. Later, most patients develop symmetrically distributed, well-demarcated, hyperkeratotic plaques with an erythematous base and a rough, ridged, or verrucous surface (i.e. erythrokeratoderma); psoriasiform plaques may also occur. The plaques favor the knees, elbows, and face, often with radial furrows around the mouth (Fig. 57.22A,B). The helices, scalp, groin, other skin folds, extremities, and, less often, trunk may be affected. A plaque-like or diffuse PPK with a grainy, reticulated, or stippled surface (reminiscent of Vohwinkel syndrome) is almost always present (Fig. 57.22C,D). Prominent follicular keratoses and cheilitis (especially perlèche) are common. Some patients develop diffuse thickening of the skin with a coarse, grainy appearance, which may also lead to deep facial furrows (see Fig. 57.22A).

Nails may be dystrophic and show leukonychia. Although most patients have normal hair, some affected individuals have lusterless hair or alopecia of the scalp, eyelashes, and eyebrows. Heat intolerance occasionally occurs.

ADDITIONAL MUCOCUTANEOUS MANIFESTATIONS OF KID (KERATITIS–ICHTHYOSIS–DEAFNESS) SYNDROME
Inflammatory
• Follicular occlusion triad (onset usually at puberty): acne conglobata, dissecting cellulitis of the scalp, hidradenitis suppurativa • Folliculitis • Cheilitis with red, "chapped", fissured lips (especially at the angles of the mouth*) • Stomatitis with erythematous patches, adherent white plaques, and erosions*
Infectious
• Recurrent or chronic mucocutaneous bacterial (e.g. *Staphylococcus aureus*), fungal (e.g. *Candida* spp.), and viral infections • Sepsis in the neonatal period (may be fatal)
Neoplastic
• Cutaneous and oral squamous cell carcinoma (10%–20% of patients; median age 25 years) • Epidermoid and pilar cysts • Proliferating pilar tumors, benign or malignant (the latter aggressive/metastasizing)
*May have candidal superinfection.

Table 57.5 Additional mucocutaneous manifestations of KID (keratitis–ichthyosis–deafness) syndrome. The spectrum of hyperkeratotic manifestations is described in the text.

The spectrum of cutaneous lesions in KID syndrome also includes folliculitis, the follicular occlusion triad, cysts, and proliferating pilar tumors (rarely aggressive/metastasizing)[139a]. Another serious complication is the development of SCC of the skin and oral mucosa, which occurs in 10%–20% of patients at a median age of 25 years, but as early as the first decade of life[136]. KID syndrome is also associated with increased susceptibility to mucocutaneous bacterial, viral, and fungal infections, in particular with *Candida albicans*.

All KID patients have congenital sensorineural hearing impairment that (in contrast to the keratitis) is not progressive. Hearing loss is generally severe and bilateral, although some patients have unilateral or moderate hearing impairment. Approximately 95% of patients have ocular involvement, which typically presents at birth, during infancy, or in early childhood with photophobia and blepharitis. Vascularizing keratitis and conjunctivitis develop and worsen with age. Scarring and neovascularization often cause a progressive decline in visual acuity and may eventuate in blindness. Dental abnormalities may include small or absent teeth, delayed eruption, or excessive caries. The Dandy–Walker malformation of the cerebellar vermis and fourth ventricle, short heel cords, other joint contractures, facial dysmorphism, and developmental abnormalities have also been reported.

A rare severe form of KID syndrome with a fatal outcome during infancy or early childhood presents with erythroderma and areas of massive, fissured hyperkeratosis on the scalp, periorificial skin, and extremities[140]. These patients also have a grainy PPK, atrichia, and nail dystrophy. Other features may include facial dysmorphism, congenital absence of the foreskin, edema and dyskeratosis of the laryngeal

Fig. 57.22 KID syndrome. A Diffusely thickened, hyperkeratotic skin with a coarse-grained texture and an erythematous component; note the characteristic radial furrows around the mouth. **B** Bright pink, keratotic periorificial plaques with crusting. mucosa, and hydrocephalus. Complications include apnea and other breathing problems requiring mechanical ventilation, severe failure to thrive, and recalcitrant bacterial and fungal infections leading to enterocolitis and sepsis.

Pathology

Histology is not specific. Acanthosis and papillomatosis of the epidermis with basket-weave hyperkeratosis and follicular plugging are the most frequent features. Vacuolization of the cells in the granular layer has also been described. The corneal epithelium may be dyskeratotic, atrophic, or absent centrally, and Bowman's membrane may be absent. The eccrine glands may be diminished in number and atrophic. In the inner ear, the organ of Corti is immature or atrophic.

Other diagnostic tests

Molecular genetic testing is available. A rapid molecular diagnosis can provide important prognostic information in infants with the severe fatal form of KID syndrome.

Differential Diagnosis

Autosomal recessive keratitis–ichthyosis–deafness syndrome results from biallelic mutations in *AP1B1* (see Table 57.7). It encodes adaptor related protein complex 1 subunit β1, which is involved in intracellular vesicular trafficking. Patients present by early infancy with ichthyosiform erythroderma accompanied by ectropion, pruritus, sensorineural hearing loss, and failure to thrive. Photophobia and PPK develop over time, and additional features distinct from those of classic KID syndrome include chronic diarrhea, hepatomegaly, thrombocytopenia, low plasma levels of copper and ceruloplasmin, and large numbers of basophilic vesicles within the epidermis[145,146]. *Autosomal recessive keratoderma–ichthyosis–deafness (ARKID) syndrome* features diffuse PPK, mild generalized ichthyosis, intellectual disability, microcephaly, short stature, and occasionally hip dislocation, pancreatic insufficiency, or copper overload. Both ARKID and the more severe arthrogryposis–renal dysfunction–cholestasis (ARC) syndrome are caused by biallelic mutations in *VPS33B* (see Table 57.7). This gene encodes vacuolar protein sorting 33 homolog B, which is involved in vesicular trafficking and biogenesis of organelles such as epidermal lamellar bodies[36,147].

EKVP and most other erythrokeratodermas are not associated with impaired hearing or keratitis. However, *MEDNIK syndrome* features EKVP-like skin findings, PPK, and sensorineural hearing loss (see Table 57.7). X-linked *ichthyosis follicularis with atrichia and photophobia (IFAP) syndrome* (*MBTPS2*; Table 57.6) and autosomal dominant *hereditary mucoepithelial dysplasia* (*SREBF1* [sterol regulatory element binding transcription factor 1]) are both characterized by follicular keratoses, psoriasiform plaques, alopecia, keratitis, and susceptibility to mucocutaneous infections, but not hearing impairment; in the latter disorder, the plaques favor the perineal area and fiery red oral mucosal patches are present. *Keratosis follicularis spinulosa decalvans* (allelic to IFAP; see Ch. 38) also features follicular keratoses and keratitis, but it progresses to scarring alopecia and does not manifest with hyperkeratotic plaques, PPK, or hearing impairment. Lastly, ichthyosis follicularis together with punctate PPK and sensorineural hearing loss due to biallelic *GJB2* mutations has been reported[148].

Treatment

Skin treatment includes use of emollients and keratolytics; topical retinoids may be beneficial. Oral retinoid therapy (e.g. acitretin) yields mixed results: the hyperkeratosis may or may not respond, the PPK is recalcitrant, and ocular side effects may aggravate keratitis and neovascularization in some patients. Successful use of oral alitretinoin (not available in the US; see Ch. 126) for patients with recalcitrant disease has also been described[149]. Use of allele-specific small interfering RNA (siRNA) to inhibit expression of mutant *GJB2* is under investigation in a human–murine chimeric skin graft model[150].

Gas-permeable contact lenses can improve vision in KID patients, while corneal transplants may have limited efficacy because of revascularization[136,151]. Hearing aids and cochlear implants have been used successfully. Mucocutaneous infections often require prolonged systemic therapy. Surveillance for the development of SCC and other tumors via periodic examination of the mucous membranes as well as the skin (including the scalp) is required.

X-LINKED DOMINANT ICHTHYOSIFORM DISORDERS

CHILD SYNDROME

Synonyms: ■ Congenital hemidysplasia with ichthyosiform erythroderma (or nevus) and limb defects ■ CHILD nevus

History

The first description of this condition in 1948 was followed by 17 case reports before Happle delineated the key features and proposed the acronym CHILD syndrome in 1980[152].

Epidemiology

This is a rare X-linked dominant disorder that occurs primarily in girls and women, as it is generally lethal in affected male embryos. Very few affected boys have been reported, one of whom had a normal karyotype and a mosaic *NSDHL* mutation[153].

Pathogenesis

CHILD syndrome is a disorder of lipid metabolism that results in disturbed cholesterol biosynthesis. Inactivating mutations in *NSDHL*, which encodes the enzyme 3β-hydroxysteroid-dehydrogenase, were initially identified in five families with right-sided skin and skeletal involvement[154]; such mutations were subsequently described in additional patients with left-sided involvement. The striking hemilateral phenotype is postulated to result from skewed X-inactivation and deficient sonic hedgehog signaling in the cells expressing the X-chromosome with an *NSDHL* mutation, resulting in selection against these cells on one side of the body. This hypothesis reflects the role hedgehog signaling plays in conferring left–right asymmetry during embryogenesis. Cholesterol has critical functions during mammalian development, including hedgehog signaling, and inborn errors in cholesterol biosynthesis cause several other malformation syndromes.

Clinical Features

CHILD syndrome classically presents at birth or in the neonatal period with a striking unilateral distribution of erythema and thickened skin with a waxy surface or yellowish adherent scale (Fig. 57.23A). The erythema most often involves the right side of the body and is sharply demarcated at the anterior and posterior midline of the trunk. The face is typically spared. Occasionally, there is partial spontaneous resolution or periodic exacerbation of the cutaneous inflammation[152]. During infancy, the erythema lessens, while hyperkeratotic plaques or bands with a verrucous surface prevail and often become more pronounced. They may follow the lines of Blaschko or uniformly affect large areas on half of the body, with affinity for the skin folds (ptychotropism). Because of the clinical resemblance to inflammatory linear verrucous epidermal nevus (ILVEN), the terms "CHILD nevus" and "psoriasiform epidermal nevus" have been used. The contralateral side of the body may have mild skin involvement in a mosaic pattern, but symmetric distribution is extremely rare. Ipsilateral linear alopecia and claw-like nail dystrophy or onychorrhexis are common.

Ipsilateral skeletal abnormalities range from hypoplasia of digits or ribs to complete amelia. Congenital or secondary scoliosis may also occur. Stippled epiphyses can be identified on radiologic examination in early infancy but tend to resolve during childhood. The teeth are typically normal but mild hearing loss and cleft palate may be present. Asymmetric organ hypoplasia most commonly affects the brain, kidneys, heart, and lungs on the affected side of the body. Occasionally, there is contralateral involvement.

FEATURES OF SELECTED SYNDROMIC X-LINKED ICHTHYOSIFORM DISORDERS							
Diagnosis	**Gene**	**Mode of inheritance**	**Incidence**	**Onset**	**Primary cutaneous features**	**Associated features**	**Diagnosis (in addition to molecular testing*)**
CHILD syndrome	*NSDHL* (3-beta-hydroxysteroid-dehydrogenase)	XL dominant	Rare	Birth	At birth, unilateral erythema and waxy, yellowish adherent scale; later, verrucous; hyperkeratosis of variable extent, with affinity for skin folds	Ipsilateral skeletal hemidysplasia, organ hypoplasia	Clinical
Conradi–Hünermann–Happle syndrome (chondrodysplasia punctata 2)	*EBP* (emopamil-binding protein)	XL dominant	Rare	Birth	*Females (>95%):* at birth, inflammatory ichthyosiform erythroderma with feathery, adherent scale along lines of Blaschko; later, follicular atrophoderma along lines of Blaschko	Unilateral or sectorial cataracts; chondrodysplasia punctata (during infancy); asymmetric skeletal abnormalities; patchy scarring alopecia	Clinical; histopathologic finding of keratotic follicular plugs with calcification; epiphyseal stippling on X-rays during infancy; accumulation of 8(9)-cholestenol and 8-dehydrocholesterol in plasma, scales, or cultured fibroblasts
Male *EBP* disorder with neurologic defects (MEND) syndrome		XL recessive			*Affected males*: occasional collodion membrane, later ichthyosis with variable erythema	Dandy–Walker malformation, hydrocephalus; cataracts; craniofacial, skeletal, and cardiovascular anomalies; cryptorchidism	
Ichthyosis follicularis, atrichia, and photophobia (IFAP) syndrome†,[170] with or without BRESHECK syndrome	*MBTPS2* (membrane-bound transcription factor peptidase site 2, a zinc metalloprotease with roles in cholesterol homeostasis and the ER stress response)	XL			*Affected males*: congenital atrichia with absence of eyebrows and lashes; follicular keratoses ("nutmeg grater" skin); psoriasiform plaques; occasionally PPK; nail dystrophy; increased susceptibility to mucocutaneous bacterial and fungal infections *"Carrier" females*: linear streaks with follicular keratoses or scaling; patchy hypotrichosis	Vascularizing keratitis and corneal ulcers leading to progressive vision impairment; BRESHECK syndrome multisystem involvement may include cerebral atrophy, brain malformations, ID, seizures; inguinal hernias; Hirschsprung disease, cleft palate; urogenital, renal, and vertebral malformations	Clinical; *histopathology*: hyperkeratosis, absent/atretic hair follicles and sebaceous glands

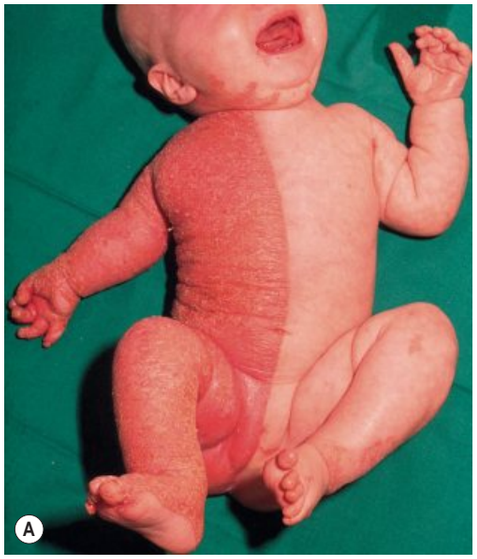
*Genetic testing is available for all ichthyosiform disorders and erythrokeratodermas with a known molecular basis; multigene panels are preferable over single gene testing if the diagnosis is not evident based on clinical and laboratory findings.
†Allelic with *keratosis follicularis spinulosa decalvans*, which features scarring alopecia (see Table 38.2), and Olmsted syndrome, which features mutilating PPK and perioral/perianal keratotic plaques (see Ch. 58). Similar clinical findings, with additional features of plaques favoring the perineal area and fiery red oral mucosal patches, are present in *hereditary mucoepithelial dysplasia*, an autosomal dominant disorder due to mutations in *SREBF1* (sterol regulatory element binding transcription factor 1).

Table 57.6 Features of selected syndromic X-linked ichthyosiform disorders. BRESHECK, brain anomalies, ectodermal dysplasia, skeletal malformations, Hirschsprung disease/hernias, ear/eye anomalies, cleft palate/cryptorchidism, kidney dysplasia/hypoplasia; ER, endoplasmic reticulum; ID, intellectual disability; PPK, palmoplantar keratoderma; XL, X-linked

Pathology

Histopathologic changes include an acanthotic and papillomatous epidermis with marked ortho- and parakeratosis, overlying a mild superficial perivascular infiltrate. Parakeratotic nuclei characteristically retain a round shape[155], and numerous vacuoles are present within the cells of the lower stratum corneum. Multiple layers of granular cells surround the sweat ducts, while the granular zone in the surrounding epidermis may be absent, normal, or thickened[155]. Over time, foamy histiocytes accumulate within the dermal papillae, giving the appearance of a verruciform xanthoma (Fig. 57.23B). Ultrastructural abnormalities include abundant pale-staining mitochondria, cytoplasmic glycogen, lipid retention in the stratum corneum, and altered intracellular and intercellular lamellar granule content.

Other diagnostic tests



Molecular analysis of the *NSDHL* gene is available. Plasma cholesterol is normal despite defective cholesterol biosynthesis.

Differential Diagnosis

Sebaceous nevus syndrome may resemble CHILD syndrome but can be differentiated clinically by its distribution pattern and the lack of erythema and scaling. ILVEN is a less extensive condition that is not associated with visceral abnormalities. Punctate epiphyseal calcifications and asymmetric limb shortening, together with CIE along the lines of Blaschko, may be seen in Conradi–Hünermann–Happle syndrome (see below). However, the skin manifestations are not unilateral and are replaced by atrophoderma by 2 years of age. In addition, skeletal defects are usually less severe than in CHILD syndrome[154].

Treatment

Case reports have noted variable improvement of skin lesions with topical tretinoin or systemic retinoid therapy, but emollients and corticosteroids are ineffective. Substantial benefit has been described with pathogenesis-based therapy targeting the underlying

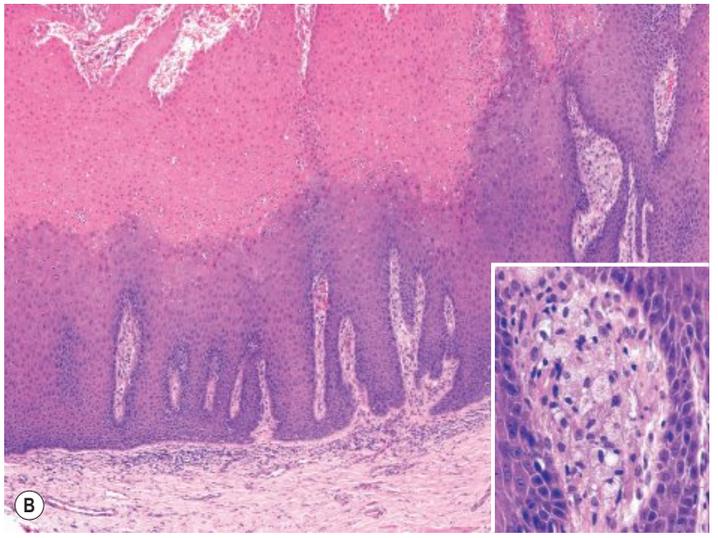


Fig. 57.23 CHILD syndrome. A Note the sharp midline demarcation on the trunk. **B** Histologic features include an acanthotic and papillomatous epidermis with marked parakeratosis and vacuoles within the lower stratum corneum. Note the foamy histiocytes in the dermal papillae (inset). The findings can mimic those of a verruciform xanthoma. *A, Courtesy R. Happle, MD, from Happle R, Mittag H, Kuster W. Dermatology. 1995;191:210–6, with permission; B, Courtesy Luis Requena, MD.*

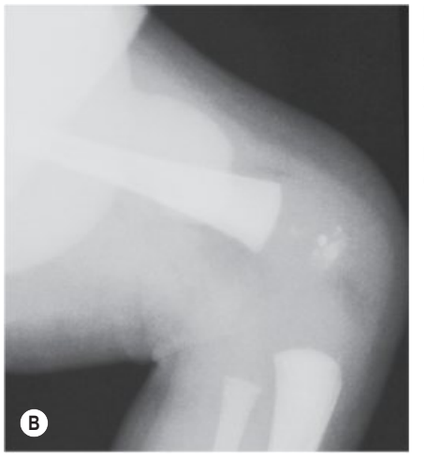

Fig. 57.24 Conradi–Hünermann–Happle syndrome. A Erythroderma and linear streaks and whorls of hyperkeratosis. **B** Epiphyseal stippling at the knee. *A, Courtesy R. Happle, MD; B, Courtesy Jean L. Bolognia, MD.*

cholesterol pathway defect via topical application of an ointment or lotion containing 5% simvastatin or 2% lovastatin or simvastatin plus 2% cholesterol[156,157]. A single report noted improvement with topical ketoconazole, possibly due to inhibition of the sterol 14α-demethylase (CYP51)[158]. Cosmetically and functionally satisfactory results from dermabrasion of affected skin followed by placement of split-thickness skin grafts obtained from the clinically normal contralateral side of the body have also been described[159]. Requirements for multidisciplinary care depend on the extent of associated organ involvement.

CONRADI–HÜNERMANN–HAPPLE SYNDROME

Synonyms: ■ X-linked dominant chondrodysplasia punctata ■ Chondrodysplasia punctata type 2 (CDPX2) ■ Conradi–Hünermann syndrome ■ Happle syndrome

History

In 1971, the dominant Conradi–Hünermann type of chondrodysplasia was differentiated from the autosomal recessive rhizomelic form. Happle subsequently reviewed the literature and established that the Conradi–Hünermann type has an X-linked dominant mode of inheritance[160].

Epidemiology

Conradi–Hünermann–Happle (CHH) syndrome is a rare X-linked dominant disorder that occurs primarily in girls and women. It is lethal in male embryos outside the setting of an XXY karyotype or mosaicism due to a postzygotic mutation in *EBP*. However, an X-linked recessive multiple congenital anomaly syndrome (MEND – male EBP disorder with neurologic defects) in which male patients often die by early childhood and female carriers are unaffected has been described with less severe germline mutations in *EBP*[161].

Pathogenesis

Conradi–Hünermann–Happle syndrome results from a cholesterol biosynthesis defect caused by mutations in *EBP*, which encodes emopamil-binding protein (EBP)[162,163]. The resulting deficiency of EBP, a widely expressed integral membrane protein with Δ8-Δ7-sterol isomerase activity, leads to accumulation of 8-dehydrocholesterol and 8(9)cholestenol[163], which can be detected in plasma, scales, and cultured fibroblasts. However, levels of the end product cholesterol sulfate are normal in plasma and fibroblasts because of X-inactivation[162,163]. Impaired cholesterol synthesis during a critical period of mammalian development is thought to be responsible for the phenotype. Hemizygous missense mutations affecting the first transmembrane domain of EBP, presumably with less deleterious effects on enzyme function, have been identified in boys with MEND syndrome[161].

Clinical Features

CHH is a multisystem disorder that involves primarily the skin, eyes, and skeletal system. Clinical presentations in female patients are variable as they depend on the pattern of X-chromosome inactivation in relevant tissues. At birth, most CHH syndrome patients have generalized erythema with thick, adherent, feathery scale; streaks and whorls of hyperkeratosis following the lines of Blaschko are often observed (Fig. 57.24A). The erythroderma resolves substantially, if not completely, within the first weeks

or months of life. In older children, hyperkeratosis is largely replaced by linear or patchy follicular atrophoderma with dilated follicular openings, ice-pick-like scars, and mild residual scaling. The atrophoderma is most pronounced on the forearms and dorsal hands, whereas the palms and soles are usually spared. Hyper- or hypopigmentation along the lines of Blaschko may coexist separately from atrophodermic areas[160]. Scalp involvement results in patchy scarring alopecia. In addition, hair may be sparse, coarse, or lusterless. Nail changes include onychoschizia and flattening of the nail plate, while teeth are normal.

Skeletal anomalies include asymmetric shortening of the proximal limbs, kyphoscoliosis, frontal bossing, malar hypoplasia, a flat nasal bridge, and a short neck. Widespread premature calcifications manifest as stippling (chondrodysplasia punctata) of the long bone epiphyses, tracheal cartilage, and vertebrae. These can be detected by fetal ultrasound in severe cases or postnatally in radiographs during infancy (Fig. 57.24B), but they are not apparent once bone maturation progresses (after ~9 months of age).

Unilateral, asymmetric, and/or sectorial cataracts, which are present at birth or develop within the first months of life, are the most common ocular abnormality and may be accompanied by microphthalmia or microcornea. Less common features include congenital heart defects, sensorineural hearing loss, CNS malformations, and congenital renal anomalies. Attenuated cases with characteristic skin findings but mild or no associated systemic anomalies have been observed[164]. Psychomotor development and life expectancy are normal.

Boys with the allelic X-linked recessive MEND syndrome have a collodion-like presentation at birth and evolution to a variable ichthyosis phenotype[161]. Additional features include cardiovascular, craniofacial, and skeletal anomalies as well as the Dandy–Walker malformation, hydrocephalus, cataracts, and cryptorchidism.

Pathology

Hyperkeratosis with focal parakeratosis is common and most prominent in follicular ostia, where dystrophic calcification may be observed within keratotic plugs. The granular layer is diminished and keratinocytes contain small vacuoles with needle-like calcium inclusions on electron microscopy.

Other diagnostic tests

Radiographs reveal premature calcifications in the cartilage of the trachea, spine, and long bones during the first year of life (Fig. 57.24B). Accumulation of 8(9)cholestenol and 8-dehydrocholesterol in plasma can be detected by gas chromatography–mass spectrophotometry in order to confirm the diagnosis. Molecular analysis of *EBP* is available.

Differential Diagnosis

Stippled epiphyses during infancy and asymmetric limb shortening are also seen in girls with CHILD syndrome, but the skin involvement usually shows striking lateralization and does not fade completely. However, some overlap in the clinical findings of CHILD and CHH syndromes is not surprising, since both represent disorders of cholesterol biosynthesis (see Table 57.6). Ichthyosis linearis circumflexa in NTS is readily distinguished by its double-edged scale, and the lesions do not follow the lines of Blaschko. Cutaneous manifestations in CIE are more generalized. Hyper- and hypopigmentation in "pigmentary mosaicism", incontinentia pigmenti, and epidermal nevi (including epidermolytic variants) follow the lines of Blaschko but lack follicular atrophoderma.

Treatment

Although the erythema gradually resolves, residual mild scaling may benefit from application of emollients and products containing urea or a keratolytic agent. Orthopedic and ophthalmologic care are essential.

OTHER ICHTHYOSES, PEELING SKIN SYNDROMES, AND RELATED DISORDERS

Additional rare ichthyoses, erythrokeratodermas, and peeling skin syndromes for which the genetic basis is known are presented in Tables 57.7 and 57.8.

FEATURES OF ADDITIONAL RARE SYNDROMIC ICHTHYOSES AND ICHTHYOSIFORM DISORDERS

Disorder	Gene (protein)	Mode of inheritance	Dermatologic features	Associated features	Diagnosis (in addition to molecular testing*)
Arthrogryposis–renal dysfunction–cholestasis (ARC) syndrome[147] (allelic with ARKID syndrome, see below)	*VPS33B* (vacuolar protein sorting 33 homolog B, in ~75%; involved in organelle biogenesis) *VIPAS39* (VPS33B-interacting protein, in ~25%)	AR	In ~half of patients, generalized fine to large scales on trunk and extremities with sparing of skin folds	Severe FTT, often lethal within first year of life; arthrogryposis; renal tubular dysfunction; neonatal jaundice, cholestasis; hemorrhage due to platelet dysfunction; osteopenia; SNHL, CNS abnormalities, congenital heart defects	Clinical; metabolic acidosis and aminoaciduria
Autosomal recessive keratoderma, ichthyosis, deafness (ARKID) syndrome[36,171]	*VPS33B* (vacuolar protein sorting 33 homolog B)	AR	Diffuse PPK, mild generalized ichthyosis without erythema; reminiscent of *GJB2*-related Vohwinkel syndrome	Progressive SNHL; microcephaly, ID; digital contractures, acromicria, short stature, hip dislocation; exocrine pancreatic insufficiency and hepatic copper overload (in single patient)	Clinical
Cerebral dysgenesis, neuropathy, ichthyosis, and keratoderma (CEDNIK) syndrome[172]	*SNAP29* (SNARE protein involved in intracellular vesicle transport)	AR	Normal skin in infancy, later widespread large scale with variable erythema; PPK	Microcephaly, neuropathy, ID; hearing impairment, optic nerve atrophy; cachexia; dysmorphic facial features; usually fatal within first decade of life	MRI showing cortical dysplasia and abnormal corpus callosum; electron microscopy showing clear vesicles within the epidermis
Mental disability, enteropathy, deafness, neuropathy, ichthyosis, keratoderma (MEDNIK) syndrome[173]	*AP1S1* (adaptor-related protein complex 1 σ-1 subunit; role in vesicular trafficking, intracellular transport of copper pumps)	AR	Erythematous patches and hyperkeratotic plaques of variable sizes and shapes; mucosal involvement	Chronic diarrhea and enteropathy; SNHL; peripheral neuropathy; ID and growth delay; abnormal copper metabolism	Clinical; elevated plasma very-long-chain fatty acids

Table 57.7 Features of additional rare syndromic ichthyoses and ichthyosiform disorders.

Continued

FEATURES OF ADDITIONAL RARE SYNDROMIC ICHTHYOSES AND ICHTHYOSIFORM DISORDERS					
Disorder	**Gene (protein)**	**Mode of inheritance**	**Dermatologic features**	**Associated features**	**Diagnosis (in addition to molecular testing*)**
Keratitis–ichthyosis–deafness, autosomal recessive (KIDAR) syndrome (MEDNIK-like syndrome; includes Desmons [Senter] syndrome)[145,146]	*AP1B1* (adaptor-related protein complex 1 β-1 subunit; role in vesicular trafficking)	AR	Ichthyosiform erythroderma from birth or early infancy; thick, adherent yellow scale on the scalp; mild PPK; pruritus	SNHL; ectropion, photophobia, and corneal scaring; FTT during infancy, mild growth and developmental delay; variable enteropathy and hepatomegaly; tooth loss; mild–moderate thrombocytopenia	*Histology*: large number of basophilic vesicles in spinous and granular layers
Congenital disorders of glycosylation (CDG)[174,175]	*DOLK* (dolichol kinase; essential for N- and O-glycosylation; CDG-Im) *MPDU1* (mannose-P-dolichol utilization defect 1; CDG-If) *SRD5A3* (steroid 5-α-reductase 3; CDG-Ig)	AR	Highly variable: dry skin, patchy desquamation (cheeks, trunk, lower legs), transient eczematous lesions, ichthyosiform erythroderma; hyper-/hypotrichosis; cutis laxa (*SRD5A3*)	FTT; severe ID, seizures, hypo-/hypertonia, ataxia, microcephaly; optic atrophy, cataracts, coloboma; vomiting, abdominal pain; congenital heart defects, cardiomyopathy (*DOLK*); abnormal coagulation	Clinical; low serum cholesterol
CHIME syndrome	*PIGL* (phosphatidylinositol glycan anchor biosynthesis class L)	AR	Migratory *i*chthyosiform dermatosis	*C*olobomas, *h*eart defects, *m*ental/intellectual disability, *e*ar anomalies, including conductive hearing loss	Clinical
Neonatal ichthyosis–sclerosing cholangitis (NISCH) syndrome[176]	*CLDN1* (claudin 1, a tight junction protein)	AR	Fine to large scales on trunk and extremities with sparing of flexures; hypotrichosis, coarse hair, scarring alopecia of scalp, eyebrows	Neonatal jaundice and hepatomegaly due to sclerosing cholangitis or congenital paucity of biliary ducts; hypodontia and enamel dysplasia	Clinical; peripheral blood smear to detect eosinophil vacuoles
Ichthyosis–hypotrichosis syndrome[177]; ichthyosis, follicular atrophoderma, and hypotrichosis[178]	*ST14* (matriptase, a transmembrane serine protease)	AR	Large scales on trunk, extensor extremities, and scalp; woolly, sparse, brittle scalp hair; absent eyebrows, eyelashes; variable follicular atrophoderma and hypotrichosis	Photophobia, corneal opacities, pitted or conical teeth	Clinical; scalp hairs with pili torti/pili bifurcati
Multiple sulfatase deficiency (mucosulfatidosis)[179]	*SUMF1* (sulfatase-modifying factor 1, responsible for post-translational modification of all sulfatases, including steroid sulfatase)	AR	Scaling develops within first two years of life; similar to steroid sulfatase deficiency, but often less severe	Findings depend upon residual sulfatase activity; may resemble metachromatic leukodystrophy or various mucopolysaccharidoses (see Ch. 48); coarse facies; broad great toes, chondrodysplasia calcificans, dysostosis multiplex; deafness; hypotonia, hydrocephalus, intellectual disability, neurologic deterioration	Reduced arylsulfatase A/B/C, heparan sulfatase, and iduronate-2 sulfatase activity/levels in fibroblasts (cultured), leukocytes, plasma, or chorionic villi
Rhizomelic chondrodysplasia punctata (autosomal recessive chondrodysplasia punctata type 1)[180]	*PEX7* (peroxisomal type 2 targeting signal receptor; functions in peroxisomal biogenesis)	AR	Ichthyosis and alopecia in ~25% of patients; at birth, erythroderma and thick, sticky vernix with underlying adherent scale; diffuse or patchy scales with feather-like edges in infancy; later, follicular atrophoderma, scarring alopecia of the scalp, sparse or absent eyebrows, eyelashes *Histology*: (during infancy) hyperkeratosis, focal parakeratosis, follicular plugging	Symmetric skeletal anomalies with rhizomelia (short proximal limbs), scoliosis, chondrodysplasia punctata (in infancy); facial dysmorphism (frontal bossing, flat nasal bridge); bilateral congenital cataracts; neurodegeneration usually results in death by 2 years of age; occasional survival with spastic tetraplegia	Stippled epiphyses on X-rays prenatally and during infancy; in plasma/RBCs: low plasmalogen in first month of life, later increased phytanic acid

Table 57.7 Features of additional rare syndromic ichthyoses and ichthyosiform disorders.

FEATURES OF ADDITIONAL RARE SYNDROMIC ICHTHYOSES AND ICHTHYOSIFORM DISORDERS					
Disorder	**Gene (protein)**	**Mode of inheritance**	**Dermatologic features**	**Associated features**	**Diagnosis (in addition to molecular testing*)**
Refsum disease (hereditary sensory motor neuropathy type IV)[181–184]	*PHYH* (phytanoyl-CoA hydroxylase, a peroxisomal enzyme) *PEX7* (peroxisomal biogenesis factor 7)	AR	Childhood onset, ichthyosis vulgaris-like in ~50% of patients; small, white scales on extremities and trunk; larger, adherent scales on legs; hyperlinear or hyperkeratotic palms and soles	Insidious onset of night blindness and neurologic symptoms in adolescence, with undulating but progressive course; mixed motor/sensory peripheral polyneuropathy, cerebellar ataxia; atypical retinitis pigmentosa; hypo-/anosmia; later SNHL, cataracts, renal tubular dysfunction, cardiomyopathy, arrhythmias, and skeletal hyperostosis *Treatment:* drastic reduction of dietary phytanic acid intake (<5 mg daily; found in dairy products, animal fats) can arrest neurologic progression but not reverse retinal changes; less strict diet can be combined with orlistat (intestinal lipase inhibitor)	Elevated plasma phytanic acid level >200 mcmol/L (normal <3); elevated CSF protein levels *Histology*: orthokeratotic hyperkeratosis and lipid-containing vacuoles in basal keratinocytes
Nephrosis with ichthyosis and adrenal insufficiency[185]	*SGPL1* (sphingosine-1-phosphate lyase 1)	AR	Generalized fine scaling; diffuse hyperpigmentation; occasionally calcinosis cutis	Steroid-resistant nephrotic syndrome by early childhood; primary adrenal insufficiency; immunodeficiency; variable neurodegeneration	Clinical

*Genetic testing is available for all types of ichthyosis with a known molecular basis; multigene panels are preferable over single gene testing if the diagnosis is not evident based on clinical and laboratory findings.

Table 57.7 Features of additional rare syndromic ichthyoses and ichthyosiform disorders. Ichthyosis can also be a presentation of *PSAT1*-related serine deficiency disorder. AR, autosomal recessive; CNS, central nervous system; CSF, cerebrospinal fluid; FTT, failure to thrive; ID, intellectual disability; MRI, magnetic resonance imaging; PPK, palmoplantar keratoderma; RBC, red blood cells; SNHL, sensorineural hearing loss.

PEELING SKIN SYNDROMES					
Disorder	**Gene (protein)**	**Mode of inheritance**	**Dermatologic features**	**Associated features**	**Diagnosis (in addition to molecular testing*)**
Generalized inflammatory peeling skin syndrome[98†]	*CDSN* (corneodesmosin, a desmosomal protein)	AR	Erythroderma with fine white scales; widespread, patchy superficial (subcorneal) peeling of the skin; pruritus; fine hair during infancy	Mild FTT and staphylococcal skin infections during infancy; atopic manifestations (e.g. asthma, food allergies); elevated serum IgE	Clinical; *histopathology*: hyperkeratosis, parakeratosis, and subcorneal or intracorneal separation
Acral peeling skin syndrome	*TGM5* (transglutaminase 5) *CSTA* (cystatin A, a protease inhibitor)	AR	Peeling and erosions (on the hands and feet, more superficial with *TGM5*); diffuse fine scaling (*CSTA*)	None	Clinical; *histopathology*: subcorneal or intracorneal separation
Autosomal recessive exfoliative ichthyosis[186]	*CSTA* (cystatin A, a protease inhibitor) *SERPINB8* (serine protease inhibitor B8)	AR	Peeling skin on palms, soles, elbows, and knees; fine white scale on trunk and extremities	None	Clinical; *histopathology*: lack of epidermolysis
Generalized non-inflammatory peeling skin syndrome[187,188]	*CHST8* (carbohydrate sulfotransferase 8) *FLG2* (profilaggrin 2)	AR	Generalized peeling skin, especially on the extremities *FLG2*: blisters or erythroderma at birth; later generalized fine scaling; trauma- and heat-induced skin peeling, most severe acrally; hyperkeratotic plaques on elbows and knees; marked improvement during childhood	None	Clinical; *histopathology* (perilesional; *FLG2*): separation in the lower stratum corneum with parakeratosis; *ultrastructure* (*FLG2*): abnormal keratin bundles, swollen corneocytes with globular inclusions
PLACK syndrome	*CAST* (calpastatin, a protease inhibitor)	AR	Generalized *p*eeling skin, *l*eukonychia, *a*cral punctate keratoses, *c*heilitis, *k*nuckle pads	None	Clinical
Erythrokeratolysis hiemalis (keratolytic winter erythema, Oudtshoorn disease)[189]	*CTSB* (cathepsin B; segmental duplications of upstream intergenic enhancer element)	AD (South African founder mutation)	Episodic or seasonal circinate erythematous plaques with scaling and centrifugal peeling; predominantly on palms/soles, may extend to legs and arms (rarely trunk and face); occasional blisters in center of new plaques; triggered by viral infection or fever; improves with age	None	Clinical; *histopathology*: parakeratosis, necrosis in the stratum spinosum, and basaloid proliferation

*Genetic testing is available for all ichthyosiform disorders and erythrokeratodermas with a known molecular basis; multigene panels are preferable over single gene testing if the diagnosis is not evident based on clinical and laboratory findings.
†Netherton syndrome can also present with a phenotype of generalized peeling skin and erythroderma.

Table 57.8 Peeling skin syndromes. AD, autosomal dominant; AR, autosomal recessive; FTT, failure to thrive; IgE, immunoglobulin E.

Palmoplantar Keratodermas 58

Dieter Metze, Kira Süßmuth and Vinzenz Oji

Key features

- Palmoplantar keratodermas can be inherited or acquired
- The three major patterns of involvement are diffuse, focal, and punctate
- The clinical presentation may be different on the hands and feet, e.g. diffuse on the soles and focal on the palms
- Additional distinguishing features include an erythematous border, transmigration to areas beyond the palmoplantar skin, and digital constrictions (pseudoainhum)
- Patients may also suffer from hyperhidrosis, maceration, blistering, fungal infections, malodor, and pain
- It is important to determine whether other features are present, e.g. nail dystrophy, hypotrichosis, oral lesions, hyperkeratosis of non-volar skin, impaired hearing, ocular findings, cardiomyopathy (in patients with woolly hair)
- Histologic examination sometimes shows findings such as epidermolytic hyperkeratosis that provide diagnostic clues

INTRODUCTION

Palmoplantar keratodermas (PPKs) represent a heterogeneous group of hereditary and acquired disorders of cornification characterized by prominent hyperkeratosis of the skin on the palms and soles. Inherited PPK sometimes represents a component of a syndromic phenotype with extracutaneous manifestations such as cardiomyopathy or deafness. Likewise, acquired PPK can be drug-induced or associated with cancer. Early diagnosis with determination of the specific subtype of PPK and recognition of associated features is therefore important[1–4] (Table 58.1).

Several classification systems for PPKs have been proposed, but none of these satisfactorily incorporates clinical presentation, pathology, and molecular pathogenesis. Traditional nomenclature is non-uniform and includes many eponyms[2]. In addition, PPK may represent a component of other genodermatoses such as ichthyoses, erythrokeratodermas, epidermolysis bullosa, and ectodermal dysplasias (Table 58.2).

A simple working classification divides PPKs into three major types based on the clinical pattern of involvement[3,5]:

- ***diffuse PPK*** – involvement of the entire palmoplantar surface, usually but not always including the central palmar skin and instep (Fig. 58.1).
- ***focal PPK*** – localized areas of hyperkeratosis, with two major patterns: (1) the *areata/nummular type* – oval lesions, located mainly over pressure points; and (2) the *striate type* – linear hyperkeratotic lesions, most commonly extending from the palms to the volar surface of the fingers, overlying flexor tendons (Fig. 58.2; see Fig. 58.15A)
- ***punctate PPK*** – multiple small keratotic papules or pits (usually from removal of a keratotic plug) that are scattered or aggregated on the palms and soles (Fig. 58.3).

Many hereditary forms of PPK do not develop until the first months or years of life. The onset and severity of disease expression depend in part on mechanical stress, e.g. exposure of the feet to friction and pressure. Some patients have diffuse PPK on the soles and focal PPK (e.g. striate) on the palms. In addition, focal involvement may evolve into a diffuse PPK over time, e.g. from infancy to adulthood. Some types of PPK don't even manifest until adulthood, while others have spontaneous improvement and recurrences over time. In addition, substantial variability can often be observed within the same family.

Further clinical classification depends upon whether there are associated cutaneous and extracutaneous features (see Table 58.1). Many PPKs demonstrate *transgrediens*, which refers to extension of the hyperkeratosis onto the dorsal aspects of the fingers, toes, hands, and feet as well as the flexor aspects of the wrists and heels, either diffusely or as callosities on pressure points (e.g. the knuckles). Confluent hyperkeratosis may also extend circumferentially around entire digits. In scarring PPKs, keratotic constriction bands (pseudoainhum) can develop around digits and may lead to autoamputation (Table 58.3). Additional associated findings include hyperhidrosis, maceration, blistering, malodor, pain, and fungal infections.

When evaluating a patient with a PPK, a thorough family history should be obtained and the entire skin surface examined as well as the mucous membranes, nails, and hair. Hearing and the ability to sweat should also be assessed. Exclusion of extracutaneous manifestations may require referral for cardiac, audiologic, ophthalmologic, or dental evaluation.

Fig. 58.1 Diffuse palmoplantar keratoderma. Hyperkeratosis of the entire palmar **(A)** and plantar **(B)** surface with sharp demarcation. *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Alfons Krol, MD, and Dawn Siegel, MD.*

PRIMARY PALMOPLANTAR KERATODERMAS (PPKS)	
Disorder	**Additional features**
Hereditary PPKs	
Diffuse PPK, isolated	
Vörner–Unna–Thost	Epidermolytic
Kimonis	Non-epidermolytic
Bothnian, Nagashima	Transgrediens and white/spongy upon water exposure; non-epidermolytic
"Greither"	Transgrediens & progrediens; variable pathology
Mal de Meleda (including Gamborg Nielsen)	Mutilating, frequent superinfections; non-epidermolytic
Keratolytic winter erythema	Recurrent erythema and peeling; see Table 58.4
Diffuse PPK with associated features	
Hearing impairment	
Vohwinkel syndrome	Mutilating, "honeycomb" PPK; starfish keratoses on knuckles
Bart–Pumphrey syndrome	Knuckle pads, leukonychia
PPK due to connexin 26 defect	"Honeycomb" PPK
Mitochondrial PPK	
*High risk of acral SCC**	
Huriez syndrome	Scleroatrophy
PPK with sex reversal	Female-to-male sex reversal
Hair & nail abnormalities	
Clouston syndrome	Pebbled/grid-like acral papules, thick nails with distal elevation, hypotrichosis
Odonto-onycho-dermal dysplasia (OODD)	Hypodontia, facial telangiectasias/erythema, thin to absent nails, hypotrichosis
Schöpf–Schulz–Passarge syndrome	Hidrocystomas, other adnexal neoplasms, features of OODD
Keratoderma–hypotrichosis–leukonychia totalis	Total leukonychia, hypotrichosis
PPK & exuberant scalp hair	Leukonychia, thick "bushy" scalp hair
*Mutilating**	
Olmsted syndrome	Periorificial/intertriginous keratotic plaques
Papillon–Lefèvre syndrome†	Periodontitis, pyogenic infections, psoriasiform plaques
Loricrin keratoderma	Mild generalized ichthyosis, "honeycomb" PPK
KLICK	Keratosis linearis, ichthyosis congenita, sclerosing keratoderma
Vohwinkel syndrome (see above)	
Mal de Meleda (see above)	
Cardiomyopathy	
Naxos disease‡	Woolly hair, arrhythmias in adolescence
Focal PPK, isolated	
Brünauer–Fuhs–Siemens, Wachters	Striate on palms, nummular on soles; see Table 58.6 for genetic subtypes
Focal PPK with associated features	
Pachyonychia congenita	Painful soles, dystrophic nails, oral leukokeratosis, steatocystomas/other cysts
Focal palmoplantar and gingival keratosis	Painful soles, gingival leukokeratosis; epidermolytic
Howel–Evans syndrome	Esophageal carcinoma
Richner–Hanhart syndrome (oculocutaneous tyrosinemia)	Dendritic keratitis, corneal ulcers, intellectual disability, painful keratosis
Carvajal syndrome‡	Striate on palms; woolly hair, dilated cardiomyopathy; occasionally skin fragility, nail dystrophy, and hypodontia
PPK and woolly hair	Striate on palms; woolly hair, hypotrichosis, leukonychia
Punctate PPK, isolated	
Buschke–Fischer–Brauer (type 1 punctate PPK)	
Spiny keratoderma (type 2 punctate PPK)	
Marginal papular keratoderma: acrokeratoelastoidosis, focal acral hyperkeratosis (type 3 punctate PPK)	
Punctate keratoses of the palmar creases	
Porokeratosis punctata palmaris et plantaris	
Punctate PPK with associated features	
Cole disease	Guttate hypopigmentation, calcinosis cutis
PLACK syndrome	*P*eeling skin, *l*eukonychia, *a*cral punctate keratoses, *c*heilitis, *k*nuckle pads

Table 58.1 Primary palmoplantar keratodermas (PPKs).

PRIMARY PALMOPLANTAR KERATODERMAS (PPKS)	
Disorder	**Additional features**
Acquired PPKs	
Keratoderma climactericum	
Aquagenic PPK	
Pityriasis rubra pilaris	
Associated with hypothyroidism/myxedema	
Associated with cancer	
Associated with lymphedema	
Arsenical keratosis	
Drug-induced keratoderma[¶] (e.g. BRAF inhibitors, tyrosine kinase inhibitors [e.g. regorafenib, sorafenib; see Table 21.16], 5-fluorouracil prodrugs [tegafur, capecitabine] > lithium, verapamil, venlafaxine, glucan)	
Induced by dioxin or halogenated herbicides	
Associated with dermatomyositis: pityriasis rubra pilaris-like (Wong) type, "mechanic's hands" in antisynthetase syndrome	

*Acral SCC can also develop in patients with mutilating PPK.
†*Haim–Munk syndrome* is an allelic disorder that also features arachnodactyly, atrophic nail changes, and acro-osteolysis.
‡The PPK in Naxos disease is occasionally focal/striate, overlapping with Carvajal syndrome.
¶Sticky palms can also be caused by oral retinoids and proton pump inhibitors.

Table 58.1 Primary palmoplantar keratodermas (PPKs). More common disorders are in **bold**. Other genodermatoses that feature PPK are listed in Table 58.2. Of note, the pattern can be different on the hands and feet, e.g. diffuse on the feet and focal on the hands. Progrediens means progressive, referring to the tendency to involve additional sites (e.g. the elbows and knees) over time. Mutilating refers to the development of digital constrictions and possible autoamputation (pseudoainhum; see Table 58.3). SCC, squamous cell carcinoma.

Fig. 58.2 Focal palmoplantar keratoderma. A Striate type with linear hyperkeratosis on the palm overlying flexor tendons. **B** Areata type on the soles. *B, Courtesy Alfons Krol, MD, and Dawn Siegel, MD.*

A skin biopsy for histologic examination may provide additional diagnostic clues (Table 58.4). The molecular defect underlying PPKs may involve epidermal proteases as well as proteins of the keratinocyte cytoskeleton, cornified envelope, desmosome (see Fig. 56.8), or gap junction (Fig. 58.4, Table 58.5); the known underlying genetic mutations are summarized in Table 58.6[5,6]. Genetic analysis is sometimes helpful to establish the specific diagnosis, facilitate identification of affected family members, and enable prenatal diagnosis.

HEREDITARY KERATODERMAS

DIFFUSE PALMOPLANTAR KERATODERMA WITHOUT ASSOCIATED FEATURES (ISOLATED, NON-SYNDROMIC)

Diffuse Epidermolytic Palmoplantar Keratoderma (EPPK)

Synonyms: ■ Unna–Thost disease ■ Vörner disease ■ Vörner–Unna–Thost type PPK ■ Keratosis palmoplantaris diffusa Vörner–Unna–Thost

History

In 1880, Thost described a family with diffuse non-transgrediens PPK. This was followed by Unna's description of a clinically identical, autosomal dominant PPK in two families. Although "Unna–Thost type" has been used to designate non-epidermolytic PPK (NEPPK), in 1992, Küster et al.[7] reviewed the family described by Thost and found the histologic features of epidermolytic hyperkeratosis, which characterize the "Vörner type" of PPK. Subsequently, after keratin mutations were reported in epidermolytic PPK (EPPK), identical mutations were found in the descendants of the family studied by Thost[8]. This confusion underscores the need for careful histologic examination and sometimes multiple biopsy specimens to identify epidermolytic hyperkeratosis.

Epidemiology

EPPK is likely the most common form of diffuse keratoderma, with an estimated incidence of ≥4.4 per 100 000 in Northern Ireland[9].

Pathogenesis

Mutations in *KRT1* and *KRT9* (encoding keratins 1 and 9) underlie diffuse EPPK. The expression of keratin 9 is limited to the suprabasal cell layers of palmar and plantar skin. In patients with diffuse EPPK, the majority of keratin 9 mutations are localized to a very small area within

OTHER GENODERMATOSES THAT FEATURE PALMOPLANTAR KERATODERMA (PPK)
Erythrokeratodermas (see Ch. 57)
Keratitis–ichthyosis–deafness (KID) syndrome*
Erythrokeratodermia variabilis*
Progressive symmetric erythrokeratoderma*
KDSR-related erythrokeratoderma*
Erythrokeratodermia–cardiomyopathy syndrome*
Other ichthyoses (see Ch. 57)
Epidermolytic ichthyosis (due to keratin 1 mutations)*
Ichthyosis hystrix Curth–Macklin*
Nonsyndromic autosomal recessive congenital ichthyoses†
Sjögren–Larsson syndrome*
Refsum syndrome
CEDNIK (*c*erebral *d*ysgenesis, *n*europathy, *i*chthyosis and *k*eratoderma) syndrome*
MEDNIK (*m*ental retardation, *e*nteropathy, *d*eafness, *n*europathy, *i*chthyosis and *k*eratoderma) syndrome*
Autosomal recessive exfoliative ichthyosis (peeling skin syndrome 4, cystatin A deficiency)
Autosomal recessive keratoderma–ichthyosis–deafness syndrome*
Other ectodermal dysplasias (see Chs. 63 and 67)
Ectodermal dysplasia–ectrodactyly–clefting (EEC) syndrome
Cleft lip/palate ectodermal dysplasia
Oculo-dento-digital dysplasia
Naegeli–Franceschetti–Jadassohn syndrome, dermatopathia pigmentosa reticularis
Ectodermal dysplasia-skin fragility syndrome*
Autosomal recessive ectodermal dysplasia due to grainyhead-like 2 (*GRHL2*) mutations*,‡
Epidermolysis bullosa (EB; see Ch. 32)
EB simplex: severe*, with mottled pigmentation > localized
Junctional EB: intermediate, with pyloric atresia
Kindler EB
Erosive skin fragility disorders*, e.g. skin fragility–woolly hair syndrome, ectodermal dysplasia–skin fragility syndrome, plakoglobin deficiency
Other
SAM (severe dermatitis–multiple allergies–metabolic wasting) syndrome
Erythropoietic protoporphyria
Rothmund–Thomson syndrome
Poikiloderma with neutropenia, Clericuzio-type
CARD14-associated papulosquamous eruption*
Dyskeratosis congenita
Darier disease (usually punctate)
Cowden syndrome (punctate)
Linear PPK associated with epidermal nevus*
Porokeratotic adnexal ostial nevus (PAON; encompasses porokeratotic eccrine ostial and dermal duct nevus [PEODDN])*
Cardio-facio-cutaneous syndrome
HOPP (*h*ypotrichosis, acro-*o*steolysis/onychogryphosis, *p*almoplantar keratoderma, and *p*eriodontitis) syndrome*
Cantu syndrome*: hyperkeratosis–hyperpigmentation syndrome
Pigmentation defects, PPK, and cutaneous SCC (see Table 67.11)*
*PPK is a major feature of the disorder.
†Include congenital ichthyosiform erythroderma, lamellar ichthyosis, and harlequin ichthyosis.
‡Features include nail dystrophy/loss, marginal PPK, hypodontia, enamel hypoplasia, oral hyperpigmentation, dysphagia, and deafness.

