Key features

- Globally, complementary and alternative medicine (CAM) is commonly utilized by patients with skin disease
- CAM encompasses a diverse group of therapies and systems, many without strong evidence of efficacy
- Among dermatology patients, the most popular forms of CAM include herbals, dietary supplements, homeopathy, and acupuncture
- Scientific research regarding CAM is ongoing, with results varying from promising to demonstrating minimal, if any, benefit

INTRODUCTION

Complementary and alternative medicine (CAM) represents a diverse set of healthcare systems, practices, and treatments that are grouped together because they are not considered part of conventional medicine (Table 133.1). More specifically, "complementary medicine" can be defined as non-mainstream modalities or approaches used *in conjunction with* conventional medicine, while "alternative medicine" typically refers to the use of non-mainstream approaches *in place of* a conventional treatment. Integrative medicine seeks to blend CAM with more conventional therapies and implies assimilation of healing practices from multiple traditions and cultures.

Multiple studies suggest that from 35% to 70% of patients with skin disease have used CAM[1]. In the US, there tends to be a greater use of CAM in women, adults 30 to 69 years of age, those with higher levels of education, and former smokers[2]. CAM utilization also correlates with the number of health conditions, number of doctor visits during the past year, and hospitalization within the past year. The overwhelming majority of CAM users in high-income countries, including those with dermatologic disorders, use CAM to complement conventional medicine rather than as a complete alternative[2]. Interestingly, individuals with skin conditions are more likely to use CAM than the general population, making this topic particularly relevant to dermatologists[3].

In this chapter, a number of the major alternative or complementary systems and therapies employed for dermatologic conditions are reviewed. In order to maximize utility, we have focused on treatments with at least some supportive evidence of efficacy (Table 133.2).

NATURAL PRODUCTS – MEDICAL APPLICATIONS

Conventional dermatology uses many products of herbal origin, including podophyllin, psoralens, oatmeal, and pyrethrins; such accepted treatments are discussed elsewhere in this textbook. This section limits its discussion to botanicals, insect-based products, and dietary supplements that may be less well known to clinicians, but nonetheless are used by patients to treat skin ailments. Side effects are also reviewed (Table 133.3; Fig. 133.1).

Aloe Vera

Aloe vera (*Aloe barbadensis*) is applied topically to treat a number of afflictions including thermal burns, ulcers, chronic wounds, and mild cutaneous infections. It has also been used successfully to treat psoriasis[4]. Aloe gel is the clear viscous material found in the inner part of the leaf of the aloe plant and is the most common component used to treat skin conditions. A yellowish layer called aloin can be found just under the skin of the aloe leaf. It contains latex and can cause allergic reactions in susceptible individuals. When applied to the skin, aloe gel's anti-inflammatory effects are thought to be due to a reduction in levels of thromboxane A2, thromboxane B2, and prostaglandin 2[5]. Although generally well tolerated, aloe vera gel may cause an allergic contact dermatitis.

Capsaicin

Capsaicin is found in hot peppers (*Capsicum*), and it is a mixture of vanillyl amides of isodecenoic acid. Topical capsaicin is used for postherpetic neuralgia, notalgia paresthetica, diabetic neuropathy, complex regional pain syndrome, and hemodialysis-related pruritus. By binding to the vanilloid receptor-1 on pain fibers, capsaicin stimulates the release and eventual depletion of the neurotransmitter substance P. Prolonged exposure leads to deactivation of these neurons[6]. While there is some concern that systemically administered capsaicin is associated with an increase in carcinogenesis, this has not been found in studies of topical capsaicin[7]. Topical capsaicin is considered safe enough to appear in multiple over-the-counter (OTC) preparations; however, the associated stinging and burning sensations can be very unpleasant, especially when applied to fissured or denuded skin and should be used with caution.

Chamomile

Chamomile (*Matricaria recutita*; *Chamaemelum nobile)* is one of the earliest and most widely used medicinal plants. It has been employed for a variety of conditions, including mucocutaneous inflammation, as well as promotion of wound healing. Chamomile is traditionally used for dermatitis and may be applied topically or ingested as a tea. When applied topically, it has been shown to be beneficial in atopic dermatitis and nonspecific skin irritation. Chamomile contains terpenoids and flavonoids that inhibit cyclooxygenase and lipoxygenase as well as regulate T-helper-cell (Th2) activation and histamine release[8]. Chamomile is a member of the ragweed family and has the potential to induce allergic contact dermatitis in addition to contact urticaria.

Colloidal Oatmeal

For decades, colloidal oatmeal has been used for its calming and soothing effects on the skin. Many OTC products are derived from whole oat kernels ground into a fine powder and then combined with emollients to create various preparations from bath powders to moisturizing creams[8]. Colloidal oatmeal is one of the few natural ingredients approved by the US Food and Drug Administration (FDA) to treat multiple skin conditions, including allergic contact dermatitis to poison ivy, irritant diaper dermatitis, and eczema[9].

The therapeutic properties of oats are thought to derive from their diverse chemical composition. Firstly, oats have a high concentration

CLASSIFICATION OF COMPLEMENTARY AND ALTERNATIVE MEDICINE (CAM)		
Biologically-based practices	Dietary supplements	Vitamins Minerals Fatty acids Amino acids Prebiotics, probiotics
	Herbal products	
	Diet-based therapies	Vegan Macrobiotic Vegetarian Paleo
Alternative medicine systems	Ayurveda Homeopathy Naturopathy	
	Traditional healers	Shaman
	Traditional Chinese medicine	Acupuncture Acupressure Moxibustion or cupping Chinese herbs
Mind–body medicine	Meditation Biofeedback Hypnotherapy Guided imagery Breath work Prayer and spirituality	
	Creative outlets	Music therapy Art therapy Dance therapy
Manipulative and body-based practices	Massage Chiropractic Reflexology Alexander technique Feldenkrais method Rolfing Osteopathy Tai chi	
Energy medicine	Reiki Therapeutic touch Craniosacral Qi gong Magnetic therapy Light therapy	

Table 133.1 Classification of complementary and alternative medicine (CAM). Based on classifications from the National Center for Complementary and Alternative Medicine (National Institutes of Health).

of starches which explains their water-holding capacity that contributes to skin barrier protection. Secondly, high concentrations of phenols provide antioxidant and anti-inflammatory properties. For example, *in vitro*, oat extracts decreased the concentrations of the proinflammatory cytokine IL-8 as well as NF-κB[9]. Lastly, its cleansing activity is thought to be due to the saponins present in the grain. Products that contain colloidal oatmeal tend to have very low allergenicity[10].

Escharotics

Escharotics include zinc chloride, bloodroot (*Sanguinaria canadensis*), and goldenseal (*Hydrastis canadensis*). These agents are caustic and can produce pain and necrotic crusts with subsequent scarring. In the past, escharotics were used topically to treat skin cancers and played a role in the fixed-tissue technique initially used in Mohs micrographic surgery, but they have since been replaced with more predictable and reliable methods.

Escharotics are commercially available as herbal supplements and are often marketed as "highly successful treatments for skin cancer"[11]. One of the greatest concerns regarding these unregulated and unsubstantiated claims, aside from inadequate treatment, is partial treatment leading to clinical but not histologic clearance and subsequently a more advanced recurrence. In an illustrative case report, after an escharotic was used to treat a basal cell carcinoma (BCC), the patient determined that it was cured. However, the tumor was still present, recurred underneath the scar, and ultimately led to metastasis[11]. These botanicals are neither safe nor effective for the treatment of skin cancers, and their use should be discouraged.

SELECTED TYPES OF COMPLEMENTARY AND ALTERNATIVE MEDICINE (CAM) WITH PROMISING EVIDENCE FOR TREATING DERMATOLOGIC DISEASES		
Skin disease	**Type of CAM**	**Comments**
Acne	• Tea tree oil (topical)	• Safe and effective; some risk for ACD or ICD
	• Dietary modification (avoiding dairy and high-glycemic foods)	• Probably decreases inflammation; adherence may be challenging
Atopic dermatitis	• Sunflower seed oil	• Enhances barrier function and may reduce pruritus
	• Coconut oil	• Antibacterial and moisturizing effects
	• Acupuncture/ acupressure	• May modestly reduce pruritus; can be expensive to see practitioner
Hidradenitis suppurativa	• Dietary modification (avoiding dairy and high-glycemic foods) • Weight reduction (via hypocaloric diet*)	• May reduce potential triggers • Reduces mechanical stress, improves insulin resistance
	• Zinc, riboflavin, vitamin D supplementation (oral)	• Zinc gluconate (90 mg daily), riboflavin (3 mg TID), and vitamin D repletion may lead to improvement
Psoriasis	• Indigo naturalis	• Anti-inflammatory effects on skin and nails; stains fabric
	• Curcumin (topical and oral)	• May have anti-inflammatory effects; color and odor can be offensive
	• Dietary modification (weight reduction via hypocaloric diet) for overweight or obese individuals	• Reduction in adipose tissue may lead to a decrease in inflammatory cytokines
Seborrheic dermatitis	• Tea tree oil (topical)	• Appears modestly effective; ACD or ICD may occur
Urticaria	• Vitamin D supplementation (oral)	• May help certain subset of population; safe
	• Acupuncture	• Multiple possible mechanisms; can be expensive to see practitioner
Verrucae	• Garlic (topical)	• Effective irritant and antiviral; unpleasant smell and ICD may deter its use
	• Zinc supplementation (oral)	• Results of clinical studies appear to be better than clinical experience; gastrointestinal upset fairly common
	• Propolis (oral)	• May be immunomodulatory; bee allergy is contraindication

*And/or bariatric surgery.

Table 133.2 Selected types of complementary and alternative medicine (CAM) with promising evidence for treating dermatologic diseases. ACD, allergic contact dermatitis; ICD, irritant contact dermatitis; TID, three times daily.

Feverfew

Feverfew (*Tanacetum parthenium*) is a flowering plant from the daisy family. Originally named for its fever-reducing properties, it is also used

DIETARY SUPPLEMENTS THAT INHIBIT PLATELET FUNCTION OR ENHANCE ANTICOAGULATION		
Effect	**Dietary supplements**	
Inhibits platelet aggregation	• Borage seed oil* • Bromelain (bromelin) • Clove • Feverfew • Garlic • Ginger • Ginseng	• Green tea • Huang qi • Kava kava • Onion • Salicylic acids† • Turmeric • Vitex
Inhibits platelet aggregation and adhesion	• Fish oil • Vitamin E	
Inhibits platelet activating factor	• Gingko	
Vitamin K antagonists: • Inhibit hepatic synthesis of vitamin K-dependent coagulation factors II, VI, IX, and X as well as proteins C and S • Potentiate effect of warfarin	Coumarin-containing compounds: • Arnica • Anise • Asafoetida • Alfalfa • Bilberry • Celery • Chamomile • Fenugreek • Goldenseal	• Horse chestnut • Horseradish • Licorice • Parsley • Passionflower • Quassia • Red clover • Rue
*Contains alpha-linoleic acid. †Includes meadowsweet and willow bark; inhibits platelet synthesis of thromboxane A2.		

Table 133.3 Dietary supplements that inhibit platelet function or enhance anticoagulation. *Adapted from Reddy KK, Grossman L, Rogers GS. Common complementary and alternative therapies with potential use in dermatologic surgery: risks and benefits. J Am Acad Dermatol 2013;68;e127–35.*

to treat headaches, arthritis, and digestive disorders. Use of topical feverfew had been limited by the presence of irritating parthenolides in the plant, but an industry-patented process now allows for removal of these irritants[12]. Feverfew possesses antioxidant and anti-inflammatory properties; it is thought to inhibit proinflammatory mediators released from macrophages and to reduce neutrophil chemotaxis[8]. It has also been shown to protect DNA against oxidative damage and appears to reduce UV radiation-induced DNA damage[13]. Dermatologic applications include treatment of irritated sensitive skin, facial erythema, and tactile roughness.

Green and Black Tea

The tea plant (*Camellia sinensis*) has been cultivated in Asia for thousands of years. Green tea is made from unfermented tea leaves and can be ingested or applied topically. It contains the highest concentration of polyphenol antioxidants of any tea, save perhaps for white tea, which is the least processed of all teas. Both topical and oral green tea can protect against inflammation, ultraviolet light-induced photodamage, chemical carcinogenesis, and photocarcinogenesis[14]. Topical green tea has been shown to decrease sebum production and may be beneficial in patients with acne[15]. While green tea is very safe both topically and systemically, topical application of a 2% preparation did lead to limited mild pruritus or stinging in 10%–15% of individuals, but this resolved within a few days despite continued use[15].

Black tea, the fully oxidized version of the same plant, was shown to be effective by day 3 when used as a compress to treat facial dermatitis in 22 adults ($p = 0.00004$), with no side effects reported[16].

Honey

In addition to fructose and glucose, honey also contains numerous proteins, amino acids, vitamins, enzymes, and minerals. While honey is used to treat a wide variety of conditions, it is most commonly applied to wounds to enhance healing. The latter effect is thought to be due to its antimicrobial properties and the enzymatic release of hydrogen peroxide. Honey has been shown to inhibit a wide variety of pathogens, e.g. *Staphylococcus aureus* (including MRSA), *Escherichia coli*, *Pseudomonas aeruginosa*, *Acinetobacterium baumannii*[17]. It has also led to improvement of several dermatitides (seborrheic, atopic, diaper), psoriasis, pityriasis (tinea) versicolor, and herpetic ulcers[17].

Active components of various honey formulations have been identified, e.g. methylglyoxal in manuka honey[18], and then associated with therapeutic benefits. Medical-grade honeys are now available by prescription, suggesting that honey may be entering the realm of conventional medicine. Although an allergic contact dermatitis to honey has been observed (probably related to propolis), there have been no reports of significant adverse events and topical application of honey is thought to be well tolerated[5].

Horse Chestnut Seed Extract

Oral horse chestnut seed extract (HCSE) (*Aesculus hippocastanum* L.) is used to treat chronic venous insufficiency. In controlled studies, there was a decrease in leg volume, calf and ankle circumferences, and pain, with an efficacy equivalent to that of grade II compression stockings[19]. HCSE contains *escin* (a triterpene saponin), which inhibits the release of elastase and hyaluronidase from leukocytes, thus preventing proteoglycan degradation and vascular leakage. Natural horse chestnut seeds are poisonous and need to be processed to remove *esculin*, a toxic component. Side effects of esculin include hepatotoxicity, renal toxicity, anaphylaxis, and possible potentiation of anticoagulation. Of note, drug interactions may limit the use of oral HCSE in patients receiving anticoagulants, aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), insulin, oral hypoglycemic agents, or other supplements that affect serum glucose levels[20].

Indigo Naturalis

Indigo naturalis is derived from the *Strobilanthes formosanus* plant and provides a well-known name for a dark blue color. Topical indigo naturalis has been observed to improve plaque psoriasis[4] as well as nail psoriasis in children[21]. The latter may be explained by an inhibition of epidermal keratinocyte proliferation by indirubin, an active component of indigo naturalis. Indirubin has been shown to down-regulate CDC25B expression, which is known to play an important role in the hyperproliferation of epidermal keratinocytes[22]. Tryptanthrin, another compound present in indigo naturalis, has been shown to inhibit production of interferon-γ, decrease levels of IL-17 and IL-6[23], and inhibit TNF. While oral indigo can cause hepatotoxicity, topical indigo is generally well tolerated. Mild pruritus has been reported and since indigo is a blue dye, staining of clothing and skin can occur.

Licorice Root

Licorice root (*Glycyrrhiza inflata*; *Glycyrrhiza glabra*) has long been considered a natural remedy. *Glycyrrhiza glabra* contains glabridin and *Glycyrrhiza inflata* contains licochalcone A, both of which have anti-irritant and anti-inflammatory properties[8]. Additionally, licorice extracts have been shown to have anti-elastase and anti-tyrosinase activity making them attractive ingredients in anti-aging products[24]. Licorice can be used to treat rosacea and dermatitis and is found in OTC preparations that target sensitive skin[25]. Licorice also contains glycyrrhizin, a substance that, if ingested in high doses, can cause hypokalemia, arrhythmias, hypertension, and/or congestive heart failure; de-glycyrrhizinated licorice (DGL) is available and may be preferable when administering licorice systemically.

Marigold

Marigold (*Calendula officinalis)* is a flower native to northern Mediterranean countries. Topically, marigold is most commonly used to treat dermatitis, but has been employed for wounds, ulcers, thermal burns, and herpes zoster. There is also evidence to support the use of calendula ointment to reduce radiation-induced skin toxicity[26]. Marigold contains flavonoids, triterpene saponins, and carotenoids which confer anti-inflammatory, antimicrobial, and immunomodulating properties. In animal studies, an increase in glycoproteins and collagen was observed in wound sites treated with topical marigold. There are rare reports of allergic contact dermatitis to *Calendula*, but it is generally well tolerated[6].

Menthol

Menthol is a naturally occurring plant compound that is used in multiple products including pharmaceuticals, pesticides, and flavoring agents. Topical preparations that contain menthol are used for their antipruritic, analgesic, and cooling properties. Menthol is thought to act through the cation channel TRPM8, a member of the TRP (transient receptor potential) family of ion channels, which is also activated by cold. However, the precise mechanism by which menthol suppresses pruritus is unclear. In addition to affecting sensory pathways, menthol exhibits antibacterial and antifungal activity[27].

Prebiotics, Probiotics, and Postbiotics

Prebiotics are non-digestible compounds in food that encourage the growth of certain desirable types of bacteria within the intestine. *Probiotics* are live microorganisms that are ingested or applied in an attempt to alter the resident flora into a more beneficial balance. In the gut, the microflora has been shown to influence gene expression and differentiation of cells involved in the immune system. These gut microbes can influence systemic inflammation and have even been found to impact the skin barrier[28]. *Postbiotics* are byproducts of probiotics that have bioactivity. Probiotics can be ingested in a tablet form or as a component of foodstuffs such as yogurt, miso, and tempeh.

Patients with eczema have been shown to have abnormal gastrointestinal flora and may have increased inflammation and intestinal permeability. Probiotics decrease intestinal inflammation and permeability, and may alter antigen presentation in a beneficial way. However, the results of clinical trials have been mixed and outstanding questions remain, including the ideal patient, the type and dosage of the probiotics, and the timing and frequency of administration[29]. Patients with acne appear to have a deficiency in short-chain fatty acid-producing bacteria in their gut microbiome. Thus far, pilot studies are promising for the use of oral probiotics in acne but expanded clinical studies are needed. More recently, a meta-analysis found that probiotics improved the efficacy of immune checkpoint inhibitors in cancer patients[29a].

Side effects of probiotics usually consist of mild gastrointestinal symptoms. While there are case reports of sepsis thought to be due to probiotics, the overwhelming body of evidence suggests that they are safe even in critically ill patients[30]. Nonetheless, before recommending probiotic supplementation in immunocompromised patients, it would be wise to carefully weigh potential benefits.

Tea Tree Oil

Tea tree oil is an essential oil from the leaves of the native Australian tree, *Melaleuca alternifolia*. The indigenous people of Australia use tea tree oil from crushed leaves as a traditional remedy to treat wounds and skin infections. It has been shown to have activity against a wide variety of bacteria, fungi, and even viruses and protozoa. Tea tree oil is commonly used as a topical antimicrobial agent and has shown efficacy in treating acne as well as fungal and bacterial infections of the skin, mucosae, and nails. The antiseptic properties of tea tree oil are thought in part to be due to disruption of bacterial membranes[31].

Tea tree oil can be very irritating and is a cause of allergic and irritant contact dermatitis. In general, it should be diluted before direct application to the skin, with concentrations of up to 10% not resulting in significant reactions[31]. In patients with onychomycosis, tea tree oil may be safely applied directly to nails.

Prepubertal gynecomastia, which was self-limited and not associated with hormonal abnormalities, developed in a boy who used a shampoo containing lavender and tea tree oil. *In vitro*, both of these essential oils can have mild estrogenic and anti-androgenic effects[32]. There are a few additional reports of essential oil-related gynecomastia, but their incorporation into numerous OTC personal care products (as a denominator) needs to be kept in mind. In a recent exchange, authors of a case study of lavender-associated prepubertal gynecomastia concluded: "It is true you cannot establish causality based on 4 case studies, but…there is value to pursuing this question in epidemiologic studies"[33].

Turmeric

Turmeric is the ground root of *Curcuma longa* and its active compound is curcumin. Curcumin is the yellow pigment that gives turmeric, curry, and yellow mustard their color, and it has been used for centuries in cooking and cosmetics. Turmeric has antimicrobial, antioxidant, anti-inflammatory, and anticancer activities[34]. It inhibits lipoxygenase and cyclooxygenase, thereby reducing levels of leukotrienes, thromboxanes, and prostaglandins. While data are limited, there are studies looking at the use of turmeric and curcumin in acne, alopecia, atopic dermatitis, oral lichen planus, photoaging, pruritus, psoriasis, radiodermatitis, and vitiligo. Oral turmeric is very safe even at high doses. Topical turmeric has been evaluated for psoriasis and wound healing[25], but color and odor can be limiting.

Vitex (Chasteberry)

An extract of vitex dried fruit (*Vitex agnus-castus*) has been used to treat menstrual cycle disorders. As a corollary, oral vitex has also been used to improve hormonal acne in women, with the German Commission E recommending 40 mg of the extract daily for acne[35]. It is thought to help reduce levels of luteinizing hormone, prolactin, fasting insulin, and testosterone, thereby improving hormonal acne. Potential adverse effects include headache, nausea, gastrointestinal disturbance, abnormal menstruation, and rash; these are typically mild and reversible. Theoretically, vitex could interfere with medications that affect dopamine pathways[36]. Given the hormonal effects of oral vitex, it should not be used by pregnant or nursing women[5].

CANNABINOIDS

There has been increasing interest in cannabinoids, the group of compounds that act on cannabinoid receptors and are often associated with *Cannabis sativa* or *Cannabis indica*. Within the field of dermatology, these compounds are of interest due to their potential antipruritic, anti-inflammatory, and anti-nociceptive properties, all of which do not require any psychoactive aspects of the plant[37]. While there is promise for both topical and oral application of a range of compounds including cannabidiol (CBD), N-palmitoylethanolamide (PEA), and even whole plant extracts, there is surprisingly little clinical evidence for any of these, let alone approved formulations that have been tested in a rigorous fashion. In fact, a recent review identified only 8 clinical studies of cannabinoids for dermatologic conditions, with 7 focused on atopic dermatitis, eczema, or pruritus[37]. Of these, 6 reported improvement based upon at least some metrics, while in the second

largest study of this group, a topical PEA-containing product led to no significant differences in chronic pruritus.

There is a need for high-quality trials to evaluate efficacy and safety of particular products, as it is simply not appropriate to generalize results about an ingredient or individual compound given all the complex variables involved: formulation, route of administration, dosage, and frequency of use.

DIET-BASED THERAPIES

Skin disorders are well represented in the long and complex history of the therapeutic use of "fad diets"[38]. Over the past several decades, there has been renewed interest in employing dietary modifications to influence cutaneous diseases. Obesity is thought to contribute to a proinflammatory state and there is some evidence that weight loss is beneficial in *psoriasis*[39]. In a subset of patients, a gluten-free diet may also improve psoriasis[40]. Dairy and high-glycemic foods may be contributing factors for *acne*, and avoiding these foods appears to significantly reduce acne severity[38].

Although dietary avoidance of certain allergens can be helpful in patients with systemic contact dermatitis, the story is much more complex in the case of atopic dermatitis. There is widespread belief outside the conventional medical community that foods are the "root cause" of atopic dermatitis, and while it is a compelling idea, there is limited evidence to support this theory[41]. Some support exists for avoiding known allergens (specifically eggs)[42], especially in infants. Overall, excluding foods in patients without specific allergies appears to have an insignificant effect[43]. Severe nutritional deficiencies and even kwashiorkor have been reported in infants on restrictive diets, underscoring the fact that there is risk associated with pronounced dietary modifications.

TRADITIONAL CHINESE MEDICINE

With a history spanning over 2000 years, traditional Chinese medicine (TCM) is a sophisticated system that encompasses health and disease. Diagnostic evaluation includes parameters such as pulse rate and appearance of the tongue as well as an assessment of tendencies and habits. An individualized TCM diagnosis is then rendered that is usually quite different from a conventional Western diagnosis. For example, patients sharing the Western diagnosis "acne" would not necessarily all be treated in the same manner because their underlying diagnoses could be vastly different, necessitating different approaches.

TCM encompasses a multitude of treatment modalities, including herbal medicine, acupuncture, massage, exercise, and dietary and lifestyle modifications (Table 133.4). For health to occur, balance and harmony must be achieved between two opposing and complementary forces, Yin and Yang. Additionally, normal flow patterns of *qi*, or life-force, are essential for health. Restoration of flow is the goal of therapy, often via acupuncture, moxibustion, and massage.

TRADITIONAL CHINESE MEDICINE (TCM) TREATMENT MODALITIES	
Modality	**Delivery methods/related modalities**
Herbal medicine	Decoctions – water is used to simmer herbs, then the decanted fluid is taken in divided doses
	Topical poultices
	Essential oils
	Lotions, creams, ointments
	Tablets, capsules
Acupuncture	Needles – stainless steel (most common), gold, silver
	Moxibustion
	Cupping, coining, rubbing
	Acupressure
	Electroacupuncture
	Auricular acupuncture
	Laser acupuncture
	Medicamentous acupuncture
	Magnet therapy
Therapeutic exercise	Tai ji (tai chi), qi gong (chi gong)
Massage therapy	Tui na, acupressure

Table 133.4 Traditional Chinese medicine (TCM) treatment modalities.
Courtesy Amy Geng and Raymond G. Dufresne, Jr.

Treatment of Dermatologic Diseases

TCM has been employed for a number of dermatologic conditions. While a complete discussion is beyond the scope of this chapter, the next sections highlight some of the evidence for its use in atopic dermatitis and psoriasis.

Atopic dermatitis

A Cochrane systematic review analyzed 28 studies of Chinese *herbal preparations* for atopic dermatitis, both ingested and applied topically. They found that in most of the studies reviewed, Chinese herbal therapy was superior to placebo in terms of reducing eczema severity and decreasing pruritus[44]. Nonetheless, the authors concluded that there is still insufficient evidence for efficacy as the quality of the studies was low. Even with the inclusion of additional studies, a similar conclusion was reached several years later – high quality randomized controlled trials were needed[45].

Herbal preparations are generally considered safe; side effects are rare and usually mild when they do occur. However, in addition to associated allergic reactions and photosensitivity, herbs may have pharmacologic effects and interact with other medications. They may also be adulterated with corticosteroids and contain arsenic or mercury[46].

Acupuncture has been used anecdotally for a variety of skin conditions, including atopic dermatitis, lichen planus, psoriasis, alopecia areata, and verrucae[47]. More support exists for the use of acupuncture for alleviation of symptoms associated with dermatologic disorders, such as pain or pruritus. A pilot study demonstrated decreased pruritus in patients with atopic dermatitis after applying acupressure to a single point on the arm[48]. Acupuncture and acupressure may work via so-called "gate control" and/or by stimulating release of neuroactive substances including endorphins and enkephalins. By altering the release of neurotransmitters, acupuncture may exert anti-inflammatory and immunomodulatory effects.

Side effects of acupuncture include pruritus, petechiae, ecchymoses and subcutaneous hematomas, but are fairly rare. Infection and pneumothorax have also been reported.

Psoriasis

TCM *herbs* with anti-inflammatory effects, in particular indigo naturalis, *Tripterygium wilfordii*, *Tripterygium hypoglaucum* and *Camptotheca acuminata*, are used to treat psoriasis. In a study of 801 psoriatic patients, over half responded to a decoction of five herbs (*Rhizoma sparganii*, *Rhizoma zedoariae*, *Herba serissae*, *Boswellia* resin, and *Commiphora myrrha*)[49]. Herbs that contain furocoumarins, such as *Radix angelicae dahuricae*, have been used in conjunction with UVA phototherapy for a psoralen-like effect. Psoriasis clearance rates were similar for *Radix angelicae dahuricae* plus UVA versus PUVA (with 8-MOP), with fewer side effects. As with other botanicals, TCM herbs have biologically active components, and they may have serious side effects. TCM should be administered under the supervision of a licensed practitioner.

Acupuncture has not been well studied in psoriasis, but there are several reports of plaques appearing at sites of acupuncture needle insertions due to Koebner phenomenon[50].

Moxibustion, Cupping and Other Treatment Modalities

Moxibustion is the practice of burning dried moxa (*Artemisia vulgaris*), arranged in small cone-shaped piles, over acupuncture points. Side effects include first- and second-degree burns.

Cupping is another method used to stimulate acupuncture points. It is accomplished by igniting alcohol-soaked cotton, placing the burning cotton in a jar, and placing the jar on the skin. A vacuum is created, and circular areas of erythema and ecchymosis may result (Fig. 133.2). Nowadays, some practitioners use a vacuum device that negates the risk of fire.

Fig. 133.2 Cupping. A Well-demarcated circular areas that are pink–purple and yellow in color and contain petechiae. **B** Circular purpura due to cupping done to relieve the pain that preceded the appearance of cutaneous lesions of herpes zoster. *A, Courtesy Donald J. Baker, MD; B, Courtesy Kalman Watsky, MD.*

Fig. 133.3 Linear ecchymoses on the back due to coining. *Courtesy Amy Geng and Raymond G. Dufresne, Jr.*

Skin scraping, also known as *coining* or spooning, is commonly practiced in Southeast Asia to improve circulation. A tool is used to rub skin that has been treated with oil; symmetric, linear ecchymoses may result (Fig. 133.3).

Any patient with cutaneous lesions in patterns suggestive of external causes should be asked about traditional medicine before accusations of abuse arise.

HOMEOPATHY

Homeopathy is a system of healing founded in Germany at the end of the 18th century. It is composed of two theories: (1) "like cures like" – the suggestion that a disease can be cured by a substance that produces similar symptoms in people who do not have the disease; and (2) "law of minimum dose" – the concept that the *lower* the dose of the medication, the greater the efficacy of the medication[51]. Homeopathic remedies come from substances that are derived from plants, minerals or animals, many of which are considered toxic in their crude form. Serial dilutions and "succussion" – a process by which a solution is violently shaken a given number of times between dilutions – create the final product. Homeopathic remedies are often prepared as sugar pellets to be placed under the tongue, but they may also be formulated as ointments, gels, drops, or creams. The FDA regulates homeopathic remedies, but unlike traditional medications, it does not evaluate them for safety and effectiveness.

In dermatology, homeopathy is most often used for the treatment of atopic dermatitis and psoriasis[52]. In general, there is little evidence to support the effectiveness of homeopathic therapies for skin disease[53], and some evidence from controlled clinical studies suggest that homeopathy is actually *ineffective* for eczema[54].

While many homeopathic remedies are highly diluted, some products sold or labeled as homeopathic may not be diluted sufficiently and may still contain active ingredients. Like any drug or dietary supplement that contains active compounds, these homeopathic remedies may cause side effects (e.g. allergic reactions, intoxications) or drug interactions[51].

AROMATHERAPY

During the early part of the 20th century, while studying the effects of essential oils on different disease states, the French chemist René-Maurice Gattefossé coined the term "aromatherapy". The latter represents the therapeutic use of aromatic essential oils which can be made from any plant part, including leaves, stems, flowers, fruits, or roots. Essential oils are typically obtained via steam distillation or by cold pressing the plant.

Essential oils contain a mixture of various organic compounds, in particular alcohols, aldehydes, esters, ketones, terpenes, lactones, aromatic aldehydes, and phenols. Oils high in ketones are used for their wound healing properties, whereas oils high in alcohols are used for their antimicrobial properties. There is evidence that essential oils, when applied topically, can enter the bloodstream[55].

In aromatherapy, essential oils may be used externally or internally. The most common routes of administration are inhalation and massage, but compresses, creams, gels, sprays, and baths are also employed. Aromatherapy may be used directly to treat dermatologic conditions, or indirectly to treat the anxiety or other symptoms associated with cutaneous disorders. Aromatherapy has been used to treat many conditions including acne, alopecia areata, pruritus, and scarring as well as for analgesia and wound healing.

Tea tree oil (*Melaleuca alternifolia*) is one of the most commonly employed essential oils in aromatherapy of skin conditions. A single-blind trial in acne patients found similar efficacies for tea tree oil 5% gel and benzoyl peroxide 5% lotion; tea tree oil had a slower onset of action but fewer side effects. In a randomized, controlled, double-blind trial for alopecia areata, an aromatherapy essential oil blend of thyme, rosemary, lavender, and cedarwood led to significantly greater improvement than did the placebo (44% vs 15%)[56].

It is important to note that essential oils have biologically active components and may be toxic. For example, oils with high concentrations of aldehydes and phenols may cause skin irritation. Phototoxicity can occur with oils derived from citrus plants due to the presence of psoralens or furocoumarins. Essential oils containing high concentrations of ketones should be used cautiously in pregnant women and infants, and a number of essential oils can cause allergic or irritant contact dermatitis (Table 133.5)[55].

MIND–BODY MEDICINE

Mind–body medicine encompasses a wide range of therapeutic modalities that emphasize the complex interactions involving the brain, the body, and behavior and the ways in which emotional, mental, social,

ESSENTIAL OILS ASSOCIATED WITH ALLERGIC AND/OR IRRITANT CONTACT DERMATITIS			
Bergamot	Grape seed	Lemongrass	Rose
Cinnamal	Jasmine	Neroli	Rosemary
Clove	Laurel	Orange	Sandalwood
Frankincense	Lavender	Peppermint	Yarrow
Geraniol	Lemon	Propolis	Ylang ylang

Table 133.5 Essential oils associated with allergic and/or irritant contact dermatitis. *Adapted from Trattner A, David M, Lazarov A. Occupational contact dermatitis due to essential oils. Contact Dermatitis 2008;58:282–4 and Bleasel N, Tate B, Rademaker M. Allergic contact dermatitis following exposure to essential oils. Australas J Dermatol 2002;43:211–3.*

spiritual, experiential, and behavioral factors can affect health. Mind–body practices include meditation, hypnosis, yoga, tai chi, qi gong, biofeedback, and cognitive behavioral therapies (see Table 133.1).

Because multiple skin disorders have significant psychological or behavioral components, stress and emotion can have a substantial impact on the skin. Acne, rosacea, alopecia areata, atopic dermatitis, seborrheic dermatitis, dyshidrotic eczema, psoriasis, herpes simplex viral infections, and pruritus are among the dermatologic diseases that have been linked to emotional triggers and stress (Table 133.6). Psychotropic drugs (e.g. antidepressants, antipsychotics, anxiolytics, sedatives) are often used to treat psychocutaneous disorders such as dermatitis artefacta, trichotillomania, and acne excoriée (see Ch. 7), and they are occasionally used when there is a significant psychological component to other chronic skin diseases. In the same way that these pharmacologic interventions may be helpful, there may be a role for mind–body modalities to help modulate the underlying stress response associated with these conditions.

Mindfulness and meditation are two of the most popular mind–body practices. While there are many different approaches to meditation, the specific type of mindfulness practice or meditation appears not to matter – it is the consistency of the practice that provides the benefit. Meditation has been shown to be helpful in treating acne, eczema, urticaria, hyperhidrosis, and psoriasis[57].

Webster's Dictionary defines biofeedback as: "the technique of making unconscious or involuntary bodily processes (such as heartbeats or brain waves) perceptible to the senses…in order to manipulate them by conscious mental control". During a biofeedback session, sensors are attached to the participant in order to detect immediate changes in physiologic functions such as heart rate, breathing, and brain activity. It has been found to have some effectiveness in treating rosacea, eczema, acne, psoriasis, and urticaria[58]. Biofeedback can be particularly helpful for people who are data-driven and respond well to immediate feedback.

Hypnosis has been used successfully for atopic dermatitis, alopecia areata, acne excoriée, herpes simplex viral infections, neurodermatitis, pruritus, verrucae, and psoriasis[59]. Mind–body modalities have also been shown to be useful preoperatively and during dermatologic procedures (e.g. cutaneous surgery). Slower breathing, biofeedback, guided imagery, hypnosis, and music can help calm and balance the patient's autonomic nervous system[60].

Mind–body medicine remains an active area of research. The hypothalamic–pituitary–adrenal (HPA) axis and autonomic nervous system (ANS) affect immunity and endocrine function via their regulation of glucocorticoid and catecholamine production, respectively. Therefore, psychological and behavioral interventions that affect the activity of the HPA axis and ANS have the potential to positively impact or treat disease. The skin itself produces enough hormones, neurotransmitters, neuropeptides, and functional receptors to form complete cutaneous neuroendocrine axes. These include cutaneous equivalents of: (1) the HPA axis; (2) the cholinergic system; (3) the catecholaminergic system; (4) the serotoninergic/melatoninergic system; (5) steroidogenic pathways; and (6) the pituitary–thyroid axis. These local neuroendocrine systems are used by the skin to preserve homeostasis[61].

Mind–body modalities have minimal side effects because neither physical nor chemical agents are used. However, they could trigger negative reactions in individuals with mental health disorders such as post-traumatic stress disorder (PTSD), schizophrenia, paranoia, or anxiety. Those who are at risk should work with experienced practitioners[62].

DERMATOLOGICAL CONDITIONS ASSOCIATED WITH PSYCHO-EMOTIONAL FACTORS	
Dermatological conditions with psycho-emotional component	
• Atopic dermatitis • Contact dermatitis • Dyshidrotic eczema • Lichen simplex chronicus • Nummular dermatitis • Pruritus (sine materia) • Urticaria • Psoriasis • Seborrheic dermatitis • Lichen planus • Vitiligo	• Telogen effluvium • Alopecia areata • Median nail dystrophy • Acne vulgaris • Rosacea • Perioral dermatitis • Hyperhidrosis • Verrucae • Herpes simplex viral infection • Gardner–Diamond syndrome
Psychocutaneous disorders	
• Dermatitis artefacta • Excoriation (skin-picking) disorder • Acne excoriée • Trichotillomania • Onychotillomania • Delusional infestation • Body dysmorphic disorder	• Somatic symptom disorder • Illness anxiety disorder • Dermatologic phobias • Venereophobia • Oncophobia • Bromidrosiphobia • Glossodynia* • Vulvodynia*
*Following exclusion of underlying medical etiologies.

AYURVEDA

Ayurveda originated in India more than 3000 years ago and still plays a prominent role in healthcare in India today. Typically, Ayurvedic medicine employs the use of herbal compounds, diet and lifestyle changes, and oil massages. The cornerstone of this modality is to determine an individual's profile and set of imbalances; once established, it becomes the foundation for clinical treatment decisions. To determine a person's constitution, an Ayurvedic practitioner describes bodily functions through the use of three descriptive units known as *doshas*.

The three doshas are *vata*, *pitta*, and *kapha*. *Vata* refers to motion such as the movement of blood, the motion of water in transepidermal water loss, or the motion of the body in general. When out of balance, *vata* leads to dryness, scaling, and loss of tissue as is seen in atopic dermatitis or in photoaging. *Pitta* refers to the metabolic processes in the body such as enzymatic activities and, when out of balance, represents inflammation in the body. Any disease such as acne, psoriasis, atopic dermatitis, or rosacea that has an inflammatory component has a pitta imbalance. *Kapha* refers to structure and substance, e.g. the level of cutaneous hydration, the presence of collagen, the strength and structure of hair. When out of balance, *kapha* leads to overproduction of substance and fibrosis as is seen in hypertrophic scars, systemic sclerosis, and scleredema.

Illness in Ayurveda is defined as an imbalance of the normal ratios of *doshas*, with therapies aimed at correcting this imbalance through the use of diet, mind–body techniques, and herbal formulations. Although there have been few clinical trials on the use of Ayurvedic medicine for dermatologic diseases, several reports suggest that topical and oral curcumin are efficacious in psoriasis. Members of the ginger family, which includes *Curcuma longa* (see above), are common ingredients in Ayurvedic medications. Curcumin is thought to down-regulate kinases in patients with psoriasis[1].

Ayurveda has a rich history of utilizing dietary restriction in skin diseases but also utilizes a variety of herbal formulations with the potential for interaction with conventional medicines. Ayurvedic herbal products are regulated as dietary supplements rather than as drugs and it is imperative to assess the safety testing of herbs. While there is concern for the possibility of heavy metal contamination in herbs, many companies now perform a battery of third-party tests to ensure that herbs are within regulatory limits.

CONCLUSION

Although for many dermatologic diseases high-quality evidence to support the use of CAM is lacking, it is still important for dermatologists to recognize and acknowledge the widespread use of CAM by patients. While it is essential to be aware of potential side effects and drug–drug interactions, it is equally important to appreciate cultural differences when caring for patients.

134 Ultraviolet Therapy

Herbert Hönigsmann† and Thomas Schwarz

Chapter Contents

Phototherapy with UVB 2362
Phototherapy with the 308 nm Excimer Laser or Lamp 2367
Phototherapy with UVA1 2367
Photochemotherapy with Psoralens (PUVA) 2367
Extracorporeal Photochemotherapy (Photopheresis) 2376

Key features

- Phototherapy represents the use of ultraviolet (UV) radiation for the treatment of skin diseases
- Currently, phototherapy encompasses irradiation with broadband UVB (290–320 nm), narrowband UVB (311–313 nm), 308 nm excimer laser, UVA1 (340–400 nm), UVA (320–400 nm) plus psoralens (PUVA) or alone, and extracorporeal photochemotherapy (photopheresis)
- Therapeutic success depends upon proper selection of the phototherapy modality for a given disease
- Proper dosimetry is required to avoid acute side effects such as a sunburn reaction, blistering, and burning sensations
- The risk of skin carcinogenesis represents the major long-term side effect of phototherapy; with the exception of PUVA, the magnitude of this risk is not yet clearly delineated

INTRODUCTION

Over the past half-century, phototherapy has greatly influenced treatment concepts in dermatology. Studies focusing on the effects of electromagnetic radiation (Fig. 134.1) on the skin have induced fruitful collaborations between basic scientists and clinicians.

Although ultraviolet (UV) radiation had been used for decades in the management of common skin diseases such as psoriasis and atopic dermatitis, the introduction of PUVA in the mid-1970s sparked a whole new series of discoveries, including high-intensity UV sources and selective spectra in the UVB and UVA range, e.g. narrowband UVB (311–313 nm) and UVA1 (340–400 nm).

PHOTOTHERAPY WITH UVB

Historical Aspects

To date, the only dermatologist to be awarded a Nobel Prize in medicine was Dr Niels Finsen in 1903. The award recognized his demonstration of the beneficial effect of UV radiation on lupus vulgaris, and he eventually became known as the "father of photomedicine". The combination of topical crude coal tar followed by UV irradiation for the treatment of psoriasis was introduced by Goeckerman in 1925 and became a standard therapy for psoriasis for half a century, particularly in the US. In the 1970s, it was observed that broadband (BB) UVB radiation alone, if given in doses that produce a slight erythema, could clear the milder forms of psoriasis, particularly the guttate type. In the 1980s, the discovery that the combination of psoralens with UVA (PUVA) exerts potent anti-inflammatory effects opened a new era of phototherapy. A further major advance was the development of fluorescent bulbs that emitted narrowband (NB) UVB radiation at 311–313 nm in the mid-1980s. This narrow spectrum is superior in clearing psoriasis and thus represents the most effective and most frequently used UVB phototherapy for psoriasis; it is also beneficial for a variety of other dermatoses that were previously treated with PUVA (see below).

Principles and Mechanisms

UVB phototherapy refers to the use of artificial UVB radiation without the addition of exogenous photosensitizers. The radiation is absorbed by endogenous chromophores, and photochemical reactions involving these UV-absorbing biomolecules mediate a variety of biologic effects, ultimately leading to the therapeutic effects. The most important chromophore for UVB is nuclear DNA. Absorption of UV by nucleotides causes the formation of DNA photoproducts, primarily pyrimidine dimers (see Ch. 86)[1].

UVB exposure reduces DNA synthesis and thus is used to suppress the accelerated DNA synthesis found in psoriatic epidermal cells. UVB also induces the expression of the tumor suppressor gene *TP53*, and this can lead to either cell cycle arrest (allowing time for DNA repair) or apoptosis of keratinocytes ("sunburn cells") if the DNA damage is too severe to be repaired. Through these mechanisms, p53 prevents photocarcinogenesis.

In addition to its effect on the cell cycle, UV induces the release of prostaglandins and cytokines. Interleukin (IL)-6 and IL-1, for example, seem to play important roles in producing the systemic symptoms of UV phototoxicity (sunburn) and immune suppression, respectively[1]. There is also increasing evidence that UV radiation can affect, in addition to DNA, extranuclear molecular targets located in the cytoplasm and cell membrane. These targets include cell surface receptors, kinases, phosphatases, and transcription factors. It was shown that nuclear and cytoplasmic/membrane effects are not mutually exclusive – rather they independently contribute to the multiple biologic effects of UVB.

Many of the therapeutic effects of UVB may be due to its immunosuppressive properties which have been linked to the formation of pyrimidine dimers. UV radiation suppresses contact allergy, delayed-type hypersensitivity, and immune surveillance against UV-induced keratinocyte carcinomas in mice. Of note, Langerhans cells are very sensitive to UVB, which alters their antigen-presenting function. Keratinocytes also secrete soluble mediators such as IL-1 and IL-6, prostaglandin E_2, and TNF in response to UVB, which by themselves can alter the immune response. Therapeutic UVB suppresses the type 1 (proinflammatory) axis as defined by IL-12, interferon (IFN)-γ, and IL-8, and can selectively reduce proinflammatory cytokine production by individual T cells[1].

The interplay of the various photobiological pathways is far from being completely understood. In psoriasis, both epidermal keratinocytes and cutaneous lymphocytes may be targeted by UVB. Immune suppression, alteration of cytokine expression, and cell cycle arrest may all contribute to the suppression of disease activity in psoriatic plaques[2]. In addition, a subset of T cells, Th17 cells, which seem to play a central role in the immunopathogenesis of psoriasis, are also downregulated by UVB[3]. More recently, evidence was presented that keratinocyte apoptosis may be a key mechanism in the clearance of psoriatic plaques[4].

Action Spectrum and Radiation Sources

Parrish and Jaenicke[5] demonstrated that for antipsoriatic activity, 304 and 313 nm were the optimally effective wavelengths (Fig. 134.2), even at suberythemogenic doses. Erythemogenic UVA doses are also therapeutically effective, but 1000 times higher fluences are needed

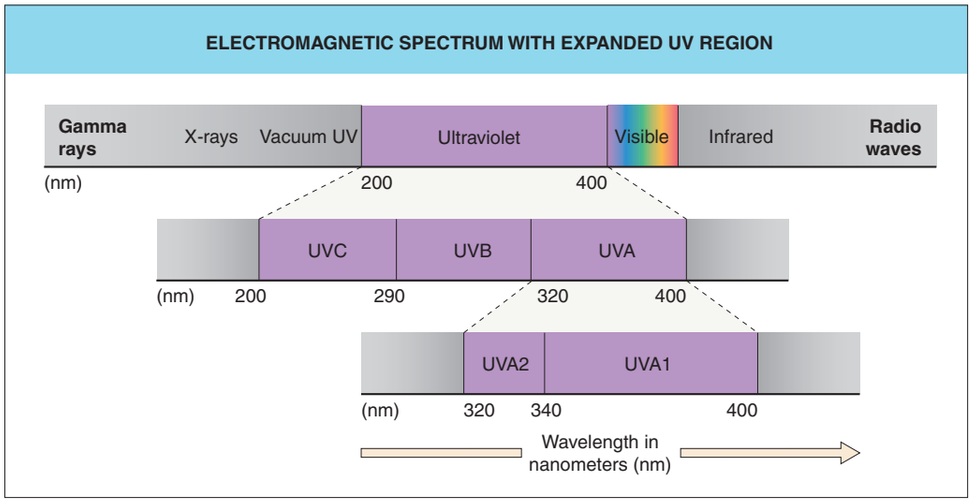

Fig. 134.1 Electromagnetic spectrum with expanded UV region.

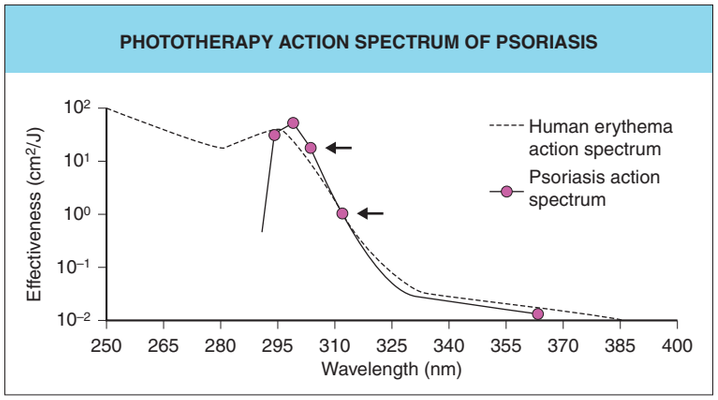

Fig. 134.2 Phototherapy action spectrum of psoriasis. The phototherapy action spectrum of psoriasis is plotted as the reciprocal of the lowest effective daily dose to clearing versus wavelength. Circles represent the reciprocal of the lowest effective daily dose for wavelengths that cleared psoriasis (295, 300, 304, 313, 365 nm); the arrows point to the wavelengths that were optimally effective (304, 313 nm). Presently, narrowband UVB sources that emit wavelengths between 311 and 313 nm are available. *Adapted from Parrish JA, Jaenicke KF. Action spectrum for phototherapy of psoriasis. J Invest Dermatol 1981;76:359–62.*

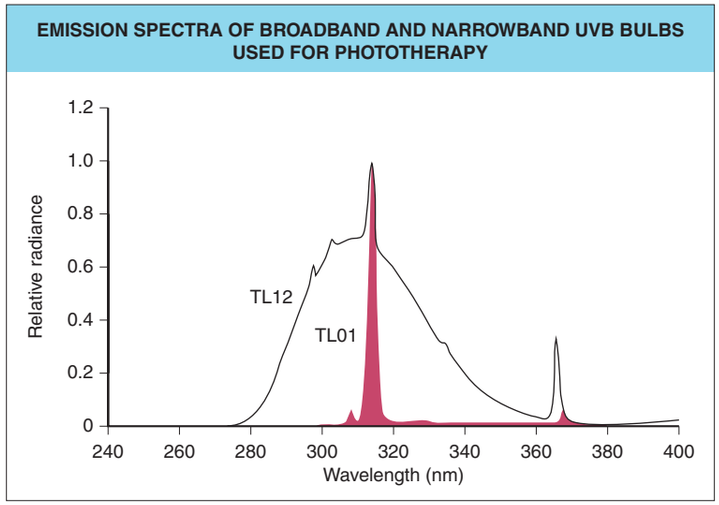

Fig. 134.3 Emission spectra of broadband and narrowband UVB bulbs used for phototherapy. Philips TL12, broadband UVB bulb; Philips TL01, narrowband UVB bulb.

(as compared with UVB) which practically speaking is not feasible. The addition of UVA also does not enhance the therapeutic efficacy of UVB in psoriasis (unlike atopic dermatitis). The Philips TL01 fluorescent lamp that emits NB-UVB (311–313 nm) was introduced to optimally meet the requirements for antipsoriatic activity (Fig. 134.3).

Devices that contain UV radiation-emitting bulbs are available in a wide range of sizes and designs including enclosed whole-body cabinets, portable flat panels, and hand-held units. When reliable patients live far distances from physician-supervised phototherapy centers or for other reasons are unable to schedule multiple treatments per week, UVB units designed for home use can be utilized. Practical guidelines for home phototherapy have been published[6].

Exposure to natural sunlight is called heliotherapy. Natural sunlight contains sufficient UVB radiation such that it is sometimes used to treat photoresponsive dermatoses. However, due to variables that affect UVB irradiance, including time of day, cloud cover, season, altitude and latitude, appropriate exposure times cannot be standardized. As a result, there is a greater probability of sunburn and an inadequate therapeutic response.

Treatment Protocols

Over the past several years, a number of dermatologic societies have published guidelines for utilizing phototherapy. They all provide more or less similar recommendations with some slight variations which are due to national differences in the health care system, reimbursement, legal requirements, availability/approval of alternative therapies, and of course traditions regarding prescribing practices. Table 134.1 lists some of the available guidelines. Most of these guidelines are updated regularly and are made available through online sources.

Before starting phototherapy, determination of the patient's UV sensitivity via phototesting is frequently recommended, since skin typing by history alone does not always reflect the actual sensitivity of a particular individual. However, phototesting is not mandatory for the experienced therapist and, for practical reasons, is often not done. Testing is performed by exposing four to six small template areas (e.g. 1 cm diameter circles or squares) of usually non-sun-exposed skin (lower back, buttocks) to an incremental series of UVB doses. In successive test sites, the incremental increases can be fixed (e.g. 10 or 20 mJ/cm^2) or proportional (e.g. 40% higher). An example is given in Table 134.2. Note that the actual doses delivered as specified in fluence units (mJ/cm^2) strongly depend on the type of UVB unit; for example, NB-UVB is much less erythemogenic than BB-UVB and consequently higher numerical doses are required.

The minimal erythema dose (MED) is defined as the lowest dose that causes a minimally perceptible erythema reaction at 24 hours after irradiation. Sunbathing or exposure to tanning lamps should be avoided before phototesting. It is crucial to document the type of lamp used for the MED determination, since the values obtained with broadband and narrowband sources differ by up to ten-fold (see Table 134.2).

Despite continued discussion as to whether visual assessment of the MED is the optimal method for establishing the initial UVB dose, it

Table 134.1 Examples of national phototherapy guidelines.

RECOMMENDED EXPOSURE DOSES (FLUENCES) FOR MED PHOTOTESTING TO BROADBAND AND NARROWBAND UVB SOURCES (mJ/cm^2)						
Broadband UVB	20	40	60	80	100	120
Narrowband UVB	200	400	600	800	1000	1200

$$\text{Time (sec)} = \frac{\text{Fluence (delivered dose of UV in mJ/cm}^2\text{ [UVB] or J/cm}^2\text{ [UVA])}}{\text{Irradiance (measured UV intensity expressed in mW/cm}^2\text{ [UVB] or W/cm}^2\text{ [UVA])}}$$

Table 134.2 Recommended exposure doses (fluences) for minimal erythema dose (MED) phototesting to broadband and narrowband UVB sources (mJ/cm^2). 1 watt (W) = 1 joule (J) of energy per second.

is an easily performed procedure that does not require any specialized equipment. An initial therapeutic UVB dose equal to 70% of the MED is typically recommended. Subsequent treatments are given two to five times weekly. Since UVB erythema peaks within 24 hours after exposure, doses may be increased with each successive treatment. However, if treatments are given five times weekly, the doses should be increased every other treatment. The rate of increase depends on treatment frequency and the response to the preceding UVB exposure. The objective of the dose increments is to achieve a minimally perceptible erythema as a clinical indicator of optimal dosimetry. For example, with thrice-weekly exposures, doses are increased by a maximum of 40% if no erythema appears, and by a maximum of 20% upon development of slight erythema. If mild erythema persists, the dose should be maintained. With daily exposures, these rates are no more than 30%, 15% and 0%, respectively. If more intensive or painful erythema develops, irradiations are stopped until the symptoms disappear. Treatment is then continued until complete remission is achieved or no further improvement can be obtained with continued phototherapy (Fig. 134.4).

Whether maintenance treatment leads to a more prolonged remission time is still a matter of debate, since minimal precise data are available. In cutaneous T cell lymphoma (CTCL), most therapists perform maintenance treatment for several months to a year. For psoriasis, some centers use a 2-month maintenance phase with twice-weekly exposures for 1 month and once-weekly exposures for another month. The last effective UVB dose is given throughout the maintenance phase. If relapses occur during the maintenance phase, treatment frequency and UVB dose are again increased until clearing. Of note, there was some evidence in a randomized study that maintenance NB-UVB may lead to longer remission times in plaque-type psoriasis[7].

Phototherapy for Psoriasis

Guttate psoriasis and minimally elevated lesions of psoriasis respond most favorably and rapidly to BB-UVB, while chronic, plaque-type psoriasis is more resistant. In terms of clearing efficiency and duration of remission, BB-UVB is inferior to both NB-UVB and PUVA. As a result, in many countries, NB-UVB has largely replaced conventional BB-UVB phototherapy. Based on several publications, NB-UVB phototherapy appears to be somewhat less effective than PUVA.

In addition to the treatment protocols mentioned above, other regimens may be used. Some schedules utilize skin type-dependent starting doses and fixed increments regardless of skin reaction. Sometimes, the patient's extremities (in particular the lower extremities which tend to respond more slowly) can be exposed to higher doses than the trunk.

Adjunctive topical agents and combination therapies are often used to improve efficacy and reduce the cumulative UVB dose, with the ultimate aim of minimizing the risk of long-term side effects. Narrowband UVB has been successfully combined with therapies such as anthralin and vitamin D analogues. The use of bland emollients before UVB treatment is laborious and time-consuming, and in our experience does not dramatically increase treatment efficacy. The concurrent use of topical corticosteroids may reduce remission times and thus is discouraged by some dermatologists.

Systemic drugs such as retinoids increase efficacy, particularly in patients with chronic plaque-type psoriasis[8,9]. In addition, retinoids may reduce the carcinogenic potential of UVB phototherapy. There have been open-label studies and small comparison studies regarding the efficacy of combining UVB phototherapy with systemic immunomodulators ("biologics")[10,11]. To date, there have been no large-scale studies, and long-term data, including remission times, are unavailable.

Phototherapy for Cutaneous T Cell Lymphoma, in Particular Mycosis Fungoides

For early stages (IA, IB, and IIA) of mycosis fungoides (MF), conventional treatment strategies include topical corticosteroids, UV radiation, topical retinoids (e.g. bexarotene), and topical cytotoxic agents (e.g. mechlorethamine [nitrogen mustard]). More advanced stages are treated with various combinations that include total body electron beam radiation therapy (see Ch. 139), local radiotherapy, systemic retinoids, PUVA, systemic chemotherapy (e.g. gemcitabine), and immunomodulators (e.g. brentuximab vedotin, mogamulizumab, IFN) (see Table 120.5), but none of these regimens have been demonstrated to induce permanent remission.

Lesions of MF frequently occur in non-sun-exposed areas of the body, and patients with early stage MF often benefit from exposure to natural sunlight. Response to phototherapy is related to the type (i.e. patch stage MF does better than the plaque type) but not the extent of skin involvement. In a more recent study, prolonged maintenance therapy (up to 30 months) resulted in a relapse-free period of 26 ± 10 months[12].

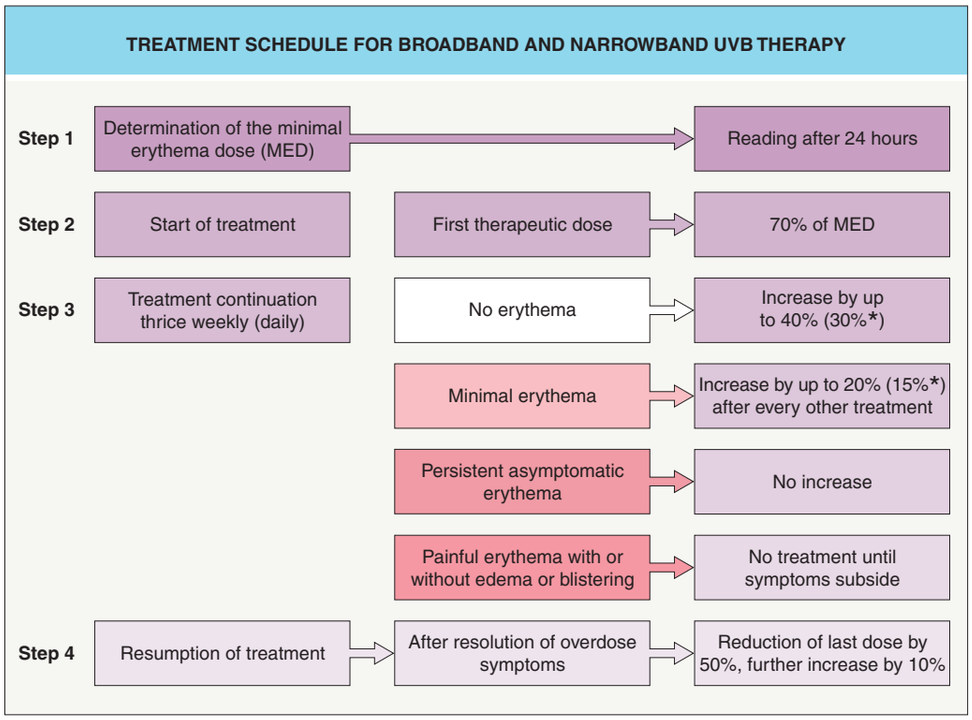

Fig. 134.4 Treatment schedule for broadband and narrowband UVB therapy. *If treatments are given five times per week or daily.

The proposed mechanisms for UVB phototherapy of MF include impairment of epidermal Langerhans cell function and alterations in cytokine production and adhesion molecule expression by keratinocytes[13]. Moreover, NB-UVB can induce apoptosis of T lymphocytes, which may more specifically contribute to the beneficial effect of this light source[14].

UVB phototherapy is clearly less efficient than PUVA, and the duration of treatment in the clearing and maintenance phases is longer and thus requires higher patient compliance. Whether patients would benefit from adding UVA, as is sometimes recommended, remains questionable. Likewise, NB-UVB and BB-UVB therapy have not been compared in MF. It is possible that combining a systemic retinoid (e.g. bexarotene) with NB-UVB may increase efficacy. Lastly, a pilot study documented the efficacy of medium- to high-dose UVA1 therapy (see below) in patients with stage IA and IB MF. However, there is no evidence that UVA1 is superior to PUVA and no long-term follow-up is available.

Phototherapy for Vitiligo

Many patients observe follicular repigmentation in areas of vitiligo following sun exposure. Because of seasonal and weather-dependent variations in sunlight intensity in moderate climates, exposure to natural sunlight is often not a practical option for inducing repigmentation. In the past, PUVA was most frequently used for the treatment of vitiligo, but exposure to artificial UVB irradiation, in particular NB-UVB, can also provide an acceptable therapeutic effect, if given for a sufficiently long period. Although the action spectrum for phototherapy of vitiligo is not known, NB-UVB has clearly become quite popular in recent years. In comparison studies of NB-UVB with PUVA, NB-UVB was as effective as PUVA but had fewer side effects (Fig. 134.5). Also, in a randomized double-blind trial of non-segmental vitiligo, NB-UVB therapy was superior to oral PUVA therapy and the color match of repigmented skin was considered to be better in the patients treated with NB-UVB[15]. UVA alone is of limited benefit.

Since intense erythema may induce the Koebner phenomenon and worsening of the disease, it is necessary to stay within a dose range that induces minimally perceptible erythema. Therefore, initial assessment of the MED in a vitiliginous area that is normally not sun-exposed (e.g. buttocks, lower back, abdomen) is recommended. The UVB doses have to be increased more carefully than in other disorders, because of the increased photosensitivity of depigmented skin.

The initial exposure is 70% of the MED in lesional skin, and subsequent doses are chosen according to the response in vitiligo areas, i.e. the goal is to induce a barely perceptible erythema that has a light pink color. The presence or absence of faint erythema is the only useful parameter for determining dosage increments. The dose should not be increased more than once weekly by 5%–20% of the preceding dose. Despite the lack of pigment, vitiliginous skin does develop photoadaptation, probably as a

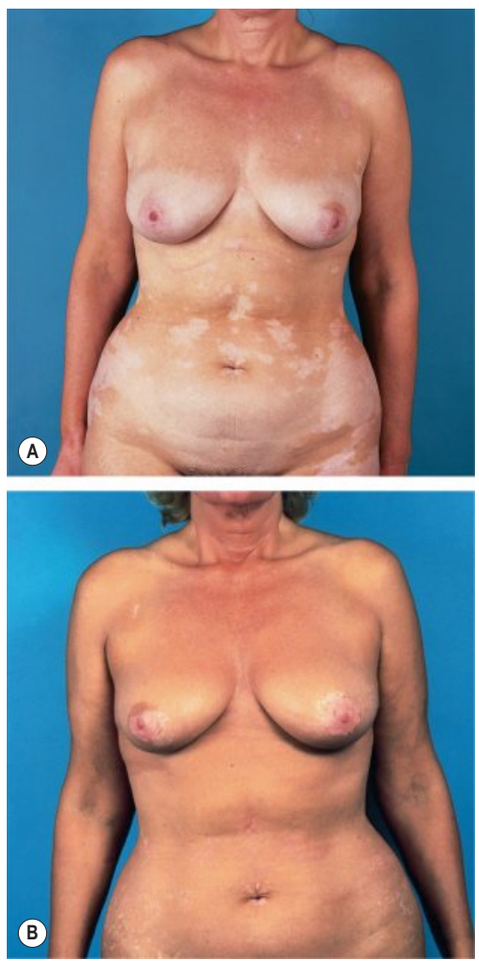

Fig. 134.5 Narrowband UVB phototherapy for vitiligo. A Before treatment. **B** After 10 months of treatment (twice weekly). Note the persistence of depigmentation of the areolae, an area which is particularly resistant to treatment.

result of epidermal hyperplasia and thickening of the stratum corneum. In contrast to previous assumptions, the risk of developing keratinocyte carcinoma is not enhanced in vitiliginous areas. Usually, a maximum dose will be reached during the first couple of months which is then used throughout the entire treatment period. Most commonly, two to three treatments per week are given. Although few controlled studies are available for any particular phototherapy regimen to be preferred over another, consensus recommendations are available[16].

More recently, the combination of an afamelanotide implant plus NB-UVB phototherapy resulted in clinically apparent, statistically significant superior and faster repigmentation compared with NB-UVB monotherapy. Afamelanotide is an analogue of α-melanocyte stimulating hormone that can induce diffuse hyperpigmentation of the skin, especially in sun-exposed sites. Of note, the response was more noticeable in patients with skin phototypes IV to VI[17]. Enhanced repigmentation with a combination of NB-UVB plus topical 1.5% ruxolitinib cream twice daily has also been reported[17a].

Phototherapy for Atopic Dermatitis

Broadband UVB (BB-UVB) phototherapy

Based on the empirical experience that sun exposure is beneficial for patients with atopic dermatitis, BB-UVB has been used to treat atopic dermatitis since the late 1970s.

UVA/UVB phototherapy

Subsequent studies suggested that a combination of UVA plus UVB irradiation (UVA/UVB therapy) is superior to conventional BB-UVB, conventional UVA, or low-dose UVA1 therapy in the management of chronic, moderate atopic dermatitis. A paired-comparison study demonstrated statistically significant differences in favor of UVA/UVB therapy, compared with BB-UVB therapy[18].

Narrowband UVB (NB-UVB) phototherapy

Earlier studies showed that NB-UVB irradiation not only improved the total clinical score, but also substantially reduced the need for topical corticosteroids. These beneficial effects were still present in the majority of patients 6 months after cessation of phototherapy. Narrowband UVB therapy has also been used successfully in conjunction with UVA1 therapy. However, due to the lack of baseline data on the duration and severity of atopic dermatitis, a final conclusion on preference of phototherapy in the acute or chronic phases cannot be drawn from available studies[19].

Phototherapy for Photodermatoses

In the majority of patients, polymorphous light eruption (PMLE) gradually abates with continual outdoor light exposure. For patients prone to PMLE, NB-UVB phototherapy can be used prophylactically to induce "hardening" of the skin before a vacation to a sunny climate or during the springtime (see Ch. 87). Two to three treatments per week for a total of 12–15 sessions are typically administered prior to an anticipated increase in exposure to sunlight. Despite using reduced UVB doses (as compared to those for psoriasis), this phototherapy regimen can induce a transient photoeruption; the latter usually responds to topical corticosteroids and smaller incremental increases in subsequent UVB doses. The precise mechanisms by which phototherapy induces adaptation to sunlight are not known, but may include thickening of the stratum corneum and modulation of cutaneous immune functions. This phenomenon is not due to hyperpigmentation, as was previously thought – patients with skin phototype I respond equally well to NB-UVB as other skin phototypes.

Narrowband UVB phototherapy has also been shown to be capable of inducing "hardening" in patients with erythropoietic protoporphyria, actinic prurigo, and solar urticaria[20]. For solar urticaria, however, the UVA rush hardening regimen appears to be preferable, since effective protection can be achieved within a few days with this protocol[21].

Phototherapy for Pityriasis Lichenoides

Both pityriasis lichenoides acuta and chronica can have a prolonged course and be rather resistant to therapy. As sunlight may lead to some improvement, UVB phototherapy has also been associated with some success. However, PUVA seems to be more effective (see below), especially in the acute form of the disease (perhaps because of the deeper extension of the dermal inflammatory infiltrate). Although some authors have recommended PUVA as the treatment of choice for the acute form[22], PUVA may be reserved for cases of pityriasis lichenoides chronica that are UVB-resistant.

Phototherapy for Seborrheic Dermatitis

Facial and truncal seborrheic dermatitis generally improves during the summer and "sunny" vacations. Accordingly, UV radiation also seems to have a beneficial effect on this condition. However, flares of dermatitis may occasionally occur. In an open prospective study, NB-UVB was found to be an effective treatment in severe cases[23]. Nonetheless, because topical therapies lead to improvement of seborrheic dermatitis in the majority of patients, phototherapy does not represent a first-line treatment.

Phototherapy for Pruritus

Both NB- and BB-UVB therapy can be of benefit in various forms of pruritus, particularly those associated with diabetes and renal or hepatic disorders, as well as in idiopathic pruritus. However, in patients with cholestatic pruritus, remissions are relatively short-lived. In a case series, NB-UVB led to improvement of uremic pruritus[24].

Side Effects of Phototherapy With UVB

Short-term side effects include erythema (Fig. 134.6), xerosis accompanied by pruritus, occasional blistering, and an increased frequency of recurrent herpes simplex viral infections. Painful erythema resulting from overexposure is treated with topical corticosteroids. Systemic nonsteroidal anti-inflammatory drugs and corticosteroids can prove useful in severe cases if administered early.

Long-term side effects include photoaging and carcinogenesis. Although UVB is a known carcinogen, its carcinogenic potential seems to be much lower than that of PUVA. In a British study involving 3867 patients who had been treated with NB-UVB, no significant association between NB-UVB treatment and basal cell carcinoma (BCC), squamous cell carcinoma (SCC), or melanoma was found[25]. There was a small increase in BCCs amongst those patients who had also been previously treated with PUVA. To determine the true carcinogenic risk of NB-UVB phototherapy, additional longitudinal studies are essential.

Fig. 134.6 Target-like appearance of psoriatic lesions secondary to phototoxicity due to UVB. Annular erythema is separated from the psoriatic plaques by Woronoff's ring.

PHOTOTHERAPY WITH THE 308 NM EXCIMER LASER OR LAMP

With the 308 nm excimer laser, monochromatic UVB radiation can be delivered to specific sites of affected skin at higher fluences than are typically administered with whole-body exposure. Clinical use of this laser for plaque-type psoriasis was first reported in 1997[26] and it is FDA-approved for this indication. Possible advantages are the lower number of treatments that may be necessary to induce clearing as well as the ability to selectively target affected skin with a reduced cumulative dose, thus perhaps reducing the long-term risk of carcinogenicity[27]. However, widespread psoriasis generally cannot be treated with this modality because the spot size is limited to just a few square centimeters.

Clearly, the excimer laser is most suitable for patients with stubborn plaques unresponsive to other treatments and/or those with difficult-to-treat localized areas such as the palms, soles, knees, and elbows. Whether it really represents a therapeutic advancement still remains to be determined by larger and longer-term studies, particularly in view of the high costs of laser treatments. However, both non-laser excimer lamps and hand-held targeted UV devices are less expensive and appear to be similarly effective[27].

Based upon case series, targeted phototherapy with the excimer laser or excimer lamp may also serve as a treatment modality for the management of stable vitiligo[28] as well as a variety of chronic inflammatory localized dermatoses such as granuloma annulare, lichen planus, lichen simplex chronicus, and alopecia areata[29].

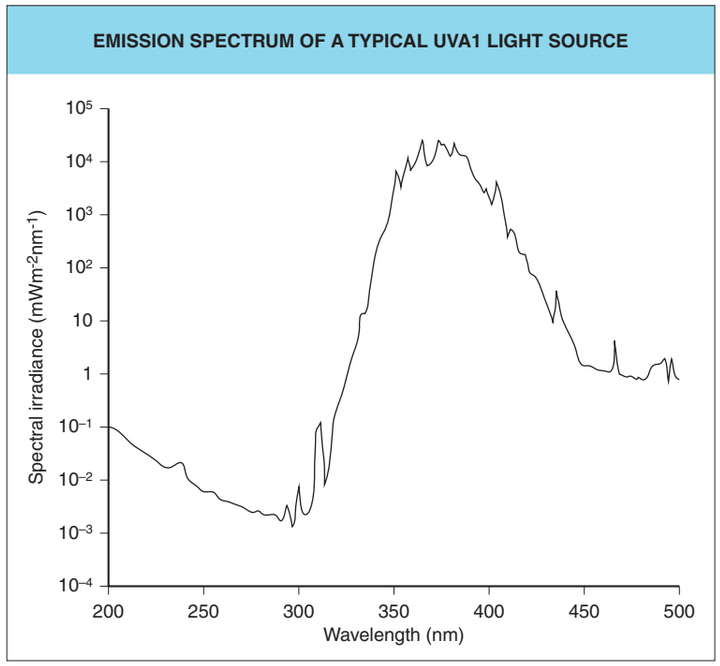

Fig. 134.7 Emission spectrum of a typical UVA1 light source (filtered metal halide lamp).

PHOTOTHERAPY WITH UVA1

The UVA spectrum (320–400 nm) has been arbitrarily subdivided into two parts: UVA1 (340–400 nm) and UVA2 (320–340 nm) (see Fig. 134.1). The main reason for this subdivision was the observation that UVA2 resembled UVB in its ability to induce erythema, immunomodulation, and photocarcinogenesis. Because of its longer wavelength, UVA1 radiation penetrates more deeply into the skin than UVA2 (see Ch. 86), and thus it affects not only epidermal structures, but also mid and deep dermal components, especially blood vessels. Since the skin is a large organ, exposure of circulating immune cells to UVA1 irradiation may have significant systemic ramifications. In particular, its ability to induce T lymphocyte apoptosis is likely to be relevant in the treatment of atopic dermatitis. UVA1 irradiation may also reduce the number of Langerhans cells and mast cells in the dermis in atopic dermatitis and cutaneous mastocytosis. In addition, it has been shown that increased collagenase expression in treated lesions of localized scleroderma (morphea) accompanies improvement with UVA1 irradiation. Perhaps the efficacy of UVA1 in localized scleroderma, and in other sclerosing conditions, is in part due to this action.

UVA1 phototherapy has been investigated as a safer alternative to PUVA for treating chronic conditions. Its major disadvantages are the higher fluences (e.g. 30–130 J/cm^2 per session) and therefore exposure times that are required as well as the higher costs for the lamps. To date, most of the UVA1 studies have been performed in Europe, where efficient sources of UVA1 radiation are more widely available (Fig. 134.7).

UVA1 can have a therapeutic effect on atopic dermatitis[30,31] (Fig. 134.8). It seems to be more effective than UVA/UVB therapy, at least for severe exacerbations of atopic dermatitis. If used as a monotherapy, medium and high daily doses are better than low doses. When UVA1 and NB-UVB were compared for the treatment of atopic dermatitis, they seemed to be equally effective[32]. However, as noted previously, there is currently no consensus as to the preferred type of UV phototherapy for atopic dermatitis[19].

UVA1 therapy has been reported to be beneficial in several other dermatoses[33], in particular sclerosing dermatoses[34], acute GVHD, and chronic sclerodermoid GVHD[35,36]. UVA1 has also been used to treat urticaria pigmentosa[33] and MF[37]. However, its efficacy, especially for the latter indication, requires confirmation in larger patient series.

Side Effects of Phototherapy with UVA1

The adverse effects of UVA1 are less severe than those of UVB and UVA2, although the high fluences usually induce marked tanning, especially in more darkly pigmented individuals. Until more is known about UVA1 therapy, its use (especially with high doses such as 130 J/cm^2) should be limited to treating diseases with periods of severe, acute exacerbations, and in general, one treatment cycle should not exceed 15–20 successively administered exposures and should not be repeated more than once a year. A European prospective longitudinal study has been initiated to monitor patients treated with UVA1 phototherapy for the development of skin cancer and photoaging. An increased expression of *TP53* and a slight increase in Bcl-2 protein expression in keratinocytes were found in human skin after UVA1 irradiation (even with suberythemogenic doses), suggesting that UVA1 may cause DNA damage[38]. In addition, UVA1 induced pro-mutagenic cyclobutane pyrimidine dimers and oxidative DNA damage (at both the genomic and nucleotide resolution level) in normal human skin fibroblasts[39]. Of note, in the years since the widespread use of UVA1 phototherapy in Europe began in 1992, no serious negative side effects in humans have been reported.

PHOTOCHEMOTHERAPY WITH PSORALENS (PUVA)

Psoralen photochemotherapy (PUVA) combines the use of psoralens (P) and long-wave UV radiation (UVA). This combination results in a therapeutically beneficial phototoxic effect, which is not produced by either of the components alone. Psoralens can be administered orally or applied topically in the form of solutions, creams, or baths with subsequent UVA exposure.

Historical Aspects

Topical exposure to extracts, seeds, or parts of plants (e.g. *Ammi majus*, *Psoralea corylifolia*) that contain natural psoralens, followed by exposure to sunlight, was used as a remedy for vitiligo for thousands of years in ancient Egypt and India[40]. In 1974, it was shown that the oral ingestion of 8-methoxypsoralen (8-MOP) and subsequent exposure to a new, high-intensity, artificial UVA radiation source was highly effective for the treatment of psoriasis[41]. This was followed by recognition of its therapeutic effect for multiple skin disorders (Table 134.3). Over the past decade, the use of PUVA has decreased significantly, due in part to the increased risk of developing keratinocyte carcinomas and melanoma, especially with prolonged use in fair-skinned individuals, in addition to the effectiveness of NB-UVB and especially systemic

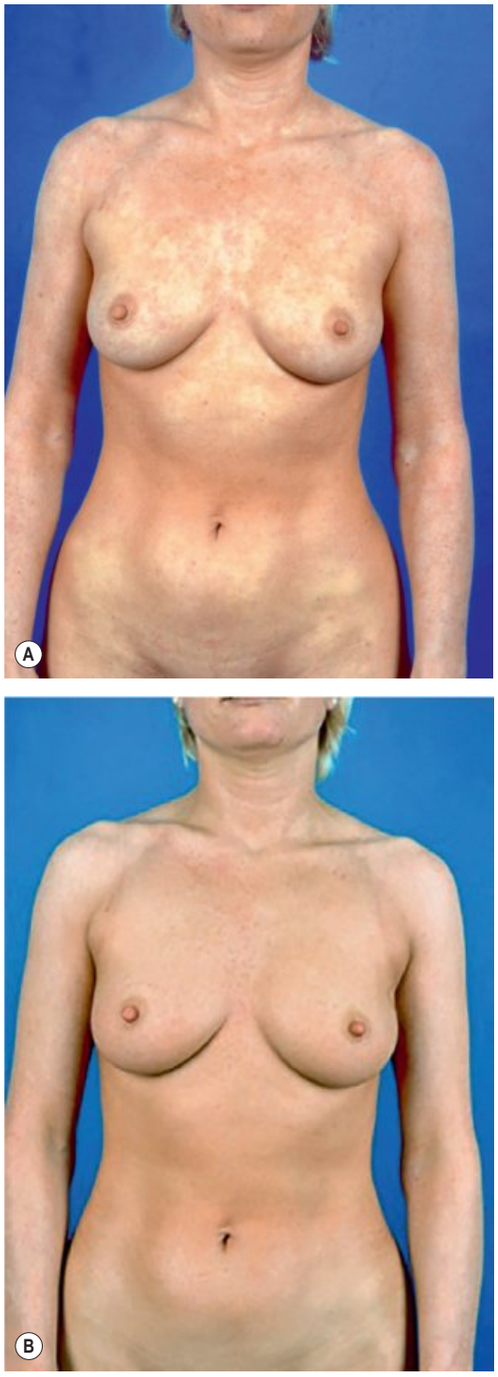

Fig. 134.8 UVA1 phototherapy of atopic dermatitis (split-body comparison). **A** Before treatment. **B** After treatment (15 exposures) with high-dose (130 J/cm^2, left side) *versus* medium-dose (65 J/cm^2, right side) UVA1 phototherapy. Note that there is no difference in the therapeutic result.

immunomodulators ("biologics") in psoriasis. Even though PUVA often represents a second-line form of phototherapy, it is essential that dermatologists become familiar with treatment regimens, potential side effects, and indications, in particular since it is still the (see meta-analysis below) therapy of choice in early stage mycosis fungoides.

Psoralens

Psoralens are naturally occurring linear furocoumarins that are found in a large number of plants, and there are several synthetic psoralen compounds. For oral and topical (bath, cream) PUVA, mainly 8-MOP (methoxsalen) is used; it is of plant origin but also available as a synthetic drug. The synthetic compound, 4,5′,8-trimethylpsoralen (TMP, trioxsalen), is less phototoxic than 8-MOP after oral administration, but more phototoxic when delivered via bath-water. TMP had been used primarily in Scandinavia for bath PUVA. 5-Methoxypsoralen (5-MOP, bergapten) is also therapeutically effective when given orally; it is less erythemogenic and is not associated with gastrointestinal intolerance (Fig. 134.9). In some European countries, it was routinely used for PUVA, but it is no longer commercially available. Oral preparations of 8-MOP contain crystals, micronized crystals, or solubilized psoralens in a gel matrix. The latter liquid preparation induces earlier, higher, and more reproducible peak plasma levels than the crystalline preparations.

The steps between the ingestion of a psoralen and its arrival in the skin include disintegration and dissolution of the drug, absorption, first-pass effect, blood transport, and tissue distribution. The absorption rate of a psoralen from the gut depends on the physicochemical properties of the molecule, the rate of dissolution, the galenic characteristics of the preparation, and the fat content of concomitantly ingested food. Peak serum levels are usually reliably and predictably achieved by liquid preparations, whereas wide time variability occurs with crystalline formulations. Before reaching the skin via the circulation, psoralens are metabolized during their passage through the liver. Plasma levels of 8-MOP administered orally at different doses show a strong non-linearity, indicating a saturable first-pass effect. Thus, small differences in the ingested doses and absorption rates of psoralens lead to large differences in plasma levels. As a practical consequence, small amounts of the drug are almost completely metabolized by the liver during the first pass and therefore may be therapeutically inactive.

8-MOP serum levels show a wide range of inter-individual differences. Even on different occasions in the same patient, serum levels may differ; however, the levels are usually sufficiently constant to provide for relatively reproducible therapeutic results. This unpredictable pharmacokinetic behavior is probably due to inter- and intra-individual variations in intestinal absorption, first-pass effect, blood distribution in the body, and metabolism and elimination of the drug.

For a given patient, serum levels of 8-MOP correspond fairly well with skin reactivity, with the peak of skin phototoxicity coinciding with peak serum levels. A correlation between 8-MOP serum levels and epidermal concentrations does exist. Whether there is a significant correlation between maximum psoralen blood concentrations and the minimal phototoxicity dose (MPD) remains equivocal.

The pharmacokinetics of topical 8-MOP depend on the mode of application. 8-MOP administered topically as a 0.15% emulsion or solution has been shown to result in plasma levels comparable to those obtained by oral delivery, when large areas of the body are treated. In contrast, due to the much lower concentrations that are typically used, plasma levels following bath-PUVA treatment of almost the entire body surface are very low. Bath-water-delivered psoralens are readily absorbed into the skin, but promptly eliminated without cutaneous accumulation[2].

Psoralen photochemistry

Psoralens react with DNA in three steps. First, in the absence of UV radiation, the psoralen intercalates into the DNA double strand. Via a photochemical reaction, absorption of photons in the UVA range results in the formation of a 3,4- or 4′,5′-cyclobutane monoadduct with pyrimidine bases of native DNA. The 4′,5′ monoadducts can absorb a second photon and this reaction leads to the formation of an interstrand cross-link of the double helix with the 5,6 double bond of the pyrimidine base of the opposite strand (Fig. 134.10).

UVA-activated psoralens can also react with molecular oxygen. The reactive oxygen species formed by this reaction cause cell membrane damage by lipid peroxidation and may activate the cyclooxygenase and arachidonic acid metabolic pathways.

The cross-linking of psoralens with epidermal DNA inhibits DNA replication and causes cell cycle arrest. Although not proven, it is generally assumed that this effect may be the therapeutic mechanism in psoriasis. Psoralen photosensitization also causes an alteration in the expression of cytokines and cytokine receptors. However, DNA cross-linking does not appear to be a prerequisite for all the therapeutic effects of PUVA, and the successful treatment of other skin diseases is unlikely to be due directly to this molecular reaction. Psoralens also interact with RNA, proteins, and other cellular components and indirectly modify proteins and lipids via singlet oxygen-mediated reactions or by generating free radicals[42,43].

PUVA can reverse the pathologically altered patterns of keratinocyte differentiation markers and reduce the number of proliferating epidermal cells. Infiltrating lymphocytes are strongly suppressed by PUVA, with variable effects on different T cell subsets. PUVA is far more potent in inducing apoptosis in lymphocytes than in keratinocytes[1], which may

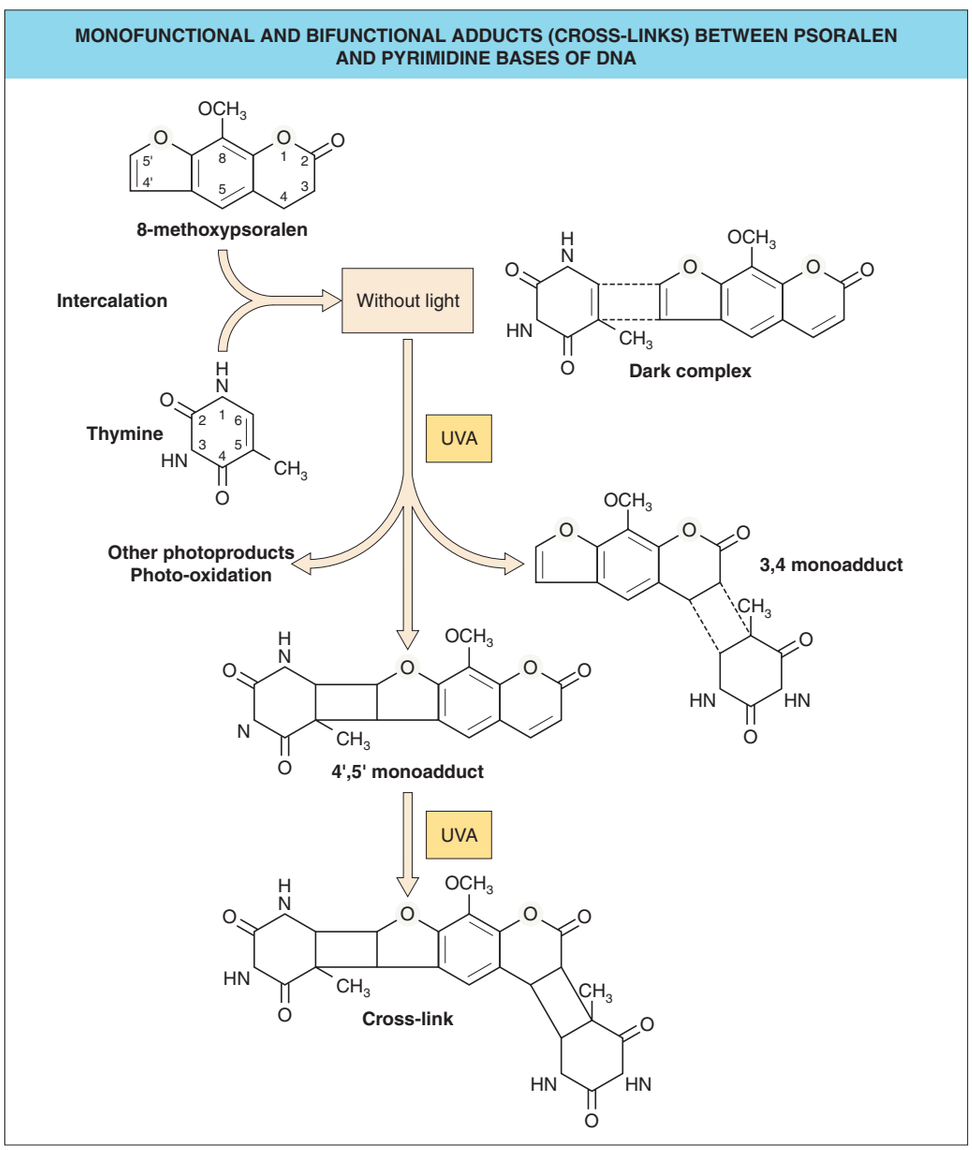

Fig. 134.10 Monofunctional and bifunctional adducts (cross-links) between psoralen and pyrimidine bases of DNA.

explain its efficacy in CTCL as well as in inflammatory skin diseases. Although much is known about pathways and mechanisms in psoralen photosensitization, the interactions and relative contributions to the clearing of a specific disease are not well understood.

Psoralens also stimulate melanogenesis. This involves the photoconjugation of psoralens to DNA in melanocytes, followed by mitosis and subsequent proliferation of melanocytes, increased formation and melanization of melanosomes, enhanced transfer of melanosomes to keratinocytes, and increased synthesis of tyrosinase via stimulation of cAMP activity (see Ch. 65).

Action Spectrum and Light Sources

The action spectrum for 8-MOP-induced delayed erythema has its maximum activity in the 330–335 nm range and the antipsoriatic activity of 8-MOP (plus UVA) appears to parallel this erythema action spectrum[44]. Conventional therapeutic UVA fluorescent tubes and broad-spectrum metal halide lamps, which are filtered in the UVB and UVC range, effectively cover the psoralen action spectrum. The typical fluorescent UVA lamp used for PUVA therapy peaks at 352 nm and emits ~0.5% in the UVB range (Fig. 134.11). Major advantages of mercury halide units are the stability of output and their high irradiance, enabling shorter treatment times.

UVA doses are given in J/cm^2, instead of mJ/cm^2 used for UVB, and are usually measured with a photometer with a maximum sensitivity at 350–360 nm. Within the phototherapy cabinet, the irradiance must be relatively uniform to ensure that the dose does not vary at different anatomic sites. UVB emission should be kept low enough to avoid erythemogenic UVB doses so that sufficient UVA is absorbed to activate the psoralen photosensitivity reaction.

Photobiologic Effects of PUVA

PUVA treatment produces an inflammatory response that manifests as delayed phototoxic erythema. The reaction depends on the dose of drug, the dose of UVA, and the individual's sensitivity (skin type). More recently, it was shown that changes in 8-MOP dose had no detectable effect on the maximum slope of the PUVA erythema dose–response curve. Thus, 8-MOP dose changes within individuals, over a narrow but clinically relevant range, appear to significantly alter the threshold response to PUVA erythema but not the rate of increase in erythema with increasing UVA dose[45].

The time course for PUVA erythema differs markedly from sunburn or UVB erythema; the latter appears after 4–6 hours and peaks 12–24 hours after exposure to UVB. PUVA erythema does not occur before 24–36 hours and it peaks at 72–96 hours or even later after exposure. It has a shallower dose–response curve than UVB erythema (by a factor of ~2) and this difference is maintained even at the time of maximum erythema[46]. PUVA erythema persists for longer periods of time (lasting up to more than 1 week) and it consists of a deeper red, even a violaceous, hue. Severe reactions may lead to blistering and to superficial skin necrosis. Overdoses of PUVA are frequently followed by edema, intense pruritus, and sometimes by a peculiar stinging sensation in the affected skin area. At present, erythema is the only clinical parameter that allows for an assessment of the magnitude of the PUVA reaction and then determination of UVA dose adjustments[2].

Pigmentation, the second important effect of PUVA, may develop without clinically evident erythema, especially when oral TMP is used. In normal skin, PUVA pigmentation peaks about 7 days after exposure and may last from several weeks to months. As with sun-induced tanning, the individual's ability to tan is genetically determined, but the dose–response curve is much steeper. A few PUVA exposures result in a much deeper tan than that produced by multiple exposures to solar radiation. When administering PUVA therapy for inflammatory and neoplastic disorders, an important strategy is to produce a clinical response prior to the induction of significant pigmentation.

Treatment Protocols

Oral PUVA

For oral PUVA, the general approach is to keep the dose of psoralen, as well as the interval between drug intake and UVA exposure, constant, and to vary the UVA dose according to the patient's sensitivity. A dosage of 8-MOP of 0.6 to 0.8 mg/kg body weight is administered orally 1–3 hours before exposure, depending on the absorption characteristics of the particular drug formulation (see above).

The initial UVA doses are selected either by skin phototyping[8,47] or by determining the minimal phototoxicity dose (MPD)[48]. In the US, skin reactivity to solar radiation is evaluated and patients are classified based on a skin phototype scheme according to their sunburn and tanning history. Therapeutic doses of UVA are then given according to an empirical scheme based on this classification[8,45] (Table 134.4). In Europe, until recently, the most widely used approach consisted of MPD determination analogous to MED determination. The MPD is defined as the minimal dose of UVA (following psoralen ingestion) that produces a barely perceptible, but well-defined, erythema. The doses range from 0.5 to 5 J/cm^2 if oral 8-MOP is used. Erythema readings are performed 72 to 96 hours after irradiation, when the phototoxicity reaction usually peaks. As with the MED, the MPD is determined on previously non-sun-exposed skin (lower back or buttocks). Since determining the MPD is rather time-consuming and can take up to a week to perform, it has been abandoned for practical reasons in most European phototherapy centers and replaced by phototyping. In several phototherapy guidelines, MPD testing is still recommended but not considered to be mandatory.

Oral PUVA should not be used in patients with hepatitis because a slower metabolism of psoralens may prolong photosensitivity. Impaired renal function may also reduce psoralen excretion.

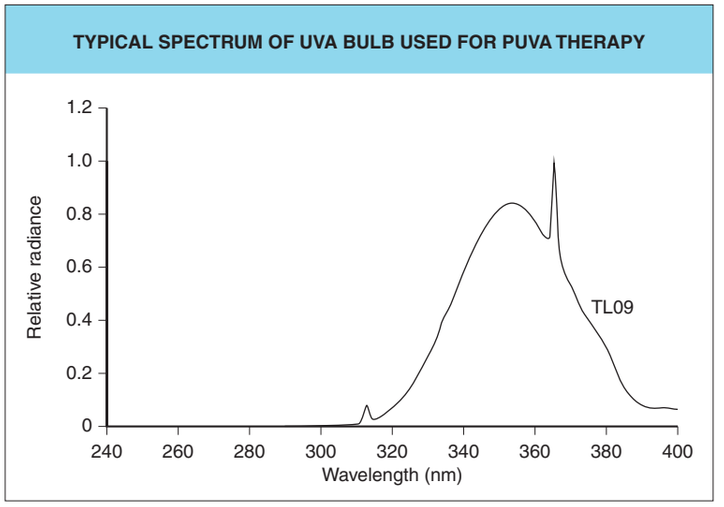

Fig. 134.11 Typical spectrum of a UVA bulb (Philips TL09) used for PUVA therapy.

SKIN PHOTOTYPES AND INITIAL DOSE OF UVA FOR PUVA THERAPY

Skin phototype*	Skin reaction	Recommended initial dose (J/cm^2)
I†	Always burns, never tans	0.25–0.5
II	Always burns, but sometimes tans	0.5–1.0
III	Sometimes burns, but always tans	1.5
IV	Never burns, always tans	2.0
V‡	Moderately pigmented skin	2.5
VI	Darkly pigmented skin	3.0

*Types I–IV are determined by history; types V and VI by physical examination (skin color).
†Patients with erythrodermic psoriasis are to be classified as skin phototype I for determination of UVA dosage.
‡Patients with this phototype should be classified into a lower skin phototype category if the sunburning history so indicates.

Table 134.4 Skin phototypes and initial dose of UVA for PUVA therapy. These irradiation doses are based upon an oral 8-MOP dose of 0.6–0.8 mg/kg.

Bath PUVA

Bath-water delivery of psoralens has become increasingly popular because it provides uniform drug distribution over the skin surface, very low psoralen plasma levels, and a rapid elimination of free psoralens from the skin, thereby reducing the period of photosensitivity. Due to the absence of systemic photosensitization, bath-water delivery of 8-MOP circumvents gastrointestinal side effects and potential ocular effects. Skin psoralen levels are highly reproducible and photosensitivity lasts no more than 2 hours. However, peak erythema is delayed as compared to the oral route; therefore erythema readings should be performed 96 to 120 hours after irradiation, which is the major reason why MPD determination has been replaced by phototyping in most phototherapy centers. The higher incidence of unwanted phototoxicity can be prevented by a lower starting dose and more cautious dosimetry during the initial treatment phase.

Originally, bath PUVA was performed with TMP, but 8-MOP is now being used as well. Bath PUVA consists of 15–20 minutes of whole body (or hand and foot) immersion in solutions of 0.5–5.0 mg of 8-MOP per liter of bath water. Irradiation has to be performed immediately thereafter, as photosensitivity decreases rather rapidly. However, one must take into account that, unlike with oral PUVA, the phototoxic threshold *declines* early on during treatment (this may be due to persistent psoralen adducts)[2]. Thus, at the onset, dose increments should be done more cautiously.

Topical PUVA

Application of 8-MOP (0.1%–0.01%) in creams, ointments, or lotions, followed by UVA irradiation, is effective but has several disadvantages. The non-uniform distribution on the skin surface may produce unpredictable phototoxic erythema reactions, and inadvertent application to surrounding uninvolved skin can lead to cosmetically unacceptable hyperpigmentation. Furthermore, if numerous lesions are present, the application is laborious and time-consuming, and the treatment does not prevent the development of new active lesions in previously unaffected, untreated areas. Finally, extensive application ("paint" PUVA) of a 0.15% 8-MOP emulsion was found to cause plasma levels comparable to those detected with oral ingestion. Therefore, topical PUVA utilizing psoralen creams, ointments, or lotions is now reserved primarily for dermatoses of the palms and soles.

Initial Treatment (Clearing) Phase

The initial treatment phase is defined as the treatment period until clearing of the disease is achieved; repeated exposures are required, with gradual dose increments as pigmentation develops. Doses that are too low frequently result in failure of treatment, except in those diseases in which induction of pigmentation is the desired objective. In most dermatoses amenable to PUVA, the frequency of treatments should be reduced after satisfactory control of the disease.

If MPD testing is performed, a safe initial therapeutic dose for oral PUVA is 50%–70% of the MPD. For bath PUVA, it is advisable to start at only 30% of the MPD, because photosensitivity is up to 10 times higher than with oral PUVA (Fig. 134.12). As noted previously, nowadays, most centers start with doses based on the patient's skin phototype.

Irradiations are given two to four times weekly. Dose increments are performed no more often than twice a week (at least 72 hours apart) and never during the first week of treatment (if initial dose is based on MPD), in order to avoid an accumulation of delayed cutaneous phototoxicity. Although not necessary for therapeutic success, a minimally perceptible erythema is considered a clinical indicator of adequate dosimetry. There exists no rigid scheme for dose increments; the major parameter for dose adjustments should be the clinical response of the disease. It is essential to note that with bath PUVA, the MPD can even decrease during the first days after initiation of treatment by up to 50%, but then increase at later stages. This may be due to persistent psoralen adducts which are converted into cross-links upon subsequent exposures.

In the absence of erythema, the UVA dose can be increased safely by 30% in both oral PUVA and bath PUVA (see Fig. 134.12). However, because of erythema formation and/or an adequate treatment response, some patients will not require dose adjustments over prolonged periods of time.

Maintenance Phase

The purpose of maintenance therapy is to prolong the duration of clinical remission. In the original European regimen, maintenance therapy consisted of one month of twice-weekly treatments utilizing the final UVA dose administered during the clearing phase, followed by another month of once-weekly exposures. However, results of a more recent study indicated that short-term maintenance therapy was not

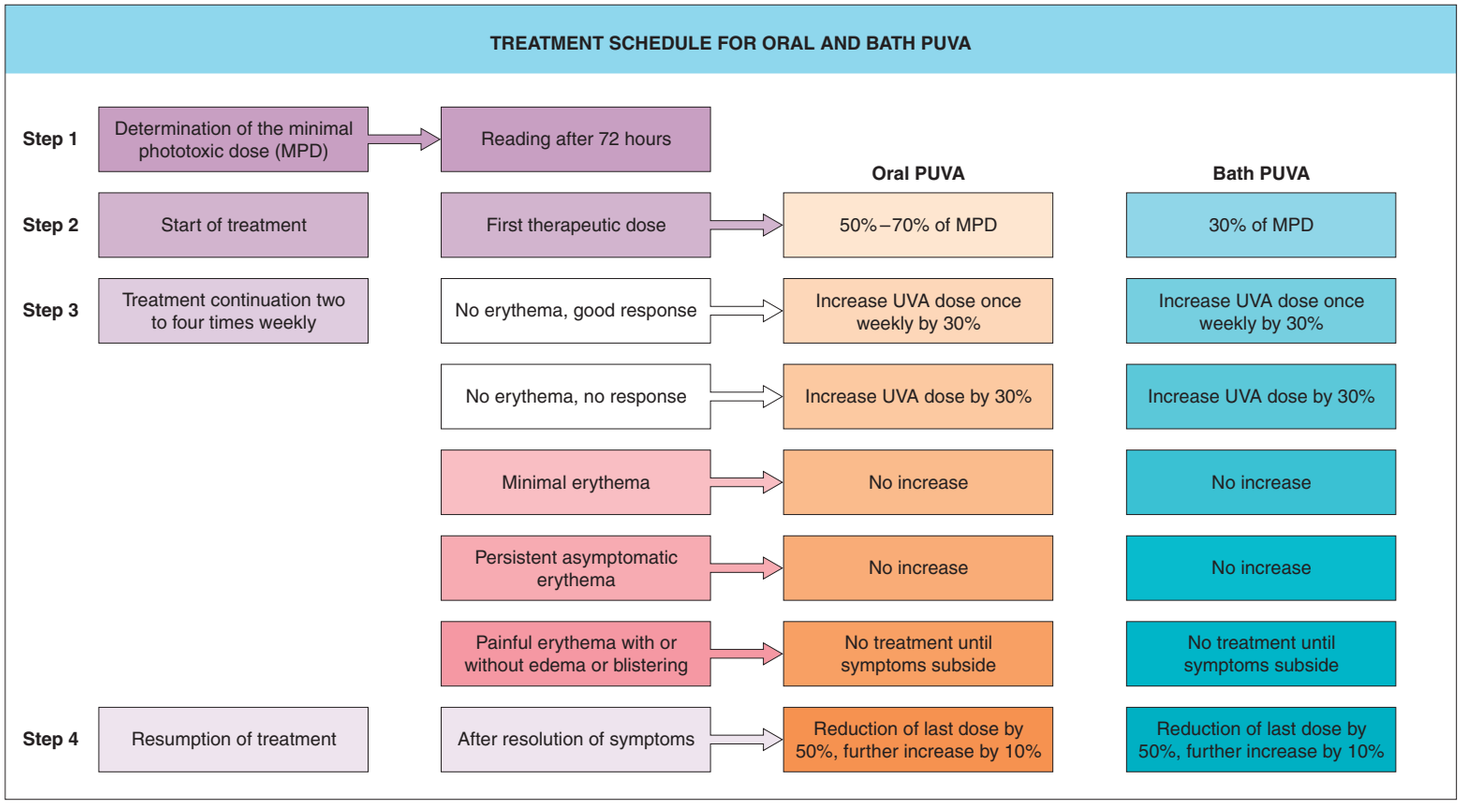

Fig. 134.12 Treatment schedule for oral and bath PUVA.

effective in preventing early relapses of psoriasis[49]. For MF, many institutions recommend some form of permanent maintenance therapy, but there is a lack of prospective studies to validate this recommendation. Perhaps a once-monthly treatment would be a feasible compromise.

Mild relapses during the maintenance phase are handled by temporarily increasing the frequency of treatments; in the case of a severe relapse, the original clearing phase schedule must be resumed until clearing is once again achieved. A disadvantage of maintenance therapy for patients in remission is the potential to overtreat the patient and to increase the potential for long-term toxicity that is related to the total cumulative dose of PUVA.

PUVA for Psoriasis

Basically, all types of psoriasis respond to PUVA (Fig. 134.13), although the management of erythrodermic or generalized pustular psoriasis is more difficult[2]. Both the US and the European regimens have proven to be highly efficient and therefore have remained in use, although with the advent of systemic immunomodulators ("biologics"; see Ch. 128), phototherapy for all types of psoriasis has lessened.

Three studies have compared bath-water delivery of 8-MOP with oral administration[50–52]. In two reports, initial doses were determined by skin phototyping and treatments were given two to three times weekly. Dosage increments were made with every treatment in the first study[50], whereas smaller increments were performed every third treatment in the second[51]. Patients in the third study were treated according to the guidelines of the standard European regimen for oral PUVA; this group had the lowest incidence of treatment failures and overdose episodes[52]. Relative to the results obtained with oral PUVA, bath PUVA showed equal clearing rates with lower numbers of exposures. The greater therapeutic efficacy could be due to a higher penetration of psoralens through the abnormal stratum corneum overlying psoriatic plaques as compared with healthy perilesional skin where phototoxicity is monitored during the therapy. The incidence of erythema and pruritus was similar or lower with bath PUVA as compared to oral therapy. In all the investigations, episodes of systemic intolerance such as nausea and vomiting were recorded only with oral PUVA[2].

PUVA alone can produce a definite remission in many cases of psoriasis, but a considerable number of patients require combination therapy (see below).

Fig. 134.13 PUVA treatment for psoriasis (four times weekly). A Before treatment. **B** After 6 weeks of treatment.

Combination Treatments

Topical combination

As with UVB phototherapy, PUVA can be combined with other treatment modalities to improve efficacy and to reduce potential side effects[2]. Topical adjuvant therapies include corticosteroids, anthralin, tar, and vitamin D analogues (see Chs. 125 & 129). However, some patients are reluctant to "retry" topical agents that previously proved unsuccessful when used alone.

Methotrexate, cyclosporine, systemic immunomodulators ("biologics")

The combination of PUVA and methotrexate (MTX) during the clearing phase reduces the duration of treatment, number of exposures, and cumulative UVA dose, and it is also effective in clearing patients unresponsive to PUVA or UVB alone[53]. To date, no increased risk of keratinocyte carcinomas has been reported for this combination. In contrast, cyclosporine plus PUVA has been clearly shown to dramatically enhance cutaneous carcinogenesis. Thus, this latter combination should be categorically discouraged[53], including the use of cyclosporine subsequent to PUVA therapy. Presently, there are no studies evaluating the safety and efficacy of biologics plus PUVA.

Retinoids

The combination of PUVA with systemic retinoids (RePUVA) is one of the most potent therapeutic regimens for psoriasis. The therapeutic efficacy of PUVA therapy is significantly enhanced upon combination with oral retinoids (acitretin [0.5–0.75 mg/kg] or isotretinoin [0.75–1 mg/kg]) that are administered daily for 5–10 days before PUVA is started, with the combination continued throughout the clearing phase. RePUVA reportedly can reduce the number of exposures by one-third and the total cumulative UVA dose by more than one-half. RePUVA can also clear "poor PUVA responders"[2].

The underlying mechanism of the synergistic action of retinoids plus PUVA may be a reduction in the inflammatory infiltrate and an accelerated desquamation of the psoriatic plaques, thereby optimizing the optical properties of the skin. In theory, retinoids may also reduce the long-term carcinogenic risk of PUVA by reducing the number of exposures and providing chemoprevention against skin cancers. Some evidence for this was presented in a study where patients with psoriasis treated with PUVA in combination with systemic retinoids showed a reduced risk of SCC but not a significantly altered incidence of BCC[54].

Short-term side effects of retinoids are completely reversible upon discontinuation, and long-term toxicity is not relevant because of the limited duration of their use (until clear). The potential teratogenicity of retinoids represents a serious concern. For women of childbearing age, the use of isotretinoin is an option, because contraception is only necessary for 1–2 months after discontinuation of therapy, as opposed to acitretin, which requires two subsequent years of contraception[2].

PUVA for Cutaneous T Cell Lymphoma, in Particular Mycosis Fungoides

Based on the empirical beneficial effect of natural sunlight on early stage MF, Gilchrest et al.[55] first reported the successful use of PUVA for MF. Patients with unsatisfactory responses to other therapies and histologically confirmed plaque or tumor stage MF or the erythrodermic form of CTCL were subjected to PUVA. Complete clearing was observed, except

in those areas that were shielded from UVA exposures, thus excluding the possibility of spontaneous remission. This also indicated that the therapeutic effect of PUVA was local rather than systemic.

Numerous studies followed which addressed the rates of initial response and average duration of remission in relation to the stage of MF, the efficacy of PUVA compared with other established treatment options, the efficacy of combination treatments, the mechanisms responsible for the therapeutic effects, and the risk of short- and long-term side effects[2].

Treatment schedules and dosimetry in the photochemotherapy of MF are essentially the same as for psoriasis, consisting of three phases – clearing, maintenance, and follow-up. Some authors suggest that remission should be confirmed by histologic examination of previously involved areas. In some institutions, maintenance therapy includes two exposures per week for one month and one exposure per week for another month. If still in remission, therapy is discontinued and the patient is monitored monthly and then bimonthly. If a relapse occurs, the patient is again treated with three or four PUVA exposures per week until complete clearing. However, other investigators advocate permanent maintenance treatment consisting of treatments once monthly or every other month, as it appears that PUVA treatment is not curative. Since the course of MF varies considerably from patient to patient, the final answer remains to be determined.

Clinical experience indicates that patients benefit most from individualized schedules. For example, a recent study described the administration of a low frequency regimen (2×/week) for early MF (stage IA–IIA)[56]. Oral PUVA was administered for up to 24 weeks in 27 patients; 19 complete and 8 partial remissions were observed and the average cumulative UVA dose was rather low (78.5 J/cm^2). Eleven of the 19 patients with a complete remission underwent maintenance therapy (14 exposures over 9 months), with 7 of those still in remission after one year. In comparison, 7 of 8 patients who did not receive maintenance therapy experienced a relapse.

Several studies involving large patient cohorts have provided information on the initial response rates of PUVA treatment in relation to disease stage. Overall, the best initial complete response rates were obtained for stages IA (~90%), IB (~76%) and IIA (~78%), as compared to stages IIB and III (~60%). There was some heterogeneity in results and the use of different treatment protocols, psoralen preparations, and light sources may have contributed to this finding. Only a few patients with stage IV disease have been treated with PUVA monotherapy, because, in this stage, PUVA is generally considered to be only a palliative or adjunctive therapy. Relapses usually respond to PUVA in the same manner as the initial response. Clinical remissions appear to be directly related to phototoxic destruction of the malignant infiltrate. Thus, complete clearing may be induced when the cells are confined to the epidermis and the superficial dermis and do not exceed the depth of UVA penetration into the skin. Patients with tumor stage MF exhibit a high rate of early recurrences, which require permanent maintenance treatment; often only the combination of PUVA with local radiotherapy and/or systemic chemo-immunotherapy can result in complete tumor resolution.

In summary, the data thus far indicate that PUVA is an excellent treatment option for early stage (IA–IIA) CTCL (Fig. 134.14). High rates of complete clearing can be achieved and a substantial percentage of patients remain free of disease for many years. In a meta-analysis of seven studies that compared PUVA versus NB-UVB for the treatment of early MF (IA–IIA), 778 patients (527 PUVA, 251 NB-UVB) were analyzed[57]. Complete remission was achieved in 74% of the patients in the PUVA group and 62% in the NB-UVB group; the remission-free interval ranged from 10 to 45 months (mean 33 months) in the PUVA group compared to 5 to 24 months (mean 15 months) in the NB-UVB group. The significantly longer remissions rates may be one of the reasons why in some treatment guidelines PUVA is regarded as the therapy of choice in early stage MF[58].

In advanced stages (IIB–IVB) of MF, PUVA is not sufficient as monotherapy, but as an adjunctive treatment it can reduce the tumor burden in the skin and can improve the quality of life for patients. Presently, no therapeutic regimen is known to arrest eventual progression of advanced stages of MF to tumor formation, dissemination, and a fatal outcome. Prolonged remissions have been observed with combinations of PUVA plus systemic retinoids (e.g. bexarotene[59]) or IFN-α-2a[60,61]. Possible long-term side effects related to frequent PUVA treatments are probably less meaningful for patients with CTCL compared with patients who have benign disorders.

Fig. 134.14 PUVA treatment for cutaneous T cell lymphoma (mycosis fungoides). A Before treatment. **B** After 12 weeks of treatment that was four times weekly.

While PUVA therapy is very effective in inducing remission as long as the lymphoma is confined to the skin, the impact of this therapy on the natural course of CTCL and on patient survival is not yet determined.

PUVA for Vitiligo

As mentioned previously, vitiligo was the first disease treated with an ancient form of psoralen photochemotherapy in India and Egypt. PUVA in its modern form stimulates melanogenesis as well as melanocyte

proliferation and migration, and it reconstitutes the normal skin color in more than 50% of vitiligo patients.

Treatment protocols and results

Nowadays, oral 8-MOP is the photosensitizer most frequently used, followed by exposure to sunlight or artificial UVA radiation. In the past, if sunlight were the radiation source, oral TMP was the preferred photosensitizer due to its weaker phototoxicity. To induce repigmentation, patients need constant long-term therapy. It is crucial that the patient understands that PUVA, like other vitiligo therapies, may require months or even years to achieve a satisfactory result. Overly optimistic prognoses regarding therapeutic efficacy and length of time to produce adequate repigmentation should be avoided. The patients must also be aware that the treatments stimulate the pigmentation of normal skin, which will intensify the contrast between normal and vitiliginous skin.

Treatments should be given at least twice a week, but not more than three times, with at least one day between treatments. If there is no response after 4–5 months or ~30–40 treatments, PUVA should be terminated. Responsiveness is defined as development of multiple perifollicular macules of repigmentation, or, in the case of small (<2 cm) lesions, contraction in size. If treatment is discontinued, reversal of acquired repigmentation may occur unless the lesion has completely repigmented. Completely repigmented areas can be stable for a decade or more without relapse.

Photochemotherapy with topical 8-MOP can be used in patients with small lesions (<5% total body surface area) or in children in whom one may hesitate to use systemic PUVA. The therapy must be done in an office setting, since home treatment involves a high risk of severe phototoxic side effects. Topical 8-MOP preparations (0.0005%–0.005% 8-MOP in a cream or ointment base) are applied evenly on the treatment area 30 minutes prior to irradiation. Exposure times (beginning at $\leq 0.25\,J/cm^2$) are increased weekly in increments of $0.25\,J/cm^2$ unless marked erythema occurs. Once- to twice-weekly treatments are recommended. With topical PUVA, the vehicle plays a major role in delivery and resulting cutaneous psoralen levels. Solutions should be avoided as they can "run", producing hyperpigmented streaks. Application of sunscreen to the surrounding uninvolved skin prior to application of the topical psoralen can reduce hyperpigmented rims.

Patient selection appears to be critically important. For oral PUVA, the patients should be ages 10–12 years or older, and for all forms, they must be available for 12–24 months of continuous therapy. Lips, distal dorsal hands, fingers and toes, palms, soles, and nipples are very refractory to treatment, as are large areas with only white hairs. Patients need to be made aware of this fact.

Stable disease, i.e. nonprogressive for at least 6 months to a year, is usually easier to treat. On average, a complete treatment regimen consists of at least 150 exposures. However, because of the different response rates in different body areas, total repigmentation is only rarely achieved, and ~30% of patients do not respond at all, despite months of therapy. As mentioned above, in a trial involving patients with non-segmental vitiligo, NB-UVB therapy resulted in a better color match when compared to oral PUVA[15]. As a result, the use of NB-UVB has increased while PUVA therapy for vitiligo has waned in most phototherapy centers.

PUVA for Atopic Dermatitis (See Ch. 12)

Many patients with moderate, severe, and even erythrodermic forms of atopic eczema can benefit from PUVA therapy[53]. The treatment guidelines are essentially the same as for psoriasis, but patients may develop a temporary flare of their dermatitis during the initial treatment phase. Also, atopic dermatitis is more difficult to treat than psoriasis and quite often a higher number of treatments is required. Although atopic dermatitis may be cleared by PUVA, recurrence rates are high and rapid, requiring frequent maintenance exposures. However, in young patients, long-term maintenance therapy should be avoided. A combination of PUVA with topical corticosteroids appears to be superior to PUVA alone in maintaining remissions, and in a more recent study involving patients with severe atopic dermatitis, PUVA provided better short- and long-term responses than did medium-dose UVA1. These latter results require further confirmation. Due to the introduction of systemic immunomodulators such as dupilumab to treat moderate-to-severe atopic dermatitis, the importance of PUVA as a therapeutic approach will likely decrease in the future.

PUVA for Lichen Planus (See Ch. 11)

In generalized lichen planus, PUVA can provide an effective alternative to systemic corticosteroids. Studies have pointed to an overall response rate between 50% and 90%, suggesting that lichen planus is less responsive than psoriasis to PUVA. In addition, more treatment sessions and higher cumulative UVA doses were generally necessary for complete remission and not all patients responded satisfactorily. Marked postinflammatory hyperpigmentation may impair the final cosmetic result. An exacerbation during PUVA treatment has been reported in a few patients. Bath PUVA also works in lichen planus, and a combined RePUVA regimen (as is used for psoriasis) may accelerate clearing in disseminated and particularly keratotic forms of lichen planus. Compared to NB-UVB, oral PUVA led to a better initial clinical response rate, but both were effective treatments and produced similar long-term outcomes[62].

PUVA for Graft-Versus-Host Disease (see Ch. 52)

Due to clinical and histologic similarities between idiopathic lichen planus and lichenoid GVHD, PUVA treatment was evaluated for the latter[63]. Beneficial effects were observed in patients who had not responded to conventional immunosuppressive therapy alone. PUVA can also improve acute GVHD[64]. Results of PUVA therapy for scleroderma-like variants of cutaneous GVHD are controversial[65]. In our experience, the more localized and circumscribed morpheaform lesions appear to respond to PUVA fairly rapidly, with softening of the associated sclerosis. However, the more advanced and widespread sclerodermoid form hardly responds to PUVA.

In contrast to other conditions, PUVA may exert not only local but also systemic effects, since improvement of mucosal erosions was observed during treatment of chronic lichenoid GVHD with PUVA, but this could have also been coincidental. Apparently, there is no improvement of GVHD of other organs, e.g. liver and gut. Of note, deterioration of liver GVHD has not been reported thus far. This is important, since psoralens are metabolized by the liver.

The therapeutic regimen used for the treatment of chronic GVHD is basically the same as for psoriasis. UVA doses should not be increased too aggressively, in order to avoid erythema and possible (re)activation of GVHD. The UVA dosage is increased by no more than $0.5\,J/cm^2$ every second to fourth exposure and patients are treated three to four times weekly. After clearing of skin lesions, exposures are reduced according to the maintenance schedule outlined for psoriasis.

There may be a slight overall increased risk of cutaneous malignancies in hematopoietic stem cell recipients, but much less than in solid organ transplant patients who receive long-term immunosuppression. If patients are receiving long-term prophylactic treatment with voriconazole, switching to posaconazole should be considered in order to reduce possible enhancement of SCC formation.

PUVA for Urticaria Pigmentosa (See Ch. 118)

PUVA causes a temporary involution of cutaneous mastocytosis[66,67]. The treatment results in loss of Darier's sign, relief of itching, and flattening and sometimes disappearance of cutaneous macules and papules. Surprisingly, even systemic symptoms such as histamine-induced migraines and flushing fade gradually as treatment is continued[66]. In most patients, the clinical manifestations recur several months after discontinuation of PUVA. The recurrences respond as well as the original lesions, and clearing of signs and symptoms can again be achieved. In children, PUVA is also often helpful, and appears to be justified in widespread, disabling mastocytosis. To avoid sudden mediator release from mast cells, a PUVA regimen of gradually increasing doses, especially during the initial phase, seems advisable, although the therapy should otherwise be undertaken according to the usual guidelines.

PUVA for Miscellaneous Dermatoses

Both acute and chronic pityriasis lichenoides[22] respond to photochemotherapy and favorable results have been reported for lymphomatoid papulosis[22,68]. Nevertheless, the experience with these conditions is limited to anecdotal cases. In pityriasis rubra pilaris, the results are

quite inconsistent. Some patients seem to respond well[22], while others may flare and some require combination treatment with retinoids or methotrexate. Generalized granuloma annulare has been reported to clear completely, but long-term maintenance treatment was required to maintain remissions[69]. There were initial reports of both topical and systemic PUVA leading to regrowth of hair in patients with alopecia areata in whom exposures were localized to the alopecia areas. The number of treatments required for regrowth varied widely, and circumscribed lesions responded better than did total alopecia. However, follow-up studies of larger patient groups concluded that PUVA is generally not effective in alopecia areata[70,71], which is in accordance with our own experience. Localized scleroderma and pansclerotic morphea have been successfully treated with bath PUVA and oral PUVA[72].

PUVA for Photodermatoses

Tolerance to sunlight can be induced in several photodermatoses with NB-UVB (see above) or PUVA[73]. Although NB-UVB is tried first due to safety concerns, PUVA represents a very effective preventive treatment for polymorphous light eruption (PMLE; via hardening)[74]. In ~70% of patients with this condition, a 3- to 4-week course of PUVA suffices to suppress the disease upon subsequent exposure to sunlight. PUVA induces pigmentation rapidly and intensively at relatively low (suberythemogenic) UVA doses that usually remain well below the threshold doses for eliciting the PMLE. About 10% of the patients develop typical lesions during the initial phase of PUVA, and as with UVB phototherapy, interventions include interruption of treatment, reduction in the UVA dose, and application of topical corticosteroids.

The therapeutic value of preventive photochemotherapy for PMLE has to be balanced against its potential long-term side effects. Given the fact that very few treatments and low cumulative UVA doses (ranging from 15 to 40 J/cm^2 per treatment course, depending on skin type and photosensitizer) are required for photoprotection and that PMLE can severely restrict outdoor activities, PUVA treatment of PMLE is justified when other preventive measures (e.g. sunscreens, NB-UVB) fail[74].

There is also some experience with PUVA prophylaxis of other photodermatoses. In solar urticaria, PUVA therapy is an effective preventive treatment and is certainly better than antihistamines[75]. Sensitivity to sunlight can be decreased by 10-fold or more after a single treatment course. The suppressive effect may last throughout the summer, depending on regularly repeated sunlight exposures. Problems may occur during the first several PUVA exposures, since in some patients the urticaria threshold dose appears to be lower than their MPD. In these cases, stepwise UVA irradiation of single quadrants of the body a few hours before each PUVA treatment has proven useful[75]. PUVA is then administered during the refractory period. Of note, UVA rush hardening appears to be equally effective as PUVA, with the advantage of inducing the hardening effect and providing protection within a few days[21].

Successful photochemotherapy has also been reported in occasional patients with chronic actinic dermatitis and hydroa vacciniforme[76].

Side Effects and Long-Term Hazards of PUVA

As discussed above, oral 8-MOP has a high incidence of nausea (30% of patients) and vomiting (10% of patients), and this may occasionally require discontinuation of the medication. These side effects are more common with liquid than with crystalline preparations, probably because of higher psoralen serum levels.

The short-term side effects of the combined action of psoralens plus UVA radiation consist of redness, swelling, and occasionally blister formation as can be seen with excessive sunburns. Generalized pruritus or tingling sensations may herald phototoxic side effects. When large areas of skin are affected, systemic symptoms of excess phototoxicity such as fever and general malaise may occur. Nonsteroidal anti-inflammatory drugs and topical and systemic corticosteroids may be required to alleviate these symptoms, but they have to be given early. Because of high epidermal psoralen concentrations, such overdosage phenomena are more common after topical psoralen application. Accumulation of phototoxic effects after several consecutive UVA exposures is also more common with topical PUVA.

Some patients experience persistent pruritus during PUVA treatment, particularly after slight UVA overdosage, and in rare cases, a stinging pain may develop in circumscribed areas. PUVA-induced skin pain unrelated to actual phototoxic burns occurs rarely, but it may necessitate discontinuation of treatment. The mechanism is unknown and the symptoms are unresponsive to antihistamines. Usually, these complaints subside slowly upon continuation of treatment.

Ophthalmologic effects

Eye protection is mandatory during UVA exposure, and UVA-opaque glasses are required for ambient exposure until the evening of the treatment day. UVA penetrates into the ocular lens and potentially could induce cataracts by forming psoralen-protein photoproducts. The higher permeability of the ocular lens at a younger age led to the relative contraindication of oral PUVA in children younger than 12 years of age. Despite the experimental data indicating a risk of premature cataract formation, clinical evaluation has shown no increase in lens opacities even in patients who neglected to practice careful eye protection[77]. Obviously, there is no risk with topical or bath PUVA.

Laboratory data

Because psoralens can cause liver damage in laboratory animals when given in excessive doses, concern was expressed in the past regarding possible hepatotoxic effects in humans. Several large-scale studies demonstrated no significant abnormal laboratory findings in patients receiving PUVA over prolonged periods of time[47,48]. In particular, serial laboratory examinations performed over a period of several years have not revealed any substantial evidence for an impairment of hepatic function. Liver biopsies after 1 year of therapy did not show signs of hepatotoxicity. Anecdotal case reports of hepatitis during PUVA treatment were most likely unrelated to therapy. Several large-scale studies have negated a possible relationship between PUVA therapy and the occurrence of anti-nuclear antibodies[78].

Potential long-term risks of PUVA

Repeated phototoxic injury to the skin can be expected to result in cumulative actinic damage regardless of whether it is induced by sunlight, artificial UV radiation, or PUVA. Although the precise action spectrum of actinic damage has not been determined, epidermal changes are attributed to UVB and dermal changes more to UVA, because the latter penetrates more deeply into the skin. Thus, chronic exposure to PUVA may produce changes in the skin that generally resemble those known as dermatoheliosis and may add to the injury induced by sunlight. High cumulative doses of whole body UVB or PUVA result in pigmentary changes, xerosis, loss of elasticity, wrinkle formation, and actinic keratoses. Additionally, PUVA may induce profuse formation of dark stellate lentigines (Fig. 134.15), termed PUVA lentiginosis[48]. These lentigines result from repeated and prolonged treatment and are commonly associated with high cumulative doses of UVA and a high number of treatments. So far, no increased risk of cutaneous melanoma

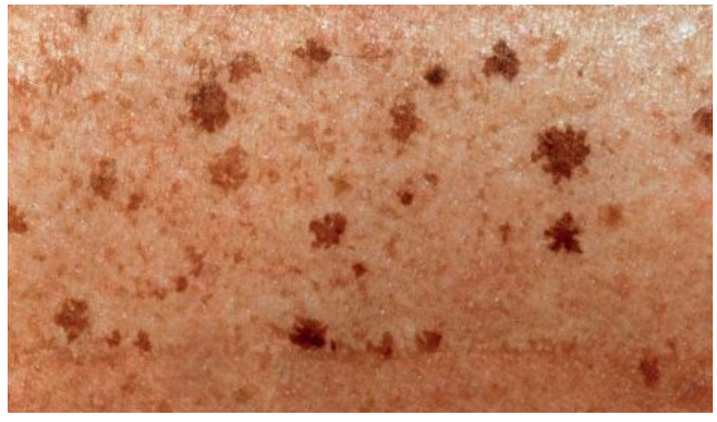

Fig. 134.15 PUVA lentigines. These develop after repeated PUVA treatments over several years and usually within a background of photodamaged skin.

associated with these lentigines has been recorded, but the cosmetic effect may be quite disturbing.

The major concern with prolonged and repeated phototherapeutic regimens is photocarcinogenesis. Therefore, from the onset, PUVA-treated patients were carefully monitored for the development of precursors and malignant skin tumors. Almost all data were obtained from psoriatics, since they represent the largest group of patients receiving PUVA.

The risk is certainly related to DNA damage, but PUVA-induced immunosuppression may play a role as well. In PUVA patients, the risk of SCC, but not of BCC, is significantly increased in comparison with matched controls, and the magnitude of the increase appears to be dose-dependent[79]. However, there is uncertainty regarding PUVA being the sole factor; many of the affected patients had previous exposure to excessive sunlight and to treatments with carcinogenic potential, including arsenic, UVB, and antimetabolite therapy[80]. Specifically, high levels of UVB exposure appear to increase the risk of keratinocyte carcinomas in PUVA-treated patients[81]. Of note, in non-White individuals who received long-term oral PUVA therapy, an increased risk of skin cancers was not observed[82]. In a more recent update from the original PUVA study, exposure to <150 PUVA treatments had, at most, modest effects on SCC risk and even high-dose exposure to PUVA did not greatly increase BCC risk[83].

According to a single study, the genitalia of male patients previously treated with tar and UVB appeared to be particularly susceptible to the carcinogenic effects of PUVA[84], but the risk seemed not to be increased if there had only been exposure to PUVA[85]. In a retrospective study from France comprised of 5400 patients treated between 1978 and 1998, no case of genital skin cancer was found, despite the fact that the genital area had not been protected during UVA exposure, raising the question as to whether genital shielding is absolutely necessary[86]. No increased risk of cutaneous carcinoma has so far been reported for patients treated with PUVA for vitiligo.

Only a few anecdotal cases of cutaneous melanoma have been described in long-term PUVA-treated psoriatics, and, to date, with one exception, no increased risk of melanoma has been observed in any reported large-scale study. However, Stern et al.[87] reported on the cohort of 1380 patients enrolled in the PUVA Follow-up Study (16-center study), and since 1975, 23 patients had developed 26 invasive or *in situ* cutaneous melanomas. Beginning 15 years after the initial exposure to PUVA, an increased risk of melanoma was observed in their cohort of PUVA-treated patients. However, the lead author concluded that perhaps PUVA has been judged unfairly. Its long-term risks have been subject to much greater scrutiny than the risks of other therapies utilized for severe psoriasis, such as methotrexate and particularly immunosuppressive therapies such as cyclosporine (CSA). Notably, several other US studies, as well as European studies, have not observed an increased risk of melanoma in patients treated with PUVA[88,89].

An increased risk of cutaneous SCC has been observed in solid organ transplant recipients who have received long-term CSA and in patients who have received CSA subsequent to PUVA therapy[90]. UVA-sparing, aggressive regimens without prolonged maintenance therapy may be safer than continuous non-aggressive regimens (see Table 134.4).

In a study of 944 Swedish and Finnish patients[91], bath PUVA with TMP appeared to have no relevant risk of carcinogenesis. In addition, no association between cutaneous carcinoma and 8-MOP bath PUVA was found in 158 Finnish psoriatic patients[92]. Perhaps related to lower cumulative UVA doses, these data on the long-term safety of bath PUVA are encouraging, but no premature conclusions should be drawn[93].

UVB and PUVA in HIV-Infected Patients

Treatment of psoriasis with oral PUVA has not induced progression of HIV disease nor was there an increase in side effects. The conclusion is that PUVA may be safe for HIV-infected patients with psoriasis. Theoretical modeling of UVB- and PUVA-induced HIV promoter activation in human skin indicated that UVB was more likely than PUVA to activate viral transcription *in vivo*. Although further studies are needed to unequivocally establish the safety of both UVB and PUVA phototherapy in HIV-associated psoriasis, the benefits are considerable, particularly in those with severe psoriasis[94].

EXTRACORPOREAL PHOTOCHEMOTHERAPY (PHOTOPHERESIS)

Extracorporeal photochemotherapy (photopheresis, ECP) was introduced in the early 1980s for the palliative treatment of erythrodermic CTCL[95]. Efficacy was observed in several uncontrolled clinical trials, and it was FDA-approved as a device in 1988 for the treatment of this disease. In 1994, at the International Consensus Conference on Staging and Treatment Recommendations for CTCL, ECP was recommended as the first line of treatment for patients with erythrodermic CTCL[96]. However, not all authorities agree (see Ch. 120).

Attempts to better characterize those CTCL patients who are more likely to respond to ECP revealed the following:

- There seems to be a significant linear association between response and CD4:CD8 ratio. Patients with a ratio <10 are more likely to respond than are patients with a ratio >10.
- There is a marginally significant linear association between response and LDH level. Patients whose LDH is not elevated at the start of treatment tend to have a better response to ECP compared to patients with an elevated LDH[97].

ECP has also been advocated for the treatment of chronic cutaneous GVHD as well as acute GVHD[98,99].

Treatment Protocols

The ECP procedure involves the passage of blood from an arm vein through a photopheresis machine and then back to the patient. Within the machine, a discontinuous flow cell separator harvests peripheral blood mononuclear cells (PBMC) within a buffy coat collection. The red cell fraction is returned to the patient without further treatment. 8-MOP solution is administered directly into the collection of the PBMC, thereby avoiding 8-MOP-induced nausea. The collection of PBMC is then exposed to 2 J/cm^2 of UVA and reinfused into the patient. This treatment is typically repeated on two successive days with 2- to 4-week intervals.

Mechanism of Action

Despite the fact that ECP has been in use for over 40 years, the mode of action still remains enigmatic. It was postulated that the response of CTCL to ECP is due to the induction of an immune response against the malignant cells. More recent experimental results suggest that infusion of autologous haptenated cells, in which apoptosis was induced by 8-MOP/UVA, induces immunologic tolerance. The nature of this tolerance is due primarily to regulatory T cells, because transfer in an animal model conferred similar protection. The demonstration of the induction of regulatory T cells may explain why, in humans, ECP exerts a beneficial effect in a wide variety of diseases which would be amenable to such activity. The generation of antigen-specific regulatory T cells may explain why generalized immunosuppression has not been noted with ECP[100,101]. Monocyte-derived immature dendritic cells may play a role as well.

Side Effects

Side effects of ECP are uncommon and consist of episodes of hypotension and vasovagal reflex due to volume shifts during treatments; the latter usually do not interfere with the treatment.

Other Indications

A number of studies have been performed in order to evaluate the efficacy of ECP in inflammatory diseases other than CTCL and chronic GVHD where autoreactive T cells play a key role. Uncontrolled clinical trials have revealed variable success in selected entities such as atopic dermatitis, systemic sclerosis, pemphigus vulgaris, and systemic lupus erythematosus[102].

Synonym: ■ Photoradiation therapy

Key features

- Photodynamic therapy (PDT) is an established, light-based therapeutic option for actinic keratoses (AKs) and superficial keratinocyte cancers, with an expanding range of applications including acne, photoaging, cutaneous infections, and vascular anomalies
- The photodynamic effect is due to photochemical reactions that generate singlet oxygen and it requires three components: photosensitizing molecules, photoactivating wavelengths of light, and tissue oxygen
- Singlet oxygen is highly reactive and initiates a series of cellular and tissue reactions that culminate in necrosis, apoptosis, and/or antimicrobial effects; host immunologic responses to singlet oxygen-altered tissue may also contribute to the overall clinical effect
- For cutaneous indications, the current standard technique is topical application of pro-photosensitizers (e.g. aminolevulinic acid and its derivatives) that are metabolized *in situ*, i.e. within the skin, to photoactive protoporphyrin IX
- Non-coherent artificial light (blue or red), daylight, or other light sources can be used to illuminate the skin and energize the photosensitizer

INTRODUCTION

Photodynamic therapy (PDT) requires the sequential administration of a photosensitizing agent that is then activated by light in order to generate singlet oxygen within biologic tissues (Fig. 135.1). Singlet oxygen is a highly reactive form of oxygen that can induce cellular necrosis and/or apoptosis while modulating a variety of biologic processes. During the latter part of the twentieth century, PDT was synonymous with the use of *systemic* photosensitizers in combination with red *laser* light to treat cancers. However, in dermatology, the practice of PDT has evolved into applying a *topical* photosensitizer precursor locally to the skin and then illuminating the treatment site(s) with artificial visible light or natural daylight.

HISTORY AND DEVELOPMENT

The photodynamic effect was originally studied in the early 1900s by a medical student who noted that cultures of *Paramecium* would die only if exposed to both an organic dye (acridine) and visible light. His professor discovered the oxygen-dependence of this effect and coined the term "photodynamic action" to describe the phenomenon. In humans, hematoporphyrin was subsequently shown by Meyer Betz to induce profound and persistent generalized photosensitivity, including when he self-injected this agent. In addition to its fluorescent properties when illuminated with a Wood's lamp, hematoporphyrin was shown to localize to neoplastic tissue and then induce tumor involution when exposed to visible light.

The modern era of clinical PDT began in the 1970s when Dougherty and colleagues combined systemically administered *hematoporphyrin derivative* with visible light to treat cutaneous and subcutaneous malignancies in humans; they also confirmed the role of singlet oxygen[1]. With the advent of lasers and fiberoptic endoscopes, the use of PDT was extended to carcinomas of the lung, bladder, and esophagus. Hematoporphyrin derivative and its subsequent porphyrin-based congeners require intravenous administration, and they induce marked generalized cutaneous photosensitivity that can last for days to weeks, necessitating strict avoidance of outdoor and bright indoor light.

Because they are relatively large molecules, porphyrins are poorly absorbed through the skin. The key breakthrough in developing PDT as a practical dermatologic therapeutic modality can be attributed to the Canadian team of Kennedy and Pottier. In the 1980s, they noted that the topical application of a naturally occurring porphyrin precursor, 5-aminolevulinic acid (ALA), as a prodrug could photosensitize the skin by inducing *local intracutaneous* production of protoporphyrin IX (PpIX; see Fig. 135.1). Their successful treatment of keratinocyte cancers[2] using topical ALA plus broadband red light abrogated the two major disadvantages associated with the use of systemic porphyrin photosensitizers (see above).

The elegance of using topical ALA for PDT lies in how it takes advantage of the endogenous porphyrin biosynthetic pathway (which is present in all nucleated cells) to generate PpIX from ALA. The simplicity of this approach greatly facilitated clinical PDT research, culminating in the FDA approval of topical ALA plus blue fluorescent light for the treatment of actinic keratoses (AKs) in 1999. Five years later, topical methyl aminolevulinate (mALA), an esterified derivative of ALA, in combination with red light-emitting diode (LED) light was approved in several countries for dermatologic PDT. It was subsequently shown that natural daylight could safely and effectively activate ALA for skin-based PDT[3].

PDT – PHOTOCHEMISTRY, PHOTOBIOLOGY, AND MECHANISM OF ACTION

PDT is somewhat analogous to PUVA (psoralen plus UVA light) therapy to the extent that both treatment modalities involve the administration of photosensitizers followed by exposure to specific wavelengths of light. Mechanistically, they involve exogenously derived photosensitizers that transfer photon energy from light to drive specific photochemical reactions within the skin. Nevertheless, there are important differences between PDT and PUVA (Table 135.1), the most fundamental of which is that, by definition, PDT generates singlet oxygen, which in turn is biologically active.

PDT Photochemistry

The transduction of energy from light to tissue can be illustrated diagrammatically by considering the resting and excited states of the molecules involved in photochemical reactions (Fig. 135.2). The photosensitizer is present within the target tissue in its ground, lower-energy resting state. Its efficiency as a chromophore for absorbing light energy

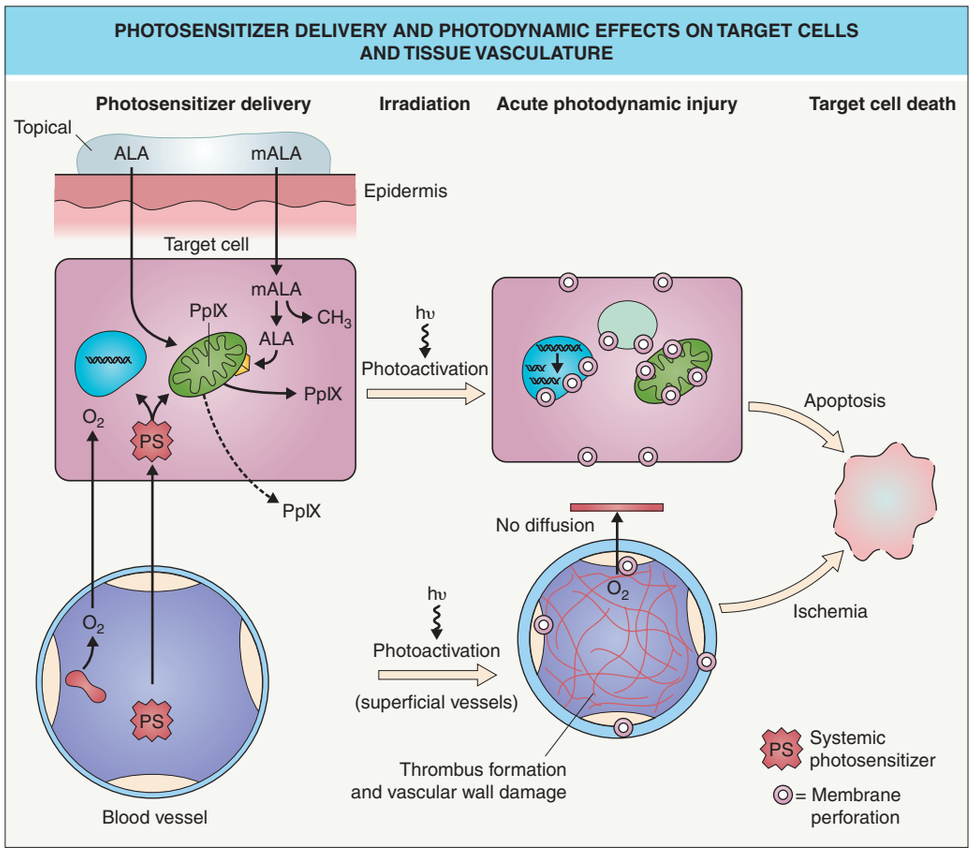

Fig. 135.1 Photosensitizer delivery and photodynamic effects on target cells and tissue vasculature. Topical photosensitizers 5-aminolevulinic acid (ALA) and methyl aminolevulinate (methyl-esterified ALA; mALA) diffuse through the stratum corneum into target epithelial cells; if systemic photosensitizers are used, they arrive through the bloodstream. Oxygen is delivered via erythrocyte circulation. ALA derived from any source is converted to protoporphyrin IX (PpIX) within mitochondria. PpIX then leaks from the mitochondria to other cellular structures. After there has been sufficient time for photosensitizer partitioning to subcellular structures, target tissue is irradiated with photoactivating light. During acute photodynamic injury, plasma and nuclear membranes lose integrity. Acute photodynamic injury within cutaneous endothelial cells leads to thrombus formation and vascular collapse. Target cell and tissue oxygen delivery cease. Both direct apoptosis and ischemic necrosis contribute to irreversible target cell injury and death.

PHOTODYNAMIC THERAPY VERSUS PUVA THERAPY

Features	PDT	PUVA
Routes of administration of photosensitizer	Topical Systemic (IV)	Topical Systemic (PO)
Photosensitizer	ALA or mALA (as prodrugs)	8-methoxypsoralen
Active form of photosensitizer	PpIX	8-methoxypsoralen
Photosensitizer activation	Visible light	Ultraviolet A
Photochemical reaction	Type II: converts O_2 to singlet O_2	Type I: covalent adducts between psoralen and DNA; non-oxygen-dependent
Relationship with skin cancer	Treats keratinocyte carcinomas	Carcinogenic
Effects of long-term use	Generally safe, can be used to treat photoaging	Skin cancer, photoaging

Table 135.1 Photodynamic therapy (PDT) versus PUVA (psoralen plus UVA light) therapy. ALA, 5-aminolevulinic acid; IV, intravenously; mALA, methyl aminolevulinate; PO, orally; PpIX, protoporphyrin IX.

is related to its absorption spectrum (Fig. 135.3). If light of an appropriate wavelength reaches the photosensitizer within tissue, photon absorption occurs and the photosensitizer is excited to a higher-energy "singlet" state. This excited singlet is short-lived, lasting nanoseconds, and then undergoes intersystem crossing to a more stable "triplet" state, which has a lifetime on the order of microseconds. The "triplet" photosensitizer can in turn transfer its stored energy to molecular oxygen, yielding singlet oxygen ($^1O_2$), and, as a result, returns to its resting ground state. Photochemical reactions that are mediated by oxygen are referred to as type II photochemical or photosensitized reactions. The singlet oxygen thus generated reacts with a variety of cellular biomolecules, including lipids, proteins, and nucleic acids.

Singlet oxygen is by no means the only active intermediate generated by the excited triplet photosensitizer; a variety of additional reactive oxygen species are also generated from molecular oxygen and undoubtedly contribute to the overall biologic effect. Being highly reactive, singlet oxygen and its related oxygen species can also chemically inactivate the photosensitizer itself by a process known as *photobleaching*, which also destroys its fluorescence properties (Fig. 135.4). This is one way by which the light exposure during PDT automatically self-limits or shuts down the overall process.

Light within the visible spectrum is typically used for PDT. This is because ultraviolet light is carcinogenic and has limited tissue penetration, while infrared radiation (>850 nm) has minimal absorption by ALA.

When PDT photosensitizers are excited to their singlet states following light absorption, they can alternatively return to their ground state via the emission of photons (see Fig. 135.2). This "re-emission" of light by the photosensitizer is termed fluorescence and the latter property permits, with Wood's lamp illumination, direct visualization of photosensitizer accumulation within tissue as well as its subsequent depletion as a result of photobleaching following therapeutic light exposure (see Fig. 135.4).

Photobiologic Mechanisms of Action

Although the precise and most relevant molecular sequence of reactions initiated by singlet oxygen has not been determined, oxidative damage (including to cellular membranes) is known to trigger cellular injury and apoptosis. For a given PDT clinical effect or indication, the specific mechanism of action depends on the target tissue, the photosensitizer and its delivery route, subcellular photosensitizer localization, and the overall drug–light dose delivered. For example, when topical ALA is applied to an epidermal neoplasm such as a superficial basal cell carcinoma (BCC), PpIX accumulates within the tumor cells themselves, with direct cytotoxicity upon light activation (see Fig. 135.1). In contrast, systemic photosensitizers are known to preferentially localize to the vascular bed of tumors. Light activation then leads to vascular collapse and ischemic tumor necrosis.

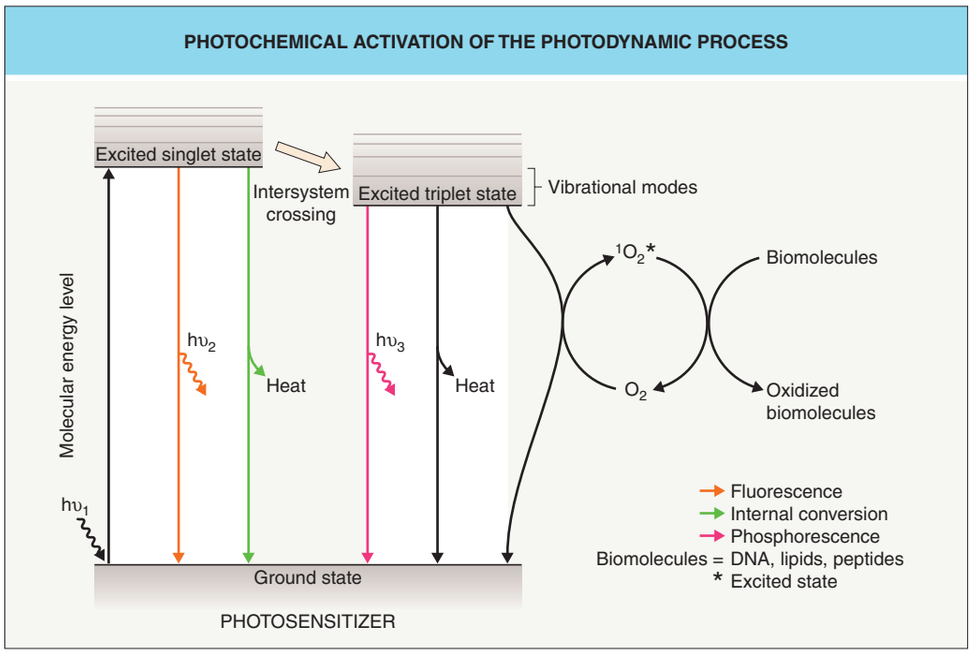

Fig. 135.2 Photochemical activation of the photodynamic process and the generation of reactive singlet oxygen: the Jablonski energy state diagram. The photosensitizer is delivered to or generated within the target tissue in its ground, lower-energy resting state. If light of an appropriate wavelength is used to irradiate the photosensitizer within tissue, photon absorption occurs and the photosensitizer is excited to a higher-energy "singlet" state. The excited singlet is short-lived, lasting nanoseconds, and then undergoes intersystem crossing to a more stable "triplet" state which has a lifetime on the order of microseconds. The "triplet" photosensitizer species can transfer its energy to molecular oxygen, yielding singlet oxygen ($^1O_2$) and as a result, returns to its resting ground state. See PDT Photochemistry section for additional details.

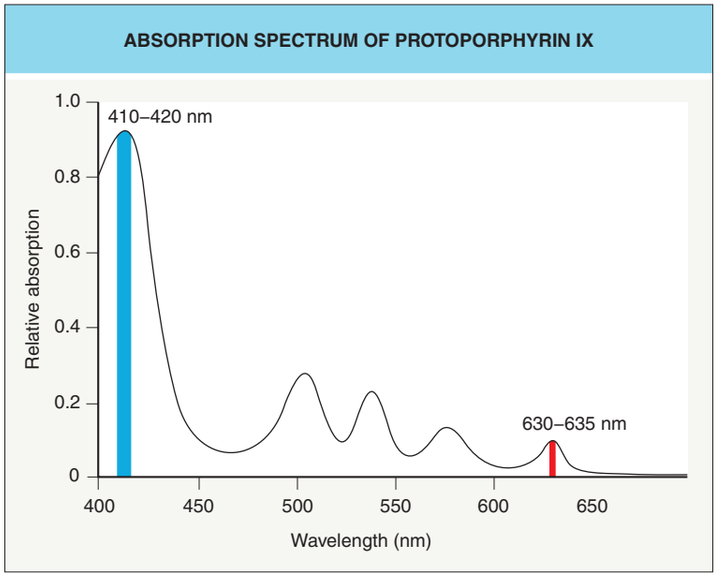

Fig. 135.3 Absorption spectrum of protoporphyrin IX (PpIX). The absorption spectrum depicts the efficiency of absorption of light as a function of wavelength. It reveals the major absorption (photoactivation) peaks of PpIX. Blue (410–420 nm) or red (630 nm) wavelengths are typically used to activate PpIX with artificial light; when daylight is used, the other PpIX absorption peaks are also activated.

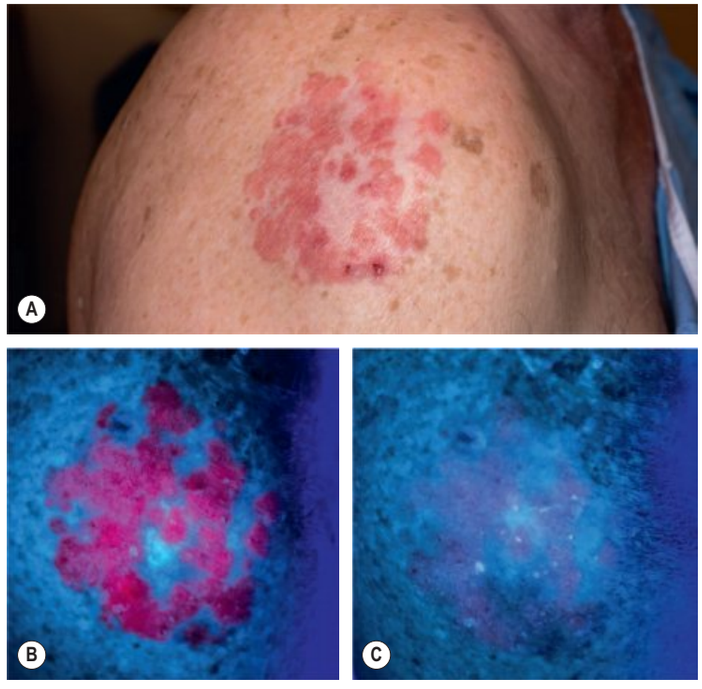

Fig. 135.4 Fluorescence of intratumor protoporphyrin IX (PpIX) when illuminated by a Wood's lamp (365 nm). A Large superficial basal cell carcinoma (BCC) of the shoulder. **B** Following application of topical methyl aminolevulinate (mALA) for 3 hours under occlusion, the BCC demonstrates selective pink-red fluorescence due to accumulation of PpIX. **C** Immediately following exposure to red light from an LED (light-emitting diode), the fluorescence almost disappears due to photobleaching.

At a high drug–light dose combination, greater levels of singlet oxygen are generated during PDT, leading to necrotic tissue damage. With lower levels of drug and/or light, damage is more limited, with predominantly apoptotic changes within cells. Because PDT is oxygen-dependent, larger targeted tumors, which can be relatively hypoxic, may be more resistant to the desired therapeutic effect.

Tissues exposed to PDT can become inflamed as a result of normal host responses to injury as well as activation of specific immunologic reactions. However, the types of immunologic reactions vary depending upon the target and mode of PDT delivery. In animal models of contact hypersensitivity, PDT suppresses local and systemic immune responses in addition to reducing epidermal Langerhans cells[4]. There is also evidence that the photosensitizers used in PDT can target activated T cells[5], providing a rationale for using PDT to treat inflammatory dermatoses or mycosis fungoides. Microbes, including viruses, bacteria, fungi and parasites, may be susceptible to singlet oxygen, and there are clinical studies attesting to the potential utility of PDT in the treatment of skin infections.

PDT Selectivity

PDT was initially conceived and developed as a method for targeted tumor destruction. Several findings help to explain this selectivity (Table 135.2). In neoplasms, where cellular metabolism is higher than normal, local factors such as enhanced perfusion, vascular and lymphatic hyperpermeability, pH, and lipoprotein receptors on target cells may lead to preferential accumulation and retention of photosensitizers within the tumor. For topical PDT, the specific site of drug application is set by the physician, thereby delimiting the area of photosensitization and treatment. Inherent differences in the permeability of skin lesions such as BCCs and AKs facilitate the selective uptake of topical ALA-like prodrugs into diseased skin.

THERAPEUTIC SELECTIVITY DURING PHOTODYNAMIC THERAPY	
Photosensitizer effects	**Light effects**
• Selective photosensitizer retention • Selective photosensitizer biodistribution and uptake • Ability to confine the area of topical photosensitizer application to lesion(s) • Incubation time of topical photosensitzer	• Spatial confinement of light exposure to the target area • Wavelength dependence for light penetration into skin • Photobleaching of photosensitizer

Table 135.2 Therapeutic selectivity during photodynamic therapy (PDT).

Selectivity is also achieved by determining the manner in which PDT light is delivered (see Table 135.2). This involves aiming the activation light at just the specific skin target (plus a limited margin of adjacent normal-appearing skin). Most clinical photosensitizers, and porphyrins in particular, exhibit multiple absorption maxima across the visible spectrum (see Fig. 135.3). Because light penetration within tissue is wavelength-dependent, the use of shorter wavelengths, i.e. blue light, will primarily limit the PDT effect to the epidermis, whereas red light will induce deeper biologic and clinical effects.

Photosensitizer localization within the skin can be readily visualized because PDT photosensitizers usually have high fluorescence quantum yields that are apparent with Wood's light examination (see Fig. 135.4). However, the intensity of this fluorescence does not necessarily correlate with the ensuing PDT reaction or ultimate clinical outcome. Following the therapeutic light exposure stage, the phenomenon of photobleaching can be confirmed visually by the absence or marked reduction of fluorescence.

Advantages and Limitations of PDT

Advantages of PDT include its relative conceptual simplicity as well as the accessibility of the skin to direct application of photosensitizing drugs and activating light. PDT photosensitizers typically have minimal dark toxicity (i.e. negligible toxicity in the absence of light) and are therefore relatively safe. PDT can also be used in patients with a variety of comorbidities, including those who are anticoagulated. PDT treatments can be repeated and there are minimal long-term side effects. Additionally, it has the advantage of being a physician-supervised therapy, which limits the effects of low adherence as can be the case with at-home topical treatments.

Nonetheless, PDT is far from a perfect therapeutic modality as it has inherent limitations. Topical photosensitization is limited by drug penetration into the epidermis and dermis, while the depth of penetration of visible light is also limited when exposure is via surface illumination. Thus, PDT is primarily useful for treating cutaneous tumors or diseases that are relatively superficial.

The multiplicity of potential drug and light dose combinations and permutations makes it complicated to determine the optimal conditions necessary for effective and safe PDT. Moreover, the literature is replete with a wide array of different reported parameters, making it difficult to standardize treatment regimens and compare clinical efficacy, even for the same indication. The commercially recommended treatment parameters are based on strict clinical trial protocols and do not provide much flexibility in terms of dosing. From the patient perspective, intraoperative local pain at the site of light exposure can be intense and even intolerable, and for many patients this represents the most significant disincentive for repeat treatments. Commercially available PDT systems (i.e. photosensitizers and artificial light sources) incur significant cost, thereby posing a practical barrier to accessing a treatment that is fundamentally based on a naturally occurring compound combined with visible light. Natural daylight activation of photosensitizers can partially circumvent the costs, pain, and apparent complexity of administering PDT.

COMPONENTS OF PDT

A range of photosensitizers have been developed and evaluated along with a multiplicity of different light sources and delivery systems (Table 135.3). The two basic pro-photosensitizers that are utilized are ALA and mALA. They were originally used with either artificial blue or red light devices. Additional light sources have been adopted and include natural daylight and investigative garments that incorporate low irradiance light-emitting diodes and are placed over the skin.

Photosensitizers

Although topical and systemic photosensitizers based on the full porphyrin structure have been developed and evaluated, to date none have become practical, either on a clinical or commercial level, for dermatologic use. Thus, for practical purposes, topical PDT relies primarily on the "ALA prodrug" approach.

ALA and mALA represent topical prodrugs that are converted within the skin into PpIX. A familiarity with porphyrinogenesis in mammalians aids in understanding the pharmacology of ALA and its congeners. ALA (5-aminolevulinic acid, δ-aminolevulinic acid) is synthesized in all nucleated cells, and it is an intermediate compound in the heme biosynthetic pathway (see Fig. 49.1); ALA synthase catalyzes the formation of ALA from succinyl-CoA and glycine. The latter reaction represents the rate-limiting step in this pathway and is inhibited by heme. When pharmacologic quantities of ALA are supplied to cells as in PDT, this regulatory step is bypassed, leading to an intracellular accumulation of PpIX, which is photodynamically active. Of note, PpIX is synthesized within mitochondria (see Fig. 135.1) and then diffuses to cellular membrane systems such as the endoplasmic reticulum and the plasma membrane.

Unlike fully formed porphyrin molecules that are relatively large, ALA is small and readily crosses the cutaneous permeability barrier via active transport mechanisms. Within the skin, the absorbed ALA induces porphyrinogenesis, thereby inducing "porphyria" at the cellular level. In some PDT applications, the skin is first prepared by gentle curettage to remove excess surface scale and crust or to remove the stratum corneum; this preparatory step can promote topical drug absorption. Within the skin, PpIX accumulates in the epidermis and sebaceous glands due to its lipophilicity.

The carboxyl moiety of ALA can be esterified by a variety of side chains, the simplest of which results in mALA. Substituted ALA congeners are absorbed into the skin by passive and active mechanisms different from those of ALA. Upon their uptake into cells, these substituents are hydrolyzed to yield free ALA (see Fig. 135.1). Both ALA and mALA are considered prodrugs or pro-photosensitizers since the skin cells themselves generate the active photosensitizer PpIX following application of these exogenous compounds.

ALA has been compounded in a variety of different vehicles for topical application and, in North America, it is currently commercially available in 10% and 20% preparations. The FDA-approved indication for ALA is treatment of AKs, although multiple off-label uses have been explored and described (Table 135.4). An incubation time allows ALA to be absorbed and converted to PpIX. When utilizing artificial light with ALA, many clinicians typically use a shorter incubation period of 1–4 hours, instead of the recommended 14–18 hours employed in the original controlled clinical trials. Pretreatment with microneedling or ablative fractional laser therapy can allow for even shorter incubation times while retaining similar efficacy in reducing AKs[6].

Mechanistically, mALA is similar in principle to ALA; it is available in a 16.8% cream formulation that must be refrigerated. The recommendation is to apply mALA for 3–4 hours under occlusion prior to exposure to red light from an LED device. It has been used for multiple different skin diseases, but depending upon the country, the approved indications include treatment of AKs and/or superficial keratinocyte carcinomas (see Table 135.4). Currently, mALA is not commercially available in the US.

Newer ALA formulations have recently been developed, including a nanoemulsion gel and an ALA-impregnated adhesive topical patch, with the latter not requiring pretreatment with curettage (see Table 135.3)[7].

Light Sources

Choosing a light source for PDT depends fundamentally on three considerations. First, the spectral output of the light should include a waveband that corresponds to one or more of the peaks in the absorption spectrum of the photosensitizer (see Fig. 135.3). Next, the desired depth of effect determines which photosensitizer absorption peak should be chosen. For PpIX, red light activation will provide a deeper clinical effect as compared to blue light. Finally, the surface area to be treated must be considered. For example, while lasers can provide precise irradiation, they may be less practical when treating broader, extensive surfaces.

COMPARISON OF ARTIFICIAL LIGHT-ACTIVATED PDT, DAYLIGHT-ACTIVATED PDT, AND ALTERNATIVE TECHNIQUES FOR PDT			
Feature	**Artificial light-activated PDT**	**Daylight-activated PDT (D-PDT)**	**Technique variations of PDT (off-label)**
Lesion preparation	• Curettage	• Application of sunscreen (15 min prior) • Curettage	• Topical keratolytics (e.g. retinoids, salicylic acid, α-hydroxy acids) • Tape stripping • Microdermabrasion • Fractional CO_2 laser • Fractional Er:YAG laser • Microneedling • Elevation of skin temperature
Drug delivery	• Topical	• Topical	• Topical • Intralesional • Intravenous • Iontophoresis • Ultrasound-assisted
Photosensitizer	• ALA 20% hydroalcoholic solution (Levulan®)* • mALA 16.8% cream (Metvixia®)*,†,‡ • ALA 10% gel (Ameluz®)*,† • ALA-impregnated patch (Alacare®)†,‡	• mALA 16.8% cream (Metvixia®) • Use of other photosensitizers for D-PDT is possible but off-label; limited published evidence	• Various other photosensitizers
Incubation time before light exposure	• ALA solution: 1–4 h (FDA-approved for 14–18 h for face and scalp, 3 hours for upper extremities; no occlusion)* • mALA: 3–4 h, under occlusion*,†,‡ • ALA gel: 3 h, under occlusion*,† • ALA patch: 8 mg/4 cm^2 apply plaster for 4 h†,‡	• Maximum 30 min, no occlusion	• Variable
Light activation	• ALA solution: blue fluorescent light (417 nm peak emission, 10 J/cm^2 [Blu-U®])* • mALA: red LED light (630 nm peak emission, 37 J/cm^2 [Aktilite®])*,†,‡ • ALA gel: red LED light (635 nm peak emission, 37 J/cm^2 [BF-RhodoLED®])*,† • 5-ALA patch: red LED light	• Daylight exposure for 2 h†	**Light sources:** • Other LED lamps • Lasers (e.g. copper vapor, KTP, pulsed dye) • Intense pulsed light • Wearable low-irradiance light source (Ambulite®) • Incandescent lamp (e.g. slide projector) • Arc lamp • Metal halide lamp • Fiberoptic probes **Light delivery:** • Fractionated (i.e. repeat) light doses within the same PDT session may enhance the effect
Pain	• Mild to severe (depending on incubation period)	• Minimal to low	• Variable

*FDA-approved; Metvixia® and Aktilite® were approved by the FDA, but are currently unavailable commercially in the US.
†Approved in multiple European countries.
‡Approved in the UK and Australia.

Table 135.3 Comparison of artificial light-activated PDT, daylight-activated PDT, and alternative techniques for PDT. ALA, 5-aminolevulinic acid; BCC, basal cell carcinoma; LED, light-emitting diode; mALA, methyl aminolevulinate.

Artificial light sources (conventional PDT)

The use of artificial lamps can be referred to as "conventional PDT". Light-emitting diodes (LEDs) and blue fluorescent lamps have been the most commonly employed and approved artificial light sources for PDT (see Table 135.3). In general, these commercial devices are relatively simple to use and can be powered by standard electrical outlets.

Off-label light sources have also been used for PDT. Lasers (e.g. copper vapor, KTP, pulsed dye) may be as effective as non-coherent artificial lights for PDT[8]. However, they are significantly more expensive, more complex to operate, and less studied. Intense pulsed light (IPL) has also been used as an artificial light source for PDT[9]. Adhesive light-emitting patches[10] and fabric garments with incorporated lights[11] have been designed to be worn by patients, and because they operate at low irradiances, there may be less pain associated with these devices.

Natural outdoor light (daylight PDT; D-PDT)

Studies have shown that natural outdoor light may be used for "daylight PDT (D-PDT)". Drug activation occurs because this light includes all the appropriate activating wavelengths. The main apprehension with daylight activation is the inability to precisely control the light dose delivered to the skin, with the possibility of phototoxicity from overexposure or lack of efficacy due to underexposure. However, randomized controlled trials have demonstrated both safety and efficacy of daylight-activated PDT (DA-PDT). Specifically, non-inferiority for effective treatment of AKs and superiority in degree of associated pain were demonstrated in a split-face trial of daylight- versus red light-activated PDT[3].

Although not yet FDA-approved, D-PDT has several practical and safety advantages. There is no requirement for a specific topical drug incubation time since patients are typically exposed to outdoor light immediately after drug application. Patient self-exposure to ambient outdoor light eliminates the requirement for staff to operate a specialized device and, perhaps most importantly, the level of PDT-related pain is much reduced with D-PDT. Published measurements of daylight doses in various cities can help clinicians identify months in which there is sufficient outdoor light to effectively administer D-PDT in their locale[12,13]. As a general rule, if the latitude is <45° (as in most of the US, southern Europe, South America, and Australia), PDT can be done year-round depending on weather conditions[14]. At higher latitudes in the northern hemisphere, it might be preferable to avoid daylight PDT from October to April. Of note, direct sunlight exposure to the skin is not necessary for daylight PDT. Lastly, non-mineral, untinted sunscreens applied to provide daylight UV protection do not interfere with the absorption of visible light by PpIX.

Light delivery

Regardless of the specific light source, the PDT light dose is measured and delivered in a manner analogous to conventional phototherapy. The ***irradiance*** of the light source is specified in units of W/cm^2, which represents the power density per unit area. Irradiance depends on the light source itself, and it can vary based on the lamp's age, overall operating conditions, and the distance from the lamp to the skin target. For D-PDT, irradiance is affected by geographic location, season, time

PHOTODYNAMIC THERAPY – DERMATOLOGIC APPLICATIONS	
FDA-approved indications	
Actinic keratoses of the face and scalp (ALA solution/blue light or ALA gel/red light) Actinic keratoses of the upper extremities (ALA solution/blue light)	
Off-label* applications with controlled studies demonstrating efficacy	
Actinic keratoses (including D-PDT and PDT of sites other than the face, scalp, and upper extremities) Superficial basal cell carcinoma Squamous cell carcinoma *in situ* (Bowen disease) Prevention of keratinocyte carcinomas	Acne Photoaging Verrucae vulgares Condylomata acuminata Leishmaniasis
Off-label applications for which PDT is *not* considered first-line therapy	
Actinic cheilitis Porokeratosis Sebaceous hyperplasia Nodular basal cell carcinoma Extramammary Paget disease Cutaneous metastases Capillary malformations (port-wine birthmarks)	Rosacea Psoriasis Hidradenitis suppurativa Necrobiosis lipoidica Chronic ulcers Superficial fungal infections
Diseases for which PDT is *not* generally recommended	
High-risk basal cell carcinoma Invasive squamous cell carcinoma	Melanoma
*Per the FDA.

of day, cloud coverage, humidity, and air pollutants. The light dose used to activate the photosensitizer is also known as the ***fluence*** and is measured in J/cm^2. The ***exposure time*** in seconds required to deliver a specified fluence can be determined from the formula:

$$\text{exposure time (seconds)} = \frac{\text{fluence (J/cm}^2\text{)}}{\text{irradiance (W/cm}^2\text{)}}$$

PDT Dosimetry

Although PDT is deceptively simple in concept, there are multiple considerations when determining the appropriate doses of photosensitizer and light. Current clinical PDT dosing guidelines have been determined by systematic as well as semi-empiric clinical investigations; nevertheless, they are based on several basic concepts unique to PDT. The net production of singlet oxygen depends on both the amount of photosensitizer and the fluence of light delivered to the target. A certain degree of reciprocity (i.e. inverse relationship) exists between these two components, in that a high photosensitizer level combined with a low fluence can in theory produce an equivalent amount of singlet oxygen as a low concentration of photosensitizer activated by a high fluence.

Another important limit to the principle of drug–light dose reciprocity relates to the irradiance of the activating light. At very high irradiances, there is significant heat production due to both non-radiative photosensitizer absorption/relaxation and nonspecific light absorption by other tissue chromophores. This leads to photothermal effects superimposed on the PDT process itself. At lower irradiances, however, there is evidence that the pain associated with PDT might be reduced[15]. In D-PDT, the reduced pain may be due to the lower irradiance and longer gradual exposure to natural outdoor light as compared to artificial lamps (i.e. hours versus minutes).

An interesting and useful variation in light delivery is to fractionate the total light dose into a series of two or more separate exposures, each punctuated by defined pauses. The potential net effect of fractionating the light dose is to achieve a greater overall PDT effect without applying more drug[16,17]. Mechanistically, there are several reasons why this can happen. During PDT, molecular oxygen is consumed, and a pause in light exposure allows oxygen to be replenished via vascular reperfusion and diffusion. Likewise, this pause may also allow more PpIX photosensitizer to be synthesized *de novo* from the residual ALA that may still be present within viable skin cells; unlike PpIX, ALA itself does not undergo photobleaching.

Other factors that can influence the PDT effect include the duration of incubation between drug application and light exposure. A longer incubation interval for topical ALA or mALA leads to greater accumulation of active photosensitizer in the skin prior to light exposure. With D-PDT, the incubation period is intentionally minimal since patients are typically instructed to go outdoors immediately after the topical agent is applied. In this way, PpIX is gradually activated as soon as it is synthesized in the skin, which is another reason why there is less overall treatment pain with D-PDT.

DERMATOLOGIC APPLICATIONS

PDT agents can photosensitize neoplastic, inflamed, and vascular tissues, modulate immunologic processes, localize to the pilosebaceous unit, and induce lethal damage to microbes. To date, good-quality clinical evidence outside of cutaneous oncology is limited; for the most part, non-oncologic uses of PDT are off-label or investigational. Dermatologic applications for PDT are summarized in Table 135.4.

Oncologic

PDT is an accepted and approved treatment for AKs. There are also multiple controlled trials on the use of topical PDT for superficial carcinomas such as superficial BCC and Bowen disease (squamous cell carcinoma *in situ*) with licensed approvals varying according to country. PDT is not indicated for cutaneous melanoma.

Based on biophysical considerations alone, AKs can be treated with either blue or red light, whereas red light should be used for superficial keratinocyte carcinomas because of its deeper tissue penetration. Multiple studies have documented that cosmesis following PDT can be superior to that following conventional therapies[18]. PDT may be particularly practical and well suited for patients with multiple synchronous AKs or larger, superficial keratinocyte carcinomas, as well as those with evidence of field cancerization. A single PDT session may be sufficient for AKs, with retreatment if required, whereas at least two separate PDT sessions are usually recommended for the treatment of superficial BCC and Bowen disease.

Actinic keratoses

Clinical trials have demonstrated that up to 90% of face and scalp AKs can be cleared with topical PDT (Fig. 135.5), with a one-year sustained clearance of ~80%[19]. ALA and mALA appear to have similar clearance rates[20]. The PDT clearance rate is superior when compared to cryotherapy, 50% trichloroacetic acid, topical diclofenac, and CO_2 laser[21–24], but less effective than topical 5% 5-fluorouracil; it is comparable to topical imiquimod for AKs on the head[25]. PDT combined with imiquimod is more effective than either treatment alone[26], and fractionation of light exposures is associated with improved outcomes[17].

On acral sites, cryotherapy may perform better than PDT (88% vs 78% clearance in one study)[27], which in turn may clear more lesions than imiquimod (58% vs 37%)[28]. Patients also report higher satisfaction with PDT than with imiquimod[29]. Resistance to PDT may be explained by the hyperkeratotic nature of AKs in acral sites, thus making them more difficult to eradicate due to drug and light penetration issues. Consequently, prior to PDT, gentle curettage debridement of scale is often recommended. Several other methods for lesion preparation to enhance PDT efficacy have been described (see Table 135.3). For hypertrophic AKs, multiple treatment sessions may be required to achieve a satisfactory overall result. PDT can also be used in combination or sequentially with other topical treatments for AKs.

In solid organ transplant recipients, the response rate to PDT appears to be lower than in immunocompetent patients (48% vs 72%)[30]. This supports a role for immune activation as part of the mechanism of action of PDT. That said, possibly due to its major effect being direct cytotoxicity, PDT has been shown to be superior to topical 5-fluorouracil or imiquimod for clearance of AKs in transplant recipients[31].

Daylight treatment of AKs has been studied extensively. In randomized controlled trials, mALA D-PDT for AKs was as effective, less painful, and scored higher for patient satisfaction compared to red LED-activated mALA PDT[3,32]. In general, two hours of daylight exposure are sufficient to deliver an effective light dose throughout the year at latitudes <45° (see above regarding higher latitudes)[14,33]. As expected, mALA D-PDT clears

Fig. 135.5 Photodynamic therapy (PDT) of facial actinic keratoses and photoaging. A Pretreatment. **B** Following 3 monthly PDT sessions utilizing topical methyl aminolevulinate (mALA), clearing of actinic keratoses and a smoother, more even skin surface texture and color. *Courtesy Luis Torezan, MD.*

Fig. 135.6 Photodynamic therapy (PDT) of a large superficial basal cell carcinoma (BCC). A Superficial BCC measuring 11.5 by 9 cm on the upper abdomen. **B** Six months following 6 sessions of PDT using topical methyl aminolevulinate (mALA) followed by irradiation with red light from an LED (light-emitting diode), there is complete clinical clearing (closer view).

thin AKs more readily than hypertrophic AKs[34]. D-PDT with either mALA or ALA nanoemulsion gel have been used successfully to treat AKs[35].

Actinic cheilitis represents a useful potential PDT application since alternative treatment approaches such as surgical vermilionectomy or laser vaporization are more complicated and have associated morbidities[36].

Basal cell carcinomas (BCCs)

Superficial BCCs respond well to PDT, with an expected primary clearance rate of 92%–97% at 12 weeks and 9% recurrence rate at 12 months (Fig. 135.6)[37,38]. Although less effective than surgery, PDT has the advantage of improved cosmetic outcome over both surgery and cryotherapy. Longer term follow-up with a two-session protocol found that the 5-year response rate for imiquimod (80%) was superior to either 5-fluorouracil (70%) or PDT (63%) for clearance of superficial BCCs[39]. More than one session of PDT is recommended to treat a given BCC and two separate illuminations per treatment session (fractionation) increases the long-term clearance rate[16].

Nodular BCCs do not appear to be as well suited to PDT in that lower and variable response rates of 35%–90% have been observed[40]. This type of BCC is best treated surgically when possible. Similarly, difficult-to-treat BCCs (e.g. high risk areas of the face, recurrent, sclerosing type) are probably best treated by Mohs micrographic surgery because of the importance of achieving deep margin control. Multiple superficial BCCs arising in the context of cancer-prone genodermatoses such as basal cell nevus syndrome are a good indication for PDT since multiple lesions can be treated during one session and multiple surgeries thereby minimized[41].

D-PDT has also been studied for the treatment of superficial and nodular BCCs, with ~75% of lesions treated with two sessions having a complete response at 12 months[42]. Because daylight activation of photosensitizers may be due predominantly to the superficially penetrating blue wavelengths within natural outdoor light[13], it is not yet known if daylight is a sufficiently effective light source for treating BCCs.

Squamous cell carcinomas (SCCs)

Bowen disease is confined, by definition, to atypical keratinocytes that span the entire epidermis, and is thus eminently within the therapeutic range of PDT. Many PDT experts consider Bowen disease to be an ideal application since PDT can be used to treat multiple lesions as well as large, extensive plaques. A PDT clearance rate for Bowen disease of ~90% can be achieved with a 2-year sustained clearance rate of ~70%[43]. For clearance of Bowen disease, PDT outperforms topical 5-fluorouracil, imiquimod, and cryotherapy[44,45]. Bowen disease of the anogenital region and lower extremity can also be an appropriate target for PDT. In the case of lower extremity Bowen disease, a single session of ablative fractional laser-assisted PDT demonstrated superior long-term efficacy compared to two standard mALA sessions, with a 5-year clearance rate of 85%[46]. In this setting, the fractional laser is not used for photosensitizer activation, but rather for treatment site preparation prior to topical drug application (see Ch. 136). PDT is not recommended for recurrent Bowen disease or microinvasive or invasive SCC[43].

PDT photochemoprevention of AKs and keratinocyte carcinomas

PDT is an effective intervention for managing field cancerization beyond just clearing visible AKs. There is increasing evidence that skin sites treated with topical PDT may develop new lesions at a slower rate, raising the possibility of a photodynamic prevention effect[47]. Photochemoprevention with PDT may prove especially beneficial in reducing the incidence of AKs and SCCs in solid organ transplant recipients, particularly when periodic "maintenance" PDT is performed[48].

Extramammary Paget disease

Treatment of *in situ* extramammary Paget disease is complicated given the difficult anatomic locations of these lesions, the high recurrence rate due to unpredictable subclinical and adnexal extension, and significant

morbidity. Although PDT is a potential treatment that would allow anatomic preservation, variable success has been reported; the absence of conclusive evidence precludes its recommendation as first-line therapy.

Other neoplasms

Because activated and malignant T cells can be selectively sensitized by exogenous ALA, PDT has been used to treat the mycosis fungoides form of cutaneous T cell lymphoma[49]. Patch- or plaque-stage lesions may be more responsive than tumor-stage mycosis fungoides. While PDT's historical roots in dermatology lie in its initial use during the 1970s to treat intracutaneous metastases[1], it is now widely accepted that PDT is far more appropriate for treating superficial carcinomas rather than advanced disease.

Non-Oncologic PDT Applications

Acneiform disorders

Not only did early studies demonstrate that exogenous ALA could induce PpIX formation within the skin, they also noted the preferential accumulation of active photosensitizer and selective phototoxicity within the pilosebaceous unit. In addition, singlet oxygen exerts antibacterial and anti-inflammatory effects. These effects, in addition to antibiotic resistance and the challenges surrounding the use of oral isotretinoin, have provided an impetus to developing PDT regimens for acne. A reduction in inflammatory acne lesions of 60%–70% was reported with both ALA and mALA PDT, with the two photosensitizers producing similar effects. Use of higher red light fluences and longer incubation times are associated with longer remission, but also with more pain and local reactions[50] (Fig. 135.7). Currently, there is no consensus as to the optimum PDT parameters for treating acne.

It should be noted that *Cutibacterium* (formerly *Propionibacterium*) *acnes* produces cutaneous porphyrins, which can be readily demonstrated with Wood's lamp examination of any sebaceous-dense area, including normal skin. Exposure to high-intensity blue light alone, in the absence of any exogenous PDT prodrug, can lead to clinical improvement of inflammatory acne lesions.

PDT has also been used to treat other acneiform disorders. It was superior to topical 1% clindamycin for the treatment of perioral dermatitis in a small split-face trial[51]. Rosacea and hidradenitis suppurativa represent other diseases for which PDT was reported as being useful[52,53]. In patients with rosacea, ALA-PDT reduced papulopustular lesions as well as flushing, pruritus, burning, and prickling sensations.

Fig. 135.7 Use of photodynamic therapy (PDT) for moderate but recalcitrant acne vulgaris. This patient declined the use of oral isotretinoin and had failed therapy with topical agents and oral antibiotics. **A** Baseline. **B** Three days after PDT utilizing topical 20% 5-aminolevulinic acid (ALA; 3 hours incubation) followed by irradiation with red light from an LED (light-emitting diode; 630 nm; 37 J/cm^2; 70 mW/cm^2); intense inflammation and pustulation is limited to treated sites. **C** Two months after single treatment session.

Photoaging

When used to treat AKs and keratinocyte carcinomas, PDT is thought to produce cosmetically favorable results, including improvement of sun-damaged skin. Well-designed trials directly comparing PDT to non-PDT treatments in which photoaging is the primary focus are sparse relative to the extent that this treatment approach is promoted and used in clinical practice (see Fig. 135.5). A randomized trial of repetitive D-PDT to prevent AKs found a significant reduction in fine lines, pigmentation, skin roughness, and erythema[54]. Optimal PDT parameters for treatment of photoaging have not yet been determined. Histologically, PDT appears to increase collagen deposition and decrease elastosis[55].

Cutaneous infections

There are several mechanisms by which PDT can treat infectious diseases. Singlet oxygen may directly destroy microbes or it may activate host immunologic reactions against the microorganisms. In addition, PDT can induce necrosis of infected tissue, for example, in the treatment of verrucae or condylomata. Conditions that have been shown, in controlled trials, to improve with PDT include verrucae vulgares[56], condylomata acuminata[57], and leishmaniasis[58]. The emergence of drug-resistant bacteria plus the need for better antibiotic stewardship have also motivated investigations into employing PDT for bacterial skin infections and colonized chronic leg ulcers[59]. In addition, PDT has been used on superficial fungal infections such as tinea pedis and onychomycosis.

Vascular anomalies

Systemic photosensitizers are biodistributed via the peripheral circulation and it stands to reason that intravascular drug activation with light would be useful in inducing the involution of abnormal vascular structures. Vascular malformations such as port-wine birthmarks have been shown to respond to systemic PDT with results that appear to be at least equivalent to those achieved with conventional pulsed dye laser therapy[60]. Experience with this technique is largely from China, where hematoporphyrin-type preparations are used systemically. Topical ALA/pulsed dye laser-activated PDT has also been described[61], taking advantage of combined photodynamic and photothermal effects.

ADVERSE EFFECTS AND COMPLICATIONS OF PDT

Neither PDT photosensitizers nor artificial visible light ordinarily possess significant inherent toxicity, and the adverse effects related to PDT are largely an extension of the photochemical and photobiologic reactions that are generated by reactive oxygen moieties. Interestingly, erythropoietic protoporphyria and X-linked dominant protoporphyria could be considered possible toxicity models for ALA and its congeners since they result in constitutive overaccumulation of PpIX.

Photosensitivity

With topical PDT, photosensitivity manifests as varying degrees of local erythema, edema, and/or blistering of any exposed site, with subjective symptoms of pain or a burning sensation. Conventional chemical sunscreens, even those with a high sun protection factor, are not useful in managing local photosensitivity since the action spectrum extends throughout the visible spectrum, which is not blocked by these sunscreens.

Pain

The incubation period, which follows application of the topical photosensitizer, is generally uneventful, but within seconds to minutes of illumination of the skin with artificial light, patients will often experience a range and series of unpleasant sensations at the site of light exposure. Various terms are relayed by patients to describe these sensations, including pain, warmth, burning, stinging, smarting, and

stabbing. The intensity will usually build with time and there can be spread of the discomfort beyond the actual treatment field. Studies of factors associated with this pain have found inconsistent associations, including older age, treatment of AKs or well-innervated areas like the face and scalp, size of the treatment area, skin phototypes I–II, use of ALA as the photosensitizer, and intensity of ALA-induced fluorescence[62].

The rate of light delivery can influence the degree of pain, with lower irradiances being more tolerable[15]. In D-PDT, a lower irradiance is used for photosensitizer activation and this technique is associated with significantly less pain[3]. Other potential strategies for modifying irradiance include increasing the distance from the light source and the use of low-irradiance, portable LED sources[10,11]. Sometimes, temporary interruption of the artificial light exposure will allow the pain to dissipate temporarily.

A variety of practical strategies have been designed to manage the pain of PDT (Table 135.5). Of note, topical anesthesia with eutectic

STEPS IN ADMINISTERING TOPICAL PHOTODYNAMIC THERAPY AND PRACTICAL CONSIDERATIONS
Preoperative phase

• Confirm that the patient is a good candidate for PDT: appropriate indication, assess comorbidities; consider PDT especially in the setting of:
  • Field cancerization
  • Multiple synchronous or metachronous superficial tumors
  • Skin cancer-prone genodermatosis
  • Solid organ transplant recipient
• Select treatment site(s) and confirm diagnosis by histologic examination if necessary
• Exclude contraindications: porphyria, photosensitivity disorder, pregnancy, photosensitizer hypersensitivity
• Provide patient with counseling and education in terms of expectations and precautions
• Determine the photosensitizer, light source, and treatment parameters that will be employed
• Determine the number of PDT sessions to be given, the number of light exposures per session (fractionation), and the time interval; for keratinocyte carcinomas, two separate PDT sessions one week apart are recommended
• Check weather report (temperature, precipitation) if daylight-activating PDT is to be used

Intraoperative phase
Topical drug application
• Confirm treatment site(s) • Consider degreasing the treatment surface with topical acetone or by microdermabrasion • Apply chemical sunscreen to all exposed skin (daylight-activating PDT only) • Prepare treatment site(s): most commonly by gentle curettage of excess stratum corneum or scale-crust if appropriate; consider using microneedling or fractional laser • Apply topical photosensitizer to the target treatment site(s); occlusion and coverage by opaque material are optional • Incubate the photosensitizer according to the indication, specific prodrug, and light source to be used
Light administration/drug activation

• Non-coherent artificial light activation
  • Remove any residual topical medication prior to light exposure
  • Confirm the presence of PpIX fluorescence by Wood's lamp examination (optional)
  • Provide protective eyewear to patient and staff
  • Position patient and lamp(s) for uniform exposure and patient comfort
  • Confirm light dose to be given, and then initiate light exposure (typically 5–15 minutes depending on the light source); a healthcare professional can assist with pain management during the light exposure if necessary (see below)
• Daylight (outdoor) activation
  • Confirm the field area to be exposed to daylight
  • Provide timer and monitor treatment duration during light exposure (~2 hours)
  • Periodically verify tolerance of treatment with patient
  • Cleanse treatment area upon return to the clinic to remove any residual topical photosensitizer
• At the completion of the light exposure, confirm photobleaching of PpIX by Wood's lamp examination (optional)

Pain management during light exposure

• Assemble tools and devices for pain control
• The physical presence of a healthcare professional is very important for providing reassurance and monitoring; verbal reassurance and distraction, especially during artificial light-activated PDT
• Reinforce to the patient that the sensation of pain indicates that the appropriate PDT reactions are occurring
• Additional specific strategies for managing pain may include:
  • Applying an ice cube or ice pack near the treatment site
  • Spraying cold water over the treatment site
  • Providing a fan that can be held by the patient
  • Directing forced cold air toward the treatment site
  • Interrupting the light exposure temporarily
  • Infiltration, nerve block, or tumescent local anesthesia
  • Hypnosis
  • Nitrous oxide/oxygen mixture inhalation
  • Transcutaneous nerve stimulation

Postoperative phase
• Reduce swelling by using ice packs • Prescribe oral analgesics to be taken if necessary • Recommend avoidance of sun exposure and bright indoor light for 48 hours • Arrange follow-up, including next PDT session if appropriate; for keratinocyte carcinomas, a repeat course/cycle of PDT may be appropriate 2–3 months after the first course/cycle if there is clinical evidence of residual disease • If lesion recurs despite multiple treatment cycles, consider alternate treatment (e.g. surgery, radiotherapy)

Table 135.5 Steps in administering topical photodynamic therapy (PDT) and practical considerations. ALA, 5-aminolevulinic acid; LED, light-emitting diode; mALA, methyl aminolevulinate; PpIX, protoporphyrin IX.

mixture of lidocaine 2.5% and prilocaine 2.5% (EMLA®), morphine gel, tetracaine gel, or capsaicin cream is generally ineffective. Moreover, in one trial, there was no difference between placebo and oxycodone plus acetaminophen in time to pain onset and level of pain[63]. Scalp nerve blocks appear superior to intravenous analgesics and forced cold air[64]. For some patients, the pain can be so intense that they will not be willing to undergo any more than one treatment session.

Inflammation

At the end of the light exposure, the treated site will usually exhibit an immediate wheal and flare reaction. Over the next 24–48 hours, localized phototoxicity may manifest as edema, induration, urticaria, purpura, pustules, and blistering, along with exudation and crusting (Fig. 135.8). Depending on the indication and the PDT drug–light dose, frank tissue necrosis may supervene accompanied by erosions and ulceration. Local reactions can evolve over the ensuing 1–4 weeks and any wounds will heal by second intention.

For the treatment of AKs, cutaneous application of mALA for 30 minutes (rather than the recommended 3 hours) and/or pretreatment with superpotent topical corticosteroids led to reduced cutaneous inflammation but equivalent efficacy[65]. D-PDT typically generates local reactions that are milder and of shorter duration.

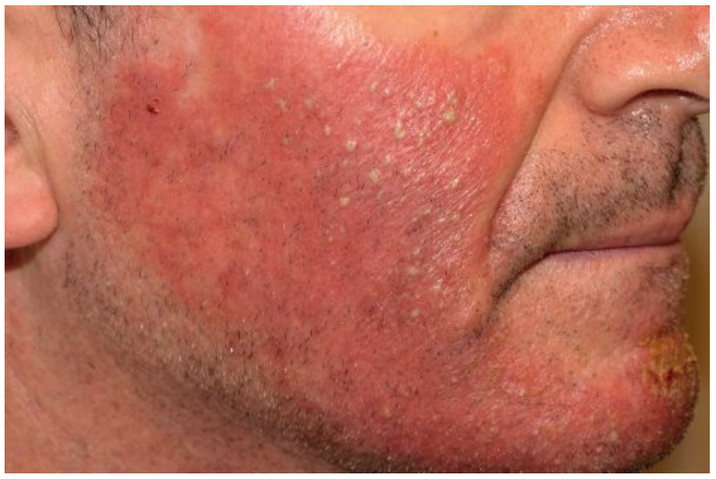

Fig. 135.8 Erythema, edema, and multiple pustules 4 days after photodynamic therapy (PDT) for actinic keratoses. Topical 20% 5-aminolevulinic acid (ALA) was followed by irradiation with red light from an LED (light-emitting diode).

Photosensitizer Allergy

Multiple case reports have documented contact hypersensitivity to mALA. In a controlled trial, contact sensitization to mALA was observed in as many as 35% of patients who had *previously* undergone five or more mALA-based PDT sessions; only 1.7% of the control subjects who had not previously undergone PDT demonstrated sensitization[66].

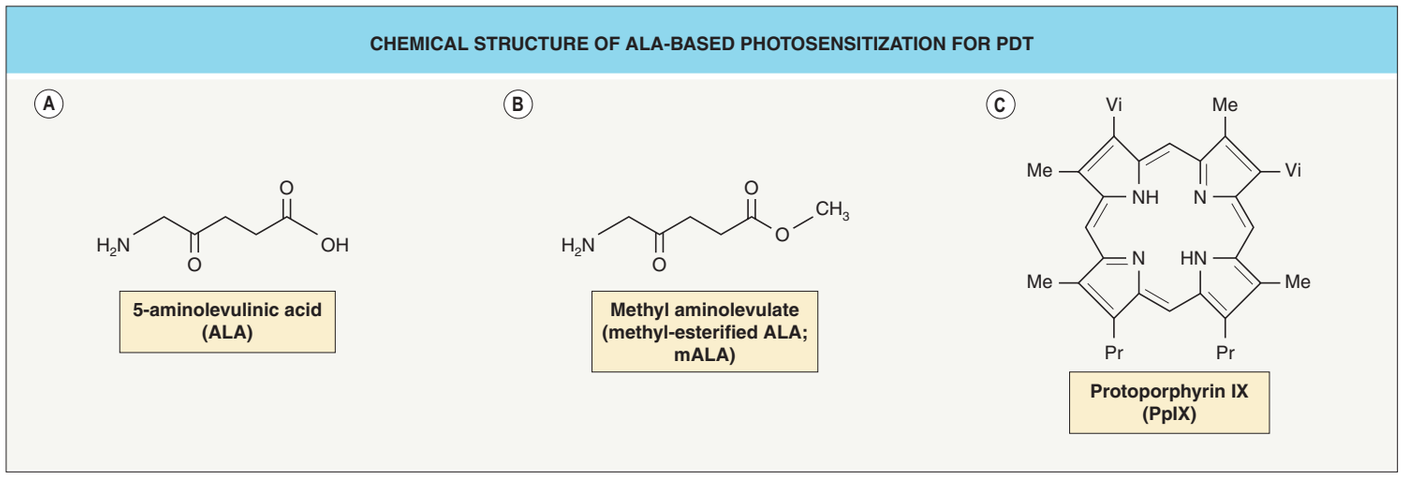
Rare, Unusual or Controversial Reactions

Exceptionally, PDT has been reported to precipitate herpes simplex reactivation[67], facial nerve palsy, hypertensive crisis, alopecia, localized bullous pemphigoid, pityriasis rubra pilaris, erosive pustular dermatosis of the scalp, and transient memory impairment. Cases of keratinocyte carcinomas recurring with more aggressive histology[68], arising *de novo*[69], or progressing within PDT fields have been reported; melanomas have also been reported following PDT, but the significance of these findings is difficult to interpret in the absence of control data.

PRACTICE AND TECHNIQUES

The practical administration of PDT requires attention to a number of details during the preoperative, intraoperative, and postoperative stages (see Table 135.5). Although the commercial PDT systems for dermatology come with officially recommended and approved protocols, the practice of PDT is not uncommonly off-label, both in terms of indications and specific procedural steps guided by the individual practitioner's experience and empiric preferences. One round of topical drug plus light (administered as a single exposure or as multiple fractionated exposures) can be considered a single PDT session. A "course" or "cycle" of PDT may involve one or more individual PDT sessions separated by a set time interval. What should not be underestimated is the time and staffing necessary to provide appropriate patient counseling and education as well as intraoperative support and supervision during the light exposure phase. Consensus recommendations and guidelines from various expert groups and dermatologic societies have been published to guide the use of PDT[13,70,71].

FUTURE DIRECTIONS



Controlled trials and cumulative clinical experience continue to redefine the spectrum of PDT applications. On the horizon are new photosensitizers and novel ways of delivering ALA. Knowledge gained from D-PDT, including less associated pain, has led to investigations in which low irradiance LED sources are used instead of conventional light sources. Advances in PDT have been accompanied by progress in imaging techniques such as confocal reflectance microscopy. Combination of the two in the future could lead to noninvasive diagnosis and delineation of cutaneous carcinomas as well as treatment and long-term evaluation.

Acronym: ■ LASER – light amplification by stimulated emission of radiation

Key features

- Laser surgery works via precise tissue heating when optical energy is absorbed within the skin
- Heat is created exactly where light is absorbed by molecules called chromophores
- The major chromophores for visible and near-infrared light are melanin and hemoglobins; water and fat are major mid- and far-infrared chromophores
- Red and near-infrared wavelengths are deeply penetrating
- Wavelength(s) of lasers or intense pulsed light (IPL) sources are often matched for absorption by chromophores in skin targets such as blood vessels, hair follicles, melanin-containing cells, tattoo ink, or tissue layers
- Selective heating and damage of targets can occur when a pulse of selectively absorbed light is delivered faster than the targets can cool by heat conduction
- The time for a tissue target to cool is its thermal relaxation time, equal in seconds to approximately the square of the target size in millimeters
- Very short (nanosecond) laser pulses, produced by Q-switched lasers, and picosecond laser pulses can precisely damage small targets such as individual melanocytes and tattoo ink particles
- Millisecond lasers and IPL sources selectively affect multicellular targets such as blood vessels, hair follicles, and tissue layers
- Fractional laser treatments create an array of microscopic thermal injury zones
- Radiofrequency electrical current, traditionally used for skin surgery, has been re-configured for a esthetic applications
- High-intensity, focused ultrasound can heat a precise focus within or below the skin
- By crystallizing lipids, controlled cooling (cryolipolysis) can reduce localized subcutaneous fat
- Laser microscopy of intact living skin is an emerging diagnostic tool

INTRODUCTION

The last century took us from Einstein's insight into the quantum nature of light, to the invention of the ruby laser in 1960, to the wide spectrum of lasers available today. In particular, the principle of selective photothermolysis guided the development of pulsed lasers that target specific skin structures such as blood vessels, melanosomes, tattoo ink, and hair follicles. Flashlamps, also called intense pulsed light (IPL) sources, can mimic these lasers to some extent. In contrast, fractional photothermolysis uses thousands of microscopic zones of thermal injury to stimulate skin remodeling. Additional energy-based technologies include focused ultrasound, radiofrequency electric current, pulsed electromagnetic field therapy, and controlled skin cooling. The field of energy-based treatments is dynamic, and a steady source of innovation.

LASERS

LASER is an acronym for *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation. It is a physical process that can be explained by Einstein's principles of electromagnetic radiation[1]. The quantum unit of electromagnetic energy is a photon, and stimulated emission occurs when one photon stimulates an excited atom to emit a second, identical photon. The idea of lasers was envisioned by Charles Townes and colleagues[2], and in 1960 the first laser, utilizing a flashlamp-excited ruby crystal, was introduced[3]. Soon thereafter, Leon Goldman[4] initiated dermatologic applications of laser technology.

All lasers have four essential components (Fig. 136.1): (1) a gas, liquid, or solid medium that can be excited to generate light (Table 136.1); (2) a source of "pump" energy for exciting the medium; (3) mirrors at the end(s) which form an optical cavity that favors the amplification process; and (4) a delivery system. Light is amplified as it travels back and forth between the laser's mirrors thereby generating a very high intensity laser beam.

Laser light has several properties that are different from other light sources. *Monochromaticity* refers to emission of a well-defined wavelength, rather than a band of wavelengths. *Coherence* describes light waves that travel in phase, both in time and space, similar to a column of soldiers marching in step. *Collimation* refers to a very parallel beam of light. Coherence and collimation allow lasers to be focused to very small spot sizes (see Fig. 136.1).

Lasers may emit a continuous beam or pulses of light, with nearly all dermatologic lasers currently in use emitting pulsed light. Q-switched lasers produce short pulses at very high peak power. "Q" refers to a quality factor for light traveling across the laser cavity, which can be changed suddenly, i.e. "switched", to produce a short, intense burst of light. Dermatologic Q-switched lasers are designed to produce pulses of ~1–100 nanoseconds, with fluence (the energy delivered per unit area) typically in the 2–10 J/cm^2 range. These short, high-power pulses are particularly useful for selective removal of tattoos and pigmented lesions while limiting thermal damage to surrounding tissues[5]. The repetition rate for pulsed lasers is expressed in hertz (Hz). Of note, some lasers emit a rapid train of low-energy pulses that behave surgically like continuous-wave lasers and are called quasicontinuous.

SKIN OPTICS

At the skin surface, 4%–7% of light of all wavelengths is **reflected** because of the change in refractive index between air (n=0) and stratum corneum (n=1.45)[6]. This is termed Fresnel reflectance because it follows Fresnel's equations relating reflectance to the angle of incidence, plane of polarization, and refractive index[7]. The remaining 93%–96% of incident light enters the skin, where it is **scattered** and/or **absorbed** (Fig. 136.2). Scattering occurs when photons "bounce" off particles and

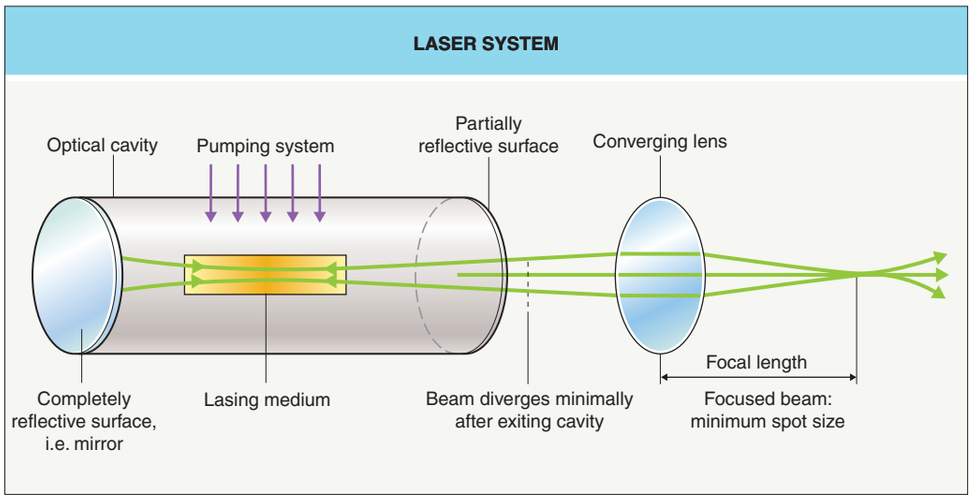

Fig. 136.1 Laser system. The pumping system stimulates the lasing medium to emit photons. The mirrors at the ends of the cavity reflect this light back and forth along one axis, leading to amplification of the stimulated emission process; one of the mirrors is only partially reflective, allowing the laser light to exit. Lasers produce beams of light with low divergence (spread) that are close to being collimated (i.e. parallel light waves). This then allows the beam to be tightly focused by a converging lens or mirror as focusing is required to produce a specific spot size.

TYPES OF LASER MEDIA

Gas	Liquid	Solid
Argon Carbon dioxide Copper vapor Helium–neon Krypton Xenon chloride*	Rhodamine dye dissolved in organic solvent†	Crystal • Alexandrite • Erbium-doped yttrium aluminum garnet (YAG) • Holmium-doped YAG • Neodymium-doped YAG • Potassium titanyl phosphate • Ruby Semiconductor • Diode (e.g. aluminum gallium arsenide)

*In excimer lasers.
†In pulsed dye lasers.

Table 136.1 Types of laser media. Lasers are often named for the medium contained within their optical cavity.

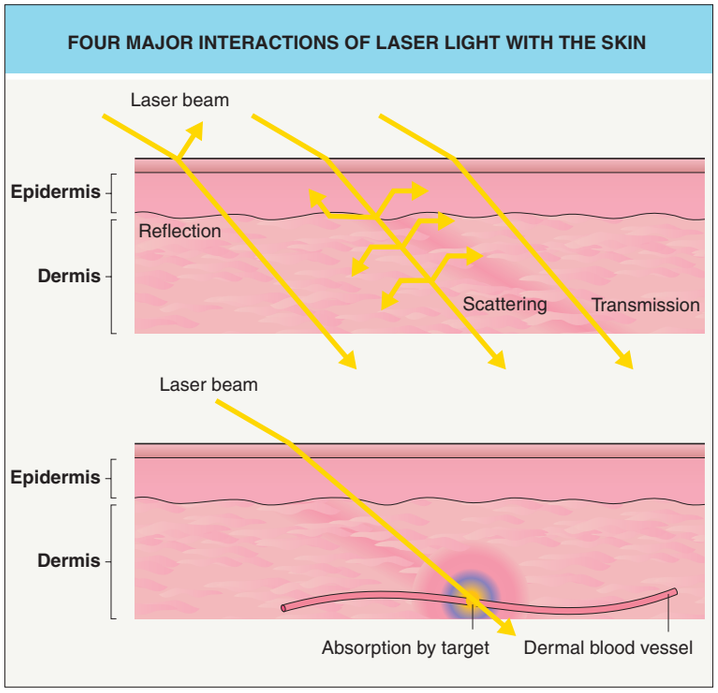

Fig. 136.2 Four major interactions of laser light with the skin. These are reflection, scattering, transmission, and absorption.

fibers within the skin, leading to diffusion of the incoming beam of light and limiting its depth of penetration. The *absorption coefficient* of any material is defined as the probability per unit path length that a photon at a particular wavelength will be absorbed, and it depends

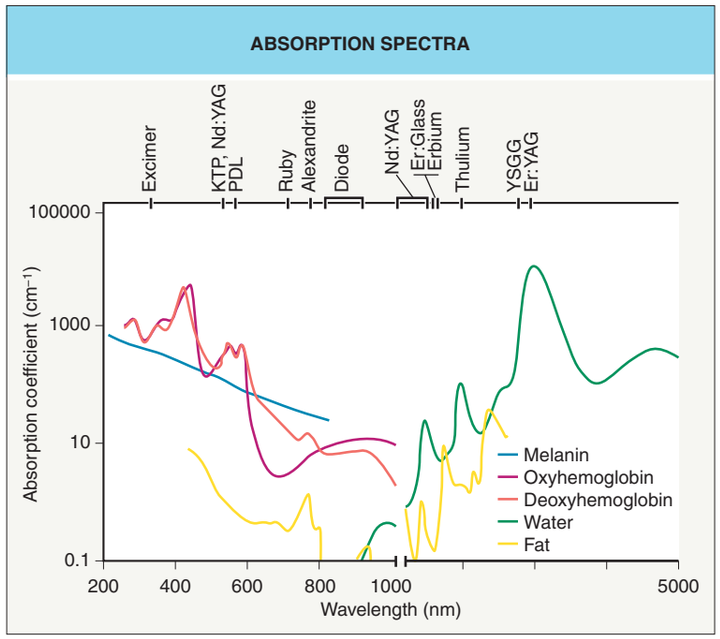

Fig. 136.3 Absorption spectra. The heterogeneous absorption spectra of chromophores allow selective photothermolysis to work. Er, erbium; KTP, potassium titanyl phosphate; Nd, neodymium-doped; YAG, yttrium aluminum garnet; PDL, pulsed dye laser; YSGG, yttrium scandium gallium garnet.

on the concentration of chromophores (absorbing molecules) present. After the energy of the photon is absorbed by the chromophore, heat or photochemical reactions lead to tissue effects.

The four primary skin chromophores are water, lipids, hemoglobin, and melanin (Fig. 136.3). Chromophores exhibit characteristic bands of absorption at certain wavelengths. It is this fact that allows for the delineation of specific targets for different laser wavelengths. While melanin absorbs broadly across the visible and ultraviolet (UV) spectrum, oxyhemoglobin and reduced hemoglobin in blood exhibit strong bands in the UV, blue, green, and yellow regions. Water and lipids have strong absorption in the infrared (IR) region (Fig. 136.4).

Optical properties of the epidermis and dermis are different. In pigmented epidermis, melanin absorption is usually the dominant process over the majority of the optical spectrum (200–1000 nm) (see Fig. 136.3). In the dermis, there is strong, wavelength-dependent scattering by collagen fibers, which attenuates penetration of light. This scattering varies inversely with wavelength. In general, between 280 and 1300 nm, the depth of penetration increases with wavelength (Fig. 136.5). Beyond 1300 nm, penetration decreases due to the absorption of light by water. The most deeply penetrating wavelengths are 650–1200 nm, while the least penetrating wavelengths are within the UV and IR regions.

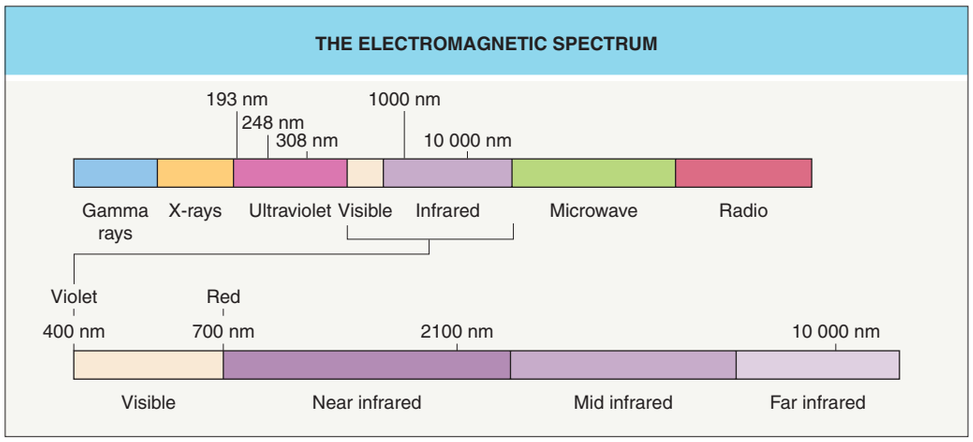

Fig. 136.4 The electromagnetic spectrum. The visible component is only a small portion of the spectrum.

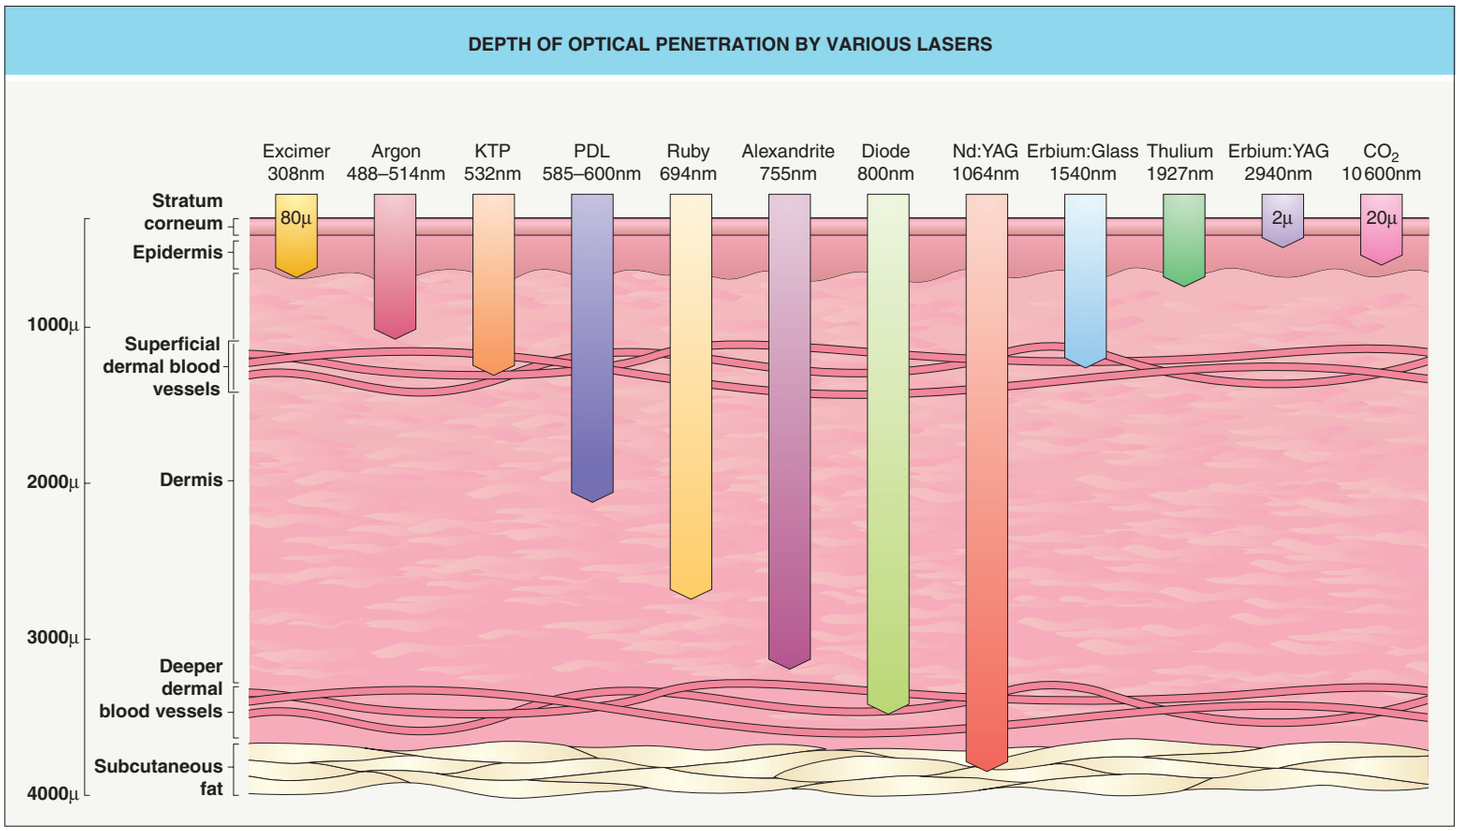

Fig. 136.5 Depth of optical penetration by various lasers. Optical penetration of about 50% of the light. It should be noted that the treatment depth can greatly exceed the optical penetration depth for ablative lasers. For example, the depth of optical penetration for CO_2 lasers is only ~20 microns, but fractional CO_2 lasers can vaporize nearly full-thickness microchannels through the dermis. KTP, potassium titanyl phosphate; μ, microns; Nd, neodymium; PDL, pulsed dye laser; YAG, yttrium aluminum garnet.

THERMAL INTERACTIONS

Most laser interactions involve heat. As temperature is raised, essential macromolecules are denatured including proteins, DNA, RNA, and cell membranes, leading to loss of function. Thermal coagulation yields cell necrosis and, if widespread, a burn. Laser skin surgery requires precise control over the placement and amount of heat-induced injury.

Most human cells can easily withstand temperatures up to 40°C. Cellular survival is dependent upon both exposure time and temperature. In most organisms, exposure to sub-lethal heat induces a cellular reaction termed the heat shock response. Normal protein synthesis is replaced by synthesis of proteins called heat shock proteins; the latter confer some resistance to thermal injury[8]. Laser-induced thermal injury is well described by an Arrhenius model[9] – the rate of denaturation is exponentially related to temperature. Thus, accumulation of denatured material rises exponentially with temperature and proportionally with time[10]. Near a critical temperature (which is different for different tissues), rapid coagulation occurs; this is what accounts for the well-defined histologic boundaries of dermal coagulation in laser and other burn injuries. In the dermis, type I collagen plays a primary role in thermal coagulation, whereas elastin is extremely thermally stable and can survive boiling without apparent injury. Fibrillar type I dermal collagen has a sharp melting and shrinkage transition at 60–70°C. At or above this temperature range, scarring becomes more likely. Selective photothermolysis permits selected heating of targets within the dermis, such as blood vessels or hair follicles, with preservation of dermis between targets. However, even with selective photothermolysis, there is an absolute need to keep the bulk skin temperature well below ~60–70°C. Clinically, immediate skin responses can indicate localized thermal damage or excessive and non-selective unwanted damage[11,12].

When laser light, intense pulsed light (IPL), radiofrequency (RF), ultrasound, or other form of energy is absorbed by tissue, heat is produced locally which immediately begins to diffuse into the surrounding tissue.

PULSE DURATIONS AND TARGETS OF SELECTIVE PHOTOTHERMOLYSIS			
Chromophore	**Diameter**	**TRT**	**Typical laser pulse duration**
Tattoo ink particle	0.01–0.5 micron	100 ps–250 ns	300 ps–50 ns
Melanosome	0.5 micron	250 ns	10–100 ns
PWB vessels	30–100 microns	1–10 ms	0.4–20 ms
Terminal hair follicle	300 microns	100 ms	3–100 ms
Leg vein	1 mm	1 s	0.1 s

Table 136.2 Pulse durations and targets of selective photothermolysis. m, milli; n, nano; p, pico; s, second; PWB, port-wine birthmark; TRT, thermal relaxation time.

Heat diffusion via conduction is also called thermal relaxation. *Thermal relaxation time* (TRT) is defined, for a given tissue structure, as the time required for the heated tissue to cool halfway towards its initial temperature. The key to clean ablation of tissue is to ablate it quickly, before much heat is conducted into surrounding tissue[13].

SELECTIVE PHOTOTHERMOLYSIS

The concept of selective photothermolysis[14] first arose to guide the design of a laser for treating pediatric port-wine birthmarks. Selective, localized heating (with focal destruction of "target" structures) is achieved by a combination of selective light absorption and a *pulse duration shorter than or approximately equal to the TRT of the targets*. Choice of wavelength(s) must correspond to absorption by chromophores within the skin targets. The wavelength must also penetrate to the anatomic depth of the skin targets.

The TRT of a target is proportional to the square of its size (Table 136.2). Thus, for a given material and shape, an object half the size will cool in one-quarter of the time. For most tissue structures, TRT (in seconds) is approximately equal to the square of the target dimension (in millimeters). Shape also affects TRT, and for a given thickness, planes cool faster than spheres. In general, the optimal pulse duration for *selective photothermolysis* is approximately equal to the TRT. Selective photothermolysis typically utilizes pulsed (rather than continuous) sources[15]. Blood vessels encompass a wide range of TRTs, including capillaries (tens of microseconds), large venules of adult port-wine birthmarks (up to tens of milliseconds), and telangiectasias and leg veins (hundreds of milliseconds). Small, pigmented targets (e.g. melanosomes within melanocytes in a nevus of Ota, tattoo ink particles within fibroblasts) are best treated with short (sub-microsecond) pulses, while larger pigmented targets (e.g. hair follicles) have longer TRTs and are best treated with longer (millisecond) pulses[16].

The potential for targeting intracellular particles and structures is increasing as lasers with even shorter pulses, e.g. picosecond (10^{-12} second) or femtosecond (10^{-15} second), are becoming available for medical use. At the extremely high intensity of femtosecond lasers, molecules can simultaneously absorb more than one photon, which opens the door to very precise sub-surface tissue cutting without thermal damage, as well as UV-like photochemistry triggered deep within the tissue. Femtosecond lasers are already in use for precise cornea surgery.

PHOTOMECHANICAL EFFECTS

Pulsed lasers can also cause mechanical effects[17]. Sudden heating induces thermal expansion with consequent acoustic and/or shock waves that can rupture or increase permeability of cell membranes. Cavitation, the violent formation and collapse of steam bubbles, may also occur. Examples of mechanical injury are purpura due to vessel rupture from pulsed dye lasers emitting pulses less than ~10 milliseconds[18], and tattoo ink particle fracture from lasers emitting picosecond pulses.

A number of parameters control laser–tissue effects, including wavelength, fluence, irradiance, spot size, and pulse duration (Table 136.3). With smaller spot sizes, scattering leads to a greater loss of photons from the beam as it penetrates the skin, as compared to larger spot sizes. The greatest effective penetration depth into skin occurs with the combination of a penetrating wavelength (600–1300 nm; see Fig. 136.5) and a large spot size.

USEFUL LASER TERMS		
Term	**Definition**	**Unit**
Energy	Fundamental unit of work	Joules (J)
Power	Rate at which energy is delivered	Watts (W)
Fluence	Amount of energy delivered per unit area	J/cm^2
Irradiance	Power delivered per unit area	W/cm^2
Pulse duration (pulse width)	Laser exposure duration	Seconds (s)
Spot size	Diameter of the laser beam on the skin surface	mm
Chromophore	Medium that absorbs light	
Thermal relaxation time	Time required for heated tissue to lose 50% of its heat through diffusion	Seconds (s)

Table 136.3 Useful laser terms.

COOLING FOR SKIN PROTECTION

Epidermal melanin is an undesired chromophore when treating dermal targets. Epidermal damage can be minimized through the use of skin cooling, which is especially important with darkly pigmented skin. All cooling methods extract heat at the skin surface via a cooling agent (gas, liquid, or solid). For dynamic cryogen spray cooling, a very cold *liquid* fluorocarbon is sprayed onto the skin. *Solid* contact cooling typically consists of a cold sapphire window held against the skin, through which laser or IPL energy is delivered. Cold *air or* cold *gels* can also be used for skin cooling.

The terms precooling, parallel cooling, and postcooling refer to cooling before, during, and after the laser exposure, respectively[19]. For pulse durations shorter than ~5 milliseconds (e.g. from many pulsed dye and all Q-switched lasers), there is not enough time for parallel cooling to extract much heat, but precooling provides some protection. For short-pulsed lasers, cryogen spray cooling represents the most aggressive and effective form of precooling. Parallel cooling is effective for pulses longer than ~5 milliseconds. Bulk skin cooling before and after laser treatments (e.g. with ice or cold air) is useful for minimizing pain, erythema, and edema[16].

APPLICATIONS OF LASER PRINCIPLES

Currently available medical lasers are outlined in Table 136.4 and their applications are discussed in Chapter 137.

Ablative (Vaporizing) Skin Resurfacing

The ablative lasers are far-IR CO_2 (10 600 nm) or erbium (Er:YAG: 2940 nm) devices which emit wavelengths strongly absorbed by water. Pulsed and/or scanned focused beams are used to precisely vaporize superficial tissue, causing a "plume" of material leaving the skin. Most of the heat is removed during vaporization, but a thin layer of residual thermal damage remains that is useful for hemostasis. Laser resurfacing is very useful for treating photoaging, scars, and lesions such as epidermal nevi and seborrheic keratoses. Resurfacing removes the old epidermis and stimulates contraction and remodeling of the dermis for many months after treatment. Being a controlled partial-thickness burn, meticulous technique and wound care are important in order to avoid infection and other complications. Scarring, transient hyperpigmentation, delayed-onset permanent hypopigmentation, prolonged erythema, and bacterial, viral, and fungal infections have been reported after laser resurfacing[20].

Interactions During Treatment of Vascular Lesions

Oxyhemoglobin has an absorption band at 577 nm, within the yellow spectrum (see Fig. 136.3). Yellow, flashlamp-pumped *pulsed dye lasers* (PDLs) that emit 0.45 to 40 millisecond pulses of 585–600 nm light are therefore frequently used to treat microvascular lesions; 532 nm green lasers and some IPLs represent alternatives. Most port-wine birthmarks require six or more treatments in order to achieve stable improvement, and only a minority can be fully removed. Treatment is more effective before 6 months of age, and resistance may be due in part to vessels deeper than 1.5 mm (see Fig. 136.5). For the treatment of deeper vessels,

LASERS IN MEDICINE							
Laser	**Wavelength (nm)**	**Mode**	**Average power (W)**	**Average energy per pulse (J)**	**Pulse duration (sec)**	**Pulse rep. rate (Hz)**	**Target chromophore**
Excimer (ArF)	193	Pulsed	10	0.1	10^{-8}	100	Proteins

Carbon dioxide	10600	CW/pulsed	1–500	0.05–0.5	10^{-5}–10^{-3}	10^{2}–10^{4}	Water

*Also 532 nm.

Table 136.4 Lasers in medicine. AlGaAs, aluminum gallium arsenide; ArF, argon fluoride; CW, continuous wave; KTP, potassium titanyl phosphate; Nd, neodymium; ns, nanosecond; XeCl, xenon chloride; YAG, yttrium aluminum garnet.

high-fluence, millisecond-domain *alexandrite* lasers (755 nm) can be employed and they are particularly effective for treating hypertrophic and/or PDL-resistant vascular lesions. Given the absorption band of reduced hemoglobin at 760 nm, alexandrite lasers are also useful for treating venous malformations, labial venous lakes, and hypertrophic port-wine birthmarks. Other lasers with wavelengths in the near-IR range (e.g. 980 nm and 810 nm diode lasers) have been utilized to target larger, deeper vessels (e.g. venous malformations).

Currently, the 585–600 nm flashlamp-pumped PDL is a standard treatment for cutaneous microvascular lesions including port-wine birthmarks, telangiectasias, erythematous scars, and when indicated, hemangiomas. The treatment fluence is decreased for more darkly pigmented skin. The principal side effect is purpura, which is dependent on pulse duration, fluence, and spot size[21]. Purpura is the result of microvascular hemorrhage, subsequent thrombosis, and delayed appearance of vasculitis. When the pulse duration exceeds ~20 milliseconds, there is little or no immediate purpura because cavitation and vessel rupture are avoided. It should be noted, however, that even when no immediate post-treatment purpura is observed, delayed purpura can still occur due to a phase of vasculitis several days after treatment[22]. *Potassium titanyl phosphate* (KTP) lasers, with a wavelength of 532 nm and variable pulse durations in the millisecond domain, are also used to treat vascular lesions. In general, there is less resultant purpura than with PDLs (see Fig. 137.2). When combined with parallel skin cooling windows, these lasers can be very versatile.

Filtered xenon flashlamps, which emit a wide range of wavelengths, serve as sources of IPL. Compared with most vascular lasers, IPL is less selective and less powerful but is still useful for selective photothermolysis of telangiectasias and poikiloderma. IPL sources typically deliver a large, uniform, rectangular exposure spot. For removal of lentigines, the telangiectasias of rosacea and poikiloderma of Civatte, or dark terminal hairs in fair-skinned individuals, IPL provides a good alternative to lasers. However, for treatment of entities that require very short pulses, e.g. tattoos or nevus of Ota, IPL should not be used.

Interactions During Treatment of Pigmented Lesions and Tattoos

Melanosomes are melanin-containing organelles that range from ~0.3–1 micron in size, and they can act as a primary target for selective photothermolysis of pigmented lesions[23]. Melanin has a broad absorption spectrum (see Fig. 136.3), which lends itself to possible targeting by a wide range of lasers[24]. Choice of treatment wavelength is based on avoiding absorption by other chromophores and on matching the depth of light penetration to the depth of the lesion. In general, red and near-IR lasers are the most selective and penetrating devices for pigment cell targeting. The TRT of melanosomes is about 70–250 nanoseconds[14], making Q-switched lasers an excellent choice for targeting melanosomes. When the fluence threshold for melanosome disruption is reached, the melanin-containing cell dies, and Q-switched lasers are able to selectively target individual pigmented cells. If the goal is to also remove adjacent, non-pigmented cells (e.g. during hair removal), millisecond pulses are used in order to allow heat transfer from pigmented to adjacent non-pigmented cells.

Treatment of tattoos with Q-switched nanosecond or picosecond lasers fragments the ink particles and selectively kills pigment-containing cells, with resultant ink particle release. Subsequent removal

Fig. 136.6 Histologic findings following ablative fractional photothermolysis. A microthermal zone (MTZ) of injury (arrow) is apparent after use of a CO_2 laser (10 600 nm) at 100 mJ/pulse. E, epidermis; D, dermis. *Courtesy Wellman Center for Photomedicine, Massachusetts General Hospital, Harvard Medical School.*

of tattoo ink particles can occur via an epidermal crust and/or lymphatic transport while some particles are rephagocytosed by dermal cells[25]. Of note, different laser wavelengths are needed for different ink colors (see Table 136.4). Picosecond (10^{-12} sec) laser pulses have long been known to be more effective than nanosecond pulses for pulverizing tattoo ink particles[26] and are now commercially available[27]. With shorter pulse durations, photoacoustic effects may be greater and photothermal effects reduced, providing a possible explanation for less inflammation and less postinflammatory hyperpigmentation.

Q-switched ruby and *alexandrite* lasers are very useful for epidermal and dermal pigmented lesions (e.g. lentigines, nevus of Ota) as well as for black and green tattoos (see Ch. 137). Café-au-lait macules and melanocytic nevi may respond to treatment with Q-switched ruby lasers (or, for nevi, long-pulsed ruby lasers that target nests of melanocytes), but recurrences are common and residual dermal melanocytes remain in laser-treated nevi[28,29]. Laser treatment of congenital melanocytic nevi is usually considered when surgical options are limited. However, laser removal of acquired melanocytic nevi is quite controversial given the potential risk for partial removal of a subtle early melanoma. Of note, postinflammatory hyperpigmentation and melasma respond poorly to laser treatment[30].

The *Q-switched Nd:YAG* laser emits at 1064 nm, with typical pulse durations of 10 nanoseconds. Its primary use is in the treatment of black tattoos and dermal melanocytoses such as nevus of Ota in highly pigmented skin. Frequency-doubling to produce 532 nm visible green light is generally available in the same device, which can effectively remove epidermal melanin pigment as well as red tattoos.

Interactions During Hair Removal

Permanent reduction of pigmented hairs is currently the most popular medical laser procedure. By damaging stem cells in the outer root sheath and/or dermal papilla, high-energy, millisecond-domain pulses at wavelengths in the red to near-IR region of the spectrum are highly effective. *Ruby*, *alexandrite*, *diode*, and *Nd:YAG* lasers are all used for this purpose, and IPL sources are also effective. However, due to the paucity of melanin, none of these devices work well for blonde or white hair. Since light must first travel through the pigmented epidermis to reach hair follicles, skin cooling is essential for safe permanent reduction of hair in individuals with darkly pigmented skin. The primary mechanism for *temporary* hair loss is induction of catagen, which can occur at low fluences whereas higher fluences produce enough follicular injury to cause permanent miniaturization or degeneration of terminal hair follicles. Low-energy IPL devices and an 810 nm diode laser source intended for home use are also available[31]. For unknown reasons, paradoxical hypertrichosis due to stimulation of a vellus-to-terminal hair transition can occur after laser or IPL treatments, particularly on the face of Mediterranean women.

Non-Ablative Skin Rejuvenation

Non-ablative facial rejuvenation for the treatment of fine lines and non-dynamic rhytides uses mid-IR lasers (e.g. 1320 nm Nd:YAG, 1450 nm diode, 1540 nm erbium:glass) whose wavelengths are weakly absorbed by water. These lasers work via thermal effects on the dermis, presumably stimulating a wound healing response. Responses to non-ablative rejuvenation are usually gradual and subtle, and well-controlled studies are lacking.

Fractional Photothermolysis

Fractional photothermolysis (FP) represents a treatment strategy in which numerous small zones of thermal injury are created (Fig. 136.6), stimulating turnover and remodeling of both the epidermis and dermis[32]. *Non-ablative* FP uses focused, mid-IR, laser microbeams to create a pixelated pattern of microscopic columns of thermal damage, called microthermal treatment zones (MTZs). Typically, ~1 million MTZs are placed per full-face treatment. Density (percentage of skin treated) and depth of thermal damage are separately controlled. The energy delivered per MTZ accurately controls the depth of treatment which is typically up to ~2 mm, i.e. well into the reticular dermis. In general, the depth of thermal damage should correlate with the depth of skin pathology being treated, e.g. a greater depth for hypertrophic scars than for atrophic scars[33].

Tissue spared around each MTZ initiates rapid repair and stimulates remodeling. Desquamation of the epidermal portion of each MTZ removes some basal layer pigment and a small amount of papillary dermal debris. Non-ablative FP has been reported to improve several skin conditions including scars, fine rhytides, telangiectasias, dermatoheliosis, and poikiloderma. There are a myriad of commercially available non-ablative, as well as ablative, FP devices (see Ch. 137).

Ablative FP uses carbon dioxide or erbium (Er:YAG) lasers to vaporize many small vertical channels that can extend deeply into the skin. Because remodeling is provided by tissue between the columns of ablation, the depth of ablation can be far deeper than with traditional ablative resurfacing procedures. Care must be taken to avoid scarring, especially in areas where thin skin has limited adnexal structures such as the infraorbital and neck regions. By creating deep channels into the dermis, ablative FP is also an effective mechanism for enhancing topical drug delivery (see below)[34–37].

Clinical applications of fractional lasers include treatment of photoaging, striae distensae, poikiloderma, and scars. Ablative FP has been shown to significantly improve the elasticity and appearance of hypertrophic traumatic or burn scars[38–40]. The mechanisms by which microscale burns within the narrow, deep, FP-induced laser wounds lead to improvement of scars from thermal burns remain largely unknown.

Ablative fractional lasers have been shown to increase topical drug absorption by orders of magnitude, especially for large molecules that are typically excluded from the skin. However, to date, large-scale dose-response and pharmacokinetic data are generally lacking. Nonetheless, laser-assisted drug delivery (LADD) has been broadly utilized as an off-label indication[40a]. Drugs that are cleared for injection or parenteral use are generally safer for LADD than are topical medications, as the latter include vehicles, solvents, or stabilizers that are not intended for entry into the skin[40b]. Further developments will hopefully lead to a reduction in both time for drug metabolism (e.g. topical anesthetics, topical prodrug photosensitizers for photodynamic therapy) and systemic side effects[40a].

Laser-Induced Optical Breakdown (Plasma Formation)

The term plasma is used to describe matter where electrons are stripped away from atoms and molecules, producing free electrons and ions. Natural examples of plasma include lightning, the sun, and a candle flame. The high intensity of a focused, pulsed laser can cause plasma formation. Laser-induced plasmas are commonly used for intraocular surgery, but cutaneous applications have recently been introduced. For example, as a treatment for epidermal pigmented lesions or photoaging, a lens array can be used to focus a picosecond pulsed laser so that it can induce optical breakdown within the epidermis[41,42].

Interactions During Laser Targeting of Lipids and Sebaceous Glands

Lipids absorb near-infrared wavelengths around 915, 1210, 1726, and 2300 nm[43,44]. Despite the depth of subcutaneous fat and sebaceous glands, controlled skin cooling allows selective photothermolysis of these lipid-rich structures[44]. That is, by extracting heat at the skin surface, deeply penetrating wavelengths absorbed by lipids can be used to selectively heat sebaceous glands or subcutaneous fat. Recently, 1726 nm laser devices have been approved to treat mild to severe acne in the US and Europe, with a reported clearance of 40–80% of inflammatory acne for up to 2 years, depending on the device.

Alternatively, for skin structures that lack specific natural chromophores, use of exogenous nanoparticles or microparticles can allow "customized" targeting. For example, in order to target sebaceous follicles, gold microparticles tailored to absorb near-infrared wavelengths have been introduced for acne treatment[45–47]. These particles absorb light very strongly by creating surface plasmon resonance; the latter occurs when the frequency of incoming light matches the frequency for electric currents to resonate in the particle. The particles are forcefully massaged into sebaceous follicles before laser treatment.

Laser-Based Diagnostics

Laser technology has been instrumental in the development of biological microscopy and tissue imaging. Optical coherence tomography (OCT) uses near-IR, low-coherence light for high-resolution cross-sectional imaging of body tissues. OCT is now a standard procedure in ophthalmology and is employed in high-resolution coronary artery imaging. Its use in dermatology is rapidly emerging.

Laser confocal microscopy captures light scattered or emitted from a thin plane "section" inside skin and can be used to delineate tumor margins. Reflectance confocal microscopy is able to view the skin *in vivo* with histology-like resolution down to a depth of ~0.3 mm, whereas OCT is capable of imaging the skin to a depth of ~2 mm. Because histochemical stains are not used, both confocal microscopy and OCT of skin tumors reveal useful diagnostic features that are different from those of conventional histopathology. While confocal microscopy is limited to imaging small areas, OCT generally does not have that limitation. The field of *in vivo* microscopy continues to rapidly advance.

PRINCIPLES OF LASER SAFETY
Potential eye injuries (patients and dermatologists)
Blindness occurs rapidly and painlessly
• Blindness can occur even if only 1% of the beam is reflected into the eye from shiny metal, glass, or plastic surfaces • Highest risk of eye injury and blindness with near-infrared lasers such as Q-switched lasers • Lasers and IPL sources used for hair removal can target the retina and uveal tract • Anterior eye injury from lasers or IPL sources usually occurs with treatment of the lower eyebrow or vascular lesions near the eye (without an eye shield properly in place) • An opaque laser eye shield covering the patient's cornea will not prevent damage if the laser or IPL directly impacts exposed sclera • Long-pulse, near-infrared laser light can penetrate through the eyelid to damage the eye
Prevention of eye injuries
Proper use of laser-protective eyewear (including eye shields)
• Wrap-around glasses and goggles are rated by optical density (OD) at specific wavelengths (corresponding to various lasers): OD=log (1/T), where T is transmittance of light through the eyewear; OD=6 implies transmittance through the goggles is 10^{-6} • After determining wavelength of laser, check goggles for required OD and wavelength ranges of protection (printed directly on eyewear) • For dermatological lasers, proper protection is an OD ≥4 at the wavelength of the laser being used • Color of the goggles is not an indication of protection
Fire hazards
• Drapes, clothing, dry hair, and plastic materials, including endotracheal tubes, can be ignited, especially when oxygen is in use • Greatest risk is with the CO_2 and erbium:YAG lasers used for skin resurfacing and ablative fractional treatments
Prevention of fires
• Remember to place the laser in STANDBY mode when not actually treating the patient • Avoid inadvertently activating the laser foot-switch • Moisten any hair near the treatment field; remove mascara and eye makeup when working around eyelids • Alcohol, acetone or other flammable skin-cleaning solutions must be allowed to completely dry before laser use • Reduce intraoperative oxygen concentration to <40% • A fire extinguisher and water should be readily available
Possible cutaneous burns
• Can occur with essentially all dermatologic laser, IPL, RF, or therapeutic ultrasound devices • Primarily due to improper device, dosimetry, and/or treatment technique
Prevention of cutaneous burns
• Knowledge and careful observation of specific clinical endpoint responses for a particular laser–lesion combination
Inhalation of laser-generated "plume" materials
• Particularly with resurfacing or vaporization of hair during its removal; the latter can release irritating sulfur and other oxides
Prevention of laser "plume" biohazards
• Smoke evacuator and good ventilation are most effective measures • Sub-micrometer surgical filter masks provide some protection when worn properly • Q-switched lasers capture particulate material in plastic cones

Table 136.5 Principles of laser safety. IPL, intense pulsed light; RF, radiofrequency.

PRINCIPLES OF LASER SAFETY

The principles of laser safety are outlined in Table 136.5[48,49].

NON-LASER ENERGY SOURCES

Flashlamps (Intense Pulsed Light)

Filtered xenon flashlamps, also referred to as intense pulsed light (IPL) sources, are used for non-ablative skin rejuvenation, pigmented hair removal, and the treatment of vascular and pigmented lesions. By utilizing filters, different wavelength bands can be chosen, which are delivered in millisecond-domain pulses. Compared with lasers, IPL devices are generally less target-selective, as they emit a wider range of wavelengths and are unable to deliver the very short pulses needed for selective photothermolysis of very small targets such as tattoo ink particles or the melanin-containing cells of nevus of Ota. Attempts to remove tattoos with IPL are inappropriate (despite advertising or FDA approvals to the contrary), as this often leads to burns and/or scarring. In a side-by-side comparative study, IPL was inferior to the PDL for the treatment of port-wine birthmarks. Despite limitations, IPL devices are very versatile and can successfully treat epidermal pigmented lesions, poikiloderma, and telangiectasias.

Photobiomodulation (PBM, also called Low Level Light Therapy; LLLT)

Over the past 50 years, lasers and light-emitting diode (LED) sources have been used for a wide variety of "biostimulation" treatments, mainly outside the US. Of note, moderate irradiances at wavelengths absorbed by cytochromes have long been reported to modulate metabolism in mammals. The FDA mandate to balance risks and benefits is such that devices posing no known risk are sometimes cleared for sale with little or no evidence of efficacy, and many sources sold for PBM do not have specific indications. The FDA has cleared low-power red lasers and/or LEDs (continuous, mW power, 630–800 nm wavelength) for treatment of carpal tunnel syndrome and for stimulating hair growth in patients with androgenetic alopecia, based on evidence from clinical trials[50,51]. Although the latter have shown a statistically significant increase in terminal hair counts relative to placebo, the clinical significance remains to be determined, and the combination of PBM with medical or surgical treatments for hair loss remains largely untested. Nonetheless, scientific and clinical evidence has been mounting in support of PBM having *bona fide* photobiologic effects mediated via mitochondrial activity. Mitochondrial signaling pathways affected by light include those that are redox-sensitive, ATP- and cyclic AMP-dependent, and/or regulated by nitric oxide[52].

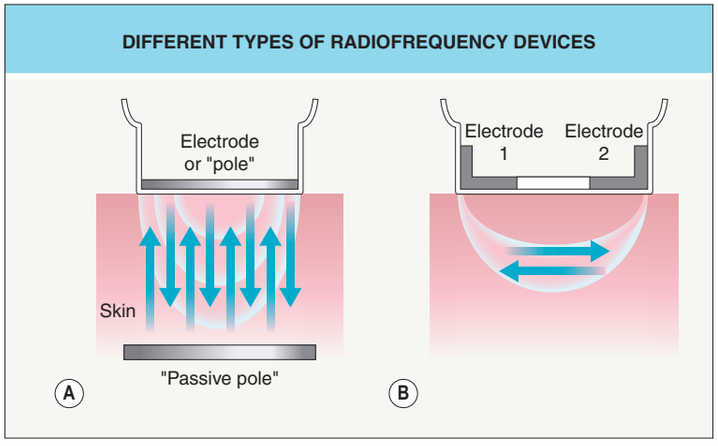

Fig. 136.7 Different types of radiofrequency (RF) devices. A A monopolar RF device has one pole located on the treatment handpiece, while the other (if present at all) is a larger "passive" electrode placed remotely on the patient's body. **B** A bipolar RF device has both poles located within the treatment handpiece and current flows between the electrodes, often in a banana-shaped pattern.

Radiofrequency

Radiofrequency (RF) describes a rapidly alternating electric current that locally heats tissue, based on both local current density and electrical impedance of the tissue. The energy deposited at a certain site is proportional to the local tissue impedance multiplied by the square of the local current density. As the name implies, RF generators operate at frequencies similar to radio bands. The current is delivered from one or more electrodes held in contact or close proximity to the skin. The number of treatment electrodes defines an RF device as monopolar, bipolar, or multipolar. In monopolar RF devices, one pole is located on the treatment handpiece, while the other (if present at all) is a large "passive" electrode placed remotely on the patient's body (Fig. 136.7A). Bipolar and multipolar RF devices have multiple active electrodes that are held against the skin, and current flows between them (Fig. 136.7B). Because electrode size and spacing have a strong influence, the pattern and depth of heating can be adjusted to some extent. Invasive RF needles are also available, which produce a fractional pattern of deep thermal injury.

Unlike most lasers and IPL sources, there is little or no intrinsic selectivity to the deposition of energy from an RF source. The single relevant exception is lipid-rich tissue such as subcutaneous fat, which has substantially higher electrical impedance due to its lower water content. A large RF electrode configured to deliver a current path through subcutaneous fat could, in theory, preferentially heat fibrous septae. This is because the septae carry a higher current density than the fat lobules which surround them. Following large-electrode, monopolar or bipolar RF, cellulite improvement has been described by several authors, but the apparent improvement in appearance does not correspond to fat destruction[53].

While many monopolar and bipolar RF devices have been described for skin "tightening" as well as removal of cellulite or fat, the quality of clinical study-based evidence is generally poor. The RF devices intended for "tightening" are designed to produce partial denaturation of type I collagen, which occurs at temperatures above ~60°C and leads to some immediate tissue contraction and subsequent new collagen synthesis[54]. Because improper electrode contact with skin is a common cause of injury (e.g. burns), some devices have integrated skin cooling systems and/or sensors that monitor proper electrode–skin contact.

At high frequencies, RF can also be transmitted across a dielectric (insulating) material, similar to radio transmissions through air. RF transmission to the skin from an emitting electrode is called capacitive coupling. At the high frequencies utilized with capacitive coupling, a combination of induced current and rotational oscillations in water molecules produces tissue heating[55]. The combination of a bipolar RF device with infrared light sources has been used to treat photoaging and to induce skin tightening[56]. More recently, multiple skin-penetrating RF microneedles have been applied in an array (i.e. a "fractional" fashion) to treat acne scars, photoaging, and striae distensae, as well as for other applications (e.g. skin tightening)[57–60]; however, most of the clinical studies are small with limited follow-up times.

High-Intensity Focused Electromagnetic (HIFEM)

In HIFEM treatments, there is application of low-frequency magnetic field pulses (3–30 Hz) using a non-contact device. The magnetic pulses induce electric currents in tissue that can stimulate action potentials, producing muscle contraction[61]. This therapeutic modality has been used for decades in sports medicine, and nowadays dermatologists are also offering HIFEM treatments for muscle toning and body contouring. Intense exercise or induced muscle contraction can reduce intramuscular fat, but (despite claims) reduction of subcutaneous fat via HIFEM treatments has not yet been proven[62].

Nano-Pulse Stimulation (NPS)

NPS consists of applying high-voltage, nanosecond electrical pulses that are delivered by parallel rows of microneedles inserted into tissue. The electrical pulses porate cellular and organelle membranes, leading to increased intracellular calcium, disruption of ATP production, and consequent cell apoptosis[63,64]. NPS has been investigated for the treatment of seborrheic keratoses[65], sebaceous hyperplasia[66], and viral warts[67], but the potential for causing useful selective and/or sublethal cellular responses remains unclear.

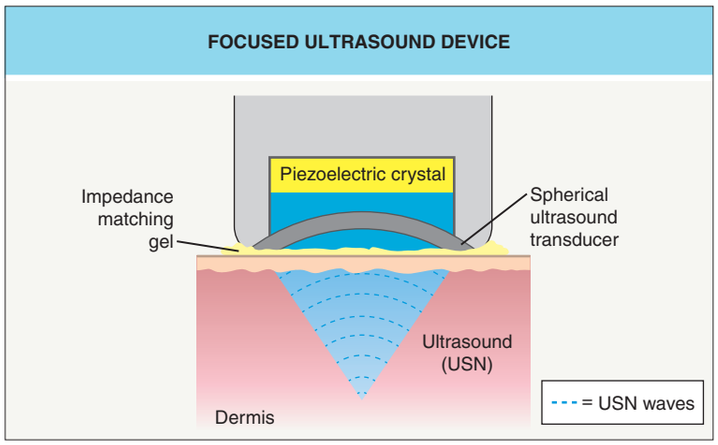

Fig. 136.8 Focused ultrasound device. The ultrasound waves are generated by a piezoelectric crystal. After passing through a spherical ultrasound transducer, they are focused deeper within the skin.

Ultrasound

High-frequency acoustic waves are routinely used for diagnostic medical imaging, at frequencies from ~20 kHz to 10 MHz. Ultrasound is an oscillating pressure (stress) wave that propagates at the speed of sound[68,69], with minimal scattering in soft tissues. This minimal scattering allows the ultrasound waves to be focused deeply within most soft tissues. Intensity is concentrated near the focal point, to the extent that tissue damage can occur by one or more of three mechanisms – heating, cavitation, or shock waves. *Heating* is favored at high ultrasound frequencies while *cavitation* (a rapidly expanding gas bubble) is favored at low ultrasound frequencies; *shock waves* are high pressure, supersonic pressure waves that can be very destructive. Therapeutically, focused ultrasound can be used to destroy targets, such as renal calculi by shock waves, tumors by heating, and thrombi by cavitation, in addition to dermatologic applications. The attenuation (absorption) of ultrasound is greater at higher frequencies, and different materials have different attenuation coefficients[69].

Focused, pulsed ultrasound devices capable of locally destroying subcutaneous abdominal fat have been FDA-cleared for waist circumference reduction (see Ch. 156). In addition, a non-invasive, focused ultrasound device, operating at MHz frequencies, has been FDA-cleared for brow lifts. This device focuses millisecond-domain pulses at the level of the deep dermis and/or superficial fascia, up to a depth of ~4.5 mm (Fig. 136.8). A small focal zone of thermal damage is produced with each pulse, sufficient to achieve tissue contraction at the focus. The treatment transducer is also used for imaging, in order to verify positioning and treatment at the proper tissue plane. This represented the first combined diagnostic and therapeutic ultrasound device for dermatologic use.

Cryolipolysis

Cryolipolysis describes a process in which lipid-rich cells are preferentially affected by cold. Because lipids crystallize at temperatures well above the freezing point of tissue water, lipid-rich cells, including adipocytes and sebocytes, suffer stress and undergo apoptosis (see Ch. 156). Following deep cooling, cold panniculitis occurs (see Ch. 100)[70], eventuating in selective loss of subcutaneous fat tissue[71,72]. Prolonged hypoesthesia is a common side effect when cryolipolysis is employed to remove unwanted subcutaneous fat; the proposed underlying mechanism is damage to the lipid-rich myelin sheaths that surround cutaneous sensory nerves. However, this effect has recently been recognized as a potential treatment for cutaneous pain and pruritus[73].

FUTURE DIRECTIONS

In vivo optical image-guided laser surgery for cutaneous malignancies would be a welcome advance[74]. Currently, dermatologists use histology-guided Mohs micrographic surgery, primarily for the removal of non-life-threatening tumors. Development of a rapid, image-guided version of Mohs micrographic surgery would represent a valuable and improved approach.

Use of Raman spectroscopy to detect inelastic light scattering from molecular vibration modes can provide a "fingerprint" image of a desired molecule, thus allowing precise *in vivo* analysis of the skin[75,76]. It may even be possible to manipulate immunologic responses, e.g. inducing tolerance, preventing inflammation; experimentally, lasers have been used to enhance the immune response to vaccines by increasing antigen-presenting cells[77].

An injectable version of cryolipolysis has been developed that utilizes ice slurries, similar in concept to a physiologic daiquiri. Injected ice slurry has been shown to produce neural selective cryoneurolysis[78] and fat reduction[79]. The same innovation may be useful as a treatment for sleep apnea[80].

A potential improvement in fractional lasers would be the ability to guide the laser microbeam based on skin imaging. For example, the precise texture of the skin could potentially be rewritten by image-guided laser ablation, similar in principle to the precise laser surgery performed to correct refractive power of the cornea.

Fractional lasers can destroy or remove nearly half of the tissue of the skin, followed by rapid healing without a scar, a capability unmatched by any classical surgical tool. However, it is clearly the microscale pattern of injury – not the laser *per se* – that underlies the skin's tolerance to fractional laser treatment. As a result, the general concept of fractional photothermolysis has spawned various other techniques. For example, in patients with photoaging, mechanical removal of full-thickness micro-columns of skin tissue via coring needles has recently been shown to produce similar esthetic results as fractional laser treatment, again with rapid and scar-free healing. Recently, a micro-coring device was FDA-approved for the treatment of lower face photoaging and laxity. Fractional coring needles can also be used to obtain full-thickness skin tissue for grafting, and recently such needle harvesting has been shown to greatly reduce donor site morbidity[81–84].

Lasers and energy-based technologies will forever be an innovative, changing, and integral part of dermatology.

INTRODUCTION

This chapter considers laser and light applications for both medical and aesthetic purposes as related to the skin. Anderson and Parrish developed the concept of selective photothermolysis[1] whereby laser energy could be used for targeted destruction of skin components (see Ch. 136). Their 1983 treatise continues to support our understanding of laser–tissue interactions and still drives new therapeutic applications of lasers in dermatology. Given the multiplicity of lasers available (Fig. 137.1), the laser surgeon must understand the capabilities and limitations of each device so that the appropriate system can be selected and the parameters tailored to treat the intended target. Safe and effective laser therapy is achieved when the operator understands the nature of the target, its location within the skin, and the potential collateral damage. Other energy-based devices, such as those that utilize radiofrequency waves, intense focused ultrasound, or microwaves, are also discussed.

TYPES OF LASERS AND INTENSE PULSED LIGHT

The earliest lasers used by dermatologists were applied to vascular lesions and consisted of continuous or quasi-continuous wave lasers, which emitted a constant beam of light. These included argon (488, 514 nm), argon pumped tunable dye (488–638 nm), copper vapor and copper bromide (511 nm, 578 nm), potassium titanyl phosphate (KTP, 532 nm), and krypton (568 nm) lasers. Although these lasers had wavelengths that corresponded to the hemoglobin absorption spectrum, the nature of their continuous beams generally induced nonspecific thermal damage to surrounding structures, leading to scarring and dyschromia. The root of the problem, a mismatch between the laser pulse duration and the thermal relaxation time of the target tissue (see Ch. 136), was effectively resolved once it was understood that laser pulse duration should approximately match the thermal relaxation time of the targeted tissue.

Pulsed Dye Laser

The pulsed dye laser (PDL) is considered to be the laser of choice for the treatment of various cutaneous vascular lesions, especially facial telangiectasias, port-wine birthmarks (PWBs), superficial hemangiomas, poikiloderma of Civatte, and erythematotelangiectatic rosacea[2]. Hypertrophic and keloidal scars, psoriasis, and warts are also amenable to treatment with PDL. While the initial PDL systems emitted 577 nm yellow light, slightly longer wavelength PDL devices (585 or 595 nm) were subsequently adopted to allow deeper tissue penetration of up to 1.2 mm.

The choice of appropriate PDL parameters affects tissue response, in terms of both efficacy and appearance. Short pulse durations (0.45–3 millisecond [ms]) cause a purpuric reaction related to intravascular coagulation or vessel leakage (Fig. 137.2C,D). While very effective for telangiectasias, the bruised appearance is not cosmetically acceptable to many patients. Although slightly less effective, longer pulse durations (6–10 ms) with multiple passes or "pulse stacking", consisting of application of a rapid succession of pulses to a particular location with cooling to achieve "purpura-free" treatments, is quite effective and less noticeable.

Epidermal protection during laser treatments, including those with PDL, is critical. Cooling helps to reduce blistering, crusting, and subsequent dyspigmentation, i.e. hypo- and hyperpigmentation. The most common cooling strategies are contact cooling, forced cold air, and cryogen spray. The Syneron-Candela PDL systems incorporate cryogen spray cooling (Dynamic Cooling Device™) which is deployed immediately before the light pulse, while Cynosure systems use forced cold air. In addition to protecting the epidermis from non-selective thermal damage, cooling allows for the use of higher fluences, with improved efficacy.

KTP Laser (Frequency-Doubled Nd:YAG Laser)

KTP 532 nm laser light is produced by passing 1064 nm light from an Nd:YAG (neodymium–yttrium–aluminum–garnet) laser through a potassium titanyl phosphate (KTP) crystal, which effectively halves the wavelength and doubles the frequency. Since this wavelength closely corresponds to the first absorption peak of hemoglobin at 542 nm, the KTP laser can be used to effectively treat some vascular lesions (e.g. telangiectasias) in a purpura-free manner (Fig. 137.2A,B). In addition, this laser is a popular device for the removal of lentigines and other epidermal pigmented lesions. While this laser is best employed in patients with skin phototypes I–III, it can used in darker skin phototypes (IV–VI) for unique applications, such as dermatosis papulosa nigra.

Nd:YAG Laser

The deeply penetrating Nd:YAG 1064 nm laser has significantly less hemoglobin absorption than the wavelengths of the PDL or KTP lasers. However, its absorption by melanin is also very limited. The latter property theoretically enhances the safety profile of the 1064 nm laser in patients with darker phototypes. This laser can be used to treat deeper vascular lesions and spider veins up to 3 mm diameter[3]. Because of its poor coefficient of absorption by hemoglobin, much higher fluences are required to produce transmural heating of blood vessels. As a consequence of the higher fluences and longer pulse widths, this wavelength has a narrow window of safety, with a significant potential for volumetric heating and collateral damage; in addition, it tends to be quite painful. Cooling is critical for epidermal protection and pain control, as well as to reduce the risk of scarring from nonspecific thermal injury. Nd:YAG lasers should be used with extra caution when treating vascular lesions.

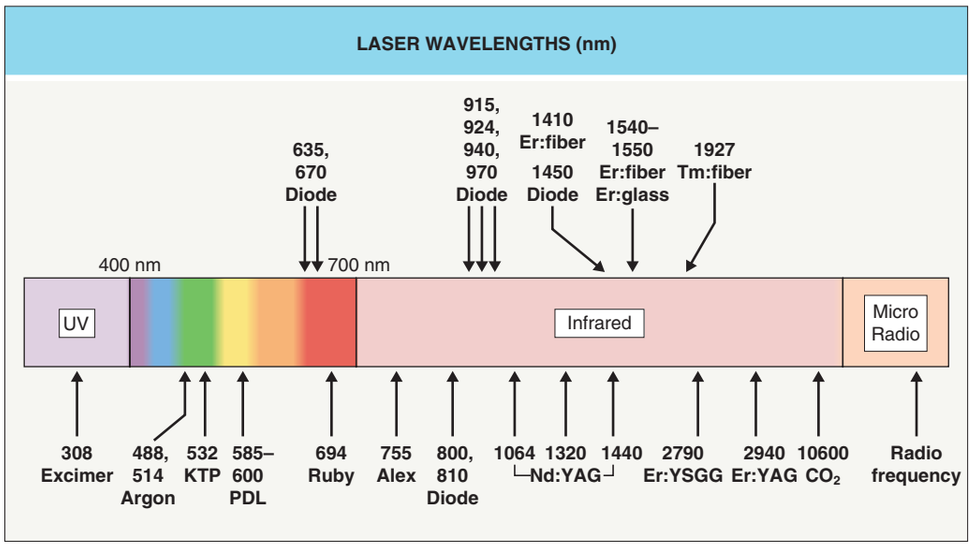

Fig. 137.1 Laser wavelengths (nm). Laser wavelengths lie predominantly within the ultraviolet, visible and infrared portions of the electromagnetic spectrum. Alex, alexandrite; Er, erbium; KTP, potassium titanyl phosphate; Micro, microwaves; Nd, neodymium; PDL, pulsed dye laser; Radio, radio waves; Tm, thulium; UV, ultraviolet; YAG, yttrium–aluminum–garnet; YSGG, yttrium–scandium–gallium–garnet.

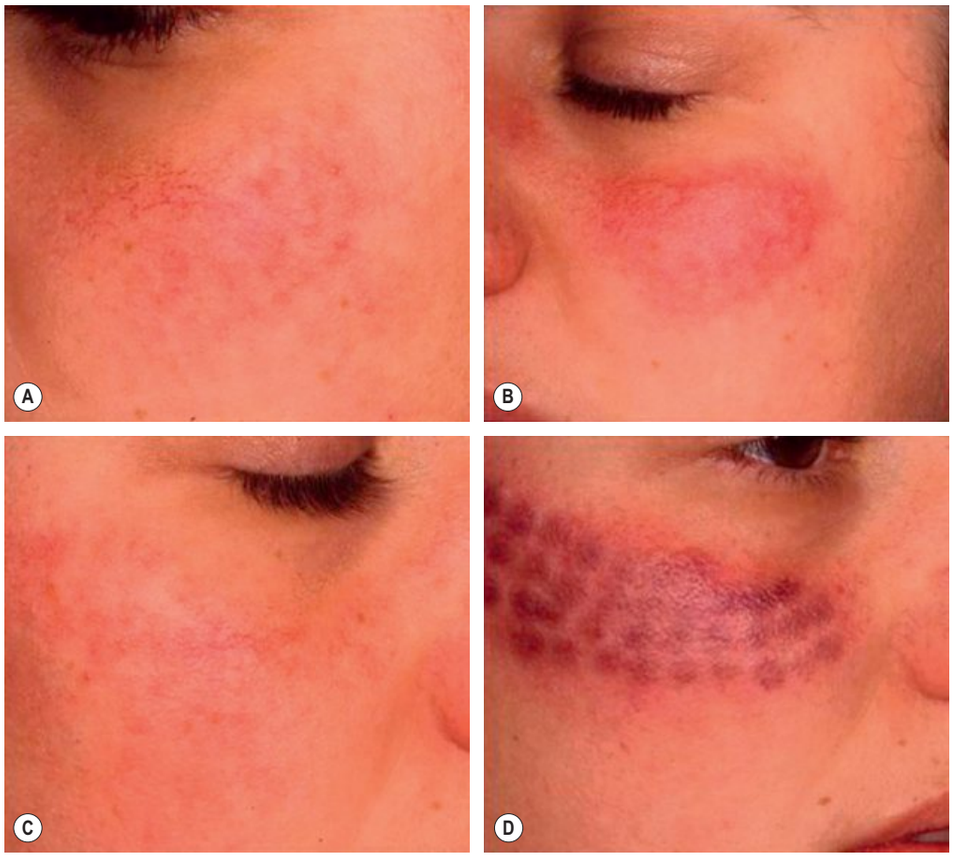

Fig. 137.2 Treatment of facial telangiectasias – potassium titanyl phosphate (KTP) laser versus pulsed dye laser (PDL). A, C Before treatment. Mild erythema follows KTP therapy (**B**) compared to circles of purpura after PDL (**D**).

Intense Pulsed Light

Intense pulsed light (IPL) systems emit filtered polychromatic light with wavelengths ranging from visible to near infrared (500–1200 nm). Sophisticated filtering and pulsing systems prevent unwanted wavelengths from damaging the skin, thus making this device more selective and quite versatile. Integrated skin cooling is a useful feature present in some devices, and it can be employed to provide epidermal protection, while at the same time allowing greater fluences to reach deeper targets. IPL systems can be used to treat a number of conditions, including rosacea, PWBs, hemangiomas, poikiloderma of Civatte and lentigines, as well as provide overall photorejuvenation.

Cold ultrasound gel or aloe vera gel should be applied both to protect the epidermis from excessive heat and to reduce the difference in refractive indexes between air and skin, thereby allowing better penetration and absorption of light. In addition, the gel enhances gliding of the handpiece from one location to the next.

Despite these measures, thermal injury to the epidermis can still occur, leading to blistering, scarring, and permanent pigmentary alterations. This is generally operator-dependent, with a greater risk when treating patients with a tan or darker skin phototypes (Fig. 137.3). IPL is most commonly used for patients with phototypes I–III with chronic photodamage or for hair removal. For treatment of patients with more darkly pigmented skin, longer wavelength filters or lower fluences plus longer pulse widths can be used (Fig. 137.4). Filters can also be used for other specific indications, e.g. treatment of vascular lesions.

The authors' preferred technique is to deliver multiple passes to a particular treatment area, with each subsequent pass oriented at

Fig. 137.3 Dyspigmentation with potential for scarring due to inappropriate intense pulsed light (IPL) treatments. Bands of hypopigmentation on the face (**A**) and arms (**B**) in two patients with darker skin phototypes.

a different angle. This allows for uniform, consistent coverage and prevents zebra-like pigmentary irregularities and skip areas. If double or triple pulses are utilized in any one area, adequate time for epidermal cooling should be allowed between passes. The observable endpoints of IPL treatment are darkening of lentigines (see Fig. 137.4B) and either a disappearance or intravascular coagulation of telangiectasias in the treated areas.

As with any of these devices, the initial pulses should be assessed in terms of the tissue response. Potential problems that should be avoided include excessive blanching, bruising, and production of the Nikolsky sign or other signs of excessive non-selective heating. If cooling is being used, it should be assessed for efficacy. Additionally, care must be taken to avoid inadvertent photoepilation of eyebrows, and in men, bearded skin.

ABLATIVE LASERS: CARBON DIOXIDE AND ER:YAG

Both the CO_2 (10 600 nm) and Er:YAG (2940 nm) lasers have wavelengths in the infrared portion of the electromagnetic spectrum (see Fig. 137.1), with the major chromophore being water. Based upon the energy absorbed per volumetric unit, the minimum fluence necessary for the CO_2 laser to produce tissue ablation has been calculated to be 5 J/cm^2. Below this fluence, tissue is not vaporized, rather it is coagulated. However, both vaporization and coagulation are useful in the treatment of skin disease, and these wavelengths can be manipulated to achieve an appropriate balance of the two. When using these resurfacing lasers, the photothermal coagulative effect is responsible for hemostasis, collagen rejuvenation, skin tightening, and, by extension, many of the complications such as scarring that can be seen with these devices.

To achieve selective photothermolysis of the skin with the CO_2 laser, it has been suggested that the ideal pulse duration is ≤1 ms. The development of high-powered, short-pulsed CO_2 lasers (as compared to their continuous wave predecessors) has allowed for more selective control of tissue vaporization and thermal injury. The first pass of the high-energy, short-pulsed CO_2 laser induces localized tissue vaporization with surrounding coagulation/desiccation. Since this residual carbonized tissue acts as a heat sink, subsequent CO_2 laser pulses tend to vaporize less and heat more, causing non-selective damage. Thus, second and subsequent passes should only be applied after removal of the desiccated "charred" material at the surface of the skin[4,5].

The Er:YAG laser emits light at 2940 nm, with water affinity being nearly 15 times greater than that of the CO_2 laser. This allows the Er:YAG laser to vaporize tissue more efficiently, leaving only a small residue of coagulated tissue. As a consequence of the limited photothermal effects, hemostasis and collagen contraction are significantly reduced with Er:YAG lasers. Sub-ablative coagulation settings, achieved by lengthening the laser pulse duration, have been incorporated into newer modulated Er:YAG laser systems (e.g. Sciton®), inducing more hemostasis and resulting in better tissue contraction. While pure Er:YAG lasers demonstrated only modest tissue tightening as compared to CO_2 lasers, modulated Er:YAG systems have produced comparable resurfacing results[5]. It is critical that the laser surgeon be constantly aware of the depth of vaporization.

The fully ablative CO_2 and long-pulsed Er:YAG lasers remain the gold standard for photorejuvenation, wrinkle reduction, and skin tightening. To date, nothing can beat the results obtained by an experienced laser surgeon using one of these lasers. Specifically, even deep, coarse and fixed perioral and periorbital rhytides can be significantly diminished or eliminated (Fig. 137.5)[4]. Redundant skin is tightened by thermal coagulation, collagen contraction, and associated fibroplasia. However, this dramatic improvement comes at the expense of slow healing. A split-face study of Er:YAG and CO_2 laser resurfacing demonstrated this duality; the side treated with the CO_2 laser had 63% improvement with 7.7 days of crusting, compared to the Er:YAG laser-treated side which had 48% improvement with an average of 3.4 days of crusting[6].

In general, more significant clinical improvement has gone hand in hand with more thermal damage, leading to more discomfort, more extensive wound care, and longer healing times. Additional side effects include persistent erythema for 3+ months, risk of scarring, a 15% chance of delayed-onset permanent hypopigmentation, and a line of demarcation between treated and untreated areas. All patients with actinic bronzing will note an improvement or lightening of their skin pigmentation in the treated areas. To avoid any demarcation lines in these regions, it is prudent to treat entire anatomic areas. This is particularly true for skin phototypes I and II. Skin phototypes IV–VI tend not to have actinic bronzing and hence focal or geographic areas can be treated.

Treatment of acne scarring is a common indication for ablative lasers. Elevated or distensible acne scars are most amenable to resurfacing, compared to icepick and non-distensible scars, which are often resistant[7]. Focal ablation has been effectively used for resurfacing benign epidermal tumors and proliferations such as seborrheic keratoses, epidermal nevi, and verrucae; actinic keratoses and actinic cheilitis can also be significantly improved[8]. Additionally, benign hyperplasia or neoplasms with an elevated component can be "debulked", e.g. rhinophyma, lymphangioma, adnexal tumors (including syringomas and angiofibromas; Fig. 137.6), and xanthomas. Based upon more limited experience and case reports, effective treatment of balanitis xerotica obliterans, porokeratosis, keratoderma, chondrodermatitis nodularis helicis, and Hailey–Hailey disease has been observed. Other possible indications for both the CO_2 and Er:YAG lasers include treatment of hidradenomas, colloid milium, eruptive hair cysts, and onychodystrophy.

Fig. 137.4 Intense pulsed light (IPL) treatment of lentigines in a patient with Fitzpatrick phototype IV skin. Because of the more darkly pigmented skin, lower energy and a longer pulse duration were carefully employed. **A** Before treatment. **B** Lentigines are appropriately slightly darker immediately following IPL. **C** Dry crusting of the skin 3 days postoperatively. **D** Excellent improvement of facial lentigines at 10 days.

Among the most significant risks with ablative resurfacing is infection, whether by bacteria, viruses, or fungi. Specifically, and especially if the treated region involves perioral skin or adjacent areas, antiviral medications (e.g. valacyclovir, famciclovir) should be initiated prophylactically the day prior to, or at least the morning of, the procedure and continued for 15 days. This is true even in the absence of prior herpetic infection so as to prevent the possibility of a generalized herpetic infection in the denuded skin. Antibiotic coverage, especially against staphylococci, may be prudent, but is much debated. Antifungal prophylaxis with fluconazole (a single-dose 200 mg tablet) given during the early postoperative period has been demonstrated to prevent candidal infection and may promote re-epithelialization.

FRACTIONATED LASERS

Traditional laser resurfacing yielded impressive facial photorejuvenation and significant tissue tightening. However, these outcomes were often at the cost of delayed healing, persistent redness and swelling, infection, unpredictable pigmentary changes (hypo- or hyperpigmentation), and scarring. In 2004, fractionated photothermolysis (FP) was introduced (Table 137.1). The development of fractionated lasers has changed the way laser surgeons practice. One can be aggressive in terms of depth and density, and yet relatively safe in terms of patient downtime, postoperative recovery, and complications. In contrast to traditional lasers where the spot size of the device defined the smallest treatment unit on the skin, hundreds of controlled microscopic zones of coagulative or ablative injury are delivered to the skin with each scan or stamp of the fractional device[9]. These areas of microscopic thermal injury are defined as microscopic treatment zones (MTZs; also referred to as microthermal zones). While MTZs appear to be minute dots on the skin, they actually represent exact columns or cylinders of epidermal and dermal thermal damage (see Fig. 136.6)[10]. MTZs are deliberate and calibrated such that the resultant depth, width, and density are defined. Each microdot or cylinder of damage is surrounded by normal unaffected skin, which acts as a reservoir for healing and enables these micro-wounds to resolve quickly with minimal discomfort (Fig. 137.7). Histologically, the healing wounds appear as microscopic epidermal necrotic debris (MENDs); the latter are composed of fragmented and damaged skin components, including epidermis, dermis, melanin, and elastin[11]. The skin surface heals within 7 days with extrusion of the MENDs.

Non-Ablative Fractional Photothermolysis

The first system to be cleared for clinical use was the Fraxel® SR750 (Reliant Technologies), which is a 1550 nm erbium-doped fiber fractionated laser that targets water as its chromophore. The laser handpiece employs a scanning system allowing for uniform deposition of MTZs. The second-generation system (Fraxel® DUAL) includes both 1550 nm and 1927 nm wavelengths. This is a major development as it increases the versatility of this device. The 1550 nm wavelength allows for adjustment of the MTZ energies up to 70 mJ with a depth of injury down to 1500 microns and treatment densities of 5%–50% (Video 137.1). The depth of these MTZs is an operator-dependent parameter and can be adjusted to match the thickness of skin or entity being treated. The 1927 nm wavelength provides a more superficial non-ablative impact in which the depth is non-linear. This wavelength is very useful for patients with photodamage and fine lines. It can be used in skin phototypes III and IV (especially Asians) with very little postinflammatory hyperpigmentation. Some like this device for the treatment of melasma, alone or in combination with nanosecond or picosecond lasers and topical agents. These two wavelengths (1550 and 1927 nm) can be used in combination in the same treatment session.

Collagen remodeling is induced with this fractionated heating of the skin. The very nature of fractional photothermolysis (FP) allows for the safe application of incredibly high fluences to narrow tissue columns, which if applied to confluent areas would certainly cause delayed healing and tissue scarring.

New indications and applications for this novel technology continue to evolve and include patients with chronic photodamage, skin laxity, rhytides, striae, and multiple types of scarring, including acne, hypopigmented, traumatic, and surgical scars (Fig. 137.8). One of the first clinical applications of FP was treatment of facial melasma. While initial studies were promising with near-complete clearance of melasma after a few treatments, this early exuberance has been tempered by a more considered and lengthy assessment of response, with the tendency of melasma to recur.

Ablative Fractional Photothermolysis

Following the success of fractionated *non-ablative* rejuvenation came the development of fractionated *ablative* rejuvenation. The first commercially available system was the Fraxel re:pair laser, originally manufactured by Reliant Technologies. This scanning fractionated CO_2 laser has the ability to place 2000 microablative MTZs per second. Indeed, many other companies have produced their own fractionated ablative devices using CO_2, Er:YAG, and Er:YSGG (yttrium–scandium–gallium–garnet) wavelengths (see Table 137.1). As an example, the re:pair® system creates MTZs ~120–150 microns wide and 200–1500 microns in depth. The speed of delivery corresponds to the speed at which the operator moves the handpiece over the skin. The fluence of each laser microbeam can be adjusted up to 70 mJ/MTZ by the operator and the density ranges from 10% to 70% of the skin surface. UltraPulse® DeepFX™ (Lumenis), an equivalent system that utilizes a galvanic scanner, creates a pattern of MTZs, each of which is 110 microns wide and 50–4000 microns deep (depending on parameters chosen)[12]. Because this greater depth of microablative channels approximates the depth of thicker scars, this system may be of greater benefit when treating such scars.

EXAMPLES OF FRACTIONATED LASER AND RADIOFREQUENCY DEVICES*				
Laser type	**Wavelength (nm)**	**Laser name™,® (examples)**	**Energy of MTZ (per micropulse)**	**MTZ depth (microns)**
Laser – ablative				
Rolling scanner				
CO_2	10 600	Fraxel re:pair	5–70 mJ/MTZ	200–1500
Stamping scanner				
CO_2	10 600	UltraPulse Deep FX	2.5–50 mJ/MTZ	50–4000
CO_2	10 600	CO2RE	1–90 mJ/MTZ	750
Er:YSGG	2790	Pearl Fractional	60–320 mJ/MTZ	1000
Er:YAG	2940	Lux 2940	≤15 mJ/MTZ	50–300
Er:YAG	2940	Pixel	14–27 mJ/MTZ	30–70
Er:YAG	2940	ProFractional	≤400 J/cm^2	1000
Laser – non-ablative				
Rolling scanner				
Erbium fiber	1550	Fraxel re:store	4–70 mJ/MTZ	500–1400
Erbium/thulium fiber	1550/1927	Fraxel DUAL	4–70 mJ/MTZ	500–1400/200
Erbium fiber	1410	Fraxel re:fine	5–20 mJ/MTZ	650
Stamping scanner				
Diode/bipolar RF	915 and bipolar RF	Matrix IR	≤70 J/cm^2	500
Nd:YAG	1440 ± 1320	Affirm	8–12 mJ/MTZ	200–300
Er:Glass	1540	Fractional 1540	15–50 mJ/MTZ	125–850
Er:Glass	1540	Mosaic	5–40 mJ/MTZ	1000
Er:Glass	1540	Matisse	≤250 J/cm^2	30–150
Radiofrequency (RF) – ablative and non-ablative				
Ablative, invasive	RF – unipolar	Pixel RF	Up to 300 W	100–150 mm (80–120 mm diameter)
Nonablative	RF – unipolar, insulated microneedles	INFINI	Up to 50 W	0.5–3.5 mm (49 or 16 microneedles)
		Fractora	≤62 mJ/pin	Up to 1 mm (20 or 60 pin tip)
		Profound	Temperature controlled	2–3 mm (7 pairs of microneedles)
	RF – monopolar or bipolar	INTRAcel	Temperature/impedance controlled	0.5–2 mm (49 microneedles)

*A partial list.

Table 137.1 Examples of fractionated laser and radiofrequency devices. CO_2, carbon dioxide; Er, erbium; Er:YAG, erbium-doped yttrium–aluminum–garnet; J, joule; mJ, millijoule; MTZ, microthermal zone or microscopic treatment zone; Nd, neodymium; RF, radiofrequency; Er:YSGG, erbium:yttrium–scandium–gallium–garnet; W, watts.

The fractional devices, both ablative and non-ablative, have been used for traditional resurfacing indications such as improvement of rhytides and acne scarring (Fig. 137.9). Initial studies utilizing re:store® for the treatment of periorbital rhytides showed mild improvement in 12% of patients, noticeable improvement in 30%, and moderate to significant improvement in 54% after one to four treatments[13]. Settings for pulse energy and treatment density should be tailored for the individual patient. Collective experience has also shown that fine to moderate rhytides respond more favorably than do deeper rhytides, and less dramatic improvement should be expected compared to fully ablative resurfacing[14].

When used for acne scarring, fractional deep dermal ablation (FDDA™) treatment has demonstrated significant efficacy. In a study of 30 patients with moderate to severe acne scarring who underwent one to three treatments[15], mild to moderate overall improvement was noted with energies ranging from 20 to 100 mJ and densities of 600–1600 MTZ/cm^2. A fractionated ablative depth of 1.5 mm or greater will likely induce optimal outcomes when treating acne scarring. The concept that a high density of fractional injury always provides better outcomes has recently been challenged, with some evidence that a low-to-medium density is as good or better. Although some patients may initially view multiple treatments as inconvenient, the benefits of rapid skin healing (within 5–7 days) and remarkably little postoperative discomfort compared to traditional laser resurfacing are distinct advantages (see Fig. 137.7).

Ablative FP offers the opportunity for relatively safe treatment of anatomic regions that were notoriously difficult to rejuvenate with conventional ablative resurfacing. Areas such as the neck and upper chest can now be more easily treated, albeit at reduced energy and density. Another advantage of fractionated systems is the ability to safely treat all skin phototypes, including patients with darkly pigmented skin (Fig. 137.10).

Evidence that fractionated laser therapies induce neocollagenesis is supported histologically. Increased expression of collagen remodeling markers such as heat shock proteins (47, 70 and 72), collagen III, proliferating cell nuclear antigen, and α-smooth muscle actin have been demonstrated within treatment areas[16,17]. In addition to inducing neocollagenesis, ablative fractionated systems induce *volumetric tissue reduction* and dermal plumping[17,18]. Taken collectively, the vaporization volume of millions of tiny-diameter cylinders of skin adds up. A standard aggressive fractionated CO_2 laser treatment can remove 5–7 cm^3 from the skin of the face[19]. The original hope was that this volumetric tissue reduction would result in impressive skin tightening. In practice, every one of these tiny holes is actually repaired with new collagen and elastin, leading to improvement in color, texture and tone, but with less skin tightening than anticipated. However, periodic treatments will improve skin laxity and could possibly prevent or delay the need for future facelift procedures.

Fractionated lasers represent a major therapeutic advance in the treatment of surgical, traumatic, and burn scars. Documented

Fig. 137.7 Improvement of depressed acne scarring following treatment with fractionated CO_2 laser (Fraxel re:pair®). A Preoperatively. **B, C** Intraoperatively, pin-point bleeding from microscopic treatment zones (MTZs; also referred to as microthermal zones) is observed. **D** Four days postoperatively. **E** One month postoperatively.

improvement in overall appearance, texture, mobility, and symptoms such as pain and itch has been well described[20]. The traditional approach was to allow scars to mature for 1–2 years prior to any intervention, but this has been demonstrated to be incorrect. Early intervention, even at the time of suture removal, can hasten healing and reduce ultimate disfigurement. A combination approach consisting of PDL, fractionated lasers (ablative or non-ablative), and/or radiofreqency microneedling (± intralesional corticosteroids or 5-fluorouracil) is likely to improve the appearance of scars[21] (see below).

Fractionated Laser Assisted Drug Delivery

Significant advances have been made in fractionated laser assisted drug delivery by disrupting the barrier function of the stratum corneum[22]. Both ablative and non-ablative lasers can dramatically increase the uptake of any topical agent. Understanding the relation of depth of fractionated ablation, the associated collar of spongy coagulation inside each channel, the density of laser channels, and the hydrophilic/lipophilic nature of the topical medications are all important.

The MTZs function as channels through which even large-sized molecules may be delivered to essentially any depth within the skin. Studies have been conducted utilizing a diverse array of therapeutic agents including anesthetics, chemotherapeutic drugs, corticosteroids, and stem cells[23,24]. Fractionated delivery of topical aminolevulinic acid (ALA) for photodynamic therapy (PDT) in areas such as the extremities can dramatically improve drug absorption and efficacy.

TREATMENT OF CHRONIC PHOTODAMAGE

While we are blessed by the sun in terms of "the good outside", chronic sun exposure wreaks havoc with our skin, inducing lentigines, telangiectasias, rhytides, and cutaneous carcinomas. Although successful laser treatment of lentigines and telangiectasias is possible based upon specific wavelengths (see above), there is a less well understood improvement that comes from nonspecific heating of the dermis, which induces the production of new collagen and elastin.

It has been said that twice yearly treatments with IPL could maintain a youthful appearance. In a study of 135 patients with poikiloderma of Civatte, IPL treatment of the neck and/or upper chest led to >75% clearance of telangiectasias and hyperpigmentation after a mean of three treatments[25]. While the emitted light is broad, IPL filters allow for more targeted treatments. It has been postulated that the shorter wavelengths are responsible for the improvement in pigmentation and telangiectasias, while the longer wavelengths are responsible for collagen remodeling via thermal effects on tissue water[26]. However, many wavelengths are absorbed by dermal water and their impact is likely the cause of improved appearance, particularly after repeated treatments.

While the ablative lasers can produce dramatic improvement in skin laxity and photodamage, their short-term side effects of discomfort, oozing, edema, persistent erythema, and extended healing time, plus the potential risks for infection, scarring, and delayed-onset hypopigmentation have led to a shift toward non-ablative laser therapies. "Subsurface remodeling" secondary to dermal wound healing responses can be seen in patients treated by IPL, PDL, and a number of other lasers. The long-pulsed PDL can be used with a multiple-pass technique for photorejuvenation. It is worthy to note that both the 585 nm and 595 nm PDLs have received FDA clearance for treatment of periocular wrinkling. While collagen remodeling has been demonstrated histologically, clinical improvement of wrinkles is variable and modest.

In addition to specifically improving pigmentation, KTP and Nd:YAG lasers have also been shown to cause a 20%–40% improvement in texture and a 20%–30% improvement in rhytides[27]. Lastly, laser surgeons must appreciate the science behind the energy delivery, rather than base assumptions on exaggerated claims by device manufacturers. No one laser or wavelength meets all of the objectives required for skin rejuvenation.

TREATMENT OF VASCULAR LESIONS

The target chromophore in vascular lesions is hemoglobin, in particular oxyhemoglobin, with absorption peaks at 418, 542 and 577 nm (see Fig. 136.3). While the primary target is hemoglobin, the structurally complex nature of the skin does not allow for simplistic "targeting". Factors such as blood vessel depth, vessel diameter, and skin phototype are also highly relevant considerations when treating vascular lesions. An equally important consideration is the structures that the laser surgeon wishes to avoid, e.g. the epidermis and hair follicles.

Fig. 137.8 Non-ablative fractionated laser therapy for scar remodeling. **A** Patient at presentation with traumatic hypertrophic and fibrotic scarring. **B** After three treatments with Fraxel re:store®. **C** Marked improvement of scarring after five treatments performed over 6 months.

The most commonly used devices for the treatment of vascular lesions include IPL and the 532 nm KTP, 595 nm PDL, and 1064 nm Nd:YAG lasers. Other systems such as the 755 nm alexandrite and the 800 nm and 940 nm diode lasers also play an important role in the treatment of vascular lesions (Table 137.2).

Clinical improvement is best achieved by photothermal vascular damage[28]. As the pulse width approximates or slightly exceeds the thermal relaxation time of the target vessel, photothermal damage results. This induces *intravascular* thrombosis or vessel rupture and subsequent collagenous fibrosis of the blood vessel wall and adjacent tissues[28]. These changes result in vessel disappearance or an immediate purpuric reaction (see Fig. 137.2D). Given the unwanted cosmetic appearance of the latter, which can last for 2 weeks, longer pulse widths (>6 ms) are often used, as they produce gentler heating of the target vessel and avoid bruising altogether. However, some degree of intravascular thrombosis may be a prerequisite for clinical improvement and resolution of vascular lesions, as is the case in port-wine birthmarks (PWBs).

Port-Wine Birthmarks (PWBs)

One of the first clinical applications of laser therapy was treatment of congenital vascular lesions, namely PWBs. PWBs are capillary malformations that involve primarily the mid to superficial dermis; they occur in 0.3%–0.5% of newborns and initially present as pink to red patches. These vascular anomalies are cosmetically and psychologically problematic and are frequently located on the face. When PWBs are bilateral and/or involve the "forehead area", there is a higher risk of Sturge–Weber syndrome[29], with somatic activating mutations in *GNAQ* found in both Sturge–Weber syndrome and non-syndromic PWBs[30] (see Ch. 104). PWBs located on the extremities may be a sign of Klippel–Trenaunay or Parkes Weber syndrome, with associated tissue hypertrophy and additional vascular malformations (venous, lymphatic, arteriovenous) present.

An early treatment of PWBs utilized the continuous wave argon laser (488 and 514 nm). Despite the wavelength's relative specificity for its vascular target, this laser caused marked scarring in up to a third of patients due to nonspecific thermal injury. The latter occurred because the pulse duration of ~200 ms dramatically exceeded the thermal relaxation time of the PWB vessels (~1–10 ms)[31]. A therapeutic paradigm shift then occurred based upon the concept of selective photothermolysis, leading to the development of the PDL which was specifically designed to treat PWBs.

While the early PDLs emitted a 577 nm wavelength, the current PDL systems deliver 585 and 595 nm wavelengths, allowing targeted delivery of laser energy deeper into the skin with increased efficacy. These longer wavelengths are less well absorbed by hemoglobin, but they penetrate slightly deeper into the skin[32]. The addition of epidermal cooling has allowed the use of higher energy fluences and treatment of all skin

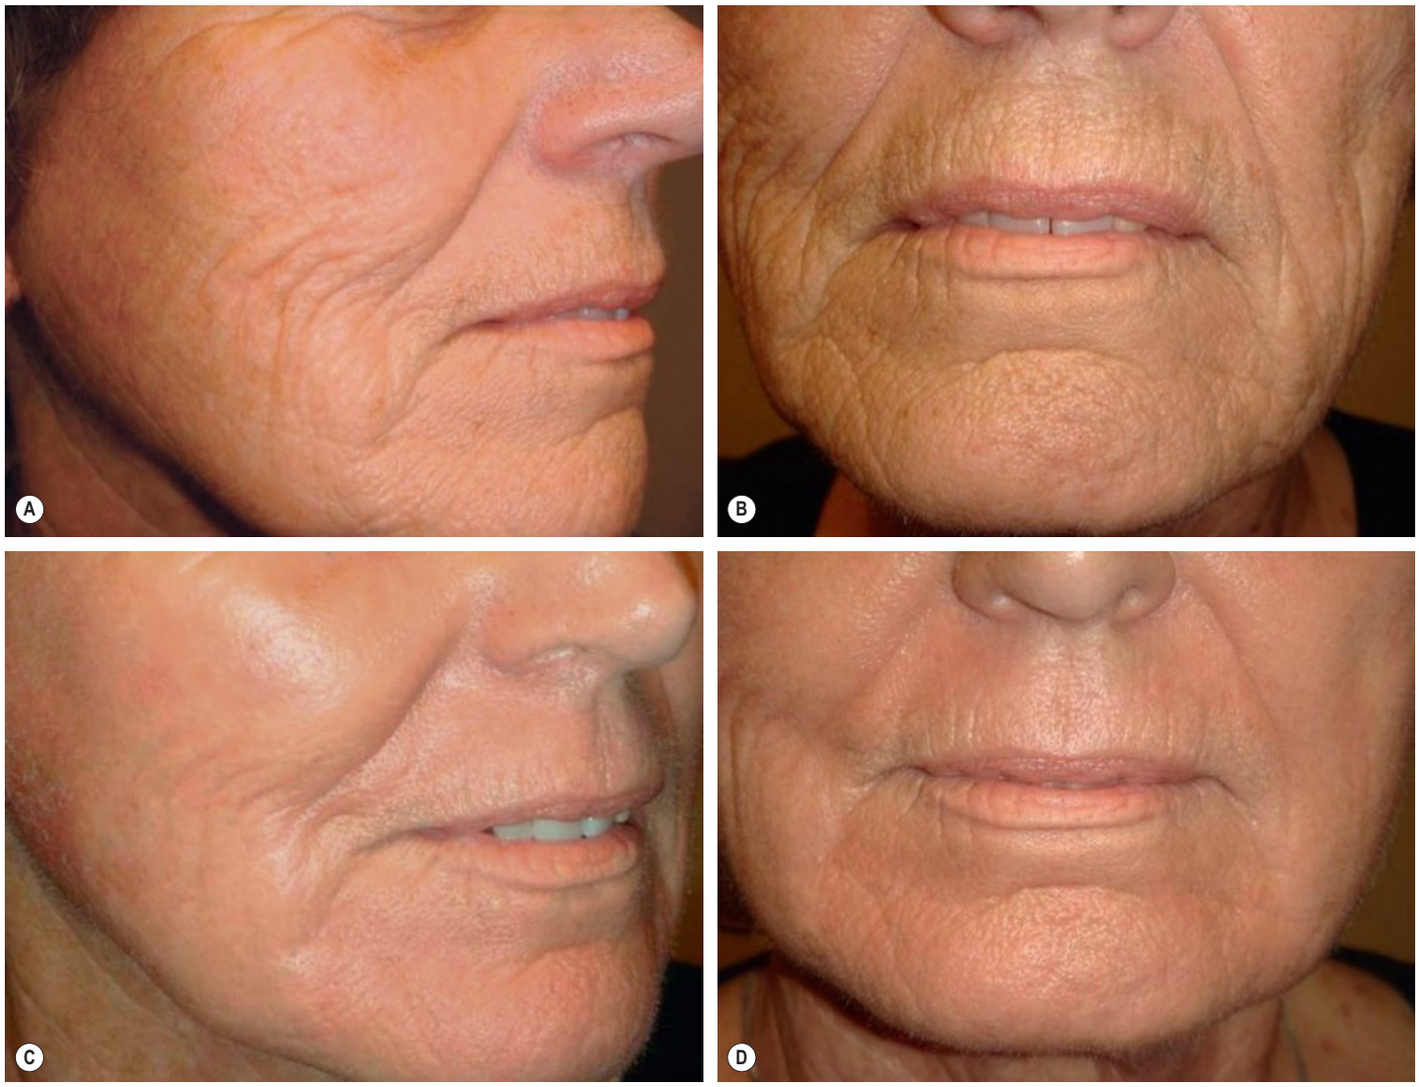

Fig. 137.9 Fractionated CO_2 laser (Fraxel re:pair®) resurfacing. A, B Coarse rhytides and solar elastosis. **C, D** Significant improvement in color, texture, tone, and wrinkling following one treatment. Mild residual erythema and edema persist at 1 month.

Fig. 137.10 Treatment of acne scarring with fractionated CO_2 laser (Fraxel re:pair®) in a patient with skin phototype IV. A Before treatment. **B** Three months after treatment, visible postinflammatory hyperpigmentation is seen. **C** Ten months postoperatively, there is improvement in postinflammatory hyperpigmentation. **D** One year postoperatively, improvement in acne scarring is noted.

phototypes, although darker skin phototypes are still more challenging. Commonly used settings range from energy fluences of 4–15 J/cm^2 with pulse widths of 1.5–10 ms and a 7–12 mm spot size.

For both technical and psychological reasons, early treatment of PWBs is recommended. The dilated and ectatic vessels of PWBs are neither proliferative nor do they self-involute. Their total surface area becomes larger in proportion to the growth of the child. Soft tissue hypertrophy and nodules may develop over time and the color can darken to deep red or purple. When these changes occur, treatment becomes more challenging and often requires the use of lasers with longer wavelengths, along with higher energy fluences and longer pulse durations, in order to effectively treat the deeper and thicker vessels. From a psychological standpoint, PWBs have been shown to impact social and cognitive development during childhood and can have lasting repercussions on adult social relationships[33]. In addition, early treatment permits shorter treatment sessions (as the lesions are smaller) and may allow resolution of the capillary malformation prior to the child starting school when social interactions increase. Laser treatment in children younger than 6 months of age has been demonstrated to be safe and effective[34].

LASERS AND OTHER DEVICES USED FOR THE TREATMENT OF VASCULAR LESIONS					
Laser/device	**Wavelength (nm)**	**Fluence (J/cm²)**	**Pulse duration (ms)**	**Target structure**	**Applications**
Skin-surface application					
Variable-pulsed KTP laser	532	Up to 40	1–100	Telangiectasia, venulectasia	Facial telangiectasias, erythematotelangiectatic rosacea, cherry angiomas, leg telangiectasias, venous malformations
Pulsed dye laser	585, 590, 595, 600	Up to 40	0.45–40	Telangiectasia	Port-wine birthmarks, erythematotelangiectatic rosacea, facial and leg telangiectasias, cherry angiomas, spider angiomas, venous lakes, infantile hemangiomas, hypertrophic scars, striae rubrae, verrucae
Long-pulsed alexandrite laser	755	Up to 100	3–100	Venulectasia, telangiectasia	Leg telangiectasias ("spider veins"), venous malformations, port-wine birthmarks
Diode laser	800, 810, 840, 940, 980	10–100	5–400	Venulectasia, telangiectasia	Leg venulectasias and telangiectasias ("spider veins"), blue reticular veins, venous malformations
Long-pulsed Nd:YAG laser	1064	5–900	0.25–500	Venulectasia, telangiectasia	Leg venulectasias and telangiectasias ("spider veins"), blue reticular veins, facial telangiectasias, venous lakes, venous malformations
Intense pulsed light	400–1200	10–80	2–200	Telangiectasia, venulectasia	Erythematotelangiectatic rosacea, leg telangiectasias ("spider veins")
Endovascular application					
Diode lasers	810, 940			Varicose veins	Saphenous vein insufficiency
Nd:YAG laser	1320			Varicose veins	Saphenous vein insufficiency
Radiofrequency energy source	Radiofrequency			Varicose veins	Saphenous vein insufficiency

Table 137.2 Lasers and other devices used for the treatment of vascular lesions. For details on endovascular applications, see Chapter 155. ms, millisecond.

While 70% of PWBs will have good or very good improvement following treatment (Fig. 137.11), a minority (<10%) will have very modest or no improvement. The degree of PWB clearance is dependent on several factors including the size of the lesion and its anatomic location[35]. For example, centrally located facial lesions (i.e. medial cheeks, upper lip, and nose) tend to be more treatment-resistant as compared to lesions located in the periorbital region or on the forehead, lateral cheeks, or chin. Likewise, PWBs on distal extremities are more treatment-resistant and require a more aggressive approach. Although a remarkable response can be obtained after one laser treatment, treatment of PWBs typically requires multiple (10 or more) sessions.

Given that PWBs are composed of various-sized blood vessels, each with its own requisite treatment parameters, the PDL may prove inadequate in eliminating the entire capillary malformation. A poor response may be related to poor laser penetration, a mismatch of parameters to vessel size, inadequate vascular heating, or scarce or poor chromophore uptake[36]. Given the limitations of the PDL, resistant components of PWBs can be treated with the alexandrite laser or IPL.

Infantile Hemangiomas

Representing the most common tumor of infancy, hemangiomas have a predilection for the head and neck region (60%), followed by the trunk and the extremities. They are present in 1%–2% of neonates and there is a higher incidence in premature infants. These tumors classically grow rapidly within the first few weeks of life. Infantile hemangiomas may have both superficial and deep components, with the superficial portions appearing red and the deeper components appearing blue. They can be categorized as focal or segmental (see Ch. 103). Their natural maturation involves a proliferative phase, a static phase, and an involutional phase. Although hemangiomas can regress leaving the affected skin with normal texture and color, many heal with hyper- or hypopigmentation and atrophy or fibrofatty change (see Fig. 103.9).

Treatment of infantile hemangiomas, if any, should be tailored to the specific lesion, with consideration of its location, size, proliferative rate, and whether it is likely to produce a functional or anatomic deficit. Currently, oral β-blockers, most commonly propranolol, are a mainstay of therapy for infantile hemangiomas that threaten vital functions, are potentially disfiguring, or have severe ulceration[37]. Other therapeutic options include monitoring, topical timolol (for thin lesions), corticosteroids (topical, intralesional or systemic), laser therapy, and less often surgical excision.

Although the role of laser therapy in the treatment of infantile hemangiomas is still controversial[38], in some studies PDL has been shown to slow progression, decrease time to involution, and promote healing of ulcerated lesions[39]. A retrospective study of 90 patients with infantile hemangiomas treated with PDL demonstrated a significant improvement in color and decrease in thickness in 81% and 64% of patients, respectively[40]. Combining systemic β-blockers with laser therapy may lead to a more rapid response and enhanced resolution; for example, in one retrospective study of infants with segmental facial hemangiomas treated concurrently or sequentially (propranolol followed by PDL), there was more complete clearance over a shorter time period following concurrent or sequential therapy (3 and 6 months, respectively) compared to propranolol alone (almost 10 months)[41].

Epidermal protection is critical in the treatment of infantile hemangiomas. Ulceration, scarring, and pigmentary changes can occur if the epidermis is not adequately protected via cooling or if excessive energies are employed.

Telangiectasias

Patients frequently present with facial telangiectasias and they are often associated with chronic photodamage and rosacea. Telangiectasias can also occur on the face and elsewhere in the setting of liver disease, autoimmune connective tissue diseases, surgical scars, and the overuse of topical corticosteroids. Facial telangiectasias are typically located on the nose, cheeks and chin; they measure 0.1–1.0 mm in diameter and are commonly treated with PDL, KTP laser, or IPL. When the PDL is used with short pulse durations, significant clearance can be achieved, albeit with significant bruising (see Fig. 137.2D). Clearance of facial vessels can be achieved with *non-purpuric energy fluences* or treatments that employ energy fluences ranging from 6 to 8.5 J/cm² with longer pulse durations (6–20 ms) and 7–12 mm spot sizes. At these settings, multiple passes and/or cautious pulse-stacking techniques (see above) are typically employed to improve efficacy. Multiple treatment sessions may be required. These techniques can also benefit patients with recurring flushing and central facial erythema (Fig. 137.12).

Treatment of telangiectasias with the KTP laser induces little or no bruising compared to the PDL (see Fig. 137.2), but edema can occur.

Fig. 137.11 Treatment of a port-wine birthmark with the pulsed dye laser (PDL). A Before treatment. **B** Purpuric response immediately after treatment with the PDL (585 nm, 0.45 ms). **C** Six weeks after the fourth treatment. *Courtesy Jeffrey Dover, MD, and Kenneth Arndt, MD.*

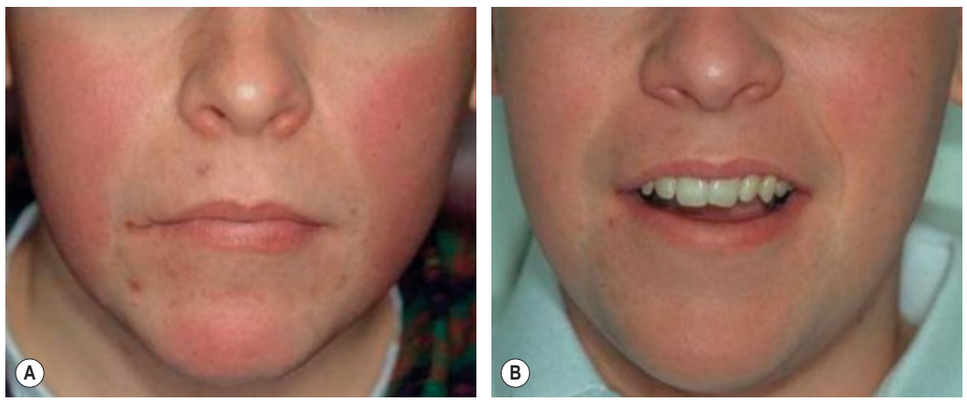

Fig. 137.12 Erythematotelangiectatic rosacea. A Before treatment. **B** Improvement of facial erythema and flushing two months following pulsed dye laser therapy.

Larger-caliber, darker, and deeper facial vessels can be effectively treated with the Nd:YAG laser, particularly in dark-skinned patients. However, to compensate for the diminished absorption of 1064 nm light by hemoglobin (nearly 10-fold less compared with 595 nm light), an increased fluence is required, making vigorous cooling necessary both for epidermal protection and to reduce patient discomfort. Even with these measures, there is a risk of scarring when the long-pulsed Nd:YAG laser is used to target blood vessels. Finally, IPL is commonly employed for purpura-free treatment of facial telangiectasias utilizing a 550 or 560 nm cut-off filter. The treatment endpoint for telangiectasias is vessel spasm or change in the vessel color to a duskier appearance.

Poikiloderma of Civatte

Poikiloderma of Civatte is a hallmark reflection of photodamage and involves the lateral aspects of the cheeks, neck, and upper chest. While a prominent component is telangiectasias, there is also epidermal atrophy and actinic dyspigmentation. Comprehensive treatment requires consideration of each component. Options include IPL, PDL, and KTP laser; newer devices such as the fractionated ablative and non-ablative lasers can also be used. When there is insufficient overlap of adjacent PDL pulses, a persistent "honeycomb-like" appearance may occur, with circles of improvement in color, texture, and tone surrounded by a network of relatively untreated skin (Fig. 137.13). This mottled look can require multiple treatments to eradicate.

Since IPL can favorably improve both dyspigmentation and telangiectasias, this system is perhaps more ideally suited to treat poikiloderma of Civatte. Several studies have reported 50%–75% improvement in both the vascular component and the actinic dyspigmentation, with a low side-effect profile[25]. The pertinent short-term side effects are transient erythema and intentional darkening of lentigines, which all disappear in about a week. Although "footprinting" is possible with IPL, it is far less common than with PDL, given the larger size of the crystal IPL handpiece.

Fig. 137.13 "Footprinting" on the cheek of a young girl following pulsed dye laser therapy of a port-wine birthmark. There is a honeycomb-like appearance due to circles of improvement surrounded by a network of relatively untreated skin.

Additionally, use of a multiple-pass technique applied in different orientations tends to minimize this unintended "footprint" consequence.

Telangiectasias and Venulectasias of the Leg ("Spider" Leg Veins)

"Spider veins" of the legs are a common cosmetic problem for which patients seek treatment. These telangiectasias and venulectasias are red and blue in color, measure 0.2 to 2 mm in diameter, and develop in dependent areas, predominantly the legs. While a number of spider veins appear independently of deeper vascular disorders, a surprisingly high percentage can be improved by treating deeper underlying venous disease. While the superficial venous system is located in the skin, subcutaneous tissue, and superficial fascia, the deep venous system is located within underlying muscle, with the two plexuses interconnected

by perforating veins (see Fig. 155.1)[42]. Whether as a consequence of age, hormonal or genetic factors, or from trauma to the vessel wall, venous valvular incompetence produces increased hydrostatic pressure and ultimately vessel dilation (see Fig. 105.2).

Whereas facial telangiectasias are generally superficial, small in caliber, and have normal hydrostatic pressures, leg veins are larger in diameter, thicker in caliber, and are situated more deeply within the skin. Additionally, as in any treatment site, there is heterogeneity in the size, color, and caliber of ectasias. These properties make treatment of leg veins even more challenging. Sclerotherapy is the first-line therapy for telangiectasias of the lower extremities (see Ch. 155). Laser treatment represents a viable option in a minority of patients such as those with needle phobias, telangiectatic matting[43], or a history of adverse reactions to sclerosing agents (see Table 137.2). The PDL and KTP lasers can be used to treat small-caliber, pink and red blood vessels which are too fine to cannulate with sclerotherapy needles, e.g. the telangiectatic matting that can be a consequence of prior sclerotherapy.

Given that leg veins are heterogeneous in their color, size, caliber and depth, and that many result from venous valvular incompetence, duplex ultrasonography can assist in determining the most appropriate treatment strategy. Combination therapy using endovenous lasers, ambulatory phlebectomy, and sclerotherapy may represent the best approach for long-term, successful treatment of lower extremity ectasias (see Ch. 155). Synergistic improvement may be achieved when these treatments are used in combination.

Pyogenic Granulomas

Pyogenic granulomas (PGs) are idiopathic, abruptly appearing, vascular neoplasms that tend to grow rapidly and bleed easily. Over half of these lesions recur after electrocoagulation, presumably because such desiccative treatments fail to ablate the deeper vascular components[44]. Both the argon and CO_2 lasers have been used to treat these neoplasms. More specific targeting of the vascular nature of PGs has been attempted with the PDL, whether used directly on the lesion or in combination with glass slide diascopy to blanch out superficial components. Higher success rates may be achieved with antecedent removal of the papular component (by shave or electrodesiccation techniques) prior to PDL targeting of the more deeply situated vessels. While shave removal followed by desiccation is still the first-line treatment for most patients, less scarring is noted with the PDL, when used either with modest energy fluences (1.5 ms pulses) *without cooling* or multiple stacked pulses (5–10 ms) *with cooling*.

Venous Lakes and Cherry Angiomas

Venous lakes are commonly seen on the lips or ears as gray–blue to purple compressible papulonodules representing dilated venules within the superficial dermis. These lesions are brought to the attention of dermatologists because of cosmetic concerns or a history of periodic bleeding. Traditionally, electrocoagulation has been used, but scarring and recurrence are common. IPL and PDL can be used but often light penetration is not deep enough. Longer wavelength devices including alexandrite laser or Nd:YAG laser may improve resolution.

Cherry angiomas, which vary in color from bright red to purple, are also benign lesions of cosmetic concern (see Ch. 114). Optimal treatment is by PDL or KTP lasers, although some clinicians still use more traditional technology such as electrocoagulation.

Verrucae

Verruca vulgaris is caused by the human papillomavirus, which induces epidermal hyperplasia and neovascularization in affected skin. The use of lasers is said to be based on the principle of targeting their vascular component, which is evident histologically as dilated blood vessels within the dermal papillae. Use of the PDL has been shown to induce intravascular thrombosis and vessel wall necrosis in patients with verrucae[45]. However, the nonspecific heat effect from lasers is likely the main mechanism underlying wart clearance with laser therapy. "Laserthermia" of warts, particularly with the Nd:YAG laser, has produced clearance in 75% of patients[46]. The mechanism may involve coagulation of epidermal proteins and blood vessels, with stimulation of a reactive inflammatory response. Although a similar tissue response is likely caused by CO_2 laser ablation of verrucae, response rates have been more variable, ranging from 30% to 80%[47]. Most notably, scarring and onychodystrophy can result from treatment of periungual verrucae with such ablative laser therapies[48].

A notable lack of bleeding and scarring makes the PDL laser a favorable choice. Given the limited penetration of the PDL, hyperkeratotic portions of the wart are first pared down. If bleeding occurs, hemostasis should be achieved, being careful to avoid application of flammable topical agents to the treatment area. Then, the lesions are treated until a dusky gray color is seen. However, rather high fluences are utilized, making this treatment quite painful, especially on the fingers. Depending upon the pain tolerance of the patient, digital nerve blocks may be needed. This procedure can be repeated every 2–4 weeks until clinical resolution.

While laser therapy for verrucae is not exclusively beneficial, it does supplement the dermatologist's armamentarium in the treatment of these recalcitrant lesions.

Pain Considerations

PDL treatment can be associated with significant discomfort and has been typically described as a "hot rubber band" snapping on the skin. Whereas this procedure is generally well tolerated by adults, children may require anesthesia. When local anesthesia is chosen (most often for localized lesions), agents that blanch the vasculature and decrease the hemoglobin target need to be avoided. In addition, topical anesthetics should not be applied to ulcerated lesions and dosing recommendations need to be followed (see Tables 143.4 & 143.5). Larger vascular anomalies in children may require injected local or general anesthesia. KTP laser therapy is associated with fleeting stinging as the laser is applied onto the skin. IPL treatments can be performed with or without topical anesthesia. Forced cold air or ice chilling is an effective method for reducing discomfort and protecting the epidermis at the same time, but associated vasoconstriction decreases the vascular target. Vibration distraction (gate theory) can also be effective. Nerve blocks are simple and effective for digital procedures.

TREATMENT OF MELANIN-CONTAINING LESIONS

Ephelides and Lentigines

Since melanin has a broad absorption spectrum (see Fig. 136.3), many lasers can be used to treat melanin-containing lesions. At the lower end of the therapeutic window, the penetration of green lasers is limited to the superficial papillary dermis. These lasers are best utilized for epidermal pigmented lesions. Thus, the frequency-doubled Nd:YAG (532 nm) laser, either Q-switched or normal mode, effectively treats lentigines and ephelides in most skin phototypes with limited recurrence[49]. Of note, in patients with a history of systemic gold therapy, Q-switched lasers will likely induce permanent darkening of the skin; such exposure needs to be determined prior to treatment. Additional lasers, e.g. the 800 nm diode, as well as IPL can also be used to treat epidermal pigmented lesions (Table 137.3). While the PDL is most commonly used for vascular lesions, 595 nm light is also well absorbed by melanin and can be used to treat pigmented lesions. By incorporating compression, the vascular component of the skin is blanched out and melanin-containing lesions can be targeted.

In general, the Q-switched ruby and alexandrite lasers are more effective when treating more deeply situated pigmented lesions (e.g. nevus of Ota), as these wavelengths have an increased depth of penetration. Q-switched ruby (694 nm) laser light is better absorbed by melanin than is alexandrite (755 nm) laser light, which might be an advantage in lighter-skinned individuals, but problematic in darker-skinned patients, given the increased likelihood of nonspecific heating of normal epidermal melanin. Q-switched Nd:YAG laser light is much less well absorbed by melanin and reaches more deeply into the skin; therefore, it is primarily used to treat dermal pigmented lesions.

For the treatment of lentigines, ephelides, and café-au-lait macules as well as nevus of Ota, understanding these profiles allows one to choose the optimal device. The clinical response of pigmented lesions to Q-switched lasers is determined by where the pigment is located (epidermal, dermal or mixed) and whether it is intracellular or extracellular, as well as the composition of the pigment (usually melanin)[50].

LASERS AND OTHER LIGHT-BASED DEVICES USED FOR THE TREATMENT OF PIGMENTED LESIONS				
Laser/device	**Wavelength (nm)**	**Fluence (J/cm^2)**	**Pulse duration**	**Applications**
Q-switched lasers (*highly pigment-specific*)				
Q-switched Nd:YAG, frequency-doubled	532	0.4–6	5–10 ns/ps	Lentigines
Q-switched ruby	694	3–12	20–40 ns	Lentigines, nevi*
Q-switched alexandrite	755	1–12	50–100 ns/ps	Lentigines, nevi*
Q-switched Nd:YAG	1064	3–12	5–10 ns/ps	Nevi*
IPL, long-pulsed lasers, and PDL with compression (*less pigment-specific*)				
Intense pulsed light (IPL)	500–1200	Up to 30	5–10 ms	Lentigines, nevi*
Diode	800	5–50	5–100 ms	Lentigines, nevi*
Nd:YAG	1064	Up to 300	1–100 ms	Nevi*
PDL with compression	595	3–5	0.45–1.5 ms	Lentigines
Long-pulsed alexandrite	755	25–50	0.5–300 ms	Lentigines, nevi*
*Treatment of pigmented melanocytic nevi (especially acquired lesions) is controversial.				

Table 137.3 Lasers and other light-based devices used for the treatment of pigmented lesions. Q-switched lasers are most effective for treating pigmented lesions due to their very short pulse durations, which effectively target the melanosome. In addition to the lasers listed above, pigment non-selective ablative lasers, such as CO_2 (10 600 nm) and erbium:YAG (Er:YAG; 2940 nm), can remove superficial pigmented lesions via nonspecific destruction. Parameters are dependent upon skin phototype, skin cooling technology and morphologic features; a test site is recommended when there are concerns regarding unwanted side effects such as hypopigmentation.

Benign Melanocytic Nevi

Laser removal of acquired and congenital nevi is controversial since no specimen is available for tissue diagnosis and margin assessment. Furthermore, the future biologic behavior of laser-resistant cells and the effect (if any) of laser thermal injury on these cells is unknown. Patients with atypical pigmented lesions should be examined carefully and regularly, preferably with total body imaging. Laser treatment of melanocytic lesions should only be considered for clinically banal lesions in patients with no personal or family history of melanoma.

Both acquired and congenital melanocytic nevi have been treated with Q-switched ruby, alexandrite, and Nd:YAG lasers[51]. The 694 and 755 nm devices can improve the appearance of acquired junctional melanocytic nevi without scarring. In general, smaller and thinner lesions are typically more treatment-sensitive. While congenital nevi can be lightened, complete eradication is much more difficult and recurrence is common. Laser therapy decreases the number of pigmented nevus cells in the papillary dermis, but is unlikely to affect deeper seated, non-pigmented cells that are closely associated with adnexal structures. This has been demonstrated histologically as persistent nests of nevus cells in the mid papillary and deeper dermis at depths of 0.16–0.44 mm. Deeper components of these nevi located within muscle or under fascia will also remain unaffected by laser surgery.

The normal mode (non-Q-switched), long-pulsed ruby and alexandrite lasers have also been used to treat acquired nevi. Some clinical lightening observed has been attributed to fibroplasia of the dermis overlying the residual nevus cells. Although fibroplasia may be cosmetically useful, this change potentially hides early signs of malignant transformation and might cause a delay in diagnosis. Therefore, patients who have any melanocytic nevi treated with lasers should understand that they need to report subsequent changes in color, shape, or size. Clinicians should remember that early cutaneous melanoma can have a subtle clinical appearance and they should have a low threshold for biopsy.

Café-au-Lait Macules and Nevus Spilus

Café-au-lait macules (CALM) are tan–brown patches, which histologically correspond to hypermelanosis of the basal melanocytes and keratinocytes. While these lesions can be seen in genodermatoses such as neurofibromatosis and McCune–Albright syndrome (see Ch. 61), they are typically isolated benign lesions. Cosmetic improvement can be achieved with the Q-switched ruby, alexandrite, and KTP lasers. However, CALM can be resistant to laser therapy, and they are prone to a high rate of recurrence. Use of the long-pulsed alexandrite laser has been reported to have a lower incidence of recurrence[52].

Nevus spilus consists of multiple lentigines and/or melanocytic nevi superimposed on a background CALM. Although the treatment of these lesions is very similar to that of CALM, these are typically more resistant and require multiple sessions. They may respond to normal-mode laser wavelengths or IPL. Rarely, malignant transformation has been described in nevus spilus, and thus caution is advised when treating with laser or light therapy.

Nevus of Ota and Nevus of Ito

Clinically, nevus of Ota and nevus of Ito appear as blue–gray patches and histologically, spindled pigment-producing melanocytes are present in the papillary dermis. These entities differ only in their anatomic location. Nevus of Ota involves the face (primarily V1/V2 distribution), while nevus of Ito corresponds to the distribution of the posterior supraclavicular and lateral brachial nerves. Both have been successfully treated with Q-switched ruby, alexandrite, and Nd:YAG lasers[53]. Generally, high energy fluences are required, with multiple treatments spaced at least 6 weeks apart. A drawback of the Q-switched ruby laser is the tendency for hypopigmentation, which is a consequence of increased absorption by normal epidermal melanin. Hypopigmentation is observed less often with Q-switched alexandrite lasers (755 nm), which also achieve deeper penetration into the dermis.

Near-infrared lasers, namely the Q-switched Nd:YAG (1064 nm), have even deeper penetration into the skin but are less well absorbed by melanin. Although these characteristics appear to negate each other, they allow for safer use in patients with darker skin and also allow for clearance of more deeply seated pigment. When in a sacral location, circumscribed dermal melanocytosis (Mongolian spot) spontaneously lightens in 95% of individuals by age 10 years. More persistent extra-sacral lesions can be treated with Q-switched lasers.

Blue nevi share some histologic features with nevi of Ota and Ito but are well-circumscribed gray–blue to blue–black papules (common) and plaques (cellular). As such, laser treatment of these lesions is similar to that of nevi of Ota and Ito. While blue nevi are clinically benign, rare malignant transformation has been reported in cellular blue nevi. In addition, the clinical differential diagnosis of blue nevi may include cutaneous melanoma and thus dermoscopy can provide useful information.

Melasma

Melasma is a complex and therapeutically challenging disorder with both intrinsic (e.g. genetic, hormonal) and extrinsic (e.g. ultraviolet light) factors (see Ch. 67). It most commonly involves the face and presents as tan to dark brown patches with sparing of photoprotected sites. Medical and procedural therapeutic strategies include sun avoidance, sunblocks, topical retinoids, hydroquinone, tranexamic acid, chemical peels, and laser therapy. While treatment regimens boast varying degrees of improvement, recurrence is the norm despite recommended measures such as strict sun protection.

Clinically, melasma is often categorized by distribution pattern and location of excess melanin. In epidermal melasma, melanin is localized to the basal and suprabasal epidermal layers and in dermal melasma, melanin is deposited within melanophages. The mixed variant includes features of both epidermal and dermal types. Although these subtypes are said to be distinguishable by Wood's lamp illumination, which accentuates epidermal pigmentation, histologic and confocal microscopy studies have shown an admixture of both types within a

single lesion. Of note, dermal deposits of melanin respond poorly to commonly prescribed topical therapeutic agents.

Since melasma is a disorder of hyperpigmentation due to increased melanin within epidermal melanocytes and dermal melanophages, it may seem intuitive that melasma should respond favorably to Q-switched lasers. However, this assumption has been demonstrated to be less than accurate. Although the melanophages present in dermal melasma can be selectively damaged by Q-switched lasers, the subsequent epidermal response frequently induces an inflammatory process that perpetuates or aggravates the problem[54]. Attempts at improving melasma by superficial laser resurfacing with Er:YAG may lead to temporary improvement, only to be followed by problematic postinflammatory hyperpigmentation.

Non-ablative, fractionated laser systems (see below) may also lead to improvement of melasma, but as with other therapies, recurrences are common and there is the potential for a deterioration in appearance. A preliminary case report described significant clinical improvement of treatment-resistant facial melasma after two treatments[55], with a subsequent study demonstrating that 60% of patients with skin phototypes III–V achieved 75%–100% improvement[56]. Although the precise explanation for how the photothermal energy improves melasma is not clear, the clinical improvements may be the direct consequence of increased hydroquinone absorption into the epidermis and dermis with the beneficial effect on dermal melanophages via microscopic channels.

Despite the multiple options described above, melasma remains a difficult-to-treat disorder, and regimens of topical retinoids, bleaching agents, and diligent sun protection remain the mainstay of therapy.

Becker Melanosis (Nevus)

Becker melanosis is a hamartoma that typically presents during childhood or early adolescence as light to dark-brown patches or plaques on the shoulder, upper back, or lateral arm (see Ch. 112). It is associated with variable amounts of hypertrichosis as well as a smooth muscle hamartoma. Because melanin is located in both the epidermis and the dermal follicular matrix, treatment of Becker melanosis may require targeting both of these components. The basal layer melanin component requires nanosecond range pulse durations, and successful lightening has been accomplished with Q-switched ruby and alexandrite lasers[57]. In contrast, the follicular melanin responds more favorably to the ms pulse durations that characterize photoepilation systems. While these simplistic distinctions allow for methodical treatment, Becker melanosis is typically somewhat resistant to therapy. Often, cosmetic improvement is more reasonably and realistically approached with the objective of photoepilation alone, as opposed to comprehensive eradication of the hamartoma.

Postinflammatory Hyperpigmentation and Drug-Induced Discoloration

Postinflammatory hyperpigmentation (PIH) is a common side effect of many dermatologic procedures, both medical and cosmetic. For patients with darker skin phototypes, PIH should be anticipated and a treatment plan promptly initiated. Common topical therapies include corticosteroids, retinoids, and bleaching creams. A newer treatment strategy is the use of fractionated photothermolysis with a low density and low to moderate energy. The fine columns (referred to as microthermal or microablative zones; see below) can be generated at a desired depth, allowing for drug delivery and increased penetration of therapeutic topical agents into the skin. For treatment-resistant patients, Q-switched ruby, alexandrite, and Nd:YAG lasers have been used to expedite resolution of PIH. However, since PIH can be caused by these devices, circumspection is appropriate.

As opposed to PIH, which is due to excess melanin, discoloration that results from sclerotherapy is a consequence of vessel destruction, erythrocyte extravasation, and interstitial hemosiderin deposition. The Q-switched ruby laser has been used successfully to treat this common sequela from sclerotherapy, with a reported 92% improvement rate[58], but the success rate is quite variable.

Drug-induced hyperpigmentation or discoloration represents deposition of drug metabolites, iron, melanin, or a combination of these components in the dermis and/or epidermis (see Table 67.5). The resultant color depends on the initiating medication and can range from blue–gray or brown to yellow or red. Use of Q-switched ruby, alexandrite, and 1064 nm Nd:YAG lasers has led to improvement of minocycline-, amiodarone-, imipramine- and silver (argyria)-induced hyperpigmentation or discoloration.

HAIR REMOVAL

Hair removal is one of the most commonly performed laser procedures. According to the American Society for Dermatologic Surgery, there were 385 000 laser hair removal procedures completed in 2018 alone[59]. While the distribution, density, and color of hair is related to sex and genetic background, the acceptability and desirability of hair are often related to societal and cultural norms. Markedly excessive hair can be a marker for an underlying endocrinopathy or a medication side effect and a possible etiology should be investigated prior to photoepilation (see Ch. 70). While most patients who undergo photoepilation have the cosmetic objective of decreasing unwanted hair, there are several medical applications of laser hair removal, such as treatment of pseudofolliculitis barbae or folliculitis decalvans.

Although the patient's ultimate desire may be to achieve total hairlessness in an anatomic region, complete eradication of hair is often an unattainable objective. Realistic expectations are key and the laser surgeon should clearly and specifically communicate these objectives to the patient. For some patients with particularly coarse, dense unwanted hair, a successful outcome might be a transition to finer, lighter hair. Potential side effects should be reviewed, including pigmentary changes (hyper- or hypopigmentation), erythema, edema, discomfort, and very rarely, scarring.

Photoepilation is based on selectively delivering energy to both pigmented and non-pigmented structures within the hair follicle. Thermal energy delivered to the melanin-rich hair shaft and hair bulb matrix will destroy surrounding follicle structures while minimizing non-selective injury to the surrounding tissues. Often, non-pigmented structures near the follicle are targeted, such as the follicular stem cells that line the outer root sheath and actually reside quite far from the pigmented hair shaft (see Ch. 68)[60]. Three mechanisms have been proposed to explain hair follicle destruction. These include: (1) photothermal injury to the follicle via direct heating of the follicle; (2) photomechanical injury by induction of shock waves and violent cavitation; and (3) photochemical injury by production of toxic intermediaries such as singlet oxygen or free radicals[61]. Heat-induced change of the follicular structures and immediate surrounding tissues can result in transient growth arrest via induction of catagen or permanent hair removal via follicular fibrosis.

Although the absorption of melanin corresponds to wavelengths from 400 to 1200 nm, the best lasers for photoepilation have wavelengths of 600 to 1100 nm, a range where there is more selective absorption by melanin and the light penetrates relatively deeply into the skin. Given this relatively broad therapeutic spectrum, many laser systems have been utilized, including the ruby (694 nm), alexandrite (755 nm), diode (800–810 nm), and Nd:YAG (1064 nm) lasers, in addition to a variety of IPL systems with different cut-off filters. The optimal wavelength is probably in the ruby laser range (694 nm), but longer pulsing beyond 3 to 4 ms is problematic, which has led to the utilization of alternative wavelengths. However, the safety and efficacy of laser hair removal is dependent on the operator's sophisticated knowledge regarding the practical application of laser–tissue interactions and the principles of selective photothermolysis. From a practical perspective, this entails accurate selection of the laser system, the optimal pulse duration, and the appropriate fluence to achieve hair removal while protecting the epidermis and minimizing non-selective dermal heat injury. Inappropriate selection can result in permanent scarring and dyspigmentation.

Selection of the appropriate pulse duration is critical for effective photoepilation. As the thermal relaxation time of a hair follicle is ~10–30 ms, the pulse duration should be adjusted to match these parameters. However, extension of the pulse duration beyond the thermal relaxation time of the follicular unit promotes delivery of thermal damage to the surrounding non-pigmented stem cells and should induce more consistent follicular destruction[60]. Coarser, thicker, and darker hairs may have relatively longer thermal relaxation times compared to thinner, finer hairs[61]. The ideal patient for hair removal is one with lighter skin (phototypes I–III) and dark brown to black hair (Fig. 137.14).

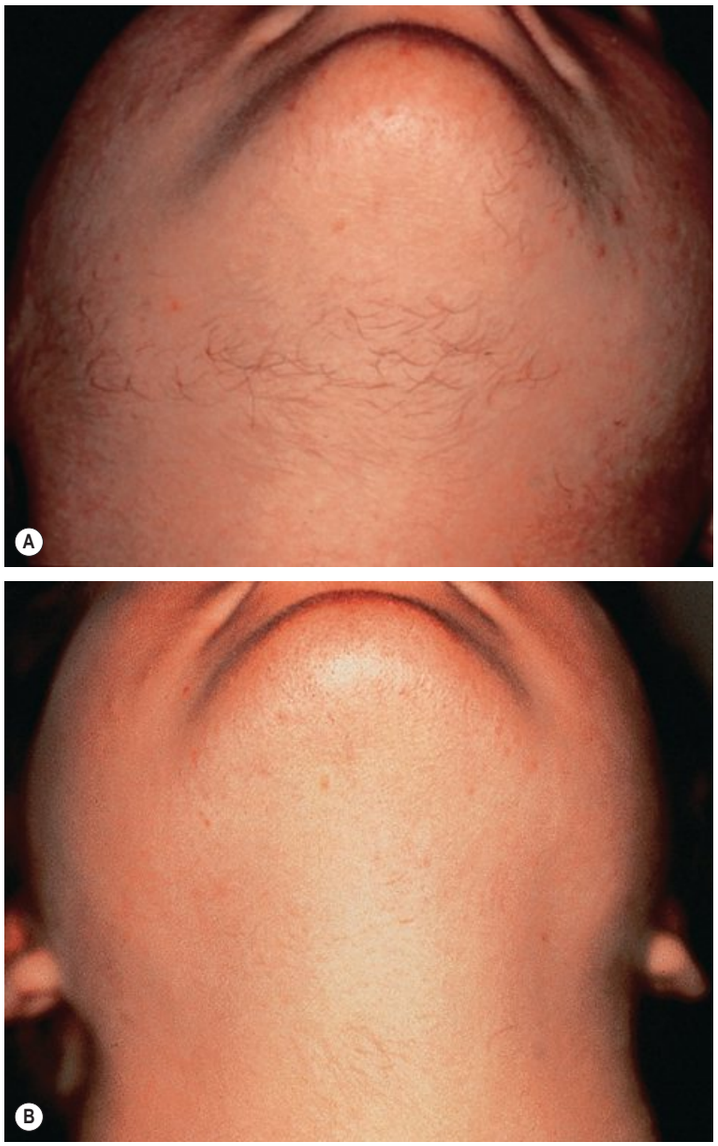

Fig. 137.14 Laser hair removal. A Before treatment. **B** Two years after three long-pulsed diode laser treatments; there is almost complete and long-term hair growth reduction. *Courtesy Jeffrey Dover, MD, and Kenneth Arndt, MD.*

In general, higher energy fluences achieve greater hair reduction. However, since overzealous energy fluences might induce excessive collateral heat, a conservative selection of parameters is recommended. Typical danger zones are the chin and lip (where there is a greater density of hair follicles) as well as pigmented genital or inguinal skin. Energy fluence can be titrated up, if necessary, with each treatment as hair becomes less dense but tissue endpoints should be carefully monitored to avoid adverse effects. Parameters are not interchangeable between devices, even those with the same laser or IPL wavelength. It is incumbent on the operator to know how to operate each system that he or she employs.

Laser hair removal in patients with darker skin can be more problematic as epidermal melanin competes with the follicular target. For patients with skin phototypes IV–VI, the long-pulsed Nd:YAG laser is generally regarded as the safest system. However, the most common criticism of the long-pulsed Nd:YAG laser is the associated pain.

Appropriate cooling of the epidermis is critical with hair removal devices. Cooling can be applied immediately prior to (pre-cooling), during (parallel cooling), or after laser pulsing (post-cooling). Aside from protecting the epidermis from excessive heat, contact cooling handpieces allow compression of the skin and facilitate delivery of more laser energy to the targeted hair follicles.

Although commercial laser and IPL companies might argue otherwise, no system is inherently superior for photoepilation. In general, lighter skin phototypes (I–III) respond better to treatment with the 755 nm alexandrite or the 800 nm diode laser, while darker skin phototypes (IV–VI) respond better to treatment with the 1064 nm Nd:YAG laser. Most studies have shown comparable efficacy rates when sufficient energy fluence is used and multiple treatments are performed. Regardless of the laser or IPL system utilized, serial treatments are required for significant, long-term hair reduction. Typically, three to ten treatments are recommended, delivered at 4- to 8-week intervals, depending on anatomic location, skin phototype, and hair regrowth. Response rates of 70%–90% hair reduction at 6-month follow-up have been reported[62]. Long-term efficacy of laser hair removal correlates with higher concentrations of eumelanin[63]. Recent attempts have been made to treat non-pigmented, gray or white hair, but so far there is little evidence of benefit.

Paradoxical hypertrichosis following the use of hair removal devices is a well-documented side effect of photoepilation. This has generally been described in patients with Mediterranean, Hispanic or Asian backgrounds, skin phototypes III or IV, and dark lanugo hair. Of note, it can occur with any of the laser or IPL hair removal systems. Initial reports suggested that affected patients should be evaluated for hyperandrogenemia, but paradoxical hypertrichosis occurs more commonly than does hyperandrogenemia[64]. The largest retrospective analysis to date of 750 patients found that the overall incidence of paradoxical hypertrichosis was 4.5% (although it is likely higher), and the hypertrichosis occurred most often on the face and neck of patients with skin phototypes III and IV. These authors postulated that the hair induction occurred at the borders of the treated areas, perhaps because of sub-therapeutic energy fluences during laser therapy and local inflammatory responses following photoepilation[65]. While paradoxical hypertrichosis can be difficult to treat, in one author's experience (CBZ), treatment with the nanosecond Q-switched Nd:YAG (1064 nm) laser can provide at least temporary improvement. It has been suggested that application of ice to the perimeter of the treatment area and use of the highest tolerated energy fluence may minimize this side effect.

Proper pre-treatment preparation of the skin prior to photoepilation allows for optimal treatment results. Failure to recognize the need to avoid treating suntanned skin has resulted in numerous burns, scars, and permanent pigmentary changes. In sunny climates, patients should be advised to apply broad-spectrum high SPF sunscreens for weeks prior to laser therapy and to avoid tanning both before and after photoepilation, in order to prevent PIH. Secondly, patients should avoid plucking, waxing, threading, and electrolysis prior to laser treatment as these will remove the target chromophore. Patients can be advised that shaving or depilatory creams are acceptable. Finally, given that photoepilation is often associated with some degree of discomfort, topical anesthetics can be applied prior to treatment. While increasing patient comfort during the procedure is an important objective, several deaths have been reported with misuse of strong topical anesthetics applied to large areas under occlusion in unsupervised situations.

During the procedure, the laser surgeon should constantly assess the skin's reaction to the laser energy and adjust parameters, if necessary. The operator should expect to observe perifollicular erythema and focal edema, indicating proper parameter selection. Skin changes to avoid are charring, blistering, crusting, or ulceration of the skin; these reflect dermal heat injury and are a marker of an energy fluence that is too high. In severe cases this may result in dermal necrosis and marked scarring.

TREATMENT OF SCARS

Laser therapy, particularly fractional laser resurfacing, has become an increasingly valuable tool for the treatment of burn and traumatic scars. It may also have the potential to improve the wound healing process and mitigate scar formation when employed prior to surgical incision[66]. When selecting specific laser treatment modalities, important characteristics to consider are scar type (hypertrophic, flat, atrophic, contracted, distensible, icepick), location on the body, erythema, dyschromia (hyperpigmented, hypopigmented), and thickness. In addition, individuals with darker skin phototypes are more susceptible to PIH. When determining settings for laser treatment depth[20], scar thickness has historically been estimated by palpation, but recently optical coherence tomography (OCT) was shown to have

greater accuracy[67]. Laser penetration should be proportional to, but not exceed, the thickness of the scar[20], with optimal laser penetration between 50%–75% of scar depth[68].

For traumatic scars characterized primarily by erythema, vascular lasers are used to target oxyhemoglobin within the scar's microvasculature[69]. PDL at low fluence settings and short pulse width is most commonly used, with treatments every 1 or 2 months until goals are reached[20]. If multiple devices are to be used during a scar treatment session, it is important to treat the erythematous element first, to avoid erythema or blood created by the other procedures being targeted by the vascular laser[69]. In patients with skin phototypes I–IV, PDL can be especially effective in improving the quality and cosmetic appearance of surgical scars when instituted early, i.e. from the day of suture removal[69].

Scar texture and dyspigmentation can be addressed with fractional laser resurfacing. For hypertrophic and contracted scars, ablative fractional lasers are the most effective treatment, as they induce robust tissue remodeling and improvement in symptoms and cosmesis can be seen within days to weeks[20]. Burn scars are most effectively treated with at least three rounds of the ablative fractional CO_2 laser at 4- to 6-week intervals[70]; low densities are recommended[71]. Hypertrophic or keloidal surgical scars respond well to intralesional injections of triamcinolone acetonide ± 5-fluorouracil after ablative fractional resurfacing[69]. Since atrophic scars reflect collagen destruction, both ablative and non-ablative fractional lasers are employed as they induce neocollagenesis and remodeling within atrophic areas. Similar results are observed, but non-ablative fractional lasers are better tolerated[20] and safer in skin phototypes IV–VI[71]. Fractional laser resurfacing may begin once the scar has stable epidermal coverage, with a minimum interval of 1 to 3 months between treatments until the desired improvement or a therapeutic plateau is reached[20].

Scar hyperpigmentation is most commonly due to deposition of melanin via a poorly understood mechanism. Hyperpigmentation refractory to traditional topical therapy may be treated with Q-switched lasers (694, 755, and 1064 nm) or non-ablative fractional resurfacing. Because darker skin phototypes are more susceptible to PIH with high-density non-ablative fractional resurfacing, lower densities are preferable. Hypopigmented scars are more difficult to treat, although they do show modest improvement in color and texture with ablative and non-ablative fractional resurfacing, especially when supplemented with prostaglandin analogues[72]. For example, the erbium-doped 1550 nm fractionated laser combined with topical bimatoprost and tretinoin have been shown to induce repigmentation in atrophic, hypopigmented surgical scars[69].

TREATMENT OF STRIAE DISTENSAE

Striae distensae are common after pregnancy, growth spurts in adolescence, or rapid weight gain. Histologically, there is thinning of the epidermis and atrophy of the dermis. In their early inflammatory stages, they often appear pink to purple in color and are called striae rubrae. The latter mature and take on a more pallid color and then are termed striae albae (see Ch. 99).

Although treatment of striae is not medically necessary, many patients seek cosmetic improvement. Several lasers, including PDL, 308 nm excimer, fully ablative, ablative fractional, non-ablative fractional (1450/1550 nm), and Q-switched or low-fluence, long-pulsed Nd:YAG (1064 nm) lasers, as well as IPL, have been used with varying degrees of success with regard to the color and texture of striae[73]. More targeted studies have correlated clinical improvement with increased elastin remodeling or formation. Fractionated photothermolysis has been shown to improve atrophic scars[4], and in a pilot study of striae in patients with skin phototypes IV–VI, epidermal thickening and remodeling of collagen and elastin fibers was observed after 1550 nm fractionated photothermolysis[74]. In spite of some wistful reports, the results of striae treatment with lasers have been quite disappointing.

TREATMENT OF CELLULITE

The treatment of cellulite is covered in Chapter 156, including the use of the minimally invasive 1440-nm side-firing laser, Rapid Acoustic Pulse™ technology, and vacuum-assisted subcision.

TREATMENT OF TATTOOS

A tattoo represents the presence of exogenous pigmented material in the skin. Although the most common purpose for tattooing is artistic and cosmetic, it has also been utilized in the medical field, in particular as radiation port markers. Additionally, tattoo pigment composed of lead, carbon, asphalt, gunpowder, or coal can be introduced explosively or traumatically. Once embedded, the exogenous pigment is taken up predominantly by dermal macrophages. These pigment particles measure from 2 to 400 nm, but generally average ~40 nm in diameter. Tattoo removal is a common patient request. Prior to advancements in laser technology, removal was frequently associated with disfiguring scarring. With the evolution of the Q-switched nanosecond and picosecond lasers, pigment eradication can now be more safely achieved, with less scarring and/or pigmentary changes.

Q-switched lasers are characterized by having extremely short pulses, which induce photomechanical and photoacoustic laser–tissue interactions. The immediate local exponential increase in temperature to 200–300°C causes dramatic expansion of organelles such as lysosomes within macrophages, followed by their equally catastrophic contraction/collapse, leading to *cavitation* of the tattoo-bearing macrophages. The exceptionally short pulse duration limits the thermal damage to just the macrophage.

Clinically, the laser tissue reaction is seen as immediate epidermal whitening, which is essentially nitrogen vapor within the epidermis and immediately adjacent to the tattoo pigment particles in the dermis (Fig. 137.15). Mechanical damage results in cell membrane rupture and the release of exogenous pigment into the extracellular space. Some of this released pigment departs the skin and drains via the lymphatics to local lymph nodes, while the remainder is simply re-phagocytosed. In addition, there is fragmentation of tattoo ink particles and this changes their optical properties and/or allows easier reuptake by macrophages followed by removal from the site.

More recently, Q-switched pulsed lasers in the shorter picosecond domain (1 trillionth of a second or 10^{-12} seconds) have been developed and they are said to be more effective in removing ultrasmall tattoo particles with extremely short thermal relaxation times[75]. Compared to Q-switched nanosecond lasers, picosecond devices have been shown to clear tattoos with fewer treatment sessions and may be more effective for blue and green tattoo pigments[75]. However, this is not always the case and traditional nanosecond lasers are still a good option for many tattoos.

Selection of the appropriate Q-switched laser is determined by the colors of tattoo pigment to be targeted (Fig. 137.16). Based on "complementary matching" of tattoo pigment, green tattoo pigment is most

Fig. 137.15 Immediate tissue whitening following treatment of a tattoo with the Q-switched alexandrite laser. *Courtesy Roy Grekin, MD.*

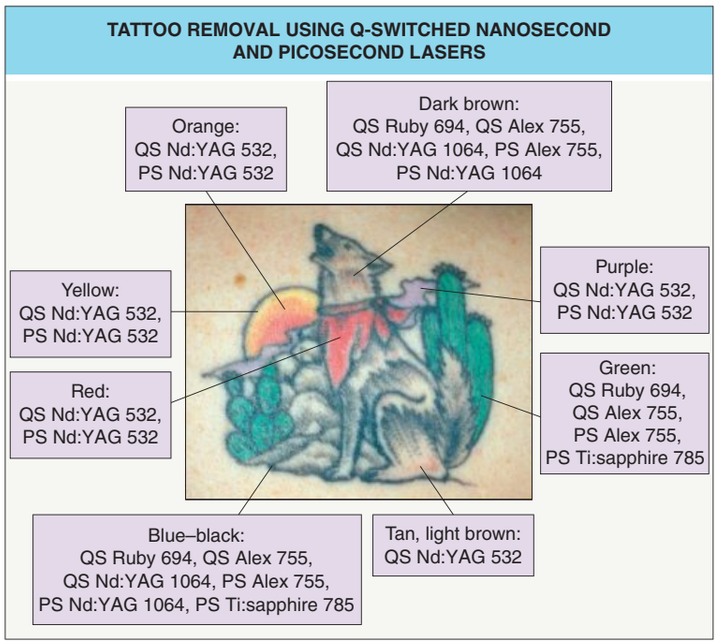

Fig. 137.16 Tattoo removal using Q-switched nanosecond and picosecond lasers. The Q-switched (QS) Nd:YAG (532 nm) laser can be used to try to remove red, orange, yellow, purple, and tan/light brown pigments. The QS alexandrite (Alex; 755 nm) and QS ruby (694 nm) lasers can be employed to remove green tattoo ink, while the QS Alex, QS ruby and QS Nd:YAG (1064 nm) lasers can remove blue–black and dark brown tattoo ink. The picosecond (PS) Alex 755 and PS Nd:YAG 1064 can remove blue, black and dark brown tattoo ink; the former can also remove green tattoo ink. The PS Nd:YAG 532 can remove red, orange, yellow and purple tattoo ink. The PS titanium (Ti):sapphire 785 nm laser is used to remove green and blue tattoo ink. See Table 137.4 for details. *Courtesy Jean L. Bolognia, MD.*

effectively removed by a red laser (694 nm), and red tattoo pigment is best removed with a green laser (532 nm). Blue and black pigments are removed with all three lasers – ruby, alexandrite, and Nd:YAG (Table 137.4). More difficult to remove are yellow and orange pigments, as these are not well absorbed by currently commercially available Q-switched laser light.

Despite all the advances in laser therapy, total eradication of tattoos can prove frustratingly difficult. One additional refinement is the so-called "R20" technique consisting of four repeated treatments (at 20-minute intervals) during the same treatment session. The 20-minute delay allows the laser-induced epidermal gas bubbles to disappear after which the treatment is repeated[76]. A further refinement is the use of topical perfluorodecalin (PFD), which immediately removes nitrogen gas bubbles, allowing for shorter time intervals[77]. The latest solution in this regard is the use of Rapid Acoustic Pulse™ (RAP™, Soliton, Inc.) technology which uses high energy tuned shockwaves to clear the epidermal and intradermal vacuolar whitening rapidly enabling multiple laser passes in a single office laser tattoo removal session[78].

Amateur tattoos often incorporate blue–black pigments that are carbon-based, such as India ink. Given that these tattoos have only a few colors and lower ink density, coupled with the observation that they may be placed at variable depths (primarily superficially) in the skin, amateur tattoos are relatively easy to remove. Professional tattoo artists incorporate a wider spectrum of colors and deposit the pigments within the deep papillary and superficial reticular dermis. Hence, removal can be problematic, even with the best devices.

Complications of tattoo removal include both hyper- and hypopigmentation. While hypopigmentation can be observed with the ruby and alexandrite lasers, hyperpigmentation commonly occurs in patients with more darkly pigmented skin. It has often been said that Q-switched lasers remove tattoo pigment without scarring. While this is often true, there can be significant textural changes after multiple treatments with high energy fluence devices. Additionally, inflammatory reactions to tattoo ink have been reported, including eczematous, granulomatous, and lichenoid reactions. When systemic reactions occur after laser treatment, they are the consequence of mobilized antigens.

Paradoxical darkening of skin-colored tattoo ink is a common phenomenon following treatment with any of the Q-switched lasers. This unfortunate event happens immediately after a single laser pulse and is caused by a shift from an oxidized state to a reduced state in the tattoo pigment. This was classically reported as darkening of red "lip liner" to dark brown or black pigment as the ferric oxide tattoo was reduced to ferrous oxide (Fig. 137.17). Similar color changes can be seen in tattoos with titanium dioxide, a common agent used to lighten tattoo pigments; when a Q-switched laser is applied to titanium, it can change from white to blue–black. Although this problematic side effect can be improved via continued treatment with any of the Q-switched lasers, a test spot is wise with such tattoos, particularly on the face.

TREATMENT OF PSORIASIS AND VITILIGO

Psoriasis affects nearly 2% of the US population and often commits patients to a lifetime of treatment. The range of therapies includes topical corticosteroids and vitamin D_3 analogues, systemic retinoids, methotrexate, phototherapy, and targeted immunomodulators ("biologic agents"; see Ch. 8). Despite the variety of treatment options available, some psoriatic plaques are recalcitrant. Application of laser therapy may represent a novel approach to resistant lesions, particularly those in "problem areas" such as the scalp and intertriginous zones. The most commonly used laser for psoriasis is the 308 nm XeCl excimer laser. As a localized narrowband UVB therapy, the excimer laser has been demonstrated to clear psoriatic plaques by impeding epidermal cell proliferation and perhaps inducing localized immunosuppression. Compared to conventional UVB phototherapy, treatment with the excimer laser cleared psoriatic plaques two times faster and with lower cumulative UVB doses[79]. Additionally, PDL has been used to treat psoriasis by targeting the underlying abnormal vasculature. While both systems are beneficial, the excimer laser has been shown to yield more favorable improvement[80].

The excimer laser has also been shown to produce impressive improvement of vitiliginous skin when used as adjuvant therapy, especially when combined with topical tacrolimus[81]. Lastly, the excimer laser has been used to repigment, at least temporarily, some of the patients who developed delayed-onset permanent hypopigmentation following standard CO_2 or Er:YAG laser resurfacing procedures.

PRE- AND POSTOPERATIVE CONSIDERATIONS, SIDE EFFECTS, AND COMPLICATIONS

Preoperative Considerations

Prior to any laser procedure (especially ablative), an appropriate medical history should be obtained, including allergies and medications. Physicians should specifically elicit any history of prior cosmetic procedures. Patients with a history of autoimmune connective tissue disease, diabetes mellitus, or drug, alcohol, or tobacco abuse should be treated cautiously, as wound healing may be impaired. Q-switched lasers are contraindicated in patients with a history of prior systemic gold therapy. Individuals with a personal or family history of vitiligo should probably not be treated with certain devices, as vitiligo could be incited or worsened (Koebner phenomenon).

During the consultation, the patient and laser surgeon must mutually identify the problem(s) to be treated and establish reasonable expectations for improvement. Whereas one ablative fractionated procedure may achieve marked improvement in rhytides and acne scarring, three to six treatments may be required with a non-ablative system if little "downtime" is required. Potential risks of laser therapy are reviewed, which may include scarring, blistering, infection, hyper- or hypopigmentation, and milia/acne formation. If an ablative fractional laser treatment is planned, then there should be a thorough discussion of postoperative wound care (see below).

Anesthesia and Eye Protection

Both ablative and non-ablative fractional resurfacing can be quite painful without appropriate anesthesia, particularly when using high energies with a high density. Application of topical anesthetics in a lipophilic ointment base or under occlusion for ~1 hour after thorough

TATTOO PIGMENTS, LASERS USED FOR THEIR REMOVAL, AND POTENTIAL COMPLICATIONS			
Color/etiology	**Pigment**	**Lasers**	**Complications**
Traumatic	Lead, dirt, gunpowder, other	QS ruby, QS alexandrite, QS Nd:YAG (1064)	Hypopigmentation, micro-explosions (gunpowder)
Amateur black	India ink, carbon	QS ruby, QS alexandrite, QS Nd:YAG (1064), PS alexandrite, PS Nd:YAG (1064)	Hypopigmentation
Professional black	Carbon, iron oxide, logwood extract	QS ruby, QS alexandrite, QS Nd:YAG (1064), PS alexandrite, PS Nd:YAG (1064), PS Ti:sapphire (785)	Hypopigmentation
Blue	Cobalt aluminate (azure blue)	QS ruby, QS alexandrite, QS Nd:YAG (1064), PS alexandrite, PS Nd:YAG (1064), PS Ti:sapphire (785)	Hypopigmentation
Green	Chromium oxide (casalis green), hydrated chromium sesquioxide (guignet green), malachite green, lead chromate, ferro-ferric cyanide, curcumin green, phthalocyanine dyes (copper salts with yellow coal tar dyes)	QS ruby, QS alexandrite, PS alexandrite, PS Ti:sapphire (785)	Hypopigmentation, allergic reactions (chromium)
Red	Mercury sulfide (cinnabar), cadmium selenide (cadmium red), sienna (red ochre; ferric hydrate and ferric sulfate), azo dyes	QS Nd:YAG (532), PS Nd:YAG (532)	Hypopigmentation, tattoo ink darkening, allergic reactions (mercury sulfide, cadmium, azo dyes)
Yellow	Cadmium sulfide (cadmium yellow), ochre, curcumin yellow	QS Nd:YAG (532), PS Nd:YAG (532)	Hypopigmentation, tattoo ink darkening, allergic reactions (cadmium)
Brown	Ochre	*Tan/light brown*: QS Nd:YAG (532) *Dark brown*: QS ruby, QS alexandrite, QS Nd:YAG (1064), PS alexandrite, PS Nd:YAG (1064)	Hypopigmentation, tattoo ink darkening
Violet	Manganese violet	QS Nd:YAG (532), PS Nd:YAG (532)	Hypopigmentation, tattoo ink darkening
White	Titanium dioxide, zinc oxide	QS Nd:YAG (532)	Hypopigmentation, tattoo ink darkening
Skin colored	Iron oxides	QS Nd:YAG (532)	Hypopigmentation, tattoo ink darkening

Table 137.4 Tattoo pigments, lasers used for their removal, and potential complications. Hyperpigmentation and textural changes also occasionally occur as complications. Hypo- and hyperpigmentation are more common in individuals with highly pigmented skin, and they are best treated with the Q-switched (QS) Nd:YAG (1064) laser to reduce this risk. PS, picosecond; Ti, titanium.

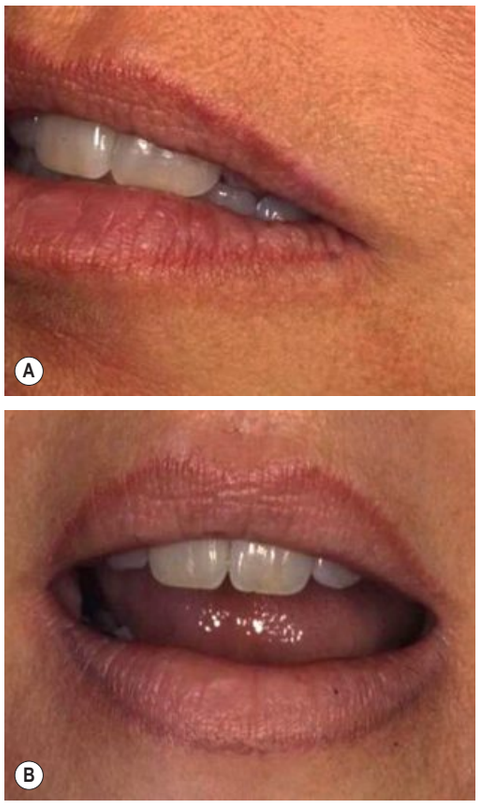

Fig. 137.17 Paradoxical tattoo darkening reaction following Q-switched laser removal of pink tattoo at the lip margin. **A** Before treatment. **B** Immediately after treatment.

skin cleansing is a simple and effective method for increasing patient comfort. Cooling strategies such as forced cold air or contact cooling can enhance patient tolerance. For more aggressive ablative procedures, supplementary anesthesia with nerve blocks, tumescent anesthesia, nitrous oxide (Pro-Nox™, Clarion Medical Technologies), systemic narcotics, or anxiolytics are often used.

Ocular injury can occur without appropriate wavelength-specific eye protection during laser procedures. An outline of safety precautions is provided in Table 136.5.

Post-therapy Considerations, Side Effects, and Complications

Following ablative fractional resurfacing, punctate bleeding and serosanguineous drainage are normal side effects (see Fig. 137.7), which dry into a thin keratinous crust within 24–48 hours. Patients are encouraged to minimize this crusting and aid in its exfoliation by applying dilute vinegar–water soaks to the treated sites every couple of hours. This is followed by a thin coat of white petrolatum ointment or generous amounts of a bland moisturizing cream until re-epithelization is completed.

Edema and erythema of treated skin is observed following both ablative and non-ablative fractionated therapies, but these side effects are much more pronounced after ablative procedures[82]. Topical application of a potent corticosteroid (e.g. fluocinonide ointment) immediately following the procedure can reduce these side effects. Non-ablative FP typically requires little or no "downtime" for healing, and the edema and erythema resolve within 24–48 hours. For ablative FP, the erythema dramatically improves within 1 week, but mild erythema and edema can persist for 3–6 weeks. Most patients are able to return to their normal activities, including work, and to apply makeup around 7 days following ablative FP. Well-documented side effects of generalized and

persistent erythema or delayed hypopigmentation that are seen with traditional resurfacing have been reported only rarely with fractionated lasers. Additionally, lines of demarcation are easily avoided by feathering the transitional skin between treated and untreated regions with near-minimal fluence and density settings.

Because only minute areas of damage are induced and the skin heals rapidly, fractionated ablative systems offer an unparalleled safety margin as compared to traditional ablative lasers. However, infection is still the most significant complication and can lead to permanent scarring. It is advised that all patients begin oral antiviral therapy the day prior to, or the morning of, the procedure. They should also have easy access to postoperative skin evaluations, especially if fever, pain, angular erythema, or pustular discharge is noted. Use of oral antibiotics and antifungal agents can be decided on a case-by-case basis.

Although scarring is an infrequent event, recent case reports have alerted laser surgeons to be cautious in "underprivileged" areas such as the neck and chest which are relatively devoid of adnexal structures[83]. Whereas skin on the cheek with its thicker dermis and abundant sebaceous glands can tolerate high energies and up to 70% ablation for certain indications, more modest energy and significantly less ablation density should be employed on thinner, finer, and less privileged areas.

Another noteworthy consideration for minimizing the risk of scarring is avoidance of immediate and direct scanned overlap of treatment areas. Use of a non-overlapping technique allows the treated skin sufficient time to cool before the application of the subsequent pass. This prevents bulk heating, a likely cause of scarring when it has occurred with fractional laser therapy. While ancillary cooling is not necessary, forced cold air is recommended as it facilitates heat dissipation, minimizes the potential for non-selective heat injury, and makes the procedure more comfortable. Where there is plume, smoke evacuation devices should be used.

PIH is a near certain side effect when treating darker skin phototypes. This predictable event can be mitigated with early application of 4% hydroquinone cream, starting shortly after non-ablative procedures. For those who have undergone ablative FP, this topical treatment can be started once the serosanguineous discharge of the immediate postoperative period has ceased. Patients with a prior history of melasma or other pigmentary disorders might be pretreated with topical hydroquinone prior to the procedure.

RADIOFREQUENCY AND ULTRASOUND

Skin Tightening

Monopolar radiofrequency (RF) energy generates dermal heat in a manner which is directly related to tissue impedance. The first commercially available monopolar RF device was ThermaCool TC™ (Thermage®) which delivered high-frequency RF energy to the skin via a thin, coupling electrode handpiece with active cooling. *In vivo* studies demonstrated that RF energy produced collagen contraction after disrupting hydrogen bonds within the collagen triple-helix structure[84].

After RF tissue tightening received FDA clearance for periorbital rhytide reduction in 2002, it was more widely used on the face and neck for improvement of skin laxity. A split-face study demonstrated average brow elevation of 2–4 mm, superior palpebral crease elevation of 1.9 mm, and reduction of jowl surface area by 22%[84]. Although other early studies reported similar conclusions, results in clinical practice were far more variable and unpredictable, and the treatments were associated with significant patient discomfort[85]. Aside from transient erythema and edema, irregular depressions ("mattress-top" irregularities) were seen, which were attributed to excessive treatment (outside the recommended parameters) causing localized fat atrophy. New algorithms and devices were developed, which increased both the reproducibility of the results and patient comfort. They included the use of: (1) lower energies over a larger tip in a multiple-pass technique[13]; (2) a transcutaneous electrical nerve stimulation (TENS)-like interruption of RF energy interspersed with hot/cold skin stimulation; (3) vibration (acting on the gate theory of pain); (4) a modulated RF profile; and (5) more distributive electrodes. In 2017, RF technology received FDA clearance for non-invasive smoothing of skin on the face, around the eyes, and body.

Bipolar RF devices create localized heat by conducting current between the two electrodes on the skin surface (see Fig. 136.7). Studies purport to have shown a 25%–50% improvement in wrinkles, skin smoothness, and texture[13]. There are reasons to believe that the bipolar devices are not as efficient as monopolar devices in their ability to tighten tissue or create new collagen.

Ultrasound (US) has emerged as a recognized technique for non-invasive tissue tightening. The primary mechanism is the absorption of either very brief focused or much longer diffuse acoustic energy. US is colorblind and thus can be used on all skin phototypes.

Ultherapy™ (Merz) utilizes *high intensity focused ultrasound* (HIFU) and has been cleared by the FDA for improvement in the appearance of the face, neck, and décolletage. Depth-specific transducers induce ms pulses of focal injury within the skin without damage to the epidermis. Use of a prototype device led to significant skin tightening, with a 1 mm eyebrow lift in >75% of treated subjects[86]. In cadaveric skin, damage was noted at a depth of 4.2 mm, including damage to the superficial muscular aponeurotic system (SMAS)[87]. This targeted approach was met with significant enthusiasm, and a number of investigators have observed good clinical improvement. However, some clinicians still remain highly skeptical about the long-term benefits. Side effects include focal bruising and pain, reported by 25% and ≤55% of patients, respectively.

SofWave™ (SofWave Medical Ltd) provides more *diffuse US* with mid-dermal heating to 60–70°C, maximally targeting a depth of 1.5 mm for 5 seconds without damage to the underlying structures including bone, nerves, fat, and blood vessels. This device has no disposables, no moving parts, and no optics. The parallel delivery of more diffuse ultrasound beams, integrated cooling, and a large contact area allow for less discomfort and faster treatments. Patients should understand that these devices are no replacement for surgical skin tightening and may take multiple treatments to achieve the desired outcome.

Radiofrequency Microneedling Devices

Radiofrequency (RF) microneedling devices have made major inroads into traditional methods for skin rejuvenation. A plethora of such devices have been FDA cleared and are used for rejuvenation, "tightening", and improvement in scarring. Some are monopolar, while others are bipolar; electrodes are either insulated or non-insulated (see Table 137.1). The original device, Profound® RF (Candela), was shown to induce new collagen and elastin within the mid dermis, leading to improvement in facial and extrafacial skin laxity. However, the procedure is quite uncomfortable, requiring topical anesthetic, nerve blocks, and possibly nitrous oxide and parenteral pain control.

In general, RF microneedling is performed 4–6 times at one-month intervals using only topical anesthesia. The needle density and length are sufficient to provide both superficial and deep controlled thermal injury (see Table 137.1). Given the relatively low cost of device acquisition, low patient downtime and lack of PIH, this device has become quite popular among aesthetic surgeons and the spa industry.

Use of microneedling devices without RF may improve acne scarring, but there remains little evidence to support touted skin tightening benefits. The addition of RF and/or the immediate use of topical agents may provide real benefits.

MICROWAVES

In the electromagnetic spectrum, microwaves lie between infrared light and radio waves. Microwaves can heat substances via a process called dielectric heating. The latter occurs when energy causes a rotation of dipole molecules. Because it is an ion, water has a high dipole moment whereas fat has a low dipole moment. As a result, there is less absorption in the subcutaneous layer and selectivity for the dermis. Furthermore, application of concurrent cooling protects the upper dermis and selectively heats the deeper dermis.

Dielectric heating by microwaves was found to induce both eccrine and apocrine sweat gland thermolysis with relative selectivity. This discovery led to the first commercially available therapeutic microwave device – miraDry® (Miramar Labs). Studies have shown that 90% of patients had at least a 50% reduction in sweating, and ~80% maintained this reduction at 12 months[88]. All subjects experienced transient swelling, discomfort, and/or numbness within the treatment area, with a few patients noting longer-lasting side effects including altered sensation in or around the treatment site, papulonodules in the axillae, and hair loss[89].

A dose-response study of a novel method of selective tissue modification of cellular structures in the skin with nanosecond pulsed electric fields. Lasers Surg Med 2020;52:315–22.*

HOME-BASED LASERS

The notion that home-based laser and light devices might someday replace office-based treatments has not caused many physicians to lose sleep. In practice, however, there are some devices that can efficiently remove hair, reduce the signs of photodamage, induce a degree of skin tightening, and improve acne. That said, there is an even larger number of devices that are totally ineffective. In general, those devices that are effective and designed by highly skilled engineers are rather expensive, while the ineffective devices are relatively cheap and therefore appealing to the consumer. Potential economic rewards have driven some companies to manufacture devices which are so ineffective that they are awarded FDA clearance by virtue of their safety alone.

Although little peer-reviewed literature is available, one well-controlled, office-based study demonstrated that nearly all of the patients were able to correctly administer their own treatments. Additionally, the observed side effects of hyper- and hypopigmentation, crusting, and blistering were transient and had resolved by the conclusion of the study[90]. Use of these devices on darker skin phototypes and tanned skin is clearly contraindicated. The patients need to assume a high degree of responsibility with these devices. There will be complications, but we should not underestimate the ability of the public to use (or abuse) these devices.

EMERGING TECHNOLOGIES

To prevent and control acne via sebaceous gland suppression, gold-coated silica microparticles can be excited with commonly available lasers at a low energy fluence[91]. Localized damage can be achieved with minimal injury to surrounding structures. Sebacia Microparticles (Sebacia, Inc.) is the first such commercially available product. In addition, when sebum was compared to water, a wavelength of 1726 nm was found to have a small but significant absorption differential. Use of a "sebum laser" led to focal damage of sebaceous glands with sparing of surrounding structures and was reported to prevent and treat acne.

Nano-Pulse Stimulation™ (NPS™) technology (Pulse Biosciences, Inc.) utilizes non-thermal energy and has a unique mechanism of action that targets only cellular morphology while sparing the non-cellular stroma (Fig. 137.18)[92,93]. Ultrafast (nanosecond) electrical energy pulses are delivered via microneedle arrays. In clinical trials, NPS has been used to treat common warts, seborrheic keratoses, sebaceous hyperplasia, and superficial basal cell carcinomas, with a reportedly low incidence of hyper- or hypopigmentation and rarely scarring. Regulated cell death has also been observed in malignant tumor-bearing animals as has a secondary immune response that leads to rejection of re-introduced malignant cells of the same lineage[94].

CONCLUSIONS

Increasingly, we are asking the question, "Lasers: what's the truth?" This reality check is necessary so that we start to ask the right questions and are critically aware of the answers. Laser engineers are very insightful and they can provide us with semi-intelligent laser, light, and other energy systems that can more precisely target the correct structures and induce appropriate healing responses. We should celebrate the enormous energy that goes into newer and more sophisticated devices, just as we should criticize and reject devices which underperform and overpromise. Those of us who are involved in new technology development know that, just around the corner, advances are going to bring us smarter, cheaper, more durable, more tunable devices. Total internal reflection of spontaneous emission of radiation (TRASER) devices, which are neither lasers nor IPL, are more efficient than lasers and are tunable. Our hope is that as new technologies come online, there will be a continued attempt to answer the ongoing tough questions pertaining to both surgical and medical dermatology.

Additional figures and video available in our eBook (see inside front cover for access code).

138 Cryosurgery

Paola Pasquali

Key features

- A minimally invasive surgical technique that utilizes subzero temperatures to destroy benign, premalignant, and malignant lesions
- Compared to standard excisional surgery, cryosurgery requires less time to perform but healing time is often more prolonged as it occurs via second intention
- Damage to surrounding structures is predictable and can be limited, with the preserved underlying stroma providing a structural framework for wound repair
- The preferred and most commonly used cryogen is liquid nitrogen due to its very low boiling point (−196 C) which allows for freezing of skin lesions at temperatures needed for their destruction; this includes malignant cells which require freezing temperatures of at least −50 C
- Cryosurgery often leads to an excellent cosmetic result, but in patients with darker skin phototypes, hypopigmentation due to destruction of melanocytes can occur

HISTORICAL BACKGROUND

Reducing the temperature of the skin was initially done to provide anesthesia or lessen inflammation. With the advent of potent cryogens, selective destruction of tissue became possible. James M. Arnott is credited with first describing the use of controlled freezing in the 1800s to destroy tumors[1]. Liquefied oxygen and carbon monoxide preceded the introduction of liquid nitrogen (LN) by Carl von Linde. By 1898, James Dewar had developed a flask that permitted storage and transportation of LN thereby rendering LN accessible to physicians.

In 1899, Archibald Campbell White reported on the successful treatment of multiple benign and malignant skin conditions with liquefied air applied via an adapted bottle; the latter could be considered the prototype of modern hand-held units. Herman V. Allington then described how LN-saturated cotton swabs could be used to treat various skin conditions. In 1961, the neurosurgeon Irving S. Cooper, together with Arnold Lee, developed the first cryosurgical probe. Increased use of LN for medical purposes followed the design of safe portable hand-held units.

PRINCIPLES OF CRYOSURGERY AND CRYOBIOLOGY

Cryosurgery is defined as a surgical procedure that utilizes very low temperatures to destroy living tissue. The term *cryotherapy* should be reserved for when living tissue is exposed to cold in order to induce physiological changes but not tissue destruction. *Cryobiology* represents the study of the effects of low temperatures on living tissues.

Heat transfers from hot to cold[2], and the larger the temperature difference between a cryogen and its target tissue, the faster the heat transfer. The ideal cryogen has the lowest possible temperature and is capable of producing the parameters necessary to destroy both benign and malignant cells; for the latter, the tissue temperature needs to be below −50°C. The most commonly used cryogen is LN which boils at −196°C (77°K; −321°F). LN is relatively safe to handle, non-toxic, and commercially available. For the treatment of actinic keratoses (AKs) and cutaneous carcinomas, LN is the recommended cryogen whereas for benign lesions, cryogens with higher boiling points (e.g. liquid nitrous oxide [−88°C], carbon dioxide gas [−78°C], other compressed organic gases [−55 to −75°C]) can also be employed.

The mechanisms of injury in cryosurgery can be attributed to both direct and indirect effects (Table 138.1). Such events are the result of fast freezing followed by slow thawing, i.e. a freeze–thaw cycle. Repeated freeze–thaw cycles increase the destructive effects of cryosurgery. The material interposed between the cryogen and the lesion to be treated is also a determinant of the speed of freezing. *Air* is a poor conductor of cold such that the greater the distance between the skin lesion and the source of the cryogen, the lesser the freezing. *Water* is a better conductor than air (e.g. a presoaked verruca freezes faster), and *ice* is better than water as in the intra- and extracellular ice crystals present after the first freeze–thaw cycle. Finally, *metal* is an excellent conductor explaining the deep and fast freezing of tissue that results from frozen metal probes placed in direct contact with the skin[3].

Different cells and tissues have different sensitivities to cold. The lethal temperature for melanocytes is around −4°C, while that for keratinocytes is −35°C. Keratinocyte cancer cells require around −50°C, sarcoma cells −60°C, and vascular endothelium −15°C to −40°C. Of note, cartilage and bone are quite resistant to freezing.

Cryoimmunology

Cryoimmunology is the study of the innate and humoral immune responses to antigens derived from frozen skin lesions. Development of newer immunologic assays has made it possible to measure such responses, which can be either immunostimulatory or immunosuppressive[4].

One major difference between conventional excisional surgery and cryosurgery is that the latter leaves the tumor "*in situ*". At the center of the frozen lesion, there will be necrosis due to direct cellular damage (see Table 138.1), leading to release of tumor-specific antigens capable of stimulating an immune response. Once the innate immune system is activated, antigen-presenting cells (APCs) engulf tumor fragments and present processed antigens to T cells, initiating both T and B cell immune responses (see Ch. 4). At the periphery, the temperatures are higher and therefore sublethal, with the cells undergoing apoptosis rather than necrosis. This leads to "silent cell death" associated with minimal inflammation (see Table 138.1)[4].

The response to cryosurgery can be enhanced by the addition of adjuvants[5]. These include agents that augment ice injury (e.g. glycine), inducers of apoptosis (e.g. topical 5-fluorouracil)[6], and immunomodulators (e.g. topical imiquimod). Such combinations have been termed *immunocryosurgery*, with promising results having been published[7]. However, further studies are needed to better understand the underlying mechanisms of cryoimmunology, define the ideal parameters for tumor destruction, and determine the precise interactions between cryosurgery and potential adjuvants.

INSTRUMENTS AND TECHNIQUES

Cryosurgical techniques can be subdivided into several types (Table 138.2):

- ***Open*** (***spray***, ***open-spray***; Fig. 138.1A). This is the most frequently used technique. The instrument consists of a metal container with spraying tips or openings through which the cryogen is released. This technique is suitable for lesions that are flat or elevated as well as benign or malignant; the key factor is achieving the correct freezing temperature. Larger openings deliver more LN and freeze tissue faster, so they are ideal for larger, bulky lesions. Smaller openings freeze tissue slower and allow for a more precise freezing. Therefore, they are ideal for small benign lesions, such as lentigines or seborrheic keratoses.

CRYOSURGERY – MECHANISMS OF INJURY				
Type of injury	**Type of cell death**	**Phase**	**Location**	**Type of response**
Direct injury	Necrosis: direct freezing of water leads to extracellular then intracellular ice crystal formation with edema and cellular lysis Temperature required: –20°C for most cells –50°C or lower for malignant cells	Freeze period	Center of treated lesion	Inflammation: +++ Short-lived, nonspecific innate immune response
Vascular injury	Ischemia due to secondary damage of vascular endothelium	Thawing(~1 hour after freezing)	Periphery of treated lesion and normal surrounding skin	Inflammation: +/++
Apoptosis	Occurs at sublethal temperatures, e.g. approx. –20°C for malignant cells	4–8 hours after thawing	Periphery of treated lesion	Inflammation: –/+
Immunologic	Antigens released from damaged cells lead to immune response	Late event	Lymph nodes	Adaptive immune response

Table 138.1 Cryosurgery – mechanisms of injury.

CRYOSURGICAL TECHNIQUES						
Technique		**Common uses**			**Advantages**	**Disadvantages**
Type	**Synonym**	**B**	**PM**	**M**		
Open	Spray Open-spray	√	√	√	Any size or surface	For small lesions, care should be taken regarding normal surrounding skin Not appropriate for pedunculated lesions
Semi-open	Confined spray Cone Confined	√			Relative sparing of normal surrounding skin	Appropriate size of cone required
Semi-closed	Chamber			√	Deep and fast freezing	Indicated for cutaneous malignanciesAppropriate size of chamber required
Closed	Contact Probe Cryoprobe	√		√	Deep and fast freezing	Appropriate size and shape of probe required
Tweezers	Cryotweezers	√			Spares normal surrounding skin Pedunculated lesions	Limited to superficial lesions
Intralesional	–	√		√	Freezing occurs from the center of the lesion	Invasive
Dipstick	Cotton-tipped applicator	√			May be less frightening for children	Variability in amount of LN within cotton tip Loss of temperature control Dripping of LN may lead to unintended sites of freezing

Table 138.2 Cryosurgical techniques. B, benign lesions; LN, liquid nitrogen; M, malignant lesions; PM, premalignant lesions.

- ***Semi-open*** (***confined spray***, ***cone***, ***confined***; Fig. 138.1B). This refers to the use of a polycarbonate plate with holes, neoprene cones, or otoscope specula to restrict sprayed LN to a limited area. All of these items are composed of non-conducting materials. Freezing is faster than with the open technique as the LN is confined to the lesion. As splattering of LN is avoided and normal surrounding tissue is spared, it tends to be less painful.
- ***Semi-closed*** (***chamber***; Fig. 138.1C). One end of a metal cone is attached to the cryogen unit while the rubber-protected distal end is held firmly against the skin. This system generates potent and deep freezing and should be reserved for skin cancers and cutaneous metastases.
- ***Closed*** (***probe***, ***contact***, ***cryoprobe***; Fig. 138.1D,E). The cryogen is delivered via a closed system, i.e. from the unit through metal probes in contact with the skin; the remaining cryogen exits by way of a rubber releasing hose. Probes come in different shapes and diameters. To ensure homogeneous freezing, they need to be applied to flat tumor surfaces. In addition, when treating hemangiomas, the probe should be applied with pressure in order to "press out" the blood and lower the final temperature. For delicate procedures, such as freezing cysts near the eye, ultrasound gel or water can be placed on the skin under the probe.
- ***Tweezers*** (Fig. 138.1F). A previously frozen Teflon® forceps is used to grasp pedunculated lesions. The freezing front is then allowed to advance just to the skin surface. This is an ideal technique for filiform lesions, with sparing of normal surrounding skin as well as minimization of post-treatment hypo- or hyperpigmentation.
- ***Intralesional*** (Fig. 138.1G). While originally developed for keloids, this technique consists of passing a thick needle through the tumor. One end of the needle is attached to the cryogen unit (screwed on or via a Luer lock), while the other end that has exited the skin allows for LN release. It can be used for large nodular tumors where freezing originating from the center of the mass provides an advantage. It is ideal for preserving surrounding tissue.
- ***Dipstick*** (Fig. 138.1H). A LN-saturated, cotton-tipped applicator is placed directly onto the lesion. This technique is still used by some physicians for verrucae and solar lentigines.

PREOPERATIVE CONSIDERATIONS

Patients need to be aware of the relative advantages and disadvantages of cryosurgery compared to other therapies (Table 138.3). A disadvantage is the longer healing times (e.g. ~2–3 weeks for the trunk and arms, >1 month for the legs) while an advantage is the lack of preoperative requirements such that cryosurgery can be performed at the time of the initial office visit. In addition, the need for postoperative

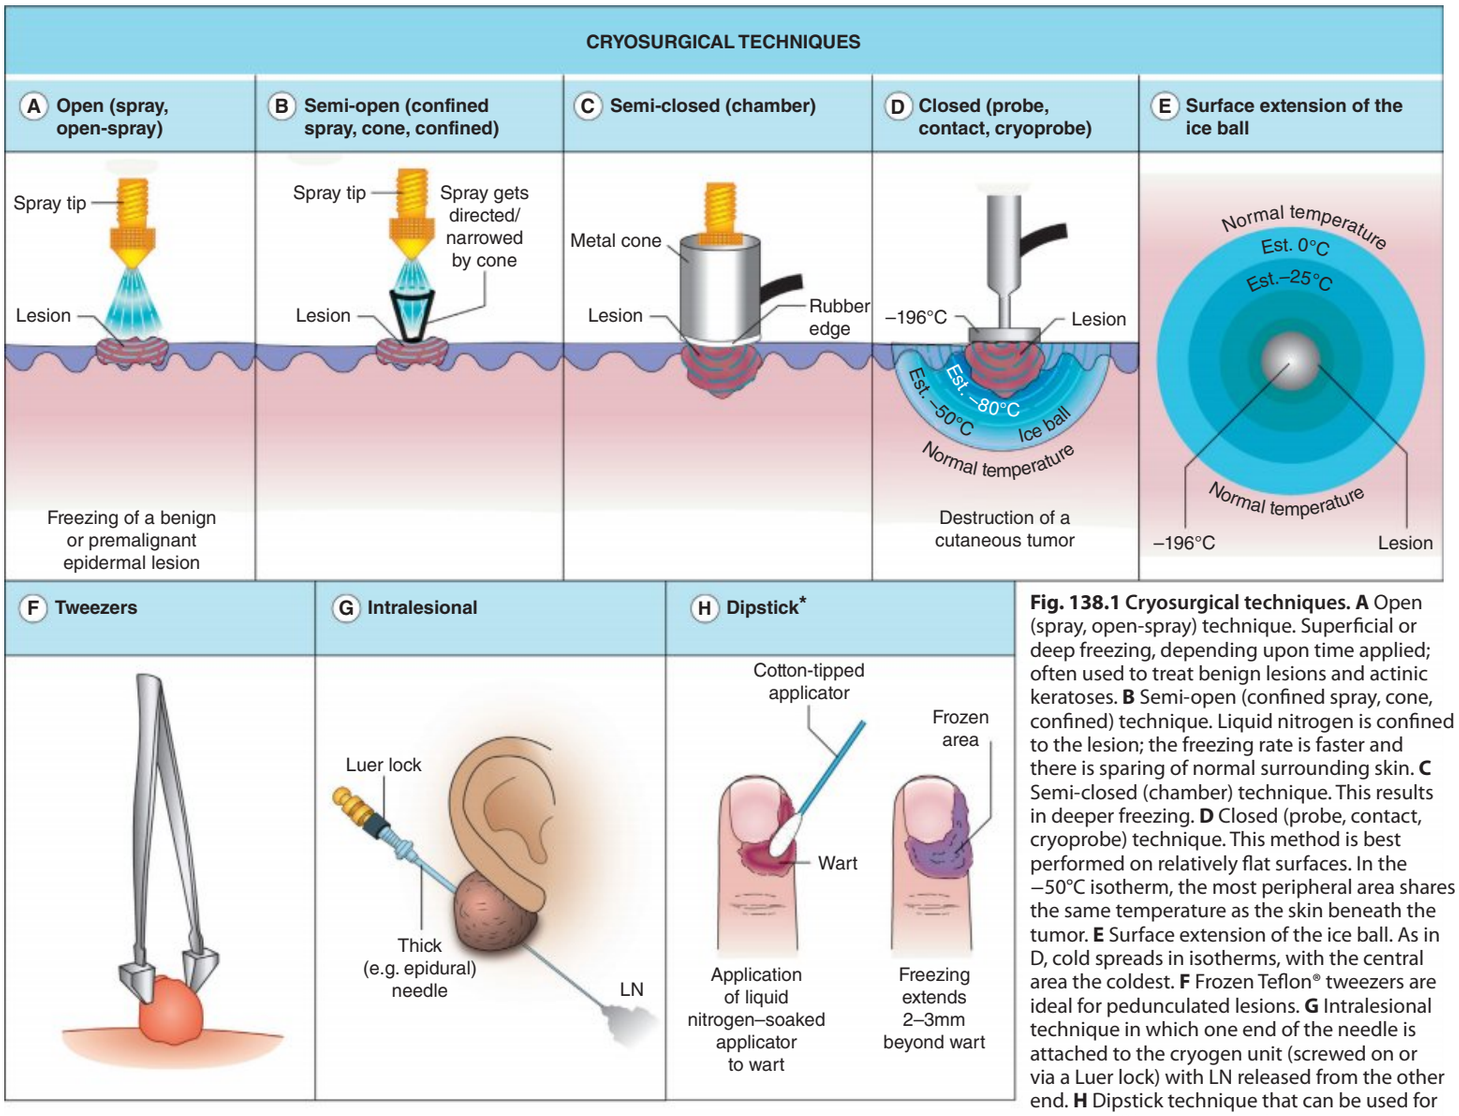

Fig. 138.1 Cryosurgical techniques. A Open (spray, open-spray) technique. Superficial or deep freezing, depending upon time applied; often used to treat benign lesions and actinic keratoses. **B** Semi-open (confined spray, cone, confined) technique. Liquid nitrogen is confined to the lesion; the freezing rate is faster and there is sparing of normal surrounding skin. **C** Semi-closed (chamber) technique. This results in deeper freezing. **D** Closed (probe, contact, cryoprobe) technique. This method is best performed on relatively flat surfaces. In the −50°C isotherm, the most peripheral area shares the same temperature as the skin beneath the tumor. **E** Surface extension of the ice ball. As in D, cold spreads in isotherms, with the central area the coldest. **F** Frozen Teflon® tweezers are ideal for pedunculated lesions. **G** Intralesional technique in which one end of the needle is attached to the cryogen unit (screwed on or via a Luer lock) with LN released from the other end. **H** Dipstick technique that can be used for verrucae. *Not recommended by the author due to the disadvantages listed in Table 138.2.

CRYOSURGERY – ADVANTAGES AND DISADVANTAGES	
Advantages	**Disadvantages**
• Safe and relatively simple procedure • Quick, low-cost procedure • Low-cost equipment (compared to other surgical modalities) • Can be done in the outpatient setting and in nursing homes • Versatility – treatment of a variety of conditions • Treatment of any area of the body, including earlobes, eyelids, nasal alae • Ideal for patients with multiple lesions, allergies to local anesthetics, fear of undergoing surgery, or significant surgical risk due to comorbidities • Minimal, if any, work or sports restrictions • Safe during pregnancy • Excellent cosmetic results	• Longer healing time with deep freezing procedures as second intention healing is required • Contraindicated in patients with cold-triggered conditions or cold-sensitive patients • Hypo- or hyperpigmentation, especially in darker skin phototypes • At free margins, scarring can lead to retraction (e.g. ectropion) • Possible alopecia following deep freezing of hair-bearing areas • Caution required when treating sites with underlying superficial nerves • Not recommended for convex areas, e.g. cheeks • In patients with rosacea, disappearance of erythema at treatment sites can lead to a Swiss cheese-like appearance

Table 138.3 Cryosurgery – advantages and disadvantages. See Table 138.8 for additional details.

care and potential side effects should be reviewed. Contraindications include cold urticaria, cold intolerance, cryoglobulinemia, and other cold-triggered conditions.

For certain clinical situations, skin preparation can improve the effectiveness of cryosurgery. Examples include: (1) removal of excess keratin (a poor conductor of cold) from verrucae via curettage, paring, or application of salicylic or lactic acid for 10–15 days prior to cryosurgery; (2) application of imiquimod to condylomata acuminata; and (3) pretreatment with topical 5-fluorouracil cream[8], diclofenac sodium gel[9], ingenol mebutate gel[10], imiquimod, or retinoic acid cream or gel[11] to remove atrophic and mildly keratotic AKs, with the remaining hyperkeratotic AKs then treated with cryosurgery.

Cryoanesthesia

Cryogens applied for just a few seconds can be used as an anesthetic, e.g. prior to needle insertion or incision and drainage of an inflamed epidermoid cyst. This technique is helpful in needle-phobic patients and can also be used prior to removal of benign lesions (Fig. 138.2)[12].

TREATMENT

Cryosurgery should not be performed without first establishing the correct diagnosis via clinical examination, dermoscopy, and/or histologic examination. The appropriate technique is then chosen (see Table 138.2).

Benign Lesions

Table 138.4 outlines benign conditions that are amenable to cryosurgical management[13]. For some, such as verrucae, it is a first-line option. The open (spray) technique is used for most benign lesions, including verrucae and acne cysts, while the semi-open technique or cryotweezers may be preferred for filiform warts and acrochordons (Video 138.1). The closed (contact, probe) technique can be employed for small adnexal cysts, pseudocysts (e.g. mucoceles), and sebaceous hyperplasia[14] as well as for vascular lesions (e.g. hemangiomas, spider telangiectasias, pyogenic granulomas) (Fig. 138.3). A single freeze–thaw cycle is usually sufficient for benign lesions and cryogens other than LN can be used (see above). Whenever using the spray technique, the use of small diameter apertures and intermittent spraying leads to a more delicate spray and less damage to normal surrounding skin.

For verrucae, removal of excess keratin and moistening of the lesion can improve the effectiveness of cryosurgery (see above). When removing verrucae and seborrheic keratoses, the freezing front should extend a few millimeters beyond the clinical margin to avoid a doughnut wart or residual lesion. If the closed or contact technique is used to treat hemangiomas and other vascular lesions, it is best to prefreeze the probe to prevent it from sticking to the skin surface and to press firmly (see Fig. 138.3). These recommendations are reflected in the PPPP rule: probe • pressure • prefreezing • patience. If the probe does become frozen to the skin lesion, simply allow for thawing before removing the probe. This approach is also recommended for mucosal lesions. Mucoceles may be drained prior to treatment with the closed technique.

Lentigines are lightened with a brief 3- to 4-second freeze and either the open spray or the dipstick technique can be employed. For keloids, the open spray technique – either alone or immediately prior to corticosteroid injection – or the intralesional technique is preferred. In darker skin phototypes, the anticipated cryosurgical technique may initially be performed in a test site that is in a cosmetically insensitive ("hidden") location. The site is then examined for hypo- or hyperpigmentation prior to cryosurgery in other locations.

Premalignant Lesions, Including Actinic Keratoses

Cryosurgery is a very effective therapeutic option for AKs and other premalignant conditions (Fig. 138.4)[15,16]. One 20- to 40-second freeze–thaw cycle is usually sufficient for a 1 cm lesion. The surface temperature reaches −15° to −20°C and, once frozen, the lesion can be grasped between two fingers (Fig. 138.5). Initial freezing should be in the center of the AK, with the freezing front then spreading laterally ~2–3 mm

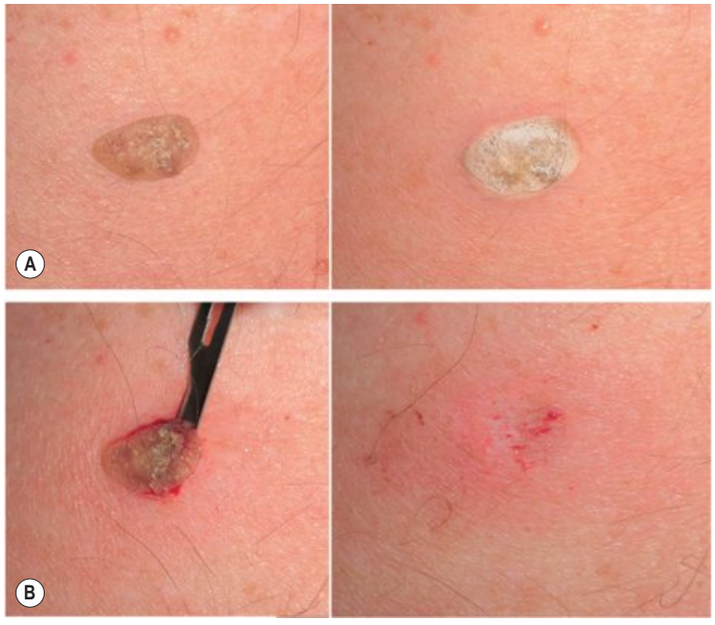

Fig. 138.2 Shave removal of a seborrheic keratosis following the use of liquid nitrogen as an anesthetic. A A seborrheic keratosis (SK) is frozen with a 2–3 mm margin. **B** Once the tissue starts thawing, a swift stroke with a curette or scalpel will make the SK "pop out". A hemostatic solution (aluminum chloride) is applied before complete thawing.

BENIGN CONDITIONS AMENABLE TO CRYOSURGERY	
• Acne cysts	• Lentigo
• Acne keloidalis nuchae	• Lichen sclerosus (of vulva)
• Acne vulgaris	• Lymphangioma
• Acquired perforating disorder	• Cutaneous lymphoid hyperplasia (lymphocytoma cutis)
• Acrochordons	• Molluscum contagiosum
• Angiofibroma	• Mucocele
• Angiokeratomas, including of Fordyce	• Myxoid cyst
• Cherry angioma	• Nevoid hyperkeratosis of the nipple
• Chondrodermatitis nodularis helicis	• Orf
• Chromoblastomycosis	• Pearly penile papules
• Clear cell acanthoma	• Porokeratosis
• Condyloma acuminatum	• Prurigo nodularis
• Dermatofibroma	• Pyogenic granuloma
• Discoid lupus erythematosus	• Rhinophyma
• Eccrine poroma	• Rosacea
• Elastosis perforans serpiginosa	• Sarcoidosis
• Epidermal nevus	• Sebaceous hyperplasia
• Erosive adenomatosis of the nipple	• Seborrheic keratosis
• Folliculitis keloidalis	• Syringocystadenoma papilliferum
• Granuloma annulare	• Syringoma
• Granuloma faciale	• Trichiasis
• Hemangioma	• Trichoepithelioma
• Herpes simplex	• Venous lake
• Keloid	• Verruca vulgaris
• Leishmaniasis	• Xanthoma

Table 138.4 List of benign lesions reported to be amenable to cryosurgical treatment. *Courtesy Emanuel G. Kuflik, MD.*

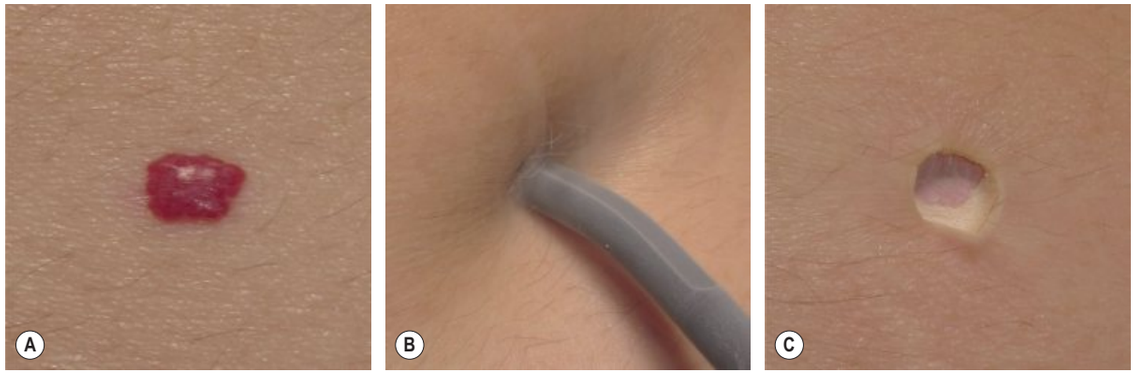

Fig. 138.3 Removal of a cherry angioma via the closed (probe, contact, cryoprobe) technique. A Prior to treatment. **B** A previously frozen probe is pressed into the lesion. **C** The frozen angioma and a transient depression can be seen.