Table 58.2 Other genodermatoses that feature palmoplantar keratoderma (PPK).

GENODERMATOSES ASSOCIATED WITH DIGITAL CONSTRICTION BANDS (PSEUDOAINHUM)

*Digital constriction bands represent a common feature.

Table 58.3 Genodermatoses associated with digital constriction bands (pseudoainhum). This is referred to as "mutilating" keratoderma. Congenital digital constriction bands can occur in the amniotic band sequence.

this gene that encodes the helix initiation motif in the 1A domain (see Ch. 56). Such mutations are highly disruptive to keratin filament assembly, causing tonofilament clumping and cytolysis that result in blistering as well as hyperkeratosis.

Within palmoplantar skin, keratin 9 is thought to partner with keratin 1. Of note, mutations in *KRT1* and *KRT10* are associated with epidermolytic ichthyosis (EI), in which epidermolytic hyperkeratosis is seen histologically (see Ch. 57). PPK in EI is predictive of a mutation in *KRT1*, which is the only type II keratin expressed in palmoplantar skin. In contrast, EI due to *KRT10* mutations rarely has involvement of palmoplantar skin, likely reflecting compensation by keratin 9, which is also a type I keratin. The majority of mutations in EI patients are in the critical 1A and 2B domains of the keratin molecule[10]. However, when keratin 1 defects underlie diffuse EPPK alone, including the "tonotubular" subtype, the mutations are typically in the beginning of the 1B domain[11]. Although *KRT1* mutations have been reported in some families with the Greither type of EPPK, other Greither variants with NEPPK not associated with *KRT1* mutations have also been described. Of note, *KRT1* mutations have also been identified in patients with focal PPK (see below).

Clinical features

The palmoplantar skin is initially red, followed by the appearance of thick, yellow hyperkeratosis by 3–4 years of age. In adults, there is confluent hyperkeratosis with a smooth, waxy surface and sharply demarcated erythematous border, sparing the dorsal aspects of the palms and soles (Fig. 58.5). Blistering and fissuring are not common but may occur during childhood or during oral retinoid therapy. Knuckle pads and thickened nails are occasionally present[2,12], and digital or palmar constriction has been described[13]. Disabling pain, especially of the palms, can occur in the "tonotubular" EPPK subtype[11]. The *Greither type* (PPK transgrediens and progrediens) presents with limited transgredient lesions, e.g. overlying the Achilles tendon, elbows, and knees.

Pathology

EPPK shows the typical pattern of epidermolytic hyperkeratosis, which is characterized by vacuolated suprabasal keratinocytes with round or ovoid eosinophilic inclusions that represent large tonofilament aggregates at an ultrastructural level[14]. In the "tonotubular" subtype, electron microscopy shows whorls of keratin containing tubular structures[11]. Histologic findings also include coarse keratohyalin granules, acanthosis, and marked orthohyperkeratosis. Intraepidermal blistering and a mild superficial dermal inflammatory infiltrate may result from keratinocyte cytolysis (Fig. 58.6A). The findings of epidermolytic hyperkeratosis are often subtle and patchy, requiring a careful search and often multiple biopsy specimens to enable their identification.

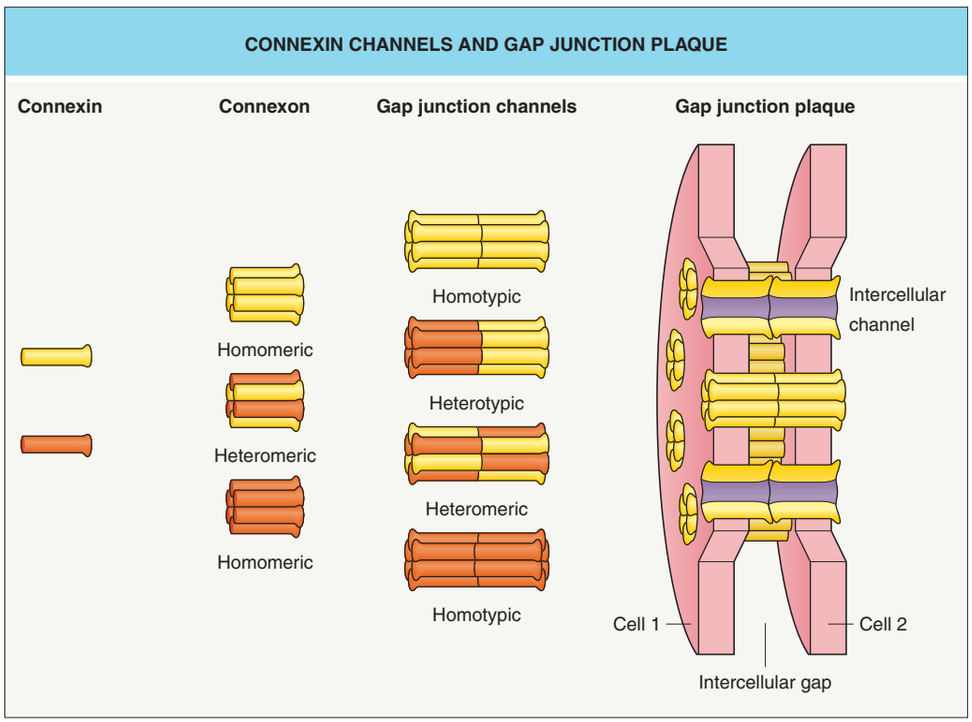

Fig. 58.4 Connexin channels and the gap junction plaque. Gap junctions are specialized transmembrane channels that connect the cytoplasm of neighboring cells, facilitating cell-to-cell communication. The status of the channels (i.e. open or closed) is controlled by mechanisms, including voltage, calcium concentration, pH, and phosphorylation. Each gap junction channel is composed of integral membrane proteins called connexins. The half-life of each connexin is short (i.e. hours), which results in a constant state of assembly and degradation of channels. Different connexins are expressed in a tissue- and differentiation-specific manner as well as in response to stimuli. Six connexin molecules oligomerize to form a connexon hemichannel with a central pore that has a maximum diameter of 2 nm. Connexons may be homomeric if all the participating molecules are of the same connexin species, or heteromeric if they differ. Connexons of adjacent cells dock in the intercellular gap to form a complete gap junction intercellular channel. *Redrawn with permission from Richard G, Smith LE, Bailey RA, et al. HISTOLOGIC PATTERNS IN SELECTED HEREDITARY PALMOPLANTAR KERATODERMAS (PPKS)
Epidermolytic hyperkeratosis*
Diffuse epidermolytic PPK: Vörner–Unna–Thost, "Greither" (epidermolytic variant) Focal palmoplantar and gingival keratosis
Orthohyperkeratosis, acanthosis, and papillomatosis
Diffuse non-epidermolytic PPK: Bothnian, Nagashima, Kimonis, "Greither" (non-epidermolytic variant) Mal de Meleda (including Gamborg Nielsen type) Huriez, Howel–Evans, Papillon–Lefèvre, and Vohwinkel syndromes
Orthohyperkeratosis with focal parakeratosis, acanthosis, and papillomatosis
KLICK (*k*eratosis *l*inearis with *i*chthyosis *c*ongenita and sclerosing *k*eratoderma) Erythrokeratodermia variabilis KID (keratitis–ichthyosis–deafness) syndrome
Orthohyperkeratosis with parakeratosis and hypergranulosis with transitional cells
Loricrin keratoderma
Eccrine syringofibroadenoma
Schöpf–Schulz–Passarge syndrome, odonto-onycho-dermal dysplasia Clouston syndrome (acral papular lesions)
Widening of intercellular spaces and partial dehiscence of keratinocytes
Striate PPK types 1 and 2 Diffuse PPK due to a *DSG1* mutation Carvajal syndrome Erosive skin fragility disorders*, e.g. ectodermal dysplasia-skin fragility and skin fragility–woolly hair syndromes
Ballooning degeneration, eosinophilic granular material and parakeratosis with absence of the granular layer
Keratolytic winter erythema
Epithelia with pale cytoplasm and eosinophilic inclusions
Pachyonychia congenita Richner–Hanhart syndrome
Orthohyperkeratotic, focally parakeratotic column overlying depressed epidermis
Punctate PPK, Buschke–Fischer–Brauer type Punctate keratoses of the palmar creases Focal acral hyperkeratosis
Orthohyperkeratotic, focally parakeratotic column overlying depressed epidermis with fragmentation and loss of elastic fibers
Acrokeratoelastoidosis
Parakeratotic column overlying depressed epidermis devoid of vacuolization and dyskeratosis
Spiny keratoderma
Parakeratotic column overlying depressed epidermis with vacuolization and dyskeratosis
Porokeratosis
*When epidermolytic hyperkeratosis is present, oral retinoid therapy can exacerbate skin fragility and should be avoided.

Table 58.4 Histologic patterns in selected hereditary palmoplantar keratodermas (PPKs).

Fig. 58.5 Diffuse epidermolytic palmoplantar keratoderma (Vörner–Unna–Thost). Diffuse, hyperkeratosis with waxy surface on the palm **(A)** and soles **(B, C)**, with sharp demarcation. Note the red borders **(A, C)**. *C, Courtesy Alfons Krol, MD, and Dawn Siegel, MD.*

Differential diagnosis

EI can be distinguished clinically by the cutaneous involvement beyond the palms and soles. EPPK and NEPPK can be differentiated histologically by the absence of epidermolytic hyperkeratosis in the latter; they are not distinguishable clinically, although the erythematous border of EPPK tends to be more pronounced.

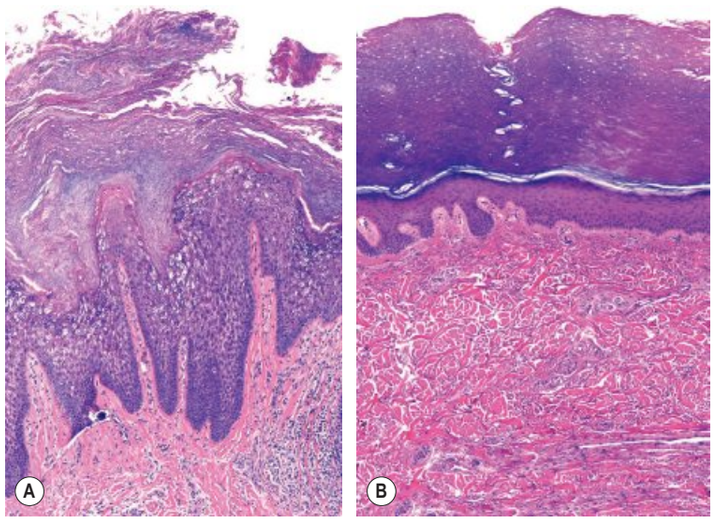

Fig 58.6 Histologic features of palmoplantar keratoderma. A In epidermolytic hyperkeratosis, suprabasal keratinocytes show vacuolated cytoplasm, intracytoplasmic eosinophilic granules, and coarse keratohyalin granules. **B** In non-epidermolytic keratoderma, an extremely thick orthohyperkeratotic horny layer and acanthotic epidermis are seen. *Courtesy Luis Requena, MD.*

Management

Factors to consider when selecting treatment for diffuse PPK include the severity of symptoms, degree of hyperkeratosis, and age of the patient. Mechanical debridement can be performed with a blade, foot file, or pumice stone and followed by application of a keratolytic agent to help avoid fissure formation. Options for keratolytic therapy include 50% propylene glycol in water under plastic occlusion several nights per week, lactic acid- and urea-containing creams and lotions, and salicylic acid 4%–6% in petrolatum; the latter should not be applied to large areas in young children to avoid salicylism from systemic absorption (see Ch. 129). Oral retinoids may improve the hyperkeratosis, but even low doses can lead to excessive peeling and increased fragility of volar skin in EPPK[15]. Topical calcipotriene (calcipotriol) has reportedly been helpful[16]. Genome editing utilizing CRISPR/Cas9 technology was shown to decrease expression of mutant keratin 9 and lead to phenotypic improvement in an EPPK-like transgenic mouse model[17].

Diffuse Non-epidermolytic Palmoplantar Keratoderma (NEPPK)

Diffuse NEPPK represents a heterogeneous group of non-syndromic forms of PPK that do not show epidermolytic hyperkeratosis histologically. This category includes *Bothnia(n)*[18], *Kimonis*[19], and *Nagashima*[20] *types* of PPK as well as *Mal de Meleda*[21]. The *Greither type* (PPK transgrediens

and progrediens) lacks a clear definition and is heterogeneous, with both epidermolytic and non-epidermolytic variants (see EPPK above)[22]. The *Gamborg Nielsen (Norrbotten) type*[23] is currently regarded as a variant of Mal de Meleda[24].

Epidemiology and pathogenesis

An autosomal dominant form of NEPPK that was initially described in families from Bothnia in Northern Sweden and the United Kingdom is due to heterozygous missense mutations in *AQP5*, which encodes aquaporin 5. Aquaporins are transmembrane proteins that allow the osmotic movement of water across the cell membrane. Aquaporin 5 is expressed by keratinocytes in the granular layer, and the gain-of-function mutations that cause Bothnian-type NEPPK lead to increased keratinocyte water uptake rather than transepidermal water loss[18].

The form of NEPPK described by *Kimonis* is caused by a heterozygous mutation in a highly conserved lysine residue in the V1 domain of keratin 1 that does not result in epidermolytic hyperkeratosis[19].

Nagashima-type NEPPK, an autosomal recessive disorder most commonly observed in Asians and also described in Finns, is caused by biallelic nonsense mutations in *SERPINB7*. More recently, biallelic mutations in *SERPINA12* were found to underlie another autosomal recessive form of NEPPK. These genes encode *ser*ine *p*rotease *in*hibitor family B member 7 and family A member 12, respectively, which are thought to regulate proteolytic activity in the skin[25,26].

Mal de Meleda is an autosomal recessive condition that was first described in inhabitants of the island of Mljet (Meleda) off the Dalmatian coast. It is caused by biallelic mutations in *SLURP1* (secreted *l*eukocyte antigen-6/*u*rokinase-type plasminogen activator related *p*rotein *1*), which is expressed in the granular layer of the epidermis[27]. *SLURP1* acts as a ligand of the α7-nicotinic acetylcholine receptor and plays a role in epidermal differentiation. Heterozygous female carriers may have a mild clinical phenotype.

Clinical features

The clinical findings and time course of the different types of NEPPK are overall similar to those of EPPK (see above). The hyperkeratosis is variably thick and hyperhidrosis is common, with frequent dermatophyte infections and pitted keratolysis. The Bothnian, Nagashima, and *SERPINA12*-related types feature transgrediens and a white spongy appearance upon exposure to water[18,28]. Acrokeratoelastoidosis-like papules have been reported in Bothnian-type PPK as has acral melanoma in Japanese patients with Nagashima-type PPK; the latter is also characterized by "soft" hyperkeratosis, prominent erythema, and a nonprogressive course[28].

In Mal de Meleda, progressive transgredient hyperkeratosis begins during early infancy and becomes severe, impairing the mobility of hands and resulting in hyperhidrotic maceration, severe malodor, and fissures (Fig. 58.7). Fungal superinfection is common, and hyperkeratosis of the fingers may lead to sclerodactyly and digital constrictions (pseudoainhum). The elbows, knees, wrists, and ankles as well as the dorsal surfaces of the hands and feet can be involved, and the nails show thickening, koilonychia, and subungual hyperkeratosis. Angular cheilitis and involvement of the lips and perioral skin may be observed[21,29]. Hyperpigmented macules, melanoma, and Bowen disease within the keratotic areas have been reported[30].

Differential diagnosis

In addition to diffuse EPPK, diagnostic considerations may include aquagenic PPK, acral peeling skin syndrome, and keratolytic winter erythema.

Pathology

Histologically, palmoplantar skin shows orthohyperkeratosis, hypergranulosis or normogranulosis, and acanthosis (Fig. 58.6B). A moderate perivascular lymphocytic infiltrate may be present. In Mal de Meleda, papillomatosis is a characteristic finding. PAS staining should be performed to exclude infection by dermatophytes.

Management

Keratolytic therapy may be helpful, such as 5%–10% salicylic acid in white soft paraffin, or 5%–6% salicylic acid in 70% propylene glycol gel; occlusion for a few nights per week enhances efficacy, and mechanical debridement can also be performed. However, salicylic acid should not be applied to large areas in young children. Low-dose acitretin (0.2–0.5 mg/kg daily) may be considered, especially for patients with functional impairment. Fungal superinfection and bacterial overgrowth should be treated. Responses to oral erythromycin and topical tacrolimus have been described in the Bothnian and Nagashima types, respectively[31,32]. Nonsense-suppression (readthrough) therapy with topical gentamicin has been shown to reduce hyperkeratosis in Nagashima-type PPK[33]. Excision of hyperkeratotic skin with split-thickness skin grafting represents an option to relieve functional impairment.

Fig. 58.7 Mal de Meleda. Diffuse, yellow hyperkeratosis characterized by maceration, erythema in areas with reduced hyperkeratosis, progression beyond the palmar area (transgrediens), and a well-defined red border.

Keratolytic Winter Erythema and *CTSB*-Related Palmoplantar Keratoderma

Synonyms: ■ Erythrokeratolysis hiemalis ■ Oudtshoorn disease

Keratolytic winter erythema (KWE) is an autosomal dominant disorder of cornification characterized by recurrent erythema followed by centrifugal peeling on the palms (Fig. 58.8), soles, occasionally the extremities, and rarely elsewhere; episodes typically occur during the winter (see Table 57.8). The term "Oudtshoorn disease" derives from a town in South Africa, where the condition was first described and is common due to a founder effect. KWE is caused by genomic duplications in a noncoding region containing an enhancer element for the cathepsin B gene (*CTSB*), which lead to upregulation of this cysteine protease that functions in keratinocyte homeostasis[34]. In addition, a missense gain-of-function *CTSB* mutation was found to underlie an autosomal dominant form of diffuse transgredient PPK with an erythematous border and associated peeling[35].

Histologically, KWE demonstrates ballooning degeneration in the upper epidermis associated with eosinophilic granular material, absence of the granular layer, parakeratosis, and variable spongiosis[34]. Regenerative basal cell hyperplasia may be evident. In *CTSB*-related PPK, orthohyperkeratosis and areas of intra- and subcorneal separation have been described[35].

DIFFUSE PALMOPLANTAR KERATODERMAS WITH ICHTHYOSIS

Loricrin keratoderma and *k*eratosis *l*inearis–*i*chthyosis *c*ongenita–sclerosing *k*eratoderma (KLICK) have distinctive skin findings beyond the palms and soles. PPK is also a component of other ichthyoses that are discussed in Chapter 57 (see Table 58.2).

Fig. 58.8 Keratolytic winter erythema ("Oudtshoorn disease"). Recurrent erythema followed by centrifugal peeling of the hands and feet. *Courtesy Sian Hartshorne, MD.*

Loricrin Keratoderma

Synonyms: ■ Camisa variant of Vohwinkel syndrome ■ Mutilating keratoderma with ichthyosis ■ Variant Vohwinkel syndrome ■ Vohwinkel syndrome with ichthyosis

This disorder is caused by mutations in the gene encoding loricrin, a glycine-rich cornified envelope protein[36] (see Ch. 56). Mutant loricrin is transported to the nucleus, where it is thought to interfere with regulation of cornification[37,38]. Recombination-induced revertant mosaicism leading to small "islands" of unaffected skin has been described[39].

Clinical and histologic features

Generalized desquamation or features of a collodion baby may be evident at birth, with subsequent evolution to a mild generalized ichthyosis. During childhood, diffuse NEPPK develops, with a "honeycomb" pattern and associated findings that overlap with those of Vohwinkel syndrome, including keratotic digital constrictions (pseudoainhum), knuckle pads, and warty keratoses on extensor surfaces[40]. However, the absence of deafness as well as the presence of ichthyosis distinguish loricrin keratoderma from Vohwinkel syndrome[41]. The differential diagnosis may also include ichthyosis hystrix Curth–Macklin due to mutations in the variable tail region of keratin 1 (see Ch. 57).

Histologic features of loricrin keratoderma include hyperkeratosis with parakeratotic cells, scattered transitional cells, and a broad stratum granulosum with focal perinuclear vacuolization[40,41]. Keratinocyte nuclei demonstrate distinctive immunoreactivity for loricrin[37].

Management

Isotretinoin has been reported to improve hyperkeratosis and prevent digital amputation[42].

Keratosis Linearis–Ichthyosis Congenita–Sclerosing Keratoderma (KLICK)

Synonym: ■ KLICK syndrome

KLICK is an autosomal recessive disorder caused by mutations in *POMP*, which encodes proteasome maturation protein[43]. The resulting proteasome insufficiency disturbs terminal epidermal differentiation and interferes with processing of profilaggrin.

Patients present with mild congenital ichthyosis and diffuse, transgredient PPK with development of digital constriction bands[44]. Other features include flexion deformity of the fingers with associated sclerosis and parallel linear arrays of keratotic papules in the flexural areas of the extremities. Erythrokeratoderma, presenting as well-demarcated erythematous, hyperkeratotic plaques on the extremities and trunk, has also been described[45]. Development of aggressive squamous cell carcinoma (SCC) in affected skin has been reported[46].

Histologic evaluation shows orthohyperkeratosis, focal parakeratosis, acanthosis, and hypergranulosis with characteristic irregular keratohyalin granules. Immunostaining for filaggrin is positive in the cornified layer rather than the granular layer.

DIFFUSE PALMOPLANTAR KERATODERMAS WITH ASSOCIATED FEATURES/SYNDROMIC

Vohwinkel Syndrome

Synonyms: ■ Keratoderma hereditaria mutilans ■ Cicatrizing keratoderma with hearing impairment ■ Keratoderma with sensorineural deafness ■ Vohwinkel syndrome with deafness

Vohwinkel syndrome is autosomal dominantly inherited and caused by mutations in the gap junction β2 gene (*GJB2*) encoding connexin 26[47,48]. This gene is also implicated in Bart–Pumphrey and keratitis–ichthyosis–deafness (KID) syndromes[49] (see Table 58.5 and Ch. 57). Connexin 26 is expressed in the palmoplantar epidermis, sweat glands, and cochlea of the inner ear. As a major gap junction protein, it is crucial for signal transduction involved in epithelial differentiation and sensorineural functions[50,51].

Vohwinkel syndrome is characterized by pitted and stippled, honeycomb-like diffuse PPK and characteristic stellate ("starfish") keratoses on the knuckles (Fig. 58.9A). Digital constriction bands may lead to autoamputation (pseudoainhum) (Fig. 58.9B)[52]. Patients may have non-progressive high-tone sensorineural hearing loss, which may be overlooked during infancy.

Fig. 58.10 Bart–Pumphrey syndrome. Leukonychia and knuckle pads in a patient with sensorineural deafness. *Courtesy Alfons Krol, MD, and Dawn Siegel, MD.*

Bart–Pumphrey syndrome is characterized by keratoses over the interphalangeal and metacarpophalangeal joints ("knuckle pads") and leukonychia (Fig. 58.10), which may improve with age, as well as a honeycomb-like PPK and hearing loss as in Vohwinkel syndrome[53,54].

Histologic findings are nonspecific, with papillomatosis and prominent orthohyperkeratosis.

Treatment with oral retinoids can improve the PPK[55], while the cicatricial bands require surgical intervention which occasionally includes the use of distant flaps[56]. Cochlear implantation may be performed for the hearing loss.

Mitochondrial Palmoplantar Keratoderma With Hearing Impairment

This PPK has a honeycomb appearance and may be either focal or diffuse, often with calluses on the heels and toes. Sensorineural hearing loss typically develops during childhood[57]. The causative mutation in mitochondrial DNA (mtDNA) affects a serine transfer RNA (tRNA)[58].

Huriez Syndrome

Synonyms: ■ Palmoplantar keratoderma with scleroatrophy ■ Sclerotylosis

This rare autosomal dominant disease is caused by mutations in *SMARCAD1* (*S*WI/SNF-related, *m*atrix-associated *a*ctin-dependent *r*egulator of *c*hromatin, subfamily *a*, containing *D*EAD/H box *1*) that lead to haploinsufficiency for a skin-specific isoform with a role in the repair of double-strand DNA breaks[59]. Diffuse scleroatrophy of the hands typically becomes evident during infancy, and there is eventual development of sclerodactyly and absent dermatoglyphs. The mild PPK presents as diffuse parchment-like skin on the palms and, to a lesser degree, the soles; circumscribed hyperkeratosis over pressure points may develop during adulthood. Hypoplastic nail changes (e.g. thinning, longitudinal ridging, fissuring) are also seen[60]. The risk of developing SCC in areas of atrophic skin is increased by ≥100-fold, and early metastasis often occurs[61]. The differential diagnosis may include Kindler epidermolysis bullosa, PPK with sex reversal and SCC, and dyskeratosis congenita.

Histologic features of the keratoderma include orthohyperkeratosis, acanthosis, and hypergranulosis. A characteristic finding is almost complete absence of Langerhans cells in the affected skin.

Palmoplantar Keratoderma With Sex Reversal and Squamous Cell Carcinoma

This rare autosomal recessive syndrome, initially described in several consanguineous Italian kindreds, is due to mutations in the R-spondin 1 gene (*RSPO1*), which encodes a protein that activates β-catenin signaling and has an important role in gonadal development[62,63]. In addition to a diffuse NEPPK that develops during infancy, there is a marked predisposition to the development of acral SCC. Affected individuals with a 46,XX genotype have either: (1) a male phenotype (i.e. female-to-male sex reversal), often associated with hypospadias and hypogonadism; or (2) ambiguous genitalia, sometimes with hermaphroditism (existence of both male and female gonadal structures). Other manifestations include sclerodactyly with variable cutaneous atrophy resembling Huriez syndrome, ichthyosiform scale on the lower legs, nail dystrophy (e.g. hypoplasia, longitudinal ridging, skin growth over the nail plate), periodontitis leading to early loss of teeth, ocular anomalies (e.g. cataracts, colobomas), and microcephaly[62,63].

Fig. 58.11 Clouston syndrome. Note the "pebbled" skin on the dorsal aspect of the toes as well as the dystrophic nail plates. *Courtesy D. Sasseville, MD, and R. Wilkinson, MD.*

Clouston Syndrome

Synonym: ■ Hidrotic ectodermal dysplasia 2

Clouston syndrome is an autosomal dominant disorder caused by missense mutations in the gap junction β6 gene (*GJB6*), which encodes connexin 30[64]. The dysfunctional connexin 30 disturbs cell–cell communication in epithelial cells. Although first reported in a large French-Canadian kindred, Clouston syndrome has also been described in a variety of other ethnic groups.

This condition features diffuse PPK in conjunction with hypotrichosis and nail dystrophy[65], thereby qualifying as an ectodermal dysplasia (see Ch. 63). The PPK initially develops over pressure points and then becomes diffuse, increasing in severity with age. In addition, thickened skin with a "pebbled" appearance is often evident on the dorsal aspects of the digits, knees, and elbows (Fig. 58.11). Small papules in a grid-like array that corresponds to eccrine acrosyringia may be seen, especially on the distal digits where the dermatoglyphs are most prominent.

Progressive hypotrichosis that can eventuate in complete alopecia affects the scalp, eyebrows, eyelashes, and axillary and genital regions; the hair is typically wiry, brittle, and pale. The nails, which may be normal or milky white at birth, gradually become thickened and dystrophic, displaying short nail plates that are easily shed (see Fig. 58.11). The nail abnormalities may mimic those of pachyonychia congenita or other syndromes of "hair–nail hypoplasia"[66].

Histologic evaluation of thickened palms and soles shows orthohyperkeratosis with a normal granular layer. Papular lesions may demonstrate proliferation of eccrine ductal structures within a fibrovascular stroma (eccrine syringofibroadenomas). Ultrastructural examination of the hair shows disorganization of the hair fibers, with a loss of the hair shaft cuticle.

Odonto-onycho-dermal Dysplasia

Synonyms: ■ Tricho-odonto-onycho-dermal dysplasia ■ Schöpf–Schulz–Passarge syndrome

Odonto-onycho-dermal dysplasia encompasses a diverse group of autosomal recessive disorders caused by mutations in *WNT10A*, which encodes a signaling molecule with a critical role in the development of ectodermal appendages[67] (see Fig. 55.6). The clinical features include various combinations of diffuse PPK, facial telangiectasias or reticulate erythema, dental anomalies (e.g. hypodontia, small teeth), nail dystrophy, and hypotrichosis (see Table 63.13)[68]. Patients with Schöpf–Schulz–Passarge syndrome also develop hidrocystomas of the eyelids and other adnexal tumors (e.g. poromas, tumors of the follicular infundibulum) during adulthood[69]. Histologic examination of the PPK demonstrates eccrine syringofibroadenomas.

Olmsted Syndrome

Synonym: ■ Mutilating PPK with periorificial keratotic plaques

Autosomal dominant and the less common autosomal recessive variants of Olmsted syndrome are caused by different gain-of-function mutations in the *t*ransient *r*eceptor *p*otential *v*anilloid *3* gene (*TRPV3*)[70,71]. TRP cation-selective ion channels are involved in epidermal differentiation, hair growth, and the modulation of inflammation, pain, and pruritus. The X-linked recessive variant of Olmsted syndrome, which presents with total alopecia and severe nail dystrophy, results from specific mutations in the *m*embrane-*b*ound *t*ranscription factor *p*eptidase *s*ite *2* gene (*MBTPS2*). The zinc metalloprotease encoded by this gene is essential for cholesterol homeostasis and endoplasmatic reticulum stress response[72]. *MBTPS2* mutations also underlie IFAP syndrome (ichthyosis follicularis with atrichia and photophobia) and KFSD (keratosis follicularis spinulosa decalvans) (see Chs. 38 and 57). In addition, heterozygous mutations in *PERP* (p53 effector related to PMP22), a component of desmosomes, underlie an autosomal dominant form of Olmsted syndrome[73].

Olmsted syndrome features a sharply defined, diffuse PPK with an erythematous border, and progression over time leads to flexion contractures and digital constriction or autoamputation. Erythema and warty hyperkeratosis develop in the perioral and perianal regions as well as in other intertriginous sites[74], resulting in pain and pruritus[75]. Keratoses in linear streaks and with a perifollicular distribution also appear in the flexures of the extremities[76]. Additional findings may include alopecia, blonde curly hair (*PERP*-related form), nail dystrophy, oral involvement (e.g. keratotic plaques, periodontal disease), corneal dysplasia, erythromelalgia, deafness, and joint laxity[76]. Recurrent skin infections are common, and the development of SCC and melanoma within areas of keratoderma has been reported[77,78].

The differential diagnosis may include Mal de Meleda, Vohwinkel syndrome, *KDSR*-related erythrokeratoderma (see Ch. 57), pachyonychia congenita, acrodermatitis enteropathica, chronic mucocutaneous candidiasis, and (early on or in milder cases) psoriasis. Histology of affected skin demonstrates acanthosis with orthohyperkeratosis and parakeratosis, papillomatosis, and a perivascular inflammatory infiltrate; an increased number of mast cells has also been observed[79].

There are reports of dramatic improvement of the PPK in patients with gain-of-function mutations in *TRPV3* following administration of the epidermal growth factor receptor (EGFR) inhibitor erlotinib[80]. This targeted therapy is based upon the observation that EGFR activation can lead to enhanced TRPV3 activity. Systemic treatment with a retinoid or sirolimus and excision of hyperkeratotic areas with skin grafting may also be of benefit[81].

Papillon–Lefèvre and Haim–Munk Syndromes

Papillon–Lefèvre syndrome is an autosomal recessive condition caused by mutations in *CTSC* which encodes cathepsin C, a lysosomal cysteine protease that activates serine proteases found in inflammatory cells as well as the skin[82,83]. This disorder is characterized by a diffuse, transgredient PPK with associated erythema. Pseudoainhum and hyperkeratotic psoriasiform plaques on the elbows and knees often develop. An additional feature is periodontitis with onset during childhood, which leads to premature loss of teeth. There is a predisposition to pyogenic infections of the skin and internal organs, including hepatic abscesses[84]. Haim–Munk syndrome is an allelic condition that also features onychogryphosis, arachnodactyly, and acro-osteolysis[85]. Acral melanoma and SCC have been reported in patients with Papillon–Lefèvre syndrome[86,87].

Oral retinoid therapy lessens the hyperkeratosis and may also decrease the risk of periodontal and infectious complications[88].

Naxos Disease

Synonym: ■ Diffuse NEPPK with woolly hair and arrhythmogenic cardiomyopathy

This autosomal recessive disorder described in families from the Greek island of Naxos is defined by keratoderma, woolly hair, and a life-threatening cardiomyopathy[89,90]. Naxos disease results from a homozygous truncating mutation in the gene encoding plakoglobin (*JUP*), a component of both desmosomes and adherens junctions in the epidermis, hair follicle, and cardiac muscle[91] (see Fig. 29.3). A member of the armadillo protein family, plakoglobin links the inner and outer portions of the desmosomal plaque by binding to the cytoplasmic domain of cadherins (e.g. desmoglein, desmocollin) (see Fig. 56.8). Other biallelic mutations in *JUP* can result in alopecia (rather than woolly hair) together with focal PPK and cardiomyopathy as well as *erosive skin fragility disorders* (see Ch. 32).

Naxos disease classically presents during the first year of life with a diffuse NEPPK, but some patients have focal (striate/areata) involvement. Woolly scalp hair is usually evident at birth. The right ventricular cardiomyopathy has virtually 100% penetrance, typically manifesting with arrhythmias, heart failure, and/or sudden death during adolescence. Therefore, cardiac evaluation is mandatory for any patient with a PPK plus woolly hair (or alopecia) and their potentially affected family members. Treatment with an automatic cardioverter-defibrillator, antiarrhythmic drugs, and heart transplantation improves outcomes[92].

The triad of PPK, woolly hair, and cardiomyopathy can also result from biallelic desmoplakin mutations (Carvajal syndrome; see below), which generally features a striate/areata PPK, and rarely desmocollin 2 mutations. PPK plus woolly hair without cardiac findings has also been reported to result from homozygous mutations in *KANK2* (*K*N motif and *ank*yrin repeat domains *2*), which encodes a sequestering protein for steroid receptor coactivators.

FOCAL PALMOPLANTAR KERATODERMA WITHOUT ASSOCIATED FEATURES (ISOLATED, NON-SYNDROMIC)

Striate/Focal Palmoplantar Keratoderma

Synonyms: ■ Brünauer–Fuhs–Siemens PPK ■ Keratosis palmoplantaris areata et striata ■ Keratosis palmoplantaris varians Wachters ■ Keratosis palmoplantaris nummularis ■ Hereditary painful callosities (historical)

Striate palmoplantar keratoderma (SPPK) is an autosomal semidominant condition caused by mutations in at least three different genes that encode proteins with roles in desmosomal function (see Fig. 56.8)[93]: (1) type 1 – desmoglein 1 (*DSG1*)[94]; (2) type 2 – desmoplakin (*DSP*)[95]; and (3) type 3 – keratin 1 (*KRT1*), V2 tail domain[96]. In addition, heterozygous mutations in *DSG1* sometimes produce SPPK with blistering or diffuse PPK[97]. SAM syndrome – *s*evere dermatitis, multiple *a*llergies, and *m*etabolic wasting – features focal PPK and can result from biallelic *DSG1* mutations; affected individuals' parents with heterozygous *DSG1* mutations have isolated milder focal PPK[98]. SAM syndrome can also be caused by a heterozygous *DSP* mutation. Focal areata NEPPK with absent or very mild associated nail dystrophy is occasionally due to mutations in keratin 6c or 16 (see Pachyonychia congenita below).

The characteristic clinical features of all three types of SPPK are linear keratotic bands on the palms and flexor aspects of the fingers and island-like areas of hyperkeratosis over pressure points on the soles (see Fig. 58.2). Lesions usually develop in adolescence or early adulthood and are exacerbated by mechanical stress (e.g. from manual labor). Larger plantar keratoses are often painful.

In addition to orthohyperkeratosis, widening of the intercellular spaces and partial dehiscence of the suprabasal keratinocytes represent characteristic findings shared by SPPK types 1 and 2, diffuse PPK due

to a *DSG1* mutation, Carvajal syndrome, ectodermal dysplasia–skin fragility syndrome (plakophilin 1 deficiency), and other erosive skin fragility disorders (see Ch. 32)[99]. At the ultrastructural level, the size of the desmosomes is reduced in type 1 SPPK, while marked perinuclear aggregation of keratin filaments is seen in type 2 SPPK[100].

There is often a good response to oral acitretin and/or application of keratolytic agents. Treatment with erlotinib 1% ointment plus salicylic acid 10% cream has been reported to improve PPK due to a keratin 16 mutation[100a].

FOCAL PALMOPLANTAR KERATODERMA WITH ASSOCIATED FEATURES/SYNDROMIC

Pachyonychia Congenita

Synonyms: ■ Pachyonychia congenita type 1 (Jadassohn–Lewandowsky; historic) ■ Pachyonychia congenita type 2 (Jackson–Lawler; historic)

History, epidemiology, and pathogenesis

Pachyonychia congenita (PC) is a group of autosomal dominant genodermatoses caused by mutations in keratins 6A, 6B, 6C, 16, and 17; ectodermal structures that are affected include the nail bed, palmoplantar skin, pilosebaceous unit, oral mucosa, and teeth[101,102]. Historically, PC was classified as type 1 (Jadassohn–Lewandowsky) due to keratin 6a/16 defects, featuring more severe PPK and oral leukokeratosis, and type 2 (Jackson–Lawler) due to 6b/17 defects, featuring pilosebaceous cysts and neonatal teeth. However, extensive genotype–phenotype analysis led to recognition of the considerable overlap between these groups, and the current classification system is based on the affected keratin: PC-6a (~40% of PC patients), PC-6b (~5%–10%), PC6c (<5%), PC-16 (~30%), and PC-17 (~15%–20%)[101–104]. The different expression patterns of the mutant keratins account for the frequencies of various phenotypic features. For example, keratin 6a is more highly expressed in the oral mucosa and nails than other keratins[105], while keratin 17 is constitutively expressed in the pilosebaceous unit[106]. Mutations in keratin 6c or 16 and keratin 17 have also been reported in patients with focal PPK[107] and steatocystoma multiplex[108], respectively, without any other features of PC.

Clinical features

Clinically, three cardinal manifestations are present in >90% of PC patients, regardless of which keratin is affected: toenail dystrophy, focal keratoderma, and plantar pain (Fig. 58.12A–D)[101,102,109]. Wedge-shaped subungual hyperkeratosis leads to elevation, thickening, and darkening of the nail plate, which may assume an "omega" shape with more prominent involvement distally than proximally. There may or may not be involvement of all of the digits, but the toes, thumbs, and index fingers tend to have more severely affected nails. In infants, erythema of the nail bed can precede the appearance of dystrophic changes. Thick yellow plantar keratoses develop in sites of pressure, with the formation of calluses, fissures, and blisters in areas of friction, particularly during the summer; spread to the dorsal feet occasionally occurs in association with trauma or infection. Severe pain often makes it difficult for patients to walk, and palmoplantar hyperhidrosis and paronychia are common findings.

Other variable features include follicular keratoses on the knees and elbows, angular cheilitis, oral leukokeratosis (Fig. 58.12E), natal teeth (primarily in PC-17), and less often pili torti or other hair abnormalities[109,110]. Steatocystomas, vellus hair cysts, and other pilosebaceous cysts (e.g. epidermoid) develop in approximately half of patients overall and >90% of those with PC-17[101,109] (Fig. 58.12F). Mucosal involvement may lead to feeding difficulties in affected infants[111], and laryngeal involvement can result in hoarseness and occasionally respiratory tract obstruction.

Pathology

In hyperkeratotic skin and oral plaques, the keratinocytes in the superficial epidermis and mucosal epithelium have a characteristic pale cytoplasm and eosinophilic inclusions. At the ultrastructural level, these findings correlate with perinuclear condensation of mutated keratin filaments and vacuolization of the peripheral cytoplasm[110]. Similar histologic findings are seen in white sponge nevus, which is caused by keratin 4 and 13 mutations.

Differential diagnosis

The differential diagnosis for PC-like nail changes includes Clouston syndrome, which is distinguished by diffuse (rather than focal) PPK and more prominent alopecia, and isolated autosomal recessive nail dysplasia due to mutations in the frizzled 6 gene (*FZD6*)[112,113].

Treatment

Symptomatic treatment for the hyperkeratotic skin and dystrophic nails includes mechanical modalities (e.g. cutting, filing, grinding) following softening via soaking, as well as application of emollients and keratolytics[114]. Surgical removal of nails with attempts at matrix ablation is usually not effective, as the keratins involved in PC are expressed in the nail bed. Use of orthotics and treatment of hyperhidrosis with botulinum toxin type A injections may reduce blistering and pain. Oral retinoids can reduce hyperkeratosis but may increase tenderness[114]. Treatment with oral erlotinib or lapatinib (an EGFR/Her2 inhibitor) has been reported to reduce plantar pain and hyperkeratosis in patients with PC, which is associated with overactive EGFR signaling[114a]; less substantial benefit was observed with application of erlotinib 0.2% cream. Treatment with small interfering RNAs (siRNAs) that specifically target and silence expression of dominant-negative mutant *K6a* has been investigated, with the pain of intradermal injection representing a limiting factor. Use of topical sirolimus or oral statins to down-regulate *K6a* promoter activity in patients with K6a defects is under investigation[115,116]. Multimodal pain control strategies may also be of benefit.

Richner–Hanhart Syndrome

Synonyms: ■ Tyrosinemia type II ■ Tyrosine aminotransferase deficiency ■ Tyrosine transaminase deficiency ■ Oculocutaneous tyrosinemia

This is a rare autosomal recessive disorder of tyrosine metabolism caused by mutations in the gene that encodes hepatic tyrosine aminotransferase (TAT)[117–119]. Photophobia and dendritic keratitis with corneal ulcerations often appear in the first year of life. Tyrosine crystal deposition is seen on slit-lamp examination, and serum and urinary tyrosine levels are elevated. Painful, focal hyperkeratotic plaques on the palms and soles represent the characteristic cutaneous finding (Fig. 58.13). The skin changes can appear during early childhood or be delayed until adolescence; blistering and hyperhidrosis may be seen. Progressive intellectual disability occurs if the patient is not treated with a restrictive diet.

The histologic findings of pale epithelia with eosinophilic inclusions resemble those of pachyonychia congenita. Electron microscopy reveals clumped tonofilaments with adherent globoid keratohyalin granules and needle-shaped tyrosine crystalline inclusions within keratinocytes[118].

A diet in which tyrosine and phenylalanine are restricted will clear the keratitis and keratoderma, and it may delay or prevent cognitive impairment[120].

Howel–Evans Syndrome

Synonyms: ■ Focal non-epidermolytic PPK with carcinoma of the esophagus ■ Tylosis–esophageal carcinoma ■ Tylosis type A

This autosomal dominant disorder, which has been reported in several families over many generations, is caused by missense mutations in the rhomboid 5 homolog 2 gene (*RHBDF2*) encoding an intramembrane protease[121]. Functional data suggest that mutant RHBDF2 increases signaling through the epidermal growth factor receptor (EGFR), which promotes epithelial hyperproliferation and dysregulation of wound repair[121].

Affected individuals develop focal PPK by 5–15 years of age, often limited to the pressure areas of the balls of the feet, with milder involvement of the palms (Fig. 58.14). Keratosis pilaris, dry rough skin, and oral leukokeratosis are often present. Affected individuals have a high risk of esophageal carcinoma, which developed by the fifth decade of life in ~40% of affected members of the originally reported family[122].

A–C Plantar hyperkeratosis accentuated over pressure points and hypertrophic nail dystrophy with wedge-shaped subungual hyperkeratosis. **D** Painful focal plantar keratoderma with associated erythema and blistering. **E** Oral leukokeratosis. **F** Steatocystomas in the axilla. *A,B,E, Courtesy Julie V. Schaffer, MD; D, Courtesy Alfons Krol, MD, and Dawn Siegel, MD; F, Courtesy Dr. J. Valverde.*

Carvajal Syndrome

Synonyms: ■ Carvajal–Huerta syndrome ■ Striate PPK with woolly hair and dilated cardiomyopathy

This condition, first described in families from Ecuador, is characterized by PPK of the areata and striate type together with woolly hair and cardiomyopathy (Fig. 58.15)[123]. It can be caused by either biallelic or heterozygous mutations in the desmoplakin gene (*DSP*), which encodes a major constituent of desmosomes and is critical to providing strength to the epidermis and cardiac tissue (see Fig. 56.8)[124,125]. The mutations typically affect the protein's carboxy-terminal tail, which binds to intermediate filaments and is important in cardiac myocytes.

The PPK usually develops during infancy, and the woolly hair is generally present at birth. Additional skin findings may include scaly plaques and keratoses on the elbows and knees or in flexural sites. Although the cardiac ventricular involvement was predominantly left-sided in the original kindred, the right or both ventricles can be affected. The onset of cardiac disease ranges from early childhood to adolescence, and it typically leads to heart failure with cardiac enlargement[124]. Patients with an autosomal dominant form of Carvajal syndrome may also have leukonychia and oligodontia, and a variant autosomal

Fig. 58.13 Richner–Hanhart syndrome (tyrosinemia II). Focal painful keratoses on the plantar surface in a patient with corneal ulcers and mental retardation. *Courtesy Jean L. Bolognia, MD.*

Fig. 58.14 Howel–Evans syndrome. Focal palmoplantar keratoderma in association with carcinoma of the esophagus. *Courtesy Alfons Krol, MD, and Dawn Siegel, MD.*

recessive form features skin fragility with acantholysis, nail dystrophy, and dental enamel defects.

Histologic findings include widening of the intercellular spaces and partial dehiscence of suprabasal keratinocytes, which have dense eosinophilic cytoplasm surrounding a pyknotic nucleus. Immunohistochemistry demonstrates perinuclear localization of keratin in these keratinocytes, suggesting a collapsed intermediate filament network. Early cardiac diagnosis and intervention is essential for survival of affected individuals[125].

The differential diagnosis of the triad of PPK, woolly hair, and cardiomyopathy includes Naxos disease, which more often presents with a diffuse PPK (see above), and desmocollin 2 defects. Other phenotypes due to genetic defects in desmoplakin include: isolated striate PPK or cardiac anomalies; skin fragility–woolly hair syndrome and other erosive skin fragility disorders (see Ch. 32); erythrokeratodermia–cardiomyopathy syndrome (see Ch. 57); and SAM syndrome (see Striate PPK above)[126–128].

Fig. 58.15 Carvajal syndrome. A Focal plaque-like hyperkeratosis over pressure points on the soles. **B** Woolly hair.

PUNCTATE PALMOPLANTAR KERATODERMA WITHOUT ASSOCIATED FEATURES (ISOLATED, NON-SYNDROMIC)

Punctate Palmoplantar Keratoderma, Buschke–Fischer–Brauer type

Synonyms: ■ Punctate palmoplantar keratoderma type 1 ■ Palmoplantar keratoderma punctata type 1 ■ Keratosis punctata palmoplantaris type Buschke–Fischer–Brauer ■ Keratoma dissipatum ■ Disseminated clavus

Punctate PPK is an autosomal dominant condition that can be caused by heterozygous mutations in *AAGAB*, which encodes the *α- a*nd *γ-a*daptin-*b*inding protein p34. This protein is involved in the intracellular trafficking of clathrin-coated vesicles[129]. Accordingly, a large number of small vesicles and a dilated Golgi apparatus can be visualized via electron microscopy of affected skin. The AAGAB defect results in impaired endocytic recycling of receptor tyrosine kinases such as EGFR and Axl, leading to increased signaling and cellular proliferation[129]. A second locus for punctate PPK on 8q was found to be associated with a heterozygous missense mutation in the collagen type XIV α1 chain gene (*COL14A1*) in a Chinese family[130].

Multiple small keratotic papules usually begin to appear on the palmoplantar surfaces during adolescence or early adulthood, although onset can be in childhood or as late as the sixth decade of life[131].

Fig. 58.16 Punctate keratoses of the palmar creases. Keratotic papules lined along a crease in an African-American.

DIFFERENTIAL DIAGNOSIS OF PALMOPLANTAR PITS
Hereditary disorders
Basal cell nevus syndrome
Basaloid follicular hamartoma syndrome
Darier disease
Reticulate acropigmentation of Kitamura
Punctate PPK (including punctate keratoses of the palmar creases)*
Cowden syndrome*
Porokeratotic adnexal ostial nevus (PAON; encompasses porokeratotic eccrine ostial and dermal duct nevus [PEODDN])*
Acquired disorders
Pitted keratolysis
Associated with Dupuytren contracture
Punctate porokeratoses*
*Characterized primarily by keratoses, which may leave a pit upon removal of the keratotic plug.

Table 58.7 Differential diagnosis of palmoplantar pits. They are rarely seen in alkaptonuria, epidermodysplasia verruciformis, Blau syndrome, and lesions of lichen nitidus, lichen planus, or psoriasis. Occasionally, lesions of circumscribed palmar or plantar hypokeratosis can be multiple and <5 mm. PPK, palmoplantar keratoderma.

The central keratotic core is initially translucent but may become opaque or verrucous over time, and a depression remains upon its removal (see Fig. 58.3). The papules can be painful or tender, and they may enlarge and aggregate to form plaques over pressure points. Environmental factors can affect the degree of hyperkeratosis. Although some older studies suggested a possible association between punctate PPK and the development of breast and colon carcinomas, it is not clear whether there is truly an excess of malignancies in affected individuals[129,132].

Histologically, there is a slight epidermal depression with an overlying column of compact orthohyperkeratosis. Focal hypogranulosis with parakeratosis and elongated, curved rete ridges may be evident. Cytologic features of HPV infection are lacking.

Punctate keratoses frequently develop in the palmar creases of adults with African ancestry (Fig. 58.16); the creases of the digits and soles may also be involved, and the lesions are worsened by mechanical stress. The relationship of this variant to other forms of punctate PPK remains to be determined[133]. The differential diagnosis of punctate PPK often includes verrucae, which are distinguished by multiple bleeding points upon paring, and punctate porokeratoses, which demonstrate a cornoid lamella rather than a column of orthohyperkeratosis histologically. Keratotic papules on palms and soles can also occur after exposure to arsenic or dioxin and in patients with Darier disease, acrokeratosis verruciformis of Hopf, and Cowden syndrome. Conditions that present with palmoplantar pits, which may be confused with punctate PPK, are listed in Table 58.7.

Comfortable footwear and mechanical paring can provide relief. Although topical retinoids and keratolytic ointments have limited efficacy, oral retinoids may be helpful[131]. Receptor tyrosine kinase inhibitors represent a possible future treatment option[134].