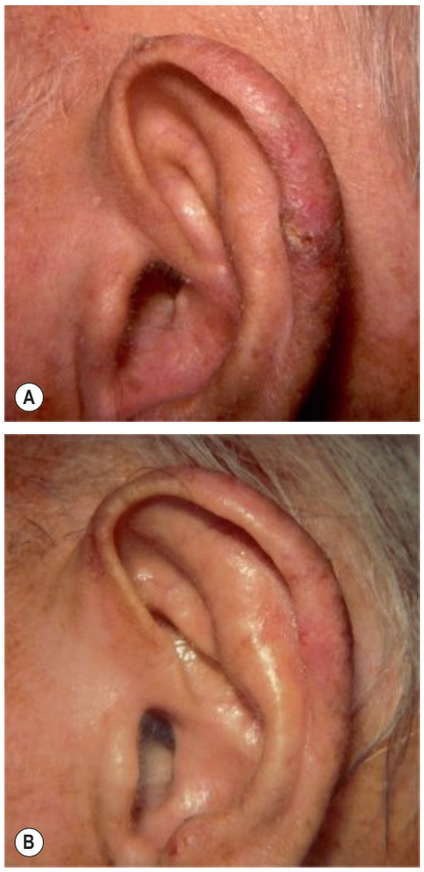

Fig. 138.4 Actinic keratosis treated with the open-spray technique. A Prior to treatment. **B** Three weeks later. *Courtesy Emanuel G. Kuflik, MD.*

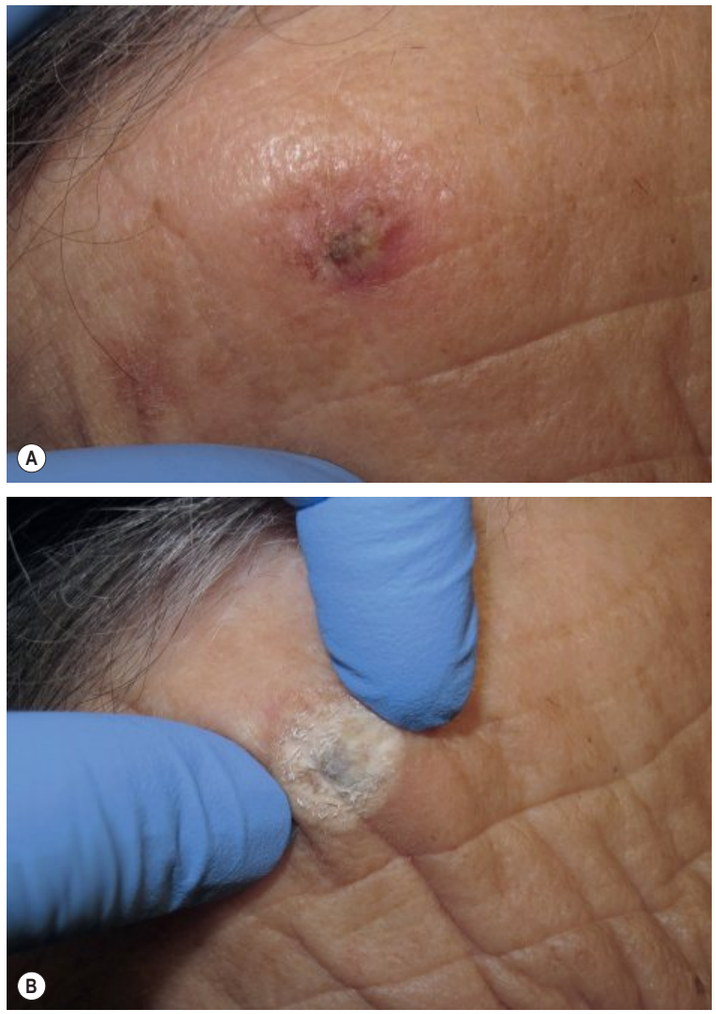

Fig. 138.5 Cryosurgery of a hypertrophic actinic keratosis. A Prior to treatment. **B** The open-spray technique should produce a block of frozen tissue that can be grabbed with both fingers; the surface temperature is approximately −15°C.

beyond the clinical margin. Some clinicians treat each lesion with two 15-sec freeze–thaw cycles. Recurrences should be assessed to determine if a squamous cell carcinoma needs to be excluded.

Within areas of significant cutaneous photodamage, there are rarely single AKs but rather multiple AKs as well as subclinical epidermal dysplasia. This is often referred to as "field cancerization" and is best treated by a combination of cryosurgery plus a topical agent (e.g. 5-fluorouracil, imiquimod) or photodynamic therapy. The latter are used to treat subclinical disease and thin lesions while cryosurgery is used to treat thicker keratotic AKs. It is more logical to first treat the field and then use cryosurgery for residual lesions[17].

Cryopeeling refers to the treatment of large areas of photodamaged skin, i.e. field treatment via cryosurgery. The areas of involvement are superficially frozen for 5–10 seconds, and given the associated pain, it is best to apply a topical anesthetic before and immediately after the procedure (see Ch. 143). Individual thicker lesions can be treated at the same time with a longer freeze time (see above)[18]. The freeze time for actinic cheilitis ranges from 10 to 20 seconds.

Cutaneous Malignancies

Cryosurgery is a reasonable alternative for the treatment of skin cancer (Table 138.5), but the lesions and techniques need to be carefully selected[19,20]. Because a double freeze–thaw cycle is more destructive, it is the recommended cryosurgical procedure for skin cancer. Except for very small lesions, local anesthesia is administered. In addition, since keratin is a poor conductor of cold, removal of excess keratin via curettage or paring will assist in reaching the correct freezing temperature at the base of the tumor, thus improving effectiveness[21].

The most commonly used techniques are open (spray) and closed (contact, probe); the closed technique is preferred as it leads to deeper and faster freezing (see Table 138.2). However, it is important to use a probe that corresponds to the size and shape of the tumor to assure complete apposition. The presence of air pockets ("interphase") between the probe and the tumor surface can prevent achievement of the desired final temperature. If the open (spray) technique is chosen, the freezing

CUTANEOUS MALIGNANCIES AMENABLE TO CRYOSURGERY		
Type	**Cryosurgery**	
	Amenable	**Not recommended**
Bowen disease, keratoacanthoma	All	–
Basal cell carcinoma	Especially useful for superficial lesions Tumors with well-defined borders	Morpheaform, infiltrative, and/or recurrent tumors Tumors with ill-defined margins or perineural invasion
Squamous cell carcinoma	Especially useful for superficial lesions Tumors with well-defined borders	Poorly differentiated, infiltrative, and/or recurrent tumors Tumors with ill-defined margins or perineural invasion
Lentigo maligna	Selected cases (e.g. elderly, mutilating surgery required)	
Kaposi sarcoma	Selected lesions that have not responded to other therapies	Avoid plantar surface
Melanoma	As palliation	

Table 138.5 Cutaneous malignancies amenable to cryosurgery.

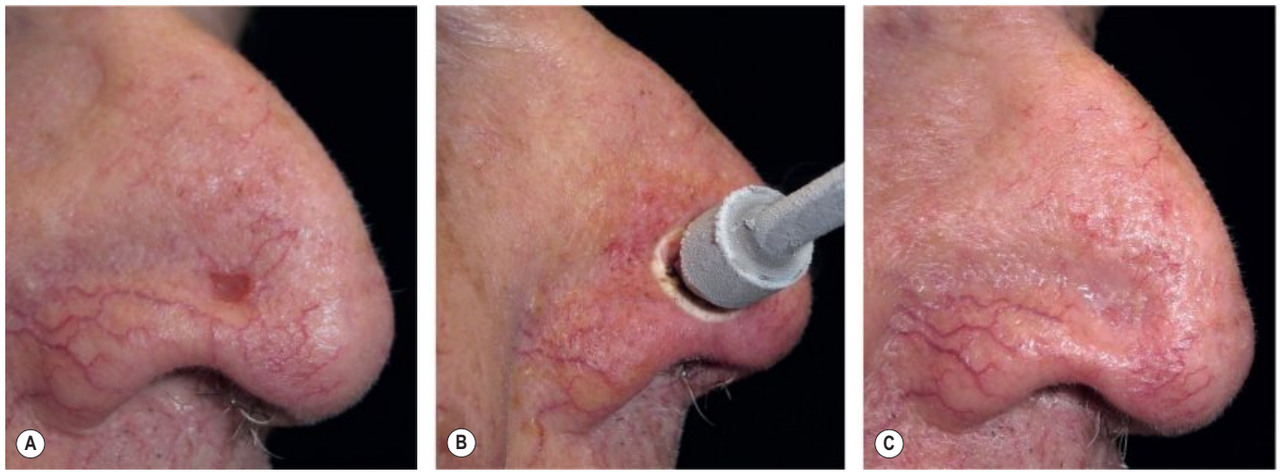

Fig. 138.6 Treatment of a basal cell carcinoma on the nose with the closed (probe, contact, cryoprobe) technique. A Prior to treatment. **B** An appropriately sized frozen cryoprobe is pressed against the tumor; a double freeze–thaw cycle is performed. **C** Healing is nearly complete a few weeks later.

should begin in the center of the tumor followed by lateral spread of the freeze front to 5 mm beyond the clinical margin of the tumor. A similar margin should be obtained with the closed technique.

Because cold advances as isotherms (see Fig. 138.1D,E), temperatures should be measured at the external margin. The temperature can be monitored by measuring (via an infrared thermometer) the surface temperature at the external margin and thereby inferring the temperature at the base of the tumor. More recently, high frequency ultrasound (HFUS; ~22 MHz) has been employed to determine the width, depth, and shape of tumors, thereby providing very useful information for selecting the optimal cryosurgical technique. For example, when basal cell carcinomas (BCCs) are thin, they can be safely treated with either the spray or the probe technique whereas for deeper nodular BCCs, the probe technique is preferred (Fig. 138.6; Video 138.2).

HFUS can also be used to monitor the freezing procedure. An initial black area is seen when the tumor is completely frozen. Re-appearance of the tumor is indicative of thawing, which first occurs at its surface and is last seen at the tumor base. By combining this information with measurement of the temperature[22] at the outer edge of the frozen tumor, the temperature at the base of the tumor can be implied[23].

For patients with multiple BCCs, dermoscopic diagnosis and HFUS of each lesion can be followed by a double freeze–thaw cycle, all in one treatment session. BCCs in several sites, including the nose, ears[24], and eyelids, have been treated successfully with cryosurgery[25]. Immunocryosurgery, consisting of a 5-week course of topical imiquimod with a double freeze–thaw cycle at week two, has also been utilized for skin cancer (Fig. 138.7). Lastly, melanocytes are known to be very sensitive to cold and cryosurgery is an option for selected cases of lentigo maligna (Fig. 138.8)[26,27]. However, it is important to ensure that melanocytes within the follicular epithelium are destroyed. Of note, cryosurgery has also been used, in combination with imiquimod, as treatment for locoregional cutaneous metastases of melanoma[28].

Fig. 138.7 Treatment of a large, ill-defined, postauricular basal cell carcinoma with immunocryosurgery. A Prior to treatment. **B** Eight months later, following a 5-week course of topical imiquimod with a double freeze–thaw cycle at week two.

Palliative Treatment

Cryosurgery has long been used for palliative (compassionate) treatment of skin cancer (Table 138.6)[29]. Detailed discussion with the patient and/or family/caretakers should be undertaken before instituting palliative treatment. The goal is to reduce pain, bleeding, infection, tissue destruction, foul smell, and/or tumoral masses that cause personal and social rejection. Palliative cryosurgery can improve quality of life in individuals with inoperable tumors or in those who reject conventional therapies or are poor surgical candidates due to underlying medical conditions.

Large tumoral masses can be treated by either: (1) the segmental technique; or (2) the fractional technique. In the *segmental* technique, the tumor is divided by imaginary lines into portions. Each segment is treated independently, allowing the freezing fronts to overlap. The aim is to avoid excessive freezing in the center of the tumor prior to the freeze front reaching the periphery. In the *fractional* technique, the center of the tumor is treated and then allowed to heal[30]. As the central

Fig. 138.8 A lentigo maligna on the forehead of a 72-year-old man. A The lesion measures 3.1 × 2.5 cm. **B** Cryosurgery to the entire lesion. Note the wide lateral spread of freeze. **C** The healed cryosurgical site 5 months after treatment. *Courtesy Emanuel G. Kuflik, MD.*

INDICATIONS FOR PALLIATIVE CRYOSURGERY
• Medical comorbidities that lead to significant surgical risk (e.g. cardiac, pulmonary, coagulopathy) • Bedridden patients • Failure of other treatment options • Patient has declined other treatment modalities, e.g. due to possibly disfiguring surgery, transportation issues for radiotherapy • The procedure improves the patient's quality of life or the caregiver's management, e.g. reducing pain, foul smell, bleeding • Mental illness that makes other procedures difficult to accomplish

Table 138.6 Indications for palliative cryosurgery.

scar contracts, it reduces the tumor diameter and residual disease can then be treated. In some patients, repeated treatment of the central tumor is performed to further reduce tumor burden.

The open (spray) technique is most commonly employed, especially in tumors with an irregular surface or in patients with a bleeding diathesis in whom curettage should be avoided. The closed (probe) technique, although ideal for skin cancer treatment, requires probes whose size appropriately matches that of the tumor, and since these tumors are usually very large, proper probes can be difficult to obtain. The semi-closed (chamber) technique, which is very destructive, is ideal for cutaneous metastases as long as the tumor fits inside the chamber. For very large tumors, the intralesional technique is an option.

EXPECTED POSTOPERATIVE EVENTS AND CARE

Compared to conventional excisional surgery, cryosurgery can be performed more rapidly but since healing is by second intention, healing time is prolonged. The latter is especially true for the lower extremities. The expected course and postoperative care are outlined in Table 138.7. Degree of edema will be determined by the depth of the freeze as well as the anatomic location, e.g. cryosurgery of eyelid lesions often leads to more edema (even with light freezing) than does a deep freeze on the arm. Patients with cold sensitivity can also develop more edema after cryosurgery.

For lesions that develop a large bulla, the fluid is often drained to decrease pressure and possibly hasten healing; the blister roof is usually left intact to serve as a biologic dressing although the recommendation of some cryosurgeons is to remove it, especially for verrucae to minimize risk of reimplantation. A gauze dressing can be placed if there is significant oozing and application of a bland topical ointment such as petrolatum enhances second intention healing. Eschars due to cryonecrosis, a later event when deep freezing is performed, should be debrided to facilitate healing.

CRYOSURGERY – POSTOPERATIVE CARE AND EXPECTED SIDE EFFECTS			
Expected side effect	**Time of appearance**	**Duration**	**Postoperative care/Treatment**
Exudation	Hours to days post procedure	Depends on depth of freezing	Wash with soap and water For deep freezing procedures, a bland ointment such as petrolatum can be applied
Pain	During the procedure and a few seconds afterwards (during thawing)	Short-lived	Usually well tolerated In sensitive patients or with deep freezing procedures, use local anesthesia
Urticarial reaction	Immediate	Minutes	None
Edema	A few minutes (sensitive areas) to 12–24 hours post procedure	Depending on the depth and site, a few days to a week Longer duration on the face	No treatment is effective
Vesicle/bulla	Minutes to 24 hours post procedure	Days	Fluid allowed to drain spontaneously or drained by the patient or surgeon
Eschar formation	After a week	Days or weeks	Can be debrided with scissors Care should be taken in vascular lesions

Table 138.7 Cryosurgery – postoperative care and expected side effects.

COMPLICATIONS

As with any surgical procedure, there is the possibility of complications. It is important to distinguish between a severe expected event and a complication, a distinction that is not always obvious. For example, treatment of a tumor in the periorbital region can lead to substantial edema such that the eyelids are swollen shut for several days, and while annoying, this would not be considered a complication. Table 138.8 outlines some of the possible complications of cryosurgery and helpful interventions.

FUTURE TRENDS (IMAGING TECHNOLOGY FOR MONITORING CRYOSURGICAL OUTCOME)

Cryosurgery is now, and will be in the future, a readily available, simple, and cost-effective surgical procedure. As the number of cutaneous

COMPLICATIONS OF CRYOSURGERY	
Complication	**Treatment**
Inadvertent freeze of patient or medical personnel from LN released from vent	Usually none (superficial injury)
LN insufflation (when spray freezing a previously curetted lesion)	None (reabsorbs spontaneously)
Bleeding after removal of eschar that was protecting an underlying vessel	Hemostasis, from simple pressure to electrocoagulation and rarely ligation of bleeding vessel
Pain (after a few days or weeks)	Topical, or occasionally oral, antibiotics if due to infection (most common cause)
Hypo- or hyperpigmentation	If secondary to superficial freezing, it usually improves spontaneously over time With deep freezing procedures, hypopigmentation can be permanent and treatment-resistant
Pseudoepitheliomatous hyperplasia	No treatment required as it resolves over time
Milia	Extraction (occasionally occurs with deep freezing procedures)
Scar retraction/notching	Permanent as due to tissue destruction from the tumor and its treatment; reconstructive surgery is an option
Alopecia	Can be permanent following deep freezing procedures in hair-bearing sites
Atrophic/depressed scar	Usually improves with time, but is sometimes permanent, especially following deep freezing procedures

Table 138.8 Complications of cryosurgery. LN, liquid nitrogen.

malignancies increases worldwide with many amenable to minimally invasive techniques, principles and proper techniques become an essential component of the scope of practice of dermatology and should be familiar to all dermatologists. Cryosurgery will clearly benefit from the newer non-invasive imaging techniques (e.g. dermoscopy, HFUS, confocal microscopy[31], optical coherence tomography[32]) that assist in diagnosis and provide information on the depth, volume, and histology of cutaneous tumors. In addition, these techniques can improve margin control while the effects of freezing can be visualized *in situ*. Non-invasive devices that measure skin temperature should also provide valuable information that can be used to standardize cryosurgical procedures.

Synonyms: ■ Radiation therapy ■ X-ray therapy ■ Radiation treatment

Key features

- Radiotherapy is an important modality in the treatment of patients with skin malignancies
- Radiotherapy may reduce morbidity (as compared to surgery), decrease the risk of recurrent disease, and even be life-saving
- Although most patients with skin cancer are adequately treated by modalities other than radiotherapy, there are factors that may favor its recommendation (e.g. comorbidities, location)
- Modern radiotherapy has an established role as a definitive, adjuvant, or palliative treatment
- Treating benign skin disease with radiotherapy must always be carefully considered in light of the risk of radiation-induced malignancy, especially in younger patients

BASICS OF RADIOTHERAPY

Indications

In dermatology, the primary role of radiotherapy is to treat basal cell carcinoma (BCC) and cutaneous squamous cell carcinoma (SCC; see Ch. 108)[1]. It is also used to treat less common, but potentially aggressive, cutaneous malignancies and, occasionally, benign diseases. The former include Merkel cell carcinoma, Kaposi sarcoma (AIDS- and non-AIDS-related), angiosarcoma, adnexal carcinoma, lymphoma, and lentigo maligna.

While the majority of skin cancers are amenable to excision or other treatment modalities (e.g. electrodesiccation and curettage) which are often more cost-effective, there are clinical settings where radiotherapy is favored. For example, *definitive* radiotherapy is often recommended when the outcome (functional and/or cosmetic) is likely to be better with radiotherapy than with surgery, especially in the situation where the clinician is constrained by the site or size of the tumor. Likewise, elderly patients with advanced lesions for whom complex surgery is best avoided are also excellent candidates for radiotherapy. The aim of *adjuvant* radiotherapy is to reduce the risk of recurrence, whereas *palliative* radiotherapy plays an important role in patients with advanced and/or incurable disease.

Mechanism of Action

X-rays are a powerful form of ionizing electromagnetic radiation and the lethal damage they produce within double-stranded DNA represents the basis for radiation therapy[2]. When X-rays (often referred to as photons) are absorbed by biological matter, an electron may be ejected from an atom with the local release of large amounts of energy resulting in DNA damage. Rapidly dividing cells, i.e. malignant cells, are more susceptible to lethal injury and mitotic death. Although normal adjacent tissues maintain mechanisms for repair following sublethal damage, there are limitations as to the dose of ionizing radiation normal tissue can tolerate, beyond which late reactions arise (see below). A therapeutic ratio is achieved when radiation is delivered in small divided doses (fractions), which allows time for repair of sublethal DNA damage in normal tissues without compromising tumor destruction.

Treatment Machines

In the modern era of radiation oncology, high-energy megavoltage (MV) photons (6–25 MV) are generated by a linear accelerator (LINAC) located within a heavily shielded concrete bunker. One of the advantages of megavoltage radiotherapy is its ability to treat deep-seated internal malignancies with relative skin sparing. However, in general, when treating cutaneous lesions, deep beam penetration and skin sparing are not desirable. Less penetrating modalities that avoid skin sparing, such as *low-energy* kilovoltage (kV) photons (50–300 kVp) supplied by a *superficial/orthovoltage* machine, superficial brachytherapy or electron beam therapy, are preferred modalities for cutaneous lesions. With these therapies, tissue penetration is measured in millimeters to centimeters and there is less normal tissue exposure. Radiotherapy modalities are summarized in Table 139.1.

Terminology

The International Unit of radiotherapy is a Gray (Gy)[3]. One Gy is equivalent to 100 cGy or 100 rads (in the older terminology). A fraction of radiotherapy refers to the dose delivered in one treatment. Treatments are typically delivered on a daily (Monday to Friday) basis. The daily outpatient treatments are only minutes in duration and treatment regimens usually consist of 10 to 30 weekday visits.

Radiotherapy Doses

Typical fractionation protocols for small SCCs and BCCs consist of 40 Gy in 10 (4 Gy) fractions or 50 Gy in 20 (2.5 Gy) fractions. Hypofractionation refers to the delivery of larger doses per fraction (4–7 Gy); typically a lower total dose is then delivered based upon the biological effective dose (BED; Table 139.2). The latter is calculated based upon a 2 Gy per fraction equivalent that is required to eradicate a tumor[4]. This calculation provides an explanation for commonly prescribed schedules: 45 Gy in 15 (3 Gy) fractions, 40 Gy in 10 (4 Gy) fractions, and 35 Gy in 5 (7 Gy) fractions.

For BCCs and SCCs, there is not a marked dose–response such that local control is similar whether a patient receives 40 Gy in 10 fractions (47 Gy BED) or 50 Gy in 20 fractions (52 Gy BED). When the tumors are larger or more infiltrative, better local control is achieved with a BED of around 60 Gy. However, late effects increase as the total dose and dose per fraction increase and it is these late effects that will impact cosmesis and late tissue damage (e.g. fibrosis, atrophy, ulceration due to necrosis).

Radiation Modalities

Low-energy photons (superficial and orthovoltage)

Superficial and orthovoltage radiotherapy are two modalities that: (1) utilize low-energy photons; (2) lack skin-sparing properties; and

RADIOTHERAPY MODALITIES AND PHYSICAL AND TECHNICAL PARAMETERS					
Modality	**Radiation type**	**Energy**	**Tumor target thickness**	**Bolus**	**Shielded room**
Superficial radiotherapy	X-ray photons	30–150 kV	< 0.5 cm	No	Yes
Orthovoltage radiotherapy	X-ray photons	100–300 kV	< 1 cm	No	Yes
Electron beam therapy	Electrons	6–15 MeV	Up to 3 cm	Yes	Yes
LINAC	X-ray photons	6–15 MV	Variable	Yes	Yes
Radioisotope brachytherapy	Ir-192, gamma photons	380 keV	< 0.5–1 cm	No	Yes
Electronic brachytherapy	X-ray photons	50–70 kV	< 3–4 mm	No	No

Table 139.1 Radiotherapy modalities and physical and technical parameters. k, kilo; Ke, kiloelectron; LINAC, linear accelerator; M, mega; Me, megaelectron; V, volts.

SUGGESTED DOSE FRACTIONATION SCHEDULES FOR BASAL CELL CARCINOMAS AND CUTANEOUS SQUAMOUS CELL CARCINOMAS		
Dose fractionation schedule	**Indication**	**Biological effective dose (BED)***
Single 8–20 Gy fraction	Elderly, infirm (palliation)	
35 Gy in 7 fractions of 5 Gy	Elderly, medical comorbidity	44 Gy
40 Gy in 10 fractions of 4 Gy	Older, otherwise well	47 Gy
45 Gy in 15 fractions of 3 Gy	Older, otherwise well	49 Gy
50 Gy in 20 fractions of 2.5 Gy	Younger and/or lesion <2–3 cm	52 Gy
60 Gy in 30 fractions of 2 Gy	Younger and/or large lesion	60 Gy
*Calculated by converting to 2 Gy/fraction using the linear quadratic equation.		

Table 139.2 Suggested dose fractionation schedules for basal cell carcinomas (BCCs) and cutaneous squamous cell carcinomas (SCCs).

(3) have source-to-surface distances (SSD) ranging from 10 to 60 cm. The qualities and "hardness" of superficial/orthovoltage photon beams are determined by the placement of filters within the radiation beam[5]. "Half value layer" (HVL) is an important concept in radiation physics and it refers to the thickness of an absorbent filter (often copper [Cu] or aluminum [Al]) that is required to reduce the beam intensity by 50%. These filters serve to remove the softer photon component and improve the penetration quality of the beam. The following are two examples of the influence of filters: a typical 100 kVp superficial photon beam with an HVL of 7 mm of Al delivers 100% of a prescribed dose to the surface, 85% at 5 mm, and 70% at 10 mm whereas a 250 kVp orthovoltage beam with an HVL of 2.5 mm of Cu delivers 95% of prescribed dose at 5 mm and 90% at 10 mm. In summary, different photon beam energies will have unique HVLs that result in varied beam qualities and dose penetration.

Superficial radiotherapy

Office-based superficial radiotherapy was once the standard modality by which dermatologists treated skin cancer[6]. Typical machines delivered photons of 30–150 kVp with a depth dose suitable for most patients with cutaneous malignancies <5 mm in depth[7]. Over time, the high cost of radiotherapy machines and increased enthusiasm and training in dermatologic surgery led to a significant decline in office-based radiotherapy. More recently, introduction of superficial radiation therapy (SRT) machines has led to renewed interest in office-based radiotherapy for BCCs and cutaneous SCCs.

Orthovoltage radiotherapy

Orthovoltage units utilize higher energy photons of 150–300 kVp, and because of greater prescribed dose depths, are utilized for lesions >5 mm in depth. Some clinicians estimate tumor thickness and then choose an appropriate beam energy and HVL that will achieve 90%–95% of the prescribed dose at the depth of the tumor. However, this latter approach requires an accurate estimate of tumor thickness.

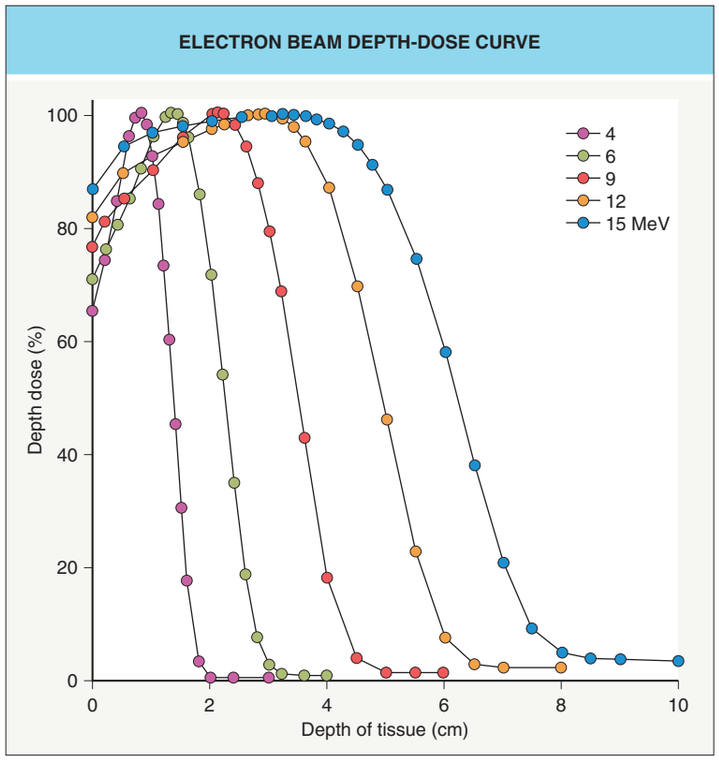

Fig. 139.1 Electron beam depth-dose curve. Electrons offer the advantage of a rapid linear decline in dose beyond a well-defined tissue depth that is a function of the selected beam energy. *Courtesy Lynn Wilson, MD.*

An important consideration when delivering orthovoltage radiotherapy is the generation of a photoelectric effect due to a higher energy range when compared to low-energy photons. A consequence of this photoelectric effect is the delivery of a higher dose of radiation to underlying bone or cartilage. The latter does not occur with electrons (see below) or low-energy photons (see above). As a result, some clinicians use this as a justification for the use of electrons when treating lesions near bone or cartilage, although supportive clinical data are limited.

Electron beam therapy

A linear accelerator can generate electrons which can be utilized in a variety of treatment settings. Unlike X-rays, electrons are particulate radiation with a negative charge. Low-energy electrons (6–8 MeV [megaelectron volts]) offer an alternative to low-energy photons when treating cutaneous tumors, but the former do have some disadvantages[8]. For example, electron beams are relatively skin-sparing (Fig. 139.1), and, as a result, a tissue equivalent bolus needs to be placed on the skin surface (Fig. 139.2). Also, utilizing electron beams for small treatment fields (<4 cm^2) may result in tumor underdosing at the deepest extent of the tumor.

Electrons offer the advantage of a rapid linear decline in dose beyond a well-defined tissue depth that is a function of the selected beam energy

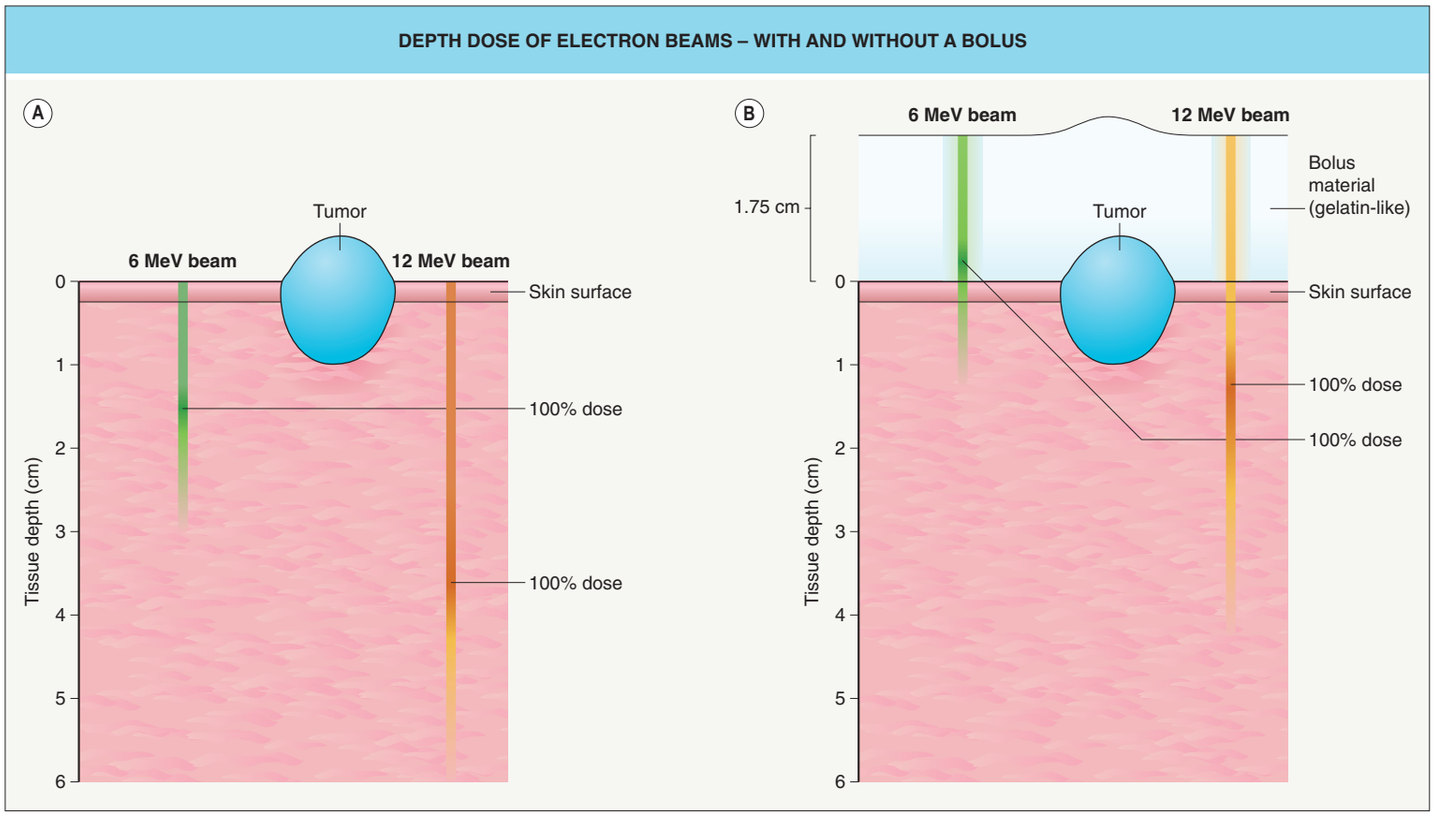

Fig. 139.2 Depth dose of electron beams – with and without a bolus. A Beams with a dose of 6 MeV and 12 MeV. **B** Demonstration of the bolus effect whereby a more appropriate dose of radiation is obtained at the skin surface. Bolus material needs to be tissue equivalent and maintain a constant thickness; its composition varies from paraffin wax to thermoplastics (e.g. Aquaplast®). *Courtesy Lynn Wilson, MD.*

(see Fig. 139.1). For example, a 6 MeV electron beam provides some of its dose (~70%–75%) at the surface, but deposits 100% of the specified dose at a depth of ~1.5 cm. Using a higher-energy beam will result in deposition of a higher percentage of the dose at the skin surface (see Fig. 139.1), but with a higher dose to subcutaneous tissues as well as the skin surface (see Fig. 139.2A). On the other hand, if a tissue equivalent bolus of 1 cm is applied in conjunction with a 6 MeV beam, close to 100% of the desired dose will be obtained at the skin surface (see Fig. 139.2B). In other words, the dose will be brought 1 cm closer to the skin surface, further minimizing the dose to underlying structures.

Tumors treated with electrons require 10–20 mm margins due to a wider penumbra (dose drop-off at the field edge). Electrons also have a lower relative biological effectiveness (RBE) in comparison to photons, leading some clinicians to recommend a 10%–15% increase in total dose to compensate. It is important to appreciate the intricacies of using electron beam therapy, in particular the limitations of dose delivery with small fields. This requires careful attention to the margin and dose distribution at the edge of the radiation field when treating small cutaneous malignancies.

Brachytherapy

Radioisotope brachytherapy

Radioisotope brachytherapy represents radiotherapy that is delivered by the direct application of a radioactive source near or inside involved tissues. Most centers utilize a high dose-rate (HDR) system that delivers more than 12 Gy/hr, with Ir-192 being the most commonly used isotope. Treatments are delivered by the placement of surface applicators onto the skin at the site of the tumor. The radioactive source is often delivered to the applicators via a remotely controlled machine in a dedicated shielded HDR suite. Applicator selection varies depending on the location and surface contours of the target area, e.g. conical surface applicators for flat surfaces, flexible mesh style "flap" applicators for molding onto curved surfaces. When treating deeper tumors, interstitial catheters may be surgically placed within the target tissue.

The dose "fall-off" is steep with brachytherapy, providing an excellent opportunity to spare adjacent normal tissue which is not easily achieved with photon- or electron-based treatments. Per American Brachytherapy Society (ABS) consensus guidelines, HDR skin brachytherapy represents a standard of care option for appropriately selected patients with keratinocyte carcinomas[9]. Because HDR delivery systems require Nuclear Regulatory Commission (NRC) oversight, special shielded vaults, and careful security and safety protocols, radioisotope brachytherapy is performed by a radiation oncologist in a controlled setting.

Electronic brachytherapy

A newer, non-isotope-generated form of brachytherapy, referred to as electronic (surface) brachytherapy, utilizes a miniature electronic X-ray source instead of a radioactive source. The currently available systems operate in the 50–70 kVp energy range, require little shielding, and are considered more portable. Electronic brachytherapy systems are not subject to NRC oversight, but may need to adhere to local regulations[10]. Similar to radioisotope brachytherapy, a steep dose fall-off allows for sparing of adjacent organs and tissues. However, there are some concerns as to tissue dose calculations as well as the potential for different radiobiological effectiveness due to the photons' low energy. Therefore, consensus guidelines for calculating tissue dosages are yet to be finalized[10,11].

As with radioisotope brachytherapy, suitable lesions need to be superficial (<3–4 mm in depth) and well-defined. While data are emerging regarding the safety and efficacy of electronic brachytherapy for the treatment of keratinocyte carcinomas, given the lack of both long-term follow-up and a consensus regarding dosimetric properties of this modality, the ABS does not advise its use outside of prospective or registry trials[10].

Advantages of Radiotherapy

Radiotherapy offers the advantage of a non-surgical approach, thereby avoiding surgical morbidity, scarring, and the need for reconstruction. In situations where reconstruction with grafts or flaps is required, improved cosmesis may result from radiotherapy[12]. Radiotherapy fields can also be tailored with generous margins in order to encompass "at-risk" areas

(e.g. possible sites of clinically inapparent tumor extensions) that, if surgically approached, would require involved and complex surgery. In addition, standard oncologic excision margins in certain sites are often difficult to achieve without causing surgical morbidity; such sites include the midface triangle, i.e. the periorbital region (especially the medial canthus), the lower eyelid, nose (especially the ala nasi and nasal tip), nasolabial fold, lip, and chin.

Disadvantages of Radiotherapy

Radiotherapy does have its disadvantages; in particular, most patients require a protracted course of treatment compared to what is often a simple outpatient excision. Patients should also be informed that because of the risk of serious late effects such as soft tissue and cartilage necrosis, a second course of definitive radiotherapy cannot be delivered to the same site. In addition, the reduced "quality" of irradiated skin may make subsequent surgery difficult if the tumor recurs or persists following radiation therapy. Over time, irradiated skin may also develop dyspigmentation, telangiectasias, and a shiny appearance. Lastly, individuals with xeroderma pigmentosum or basal cell nevus syndrome should not be irradiated owing to their marked predisposition for developing multiple and recurrent skin cancers, often at a young age.

Tumors that have deeply invaded cartilage or bone often do better with a combination of excision plus adjuvant radiotherapy, although definitive radiotherapy still remains an option. Radiotherapy of lesions located on the foot, anterior lower leg, or dorsum of the hand, although not contraindicated, should be avoided if possible; lesions in such sites are best treated with excision. Unfortunately, radiotherapy to poorly vascularized tissue is often associated with poor healing, thus irradiation of skin cancers arising in sites of chronic ulceration, trauma, or thermal burns should be avoided, if possible. In addition, patients with systemic sclerosis and other causes of cutaneous fibrosis may experience severe fibrotic reactions following radiotherapy.

Radiotherapy has a very small (~1 in 1000) risk of causing a radiation-induced in-field malignancy (often soft tissue/bone sarcoma) 10–15 or more years after exposure. However, these data were obtained from studies involving many different malignancies treated by various techniques and dosing schedules. It is likely that with modern radiotherapeutic techniques as well as the smaller volumes being irradiated when treating skin cancers, a figure of 1 in 1000 represents an overestimate of the real risk. Nonetheless, for younger patients (<50–60 years of age), this is an important issue and patients need to be informed of the potential 5-10X greater risk of a second malignancy within the treatment field when compared to individuals not receiving radiotherapy[12a].

RADIOTHERAPY OF BENIGN SKIN DISORDERS

Background

The role of radiotherapy in treating benign cutaneous disorders has markedly diminished over the past several decades. It is no longer ethical to offer radiotherapy as a treatment for acne, warts, hirsutism, or tinea capitis. The role of radiotherapy in treating inflammatory skin conditions (e.g. dermatitis, psoriasis, lichen planus) is historical due to efficacious alternative treatments (e.g. corticosteroids, phototherapy, systemic immunomodulators), and the risk of exposing patients to ionizing radiation. Superficial radiotherapy has occasionally been used to treat recalcitrant Hailey-Hailey disease.

Keloids

Recurrent keloids, often refractory to re-excision and intralesional corticosteroid injections, can have significant cosmetic, functional, and psychologic sequelae for patients. The addition of low-dose (12–20 Gy) adjuvant radiotherapy delivered in three to five fractions, beginning within 24–48 hours following surgery, can markedly and safely reduce the incidence of recurrence[13]. A recent dose-response study involving 250 keloids concluded that 20 Gy delivered in 5 fractions was the optimal postoperative regimen, when balancing relapse rate (2%) against adverse effects[14]. A common site for keloids is the earlobe and patients can be treated with low-energy photons plus lead shielding of surrounding tissues. Young patients with keloids of the lower anterior neck (in close proximity to the thyroid gland) should not be irradiated.

Cutaneous Lymphoid Hyperplasia (Cutaneous Pseudolymphoma)

Cutaneous lymphoid hyperplasia (cutaneous pseudolymphoma) often arises on the face (see Ch. 121). When lesions fail to respond to intralesional corticosteroids, low-dose fractionated radiotherapy utilizing low-energy photons (10–15 Gy in five fractions) is an efficacious treatment option with minimal, if any, side effects.

RADIOTHERAPY OF *IN SITU* CUTANEOUS MALIGNANCIES

Squamous Cell Carcinoma *In Situ* (Bowen Disease)

Radiotherapy can be used, albeit infrequently, to treat SCC *in situ*. The malignancy is limited to the epidermis and its appendages, arises more commonly in sun-exposed sites, and usually presents as a slowly growing, scaly, erythematous plaque. A biopsy is important to exclude the possibility of eczema or psoriasis. Only a small minority (<5%) become invasive SCCs, although this may be higher (10%–30%) in genital lesions such as erythroplasia of Queyrat. Patients are treated with 40–50 Gy in 10–20 fractions using superficial low-energy photons (110–150 kVp), with reported local five-year cure rates of 98%–100%[15].

Patients with widespread actinic keratoses have been treated with radiotherapy under special circumstances. Given that other very effective therapies are readily available (see Ch. 108), radiotherapy should not be considered a first-line treatment modality.

Lentigo Maligna

Lentigo maligna (melanoma *in situ* arising within photodamaged skin) often presents as a longstanding and large-sized hyperpigmented patch on the face of elderly patients (see Ch. 113). The size and location often preclude simple excision, and radiotherapy remains a well-established, evidenced-based option with excellent five-year cure rates of 90%–95%[16] (Fig. 139.3). Reported doses range from 35 to 100 Gy administered in 5–10 fractions, i.e. large doses per fraction. However, dose fractionation schedules of 40–50 Gy in 10–20 fractions would also be efficacious[17]. Field margins of 1–1.5 cm are recommended, demarcated by Wood's lamp examination or confocal microscopy (if available), and treating to a depth of at least 5 mm.

Fig. 139.3 Lentigo maligna (melanoma *in situ*). A An 82-year-old man with a lentigo maligna on his right cheek. **B** Three months after superficial radiotherapy (45 Gy in 15 daily fractions, 120 kVp, HVL 4.2 mm Al).

RADIOTHERAPY OF INVASIVE CARCINOMAS, SARCOMAS, AND LYMPHOMAS

Basal Cell Carcinoma

Definitive radiotherapy

BCCs – in particular primary tumors <2 cm in diameter – can be treated with a number of therapeutic modalities. However, there is a paucity of randomized controlled trials comparing these different modalities. In a Cochrane Review focusing on BCCs, the authors analyzed the published results of seven different treatment categories[18]. Although they suggested the need for further research, surgery and radiotherapy appeared to be the two most efficacious modalities, with surgery probably leading to the lowest recurrence rates[18]. Of note, Mohs micrographic surgery is said to result in some of the highest long-term cure rates[19].

While local control rates (90%–95%) for either excision or radiotherapy are probably similar, management decisions are often based on other factors (Table 139.3). For example, radiotherapy would be favored in an elderly patient with a BCC located on the nasal tip or nasal alae (Fig. 139.4). In the locations outlined in Table 139.3, excision followed by primary closure is often difficult to accomplish and grafts or flaps are frequently required if surgical excision is chosen (Fig. 139.5). In addition, achieving negative deep margins via excision may be difficult in these locations. Although larger lesions (>20 mm) can still be eradicated via definitive radiotherapy (see below), with increasing size and depth of invasion, local control rates decrease. Therefore, surgery combined with adjuvant radiotherapy is often recommended to try to achieve better local control.

PATIENT FACTORS AND TUMOR CHARACTERISTICS THAT FAVOR RADIOTHERAPY	
Patient factors	Older age (>70 years)
	Patient preference (avoidance of surgery)
	Receiving medications that affect coagulation and platelet function
	Significant medical comorbidities
Tumor characteristics	Site: Ala nasi, nasal tip, nasal bridge, lower eyelid, medial canthus, helix
	Size/depth: Extensive and superficial
	Stage: Locally advanced requiring complex surgery

Table 139.3 Patient factors and tumor characteristics that favor radiotherapy. Many of these indications are relative.

Superficial BCCs that involve large areas are also treated with radiotherapy (Fig. 139.6), although alternatives such as photodynamic therapy, electrodesiccation and curettage, and topical imiquimod are reasonable options. It is important to note that tumors can take many weeks to completely regress after radiotherapy and, therefore, early re-biopsy is not recommended. Dose fractionation schedules vary and are determined by patient and tumor factors (see below).

Adjuvant (postoperative) radiotherapy

A recommendation for radiotherapy is often made in the setting of incomplete excision of a BCC. A positive deep margin is always a concern, especially when a local flap has been used for reconstruction, because deep recurrences can be difficult to detect. In particular, undetected deep recurrences of tumors located within the midface and periorbital regions may be associated with significant local morbidity. It is accepted that at least 20%–30% of incompletely excised BCCs will

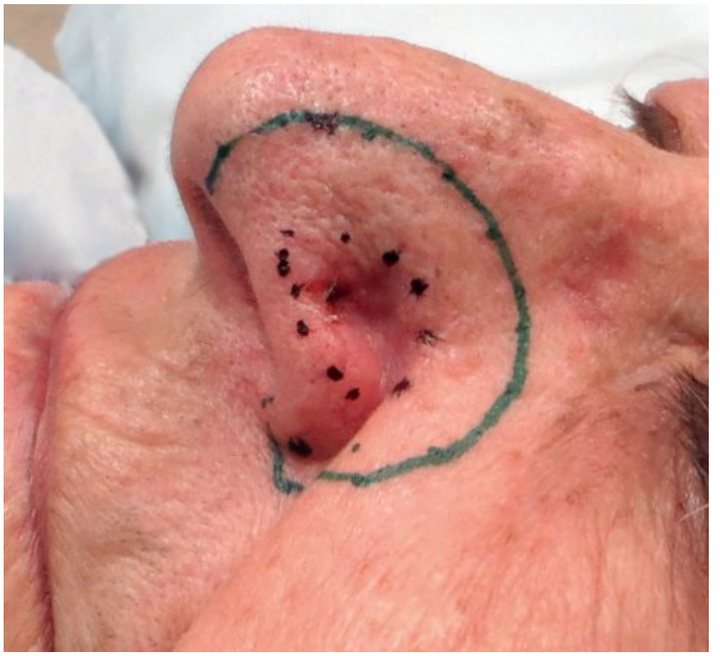

Fig. 139.4 Superficial basal cell carcinoma (BCC). A 78-year-old woman with a 1.5 cm BCC on the left ala nasi. The tumor was treated with definitive radiotherapy using superficial energy photons (45 Gy in 15 daily fractions, 100 kVp, HVL 7 mm Al). Note the 1 cm field margin to encompass subclinical extension of this poorly defined BCC.

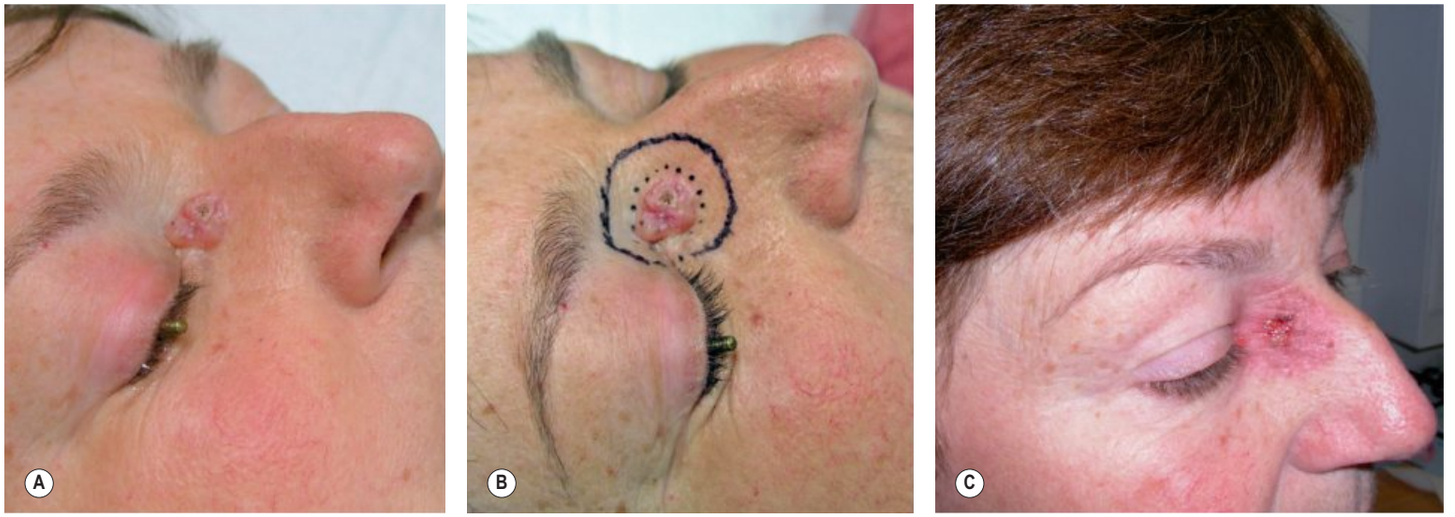

Fig. 139.5 Nodular basal cell carcinoma. A A 56-year-old woman with a 1.5 cm nodular basal cell carcinoma of the right medial canthus. The patient received 55 Gy in 25 daily fractions using orthovoltage energy photons (250 kVp, HVL 2.5 mm Cu) following pre-treatment insertion of an internal eye shield. **B** A 10 mm radiotherapy field margin has been placed around the patient's tumor so as to encompass both macroscopic disease and possible surrounding microscopic (subclinical) spread. **C** At completion of radiotherapy, the tumor has regressed markedly. Note the confluent erythema demarcating the treatment field.

Fig. 139.6 Extensive basal cell carcinoma. **A** An elderly woman with a large basal cell carcinoma occupying much of the left temple region. **B** Three months after 40 Gy in 10 daily fractions using superficial energy photons (100 kVp, HVL 7 mm Al).

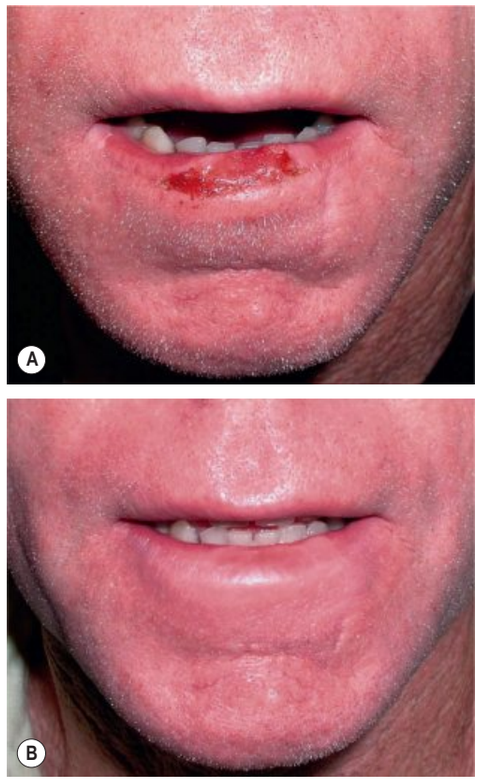

Fig. 139.7 Squamous cell carcinoma. **A** A 55-year-old man with a squamous cell carcinoma occupying most of his mid lower vermilion lip. The patient decided to undergo definitive radiotherapy and received 55 Gy in 25 daily fractions using orthovoltage energy photons (250 kVp, HVL 2.5 mm Cu) and had an oral cavity lead shield fitted to protect his teeth and mandible. **B** Four months after radiotherapy, he is disease-free and has experienced an excellent cosmetic result.

recur. In one study, 69 of 100 patients with incompletely excised BCCs had residual tumor identified histologically at the time of re-excision[20]. While re-excision is favored when there is a positive margin, sometimes the anatomic site precludes safe re-excision (e.g. the periosteum of the nose) and thus adjuvant radiotherapy is an option.

The aim of adjuvant radiotherapy is to reduce the incidence of local recurrence by eradicating residual microscopic BCC. In a Canadian trial, the addition of adjuvant radiotherapy improved the 5-year local control rate from 61% to 91%[21]. Because the majority of recurrences were successfully salvaged via surgery, the 10-year local control rates were similar (92% vs 90%).

Squamous Cell Carcinoma

Definitive radiotherapy

The approach to treating patients with cutaneous SCC is influenced by the small risk (<5%)[22] of metastatic spread to regional lymph nodes and the need to achieve local control. Of note, some patients can be considered as having high-risk SCC when certain unfavorable features are present; these include recurrent tumor, diameter >2 cm, thickness >2 mm, invasion beyond fat, high-grade (i.e. poorly differentiated) histology, perineural invasion, ear or non-hair-bearing lip as the primary site, and immunosuppressed host. These SCCs have a greater risk of developing recurrence and metastatic nodal disease[23].

In general, high-risk patients should have lesions excised with wider margins and be followed closely for at least 5 years[24]. However, depending upon the circumstances, some patients are treated with definitive (or adjuvant) radiotherapy. Definitive radiotherapy of cutaneous SCC is an excellent treatment option, especially in the clinical settings outlined in Table 139.3. For example, multiple medical comorbidities may preclude patients from having extensive surgery. In addition, for sites such as the lower lip, radiotherapy can result in excellent maintenance of function (even with more extensive tumors; Fig. 139.7), as well as cure rates comparable to surgery (see section on lip SCC)[25].

To date, there is no consensus as to which high-risk patients should be offered elective treatment (e.g. surgical, radiotherapy) of regional lymph nodes. Future sentinel lymph node biopsy (SLNB) studies may help resolve this issue. Compared to CT and MRI, SLNB is more sensitive at detecting occult nodal metastases, but its impact on overall survival needs to be determined. In a meta-analysis of studies in which patients with high-risk SCCs underwent SLNB, a positive SLN was observed in 12.3% of patients, all of whom had SCCs >2 cm in diameter[26].

The currently recommended margins for the surgical excision of SCC are 4–6 mm, with wider margins for high-risk tumors[27]. For the latter, Mohs micrographic surgery or wide local excision under general anesthesia may be utilized. In a study of cutaneous SCCs, 95% of tumors <2 cm in diameter had negative margins if excised with a 4 mm margin as did 95% of tumors >2 cm when excised with a 6 mm margin[28]. It is generally not appropriate to merely observe an incompletely excised SCC. Recurrent SCCs are associated with a lower control rate and a higher incidence of regional metastases, when compared to previously untreated SCCs[29].

Adjuvant (postoperative) radiotherapy

Adjuvant radiotherapy is an option when excision of an SCC is incomplete and re-excision is not advisable. In addition, it is considered when there are high-risk features such as perineural invasion, an immunocompromised host, and an anatomic site that has a high risk of recurrence. Special clinical situations are outlined below.

Keratoacanthomas

A keratoacanthoma (KA) typically presents as a rapidly enlarging papulonodule with a central keratin plug. Difficulty often arises in distinguishing these tumors histologically from well-differentiated SCCs, and many authorities consider most KAs to be a well-differentiated variant of SCC. Although KAs can regress spontaneously, a significant number become large and unsightly with destruction of underlying tissue. If surgery is not considered, radiotherapy consisting of 25 Gy in 5 fractions can lead to durable regression. If the diagnosis of KA versus well-differentiated SCC is uncertain, a dose fractionation schedule appropriate for an SCC should be prescribed.

Special clinical situations

SCC of the lip

In regions of the world that have a high incidence of keratinocyte carcinomas (e.g. Australia), SCC of the lip is considered a skin cancer, not an oral cancer[25]. Compared to oral SCC, there is a lower propensity for spread to regional nodes. Nearly all lesions arise on the lower lip, usually as a consequence of chronic sun exposure.

For SCCs of the lip, the outcome with surgery versus radiotherapy is similar. The laxity of the lip means that wedge excision (± vermilionectomy) is the procedure of choice, with primary closure often possible. When >30%–50% of the lip is involved, excision with appropriate margins is usually not achievable without risking function (e.g.

oral competency). Complex reconstruction is an option (see Ch. 147), but insensate tissue may be needed for reconstruction and this can have an impact on function. Therefore, radiotherapy is an excellent treatment option for SCC of the lip. The lower lip lends itself very well to treatment with orthovoltage photons following insertion of a 3 mm intraoral lead shield to protect the mandible and teeth (see Fig. 139.7). Doses are similar to those for any other equivalent-sized SCC, with a recommended total dose of 50–55 Gy in 20–25 fractions[30].

Lymph node metastases of SCC

Patients with metastatic SCC involving regional lymph nodes (usually of the head and neck) are best referred to a multidisciplinary cancer service[31]. Parotid lymph nodes represent a common site for metastases from a previously treated scalp, forehead, or ear SCC; in such cases, surgery (parotidectomy ± neck dissection) is required.

To improve locoregional control, adjuvant radiotherapy is nearly always recommended in patients with nodal metastases, as the risk of nodal relapse remains high despite surgery. Even patients with multiple unfavorable features (e.g. involvement of multiple nodes, extranodal spread, close margins) can still expect a 5-year disease-free survival of 70%–75% with the combination of surgery plus adjuvant radiotherapy[32].

Perineural invasion of SCC and BCC

Perineural invasion is an uncommon but serious consequence of SCC and, to a lesser extent, BCC[33]. Up to 2% and 5% of excised BCCs and SCCs, respectively, are noted to have incidental perineural invasion, with a minority of patients presenting clinically with neurologic signs (e.g. motor deficit) or symptoms. Formication (sensation of ants crawling) may herald the diagnosis of perineural invasion, but dysesthesias, paresthesias, numbness, and pain are all suggestive symptoms. The diagnosis is frequently delayed because perineural invasion is often not suspected.

A consensus is lacking regarding the most appropriate treatment following the diagnosis of perineural invasion and no universally accepted guidelines exist[33]. After surgical excision, consideration is given to adjuvant radiotherapy, with some centers factoring in whether there is invasion of small-caliber (<0.1 mm) versus large-caliber (≥0.1 mm) nerves[34]. If perineural invasion is limited to small-caliber nerves, some institutions favor observation.

Radiotherapy alone is often recommended for those with advanced disease extending into the cranial cavity. As expected, prognosis is poor once signs (e.g. craniopathies) or symptoms develop. When periorbital SCCs, especially those in the supraorbital area, are associated with perineural invasion, adjuvant radiotherapy should be considered[34]. In some circumstances, additional surgery may be undertaken to explore and dissect out potentially involved nerves. Alternatively, radiotherapy, often requiring multi-field megavoltage photons to treat neural pathways to the brainstem as well as first echelon lymph nodes, can be recommended[33–35]. While radiotherapy (e.g. 50–70 Gy; 2 Gy/fraction) has the advantage of avoiding surgery, there is some risk of late radiation damage to orbital and CNS structures. The utilization of very conformal, volume-based, intensity-modulated radiotherapy (IMRT) allows for safer delivery of radiation to important CNS structures[35].

Immunosuppressed hosts

Solid organ transplant recipients and individuals with chronic lymphocytic leukemia[36], especially those undergoing therapy (e.g. fludarabine, alemtuzumab), have a significantly increased risk of developing cutaneous SCCs, including aggressive and metastatic SCCs. The role of reduction of immunosuppression and chemoprophylaxis with retinoids is discussed in Chapter 108.

The basic tenets of obtaining adequate surgical margins and examining for perineural invasion are of particular importance in this group of patients. Whilst prophylactic treatment to regional lymph nodes is not recommended, adjuvant radiotherapy to incompletely excised tumors or those with significant perineural invasion should be strongly considered. Transplant patients usually tolerate radiotherapy well, with no greater degree of acute toxicity[37].

Dose fractionation schedules and fields

An appropriate dose fractionation schedule depends upon both patient and tumor factors[38]. However, decisions should not be based on age alone, as the presence or absence of relevant comorbidities must also be considered. As a generalization, smaller lesions (2–3 cm) in older patients (>70 years of age) are adequately treated by using 40–45 Gy in 10–15 daily fractions, resulting in acceptable local control and cosmesis (see Table 139.2). Elderly or infirm patients may be best served by prescribing single large fractions (see palliation below) or just three to five fractions. For larger invasive lesions (>3–4 cm) and/or younger patients, a lower fraction size (2–2.5 Gy) and total doses of 50–60 Gy are recommended so as to optimize local control and produce acceptable late effects. Some clinicians administer a higher dose for cutaneous SCCs than for equivalent-sized BCCs. However, the data to support this practice are conflicting, and, in the opinion of the authors, this is not required. Also, the dose for different subtypes or grades of BCC or SCC does not need to vary nor does the dose prescribed in the adjuvant setting.

A field margin of 5–10 mm beyond macroscopic disease or a surgical site is usually adequate (see Fig. 139.5B). For a small, well-defined BCC, a 5 mm field margin is adequate if superficial photons are used. For SCCs and infiltrative BCCs, a wider margin of 10–15 mm is required in order to encompass surrounding subclinical spread. Ideally, adjuvant treatment should start within 6–7 weeks of excision. While some clinicians are reluctant to administer radiotherapy to a grafted site, it is uncommon for a healed skin graft to be lost because of radiotherapy[39].

Merkel Cell Carcinoma

Merkel cell carcinoma is a primary cutaneous neuroendocrine (small cell) carcinoma that most often arises in the head and neck region (see Ch. 115)[40]. These tumors often lack diagnostic clinical features but usually have grown rapidly. Merkel cell carcinomas are aggressive, having a high propensity for locoregional relapse and distant spread, and patients need to be appropriately evaluated prior to instituting therapy.

Currently, wide local excision of the primary lesion with margins of at least 15–20 mm or Mohs micrographic surgery is recommended. Guidelines also advocate sentinel lymph node biopsy (SLNB) if the draining lymph nodes are not palpable (see Fig. 115.19); assessment of the regional lymph nodes is a critical component of management[41]. When adjuvant locoregional radiotherapy is administered, there is evidence that extensive local surgery may not necessarily lead to a better outcome[42]. In patients considered medically or technically inoperable, radiotherapy alone (50–60 Gy in 20–33 fractions) can result in excellent in-field control in most patients (75%–80%), with death usually from distant relapse[43].

Adjuvant locoregional radiotherapy improves recurrence rates and disease-free survival[44,45] and is recommended unless the patient has a low-risk Merkel cell carcinoma (primary ≤1 cm, no lymphovascular invasion histologically, negative margins, SLNB negative, and immunocompetent host). Treatment should include the excision site, in-transit tissue (because of the risk of in-transit metastases), and the draining lymph node basin (Fig. 139.8). Adjuvant radiotherapy of in-transit tissue does vary, from most frequently performed in the head and neck region to not performed in the distal extremities. In an attempt to reduce the risk of locoregional relapse (which can occur in 40%–50% of patients treated with surgery alone), a typical dose fractionation schedule would be 50 Gy in 20–25 daily fractions[46]. Palliative radiotherapy and immunotherapy or chemotherapy can be offered to patients with advanced or metastatic disease.

Angiosarcoma

Most angiosarcomas present as violaceous plaques on the scalp and face of older adults (see Ch. 114). These tumors often extend well beyond the clinically apparent margins[47] and locally extensive disease is usually present at the time of diagnosis. Unfortunately, excision alone is usually followed by local recurrences because of the multicentric and insidious nature of this tumor. Relapses can occur at the periphery of treated sites as well as regionally.

Angiosarcomas tend to be radio-responsive and therefore can be treated with radiotherapy. Patients with limited and operable disease may undergo excision followed by *adjuvant* radiotherapy. Alternatively, *definitive* radiotherapy is also an option, with a reasonable likelihood of obtaining in-field control[48]. In the case of scalp involvement, a

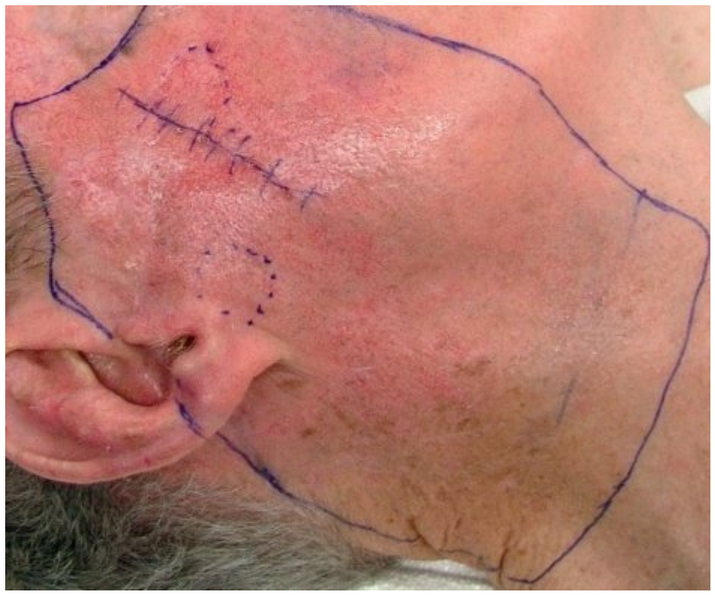

Fig. 139.8 Merkel cell carcinoma. Following local surgical excision, this 68-year-old man underwent wide-field radiotherapy (9 MeV electron beam with a tissue equivalent bolus, 55 Gy in 25 daily fractions); the field encompassed the primary excision site, in-transit tissue, and non-palpable regional draining nodes of the parotid and upper neck. The obvious pre-auricular lymph node (circled) contained biopsy-proven, low-grade parotid tumor which was treated concurrently with radiotherapy.

technique can be used that encompasses the entire scalp and combines matching photon and electron fields[47]. Other options include multiple static electron fields or electron arcs. Lastly, various combinations of medications (e.g. paclitaxel, propranolol, pazopanib, carotuximab, erbulin mesylate) have been administered in patients with recurrent disease.

Kaposi Sarcoma

Kaposi sarcoma (KS) is a type of spindle cell malignancy that arises from the vascular endothelium, usually presenting as violaceous papules and plaques (see Ch. 114). Classic KS favors the legs of elderly men of Mediterranean or Jewish origin[49], whereas AIDS-associated KS has a more widespread distribution pattern, including the oral cavity (see Ch. 78).

While the role of radiotherapy for AIDS-related KS has markedly diminished with the advent of antiretroviral therapy, it is a radioresponsive tumor and various dose fractionation schedules have been used to effectively treat cutaneous lesions. Regimens range from a single 8 Gy irradiation to 30–40 Gy in 10–20 daily fractions[50]. Because patients often develop acute painful reactions from radiotherapy to the oral cavity and the plantar surface, they should undergo radiotherapy to only one foot at a time.

Classic KS usually has a long and indolent clinical course. Patients with localized resectable tumors that are symptomatic may undergo excision. Radiotherapy is also an effective modality for palliating areas of symptomatic disease. Single small doses of 8–12 Gy are reported to result in symptom relief and tumor reduction in most patients; however, in some circumstances, higher, more-fractionated doses may be considered to sites of limited disease. Occasionally, there is a sense of chasing the disease, as lesions gradually appear at the periphery of irradiated sites. For patients with widespread disease, total skin electron beam therapy (see below) has been utilized.

Cutaneous Lymphomas

Cutaneous lymphomas are exquisitely radiosensitive. However, except for primary cutaneous B cell lymphoma (see Ch. 119) and selected patients with cutaneous T cell lymphoma (CTCL; see Ch. 120), the role of radiotherapy is essentially palliative. Patients with sites of symptomatic local disease (lymph nodes, dermal nodules and plaques, ulcers) can be palliated with doses of 12–30 Gy, often requiring orthovoltage or megavoltage energy photons. In the indolent forms of primary cutaneous B cell lymphoma, local radiotherapy with doses of 36–40 Gy may be curative[51].

Total skin electron beam therapy

Selected patients with mycosis fungoides (MF) and Sézary syndrome may be treated with total skin electron beam therapy (TSEBT). This treatment, which is complex and usually delivered by specialized centers of radiation oncology, has particular advantages. They include comprehensive coverage of the entire skin surface and an acceptable toxicity profile, in addition to the option of repeating TSEBT if other treatments fail. Historically, TSEBT consisted of 36 Gy administered over 9 weeks, but in recent trials, 12 Gy over 3 weeks provided excellent response rates (~90%)[52,53]. Although TSEBT can be offered to patients with all stages of disease, it is usually reserved for more advanced stages (IIB, III, IV) and/or disease that has failed to respond to less aggressive therapies (e.g. phototherapy, topical alkylating agents, oral retinoids).

Treatment consists of a 4–6 MeV beam (see Fig. 139.1) with patients often treated in the standing position at a distance of 7 meters from the linear accelerator. Irradiation is administered four days per week[54]. X-ray contamination is less than 2% of the dose. Each week, the entire skin surface receives two cycles of treatment and a total of 2 Gy is given to the entire skin surface during each cycle. The perineum, plantar surface, and scalp receive supplemental "boosts", as these areas are not adequately treated with the patient in the standing position. Lead contact lenses are used to shield the eyes, and depending upon the total anticipated dose, the hands and feet can also be shielded for a portion of the cycle. Patients with tumor stage disease often receive supplemental boosts via orthovoltage or electrons at the completion of TSEBT.

As there is no significant dose of radiation to the bone marrow or viscera, patients receiving TSEBT do not typically have systemic sequelae (e.g. cytopenias, nausea, vomiting, diarrhea), although patients can develop erythema, blisters, and/or skin pain[55]. Alopecia, dyspigmentation, and hypohidrosis are often seen as well and can be permanent with higher-dose regimens. A repeat course of TSEBT may be given months to years later for those who develop recurrent treatment-resistant disease. The most suitable candidates for repeat TSEBT are individuals with longer intervals between courses (>6 months) and those who had a longer disease-free interval following the first course.

Adnexal Carcinomas

Adnexal (appendageal) carcinomas, such as microcystic adnexal carcinoma and sebaceous, eccrine, or apocrine carcinoma, are rare and therefore any treatment approach needs to be individualized (Ch. 111). Many of these tumors are aggressive in nature, with a propensity to develop regional and distant metastases. While patients with operable cancers should have them excised with appropriate margins, inoperable lesions may respond to radiotherapy[56]. Adjuvant radiotherapy may also be recommended in the setting of incomplete excision. Doses similar to those employed for equivalent keratinocyte carcinomas should be administered (see Table 139.2).

PALLIATION

Locally Advanced Tumors

Occasionally, elderly, debilitated, or mentally ill patients present with advanced and neglected skin cancers, which, though not curable, can be palliated. Such tumors are often painful, bleeding, and infected, causing problems for both the patient and the caregiver. With the addition of a bolus (see Fig. 139.2), single large fractions of 8–20 Gy can be given quickly (within minutes) using megavoltage photons. Uncooperative patients may require mild sedation prior to treatment. These large single fractions are well tolerated with minimal toxicity. Alternative regimens include multiple, medium-sized fractions given once or twice a week (e.g. 8 Gy × 3). In elderly patients who are otherwise well, higher total dose fractionation schedules such as 35 Gy in 5–7 fractions or 40 Gy in 10 fractions (Fig. 139.9) may be more appropriate and can be considered more aggressive in intent. These are often given as two or three fractions per week.

Fig. 139.9 Metastatic squamous cell carcinoma involving the parotid lymph nodes. A An 85-year-old man with advanced and inoperable SCC of his right parotid lymph nodes. **B** Following a two-week course of palliative radiotherapy (40 Gy in 10 daily fractions using 12 MeV electrons plus a tissue equivalent bolus), he experienced a complete clinical response.

Metastases

Dermal-based metastases occur most frequently in patients with lung and breast cancer, and, in general, are associated with a poor prognosis (see Ch. 122). Both in-transit metastases and distant dermal metastases can develop in patients with cutaneous SCC, Merkel cell carcinoma, and melanoma. Cutaneous metastases may also present as rapidly enlarging subcutaneous masses with intact overlying skin.

Ulceration and bleeding are complications of cutaneous metastases that respond to palliative radiotherapy. Orthovoltage photons or megavoltage photons (with a bolus) administered as a single 8 Gy fraction or as 20 Gy in five fractions are effective regimens. Metastatic deposits elsewhere (e.g. skeletal) are also palliated with a similar dose fractionation schedule.

REACTIONS AND COMPLICATIONS

Acute Reactions (Acute Radiodermatitis)

Acute morbidity from skin-directed radiotherapy is usually minimal (in-field cutaneous erythema and desquamation) and limited to the irradiated area (Table 139.4). Systemic side effects such as fatigue, nausea, and vomiting do not occur.

Daily washing with water (± mild soap or soap-free cleansers) is recommended while receiving radiotherapy, including non-skin-directed. Use of prophylactic topical corticosteroids (e.g. mometasone) may reduce the severity of acute radiodermatitis and improve comfort and pruritus[57]. Given the limited time period of application, cutaneous atrophy is usually not an issue. No particular dressing has proven to be superior[58].

Most patients can expect to have local discomfort and moist desquamation by the conclusion of radiation therapy (Fig. 139.10), which then lasts for a few weeks. Hemorrhagic crusting can also develop and re-epithelialization usually occurs by week 3 or 4 following completion of radiotherapy. Delayed healing (beyond 6–8 weeks) is uncommon, as is associated soft tissue infection.

In-field radiation *recall* can occur following administration of antineoplastic drugs, including chemotherapeutic agents (e.g. anthracyclines, taxanes, antimetabolites; see Table 21.15), immunotherapies, and targeted therapies (e.g. inhibitors of EGFR, mTOR, and BRAF). Rarely, it develops following other medications or vaccines (e.g. SARS-CoV-2). Radiation *enhancement* characterized by higher grade, in-field skin toxicity and mucositis can also occur, including with the concurrent use of epidermal growth factor receptor inhibitors (EGFRi)[59]. This may be complicated by secondary staphylococcal infections.

RADIOTHERAPY REACTIONS AND COMPLICATIONS	
	Reaction or complication
Acute radiodermatitis	Grade 1: faint erythema or dry desquamation
	Grade 2: moderate to brisk erythema, moderate edema, moist desquamation confined to skin folds
	Grade 3: moist desquamation in areas other than skin folds, bleeding induced by minor trauma or abrasion
	Grade 4: life-threatening consequences, skin necrosis or ulceration of full-thickness dermis, spontaneous bleeding from involved skin, skin graft indicated
Late effects*	Hypo- or hyperpigmentation†
	Telangiectasia†
	Epidermal atrophy† and fragility
	Permanent epilation/alopecia, sweat gland atrophy
	Subdermal fibrosis and contracture (e.g. breast contracture)
	Necrosis of soft tissue, cartilage and/or bone
	Atypical vascular proliferation
	Benign tumors – eccrine poromas (also referred to as eccrine poromatosis)
	Radiation-induced malignancy‡ – SCC, BCC, angiosarcoma, osteosarcoma, pleomorphic undifferentiated sarcoma (previously referred to as malignant fibrous histiocytoma), and other soft tissue sarcomas

*Many late effects are uncommon.
†Components of poikiloderma; a TP53 haplotype containing two variant alleles was associated with almost a twofold increase in risk for telangiectasia. Variants in *TP53* may therefore modify the risk of late skin toxicity after radiotherapy.
‡Many reports have been in patients whose dose fractionation schedules and techniques are now historical in nature.

Table 139.4 Radiotherapy reactions and complications. BCC, basal cell carcinoma; SCC, squamous cell carcinoma.

Late Reactions

The late effects of radiotherapy (e.g. telangiectasia, epidermal atrophy, dyspigmentation, fibrosis; see Table 139.4 & Fig. 139.10) often appear months to years later. They are more likely to appear with continued unprotected sun exposure, when a large dose per fraction (>3–4 Gy) was delivered, if the total dose was >55 Gy, and when large fields were irradiated. Chronic non-healing, radiation-induced ulcers represent poorly vascularized tissue that requires the importation of well-vascularized tissue to enable healing. The latter usually consists of local skin flaps or sometimes staged skin–muscle or axial pedicle flaps of non-irradiated tissue; grafts do not take well on irradiated tissue due to the poor vascular bed.

In a review of over 400 patients treated with radiotherapy, 92% were considered to have a good or excellent cosmetic result[60]. However, 36% of those receiving >60 Gy in ≤2 Gy fractions had only a fair (16%) or poor (20%) cosmetic result. Smaller treatment fields (2–3 cm) tolerate hypofractionation better than do larger areas, but, even so, if cosmesis is an important consideration, larger fractions should be avoided. Patients should also be warned of the small risk (<5%) of late soft tissue and cartilage necrosis, which are related to larger tumor size and larger doses per fraction.

Younger Patients

When irradiating younger patients, better long-term cosmetic results are more likely if a low dose per fraction (2 Gy/fraction) is administered. A typical dose for a small BCC would be 50–54 Gy delivered in

Fig. 139.10 Acute and chronic cutaneous side effects of radiation therapy. A Confluent moist desquamation and marked edema in a patient near completion of radiotherapy for a squamous cell carcinoma with neurotropism (grade 2 acute radiodermatitis). **B** Confluent moist desquamation and superficial ulcerations on the breast after three weeks of radiotherapy for breast cancer (grade 3). **C** Dry desquamation of the neck several weeks following radiation therapy for a pharyngeal squamous cell carcinoma (grade 1). **D** Development of morphea and lichen sclerosus within irradiated skin; note the purpura that accompanies lichen sclerosus. **E** Permanent scarring alopecia and telangiectasias of the occipital scalp after radiotherapy for anaplastic cerebellar astrocytoma. **F** In-field telangiectasias; note the square distribution pattern. *A, F, Courtesy Jean L. Bolognia, MD; B, D, E, Courtesy Jonathan Leventhal, MD.*

DISEASES INDUCED BY RADIATION THERAPY
Disease not confined to the sites of irradiation
• Autoimmune bullous diseases (bullous pemphigoid, pemphigus foliaceus, pemphigus vulgaris, paraneoplastic pemphigus) • Eosinophilic, polymorphic, and pruritic eruption associated with radiotherapy (EPPER) syndrome • Erythema multiforme, including EMPACT syndrome* • Herpes zoster
Disease limited to sites of irradiation
• Autoimmune bullous diseases (bullous pemphigoid, pemphigus vulgaris) • Atypical vascular proliferation, angiosarcoma** • Comedonal acne, folliculitis • Digitate keratosis (also referred to as postirradiation minute digitate hyperkeratosis) • Erythema multiforme, including EMPACT syndrome* • Graft-versus-host disease • Grover disease (transient acantholytic dermatosis) • Lichen planus • Lichen sclerosus • Morphea (localized scleroderma) • Postirradiation pseudosclerodermatous panniculitis (also referred to as sclerosing postirradiation panniculitis) • Psoriasis† • Radiation recall, radiation enhancement (see Tables 21.15 & 21.16) • Urticaria pigmentosa • Vitiligo
Lesions that spare irradiation sites
• Exanthematous drug eruption
*EMPACT begins in the site(s) of radiation but then may generalize. **In or near irradiation site. †May generalize.

Table 139.5 Diseases induced by radiation therapy. Neoplasms are listed in Table 139.4. EMPACT, erythema multiforme associated with phenytoin and cranial radiation therapy.

25–27 daily fractions[61]. However, even with this dose fractionation schedule, patients can still expect some degree of in-field hypopigmentation and telangiectasia; the latter can be addressed via pulsed dye laser treatment and camouflaging cosmetics (see Ch. 153). Other options, therefore, should be considered prior to recommending radiotherapy to younger patients. The risk of a radiotherapy-induced in-field malignancy arising decades after high-dose, therapeutic, skin-directed radiotherapy is rare and poorly documented in the literature (see Table 139.4).

Cutaneous Diseases Induced by Radiation Therapy

Table 139.5 outlines the cutaneous disorders that are induced by radiotherapy, with some occurring outside the field of radiation[62] as well as others limited to the site of irradiation.

FUTURE TRENDS

Modern radiotherapy has entered a new and exciting era. Accurate conformal radiotherapy is being delivered via sophisticated three-dimensional CT-based planning and treatment systems. Intensity-modulated radiotherapy (IMRT)[63] is allowing tumor doses to escalate and normal tissue doses to decrease. The integration of MRI and functional imaging such as positron emission tomography (PET) into planning systems further enhances the accurate delivery of radiotherapy as may reflectance confocal microscopy.

Key features

- Electrosurgery encompasses a group of procedures by which tissue is removed or destroyed through the application of electrical energy
- True ***electrocautery*** uses direct current to create a red-hot tip, which can be safer for patients with pacemakers and implantable cardioverter-defibrillators
- In modern electrosurgery, high-frequency alternating current is converted to heat within the treated tissues as a result of resistance to its passage
- ***Electrodesiccation*** is superficial ablation by touching the tissue with a monoterminal device
- ***Electrofulguration*** is superficial ablation via the use of a monoterminal device whose electrode is held at a slight distance from the tissue, allowing a spark to jump to the tissue
- ***Electrocoagulation*** uses a biterminal device for deeper coagulation
- ***Electrosection*** uses a biterminal device to cut while achieving hemostasis by mild lateral heat spread
- In order to minimize adverse sequelae, lateral heat spread should be kept to a minimum by using the appropriate waveform, power setting, and electrode size

INTRODUCTION AND BACKGROUND

Definition

Modern electrosurgery encompasses a group of techniques by which high-frequency alternating electrical current is applied to living tissues in order to achieve superficial coagulation, deep coagulation, or cutting of the skin. Since living tissue is a poor conductor of electricity, the flow of electrical current is hampered and builds up at the site of application. This resistance to the flow of electricity results in its conversion to heat. The use of different varieties of electrosurgical current, each characterized by a distinctive waveform, results in unique biologic outcomes, including desiccation, coagulation, or section of treated skin.

Electrocautery

The forerunner of modern electrosurgery was electrocautery (from Greek *kauterion*, branding iron)[1]. In electrocautery, invented in 1875, a metal wire is heated by resistance to the flow of direct current electricity, as in an electric toaster. Hemostasis (even in a wet field) can be obtained with electrocautery, but the resulting third-degree burn may result in prolonged healing times and may cause inferior cosmetic outcomes.

Of note, electrocautery, with its hot element (Fig. 140.1), is different from modern electrosurgery, in which high-frequency alternating current is applied via an unheated electrode. Electrocautery units are of value for providing hemostasis for surgical patients with implantable cardioverter-defibrillators (ICDs) because external electromagnetic fields may compromise the function of these devices; with modern-era permanent pacemakers the latter is primarily a concern when electrosurgery is performed within 5 cm of the device[2]. A number of electrocautery units are currently produced; among them is the Geiger TCU Thermal Cautery Unit. Disposable battery-powered electrocautery instruments are also available, but the desired temperature can diminish during contact with tissue.

Historical Aspects

Although used by most dermatologists on a daily basis, high-frequency electrosurgery could not have been developed if several major advances in the knowledge of electricity had not occurred. In order for alternating current electricity to be utilized for medical purposes, it was necessary for high-frequency currents to be produced. A generator that could provide such current was developed in 1889 by Thompson, who noted heat in his wrists when current was passed through his hands when immersed in saline solution[3]. Experiments conducted by Jacques Arsène d'Arsonval in 1891 established that the application, in human subjects, of electric currents with frequencies greater than 10 000 cycles per second (10 KHz) failed to cause neuromuscular stimulation and the associated tetanic response[4,5]. Also in the 1890s, Oudin, following some modifications to d'Arsonval's equipment, was able to generate a spray of sparks that caused superficial tissue destruction.

At the turn of the twentieth century, Rivière conceived the notion of using very small treatment electrodes in order to concentrate the current density. This would enable one to treat a skin lesion with an electric spark[6]. Walter de Keating-Hart and Pozzi[7] in 1907 introduced the term "fulguration" (from Latin *fulgur*, lightning), referring to the superficial carbonization that resulted when the spark from the Oudin coil was used to treat skin. They claimed that this modality was ideal for treating skin cancer and that the spark could selectively destroy tumor cells by interfering with their source of nutrition.

In 1909, Doyen[8] introduced the term "electrocoagulation" (from Latin *coagulare*, to curdle) to describe a different form of electrosurgery in which tissue was touched directly with the treatment electrode and an indifferent electrode was added to the circuit. The indifferent electrode allowed for direct removal of the electricity entering the patient and caused the latter to flow back into the electrosurgical device. By removing this static energy build-up, shocks were avoided in surgeons and other bystanders. The amperage was effectively increased while the "recycling" of electrical current allowed for lower voltages to be utilized. The current produced with this biterminal arrangement penetrated more deeply than fulguration and directly coagulated tissues rather than causing only surface carbonization. Doyen claimed that this more deeply penetrating current was more likely to be effective in the destruction of tumor cells.

William Clark, in 1911, reported on the use of an electrosurgical output that caused dehydration of tissue without carbonization at the surface[9]. He substituted a multiple spark gap for the usual single one

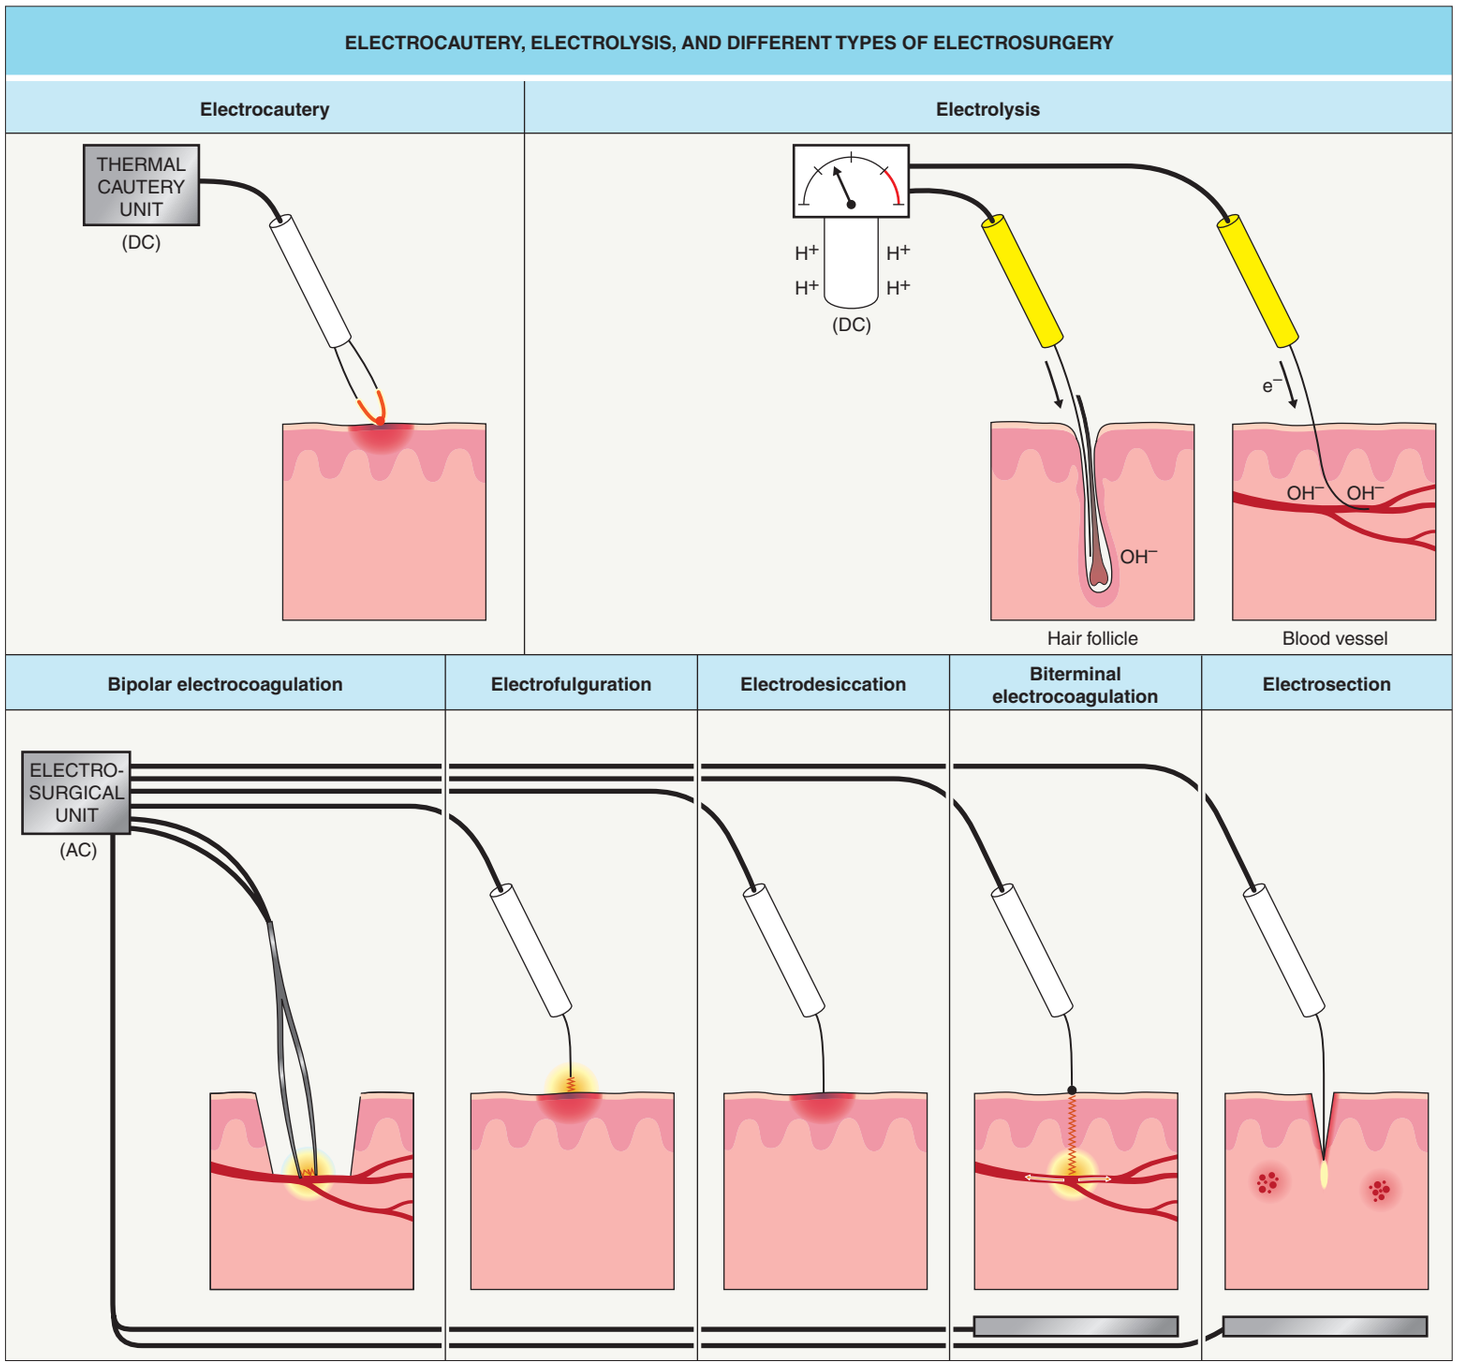

Fig. 140.1 Electrocautery, electrolysis, and different types of electrosurgery. AC, alternating current; DC, direct current; e^-, electron; H^+, proton; OH^-, hydroxide ion.

in a monoterminal Oudin current generator. This provided a smoother current that resulted in the production of fine sparks as opposed to the long, thick sparks seen with electrofulguration. Clark used the term "desiccation" (from Latin *desiccare*, to dry out) to describe this action.

The next major event in the development of electrosurgery came in 1923 when Dr George A. Wyeth, a noted tumor surgeon, used electrosurgery for cutting tissues[10]. His apparatus, which he termed an "endotherm knife" (Greek *endo*, within; *thérmē*, heat), used a thermionic vacuum tube instead of a spark gap[11]. Wyeth called the technique "electrothermic endothermy". He believed that the technique was particularly applicable to tumor surgery since it sealed off not only the smaller blood vessels but also the lymphatics that might otherwise provide for dissemination of metastatic disease.

A Harvard physicist, William Bovie, PhD, probably made the most important contribution to the development of electrosurgery. With financial assistance from the Liebel-Flarsheim Company of Cincinnati, he built an operating room electrosurgical device that offered both coagulating and cutting currents[12]. Dr Harvey Cushing, a distinguished neurosurgeon, became quite interested in these techniques and, with Bovie at the controls, began using electrosurgery for controlling bleeding and cutting through tissues during surgical procedures at Peter Bent Brigham Hospital in 1926. Dr Cushing's favorable impressions of electrosurgery assured acceptance of this technique by the surgical world. The subsequent impact of Bovie's machine upon medicine was so great that the word "bovie" is still often used generically as a noun to refer to an electrosurgical apparatus or even as a verb to describe the act of performing electrosurgery[13].

Electrosurgical Devices and Outputs

The circuitries of all electrosurgical instruments share certain design features necessary for production of suitable electrical outputs for electrosurgery. Standard household current first passes through a transformer which alters the voltage, providing the levels and characteristics

required for the instrument's various circuit functions. The current next travels through an oscillating circuit that may employ a spark gap, a thermionic vacuum tube, or solid-state transistors to increase electrical frequency. Finally, this altered electrical energy is delivered to the treatment electrode.

Each electrosurgical current produces its own unique wavy pattern of current flow, or *waveform*. The latter may be either *damped* or *undamped*, depending on the type of oscillating circuit used. In general, damped waveforms provide electrodesiccation and electrofulguration, whereas the application of moderately damped and undamped currents results in electrocoagulation and cutting currents, respectively (Fig. 140.2). The spark gap generator produces a damped wave, consisting of bursts of energy in which successive wave amplitudes gradually return to zero. This occurs due to the resistance to energy flow presented by the gap.

Use of a thermionic tube results in a more uniform output. The valve tube circuit is able to neutralize the internal resistance responsible for the damping effect seen in the spark gap circuit, and the amplitude of output therefore remains unchanged. Depending on the circuitry used, the output can be moderately damped (partially rectified) or slightly damped (fully rectified). A filtered, fully rectified output is essentially continuous and uniform, similar to an undamped wave. The different types of waveforms each result in different biologic outcomes and are, therefore, used for different electrosurgical procedures[14,15].

Terminology: Monopolar, Bipolar, Monoterminal, and Biterminal

The terms *monopolar* and *bipolar* denote the number of tissue contacting tips at the end of the surgical electrode. When the surgical electrode has only one tip projecting from its end, it is a monopolar electrode. If it has two tips, it is a bipolar electrode. Therefore, an electrosurgical forceps (that plugs into two ports on the electrosurgical device) is considered to be bipolar, as opposed to a pointed electrode, which is monopolar (and plugs into one port on the device).

Monoterminal refers to the use of a treatment electrode without an indifferent or dispersive electrode ("ground plate"). *Biterminal* denotes that both treatment and indifferent electrodes are used (see Fig. 140.1). Such is the case with electrocoagulation and electrosection, in which use of the indifferent plate, although not *technically* necessary for the machine to work, will definitely enhance the efficiency of the electrosurgical apparatus. In biterminal electrosurgical applications, there is "recycling" of the energy that comes out of the treatment electrode, passes through the patient and is then removed from the patient via the indifferent electrode. Electrodesiccation and its variant, electrofulguration, are monoterminal procedures in which the indifferent electrode serves no purpose and, in most instances, is not even connected to the patient.

A simple way to visualize this is to think of the wires coming out of the machine as terminals. If only one wire (the handpiece for the electrode) is attached to the machine, then the application is monoterminal in nature. If, in addition, a "ground plate" is used, requiring a second wire to be attached to the machine, then the procedure is biterminal (see Fig. 140.6).

When a ball electrode is used to electrocoagulate a bleeding vessel, one is using biterminal, monopolar electrosurgery. In the case of bipolar forceps in which the electrode is connected to both the active and the dispersive electrode termini, we are using a bipolar modality.

INDICATIONS/CONTRAINDICATIONS

The simplest way to think of electrosurgical applications in the clinical setting is to consider the three major capabilities of electrosurgery units. These include superficial tissue destruction (electrodesiccation), deep tissue destruction (electrocoagulation), and cutting (electrosection)[16,17]. Destruction or excision of skin lesions by electrosurgery should be accomplished with the smallest possible amount of damage to normal tissues. Whether electrosurgery, cryosurgery or ablative laser surgery is used, the greater the penetration of the destructive modality into the skin, the greater the likelihood that unacceptable scarring will result. Because the destructive effects of electrocoagulation extend more deeply than those of electrodesiccation, the clinician must consider the histologic characteristics of the lesion to be treated when selecting the appropriate current. A partial list of dermatologic conditions that are commonly treated by each electrosurgical modality is found in Table 140.1.

There are no absolute contraindications to the use of electrosurgery, but precautions should be taken during the treatment of patients with cardiac implantable electronic devices (see Variations/Unusual Situations, below).

PREOPERATIVE HISTORY AND CONSIDERATIONS

The preoperative assessment of patients undergoing electrosurgery should concentrate on potential hazards to either the patient or the treatment team. A patient history of previous allergic reactions to skin cleansers, anesthetics, or postoperative topicals and dressings should be sought. Electrosurgery should be used with care in patients with cardiac implantable electronic devices.

Smoke evacuation equipment should always be available to safely remove the smoke plume when extensive electrosurgery, particularly electrosection, is performed. In such procedures, the operator and assistants should wear masks and use eye protection to prevent exposure to smoke-borne microbes and noxious particles. Gloves should always be worn when electrosurgical procedures are performed.

Preparatory to electrosurgery, the lesion and surrounding skin should be cleansed with a non-alcoholic skin cleanser such as chlorhexidine or povidone iodine. There is a potential for alcohol to ignite with electrosurgery, so it should be avoided or allowed to thoroughly dry prior to therapy.

Local anesthesia, usually via 1% lidocaine with epinephrine (adrenaline), is almost always used when performing electrosurgery. The usual exception is in the treatment of small facial telangiectasias, in which anesthesia is omitted. Local infiltration is most often used for anesthetizing localized superficial lesions, whereas field blocks and/or nerve blocks should be considered when performing larger electrosurgical procedures such as rhinophyma repair. When a local anesthetic is used prior to treatment of a dome-shaped lesion, such as a large angioma, it is helpful to massage the swollen anesthetized treatment site prior to electrosurgery, in order to flatten it. This prevents the development of a depressed scar subsequent to the procedure.

Prior to activating the electrosurgery unit, the operator should determine that the appropriate current and power settings for the

COMMON DERMATOLOGIC INDICATIONS FOR ELECTROSURGERY
Electrofulguration/electrodesiccation (superficial skin ablation)
Acrochordon
Actinic keratosis
Angioma (small)
Dermatosis papulosa nigra
Epidermal nevus
Hemostasis (capillary bleeding)
Lentigo
Seborrheic keratosis
Verruca plana
Electrocoagulation (deep skin ablation)
Angiofibroma
Angioma (large)
Basal cell carcinoma
Bowen disease (squamous cell carcinoma *in situ*)
Hemostasis (arterial bleeding)
Hirsutism (electroepilation)
Ingrown toenail matrixectomy
Banal melanocytic nevi
Sebaceous hyperplasia
Squamous cell carcinoma
Syringoma
Telangiectasia
Trichoepithelioma
Verruca vulgaris (all locations)*
Electrosection (skin incision/excision)
Acne keloidalis nuchae
Blepharoplasty incision
Debulking procedures
Rhinophyma repair
Rhytidectomy incisions and undermining
Scar revision
Shave removal of benign skin lesions (e.g. fibromas, melanocytic nevi)
Skin flap incisions and undermining
Skin resurfacing
Surgical excision of malignant or benign skin lesions
*Some clinicians use electrodesiccation and curettage.

Table 140.1 Common dermatologic indications for electrosurgery.

particular procedure have been selected, that the dispersive electrode has been properly placed, and that the correct treatment electrode has been chosen. Disposable sleeves that slip over the handle of the wand and disposable electrode tips are often utilized. It is unacceptable to use the same electrode tip on multiple patients without sterilization, erroneously assuming that heat will destroy pathogens.

DESCRIPTION OF TECHNIQUES

Electrodesiccation and Electrofulguration

For very superficial lesions, such as those involving only the epidermis, electrosurgical destruction by *electrodesiccation* can be achieved with little, if any, scarring. The markedly damped, high-voltage current generated by spark gap electrosurgical units causes superficial tissue damage by dehydration of the treatment site. It is delivered in a monoterminal (concentrative) fashion (see Fig. 140.1). If the electrode is held at a slight distance from the tissue, a spark is formed between the electrode and the tissue. This technique, termed *electrofulguration*, achieves very superficial destruction because the surface carbonization it produces insulates the underlying tissues from thermal heat spread.

Dermatologists who employ a Hyfrecator® or similar device often utilize this type of waveform. As the surface becomes charred by sparking at the surface, it is common for blood to appear in droplets that penetrate through the surface char. This is because the electrical current does not penetrate deeply enough to seal nearby blood vessels. Therefore, when surgical excision is undertaken, electrocoagulation is a better current to employ in order to provide hemostasis (see below). However, for treatment of small very superficial epidermal lesions, electrofulguration should be considered the waveform of choice. For example, it is very effective for the treatment of dermatosis papulosa nigra.

Electrodesiccation is the method of choice when superficial tissue destruction is desired. For example, it is ideal for treatment of epidermal lesions such as seborrheic or actinic keratoses (Fig. 140.3), acrochordons, verrucae planae, or small epidermal nevi. Hemostasis of mild capillary bleeding can also be achieved by use of electrodesiccation. A standard technique for treating keratoses by this method is to move the electrode slowly across the surface of the lesion (for small lesions) or to insert it directly into the lesion (for larger lesions), while applying current at a low power setting. After a few seconds, the lesion bubbles as the epidermis separates from the underlying dermis. It can then be easily removed with a curette or simply by rubbing a piece of gauze across the treatment site. The clinical endpoint in treating epidermal lesions is punctate bleeding, which is controlled with pressure, by spot electrocoagulation, or by topical hemostatic agents such as aluminum chloride. More profuse bleeding indicates probable damage to the dermis, with a greater likelihood of subsequent scarring. Extremely small superficial lesions can be treated by electrofulguration, which causes the least amount of damage to adjacent tissues.

Electrocoagulation

In electrocoagulation, a moderately damped current is applied in a *biterminal* manner (both concentrative and dispersive electrodes are used). This current is of higher amperage and lower voltage than that utilized for electrodesiccation. Because this type of current penetrates more deeply, it has the potential for greater tissue destruction.

Electrocoagulation is particularly useful for deep tissue destruction and surgical hemostasis. It is our preferred modality for treating small and uncomplicated primary basal cell and squamous cell carcinomas, as well as other lesions such as trichoepitheliomas, which extend into the dermis. Much of the literature refers to "curettage and electrodesiccation (C&E)" or "electrodesiccation and curettage (ED&C)", but, in fact, electrocoagulation may be the preferred electrosurgical waveform for all but the most superficial tissue destruction.

When performed properly, electrosurgery plus curettage yields cure rates of 90%–95% for uncomplicated basal cell carcinomas and superficial squamous cell carcinomas, making it an efficient, cost-effective treatment. Thorough curettage is likely the key element affecting success. Initially, a large curette (4–6 mm) is used to debulk the tumor, followed by a smaller curette (2 mm). The curette should be scraped across the surface of the treatment site in every direction, from superior to inferior, inferior to superior, left to right and right to left, using fairly firm downward pressure. In this way, all tumor extensions are eradicated.

After thorough curettage, the electrode is brought into direct contact with the tissue to be treated and is moved slowly around the periphery and across the curetted portion of the lesion, which eventually becomes charred. A curette may then be used to gently remove the charred tissue. For treatment of skin cancers, this procedure is repeated two or more times in an attempt to remove any small tumor extensions (Fig. 140.4). During the last curettage, a very small curette (1 mm) may be used to remove the final tiny "roots" of the tumor. Scarring must be expected with this procedure, and wounds following curettage and electrosurgery are allowed to heal by second intention.

Electrocoagulation is also effective for treatment of superficial telangiectasias (Fig. 140.5), unwanted hair (electroepilation), and ingrown toenails (electrosurgical matrixectomy). Hemostasis using electrocoagulation can be achieved by either monopolar or bipolar means. Because the electrosurgical energy may be transmitted for several millimeters along the vessel wall, it is important to use the minimum effective exposure time and power setting in order to prevent delayed bleeding from damaged vessels. We often use monopolar electrocoagulation, in which the electrode is touched directly to the bleeding vessel. Coagulation can also be achieved by touching the electrode to a hemostat that has been clamped on the severed vessel. In bipolar electrocoagulation (Fig. 140.6), a bipolar forceps is used to provide more directed pinpoint hemostasis. Electrocoagulation current delivered in this manner causes less adjacent tissue damage but requires a dry operative field to be effective.

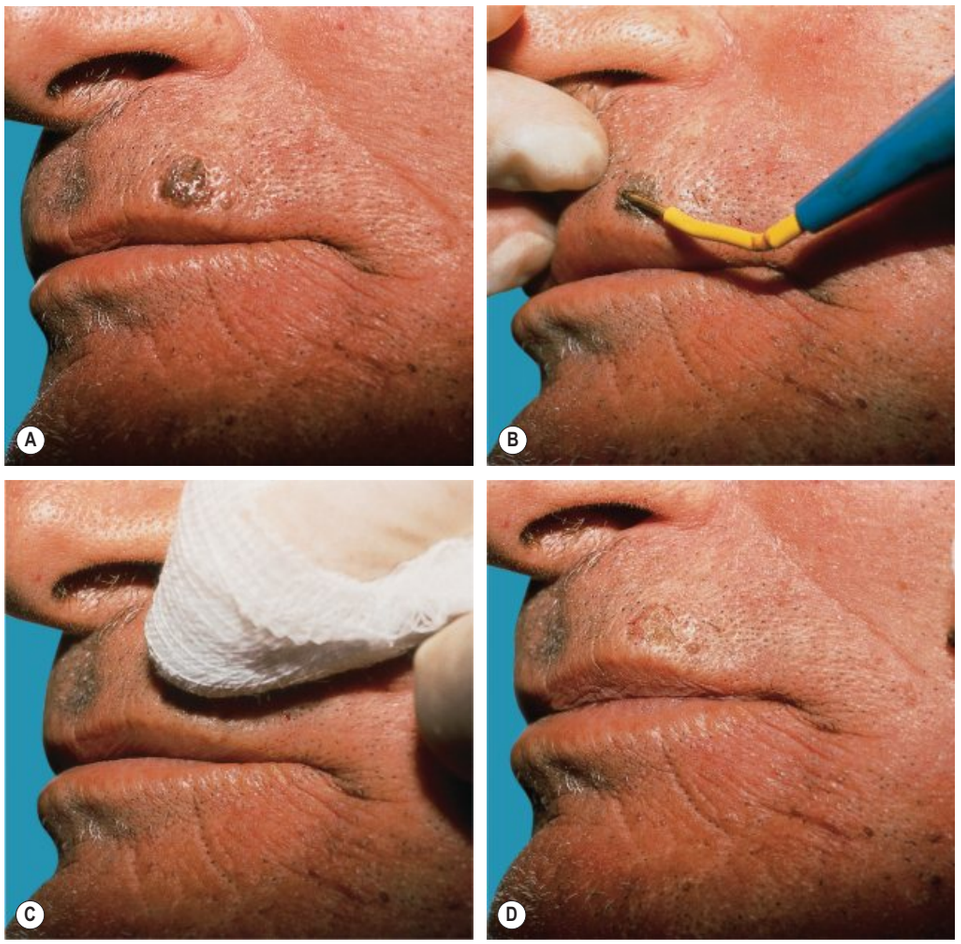

Fig. 140.3 Seborrheic keratosis on the upper lip. A Given its epidermal location, electrosurgical destruction should employ a current that provides the most superficial type of tissue damage. **B** Under local anesthesia, the lesion is treated by electrodesiccation. Delivery of current is stopped when the lesion begins to "bubble". **C** In lieu of a curette, a gauze pad is useful for removing charred tissue after desiccation of superficial lesions. **D** There is minimal bleeding, indicating that damage did not penetrate deeply into the dermis.

Fig. 140.4 Basal cell carcinoma on the right deltoid area, treated by curettage and electrosurgery. A Nodular basal cell carcinoma preoperatively after injection of local anesthesia. **B** The tumor is curetted to debulk all friable tissue. **C** Further curettage, often with a smaller-diameter curette, should proceed in all directions to remove small extensions of tumor. **D** Following thorough curettage, the surface and periphery of the wound are treated by electrocoagulation current to stop bleeding and potentially remove further tumor. **E** Final wound – curettage and electrosurgery have been repeated twice more, until all friable tissue has been removed. Healing occurs over 4–6 weeks, depending upon the site.

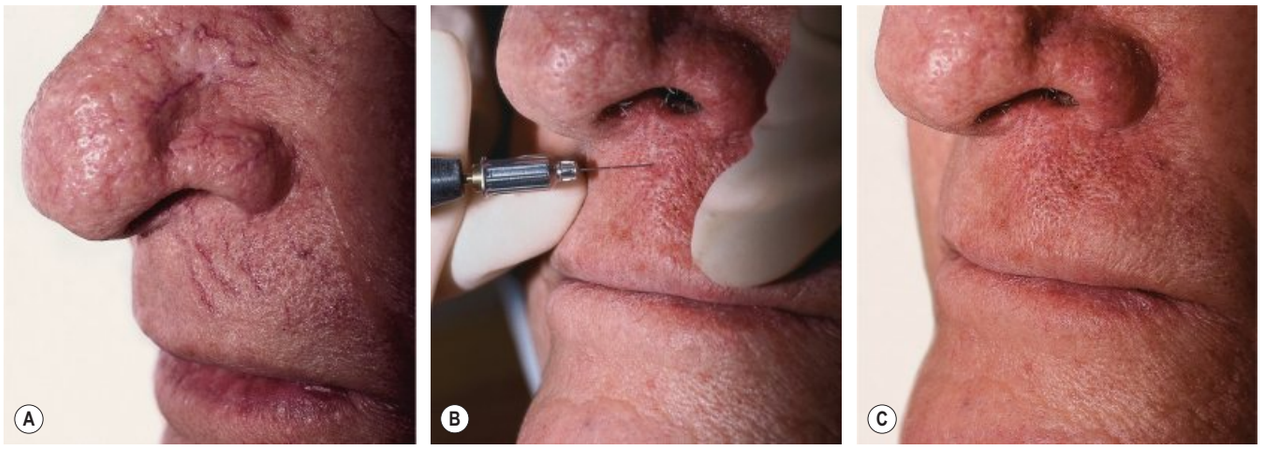

Fig. 140.5 Telangiectasias on nose and upper lip being treated by fine-needle electrocoagulation. A Preoperative photograph shows linear telangiectasias on the nose and upper lip. **B** The electrode consists of a hub adapter with a 30-gauge metal-hubbed needle attached. The machine is energized at a low power setting and the electrode momentarily touches the skin surface, along the length of the vessel being treated, at 3 to 4 mm intervals. The patient experiences some discomfort during the procedure, but this is usually tolerable. **C** The same patient immediately after treatment. This technique is usually performed quickly without anesthesia.

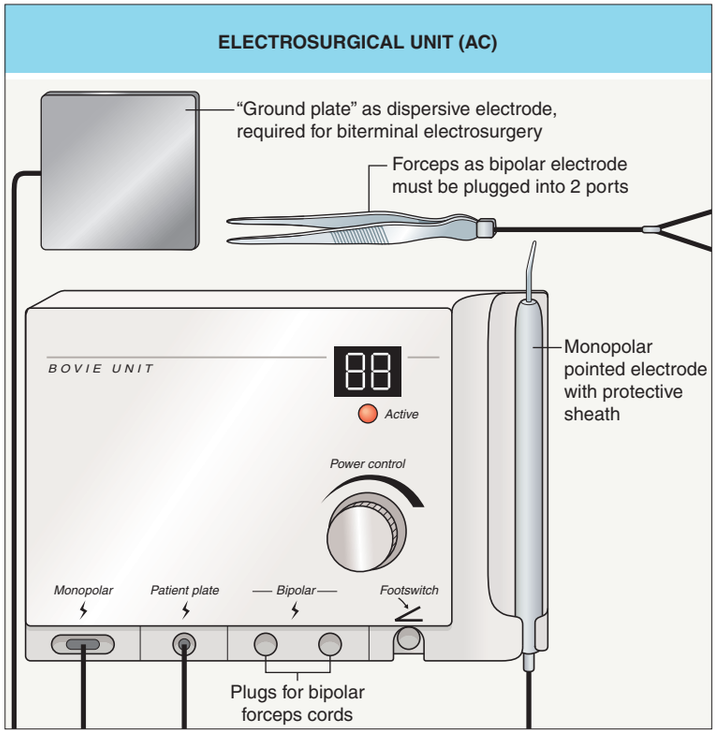

Fig. 140.6 Electrosurgical unit (AC) with attached electrosurgery pencil. The monopolar pencil is used for electrodesiccation and electrofulguration. When used with the grounding plate, it is utilized in a biterminal mode for electrocoagulation. Alternatively, the unit can be used with the bipolar forceps to provide pinpoint electrocoagulation for hemostasis. Bipolar electrocoagulation is also recommended for use in patients with cardiac implantable electronic devices. AC, alternating current.

Electrosection (Cutting)

Electrosection involves the biterminal application of a slightly damped current. The current, of low voltage and high amperage, causes minimal lateral heat spread and tissue damage, and it has the additional advantage of simultaneously achieving hemostasis and cutting. "Pure" cutting can be obtained using a true undamped tube current, which provides the least amount of lateral heat spread and causes vaporization of tissue without hemostasis. Such current has been suggested by Chiarello[18] to be useful in debulking large skin cancers, contouring surrounding skin following shave excisions, scar revision following skin flaps and grafts, and rhinophyma repair. When electrosection is performed using a filtered, fully rectified current, subsequent spot electrocoagulation can be achieved by changing to the electrocoagulation current.

Electrosection can be used to perform rapid and effortless excisions or incisions. Virtually no manual pressure by the operator is required. Electrodes configured as loops, triangles, or diamonds can be used for quick removal of skin tags, papillomas, intradermal nevi, and other exophytic skin lesions. A straight, narrow electrode is most often used to incise the skin and is applied to the tissue in brisk, continuous paintbrush-like strokes. The difference between electrosection and scalpel excision is immediately apparent to the first-time user of electrosection. At the appropriate power setting, the electrode passes smoothly through the tissue like a "hot knife through butter". If perceptible sparking occurs during incision, the power setting is too high; if the electrode "drags", the power setting is too low.

Slightly damped currents cause some charring at the margins of the excised tissue. Therefore, when a specimen suitable for histopathologic analysis is required, the filtered current (see Fig. 140.2) should be used because it does not create significant electrosurgical artifact. It is recommended that the new initiate to electrosection develops technical skills and concepts by practicing on beefsteak before utilizing this technique in the clinical arena.

The major advantage of electrosection over scalpel surgery is that when a blended cutting and coagulating current is utilized, hemostasis is achieved immediately as the incision is made. However, larger blood vessels (>2 mm) require additional spot electrocoagulation at the completion of the excision. Another drawback is that vaporization of the tissue generates a smoke plume, which can be unpleasant for both the patient and the operator and may contain potentially infectious viral particles (see below). Consequently, effective smoke evacuation equipment should be available during such procedures.

Electrosection is extremely useful for achieving relatively bloodless excision of large, bulky lesions, such as acne keloidalis nuchae and rhinophyma (Fig. 140.7), in which the surgical defect is allowed to heal by second intention. Electrosurgical excision followed by primary closure can also be undertaken with no impairment of wound healing, as compared with conventional scalpel surgery. This modality has been used, without complication, to create skin flaps and perform cosmetic facial surgery, including blepharoplasty and rhytidectomy, with excellent outcomes.

VARIATIONS/UNUSUAL SITUATIONS

Cardiac Implantable Electronic Devices

The use of electrosurgery in patients with cardiac implantable electronic devices raises the question of whether the flow of electrical energy during electrosurgery might interfere with the function of these devices[19]. Although modern permanent pacemakers and ICDs have improved shielding technology to guard them from the influence of

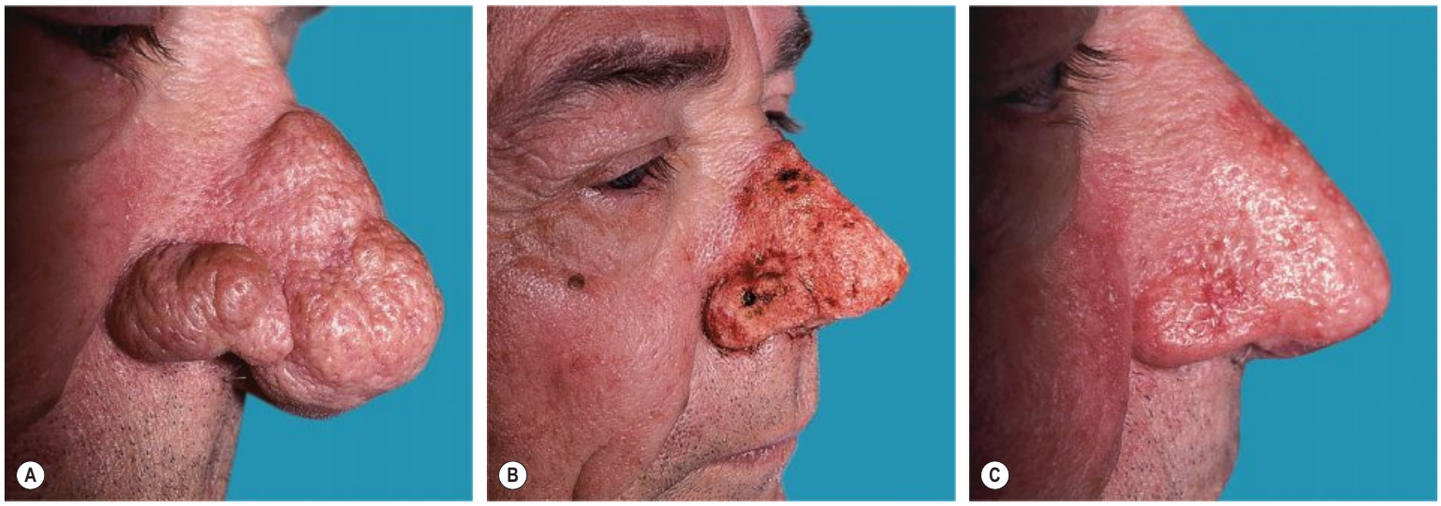

Fig. 140.7 Rhinophyma. A Moderately severe rhinophyma in a middle-aged man. **B** Immediately after electrosurgical planing of excess sebaceous glands. Care is taken to perform subtotal removal as very aggressive therapy can result in significant scarring and possible deformity caused by scar contracture. **C** Four weeks later, healing with good cosmetic outcome is noted. During healing, the wound is kept moist with an ointment (e.g. petrolatum) and semi-occlusive dressings.

external electromagnetic currents, prudence requires that a modicum of precaution be taken. If used indiscriminately in these patients, electrosurgery can occasionally trigger skipped beats, reprogramming of a pacemaker, firing of an ICD, asystole, or bradycardia.

Routine precautions recommended when using electrosurgery in patients with cardiac implantable electronic devices include: (1) utilize short bursts of energy that are less than 5 seconds in duration; (2) keep power settings as low as possible; (3) avoid the use of cutting current; and (4) avoid use on the skin around the device. Although recommended in the literature, most dermatologists do not follow specific precautions such as intraoperative monitoring, preoperative cardiology consultation, or postoperative evaluation of the cardiac device by a cardiologist. This may be due to the fact that to date there have been no reported cases of interference with a pacemaker or ICD in a dermatologic setting. Also, at least one article suggests that practical experience of complications due to electrosurgical interference is rare among dermatologic surgeons[20].

There is less risk of potential side effects when the electrosurgical current is confined to a very small area, as is the case when bipolar forceps are used as electrodes. A way to virtually eliminate such risk in very unstable cardiac patients or those with ICDs is to use true electrocautery, rather than other forms of electrosurgery[21]. Although use of this modality may cause more of a burn injury than is seen with true electrosurgery, there is no flow of current to cause electrical interference. In a survey of Mohs surgeons, 34% used electrocautery and 19% used bipolar forceps in patients with pacemakers or ICDs. Among this group, there was only one reported case of interference in one of the electrocautery patients. However, since there is no current flow in true electrocautery, this was likely an error in reporting.

It is the author's belief that the use of either electrocautery or bipolar forceps as electrodes in patients with cardiac implantable electronic devices will eliminate the need for intraoperative monitoring, preoperative cardiology consultation, or postoperative evaluation by a cardiologist in the majority of patients.

POSTOPERATIVE CARE

Standard postoperative wound management, incorporating an ointment (e.g. petrolatum) and/or semi-occlusive dressings, is followed. For superficial skin ablations, such as those following electrodesiccation or electrofulguration, twice-daily application of an ointment such as petrolatum is generally all that is required. An adhesive plaster may be used if the area is prone to rubbing. An eschar forms within a few days and separates in about 10 days. For deeper wounds, in which healing can take 2–4 weeks (or longer on the lower extremities), once- or twice-daily application of an ointment (e.g. petrolatum) followed by an adhesive plaster is recommended. For larger wounds, such as those following rhinophyma repair, Telfa™ sheets are cut to size to cover the defect and kept in place with semi-occlusive paper tape (e.g. Micropore™, 3M Corporation).

COMPLICATIONS

Patients should be warned of the possibility of delayed bleeding and should be reassured that it can, in the vast majority of cases, be controlled by 20–30 minutes of *constant* direct pressure over the wound. Trips to the local emergency room to stop postoperative bleeding are unusual but can occur. Patients should also be advised that for ablative procedures including electrocoagulation, scarring, in the form of a hypopigmented area, may occur.

Other potential hazards of electrosurgery are briefly discussed below.

Fire

There is a risk of fire or explosion if electrosurgical procedures are conducted in the presence of alcohol, oxygen, or bowel gases (methane). Care should be taken to be certain that the operative site is free of alcohol residue, i.e. confirm any alcohol-containing skin preparation has completely dried before proceeding with electrosurgery. Of note, aluminum chloride solutions used for hemostasis can contain over 90% alcohol (v/v). Oxygen is usually not a problem except in the operating room setting. Bowel gases are highly flammable! Use care in the perianal region.

Thermoelectric Burns

Although modern generators are isolated from earth, and are often equipped with sophisticated monitoring systems, current can still be diverted away from the return electrode and cause an accidental burn at the point at which it leaves the patient's body. Alternative pathways occur when the current is diverted from the return electrode and finds an alternative path to return to the generator. When the point of contact between the patient and the grounded object is small, even a relatively low-power current can generate sufficient current density to cause a burn. Grounded objects may include metal parts of the operating table, table accessories, or ECG electrodes. This problem is reduced, but not eliminated, by the use of isolated electrosurgical units, which have little or no connection to the ground.

Microorganism Transmission

The potential exists for transmission of microorganisms either via the electrode[22,23] or via smoke plume inhalation. Neither possibility has been investigated in sufficient depth to yield conclusive results. Practitioners should minimize the risk of possible electrode transmission by using

disposable or sterilized electrodes. Adapters are available that allow disposable metal hypodermic needles to be used as electrodes.

Surgical Smoke

During surgical procedures using a laser or electrosurgical unit, the thermal destruction of tissue creates a smoke by-product. Research studies have confirmed that this smoke plume can contain toxic gases and vapors such as benzene, hydrogen cyanide and formaldehyde, bioaerosols, dead and live cellular material (including blood fragments)[24], and viruses[25]. At high concentrations, the smoke causes ocular and upper respiratory tract irritation in healthcare personnel and creates visual problems for the surgeon. The smoke has unpleasant odors and has been shown to have mutagenic potential[26].

Research by the National Institute for Occupational Safety and Health (NIOSH) has shown that airborne contaminants generated by these surgical devices can be effectively controlled by appropriate ventilation using a portable smoke evacuation system. Smoke evacuators contain a suction unit (vacuum pump), filter, hose, and an inlet nozzle. The smoke evacuator should have high efficiency in airborne particle reduction and should be used in accordance with the manufacturer's recommendations to achieve maximum efficiency. A capture velocity of approximately 100–150 feet per minute at the inlet nozzle is generally recommended. It is also important to choose a filter that is effective in collecting the contaminants. A high-efficiency particulate air (HEPA) filter or equivalent is recommended for trapping particulates. Various filtering and cleaning processes also exist which remove or inactivate airborne gases and vapors. The different filters and absorbers used in smoke evacuators require monitoring and replacement on a regular basis and are considered a possible biohazard requiring proper disposal.

The smoke evacuator hose inlet nozzle must be kept within 2 inches of the surgical site to effectively capture airborne contaminants generated by these surgical devices. The smoke evacuator should be activated at all times when airborne particles are produced during an electrosurgical procedure that generates a significant smoke plume. After each procedure, all tubing distal to the filter must be considered infectious waste and be disposed of appropriately. The filters themselves may be used for the cumulative time specified by the manufacturer before replacement.

ELECTROEPILATION

Electroepilation is the use of electricity for the permanent removal of hair[27]. It predated the development of laser hair removal and is still used, in a variety of forms, by aestheticians and electrologists. The word *electrolysis*, which is used by most people as a generic term to mean the electrical destruction of hair, is technically the use of direct (galvanic) current for hair removal. Hair destruction with an alternating current occurs as a result of the accumulation of heat in the vicinity of the hair bulb and is designated *thermolysis*.

Electrolysis vs Thermolysis

Electrolysis uses direct current to create a destructive chemical reaction at the hair root. The negative electrode (anode) is inserted into the hair follicle (see Fig. 140.1). The positive electrode (cathode) is a moistened pad held in the patient's hand. When direct current is applied, a chemical reaction at the tip of the anode causes the production of sodium hydroxide. The latter acts as a caustic and destroys the hair root. This process may take from 30 to 60 seconds to occur, so pure "galvanic electrolysis" is a tedious procedure to perform. Of note, electrolysis can also be used to treat small telangiectasias (see Fig. 140.1).

Thermolysis relies on heat to cause hair destruction. A high-frequency (13.56 MHz) alternating current is used. As the current passes through tissue, it encounters resistance, causing the current to stall and convert to heat. Current can be applied by the "slow" (manual) technique or the "flash" technique. Lower heat is used over 3–10 seconds in the slow technique. Gentle traction of the hair allows the operator to determine when destruction is complete. The flash technique uses higher heat, delivered by a preset mechanical timer (<1 second). Several such pulses may be required to cause hair root destruction. Theoretically, the flash technique is less painful.

The technique for needle insertion is the same as for electrolysis. A patient hand-held electrode is not required since the patient is not included in the electrical circuit. The speed of thermolysis allows for treatment of much larger areas over a shorter time period. For this reason, it has replaced galvanic electrolysis as the preferred manner of electroepilation. The *blend* is a form of electroepilation that takes advantage of attributes of both electrolysis and thermolysis, by blending the two types of current in one machine. The blend is slower than thermolysis, but may offer some advantages in rate of hair root destruction, particularly for coarser hairs.

Side Effects

Thermolysis and the blend are more painful than classic galvanic electrolysis and the risk of scarring and hair regrowth may be higher. However, highly motivated patients generally tolerate the pain and are treated with 30- to 60-minute sessions once or twice weekly. The use of topical anesthetics under occlusion for 1–2 hours pretreatment decreases the pain in some patients. Scarring is a real risk and is operator-dependent. Generally, when this occurs, it presents as punctate or ice pick-like depressed scars. In some patients, small hypertrophic papules may appear.

Hair regrowth has been reported in the range of 15% to 50%, and this is also technique-dependent. Regrowth may be related, in part, to the hair cycle. Hairs treated while in telogen phase may not experience root destruction. Some electrologists recommend shaving 2 days prior to treatment so that only actively growing hairs will be apparent.

Varying degrees of erythema and edema may be present shortly after the procedure. Postinflammatory hypo- and hyperpigmentation have been reported. The theoretical risk of infections, both local and systemic, exists, but proper skin cleansing helps prevent this problem. Some patients have a higher propensity for developing post-treatment folliculitis and it is recommended that they cleanse with an antibacterial cleanser (e.g. chlorhexidine), before and after treatment. Disposable needles are the norm in the practice of permanent hair removal.

IONTOPHORESIS

In some patients, tap or deionized water iontophoresis can be used successfully to treat localized hyperhidrosis of the palms, soles, or axillae. In this technique, direct electrical current is passed through the treatment site while the patient is in contact with an aqueous ionic solution. The electric current introduces ions from the solution into the patient's skin and appears to inhibit sweating by occluding the eccrine ducts at the level of the stratum corneum[28].

A battery-powered unit for home use (Drionic®) is available. It is more effective for treatment of palmoplantar hyperhidrosis than for axillary hyperhidrosis. Cessation of sweating usually requires treatment of each palm or sole with 20 mA of current for 30 minutes daily. The recent use of botulinum toxin type A injections for hyperhidrosis has provided many hyperhidrosis sufferers with a more efficient and longer-lasting treatment modality, albeit at greater expense.

FUTURE TRENDS

Interest and innovation in electrosurgery have actually increased over the past three decades, since continuous wave CO_2 laser systems were introduced. Practitioners came to realize that superficial ablation, deep ablation, and tissue incision with immediate hemostasis were available through electrosurgery without the need for expensive laser systems. As examples, specially adapted electrosurgery equipment that utilizes electricity to remove the epidermis and upper dermis for facial skin resurfacing has been introduced[29] as has the use of electrosurgical cutting current (Ellman® Surgitron®) to resurface surgical scars. The latest electrosurgical development is use of a standard radiosurgery device (Surgitron® Dual RF™) for non-ablative tightening of skin laxity[30]. Radiofrequency current produces heat because of resistance in the dermis and subcutaneous tissue. When heated, collagen fibrils will denature and contract, presumably leading to the observed tissue tightening.

Key features

- Wound healing is a complex and dynamic biologic process, with consecutive cascades consisting of early-stage coagulation and inflammation, intermediate tissue formation and proliferation, and late-stage resolution and tissue remodeling
- Effective wound healing requires spatial and temporal synchronization of cell–cell and cell–matrix interactions as well as an interplay of nutrients, metabolites, and cytokines
- Extracellular matrix proteins are multifunctional molecules that bind directly to cell surface receptors (e.g. integrins); in addition to tissue stability and dynamics, matrix proteins influence cellular growth factor signaling (e.g. VEGF, TGF-β)
- In children and adults, cutaneous wound healing represents a *reparative* process that can lead to fibrosis (scar), whereas injured fetal tissue can heal without fibrosis, in a process resembling *regeneration*
- Several medical disorders (e.g. venous hypertension, atherosclerosis, diabetes mellitus, autoimmune inflammatory diseases) as well as local (e.g. pressure, infection) and systemic (e.g. aging) factors are associated with chronic non-healing wounds

INTRODUCTION

Restoration of skin integrity and homeostasis following injury is a fundamental process that ensures survival. The primary goal of the wound healing response is to promptly re-establish a functional skin barrier. Ideally, the wound healing response would lead to complete regeneration of skin tissue and its adnexal structures, with complete restoration of original skin function and morphology. Unfortunately, precise replication of the latter is often not the final result of wound repair and the quality of newly formed skin tissue varies considerably. Beyond age, a multitude of local and systemic factors impact the outcome of the wound healing response (Table 141.1).

Regeneration Versus Repair

In children and adults, the cutaneous wound healing response characteristically replaces damaged tissue with fibrosis, leading to scar formation. In addition, adnexal structures (e.g. hair follicles, sweat and sebaceous glands), as well as the components and architecture of the dermal extracellular matrix, may fail to regenerate. This can result in a loss of normal skin function and impaired morphology. Because this type of wound healing is not ideal, it is referred to as a *reparative process*. In contrast, during embryogenesis injured fetal skin can heal completely without fibrosis, a process that resembles *regeneration*[1].

The underlying mechanisms that determine whether tissue regeneration versus tissue repair will occur remain a mystery. It is not clear whether the loss of regenerative capacity after birth is due to systemic factors or an intrinsic incapability of cells to form competent stem cells. New insights will hopefully come from experimental studies in model organisms (e.g. amphibians, fish) that retain throughout their adult life the capability to regenerate tissues after injury as well as from studies of wound repair in fetal skin[2]. In the future, these insights may lead to methods for transforming repair into regeneration and may provide novel therapies that allow wound healing with minimal scarring.

Effect of Immune Response on Wound Healing

The immune system, including both innate and adaptive immune responses, plays a critical role in wound healing. By influencing multiple repair mechanisms (e.g. angiogenesis, fibroplasia, connective tissue deposition, epithelialization), inflammation has an impact on all stages of the repair response and ultimately on the extent of scarring (Fig. 141.1). In several models, there appears to be an inverse correlation between the appropriateness of the inflammatory immune response and the ability to undergo regeneration, with inappropriate immune reactions leading to tissue damage and impairment of tissue repair. However, this paradigm has recently been challenged by studies in which inflammatory signals were found to be crucial for promoting timely repair and inducing fundamental processes involved in regeneration[3]. Interestingly, these findings emerged from well-established models within the field of tissue regeneration (e.g. heart regeneration in mice) and not immunology[4,5].

MECHANISMS OF TISSUE REPAIR AND REGENERATION ARE EVOLUTIONARILY CONSERVED

Amphibians

Among vertebrates, amphibians and fish are exceptional in their capacity to regenerate anatomically complete and fully functional tissues and organs during adulthood. In particular, urodele amphibians (newts and salamanders) can regenerate a range of organs and tissues[2,6]. Cellular and molecular studies have focused primarily on limb regeneration after amputation and in adult salamanders, the immediate influx of macrophages after tissue damage (preceding blastema formation) was found to be an essential component of regeneration[7]. In axolotl, dedifferentiation of connective tissue cells (e.g. fibroblasts) enables successful regeneration, while in frogs intrinsic restrictions that impede dedifferentiation of connective tissue cells prevent regeneration[8].

Zebrafish

Zebrafish also represent a valuable model for the study of regeneration. Adult zebrafish maintain regenerative capacity, not only after caudal fin amputation but also following skin injury[9]. Interestingly, infiltration of myeloid inflammatory cells occurs during both fin and skin regeneration, suggesting that in principle regeneration can occur in the presence of inflammatory signals. Thus, by examining skin wound healing in zebrafish it may be possible to distinguish between beneficial and harmful inflammatory mediators and how they influence scar formation.

Mammals

The effects of inflammation on regeneration and repair have also been studied in mammals, primarily in mice, but also in humans. In addition

LOCAL AND SYSTEMIC FACTORS THAT CONTRIBUTE TO THE QUALITY OF THE WOUND HEALING RESPONSE
Characteristics of the damaged tissue/organ
• Tissue architecture • Resident and recruited cell types • Transcriptional networks • Regenerative capacity
Characteristics of the type of tissue damage
• Mechanical, ultraviolet, chemical, microbial • Extent and severity of the injury
Wound microenvironment
• Perturbed tissue architecture • Altered cell–cell and cell–matrix interactions • Tissue oxygenation • Microbial contamination
Systemic factors
• Genetic background • Age • Obesity, diabetes mellitus, peripheral arterial disease • Autoimmune connective tissue diseases (e.g. systemic sclerosis, rheumatoid arthritis) • Medications (e.g. corticosteroids, angiogenesis inhibitors such as bevacizumab) • Diet, nutritional status • Smoking

Table 141.1 Local and systemic factors that contribute to the quality of the wound healing response.

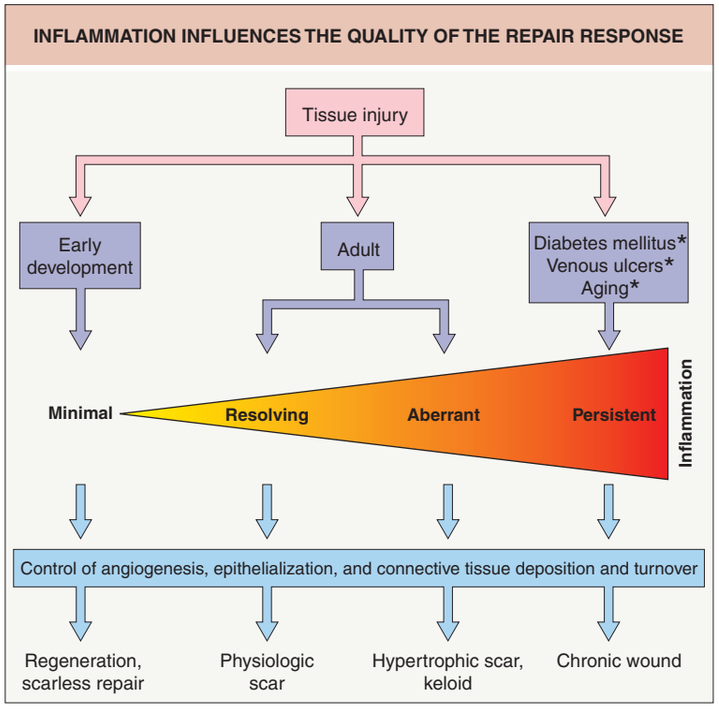

Fig. 141.1 Inflammation influences the quality of the repair response. Modulation of the local immune response at the site of injury can influence repair mechanisms and the quality of tissue restoration. *The underlying etiology of chronic, non-healing ulcers is multifactorial and it includes hypoxia due to vascular disease or sustained pressure and infection, as well as persistent inflammation (see Ch. 105).

to transgenic mouse models, refined mouse models that allow inducible and time-restricted depletion of specific immune cells have unraveled critical functions of individual immune cell lineages in skin repair. For example, in addition to the central role macrophages play in clearing cell detritus and microorganisms, they exert distinct functions during the different phases of repair[10]. In particular, macrophages recruited immediately after injury are essential for inducing vascular sprouts and angiogenesis[11]. Once the wound begins to contract, focal adhesion kinase/extracellular signal-regulated kinase (FAK-ERK) is activated within fibroblasts, leading to the release of chemokine ligand 2 (CCL2), one of the major chemokines known to drive monocyte/macrophage recruitment[12]. Thus, a close interaction between macrophages and fibroblasts is envisioned.

In the presence of a functional immune system, higher vertebrates, including rodents and humans, can undergo post-amputation fingertip regeneration[13,14]. Previously it was thought that the blastema, an undifferentiated pluripotent cell population that is thought to arise from mature cells via dedifferentiation, was responsible for mouse distal digit regeneration. However, genetic fate mapping and clonal analysis of individual cells revealed that rather than pluripotent blastema cells a wide range of lineage-restricted tissue stem/progenitor cells contribute to the restoration of the mouse distal digit[14]. In humans, conservatively managed amputation injuries in children (but not adults) can be followed by restoration of the contour, fingerprints, and normal sensation and function of the digit with minimal scarring[15]. While the molecular mechanisms underlying this phenomenon are not yet understood, investigation of conserved mechanisms in more easily trackable non-human models will hopefully allow extrapolation to humans.

Clinical Implications

The underlying etiology of chronic, non-healing ulcers is multifactorial (see Ch. 105). It includes hypoxia due to vascular disease or sustained pressure, infection, and persistent inflammation[16]. How inflammation impairs healing is still not well understood, but increased protease activity (e.g. metalloproteinases [MMPs], serine proteinases) and generation of reactive oxygen species are thought to play a major role. Unraveling the underlying molecular pathophysiology of chronic wounds in humans will clearly involve studies of both regeneration and repair.

IMPACT OF WOUND DEPTH ON WOUND HEALING

In clinical practice, skin wounds are often categorized according to their depth (Fig. 141.2). Defects that affect only the epidermis (or a portion of the epidermis) are referred to as *erosions*. When the wound extends into the dermis, it is termed an *ulceration*. In *"partial-thickness"* wounds, the epidermis and papillary dermis are missing, with the ulcer extending into the mid dermis, but the adnexal structures remain. *Full-thickness* wounds, on the other hand, involve the entire dermis and extend into the subcutaneous fat. As a result, adnexal structures are lost as a source of keratinocytes for re-epithelialization.

The depth of a skin injury affects the capacity of the skin to repair or regenerate (see Fig. 141.2). When erosions heal, there is regeneration of the entire epidermis without scarring. Ulcerations, however, heal via a reparative process and are associated with scar formation. In partial-thickness wounds, the preserved adnexal structures serve as a source of epithelial cells to repopulate the epidermis. Epithelia from these structures, as well as from the wound edge, migrate across the wound surface to provide coverage. In contrast, re-epithelialization can only occur from the wound edges in full-thickness wounds because adnexal structures are lost.

Healing of full-thickness wounds includes, to some extent, contraction whereas in partial-thickness wounds contraction is minimal. Contraction may be mediated by mechanical or biologic factors, e.g. the differentiation of fibroblasts into myofibroblasts. More recent studies in mice suggest that the contributions of different stem cell sources for wound fibroblasts may determine the outcome of the repair response. These include a superficial cell population that is critical for hair development and a deeper cell population that forms the lower dermis and may provide a source of locally derived wound fibroblasts that can develop into myofibroblasts[17]. Human dermal fibroblasts in the papillary versus reticular dermis differ in their sphingolipid content and as a result, FGF receptor signaling promotes a proliferative lipotype versus a fibrogenic lipotype, respectively[18].

During contraction, the wound area decreases via centripetal movement of *pre-existing* tissue, not the formation of new tissue. Unfortunately, contraction of wounds may result in cosmetically disfiguring contractures. However, the contraction of wounds occurs in

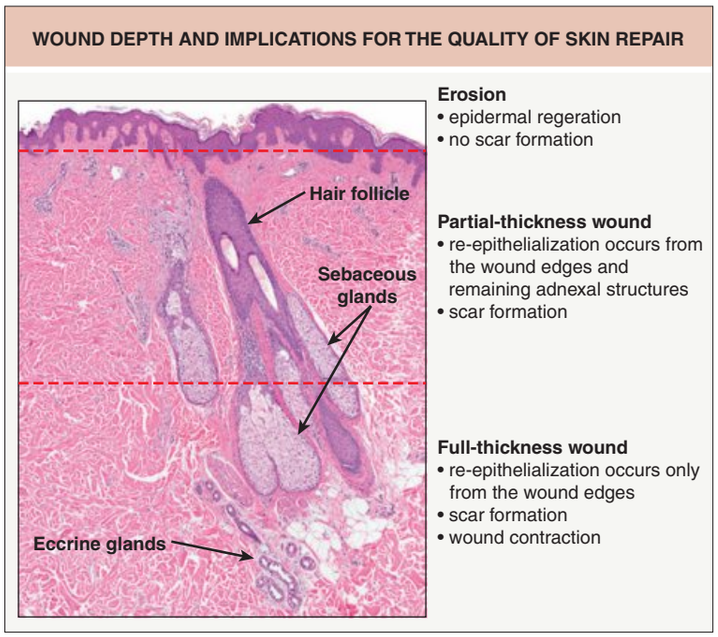

Fig. 141.2 Wound depth and implications for the quality of skin repair. The depth of skin injury determines the ability of the skin to repair versus regenerate. The red dashed lines indicate the levels of injury: injury limited to the epidermis has the capability for regeneration, while injuries to the dermis heal with scar formation. If adnexal structures are present, they contribute to re-epithelialization and faster wound closure. If these structures are lost, epithelia can only migrate from the wound edges and complete restoration of the epidermis will require a longer time period.

predictable directions (in relation to "skin tension lines"), and in order to direct the contracture, surgical incisions should be placed parallel to these skin tension lines whenever possible. Also, an argument in favor of using full-thickness skin grafts is to prevent wound contraction and subsequent contracture (see Ch. 148).

Primary Versus Second Intention Healing

When an acute wound (e.g. a surgical excision) is allowed to heal on its own, this is termed *second intention healing* (see Ch. 146). In *primary intention healing*, wound closure is accomplished by approximating the wound edges, e.g. side-to-side closures, flaps, grafts. *Tertiary intention healing* refers to wounds that are closed with the goal of primary intention healing, but dehiscence occurs, and the wound is then allowed to heal by second intention. In second intention healing, the time interval until complete re-epithelialization depends on several factors including wound depth, anatomic location (e.g. facial wounds heal faster than acral wounds), secondary infection, vascular supply, geometric shape (a more narrow diameter will heal faster), age, and systemic disorders (e.g. diabetes mellitus).

For smaller wounds, especially those that are partial-thickness, primary and second intention healing can produce similar cosmetic results. Once wounds have a diameter >8 mm, primary intention healing leads to better cosmetic results. The decision to choose primary versus second intention wound healing depends on several factors including the patient's overall medical status and cosmetic concerns as well as the depth, size, and location of the defect, in particular whether it is located on a convex or concave surface. In addition to comorbidities such as atherosclerosis, venous hypertension and diabetes mellitus, the risk of infection (which may be increased in open wounds) and the patient's preference also influence the decision.

SKIN REPAIR – CELLULAR AND MOLECULAR ASPECTS

In most mammalian organ systems, the repair response involves a complex and dynamic interplay of numerous cell types, including cells that reside within the tissue (e.g. keratinocytes, endothelial cells, fibroblasts) and hematopoietic cells, either tissue-resident or recruited to the site of tissue damage. For simplicity, three sequential phases of wound healing have been delineated: Inflammation, Proliferation, and Remodeling (Fig. 141.3)[19].

The Phases of Wound Healing

Tissue injury causes leakage of blood constituents into the wound site and the release of vasoactive factors, resulting in the activation of the clotting cascade and resultant hemostasis. Clotted blood forms a matrix that allows for cell adhesion and migration. Not only do platelets trapped within the clot play an important role in hemostasis, they also provide a rich source of growth factors (e.g. PDGF) and proinflammatory cytokines that mediate the recruitment of inflammatory cells and fibroblasts into the wound.

The *inflammatory phase* of repair is characterized by chemoattraction and local activation of innate immune functions, both of which lead to an early influx of polymorphonuclear leukocytes (PMNs; neutrophils). This is followed by invasion of blood monocytes, which differentiate into tissue macrophages[10,11]. While one function of the inflammatory infiltrate is to combat invading microbes, another equally important function is the release of cytokines and growth factors (e.g. IL-1, IL-6, vascular endothelial growth factor [VEGF], tumor necrosis factor [TNF], TGF-β; Table 141.2), which are critical for initiating the proliferative phase of skin repair.

During the *proliferative phase*, granulation tissue is newly formed and consists primarily of invading macrophages, fibroblasts, and endothelial cells (as vessel precursors). This granulation tissue serves to cover and fill the wound area. Fibrin, fibronectin, vitronectin, type III collagen, and tenascin are important components of the provisional extracellular wound matrix that facilitate cell adhesion, migration, and proliferation. At the wound edge, epidermal–mesenchymal interactions stimulate keratinocyte proliferation and migration, leading to re-epithelialization[20].

Once epithelialization is complete, cell proliferation and neovascularization cease, scar tissue forms, and the wound enters the *remodeling* (*maturation*) *phase*, which lasts for several months. The remodeling phase is characterized by a balance between the synthesis of new components of the scar matrix and their degradation by proteases. This balance determines whether the scar will eventually be normal or abnormal (e.g. atrophic scars, hypertrophic scars, keloids). The mechanisms underlying granulation tissue regression and its transformation into scar tissue are largely unknown. Typically, there is also regression of vascular structures, transformation of fibroblasts into myofibroblasts, substitution of the provisional extracellular matrix (ECM) with a permanent collagenous matrix, and a final resolution of the inflammatory response.

However, if the inflammatory response persists, a disturbed healing response may lead to chronic skin ulcers (see Fig. 141.3). Although the mechanisms that direct resolution of the inflammatory response are not well understood, recent studies in patients and in experimental models have found that transitioning from early proinflammatory macrophages to resolving late-stage macrophages is a pivotal component of wound healing[11,21,22]. In addition, resolution involves increased production of anti-inflammatory mediators, active suppression of proinflammatory factors, normalization of microvascular permeability, clearance of inflammatory cells, and epithelialization.

Cellular Components

Keratinocytes

Within hours after injury, keratinocytes at the wound edge are activated and undergo fundamental phenotypic and functional changes that are required to re-epithelialize the wound bed (Fig. 141.4). To initiate migration, keratinocytes need to modify their junctions and adhesion molecules: hemidesmosomes become detached and collagen-binding receptors are replaced by integrins that allow keratinocytes to adhere to the newly formed provisional wound matrix. In addition, keratinocytes begin to proliferate as they reduce their production of proteins normally expressed by differentiated stratified epidermis, in particular specific keratins (see Ch. 56). During wound healing, a classic marker of activated keratinocytes is the expression of keratins associated with proliferation such as keratins 6 (K6) and K16. The cytoskeletal changes

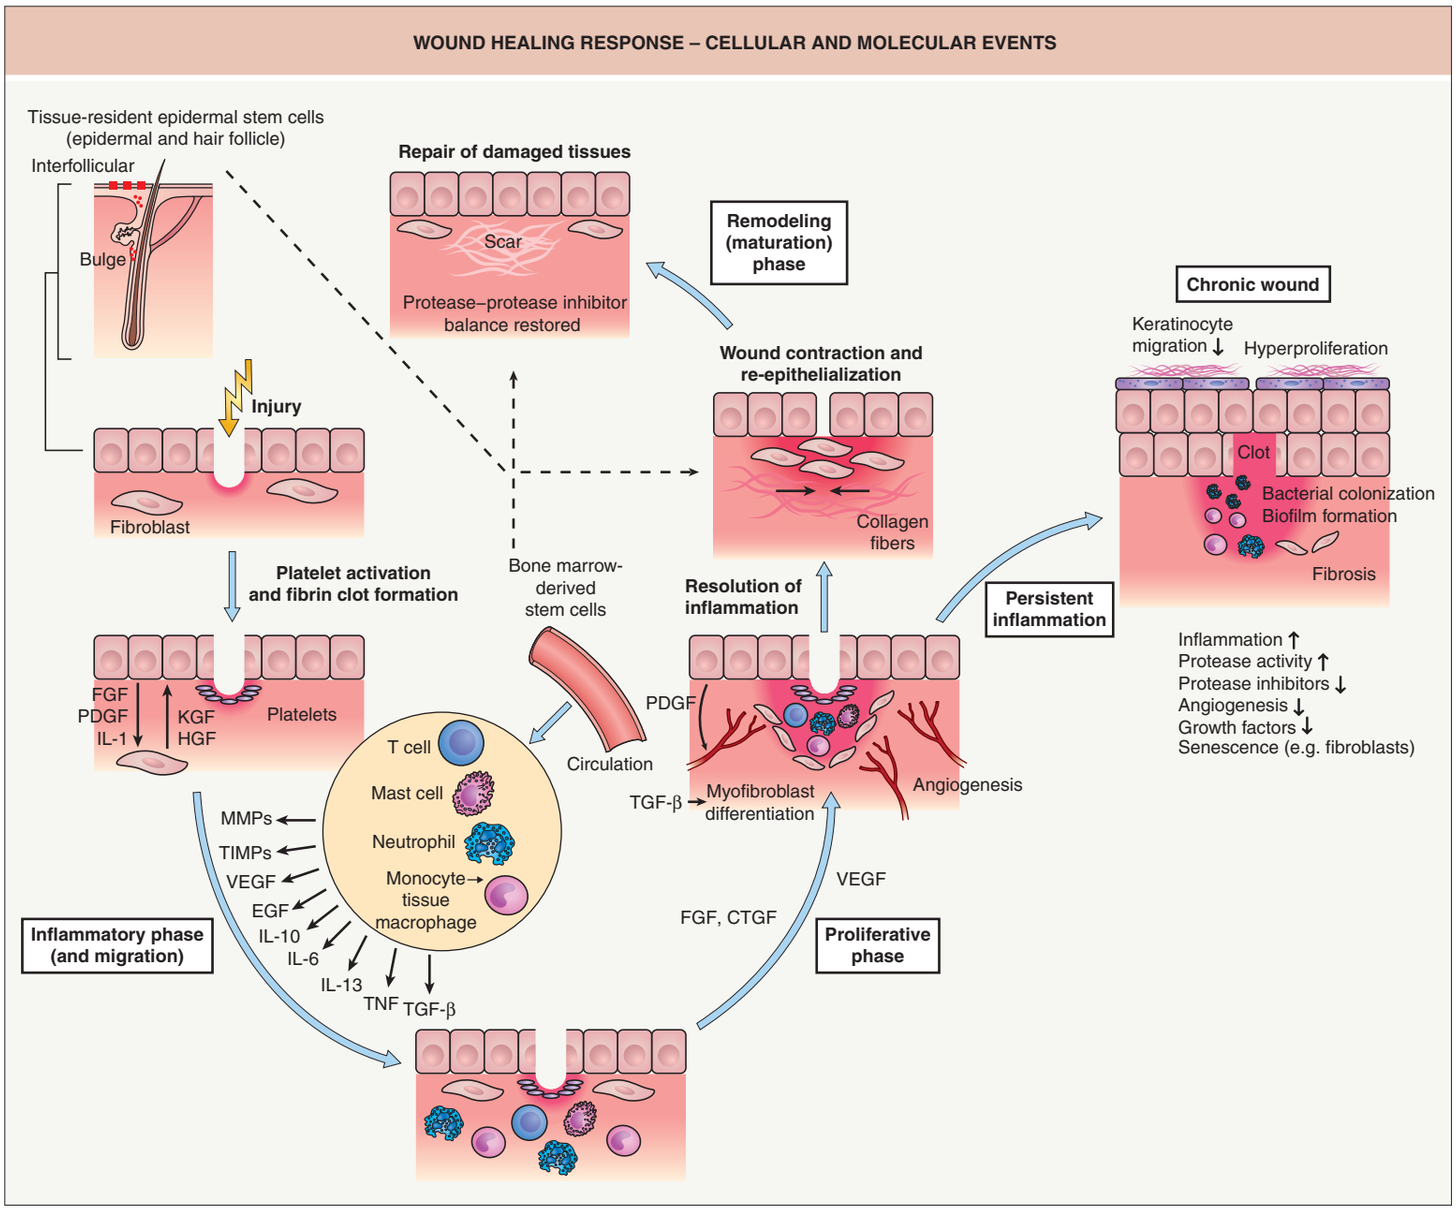

Fig. 141.3 Wound healing response – cellular and molecular events. Leakage of blood constituents and vasoactive factors into the wound site leads to hemostasis. The fibrin clot consists of platelets as well as extracellular matrix molecules (e.g. fibronectin, vitronectin) which facilitate the infiltration and migration of cells. Influx of different subsets of leukocytes characterizes the *inflammatory phase* of repair. These cells release angiogenic growth factors and proinflammatory cytokines, which then induce the recruitment of additional inflammatory cells, fibroblasts, and endothelial cells into the wound site. During the *proliferative phase* in which there is formation of granulation tissue, activated macrophages, endothelial cells, and fibroblasts form a functional unit essential for efficient blood vessel growth. Transformation of granulation tissue and provisional wound matrix into scar tissue occurs during the *remodeling phase* and this is characterized by a decrease in inflammation and regression of vascular structures. Lastly, stem cells that are intrinsic to the skin (e.g. epidermal stem cells) as well as circulating stem cells contribute to the repair response. If the inflammatory response persists, a disturbed healing response may ensue leading to chronic skin ulceration. The microenvironment of chronic ulcers is characterized by multiple hostile factors including increased protease activity, proinflammatory factors, senescent cells, fibrosis, and impaired cellular migration. CTGF, connective tissue growth factor; EGF, epidermal growth factor; FGF, fibroblast growth factor; HGF, hepatocyte growth factor; IL, interleukin; KGF, keratinocyte growth factor; MMPs, matrix metalloproteinases; PDGF, platelet-derived growth factor; TGF, transforming growth factor; TIMPs, tissue inhibitors of metalloproteinases; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor. *Adapted from Wynn TA. Common and unique mechanisms regulate fibrosis in various fibroproliferative diseases. J Clin Invest 2007;117:524–9.*

associated with keratinocyte activation provide plasticity and flexibility, while maintaining resilience of the intracellular scaffold that is important for migration[23]. Many of the growth factors active during wound healing, such as keratinocyte growth factor (KGF) or hepatocyte growth factor (HGF), are potential regulators of these processes. These growth factors can be synthesized either by activated keratinocytes (and act in an autocrine loop) or by cells present in the dermis, in particular fibroblasts, and then they act in a paracrine fashion[24].

As the stratified epithelium consists of keratinocytes committed to multiple stages of differentiation, it is important to know which keratinocytes can be activated for regeneration. Experimental data from mice expressing a transgene within defined keratinocyte subpopulations revealed that interfollicular epidermal stem cells, transient amplifying cells, and early differentiated cells have the ability to form a fully differentiated epidermis[25]. These data suggest that primarily skin stem cells and transient amplifying cells contribute to wound healing and that keratinocytes become irreversibly committed to the differentiation process relatively quickly and then respond poorly to activating signals. Once keratinocytes process profilaggrin into filaggrin, they undergo specific changes that mark late terminal differentiation, which seemingly demarcates the final "line of regenerative potency" within the differentiating keratinocyte population (see Fig. 141.4)[26].

Studies in mice that focused on the contribution of stem cells to the formation of a new epidermis after injury concluded that multiple

GROWTH FACTORS INVOLVED IN WOUND HEALING			
Growth factor	**Abbreviation**	**Source**	**Functions**
Platelet-derived growth factor	PDGF	Platelets, keratinocytes, fibroblasts, endothelial cells, perivascular cells	Fibroblast proliferation, chemotaxis & collagen metabolism; angiogenesis
Transforming growth factor-β	TGF-β	Platelets, keratinocytes, fibroblasts, endothelial cells, macrophages	Fibroblast proliferation, chemotaxis & collagen metabolism; angiogenesis; immunomodulation
Transforming growth factor-α	TGF-α	Platelets, keratinocytes	Keratinocyte proliferation & migration
Epidermal growth factor	EGF	Platelets	Keratinocyte proliferation & migration
Interleukins	IL-1, IL-10	Leukocytes, keratinocytes	Fibroblast proliferation; proinflammatory (IL-1); anti-inflammatory (IL-10)
Tumor necrosis factor	TNF	Leukocytes, keratinocytes	Promotes inflammation
Connective tissue growth factor	CTGF	Fibroblasts, endothelial cells	Fibroblast proliferation, chemotaxis & collagen metabolism
Fibroblast growth factor	FGF	Keratinocytes, macrophages	Fibroblast & epithelial cell proliferation; matrix deposition, wound contraction; angiogenesis
Keratinocyte growth factor	KGF	Fibroblasts	Keratinocyte proliferation
Insulin-like growth factor 1	IGF-1	Fibroblasts	Keratinocyte proliferation & differentiation
Hepatocyte growth factor	HGF	Fibroblasts, macrophages	Keratinocyte proliferation
Vascular endothelial growth factor	VEGF	Platelets, keratinocytes, macrophages, neutrophils	Angiogenesis; vascular permeability; macrophage chemotaxis

Table 141.2 Growth factors involved in wound healing.

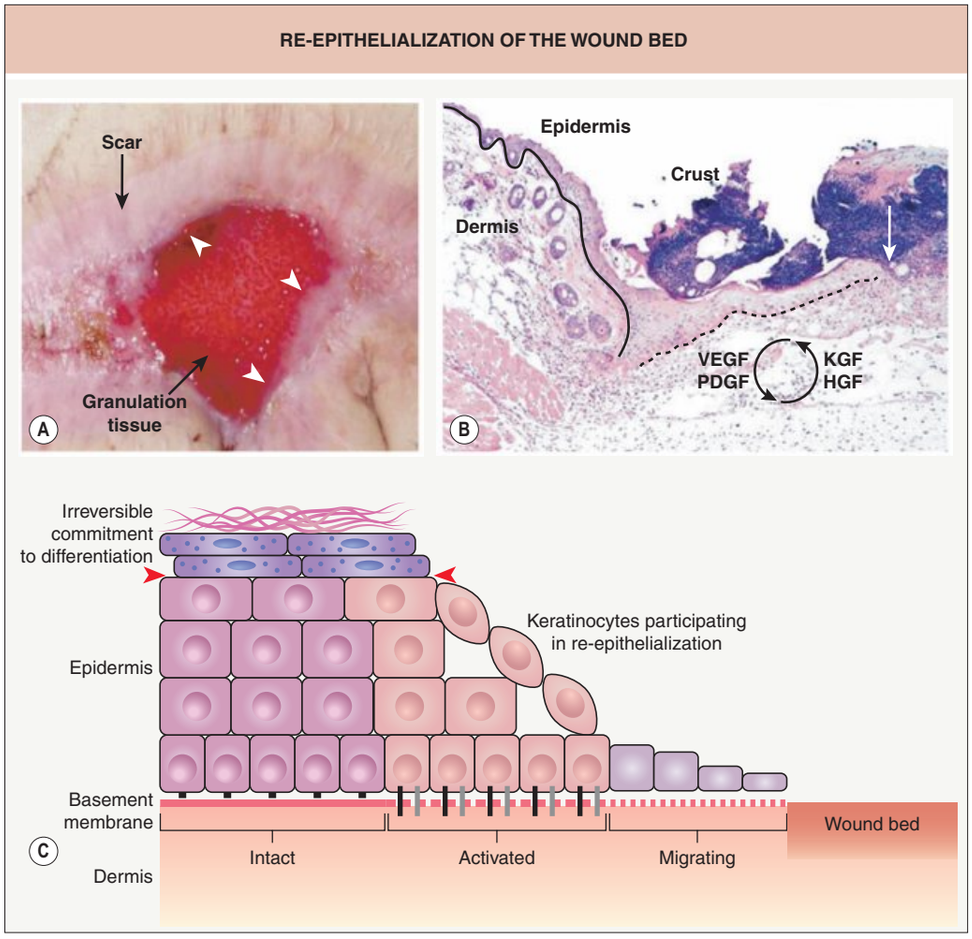

Fig. 141.4 Re-epithelialization of the wound bed. **A** Clinical appearance of a re-epithelializing wound; arrowheads indicate the epithelial wound edge. **B** Histology of the wound edge demonstrating the migration of keratinocytes over the wound bed; this process is in part regulated by growth factors synthesized by fibroblasts such as keratinocyte growth factor (KGF) and hepatocyte growth factor (HGF). The white arrow indicates the tip of the epithelial tongue, the black dashed line indicates activated and migrating epithelium, and the black solid line indicates intact epithelium. **C** Epithelial cells present at the wound edge undergo marked morphologic and functional alterations. They lose their contacts with neighboring cells and the underlying extracellular matrix, then proliferate and migrate toward the center of the wound. The red arrowheads demarcate the terminally differentiated cells that are irreversibly committed.

populations of stem cells reside within different locations of the epidermis and skin appendages. Under normal homeostatic conditions, stem cells residing in different locations maintain the differentiated lineages specific to those locations, i.e. hair follicle stem cells (HFSCs) maintain the hair lineages, sebaceous gland stem cells produce differentiated sebocytes, and stem cells within the interfollicular epidermis (IFE) give rise to the outermost barrier layers of the epidermis[27]. Although in principle cells from all stem cell populations are capable of participating in epithelialization after a cutaneous injury, their specific contributions vary[27,28]. The current view is that stem cells from the interfollicular epidermis as well as cells that lie within the lower bulge area (region of the hair follicle defined as the attachment site of the arrector pili muscle) and above the bulge (the isthmus) contribute long-lasting progeny during re-epithelialization, whereas cells located in the bulge play a minor role[27–29]. These findings are supported by studies in which epidermal wound repair still occurred despite the absence of

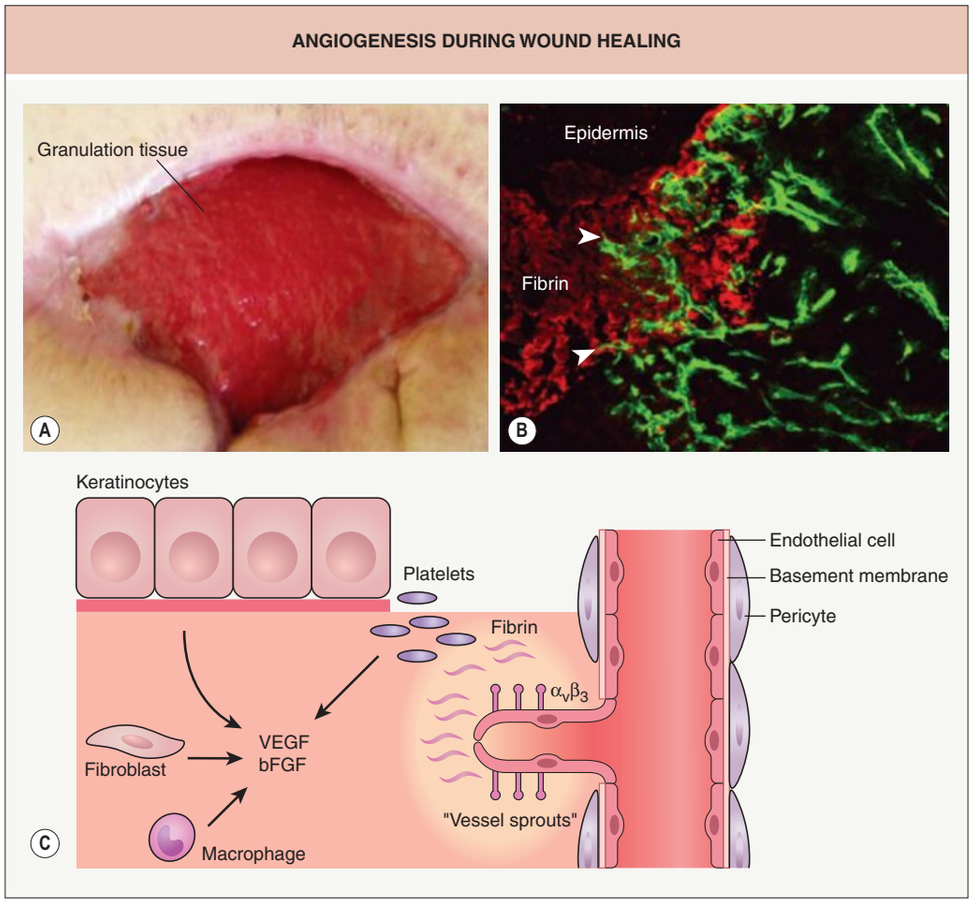

Fig. 141.5 Angiogenesis during wound healing. **A** Clinical appearance of a highly vascularized wound bed. **B** Immunohistochemical staining demonstrating endothelial invasion ($CD31^+$ [green]) into a fibrin matrix (red); white arrowheads indicate sprouting capillaries. **C** Capillary sprouts invade the fibrin/fibronectin-rich provisional wound matrix and within a few days they organize into a microvascular network throughout the granulation tissue. The process is regulated by dynamic interactions amongst endothelial cells, growth factors (e.g. VEGF, bFGF), and the extracellular matrix. In particular, the $\alpha_v\beta_3$ integrin appears to be required for endothelial cell attachment and wound angiogenesis. bFGF, basic fibroblast growth factor; VEGF, vascular endothelial growth factor.

hair follicles in mutant mice. Nonetheless, an acceleration of epidermal wound healing has been observed during the growth phase of the hair cycle. Collectively, these findings help to explain how depth of injury affects a wound's capability to repair and to re-epithelialize.

Endothelial cells

Activated and proliferating endothelial cells that form blood vessels normally express $\alpha_v\beta_3$ integrins and are major contributors to angiogenesis, which is a vital component of wound healing (Fig. 141.5)[30]. New blood vessels ensure the delivery of nutrients to meet the increased metabolic requirements of wound tissue and they help to reverse the hypoxic and acidotic milieu[31]. Neoangiogenesis in wounds occurs via both *angiogenesis* (sprouting of capillaries from existing blood vessels) and *vasculogenesis* (mobilization of bone marrow-derived endothelial progenitor cells; see Ch. 102). This is a highly complex process – it requires dynamic, temporally and spatially regulated interactions amongst endothelial cells, soluble angiogenic growth factors, and ECM molecules. In addition, wound angiogenesis is, at least in part, induced by the innate immune response. Immediately after injury, different subsets of leukocytes, especially macrophages, are attracted to the wound site where they release multiple pro-angiogenic mediators (e.g. VEGF-A, IL-6, IL-8, TNF) that trigger and sustain the angiogenic response[11,22].

During neoangiogenesis, degradation of the surrounding ECM occurs via MMPs and serine and cysteine proteases[32], with new vessels sprouting from existing vessels and growing along a growth factor gradient determined primarily by VEGF. Importantly, as shown for VEGF-A, the time of action, cellular source, and concentration of a given cytokine determine whether it activates, terminates, or inhibits angiogenesis. The delayed healing response observed in patients receiving anti-VEGF-A agents (e.g. bevacizumab) highlights the critical role VEGF-A plays in angiogenesis during tissue repair[33]. Of note, both the ECM (often via integrins) and growth factor concentrations provide signals that balance the formation of new blood vessels and the prevention of aberrant angiogenesis.

Genetically engineered mice have also provided evidence that wound angiogenesis requires dynamic interactions amongst endothelial cells, pro- and anti-angiogenic growth factors, and the ECM environment[30]. For example, basement membrane proteins provide essential information for the organization and orientation of endothelial cells. Anchoring of endothelial cells to this dense polymer layer is crucial for the proper function of blood vessels, and removal of major components of the basement membrane leads to leakiness of blood vessels. A vital role for these components (laminins, nidogens, types III and IV collagens, heparin sulfate proteoglycans) is reflected in genetic disorders such as the vascular form of Ehlers–Danlos syndrome, in which reduced or abnormal type III collagen fibers are associated with vascular fragility.

Leukocytes and platelets

The inflammatory response in normal wound healing is characterized by spatially and temporally changing patterns of various leukocyte subsets. The well-defined chronology of these events appears essential for optimal repair.

Platelets and polymorphonuclear leukocytes

Immediately after injury, extravasated blood components form a hemostatic blood clot (Fig. 141.6). Platelets then aggregate within the clot and release a wide spectrum of factors that amplify the aggregation response, trigger the coagulation cascade, and act as chemoattractants for cells involved in the inflammatory phase.

Within a few hours following the injury, polymorphonuclear leukocytes (PMNs; neutrophils) transmigrate across the endothelial cell wall of capillaries. Upon activation, neutrophils release proinflammatory cytokines including IL-8 and TNF as well as the chemokines growth-related oncogene-α (GRO-α) and monocyte chemoattractant protein-1 (MCP-1)[34,35]. This leads to expression of adhesion molecules (selectins, ICAM, VCAM) that are essential for leukocyte adhesion and diapedesis (see Fig. 141.6 and Ch. 102)[36]. Neutrophils can further amplify their own recruitment via IL-8 and GRO-α.

Bacterial products such as lipopolysaccharides and formyl-methionyl peptides, which accumulate within infected wounds, can accelerate directed neutrophil locomotion. In addition to controlling infectious agents, recruited neutrophils play a major role in the debridement of devitalized tissue. To accomplish these tasks, they release a large variety of

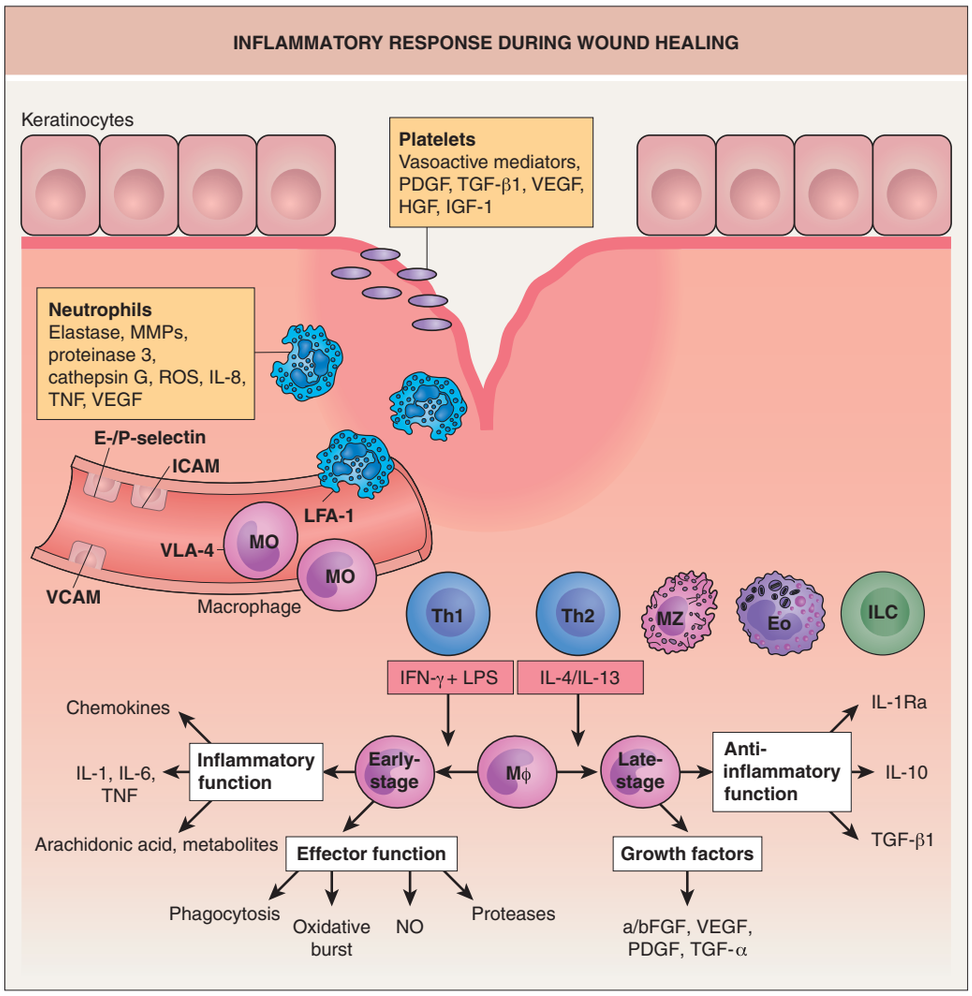

Fig. 141.6 Inflammatory response during wound healing. During normal wound healing, the inflammatory response is characterized by spatially and temporally changing patterns of leukocyte subsets. A well-defined chronology and interplay is essential for optimal repair. Within a few hours after injury, neutrophils transmigrate across the endothelial cell wall of blood capillaries; recruited neutrophils begin to debride devitalized tissue and attack infectious agents by releasing a number of antimicrobial molecules, proteases, and cytokines. Shortly after the neutrophils appear, monocytes migrate from the blood vessels into the dermis, become activated within the wound environment, and then transform into tissue macrophages. In addition to functioning as antigen-presenting cells and phagocytes, macrophages are thought to play an integral role in wound healing due to their release of numerous growth factors. Their morphologic and functional heterogeneity is a reflection of factors released by other cells, e.g. T cells or mast cells, present in the wound environment. Eo, eosinophil; FGF, fibroblast growth factor; HGF, hepatocyte growth factor; ICAM, intercellular adhesion molecule; IFN, interferon; IGF, insulin-like growth factor; IL, interleukin; IL-1Ra, interleukin-1 receptor antagonist; ILC, innate lymphoid cell; LFA-1, lymphocyte function-associated antigen 1; LPS, lipopolysaccharide; MMPs, matrix metalloproteinases; MO, monocyte; Mϕ, macrophage; MZ, mast cell; NO, nitric oxide; PDGF, platelet-derived growth factor; ROS, reactive oxygen species; TGF, transforming growth factor; TNF, tumor necrosis factor; VCAM, vascular cell adhesion molecule; VEGF, vascular endothelial growth factor; VLA-4, very late antigen-4.

highly active antimicrobial substances (reactive oxygen species, cationic peptides, eicosanoids) and proteases (elastase, cathepsin G, proteinase 3, urokinase-type plasminogen activator). However, uncontrolled release of these factors can cause severe damage to the tissues of the host[16,36]. The important role of neutrophils in phagocytosis and debridement is underlined by the observation that patients with defined deficiencies in PMN function, such as the leukocyte-adhesion deficiency syndrome 1 (LAD1)[37] or attenuated PMN actin polymerization[38], in which neutrophil locomotion is impaired, also display impaired wound healing.

Blood monocytes and tissue macrophages

The attraction of blood monocytes into the wound site occurs via chemotactic factors including growth factors, proinflammatory cytokines, and chemokines. Examples of the latter are macrophage inflammatory protein 1α (MIP-1α), MCP-1, RANTES, and fractalkine[34]. Within the wound, the major sources of chemoattractants include platelets trapped in the fibrin clot, hyperproliferative keratinocytes at the wound edges, fibroblasts, and various subsets of leukocytes including macrophages. When monocytes extravasate from the blood vessel, they become activated and differentiate into mature tissue macrophages.

Macrophages have a variety of functions during wound healing[10,11,22]. While their role as antigen-presenting cells may be less important in this setting (e.g. RAG1 knockout mice lacking mature T cells have normal wound healing)[39], they are important phagocytes. Macrophages are also a major source of growth factors, such as TGF-β, TNF, PDGF, bFGF, Relm, and VEGF. These factors critically regulate angiogenesis, keratinocyte motility, the recruitment and activation of immune cells, and the synthesis of ECM molecules.

The central role that macrophages play in wound healing was established over 30 years ago. In rats, a significant delay in wound healing was observed when antisera was used to deplete macrophages[40]. More recent studies have supported and extended these observations[10,11,22]. For example, ICAM-1-deficient mice, P- and E-selectin-double-deficient mice, and mice deficient in β-1,4-galactosyltransferase (which glycosylates P- and E-selectins) all have profound delays in wound closure (see Fig. 141.6); this delay is associated with a significantly reduced infiltration of macrophages. These studies demonstrate the importance of cell adhesion molecules in regulating blood monocyte recruitment and infiltration into the wound site.

Differentiation of monocytes into tissue macrophages involves profound changes in gene expression and cellular function. This activation is directed by mediators present in the microenvironment and is thought to be crucial for the proper adaptation of macrophage functions to the specific requirements of the wound site[41]. Macrophages sense their microenvironment via numerous cell surface receptors, including Toll-like receptors, complement receptors, Fc receptors, and cytokine receptors[42].

One model of tissue macrophage activation is based on the observation that macrophages acquire distinct states of activation (see Fig. 141.6)[38]. Traditionally it was thought that macrophages at one end of the spectrum exhibited proinflammatory activities such as the production of IL-1 and nitric oxide (NO). This led to promotion of type I immune responses and eradication of invading microorganisms, and these cells were termed *M1* or *"classically activated"* macrophages. At the other end of the spectrum, the macrophages had a rather non-inflammatory phenotype, produced IL-10, and were hyporesponsive to proinflammatory stimuli. These cells were involved in debris scavenging, tissue remodeling, resolving inflammation, and promoting repair and were termed *M2* or *"alternatively activated"* macrophages. However, recent studies have challenged this model by demonstrating that the phenotypes of activated macrophages are much more complex. For example, injury-associated macrophages displayed substantial heterogeneity across activation patterns and metabolic signatures that critically affected the outcome of the healing response[22].

Studies in mice and humans have shown that early and late wound stages are characterized by specifically activated *early-stage inflammatory* macrophages and *late-stage non-inflammatory* macrophages, respectively (see Fig. 141.6)[7]. Cells associated with different stages

are characterized by distinct gene expression profiles[22,43]. Early-stage wound macrophage activation is mediated by cytokines, in particular interferon-γ (IFN-γ), followed by Toll-like receptor (TLR)-mediated triggers such as lipopolysaccharide signaling via TLR4. Key mediators of late-stage macrophage activation are IL-4 and IL-13, acting through the common receptor chain IL-4Rα.

T cells

During the tissue remodeling phase, when wound closure is complete and local infections have been overcome, cells of the *adaptive* immune response, in particular T cells, are the most frequent leukocyte subset in human skin wounds[44]. $CD4^+$ T cells can differentiate into different subsets, e.g. Th1 and Th2 cells (see Ch. 4), thereby influencing the wound microenvironment by secreting distinct cytokine profiles (see Fig. 141.6)[45]. Th1 cells are a primary source of IFN-γ, while Th2 cells are the major source of IL-4 and IL-13. These cytokines have a major effect on the state of macrophage activation. Thus, even though they are not mandatory for wound healing, $CD4^+$ T cell cytokines influence two important components of wound healing: macrophage function and angiogenesis. However, additional investigations are needed to understand why wound healing appears to be unaffected in T cell-deficient mice (e.g. RAG1 knockout mice).

Mast cells

Mast cells are a hematopoietic cell population that normally resides in skin and mucous membranes. They are an important source of a number of mediators such as prostaglandins and biogenic amines as well as pro- and anti-inflammatory cytokines (e.g. TNF, IL-8) that strongly influence inflammation, tissue modulation, and vascular modeling. However, almost entirely normal wound healing was observed in mice genetically depleted of mast cells, suggesting that mast cells may only play a fine-tuning role during wound repair[46].

Fibroblasts

Connective tissue, including the dermis, is usually composed of large amounts of ECM in which a small number of relatively quiescent fibroblasts are embedded. During development, fibroblasts establish a "resting" tension by actively synthesizing and cross-linking fibrillar ECM proteins such as collagen and elastin (see Ch. 95). This establishes the shape of the skin and ensures that the skin retains its shape in response to mechanical stress.

During tissue repair, fibroblasts next to the site of injury become activated, reconstitute new ECM, and restore proper matrix tension. To achieve these goals, fibroblasts acquire smooth muscle cell-like features including contractile stress fibers and *de novo* expression of α-smooth muscle actin (α-SMA), thus differentiating into myofibroblasts (Fig. 141.7)[43]. The transition of fibroblasts into myofibroblasts depends on the concerted action of both cytokines and ECM proteins, in particular TGF-β1 and the cellular fibronectin splice variant ED-A, respectively[47]. Acquisition and maintenance of the myofibroblast phenotype also depend on mechanical tension, which is regulated by the interaction between the rigidity of the ECM and the contractile activity of its cells. Rho-ROCK signaling serves as an important integrator of profibrotic pathways and it can be activated by integrin signaling in a FAK-dependent manner or by TGF-β and Engrailed 1 (EN1)[48].

After wound closure, apoptosis of myofibroblasts or reverse differentiation into fibroblasts normally occurs. However, abnormal persistence of myofibroblasts has been observed in hypertrophic scars and keloids (see Fig. 141.7). Determining how the perception of mechanical signals translates into myofibroblast differentiation may lead to therapeutic strategies for exaggerated scarring[49,50].

Stem cells

Stem cells are defined as cells that have self-renewing capabilities and can differentiate into multiple cell lineages (see Ch. 2). *Embryonic stem cells* are derived from mammalian embryos in the blastocyst stage and have the ability to generate any terminally differentiated cell in the body. *Adult stem cells* – previously thought to be restricted to their tissue of origin – can be reprogrammed to differentiate into various cell types and to replenish damaged tissues, including muscle, liver, and skin[51]. During wound healing, tissue-resident stem cells (e.g. epidermal stem cells, hair follicle stem cells, mesenchymal stem cells) as well as stem cells recruited from the bloodstream can participate in the repair process (see Fig. 141.3)[27,51].

To date, the best-studied model of adult stem cells is the hematopoietic system, in which long-term self-renewal is achieved solely by specific and rare hematopoietic stem cells (HSC). These cells reside within the bone marrow niche and can give rise to all blood cell lineages. In addition to hematopoietic progenitors, other cells with stem cell-like qualities, such as mesenchymal stem cells (MSCs) and multipotent adult progenitor cells (MAPC), have been cultured from human and murine bone marrow[52].

MSCs were first isolated from bone marrow and later from various tissues including adipose, pancreas, skeletal muscle, neural tissue, and skin. After appropriate stimulation, these cells differentiate into mature committed cells. In animal studies, they migrated from their bone marrow niche to injury sites and differentiated appropriately, e.g. into endothelial, neural, or cardiac tissues. Within injured murine skin, differentiation into fibroblasts, endothelial cells, and keratinocytes was observed[53]. However, the percentage of MSCs recruited into small cutaneous wounds in mice appears to be low[47]. Nonetheless, there is significant therapeutic interest in delivering stem or progenitor cells to skin wounds to promote repair or optimize the quality of the repair response (see below)[51,52,54].

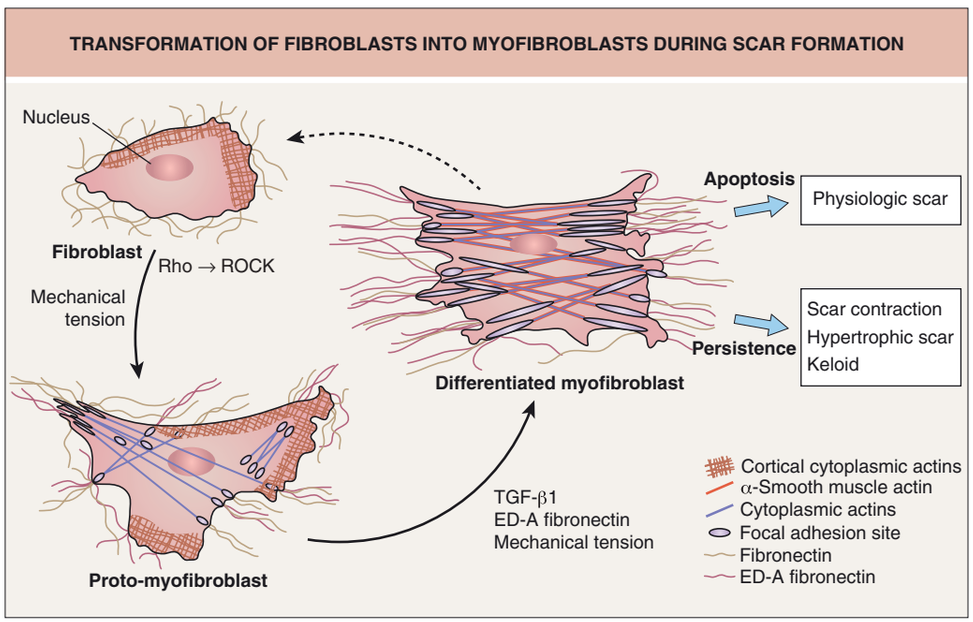

Fig. 141.7 Transformation of fibroblasts into myofibroblasts during scar formation. Fibroblasts undergo a series of phenotypic and functional changes during granulation tissue formation and then scar formation. This process has beneficial (e.g. release of growth factors[76], regeneration of adipocytes[77]) as well as harmful (e.g. fibrogenesis) effects. Under mechanical stress, fibroblasts differentiate into proto-myofibroblasts which are characterized by the expression of a fibronectin variant ED-A; the latter, in combination with TGF-β1, promotes the differentiation of proto-myofibroblasts into myofibroblasts. The Rho/ROCK signaling pathway also plays an important role. Typically, myofibroblasts express α-smooth muscle actin (SMA) and can generate potent contractile forces. The persistence of myofibroblasts within the scar may lead to disabling scar contraction. *From Tomasek JJ, Gabbiani G, Hinz B, et al. Myofibroblasts and mechano-regulation of connective tissue remodelling. Nat Rev Mol Cell Biol 2002;3:349–63.*

Growth Factors and Their Receptors

In addition to cell–matrix interactions (see below), all stages of the repair process are influenced by a complex network of soluble peptide growth factors, chemokines, and hormones as well as their receptors (see Figs. 141.3, 141.5 & 141.6)[55]. Major growth factor families that contribute significantly to the wound healing process include PDGF, FGF, VEGF, and TGF-β (see Table 141.2). These growth factors are synthesized and secreted by various cell types involved in the wound healing process, including keratinocytes, fibroblasts, vascular endothelial cells, platelets, and inflammatory cells. Growth factors may act on the producer cell (*autocrine* stimulation), an adjacent cell (*paracrine* stimulation), or distant cells (*endocrine* stimulation)[55]. Following binding of growth factors to their respective receptors, complex signaling cascades result in cellular functions crucial for wound healing, including cellular proliferation and migration[56].

Extracellular Matrix

Although the ECM was long viewed as an inert scaffold upon which cells were arranged, it has been redefined as a dynamic, mobile, and flexible structure that plays a key role in regulating cellular behavior. Genetically modified mice have greatly accelerated our understanding of the multifunctionality of the ECM in both developmental and regenerative processes[57].

During the three phases of wound healing, the components of the ECM continuously change in order to support wound phase-specific repair mechanisms. In the inflammatory phase, the initial wound matrix (consisting primarily of blood constituents such as fibrin and fibronectin) provides a substrate for migration and in-growth of various cell types, including macrophages and fibroblasts (Fig. 141.8). During the proliferative phase, granulation tissue is formed and components of the provisional matrix (e.g. vitronectin, tenascin) facilitate cell adhesion, migration, and proliferation (see Fig. 141.3). In the remodeling phase, the provisional matrix matures and is replaced by type I collagen which increases the tensile strength of the wound.

Matrix molecules can regulate cellular functions via interaction with specific transmembrane receptors on the cell surface (e.g. integrins; see below) or they can bind growth factors, e.g. TGF-β. For example, in Marfan syndrome, the reduction in fibrillin-1 synthesis leads to decreased levels of extracellular fibrillin-rich microfibrils, which normally act as a reservoir for TGF-β (see Fig. 95.6). Thus, mutations affecting a component of the ECM can give rise to a phenotype that reflects disturbances in TGF-β signaling[58].

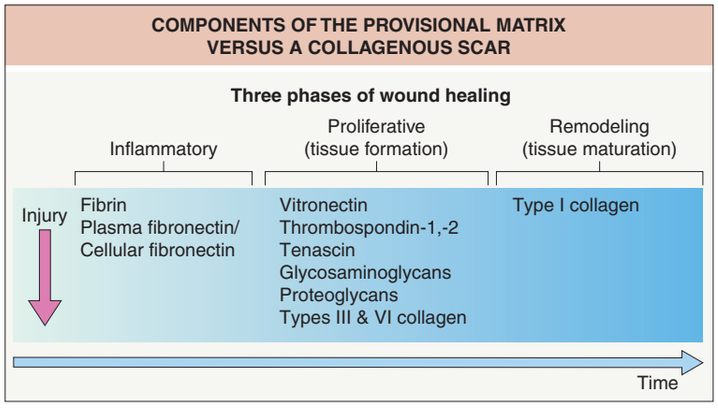

Fig. 141.8 Components of the provisional matrix versus a collagenous scar. The first extracellular matrix to be deposited within the wound space and surrounding tissue is the fibrin clot. Leukocytes, fibroblasts, and endothelial cells invade the fibrin clot, which is then lysed. These cells begin to deposit a network of ECM components, including fibronectin, vitronectin, tenascin, and type III collagen. Following complete re-epithelialization, fibroblasts start to deposit a stable matrix composed of type I collagen. Thus the wound evolves from an initial plasma-derived provisional matrix to an *in situ* cell-derived provisional matrix and finally to a mechanically stable collagen matrix. Examples of glycosaminoglycans are hyaluronic acid, chondroitin-4-sulfate, and dermatan sulfate, while examples of proteoglycans are decorin, biglycan, versican, and syndecan (see Ch. 95).

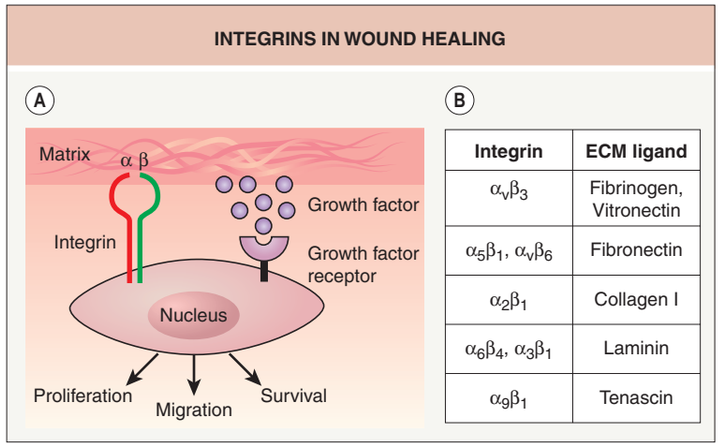
Integrins



Integrins are transmembrane receptors on the cell surface that recognize and bind to ECM proteins. They are heterodimers composed of α-subunits and β-subunits. Eighteen α-subunits and eight β-subunits can assemble in 24 different combinations, with overlapping substrate specificity and cell type-specific expression patterns[59]. For example, integrins containing β1 or β3 chains are ECM receptors, whereas those containing β2 chains are leukocyte cell–cell receptors. The composition of integrins expressed by a particular cell determines to which ECM components that cell can bind. For example, $\alpha_9\beta_1$ binds to tenascin and $\alpha_V\beta_6$ to fibronectin (Fig. 141.9).