Spiny Keratoderma

Synonyms: ■ Punctate palmoplantar keratoderma type 2 ■ Palmoplantar keratoderma punctata type 2 ■ Music box spine keratoderma ■ Filiform hyperkeratosis ■ Digitate keratosis

Spiny PPK is an autosomal dominant condition characterized by numerous tiny keratotic spines projecting from the palms and soles, usually beginning in the first to third decades of life[135] (Fig. 58.17). Discomfort can be caused by a tendency to catch on clothing and other objects[136]. This disorder should be differentiated from acquired forms of spiny PPK, which typically develop after 50 years of age; possible associations with the latter based upon case reports include various malignancies (visceral carcinoma, melanoma, leukemia, multiple myeloma), hyperlipidemia type IV, chronic kidney disease, and polycystic kidney disease with liver cysts[137]. Some authors group this entity under the umbrella term multiple minute digitate hyperkeratosis.

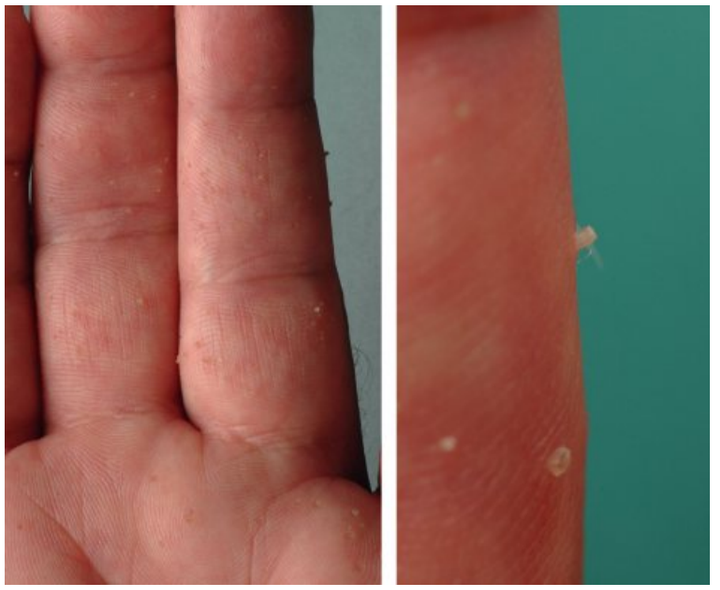

Fig. 58.17 Spiny palmoplantar keratoderma. Multiple tiny keratotic spines project from palms and soles.

Histologically, an epidermal depression with an overlying column of parakeratosis is seen. In contrast to porokeratosis and porokeratotic adnexal ostial nevus, the stratum granulosum is preserved while vacuolization, pleomorphism, and dyskeratosis of underlying keratinocytes are not evident.

Mechanical debridement, including via dermabrasion, may be more effective than topical keratolytics. Oral retinoids may provide temporary benefit. Topical 5-fluorouracil ointment has been tried with variable results[136].

Marginal Papular Keratoderma: Acrokeratoelastoidosis and Focal Acral Hyperkeratosis

Synonyms: ■ Punctate palmoplantar keratoderma type 3 ■ Palmoplantar keratoderma punctata type 3 ■ Acrokeratoelastoidosis of Costa

Both forms of marginal papular keratoderma can have an autosomal dominant inheritance pattern, and onset is typically in childhood or adolescence. Focal acral hyperkeratosis (FAH) classically favors female patients with African ancestry. These conditions are both characterized by small, keratotic papules along the margins of the palms, soles, and digits (Fig. 58.18). The papules tend to be skin-colored to hyperpigmented in FAH and yellowish in acrokeratoelastoidosis. Lesions may be umbilicated and occasionally they extend to the dorsal aspect of the hands and feet. While acrokeratoelastoidosis histologically shows fragmentation and degeneration of elastic fibers in the dermis as well as hyperkeratosis, FAH lacks elastorrhexis[138].

There is ongoing debate as to whether a form of acral keratosis with polygonal papules in a "jigsaw puzzle" pattern reported in African patients represents a variant of marginal keratoderma[139]. The primary sites of involvement in these patients are the ankles, shins, and dorsal aspect of the hands and feet. *Keratoelastoidosis marginalis* (digital papular calcific elastosis) is an acquired condition that presents with degenerative collagenous plaques forming a linear band around the thumb and index finger at the margin of the volar and dorsal surfaces in patients with severe photodamage[140].

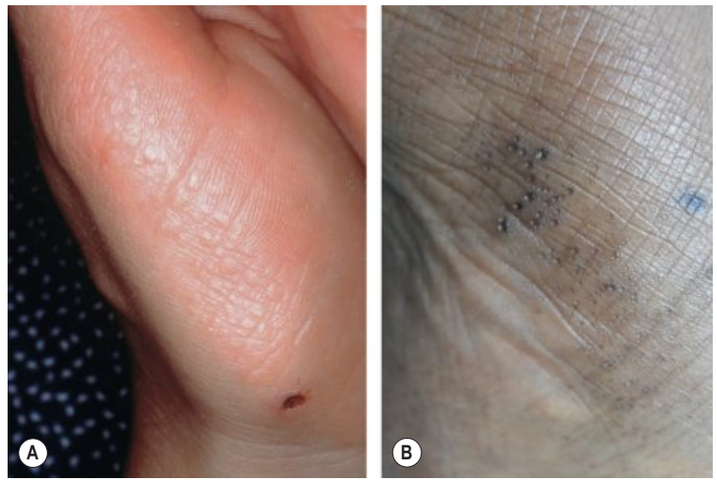

Fig. 58.18 Marginal papular keratoderma. A Acrokeratoelastoidosis presenting with multiple skin-colored to yellowish papules at the margin of the palmar skin. **B** Focal acral hyperkeratosis presenting with umbilicated keratotic papules at the margin of volar skin in an African-American woman. *B, Courtesy Boni Elewski, MD.*

PUNCTATE PALMOPLANTAR KERATODERMA WITH ASSOCIATED FEATURES/SYNDROMIC

Cole Disease

Synonym: ▪ Guttate hypopigmentation and punctate palmoplantar keratoderma with or without ectopic calcification

Cole disease is a rare autosomal dominant condition characterized by a congenital or early childhood onset of punctate PPK together with irregularly shaped hypopigmented macules on the extremities[141]. Electron microscopy shows defective melanosome transfer from melanocytes to keratinocytes. Cole disease is caused by heterozygous mutations in *ENPP1*, which encodes ectonucleotide pyrophosphate/phosphodiesterase 1. The latter is a cell-surface protein that catalyzes the hydrolysis of ATP to AMP and generates extracellular inorganic pyrophosphate, which is a major inhibitor of mineralization[142]. Recessive mutations in *ENPP1* underlie inherited forms of ectopic calcification, and calcific tendinopathy and calcinosis cutis have been observed in patients with Cole disease.

ACQUIRED KERATODERMAS AND RELATED CONDITIONS

Keratoderma Climactericum

This common, acquired form of focal plantar hyperkeratosis favoring women >45 years of age was first described by Haxthausen in 1934. It is often associated with obesity, cold dry climates, and wearing backless shoes (e.g. sandals). Hyperkeratosis begins over pressure points on the heels, and the formation of fissures makes walking painful. If present, involvement of the hands is much milder. Endocrine dysfunction, vitamin A deficiency, contact dermatitis, and fungal infection were excluded in reported patients[143]. Treatment options include keratolytic preparations containing 20%–40% urea or 12% ammonium lactate and, if severe, a low-dose oral retinoid. Similar changes described in young women following bilateral oophorectomy responded to estrogen replacement therapy.

Keratoderma and Cancer

Acquired diffuse PPK has been observed in association with bronchial carcinoma[144], and filiform PPK has been reported in patients with cancer of the breast, colon, and kidney[145]. "Tripe palms" refers to velvety, thickened palmar skin with exaggerated ridges. It is often associated with acanthosis nigricans and may herald malignancies of the lung, stomach, or genitourinary tract[146]. Bazex syndrome (acrokeratosis paraneoplastica) is discussed in Chapter 53. Esophageal carcinoma in association with focal PPK (Howel–Evans syndrome) as well as the increased risk of acral SCC in patients with Huriez syndrome and PPK with sex reversal are discussed above. Acral melanoma and the epithelioma cuniculatum variant of SCC have also been reported in individuals with mutilating forms of PPK and (for acral melanoma in Asians) Nagashima-type PPK. In addition, an autosomal recessive syndrome featuring pigmentation defects, PPK, and cutaneous SCC can result from mutations in *SASH1* (SAM and SH3 domain-containing 1; see Table 67.11). Mycosis fungoides represents another diagnostic consideration in patients with acquired PPK[147].

Arsenical keratoses present as small, corn-like areas of hyperkeratosis on the palms and soles (see Fig. 88.8). Over time, the lesions enlarge, thicken, and increase in number, spreading to the dorsal surfaces of the hands and feet. Ulceration often occurs when SCC develops. On histologic examination, epidermal changes vary from benign hyperplasia to moderate atypia or frank SCC. The latent period between ingestion of inorganic arsenic and onset of keratoses is 10 to 30 years or longer[148]. Visceral malignancies, particularly of the lung and genitourinary tract, usually develop after the onset of skin tumors.

Other Etiologies of Acquired Keratoderma

Diffuse or focal palmoplantar hyperkeratosis can develop in association with *hypothyroidism*, often in the setting of myxedema. The PPK improves or resolves with thyroid replacement therapy[149].

With the increasing use of targeted therapies for the treatment of malignancies, in particular tyrosine kinase inhibitors, drug-induced palmoplantar hyperkeratosis also needs to be considered (see Table 21.16).

Other conditions that have been associated with keratoderma are listed in Table 58.1[150–152].

Aquagenic Palmoplantar Keratoderma

Synonyms: ▪ Transient reactive papulotranslucent acrokeratoderma ▪ Aquagenic syringeal acrokeratoderma ▪ Acquired aquagenic palmoplantar keratoderma ▪ Aquagenic wrinkling of the palms and soles ▪ Transient aquagenic keratoderma

Patients with aquagenic PPK develop thickening and white to translucent, "pebbly" changes on their palms shortly after immersion in water (e.g. within 3 minutes) (Fig. 58.19). Often, there is associated edema and burning pain[153,154]. Involvement of the dorsal hands or soles is less frequently observed[155]. These findings disappear shortly after drying the hands. Onset is typically during the second decade of life, with a predilection for girls and women. By dermoscopy, the papular lesions are at sites of dilated acrosyringeal ostia[156]. Histologically, normal skin or dilated eccrine ostia and a mildly hyperkeratotic stratum corneum may be seen.

Fig. 58.19 Aquagenic wrinkling of the palms. These exaggerated changes occur after water immersion. *Courtesy Cindy E. Owen, MD.*

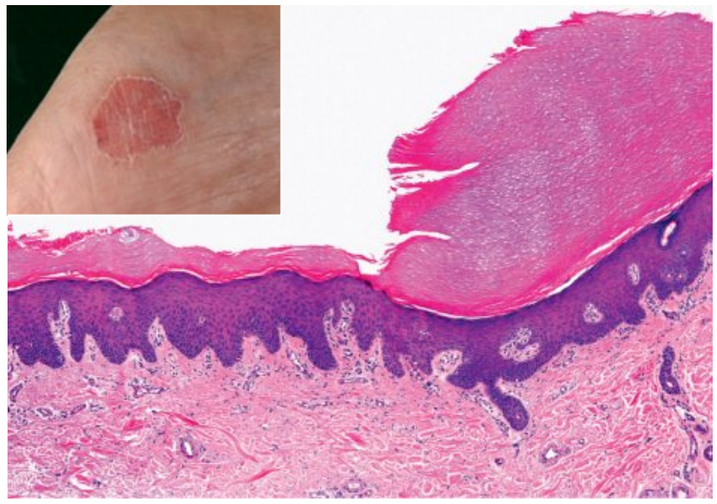

Fig. 58.20 Circumscribed palmar hypokeratosis. A sharp drop-off is seen between the lesional epidermis, which has a very thin stratum corneum, and the surrounding skin. Clinically, a well-circumscribed pink depression is seen (inset). *Courtesy Luis Requena, MD.*

Autosomal recessive or dominant inheritance of aquagenic PPK has been described, and an onset associated with the use of cyclooxygenase-2 inhibitors was reported[157]. Aquagenic wrinkling of the palms can be observed in ~50% of patients with cystic fibrosis and ~10%–25% of heterozygous carriers of *CFTR* mutations[158]. Aquagenic PPK should be differentiated from hereditary papulotranslucent acrokeratoderma, in which lesions are persistent once they appear[159], and other forms of PPK that are accentuated upon exposure to water, e.g. the Bothnian and Nagashima types of diffuse NEPPK (see above).

Improvement has been described with botulinum toxin injections, application of 20% aluminum chloride hexahydrate followed by urea cream, tap water iontophoresis, and oral acitretin[160].

Circumscribed Palmar or Plantar Hypokeratosis

This entity, which was first described in 2002, presents as a well-circumscribed, mildly erythematous, circular depression on the thenar or hypothenar region of the palm or less often the medial sole (Fig. 58.20)[161]. Lesions are solitary, or rarely few in number, and have a maximum diameter of 3 cm. They typically develop in women 40–85 years of age[162], although congenital lesions have been described. Sometimes there is a history of prior trauma or a burn at the site. The clinical differential diagnosis may include Bowen disease or porokeratosis.

Histologically, abrupt thinning of the stratum corneum over a diminished granular layer forms a sharp drop-off between normal and involved skin (see Fig. 58.20). To date, malignant transformation has not been reported. The etiology remains unknown, with postulated roles for trauma and loss of the keratinocytes' ability to undergo palmoplantar differentiation. The latter is supported by the observation of diminished keratin 9 expression[163]. Molecular studies have failed to detect human papillomavirus (HPV) apart from a single report of HPV type 4 DNA[164].

Treatments that have been reported include topical calcipotriene or 5-fluorouracil, cryotherapy, photodynamic therapy, fractional carbon dioxide laser, and excision[165].

Hailey–Hailey Disease. 957

DARIER DISEASE

Synonyms: ■ Darier–White disease ■ Keratosis follicularis ■ Dyskeratosis follicularis

Key features

- Autosomal dominant disorder in which mutations in *ATP2A2* result in dysfunction of an endoplasmic reticulum Ca^{2+} ATPase (SERCA2), thus interfering with intracellular Ca^{2+} signaling
- Keratotic and crusted papules and plaques favor seborrheic areas; additional features include palmoplantar papules, variable nail changes, and whitish oral mucosal papules
- Clinical subtypes include an acral hemorrhagic variant and segmental forms due to type 1 and type 2 mosaicism
- Characterized histologically by acantholytic dyskeratosis with suprabasilar clefting, "corps ronds", and "grains"

Introduction

Darier disease is an autosomal dominant genodermatosis with characteristic mucocutaneous findings such as keratotic papules on the upper trunk and longitudinal erythronychia. Insufficient function of the 2b isoform of the sarco/endoplasmic reticulum Ca^{2+} ATPase (SERCA2b) leads to abnormal intracellular Ca^{2+} signaling, notably involving the endoplasmic reticulum. The result is a loss of suprabasilar cell adhesion (acantholysis) and an induction of apoptosis (dyskeratosis).

History

In 1889, the French dermatologist Jean Darier[1], at the Hôpital Saint-Louis in Paris, and James C. White[2], Professor of Dermatology at Harvard University, independently reported a skin disease characterized by brown, crusted, malodorous lesions with a follicular distribution. Darier called the disease "psorospermose folliculaire végétante" because of his histopathologic studies, where throughout the malpighian layer he saw a large number of round bodies surrounded by a double-layered membrane. He and others thought that these bodies represented psorosperms, a type of parasitic protozoa now referred to as coccidia, which they postulated were the causative agents for the disease. However, attempts to culture or inoculate the supposed parasites failed, and the histologic changes were subsequently recognized as sequelae of abnormal keratinization. The supposed follicular origin of the disease could not be confirmed either, as lesions were noted to occur outside the pilosebaceous unit. It was White who first suggested the hereditary character of the disorder, when the daughter of his initially described patient developed similar skin lesions.

Epidemiology

The reported prevalence of Darier disease ranges from 1 in 100 000 in Denmark to 1 in 30 000 in Scotland, and the estimated incidence is 4 per million per 10 years[3]. Men and women are equally affected. Darier disease has an autosomal dominant mode of inheritance with complete penetrance and variable expressivity. For example, in a series of 42 patients with Darier disease, 7 of 18 affected individuals who recalled no family history were found to be members of known Darier kindreds with mildly affected parents[4]. The clinical severity varies among different families carrying identical mutations and among members of the same family. Indeed, subtle changes of the skin or nails may remain unnoticed by affected persons.

Pathogenesis

Mutations in *ATP2A2* which encodes an endoplasmic reticulum (ER) Ca^{2+} ATPase pump, SERCA2, leads to both acantholysis and apoptosis, accounting for the characteristic histologic finding of acantholytic dyskeratosis. SERCA2 haploinsufficiency has been hypothesized to underlie the condition's dominant inheritance pattern[5], but a more recent study found that aggregates of mutant SERCA2 may exert a dominant negative effect by inducing ER stress and keratinocyte apoptosis[6]. Although both SERCA2a and SERCA2b isoforms are found within the epidermis, SERCA2b is the major protein product and its dysfunction alone can produce Darier disease[7]. While SERCA2 is ubiquitously expressed, a lack of compensatory SERCA3 expression in keratinocytes may explain the particular vulnerability of these cells to SERCA2 deficiency.

Close to 300 pathogenic *ATP2A2* mutations have been identified, primarily missense and frameshift alterations. In general, there is no clear genotype–phenotype correlation[8]. Likely exceptions include a particular *ATP2A2* mutation underlying the allelic acrokeratosis verruciformis of Hopf[9,10] (see below) and mutations in the S4-M4 region associated with more severe neuropsychiatric manifestations[11]. Several pathogenic mechanisms have been proposed for the acantholytic dyskeratosis of Darier disease. *ATP2A2* mutations result in chronically low Ca^{2+} stores within the ER (Fig. 59.1)[12], which is aggravated by cellular stress. This Ca^{2+} depletion leads to *acantholysis* via impaired processing, folding and trafficking of junctional proteins such as desmoplakin[13] and E-cadherin[14]. Impaired membrane translocation of protein kinase C α, an important Ca^{2+}-dependent regulatory enzyme that interacts with membrane phospholipids, is thought to mediate the disruption of desmosome assembly[15]. Studies have also shown that SERCA2 inhibition in keratinocytes causes increased levels of sphingosine, which inhibits protein kinase C α[14,16].

ER stress due to depleted Ca^{2+} stores and accumulation of unfolded proteins produces the "unfolded protein response", which can induce apoptosis[16,17]. ATP receptors, which are thought to have roles in apoptosis and calcium signaling, localize abnormally in lesional Darier disease epidermis, with decreased P2Y2 (a G protein-coupled receptor) but increased P2X7 (a death receptor) in the plasma membrane of acantholytic cells[18].

Clinical Features

Onset and clinical pattern

In ~70% of patients, Darier disease becomes apparent between the ages of 6 and 20 years, with a peak onset during puberty (ages 11–15 years)[19]. The primary lesions are keratotic, sometimes crusted, red to brown papules, which develop preferentially in a "seborrheic" distribution involving the trunk (Fig. 59.2), scalp (especially its margins; Fig. 59.3), face, and lateral aspects of the neck (Fig. 59.4). Despite its initial description as follicular dyskeratosis, the papules are not limited to a perifollicular location. The lesions tend to become confluent and may form papillomatous masses (Fig. 59.2B,D). Small (2–3 mm) hypomelanotic macules may be admixed with the keratotic papules

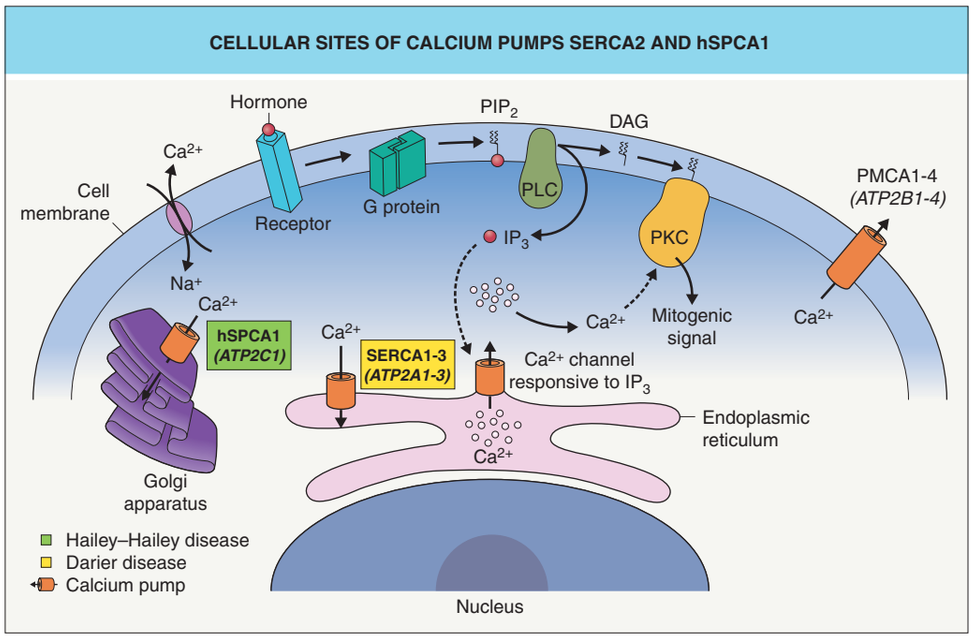

Fig. 59.1 Cellular sites of calcium pumps SERCA2 and hSPCA1. Darier disease is due to mutations in *ATP2A2* which encodes SERCA2. PIP_2, phosphoinositol diphosphate; IP_3, inositol triphosphate; PLC, phospholipase C; DAG, diacylglycerol; PKC, protein kinase C.

Fig. 59.3 Darier disease. **A** Crusted papules at the hairline on the face and in the posterior auricular area. **B** Extensive facial involvement leading to ectropion.

and occasionally are the predominant feature (Fig. 59.5). Rarely, sterile vesicles or bullae are prominent, and, in these cases, herpetic infection (Kaposi varicelliform eruption) must be excluded[20,21].

Most patients have lesions in the axillae, groin, and/or inframammary area (Fig. 59.6). Although these intertriginous lesions are usually mild, they are occasionally the predominant finding and may result in the misdiagnosis of Hailey–Hailey disease (HHD)[22]. Occasionally, macerated, fungating masses are seen in the axillae or groin. Malodor is a frequent and distressing feature of Darier disease.

In ~50% of patients, 2–4 mm, skin-colored or brownish, flat-topped papules, reminiscent of flat warts, are found on the dorsal aspects of the hands and feet, and less often, on the forearms and legs (Fig. 59.7). Rarely, acral hemorrhagic vesicles may also be seen. Palmoplantar papules, many of which are keratotic, and keratin-filled depressions are almost invariably present (Fig. 59.8). Subtle changes can be detected by obtaining finger or palm prints, which show interruption of the dermatoglyphic pattern. Nail changes include longitudinal red and/or white lines, longitudinal ridging and fissuring, and wedge-shaped subungual hyperkeratosis (Fig. 59.9). The nails are brittle and tend to break distally, forming V-shaped notches[23].

Painless whitish papules or rugose plaques are noted on the oral mucosa in 15%–50% of patients with Darier disease. The hard palate is the most common site of involvement, followed by the gingiva, buccal mucosa, and tongue (Fig. 59.10)[19].

Symptoms

Most patients complain of moderate itching. Equally distressing are the appearance and the odor, which can lead to social isolation.

Modifying factors

This condition frequently worsens during the summer. In patients with Darier disease, characteristic lesions can be experimentally induced in clinically uninvolved skin by UV irradiation, and UVB irradiation has been shown to suppress *ATP2A2* expression in keratinocytes[23]. Sweating, heat, and occlusion represent additional factors that trigger exacerbations primarily in covered and intertriginous areas (e.g. after a long airplane flight), and this predisposes patients to infections (see below). Interferon β-1a or lithium carbonate[24,25] can provoke flares of Darier disease.

Course of the disease

Darier disease follows a chronic course with fluctuations in disease severity. While some patients report improvement over time, others experience worsening.

Infectious complications

Areas of skin affected by Darier disease are prone to secondary infections with bacteria, yeast, and dermatophytes, often leading to malodor and vegetating plaques. A study of 75 adult patients found a high prevalence of *Staphylococcus aureus* colonization in lesional skin (~70%) and the nares (~50%), which correlated with a more severe phenotype[26].

Affected individuals are also susceptible to the development of widespread cutaneous infections with human papillomaviruses (HPV) and herpes simplex virus (HSV). When there is a sudden onset and rapid spread of vesicular and crusted lesions, often accompanied by fever and malaise, the clinician should have a high index of suspicion for the development of Kaposi varicelliform eruption (KVE; Fig. 59.11)[21]. The latter requires systemic antiviral therapy (e.g. valacyclovir, acyclovir). Generalized cowpox infection has also been reported.

Disruption of the epidermal barrier likely plays an important role in the increased frequency and severity of skin infections in patients with Darier disease. Immunologic studies have shown no consistent systemic abnormalities[27]. However, an immunohistochemical analysis found evidence for an impaired local immune response, with a decrease in Langerhans cells and plasmacytoid dendritic cells[28]. In a recent study, SERCA2 activity was shown to be required for efficient V(D)J recombination, and 6/16 patients with Darier disease were found to have an abnormally low proportion of $CD19^+$ B cells in their peripheral blood lymphocytes[29].

Salivary glands

In some patients, obstruction of salivary gland ducts can lead to painful glandular swelling. Darier-like histologic changes within the ducts are thought to be responsible for the obstruction[30].

Neuropsychiatric disorders

Various neuropsychiatric conditions such as intellectual impairment, mood disorders, and epilepsy have been reported in association with Darier disease. Neuropsychiatric assessment of Darier disease patients from the UK revealed higher lifetime rates of major depression (30%), suicide attempts (13%), bipolar disorder (4%), and epilepsy (3%) than in the general population[31]. In a study based on the Swedish national registry, Darier disease patients (n = 770) were more likely to be diagnosed with intellectual disability (6.2-fold), bipolar disorder (4.3-fold), and schizophrenia (2.3-fold) than matched individuals from the general population[32].

More severe neuropsychiatric manifestations have been observed in patients with *ATP2A2* mutations in the S4-M4 region[11,31]. *ATP2A2* is expressed in the brain, and hypotheses regarding potential mechanisms for neuropsychiatric findings in Darier disease include disruption of intracellular calcium signaling, an impaired endoplasmic reticulum stress response, and accumulation of insoluble SERCA2 aggregates within neurons[6,11]. In addition, the disfigurement and social isolation associated with severe skin conditions often lead to psychological morbidity, which may contribute to depression and suicidal ideation in patients with Darier disease[22].

Fig. 59.6 Darier disease. Severe involvement in intertriginous zones, including the abdominal fold and groin.

Others

Dry eyes and blepharitis are common in patients with Darier disease[33], although more serious ocular complications, e.g. corneal ulcerations or staphylococcal endophthalmitis, are rare. There have been a few reports of squamous cell carcinomas arising in cutaneous or mucosal sites chronically affected by Darier disease[34]. Malignant transformation is a rare event and may be related to infection with oncogenic types of HPV or changes in keratinocyte adhesion and proliferation secondary to SERCA2 haploinsufficiency, which has been associated with squamous cell carcinomas of the skin and upper gastrointestinal tract in mice. Swedish cross-sectional case–control and population-based studies have suggested that Darier disease is associated with an increased risk of heart failure and type 1 diabetes mellitus[35]. Observations of bone cysts, renal agenesis, and autoimmune thyroiditis in patients with Darier disease are thought to represent chance associations.

Clinical subtypes of darier disease

Acral hemorrhagic type (Table 59.1)

In addition to classic clinical features, a small subset of patients develop sharply demarcated, red to blue–black macules on the palms and soles as well as the dorsal aspects of the hands. These irregularly shaped lesions represent hemorrhage into acantholytic vesicles. A particular *ATP2A2* missense mutation (N767S) has been identified in several non-related families with the acral hemorrhagic type of Darier disease[11], as well as in individuals with a classic Darier disease phenotype[8].

Segmental types 1 and 2

Two types of segmental Darier disease have been described, both with a distribution of lesions along the lines of Blaschko (see Ch. 62). With the more common type 1 mosaicism (Fig. 59.12), the age of onset, severity, and histologic findings within the streaks are similar to those of generalized Darier disease. Type 1 segmental Darier disease results from a postzygotic mutation in *ATP2A2* during embryogenesis, which leads to a mosaic pattern of skin involvement. Heterozygous *ATP2A2*

mutations in affected, but not background, skin have been documented in patients with this form of segmental Darier disease[36]. If there are mutant cells in the gonads, a patient with type 1 segmental manifestations may have offspring with generalized Darier disease.

Patients with type 2 mosaicism have generalized Darier disease plus linear streak(s) with increased severity[37]. Type 2 segmental manifestations of autosomal dominant disorders occur when patients with a heterozygous germline mutation also have a postzygotic inactivating mutation in the *other* allele of the same gene (i.e. a "second hit" causing loss of heterozygosity), which leads to more severe manifestations in a mosaic distribution (see Fig. 62.2). Of note, a second hit in *ATP2A2* was identified in skin from erosive patches following the lines of Blaschko in a 1-year-old boy with a family history of Darier disease[38].

LESS COMMON PRESENTATIONS OF DARIER DISEASE
Morphologic variants
• Guttate hypopigmentation (see Fig. 59.5) > hyperpigmented flat-topped papules and macules ("freckle-like")*
• Vesiculobullous lesions
• Acral hemorrhagic lesions
• Keratoderma (spiked; see Fig. 59.8B)
• "Cornifying" (e.g. with cutaneous horns)
• Comedones†, facial cysts, acne conglobata
• Periocular nodulocystic lesions
• Alopecia, cutis verticis gyrata
Distribution patterns
• Predominantly involving intertriginous areas, sun-exposed skin, the extremities, acral sites, or the scalp (pityriasis amiantacea-like)
• Segmental (type 1 > 2) (see Fig. 59.12)
Extracutaneous
• Oral mucosal erosions
• Corneal opacities or ulcers
• Salivary gland obstruction
• Laryngeal involvement
*A persistent acantholytic dermatosis and extensive lentiginous "freckling" without an underlying *ATP2A2* mutation has also been described.
†The differential diagnosis may include familial dyskeratotic comedones.

Table 59.1 Less common presentations of Darier disease.

Fig. 59.12 Type 1 segmental Darier disease. Note the distribution of the papules along the lines of Blaschko.

Pathology

There are two prominent histologic features in Darier disease, acantholysis and dyskeratosis (Fig. 59.13). Acantholysis is due to a disturbance in cell adhesion that leads to suprabasilar cleft formation. At the ultrastructural level, this corresponds to a loss of desmosomes and detachment of keratin filaments from the desmosomes[39]. Dyskeratosis is due to apoptosis of keratinocytes and is characterized by nuclear condensation and perinuclear keratin clumping. Two types of dyskeratotic cells are observed in Darier disease[40]:

- "Corps ronds" – acantholytic enlarged keratinocytes in the malpighian layer with darkly staining and partially fragmented nuclei surrounded by a clear cytoplasm and encircled by a bright ring of collapsed keratin bundles.

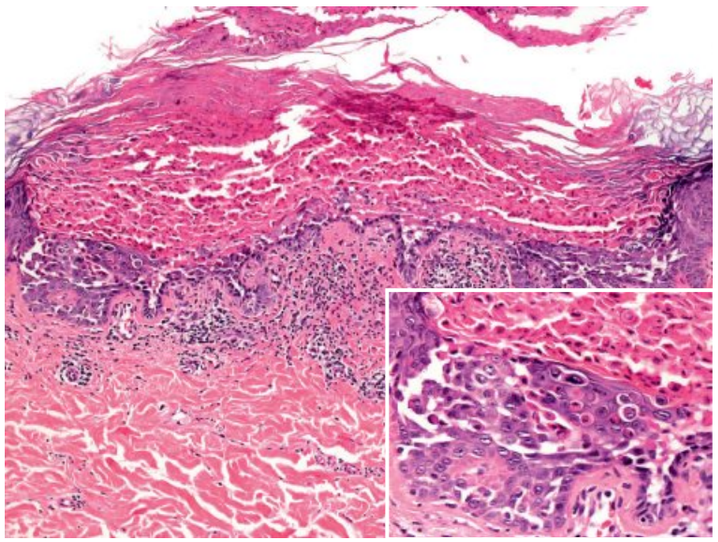

Fig. 59.13 Histopathology of Darier disease. Hyperkeratosis, grains and corp ronds (inset) are seen in addition to acantholysis leading to suprabasilar clefting. *Courtesy Lorenzo Cerroni, MD.*

- "Grains" – small, oval cells in the stratum corneum characterized by an intensely eosinophilic cytoplasm composed of collapsed keratin bundles containing shrunken parakeratotic nuclear remnants. "Grains" are likely derived from "corps ronds", but formal proof that they indeed represent different stages of the same pathologic process has not been provided.

The epidermis overlying acantholytic and dyskeratotic foci is thickened and shows papillomatosis and hyperkeratosis. In the superficial dermis, there is a mild to moderate perivascular inflammatory infiltrate. Diagnostic histologic changes are often focal, necessitating a careful search. Similar histologic features may be observed in Grover disease, but in the latter there tends to be more acantholysis, less dyskeratosis, and fewer "corps ronds" or "grains". The two conditions can be histologically indistinguishable, but the findings are typically broader in Darier disease, i.e. in a given biopsy specimen a larger portion of the epidermis is affected, sometimes with skip areas. Presence of eosinophils within the inflammatory infiltrate favors Grover disease.

Differential Diagnosis

Acrokeratosis verruciformis of Hopf

Flat-topped, wart-like papules on the dorsal aspects of the extremities are a common manifestation of Darier disease. They are clinically indistinguishable from the lesions that characterize the autosomal dominant disorder described by Hopf as "acrokeratosis verruciformis" (Fig. 59.14)[41]. There has been debate as to whether acrokeratosis verruciformis is a separate entity or an allelic forme fruste of Darier disease. A particular *ATP2A2* missense mutation that leads to Pro602Leu in SERCA2 has been identified in families with isolated acrokeratosis verruciformis as well as a Swiss kindred with acral warty lesions followed by the development of more widespread papules after intense sun exposure (author's unpublished observation), but not classic Darier disease[9,10].

Acrokeratosis verruciformis and Darier disease have traditionally been separated on the basis of their histologic features, with the former lacking acantholysis and dyskeratosis. However, serial sectioning is often required to find foci of acantholysis and dyskeratosis in acral skin biopsy specimens from patients with Darier disease[42]. In addition, Hopf actually described nail changes and palmoplantar keratotic papules in his initial report of acrokeratosis verruciformis[41], and there have been subsequent observations of families where some members had only acrokeratosis verruciformis while others exhibited the classic skin findings of Darier disease[43]. Because patients with Darier disease often develop warty lesions on the extremities before keratotic papules appear in a seborrheic distribution, some individuals who present with acrokeratosis verruciformis may later be diagnosed as actually having Darier disease[4].

Fig. 59.14 Acrokeratosis verruciformis of Hopf. Involvement of the dorsal aspect of the foot with flat-topped papules.

Other conditions

Although the clinical differential diagnosis may include severe seborrheic dermatitis and Grover disease (transient acantholytic dermatosis; see Fig. 59.4 and Ch. 87), Darier disease is readily distinguished by involvement of acral skin, the nails, and the oral mucosa. A family history may also be a clue to the diagnosis of Darier disease, and histologic findings differentiate it from seborrheic dermatitis. In Grover disease, the pruritic crusted papules are not confluent, and they typically develop after occlusion and/or sweating. However, in a persistent form of acantholytic dermatosis that affects patients with significant actinic damage, the papules are scalier and the histologic features closely resemble those of Darier disease[44].

In patients with predominantly flexural involvement, pemphigus vegetans (Hallopeau type), pemphigoid vegetans, blastomycosis-like pyoderma (pyoderma vegetans), and HHD may represent diagnostic considerations. Pemphigus vegetans usually develops at an older age and is characterized histologically by exocytosis of eosinophils as well as acantholysis but not dyskeratosis; direct immunofluorescence (DIF) shows the intercellular pattern of the pemphigus group, and antidesmoglein antibodies can be detected by ELISA. Pyoderma vegetans features a neutrophilic infiltrate, and acantholysis is not observed. HHD is sometimes difficult to separate clinically from primarily intertriginous Darier disease. The presence of palmoplantar papules, longitudinal erythronychia, distal notching of the nails, mucosal lesions, and prominent dyskeratosis as well as acantholysis histologically can serve as clues to the diagnosis of Darier disease. Occasionally, a sporadic disorder referred to as "papular acantholytic dyskeratosis" may be localized to the vulvocrural area and in an affected individual, identical somatic *ATP2A2* mutations have been detected within the papules.

Treatment

General measures

Therapies directed against hyperkeratosis, inflammation, and infection are employed as needed. Lightweight clothes and sun protection help prevent aggravation due to heat, sweating, and exposure to UV radiation. Skin care includes the use of antimicrobial cleansers and/or bleach baths (0.5 cup of household bleach [6%–8.25% sodium hypochlorite] in a full standard bathtub once or twice weekly) to prevent malodorous bacterial colonization as well as keratolytic emollients to reduce scaling and irritation.

Topical and intralesional therapy

Topical retinoids are more effective as monotherapy[45,46] than topical vitamin D analogues[47], which had no benefit in a small randomized controlled study[48], or corticosteroids. However, retinoid-associated irritation is common and can be reduced by alternate-day application, liberal use of emollients[45,49], and combination therapy with mid-potency topical corticosteroids[45,49]. Improvement following treatment with topical calcineurin inhibitors has also been reported[48]. Intermittent use of topical antibiotics and antifungal agents is helpful in reducing malodor due to microbial colonization and mild secondary infections.

Several case reports have suggested that topical 5-fluorouracil (1% or 5%) may be efficacious alone or in combination with oral alitretinoin (see below)[50]. Benefit from topical application of diclofenac sodium 3% gel has also been described[51], and cyclooxygenase-2 (COX-2) inhibition has been shown to rescue keratinocytes from UVB-induced downregulation of *ATP2A2* expression[52].

Systemic therapy

Isotretinoin, acitretin, and alitretinoin represent effective treatments for Darier disease, producing significant improvement in ~90% of patients[22,53]. However, the use of these agents is limited by their side effects, and relapse occurs after cessation of therapy. Thus, it is generally recommended that systemic retinoids be reserved for patients with severe disease unresponsive to topical treatment. Because of the teratogenic potential of systemic retinoids, contraception is mandatory for women of childbearing potential (see Ch. 126). Individual dose titration is important to optimize the benefit–risk balance and avoid excessive dose-related side effects, such as mucocutaneous dryness and elevation of serum lipids. Intermittent therapy to prevent exacerbations during the summer months is a useful approach. In patients with predominantly bullous or intertriginous lesions, oral retinoids may aggravate the disease and are not recommended[54].

Oral contraceptives may mitigate symptoms in women with premenstrual exacerbations[55]. Cyclosporine represents an option for patients with severe Darier disease who cannot tolerate or do not respond to oral retinoids[56]. Low-dose intravenous immunoglobulin was also reported to reduce crusting and pruritus in a patient with Darier disease[57]. Oral antibiotics and antifungal medications are often required for significant infections, and oral antivirals (e.g. valacyclovir) are necessary for KVE.

Surgical therapy

Surgical therapy may be an effective alternative for focal recalcitrant lesions, particularly in the flexural and gluteal areas. Excision followed by split-thickness grafting, dermabrasion, or laser removal (CO_2 or erbium:YAG) may yield a long-term remission[58]. Destructive treatment must include the follicular infundibulum in order to prevent recurrences. Experience is necessary to avoid scarring, particularly in body areas at risk for hypertrophic scar or keloid formation. From this standpoint, the erbium:YAG laser might have an advantage over the CO_2 laser[59]. In small case series, improvement has been observed following pulsed dye laser and photodynamic therapy[60].

HAILEY–HAILEY DISEASE

Synonym: ■ Familial benign chronic pemphigus

Key features

- An uncommon autosomal dominant disorder in which mutations in *ATP2C1* result in dysfunction of a Golgi-associated Ca^{2+} ATPase, thus interfering with intracellular Ca^{2+} signaling
- Clinically, flaccid blisters and erosions are seen in intertriginous areas, especially the axillae and groin; moist, malodorous vegetations and fissures may develop
- Segmental variants (types 1 and 2 mosaicism) can occur
- The major histologic finding is acantholysis throughout the spinous layer, sometimes referred to as a "dilapidated brick wall"

Introduction

HHD is an autosomal dominant genodermatosis characterized by vesicular and erosive lesions that favor the intertriginous areas,

especially the axillae and groin. Mutations in *ATP2C1*, which encodes the Golgi-associated Ca^{2+} ATPase hSPCA1, lead to abnormal intracellular Ca^{2+} signaling, resulting primarily in a loss of cellular adhesion (acantholysis) in the stratum spinosum.

History

In 1939, Howard and Hugh Hailey, brothers working in the Department of Dermatology at Emory University School of Medicine in Atlanta, Georgia, described a chronic dermatosis in two sets of brothers. The disorder was characterized by recurrent blisters and erosive, crusted lesions on the neck (in one pair of brothers) and in the axillae and groin (in the second pair)[61]. Histologic sections from all four patients showed similar features – intraepidermal vesicles, mild dyskeratosis, hyperkeratosis, and a moderate dermal lymphocytic infiltrate. Different dermatopathologists interpreted these findings variably as pemphigus, pemphigus-like, or Darier disease. The authors themselves rightly believed that they were dealing with a novel entity separate from Darier disease and coined the name "familial benign chronic pemphigus".

A disease called "pemphigus congénital familiale héréditaire" had been described 6 years prior to the report by the Hailey brothers. Therefore, some believe that HHD should also bear the name of the French dermatologists Gougerot and Allée. However, they did not perform a biopsy, and the early onset and initial localization on pressure points suggest that their patients may have actually suffered from epidermolysis bullosa simplex[62]. The subsequent controversy as to whether "familial benign chronic pemphigus" was a distinct disorder or a phenotypic variant of Darier disease was eventually solved by our understanding of the molecular genetics of both disorders.

Epidemiology

There are no data regarding the exact prevalence of HHD. Based upon clinical experience, HHD is seen nearly as often as Darier disease. The mode of inheritance is autosomal dominant with complete penetrance, but the age of onset and expressivity vary markedly amongst affected family members[63,64]. Particular mutations may be associated with primarily genitoperineal involvement[65] or milder phenotypes[66].

Pathogenesis

HHD is caused by mutations in *ATP2C1*[67,68], which encodes hSPCA1, a Ca^{2+} ATPase that is localized to the Golgi apparatus[69,70] (see Fig. 59.1). hSPCA1 transports Ca^{2+} and Mn^{2+}, and it sequesters Ca^{2+} within the Golgi lumen. HHD is likely caused by haploinsufficiency and most *ATP2C1* mutations encode premature termination codons[71,72].

Acantholysis due to *ATP2C1* mutations appears to be mediated via impaired Ca^{2+} sequestration, resulting in depletion of Ca^{2+} within the Golgi lumen[69]. Normal Golgi Ca^{2+} levels are required for proper protein processing[73], and Golgi Ca^{2+} depletion in HHD keratinocytes impairs the processing and translocation of junctional proteins that function in cell–cell adhesion. Lesional skin from HHD patients shows decreased staining for extracellular desmosomal components[74], and altered synthesis of tight junction proteins has been observed in hSPCA1-deficient keratinocytes[75]. Reduced ATP levels in HHD keratinocytes have also been associated with impaired actin reorganization, which may affect adherens junction formation[76]. Lastly, decreased calcium levels in basal keratinocytes of lesional HHD epidermis may be linked to abnormal localization of ATP receptors and aberrant expression of keratins 10 and 14[18].

Clinical Features

Onset and clinical pattern

The initial lesions and associated symptoms usually develop during the second or third decade of life but may be delayed until the fourth or fifth decade[63]. HHD has a predilection for intertriginous sites, such as the axillae, groin, lateral aspects of the neck, and perianal region (Fig. 59.15A & C; see Fig. 59.4). The scalp, antecubital and popliteal fossae, and trunk are less frequently involved[77] (Fig. 59.15D). Inframammary and vulvar lesions are common in women (Fig. 59.15B), and female patients occasionally present with isolated vulvar disease[78].

The primary lesion is a flaccid vesicle on erythematous or normal-appearing skin, which ruptures easily and therefore is often overlooked (see Fig. 59.15A). The blisters give rise to macerated or crusted erosions (see Fig. 59.15B–D), which tend to spread peripherally, producing a circinate border with crusts and small vesicles when examined carefully

Fig. 59.15 Hailey–Hailey disease. A Erythematous, eroded plaque in the axilla. Note the intact flaccid vesicles at 2 and 7 o'clock. **B** Chronic submammary lesion with erosions in a worm-eaten pattern. **C, D** Vegetative plaques with erosions on the neck (**C**) and central chest (**D**). *C, D, Courtesy Jonathan S. Leventhal, MD.*

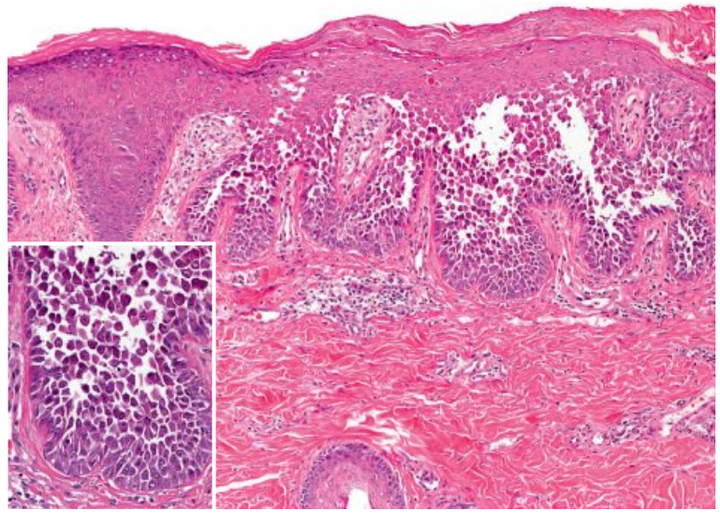

Fig. 59.17 Histopathology of Hailey–Hailey disease. Focal crusting and acantholysis beginning in the suprabasilar area and extending throughout the epidermis. The latter has been likened to a "dilapidated brick wall". *Courtesy Lorenzo Cerroni, MD.*

(Fig. 59.16). Development of chronic, moist, malodorous vegetations and painful fissures is common. Healing occurs without scarring, leaving postinflammatory hyperpigmentation.

Longitudinal leukonychia of the fingernails may serve as a subtle diagnostic clue in patients with limited or atypical disease[79]. Involvement of the buccal, vaginal, or conjunctival mucosae is rare[80–82].

Symptoms

Painful intertriginous erosions and crusting may interfere with activities of daily living. Fetid odor and pruritus add to the psychosocial distress experienced by HHD patients.

Modifying factors

Given the abnormal cell–cell adhesion within the epidermis, friction can induce new lesions. Heat and sweating can also exacerbate HHD, and patients often note worsening during the summer months. Although *ATP2C1* mRNA expression in keratinocytes can be suppressed by UVB irradiation[23], UV exposure does not appear to influence the course of HHD[63]. Microbial colonization and secondary infections are important modifying factors, as discussed below. In particular, staphylococcal infection potentiates acantholysis and may lead to severe and widespread blistering[83].

Course of the disease

Complete remissions as well as flares are common, and the clinical course in an individual patient is difficult to predict. Some patients report attenuation of the disease at an older age, whereas others experience no change or worsening over time[77]. Life expectancy is not altered.

Complications

Infections

As in Darier disease, colonization and secondary bacterial, fungal, and viral infections play an important role in disease exacerbation and persistence[84,85]. Vegetating lesions and malodor suggest bacterial and/or fungal overgrowth. Topical and/or systemic antimicrobial agents may be required to induce a clinical remission.

Recalcitrant intertriginous lesions have been described in association with HSV infections[84]. PCR-based testing, direct fluorescent antibody assays, or viral culture of infected keratinocytes can confirm this diagnosis; occasionally, a skin biopsy is required. KVE due to HSV is a rare complication of HHD[86]. It is characterized by fever and a rapidly spreading vesicular eruption, and prompt treatment with a systemic antiviral medication (e.g. valacyclovir, acyclovir) is required.

Malignant transformation

There are a few case reports of cutaneous squamous cell carcinoma developing within chronic lesions of HHD in the anogenital region[87]. It is possible that impairment of the structural integrity of the epidermis may predispose patients to infection with oncogenic strains of HPV (see Ch. 79).

Clinical subtypes of Hailey–Hailey disease

Segmental type 1

Segmental type 1 HHD is caused by a heterozygous postzygotic mutation in an otherwise normal embryo, resulting in a mosaic distribution of disease with age of onset and severity similar to the non-mosaic phenotype. Only a few cases of segmental type 1 involvement in HHD have been reported.

Segmental type 2

There are rare patients with generalized HHD who also have a segmental area of more pronounced involvement with earlier onset, analogous to type 2 segmental lesions described previously for Darier disease. This results from postzygotic inactivation of the normal *ATP2C1* allele (loss of heterozygosity), which leads to more severe disease in a mosaic pattern[88]. Unlike HHD due to a heterozygous mutation, the affected segments display acantholysis within adnexal structures, which might make it impossible to eradicate foci of blistering using superficial ablative methods (see below).

Pathology

Whereas acantholysis in Darier disease occurs primarily within discrete foci, the loss of intercellular bridges in HHD is generally more widespread within the epidermis. Thus, larger areas of dyscohesion with single or groups of acantholytic cells are seen, which have been likened to a "dilapidated brick wall". Dermal papillae, lined by a single layer of basal cells, protrude into the blister cavities and are referred to as "villi" (Fig. 59.17). In contrast to Darier disease, necrotic keratinocytes are uncommon, and only rare acantholytic dyskeratotic cells (e.g. "corps ronds") may be observed. In more chronic lesions, epidermal hyperplasia, parakeratosis, and focal crusts are found. A moderate perivascular lymphocytic infiltrate is observed in the superficial dermis.

Histologically, Grover disease may be indistinguishable from HHD, but these two entities are readily distinguished on the basis of clinical features. DIF is negative, thus excluding pemphigus vulgaris.

Differential Diagnosis

The blisters in HHD are typically fragile and rupture easily. Therefore, clinical experience and a high index of suspicion may be necessary to diagnose HHD, especially in patients with limited disease. Lesions confined to the axillae or groin may be mistaken for intertrigo or candidiasis (see Fig. 13.4). Isolated perianal maceration is easily misdiagnosed as irritant dermatitis, and vulvar involvement may resemble lichen simplex chronicus[78]. Histologic examination of affected skin is often the key to the diagnosis.

The lesions of inverse psoriasis have sharper borders, fewer erosions, and less crusting. A total skin examination, looking for additional sites of involvement and associated signs, e.g. nail pitting, will aid in the diagnosis. Vegetating intertriginous lesions in HHD may be identical to those of pemphigus vegetans (Hallopeau type) or pemphigoid vegetans, but the latter can be differentiated by positive DIF of perilesional skin.

The cutaneous features of HHD and Darier disease may overlap. Older reports described patients with characteristic skin findings of both genodermatoses who therefore carried two diagnoses[89], but genetic analysis can now establish a single diagnosis in such individuals. In general, the two disorders have different patterns of distribution that are fairly easily distinguished (see Fig. 59.4). Moreover, a predominantly vesicular eruption in patients with Darier disease is rare[20]. Additional features such as V-shaped notches in the distal free edge of the nail plate, longitudinal erythronychia, and oral papules point to the diagnosis of Darier disease.

Treatment

General measures

There is no specific therapy for the acantholysis. Wearing lightweight clothes is recommended to avoid friction and sweating, and adhesive dressings should be avoided. Colonization and secondary bacterial, fungal, and viral infections are addressed via antimicrobial cleansers or bleach baths and appropriate topical and/or systemic antimicrobial agents, respectively.

Topical and intralesional therapy

Topical corticosteroids often help to reduce inflammation and can be combined with topical antimicrobials and cleansers. Early application of corticosteroids may ameliorate flares[63], and injections of intralesional corticosteroids can be tried for persistent lesions. In order to minimize the potential side effects of topical corticosteroids in intertriginous zones (e.g. atrophy, striae, telangiectasias), the lowest potency that is effective should be used and they should be applied intermittently. Both improvement and worsening following treatment with topical calcineurin inhibitors have been described[90,91].

In case reports, improvement has been observed with topical application of 5-fluorouracil[92] and vitamin D analogues[93]. Of note, there are multiple reports of substantial improvement of HHD in the axillae, inframammary area, and groin after chemodenervation of sweat glands with botulinum toxin injections[94,95]. Application of zinc oxide paste in skin folds to protect against friction and moisture may also be helpful[90].

Surgical and physical therapy

Surgical therapy may be considered for disease unresponsive to general measures and topical treatments. While wide excision followed by grafting has been reported to be successful[96], this aggressive approach has been replaced by more superficial ablative techniques. The most well-documented method is dermabrasion[97], but laser vaporization of the epidermis (scanned CO_2 or erbium:YAG) seems to be equally effective[59]. Removal of the diseased epidermis plus its dermal niche of fibroblasts, which can extend to the level of the mid dermis, is recommended. Re-epithelialization from the spared adnexal structures normally occurs within 7–14 days. Benefit has also been reported with electron beam radiation[98], photodynamic therapy[99], and combination of narrowband UVB phototherapy with an oral retinoid[100].

Systemic therapy

With the exception of antimicrobial agents for secondary infections, there is no strong evidence to support the use of systemic therapies in HHD. A case series described improvement with long-term continuous or intermittent doxycycline administration in 6 patients with HHD[101], but the benefits of this treatment regimen vary (author's personal observations). Low-dose naltrexone may have some efficacy and is well-tolerated; results in case series have ranged from clinical improvement in 7 of 8 patients, with a 77% mean reduction in areas of involvement, to a sustained response in only 2 of 14 patients, with initial improvement then relapse in 6 and no response in 6 individuals[102]. Oral acitretin and isotretinoin also have variable efficacy[63], while successful results with alitretinoin have been reported in several patients[103]. There are anecdotal reports of severely affected individuals improving with the use of immunomodulatory drugs, e.g. prednisone, cyclosporine, methotrexate, dapsone, or afamelanotide[104–106]. In one case series, apremilast led to improvement in 4 patients (with relapse in 2 individuals after >6 months of treatment), but another report described no response to apremilast in 4 of 5 patients[107–109].

INTRODUCTION

Primary immunodeficiencies represent a heterogeneous group of inherited disorders characterized by immune system defects that result in susceptibility to infections as well as additional manifestations such as autoimmunity, allergy, and malignancy. The molecular bases have been defined for >450 monogenic primary immunodeficiency diseases, providing valuable insight into the functions of the human immune system[1–4].

Patients with genetic immunodeficiency disorders often manifest with cutaneous abnormalities[1,3]. Some of these skin findings are highly characteristic of a particular disorder, while others, such as eczematous or granulomatous dermatitis, are shared by other immunodeficiencies[5,6] (Table 60.1). Table 60.2 provides an overview of the current classification system for immunodeficiency disorders and lists conditions that are covered in other chapters.

In general, immunodeficiency should be suspected when patients have recurrent infections of longer duration and greater severity or caused by unusual organisms. Additional signs may include incomplete clearance of infections or a poor response to antimicrobial therapy. Screening laboratory tests for a patient with recurrent cutaneous infections that raise suspicion of a primary immunodeficiency are listed in Table 60.3[7]. Determination of the genetic etiology, which may require multigene panels or whole-exome sequencing, can provide prognostic information and improve management[8].

ATAXIA–TELANGIECTASIA

Synonym: ■ Louis–Bar syndrome

Key features

- Progressive cerebellar ataxia
- Oculocutaneous telangiectasias, initially of the bulbar conjunctivae
- Selective deficiency of humoral and cell-mediated immunity, leading to sinopulmonary infections
- Increased sensitivity to ionizing radiation
- Leukemias and lymphomas

Introduction

Ataxia–telangiectasia (AT) is characterized by oculocutaneous telangiectasias, progressive cerebellar ataxia beginning in infancy, a variable immunodeficiency with a tendency to develop sinopulmonary infections, and chromosomal instability with persistent DNA damage after exposure to ionizing radiation.

Epidemiology

AT is an autosomal recessive disorder that occurs in 1 in 40 000 to 100 000 live births, with a carrier rate of up to 1% of the population.

Pathogenesis

AT results from mutations in the ataxia–telangiectasia mutated gene (*ATM*), which encodes a phosphatidylinositol 3-kinase-like serine/threonine protein kinase that plays a central role in activating apoptotic and cell cycle responses to DNA damage, particularly double-stranded breaks[9]. These DNA breaks are sensed directly by the MRN (MRE11–RAD50–nibrin [NBN]) complex, which recruits ATM and triggers its dissociation from inactive multimers to active monomers[10,11]. Autophosphorylated ATM monomers subsequently activate (via phosphorylation) a variety of targets, including p53, BRCA1, FANCD2, and Artemis in addition to NBS1 and MRE11. The result is cell cycle arrest and facilitation of DNA repair, both in the setting of external insults (e.g. ionizing radiation) and in the processing of physiologic DNA breaks that occur during V(D)J recombination in lymphocytes, telomere maintenance, and meiosis[9]. This provides an explanation for the sensitivity to ionizing radiation, immunodeficiency, premature aging, and defective spermatogenesis that are observed in patients with AT. Progressive neurologic deterioration in affected individuals likely reflects defective DNA repair in a cell population that cannot replicate. Oxidative stress related to ATM dysfunction has also been implicated in the pathogenesis of the disease.

Of note, mutations in genes encoding components of the MRN complex cause conditions with manifestations similar to AT. *MRE11* mutations underlie the *AT-like disorder*, which features radiosensitivity and neurologic manifestations but no telangiectasias, and *NBN* or rarely *RAD50* mutations result in *Nijmegen breakage syndrome* characterized by microcephaly, immunodeficiency, chromosomal instability, and cancer predisposition.

Clinical Features

The first manifestation of AT is usually ataxia, which typically appears when the affected child begins to walk. However, the diagnosis is often not recognized until the oculocutaneous telangiectasias are well developed, at a median age of 6 years[12]. The telangiectasias first appear at 3–6 years of age on the lateral and medial bulbar conjunctivae as red, symmetric horizontal streaks (Fig. 60.1A). Telangiectasias subsequently develop on the ears, eyelids, malar prominences, antecubital and popliteal fossae, and presternal area, and less commonly on the dorsal aspects of the hands and feet as well as the hard and soft palate. The non-facial cutaneous telangiectasias are often subtle, resembling fine petechiae (Fig. 60.1B).

Progeric changes of the skin and hair are noted in almost 90% of patients. Subcutaneous fat is lost early and the facial skin tends to become atrophic and sclerotic. Gray hairs frequently appear in young children, and diffuse graying of the hair may occur by adolescence. Another common manifestation of AT is cutaneous granulomas (Fig. 60.1C), which are often associated with persistent rubella virus

CUTANEOUS FINDINGS IN PRIMARY IMMUNODEFICIENCY DISORDERS										
Disorder	***S. aureus* infections**		**CMC**	**Warts**	**Eczematous dermatitis**	**Granulomatous dermatitis***	**LE**	**SVV**	**Ulcers (PG-like)**	**Other findings**
	Superficial pyodermas	**Abscesses**								
Ataxia–telangiectasia	+	+			+	+ (often ulcerate)				Oculocutaneous telangiectasias, progeric changes, CALM, BCC
Chédiak–Higashi syndrome	+	+							+	Pigmentary dilution, hyperpigmentation in sun-exposed sites, silvery hair, bleeding diathesis, gingivitis
Chronic granulomatous disease	++	++	+		+	++ (nodular, necrotic)	+		+	DLE in female carriers, Sweet syndrome, oral ulcers
Chronic mucocutaneous candidiasis			++			(++, but infectious due to *Candida*)				Dermatophyte infections, vitiligo, alopecia areata
Common variable immunodeficiency	+	+	+	+	+	++	+	+	+	Dermatophyte infections, vitiligo, alopecia areata
Complement deficiencies	+	+	+				++	+	+	Dermatomyositis, urticaria, lipodystrophy (C3), JIA
DiGeorge syndrome†			+		+	+				
Hyper-IgE syndromes (HIES)	++	++ (cold)	+	‡	++					Neonatal papulopustular eruption (STAT3)
Hyper-IgM syndrome	+	+		+		+	+		+	Oral ulcers
Idiopathic $CD4^+$ lymphocytopenia			+	++			+			$CD4^+$ T cells <300/mm^3 or <20%¶, severe HSV infections, cryptococcal meningitis, non-tuberculous mycobacterioses, lymphoma
IgA deficiency	+	+	+		+		+	+	+	Vitiligo, lipodystrophia centrifugalis abdominalis
IgM deficiency	+	+		+	+		+			
IL-1 receptor-associated kinase-4 (IRAK-4) deficiency	++	++ (cold)	+							
Leukocyte adhesion deficiency		++ (necrotic)							++	Poor wound healing, delayed separation of the umbilical stump, gingivitis
SCID	+	+	+	+	+	+*				GVHD, erythroderma; Omenn syndrome
TAP deficiency						++		+	+	
WHIM syndrome	+	+		++		+				
Wiskott–Aldrich syndrome	++	+			++	+		+		Bleeding diathesis
X-linked agammaglobulinemia	+	++			+	+				Dermatomyositis-like eruption (due to echovirus); ecthyma gangrenosum

*Granulomatous dermatitis associated with persistent rubella virus infection (vaccine derived > wild type) has been identified in patients with these and other disorders characterized by T cell lymphopenia and/or defective lymphocyte cytotoxicity, including Griscelli syndrome type 2 and familial hemophagocytic lymphohistiocytosis. Extensive cutaneous and extracutaneous granulomatous disease (including destructive midfacial granulomas) has also been described in children with hypomorphic *RAG1* or *RAG2* mutations.
†Defective thymic function, hypocalcemia secondary to hypoparathyroidism, congenital heart defects, and craniofacial anomalies; due to 22q11 deletions.
‡Patients with DOCK8 deficiency are also at increased risk of developing mucocutaneous squamous cell carcinoma and severe warts, molluscum contagiosum, and herpes simplex or varicella–zoster viral infections.
¶On more than one occasion with no evidence of HIV infection and the absence of any defined immunodeficiency or immunosuppressive therapy.

SCREENING LABORATORY TESTS TO ASSESS FOR A PRIMARY IMMUNODEFICIENCY IN A PATIENT WITH RECURRENT CUTANEOUS INFECTIONS		
Test	**Finding**	**Immunodeficiency identified**
Complete blood count with differential, platelet count, and examination of smear	• Giant granules within neutrophils, ± neutropenia • Neutrophilia • Small platelets, thrombocytopenia	Chédiak–Higashi syndrome Leukocyte adhesion deficiency Wiskott–Aldrich syndrome
Hair shaft examination	• Small, regular clumps of melanin • Large, irregular clumps of melanin	Chédiak–Higashi syndrome Griscelli syndrome (type 2; *RAB27A*)
Quantitative immunoglobulins	• All Ig ↓ • IgA ↓, IgG ↓, ± IgM ↓ • IgA ↓ or IgM ↓ • IgM ↑, all other Ig ↓ • IgM ↑, ± IgA ↑, ± IgG ↓ • IgA ↓, IgE ↓, $IgG_{2,4}$ ↓ • IgE ↑↑ • IgM ↓, ± IgG ↓, IgA ↑, IgE ↑	X-linked agammaglobulinemia Common variable immunodeficiency Selective IgA or IgM deficiency Hyper-IgM syndrome Hypohidrotic ectodermal dysplasia with immunodeficiency Ataxia–telangiectasia Hyper-IgE syndrome Wiskott–Aldrich syndrome
Total hemolytic complement (CH50)	• Marked ↓	Various complement deficiencies
Dihydrorhodamine (DHR) flow cytometric assay	• Marked ↓ fluorescence (% of neutrophils and intensity)	Chronic granulomatous disease
T and B cell analysis by flow cytometry	• Lack of T cells ± B cells	Severe combined immunodeficiency

Table 60.3 Screening laboratory tests to assess for a primary immunodeficiency in a patient with recurrent cutaneous infections.

infection (vaccine strain > wild type)[13,14]. These granulomatous plaques tend to be persistent and ulcerate, leading to significant discomfort. Children with AT often have hyper- or hypopigmented macules as well as hyper- and/or hypopigmentation along the lines of Blaschko, with chromosomal instability likely explaining their predisposition to pigmentary mosaicism. Other dermatologic findings that have been described in individuals with AT include a facial papulosquamous rash, poikiloderma, hypertrichosis favoring the arms, warts, and acanthosis nigricans[15].

Cerebellar ataxia usually begins during infancy and is characterized by swaying of the head and trunk. Choreoathetosis, dysarthric speech, oculomotor abnormalities, and myoclonic jerks often become prominent during childhood. Despite good muscle strength, patients are typically confined to a wheelchair by 11 years of age. The facies become dull and hypotonic, with mask-like changes developing concurrently with progressive progeric features. Of note, milder AT with onset of neurologic manifestations in adulthood has been described in individuals with *ATM* mutations that result in residual kinase activity.

Chronic or recurrent sinopulmonary infections occur in >80% of AT patients[16], with the most common cause of death being bronchiectasis with respiratory failure. The majority of affected individuals also have evidence of glucose intolerance, hyperinsulinemia, and insulin resistance. Additional manifestations of AT include growth delay (>70%), hypogonadism (especially in female patients), and intellectual disability (~30%)[17].

Although lymphoid malignancy has been reported as the presenting sign of AT during infancy, most neoplasias occur in young adults. Patients who survive into their late teenage years have an up to 40% risk of developing a malignancy, especially leukemia (70-fold increase compared to unaffected individuals) and lymphoma (200-fold increase). Occasionally, patients develop basal cell carcinomas (BCCs) during the third decade of life.

Carriers of heterozygous ATM mutations have a two- to threefold increase in both the risk of developing breast cancer and the likelihood of death from cancer, including malignancies of the stomach, colon, and lung as well as the breast. There is greater excess mortality in individuals <50 years of age[18].

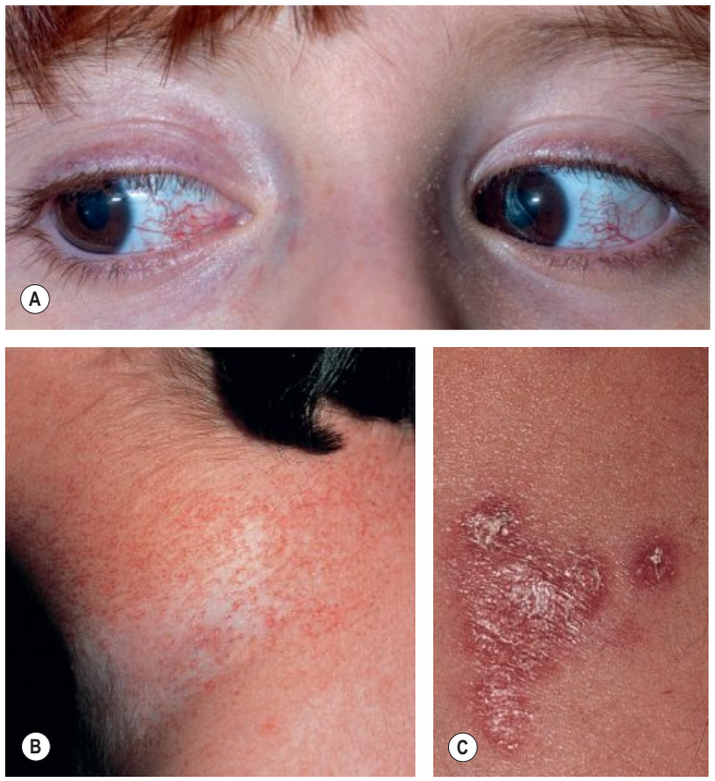

Fig. 60.1 Ataxia–telangiectasia (AT). A Linear telangiectasias on the medial and lateral bulbar conjunctivae of a girl with AT. Punctate and smaller linear telangiectasias are also present on the eyelids. **B** Extensive telangiectasias on the neck of a young woman with AT. **C** Persistent granulomatous plaques on the leg of a child. These lesions often ulcerate and are difficult to manage. *A, Courtesy Edward Cowen, MD.*

Laboratory Findings

Immunologic defects in patients with AT include: (1) decreased serum levels of IgE, IgA, and IgG (especially IgG_2 and IgG_4) in ~80%, 70%, and 60% of patients, respectively; (2) low-molecular-weight (8 S) IgM (in 80% of patients) and increased serum levels of IgM (in a minority of patients); and (3) defects in cell-mediated immunity such as lymphopenia (in 70% of patients) and deficient *in vitro* responses to antigens and mitogens[16]. Affected individuals tend to have a relative deficiency of $CD4^+$ T cells and an excess of γ/δ T cells as well as elevated serum levels of interleukin-8 (IL-8), a chemokine that may contribute to pathogenic inflammation in AT. Most patients have an absent or abnormal thymus. Individuals with no ATM activity have more severe immunologic deficits than those with low levels of ATM activity[19].

Spontaneous chromosomal abnormalities such as fragments, breaks, gaps, and translocations occur 2–18 times more frequently in patients with AT than in unaffected individuals, and an increased rate of telomeric shortening is also observed. Rearrangements of chromosomes 7 and 14 are particularly common and may predict the development of lymphoma. Fibroblast DNA from both patients and carriers is extremely sensitive to ionizing radiation and to radiomimetic agents such as bleomycin.

Almost all patients with AT have elevated levels of α-fetoprotein and carcinoembryonic antigen, and measuring the former can support the diagnosis in individuals ≥2 years of age. Hepatic transaminase levels are also mildly elevated in approximately half of patients, and MRI often shows cerebellar atrophy by early childhood. Additional traditional diagnostic clues include radiosensitivity testing with the colony survival assay, analysis of radioresistant DNA synthesis (which demonstrates an abnormal S phase checkpoint), and karyotyping to identify 7;14 translocations. Sequencing the *ATM* gene or immunoblotting for the ATM protein may be utilized to confirm the diagnosis. Prenatal diagnosis of AT can be performed when parental mutations have been identified.

Differential Diagnosis

Children with AT may be thought to have Friedreich ataxia until the ocular telangiectasias become apparent. The conjunctival telangiectasias are occasionally misdiagnosed as conjunctivitis, but the chronicity and size of the telangiectatic vessels distinguish AT. Bloom syndrome can present with facial and occasionally conjunctival telangiectasias, café-au-lait macules, decreased immunoglobulin levels, recurrent respiratory infections, and hematologic malignancies, but patients do not have neurologic abnormalities (see Ch. 87). FILS syndrome – *f*acial dysmorphism, *i*mmunodeficiency, *l*ivedo, and *s*hort stature – due to polymerase ε 1 (*POLE1*) mutations has overlapping features and can also present with telangiectasias or poikiloderma. RIDDLE syndrome is an autosomal recessive condition that features *r*adiosensitivity, *i*mmunodeficiency, facial *d*ysmorphism, *d*ifficulty *le*arning, abnormal motor control, and short stature due to mutations in *RNF168*, which encodes a protein that mediates ubiquitin-dependent signaling at sites of DNA double-stranded breaks.

Treatment

The median lifespan in patients with AT is now >25 years. More than half of patients die from chronic sinopulmonary disease and up to a third succumb to a malignancy or complications of cancer treatment. Some of the patients who survive into adulthood show improvement in neurologic and immunologic status.

Therapy is supportive:

- antibiotics for infections; prophylactic antibiotics and IVIg replacement therapy for patients with severe immunodeficiency
- avoidance of sun exposure and use of sunscreens
- early physiotherapy for patients with bronchiectasis and consideration of systemic corticosteroid therapy for interstitial lung disease
- physical therapy to prevent contractures related to neurologic dysfunction
- screening for the development of malignancy.

If malignancy occurs, chemotherapy is typically necessary; radiation and radiomimetic chemotherapeutic agents, especially bleomycin, should be avoided. AT patients have a decreased threshold for postradiation erythema, tissue necrosis, and radiation-induced cutaneous malignancy. If radiation is necessary, restriction of the fractions to 1 Gy and total radiation to <20 Gy is recommended. Allogeneic hematopoietic stem cell transplantation with a reduced intensity conditioning regimen has been utilized in AT patients with hematopoietic malignancies or severe manifestations of immunodeficiency, including destructive rubella virus-associated cutaneous granulomas[20]. Because oxidative stress is thought to contribute to chromosomal instability, neurodegeneration, and malignancy in patients with AT, administration of antioxidants such as α-lipoic acid is often recommended; however, treatment with the latter together with nicotinamide did not improve neurologic or pulmonary function in a small controlled study[21]. In patients with truncating *ATM* mutations, treatment with aminoglycosides can induce read-through of premature termination codons and restore production of functional ATM protein, providing the basis for a potential therapeutic approach[22].

CHRONIC MUCOCUTANEOUS CANDIDIASIS

Key features

- Heterogeneous group of conditions characterized by recurrent and progressive candidal infections of the skin, nails, and mucosae
- Due to an impaired interleukin-17 response, which has a critical role in immune defense against *Candida*
- May be associated with additional autoimmune and infectious manifestations

Introduction

Chronic mucocutaneous candidiasis (CMC) represents a heterogeneous group of disorders characterized by progressive and recurrent infections of the skin, nails, and mucous membranes with *Candida* spp[23]. Affected individuals demonstrate an ineffective immune response against this

organism, and patients with an earlier onset and greater severity of candidal infections typically have more severe underlying immunologic abnormalities.

Epidemiology

*A*utoimmune *p*olyendocrinopathy–*c*andidiasis–*e*ctodermal *d*ystrophy syndrome (APECED) has autosomal recessive inheritance[24], and other familial forms of CMC have autosomal dominant or recessive inheritance patterns (Table 60.4).

Pathogenesis

Patients with CMC have an abnormal immune response to *Candida* spp. and sometimes to other infectious organisms (Table 60.4).The immune defects that underlie selective predisposition to *Candida* infections in both APECED and non-APECED CMC patients involve an impaired response by T helper 17 (Th17) cells, which have a critical role in immune defense against *Candida* (Fig. 60.2)[25–27].

APECED results from mutations in the *AIRE* (*a*uto*i*mmune *re*gulator) gene, which encodes a transcription factor[28]. The AIRE protein regulates

VARIANTS OF CHRONIC MUCOCUTANEOUS CANDIDIASIS (CMC) IN CHILDREN AND ADOLESCENTS	
Subgroup	**Features**

CMC due to increased STAT1 signaling (most common form)	• Autosomal dominant due to gain-of-function *STAT1* mutations; see Fig. 60.2
	• Onset of mucocutaneous candidal infections at a mean age of 1 year – oropharynx (>95%), nails (60%), skin (50%)
	• Dermatophyte infections of skin and/or nails (15%)
	• Cutaneous autoimmune disorders, e.g. vitiligo, alopecia areata (10%)
	• Autoimmunity (40%)
	  • thyroid disease (25%)
	  • type 1 diabetes mellitus (5%)
	  • cytopenias (5%)
	  • colitis or celiac disease (5%), hepatitis (2%)
	  • systemic lupus erythematosus (2%)
	• Other infections (variable)
	  • cutaneous staphylococcal
	  • demodicosis
	  • bacterial pneumonia (e.g. pneumococcal, *Pseudomonas*; 50%), otitis, sinusitis
	  • recurrent/severe viral (e.g. HSV, VZV, EBV, CMV, orf; 40%)
	  • invasive fungal (e.g. *Candida*, *Aspergillus*, *Cryptococcus*, endemic dimorphic, mucormycosis, *Fusarium*; 10%)
	  • mycobacterial (tuberculosis, non-tuberculous; 5%)
	• Aneurysms (e.g. cerebral, aortic; 5%), mucocutaneous SCC (5%), dental enamel defects

CMC representing the main clinical phenotype (“CMC disease”)	• Autosomal dominant due to mutations in IL-17F (*IL17F*) or Jun N-terminal kinase 1 (JNK1; *MAPK8*); autosomal recessive due to mutations in IL-17 receptor A or C (*IL17RA* or *IL17RC*) and TRAF3-interacting protein 2 (*TRAF3IP2*; *ACT1*); see Fig. 60.2 • Oral candidiasis usually begins by age 6 months to 2 years • Cutaneous and ungual candidiasis also common • No associated endocrinopathy • Cutaneous staphylococcal infections (IL17RA or TRAF3IP2 deficiency) • Ehlers–Danlos syndrome-like joint hypermobility, skin hyperextensibility (mild), and atrophic scarring (JNK1 deficiency)

Autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy syndrome (APECED)*	• Caused by mutations in *AIRE*, usually with autosomal recessive inheritance
	• Increased prevalence among Finns, Iranian Jews, and Sardinians
	• *Mucocutaneous candidal infections*† with mean onset at age 3 years
	• Candidal granulomas, especially of the face and scalp
	• Autoimmune endocrinopathies, which may not be apparent until teenage or even adult years
	  • *hypoparathyroidism*† (90%)
	  • *hypoadrenocorticism*† (80%)
	  • hypogonadism (30%–50%)
	  • thyroid disease (20%)
	  • type 1 diabetes mellitus (20%)
	  • hypopituitarism (e.g. growth hormone deficiency; 15%)
	• Cutaneous autoimmune disorders
	  • alopecia areata (30%)
	  • vitiligo (20%)
	  • urticarial eruption‡ (up to 60%)
	  • lupus-like panniculitis
	• Other autoimmune disorders
	  • pernicious anemia (15%)
	  • hepatitis (15%–40%)
	  • pneumonitis (15%–40%)
	  • Sjögren-like syndrome (20%–40%)
	• Dental enamel hypoplasia (70%), chronic diarrhea (20%–80%), keratoconjunctivitis (20%), hyposplenism (15%), hypertension (15%), oral/esophageal SCC
	• Anti-type I interferon antibodies (nearly 100%); anti-thyroglobulin, anti-microsomal, anti-parietal cell, and anti-adrenal antibodies; rheumatoid factor
	• An autosomal dominant form of CMC associated with autoimmune thyroid disease may occur due to dominant-negative *AIRE* mutations and has also been linked to chromosome 2p in one family

CMC plus susceptibility to mycobacterial infections	• Autosomal recessive due to mutations in the retinoic acid receptor-related orphan receptor C gene (*RORC*) that lead to decreased IL-17 and interferon-γ production
CARD9-associated CMC	• Autosomal recessive form of CMC due to mutations in *CARD9*; see Fig. 60.2 • Chronic oral and vulvovaginal candidiasis; also dermatophytosis • Invasive fungal infections, e.g. candidiasis (especially of the brain during the second decade of life), dermatophytosis, phaeohyphomycosis

Table 60.4 Variants of chronic mucocutaneous candidiasis (CMC) in children and adolescents.

VARIANTS OF CHRONIC MUCOCUTANEOUS CANDIDIASIS (CMC) IN CHILDREN AND ADOLESCENTS	
Subgroup	**Features**
Dectin-1 deficiency	• Due to biallelic polymorphisms that result in a truncated dectin-1 protein; see Fig. 60.2 • Chronic/recurrent vulvovaginal candidiasis and onychomycosis
Late-onset CMC	• Initial infections in late childhood or early teenage years • Milder involvement than in other subgroups • Responses against *Candida albicans* may normalize after effective therapy
Familial chronic nail candidiasis	• Autosomal dominant form of CMC mapped to the pericentromeric region of chromosome 11 in a five-generation Italian family • Onset in infancy of candidiasis limited to the nails of the hands and feet • Association with low serum levels of intercellular adhesion molecule-1 (ICAM-1)
CMC associated with other immunodeficiency disorders	• Hyper-IgE syndromes due to STAT3 and DOCK8 deficiencies • Severe combined immunodeficiency • DiGeorge syndrome • Interleukin-12 receptor β1 and interleukin-12B (p40) deficiencies (see Fig. 60.2 and Table 60.13) • Autosomal dominant hypohidrotic ectodermal dysplasia with immunodeficiency (*NFKBIA* mutations) • Keratitis–ichthyosis–deafness (KID) syndrome
CMC associated with metabolic disorders	• Multiple carboxylase deficiency • Acrodermatitis enteropathica • Ectodermal dysplasia–ectrodactyly–clefting syndrome

*Ectodermal dystrophy refers primarily to dental enamel hypoplasia; also known as autoimmune polyendocrine syndrome type 1.
†*Two of these three manifestations are classically required for diagnosis.*
‡Mean onset at age 1.5 years; histologically, focal vacuolar interface dermatitis plus mixed superficial and deep dermal perivascular infiltrates with karyorrhexis.

Table 60.4 Variants of chronic mucocutaneous candidiasis (CMC) in children and adolescents. CARD9, caspase recruitment domain family member-9; IL, interleukin; CMV, cytomegalovirus; EBV, Epstein–Barr virus; HSV, herpes simplex virus; MAPK9, mitogen-activated protein kinase 8; SCC, squamous cell carcinoma; STAT, signal transducer and activator of transcription; VZV, varicella–zoster virus.

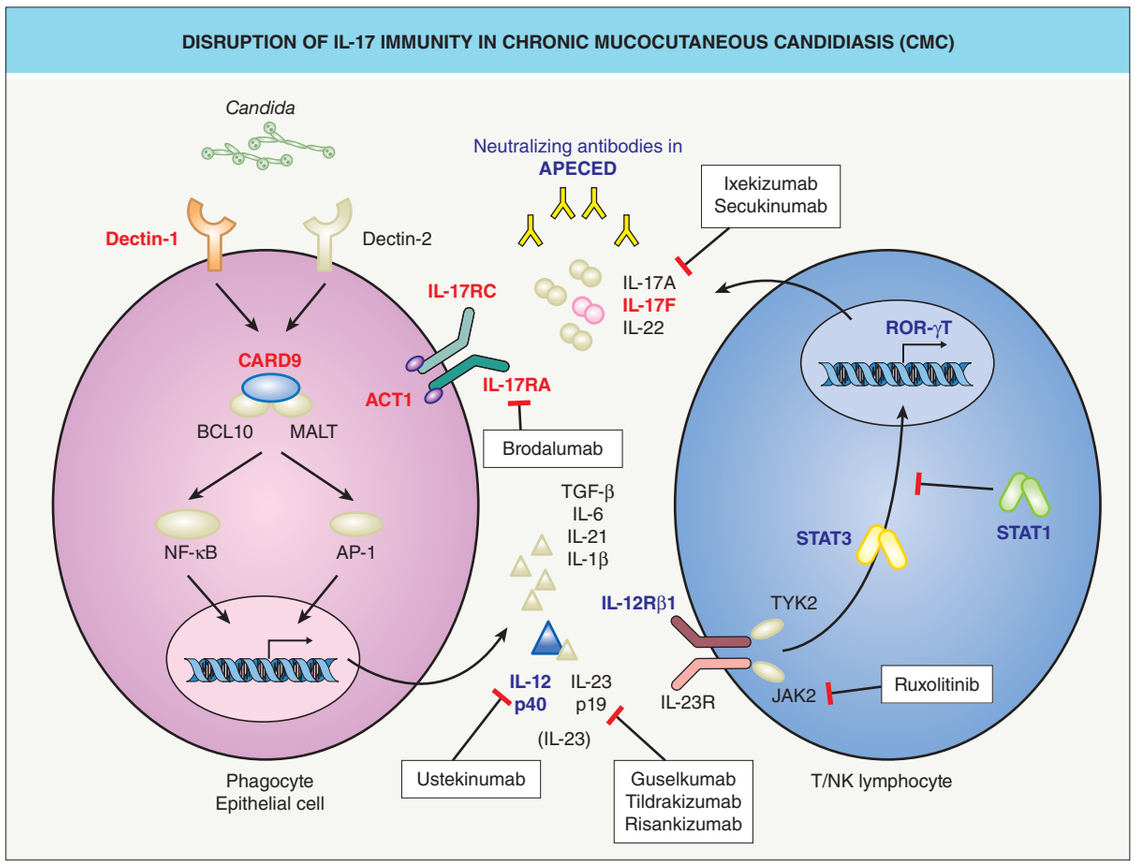

Fig. 60.2 Disruption of IL-17 immunity in chronic mucocutaneous candidiasis (CMC). Phagocytes, keratinocytes, and other epithelial cells detect *C. albicans* via pattern recognition receptors such as dectin-1/2 and produce proinflammatory cytokines including interleukin (IL)-6 and IL-23. This results in activation of T cells via signal transducer and activator of transcription 3 (STAT3) signaling, which upregulates expression of retinoic acid receptor-related orphan receptor γT (encoded by *RORC*) and leads to production of IL-17A, IL-17F, and IL-22. IL-17A/F signal via the IL-17 receptor (IL-17RA/C) and its ACT1 adaptor protein (TRAF3-interacting protein 2). Of note, STAT1 activation represses IL-17 production. In addition to genetic disorders that lead to CMC, several targeted immune modulators disrupt IL-17 immunity and can increase the risk of candidiasis, especially IL-17A and IL-17 RA inhibitors. **Red**: genetic defects implicated in *nonsyndromic* CMC ("CMC disease"). **Blue**: genetic defects and neutralizing antibodies implicated in *syndromic* CMC. See Table 60.4 for additional information on genetic forms of CMC. AP-1, activator protein 1; APECED, *a*utoimmune *p*olyendocrinopathy–*c*andidiasis–*e*ctodermal *d*ystrophy syndrome; CARD9, caspase recruitment domain family member-9; JAK2, Janus kinase 2; TGF-β, transforming growth factor β; TYK2, tyrosine kinase 2. *Adapted from Okada S, Puel A, Casanova JL, Kobayashi M. Chronic mucocutaneous candidiasis disease associated with inborn errors of IL-17 immunity. Clin Transl Immunol 2016;5:e114.*

the ectopic expression of self antigens in the thymus, which allows the development of peripheral tolerance via negative selection of autoreactive T cells and the generation of antigen-specific regulatory T cells[29,30]. In APECED patients, failure to delete autoreactive T cells leads to autoimmune disease[31]. Neutralizing autoantibodies targeting Th17-associated cytokines (e.g. IL-17A/F, IL-22) have been identified in APECED patients as well as individuals with thymoma-associated CMC[32].

Heterozygous gain-of-function mutations in *STAT1* (*s*ignal *t*ransducer and *a*ctivator of *t*ranscription *1*) have emerged as the most common cause of CMC[27,33]. The resulting STAT1 protein activation leads to increased interferon-α/β and -γ signaling as well as repression of IL-17 production, and clinical manifestations can include predisposition to other infections, autoimmunity, and aneurysms (Fig. 60.3; see Table 60.4)[34,35]. Other autosomal dominant forms of CMC are caused by deficiency in IL-17F or rarely Jun N-terminal kinase 1 (JNK1); the latter leads to decreased transforming growth factor β (TGF-β) as well as IL-17 signaling, producing features of hypermobile Ehlers–Danlos syndrome[36] (see Ch. 97). In addition, autosomal recessive forms of CMC can result from: (1) biallelic *IL17RA* or *IL17RC* mutations that disrupt function of the IL-17 receptor; or (2) *TRAF3IP2* (*ACT1*) mutations that prevent interaction between the IL-17 receptor and its TRAF3-interacting protein 2 adaptor molecule[27,37–40] (see Fig. 60.2).

CMC variants with autosomal recessive inheritance can also result from defects in the genes encoding dectin-1, a pattern-recognition receptor that binds to β-glucan in the *Candida* cell wall, and CARD9 (*ca*spase *r*ecruitment *d*omain family member-*9*), proteins that act together to activate a Th17 response (see Table 60.4)[41,42]. Decreased neutrophil function is also thought to contribute to invasive fungal infections in patients with CARD9 deficiency[32]. In other types of CMC, inadequate production of IL-23 and overproduction of IL-6, which result in an inefficient IL-17 response, have been observed.

Clinical Features

The clinical severity of CMC ranges from recurrent, treatment-resistant thrush (see Fig. 60.3A) or a few erythematous scaly plaques and dystrophic nails to severe, generalized, crusted granulomatous plaques. The cutaneous plaques occur most frequently on the scalp and in periorificial and intertriginous sites. Scalp infections may lead to scarring alopecia. Affected nails are thickened, brittle and discolored, with associated paronychia (Fig. 60.4). Although mucosal involvement is usually limited to oral thrush with hyperkeratotic plaques, chronic lesions of esophageal, genital, and laryngeal mucosae with resultant stricture formation may occur. Systemic candidiasis is rare, but cutaneous dermatophyte infections are common (see Fig. 60.3B,C). Up to 80% of patients with childhood-onset CMC develop recurrent or severe infections with organisms other than *Candida*, including occasional bacterial septicemia.

Subgroups of CMC in children and adolescents include those described in Table 60.4. An association of CMC with abnormalities of iron metabolism or (as noted above) thymoma has also been described in adult patients.

Laboratory Findings

Candidal organisms are confined to the stratum corneum and are demonstrable in scrapings and cultures. Approximately 70% of patients have direct evidence of an immunologic defect, including decreased lymphocyte proliferation *in vitro*, impaired cytokine production, and absent delayed-type hypersensitivity (DTH) in response to *Candida*, as well as nonspecific findings such as abnormal leukocyte chemotaxis or phagocytosis, depressed IgA levels, and complement dysfunction. These heterogeneous immune abnormalities reflect the variety of underlying etiologies. Candidal polysaccharides may act as serum factors that inhibit the immune response, and, in some patients, DTH to candidal antigens has been restored after antifungal therapy[28]. Autoantibodies against type I interferons have been shown to represent a sensitive and specific marker for APECED.

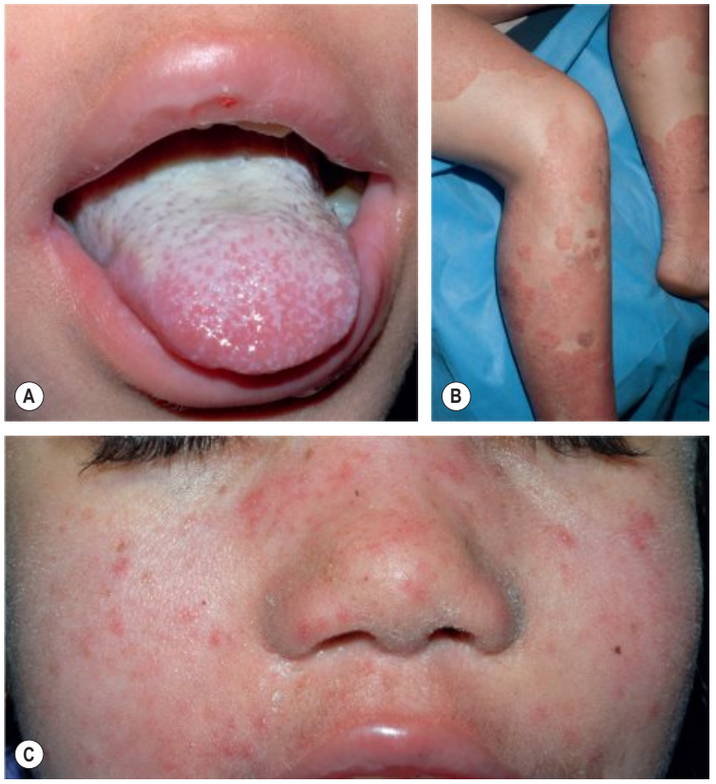

Fig. 60.3 Chronic mucocutaneous candidiasis and dermatophytosis due to increased STAT1 signaling. A Recalcitrant thrush on the tongue of a 6-year-old child. **B** Extensive tinea corporis with coalescing annular and polycyclic plaques on the legs. **C** Tinea faciei presenting as small pustules and diffuse scaling.

Fig. 60.4 Chronic mucocutaneous candidiasis. A, B Marked onychodystrophy with significant paronychial swelling and erythema (**A**) and crusted plaques on the palm (**B**) in patients with chronic mucocutaneous candidiasis. **C** Recurrent cutaneous candidiasis presenting as erythema, pustules, and scale-crust near the site of an intravenous line on the arm in an infant with DiGeorge syndrome.

Differential Diagnosis

Candidal infections, particularly thrush, are fairly common in infants. Recurrent thrush in young children with frequent otitis media may reflect alterations in bacterial flora caused by the administration of systemic antibiotics; this is seen much more often than CMC or other immunodeficiencies. Recurrent or recalcitrant candidal infections should prompt consideration of HIV infection. Clearance after traditional therapy helps to distinguish secondary candidal infections from mild CMC.

The IPEX (*i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked) syndrome (see below) can present with autoimmune skin conditions and endocrinopathies together with recurrent infections, but the latter are typically bacterial rather than candidal. Autoimmune endocrinopathies, enteropathy, eczematous dermatitis, and a predisposition to bacterial, viral, and fungal infections have also been described in patients with IL-2 receptor α-chain deficiency (see Table 60.6).

Treatment

Patients with CMC do not respond well to standard topical medications, and the cutaneous granulomas are especially difficult to treat. Most patients benefit from long-term therapy with systemic antifungal agents such as itraconazole and fluconazole, and alternative drugs that can be helpful in treating fluconazole-resistant *Candida* isolates include posaconazole, voriconazole, and echinocandins[43]. Adjunctive therapy with granulocyte colony-stimulating factor (G-CSF) may increase IL-17 production[44]; nail avulsion, drainage of abscesses, and debridement of thick crusted cutaneous plaques can also be beneficial. In patients with gain-of-function *STAT1* mutations, JAK inhibitors such as ruxolitinib may improve associated infectious and autoimmune disease[45].

Patients should be evaluated at least annually for the development of endocrinopathies, particularly if they have a diagnosis or family history of APECED or other forms of CMC with autoimmune manifestations.

CARTILAGE–HAIR HYPOPLASIA SYNDROME

Synonym: ■ McKusick-type metaphyseal chondrodysplasia

Key features

- Fine, sparse, hypopigmented hair
- Short-limbed dwarfism with metaphyseal dysostosis
- Doughy skin with abnormal elastic tissue
- Defective cell-mediated and (in a minority of patients) humoral immunity

Cartilage–hair hypoplasia (CHH) syndrome is a pleiotropic autosomal recessive disorder that occurs most commonly in Amish individuals and Finns. The condition results from mutations in *RMRP* which encodes the RNA component of a ribonucleoprotein endoribonuclease, RNase MRP; the latter cleaves RNA primers responsible for DNA replication in mitochondria and processes pre-rRNA in the nucleolus[46]. Impaired telomerase activity leading to decreased telomere length in lymphocytes may also have a pathogenic role in the immune deficiency associated with CHH[47].

Affected individuals are most likely to visit the dermatologist for their fine, sparse, hypopigmented hair, although they may also have soft, doughy skin with degenerated elastic tissue[48]. The short-limbed dwarfism results from metaphyseal dysostosis, and ligamentous laxity is often observed. Most patients have some degree of defective cell-mediated immunity, which predisposes them to severe varicella and herpes simplex viral (HSV) infections. Approximately a third of patients also have abnormal humoral immunity[49], most frequently an IgA or IgG deficiency, which increases their susceptibility to recurrent respiratory tract infections that can lead to bronchiectasis. Occasionally, affected individuals present with severe combined immunodeficiency and an Omenn syndrome-like phenotype with erythroderma, eosinophilia, chronic diarrhea, lymphadenopathy, and hepatosplenomegaly (see below). Neutropenia and anemia can develop due to autoimmunity or bone marrow hypoplasia. Hirschsprung disease, other autoimmune disorders, and impaired spermatogenesis represent additional manifestations of CHH. Patients also have an increased risk of developing non-Hodgkin lymphoma and BCCs.

Hematopoietic stem cell transplantation, which can restore function of the immune system and bone marrow, should be considered in patients with severe immunodeficiency or cytopenias.

CHÉDIAK–HIGASHI SYNDROME

Synonyms: ■ Béguez César–Steinbrinck syndrome ■ Chédiak–Higashi disease ■ Chédiak–Steinbrinck–Higashi syndrome ■ Chédiak–Steinbrinck anomaly

Key features

- Autosomal recessive disorder of vesicle trafficking that results in giant organelles, including melanosomes, leukocyte granules, and platelet dense granules
- Silvery hair is accompanied by mild diffuse pigmentary dilution, often with an admixture of hyper- and hypopigmentation in sun-exposed sites; a variable degree of photophobia and nystagmus
- Recurrent pyogenic infections and a mild bleeding diathesis
- An "accelerated phase" with pancytopenia and organomegaly due to lymphohistiocytic infiltration, which is fatal without hematopoietic stem cell transplantation
- Progressive neurologic deterioration in survivors

Epidemiology

Chédiak–Higashi syndrome (CHS) is a rare autosomal recessive disease reported most often in individuals of Northern European, Spanish, Middle Eastern, and Japanese ancestry[50]. Patients of African descent have also been described[51].

Pathogenesis

CHS represents a disorder of vesicle trafficking and is caused by mutations in the *lys*osomal *t*rafficking regulator gene (*LYST*)[52]. Most patients have frameshift or nonsense mutations that result in a truncated protein and lead to a severe phenotype with progression to a fatal lymphoproliferative "accelerated phase" during childhood, but 10%–15% of affected individuals have missense mutations that are associated with a milder phenotype and survival to adulthood[53].

The giant intracytoplasmic granules that characterize CHS result from dysregulated fission/fusion of lysosome-related organelles, which include melanosomes, platelet dense granules, and leukocyte cytolytic granules[50]. The latter granules cannot effectively migrate or discharge their peroxidative and proteolytic enzymes, leading to defective target cell killing. Localization of cytotoxic T lymphocyte-associated antigen (CTLA-4) to enlarged vesicles rather than the cell surface may play a role in the development of lymphoproliferative disease. In addition, defective autophagic lysosome reformation in neurons, generalized impairment in plasma membrane repair, and abnormal antigen presentation by B cells may contribute to the pathogenesis of CHS.

Clinical Features

Patients with CHS usually present in infancy with mild diffuse pigmentary dilution of the skin, hair, and eyes. In individuals with relatively dark constitutive pigmentation, areas of bronze to slate-gray hyperpigmentation may be evident in sun-exposed sites, often admixed with guttate hypopigmented macules. Hair color is variable, but a silvery, metallic sheen is characteristic. Decreased ocular pigment can result in photophobia, nystagmus, and strabismus, but visual acuity is usually normal.

Infections primarily involve the skin and respiratory tract, and they are typically caused by *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Streptococcus pneumoniae*. The skin infections are most often superficial pyodermas. Cutaneous ulcerations resembling pyoderma gangrenosum, gingivitis, and ulceration of the oral mucosa have also been described. Although the bleeding diathesis of CHS is generally mild, some patients experience easy bruising, petechiae, and epistaxis.

Approximately 85% of patients with CHS enter a lymphoproliferative "accelerated phase" characterized by pancytopenia and lymphohistiocytic infiltration of the liver, spleen, lymph nodes, oral mucosa, and other internal organs. This "hemophagocytic syndrome" results from uncontrolled T cell and macrophage activation, possibly associated with Epstein–Barr virus (EBV) infection, and typically leads to death by age 10 years from overwhelming infection or hemorrhage unless hematopoietic stem cell transplantation is performed.

Patients with CHS who survive the first decade of life experience progressive neurologic deterioration with abnormal gait, paresthesias, and developmental delay. Peripheral and cranial neuropathies, spinocerebellar degeneration, spastic paraplegia, parkinsonism, and dementia can manifest in adult patients who were treated with hematopoietic stem cell transplantation as children as well as in those with otherwise mild disease.

Pathology

The silvery hair of patients with CHS is characterized by clumps of melanin microscopically (Fig. 60.5), and giant melanosomes may be evident within melanocytes in skin biopsy specimens. A peripheral blood smear demonstrating abnormally large granules in the perinuclear area of granulocytes can assist in establishing the diagnosis. Immunologic defects in CHS include neutropenia, diminished leukocyte chemotaxis, impaired antibody-dependent cell-mediated cytotoxicity, reduced cytotoxic and regulatory T cell activity, and markedly decreased natural killer (NK) cell function.

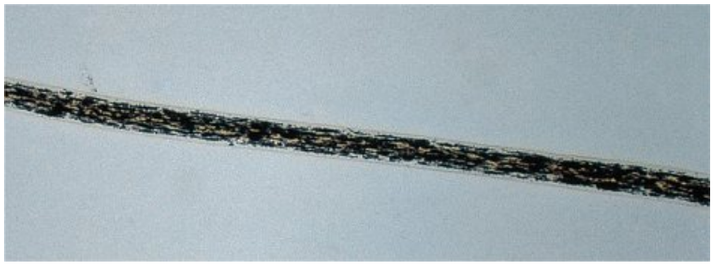

Fig. 60.5 Chédiak–Higashi syndrome. Light microscopic examination of hair shows small, regularly spaced clumps of melanin in patients with Chédiak–Higashi syndrome.

Differential Diagnosis

The features of CHS and the three types of Griscelli syndrome (GS), another autosomal recessive disorder that can present with immune dysfunction and silvery hair, are compared in Table 60.5 (see also Ch. 66). Although leukocytes generally have a normal appearance in GS, hypogammaglobulinemia can be observed. Hermansky–Pudlak syndrome (HPS) types 2, 9, and 10 (*AP3B1*, *BLOC1S6*, and *AP3D1* mutations, respectively; see Table 65.1) can result in recurrent infections due to abnormal cytotoxic T cell function; additional manifestations include a bleeding diathesis, neurologic manifestations (in HPS9 & HPS10), and diffuse pigmentary dilution, but not silvery hair. Trichohepato-enteric syndrome, an autosomal recessive disorder caused by mutations in *SKIC2* or *SKIC3* which encode the SKI2 and SKI3 subunits of superkiller complex, can present with diffuse pigmentary dilution of the skin and hair, immunodeficiency, and platelet abnormalities; unlike CHS, it is also characterized by brittle hair with trichorrhexis nodosa, intractable diarrhea during infancy, primary liver disease, facial dysmorphism, and cardiac defects. Other inherited disorders characterized by lymphoproliferation due to immune dysregulation are presented in Table 60.6.

Treatment

Hematopoietic stem cell transplantation (HSCT) can reverse the immunodeficiency of CHS and may also be performed following immunochemotherapy to abrogate the lymphoproliferative accelerated phase. However, HSCT has no effect on pigmentary alteration and does not halt neurologic degeneration. Management of the CHS is otherwise largely supportive, with administration of prophylactic antibiotics to prevent recurrent infections.

FEATURES OF CHÉDIAK–HIGASHI SYNDROME AND GRISCELLI SYNDROME				
	CHS	**GS1***	**GS2**	**GS3**
Gene defect	*LYST*	*MYO5A*	*RAB27A*	*MLPH*
Major sites of gene expression	Melanocytes, platelets, granulocytes, CNS	Melanocytes, CNS	Melanocytes, cytotoxic T cells	Melanocytes
Cellular defect	Vesicle trafficking (e.g. fission/fusion)	Vesicle movement/transfer		
Pigmentary dilution of the skin†	+	+	+	+
Silvery/metallic hair	+	+	+	+
Hair microscopy: clumps of melanin	Small, regularly spaced	Larger, irregularly distributed		
Melanocytes	Giant melanosomes	"Stuffed" with melanosomes		
Neutrophils	Giant granules	Normal-appearing granules		
Ocular findings	+	–	–	–
Bleeding diathesis	+	–	–	–
Recurrent infections	+	–	+	–
Accelerated phase	+	–	+	–
Primary neurologic abnormalities	+	+	–‡	–

*A form of GS with manifestations limited to the skin and hair can result from deletion of the *MYO5A* F-exon, which is only expressed in melanocytes.
†Often accompanied by hyperpigmentation ± guttate hypopigmented macules in acral and sun-exposed sites.
‡May develop neurologic symptoms secondary to the hemophagocytic syndrome of the accelerated phase.

Table 60.5 Features of Chédiak–Higashi syndrome (CHS) and Griscelli syndrome (GS). The latter is caused by defective attachment of organelles to the actin cytoskeleton (see Ch. 65). Elejalde syndrome (neuroectodermal melanolysosomal disease), which presents with pigmentary features of GS plus severe neurologic dysfunction, likely represents a variant of GS1. CNS, central nervous system.