Upon binding of an integrin to its ligand, the integrin may change its configuration and transform into an activated state[60]. This can trigger a signaling cascade within the cell that leads to alterations in gene expression as well as a change in the integrin's binding characteristics. Integrin-mediated signaling is also influenced by the binding of growth factors and cytokines to their respective receptors, along with various levels of cross-talk (see Fig. 141.9). For example, $\alpha_V\beta_3$ binding in conjunction with VEGF-A binding to its receptor leads to synergistic downstream effects which regulate endothelial cell function. Thus, it is well established that integrins are more than just simple receptors mediating the physical attachment of cells to their environment.

Proteases (Proteinases)

Proteases are enzymes that cleave peptide bonds at specific sites along polypeptides. They can be classified into distinct groups based upon the biochemical mechanisms responsible for their catalytic activities[61]. Proteases are crucial for tissue remodeling, which is a fundamental process in all stages of wound repair, i.e. they are active during inflammation, angiogenesis, and re-epithelialization. For skin repair, the most important proteases are serine proteases and metalloproteinases. In addition to matrix degradation, these proteases are crucial for growth factor activation and they exert antimicrobial activities. However, to protect tissues from excessive and uncontrolled proteolytic degradation, protease activity has to be tightly regulated by protease inhibitors. An imbalance with high levels of proteases and low levels of protease inhibitors is a major contributor to chronic, non-healing skin ulcers (see Fig. 141.3)[16,62].

Serine proteases have a catalytically essential serine residue in their active site. Neutrophils and macrophages are an important source of serine proteases, which includes neutrophil elastase, cathepsin G, and proteinase 3. Furthermore, plasmin and its activators, tissue-type plasminogen activator (tPA) and urokinase-type plasminogen activator (uPA), are serine proteases that are fundamental for wound repair. In addition to dissolving the fibrin clot, the plasmin-related proteases are involved in activating matrix metalloproteinases (MMPs) and numerous growth factors.

Integrin	ECM ligand
$\alpha_v\beta_3$	Fibrinogen, Vitronectin
$\alpha_5\beta_1$, $\alpha_v\beta_6$	Fibronectin
$\alpha_2\beta_1$	Collagen I
$\alpha_6\beta_4$, $\alpha_3\beta_1$	Laminin
$\alpha_9\beta_1$	Tenascin

Fig. 141.9 Integrins that play a role in wound healing. A Integrins are transmembrane receptors that recognize and bind to extracellular matrix (ECM) proteins. They are heterodimers composed of one α-subunit and one β-subunit. Integrins allow cells to attach to the ECM and they interact with growth factor receptors, ultimately controlling cellular functions essential for wound healing. **B** The composition of integrins expressed by a cell determines the ECM components to which that cell can bind.

The major *ser*ine *p*rotease *in*hibitors (SERPINs; e.g. α_1-antichymotrypsin) and α_2-macroglobulins are synthesized by hepatocytes and released into the plasma. In contrast, *s*ecretory *l*eukocyte *p*rotease *i*nhibitor (SLPI) and elafin are synthesized locally by keratinocytes. Plasminogen activator inhibitors (PAIs) are the major inhibitors of uPA and are produced by endothelial cells.

The family of MMPs shares a common domain structure and includes collagenases, gelatinases, and stromelysins. Collectively, they are capable of degrading all the components of the ECM. At least 28 members of the human MMP family have been identified and are differentially expressed by diverse cell types[63]. MMPs can be subdivided into several groups based upon substrate specificity, and they are inhibited by *t*issue *i*nhibitors of *m*etallo*p*roteinases (TIMPs) which are synthesized by connective tissue cells and leukocytes.

IMPAIRED WOUND HEALING – RISK FACTORS

The complex network of cell–cell and cell–matrix interactions leading to wound healing can be disturbed. This may result in either a delayed healing response and ultimately a chronic wound or excessive scarring as in hypertrophic scars or keloids. Dysfunctional wound healing represents a major clinical and socioeconomic problem, and the development of effective therapies is essential.

Impaired healing can be classified according to whether it results from systemic factors or the local microenvironment (see Table 141.1)[16]. A chronic wound is a symptom of an underlying disease rather than a disease entity. The most common systemic factors influencing wound repair are venous insufficiency, advanced age, atherosclerosis, and diabetes mellitus-associated microangiopathy (see Fig. 105.1); less commonly vasculitis, hypercoagulability, malnutrition, and concomitant therapies (e.g. hydroxyurea, immunosuppressives) play a role. Local factors include inadequate blood supply, necrotic tissue, increased proteolytic activity, mechanical irritation, pressure, bacterial components, local toxins, and growth factor deficiency (Table 141.3). Each of these factors has to be critically considered when assessing factors responsible for impaired healing and when outlining a treatment regimen for a non-healing wound.

Wound Healing and Aging

The prevalence of chronic wounds increases with age[64], as does the prevalence of venous hypertension, peripheral artery disease, and diabetes mellitus. Aging can be regarded as an accumulation of molecular changes that leads to functional failure in different tissues, including impaired wound healing. Aging may be triggered by two principal mechanisms: telomere shortening (see Fig. 67.22) and DNA damage. Telomere shortening or dysfunction leads to instability of chromosomes. A functional link between age-dependent telomere shortening and impaired wound healing has been demonstrated in telomerase-deficient mice (telomerase is an enzyme that prevents telomere shortening)[65]. How telomere shortening translates into impaired cell function during the healing response is not understood. Patients with Werner syndrome have impaired DNA repair and also develop chronic skin ulcers. Furthermore, mice with increased activation of the transcription factor p53 within the epidermis develop an early aging phenotype of their skin with impaired wound healing[66].

THERAPEUTIC OPTIONS FOR CHRONIC WOUNDS

Wound Dressings

A large variety of wound dressings is currently available, with recommendations for specific dressings based on the characteristics of the wound (see Ch. 145). Clinical experience, rather than controlled trials, forms the basis of many of these recommendations. There is still no consensus on the mechanisms of action, but most dressings are thought to support wound healing by acting as a barrier between the wound and the environment, by preventing drying of the tissue[67], or by allowing autolytic debridement. Only a few dressings appear to be able to interfere with cellular and molecular mechanisms of the wound microenvironment or to counteract mechanisms that are detrimental to repair, e.g. elevated protease activity or increased inflammation (see Fig. 141.3). Of note, controlled trials have shown the benefit of compression therapy in the case of venous ulcers.

COMMON ENVIRONMENTAL FEATURES OF ACUTE VERSUS CHRONIC SKIN WOUNDS IN HUMANS, IRRESPECTIVE OF UNDERLYING SYSTEMIC DISEASE

Acute wounds (healing)	Chronic wounds (non-healing)
Limited tissue damage	Sustained tissue damage
Injury induces cascade of successive phases of hemostasis, inflammation, proliferation, and scar formation	Uncontrolled activation of multiple repair phases
Healing cascade is transient and self-limiting	Continuous cell activation
Dynamic process	"Deadlocked" processes
Limited inflammatory response	• Deregulated and persistent inflammation with multiple sequelae: abundant proinflammatory mediators; increased protease activity; and degradation of critical growth factors and ECM molecules • Proteolytic cleavage of growth factors and ECM results in fragments with new functions
Controlled cellular proliferation	Sustained cellular proliferation
Cellular migration	Disturbed cellular migration
Controlled angiogenesis	• Altered vascular function, vascular leakage, and reduced angiogenesis • Excessive tissue fibrosis results in deregulation of cellular and ECM function as well as mechanotransduction
Normal epidermal–dermal interactions	• Disturbed epidermal–dermal interactions due to an absent epidermis • Exhaustion of stem cells • Increase in necrotic and apoptotic cells • Increase in senescent cells, e.g. fibroblasts • Increased bacterial load and formation of biofilms • Eventually malignant transformation can occur

Table 141.3 Common environmental features of acute versus chronic skin wounds in humans, irrespective of underlying systemic disease. Although many chronic skin wounds result from a combination of underlying systemic diseases that prevent healing (see Ch. 105), it remains unresolved as to what extent the pathophysiology of the local microenvironment overlaps with that of the different underlying systemic diseases. ECM, extracellular matrix.

Growth Factors

Growth factors are essential regulators of cellular function during repair. Experimental studies have shown that the topical application of specific growth factors can modify and probably even accelerate wound repair[56,68]. Based on these observations, clinical trials to determine whether tissues with inherently poor or pathologically altered healing potential could benefit from therapeutic growth factor interventions have been conducted. PDGF-BB was the first and, to date, only approved recombinant growth factor for the topical treatment of diabetic foot ulcers, but due to limited efficacy, its use in daily clinical practice is limited (see Ch. 105).

The limited success of clinical trials with growth factors underscores an important aspect of the growth factor/tissue repair paradigm: the effective delivery of growth factors to the wound site. The latter is biologically and biochemically complex, and in settings such as a chronic or infected wound, the environment is hostile to repair. Current drug delivery strategies suffer from the inherent loss of drug activity due to the combined effects of physical inhibition and proteolytic degradation. While this loss of activity may be one reason for the limited success of clinical studies and delivery of growth factors via genetically modified cells could represent a better approach, a major remaining factor is poor blood supply.

Cell- and Tissue-Based Therapies

When skin defects are too large to heal by second intention, skin grafts and cell-based treatments can be used to cover the wound and replace the defect. Split-thickness skin grafts are commonly used to treat acute surgical or chronic wounds (see Ch. 148). In addition, "pinch" grafts, which are 2–5 mm superficial skin biopsies often obtained from the anterolateral thigh, can be placed dermis-down in a clean wound bed.

To aid in the healing of acute surgical or chronic wounds as well as extensive thermal burns, efforts have been made to develop skin substitutes that have properties similar to native skin[69,70]. Both autologous and allogeneic components have been incorporated into bioengineered human skin equivalents (see Ch. 145). Clinical studies have demonstrated a beneficial effect on chronic wounds refractory to conventional therapy, but these skin substitutes tend to be expensive and grafted cells are eventually lost.

FUTURE DIRECTIONS

Currently limitations in the treatment of chronic wounds are partly due to an incomplete understanding of the molecular mechanisms hindering repair and a lack of animal models that reflect the complex multifactorial nature of chronic ulcers. In addition, clinical research is often hampered by a heterogeneous patient population with a range of comorbidities. The success of innovative therapies will depend on comprehensive knowledge of the underlying pathomechanisms and correction of pathogenic factors, with advances in molecular diagnostics and material sciences playing a key role[16,68].

Stem Cells

Recent advances in stem cell biology may provide novel treatment strategies for acute and chronic wounds (Fig. 141.10)[27]. There is great interest in delivering stem or progenitor cells, either applied topically or via stimulation of their recruitment from the circulation into the wound site. Preliminary work suggests that topically applied autologous bone marrow-derived cells promote the healing of treatment-resistant chronic wounds[69]. Furthermore, recruitment of $CD34^+$ cells from the circulation has shown promise in ischemic limbs[70]. Adipose tissue also serves as a reliable source of mesenchymal stromal/stem cells. Lastly, advances in induced pluripotent stem cell (iPSC) technology and gene editing of somatic cells hold great promise for improving the skin's regenerative capacity[71]. However, stem cell therapy still poses many questions regarding potential side effects and stem cell survival and differentiation within the hostile "chronic wound" environment.

Molecular Modeling of Growth Factors

Advances in biomaterial science and protein engineering are expected to contribute to the development of novel therapies for tissue repair. For example, the creation of protease-resistant growth factors might circumvent the imbalance in proteolytic activity that is characteristic of chronic wounds[72]. When growth factors were engineered to have enhanced binding to ECM molecules, they demonstrated augmented biologic properties associated with tissue repair[73]. This approach not only utilizes the ECM as a carrier, but it also mimics the natural interactions between growth factors and the ECM, which appears to be crucial for the physiologic actions of growth factors.

Biomaterials and Tissue Engineering

Currently, collagen- or fibrin-based products are the most commonly employed biomaterials for guiding tissue regeneration. They are used as carriers for transplanted cells, as acellular scaffolds, or as an immediate coverage for large trauma- or disease-associated skin defects[68]. However, their mechanisms of healing action remain speculative and well-controlled clinical trials are needed.

Preclinical studies of various synthetic materials are underway in which three-dimensional extracellular microenvironments are being used to mimic natural extracellular matrices[73]. For example, bioactive components, including heparin, cyclic Arg-Gly-Asp (RGD) adhesion peptides, and growth factors, have been integrated into polyethylene glycol (PEG)-based hydrogel matrices. Clinical studies will need to establish the physiologic relevance of these synthetic materials and their ability to encourage new tissue growth within wounds.

Wound Metabolism

Wound healing represents a metabolically demanding process and during the healing response cells have to adapt to their different metabolic requirements. In general, the resulting metabolites are regarded as waste products and cellular metabolism is viewed as necessary for controlling energy homeostasis. However, there is emerging evidence that metabolites have critical signaling functions and cellular metabolism is tightly linked to the orchestration of cell activation and function[74]. Enhanced understanding of how cell-intrinsic and -extrinsic metabolic changes are linked to wound healing will be important in the future as this could lead to the development of new diagnostic and therapeutic approaches that enforce endogenous repair mechanisms and normalize pathologic healing conditions[74].

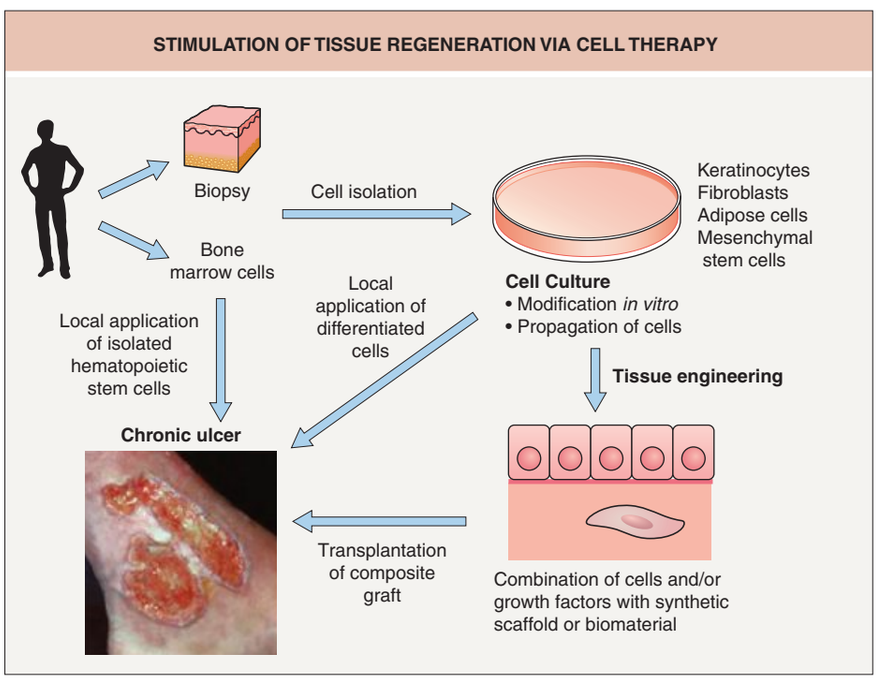


Fig. 141.10 Stimulation of tissue regeneration via cell therapy. Wounding stimulates the engraftment of bone marrow-derived stem/progenitor cells to the skin and induces bone marrow-derived cells to incorporate into skin structures. Therefore, bone marrow might provide a valuable source of stem cells for skin repair. Furthermore, differentiated cells can be isolated from skin biopsies, propagated and/or genetically modified *in vitro*, and either applied directly to the wound bed or combined with biologic/synthetic biomaterials to be applied as composite skin graft.

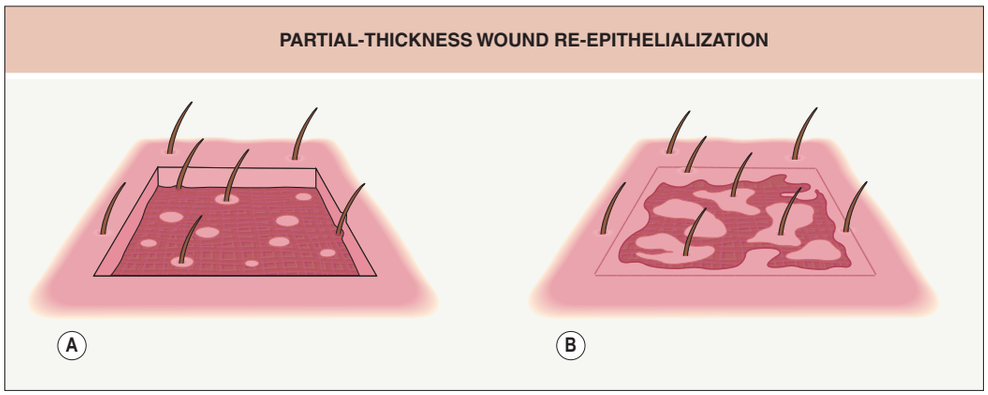
Advances in Systemic Drug Development



Chronic wounds and excessive tissue fibrosis are often symptoms of an underlying systemic disorder (e.g. vasculitis, pyoderma gangrenosum) or predisposing condition (e.g. older age). Over the past decade, there have been significant drug developments as well as an escalation in drug repurposing of immunomodulators (e.g. biologics, small molecules) and anti-aging medications (e.g. metformin, mTOR inhibitors). In other words, the efficacy of drugs that target a single cytokine or signaling pathway in several different organs (e.g. joints, gut, skin) has stimulated a shift from organ-based to molecular-based disease concepts[75]. Importantly, impaired cutaneous wound healing associated with inflammatory systemic disorders (e.g. vasculitic ulcers in rheumatoid arthritis, pyoderma gangrenosum) has been found to improve with cytokine-specific therapeutic strategies[16,75]. It is therefore likely that in the future patients with impaired wound healing will indirectly benefit from advances in drug development where the intended disease indications did not include enhanced wound healing.

Additional figures and tables on Chemical mediators of inflammation that play a role in wound healing and Different types of matrix metalloproteinases involved in wound repair, available in our eBook (see inside front cover for access code).

DIFFERENT TYPES OF MATRIX METALLOPROTEINASES INVOLVED IN WOUND REPAIR	
Enzyme	**MMP number**
Collagenase-1	MMP-1
Collagenase-2	MMP-8
Collagenase-3	MMP-13
Collagenase-4	MMP-18
Stromelysin-1	MMP-3
Stromelysin-2	MMP-10
Stromelysin-3	MMP-11
Gelatinase-A	MMP-2
Gelatinase-B	MMP-9
Matrilysin	MMP-7
Macrophage metalloproteinase (elastase)	MMP-12
MT1-MMP	MMP-14

eTable 141.2 Different types of matrix metalloproteinases (MMPs) involved in wound repair. MT1, membrane-type 1.

CHEMICAL MEDIATORS OF INFLAMMATION THAT PLAY A ROLE IN WOUND HEALING	
Chemical mediator	**Action**
Histamine	Increased vascular permeability
Serotonin	Stimulation of fibroblast proliferation Cross-linking of collagen molecules
Kinins	Increased vascular permeability
Prostaglandins	Increased vascular permeability
	Sensitize pain receptors
	Increased synthesis of GAGs
Complement	Increased vascular permeability
	Increased phagocytosis
	Enhanced bacterial lysis
	Mast cell and basophil activation

eTable 141.1 Chemical mediators of inflammation that play a role in wound healing. GAGs, glycosaminoglycans.

142 Surgical Anatomy of the Head and Neck

Franklin P. Flowers, Charya B. Goldsmith and Matthew Steadmon

Chapter Contents

Topographic Anatomy of the Head and Neck 2464
Skin Tension Lines 2465
Cosmetic Subunits 2467
Free Margins 2467
The Superficial Musculoaponeurotic System 2469
Muscles of Facial Expression 2471
Vascular Anatomy 2473
The Facial Nerve 2474
Sensory Innervation of the Head and Neck 2476
Lymphatic Drainage of the Head and Neck 2477

Key features

- The muscles of facial expression all arise from the second branchial arch, are concentrated in the central facial region, and receive their motor innervation from the facial nerve (cranial nerve VII)
- The superficial musculoaponeurotic system (SMAS) is a fibromuscular layer that ensheathes and connects the facial muscles and plays an intricate role in coordinating facial expressions
- The SMAS can be utilized as a guide to dissection, tissue mobilization, and closure, thereby minimizing trauma to neurovascular tissues
- The three branches of the trigeminal nerve (cranial nerve V) provide sensory innervation to the face, while various branches of the cervical plexus provide sensory innervation to the neck, parts of the ear, and posterior scalp
- Familiarity with the muscular and neurovascular structures of the head and neck region allows the surgeon to properly approach the "danger zones", e.g. Erb's point in the neck, the temporal nerve as it crosses the zygomatic arch, and the marginal mandibular nerve at the jawline just anterior to the masseter muscle
- The rich and anastomosing vascular supply of the face and scalp, derived from both the external and internal carotid arteries, explains the excellent healing potential and viability of local flaps and grafts in this region
- Cosmetic subunits and the junction lines separating them should be considered when planning excisions, repairs, and cosmetic procedures of the head and neck

The dermatologic surgeon must have a comprehensive knowledge of regional anatomy in order to obtain acceptable operative results. Proper tissue movement on the face and neck is essential for obtaining closures that are under minimal tension without cosmetic distortion or functional loss of vital structures. In addition to reducing postoperative morbidity, a fundamental appreciation for the macromechanics of the head and neck leads to preservation of tissue viability as well as sensory and motor innervation[1,2]. The fascial planes, vascular supply, innervation, and cosmetic subunits of the face must be considered when planning a surgical or cosmetic procedure. In order to accurately and thoroughly counsel patients regarding procedural risks and benefits, the surgeon must have a thorough appreciation of head and neck anatomy.

TOPOGRAPHIC ANATOMY OF THE HEAD AND NECK

It is possible to pinpoint underlying anatomic structures of the head and neck by observing surface anatomy. The bony structure of the face serves as a simple anatomic framework (Fig. 142.1). The supraorbital ridges are formed by the frontal bone and are more prominent in men. The supraorbital foramen transmits the supraorbital nerve (from the ophthalmic division of the trigeminal nerve) and its associated artery and vein. This foramen is palpable on the bony supraorbital ridge at the vertical midpupillary line. This line lies approximately one fingerbreadth lateral to the lateral nasal root or 2.5 cm lateral of the midline on the face (Fig. 142.2). Other important foramina lie in this midpupillary line and transmit important neurovascular bundles. The infraorbital foramen is located 1 cm below the infraorbital rim in the midpupillary line. It transmits the infraorbital nerve (from the maxillary division of the trigeminal nerve) and its associated artery and vein. The mental foramen lies in the same vertical line in the midportion of the mandible. The mental neurovascular bundle emerges here as a terminal sensory branch of the mandibular division of the trigeminal nerve.

The anterior border of the temporalis muscle can be palpated in the temporal fossa above the zygomatic bone. The latter bone forms the malar eminence of the cheek. The buccal fat pad provides fullness to the cheek; elderly or cachectic patients often have very prominent zygomatic arches. These arches form the widest points on the face and serve as the point of attachment for several muscles of facial expression and for the masseter muscle. The masseter muscle spans the zygomatic arch and mandibular ramus, serving as a muscle of mastication innervated by a motor branch of the trigeminal nerve (see below). This muscle is easily palpated by clenching the jaw.

The parotid gland lies beneath the subcutaneous fat of the lateral cheek and is invested by parotid fascia. The superficial lobe of the parotid covers the posterior half of the masseter muscle and extends from the preauricular sulcus to the angle of the mandible. The deep lobe lies on the medial side of the ramus of the mandible and is connected to the superficial lobe by an isthmus. The superficial temporal artery and vein, as well as branches of the facial nerve (which provides motor innervation to the muscles of facial expression), course through the parotid gland in channels between glandular tissue[3]. The duct of the parotid gland (Stensen's duct) travels across the anterior surface of the masseter muscle (Fig. 142.3). After crossing the muscle surface, the duct penetrates deeper to pierce the buccinator muscle and eventually drains into the mouth at the level of the second upper molar. It can be palpated as a "cord" crossing a clenched masseter muscle. If the duct is transected, a chronic draining fistula will form, requiring corrective surgical intervention. Stensen's duct can be identified topographically by drawing a line between the tragus and the midportion of the cutaneous upper lip. The duct traverses the masseter muscle at the middle one-third of this line (see Fig. 142.3).

Several structures of importance can be located by observing the surface anatomy of the neck. The sternocleidomastoid muscle is comprised of two heads originating from the sternum and the medial one-third of the clavicle. It inserts onto the outer surface of the mastoid process and nuchal ridge, dividing the neck into anterior and posterior triangles. A dermatologic surgeon should be familiar with the anatomic structures that lie within each of these topographic triangles. Although the sternocleidomastoid muscle covers and protects most of the major anatomic structures in the neck, the external jugular vein traverses its surface with many cutaneous sensory nerves of the cervical plexus (Fig. 142.4). In addition, the posterior triangle of the neck contains trunks of the brachial and cervical plexus as well as the spinal accessory

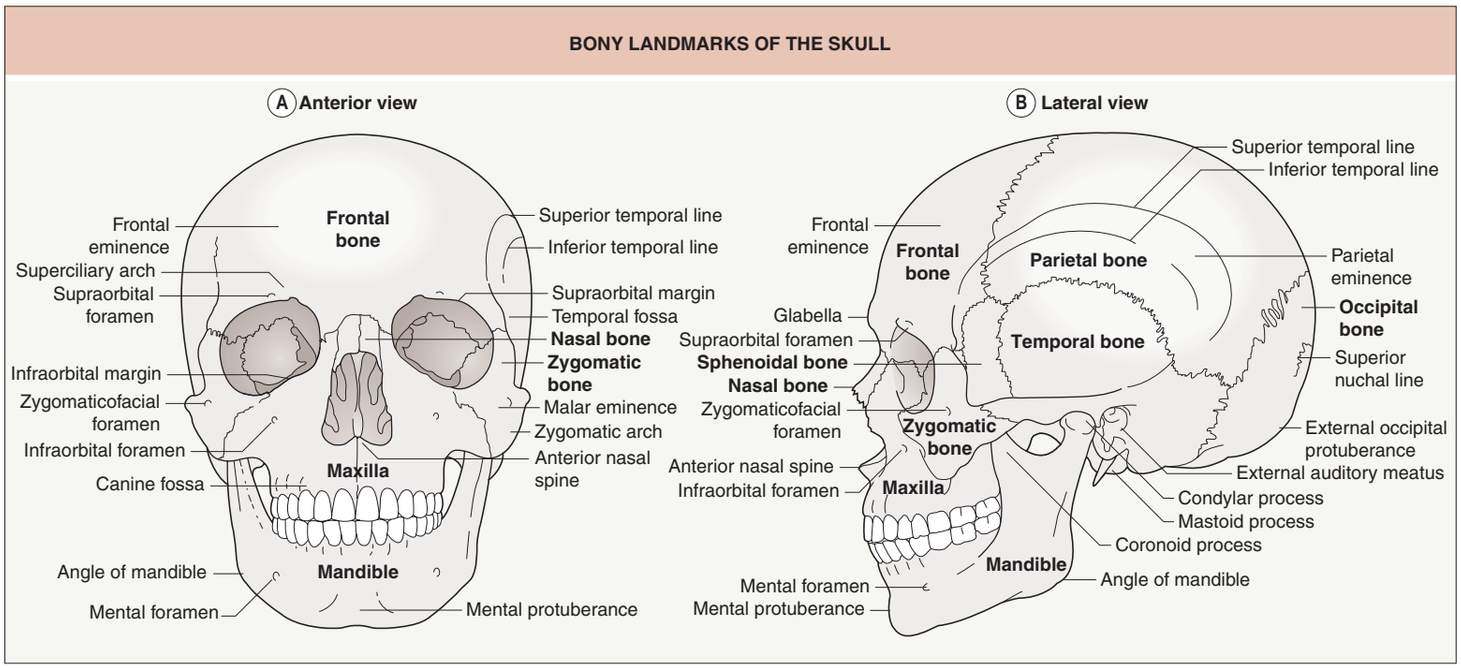

Fig. 142.1 Bony landmarks of the skull. A Anterior view. **B** Lateral view.

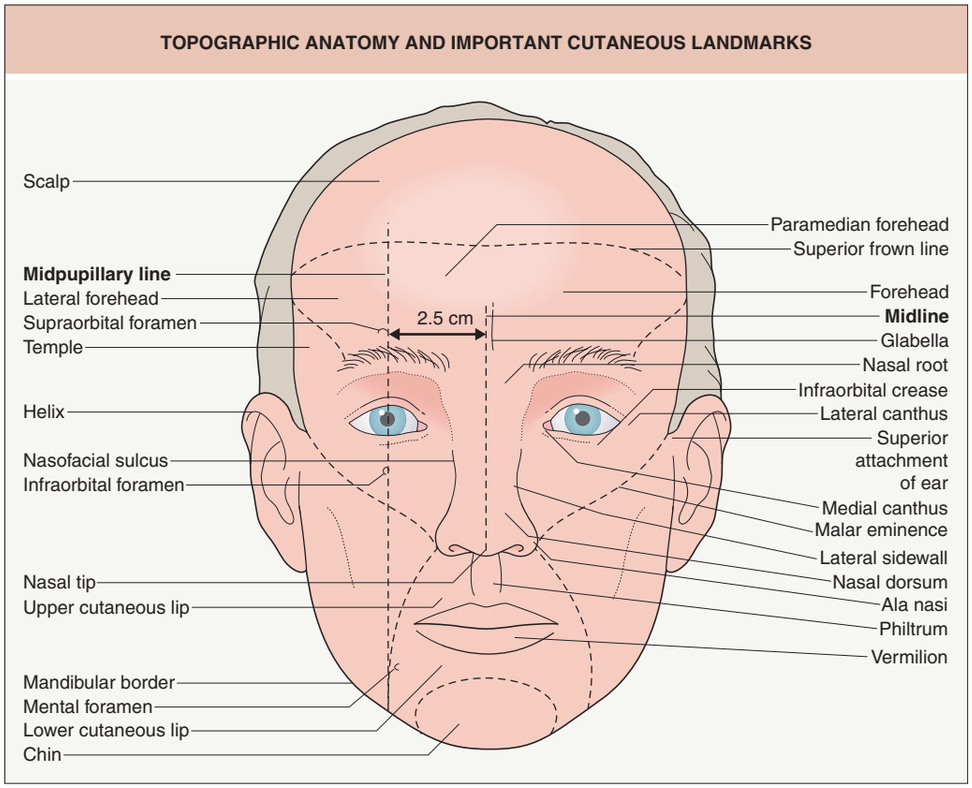

Fig. 142.2 Topographic anatomy and important cutaneous landmarks.

nerve (cranial nerve XI). Cranial nerve XI innervates the trapezius muscle of the back. It may be damaged when operating in the posterior triangle. This may result in chronic shoulder and neck pain, shoulder drop and trapezius atrophy, "winged" scapula, arm paresthesias, and the inability to abduct the arm greater than 80°.

Erb's point designates the area where the cervical plexus emerges from the posterior margin of the sternocleidomastoid muscle (see Figs. 142.4 & 151.6). The spinal accessory nerve also courses through this area on its way to the trapezius muscle (see Fig. 142.4). This surgical danger zone can be visualized by drawing a line connecting the angle of the jaw to the mastoid process. In an adult, a perpendicular line dropped 6 cm from the midpoint of this connector will intersect the posterior border of the sternocleidomastoid where the spinal accessory nerve and cervical plexus emerge[4]. Extreme caution is warranted when dissecting around these anatomic structures, in order to avoid loss of innervation to the trapezius muscle.

SKIN TENSION LINES

Collagen and elastin afford flexibility and extensibility to the skin, and derangements of their architecture or abundance contribute to the aging process. Wrinkles (rhytides) develop over time in predictable areas on

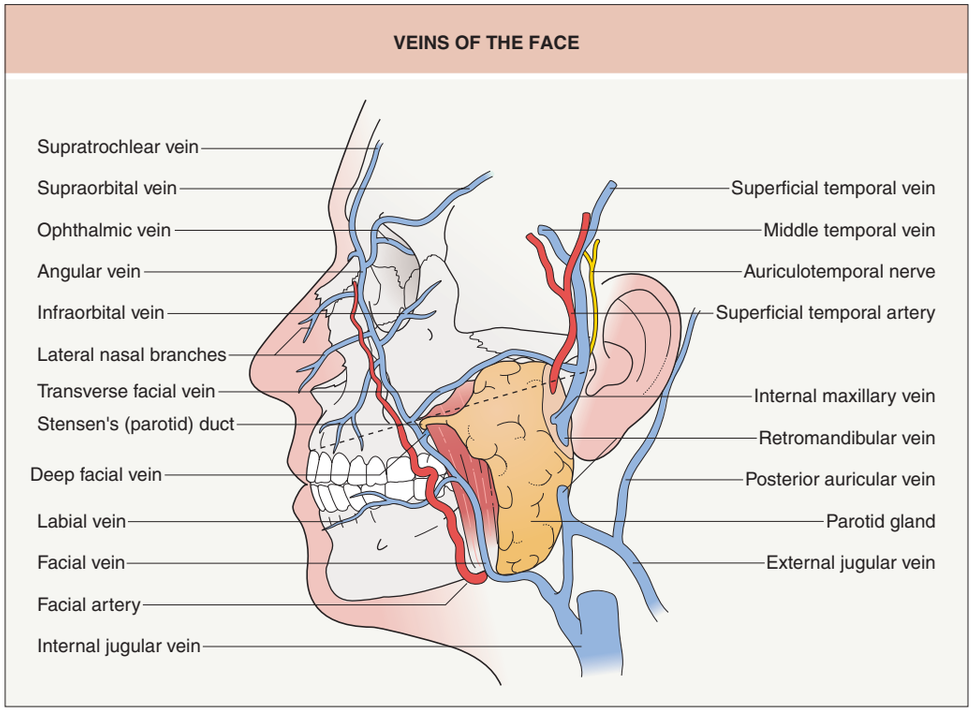

Fig. 142.3 Veins of the face. Stensen's duct can be identified topographically by drawing a line between the tragus and midportion of the cutaneous upper lip (dotted line). It can be palpated as a cord at the middle third of this line.

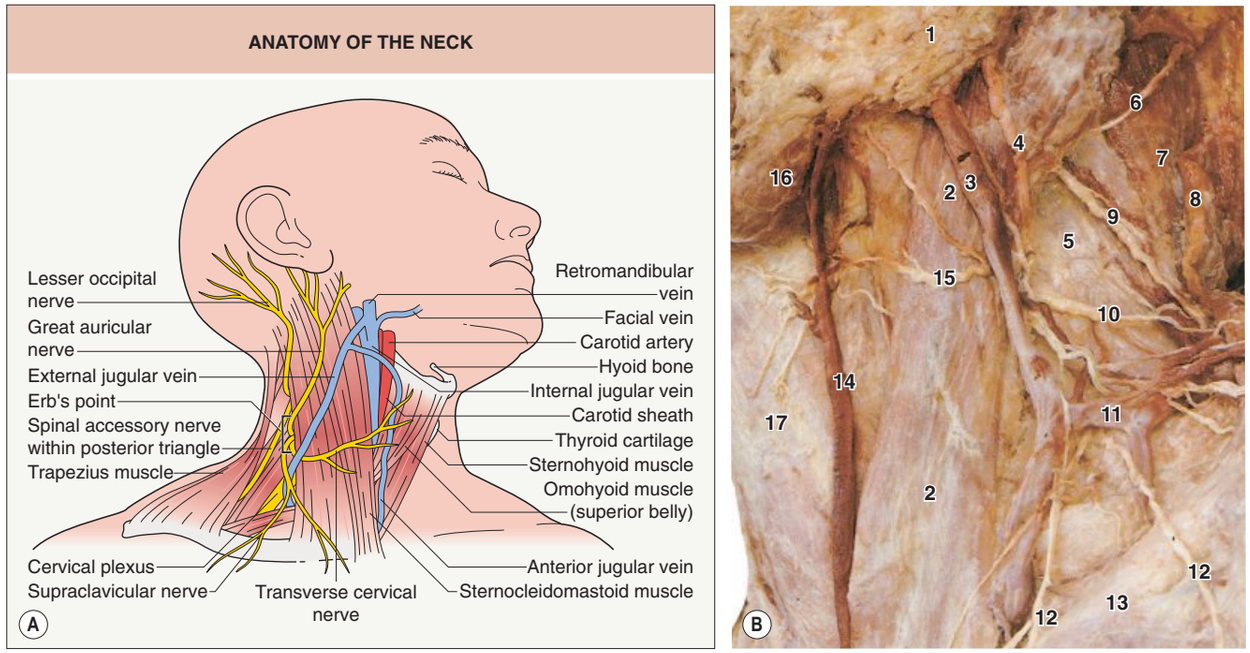

Fig. 142.4 Anatomy of the neck. A The sternocleidomastoid muscle (SCM) divides the neck into anterior and posterior triangles; Erb's point designates the area where the cervical plexus emerges from the posterior margin of the SCM. **B** The platysma was removed completely and the investing layer of deep cervical fascia was removed only from the posterior triangle. The following structures are identified: 1, parotid gland; 2, sternocleidomastoid muscle; 3, external jugular vein; 4, great auricular nerve; 5, prevertebral fascia overlying levator scapulae muscle; 6, lesser occipital nerve; 7, splenius capitis muscle; 8, trapezius muscle; 9, spinal accessory nerve; 10, cervical nerves to the trapezius; 11, superficial cervical vein; 12, supraclavicular nerves; 13, clavicle; 14, anterior jugular vein; 15, transverse cervical nerve; 16, submandibular gland; and 17, investing layer of deep cervical fascia. *B, From Logan B, Reynolds P, Rice S, Hutchings R. McMinn's Color Atlas of Head and Neck Anatomy. 5th ed. Neck superficial dissection II. London: Elsevier; 2017.*

the face. The fine wrinkles seen on an aged face may be referred to as the skin tension lines (Fig. 142.5); on the body, skin tension lines are an important consideration when designing surgical excisions (Fig. 142.6). Many environmental and intrinsic factors, such as ultraviolet exposure, smoking, underlying facial muscles, etc., contribute to the appearance of the expressive human face. A thorough understanding of the derivation and implications of skin tension lines is essential to successful dermatologic surgery.

Continuous tension is exerted on the skin of the head and neck by the muscles of facial expression. A complicated network composed of muscles, elastin, fibrous septae of collagen, and fascial planes contributes to this stress, which eventually results in sagging, wrinkling, and redundant skin. Collagen is flexible but much less extensible than elastic fibers. The resistance to tensile forces by collagen promotes a "youthful" appearance. Over time, the prolonged tension exerted on the skin from many factors forces collagen fibrils to accommodate by way of elongation. Eventually, aged skin manifests the consequences of persistent skin tension. The collagenous tissue becomes increasingly intertwined, diminished in volume, and permanently elongated. This causes the accentuation of skin tension lines[4].

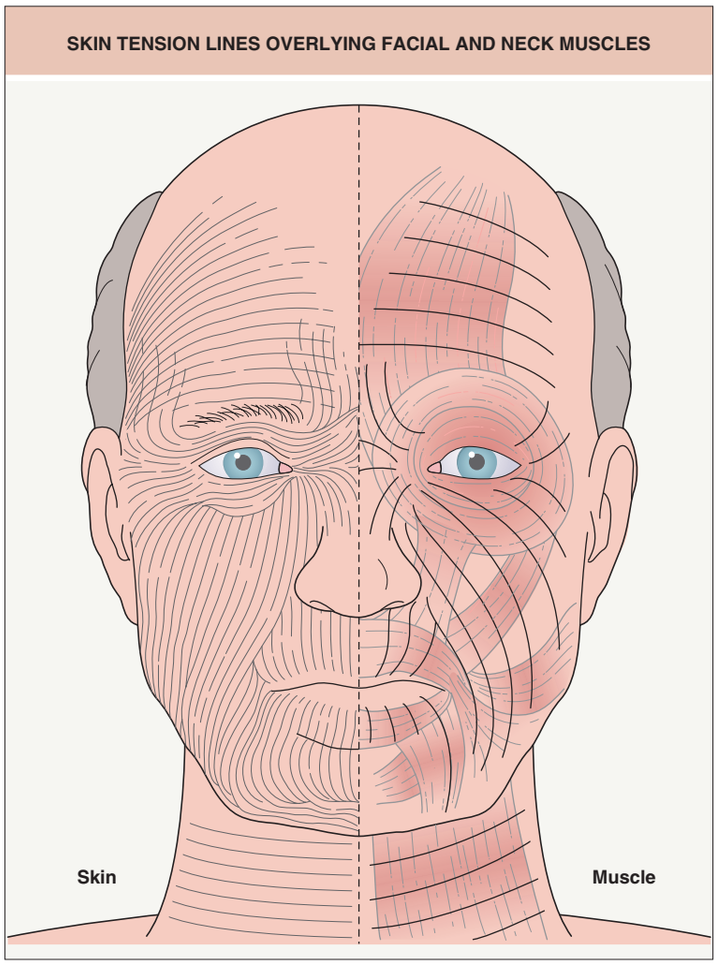

Fig. 142.5 Skin tension lines overlying facial and neck muscles. Note that wrinkles are often directed perpendicularly to the underlying muscle fibers of facial expression.

Elastic fibers promote extensibility (i.e. the ability of skin to stretch) and elasticity (i.e. the skin's capacity to restore its original shape after physical stress). They contribute to the skin tension lines by promoting vector distribution of tension along fascial planes. The elastic properties of the skin explain the phenomenon whereby round surgical wounds relax into an axis parallel to the patient's wrinkles. Tension vectors are increased parallel to the skin tension lines and are diminished perpendicular to them; therefore, the linear appearance of wrinkles is often directed perpendicularly to the underlying muscle fibers of facial expression (see Fig. 142.5). The continuous tension exerted on the overlying skin by these muscles challenges the competency of elastic tissue and collagen. They induce this geometric linearity via fibrous connections to the dermis via the SMAS. For example, the forehead undergoes transverse wrinkling due to contractions of the frontalis muscle, whose fibers run in a cephalocaudad direction. Periocular rhytides are often radially oriented due to underlying contraction of the orbicularis oculi. Similarly, perioral wrinkling occurs under the influence of the concentric orbicularis oris muscle, which induces a radial arrangement of skin tension lines. The procerus muscle causes transverse nasal root lines, and vertical glabellar lines are determined by the corrugator supercilii muscles (Fig. 142.7).

Knowledge of these functional anatomic principles is necessary in surgical and cosmetic dermatology. For example, the successful use of botulinum toxin for the diminution of rhytides requires an understanding of the anatomic relationships between various muscle groups and their influence on the skin tension lines. Proper surgical technique entails placement of incision lines parallel to the skin tension lines in order to achieve excellent cosmesis. It is helpful to determine and even sketch the patient's skin tension lines with a surgical marking pen. This will help orient the axis of incision and guide the closure parallel to, and preferably "buried" within, individual lines of tension.

COSMETIC SUBUNITS

Cosmetic units (i.e. aesthetic, topographic, or regional units) represent the major structural areas of the face that are separated by contour or junctional lines or boundaries (Fig. 142.8). Units are designated based upon their similarity in topographic anatomy, texture and color, solar exposure, hair density, and sebaceous features. The forehead, temples, eyelids, nose, cheeks, upper and lower lips, chin, and ears represent the major cosmetic subunits of the face. Within each division, smaller units are designated that further guide surgical closures. The junctional or contour lines between cosmetic units serve as excellent locations to place incisions and hide surgical scars. They include the hairline, alar and nasolabial creases, eyebrows, the philtrum, the labiomental crease, and the upper and lower vermilion–cutaneous interfaces (see Figs. 142.2 & 142.12).

In general, defects should be repaired with tissue from within the same cosmetic unit in order to preserve topographic consistency and to match skin color and texture. If this cannot be achieved, it is reasonable to utilize tissue from an adjacent aesthetic unit, which will most closely match the skin of the recipient cosmetic unit. The goal is to optimize the match in skin texture, color, actinic damage, and thickness. Scars that cross aesthetic units and boundary lines are obvious and often cosmetically unacceptable. A primary goal of cutaneous surgery is to "respect" the cosmetic subunits.

An appreciation for cosmetic units and contour lines also helps the surgeon determine areas of "recruitable" tissue for closures. Redundant or freely mobile skin can be mobilized from the preauricular folds, neck, nasolabial folds, temple, glabella, the lower and lateral cheeks, and the "jowls"[5]. The potential for such tissue recruitment depends on the patient's age, degree of actinic damage, and skin elasticity. Areas of redundancy or high elasticity may serve as excellent donor sites within or adjacent to the cosmetic subunit which contains a given surgical defect. For example, cheek advancement flaps and temple to lateral forehead advancement and rotation flaps are frequently used for defect repairs.

The forehead unit can be divided into the glabella, temple, and supra-eyebrow aesthetic subunits. The transverse creases of this region serve as excellent sites to place cosmetically acceptable incisional scars. The eyelids represent a major cosmetic subunit of the face whose subdivisions correspond to portions of the orbicularis oculi muscles[6] (Fig. 142.9). The inferior pretarsal portion of the upper eyelid is relatively fixed, while the preseptal unit becomes increasingly redundant with age. Over time, progressive laxity of the preseptal unit can cause functional visual impairment in some patients. It is the preseptal unit of the palpebral portion of the lid that is reduced in a blepharoplasty. The infraorbital crease lies between the lower eyelid and the upper cheek.

Nasal cosmetic subunits include the alar groove (which defines the ala nasi) and the columella, which extends from the nasal tip to the junction with the upper cutaneous lip. The root, dorsum, lateral sidewalls, soft triangles, and nasal tip are important landmarks that pose a significant challenge in dermatologic surgery (Fig. 142.10). The nasal tip unit forms the shape of a chevron or heart due to the anatomy of the nasal cartilage (Fig. 142.11). When possible, surgical defects should be contained within the boundaries of a given nasal subunit in order to produce acceptable cosmesis[7].

The philtrum is located above the upper vermilion lip and extends superiorly to the columella of the nose (Fig. 142.12). Because it is a midline structure, even minimal anatomic distortion results in a poor cosmetic outcome. The vermilion lip extends from the vermilion lip–cutaneous junction to the mucous membrane junction. It is a modified epithelium that usually does not contain adnexal structures or salivary glands. Approximation of the vermilion border is crucial to maintaining facial symmetry. The melolabial or nasolabial crease serves as a useful landmark that separates the cheek from the mouth and chin aesthetic units. It is an ideal place to hide suture lines and often serves as a generous donor site for repairs.

The external ear (auricle or pinna) consists of a single cartilaginous plate that results in the complex curves and folds of the ear (Fig. 142.13). The skin is loose on the posterior portion but tightly adherent on the anterior surface.

FREE MARGINS

Free margins of the face are anatomic structures that are in some way discontinuous with adjacent skin. They include the lips, helices, eyelids,

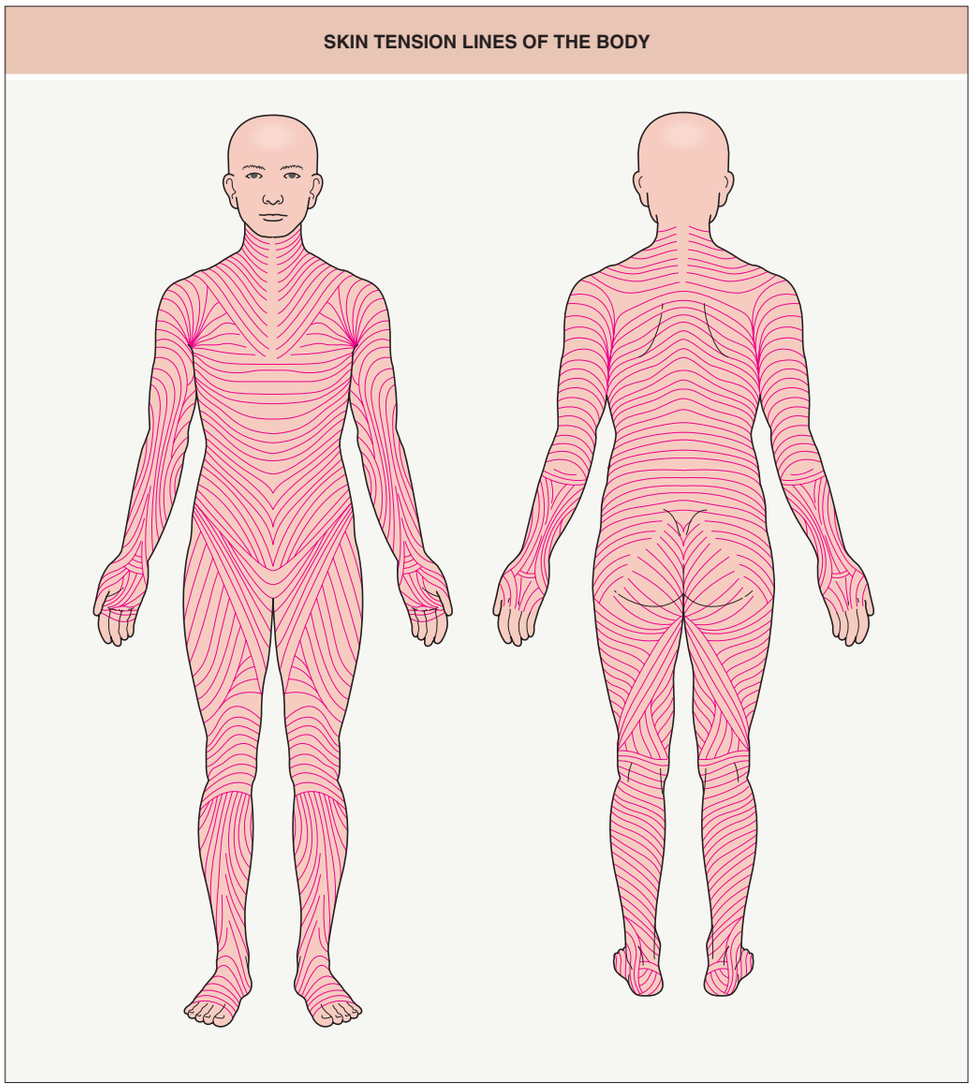

Fig. 142.6 Skin tension lines of the body. See Fig. 142.5 for the skin tension lines of the face and neck.

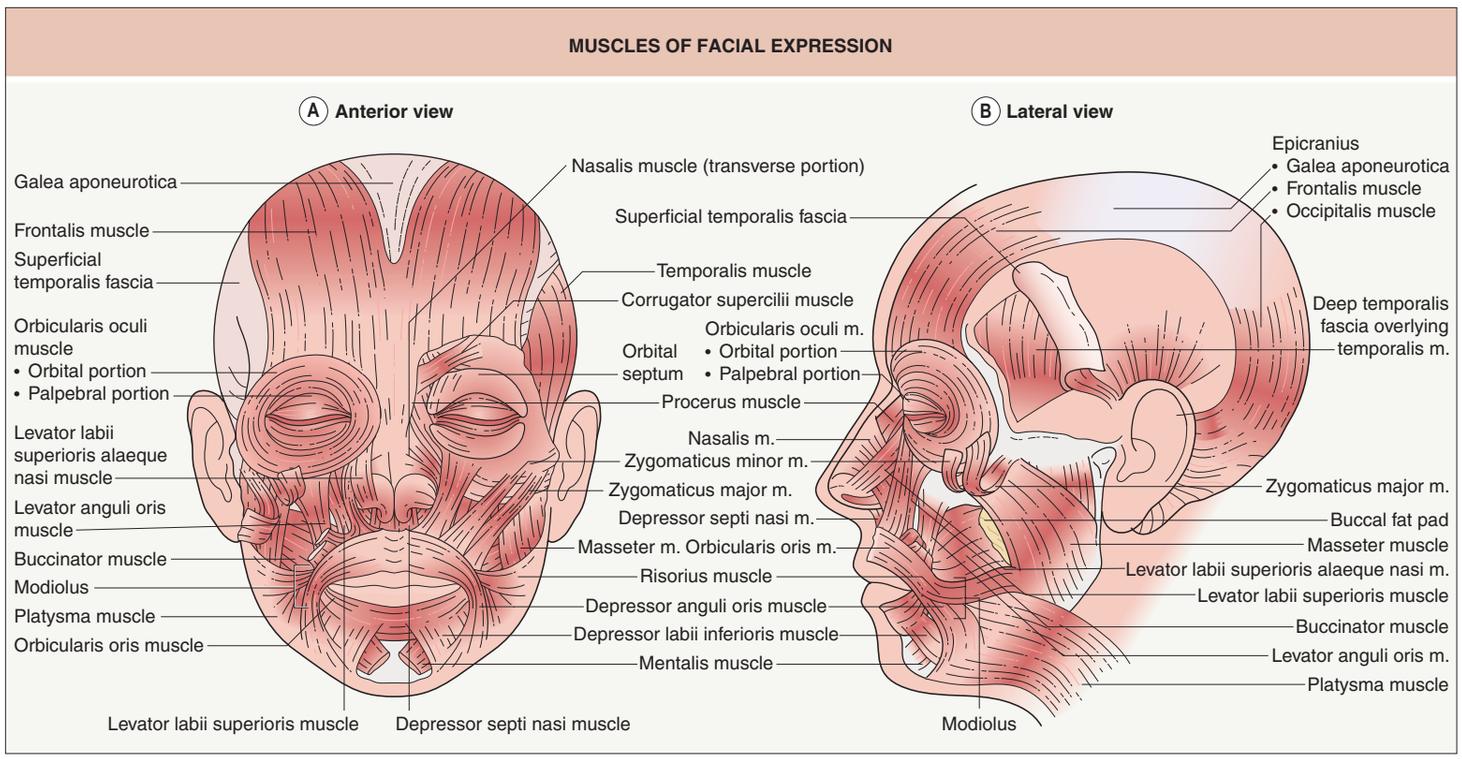

Fig. 142.7 Muscles of facial expression. A Anterior view. **B** Lateral view. The transverse portion of the nasalis muscle is identified. m, muscle.

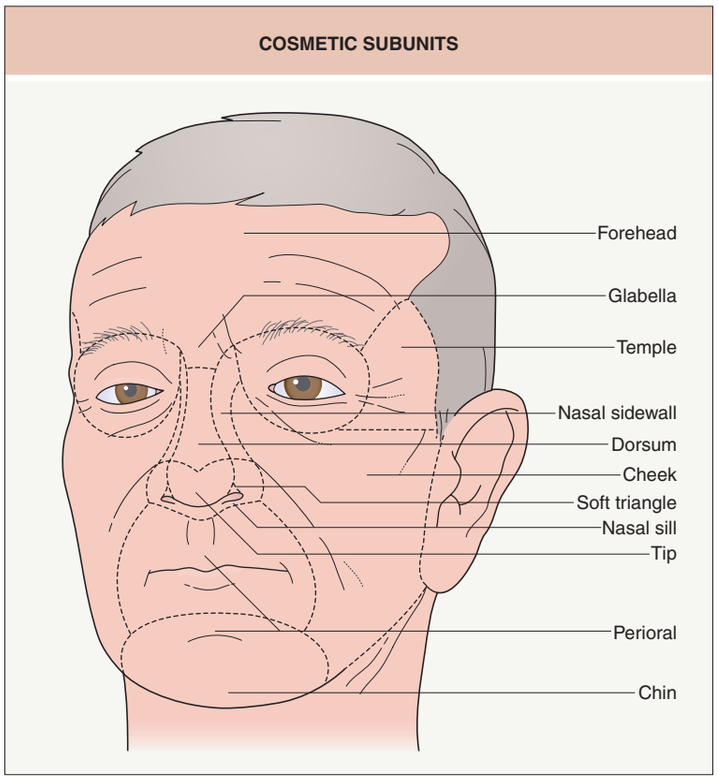

Fig. 142.8 Cosmetic subunits.

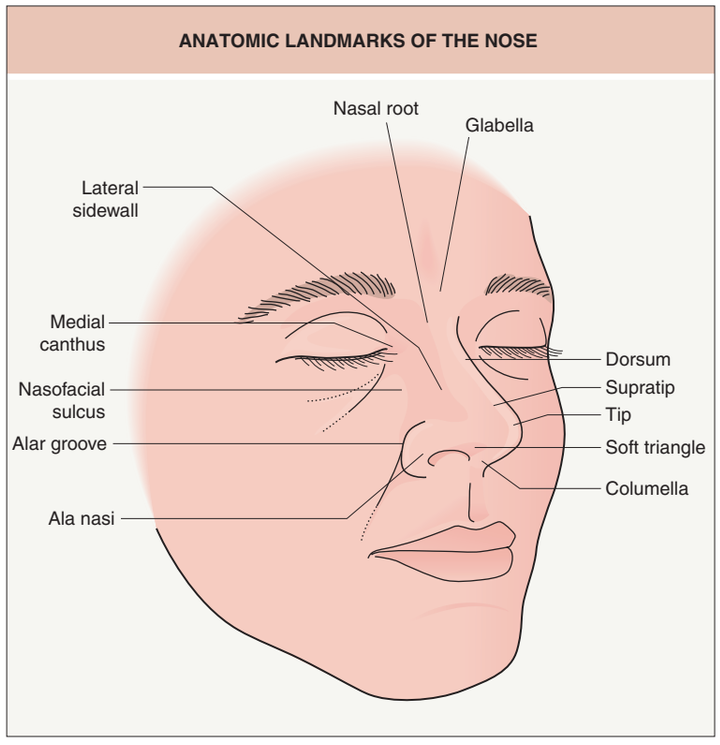

Fig. 142.10 Anatomic landmarks of the nose.

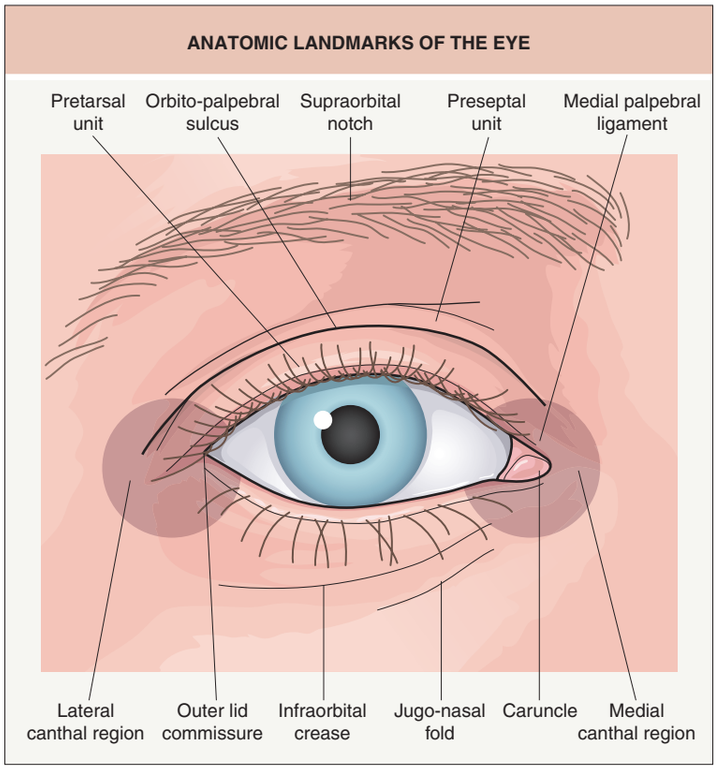

Fig. 142.9 Anatomic landmarks of the right eye.

and nostrils. These areas deserve special attention from the dermatologic surgeon because they do not have evenly distributed tension vectors. This characteristic makes the free margins especially vulnerable to any iatrogenic directional pull. Surgical closures, wound healing, and scar contraction can cause these free margins to lose their cosmetic or functional integrity. Ectropion (eyelid eversion) or eclabium (lip eversion) may ensue. Primary elliptical closures that are parallel to a free margin and second intention healing are not frequently used in these areas.

The opposing force inflicted upon a free margin depends on closure axis orientation, flap or graft design, and the tensile strength and elasticity of the skin. Aged skin is often less able to resist directional vectors. The lower eyelid often becomes especially lax with cumulative actinic damage and age. The "pinch" or "snap" test can be used in free margin evaluation by gently pulling the lower lid away from the eye. Upon release, a competent lower lid should assume its original shape against the globe, while a lax lid will regain its configuration slowly[4]. Instruct the patient to open his or her mouth and gaze upwards while simulating closure options under the eye. This generates the maximum intraoperative tension on the lower eyelid and can help to estimate the risk for distortion of this free margin. No more than 2 mm of inferior pull or "drag" on the lower eyelid can generally be tolerated during cutaneous surgical repairs. Any additional inferior tension puts the patient at high risk for ectropion[8].

Maintenance of cosmesis and function of the lip vermilion is of utmost importance. Elliptical closures often create drag on these free margins, but careful redirection of tension vectors may allow simple closures here. Flaps that can be performed in this area are reviewed in Chapter 147. Although the helical rims are free margins, they are far more "forgiving" than the aforementioned sites. Second intention healing and axial elliptical closures can achieve excellent results on the ear. The tissue is easily dissected and the posterior auricular skin provides excellent mobility. Most patients have some ear asymmetry at baseline, thus making this free margin less cosmetically sensitive.

The nasal tip, alae, and adjacent lateral sidewall require special consideration due to their classification as "free margins" and the underlying cartilage framework that prevents significant tissue mobility. Elevation and distortion of the nasal rim may occur if second intention healing or simple primary closure is attempted (see Fig. 148.9). Full-thickness skin grafts and transposition or rotation flaps from adjacent areas are particularly appealing repairs in this cosmetically sensitive area[9].

THE SUPERFICIAL MUSCULOAPONEUROTIC SYSTEM

The superficial musculoaponeurotic system (SMAS) or superficial fascia of the head and neck region plays an intricate role in coordinating and exaggerating facial expressions. It is a fibromuscular layer that ensheathes and connects the facial muscles. When the regional muscles contract, their impulse is distributed by the SMAS via fibrous

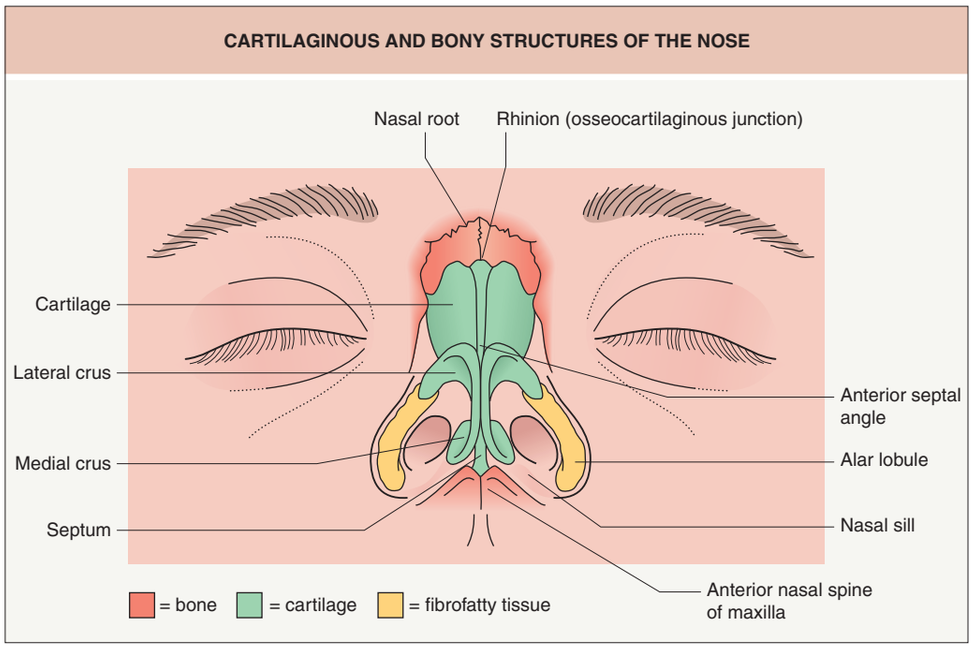

Fig. 142.11 Cartilaginous and bony structures of the nose.

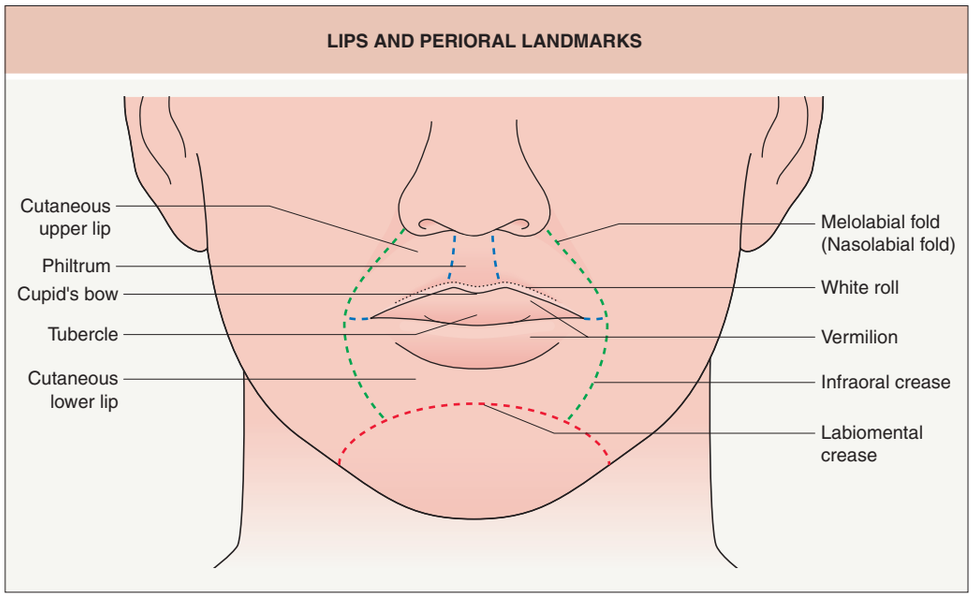

Fig. 142.12 Lips and perioral landmarks.

connections to the skin and other muscle groups. This contributes to organized movements, symmetry in facial expression, and the appearance of skin tension lines. In certain areas where facial musculature is absent, the SMAS layers form a thick, inelastic membrane. These regions are clinically identifiable as the galea aponeurotica of the scalp and the superficial temporalis fascia. Major anatomic structures predictably course in and around the superficial fascia. The dermatologic surgeon can maximize this relatively avascular dissection plane and minimize trauma to important neurovascular structures by using the SMAS as a guide to dissection, tissue mobilization, and closure. Rejuvenation procedures such as facelifts rely on the redistribution and manipulation or plication of the head and neck SMAS.

The deep fascia of the face covers bone, cartilage, muscles of mastication, and visceral structures. It is a continuous sheath, forming periosteum, perichondrium, temporalis muscle fascia, and the parotid–masseteric fascia[1]. This fascia is resistant to stretch and particularly impedes tissue movement on the scalp. Plication or suspension sutures are often used to "tack" overlying structures to the deeper fascia in order to secure tissue and redirect tension vectors.

The SMAS of the cheek is located between the skin and the deeper muscles of mastication. By mobilizing the preauricular SMAS plane, the anterolateral neck and lower cheek below the zygomatic arch can be repositioned as a whole. The SMAS of the cheek is continuous with the orbicularis oculi muscle of the lower eyelid and has several bony attachments in the periocular region[10]. Note that the SMAS of the upper face is discontinuous with the SMAS below the zygoma. This separation is due to different embryologic development patterns of the upper and lower facial muscle groups. The galea aponeurotica of the scalp and the fascia of the superficial temporalis muscle split to envelop the frontalis muscle of the forehead and the occipitalis muscle of the posterior scalp. This superior SMAS terminates 1 cm below the zygomatic arch.

The parotid gland, Stensen's duct, and emerging branches of the facial nerve lie on the deep masseteric fascia. They are covered by thin fibrotic platysma remnants called the parotid fascia, which is covered by the SMAS. The aponeurotic investiture of the central face is thin and often indistinct. The intrinsic nasal muscles and lip elevators and depressors are essentially devoid of superficial fascial interconnections. This makes dissection in this area challenging, because the planes are often difficult to establish and many important anatomic structures are under threat of compromise.

Large sensory nerves and axial blood vessels that supply the face ascend to lie within the SMAS or between the SMAS and subcutaneous fat (Fig. 142.14). Motor nerves run deep to the SMAS and penetrate the muscles of facial expression from their undersurface. Knowledge

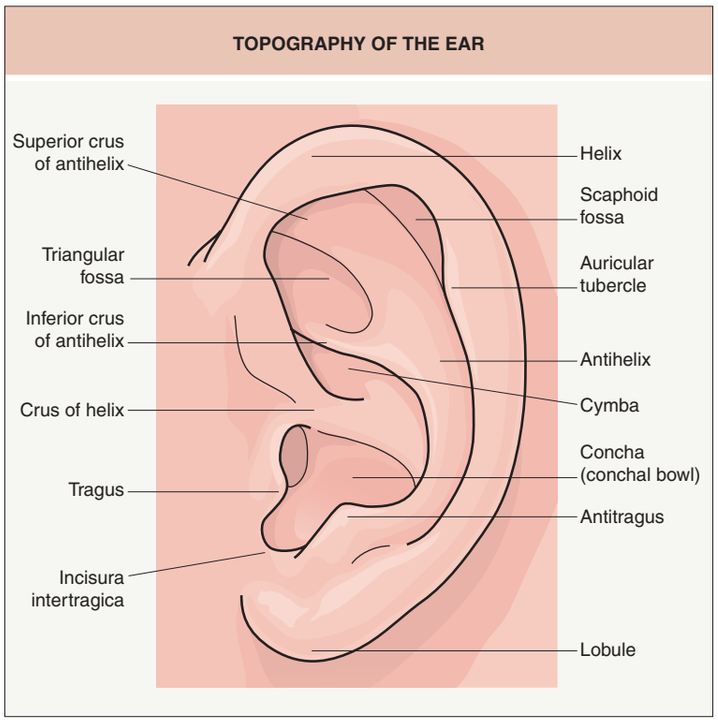

Fig. 142.13 Topography of the ear.

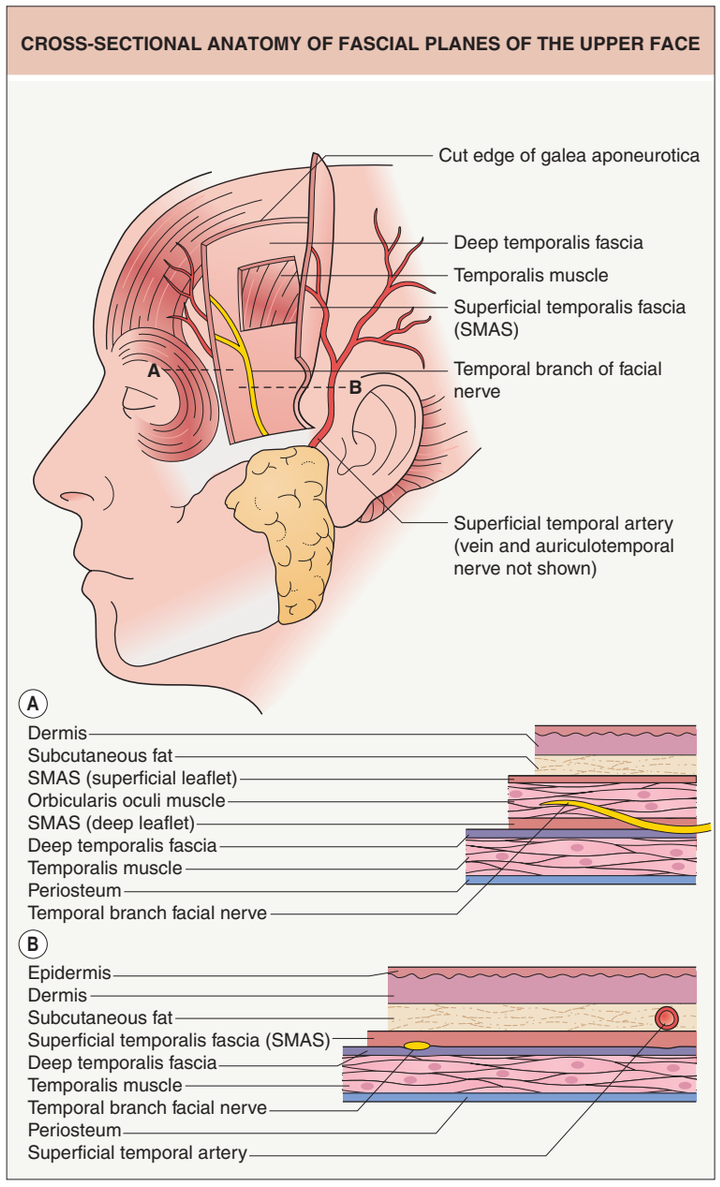

Fig. 142.14 Cross-sectional anatomy of fascial planes of the upper face. SMAS, superficial musculoaponeurotic system.

of these anatomic relationships assists the surgeon in establishing a relatively avascular and safe plane of dissection. Blunt dissection of the scalp SMAS separates the galea aponeurotica from the skull periosteum, the superficial temporalis fascia from the deep temporalis fascia, and the subfrontalis SMAS from the forehead periosteum. This is called the subgaleal plane, and it is the ideal avascular dissection plane for scalp surgery. Beware of the supraorbital/supratrochlear neurovascular bundles above the eyebrows when dissecting to the deep galea, as these can be damaged as they exit their respective foramina. In the SMAS–parotid fascial plane of the cheek, the buccal and zygomatic branches of the facial nerve are endangered due to thin protective aponeurotic tissue in this area. The superficial temporal vessels and auriculotemporal nerve course within the superficial temporalis fascia above the zygomatic arch, then assume a superficial plane in the subcutaneous fat.

Surgical undermining and dissection should maximize the horizontal planes provided by the superficial fascial network of the head and neck. Undermining in the subcutaneous fat of the face below the subdermal plexus minimizes the risk to motor nerves, but remember that sensory branches and blood vessels course through this area. There is sparse subcutaneous fat on the dorsal nose, forehead, upper lip, and eyelid. With the exception of the forehead where dissection is usually in the subgaleal plane, the ideal dissection plane in these regions lies just superficial to the thin investing fascia (SMAS) covering the regional muscles of facial expression[11].

In short, the SMAS acts as a unifying infrastructure to the head and neck that creates an anatomic plane for identification and protection of key structures. Knowledge of neurovascular anatomy with respect to the superficial investing fascia will promote effective surgical dissection and closures that minimize functional compromise and maximize cosmesis.

MUSCLES OF FACIAL EXPRESSION

The muscles of facial expression arise from the second branchial arch, are innervated by the facial nerve (cranial nerve VII), and are concentrated in the central facial region. They insert into overlying skin and other local muscle groups and contribute to the relaxed skin tension lines of this region. Fluidity of facial movements is orchestrated by their interaction with the SMAS. A surgeon must have detailed knowledge of these muscles and the potential consequences of disrupting their innervation (Table 142.1).

The epicranius or occipitofrontalis muscle of the scalp has an anterior and posterior region connected by the galea aponeurotica (see Fig. 142.7).

Contraction of these muscles allows the skin to slide over the scalp. However, humans no longer have voluntary control of the posterior muscle group, which is innervated by the posterior auricular branch of the facial nerve. The *frontalis* muscle, a member of the epicranius complex, begins at the anterior hairline and inserts into the forehead and eyebrow skin. It also connects with the procerus, orbicularis oculi, and corrugator supercilii muscles. Midline vertical forehead skin tension lines occur due to variation in distance between the left and right frontalis bellies. Horizontal skin tension lines occur perpendicular to the frontalis contractile orientation (see Fig. 142.5).

The small *periauricular* muscles, also referred to as the temporoparietalis group, arise from the superficial temporalis fascia and the lateral galea. They help draw back the temporal skin and are innervated by the posterior ramus of the temporal branch of the facial nerve. The *orbicularis oculi* muscle complex is the major group that acts on the eyelid and periorbital skin. It inserts into the medial and lateral canthal tendons and encircles the eye region. Its palpebral portion has a preseptal component overlying the orbital septum and a pretarsal portion overlying the tarsal plate of the eyelid. The orbicularis oculi is intertwined with the procerus, corrugator supercilii, and frontalis muscles and attaches to the superficial temporalis fascia at its lateral border[12].

The *corrugator supercilii* muscle is located over the medial upper orbital rim. It contributes to a "scowling" facial expression by drawing

MUSCLES OF FACIAL EXPRESSION INNERVATED VIA CRANIAL NERVE VII (THE FACIAL NERVE)			
Muscle	**Innervation – facial nerve branch(es)**	**Functions**	**Ipsilateral complications from functional loss**
Frontalis	Temporal	• Raises eyebrows • Aids in opening eyes widely (in conjunction with orbicularis oculi)	• Flattening of horizontal forehead tension lines • Inability to raise lowered/"droopy" eyebrow • May be unable to open eyes widely • Only 15% of patients have cross-innervation*
Corrugator supercilii	Temporal	• Draws brows medially & downward (scowl expression)	• Difficulty scowling/furrowing brow • Rarely occurs due to cross-innervation†
Orbicularis oculi – upper portion	Temporal	• Closes upper eyelids • Voluntary tight closure (orbital component) • Gentle eye closure & blinking (palpebral component) • Aids in tear extraction (palpebral component)	• Difficulty with eye closure • Rarely occurs due to cross-innervation†
Auricular – anterior and superior (also referred to as temporoparietalis)	Temporal	• Draws back temporal skin	
Auricular – posterior	Posterior auricular	• Draws back temporal skin	
Orbicularis oculi – lower portion	Zygomatic	• Closes lower eyelids • Tight and gentle eye closures – similar to upper portion (see above) • Aids in tear extraction	• Difficulty with tight eyelid closure • Lower eyelid droop • Complete loss uncommon due to cross-innervation by temporal branch
Nasalis – alar portion	Zygomatic	• Facilitates alar flaring & compression	
Procerus	Zygomatic	• Causes foreshortening of the nose & "bunny" lines (with nasalis)	
Levator anguli oris	Zygomatic and buccal	• Elevates & retracts mouth angles	• Difficulty smiling • Difficulty with lip seal
Zygomaticus major	Zygomatic and buccal	• Elevates & retracts mouth angles	• Difficulty smiling • Difficulty with lip seal
Buccinator	Buccal	• Pursing of lips • Apposition of cheeks to teeth & gingivae • Prevents cheek overextension during high intraoral pressure	• Inability to whistle • Food accumulates between teeth & buccal mucosa with chewing
Depressor septi nasi	Buccal	• Pulls columella down toward lip	
Nasalis – transverse portion	Buccal	• Facilitates alar flaring & compression	
Zygomaticus minor	Buccal	• Elevates & retracts mouth angles	• May have an effect on smiling expression
Levator labii superioris	Buccal	• Elevates upper lip	
Risorius	Buccal and/or marginal mandibular	• Elevates & retracts mouth angles	• Asymmetric "crooked" smile at rest
Orbicularis oris	Buccal and marginal mandibular	• Pursing & puckering of lips • Apposition of corners of the mouth • Pulls lips against teeth & gingivae	• Difficulty with feeding • Drooling • Muffled speech • Inability to enunciate the letters M, V, F, P, or O
Depressor anguli oris	Marginal mandibular	• Depresses & retracts lip	• Inability to smile‡
Depressor labii inferioris	Marginal mandibular	• Depresses & retracts lip	• Inability to smile‡
Mentalis	Marginal mandibular	• Depresses & retracts lip • Elevates chin • Protrudes lower lip • Dimpling of chin	• Inability to smile‡
Platysma	Marginal mandibular and cervical	• Minor role in retracting mouth angles	

*By the zygomatic branch of the facial nerve.
†By other motor nerves.
‡Normal at rest, but asymmetric expression when smiling.

Table 142.1 Muscles of facial expression innervated via cranial nerve VII (the facial nerve)[4]. Due to a high degree of anastomoses, damage to the zygomatic or buccal branches is often temporary and less debilitating than a similar injury to the temporal branch.

the eyebrows medially and downward. It interdigitates with and is covered by the frontalis and orbicularis oculi muscles. The vertical and oblique skin tension lines of the glabella are caused by contraction of this muscle. The *procerus* muscle overlies the nasal bone and attaches to the nasal root skin. It is responsible for "bunny lines", i.e. skin tension lines exaggerated by wrinkling up the nose. Adjacent to the procerus is the *nasalis* muscle, which courses across the nasal dorsum. Inferiorly, the *depressor septi nasi* muscle, which lies deep to the orbicularis oris, pulls the columella down toward the lip and can form a transverse skin tension line across the philtrum.

An intricate network of interdigitating agonist and antagonist muscle groups contributes to lip movements and oral expression. Lip elevators, depressors, and retractors assist the sphincteric *orbicularis oris* muscle in lip movement. The orbicularis oris muscle is unique in that it has no

bony or cartilaginous attachment. Facial arteries and veins are covered and protected from damage by the lip elevator muscles. The quadratus labii superioris muscle group is comprised of several lip elevators. The *levator anguli oris* and *risorius* muscles are mouth angle retractors and elevators. The *zygomaticus major* muscle travels from the zygoma downward and diagonally to the upper corner of the mouth, where it contributes to the nasolabial fold. *Zygomaticus* major and *minor* muscles are the main contributors to smile formation. The risorius muscle also contributes to a smiling facial expression. The modiolus platform is formed by the convergence of fibers from the orbicularis oris and lip elevators and depressors. It is located 1 cm lateral to the mouth angle and accounts for cheek "dimples" in some patients. It works in synergy with the perioral muscles to facilitate speech enunciation.

The *buccinator* muscle constitutes a large area of the cheek as it courses from the posterior maxillary area to the upper medial surface of the mandible, where it interdigitates with the orbicularis oris. The facial vascular bundle crosses its surface. The parotid duct and transverse facial artery run parallel to each other as the duct pierces the buccinator to enter the mouth at the second maxillary molar. The *depressor anguli oris* (triangularis), *depressor labii inferioris* (quadratus), and the *mentalis* muscles are lip depressors and retractors that antagonize the superior perioral muscle groups. The mentalis muscle has bellies with variable proximities to each other, and a patient with a chin "dimple" or "cleft chin" has a larger distance between mentalis muscle bellies. This is a normal anatomic variant.

The *platysma* muscle runs from the superficial fascia of the chest across the anterior and lateral neck over the mandible to intercalate with the lower lip depressors and retractors. It is continuous with the superficial fascia or SMAS of the lower face. The platysma muscle provides only a thin protective cover to the anterior facial vascular bundle and mandibular branch of the trigeminal nerve.

VASCULAR ANATOMY

The internal carotid artery supplies the eyelids, upper nose and nasal dorsum, forehead, and scalp via sub-branches of its ophthalmic branch. The ophthalmic artery arises behind the eye and branches into the orbital and ocular group. The ocular group supplies the eye itself and its associated muscles. The orbital group includes the supraorbital, supratrochlear, dorsal nasal, and anterior ethmoidal arteries (Fig. 142.15). The supraorbital artery exits the orbit through the supraorbital foramen alongside the supraorbital nerve and perforates the frontalis muscle to ultimately course in the subcutaneous tissue of the forehead and scalp. The supratrochlear artery exits the medial orbit and courses medial to the supraorbital artery to supply the nasal root and the low midline forehead. This artery serves as the axial blood supply for the midline forehead flap often used to repair nasal defects. The success of this flap depends upon isolation and preservation of the supratrochlear artery. The anterior ethmoidal artery exits the nasal passage at the interface of the nasal bone and nasal cartilage to provide arterial supply to the nasal dorsum. The dorsal nasal artery and supratrochlear artery are two of the terminal branches of the ophthalmic artery. The dorsal nasal artery supplies the dorsal nose and crosses the midline over the nasal root to anastomose with the contralateral angular artery. Knowledge of the ophthalmic artery and its branches is of particular importance when planning cosmetic filler injection. Because of their proximal connections, the orbital group of vessels represents a potential site for embolus introduction into the central retinal artery that can lead to complications including blindness (see Fig. 142.15)[13].

While the internal carotid artery contributes to some areas of the scalp and upper face, the external carotid artery supplies most of the face. The facial artery branches off from the external carotid artery and courses deep to the mandible up through or behind the submandibular salivary gland. It passes over the mandible onto the face and can be palpated anterior to the masseter muscle. Its tortuous course maintains a diagonal and superior direction passing alongside the nose and terminating at the medial canthus where it anastomoses with the dorsal nasal artery. The platysma and risorius muscles protect the facial artery near the mandible. As the vessel traverses up the face, it becomes covered by the zygomaticus muscles of the midface and the orbicularis oculi as it nears the medial canthus.

The facial artery gives rise to the inferior and superior labial arteries that course horizontally below and above the lips, respectively. These arteries are found deep to the orbicularis oris in the submucosal plane, but can course more superficially into the submucosa of the lip in elderly patients. After forming the superior labial branch, the facial artery becomes known as the angular artery (Fig. 142.16). At its endpoint near the medial canthal tendon, the angular (or facial) artery anastomoses with the dorsal nasal branch of the ophthalmic artery. Since the ophthalmic artery is a branch of the internal carotid system, this anastomosis joins the internal and external carotid arterial systems. During most of their course, the facial artery and vein are covered by the superficial muscles of facial expression. The facial artery also anastomoses with branches of the internal maxillary (the infraorbital branch)

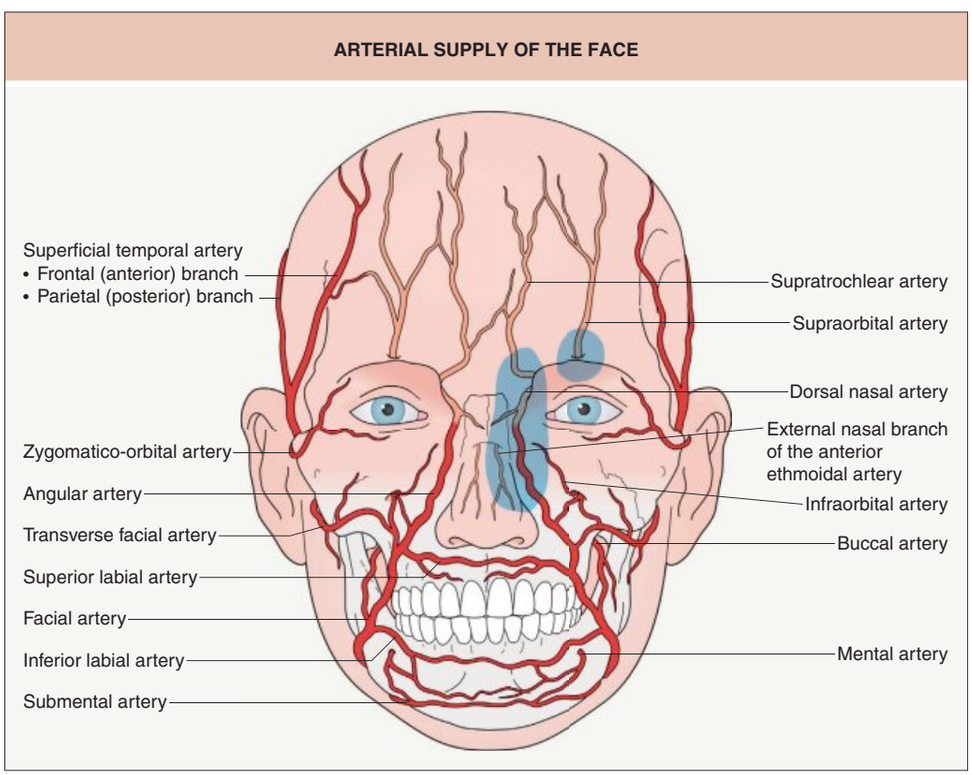

Fig. 142.15 Arterial supply of the face. Light pink designates arteries derived from the internal carotid artery; dark pink, from the external carotid artery. Blue highlighted areas denote high risk for filler injection.

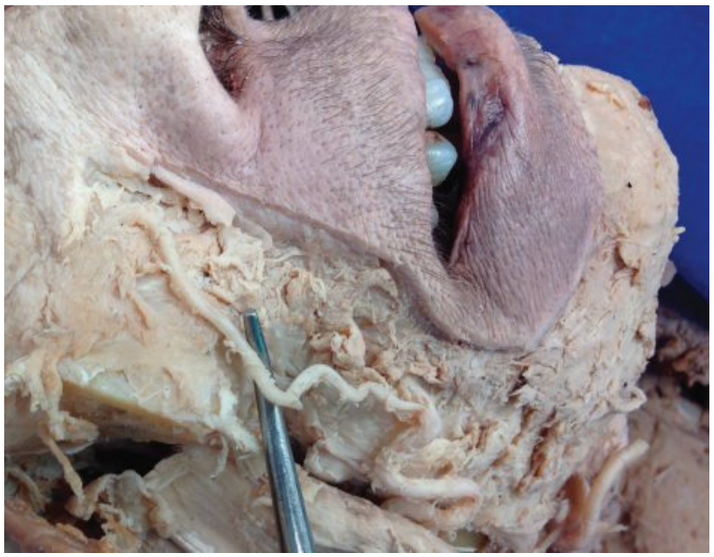

Fig. 142.16 The angular artery. After forming the superior labial branch, the facial artery becomes known as the angular artery.

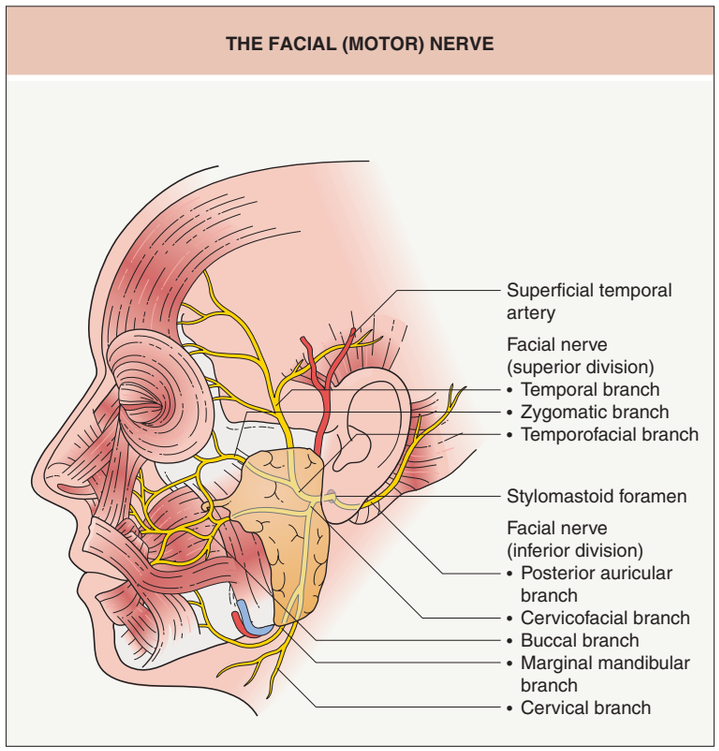

Fig. 142.17 The facial (motor) nerve.

and superficial temporal (transverse facial) arterial trees. This allows excellent blood supply to the facial skin even if distal arterial branches are cut or tied off during surgery. The high density of arterial supply to the head and neck accounts for its excellent healing potential and viability of local flaps and grafts.

The lateral face, scalp, and forehead are primarily supplied by the superficial temporal artery and its branches. This artery arises in the superficial lobe of the parotid gland as the terminal branch of the external carotid artery. It courses superficially to the main facial nerve trunks, then gives off the transverse facial artery before exiting the parotid gland superficially. The transverse facial artery runs parallel to and 2 cm below the zygomatic arch[4]. The superficial temporal artery exits the parotid and enters the subcutaneous fat in the preauricular crease, where it assumes an ascending vertical course over the zygomatic arch (see Fig. 142.14). It can be easily palpated just medial to the upper tragus of the ear. It runs alongside and superficial to the auriculotemporal nerve within, then above, the SMAS layer of the temple and lateral forehead. The most superficial portion of the superficial temporal artery is often visible in aged patients within the subdermal fat above the galea aponeurotica as it courses cephalad above and anterior to the ear. Here it forms the frontal (anterior) and parietal (posterior) arterial branches that originate just above the uppermost attached portion of the ear (see Fig. 142.15). The forehead, eyebrows, and lateral scalp receive their arterial supply from these branches of the superficial temporal artery. There are many anastomoses on the scalp between the bilateral superficial temporal arteries. Because of this rich supply chain, the entire scalp tissue remains viable even if one of these arteries is occluded. This rich anastomotic network also explains why scalp surgery can be a bloody process. Surgical dissection at the level of the galea aponeurotica may serve to avoid transection of the copious subdermal vascular supply.

Most of the arteries of the face run anterior to and parallel with their corresponding veins (see Fig. 142.3). The veins lack valves and therefore permit two-way flow of venous blood. The facial vein connects to the deep facial vein as it drains the cheek. The deep facial vein parallels the internal maxillary artery and anastomoses with the pterygoid venous plexus medial to the upper mandibular ramus. The facial vein crosses over the submandibular gland, while its corresponding artery passes beneath. It then drains into the internal jugular vein, which connects with the external jugular vein via the retromandibular vein. The facial vein can communicate with the cavernous sinus of the brain via the ophthalmic vein or the pterygoid plexus. The paranasal area and upper lip are the regions drained by this network. This interface may permit skin or wound infections to gain access to the cavernous sinus of the brain from the draining facial or ophthalmic veins, with potentially devastating consequences.

Arterial blood supply to the face is delivered by a rich subdermal plexus that is fed by larger perforating arteries. Wound healing and flap success depend on maximal blood supply to the area. Axial flaps, such as the paramedian forehead flap, incorporate a named subcutaneous artery (e.g. the supratrochlear artery) into their design. Random pattern flaps are maintained by the subdermal arterial plexus and do not rely on a single feeder artery to maintain blood flow. The anastomotic vascular network permits facial arteries to be clamped or tied off during surgery without compromising tissue viability. Nearby ipsilateral or contralateral anastomotic arterial branches can often compensate for any loss in local blood supply.

THE FACIAL NERVE

The muscles of facial expression are innervated by the facial nerve, or cranial nerve VII. Upon exiting the skull at the stylomastoid foramen near the level of the earlobe, the facial nerve immediately gives off the posterior auricular branch, which provides motor innervation to the occipitalis and posterior auricular muscles (Fig. 142.17). The remainder of the nerve trunk enters the parotid gland and bifurcates into the lower cervicofacial and the horizontally oriented temporofacial branches. The temporal, zygomatic, buccal, marginal mandibular, and cervical branches arise from these two major rami of the facial nerve. If a line is drawn from the superior border of the tragus to the angle of the mandible, the entrance site of the facial nerve trunk into the parotid gland lies at the midpoint.

After coursing through glandular parotid tissue, branches of the facial nerve travel between the SMAS and the deep fascia before penetrating the lateral underside of the facial muscles. There is significant variability in the course and arborization of this nerve from patient to patient. Cranial nerve VII has two major roots, the smaller of which, via the chorda tympani branch, provides taste sensation to the anterior two-thirds of the tongue; the chorda tympani nerve travels with the lingual nerve (cranial nerve V_3) to the tongue. Sensory innervation to a portion of the external auditory meatus, soft palate, and pharynx is also derived from this small facial nerve root. The submaxillary, submandibular, and lacrimal glands contain parasympathetic fibers of the facial nerve that have secretory effects. In addition to the muscles of facial expression (see Table 142.1), the buccinator, stapedius, posterior belly of the digastric, stylohyoid, and platysma muscles are all innervated by branches of the facial nerve.

While the facial nerve trunk is well protected in adults at its exit from the skull by the mastoid process, tympanic ring, and mandibular

ramus, the surgeon must beware when performing procedures in this anatomic region in children. Because the mastoid process is not fully developed until age five, the main facial nerve trunk lies in a superficial subcutaneous plane behind the earlobe and may be damaged in superficial cutaneous procedures[14]. The major facial nerve branches on the cheek are protected only by a small amount of parotid tissue (superficial lobe), parotid fascia, and subcutaneous fat (Fig. 142.18). If a surgical procedure requires violation of the parotid fascia, meticulous dissection is necessary to avoid major facial nerve damage and subsequent functional disability. Of note, the motor nerves of the face course deeper than the sensory nerves or axial vasculature.

Fig. 142.18 Branches of the facial nerve. Following dissection of the parotid gland, multiple branches are visible; those lifted by the dissecting probe include (from top to bottom): temporal, zygomatic (2 branches), and buccal.

Temporal Branch

The temporal branch of the facial nerve provides motor innervation to the frontalis, upper orbicularis oculi, and corrugator supercilii muscles. It usually has three to five rami that originate over the middle third of the zygomatic arch for a combined approximately 2.5 cm "danger" zone in this area (Table 142.2; see Fig. 151.6). As the most anterior branch of the temporal nerve crosses over the zygomatic arch, it is almost always located, at a minimum, 2 cm posterior to the orbital rim[15]. The most posterior ramus of the temporal branch can be topographically located on the temple 1 cm anterior to a vertical line drawn from the anterior insertion of the ear to the scalp. This posterior ramus runs anterior to the superficial temporal artery and vein. The dermatologic surgeon must exercise caution when working in this area as the superficially located temporal branch is at highest risk for injury within this zone[16].

The temporal branch of the facial nerve courses between the superficial and deep temporalis fascia, penetrating the underside of the frontalis muscle from its lateral edges (see Fig. 142.17). The superficial temporal artery and vein as well as the auriculotemporal sensory nerve run posterior to but more superficially than the temporal nerve branch (see Fig. 142.3). This neurovascular bundle lies in the subcutaneous fat overlying the SMAS of the temple and lateral forehead region. Remember that once the temporal nerve reaches the lateral underbelly of its ipsilateral target muscles, it is most protected. In order to avoid damaging this facial nerve branch, the surgeon should either remain superficial to the SMAS (i.e. the superficial temporalis fascia) or dissect in the subgaleal plane from the medial to lateral forehead. Similar to the other facial nerve divisions, the greatest potential for nerve damage lies in the lateral regions of the face. The central face has many nerve arborizations and protective muscles that usually afford minimal risk for facial motor nerve damage.

Damage to a ramus of the temporal branch of the facial nerve can result in notable cosmetic and functional loss. The temporal branch consists of long, usually singular, and often superficially coursing rami that have few arborizations or cross-innervations. These characteristics make nerve damage and permanent sequelae more likely when cutaneous procedures are performed in the lateral forehead and temporal regions. Even though the upper orbicularis oculi and corrugator supercilii muscles are innervated by the temporal branch, minimal functional or cosmetic compromise occurs, due to cross-innervation by other motor nerves. However, only 15% of patients will have any cross-innervation to the frontalis muscle by the more inferior zygomatic branch of the facial nerve. Such arborization permits retention of some functional mobility of the frontalis should the temporal branch be sacrificed. For the other 85% of patients, violation of the temporal nerve results in motor denervation and the inability to raise a now lowered or "droopy"

SURGICAL DANGER ZONES OF THE HEAD AND NECK

Danger zone	Nerve(s)	Function	Location most susceptible to injury	Injury/deficit
Erb's point	• Spinal accessory • Cervical plexus (lesser occipital, great auricular, transverse cervical, supraclavicular nerves)	• Motor innervation to the trapezius (spinal accessory) • Sensory innervation (cervical plexus)	Draw a line connecting the angle of the mandible to the mastoid process, *then* from the midpoint of this line draw a 6 cm vertical line; the intersection of the lowermost point of the vertical line and the posterior border of the sternocleidomastoid muscle identifies Erb's point	• Inability to elevate the shoulder or abduct the arm >80° • Winged scapula • Loss of sensation to areas of the head/neck
Temple	Temporal branch (facial)	• Motor innervation to the frontalis, orbicularis oculi, corrugator supercilii, and anterior and superior auricular muscles	Draw 2 lines to delineate the zone*: (1) from the inferior earlobe to the lateral edge of the eyebrow; and (2) from the tragus to just above and lateral to the highest forehead crease	• Inability to elevate ipsilateral frontalis muscle • Flattening of forehead tension lines • Brow ptosis
Mandible at the site of the facial artery	Marginal mandibular branch (facial)	• Motor innervation to the orbicularis oris, risorius, and depressors of the lower lip (depressor anguli oris, depressor labii inferioris, and mentalis) muscles	Exits the inferior portion of the parotid gland, then courses over the mandible anterior to the facial artery; it is located 1–2 cm above the inferior border of the mandible	• Inability to smile/ipsilateral crooked smile • Drooling

*In this area, the temporal nerve is protected only by skin, subcutaneous fat, and a thin layer of SMAS.

Table 142.2 Surgical danger zones of the head and neck. See Fig. 151.6 which also includes the buccal branch of the facial nerve, but the latter is rather deep in the cheek and much less at risk.

eyebrow[4] (see Fig. 151.7). Flattening of the forehead with diminished visibility of wrinkles and skin tension lines on the ipsilateral side is easily noted. The functional loss of the frontalis muscle significantly hampers a patient's ability to communicate non-verbally via facial expression and may have devastating psychosocial consequences. Over time, the inability to raise one's eyebrow can lead to eyebrow and eyelid ptosis and upper visual field compromise as muscular disuse atrophy progresses. Unilateral brow lifts and blepharoplasty may be necessary if the temporal nerve branch is permanently damaged.

Zygomatic and Buccal Branches

The **zygomatic** branch of the facial nerve provides motor innervation to the lower orbicularis oculi, procerus, mouth elevator, and nasal muscles (see Fig. 142.17). Its fibers course horizontally and upwards after emerging from the parotid gland as the second division of the facial nerve (see Fig. 142.18). There is marked variability in the innervation it provides to these muscles; thereby, damage to this nerve branch can have unpredictable outcomes. Generally, injury to the zygomatic branch results in decreased orbicularis oculi function and a diminished ability to close the ipsilateral eyelid tightly. The orbicularis oculi is also innervated in its supraorbital aspect by the temporal branch of the facial nerve. Therefore, complete loss of circumferential periocular motor function is highly unlikely. Other effects may include dysfunction of nasal muscles and lip elevators.

The **buccal** branch is the third division of the facial nerve, and it courses inferiorly to the zygomatic branch in a downward direction on the cheek (see Fig. 142.17). It innervates the orbicularis oris, zygomaticus major and minor, lip elevator, buccinator, and nasal muscles to a variable extent. Damage to this nerve causes buccinator dysfunction that results in accumulation of food between the teeth and the buccal mucosa with chewing, as well as an ipsilateral crooked smile at rest. Approximately 80% of patients have anastomoses between the fibers of the zygomatic and buccal branches[17]. Each branch has two points of arborization, with the first occurring 2 cm anterior to the anterior edge of the parotid gland and the second usually occurring under the modiolus 1 cm lateral to the oral commissure at the anterior aspect of the buccal fat pad. Here the nerves may be damaged due to their superficial anatomy, protected only by the thin fascia of the SMAS, an often underdeveloped risorius muscle, and the subcutaneous fat. At the first branching site near the parotid, the zygomatic and buccal nerves lie between the masseter muscle and the posterior side of the buccal fat pad.

Although damage to the zygomatic or buccal branches of the facial nerve may occur during surgical procedures, subsequent motor dysfunction is often temporary and far less debilitating than a similar injury to the temporal nerve. The high degree of anastomoses between the zygomatic and buccal branches minimizes functional damage and promotes nerve recovery after trauma. Partial paralysis of the perioral muscles may occur, causing variable symptomatic defects in facial expression, including a diminished ability or unilateral defect in forming a smile or pucker, lip pursing, and lip seal formation. Drooling, food accumulation between the cheeks and gingivae, and muffled speech may occur secondary to buccal or zygomatic nerve damage. Orbicularis oculi defects have already been discussed and include lower eyelid droop, which can lead to chronic conjunctivitis, sicca symptoms, and ectropion. Difficulty wrinkling up the nose and inability to flare the nostrils may also occur with zygomatic or buccal branch trauma. Fortunately, most of these symptoms resolve within 6 months due to the extensive ramification and cross-innervation of these branches of the facial nerve.

Marginal Mandibular Branch

The orbicularis oris, mentalis, and lip depressor muscles are innervated by the marginal mandibular branch of the facial nerve. The nerve courses along the angle of the mandible below the parotid gland and continues up over the mandibular body anterior to the facial artery, which can be palpated easily as it courses over the medial mandible (see Fig. 142.17). The marginal mandibular nerve is very susceptible to damage due to its superficial location over the bony edge of the jaw, where it is covered only by fascia and an often unpredictably thin or poorly developed platysma muscle. This facial nerve branch is often composed of only one ramus. The marginal mandibular nerve "communicates" with the buccal branch of the facial nerve in only 10% of patients; therefore, damage to the marginal mandibular nerve can lead to permanent disfiguring and functional defects in facial expression[4]. Normal symmetric facial expression and function of the mouth depends upon the equal and opposite effects exerted by the lip depressors and elevators in conjunction with the orbicularis oris muscle. Characteristically, a patient with marginal mandibular nerve damage cannot form a symmetric smile. There is inability to pull the ipsilateral lower lip downward and laterally or evert the corresponding vermilion border. The end result is a "crooked" smile. The defect is appreciated upon smiling, but is not as apparent when the patient is at rest.

Cervical Branch

The cervical branch of the facial nerve innervates the platysma muscle. This muscle receives nerve fibers from the marginal mandibular nerve as well. Damage incurred to the cervical branch rarely causes functional or cosmetic defects.

SENSORY INNERVATION OF THE HEAD AND NECK

The trigeminal nerve, or cranial nerve V, provides the primary sensory innervation to the face, while the upper cervical nerves (C2, C3) provide sensory supply to the neck, part of the ear, and posterior scalp (Fig. 142.19). The facial, glossopharyngeal, and vagus nerves provide a small portion of sensory innervation to the ear[18]. The trigeminal nerve is the largest cranial nerve. It has motor (to the muscles of mastication), sensory, and parasympathetic functions, supplying secretory fibers (originating from the facial and glossopharyngeal nerves) to the lacrimal and parotid glands. The sensory branches of the trigeminal nerve course more superficially than the trunk of the facial nerve and are therefore readily subject to damage during surgical procedures. Fortunately, most resulting sensory dysfunction is not debilitating or permanent. Transmedian re-innervation after unilateral trigeminal root transection has been demonstrated. This is due to collateral sprouting of sensory nerves from the contralateral trigeminal nerve root[19]. The sensory nerves exist in the superficial plane between the subcutaneous fat and

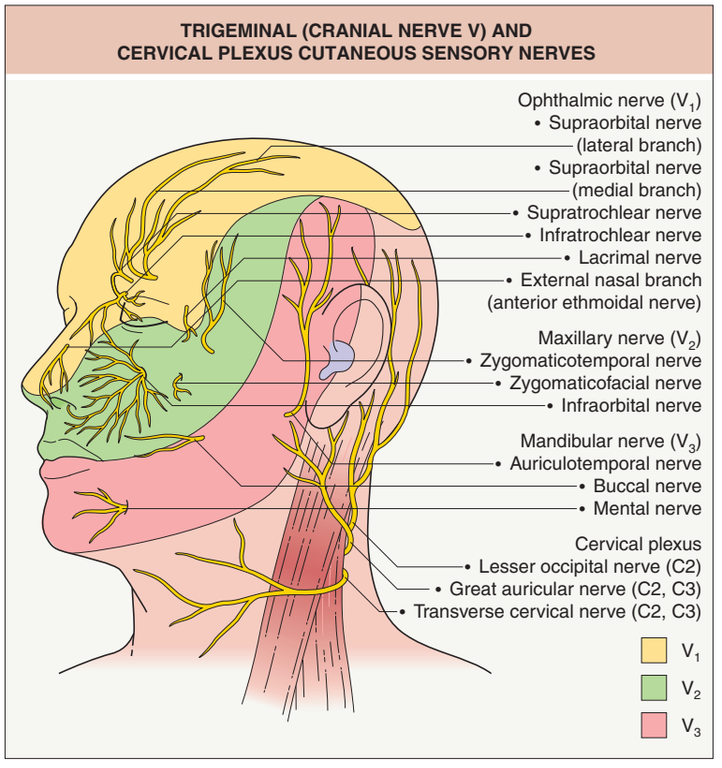

Fig. 142.19 Trigeminal (cranial nerve V) and cervical plexus cutaneous sensory nerves. The concha and external auditory canal are variably innervated by branches of the vagus (cranial nerve X), facial (VII), and auriculotemporal nerves (purple–gray). The upper cervical nerves (C2, C3) also provide sensory innervation to part of the ear as well as to the neck and posterior scalp.

the SMAS and often run together with arteries and veins in neurovascular bundles. Knowledge of the sites where the major branches of sensory nerves emerge from the skull assists the surgeon in performing regional nerve blocks that facilitate facial surgery and improve patient comfort (see Ch. 143).

The trigeminal nerve is divided into three main branches: ophthalmic (V_1), maxillary (V_2), and mandibular (V_3) (see Fig. 142.19). The smallest, uppermost sensory branch is the **ophthalmic** division, which gives off three branches (nasociliary, frontal, and lacrimal nerves) before exiting the orbit. Sensory fibers to the sinuses and upper nasal septal mucosa, as well as secretory parasympathetic fibers to the lacrimal gland (that originate from the facial nerve), are also provided by the ophthalmic branch of the trigeminal nerve. The nasociliary branch gives rise to the infratrochlear nerve and the external branch of the anterior ethmoidal nerve. Sensory innervation to the root of the nose and part of the medial canthus is supplied by the infratrochlear nerve. The nasal dorsum, tip, supratip, and columella derive cutaneous innervation from the external nasal branch of the anterior ethmoidal nerve, which emerges between the upper nasal cartilage and nasal bones. Nerve blocks for the nose rely on knowledge of these anatomic relationships among the sensory nerves. The nasociliary branch also supplies the corneal surface via the ciliary nerve. If an episode of herpes zoster involves the nasal tip, then close ophthalmologic follow-up is warranted due to presumed corneal involvement.

The frontal nerve branch of the ophthalmic division forms the supratrochlear and supraorbital nerves. The exit route (supratrochlear ridge) of the supratrochlear nerve lies 1 cm lateral to the midline on the supraorbital ridge. This branch of the frontal nerve provides sensory innervation to the medial upper eyelid, medial forehead, and frontal scalp. The supraorbital foramen (through which emerges the supraorbital neurovascular bundle) lies 2.5 cm lateral to the midline on the supraorbital ridge (see Fig. 142.2). After penetrating the frontalis muscle to emerge above the frontalis SMAS, the supraorbital nerve provides cutaneous sensation to the forehead, scalp, and upper eyelid. A small lacrimal nerve branch of the ophthalmic division of cranial nerve V innervates the lateral eyelid skin and lies near the upper lateral orbital rim. Frontal nerve blocks, and specifically the supratrochlear and supraorbital block, offer quick and effective anesthesia for surgical procedures of the forehead.

The **maxillary** branch (V_2) of the trigeminal nerve forms the infraorbital, zygomaticofacial, and zygomaticotemporal cutaneous sensory branches (see Fig. 142.19). The infraorbital foramen lies 2.5 cm lateral to midline and 1 cm inferior to the infraorbital rim, in the same vertical line as the supraorbital and mental foramina. The infraorbital neurovascular bundle emerges here to provide significant sensory innervation to the medial cheek, upper lip, nasal sidewall and ala, and the lower eyelid. Infraorbital nerve blocks offer simple and effective anesthesia for much of the cheek, lower eyelid, upper lip, and nose. Lateral to the infraorbital foramen, the zygomaticofacial nerve emerges to innervate the skin of the malar eminence. Cutaneous innervation of the temple and supratemporal scalp region is provided by a third branch of the maxillary division, the zygomaticotemporal nerve. It emerges from the lateral orbital margin at the zygomatic bone. The superior alveolar and palatine nerves are deeper branches of V_2 that provide sensory innervation to the upper teeth, palate, nasal mucosa, and gingiva.

The **mandibular** branch (V_3) is the largest division of the trigeminal nerve and the only one to carry both cutaneous sensory and motor fibers. It supplies cutaneous sensory innervation to the face as well as motor innervation to the muscles of mastication[20]. The auriculotemporal, buccal, and inferior alveolar nerves represent the three main cutaneous branches of V_3. The auriculotemporal nerve emerges from behind the neck of the mandible to course just deep to the superficial temporal artery from the superior margin of the parotid gland in the preauricular sulcus up towards the lateral scalp (see Fig. 142.19). It provides sensory innervation to the external ear and auditory canal, temple, temporoparietal scalp, temporomandibular joint, and tympanic membrane. It also carries parasympathetic secretory fibers to the parotid gland.

The buccal nerve supplies sensory innervation to the cheek, buccal mucosa, and gingiva. It runs deep to the parotid gland over the pterygoid muscle to the upper surface of the buccinator, which it pierces to reach the overlying skin. Because the terminal branches of the buccal nerve are small and numerous, regional buccal nerve block techniques are not feasible anesthetic options. The inferior alveolar branch of V_3 innervates the mandibular teeth as it courses through the mandibular sulcus. Its terminal branch forms the mental nerve, which emerges from the mental foramen in the same topographic line as the supraorbital and infraorbital neurovascular bundles (i.e. 2.5 cm lateral to the midline). The mental vein, artery, and nerve emerge from the mental foramen below the lower second premolar. The lingual nerve supplies sensory innervation to the anterior two-thirds of the tongue, the floor of the mouth, and the lower gingivae. It arises from V_3 and courses parallel and superior to the inferior alveolar nerve.

The cervical plexus is a network of arborizing and anastomosing nerve branches of the ventral rami of the four most superior cervical nerves. It emerges from the mid-posterior margin of the sternocleidomastoid (SCM) muscle at Erb's point to give off three branches, designated as C2, C3, and C4. C2 and C3 compose the great auricular nerve, which runs from the posterior edge of the SCM towards the earlobe in the same plane and path as the external jugular vein (see Figs. 142.4 & 142.19). It innervates the skin of the lateral neck, angle of the jaw, and part of the auricular and postauricular skin.

The lesser occipital nerve (C2) emerges from the same point at the SCM and assumes a course parallel to the SCM upward to innervate the skin of the neck, posterior ear, and postauricular scalp. The transverse cervical nerve (C2 and C3) likewise emerges from behind the SCM and arcs anteriorly around and across the SCM in a transverse direction. Its many terminal branches supply the skin of the anterior neck. The supraclavicular nerve (C3 and C4) emerges from the same point at the SCM posterior margin, then courses inferiorly until it reaches the supraclavicular region, where it terminates, and provides sensory innervation to the anterior chest and shoulder skin (see Fig. 142.4).

Perineural invasion of cutaneous tumors may be encountered by the clinician. Patients are often asymptomatic from dermal nerve twig infiltration by tumor cells, with the diagnosis made only by histopathologic tissue examination. However, some patients may experience sensory abnormalities and, rarely, motor dysfunction. Most of these scenarios occur in the setting of SCC (incidence rates range from 3% to 14%) with <1% of BCCs showing any histologic evidence of perineural spread[17]. Knowledge of the neuroanatomy of the head and neck assists the surgeon in planning adjuvant therapy for patients with nerve involvement.

LYMPHATIC DRAINAGE OF THE HEAD AND NECK

Melanomas, SCCs, Merkel cell carcinomas, and other cutaneous neoplasms may spread via the lymphatics to regional lymph nodes. It is important for the clinician to have a thorough understanding of the lymphatic drainage of the head and neck (Fig. 142.20), as well as the remainder of the body, in order to appropriately stage and manage patients. Before any surgical endeavor is undertaken for a malignancy

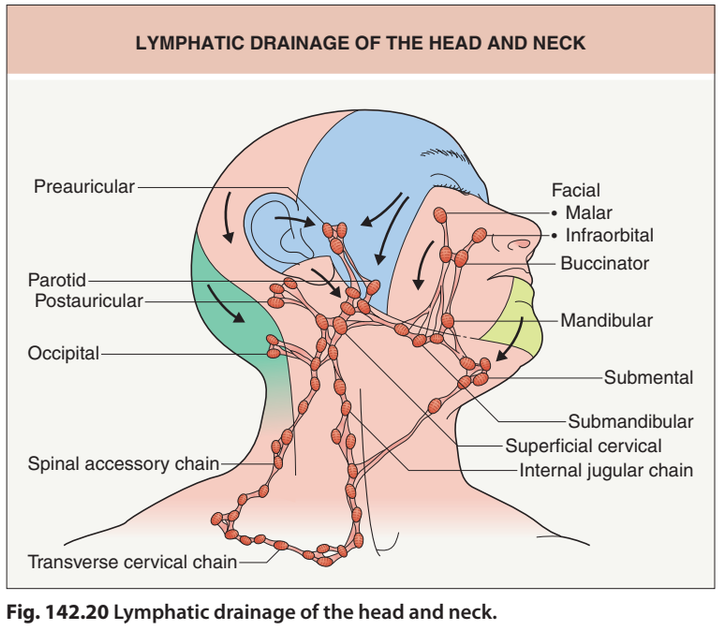

Fig. 142.20 Lymphatic drainage of the head and neck.

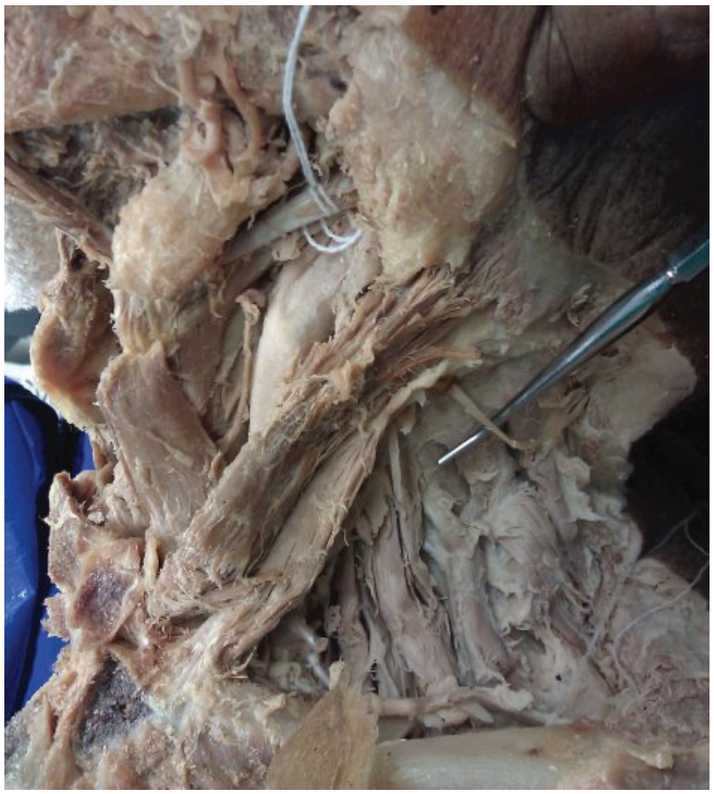
with metastatic potential, palpation of regional lymph nodes and basins should be performed. Head and neck cancers usually spread to adjacent lymph nodes in a diagonal direction from cephalad to caudad (see Fig. 142.20). There is a large degree of variability in drainage pathways, but the anatomic location of individual lymph nodes is more consistent from patient to patient. Cutaneous malignancies that breach the papillary dermis may spread from small lymph capillaries to progressively larger and deeper lymphatic trunks in the area. Lymph channels often course along the same directional pathway as the head and neck veins. They are more numerous and often more superficial than the corresponding veins and lie predominantly between the superficial and deep fascial layers.

Important primary lymphatic drainage patterns of the head and neck region include the following: parotid nodes, which often collect from the forehead, temple, and eyelids (upper lateral face); submandibular nodes, from the lower and medial face; and submental nodes, from the central lower lip and chin. Lateral cervical nodes are the common subsequent lymph collection site from these areas.

Parotid nodes may be extraglandular or intraglandular. The extraglandular channels are invested within the parotid sheath. Two-thirds of all individuals will also have one to three pretragal and infra-auricular lymph nodes that are considered part of the parotid node basin[4]. These pre- and infra-auricular nodes drain the ear, the lateral lower cheek, the frontolateral scalp, and the forehead, as well as the nasal root. Drainage of the parotid unit may then follow the external or internal jugular vein in the jugular lymph node chain; therefore, palpation for nodes from the site of the cutaneous lesion to the supraclavicular and even axillary nodal basins is recommended.

Submandibular nodes should be examined as the patient relaxes the neck muscles and tilts the chin down. This nodal group drains the gingival and mucous membranes, lower eyelids, anterior two-thirds of the tongue, lips, nose, and medial cheeks. The submental nodes (up to eight) of the neck lie beneath the platysma and drain the anterior third of the tongue and floor of the mouth, in addition to the lower middle lip, chin, and medial lower cheeks. They are best examined by elevating the chin and asking the patient to engage the platysma. Submental nodes frequently drain bilaterally or contralaterally and empty into the submandibular basin or directly into the internal jugular lymphatic chain. Note that up to one-quarter of healthy individuals have small (less than 1 cm), non-fixed, palpable submental nodes[4].



The superficial lateral cervical nodes are adjacent to the infra-auricular parotid nodes and lie near the high external jugular vein. Use the sternocleidomastoid muscle as a landmark to palpate these nodes (up to four) over its cephalad portion. Deeper lateral cervical nodes include the spinal accessory, internal jugular, and transverse cervical chains, which form a triangle on the neck. The internal jugular chain is the main lymphatic collection trunk of the head and neck and may contain up to 25 lymph nodes in each patient. The internal jugular chain on the right often drains into the subclavian vein, whereas the left-sided lymphatic chain empties into the thoracic duct. These nodes can be palpated by rolling two fingers over the area of the carotid triangle.

Acute or chronic lymphedema may ensue after transection of larger lymphatic channels or nodes, or even after disruption of smaller channels in areas (e.g. infraorbital) with limited or vulnerable lymphatic drainage. Adequate drainage can be achieved by orienting flaps in the same direction as lymphatic patterns. The surgeon must be mindful of the variability in drainage patterns and sites and the fact that malignancies do not respect the midline. Since cross-communication between lymphatics may result in contralateral drainage, bilateral examination for lymphadenopathy should be undertaken before a neoplasm is excised.

SENSORY INNERVATION OF THE HEAD AND NECK

- **Trigeminal nerve**
  - Ophthalmic branch (V_1)
    - Nasociliary – anterior nasal septum, nasal wall, cornea, iris, ethmoid/sphenoid sinuses
    - Infratrochlear – root of nose, medial canthus
    - Anterior ethmoidal (external nasal branch) – nasal dorsum, tip, supratip, columella
    - Ciliary – corneal surface
    - Frontal
      - Supratrochlear – medial upper eyelid, medial forehead, frontal scalp
      - Supraorbital – forehead, scalp, upper eyelid
    - Lacrimal – lateral eyelid
  - Maxillary branch (V_2)
    - Infraorbital – medial cheek, upper lip, nasal sidewall and ala, lower eyelid
    - Zygomaticofacial – malar eminence
    - Zygomaticotemporal – temple, supratemporal scalp
    - Superior alveolar and palatine – upper teeth, palate, nasal mucosa, gingiva
  - Mandibular branch (V_3)
    - Auriculotemporal – external anterior ear and external auditory canal, temple, temporoparietal scalp, temporomandibular joint, tympanic membrane
    - Buccal – cheek, buccal mucosa, gingiva
    - Inferior alveolar – mandibular teeth; chin and lower lip (mental nerve)
    - Lingual – anterior two-thirds of tongue, floor of mouth, lower gingivae
- **Vagus nerve** (X) – external auditory canal, concha, postauricular sulcus
- **Facial nerve** (VII) – external auditory canal, postauricular sulcus
- **Great auricular nerve** (C2, C3) – lateral neck, angle of the jaw, posterior and inferior ear, portions of the helical rim, postauricular scalp
- **Facial nerve (VII)** – external auditory canal, concha, postauricular sulcus
- **Vagus nerves** – external auditory canal, concha, postauricular sulcus
- **Lesser occipital nerve** (C2) – neck, postauricular scalp
- **Transverse cervical nerve** (C2, C3) – anterior neck
- **Supraclavicular nerve** (C3, C4) – anterior chest, shoulder

143 Anesthesia

George J. Hruza

Key features

- Local anesthetics are classified into two groups – amides and esters – depending upon the linkage in their intermediate chain
- "Anesthetic allergies" vary from palpitations secondary to epinephrine and vasovagal reactions, to urticaria and anaphylaxis from preservatives or the local anesthetic (especially esters)
- Additives to the local anesthetic include epinephrine, sodium bicarbonate, and hyaluronidase
- Nerve blocks are particularly helpful when performing procedures on the face, digits, and palmoplantar surfaces

INTRODUCTION

Effective anesthesia is an essential component of dermatologic surgery, and almost all dermatologic surgical procedures can be performed under local anesthesia. Local anesthetics have been in use since the 1880s with the introduction of cocaine hydrochloride, which was extracted from the leaves of the South American bush *Erythroxylon coca*[1]. This was followed by procaine in 1904, tetracaine in 1930, and lidocaine, the first amide local anesthetic, was introduced in 1943[1]. The introduction of lidocaine was a major breakthrough because lidocaine is far less likely to cause an allergic reaction than the ester-type anesthetics that preceded it.

Local anesthesia has several advantages over general anesthesia, including reduced morbidity (especially in poor-risk patients), reduced cost, reduced procedure time, and faster recovery. The main disadvantages are some limitation on the extent of a procedure and the possibility of greater patient discomfort from the injections. Knowledge of the physiology, dosage, side effects, and proper "painless" local anesthesia technique are essential for performing dermatologic surgery and to keep patients safe and satisfied[2].

DISCUSSION

Physiology and Structure

Local anesthetics act by blocking sodium channels in the axon cell membrane, and this prevents sodium from entering the nerve cell. The nerve cell is not depolarized and consequently the action potential is blocked. The cationic form of the anesthetic appears to bind to the inner pore of voltage-gated sodium channels, possibly leading to both narrowing of the pore lumen (steric block) and creation of an electrostatic barrier to permeation[3]. Smaller unmyelinated C-type nerve fibers that conduct pain sensation are blocked more quickly and easily than intermediate fibers that also carry sensations of heat and cold. The myelinated A-type fibers that carry pressure sensation and motor fibers are blocked last. Clinically, this is evident when an area seems fully anesthetized for scalpel surgery, but the patient still feels the pressure of the surgeon's fingers at the surgical site.

All local anesthetics consist of three parts (Fig. 143.1):

- a secondary or tertiary amine end
- an aromatic end
- an intermediate connecting chain that contains an ester or amide.

The aromatic portion is hydrophobic and lipophilic. This is essential to allow the anesthetic to diffuse through nerve cell membranes. The amine portion is hydrophilic and is responsible for the anesthetic's water solubility, which is important for preparing, storing, and administering the anesthetic[3].

Local anesthetics are weak organic bases, which, to be water-soluble and injectable, require the addition of a hydrochloride salt. In aqueous solution, the salt equilibrates between the ionized and non-ionized form. The ionized form is water-soluble, allowing injection into and diffusion through tissue. However, it is the non-ionized, lipid-soluble base that can diffuse into the nerve cell membrane. Within the sodium channel's inner pore, it is the ionized cation that is responsible for blocking nerve conduction (see above)[3].

The dissociation constant (pKa) of each anesthetic determines the proportion of the anesthetic base and its cation at a given pH. The pKa of all local anesthetics is higher than physiologic pH. For most local anesthetics at a pH of 7.4, 80% or more is in the cationic ionized form. Alkalinization of the anesthetic solution, as is done with the addition of sodium bicarbonate, will speed its onset of action as more of the anesthetic will be in the non-ionized form. However, if the pH is raised too much, the anesthetic may precipitate out of solution. Anesthetic sensitivity to pH also helps explain why infected tissue is difficult to effectively anesthetize[4]. The inflammatory response surrounding the infection acidifies the site (reduces the pH), which reduces the proportion of the anesthetic in the non-ionized, lipid-soluble form.

Pharmacology

Local anesthetics are classified into two groups, depending on the linkage in the intermediate chain (Table 143.1). Amide anesthetics have an amide linkage and ester anesthetics have an ester linkage (Fig. 143.1). They differ in how they are metabolized and in the risk of sensitization. Ester anesthetics are hydrolyzed by plasma pseudocholinesterase, and the metabolites are excreted by the kidneys. Patients with a deficiency of functional pseudocholinesterase, who are often diagnosed after prolonged paralysis following administration of standard doses of succinylcholine, are at an increased risk of ester anesthetic toxicity. The metabolite para-aminobenzoic acid (PABA) is responsible for the allergic reactions seen with ester anesthetics. Amide anesthetics are metabolized by the hepatic microsomal cytochrome P450 enzyme system, and the metabolites are excreted by the kidneys. Patients with severe liver disease may be at increased risk of amide anesthetic toxicity.

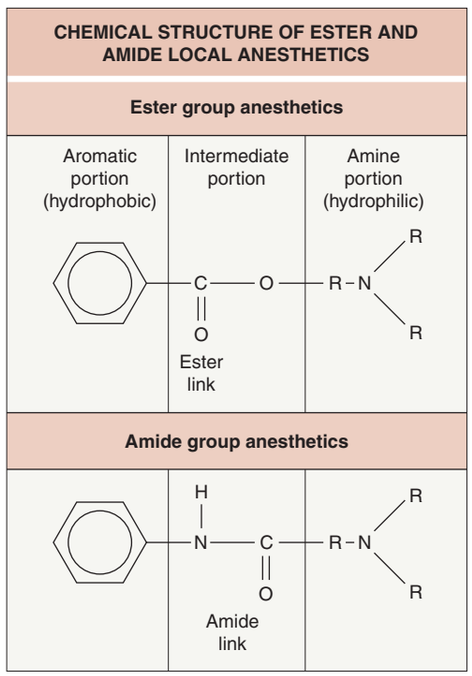

Fig. 143.1 Chemical structure of the ester and amide group local anesthetics. The aromatic (hydrophobic and lipophilic) end is joined to the amine (hydrophilic) end with an ester or amide linkage.

LOCAL ANESTHETICS FOR INFILTRATIVE AND NERVE BLOCK ANESTHESIA					
Generic name	**Trade name®**	**Onset (min)**	**Duration plain (h)**	**Maximum dose plain (mg for 70 kg person)**	**Maximum dose with epinephrine (mg for 70 kg person)**
Amides					
Articaine	Septocaine	2–4	0.5–2	350	500
Bupivacaine hydrochloride	Marcaine	5–8	2–4	175	225
Etidocaine	Duranest	3–5	3–5	300	400
Levobupivacaine hydrochloride	Chirocaine	2–10	2–4	150	Not available
Lidocaine	Xylocaine	Rapid	0.5–2	350	500 (3500 dilute)
Mepivacaine	Carbocaine	3–20	0.5–2	300	500
Prilocaine hydrochloride	Citanest	5–6	0.5–2	400	600
Ropivacaine*	Naropin	1–15	2–6	200	Not available
Esters					
Chloroprocaine hydrochloride	Nesacaine	5–6	0.5–2	800	1000
Procaine	Novocaine	5	1–1.5	500	600
Tetracaine	Pontocaine	7	2–3	100	Not available
*Addition of epinephrine has no effect on onset or duration of action of ropivacaine.					

Table 143.1 Local anesthetics for infiltrative and nerve block anesthesia. In clinical practice, the duration of anesthesia appears to be less than stated, especially for head and neck areas. Addition of epinephrine prolongs anesthesia by a factor of two. 1% lidocaine solution = 10 mg/ml.

Local anesthetics differ in the speed of onset, duration of action, and potency, depending on each compound's intrinsic chemical characteristics (Table 143.1). A low pKa leads to rapid onset of anesthesia, as more of the anesthetic will be in the non-ionized form. Greater lipid solubility is associated with higher anesthetic potency, as the compound penetrates the nerve cell membrane more easily. Duration of action is determined by the strength of anesthetic binding to the sodium channel pore.

For pregnant women, the local anesthetic of choice is lidocaine. It is historically classified as FDA pregnancy category B, which means that, in animal studies, no teratogenic effects have been documented. Studies in pregnant women who received lidocaine during the first trimester of pregnancy have shown no increase in anatomic abnormalities in the newborns. However, it is recommended that lidocaine, as with all other pharmacologic agents, be used cautiously during the first 4 months of pregnancy, when maximum organogenesis takes place. Lidocaine crosses the placenta into the fetus. Lidocaine can be safely used in nursing mothers with the realization that some of the anesthetic may be excreted in the mother's milk.

Lidocaine can be safely used in children, but the maximum recommended dosage should be adjusted downward based on the child's weight and age. Care must be taken in premature infants due to cardiovascular effects. Parabens, used as preservatives, are bound to albumin. In a jaundiced newborn, they could displace bilirubin from the albumin, worsening the hyperbilirubinemia[5]. For this reason, only paraben-free anesthetics should be used in newborns.

Additions to Local Anesthetics

Epinephrine

All local anesthetics, except for cocaine hydrochloride, relax vascular smooth muscle, which results in vasodilation. This causes increased bleeding at the operative site and reduced duration of anesthetic action as the anesthetic is rapidly removed from the surgical site via the dilated blood vessels. The addition of epinephrine (adrenaline) has the beneficial effect of constricting blood vessels, which prolongs the duration of anesthesia 100% to 200% by slowing removal of the anesthetic from the surgical site. Also, there is reduced intraoperative bleeding due to the vasoconstriction. The addition of epinephrine provides more effective anesthesia by decreasing the volume of anesthetic needed. The reduced absorption rate decreases anesthetic toxicity and allows larger doses to be used safely. The vasoconstrictive effect of epinephrine, manifested by skin blanching, takes about 15 minutes to fully develop. While they usually coincide, blanching does not always denote the anesthetized area.

Epinephrine is premixed with local anesthetics at a concentration of 1 : 100 000 or 1 : 200 000. However, concentrations as low as 1 : 1 000 000 achieve effective vasoconstriction, while concentrations >1 : 100 000 are associated with a greater risk of side effects. The concentration used in a given patient should be individualized. Patients who have relative contraindications to epinephrine should receive lower concentrations, while highly vascular areas such as the scalp should receive higher concentrations. At an epinephrine concentration of 1 : 100 000, the maximum dosage used is determined by the anesthetic with which the epinephrine is premixed (Table 143.1).

Epinephrine is a strong β- and α-agonist and, as such, it must be used cautiously in patients with altered β- and α-receptors. Absolute contraindications to the use of epinephrine include hyperthyroidism and pheochromocytoma. Patients taking β-blockers, monoamine oxidase inhibitors, tricyclic antidepressants, and phenothiazines are more sensitive to epinephrine. Therefore, epinephrine should be used with caution, with the dose and concentration reduced accordingly. In patients taking β-blockers, severe hypertension developing after injection of epinephrine-containing anesthetics has been reported[6]. This is probably due to unopposed α-adrenergic activity with its associated vasoconstriction. Fortunately, this reaction seems to be quite rare[7], and mainly occurs when higher doses are used. Patients with severe hypertension or with severe cardiovascular disease (especially coronary artery disease) may have their underlying disease exacerbated if large amounts of epinephrine are administered with the local anesthetic. High doses of epinephrine can induce labor. However, the low doses of epinephrine used in cutaneous surgery can be safely used during pregnancy. Epinephrine use in the periorbital area in patients with narrow angle glaucoma should be avoided, as it may aggravate the patient's glaucoma.

The use of epinephrine on digits has been controversial. Historically, epinephrine was not used on digits for fear of causing vasoconstriction that might result in digital necrosis. More recent studies have not demonstrated any increased risk from epinephrine in digital anesthesia. It appears that most cases of digital necrosis occurred due to vessel compression from too much anesthetic volume being injected (tamponade), constricting circumferential dressings, tourniquets, postoperative hot soaks (possibly due to heat-induced edema), infection, use of vasoconstrictive anesthetics such as cocaine hydrochloride, or non-standard mixing of lidocaine with epinephrine[8]. There is no evidence of digital necrosis due solely to commercially available lidocaine with epinephrine[8]. However, epinephrine is contraindicated for digital anesthesia in patients with peripheral artery disease. We have found that combining lidocaine with dilute epinephrine (1 : 500 000) and small volumes provides safe digital anesthesia. Ring blocks of the digit should be avoided.

Self-limited systemic side effects of epinephrine include palpitations, anxiety, fear, diaphoresis, headache, tremor, weakness, tachycardia, and elevated blood pressure. These signs and symptoms can be seen on occasion even with normal doses used for skin surgery, but they usually resolve within a few minutes (Table 143.2). They are more commonly seen when injecting highly vascular areas, especially the face and scalp. Skin necrosis from vasoconstriction is an extremely rare complication of epinephrine injection and would be an issue only in patients with severe vascular compromise at the injection site.

Serious side effects of epinephrine injection include cardiac arrhythmias (e.g. ventricular tachycardia, ventricular fibrillation), cardiac arrest, and cerebral hemorrhage. None of these should be expected to occur at the doses used for skin surgery. However, it is prudent to limit the total dose injected in patients with severe cardiac disease.

Epinephrine is stable only in an acidic environment. Therefore, when epinephrine is premixed with local anesthetics, the pH is lowered into the 3.5 to 5.5 range with the addition of acidic preservatives such as sodium metabisulfite to stabilize the epinephrine. This acidic solution not only is more painful at the time of injection[9], but also slows the onset of anesthetic action, as less anesthetic is in the non-ionized form. By preparing the mixture fresh daily and using it by the end of the day, the mixture has a higher pH, which is less painful. Adding 0.5 ml epinephrine (1 : 1000) to 50 ml plain lidocaine will give a final concentration of 1 : 100 000 epinephrine. Alternatively, the lidocaine with epinephrine can be neutralized with sodium bicarbonate (see below).

Sodium bicarbonate

Injecting the standard mixture of lidocaine with epinephrine at a pH of 3.5 to 5.5 is quite painful, with significant stinging due to the acidic pH. The pH can be neutralized with the addition of sodium bicarbonate. Adding one part of 8.4% sodium bicarbonate to ten parts lidocaine with epinephrine will bring the pH into a more physiologic 7 to 8 range. This mixture significantly reduces the pain of anesthetic injection[9,10]. Both components can be drawn up into the syringe, immediately before injection. Alternatively, 5 ml sodium bicarbonate (8.4%) can be added to a 50 ml bottle of lidocaine with epinephrine. As the epinephrine activity is lost at a rate of 25% per week in an alkaline or neutral environment, the mixture should be labeled with the date prepared, kept refrigerated, and used within about 1 week. There is evolving FDA and United States Pharmacopeia (USP) <https://www.usp.org/compounding/general-chapter-797> guidance that requires any buffered local anesthetic (in office "compounding") to be used within 4 hours of preparation. As state boards of pharmacy adopt this guidance, physicians in those states will be required to comply. Several dermatology societies are developing a USP monograph to extend the time that buffered lidocaine can be used after preparation.

Hyaluronidase

Hyaluronidase (derived from bovine testicular hyaluronidase) depolymerizes hyaluronic acid, which breaks up ground substance, allowing anesthetics to diffuse further away from the injection point. In addition, there is less distortion of the injected structures[11]. The greater diffusion of anesthetic may decrease its duration of action. Hyaluronidase is most useful for periorbital surgery and to increase the rate of successful nerve blocks. It is prepared by adding 150 units (U) to 30 ml of local anesthetic. Allergic reactions to hyaluronidase are rare, but they can occur. Some surgeons recommend an intradermal skin test before using hyaluronidase. In addition, the preparation may contain thimerosal preservative, which can cause contact dermatitis.

Anesthetic Mixtures

In an attempt to take advantage of different anesthetic properties, some surgeons combine two local anesthetics in one syringe. For example, a combination of lidocaine, for its rapid onset of action, with bupivacaine hydrochloride, for its longer duration of action, is often used. However, a study looking at such combinations has found that these mixtures do not live up to their promise. The mixture seems to take on the properties of one of the components to the exclusion of the other[12]. Therefore, most surgeons will inject the rapid-onset anesthetic first and the longer-acting anesthetic later, to minimize the pain of injection and maximize the duration of action.

Side Effects

Vasovagal reactions

By far the most common side effect of local anesthetic injection is a vasovagal reaction, in which the vagus nerve discharges due to patient anxiety, resulting in an increase in parasympathetic tone (Table 143.2). Vasovagal reactions are manifested by dizziness, diaphoresis, syncope, bradycardia, and hypotension. Placing the patient in the Trendelenburg position will rapidly relieve the patient's symptoms. A cold towel on the forehead can also be helpful. Oxygen, fluids, atropine, or epinephrine are usually not necessary. To avoid significant vasovagal reactions, patients should have local anesthetic infiltrated in the recumbent position.

Allergic reactions

The most important side effect of local anesthetics is the development of allergic reactions. The allergy is usually a type I IgE-mediated reaction manifested by urticaria, angioedema, bronchospasm, and, on rare occasions, anaphylaxis with associated hypotension and tachycardia (Table 143.2). Most true local anesthetic allergies have been reported with ester anesthetics; amide anesthetics are implicated only very rarely. Preservatives added to multidose vials, especially methylparaben and sodium metabisulfite, have frequently been shown to be the cause of "local anesthetic" allergy[13].

There is some allergy cross-reactivity amongst the various ester anesthetics and amongst the amide anesthetics, but there is no cross-reactivity between the ester and amide anesthetic classes. It is PABA

DIFFERENTIAL DIAGNOSIS OF LOCAL ANESTHETIC SYSTEMIC REACTIONS

Diagnosis	Pulse rate	Blood pressure	Signs and symptoms	Emergency management
Vasovagal reaction	Low	Low	Excess parasympathetic tone; diaphoresis, hyperventilation, nausea	Trendelenburg position, cold compress, reassurance
Epinephrine reaction	High	High	Excess α- and β-adrenergic receptor stimulation; palpitations	Reassurance (usually resolves within minutes), phentolamine, propranolol
Anaphylactic reaction	High	Low	Peripheral vasodilation with reactive tachycardia; stridor, bronchospasm, urticaria, angioedema	Epinephrine 1 : 1000 0.3 ml subcutaneous, antihistamines, corticosteroids, fluids, oxygen, airway maintenance
Lidocaine overdose				
1–6 mcg/ml	Normal	Normal	Circumoral and digital paresthesias, restlessness, drowsiness, euphoria, lightheadedness	Observation
6–9 mcg/ml	Normal	Normal	Nausea, vomiting, muscle twitching, tremors, blurred vision, tinnitus, dysgeusia (e.g. metallic taste), confusion, excitement, psychosis	Diazepam, airway maintenance
9–12 mcg/ml	Low	Low	Seizures, cardiopulmonary depression, arrhythmia	Respiratory support
>12 mcg/ml	Severely low	Severely low	Coma, cardiopulmonary arrest	Cardiopulmonary resuscitation and life support

Table 143.2 Differential diagnosis of local anesthetic systemic reactions. In case of systemic reactions during or after local anesthetic injections, hemodynamic signs are helpful in determining the cause of the reaction.

(the metabolite of ester anesthetics) that is thought to be responsible for ester anesthetic allergic reactions. Ester anesthetics can also cause type IV delayed hypersensitivity reactions and cross-react with several contact sensitizers, including PABA, para-amino salicylic acid, and para-phenylenediamine (PPD).

Patients who present with a history of "local anesthetic" allergy need to be questioned in detail about the "allergy" with a review of relevant medical records whenever possible. Often, the "allergy" is a result of a vasovagal reaction or epinephrine sensitivity. If the reaction seems to represent a true allergic reaction and the offending anesthetic is known (usually an ester), using an anesthetic from the other class (usually an amide) in a preservative-free solution is a reasonable option. Skin testing, by an allergist, may be warranted if the offending agent is not certain[14]. The testing should include pinprick followed by intradermal tests of an ester anesthetic, an amide anesthetic, methylparaben, and sodium metabisulfite. Alternatively, for small procedures, adequate anesthesia can be obtained with intradermal injection of 1% diphenhydramine solution. Epinephrine may be added to counteract vasodilation caused by diphenhydramine, to enhance the anesthetic effect, and to reduce systemic antihistamine symptoms[15]. Intradermal normal saline with benzyl alcohol preservative will achieve very brief anesthesia through pressure effects on cutaneous nerve endings and the anesthetic properties of the benzyl alcohol preservative. It can be used for very short procedures such as a shave biopsy[16].

Limited allergic reactions can be managed with oral antihistamines and prednisone. However, patients developing bronchospasm, angioedema, or hemodynamic compromise require immediate emergency management including subcutaneous epinephrine, bronchodilators, parenteral antihistamines, corticosteroids, intravenous fluids, and oxygen (Table 143.2).

Local side effects

Bruising and edema are frequently seen after local anesthetic infiltration, especially in the periorbital area. Periorbital edema will often develop after surgery on the forehead and frontal scalp. Transient motor nerve paralysis is sometimes seen. This may be delayed for some time after the sensory nerves have become anesthetized, because of the large myelinated nerve fibers involved. The paralysis may persist for several hours after the sensory nerves have returned to normal. Informing the patient when a motor nerve has been affected by the anesthetic will eliminate distressed patient telephone calls. Prolonged sensory nerve paresthesia may develop if a sensory nerve is injured due to intraneural injection. This is most commonly seen after nerve blocks. It can be minimized by avoiding intraneural injections and by using small-gauge needles for injection.

Overdosage

If the local anesthetic dosage administered is kept within recommended ranges, clinical symptoms of local anesthetic overdose are unlikely to be encountered. Maximum recommended dosages of *lidocaine* are 5 mg/kg plain (i.e. with no epinephrine), 7 mg/kg if with epinephrine and at standard (1%–2%) concentrations, and 35–50 mg/kg for tumescent lidocaine anesthesia consisting of dilute 0.05%–0.1% lidocaine with 1 : 1 000 000 epinephrine (Table 143.1)[17,18].

The symptoms of local anesthetic overdose are directly related to its serum blood level, with worsening CNS and cardiovascular signs and symptoms as the level increases (Table 143.2). CNS symptoms start with circumoral and digital numbness and tingling, followed by lightheadedness, tinnitus, visual disturbances, slurred speech, muscle twitching, and, finally, seizures and coma. Cardiovascular and pulmonary symptoms develop at significantly higher doses than do early CNS symptoms and include hypotension, arrhythmias, respiratory depression, and cardiac arrest.

When lidocaine is administered, there are over 150 potential drug–drug interactions. Most are minor or only relevant when large doses of lidocaine are used. Patients receiving medications that inhibit the liver's cytochrome P450 system (e.g. erythromycin, ketoconazole, itraconazole; see Ch. 131), and therefore inhibit lidocaine metabolism, can exhibit signs of lidocaine overdose at lower doses. With large doses of lidocaine, patients taking class I and III antiarrhythmic drugs (e.g. amiodarone) are at increased risk of cardiac arrhythmias and those taking CNS depressants (e.g. opiates) are at increased risk of CNS toxicity.

Bupivacaine hydrochloride has a greater risk of cardiac toxicity than lidocaine. *Prilocaine hydrochloride* metabolizes to ortho-toluidine, which is an oxidizing agent capable of converting hemoglobin to methemoglobin. This can become significant with large doses of more than 500 mg. *Benzocaine* has also been implicated in causing methemoglobinemia when used on mucosal surfaces[19]. The treatment of methemoglobinemia is methylene blue infusion.

Topical Anesthetics

Skin

Historically, the only anesthetic used for topical anesthesia of keratinized skin was benzocaine, which is an ester anesthetic. Anesthesia was generally effective only when applied to traumatized skin. Little, if any, anesthesia was achieved in intact normal skin. Of greater concern was the high rate of allergic contact dermatitis seen with benzocaine.

There are now several topical anesthetics that achieve moderate superficial anesthesia of intact skin (Table 143.3). EMLA® is available in a cream formulation or as a disc. It is a eutectic mixture of 2.5% lidocaine and 2.5% prilocaine hydrochloride. EMLA® is able to achieve superficial anesthesia, with the degree of anesthesia related to the amount and duration of application before surgery. The cream is applied as a thick layer under occlusion at least 1 hour before the procedure while the disc itself provides occlusion. It is especially useful for reducing the pain of non-ablative laser procedures and to reduce the pain of local anesthetic or other injections. Some dermatologists who perform CO_2 laser ablative resurfacing solely under EMLA® anesthesia prepare the skin with vigorous degreasing followed by two applications of EMLA® 1 hour apart under occlusion. Additional EMLA® is applied to the skin after the first pass with the laser has removed the epidermis.

EMLA® appears to be safe, but some caution is advised when using large amounts on skin with a damaged skin barrier and in infants who might be susceptible to methemoglobinemia from too much prilocaine hydrochloride absorption. For recommended applications in children, see Table 143.4. It should not be used in patients with G6PD deficiency. EMLA® often blanches the skin after application, followed by vasodilation 30–60 minutes after its removal. The vasodilation is usually of no clinical significance, but there are reports of petechiae and purpura developing at the site of EMLA® application. Additional reported side effects include occasional burning and irritation, chemical injury to the eye, contact urticaria, and allergic contact dermatitis, with the latter two reactions most often due to the prilocaine component.

Other preparations that have been optimized for epidermal penetration include: LMX®, containing 4% or 5% lidocaine (Table 143.5); Topicaine®, containing 4% lidocaine; 4% tetracaine gel; 30%–40% lidocaine in acid mantle cream; and various other compounded mixtures of lidocaine, benzocaine, and tetracaine (Table 143.3). Due to safety issues reported with compounded medications (see below), the FDA has severely restricted access to compounded topical anesthetics.

In a comparison study, EMLA® and LMX® 4% were found to achieve superior anesthesia to tetracaine 4% gel, which was superior to Betacaine LA®, which was superior to control[20]. According to the manufacturer, LMX® does not require occlusion to be effective. A comparison of EMLA® under occlusion and LMX® unoccluded found that LMX® achieved equivalent anesthesia to EMLA® after less than one-third of application time[21]. None of the topical anesthetics have any significant effectiveness for palmar or plantar surfaces.

Pliaglis® is a 7% lidocaine/7% tetracaine preparation that, when cold, is a cream, but when placed on the skin and exposed to air it becomes a flexible membrane. Once anesthesia has been achieved (after about 30 minutes), the membrane can be peeled off prior to the procedure. This product is useful for laser procedures[22]. The anesthetic level is equivalent to that of the other topical anesthetics.

Iontophoresis of 1%–4% lidocaine with epinephrine can enhance the depth and effectiveness of topical anesthesia. It is practical only for rather small areas, but anesthesia can be achieved within a few minutes with a 1 mA current. The main drawback is the additional equipment and supplies needed. Ultrasound or warm steaming of the skin also enhances the effect of topical anesthetics, probably by enhancing anesthetic penetration. In addition, fractionated ablative lasers and skin microneedling devices have been shown to enhance penetration of topical anesthetics, leading to improved local anesthesia[23]. When performing multi-pass laser treatments of large areas, these techniques may reduce the need for injectable anesthetics.

TOPICAL ANESTHETICS FOR MUCOUS MEMBRANE AND INTACT SKIN ANESTHESIA				
Generic name	**Trade name®**	**Concentration (%)**	**Type**	**Primary use**
Benzocaine	Americaine otic	20	Ester	Tympanic membrane
Benzocaine gel, liquid, spray	HurriCaine	20	Ester	Mucous membranes
Benzocaine/tetracaine/butamben (butyl aminobenzoate) gel, liquid, spray	Cetacaine, Exactacain		Esters	Mucous membranes
Benzocaine/lidocaine/tetracaine	compounded	Various	Ester/amide/ester	Intact skin
Cocaine hydrochloride nasal solution	Goprelto, Numbrino	2–10	Ester	Nasal mucosa
Dibucaine (cinchocaine)	Nupercainal	1	Amide	Mucous membranes
Lidocaine cream	LMX	4–5	Amide	Intact skin (4%); anorectal (5%)
Lidocaine gel	Topicaine 4	4	Amide	Intact skin
Lidocaine solution	Xylocaine	2–5	Amide	Mucous membranes
Lidocaine in acid mantle cream	compounded	30–40	Amide	Intact skin
Lidocaine/prilocaine eutectic mix [cream or disc]	EMLA	2.5/2.5	Amides	Intact skin
Lidocaine/prilocaine cream	Lidopril	2.5/2.5	Amides	Intact skin
Lidocaine/tetracaine peel	Pliaglis	7/7	Amide/ester	Intact skin
Lidocaine/tetracaine patch	Synera	7/7	Amide/ester	Intact skin
Proparacaine (proxymetacaine) ophthalmic solution	Alcaine	0.5	Ester	Conjunctiva
Tetracaine gel	Tetracaine gel	4	Ester	Intact skin
Tetracaine ophthalmic solution	Pontocaine	0.5	Ester	Conjunctiva

Table 143.3 Topical anesthetics for mucous membrane and intact skin anesthesia. Anesthetics for topical skin anesthesia require application 0.5–2 hours prior to surgery under occlusion for maximal effect. Benzocaine is a potent topical sensitizer.

MAXIMUM RECOMMENDED EMLA® APPLICATION IN CHILDREN				
Age	**Weight (kg)**	**Maximum total dose of cream (g)**	**Maximum area (cm^2)**	**Maximum time (hours)**
<3 months	<5	1	10	1
3–12 months	5–10	2	20	4
1–6 years	10–20	10	100	4
7–12 years	>20	20	200	4

Table 143.4 Maximum recommended application of eutectic mix of lidocaine 2.5%/prilocaine 2.5% (EMLA®) in children. Because of the prilocaine, the product should not be used in: (1) premature neonates with a gestational age <37 weeks because of increased risk of methemoglobinemia due to immature reductase pathways; and (2) young children (especially those <1 year of age) receiving medications that may increase the risk of methemoglobinemia (e.g. acetaminophen, antimalarials, dapsone, nitrofurantoin, nitroglycerin, phenobarbital, phenytoin, sulfonamides).

MAXIMUM RECOMMENDED LIDOCAINE 4% LIPOSOMAL CREAM (LMX4®) APPLICATION IN CHILDREN			
Age	**Weight (kg)**	**Maximum area**	**Maximum time (hours)**
<12 months	<10	100 cm^2 (4 × 4 in)	1
1–6 years	10–20	200 cm^2 (5.5 × 5.5 in)	2
7–12 years	>20	600 cm^2 (9 × 9 in)	2*

*0.072 mg 4% lidocaine absorption/cm^2/h × 600 cm^2 × 2 h = 86 mg (≤4 mg/kg).

Table 143.5 Maximum recommended lidocaine 4% liposomal cream (LMX4®) application in children. Cream should be applied to intact skin, with or without occlusion. Currently not FDA approved for children <2 years of age, so its application in that age group represents an off-label use. *Courtesy Julie V. Schaffer, MD.*

Topical skin anesthetics are useful for primarily non-invasive laser, intense pulsed light, and other energy-based therapies (see Ch. 137). They are very helpful in reducing the pain of needle insertion as well as some of the pain of injection when injecting local anesthetics, botulinum toxin, or filler materials such as the various hyaluronic acid-based filler materials that, due to their acidity, sting on injection. Of note, filler materials are now frequently premixed with lidocaine to reduce the pain of their injection (see Table 158.4). However, anesthesia is too unpredictable to use topical skin anesthetics even for minor surgical procedures such as skin biopsies, curettage, or electrodesiccation.

The various preparations have different recommendations regarding times of application and need for occlusion. However, for maximal effectiveness, the anesthetic should be applied as a thick layer under occlusion to the proposed treatment area for at least 1 hour. Caution should be exercised when large areas are to be anesthetized, especially when using compounded mixtures with high lidocaine concentrations, as several deaths have been reported in patients applying compounded topical anesthetics under occlusion to their entire lower extremities.

Mucous membranes

Topical anesthetics for mucous membranes are far more effective than skin anesthetics, as the stratum corneum barrier is absent (Table 143.3). One to two drops of 0.5% tetracaine into each eye achieves complete conjunctival anesthesia after a few seconds of stinging. This allows for insertion of eye shields or painless injection through the conjunctiva. Proparacaine (proxymetacaine) hydrochloride is an equally effective alternative conjunctival anesthetic that has less associated stinging sensations.

A 2%–10% solution of cocaine hydrochloride is the topical anesthetic of choice for intranasal anesthesia because of its excellent vasoconstrictive and hemostatic properties. However, onerous record-keeping requirements make it relatively impractical for in-office use. Due to its significant cardiac stimulatory effects, cocaine hydrochloride should be used with caution in patients with significant heart disease.

Oral and anal mucosa can be effectively anesthetized within a couple of minutes with 2%–4% lidocaine jelly or viscous lidocaine as well as various benzocaine-containing preparations. Topical intraoral anesthesia is especially helpful in reducing the pain of nerve block injections done via the intraoral route.

Cryoanesthesia

Rapid cooling of the skin surface is used routinely for many non-ablative laser procedures. The anesthesia is achieved with one of the following: a short burst of cryogen sprayed onto the skin surface (Dynamic Cooling

COMPRESSED AIR DELIVERY SYSTEMS FOR LIDOCAINE					
Generic name	**Delivery system**	**Trade name®**	**Amount/concentration**	**Type**	**Primary use**
Lidocaine HCl monohydrate powder	Pressurized helium	Zingo	0.5 mg (pre-filled)	Amide	Intact skin
Lidocaine buffered powder	Compressed carbon dioxide	J-tip	1% or 2%	Amide	Intact skin

Table 143.6 Compressed air delivery systems for lidocaine. Lidocaine is delivered into the dermis.

Device™); a cold glass window placed directly onto the site being treated (contact cooling); an iced gel placed on the surface being treated (passive cooling); or −5°C refrigerated air blown onto the skin surface with a coupling gel in place (Cryo 5™). All of these methods cool the skin to reduce pain of laser treatment and to protect the epidermis from laser-induced heat injury.

Cryoanesthesia can also be helpful in skin surgery. Dermabrasion can be done entirely under cryoanesthesia by freezing the skin with a cryogen spray before dermabrading. Unfortunately, the most effective and safe cryogen sprays (Frigiderm®, Fluro-Ethyl®) contain chlorofluorocarbons that are harmful to the ozone layer, and their manufacture has been discontinued. Ethyl chloride spray can, through evaporative cooling, achieve brief anesthesia to reduce the pain of needle insertion. An ice cube or −5°C forced air cooling (see above) will likewise numb the skin just long enough to reduce the pain of needle insertion. We have found forced air cooling helpful in reducing the pain of palmar and finger injections of botulinum toxin A for hyperhidrosis. However, if the cold air is aimed directly onto the needle, the liquid within the needle may freeze momentarily, making it seem that the needle is clogged. Moving the cold air blower away from the needle for 5 to 10 seconds will permit the contents of the needle to thaw out, allowing injection to continue.

Anesthetic Injection Techniques

Local infiltration

The great majority of dermatologic surgical procedures are done under anesthesia achieved with local infiltration. There are several maneuvers that can significantly reduce the pain of injection[24]. The pain of needle insertion is reduced by reassurance, verbal distraction, and mechanical distraction such as a pinch at the site of injection. Mechanical distraction works via the gate theory of pain. The pinching stimulates cutaneous nerves, making them somewhat refractory to the immediately following pinprick sensation from needle insertion. A very useful adjunct, which also takes advantage of the gate theory of pain, is the use of vibration at or immediately proximal to the injection site. This is very useful when injecting anesthetic in very anxious or young patients and has made it feasible for us to eliminate the need for nerve block anesthesia when injecting botulinum toxin A into the palms and soles in many patients. Care must be taken when applying a vibrator to the injection site, as the needle may move unpredictably across the skin surface due to the vibration before being inserted into the skin. Small 30-gauge needles that are inserted quickly further reduce pain. Slow, timid needle insertion is felt more by the patient than a quick needle insertion. Topical anesthesia, as noted above, can almost completely eliminate the pain of needle insertion.

The actual injection of the anesthetic causes a significant stinging sensation that is usually far more painful than the needle insertion. Buffering the anesthetic to a physiologic pH and using an anesthetic that has been warmed to body temperature will reduce the stinging sensation[9,10,25]. Injecting the anesthetic as slowly as practical will reduce the pain from tissue distention by the anesthetic fluid, and this also allows the injection of additional anesthetic to be done through an already numb area. Additional sticks should be made through an already numb area, and the injection should start on the side that the sensory innervation is coming from and proceed distally. Using the smallest practical syringe size, usually 1 or 3 ml, will allow for low pressures of injection, which are less painful. Subcutaneous anesthetic injection is less painful than intradermal injection, but the onset of anesthesia is slower and of shorter duration. We usually start by creating a small intradermal wheal, followed by subcutaneous injection, and finishing with intradermal injection at the incision line to enhance anesthesia and hemostasis.

TUMESCENT ANESTHESIA FORMULA	
Ingredient	**Quantity (ml)**
Lidocaine 1%	50–100
Epinephrine (1 : 1000)	1
Sodium bicarbonate 8.4%	10
Hyaluronidase 150 U/ml	6 (optional)
Triamcinolone acetonide 40 mg/ml	0.25 (optional)
Normal saline 0.9%	900–950

Table 143.7 Tumescent anesthesia formula. For tumescent anesthesia, a final concentration of 0.05% to 0.1% lidocaine with 1 : 1 000 000 epinephrine is prepared. Hyaluronidase may be added to enhance diffusion and corticosteroids may be added to reduce inflammation, edema, and possibly fibrosis.

There are also compressed air delivery systems for administering lidocaine into the dermis and they may be useful in children (Table 143.6).

Field block anesthesia

Field block anesthesia involves injecting a ring of anesthetic around the proposed surgical site. It is useful for anesthetizing large areas while conserving the amount of anesthetic used and minimizing distortion of the surgical site. Injecting a ring of anesthesia around a cyst will avoid puncturing the cyst. Ring block anesthesia is practical only in areas where innervation arrives horizontally through the skin, such as is seen on the scalp, rather than vertically from deeper tissues, as is seen on the eyelid. A ring block may achieve anesthesia, but there will be no hemostasis at the incision site. Therefore, the addition of intradermal anesthetic with epinephrine at the proposed incision site is recommended. The most frequent use of ring block anesthesia is on the scalp, nose (for rhinophyma repair), ear pinna, and on the trunk and extremities (where the injection is started as a ring block but often finished with infiltration inside the ring block).

Tumescent anesthesia

Tumescent anesthesia involves the subcutaneous infiltration of large amounts of dilute 0.05%–0.1% lidocaine with 1 : 1 000 000 epinephrine (Table 143.7). It has been used most extensively for liposuction under local anesthesia (see Ch. 156), ambulatory phlebectomy, hair transplantation, and dermabrasion. The anesthetic is infiltrated with the help of a pump, with the injection carried out through long 18- to 20-gauge 3.5 inch (8.9 cm) spinal needles or specially designed multiport cannulas. The infiltration is started slowly with small needles and then gradually speeded up utilizing spinal needles and finally infiltration cannulas. Infiltration of the deep subcutaneous plane is done first, followed by the superficial fat compartment. The solution is injected until firm tumescence of the tissue has been achieved. Anesthesia and epinephrine-induced hemostasis develop within about 20 minutes and last for several hours, which is significantly longer than the duration of anesthesia achieved with conventional concentrations of lidocaine with epinephrine. In the subcutaneous fat, dilute lidocaine is absorbed at a much slower rate than standard lidocaine concentrations. Doses as high as 35–50 mg/kg lidocaine have been found to be safe when used in tumescent anesthesia[17,18].

Nerve Block Techniques

Nerve blocks are an effective and efficient way to anesthetize large areas using the least amount of anesthetic, minimizing both patient discomfort and distortion of the operative site. When injecting in the

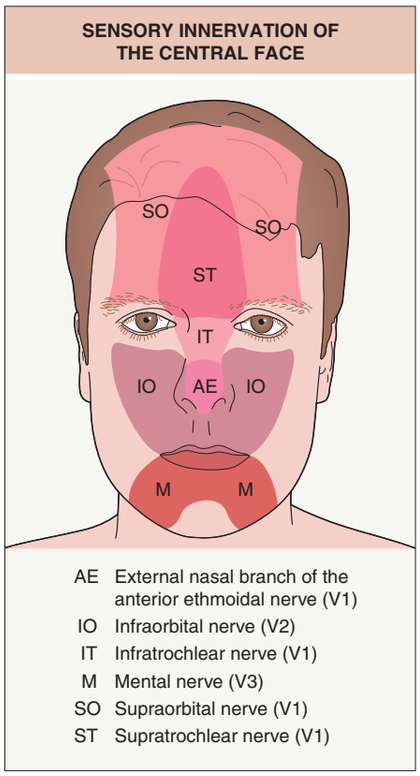

Fig. 143.2 Sensory innervation of the central face.

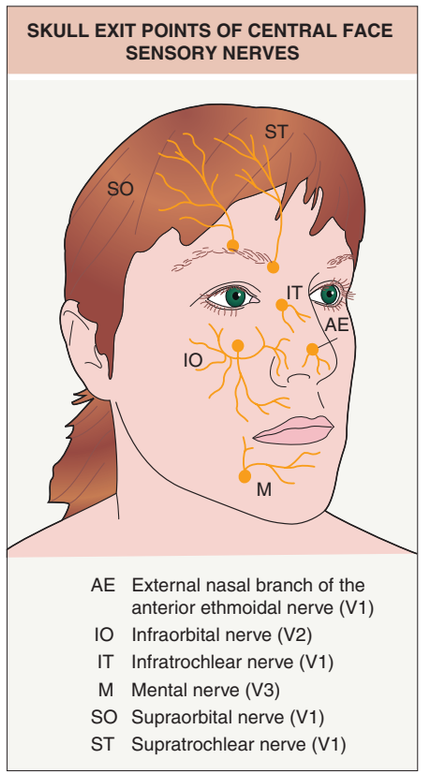

Fig. 143.3 Skull exit points of central face sensory nerves.

region of a nerve, care must be taken not to inject the accompanying blood vessels. Using larger, 25- to 27-gauge needles allows one to draw back to make sure that the needle is not intravascular. To reduce pain of injection, an intradermal wheal using a 30-gauge needle should be placed first. The aim of nerve block injections is to deposit the anesthetic near, but not into the nerve, as intraneural injection may cause nerve injury and subsequent dysesthesia. Insertion of the needle into a nerve is usually felt by the patient as a sharp pain radiating along the nerve. If this happens, the needle should be pulled back and repositioned slightly. Intra-foramina injections should also be avoided to minimize risk of nerve injury. With proper placement, most nerves can be blocked with a 1–2 ml injection. The addition of hyaluronidase will enhance diffusion of the anesthetic and increase the rate of nerve block "take".

For most nerve blocks, 1% lidocaine with epinephrine and sodium bicarbonate is used. If prolonged anesthesia is desired, 0.25% bupivacaine hydrochloride with epinephrine can be added. As the sensory nerves are large and myelinated, anesthetic effect may take 10 to 20 minutes to develop[26]. Using 2% lidocaine may increase success of the nerve block. Articaine 4% with or without epinephrine supplied in dental carpules seems to be especially effective for relatively painless facial nerve blocks, with very small volumes (often <0.2 ml/injection site) of anesthetic needed for effective anesthesia. This seems to be due to its more effective diffusion from the site of injection compared to lidocaine. Some surgeons omit epinephrine from the nerve block anesthetic as it is not needed for vasoconstriction at the site of the nerve. We use it as part of our anesthetic mix to prolong the duration of the nerve block. Once a nerve has been effectively blocked, local infiltration of lidocaine with epinephrine along the proposed incision line to achieve local vasoconstriction may be helpful in reducing bleeding.

Facial nerve blocks

The forehead and frontal scalp above the eyebrows are innervated by the *supraorbital nerve* (Fig. 143.2), which exits the skull through the supraorbital foramen at or immediately above the orbital rim in the midpupillary line (Fig. 143.3). The notch can often be palpated on the patient. Approximately 1 ml of anesthetic is infiltrated through a 0.5 inch (1.3 cm) needle inserted perpendicularly into the skin immediately superficial to the periosteum at the orbital rim in the midpupillary line (Fig. 143.4). The *supratrochlear nerve* innervates the midforehead, glabella, and frontal scalp (Fig. 143.2). It exits the skull at the upper

Fig. 143.4 Locations of needle insertions for central face nerve blocks. From superior to inferior, the supraorbital, infraorbital, and mental nerves are marked with an "x" and the supratrochlear, infratrochlear, and external nasal nerves are marked with a rectangle.

medial portion of the orbit (Fig. 143.3). Injecting 1 ml of anesthetic immediately superficial to the periosteum at the superomedial orbital rim at the junction of the glabella and eyebrow will block the supratrochlear nerve (Fig. 143.4). To achieve complete forehead and frontal scalp anesthesia requires extending a line of anesthetic injected into the subcutaneous plane laterally from the supraorbital nerve to the region immediately superior and posterior to the attachment of the ear pinna. This will block the auriculotemporal nerve and greater auricular nerve branches that innervate the forehead, temple, and frontal scalp (see Ch. 142).

The *infraorbital nerve* exits the skull through the infraorbital foramen (Fig. 143.3) and innervates the medial cheek, upper lip, and nasal ala (Fig. 143.2). With a 1 inch (2.5 cm) needle inserted perpendicularly to

the skin, 2 ml of anesthetic is injected approximately 1 cm inferior to the orbital rim in the midpupillary line, immediately superficial to the maxillary bone periosteum (Fig. 143.4). A less painful and more reliable alternative is to block the infraorbital nerve through the intraoral approach. The needle is inserted between the first and second premolars (bicuspids), moving cephalad parallel to the periosteum until the horizontal portion of the maxillary bone is reached (Fig. 143.5). The needle is pulled back slightly and the anesthetic is injected. The pain of needle insertion can be lessened by applying a topical anesthetic to the mucosa a couple of minutes prior to injection. The *infratrochlear nerve*, which innervates the lateral and dorsal nose (Fig. 143.2), can be blocked by injecting anesthetic superficial to the periosteum at the inferomedial orbital rim at the superior end of the nose–cheek concavity (Fig. 143.4). The nasal tip receives innervation from the external nasal branch of the *anterior ethmoidal nerve* (Fig. 143.2), which emerges at the nasal cartilage and bone junction slightly lateral from the midline (Fig. 143.3). Perichondrial infiltration of anesthetic at this spot will anesthetize the nasal tip (Fig. 143.4). To complete nasal anesthesia, a few drops of anesthetic at the base of the columella may be needed as well.

The lower lip and portions of the chin are innervated by the *mental nerve* (Fig. 143.2), which exits the mandible through the mental foramen in the midpupillary line (Fig. 143.3). A 0.5 inch (1.3 cm) needle is inserted perpendicular to the skin to the level of the periosteum in the midpupillary line halfway cephalad along the mandible, and 1 ml of anesthetic is injected to block the mental nerve (Fig. 143.4). The intraoral route is less painful and more reliable. The needle is inserted between the first and second premolars (bicuspids) caudally along the periosteum to a halfway point down the mandible (Fig. 143.6).

Digital nerve blocks

Nerve blocks for the fingers and toes are technically very similar. There are two options to anesthetize a digit. The technique most commonly used by dermatologists blocks the sensory nerves coursing laterally along the digit. A 0.5 inch (1.3 cm) needle is inserted perpendicular to the digit near its base in the horizontal plane until the bone is touched. At this point, the needle is withdrawn slightly, positioned dorsally and anesthetic is injected. Next, the needle is positioned ventrally and additional anesthetic is injected. This process is repeated on the other side of the digit. This block can be done without epinephrine or with dilute 1 : 500 000 epinephrine, and small volumes (usually <1.5 ml) should be injected to minimize the risk of ischemic injury from mechanical circumferential compression of the blood supply to the digit. However, as noted previously, there is no documented risk of ischemic injury from standard 1 : 100 000 epinephrine concentrations when used for digital anesthesia in patients without significant peripheral vascular compromise (as long as the injected anesthetic volume is limited).

Alternatively, the digit can be blocked at the level of the metacarpal or metatarsal bone. A 1.5 inch (3.8 cm) needle is inserted dorsally between the metacarpal/metatarsal bones, and anesthetic is infiltrated as the needle is advanced ventrally, with most of the anesthetic injected just dorsal to the palmar/plantar skin. This injection will block the metacarpal/metatarsal nerve, which travels immediately superficial to the flexor retinaculum. The process is repeated on the other side of the metacarpal/metatarsal bone of the digit being anesthetized. The advantage of this block is that there is less risk of compression injury than can occur with the more commonly performed digital block.

Penile nerve block

The dorsal nerve of the penis is a branch of the pudendal nerve. It divides into major anterior (dorsal) and minor posterior (ventral) branches at the base of the penis. By injecting a ring of anesthesia without epinephrine or with 1 : 500 000 epinephrine in the subcutaneous plane around the base of the penis, most of the penis will be anesthetized. The only areas that may require additional anesthetic infiltration will be the periurethral region of the glans and, sometimes, the ventral glans and frenulum.

Hand nerve block

With the popularity of botulinum toxin A for palmar and plantar hyperhidrosis, a method to anesthetize the palmar surface is necessary. Topical anesthetics are ineffective on palmoplantar skin, and local anesthetic injections into the palms and soles are very painful. Nerve block of the median nerve will anesthetize the palmar surface of the first three and a half fingers plus two-thirds of the palmar surface (Fig. 143.7). Block of the ulnar nerve will anesthetize the rest of the fingers and palm (Fig. 143.7). The median nerve lies in the carpal tunnel, deep to the palmaris longus tendon and between the flexor digitorum superficialis and flexor carpi radialis tendons. By apposing the thumb and fifth finger with the wrist slightly flexed, the palmaris longus tendon will become apparent. A 0.5–1 inch (1.3–2.5 cm) needle is inserted at the first (proximal) wrist crease, immediately medial (ulnar) to the palmaris longus tendon (Fig. 143.8). It is then advanced deep into the

Fig. 143.5 Intraoral route for infraorbital nerve block. The needle is inserted cephalad between the premolar (bicuspid) teeth in the midpupillary line.

Fig. 143.6 Intraoral route for mental nerve block. The needle is inserted caudally between the premolar (bicuspid) teeth in the midpupillary line.

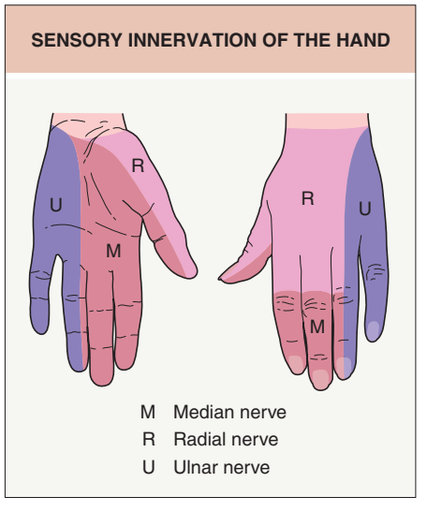

Fig. 143.7 Sensory innervation of the palmar surface and dorsal surface of the right hand.

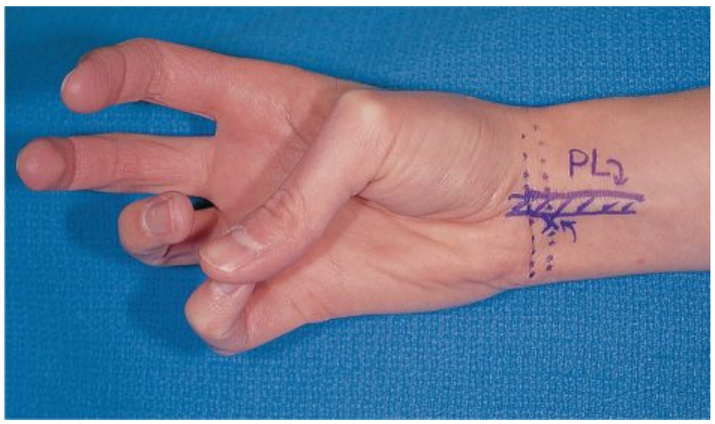

Fig. 143.8 Cutaneous markers for the median nerve location at the wrist. Note thumb and little finger apposition and wrist flexion to visualize the palmaris longus (PL) tendon. X, needle entry point.

carpal tunnel and a few milliliters of anesthetic are injected. A slight "popping" or reduction in resistance can be felt as the needle enters the carpal tunnel.

The ulnar nerve is most easily blocked at the elbow where it travels between the olecranon process and the epicondyle of the humerus. The ulnar nerve is the "funny bone". The patient's arm is flexed, and the needle is inserted between the bones with several milliliters of anesthetic injected.

An alternative is to have an anesthesiologist perform a Bier block, in which the blood is pushed out of the arm with a compressive bandage, a tourniquet is applied, and dilute lidocaine is injected intravenously. Anesthesia of the hand will develop in 5 to 10 minutes and last for about 1 hour. Once the procedure is complete, the tourniquet is gradually released and the anesthetic is released into the general circulation. Therefore, the dose administered should be monitored to keep it at a safe level.

Foot nerve block

Anesthesia of the plantar surface requires nerve blocks of the posterior tibial nerve, which innervates the heel and middle of the sole of the foot; the sural nerve, which innervates the fifth toe and the lateral side of the sole of the foot; the superficial peroneal nerve, which innervates the skin of the toes; the saphenous nerve, which innervates the instep; and the deep peroneal nerve, which innervates the skin between the first and second toes (Fig. 143.9). Before starting injections around the ankle, the area should be thoroughly prepped with antiseptic to minimize the risk of infection.

The patient is placed in the prone position. The posterior tibial artery is palpated or located using a Doppler ultrasound probe, and a 1.5 inch (3.8 cm) needle is directed anteriorly and laterally, immediately lateral to the arterial pulse, until the bone is touched. The needle is pulled back slightly, and several milliliters of anesthetic are injected in the groove between the medial malleolus and the Achilles tendon (Fig. 143.10). The sural nerve is blocked by injecting anesthetic in the groove between the lateral malleolus and Achilles tendon in an identical fashion to the tibial nerve injection (Fig. 143.10).

With the patient in the supine position, the saphenous and superficial peroneal nerves are blocked by infiltrating anesthetic subcutaneously from malleolus to malleolus along the dorsum of the foot (Fig. 143.11). The deep peroneal nerve is blocked by inserting a 1.5 inch (3.8 cm) needle lateral to the extensor hallucis longus tendon (toward the middle of the foot) down to the bone (Fig. 143.11). Next, the needle is pulled back slightly, and several milliliters of anesthetic are injected. The tendon is identified by having the patient dorsiflex his or her great toe against resistance. Alternatively, local anesthetic can be infiltrated between the first and second toes for easier and more expeditious anesthesia.

Higher Levels of Anesthesia

In anxious patients, or when relatively large areas are to be anesthetized, oral or sublingual anxiolytics such as triazolam (Halcion®) 0.25–0.5 mg or zolpidem tartrate (Ambien®) 5–10 mg will reduce anxiety and may even generate a certain degree of amnesia for the procedure. Diazepam (Valium®) 5–10 mg is useful for longer procedures due to its longer duration of action, but it does not produce amnesia for the procedure. The addition of a narcotic analgesic such as oxycodone (10 mg)/acetaminophen (325 mg) orally (Percocet®) or meperidine hydrochloride (Demerol®) 50 mg intramuscularly will act synergistically with the anxiolytics to achieve a greater degree of sedation as well as reducing the pain of local anesthetic infiltration. We find these useful for longer procedures done under tumescent anesthesia. Of course, consent for the procedure has to be obtained before taking any of these medications and patients must have someone else take them home after the procedure.

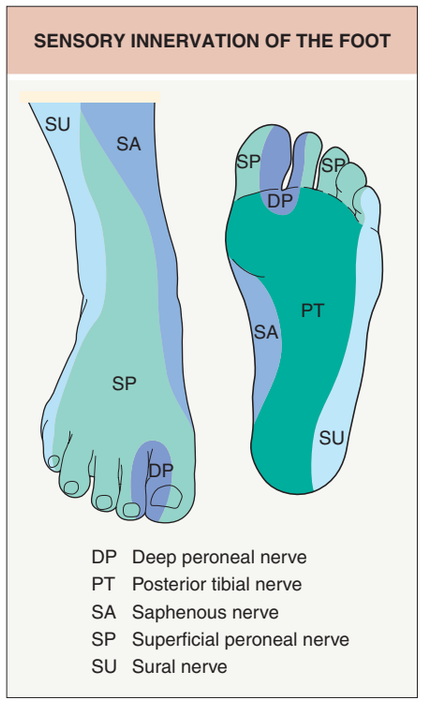

Fig. 143.9 Sensory innervation of the dorsal surface and plantar surface of the right foot.

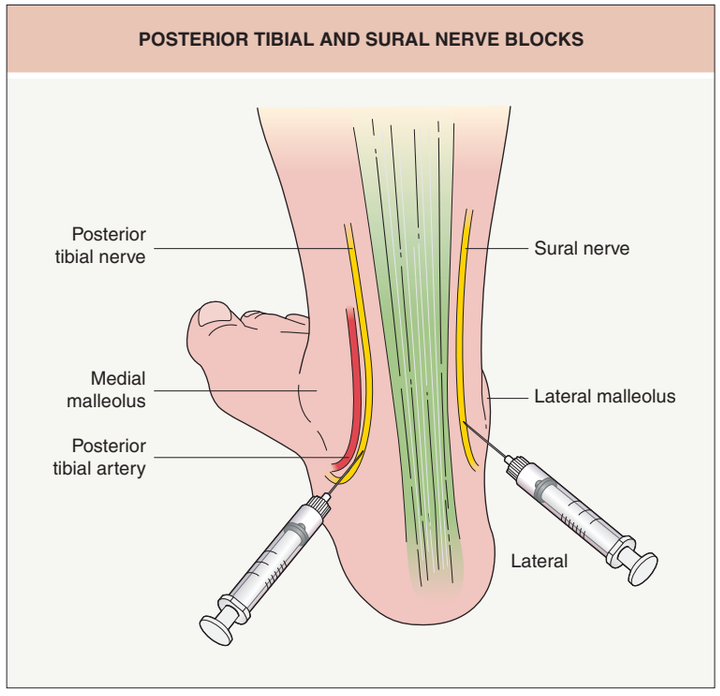

Fig. 143.10 Posterior tibial and sural nerve blocks.

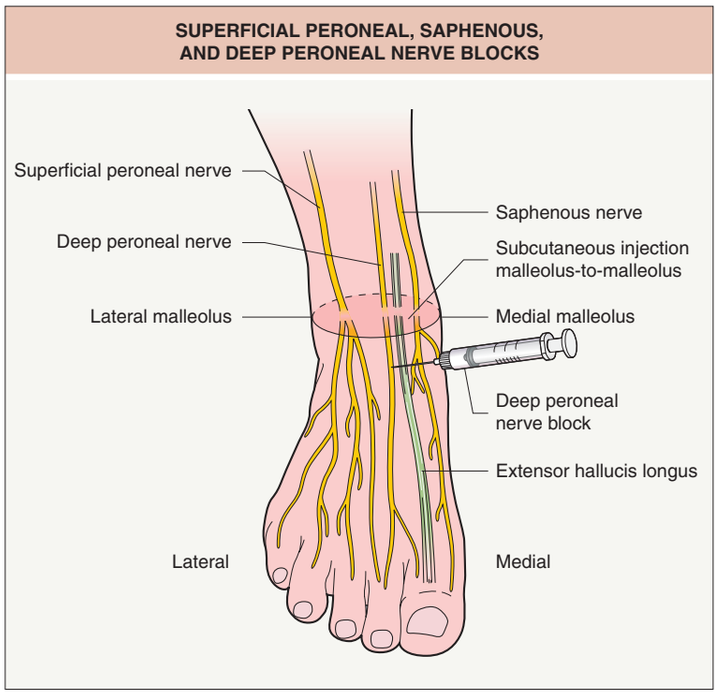

Fig. 143.11 Superficial peroneal, saphenous, and deep peroneal nerve blocks. Great toe dorsiflexion aids in visualizing the extensor hallucis longus tendon.

Credentialing for higher levels of anesthesia may be regulated by state or national (outside the US) medical licensure authorities and hospitals, and the physician must be in full compliance with the rules in his or her particular state or country. Most of the regulations require procedures done under general anesthesia or with intravenous sedation to be done in an ambulatory surgery center or hospital with a supervising anesthesiologist. Higher levels of anesthesia involving the use of intravenous medications such as midazolam hydrochloride (Versed®) and fentanyl should be done in a monitored environment with appropriate resuscitative equipment readily available. Nitrous oxide administration is a useful form of moderate analgesia, with the degree depending on the concentration administered. At a 20% concentration, the analgesia is equivalent to giving a narcotic analgesic. At an 80% concentration, most patients will become unconscious. The advantage of nitrous oxide is the rapid reversal of anesthetic effect as soon as the gas is turned off. With proper training, nitrous oxide can be safely administered in the office, as it has been done for many years in many dental offices. An easier version of nitrous oxide analgesia, Pro-Nox™ (Clarion Medical Technologies), delivers a fixed ratio of 50% nitrous oxide and 50% oxygen. The patient holds the mouthpiece and controls how much they inhale, remaining conscious throughout the procedure[27]. General inhalation anesthesia or deep intravenous sedation with propofol should generally be performed by anesthesiologists.

Wound Closure Materials and Instruments

144

Todd V. Cartee and Christie R. Travelute

Key features

- The characteristics ascribed to a suture include:
  - capillarity
  - USP size
  - coefficient of friction
  - plasticity
  - tensile strength
  - physical configuration
  - elasticity
  - memory
  - pliability
  - tissue reactivity
- Sutures used to approximate the dermis and deeper tissue layers are generally absorbable, while percutaneous sutures can be either absorbable or nonabsorbable
- The most commonly employed needle in dermatologic surgery is a 3/8 circle that is triangular in shape, with a reverse cutting surface
- Needle holders with small smooth jaws accommodate finer needles and those with large serrated jaws are best for larger needles
- The major types of scissors used in dermatologic surgery are Gradle, tissue, undermining, serrated, suture-cutting, and bandage-cutting

INTRODUCTION

As dermatologic surgery continues to expand as a specialty, so does the variety of materials and instruments that are available to facilitate the ever-growing complexity of tissue excision and repair that are encountered during its practice. A thorough working knowledge of these tools is essential and allows the physician to optimize the cosmetic and functional outcome for a given procedure. For example, the suture material and surgical instruments for a melanoma excision on the back will vary greatly from those chosen for a blepharoplasty. This chapter will review the wound closure materials and surgical instruments of the greatest value to the dermatologic surgeon. Helpful hints and model surgical tray setups are included to assist in the preparation for dermatologic surgery in specific anatomic locations.

DISCUSSION

Sutures

Since prehistoric times, humans have been using various materials to close skin wounds. The first known reference appears in the Edwin Smith Papyrus (c. 1600 BCE)[1]. Although the precise suture material was not described, examination of artifacts from that time period suggests that it was most likely linen. Hippocrates has been credited with being the first to use the term "suture" in reference to sewing human tissue in 400 BCE.

Over the centuries, suture materials that have been employed include cotton, leather, flax, insect mandibles, horse and even human hair[2–8]. Ancient Roman physicians would braid the hair of gladiators tightly to close their scalp wounds and by doing this, these innovative surgeons demonstrated the understanding that sutures can produce immediate hemostasis in addition to wound edge approximation.

The ideal suture, were it to exist, would handle easily, hold a secure knot, and have high tensile strength. It would neither cause inflammation nor promote infection, and it would gradually dissolve, thereby obviating the need for suture removal. Unfortunately, the perfect suture material does not exist. However, the ever-widening array of choices available to the dermatologic surgeon and a knowledge of each suture's individual characteristics increases the likelihood of choosing the best possible materials for each surgical situation.

Suture materials are divided into two categories: (1) absorbable; and (2) non-absorbable. Studies of wound-healing by Levenson et al.[9] have shown that during the first 1–2 weeks after surgery, the intrinsic tensile strength of the wound is ~7%–10% of native bursting pressure. At 5 weeks, the intrinsic tensile strength is ~60%, and, in general, after 1 month, dehiscence is unlikely with normal activity. During this time period, absorbable buried dermal sutures are utilized to alleviate tension and maintain wound edge approximation. Transepidermal, non-absorbable sutures are non-tension-bearing, but allow for fine adjustments of the epidermal edges.

The characteristic attributes ascribed to a suture are defined and standardized by the United States Pharmacopeia (USP) as follows:

- Two **physical configurations** exist: monofilament and multifilament. Multifilament suture can be spun, twisted, or braided. Braiding serves to increase pliability, strength, knot security and handling[10], but may abrade or shear tissue. Braiding also potentially increases the risk of infection by allowing bacteria to become entrapped within filament strands[11]. Monofilament sutures have a low coefficient of friction and slide easily through tissue (see below)[12]. Their drawback is that they are traditionally stiffer than braided suture and may have decreased knot security, requiring additional throws to ensure that the knot is secure.
- **Capillarity** is defined as the ability of a suture to absorb and transfer fluid. Multifilament sutures have greater capillarity than monofilament.
- The **USP size** of a suture is determined by the diameter needed to achieve a given tensile strength, and this is expressed in multiples of zeros; the smaller the cross-sectional diameter of the suture, the more zeros. For example, 7–0 polyglactin 910 (Vicryl®, Polysorb®) is a much finer suture than 3–0 polyglactin 910. The actual diameter of a given USP size varies depending upon the composition of the suture, with a 4–0 surgical gut being a larger-diameter suture than 4–0 polypropylene because polypropylene is innately stronger. In general, the smallest suture that will provide adequate tensile strength for the indicated repair should be utilized.
- **Elasticity** refers to the ability of a suture to regain its original length after being stretched. An elastic suture, such as polybutester, allows for tissue swelling and then maintains tension on the wound edges after the edema has resolved.
- The **coefficient of friction** determines the ease with which a suture will pull through tissue. A suture with a low friction coefficient, such as polypropylene, slides easily through tissue. For this reason, polypropylene is commonly used for the running subcuticular suture (see Ch. 146). Knot strength is directly proportional to the friction coefficient of the suture material. The more slippery the suture material, the more likely it is that the resulting knot will unravel. Hence, when suturing with polypropylene, it is prudent to place several additional throws for each knot.
- **Memory** is defined as a suture's tendency to retain its natural configuration and is determined by the elasticity and plasticity of the suture material. Memory is a useful property for maintaining closure during the postoperative period. High-memory sutures, such as nylon, are widely used for surface approximation. Drawbacks of high-memory sutures are that they do not handle very easily and have a relatively low knot strength. As with sutures that have a low coefficient of friction, a few extra throws may be helpful to ensure a secure knot. Suture material with low memory, such as silk, is easy to handle and rarely becomes untied.
- **Plasticity** is the ability of the suture to be molded or retain its new length and form as well as tensile strength after it has been stretched. This is an important characteristic for a suture material that is to be used in situations with tissue edema.

Sutures with plasticity, such as polypropylene, will stretch to accommodate edema and not cut into tissue[13].

- **Pliability** refers to how easily the suture can be bent. Braided suture materials, such as silk, are the most pliable, and they are capable of being tied readily into a knot.
- The **tensile strength** of a suture is determined by the force required to snap it divided by the cross-sectional diameter of the suture. In general, synthetic materials are stronger than natural materials. A suture that has been knotted has approximately one-third the tensile strength of the same material unknotted[14].
- **Tissue reactivity** is the degree of foreign body inflammatory response evoked by a suture when placed into a wound. In general, natural materials (such as surgical gut) are degraded by proteolytic enzymes and cause a far greater inflammatory response than do synthetic materials (such as poliglecaprone 25) which are absorbed by hydrolysis[12,15].

Types of Suture Material

Sutures are characterized as absorbable or non-absorbable based upon their ability to be enzymatically digested or hydrolyzed. Most absorbable sutures lose the majority of their tensile strength long before they are fully absorbed. Sutures that are absorbable do not require removal. In contrast, non-absorbable sutures are resistant to hydrolysis and enzymatic degradation. Non-absorbable sutures such as nylon and polypropylene are usually used as surface or cutaneous sutures, and they are routinely removed 5–14 days after surgery (earlier on the face and later on the trunk and extremities).

Absorbable sutures

The most commonly used absorbable sutures are described below and summarized in Table 144.1[16].

Surgical gut

Surgical gut (catgut), one of the first sutures ever mass-produced, is composed of 97%–98% purified collagen fibers derived from bovine or ovine intestine. It is a natural tan fiber that is packaged wet in alcohol and dries quickly when exposed to air. Plain surgical gut is not commonly used nowadays because of high tissue reactivity and slow digestion but rapid loss of tensile strength. Specifically, when used as a buried suture, plain gut loses its tensile strength within 7 to 10 days but requires 60 to 70 days for complete digestion[17].

Chromic gut is plain gut that has been processed with chromium salts to increase its resistance to enzymatic degradation and decrease its tissue reactivity. The tensile strength of chromic gut typically lasts for 10 to 14 days. Chromic gut is still widely used for suturing of mucosal surfaces.

Fast-absorbing gut is plain gut that has been heated to begin breakdown of the collagenous material within the suture prior to use. It maintains its tensile strength for 5 to 7 days[18]. Fast-absorbing gut has become popular for suturing skin grafts and for placing surface sutures in wounds that are well approximated by buried sutures. No increase in wound infections has been observed in comparative studies, and this suture is convenient for the surgeon and the patient because it does not require removal[18,19]. However, its relatively high coefficient of friction leads to noticeable tissue drag when suturing skin. This disadvantage

COMMONLY USED ABSORBABLE SUTURES

Suture	Configuration	Tensile strength	Ease of handling	Knot security*	Tissue reactivity	Uses
Surgical gut (plain)	Virtually monofilament	Poor at 7–10 days	Fair	Poor	Moderate	Rarely used nowadays in skin
Surgical gut (chromic)	Virtually monofilament	Poor at 21–28 days	Poor	Poor	Less than plain	Skin grafts, surface sutures for mucosae
Surgical gut (fast-absorbing)	Virtually monofilament	50% at 5–7 days	Fair	Poor	Low	Skin grafts, epidermal closure
Polyglycolic acid (Dexon®)	Braided†	20% at 21 days	Good	Good	Low	Subcutaneous closure, vessel ligature
Polyglactin 910 (Vicryl®, Polysorb®)	Braided†	75% at 14 days 50% at 21 days 25% at 28 days	Good	Good	Low	Subcutaneous closure, vessel ligature
Polydioxanone (PDS II®)	Monofilament	wks / 4/0 and smaller / 3/0 and larger 2 / 60% / 80% 4 / 40% / 70% 6 / 35% / 60%	Poor	Moderate	Low	Subcutaneous closure (high-tension areas)
Polyglyconate (Maxon®)	Monofilament	80% at 14 days 60% at 28 days	Fair	Good	Low	Subcutaneous closure (high-tension areas)
Poliglecaprone 25 (Monocryl®)	Monofilament	50%–60% at 7 days 20%–30% at 14 days 0% at 21 days	Fair	Moderate	Minimal	Subcutaneous closure (avoid if high-tension site)
Glycomer 631 (Biosyn®)	Monofilament	75% at 14 days 40% at 21 days	Fair	Moderate	Minimal	Subcutaneous closure; similar to poliglecaprone 25 plus an additional week of tensile strength
Polyglytone 6211 (Caprosyn®)	Monofilament	20% at 10 days	Fair	Moderate	Minimal	Subcutaneous closure; more rapid absorption than poliglecaprone 25

*Directly proportional to the friction coefficient and indirectly proportional to memory.
†Multifilament.

can be ameliorated by the addition of a thin layer of petrolatum ointment[20] (known as "greasing the gut").