INHERITED DISORDERS CHARACTERIZED BY LYMPHOPROLIFERATION DUE TO IMMUNE DYSREGULATION				
Disorder	**Inh**	**Gene**	**Protein (function)**	**Clinical features**
Chédiak–Higashi syndrome	AR	*LYST*	See Table 60.5	See Table 60.5
Griscelli syndrome type 2	AR	*RAB27A*		
Familial hemophagocytic lymphohistiocytosis	AR	*PRF1*	Perforin (major cytolytic granule protein of CTL and NK cells)	• HLH • Absent NK cell cytotoxicity • Fatal during early childhood unless hematopoietic stem cell transplantation is performed
	AR	*UNC13D*	Unc13 homolog D (primes cytolytic granules for secretion)	
	AR	*STX11*	Syntaxin 11 (involved in cytolytic granule trafficking and fusion)	
	AR	*STXBP2*	Syntaxin-binding protein 2 (regulates cytolytic granule trafficking)	
NOCARH	AD	*CDC42*	Cell division cycle 42	• *N*eonatal-onset cytopenias with dyshematopoiesis, *a*utoinflammation, *r*ash, and *H*LH
X-linked lymphoproliferative syndrome (Duncan disease)	XR	*SH2D1A*	Signaling lymphocyte activation molecule-associated protein (adaptor protein that regulates B, T, and NK cell function; particularly important for immune responses to EBV)	• Severe EBV-related infectious mononucleosis in childhood or adolescence (e.g. fever, pharyngitis, LAN, HSM), often associated with morbilliform eruptions, purpura and/or jaundice • Hypogammaglobulinemia • Fatal EBV-related B cell lymphoma (70%) • Lymphocytic vasculitis
	XR	*XIAP*	X-linked inhibitor of apoptosis	
EBV-associated lymphoproliferative syndrome	AR	*ITK*	IL-2-inducible T cell kinase	
XMEN (*X*-linked immunodeficiency with *m*agnesium defect, *E*BV infection, and *n*eoplasia)	XR	*MAGT1*	Magnesium transporter 1	• Decreased $CD4^+$ T cells • EBV infection with persistent viremia; recurrent sinopulmonary infections • EBV-associated lymphoma
STK4 deficiency	AR	*STK4*	Serine/threonine kinase 4	• EBV-associated lymphoproliferation and lymphoma • Recurrent bacterial, viral (including warts, molluscum, HSV), and candidal infections • Autoimmune cytopenias
Autoimmune lymphoproliferative syndrome (Canale–Smith syndrome) and related conditions*	AD >AR	*TNFRSF6*	CD95 (Fas; cell-surface apoptosis receptor)	• Massive LAN and/or splenomegaly • Increased $CD4^-/CD8^-$ α/β T cells • Autoimmune cytopenias, LE, small vessel vasculitis • Recurrent bacterial and viral infections (*CASP8*) • Increased risk of lymphoma
	AD >AR	*TNFSF6*	CD95L (Fas ligand)	
	AR	*FADD*	Fas-associated death domain	
	AD > AR	*CASP10*	Caspase 8 and 10 (proteases in intracellular apoptosis cascade)	
	AR	*CASP8*		
	Mosaic	*NRAS*, *KRAS*	NRAS, KRAS (gain of function leads to decreased lymphocyte apoptosis)	
	AR	*PRKCD*	Protein kinase C δ (regulates B cell proliferation)	
	AD	*CTLA4*	Cytotoxic T lymphocyte-associated protein 4 (costimulation of T cells)	
Immunodeficiency with lymphoid proliferation	AR	*IL2RA*	IL-2 receptor α-chain (apoptosis of developing T cells in the thymus)	• Bacterial, viral, and fungal infections • Extensive lymphocytic infiltration of the liver, lung, gut, and bones • Eczematous dermatitis; autoimmune polyendocrinopathy, cytopenias, and enteropathy
	AR	*IL2RB*	IL-2 receptor β-chain	
SOCS1 haploinsufficiency	AD	*SOCS1*	Suppressor of cytokine signaling	• Early-onset multisystem autoimmunity, HSM, psoriasis, eczematous dermatitis, discoid LE • Recurrent bacterial infections

*LRBA mutations (see Table 60.15) and gain-of-function *CARD11* or *STAT3* mutations can also lead to autoimmune lymphoproliferative syndrome-like disorders.

Table 60.6 Inherited disorders characterized by lymphoproliferation due to immune dysregulation. Hemophagocytic lymphohistiocytosis (HLH) results from uncontrolled T cell and macrophage activation, manifesting with fever, pancytopenia, hepatosplenomegaly (HSM), lymphadenopathy (LAN), hypertriglyceridemia, and hypofibrinogenemia. AD, autosomal dominant; AR, autosomal recessive; CTL, cytotoxic T lymphocytes; Inh, inheritance; LE, lupus erythematosus; NK, natural killer; XR, X-linked recessive.

COMPLEMENT DISORDERS

Key features

- Deficiency or dysfunction of early complement components increases susceptibility to pyogenic infections caused by encapsulated bacteria and autoimmune disorders, especially systemic lupus erythematosus
- Deficiency of late complement components leads to a markedly increased risk of neisserial infections

Introduction

The complement system represents an important effector of the innate immune response (see Ch. 4). An enzymatic cascade of complement activation can be triggered by three different pathways: classical, alternative, and lectin (Fig. 60.6). In addition to their roles in killing microbial pathogens, complement proteins serve as regulators of a variety of humoral and cellular immune functions (Table 60.7). As a result, clinical manifestations of complement deficiency include autoimmune diseases as well as increased susceptibility to infection[54,55].

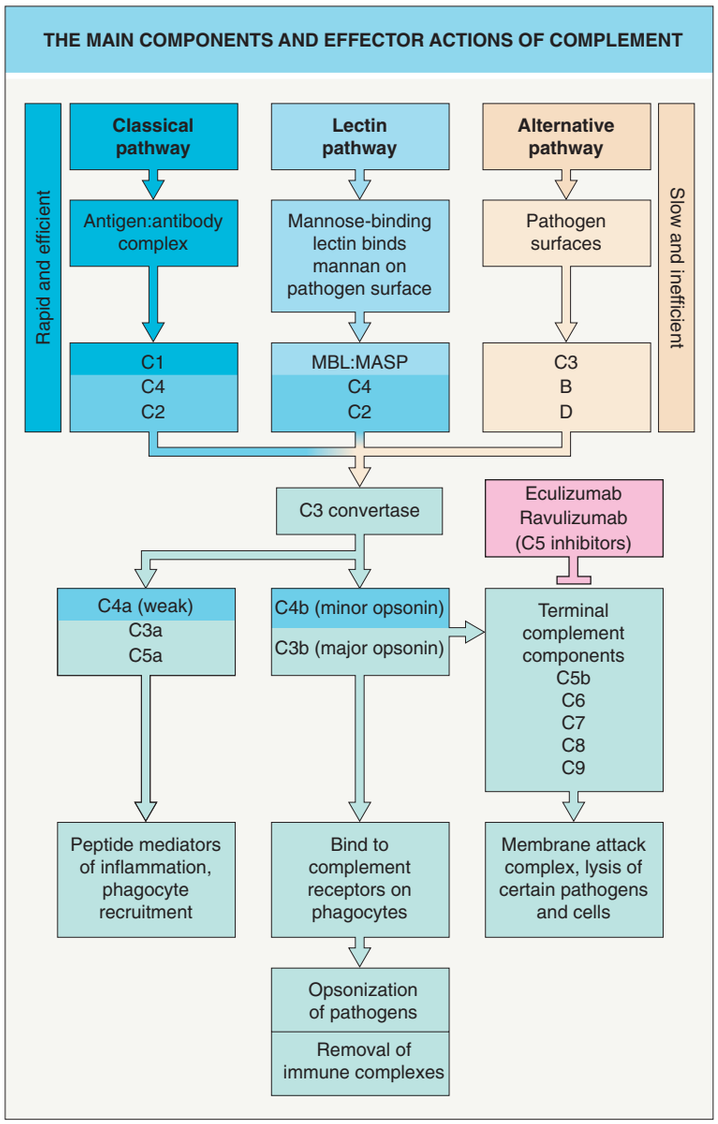

Fig. 60.6 The main components and effector actions of complement. The C3b bound to the C3 convertase binds C5, allowing the C3 convertase to generate C5b, which associates with the bacterial membrane and triggers the late events. MBL, mannose-binding lectin; MASP, MBL-associated serine protease. *© 2005 from Immunobiology by Charles A. Janeway, et al. Adapted with permission of Garland Science/Taylor & Francis Books, Inc.*

Epidemiology

Deficiency of C2 represents the most common hereditary complement disorder[54]. Homozygous C2 deficiency occurs in ~1 in 20 000 individuals, and 1%–2% of the population has the heterozygous form. Homozygous deficiencies of C1q, C1r, C1s, and C4 are rare, but affected individuals manifest with autoimmune disease more frequently than those with homozygous C2 deficiency. Heterozygotes usually make enough protein to ensure function and are generally asymptomatic, so most of the complement disorders are inherited as autosomal recessive traits. One exception is hereditary angioedema (HAE), an autosomal dominant condition due to deficiency or dysfunction of the C1 inhibitor (see Ch. 18).

In contrast to the low prevalence of deficiencies in components of the classical complement pathway, 5% of the population is homozygous or compound heterozygous for alleles that lead to a lack of functional mannose-binding lectin (MBL), the major recognition factor of the lectin pathway of complement activation[56]. Although the clinical penetrance of MBL deficiency is low, it may have a substantial impact on immunity and autoimmunity at the population level. In addition, ~1 in 10 000 individuals has a homozygous deficiency in the MBL-associated serum protease (MASP) that functions in this pathway.

Pathogenesis

Deficiency of C2 can result from a defect in either protein synthesis (type 1) or secretion (type 2). Defects involving the early components of the classical complement pathway (C1, C4, C2) manifest with an increased risk of autoimmune disorders, especially systemic lupus erythematosus (SLE)[57] (Table 60.8). The genes that encode these complement components, including four highly polymorphic genes for C4 (two each for C4A and C4B), are located within the HLA region on chromosome 6. C4-null alleles have been linked with SLE, and *C4A* is deleted in the HLA A1-B8-DR3 extended haplotype that is strongly associated with SLE.

The pathogenesis of SLE in the setting of complement deficiency may also be related to impaired physiologic clearance of autoantigen-containing apoptotic cells[57]. Epidermal keratinocytes undergoing UVB-induced apoptosis preferentially display autoantigens such as SSA/Ro in plasma membrane blebs. Binding of C1q to these blebs and the nucleolus results in activation of the classical complement pathway and removal of the apoptotic cells by phagocytes[58]; in the absence of C1q, autoantibodies have the opportunity to bind to SSA/Ro, leading to activation of B and T cells and loss of immune tolerance. Decreased MBL-mediated clearance of apoptotic debris and DNA might likewise explain the predisposition to SLE associated with MBL deficiency. Furthermore, the complement system may enhance the elimination of self-reactive B cells during lymphocyte development, with complement deficiency leading to a lack of B cell self-tolerance. Complement components are also important for handling immune complexes and regulating production of cytokines (e.g. type I interferons) that have a key role in SLE pathogenesis.

The variety of recurrent infections associated with complement deficiencies underscores the central role of complement in bacterial clearance. Patients deficient in the early classical components, especially C2, have increased susceptibility to infections with encapsulated bacteria, especially *Str. pneumoniae*. Opsonization of bacteria and fungi may be ineffective in disorders of the classical pathway because of the slow, inadequate formation of C3b. However, because the lectin and alternative pathways can bypass early classical components to intersect with the cascade at the level of C3 (see Table 60.7 & Fig. 60.6), these deficiencies do not usually lead to overwhelming infections. C5 deficiencies result in impaired generation of chemotactic factors, which may lead to inadequate neutrophil function.

Individuals with C5 to C9 (membrane attack complex; MAC), properdin, and factor D deficiencies develop recurrent neisserial infections in their teenage years. This underscores the importance of the bactericidal MAC complex and the alternative complement pathway (which requires properdin and factor D) in the destruction of these organisms. However, because a lack of lytic activity limits release of bacterial products (e.g. lipopolysaccharide) that stimulate a damaging cytokine response, the mortality of meningococcal infections in patients with MAC deficiency is actually lower than that in immunocompetent individuals. In contrast, patients with a properdin or factor D deficiency are unable to eradicate *Neisseria* spp. via opsonophagocytosis and have severe disease that is often fatal.

Clinical Features

Individuals with homozygous deficiencies in the early components of the classical complement pathway (C1, C4, C2) have a risk of SLE that ranges from >90% for C1q to 10%–20% for C2. Among those with C2 deficiency, features of lupus erythematosus (especially photosensitivity and subacute cutaneous lupus erythematosus) are most common in women, with the age at onset ranging from early childhood to adulthood (median 30 years). Other manifestations of C2 deficiency-associated SLE are presented in Table 60.9. SLE in the setting of C1q/r/s or C4 deficiency usually develops during childhood, affects boys and girls equally, and is often associated with renal disease and palmoplantar keratoses as well as photosensitivity. Other autoimmune and/or inflammatory disorders and susceptibilities to infection associated with complement deficiencies are listed in Table 60.8. C2 deficiency may coexist with common variable immunodeficiency, and the development of Hodgkin lymphoma has occasionally been reported.

COMPLEMENT SPLIT PRODUCTS AND COMPLEXES			
Split product	**Function**	**Complex**	**Function**
C1q	Recognition factor of CP (binds Ag–Ab complexes) Activates C1r	C1inh-C1r-C1s	Formed during C1 activation
C1r	Cleaves C1s to an active protease		
C1s	Cleaves C4 and C2		
C4a	Anaphylatoxin (weak)	C4b2a	CP C3 convertase
C4b	Part of the CP C3 and C5 convertases Opsonization		
C2a	Part of the CP C3 and C5 convertases		
C2b	Unknown		
C3(H_2O)	Recognition factor of AP (binds bacterial surfaces, including lipopolysaccharide)	C3bBb	AP C3 convertase
C3a	Anaphylatoxin Chemotaxis (eosinophils) Direct antimicrobial effect	C4b2a3b	CP C5 convertase
C3b	Part of CP C5 and AP C3/C5 convertases		
	Opsonization	C3b(n)Bb	AP C5 convertase
C5a	Anaphylatoxin (strong) Chemotaxis (neutrophils and monocytes) Regulation of apoptosis		
C5b	Part of membrane attack complex	C5b-9n SC5b-9	Membrane attack complex Soluble terminal complement complex

Table 60.7 Complement split products and complexes. Dark blue, classical pathway (CP); medium blue, CP and lectin pathway; yellow-tan, alternative pathway (AP); green, all three pathways. Anaphylatoxins are inflammatory mediators that increase vascular permeability and cause mast cell degranulation. Opsonization represents binding of a protein to the pathogen surface in order to target it for destruction. C1 inh, C1 esterase inhibitor; SC, soluble complex.

MBL deficiency may confer an increased risk of acute respiratory infections in children aged 6–18 months, who no longer have maternal antibodies but are not yet able to mount an efficient antibody response to the carbohydrate antigens of encapsulated bacteria[56]. Several studies have shown that MBL deficiency is associated with an increased risk of developing SLE or dermatomyositis and a higher incidence of infections in the setting of immunosuppressive therapy.

Pathology

The total hemolytic complement (CH50) is markedly decreased or undetectable in complement deficiencies other than hereditary angioedema. The alternative pathway lytic test (AP50) can be used to screen for deficiencies in components of this pathway, although it is less sensitive than the CH50. Immunoprecipitation assays (e.g. radial immunodiffusion, ELISA) can determine the levels of specific complement components and MBL[59], and functional studies of individual components may be informative when antigen levels are normal. Genetic analysis can be utilized to confirm the diagnosis.

Differential Diagnosis

Complement components may be specific targets of autoimmune responses; for example, anti-C1q antibodies are found in 30%–50% of patients with SLE (often with renal involvement) and virtually all of those with hypocomplementemic urticarial vasculitis. The "*Leiner phenotype*" of exfoliative dermatitis, failure to thrive, chronic diarrhea, and recurrent infections has been observed in infants with C3 or C5 deficiency or C5 dysfunction. However, this constellation of findings can also develop in patients with other disorders such as X-linked agammaglobulinemia, hyper-IgE syndrome, and severe combined immunodeficiency. Low complement levels related to bacterial and viral infections should also be differentiated from primary complement deficiencies. Of note, patients treated with the C5 inhibitors eculizumab and ravulizumab are at risk for the development of severe meningococcal infections.

Treatment

Conservative therapy is often effective for patients with autoimmune manifestations of complement deficiency. The use of topical corticosteroids and sun protection may be sufficient to treat cutaneous lupus erythematosus in these individuals. Antimalarial drugs, systemic corticosteroids, and other immunomodulatory medications are required in more severe cases, with consideration of the increased risk of infections in patients with complement deficiencies. The use of plasma transfusions to replace the deficient components may actually activate the cascade and accelerate immune complex deposition.

Infections should be treated with early, aggressive antibiotic therapy. Pneumococcal vaccination is recommended for individuals with an early component complement deficiency and meningococcal vaccination for those with a C3, C5–C9, properdin, factor D, or factor H deficiency.

CHRONIC GRANULOMATOUS DISEASE

Synonyms: ■ Chronic granulomatous disorder ■ Bridges–Good syndrome ■ Quie syndrome

Key features

- Inability to kill intracellular organisms through generation of oxidative metabolites
- X-linked recessive or autosomal recessive inheritance
- Recurrent pneumonias and cutaneous infections, lymphadenopathy, and hepatosplenomegaly
- Patients develop granulomas as a compensatory effort to confine organisms

Introduction

Chronic granulomatous disease (CGD) is a group of disorders characterized by severe, recurrent infections due to an inability of leukocytes to kill phagocytosed bacteria and fungi by generating oxidative metabolites[60]. The activity of the nicotinamide dinucleotide phosphate (NADPH) oxidase complex is reduced in all forms of CGD.

COMPLEMENT DISORDERS		
Complement component	**Common infectious agents**	**Autoimmune/inflammatory disorders**
Classical pathway		
C1q	Encapsulated bacteria, *Candida* spp.	SLE*, dermatomyositis, GN
C1r	Encapsulated bacteria	SLE*, GN
C1s	Encapsulated bacteria	SLE*
C1 inhibitor		Hereditary angioedema ≫ SLE, GN, partial lipodystrophy, vasculitis
C4	Encapsulated bacteria	SLE* with PPK and scars, HSP, GN, urticaria, JIA‡
C2†	Encapsulated bacteria, especially *Streptococcus pneumoniae*	SLE*, SCLE, DLE, dermatomyositis, HSP, other vasculitides, atrophoderma, cold urticaria, JIA‡, IBD, atherosclerosis
Lectin pathway		
MBL¶	Encapsulated bacteria, especially *N. meningitides*	SLE, dermatomyositis, atherosclerosis, chronic pulmonary disease
MASP-2	Encapsulated bacteria, especially *S. pneumoniae*	SLE, IBD
C3 and alternative pathway		
C3	Encapsulated bacteria (severe infections)	SLE, vasculitis, lipodystrophy (partial [cephalo]thoracic), GN, "Leiner phenotype"
Factor H	Encapsulated bacteria	SLE, HUS, GN, age-related macular degeneration
Factor I (C3b inactivator)	Encapsulated bacteria	SLE, HUS, aquagenic urticaria, angioedema
Properdin (XLR)	*Neisseria* spp. (fulminant infections)	
Factor D	*Neisseria* spp.	
Membrane attack complex		
C5 dysfunction	Gram-negative bacteria	"Leiner phenotype"
C5 deficiency	*Neisseria* spp., *S. pneumoniae*	SLE
C6	*Neisseria, Brucella, Toxoplasma* spp.	SLE, JIA, GN
C7	*Neisseria* spp.	SLE, limited systemic sclerosis, ankylosing spondylitis
C8α	*Neisseria* spp.	SLE, fever with HSM, eosinophilia, hypergammaglobulinemia
C8β	*Neisseria* spp.	SLE, JIA
C9	*Neisseria* spp.	

*Hierarchy of SLE risk with homozygous mutations: C1q (~90%) > C1r/s > C4 > C2 (~10%–20%).
†Most common of the homozygous complement deficiencies.
‡Especially in heterozygous girls.
¶Very low penetrance.

Table 60.8 Complement disorders. Unless otherwise specified, affected individuals usually have biallelic defects. Pyogenic infections caused by encapsulated organisms (e.g. *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Streptococcus pyogenes*) in individuals with classical pathway component deficiencies are not as frequent as neisserial infections in those with membrane attack complex component deficiencies. The C3 inhibitor pegcetacoplan is FDA-approved for the treatment of paroxysmal nocturnal hemoglobinuria. DLE, discoid lupus erythematosus; GN, glomerulonephritis; HSM, hepatosplenomegaly; HSP, Henoch–Schönlein purpura; HUS, hemolytic uremic syndrome; IBD, inflammatory bowel disease; INH, inhibitor; JIA, juvenile idiopathic arthritis; MBL, mannose-binding lectin; MASP, MBL-associated serum protease; PPK, palmoplantar keratoderma; SCLE, subacute cutaneous lupus erythematosus; SLE, systemic lupus erythematosus; XLR, X-linked recessive. *Adapted with permission from Torrelo A (ed). Schachner and Hansen's Pediatric Dermatology, 5th edn. London: Mosby, 2023.*

Epidemiology

The incidence of CGD is ~1 in 200 000 live births[61,62]. Ninety percent of patients are boys. Approximately three-quarters of cases have X-linked recessive transmission, while the remainder are autosomal recessive[63]. A small subset of male patients with X-linked CGD due to a contiguous gene deletion also have McLeod neuroacanthocytosis syndrome, with additional central nervous system, neuromuscular, cardiovascular, and hematologic (e.g. reduced Kell antigens on red blood cells) manifestations.

Pathogenesis

The defects in CGD involve subunits of the NADPH oxidase found in phagocytes. These include: (1) membrane-bound gp91^{phox} (phagocyte oxidase) and p22^{phox} as well as the EROS (*e*ssential for *r*eactive *o*xygen *s*pecies) chaperone protein required for their expression; and (2) cytoplasmic p47^{phox}, p67^{phox}, and p40^{phox} (Table 60.10). The failure of microbial killing that characterizes CGD results from an inability of the NADPH oxidase system to rapidly generate toxic reactive oxygen species (ROS) by transferring electrons from NADPH to molecular O_2 (the "respiratory burst") after phagocytosis of a pathogen. Regardless of the gene affected in patients with CGD, having residual NADPH oxidase activity and the resultant ability to generate ROS is associated with less severe disease and longer survival[64,65].

NADPH oxidase activity results in the activation of antimicrobial proteases within the phagosome and the formation of microbicidal "neutrophil extracellular traps" (NETs)[66,67]. In addition to killing and degrading microorganisms, ROS produced by the NADPH oxidase system have roles in the regulation of cytokine synthesis as well as induction of neutrophil apoptosis, which prevents tissue damage at sites of inflammation. Animal models of CGD have shown that a lack of ROS leads to excess inflammation via decreased regulatory T cell activity, unrestrained γ/δ T cell activity, and augmented production of cytokines such as IL-1β, IL-8, and IL-17. NADPH oxidase also has a role in modulating MHC class II antigen presentation by B cells[68].

Clinical Features

The skin, perianal area, lymph nodes, and lungs are the sites most often affected by CGD. In general, the X-linked form tends to be more severe than the autosomal recessive forms, with a younger mean age at diagnosis (3 years vs 8 years)[61]. Organisms that commonly cause

infections in patients with CGD are listed in Table 60.11[69]. Most carriers of CGD do not have an increased susceptibility to infections.

The earliest manifestations of CGD are usually staphylococcal infections of the skin around the ears and nose, which may begin in the neonatal period and progress to extensive purulent dermatitis with regional lymphadenopathy during infancy. Initial presentation of CGD as ecthyma gangrenosum in the neonatal period has also been described[70]. Cutaneous abscesses occur in 40% of patients, usually due to *S. aureus* but also *Serratia marcescens*; these infections sometimes present as large, poorly healing cutaneous ulcers[71]. Non-infectious purulent inflammatory reactions may develop at sites of minor cutaneous trauma or regional lymph node drainage and heal slowly with scarring. Sterile cutaneous granulomas, which are often nodular and necrotic, occur less frequently than infections.

Additional cutaneous manifestations include acute or chronic cutaneous lupus erythematosus-like skin lesions, most commonly discoid[72] (Fig. 60.7A,B); Sweet syndrome-like lesions; ulcers involving the oral mucosa (resembling aphthous stomatitis), the perioral area, and other cutaneous sites (Fig. 60.7C); and seborrheic dermatitis or folliculitis of the scalp. Female carriers of X-linked CGD occasionally present with discoid lesions, lymphocytic infiltrate of Jessner, photosensitivity, Raynaud phenomenon, severe aphthous stomatitis, and granulomatous cheilitis.

The extracutaneous organs most frequently involved in CGD are the lymph nodes, lungs, liver, spleen, and gastrointestinal tract (Table 60.12). Suppurative lymphadenitis develops in half of patients, most often affecting cervical nodes and leading to abscess and fistula formation. Granulomas of the lungs, liver, spleen, and gastrointestinal and genitourinary tracts occur more frequently than those of the skin. These granulomas can lead to obstruction of the gastric outlet or urinary tract. Excessive inflammatory responses may also lead to wound dehiscence, pneumonitis, and hemophagocytic lymphohistiocytosis. Approximately 40%–80% of CGD patients develop gastrointestinal manifestations (e.g. chronic diarrhea, fistulas) similar to those of inflammatory bowel disease; clinical presentations can also mimic sarcoidosis, rheumatoid arthritis, and IgA nephropathy[62,73,74].

Pathology

Common nonspecific abnormalities in CGD include leukocytosis, anemia, elevated ESR, hypergammaglobulinemia, a decreased number of T cells, and an abnormal chest radiograph. Skin testing for delayed-type hypersensitivity is normal, as are studies of phagocytosis and chemotaxis.

FEATURES OF SYSTEMIC LUPUS ERYTHEMATOSUS IN C2 DEFICIENCY	
Common features	**Features more suggestive of C2 deficiency-associated SLE than classic SLE**
• Photosensitivity* • SCLE*, ACLE, or DLE • Cicatricial alopecia • Oral ulcerations (50%) • Fever (>50%) • Arthralgias and/or arthritis (80%) • Leukopenia (50%) • Anti-SSA/Ro antibody (75%) • Rheumatoid factor (40%)	• Childhood onset • Extensive, treatment-resistant skin lesions • Mild or absent renal disease • Absent or low-titer ANA and anti-dsDNA antibodies • Negative lupus band test • Less severe disease overall • Pyogenic infections with encapsulated bacteria, e.g. *Streptococcus pneumoniae* • Increased risk of atherosclerosis
*Most common cutaneous manifestations.	

Table 60.9 Features of systemic lupus erythematosus (SLE) in C2 deficiency. Less frequent manifestations include central nervous system vasculitis, pleuritis, pericarditis, Raynaud phenomenon, thrombocytopenia, anti-Sm or anti-RNP antibodies, circulating immune complexes and a positive RPR. ACLE, acute cutaneous lupus erythematosus; DLE, discoid lupus erythematosus; SCLE, subacute cutaneous lupus erythematosus. *Adapted with permission from Torrelo A. Schachner and Hansen's Pediatric Dermatology, 5th edn. London: Mosby, 2023.*

ORGANISMS THAT CAUSE INFECTIONS IN PATIENTS WITH CHRONIC GRANULOMATOUS DISEASE		
Type of organism	**Common causes**	**Less frequent causes**
Gram-positive bacteria	*Staphylococcus aureus** *Nocardia* spp.	*Cutibacterium* (formerly *Propionibacterium*) spp.
Gram-negative bacteria	*Burkholderia cepacia* *Klebsiella* spp. *Serratia marcescens*†	*Acinetobacter* spp. Other *Burkholderia* spp. *Chromobacterium violaceum* *Enterobacter* spp. *Escherichia coli* *Granulobacter bethesdensis* *Francisella philomiragia* *Proteus* spp. *Pseudomonas* spp. *Salmonella* spp.
Mycobacteria		*Mycobacterium tuberculosis* Atypical mycobacteria Bacillus Calmette–Guérin (BCG)‡
Fungi	*Candida* spp. *Aspergillus* spp.¶	*Paecilomyces* spp. *Talaromyces (Penicillium)* spp. Phaeohyphomycetes *Phellinus* spp. *Trichosporon* spp.
*Most common cause of cutaneous infections, abscesses, and suppurative adenitis. †Most common cause of osteomyelitis; also a frequent cause of cutaneous abscesses and ulcers. ‡Including severe and disseminated infections. ¶Most common cause of pneumonia.		

Table 60.11 Organisms that cause infections in patients with chronic granulomatous disease.

GENETIC DEFECTS AFFECTING COMPONENTS OF THE PHAGOCYTE NADPH OXIDASE					
Disorder	**Gene**	**Protein**	**Location within NADPH oxidase**		**Approximate % of CGD patients**
			Resting state	**Active state**	
X-linked recessive chronic granulomatous disease	*CYBB*	gp91^{phox}	Membrane-bound subunits of flavocytochrome b_{558} and their chaperone protein (EROS)	Same	70

Table 60.10 Genetic defects affecting components of the phagocyte NADPH oxidase. CGD, chronic granulomatous disease; *CYBC1*, cytochrome b-245 chaperone 1; Eros, essential for reactive oxygen species; *NCF*, neutrophil cytosolic factor; RhoGDI, Rho GDP-dissociation inhibitor.

Fig. 60.7 Chronic granulomatous disease. Lupus erythematosus-like annular plaques and papules on the infraorbital cheek (**A**) and neck (**B**). Pyoderma gangrenosum-like ulcers at an ostomy stoma site (**C**). *Courtesy Edward Cowen, MD.*

Biopsy specimens from cutaneous granulomas that develop in CGD patients demonstrate histiocytic infiltrates associated with foreign body giant cells and accumulation of neutrophils with necrosis. Lupus erythematosus-like skin lesions in CGD patients and carriers may have histologic features similar to classic discoid lesions, but they sometimes lack vacuolar degeneration of basal keratinocytes; immunofluorescence examination of lesional skin is negative in most cases.

The traditional screening test for CGD was the nitroblue tetrazolium (NBT) reduction assay. NBT is yellow in its soluble, oxidized form; when reduced, the dye precipitates and becomes blue (formazan precipitate). Only 5%–10% of leukocytes from patients with CGD are able to reduce NBT during phagocytosis, compared to 80%–90% of leukocytes from unaffected individuals and ~20%–70% of leukocytes from carriers of X-linked CGD. The dihydrorhodamine (DHR) flow cytometric assay is more accurate and quantitative in measuring the neutrophil respiratory burst, and it is commercially available for verifying the diagnosis of CGD[75]. However, the DHR assay is not sensitive for detecting $p40^{phox}$-related CGD.

Immunoblot analysis may demonstrate lack of the $gp91^{phox}$ and $p22^{phox}$ proteins; however, gene sequencing must still be done to ascertain which gene is affected, since mutations resulting in the absence of one of these proteins or EROS lead to the absence of the other(s). A lack of the $p47^{phox}$, $p67^{phox}$, or $p40^{phox}$ protein by immunoblot analysis indicates the affected gene.

FREQUENCY OF SIGNS AND SYMPTOMS IN PATIENTS WITH CHRONIC GRANULOMATOUS DISEASE	
Symptom	**Approximate % of patients**
Lymphadenopathy	90
Hepatosplenomegaly	85
Pneumonia	80
Underweight	75
Short stature	50
Persistent diarrhea and/or abdominal pain	40
Hepatic/perihepatic abscess	35
Pleuritis/empyema	35
Septicemia or meningitis	35
Osteomyelitis	25
Conjunctivitis and/or chorioretinitis	25
Facial periorificial dermatitis	20
Perianal abscess	15
Lung abscess	15
Ulcerative stomatitis	15
Peritonitis	10
Onset by age 1 year	65
Onset with lymphadenitis	25

Table 60.12 Frequency of signs and symptoms in patients with chronic granulomatous disease.

Differential Diagnosis

Laboratory tests allow differentiation of CGD from other immunodeficiency disorders characterized by increased susceptibility to bacterial infections. Additional inherited phagocyte disorders are listed in Table 60.13.

Treatment

The use of antibiotics and antifungals has markedly reduced the morbidity and mortality rates of CGD. Although cutaneous and nodal infections are often readily apparent, localized foci of internal infection (which may or may not be associated with fever) can be difficult to detect. Thorough periodic evaluation of the lungs, liver, and bones by routine radiographs, ultrasounds or CT, MRI, positron emission tomography (PET), and bone scans often uncovers occult foci of inflammation or infection. Cultures should be performed to identify the infectious agent, and invasive procedures may be necessary to obtain adequate tissue samples. While awaiting culture results or in situations where material from the affected site cannot be obtained, patients with evidence of infection should be treated empirically with broad-spectrum parenteral antibiotics that cover *S. aureus* as well as Gram-negative bacteria, with a high index of suspicion for fungal infection if despite antibiotics symptoms persist. Surgical interventions such as debridement, irrigation, and prolonged drainage are important for deeper infections.

Chronic prophylaxis with trimethoprim–sulfamethoxazole has been shown to decrease the incidence of bacterial infection in CGD patients.

OTHER INHERITED DEFECTS OF PHAGOCYTES AND INNATE IMMUNITY				
Disorder	**Inh**	**Gene**	**Protein (defect or function)**	**Clinical features**
Selected disorders featuring neutropenia or neutrophil defects				
Severe congenital neutropenia	AD	*ELANE*	Neutrophil elastase (abnormal elastase trafficking and accumulation)	• Neutropenia • MDS, AML
	AD	*GFI1*	Transcriptional repressor of elastase (abnormal elastase accumulation)	• Neutropenia, lymphopenia • Circulating myeloid progenitors
	AR	*HAX1*	Mitochondrial HS1-associated protein X1 (protects against apoptosis in myeloid cells)	• Neutropenia • Increased apoptosis of myeloid cells
	AD	*CSF3R*	Granulocyte colony-stimulating factor receptor	• Neutropenia • Severe myeloid hypoplasia
	AR	*G6PC3*	Glucose 6 phosphatase catalytic subunit 3 (glucose metabolism)	• Neutropenia, thrombocytopenia • Urogenital and cardiac malformations • Ectatic veins on trunk/extremities
Cyclic neutropenia	AD	*ELANE*	Neutrophil elastase	• Alternating 21-day cycles of neutropenia & monocytopenia • Fever and oral ulcers at nadir
X-linked neutropenia	XR	*WASP*	WASP (gain of function; see text, Wiskott–Aldrich syndrome)	• Neutropenia
p14 deficiency	AR	*LAMTOR2*	Endosomal adaptor protein p14 (p14; endosomal biogenesis)	• Neutropenia • Pneumococcal infections • Diffuse pigmentary dilution of the skin and hair • Short stature, coarse facies
Shwachman–Bodian–Diamond syndrome	AR	*SBDS*	SBDS protein (ribosomal RNA metabolism)	• Neutropenia > pancytopenia • MDS, AML • Exocrine pancreatic insufficiency • Chondrodysplasia
Poikiloderma with neutropenia, Clericuzio type	AR	*USB1*	U6 snRNA biogenesis phosphodiesterase 1	• Neutropenia • Dermatitis → poikiloderma, keratotic papules • Recurrent skin & respiratory infections
Specific granule deficiency	AR	*CEBPE*	C/EBPε transcription factor (granulocyte differentiation)	• Bilobed neutrophils • Recurrent bacterial infections
Myeloperoxidase deficiency	AR	*MPO*	Myeloperoxidase (microbial killing by granulocytes)	• *Candida* spp. and *S. aureus* infections • Often asymptomatic
Leukocyte adhesion deficiencies (LADs) and related conditions				
LAD-I	AR	*ITGB2*	β_2-integrin subunit of LFA-1, CR3, and p150 (see text)	• Neutrophilia; ↓ tissue neutrophils • Necrotic abscesses, ulcers • Poor wound healing, delayed umbilical stump separation • Gingivitis • Bleeding diathesis (LAD-III)
LAD-II	AR	*SLC35C1 (FUCT1)*	GDP-fucose transporter 1 (sialyl-Lewis X expression; see text)	
LAD-III	AR	*FERMT3*	Kindlin-3 (defective integrin activation; see text)	
Rac2 deficiency	AD	*RAC2*	Rac2 GTPase (NADPH oxidase, integrin-dependent adhesion, and neutrophil migration; see Table 60.10)	
Defects resulting in predisposition to specific infections				
Defects of the interleukin-12/interferon-γ axis	AR	*IL12B*	Subunit of IL-12 and IL-23 (stimulation of IFN-γ production)	• Severe mycobacterial and *Salmonella* infections • Disseminated BCG infection • Chronic mucocutaneous candidiasis (*RORC*, *IL12RB1* > *IL12B*) • Viral infections (*STAT1, TYK2*) • Hyper-IgE syndrome (*TYK2*; see text)
	AR	*IL12RB1*	IL-12 and IL-23 receptor β1 chain	
	AR, AD	*IFNGR1*	IFN-γ receptor (ligand binding)	
	AR	*IFNGR2*	IFN-γ receptor (signaling)	
	AR, AD	*STAT1**	Signal transducer and activator of transcription 1 (STAT1)* (IFN receptor signaling is impaired by loss-of-function mutations)	
	AR	*TYK2*	Tyrosine kinase 2 (IFN/IL-12/other cytokine receptor signaling)	
	AD	*IFR8*	IFN regulatory factor 8 (IL-12 signaling)	
	AR	*ISG15*	IFN-α/β-inducible ubiquitin-like modifier	
	AR	*RORC*	Retinoic acid receptor-related orphan receptor C (IFN-γ and IL-17 signaling)	

Table 60.13 Other inherited defects of phagocytes and innate immunity.

Continued

OTHER INHERITED DEFECTS OF PHAGOCYTES AND INNATE IMMUNITY				
Disorder	**Inh**	**Gene**	**Protein (defect or function)**	**Clinical features**
Defects in Toll-like receptor (TLR) signaling	AD	*TLR3*	TLR3 (signals IFN-α/β production)	• Herpes simplex encephalitis
	AR	*UNC93B1*	UNC-93B (endoplasmic reticulum protein required for TLR3 signaling)	
	AD	*TRAF3*	TNF receptor-associated protein 3 (TLR3 signaling)	
	AD, AR	*TICAM1* (*TRIF*)	TLR-adaptor molecule 1 (TLR3/4 signaling)	
	AD	*TBK1*	TANK-binding kinase 1 (TLR3 signaling)	
	AR	*IRAK4*	IL-1 receptor associated kinase-4 (IL-1 receptor & TLR signaling)	• Recurrent pyogenic sinopulmonary and skin infections with *Streptococcus pneumoniae* and *S. aureus*, respectively
	AR	*MYD88*	Myeloid differentiation primary response gene 88 (recruits IRAK4 to the IL-1 receptor and TLRs)	
GATA2 deficiency/ MonoMAC syndrome	AD	*GATA2*	GATA binding protein 2	• Monocytopenia, B/NK lymphopenia, myelodysplasia, myeloid leukemia • Mycobacterial and fungal infections (e.g. histoplasmosis) • Recalcitrant warts • Lymphedema, panniculitis, granulomatous dermatitis • Alveolar proteinosis

*Gain-of-function *STAT1* mutations lead to chronic mucocutaneous candidiasis (see Table 60.4) and/or confer susceptibility to endemic dimorphic fungal infections; *loss*-of-function *STAT3* mutations underlie AD hyper-IgE syndrome (see text) while *gain*-of-function *STAT3* mutations can result in lymphoproliferation, autoimmunity, hypogammaglobulinemia, mycobacterial infections, and occasionally psoriasiform dermatitis; defects in STAT5B, which is involved in IL-2 and growth hormone receptor signaling, lead to an AR syndrome of growth hormone insensitivity, decreased $CD4^+/CD25^+$ regulatory T cells, viral infections, and eczematous dermatitis.

Table 60.13 Other inherited defects of phagocytes and innate immunity. See text and Tables 60.5 and 60.10 for Chédiak–Higashi syndrome and chronic granulomatous disease. AD, autosomal dominant; AML, acute myeloid leukemia; AR, autosomal recessive; BCG, bacillus Calmette–Guérin; IFN, interferon; IL, interleukin; Inh, inheritance; LFA-1, lymphocyte function-associated antigen-1; MDS, myelodysplastic syndrome; WASP, Wiskott–Aldrich syndrome protein; XR, X-linked recessive.

The frequency and mortality of invasive fungal infections (e.g. with *Aspergillus* spp.) have likewise been reduced with itraconazole prophylaxis as well as treatment with other azoles (e.g. voriconazole, posaconazole, isavuconazonium sulfate)[76,77]. However, invasive fungal infections remain the most common cause of death in CGD. Administration of interferon-γ, which likely augments oxidant-independent antimicrobial pathways, may help to decrease the risk of serious infections[78]. Granulocyte transfusions have been used for rapidly progressive, life-threatening infections.

Short courses of systemic corticosteroids have been helpful for patients with obstructive granulomas of the bronchopulmonary, gastrointestinal, or genitourinary tract[58]. Additional immunomodulatory therapies with potential benefit for inflammatory manifestations of CGD include azathioprine, hydroxychloroquine, anakinra, thalidomide, pioglitazone (increases ROS production and efferocytosis), ustekinumab, and sirolimus[79,80]; tumor necrosis factor (TNF) inhibitors may improve colitis but increase the risk of infectious complications.

Hematopoietic stem cell transplantation represents a potentially curative treatment for CGD. Although younger patients without infection at the time of transplantation have the best outcomes (survival >95%), use of reduced-intensity conditioning regimens has enabled successful transplantation of higher-risk patients such as adults and individuals with recalcitrant infections or inflammatory manifestations[81]. Children with CGD who undergo transplantation have improved growth and fewer infections, surgical interventions, and hospital admissions than those managed conservatively[82].

In the 1990s, gene therapy was performed in five adults with the $p47^{phox}$-deficient form of CGD, and a single infusion of transduced $CD34^+$ peripheral blood stem cells led to peak levels of corrected granulocytes in 3–6 weeks with persistence for as long as 6 months[83]. Subsequently, two young men with X-linked recessive CGD were treated with non-myeloablative conditioning prior to the infusion of $CD34^+$ peripheral blood stem cells transduced *ex vivo* with a retroviral vector expressing $gp91^{phox}$; this led to sustained engraftment of functionally corrected phagocytes. However, following initial resolution of infections, the transgene was silenced due to methylation of the viral promoter in both patients, and within 3 years they developed myelodysplasia with monosomy 7 as a result of insertional activation of ecotropic viral integration site 1 (*EVI1*)[84]. To increase the safety and efficacy of gene therapy for CGD, current investigations are utilizing approaches such as self-inactivating lentiviral vectors, targeted integration of transgenes into a genomic "safe harbor" site, or the CRISPR-Cas9 site-specific nuclease system to encourage repair of the endogenous gene via homologous recombination (see Ch. 3)[77]. In a recent study, 6 of 9 patients with severe X-linked CGD who received *ex vivo* autologous $CD34^+$ hematopoietic stem/progenitor cell-based lentiviral gene therapy following myeloablative conditioning recovered functional oxidase activity, with no new CGD-related infections or evidence of genotoxicity after a follow-up period of 1 year[85].

DHR flow cytometric studies may be utilized in determining the carrier status of the sisters and other female relatives of patients with X-linked CGD, which is important for genetic counseling prior to pregnancy. Prenatal diagnosis of CGD is also possible.

HYPERIMMUNOGLOBULIN E SYNDROMES

Synonyms: ■ Hyper-IgE syndromes ■ Job syndrome ■ Buckley syndrome

Key features

- Characterized by recurrent skin and sinopulmonary tract infections, early-onset eczematous dermatitis, and extremely elevated IgE levels
- The classic form, an autosomal dominant disorder due to STAT3 deficiency, features skin infections caused primarily by *S. aureus* (in particular "cold abscesses") and, especially during infancy, *C. albicans*, in addition to a neonatal papulopustular eruption, progressively coarse facies, osteopenia with fractures, scoliosis, and dental abnormalities
- Autosomal recessive forms have a broader spectrum of infectious complications

Introduction and History

Hyperimmunoglobulin E syndromes (HIESs) are characterized by the triad of recurrent cutaneous and sinopulmonary infections, dermatitis beginning in infancy or early childhood, and extremely elevated IgE levels[86]. Job syndrome is a subgroup of autosomal dominant (AD) HIES that was originally described in female patients with fair skin, red hair, and hyperextensible joints as well as the typical features of HIES. In 2007, classic AD HIES was found to result from STAT3 deficiency[87,88] (see Pathogenesis). Since then, multiple additional forms of HIES caused by defects in proteins with roles in STAT3 signaling or other pathways of immune regulation have been identified[89].

Epidemiology

As noted above, classic HIES is inherited in an AD fashion with variable expression. Additional AD and autosomal recessive (AR) forms of HIES with variable clinical features have also been described[89–93].

Pathogenesis

Heterozygous mutations in the gene encoding STAT3 (*s*ignal *t*ransducer and *a*ctivator of *t*ranscription *3*) cause classic AD HIES, commonly referred to as STAT3-HIES[87,88]. Different combinations of receptor-associated Janus kinases (JAKs) and STAT proteins transduce cytokine signals; upon phosphorylation by JAKs, the latter dimerize, translocate to the nucleus, and activate target genes (see Fig. 128.11). Susceptibility to bacterial and candidal infections in HIES reflects the roles of STAT3-dependent cytokines (e.g. IL-6, IL-21, IL-23) in the differentiation of IL-17-producing $CD4^+$ T cells that help to defend against these organisms (see Fig. 4.10)[94]. A lack of stimulation of β-defensin production by IL-22, which is produced by Th17 cells and signals via STAT3, may contribute to the development of infections at epithelial surfaces (e.g. skin, lungs) in STAT3-HIES.

STAT3 is critical to the signaling pathways for both IL-6, which promotes acute phase responses and acts as a pyrogen, and IL-10, an anti-inflammatory cytokine. STAT3 dysfunction provides an explanation for the "cold" abscesses and destructive inflammation (e.g. in the lung) that characterize HIES. Defective generation of IL-10-induced tolerogenic dendritic cells and $FOXP3^+$-induced regulatory T cells may contribute to other inflammatory features of HIES, such as the atopic-like dermatitis and high IgE levels[95]. STAT3 also downregulates differentiation of osteoclasts, and osteoporosis represents a feature of STAT3 deficiency in mice as well as HIES. Lastly, leukocytes from STAT3-deficient individuals produce higher levels of interferon-γ and tumor necrosis factor (TNF) upon stimulation with IL-12 and lipopolysaccharide/interferon-γ, respectively, than do leukocytes from unaffected controls[87,88].

Other variants of HIES can also result from disruption of STAT3 signaling, including deficiencies in the following proteins: the *IL-6 receptor* (AR) and *IL-6 signal transducer* (*gp130*; AD or AR); *phosphoglucomutase 3* (PGM3; AR), which promotes gp130 expression; *ZNF341* (AR), which regulates STAT3 expression; and *ERBIN* (AD), expression of which is stimulated by STAT3. In general, these disorders have clinical findings that overlap with those of STAT3-HIES, with additional manifestations such as autoimmunity and neurocognitive abnormalities in PGM3 deficiency and craniosynostosis in AR gp130 deficiency[89,93].

DOCK8 (dedicator of cytokinesis 8) deficiency is an AR condition with features of HIES (see below)[91,92]. The DOCK8 protein interacts with the Wiskott–Aldrich syndrome protein (WASP) in a complex that links T cell receptors to the actin cytoskeleton[96]. DOCK8 deficiency results in an increase in Th2 cells and production of the pruritogen IL-31, but a decrease in Th1 and Th17 cells[97,98].

CADINS (CARD11-associated atopy with dominant interference of NF-κB signaling) results from heterozygous dominant negative mutations in *CARD11*, which encodes a scaffolding protein involved in lymphocyte receptor signaling[99]. Patients present with the characteristic HIES triad together with additional atopic manifestations and B cell lymphopenia. The features of HIES have also been identified in a subset of patients with homozygous mutations in the gene encoding *tyrosine kinase 2 (TYK2)*, a member of the JAK family[100]. Affected individuals have defects in signaling pathways for IL-12 and interferon-α/β, which lead to susceptibility to mycobacterial and viral infections (see Table 60.13), as well as IL-6 and IL-10.

Clinical Features

Patients with *STAT3-HIES* typically present during the first month of life with a non-infectious, folliculocentric papulopustular eruption involving the face, scalp, neck, axillae, and diaper area[101,102]. Chronic candidiasis of the oral mucosa, periungual areas, and nails occurs in ~80% of HIES patients and may represent the initial infectious manifestation during infancy.

Cutaneous staphylococcal infections include impetiginized plaques and retroauricular fissures, folliculitis, furunculosis, abscesses, cellulitis, lymphangitis, and paronychia leading to nail dystrophy[102]. The cutaneous abscesses are often large, and they most commonly involve the neck, scalp (Fig. 60.8A), periorbital area, axillae, and groin. Such lesions are referred to as "cold abscesses" because they are not as red or tender as those that develop in healthy individuals. Patients are often afebrile or have only a low-grade fever. Although the abscesses tend to be staphylococcal, many patients have recurrent skin infections with other organisms, including *Str. pyogenes* as well as *C. albicans*.

The eczematous rash of HIES shares many clinical features with atopic dermatitis, including severe pruritus, lichenification, and staphylococcal superinfection[102]. It is almost always present in young children with STAT3-HIES but frequently clears by adolescence. Unlike individuals with atopic dermatitis, patients with STAT3-HIES do not commonly exhibit allergic rhinitis, asthma, or other cutaneous signs of atopy.

Although some STAT3-HIES patients have only cutaneous manifestations, most also develop recurrent bronchitis and pneumonias. *S. aureus* and *Haemophilus influenzae* usually cause the pulmonary infections, which may result in empyema, bronchiectasis, and pneumatocele formation. The pneumatoceles tend to persist and become the site of further infections with bacterial or fungal organisms, particularly *Aspergillus*

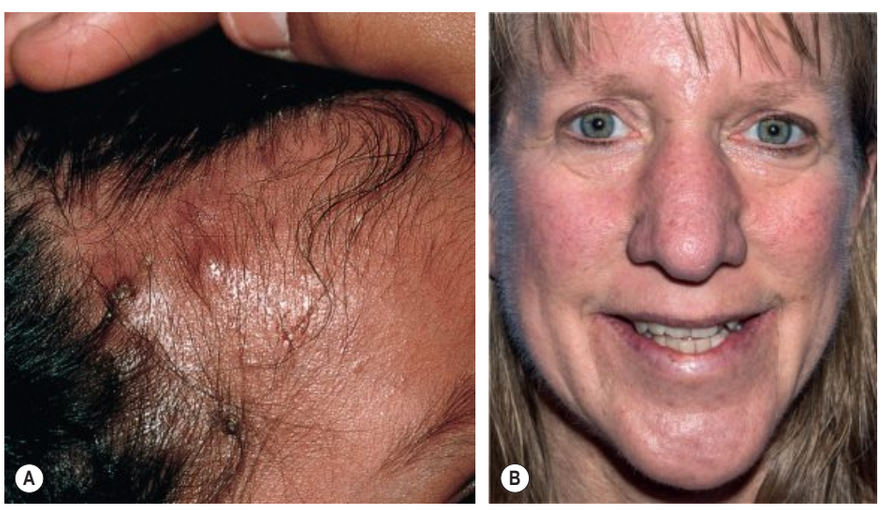

Fig. 60.8 STAT3-hyperimmunoglobulin E syndrome. A Several erythematous, slightly purulent "cold" abscesses are apparent on the forehead and scalp of this infant. **B** Coarse facial features that developed progressively over time in an affected woman. Note the prominent follicular ostia, doughy skin, and broad nasal bridge. *B, Courtesy Edward Cowen, MD.*

spp. Massive hemoptysis occasionally ensues. *Pneumocystis jirovecii* pneumonia can also occur in infants and children with STAT3-HIES. Other common sites of infection include the ears, oral mucosa, sinuses, and eyes. Visceral infections other than pneumonia are unusual.