Polyglycolic acid

Polyglycolic acid (Dexon®), introduced in 1970, was the first synthetic absorbable suture and its reduced tissue reactivity and predictable absorption profile represented a vast improvement over surgical gut[21]. It is a braided glycolic acid polymer with easy handling qualities, and it maintains 20% of its tensile strength at 3 weeks. Polyglycolic acid suture is available plain or coated with poloxamer 188. This lubricant coating allows the suture to pass more easily through tissue and makes it more pliable, which facilitates knot tying.

Polyglactin 910

Polyglactin 910 (Vicryl®, Polysorb®), a synthetic, braided copolymer of glycolide and L-lactide, was first introduced in 1974 and supplanted polyglycolic acid as the most popular buried absorbable suture in cutaneous surgery[22]. The water-repelling properties of lactide delay penetration of water and delay the loss of tensile strength. Polyglactin 910 maintains 75% of its tensile strength at 2 weeks and 50% at 3 weeks. Although stronger than polyglycolic acid, polyglactin 910 absorption is generally complete by 90 days, whereas polyglycolic acid is usually still being absorbed at 120 days[23].

Polyglactin 910 is available either undyed or dyed violet. Although the violet color usually dissipates, some surgeons avoid the dyed form because occasionally it may be visible when embedded in the skin[24]. Polyglactin 910 comes coated with a mixture of polyglactin 370 and calcium stearate that serves as a lubricant, facilitating the passage of the suture through tissue. Polyglactin 910 is immensely popular due to its easy handling characteristics and because it holds knots well and does not tear tissue.

Although polyglactin 910 is traditionally used as an absorbable dermal suture, it may be used safely for wound edge approximation as a running cutaneous suture and removed in 5–14 days[25]. This method still requires suture removal, but the use of a single suture for both the dermal and surface wound closure results in a 50% savings in suture cost per reconstruction. In the authors' experience, polyglactin 910 is also an excellent choice for the vermilion lip as it does not irritate the opposing mucosal surfaces and leads to much less inflammation than silk.

Polyglactin 910 is also available in a partially hydrolyzed form (Vicryl Rapide®), which is useful as a percutaneous suture that does not need to be removed as it spontaneously dislodges in 7–14 days. This suture is indicated for wound edge approximation where only 1–2 weeks of support will be needed and suture removal may be painful or is inconvenient.

Polydioxanone

Polydioxanone (PDS II®) is a monofilament polymer made from the polyester poly (*p*-dioxanone). The primary advantage of polydioxanone over polyglycolic acid and polyglactin 910 is prolonged tensile strength[26]. It maintains ~70% of its tensile strength at 2 weeks and 50% at 4 weeks. Traces of buried polydioxanone are present in 6-month histologic preparations[27]. Polydioxanone is employed in high-tension areas, such as the proximal extremities and trunk. When compared with polyglycolic acid in closure of skin wounds under tension, polydioxanone was associated with less scar spread and a lower incidence of hypertrophic scar formation[28].

Similar to polyglycolic acid and polyglactin 910, polydioxanone has minimal tissue reactivity[26] although it is slightly higher than poliglecaprone 25 in a murine model[27]. As a monofilament suture, it retains packaging memory[27] and can be relatively stiff and difficult to tie[29]. However, polydioxanone glides through tissue easily[27].

Polyglyconate

Polyglyconate (Maxon®), a copolymer of glycolic acid and trimethylene carbonate, is also an absorbable monofilament suture. Its overall properties and indications are similar to polydioxanone. It maintains 80% of its tensile strength at 2 weeks and 60% at 4 weeks[30], with complete absorption occurring via hydrolysis by ~180 days. Despite this prolonged absorption, there is minimal tissue reactivity. Polyglyconate may be most useful for large surgical procedures on the trunk or extremities that are under substantial tension and require prolonged, suture-based approximation during healing.

Poliglecaprone 25

Poliglecaprone 25 (Monocryl®) is an absorbable monofilament suture consisting of a copolymer of glycolide and ε-caprolactone. It exhibits very high *initial* tensile strength, but this declines rapidly in the early postoperative period with ~50%–60% of its tensile strength at 1 week, only 20%–30% at 2 weeks (undyed), and essentially 0% at 21 days[31]. This absorption profile limits its use in areas where prolonged dermal support is desired. Complete absorption occurs at ~90 days[27].

Poliglecaprone 25 offers supple handling and minimal tissue reactivity, which led to a lower incidence of hypertrophic scarring when compared to partially hydrolyzed polyglactin 910 (Vicryl Rapide®) for skin approximation in a breast reduction scar model[32]. Furthermore, poliglecaprone 25 demonstrates better knot tying and security than other commonly used absorbable monofilament suture materials[27]. Because poliglecaprone 25 induces less inflammation than polyglactin 910 and glides easily through tissue, for many dermatologic surgeons it has become the absorbable suture of choice for low tension closures in the head and neck region. In a randomized study of deep dermal sutures for repair of Mohs defects, a statistically higher rate of suture extrusion occurred with polyglactin 910 (11%) versus poliglecaprone 25 (3%), but there was no difference in ultimate cosmesis[33].

Its minimal tissue reactivity permits the use of poliglecaprone 25 for epidermal approximation (with removal at 5–14 days), thereby eliminating the need for separate dermal and surface sutures. A randomized, blinded, split-scar study comparing running 5–0 poliglecaprone 25 versus 6–0 polypropylene for facial surface closures found no significant differences in cosmetic outcome at 1 week or 4 months[34]. Poliglecaprone 25 can also achieve epidermal approximation as a running subcuticular suture that does not require removal[35].

Glycomer 631 and polyglytone 6211

Glycomer 631 (Biosyn®) and polyglytone 6211 (Caprosyn®) are absorbable monofilament sutures with comparable physical characteristics to poliglecaprone 25. Complete absorption of glycomer 631 occurs between 90 and 110 days, with low tissue reactivity. Polyglytone 6211, introduced in 2002, was designed to offer the most rapid absorption profile within this class of suture (20% tensile strength at 10 days; complete absorption at 56 days). This property was postulated to underpin its reported low rate of suture extrusion[36].

Non-absorbable sutures

The most commonly used non-absorbable sutures are described below and summarized in Table 144.2[16].

Silk

Silk is a braided, natural suture. It represents the gold standard for ease of handling, knot formation and knot stability, by which newer synthetic sutures are measured. Because braided silk is very soft and pliable, it is commonly used on mucosal surfaces and in intertriginous regions. Despite these advantages, there are major drawbacks to its use in cutaneous surgery. Silk has a low tensile strength, its braided configuration produces a high coefficient of friction, and the high capillarity increases the risk of infection. In fact, the presence of one braided silk suture in a contaminated wound was shown to increase the virulence of staphylococci by 10 000-fold[37]. As an organic, foreign protein (fibroin) made by the silkworm, silk has very high tissue reactivity.

Nylon

Nylon (Ethilon®, Dermalon®), a monofilament polymerized polyamide, was the first synthetic non-absorbable suture to become commercially available. Because of its low cost, high tensile strength and low tissue reactivity, nylon is the most commonly used non-absorbable suture in dermatologic surgery[38,39]. It is also available as a braided suture (Surgilon®, Nurolon®) which handles more easily but is more expensive.

Nylon's elasticity allows it to expand and contract with transient wound edema but its stiffness and memory lead to decreased knot security[39]. In practice, this can be easily counteracted by firmly setting knots and increasing the number of knot throws. This monofilament is available as clear or dyed in a black or green color. The green suture can be helpful when working in dark hair-bearing areas.

Traditionally, nylon is placed as a cutaneous suture but clear nylon may be used as a tension-bearing deep suture that is not removed.

COMMONLY USED NON-ABSORBABLE SUTURES						
Suture	**Configuration**	**Tensile strength**	**Ease of handling**	**Knot security***	**Tissue reactivity**	**Uses**
Silk	Braided†	No decrease in 365 days	Gold standard	Good	Moderate	Mucosal surfaces
Nylon:						
Ethilon®	Monofilament	Decreases 20% per year	Good to fair	Poor	Low	Epidermal closure
Dermalon®	Monofilament	Good	Good to fair	Poor		
Surgilon®	Braided†	Good	Good	Fair		
Nurolon®	Braided†	Good	Good	Fair		
Polypropylene (Prolene®, Surgilene®, Surgipro®)	Monofilament	Extended	Good to fair	Poor	Minimal	Running subcuticular suture
Polyester (Dacron®, Mersilene®, Ethibond®)	Braided†	Indefinite	Very good	Good (coating decreases)	Minimal	Mucosal surfaces
Polybutester (Novafil®)	Monofilament	Extended	Good to fair	Poor	Low	Epidermal closure

*Directly proportional to the friction coefficient and indirectly proportional to memory.
†Multifilament.

Table 144.2 Commonly used non-absorbable sutures. *Adapted from Garrett AB. Wound closure materials. In: Wheeland R (ed). Cutaneous Surgery. Philadelphia: WB Saunders, 1994:199–205.*

It can be very useful when approximating the orbicularis oris muscle in a lip wedge repair or tacking tissue to the periosteum in situations where prolonged wound strength is desired.

Polypropylene

Polypropylene (Prolene®, Surgilene®, Surgipro®) is a monofilament polymer of propylene. It is an inert plastic that has minimal tissue reactivity. The major advantage of this suture is its low coefficient of friction, which allows for a gentle, smooth pull through tissue[40]. Even after extended periods of time, it can be withdrawn easily without disrupting the wound (Fig. 144.1). This characteristic makes it a good choice for the running subcuticular suture. Polypropylene also has high plasticity and stretches with tissue swelling, thus reducing the likelihood of postoperative track marks[13,39]. Disadvantages of this suture are its memory (which compromises knot security) and increased cost compared to nylon. It is available in clear and dyed blue forms. Similar to nylon, polypropylene may be used as a subcutaneous suture in areas of high tension to provide prolonged support.

Fig. 144.1 Polypropylene suture. The blue color of the polypropylene suture is visible under the skin one year after its placement as a running subcuticular closure; the patient had neglected to return for suture removal. The suture was easily removed even after one year given its very low coefficient of friction and minimal tissue adherence.

Polyester

Polyester sutures (Dacron®, Mersilene®, Ethibond®) are braided, multifilament sutures with high tensile strength, very good handling, and low tissue reactivity. Ethibond® comes coated with polybutilate, which decreases its drag through tissue (decreased friction coefficient). Similar to polyglactin 910, polyester sutures are of great assistance for approximation of mucosal tissues, particularly the vermilion lip. They combine the soft feel of silk with a lack of tissue reactivity.

Polybutester

Polybutester (Novafil®) is a monofilament suture of polyglycol terephthalate and polybutylene terephthalates. Its major advantages are good handling, low coefficient of friction, high elasticity, and low tissue reactivity[41].

Suture Selection

In general, a surgeon should select the smallest suture that will provide adequate strength for a given closure (Table 144.3). For facial repairs under low tension, 4–0 or 5–0 polyglactin 910 or poliglecaprone 25 are common absorbable sutures, and 5–0 or 6–0 nylon, polypropylene or fast-absorbing gut are typical cutaneous sutures. Poliglecaprone 25 is popular as a dermal suture due to its relatively fast absorption and reduced rate of suture extrusion. Polypropylene (removed at 7–14 days) or poliglecaprone 25 (buried and left in place) are the most commonly used sutures for running subcuticular closures. Polyglactin 910 (buried and left in place) may also be employed as a subcuticular suture despite concerns over tissue reactivity with such superficial placement. Indeed, in a randomized controlled trial (RCT), polyglactin 910 resulted in better scar appearance than polypropylene removed at 14 days[42].

For larger truncal defects, 3–0 or 4–0 polyglactin 910 or poliglecaprone 25 for buried sutures and 3–0 or 4–0 nylon for superficial closure are good choices. Alternatively, running subcuticular closures are particularly valuable on the trunk and extremity to eliminate the possibility of suture track marks[43], which are common in these locations. Polydioxanone and polyglyconate offer the most prolonged dermal support and are a consideration for wounds under significant tension, while poliglecaprone 25's rapid loss of tensile strength makes it a poor choice for such closures. An alternative to traditional sutures are skin staples. They offer a quick, strong method for surface closure of large scalp and truncal defects[44].

Fast-absorbing gut (5–0 or 6–0) is a convenient suture for skin grafts and for any head and neck reconstructions that are well approximated with buried sutures. While some surgeons are concerned that fast-absorbing gut's relatively higher tissue reactivity might increase early peri-incisional erythema and suture track marks, this has not been the

COMMONLY UTILIZED SUTURES BY SITE			
Site	**Deep suture**	**Surface suture**	**Other suture**
Face	4–0/5–0 polyglactin 910 or poliglecaprone 25	(1) 5–0/6–0 nylon or polypropylene (2) 6–0 fast-absorbing gut or partially hydrolyzed polyglactin 910	
Neck and distal extremities	4–0 polyglactin 910 or poliglecaprone 25	(1) 4–0/5–0 nylon or polypropylene (2) 4–0/5–0 poliglecaprone 25 running subcuticular	
Trunk, proximal extremities, and scalp	3–0/4–0 polyglactin 910 (any) or poliglecaprone 25 (low tension) or polydiaxonone (high tension)	(1) 3–0/4–0 nylon or polypropylene (2) 4–0/5–0 poliglecaprone 25 running subcuticular	
Mucosa	None	(1) 5–0 silk (2) 5–0 polyester or 5–0/6–0 polyglactin 910	
Vascular ligature			3–0/4–0 polyglactin 910

Table 144.3 Commonly utilized sutures by site. In practice, there is considerable variation, depending upon the preference of the surgeon and the characteristics of the wound, and this table reflects the bias of the authors and editors. For surface sutures: (1) = option if sutures are to be removed and (2) = option if sutures are left in place.

authors' experience. An RCT comparing 5–0 fast-absorbing gut and 5–0 polypropylene did find a small, but statistically significant, difference in cosmetic outcome that favored polypropylene; no difference in erythema was observed[45]. Another properly powered RCT focusing on facial skin closures found no difference in cosmetic outcomes between 5–0 and 6–0 fast-absorbing gut[46]. However, this study did not include repairs on the nose, lip, or eyelid.

Cyanoacrylate tissue adhesives (e.g. 2-octyl-cyanoacrylate [Dermabond®], a blend of 2-octyl-cyanoacrylate and *n*-butyl-cyanoacrylate [GluSeal®, LiquiBand®]) offer a practical and rapid alternative method of epidermal closure for wounds that are well-approximated with deep sutures[47,48]. Wound closure tapes offer a non-traumatic alternative to epidermal sutures, and they are useful when applied to healing wounds following suture or staple removal. Additionally, they can be used over a running subcuticular suture at the time of surgery, relieving tension on the wound edges and providing a cosmetic, convenient alternative to a daily dressing change[49]. Maloney and colleagues[50] demonstrated that the optimal application of wound closure tapes is in a parallel non-overlapping pattern, following complete coating of the skin surface with liquid gum mastic adhesive. MicroMend® is a wound closure device that mimics a butterfly closure and can be removed by the patient. It consists of two arrays of microstaples anchored onto the skin and connected by a bridge. Although this device is an efficient alternative to sutures, studies are needed to determine its value compared to other wound closure options.

Complications

Suture-related complications are generally associated with placement technique, e.g. tied too tightly with strangulation of the tissue, tied too loosely and not approximating the wound edges well, or placed too superficially and extruding through the suture line. However, suture materials can also create complications due to their inherent properties. Some suture material, such as surgical gut and silk, are quite inflammatory. Synthetic absorbable sutures, such as polyglactin 910 and poliglecaprone 25, generally create little tissue reaction, but occasionally they may cause a granulomatous foreign body reaction (see Fig. 151.18).

Patients can develop a sterile pustule or suture abscess with associated inflammation ranging from mild to marked with focal ulceration (Fig. 144.2). These reactions can be distressing, especially if the patient has not been warned of the possibility that they may occur. In patients receiving anticoagulants, the reaction may be hemorrhagic rather than purulent (see Fig. 144.2C,D). Rarely, they may become secondarily infected, and those reactions that are particularly purulent or exudative should be cultured for bacteria. Deep sutures may also extrude or "spit," sometimes creating a sinus track within the skin.

Removal of the offending suture is the basic treatment for both suture abscess and suture extrusion. If it is readily accessible, the suture should be grasped with a smooth forceps and snipped. A comedone extractor may help to express a suture that is slightly embedded; otherwise, the intact skin overlying the suture may need to be nicked with a #11 blade and then gently probed with a tissue forceps. Antibiotics are rarely necessary. Removing the foreign suture material is usually sufficient to resolve the reaction.

Needles

The ideal needle is sharp and strong, and closely matches the suture diameter. The needle should be strong enough to hold its shape and retain its sharpness, pass after pass. The best needles are made of high-quality stainless steel, and the size and shape of the needle should be selected to correspond to the thickness and toughness of the tissue to be sutured.

There are several major brands of suture materials and each manufacturer uses a different needle nomenclature (Fig. 144.3). Most manufacturers, however, provide needle comparison reference guides. In general, the needle is the most expensive component of the needle/suture and the latter is the most expensive disposable used in dermatologic surgery.

A needle is composed of three parts: the shank, the body and the point (Fig. 144.4)[51]. In dermatologic surgery, most needles have a swaged shank with a hollow proximal end into which the suture is inserted and then crimped. The suture track is determined by the size of the needle shank, not the suture size. The body of the needle can be straight, 1/4 circle, 3/8 circle, 1/2 circle, or 5/8 circle (Fig. 144.5). The most common shape used in skin surgery is the 3/8 circle. Alternatively, 1/2 circle needles are valuable for suturing in tight spaces such as placing deep dermal sutures within small (<1 cm) nasal and eyelid defects or fitting multiple buried sutures into high tension wounds on the back or scalp. For the former, the authors use the P-2 needle[52] and for the latter, find the RB-1 taper point needle an excellent choice.

The most common needle used in cutaneous surgery is the triangular, reverse-cutting type (see Fig. 144.4). Triangular "cutting" needles pass through dense tissues more easily than round taper point needles. The *conventional cutting* needle has its sharp edge on the inside arc of the needle while the sharp edge of the *reverse cutting* needle faces outward. Reverse cutting needles are preferred as they minimize the risk of tearing through the wound edge during suture placement. Taper point needles do not pierce dense tissue easily, but they are less likely to tear delicate tissues such as nasal mucosa.

For the majority of wound closures on the face, the Ethicon P ("plastic") and PS ("plastic skin") or an equivalent series are adequate and economical (see Fig. 144.3). The PS-2 and P-3 needles are particularly suited to dermatologic surgery. They are reverse cutting and their tips are electropolished for added sharpness. The PC ("precision cosmetic") series represents Ethicon's superior skin surgery needles, and they can be used for fine, delicate work. These needles have the sharpest tips and have flattened bodies for better grasping and needle strength. If wound edges are fragile, one must exercise some caution when using PC needles with conventional cutting points. The PC-1 needle is a very fine, sharp, 13 mm needle ideal for delicate facial repairs and is the only PC needle attached to fast-absorbing gut.

The FS ("for skin") and equivalent series of needles are not finely honed, and they are less sharp and less expensive. These needles are adequate for skin surgery on the trunk or extremities. SC-1 is a 13 mm straight needle that the authors believe facilitates full-thickness through and through quilting sutures placed to conform flaps and grafts to the topography of the ear[53].

The number after the series designation denotes the needle size. Most needles are drawn to size on the package (Fig. 144.6). The smallest needle/suture unit that will provide adequate tensile strength for a

given repair should be utilized. In areas with thick dermis such as the back, larger needles (e.g. PS-1 or PS-2) are much easier to pass through the tissue without bending.

Instruments

Instruments that provide the greatest precision and speed for a given procedure should be selected. There is a wide variation in the cost and quality of surgical instruments. Low-quality, low-cost instruments should be avoided as they are poorly finished and, therefore, are more difficult to use and lack durability. A high-quality instrument will more than make up for its cost by performing well day after day in countless procedures. Modern instruments are a blend of surgical stainless steel with carbon alloy, chromium, nickel and tungsten carbide. Tungsten carbide is a very hard alloy that enhances the function and durability of the blades of scissors and the jaws of needle holders. Quality instruments are usually covered by a warranty which will range from 1 to 5 years or even the life of the instrument, depending on the instrument type and cost.

It is important to keep instruments in good condition by properly caring for them and keeping them sharp. For example, using delicate scissors to cut suture will dull them quickly. Rough handling of delicate forceps and needle holders during surgery or the sterilization process may cause them to become misaligned. Any instrument that is not fully functional should be removed from the surgical tray and sent to the manufacturer for repair.

Some of the authors' instruments of choice for given procedures are listed and shown in Figures 144.7 through 144.9.

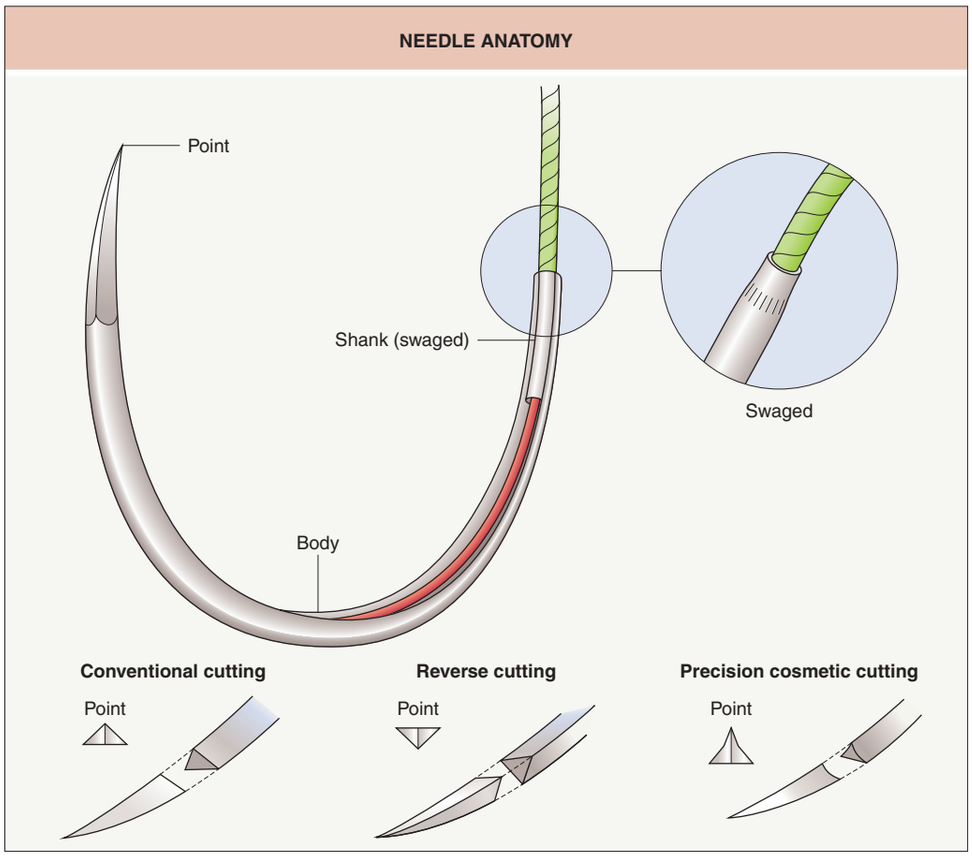

Fig. 144.4 Needle anatomy. The shank body and point are shown as are specific needle points for different types of cutting. Needles should be grasped at approximately one-third of the distance from the swaged area to the point. Avoid placement on or near the swaged area or near the tip.

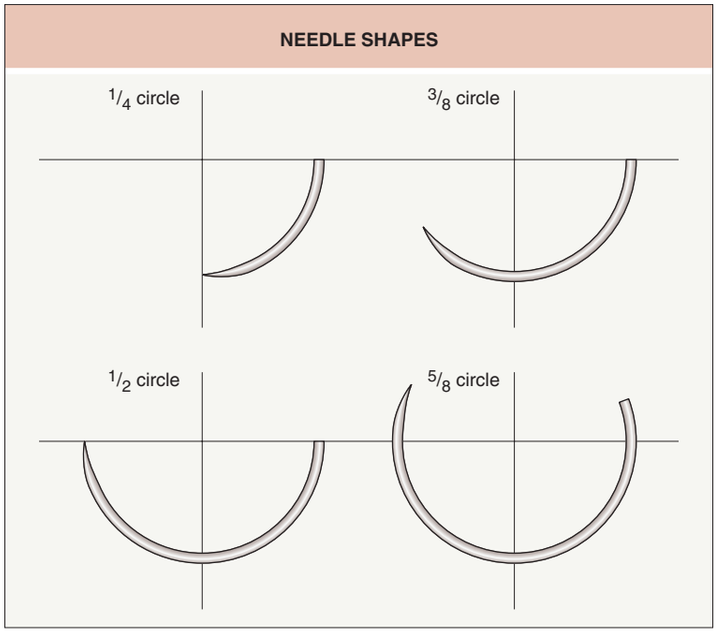

Fig. 144.5 Needle shapes. The most common curvature used in skin surgery is the 3/8 circle. The 1/2 circle curvature is useful when working in confined spaces.

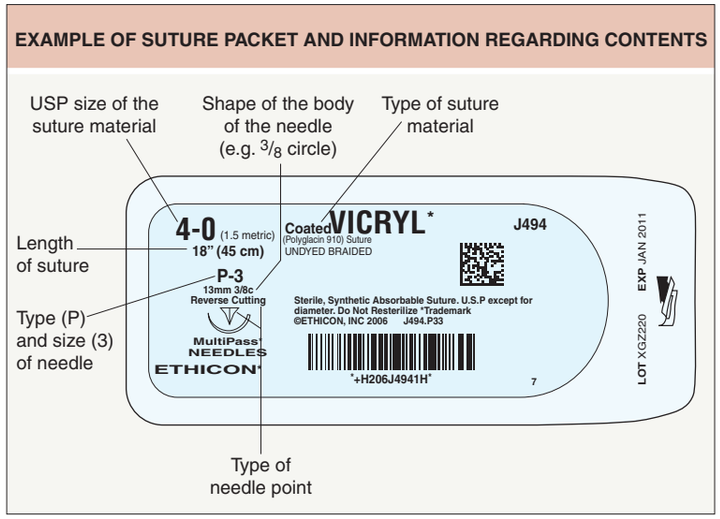

Fig. 144.6 Example of suture packet and information regarding contents.

Curettes

Developed in the late 1800s, the dermal curette has been used to treat a wide variety of cutaneous neoplasms, both benign and malignant. Common curettes are straight with a round head (Fox) or possess an oval head set at an angle from the stem (Cannon). They are labeled by size, depending upon the aperture of the cutting surface of the curette. Mancuso–Fox and Mancuso–Cannon curettes are also available, which have a ruler on the handle. For standard curettage and electrodesiccation, a set of curettes ranging from 6 mm down to 2 mm may be employed. Generally the larger curette is used first to debulk the tumor. This is followed by the smaller curette, which is used to remove small pockets of residual tumor. Smaller curettes (1–2 mm) are excellent instruments for obtaining subungual keratotic debris for fungal culture and KOH examination or detection of scabies mites. Curettes can also be used to debulk tumors, thereby better delineating their margins prior to excision[55]. With repeated use, curettes will become dull and must be periodically sharpened. There are disposable, single-use curettes; however, they tend to be very sharp and may cut into healthy tissue.

Fig. 144.7 Facial surgical instruments. Authors' tray for facial surgery/repair includes (from left to right) two curved Mosquito hemostats, suture scissors, a double-pronged and a single-pronged skin hook, delicate Webster needle holder, curved iris scissors, delicate Supercut® Shea undermining scissors, 0.9 mm Castroviejo forceps, and Siegel blade handle with #15 blade. Two towel clamps are at the top.

Fig. 144.8 Trunk or extremity surgical instruments. Authors' tray for larger procedures in thicker skin includes (from left to right) curved Mosquito hemostats, suture scissors, skin hooks, Mayo–Hegar needle holder, curved iris scissors, Supercut® Metzenbaum undermining scissors (excellent when extensive undermining is anticipated; otherwise, baby Metzenbaum or Shea scissors are sufficient), Adson toothed forceps, and #3 handle with #10 blade. Two towel clamps are at the top.

Scalpels

The choice of scalpel handle and blade is based on the surgical site and personal preference of the surgeon (Fig. 144.10). The flat, standard #3 handle is the one used most frequently in dermatologic surgery as it is durable, inexpensive, and adequate for the majority of cutaneous procedures. This instrument is available with or without a ruler on the handle. Ergonomic refinements have led to the introduction of several additional handles that offer more precise control and better grip, e.g. the thinner, longer, grooved #7 handle. The Siegel handle, which is a thin, round, knurled and well-balanced handle, is well suited for Mohs micrographic surgery. It is easily rolled with the fingers to facilitate very subtle adjustments in the cutting angle. For small procedures, such as those on the eyelid and/or ear, some surgeons prefer short, round, knurled blade handles that hold slender specialized mini-blades (see below).

The most commonly used blades in dermatologic surgery are #15, #10, and #11. The #15 blade is the most popular blade. It is gently curved and is appropriate for the majority of skin surgery. The #10 blade is a wide blade, similar in shape, but larger than the #15 blade; it is favored when cutting through sites with thick dermis such as the back. The #11 blade is tapered to a sharp point; it is used to create stab incisions for drainage procedures, the removal of milia, precise standing cone removal, and "through and through" excisions. It is often used with the cutting surface up, which is opposite to the positioning of the #10 and #15 blades. Scalpel blades are made of either stainless steel or sharper, more expensive, Teflon®-coated carbon steel. Disposable scalpels attached to plastic handles are available, but they are not weighted and are usually less sharp.

Needle holders

Needle holders for facial and hand surgery are small and light with narrow, fine jaws, while larger needle holders with wide sturdy jaws are designed for work on the trunk and proximal extremities. The jaws of needle holders are either smooth or serrated (Fig. 144.11). Serrations prevent twisting of larger needles (e.g. Ethicon PS-2 and FS-2) during suturing. Smooth jaws are less damaging to fine-caliber needles (e.g. Ethicon P-3) and will not tear finer sutures (6–0), but suture needles may slip if not grasped carefully. Alloy inserts of tungsten carbide serve to increase the strength and hardness of the jaws and these inserts improve the grip on needles in smooth-jawed needle holders

Fig. 144.9 Eyelid tray. Tray setup for eyelid surgery includes (bottom row, left to right) hand-held electrocautery, #3 blade handle, iris scissors, Westcott (or Castroviejo) scissors, Castroviejo needle holder, and two 0.5 mm Castroviejo forceps, in addition to (top row, left to right) Castroviejo calipers (used for measuring dimensions of eyelid skin grafts and planning tarsoconjunctival flaps[54]), 2-pronged delicate skin hooks, 4-pronged skin hooks (rakes), and curved Mosquito clamp.

Fig. 144.10 Scalpel handles and blades. From left to right: #3 handle with #10 blade, Siegel handle (authors' preference) with #15 blade, and Beaver handle with #64 blade.

(see Fig. 144.11). Instruments with tungsten carbide inserts are readily identified by their gold finger handles; they are more expensive but are typically guaranteed for five years. There are also small needle holders that have delicate serrated jaws, which allow for a good grip on fine needles without shredding fine sutures. Large needles should not be used with fine needle holders as this may lead to damage to the inserts of these delicate instruments.

Popular models such as the 4.5- to 5-inch long Webster and Halsey needle holders, which have smooth or delicately serrated jaws and tapered tips, are ideal for the small needles and fine suture materials that are commonly used for cutaneous facial surgery (see Figs. 144.7 and 144.11). However, use of these instruments for procedures on the trunk will quickly lead to their misalignment. The Crile-Wood needle holder has a gently tapered blunt tip; it is designed to hold larger needles and is more appropriate for skin surgery on the trunk or extremities. Baumgartner and Mayo–Hegar holders are durable, strong drivers with short tips and serrated jaws, providing a mechanical advantage with larger needles in thicker skin (see Figs. 144.8 and 144.11). The Olsen–Hegar needle holder has suture-cutting scissors behind the jaws and is convenient to use when working alone although it is easy to inadvertently cut the suture when attempting to regrasp the needle.

Scissors

Surgical scissors are required for cutting skin, undermining the subcutis and deeper fascial layers, cutting sutures, and removing wound dressings (Fig. 144.12). Scissors may have long or short handles, and the blades are straight or curved and serrated or smooth. The tips may be sharp or blunt. Scissors used in cutaneous surgery can be either completely stainless steel (most popular, least expensive) or have tungsten carbide inserts to strengthen the blades.

Gradle scissors are small, delicate, sharp-tipped, and tapered to a very fine point with a gentle curve. Due to their sharpness and precision, Supercut® Gradle scissors are ideal for removing thin stages during Mohs micrographic surgery and for removing skin tags. Gradle scissors must be used with care, and they should never be used to cut sutures. With improper use, they are quickly dulled, the cutting surfaces are nicked, and the tips are easily malpositioned.

Tissue scissors have relatively short handles and sharp tips. They are available in straight or curved models, with or without the serrations that prevent tissue motion during cutting. Of the various models available, the authors prefer curved Supercut® iris scissors to cut tissue and for sharp dissection. Supercut® iris scissors have the sharpest edge and they are easily recognized by their black handles. These scissors have a fine beveled angle at the cutting edge, and they are available with smooth edges or one serrated edge. The "razor-like" edge of these scissors enables the surgeon to cut tissue in a smooth, easy motion.

Westcott and Castroviejo scissors are delicate, spring-loaded tissue scissors with very sharp tips (see Fig. 144.9). The configuration of their handle and spring-loaded action make them ideal for manipulation in small delicate sites. For this reason, they are popular with oculoplastic surgeons. They should only be used for cutting thin tissue, such as that encountered in eyelid surgery, or they will dull quickly.

Large, less expensive scissors are sufficient for cutting sutures. Tissue scissors should never be used to cut sutures. Specially designed suture-removal scissors with a half-moon hook on the lower blade are available

Fig. 144.11 Comparison of delicate Webster and Mayo–Hegar needle holders. This Webster needle holder (right) features tungsten carbide jaw inserts which add strength and improve the grip on fine needles in smooth-jawed needle holders. The serrated jaws of the larger Mayo–Hegar needle holder (left) provide a firm grip on large needles, but may shred fine suture and optimally should only be used with 2–0 to 4–0 suture.

Fig. 144.12 Standard scissors. From left to right: Supercut® Gradle scissors, Supercut® iris scissors, and Supercut® baby Metzenbaum scissors. *Courtesy Glenn Goldman, MD.*

and the small hooked tip easily grasps the loop and prevents accidental sticks.

Undermining scissors are usually blunt-tipped (for safety) and have longer handles (for comfort). They are available in different sizes to accommodate the various anatomic regions in which skin surgery is performed. Baby Metzenbaum scissors have a high handle-to-blade length ratio, and, with the resultant small blade arc, they have become the most widely used scissor for sharp or blunt undermining (see Fig. 144.12). Larger Metzenbaum scissors are appropriate for extensive undermining in fascial planes on the scalp, trunk, and extremities (see Fig. 144.8). Stevens tenotomy scissors and Supercut® Shea undermining scissors are utilized for more superficial, delicate undermining (see Fig. 144.7). The tips of these scissors allow for sharp, less traumatic undermining.

For bandage-cutting, 5.5-inch Lister scissors are the most popular, with their angled blades and large blunt tips that easily slide under a dressing without damaging the underlying skin. The Universal scissor is also a popular choice. The serrated edges and larger rings provide greater cutting power.

Forceps

Proper forceps are essential for delicate, safe handling of tissue and suture needles during skin surgery. The most useful forceps in skin surgery are lightweight and have fine tips. The tips may be toothed, serrated, or smooth. Serrated forceps can exert excessive pressure on tissues, resulting in crush injury. Toothed forceps have opposing fine teeth and thus exert less pressure overall. Only toothed forceps should be used to grasp the epidermis and superficial dermis. For cutaneous surgery, the most popular tissue forceps (Adson) has 1×2 teeth. Some forceps have both distal teeth for handling of tissue and a more proximal raised platform for firmly grasping suture needles, allowing the surgeon to avoid manual handling of sharp needles.

Forceps are available with delicate (≤0.9 mm), regular (1–1.5 mm), or heavy (≥1.6 mm) tips. Adson forceps are the standard large forceps used for excisional surgery on the trunk and proximal extremities. Bishop–Harmon forceps and Foerester forceps are very lightweight, fine-tipped, and ideal for delicate work on the face and hand. Because these forceps are easily bent and misaligned, they must be handled with care, and they should not be used for manipulating the thicker skin of the trunk or proximal extremities. Castroviejo forceps usually feature a suturing platform and offer the delicate tip of a Bishop–Harmon forceps, but with a sturdier build and wider grip (see Fig. 144.7).

Both epilating and jewelers' forceps have fine, sharp points and are useful for suture removal. Splinter forceps have fine, extra-fine or superfine delicate pointed tips, and they are used in hair transplants, for splinter removal, and for removing embedded sutures.

Hemostats

Hemostats are used to grasp bleeding vessels prior to ligation. The most popular hemostat is the Halsted Mosquito model which is available in 3.5-inch and 5-inch lengths, either curved or straight, and either delicate- or regular-tipped. A modified instrument known as an Allis clamp is particularly helpful during cyst or lipoma removal (Fig. 144.13). It has finger grips and a locking mechanism similar to a hemostat, however, the jaws have opposing sharp teeth that grasp tissue firmly. Since these teeth can devitalize tissue, the Allis clamp is only used to provide traction on tissue that is being excised, such as a cyst wall.

Skin hooks

Skin hooks enable the surgeon to handle tissue with minimal trauma, and they are particularly useful for elevating flaps and reflecting skin edges during undermining[55]. Many surgeons also use skin hooks to visualize bleeding vessels for hemostasis and for placement of dermal sutures. Skin hooks possess a sharp tip that has the potential to inflict a perioperative sharps injury. Thus, these instruments should be handled with caution and the tips shielded on the tray when not in use as is done with scalpels and needles.

Skin hooks are available in single-, double- or multiple-pronged patterns. The multiple-pronged instruments are used mainly for rhytidectomies and larger truncal procedures in which large flaps are being elevated. Single-pronged hooks are used most frequently for undermining delicate skin or for placing sutures. The single shepherd hook – which has a more circular shape – holds tissue better than does the single standard hook, but it does not release as easily. Some surgeons prefer the double-pronged skin hook due to its lower risk of puncture injury to the operator or assistant.

Special Instruments

For delicate work near the eye, the dermatologic surgeon needs fine instruments that allow for precise cutting and carefully controlled tissue manipulation. The Beaver handle, which comes in a variety of sizes, can be rolled with one's fingertips, providing greater precision and control (see Fig. 144.10). Beaver handles are fitted with specialized smaller, sharper blades. The #64 blade has a rounded tip that one may prefer for work around the eye. The #67 and #65 blades are smaller versions of the #15 and #11 blades, respectively. However, these mini-blades dull more rapidly than do the standard #15 blades. Angled Beaver blades (Beaver® 6600) are useful for taking Mohs stages or biopsies in the ear canal.

The Castroviejo needle holder is ideal for suturing the delicate skin near the eye. This needle holder has spring handles and an optional

Fig. 144.13 Allis clamps. The inset highlights the sharp teeth which can firmly grasp a cyst or lipoma to facilitate removal.

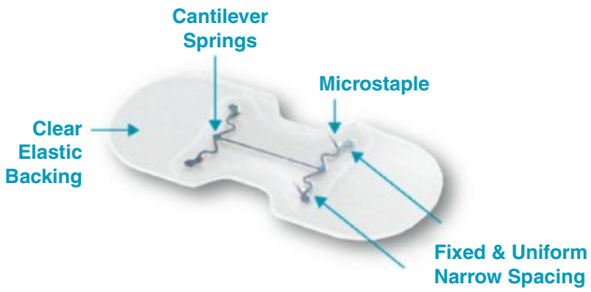
self-locking device. Castroviejo and Westcott scissors (see above) provide meticulous control when cutting eyelid skin. Lightweight forceps, such as Bishop–Harmon, Foerester or Castroviejo, aid in achieving the delicate handling of tissues necessary in this region. Plastic, Teflon®, and metal eye shields may be used to protect the globe when the lid margin will be breached. Plastic shields are popular as they do not conduct heat or electricity from electrosurgical devices. However, they must never be used with lasers; instead a non-reflective stainless steel shield should be employed.

Chalazion clamps are commonly used for immobilizing earlobes, lips, and tongues during procedures on these areas and provide excellent hemostasis in these highly vascularized tissues. Nail nippers, splitters, and elevators are necessary for nail surgery and are reviewed in Ch. 149.

Antiseptics and Sterilization

A summary of sterilization methods is presented in Table 144.4[56].

Additional figures available in our eBook (see inside front cover for access code).



STERILIZATION METHODS		
Method	**Advantages**	**Disadvantages**
Steam autoclave	Most popular in office; easiest; safest	Must use 20–30 min at 2 atm pressure and 121°C; corrosive; may dull sharp instruments
Chemiclave	Lower humidity than steam; less dulling of sharp instruments; instruments are drier	Special chemical needed (mixture of formaldehyde, methyl ethyl ketone, acetone, and alcohols)
Dry heat (oven)	Inexpensive; no corrosion or dulling	High temperature, longer time (1 h at 171°C; 6 h at 121°C); cannot use cloth, paper, or plastic
Gas sterilization	Good for large volumes (mostly used in hospitals)	Expensive equipment; prolonged times (1 day for paper, 7 days for polyvinyl chloride); toxic and mutagenic gas
Cold sterilization: glutaraldehyde or ortho-phthalaldehyde solutions	Simple; inexpensive; used for heat-sensitive equipment (e.g. endoscopes)	Irritating to skin (glutaraldehyde); not recommended as only method; not always effective against bacterial spores (ortho-phthalaldehyde has superior sporicidal activity)

Key features

- Wound dressings have evolved from simple wound coverings to more active wound management tools that directly interact with the wound environment
- No perfect dressing exists for all wounds but when used appropriately, dressings can improve healing time and cosmesis as well as reduce pain and infections
- Semipermeable or occlusive dressings provide a moist environment, retain wound fluid that contains growth factors conducive to healing, and promote a low tissue oxygen tension that stimulates angiogenesis and deposition of collagen
- The major types of moisture-retentive dressings include films, foams, hydrogels, alginates, gelling fibers, hydrocolloids, and superabsorbents

INTRODUCTION

Dermatologists are involved in the care of a variety of acute and chronic wounds including surgical incisions. The range of treatment options is substantial and expanding, providing therapeutic flexibility. Appropriate wound dressing selection requires an understanding of the properties of various dressings, as well as their advantages and disadvantages. As the wound heals, the ideal dressing may change based on the amount of exudate, necrotic tissue, and pain or the presence or absence of infection (Table 145.1).

MOIST HEALING ENVIRONMENT

Providing a moist wound environment is an important principle of wound healing. There are several mechanisms by which moisture assists the healing process, the most basic of which is reduced tissue desiccation and prevention of crust formation. Studies by Winter[1] demonstrated that uncovered, air-dried wounds re-epithelialized at a slower rate (see below). This slower rate has been attributed to the requirement of the regenerating epidermis to migrate below an overlying crust and other dry fibrous tissue to a region of moisture where live cells survive. It is only in such an environment that epidermal cells can move toward bridging the defect of the wound; therefore, the thicker the crust, the deeper the migration that is required. While scarring is associated with deep wounds and the loss of adnexal structures, improved cosmetic outcome has been observed following the use of occlusive dressings[2].

By reducing moisture transmission, moisture-retentive dressings optimize healing via several possible mechanisms. These include providing a moist environment (Fig. 145.1), increasing the availability of growth factors and matrix materials, and maintaining an electrical gradient within the wound, which also promotes healing.

HISTORY OF WOUND DRESSINGS

The use of wound dressings dates back to antiquity. For at least 4000 years, fabrics such as linen were employed, until woven absorbent cotton gauze was introduced in 1871. The Edwin Smith Surgical Papyrus, which is one of the earliest medical treatises (circa 1615 BCE), describes the use of linen strips and plaster to dress wounds, stating that closed wounds would heal more quickly than open wounds[2]. Ancient documents disclose how lint was used to pack and fill open wounds and how bandages were used to re-approximate wounds in order to facilitate healing. Linen strips were sometimes coated with grease or oil in order to prevent adherence to wounds or with honey to create a semi-occlusive and adherent dressing[3].

Until Lister connected the presence of pus with infection, pus had been viewed as beneficial ("laudable pus"). However, this association became linked so strongly that it was held that one is always indicative of the other, which is not always true. The association significantly interfered with the acceptance of occlusive dressings, despite better and faster healing, due to the fear of an increased number of bacteria under the dressing. Although the work of Pasteur, Koch, and Lister in the late 1800s on the cause of bacterial infections spurred the investigation of specific therapies for wound management, it was not until the mid-1900s that the understanding of wound healing changed.

Despite the teaching of the Smith Papyrus, it was believed that wounds healed faster if kept dry and uncovered. However, in 1948, Oscar Gilje described a "moist chamber effect" for wound healing[4]. Two years later, Schilling and colleagues studied common minor wounds with highly occlusive or semi-occlusive nylon films and found semi-occlusive dressings to be more effective for healing than open treatment. The finding that semi-occlusive dressings were more effective than the highly occlusive dressings is thought to have set back further study. In 1962, George Winter conducted the landmark study on moist wound healing, demonstrating a 30% greater benefit of occlusive dressings compared with air drying of wounds[1]. Many studies conducted since Winter's seminal work, including in the porcine model of wound healing, have supported the benefits of moist wound healing by occlusive dressings[5].

FUNCTIONS OF A WOUND DRESSING

The essential function of every dressing is to optimize the healing environment, but because the process of wound repair is dynamic (see Ch. 141), each stage may require a different dressing. While an ideal wound dressing would have many positive features (see Table 145.1), they should at the minimum protect the wound from trauma, bacterial invasion, or exposure to caustic substances; this is especially important during the acute inflammatory stage when promotion of granulation tissue formation and epithelialization is crucial. In addition, the dressing should be composed of a material that does not shed fibers or other material into the wound that could lead to foreign body reactions or irritant or allergic contact dermatitis[6]. The "ideal" dressing that meets all of these requirements for every wound type does not yet exist (Table 145.2). However, given the array of dressings available, it is possible to achieve one's goal.

TRADITIONAL WOUND DRESSINGS

Wound dressings can be categorized either by the dressing technique and how the dressing is utilized relative to the wound (see below) or by the composition and structure of the dressing[2]. Naturally occurring materials such as cotton, silk, linen, or cellulose-based substances have a long history of use and have been produced in various combinations for maximum clinical usefulness.

The basic cotton gauze bandages in use today are frequently composed of cotton plus cellulose acetate (added for increased absorbency) and are manufactured with or without various substances incorporated into the fabric. Gauze bandages are inexpensive and easy to use but have limited moisture-retentive capacity and may adhere to the wound; the moisture retentive properties can be enhanced by impregnation with hydrophobic coatings. White petrolatum and other ointments such as soft paraffin wax (e.g. Vaseline® gauze, Aquaphor® gauze, Adaptic™ dressing), with or without antimicrobial agents such as povidone-iodine (Betadine®), sulfadiazine, bismuth tribromophenate (Xeroform™ dressing), framycetin or chlorhexidine, are examples of impregnated substances. Balsam of Peru is found in the tulle gras dressing used predominantly in Western Europe. These medicated dressings are often composites of rayon, nylon, or gauze and are used for malodorous wounds such as chronic ulcers. Activated charcoal cloths (with or without antibacterial silver salt) are also used to control odor.

Because these impregnated dressings have less adherence to the wound, they are placed directly against the wound bed. In addition, they are less painful to remove and can be molded into the depression of deeper wounds for the purpose of filling dead space and providing absorption. The disadvantage of this type of dressing is the potential for maceration of the wound and the surrounding skin, should the dressing remain in place for an extended period of time. While traditional dressings such as gauze are relatively inexpensive and readily available, they require frequent replacement, which is time-consuming and can be costly due to the expense of nursing care[7].

SELECTION OF APPROPRIATE DRESSINGS	
Wound factor	**Dressing**
Exudate	
• Provides moisture	Hydrogel
• Maintains moisture	Film, hydrocolloid
• Absorbs moisture	Foam, alginate, gelling fibers, superabsorbent
Pain	
• Reduces pain	Hydrogel, soft silicone, contact layers
Bleeding	
• Contains hemostatic agents	Alginates
Superficial infection	
• Reduces number of microorganisms	Impregnated with silver, chlorhexidine, polyhexamethylene biguanide, iodine, honey, copper oxide, dialkylcarbamoyl chloride, or methylene blue plus gentian violet as antiseptics

Table 145.1 Selection of appropriate dressings. Availability and cost are two additional factors that are not wound-related.

Primary dressings are those that are in contact with the wound whereas *secondary* dressings cover the primary dressing and/or secure the primary dressing in place. Most conventional dressings are "layered" and are constructed as either "pressure" or "non-pressure" dressings. A layered dressing is usually created in three parts: (1) the contact or interface layer, which is usually a non-adherent, fluid-permeable material that makes direct contact with the wound; (2) the absorbent layer, usually a cotton pad, gauze or other such material, which is placed on top of the contact layer to "wick in" and retain wound exudate and help the dressing mold to the shape of the wound; and (3) the outer layer or wrap, often tape or other banding material for retention of the underlying layers. Each layer is placed in close approximation to the prior one, without gaps or air pockets, and should increase in size and degree of overlap, from wound bed to outermost layer.

A "pressure" dressing has more bulk added to the absorbent layer and is used to assist in hemostasis and to act as a bolster. Usually applied immediately after a surgical procedure such as debridement or graft placement (enhances graft–wound bed interaction), a pressure dressing is changed to a lighter dressing within 24 hours. In addition to limiting bleeding, the pressure dressing also reduces local edema. However, it is important to be aware of the amount of pressure exerted upon the wound bed so as not to create localized ischemia, potentially resulting in tissue necrosis[8].

FIRST AND SECOND INTENTION HEALING

Typically, primary closure is employed for postsurgical wound defects that are clean and free of debris. Aseptically placed sutures provide hemostasis, reduce the possibility of wound infection, and may improve

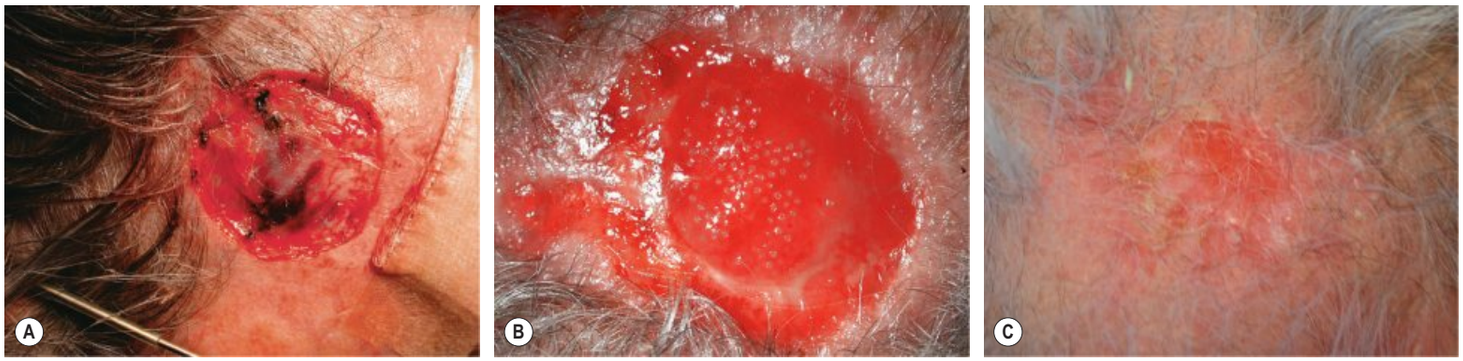

Fig. 145.2 Second intention healing. A Surgical wound immediately following Mohs micrographic surgery; a semi-occlusive dressing will be applied. **B** Three weeks following surgery. Note the abundance of pink–red granulation tissue. **C** Fully re-epithelialized wound six weeks following surgery. *Courtesy Gregg M. Menaker, MD.*

the ultimate cosmetic result. After suture removal, the use of external splinting tape (e.g. Steri-Strips™) or tension-relieving dressings (e.g. embrace®) supports the tissues, enabling favorable collagen remodeling that may limit scar formation and hypertrophy. Use of an antimicrobial ointment under the dressing does not reduce the rate of infections but does increase the risk of contact dermatitis, while the use of any ointment did not reduce complications[9,10].

Second intention healing is often employed following cutaneous surgical techniques such as tangential biopsy, curettage, cryosurgery, laser surgery, and excision in concave sites (Fig. 145.2). In such cases, moisture in the wound bed is the key to optimal healing. A semi-occlusive dressing is the treatment of choice, with the topical application of ointment directly on the wound. Monitoring the wound for signs of infection and preventing the wound bed from drying until re-epithelialization has occurred are usually sufficient measures for the management of this type of surgical wound[11].

ROLE OF DEBRIDEMENT

Debridement is the removal of necrotic, contaminated, or foreign material from a wound or from areas adjacent to the wound. Although data from controlled trials are limited, it is considered a key component of wound management due to its purported ability to induce acute healing and reduce microorganisms[12]. Five types of debridement exist: surgical, mechanical, autolytic, enzymatic, and biologic. Although *surgical* debridement is often the fastest and most direct way of removing unhealthy tissue, it may not be the method of choice for all patients. Factors such as the frequent need for analgesics, possible bleeding, the extent of non-viable tissue, patient preferences, and the practitioner's level of expertise need to be considered. An example of *mechanical* debridement is the wet-to-dry dressing that is employed for wounds with significant necrotic tissue, but it does not distinguish between viable and non-viable tissue.

In *autolytic* debridement, occlusive dressings provide a moist wound environment which promotes the lytic activity of enzymes present in accumulated wound fluid. This assists in the clearance of residual debris during early wound healing. *Enzymatic* (chemical) debridement involves the topical application of an enzymatic agent and this can be used to supplement autolytic debridement. Currently, one agent is FDA-approved: collagenase (Santyl®) ointment. It assists in the removal of devitalized tissue and aids in granulation tissue formation and re-epithelialization.

Biologic debridement employs fly larvae (maggots) and has been used for centuries to debride chronic ulcers. Nowadays, the most commonly used maggots are those of the green bottle fly, *Lucilia sericata*. Maggots digest necrotic tissue via collagenases and trypsin-like enzymes, thereby exposing healthy tissue. They also have antimicrobial effects, including secretion of antibacterial compounds (e.g. phenylacetic acid, phenylacetaldehyde) in addition to ingestion and subsequent killing of Gram-positive bacteria (including MRSA) and, to a lesser extent, Gram-negative bacteria. In a clinical trial of 267 patients with leg ulcers, larval therapy led to faster debridement than hydrogel therapy, but larval therapy has not been shown to improve healing rates or decrease bacterial load[13,14].

WOUND CLEANSERS

The removal of loose debris from the wound surface is termed *wound cleansing* and is a component of local wound care[15]. Optimal wound cleansers should have low cytotoxicity and they include water, isotonic normal saline (0.9% sodium chloride), and in some cases, dilute acetic acid or other mild acid solutions. Isotonic normal saline is a good cleanser for the majority of wounds and a Cochrane collaboration review found clean tap water as a suitable alternative[16].

Wound cleansing can be performed via several methods: compresses (gauze squeezed so no excess fluid), soaking (saturated gauze), cleansing sprays, and high-pressure irrigation. Irrigation can cause trauma to the wound bed and is not recommended for deep wounds unless one makes sure no cleansing fluid is retained within a "pocket" in the wound.

TOPICAL ANTIMICROBIALS AND DRESSINGS THAT CONTAIN ANTIMICROBIAL AGENTS

The presence of bacteria in wounds may delay acute wound healing, depending upon the quantity, species, and variants of bacteria as well as their organization within the wound (e.g. biofilms). They may also contribute to delayed healing of chronic wounds, but because resident bacteria are often held in check by host resistance, most chronic wounds heal with bacteria present. That said, bacteria do compete with adjacent cells for oxygen and nutrients and they can also produce toxins that delay healing. Bacteria within wounds can also form biofilms which are complex adherent accretions that are difficult for antibiotics to penetrate. Clinically differentiating a wound in bacterial balance from a wound where bacteria are delaying healing remains a challenge.

While a clean wound created with good aseptic technique (e.g. sutured surgical excision) does not require topical antimicrobials[9,10], they may be needed for some acute and chronic wounds with critical colonization. Topical antimicrobial agents include antiseptics and antibiotics. Antiseptics non-selectively destroy or inhibit the growth of microorganisms, whereas antibiotics are only effective against specific bacteria[17]. Due to the emergence of bacterial resistance and the risk of development of allergic contact dermatitis, topical *antibiotics* are typically reserved for superficial cutaneous infections such as impetigo. Mupirocin, retapamulin, ozenoxacin and fusidic acid are indicated for the treatment of cutaneous infections due to *Staphylococcus aureus* or *Streptococcus pyogenes*[18,19]. Silver sulfadiazine has broader antimicrobial coverage, but a pseudo-eschar can form and may delay healing[19,20]. Triple antibiotic cream or ointment formulations available over the counter may contain combinations of polymyxin, gramicidin, bacitracin, and/or neomycin; however, the latter two are amongst the most common allergens in North America (see Ch. 14).

Because *antiseptics* often affect cellular metabolism (including cell wall formation), they are less often associated with the emergence of resistant organisms. The antimicrobial activity and cellular toxicities of various antiseptics are listed in Table 145.3[17,21]. ***Silver*** has been used since ancient times for treating wound infections due to its antimicrobial activity. When in contact with wound fluid, silver metallic salt (Ag^0) becomes ionized (Ag^+) and highly active against bacteria.

DRESSINGS THAT CONTAIN ANTISEPTICS				
Antimicrobial agent	**Examples of dressings**	**Coverage spectrum**	**Advantages**	**Disadvantages**
Silver	Acticoat® Flex 7 Silver, Actisorb® Silver 220, Algicell® Ag (alginate), Aquacel® Ag, Contreet® Biatain Ag Foam, ColActive® Plus Ag, Mepilex® Ag, Opticell™ AG+ (gelling fiber), PolyMem®/ PolyMem MAX Silver, SilvaSorb® (hydrogel), Silvercel® (alginate), Silverlon®, Tegaderm™ Ag (alginate), UrgoTul® Ag/Silver, UrgoTul® SSD	Broad-spectrum antibacterial, including MRSA and VRE	• Release antibacterial levels of silver for 3–7 days • Appear to decrease the levels of matrix metalloproteinases that are upregulated in non-healing, chronic wounds • Microbial resistance is rare • Variety of products available for different wound situations • Infrequent application required	• Silver may stain tissues (localized argyria) • Relatively expensive • Slows acute wound healing
Chlorhexidine or polyhexamethylene biguanide (PHMB), a chlorhexidine derivative	Bactigras™ (chlorhexidine), GemCore360° (PHMB), Kendall™ AMD foam (PHMB), Kerlix™ AMD gauze (PHMB), PuraPly® AM (PHMB)	Broad-spectrum antibacterial and antifungal	• Low tissue toxicity • Different forms available, including foam, ribbons, and gauze • Comforting so recommended for painful wounds	• May cause stinging and ICD • Cytotoxicity – cornea, inner ear (in the setting of tympanic membrane rupture), and cartilage • Systemic and local hypersensitivity reactions
Povidone-iodine* Cadexomer-iodine polymer* Other iodophors	Inadine®, Betadine® cream applied to gauze, Iodoflex™, Iodosorb® (gel), Ioplex®	Broad-spectrum antimicrobial – bacteria, fungi, viruses	• Less irritating to skin than iodine alone • Cadexomer-iodine polymer does not inhibit wound healing	• May cause stinging • ICD, ACD • Povidone-iodine can inhibit wound healing
Honey	Activon Tulle, First Honey® Manuka, MEDIHONEY® Calcium (alginate), MEDIHONEY® gel	Broad-spectrum antimicrobial – bacteria, fungi, viruses	• Low tissue toxicity • Autolytic debridement	• May cause maceration • ACD to propolis
Methylene blue and gentian violet	Hydrofera Blue® Classic, READY, READY-Transfer	Broad-spectrum antibacterial, including MRSA and VRE, and anti-candidal	• Less irritating • Good absorptive capacity for cavity wounds	• Bacteriostatic
Methylene blue, gentian violet, and silver	RTD™ (Retro-Tech Dressing)	Broad-spectrum antibacterial, including MRSA and VRE, and anti-candidal	• See silver above • See methylene blue and gentian violet above	• See silver above • See methylene blue and gentian violet above
Hypertonic saline	Mesalt®	Broad-spectrum antibacterial	• Less irritating to skin	
Copper oxide	MedCu®	Broad spectrum antibacterial, antifungal and antiviral	• Can be incorporated into fabric, including masks	
Dialkylcarbamoyl chloride (DACC)	Cutimed® Sorbact® (contact layer)	Broad spectrum, anti-candidal	• Reduces inflammation by trapping bacteria rather than killing bacteria • Variety of dressing types available	• Bacteriostatic

*Not to be used in young children, pregnant or lactating women, or individuals with a known iodine sensitivity; to be used cautiously in patients with thyroid disorders.

Table 145.3 Dressings that contain antiseptics. ACD, allergic contact dermatitis; ICD, irritant contact dermatitis; MRSA, methicillin-resistant *Staphylococcus aureus*; VRE, vancomycin-resistant enterococci. From refs 18, 19, 23–25, 27, 31, 33, 36, e2, e3.

The bactericidal action of ionized silver can be explained by the binding of silver ions to tissue proteins or by reactions with chloride anions, which then bind to bacterial DNA and RNA and alter bacterial cell walls and nuclear membranes[22]. Silver also has anti-inflammatory effects and may have angiogenic properties. In addition, silver ions decrease the levels of matrix metalloproteinases (MMPs) that are often upregulated in non-healing wounds. Despite these effects, a recent Cochrane review found no significantly higher healing rates with silver dressings, suggesting that short-term use is optimal[23,24]. Newer dressings, in which high-density polyethylene mesh is impregnated with nanocrystalline silver (Fig. 145.3)[25], can release antibacterial levels of silver for 3–7 days[26].

Chlorhexidine gluconate is a biguanide antiseptic with a wide range of antimicrobial activity against Gram-positive and Gram-negative bacteria, yeasts, and molds, but it is recommended for intact skin not open wounds as it works by disturbing the cytoplasmic membrane[27]. Despite data that it can inhibit re-epithelialization, chlorhexidine-containing dressings have been used in wounds and burns with reported benefit[28]. Because there can be associated cytotoxicity, especially to the cornea, inner ear (in the setting of tympanic membrane rupture), and cartilage, exposure to these structures should be avoided[29]. Systemic and local hypersensitivity reactions have also been observed. A chlorhexidine derivative, polyhexamethylene biguanide (PHMB), appears to be safer and has been added to several wound dressings including gauze, ribbons, foam, and hydrogels.

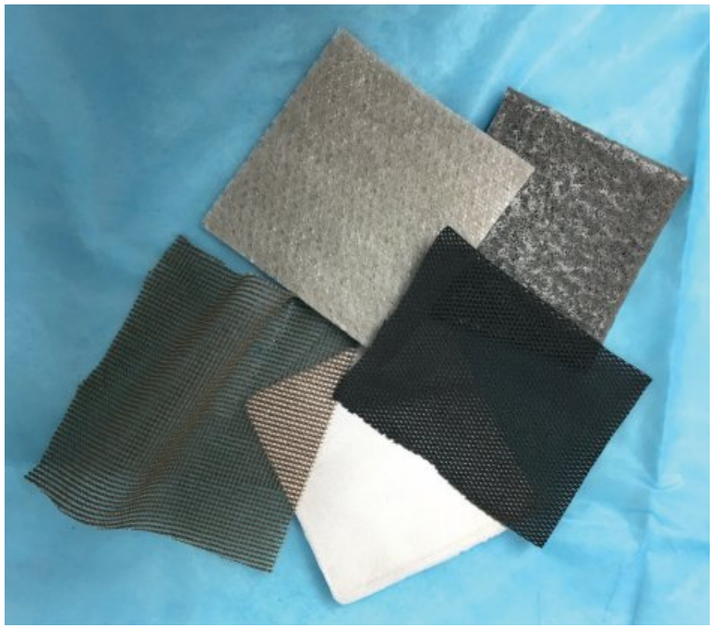

Fig. 145.3 A variety of silver dressings. Clockwise from 2 o'clock, Silvercel®, PolyMem® MAX® Silver, Acticoat® Flex 7 Silver, ColActive® Plus Ag, and Restore® Silver.

Iodine is a broad-spectrum antiseptic that is available in different formulations[30]. However, povidone-iodine, a commonly used antiseptic, can inhibit wound healing. In contrast, newer formulations such as cadexomer-iodine polymer, which slowly releases iodine from dextran beads, do not slow healing and have not been found to have toxic effects on keratinocytes. The starch lattice in the cadexomer-iodine polymer is highly absorptive (1 gram absorbs up to 7 ml of fluid) and as the fluid is absorbed, the iodine is slowly released[31]. The iodine confers antimicrobial activity for several days, but is in a low enough concentration that cytotoxic effects are avoided. The frequency of dressing changes is determined by the rate of iodine release, which is largely dependent on wound exudate[32].

Studies in patients with venous leg ulcers have shown a significant decrease in ulcer size when cadexomer-iodine was compared to hydrocolloid and paraffin gauze dressings[33]. When compared to other treatments for diabetic foot ulcers, cadexomer-iodine was associated with a cost benefit[34]. Because iodine can be absorbed systemically, caution is required when using these dressings in patients with a history of thyroid disease. They should not be used in young children, pregnant or lactating women, or patients with known iodine sensitivity.

While first used centuries ago, ***honey*** has experienced a resurgence due to recognition of its antimicrobial properties. The latter is related to honey's high osmolality, which minimizes the availability of water to bacteria[35]. Manuka honey, a commonly used type of honey, also contains flavonoids and aromatic acids that have antimicrobial properties. In addition, honey exhibits an anti-odor effect by decreasing the wound pH; release of hydrogen peroxide and glucuronic acid stimulates macrophages/monocytes, promotes inflammatory cytokine production, and provides analgesic and antibacterial effects[36]. A Cochrane review found that topical treatment of superficial and partial-thickness burns with honey may improve healing when compared to some conventional dressings[37,38].

Methylene blue and ***gentian violet***, two organic dyes, have been combined in a polyvinyl alcohol sponge to produce an antimicrobial dressing (Hydrofera Blue® Classic, READY, READY-Transfer)[39]. These dyes are not released from the dressing, thus avoiding previously reported tissue toxicities. The dressing has broad-spectrum activity against Gram-positive bacteria, Gram-negative bacteria, and *Candida* spp. These two organic dyes have also been combined with silver in a polymer matrix-containing foam dressing (RTD™).

Copper oxide has demonstrated broad-spectrum bactericidal as well as pro-angiogenic effects and therefore has been incorporated into a dressing[40]. In wounded diabetic mice treated with copper oxide dressings, enhanced angiogenesis post-wounding was observed along with upregulation of proangiogenic factors, including placental growth factor, hypoxia-inducible factor-1 alpha, and vascular endothelial growth factor[41].

Dialkylcarbamoyl chloride (DACC) is a highly hydrophobic fatty acid derivative that can irreversibly bind bacteria via hydrophobic interactions. DACC has been incorporated into a variety of dressings and in a controlled clinical trial reduced the short-term incidence of postsurgical skin infections compared to a standard dressing[42].

MOISTURE-RETENTIVE DRESSINGS

Moisture-retentive dressings, traditionally called passive dressings, are distinct from active dressings, with the former commonly divided into six major groups: films, foams, hydrogels, alginates/gelling fibers, hydrocolloids, and the most recent addition, superabsorbent dressings (Fig. 145.4; Table 145.4). In choosing the most appropriate dressing for a particular wound, it is important to strike a moisture balance, i.e. not too dry and not too wet.

Films

Polymer films are thin, self-adhesive, transparent sheets of polyurethane or other synthetic semipermeable material (Fig. 145.5). These dressings are gas permeable, allowing for the exchange of oxygen, carbon dioxide and water vapor, but impermeable to larger molecule efflux, due to their pore size. Therefore, bacteria, proteins and wound fluid are prevented from moving across the dressing. Its permeability to water vapor allows for the release of insensible water and sweat from the skin. This provides the potential advantage of preventing maceration of the wound and surrounding skin. The semi-occlusive nature of this dressing allows for passage of oxygen to the wound, which had been considered to be an important feature when these dressings were initially introduced. Since then, evidence has indicated that low pO_2 levels (similar to those that actually exist under the dressings) facilitate healing.

Advantages/disadvantages

The advantages of this type of dressing include translucency, thereby allowing direct visualization of the wound without removal of the dressing; permeability to water vapor; and tendency to reduce postoperative pain. They enhance re-epithelialization of graft donor sites, with a reported increase in healing rates of 25%–45%[43]. One disadvantage of film dressings is that they are difficult to place properly, requiring uniform tension on the film to prevent wrinkling and its adherence to itself (similar to what is experienced with Saran™ Plastic Wrap). As the film usually only adheres to intact skin, a 1–2 cm application margin is recommended. In addition, due to shearing forces, it is best to avoid using films on thin or fragile skin.

Films may adhere to the wound as drying progresses, thereby risking disruption or stripping of the newly formed epithelium that is not yet tightly bound to the underlying dermal layer. It is also possible to traumatize newly grafted skin tissue during dressing changes. For these reasons, it is advisable to allow the film dressing to remain in place until it spontaneously falls off, which occurs after 1–2 weeks[44]. Any wrinkling of the film during placement can create a conduit for bacterial penetration and leakage of wound exudate. It is therefore recommended that for exudative wounds the film have a complete 2–3 cm adhesion margin to prevent this leakage.

Another disadvantage of film dressings is that they are non-absorbent; therefore, wound fluid can accumulate under the dressing layer, especially with highly exudative wounds. This is often the case during the first 7–10 days after the creation of a wound, with the adherent properties of film dressings making frequent changing undesirable.

Foams

Polymer foams are semi-occlusive, bilaminate, and polyurethane- or silicone-based dressings. They consist of a hydrophilic foam with a hydrophobic backing, which can prevent leakage, provide a barrier against bacterial penetration, and provide the moist environment afforded by films, but with the addition of some absorbency (Fig. 145.6). The inner layer is composed of an absorbent, gas-permeable polyurethane foam mesh, which lies adjacent to the wound. The outer layer is a semipermeable, non-absorbent membrane composed of polyurethane, polyester, silicone or Gore-Tex®, surrounded by a polyoxyethylene glycol foam. This layer protects against outside bacterial contamination to some extent and against the drying out of the underlying layers.

Foam dressings are typically non-adherent, thereby requiring secondary dressing layers to ensure secure placement with a good seal. The quality of the seal is important to prevent leakage, desiccation, and problems with adherence. There are, however, some foams available with an adhesive surface and/or border, usually surrounding a central absorptive core. Ideally, once a foam dressing has absorbed some amount of exudate, it should be able to retain that fluid, even if exposed to pressure. Some brands are described as having such a quality.

Advantages/disadvantages

Although absorbent, there is usually a limit to the amount of wound exudate this type of dressing can absorb. Therefore, it should be changed every 1–3 days. The permeability of foams to both gas and water vapor makes them suitable for mild to moderately exudative wounds, although some brands may accommodate highly exudative wounds.

Silicone-based rubber foams, known as silastic foams, are composed of a silicone mixture to which a stannous octoate catalyst has been added. This type molds and contours to the shape of the wound and therefore can be used for packing cavities or deep ulcers such as pilonidal sinuses. The additional advantages are absorbency, non-adherence, increased comfort for the patient, a tendency to be less expensive, and dressing changes that do not generally require skilled nursing care[45].

The disadvantages of foam dressings are the inability to use them with dry wounds, their opacity, which prevents visual monitoring of the wound, and the need for frequent changing, perhaps as often as every day. Infrequent changing could risk incorporation of the dressing

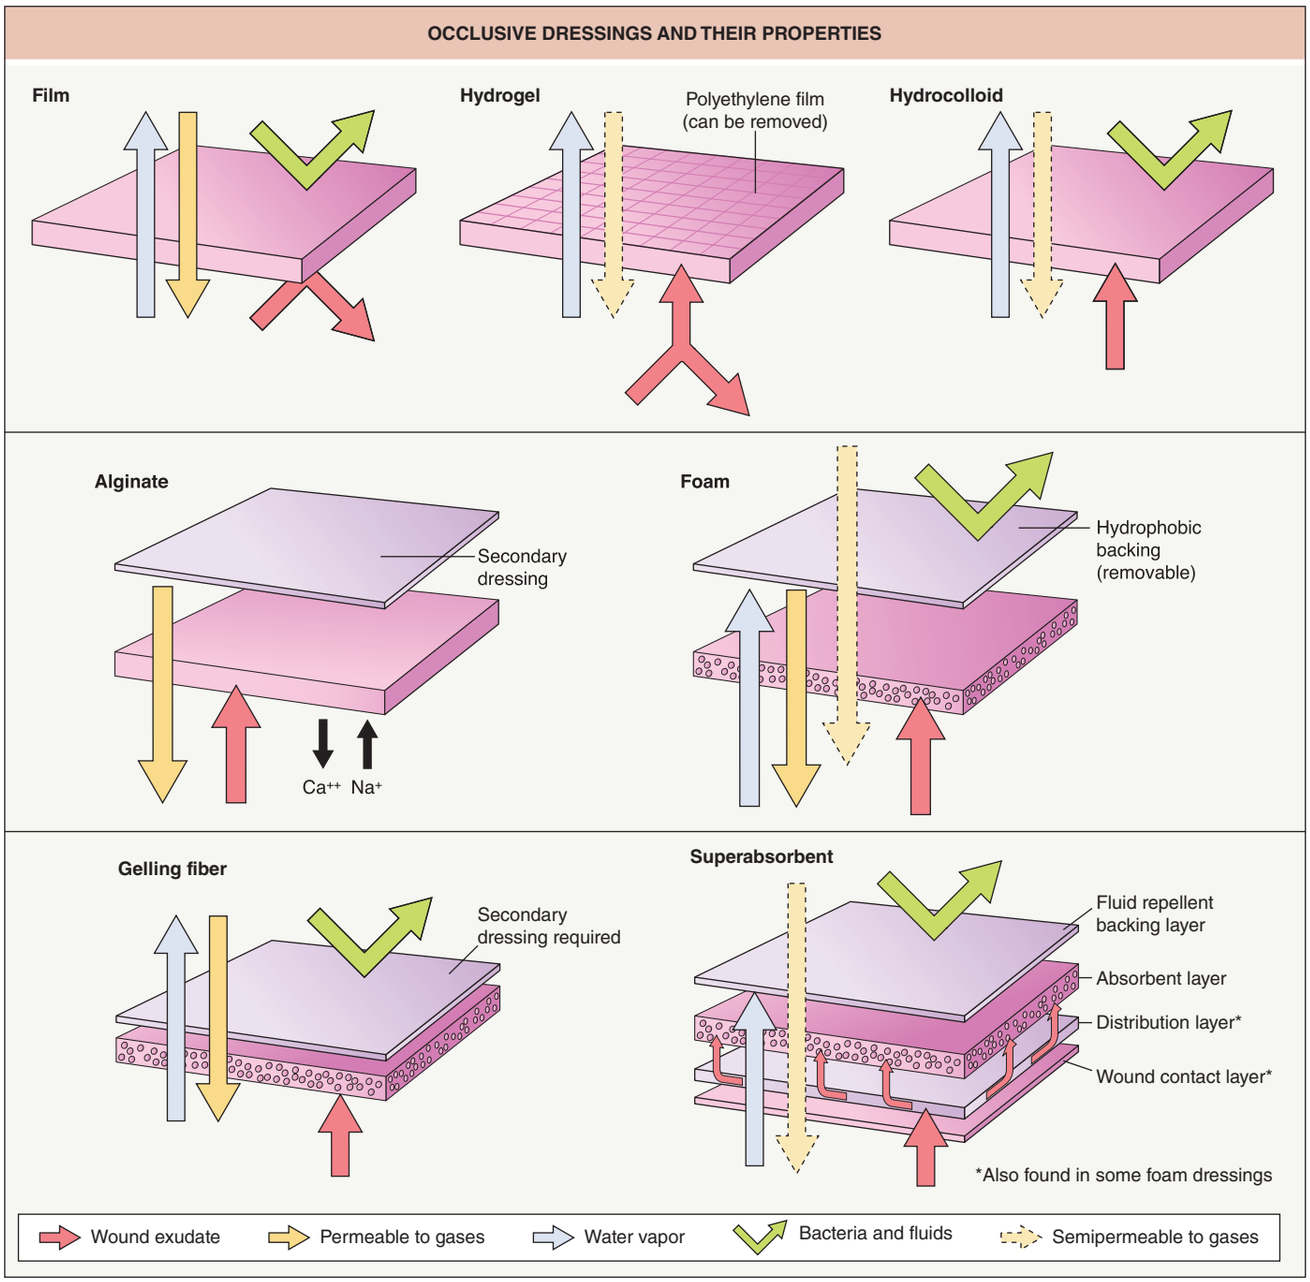

Fig. 145.4 Occlusive dressings and their properties. The six major dressings are polymer films, polymer foams, hydrogels, alginates/gelling fibers, hydrocolloids, and superabsorbents. *Courtesy Gregg M. Menaker, MD.*

material into the wound itself. There is also the possibility of an undesirable drying effect of the wound if drainage is insufficient to maintain a moist environment.

Hydrogels

As their name implies, hydrogels are composed primarily of water – up to 96% of the content. This dressing type consists of a cross-linked hydrophilic polymer network composed of polyvinyl alcohol, polyacrylamide, polyethylene oxide or polyvinyl pyrrolidone; it is produced as sheets, amorphous gels (pre-mixed or dry), or as impregnated dressings (Fig. 145.7). Hydrogels are semitransparent (allowing visual inspection of the wound), have a high absorptive capacity (between 100% and 200% of their volume), and are able to maintain a moist wound environment. The absorptive action is delayed in its onset and increases slowly as it provides for continuous, long-term absorption. Hydrogels are described as semi-adherent or completely non-adherent, depending upon the type, and therefore require a secondary dressing to hold them in place[46]. The latter is necessary, as hydrogels provide a poor bacterial barrier and selectively permit Gram-negative organisms to proliferate[47].

In general, the *sheet form* of a hydrogel dressing is constructed by sandwiching the hydrophilic polymer between two removable thin sheets of polyethylene film, with some types containing a supportive inner gel mesh. For application to the wound, the film on the contact side is removed, leaving the outer film in place. With this mode of application, the dressing is semipermeable to gases (including oxygen) and water vapor. If the outer film is also removed, then the dressing becomes permeable to fluid as well; as a result, exudate can pass to a secondary gauze dressing. The polymer sheets can be removed easily without trauma to the wound bed.

The *amorphous type* of hydrogel is composed of a cornstarch-derived, polymerized compound that forms a gel upon hydration at the time of its use. It is available commercially in a powdered or pre-mixed form, is applied wet to the wound defect, requires a secondary outer dressing, and requires water application to the surface for removal.

Advantages/disadvantages

One significant advantage of hydrogel dressings is a reduction in postoperative pain and inflammation. Another is that hydrogels have been shown to accelerate the rate of wound healing when compared to gauze

MOISTURE-RETENTIVE DRESSINGS						
Dressing type	**Examples**	**Composition**	**Permeability**	**Indicated uses**	**Advantages**	**Disadvantages**
Films	Bioclusive™, Blisterfilm™ Transparent Film Dressing (TFD), Carrafilm™, Derma View II, Mefilm®, Mepore® Film, Opsite™, Polyskin® II, Tegaderm™ Film, Transeal® TFD	Thin polyurethane sheet	Semipermeable	• Intravenous sites • Skin tears • Split-thickness graft donor sites • Laser resurfacing • Mohs surgery defects • Holding pinch grafts in place for venous leg ulcers	• Translucent • Permeable to water vapour • Pain reduction • Creates bacterial barrier	• Difficult to position properly • May adhere to wound as it dries • Possible exudate accumulation • Non-absorbent
Foam	*Adherent and non-adherent*: Allevyn™, Biatain™, Biopatch®, CuraFoam™, Flexzan®, Hydrasorb®, Lyofoam®, Mepilex®, Optifoam®, PolyMem®, Reston™, Sof-Foam™	Bilaminate polyurethane or silicone	Semipermeable	• Chronic wounds • Surgical excisions • Dermabrasion • Burns • Mohs surgery defects • Laser resurfacing	• Absorbent • Permeable to water vapour • Conforms to wound shape • Thermally insulates • Comfortable	• Opaque • Cannot be used on dry wounds • Possible undesirable drying effect on inadequately exudative wounds
Hydrogels	*Hydrogel sheets*: ActiFormCool®, AquaDerm™, Aquaflo®, AquaSite®, CarraDres™, CarraSorb™ M Freeze Dried Gel, Flexigel®, Vigilon® *Amorphous gels*: Biolex® Wound Gel, Carrasyn® Hydrogel, Hydrogel GRX®, Hypergel®, Intrasite™ Gel, Normlgel®, Tegagel™ Hydrogel Wound Filler *Impregnated dressings*: AquaSite™ gauze, Curafil® gauze, Curagel®, DermaGauze™, Tegagel™ Hydrogel Wound Filler with gauze	Hydrophilic polymer sheets, gel, and impregnated dressings	Semipermeable with outer membrane in place	• Dry wounds • Dermabrasion • Laser resurfacing • Superficial thermal burns • Chemical peels • Graft donor sites • Partial thickness wounds	• Semitransparent • Donates fluid to necrotic tissue • Soothing, cushioning and cooling effect, reduction of postoperative pain • Available in sheets, powdered or pre-mixed amorphous gels • Low trauma at dressing changes • Reportedly helpful for pruritus	• No spontaneous sucking ability • Absorption is slow • Requires secondary dressing • Caution in infected wounds
Alginates	Algicate Ag, AlgiCell®/ Algicell® Ag, AlgiSite™ M, Algosteril®, CarraGinate™, CarraSorb™ H, Fibracol® Plus (collagen [90%]–alginate [10%]), Kalginate™, Kaltostat®, Maxorb®, MedVance™, Melgisorb® Plus/Melgisorb® Ag, Sorbsan®/Sorbsan® Silver	Seaweed-based complex polysaccharide	Semipermeable	• Chronic highly exudative wounds • Full-thickness burns • Surgical wounds • Split-thickness graft donor sites • Mohs surgery defects	• Highly absorbent with spontaneous sucking ability • Hemostatic properties • Non-adherent • Conforms to wound shape • Soluble for low trauma dressing changes with normal saline	• Requires a secondary dressing to prevent desiccation • Gel has unpleasant appearance and odor • Mild burning sometimes reported upon application
Gelling fibers	Aquacel®, Exufiber®, Opticell®	Polyvinyl alcohol, sodium carboxymethyl cellulose, chitosan-based polysaccharide polymers	Semipermeable	• Moderate to highly exudative wounds	• Handles heavy exudate • Locks in exudate to reduce maceration • When removed, does not fall apart	• If no exudate, can adhere to wound • Requires a secondary dressing
Hydrocolloids	Allevyn™, Comfeel®, DuoDERM®,DynaDerm®, Exuderm®, Hydrocol® II, MedVance™, Nu-Derm®, Primacol®, RepliCare™, Restore®, Tegaderm™ Hydrocolloid, Tegasorb™	Starch or plastic woven polymer, dextran, polyethylene glycol, water	Semipermeable	• Chronic ulcers • Burns • Traumatic wounds • Surgical wounds • Dermabrasion • Inflammatory disorders (e.g. lichen simplex chronicus)	• Capillary action facilitates debris removal • Conforms to wound shape • Directly adheres to wound site and is easy to use • Increased patient comfort • Thermal insulation	• Risk of maceration of surrounding skin • Possible wound trauma with dressing change • Gel has unpleasant appearance and odor • Opaque • Caution in infected wounds • Collected exudate often confused with wound infection • Excessive granulation tissue (prolonged use)

Table 145.4 Moisture-retentive dressings[40,49].

Continued

MOISTURE-RETENTIVE DRESSINGS						
Dressing type	**Examples**	**Composition**	**Permeability**	**Indicated uses**	**Advantages**	**Disadvantages**
Superabsorbent	Flivasorb®, KerraMax®, Mextra®, OptiLock®, Sorbion®	Polyacrylic acid polymers	Semipermeable	• Moderate to highly exudative wounds	• Handles heavy exudate • Locks in exudate to reduce maceration • When removed, does not fall apart	• Caution when applied under compression • May adhere to wound if exudate dries
Contact layers	Adaptic Touch™, Cutimed Sorbact WCL, Mepitel® One, UrgoTul®	Flexible polyester mesh	Permeable (non-occlusive)	• Contact layer for wounds	• Non-adherent • Less pain with dressing change	• Not recommended for stage 1 pressure ulcers, third-degree burns or wounds with eschar
Silicone dressings	Mepilex® (foam), Mepitel® (film), Mepilex® Transfer (foam), Mepitel® Border (foam)	Silicone-based	Semipermeable Suitable as primary or secondary dressings	• Bullous disorders including epidermolysis bullosa • Fragile skin	• Absorbent • Non-adherent	• Opaque

Table 145.4 Moisture-retentive dressings[40,49].

Fig. 145.5 A transparent film dressing is used to occlude a dry wound. This example is Tegaderm™.

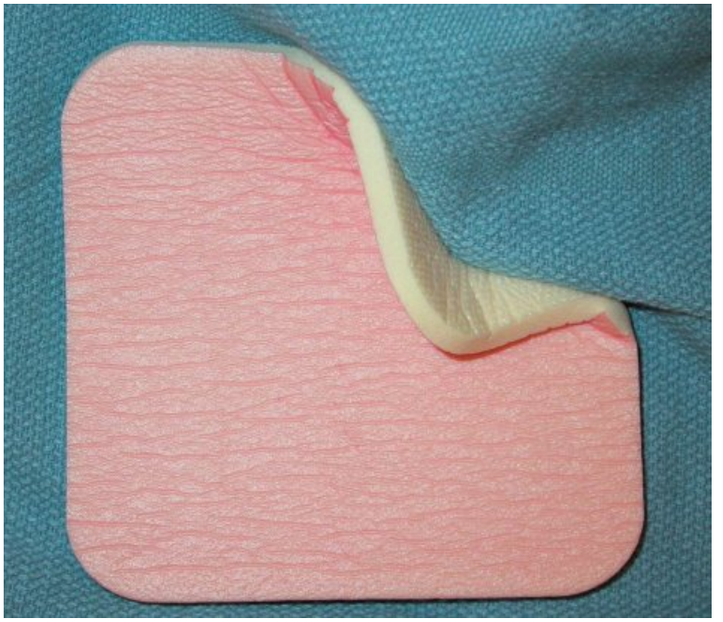

Fig. 145.6 Polymer foam dressing. It consists of hydrophilic foam with a hydrophobic backing (pink).

dressings and non-adherent dressings such as Telfa™. For example, the rate of re-epithelialization of split-thickness porcine wounds was 25%–45% faster with hydrogels, and 100% of the hydrogel-treated wounds healed by postoperative day 4 compared with 32% of open-air (control) wounds[48]. Hydrogels have also been credited with faster healing rates in studies of dermabrasion and hair transplant donor and recipient sites, when compared to standard non-adherent dressings[49].

Hydrogels are not recommended for infected wounds. In addition, the semi- or non-adherent nature of hydrogels often results in more frequent dressing changes than is needed with other occlusive dressings.

Alginates

Highly absorbent alginate dressings are composed of a natural, complex polysaccharide derived from various types of algae or kelp (seaweed). An extraction process produces a sodium salt form of alginic acid and, during a second step, sodium ions are exchanged for calcium, zinc, and magnesium. The end result is an alginate fiber; non-woven mats or twists of this fiber are then made into a dressing (Fig. 145.8). Upon application of the dressing, a reverse ion exchange occurs between the calcium within the alginate fibers and the sodium from blood or the wound exudate. This results in the formation of a soluble sodium alginate gel that fills and completely covers the wound in a non-adherent manner, providing a moist wound healing environment. The extent and rate of gel formation depends on the amount of wound exudate. Alginate dressing materials also have hemostatic properties, believed to be the result of the release of free calcium by the fibers during the ion exchange. This release of calcium augments the clotting cascade, producing the hemostatic advantage.

Because alginate gel dressings are highly absorbent, they can remain in place at the wound site for several days at a time, thereby minimizing dressing changes. To secure an alginate dressing, a secondary dressing is required. A dressing change is indicated when the dressing has been in place for several days or when exudate soaks through to the secondary dressing[50]. Removal of the dressing in a dried state can re-injure the wound.

Advantages/disadvantages

Alginate dressings are soluble and can be removed by saline irrigation, permitting less painful dressing changes. They have been shown to encourage wound healing and are metabolized by the body, should residual material remain at the wound. Despite concerns about the potential toxicity of alginates, they have been used for over 50 years without any commonly reported complications. However, removal of the secondary outer dressing is necessary to visually inspect the wound and to monitor for desiccation.

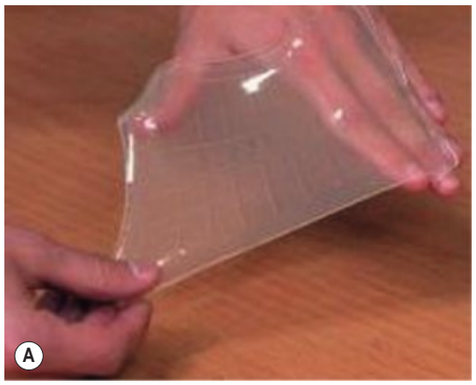

Fig. 145.7 Hydrogels. **A** Hydrogel sheet. **B** Premixed amorphous hydrogel.

Fig. 145.9 Hydrocolloid dressing placed over a healing wound on the ankle. This example is DuoDERM®.

Fig. 145.8 Collagen–alginate complex dressing. Alginate dressings have hemostatic effects and can be used post-debridement.

Gelling Fibers (Hydrofibers)

Highly absorptive hydrofibers are another category of dressings with similarities to alginates. They are composed of carboxymethyl cellulose fibers that interact with wound fluid, turn into a gel, and aid in autolytic debridement[51]. Gelling fibers are up to three times more absorbent than alginates. An additional advantage over alginates is their vertical uptake of wound fluid, thereby decreasing the risk of peri-wound maceration.

Hydrocolloids

Colloid is a Greek term for a two-phase system comprised of a uniform dispersion of one phase of matter (unfilterable small particles) into another phase of matter or matrix. Mutually attractive charges exist between the particles, which contributes to the diffusible properties of colloids. Colloids are characterized by the strength of attraction of the particles to the continuous medium and to the proportion of water within that medium. This property accounts for the absorptive and expansive capacity of colloid gels, which function as a semipermeable membrane. Gel swelling occurs because the particle concentration of the gel is usually higher than that of the surrounding medium, thereby drawing water from the surroundings into the gel.

Hydrocolloid dressings were first employed as ostomy products and are now available in multiple forms. The most commonly used hydrocolloid dressings (e.g. DuoDERM®) are available as sheets with an inner adhesive layer consisting of a hydrophilic colloid base that is a mixture of pectin, karaya, guar or carboxymethyl cellulose plus an adhesive containing polyisobutylene, styrene isoprene, or ethylene vinyl acetate (Fig. 145.9). The outer layer is composed of a thin semipermeable material such as polyurethane. A gel is formed in the presence of wound exudate, and as a unit, the dressing is semipermeable to water vapor and gases[52].

Another type of hydrocolloid dressing is a synthetic, non-adherent, high-density plastic woven polymer (e.g. N-Terface®). Fluid is able to flow through this matrix to be absorbed by an overlying dressing without adherence to the new epithelial surface.

Advantages/disadvantages

When in sheet form, these dressings can be cut and conformed to the shape of the wound. They are waterproof and adhere directly; as a result, they do not require a secondary dressing. In addition, these dressings have a cushioning or pressure-relieving effect (especially at bony sites), which increases as the dressing absorbs exudate. The resulting colloidal gel that forms prevents the dressing from adhering to the wound base. Accumulation of the exudate itself in a moist, semipermeable environment becomes a source of phagocytic cells and endogenous enzymes. This feature, along with the gel, results in autolytic debridement that can be washed away with saline irrigation of the wound bed[53]. Because hydrocolloids are impermeable to water, oxygen, and carbon dioxide, they are popular "waterproof" dressings[54].

Due to their semipermeable outer barrier, hydrocolloids have also been shown to stimulate angiogenesis and increase the rate of healing by as much as 40% when compared to open-air controls. A comparison of hydrocolloids versus wet-to-dry saline gauze dressings in the treatment of decubitus ulcers found that hydrocolloids do not require as many dressing changes as traditional wound dressings. Although the cost of individual hydrocolloid dressings was greater than gauze dressings and the healing rates were the same, the savings were in the cost of nursing time. In addition, the dressing changes tend to be simple and painless for the patient[55].

Disadvantages of hydrocolloids include maceration of the skin surrounding the wound, a potential for irritant or allergic contact dermatitis (e.g. to adhesives), and the risk of forming excessive granulation tissue. Similar to alginate dressings, the end product of hydrocolloids is a thick, yellow–brown, often foul-smelling gel resembling purulent discharge[56]. The patient needs to be educated regarding the distinction.

Superabsorbent Dressings

This expanding category of dressings is characterized by enhanced absorption, with exudate pulled up and often laterally into the construct of the dressing. By using a larger interface surface, more viscous drainage can be absorbed. Superabsorbent dressings contain particles composed of three-dimensional networks of polyacrylic acid polymers that are crosslinked by covalent bonds and swell upon contact with aqueous solutions. As water enters the dressing, the carboxylic acid groups of the polymer ionize and are electrostatically repelled from each other; this results in significant space for water and each particle can absorb hundreds of times its own weight in fluid. Superabsorbent dressings are indicated for exudative wounds and can also aid healing by trapping bacteria[57] and proteolytic enzymes[58]. If overlying pressure is placed (e.g. compression), it is important to remember that these dressings swell over time and this can increase pressure on the wound, potentially inhibiting healing[59].

Contact Layers

Contact layers are single-layer constructs that are applied directly to the wound surface. They are non-absorbent, non-adherent, woven polyethylene mesh dressings impregnated with different materials such as petrolatum, hydrocolloid, and silicone. These contact layers serve as primary dressings and are covered by a secondary dressing[60]. Wound exudate can flow through them while they protect the wound bed from the trauma of dressing changes. Contact layers are commonly used to secure and protect advanced tissue products (see below) and may stay in place for up to two weeks while the secondary dressings are changed more frequently.

Composite Dressings

The designs of occlusive dressings are constantly changing with the goal of improved and simplified care for a greater range of wounds. Several newer types of composite dressings, which combine two or more types of semi-occlusive dressings into one product, are commercially available. They have three components: (1) a semi- or non-adherent layer that contacts the wound (like a hydrogel, hydrocolloid, foam or alginate; Fig. 145.10); (2) an absorptive layer; and (3) an outer layer (like a film with an adhesive border). This maximizes the efficiency and comfort of the dressing by expanding absorbency as well as lessening the chance of maceration[61]. Other features include the lack of need for secondary retention dressings and better waterproof coverings, which enable the patient to shower or bathe.

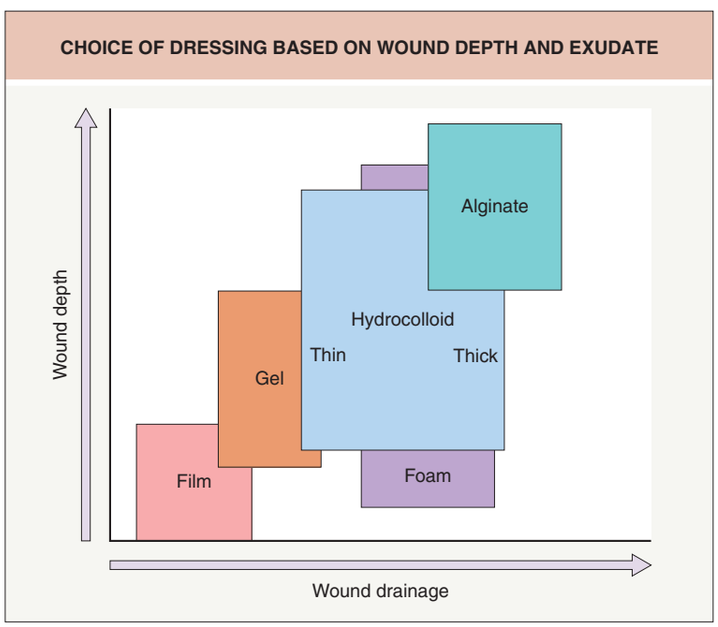

Fig. 145.10 Choice of dressing based on wound depth and exudate. *Courtesy Gregg M. Menaker, MD.*

ADVANCED WOUND THERAPIES

Scientific and clinical advances have increased the therapeutic options for chronic wounds. For example, topical growth factors and tissue-engineered skin equivalents can be combined with standard treatments[62–64].

Topical Growth Factors

Growth factors are critical to the wound healing process, as they stimulate fibroblasts, promote angiogenesis, and encourage migration of keratinocytes. Fluid from acute wounds contains multiple growth factors including platelet-derived growth factor (PDGF) and epidermal growth factor (EGF). Maintaining contact of this fluid with the underlying wound bed via the use of occlusive dressings has been shown to augment wound healing. A topical formulation of recombinant human PDGF, becaplermin (Regranex®) gel, has been shown to increase the complete closure rate of diabetic foot ulcers by 43%. Its current FDA indication is for non-healing diabetic neuropathic foot ulcers[65]. Unfortunately, *in vivo* results with other growth factors failed to translate into improved wound healing in human clinical trials, highlighting the complex microenvironment of a chronic wound.

Tissue-Engineered Skin Equivalents or Skin Substitutes

Advances during the 1970s in tissue culture techniques for keratinocytes and fibroblasts, including the ability to generate large quantities of these cells, resulted in the production of a new group of wound dressings. A variety of tissue-engineered skin equivalents, both cellular and acellular, are commercially available and Table 145.5 outlines some of these products. A true skin substitute provides both the physiologic and mechanical functions akin to an autologous skin graft. Advantages of tissue-engineered dressings include no painful donor sites and the potential for providing coverage of large areas.

Chronic wounds treated with engineered dressings often undergo an "edge effect", characterized by promotion of epithelialization from the edge of the ulcer toward its center, likely due to a release of cytokines by the donor cells[66]. There are currently three types of skin substitutes: epidermal grafts, dermal replacements (acellular or cellular), and composite grafts (with both an epidermal and dermal component). Tissue-engineered dressings can also be classified as autologous, allogeneic (human donor), or xenogeneic (usually bovine or porcine). Currently, the primary allogeneic sources are cadaveric dermis and neonatal foreskin. *Cellular and tissue-based products*, which includes skin equivalents and substitutes, is a term used by the FDA to signify those products regulated by the Center for Biologics Evaluation and Research.

Epidermal Grafts

The first cultured epidermal autografts were successfully cultivated in 1975 by Rheinwald and Green. They have been used successfully in a variety of clinical situations including burns, chronic ulcers, vitiligo, and postsurgical wounds.

Epicel® represents an epidermal autograft in which a skin biopsy is obtained from the patient and then the *autologous* keratinocytes are co-cultured with irradiated murine fibroblasts that serve as a feeder layer[67]. A sheet of keratinocytes two to eight cells thick forms and is attached to petrolatum gauze. The graft is then sutured in place and the gauze backing is removed at 1 week when the keratinocytes have attached to the wound. Skin biopsies obtained 6–12 months post-grafting show anchoring fibrils and neovascularization. This epidermal autograft is approved for use in partial- and full-thickness burns. Disadvantages include the several-week period required to culture the keratinocytes, graft fragility, a short shelf life, and the cost of processing.

For decades, the roofs of suction blisters created in uninvolved skin have been used to repigment vitiligo. More recently, an automated system for epidermal autologous grafting was introduced that uses heat and suction to produce small epidermal microdomes, with consistent cleavage at the lamina lucida[68]. Advantages include no requirement for anesthesia or a highly skilled surgeon, performance in an outpatient setting, minimal donor site pain, and lack of scarring. The grafts have been applied to a variety of chronic and acute wounds and pathergy has not been observed in patients with pyoderma gangrenosum.

TISSUE-ENGINEERED SKIN EQUIVALENTS			
Examples (name and description)	**Possible uses**	**Advantages**	**Disadvantages**
Single layer – viable cells			
Autologous			
Epicel® – sheet of cultured **keratinocytes** (derived from a skin biopsy) attached to petrolatum gauze [commercially available, FDA-approved for burns ≥30% BSA]	Partial- and full-thickness burns, congenital melanocytic nevus excision sites, pyoderma gangrenosum (non-inflammatory; see Ch. 26)	• Small donor site wound • Capable of self-repair • Single application is often sufficient • Permanent and cosmetically acceptable • Good adherence	• Very expensive • Minimal shelf life; must be used soon after delivery from manufacturer • Several-week culture period • Needs biopsy of normal skin • Contraindicated if history of anaphylaxis due to vancomycin, amikacin, or amphotericin
Allogeneic			
Dermagraft® – neonatal foreskin **fibroblasts** grown on a biodegradable mesh; FDA-approved for diabetic foot ulcers (see Table 145.6)	Diabetic foot ulcers	High level of evidence for effectiveness	• Fragile construct – sensitive to physical manipulation
Single layer – acellular or non-viable cells			
Xenogeneic (see Table 145.6 for additional information)			
Porcine collagen			
Oasis® Wound Matrix, Ultra Tri-Layer Matrix – porcine intestinal collagen type I and extracellular matrix (Fig. 145.11)	Chronic ulcers, including diabetic and venous, burns, skin tears, split-thickness graft donor sites, post-laser resurfacing	• Long shelf life* • Non-human origin avoids human pathogen transmission* • Immediately available* • Reduces pain of some wounds* • Stored at room temperature	• Expensive* • May adhere to wound strongly enough to damage new epithelium • Usually needs multiple applications • May have higher infection rate
Permacol® – acellular porcine dermal collagen (approved as surgical implant)	Used primarily for surgical repairs, e.g. abdominal, hernia	Stored at room temperature	
Biobrane® – acellular porcine collagen type I		Stored at room temperature	
Bovine collagen			
INTEGRA® Dermal Regeneration Template – bovine tendon collagen and shark chondroitin	FDA-approved for burns and diabetic foot ulcers	• High level of evidence of effectiveness for diabetic foot ulcers • Stored at room temperature • Flexible	• Possible bovine allergy
Matriderm® – bovine collagen types I, III and V plus solubilized elastin		• Stored at room temperature • Flexible	• Possible bovine allergy
Allogeneic (see Table 145.6 for additional information)			
AlloDerm® Regenerative Tissue Matrix, GRAFTJACKET NOW™ Acellular Dermal Matrix – cadaveric decellularized dermis	Burns and split-thickness skin graft sites	• Decreased pain • Immediate availability • Single application	• Theoretical risk of transmission of human pathogens
Human amniotic membrane (HAM) – inner layer of the amniotic sac	Diabetic foot ulcers	• Non-immunogenic • Applied without immobilization • Long shelf life (cryopreserved)	• Does not survive in chronic wounds after 2–4 weeks
Composite – cellular			
Xenogeneic & allogeneic			
Apligraf® – neonatal foreskin keratinocytes and fibroblasts plus bovine collagen type I; bilayered; FDA-approved for venous ulcers and diabetic foot ulcers	Diabetic foot ulcers (>6 weeks) and venous ulcers (>4 weeks) Epidermolysis bullosa	• High level of evidence • Self-repair ability • Single application (can be repeated up to 5 times) • Stored at room temperature • Immediately available (no several-week culture period as with autologous keratinocyte products)	• Several-week shelf life • Possible transmission of infectious diseases because of human donors but sources are screened
StrataGraft® – cultured human keratinocytes (NIKS cells) and dermal fibroblasts in murine collagen; FDA approved for deep partial-thickness burns	Deep partial- and full-thickness burns, chronic non-healing ulcers	• Promotes self-repair • Single application may be sufficient • Immediately available • Long shelf life (can be cryopreserved)	• Expensive • Avoid in patients with glycerin intolerance • Possible transmission of infectious diseases because of human donors but sources are screened
*Applies to all xenogeneic products.			

Table 145.5 Tissue-engineered skin equivalents. BSA, body surface area; min, minutes; NIKS cells, spontaneously immortalized human keratinocyte cell line. From refs 46, 56, 58, 60, 61, 63, e4–e6.

Dermal Replacements

There are two types of dermal replacements: xenogeneic and allogeneic (Table 145.6). Neither of these is permanent: DNA analysis of wounds after the application of non-autologous skin substitutes shows almost complete disappearance of the grafted cells after two months[69]. The goal of these dermal grafts is to provide a temporary biologic scaffold in order to stimulate the healing process. They are placed over the wound, extending slightly onto normal skin, and then bolstered into place. Secondary dressings must be applied. It is advisable to keep the primary dressing in place for up to a week following its placement and to follow the individualized product instructions. The major component of dermal replacements is collagen; other elements of the extracellular matrix, e.g. glycosaminoglycans (GAGs), may be included and in the case of cellular products, fibroblasts.

Xenogeneic

Although other sources are available, xenogeneic grafts are usually composed of porcine or bovine collagen (see Table 145.6). The advantages of these products are: (1) their ability to effect hemostasis and to provide immediate closure as well as cosmetically acceptable scars with second intention healing; (2) safety from potential human pathogen transmission due to their animal origin; and (3) an adequate shelf life, facilitating off-the-shelf access.

Oasis® Wound Matrix and Biobrane® are examples of acellular matrices derived from porcine collagen (Fig. 145.11). They have significant elasticity, enabling a full range of motion of the covered body part, and there is no requirement for dressing changes once it has adhered to the wound bed. However, Biobrane® may adhere to the wound so tightly that it can damage newly developed epithelium[70].

INTEGRA® Dermal Regeneration Template is composed of two layers: an outer silicone layer overlies a layer composed of bovine tendon

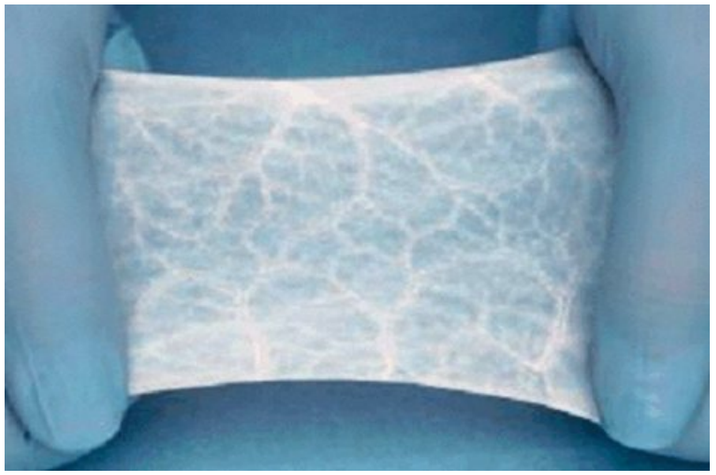

Fig. 145.11 An acellular xenogeneic dressing. This particular wound matrix is derived from porcine small intestine submucosa (Oasis®) and serves as a dermal graft.

SELECTED DERMAL REPLACEMENT GRAFTS		
	Description	**Comments**
Xenogeneic		
Biobrane®	Bilayer dressing: inner nylon mesh fabric coated with **porcine** type I collagen ("dermis") bonded to a semipermeable silicone film membrane ("epidermis")	• Tissue ingrowth into the nylon fabric following binding of collagen to fibrin • Trilaminar nylon (better for clean, partial-thickness burn wounds or donor sites) and monofilament nylon (better for meshed autografts) • Approved for partial-thickness burns
Oasis® Wound Matrix, Ultra Tri-Layer Matrix	Derived from porcine small intestine submucosa (mucosa and muscle removed) **Porcine** type I collagen, extracellular matrix (e.g. hyaluronic acid, fibronectin), and growth factors (FGF, TGF-β)	• In study of 120 patients with venous leg ulcers, after 12 weeks of treatment, 55% of Oasis® + compression group healed vs 34% in compression alone group; at 6 months, 100% and 70% remained healed, respectively • Approved for venous, diabetic and pressure ulcers, second-degree burns, graft donor sites, surgical wounds, and full-thickness skin injuries
INTEGRA® Dermal Regeneration Template	Bilayer dressing: **bovine** tendon collagen admixed with **shark** cartilage-derived, modified GAGs ("dermis") plus an outer silicone membrane	• Debridement required prior to graft placement with sutures or staples • Outer silicone cover removed after several weeks; in large wounds, replaced by ultrathin autograft (two-step process) • In a controlled trial of diabetic foot ulcers, improved time and rate of wound closure when compared to standard of care treatment • Approved for life-threatening third-degree burns and diabetic ulcers
Allogeneic		
AlloDerm® Regenerative Tissue Matrix*	Human cadaveric skin, chemically treated and purified to remove epidermis, all cellular components, and pathogens Cryopreserved (shelf life of 6 months)	• Repopulation of host fibroblasts and endothelial cells seen within 10 days of grafting • Approved for repair or replacement of damaged or inadequate integumental tissue, e.g. breast reconstruction
Dermagraft®	Neonatal foreskin fibroblasts are seeded onto a 3-D scaffold of biodegradable polyglactin mesh	• Similar time to graft take and similar fibroblast function as TransCyte™ (see below) • In 245 patients with diabetic ulcers, significant improvement in wound closure by week 12: Dermagraft® 30% versus conventional therapy 18% • Approved for full-thickness diabetic foot ulcers present >6 weeks that are deep but do not involve tendons, muscle or bone; HDE for ulcers in epidermolysis bullosa
Xenogeneic & allogeneic		
Transcyte™	Biobrane® (see above) plus neonatal foreskin fibroblasts	• Requires ~2 weeks for graft take • Fibroblasts initially secrete extracellular matrix (including collagen) and growth factors that stimulate granulation tissue and epithelialization but then die • In a controlled trial of excised burns, easier to use and similar outcomes when compared to human cadaveric skin • Approved for deep partial- and full-thickness burns

*Additional allogeneic grafts include those derived from human umbilical cord (EpiCord®) and placental membranes (AmnioBand® EpiFix™, Grafix®, NuShield®). Other acellular dermal matrices (ADMs) that may be used for venous and diabetic ulcers as well as breast reconstruction include AlloMax™, AlloPatch®, DermACELL™, DermaMatrix™, Flex HD®, Strattice™, SurgiMend®, and TheraSkin®.

Table 145.6 Selected dermal replacement grafts. FGF, fibroblast growth factor; GAGs, glycosaminoglycans; HDE, humanitarian device exemption; TGF-β, transforming growth factor-β. *From refs 46, 57, 60, 61, 63, e4–e11. Courtesy Gregg M. Menaker, MD.*

collagen and shark cartilage GAGs. The latter is thought to simulate dermal matrix. Because INTEGRA® has a complicated application procedure, the FDA requires that all physicians complete a company-sponsored training program.

Allogeneic

Allogeneic dermal grafts are composed of cadaveric dermis or neonatal foreskin fibroblasts (see Table 145.6). The advantages of these products include their ability to provide immediate closure and cosmetically acceptable scars with second intention healing, in addition to an adequate shelf life, facilitating off-the-shelf access. However, there is a risk of graft rejection due to T cell recognition of donor T cells[71]. Examples include AlloDerm® Regenerative Tissue Matrix which consists of decellularized cadaveric dermis and GRAFTJACKET NOW™ Acellular Dermal Matrix which is derived from processed acellular cadaveric skin (see Table 145.5). The FDA currently categorizes both AlloDerm® and GRAFTJACKET NOW™ as banked human tissue for transplantation. Dermagraft® is a biodegradable scaffold seeded with neonatal foreskin fibroblasts and is FDA-approved for the treatment of diabetic foot ulcers[72].

Composite Grafts

Engineered composite grafts are bilayered skin equivalents. Current products consist of an epidermal layer composed of human keratinocytes and a dermal layer composed of bovine collagen matrix seeded with human fibroblasts. In Apligraf®, both cell types are derived from human neonatal foreskins (Fig. 145.12). This composite graft produces its own matrix proteins and growth factors and, if wounded, it can repair itself. Although FDA-approved for venous leg ulcers and diabetic foot ulcers, Apligraf® has been used to treat acute and chronic wounds that failed to heal by standard means, including those due to epidermolysis bullosa, pyoderma gangrenosum, burns, and surgical excisions. Whereas several applications of the material may be required to completely heal chronic wounds, a single application may be sufficient to initiate a satisfactory healing response. Chronic venous ulcers that were randomized to receive compression plus Apligraf® healed in a shorter time period compared to compression alone, especially in the case of larger defects[72,73].

More recent evidence suggests that Apligraf® modulates an array of cellular pathways in the epidermis at the wound's edge, ultimately transforming a chronic wound into an acute one[74]. In venous leg ulcers, Apligraf® also stimulates antifibrotic changes within the wound bed[75]. This includes decreased expression of gene targets of profibrotic TGF-β1, increased levels of the TGF-β inhibitor decorin, and upregulation of fibroblast-derived matrix metallopeptidase 8.

A point-of-care delivery system named RECELL® was recently developed that allows delivery of autologous skin to the wound bed via a cell spray containing keratinocytes, melanocytes, Langerhan cells, and papillary dermal fibroblasts[76]. This onsite cell harvesting device can create 1 ml of cell suspension from a 1 cm^2 piece of split-thickness donor tissue; the former can then be sprayed onto an area of up to 80 cm^2. The maximum per device is 24 ml of cell suspension. In a randomized controlled study in burn patients that compared standard split-thickness skin grafts (STSGs) versus the application of RECELL® Spray-On Skin™ cells to widely meshed STSGs, the cell spray had similar efficacy and safety but decreased the donor site area by ~30%[77].

Apligraf® and similar products are costly, but they have an excellent safety profile as well as the advantage of accelerating healing and reducing long-term costs.

Negative Pressure Wound Therapy (NPWT)

NPWT, developed in the 1990s, is based on the delivery of sub-atmospheric pressure to the wound bed. In this vacuum-assisted closure (VAC) system, a polyurethane or polyvinyl alcohol foam is cut and placed on the wound surface. The foam is then sealed over by a transparent drape in order to provide a closed airtight system (Fig. 145.13). A vacuum pump, connected to this space via a plastic tube, provides a negative pressure environment. NPWT removes interstitial fluid, stimulates angiogenesis, and enhances circulation as well as lymphatic drainage. There is evidence to support the use of NPWT for acute postsurgical wounds[78]. Although there is some evidence that NPWT improves healing of diabetic foot ulcers, more information regarding appropriate patient selection, duration of treatment, and use of combined treatments is required[79].

Nowadays there are portable, often single-use, systems that can deliver effective negative pressure to a variety of low-to-moderately exudative wounds. Some of these systems use superabsorbent dressings, rather than a canister, to retain wound exudate[80]. The dressing is placed under a sealed film covering and is linked to a battery-operated, portable pump that can be harnessed around the thigh, allowing for patient mobility[80]. Single-use NPWT systems appear to lead to similar, if not improved, wound healing and they reduce the cost of care given the outpatient setting[81]. Another modification is lavage of the wound bed by a wound cleanser or antiseptic while the NPWT is functioning[82].

Oxygen Therapy

Because multiple studies have pointed to hypoxia as one of the major factors leading to a delay in wound healing, both hyperbaric oxygen therapy (HBOT) and topical oxygen therapy have been utilized.

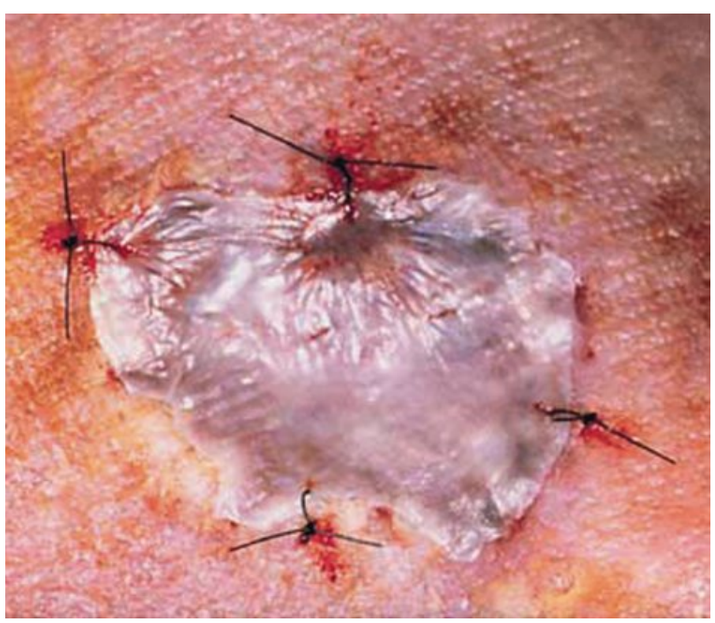

Fig. 145.12 Example of an engineered composite (xenogeneic and allogeneic) graft sutured into place (Apligraf®). *Courtesy Gregg M. Menaker, MD.*

Fig. 145.13 Negative pressure wound therapy. In negative pressure wound therapy, a polyurethane (this patient) or polyvinyl alcohol foam is cut and placed on the wound surface. The foam is then sealed over by a transparent drape. A vacuum pump, connected via a plastic tube, provides a negative pressure environment. The sterile polyurethane foam has large pores and stimulates granulation tissue.

In HBOT, oxygen is administered at pressures greater than one atmosphere. Patients are placed in a pressure chamber where they breathe oxygen at this increased pressure. Systemic HBOT sessions last 45–120 minutes and are conducted once or twice daily for 20–30 sessions. This oxygenation of hypoxic tissue induces vasoconstriction and reduces edema and congestion. At a cellular level, there is increased fibroblast replication, collagen synthesis, and neovascularization as well as upregulation of growth factors.

To screen for a potential response to HBOT, the patient has transcutaneous oxygen levels measured in the peri-wound region both at baseline and while breathing 100% oxygen; at least a doubling of the levels is preferred. While a systematic review concluded that there was short-term but not long-term improvement of diabetic ulcers with HBOT[83], randomized controlled trials with small sample sizes reported the effectiveness of HBOT[84]. A data analysis of 6259 patients did not support the use of HBOT for diabetic foot ulcers, highlighting the need for large randomized controlled trials[85]. Additional methods for oxygenation of wounds include topical pressurized oxygen, topical continuous diffusion of oxygen, and dressings that release oxygen, but proper selective application of these interventions is required[86].

COMPRESSION THERAPY

Based on substantial scientific and clinical evidence, compression therapy represents the mainstay of treatment for all cutaneous manifestations of chronic venous insufficiency, from varicose veins and edema to lipodermatosclerosis and venous leg ulcers. The physiologic effects of compression include acceleration of the velocity of venous flow, augmentation of venous return toward the heart, reduction of venous reflux and edema, promotion of oxygenation to the surrounding dermis, and stimulation of fibrinolysis[87]. Compression therapy is also employed following lower extremity surgical procedures.

Types of Compression

There are several different methods of compression therapy, ranging from stockings and compression bandages to devices such as intermittent pneumatic compression systems (Table 145.7). Compression stockings are graded from Class I to IV based upon the pressure at the ankle (see Table 105.4) whereas compression bandages are classified as either long stretch (elastic with substantial extensibility) or short stretch (inelastic with limited extensibility). Multiple factors influence the sub-bandage pressure including: (1) the tension or amount of force that is used to stretch the bandage during application; (2) the width of the bandage – wider bandages are associated with decreased compression; (3) the size of the leg – a larger circumference leads to reduced pressure; and (4) the number of layers of compression – a higher number increases pressure[88]. This is reflected in a modified Laplace law[89]:

$$\text{Sub-bandage pressure (mmHg)} = \frac{\text{tension (KgF)} \times \text{number of layers} \times \text{a constant}}{\text{limb circumference (cm)} \times \text{bandage width (cm)}}$$

In addition to the type of bandage material and the method of wrapping, the amount of pressure also depends on muscle contraction.

Although the definitive optimal pressure required to prevent capillary leakage secondary to venous hypertension has not been delineated, an ankle pressure of 30–40 mmHg is recommended for leg ulcers[90]. The higher compression pressure of 40 mmHg should be considered for persons with an ankle–brachial index (ABI) of 0.8 to 1.3, indicating adequate vascular supply (see Table 105.8). In patients with predominantly venous disease, but coexisting arterial compromise (ABI = 0.66–0.8), modifications in the form of inelastic (rather than elastic) compression and fewer layers of compression is recommended[91,92]. Individuals with an ABI of 0.5 to 0.65 should have further modifications, e.g. one or two layers of a tubular bandage that can be easily removed. Inappropriate compression bandaging in patients with arterial disease can lead to ischemia and is therefore potentially harmful. Patients with congestive heart failure (CHF) may have difficulty tolerating compression therapy because compression of the lower extremities may increase preload volume and worsen CHF.

Compression stockings

With graduated compression stockings, the patient is afforded some independence in the application of the device. However, for arthritic

TYPES OF COMPRESSION SYSTEMS			
Compression system	**Examples**	**Advantages**	**Disadvantages**
Long stretch (elastic) bandages	ACE™, Biflex® (also short), Dauerbinde® K, SurePress®	• Base of the toes to knees • Low working pressure • High resting pressure • 100%–200% extensibility • Can be applied as spiral or figure-of-eight • Inexpensive; washable and reusable forms available	• Tend to unravel • Do not provide a sustained compression • Risk of incorrect application • Can lose elasticity with continued use
Short stretch (inelastic) bandages	Zinc paste (Viscopaste®/Unna boot), Actio®, Biflex® (also long), Comprilan®, Panelast®, Porelast®	• Comfortable so better tolerated • Minimal interference with daily activities • Some (e.g. Viscopaste®) can generate high working pressure	• Can lose compression after application • Not good for highly exudative wounds • Viscopaste®/Unna boot needs to be applied by well-trained staff
Devices	CircAid® (with Velcro®), FarrowWrap® (with Velcro®), Sigvaris CoolFLEX® (with metal fastening clasps)	• Adjustable compression • Easy to put on and remove	• Expensive • Bulky
Multicomponent bandages	Coban™ 2, Coban™ 2 Lite, Profore® (5 layers), Profore® Lite (4 layers), Actico®2 C	• Higher compression and sustained high compression • Graduated compression • Reduced ("Lite") compression available for patients with mixed venous and arterial disease	• Needs to be applied by well-trained staff
Intermittent compression devices	Lympha Press® (pneumatic pump)	• Enhance fibrinolytic activity	• Expensive • Requires being immobile for a few hours per day
Tubular system	Tubigrip® (contains latex) EdemaWear® Medigrip LF™	• Easy to use • Tubular bandage doubled back over limb to increase compression	• Low compression (unless that is what is desired because of coexisting arterial disease)

Table 145.7 Types of compression systems. LF, latex free. From refs 70, 73, 83, e12–e14.

Fig. 145.14 Unna boot. Non-elastic compression therapy with a zinc-impregnated compression wrap.

and/or elderly patients, application can be difficult unless the stockings have zippers or Velcro® fasteners. Although compression stockings are commonly used as maintenance therapy, recent studies have observed that they are comparable to bandaging systems for the treatment of venous leg ulcers, including producing similar healing rates[93]. A systematic review found no significant differences between compression stockings and compression bandages with respect to ulcer healing, time to ulcer healing, or ulcer recurrence[94]. In general, compression stockings are more tolerable, less costly, and less bulky. Patient education and demonstration can lead to increased compliance.

Compression bandages

In the 1880s, Paul Gerson Unna introduced a bandage, now referred to as the Unna boot, for the treatment of venous leg ulcers and selected eczematous dermatoses. It was originally a cotton bandage impregnated with zinc oxide, gelatin, and glycerin paste. Applied in a semi-rigid state, the Unna boot confers (semi-rigid) compression, along with the advantages of a moisture-retaining occlusive dressing (Fig. 145.14). It should be applied by a qualified medical professional and changed once a week unless heavy drainage from the wound necessitates more frequent replacement. Correct application of the Unna boot prevents excessive or abnormal pressure to the limb, compromised circulation, skin breakdown, additional ulcer formation, or further limb deterioration (Video 145.1). Over a century later, the Unna boot is still a frequently employed compression bandage for venous leg ulcers[95].

Medicated paste bandages such as the Unna boot can be used alone (inelastic) or underneath an additional layer of cohesive bandaging (e.g. Coban™ [elastic]), especially on the lower extremities. By creating an absorptive, protective contact layer, they can also address the stasis dermatitis often associated with leg ulcers. In addition to preservatives, these open-weave cotton bandages are impregnated with: (1) zinc oxide paste, calamine, or ichthammol, all of which have a soothing action on irritated skin; (2) coal tar, which has an anti-inflammatory effect; or (3) clioquinol, which has deodorizing and antibacterial actions. Preservative-free zinc oxide products are commercially available as are combinations of zinc oxide with each of the above components or calamine plus clioquinol.

Short stretch (inelastic) versus long stretch (elastic) bandages

Elastic bandages provide both easy stretchability and a sustained squeeze on tissue (see Table 145.7). This is because these bandages recoil back to their original length due to the presence of elastomeric fibers. In contrast, inelastic bandages such as the Unna boot and short stretch bandage (more commonly used in Europe) form a rigid covering that resists lateral expansion of the calf muscle during active contractions. Of note, contractions of the calf muscle act as a pump that generates a propelling force to promote venous return (see Fig. 105.2).

Compression bandages may be composed of a single component or multiple combined components. In a meta-analysis[96], short stretch bandages were found to be as efficacious in promoting healing of venous leg ulcers as more complex multi-component bandaging systems, in both ambulatory and non-ambulatory patients. However, Cochrane reviews suggest that the evidence supports multi-component systems (over single-component systems) and systems with an elastic component (over those with an inelastic bandage)[97]. Lastly, tubular systems (Tubigrip®, EdemaWear®) provide low compression and can be used by patients with reduced ABIs (see above).

Compression devices

Intermittent pneumatic compression (IPC) devices deliver sequential pressure to the limb. IPC is a beneficial adjunct to other forms of compression in the treatment of venous leg ulcers, especially for non-ambulatory patients[98,99]. When the calf muscle pump is not active, the use of a dynamic compression system is more beneficial than a passive system[99–101]. Portable IPC devices that are relatively easy to operate are available for home use. In a randomized controlled trial, patients with lymphedema and venous leg ulcers healed faster and with less pain when a 4-layer compression system was combined with daily home-based IPC as compared to 4-layer compression alone[102]. Both self-adjustable Velcro® devices and hybrid systems are alternative compression therapy choices that may increase compliance.

FUTURE DIRECTIONS

Wound dressings are an essential component of wound care, compression therapy for venous leg ulcers, and pressure redistribution for pressure ulcers. Over the past century, dressings have moved from a passive to more active role with improvements in moisture-retentive products and delivery systems. However, incorporation of active ingredients into traditional dressings increases their cost and raises regulatory issues as to whether a dressing is a drug or a medical device. Advances based on growth factors, cellular therapy, and skin substitutes will continue, but selection of the most appropriate dressing for a given clinical scenario will remain the key decision for the physician.

Key features

- Choice of a particular biopsy technique is based upon the anatomic site, type of skin lesion, desired histologic information, and patient preference
- Wound closure is accomplished via suturing (primary intention) or second intention
- Choice of a specific suturing technique depends upon the needs of the wound (e.g. eversion of the edges), with the goal being an optimal functional and aesthetic result
- Excision *in toto* with repair is a common surgical procedure for dermatologists and it is accomplished through a series of well-defined steps
- Postoperative care and instructions minimize the risk of complications

INTRODUCTION

The cornerstone of dermatologic diagnosis is the correlation of clinical and histologic findings. A biopsy procedure is required in order to obtain tissue for pathologic examination and, fortunately, the skin is more accessible than most other tissues. Modern instruments and techniques allow cutaneous biopsies to be performed efficiently with minimal tissue distortion. In some situations, a biopsy procedure is also curative, either coincidentally or intentionally. Knowledge of basic excisional surgical techniques can minimize cosmetic and functional impairment. A well-planned and timely skin biopsy may also circumvent the need for more invasive procedures. Even critically ill patients can undergo a skin biopsy with minimal risk.

KEY CONCEPTS

Site Selection

Performance of a biopsy that will yield accurate and relevant histologic information depends upon the selection of an appropriate lesion or site within a lesion (Table 146.1).

The anticipated depth of the lesion to be biopsied must also be considered. A superficial lesion, e.g. an actinic keratosis versus squamous cell carcinoma *in situ*, can be assessed via a thinner horizontal biopsy that extends to the papillary dermis. On the other hand, accurate diagnosis of a subcutaneous nodule, e.g. panniculitis versus polyarteritis nodosa, requires a biopsy that extends into the deeper portions of the subcutaneous fat. Occasionally, fascia must be obtained, e.g. morphea profunda versus eosinophilic fasciitis. Disorders that primarily affect the collagen and elastic fibers within the dermis may have subtle histologic findings (e.g. atrophoderma of Pasini and Pierini) and longitudinally sectioned wedge biopsies that include both the affected area as well as adjacent normal-appearing skin prove most helpful.

Biopsy Technique Selection

Seven major methods are employed to biopsy skin: curettage, snip or scissors biopsy, shave biopsy, saucerization biopsy, punch biopsy, incisional biopsy, and excision *in toto* (Table 146.2). Depending upon the type of lesion and its size, several of these procedures are also curative, especially excision *in toto*. However, these methods differ with regard to the quality and quantity of skin obtained. Lesional characteristics and operator experience are factors that influence the choice of a particular procedure.

Curettage is frequently used to remove clinically benign epidermal lesions such as verrucae or seborrheic keratoses as well as actinic keratoses (AKs) and basal cell carcinomas (BCCs), especially the superficial type. The curettings can also be used to confirm the clinical diagnosis, but histologic interpretation may prove challenging if the tissue specimen is fragmented and its orientation becomes problematic. *Snip or scissors biopsy* is an efficient technique for assessing pedunculated lesions as well as removing benign growths (e.g. acrochordons, filiform warts).

The *shave biopsy* usually provides a specimen consisting of epidermis, papillary dermis, and sometimes reticular dermis (particularly in elevated lesions). It is a popular biopsy technique for recontouring papular, clinically benign lesions (e.g. irritated or unwanted compound and dermal melanocytic nevi, fibrous papules of the nose) where histologic confirmation is desired. Shave biopsy is also a useful procedure for diagnosing superficial carcinomas, e.g. nodular and superficial BCCs, squamous cell carcinoma (SCC) *in situ*, and lentigo maligna. However, for lentigo maligna, palpation beforehand to exclude induration and a possible desmoplastic component is recommended.

When tissue is procured via a *saucerization procedure*, the depth of the biopsy specimen is intentionally deeper due to angulation of the blade. This technique is often used to biopsy melanocytic nevi with atypical features when the differential diagnosis includes a thin melanoma[1]. Its advantage is that it allows histologic examination of the entire lesion or a large portion of the lesion, which increases diagnostic accuracy (as compared to partial punch biopsy). Saucerization is also performed to confirm the clinical diagnosis of minimally invasive SCC or keratoacanthoma and to distinguish the former from a hypertrophic AK.

BIOPSY SITE SELECTION	
Lesion/disorder	**Appropriate site**
Tumor	Thickest portion; avoid necrotic tissue
Blister	Edge of lesion, including perilesional skin (see Fig. 29.12)
Ulcerated/necrotic lesion	Edge of ulcer or necrosis plus adjacent skin
Generalized polymorphous eruption	Characteristic well-developed lesion of recent onset. If multiple biopsies are obtained, include different morphologies
Small vessel vasculitis	Characteristic lesion of recent onset
Livedo racemosa	Pale center of broken ring. Multiple biopsies increase diagnostic yield

Table 146.1 Biopsy site selection.

SELECTION OF TYPE OF BIOPSY TECHNIQUE				
Method	**Indication**	**Type of specimen obtained**	**Anesthetic technique (Fig. 146.1)**	**Closure**
Curettage	• Lesions involving the epidermis (e.g. SKs, AKs, verrucae) • Confirm clinical diagnosis of BCC prior to definitive treatment	Epidermal sheet or fragments of epidermis and dermis	Wheal	Second intention
Scissors biopsy	• Pedunculated lesion	Tissue above connection to the epidermis	None or wheal	Second intention
Shave biopsy	• Lesions involving the epidermis ± superficial dermis • Elevated lesion	Epidermis, papillary dermis, and occasionally reticular dermis (elevated lesions)	Wheal	Second intention
Saucerization biopsy	• Lesions involving the epidermis and dermis • Atypical melanocytic nevus versus thin melanoma • Hypertrophic AK versus minimally invasive SCC	Similar to a shave biopsy, but specimen is thicker (i.e. contains reticular dermis)	Wheal or deep infiltration	Second intention
Punch biopsy	• Process (e.g. tumor, inflammation) involves the dermis • Depressed lesion	Epidermis, dermis, and sometimes subcutaneous fat	Wheal or deep infiltration	Primary intention; simple suture
Incisional biopsy	• Process (e.g. tumor, inflammation) involves the subcutaneous fat or fascia • Large-sized tumors • Subtle disorders of dermal connective tissue	Epidermis, dermis, and subcutaneous fat Can include fascia where needed	Deep infiltration	Primary intention; layered closure
Excision *in toto*	• Biopsy intended to be definitive treatment • Strong clinical suspicion of cutaneous malignancy (e.g. invasive melanoma)	Epidermis, dermis, and subcutaneous fat Can include fascia where needed	Deep infiltration	Primary intention; layered closure

Table 146.2 Selection of type of biopsy technique. AKs, actinic keratoses; BCC, basal cell carcinoma; SCC, squamous cell carcinoma; SKs, seborrheic keratoses.

The *punch biopsy* supplies a cylindrical to conically shaped specimen consisting of epidermis, dermis, and sometimes subcutaneous fat. The volume of tissue sampled correlates with the size of the punch biopsy instrument. The diameter of the metal "barrel" can vary from 2 to 8 mm; the wider the diameter, the greater the likelihood of obtaining subcutaneous fat. However, the thickness of the dermis must be kept in mind in addition to the amount of subcutaneous fat required to address possible clinical diagnoses. Punch biopsies are particularly helpful for examining processes within the dermis such as tumors or inflammation (see Table 146.2). In the case of tumors, sampling a majority of the lesion is desirable, so that for large-sized tumors, multiple punch biopsies may be required.

The *incisional* biopsy removes a wedge of tissue from the center or edge of a lesion (see Site Selection) and is the best option for obtaining deep subcutaneous fat or fascia for histologic examination. It is also used to sample a significant portion of large-sized tumors. Excision *in toto* removes the entire lesion and includes epidermis, dermis, and subcutaneous fat. For these reasons, it is often utilized when the leading clinical diagnosis is invasive cutaneous melanoma.

Specimen Handling

Transportation of the biopsy specimen to the laboratory differs according to the processing and type of examination required. Most specimens are placed in formalin, but, occasionally, special carrier media are necessary (Table 146.3). Fresh tissue specimens are sent on saline-moistened gauze and promptly delivered to the laboratory; the laboratory must be in reasonable proximity and have the capability of quickly processing the tissue. Occasionally, fresh or frozen tissue is sent overnight with cold packs or on dry ice, respectively, to a more distant laboratory (see Fig. 76.10). When handling small or thin biopsy specimens, it is important to confirm that they are clearly within the formalin solution and not adhering to the upper portions of the container or lid to prevent desiccation artifact.

A protocol must be established within the clinician's practice to ensure that specimens and results are appropriately tracked and assigned to the correct patient. Immediately after the biopsy specimen has been obtained, it should be placed in a container prelabeled with the patient's name and other identifying information. If multiple biopsies are to be performed, pre-labeling the containers alphabetically and with the respective sites avoids confusion. A specimen log book (Table 146.4) ensures notification of the results to the patient and disposition of recommended care.

SPECIMEN HANDLING		
Proposed laboratory test	**Carrier medium**	**Comments**
Routine microscopy, immunohistochemistry, PCR assay	10% neutral buffered formalin	Fixation process begins immediately
Direct immunofluorescence	Michel's medium -or- Fresh*	Depends on laboratory preference or availability
Flow cytometry	Fresh*	Lymphoma cutis
Culture for bacteria, mycobacteria or fungi	Fresh* -or- Minced in sterile culture/carrier medium appropriate for organism (mincing usually performed by laboratory)	
Culture for viruses	Viral transport medium (e.g. M4RT®)	
Electron microscopy	Glutaraldehyde	

*Laboratory must be in close proximity and specimen placed on saline-moistened gauze, but need to avoid bacteriostatic saline solution when culturing for microbes.

Table 146.3 Specimen handling. PCR, polymerase chain reaction.

Patient Preparation

A discussion of the reason(s) to do the biopsy, the site to be biopsied, and the technique to be used can be brief and to the point. Informed consent requires a discussion of the major risks, which include bleeding, discomfort, infection, and scarring (see Ch. 151). Bleeding can usually be controlled by firm pressure at the site of the wound, but may require more aggressive forms of hemostasis. Discomfort is usually minimal, although some sites such as the forehead, fingers, and feet may throb.

Infection is unusual. Except when the area to be biopsied is already infected or the site is mucosal, the skin can be prepared by application of an antiseptic agent and the procedure is then considered to be a *clean* procedure. For clean procedures of non-mucosal, non-infected sites, preoperative prophylactic antibiotics are currently not recommended, even in patients with artificial valves or joints (with the possible exception of sites at high risk of infection, e.g. groin, during

LOG BOOK FOR BIOPSY SPECIMENS			
Date	2/21/22	2/21/22	2/22/22

SITE PREPARATION PROTOCOL	
Sequential steps	**Comments**
Mark site with surgical pen or ink	Local anesthesia may obscure site, especially when the erythematous color is due to vasodilation or when there is a minimally elevated dermal tumor
Time out for patient and site identification	JCAHO universal protocol for patient safety
Photograph site or record landmarks	Up to ~15% of biopsy sites may be later incorrectly identified by the patient and ~5% by the surgeon[8]
Clip hair as needed	Shaving hair increases incidence of infection
Cleanse skin surface	Antiseptic agents listed in Table 146.6
Drape	Gauze (small biopsies) or sterile towels
Anesthetize	Local instillation of anesthetic agent

Table 146.5 Site preparation protocol. JCAHO, Joint Commission on Accreditation of Healthcare Organizations.

ANTISEPTIC AGENTS		
Agent	**Advantages**	**Disadvantages**
Povidone–iodine (Betadine®)	Broad antimicrobial spectrum, including fungi	Irritant and allergic contact dermatitis Residual color May cross-react with iodine in radiocontrast media and iodides in medications
Chlorhexidine (Hibiclens®)	Broad antimicrobial coverage Limited systemic absorption Prolonged suppression of bacterial growth	Keratitis due to ocular exposure Cochlear damage if enters middle ear Irritant and allergic contact dermatitis Contact urticaria Very rarely, anaphylaxis
Isopropyl alcohol	Inexpensive Denatures protein, including bacterial cell walls Immediate (but not prolonged) effect	Weak antimicrobial activity Flammable in the setting of cautery Skin irritant Skin must remain wet for 2 minutes for maximum effect
Chlorhexidine–isopropyl alcohol combination (ChloraPrep®)	Combination provides both short-term and long-term effects Evidence it is more effective than povidone–iodine[10]	Those of either agent alone (see above)
Hexachlorophene (pHisoHex®)	Strong effect against Gram-positive cocci	Little effect on Gram-negative organisms or fungi Teratogen Absorbed through skin with potential neurotoxicity in infants
Soap and water	Traditional preoperative handwashing regimen Disinfects hands as well as alcohol-based rubs[64] Better against *Clostridium difficile* and Norwalk virus	At operative site, cumbersome and messy No prolonged antisepsis
Hydrogen peroxide	Readily available Inexpensive	No significant antiseptic properties Cytotoxic to keratinocytes *in vitro*

Table 146.6 Antiseptic agents.

the first 2 years after joint placement)[2–4]. The overall goal is a reduction in the emergence of antibiotic-resistant bacteria and in one study, for example, preoperative prophylactic antibiotics increased nasal carriage of methicillin-resistant *Staphylococcus aureus*[5]. Tables 151.2 and 151.3 review the guidelines for antibiotic prophylaxis as well as regimens for both oral and non-oral sites. If preoperative antibiotics are given, they are administered within a 2-hour window before the incision; there is debate as to whether or not a second dose is administered 6 hours later and under which circumstances antibiotics should be continued for 48–72 hours[6]. When pretreated with a 5-day regimen of intranasal mupirocin ointment (twice daily) and a total body wash with chlorhexidine soap (daily avoiding the eyes and ears), nasal carriers of *S. aureus* were observed to have fewer postoperative infections[7].

Most patients are primarily interested in discussing whether or not there will be visible scarring. This is best predicted by the type of biopsy to be performed and the anatomic site. Generally, patients can be reassured that small biopsies may be done without grossly noticeable permanent "marks".

Many patients are anxious about the needle sticks required for administration of the local anesthesia and the pain of the procedure. The patient's cooperation is easily obtained in an organized and peaceful environment with a calm and reassuring staff. A well-informed, comfortable patient in a supine position will tolerate the procedure without difficulty.

Site Preparation and Anesthesia

Effective site preparation is most efficient if a standard clinical protocol has been established (Table 146.5). Marking and photographing the site[8,9], cleansing the skin (Table 146.6)[10], and draping are important procedures prior to the instillation of local anesthesia. Local anesthesia is adequate for all skin biopsies and is reviewed in detail in Chapter 143.

When the local anesthetic agent is instilled into a deep compartment (i.e. subcutaneous fat; Fig. 146.1A), 5 to 10 minutes is required for anesthesia to develop on the surface of the skin. Gentle massage of the site may assist in spreading the agent subepidermally and achieving good anesthesia. Injection of the agent superficially, creating an edematous wheal, has immediate efficacy but is more painful (Fig. 146.1B). Since a punch or shave biopsy requires very little agent and therefore a very short injection time, superficial instillation is the technique often used. In addition, a wheal is helpful prior to a shave biopsy as the lesion is further elevated from the plane of the surrounding skin. Of note,

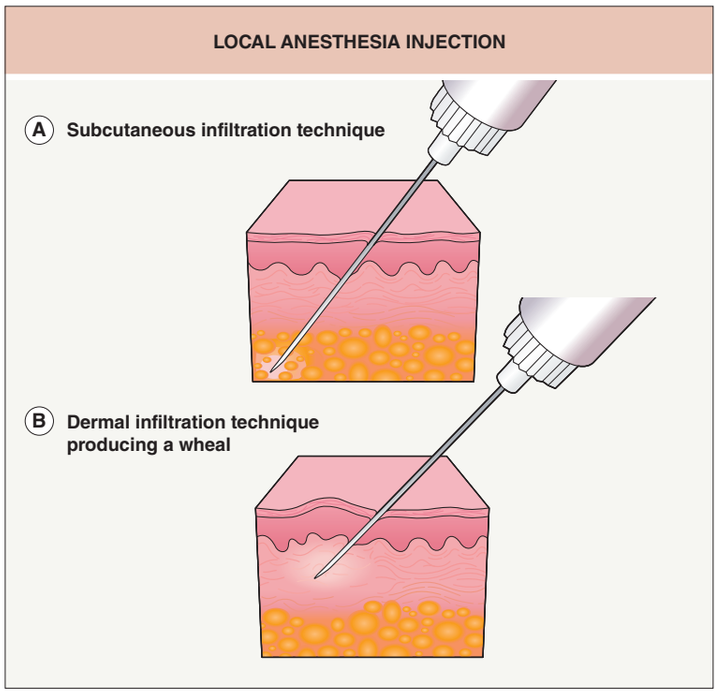

Fig. 146.1 Local anesthesia injection. A Deep infiltration. **B** Superficial infiltration.

METHODS OF HEMOSTASIS

Method	Comments
Compression	• Appropriate for small-diameter, superficial wounds • Folded dry sponge with tightly applied bandage
Styptics: aluminum chloride hexahydrate (Drysol™, Xerac AC™), silver nitrate, or ferric subsulfate (Monsel's solution)*	• Apply pressure to diminish active bleeding • Then apply styptic with cotton-tipped swab and pressure to wound bed for 30 sec–2 min
Absorbable hemostatic sponge: Gelfoam®, Instat®, Oxycel®	• Apply pressure to diminish active bleeding • Then place sponge in wound and bandage in place with pressure • Warn patient of presence of "foreign body"
Electrocoagulation and heat cautery	• Reviewed in Chapter 140
Sutures	• When used for wound closure, generally creates sufficient hemostasis in the sidewalls of the wound • Figure-of-eight suture, utilizing an absorbable suture (Fig. 146.2), may be required for a large-caliber vessel

*Ferric subsulfate (Monsel's solution) can result in a tattoo.

Table 146.7 Methods of hemostasis.

since epinephrine (adrenaline) requires up to 15 minutes to produce maximal vasoconstriction and thereby minimize bleeding[11], lidocaine without epinephrine is sufficient for an immediate biopsy. Regardless of other considerations, it is critical to have the local anesthesia in the compartment that is to be biopsied, i.e. a superficial wheal may be entirely adequate as anesthesia for a shave biopsy but will not suffice for an incisional wedge biopsy that extends into the subcutaneous fat.

Hemostasis

All biopsy procedures require attention to hemostasis of the wound bed (Table 146.7; see Table 151.5). While styptics and absorbable hemostatic sponges are used for those wounds healing by second intention, suturing provides sufficient hemostasis for punch biopsy sites. Wounds created during an incisional biopsy or excision *in toto* may require electrocoagulation for hemostasis before closure (see Ch. 140). The endpoint is no active bleeding in the wound bed. Bleeding within the dermis in the sides of the wound can be controlled by suturing and does not need cautery. At times, to produce hemostasis, a large actively bleeding vessel may need to be identified, grasped with a hemostat, and tied off with an absorbable suture and a figure-of-eight suture (Fig. 146.2).

Wound Closure

Closure of wounds created by a biopsy procedure may occur by either second or primary intention healing. Second intention healing repairs wounds by the processes of granulation tissue formation, epidermal cell migration, and contraction (see Ch. 141). These processes occur simultaneously, beginning within the first few days after surgery and continuing until the wound has completely re-epithelialized. For the remainder of the patient's life, maturation of the scar occurs, with gradual improvement in color, texture, and contour. Indications, disadvantages, and contraindications for second intention healing are outlined in Table 146.8.

Closure of the wound via suturing is regarded as primary intention healing. The same processes of granulation tissue formation, epithelial migration, and contraction occur; however, they are significantly reduced, because the sides of the wound are already apposed. Processes related to fibroblast activity and collagen deposition play a more important role in primary intention healing, allowing adequate tensile strength to develop to keep the wound closed[12]. These scars also undergo maturation throughout the remainder of the patient's life. Both second and primary intention healing are promoted by appropriate wound care and dressings.

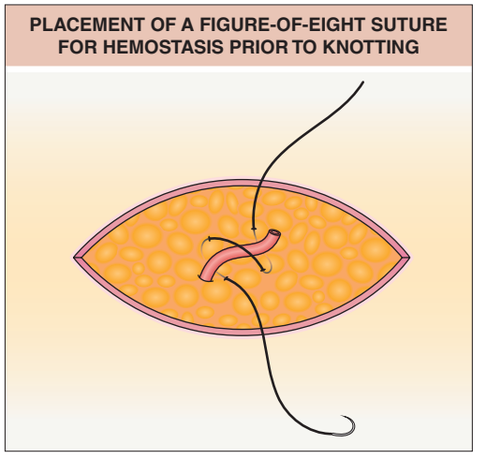

Fig. 146.2 Placement of a figure-of-eight suture for hemostasis prior to knotting.

For primary intention healing, wounds may be closed either by placement of a simple full-thickness suture or by layered closure. In a layered closure, subepidermal buried sutures appose subcutaneous and dermal tissue, provide alignment of the wound edges, set up the wound edges for eversion, and assist with hemostasis by occluding any vessels bleeding within the edge of the wound. In addition, the subepidermal sutures supply strength to handle tension within the closure. Although subepidermal sutures are generally absorbable, they remain intact within the tissue for 8 to 12 weeks, the period during which the scar is slowly acquiring tensile strength. As a result, they prevent dehiscence and spread of the scar. Epidermal or skin sutures appose the epidermal edges and complete eversion. They can also correct minor degrees of misalignment in the closure. Satisfying these objectives via conscious placement of sutures improves the function and appearance of the scar[13,14].

Knotting is the means for stabilizing the placement of the suture, usually produced with an instrument tie (Fig. 146.3). The first throw of the knot is started by pulling the long end of the suture tight with the fingers of the non-dominant hand and looping it around the needle holder once or twice. The needle holder then grasps the short end and pulls it through the loops. The loops are pulled across the wound so that they lie flat. These steps are then repeated to produce the second throw of the knot, but this time with the loop in the opposite direction around the needle holder. When this second loop is pulled across the wound, a square knot is created. Depending on the memory and thickness of

SECOND INTENTION HEALING – INDICATIONS, DISADVANTAGES AND CONTRAINDICATIONS
Indications
• Shallow wounds • In combination with a primary closure in which the deepest portion is closed primarily • Concave sites, e.g. medial canthus, conchal bowl, alar crease, temple • Mucosal sites, e.g. conjunctivae, lip, genitalia • Infected, necrotic, or easily infected sites • Sites under significant tension because of physical exercise or size of the wound • Preferred by patient – simple, no sutures, normal activities
Disadvantages
• Sometimes prolonged healing time, especially on distal lower extremities • Scarring which may be depressed and angulated or circular, especially if not in concave site
Contraindications
• Relative: wound into muscle or fascia • Relative: wound at a free margin – contraction can lead to distortion, e.g. ectropion, elevated alar rim (see Fig. 148.9) • Absolute: inability to stop bleeding without a suture

Table 146.8 Second intention healing – indications, disadvantages and contraindications.

the suture material (see Ch. 144), three to six throws may be required to properly secure the knot. Care is taken to ensure that the knot lies flat without significant tension or tightness[15]. Sometimes, a loose loop is left in the second throw, to allow the suture to adjust to any wound swelling that may develop.

Sutures commonly used for subepidermal placement are composed of synthetic absorbable materials such as braided polyglactin (Vicryl®) or monofilament polydioxanone (PDS®). The *interrupted buried dermal suture* (Fig. 146.4A) is designed such that the suture is in the dermis and fat and the knot is inverted (buried). The needle enters the undermined deep surface of the wound (not the sidewall) and passes up into the dermis. After crossing the wound, it enters the opposite side of the wound at the same level in the dermis and then exits the deep surface. The knot is then tied and the ends of the suture cut. When the suture material is released, the knot settles within the deep portion of the wound, minimizing tissue reaction to the suture and extrusion through the wound. Enough buried dermal sutures are placed such that tension is eliminated and the deep tissues are completely apposed. In order to facilitate eversion, this basic suture may be modified, creating a *buried vertical mattress suture*[16]. The suture is nearest to the skin surface (within the superficial dermis) at a point 3–4 mm lateral to the wound edge, and then it exits the wound deeper in the dermis (Fig. 146.4B). A very subtle dimple may be appreciated above the suture where it lies superficially in the dermis.

On occasion, a *running dermal suture* is used to close the deep component. This suture is begun similarly to the interrupted buried dermal suture, but, after tying, only the short end of the suture is cut. The needle then draws the suture through the subcutaneous fat and dermis on one side, passing to the other side, and then continuing along the length of the wound. At each step, the suture is pulled tightly to appose the edges. At the end of the wound, the knot is achieved by tying the loose end to the last loop. This suture is only used when there is little tension in the wound, as rupture of the suture material anywhere along the suture line would release the suture for the entire length of the wound, allowing dehiscence or spread of the scar.

Monofilament nylon (Ethilon®) or polypropylene (Prolene®) are commonly used epidermal sutures. The *simple interrupted epidermal suture* is placed by passing the needle through the epidermis into the superficial dermis in a plane just superior to the buried suture, across the wound, into the dermis on the opposite side and then up through the epidermis (Fig. 146.4C). Eversion is assisted by placing the suture closer to the wound edge but relatively deeper in the wound so that the epidermal surface does not roll. Using the curve of the needle to create the path for the suture also facilitates eversion. If there are no buried sutures, the suture apposes the edges for the full depth of the wound (e.g. for closure of punch biopsies).

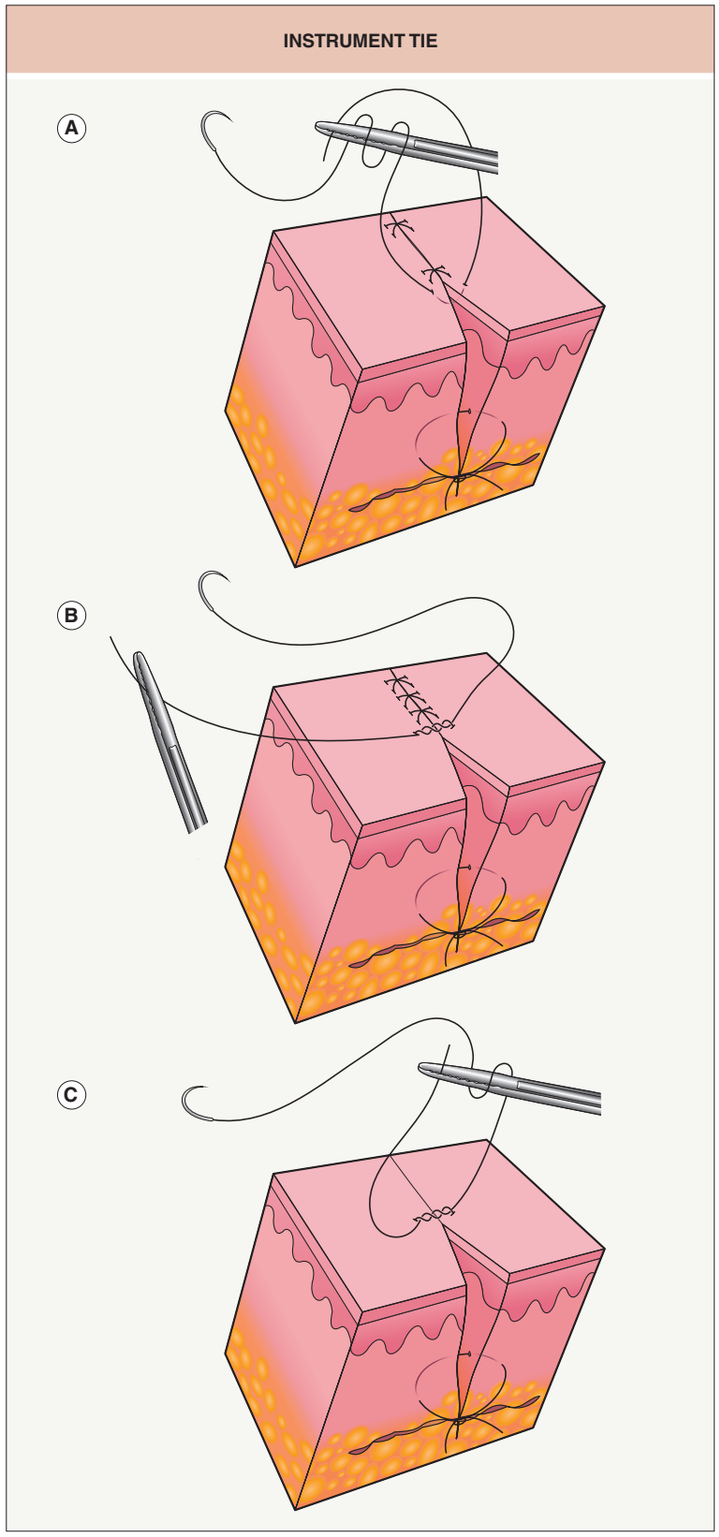

Fig. 146.3 Instrument tie. A The suture is looped around the needle holder, then the needle holder grasps the short end and pulls it through the loops to create a knot. **B** The suture is drawn over the wound so that the knot lies flat across the wound. **C** A loop is made around the needle holder in the opposite direction. The needle holder then grabs the short end and pulls it through so that the knot lies flat on the skin surface.

The *vertical mattress suture* (Fig. 146.4D) is sometimes used for wounds in thicker skin where eversion may be difficult and when a single suture apposing the deep and superficial edges is desired. This suture has four points of entry into the skin. It is started by passing the needle through the epidermis 5–8 mm lateral to the wound edge, exiting from the deep portion of the wound. It re-enters the opposite side of the wound in the same deep position, and exits from the epidermis equidistant

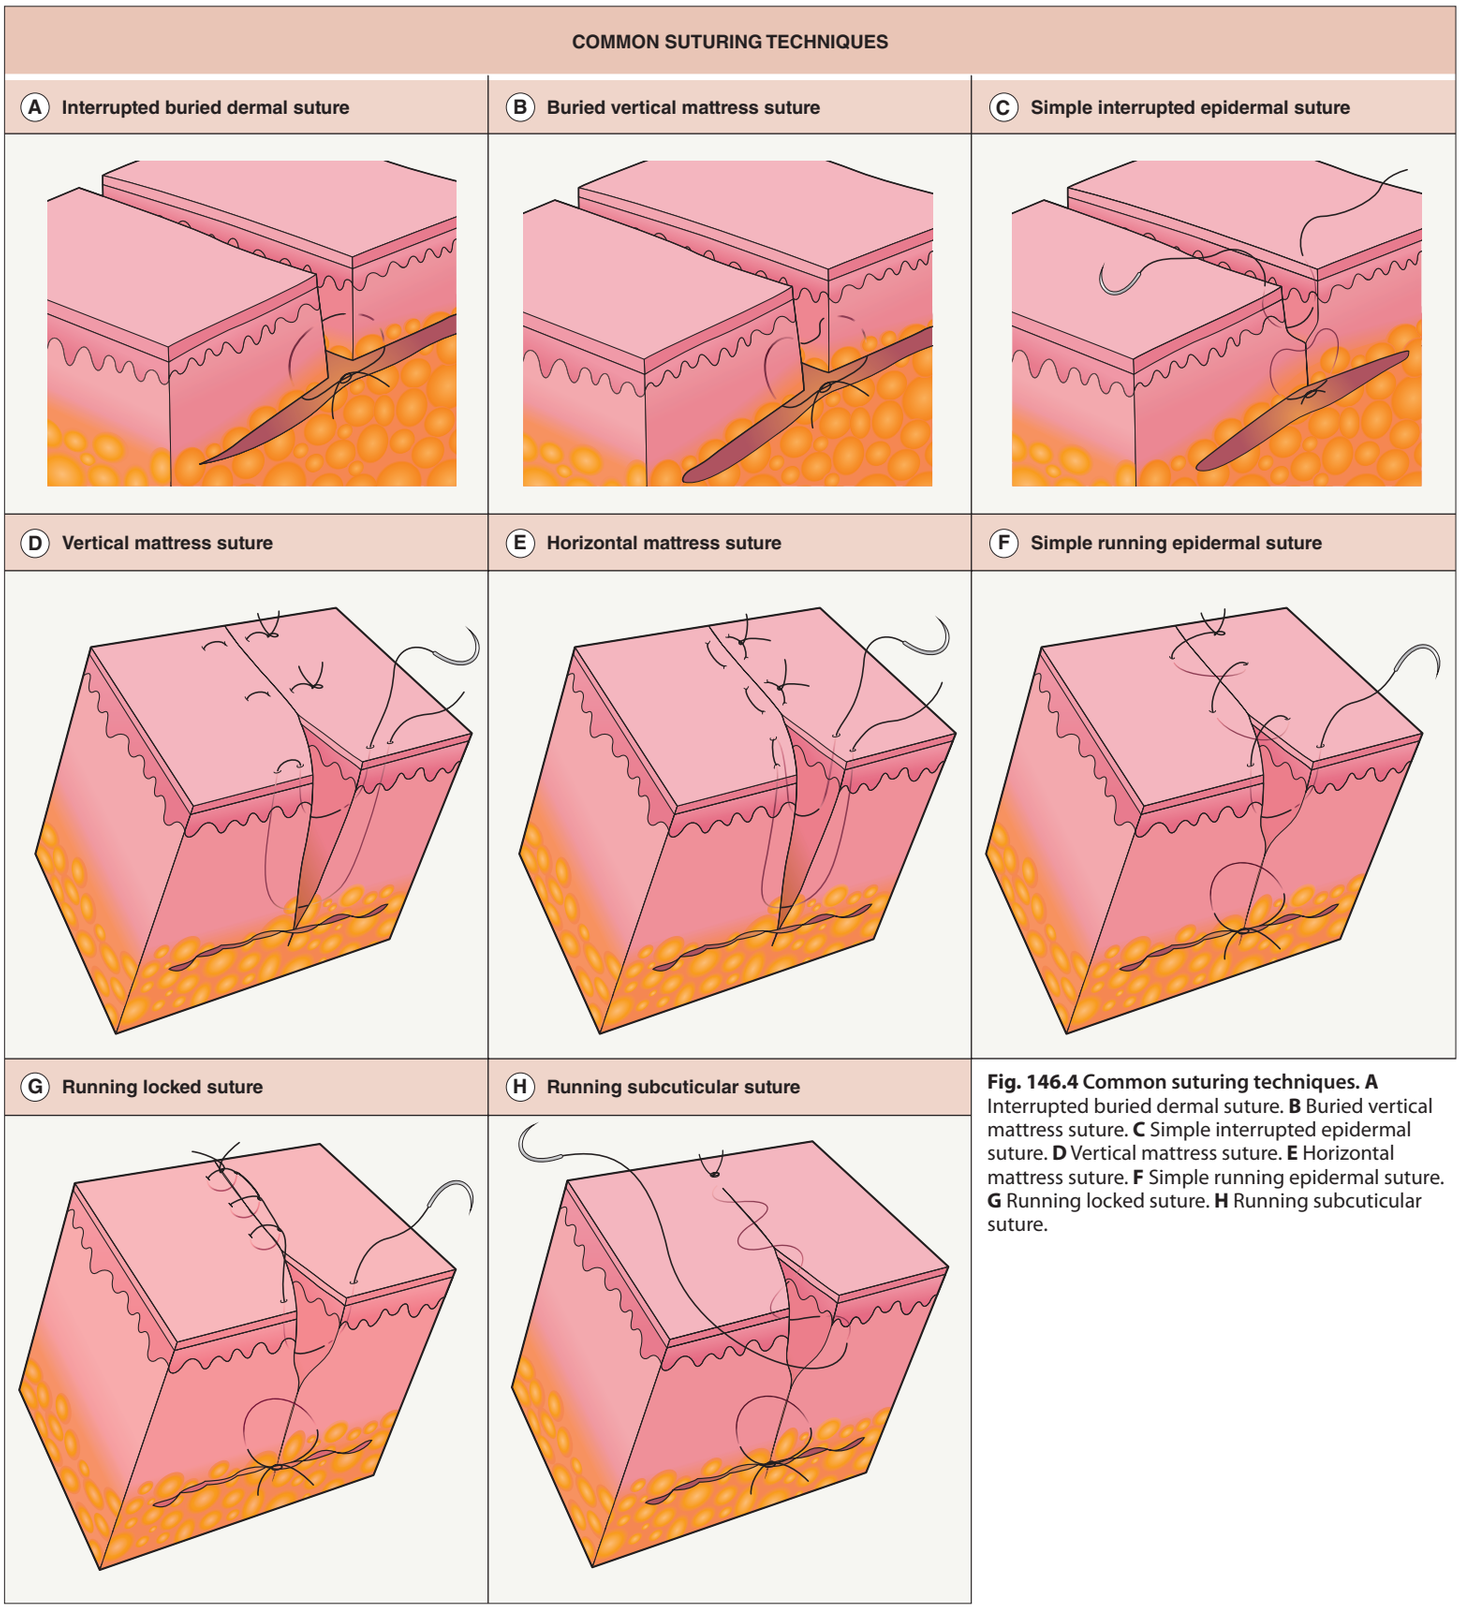

Fig. 146.4 Common suturing techniques. A Interrupted buried dermal suture. **B** Buried vertical mattress suture. **C** Simple interrupted epidermal suture. **D** Vertical mattress suture. **E** Horizontal mattress suture. **F** Simple running epidermal suture. **G** Running locked suture. **H** Running subcuticular suture.

from the wound edge as the entry point. The needle is reversed and the epidermis is re-entered *closer* to the wound edge; it is then drawn through the upper dermis before crossing the wound, entering the dermis and finally exiting close to the wound edge. Once tied, the knot is positioned on one side of the wound, not over the line of closure.

A *horizontal mattress suture* can be used in thinner skin such as the neck or the dorsum of the hand, and it also has four points of entry into the skin. The first two points of entry are the same as in the vertical mattress suture (Fig. 146.4E), but closer to the wound edge (i.e. 3–5 mm). However, after the needle is reversed, the third point of entry into the epidermis is 3–4 mm from the exit point, on the same side of the wound edge and equidistant from the wound edge. The suture is then drawn through the upper dermis, crosses the wound, enters the opposite sidewall in the same dermal position and finally exits at the same distance from the wound edge, 3–4 mm from the first entry point. This knot, when tied, is also positioned on one side of the wound, not over the line of closure (Video 146.1).

Since sutures of both the vertical mattress and horizontal mattress sutures must be removed within 1–2 weeks (depending upon the site), they are not good sutures to use as the sole means of closure in a wound

with tension. Of note, a variant, the running combined simple and vertical mattress suture, also everts well and saves surgical time[17].

In the presence of buried sutures that have produced even alignment of the epidermal edges, a *simple running epidermal suture* can be used to complete the closure (Video 146.2). This running suture may be passed via the dermis and the epidermis in a fashion similar to the simple interrupted epidermal suture (Fig. 146.4F). In addition, the needle may be passed under the superficial loop of the previous suture, thus creating the *running locked suture* (Fig. 146.4G). This suture can assist with hemostasis and will not completely unravel if the suture breaks under wound tension. Irrespective of the epidermal suture that is chosen, track marks can appear due to tension, inadequate undermining, and ineffective buried dermal sutures, as well as poor placement of the epidermal sutures.

Alternatively, the suture may be placed entirely within the upper dermis, referred to as a *running subcuticular suture* (Fig. 146.4H, Video 146.3). This suture is placed with the needle and non-absorbable suture passing in and out of the upper dermis in a plane horizontal to the surface. Two knots are tied, one on each end of the wound, and they are the only visible portions of the suture. A fully buried running subcuticular suture with absorbable suture can also be placed. Running sutures are frequently used to save time, but they can accentuate minor misalignments of the wound edges[18].

Non-absorbable sutures that pass through to the surface of the skin should be removed as they can cause tissue inflammation and create a less than optimal functional and cosmetic result. To remove a suture, the thread is severed near the knot with either fine-tipped scissors or a #11 blade. The knot is then pulled over the line of closure so that the wound edges are not pulled apart. Sutures on the face are generally removed after 5–7 days, and sutures elsewhere at 10–14 days. If buried dermal sutures are used, the epidermal sutures may be removed at the earlier times. Sometimes, absorbable suture material is used for superficial closures, especially in the simple running epidermal suture, precluding the need for suture removal. Sterile adhesive tapes such as Steri-Strips™ or tissue glue (Dermabond®) are also occasionally used instead of epidermal sutures to avoid the need for suture removal, but they are ineffective in producing eversion and in dealing with tension. When compared to traditional epidermal sutures, adhesive tapes in one study produced an equivalent result in overall scar cosmesis, *if* subcutaneous closure had been achieved with no tension and there was perfect alignment of the surface[19]. Of note, in another study, no differences in cosmetic outcome were observed when adhesive tapes plus dermal sutures were compared to dermal sutures alone[20]. The use of adhesive tapes after suture removal may, however, reduce the amount of scar spreading when they are left in position for several weeks[21]. Table 146.9 outlines alternatives to sutures for wound closure[22–25].

WOUND CLOSURE – ALTERNATIVES TO SUTURING	
Adhesive tapes (Steri-Strips™)	• For perfectly apposed lacerations or wound edges under little tension • Often used with a liquid adhesive, e.g. Mastisol® • May be used for epidermal closure after subcutaneous closure completed by suturing
MicroMend® wound closures	• Metal clips are incorporated into adhesive bandage • For wounds that are fairly well apposed and under only modest tension • Available OTC for lacerations
Staples*	• Highest tensile strength • Good for wounds under tension
Tissue glues (e.g. 2-octyl cyanoacrylate [Dermabond®], fibrinogen [Tisseel™], hydrogel [Duraseal™])	• Can be considered for epidermal closure of wounds under little tension • Less effective than dermal suturing for minimizing dehiscence[24] • Side effects include allergic contact dermatitis, sensation of heat when applied
Laser welding (Nd:YAG, CO_2 lasers)	• Experimental and used infrequently in the clinical setting
Photochemical welding (Rose Bengal plus green light)	• Experimental

*Also requires skin stapler and staple remover.

Table 146.9 Wound closure – alternatives to suturing. OTC, over-the-counter.

EXAMPLES OF DISORDERS ASSESSED VIA BIOPSY OF NORMAL SKIN	
Disease	**Comments**
Neurologic • Small fiber neuropathy • Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) • Neuroaxonal dystrophy • Peripheral autonomic neuropathy	• Pathologic metrics for diagnosis of small fiber neuropathy based on 3 mm punch biopsy at the ankle
Intravascular lymphoma	• Incisional biopsy recommended
Systemic amyloidosis	• Punch biopsy of abdominal fat pad (versus needle aspiration of subcutaneous fat)

Table 146.10 Examples of disorders assessed via biopsy of normal skin. Tissue can also be used (as comparison) to confirm mosaicism and to assist in diagnosing inherited disorders (e.g. muscular dystrophies, sarcoglycanopathies).

INDICATIONS/CONTRAINDICATIONS

A biopsy is indicated when the clinical diagnosis of a cutaneous disorder is unclear or must be substantiated before a course of treatment is undertaken. Inflammatory disorders are often biopsied to assist in the differentiation of multiple processes that may have a similar clinical appearance. Infectious processes are biopsied to detect the causative organism in tissue sections and/or to obtain tissue for culture. Lesions suspicious for malignancy are biopsied in order to develop a surgical plan appropriate for the tumor type. Biopsies of normal skin may also be performed to assist in the diagnosis of systemic diseases or to obtain tissue for genetic studies (Table 146.10)[26–28]. Skin biopsies may even be performed prenatally.

Most patients can safely undergo a skin biopsy, so contraindications are not absolute. A skin biopsy may save the patient from a more invasive procedure if the disease process can be determined via histologic examination of the skin. Patients who are immunosuppressed because of medications (e.g. prednisone, chemotherapy, tacrolimus) or underlying diseases (e.g. HIV infection, lymphoma, leukemia) often require biopsies because of the complicated interplay between the underlying disorders and the side effects of therapy (e.g. infections, drug reactions).

In addition, there are no cutaneous or mucosal sites where a biopsy is contraindicated. Diagnostically, it is more useful to biopsy a lesion from the hand or the face that provides accurate information than it is to biopsy a late-stage, nonspecific lesion on the arm. Biopsies can be done on the legs of patients with diabetes mellitus as well as the digits of patients with vascular compromise, although greater attention to postoperative care is often necessary. For patients with coagulation or platelet disorders (due to either underlying diseases or medications), it may be preferable to biopsy a site that can be compressed to produce hemostasis. For example, if an arm or leg were biopsied, postoperative bleeding can be controlled by pressure applied by an elastic circumferential bandage.

In certain anatomic sites, it may be necessary to exercise caution to avoid injuring a vital structure (see Chs. 142 & 151). The temporal nerve lies in a superficial location, just beneath thin dermis and subcutaneous fat, midway between the eyebrow and the temporal hairline. The spinal accessory nerve also courses superficially at the posterior edge of the sternocleidomastoid muscle, approximately one-third of the distance between the mastoid process and the inferior attachments of the muscle. Severing these nerves leads to motor dysfunction; thus, these sites are best biopsied in a superficial manner. The temporal and thyroid arteries are also relatively superficial; cutting them leads to temporary difficulty with hemostasis but without long-term adverse effect.

Some lesions require special consideration before performing a biopsy. A mass that is pulsatile may indicate large arterial vessel involvement, a situation requiring additional clinical evaluation prior to biopsy and special surgical arrangements in case of bleeding. A post-traumatic cephalic mass or cystic midline lesion may need preoperative radiologic examination to identify any possible connection to the intracranial

PREOPERATIVE HISTORY
Allergies
Medications, including nutritional supplements and over-the-counter preparations (see Ch. 133)
Past reactions to local anesthesia
Difficulties with hemostasis during previous procedures
Past problems with wound healing, e.g. infection, keloid formation
Pacemaker or implantable cardioverter-defibrillator (ICD)
Disease or past replacement of the cardiac valves
Past orthopedic surgery with joint replacement
Hypertension
Diabetes mellitus
Immunosuppression
Infection or vascular compromise at the biopsy site
Smoking habits and willingness to discontinue
Possible pregnancy

Table 146.11 Preoperative history.

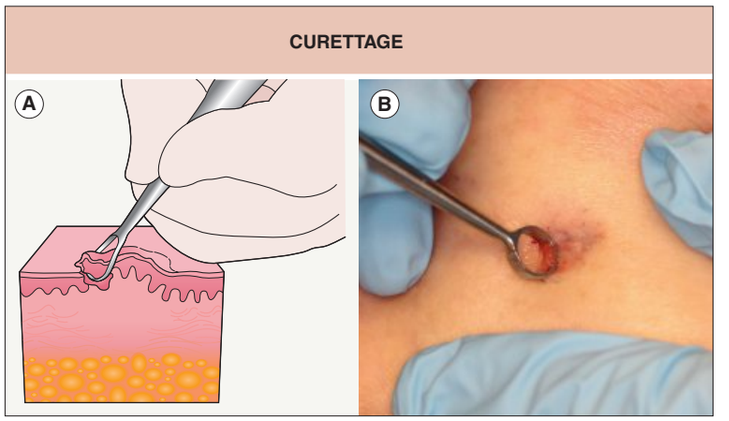

Fig. 146.5 Curettage. A Diagram. **B** Demonstration of technique.

or intraspinal space[29]. Excision of a benign lesion, e.g. epidermoid inclusion cyst, on the upper trunk or shoulders of a patient who tends to form keloids must be carefully discussed, weighing the possibility of keloid formation against how bothersome the lesion is. Hypertrophic scars, on the other hand, are common and resolve with time and/or pressure as well as corticosteroid injections, and need not interfere with the performance of a biopsy.

PREOPERATIVE HISTORY AND CONSIDERATIONS

While there are no absolute contraindications to performing a biopsy, a clinician will want to be aware of certain features of a patient's medical and surgical history in order to formulate an adequate surgical plan and to predict the need to manage possible complications. Table 146.11 summarizes information pertinent to the issues previously discussed. In particular, patients who are taking medications or have underlying disorders that lead to abnormalities in coagulation or platelet function should be identified in advance. Almost all procedures can be done despite a patient receiving warfarin, heparin, clopidogrel, apixaban, rivaroxaban[30], or aspirin if the site of the biopsy is planned carefully and the options for hemostasis are readily available. The bleeding time may also be affected by alcohol ingestion, oral vitamin E, and nonsteroidal anti-inflammatory drugs, in addition to a number of alternative therapies, including garlic, gingko, ginger, ginseng, feverfew, fish oil, and green tea[31] (Table 133.3). While biopsies may be done safely during pregnancy[32], the emotional turmoil surrounding a coincidental miscarriage or pregnancy mishap is great enough to defer elective procedures (e.g. shave biopsy of an unwanted intradermal nevus) to the postpartum period, whereas biopsies of atypical pigmented lesions in which the differential diagnosis includes melanoma are not deferred. Biopsies and excisions can also be done safely under local anesthesia in children as long as they can cooperate.

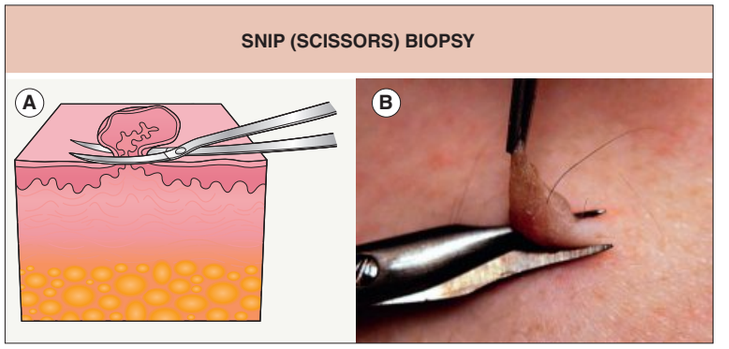

Fig. 146.6 Snip (scissors) biopsy. A Diagram. **B** Demonstration of technique.

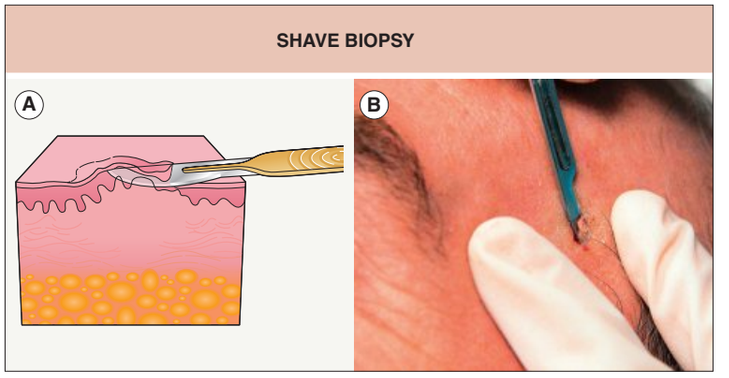

Fig. 146.7 Shave biopsy. A Diagram. **B** Demonstration of technique.

TECHNIQUES

Curettage

Local anesthesia is achieved by wheal formation (see Fig. 146.1). Depending upon the size and thickness of the lesion, a curette 3–5 mm in diameter is held like a pencil and drawn with pressure across the lesion (if epidermal) or through the lesion (e.g. presumed BCC). With one smooth movement and moderate pressure (as well as opposing traction by the non-dominant hand), an epidermal sheet or ball of tissue may be obtained (Fig. 146.5). In the case of incomplete removal, further fragments may be obtained by repeated curettage. This type of biopsy assumes that healing will be by second intention. Hemostasis may be obtained by a styptic, electrodesiccation, absorbable hemostatic sponge, or pressure. The resulting scar is usually minimal in the case of epidermal lesions or of no significant concern in the case of a BCC, since later definitive treatment will produce the final scar.

Snip or Scissors Biopsy

Pedunculated lesions can be biopsied via a snip or scissors biopsy (Fig. 146.6). Local anesthesia is obtained by wheal formation in the upper dermis just under the narrow attachment of the lesion to the skin surface. For tumors with a very narrow neck, this type of biopsy can be done quickly without anesthesia. Scissors, usually fine iris scissors or sharp Gradle scissors, are used to separate the lesion from its base at the level of the skin surface. A toothed forceps is often used to handle the tissue. Healing is by second intention, and a styptic, electrodesiccation, absorbable hemostatic sponge, or pressure may be required for hemostasis. Scarring produced by this type of biopsy procedure is a small, subtle, often hypopigmented macule.

Shave Biopsy and Saucerization Biopsy

Shave biopsy is the most commonly used technique for obtaining a skin specimen for histologic examination (Fig. 146.7). A local anesthetic is used to produce a wheal under the lesion so that it is elevated above the plane of the surrounding skin. A #15 blade on a blade handle is used (almost parallel to the skin surface) to cut the specimen from its bed. Alternatively, only the blade without the blade handle is used. Cutaneous surgeons generally hold the blade or the blade handle like a pencil, to facilitate control of small movements. It is helpful to begin

on one edge by holding the blade vertically and incising only through the epidermis. The blade is then turned to a horizontal position and a smooth sawing motion is used to complete the removal of the specimen. A good specimen may also be obtained by a single-edged razor blade held in a semi-curved shape[33].

The goal is a shallow, saucer-shaped defect and a single piece of unfragmented tissue; edges should be smooth. Forceps may be used to hold the specimen while *in situ* in order to supply traction against the movement of the blade and then to remove the entire specimen and place it in the appropriate container. However, the tissue must be handled gently so that crush artifact does not confuse the microscopic appearance. Toothed, as opposed to smooth or ridged, forceps minimize crushing of the tissue. The specimen should include full-thickness epidermis and superficial dermis. The most common error when first performing shave biopsies is to remove only keratotic debris or the upper portion of the epidermis. The latter is especially true in areas with thick stratum corneum (e.g. palms, soles). Therefore, the dermatologist needs to appreciate the angulation of the blade that is required in order to obtain the full thickness of the epidermis plus some of the superficial dermis. Observation of the wound bed and review of the tissue sections will help refine the skills needed to perform this procedure.

In a saucerization procedure, the depth of the biopsy specimen is intentionally deeper due to the angulation of the blade, which may or may not be attached to a handle (Fig. 146.8). Fat may even be included in the base of the specimen in sites with a thin dermis, but in general the biopsy extends to at least the mid reticular dermis. Both saucerization and shave biopsy sites heal by second intention. As with curettage and snip biopsy, hemostasis is easily obtained with a styptic, electrodesiccation, absorbable hemostatic sponge, and/or pressure. With practice and skill, as well as choosing the appropriate lesion to biopsy in this manner, the resulting mature scar is flat or slightly depressed with slight hypopigmentation.

Punch Biopsy

A punch biopsy is routinely used to sample processes within the mid to deep dermis or depressed lesions. As discussed above, the volume of tissue obtained varies depending upon the diameter of the metal "barrel". For example, the specimen obtained with a 2 mm punch biopsy is very small and may not yield sufficient pathologic findings for an accurate diagnosis. In one study, however, where 2 mm punch biopsy specimens (examined by a dermatopathologist) were compared to excisional specimens, an accurate diagnosis (primarily AKs, BCCs, SCCs, inflammatory dermatoses) was made in 79 of 84 cases[34]. For most punch biopsies, an instrument with a 3 to 4 mm diameter is adequate. Occasionally, a 6 or 8 mm punch biopsy is performed to increase the likelihood of obtaining subcutaneous fat. However, as stated previously, the thickness of the dermis and the amount of subcutaneous fat required to establish the diagnosis must be kept in mind.

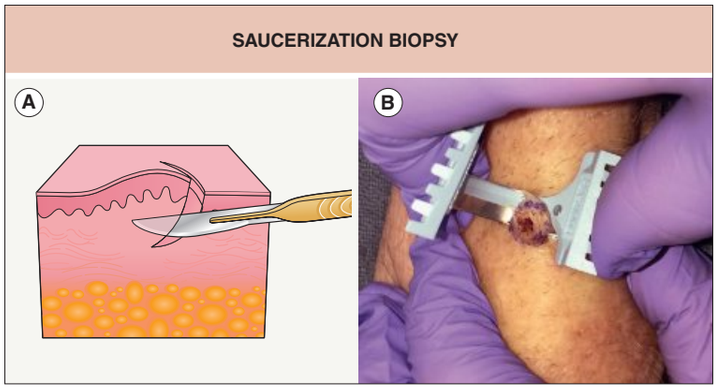

Fig. 146.8 Saucerization biopsy. A Diagram. **B** Demonstration of technique.

Disposable punch biopsy instruments are generally used. Reusable stainless steel instruments are available but must be sterilized following each procedure and sharpened frequently. Toothed forceps, scissors, needle holder, and suture material are also required. Local anesthesia is achieved with either superficial or deep infiltration of the agent.

An optimal aesthetic result is obtained when the round punch biopsy instrument is used to produce an oval-shaped defect that can be closed without "dog-ear" formation when sutured into a straight line parallel to the other skin lines in the region. This is accomplished with traction produced by stretching or spreading the skin with the index finger and thumb of one hand in a direction perpendicular to the desired wound closure line; the punch is then pushed into the skin and rotated in one direction with the other hand (Fig. 146.9). Back-and-forth twisting is not recommended as epidermis may be sheared off. Generally, the instrument is pushed and rotated until the subcutaneous plane is reached, as indicated by loss of the resistance encountered while cutting through the dermis. At times, the punch biopsy is utilized to just incise the skin superficially as when the skin is very thin (e.g. on the ear). The punch biopsy instrument is then removed and forceps are used (peripherally at one superficial edge) to gently extricate the specimen from the wound. Scissors may be needed to detach the base of the specimen, which can then be transferred to the appropriate prelabeled container. In the case of fibrotic tumors or disorders, pressure may need to be applied to the surrounding skin to elevate the biopsy specimen.

Although a punch biopsy wound can be left to heal by second intention after achieving hemostasis, the resulting scar may be depressed and takes several weeks to heal. Usually this wound is closed primarily, and the resulting scar is generally white or hypopigmented and has a linear or cruciate configuration. On the trunk or extremities, one or two simple interrupted epidermal sutures of 4–0 nylon or polypropylene monofilament suture achieve closure and hemostasis. On the face, neck, or hands, the resulting scar may be less apparent if 5–0 or 6–0 simple interrupted sutures are utilized. Some physicians use fast-absorbing gut for patients who are unable to return for suture removal. However, it is also reasonable to have the patient return for a face-to-face discussion of the biopsy results, since the biopsy is being done to establish a diagnosis and determine a treatment plan. Sutures on the face are removed at 5–7 days, and on the trunk or extremities, at 10–14 days. A pathology report is usually available within 7 days.

Table 146.12 highlights special considerations when performing a punch biopsy on the face.

Incisional Biopsy

Large lesions in which the characteristic pathology is within the dermis or subcutis are often biopsied via an incisional or wedge biopsy

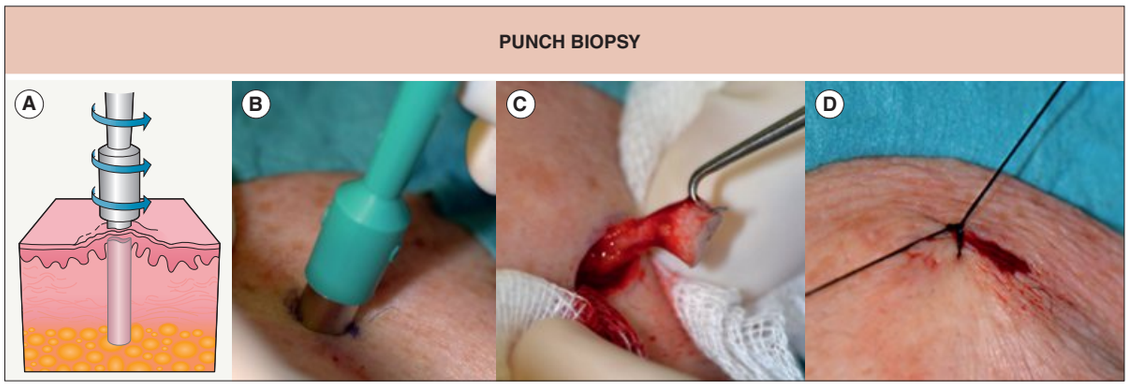

Fig. 146.9 Punch biopsy. A Diagram. **B** Punch biopsy instrument rotated into the skin. **C** The biopsy specimen is gently removed with a skin hook placed peripherally and superficially in order to avoid crush artifact. **D** Closure of the biopsy wound with a simple epidermal suture. *Photographs courtesy Luis Requena, MD.*

SPECIAL CONSIDERATIONS FOR A PUNCH BIOPSY ON THE FACE
• Position patient in a supine position with draping or gauze to protect the eyes from light or inadvertent damage by suture or instrument • Use a 3 mm punch biopsy instrument (if possible); a 4 mm punch biopsy wound can produce standing cones when closed • Choose a site with low visibility (if possible), e.g. in the shadows of the face, at cosmetic unit boundaries, or off/beyond the center of the face • Protect underlying tissue with an anesthetic wheal • Tailor depth of excision to depth of pathology rather than rotating and pushing the punch biopsy instrument to its hub • Control bleeding with suture(s) – simple interrupted sutures of monofilament 5–0 or 6–0 nylon or polypropylene • Protect with bandage and remove sutures at 5–7 days

Table 146.12 Special considerations for a punch biopsy on the face.

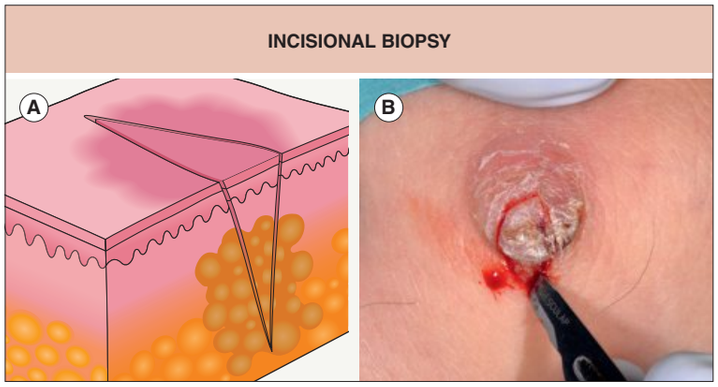

Fig. 146.10 Incisional biopsy. A Diagram. **B** Demonstration of the procedure.

(Fig. 146.10). The specimen may be entirely lesional or may contain an edge of clinically normal skin, which allows comparison of involved versus uninvolved skin as well as examination for any microscopically apparent early changes at the edge of the lesion. The goal is to obtain a wedge of tissue 3–4 mm wide and as deep as necessary. The tissue should be in one piece for accurate orientation of the specimen during preparation; depending upon the possible diagnoses, longitudinal sectioning may be requested. The length of the wedge varies, but should be long enough to avoid cutaneous cone formation in the final closure.

Local anesthesia is obtained by deep and slow infiltration of the agent. It is advisable to wait 10 to 15 minutes after instillation to allow for complete anesthesia and to obtain the maximal vasoconstrictive effect of epinephrine. With a #15 blade (mounted on a blade handle) held perpendicular to the skin surface, a superficial incision into the epidermis scores one long side of the wedge using a light touch and one long motion, facilitated by traction by the non-dominant hand or an assistant. The second long side is then scored similarly. These lines are then redrawn with the blade held in the same manner but with firm pressure, incising into deep tissue, first one side, then the other. The incision is continued until the desired depth has been reached, usually in one or two more cutting movements. The incision is angled toward the center axis so that deep within the tissue, the two incisions meet and complete the separation of the tissue. A forceps is used to lift the tissue out of the wound. If the tissue is still connected at its base, the blade or tissue scissors may be used to complete the detachment.

Hemostasis is best achieved by point electrocoagulation. Large arterioles may require tying off with absorbable suture. An incisional biopsy wound is generally closed with suturing. In some circumstances, such as a site compromised by necrosis or infection, second intention healing may be the best option, even if it is slow and prolonged (see Table 146.8). Deep interrupted sutures of absorbable suture material, 4–0 or 5–0 in caliber, with the knot inverted are utilized to close the subcutis and the dermis (see Fig. 146.4). The epidermis is then closed with simple interrupted sutures of nylon or polypropylene monofilament. The size of the epidermal suture varies depending upon the site; the face is generally closed with 6–0 suture and other sites by 4–0 or 5–0 suture.

EXCISION OF COMMON BENIGN CUTANEOUS LESIONS	
Lesion	**Comments**
Epidermoid inclusion cyst	Dissection facilitated by injection of liberal amount of local anesthesia into surrounding tissue; allows surgeon to work in plane between resulting edema and cyst wall[65] Fusiform excision should include any poral opening or scarring attaching the cyst to the surface Fusiform excision may be smaller than the area deformed by the cyst, but enough of the redundant expanded tissue should be excised so that the scar lies flat
Pilar cyst	See epidermoid inclusion cyst; dissection usually easier
Lipoma	The extent can be appreciated by palpation, then marked with surgical marking pen. A linear incision is made in the middle of the skin covering the lipoma. The tumor is more firm and dense than the surrounding normal subcutaneous fat
Dermatofibroma	Patient needs to be warned that scar may be more noticeable than original lesion, especially on the lower extremities
Melanocytic nevi	See text

Table 146.13 Excision of common benign cutaneous lesions.

Excisional Biopsy (Excision *in toto*)

Excision represents the workhorse of dermatologic surgery[35]. The procedure is designed to remove entire lesions for histopathologic examination as well as for surgical cure. Lesions such as a clinically typical BCC or an unsightly or troublesome subepidermal lesion presumed to be benign are commonly biopsied as well as excised in this fashion (Table 146.13). Atypical pigmented lesions highly suspicious for invasive melanoma are typically excised *in toto* as a biopsy procedure because the degree of atypia and depth of invasion may not be uniform; the excision allows the pathologist to examine the entire lesion and decreases the likelihood of sampling error. In addition, excision is frequently the treatment of choice after the diagnosis of a cutaneous malignancy has been established by a previous biopsy. The excision specimen is again submitted for histologic examination in order to confirm the diagnosis and for comment as to whether the margins of the specimen are clear of tumor. Some surgeons will place a nick or a suture in one edge of the specimen to assist in orientation. Although the basic concepts discussed above with regard to an incisional biopsy also pertain to this procedure, an excision *in toto* is more complicated because it is intended to be the final definitive procedure. Therefore, margins required for cure, as well as cosmetic and functional challenges with respect to the final scar, must be carefully considered in advance.

Recommended margins for removal of an entire lesion depend on the clinical diagnosis. Most benign lesions can be removed completely by including a 1–2 mm margin of normal-appearing skin around the circumference of the tumor. A small, clinically well-demarcated BCC or SCC is generally, though not always, cured with 4–5 mm margins[36,37]. Atypical nevi are frequently excised with 3–4 mm margins. While 4 mm may not be required for complete removal of the lesion, it may save some patients from a second procedure since it is standard practice to re-excise a nevus with severe atypia that is still present at the margins microscopically. The suggested margin for melanoma *in situ* is 5 mm although excision of lentigo maligna may require wider margins. For invasive melanoma, the recommended margin depends on the Breslow depth, e.g. 1 cm margins for tumors ≤1.0 mm in depth (see Ch. 113). The depth of the defect to be created must also be planned in advance[38]. Primary closure is facilitated when the base of the surgical wound lies within subcutaneous fat. In the case of melanomas, the excision should include full-thickness skin and subcutis with fascia often visible at the wound base.

Although an excision is often referred to as an ellipse, the actual shape is fusiform (Fig. 146.11). The optimal geometry of the wound varies depending on the contour of the site and the elasticity and thickness of the skin[39]. The angle at each end of the excision varies from 30 to 75 degrees[40]. In order to minimize standing cone formation, each side of the fusiform shape is three to four times as long as it is

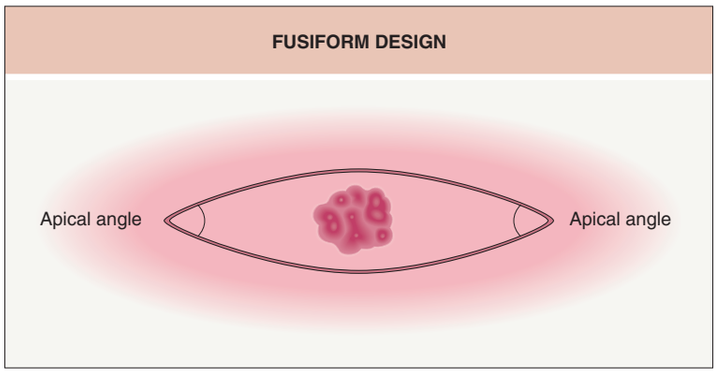

Fig. 146.11 Fusiform design.

wide. The central axis becomes the line of closure and dictates where the surface scar will be visible. A mature scar should appear as a thin line, although some spreading may be seen on the upper trunk and shoulders. From a cosmetic standpoint, an optimal scar results when the line of closure is placed within major skin folds, superficial skin tension lines, wrinkles, or boundaries between distinct cosmetic units (see Ch. 142). Movement of underlying muscles may distort the line of closure, but this can be predicted in advance and the excision plan adjusted. For hair-bearing areas, the line of closure should follow the normal patterns of hair growth.

The process of excision and repair can be divided into a series of steps (Fig. 146.12, Video 146.4). Local anesthesia is best obtained by injection into the subcutaneous tissue. The planned excision, which is delineated with surgical marking dye *prior* to injection, is ringed by the anesthetic agent, with the needle pointed outward to include the area needed for undermining. After ensuring that anesthesia has developed, the site is cleansed and draped with sterile towels or drapes. The excision is begun by stabilizing the site either with the non-dominant hand or by an assistant. As with an incisional biopsy, the epidermis is scored on both sides by drawing lightly with a #15 blade (mounted on a blade handle) along the lines chosen to create the fusiform shape. With continued traction, the incision is completed to the base of the wound by drawing the blade with increased pressure. Unlike with the incisional biopsy, the blade is held vertically throughout the procedure so that the edges of the wound are perpendicular to the skin surface, not angled inward to create a wedge. Completing the incision in one to two strokes after scoring minimizes ragged edges. Care is taken at both apical angles to completely incise to the same depth as that reached at the center of the wound. When the fusiform incision is complete, to either the level of the subcutaneous fat or the fascial plane, the specimen sits up from its base like an island. The specimen is then dissected from the base of the wound using scissors or a blade and the specimen is transferred to the appropriate container. The end result of the excision is a fusiform-shaped wound with vertical sides and a flat even base consisting of subcutaneous fat or fascia. Hemostasis is achieved by electrocoagulation.

The remainder of the procedure deals with the creation of a cosmetically acceptable and functional closure. In order to free tissue for movement into the wound, undermining is performed at the edges of the wound with either scissors or a scalpel. A favorite technique is to use scissors with rounded tips for insertion and then spreading of the tissue to produce blunt dissection in the plane of undermining, a procedure advocated because of the belief that it is less likely to cut arteries or nerves. Using the same scissors, but with a snipping or cutting motion to sharply dissect, is also safe and more effective in generating a smooth, less ragged unit of skin[41]. Sometimes, the two techniques are combined, with spreading followed by snipping of the intervening tethering strands. Undermining can also be done with a blade, sweeping horizontally from the depth of the wound into the surrounding tissues. Regardless of the technique chosen, good exposure and visualization is achieved by maintaining adequate hemostasis as the dissection proceeds, with undermining done in a controlled fashion. Tactile confirmation of the position of the tips of the scissors is also helpful.

In order to fill the defect with skin that matches with regard to thickness, the level of undermining is almost always at the same depth as the base of the wound, i.e. within the subcutaneous fat or at the fascial plane. Rarely, when there are superficially located arteries and nerves to be avoided, the plane of undermining is more superficial than the base of the wound. The use of curved scissors with the tips pointed upwards may facilitate staying in the appropriate plane.

The goals of undermining are to mobilize a unit of skin to be moved into the defect[42] in order to reduce wound closure tension[43], to allow proper wound edge eversion[44], and to provide a wide area for distribution of redundant tissue over the base of the wound (see Fig. 147.1). Undermining around the entire wound to a distance that is at least the diameter of the wound may be required to meet these goals. When little undermining is done, apposed wound edges are pulled inward and redundant tissue bunches up in the wound bed. This redundant tissue has a force and mass that may apply pressure to the healing wound and produce a wide atrophic scar (Fig. 146.13). During closure, wide undermining disperses the redundant tissue over a large area of wound bed. It may also serve to create a plate-like horizontal scar that distributes the forces of contraction and stabilizes the final result (see Fig. 147.2). Undermining must include the apical angles, where it facilitates the rotation that occurs as the two sides of the fusiform shape are brought together. The adequacy of the width of undermining can be tested either by picking up both wound edges with toothed forceps or skin hooks and opposing them or by placing a large temporary suture. The temporary suture may also supply some intraoperative tissue expansion that will facilitate closure. Braided polyester (e.g. Ethibond®) suture is commonly used for this purpose since it is soft and will not cut through tissue. If, with these tests, the wound edges cannot be draped easily for closure, undermining can be extended.

Once undermining is adequate and after again ensuring that the wound is dry, subcutaneous and epidermal sutures are placed to complete the closure. As with the incisional biopsy, deep interrupted sutures of absorbable suture material (4–0 or 5–0 in caliber, with the knot inverted) close the subcutis and the dermis. If the wound is thick or under tension, optimal closure may entail two layers of subcutaneous sutures. The epidermis is then closed with simple interrupted or running sutures with a smaller caliber. For a fusiform excision *in toto*, the end result of the procedure is a straight or curved line of closure that has the wound edges completely apposed and everted. The line of closure sits above the surrounding skin, sometimes described as having the appearance of the ridge line of a tent or a mountain range. The healing of a tensionless everted wound edge results in a flat, hairline scar.

Cutaneous Cone (Dog-Ear) Repair

Closure of a fusiform excision may create cutaneous cones, i.e. tissue redundancies that distort the normal contour of the skin at the apical angles[45]. These cutaneous cones are also referred to as "dog-ears" and may consist of standing cones, lying cones, inverted cones, or protruding cones. Inverted cones can be the most difficult to diagnose, as the appearance is that of a subtle dimple rather than a protrusion. Regardless of their subtle nature, these redundancies will distort the final scar unless they are repaired. Cutaneous cones are also produced by tissue movement during flap closures.

Standing cones primarily result from geometric factors (Fig. 146.14). They may appear in closures of fusiform excisions (with sides of equal length) when the sides are of insufficient length compared to the width of the excision. The resulting apical angles are too wide to rotate in and maintain a flat contour to the skin surface. For this reason, linear closure of a circle, an oval, or an ellipse will always create standing cones. Also, cutaneous cones always form during closure of fusiform shapes that have sides of unequal length; redundant tissue becomes apparent on the longer side. Notably, when an excision is performed on a convex surface, standing cones may occur despite seemingly small apical angles. With suture placement, collagen bundles are pulled together and act as rigid rods that will not lie flat on a curved surface.

In addition to geometric forces, protrusions are produced when there is excessive subcutaneous tissue in the base of the wound at the apices (as compared to the center of the wound). A lack of adequate undermining at the apices will then magnify these protrusions. This process is usually called "boating" or "pseudo dog-ear" formation. It is important to distinguish boating from true standing cone formation because repair

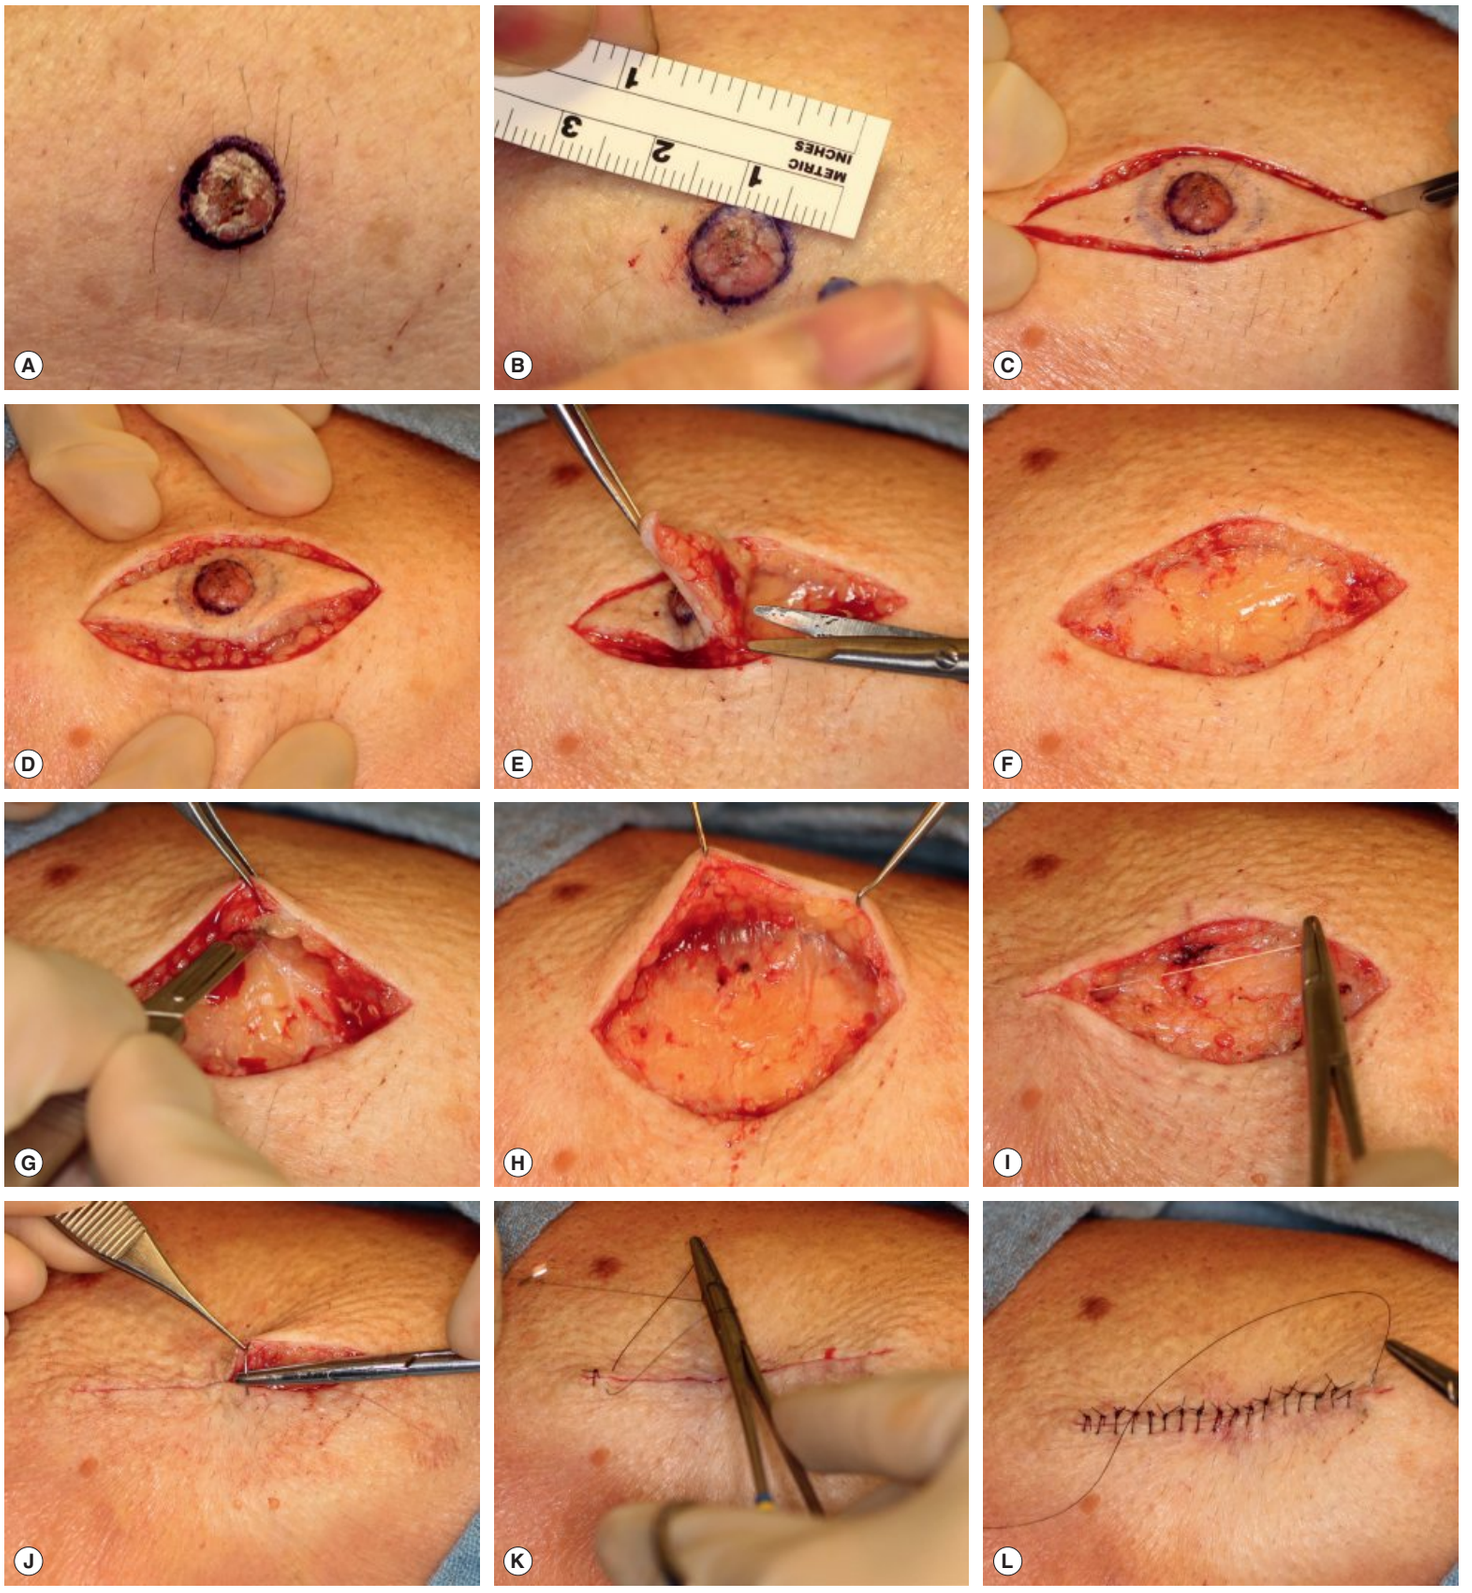

Fig. 146.12 Fusiform excision of a squamous cell carcinoma. A,B After the lesion and appropriate margins are marked, the site is anesthetized, prepped with an antiseptic agent, and draped with sterile towels. **C** Stabilizing the site with traction, the epidermis on one side of the fusiform design is scored using a #15 blade and then the opposite side is scored. **D** The incision is completed into the appropriate plane in the subcutaneous tissue and the specimen then sits up in the middle of the wound like an island. **E,F** The base of the specimen is dissected with scissors or a blade. **G,H** The wound edges are then undermined in the same plane as the base of the wound with blunt-tipped scissors or a blade. Electrodesiccation or electrocoagulation is used to address small actively bleeding vessels to achieve hemostasis. **I,J** The subepidermal space is closed with buried sutures. **K,L** The epidermal edges are apposed by simple interrupted sutures.

of the former requires removal of the excess subcutaneous tissue and appropriate undermining as opposed to the techniques described below.

Many standing cones are small and can be repaired via a closure that employs the rule of halves (Fig. 146.15). The midpoint of each side is apposed with a suture, bisecting the wound. Each unclosed half is then bisected again and the closure is continued until all tissue has been apposed. For a fusiform shape with unequal sides, repair of standing cones in this manner produces a curved line of closure. The curvature is directly proportional to the size of the dog-ear. If the wound is in a site such as the forehead, which lacks loose tissue to free up and mobilize,

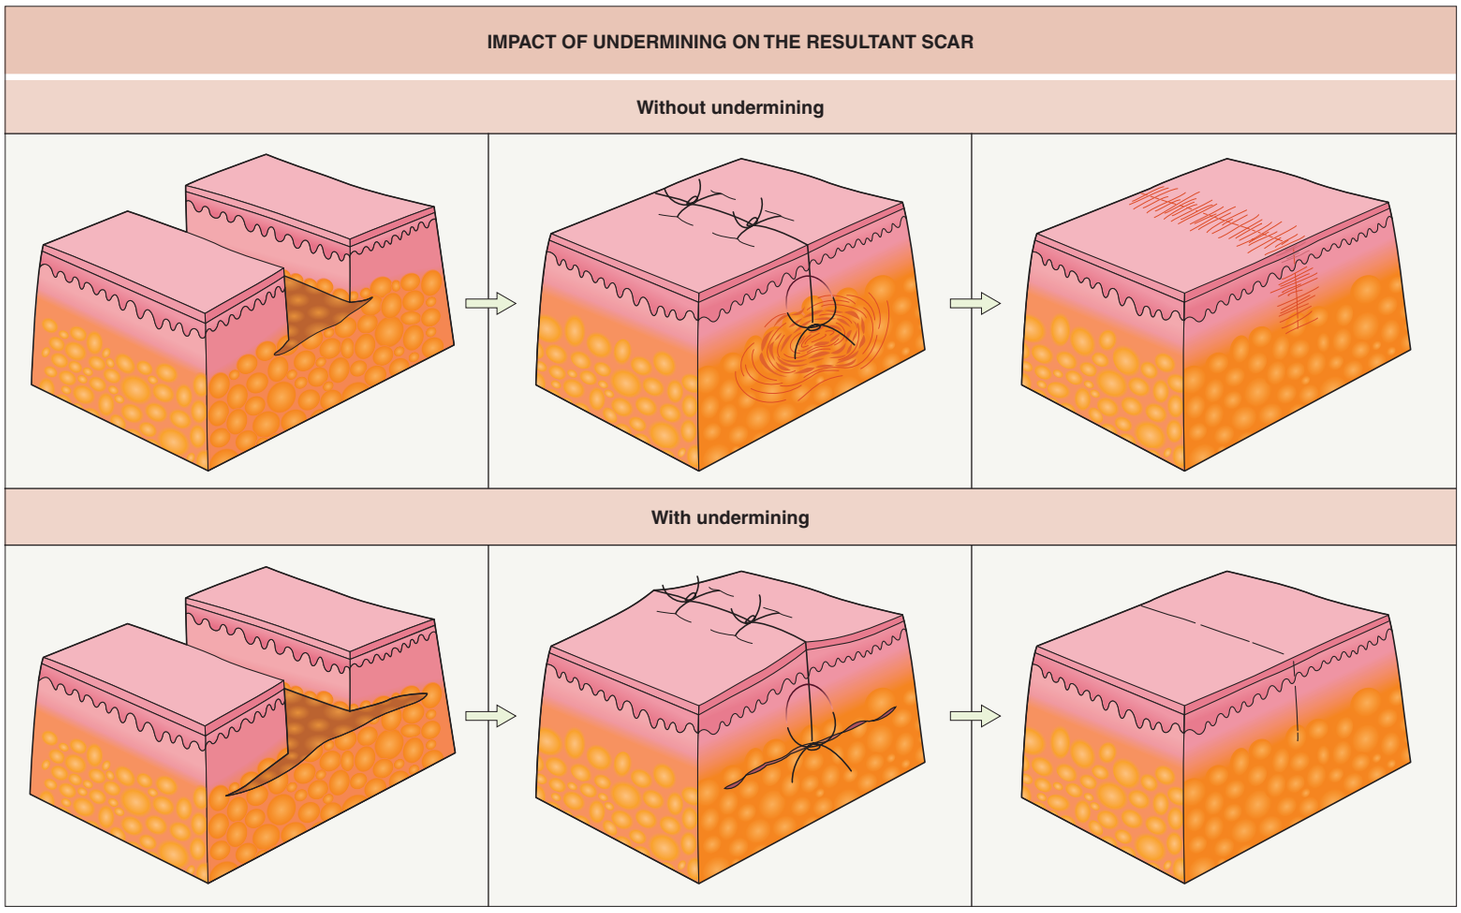

Fig. 146.13 Impact of undermining on the resultant scar. Without undermining, there is tension on the wound and eversion of the wound edges does not occur. Another consequence is spreading of the scar.

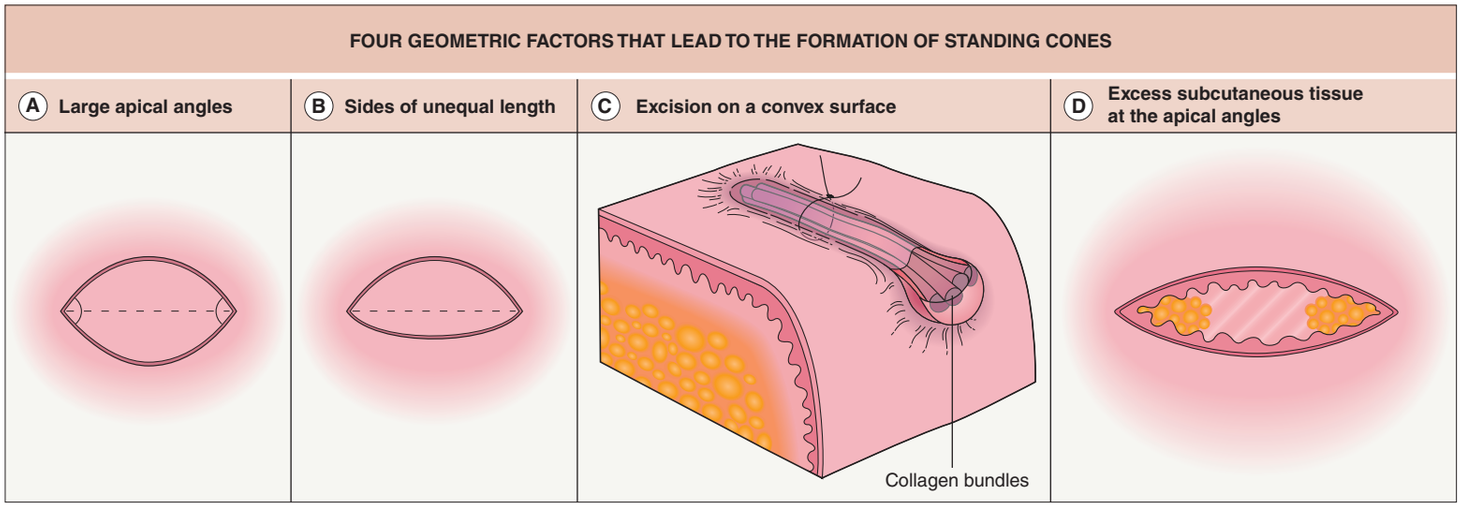

Fig. 146.14 Four geometric factors that lead to the formation of standing cones.

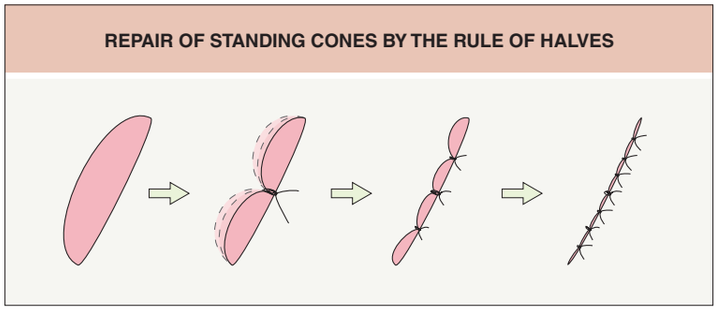

Fig. 146.15 Repair of standing cones by the rule of halves.

the line of closure may remain straight; however, there will be noticeable gathering on one side of the line and a depressed contour on the opposite side of the line where the skin is thinned as it was stretched to fit.

Simple straight, curvilinear, or angled excisions of standing cones will also restore the desired contour of the site, even though they lengthen the scar (Fig. 146.16). The first step is to close the center portion of the wound with subcutaneous sutures. It is helpful to continue to appose subcutaneous tissue from the center of the wound outward until the standing cones become visible. Epidermal sutures may also need to be placed since any gaping at the center of the wound will underestimate the size of the dog-ears. After undermining, one limb of the standing cone is cut through to the base of the wound along the line that is desired for final closure. Undermining is repeated until the

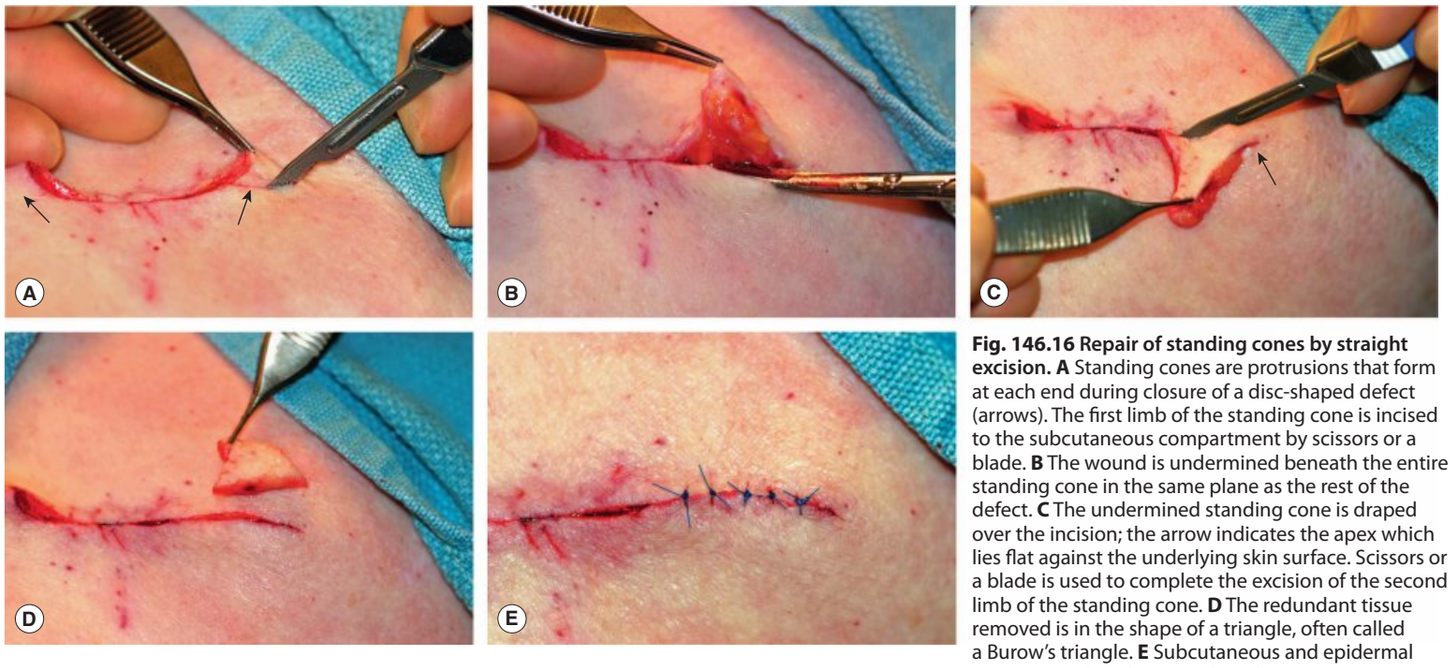

Fig. 146.16 Repair of standing cones by straight excision. A Standing cones are protrusions that form at each end during closure of a disc-shaped defect (arrows). The first limb of the standing cone is incised to the subcutaneous compartment by scissors or a blade. **B** The wound is undermined beneath the entire standing cone in the same plane as the rest of the defect. **C** The undermined standing cone is draped over the incision; the arrow indicates the apex which lies flat against the underlying skin surface. Scissors or a blade is used to complete the excision of the second limb of the standing cone. **D** The redundant tissue removed is in the shape of a triangle, often called a Burow's triangle. **E** Subcutaneous and epidermal sutures are placed to complete the closure.

excess tissue can be draped over the cut edge. The new apical angle will lie flat if the limb has been adequately cut and if undermining has been sufficient. The second limb of the standing cone is then addressed by cutting from the wound to the new apical angle. The excess tissue that is removed will be in the shape of a triangle that is referred to as a Burow's triangle[46]. An alternative method, helpful for novices wanting to create a straight line closure, is bisection of the standing cone, laying each half out along the skin surface and then cutting the two triangles of excess tissue. Closure is then completed with subcutaneous and epidermal sutures.

An *M-plasty* is a dog-ear repair that shortens the total scar length (Fig. 146.17). Depending upon the site, M-plasty scars may also fit within prominent lines and folds more accurately. This procedure is particularly helpful in sites that are not flat. The first step, as above, is to close the center portion of the wound and adequately undermine the apical angle. *Both* lateral limbs are cut at an obtuse angle from the end of the wound to about halfway toward the apex of the redundancy. The excess tissue is then draped over the cut edge and an M is now apparent. Cutting from the central tip to the two new apical angles removes two pieces of tissue that are also triangular in shape. The area of these two triangles is equal to the area of the single triangle that would have been removed if a simple excision of the standing cone had been performed. Once the central tip lies in a good position, then a standard closure is performed. If the tip needs to be advanced to approximate the wound edges and fill the defect, a *half-buried horizontal mattress suture* (also called a *tip stitch* or *three-corner stitch*) is used (see Fig. 146.17E). Care must be taken with the three-corner stitch, as necrosis of the tip can occur with too much tension.

A dog-ear may also be displaced to a distant site. After closure of the central portion of the wound, an incision is made perpendicular to the dog-ear to an appropriate site where there is enough redundant tissue such that it can be removed as a triangle (Fig. 146.18). Undermining is required over a wide area so that tissue can be moved without tension. This procedure is also referred to as a Burow's advancement flap (see Ch. 147). It is commonly used to avoid dog-ear repair in a free margin or in a cosmetically or functionally sensitive area.

Finessing closure of fusiform excisions may require changing the axis of the line of closure so that the scar blends better with the prominent lines and folds of the site. Changing the axis will produce dog-ears that can be repaired by any of these methods.

VARIATIONS/UNUSUAL SITUATIONS

A *disc excision* (with straight or angled edges) may be performed either for biopsy purposes or for biopsy and definitive treatment. This option is chosen when healing by second intention is preferred[47] or when it is desirable to remove the tumor first and then repair the dog-ears during the closure. Second intention healing may be advantageous when the risk of adverse reactions with primary closure is high. For example, excisions of even small tumors on the anterior lower leg that are closed primarily can produce wounds with tension and wounds that are more likely than those at other sites to dehisce, become infected, or be painful. This is especially true if undermining is inadequate and weight-bearing and limb dependency is not minimized for the first 5–7 postoperative days.

Another option for wounds with too much tension on the anterior lower leg is the placement of a skin graft, but postoperative care requires leg elevation and the absolute avoidance of weight-bearing. Alternatively, the wound can be closed, either partially or completely, with a *purse-string suture*[48,49]. The latter is a running suture that is placed around the entire perimeter of the disc. After its placement, tension is applied to the ends of the suture until maximum constriction is obtained and then the ends are knotted. Advantages of the pursestring suture are speed, distribution of tension circumferentially, and amelioration of the need for the removal of excess normal skin in order to complete a fusiform excision. Since the time for complete re-epithelialization of a wound undergoing second intention healing is related to the diameter of the largest circle that can be drawn within the wound, even closure of a wound by 30% can result in a significant reduction in healing time. This smaller wound can also be grafted if desired.

When wounds heal by second intention, postoperative care is less burdensome, as the patient may resume normal activities almost immediately while dressing and bandaging the wound daily. However, compared to a linear excision, re-epithelialization requires a significantly longer period of time; the latter varies directly with the size of the wound and can range from 2 weeks to several months on the distal lower extremities. The patient also needs to consider the resultant scar, i.e. a depressed circular scar versus a graft versus a linear scar.

Removal of melanocytic nevi on the upper trunk and shoulders via disc excision or saucerization (angled edges) results in a smaller, often more cosmetically acceptable scar than does a fusiform excision. Also, the excision of tumors in sites such as the ear may be amenable to disc excision followed by second intention healing.

Performing a disc excision and then repairing the dog-ears during the closure allows the surgeon to pay particular attention to the issue of appropriate curative margins without dealing simultaneously with the cosmetic and functional issues of the closure. Once the tumor has been removed and the area widely undermined, the line of closure can be determined, that is, the closure with the least amount of tension that fits into the dominant lines of the site[50,51]. The central portion of the

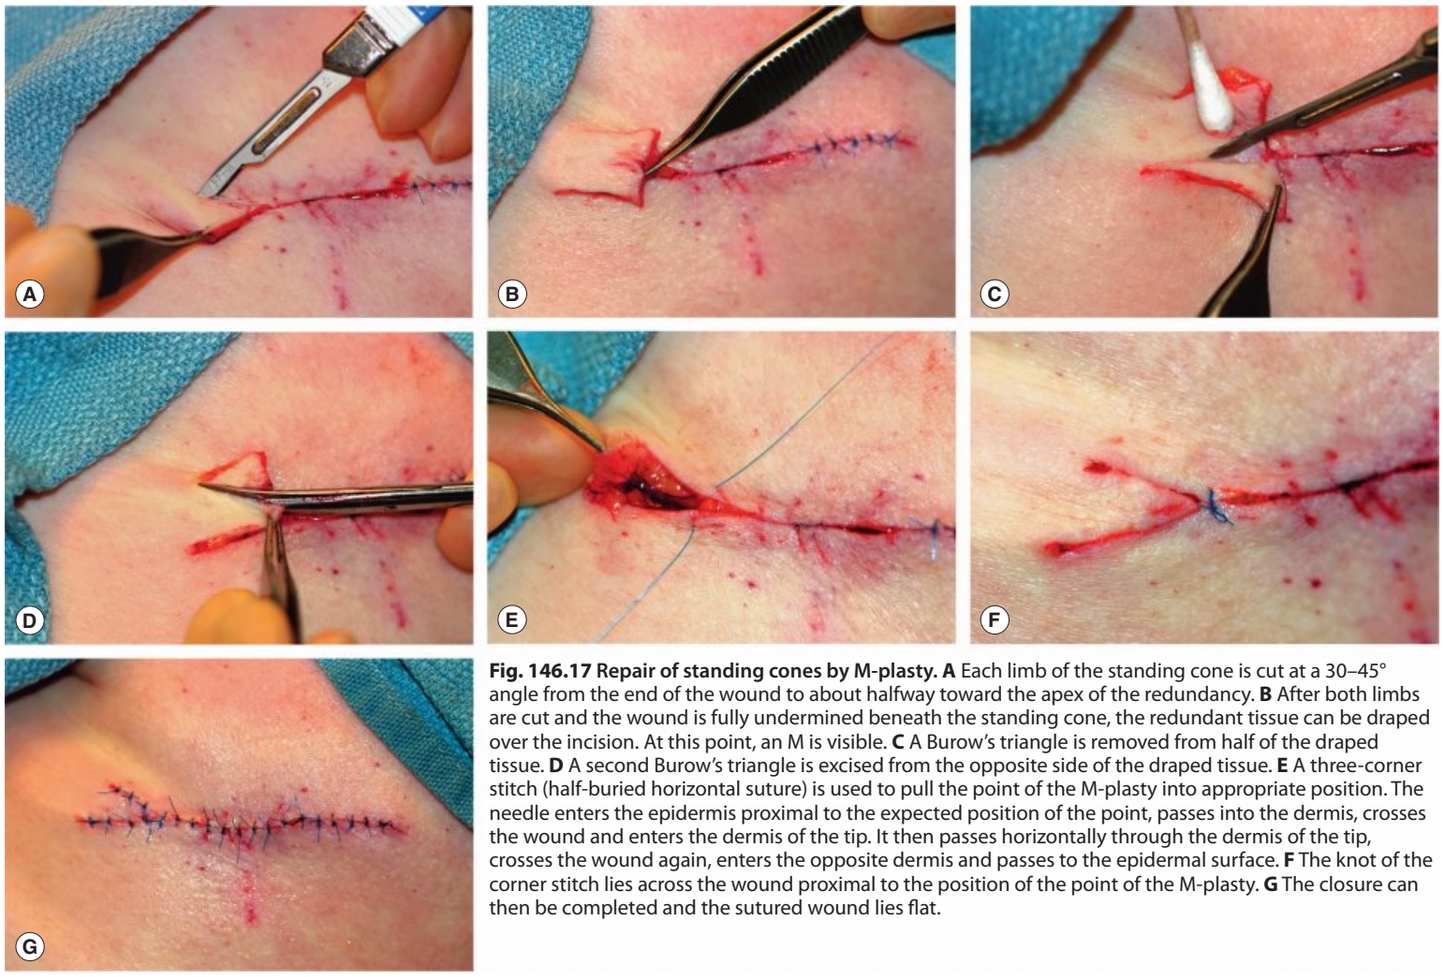

Fig. 146.17 Repair of standing cones by M-plasty. A Each limb of the standing cone is cut at a 30–45° angle from the end of the wound to about halfway toward the apex of the redundancy. **B** After both limbs are cut and the wound is fully undermined beneath the standing cone, the redundant tissue can be draped over the incision. At this point, an M is visible. **C** A Burow's triangle is removed from half of the draped tissue. **D** A second Burow's triangle is excised from the opposite side of the draped tissue. **E** A three-corner stitch (half-buried horizontal suture) is used to pull the point of the M-plasty into appropriate position. The needle enters the epidermis proximal to the expected position of the point, passes into the dermis, crosses the wound and enters the dermis of the tip. It then passes horizontally through the dermis of the tip, crosses the wound again, enters the opposite dermis and passes to the epidermal surface. **F** The knot of the corner stitch lies across the wound proximal to the position of the point of the M-plasty. **G** The closure can then be completed and the sutured wound lies flat.

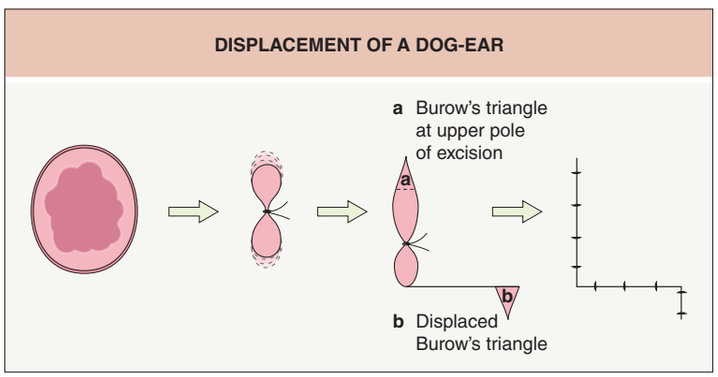

Fig. 146.18 Displacement of a dog-ear.

wound is apposed by subcutaneous and epidermal sutures or by a large simple interrupted temporary suture and then the dog-ears are repaired. Since the cosmetic and functional issues are addressed after excision of the tumor and undermining, the resulting scar can be optimized.

The shape of the excision can also be modified via a procedure known as an *S-plasty*[52]. Most useful on convex surfaces, this variation increases the total length of the scar while keeping the linear distance between the two apices constant. In a simple fusiform excision, the tension is located primarily in the center of the wound and is exerted along a single vector that is perpendicular to the axis of the wound. On the other hand, an S-plasty redirects and redistributes tension into multiple vectors along the wound, thereby minimizing tension in the center of the wound; in addition, the central tension vector is perpendicular to the primary tension vectors at the apices of the wound. Because much of the tension is displaced from the area of maximal convexity, the likelihood of a central depression or dehiscence is reduced.

POSTOPERATIVE CARE

Wound care and bandaging both play an important role in minimizing the risk of complications and in obtaining optimal cosmetic and functional results. Wound care removes surface debris and promotes re-epithelialization. A good bandage supports and stabilizes the wound in the closed position, wicks away excessive blood or tissue fluid, supplies pressure to the wound for hemostasis, and protects the wound from the dryness and bacterial contamination of the external environment.

A small shallow wound that is to heal by second intention is cared for by daily cleansing of the site with mild soap and water, application of petrolatum[53], and coverage with an adhesive bandage such as a Band-Aid® (with a central non-adherent area). There is little to no evidence that topical antibiotic ointments are better than petrolatum. In addition, bacitracin and Neosporin® (bacitracin, polymyxin B +/– neomycin) ointments are associated with a substantial risk of developing contact dermatitis. Topical mupirocin is also not recommended because of the high prevalence of antibiotic resistance[54]. A liquid adhesive bandage was reported to be effective as well as easy to use[55] in a trial focusing on minor cuts and abrasions. A large shallow wound that is to close by second intention may need a bandage fashioned specifically for that site, usually consisting of layers composed of petrolatum, Telfa®, gauze or cotton, and then tape or other means of adhering the bandage at the site.

A layered bandage is also required for a sutured wound. A liquid adhesive (e.g. Mastisol®) is applied to the skin surface surrounding the sutures. Petrolatum is applied in a thin line onto the wound edge. Sterile tapes such as Steri-Strips™ may be placed perpendicular to the line of closure. The final layer is rolled gauze or cotton, which is then taped in place with paper tape, Scanpor® tape, Kind Removal® Silicone Tape, or Hy-Tape® ("pink" tape). Elastic dressing (e.g. Coban®) can be used for compression, but should be released and reapplied if it is used circumferentially, so that vascular compromise distally does not occur.

Patients need oral and written instructions regarding the care the wound will require at home. Most simple wounds are cleansed daily with soap and water and redressed until the sutures are removed or the wound has completely re-epithelialized. Patients should understand that they need to remove any crusting or debris from the wound as they cleanse it and they may prefer to use cotton-tipped swabs or gauze. Instructions regarding bandages should likewise be clear. Leaving the wound open to the air or allowing it to become dry retards re-epithelialization and may compromise the final appearance or the scar[56].

Bandages that minimize the need for wound care are preferred by many patients. In addition, the stability and protection afforded by a bandage that stays in place for a week or more may further optimize the results, especially for wounds closed primarily. These bandages may be constructed in layers as discussed above and should be kept dry to prevent maceration of the covered skin. On the trunk and extremities, a bandage can be made of a polyurethane foam dressing (e.g. Cutinova Hydro®) covered by a water repellent film (e.g. Bioclusive®), precluding the need for any care and allowing ease of movement and a normal regimen for bathing.

Once the sutures have been removed and the wound cleaned, the use of liquid adhesive and sterile tapes for another week or two further stabilizes the wound. Many specialized bandaging systems are available for complicated wounds (see Ch. 145).

SHORT-TERM AND LONG-TERM COMPLICATIONS OF BIOPSY PROCEDURES AND EXCISIONS
Short-term complications
• Irritant or allergic contact dermatitis to topical antibiotics and/or tapes and bandages • Hemorrhage • Poor wound healing; dehiscence of closed wounds • Pain • Infection • Pruritus, paresthesias
Long-term complications
• Atrophic scars (thin, depressed, spread) • Hypertrophic scars (red, thickened) • Keloids • Distortion of normal structures (e.g. ectropion, elevated nasal ala, notching of the lip or helix of the ear) • Hyper- or hypopigmentation • Hypoesthesia, anesthesia • Paralysis (e.g. due to injury to facial nerve branches)

Table 146.14 Short-term and long-term complications of biopsy procedures and excisions.

COMPLICATIONS

Short-term complications of biopsies and excisions are few in number and engender limited morbidity (Table 146.14)[57]. In addition, the smaller the procedure, the fewer the complications, which explains why shave biopsies and snip biopsies are quite safe. Bleeding is the most common complication and may occur from the time of the procedure to after the patient has returned home, but usually within the first 24 hours. Taking care to achieve hemostasis during the procedure minimizes adverse bleeding events even for patients taking anticoagulants and antiplatelet medications[58].

Infection occurs rarely, i.e. in <1% of most procedures[59], in contrast to the development of irritant or allergic contact dermatitis which is more common. The latter is usually due to adhesives and less often topical antibiotics (see above)[60]. Dermatitis can frequently be managed with a change in the wound care regimen but if there are significant symptoms or risk of postinflammatory hyperpigmentation, topical corticosteroids may be applied. Biopsies performed on the lower limbs, limbs affected by lymphedema, intertriginous areas, and ears are most susceptible to infections. If an infection develops, culture and oral antibiotics may be required.

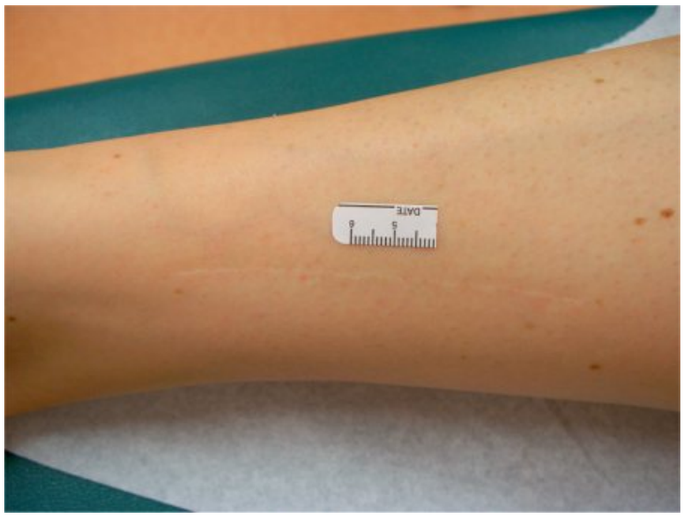
Pain is generally minimal. When it occurs 3–5 days after the procedure, infection is the most likely cause, even in the absence of erythema, tenderness, and purulence. Very rarely, paresthesias may result and can persist for several months, especially on the forehead and scalp. Wounds that are closed primarily may dehisce because of tension, hematoma formation, poor wound healing, or infection. These wounds are thereafter managed for second intention healing and a delayed reconstruction can be undertaken, if needed, once the attendant inflammation has resolved.

Long-term complications (see Table 146.14) generally consist of functionally or cosmetically adverse scarring[61]. Depressed scars may occur if not enough subcutaneous tissue is brought into the line of closure. Atrophic and widened scars occur in areas where there is intermittent stretching of the scar as it overlies major muscle groups. Careful surgical technique that includes adequate undermining, minimization of tension at the line of closure, and the use of multiple subcutaneous sutures can reduce the likelihood of this complication.

Scars may pursue a prolonged course of healing with erythematous thickening at the line of closure. These hypertrophic scars do resolve with time. To speed their resolution, practitioners often advise massage or inject triamcinolone acetonide (10–40 mg/ml) into the scars. Silicone dressings are also recommended, but they are probably no more effective than non-silicone gel dressings[62]. In addition, scars may have a fragile surface (due to reduced dermal–epidermal attachments), pruritus, or paresthesias, most of which resolve with time.

A true keloidal scar is one that grows beyond the boundaries of the original surgical injury and appears as a thickened erythematous or hyperpigmented nodule or plaque (see Ch. 98). It occurs in predisposed individuals who may have a history of previous keloid formation. Keloidal scarring is most commonly observed when procedures are performed on the upper trunk and shoulders and may be very difficult to treat.

FUTURE TRENDS



For the foreseeable future, histologic examination of tissue specimens will remain the mainstay of dermatologic diagnostic testing. Excisions likewise will be frequently utilized, both to remove a specimen for diagnosis as well as to clear pathologic tissue completely. Hopefully, in the future, there will be improved means of anesthesia[63] and improved wound care with the development of affordable agents that speed healing and minimize scarring. Advances in dermoscopy, confocal laser microscopy, and ultrasound allow visualization of microscopic tissue architecture and cellular detail *in vitro*, but for diagnostic purposes, this technology has not replaced standard biopsy techniques. However, they may direct site selection for biopsies, improving diagnostic accuracy.

147 Flaps

David G. Brodland

Key features

- A cookbook approach to flap reconstruction is not realistic
- The mnemonic STARTS lists basic reconstruction options: simple side-to-side closures, transposition flaps, advancement flaps, rotation flaps, tissue importation flaps, and skin grafts
- Understanding the dynamics of a flap optimizes its execution
- For reconstruction, the simplest approach that achieves the desired result is often best
- Extensive undermining, everted wound edges, meticulous hemostasis without excessive electrocoagulation, and technical precision are important in achieving an outstanding result

INTRODUCTION

Cutaneous reconstruction has played an important role in the establishment of dermatologic surgery as a vital discipline within dermatology. An in-depth understanding of reconstructive techniques, combined with a dermatologist's intimate familiarity with skin, enables optimal aesthetic and functional results. Equally important is an in-depth understanding of the tissue dynamics of flaps, why they work, what problems each flap type can address, and their limitations. A cookbook approach to flap reconstruction is not realistic because of the many variables relating to the characteristics of the defect, the donor skin, the patient, and the surgeon. It is better to develop a foundation of basic concepts from which the individual can build his or her skills and unique style of reconstruction.

BACKGROUND

At the patient's side, it is always helpful to have an on-demand recall of flap options. With experience, this is automatic, but those with less experience may find the mnemonic STARTS helpful (Table 147.1). It is incumbent upon the surgeon to synthesize the many factors that may affect the choice of the most appropriate flap for a defect. The characteristics of the wound, qualities of the adjacent skin, the functional aspects of the affected anatomic site, the pertinent aesthetic considerations, the anatomic borders in proximity to the defect, and the age and expectations of the patient all contribute to deciding the most appropriate reconstruction.

The most important goal in reconstruction is functional aesthetics. This means that the reconstruction should first and foremost maintain all vital functions and accomplish this aesthetically. Not all aesthetic reconstructions are functional, but all functional reconstructions can be aesthetic.

Fundamentals of Flap Design and Suturing Technique

Technical precision, including suturing technique, may be the most important variable in achieving an outstanding result. The first important step is to prepare the wound edges of both the defect and the flap. All incisions should be made at a 90° angle to the skin surface such that the wall of the defect and the edge of the flap are square. Secondly, the wound base should be made a uniform depth. Whether reconstructing with an elliptical side-to-side closure or with any of the more intricate flaps, the contour of the wound base will persist and may affect the long-term appearance of the wound. Likewise, the thickness of the flap should be uniform. Although the optimal plane of flap dissection is somewhere between the upper mid subcutaneous and deep subcutaneous tissue, the ideal thickness of a flap varies and must be determined on a case-by-case basis. Flaps constructed too thinly can develop vascular compromise or may lead to an unnatural appearance. Conversely, a very thick flap may be bulky, have decreased mobility or be more difficult to manipulate while suturing, and it may unintentionally damage underlying neurovascular structures or muscles. Hair-bearing skin mandates attention to the level of the hair follicles.

Widespread undermining of the subcutaneous tissue adjacent to both the defect and the donor site defect is important for creating a broad "plate-like scar" (Fig. 147.1). This results in an even distribution of scar contraction over a greater area and diffuses the effects of contraction such that it is not focused on the flap itself or the incision lines of the flap (Fig. 147.2). Undermining should be uniform and complete, including the areas of low tissue tension such as the tips of an ellipse or the pivot points of flaps[1,2].

Next, meticulous pinpoint hemostasis with complete visualization of all undermined skin with the help of an assistant is critical. Excessive postoperative bleeding within a sutured wound often results in an inferior outcome. It should be emphasized, however, that extensive tissue injury caused by electrosurgical hemostasis should be avoided as fervently as postoperative bleeding, since this can contribute equally to unwanted results. With a well-prepared wound and flap that are characterized by uniformity in thickness, sharply squared edges, well-loosened tissue margins, and excellent hemostasis, the wound is ready for suturing.

An adequately undermined flap may still lead to distortion of delicate structures if the flap is large, heavy, or moves under considerable tension. A flap suspension suture may be necessary to avoid distortion or displacement of delicate tissue. These sutures are placed in fixed or rigid structures underlying the flap. Periosteal sutures represent a common anchoring technique and they are placed from the periosteum through the undersurface of the flap into the deep dermis[3]. When this suture is placed in the undersurface of the flap, it should correspond topographically to its desired location relative to the periosteal suture. More than one suspension suture may be needed and should be placed in a direction parallel to the flap blood supply to avoid vascular compromise of the flap.

Whether it is a side-to-side closure or a flap, eversion of the skin edges (along with undermining) is also essential (see Fig. 147.1). Given their longer period of effectiveness, as compared to epidermal sutures, the author prefers the use of subcutaneous ("buried") vertical mattress sutures to achieve eversion (see Ch. 146)[4,5].

Flap Movement Characteristics

It is helpful to broadly characterize flap types according to their mechanism of skin movement and rearrangement. By understanding the dynamics of each flap, it is easier to select one that will provide

functionally aesthetic results. Upon consideration of the unique characteristics of the defect, the donor skin, and the functional and aesthetic issues of reconstruction in the context of the mechanics of flap tissue movement, a rational decision regarding the method of closure can be made. The components that flaps share include the flap body, the pedicle or vascular base, primary and secondary defects, and, as an integral part of flap dynamics, the primary and secondary movements (Table 147.2, Fig. 147.3)[6].

Most tissue movement results in some degree of tension. This tension creates vectors of force that tend to return moving skin back to its original position. The primary movement of a flap creates a primary tension vector, while the secondary movement (during closure of the donor site defect) creates a secondary tension vector. Consideration of these forces and the effects of these forces on adjacent tissue and even the blood supply of the flap is the primary factor in selecting one flap over another[7]. The most perfectly executed flap that, via tension vectors, results in the distortion of a free margin (e.g. a lip or eyelid) is of little value to the patient or the goal of aesthetic restoration. Therefore, the initial and most important skill required for the proper execution of flaps is the ability to anticipate the direction and amount of tension created by a particular flap and to predict what effects this tension will have on adjacent structures (see Figs. 147.2 & 147.3). Secondarily, judicious use of tension sutures is helpful.

There are four broad categories of flaps based upon how the tissue is rearranged to achieve closure (Table 147.3). In the first category, one or both Burow's triangles that would be removed if the wound were closed by a simple side-to-side closure are displaced. The second includes the flaps that reconfigure defects, while the third includes flaps that reorient tissue from adjacent pools of laxity into the defect. Finally, there is a category of flaps that enables defect closure by tissue importation.

Burow's triangle displacement flaps

Flaps that displace Burow's triangles to a "convenient" location distant from the defect include the single tangent advancement flap (Burow's flap), the bilateral single tangent advancement flap (A-to-T flap), the double tangent advancement flap (U-flap), the bilateral double tangent advancement flap (H-flap), and rotation flaps (e.g. the dorsal nasal or Rieger flap, Mustarde flap, helical advancement flap) (Fig. 147.4).

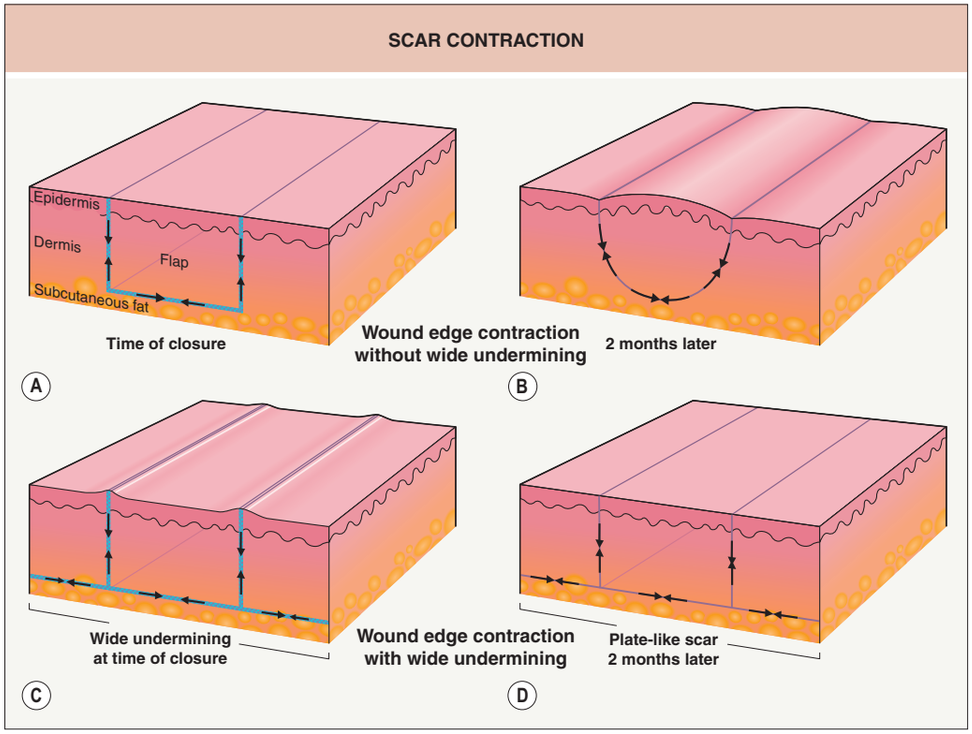

Fig. 147.1 Scar contraction. A Sutured wound without wound edge eversion and without undermining of the surrounding tissue. **B** The results of scar contraction, leading to inversion of the scars and trapdoor deformity of the flap. **C** A wound sutured with eversion and wide undermining. **D** The canceling effect of scar contraction and wound eversion as well as the diffusion of scar contraction in the deep, undermined wound plane ("plate-like" scar).

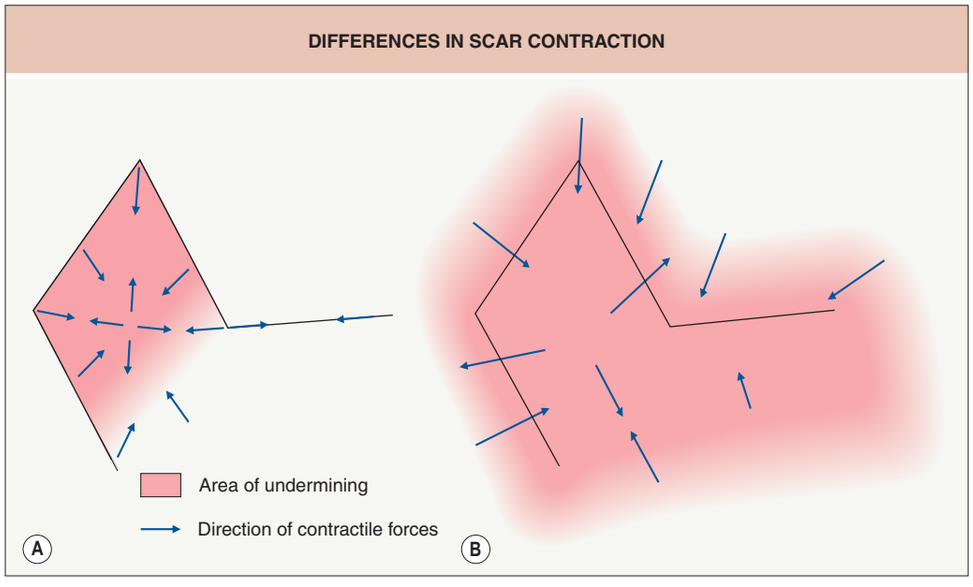

Fig. 147.2 Differences in scar contraction. Depiction of differences between wounds that are undermined and those that are not undermined prior to suture placement. **A** The contraction forces are focused on the margins of the flap in a wound that was not widely undermined. **B** Broad diffusion of contractile forces that are not concentrated at the flap margins, making trapdoor deformity ("pincushioning") less likely in the widely undermined flap.

DEFINITIONS OF FLAP COMPONENTS	
Body	The skin being advanced, transposed, rotated, interpolated, or imported into the primary defect
Pedicle (vascular base)	The conduit of the vascular supply that will remain intact and maintain the vascularization of the body of the flap intraoperatively and for the early postoperative period
Primary defect	The area deficient in skin that will be reconstructed by the movement of the body of the flap
Secondary defect (donor site defect)	The area devoid of skin created by the movement of the body of the flap
Primary flap movement	The movement of the flap body into the defect
Secondary flap movement	The tissue movement necessary to close the void or donor site defect created by the movement of the body of the flap
Primary tension vector	The direction of the force tending to counteract the movement of the body of the flap
Secondary tension vector	The direction of the force created by the closure of the donor site defect

Table 147.2 Definitions of flap components. See Fig. 147.3 for illustration of these definitions.

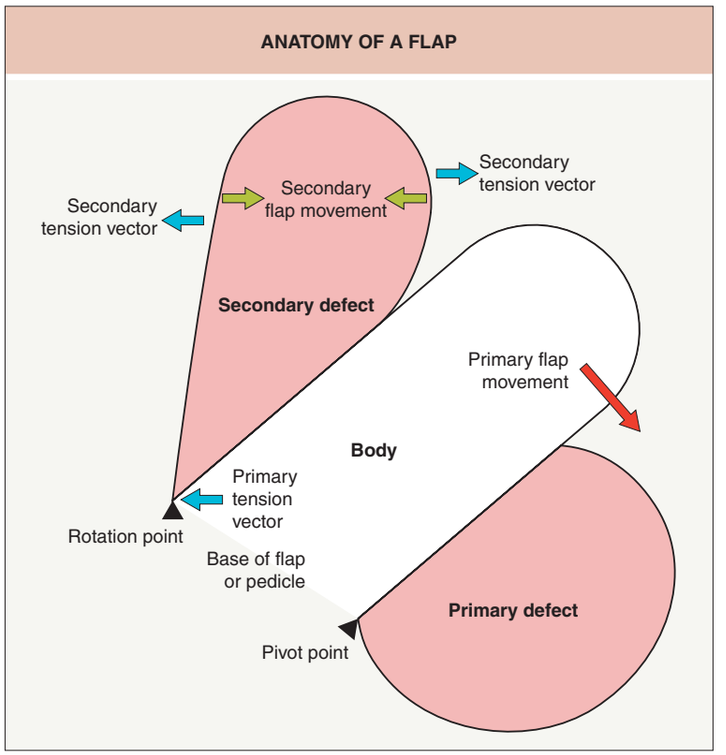

Fig. 147.3 Anatomy of a flap. Definitions of the components of a flap are outlined in Table 147.2.

CLASSIFICATION OF FLAPS BASED ON DESIGN CHARACTERISTICS					
Flap category	**Flap variations**	**Synonyms**	**Mechanism of tissue movement**	**Advantages**	**Disadvantages**
Burow's triangle displacement flaps	Single tangent adv flap	Burow's flap	• Tissue advancement: dependent upon intrinsic tissue elasticity	• Enables closures adjacent to vital structures through displacement of Burow's triangles • Single tangent flaps have excellent blood supply	• Depends on intrinsic skin laxity of the flap skin • Requires extensive undermining • Double tangent flaps have a more limited blood supply
	Bilateral single tangent adv flap	A-to-T flap, O-to-T flap			
	Double tangent adv flap	U-flap			
	Bilateral double tangent adv flap	H-flap			
	Curvilinear tangent adv flap	Rotation flap, Karapandzic flap, Mustarde flap			
Defect reconfiguration flaps	Pedicled V-to-Y flap	Kite flap, myocutaneous pedicle flap, island pedicle flap	• Tissue advancement: dependent upon intrinsic elasticity of subcutaneous pedicle • Tissue movement results in reconfiguration of the defect	• Tissue-conservative due to reconfiguration of the defect without removal of Burow's triangle	• Blood supply is limited to the subcutaneous pedicle • Use limited to locations with spongy, elastic subcutaneous tissue
Tissue reorientation flaps	Rhombic transposition flap	Limberg flap, Dufourmentel flap, Webster's 30° flap, banner flap	• Reorientation of adjacent tissue laxity	• Effective for tight closures • Directional tissue gain can be achieved in direction of tissue deficit	• Depends on laxity adjacent to the defect • Multidirectional incisions; difficult to place all in RSTL
	Bilobed transposition flap				
	Nasolabial transposition flap	Melolabial fold flap			
	Nasolabial flap with a twist (Spear's flap)*				
Tissue importation flaps	Forehead flap	Indian flap	• Importation of tissue from a distant site	• Coverage of large wounds • Can provide vascularity for coverage of avascular grafts such as cartilage grafts	• Two-stage flap • Vascular supply limited to narrow pedicle
	Nasolabial interpolation flap	Melolabial interpolation flap			
	Retroauricular pedicled flap	Pin back flap			
	Subcutaneous tunneling island pedicle flap**				
	Modified Hughes flap Abbe cross-lip flap				

*This flap has features of both reorientation and tissue importation flaps.
**Can be single stage flap.

Table 147.3 Classification of flaps based on design characteristics. adv, advancement; RSTL, relaxed skin tension lines.

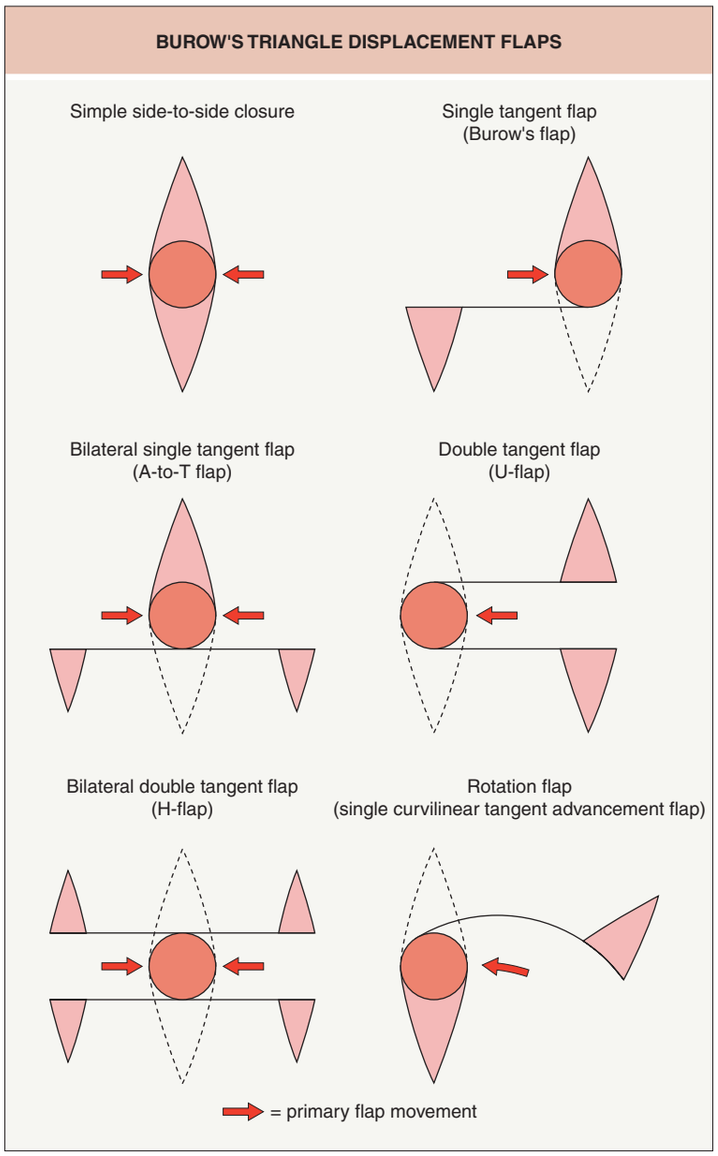

Fig. 147.4 Burow's triangle displacement flaps.

These flaps displace Burow's triangles along straight or curved incision(s) tangential to the wound[8].

The key features of these flaps are: (1) they displace Burow's triangles to a distant site; (2) there is limited reorientation of tissue; and (3) their movement is dependent upon the intrinsic elasticity of the skin. Just as a simple side-to-side closure performed in stiff, inelastic skin would result in a tense closure, so would a Burow's triangle displacement-type flap. When the surrounding skin is elastic and "loose", the wound edges can be closed under minimal tension in both a side-to-side closure and with these flaps. Thus, the only advantage that these flaps confer over a side-to-side closure in tight skin is that a larger area of skin is typically undermined, which releases the flap from the tethering effect of the subcutaneous tissue. This allows for a modest decrease in wound closure tension. The primary utility of these flaps is in defects where, for functional or aesthetic reasons, it is inconvenient to remove a Burow's triangle immediately adjacent to the defect. An example of this is a defect above or below the eye in which displacement of the Burow's triangle is useful to avoid removing a triangle from the eyebrow or eyelid (Fig. 147.5).

Defect reconfiguration flaps

The pedicled V-to-Y advancement flap is unique in that it is an advancement of tissue with its vascular base as a pedicle of subcutaneous tissue and muscle oriented in a plane perpendicular to the skin and at 90° to the more traditional advancement or rotation flaps. In this case, the tissue redundancy created at the pivot point of the flap is buried in the subcutaneous plane at the advancing edge of the flap (see below). Fundamentally, the pedicled V-to-Y flap reconfigures the typical roundish shape of the wound to a sharp, angled, geometric shape that is easily closed without standing cones or distortion of surrounding structures (Fig. 147.6). Movement of this flap is entirely dependent on the elasticity of the tissue that comprises the vascular pedicle of the flap.

Tissue reorientation flaps

Tissue reorientation flaps are characterized by the lifting of skin from an adjacent donor site and reorienting it through the transposition of the flap over a peninsula of skin between the donor site and the defect. There is a pivot point at the base of this flap (see Fig. 147.3). The tissue movement depends on the presence of *laxity in adjacent tissue*. Although intrinsic elasticity of the flap skin may facilitate the ease of execution, without ample laxity in the donor site, the transposition cannot be performed. Some of the flaps that fall into this category include the rhombic transposition flap (see Fig. 147.2), the bilobed transposition flap, and the nasolabial transposition flap (see Table 147.3).

To better understand the reorientation of tissue that occurs in these flaps, a review of the most basic tissue reorientation flap, the Z-plasty, is helpful. Z-plasties transpose two angular flaps, placing them in a complementary fashion into the defects of the other flap (Fig. 147.7). This reorientation of tissue ultimately results in the lengthening of the skin in the direction of the middle arm of the Z-plasty (Fig. 147.8). There is a complementary decrease in the length of skin perpendicular to this same arm. The amount of lengthening is proportional to the angles of the flap(s). Put another way, tissue gain in the direction of the middle arm is proportional to the width of the base of the flaps. This is effectively the mechanism of tissue reorientation in transposition flaps. Upon careful examination, Z-plasties can be found within the design of transposition flaps (Fig. 147.9). Therefore, just as with Z-plasties, transposition flaps work because the reorientation of the tissue results in lengthening of tissue in the direction of the skin deficit at the expense of the laxity in the donor site.

It is helpful to understand the utility of these principles of reorientation – an example of this would be a defect on the nasal tip (Fig. 147.10). The skin is typically very tight in this area, making simple side-to-side closure in the vertical direction difficult. Side-to-side closure in the horizontal direction is impractical because of the distortion that would occur to the free margin of the ala. When one looks for donor sites, there is typically a substantial amount of laxity on the mid nasal dorsum and nasal sidewall. A bilobed flap allows utilization of this laxity through tissue reorientation using two lobes[9]. The underlying mechanism of tissue reorientation is a series of Z-plasties inherent in this flap. Since tissue gain in Z-plasties is in the direction of the middle arm of the Z-plasty, a substantial reorientation and lengthening of tissue in the desirable direction for repair of the defect occurs without distortion[10]. In contrast to the Burow's triangle displacement flap, this flap does not rely upon intrinsic elasticity of the flap skin. This is key to avoiding distortion of the alar rim.

Tissue importation flaps

Large defects, or defects in areas where tissue laxity is lacking, may be reconstructed by importing vascularized skin from a site that is not adjacent to the defect (see Table 147.3)[11]. Tissue importation flaps are typically derived from a distant donor site with ample tissue laxity and, most importantly, an excellent blood supply. This blood supply may be based on a particular artery (e.g. paramedian forehead flap based on the supratrochlear artery) or by a rich, random-pattern blood supply (e.g. the retroauricular pedicle flap).

These flaps are typically two-staged flaps requiring a period of vascular ingrowth from the wound bed of the defect. This period ranges from 2 to 6 weeks, with 3 weeks being the most commonly reported time point for transection of the pedicle. In the head and neck region, defect sites where tissue importation flaps are commonly employed include the nose, ear, eyelid, and lip.

There are also single-staged tissue importation flaps. These are tunneled flaps in which skin from a non-adjacent site with a subcutaneous and muscular pedicle is passed through a "tunnel" to the defect site. The pedicle lies within the tunnel providing blood supply to the flap.

The appropriate selection and execution of these four broad flap categories are discussed in more detail below.

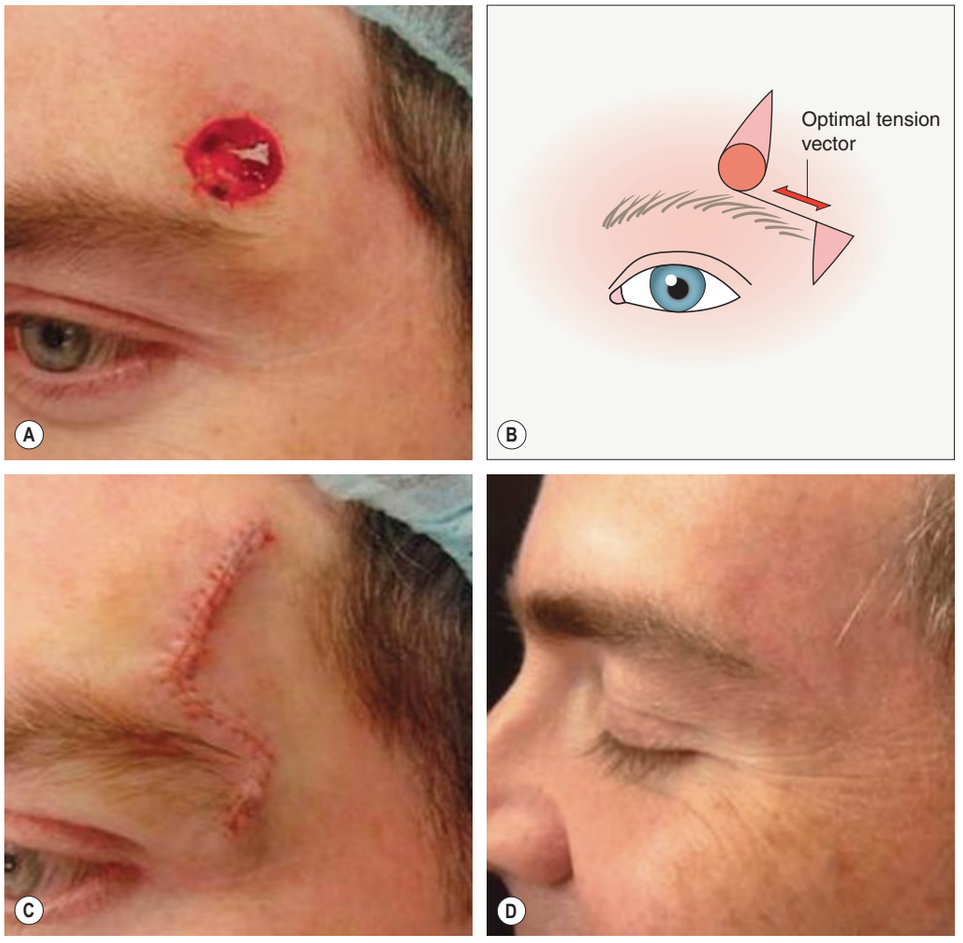

Fig. 147.5 Single tangent advancement flap (Burow's flap). A The wound extends to the brow. **B** Determine the tension vector that will cause the least distortion and make the tangential incision parallel to this optimal tension vector. Both Burow's triangles (displaced and adjacent to defect) are oriented perpendicular to the optimal tension vector. **C** Closure with a single tangent advancement flap with the tangent extending lateral to the brow and displacing a Burow's triangle to the temple and lateral orbit. **D** The eyebrow is entirely preserved.

DESCRIPTION OF TECHNIQUE

Burow's Triangle Displacement Flaps

Single tangent advancement flaps (STAFs) and rotation flaps

There are several variants of Burow's triangle displacement flaps that are differentiated by the number of Burow's triangle displacements, or the configuration of the tangential line extending to the displaced triangle (see Fig. 147.4). Ideally, the design of these flaps should, when possible, place surgical scars at cosmetic subunit borders and within relaxed skin tension lines. Therefore, when a defect is located near an arcing junction of a cosmetic subunit or if the relaxed skin tension lines are curved such as on the cheek (Fig. 147.11), then the Burow's triangle displacement flap, classically known as the rotation flap, may be an excellent option[12]. On the other hand, when the cosmetic subunit junctions or relaxed skin tension lines are relatively straight, the STAF, or "Burow's advancement flap", may be optimal. A variation, the crescentic advancement flap, can be employed when the anatomic structures are naturally curved (Fig. 147.12).

Fig. 147.8 Classic Z-plasty flap. A Defect close to the eyelid margin. The middle arm of this Z-plasty flap is composed of the defect *plus* the Burow's triangles excised above and below it to facilitate the transposition of the flaps (*). The medial flap is transposed over the lateral flap (arrows). **B** The wound is closed via a Z-plasty closure with the transposition of flaps at the upper medial and lower lateral aspects of the wound. This is done to lengthen tissue in the direction of the palpebral margin in order to prevent ectropion as demonstrated at the 4-month postoperative visit (**C**).

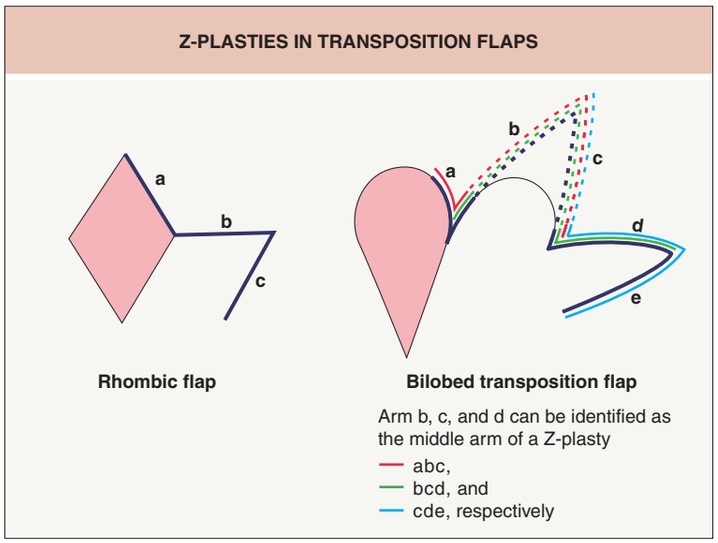

Fig. 147.9 Z-plasties in transposition flaps. Z-plasties are highlighted within the designs of both the rhombic and the bilobed transposition flap. Note in the rhombic flap the middle arm of the Z-plasty is line (b) and is the direction of anticipated tissue lengthening. In the bilobed transposition flap diagram, there is a series of three Z-plasties all contributing to tissue gain in the desired direction of the defect.

Once the need to displace a Burow's triangle so as to avoid a vital structure is established, the incision lines should be planned in the optimal location. The incision, whether straight or arced, should extend to the point of preferred triangle displacement. The triangle should then be excised, commensurate in depth to the thickness of the flap. After undermining and hemostasis, the first point of suturing is the closure of the displaced Burow's triangle. The second point of suturing is then the closure of the other Burow's triangle. The remainder of the flap can then be completely sutured into the defect with even distribution of the remaining edges of the flap to the defect's wound edges.

Double tangent advancement flaps (DTAFs)

DTAFs displace both Burow's triangles along parallel tangents (see Fig. 147.4). Therefore, these flaps are typically peninsular in configuration with an isolated vascular base at the distal ends of the tangents. The execution of this flap is very similar to that of an STAF, except that one must be mindful of the more limited vascular supply (Fig. 147.13). This isolated vascular supply necessitates limiting the length of the flap to three to four times its width. As with other advancement flaps, the first closure points are at the site of the displaced Burow's triangles. Suturing the advancing flap with even distribution of the flap along the recipient tissue margins completes the execution of this flap[8].

Site-Specific Variations of Burow's Triangle Displacement Flaps

Helical advancement flaps

Helical advancement flaps are often discussed as a unique entity, but they are merely variants of Burow's triangle displacement flaps. The characteristics of the helix are unique owing to its highly distortable free margin that is curved in nearly every dimension and its limited pool of adjacent tissue laxity[13,14]. The common variant of the helical advancement flap is directly analogous to the DTAF in that parallel tangents are incised from the helical defect along the anterior rim of the helix and the posterior helix. Another variant is an STAF in which a single incision is made along the anterior helical rim while a non-displaced Burow's triangle is excised directly posterior to the defect onto the posterior ear. Both the DTAF variant and this STAF variant can be either a single flap (derived superior or inferior to the defect) or two flaps (derived both above and below the defect). As with all Burow's triangle displacement flaps, the helical advancement flap displaces the Burow's triangle to a more convenient location. Most of these flaps derive donor skin inferiorly. The donor pool from the superior helix is typically less abundant but can be very beneficial, both in large mid-helical defects when two flaps are used and in defects of the superior helix[15].

A common use of the helical advancement flap is for a small to medium-sized defect on the mid helix not involving the cartilage (Fig. 147.14). While a wedge closure of the ear could be considered, displacing the anterior triangle by utilizing the lax skin of the lower helix and earlobe obviates the need to do a wedge resection of the auricular cartilage and avoids disruption of its delicate architecture. Burow's triangles can easily be displaced to the earlobe, which facilitates the advancement of the helical skin into the defect. Despite the resultant decrease in the size of the earlobe, the aesthetic impact tends to be minimal as long as the anterior profile of the ear is maintained. Since the earlobe is most visible on the lateral view and because the opposite earlobe is not simultaneously visible, subtle changes in size tend to go unnoticed.

With a more superiorly located defect, the donor pool is at the anterior aspect of the helical rim. Although the extent of tissue movement from the anterior helix is often less than can be expected on the inferior helix, this varies greatly and must be determined for each case.

With the helical advancement flap variant, which is a *double* tangent flap or "U-flap", the parallel lines are well hidden in the helical groove or on the helical rim and on the ear posteriorly. A possible disadvantage is the very narrow flap base with its attenuated blood supply. However, the helical rim has a rich vascular supply and is more forgiving even when tension on the wound edges is considerable. Nevertheless, under tension there is a risk of distal necrosis of this type of helical advancement flap.

Notably, the helical advancement flap variant with a *single* tangential incision does not have the same narrow base. Its posterior Burow's triangle is excised directly posterior to the defect. The same anterior

Fig. 147.10 Bilobed flap. A Defect on the nasal tip adjacent to the free margin of the ala. Bilobed flap reconstruction with minimal distortion of the alar rim (**B**) and long-term result (**C**).

Fig. 147.11 Rotation flap. Large defect (**A**) on the medial cheek and lower eyelid reconstructed with a rotation flap (Mustarde flap) with displacement of the superior Burow's triangle laterally along the curvilinear tangent which follows the relaxed skin tension lines (**B**). **C** Final results with no distortion of the eyelid and incision lines nicely camouflaged along cosmetic subunit borders and relaxed skin tension lines.

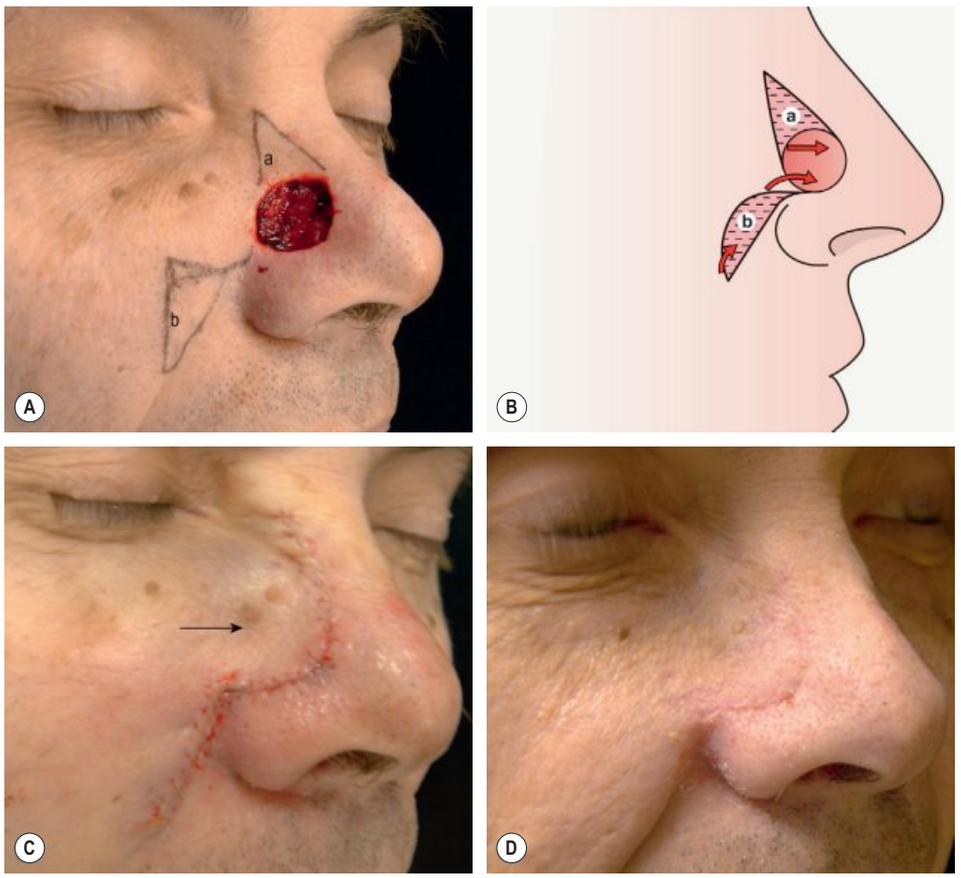

Fig. 147.12 Crescentic advancement flap. A Medium-sized defect on the right inferior nasal sidewall. A single tangent advancement flap (Burow's flap) is planned with a crescent-shaped Burow's triangle on the medial cheek. **B** The crescent (b) fits nicely into the naturally curved anatomic configuration of the alar crease and creates a "wound edges of unequal length" situation which further contributes to the advancement of skin onto the nose. **C** Flap sutured in place; note the subtle indentation (arrow) that corresponds to a periosteal suture placed at the nasofacial sulcus in order to prevent tenting and to recreate the sulcus. **D** Four-month postoperative appearance.

Fig. 147.13 Double tangent advancement flap. A Defect with preoperative plan to advance skin from lateral to the defect, incorporating the residual brow. **B** Sutured flap realigning the brow. **C** Six months postoperatively with reconstitution of the brow. This technique was used to reconstruct and preserve the continuity of the eyebrow in this patient.

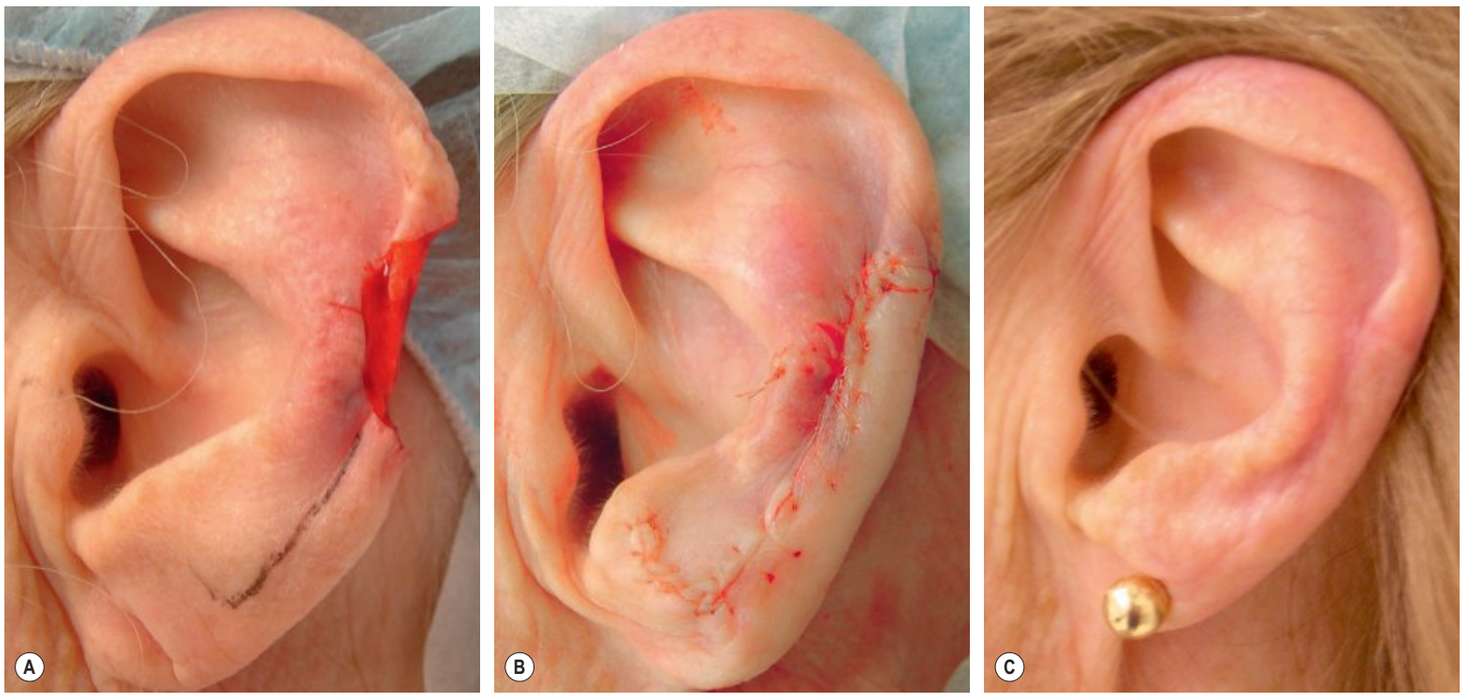

Fig. 147.14 Helical rim advancement flap. A Defect of the mid helix involving a small amount of cartilage. A single tangential incision is planned inferiorly within the helical groove to the earlobe. A Burow's triangle excision is planned directly behind the defect on the posterior ear. The flap will be raised by dissection of the skin from the posterior ear above the perichondrium. The displaced Burow's triangle will be removed from the earlobe and the skin of the flap will be redraped through upward advancement into the defect. **B** The flap is sutured after a very small wedge of cartilage has been removed to reconstitute the helical rim of cartilage. **C** Three-month postoperative appearance.

incision is made along the helical rim (see Fig. 147.14), but the base of the flap now becomes the entire posterior ear. The flap can be dissected from the cartilage posteriorly and redraped with advancement over the defect. Equally excellent cosmetic results can be obtained with this variant and with very little downside.

Dorsal nasal flap

The dorsal nasal flap (Rieger flap) is a specialized, site-specific variant of the Burow's triangle displacement flap that is useful for reconstructing moderately sized distal nasal defects. The basic design of this flap is predicated upon the fact that it is often inconvenient or unfeasible to remove a large Burow's triangle on the nasal tip. The design of this flap displaces a Burow's triangle from the nasal tip to the glabella along an incisional arc that extends from the more inferior aspect of the defect (above the alar crease) to the nasofacial sulcus and finally onto the glabella (Fig. 147.15).

The dorsal nasal flap relies on the rich blood supply of the medial canthal plexus that is largely supplied by the angular and infratrochlear arteries. This rotation flap employs a "back-cut" which slightly alters the dynamics of the flap, with the back-cut serving as the displaced Burow's triangle. However, this maneuver simultaneously narrows the base of the flap which improves its ease of rotational movement. Based on the rich vascular supply of the medial canthus, the narrowed base is robustly supplied by the angular artery. The back-cut also enables the incorporation of some glabellar skin into the flap, contributing to the closure of the secondary defect and reducing distortional tension on the nasal tip.

The most important aspect in the execution of the dorsal nasal flap is creation of a broad-enough arc by extending to the nasofacial sulcus, but skirting the medial canthal skin, *en route* to the glabella. The second key element is the plane of dissection when elevating the flap. While the portions of the flap that will be covering the nasal defect can be trimmed and thinned to match the native skin and defect, the body of the flap must be dissected at the level of the perichondrium and periosteum. This assures adequate blood supply from the canthal plexus. When these principles are observed, this flap is robust and can reconstruct moderately large nasal tip defects without distortion and with an excellent tissue match.

While the surgeon must be aware of important variables that can substantially affect the successful use of any flap, this is especially true

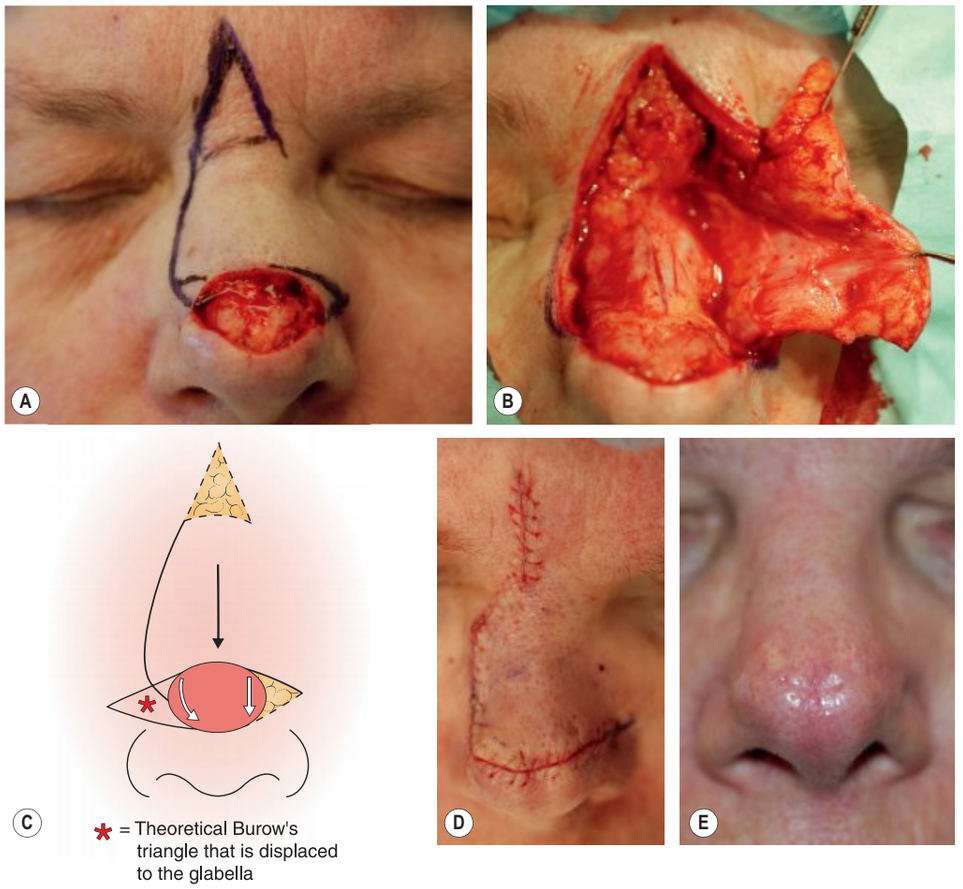

Fig. 147.15 Dorsal nasal (Rieger) flap. A Moderate-sized defect of the nasal tip. **B** The flap is incised and reflected demonstrating the deep plane of dissection just above the nasal periosteum. The flap will be redraped over the tip of the nose with primary closure of the displaced Burow's triangle on the glabella. **C** Displaced Burow's triangles (*) are depicted as is downward tissue advancement via rotation of nasal tissue on a lateral base. **D** Flap sutured into place. **E** Result four months postoperatively.

in the case of the dorsal nasal flap. The ideal situation is a patient with very non-sebaceous and elastic or "loose" skin of the nasal dorsum. Characteristics that raise concern about whether this flap can be successfully executed include thick, inflexible, and highly sebaceous skin. Also, prior surgeries on the nose or the medial canthus should be viewed as a potential source of compromised vascular supply. Distortion of the distal nose structures may occur if there is severe structural compromise of the free margin or the cartilage of the nasal tip and consideration should be given to other reconstructive options (e.g. a tissue importation flap). The dorsal nasal flap should be reserved for defects that are too large to be reconstructed with a small local flap such as the bilobed flap, yet smaller than a defect for which a tissue importation flap would be more ideally suited. The most difficult aspect of successfully executing a dorsal nasal flap is anticipating and dealing with the secondary motion inherent in this flap. The more curved the flap, the greater the secondary defect on the nasal sidewall/nasofacial sulcus.

Other Site-Specific Flaps

Alar rotation flap (ARF) and spiral rotation flap (SRF)

There are two flaps which, like the dorsal nasal flap, are rotation flaps with back-cuts that are particularly useful for alar defects. The ARF is best suited for smaller defects limited to the ala while the SRF is useful for larger defects involving both the ala and lower nasal sidewall.

When defects are limited to the ala, the **ARF** is a good alternative to full-thickness skin grafts; the ideal defect is <75% of the vertical height of the ala and is located on the mid to medial ala. Classically, the superior edge of the defect is near the alar crease. The flap design displaces the triangle laterally along an arcing incision that is made within the crease and extends off the nose onto the apical triangle at the junction of the nose, cheek, and upper lip (Fig. 147.16). This incision is further extended a short distance along the nasolabial fold to where the back-cut is made. The size of the back-cut should be proportional to the defect, i.e. about the size of a Burow's triangle had it been excised superior to the defect. The flap, which is thick and incorporates the rich blood supply of the lateral ala, is then elevated. A diminutive Burow's triangle is excised inferolateral to the alar defect.

The key suture of the ARF is placed at the alar–labial junction to close the back-cut defect. This nicely recreates the alar–labial junction. The second key stitch closes the alar defect. With the flap in position, the surgeon looks to incorporate enough of the back-cut portion of the flap onto the ala to replace the tissue volume of the defect. This is important because the ala is typically highly sensitive to tissue loss and the back-cut creates the opportunity to incorporate tissue from the apical triangle onto the nose. This restores and preserves the normal tissue volume of the ala.

An analogous flap may be used for alar defects located near the alar rim. The design of the flap is simply inverted and the arcing incision is made along the alar rim to the alar–labial junction where the back-cut is similar to that just described, but is inverted. A diminutive Burow's triangle is excised superior to the defect and the flap is rotated onto the nose and into the defect in the same fashion.

The **SRF** is an excellent way to reconstruct defects involving the ala and the lower nasal sidewall[16]. It enables reconstruction of the ala and alar crease in a single stage. The design is that of a 270° rotation flap with a back-cut on the medial cheek, and it represents an alternative to the nasolabial transposition flap.

An arcing incision is made from the inferomedial aspect of the wound onto the nasal sidewall and extended laterally onto the upper medial cheek (Fig. 147.17). The arc is extended inferiorly to the nasolabial fold. From there a back-cut incision is made superiorly along the fold. The proportions of the flap are important and the flap can be conceptualized as having three parts: (1) the alar portion; (2) the body; and (3) the tail. The alar portion of the flap will reconstruct the alar portion of the defect and is equal in size to this area. The body and tail of the flap are equal in size to the vertical dimension of the entire defect. This proportional sizing of the flap assures successful restoration of the nasal defect, with the skin of the medial cheek ultimately serving as the donor site. Just as with the ARF, the back-cut tissue, which in an SRF is the tail of the flap, is incorporated

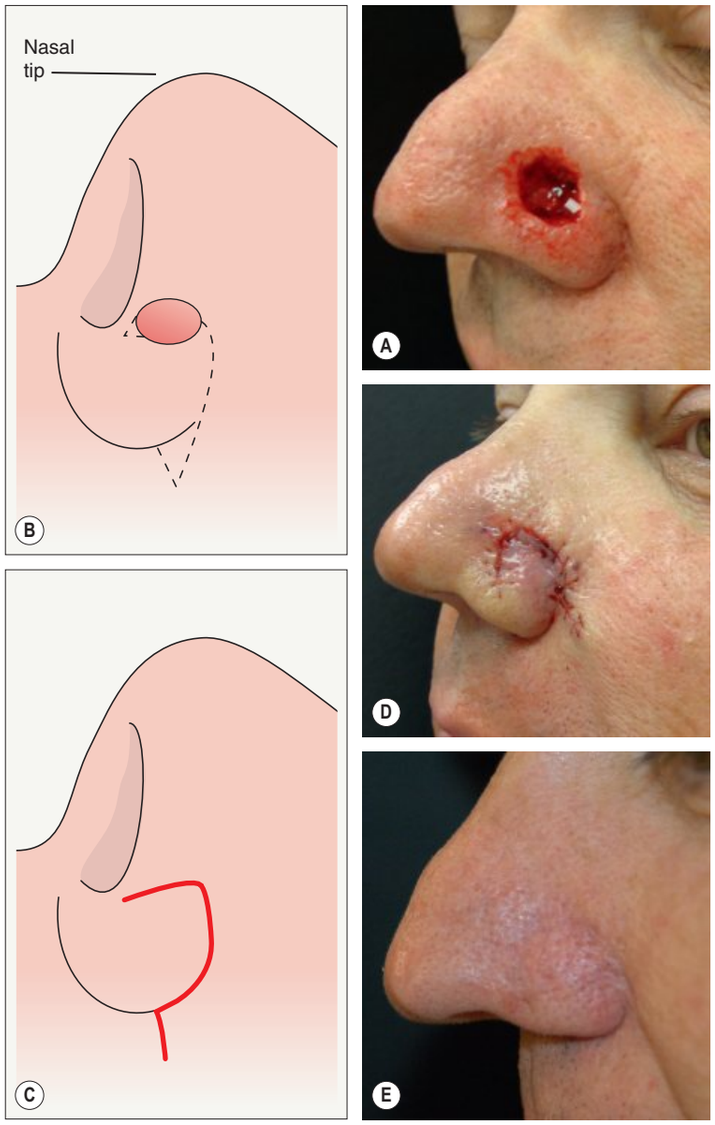

Fig. 147.16 Alar rotation flap (ARF). A These flaps are best suited for mid to medial defects that are <75% of the vertical height of the ala. **B** The design is a rotation flap with a back-cut incised within the alar crease to the apical triangle at the alar–labial junction. **C** Closure of the back-cut recreates the crease at the alar–labial junction. **D** Incorporation of the back-cut skin onto the ala prevents distortion of the ala. **E** Long-term follow-up.

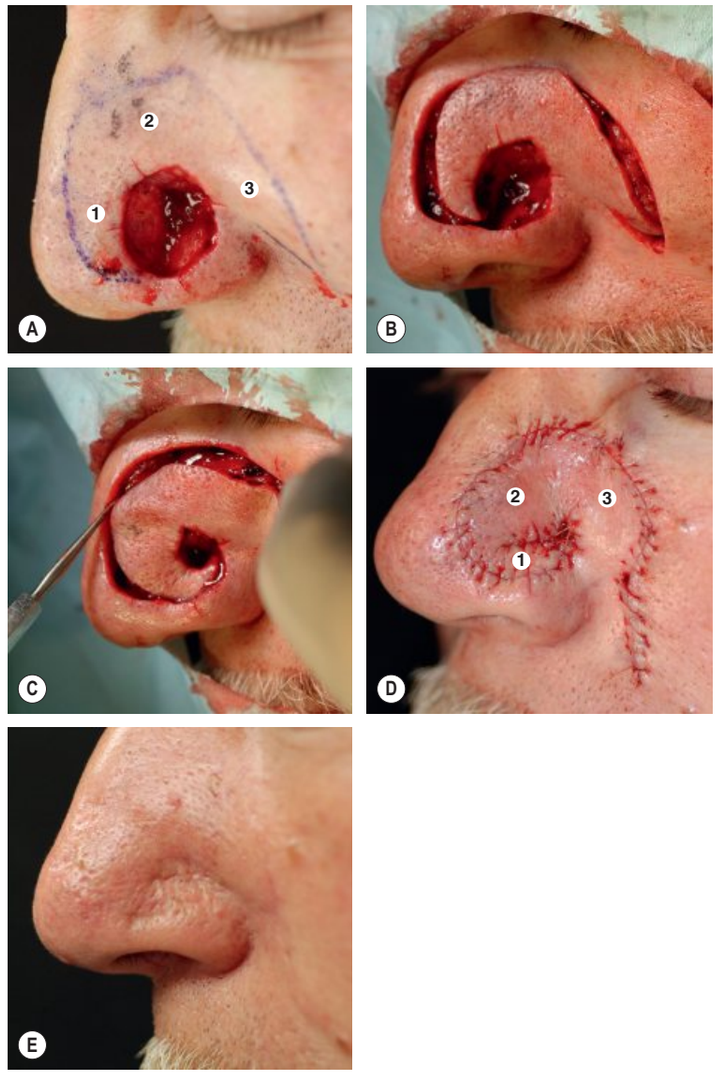

Fig. 147.17 Spiral rotation flap (SRF). A These flaps are well suited for larger defects involving the ala, alar crease, and lower nasal sidewall. The flap (outlined in ink) can be conceptualized as having three parts: (1) the alar portion (equals the size of the alar defect); (2) the body; and (3) the tail; the latter two components equal the size of the entire wound. **B** Incision of the flap with a back-cut on the medial cheek along the melolabial junction. **C** After undermining, with the flap base created at the inner aspect of the spiral flap, demonstration of the spiral rotation of the flap into the alar portion of the defect. **D** Sutured flap. **E** Three-month follow-up.

as much as possible into the closure. Some of the tail will be trimmed, but incorporation of as much of this tissue as possible helps to restore the tissue volume on the nose. This restoration, in turn, prevents distortion of the free margin and other structures.

The method of undermining and raising of an SRF deserves mention. The alar portion is completely detached from the underlying tissue as is the tail. The perimeter of the flap body is undermined to enable rotation and advancement. Vascular supply of the flap is based upon the rich vascular plexus of the lateral ala and upper lateral lip located beneath the "inner" edge of the spiral. In this way, the flap is similar to the pedicled V-to-Y flap since its base is largely deep to the flap and care must be taken to preserve this base.

Cheiloplasty of the lip

Cheiloplasty of the lip is a special form of the simple elliptical closure. It is used in small to moderate-sized defects of the lip that involve the vermilion or the vermilion border. It is traditionally taught as a wedge closure with a full-thickness excision of skin, mucosa, submucosa, and musculature. However, when tissue-conserving excisions (e.g. Mohs micrographic surgery) are employed and much of the orbicularis oris muscle is preserved, a subtotal wedge excision of the muscle (cheiloplasty) is preferred due to its simplicity as well as the decreased chance of lip dysfunction and other complications[17].

Careful realignment of the vermilion border is essential. Prior to excision of the tumor, hash marks are made with a scalpel along the vermilion border as precise reference points. The hash marks enable precise realignment of the vermilion border (Fig. 147.18).

The surgeon surveys the amount (if any) of redundant soft tissue that forms when the wound edges are approximated. Usually, the apex of the wedge (after removal of redundant muscle) is obtuse, creating a very slight trough in the lip in an anterior-to-posterior direction. In our experience, the less muscle that is removed, the less likely a noticeable notch in the vermilion lip will form and the function of the lip is beautifully maintained. After excision of Burow's triangles on the external lip and the internal lip (see Fig. 147.18B), and after undermining the cutaneous portion of the defect, the key suture is the one that reapproximates the medial and lateral muscle edges. This is best done by the placement of a "figure-of-eight" suture, which is similar to a horizontal mattress suture and snares the bellies of the anterior edge of the orbicularis oris muscle and precisely approximates them (see Fig. 147.18C–E). Upon healing, the ridge created by this approximation becomes a functional and aesthetic component of the lip and recreates

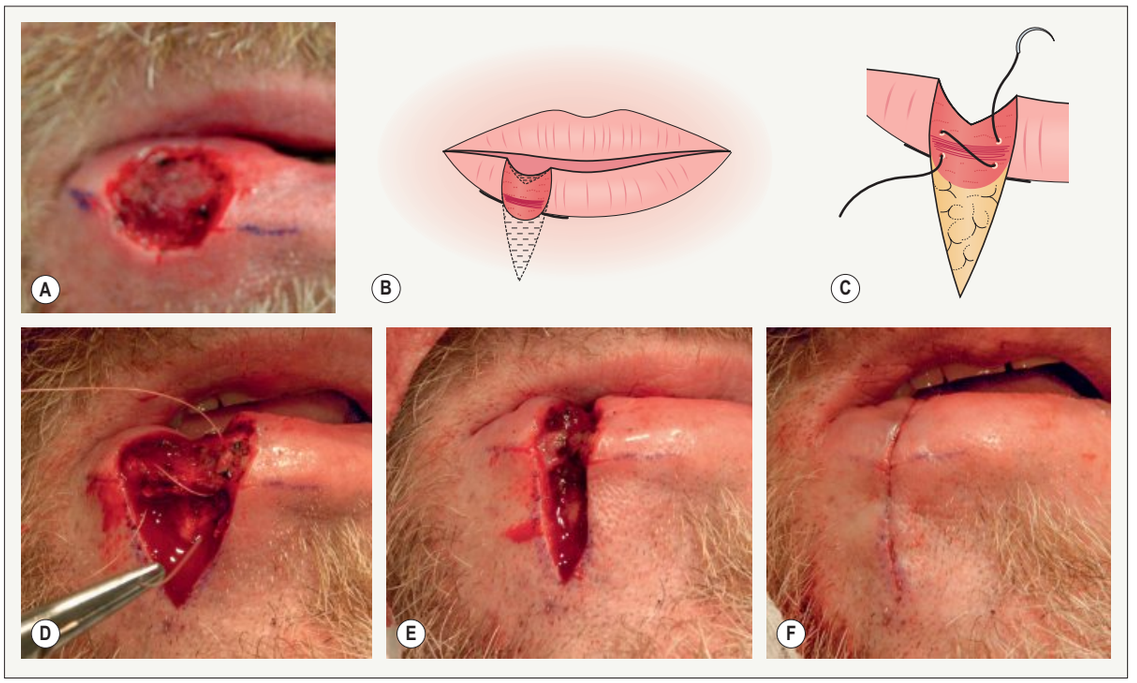

Fig. 147.18 Wedge closure of the lip. A Typical defect after Mohs surgical excision of a squamous cell carcinoma. Note indelible ink lines and nicks in the skin that demarcate the vermilion border, facilitating precise realignment. **B** Burow's triangles are excised intraorally and extraorally perpendicular to the vermilion border. After determining the minimal amount of muscle that must be removed to avoid excessive redundancy when the wound edges are approximated, an obtuse wedge of muscle is removed. **C** The anterior margin of the orbicularis oris muscle is identified medially and laterally. A "figure-of-eight" stitch is placed to reapproximate the muscle margins. **D** "Figure-of-eight" suture in place prior to reapproximation of muscle edges. **E** Realignment of the anterior edge of the orbicularis oris muscle. **F** Wound closure prior to the placement of superficial epidermal sutures. Note the near perfect realignment of the vermilion border and the well-proportioned recapitulation of the lower lip.

the appropriate muscular bulge at the vermilion border. Adjustment of the wound edges to perfectly realign the previously placed hash marks with epidermal sutures will ensure a perfectly realigned vermilion border. Some surgeons use braided rather than monofilament sutures to minimize irritation of the mucosal portion of the other lip.

Defect Reconfiguration (Pedicled V-to-Y) Flaps

The pedicled V-to-Y flap (PVYF) is a unique advancement flap in that the creation of an island of epidermis and dermis eliminates any blood supply from the rich vascular plexus within the deep dermis and superficial subcutaneous skin[18]. In effect, the vascular supply is isolated to the subcutaneous tissue. The two variations in pedicle design hinge upon whether the pedicle is created immediately beneath the island or from the subcutaneous tissue lateral to the island (Fig. 147.19). The variant with the vascular pedicle immediately beneath the island of skin is created by dissecting away surrounding superficial subcutaneous tissue and eliminating the tethering effects of the tissue adjacent to the pedicle. The PVYF with laterally based pedicles is created by tunneling immediately beneath the island while carefully maintaining vascularized sheets of subcutaneous and muscle tissue, either bilaterally or unilaterally to the side of the island (Fig. 147.20). Selection of which pedicle variation is best depends upon the site. PVYFs in locations with elastic, spongy subcutaneous tissue do well with deep pedicles whereas lateral pedicles are preferred for defects within tighter skin with less spongy subcutaneous tissue and with a good lateral blood supply; the latter often comes in the form of facial muscle[19].

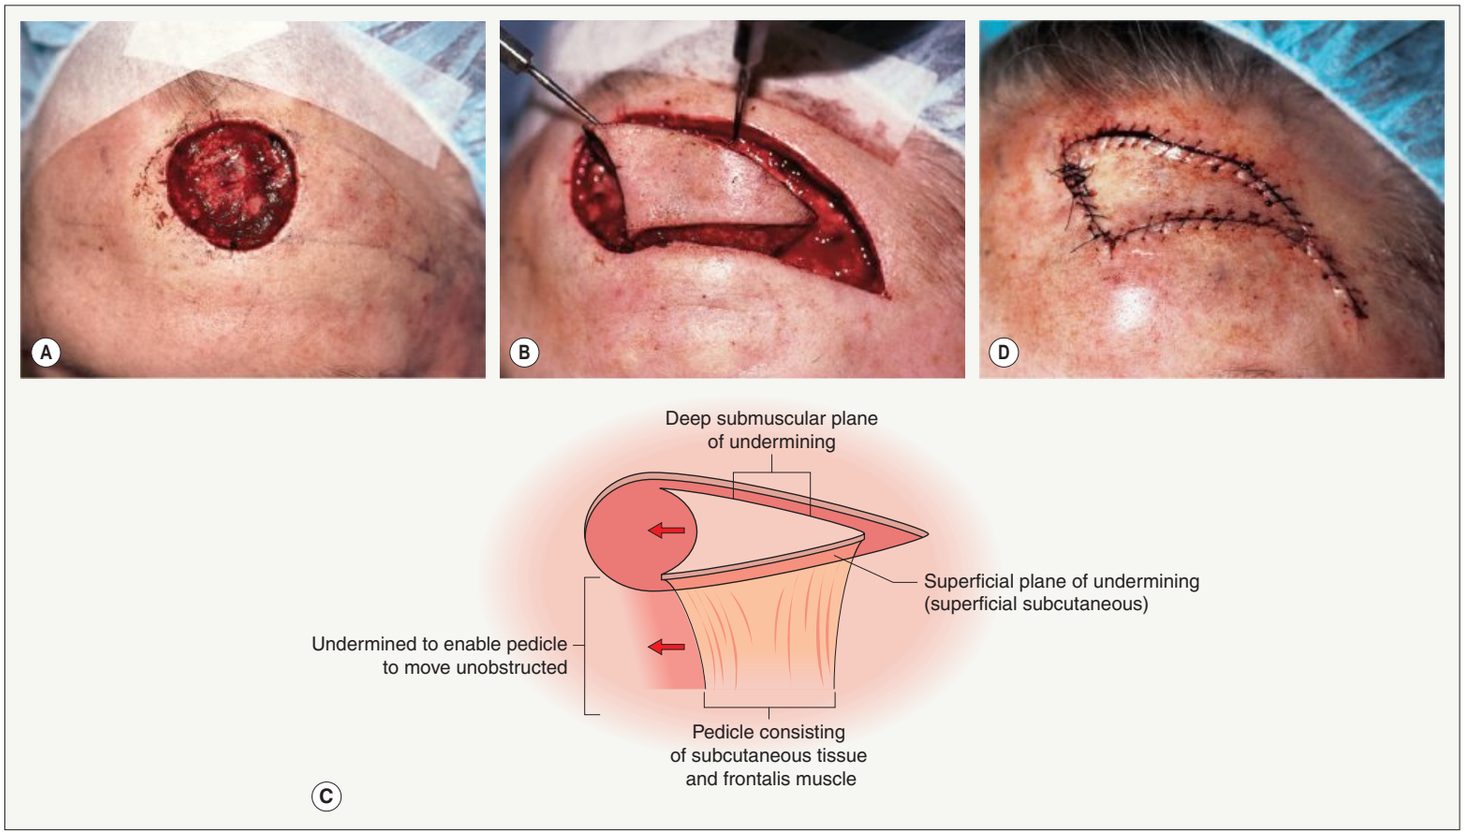

Fig. 147.20 The pedicled V-to-Y flap. A Large mid-upper forehead defect. **B** Intraoperatively, the pedicled V-to-Y flap is designed with a single inferior muscular pedicle based on the rich blood supply of the supratrochlear and supraorbital arteries. **C** The frontalis muscle serves as the inferiorly based pedicle for the flap. This muscular pedicle is constructed via undermining in the subcutis beginning at the lower edge of the flap (superficial plane) and undermining in the submuscular plane which is begun at the superior edge of the flap (deep plane). The skin medial to the pedicle must also be undermined to facilitate its advancement in the direction of the defect. **D** The defect is now comprised of acute angles which are easier to close primarily.

In general, it is appropriate to think of the PVYF as an advancement of what would be one of the Burow's triangles in a simple side-to-side closure. The PVYF is an extremely tissue-efficient flap in which little or no tissue is discarded and yet often provides outstanding clinical results. The mechanism for tissue conservation involves a reconfiguration of the roundish defect into an angular shape (see Fig. 147.6). The original shape of the defect is reconfigured behind the advancing island to a defect of equal area, but very angular in shape that can be closed without tissue redundancy.

It is conceptually useful to recognize that a PVYF (especially with the pedicle based immediately beneath the island) is essentially a rotation flap turned perpendicular to the surface of the skin (Fig. 147.21). Whereas, in a rotation flap, the vascular source lies parallel with the skin, the analogous vascular supply of the PVYF runs perpendicular to the skin. Similarly, the plane of tissue movement in the traditional rotation flap is parallel with the skin, but is perpendicular to the skin in a PVYF. Once this analogy between a rotation flap and a PVYF is understood, it is easy to see that movement of the PVYF is facilitated by the same factors that facilitate movement of a rotation flap. For example, excision of the Burow's triangle facilitates the rotation and advancement of the rotation flap. Likewise, the advancement of a PVYF is facilitated by the removal of the tissue analogous to the Burow's triangle, i.e. any subcutaneous tissue at the base of the defect (Fig. 147.21B). Without its removal, the subcutaneous tissue left in the wound base serves as a physical impedance to the advancing flap.

Another technique for enhancing rotation flap mobility, the back-cut, is also applicable to the PVYF. A back-cut for a rotation flap releases some of the restraining tension of the flap and is helpful in its mobilization. The equivalent of a back-cut can also improve the mobility of a PVYF. This is done by incising the subcutaneous pedicle at the trailing edge of the flap in a direction beveled slightly into the pedicle (see Fig. 147.21B).

In order to enable eversion of the skin edges of a PVYF, the island is very slightly undermined at the dermal–subcutaneous junction to facilitate its eversion. In addition, the skin surrounding the flap is widely undermined in the superficial subcutaneous tissue. The flap is then advanced into the defect, with closure of the donor site behind the flap in a V-to-Y fashion and closure of all skin edges.

Pedicled V-to-Y flap variation: the pincer flap

Altering the shape of the pedicled flap or the nature of the pedicle affords advantages in site-specific reconstructions. For example, the pincer flap is used to reconstruct the cupid's bow of the upper lip (Fig. 147.22). In the pincer flap, the shape of the flap is altered by extending its lateral incisions outside of the lateral margins of the defect, thereby creating peninsular extensions of the flap. These, unlike the body of the flap, are detached from the underlying tissue so they can be folded inwardly in a "pincer" fashion, thus forming a teardrop-shaped flap (see Fig. 147.22B). Upon suturing, this curved advancing edge recreates and preserves the curvaceous vermilion border at the cupid's bow. In addition to preserving function, it beautifully avoids disruption of an aesthetically critical facial feature.

Tissue Reorientation Flaps

Transposition flaps are among the most useful flaps because of their ability to tap into adjacent tissue reservoirs and repair defects in anatomic locations with minimal laxity. These flaps allow for repair of even large defects with minimal or no skin tension and without distortion of important surrounding anatomic structures. The classic transposition flap is the rhombic flap, with other useful transposition flap variants being the bilobed flap and the single-staged nasolabial transposition flap[20]. All these reorientation flaps are fundamentally based upon the Z-plasty.

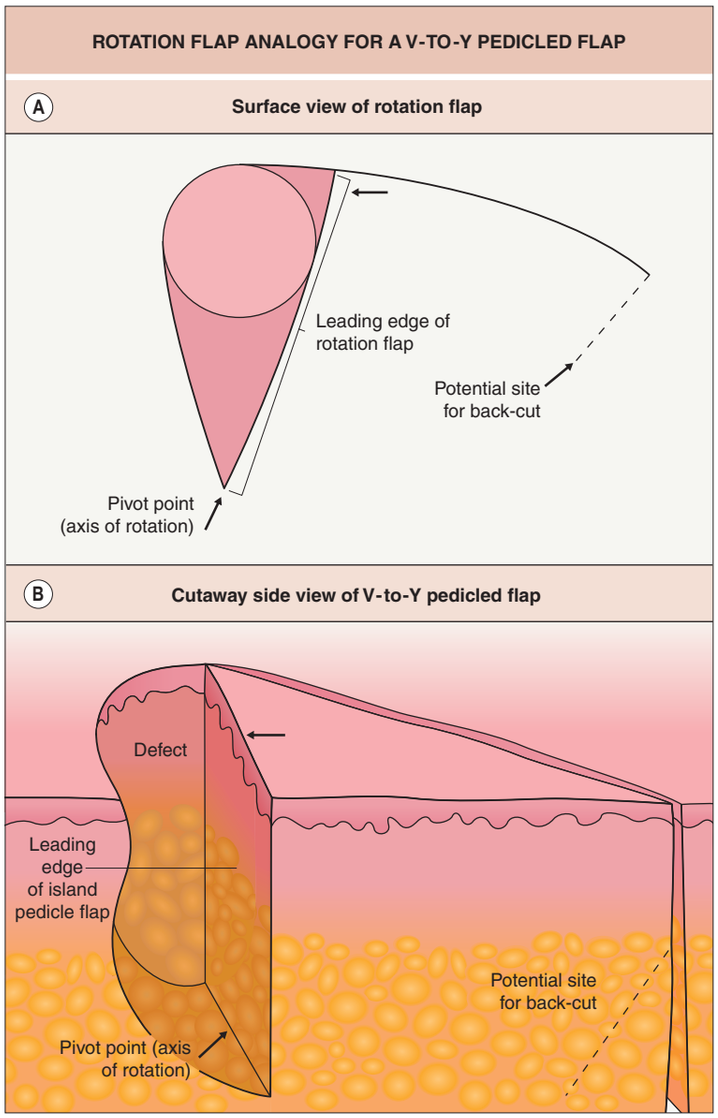

Fig. 147.21 Rotation flap analogy for the pedicled V-to-Y flap. A A rotation flap with standard removal of a Burow's triangle adjacent to the defect and the site of a potential back-cut which would facilitate flap movement. **B** Side view of a defect and the pedicled V-to-Y flap. The plane of rotation is perpendicular to the skin surface. The shaded area is where the equivalent of a Burow's triangle has been removed to facilitate flap movement. The dotted line is analogous to the back-cut of a rotation flap. Note the similarities between a rotation flap and the pedicled V-to-Y flap.

Rhombic transposition flap

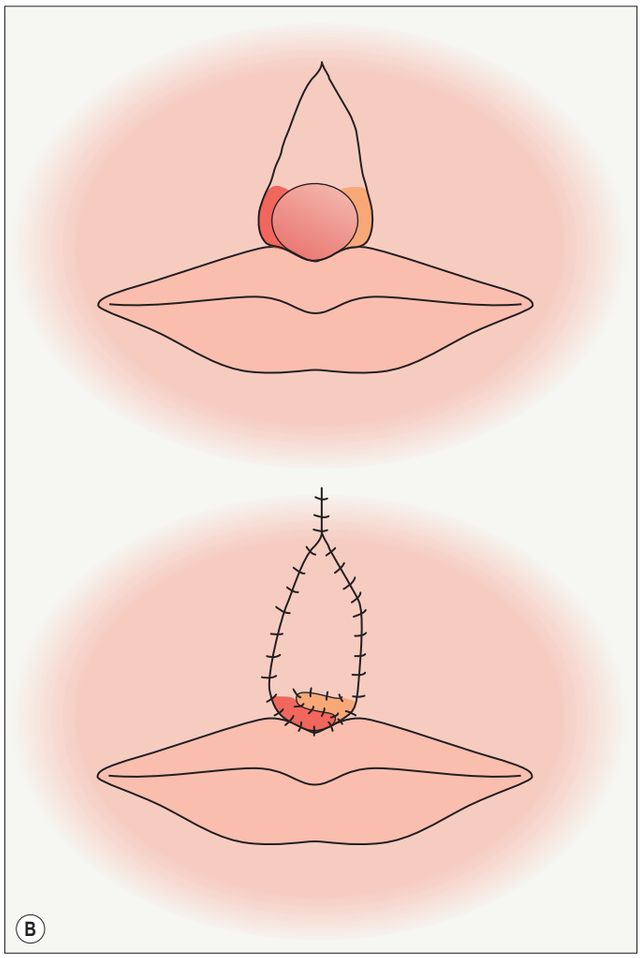
The classic rhombic flap, originally described by Limberg in 1963, was based on the concept of placing the tension vector of the secondary defect nearly perpendicular to that of the primary defect (Fig. 147.23A). After closure of the donor site, the Limberg flap allowed for repair of the primary defect with essentially no wound edge tension. Dufourmentel added important modifications that made the closure of the donor site easier by placing the secondary defect at an acute angle (60°) to the primary defect. Thus, the flap passes through a shorter arc in order to be positioned within the primary defect (Fig. 147.23B). Webster modified the rhombic flap further by making the angle of the secondary defect even more acute (30°) to further facilitate closure of the secondary defect (Fig. 147.23C). The smaller flap size of the Webster variant allows the surgeon to position the flap in almost any location relative to the primary defect in order to tap into the most lax skin available. However, as the angle of the secondary defect becomes more acute, more of the wound tension is transferred from the donor site to the primary defect. Care must be taken to ensure that the tension on the flap does not compromise its vascular supply and flap viability. Another important concept to bear in mind is that as more tension is transferred to the primary defect, nearby anatomic structures will be more prone to distortion.

Careful planning is required prior to incising the rhombic transposition flap in order to ensure that the donor site comes from an area adjacent to the defect with adequate tissue laxity. This donor site, most commonly, parallels the relaxed skin tension lines. The Burow's triangle is removed at the pivot point prior to insetting of the flap. This ensures more accurate incision lines and allows more precise suture placement in order to distribute the flap tension evenly. After undermining and hemostasis, the first suture is placed to close the secondary defect. Next, the flap is inset into the defect, trimmed to fit, and sutured.

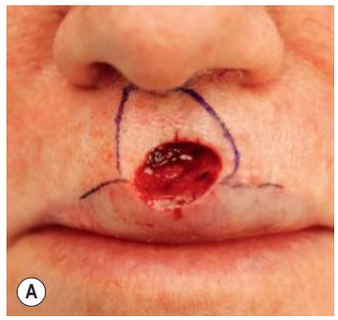
Although extremely versatile, there are specific areas where the rhombic flap provides reliable and reproducible results. The lateral upper two-thirds of the nose and the lateral forehead are ideally suited for the rhombic flap because of the frequent difficulty in closing defects in these areas primarily (Fig. 147.24). The adjacent tissue laxity available on the nasal sidewall and the lateral cheek provide ample reservoirs of donor tissue. Large defects of the central cheek may be closed by the rhombic flap when simpler options are not possible. One significant drawback of this flap is the difficulty in concealing the geometric shape of the incision lines.

Bilobed transposition flap

The bilobed flap is essentially two transposition flaps in series, and it is one of the most useful flaps for repair of defects of the lower one-third of the nose. The easily distorted alar rim can be protected from distortional tension by virtue of the inherent series of Z-plasties within this flap, with the Z-plasties serving to reorient skin in the direction of the alar rim. The bilobed flap was first described by Esser in 1918 and important modifications to the flap were described by Zitelli in 1989[9]. Zitelli modified the classic flap to decrease the pivot angle of the flap from 180° to 90–100° (Fig. 147.25). This simple modification helps to minimize two of the most common problems associated with the bilobed flap – a trapdoor deformity (pincushioning) of the primary lobe and the tendency for standing cones to form at the pivot point of the flap.



Careful planning is required for the bilobed flap to ensure minimal distortion of surrounding structures. Fig. 147.25B depicts a reliable method for planning the incisions of the bilobed flap. Drawing with a sterile marker on the patient ensures that the incision lines are placed in such a way as to maximize both functional and aesthetic results. For nasal defects, the flap should be designed so that the tertiary defect is closed perpendicular to the alar rim. This ensures that the contralateral ala is not lifted during closure of the tertiary defect. On the side of the flap where the pivot point is located, the plane of undermining is carried to the nasofacial groove in order to facilitate mobilization of the flap with no distortion of surrounding structures. Closure of the tertiary site is followed by closure of the Burow's triangle adjacent to the defect. Next, the flap is inset and sutured into the defect. The secondary flap is then trimmed to match the secondary defect and sutured in place (Fig. 147.26).



Defects of the lower one-third of the nose measuring 0.5–1.5 cm are the ideal size for the bilobed flap. Smaller defects can often be closed in a primary fashion and larger defects may need either a skin graft or a two-staged tissue importation flap. Although the bilobed flap is most commonly used for the distal third of the nose, it may be used in other anatomic sites, especially when there is potential for distortion of a free margin. Bilobed flaps can be combined with other flaps to repair relatively large defects located adjacent to the alar rim. This avoids distortion and enables the use of a smaller flap. Video 147.1 illustrates the combination of a bilobed flap and an island pedicle flap.

Trilobed flap and rhombic flap with Z-plasty

Useful variants of the rhombic and bilobed flaps include the trilobed flap and the rhombic flap with Z-plasty[21,22]. These flaps expand on the concept that transposition flaps which are arranged in series include more Z-plasties and, therefore, enable greater tissue movement without distortion of free margins. Again, the most common site for these flaps is the distal nose. In particular, they are useful for defects located very distally on the nasal tip (Fig. 147.27), for defects on delicate, easily distortable noses, or for defects that are larger than what a bilobed flap can effectively close.

The only difference between a bilobed and trilobed flap and a rhombic flap with a single or multiple Z-plasties is the size of the second subsequent lobe(s). The latter uses a diminutive lobe (the Z-plasty) that, when transposed into the defect, only partially fills it. The remainder of the tertiary defect(s) is closed primarily.

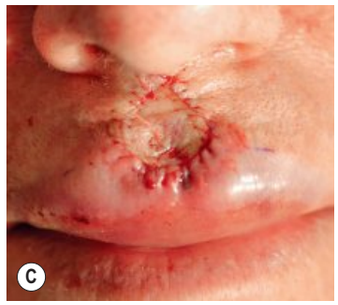


Fig. 147.22 Pincer flap. A This variant is site-specific for the cupid's bow. **B** The pedicled V-to-Y flap with pincer-like extensions on the lateral edges of the defect (shading). These "pincers" are folded upon one another to recreate the teardrop shape of the philtrum and cupid's bow. **C** Pincer flap sewn into place with side-lighting to show the recreation of the concavity of the philtrum at the cupid's bow. **D** Four-month follow-up.

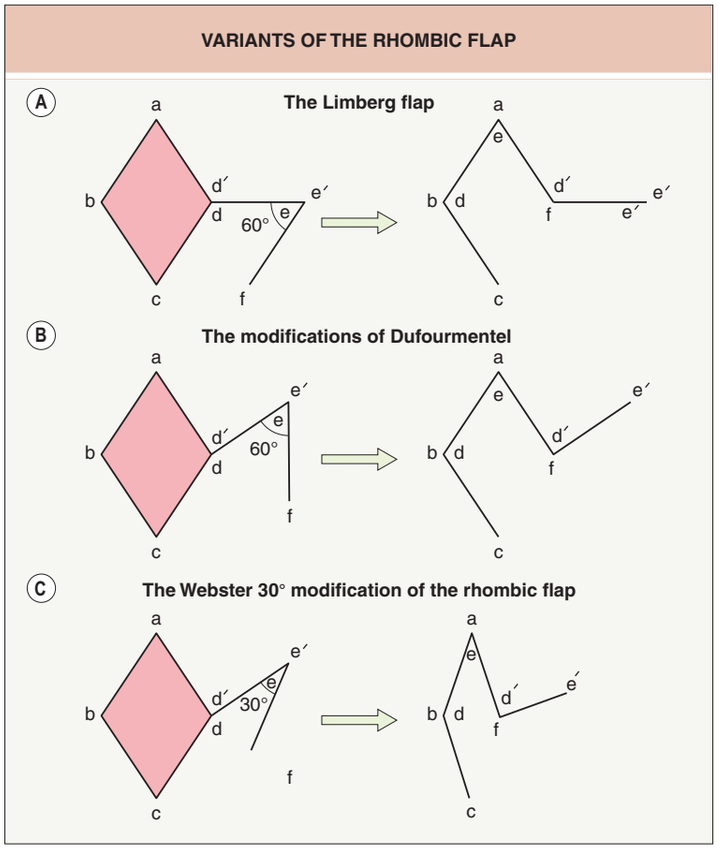

Fig. 147.23 Variants of the rhombic flap. A The Limberg flap is the standard rhombic flap. **B** The modifications of Dufourmentel. **C** The Webster 30° modification of the rhombic flap.

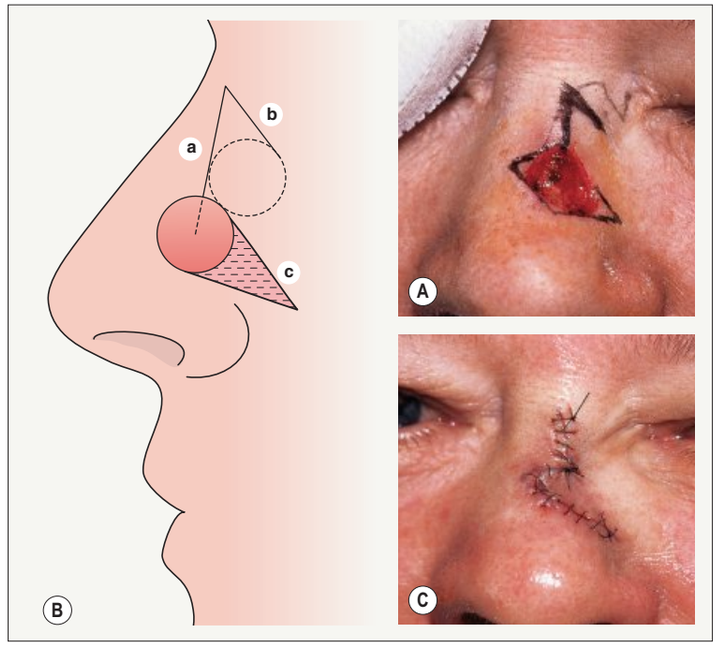

Fig. 147.24 Rhombic transposition flap on the upper lateral nose. A, B Key to the correct design of this flap is identification of the center point of the defect. The first incision for the flap is made in a line (a) along a vector radiating from the central point into the donor skin. The second incision (b) is made at an angle between 45° and 60° to this radiating incision, keeping in mind that the width of the flap must equal the width of the defect. Next, a 30° Burow's triangle is excised such that the flap side of the incision (c) is parallel to the lateral edge of the rhombic flap (b). **C** The tip of the flap is trimmed to fit the defect and the wound edges are sutured.

Nasolabial transposition flap

The single-staged nasolabial (melolabial) flap is a transposition flap variation that can be used to reconstruct defects of the nasal sidewall or large alar defects. Traditional designs of the nasolabial flap resulted in significant blunting of the nasofacial sulcus and frequently in a trapdoor deformity, often requiring one or more postoperative revisions. This is perhaps why this flap has been underutilized in reconstruction of the nose. In 1990, Zitelli described several modifications of the traditional design that helped to minimize the need for surgical revisions[23]. The flap should be designed to include the preplanned excision of the Burow's triangle along the lateral nasal sidewall (Fig. 147.28). The donor site should parallel the nasolabial fold and, once incised and elevated, should be widely undermined; the recipient site should be undermined in the submuscular plane on the nose.

The first stitch is a periosteal suture placed in the undersurface of the flap corresponding to the new location of the nasofacial sulcus. This is secured to the periosteum of the lateral nasal sidewall, thus recreating the sulcus while eliminating tension on the flap. The periosteal sutures also minimize secondary flap movement that might pull the ala laterally. The distal flap should then be thinned and sutured in place. Tacking sutures are placed in the undersurface of the flap in an attempt to recreate the alar crease and to prevent collapse of the internal nasal valve. The tip of the flap is finally trimmed to match the defect and sutured in place.

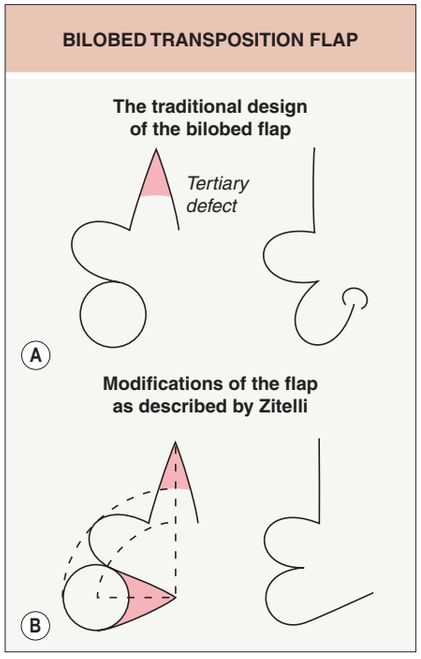

Fig. 147.25 Bilobed transposition flap. A The traditional design of the bilobed flap results in tissue protrusion at the pivot point. **B** Modifications of the bilobed flap as described by Zitelli.

Tissue Importation Flaps

Tissue importation flaps are a loosely associated group of flaps that employ the concept of transferring tissue from a distant reservoir into a defect when other adjacent repair options are unsatisfactory. The flap itself is supported by either: (1) a single vessel as with an axial flap; or (2) a rich plexus of subcutaneous perforating vessels that enter the flap pedicle through underlying muscle (random pattern flap). Tissue importation flaps are ordinarily two- or three-stage procedures. The first stage includes the initial planning and implementation of the flap. The vascular pedicle is left in place after the first stage to ensure adequate blood supply. The second stage involves the separation of the pedicle and insetting of the proximal flap. Tissue importation flaps are most useful for reconstruction of large defects and are especially valuable when cartilage grafting is required to rebuild normal anatomic substructure and preserve proper function.

Forehead flaps

The *paramedian forehead flap* is classically an axial flap based on the supratrochlear artery[24,25]. It is the most useful flap for reconstruction of subtotal and total nasal defects. The excellent vascular supply supports both the flap and any cartilage grafts that are used to rebuild the cartilage framework of the nose (see Ch. 148). The paramedian forehead flap also provides excellent color and texture match and often exceeds the cosmetic results of a skin graft.

An important concept in flap design includes the enlargement of the nasal defect to encompass the entire cosmetic unit when possible. This makes the junction of the flap and the remaining nasal skin less conspicuous and is more likely to result in an excellent cosmetic outcome. If necessary, proper mucosal lining is ensured by using a nasal mucosal flap, a turndown flap, or a split-thickness skin graft (Fig. 147.29). If cartilage support is required, conchal or nasal septal cartilage is used to rebuild the normal cartilage framework (see Ch. 148). Next, a foil template of the defect is constructed and used to outline the flap on the forehead. A 4×4-inch gauze is used to simulate the length of the pedicle.

For tissue importation, the design of the pedicle is a critical step since it is the conduit for blood supply to the flap. Classically, the paramedian forehead flap is considered an axial flap based upon the supratrochlear artery (STA). Doppler identification of its precise location is often done to assure inclusion of the STA and optimization of blood flow. However, the need to meticulously include the Doppler-identified artery has recently been challenged. In a study that compared flaps based on a Doppler-localized STA versus paramidline forehead flaps based medial

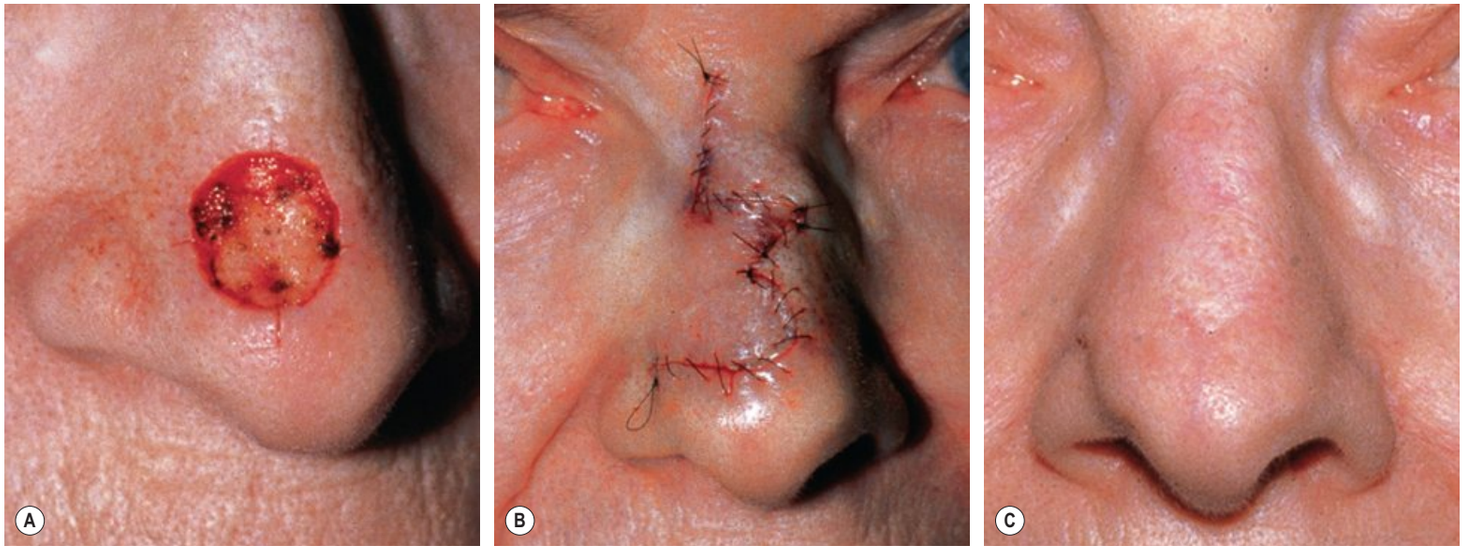

Fig. 147.26 Bilobed flap. A Distal nose defect. **B** Defect reconstructed with a bilobed transposition flap. **C** Cosmetic result at 1 year postoperatively.

to the STA without the use of Doppler (see Fig. 147.29E), similar clinical results were observed[26]. Furthermore, histologic examination of the proximal and distal portions of the pedicle found little differences in vascular composition when the two groups were compared. The only histologic difference was more blood vessels in the pedicles of the paramidline forehead flaps than in the STA-based flaps.

The *paramidline forehead flap* design utilizes the exact midline of the glabella for the medial pedicle incision. The lateral incision is made 1.2 cm lateral to this without respect to the location of the STA. All other aspects of the forehead flap execution are the same as with the STA-centered flap design (see Fig. 147.29E).

Irrespective of how the forehead flap is designed, flap procurement is begun by incising the distal flap (on the upper forehead) in the subcutaneous plane, and as dissection progresses inferiorly, it is gradually deepened. That is, the distal one-third of the flap is dissected in the superficial subcutaneous plane, with deepening over the middle one-third to just above the periosteum in the proximal one-third (just above the brow). When dissecting the glabellar portion of the pedicle, care must be taken to ensure that the axial arteries are not severed as they exit the supraorbital foramen. Bilaterally, the forehead donor site is undermined in the subgaleal plane and then closed in a layered fashion. The widest part of the forehead defect may not close, but heals well by second intention. Finally, the distal end of the flap is thinned to match the thickness of the remaining nasal skin before it is inset.

The second stage of the forehead flap is typically performed 3 weeks later (see Fig. 147.29G). The pedicle is severed near its base and closed primarily. After carefully trimming and thinning the proximal edge of the nasal flap as well as freshening its margin, it is inset into the defect.

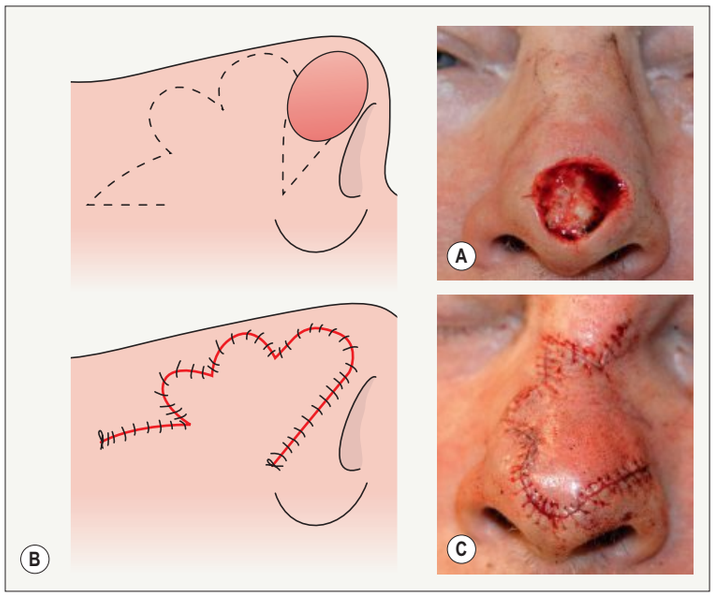

Fig. 147.27 Trilobed flap. A Large subtotal defect of the nasal tip. **B** Trilobed flap with tertiary lobe oriented perpendicular to the alar rim. These three lobes are transposed inferiorly and sequentially into the defects. A total of five Z-plasties are incorporated within this design enabling nearly tension-free redistribution of skin from the upper nose to the nasal tip. **C** Closed wound with minimal distortion of the nasal tip and alar structures.

Nasolabial interpolation flap

The nasolabial (melolabial) interpolation flap has been utilized primarily for defects of the nasal ala. This flap is especially useful for large defects and complex defects involving the alar rim. In certain circumstances, the flap may be utilized for the repair of nasal tip defects when the latter are moderate in size and a paramedian forehead flap is less optimal[27,28].

When utilizing the nasolabial interpolation flap for the repair of alar defects, excision of the remainder of the cosmetic unit of the ala ensures a better aesthetic and functional result (Fig. 147.30). After providing any necessary cartilage support, a foil template is made of the contralateral ala and then it is flipped over and placed on the ipsilateral nasolabial skin. A 4 × 4-inch gauze can be utilized to ensure proper flap length. The flap on the cheek is incised and dissected to a well-vascularized pedicle deep in the subcutis.

The flap can be based either superiorly or inferiorly. The former is best for larger or more medial defects (see Fig. 147.30), but in men, this design is limited by hair-bearing skin. In women, longer flaps can be designed affording greater reach medially. The inferiorly based flap, incised from the nasofacial sulcus, is more limited in length and width. However, the skin is more delicate and free of hair follicles, often resulting in better skin match. The flap is twisted on its pedicle, trimmed, and sutured into place. The donor defect is closed up to the base of the pedicle.

Three weeks later, the patient returns for separation of the pedicle (see Fig. 147.30C,D). The surgeon amputates, trims, and sutures the flap and the cheek to ensure recreation of the normal complex anatomic features of this aesthetically important area. Fusiform excision of the

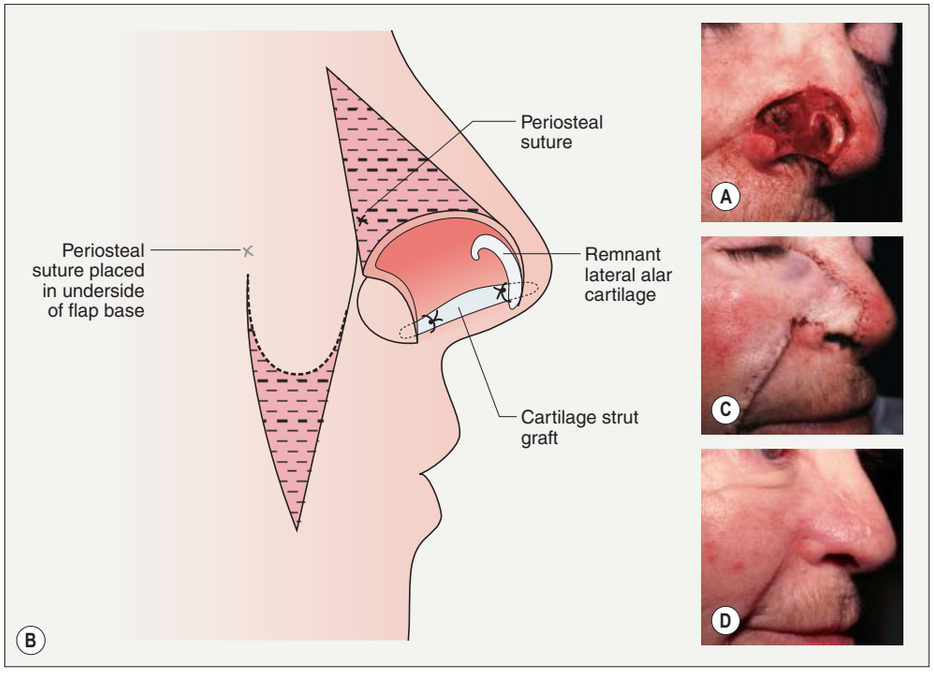

Fig. 147.28 Nasolabial transposition flap. A Large nasal defect involving loss of cartilage and extending to the intranasal skin. **B** Excision of a Burow's triangle on the nasal sidewall is oriented towards the medial canthal tendon. The lateral incision of the flap should extend no higher than the apex of alar skin over which the flap is to be transposed. In this case, an auricular cartilage strut graft is placed along the alar rim and inserted into medial and lateral dermal pockets and anchored with deep sutures into the wound base. The points of placement of the periosteal sutures into the undersurface of the advancing flap are indicated with an X. The distal flap is aggressively defatted. **C** The flap is trimmed to fit the defect, wrapped around the alar rim and folded onto itself, reforming the rim. **D** Cosmetic result at 6 months postoperatively.

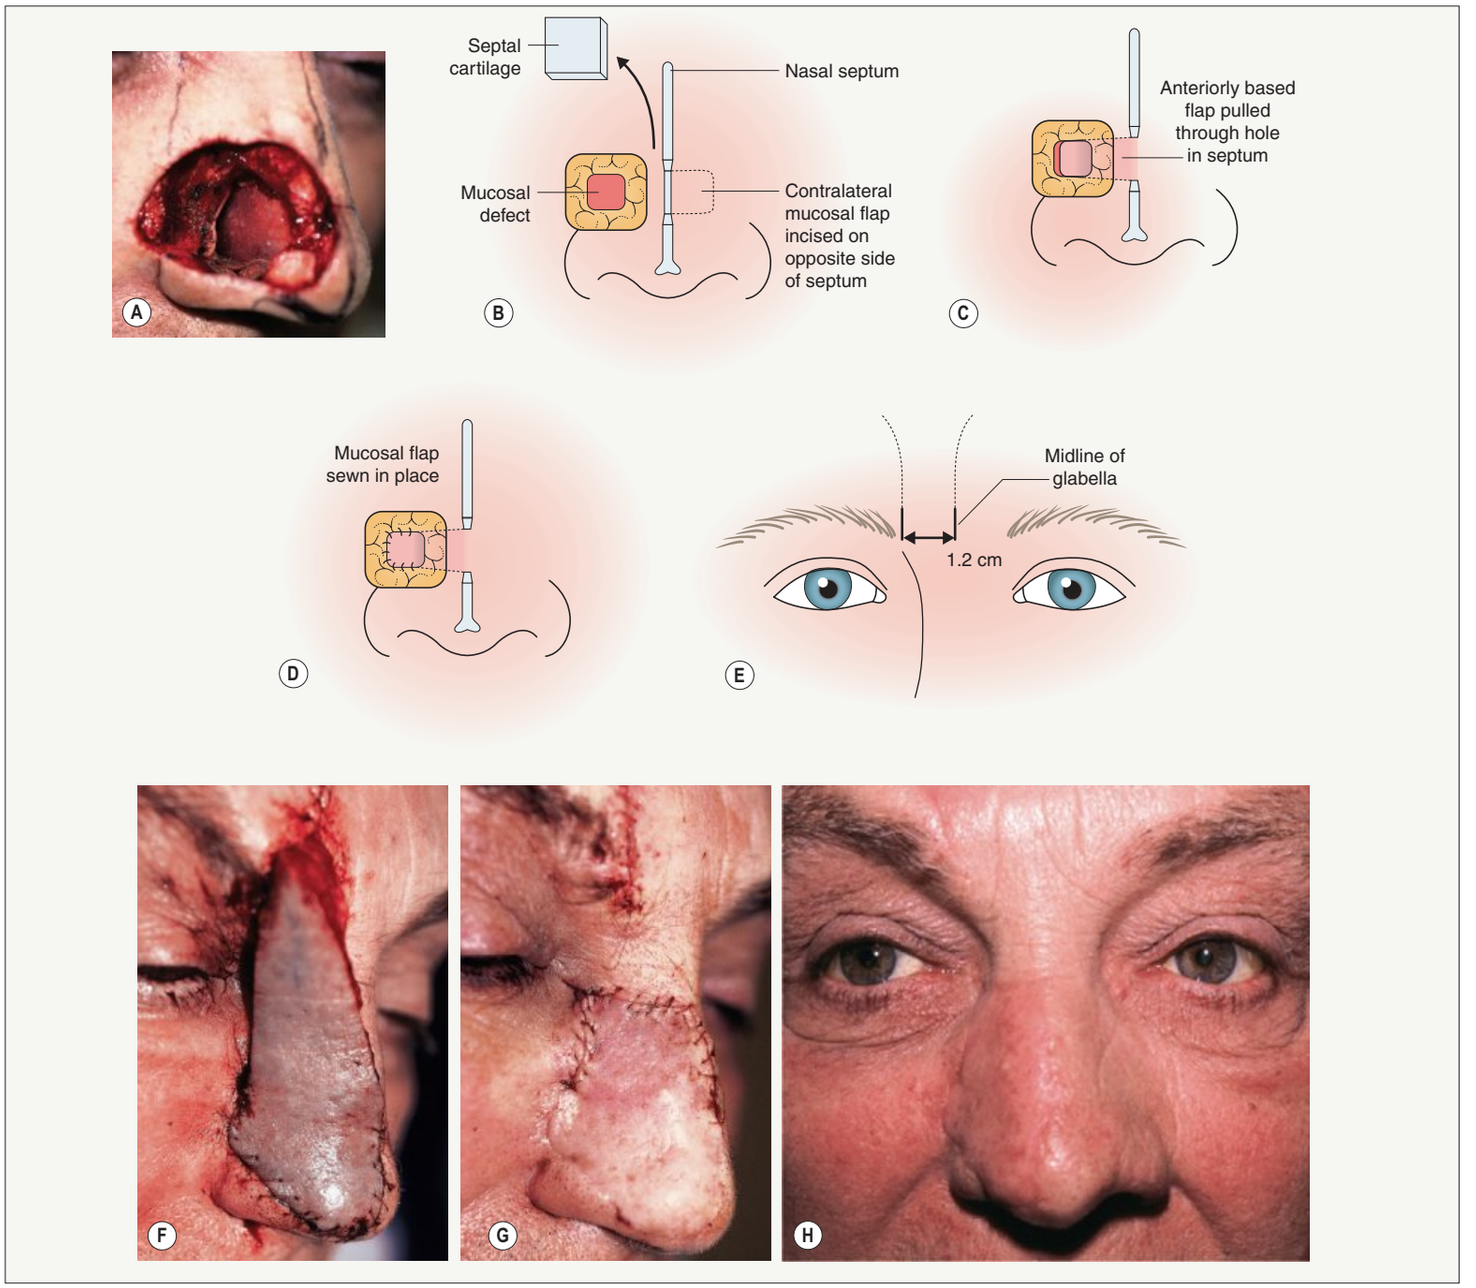

Fig. 147.29 Paramidline forehead flap. A Large full-thickness defect of the right half of the distal nose. **B** The mucosal defect is reconstructed with a contralateral septal mucosal pull-through flap. A U-shaped incision is made in the contralateral septal mucosa, based anteriorly and correctly sized to cover the defect. In addition, a 15 mm^2 cartilage graft is harvested from the nasal septum and used to reconstitute the structural integrity of the nasal sidewall. (Note that the remainder of the nasal sidewall cosmetic subunit and the right nasal tip subunit will be excised prior to reconstruction with the forehead flap.) **C** The mucosal flap is delivered through the septal defect into the right nasal vestibule. **D** The mucosal flap is sutured into place. **E** The design of the pedicle uses the midline of the glabella as the medial incision point; the lateral incision is made 1.2 cm lateral to the midline. Using a template, the forehead flap is then incised and raised on this 1.2 cm-wide pedicle. **F** Immediately postoperatively. **G** Immediately after takedown of flap 3 weeks later. **H** Early cosmetic results with no revision 2 months postoperatively.

pedicle stump provides for the most aesthetically pleasing repair of the cheek donor site.

Retroauricular flap

The two-staged retroauricular flap is useful for large defects of the helical rim, antihelix, and scapha (Fig. 147.31). The retroauricular flap is a random pattern flap without a single vascular pedicle. Nonetheless, because of the rich blood supply of scalp skin, this represents one of the best vascularized random pattern tissue importation flaps and easily supports cartilage grafts (if needed)[13,14].

After providing cartilage support (if needed; see Ch. 148), a foil template of the defect is fashioned and placed on the skin of the postauricular scalp. The distal flap may originate anywhere from the retroauricular sulcus to the posterior surface of the ear, depending on how far anteriorly it must reach. The incisions are then made, extending posteriorly to the hairline. The flap is dissected in a subcutaneous plane and the tip judiciously thinned to match the thickness of the skin at the defect. The flap is sutured into place being sure to minimize tension as the flap curls around the anterior helical rim. The use of bolster sutures can be very helpful in recreating the curve of the antihelix. Three weeks later, the pedicle is severed near the scalp and inset. The donor site can be closed primarily, with a skin graft, or left to heal by second intention.

Spear's flap

The inverted nasolabial (melolabial) pedicle flap, described by Spear[29], is useful for reconstruction of full-thickness defects of the ala that involve the attachment point of the lateral ala to the cheek (Fig. 147.32).

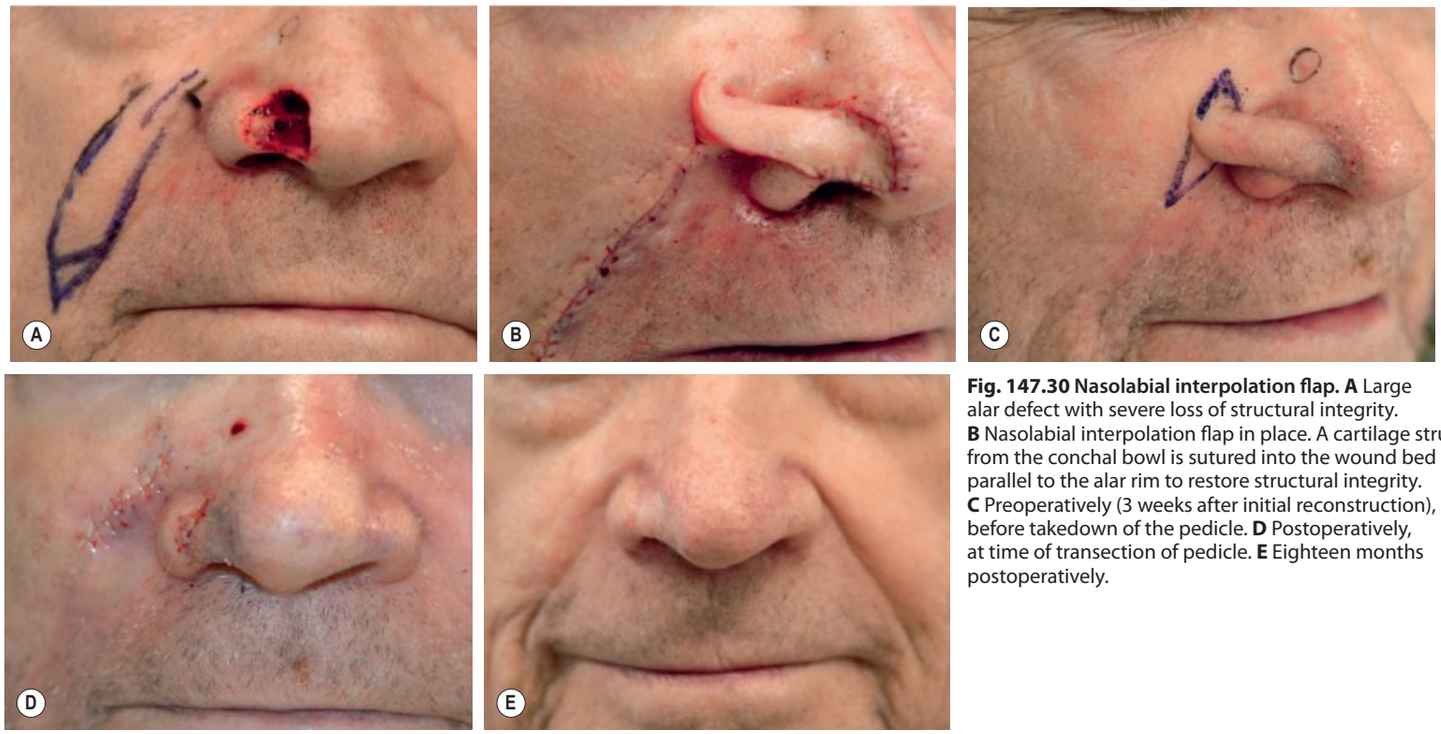

Fig. 147.30 Nasolabial interpolation flap. A Large alar defect with severe loss of structural integrity. **B** Nasolabial interpolation flap in place. A cartilage strut from the conchal bowl is sutured into the wound bed parallel to the alar rim to restore structural integrity. **C** Preoperatively (3 weeks after initial reconstruction), before takedown of the pedicle. **D** Postoperatively, at time of transection of pedicle. **E** Eighteen months postoperatively.

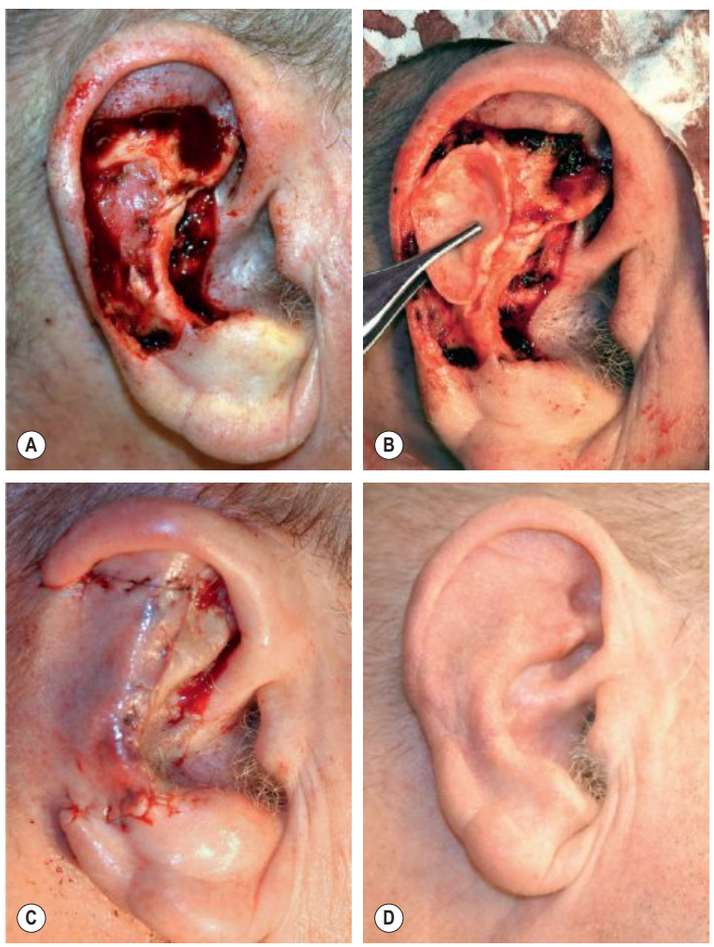

Fig. 147.31 Retroauricular flap. A Large defect of the anterior ear including substantial loss of cartilage of the mid antihelix and helical rim. **B** A cartilage graft harvested from the contralateral conchal bowl is used to restore structural integrity of the infrastructure of the auricle. **C** Closure of the retroauricular flap with resurfacing of the helix and antihelix. A split-thickness skin graft is used to resurface the crus of the antihelix and a portion of the conchal bowl. The pedicle from the retroauricular skin will be divided at 3 weeks. **D** Reconstructive results at 4 months.

The design of the Spear's flap is planned in a manner similar to that of the single-staged nasolabial interpolation flap, with the use of a foil template made from the contralateral ala. This template is placed upside down on the skin of the cheek lateral to the nasolabial fold and the flap is incised to a point just lateral to the superior edge of the defect. The flap is then dissected to a well-vascularized pedicle deep in the subcutis. Next, the flap is twisted on its pedicle and the edge of the mucosal defect adjacent to the nasal tip is sutured to the under-turned skin of the medial edge of the flap. The lateral portion of the under-turned flap is then sutured to the lateral mucosal defect. By folding the flap upon itself, the alar rim and the external surface of the ala are recreated, and the tip of the flap is carefully trimmed to match the contralateral ala. The surface of the flap is closed in a layered fashion. As with the other nasolabial flaps, the donor site is closed after widely undermining the skin of the cheek. Occasionally, a standing cone is created superolaterally to the new ala and it needs to be excised and sutured to complete the repair. Postoperatively, the newly formed ala may be positioned too far laterally and may require repositioning using a Z-plasty transposition of the alar base medially in a revision performed two or more months later.

Tunneled flaps

Tunneled flaps are variants of tissue importation flaps in that skin from a non-adjacent site is used to reconstruct a defect. They can be single-stage flaps, but may require revision because of the deformation the pedicle can create along the path of the tunnel. Examples of these flaps include the nasolabial to lip pull-through flap, the paranasal to ala flap, and the retroauricular pull-through flap (flip-flop flap)[30–32].

These flaps are based upon a pedicle that, like the PVYF but unlike other tissue importation flaps, is composed entirely of subcutaneous and muscular tissues and includes an axial vascular bundle within the pedicle. The flap skin and its pedicle are then passed through a tunnel of intervening skin (or cartilage) to the defect. As a result, it is a higher-risk flap than most PVYFs and tissue importation flaps. The initial key step is finding suitably vascular locations for these flaps. Sites most often chosen for flap placement include the nose, lip, and ear. Of note, the subcutaneous tunneling island pedicle flap (IPF) is not a traditional advancing IPF and technically is not a defect reconfiguration flap. Rather, it is a type of tissue importation flap (see Table 147.3).

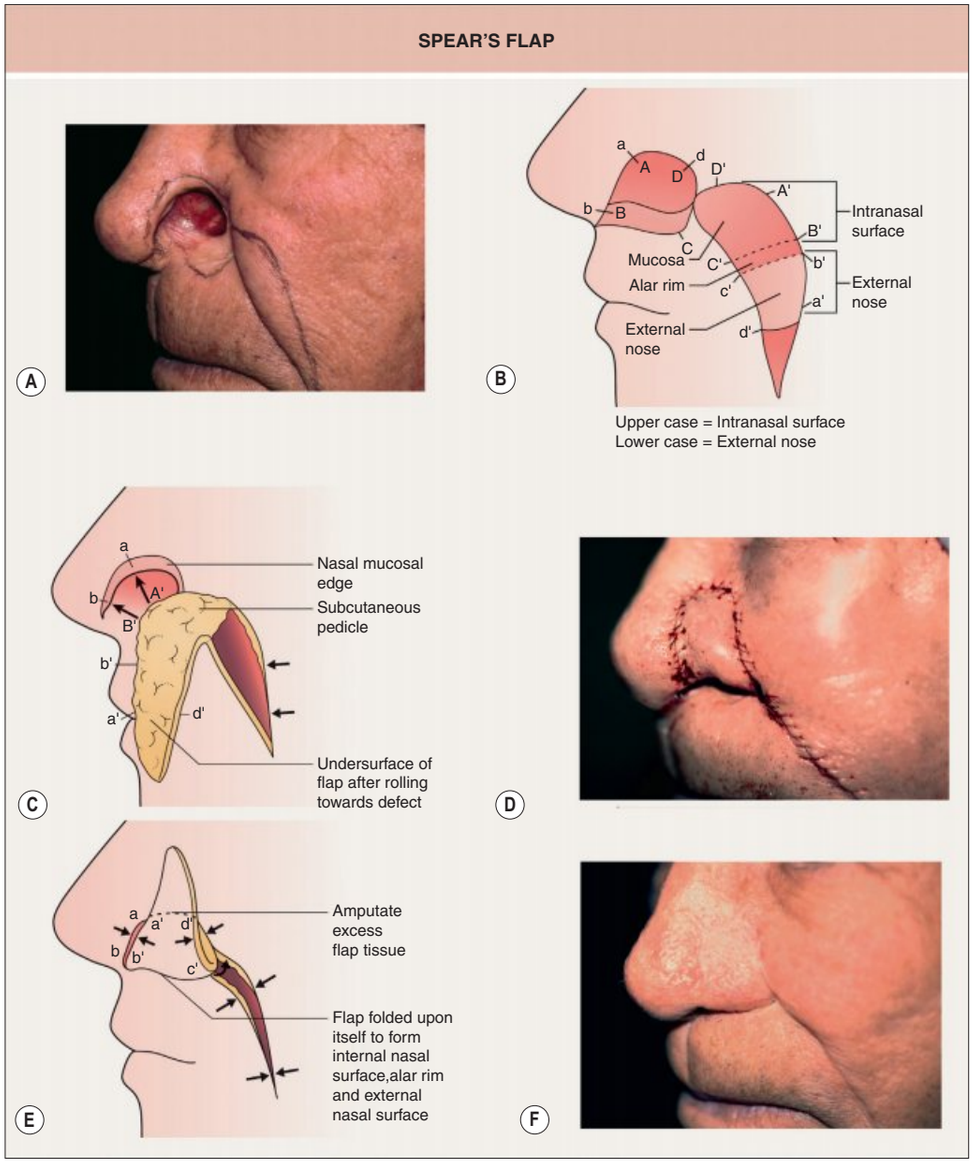

Fig. 147.32 Spear's flap. A Nasal defect involving the entire nasal ala and a portion of the nasal sidewall with the plans marked for a nasolabial transposition flap with a twist as described by Spear. **B** Flap incised prior to rolling towards defect. **C** Initial movements of flap. **D** Flap in place having been twisted on a subcutaneous pedicle sutured into the mucosal side of the defect and folded upon itself followed by suturing of the cutaneous side of the defect. **E** Corresponding schematic demonstrating placement of the flap and amputation of the distal portion. **F** Early results after second revision.

First, the donor skin is identified in an area with a suitably vascular pedicle. Careful measurements of both the defect and the length of the subcutaneous pedicle are necessary so that the latter reaches the defect under minimal tension. Next, the island is incised and a pedicle deep to the island is developed. It may be helpful to elevate the skin overlying the prospective pedicle to visualize its development. Once an adequate pedicle is developed, the skin between the base of the pedicle and the defect is undermined, creating a tunnel. The tunnel must be large enough for the tissue to pass and not be compressed; cautious defatting of the tunnel walls is often helpful to ensure ample room. This defatting also decreases the degree of fullness of the intervening skin created by the bulk of the pedicle. The length of the pedicle should be limited to three to four times its diameter, unless it is an axial flap. It is prudent to anticipate a 10%–20% "shortening" of the pedicle as it is rotated and stretched through the tunnel into the defect.

Larger alar defects can likewise be repaired with the *paranasal to ala tunneled flap* (Fig. 147.33). This flap also uses skin from the medial cheek, with a pedicle developed from the paranasal subcutaneous tissue and muscle. A short tunnel is developed between the flap and the defect through which the flap is passed. As noted previously, debulking of the soft tissue around the tunnel facilitates the passing of the flap and pedicle through it. The donor site is closed primarily and the flap is inset and sutured into the wound.

In the *retroauricular pull-through flap (flip-flop flap)*, an island of skin is pulled through a "tunnel" (created either by the surgeon or in the process of cancer removal) that goes through the cartilage of the conchal bowl in order to repair the anterior surface of the ear (Fig. 147.34). The principles of developing the pedicle and assuring that adequate space exists within the tunnel apply to this flap as well. The flap itself originates from the postauricular skin and is pedicled upon the rich vascular plexus of the retroauricular sulcus. It is flipped like a book page on its pedicle, pulled through to the anterior surface of the ear, and sutured. The donor site may heal by second intention, be closed (partially or completely) primarily, or grafted.

Combination Flaps

Not all defects can be conveniently closed with a single flap. There are times when a combination of closure techniques is employed, either because the defect is too large or because the defect involves more than one cosmetic subunit. These types of wounds are better closed using a combination of flaps or flaps plus grafts (see Fig. 147.31). Combination closures for very large defects are usually employed when a flap is able to close a significant portion, but not all, of the defect. In that situation, a full-thickness graft may be used to supplement a flap and complete the coverage of a defect. Grafts can be harvested from any of the common donor sites, depending on tissue match and the adequacy of donor skin (see Ch. 148). When reconstructing a wound after Mohs micrographic surgery (i.e. a high degree of certainty of cancer-free margins exists), tissue adjacent to the wound can be safely used as "Burow's grafts".

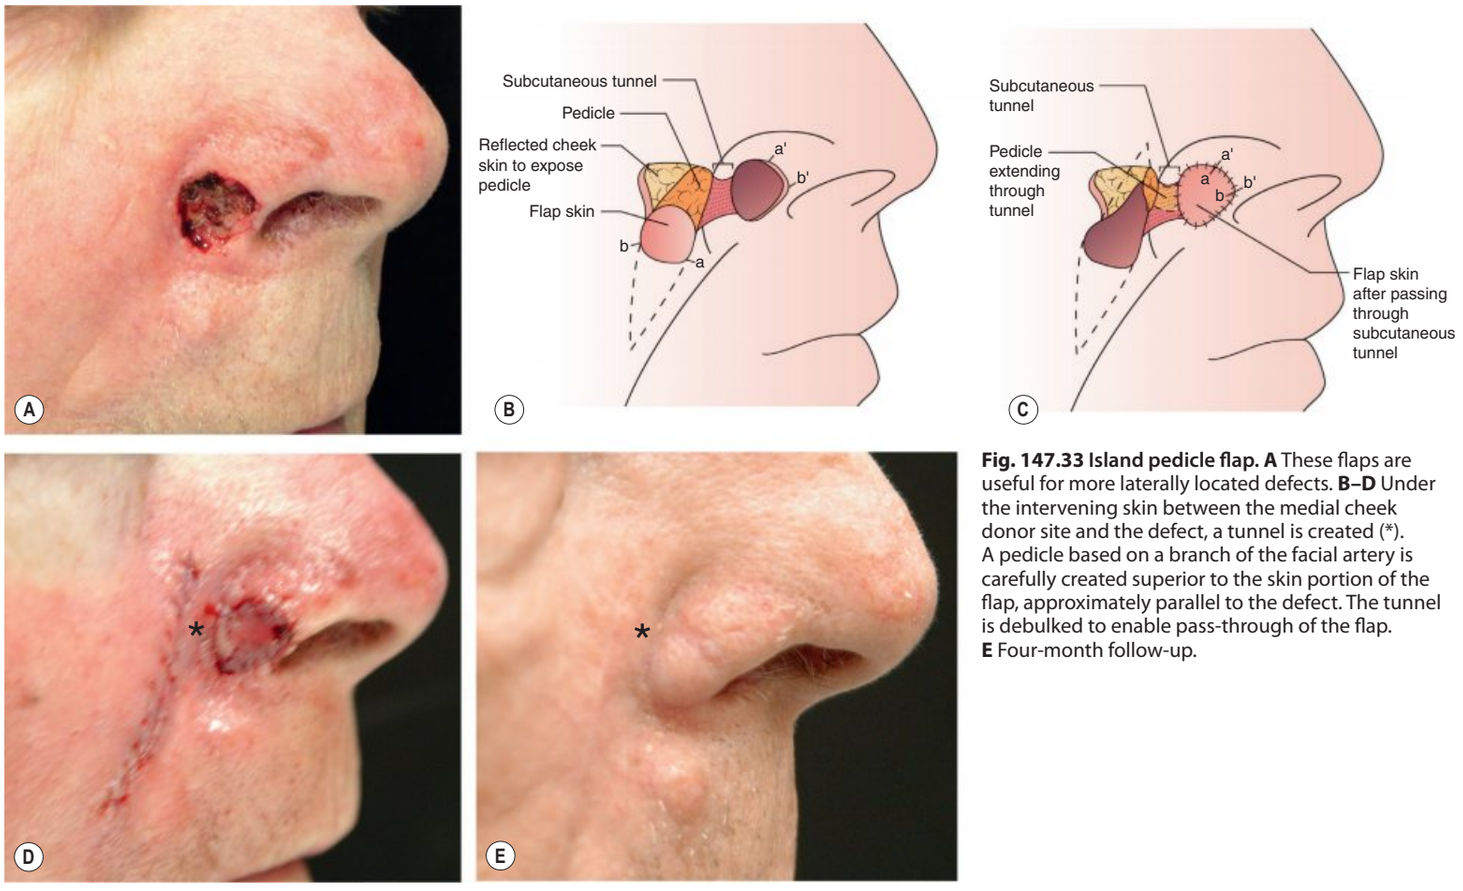

Fig. 147.33 Island pedicle flap. A These flaps are useful for more laterally located defects. **B–D** Under the intervening skin between the medial cheek donor site and the defect, a tunnel is created (*). A pedicle based on a branch of the facial artery is carefully created superior to the skin portion of the flap, approximately parallel to the defect. The tunnel is debulked to enable pass-through of the flap. **E** Four-month follow-up.

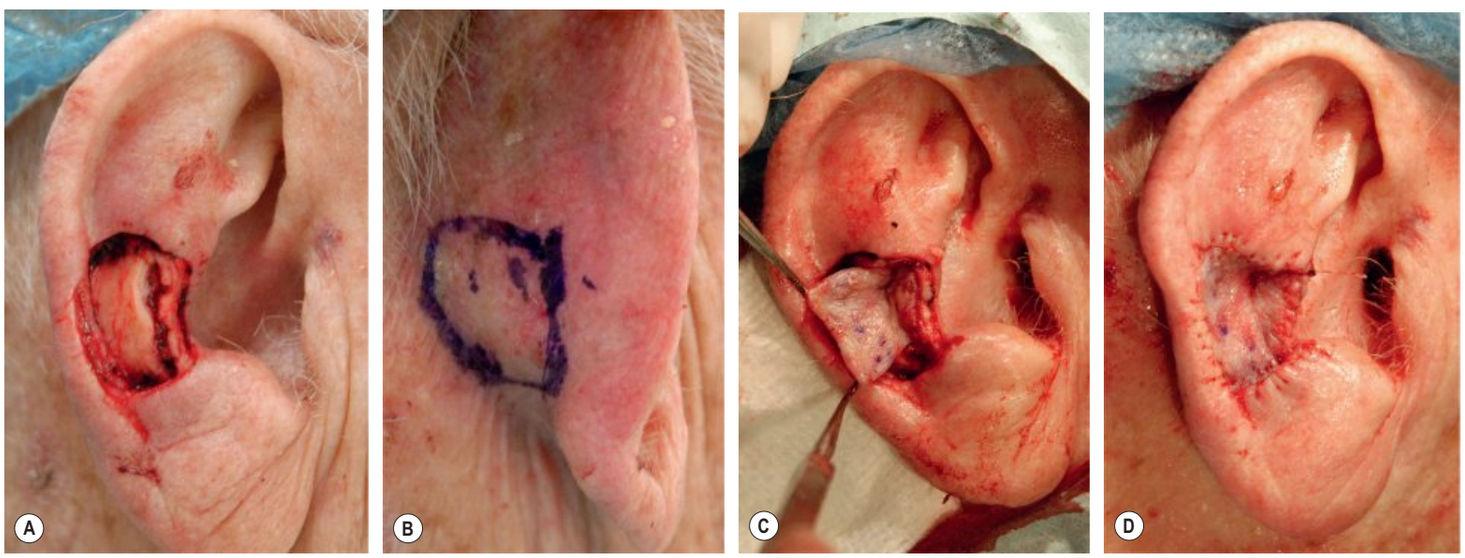

Fig. 147.34 Retroauricular pull-through flap (flip-flop flap). A This flap is ideally suited for large deep defects of the anterior ear, especially when cartilage is lost or compromised. **B** The donor site is designed for a book page-like flap movement, with the posterior-most portion of the flap sutured into the posterior-most aspect of the defect nearest the helix. **C** The flap being passed through the cartilage defect is based upon retroauricular subcutaneous and muscular tissue. **D** Flap sutured into place.

The Burow's triangle(s) of a flap can be defatted and trimmed to fit the remaining defect rather than being discarded.

Sometimes, flap and graft combinations are used to reconstruct defects that involve more than one cosmetic subunit. In such a wound, a flap is used to reconstruct one cosmetic subunit while a full-thickness skin graft is used to reconstruct the other, maintaining the "separateness" of each cosmetic subunit. The principle of maintaining the boundaries between cosmetic subunits is very useful in achieving a much less noticeable cosmetic result. If flaps or grafts are applied across cosmetic subunits, the aesthetic disruption that occurs becomes more visible.

There are also defects that involve multiple cosmetic subunits that are best repaired individually with different flaps. The same principle applies in that maintaining the integrity of individual cosmetic subunits is an important consideration in achieving a more natural and less noticeable result. These types of closures require creativity and sometimes ingenious methods to accomplish complete closure.

Table 147.4 summarizes previously discussed flaps and areas of the face where the specific flaps are most useful for providing excellent functional and aesthetic results.

COMMON LOCATIONS FOR FLAP TYPES
Burow's triangle displacement flaps
Burow's flap (single tangent advancement flap) and bilateral single tangent advancement flap (A-to-T flap)
• Distal, lateral nasal sidewall • Upper lateral lip • Infranasal upper lip • Eyebrow and suprabrow forehead • Mid helix
Unilateral or bilateral double tangent advancement flap (U- or H-flap)
• Forehead • Helix • Large defect of upper lip
Rotation flap(s)
• Upper cheek • Medial chin • Nasal dorsum (Rieger flap) • Lower eyelid
Defect reconfiguration flaps
Pedicled V-to-Y flap
• Upper lateral and mid upper cutaneous lip • Mucosal lip • Lateral chin and lower lip • Distal nasal sidewall • Preauricular cheek • Eyebrow
Tissue reorientation flaps
Rhombic transposition flap
• Nasal sidewall • Temple and lateral forehead • Lateral canthus and lateral lower lid • Lateral chin and lower lip • Superior and anterior helix
Bilobed transposition flap
• Nasal tip and supratip • Lower lateral lip • Periocular skin
Nasolabial transposition flap
• Alar defects, especially those involving the lateral portion of the ala • Lateral alar crease and distal nasal sidewall
Tissue importation flaps
Paramedian/paramidline forehead flap
• Large nasal defects • Moderate-size nasal tip defects • Nasal defects with loss of cartilage and/or nasal lining • Large medial canthus defects
Nasolabial (melolabial) interpolation flap
• Nasal ala and alar rim • Nasal tip • Mid upper lip
Melolabial flap with a twist (Spear's flap)
• Full-thickness alar defects involving the junction of the lateral ala and the cheek/upper lip
Retroauricular flap
• Large defects of the anterior ear or helix • Full-thickness defects requiring cartilage graft reconstruction
Subcutaneous tunneling island pedicle flap
• Inferior nasal defects • Medial upper lip • Conchal bowl and antihelical ear (flip-flop flap)

Table 147.4 Common locations for flap types.

POSTOPERATIVE CARE

Postoperative care after flap surgery varies from practice to practice. Some surgeons have the patient change the bandage once to several times a day, cleansing the wound at each bandage change. Others apply a bandage for a day or two and leave the sutured wounds open to air thereafter. Still others apply a single bandage at the time of the surgery and leave it undisturbed for up to a week. Regardless of how the postoperative care is accomplished, there are common goals to achieve during the postoperative period.

One of these common goals is to prevent postoperative bleeding. The first 48 hours is the time period during which bleeding and hematomas most commonly occur. Efforts to reduce these complications include meticulous intraoperative hemostasis and the postoperative application of pressure to the wound. Pressure can be applied by using taping techniques, pressure wraps, or specialized pressure garments. Normally, pressure becomes less important after 24 to 48 hours. In the patient at higher risk for bleeding, it may be necessary to maintain pressure for a more prolonged period of time. In some patients with a very high risk of postoperative bleeding, it may be helpful to use a tie-over bolster dressing directly over the wound to ensure constant firm pressure throughout the postoperative period.

Another common goal in the postoperative care of flaps is to reduce the risk of infection. All forms of infection can complicate the postoperative course and affect the cosmetic and functional results. Prevention of postoperative infections is covered in Chapter 151. However, good surgical technique and observance of sterile technique during reconstruction is paramount. One novel approach, particularly well-suited for cutaneous reconstructions, is the direct infiltration of the unclosed wound preoperatively with local anesthesia containing antibiotics. The benefit of intralesional nafcillin and clindamycin has been studied and this procedure is used routinely in some practices prior to reconstruction[33,34].

An additional important goal in the postoperative care of flap reconstruction is protection of the flap tissue from all environmental insults, including contamination, physical injury, temperature extremes, excessive movement and stretching of the sutured skin during the early postoperative period, and ultraviolet radiation. This is best accomplished by occlusive bandaging techniques and thorough education of the patient.

Presented here are the details of postoperative flap care as routinely implemented in one surgical practice. After the completion of flap reconstruction, a light bandage consisting of hypoallergenic tape over Steri-Strips™ is placed directly over the incision lines. The tape completely covers the sutured skin resulting in complete occlusion of the wound. A "bulky" secondary bandage is then applied on top of this thin primary bandage. The bulky bandage consists of rolled or fluffed absorbent gauze, which is affixed with hypoallergenic paper tape, using a technique of taping which applies downward pressure. This is accomplished by the placement of one end of the tape on the skin of one side of the wound and stretching it over the top of the bulky gauze and then attaching the other end to the opposite side of the flap under tension. This is repeated numerous times with thin, 1-cm-wide strips of tape until the bulky gauze is entirely covered and firmly affixed by the tape. The patient is instructed to remove the bulky secondary bandage 24 to 48 hours after surgery, leaving the thin, flat primary bandage in place. This bandage is left undisturbed and kept dry for the remainder of the week.

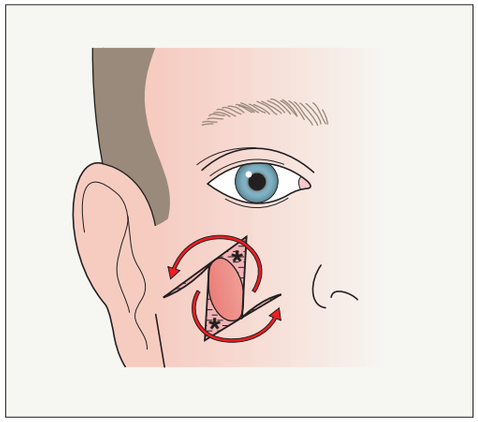
The patient returns to the office after 1 week for bandage removal, suture removal, and evaluation of the wound. Any evidence of hematoma, infection, or other complication is addressed. The skin is cleansed and another thin bandage consisting of Steri-Strips™ and hypoallergenic tape is applied for one more week. The patient is instructed again to keep this bandage dry and to remove it in 1 week (i.e. 2 weeks after the surgery). The patient is encouraged to contact the physician during the postoperative period if there are any problems and to return in 3 months for a final evaluation of the wound healing process. Minor revisions may be made at that time to optimize the aesthetic and functional results.

COMPLICATIONS

In the immediate postoperative period, the potentially serious sequelae are primarily postoperative bleeding and infection. Both adverse events

are rare if meticulous surgical technique is used[35]. Nonetheless, failure to recognize either complication and intervene appropriately can lead to disastrous postoperative results. Postoperative bleeding that results in a hematoma requires immediate attention. The most effective intervention is an immediate return to the operating suite to remove the sutures, evacuate the hematoma, locate and ligate the bleeding vessel, and re-suture the wound. Failure to do so risks flap necrosis. If a postoperative infection is present, immediate oral antibiotics and drainage of any abscess are required.

In the mid-postoperative period, the most common complication requiring intervention is the development of a hypertrophic scar or trapdoor deformity. This usually becomes evident about 4 to 8 weeks after surgery and occasionally develops despite wide undermining, appropriate flap thinning, and meticulous suturing technique at the time of surgery. Often, the patient is advised to aggressively massage the site many times per day. Massage and tincture of time often promote adequate remodeling of the healing wound. Occasionally, active intervention is necessary. Varying concentrations of intralesional triamcinolone acetonide injections may be helpful (5–40 mg/ml), depending upon the scar's location and thickness.



Late postoperative complications include persistent trapdoor deformity, surface irregularities, blunting or ablation of the junction between cosmetic units, and surface telangiectasia. Persistent trapdoor deformity and minor surface irregularities can be addressed as early as 6–12 weeks postoperatively with the use of a scalpel to plane the surface and dermabrasion or dermasanding to blend the planed surface. In order to redefine the junction between cosmetic units that may have been ablated by the placement of a flap (e.g. the alar crease in a nasolabial transposition flap), incising the area, thinning the subcutis, and re-suturing the skin edges to recreate the natural fold is usually all that is required. Laser ablation of telangiectasia around the incision lines of large nasal flaps can be done for any unremitting perincisional blood vessels.

Sometimes, regardless of proper patient selection, flap planning and suturing technique, some amount of postoperative refinements may be necessary. These vary from simple procedures to correct surface irregularities to more complicated interventions requiring further scalpel surgery. The key to a successful outcome from a postoperative intervention is recognizing the circumstances where an intervention would be helpful and then choosing the appropriate intervention. Understanding the normal sequence of healing after a surgical procedure helps the surgeon to decide when and by what means to intervene in this process.

Wound Healing Considerations 2556
Full-Thickness Skin Grafts 2557
Split-Thickness Skin Grafts 2561
Composite Grafts 2565
Free Cartilage Grafts 2566

Key features

- Free skin grafts are pieces of skin that have been severed from their local blood supply and transferred to another location
- Grafts for soft tissue reconstruction can be divided into four types: full-thickness skin grafts, split-thickness skin grafts, composite grafts, and free cartilage grafts
- In dermatologic surgery, grafts are most commonly used to repair defects created after removal of skin cancers; grafts also provide coverage and more rapid healing of leg ulcers
- The clinical situation determines the type of graft to be placed
- A working knowledge of the indications, techniques, donor site considerations, postoperative care, and postoperative complications of all types of skin grafting is essential for optimal soft tissue reconstruction

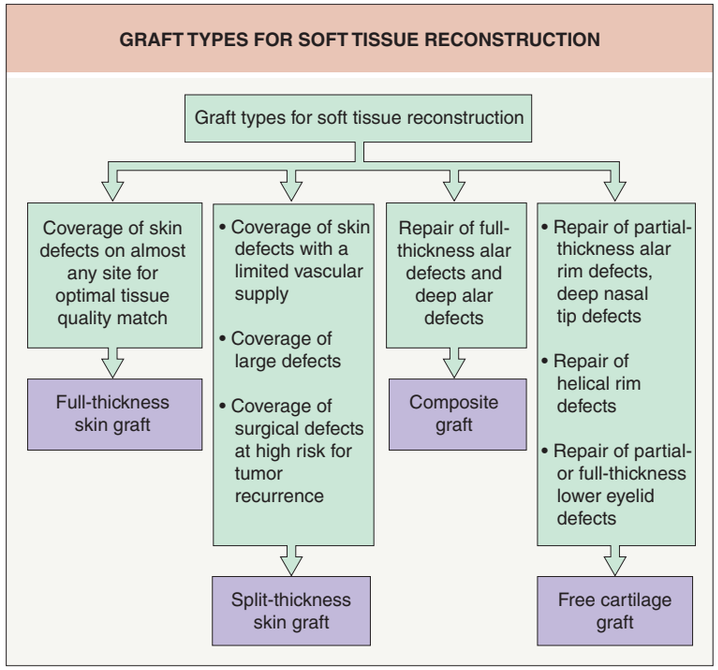

Fig. 148.1 Graft types for soft tissue reconstruction.