STAT3-HIES patients develop progressive facial coarsening with thickened doughy skin, large follicular ostia, pitted scarring, a broad nasal bridge, a wide fleshy nasal tip, deep-set eyes, a prominent forehead, and irregularly proportioned cheeks and jaw (Fig. 60.8B). Osteopenia is frequently present and is associated with an increased risk of fractures of the long bones, ribs, and pelvis. More than half of adolescents and adults with STAT3-HIES have had at least three fractures, often due to unrecognized or minor trauma. Scoliosis occurs in 75% of patients ≥16 years of age, and joint hyperextensibility affects ~70% of patients. Approximately half of individuals with STAT3-HIES have a high-arched palate, and retention of primary teeth due to failure of root resorption and lack of eruption of secondary teeth are characteristic dental manifestations. Several brain abnormalities have been described, including Chiari malformations, lacunar infarctions, and focal hyperintensities in white matter on T2-weighted MRI sequences. Development of coronary artery aneurysms during adulthood has also been reported. HIES is associated with an increased risk of non-Hodgkin lymphoma of B cell origin.

DOCK8 deficiency shares some features with STAT3-HIES, including highly elevated serum IgE levels, peripheral eosinophilia, chronic eczematous dermatitis (Fig. 60.9A), recurrent staphylococcal skin infections (including cold abscesses), respiratory tract infections, and mucocutaneous candidiasis. However, skeletal and dental abnormalities, facial coarsening, and pneumatoceles are not characteristic features[90,103]. Patients with DOCK8 deficiency are predisposed to the development of warts, molluscum contagiosum, severe herpes simplex and varicella–zoster viral infections, and opportunistic infections[90,103,104] (Fig. 60.9B,C). Additional manifestations include asthma, food allergies resulting in anaphylaxis, autoimmunity, cerebral vasculitis, mucocutaneous squamous cell carcinomas, and lymphomas. Up to half of patients die by 20 years of age from infection, malignancy, or CNS disease[90,103].

Laboratory Findings and Pathology

HIES patients have markedly elevated serum levels of polyclonal IgE, usually peaking at >2000 IU/ml and sometimes declining during adulthood. Patients develop particularly high levels of anti-staphylococcal and anti-candidal IgE antibodies and often have immediate wheal-and-flare reactions to a variety of foods and environmental allergens. Many affected individuals also have eosinophilia of the peripheral blood and sputum. Cell-mediated immunity is often abnormal, as manifested by anergy to skin testing and impaired *in vitro* lymphoproliferative responses to specific antigens. Serum levels of IgG, IgA and IgM are usually normal in STAT3-HIES, as are lymphocyte subsets. In contrast, DOCK8 deficiency represents a combined immunodeficiency that is characterized by lymphopenia with a paucity of $CD4^+$ T cells > $CD8^+$ T cells > B cells, low IgM levels, and variable IgG levels as well as elevated IgE levels and peripheral eosinophilia[91,92].

The infantile papulopustular eruption of STAT3-HIES is characterized histologically by eosinophilic folliculitis, eosinophilic spongiosis, and a superficial and deep perivascular infiltrate with abundant eosinophils[101,102].

Differential Diagnosis

Current diagnostic criteria for STAT3-HIES include an IgE level >1000 IU/ml and a weighted score of five clinical features (Table 60.14)[105]; these characteristics plus a lack of Th17 cells or the detection of a heterozygous *STAT3* mutation allow for a probable or definitive diagnosis, respectively.

HIES must be differentiated from a number of other disorders that can feature elevated IgE levels and a cutaneous eruption, including atopic dermatitis, Wiskott–Aldrich syndrome, Netherton syndrome, Omenn syndrome, DiGeorge syndrome, IPEX syndrome, ARPC1B (actin-related protein 2/3 complex subunit 1B) deficiency, Loeys–Dietz syndrome, and GVHD. Atopic dermatitis and Wiskott–Aldrich syndrome are most easily confused with HIES because they present with eczematous dermatitis and staphylococcal infections. However, the development of cold abscesses, recurrent pneumonia, coarse facial features, and osteopenia help to differentiate STAT3-HIES from these disorders, and platelet abnormalities distinguish Wiskott–Aldrich syndrome as well as ARPC1B syndrome. In a series of pediatric patients who had a serum IgE level of >2000 IU/ml, 69% (48/70) had atopic dermatitis and only 8% (6/70) had HIES; no correlation was observed between the IgE level and diagnosis of HIES[106]. Elevated IgE levels, susceptibility to pyogenic infections, and eczematous dermatitis have

Fig. 60.9 DOCK8 deficiency. **A** Eczematous dermatitis with prurigo nodularis lesions. **B** Extensive molluscum contagiosum. **C** Numerous coalescing facial warts. *A, B, Courtesy Edward Cowen, MD.*

DIAGNOSTIC GUIDELINES FOR HYPERIMMUNOGLOBULIN E SYNDROME (AD-HIES) DUE TO *STAT3* MUTATIONS							
Clinical finding	**Points**						**Multiplication factor**
	0	**2**	**4**	**5**	**6**	**8**	
Pneumonias (X-ray proven, total #)	none	1	2	–	3	>3	2.5
Newborn papulopustular eruption (during first 3 weeks of life)	absent	–	present	–	–	–	2.1
Pathologic bone fractures	none	–	1–2	–	–	>2	3.3
Characteristic facies	absent	mild	–	present	–	–	3.3
High-arched palate	absent	present	–	–	–	–	2.5
Possible AD-HIES: IgE >1000 IU/ml *plus* weighted score of >30 **Probable AD-HIES**: As above plus lack of Th17 cells by peripheral blood flow cytometry *or* a family history of definitive AD-HIES **Definitive AD-HIES:** As above plus a dominant-negative heterozygous mutation in *STAT3*							

Table 60.14 Diagnostic guidelines for autosomal dominant hyperimmunoglobulin E syndrome (AD-HIES) due to *STAT3* mutations[105].

also been described in patients with prolidase deficiency, an autosomal recessive condition due to *PEPD* mutations that also features chronic leg ulcers, facial dysmorphism, and intellectual disability. Patients with CGD and myeloperoxidase deficiency develop bacterial and candidal abscesses, but they do not typically have markedly elevated levels of IgE.

In addition to DOCK8 deficiency and the other six conditions noted in Table 60.1, primary immunodeficiencies that result in increased susceptibility to warts include epidermodysplasia verruciformis (see Ch. 79), Netherton syndrome (see Ch. 57), and activated phosphoinositide-3-kinase δ syndrome (see Table 60.15) as well as deficiencies of serine/threonine kinase 4 (STK4), GATA2 (see Table 60.13), TNF-like weak inducer of apoptosis (TWEAK; see Table 60.15), coronin 1A (see Table 60.16), RhoH GTPase, minichromosome maintenance complex component 4 (MCM4; also herpesvirus infections), and capping protein regulator and myosin 1 linker 2 (CARMIL2; also severe molluscum contagiosum). Of note, $CD4^+$ lymphocytopenia can be a prominent feature of DOCK8 deficiency and other wart-prone immunodeficiency syndromes.

Treatment

Treatment of the infectious complications of HIES includes incision and drainage of abscesses as well as therapeutic and prophylactic administration of antibiotics. Interferon-γ has been shown to help control infections, and IVIg may improve the dermatitis, prevent infections, and lower IgE levels. Treatment with dupilumab and omalizumab has been reported to improve the eczematous dermatitis of HIES[107].

IMMUNOGLOBULIN DEFICIENCIES

Synonyms: ■ X-linked agammaglobulinemia ■ Bruton agammaglobulinemia ■ Bruton–Gitlin syndrome ■ Congenital hypogammaglobulinemia ■ X-linked hypogammaglobulinemia

Key features

Agammaglobulinemia

- The inheritance pattern is X-linked recessive in ~90% of patients and autosomal recessive in ~10%
- Recurrent bacterial infections begin in the first few years of life

Common variable immunodeficiency (CVID)

- Heterogeneous group of disorders with defects in both humoral and cell-mediated immunity
- May manifest during childhood or adulthood, with clinical onset at an average age of 30 years
- Variable severity of infectious and autoimmune complications

Selective IgA deficiency

- Most common immunoglobulin deficiency, but usually asymptomatic, with clinical manifestations in only 10%–15% of affected individuals
- Bacterial sinopulmonary infections and autoimmune disorders may occur

Hyper-IgM syndromes

- Usually has an X-linked recessive inheritance pattern, but autosomal recessive forms also exist
- Recurrent sinopulmonary and gastrointestinal infections with pyogenic bacteria and opportunistic organisms
- Oral ulcerations and verrucae may develop

The most common immunoglobulin deficiency is selective IgA deficiency, overall found in ~1 in 500 persons with an equal sex distribution. Panhypogammaglobulinemia has a prevalence of 1 in 25 000, with X-linked agammaglobulinemia[102] (affecting primarily boys) and common variable immunodeficiency[108] (CVID; no sexual predilection) representing the most frequent forms. CVID has its clinical onset at a mean age of 30 years whereas X-linked agammaglobulinemia often manifests during the first few years of life, after levels of maternal antibodies wane at ~6 months of age. Approximately 15% of patients with CVID have family members with selective IgA deficiency. The pathogenesis and clinical features of immunoglobulin deficiencies are presented in Fig. 60.10 and Table 60.15[108–115].

The treatment of hypogammaglobulinemia is antibody replacement by IVIg or subcutaneous immunoglobulins and antibiotic therapy for infections[116]. However, IVIg and other blood products containing IgA should be avoided in individuals with profound IgA deficiency, who may develop anti-IgA antibodies; fatal anaphylactic reactions have been reported. Recalcitrant non-infectious cutaneous and extracutaneous granulomas in patients with CVID may respond to treatment with TNF inhibitors.

Female carriers of X-linked agammaglobulinemia may be detected via examination of B cell X-inactivation patterns, which show skewing towards cells with inactivation of the mutated X chromosome. DNA-based prenatal diagnosis is possible when the genetic defect in affected family members has been identified.

IPEX SYNDROME

Key features

- X-linked recessive disorder due to mutations in *FOXP3*
- Cutaneous findings include a widespread eczematous dermatitis during infancy and a variety of autoimmune skin conditions
- Also features enteropathy and endocrinopathies with autoimmune etiologies

IPEX – *i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked – syndrome is an X-linked recessive disorder caused by *FOXP3* mutations that result in abnormal development of regulatory T cells. Affected individuals typically present during infancy with severe diarrhea secondary to autoimmune enteropathy and develop a variety of autoimmune endocrinopathies such as early-onset type 1 diabetes mellitus, thyroiditis, and cytopenias. Most IPEX patients have a widespread eczematous dermatitis and elevated IgE levels during early infancy, and this is often complicated by staphylococcal superinfections and sepsis. Cutaneous manifestations of IPEX can also include psoriasiform dermatitis, cheilitis, nail dystrophy, and autoimmune skin conditions such as alopecia areata, chronic urticaria, and bullous pemphigoid[117].

IPEX-like clinical presentations can occur in patients with IL-2 receptor α-chain (CD25) deficiency[118], LPS-responsive beige-like anchor protein (LRBA) deficiency, *gain*-of-function *STAT1* or *STAT3* mutations, and *loss*-of-function *STAT5B* mutations[119] (see Tables 60.4, 60.13, 60.15). In addition, an autosomal recessive disorder due to mutations in *ADAM17*, which encodes the TNF converting enzyme, features a widespread psoriasiform dermatitis with pustular flares, brittle hair, staphylococcal skin infections, and chronic diarrhea[120].

LEUKOCYTE ADHESION DEFICIENCY

Key features

- Group of autosomal recessive disorders characterized by decreased ability of leukocytes to adhere to the vascular endothelium and migrate to sites of tissue injury and infection
- Gingivitis and periodontitis
- Necrotic ulcerations clinically resembling pyoderma gangrenosum
- Poor wound healing; delayed separation of the umbilical stump
- Life-threatening bacterial and fungal infections

Introduction

Leukocyte adhesion deficiency (LAD) comprises three autosomal recessive disorders that affect the ability of neutrophils, monocytes, and lymphocytes to adhere to the vascular endothelium and migrate to sites of infection and tissue injury[121,122].

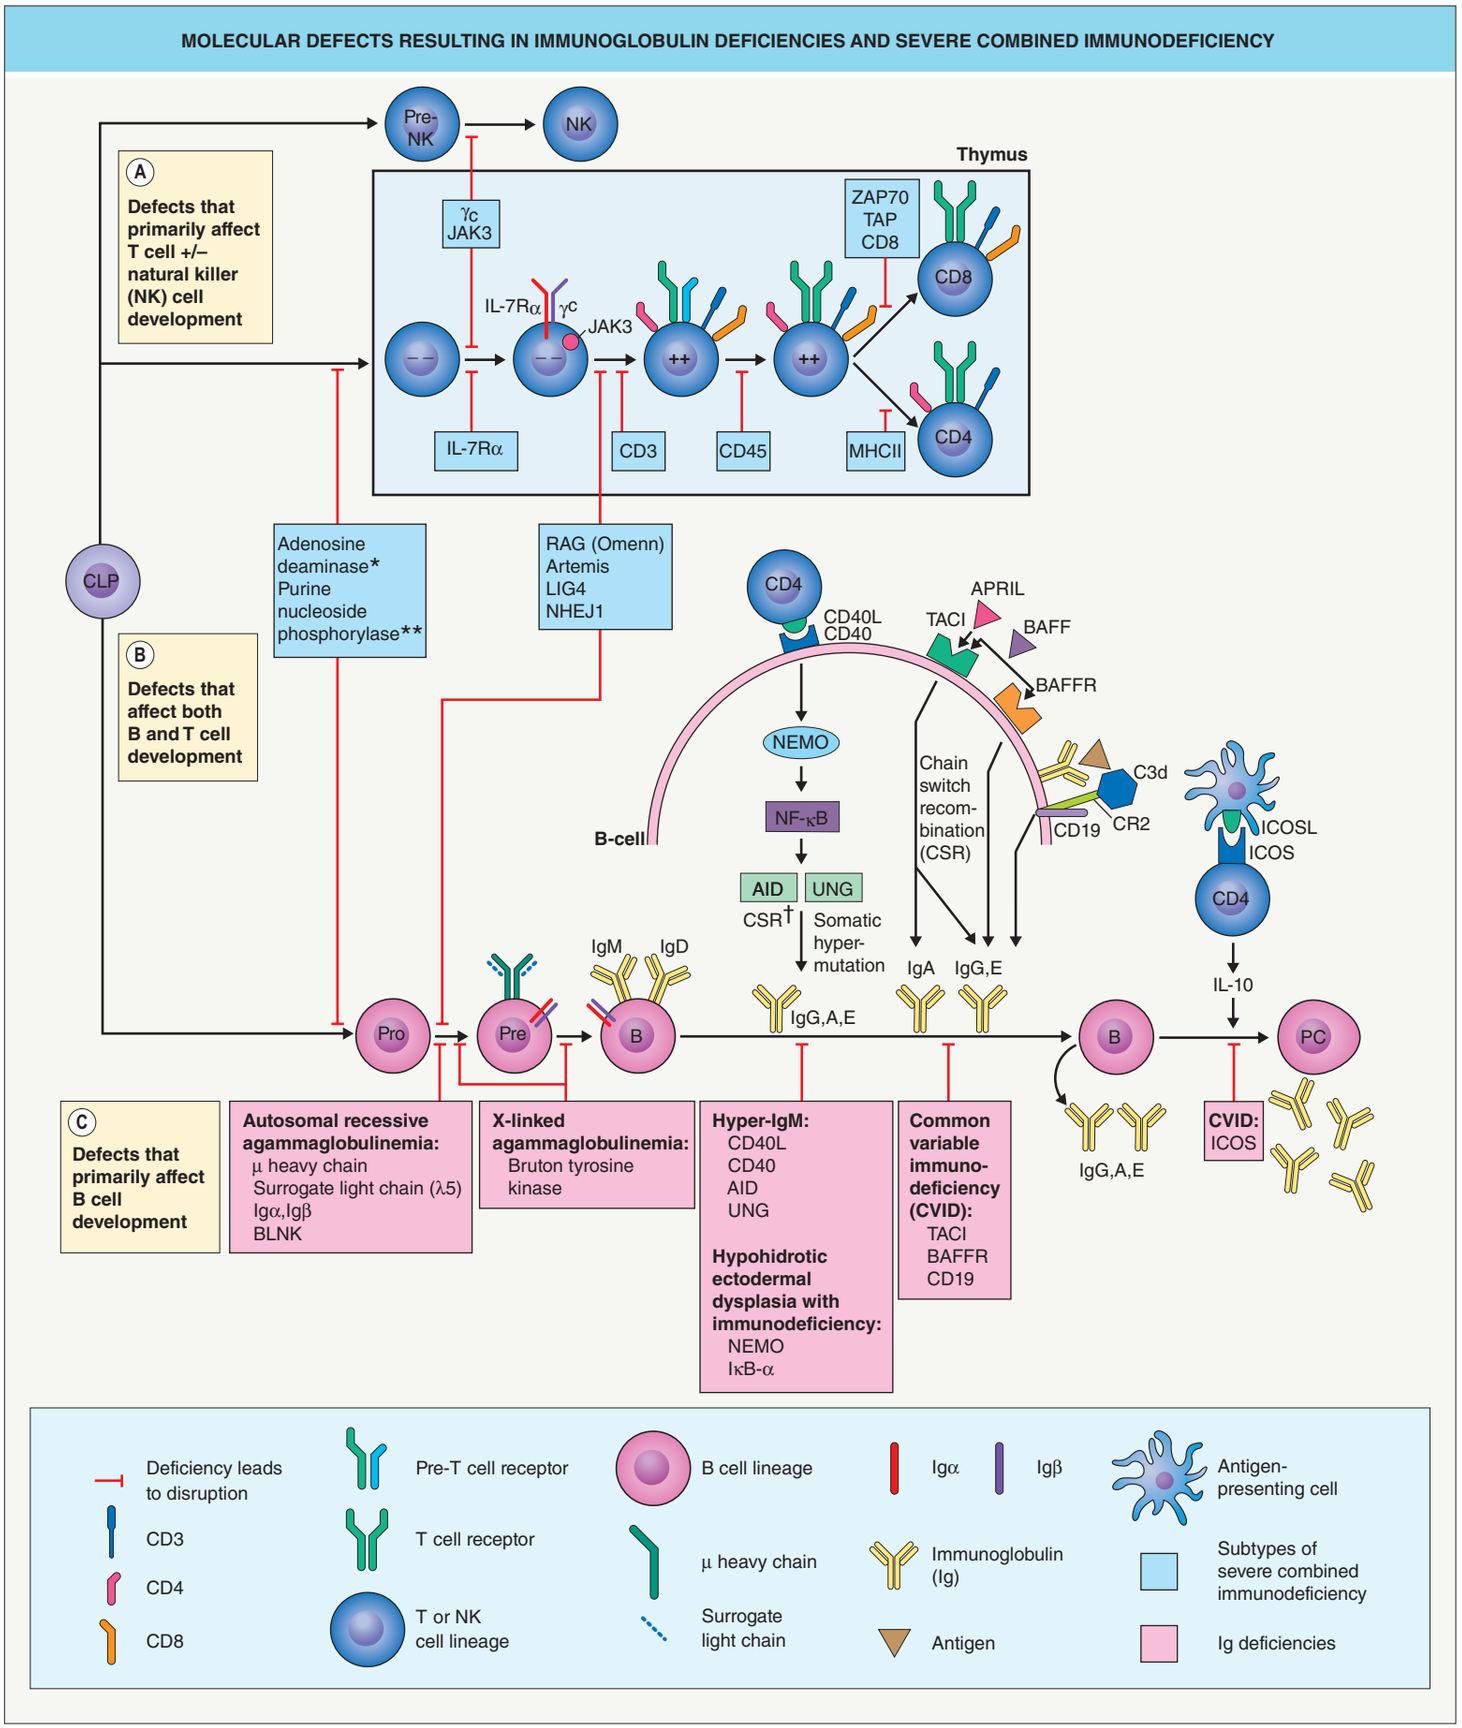

Fig. 60.10 Molecular defects resulting in immunoglobulin deficiencies and severe combined immunodeficiency (SCID). *Also important for B cell maturation in germinal centers. **Affects T cells more than B cells. †Switch from IgM to IgG, IgA, or IgE. AID, activation-induced cytidine deaminase; APRIL, *a p*roliferation-*i*nducing *l*igand; BAFF(R), B cell activating factor (receptor); BLNK, B cell linker protein (binds Bruton tyrosine kinase); CD40L, CD40 ligand; CLP, common lymphoid precursor; CR2, complement receptor 2; γ_c, common γ chain; ICOS(L), inducible costimulator on activated T cells (ligand); IκB-α, inhibitor of κB-α; IL, interleukin; IL-7Rα, IL-7 receptor α-chain; MHC, major histocompatibility complex; NEMO, NF-κB essential modulator; NHEJ1, non-homologous end-joining 1 (Cernunnos); NK, natural killer cell; PC, plasma cell; TACI, transmembrane activator and CAML interactor; TAP, transporter associated with antigen processing; UNG, uracil-DNA glycosylase; _ _, double-negative thymocyte; ++, double-positive thymocyte.

PRIMARY IMMUNOGLOBULIN DEFICIENCY DISORDERS						
Disorder	**Gene**	**Protein (function)**	**Ig levels**	**B cells**	**Infectious and systemic manifestations**	**Cutaneous manifestations**
Block in B cell differentiation at the pro-B to pre-B cell transition						

X-linked agammaglobulinemia	*BTK*	Bruton tyrosine kinase (pre-B cell receptor [BCR] signaling)	All ↓	↓↓	• Recurrent infections with *Staphylococcus, Streptococcus, Pneumococcus, Haemophilus* and *Pseudomonas* spp.
					• Hepatitis B and enteroviral infections
					• Lymphomas (~5%)
						• The skin is the most common site of infection
						  • Furuncles and cellulitis
						  • Ecthyma gangrenosum
						• Eczematous dermatitis
						• Papular dermatitis due to lymphohistiocytic infiltration
						• Non-infectious granulomas
						• Dermatomyositis-like disorder associated with chronic echoviral meningoencephalitis

AR agammaglobulinemia	*IGHM*	μ heavy chain of IgM (component of pre-BCR)				
	CD79A, CD79B	Igα chain, Igβ chain (bind μ heavy chain)				
	IGLL1	λ5 (surrogate light chain of pre-BCR)				
	BLNK	B cell linker protein (binds Bruton tyrosine kinase)				
AD agammaglobulinemia	*LRRC8A*	Leucine-rich repeat-containing 8 family member A				
Defective class switch recombination (e.g. from IgM to IgG, IgA or IgE), somatic hypermutation*, and related mechanisms						
Common variable immunodeficiency (CVID)[†]	*ICOS*	Inducible costimulator on activated T cells (T cell help for B cell differentiation)	IgG, A ↓; ± IgM ↓	Nl or ↓	• Bacterial sinopulmonary infections (organisms similar to X-linked agammaglobulinemia) • *Giardia* spp. gastroenteritis • Autoimmune diseases, especially hemolytic anemia and idiopathic thrombocytopenic purpura • Increased risk of cancer (10-fold overall) and lymphoma (400-fold)	• Pyodermas and mucocutaneous candidiasis • Extensive warts and dermatophyte infections • Eczematous dermatitis • Non-infectious granulomas (Fig. 60.11), which may also involve the lungs, liver and spleen • Autoimmune conditions such as vitiligo, alopecia areata and vasculitis • Clonal $CD8^+$ lymphocytic infiltration of the skin • Clinical manifestations of LRBA deficiency variable; include an IPEX-like presentation (see text) and autoimmune lymphoproliferative syndrome (see Table 60.6)
	TNFRSF13B (AD or AR)	Transmembrane activator and CAML interactor (TACI; B cell isotype switching)				
	TNFRSF13C	B cell activating factor receptor (BAFFR; B cell isotype switching)				
	CD19[‡]	CD19 antigen (B cell survival and differentiation)				
	MSH5 (AD)	Mismatch repair protein (regulates class switch recombination)				
	LRBA (AR)	LPS-responsive beige-like anchor protein				
Selective IgA deficiency	*TNFRSF13B* (AD)	See CVID section above	IgA ↓[¶]; anti-IgA antibodies in ~half	Nl	• Clinical manifestations in 10%–15% • Similar to CVID	• Mucocutaneous candidiasis • Eczematous dermatitis • Autoimmune conditions such as SLE, vitiligo, and lipodystrophia centrifugalis abdominalis
	MSH5 (AD)					
Selective IgM deficiency	?	?	IgM ↓	Nl	• Recurrent bacterial infections • Autoimmune diseases	• Extensive warts • Eczematous dermatitis • SLE
TWEAK deficiency	*TWEAK*	TNF-like weak inducer of apoptosis	IgM, A ↓	Nl	• Pneumonia, other bacterial infections • Thrombocytopenia, neutropenia	• Warts
Activated PI3Kδ syndrome	*PIK3CD, PIK3R1*	Phosphoinositide-3-kinase catalytic subunit δ (gain-of-function) or regulatory subunit 1 (loss-of-function)	IgG/G_2, A ↓; IgM ↑; also often CD4 lymphopenia	Nl or ↓	• Recurrent sinopulmonary infections • Chronic EBV and CMV infections • LAN, HSM • Lymphoma • Autoimmune diseases, e.g. cytopenias • Growth retardation (*PIK3R1*)	• Staphylococcal abscesses, cellulitis • Severe/recurrent HSV and VZV infections, warts, molluscum contagiosum

Table 60.15 Primary immunoglobulin deficiency disorders.

Continued

PRIMARY IMMUNOGLOBULIN DEFICIENCY DISORDERS						
Disorder	**Gene**	**Protein (function)**	**Ig levels**	**B cells**	**Infectious and systemic manifestations**	**Cutaneous manifestations**
X-linked hyper-IgM syndrome	*CD40LG*	CD40 ligand (on T cells)	IgM ↑; isohemagglutinins ↑; IgA, E, G ↓↓	NI	• Recurrent sinopulmonary and GI infections with pyogenic bacteria and opportunistic organisms (e.g. PCP) • Neutropenia • Small lymph nodes • Autoimmune diseases, especially thyroiditis and hemolytic anemia	• Pyodermas • Extensive warts • Oral and anogenital ulcers • Non-infectious granulomas • Autoimmune conditions such as SLE
AR hyper-IgM syndromes	*CD40*	CD40 (on B cells)				
	AICDA	Activation-induced cytidine deaminase			• As above, but massive HSM/LAN (with germinal centers) and no opportunistic infections	• Pyodermas
	UNG	Uracil-DNA glycosylase				
Hypohidrotic ectodermal dysplasia with immunodeficiency	*IKBKG (NEMO)* (X-linked recessive)	NF-κB essential modulator (activates NF-κB, which is involved in CD40 signaling)	IgM ↑; ± IgA ↑; ± IgG ↓	NI	• Pyogenic bacterial and opportunistic infections • Subset of *NEMO* patients with osteopetrosis and lymphedema	• Pyodermas • Ectodermal dysplasia (see Ch. 63)
	NFKBIA (AD, gain of function)	NF-κB inhibitor α				
	IKBKB	Inhibitor of NF-κB kinase β				
Abnormal DNA methylation leading to defective B cell negative selection and terminal differentiation						
*I*mmunodeficiency, centromeric instability, and *f*acial anomalies (ICF) syndrome	*DNMT3B, ZBTB24*	DNA methyltransferase 3β, zinc finger and BTB-containing 24	All ↓	NI or ↓	• Bacterial sinopulmonary and GI infections • Abnormal facies, intellectual disability	• Telangiectasias (uncommon) • Nevoid hyperpigmentation
Aberrant chemokine signaling						
WHIM syndrome§	*CXCR4* (AD, gain-of-function)	CXC chemokine receptor 4 (binds CXCL12; key role in bone marrow homeostasis and lymphocyte trafficking)	IgG ↓; ± IgA, M ↓	↓	• Recurrent bacterial sinopulmonary infections • Myelokathexis (mature neutrophils fail to exit the bone marrow)	• Cellulitis and pyodermas • Extensive verruca vulgaris and condyloma acuminata (Fig. 60.12) • Treatment with mavorixafor, a CXCR4 inhibitor, decreased warts and other infections in a phase 3 clinical trial
Delayed maturation of helper T cell function						
Transient hypogammaglobulinemia of infancy	?	?	IgG, A ↓ (resolves by age 3 y)	NI	• Failure to thrive in infancy • Recurrent sinopulmonary and GI infections	• Recurrent pyodermas and abscesses • Eczematous dermatitis

*T cell priming may also be defective, particularly in CD40–CD40L disorders (leading some authors to classify the latter as subtypes of severe combined immunodeficiency).
†Relatively common, heterogeneous group of disorders characterized by decreased levels of at least two classes of immunoglobulins (IgG, IgA > IgM) and variable defects in T cell function; currently, ≤10% of patients have an identifiable disease-causing mutation; several additional genes have also been associated with CVID[114].
‡*CD81* is required for CD19 expression, and a homozygous mutation in the *CD81* gene was reported in a patient with hypogammaglobulinemia and autoimmune vasculitis.
¶Symptomatic patients often develop the immunodeficiency pattern of CVID.
§Warts, hypogammaglobulinemia, infections, and myelokathexis; in a phase 1 trial, treatment with plerixafor (AMD 3100), a CXCR4 antagonist, led to higher neutrophil counts and improvement of warts.

Table 60.15 Primary immunoglobulin deficiency disorders. Conditions are autosomal recessive (AR) unless otherwise specified. AD, autosomal dominant; CAML, calcium-modulating cyclophilin ligand; GI, gastrointestinal; HSM, hepatosplenomegaly; HSV, herpes simplex virus; Ig, immunoglobulin; *IKBKG*, inhibitor of NF-κB kinase regulatory subunit γ; LAN, lymphadenopathy; NI, normal; PCP, *Pneumocystis jirovecii* pneumonia; SLE, systemic lupus erythematosus; VZV, varicella–zoster virus.

Pathogenesis

Leukocyte adhesion requires a group of cell surface integrins that share the 95-kDa β_2-subunit known as CD18. This β_2-subunit can be linked to different α-chains to form distinct cell surface glycoproteins including: (1) lymphocyte function antigen 1 (LFA-1 – CD18 paired with CD11a); (2) complement receptor type 3 (CR3/$iC3_b$ receptor/Mac-1 – CD18 paired with CD11b); and (3) p150,95 (complement receptor type 4 – CD18 paired with CD11c). The primary ligand for these glycoproteins is intercellular adhesion molecule-1 (ICAM-1), which participates in the initiation and evolution of localized inflammation in the skin and other tissues (see Fig. 102.10). LAD-I is caused by mutations in *ITGB2* which encodes CD18, and it manifests with dysfunction of all three glycoproteins. This leads to profound impairment of leukocyte firm adhesion to the vascular endothelium and mobilization into extravascular sites of inflammation, as well as defective neutrophil and monocyte chemotaxis and phagocytosis.

LAD-II is due to mutations in *SLC35C1* (solute carrier family 35 member C1), which encodes the GDP-fucose transporter-1 (FUCT1) that is required for formation of sialyl-Lewis X, the fucosylated ligand for selectins on the surface of leukocytes[123]. This causes a defect in the initial steps of tethering and rolling of leukocytes on the endothelial cell surface via interaction of sialyl-Lewis X on leukocytes with E- or

Fig. 60.12 Extensive, recalcitrant perianal warts in a child with WHIM syndrome. *Courtesy Edward Cowen, MD.*

P-selectin on endothelial cells. These contacts are required for their targeting to sites of infection and inflammation.

In order to undergo firm adhesion and subsequently extravasate from the bloodstream, circulating leukocytes must activate integrins *in situ* to rapidly increase their affinity and avidity for endothelial ligands. Patients with LAD-III have impaired integrin activation in hematopoietic cells, which leads to impaired leukocyte β_1- and platelet β_3-integrins in addition to leukocyte β_2-integrins as in LAD-I. It is caused by loss-of-function mutations in the fermitin family member 3 gene (*FERMT3*) that encodes kindlin-3, an effector of integrin activation in hematopoietic cells[124].

Clinical Features

The most common manifestation of LAD is gingivitis with periodontitis, which often leads to tooth loss and alveolar bone resorption and is thought to be related to excessive production of interleukin-17. Minor injuries to the skin may rapidly expand to form large, chronic ulcerations that can resemble "burnt out" pyoderma gangrenosum (Fig. 60.13). Poor wound healing also results in paper-thin, atrophic scars. A history of delayed separation of the umbilical stump represents a clue to the diagnosis.

Patients with LAD develop recurrent otitis media, pneumonia, and cutaneous infections caused by pyogenic bacteria. The latter often present as cellulitis and necrotic abscesses with relatively little production of purulent material, typically located in the perianal area or on the face. Life-threatening bacterial, fungal, or (less frequently) viral infections may also occur. More than three-quarters of patients with severe LAD-I (<1% of normal CD18 levels) die within the first 5 years of life, whereas approximately half of patients with moderate disease (1%–10% of normal CD18 levels) live to age 30 years[122].

Additional clinical manifestations of LAD-II include intellectual disability, microcephaly, hypotonia, short stature, and facial dysmorphism[123]. Patients with LAD-III often present with a bleeding tendency as well as variable osteopetrosis and hepatosplenomegaly. Dermal hematopoiesis with a "blueberry muffin" appearance secondary to myelodysplastic syndrome has been described in infants and children with LAD-III[125].

Fig. 60.13 Chronic ulcer in leukocyte adhesion deficiency type I. This 7-year-old boy was scratched by his sister, resulting in a large gaping wound that healed poorly. *Reprinted with permission from Torrelo A (ed). Schachner and Hansen's Pediatric Dermatology, 5th edn. London: Mosby, 2023.*

Pathology

Individuals with LAD have marked *peripheral blood neutrophilia* (5–20 times normal levels). Although cutaneous ulcerations may resemble pyoderma gangrenosum clinically, histologic examination reveals a relative *paucity of tissue neutrophils*. Flow cytometric analysis reveals markedly decreased leukocyte CD18 expression in individuals with LAD-I. Patients with LAD-II have the Bombay red blood cell type due to a lack of the H blood group antigen, and those with LAD-III have abnormal platelet aggregation due to defective activation of β_3-integrin and less often have anemia.

Differential Diagnosis

A mutation in the gene encoding the Rac2 GTPase, which has a role in phagocyte NADPH oxidase activation as well as integrin-dependent adhesion and neutrophil migration, can lead to clinical features similar to those of LAD, including delayed separation of the umbilical stump, poor wound healing, neutrophilia, and recurrent perirectal abscesses with an absence of pus (see Tables 60.10 & 60.13).

Treatment

Soft tissue infections in LAD patients require prolonged courses of antimicrobial therapy and, in some cases, surgical debridement. Meticulous dental hygiene is important in reducing the severity of the periodontitis. Granulocyte transfusions have potential benefit in LAD-I and -III, and oral administration of fucose may improve immune function in patients with LAD-II[123]. In LAD-I, healing of chronic oral and cutaneous ulcers following administration of IVIg or ustekinumab has been reported[126]. Hematopoietic stem cell transplantation represents the only definitive therapy for LAD, but it is limited by infectious complications and GVHD.

Two patients with severe LAD-I were treated without prior conditioning with an infusion of autologous hematopoietic stem cells that had been corrected *ex vivo* with a retroviral vector encoding CD18, but circulating $CD18^+$ cells persisted for <2 months[122]. However, canine LAD-I has been successfully treated with non-myeloablative conditioning followed by infusion of autologous hematopoietic stem cells transduced *ex vivo* by a CD18-expressing foamy virus vector, which has less potential for genotoxicity than a retroviral vector; this led to complete reversal of the LAD phenotype that was sustained for more than 4 years[127]. Preclinical studies have also investigated lentiviral-mediated gene therapy for LAD-I, with correction of the phenotype in a mouse model.

SEVERE COMBINED IMMUNODEFICIENCY AND OMENN SYNDROME

Synonyms: ■ Severe combined immunodeficiency (SCID) syndrome ■ Severe mixed immunodeficiency syndrome ■ Glanzmann–Riniker syndrome ■ Alymphocytosis ■ Thymic alymphoplasia

Key features

- Group of conditions characterized by defective function of both cell-mediated and humoral immunity
- Recurrent infections, diarrhea, and failure to thrive within the first 3–6 months of life
- Risk of GVHD, especially from unirradiated blood products
- Lack of lymphoid tissue

Introduction

Severe combined immunodeficiency (SCID) is a heterogeneous group of disorders that share clinical manifestations related to defective function of both cell-mediated and humoral immunity[128–130] (Table 60.16).

Epidemiology

SCID occurs in ~1 in 50 000 live births[131], and three-quarters of affected patients are boys. Approximately 40% of cases have X-linked recessive inheritance, primarily due to defects in the gene encoding the common γ (γ_c) chain of the IL-2 receptor, while the remainder are autosomal recessive. Other relatively frequent causes of autosomal recessive SCID include deficiencies of adenosine deaminase (ADA), the IL-7 receptor, or JAK3, each accounting for 5%–15% of cases[131].

Pathogenesis

Molecular defects that can lead to the SCID phenotype are presented in Fig. 60.10 and Table 60.16.

Clinical Features

Infants with SCID may present with widespread seborrheic-like dermatitis or morbilliform eruptions, often reflecting maternofetal GVHD. Cutaneous findings may also resemble lichen planus, acrodermatitis enteropathica, Langerhans cell histiocytosis, ichthyosiform erythroderma, and systemic sclerosis. Extensive eczematous dermatitis or exfoliative erythroderma, often associated with diffuse alopecia, may also occur in infants with *Omenn syndrome (RAG1* or *RAG2)*, which also features lymphadenopathy, hepatosplenomegaly, chronic diarrhea, peripheral eosinophilia, leukocytosis, and elevated IgE levels in the setting of SCID (see Tables 10.2 and 60.16). Of note, extensive cutaneous and extracutaneous granulomas (including destructive midfacial lesions) can develop in children with hypomorphic *RAG1* or *RAG2* mutations (Fig. 60.14).

Recurrent infections, chronic diarrhea, and failure to thrive are apparent within the first few months of life. Common early infections include mucocutaneous candidiasis, persistent viral gastroenteritis, and pneumonias due to bacteria, viruses, or *P. jirovecii*. Cutaneous infections are most often caused by *C. albicans*, *S. aureus*, and *Str. pyogenes*. Despite recurrent infections, patients with SCID typically lack tonsillar buds and palpable lymphoid tissue. SCID due to ADA deficiency is associated with an increased risk of developing dermatofibrosarcoma protuberans, often multiple and morpheaform, during the first two decades of life[130].

Laboratory Findings and Pathology

Nearly all patients with SCID have a profound T cell deficiency and a low absolute lymphocyte count. Patients are further classified by the results of fluorescent activated cell sorter (FACS) analysis into those with and without B lymphocytes and NK cells. The laboratory abnormalities observed in different types of SCID are noted in Table 60.16. Certain forms of SCID show distinctive radiographic manifestations; for example, patients with ADA deficiency demonstrate cupping and flaring of the costochondral junction on chest radiographs. Flow cytometric analysis of peripheral blood mononuclear cells with antibodies directed against a particular protein that is missing from the cell surface (e.g. γ_c, JAK3) as well as genetic testing (e.g. a multigene panel) can help to establish a specific diagnosis.

Maternal T cell engraftment accounting for ≥1% of peripheral blood leukocytes is present in approximately half of infants with SCID. The presence of maternal T cells is often asymptomatic, but a third of patients have mild changes such as cutaneous erythema and scale, a morbilliform eruption, elevated hepatic transaminases, and eosinophilia. Skin biopsy specimens show the histopathologic features of GVHD (see Ch. 52). Maternofetal GVHD is typically less severe than that resulting from postnatal inoculation of allogeneic lymphocytes, such as from unirradiated blood product transfusions, which can be fatal.

Histologically, the erythroderma of Omenn syndrome shares some features with GVHD such as necrotic keratinocytes but also has epidermal acanthosis, parakeratosis, and a dense dermal infiltrate composed primarily of T cells.

Differential Diagnosis

SCID must be differentiated from other immunodeficiency disorders, especially HIV infection. The latter is distinguished by normal to increased immunoglobulin levels, a relative decrease in $CD4^+$ T cells, and the presence of anti-HIV antibodies and HIV RNA.

Treatment

Without intervention, the outcome for SCID patients is death by 1 year of age. Early diagnosis of SCID is critical, preferably before the administration of live vaccines or unirradiated blood products. Newborn screening for SCID is performed in the US and several other countries. Infants with SCID should be kept in protective isolation and monitored for the development of infections, which should be treated aggressively; administration of IVIg and prophylaxis for *P. jirovecii* pneumonia are also recommended.

Hematopoietic stem cell transplantation (HSCT) during infancy is currently the first-line treatment for SCID. Because the patient's immune system is unable to reject the transplanted cells, myeloablative therapy is not required. The result is engraftment of donor T and NK cells, but usually not B cells. With an HLA-identical sibling donor, T cell reconstitution typically occurs within 3–4 months, GVHD is uncommon, and the long-term survival rate is >90%. Transplantation of haploidentical parental stem cells, which can be depleted of postthymic T cells to reduce the risk of GVHD, often requires some chemotherapeutic conditioning to facilitate engraftment and results in ≤80% survival. *In utero* injection of haploidentical $CD34^+$ cells has also been used to treat X-linked SCID. SCID patients often require IVIg replacement therapy for persistent B cell deficiency following HSCT, and T cell function may decline over time. Administration of virus-specific T cells from their stem cell donor or a third-party donor may be useful for the treatment and prevention of viral infections (e.g. with EBV or cytomegalovirus) in HSCT recipients with SCID[132].

Enzyme replacement via injection of polyethylene glycol-conjugated ADA can lead to improved immune function in children with ADA deficiency. Gene therapy has been successfully performed in more than 50 children with X-linked SCID or ADA deficiency via retroviral-mediated *ex vivo* gene transfer into $CD34^+$ cells[133,134]. Follow-up studies on 19 of these patients (4 months–4 years after treatment) showed

TYPES OF SEVERE COMBINED IMMUNODEFICIENCY (SCID)			
Disorder	**Gene**	**Protein function and specific clinical features**	**Cells**
Defects in cytokine receptors and their signaling			
X-linked SCID	*IL2RG*	Common γ chain (γ_c) of the receptors for IL-2, 4, 7, 9, 15, and 21	$T^-/B^+/NK^-$
JAK3 deficiency	*JAK3*	Tyrosine kinase with a role in signal transduction via the receptors for IL-2, 4, 7, 9, 15, and 21	$T^-/B^+/NK^-$
Interleukin-7 receptor deficiency	*IL7R*	α-chain of the IL-7 receptor; critical for development and differentiation of T cells; possible Omenn syndrome phenotype	$T^-/B^+/NK^-$
Increased apoptosis of lymphocytes ± other hematopoietic cells			
Defects in purine pathway enzymes that result in the build-up of toxic metabolites			
Adenosine deaminase (ADA) deficiency	*ADA*	Enzyme in the purine salvage pathway	$T^-/B^-/NK^-$
Purine nucleoside phosphorylase (PNP) deficiency	*PNP*	Enzyme in the purine salvage pathway (downstream of ADA)	$T^-/B^-/NK^-$
Defects disrupting mitochondrial energy production			
Reticular dysgenesis (aleukocytosis)	*AK2*	Adenylate kinase 2, a mitochondrial enzyme that regulates ADP levels in leukocytes; profound neutropenia and sensorineural deafness	$T^-/B^-/NK^-$
Defects disrupting actin polymerization			
Coronin 1A deficiency	*CORO1A*	Actin regulator expressed in T cell precursors; severe warts, molluscum contagiosum, and herpesvirus infections	$T^-/B^-/NK^+$
Defects in (pre-)T cell receptors (TCRs) ± B cell receptors (BCRs) and their signaling			
Omenn syndrome	*RAG1* and *RAG2*	Mediate V(D)J recombination of the genes that encode BCRs (immunoglobulins) and TCRs*; erythroderma, alopecia, LAN, HSM, diarrhea, eosinophilia, elevated IgE levels (see text)	$T^-/B^-/NK^+$
Artemis deficiency	*DCLRE1C (Artemis)*	Repairs the DNA double-stranded breaks that occur during V(D)J recombination and from ionizing radiation*; possible Omenn syndrome phenotype	$T^-/B^-/NK^+$
PRKDC deficiency	*PRKDC*	DNA-activated protein kinase catalytic subunit critical for V(D)J recombination*	$T^-/B^-/NK^+$
LIG4 syndrome	*LIG4*	Ligase component of the DNA non-homologous end-joining (NHEJ) machinery required for the repair of DNA double-stranded breaks*; photosensitivity, telangiectasias, bird-like facies, microcephaly	$T^-/B^-/NK^+$
NHEJ1 (Cernunnos) deficiency	*NHEJ1*	NHEJ factor required for the repair of DNA double-stranded breaks*; bird-like facies, microcephaly	$T^-/B^-/NK^+$
T cell receptor deficiencies	*CD3γ, CD3δ, CD3ε*, and *CD3ζ*	TCR-associated proteins required for cell surface expression of and signal transduction by the TCR; most severe with defective CD3δ	$T^-/B^-/NK^+$
	TRAC	TCR-α constant region; relatively mild immunodeficiency	
CD45 deficiency	*PTPRC*	Transmembrane tyrosine phosphatase with a role in TCR signaling	$T^-/B^+/NK^+$
ZAP70 deficiency	*ZAP70*	Tyrosine kinase with a role in TCR signaling	$CD4^+CD8^+/B^+/NK^+$
CD8 deficiency†	*CD8A*	Co-receptor for TCRs recognizing MHC class I-associated peptides; role in TCR signaling	$CD4^+CD8^+/B^+/NK^+$
Calcium channel deficiency	*ORAI1*	Pore-forming subunit of calcium channel with a role in TCR signaling; hypohidrotic ectodermal dysplasia and myopathy	$T^+/B^+/NK^+$
	STIM1	Calcium channel component with a role in TCR signaling; LAN, HSM, autoimmune cytopenias, dental dysplasia, myopathy	$T^+/B^+/NK^+$
Antigen presentation defects (bare lymphocyte syndromes)			
MHC class II deficiency	*CIITA, RFXANK, RFX5, and RFXAP*	Transactivate the MHC class II promoter; MHC class II molecules are required for the positive selection of $CD4^+$ T cells in the thymus as well as for antigen presentation to $CD4^+$T cells	$T^+/B^+/NK^+$, but fewer and dysfunctional $CD4^+$ T cells
MHC class I deficiency†	*TAP1, TAP2, TAPBP, B2M*	Transporter associated with antigen processing (TAP) and the TAP binding protein (tapasin); translocate peptides from the cytosol to MHC class I molecules in the ER; cutaneous granulomas in TAP deficiency	$CD4^+CD8^-/B^+/NK^+$
Defective thymic development			
Winged helix nude (forkhead box N1) deficiency	*WHN (FOXN1)*	Transcription factor important to thymic development; complete congenital alopecia and nail dystrophy (human equivalent of "nude" mice)	$T^-/B^+/NK^+$

*Patients have increased sensitivity to ionizing radiation.
†Not true SCID

Table 60.16 Types of severe combined immunodeficiency (SCID). "Leaky SCID" refers to less severe deficits in T cell number and function due to hypomorphic (milder) mutations in SCID-associated genes. Cartilage–hair hypoplasia (see text) also occasionally presents as SCID with an Omenn-like phenotype. Two most common forms of SCID, accounting for approximately two-thirds of cases, are shaded. B2M, β2-microglobulin; *DCLRE1C*, DNA cross-link repair protein 1C; ER, endoplasmic reticulum; HSM, hepatosplenomegaly; LAN, lymphadenopathy; MHC, major histocompatibility complex; V(D)J, variable/diversity/joining.

Fig. 60.14 Non-infectious ulcerated granulomatous plaque in an adolescent with hypomorphic RAG1 deficiency. *Courtesy Edward Cowen, MD.*

that transcriptional start sites and coding regions of active genes were the preferred retroviral integration sites in circulating T cells as well as in pre-infusion transduced CD34$^+$ cells; in the former cells, ~25% of all integrations were clustered at common sites, suggesting *in vivo* selection of transduced cells with a higher capacity for engraftment, survival, and proliferation[135]. Although T and NK cell function was restored, at least five patients with X-linked SCID have developed T cell leukemias (2–6 years after treatment) related to activation of proto-oncogenes such as *LMO2* by the retroviral vector[136]. These complications raised serious concerns, which led to protocol modifications and investigation of alternative approaches such as lentiviral vectors, *in situ* gene transfer, and gene editing techniques (e.g. CRISPR/Cas)[137]. More recently, gene therapy with self-inactivating lentivirus vectors following low-dose busulfan conditioning has been safely and successfully utilized in patients with X-linked SCID and ADA deficiency, resulting in functional immune reconstitution and high survival rates[138,139].

Prenatal diagnosis of SCID can be performed by fetal DNA analysis in families with a known genetic defect.

WISKOTT–ALDRICH SYNDROME

Synonyms: ■ Wiskott–Aldrich–Huntley syndrome ■ Eczema–thrombocytopenia–immunodeficiency syndrome

Key features

- X-linked recessive immunodeficiency disorder characterized by the classic triad of atopic-like dermatitis, a bleeding tendency due to microthrombocytopenia, and recurrent sinopulmonary infections
- Onset of bacterial infections is early in life, with later development of viral and *P. jirovecii* infections
- Patients are also at risk of autoimmune diseases and lymphomas

Introduction

Wiskott–Aldrich syndrome (WAS) is characterized by recurrent pyogenic infections, bleeding due to thrombocytopenia and platelet dysfunction, and recalcitrant eczematous dermatitis[140,141]. The full triad develops in a minority of patients, with platelet abnormalities representing the most constant feature.

Epidemiology

Most patients with this X-linked recessive immunodeficiency are boys, but girls are occasionally affected in the setting of non-random X-chromosome inactivation or homozygosity for a mild mutation. WAS has an incidence of ~1 in 250 000 live male births in European populations; it is less common in Black individuals and Asians.

Pathogenesis

WAS is caused by loss-of-function mutations in *WASP*, which is constitutively expressed in hematopoietic cell lineages. The WAS protein (WASP) controls the assembly of actin filaments, which are required for microvesicle and pro-platelet formation as well as T cell activation and polarization toward antigen-presenting cells[142]. Loss-of-function *WASP* mutations also cause isolated X-linked recessive thrombocytopenia, while gain-of-function *WASP* mutations can lead to X-linked congenital neutropenia.

Abnormal T cell function is central to the immunologic defect in WAS, with resultant diminution of both cell-mediated and humoral responses[142]. Although the number of T cells in WAS patients has been observed to decrease with age, affected infants also have reduced numbers of T cells (especially naive T cells) and B cells[143]. This suggests that impaired lymphocyte maturation and output from the thymus are central to the immunodeficiency of WAS. WASP function is required for the activation of regulatory T cells, helping to explain the autoimmune manifestations of WAS. Defects in B cell migration, differentiation, and organization into germinal centers have roles in the impaired humoral immunity of WAS, with reduced expression of the CD21 and CD35 complement receptors involved in antigen capture and presentation also potentially contributing to autoimmunity[143,144]. Although NK cells are not decreased in number, their cytolytic activity is abnormal in WAS. Lastly, small, structurally abnormal platelets with a reduced half-life (due in part to splenic destruction) account for the thrombocytopenia of WAS[142].

Clinical Features

Because thrombocytopenia and platelet dysfunction are present from birth, the first clinical signs of WAS are usually petechiae and ecchymoses of the skin and oral mucosa. Spontaneous bleeding from the oral cavity, epistaxis, hematemesis, melena, and hematuria are commonly observed.

The dermatitis of WAS typically develops during the first few months of life, and it fulfills the diagnostic criteria for atopic dermatitis (see Table 12.1). The face, scalp, and flexural areas are most severely affected, although patients often have widespread involvement with progressive lichenification. Exfoliative dermatitis occasionally develops. Excoriated areas frequently have serosanguineous crusts and petechiae (Fig. 60.15). Secondary bacterial infections are common, as are eczema herpeticum and molluscum contagiosum.

Recurrent bacterial infections begin during the first 3 months of life, coincident with diminishing levels of placentally transmitted maternal antibodies. These infections include otitis externa and media, pneumonia, sinusitis, conjunctivitis, furunculosis, meningitis, and septicemia. Encapsulated bacteria such as *Str. pneumoniae, H. influenza*, and *Neisseria meningitidis* are the predominant organisms. With advancing age, there is increased susceptibility to infections with viruses (e.g. herpes simplex) and *P. jirovecii*.

Most children with WAS develop at least one autoimmune disease, most commonly cutaneous small vessel vasculitis (often associated with painful edema), autoimmune cytopenias, arthritis, inflammatory bowel disease, and cerebral vasculitis[145]. IgE-mediated conditions such as urticaria, food allergies, and asthma also occur with increased frequency. Lymphomas develop at a mean age of 10 years in ~15% of WAS patients who do not undergo successful HSCT, especially those with a history of autoimmune disease. Non-Hodgkin lymphomas predominate, most often diffuse large B cell types with extranodal and brain involvement as in AIDS-related lymphomas.

The median survival for WAS patients who do not receive a HSCT is ~15 years, with infection (50%), bleeding (25%), and malignancy (25%) representing the most common causes of death.

Fig. 60.15 Severe atopic dermatitis in an infant with Wiskott–Aldrich syndrome. This young boy was successfully treated with bone marrow transplantation, and his dermatitis virtually cleared owing to the T cell engraftment.

Laboratory Findings and Pathology

The most frequent laboratory abnormalities in WAS are persistent thrombocytopenia (platelet counts <70 000/mm^3) and low mean platelet volume (<5.0 fl). WAS patients may also have lymphopenia and eosinophilia. Serum IgM and IgG_2 levels are typically low, while IgA, IgE, and IgD levels tend to be elevated. Antibody responses to polysaccharide antigens are markedly diminished. Delayed-type hypersensitivity skin test reactions are usually absent, and responses to mitogens are often depressed, especially in older patients. Monocyte and neutrophil chemotaxis may also be defective.

Assessment of WASP expression in peripheral blood mononuclear cells by flow cytometry-based assays or immunoblot analysis can be performed in patients suspected to have WAS prior to mutational analysis. Patients with a complete lack of WASP expression in circulating cells tend to have a more severe phenotype.

Differential Diagnosis

Although several other immunodeficiency syndromes feature eczematous dermatitis together with susceptibility to infection (see HIES Differential Diagnosis), WAS can usually be differentiated by the bleeding tendency and laboratory evidence of microthrombocytopenia. Of note, deficiency of the actin-related protein 2/3 complex subunit 1b (ARPC1B), which interacts with WASP, presents with overlapping features including eczematous dermatitis, thrombocytopenia (with variably sized platelets), recurrent infections, autoimmune manifestations, vasculitis, and colitis[146].

An approach to the differential diagnosis of infantile erythroderma is presented in Fig. 10.11.

Treatment

HSCT is the treatment of choice for patients with WAS. Full engraftment results in normal platelet numbers and function, restoration of immunologic status, and clearance of the dermatitis. Affected children who receive a HSCT have an overall survival rate of >90%, with lower rates in those transplanted at >5 years of age with an unrelated donor[147,148]. Gene therapy using lentivirally transduced, WASP-reconstituted, autologous $CD34^+$ cells can lead to sustained resolution of the dermatitis and susceptibility to infection as well as improvement in the bleeding diathesis and autoimmunity, without the high risk of leukemic transformation that was observed with utilization of a retroviral vector[149–151].

Prophylactic use of antibiotics can decrease the risk of fatal infections in WAS patients[152]. IVIg therapy also helps to prevent infections and may potentially improve the dermatitis. Topical corticosteroids remain a mainstay of treatment for the latter. Although splenectomy may reduce bleeding complications in patients with recurrent severe hemorrhage, it further increases the risk of infections with encapsulated organisms. Platelet transfusions may be given prior to surgery and in the setting of life-threatening hemorrhage. Systemic corticosteroids, rituximab, and other immunosuppressive agents may be utilized for autoimmune disorders.

Genetic counseling is important for the sisters and other female relatives of WAS patients. Female carriers may be detected by genetic analysis or detection of selective inactivation of the abnormal X chromosome in lymphocytes and platelets. Prenatal diagnosis can be performed by mutational analysis.

61 Neurofibromatosis and Tuberous Sclerosis Complex

Hensin Tsao and Su Luo

Chapter Contents

Neurofibromatosis Type 1 992
Tuberous Sclerosis Complex 1002

INTRODUCTION

Neurofibromatosis (NF) and tuberous sclerosis complex (TSC) are neurocutaneous disorders, or phakomatoses. They are characterized by cutaneous lesions as well as peripheral and/or central nervous system neoplasms. Like most hereditary cancer syndromes, NF and TSC are autosomal dominant in inheritance. Despite a high penetrance for both diseases, new cases of NF type 1 (NF1) and TSC frequently represent *de novo* mutations. The pleiotropic nature of these two neurocutaneous syndromes has led to complex schemes for their classification and diagnosis. Dermatologists are frequently asked to participate in the clinical diagnosis of patients with NF1 and TSC due to the early appearance of cutaneous, especially pigmentary, findings. Advances in the molecular characterization of these disorders have revealed related, but distinct, pathogenic mechanisms.

In 1982, Riccardi proposed a classification scheme for patients with NF that included seven subtypes. Elucidation of the molecular bases of NF1, NF2, mosaic/segmental NF1 (formerly known as NF5), and "NF1-like" syndromes has further refined the categorization of patients. Among these conditions, NF1 has the most well-characterized and diagnostic skin findings and is the main focus in this chapter.

NEUROFIBROMATOSIS TYPE 1

Synonym: ■ von Recklinghausen disease

Key features

- NF1 is an autosomal dominant disorder with an incidence of ~1 in 2000–3000 births
- Characteristic clinical features include café-au-lait macules, neurofibromas, freckling in the axillae and groin, Lisch nodules, and bony defects. Nevus anemicus represents another common early finding.
- Patients with NF1 have an increased risk of developing juvenile xanthogranulomas, juvenile myelomonocytic leukemia and a variety of extracutaneous tumors, including optic pathway gliomas, malignant peripheral nerve sheath tumors, pheochromocytomas, and other CNS tumors
- Up to 50% of patients with NF1 have a new spontaneous mutation rather than an inherited mutation
- The protein product of *NF1* (neurofibromin) is involved in the negative regulation of RAS signaling
- Other well-characterized forms of NF include mosaic/segmental NF1 and NF2 (vestibular schwannomas)

History

Individuals with NF1 have been described throughout history[1,2]. In 1882, von Recklinghausen[3] provided the first in-depth report of the clinical and pathologic nature of the neurofibromas. Fifty years later, the Viennese ophthalmologist Lisch described the iris nodules that were more recently recognized as an important criterion in the clinical diagnosis of NF. In the mid twentieth century, Crowe, Schull, and Neel compiled a landmark monograph with a comprehensive description of the manifestations of this disease[4].

Epidemiology

NF1 occurs worldwide. Its incidence is ~1 in 2000 to 3000 births[5–7].

Pathogenesis

NF1 is inherited in an autosomal dominant manner. Most large series have found that 30%–50% of patients have no affected relatives and thus likely harbor new spontaneous mutations[4,8,9]. There is also the possibility of germline mosaicism in a parent, especially when two siblings develop NF1 in the absence of a prior family history. The penetrance of NF1 approaches 100% in carefully examined adults[10], but expressivity is variable. A wide range of clinical findings and complications can develop among individuals with the same underlying mutation. The specific *NF1* mutation is therefore not the only factor that determines phenotype.

In 1987, an international consortium found evidence of linkage to the pericentromeric region of chromosome 17 in families with NF1[11]. Subsequent descriptions of two NF1 patients with balanced translocations involving the long arm of chromosome 17 (17q11.2) further refined the position of the *NF1* locus[12,13]. The localization data derived from these studies led to the cloning of the *NF1* gene[14–16].

NF1 encodes neurofibromin, a 327 kDa protein composed of 2818 amino acids, and consists of at least 59 exons (Fig. 61.1)[17]. Over 80% of NF1 patients have a mutation that predicts truncation of the neurofibromin protein, and ~5% of patients have a large deletion ("microdeletion") that encompasses the entire *NF1* gene plus variable flanking genes[18]. Although there is usually no clear genotype–phenotype correlation, exceptions include: (1) the single amino acid deletion p.Met922del and a missense mutation affecting p.Met1149 or p.Arg1809 are all associated with an absence of neurofibromas and the latter two with a Noonan syndrome-like phenotype[19–21]; (2) p.Arg 1276 or p.Lys1423 are associated with cardiovascular abnormalities, a Noonan syndrome-like phenotype, and (for the former) symptomatic spinal neurofibromas[21]; (3) missense mutations in *NF1* codons 844–848 result in a higher likelihood of major plexiform neurofibromas, symptomatic spinal neurofibromas, optic gliomas, skeletal abnormalities, and malignancies[22]; and (4) a recurrent 1.4-mega-base pair deletion ("type 1 microdeletion") results in a more severe phenotype[23]. The latter includes an earlier onset and larger number of neurofibromas, an increased risk of malignant peripheral nerve sheath tumors, intellectual disability, facial dysmorphism, overgrowth, connective tissue dysplasia (e.g. hyperextensible skin, joint laxity), and cardiac defects[23].

Sequence similarities between a central 300–400 amino acid domain within neurofibromin and *G*TPase-*a*ctivating *p*roteins (GAPs) led to recognition of neurofibromin's role in the negative regulation of the RAS–*m*itogen-*a*ctivated *p*rotein *k*inase (MAPK) pathway that promotes cell survival and proliferation (see Fig. 61.1 and Fig. 55.4)[24]. Like all G proteins, RAS activity requires GTP. Neurofibromin and other GAPs accelerate the hydrolysis of GTP to GDP, thereby terminating the RAS signal and functioning as tumor suppressor proteins. Neurofibromin also associates with microtubules[25], although the consequences remain unclear.

As observed in other autosomal dominant genodermatoses (e.g. basal cell nevus syndrome) caused by a defective tumor suppressor gene, a *somatic* "second-hit" mutation inactivating the remaining allele of the gene (i.e. causing loss of heterozygosity [LOH]) can be found within skin lesions of NF1. Biallelic *NF1* inactivation has been identified in

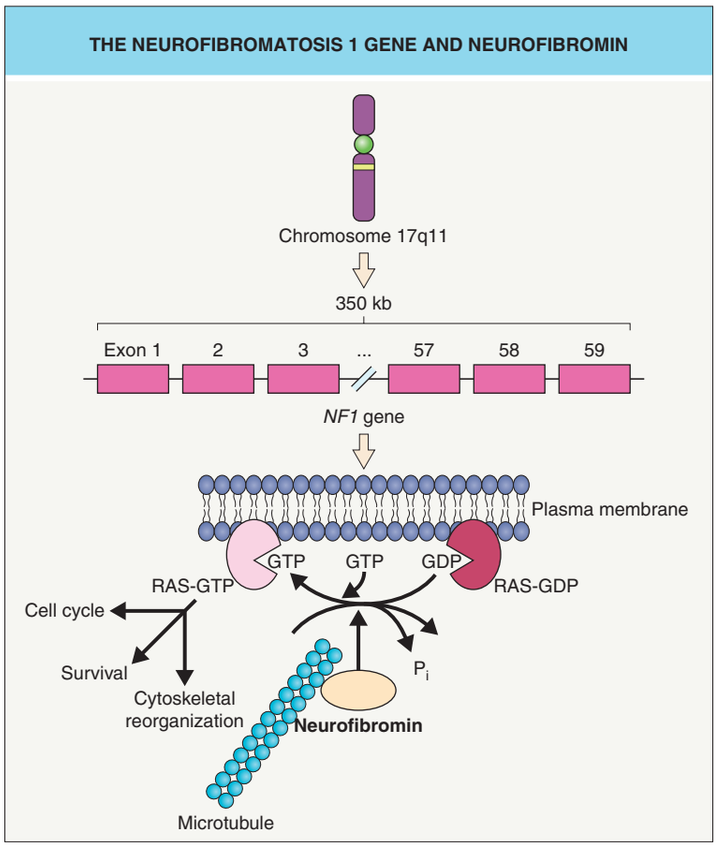

Fig. 61.1 The neurofibromatosis 1 gene and neurofibromin. *NF1* is located on chromosome 17q11.2 and encodes the *G*TPase-*a*ctivating *p*rotein (GAP)-related protein neurofibromin. One of the functions of neurofibromin is to negatively regulate the activity of RAS proteins. RAS, like other related G proteins, is dependent upon GTP binding for its full activity, and GAP proteins shut off the signal by accelerating the hydrolysis of GTP to GDP.

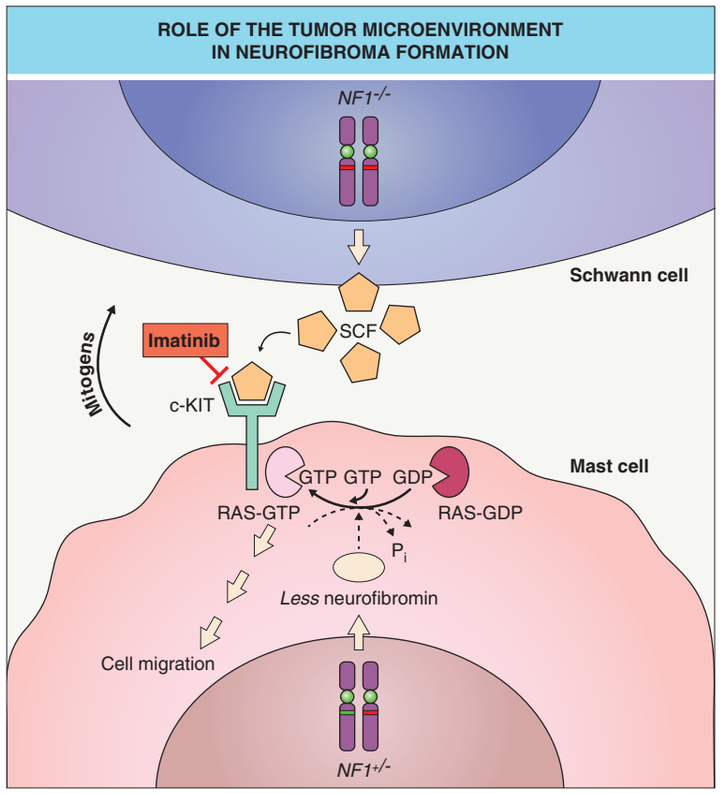

Fig. 61.2 Role of the tumor microenvironment in neurofibroma formation. *NF1* nullizygous (*NF1*$^{-/-}$) Schwann cells oversecrete stem cell factor (SCF), which binds the KIT receptor on *NF1* heterozygous (*NF1*$^{+/-}$) mast cells. This leads to mast cell recruitment and their activation to produce growth factors that stimulate neurofibroma development. Inhibition of KIT signaling by imatinib mesylate can block neurofibroma formation and progression.

Schwann cells from neurofibromas as well as melanocytes from café-au-lait macules in patients with NF1[26,27]. In a mouse model, *Nf1* nullizygosity (*Nf1*$^{-/-}$) in Schwann cells was shown to be necessary, but not sufficient, for neurofibroma formation[28]; however, plexiform neurofibromas did arise from *Nf1*$^{-/-}$ Schwann cells when the microenvironment included *Nf1*$^{+/-}$ (rather than wild-type) mast cells[29]. The latter cells appear early in neurofibroma development and are hypermotile in response to the KIT ligand (stem cell factor), which is oversecreted by *Nf1*$^{-/-}$ Schwann cells. Once recruited, mast cells produce growth factors that likely promote neurofibroma tumorigenesis (Fig. 61.2). Of note, genetic or pharmacologic attenuation of KIT signaling in *Nf1*$^{+/-}$ mast cells has been found to diminish neurofibroma initiation and progression (see Management section below).

Clinical Features

The clinical features of NF1 (Table 61.1) are myriad and vary in frequency[4,8,9,30–40]. Almost every organ system has been found to be involved in NF1, which can lead to a wide range of morbidities and mortality[7]. The cutaneous manifestations of NF1 represent particularly important clinical features that have a central role in its diagnosis[41].

Oculocutaneous manifestations

Café-au-lait macules (CALMs) are tan to dark brown (depending on the degree of constitutive pigmentation), uniformly pigmented macules and patches that are randomly distributed on the body, with the exception of the scalp, palms, and soles. The CALMs of NF1 are sharply demarcated with regular borders and often have an oval shape (Fig. 61.3); the diameter can vary from a few millimeters to >4 cm. CALMs may not be apparent at birth and frequently become more noticeable during the first year of life; fading of these lesions during later adulthood has also been described[42]. When located within areas of dermal melanocytosis, CALMs may be surrounded by a rim of normally pigmented skin (see Ch. 112). Larger CALMs, especially those with associated hypertrichosis, should be palpated to exclude the possibility of an underlying plexiform neurofibroma (see below).

Crowe et al.[4] reported that 10% of the normal population has one to five CALMs, and Burwell et al.[43] found that 26% of 732 White schoolchildren had at least one CALM >1 cm in diameter. In the latter study, ≥6 CALMs were found in only three children (0.4%) and they were siblings with a parent who had NF1. For the clinical diagnosis of NF1, a minimum of six CALMs is required to meet the specificity of this criterion (Table 61.2 and 61.3). To avoid confusion with lentigines, CALMs must be >5 mm in prepubertal individuals and >15 mm in postpubertal individuals in order to satisfy this diagnostic criterion for NF1.

"Freckling" in the axillae and groin in NF1 patients was first noted by Crowe[4] and is referred to as "Crowe sign" (see Fig. 61.3B). Numerous 1–3 mm brown macules (more akin to lentigines than ephelides) typically populate these intertriginous zones, the neck, and occasionally the majority of the skin surface (see Fig. 61.3C,D & 61.4). Involvement of the axillae is most common, occurring in ~80% of NF1 patients[44,45]. The lesions usually arise by 4–6 years of age, following the emergence of CALMs but preceding the development of neurofibromas. As a result, intertriginous "freckling" is a useful clinical sign in the evaluation of a young child with multiple CALMs[46].

In its fullest expression, NF1 can manifest with thousands of neurofibromas in an affected individual, hence the appellation *neurofibromatosis* (Fig. 61.4). Several variants of neurofibromas are observed in NF1. Most commonly, proliferations of spindle cells occur within the dermis, leading to *cutaneous* neurofibromas (CNFs). CNFs are skin-colored to pink, tan, or brown papulonodules that are soft or slightly rubbery in texture and can range from a few millimeters to several centimeters in diameter. While fully formed CNFs are often dome-shaped or pedunculated, early lesions may be barely elevated. They invaginate easily with gentle pressure, exhibiting the pathognomonic "buttonhole" sign. Although usually asymptomatic, lesions may become pruritic or, occasionally, irritated. CNFs appear as early as 4–5 years of age but

MAJOR CLINICAL FEATURES OF NEUROFIBROMATOSIS TYPE 1
Cutaneous
• Neurofibromas (60%–90%) • Café-au-lait macules (>90%) • Axillary and/or inguinal freckling (~80%) • Plexiform neurofibroma (25%; up to 50% with detection via whole-body MRI) • Nevus anemicus (30%–50%) • Juvenile xanthogranuloma (15%–35% in first 3 years of life)
Ocular
• Lisch nodules (~90% by 20 years of age) • Choroidal abnormalities (>80% of adults, 60%–70% of children) • Neovascular glaucoma, retinal vasoproliferative tumors
Skeletal
Cranial
• Macrocephaly (20%–50%) • Hypertelorism (25%) • Sphenoid wing dysplasia (<5%)
Spinal
• Scoliosis (5%–10%) • Spina bifida
Limbs
• Dysplasia of long bone cortex (5%), pseudarthrosis (2%)
Other
• Generalized osteopenia (~50%), osteoporosis (~20%) • Short stature (~30% <3rd percentile) • Pectus deformity (30%–50%)
Tumors
• Optic pathway glioma (15%–20% of children) (± precocious puberty) • Malignant peripheral nerve sheath tumors (3%–15%) • Pheochromocytoma (~1%) • Juvenile myelomonocytic leukemia • CNS tumors other than optic pathway gliomas (~5%) • Rhabdomyosarcoma, especially of the genitourinary tract • Duodenal carcinoid • Somatostatinoma • Parathyroid adenoma • Gastrointestinal stromal tumors (GIST) • Breast cancer (~5- and ~10-fold increased risk in women <50 and <40 years of age, respectively)
Neurologic
• T2 hyperintensities on brain MRI (50%–75%) • Learning difficulties (30%–50%) • Seizures (~5%) • Intellectual impairment (severe in <5%) • Aqueductal stenosis and hydrocephalus (~2%)
Cardiovascular
• Hypertension (~30%): essential > renal artery stenosis or pheochromocytoma • Pulmonic stenosis (~1%) • Renal artery stenosis (~2%) • Cerebrovascular anomalies (2%–5%), including vascular stenoses and aneurysms

Table 61.1 Major clinical features of neurofibromatosis type 1.

more typically develop around puberty, with occasional acceleration of growth during pregnancy.

Subcutaneous neurofibromas (SNFs) occur deeper in the dermis and subcutis, tending to be firmer and less well-circumscribed than CNFs. Nearly one-fifth of NF1 patients have at least one SNF[44], and one-quarter of these individuals develop tumor-related local complications. Less common cutaneous presentations of neurofibromas in patients with NF1 include: (1) *blue–red macules* due to thick-walled blood vessels as well as neurofibromatous tissue within the papillary dermis (Fig. 61.5); and (2) *pseudo-atrophic macules* due to replacement of collagen in the reticular dermis with neurofibromatous tissue[47].

Plexiform neurofibromas (PNFs; Fig. 61.6) may track along nerves to create tender, firm nodules or masses in the subcutaneous tissue with a "bag of worms" consistency upon palpation, or they can infiltrate diffusely to involve various layers of the skin, fascia, muscle, or even internal structures. Approximately 25% of NF1 patients have clinically apparent PNFs. Larger lesions may cause soft tissue and bony hypertrophy, and massive distortion of the head and neck or extremities occasionally develops. Impingement upon nerves can lead to neurologic deficits, and (peri)orbital PNFs may result in visual loss as well as facial deformity[48].

Unlike other neurofibromas, PNFs are probably all congenital in origin. Superficial and/or diffuse lesions usually become clinically apparent by the age of 4 or 5 years[30], while deep/internal nodular lesions may remain undetected even in adulthood unless full-body magnetic resonance imaging (MRI) is performed[49]. Older children without evidence of soft tissue overgrowth related to a PNF are unlikely to develop this finding later in life. Both hyperpigmentation and hypertrichosis can overlie PNFs[50], sometimes leading to the misdiagnosis of congenital melanocytic nevus (see Fig. 61.6).

The transformation of PNFs into malignant peripheral nerve sheath tumors (MPNSTs, also known as "neurofibrosarcomas") occurs in 8%–15% of patients with NF1[9,44,51], with a peak incidence in young adults. The onset of rapid growth, increased firmness, or persistent pain within an established PNF or the development of a new neurologic deficit may herald malignant degeneration (Table 61.4; see Management section). MPNSTs can be very aggressive and are often fatal[52]. As many as 15%–35% of children with NF1 develop one or more juvenile xanthogranulomas (JXGs) during the first 2–3 years of life, making these lesions a potential early sign of NF1 when they coexist with multiple CALMs[53–55]. Young children with NF1 also have a 200- to 500-fold greater risk of developing juvenile myelomonocytic leukemia (JMML; incidence 1/2000–1/5000) than does the general pediatric population. Although a "triple association" between NF1, JMML, and JXG has been described[56], the magnitude of additional risk of JMML in children with NF1 plus JXGs compared to NF1 alone remains to be determined. Neurofibromin is known to regulate the proliferation of myeloid cells, but the exact etiopathogenesis of the "triple association" remains unclear.

Vascular anomalies that have been recognized as manifestations of NF1 include nevus anemicus and glomus tumors[54,57,58]. In two prospective studies, a nevus anemicus was identified in a total of 55% (92/166) of children and 36% (19/53) of adults with NF1, compared to only 2% (6/302) of age- and sex-matched controls[57,58]. These lesions favor the trunk, especially the mid chest, and become more evident after rubbing the skin. Because nevus anemicus is prevalent in NF1 patients and apparent by early childhood, its use as a diagnostic criterion has been proposed but not yet adopted[54,57,58].

Biallelic inactivation of *NF1* has been documented within glomus tumors in NF1 patients[59]. The tumors are often multiple and develop on the fingers > toes; like their sporadic counterpart, they can present with paroxysmal pain and sensitivity to cold (see Ch. 114). Focal swelling, ill-defined reddish discoloration (often of the nail bed), and nail dystrophy may be observed.

Pigmented iris hamartomas, or Lisch nodules, begin to develop at about 3 years of age and are found in ~90% of NF1 patients by 20 years of age[36,44,60,61]. These 1–2 mm, dome-shaped, yellow–brown papules are best seen on slit-lamp examination (Fig. 61.7). Lisch nodules rarely lead to symptoms or complications. Asymptomatic choroidal nodules are also present in 80%–100% of adults and 60%–70% of children with NF1, and this finding has been added to the recently published revised diagnostic criteria[62]. However, the near-infrared reflectance imaging required for detection of these lesions may be technically challenging in younger children[41].

In mosaic (segmental) NF1 (formerly known as NF5), CALMs, "freckling", and/or neurofibromas are present in mosaic distribution patterns such as blocks with midline demarcation, often with relative hyperpigmentation in the background of the affected segment[63–65] (Fig. 61.8). This form of NF1 results from a postzygotic *NF1* mutation, and up to 30% of patients also have extracutaneous manifestations of NF1[63]. If the mutation involves the gonads (germline mosaicism) as well as the skin, there is a chance of full-blown NF1 in the patient's offspring.

Fig. 61.3 Café-au-lait macules and "freckling". Oval-shaped, light- to medium-brown patches with regular borders and uniform pigmentation (**A**–**C**). Numerous 1–3 mm lentigines are most commonly found in the axillae (Crowe's sign) (**B**) but can also develop in other locations such as the chest (**C**) and perioral region (**D**). *A–D, Courtesy Julie V. Schaffer, MD.*

REVISED DIAGNOSTIC CRITERIA FOR NEUROFIBROMATOSIS TYPE 1 (NF1) AND MOSAIC NF1
Diagnostic criteria for NF1
Requires **two or more** of the following in an individual ***without a parent diagnosed with NF1*** and **one or more** of the following in an individual ***with a parent diagnosed with NF1***: • Six or more café-au-lait macules >5 mm in prepubertal individuals and >15 mm in postpubertal individuals* • "Freckling" in the axillary or inguinal region* • Two or more neurofibromas of any type *or* one plexiform neurofibroma • Optic pathway glioma • Two or more Lisch nodules (iris hamartomas) or two or more choroidal abnormalities† • A distinctive osseous lesion such as sphenoid dysplasia, anterolateral bowing of the tibia, or pseudoarthrosis of a long bone • A heterozygous pathogenic *NF1* variant with a variant allele fraction of 50% in apparently normal tissue (e.g. white blood cells)
Diagnostic criteria for mosaic NF1
Requires any of the following in an individual ***without a parent diagnosed with NF1***: • A heterozygous pathogenic *NF1* variant with a variant allele fraction of significantly <50% in apparently normal tissue (e.g. white blood cells) **AND** one of the other NF1 criteria above • An identical heterozygous pathogenic *NF1* variant in two anatomically independent affected tissues, in the absence of a pathogenic *NF1* variant in unaffected tissue • A clearly segmental distribution of café-au-lait macules or cutaneous neurofibromas **AND** *either* another NF1 criterion‡ *or* offspring diagnosed with NF1 • One of the *clinical* NF1 criteria above *other than* café-au-lait macules **AND** offspring diagnosed with NF1
*If only café-au-lait macules and freckling are present, at least one should be bilateral; in this scenario, the diagnosis is most likely NF1 but may rarely be another condition such as Legius syndrome. †Defined as bright, patchy nodules imaged by optical coherence tomography/near-infrared reflectance imaging. ‡If only café-au-lait macules and freckling are present, the diagnosis is most likely mosaic NF1 but may rarely be mosaic Legius syndrome or constitutional mismatch repair deficiency syndrome (see Table 61.3).

Table 61.2 Revised diagnostic criteria for neurofibromatosis type 1 (NF1) and mosaic NF1.

DISORDERS ASSOCIATED WITH MULTIPLE CAFÉ-AU-LAIT MACULES	
Disorder	**Notes**
Neurofibromatosis and related disorders	
Neurofibromatosis type 1 (NF1)	AD; six or more CALMs in >90% of patients; mutations in *NF1* gene; see text
Neurofibromatosis type 2	AD; six or more CALMs in minority of patients; mutations in *NF2* gene; see Table 61.5
Mosaic (segmental) NF1 (formerly neurofibromatosis type 5)	Neurofibromas alone or CALMs ± "freckling" in a block-like or other mosaic pattern; due to a postzygotic *NF1* mutation, which may involve the gonads in some patients
Legius syndrome	AD; six or more CALMs in >80% and intertriginous "freckling" in ~50% of patients; lack neurofibromas, Lisch nodules, optic pathway gliomas, and typical osseous lesions of NF1; macrocephaly and learning disabilities are common; lipomas, hypopigmented macules, and vascular anomalies in minority; loss-of-function mutations in *SPRED1* gene, the protein product of which inhibits MAPK signaling
Watson syndrome	AD; short stature; pulmonic stenosis; ID; may also have Lisch nodules, axillary/inguinal freckling, and neurofibromas; allelic with NF1; 60/100*
Jaffe–Campanacci syndrome	AD; disseminated non-ossifying fibromas of long and jaw bones; hypogonadism or cryptorchidism; ID; giant cell granulomas (jaws); usually due to *NF1* mutation
Noonan syndrome	AD; short stature; pterygium colli; characteristic facies; cardiac defects, esp. pulmonic valve stenosis; skeletal and testicular abnormalities; keratosis pilaris atrophicans; lymphedema; melanocytic nevi; activating mutations in *PTPN11* > *SOS1, RAF1, RIT1* > *KRAS, NRAS, MAP2K1, LZTR1, SHOC2* (with loose anagen hair), and rarely other genes; patients with an NF1–Noonan overlap phenotype may have mutations in *NF1* gene
Noonan syndrome with multiple lentigines (LEOPARD syndrome)	AD; darker "café noir" macules; *L*entigines, *E*CG abnormalities, *O*cular hypertelorism, *P*ulmonic stenosis, *A*bnormal genitalia, *R*etardation of growth, *D*eafness syndrome; mutations in *PTPN11*; 38/100*
Cardio-facio-cutaneous syndrome	AD; short stature; characteristic facies; low-set ears; cardiac defects; ID; sparse curly hair; dry skin to generalized ichthyosiform eruption; activating mutations in MAPK pathway genes – *BRAF* > *MEK1, MEK2* > *KRAS*
Constitutional mismatch repair deficiency syndrome (formerly Turcot syndrome type 1)	AR; multiple CALMs ± axillary freckling, neurofibromas and/or CNS gliomas (features of NF1) as well as hypopigmented macules, pilomatricomas, hematologic malignancies, and colorectal carcinoma; NF1-like skin findings are often in a mosaic distribution pattern; patients have mutations in both copies of a DNA mismatch repair gene (*PMS2* > *MSH6* > *MLH1, MSH2*) and evidence of microsatellite instability (e.g. in peripheral blood leukocytes); hereditary non-polyposis colorectal cancer (HNPCC; Lynch) syndrome in heterozygotes
McCune–Albright syndrome	Sporadic, presumably lethal unless in mosaic state; polyostotic fibrous dysplasia; hyperfunction of endocrine glands, esp. gonads (e.g. precocious puberty); CALMs are usually apparent during infancy and often several shades darker than background skin with irregular borders; CALMs classically end at midline (as may larger CALMs of NF) and may follow lines of Blaschko in broad bands; activating mutations in the *GNAS1* gene that encodes $G_s\alpha$; 35/100*
Other disorders¶	
Tuberous sclerosis complex (TSC)	AD; ID; seizures; hypopigmented macules; angiofibromas; fibrous plaques; mutations in *TSC1* and *TSC2* genes; see text
Piebaldism	AD; CALMs in involved as well as uninvolved skin; mutations in *KIT* proto-oncogene
Familial progressive hyper- and hypopigmentation	AD; CALMs of variable sizes admixed and overlapping with lentigines and hypopigmented macules and patches; activating mutations in *KITLG* gene
Westerhof syndrome	AD; congenital hypo- and hyperpigmented macules; ID; growth retardation
Carney complex (NAME and LAMB syndromes)	AD; darker "café-noir" macules, lentigines, blue nevi; cutaneous and atrial myxomas; endocrine neoplasia of adrenal glands, pituitary gland, and/or testes; mutations in *PRKAR1A*
Partial unilateral lentiginosis	Unilateral agminated lentigines; unilateral CALMs may also be present; debatable if associated neurologic or psychiatric problems; possible relationship to mosaic NF1
Bannayan–Riley–Ruvalcaba syndrome‡	AD; penile lentigines; vascular malformations; lipomas; intestinal hamartomas; macrocephaly; mutations in *PTEN* gene; ≤10% of patients have CALMs
Cowden syndrome‡	AD; multiple tricholemmomas; cobblestoning of oral mucosa; palmoplantar keratoses; sclerotic fibromas, hamartomas and carcinoma of breast, thyroid, genitourinary system, colon; mutations in *PTEN* gene; ≤10% of patients have CALMs
Ataxia–telangiectasia	AR; telangiectasias of conjunctivae, head/neck, and acral sites; premature canities; cerebellar ataxia; abnormal DNA repair; lymphomas and leukemias; immunodeficiency; sinopulmonary infections; mutations in *ATM* gene; 20/100*
Bloom syndrome	AR; telangiectatic erythema of face; photosensitivity; growth retardation; increased sister chromatid exchanges; malignancies; hypogonadism; mutations in *BLM* gene that encodes the RecQ protein-like-3 DNA helicase
Fanconi anemia	AR; generalized hyperpigmentation, esp. flexural ± guttate hypopigmented macules; pancytopenia; skeletal malformations, e.g. aplasia radii; chromosomal fragility and malignancies, e.g. acute myelogenous leukemia; see Table 67.10
Mosaic chromosomal anomalies	In particular, ring chromosomes (7, 11, 12, 15, 17); rearrangements of 7 and 14; ring 7 also associated with vascular lesions (hemangiomas and capillary malformations) and congenital melanocytic nevi
Extensive epidermal and sebaceous nevi	Mosaic; "syndrome" includes seizures, ID, musculoskeletal and ocular abnormalities; hypophosphatemic vitamin D-resistant rickets; see Table 62.6 for genes
Multiple endocrine neoplasia 1	AD; tumors of the pituitary, parathyroid, and pancreatic islet cells; multiple facial angiofibromas, collagenomas, gingival papules, confetti-like hypomelanotic macules, lipomas; *MEN1* gene
Multiple endocrine neoplasia 2B	AD; mucosal neuromas; marfanoid habitus; medullary thyroid carcinoma; intestinal ganglioneuromatosis; pheochromocytoma; mutations in *RET* proto-oncogene

Table 61.3 Disorders associated with multiple café-au-lait macules (CALMs).

DISORDERS ASSOCIATED WITH MULTIPLE CAFÉ-AU-LAIT MACULES	
Disorder	**Notes**
Silver–Russell syndrome	Growth retardation; triangular face; clinodactyly 5th finger; hemihypertrophy; epigenetic changes on chromosome 15p13 or maternal uniparental disomy of chromosome 7; 45/100*
Tricho-hepato-enteric syndrome	AR; CALM and lentigines on hips and legs; diffuse pigmentary dilution (skin & hair), woolly hair; dysmorphic facies with hypertelorism; intractable diarrhea, liver disease; immune deficiency; mutations in *TTC37* or *SKIV2L*
Tay syndrome†	?AR; growth retardation; ID; triangular face; cirrhosis; trident hands; premature canities; vitiligo
Gastrocutaneous syndrome†	AD; multiple lentigines; peptic ulcer/hiatal hernia; hypertelorism; myopia
Mukamel syndrome	AR; premature graying (infancy); lentigines; depigmented macules; ID; spastic paraparesis, microcephaly, scoliosis
Johnson–McMillin syndrome	Probable AD; alopecia; anosmia; deafness; hypogonadism; microtia

*Estimates of prevalence of CALMs[90].
†To date, observed in a single family.
‡Overlapping conditions collectively referred to as PTEN hamartoma tumor syndrome.
¶To date, single case reports of multiple CALMs in association with X-linked hypohidrotic ectodermal dysplasia, woolly hair, and osteoma cutis.

Table 61.3 Disorders associated with multiple café-au-lait macules (CALMs). Multiple CALMs may also be seen in patients with segmental pigmentation disorder (see Ch. 67). AD, autosomal dominant; AR, autosomal recessive; ID, intellectual disability; *KITLG*; KIT ligand; MAPK, mitogen-activated protein kinase.

Neurologic manifestations

Optic pathway gliomas occur in 15%–20% of children with NF1, usually developing prior to 10 years of age and leading to symptoms in 30%–50% of affected individuals[66]. The behavior of these CNS neoplasms is variable, ranging from spontaneous regression to progressive visual compromise and proptosis due to tumor expansion[5]. Precocious puberty occurs in about 3% of children with NF1, typically in association with an optic pathway glioma[67,68]. Non-optic CNS tumors occur in ~5%[45] and pheochromocytomas in ~1% of NF1 patients[30,69].

Hyperintense lesions on T2-weighted MRI of the brain (T2 hyperintensities; "unidentified bright objects") can be observed in 50%–75% of children with NF1[70]. These are most commonly seen in the basal ganglia, brainstem, and cerebellum. T2 hyperintensities have been shown to evolve over time[71], and they may contribute to cognitive impairment via thalamocortical dysfunction[72].

Although severe intellectual impairment is uncommon, learning difficulties occur in 30%–50% of affected children[44,73]; there is also an increased likelihood of attention deficit disorder, headaches, and sleep disturbances. Seizures develop in about 5% of NF1 patients, although no specific cortical lesions have been linked to the abnormal EEG activity[35].

Skeletal manifestations

Macrocephaly[31,74], hypertelorism, and scoliosis[39,73] are common cranioskeletal abnormalities in individuals with NF1. Osteopenia is another frequent finding, with potential pathogenic factors including vitamin D deficiency and increased bone turnover[75]. A highly distinctive but less common manifestation is pseudarthrosis of the long bones, most often the tibia. This congenital defect begins as bowing and eventually results in erosion of the bone cortex, leading to pathologic fractures and false joint formation (pseudarthrosis)[30,44]. Sphenoid wing dysplasia is a congenital, typically unilateral bony defect in the posterior wall of the orbit that may present as pulsating exophthalmos[44].

Cardiovascular manifestations

Hypertension is a common finding in NF1 patients. Although essential hypertension is most frequent, renovascular stenosis[76] (especially in children) and unsuspected pheochromocytomas[77] may be the cause in some patients. Other cardiovascular manifestations are listed in Table 61.1.

Timing of onset of clinical manifestations

The prevalence of various clinical features in patients with NF1 evolves over the first two decades of life (Fig. 61.9). PNFs and skeletal defects are probably congenital, while CALMs and nevus anemicus may be evident at birth or become apparent during the first few years of life. Intertriginous "freckling", Lisch nodules, and optic pathway gliomas usually occur by the school-age years, and multiple CNFs typically start to develop closer to puberty. A diagnosis of NF1 can be established via classic clinical criteria (i.e. not including genetic testing) in 97% of affected individuals by age 8 years and 100% by age 20 years (see Table 61.2)[36].

Pathology

The CALMs, CNFs, and MPNSTs associated with NF1 are histologically similar to their sporadic counterparts. CALMs from affected individuals are characterized primarily by increased epidermal melanin; other nonspecific findings may include giant melanosomes and a higher number of melanocytes compared to the surrounding skin[78].

CNFs feature a well-circumscribed but unencapsulated dermal collection of small nerve fibers and loosely arranged spindle cells; the latter have scanty pale cytoplasm and elongated wavy nuclei (see Ch. 115). These spindle cells represent a mixture of fibroblasts, Schwann cells, and perineural cells all set in a collagenous stroma with varying amounts of mucin and scattered mast cells. The nuclei are bland and mitotic activity should raise a suspicion of malignancy.

PNFs are specific to NF1. Histologically, they are composed of large, hypertrophied nerves surrounded by spindle-shaped fibroblasts and Schwann cells embedded in a myxoid matrix and growing in a plexiform pattern (see Ch. 115). In some PNFs, neurofibromatous changes extend diffusely into the papillary and reticular dermis. The stroma may be more collagenous than myxoid and organoid differentiation may occur, forming structures resembling Meissner corpuscles.

MPNSTs are characterized by tight intersecting bundles of spindle cells. There are often alternating cellular and myxoid areas. The cells (as in neurofibromas) stain positively with S100, but they are much more pleomorphic, with wavy and hyperchromatic nuclei (see Ch. 115). Increased mitotic activity and perivascular whorling of tumor cells are often observed. Areas of bony or cartilaginous differentiation may also be present, along with hyalinized nodules.

Differential Diagnosis

In an affected individual with complete expression of NF1, *classic* clinical criteria[79] are met and the diagnosis is usually straightforward. In infants, establishing the diagnosis can sometimes be difficult because age-dependent features have not yet developed[80]. Recently published revised diagnostic criteria for NF1 developed by an international consensus group incorporate genetic testing, update the clinical features (primarily the addition of choroidal abnormalities), and emphasize distinction from mosaic NF1 and conditions with overlapping findings (e.g. Legius syndrome) (see Table 61.2)[62].

An approach to children with multiple CALMs (NF1 suspect)[81] is outlined in Figure 61.10. In a series of 110 children (median age 3 years; range, 1 month to 17 years) who presented to an NF1 clinic with CALMs but no other features of NF1, 34/44 (77%) of those with ≥6 "typical" CALMs (distinct regular borders, uniform pigmentation) eventually met criteria for NF1 (almost all before age 6 years), compared to 2/15 (15%) of those with ≥6 "atypical" CALMs (smudgy irregular borders, non-homogeneous pigmentation) and 0/51 of those with <6 CALMs[82].

Comprehensive, highly sensitive analysis of *NF1* is available, with methods including targeted massively parallel/next-generation sequencing (NGS), multiplex ligation-dependent probe amplification (MLPA; assesses copy number variation), and RNA-based testing[83].

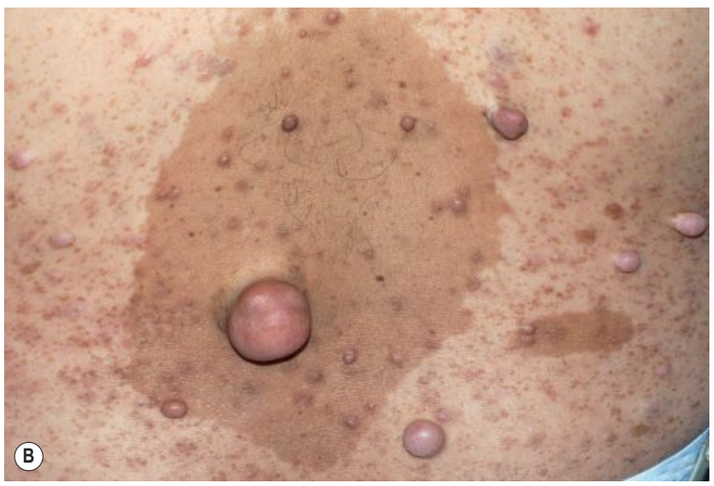

Fig. 61.4 Multiple cutaneous neurofibromas. Soft, skin-colored to pinkish-tan, dome-shaped or polypoid, well-demarcated papules and nodules of various sizes (**A**–**C**) can occur in patients with NF1. Neurofibromas may be superimposed on café-au-lait macules and lentigines (**B**, **C**). *A,B, Courtesy Julie V. Schaffer, MD.*

Fig. 61.5 Spectrum of cutaneous neurofibromas. Lesions range from subtle blue–red macules (**A**) to exophytic nodules with associated hypertrichosis (**B**). *Courtesy Julie V. Schaffer, MD.*

These techniques can identify the underlying pathogenic variant in ≥95%–98% of non-founder patients who fulfill classic clinical diagnostic criteria[79]. This is because they can detect low-level mosaicism (down to 3%–5% variant allele frequency with NGS) as well as deep intronic splice variants and deletions that are missed by conventional genomic DNA-based sequencing. Molecular testing allows for more accurate diagnoses in young children and individuals with atypical clinical presentations. It also makes prenatal or preimplantation diagnosis an option for affected families.

In addition to mosaic NF1 (see above), unilateral lentigines in the axilla or groin may be seen in patients with partial unilateral lentiginosis (PUL) or a large speckled lentiginous nevus (nevus spilus)[84]. These segmental conditions are characteristically sharply demarcated at the midline, but bilateral involvement occasionally occurs. The presence of CALMs in addition to lentigines increases the likelihood of NF1. When individuals suspected of having mosaic NF1 do not have a detectable mutation in the peripheral blood, the diagnosis can be confirmed by analyzing *NF1* in melanocytes or Schwann cells cultured from a lesional skin biopsy specimen (e.g. of a CALM or neurofibroma, respectively).

Some patients with a familial tendency to develop multiple "typical" NF1-like CALMs, often in association with intertriginous "freckling", do not develop neurofibromas or Lisch nodules and lack an underlying *NF1* mutation. Approximately 70% of such individuals have a heterozygous germline mutation that inactivates *SPRED1*, which encodes a protein that inhibits RAS–RAF interaction and thereby (like neurofibromin) negatively regulates MAPK signaling (see Fig. 55.4)[85,86]. This autosomal dominant condition, known as *Legius syndrome*, accounts for ~2% of all patients who meet classic clinical NF1 criteria[86].

Constitutional mismatch repair deficiency (CMMRD) due to biallelic germline mutations in a mismatch repair gene frequently presents with multiple CALMs, sometimes together with other features of NF1 such as intertriginous freckling, neurofibromas, and gliomas (Fig. 61.11A). There is often a segmental/regional distribution of skin findings, and postzygotic *NF1* mutations have been documented in affected tissues[87].

Fig. 61.6 Plexiform neurofibromas. Clinical presentations include: hyperpigmented plaques that may be misdiagnosed as a café-au-lait macule (if not palpated) (**A**) or congenital melanocytic nevus (**B**); and a poorly circumscribed, sagging pink mass (**C**). *A, Courtesy Antonio Torrelo, MD; B,C, Courtesy Julie V. Schaffer, MD.*

EVALUATION AND MANAGEMENT OF PATIENTS WITH NEUROFIBROMATOSIS TYPE 1 (NF1)
At the time of diagnosis and annually

• Offer genetic testing at the time of diagnosis, especially if atypical clinical features or helpful for reproductive planning
• Dermatologic examination, especially if a plexiform neurofibroma (PNF) involves the skin
  • Surgical consultation if painful, disfiguring, or bothersome neurofibromas
  • Consider baseline MRI if deeper extension of PNF
  • Urgent PET-CT if rapid growth, increased firmness, or persistent pain within an established PNF or the development of a new neurologic deficit
• Neurologic evaluation
  • Consider baseline brain/orbital MRI in pediatric patients*
  • Brain/orbital and/or spinal MRI if neurologic signs/symptoms develop
• Cardiac assessment (*at initial diagnosis*) and measurement of blood pressure
  • Renal MRA (or spiral CT/CT angiography if impaired renal function) and plasma free metanephrines if hypertension develops
• Evaluation for scoliosis (via forward bend test), other skeletal abnormalities (e.g. tibial bowing), and vitamin D deficiency†
  • Referral to orthopedics and vitamin D supplementation as indicated

At the time of diagnosis ± annually, *depending on the age of the patient*
• Ophthalmologic examination with visual testing and assessment for pubertal development/accelerated linear growth (*prior to puberty; consider twice yearly ophthalmologic examination until age 6 years*)   • Brain/orbital MRI if signs/symptoms of optic pathway glioma • Neurodevelopmental/behavioral evaluation (*annually only in children/adolescents*) • Measurement of head circumference (*annually only in young children*) • Screening for breast cancer with clinical examination + mammography ± MRI (*beginning at age 30 years*)
Potentially affected family members
• Consider genetic testing for the mutation identified in the proband • Dermatologic examination for cutaneous manifestations of NF1 • Ophthalmologic examination for Lisch nodules
*The role of neuroimaging in asymptomatic patients is controversial. †Considering that osteoporosis occurs at an earlier age in individuals with NF1, screening with dual-energy X-ray absorptiometry can be considered based on age and other risk factors.

Table 61.4 Evaluation and management of patients with neurofibromatosis type 1 (NF1)[94,95]. During yearly visits, patients with NF1 should also be asked about fingertip pain from glomus tumors, other chronic pain or itch, signs/symptoms of pheochromocytoma (e.g. palpitations, sweating), and depression. CT, computed tomography; MRA, magnetic resonance angiography; MRI, magnetic resonance imaging; PET-CT, positron emission tomography–computed tomography.

Additional findings suggestive of this diagnosis in children with manifestations of NF1 but who lack an *NF1* or *SPRED1* mutation include siblings but not parents with features of NF1, a personal or family history of malignancies (especially Lynch syndrome-related cancers; see Ch. 63), and consanguinity[88].

Additional disorders associated with multiple CALMs, some of which are caused by other genetic defects that lead to increased MAPK signaling, are presented in Table 61.3. NGS panels are now available to assess *NF1*, *SPRED1*, and other "RASopathy" genes.