INTRODUCTION AND BACKGROUND

Skin grafting procedures originated approximately 2500 to 3000 years ago, when surgeons of the Hindu Tilemaker caste replaced noses amputated as punishment for theft and adultery with skin grafts harvested from the gluteal region[1]. It was not until the nineteenth century that skin grafting was reintroduced. In 1869, Reverdin's account of pinch grafting for leg ulcers was published; in subsequent decades, Ollier and Thiersch's accounts of thin split-thickness skin grafting, and Wolfe and Krause's accounts of full-thickness skin grafting, appeared in the literature. While these and other nineteenth-century surgeons used skin grafts to address only the most difficult problems of surgical management, skin grafting has since evolved into a reconstructive option that is routinely, and sometimes preferentially, used for the surgical repair of skin defects.

Free skin grafts are pieces of skin which have been severed from their blood supply and transferred to another location. They can be divided into four types: full-thickness skin grafts (FTSGs), split-thickness skin grafts (STSGs), composite grafts, and free cartilage grafts (Fig. 148.1; Tables 148.1 and 148.2)[2,3]. FTSGs are composed of the entire epidermis and the full thickness of dermis, including adnexal structures such as hair follicles and sweat glands. STSGs are composed of the full thickness of the epidermis and partial thickness of dermis. These can be subdivided into thin, medium, and thick grafts, depending on the amount of dermis included in the graft. Composite grafts are composed of at least two different tissue types, usually skin and cartilage. Free cartilage grafts consist of cartilage with its overlying perichondrium.

WOUND HEALING CONSIDERATIONS

Wound healing after skin grafting proceeds through a unique series of events[2,4]. The first 24-hour period following graft placement is termed the stage of plasmatic imbibition, during which fibrin glue attaches the graft to its recipient bed, allowing it to take up the underlying wound exudate and to become edematous, gaining up to 40% in weight. The graft thereby remains hydrated and obtains a supply of nutrients, which maintains graft vessel patency until revascularization begins. The fibrin beneath the graft is subsequently replaced by granulation tissue, which attaches the graft permanently to its bed.

With proper apposition of the graft to its bed, revascularization may proceed. Anastomoses begin to form within 48–72 hours of grafting between the recipient bed and pre-existing vessels in the dermis of the graft, a process known as inosculation. Vascular proliferation occurs next, with sprouting and budding of vessels in the graft and its bed. Even relatively avascular tissue may be grafted, as long as the avascular area is small and surrounded by a rich vascular supply. Through a process known as the bridging phenomenon, vascular connections arising from the vascularized part of the recipient bed allow blood flow to occur through pre-existing graft vasculature, so that nutrients reach the part of the graft overlying the avascular area. Full circulation is restored to the graft within 4–7 days.

Restoration of the lymphatic circulation parallels restoration of the blood supply over the first week. Epidermal proliferation occurs between the 4th and 8th day post-transplant and persists for several weeks. Degeneration of sebaceous and eccrine glands may occur initially, but subsequent glandular regeneration may allow partial function to be maintained. Graft reinnervation and return of sensory nerve function may begin as early as 2–4 weeks after grafting, although patients do not usually regain full sensation for many months.

If extension of the ischemic period occurs, decreased graft survival may result (Table 148.3). Hematoma or seroma formation, infection, or mechanical shear forces may disrupt the fragile vascular connections between the graft and its bed. These complications tend to affect FTSGs (which have a greater volume to nourish and revitalize) more than STSGs.

COMPARISON OF GRAFT TYPES USED IN SOFT TISSUE RECONSTRUCTION								
Graft type	**Tissue match**	**Nutritional requirements**	**Requirement for recipient bed vascularity**	**Infection risk**	**Graft contraction risk**	**Durability**	**Sensation**	**Adnexal functions**
FTSG	Good to excellent	High	High	Low	Low	Good to excellent	Good	Excellent
STSG	Poor to fair	Low	Low	Low	High	Fair to good	Fair	Poor
Composite	Good	High	Very high	Moderate	Low	Fair	Fair	Good
Free cartilage	NA	Moderate	High	Moderate	Migration or deformation possible, with subsequent resorption	Good	NA	NA

Table 148.1 Comparison of graft types used in soft tissue reconstruction. FTSG, full-thickness skin graft; NA, not available; STSG, split-thickness skin graft.

INDICATIONS, CONTRAINDICATIONS, ADVANTAGES, AND DISADVANTAGES OF GRAFT TYPES USED IN SOFT TISSUE RECONSTRUCTION				
Graft type	**Indications**	**Contraindications**	**Advantages**	**Disadvantages**
Full-thickness skin graft (FTSG)	Coverage of skin defects, usually located on the face or scalp, requiring an optimal tissue quality match	Avascular graft bed	Excellent color and texture match Minimal graft contraction	Time consuming Donor site requires closure Requires meticulous technique
Split-thickness skin graft (STSG)	Coverage of large defects and defects with a limited vascular supply or at sites at high risk for tumor recurrence	Defects near free margins Facial defects in cosmetically sensitive areas	Increased chance of survival Ease of application Ability to cover large defects Able to act as a "window" to detect recurrence of high-risk tumors	Suboptimal cosmetic appearance Decreased durability Presence of granulating donor site wound Greater graft contraction Special equipment required to harvest larger grafts
Perichondrial cutaneous graft	Repair of deep nasal tip and alar defects, especially those with exposed cartilage	Avascular graft bed	Thicker than FTSG Contract less than FTSG Increased chance of survival under conditions of vascular compromise (compared to FTSG)	
Composite graft	Repair of full-thickness alar defects or nasal tip defects (<2 cm in diameter) with cartilage loss	Defects >2 cm in diameter	Single-stage procedure May yield good functional and aesthetic results when used to repair appropriately sized defects	Greater risk of graft failure under conditions of vascular compromise Graft size limitations (<2 cm) Limited donor tissue available Donor site may require flap or complex closure Increased risk of infection and graft displacement
Free cartilage graft	Repair of defects of nasal ala, tip or sidewall, ear or eyelid requiring restoration of structural support or preservation of contour of free margins	None	Provide structural support for selected facial and ear defects	Donor site may be painful Increased risk of postoperative infection Increased risk of graft displacement

Table 148.2 Indications, contraindications, advantages, and disadvantages of graft types used in soft tissue reconstruction.

Even after the ischemic period is past, other factors may decrease the vascular supply nourishing the undersurface of the graft[2,3,5]. The most important of these is cigarette smoking or use of other nicotine-containing products,[5] but diabetes mellitus, protein deprivation, and severe trace element or vitamin deficiencies may also increase the risk of graft failure. Certain systemic medications, such as corticosteroids, chemotherapeutic agents, other immunosuppressive drugs and anticoagulants, may interfere with wound healing as well.

Other causes of graft failure include: insufficient vascularity due to necrotic debris within the recipient bed, hematoma, seroma, an avascular wound bed, previous radiotherapy, infection, excessive graft tension, mechanical shearing forces, and improper postoperative care (see Table 148.3)[2,3]. The most common infectious agents associated with graft failure include coagulase-positive staphylococci, β-hemolytic streptococci, and *Pseudomonas* spp. Pseudomonal infections are particularly common in auricular grafts. For all of these reasons, a thorough preoperative evaluation, meticulous intraoperative technique, and good postoperative care are essential to maximize graft survival.

FULL-THICKNESS SKIN GRAFTS

Indications/Contraindications

FTSGs are most commonly used to repair facial defects resulting from skin cancer removal. They may be used to repair defects at virtually any site, as long as the recipient bed has a sufficiently rich vascular supply to promote capillary regrowth and fibroblasts to supply collagen for graft adherence. Small avascular areas may be grafted due to the bridging phenomenon. Larger avascular areas, including patches of exposed bone, cartilage, tendon or nerve devoid of periosteum, perichondrium, peritenon or perineurium, respectively, are unable to support FTSGs. For this reason, FTSGs should not be placed over larger areas of avascular tissue.

Under the proper circumstances, FTSGs can provide excellent color, texture, and thickness match for facial defects because they include the full thickness of epidermis and dermis. Wound contraction is minimized since the full thickness of dermis is present, and adnexal structures remain intact[6]. FTSGs may be especially useful for the cosmetically and functionally acceptable repair of defects of the nasal tip, dorsum, ala and lateral sidewall, as well as the lower eyelid and ear (Fig. 148.2)[7].

Preoperative History and Donor Site Considerations

A thorough preoperative evaluation that includes questions regarding bleeding tendencies, alcohol use, use of anticoagulant medications (including aspirin and nonsteroidal anti-inflammatory drugs), and a history of hypertension can help assess the risk of excessive bleeding and clot formation beneath the graft[2,3]. Diabetes mellitus, nutritional deficiencies, cigarette smoking, or the use of other nicotine-containing

CAUSES OF GRAFT FAILURE	
Poor graft–bed contact	Hematoma
	Seroma
	Shearing forces due to excessive postoperative activity
	Shearing forces due to inadequate immobilization of graft
Poor recipient bed vascularity	Inadequate vascular bed (e.g. previous radiotherapy)
	Exposed cartilage, bone, tendon
	Nicotine-induced vasoconstriction
Infection	Coagulase-positive *Staphylococcus* spp.
	Beta-hemolytic *Streptococcus* spp.
	Pseudomonas spp.
Host factors	Diabetes mellitus
	Immunosuppression
	Poor general health
	Nutritional deficiencies, including hypoalbuminemia
	Systemic conditions with vascular compromise
Technique	Rough handling of tissue
	Excessive devitalized tissue in recipient bed due to cautery
	Increased tension on graft due to inadequate size
	Inadequate hemostasis
	Inadequate trimming of adipose layer
	Placement of upside-down graft (more common with STSG)
	Inadequate anchoring (composite and free cartilage grafts)

Table 148.3 Causes of graft failure. STSG, split-thickness skin graft.

Fig. 148.2 Full-thickness skin graft. A Full-thickness skin graft taken from the preauricular region was used to repair this defect of the right upper anterior ear. **B** Eight-week postoperative result.

products may increase the risk of graft failure, and any history of these should be identified preoperatively.

Selection of a donor site for full-thickness skin grafting depends upon the color, texture, thickness, and sebaceous qualities of the skin surrounding the defect (Tables 148.4 and 148.5). Most FTSGs are taken from sun-exposed areas above the shoulders whose color, vascular pattern, texture, and distribution of adnexal structures best match the skin surrounding facial defects. The thinnest grafts are usually harvested from the upper eyelid or the postauricular sulcus. Medium-thickness grafts are often harvested from the preauricular and cervical regions, while thicker grafts may be taken from the supraclavicular or clavicular region, conchal bowl, or nasolabial fold. Donor skin thickness, irrespective of site, will vary from one patient to another. It is therefore important to examine all sites carefully to find the best possible tissue match. This approach will ensure optimal donor site selection for each individual patient and surgical defect.

DONOR SITE CONSIDERATIONS FOR FULL-THICKNESS SKIN GRAFTS	
• Pattern of sun exposure • Color • Vascular pattern • Texture • Sebaceous quality	• Skin thickness • Skin consistency • Sufficient tissue available for harvesting • Ability to camouflage donor site scar

Table 148.4 Donor site considerations for full-thickness skin grafts.

SUMMARY OF POSSIBLE FULL-THICKNESS SKIN GRAFT DONOR SITES FOR DEFECTS IN DIFFERENT LOCATIONS	
Defect sites	**Donor sites**
Nasal dorsum, sidewalls, tip	Preauricular region, supraclavicular region or lateral neck (if large)
Nasal tip, ala	Preauricular region, conchal bowl, nasolabial fold
Junction of nasal dorsum/tip	Burow's graft
Ear	Postauricular sulcus, preauricular cheek
Lower eyelid/ medial canthus	Upper eyelid, postauricular sulcus
Scalp	Supraclavicular region, lateral neck, inner upper arm
Forehead	Burow's graft, supraclavicular region, lateral neck, inner upper arm (if large)

Table 148.5 Summary of possible full-thickness skin graft donor sites for defects in different locations.

A regional approach may, at times, be used to obtain the best possible match for a given defect. Grafts taken from redundant upper eyelid skin may be used to repair lower eyelid defects, providing a good color and texture match in addition to a well-camouflaged donor site scar. Grafts used for lower eyelid defects should be oversized by 100%–200% to allow for contraction and to avoid ectropion. Due to its relatively large size and inconspicuous location, postauricular skin may also be useful as a donor site for eyelid and auricular defects. Because postauricular skin is relatively non-sun-exposed, grafts harvested from this region may not provide a good color or texture match for other facial defects.

Preauricular skin is more versatile and can be used to repair most nasal defects, since the thickness and degree of sun exposure of these areas tend to be comparable. Donor site scars in this region can be easily camouflaged, as in facelift surgery, to provide a cosmetically desirable result. Even bearded individuals have a 1–2 cm hairless zone in the preauricular region. Care must be taken not to harvest hair-bearing skin in grafts taken from this area. Accidentally including mature follicular units may produce undesirable hair growth within the graft. Hair-bearing skin from the temporoparietal region may be used to repair eyebrow defects, where survival of the follicular units after transplantation may produce a superior cosmetic result. Skin from the nasolabial fold or the conchal bowl can sometimes be used to graft small nasal tip or ala defects with good tissue match[8]. At times, sufficient skin laxity may be present, particularly on the nose or forehead, to allow for partial defect closure, utilizing the adjacent Burow's triangle as a FTSG to repair the remainder of the defect, providing an excellent tissue match[9–11].

For larger defects requiring FTSGs of sun-damaged skin, such as the forehead and scalp vertex, the supraclavicular region or lateral neck can be used as donor sites. Again, care must be taken not to harvest

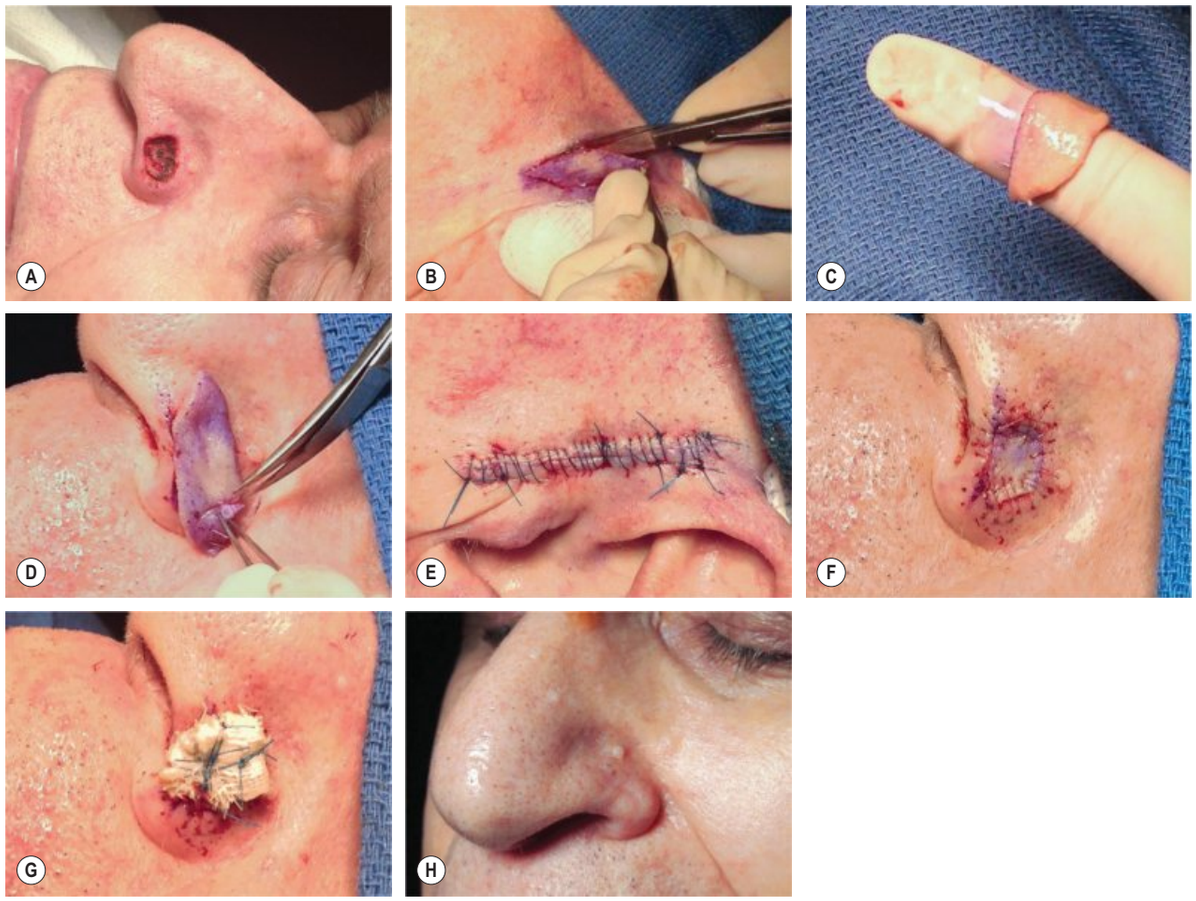

Fig. 148.3 Placement of a full-thickness skin graft. A Defect of the left nasal ala, measuring 1.8 × 1.2 cm, is present after removal of basal cell carcinoma via Mohs micrographic surgery. A preauricular donor site will provide the best match based upon color, sebaceous quality, degree of photodamage, and thickness. **B** With a sterile marker, a template has been made from the periphery of the recipient site and the template is then used to produce an inked margin at the donor site (center of wedge). Next, Burow's triangles are outlined on either side of the template. Marking the donor site prior to injecting local anesthesia prevents incorrect sizing due to tissue stretch from lidocaine infiltration. The donor site is excised with a scalpel to the level of the subcutaneous fat. **C** The graft is carefully defatted with curved iris scissors so that only the white, glistening surface of the dermis remains. **D** The full-thickness skin graft is trimmed with curved iris scissors to ensure a perfect fit. **E** The preauricular donor site is closed primarily. **F** Full-thickness skin graft sewn into place with 6–0 fast-absorbing gut sutures. **G** Xeroform™ bolster sewn into place over the full-thickness skin graft with 5–0 polypropylene tie-over sutures. **H** Sixteen-week postoperative result. The graft shows good color and texture match with the surrounding skin.

unwanted hair along with the graft. These donor sites are often more difficult to camouflage, especially in areas that might not always be covered by clothing, and must be carefully oriented. Although their color and texture match may be suboptimal, areas below the neck with thin, redundant skin, such as the upper inner arms, forearms and inguinal area, can also be considered as donor sites.

Description of Technique

Varying techniques for harvesting and placing FTSGs have been described[2,3,9–11]. To perform a FTSG, a template of the defect is first made, using any flexible material, such as gauze, Telfa™ or aluminum foil, which can be bent to conform to the defect (Fig. 148.3A). After marking the periphery of the recipient site with a sterile marker, the template material is pressed against the defect, and the resulting outline of the inked margin serves as a guide to cut a perfect template. The template is applied to the donor site, and inking material is applied around it (Fig. 148.3B). The graft should be 3%–5% larger than the true template to allow for the natural contraction and shrinkage of the graft after it has been harvested. Often, just cutting around the outside of the inked margin accounts for this extra "safety" skin. For eyelid defects, grafts should be oversized significantly to minimize the risk of ectropion. Marking the donor site prior to local anesthesia prevents incorrect sizing due to tissue stretch from lidocaine infiltration. It is important to note that a donor site ellipse with a 3:1 ratio may not always be required, allowing for smaller donor defects[12].

After the donor site is marked, local anesthesia is injected into the donor and recipient sites. Epinephrine (adrenaline) may be used without compromising graft survival. If waterproof ink is not available for template marking, the outline of the template may be scored on the donor site with a needle. The donor site and recipient beds are then scrubbed with an antibacterial preparation such as povidone–iodine (especially around the eyes and ears) or chlorhexidine, excess scrub is removed, and sites are draped with sterile towels.

The donor site is excised with a scalpel to the level of the subcutaneous fat (Video 148.1). The graft is placed in a sterile bowl or Petri dish containing sterile normal saline, where it may remain for up to 1–2 hours. Grafts may be utilized up to 24 hours after harvesting if refrigerated or kept on ice. Before suturing the graft into place, defatting should occur. This is an essential step, since direct contact between the graft and its bed promotes connections between existing vessels as well as new vessel growth and nutritional support from the base of the defect. Adipose tissue adherent to the graft is poorly vascularized and is therefore not an effective medium for vessel growth between the graft and its bed.

When defatting is performed, the graft is placed dermal-side-up on the fingers or in the palm. All fat is trimmed from the underside using sharp scissors (Video 148.2). Fat is adequately removed when all of the yellow globular material is gone, leaving a white glistening dermal surface (Fig. 148.3C, Video 148.3). If indicated, part of the dermis can also be trimmed to allow for differences in recipient site depth, although adnexal structures may be removed in the process, potentially altering the cosmetic result. The graft is then placed dermis-down in its bed, and rotated and trimmed if necessary, to achieve a perfect fit (Fig. 148.3D, Videos 148.4 and 148.5). While one surgeon is trimming the graft, another may close the donor site, usually in a linear layered

fashion with bilateral removal of standing cones (Fig. 148.3E). For conchal bowl donor sites, a 2- or 3-mm punch biopsy instrument may be used to remove full-thickness discs of cartilage, thereby facilitating second intention healing from the underlying dermis.

Contouring of donor skin in FTSGs may be challenging, particularly when repairing defects on the nasal tip, ala, lateral nasal sidewall, helical rim, and eyelid[13]. Graft contouring often requires multiple trial placements within the recipient bed, as well as multiple trimmings, to obtain an optimal result. Removal of cartilage not needed for structural support from the recipient site may increase the chance of graft survival, particularly for auricular defects, without compromising the aesthetic appearance of the repair[14].

Securing the Graft

Perimeter sutures, basting sutures, support dressings, or a combination of any or all of these can be used to anchor the FTSG. Depending upon the graft's size, four to eight interrupted 4–0 or 5–0 absorbable or non-absorbable sutures may be placed at opposite edges of the graft periphery (e.g. at 3, 6, 9 and 12 o'clock) to tack down its four quadrants. A simple running suture, such as 6–0 fast-absorbing chromic gut suture, may then be placed around the graft's perimeter (Fig. 148.3F, Video 148.6). Great care is taken to achieve perfect epidermal wound approximation. The running suture is placed in almost epicuticular fashion, passing the needle first through the graft and then through the surrounding skin. Placing the suture slightly higher in the dermis on the graft side and slightly deeper in the dermis of the surrounding skin makes suture placement easier, prevents tenting of the graft edges, and maximizes graft–recipient bed contact.

Using tissue adhesives in full-thickness skin grafting has been investigated. In a pilot study, it was found that applying cyanoacrylate tissue adhesive to secure FTSGs to their recipient bed wound edges produced cosmetic results essentially identical to those achieved with suturing[15]. Because these adhesives set virtually instantaneously, the graft must be perfectly trimmed and aligned before adhesive application, since fine adjustments in positioning the graft's edges are not easily made. Tissue adhesives may represent a time-saving alternative for securing the periphery of certain grafts, particularly those in relatively immobile areas such as the temple, forehead, and distal nose.

Basting or quilting sutures, usually simple interrupted 6–0 fast-absorbing gut sutures, can occasionally be placed to secure the central portion of the graft. They can be useful in securing large grafts to provide extra support against movement, as well as grafts placed on a concave surface where tenting could possibly occur. All sutures should be snug, but not strangulating, so as not to compromise graft survival.

Immobilization of the graft over its bed can be maximized with pressure dressings. Classically, tie-over bolster dressings have been employed to immobilize grafts, using anchoring stents to ensure direct contact between the graft and its bed[2,3]. These stents may consist of various materials including Xeroform™ gauze (bismuth tribromophenate-petrolatum-impregnated gauze), cotton balls, foam rubber, sponges, plastic beads, or disks. Although sutures or skin staples are usually employed to anchor the stent, adhesive wound closure tapes or Steri-Strips™ can also be applied to exert even pressure on the bolster[16]. Adherence of the dressing to the graft, which tends to pull the graft from its bed at the time of dressing removal, is minimized by first applying petrolatum ointment, a non-adherent contact dressing, or Xeroform™ gauze to the graft site. Pressure or tie-over dressings help immobilize the newly placed graft during the critical period of revascularization, thereby preventing hematoma or seroma formation. While such dressings may not be necessary to secure very small FTSGs[17], a recent literature review found that graft take, cosmetic outcomes, and postoperative complications after use of either tie-over bolsters or quilting sutures were comparable[18].

The simplest bolster consists of Xeroform™ gauze alone, which is molded and placed to apply pressure to the graft. One end of each peripheral non-absorbable suture is cut long, to a length of approximately 3–6 cm, and its opposing suture is left uncut (Video 148.7). The suture ends can then be tied over the dressing two at a time (i.e. 12 o'clock to 6 o'clock and 3 o'clock to 9 o'clock) to secure the bolster (Fig. 148.3G, Video 148.8). Alternatives to tie-over sutures include the running bolster suture, staples, and the "Lilliputian" technique[19,20]. A light dressing consisting of Telfa™ and Hypafix® may be placed over the graft. A pressure dressing should be placed over the donor site for 24 hours.

Postoperative Care

After the pressure dressings are removed, careful wound care should be performed once to twice daily. One method is to gently clean both the donor site and the area immediately surrounding the bolster with hydrogen peroxide to remove all crusts, followed by application of petrolatum ointment (Vaseline®). The bolster is not disturbed until dressing removal at 1 week, at which point the bolster and all tie-over sutures are removed. Steri-Strips™ may be applied to the donor site as needed after suture removal.

The ideal graft is light pink when the bolster is removed. Its color may range, however, from pink or red to darker blue or purple, depending on the extent of graft revascularization. Patients should be cautioned about these color changes beforehand. A bluish tinge may be a sign of ecchymosis rather than graft failure. At the 1-week time point, a white graft is a sign that the graft has not revascularized and will fail, requiring the underlying wound to heal secondarily. A black graft signals necrosis and is also undesirable. It is possible that the entire epidermal surface may become black and necrotic and then slough without adversely affecting the graft's dermal portion, as re-epithelialization can occur from adnexal structures and the epithelial edges, with an acceptable cosmetic result. Therefore, eschars should not be debrided, since they can serve as natural dressings under which healing will progress. Patients should be counseled that the graft's vascular supply remains fragile for weeks. For this reason, trauma, including direct shower water to the area, and excessive activity should be avoided for an additional 1 to 2 weeks.

When there is a good color and texture match between the FTSG and the surrounding skin, the cosmetic result is excellent (Fig. 148.3H).

Variations/Unusual Situations

Purse-string suture

The purse-string suture is a subcuticular stitch placed around the periphery of a circular or oval surgical defect[21]. This type of suture allows partial defect closure by advancing skin from the entire periphery of the wound and may help to cover areas of exposed cartilage or bone at the wound edges that could inhibit graft take. In addition, the graft required to cover the remainder of the defect is greatly reduced in size due to an ~50% decrease in the defect area. Because of this reduced defect size, the graft needed to complete the repair may be harvested from traditional preauricular, postauricular or supraclavicular donor sites, which provide the best color, texture, and thickness match for most sun-exposed areas. Furthermore, FTSG placement decreases the risk of significant wound contraction, resulting in better cosmetic and functional results than would be produced by split-thickness skin grafting or second intention healing.

Large scalp defects extending to bone can present a significant management challenge, which can be handled by placing a purse-string suture followed by a galeal hinge flap[22]. After purse-string placement, the galea aponeurotica adjacent to the scalp defect is scored with a scalpel, and a partial-thickness galeal flap of sufficient size to cover all or a portion of the exposed periosteum or bone may be dissected free and transposed into place, using the same motion as turning a page of a book. This hinged galeal tissue serves to recreate the vascular bed required for successful graft placement and thus permits repair of deep and often difficult scalp defects in a single operative session.

Burow's grafts

Defects of the nasal sidewall and dorsum, and sometimes of the forehead, lateral neck or other areas, may be repaired with Burow's grafts[9–11]. Because Burow's grafts utilize skin adjacent to the defect, they tend to provide a cosmetically superior match compared to grafts harvested from distant locations. In general, these grafts are harvested from the skin superior to the defect if on the nose, and medial or lateral to the defect if on the forehead. The Burow's triangle is excised (see Ch. 146) and the resulting donor defect is closed primarily, thereby partially decreasing the original defect size. The triangle is defatted, trimmed, and sutured into the defect. Operating time is decreased because a separate donor site is not required. Burow's grafts tend to be limited in size. When insufficient laxity is present for partial donor site closure, or if the Burow's triangle is not sufficiently large to cover the remaining defect, alternative donor sites should be sought.

Deep nasal defects

Deep postsurgical defects on the nose may, at times, pose a challenge for repair. Delaying FTSG placement for 12 to 14 days may increase the likelihood of graft survival over defects of the nasal tip and ala with denuded cartilage[2,3]. Also, when tissue loss is deep in these areas, delaying skin grafting for 7 to 14 days may allow granulation tissue to fill in the defect such that a better contour may ultimately be achieved[2,3]. Because the early granulating wound produces an excellent vascular bed, delayed grafting may be considered in patients with reduced wound bed vascularity, e.g. those who smoke or have had previous radiotherapy. At the time of delayed graft placement, the wound bed is debrided by rubbing with dry gauze and the wound edges refreshed by scraping them with a scalpel oriented perpendicular to the wound edges. Prophylactic antibiotics are often prescribed when placing delayed grafts.

If a depressed defect is anticipated, but immediate reconstruction is preferred, dermal grafts can be used as tissue filler prior to FTSG placement[24]. Dermal grafts can effectively fill the defect, with little risk of resorption, and eliminate the need for a more complicated repair choice. The "drumhead" graft repair of deep nasal alar defects involves application of an overlying rigid plastic suspension coupled with an undersized graft, thereby preventing graft depression and nasal valve collapse; a cut portion of the periphery of the sterile plastic packaging from a suture packet can serve as the plastic suspension[25]. It enables the graft to remain apposed to the recipient bed, suspended as it would be in its natural form if it were supported both by soft tissue and by nasal cartilage. A bolster can be placed overlying the graft.

Perichondrial cutaneous grafts (PCCGs) are actually composite grafts composed of full-thickness skin and subjacent perichondrium; PCCGs may be used as substitutes for FTSGs when reconstructing deep nasal tip and alar defects, particularly those with exposed cartilage[26,27]. PCCGs are harvested from the conchal bowl, utilizing the subperichondrial plane as the plane of dissection. The cartilage is not removed, making this graft more analogous to a FTSG than a cartilage-containing composite graft. The advantages of PCCGs over FTSGs include the following: PCCGs are thicker, have a greater chance of survival under conditions of vascular compromise, contract less than FTSGs, and may achieve better skin texture match on the distal nose due to the sebaceous nature of conchal bowl skin.

Postoperative Complications

Complications of full-thickness skin grafting can be divided into short-term problems of graft failure and long-term functional and cosmetic problems[2,3]. Short-term problems include infection, hematoma, seroma, and shearing of the graft over its bed. These problems are significant when they occur, but can usually be avoided. Infection after grafting of facial defects, in particular, is not often encountered, and oral antibiotics are not routinely given postoperatively. Nevertheless, it is important to be gentle while handling tissue intraoperatively and to minimize devitalized tissue created by electrocoagulation to minimize the risk of infection. Prophylactic oral antibiotics covering *Staphylococcus* and *Streptococcus* spp. may be helpful in selected patients, especially those with diabetes mellitus, immunosuppression, or a prolonged intraoperative time. Grafts on the ears, fingers, and legs may benefit from prophylactic antibiotics, as these sites can be prone to postoperative wound infections.

Hematoma and seroma formation can be avoided by meticulous intraoperative hemostasis, pressure dressings, and postoperative caution. After consultation with the patient's internist, cardiologist, or primary care physician, patients may be instructed to avoid aspirin for 10 days before surgery, nonsteroidal anti-inflammatory drugs for 5 days before surgery, and alcohol for 2 days before and 2 days after surgery. In the past, patients taking antithrombotic medications were advised to discontinue them before surgery if their internist or cardiologist was in agreement. The current recommendations for management have, however, changed. While the risk of bleeding complications increases slightly if oral anticoagulants are not discontinued, most dermatologic surgeons do not routinely request that these medications be discontinued preoperatively, since the risk of morbidity from hemorrhagic complications is minimal compared to that of the thrombotic events potentially associated with their discontinuation[28]. Patients are also advised not to engage in vigorous activity, heavy lifting, or bending for at least 2 weeks postoperatively. The latter measures help to inhibit graft movement and supplement the bolster's effectiveness in minimizing shearing of the graft over its bed.

Long-term complications of FTSGs consist of cosmetic and functional problems. It is imperative to stress to the patient prior to graft placement that FTSGs usually take months to look natural. Preoperative counseling may help to alleviate fears concerning the graft's appearance during the first weeks after bolster removal. Make-up can usually be applied 3–4 weeks after grafting. It is important to note that FTSGs are often depressed during their first 2–4 weeks. This depression will usually correct itself within 4–6 weeks.

Although careful donor site selection will minimize the color, texture, and contour deformities that can occur, patient and physician satisfaction with the cosmetic result may not be complete after healing has finished. Spot dermabrasion or laser resurfacing has traditionally been performed at 6 weeks to 6 months after grafting to correct differences in elevation between the graft and its surrounding skin, as well as to improve color and texture mismatch[29]. While studies have focused on pulsed dye laser (PDL) treatment of postsurgical scars rather than FTSGs or STSGs, a meta-analysis found an average 72% rate of improvement or no recurrence of hypertrophic scars and keloids with PDL therapy[30]. Graft hyperpigmentation can be addressed with a brief course of topical hydroquinone and/or tretinoin.

Functional complications of FTSGs occur primarily as a result of wound contraction. Grafts contract secondary to the centripetal movement of unopposed elastic fibers. A variable amount of shrinkage can therefore be expected, depending upon donor site thickness and elasticity[6,31]. In one study, it was found that the area of FTSGs contracted by a mean of 38% by 16 weeks after placement, with grafts applied to the periorbital area and nose contracting more than those on the scalp and temples[32]. Contraction usually increases as graft thickness decreases, and it is thought to occur in the fibrous layer under the graft, either in the bed itself or in the layer of scar tissue wedged between the graft and its bed[6]. Complications due to graft contraction are usually minimal in FTSGs. If wound contraction does produce functional or cosmetic abnormalities, revisional surgery may be needed.

Future Directions

For defects with an inadequate vascular bed, full-thickness skin grafting may not be possible, necessitating repair with a less cosmetically elegant STSG. High-density, porous, polyethylene implants have therefore been designed which permit ingrowth of fibroneovascular tissue without changing the size or shape of the implant[33]. When these prefabricated implants were placed in rabbits, it was found that they developed sufficient vascularity to sustain FTSGs. This technology holds promise for patients with deep nasal and ear defects, in whom an anatomically correct structure could be implanted, after which time would be allowed for fibrovascular tissue ingrowth, with full-thickness skin grafting performed later for a superior cosmetic result.

Progress is also being made on incorporating complex blood vessels into bioengineered skin equivalents, while 3D printing techniques have been investigated as a means of generating skin equivalents. Recently, a vascularized, perfusable skin graft was fabricated via 3D printing utilizing a bioink that contained human foreskin dermal fibroblasts, endothelial cells, and placental pericytes suspended in rat tail type I collagen to form a dermis. This was followed by 3D printing with a second bioink containing human foreskin keratinocytes to form an epidermis. *In vitro*, the keratinocytes replicated and matured to form a multilayered barrier while the endothelial cells and pericytes self-assembled into interconnected microvascular networks[34]. With these advances in technology, it seems possible that, at some point, 3D printing of complex tissue-like constructs to use as skin grafts could become routine.

SPLIT-THICKNESS SKIN GRAFTS

Split-thickness skin grafts (STSGs) consist of epidermis and a portion of the dermis. These grafts vary in thickness from ~0.005 to 0.030 inches (0.13–0.78 mm), and are classified as thin, medium, or thick, depending upon the amount of dermis included within the graft (Table 148.6).

CLASSIFICATION OF SPLIT-THICKNESS SKIN GRAFTS	
Thin	0.005–0.012 in/0.13–0.30 mm
Medium	0.012–0.018 in/0.30–0.46 mm
Thick	0.018–0.030 in/0.46–0.76 mm

Table 148.6 Classification of split-thickness skin grafts.

Indications/Contraindications

STSGs contain less tissue requiring revascularization than FTSGs and are therefore more likely to survive when placed on almost any recipient bed, including those with a limited vascular supply. As a result, these grafts may be placed over periosteum, perichondrium, peritenon, and perineurium. STSGs are also used to cover large defects (Fig. 148.4A), particularly those that cannot be covered by a flap or would heal too slowly by second intention, as well as refractory venous leg ulcers[2,3]. STSGs may be useful for covering surgical defects in sites at high risk for tumor recurrence, since recurrent tumor is usually visible when growing through split-thickness skin. If the tumor has not recurred after 1–2 years, the graft can be removed and definitive reconstruction performed.

Advantages of STSGs over FTSGs include their improved chance of survival under conditions of vascular compromise, their ease of application, their ability to cover large defects, and their ability to act as a "window" for recurrence of high-risk lesions. The principal disadvantages of STSGs include their suboptimal cosmetic appearance, the presence of a granulating donor site wound requiring postoperative care, greater contraction, and the special equipment required to harvest larger grafts. Furthermore, because of their relative thinness, STSGs may be less durable than FTSGs, necessitating regrafting or partial healing by second intention.

While thicker STSGs tend to be cosmetically superior to thinner ones, poor color and texture match with the surrounding skin often occurs after STSG placement. STSGs tend to be pale or white in color, hairless, and smooth, with impaired sweating due to the fact that adnexal structures are not removed in their entirety with the graft and do not survive. The contrast between the STSG and its surrounding skin can therefore produce a "tire-patch" appearance (Fig. 148.4B), which is more pronounced than that seen with FTSGs.

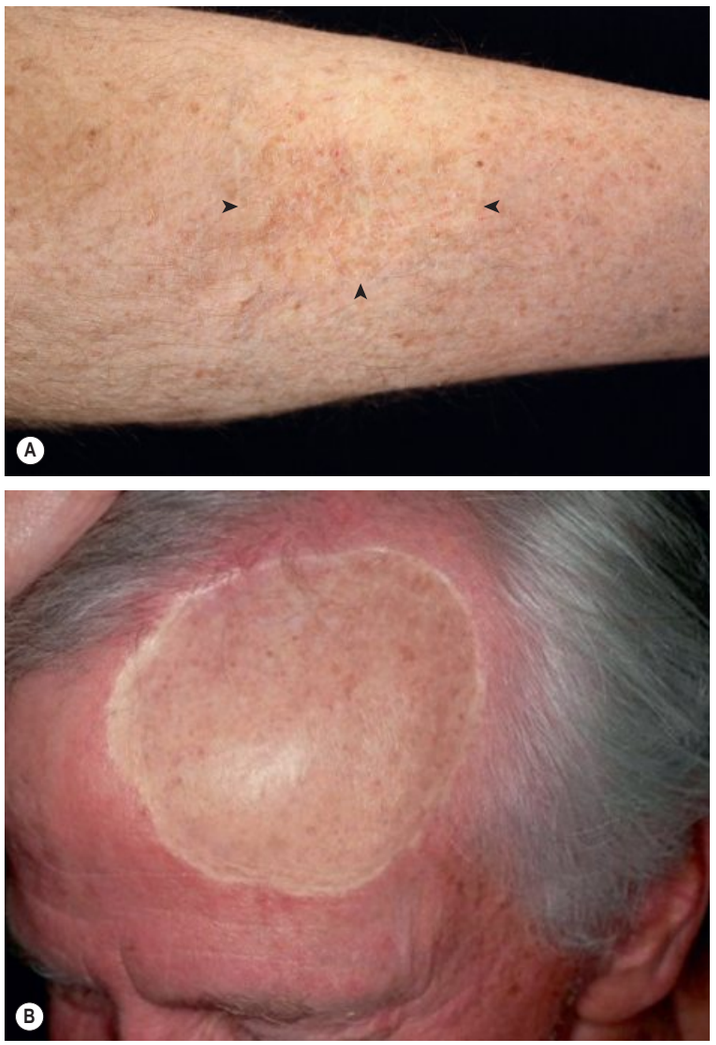

Fig. 148.4 Split-thickness skin grafts (STSGs). A A relatively thick STSG placed on the medial aspect of the lower extremity with excellent cosmetic results; arrowheads denote the edges of the graft. **B** STSG placed on the forehead and scalp several years prior, following excision of a cutaneous melanoma. Note the relative hypopigmentation, altered texture, and depression of the STSG compared to the normal surrounding skin. *Courtesy Jean L. Bolognia, MD.*

Preoperative History and Donor Site Considerations

Donor scar cosmesis should be taken into consideration when selecting a split-thickness donor site. The ease of postoperative care and the type of instrument used to harvest the graft may also help dictate donor site choice. Ideally, STSGs should be harvested from a site where a broad area of skin can be removed while still being concealed beneath clothing. The most common donor sites include the anterior, medial, and lateral portions of the upper thigh, the inner and outer aspects of the upper arm, and the inner aspect of the forearm. Lower back and abdominal skin can also be harvested. The anteromedial thigh is most frequently used as the donor site for STSGs, as harvesting and wound care are convenient, and wounds in this location do not interfere with ambulation. Donor site wounds on the buttocks tend to require assisted postoperative care, although their scars are ideally placed from a cosmetic standpoint. Power-driven dermatomes and large freehand knives require large flat donor surfaces, which may limit donor sites to the thighs, abdomen, and buttocks, while smaller grafts can be harvested freehand or with a power-driven dermatome.

Description of Grafting Techniques

A wide variety of techniques for harvesting and placing STSGs have been described[2,3]. The instruments used to harvest STSGs can be classified into freehand and electric dermatomes. Freehand dermatomes include scalpel blades, double-edged razor blades, and knives such as the Weck blade. Although acceptable grafts can be obtained using these freehand devices, considerable technical expertise is required to harvest them.

A standard #15, #15c, or #10 blade can be an effective tool for harvesting small STSGs of medium thickness. After a template of the defect is made, the donor site is marked, anesthetized with 1% or 2% lidocaine, or with a dilute lidocaine solution if the tumescent technique is to be employed, and scored lightly with the blade. The graft is then harvested by orienting the blade parallel to the skin and gently sweeping it just below the level of the epidermis, so that the blade is visible beneath the skin (Fig. 148.5). It is helpful to have an assistant apply traction to the donor site while the graft is harvested. Several blades may be required for harvesting, as blade sharpness diminishes quickly with multiple passes. This technique may be especially useful in harvesting small medium-thickness STSGs to repair auricular and postauricular defects.

Power-driven dermatomes became the standard method of harvesting larger STSGs after Brown developed the first such instrument in the 1940s. Electric dermatomes designed to harvest STSGs of varying thicknesses and widths, from several centimeters up to nearly 15 cm, are now commonly employed, and lithium ion battery-powered units are also available. Although STSGs can be obtained easily and reliably with any of these devices when properly used, graft quality is technique-dependent, and substantial irregularity in graft thickness and width may occur. The Zimmer dermatome, which was originally powered by compressed water-pumped nitrogen and subsequently modified into an electrically powered version, tends to harvest uniform grafts of predetermined width and thickness such that consistent graft quality tends to be less dependent on the operator's technique. Multipurpose motor systems now exist which include a control box, foot switch, and autoclavable motor that can be used not only with dermatomes,

but also with diamond fraises for dermabrasion, adjustable skin graft meshers, and other types of surgical handpieces, allowing a wide array of procedures to be performed using a single unit.

After the dermatome is prepared, the donor and recipient sites are anesthetized, prepped and draped in the usual sterile fashion. If chlorhexidine surgical scrub is used, a saline wash is employed to remove any excess scrub. The donor site is lubricated in advance with sterile mineral oil or another lubricant to ease travel of the dermatome over the skin. The handpiece is held on the donor site at an angle of 30–45°. A throttle control is pressed to start the cut, and the unit is guided forward using light downward pressure to ensure that the cutting edge remains in continuous contact with the donor site. An assistant applies tension by pulling the skin away from the donor area to create a flat, even surface. As the dermatome glides over the donor skin, the graft emerges from the pocket of the dermatome, and is lifted away from the machine with tissue forceps or hemostats (Fig. 148.6A). Once a sufficiently large graft has been harvested, the dermatome is pulled away from the skin and the graft is placed in sterile saline or on sterile saline-soaked gauze (Fig. 148.6B). A modified harvesting technique using tumescent anesthesia and placement of a polyurethane membrane over the donor site has been reported to prevent graft shrinkage and dehydration and to facilitate graft fixation at the recipient site[35].

Fig. 148.5 Freehand harvesting of a small split-thickness skin graft from the upper outer arm. The blade is oriented parallel to the skin, and gently swept just below the level of the epidermis, so that it is just visible through the graft. An assistant applies traction to the donor site to facilitate harvesting.

Securing the Graft

As in the case of FTSGs, STSGs should be secured so that infection, hematoma or seroma formation, and mechanical shearing forces can be prevented. Both the perimeter and the central portion of the graft must be secured for adequate nutritional support and to ensure graft survival. The edges of STSGs need not be as closely approximated to the surrounding wound edges as those of FTSGs, since overlapping skin will slough without affecting the ultimate cosmetic result. After the graft has been placed with the dermal side adherent to the recipient bed, its perimeter may be secured with sutures or staples. Centrally placed basting sutures may also be helpful in ensuring apposition of the graft to its bed. Once the graft has been secured and its bolster sewn into place, a non-adhesive dressing or pressure dressing may be applied as an additional precaution. Sutures or staples are removed after 7–10 days.

Donor Site Care

Harvesting STSGs creates a second wound, the donor defect, which often causes more postoperative discomfort than the grafted area itself.

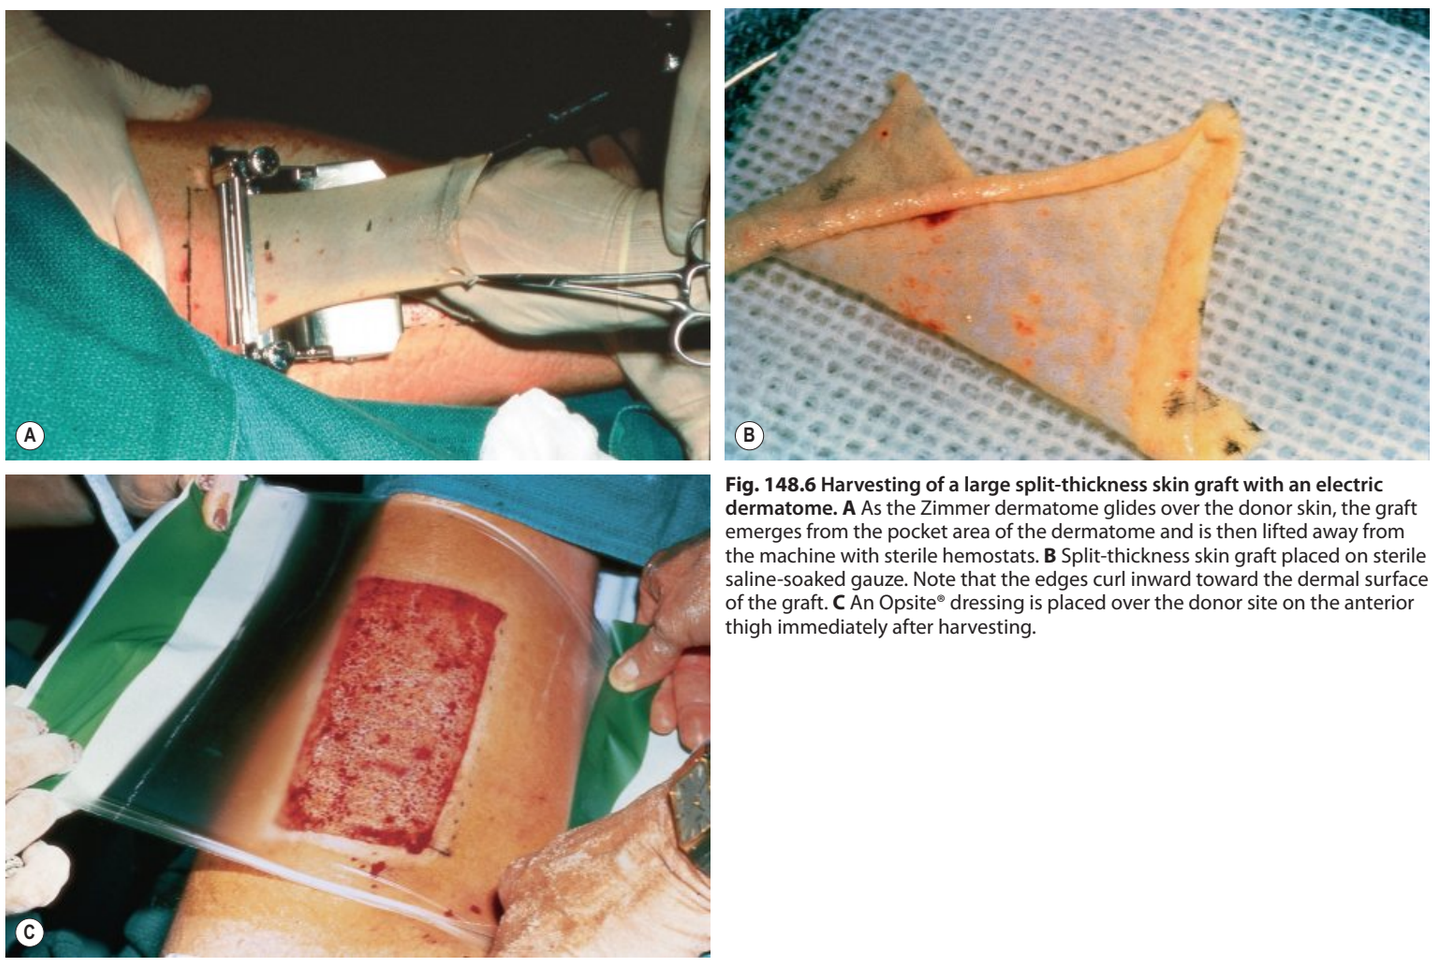

Fig. 148.6 Harvesting of a large split-thickness skin graft with an electric dermatome. A As the Zimmer dermatome glides over the donor skin, the graft emerges from the pocket area of the dermatome and is then lifted away from the machine with sterile hemostats. **B** Split-thickness skin graft placed on sterile saline-soaked gauze. Note that the edges curl inward toward the dermal surface of the graft. **C** An Opsite® dressing is placed over the donor site on the anterior thigh immediately after harvesting.

This partial-thickness wound heals by second intention. While STSG donor sites were once treated with bulky occlusive dressings left in place for 10–14 days, the advent of transparent, vapor-permeable dressings such as Opsite® has improved both patient comfort and ease of care in the postoperative period (Fig. 148.6C)[36]. These dressings are advantageous because they allow the serosanguineous drainage that inevitably accumulates at the donor site to collect, keeping the wound moist and thereby shortening healing time. Because these dressings are transparent, the wound can easily be observed for complications during healing. In one review, these dressings were associated with the fastest healing rates, low infection rates, the least amount of pain, and lower cost when compared with other dressings[37].

After the skin around the donor site area is cleaned and dried, a thin coat of an adhesive such as Mastisol® is applied around the wound and allowed to dry. An Opsite® dressing is then placed over the wound. Paper tape is placed around the perimeter of the Opsite®, followed by a gauze dressing and an elastic bandage (e.g. Ace™ wrap).

Variations/Unusual Situations

Meshing the graft with scalpel slits may be performed to allow drainage of accumulated blood or serosanguineous material that could otherwise inhibit graft–bed contact. This technique may also be used to expand the surface area of STSGs. A meshing machine may be utilized to expand the graft's surface area further by ratios ranging from 3:1 to 9:1. Meshing can facilitate coverage of a large recipient area with smaller donor grafts. Expanded meshed grafts placed experimentally on contaminated recipient beds have been found to exhibit increased take as compared to non-meshed donor skin[38].

Postoperative Care

During the first 24 hours after grafting, a large amount of serosanguineous fluid may accumulate beneath the donor site dressing. Patients need to be forewarned about this possibility so that they do not become alarmed. If necessary, the fluid can be drained with a needle and syringe, and an Opsite® patch applied. Alternatively, a new Opsite® dressing can be placed. The dressing can then be left in place until healing is complete. Depending on the STSG's thickness, the donor site should fully re-epithelialize in 7–21 days. The scar usually evolves in color from pink to white over a period of months.

Complications

The complications of split-thickness skin grafting can be divided into early complications, which stem from failure of engraftment, and late complications[2,3]. Failure of engraftment may result from hematoma or seroma formation, infection, or shearing forces. Late complications can be divided into cosmetic and functional problems (Fig. 148.7).

Color and texture mismatch of STSGs with the surrounding skin is predictable and expected. Grafts often remain erythematous for months to years after placement. More importantly, they may exhibit significant postoperative hyperpigmentation or hypopigmentation. Darker-skinned patients are especially prone to graft hyperpigmentation, despite observance of preventive measures. Patients should therefore minimize graft exposure to the sun without sunscreens for 6 months, and wear sunscreens consistently thereafter. The absence of adnexal structures predisposes to xerosis and a build-up of keratinous debris. The resultant scaling, pruritus, and dryness can be minimized with liberal emollient use.

Functional considerations are of paramount concern, since STSGs contract more than FTSGs and can create forces powerful enough to produce joint contracture if placed over or near joints. Contraction of facial grafts, especially near the nasal ala, the eyelid, the helical rim and the free margins of the vermilion border, may produce significant cosmetic deformities, including alar retraction, ectropion, helical rim distortion, and vermilion border distortion, respectively. Hypertrophic scarring of the graft and donor sites may also occur, which can be treated with corticosteroid-impregnated tape, intralesional corticosteroids, or pulsed dye laser. Graft fragility and breakdown can occur in areas of trauma, particularly in sites such as the lower leg, or in areas with little underlying soft tissue support, such as those directly overlying perichondrium or periosteum. These complications are not always avoidable, but forewarning patients may reduce unnecessary trauma to the area. Lastly, bullae can occur within graft sites, presumably related to decreased anchoring properties of the basement membrane zone (see Ch. 33).

Future Directions

In recent years, biosynthetic and tissue-engineered living skin replacements have been the focus of research in skin transplantation[39–41]. Cultured human keratinocytes have been seeded onto type I collagen membranes petrolatum gauze to reconstitute the epidermis, enabling

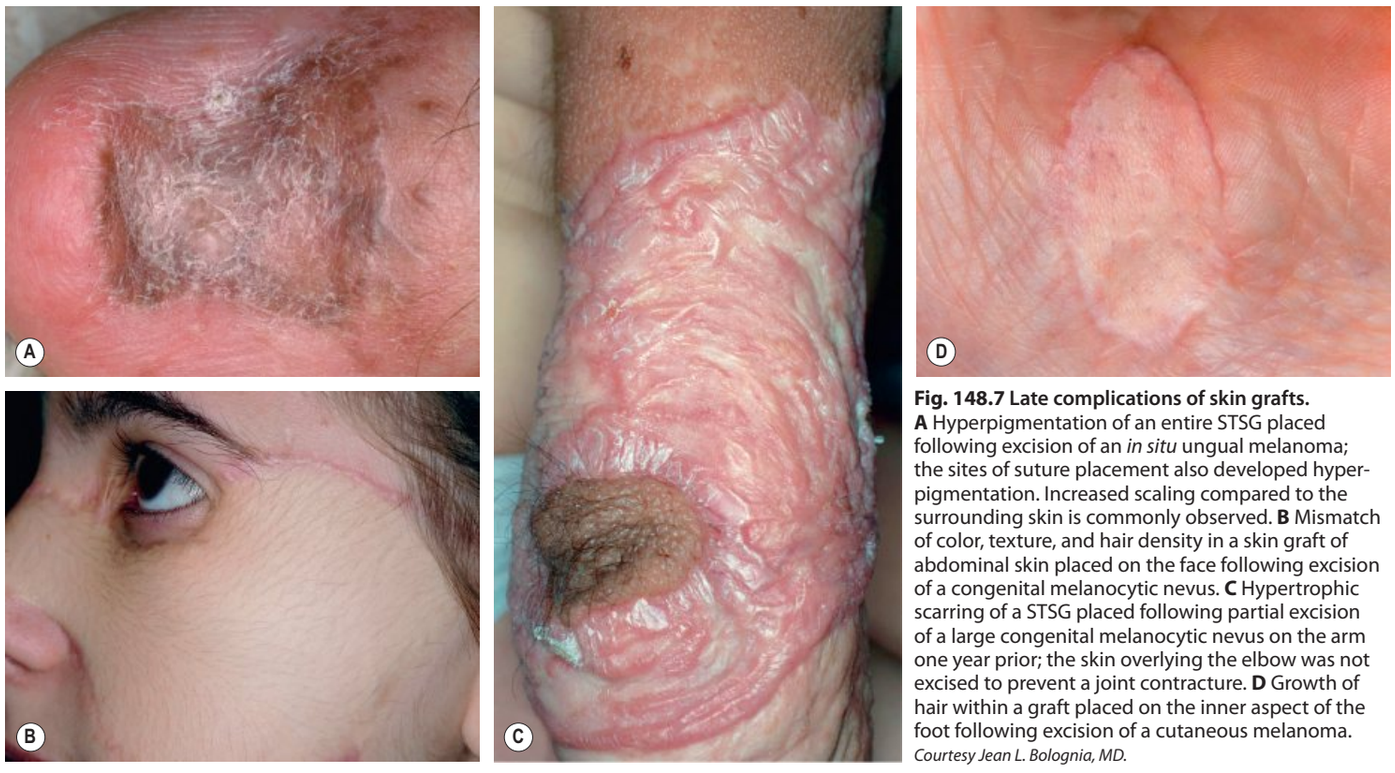

Fig. 148.7 Late complications of skin grafts. **A** Hyperpigmentation of an entire STSG placed following excision of an *in situ* ungual melanoma; the sites of suture placement also developed hyperpigmentation. Increased scaling compared to the surrounding skin is commonly observed. **B** Mismatch of color, texture, and hair density in a skin graft of abdominal skin placed on the face following excision of a congenital melanocytic nevus. **C** Hypertrophic scarring of a STSG placed following partial excision of a large congenital melanocytic nevus on the arm one year prior; the skin overlying the elbow was not excised to prevent a joint contracture. **D** Growth of hair within a graft placed on the inner aspect of the foot following excision of a cutaneous melanoma. *Courtesy Jean L. Bolognia, MD.*

transfer of actively proliferating keratinocytes onto partial-thickness wounds. Human epidermal tissues mimicking the biochemical and morphologic properties of human skin have been established *in vitro* by growing human keratinocytes on a dermal fibroblast-containing collagen gel. Such skin-equivalent cultures are being used to reconstitute the epidermis in patients with full-thickness burn wounds and chronic ulcers (see Ch. 145).

Artificial dermis is now routinely used prior to full-thickness grafting, and an acellular allograft dermal matrix has been shown to provide a good bed for STSGs in patients with full- and partial-thickness burns. A tissue-engineered human skin equivalent, i.e. a bilayered product containing living human fibroblasts, keratinocytes and bovine collagen, is commercially available for the repair of surgical defects and coverage of lower leg ulcers that would previously have been repaired with STSGs. Dermal–epidermal composites using autologous keratinocytes and human allodermis may in the future be used for grafting full-thickness wounds in patients with burns, leg ulcers, or surgical wounds.

COMPOSITE GRAFTS

Indications/Contraindications

Composite grafts are modified FTSGs, consisting of two or more tissue layers. In dermatologic surgery, these grafts are usually composed of skin and cartilage, although they may be composed of skin and fat or skin and perichondrium[3,26,42–48]. Composite grafts are especially useful for repairing full-thickness alar rim defects, as well as nasal tip defects with cartilage loss[46,47]. Full-thickness nasal mucosal defects can be repaired using composite grafts to provide mucosal lining and structural support with a nasolabial or forehead flap placed thereafter to reconstruct the overlying soft tissue defect (see Fig. 147.29). As discussed earlier, conchal bowl composite grafts or PCCGs, consisting of skin and perichondrium, may be used (with or without an underlying cartilage graft) for deeper nasal defects requiring skin coverage, especially defects with exposed cartilage[48].

Preoperative History and Considerations

Composite grafts require rapid revascularization to survive. Early re-establishment of circulation occurs via direct vessel anastomoses between the subdermal plexus of the graft and the subdermal plexus of the wound edge. Since composite grafts are dependent upon this bridging phenomenon for their survival, they are of necessity limited in size, with no point being more than 1 cm from a vascular source, as the risk of central necrosis increases significantly at graft diameters >2 cm[3,47]. Composite grafts for nasal ala and ear reconstruction are possible because of the rich vascular supply of the nose and ear, and because of the small surface areas generally involved. Composite grafts, like FTSGs, are threatened by excessive shearing forces of the graft over its bed, which prevent revascularization.

Composite grafts pass through four stages as they heal[3,47]. After graft placement, the tissue blanches completely. By 6 hours, the graft becomes pale pink, signifying anastomosis of the graft vessels with those of the recipient site. At 12–24 hours, the graft appears dusky blue, reflecting venous congestion, and by 3–7 days, it should be pink, indicating graft survival.

Donor Site Considerations for Composite Grafts

The complexity of nasal ala anatomy makes reconstruction of full-thickness defects in this area difficult. There may be insufficient nasal skin to develop adequate local flaps, and nasolabial flaps, which provide reasonable defect coverage, generate other cosmetic deformities. Loss of alar tissue support also creates a functional deficit, as the alar skin is liable literally to "blow in the breeze" on inspiration and expiration. Composite grafts provide an excellent cosmetic and functional alternative for repair of full-thickness alar rim defects <2 cm in diameter[46]. Grafts taken from the earlobe have been used successfully for this type of repair, although grafts taken from the cartilaginous portion of the ear are more frequently used[43,46].

Donor sites for harvesting auricular composite grafts include the helical crus, helical rim, and conchal bowl (see Ch. 142)[46–48]. Small alar defects with cartilage loss can be elegantly repaired using the helical crus as donor site, while more substantial defects may require repair using the helical rim or conchal bowl, since the crus may not provide sufficient inner lining for the graft. Donor defects involving the helical crus can be repaired with minimal scar formation, while wedge excisions are usually necessary to repair helical rim donor sites. Conchal bowl donor sites heal by second intention.

The advantages of auricular composite grafts in repairing full-thickness alar rim defects relate mainly to the presence of cartilage, which provides structural support and stability, with prevention of alar distortion during inspiration and at rest[46,48]. Disadvantages include a higher risk of graft failure with an increased number of tissue layers, substantial graft size limitations, and limited donor tissue availability. Nevertheless, these grafts, when properly applied, can yield outstanding results. In one animal study, maintaining an intact skin-to-cartilage interface and an equivalent skin-to-cartilage ratio improved composite graft survival; however, when cartilage size exceeded skin size, or when skin and cartilage were separated before transfer, survival decreased, highlighting the importance of an intact skin-to-cartilage interface in optimizing graft survival[49].

Composite grafts used for full-thickness nasal mucosal repair are usually obtained from the triangular fossa, scapha, conchal cavum, cymba, or helical crus (see Fig. 142.13). The appropriate donor site is that which best matches the contour of the surgical defect. These donor sites are usually allowed to heal by second intention, with good aesthetic outcomes.

Description of Technique

Composite grafts used for alar repair are performed as follows (Fig. 148.8)[42,46,48]: the donor and recipient sites are anesthetized using local anesthesia, and prepped with an antiseptic solution. If the alar tissue is scarred and retracted, the area must be vigorously debrided to assure the best possible blood supply for the graft. The defect is then

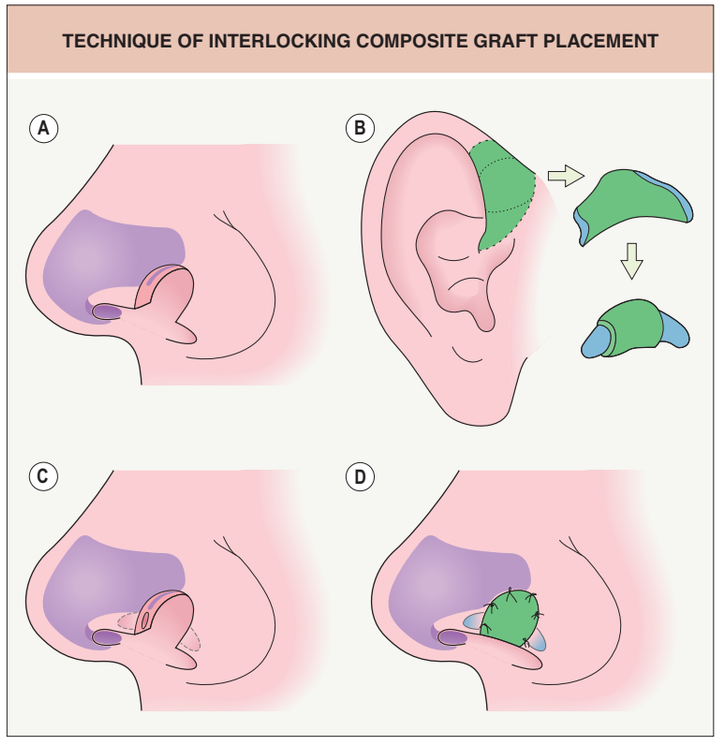

Fig. 148.8 Technique of interlocking composite graft placement. A A full-thickness nasal ala defect extending through both skin and cartilage requires repair. **B** Donor site at the crus of the helix. An area of skin ~5%–10% greater in area than the actual defect is marked out, with cartilaginous wings marked out on either side. After the graft is harvested, the skin is removed on both sides to expose the cartilaginous portion of the graft, such that two cartilaginous pegs with their overlying perichondrium (blue color) frame the lateral aspects of the graft. **C** A pocket is undermined on either side of the recipient site into which the cartilaginous pegs will be placed. **D** The cartilaginous pegs are inserted into the holes prepared within the alar tissue on either side of the defect. The graft is then sutured into place.

measured and a template made as described previously. The donor site is marked and anesthetized, and the graft is harvested. The tissue is handled very gently and placed in sterile saline until ready for placement.

Due to the fragility of composite grafts, a tongue-in-groove technique is recommended to maximize graft stability and increase graft survival[46]. Two cartilaginous wings are marked out and anesthetized on either side of the donor site prior to graft harvesting. After the graft is harvested, the skin overlying these two cartilaginous wings is removed, leaving the cartilage with its overlying perichondrium (Fig. 148.8B). These wings are then inserted into pockets prepared within the alar tissue of both sides of the defect (Fig. 148.8C) such that the graft interlocks with its recipient bed (Fig. 148.8D). Interlocking the graft with its bed may help to minimize shearing forces and provide a larger surface area for revascularization.

The graft is sutured into place in two layers. The undersurface of the graft, which replaces the inner lining of the nose, can be secured first using a 6–0 absorbable suture. The skin is then closed with a 6–0 non-absorbable suture, taking very small tissue bites to minimize vessel strangulation and to maximize the number of potential vessels available for reanastomosis. The needle should pass through the mucosal portion of the graft first, then through the outer epithelial edge of the graft, so that the knots are tied externally, and are not buried between the graft and its recipient bed. The cartilage does not need to be sutured, as it will heal on its own. A Vaseline® gauze or Xeroform™ dressing can then be placed in the nasal vestibule for support, and petrolatum ointment applied to the external suture line. A non-stick dressing is then applied to protect the graft from external injury.

Conchal bowl composite grafts used for reconstruction of deep alar defects are harvested in essentially the same way as composite grafts taken from the helical crus[47]. Potential advantages of the conchal bowl technique include increased bulk, which may be superior in filling deep partial-thickness alar defects, and an excellent cosmetic match for the sebaceous skin of the nose.

Donor Site Closure[48]

Helical crus defects can often be closed in a side-to-side fashion. A simple advancement, rotation, or transposition flap may also be utilized to take advantage of loose preauricular skin. Helical rim defects are usually closed with an ear wedge resection. Auricular grafts obtained from the triangular fossa, scapha, conchal bowl, or cymba heal well by second intention. Conchal bowl defects may heal more rapidly if a 2 or 3 mm punch biopsy instrument is used to remove small plugs of conchal cartilage, which allows healing by second intention from the dermis on the opposite side.

Variations/Unusual Situations

When securing composite grafts onto the nasal ala, delayed intranasal knot tying has been recommended by some authors to facilitate wound closure by improving visualization, allowing gentler manipulation of tissue, and enabling precise suture placement in a confined space[50]. When placing intranasal sutures, the needle of the 6–0 fast-absorbing chromic gut suture is first passed through the nasal mucosa, and then through the corresponding location on the "mucosal" side of the graft. Sutures are placed at 1–2 mm intervals along the defect and graft, and their free ends are held separately by hemostats to prevent tangling. After all intranasal sutures have been placed, the composite graft is placed into the alar defect and the cartilaginous wings inserted. The most internal intranasal sutures are then tied first, followed by the more accessible external sutures.

Postoperative Care

To minimize edema, ice packs should be applied to the grafted area as often as possible for up to several days postoperatively. Oral antibiotics are generally advisable because of the high bacterial colonization around the nares and the higher risk of failure with composite grafts. Sutures are removed after 1 week.

Complications

As with other types of grafts, there is a risk of necrosis in the early stages of healing, and contraction, textural changes, atrophy, and contour irregularities thereafter. If the graft survives but the cosmetic result is suboptimal, dermabrasion or laser resurfacing may be performed 6 weeks to 6 months postoperatively to correct textural differences between the graft and the surrounding skin, and to improve the color match between them. Resurfacing of the entire cosmetic unit may provide superior cosmetic results. In the event of composite graft failure, a two-stage revision with placement of a cheek interpolation flap may be performed or, alternatively, a second composite grafting procedure may be undertaken.

Conchal bowl donor sites are at somewhat greater risk of postoperative bleeding than other areas if left to heal by second intention. Application of pressure dressings over the front and back of the ear to "sandwich" the conchal cartilage with placement of hemostatic foam over the donor site may decrease this risk. Other types of complications at auricular donor sites are rare[51].

The ear is also prone to infection with *Pseudomonas* spp., which reside in the external auditory meatus. Cleaning the ear with a dilute vinegar solution, applying topical gentamicin ointment, and oral quinolone antibiotics are all helpful prophylactic measures which should be considered after harvesting auricular cartilage. If infection is suspected, oral quinolone antibiotics should be started immediately, and therapy guided thereafter by the results of cultures and sensitivities. If the infection does not resolve with appropriate antibiotics, the presence of a fungal infection, most often secondary to *Candida*, should be excluded.

FREE CARTILAGE GRAFTS

Indications/Contraindications

Free cartilage grafts are used most commonly in dermatologic surgery to reconstruct the nasal ala, tip and sidewall, the ear, and the eyelid[42,44,51–53]. These grafts may be used to restore the architecture of an anatomic site that has undergone significant cartilage loss. Free cartilage grafts are also useful in stabilizing the position and contour of free margins against the forces of contraction during wound healing.

Nasal Ala

Partial-thickness alar defects extending into deep soft tissue or approaching the alar rim often lead to rim collapse, producing a functional as well as a cosmetic deficit. Placement of cartilage grafts, consisting of cartilage with its overlying perichondrium, can be used to avert this potential problem[51–53]. The grafted cartilage provides a rigid but flexible framework that braces the alar rim against collapse during inspiration and expiration. Cartilage grafts may be used in conjunction with flaps and FTSGs to maintain airway patency and to minimize the risk of alar retraction during healing (Fig. 148.9)[44,51–53].

The usefulness of the free cartilage graft lies in its ability to prevent alar retraction. It is possible that long-term survival of the cartilage itself may not ultimately be important, as the mere presence of the rigid framework of the graft in the initial stages of wound healing seems to be sufficient to inhibit alar retraction.

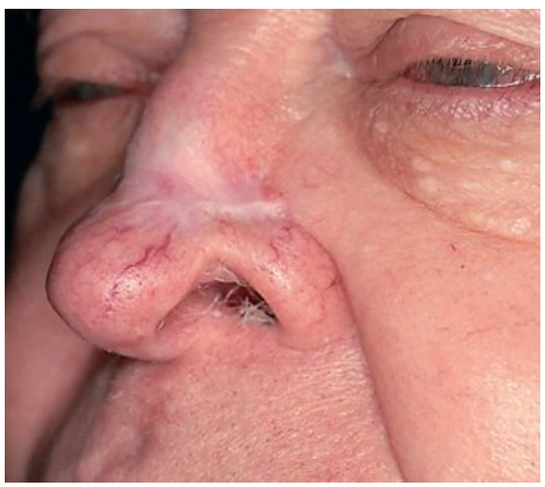

Fig. 148.9 Distortion of the nasal alar rim due to scar retraction from second intention healing following removal of a basal cell carcinoma. Use of free cartilage grafts or composite grafts composed of skin and cartilage can help to prevent this complication. *Courtesy Jean L. Bolognia, MD.*

Nasal Sidewall and Tip

Deep nasal sidewall defects may, at times, involve loss of the upper lateral nasal cartilage. Nasal valve obstruction may result, which becomes noticeable with inspiration and resolves on expiration. Delayed nasal valve obstruction can also occur if unresisted scar contracture collapses the remaining cartilaginous structure of the nasal sidewall. Replacing lost cartilage at the time of reconstruction can avert these potential problems. Similarly, loss of cartilage at the distal nasal tip necessitates structural support replacement for optimal function and cosmesis.

Ear

Auricular defects involving cartilage loss are generally repaired for cosmetic, rather than functional, reasons. Cartilage grafts may be used as braces along the helical rim to minimize the risk of contracture, and may also be used in the conchal bowl to assist in hearing-aid placement[42].

Preoperative History and Donor Site Considerations

Potential donor sites for free cartilage grafts include the conchal bowl, the auricular helix, the antihelix, nasal septum, and ribs[42]. The conchal bowl and antihelix are the donor sites most frequently used by dermatologic surgeons[44,48,53]. Conchal cartilage is elastic, has a high degree of memory, and has varied contours that can be matched to the desired alar contour. Although an anterior approach to the conchal bowl may be used, the posterior approach results in better camouflage of the donor site scar and preservation of the shape of the ear. If the antihelix is used as a donor site, it is recommended that subtotal resection of the antihelical cartilage be performed, leaving a complete rim of intact helical cartilage to prevent distortion.

Description of Technique

Nasal ala

The techniques for alar batten cartilage grafting have been well described[42,44,48,51]. The alar batten provides a rigid but flexible cartilaginous framework to brace against alar rim collapse. The length of the cartilage graft is determined by measuring the distance between the lateral and medial borders of the defect at the alar rim, and adding to that measurement an extra 4–5 mm. The conchal bowl donor site is incised anteriorly or posteriorly, whereas the antihelical donor site is incised anteriorly. The skin overlying the cartilage is then undermined with blunt-scissor dissection to expose the perichondrial surface. The desired length of cartilage is incised with a scalpel (Fig. 148.10A), and a second incision is made exactly parallel to the first, creating a cartilaginous strip that may be 3–6 mm in width, depending upon the desired width of the graft (Video 148.9). Alternatively, a larger disk or oblong-shaped piece may be harvested to match the base of the defect. The cartilage is easily separated from the overlying skin with sharp-scissor dissection. The graft is placed in sterile saline while the donor site is reapproximated with non-absorbable sutures.

The cartilage graft is secured by undermining the soft tissue of the recipient bed medially and laterally with a hemostat or blunt-scissor dissection, and the ends of the graft are inserted into the undermined pockets such that the graft interlocks with its bed (Fig. 148.10B, Videos 148.10 and 148.11). The graft is anchored to its bed with one or two 5–0 absorbable sutures for additional security (Video 148.12). A disk- or oblong-shaped cartilage graft also requires suturing for secure placement.

After the graft has been anchored, a nasolabial transposition flap or FTSG is sutured into place to complete the closure (Fig. 148.10C,D, and see Videos 148.1, 148.2, 148.3, 148.4, 148.5, 148.6). A standard tie-over bolster is placed over the FTSG and secured with 5–0 non-absorbable sutures (see Videos 148.7, 148.8). Sutures are removed at 1 week.

Fig. 148.10 Harvesting and placement of a free cartilage graft. A The posterior conchal bowl donor site has been incised to the level of the perichondrium. The desired length of cartilage was incised with the scalpel, and a second incision made parallel to the first to isolate a cartilaginous strip with its overlying perichondrium. **B** The ends of the cartilaginous strip with its overlying perichondrium have been inserted into pockets undermined on either side of the recipient bed, such that the graft interlocks with its recipient bed on the left nasal ala. The graft is sutured to the underlying dermis with one 5–0 absorbable suture for additional security. **C** A full-thickness skin graft has been sutured into place over the free cartilage graft. **D** Eight-week postoperative view of the full-thickness skin graft and underlying free cartilage graft on the left nasal ala. The alar rim remains in perfect alignment.

Nasal sidewall and tip

Free cartilage grafts used for nasal sidewall and tip reconstruction are harvested in much the same way as free cartilage grafts for alar reconstruction[42]. Nasal sidewall grafts tend to be wider and broader than alar grafts, since they must brace a broader area against the forces of inspiration. Alternatively, multiple cartilaginous strips can be placed perpendicular to the lateral nasal sidewall, and then secured with absorbable or non-absorbable sutures to brace the side of the nose against collapse. After the cartilaginous structure is in place, a flap or FTSG may be performed to cover the remaining cutaneous defect.

Nasal tip grafts for distal nasal reconstruction are organized to provide both proximal and distal structural support, thus optimizing the aesthetic and functional result[42,51,52]. The proximal grafts consist of bilateral batten grafts secured to the lateral cartilages with 5–0 or 6–0 non-absorbable sutures. On top of these may be sewn a dorsal nasal cartilage graft. A columellar strut of cartilage often provides distal support, on top of which may be sewn an additional tip graft. Alar batten grafts secured to the columellar strut and lateral alar soft tissue provide alar rim support. A paramedian forehead flap or melolabial interpolation flap may be placed thereafter to provide coverage of the cutaneous defect.

Ear

If conchal cartilage is used to repair a large helical defect, the cartilage graft should match the defect as closely as possible in size and shape[42]. Harvesting and placing a narrow strip of cartilage matching the helical defect alone will result in helical rim collapse under the forces of wound contraction. If necessary, a partial wedge closure of the defect may be performed to decrease the size of the defect requiring replacement of structural support. The cartilage graft is secured by sewing it to the intact cartilaginous framework with 5–0 absorbable or non-absorbable sutures. The graft is then generally covered with a pedicled retroauricular advancement flap.

Eyelid

Partial-thickness lower eyelid defects with loss of the tarsal plate, as well as full-thickness lower eyelid defects, may be repaired with cartilage grafts. Stabilization of the eyelid margin with free cartilage grafts provides structural support, minimizing the risk of ectropion and preventing corneal desiccation. The technique for performing free cartilage grafts to repair full-thickness and partial-thickness lower eyelid defects is beyond the scope of this chapter, but is well described by Otley and Sherris[42].

Postoperative Care

Regardless of the site of cartilage grafting, care must be taken postoperatively to minimize movement of the graft. Routine wound care is performed to the flap or skin graft overlying the free cartilage graft. Trauma to the area should be minimized.

Complications

Postoperative complications following cartilage grafting are rare. There is a risk of postoperative infection at conchal bowl donor sites, particularly with Gram-negative bacilli, which reside within the external auditory meatus. Appropriate bacterial and fungal cultures of any exudate should be obtained if infection is suspected. Empiric therapy with quinolone antibiotics should be initiated, and modified as sensitivities dictate. When prophylactic antibiotics and appropriate operative technique are used, the risk of suppurative chondritis is extremely low[54].

Postoperative tenderness, swelling, and erythema may herald inflammatory chondritis or perichondritis, which should be treated with cool compresses and nonsteroidal anti-inflammatory drugs for several weeks or even months postoperatively.

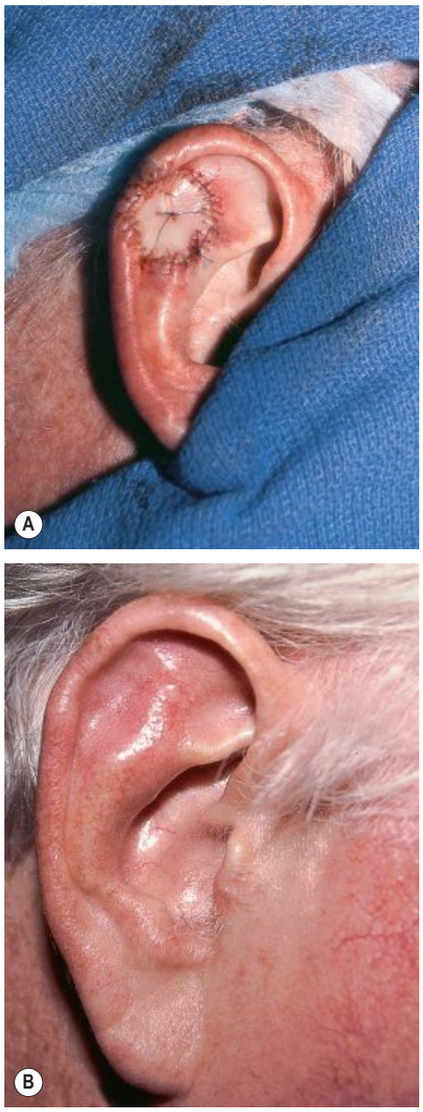
Later complications may include graft resorption, displacement or deformation after placement, and extrusion. Surgical revision may be required if these complications occur. Auricular and nasal recipient sites are subject to trauma and are therefore at increased risk of graft displacement and resorption. Every effort should therefore be made intraoperatively to utilize grafts of sufficient thickness and stiffness to resist the forces of trauma and wound contracture, and to anchor these grafts to maximize their stability.

Future Trends

While autologous cartilage is considered the optimal grafting material due to its pliability, accessibility, and ease of harvesting under local anesthesia, its supply may be limited, and harvesting may entail additional morbidity. Other implantable materials for nasal reconstruction have been investigated, including porous, high-density polyethylene implants, which have been well tolerated as replacements for native cartilage in patients requiring rhinoplasty or nasal reconstruction[55,56].

Tissue engineering has been used to generate autologous cartilage implants to fill defects of the nose or outer ear[57]. Chondrocytes can be stimulated with growth factors to increase their proliferative rate and extracellular matrix production. Such chondrocytes, when implanted in a resorbable synthetic scaffold, can thereby be induced to produce three-dimensional aggregates of cartilage. In one study, collagen lattices containing cultured chondrocytes implanted into rabbit auricular cartilage generated new cartilage within 5 weeks[57]. *In vitro* engineering of human cartilage could be the ideal replacement method, without the risk of infection and with the possibility of reconstructing large defects with different configurations. In a first-in-human trial, autologous chondrocytes harvested from the nasal septum were cultured in media with autologous serum and seeded onto collagen type I and type III membranes[58]. After 4 weeks, the resulting engineered cartilage grafts, 25 × 25 × 2 mm, were successfully implanted beneath forehead or nasolabial flaps, just as native auricular cartilage would have been, with comparable aesthetic and functional results. These and newer implantable materials should become increasingly available over time, and will undoubtedly be useful for surgeons who perform nasal reconstruction.

CONCLUSIONS



A working knowledge of the indications, techniques, donor site considerations, and postoperative complications of all types of skin grafts is necessary for soft tissue reconstruction. As the incidence of skin cancer continues to rise, increasing numbers of patients are likely to undergo reconstructive procedures requiring full-thickness skin and/or cartilage grafting. Lower extremity ulcers are another common problem, and split-thickness skin grafting remains an effective, reasonable treatment for such patients. With proper defect assessment, reconstructive planning, and attention to detail preoperatively, intraoperatively and postoperatively, optimal cosmetic and functional results can be achieved using the full range of grafting techniques, a thorough understanding of which is therefore invaluable for all physicians performing reconstructive surgery.

Key features

- A thorough understanding of the anatomy and physiology of the nail unit is a prerequisite for performing successful nail surgery
- The nail matrix forms the nail plate; any damage to the matrix (including from surgical procedures) can cause permanent nail dystrophy
- Because there is no subcutaneous tissue in the nail unit, the dermis of the nail bed sits on the periosteum of the distal digit
- Preoperative evaluation prior to nail surgery is essential and should include appropriate diagnostic imaging

INTRODUCTION

An accurate diagnosis of nail disorders often requires clinicopathologic correlation. When performing a biopsy of the nail unit, it is important that: (1) the most appropriate surgical procedure be performed correctly; (2) there is precise handling of the specimen in the histopathology laboratory; and (3) a dermatopathologist with knowledge of the nuances of nail pathology examine the tissue[1,2]. A range of disorders require nail surgery, from nail tumors to ingrown toenails. As with surgical procedures performed elsewhere, the major goals include establishing a diagnosis and/or providing treatment safely and with minimal pain or scarring[3]. Because dermatologists are the physicians who understand and manage nail disorders, they are well suited to perform nail surgery. A solid grasp of the anatomy and physiology of the nail unit is a prerequisite for successful nail surgery. Additional requirements for an optimal outcome include a well-prepared patient, adequate anesthesia, proper surgical technique, and hemostasis (Table 149.1).

SURGICAL ANATOMY OF THE NAIL UNIT

Basic Anatomy

The components of the nail unit are the nail plate, nail matrix, nail bed, hyponychium, and proximal and lateral nail folds.

The **nail matrix** rests on the midportion of the distal phalanx and has a broad crescent shape (Fig. 149.1). It is covered in large part by the proximal nail fold and extends on average half the distance from the nail fold to the central crease of the distal interphalangeal (DIP) joint. On the great toe, the lateral horns of the matrix can extend as far as the midline of the lateral aspect of the digit or even farther (Fig. 149.2). This is an important concept, especially when performing a phenol matricectomy for ingrown nails or a lateral longitudinal biopsy. The distal portion of the nail matrix is visible through the proximal nail plate on the thumbs and sometimes other fingers as the white half-moon-shaped structure called the lunula. While the proximal portion of the matrix produces the upper third of the nail plate, the distal portion provides the lower two-thirds (see Fig. 149.2). Consequently, surgery involving the distal matrix has a very low risk of producing nail dystrophy, as the upper layers of the nail plate will cover the defect[4,5].

The **nail bed**, sometimes referred to as the sterile matrix, extends from the distal lunula to the hyponychium. A rich vascular supply leads to the pink color that is visible through the translucent nail plate. The nail bed is composed of longitudinal ridges and grooves which interlock with opposing structures on the undersurface of the nail plate, contributing to the tight adhesion of the plate to the bed. Surgery of the nail bed rarely leads to permanent dystrophy of the nail apparatus, but it may result in mild onycholysis. An important feature of the nail bed is that there is no subcutaneous tissue beneath it. The dermis of the nail bed sits directly on the periosteum of the distal digit. The lack of subcutaneous tissue in the nail unit explains why nail surgical specimens should extend to the level of the periosteum.

The **hyponychium** begins at the most distal part of the nail bed, where the nail plate detaches to form its free edge and just proximal to the distal groove; it then becomes contiguous with the volar skin of the digit. Just proximal to the hyponychium is the onychodermal band, the area of maximal attachment between the nail plate and its bed which seals and protects the nail unit from environmental factors. Trauma- or disease-induced disruption of the onychodermal band can result in onycholysis, followed by bacterial and fungal contamination. The **proximal nail fold** covers and protects most of the matrix and the newly formed plate. The most distal portion of the proximal nail fold gives rise to the cuticle, which adheres tightly to the proximal nail plate, thereby sealing and protecting the nail pocket from environmental pathogens and irritants.

The **lateral folds** ensheath the lateral aspects of the plate. Proximally, they merge with the proximal nail fold and distally with the hyponychium. The proximal and lateral nail folds are collectively called the paronychium. The term perionychium refers to the paronychium plus the hyponychium and nail bed[5].

The insertion of the **extensor tendon** of the digit onto the phalanx is just proximal to the most proximal portion of the matrix. In an adult, this is ~12 mm proximal to the cuticle. Except in the most extensive nail surgical procedures such as nail unit ablation, this tendon is not observed within the surgical field.

Innervation

Paired palmar and dorsal nerves course along the lateral sides of the digit in close approximation to the digital arteries (see Fig. 149.1). In general, the index, middle and ring fingertips get their innervation from the palmar digital nerves whereas the thumb and little (fifth) finger are innervated by the dorsal nerves[6]. This is an important consideration when performing a digital block.

Vascular Supply

The paired proper digital arteries, which run along the lateral and volar sides of the digit, comprise the main blood supply to the nail unit (see Fig. 149.1). They anastomose to form three arcades: (1) the superficial arcade – supplies the area overlying the DIP joint; (2) the proximal arcade – supplies the proximal nail fold and matrix; and (3) the distal arcade – supplies the nail bed and hyponychium.

PREREQUISITES FOR SUCCESSFUL NAIL SURGERY
1. Understanding of nail anatomy and physiology
2. Proper patient selection and preparation
3. Adequate anesthesia
4. Hemostasis
5. A nail condition that has eluded diagnosis by routine clinical inspection, history, diagnostic imaging, and/or microbiologic evaluation
6. A dermatopathologist who is familiar with the histopathologic idiosyncrasies of the nail unit

Table 149.1 Prerequisites for successful nail surgery.

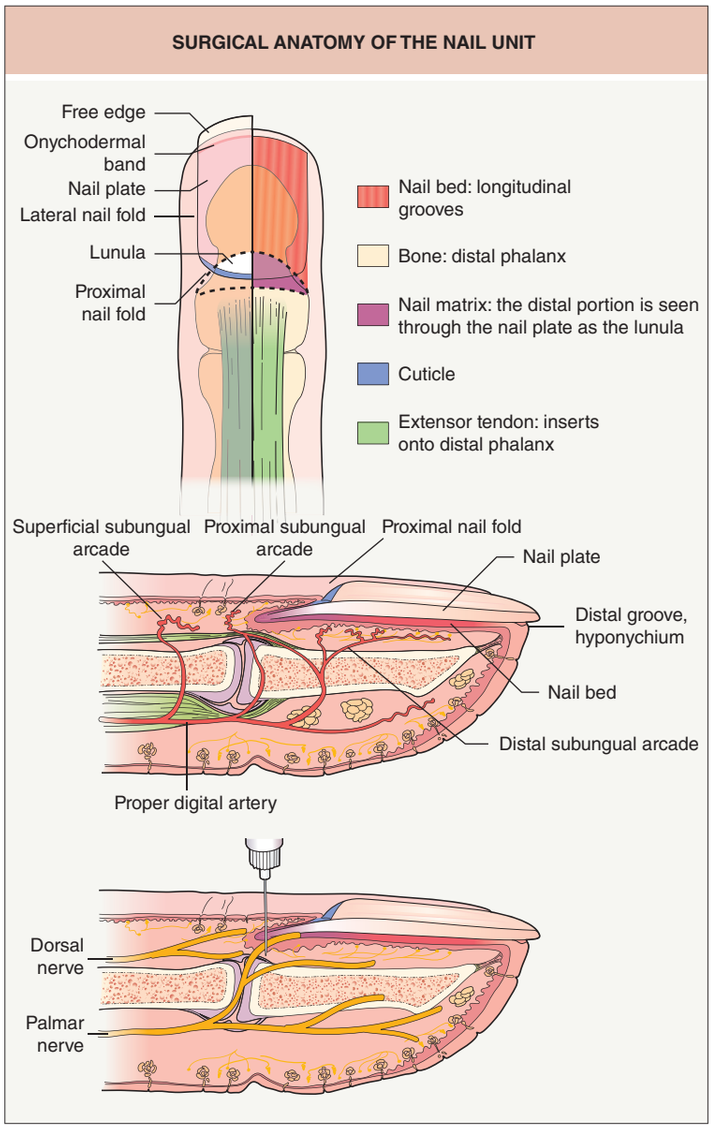

Fig. 149.1 Surgical anatomy of the nail unit. There are three arcades of blood vessels as well as both a dorsal and palmar nerve. In the distal digital block, after local anesthesia is injected around the dorsal nerve branch, the needle is advanced vertically towards the palmar surface where additional anesthesia is injected around the palmar nerve (see Fig. 149.3A).

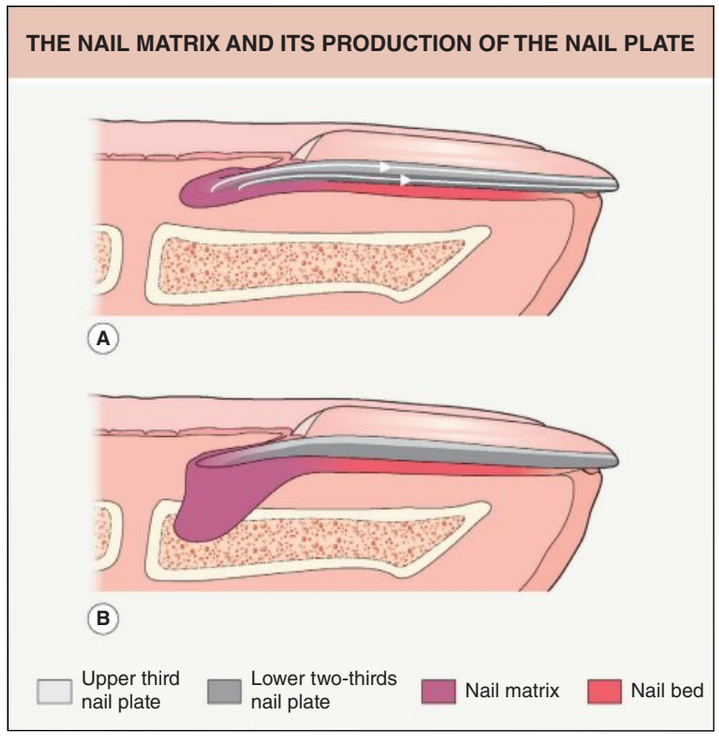

Fig. 149.2 The nail matrix and its production of the nail plate. A The proximal portion of the matrix produces the upper third of the nail plate (light gray) and its distal part the lower two-thirds (dark gray). **B** On the great toe, the lateral horns of the matrix can extend as far as the midline of the lateral aspect of the digit or even farther.

PREOPERATIVE EVALUATION AND PATIENT PREPARATION

A thorough and efficient preoperative evaluation is required prior to nail surgery. Screening for underlying diseases, especially those that predispose to peripheral vascular disease (e.g. diabetes mellitus, Raynaud phenomenon, atherosclerosis), should be done, in addition to a review of medications, allergies (e.g. povidone–iodine, antibiotics, narcotics, anesthetics, latex), smoking history, and past surgical procedures, in particular the presence of prosthetic heart valves and joint replacements (see Table 151.2). Diagnostic imaging can detect underlying bony defects as well as define space-occupying lesions and their anatomic relationships prior to nail surgery. A full "procedure, alternatives, and risks" (PAR) discussion should include the possibility of bleeding, pain, infection, and permanent nail dystrophy. Information regarding work disruption should be provided. Premedication is not particularly useful, except in those who are very anxious. No systemic drugs, including anticoagulants and antiplatelet agents, should be discontinued. Prophylactic antibiotics are only indicated for individuals with high-risk cardiac conditions or prosthetic joint replacements at high risk for infection (see Tables 151.2 & 151.3). While not mandatory, clinical photographs of the preoperative nail may prove worthwhile. The digit is then prepped with alcohol, chlorhexidine, or povidone–iodine and sterilely draped.

ANESTHESIA OF THE NAIL UNIT

The choice of anesthetic will depend on the pain expected postoperatively. Plain 1% or 2% lidocaine and ropivacaine (2 mg/ml) have a more rapid onset while 0.5% bupivacaine provides adequate anesthesia after 15 minutes; there is a longer duration of anesthesia with the latter two local anesthetics (see Ch. 143). Multiple studies involving thousands of patients support the premise that lidocaine with epinephrine (adrenaline) can be safely injected into digits, as long as patients have no history of peripheral vascular compromise and the recommended volume is injected (see below)[7]. However, as nail surgery is usually performed with a tourniquet, there is little need for the vasoconstrictive effect of epinephrine.

Pain during anesthesia comes from several factors: the needle prick, rapid injection, and acidity of the anesthetic. In order to reduce these side effects, the surgeon should use thin needles (30-gauge), inject very slowly, and buffer the lidocaine (see Ch. 143).

Anesthesia can be administered as a nerve block (distal digital block) or as infiltrative anesthesia (wing procedure). In the *distal digital block*, the needle is inserted vertically, 1 cm lateral and proximal to the junction of the proximal and lateral folds; here 0.5 ml of the anesthetic is injected in order to anesthetize the dorsal nerve branch (Fig. 149.3A). The needle is then advanced vertically towards the palmar surface,

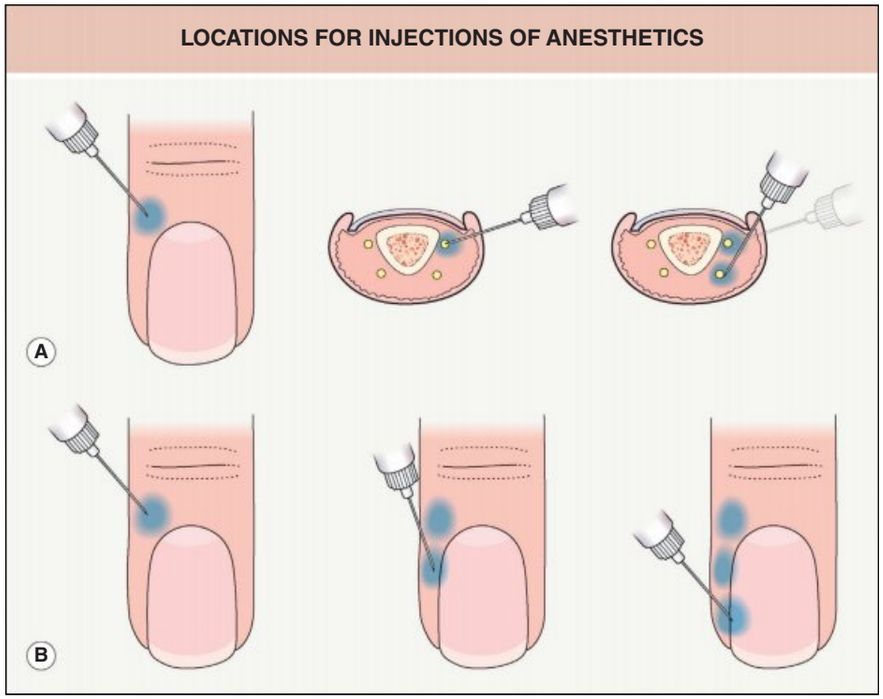

Fig. 149.3 Locations for injections of anesthetics. A Distal digital nerve block. **B** Infiltrative wing procedure.

where an additional 0.5 ml is injected around the palmar nerve branch. The procedure is then repeated on the opposite side to obtain full anesthesia of the nail unit. This nerve block has several advantages over the proximal digital (ring) block: (1) the onset of action is quicker; (2) less volume of anesthetic is required; (3) less risk of injuring the neurovascular bundles at the base of the finger; and (4) the injection is more comfortable.

In the *wing procedure*, anesthetic is injected to produce a dermal wheal at the most proximal portion of the lateral nail fold. The anesthetic progressively diffuses distally within the lateral nail fold, thus resembling a wing. Moving distally around the nail, anesthetic is repeatedly injected into the distal edge of the previously anesthetized skin until the surgical field is adequately numbed (Fig. 149.3B). The associated tissue edema provides a certain degree of hemostasis[8]. Injecting a longer-acting anesthetic (e.g. bupivacaine) postoperatively provides prolonged anesthesia and reduces bleeding after removal of the tourniquet due to the extra liquid-based pressure on the lateral digital arteries[9].

INSTRUMENTS FOR NAIL SURGERY

Most of the instruments used in nail surgery are standard instruments used in cutaneous surgery. A few specific instruments are needed in order to make nail surgery easier to perform. An *elevator* allows atraumatic detachment of the plate from the bed and several types are available, such as the Freer nail elevator or Locke elevator (Fig. 149.4). *Nail nippers* are essential for cutting the nail plate. When cutting thick nails, the dual-action nail nipper is invaluable. The English nail splitter is very popular but has a major drawback: its thicker lower jaw induces lateral onycholysis ahead of the cutting line. Straight nail nippers with their sharp, thinner, beveled jaws are less traumatic (Fig. 149.5).

As nail surgery requires a bloodless surgical field, a tourniquet, applied for a maximum of 20 minutes, is very useful. Several options are available. The Penrose drain, clamped with a sturdy hemostat, is commonly used but studies have shown that it delivers high and unreliable pressure that has the potential for lateral nerve damage, and thus it is not recommended for digits. A sterile glove, half a size smaller than the adequate size, can be employed; the corresponding fingertip of the glove is pierced with scissors and then rolled back to the base of the proximal phalanx (Fig. 149.6). This technique exsanguinates the digit and delivers an acceptable pressure around 500 mmHg. The remainder of the glove serves as a sterile field[9]. T-Ring®, a digital tourniquet specifically designed to ensure hemostasis with the lowest efficient pressure (~150 mmHg), is commercially available. Its limitation is cost (currently $10 USD per unit).

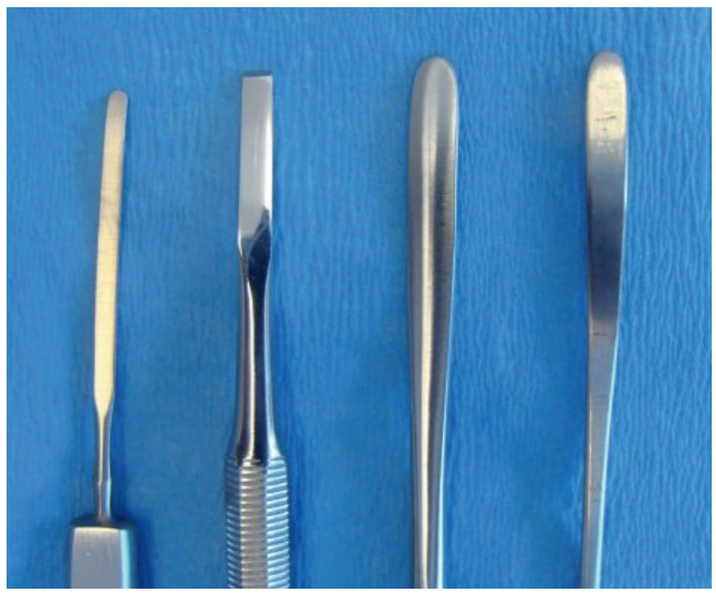

Fig. 149.4 Different types of nail elevators. From left to right, McKenty periosteal elevator, dental spatula, Freer nail elevator, and dura mater elevator.

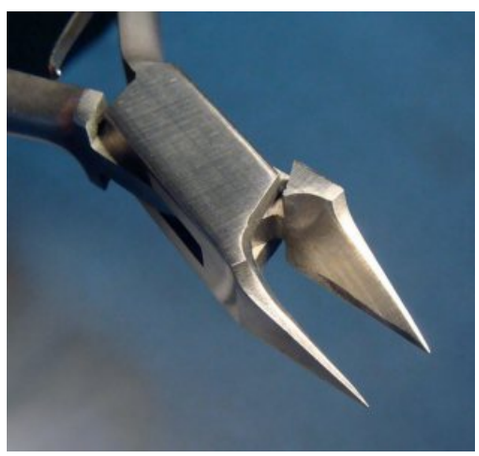

Fig. 149.5 Sharp-pointed and beveled nail nippers.

NAIL PLATE AVULSION

Nail avulsion is the most basic procedure in nail surgery and is a prelude to most other nail unit procedures. It allows visualization of the nail bed and matrix, thus providing good exposure for biopsy or excision (Fig. 149.7). Except for patients with retronychia, total nail avulsion should be discouraged because as the counterpressure exerted by the nail plate disappears, the distal wall and pulp raise upward in combination with a shrinkage of the nail bed. The result is more bulky soft tissue at the end of the digit and an increased risk of distal embedding during nail regrowth. Partial nail avulsion is therefore preferred[10], with the remaining normal nail plate reducing the risk of distal embedding[1]. Partial nail avulsion serves as an adjuvant therapeutic intervention in onychomycosis as it reduces the fungal mass, especially of a dermatophytoma (Fig. 149.8). In addition, nail avulsion is an early step in chemical matricectomy (see below), may be performed to drain an acute paronychia, and is a must when exploring pigmented lesions within the nail matrix. There are two approaches to nail avulsion – distal and proximal, although the latter is rarely used.

Fig. 149.6 Sterile glove used as a tourniquet and sterile field. One fingertip of the glove is pierced with scissors and rolled back to the base of the proximal phalanx.

For *distal nail plate avulsion*, an elevator is first pushed under the proximal nail fold and slid back and forth from one side to the other in order to detach the fold from the plate (Fig. 149.9A). The elevator is then inserted under the free edge of the nail plate in a distal to proximal direction to free the plate from its bed (Fig. 149.9B). As the instrument reaches the matrix area where the attachment of the nail plate is looser, a decrease in resistance is felt. To loosen the entire plate, the instrument is inserted under the plate at several sites, advancing from the hyponychium to the matrix. Lateral motions across the nail bed should not be done to loosen the nail plate as this can injure the fragile longitudinal nail bed ridges. The plate is then grasped on one lateral edge by a hemostat or a nail puller, rotated (Fig. 149.9C), and pulled off the nail bed.

If the avulsion is performed to explore the entire matrix area, avulsion alone will not suffice. Two releasing incisions, ~1 cm in length, are made at each junction of the proximal and lateral nail folds, angling laterally and proximally. This allows the nail fold to be reflected so that the matrix can be inspected (Fig. 149.10). When performing a biopsy or excisional surgery, skin hooks or sutures help to maintain the reflection of the proximal nail fold. At the end of the procedure, the fold is placed back into its original position and secured with simple interrupted sutures or adhesive strips. The nail plate, if not needed for

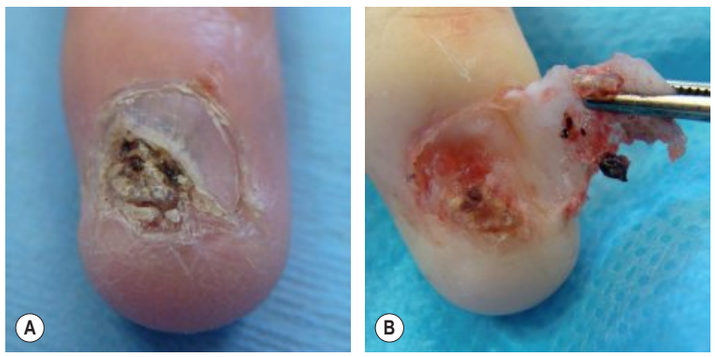

Fig. 149.7 Lateral avulsion of the plate to expose the nail bed. A Keratotic lesion suspicious for squamous cell carcinoma is extending from under the nail plate. **B** Lateral avulsion allows examination of the nail bed and biopsy of the tumor.

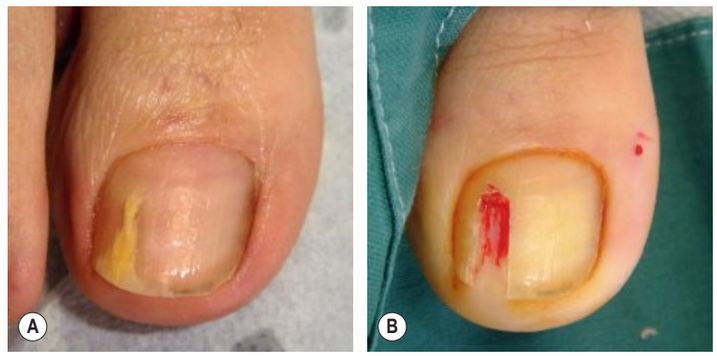

Fig. 149.8 Treatment of a dermatophytoma. A Yellow spike due to a dermatophytoma. **B** Partial avulsion of the nail plate and removal of the fungal mass.

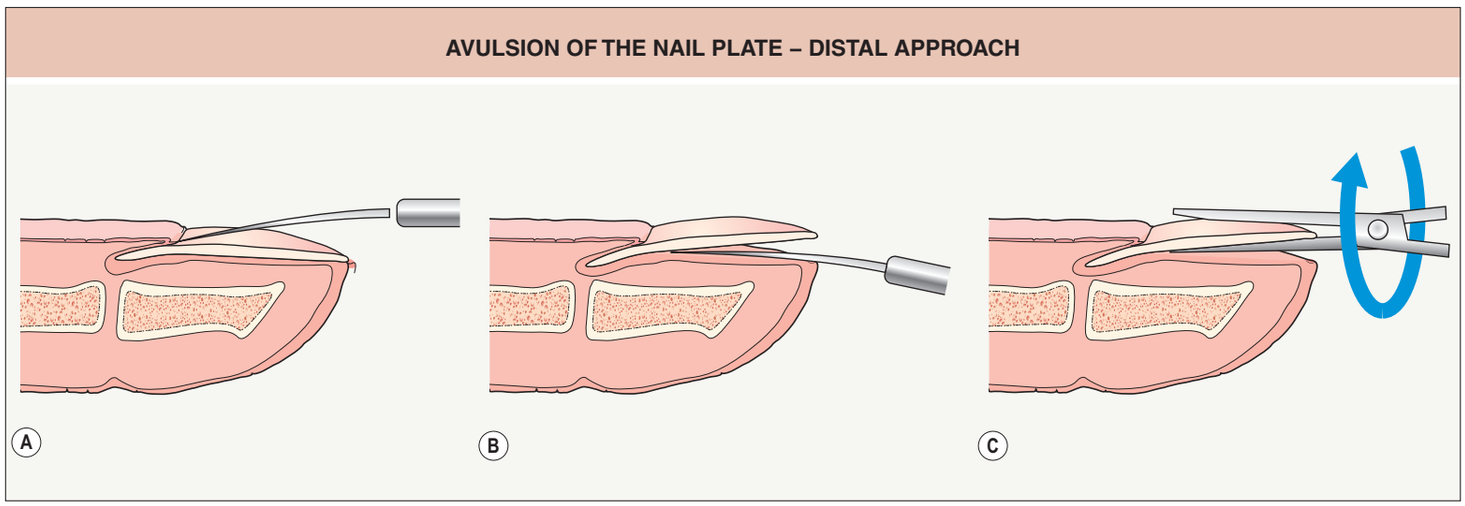

Fig. 149.9 Avulsion of the nail plate – distal approach. A An elevator is first pushed under the proximal nail fold, moving back and forth from one side to the other in order to detach the fold from the plate. **B** The elevator is then inserted under the free edge of the plate in a distal to proximal direction to free the plate from its bed. **C** The plate is then grasped by a hemostat or a nail puller and rotated off the nail bed.

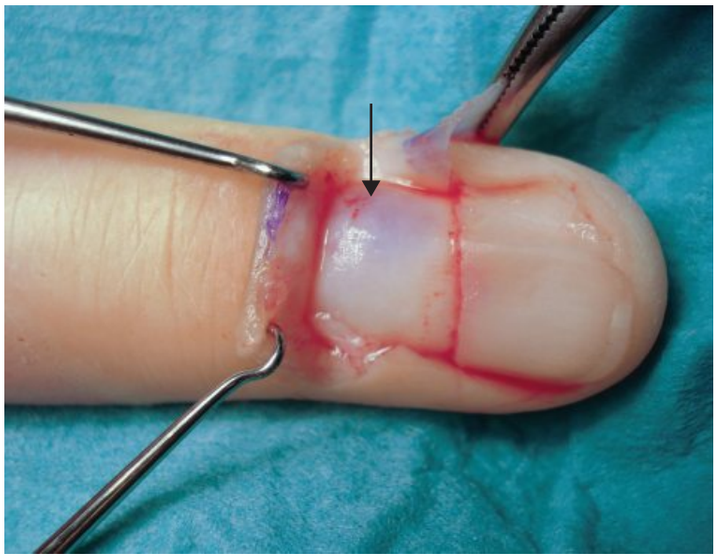

Fig. 149.10 Visualization of a glomus tumor within the proximal nail matrix. Following two oblique incisions at the junction of the lateral and proximal nail folds, retraction of the proximal nail fold, and proximal lateral avulsion of the nail plate, the entire nail matrix is exposed. The glomus tumor within the matrix (arrow) is identified prior to removal.

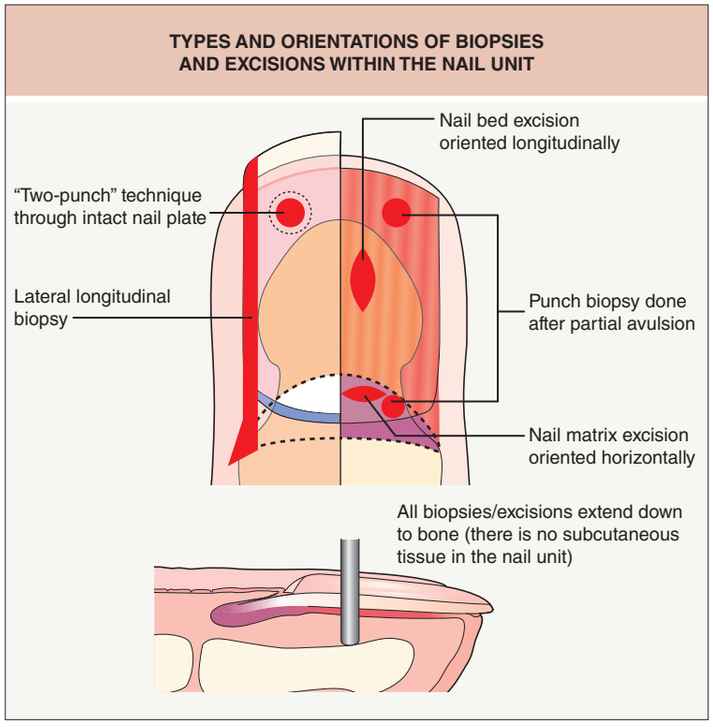

Fig. 149.11 Types and orientations of biopsies and excisions within the nail unit.

CLINICAL FEATURES OF NAIL BED DISORDERS IN WHICH A BIOPSY MAY FACILITATE DIAGNOSIS AND SUBSEQUENT TREATMENT	
Diagnosis	**Clinical features**
Malignant tumors of the nail bed	
Squamous cell carcinoma, Bowen disease	Hyperkeratosis, dyschromia, onycholysis, destruction of the nail plate
Keratoacanthoma	Multiple or solitary, nail plate destruction, mass, erosion, granulation tissue, pain
Melanoma	Pigmentation of the nail bed, erosion, destruction of the nail plate; 25% are amelanotic
Metastatic carcinomas	Mass, pseudo-clubbing, nail dystrophy, dusky red color, ± pain
Basal cell carcinoma	Rare, variable clinical appearance
Benign tumors of the nail bed	
Pyogenic granuloma	Exuberant friable mass, needs to be distinguished from amelanotic melanoma
Glomus tumor	Spontaneous pain, blue–red mass
Epidermoid cyst	Mass, nail plate deformity
Fibroma	Mass, elevation, distortion of the nail (if presses on matrix, distal groove; if underneath nail plate, elevation of plate)
Exostosis	Mass, elevation of the nail plate, tenderness
Osteochondroma	Enlargement of digit, elevation or destruction of the nail plate
Enchondroma	Mass, alteration of the nail plate, pain
Infectious conditions of the nail bed	
Onychomycosis	Hyperkeratosis, dyschromia, nail dystrophy, onycholysis
Verruca vulgaris	Verrucous mass, sometimes painful, nail plate deformity or destruction, must distinguish from verrucous or squamous cell carcinoma
Crusted scabies	Hyperkeratosis of hyponychium
Inflammatory dermatoses involving the nail bed	
Psoriasis	Onycholysis, hyperkeratosis, splinter hemorrhages, oil drop discoloration
Lichen planus	Violaceous discoloration, atrophy of nail bed; if nail matrix is involved, trachyonychia, hapalonychia (soft nails), dorsal pterygium
Other nail bed conditions	
Hemorrhage, trauma	Red–violet to black discoloration under nail plate; persistent or non-migrating discoloration needs to be distinguished from melanoma

Table 149.2 Clinical features of nail bed disorders in which a biopsy may facilitate diagnosis and subsequent treatment.

pathologic examination or culture, should be repositioned to cover and protect the wound during the early stages of the healing process. It can be secured by sutures or adhesive. Although the plate will not reattach and is eventually shed, it provides protection and minimizes discomfort during the immediate postoperative period.

BIOPSY TECHNIQUES

To minimize scarring and offer the best functional and cosmetic outcome, nail surgical procedures should follow a few rules. Within the nail bed, the incision should be oriented longitudinally, whereas within the matrix it should ideally be oriented horizontally (Fig. 149.11). The surgical approach depends upon the location of the pathology within the nail unit.

Nail Bed Biopsy

Nail bed biopsy is a simple and safe technique for the diagnosis of a variety of nail bed disorders, from onycholysis to tumors (Table 149.2). The nail plate is usually partially avulsed prior to the nail bed biopsy (Fig. 149.12A). If the defect is >4 mm, re-approximation of the edges is recommended. However, the nail bed is fragile and suturing of the margins may be difficult. To facilitate closure of the wound, generous lateral undermining should be performed at the level of the periosteum. Nonetheless, it is amazing how very large defects of the nail bed (e.g. after Mohs surgery) may regenerate totally by second intention[1].

For the removal of tumors such as onychopapillomas, elliptical excisional biopsies of the nail bed along a longitudinal axis are recommended (Fig. 149.12B,C). Closure is performed with absorbable sutures (e.g. Vicryl®) (Fig. 149.12D).

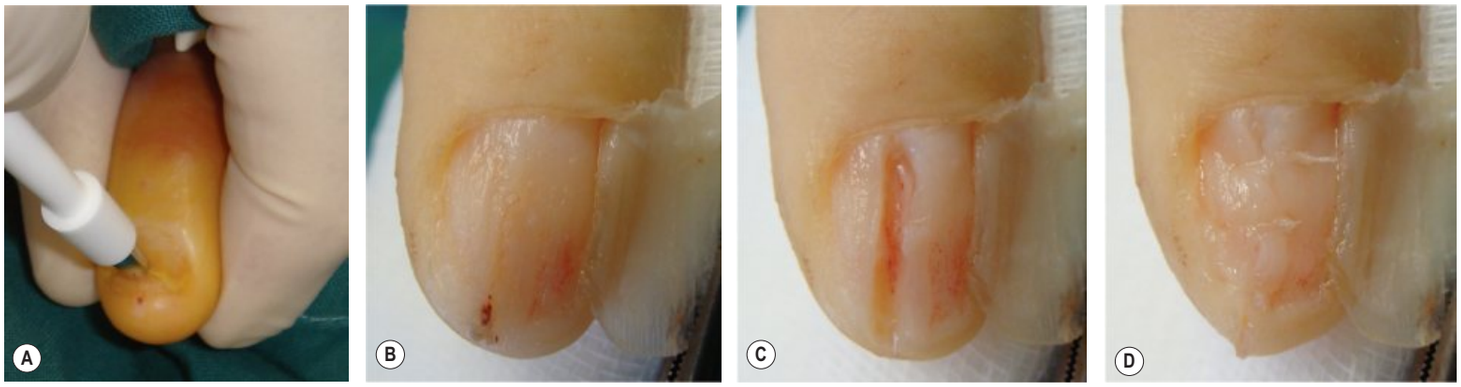

Fig. 149.12 Nail bed biopsy – punch biopsy versus longitudinal excisional biopsy. A After partial nail avulsion, the punch biopsy instrument is rotated with pressure until there is contact with bone. **B** Lateral avulsion of the nail plate exposes an onychopapilloma along the nail bed. **C** Longitudinal incision allows delicate dissection of the tumor from the bone. **D** Suturing of the nail bed; the nail plate will be returned to its original location and secured to the lateral fold.

Nail Matrix Biopsy

Nail matrix biopsy has one major indication: determination of the cause of longitudinal melanonychia (see Ch. 71). The biopsy must be taken from the nail matrix because that is where the pigment is generated. Fortunately, in ~95% of patients, the pigment's origin is within the *distal* matrix[11]. Since the latter synthesizes the ventral portion of the nail plate (see Fig. 149.2), the primary sequela is a nail plate thinned from below. If the pigment origin is located within the *proximal* matrix, then nail plate dystrophy will result, usually as a longitudinal fissure; this is because the proximal matrix generates the dorsal (upper) one-third of the nail plate.

In order to expose the entire matrix area, both retraction of the proximal nail fold and proximal nail avulsion are performed (Fig. 149.13). Once the matrix is exposed, the appropriate surgical technique is chosen based upon the width and shape of the pigmented band. The entire pigmented area is removed to ensure complete histologic examination.

- If the pigment origin is roundish and fits within a 3 mm punch biopsy trephine, it can be removed with that instrument. However, two caveats apply: (1) the trephine should be advanced down to bone, with the specimen severed at the level of the periosteum; and (2) the specimen should be harvested with delicate curved, fine-tipped scissors. Handling fragile matrix tissue with forceps will crush it and induce artifacts[12]. The defect does not need to be sutured.
- If the pigment origin has a longitudinal orientation, then a narrow elliptical excision down to the bone is recommended. Delicate lateral undermining allows closure of the defect with 5-0 absorbable sutures.
- If the pigment origin involves a wide area of the matrix, a tangential excision is indicated. This technique virtually "shaves" the matrix, removing the matrix epidermis and a small portion of dermis. It allows the pathologist to examine the entire lesion, but the margins are usually difficult to assess. The resultant specimens have been shown to provide adequate tissue for accurate histopathologic diagnosis. In general, postoperative nail plate dystrophy is not observed even if nearly the entire *distal* matrix has been removed. In contrast, tangential excision of the *proximal* matrix results in nail thinning and brittleness in most patients, but rarely pterygium. It is noteworthy that this technique avoids mutilating surgery, especially since the cause of longitudinal melanonychia is often a benign process[13]. Lastly, the nail plate is put back in place and secured to the lateral nail fold.
- When the pigmented streak is located within the lateral third of the nail plate, a lateral longitudinal biopsy (see next section) is appropriate.

Lateral Longitudinal Biopsy

This procedure permits examination of the entire nail apparatus including the proximal nail fold, matrix, nail bed, nail plate, and hyponychium. It is especially helpful in diseases involving the proximal portion of the nail apparatus (often presenting as alterations of the surface of the nail plate) and for inflammatory disorders in which all these structures are affected concomitantly. Obvious clinical involvement of the lateral aspect of at least one nail is required. The patient must be warned that this type of biopsy will narrow the nail permanently due to the partial amputation of the lateral horn of the matrix. In order to avoid postoperative lateral deviation, the specimen should be <3 mm in width[14].

The incision begins halfway between the cuticle and the crease of the DIP joint and extends distally through the proximal nail fold, then the nail plate and its bed until the hyponychium is reached. A second parallel incision is made in the lateral nail groove, joining the initial incision at the fingertip (Fig. 149.14A). Proximally, the incision curves laterally in order to remove the lateral horn of the matrix[15]. The latter is especially important with the great toenail (see Fig. 149.2). The specimen is then carefully detached from the bone with delicate scissors. Detaching the matrix from the bone at the proximal tip of the biopsy specimen is a critical step, and care should be taken to avoid curving the scissors upward too soon and foreshortening the specimen[16]. Residual lateral nail matrix tissue leads to nail spicule formation (Fig. 149.15). The defect is re-approximated with horizontal mattress sutures in order to recreate a lateral nail fold (Fig. 149.14B). This technique may be utilized for various tumors, including longitudinal melanonychia of the lateral third of the nail plate.

Proximal Nail Fold Biopsy

Lesions of the proximal nail fold can be biopsied via shave, punch, or incisional techniques as well as excised *en bloc*, similar to cutaneous lesions elsewhere. A Freer elevator may be inserted beneath the proximal nail fold to shield the matrix from inadvertent damage from the scalpel (Fig. 149.16).

SURGICAL PROCEDURES FOR DISORDERS OF THE NAIL UNIT

Acute Paronychia

Unless there is spontaneous drainage, acute paronychia requires prompt surgical intervention. In addition to the associated pain, long-standing pressure on the matrix from the collection of pus may impair normal regrowth of the nail plate, especially in children. Incision of the proximal nail fold is discouraged as this can lead to retraction and distortion of the fold. If the abscess is under the proximal nail fold or around the base of the nail ("runaround"), avulsion of the proximal third of the nail plate will allow immediate drainage and bacterial culture (Fig. 149.17A–C). This also allows for the nail pocket to be rinsed with an antiseptic solution. Avulsion of a lateral strip of nail plate can be done if the abscess is within the lateral nail fold.

Chronic Paronychia

When medical treatment of chronic paronychia fails (see Ch. 71), surgical treatment can be considered (Fig. 149.18A). There are two recommended procedures: (1) *en bloc crescentic excision*; and (2) *square-flap technique*. In the former, a Freer elevator is inserted under the proximal nail fold in order to protect the matrix. A #15 surgical blade is then used to excise *en bloc* a crescent-shaped, full-thickness piece of skin that is 4 mm at its greatest width, extending from one lateral nail fold to the other (Fig. 149.18B). A beveled incision angled

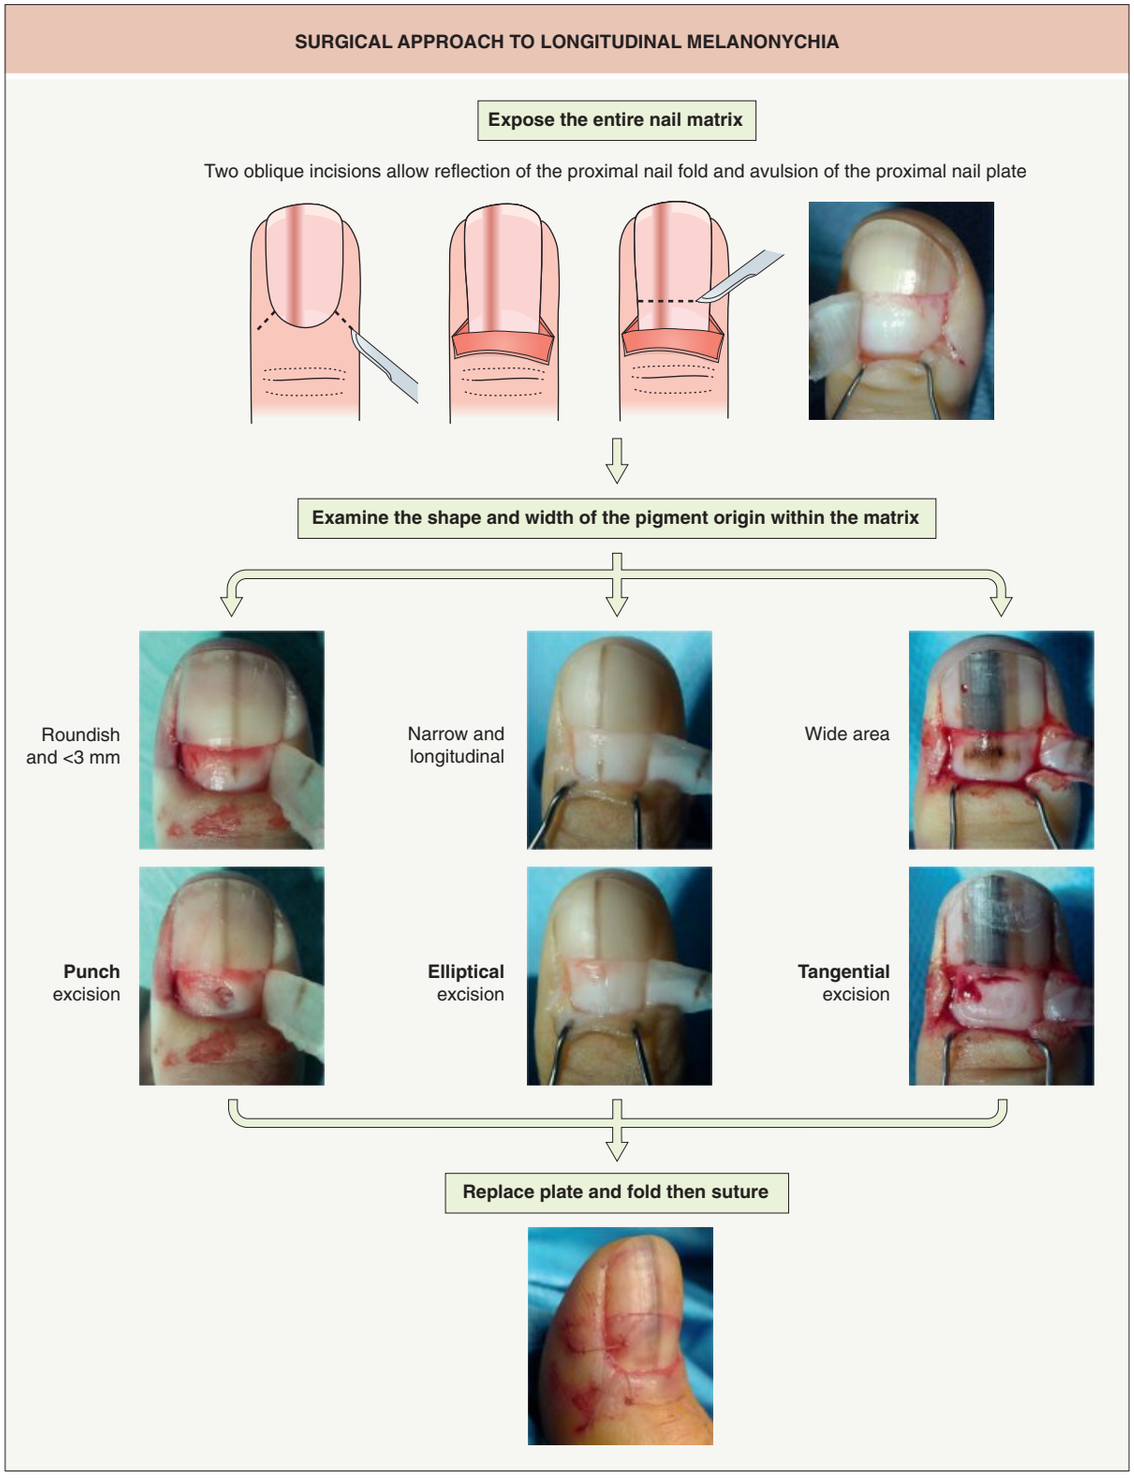

Fig. 149.13 Surgical approach to longitudinal melanonychia. Following two oblique incisions at the junction of the lateral and proximal nail folds, retraction of the proximal nail fold, and proximal lateral avulsion of the plate, the entire matrix, including the origin of the pigmented band, is visualized. The type of biopsy depends upon the size and shape of the pigment origin. At the conclusion of the procedure, the plate and the proximal nail fold are placed back in their original positions and secured. A fourth option is a lateral longitudinal biopsy when the pigmented streak is located within the lateral third of the nail plate (see Fig. 149.14A).

at 45° prevents removal of the nail-producing tissues of the proximal nail fold responsible for the normal shine of the nail plate[17]. Complete healing by second intention restores the proximal nail fold with its cuticle within 8–10 days (Fig. 149.18C). The cosmetic outcome is excellent, with only a greater portion of the nail plate and lunula visible. In the square-flap technique, two lateral oblique releasing incisions allow the proximal nail fold to be tilted backwards exposing its fibrotic undersurface. All fibrotic material is removed and the flap returned to its original position and sutured. The major advantage of this procedure is that lengthening of the visible nail plate does not occur[18].

Ingrown Toenail

There is an ongoing debate regarding both the treatment and the cause of this painful condition, i.e. is the nail itself or the surrounding tissues at fault? There are two major surgical approaches: (1) narrow the nail plate; or (2) debulk surrounding soft tissues. The surgeon must select the most appropriate approach on an individual basis[19].

Lateral matricectomy via chemical cautery represents the easiest and most useful technique for patients with laterally ingrown toenails. The key is to destroy the portion of the nail matrix associated with the ingrown part of the nail. Two successive systematic Cochrane reviews found that the use of phenol (88%) was the most effective therapeutic approach in terms of morbidity and success rate (based upon recurrences at 6+ months), as compared to excisional surgical procedures[20]. In most large studies, the success rate has been 95% or greater[21–23]. Phenol has three relevant properties: it is necrotizing, a disinfectant, and an anesthetic. This leads to a very comfortable postoperative period, as phenol induces demyelination of terminal nerve endings for several weeks[24].

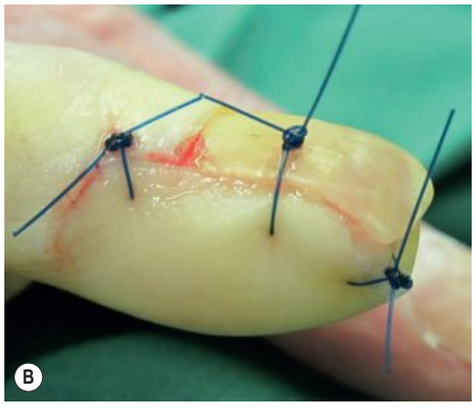

Fig. 149.14 Lateral longitudinal biopsy. **A** Note the downward curve of the proximal portion of the excision; this ensures removal of the lateral horn of the matrix. **B** Sutures are placed to close the defect and the lateral fold is re-created. *Courtesy Marie Caucanas, MD.*

A Loss of the cuticle, rolled proximal nail fold, and dystrophy of the nail plate with yellowing, ridging, and roughness. **B** Crescent-shaped resection of the proximal nail fold, extending from one lateral nail fold to the other. Note the beveled 45° angle of the incision. **C** Appearance on postoperative day 8.

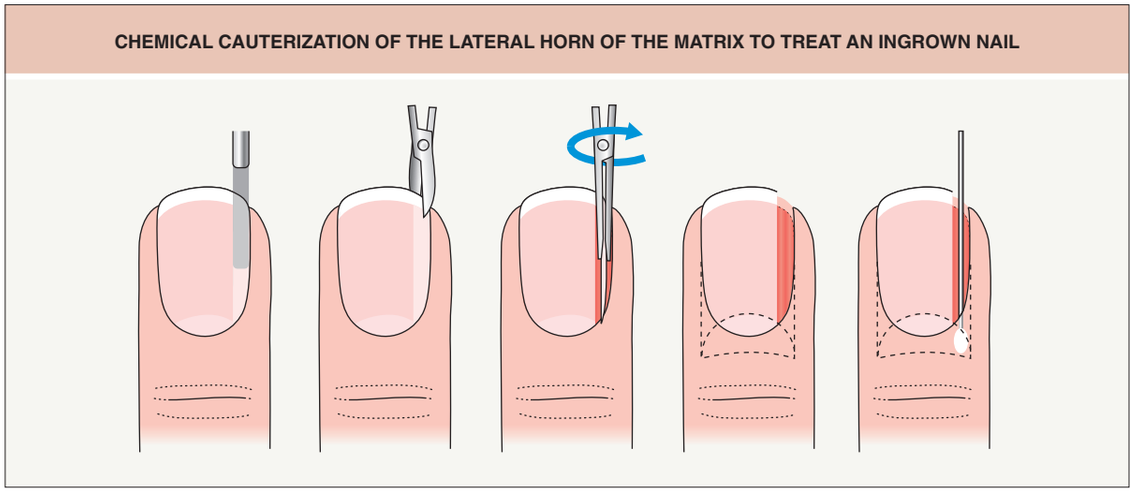

Fig. 149.19 Chemical cauterization of the lateral horn of the matrix to treat an ingrown nail. A strip of nail plate ~3 to 5 mm in width is elevated, cut, and then avulsed up to its origin under the proximal nail fold. The cauterant, usually 88% phenol, is applied onto the exposed lateral horn of the matrix and bed with a wisp of cotton wool (see Videos 149.1–149.5).

After anesthesia is established, a tourniquet is placed to ensure a completely bloodless field. Granulation tissue, if present, is curetted for a better view of the lateral part of the nail plate, so as to avoid excessive nail plate removal. A lateral or bilateral (if the condition affects both sides) strip of nail plate ~3 to 5 mm in width is avulsed up to its origin under the proximal nail fold (Fig. 149.19). *Phenol* (88%) is applied onto the exposed lateral horn of the matrix and bed with a wisp of cotton wool, urethral swab, nasopharyngeal swab, or the elevator itself (Videos 149.1–149.5). Cotton swabs should not be oversoaked as this may result in cauterant spilling onto periungual tissue or seeping under the remaining nail plate (and leading to unwanted destruction). Phenol acts by coagulating tissue proteins and a bloodless field is mandatory at this point otherwise the phenol coagulates blood proteins rather than matrix epithelium. This is the most common reason for recurrences.

Based upon histologic studies in cadavers, the ideal application time is four minutes[25]. Curettage of the matrix prior to applying the cauterant does not increase the success rate[26], and rinsing with alcohol merely dilutes the phenol but does not neutralize it[27]. Bleeding after removal of the tourniquet will inactivate the cauterant. Phenol is safe in diabetics[28] and children[29] and for recalcitrant ingrown nails from epidermal growth factor receptor (EGFR) inhibitors[30]. The major drawback of this technique is oozing for 2 to 4 weeks. This may promote infection, especially in patients with poor hygiene. However, in view of the numerous phenol matricectomies performed, infections remain very rare. Pincer nails, characterized by hypercurvature of both sides of the nail, can also be managed with bilateral phenol matricectomy.

Trichloracetic acid (100%) is an excellent alternative as success rates and postoperative morbidity are similar to phenol[31]. Application time is one minute[32]. For distal embedding and very hypertrophic and exuberant lateral folds, wide debulking with second intention healing is easy to perform and very effective with an excellent cosmetic outcome[33,34]. The main drawback is the prolonged healing time.

Tumors and Cysts

The clinical features of the following tumors and cysts are discussed in Chapter 71.

Fibrokeratoma

For subungual fibrokeratomas, reflection of the proximal nail fold following two oblique incisions is mandatory to expose the cul-de-sac. In most instances, the fibrokeratoma originates either at the most proximal portion of the cul-de-sac or from the undersurface of the proximal nail fold. The tumor should be delicately dissected using fine scissors until reaching its base, where it is severed. Injury to the matrix is quite unlikely as the nail plate remains in place. The proximal nail fold is then returned to its original position and secured with 5-0 sutures. Incomplete resection leads to recurrence[35]. Fibrokeratomas of the nail bed are rare and should be excised via a longitudinal ellipse after plate avulsion.

Subungual exostosis

After nail avulsion, either dissection with preservation of the nail bed or *en bloc* resection of the tumor with a bone rongeur followed by second intention healing works well. Both procedures should expose spongious bone[36,37] and be performed under full aseptic conditions.

Glomus tumor

After avulsion of the plate, the tumor is gently extirpated with fine curved scissors via a longitudinally or transversally oriented incision; the orientation depends upon whether the tumor is within the nail bed (longitudinal) or the nail matrix (transverse) (see Fig. 149.11). The incision is closed with interrupted absorbable sutures and the nail plate is placed back and secured to the lateral folds (Fig. 149.20).

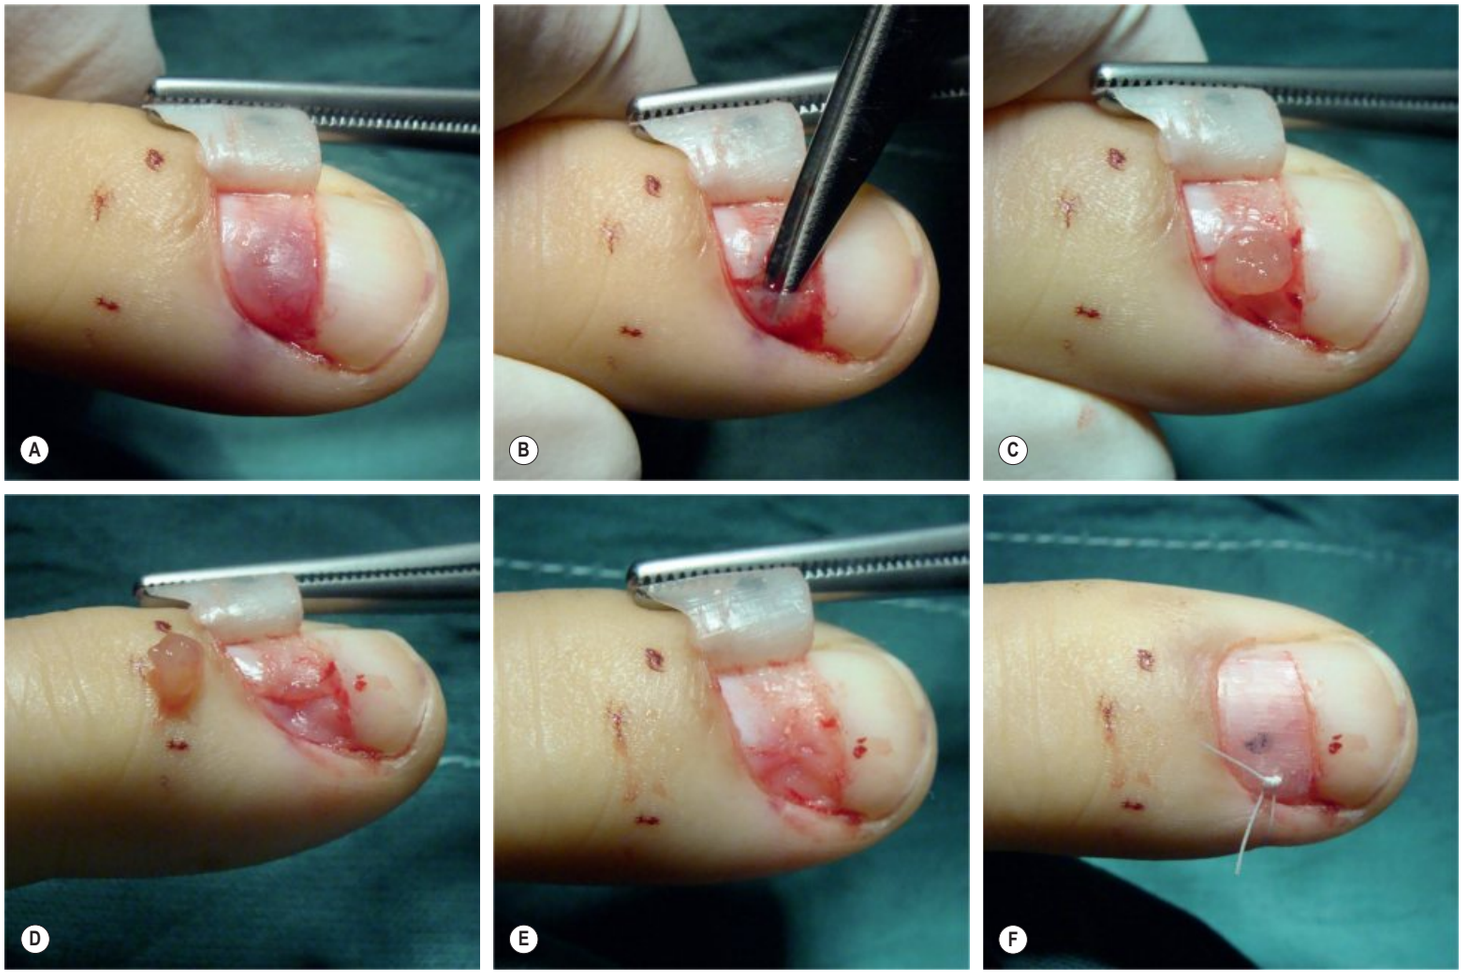

Fig. 149.20 Removal of a nail bed glomus tumor. A Proximal lateral avulsion of the nail plate exposes the tumor within the nail bed. **B** A longitudinal incision allows delicate dissection of the tumor from the bone with smooth-tipped curved scissors. **C, D** Extirpation of the tumor. **E** Suturing of the nail bed. **F** The nail plate is returned to its original location and secured to the lateral fold.

Onychomatricoma

A delicate distal (to proximal) avulsion, taking care not to tear the digitations, exposes a villous tumor resting on the matrix. The proximal nail fold is tilted backwards. The tumor is tangentially excised from the matrix with a Teflon™-coated blade[38,39]. To avoid any adherence between the ventral aspect of the proximal fold and the matrix that could result in a pterygium, the surgeon can slide some tulle gras into the nail pocket and secure it with two sutures for three weeks. Lastly, the proximal nail fold is placed back into its original location and the two lateral incisions sutured closed.

Digital myxoid cyst (pseudocyst)

For pseudocysts resting over the DIP joint (type A), the best option is drainage followed by cryotherapy (double freeze-thaw). When located in the dorsal nail fold and pressing onto the underlying matrix (type B), drainage followed by compressive dressings for several weeks is associated with a high success rate. The same procedure is recommended for myxoid pseudocysts expanding under the matrix (type C). If the patient has experienced several relapses with the conservative approach or wishes to undergo a definitive procedure, methylene blue-guided surgery to ligate the joint fluid leak is an elegant, comfortable, and efficient technique[40]. Sometimes a proximal nail fold flap is raised to dissect the pseudocyst.

Squamous cell carcinoma

The goal is to preserve the digit and its function[41]. Surgical excision with histologic control of the margins is recommended, including performing Mohs micrographic surgery[42]. Closure may be accomplished via a flap, graft, or second intention healing. Recurrence is possible as human papillomavirus is causative in about up to two-thirds of patients[43,44]. If bony involvement is demonstrated radiographically or histologically, amputation of the distal phalanx is indicated.

Melanoma

In several series with long-term follow-up as well as in a meta-analysis[45], *in situ* or thin melanomas (Breslow depth ≤0.5 mm) treated with *en bloc* removal of the nail unit, with >6 mm margins, has resulted in an excellent survival rate (100%)[46–48]. Because the dermis of the matrix and nail bed rests directly on bone, ensuring that the deep margin is clear of tumor requires greater attention. Closure is obtained with second intention healing or a full-thickness graft (see Fig. 148.7A). For deeper melanomas, there is accumulating evidence to support recommending digit-sparing surgery versus amputation[49–51].

Hemostasis

Intraoperative hemostasis is ensured with a tourniquet. Postoperative bleeding varies depending upon the type of surgery. For limited bleeding, application of a cotton-tipped applicator dipped in 35% aluminum chloride will suffice. If bleeding is moderate, oxidized cellulose or gelatin sterile sponges work well. For severe postoperative bleeding, injection of local anesthetic (0.5 ml) into the lateral aspect of the digit at the level of the digital artery will act as a volumetric tourniquet, until clotting occurs. The use of a bulky dressing for at least 48 hours combined with elevation of the limb limits the risk of excessive postoperative bleeding[52].

POSTOPERATIVE CARE

Proper dressings can reduce postoperative pain and throbbing and minimize complications. The dressing should be nonadherent, absorbent, and perfectly fitted so it remains in place. Applying large amounts of ointment (possibly containing antiseptics) covered with a nonadherent dressing such as petrolatum-impregnated gauze (e.g. Vaseline™ gauze,

Tulle gras, Adaptic®), or with added antiseptics (e.g. Xeroform™ gauze, Bactigras®, Betadine Tulle®), will protect the wound from drying and will allow an easy and painless removal. If postoperative bleeding is noticed, a bulky dressing made of two or three loose layers of mesh gauze will absorb bleeding and provide protection against trauma. A bandage or tube gauze such as Xspan® secures the dressing in place. Given the likelihood of postoperative edema, the dressing should not be too constrictive.

Postoperative pain management relies on two major interventions: elevation of the limb for 48 hours and analgesics. The latter should be adapted to the expected pain from the surgery. Acetaminophen and/or nonsteroidal anti-inflammatory drugs (NSAIDs) are usually enough, but for some painful procedures, narcotic analgesics are sometimes prescribed. Keeping the limb elevated will minimize throbbing. Bleeding into the dressing can result in the bandage sticking to the surgical site. If this occurs, soaking the bandage will loosen it prior to its removal. Written instructions on how to perform postoperative care at home are highly recommended. Patients should also be informed about long-term paresthesias, especially at the digit tip, that can follow nail surgery and may last up to six months[53].

COMPLICATIONS OF NAIL SURGERY

Nail surgery is safe and effective. However, as with any surgical procedure, complications may occur. General complications are similar to those observed at other anatomic sites, e.g. hematomas, infection, necrosis, bleeding, keratin implantation cysts, tumor recurrence, and hypertrophic scars or keloids. Nail surgery-specific complications include lateral deviation of the plate after partial ablation of the nail apparatus, nail dystrophy, distal embedding of the plate, and formation of nail spicules (see Fig. 149.15). In addition, nail surgery can lead to pyogenic granuloma formation, complex regional pain syndrome (reflex sympathetic dystrophy)[54], and deep infections such as osteomyelitis and septic arthritis (Table 149.3). When the principles of nail surgery are carefully followed by the surgeon and if the patient adheres to the specific instructions from the physician regarding wound care and postoperative treatment regimens, significant complications are rare[52,55]. If necessary, the dermatologic surgeon should involve fellow dermatologists, hand surgeons, or infectious disease specialists who may be able to offer their assistance and expertise with difficult cases.

COMPLICATIONS OF NAIL SURGERY
Short-term (within 14 days of surgery)
• Bleeding, pain, infection (including septic arthritis, osteomyelitis), pyogenic granuloma
Long-term (>3 months following surgery)
• *Neurologic:* Paresthesias (common) Complex pain syndrome (reflex sympathetic dystrophy) (very rare)
• *Dystrophy:* Lateral deviation of the plate (if lateral removal >3 mm) Plate dystrophy, e.g. splits, ridges, grooves, thinning, from matrix scarring Pterygium due to scarring within the proximal fold and matrix Onycholysis due to nail bed scarring Cuticle retraction due to cuticle scarring
• *Distal embedding* from nail shedding and dorsal distortion of the pulp
• *Nail spicules* due to incomplete removal of the lateral horns of the matrix
• *Recurrence of tumor* because of incomplete removal
• *Implantation cyst* (common after full-thickness grafting)
• *Hypertrophic scars and keloids* (latter very rare even in populations at risk)

Table 149.3 Complications of nail surgery.

PATIENT EVALUATION PRIOR TO NAIL SURGERY
History

• Medical history
  • Diabetes mellitus
  • Peripheral artery disease
  • Autoimmune connective tissue disease
  • Raynaud phenomenon
  • Arthritis
  • Prosthetic joints or heart valves
  • Bleeding diathesis
• Drug history
  • Allergies
  • Use of anticoagulants, antiplatelet agents (salicylates, thienopyridines, NSAIDs)
  • Use of herbal medicine
• Cutaneous history
  • History of the nail condition (duration, progression, exposures, trauma)
  • Psoriasis, lichen planus or other cutaneous disorders with nail manifestations
  • Previous malignancies
• Previous fungal, bacterial and/or viral cultures or diagnostic tests
  • Occupation and hobbies

Examination
• All 20 nails, good lighting and magnification • Mucous membranes, hair, and scalp • Pertinent cutaneous examination • Peripheral pulses, especially in toenail surgery
Laboratory tests
• Radiography, diagnostic imaging studies (e.g. MRI) • Mycology, microbiology or virology studies
"Procedure, alternatives and risks" discussion (see Table 149.3)
• Possibility of permanent dystrophy • Possibility of no diagnosis • Length of time for nail to regrow • Bleeding, infection, and pain, as with any surgery

eTable 149.1 Patient evaluation prior to nail surgery. MRI, magnetic resonance imaging; NSAIDs, nonsteroidal anti-inflammatory drugs.

ETIOLOGIES OF A PSEUDO-HUTCHINSON SIGN
Pigment present in paronychium
• Normal variant for Fitzpatrick skin phototypes IV, V and VI • Laugier–Hunziker syndrome, Peutz–Jeghers syndrome • Radiation exposure • Malnutrition • Medications (e.g. minocycline, zidovudine [AZT]) • Postinflammatory • Benign melanocytic nevi, lentigines • Regressing nevoid melanosis in childhood • Subungual hematoma
Pigment visible through paronychium
• Neoplasms (benign nevi, squamous cell carcinoma, basal cell carcinoma) • Subungual hematoma

eTable 149.3 Etiologies of a pseudo-Hutchinson sign.

NAIL UNIT TUMORS: RADIOGRAPHIC FINDINGS AND SURGICAL TREATMENTS		
Tumor	**Radiographic findings**	**Surgical treatment**
Subungual exostosis	Radiopaque bone growth that is well circumscribed	Nail plate avulsion followed by surgical removal (can use bone rongeur)[e1]
Keratoacanthoma	Cup-shaped radiolucent defect (early)	Surgical excision[e2]
Enchondroma	Central round radiolucent defect	Surgical excision*
Squamous cell carcinoma	Radiolucent defect (late)	Microscopically controlled (Mohs) surgery)[e3–e5]
Glomus tumor	Occasional radiolucent defect; can visualize via MRI	Surgical excision (nail bed – longitudinal axis; nail matrix – horizontal axis)[e6]
Myxoid cyst	Osteoarthritis	Cryosurgery, surgical excision (can use nail elevator to protect matrix)[e7]

Synonyms: ■ Mohs surgery ■ Chemosurgery ■ Mohs chemosurgery (fresh tissue technique and fixed tissue technique)

Key features

- Based upon the concept of contiguous spread of a tumor from a single focus
- 100% microscopic tissue margin examination
- Highest evidence-based cure rate for cutaneous malignancies, but success is dependent on resources and skills of the surgeon and histotechnician
- Same physician serves as both surgeon and pathologist
- Precise excision of cancerous tissue
- Preservation of the maximum amount of non-cancerous tissue
- Total tissue control and precise mapping
- Immediate re-excision of residual cancerous tissue as indicated
- Reconstruction typically performed by Mohs surgeon
- Exceedingly low complication rate

INTRODUCTION

Mohs micrographic surgery (MMS) is a specialized method for skin cancer removal that combines surgery with pathology resulting in an excellent cure rate. The goals are to remove only the cancerous tissue while viewing the complete margin, thereby preserving the maximum amount of normal tissue (i.e. tissue-sparing). From a functional, aesthetic and reconstructive perspective, tissue-sparing is especially important for skin cancers in the periorbital, nasal, auricular, perioral, digital, and anogenital areas. MMS is also the preferred treatment method for skin cancers that are clinically poorly defined, recurrent, and/or have a higher risk of recurrence because of histologic features or anatomic location (Table 150.1).

There are four major components: surgical excision, histopathologic examination, precise mapping, and wound management. The *surgical* component consists of removing a disc of tissue with a beveled surgical margin (Fig. 150.1A). The disc of tissue, or "layer", ensures that the entire 360° of tumor margin is circumferentially removed and examined. The *histopathologic* component involves cryopreserving this disc and cutting it in a horizontal fashion, then mounting sections onto glass slides, followed by staining and microscopic examination for residual tumor. This processing technique differs from standard excisions in which specimens are formalin-fixed, paraffin-embedded (FFPE) and cut in a "bread-loaf" fashion (Fig. 150.1B). Precise *mapping* entails marking any residual tumor on the map of the excision with the remaining positive area of tumor re-excised as indicated. This three-step process is repeated until there is no residual tumor identified microscopically. During this procedure, the Mohs surgeon has complete control of the excised tissue, including laboratory processing and interpretation of the tissue sections, as well as precise mapping. In the fourth step, *wound management*, the tumor-free defect is surgically closed or allowed to heal by second intention.

INDICATIONS FOR MOHS MICROGRAPHIC SURGERY FOR NON-MELANOMA SKIN CANCER (KERATINOCYTE CARCINOMA)
Tumor characteristics[1]

• Recurrent
• High-risk* anatomic location (Area H): "Mask areas" of the face (central face, eyelids, eyebrows, nose, lips, chin, ear, and periauricular skin/sulci, temple; Fig. 150.2), anogenital region, hands, feet, nail units, ankles, and nipples/areola
• Medium-risk† anatomic location (Area M): Face outside of area H, scalp, neck, pretibial leg
• Aggressive histologic subtype:
  • BCC: morpheaform (sclerosing), micronodular, basosquamous (metatypical), infiltrating
  • SCC: Breslow depth >2 mm, Clark level >III, deeply penetrating, poorly differentiated or undifferentiated‡, spindle cell, sclerosing, small cell, clear cell, lymphoepithelioma-like, sarcomatoid, acantholytic¶
• Perineural invasion
• Large size (>2 cm diameter)
• Poorly defined clinical borders (lateral and/or deep)
• Rapid growth
• Positive margin on recent excision

Characteristics of background skin
• Prior exposure to ionizing radiation • Chronic scar (Marjolin ulcer)
Patient characteristics
• Immunocompromised: solid organ transplant recipient, chronic lymphocytic leukemia, HIV infection, pharmacologic immunosuppression • Underlying genetic syndrome, e.g. xeroderma pigmentosum, basal cell nevus syndrome, Bazex–Dupré–Christol syndrome • Patient known to have previous high-risk tumors without other known health risk factors
*High risk for recurrence. †Medium risk for recurrence. ‡High degree of nuclear polymorphism, high mitotic rate, or low degree of keratinization. ¶Not included in the Appropriate Use Criteria (AUC) criteria[1].

Table 150.1 Indications for Mohs micrographic surgery for non-melanoma skin cancer (keratinocyte carcinoma). BCC, basal cell carcinoma; SCC, squamous cell carcinoma.

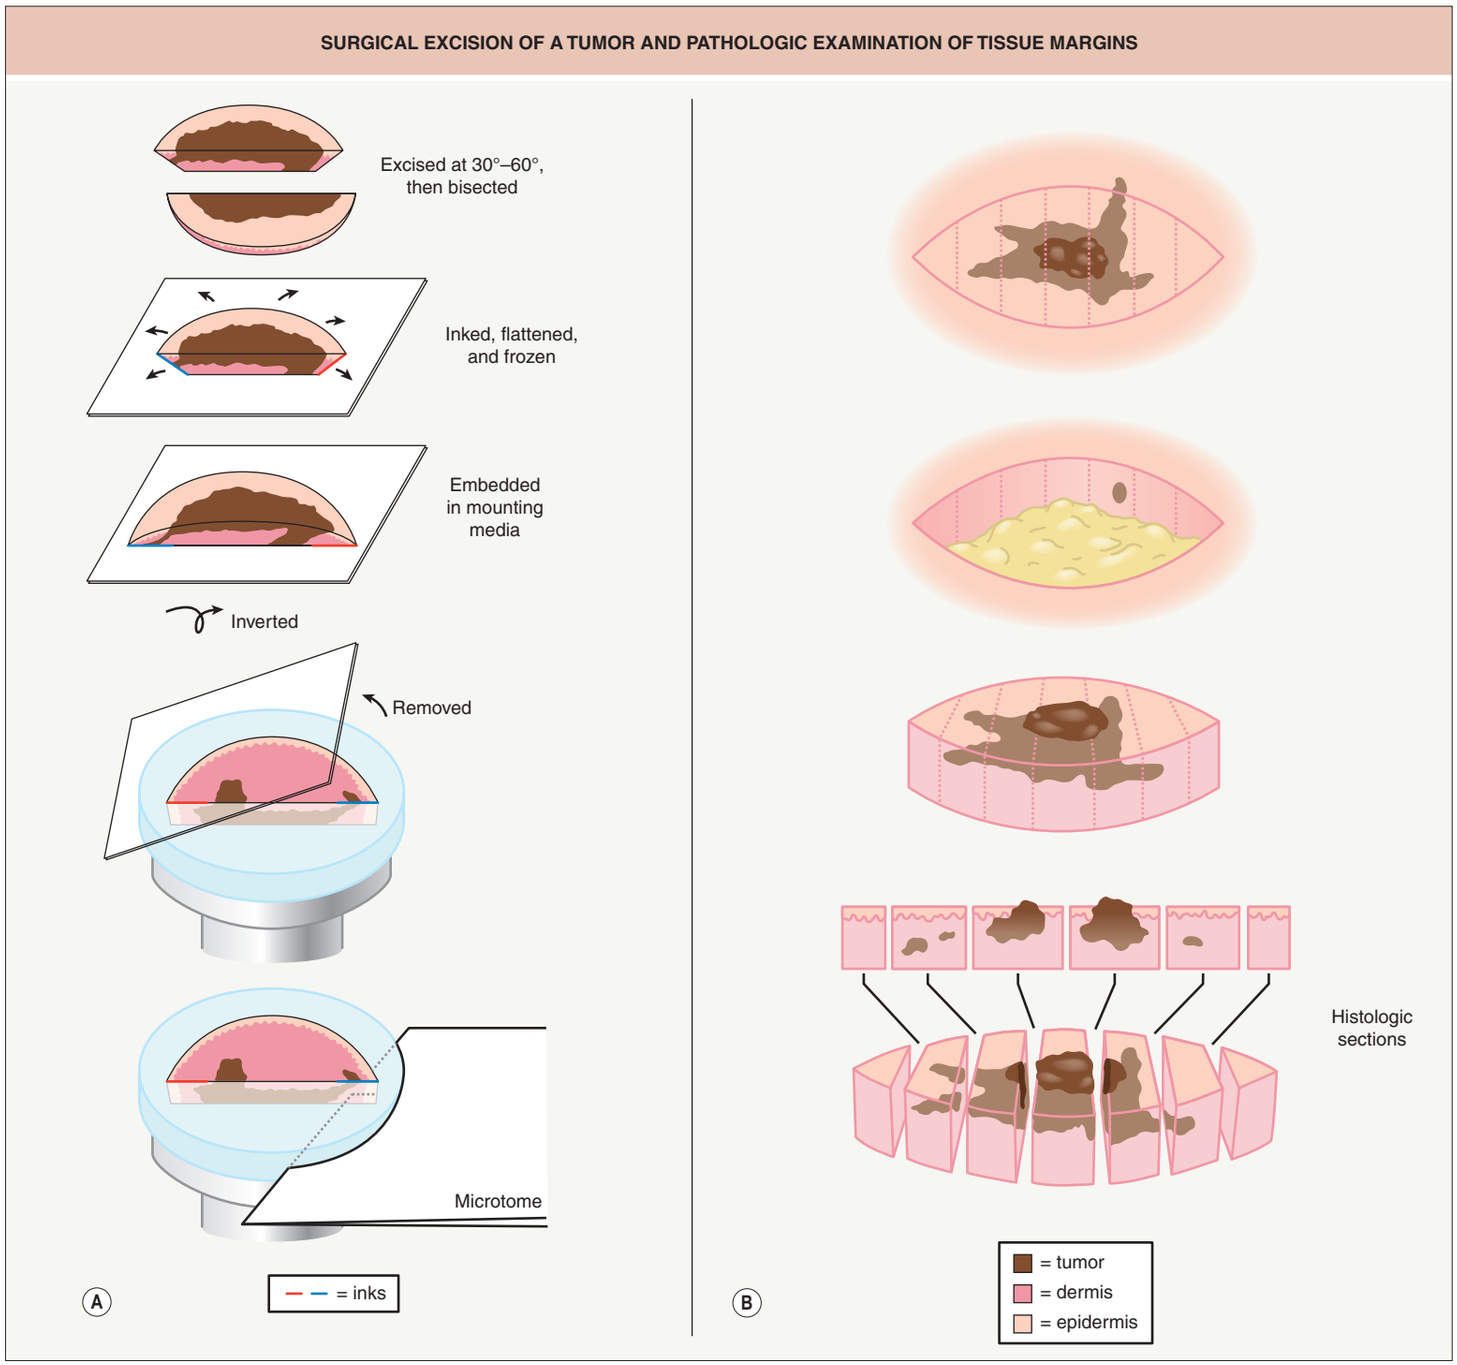

Fig. 150.1 Surgical excision of a tumor and pathologic examination of tissue margins. A Mohs micrographic surgery in which 100% of the total margin is examined. Following excision with a narrow margin, the specimen is flattened so that when the tissue is horizontally sectioned, the skin edge is in the same plane as the deep margin. Note the inversion of the tissue prior to sectioning. **B** Standard elliptical excision with vertical tissue sectioning ("bread loafing"). Histologically, the margins may appear clear even though there is still residual tumor.

HISTORY

Originally termed *chemosurgery*, MMS was developed by Dr Frederic E. Mohs at the University of Wisconsin-Madison and first published in 1941[2]. His original clinical technique involved the application of a zinc chloride paste to cancerous tissue 24 hours prior to surgical removal of the tumor. The paste fixed and isolated the tumor *in vivo*. Subsequently, the tumor was excised and processed in a manner similar to the technique used today. However, if there were residual tumor at the margins, zinc chloride paste was re-applied to cancerous margins for 24 hours prior to any further tissue resection. These steps were repeated until complete tumor clearance was obtained[3].

Limitations of this process include a long incubation period and tissue necrosis from the zinc chloride paste which renders wounds unsuitable for surgical reconstruction. The latter led to Dr Mohs' second major innovation – an objective analysis of second intention wound healing. Historically, surgical dogma held that second intention healing produced inferior cosmetic results compared to reconstruction, the surgeon's "first intention for healing". The acceptable, and at times superior, cosmetic outcome associated with second intention healing, particularly on concave surfaces, imparts its rightful place among valid reconstructive techniques.

Over 40 years ago, the zinc chloride-based, fixed tissue technique evolved into the fresh-frozen tissue technique[3], which was popularized by Tromovitch and Stegman[4]. The fresh-frozen section technique eliminated the need for the escharotic zinc chloride paste, and it allowed complete tumor clearance via multiple resections in a single day. Furthermore, without a zinc chloride-induced necrotic base, immediate

surgical reconstruction could be performed. The fresh tissue technique has now become the standard protocol for MMS.

TRAINING IN MOHS MICROGRAPHIC SURGERY

Training in MMS involves all aspects of cutaneous oncology, tumor resection, tissue preparation, histologic interpretation, and reconstruction. The substantial clinical, surgical, and histopathologic training received during a dermatology residency provides the background for specialized training in MMS. One of the unique advantages of Mohs surgical training is the degree of expertise in clinicopathologic correlation, which derives from dual training in both clinical and pathologic tumor assessment. The dermatologic surgeon must also acquire a mastery of cutaneous and soft tissue anatomy as well as reconstruction. MMS training programs differ depending upon the country, with a one-year Accreditation Council for Graduate Medical Education (ACGME) fellowships available in the US[5].

Both the American Board of Dermatology (ABD) and the American Osteopathic Board of Dermatology offer subspecialty certification in Micrographic Dermatologic Surgery. After 2025, a prerequisite for the ABD certifying examination will be completion of an ACGME-approved Micrographic Surgery and Dermatologic Oncology fellowship.

APPROPRIATE USE CRITERIA AND COST-EFFECTIVE CARE

In 2012, there was a multi-society collaboration to develop appropriate use criteria (AUC) for MMS[1]. For each of 270 clinical scenarios, a panel of surgical and medical dermatologists examined the rational use of MMS, taking into account multiple factors including size, behavior, and location (Fig. 150.2)[1,6]. In addition, tumors that did not require MMS, e.g. small basal cell carcinomas on the trunk, were identified (www.aad.org/education/appropriate-use-criteria/mohs-surgery-auc). The National Comprehensive Cancer Network (NCCN) guidelines for the treatment of cutaneous malignancies is also available as a reference[7].

Studies on the cost-effectiveness of MMS have produced variable results and conclusions, depending on the study location and methods[8,9]. When standard excision with FFPE sections and immediate repair is compared with MMS, the costs are either similar or the former is slightly less expensive than MMS. However, the cost-effectiveness of MMS is enhanced when the following factors are taken into account: the physical location of the surgical procedure (office-based vs. ambulatory surgery center or hospital), specimen processing (frozen vs. permanent sections), type and extent of reconstruction required (smaller defect size due to tissue-sparing vs. standard wide local excision), and the need for additional surgery for tumor recurrences[8–12]. Hopefully, application of MMS AUC[1] will lead to even greater cost savings.

INDICATIONS

Most skin cancers are locally invasive and, depending on their location, can invade vital structures such as the eye, nose, lips and ears, leading to significant tissue destruction. With time and neglect, metastasis may develop. The majority of non-melanoma skin cancers are low-risk and do not fulfill the criteria outlined in Table 150.1. For such tumors, cost-efficient superficial ablative techniques (e.g. electrodesiccation and curettage) or simple excision can be performed. Currently, ~25% of skin cancers are treated with MMS in the US[10]. MMS is well suited for skin cancers at high risk for recurrence and for those tumors located in regions requiring tissue conservation and complete margin control[10]. This includes large lesions in cosmetically sensitive areas.

Factors that identify a "high risk" skin cancer include clinical and histologic characteristics of the tumor, anatomic site, and history of prior treatment(s) (see Table 150.1). Because of the complete histologic examination of surgical margins, MMS allows tracking of unpredictable superficial or deep projections of tumor (see Fig. 150.1A). MMS is very useful for tracking tumors that involve embryonic fusion planes, the periorbital region, nerves, and bone. It is these deep and irregular tumor extensions that are primarily responsible for the higher recurrence rates observed with other techniques. Importantly, the indications for MMS are not absolute, and any treatment decision needs to be made in collaboration with the patient's preferences (e.g. local vs. general anesthesia for extensive procedures), performance status, and understanding of alternative treatment options and associated cure rates.

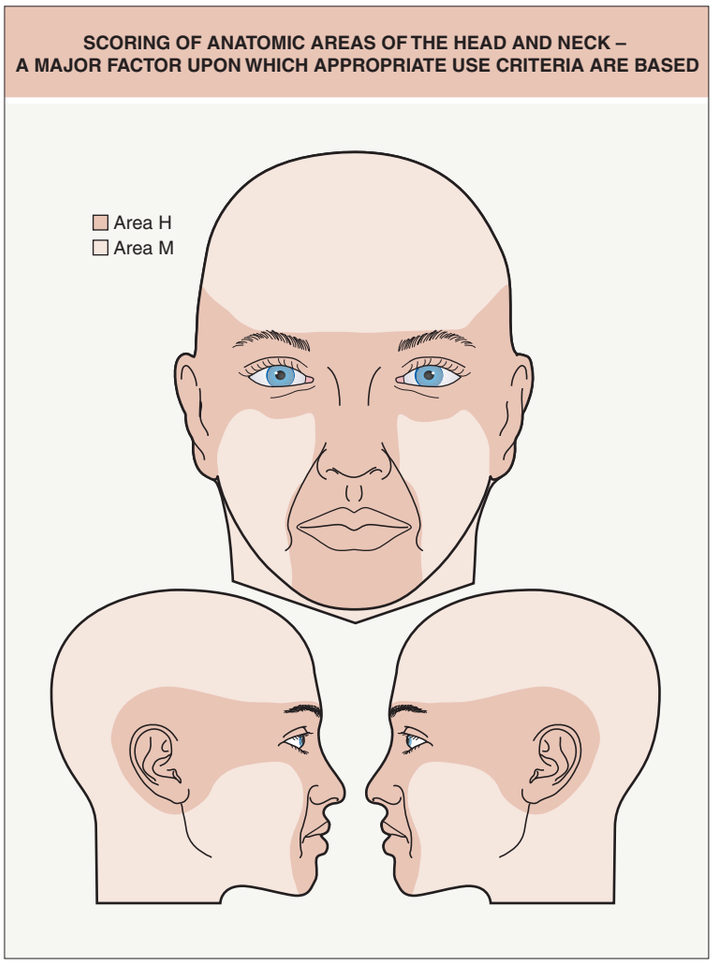

Fig. 150.2 Scoring of anatomic areas of the head and neck – a major factor upon which appropriate use criteria are based. Area H represents the anatomic sites with the highest risk for recurrence and the greatest need for tissue sparing, followed by Area M. The majority of the trunk and extremities is labeled as Area L (lowest need for tissue sparing and risk of recurrence), with the hand, foot, ankle, nail unit, nipple/areola, and anogenital region representing additional Area H sites and the shins an Area M site[1]. See www.aad.org/education/appropriate-use-criteria/mohs-surgery-auc as well as the Mohs AUC app.

The use of MMS for the more commonly managed cutaneous malignancies will be reviewed first, followed by its use for unusual neoplasms (Table 150.2).

Basal Cell Carcinoma

For primary BCCs, cure rates of 87% to 95% can be obtained with superficial ablative therapies and excision, especially on the trunk and extremities. In a meta-analysis by Rowe et al.[13], the 5-year cure rate for *primary* BCC treated with MMS was 99%, as compared to 90% to 93% using standard treatments (Table 150.3). For *recurrent* BCC treated with MMS, the 5-year cure rate was 90%–94% as compared to 80% for standard treatments (surgical excision, radiotherapy, cryotherapy, electrodesiccation and curettage)[14].

MMS provides superior cure rates for high-risk BCCs that are more likely to recur, including those that are large in size (>2 cm) or have aggressive histologic subtypes (e.g. basosquamous carcinoma[38]) or perineural invasion[39,40].

Squamous Cell Carcinoma

MMS offers the highest cure rates for patients with high-risk primary or recurrent SCCs. The local recurrence rates, based on a retrospective review of MMS versus non-MMS modalities for primary SCC, are outlined in Table 150.3[16].

MMS is indicated for management of SCCs with one or more risk factors for recurrence or metastasis (see Table 150.1). These indications include large SCCs (>2 cm), recurrent tumors, incompletely excised SCCs, and tumors with ill-defined clinical margins, rapid growth, an aggressive histologic subtype, and/or perineural invasion (Fig. 150.3), as well as SCCs arising in chronic scar tissue (Marjolin ulcer)[41]. Immunosuppressed patients, including those with solid organ transplants and chronic lymphocytic leukemia, as well as patients receiving medications such as voriconazole and unopposed vemurafenib, can develop rapidly growing SCCs that benefit from MMS.

In addition, SCCs arising in high-risk anatomic sites may be managed with MMS. For example, tumors of the lip have a high propensity for recurrence and metastasis with cure rates as high as 92% achieved with MMS[42]. MMS is also well suited for SCCs occurring in anogenital areas and on the digits, where tissue conservation is important. When compared with conventional methods, MMS for the treatment of penile SCC offers comparable survival rates. Prior to MMS, SCCs involving the nail unit were often treated with amputation or radiation. MMS provides an excellent choice for treatment of periungual and subungual SCC without osseous involvement, with cure rates of up to 96%[43].

Erythroplasia of Queyrat (EQ) is a term used for SCC *in situ* (SCCIS) arising in anogenital mucosae, especially in men. An erythematous thin plaque is typically seen on the inner surface of the foreskin, glans penis, and/or coronal sulcus of an uncircumcised man (see Chs. 73 & 108). In women, differentiated vulvar intraepithelial neoplasia (dVIN) and high-grade squamous intraepithelial lesion (HSIL) are the preferred terms, with oncogenic human papillomaviruses (HPVs) often playing an etiologic role in the latter. HPV infection also increases the risk of anogenital SCC in immunosuppressed individuals (e.g. HIV-infected).

MMS is an effective treatment for EQ, with a 5-year cure rate of 90%[17]. When excising EQ of the glans penis, Mohs layers should be very thin in order to minimize entry into and resection of the corpus spongiosum and cavernosum. If either is entered, achieving hemostasis can be challenging. EQ can often extend into the urethra and differentiation of SCCIS from transitional epithelium is often difficult on frozen sections. With deep extension along the urethra, collaboration with a urologist and completion of the surgery under general anesthesia are recommended.

CUTANEOUS TUMORS TREATED WITH MOHS MICROGRAPHIC SURGERY AND REPORTED CURE RATES	
Cutaneous tumors	**Cure rates (5-year)**
Basal cell carcinoma	99% (primary tumors)[13] 90%–93% (recurrent tumors)[14]
Squamous cell carcinoma	92%–99% (primary tumors)[15] 90% (locally recurrent tumors)[16]
Erythroplasia of Queyrat	90%[17]
Cutaneous melanoma *in situ*, including lentigo maligna	67%–100%[19–24]
Atypical fibroxanthoma	93%–100%[25]
Dermatofibrosarcoma protuberans	97%–100%[26–29]
Merkel cell carcinoma	84%[30]
Microcystic adnexal carcinoma	90%[31–33]
Sebaceous carcinoma	89%[34]
Extramammary Paget disease	92%–97%[35,36]
Leiomyosarcoma (superficial)	87%[37]

Table 150.2 Cutaneous tumors treated with Mohs micrographic surgery and reported cure rates. For eccrine porocarcinoma, angiosarcoma and lymphoepithelioma-like carcinoma, efficacy based only upon case reports. For mucinous eccrine carcinoma, increased efficacy relative to wide excision not established. Some surgeons also use Mohs surgery for invasive cutaneous melanoma.

FIVE-YEAR CURE RATES FOR PRIMARY BCC AND SCC		
Treatment modality	**5-year cure rate**	
	BCC (%)	**SCC (%)**
Surgical excision	90	92
Electrodesiccation & curettage	92	96
Radiation	91	90
Cryotherapy	93	N/A
All non-Mohs modalities	91	92
Mohs micrographic surgery	99	97

Table 150.3 Five-year cure rates for primary basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) by treatment modality. Based upon refs 1 and 4. There is some inherent bias in these data as the studies quoted in this table did not all use the same patient selection criteria. For example, techniques such as electrodesiccation and curettage appear to have higher cure rates for SCC than does excision to the adipose layer, but it is likely that patients who had curettage selected as a definitive treatment had superficial tumors. N/A, not available.

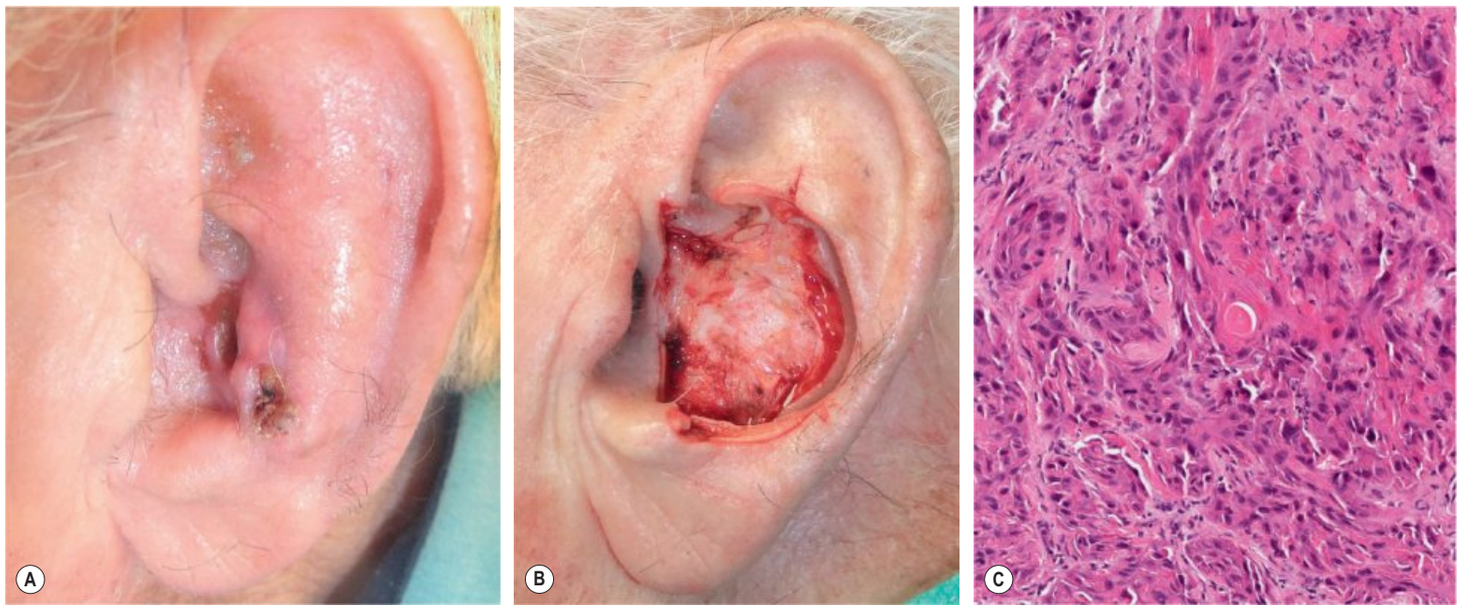

Fig. 150.3 Recurrent, biopsy-proven, moderately differentiated squamous cell carcinoma (SCC) of the left conchal bowl. A Prior to Mohs micrographic surgery. **B** Tumor extirpation resulted in a through-and-through defect of the ear. **C** Histologic features of this aggressive SCC include nests and cords of polygonal cells with enlarged, pleomorphic nuclei and only small foci of keratinization.

Keratoacanthomas (KAs) classically grow quickly and then can spontaneously involute. However, management of KAs remains controversial[18]. Microscopically, some KAs are difficult to distinguish from SCC and there are reports of non-regressing and metastatic KAs, implying that the tumor was actually an SCC. Currently, most KAs are considered to be well-differentiated SCCs. MMS may be particularly beneficial for large lesions, as well as those occurring in anatomically sensitive areas.

Verrucous carcinoma is considered a variant of SCC, and it can be associated with HPV infection. Tumors most commonly occur in the oral cavity, on the plantar foot, or on the penis (see Ch. 108). While generally considered a low-grade carcinoma, there are reports of metastasis. Histopathologic interpretation of frozen sections can be challenging because the tumor cells are very well differentiated with minimal nuclear atypia, making distinction from pseudoepitheliomatous hyperplasia, verruca vulgaris, or condyloma acuminatum challenging. In patients with a clear-cut clinical diagnosis verified by histologic examination, the irregular architectural pattern of verrucous carcinoma may aid in evaluating the margins of excision by MMS.

Cutaneous Melanoma

Melanoma in situ *(lentigo maligna) of the head and neck region*

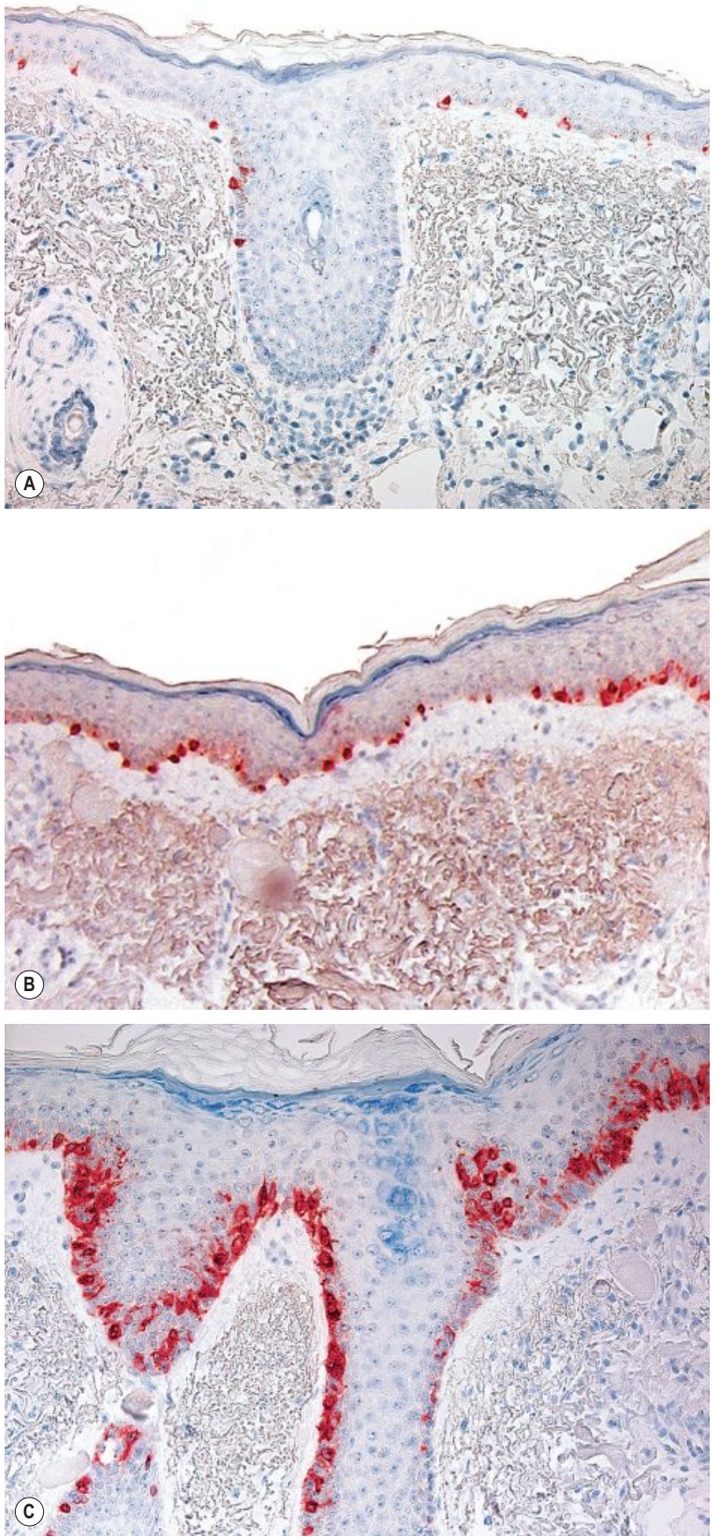
Treatment of melanoma *in situ* (MIS), in particular lentigo maligna (LM), of the head and neck region is a subject of debate. Controversies include width of surgical margins, MMS versus standard surgical excision, and use of pre- or postoperative topical imiquimod. Even within MMS, there are different techniques, from classic MMS with frozen sections to "slow Mohs" utilizing "rush" permanent sections. Reasons for the debate include: (1) the difficulty in distinguishing atypical melanocytes of photodamaged skin from melanoma cells (Fig. 150.4), especially in frozen sections stained with H&E or antibodies that recognize melanosomes; and (2) the natural history and prognosis of LM. The first can lead to residual tumor or unnecessary excision of photodamaged skin while the second can complicate determining an impact on survival.

Current NCCN guidelines recommend surgical treatment with margins of 0.5–1.0 cm, allowing for narrower margins depending upon anatomical and functional considerations[44]. However, LM treated with surgical excision alone may require wider margins as lesions tend to be ill-defined with subclinical spread[44] and a local recurrence rate of 6%–20% has been reported with standard excision[45]. Although still employed in a minority of patients, the use of MMS to treat cutaneous melanoma has increased over the past two decades, from 2.6% (2001) to 7.9% (2016)[46].

There are no randomized controlled trials comparing wide local excision (WLE) versus MMS to treat MIS of the head and neck region. Database studies, including a retrospective review of a prospective database that compared H&E-based MMS with WLE[24], reported comparable rates of overall and melanoma-specific survival. In the retrospective review, there was also no difference in recurrence rates[24]. Studies from single institutions have also observed low recurrence rates[21–23], e.g. <1% with a mean follow-up of 2.8–3.7 years[21,22].

As noted previously, distinguishing atypical melanocytes of photodamaged skin from melanoma cells in frozen sections can prove challenging. In addition to similar cellular features, processing artifacts (e.g. freeze-induced vacuolization within keratinocytes that resembles vacuolization in melanocytes) may lead to misinterpretation[47]. Detection of a transition zone between photodamaged skin and MIS in FFPE vertical sections can assist in determining clear margins, but this is not possible with *en face* processing of LM margins. To address this potential problem, a prospective cohort study (n = 167) was conducted that examined the accuracy of MIS margin assessment with MMS and H&E-stained frozen sections; the authors reported an accuracy rate of 95%[48]. The latter was determined by excising an additional 1 mm margin followed by its examination by a dermatopathologist. Other approaches include: (1) vertically processing the central debulk plus a narrow margin[22]; (2) obtaining shallow biopsies from the patient's normal-appearing adjacent skin or both perilesional and distant skin[49]; and (3) examination of FFPE tissue margins to confirm that the final MMS margin is negative[50,51].

Potential improvements include immunohistochemical (IHC) staining with antibodies that recognize melanocyte-specific transcription factors (e.g. MITF) rather than melanosomal proteins (e.g. Melan-A/MART-1) (Table 150.4). This prevents staining of melanosome-containing keratinocytes and overestimating the density of melanocytes within photodamaged skin[52] as well as falsely diagnosing pigmented actinic keratoses as LM. Of note, in a survey of Mohs surgeons, only 36% felt comfortable interpreting MART-1-stained frozen sections and a need for additional education was noted as was recognition that formal training is not offered in all fellowship training programs[53].



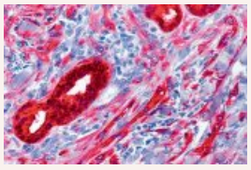


Fig. 150.4 Immunostaining with Melan-A/MART-1. A Normal density of melanocytes. **B** Melanocytic hyperplasia with scattered atypical melanocytes in sun-damaged skin. **C** Lentigo maligna with atypical melanocytic proliferation, some pagetoid spread, and adnexal extension. *Courtesy Clark C. SPECIAL AND IMMUNOHISTOCHEMICAL STAINS USED IN MOHS MICROGRAPHIC SURGERY							
	SCC*	**BCC**	**DFSP**	**EMPD**	**Sebaceous carcinoma**	**Melanoma†**	**MAC**
Special stains	–	Toluidine blue	–	PAS	Oil red O‡	–	Toluidine blue[e1]
Immunohistochemical stains	AE1/AE3 (inset) 	AE1/AE3, Ber-EP4	CD34	CK7, CEA	Adipophilin, CK (e.g. AE1/AE3)	MITF, Melan-A/MART-1 (Fig. 150.4), Mel-5, SOX10, HMB45	CK (e.g. AE1/AE3)

*To detect perineural invasion and high-risk histologic subtypes, e.g. infiltrating, spindle cell, single cell.
†Includes lentigo maligna and other types of melanoma *in situ*.
‡Being replaced by adipophilin stain.

Table 150.4 Special and immunohistochemical stains used in Mohs micrographic surgery. AE1/AE3, pankeratin marker; Ber-EP4, stains cellular glycoproteins in BCCs, sweat glands, and some hair follicles; BCC, basal cell carcinoma; CEA, carcinoembryonic antigen; CK7, cytokeratin 7; DFSP, dermatofibrosarcoma protuberans; EMPD, extramammary Paget disease; MAC, microcystic adnexal carcinoma; MART-1, melanoma antigen recognized by T cells; MITF, microphthalmia transcription factor (nuclear stain); PAS, periodic acid Schiff; SCC, squamous cell carcinoma. *Photomicrograph: Courtesy Luis Requena, MD.*

Invasive melanoma

Based on large randomized controlled trials (RCTs), WLE with recommended margins is the gold standard for treatment of invasive melanoma (see Ch. 113). In patients undergoing sentinel lymph node biopsy, the WLE is routinely performed in tandem[54]. Cutaneous melanomas in general are well-defined, with the exception of some cases of LM and acrolentiginous melanoma. For locally recurrent melanomas, ill-defined or amelanotic melanomas, or melanomas in anatomic sites such as the genitalia, digits, eyelids, nose and ears, a multidisciplinary approach that includes MMS can be considered. There is also some evidence suggesting the utility of MMS for thin melanomas[11,19,55,56].

Staged excisions ("slow Mohs") for melanoma

One variant of MMS is staged excisions ("slow Mohs")[50,51,57] in which the tissue specimen is sent for "rush" FFPE sections that are read by a dermatopathologist the next day. The wound is kept open and covered with a pressure dressing. Some surgeons debulk the visible tumor and determine its depth via vertical processing while assessing the peripheral margin in an *en face* fashion, whereas others cut the tissue radially, allowing the pathologist to appreciate the transition from tumor to actinically damaged skin. If there is residual melanoma, another layer is removed until a negative (tumor-free) margin is achieved. The obvious major disadvantage is the inconvenience of a multi-day procedure. Reported recurrence rates range from <1% to 7.3%, with follow-up ranging from 3 to 57 months[45,58].

Additional staged-excision techniques include the square technique[59], geometric staged excision[60], and the spaghetti technique[61]. In the ***square technique***, two closely spaced, parallel blades are used to create a square-shaped defect (thin and frame-like) with the tumor and presumed adequate margins left intact. If the excised peripheral tissue has clear margins, then the central square is removed surgically[59]. When the square technique was used to treat 834 melanomas, the mean margin required for histologic clearance was 9.33 mm for MIS and 13.7 mm for invasive melanoma. With a median follow-up of 9.3 years, the projected recurrence rate was 2.2% at 10 years[62].

In the ***geometric staged excision***[60], the entire specimen is excised in a geometric pattern; the margins are inked and strips are cut off along the margins. The cut strips are oriented, processed and cut *en face* while the central portion is cut vertically to determine tumor depth. As a result, the entire peripheral margin is examined, which is where the tumor may extend a significant distance from the clinically apparent lesion. In addition, the vertical sections of the central portion confirms or adjusts the tumor thickness. Some dermatopathologists prefer this method because it may be easier to process the tissue for examination of the entire peripheral epidermal and dermal margin[63,64]. In the ***spaghetti technique***, thin strips at the peripheral margin of the visible tumor are excised in stages until the whole tumor is mapped out, then the central lesion is removed. This allows for closure between each stage. A local recurrence rate of 4.76% at a median follow-up of 25 months has been reported[61].

A potential disadvantage of the square and geometric pattern techniques is that a few extra millimeters of skin are sacrificed in order to provide the straight lateral margins. For small tumors, this difference is marginal but if several layers are required and/or the tumor is irregularly shaped, reconstruction can become more complex.