Historically, *neurofibromatosis type 2* (NF2) has been discussed in the context of NF1. However, the clinical manifestations and molecular genetics of NF2 are distinct from those of NF1 (Table 61.5). NF2 is less common and has a lower frequency of cutaneous findings than NF1; Lisch nodules are not a feature of NF2. The tumor upon which a diagnosis of NF2 typically rests is the vestibular schwannoma. In the 1990 diagnostic criteria for NF2, neurofibromas were included as one of the index tumors[89]. However, in a 1997 update, neurofibromas were excluded from the diagnostic criteria for NF2[90]. Mautner et al.[91] found that 60% of NF2 patients had skin tumors, usually schwannomas appearing as flat or spherical, nodular subcutaneous tumors of the peripheral nerves on the limbs and trunk. Although one-third of the

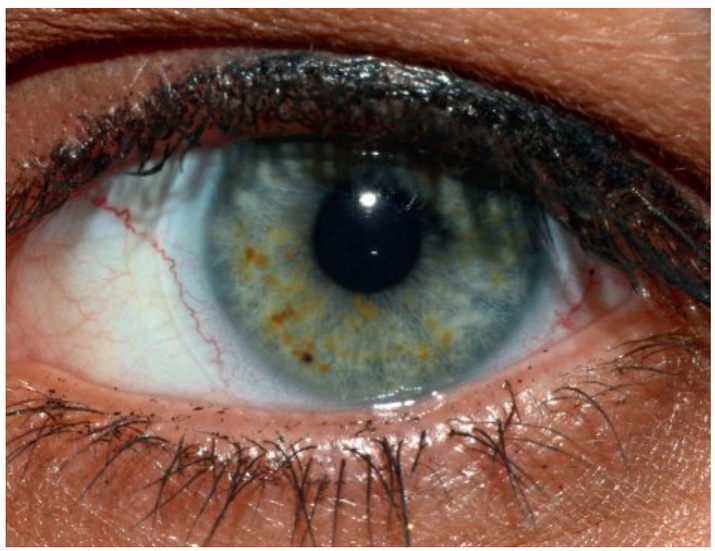

Fig. 61.7 Lisch nodules. Multiple yellow–brown papules on the iris. Although best seen using a slit lamp, Lisch nodules may also be evident on clinical examination in patients with lightly pigmented eyes. *Courtesy Julie V. Schaffer, MD.*

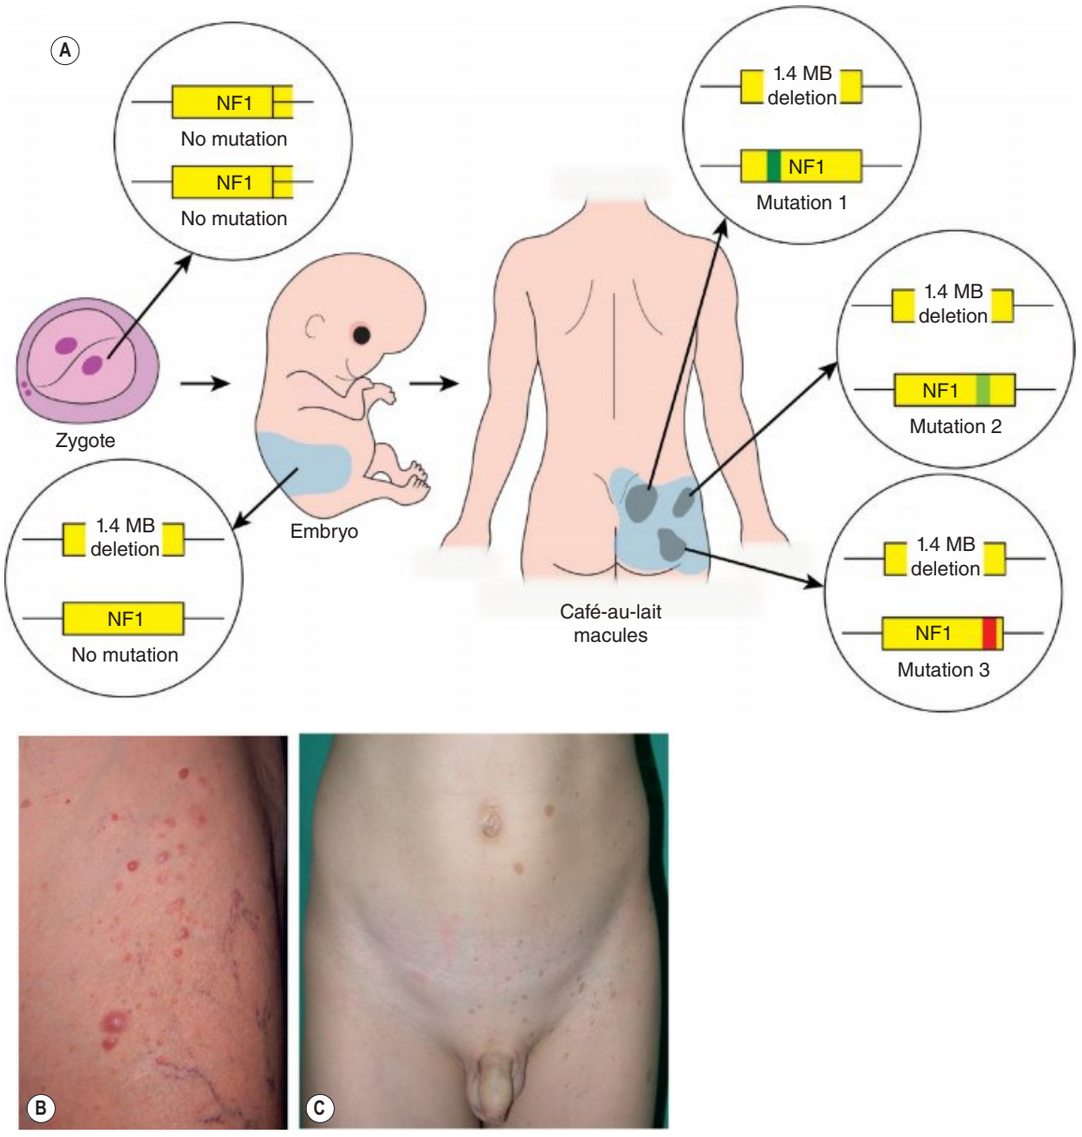

Fig. 61.8 Mosaic neurofibromatosis type 1 (NF1). A Mosaic NF1 results from a heterozygous postzygotic *NF1* mutation (e.g. the deletion depicted here), which can affect one or more regions of skin. Within such areas, somatic "second-hit" mutations that inactivate the remaining *NF1* allele result in skin lesions such as café-au-lait macules, lentigines, and neurofibromas. **B** A cluster of soft, pink to pink–brown papules limited to the thigh. There were no associated café-au-lait macules. **C** Multiple small café-au-lait macules and "freckling" limited to the left side of the trunk and groin, with slight extension past the midline. *A, Courtesy Jean L. Bolognia, MD; B, Courtesy Antonio Torrelo, MD.*

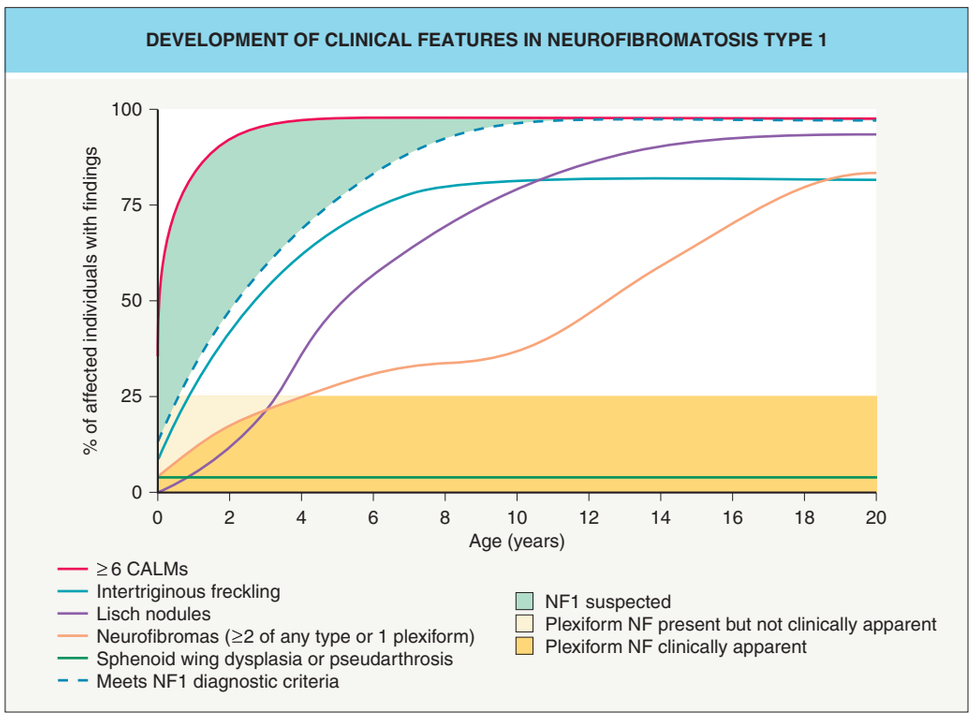

Fig. 61.9 Development of clinical features in neurofibromatosis type 1. The time course of major diagnostic lesions that develop in NF1. During the first few years of life, a child may have only café-au-lait macules. *Adapted from DeBella K, Szudek J, Friedman JM. Use of the National Institutes of Health criteria for diagnosis of neurofibromatosis 1 in children. Pediatrics 2000;105:608–14.*

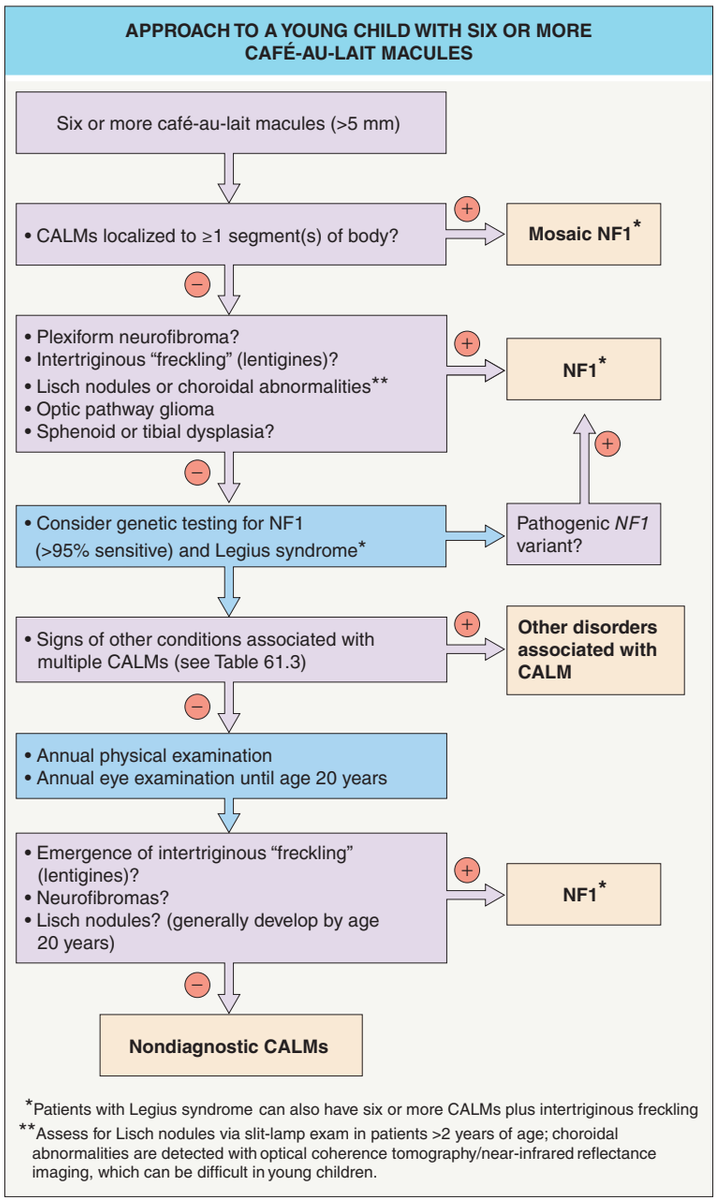

Fig. 61.10 Approach to a young child with six or more café-au-lait macules. More than half of these patients have NF1 or, less often, one of the other CALM-associated syndromes (see Table 61.3). Additional early signs of NF1 that are not included in the diagnostic criteria include nevus anemicus, juvenile xanthogranulomas, macrocephaly, and T2 hyperintensities on brain MRI.

Fig. 61.11 Entities in the differential diagnosis of neurofibromatosis type 1. A Grouped café-au-lait macules and lentigines in a 6-year-old boy with constitutional mismatch repair deficiency. **B** A cutaneous schwannoma with hypertrichosis and slight hyperpigmentation in a 2-year-old boy with neurofibromatosis type 2; such lesions may be misdiagnosed as a congenital melanocytic nevus or smooth muscle hamartoma. *Courtesy Julie V. Schaffer, MD.*

KEY FEATURES OF NEUROFIBROMATOSIS TYPE 2
• Autosomal dominant transmission; affects approximately 1 in 40 000 individuals
• Approximately half of the cases are due to *de novo* mutations rather than inherited germline mutations (similar to NF1)
• Bilateral vestibular schwannomas, meningiomas, and spinal tumors
• Two-thirds of patients develop cutaneous schwannomas, and approximately 50% develop café-au-lait macules (CALMs), but fewer in number compared to NF1*
• No Lisch nodules or mental retardation/learning disabilities
• *NF2* gene is located on chromosome 22q12 and encodes a cytoskeleton-associated protein of ~600 amino acids named merlin/neurofibromin 2, which is structurally related to the ERM (ezrin-radixin-moesin) protein family of membrane-cytoskeleton linkers
*In two large series of patients with NF2 (n = 161), only two individuals had more than five CALMs of the required size to meet NF1 criteria and over half of those with any CALMs had only one (41 of 72).

Table 61.5 Key features of neurofibromatosis type 2 (NF2).

affected individuals in this series had CALMs, only 2 of 88 patients had six or more CALMs. In young children with NF2, schwannomas may present as hypertrichotic, slightly hyperpigmented plaques (Fig. 61.11B).

McCune–Albright syndrome also features CALMs that are present at birth or become apparent during infancy. Additional manifestations of this sporadic mosaic disorder include polyostotic fibrous dysplasia and endocrine hyperfunction, most commonly precocious puberty. Affected tissues harbor an *activating* mutation in the gene encoding $G_s\alpha$ (i.e. the α-subunit of the G protein that stimulates adenylate cyclase), which leads to increased intracellular levels of cyclic AMP. Compared to the CALMs that occur in NF1, those of McCune–Albright syndrome and other forms of "pigmentary mosaicism" are generally larger, have a linear (e.g. broad bands along the lines of Blaschko) or segmental distribution pattern, usually do not cross the midline, and have an irregular border that may resemble the "coast of Maine". The most common sites are the head, neck, trunk, and buttocks.

PNFs need to be distinguished from congenital melanocytic nevi, especially when they are hyperpigmented with hypertrichosis. It is equally important not to misdiagnose patients who have large congenital melanocytic nevi with smaller "satellite" lesions and prominent neurotization as having NF1.

Management

Management of NF1 patients requires a multidisciplinary approach[79,90]; if available, a multispecialty NF clinic can help to optimize care. Dermatologists are often consulted to assist in establishing the diagnosis in affected children. Evaluation of individuals newly diagnosed with NF1 should include a thorough history (personal and family) and physical examination, with particular attention to signs and symptoms of disease manifestations (see Table 61.1). As part of the initial care of NF1 patients, an in-depth educational discussion should include the natural history of the condition, possible medical complications and neurodevelopmental sequelae, and psychosocial considerations; genetic counseling should also be provided. Table 61.4 summarizes recommendations for the evaluation and management of NF1 patients[92–95]. Goals of longitudinal care include early recognition and treatment of complications, maximization of academic and vocational achievement, and minimization of the disease's psychosocial impact.

The cutaneous lesions of NF1 can lead to a variety of age-dependent management issues. PNFs may grow into large, bulky tumors during

early childhood. Multidisciplinary teams are often required to excise deep and extensive neurofibromatous tissue, and the lesions tend to recur following surgery. CALMs do not need or respond well to treatment, although it may be desired for cosmetic purposes. When laser therapy is performed, CALMs tend to persist or recur (see Ch. 137). During adolescence and adulthood, removal of CNFs may be indicated for functional or cosmetic reasons. Simple surgical excision is the treatment of choice for selected bothersome lesions; laser ablation or electrocautery can be used to remove numerous small CNFs[96,97], but recurrences are common and hypertrophic scarring may develop.

Lifelong surveillance for the development of MPNSTs is essential, particularly for patients at increased risk of this malignancy due to the known presence of PNFs, polyneuropathy secondary to multiple nerve root tumors, a history of radiation therapy (with reports of MPNSTs arising in the radiation field), or a germline *NF1* microdeletion[49]. An increase in the growth rate, firmness, pain, or neurologic symptoms associated with a PNF merits further evaluation. ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography–computed tomography (PET-CT) or functional MRI with diffusion-weighted imaging/apparent diffusion coefficient (DWI/ADC) mapping can aid in the early detection of malignant transformation within PNFs and guide biopsy of suspicious areas[98,99]. Histologic evaluation has been recommended for symptomatic lesions with a maximum standardized uptake value (SUVmax) of ≥3.5 on PET-CT with delayed imaging (4 hours after ^{18}F-FDG injection).

The MEK inhibitor selumetinib was FDA approved in 2020 for treatment of symptomatic, inoperable PNFs in pediatric patients (≥2 years of age) with NF1; clinical trials showed durable tumor shrinkage (median 28%)[100]. Selumetinib and other MEK inhibitors (e.g. trametinib) have shown clinical benefit for gliomas as well as PNFs in patients with NF1[101]. Targeted therapies that are under investigation for PNFs and other tumors in NF1 patients also include inhibitors of the KIT receptor on mast cells and other tyrosine kinases (e.g. imatinib mesylate, cabozantinib; see Pathogenesis section and Fig. 61.2), mechanistic target of rapamycin (mTOR; e.g. sirolimus), vascular endothelial growth factor receptors (VEGFRs), and other components of the MAPK pathway as well as the *p*hosphatidyl*i*nositol 3-*k*inase (PI3K)/AKT, JAK/STAT3, and Hippo/YAP pathways[102–105].

Resources for patients and families include Neurofibromatosis Network (www.nfnetwork.org), the Neurofibromatosis Clinics Association (www.nfpittsburgh.org), the Children's Tumor Foundation (www.ctf.org), and Nerve Tumours UK (www.nervetumours.org.uk).

TUBEROUS SCLEROSIS COMPLEX

Synonyms: ■ Tuberous sclerosis ■ Bourneville disease ■ Bourneville–Pringle disease ■ Epiloia (*epi*lepsy, *l*ow *i*ntelligence, *a*ngiofibroma)

Key features

- Tuberous sclerosis complex is an autosomal dominant disorder with an incidence of ~1 in 10 000 births
- Key cutaneous features include hypopigmented macules, facial angiofibromas, collagenomas, and ungual fibromas
- The characteristic oral findings are gingival fibromas and dental enamel pits
- Hamartomas can be found in the eye as well as several internal organs, including the brain, kidneys, heart and lungs
- Seizures, mental deficits, and neuropsychiatric disturbances are common
- Up to 75% of cases are due to new spontaneous mutations
- Mutations have been identified in two genes: *TSC1* and *TSC2*; their protein products are hamartin and tuberin, respectively

Introduction

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder characterized by seizures, intellectual deficits, and skin findings including hypomelanotic macules and facial angiofibromas. As with NF1, cutaneous lesions are often the initial clinical features, and dermatologists are routinely called upon to assist in the diagnosis of TSC.

History

During the mid-1800s, Virchow recognized scleromas in the brain and von Recklinghausen described a similar patient with both scleromas and myomata in the heart[44]. Between 1880 and 1900, Bourneville provided the first systematic descriptions of the disease, including neural and cutaneous findings. Vogt posited the classic triad of epilepsy, low intelligence, and angiofibromas (termed the Vogt triad) in 1908, and Sherlock coined the term "epiloia" a few years later. In 1920, van der Hoeve described the significance of retinal hamartomas, which he termed "phakomas" (hence the designation "phakomatosis")[106]. At that time, examination of the ocular fundi was the only external access to the CNS before death.

Epidemiology

TSC has an incidence of ~1 in 10 000 births, and the overall prevalence is estimated to be between 1 in 10 000 and 1 in 30 000[107,108].

Pathogenesis

TSC is a hamartomatous condition characterized by disordered cellular proliferation, migration, and differentiation. It has an autosomal dominant pattern of inheritance. However, the majority of affected individuals have new spontaneous mutations.

In the 1980s, TSC kindreds from around the world were analyzed and the disease locus was mapped to chromosome 9q34 in a subset of affected families. Further study led to the discovery of a second disease locus on chromosome 16p13[109]. In 1994, Povey et al.[110] studied 32 TSC families and found that about half demonstrated linkage to chromosome 9q34 (*TSC1*), whereas the other half showed linkage to chromosome 16p13 (*TSC2*).

In 1993, the *TSC2* gene on chromosome 16 was identified and found to be deleted or mutated in the subset of TSC families linked to this region[111]. *TSC2* is composed of 41 exons that encode an 1807 amino acid, 200 kDa protein referred to as *tuberin*. Like neurofibromin, tuberin contains a GAP domain (Fig. 61.12). Tuberin stimulates the GTPase activities of RAB5, a protein involved in endocytosis[112], and RHEB, a RAS-related protein that activates the mTOR pathway. By "turning off" RHEB, tuberin inhibits the cell growth and proliferation that result from mTOR signaling. The latter is a central regulator of cellular responses to nutrition, energy levels, and a variety of growth factors.

The *TSC1* gene, which was identified in 1997, consists of 23 exons that encode a 130 kDa protein termed *hamartin*[113]. Hamartin shares no sequence homology with tuberin or other known tumor suppressor genes. However, hamartin interacts with tuberin[114] and other cytoskeletal components, and it functions together with tuberin to negatively regulate mTOR signaling[115,116]. In patients with TSC, mTOR inhibition by sirolimus (rapamycin) and related agents can have therapeutic benefit (see Fig. 61.12 and Management section).

In large series of TSC patients, *TSC2* mutations have been identified more frequently than *TSC1* mutations, with an overall ratio of approximately 3 : 1[117,118]. However, in familial cases, there is a more equal proportion of *TSC2* and *TSC1* mutations. Of note, individuals with *TSC2* mutations tend to have a more severe phenotype than those with *TSC1* mutations. Familial TSC due to *TSC2* mutations tends to have a milder phenotype than *de novo* cases[117,118], which likely reflects a decreased likelihood of reproduction in more severely affected individuals. Some patients with mild sporadic TSC are mosaics for a mutation in *TSC1* or *TSC2*; if there is gonadal involvement, they may pass on generalized disease to their offspring.

In mouse models, heterozygous TSC1 mutant (*Tsc1*$^{+/-}$) mice develop renal and extrarenal tumors such as hepatic hemangiomas with loss of the wild-type *Tsc1* allele. Heterozygous TSC2 mice (*Tsc2*$^{+/-}$) display a high incidence of multiple bilateral renal cystadenomas, liver hemangiomas, and lung adenomas. Progression to renal carcinoma, fatal bleeding from the liver hemangiomas, and angiosarcomas are occasionally observed[119]. These mice also have abnormalities in learning and memory associated with hyperactive hippocampal mTOR signaling. Treatment of adult mice with the mTOR inhibitor sirolimus resulted in improved cognitive function[120].

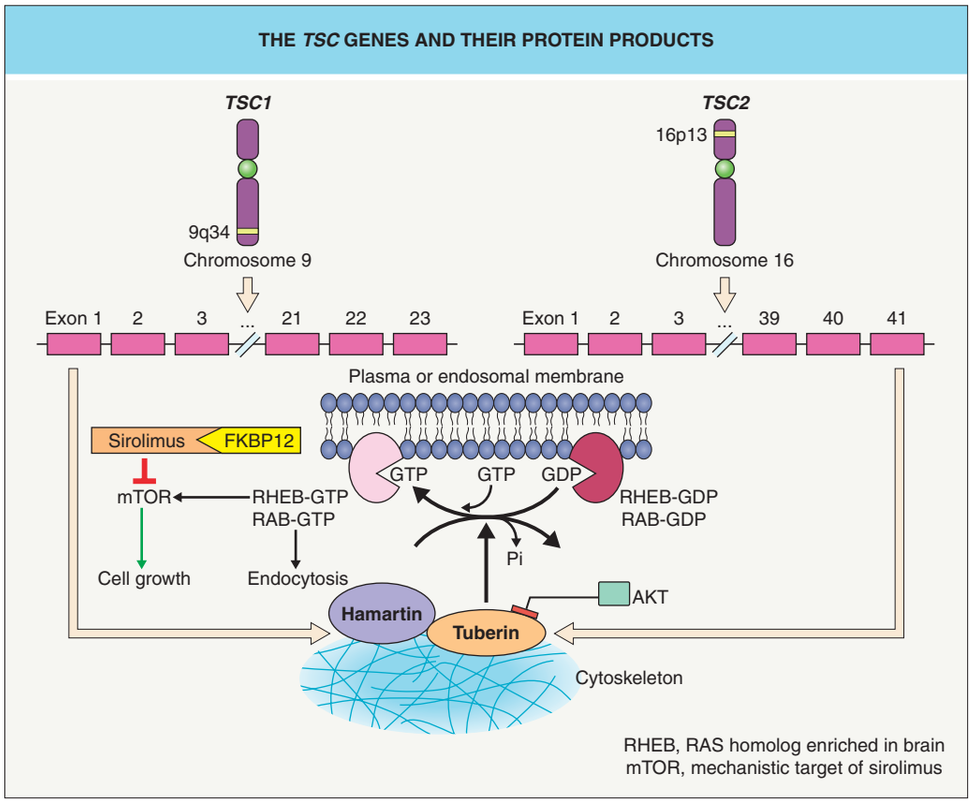

Fig. 61.12 The *TSC* genes and their protein products. *TSC1* and *TSC2* are located on chromosomes 9q34 and 16p13, respectively. The *TSC1* product, hamartin, interacts with the *TSC2* product, tuberin, and negatively regulates signaling by the small GTPases RAB and RHEB. Like RAS, the activity of RAB and RHEB is dependent upon bound GTP, and tuberin (like neurofibromin) accelerates hydrolysis of GTP to GDP in order to turn off RAB and RHEB. Sirolimus (rapamycin) and its analogues (e.g. everolimus) form a complex with the FK506-binding protein-12 (FKBP12), and together they bind to and inhibit mTOR. AKT, human homolog of the murine AKT8 retrovirus transforming sequence.

Clinical Features

As with NF1, the diagnosis of TSC often involves a dermatologist, as some of the earliest findings of TSC are cutaneous (Table 61.6).

Oculocutaneous manifestations

The time course for developing the cutaneous findings of TSC is shown in Fig. 61.13. The hypomelanotic macules are not depigmented, as in vitiligo, but instead are hypopigmented (Fig. 61.14). A Wood's lamp can help to detect these lesions, which may be very subtle in children with lightly pigmented skin. The macules are usually present at birth or within the first few months of life, although their appearance is sometimes delayed until early childhood in individuals with fair skin. They may adopt several configurations, and small (<2 cm) polygonal or "thumbprint"-shaped macules are most common[121]. The lance-ovate hypopigmented macule or "ash leaf spot" (named after the Eastern Mountain ash tree) is rounded at one end and tapered at the other, and it can range from 1 to 12 cm in size. Although less frequent than polygonal macules, ash leaf spots are characteristic of TSC.

Over 90% of TSC patients have more than one hypomelanotic macule[122], and some have >100 lesions. Scores of 1–2 mm, "guttate" hypopigmented macules (also known as "white freckles" or "confetti" macules) may also be seen, especially on the extremities (Fig. 61.15). Although these guttate lesions occur in <5% of affected infants, they are probably the most specific pigmentary manifestation of TSC[121,122].

Approximately 1%–4% of healthy infants and children have a circumscribed hypopigmented macule or patch, i.e. a nevus depigmentosus (see Ch. 66)[121,123,124]. Debard and Richardet[123] examined the skin of 9737 infants aged 1–18 months and found that 0.7% had one or two white spots that were larger than 1 cm; however, no unaffected infant had more than three spots. Thus, the presence of three or more hypomelanotic macules (≥5 mm in diameter) was chosen as a major criterion for diagnosis of TSC[125,126] (Table 61.7). Clusters of scalp hair, eyebrows, or eyelashes may be lighter or white (poliosis) when the underlying skin is affected.

Café-au-lait macules (CALMs) have been reported in up to 30% of patients with TSC and are usually evident within the first few months of life[121,122]. Most TSC patients, however, have fewer than the six CALMs required to diagnose NF1.

Angiofibromas, previously referred to as "adenoma sebaceum", are not typically present at birth. They begin to appear in the centrofacial area as early as the first 2 years of life, and by adolescence angiofibromas are present in ~80% of TSC patients. A high frequency of somatic second-hit CC>TT "UV signature" mutations has been identified in TSC-related facial angiofibromas, suggesting a role for UV light in their pathogenesis[127]. The lesions may begin as erythematous macules on the cheeks and forehead and then mature into pink to red or red–brown papules or papulonodules, which may coalesce into plaques. The papules are often dome-shaped and have a smooth, shiny surface (Fig. 61.16A,B). With the exception of mosaic TSC, facial angiofibromas have a bilateral and symmetric distribution. Because one or two angiofibromas (fibrous papules) are relatively common in the general population, the presence of at least 3 angiofibromas is required as a diagnostic criterion for TSC[125].

The fibrous cephalic plaque represents a larger variant of an angiofibroma that develops on the face or scalp in ~20% of TSC patients[122,125]. These plaques favor the forehead and are usually firm and yellow–brown to pink–tan in color (Fig. 61.16C). They may slowly enlarge over time and when on the scalp typically lack hair.

A characteristic truncal lesion is the shagreen ("leather") patch, which represents a type of collagenoma (see Ch. 116). Shagreen patches occur most commonly in the lumbosacral area and typically begin to develop at around 2 years of age, although occasionally they are apparent earlier. Eventually these lesions are observed in approximately half of TSC patients[122]. Clinically, they typically appear as skin-colored to hyperpigmented plaques that can reach up to 10 cm in diameter and often have an uneven surface (Fig. 61.17A). Multiple lesions may be present. A distinctive feature is prominent, but slightly depressed, follicular openings, giving rise to a pigskin-like appearance. A "folliculocystic and collagen hamartoma" (FCCH) featuring comedones and keratin-containing cysts as well as collagen deposition has also been described in patients with TSC (Fig. 61.17B)[128]. When present in patients with TSC, fibrous cephalic plaques, shagreen patches and FCCH, in addition to segmental forms of hypomelanosis, congenital lymphedema and lipomatosis, are thought to reflect superimposed (type 2) mosaicism due to a second-hit mutation arising during an early stage of prenatal development[129] (see Ch. 62).

Ungual fibromas (Koenen tumors) begin to develop later in childhood and can continue to form throughout adulthood. *Periungual* fibromas

MAJOR CLINICAL FEATURES OF TUBEROUS SCLEROSIS COMPLEX
Cutaneous
• Facial angiofibromas (~80%) and fibrous plaque of the forehead (~20%) • Hypomelanotic macules (90%–100%) – polygonal; lance-ovate (ash leaf); confetti • Shagreen patch (40%–50%) • Ungual fibromas (30%–60%) • Molluscum pendulum • Café-au-lait macules
Ocular
• Retinal hamartomas (~40%) • Achromatic retinal patches (~40%) • Retinal astrocytoma
Skeletal
• Cystic areas of bone rarefaction, especially phalanges
Dental
• Pitted enamel (>90%) • Intraoral fibromas (up to 70%)
Pulmonary
• Lymphangioleiomyomatosis (≥30%–40% of women)
Renal
• Multiple bilateral angiomyolipomas (75%–90%) • Cysts (30%) • Carcinoma
Endocrine
• Precocious puberty • Hypothyroidism
Neurologic
• Cortical dysplasia (cortical tubers and cerebral white matter radial migration lines) (>90%) • Subependymal nodules* (>80%) • Subependymal giant cell astrocytoma† (5%–15%) • Seizures (70%–95%), including infantile spasms (~60%) • Intellectual impairment (>50%)
Cardiovascular
• Myocardial rhabdomyoma‡ (80% of infants) • Wolff–Parkinson–White syndrome
*Nearly all patients by puberty. †Also known as subependymal giant cell tumor ‡Increasingly difficult to distinguish from normal myocardium after the first few years of life.

Table 61.6 Major clinical features of tuberous sclerosis complex.

arise from the proximal or lateral nail fold and occur most commonly around the toenails (Fig. 61.18A). In contrast, *subungual* fibromas that originate under the nail plate and longitudinal red streaks with proximal narrowing ("red comets") favor the fingernails (Fig. 61.18B). In addition, lesions can lead to distortion of the nail plate (e.g. a longitudinal groove) without a visible tumor (see Fig. 61.18A).

Soft, pedunculated, skin-colored papules and nodules (molluscum pendulum) develop in some TSC patients. These lesions resemble large acrochordons and favor flexural areas, such as the neck, axillae, and groin.

Intraoral fibromas have been described in 20%–70% of individuals with TSC, with a higher prevalence in adults than in children[121,130]. The gingiva is the most common location, but lesions can also occur on buccal or labial mucosa and occasionally the tongue. Dental enamel pits are seen in nearly all TSC patients, compared with <10% to (upon close examination) 70% of unaffected individuals[131,132]. However, one study found >10 pits in 70% of TSC patients but only 4% of controls[132].

Retinal lesions are present in about half of TSC patients, with retinal hamartomas seen in ~40% (Fig. 61.19). The most common morphologic type of hamartoma is the flat, translucent lesion (70%), followed by the multinodular "mulberry" lesion (55%) and the transitional-type

2012 REVISED DIAGNOSTIC CRITERIA FOR TUBEROUS SCLEROSIS COMPLEX (TSC)	
Major Features	
Hypomelanotic macules (≥3, diameter ≥5 mm)	
Facial angiofibromas (≥3) or fibrous cephalic plaque	
Ungual fibromas (≥2)	
Shagreen patch	
Multiple retinal hamartomas	
Cortical dysplasias (including tubers and cerebral white matter radial migration lines)	
Subependymal nodules	
Subependymal giant cell astrocytoma	
Cardiac rhabdomyoma	
Lymphangioleiomyomatosis	
Angiomyolipomas (≥2; renal >> other organs, e.g. liver)	
Minor Features	
"Confetti" skin lesions	
Dental enamel pits (≥3)	
Intraoral fibromas (≥2)	
Retinal achromic patch	
Multiple renal cysts	
Non-renal hamartomas	
Definite *clinical* diagnosis	
• Either two major features* *or* one major feature plus ≥2 minor features	
Possible *clinical* diagnosis	
• Either one major feature *or* ≥2 minor features	
Definite *genetic* diagnosis	
• Identification of a pathogenic variant in either *TSC1* or *TSC2* in DNA from the blood or normal tissue	
Key:	
Cutaneous	*Extracutaneous*
*With the exception of lymphangioleiomyomatosis + angiomyolipomas.	

Table 61.7 2012 revised diagnostic criteria for tuberous sclerosis complex (TSC)[125,141].

lesion (9%). Punched-out areas of retinal depigmentation can also be found in about 40% of affected individuals[133]. Most ocular lesions in TSC patients do not lead to visual loss.

Neurologic manifestations

Infantile spasms occur in ~70% of infants with TSC. These seizures last for several minutes and are characterized by massive flexion or extension of the limbs, trunk, and head for <1–3 seconds, occurring in series separated by intervals of a few seconds. These spasms typically begin at about 3 months of age, as opposed to other types of TSC-associated seizures, which usually develop after 1 year of age[134]. The EEG changes that characterize infantile spasms are termed hypsarrhythmia[134,135].

Intellectual disabilities of varying degrees occur with a high frequency in children and adults with TSC[134,135]. The spectrum of *T*SC-*a*ssociated *n*europsychiatric *d*isorders (TAND) also includes autism, attention deficit disorder, aggressive behaviors, and psychiatric conditions[136–138].

Multiple subependymal nodules along the ventricular surface can be seen on MRI (more sensitive) or CT scan in >80% of TSC patients by 2 years of age. These nodules progressively calcify and are found in almost all patients by puberty[139]. Subependymal giant cell astrocytomas (SEGAs), which affect 5%–15% of patients with TSC, usually develop during childhood[140]. Unlike subependymal nodules, SEGAs tend to enlarge over time, which may lead to hydrocephalus and neurologic symptoms; they exhibit contrast enhancement on MRI or CT[141]. Types of cortical dysplasia in TSC include cerebral white matter radial migration lines as well as the highly characteristic tubers (glioneuronal hamartomas) that can be detected by MRI in ~90% of patients[139].

Cardiovascular manifestations

Cardiac rhabdomyomas, which can be detected prenatally as well as after birth by echocardiography or MRI, are found in >80% of infants with TSC[139]. However, cardiac rhabdomyomas tend to involute during

Fig. 61.17 Collagenomas in tuberous sclerosis complex. A Shagreen patches are actually plaques, which can be hyperpigmented or skin-colored. The surface is said to resemble leather or pigskin. **B** The "folliculocystic and collagen hamartoma" features comedones and keratin-filled cysts as well as collagen deposition. *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Thomas Darling, MD.*

the first 3 years of life[142], and they often disappear altogether by adulthood. Arrhythmias, especially Wolff–Parkinson–White syndrome, appear to be more common in affected individuals[143].

Renal manifestations

Multiple bilateral angiomyolipomas are frequently noted on routine renal ultrasounds of TSC patients. Most of these lesions are asymptomatic, especially during childhood and when they measure <4 cm in diameter[142]. However, angiomyolipomas tend to enlarge and increase in number with age, and they may lead to life-threatening hemorrhage[144]. Children with TSC who develop severe renal cysts often have a contiguous gene syndrome in which both *TSC2* and the polycystic kidney disease (*PKD*) genes are lost in a single large chromosomal deletion[145]. Occasionally, renal cell carcinomas develop in TSC patients.

Other manifestations

Pulmonary lymphangioleiomyomatosis is often asymptomatic and occurs in at least 30%–40% of women with TSC. On high-resolution CT scan, these lesions appear as cysts. Men rarely develop this manifestation of TSC[146], and estrogen is suspected to be involved in stimulating growth of smooth muscle cells in the lung[147]. Of note, lymphangioleiomyomatosis can occur sporadically due to biallelic somatic *TSC2* mutations, and renal angiomyolipomas also develop in a subset of these patients. Multifocal micronodular pneumonocyte hyperplasia, hamartomatous gastrointestinal polyps, congenital segmental lymphedema, other vascular anomalies, segmental lipomatosis, and hemihypertrophy have also been reported in individuals with TSC[129,148–150].

Pathology

Hypopigmented macules have a reduction in the amount of epidermal melanin but a normal number of melanocytes. The melanocytes have poorly developed dendrites[151]. On electron microscopy, small, immature melanosomes are seen whose number, degree of melanization, and transfer to keratinocytes are reduced[151–153].

Angiofibromas consist of an irregular proliferation of fibrous tissue and blood vessels. Expansion of the hamartomatous process can lead to compression of adnexae. Characteristically, there is concentric perifollicular fibrosis. *Fibrous cephalic plaques* have similar histopathologic findings[154].

Fig. 61.19 Retinal hamartomas of tuberous sclerosis complex. *Courtesy Jean L. Bolognia, MD.*

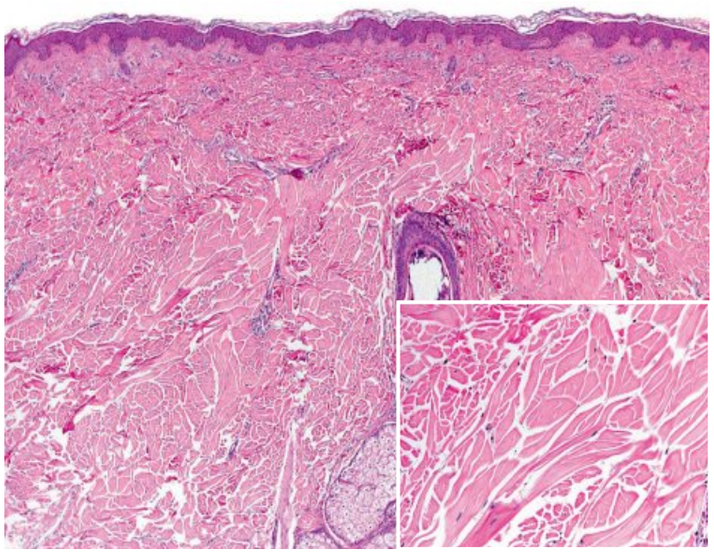

Fig. 61.20 Histology of a shagreen patch. Increased collagen forming thickened bundles in the dermis. *Courtesy Lorenzo Cerroni, MD.*

The *shagreen patch* (Fig. 61.20) and *ungual fibromas* represent collagenomas. The dermis is replaced by thick bundles of collagen, and elastin fibers are typically absent. The fibroblasts may be large and morphologically atypical. It is thought that the various fibrous lesions seen in TSC belong to the same histopathologic spectrum, with perifollicular fibrosis representing a characteristic feature; a cystic component is occasionally evident, as observed in FCCH[154,155].

Differential Diagnosis

The diagnostic criteria for TSC were revised in 1998 and then updated in 2012 (see Table 61.7)[125,126,141]. Four of the major features are cutaneous, and a thorough dermatologic examination frequently helps to establish the diagnosis. Although seizures occur in the majority of affected infants, the possibility of TSC is often considered in asymptomatic infants with multiple hypomelanotic macules. An approach to this clinical situation is outlined in Fig. 61.21. Echocardiography can be helpful in establishing the diagnosis in infants and is easier to perform in this age group than is a brain MRI to detect CNS lesions.

Conventional genetic testing, including sequencing and deletion/duplication analysis, identifies a pathogenic variant in *TSC1* or *TSC2* in ~85% of individuals who meet the clinical criteria for TSC. Use of targeted next-generation sequencing (including deletion/duplication analysis) can increase the yield to ~95%, enabling detection of intronic splice site and mosaic pathogenic variants that tend to result in relatively mild disease[156,157]. Analysis of DNA from a lesional skin biopsy specimen (e.g. angiofibroma) may be necessary for mosaic TSC with more limited involvement[156].

Multiple facial angiofibromas, collagenomas, gingival papules, and confetti-like hypomelanotic macules can occur in patients with multiple endocrine neoplasia type 1 (MEN 1; see Ch. 63). Multiple facial angiofibromas and collagenomas have also been observed in adults with Birt–Hogg–Dubé syndrome (see Ch. 111), whereas multiple collagenomas can occur in Cowden syndrome (storiform variant, also referred to as sclerotic fibromas; see Ch. 63), Buschke–Ollendorf syndrome (dermatofibrosis lenticularis disseminata; see Ch. 116), and familial cutaneous collagenoma. The clinical differential diagnosis for facial angiofibromas may include acne vulgaris and trichoepitheliomas, but individual acneiform lesions should resolve over a period of weeks. Trichoepitheliomas are usually less red in color, although a biopsy is often required to establish the diagnosis. Additional causes of multiple facial papules are listed in Table 36.2 and Figure 111.5.

As discussed above, a nevus depigmentosus represents a common cause of a congenital hypopigmented macule or patch, and some infants have more than one of these lesions. A larger nevus depigmentosus that has a segmental distribution (segmental pigmentation disorder) or follows the lines of Blaschko may be composed of multiple hypopigmented macules and patches within the affected areas. Features that distinguish the hypopigmented lesions of TSC from postinflammatory hypopigmentation (e.g. due to atopic or seborrheic dermatitis) and the amelanosis of piebaldism or vitiligo are presented in Figure 61.21. Idiopathic guttate hypomelanosis (IGH) may resemble the confetti-like leukoderma of TS; however, IGH is an acquired condition that favors the shins and extensor forearms of older adults.

A congenital smooth muscle hamartoma can present during infancy as a firm, skin-colored to hyperpigmented plaque that may resemble a shagreen patch; however, it accentuates with rubbing (pseudo-Darier sign), contains follicular papules due to hyperplastic arrector pili muscles, and has associated hypertrichosis rather than prominent but depressed follicular orifices. Histologically, smooth muscle hamartomas feature intradermal bundles of smooth muscle rather than collagen.

Management

Nearly every organ can be affected by TSC, and clinical findings vary tremendously even within families. Certain signs and complications typically appear at birth, whereas others develop much later in life. The 2012 International TSC Consensus Conference Recommendations and 2019 United Kingdom Guidelines for the evaluation and management of individuals with TSC are summarized in Table 61.8[142,158–160]. Investigations in TSC patients should focus on detecting disease manifestations and complications that are potentially significant and treatable, and it is important to provide genetic counseling to affected individuals and families. In clinical trials involving TSC patients, systemic therapy with the mTOR inhibitors sirolimus and everolimus has led to regression of SEGAs, control of recalcitrant seizures, reduction in the size of renal angiomyolipomas, and improvement of lung function in women with lymphangioleiomyomatosis[161–163].

Considering the UV-induced mutations implicated in facial angiofibromas, sun protective measures may be of utility[127]. Use of electrosurgery, dermabrasion, and ablative fractional or pulsed dye lasers has led to variable results.

Topical sirolimus (rapamycin) has been employed to treat angiofibromas as well as fibrous plaques and hypomelanotic macules, with limited systemic absorption. More irritation is produced by topical application of the commercially available 0.1% solution (Rapamune® 1 mg/ml) than with compounded 0.1%–1% ointment, cream, and gel formulations[164–167]. Reduced erythema and flattening of the angiofibromas are typically seen within 3 months of initiating daily topical therapy, especially if treatment is initiated at ≤10 years of age. In randomized placebo-controlled studies in adults and children with TSC, angiofibromas improved in 60% (18/30) of patients treated topically with sirolimus 0.2% gel twice daily for 3 months and 82% (45/55) of those treated with sirolimus 1% daily for 6 months (vs 0% [0/31] and 25% [13/51], respectively, with placebo; $p<0.001$)[167,168]. Relapses typically occur upon discontinuation; although maintenance with thrice weekly

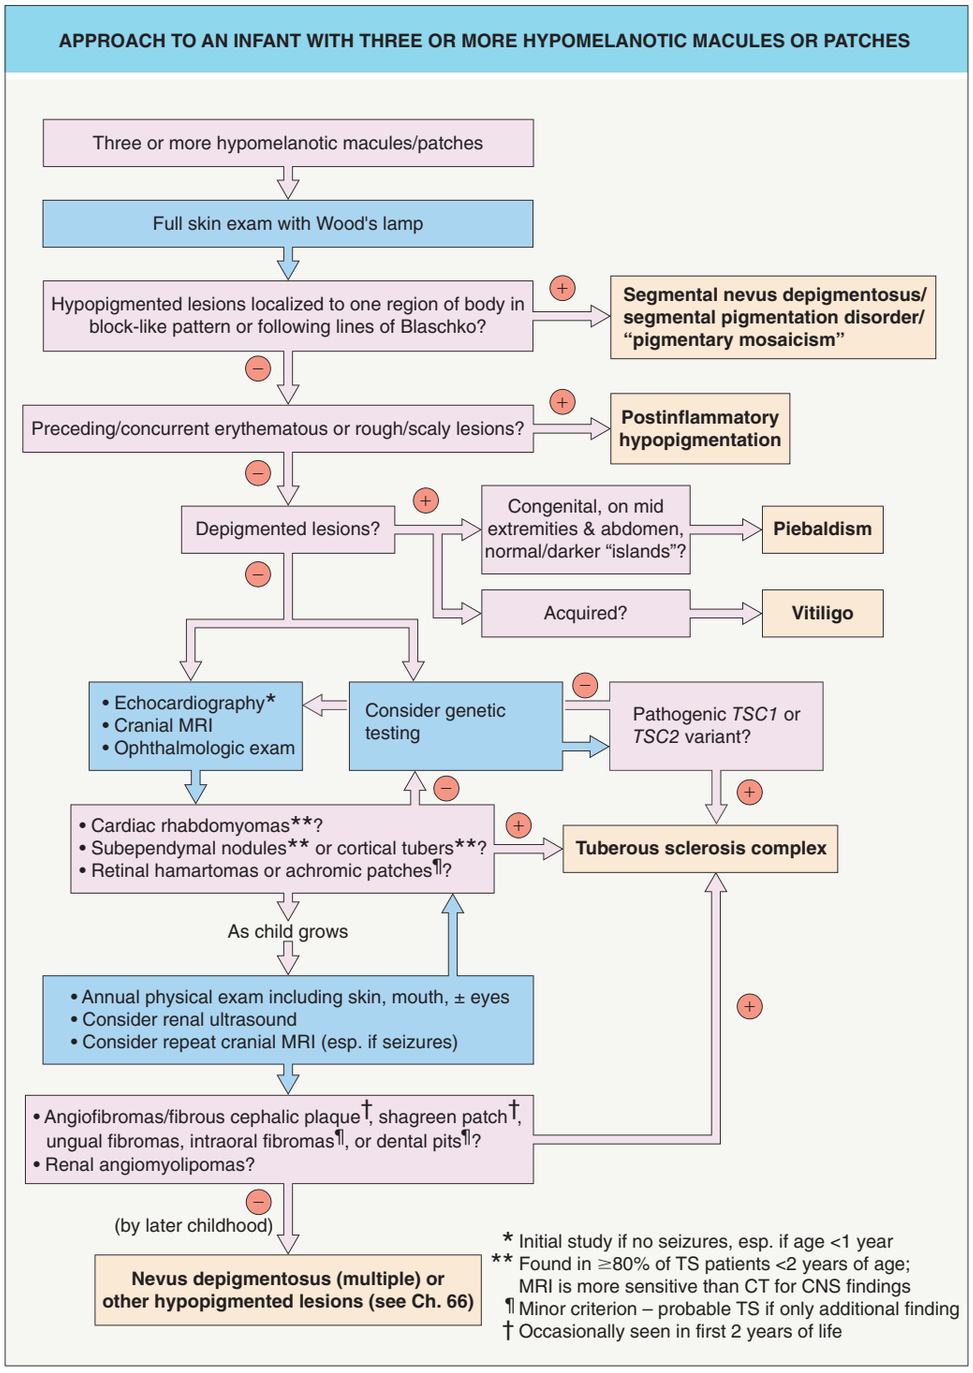

Fig. 61.21 Approach to an infant with three or more hypomelanotic macules or patches. A child with fewer than three macules and no family history of tuberous sclerosis complex (TSC) has an extremely low likelihood of having this disease.

applications has limited efficacy[166], a combination of topical sirolimus 0.1% and calcitriol 0.0003% may result in a more durable response than sirolimus alone[169].

Resources for patients and families include the TSC Alliance (www.tscalliance.org), the National Institute of Neurological Disorders and Stroke (www.ninds.nih.gov/health-information/disorders/tuberous-sclerosis-complex), and the Tuberous Sclerosis Association (www.tuberous-sclerosis.org).

Additional figures and table on Riccardi's classification of neurofibromatosis, available in our eBook (see inside front cover for access code).

EVALUATION AND MANAGEMENT OF TUBEROUS SCLEROSIS (TSC) PATIENTS
Newly diagnosed
• Offer genetic testing, especially if the TSC diagnosis cannot be clinically confirmed or would provide helpful information for reproductive planning • Neurodevelopmental and behavioral evaluation (especially for children) for features of TSC-associated neuropsychiatric disorder (TAND) • Brain MRI with and without gadolinium to assess for tubers, migrational defects, subependymal nodules, and SEGA* • Electroencephalogram (EEG); consider 24-hour video EEG if cognitive, behavioral, neurological, or sleep symptoms not explained by EEG; educate parents to recognize infantile spasms • Ophthalmologic examination including dilated fundoscopy • Electrocardiogram (ECG); echocardiography in children (especially if <3 years) and symptomatic adults • Abdominal MRI to detect angiomyolipomas and renal cysts (favored over CT or ultrasonography) • Assess blood pressure and determine glomerular filtration rate (GFR) • High-resolution chest CT and pulmonary function tests (PFTs) to detect LAM (all women ≥18 years of age; adolescents and men if symptomatic); counsel on risks of estrogen use and smoking as appropriate • Detailed dental assessment and dermatologic examination using a Wood's lamp
Established (to monitor for complications)
• Screening for TAND annually; comprehensive formal evaluation for TAND at transition periods, e.g. ages 0–3, 3–6, 6–11, and 12–18 years • Brain MRI every 1–3 years until age 25 to monitor for SEGA*; in patients with SEGA, perform MRI more frequently if symptoms or a large/growing lesion† and after age 25 as indicated • EEG if known/suspected seizure activity or behavior change/cognitive decline • Ophthalmologic examination with fundoscopy annually • ECG every 3–5 years in asymptomatic patients; echocardiography every 1–3 years in asymptomatic pediatric patients with cardiac rhabdomyomas until regression is documented • Abdominal MRI for angiomyolipomas and renal cysts every 1–3 years until early adulthood if no known renal lesions and yearly if renal lesions‡; may consider alternating with ultrasonography or fast low-dose CT, especially if general anesthesia is needed for MRI • Assess blood pressure and determine GFR at least annually in patients with renal lesions • High-resolution chest CT every 5–10 years until menopause in women without known LAM; annual PFTs in patients with LAM‡ • Dental examination every 6–12 months; panoramic radiographs by age 7 years if asymmetry, swelling, or abnormal tooth development • Annual dermatologic examination; counsel on sun protection • Offer genetic counseling/testing in patients of reproductive age or considering having children
Potentially affected family members (especially first-degree relatives)
• Consider genetic testing for the mutation identified in the proband • Dermatologic and (if skin findings not diagnostic) ophthalmologic examinations for manifestations of TS
*CT (or head ultrasound in infants with open fontanelles) is suboptimal but may be done if MRI is not possible. †Treatment options for enlarging and/or symptomatic SEGA include surgical resection (first-line) and mTOR inhibitors. ‡mTOR inhibitors represent first-line therapy for asymptomatic enlarging angiomyolipomas >3 cm in diameter and LAM resulting in progressive loss of lung function; embolization followed by corticosteroid therapy is recommended for acute hemorrhage of an angiomyolipoma.

Table 61.8 Evaluation and management of tuberous sclerosis (TSC) patients[159,160]. CT, computed tomography; MRI, magnetic resonance imaging; SEGA, subependymal giant cell astrocytoma; LAM, lymphangioleiomyomatosis.