Currently, evidence-based support for the use of MMS to treat cutaneous melanoma is limited by single institution experiences, inclusion of heterogenous tumor types, variable (and sometimes limited) observation periods, and outcome measures based upon local recurrence rates. Given the natural history of LM, the latter can be problematic. Whether a multi-center, randomized, controlled, prospective trial comparing WLE with MIS will ever be conducted remains uncertain.

Uncommon or Rare Cutaneous Neoplasms

Due to the relative rarity of these uncommon tumors, the efficacy of MMS is based primarily on case series from a single institution or case reports.

Atypical fibroxanthoma/pleomorphic dermal sarcoma

Atypical fibroxanthoma (AFX) is a dermal-based mesenchymal neoplasm that develops within photodamaged skin and has minimal, if any, metastatic potential (see Ch. 116). Tumors with similar pathologic features but which demonstrate subcutaneous invasion, necrosis, and/or lymphovascular or perineural invasion are associated with a worse outcome and are referred to as pleomorphic dermal sarcoma (PDS). Typically, AFX presents as a nodule in the head and neck region of an elderly person with significant actinic damage. Its histologic features are said to be relatively easy to identify in frozen sections. For AFX, MMS has been reported to result in lower recurrence rates and greater tissue preservation whereas in PDS, the data is limited[65].

Dermatofibrosarcoma protuberans

Dermatofibrosarcoma protuberans (DFSP) is a slowly growing, locally aggressive soft tissue sarcoma that most often arises on the trunk of young to middle-aged adults (see Ch. 116). It typically extends in an irregular fashion beyond the clinically visible tumor margins. Based upon pooled raw data collected over a 20-year period, recurrence rates following WLE have ranged from 6% to 60% versus 1% to 3% following MMS[26,66–68]. A possible explanation for this difference is the inclusion of patients with primary DFSP, recurrent DFSP, and DFSP with fibrosarcomatous changes, which can lead to biased results as patients with more aggressive disease tended to have WLE (compared to MMS)[66–68]. Of note, a recent retrospective, multicenter study comparing MMS vs. WLE for DFSP on the trunk and extremities found no difference in outcomes[69] while emphasizing the need for complete resection with precise margin control[70]. In the head and neck region, MMS can be advantageous given the potential for conserving tissue while offering margin control[71].

DFSP is often a large-sized tumor and as a result, MMS can be a time-consuming procedure. If tumor identification proves difficult in frozen sections, staged excision ("slow Mohs"; see above), utilizing anti-CD34 IHC staining, can be performed[72,73].

Merkel cell carcinoma

Merkel cell carcinoma (MCC) is a very aggressive malignancy, often arising in older adults with photodamage or who are immunosuppressed (see Ch. 115)[74]. Clinically, the tumor usually presents as a pink–red to violaceous papulonodule that favors the head and neck region. Microscopically, the tumor cells are aggregated into large sheets, allowing them to be easily identified in frozen sections. NCCN guidelines recommend WLE plus sentinel lymph node biopsy (SLNB) followed by radiotherapy to the primary site and regional lymph nodes (unless the lesion is low risk [≤1 cm on the trunk or an extremity with no lymphovascular invasion and negative surgical margins in the setting of a negative SLNB]; (see Fig. 115.19). However, a database study found that patients who underwent MMS were less likely to have a sentinel lymph node biopsy performed[75]. That said, when 22 MCCs were removed via MMS, positive margins were noted in 57% of the cases despite the surgical margins taken meeting or exceeding NCCN guidelines of 1–2 cm margins; however, 92% of the positive cases involved the deep margin[76].

Microcystic adnexal carcinoma

Microcystic adnexal carcinoma (MAC) is a locally aggressive tumor that typically involves the face of older adults (Fig. 150.5). Histologically, it has an infiltrative growth pattern with frequent perineural invasion (Fig. 150.6). With an overall recurrence rate reported in the literature approaching 40%, MMS offers an advantage. Based upon several studies, a five-year cure rate of 90% has been observed following MMS (see Table 150.2)[31]. In one of these studies, defects following MMS were four times larger than clinical estimates[32].

Sebaceous carcinoma

Sebaceous carcinoma can develop in any site that contains sebaceous glands, but it has a predilection for periocular skin. MMS is often employed for tumors in the latter location. Based upon a review of the literature, WLE of sebaceous carcinomas was associated with a local recurrence rate of 4%–37% and a nodal metastatic rate of 3%–28%[77]. In comparison, MMS had a local recurrence rate of 11% (2 of 18 patients) with nodal metastases developing in 1 patient[34]. A more recent

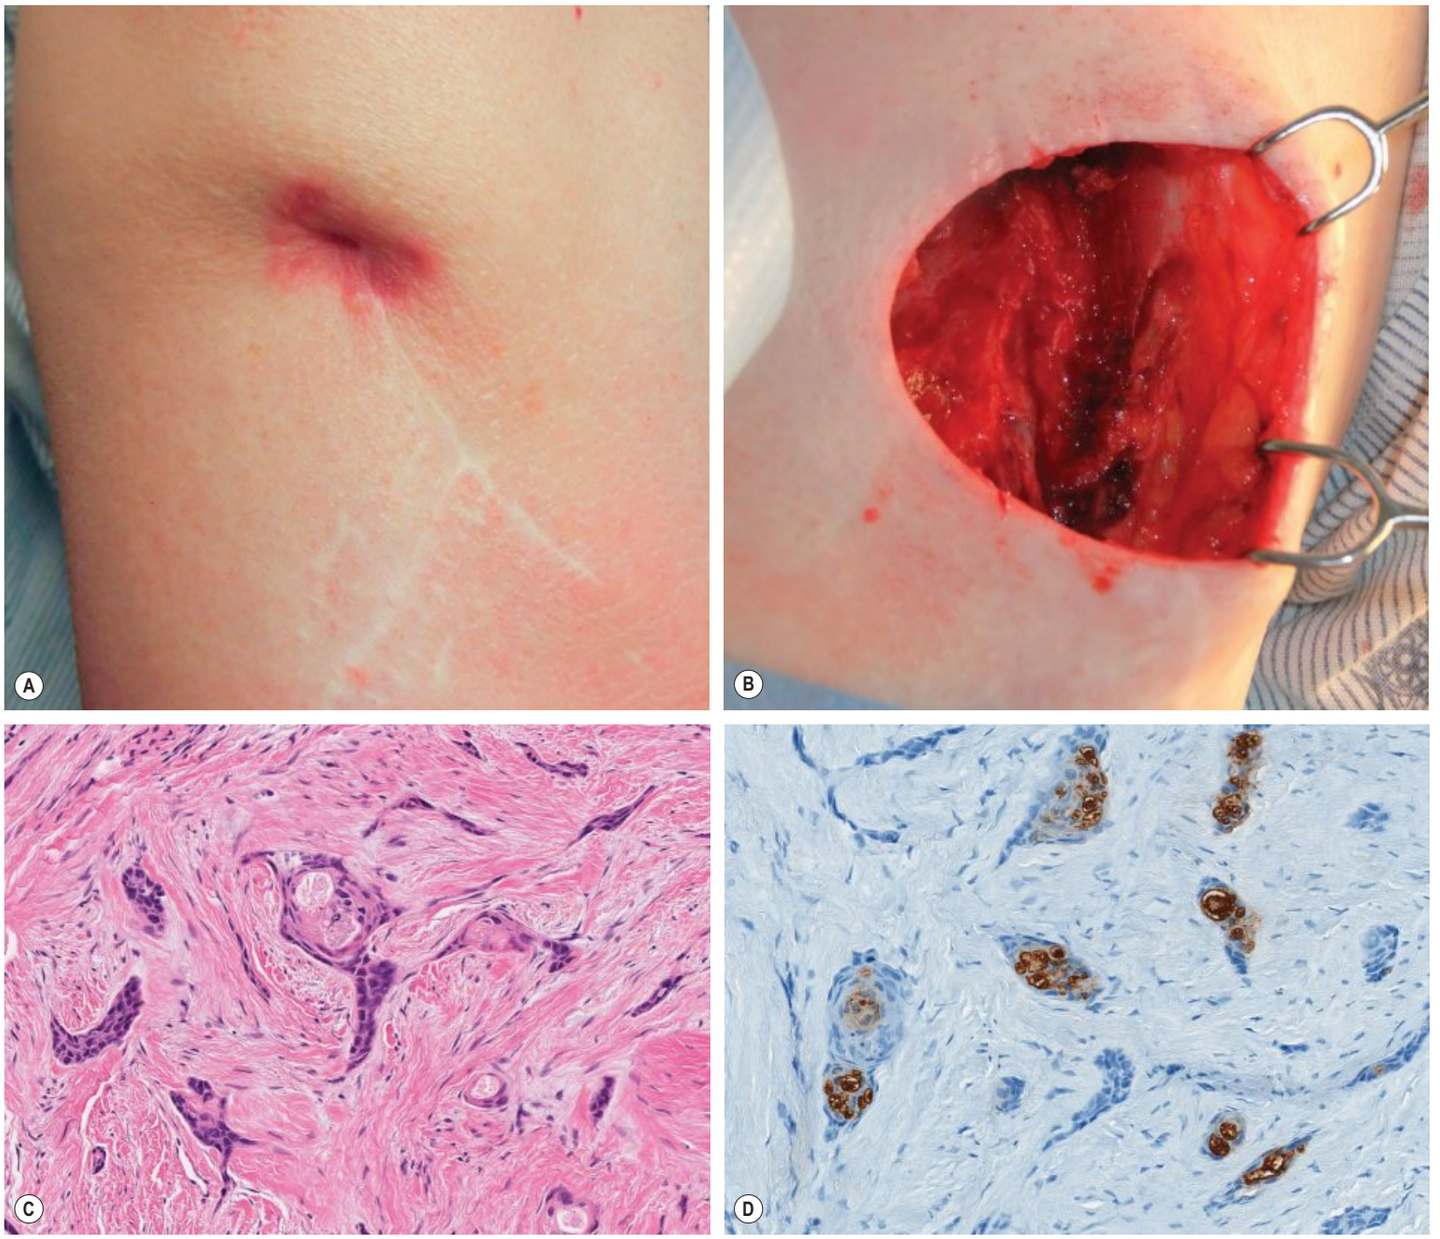

Fig. 150.5 Recurrent basal cell carcinoma (BCC) plus microcystic adnexal carcinoma (MAC). A Recurrent, biopsy-proven BCC of the right upper lateral arm that had been previously treated four times (electrodesiccation and curettage; excision; Mohs micrographic surgery [MMS] twice) over a twenty-year period. An indurated nodule was present at the scar site. **B** Defect after two MMS stages; there was deep infiltration of the subcutaneous tissue, muscle, and periosteum of the humerus. **C** Histologically, small infiltrative basaloid tumor strands embedded within a desmoplastic stroma were seen; there was also ductal differentiation. Because the possibility of a coexisting MAC was raised, the tissue was thawed and submitted for formalin-fixed paraffin-embedded (FFPE) sections. **D** Immunohistochemical staining of FFPE sections demonstrated CEA-positivity of ductal cells, supporting the diagnosis of MAC.

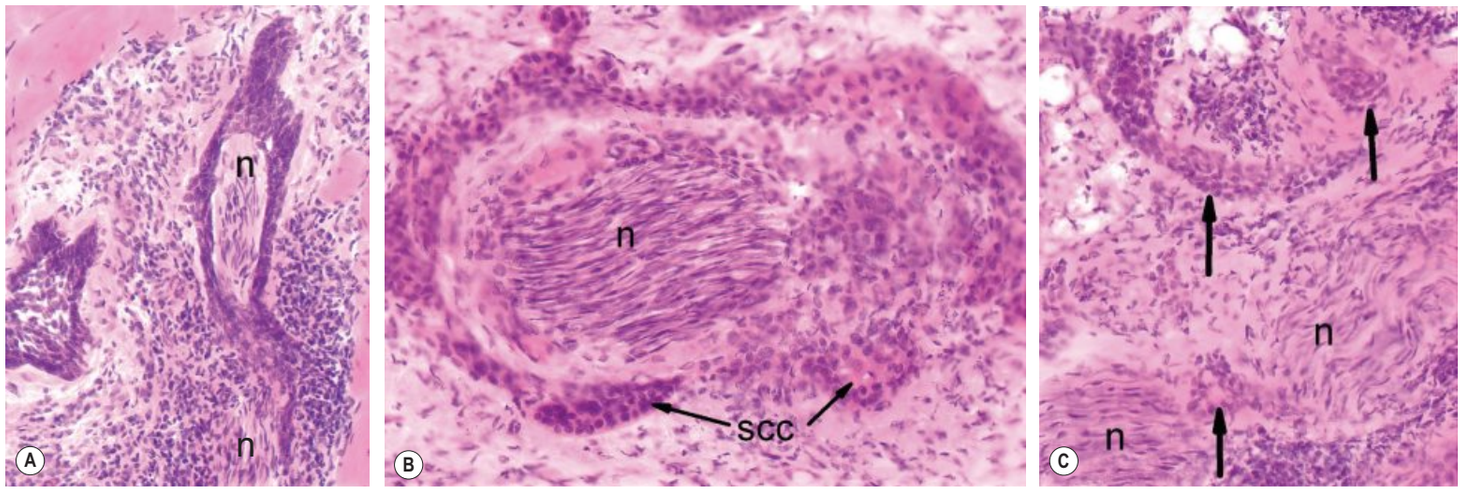

Fig. 150.6 Perineural involvement by various cutaneous tumors (frozen sections). A Basal cell carcinoma with a halo of basal cells enveloping a cutaneous nerve (n). **B** Squamous cell carcinoma (SCC) surrounding nerve fiber (n). **C** Microcystic adnexal carcinoma with perineural invasion by dominant pilar structures (arrows) in the deep subcutaneous portion of the tumor; n, nerve. *Reproduced with permission from Snow S. Atlas of Mohs Surgery Frozen Sections. Madison, WI: Scope Publishing, 2010.*

retrospective review of 45 sebaceous carcinomas treated with MMS found no local recurrences, metastases, or disease-specific deaths, with a mean follow-up of 3.6 years[78]. One challenge associated with these tumors is discontiguous growth, which can thwart any method of histologic margin evaluation. The removal of an extra safety margin of tissue for permanent sections is a reasonable strategy.

Other adnexal carcinomas

This group consists of the uncommon tumors that have sweat gland (eccrine, apocrine), sebaceous gland, or follicular differentiation and includes mucinous carcinoma, eccrine porocarcinoma, adenoid cystic carcinoma, papillary adenocarcinoma, and trichilemmal carcinoma (see Ch. 111). These tumors are usually locally destructive with extensive unpredictable local tissue invasion and therefore have a high rate of local recurrence following excision. Typically, their microscopic features are readily recognizable in frozen sections so they are amenable to MMS[79]. Rapid IHC staining can aid in diagnosis (see Table 150.4).

Miscellaneous tumors

MMS has been utilized for other malignant neoplasms, including angiosarcoma, lymphoepithelioma-like carcinoma, leiomyosarcoma and extramammary Paget disease, as well as cutaneous breast metastases[35–37,80,81]. Occasionally MSS is employed for benign tumors that have a predilection for recurrence such as infantile digital fibroma, desmoplastic trichoepithelioma, and granular cell tumor. Rarely, it is used to eradicate drug-resistant cutaneous fungal infections.

CONTRAINDICATIONS

Discontiguous tumors can lead to the problem of false-negative margins, both with MMS and with WLE. Therefore, this feature is not an absolute contraindication. When the tumor cells cannot reliably be identified in frozen sections this is a relative contraindication. If patients are unwilling or unable to undergo surgery that is time intensive, then standard excision or a non-surgical approach such as radiotherapy may be a better option. However, for some patients with serious medical problems, MMS done under local anesthesia may be safer than surgery performed under general anesthesia[82–84].

PREOPERATIVE HISTORY AND CONSIDERATIONS

A history and focused skin examination should be performed at the time of consultation, which can be the same day as the surgical procedure. The pathology report should be reviewed and, if the diagnosis appears questionable, the histologic sections should be re-examined. Indications for antibiotic prophylaxis should be evaluated and then reviewed with the patient's primary physician, cardiologist or orthopedic surgeon if necessary (see Table 151.2)[85]. Similarly, the management of any implanted electronic medical device as well as anticoagulants and antiplatelet agents needs to be addressed (see Ch. 151).

A thorough review of allergies, including past reactions to antibiotics, local anesthetics, povidone–iodine preparations, latex and adhesives, is conducted. MMS routinely employs only local anesthetics (see Ch. 143), but depending upon the patient oral anxiolytics may also be prescribed. Although lidocaine allergy is rare, the surgeon should be prepared for an emergency response if required.

Upon completion of the medical evaluation, the Mohs surgeon should explain the nature of the tumor, therapeutic options, the key features of MMS, and repair options. In order to prevent wrong-site surgery, photographs of biopsy sites are strongly encouraged. Visualization and confirmation of the biopsy site with the patient are essential[86]. Following informed consent, a standardized time-out is taken prior to the procedure. Patients should be encouraged to continue regular medications and eat a light meal on the morning of surgery, unless conscious sedation is planned.

Individuals with extremely large, recurrent, fixed, deeply invasive tumors and/or clinical signs of perineural invasion can benefit from preoperative radiologic imaging[87,88]. For detection of perineural invasion and intracranial extension (including meningeal), magnetic resonance imaging (MRI) represents the most sensitive imaging modality. However, detection of small nerve involvement is limited and immediate post-resection changes may distort findings. A computed tomography (CT) scan is more sensitive in identifying subtle bone erosion while both CT and MRI are used to evaluate regional lymph nodes.

Very complex cases requiring a multidisciplinary approach should be evaluated preoperatively by other subspecialties (e.g. oculoplastics, otolaryngology, neurosurgery, plastic surgery, radiation oncology) as needed. Following removal of the tumor by or with the assistance of the Mohs surgeon, the most appropriate specialist performs the repair.

TECHNIQUE

Table 150.5 provides a flow sheet for performing MMS and Fig. 150.7 depicts the procedure. (Also see Video 150.1)

VARIATIONS/REFINEMENTS

There are several modifications/variations of MMS that are used to improve: the speed of tissue processing[89]; the efficiency of tumor removal; and the recognition of individual tumor cells for better margin control. For descriptions of staged-excision ("slow Mohs") techniques, see the Cutaneous Melanoma section.

The *single section method* can be used for smaller tumors[90]. It consists of a highly beveled specimen with relaxing incisions on the superior, tumor-bearing portion to allow all peripheral edges to fold outward into a single plane. This method is particularly useful for tumors in which a shallow Mohs layer can be taken and then the surgical defect

allowed to heal by second intention. The unaltered examination of the complete deep margin also reduces the possibility of missed deep margins due to tissue subdivision.

A *non-beveled 90° incision* can be used for MMS on the extremities. The resulting vertical edges are ideal for reconstruction. Although a traditional beveled edge can be trimmed prior to reconstruction, a true, sharp, straight 90° angle is more difficult to obtain. Disadvantages include excision of more tissue and the necessity to manipulate the specimen to make the tissue flatten into a single plane.

In *wide excision MMS* ("wide Mohs"), a larger, clinically tumor-free margin (5–20 mm) is taken. It can be used for tumors that have a high propensity for recurrence or metastases (including satellite metastases), in particular melanoma, Merkel cell carcinoma, and cutaneous sarcomas[17]. In these scenarios, margin control is prioritized over tissue sparing[5].

During MMS, *rapid immunohistochemical (IHC) staining* can be utilized to assist in histologic evaluation (see Table 150.4)[91]. Some surgeons find it especially helpful for challenging and high-risk tumors[52,92,93]. However, there has been rather limited adoption of IHC staining by Mohs surgeons due to the additional cost and time required as well as concerns regarding reliability. In a 2013 survey of Mohs surgeons, only 22% of the respondents (n = 378) incorporated IHC staining into their practice following fellowship training[53].

CHALLENGES AND PITFALLS

The success of the procedure is dependent upon the precision and meticulousness of each step. Recurrences following MMS have been linked to inherent tumor characteristics such as morphology, size or location as well as errors in the procedure[94]. Errors encountered during MMS can be divided into technical (e.g. excess epidermal tissue in the central portion of the layer pushed down to cut margin and interpreted as tumor, incorrect bevel angle or relaxing incisions) and pathologic interpretation (Fig. 150.8)[95,96]. A limitation of MMS arises when the invasiveness of the tumor prevents continued tracking and consultation with the appropriate surgical specialist is indicated.

There are several clinical scenarios in which it is appropriate to send tissue for FFPE including: (1) a second opinion is required during removal of a cutaneous melanoma; (2) further assessment is needed of an aggressive, deep, or histologically unusual tumor; (3) confirmation of the presence of a different tumor than was diagnosed preoperatively (Figs. 150.5 and 150.9); (4) a significant amount of tissue is available for complete staging of the primary tumor; (5) unusual histologic findings in the frozen sections require a second opinion; (6) frozen section interpretation is insufficient to assess the tissue margin reliably; (7) a tumor diagnosed solely by frozen section prior to surgery, i.e. no preoperative biopsy was sent for routine histology; or (8) special stains

MOHS MICROGRAPHIC SURGERY (MMS) FLOW SHEET
Preoperative assessment
• Upon arrival, the patient's demographic information is confirmed, allergies, pertinent medications and vital signs are recorded, and the preoperative biopsy is reviewed • Any prophylactic antibiotic, anti-anxiety drug or cardiac device is either administered or managed as needed • The tumor is closely examined (Fig. 150.7A) and the clinical margin is marked (e.g. with gentian violet) • Reference to diagrams, landmarks and photographs is made to ensure correct site identification and every patient is asked to confirm the tumor location with a mirror[86] • The planned procedure and possible reconstruction are reviewed and consent obtained
Preparation of the site and first Mohs surgery layer

• The site is then wiped with alcohol, local anesthetic (see Ch. 143) is infiltrated, and the site is prepped with chlorhexidine or povidone–iodine
• The central portion of the tumor is de-bulked with a curette to further define subclinical tumor extension (Fig. 150.7B); this step may be omitted when tumors are very small or on thin eyelid skin
• The first MMS layer includes all clinically evident tumor plus a small margin of normal-appearing tissue (Fig. 150.7C)
  • Depending on the histologic subtype and likelihood of subclinical tumor extensions, the margin of normal skin may range from 1 to 10 mm
  • For shallow tumors or those at sites favorable for second intention healing, the first MMS layer is planned as a shallow excision
  • For deep tumors or at sites where second intention healing is not a good option, a full-thickness excision to subcutaneous fat is performed
• For recurrent tumors, the most thorough approach is to resect all tissue involved by the previous treatments, including the primary site and reconstruction scar; if the recurrence is clearly isolated to only one site and/or complete resection would cause difficulties, then a localized resection of the clinically recurrent area can be considered
• When excising the MMS layer, the scalpel is held at a 30–60° angle to the skin surface to create a beveled incision (Fig. 150.7C)
• Before the layer is completely removed, both the layer and the adjacent surrounding tissue are marked with shallow scalpel cuts or a marking pen to help orient the specimen to the defect[e2] (Fig. 150.7D)
• The layer is removed and placed on a transfer card or marked gauze while maintaining correct orientation relative to the defect (Fig. 150.7E)
• Hemostasis is obtained using electrocoagulation or thermocautery as indicated
• A sterile pressure dressing is placed on the wound and the patient is discharged to a waiting room while the tissue is processed

Handling of the tissue specimen
• A map of the specimen is drawn that is relative to anatomic landmarks including the skin notches (Fig. 150.7H) • The specimen is sectioned precisely in order to fit on the cryostat chuck and microscope slide (Fig. 150.7F) • Attention must be paid to maintaining proper numbering, inking and mapping of specimens • All cut margins, except the epidermal edge, are inked systematically with different colored dyes and recorded on the specimen map (Fig. 150.7G,H) • The technician prepares the tissue pieces for freezing by flattening them so that the epidermis lies in the same plane as the dermis and deep margins, using one of several available techniques; if any edge or portion of the specimen curves upward, relaxing cuts are placed on the top surface of the specimen • The technician embeds the tissue piece (deep surface upward) on a chuck with embedding medium and freezes it in the cryostat • Frozen sections are then cut, mounted on slides, and stained with hematoxylin and eosin (H&E)   • Toluidine blue stain can also be used because it is rapid and the purplish metachromatic stromal staining helps to distinguish BCCs from adnexal structures
Histopathologic assessment and additional layers
• The surgeon examines the frozen sections and marks any residual tumor foci on the specimen map (Fig. 150.7J) • If further resection is required, the surgeon precisely removes additional tissue in the area of residual tumor, using the map and skin notches present on the patient for orientation (Fig. 150.7K) • This process is repeated until all tissue margins are microscopically free of tumor • Once the tumor is completely removed, the final defect is measured and photographed and wound management options are discussed and implemented

Table 150.5 Mohs micrographic surgery (MMS) flow sheet. MSS requires a high-complexity approved laboratory, e.g. by CLIA (www.cms.gov/regulations-and-guidance/legislation/clia). Fig. 150.7 depicts the procedure. BCCs, basal cell carcinomas.

are required that cannot be performed reliably on frozen sections[97]. In addition, when there is histologic evidence of a second neoplasm or the histologic features of the tumor being removed via MMS and the preoperative diagnosis differ, the original FFPE sections should be reviewed.

Although infrequent, cutaneous neoplasms can invade bone. This may be the consequence of previous inadequate treatment, anatomic site (e.g. embryonic fusion planes, areas with thin overlying skin such as the scalp, sternum, and distal phalanx), tumor biology, and patient comorbidities (e.g. chronic lymphocytic leukemia, solid transplant-related immunosuppression). In addition, tumors with perineural invasion can gain access into bone via bony foramina. When tumors invade bone, the following strategies are used to control its growth and potentially effect a cure: (1) establish the diagnosis and mode of invasion of the tumor histologically; (2) obtain radiologic imaging to determine the macroscopic extent of bone involvement and status of the regional lymph nodes (see above); and (3) refer to a related subspecialist for bone

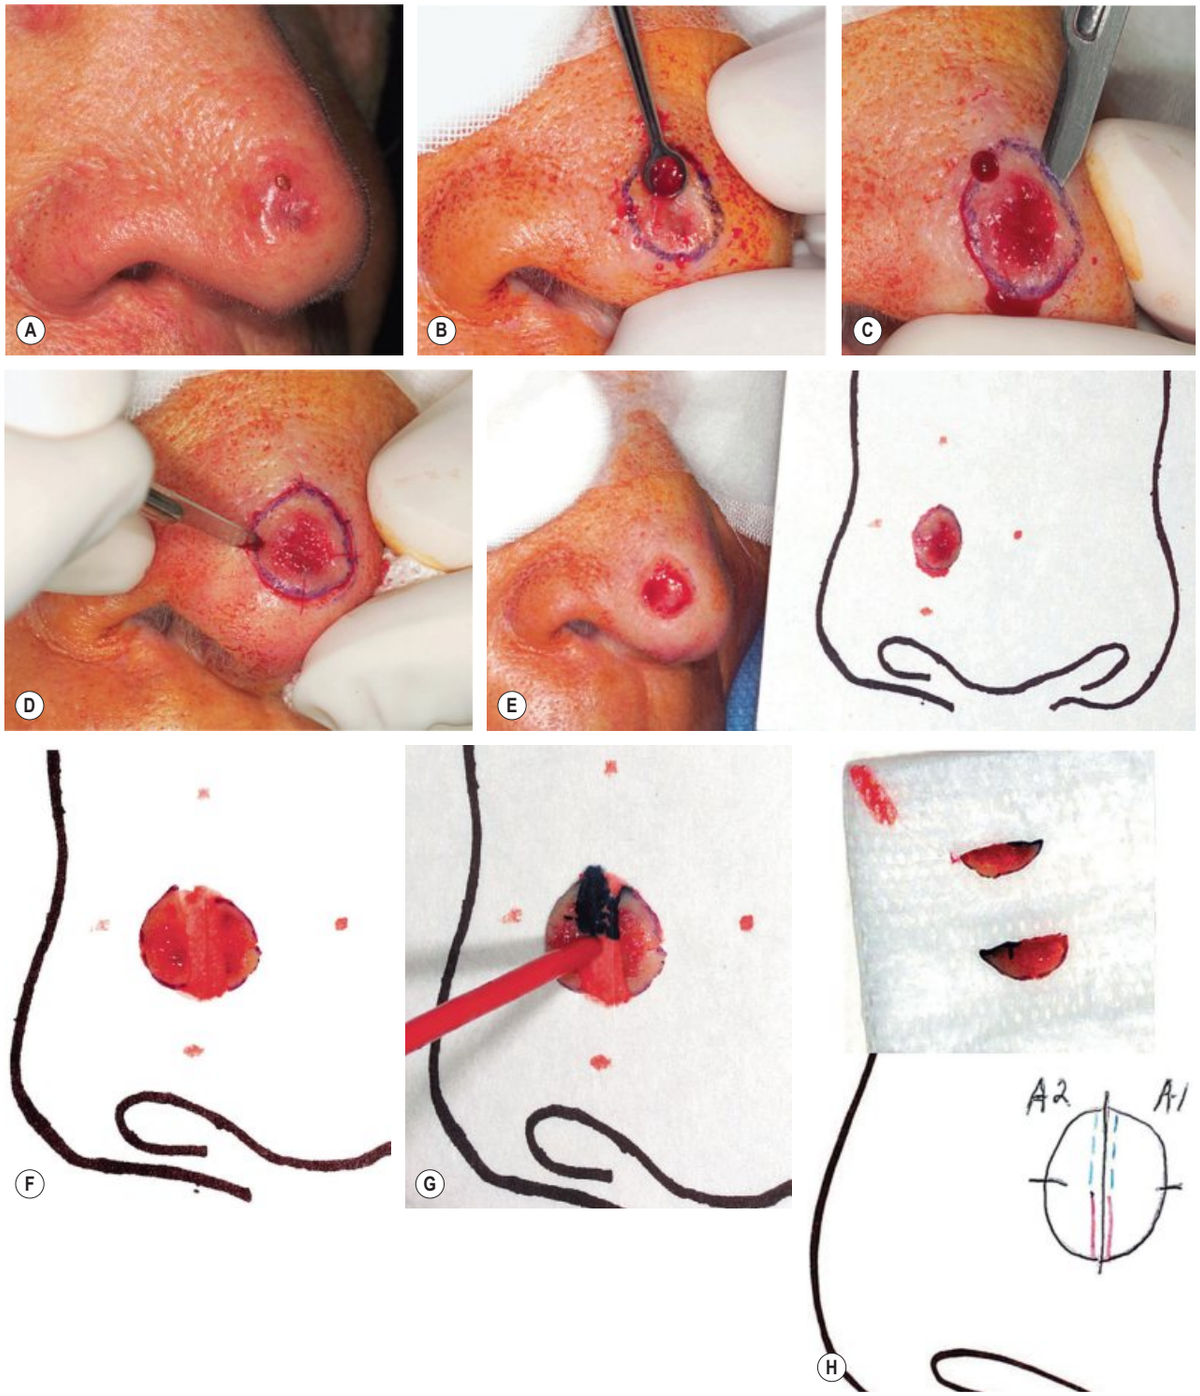

Fig. 150.7 Mohs micrographic surgery technique. A Preoperative appearance of a basal cell carcinoma on the nose. **B** Debulking of the tumor via curettage. **C** Beveled excision (with scalpel at a 45° angle) of all clinically evident tumor plus a small margin of normal-appearing skin. **D** Placement of skin notches at 3, 6, 9 and 12 o'clock positions in the specimen and adjacent surrounding tissue. **E** Orientation of the excised specimen on an anatomic card. **F** Specimen sectioned into two pieces and flattened. **G** Marking of the cut margins of the specimen with red and blue inks. **H** Matching Mohs map and tissue specimen ready for histologic preparation. A red mark on the gauze denotes the location of the first specimen with the second specimen always placed below. Different systems are used but precision is common to all.

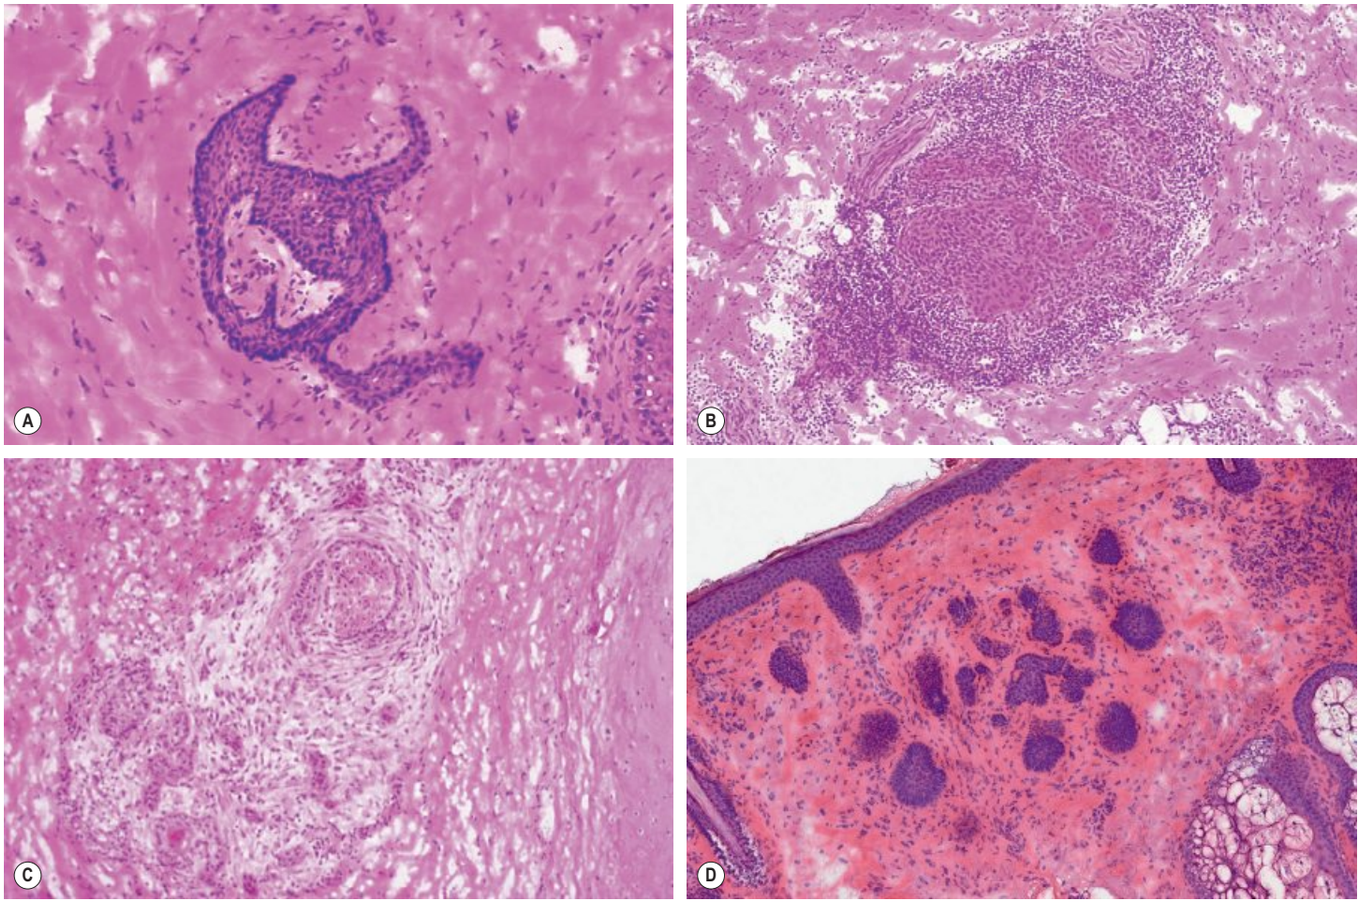

Fig. 150.8 Histopathologic challenges in Mohs surgery. A Folliculocentric basaloid proliferation may mimic basal cell carcinoma; however, the lack of clefting adjacent to the cells, apoptosis, or mitotic figures as well as the presence of a fibrous sheath permits distinction. **B** Dense inflammation can obscure tumor cells, as seen here with a squamous cell carcinoma in a patient with chronic lymphocytic leukemia. **C** Careful evaluation is required to identify subtle foci of perineural squamous cell carcinoma. **D** Follicular remnants can mimic basaloid islands. *A–C, Courtesy Clark C. Otley, MD, and Randall K. Roenigk, MD.*

resection as indicated. In difficult tumors with perineural invasion, additional Mohs layers may be taken to assure a tumor-free plane.

Small foci of sinus, nasal, or scalp bone may be excised locally with a bone rongeur or a chisel and mallet. Even when bone is exposed during tumor surgery, second intent healing is possible. If more than 1 cm of bone is exposed, burring, abrasion, or chiseling of spots 1 cm apart to reach bleeding spots can facilitate granulation. The procedure should be done with the patient recumbent to minimize the extremely rare risk of air embolus into the cavernous sinus (to date 2 cases reported). If sufficient granulation tissue can be stimulated to cover the exposed facial or scalp bone relatively quickly, cellulitis and osteomyelitis rarely occur[98]. Other options include coverage with an acellular dermal matrix or a split-thickness skin graft. These three methods of wound management are frequently preferred over more complex flaps that may delay detection of recurrent tumor. Close clinical surveillance is imperative.

RECONSTRUCTION

After complete tumor clearance, multiple options exist for management of tissue defects. The management strategy takes into account anatomic location, patient comorbidities, tumor severity, and the aesthetic needs of the patient. With guidance from the Mohs surgeon, patients are able to select the best options for reconstruction.

Surgical defects that heal by second intention may result in excellent cosmetic results especially in concave regions. Second intention healing can also be used for recurrent tumors in which flaps or grafts might hinder surveillance. Patients must be willing to attend to the area over a 2- to 8-week healing period. Typically, wound care regimens involve cleansing the wound daily with a saline solution or soapy water, applying a layer of ointment, and then covering with a non-adherent dressing. Wound care after cutaneous reconstruction is similar to second intention wound care, although limited to 1–2 weeks. A discussion of cutaneous reconstruction can be found in Chapters 146–148.

POSTOPERATIVE CARE

In addition to those given preoperatively (see Table 151.3), antibiotics may be given postoperatively for wound infection prophylaxis if surgery is extensive as well as for any debilitated patient for whom proper wound care is a concern[85]. Additionally, surgical reconstruction on highly sebaceous noses and distal lower extremities (below the knee) plus those near the nares and mouth may require prophylactic antibiotics. Pain control is assessed on a case-by-case basis. Substantial pain following MMS is uncommon. Acetaminophen is usually sufficient for postoperative discomfort, especially for smaller defects and simple repairs. Oral narcotic analgesics may be prescribed for patients with low pain thresholds, large tumors, complex reconstruction, or wounds in anatomic locations of high tension (e.g. scalp) or sensitivity (e.g. lip, nose, ear)[99]. One randomized controlled trial found the combination of acetaminophen and ibuprofen superior in controlling postoperative pain compared to acetaminophen with codeine and acetaminophen alone[99].

Ongoing surveillance at least annually for new primary and recurrent cancer is recommended for all patients, given that 50% of patients with keratinocyte carcinomas will experience another skin cancer during the subsequent 5 years.

COMPLICATIONS

Complications and adverse events from MMS are uncommon and the procedure has an undetectable mortality rate[100,101]. A large, multicenter, prospective cohort study of adverse events in MMS found that the rate of adverse events was <1%, with the majority being minor[100].

Intraoperative considerations include anxiety, pain (with local anesthesia injection), bleeding, nerve damage, and allergic reactions. If warranted, oral midazolam can be given in the range of 5–15 mg for healthy adults. Knowledge of vascular, muscular, and neural anatomy, especially within the "danger zones" of the face (see Ch. 142), helps to avoid and anticipate specific complications. Hemorrhage is a potential risk during surgery and is minimized with meticulous hemostasis and pressure bandaging. The superficial temporal artery is the most common major artery that may be transected, and its transection usually requires suture ligation. Epinephrine (adrenaline) included in the local anesthetic temporarily improves hemostasis. To date, there is no evidence that patients taking aspirin or warfarin for serious medical problems experience increased risks of serious hemorrhage or bleeding complications following MMS. In addition, while there is a significantly increased risk of bleeding complications in patients on thienopyridines (e.g. clopidogrel, ticlopidine) undergoing dermatologic surgery, these medications are typically continued due to the possible risk of internal thrombotic complications[102,103].

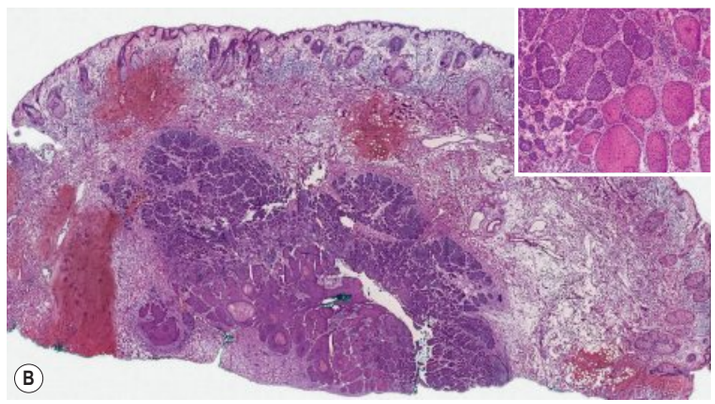

Fig. 150.9 Collision tumor – basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). A A biopsy-proven micronodular/nodular BCC on the ear. **B** Frozen sections demonstrated distinct aggregates of uniform basaloid cells as well as variably large, irregular complexes of polygonal cells with eosinophilic cytoplasm and enlarged, partly pleomorphic nuclei (*inset*).

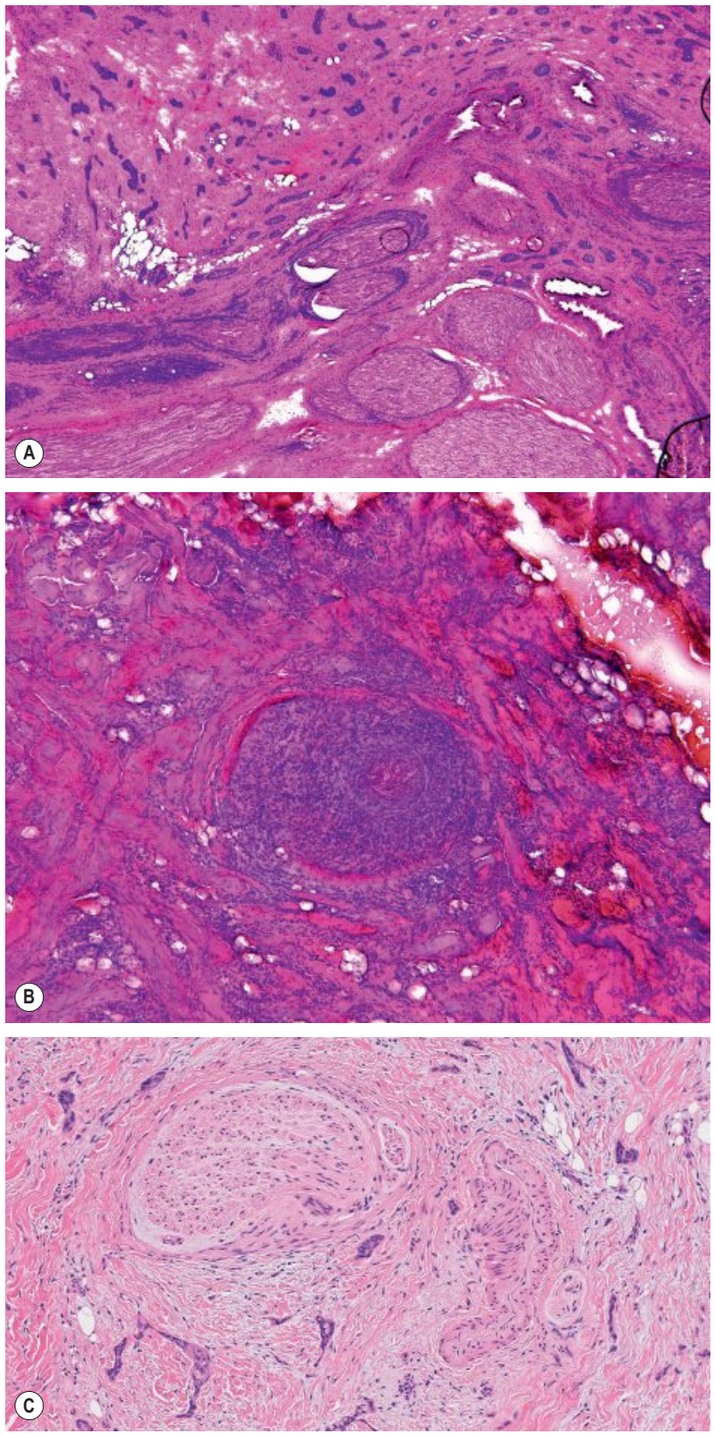
Injury to cutaneous sensory nerves occurs during all cutaneous surgery. Transection of significant motor nerves is occasionally necessary for removal of deeply invasive tumors, especially in the temporal region. Whenever possible, the surgeon should inform the patient before surgery of any possible loss of function or sensation.

Additional postoperative complications include infection, dehiscence, partial- or full-thickness necrosis, and seroma formation (see Ch. 151). Based upon several studies, the infection rate post MMS is very low (0.7%)[101,104,105].

FUTURE TRENDS

The history of MMS is one of continuous innovation and improvement. Potential enhancements include perioperative tumor definition via noninvasive imaging (e.g. reflectance confocal microscopy, optical coherence tomography) in order to visualize subclinical tumor involvement, use of rapid immunostains that enhance diagnostic sensitivity and specificity, new indications for MMS based upon evidence-based



medicine, and further refinements of practice guidelines centered on patient-related outcomes[1]. With the increase in the incidence of skin cancer, the demand for MMS will continue to rise. Given the risk of overuse of MMS, it is important to be mindful of its appropriate use, other viable treatment options, and shared decision-making with patients[1,5]. Current ongoing, large, multicenter database studies aim to further establish MMS as the treatment of choice for high-risk cutaneous neoplasms due to high cure rates, tissue sparing potential, safety, low complication rate, convenience of an outpatient procedure, and cost effectiveness[20,28–30,33].

eFig. 150.2 Histopathologic challenges in Mohs surgery. A Incomplete histologic margins (e.g. due to a small portion of missing epidermis) can lead to false-negative readings. **B** Electrocoagulation artifact. **C** Gelfoam artifact. **D** Incidental syringoma can lead to false-positive reading. **E** Floaters can lead to false-positive readings. *A, Courtesy Clark C. Otley, MD, and Randall K. Roenigk, MD.*

MOHS MICROGRAPHIC SURGERY – CHALLENGES, PITFALLS, AND RECOMMENDATIONS		
	Challenges/pitfalls	**Recommendations**
Technical		
Tissue characteristics	• Photodamaged skin is more fragile and will tear and fragment • Sebaceous skin	• Careful curettage • Iris scissors to remove layer
	• Complex tissue location (e.g. inner ear) and components such as muscle, cartilage and bone (latter must be decalcified before sectioning)	• Iris scissors to remove layer • 15c blade to remove layer • "Hockey stick" beaver blade
	• Fatty tissue requires intense freezing, which can lead to an increase in epidermal freeze artifacts, tissue fractures, and specimen chipping	• Define tumor with curette and only remove what is necessary
Debulking	• Curettage may cause irregular borders, epidermal loss, or induce floaters* • Within layer, excess epidermal tissue centrally can be pushed down to cut margin and interpreted as tumor	• Only curette when indicated • Saline irrigation • Cut off any attached tumor
Excising	• Cutting into cancerous tissue if bevel <15°	• Bevel angle of 30° to 45°
	• Tissue has thick and tall edges if bevel angle >45°	• Use relaxing incisions on tissue to allow the epidermis to lie flat
	• Cutting marginal surfaces when making the relaxing incisions	• Make relaxing incisions near the center of the layer
Electrocoagulation	• Excessive electrocoagulation can cause elongation of the nuclei and cytoplasm of epidermal keratinocytes in addition to basement membrane retraction artifact	• Use of lidocaine with epinephrine (adrenaline) allows constriction of blood vessels and less need for electrocoagulation
Orienting	• Tissue rotation	• Double hash or asymmetric hash marks
	• Induction of floaters when making hash marks	• Saline irrigation • Ink marker[e2]
Mapping	• Inaccurate mapping	• Consistency
Sectioning	• Tissue lacerations mistaken for hash marks	• Caution when grasping tissue with forceps
Inking	• Placing ink on wrong margin	• Per CLIA requirements, inking performed by either surgeon or other qualified laboratory personnel
	• Inadequate inking	• Consistent process
	• Ink running into the wrong section	• High quality ink
Tissue flattening and freezing	• Ice crystal formation if specimen frozen too slowly, leading to cracks and hole in the specimen	• Appropriate temperature is –22° to –30°C
	• Curling of tissue if blades are not cold enough	• Cold cutting blades
Cutting	• Tearing or curling of tissue	• Sharp blades • Check blade for nicks
	• Specimen too thin or too thick	• Loose screws can result in a thick specimen • Adjust blade angle
	• Floaters	• Clean blades
	• Chatter or incomplete sections due to dull blades	• Change blades
Slide fixation	• Artifact due to short dehydration time	• Appropriate dehydration time
	• Tissue doesn't attach or falls off due to defects on the slides	• Check for defects on the slide; use charged or adhesive coated slides
	• Errors in labeling	• Proper labeling
Staining[e3]	• Weak or excessive staining	• Identify problematic step
	• Artifacts due to not enough time for dehydration	• Complete dehydration
	• Floaters if staining solution is contaminated	• Change staining solution frequently
Cover slipping	• Bubbles	• Align with length of slide and closely roll onto slide
	• Water beads	• May have skipped xylene clearing step while staining[e3]
Pathologic interpretation (Fig. 150.8)		
Floater[e4,*]	• Curettage	• Wipe blade between cuts when separating the layer into subunits • Change blade between layers • Saline irrigation after excision
	• Orientation marks	• Process layer in one piece • Ink marker
	• Cutting	• Keep the blades clean
	• Inking	• Change inking solution frequently

eTable 150.1 Mohs micrographic surgery – challenges, pitfalls and recommendations.

Continued

MOHS MICROGRAPHIC SURGERY – CHALLENGES, PITFALLS, AND RECOMMENDATIONS		
	Challenges/pitfalls	**Recommendations**
Missing epidermis[94,e5] = false negative	• Aggressive curettage	• Attention to margin of tumor
	• Incomplete margin around site of debulking	• Bevel blade
	• Tissue edges do not lie flat	• Relaxing cuts
Dermal tissue drop-out[94,e5] = false negative	• Inadequate freezing of tissue	• Freeze tissue appropriately • Assure full section is cut
Inflammation vs tumor	• Inflammation can obscure or resemble the tumor, especially SCCs	• Examine deeper section within block • Immunostaining • Awareness of patient's comorbidities (e.g. CLL)
Unexpected pathology	• Frozen pathology incongruent with biopsy report • Superficial or partial biopsy[e6,e7]	• Confirmation of biopsy site • Collision tumor (Fig. 150.9) • Send tissue for FFPE sections • Immunostaining
BCC vs benign entities	• Tangentially sectioned hair follicles mimic BCC • Benign folliculocentric proliferation	• Examine multiple sections • Look for retraction and stromal changes of BCC
BCC vs other neoplasms	• Trichoepithelioma, spiradenoma, cylindroma, MAC, and metastatic breast cancer may resemble BCC	• Examine multiple sections • Thaw the block and send for FFPE sections • Immunostaining
AK vs SCCIS vs SCC	• Misreading AK for SCCIS or reverse	• Standardize definition of AK and SCCIS
	• Missing SCC clumps within the dermis	• Evaluate the dermis carefully for cells of SCC • Immunostaining
SCC vs benign conditions	• Healing wound and biopsy sites mistaken for SCC	• Identify biopsy site grossly and microscopically
	• Tangential sectioning of epidermis resembling SCC	• Examine multiple sections for lumina, fragments of hair, and hair papillae
SCC vs other neoplasms	• Inflamed seborrheic keratosis or verruca vulgaris mistaken for SCC • Adnexal tumor mistaken for SCC	• Examine multiple sections • Thaw the block and send for FFPE sections • Immunostaining
Perineural invasion	• Missing perineural invasion • Mistaken as peritumoral fibrosis, reparative perineural proliferation, or epithelial sheath neuroma	• High index of suspicion in invasive SCC • Examine multiple sections • Consider processing final full margin via FFPE sections • Immunostaining
Infiltrative tumors	• Missing subtle cords and nests of infiltrative BCC or MAC within the dermis	• Toluidine blue staining[e1] • Send for FFPE sections (Fig. 150.5D)
Melanoma	• Difficulty recognizing atypical melanocytes • Lack of cellular detail	• Immunostaining • Discuss with dermatopathologist • "Slow Mohs" or geometric staged excision
Other tumors	• Skip areas in Merkel cell carcinoma, EMPD, and sebaceous carcinoma • Scar mistaken for DFSP • Normal pilar apparatus mistaken for leiomyosarcoma	• Awareness of potential for false-negative clear margin in multifocal tumors • Consider an additional excision of margins for FFPE sections • Immunostaining
*Floaters are dislodged pieces of tissue that occur during excision, embedding, cutting or staining that can hinder histologic interpretation in frozen sections.		

eTable 150.1 Mohs micrographic surgery – challenges, pitfalls and recommendations. AK, actinic keratosis; BCC, basal cell carcinoma; CLL, chronic lymphocytic leukemia; DFSP, dermatofibrosarcoma protuberans; EMPD, extramammary Paget disease; FFPE, formalin-fixed, paraffin-embedded; MAC, microcystic adnexal carcinoma; SCC, squamous cell carcinoma; SCCIS, squamous cell carcinoma *in situ*. *Adapted from Bernstein SC, Roenigk RK. 151 Surgical Complications and Optimizing Outcomes

Stacy L. McMurray and Anna S. Clayton

Key features

- A thorough preoperative assessment of the patient is required to increase the probability of a successful outcome for any surgical procedure
- Attention to detail, selection of the simplest procedures that will produce the desired result, and meticulous intraoperative technique will prevent many complications
- Anticipation of avoidable complications and careful management of unavoidable ones optimize results
- Clear communication between patient and surgeon must begin before the start of the procedure and continue through every stage, including the recovery and healing phases
- Because many complications do not manifest until several days to months postoperatively, patients must be monitored periodically to ensure that all parties are satisfied with the final outcome

INTRODUCTION

Surgical complications are deviations from the original planned outcome, usually resulting from multiple interrelated events (Fig. 151.1). Although complications in dermatologic surgery are uncommon[1,2], potential complications can often be avoided or minimized with careful planning and meticulous technique.

Complications vary widely, from impacting cosmetic appearance to life-threatening. Life-threatening emergencies in cutaneous surgery are rare, but the surgeon must be prepared to deal with problems such as cardiac arrhythmias and anaphylaxis. Proper, well-maintained resuscitation equipment must be readily available, and staff should maintain Basic Life Support (BLS) training, including the use of an automated external defibrillator (AED). Physicians in offices where extensive cutaneous surgery is performed should also have Advanced Cardiac Life Support (ACLS) training.

A thorough preoperative assessment, including history and directed physical examination, can identify pre-existing conditions that may impact healing. Informed consent obtained at this time, and again just prior to the procedure, ensures that the patient has realistic expectations. This education minimizes future misunderstandings regarding known risks of the procedure.

Prevention of an unsatisfactory outcome starts during the planning stage and continues with good intraoperative surgical technique and postoperative care. Anticipation of avoidable complications and management of unavoidable ones optimizes results. Throughout the process, it is essential to involve patients in their care.

DISCUSSION

Preoperative Assessment

A thorough preoperative assessment is a valuable tool for identifying conditions that could lead to surgical complications. A simple preoperative questionnaire can be completed by the patient at the time of the initial evaluation. "Yes" or "no" answers to specific questions can indicate a need for further evaluation or for a change in the operative plan (Fig. 151.2).

Potential for bleeding

Although some bleeding is expected during any surgical procedure, excessive bleeding is a common complication. The discovery of a bleeding disorder prior to surgery allows for correction of the condition if it is reversible, or changing plans for surgery if it is not. The bleeding disorder may be due to abnormalities in the *coagulation cascade*, *platelets*, or both. Platelet disorders result from abnormalities in *production*, *survival*, or *function*.

Laboratory evaluation

If the history does not suggest a bleeding disorder and the patient is otherwise well, laboratory testing is usually unnecessary. Appropriate screening tests should be checked if there is suspicion for a hereditary or acquired bleeding disorder. A platelet count only identifies a quantitative abnormality. The bleeding-time test measures platelet function, but accurate determination of results is operator-dependent. An *in vitro* bleeding-time assay, the platelet function analyzer 100 (PFA-100), provides an easy method for rapidly assessing platelet function. Unlike the bleeding time, the PFA-100 can be performed on a collected blood specimen. Additional screening tests include a PT (prothrombin time) and an aPTT (activated partial thromboplastin time) to determine defects in the extrinsic and intrinsic coagulation pathways, respectively. The international normalization ratio (INR) is discussed in the next section.

Medications and dietary supplements

The preoperative assessment should include a review of medications and dietary supplements (see Table 133.3), in particular antiplatelet and anticoagulant medications. When these drugs are prescribed for cardiac or neurologic indications, discontinuation can potentially lead to serious events (e.g. coronary artery stent thrombosis). In general, surgeons should not discontinue these medications but should instead focus on intraoperative precautions, such as meticulous hemostasis and minimal undermining[3,4].

Aspirin and aspirin-containing products are well-documented sources of bleeding problems. Platelet aggregation is irreversibly altered when aspirin acetylates cyclooxygenase. Patients taking aspirin for general health benefits, rather than specific medical indications, may discontinue the aspirin from ≥10 days *before* until 5–7 days *after* surgery. *Nonsteroidal anti-inflammatory drugs* affect the same enzyme, although the block is neither as severe nor irreversible[5]. If possible, the patient should stop these medications 1–4 days prior to surgery, depending on the half-life of the drug.

Dipyridamole suppresses platelet aggregation by inhibiting phosphodiesterase and increasing cyclic adenosine monophosphate (cAMP) levels within platelets. It is used in combination with aspirin for secondary prevention of thromboembolic events. The antiplatelet effect of dipyridamole is less than that of aspirin, and it does not appear to increase bleeding complications[6].

Thienopyridines (e.g. *clopidogrel*, *ticlopidine*, *prasugrel*) irreversibly inhibit platelet aggregation via inhibition of $P2Y_{12}$, a platelet ADP receptor. *Cilostazol* is a selective type 3 phosphodiesterase inhibitor with weaker $P2Y_{12}$ inhibition; it is typically used for claudication. Normal platelet function usually returns 5–7 days after discontinuation. Despite the slightly increased risk of complications in patients receiving $P2Y_{12}$ inhibitors, these medications can typically be continued without significant issues[7,8].

Several studies have been published in the vascular, oral, orthopedic, and dermatologic surgery literature supporting the viewpoint that surgery can be performed without stopping *warfarin*. An INR should be checked prior to surgery. Most authors advocate an upper limit of 3 or 3.5[8–12]. The safety of dermatologic surgery with INRs >3.5 has not been well studied, though one study found a poor correlation between bleeding complications and INR levels, with complications also occurring in the setting of in-range INRs[13]. If warfarin is discontinued in consultation with the prescribing physician, it should be held for 4–5 days preoperatively. If a patient on warfarin develops significant

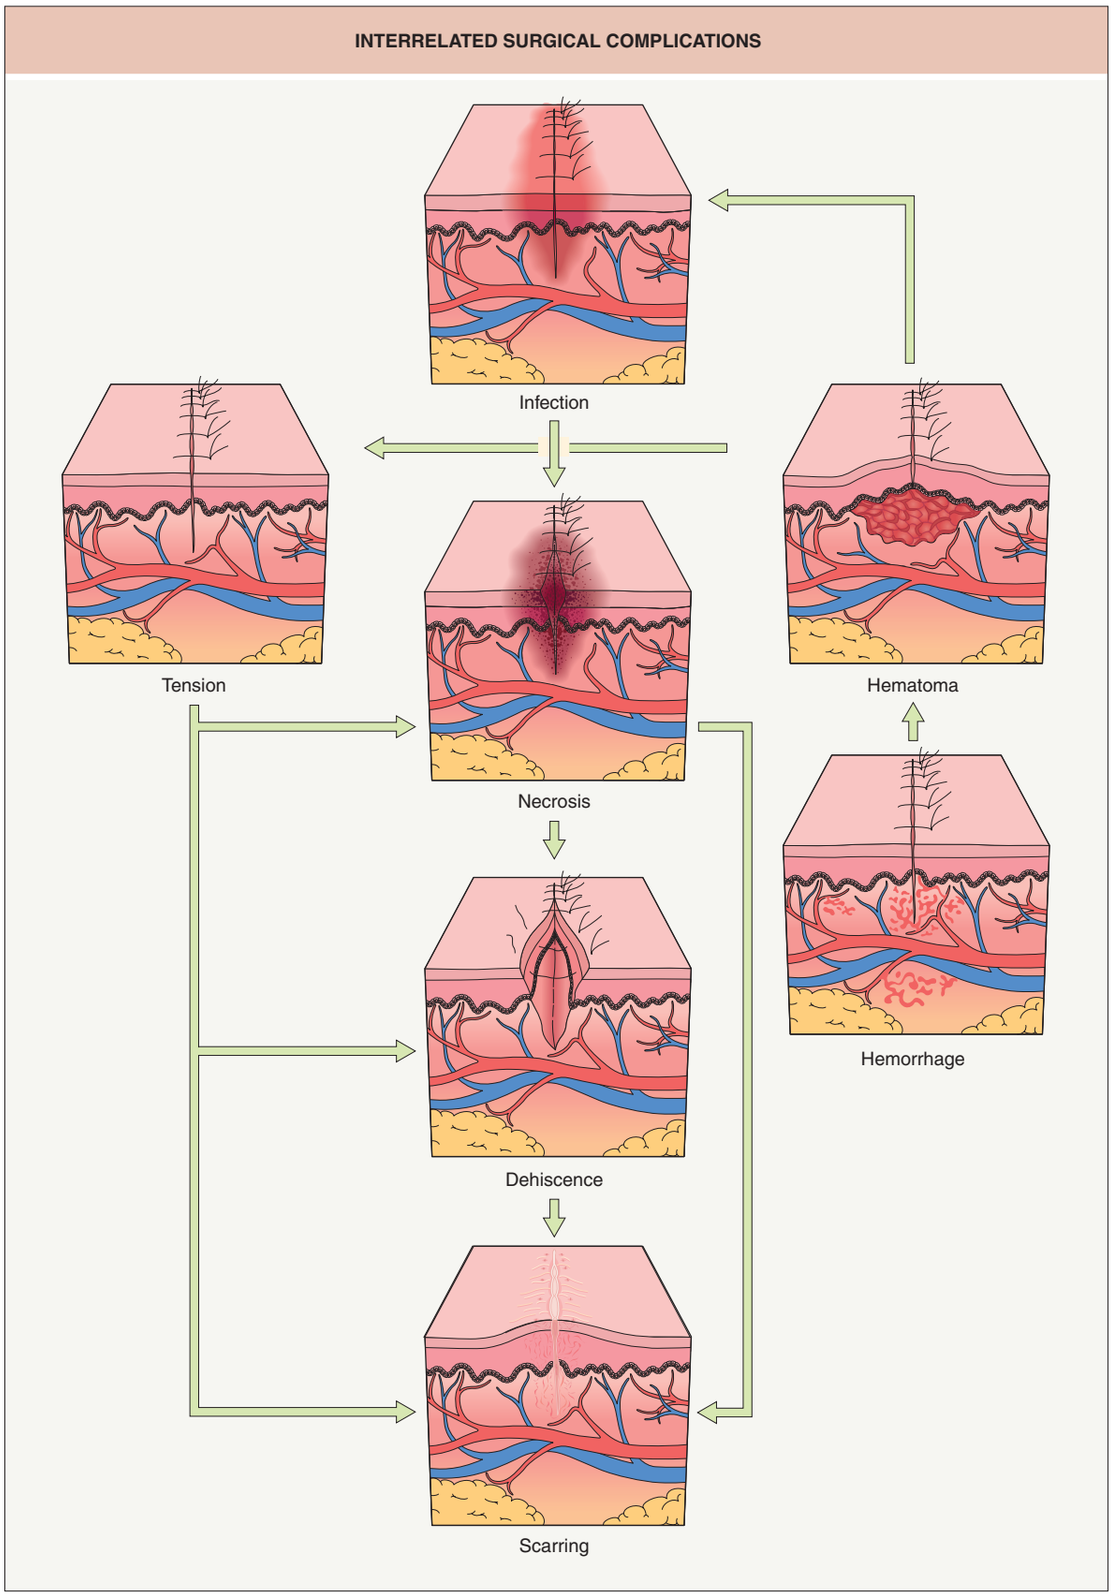

Fig. 151.1 Interrelated surgical complications.

postoperative bleeding, the anticoagulation can be reversed with one or more of the following: oral or intravenous vitamin K, fresh frozen plasma, and four-factor prothrombin complex concentrate.

Factor Xa inhibitors *apixaban* and *rivaroxaban* are often used as alternatives to warfarin while the direct thrombin inhibitor *dabigatran* is occasionally used as an alternative; this group of drugs is referred to as DOACs (direct oral anticoagulants; see Table 22.8 and Fig. 22.6). Literature remains sparse regarding these agents in dermatologic surgery. One large randomized trial of invasive, non-dermatologic procedures found similar rates of bleeding complications with warfarin versus dabigatran, but both medications were held preoperatively[14]. A more recent single-center, retrospective analysis found that patients receiving a DOAC at the time of Mohs micrographic surgery had a significantly greater risk for developing postoperative hemorrhagic complications compared to patients treated with traditional oral anticoagulants[15]. The authors recommend similar intraoperative precautions with these medications (see above). Idarucizumab is approved for reversing dabigatran, and andexanet alfa is a specific antidote for apixaban and rivaroxaban, but this is less of an issue because of their shorter half-lives of ≤12 hours.

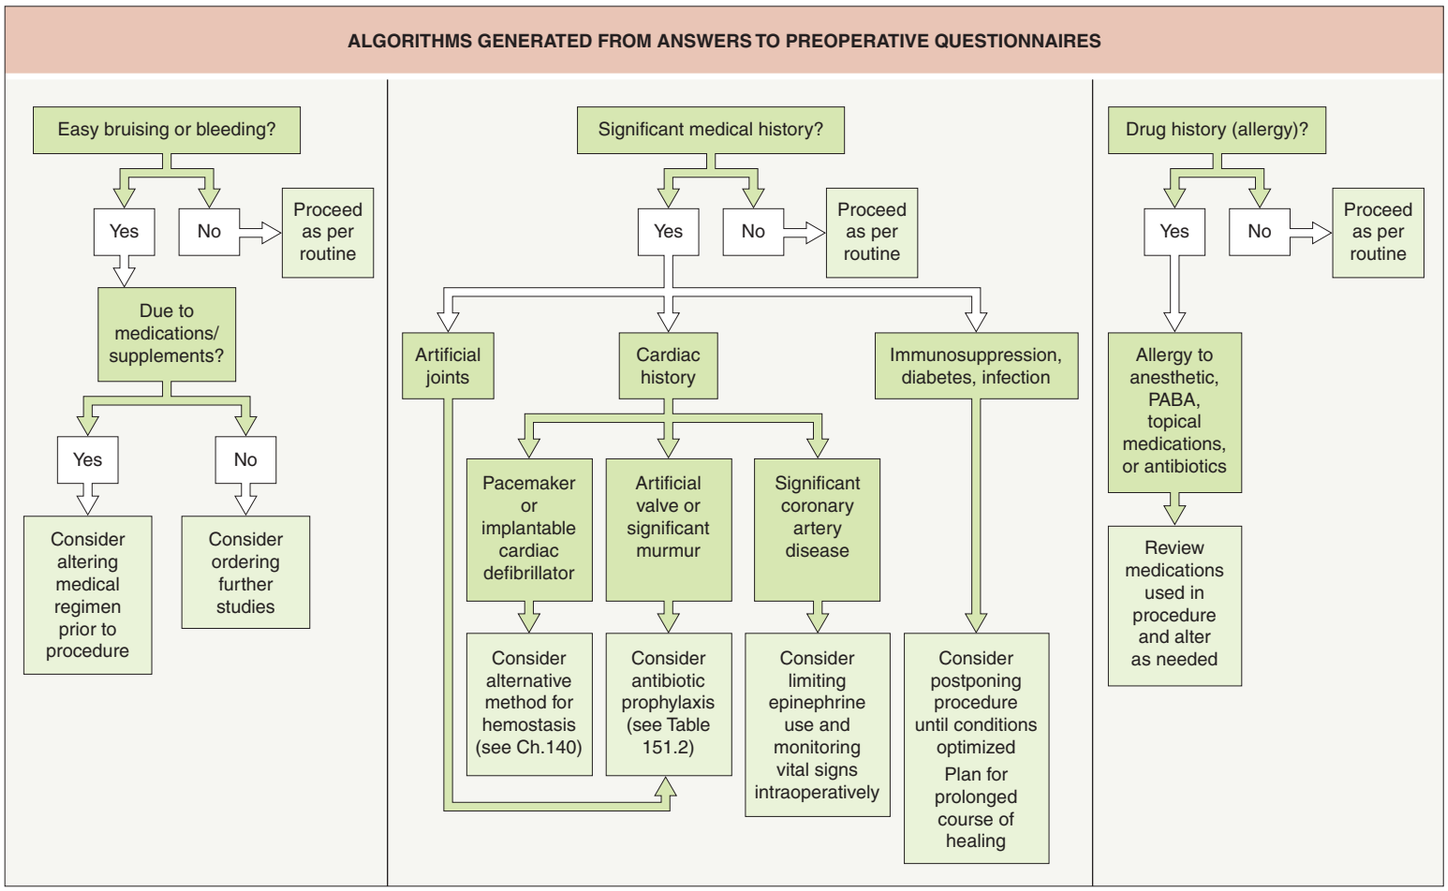

Fig. 151.2 Algorithms generated from answers to preoperative questionnaires. PABA, para-aminobenzoic acid.

Heparin acts as an antithrombin factor. Intravenous, unfractionated heparin has a short half-life of ~1 hour and can be rapidly reversed by intravenous protamine sulfate. *Low-molecular-weight heparin* (LMWH) has a half-life of 3–5 hours and is administered subcutaneously. Either form can be used to bridge patients in whom discontinuing warfarin preoperatively has been deemed necessary. LMWH is discontinued 24 hours prior to surgery, whereas unfractionated heparin is stopped five hours preoperatively. Either form of heparin is then restarted, together with warfarin, 24 hours post-procedure, with the heparin discontinued after a therapeutic INR has been attained.

Complementary and alternative therapies can inhibit platelet function or enhance anticoagulation. Common agents include *vitamin E*, *garlic*, and *eicosapentaenoic acid* (fish oil). Table 133.3 has a more comprehensive list of *dietary supplements* that have effects on platelet function and coagulation[16]. Patients should discontinue these supplements prior to surgery. More recently, enhanced bleeding has been observed in patients receiving *ibrutinib*, a Bruton tyrosine kinase (BTK) inhibitor used to treat lymphomas and chronic lymphocytic leukemia. This is thought to be related to the role of BTK and other kinases in platelet signaling pathways. This is less of an issue with second- and third-generation BTK inhibitors, e.g. acalabrutininib, zanubrutinib, pirtobrutinib.

Ethanol is a potent vasodilator that inhibits platelet aggregation and platelet granule release, as well as accentuating the increase in bleeding time caused by aspirin[17]. Excessive alcohol consumption may also decrease the patient's attention to optimal wound protection. Patients should be advised to avoid alcohol consumption during the immediate perioperative period.

Wound healing

The principles of wound healing are covered in detail in Chapter 141. To forestall complications due to poor wound healing, close attention should be paid to pre-existing medical conditions and medications that affect wound healing. Postponing surgery may be a wise decision for some patients. If the procedure cannot be postponed, the patient should be forewarned that the postoperative healing phase could be prolonged. Any chronic debilitating illness can predispose patients to secondary infections.

Systemic *corticosteroids* can delay healing and predispose patients to secondary infections. Patients on other immunosuppressive medications such as cyclosporine may also be prone to infections and prolonged healing. *Inhibitors of vascular endothelial growth factor* (VEGF), including monoclonal antibodies (e.g. *bevacizumab*) and oral tyrosine kinase inhibitors (e.g. *sorafenib*), have been associated with delayed healing and wound dehiscence (see Fig. 102.16). These agents should be held for at least 4–6 weeks prior to surgical procedures[18,19].

Cigarette smoking interferes with wound healing in a dose-dependent manner, and flaps or grafts are particularly susceptible[20–22]. Ideally, patients should avoid smoking for at least 3 weeks before surgery, but one study found that over 85% of smokers continued smoking preoperatively despite instructions to stop. At a minimum, patients should be strongly encouraged to decrease consumption to less than half a pack per day or switch to nicotine replacement patches for at least 2 weeks preoperatively and 1 week postoperatively[23,24]. Compared to cigarettes, the patches do not result in the high peak blood nicotine levels that lead to peripheral vasoconstriction and reduced wound tissue oxygen tension.

There is literature to support delaying cosmetic procedures for up to one year after cessation of *isotretinoin* therapy due to the risk of poor wound healing and the formation of excessive granulation tissue[25–27]. However, most reported problems have been individual case reports involving resurfacing procedures after courses of isotretinoin for acne therapy. More recent data from larger cohort studies suggest that procedures, including laser hair removal, dermabrasion, and laser resurfacing for acne scars, may be safe to perform during or shortly after a course of isotretinoin therapy[28–32].

Reactivation of herpes simplex virus (HSV) infection can dramatically interfere with the postoperative course. Patients with a history of herpes labialis or other facial herpetic infections should receive prophylactic antiviral therapy prior to dermabrasion, laser resurfacing, chemical peels, or surgery involving known trigger area(s). Antiviral therapy, such as oral valacyclovir 500 mg twice daily, should start on the day of the procedure and continue for 10 days postoperatively or until the skin has re-epithelialized[33]. Alternative regimens include oral famciclovir 250 mg three times daily or oral acyclovir 200 mg five times daily.

Prophylactic antibiotics

Antibiotic prophylaxis is administered to prevent surgical site infection, bacterial endocarditis, or infection in implanted prosthetic devices. The risk and consequences of infection must be weighed against the risk and cost of the antibiotic.

Wounds are placed into four general categories (Table 151.1). The majority of dermatologic surgical procedures are clean or clean-contaminated and do not need prophylaxis. However, prophylactic antibiotics may be helpful in certain clean-contaminated wounds. For example, antibiotics can be considered for procedures involving the oronasal mucosa, axilla, or anogenital region, although there are no controlled studies. Procedures that approach the ear canal may be at higher risk for infection with Gram-negative organisms. Long procedures are also more likely to develop wound infections: the infection rate almost doubles with each hour of operation. Prophylactic antibiotics are recommended for procedures at increased risk for surgical site infection, including surgery on the lower extremities or in the groin, wedge excisions of the lip or ear, flaps on the nose, all skin grafts, and in patients with extensive inflammatory skin disease[34]. When possible, prophylactic antibiotics should be prescribed in anticipation of these types of repairs. Unless the patient is in a special group (see below), some surgeons limit prophylactic antibiotics to just excisions on the lower extremities and ears, especially if the cartilage is exposed. Antibiotics are therapeutic, not prophylactic, for contaminated and infected wounds.

WOUND CLASSIFICATION		
Class	**Attributes**	**% that develop infections**
Clean	Immaculate technique Non-inflammatory	1–4
Clean-contaminated	Small breaks in technique Gastrointestinal, respiratory, or genitourinary tracts entered without gross contamination	5–15
Contaminated	Major breaks in technique Gross contamination from gastrointestinal, genitourinary, or respiratory tracts	6–25
Dirty and/or infected	Wound with acute bacterial infection ± pus	>25

Table 151.1 Wound classification[1]. Technique in the table refers to sterile surgical technique.

Two special patient groups should be considered for antibiotic prophylaxis: (1) those at risk for infective endocarditis; and (2) those at risk for bloodborne infection of total joint replacements (Table 151.2)[34]. In patients with total joint replacements or specific cardiac diseases, no prophylaxis is indicated if the surgical procedure is in a non-infected cutaneous site. In general, prophylactic antibiotics are no longer recommended by the American Academy of Orthopedic Surgeons and American Dental Association for patients with prosthetic joint replacements undergoing dental procedures; possible exceptions, including mucosal incision in a patient with a history of joint surgery complications, are outlined in Table 151.2[35,36]. However, to date, recommendations specific to dermatologic procedures are lacking. Table 151.3 summarizes suggestions for antibiotic prophylaxis regimens. If any question arises, consider consultation with the patient's cardiologist, internist, or orthopedic surgeon.

Implantable electronic medical devices

Cardiac defibrillators and pacemakers

The electrosurgical instruments often used in cutaneous procedures have the potential to interfere with the function of pacemakers and implantable cardioverter-defibrillators (ICDs), though the risk is quite low with modern devices (see Ch. 140)[37]. Alternatives to electrosurgery include battery-operated and AC-powered *thermal cautery units* that do not produce high-frequency electromagnetic interference (EMI) or electrical currents traversing the body. *Bipolar instruments* (e.g. forceps) concentrate the current across the tips, minimizing the chance of interference. If conventional electrosurgery is used, the active tip should not be applied within 5 cm of the implanted device whenever possible. Electrocoagulation should also be kept at as low a setting as possible and delivered in bursts lasting <5 seconds to minimize the chance of prolonged inhibition[38].

If conventional electrosurgery is used in a patient with an ICD, a contingency plan should be in place to deal with an arrhythmia should it occur, and an AED should be immediately available. If the device is deactivated or its function altered for the procedure, it is the surgeon's responsibility to ensure that patients return to their cardiologists within a reasonable time period for readjustment and evaluation.

Deep brain stimulators

There are few reports of patients undergoing dermatologic surgery who have an implanted deep brain stimulator (DBS). These devices are used to treat Parkinson disease and can be turned off with an external magnet if the resultant tremor does not interfere with surgery. Bipolar forceps or electrocautery are preferred to limit EMI. If a monopolar device is necessary, the dispersive plate should be positioned so that the pulse generator and lead wires are not located between the plate and the surgical site[39].

ANTIBIOTIC PROPHYLAXIS FOR DERMATOLOGIC SURGERY – PATIENT GROUPS AT RISK FOR INFECTIVE ENDOCARDITIS AND INFECTION OF TOTAL JOINT REPLACEMENTS
High-risk cardiac conditions (infected skin or breach of oral mucosa)
• Prosthetic heart valve or prosthetic material used in valve repair • History of infective endocarditis • Unrepaired cyanotic congenital heart disease (includes palliative shunts and conduits) • Completely repaired congenital heart defects with prosthetic materials or devices* • Repaired congenital heart disease with residual defects at or adjacent to site of prosthetic patch or prosthetic device • Cardiac transplant recipients who develop cardiac valvulopathy
Prosthetic joint replacements *(infected skin, breach of oral mucosa†; non-infected site at high risk of surgical site infection†)*
• First 2 years after joint placement • Previous prosthetic joint infections • Type 1 diabetes mellitus • Immunosuppression (HIV infection, medications, underlying malignancy) • Malnourishment • Hemophilia
*First 6 months after procedure (surgical or catheter intervention). †The American Academy of Orthopedic Surgeons (AAOS) and American Dental Association no longer recommend the general use of prophylactic antibiotics in patients with prosthetic joints undergoing dental procedures, but they can be considered for patients with a history of complications associated with their joint replacement surgery who are undergoing procedures such as gingival manipulation or mucosal incision[35,36]; however, to date, there are no AAOS recommendations specific to non-infected, high-risk sites.

Table 151.2 Antibiotic prophylaxis for dermatologic surgery – patient groups at risk for infective endocarditis and infection of total joint replacements. HIV, human immunodeficiency virus. Adapted from the American Heart Association, the American Dental Association, the American Academy of Orthopedic Surgeons, and reference 34.

RECOMMENDATIONS FOR ANTIBIOTIC PROPHYLAXIS IN PATIENTS AT RISK FOR INFECTIVE ENDOCARDITIS AND INFECTION OF TOTAL JOINT REPLACEMENTS			
Surgical site/ procedure	**Allergy**	**Antibiotic**	**Dose†**
Non-oral – wedge excisions of lip or ear, nasal flaps, all grafts	None	Cephalexin* or dicloxacillin*	2 g PO
		– *or* –	
		cefazolin/ceftriaxone*	1 g IM/IV
Non-oral – wedge excisions of lip or ear, nasal flaps, all grafts	Penicillin	Clindamycin or azithromycin/ clarithromycin*	600 mg PO 500 mg PO
		– *or* –	
		clindamycin	600 mg IM/IV
Oral mucosa breached	None	Amoxicillin	2 g PO
		– *or* –	
		cefazolin/ceftriaxone or ampicillin	1 g IV/IM 2 g IV/IM
Oral mucosa breached	Penicillin	Clindamycin or azithromycin/ clarithromycin	600 mg PO 500 mg PO
		– *or* –	
		clindamycin	600 mg IM/IV
Lesions in the groin or on the legs	None	Cephalexin* or TMP–SMX DS	2 g PO 1 tablet PO
		– *or* –	
		ceftriaxone*	1–2 g IV
Lesions in the groin or on the legs	Penicillin	TMP–SMX DS or levofloxacin*	1 tablet PO 500 mg PO
		– *or* –	
		clindamycin and gentamicin	600 mg and 2 mg/kg IV

*In communities with increased risk for methicillin-resistant *Staphylococcus aureus*, consider prophylaxis with TMP–SMX DS (1 tab PO) or clindamycin (600 mg PO).
†Give single dose (PO, IM or IV) 30–60 minutes before procedure.

Table 151.3 Recommendations for antibiotic prophylaxis in patients at risk for infective endocarditis and infection of total joint replacements[34]. IM, intramuscular; IV, intravenous; PO, by mouth; TMP–SMX DS, trimethoprim–sulfamethoxazole double-strength.

Cochlear implants

Cochlear implants (CIs) provide a sense of sound by direct stimulation of the auditory nerve. They consist of an external part that sits behind the ear and another part implanted below the skin. While potential for EMI exists, there are limited studies examining electrosurgery in patients with CIs. The British Cochlear Implant Group and CI manufacturer guidelines recommend against the use of monoterminal electrosurgery in the head and neck region; biterminal electrosurgery can be used safely if not within 1 to 2 cm of the CI[39]. A conservative approach may be prudent, with use of electrosurgical instruments below the clavicles and only electrocautery in the vicinity of the implant.

Nerve stimulators

Implantable nerve stimulators (e.g. vagal nerve, sacral nerve, phrenic nerve, spinal cord stimulators) are now available for a variety of indications. There are also implantable neurostimulators (e.g., NeuroPace® RNS® System) for epilepsy. Some of these devices can be temporarily turned off during electrosurgery without adverse effects. Electrocautery is recommended when possible to minimize risk of EMI. Other techniques to minimize interference include use of bipolar forceps and positioning of dispersive pads away from the implanted device. When in doubt, the authors advise consultation with the prescribing physician for further recommendations.

Allergies

True allergic reactions to local anesthetics may be type I (immediate) or type IV (delayed-type hypersensitivity) (see Ch. 143). Patients with a type IV sensitivity to one major group of local anesthetics (ester or amide) are usually not allergic to members of the other group. Type I reactions are more commonly associated with the ester anesthetics and their para-aminobenzoic acid (PABA) metabolite. Although the lack of cross-reactivity between ester and amide anesthetics is true for type IV sensitivity, it has not been adequately studied for anaphylaxis. If there is a possible history of a type I amide allergy, referral to an allergist for a progressive challenge protocol can be considered. It is important to consider the possibility that the allergic reaction is due to the preservative (e.g. methylparaben, metabisulfite). Use of preservative-free anesthetics can resolve this problem.

Epinephrine (adrenaline) is a vasoconstrictive agent commonly added to local anesthetics to reduce bleeding and prolong the duration of anesthesia. Patients occasionally report a history of an "allergy" to local anesthetic, describing their symptoms as palpitations, headache, tachycardia, tachypnea, or tremor (see Ch. 143). Such reports likely represent reactions to epinephrine given in high doses or inadvertently injected intravascularly. Since the half-life of epinephrine in serum is short, specific therapy for these reactions is usually not necessary. In order to avoid them, the lowest dosage and concentration of epinephrine (<1:100 000) should be used, and injection of significant amounts intravascularly should be avoided using proper infiltration technique[40].

Another common systemic side effect often mistaken as an allergic reaction is the vasovagal reaction. The patient recalls becoming pale, sweaty, and lightheaded, perhaps even fainting. Hypotension can occur, but in contrast to a true toxic or allergic reaction, the pulse is slow and regular (see Table 143.2). Urinary incontinence and abnormal limb movements may occur during a vasovagal reaction and are not diagnostic of seizure activity[41]. Treatment consists of keeping the patient supine or in the Trendelenburg position and giving reassurance. Once the patient has recovered, they can gradually sit up and ambulate.

Chlorhexidine gluconate is a frequently utilized surgical skin preparation (see Table 146.6). It is a broad-spectrum antibacterial of the halogenated phenol class. Despite its very weak sensitizing potential, it has been reported to cause allergic contact dermatitis[36,42]. Similar reactions have occurred with the iodophor povidone–iodine (Betadine®)[43]. Both compounds can be skin irritants, especially when occluded. Care must be taken to remove all traces of cleanser prior to dressing application.

Topical antibiotics can cause allergic contact dermatitis. Although neomycin is the most common sensitizer, bacitracin can also cause sensitization. Co-reactivity against both neomycin and bacitracin is common. Cross-sensitivity between neomycin, gentamicin, kanamycin, streptomycin, and tobramycin can occur. Mupirocin or erythromycin ointment are alternatives if the patient is allergic to both neomycin and bacitracin. As there is no convincing evidence that topical antibiotic ointments prevent infection, plain petrolatum ointment may be the best agent for wound dressing.

Informed consent

The lines of communication should be open between the surgeon and the patient before the procedure begins. The physician should explain the condition, how it affects overall health, risks and benefits of the procedure, and treatment alternatives in layman's terms. Common complications (e.g. bleeding, infection, allergic reactions, scarring) and strategies for dealing with them should also be discussed. In turn, the patient must accept responsibility for preoperative preparation and postoperative wound care. When complications arise, as they inevitably will, the surgeon should be honest with the patient about treatment options and outcomes.

Intraoperative Considerations

Contamination

The risk of infection in cutaneous surgery is very low. Two often-cited studies estimated the risk at 2.3%–2.4%[44,45], but more recent data suggest the rate is likely <1%[46,47]. Wound infections usually do not become evident until 4–8 days postoperatively, but in most cases the infection truly begins at the time of surgery. The surgical team should prepare the surgical field and wear the correct protective equipment to reduce the incidence of infection.

The skin cannot be sterilized, but the majority of the resident flora and pathogenic bacteria can be removed with mechanical cleansing and antiseptic agents. The extent of skin preparation varies with the invasiveness and complexity of the proposed surgical procedure. A 2-second wipe with 70% isopropyl alcohol or a 10-second cleansing with an iodophor swab is adequate for superficial biopsies. Chlorhexidine is the most frequently utilized preoperative preparation for skin surgery. It produces rapid destruction of a wide range of Gram-positive and Gram-negative bacteria, and it binds with the protein of the stratum corneum, providing residual action. However, chlorhexidine is irritating to the conjunctiva and toxic to the cornea, tympanic membrane, and middle ear; caution must be exercised in these areas. Iodophors are another excellent antiseptic; one advantage is that the prepared area is readily apparent because of the brownish-orange color. They are effective against Gram-positive and Gram-negative bacteria and some fungal spores, but iodophors have a slower and shorter duration of action than chlorhexidine. As noted earlier, they can cause irritant or allergic contact dermatitis. There are also rare reports of anaphylaxis to chlorhexidine used as a surgical scrub.

Use of a surgical mask may help protect the patient from surgical personnel with active upper respiratory tract infections. The mask protects the surgical team from contamination by saliva droplets or blood from the patient. It is also essential to protect the eyes from accidental splashes of body fluid. Appropriate personal protective equipment is advocated in all surgical situations as part of universal precautions. In cases where sterility is not necessary, non-sterile examination gloves can be used. Recent data suggest that Mohs micrographic surgery can be performed as a clean procedure with low infection rates[48].

For all surgical procedures, proper handling of sharps is essential. Needles should never be recapped, and blades should not be changed by hand. Despite best intentions, needlestick injuries may still occur, and surgeons must have a plan for testing and treatment when appropriate (Table 151.4). The current recommendations for treating needlestick injuries are available online from the National Institute for Occupational Safety and Health (OSHA) or from the Clinicians' Post-Exposure Prophylaxis Hotline (PEPline) at 1-888-448-4911.

Bleeding and hemostasis

Hemostasis can be approached based on the amount of bleeding encountered (Fig. 151.3). Bleeding that occurs during shave biopsies can be controlled through the use of mechanical pressure, topical hemostatic agents such as aluminum chloride, or electrodesiccation. Bleeding during more extensive procedures may require suturing, use of other hemostatic agents (Table 151.5), electrocoagulation, or a combination of techniques.

Intraoperative bleeding can obscure the surgical site and can be bothersome to both the surgeon and the patient. If bleeding continues after closure, it may result in a hematoma that can lead to infection, increased tension on wound edges, dehiscence, flap necrosis, and graft loss (see Fig. 151.1). A careful history assists in identifying patients prone to bleeding. When not contraindicated (e.g. procedures on toes or fingers in patients with peripheral vascular disease), use of epinephrine with the anesthetic is helpful (see Ch. 143). Suction provides good visualization in an otherwise bloody field. An assistant can place traction across the wound surface or pressure at the periphery of the site. Frequent blotting with sponges or cotton-tipped applicators also helps to keep the field clear.

Bleeding should be controlled promptly; individual small vessels should be isolated and precisely cauterized (to avoid excessive char) or ligated. It may be prudent to ligate visible vessels lying adjacent to the wound bed as they might be nicked or partially cut during the procedure. Large vessels noted in the surgical wound should be tied off or cauterized at both visualized ends if the surgeon is sure there is adequate collateral circulation to the area. Tying off visible vessel ends using a figure-of-eight technique with an absorbable suture provides reliable hemostasis (see Fig. 146.2). Of note, bleeding, which may not be apparent at the time of the closure, may develop once the effect of epinephrine diminishes. The surgeon must ensure that the surgical field is as dry as possible prior to closure. Particular attention should be paid to apices, where visualization can be more difficult, or cut muscle that can steadily ooze.

If, at the beginning of the procedure, bleeding is more than usual, undermining should be minimized, and a linear closure should be

TRANSMISSION OF VIRAL INFECTIONS VIA NEEDLESTICK INJURIES

Viral infection		Transmission risk	Postexposure prophylaxis (PEP)	Comments	Follow-up laboratory evaluation
Human immunodeficiency virus (HIV)		0.3%	• 3 (or more) antiretroviral drugs* • Preferably begun within hours of exposure • Four-week course, if tolerated • Discontinued if source patient determined to be HIV-negative	• HIV testing: rapid test for HIV Ab or p24 Ag/HIV Ab test • Expert consultation, especially if source patient has resistant disease, exposed person is pregnant or breastfeeding • Counseling, including prevention of secondary transmission, drug toxicities	HIV testing: • baseline, 6 weeks, 12 weeks, and 6 months postexposure unless 4th-generation p24 Ag/HIV Ab test utilized, then baseline, 6 weeks, and 4 months (see Fig. 78.3) • at any time if acute retroviral syndrome suspected
Hepatitis B virus (HB, Hep B)	Source patient: HBsAg + HBeAg –	1%–6%	• *If unvaccinated, incomplete series*†, *or known vaccine non-responder*, HBIG ×1 and first dose of Hep B vaccine series, both within 24 hours • *If known responder to Hep B vaccine*‡, no treatment	• If antibody response of exposed person unknown, test for anti-HBs Ab • Similar protocol if exposed person pregnant or breastfeeding • Refrain from donating blood, plasma, organs, tissue, or semen	Anti-HBs Ab titer 2 months after completing vaccine series (4 months if received HBIG)
	Source patient: HBsAg + HBeAg +	~20%–30%			
Hepatitis C virus (Hep C, HCV)		1.8%	Not recommended	• Risk may be limited to hollow-bore needlesticks • Test source patient for anti-HCV Ab¶	Anti-HCV Ab titer¶ and serum ALT level: • baseline and 4–6 months HCV RNA levels: 4–6 weeks

*Currently recommended 3-drug regimen (2016): raltegravir 400 mg po twice daily (or dolutegravir 50 mg daily) plus Truvada®, 1 tablet po once daily (contains tenofovir 300 mg and emtricitabine 200 mg).
†Complete series = 3 doses.
‡Serum HBs Ab ≥ 10 mIU/ml.
¶Confirm positive ELISA results with supplemental test, e.g. recombinant immunoblot assay.

HEMOSTATIC AGENTS			
Generic name	**Trade name®,™**	**Advantages**	**Disadvantages**
Bone wax	Bone wax	Effectively controls bony surface bleeding (skull)	Impedes bacterial clearance; nidus for infection
Gelatin foams, gelatin sponges	Gelfoam, Gelfilm, Surgifoam	Non-antigenic; absorbed within 4–6 weeks; controls small vessel and bony bleeding	Significant swelling occurs
Oxidized cellulose	Surgicel	Low pH has antimicrobial effect; dissolves in 2–6 weeks	May cause foreign body reaction; may not combine with thrombin
Microfibrillar collagen	Avitene, Helistat, Instat, Collastat	Swelling not significant; absorbed in <8 weeks	Less effective in thrombocytopenic patients
Thrombin	Thrombin-JMI, Evithrom, Recothrom	Fast; controls minor capillary and small venule bleeding	Do not use in individuals who react to human blood products
Thrombin with gelatin	Surgiflo, Floseal	Controls moderate arterial bleeding	Can swell up to 20%; needs contact with blood which serves as fibrinogen source
Fibrin sealants	Tisseel, Evicel, Vistaseal	Controls venous oozing from raw surfaces	Can be denatured by antiseptics containing alcohol, iodine, or heavy metal ions
Ferric subsulfate (20% solution)	Monsel's solution	Inexpensive; low pH resists bacterial contamination	Can cause tattoo/discoloration; for superficial oozing
Silver nitrate (applicator sticks)		Easily stored; some bacteriostatic properties	Tattoo risk; for superficial oozing
Aluminum chloride (20%–40% solution)	Drysol (20%)	Inexpensive	Some formulations flammable; may delay wound healing; for superficial oozing
Powders composed of hydrophilic polymers with potassium salts	QR powder	Fast, inexpensive	Can only be used on wounds healing by second intention
Powders composed of microporous polysaccharide hemospheres	Arista AH	Absorbed by body so can be used on wounds that will be closed	

Table 151.5 Hemostatic agents.

considered over a flap or graft. Blood easily accumulates unnoticed in non-visualized "dead space". Drain placement should be considered for larger flaps or complex multilayered linear closures to avoid hematoma formation. Drains can be open or closed systems. An open system, such as a Penrose drain, lacks an enclosed network or collecting system. It is a passive drain that allows fluids to flow by gravity into gauze. For dermatologic surgery, a fenestrated small Penrose drain can often suffice (Fig. 151.4). It should be removed after 24–48 hours, once the chance for hematoma formation has diminished. Closed systems, such as the Mini-Flap wound suction drain and the Jackson–Pratt drain, are sealed,

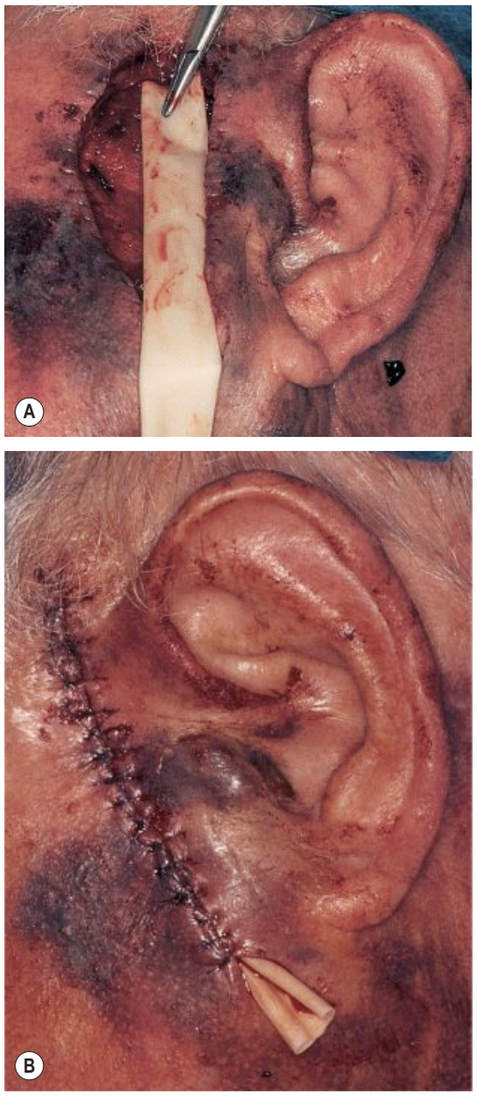

Fig. 151.4 Placement of Penrose drain because of excessive bleeding. *Courtesy Thomas Stasko, MD.*

Fig. 151.5 Postoperative appearance of wound closed under tension with resulting necrosis. *Courtesy Thomas Stasko, MD.*

with a draining tube connected to a container. Active suction draws the fluid from the tissue cavity into the container. In open wounds that bleed despite adequate attempts at hemostasis, hemostatic agents such as gelatin foams (Gelfoam®), oxidized cellulose (Oxycel®, Surgicel®), microfibrillar collagen (Avitene™, Collastat®), or topical thrombin can be applied to the wound. These agents provide a matrix to speed coagulation (see Table 151.5)[49,50]. Caution should be exercised when using oxidized cellulose because excessive amounts can result in foreign body reactions[51].

Tissue injury

Some tissue injury is unavoidable during invasive procedures. Gentle handling of the wound edges minimizes trauma and allows the viable tissue to heal more rapidly. Skin hooks or single-toothed forceps should be used to grasp tissue without crushing it. Indiscriminate and excessive electrocoagulation should be avoided. Large areas of charred and necrotic tissue within the wound increase the risk of poor healing and infection[52].

Tension

Excessive tension at the closure site can lead to tissue necrosis and dehiscence (see Fig. 151.1). Postoperatively, tension can cause increased discomfort for the patient once the local anesthesia has dissipated. Surgeons tend to tighten surface sutures when wounds gape open, but such action can result in "train track" scars. Closures should be planned to minimize wound tension. Buried absorbable sutures should bear the tension, minimizing the need for tight surface sutures. Adequate undermining and appropriate orientation of the closure will help achieve maximal tissue movement. Instead of a linear closure, a flap or graft can minimize tension in appropriate circumstances. Relaxing incisions can also be performed 2–3 cm from the wound edge, parallel to the incision site, to share tension over a larger area. If the defect cannot be completely closed due to excessive tension, partial closure can be performed, and the remainder of the wound allowed to heal secondarily. If the site is chosen well (usually in concave areas), this method yields excellent cosmetic results. Intraoperative or preoperative tissue expansion may also allow for the safe closure of large defects[44]. If a wound appears too tight at the time of closure, it probably is.

Necrosis

Necrosis is usually the result of a hematoma, an infection, or wound tension compromising blood flow to the skin edge (see Fig. 151.1). Although pale tissue at a flap or wound edge may be a warning of compromised perfusion, actual necrosis will not become evident until the postoperative period (Fig. 151.5). The factors leading to necrosis, however, begin preoperatively. The hazards of smoking have been discussed previously, but they cannot be overemphasized. Smoking decreases perfusion and increases the risk of necrosis. Patients should be counseled repeatedly to stop, or at least decrease, their exposure to tobacco and nicotine-containing products (e.g. e-cigarettes).

The blood supply to the skin arises primarily from the subdermal plexus. Extensive superficial undermining may damage this plexus and the segmental arteries supplying it. Hematoma formation and even normal postoperative edema can compromise blood flow via pressure on this plexus. Sutures tied too tightly may also decrease perfusion. The use of a loop stitch, leaving space between the first and second loops of the surgeon's knot, allows for tissue expansion from postsurgical edema, decreasing the risk of tissue necrosis.

Surgical dogma long held that epinephrine was contraindicated in digits and other areas of limited collateral circulation. However, several reviews and one large series of 3110 consecutive patients have demonstrated that injecting anesthesia with epinephrine into digital skin is safe[45–47,53]. It would be reasonable, though not requisite, to use a more dilute epinephrine concentration in these areas (e.g. 1:500 000 instead of 1:100 000). Caution should still be exercised in patients with Raynaud phenomenon or other peripheral vascular disease.

Flap tips can become necrotic because of an inadequate blood supply. Exceeding the 3:1 length-to-base ratio decreases circulation to the distal tip. When correcting redundancies caused by rotation at the flap base, the surgeon must ensure that the pedicle is not narrowed excessively. Correction of the redundancy can be delayed to protect the vascular supply.

Grafts may become necrotic if an adequate blood supply from the wound bed is not established. In general, full-thickness skin grafts require more nutrients than split-thickness grafts (see Ch. 148). Areas with a poor or absent vascular supply, such as exposed bone, exposed cartilage, or sites of previous therapeutic radiation, often cannot support full-thickness grafts and may not fully support even split-thickness grafts. In particular, sites with greater than 1 cm^2 of exposed

bone or cartilage have a greater incidence of graft failure. Delaying graft placement for about 10 days may improve graft take.

The graft must also be well-apposed to the wound bed. Strict hemostasis is required to prevent blood from accumulating in the space between the graft and the wound. However, excessive electrocoagulation should be avoided because of the resultant necrotic debris. Absorbable hemostatic agents may also interfere with engrafting. The placement of basting sutures and tie-down bolsters increases contact between the graft and the wound bed (see Ch. 148).

Nerve deficits

The preoperative evaluation should include a quick survey of neurologic function in the areas potentially affected by the proposed procedure (e.g. lifting eyebrows, tightly closing eyelids, smiling). During surgery, sensory and motor nerves may be injured or cut (see Ch. 142). It is essential to document – and, more importantly, make the patient aware of – pre-existing deficits before infiltrating the anesthetic (see Ch. 143). Local anesthesia or nerve blocks can cause temporary deficits lasting 6–12 hours. However, full evaluation of nerve injuries may not be possible until several weeks after surgery.

Skin surgery will result in the transection of cutaneous nerves. Patients frequently note temporary *sensory* deficits at the site of primary closures or flaps and almost all will experience hypoesthesia in skin grafts. Most areas have diverse sensory innervation, and unless a major nerve is injured, there are very few significant permanent deficits. Sensory nerves often do regenerate, but this may take months to occur. The patient should be aware preoperatively that there may be paresthesias in the area as it heals. Occasionally, normal sensation never returns. Areas most prone to noticeable sensory defects are the digits, the forehead, and the scalp.

Injury to *motor* nerves can be more alarming, since this can result in paralysis of the denervated muscles. The closer the injury to the nerve root, the more severe the consequence. Thankfully, most of the larger branches of the facial nerve are deep to the muscle fascia and well protected. As a result, injuries to the main trunk of the facial nerve (or its zygomatic and buccal branches) rarely occur in dermatologic surgery.

The area of highest consequence on the cheek lies lateral to a line drawn from the lateral canthus of the eye to the angle of the mouth and medial to where the nerve divides into five major branches near the surface of the parotid gland (Fig. 151.6). Medial to this area, innervation is usually diverse enough to render the results of transection of a single nerve mild. Lateral to this area, the main trunk lies deep within the parotid gland and is relatively well protected[54]. Unless the procedure is a deep excision of an infiltrative skin cancer, the majority of cutaneous surgeons are unlikely to cause significant motor nerve injury except in the following important danger zones:

- The *temporal branch of the facial nerve* courses very superficially as it crosses the zygomatic arch and traverses the temple. Here it is covered only by the superficial temporalis fascia, with very little subcutaneous fat. The nerve lies deep to the superficial temporal artery. Paralysis of the frontalis muscle, manifesting as an inability to elevate the forehead, results from transection of the nerve in this location (Fig. 151.7A). This loss is often of only cosmetic concern; however, if there is pre-existing brow ptosis, the paralysis may result in a severe ptosis that interferes with vision and requires surgical correction with a browpexy.
- The *zygomatic branch of the facial nerve*. Damage to this nerve, although less common than damage to the temporal branch, impairs the function of the orbicularis oculi muscles. This can lead to an inability to completely appose the upper and lower eyelids and subsequent corneal desiccation.
- The *mandibular branch of the facial nerve* is subject to injury as it crosses the mandible, near the facial artery and vein. It is covered at this point only by skin and thin, variably present, platysma muscle. This nerve innervates the lip depressors, and injury can cause asymmetry visible when the patient smiles or grimaces. In addition, mouth function may be compromised, resulting in drooling.
- The *spinal accessory nerve* can be damaged as it exits from behind the sternocleidomastoid muscle at Erb's point in the posterior triangle of the neck. Damage paralyzes the trapezius muscle leading to winging of the scapula and difficulty abducting the arm. Pain frequently accompanies injury to the spinal accessory nerve.

The surgeon must be aware of these danger zones (see Fig. 151.6). Injury is sometimes unavoidable, especially if a neoplasm involves the nerve. Early consultation, even preoperatively, with the appropriate specialties (neurology, neurosurgery, radiation oncology) may allow for optimal management of the problems. Regeneration of motor nerves is possible but unpredictable. When major motor branches are cut, surgical reapproximation or nerve grafts may be necessary. Muscle stimulation may prevent atrophy while awaiting return of function. At times it may be practical to simply address the functional problems created, such as placing gold weights to allow eye closure (Fig. 151.7B).

Unsatisfactory scarring

Although scars do not acquire their final appearance until many months following surgery, operative techniques can greatly affect the appearance. Though scar spreading may be unavoidable in certain anatomic areas (e.g. upper trunk, shoulders), use of longer-lasting absorbable or non-absorbable sutures in the deeper layers of the closure can reduce the risk[55].

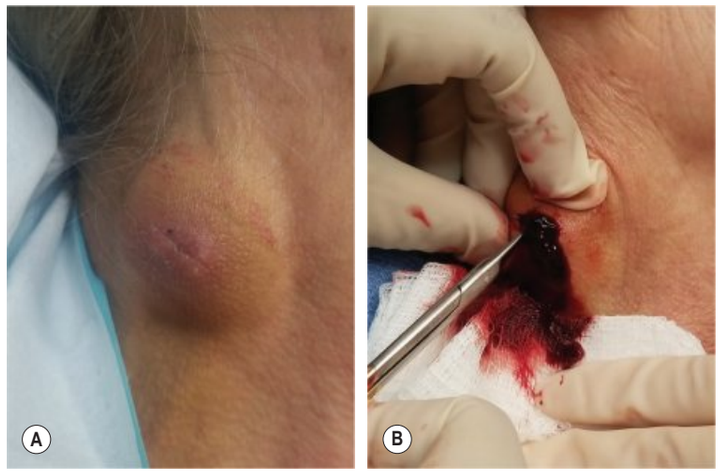

Fig. 151.9 Hematoma. A Postoperative hematoma formation. **B** Evacuation of gelatin-like clot.

A trapdoor or pincushion-like appearance may develop in transposition flaps (Fig. 151.8). Wide undermining at the time of repair, squaring off the corners, and basting sutures may reduce the incidence of this complication[56]. Removing excess subcutaneous tissue underneath the flap and trimming the flap to minimize redundancy may also help.

Postoperative Considerations

Before the patient leaves the office, detailed wound care instructions should be reviewed with the patient and caregiver(s). The surgeon must provide easily understood, written postoperative wound care instructions that include answers to the most commonly asked questions – for example, "How do I know if it is infected?", "How much bleeding is too much bleeding?", "When can I take a shower/bath?", "When can I play golf/tennis?". The patient should also have a direct method of contacting the physician or a suitable representative 24 hours a day if questions or concerns arise. A little foresight and education can greatly reduce the number of midnight calls and allow rapid identification and correction of complications. It is imperative that the contact physician be available and responsive. It is helpful for the physician or designee to call every patient postoperatively to check in and answer questions.

Bleeding/hematoma/ecchymosis

Some cases of postoperative bleeding will occur despite exhaustive preoperative evaluation, preparation, and careful intraoperative hemostasis. Most bleeding occurs within the first 24 hours, with the majority occurring within 6 hours. During this period, clots are fragile, and movement can easily dislodge them. As epinephrine from the local anesthetic dissipates, small vessel bleeding may increase. A pressure dressing applied immediately after the procedure helps prevent this problem. The patient should be instructed to leave the dressing in place for at least 24 hours. If the surgical procedure was more involved than a superficial shave or punch biopsy, the dressing should consist of multiple layers: petrolatum, then a non-adherent contact layer (e.g. Telfa™, CURAD® Non-Stick Pads), followed by a bulky absorbent layer (e.g. gauze, cotton, sponges, eye pads). An outer layer of tape or stretchable wrap (e.g. Ace Wrap®, Coban®) then covers all of these. The bandage should provide pressure but not cause ischemia.

A small amount of bleeding is normal; however, bleeding which soaks the dressing needs attention. The patient should be instructed to remove the old dressing, as saturated dressings no longer provide meaningful pressure, and apply firm pressure without release for 15–20 minutes as timed *by the clock*. If pressure stops the bleeding, then the dressing should be reinforced with additional gauze and tape. If bleeding persists at a reduced level, pressure should be reapplied for an additional 15–20 minutes. If bleeding persists, then the patient needs to be evaluated by the surgeon.

The surgeon can once again attempt direct pressure. If this fails, the wound should be exposed and the area re-anesthetized and explored. If a single bleeding vessel is identified, it can be electrocoagulated or ligated. Frequently, a single source is not identified. Bleeding can occur in multiple areas and each must be addressed. A drain may be helpful if a very dry surgical field cannot be achieved. If possible, surgical procedures should be scheduled early in the day to prevent late-night bleeding events.

If blood collects in the dead space of a wound, a hematoma forms. Hematomas can lead to dehiscence or necrosis due to pressure, and they may act as a nidus for infection (see Fig. 151.1). Hematomas consist of gelatin-like clots that are usually too firm to evacuate without removing sutures. The presenting symptom may be an acute, throbbing pain (large hematomas) or a pressure sensation (smaller hematomas). Early, expanding hematomas should be evacuated after re-anesthetizing the site. After evacuation (Fig. 151.9), the area should be irrigated, and any residual bleeding controlled. The wound may be re-closed, with particular attention to closing any dead space. Placing a drain is often appropriate. Many surgeons advocate empiric antibiotics after hematoma evacuation, because of an increased risk of infection.

If the hematoma goes unnoticed and untreated for several days, the clot becomes organized (Fig. 151.10A). It is then thick, fibrous, and adherent to the surrounding tissue. If large or actively expanding, it should still be evacuated (Fig. 151.10B). In most circumstances, the resulting wound should be allowed to heal by second intention with possible delayed closure or scar revision (Fig. 151.10C).

Small, organized hematomas can be allowed to resorb without evacuation. If, around 1–2 weeks later, there is significant liquefaction leading to a fluctuant mass, the fluid can be aspirated with a large bore (16- to 18-gauge) needle. Warm compresses applied for 30- to 60-minute intervals several times daily speed resolution.

Bromelain (bromelin), found in the pineapple plant, has long been used as a medicinal. One placebo-controlled study found that oral bromelain decreased the time required for resorption of surgery-associated hematoma. The recommended dose was 500 mg immediately postoperatively and then three to four times a day on an empty stomach until the hematoma resolved. Patients not allergic to pineapple reported no side effects[15].

Ecchymoses occur when there is leakage of a small amount of blood into the interstitial space. Significant bruising is common following surgical procedures involving areas with loose distensible tissue, such as the periorbital area, the neck, or the upper chest in the elderly. It can be alarming to the patient who is not counseled to expect this possibility. The involved area changes color from deep purple, black and blue, to green, and then to yellow as the hemoglobin is degraded to bilirubin. The ecchymosis can extend widely, usually migrating to dependent areas. The concern is mainly cosmetic as ecchymoses are temporary with most resolving without sequelae.

Infection

Although most cases of infection begin at the time of surgery, postoperative contamination is possible without good wound care. Blood-soaked dressings are breeding grounds for bacteria. Patients and caregivers

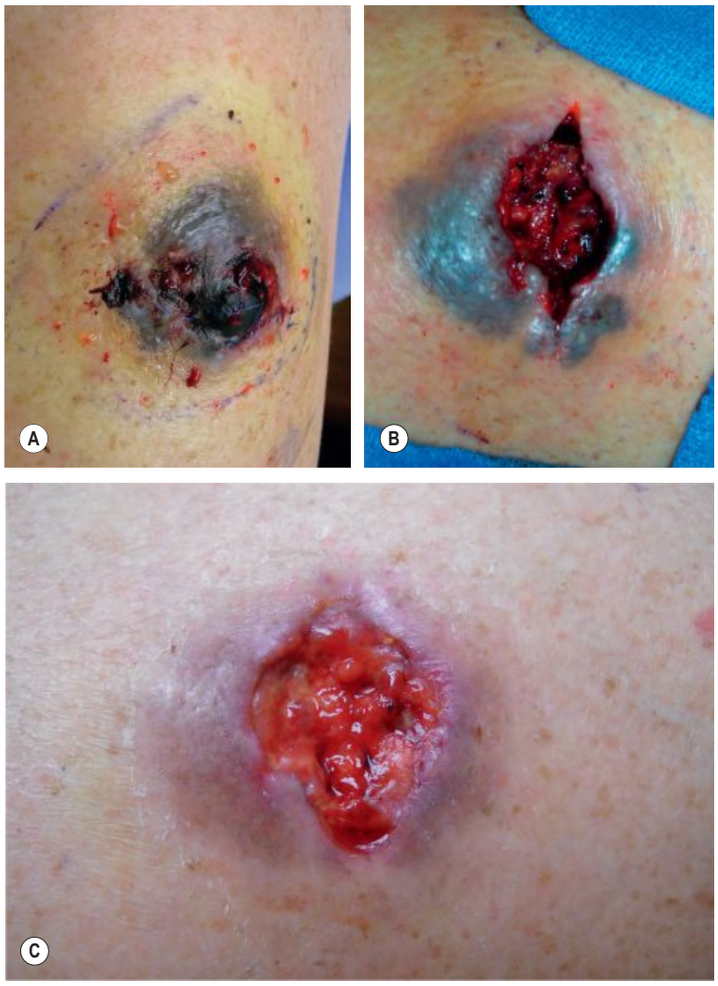

Fig. 151.10 Evacuation of an organized hematoma. Prior to (**A**) and immediately after (**B**) evacuation of the clot. **C** After 2 weeks of healing by second intention.

should be instructed to wash their hands carefully prior to changing any dressings or cleaning the wound site. Excessive exposure or manipulation of the wound site during the first 24–48 hours after the procedure should be avoided.

Infection usually does not become evident until 4–8 days after surgery. The patient may note increasing erythema (Fig. 151.11) and worsening pain and tenderness. Ascending red streaks (lymphangitis), swelling, and a purulent discharge may develop. Systemic symptoms of fever and chills indicate spread of the infection.

The area should be treated with rest, elevation, and heat. If the infection appears significant, sutures should be removed, and the defect left open. Abscesses should be drained, and the discharge sent for culture, primarily bacterial and occasionally also fungal. Deep cavities should be packed lightly with iodoform gauze with the packing changed daily until drainage stops. Antibiotics should be initiated based on the most likely causative organism(s) and then adjusted according to culture results.

Staphylococcus aureus is the most frequent culprit in the skin. A first-generation cephalosporin, a β-lactamase-resistant penicillin, or a penicillin/β-lactamase inhibitor combination would be an appropriate choice (see Ch. 127). If *Pseudomonas aeruginosa* is suspected, as in postoperative chondritis of the external ear, a fluoroquinolone would be appropriate. Rapid spread, systemic symptoms, or extensive lymphangitis may require parenteral antibiotics, more aggressive wound care, and possible hospitalization.

Given the rise in the incidence of methicillin-resistant *S. aureus* (MRSA), the surgeon should be aware of the rates of MRSA in the local community. After culture of the site, if there is a high index of suspicion for MRSA infection, empiric coverage with oral doxycycline, trimethoprim–sulfamethoxazole, or clindamycin should be considered.

Fig. 151.12 Contact dermatitis to antibiotic ointment. *Courtesy Thomas Stasko, MD.*

Fig. 151.13 Inflammatory suture reaction. *Courtesy Thomas Stasko, MD.*

Penicillins and cephalosporins are considered safe during pregnancy by the American Academy of Pediatrics (formerly FDA category B). When indicated, safe second-line alternatives include erythromycin and clindamycin[57]. Tetracyclines (previous category D) are contraindicated beyond 15 weeks of gestation due to fetal risk of discoloration of teeth and inhibition of bone growth[58].

Contact dermatitis, candidiasis, or dermatophyte infections may mimic bacterial infection. Contact dermatitis due to topical antibiotics frequently presents with pruritus rather than pain and with erythema in all the areas of cream or ointment application (Fig. 151.12). Contact dermatitis from bandage adhesives will usually be strikingly limited to the area of adhesive contact. Inflammatory suture reactions can occur without infection (Fig. 151.13).

Necrosis

The earliest sign of necrosis may be pallor or cyanosis at the periphery of the flap or graft. Early intervention could include judicious suture removal or replacement to reduce tension, elevation to reduce edema and thereby improve blood flow, and gentle heat to the area to improve circulation. Treatment with hyperbaric oxygen may be considered in the face of early necrosis of a large or vital reconstruction.

Once necrosis is established, minimal cleaning and debridement should be undertaken until the full extent of necrosis is clearly demarcated. Vigorous debridement may extend the process further. An eschar

eventually forms and then separates from the wound base as the latter heals by second intention (Fig. 151.14). If infection is present, it should be treated appropriately. Delayed scar revision is an option if the site does not heal with an acceptable appearance.

Dehiscence

Wound edges separate because of excessive tension, infection, or necrosis (see Fig. 151.1; Fig. 151.15). Dehiscence most often occurs at the time of suture removal. Scar tensile strength never exceeds 80% of the strength of uncut skin, and maximum tensile strength is not achieved until months after the procedure. At 2 weeks after surgery, tensile strength is less than 10% of normal (Fig. 151.16)[59]. Patients should be told specifically which activities they may or may not undertake (i.e. no lifting more than "x" pounds, no running, no jogging, no sit-ups, etc.).

If prolonged support is needed, sutures may be removed in stages. Adhesive strips provide some short-lived support for 1–2 days after suture removal. If the wound opens at suture removal because of excessive tension or too much activity (Fig. 151.17), the surgeon can consider resuturing if there is no infection, hematoma, or necrosis. If dehiscence is due to another underlying complication, such as infection or hematoma, that condition should be treated first.

Wound appearance

Postoperative wound appearance may be a source of anxiety for both patient and surgeon. Problems range from simple (e.g. a spitting subcutaneous suture) to more complex (e.g. a trapdoor deformity or spread scar). A key to dealing with most of these problems is continued and open communication. The patient who does not feel free to express concerns in the office may all too readily do so elsewhere.

Buried sutures should be absorbed uneventfully by the body within the time period specified by the manufacturer. Unfortunately, nature does not always adhere to package inserts. As digestion of the suture takes place, pustules reflecting sterile abscesses or papules due to granulomatous inflammation can appear along the suture track (Figs. 151.18 & 151.19). In addition, sutures may extrude or be "spit" from the skin intact (Fig. 151.20); while some authors believe this is more likely to occur if the sutures are placed too superficially within the dermis, even deeply placed sutures can be extruded in some patients. These events may occur anywhere from 1 to 4 months postoperatively, most commonly at about 6 weeks. The pustules can be opened with a sterile needle and the remaining suture gently removed. Sometimes, the papules are deeper. If the appearance is consistent with a suture reaction, the patient can be reassured then instructed to gently massage the site. If the suture is protruding, it can be removed. The ultimate appearance of the scar is usually unaffected by this process.

In sites with severe photodamage (e.g. the shins in women), atypical squamous proliferations can appear at the margins of completely

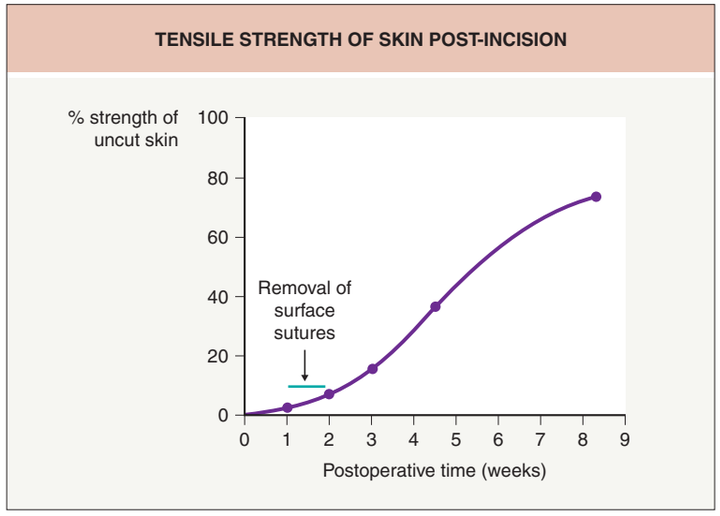

Fig. 151.16 Tensile strength of skin post-incision.

Fig. 151.23 Hypertrophic scar. One month after excisional surgery. *Courtesy Thomas Stasko, MD.*

excised skin cancers (Fig. 151.21). These lesions are likely triggered by inflammation and growth factors involved in wound repair. A biopsy can be performed, especially if the original tumor was a squamous cell carcinoma or keratoacanthoma. Treatment options include intralesional injections of triamcinolone, 5-fluorouracil, and methotrexate (see Table 108.9) or oral acitretin for more extensive involvement.

Suture tracks (railroad tracking) are caused by tight sutures left in place too long (Fig. 151.22). The best way to avoid this appearance is to minimize wound tension with proper placement of buried sutures in order to allow for early suture removal.

Some anatomic sites are more prone to the development of keloids and hypertrophic scars (Fig. 151.23), and some individuals may have a genetic predisposition to keloid development. Intervention at the early stages of a hypertrophic scar can yield a more acceptable result. High-potency topical or intralesional corticosteroids may decrease the thickness of the scar and the accompanying pain and pruritus. However, there is a risk of telangiectasias, atrophy, or widening of the scar[60]. Anecdotally, smaller hypertrophic scars may respond to simple massage, though the ideal duration and frequency have not been defined[61]. Silicone gel sheeting applied to the scars and worn for

12–24 hours per day for at least 2 months has been shown to improve the appearance of hypertrophic scars and keloids[62]. Simple occlusion and hydration may be just as effective without silicone[63]. One study using topical onion extract found that it was ineffective in improving erythema or pruritus of postsurgical scars, while petrolatum-based ointment alone did improve appearance[64].

Scar appearance can be improved by dermabrasion or ablative laser resurfacing. When performed during the 4- to 8-week interval following the initial injury, it superimposes the mechanisms of second intention wound healing on the remodeling phase of the primary scar. This appears to re-establish a normal-appearing epidermis across initial scar boundaries[65]. Lasers (e.g. carbon dioxide (CO_2) laser, 585 nm pulsed dye laser) may be used to improve the appearance of scars as well as in the treatment of hypertrophic scars and keloids (see Ch. 137)[66].

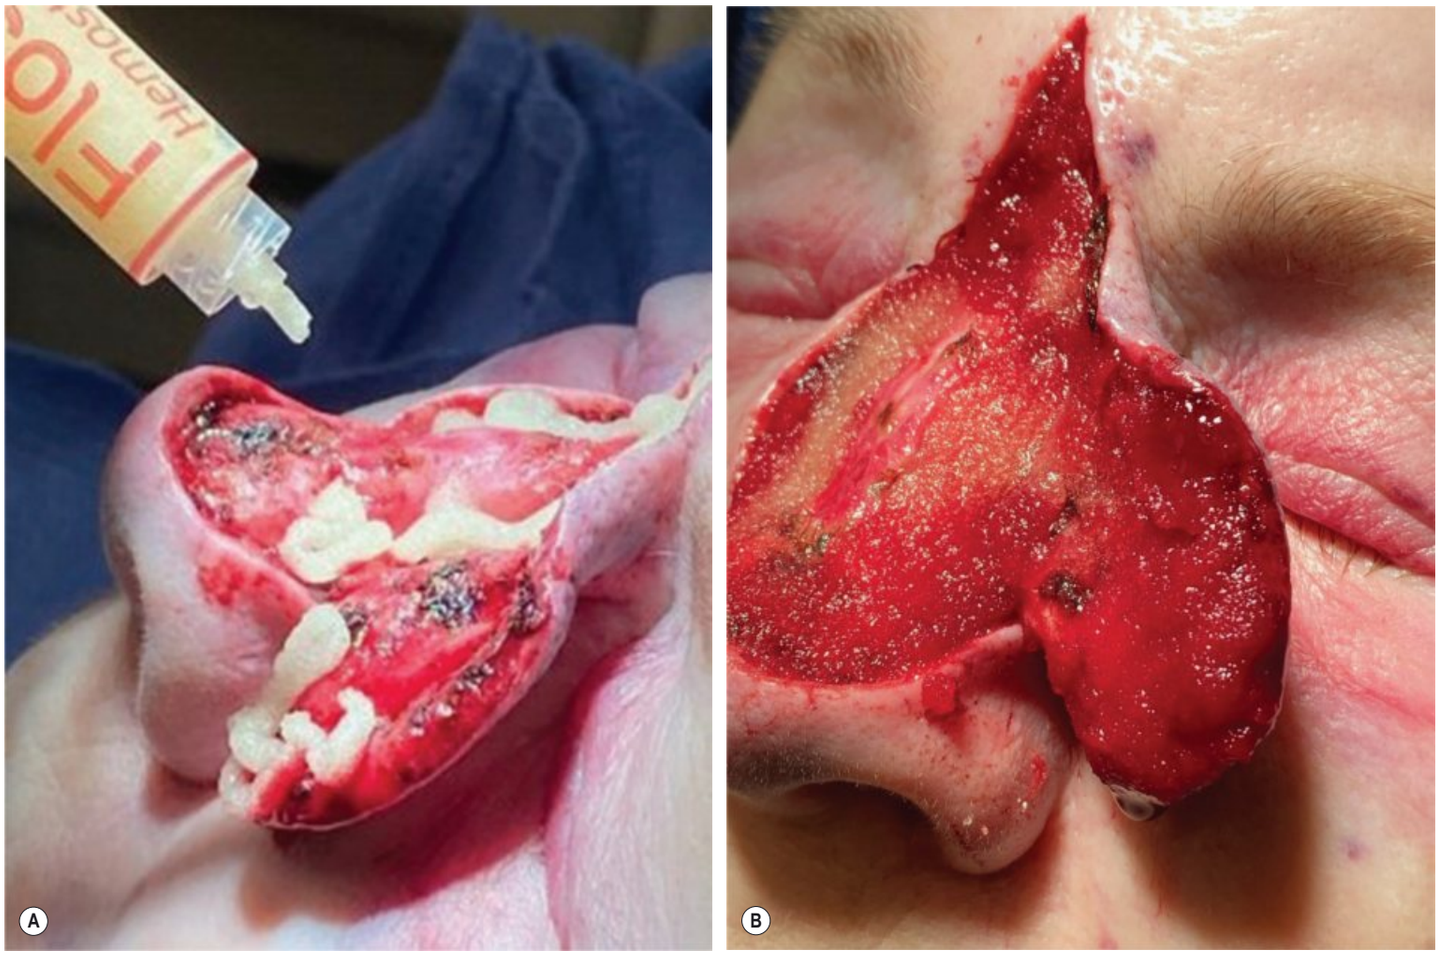
Keloids develop more frequently on the earlobes, neck, and trunk. In predisposed individuals, even superficial shave biopsies can result in keloids. Patients at risk should be counseled about this prior to the procedure. There are several treatment options for keloids and they have varying degrees of success (see Ch. 98).

Even well-approximated wound edges can produce spread scars. Scar spreading is more common on the back, chest, and shoulders, especially in younger patients. Patients who need excisions in these areas should be counseled preoperatively about the possibility that an initially thin scar may widen over time. Most widening occurs within 6 months after the surgery.

Corticosteroid injections can improve the appearance of a trapdoor deformity in the area of a flap. The patient should also be instructed to massage the area. Revision can be considered if these interventions do not produce an acceptable cosmetic result. Multiple small Z-plasties along the scar line, "defatting", and peripheral undermining can also improve the appearance[67]. However, patience often produces the best results.

Patients should be warned about the possibility of hyper- or hypopigmentation. Pigmentary variations are more pronounced in individuals with darker skin phototypes. The wound site should be strictly protected from UV exposure. Early epidermal hyperpigmentation can be improved with topical hydroquinone, though this is ineffective unless combined with UV protection.

CONCLUSIONS



Avoiding complications requires planning and careful evaluation at each stage of the procedure: preoperative, intraoperative, and postoperative. Despite the best intentions, careful planning, and the most expert hands, complications still occur. The surgeon must remember to treat the patient, not just the condition. The patient who feels abandoned may not be happy with any outcome, no matter how technically perfect.

INTRODUCTION

"It is amazing how complete is the delusion that beauty is goodness."
~Leo Tolstoy

"The only lasting beauty is the beauty of the heart." "The beauty you see in me is a reflection of you." "Beauty surrounds us."
~Rumi

"Perhaps the mission of an artist is to interpret beauty to people – the beauty within themselves."
~Langston Hughes

"In diversity, there's beauty and there's strength."
~Maya Angelou

Nancy Etcoff, in *Survival of the Prettiest: The Science of Beauty*, explains that beauty is a universal component of the human experience which promotes pleasure, rivets attention, and impels action that helps ensure survival of our genes[1].

Striving to be more beautiful is not a new phenomenon. Human preoccupation with beauty and a youthful appearance dates back as far as recorded history. Anthropologists have determined that over 40 000 years ago, red ochre paints were used in southern Africa for facial and body ornamentation[2]. In 5 BCE, the Roman author Ovid wrote *The Art of Beauty*, the first known book on beauty and cosmetics, detailing the use of black eye shadow made from wood ash and golden eye shadow made from saffron.

Few human traits are as ingrained as beauty. It is thought to be hardwired into our brains and can even be detected in infants. Studies have shown that by the age of 3 months, babies stare longer at attractive faces than those deemed to be less attractive. Also, 1-year-old toddlers will play longer with attractive dolls than with plain dolls[3]. In functional magnetic resonance imaging studies where subjects were shown photographs of attractive men and women, viewing beautiful faces activated reward circuitry within the brain and dopamine pathways[4]. Studies have shown that humans can make judgements on facial attractiveness in 100 msec, and with longer exposure times the judgment is not changed, only strengthened[5]. There is even a dedicated special area of the ventral stream of the temporal lobe of the brain that helps humans with the task of recognizing faces quickly called the fusiform face area[6]. This area is highly specialized in the task of facial recognition in all humans and is thought to have evolved to aid our ancestors in rapidly assessing the trustworthiness of other humans.

If examined from an evolutionary standpoint, this innate attraction to beauty certainly makes sense. Beauty has been interpreted in terms of reproductive potential as it provides an advantage in selecting or being selected as a mate for sexual reproduction. Attraction to beauty also makes sense from a disease perspective. It is said that "beauty is a burden that only the healthy can carry". In other words, the sickly are by nature less attractive. Those with an ideal physique and youthful proportions are much more likely to be healthy and be able to reproduce. By choosing an attractive healthy mate, one is increasing the odds that his or her genes will be passed on.

In one study, 20 subjects were asked to grade graduates from a 1920s high school yearbook on their attractiveness. When the actual lifespans of these graduates were determined, facial attractiveness correlated with increased lifespan. Correlations between beauty and health help to explain why, from an evolutionary standpoint, the notion of beauty may become an innate concept within a species[7].

Besides being considered a more ideal mate, attractiveness may also have a number of other benefits. Nancy Etcoff has stated that people tend to respond positively to good-looking people without expectation of reward, and, further, that good-looking people tend to be less penalized for everything from shoplifting to cheating at exams[1]. In the same workplace, attractive people were found to earn up to 12% higher wages as compared to co-workers who were considered average-looking[2]. Also, pharmaceutical representatives have been shown to have a 1.9% increase in sales for every unit increase in the Likert Scale for attractiveness. While the average height of a man in the US is 5′ 7″ (170.2 cm), the average height of Fortune 500 CEOs is 6′ 1″ (185.4 cm). Statistically, US Presidents have also been found to be significantly taller than their constituents. Lastly, even West Point graduates who had higher scores on an attractiveness scale rose to higher military ranks.

The advent of more accessible photography with smartphone devices and app filters has further exemplified what an important role light and shadows play in the appearance of attractiveness. Renowned makeup artist Kevyn Aucoin recognized the importance of highlights and shadows in his work. Part of aesthetic dermatology work involves restoring or optimizing highlights and shadows with procedures to achieve a more attractive appearance.

EVALUATION OF BEAUTY

Recognizing beauty and understanding its significance may be far easier than actually defining it[8]. Anthropometry represents the quantitative measurement of facial features and an assessment of resultant ratios. It is based on proportional relationships of the face that are known as the neoclassical canons, which have been studied and revised for centuries. As originally proposed by Leonardo da Vinci, the ideal face can be divided horizontally into three equal parts; these parts are composed of the distances between: (1) the frontal hairline and the inferior edge of the frontal bone; (2) the supraorbital margin and the base of the nose; and (3) the base of the nose and the inferior aspect of the chin (Fig. 152.1A)[9]. In general, mathematically idealized facial proportions translate into a symmetric, oval- or heart-shaped face, with prominent cheekbones, tapered jaw line, narrow nasal base, and thin lips. These proportions, however, are largely based on facial features in White women and ethnic variations of these "ideal" proportions should be emphasized.

Some of the other features that are consistently shown to be rated as beautiful across nationalities include symmetry and averageness. Symmetry could be considered the optimal outcome of development from a two-celled embryo, dividing perfectly every single time. The closer the ability to do so in the face of various environmental pressures, the higher the genetic quality of those cells. In fact, symmetry is positively related to growth rate, survivability, and fitness across species[10]. When

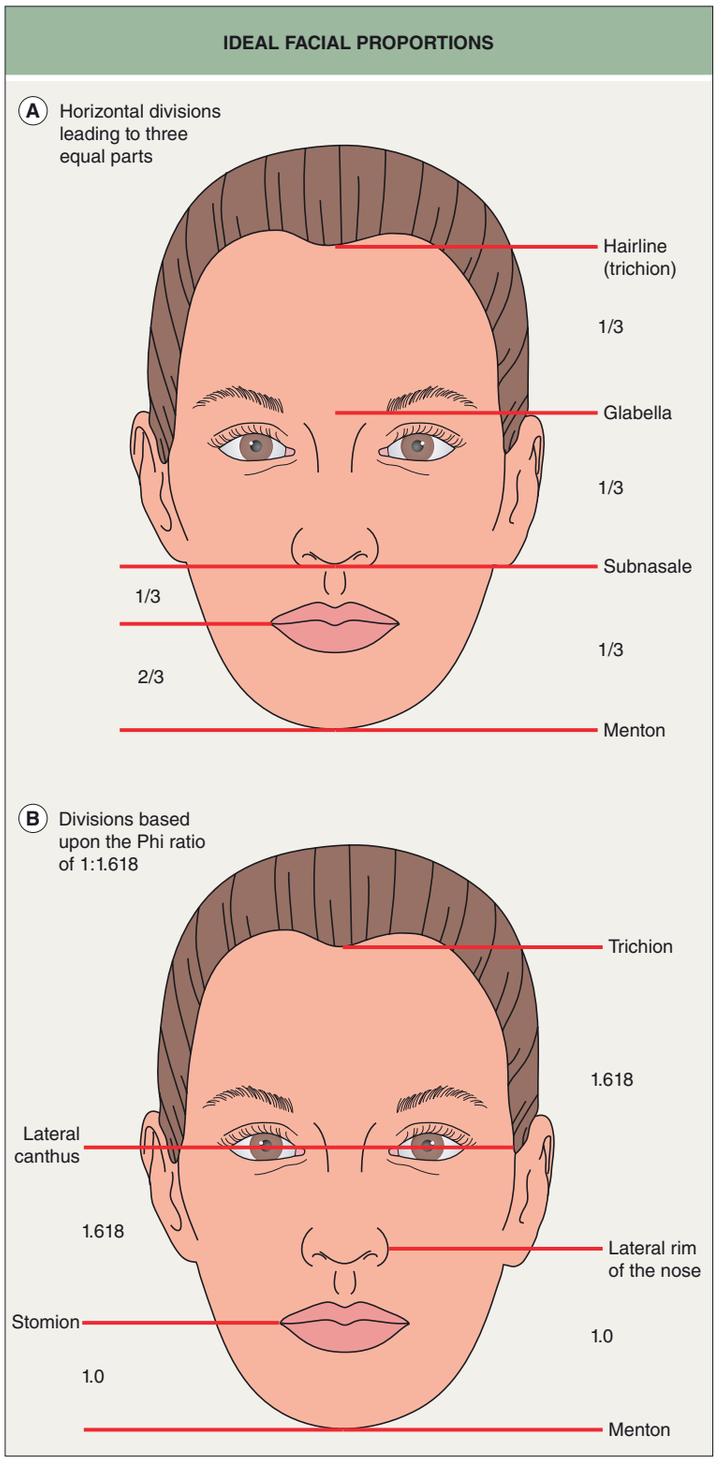

Fig. 152.1 The "ideal" face. A Horizontal divisions leading to three equal parts creates an "ideal" face. These three parts are composed of the distances between: (1) the frontal hairline and the inferior edge of the frontal bone; (2) the supraorbital margin and the base of the nose; and (3) the base of the nose and the inferior aspect of the chin. The divisions were originally proposed by Leonardo da Vinci. **B** Ideal facial proportions based upon the Phi ratio of 1 : 1.618. *Adapted from Milutinovic J, Zelic K, Nedeljkovic N. Evaluation of facial beauty using anthropometric proportions. Scientific World J 2014:2014:428250.*

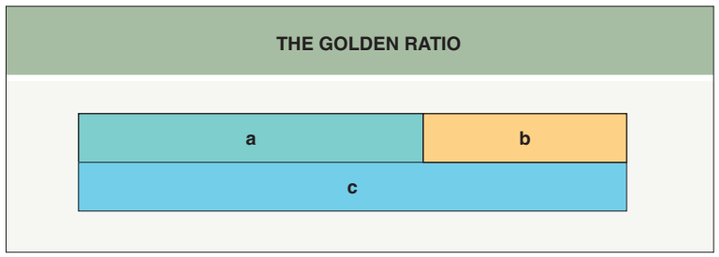

Fig. 152.2 The golden ratio based upon Phi. Phi is the unique point on a line that divides the line into two lines in such a manner that the ratio of the smaller portion (b) to the larger portion (a) is the same as the ratio of the larger portion (a) to the whole line (c). In other words, "b" is to "a" as "a" is to "c". This ratio is a repeating number that is rounded off to 1 : 1.618. A triangle composed of lines with lengths in the Phi ratio is referred to as a golden triangle.

images are manipulated to make them more or less symmetric, the more symmetric image is usually chosen as the more attractive one[11]. Averageness is also seen as being attractive and can also be viewed as being genetically more diverse and stronger. As different populations are subjected to different pathogens, they are more likely to acquire protective mutations against those pathogens. The greater the genetic mixing, the more inherited protective mutations and adaptability to the environment one is likely to have[12]. Facial averageness has been positively correlated with medical health[13]. In sum, both symmetry and averageness can be seen as being genetically healthy and therefore make sense to be markers of what is considered beautiful to a species.

A more exact mathematical method for calculating beauty across nature via mathematical proportions is the concept of "Phi", or the golden ratio. A ratio of 1 : 1.618 was described by ancient Greeks as a mathematical method for calculation of the optimal proportions for all structures in nature (Fig. 152.1B). In fact, some authorities believe that the neoclassical canons (see above) are modifications of Phi. Phi represents the unique point on a line that divides the line into two lines in such a manner that the ratio of the smaller portion to the larger portion is the same as the ratio of the larger portion to the whole line (Fig. 152.2). This ratio is a repeating number that is rounded off to 1 : 1.618. Of note, there are innumerable examples of the use of the Phi ratio in nature and art, including the Parthenon, the Great Pyramid of Giza, the sculpture Venus de Milo, the length of each section of our finger, the shell of a nautilus, pinecones, and the petals of a sunflower.

A triangle composed of lines with lengths in the Phi ratio is referred to as a golden triangle. When expanded, one can even create golden pentagons and golden decagons. Stephen Marquardt trademarked the "Phi mask", a facial mask composed of proportions that incorporate the 1 : 1.618 ratio, to describe the mathematically ideal attractive face. Although the Phi mask has been applied to persons of all races and ethnicities, Marquardt recognized that ethnic variations exist and has incorporated modifications for three different ethnic groups – White, Asian, and African. However, pitfalls against using the mask to denote attractiveness among all ethnic groups, particularly in sub-Saharan Africans, East Asians, and White women, has been described[14].

A novel model to describe or measure attractiveness has been described by Steven Dayan. It can be employed when description of natural beauty, both at baseline and after a cosmetic procedure, is desired. In this model, "attractiveness consists of a 3-dimensional area defined by beauty, genuineness, and self-esteem. When all three variables are at a maximum, a desirable attractive appearance is achieved that can be interpreted as 'natural'. Similar to the time-space dilemma, attractiveness is relative, dynamic, and highly dependent on the position of the projector and the interpreter. The 3D cube of attractiveness is therefore contained within a 4th dimension that takes into account the perspective of the judger"[15]. Similarly, Dayan et al.[16] also demonstrated in a pilot observational study that visually blind individuals can detect beauty, supporting the idea that beauty may rely on primal forms of messaging that are subconsciously appreciated.

As there is no single ideal of beauty, ethnic variations should be celebrated and recognized such that not every person is treated with aesthetic procedures to look the same and potentially look "pretty" but lose their unique beauty. For example, when a surgeon has perfected a rhinoplasty of one size and shape, e.g. a thin upsloped nose, it may look attractive in a White woman and others with similar features, but look unattractive in those without those features, especially in individuals from other ethnic groups.

It should be noted that sometimes features that are unique and do not conform to the neoclassical canons or golden ratio, including prominent brows, eyes, nose shape or lips, as well as confidence, persona, hair, the way the body is decorated with clothing or adorned with body art, health, and the beauty that exudes from within, can uniquely make people look more attractive.

Fig. 152.3 Rhytides of the aging face. Rhytides form as a result of UV radiation-induced damage, loss of skin elasticity, repetitive movement of underlying facial musculature, changes in volume from fat redistribution, and bone as well as cartilage resorption.

ANATOMIC BASIS FOR THE AGING APPEARANCE

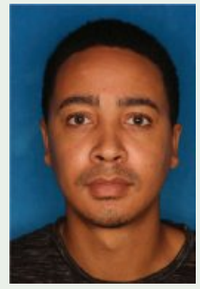
Knowledge of facial anatomy and anatomic changes that occur with aging is essential for properly evaluating and treating the aesthetic patient. With aging, both the golden ratio (Phi) and the neoclassical canons start to shift. The upper one-third of the face *elongates* due to recession of the frontal hairline and brow ptosis, while proportionately the middle third remains relatively stable (but may elongate with nasal tip ptosis). However, midface volume loss can occur as a result of fat redistribution and skeletal changes. The lower third of the face becomes *shortened* with perioral fat redistribution and significant resorption of the bony mandible, which may also lead to shifts in dentition, further affecting aesthetics of the lower face and smile.

The appearance of the aging face is multifactorial and does not appear to simply be a matter of sagging from the effect of years of gravitational forces pulling the face downwards. Rather, a complex ongoing alteration in proportions occurs as one ages. Notably, studies by Rohrich and Pessa[17] have shown that there is not one large confluent layer of subcutaneous fat in the face but rather multiple distinct compartments that act independently from one another (see below, Volume changes). For example, the malar fat pad in the mid cheek is composed of three separate compartments; as these compartments change in size, the ligaments separating the compartments become more evident and a smooth, rounded, youthful appearance transforms into the multicontoured aged face.

After examining numerous photographs of patients as they aged, Lambros[18] concluded that there is actually very little positional change in the midface region. Despite the common perception that the face drops inferiorly with age, he noted that the eyelid–cheek margin did not change with advancing years, nor did facial nevi of the midface descend with age. Just as individual water molecules simply move up and down rather than actually traveling with waves at sea, the wave of downward motion "seen" in an aging face may simply represent shifts in subcutaneous tissue.

Rhytides also play a key role in producing an aged appearance. The underlying causes of rhytides are multiple and include ultraviolet radiation-induced damage, loss of skin elasticity, repetitive movement of underlying facial musculature, changes in volume from fat redistribution, and bone as well as cartilage resorption (Fig. 152.3).

PHOTOAGING



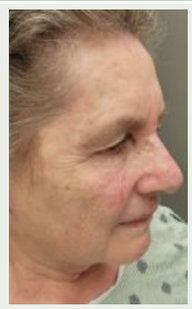
Cumulative exposure to sunlight and environmental pollution/toxins is a major factor in aging skin. Clinical signs of cutaneous photoaging include: rhytides, lentigines, keratoses, telangiectasias, loss of translucency, loss of elasticity, and a sallow color[19,20]. The Fitzpatrick Scale of Skin Phototypes (see Table 0.6) serves as a good indicator of the potential for developing signs of photoaging.

A simple systematic classification of patient photoaging types (types I through IV) was developed by Dr Richard Glogau (Table 152.1)[21]. However, the generalizations outlined in this table are influenced by the amount of cumulative sun exposure and usually apply at a later age and to a lesser degree in those with more darkly pigmented skin. Type I refers to younger patients with no rhytides, even when the face is animated by talking or expression. Type II refers to patients with "wrinkles in motion", who demonstrate the influence the underlying musculature has on the skin.

GLOGAU PHOTOAGING CLASSIFICATION – WRINKLE SCALE

Type I – "No wrinkles"

- Early photoaging
  - Skin uniform in color to mild pigmentary changes
  - No keratoses
- Wrinkles
  - No wrinkles, even at the corners of the eyes and mouth
- Patient age (yrs) – 20s or 30s
- Minimal or no makeup



Type II – "Wrinkles in motion"

- Early to moderate photoaging
  - Early solar lentigines visible
  - Keratoses palpable but not visible
- Wrinkles
  - *When the face is at rest*, the patient appears similar to type I
  - *When the face is animated by expression*, parallel lines appear – first at the corners of the mouth, then parallel to the melolabial folds, then at the corners of the eyes, and finally over the malar cheeks
- Patient age (yrs) – late 30s or 40s
- Usually wears some foundation

Type III – "Wrinkles at rest"

- Advanced photoaging
  - Obvious dyschromia, telangiectasias
  - Visible keratoses
- Wrinkles
  - Present even when not moving facial muscles
- Patient age (yrs) – 50s or older
- Wears heavy foundation

Type IV – "Only wrinkles"

- Severe photoaging
  - Yellow–gray color of skin
  - Prior skin malignancies
- Wrinkles
  - Wrinkled throughout with no normal skin
  - Total replacement of normal skin with minute, rhomboid and geometric rhytides may be most obvious in the perioral skin
- Patient age (yrs) – 60s to 70s
- Can't wear makeup – "cakes and cracks"

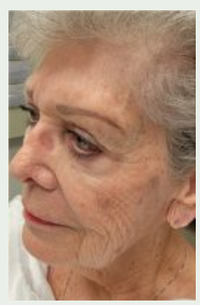


Table 152.1 Glogau photoaging classification – wrinkle scale. Changes appear at a later age and to a lesser degree in those with more darkly pigmented skin. yrs, years. *Adapted from Glogau RG. Chemical peeling and aging skin. J Geriatr Dermatol 1994;2:30–5.*

As the photoaging process advances, there is greater damage to collagen and elastic fibers. Of note, collagen production is maintained by dynamic mechanical tension placed on fibroblasts by intact collagen fibers. With age and particularly sun-related damage, type I collagen (most prevalent form with a half-life of 15 years) becomes more and more fragmented. As more collagen becomes fragmented, there is less stretching tension placed on fibroblasts and they respond by making more metalloproteases and less collagen. This creates a vicious cycle of increasing collagen loss and subsequent thinning of the skin[22]. Eventually, with substantial breakdown of collagen and elastic fibers, the wrinkles produced by dynamic movement of the face persist, even when the face is at rest.

Generally, by the sixth or later decade of life, there are visible parallel lines lateral to the eyes ("crow's feet"), at the corners of the mouth, and radiating down from the lower eyelids onto the malar cheeks, as well as around the upper and lower lips. These patients appear lined, even when their face is at rest, and are classified as type III, "wrinkles at rest". The repetitive effect of underlying muscular expression is now permanently "ingrained" into the skin, i.e. lines are readily visible even without active muscular contraction.

With continued photoaging, the wrinkles gradually spread to cover the majority of the facial skin, while the dermis becomes totally engorged with accumulations of poorly staining ground substance, giving a thickened, coarse quality to the skin. This is classified as photoaging type IV, "only wrinkles".

PIGMENTARY SYSTEM

The Fitzpatrick skin phototype classification scheme is based upon the skin's response to UV light (Table 0.6)[23]. The patient's skin phototype also serves as a good indicator of the potential for developing dyschromia following epidermal/papillary dermal injury.

VOLUME CHANGES – THE LOSS OF SUBCUTANEOUS FAT

A major component of aesthetic disharmony in the aging face is the loss or redistribution of subcutaneous fat. Detailed studies by Rohrich and Pessa[17], utilizing cadaver dissections and staining techniques, have demonstrated that facial fat (unlike fat elsewhere in the body) is partitioned into discrete compartments which may age independently of one another (Fig. 152.4). Redistribution and loss of these fat pads contribute to formation of the nasojugal fold, malar crease, nasolabial fold, pre-jowl sulcus, and marionette lines as well as wasting of the temples, superior brow, and buccal fat (Fig. 152.5).

While in some areas (e.g. the submental region and buccal fat pad), unwanted subcutaneous fat may lend itself to removal via liposuction, cryolipolysis, or deoxycholic acid injection, in general, there is now a new appreciation that removal of fat should be done with caution due to the flattening or hollowing of contours that could result and possibly lead to a more aged appearance. Due to a loss of subcutaneous fat, the older face has a flattened quality to the cheekbones, a sunken appearance to the lips, a bulging of the inferior fat pads of the eye, and, in general, a loss of the fullness and roundness of youth. Experienced aesthetic surgeons have recognized this and are moving away from excessive fat removal to a combination of fat repositioning and restoration, along with SMAS (superficial musculoaponeurotic system) repositioning, restoration of bony loss with implants or injectable fillers, and skin resurfacing or optimization. Dr Steven Hoefflin has written: "In the aging face it is not the tightness of the SMAS or skin that makes the difference, but the quantity and position of subcutaneous fat"[24].

As an example, the routine removal of the infraorbital fat as a part of blepharoplasty, which often accentuated the deep grooves between the lower eyelid and the cheek, has become outdated. Now surgeons prefer to utilize an arcus marginalis release and mobilize the fat medially and anteriorly to fill in the groove and return a more youthful appearance to the lower eyelids through restoration of lower lid convexity. Similarly, repositioning of the premalar fat has become an important part of routine face-lifting, reversing the aged appearance that comes from flattening of the cheekbone contours.

In the 1950s, Dr Ulrich Hinderer, a plastic surgeon, devised facial lines that aided in the optimal placement of cheek implants. In addition to cheek implants, Hinderer's lines can be used to guide the optimal placement of soft tissue fillers and fat transfers in order to create midface volume restoration or enhancement. These lines are drawn: (1) from the lateral canthus to the lateral commissure; and (2) from the mid tragus to the mid nasal ala (Fig. 152.6). These lines demarcate three different regions of the midface: the zygomaticomalar, the anteromedial, and the submalar. The region immediately above where the lines intersect in the zygomaticomalar region is the area of maximal light reflection and is where the apex of the cheek should be, particularly in women.

An optimal S-curve, which is seen in young rather than older individuals, can be achieved via injection of soft tissue fillers into the midface[25]. Improvement in patients' feelings of facial attractiveness has been observed following restoration of midface volume loss by soft tissue fillers (Fig. 152.7; see Ch. 158)[26].

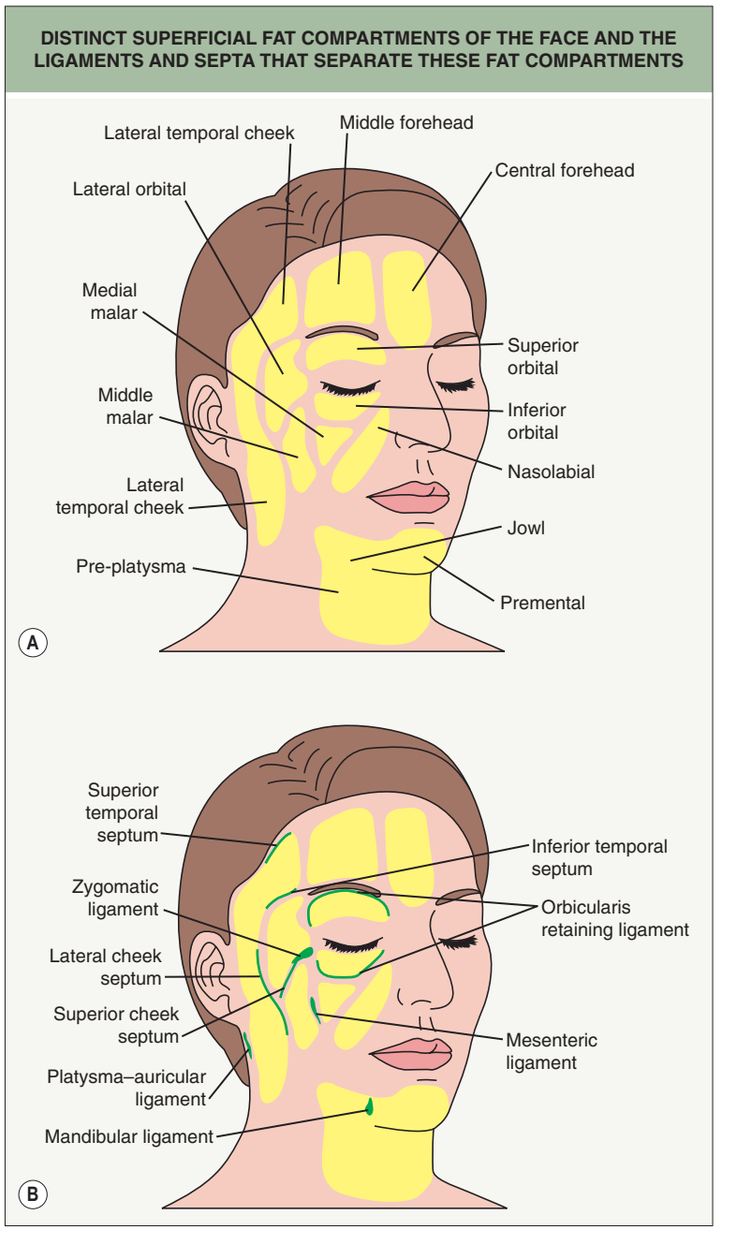

Fig. 152.4 Distinct superficial fat compartments of the face and the ligaments and septa that separate these fat compartments. A The superficial fat compartments of the face are separated by delicate fascial tissue and septa. With aging, volume loss and volume shifts appear to occur at different rates in different compartments, leading to irregularities in facial contour; this is in distinction to the smooth transitions between facial concavities and convexities associated with a youthful appearance and beauty. **B** Where the adjacent compartments meet, the septa converge to form retaining ligaments. In addition, facial muscles (e.g. the zygomaticus major muscle) attach through these fibrous septa to overlying superficial fat compartments. *Adapted from Shiffman MA, Di Giuseppe A, Cosmetic Surgery: Art and Techniques. Springer, 2013.*

Fig. 152.5 Laser resurfacing. A Before a full-face ablative resurfacing procedure. **B** After the procedure, she looks "better" but not "younger", because no attention has been paid to volume changes.

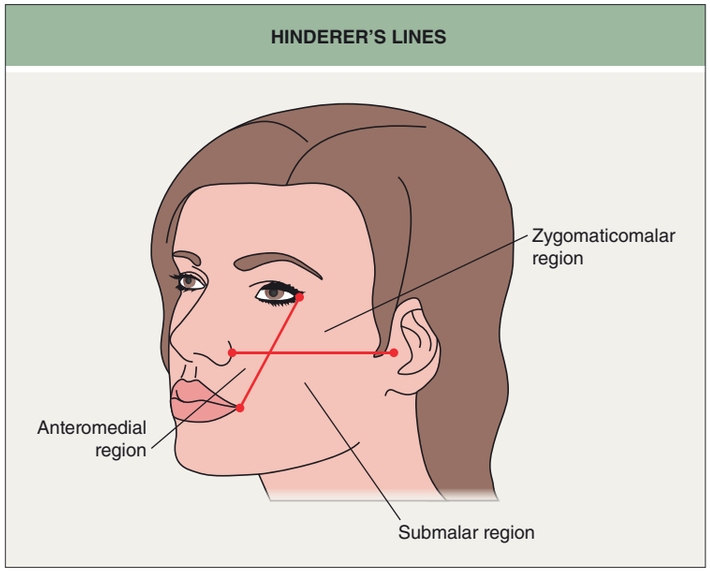

Fig. 152.6 Hinderer's lines. These lines are drawn: (1) from the lateral canthus to the lateral commissure; and (2) from the mid tragus to the mid nasal ala. They can be used to guide the optimal placement of soft tissue fillers and fat transfers (as well as cheek implants) in order to create midface volume enhancement.

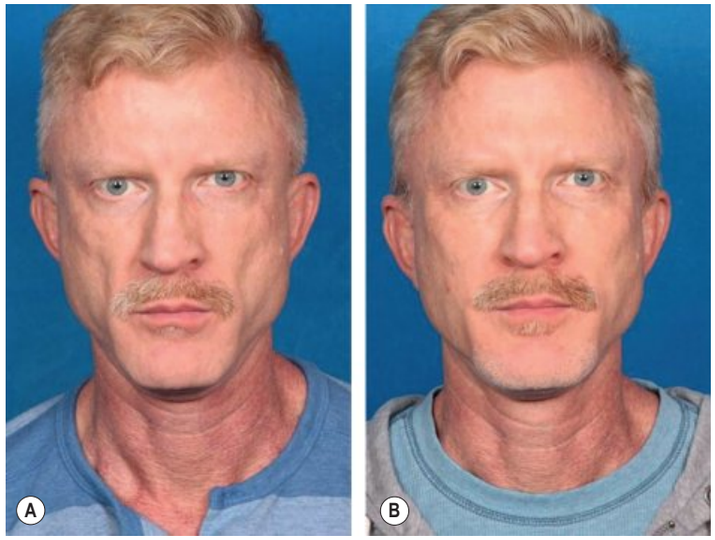

Fig. 152.7 Restoration of midface volume loss by soft tissue fillers. A Before soft tissue filler injection. **B** After injection. Even replacing small amounts of volume in the midface can lead to a natural look and provide the patient with a more youthful and attractive appearance.

CHANGES IN FACIAL MUSCULATURE

Perhaps nothing has driven home the impact of facial musculature on facial aging like the introduction of botulinum toxin type A (BoNT-A) for selective chemical denervation of muscles of the face. Paralysis or partial weakening of the glabellar corrugator/procerus complex, the forehead frontalis muscle, and the lateral orbicularis muscles has revolutionized the management of the upper third of the aging face. In addition, judicious use and careful placement of neuromodulators into the orbicularis oris, depressor anguli oris, masseters, and platysmal neck bands can aid in managing creases, wrinkling, and banding of the lower face and neck (see Ch. 159).

Brow position is closely associated with emotional states, and the medial and lateral portions of the brow function independently in this regard. Surgeons must be conscious of the strong impact that brow shape and position can have on appearance and even interpersonal relationships. For example, people tend to treat you better if you do not have a glabellar scowl, if your eyebrows arch properly (if you are female), and if the relationship between the lateral and medial brow is flattering.

In young women, the arch of the brow has been found to be most attractive when located above the lateral limbus (Fig. 152.8). Photographs of patients following botulinum exotoxin A injection were rated by 40 subjects to be 40% less angry, 49% less fearful, 10% less sad, and 71% more happy than photographs of the same patients prior to their injections[27]. In a small series of 10 patients suffering from depression, nine reported significant improvement in their symptoms to the point of no longer feeling depressed two months following botulinum toxin injection[28]. It may be that when people feel that they are more attractive, they become more confident and have more positive interactions with others. Alam et al.[29] postulated that muscular manipulations which

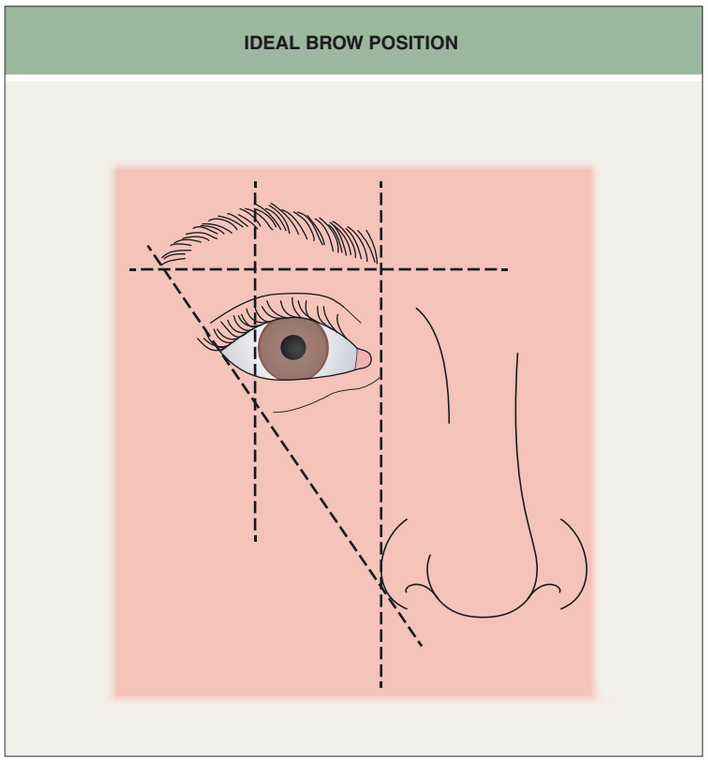

Fig. 152.8 Ideal brow position. In young women, the arch of the brow has been found to be most attractive when it peaks above the lateral limbus.

result in more positive facial expressions may lead to more positive emotional states. Likewise, reducing external signs of anger, fear, and sadness may reduce internal negative emotions.

CHANGES IN UNDERLYING CARTILAGE AND BONE

Due to changes in the underlying cartilage, the aging nose elongates and the tip droops. The aging mouth is affected by bony resorption and remodeling of the maxilla, while the chin sharpens and protrudes. The ears appear to lengthen as the lobes droop. The tarsal plate softens and no longer holds the lower lid margin in its proper position or curve. Various surgical procedures address these problems, including tip rhinoplasty, tarsal lid tightening, canthoplasty, and chin implants. Both dental implant procedures and maxillofacial surgery can address intrinsic changes affecting the lower face while BoNT-A injected into the depressor septi nasi and dilator naris muscles temporarily improves nasal tip ptosis. In addition, soft tissue fillers can be used to correct the aging changes associated with bony resorption and may result in a more natural appearance and feel than an implant. For example, these fillers may be placed in the nasal dorsum, jawline, marionette lines, pre-jowl sulcus, mentum, ear lobes, tear troughs, and midface (see above).

The diagnostic eye of the cosmetic surgeon should not overlook the contribution of the underlying hard structures of the face, particularly when assessing for the presence (or, more commonly, absence) of facial symmetry. Patients often present with requests for the treatment of facial problems without appreciating the contribution of underlying structures to their facial asymmetry. Recognizing, photographing, and discussing pre-existing facial asymmetry due to underlying bony or cartilaginous structural differences is an important component of setting realistic patient expectations.

INHERENT LOSS OF ELASTICITY

As the facial soft tissue ages, both the skin and the underlying supporting structures, while sagging under the effects of gravity, also lose their inherent resiliency or ability to resist stretching. Skin laxity occurs as a result of a decreased underlying framework, a thinned and damaged dermis, and a breakdown in elastic and collagen fibers[22].

SEX AND GENDER DIFFERENCES IN CHARACTERISTICS OF ATTRACTIVE HUMAN FACES

Idealized female facial features	Idealized male facial features
A larger, smooth forehead	Wider face
Eyebrows that have an arch or gull-wing shape	An overhanging, horizontal brow with minimal arch
Eyes that are set wider apart, creating a bigger look	Deeper set eyes that look closer together
Prominent cheekbones, a smaller nose	A somewhat larger nose
A heart-shaped taper to the lower face, with a smaller lower : upper face ratio	A squared lower face and prominent jawline with a more equal ratio of lower : upper face
Full vermilion lips	A wider mouth A beard or coarser texture to the lower facial skin, and laryngeal prominence of the thyroid cartilage (Adam's apple)

Table 152.2 Sex and gender differences in characteristics of attractive human faces. These characteristics are cross-culturally persistent.

In the lower third of the face, a facelift procedure may be essential for a successful aesthetic outcome. Redraping, repositioning, and judicious removal of skin and soft tissue that has lost its elasticity can lead to the restoration of a youthful appearance that sometimes cannot be achieved with a combination of resurfacing, fillers, fat transfer, and/or BoNT-A. However, while facelift procedures have been shown to decrease the estimated age of a person by a mean of 3.1 years (range, −4.0 to 9.4 years), they did not consistently improve attractiveness in one study when assessed at least six months postoperatively[30]. Recognizing what an individual views as ideal beauty is as important as using a multifaceted corrective approach.

SEX AND GENDER DIFFERENCES

The idealized female face tends to exhibit several characteristics that are reproducible from culture to culture and across the ages. Attractive masculine faces tend to have a very different set of characteristics (Table 152.2), although they have not been studied as extensively as those of women.

When compared to women, the skin of men tends to have higher sebum content, less transepidermal water loss (TEWL), and a lower pH[31]. In both sexes, hydration decreases and pH increases with aging, but not to the same degree in men as in women. An age-associated decrease in sebum content also occurs in women, but it is minor in men[32].

Facial hair patterns can also play a role in camouflaging the appearance of aging in men, particularly the presence of marionette lines and pre-jowl sulci, the loss of jawline definition, and submental fullness or neck skin laxity. In one study, women viewed facial hair in men as a sign of attractiveness[33].

Ideals of beauty may also differ depending on how a person self-identifies their gender. Cisgender, transgender, nonbinary, genderfluid, or transitioning patients may desire a more masculine, feminine, or androgynous appearance depending on the ideal. Care should be taken to know a patient's gender identification and then align specific goals with the procedures being planned.

ETHNIC DIFFERENCES

According to the American Society of Plastic Surgeons, more than 4.8 million cosmetic procedures were performed on ethnic minority patients in 2019, an increase of 410% since 2000. Based upon US Census Bureau projections, by the year 2056, >50% of the US population will be of non-White descent. While mathematical anthropometric measurements of the ideal facial structure have been determined, most of these measurements were based on the White face. Future anthropometric facial analyses need to take into account not only ethnocentric variations in facial structure and the effects of aging, but also ethnically diverse perceptions of beauty. Ethnic patients do not necessarily desire a "westernized" look, as what constitutes beauty is influenced by racial, cultural, and

OBJECTIVE DIFFERENCES IN SKIN STRUCTURE AND PHYSIOLOGY BASED ON ETHNICITY		
Evidence supports:	**Insufficient evidence* for:**	**Inconclusive:**

environmental factors. Descriptions of ethnocentric variability in these ideals have begun to appear in the dermatologic literature[34].

The cosmetic concerns of ethnic patients also vary due to inherent differences in skin structure and physiology (Table 152.3)[34a], mechanisms of aging, and facial anatomy (Fig. 152.9)[35]. In more darkly pigmented individuals, the initial signs of aging may consist of midface volume shifts rather than the solar lentigines and rhytides seen in lightly pigmented individuals. Due to the protective effects of melanin, lentigines and facial rhytides can appear decades later in darkly pigmented individuals. However, dyschromia can be a significant cosmetic concern in these patients.

COMBINATION THERAPIES

Optimal improvement in appearance can more often be obtained by combining procedures. Topical agents to even out skin tone and rhytids such as tretinoin, α-hydroxy acids, hydroquinone, antioxidants, peptides, and growth factors can be employed in addition to treatments for actinic keratoses (e.g. 5-fluorouracil, imiquimod, tirbanibulin, photodynamic therapy) which can inhibit or reverse UV radiation-associated changes in aging skin. Treating diseases such as acne and melasma also improves overall facial appearance. At the other end of the therapeutic spectrum, rhytidectomy, blepharoplasty, brow lift, and suction-assisted lipectomy often provide dramatic results in facial rejuvenation. The choice of specific therapies rests on the ability of the surgeon to look at the face, analyze the anatomic components of the aging appearance, and then prioritize them, matching the risk : benefit ratios of various procedures to each element with the priorities of the patient in mind. Is the predominant problem photodamage, dynamic rhytides, sagging, or the loss or shift of facial volume? Often there are also overriding constraints, e.g. the "downtime", surgical risk, cost, likelihood of benefit, that all weigh in on the selection of the appropriate therapy. However, underlying all these choices must be a rational analysis of the various elements that comprise the aging face. The more an aesthetic surgeon is able to specifically tailor treatments to the individual patient, the more likely the outcome will be aesthetically optimal and be associated with a higher degree of patient satisfaction.

Cosmetics and Cosmeceuticals 153

Zoe Diana Draelos

Synonyms: ■ Cosmeceuticals – bioactive cosmetics, functional cosmetics ■ Skin care products – moisturizers, cleansers, astringents ■ Hair care products – shampoos, conditioners ■ Nail products – nail polish, nail sculptures ■ Cosmetics – facial foundation, blush, eyeshadow, mascara, lipstick

Key features

- Colored cosmetics and skin care products have an important role in the prevention of dermatologic disease and the maintenance of skin health
- Hair is a non-living structure whose appearance and behavior can be improved via the use of shampoos and conditioners
- Nail cosmetics primarily adorn the nails, but improper use can lead to nail disease
- Cosmeceuticals are non-prescription products designed to improve the functioning of the skin, primarily by targeting the aging process
- Skin, hair, and nail care products have a profound impact on these structures, and they should be part of the working knowledge of every dermatologist

INTRODUCTION

Cosmetics and skin care products are assuming an increasingly important role within dermatology as the sophistication of raw materials and the resulting formulations provide for the development of products that impact the functioning of the skin. It was traditionally thought that the stratum corneum was a non-living, biologically inert layer of the skin upon which skin care products and cosmetics impinge. It was also thought that the stratum corneum was a complete barrier unaffected by the application of non-prescription topical agents. An improved understanding of stratum corneum function, primarily obtained through the use of non-invasive bioengineering techniques, has demonstrated that the stratum corneum can be dramatically influenced by non-prescription topical agents, and that these agents can indeed penetrate the stratum corneum and influence skin function.

Recognition of the biologic importance of the stratum corneum to skin health led to the development of a new category of skin care product, referred to as the cosmeceutical[1]. A cosmeceutical is a scientifically designed, useful product intended for external application to the human body that has desirable aesthetic effects and meets rigid chemical, physical, and medical standards[2]. Even though many cosmeceuticals currently exist for use on the skin, hair and nails, there is no regulatory description that acknowledges the current scientific sophistication of these formulations. Rather, a cosmetic is defined by the US Federal Food, Drug and Cosmetic Act, written in 1938, as "articles intended to be rubbed, poured, sprinkled, or sprayed on, introduced into, or otherwise applied to the human body or any part thereof for cleansing, beautifying, promoting attractiveness, or altering the appearance", without affecting structure or function[3].

Cosmeceuticals are now a reality due to the ever-expanding dermatologic knowledge base, which has rendered obsolete the prior outdated clear distinction between cosmetics and drugs[4]. It is somewhat bewildering to realize that water is a cosmeceutical given that water profoundly influences the structure and function of the viable epidermis. Many substances can function as cosmeceuticals if entry into and through the stratum corneum is facilitated via the use of penetration enhancers, such as propylene glycol, isopropyl myristate, or pyrrolidone derivatives. Propylene glycol profoundly alters the barrier characteristics of the stratum corneum, while isopropyl myristate is capable of penetrating into the lipid bilayer of cell membranes. Pyrrolidone derivatives interact with both keratin and stratum corneum lipids to drive substances into the skin. These enhancers are commonly found in cosmetic formulations; however, improved understanding of skin physiology allowed recognition of their profound effects on the skin, which were previously unknown.

DISCUSSION

Skin Care Products

The three basic categories of skin care products are cleansers, moisturizers, and astringents. Cleansers are designed to remove sebum, desquamating corneocytes, bacteria, fungi and environmental dirt from the face and body, while leaving the intercellular lipid barrier intact. Astringents represent a subset of cleansers designed to supplement the failure of the cleanser to perform its intended function. Moisturizers are designed to minimize the barrier damage induced by cleansing. Thus, these three skin care products work together to balance the hygiene needs of the skin with the important task of preserving barrier function.

Cleansers

The development of soaps designed to cleanse the skin has been the single most important advance in decreasing disease worldwide. Even though soap is ubiquitous in the developed world, one of the main goals of global health organizations is to introduce the concept of cleansing with soap to regions of the world where contagious diseases run rampant. In basic chemical terms, soap is a fatty acid salt resulting from a reaction between a fat and an alkali[5]. The soap solubilizes sebum and environmental dirt, such that it can be rinsed away with water. The mechanics of rubbing soap over the skin with the hand or a bathing implement results in the physical removal of desquamating scales, bacteria and fungi from the skin surface. In high-income countries, where bathing has become a daily ritual, excessive use of soap has resulted in dermatologic conditions such as xerotic eczema. This has led to the development of cleansers with skin conditioning benefits that are chemically not true soaps, and they are referred to as detergents.

Cleansers, whether formulated as bars or liquids, can be divided into three basic types: *soaps, syndets and combars* (Table 153.1). True soaps are composed of long-chain fatty acid alkali salts with a pH between 9 and 10. This alkaline pH raises the pH of the skin following cleansing, resulting in stratum corneum barrier disruption and the resultant feeling of tightness following bathing. Alkalinization of the skin disrupts the natural acid mantle, which may be significant in dermatitic skin. Recognition of the need to preserve skin pH at 5.4 led to the development of *syn*thetic *det*ergents, known as syndets, such as sodium cocoyl isethionate. Syndet cleansers, also known as beauty cleansers, contain less than 10% soap and are designed with a pH of 5.5–7.0 so as to minimize cutaneous alkalinization[6]. The third type of cleanser, known as a combar, is composed of an alkaline soap to which surface-active agents with a pH of 9–10 have been added. Combars are milder cleansers than true soaps but induce more thorough cleansing than syndets. For example, true soap is a good cleansing choice for excessively oily or dirty skin, while a combar is a good cleanser for normal skin with a moderate amount of environmental dirt. Syndets would be the least damaging to the cutaneous barrier in persons with xerosis or any form of dermatitis.

The many brands of cleansers currently on the market fall into one of the three aforementioned groups, yet there must be something unique, for marketing purposes, about each cleanser. The unique aspects of each cleanser are created through the addition of specialty

CATEGORIES OF CLEANSING PRODUCTS		
Product type	**Composition**	**Product examples®,™**
Bar soap	True soap in bar form; pH 9–10	Ivory Bar Soap (Procter & Gamble)
Syndet bar cleanser	Synthetic detergents (no soap), in bar form; pH 5–7	Basis Sensitive Skin Bar (Beiersdorf)
		Cetaphil Gentle Cleansing Bar (Galderma)
		Dove Bar (Unilever)
		Olay Quench Moisturizing Bar (Procter & Gamble)
Syndet liquid	Synthetic detergents, in liquid form; pH 5.5–7	Dove Body Wash (Unilever)
		Olay Foaming Face Wash (Procter & Gamble)
Combar soap	Combination of true soap and synthetic detergent; pH 9–10	Dial Antibacterial Bar Soap (Henkel Corporation)
		Irish Spring Original Bar Soap (Colgate-Palmolive)
Body wash	Emulsion system applied with a puff, allowing synthetic detergent cleansing combined with enhanced skin moisturization and emolliency	Aveeno Daily Moisturizing Body Wash (Johnson & Johnson)
		Cetaphil Ultra Gentle Body Wash (Galderma)
		Dove Deep Moisture Body Wash (Unilever)
		Olay Moisture Ribbons Plus Body Wash (Procter & Gamble)
Lipid-free cleanser	Cleans without fats; may contain glycerin, cetyl alcohol, stearyl alcohol, sodium lauryl sulfate and, occasionally, propylene glycol	Aquanil Cleanser (Person & Covey)
		CeraVe Hydrating Cleanser (L'Oréal)
		Cetaphil Gentle Skin Cleanser (Galderma)
Cleansing cream	Waxes and mineral oil with detergent action from borax	Noxzema Original Deep Cleansing Cream (Unilever)*
		Pond's Cold Cream (currently contains sodium borate)
Astringent/toner	Alcohol-based product that may contain witch hazel, salicylic acid or glycolic acid	Clarifying Lotion 2, 3, 4 (Clinique)
Moisturizing astringent/toner	Glycerin-based humectant moisturizer	Clarifying Lotion 1 (Clinique)
Exfoliant cleanser	Glycolic acid- or salicylic acid-containing cleanser	Oil-Free Acne Wash (Neutrogena)
Abrasive cleanser	Hydrated silica grains within the syndet cleanser	Clinique 7 Day Scrub Cream (Estée Lauder)
		Olay Age Defying Daily Renewal Skin Cleanser (Procter & Gamble)
		Cetaphil Extra Gentle Daily Scrub (Galderma)
*Does not contain borax.		

Table 153.1 Categories of cleansing products.

additives (Table 153.2). Common cleanser additives include various fragrances as well as foaming agents designed to alter the aesthetics of the lather, but the most dermatologically relevant additives are antibacterial agents. The most widely used antibacterial in both bar and liquid cleansers is benzalkonium chloride, a quaternary ammonium compound that disrupts the cellular membrane of microbes. It is bacteriostatic against Gram-positive and some Gram-negative bacteria in addition to being fungistatic. However, benzalkonium chloride is not active against nonenveloped viruses, and some species of *Staphylococcus aureus* contain a gene that leads to resistance to quaternary ammonium compounds[7].

Another important dermatologic need with regard to skin cleansing is minimization of skin barrier dysfunction. Unfortunately, surfactants cannot distinguish unwanted sebum and oil-soluble dirt from intercellular lipids. Thus, increases in transepidermal water loss are typically noted in direct proportion to the cleansing ability of the cleanser. An attempt to provide cleansing and barrier restoration in the same product has led to the development of body washes. Since body washes are liquids, incorporating both hydrophilic and lipophilic ingredients emulsified into a single phase, it is possible to cleanse and moisturize simultaneously while allowing for rinsing away of the surfactants. Body washes must be used with a puff to introduce both water and air into the cleanser emulsion in sufficient quantity to allow cleansing and moisturization to occur. The syndet detergents, primarily ammonium laureth sulfate, solubilize oil-soluble dirt into the rinse water for removal during the cleansing phase when the body wash concentration is high and the water concentration low, while occlusive moisturizing substances (e.g. petrolatum) and emollients (e.g. soybean oil) are left behind to retard transepidermal water loss and improve skin smoothness during the rinse phase when the body wash concentration is low and the water concentration is high.

Other cleanser variants for persons with dry, dermatitic skin include lipid-free, non-foaming cleansers and cold creams. These products are excellent at removing cosmetics and low levels of environmental dirt. Lipid-free cleansers are non-foaming, soap-free liquid products applied to dry or moistened skin, rubbed to produce minimal lather, and rinsed or wiped away. They possess low surfactant capabilities, and they can only remove bacteria through mechanical means, yet they are important in persons with barrier disruption[8]. The classic cleanser for dry, dermatitic skin is cold cream, which combines the effect of a lipid solvent, such as wax or mineral oil, with detergent action from borax[9]. However, not all formulations of cold creams contain borax (sodium borate).

Occasionally, a dermatologic need arises for specialty cleansers designed to offer a skin benefit beyond pure removal of sebum and environmental dirt. For example, it may be desirable to induce corneocyte disadhesion in older patients requiring an exfoliant cleanser. This can be accomplished through the addition of chemical exfoliants, such as salicylic or glycolic acid, to the cleanser formulations discussed previously. Exfoliant cleansers containing benzoyl peroxide or salicylic acid are sometimes used as an adjunct in topical acne treatment. Exfoliation can also be induced mechanically through the incorporation of fine abrasive particles (such as aluminum oxide, hydrated silica grains, ground fruit pits, or sodium tetraborate decahydrate granules) in a liquid syndet cleanser to remove skin scale. Lastly, mechanical exfoliation can be encouraged by using specially woven face cloths, designed to remove skin scale without inducing epidermal damage.

The development of novel detergents and cleansing specialty additives has created a confusing plethora of consumer products, yet the goal remains the same: to allow adequate skin hygiene without barrier damage. Our next concern is the discussion of moisturizers, designed to replace skin sebum and natural moisturizing factors in instances where the stratum corneum barrier has been damaged from exuberant cleansing.

SPECIALTY SOAP FORMULATIONS	
Type of soap	**Unique ingredients**
Superfatted soap	Increased oil and fat, representing up to 10%
Castile soap	Olive oil used as main fat
Deodorant soap	Antibacterial agents
French milled soap	Additives to reduce alkalinity
Floating soap	Extra air trapped during mixing process
Oatmeal soap	Ground oatmeal added (coarsely ground to produce abrasive soap; finely ground for gentle cleanser)
Acne soap	Sulfur, resorcinol, benzoyl peroxide and/or salicylic acid added
Facial soap	Smaller bar size, no special ingredients
Bath soap	Larger bar size, no special ingredients
Aloe vera soap	Aloe vera added to soap, no special skin benefit
Vitamin E soap	Vitamin E added, no special skin benefit
Cocoa butter soap	Cocoa butter used as major fat
Nut or fruit oil soap	Nut or fruit oils used as major fat
Transparent soap	Glycerin and sucrose added
Abrasive soap	Pumice, coarse oatmeal, maize meal, ground nut kernels, dried herbs, or flowers added
High impact soap	Strong, high-concentration fragrance added to scent skin after cleansing
Soap-free soap	Contains synthetic detergents (syndet bar)

Table 153.2 Specialty soap formulations.

DIFFERENT TYPES OF MOISTURIZERS		
Moisturizer type	**Composition**	**Product examples®,™**
Oil only	Petrolatum	Vaseline petroleum jelly (Unilever)
Oil-in-water emulsion	Water, petrolatum	Eucerin Original Healing Cream (Beiersdorf)
		Vanicream (Pharmaceutical Specialties)
Polymer-based	Water, polyglycerylmeth-acrylate, petrolatum	Cetaphil Moisturizing Cream (Galderma)
Vegetable oil and wax	Castor oil, corn oil, ozokerite, beeswax, paraffin, carnauba wax	Norwegian Formula Lip Moisturizer (Neutrogena)
Glycerin-rich	Water, glycerin, petrolatum	Norwegian Formula Hand Cream (Neutrogena)
		Curél Daily Moisture Original Lotion (Kao Corporation)
Dimethicone and ceramides	Water, petrolatum, dimethicone, ceramides	CeraVe Moisturizing Cream (L'Oréal)
		EpiCeram (Primus Pharmaceuticals)

Table 153.3 Different types of moisturizers. Additional prescription moisturizers are available, e.g. ones based upon glycyrrhetinic acid plus shea butter (Atopiclair® cream) or castor oil (Promiseb™ cream); a complete list is provided in Table 129.12.

Moisturizers

The term "moisturizer" is somewhat misleading to the consumer, who assumes that the cream or lotion puts moisture or water back into the skin[10]. Moisturizers do not put water back into the skin externally, nor do they get incorporated into the intracellular lipids. Moisturizers simply attempt to retard transepidermal water loss and create an optimal environment for restoration of the stratum corneum barrier[11]. The optimal water content for the stratum corneum is between 10% and 30%, depending on the measurement technique employed, and moisturizers can function to raise the cutaneous water content through occlusion or humectancy via a variety of active agents (Table 153.3)[12].

Occlusive moisturizers prevent evaporative water loss to the environment by placing an oily substance on the skin surface through which water cannot penetrate, thus replenishing the stratum corneum moisture by water movement from the lower viable epidermal and dermal layers[13]. There are many different classes of chemicals that can function as occlusive moisturizers[14], for example, hydrocarbon oils and waxes (petrolatum, mineral oil, paraffin, squalene), silicones (cyclomethicone, dimethicone), vegetable oils (castor oil, corn oil, grape seed oil, soybean oil), animal oils (mink oil, emu oil), fatty acids (lanolin acid, stearic acid), fatty alcohols (lanolin alcohol, cetyl alcohol), polyhydric alcohols (propylene glycol), wax esters (lanolin, beeswax, stearyl stearate), vegetable waxes (carnauba wax, candelilla wax), phospholipids (lecithin), and sterols (cholesterol, ceramides)[15].

The most effective occlusive moisturizer is petrolatum, since it reduces transepidermal water loss by 99%[16]. Total occlusion of the stratum corneum is undesirable, since transepidermal water loss is the cellular signal that initiates barrier repair and the resulting synthesis of intercellular lipids[17,18]. Complete cessation of transepidermal water loss results in no barrier repair, allowing water loss to return to its pretreatment level once complete occlusion has been removed[17–19]. Petrolatum allows barrier repair while permeating throughout the interstices of the stratum corneum[20].

Another technique for rehydrating the stratum corneum is the use of humectants. Humectants are substances that attract moisture; they include glycerin, honey, sodium lactate, urea, propylene glycol, sorbitol, pyrrolidone carboxylic acid, gelatin, hyaluronic acid, and some vitamins and proteins[14,21]. The body utilizes hyaluronic acid and other glycosaminoglycans in the dermis as biologic humectants to prevent desiccation of the skin. Humectants can only hydrate the skin from the environment when the ambient humidity exceeds 70%. Consequently, rehydration of the stratum corneum generally occurs by water that is attracted from the deeper epidermal and dermal tissues. Most moisturizers combine both occlusive and humectant moisturizing ingredients, since water drawn by a humectant to a damaged stratum corneum barrier will be lost to the atmosphere unless trapped by an occlusive[22,23]. Humectants also help to improve the smoothness of xerotic skin by inducing corneocyte swelling and minimizing voids between the desquamating corneocytes[24].

In summary, remoisturization of the skin must occur in four steps:

- initiation of barrier repair (see Ch. 124)[25]
- alteration of surface cutaneous moisture partition coefficient
- onset of dermal–epidermal moisture diffusion
- synthesis of intercellular lipids[26].

Moisturizers attempt to increase stratum corneum water content through the principles of occlusion and humectancy. The discovery of aquaporin-3 channels in the skin and their modulation by glycerin and urea has increased research into osmotic cell balance as another mechanism for moisturization.

Astringents

Occasionally, patients use skin care products that either correct the deficiencies of the cleanser or supplement the effects of the moisturizer. These products are known as astringents or toners (see Table 153.1). They are used after cleansing but before moisturizing, and they are left on the face following use. Astringents are usually liquids wiped over the face with a cotton ball. Originally, astringents were intended to remove soap scum left behind on the face from the use of lye-based soaps and hard water. If left behind, this soap scum could cause irritant contact dermatitis. The original astringents were fragranced isopropyl alcohol or propylene glycol solutions designed to remove oil-soluble residue. The development of synthetic detergents and treated water has made this original intent obsolete, yet astringents remain popular.

Currently, astringents are used to remove the oily residue left behind after cleansing of the face with lipid-free cleansers or cleansing creams, discussed previously. Oily complexion astringents are formulated to remove any remaining sebum from the face following synthetic detergent cleansing or to deliver keratolytics, such as salicylic acid, glycolic acid or witch hazel. Some astringents designed for dry skin contain a humectant liquid moisturizer, such as propylene glycol or glycerin, and skin soothing agents, such as allantoin, guaiazulene or quaternium-19[27].

FUNCTIONS OF FACIAL FOUNDATION
• Add facial color
• Blend facial color
• Camouflage pigmentation irregularities
• Normalize facial skin
• Provide sun protection
• Act as a treatment product

Table 153.4 Functions of facial foundation.

A complete cosmetic-counter facial treatment routine involves a cleanser followed by an astringent and then a moisturizer. Once the skin has been prepared in this manner, colored cosmetics are applied.

Colored Facial Cosmetics

Colored facial cosmetics are intended to adorn the eyes, lips, and cheeks with color for the purposes of creating a fashionable appearance, highlighting certain desirable features, and camouflaging facial flaws. Colored cosmetics are of importance to the dermatologist for their role in maintaining skin health, inducing dermatitis, and camouflaging surgical defects.

Facial foundations

Formulation

Facial foundations are the first cosmetic applied to the face following the use of a moisturizer and are basically pigmented moisturizers worn for 8 hours or longer before removal. Consequently, this class of colored facial cosmetics has the greatest impact on the integrity of the skin. Facial foundations are available for every complexion type and skin color, fulfilling the needs listed in Table 153.4.

There are four basic facial foundation formulations: oil-based, water-based, oil-free, and water-free or anhydrous forms[28]. Oil-based products are designed for dry skin, while water-based products can be adapted for all skin types. Oil-free formulations are used in oily skin foundations, while anhydrous forms are extremely long-wearing and used for camouflage or theatrical purposes.

Oil-based foundations are water-in-oil emulsions containing pigments suspended in oil (e.g. mineral oil) or lanolin alcohol. Vegetable oils (grape seed, coconut, sesame, safflower) and synthetic esters (isopropyl myristate, octyl palmitate, isopropyl palmitate) may also be incorporated. The water evaporates from the foundation following application, leaving the pigment in oil on the face. This creates a moist skin feeling, especially desirable in dry complected patients. Because the color is fully developed within the oily phase of the formulation, oil-based foundations do not shift color as they mix with sebum. These foundations are easy to apply, since the pigment can continue to be spread over the face for up to 5 minutes, prior to setting.

Water-based facial foundations are oil-in-water emulsions containing a small amount of oil, in which the pigment is emulsified, and a relatively large quantity of water. The primary emulsifier is usually a soap, such as triethanolamine, or a non-ionic surfactant. The secondary emulsifier, present in a smaller quantity, is usually glyceryl stearate or propylene glycol stearate. These popular foundations are appropriate for minimally dry to normal skin. Since the pigment is already developed in oil, this foundation type is also not subject to color drift. The amount of time the product can be moved over the face, known in the industry as playtime, is shorter than with oil-based foundations.

Oil-free facial foundations contain no animal, vegetable, or mineral oils. They contain other oily substances, such as dimethicone or cyclomethicone. These foundations are usually designed for oily complected individuals, since they leave the skin with a dry feeling. Dimethicone is non-comedogenic, non-acnegenic and hypoallergenic, accounting for the tremendous popularity of this type of facial foundation formulation. Both water-based and oil-free foundations are usually packaged in a bottle.

Water-free, or anhydrous, foundations are waterproof. Vegetable oil, mineral oil, lanolin alcohol and synthetic esters form the oil phase, which may be mixed with waxes to form a cream. High concentrations of pigment can be incorporated into the formulation, yielding an opaque facial foundation. The coloring agents are based on titanium dioxide with iron oxides, occasionally in combination with ultramarine blue. Titanium dioxide acts both as a facial concealing agent and sunscreen. These products can be dipped from a jar, squeezed from a tube, wiped from a compact, or stroked from a stick. Water-free foundations are well suited for use in people who require facial camouflaging. They can be combined with a high-coverage powder foundation to increase the opacity of the cosmetic.

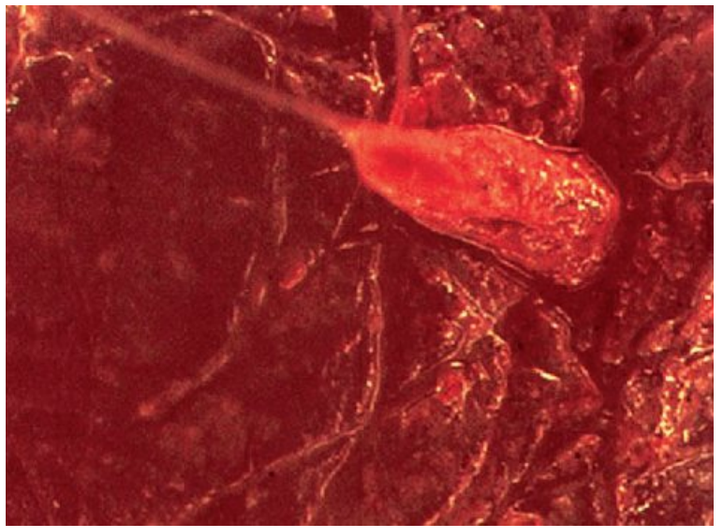

Fig. 153.1 Migration of iron oxide particles in facial foundation to follicular ostia. As seen by video microscopy (400×), this migration tends to occur as sebum and eccrine secretions mix with the cosmetic film.

Application and cutaneous effects

Facial foundations must be evenly applied to create the optimal cosmetic appearance and achieve the secondary benefit of sun protection. The iron oxide pigment and other covering agents, e.g. titanium dioxide, zinc oxide and kaolin, are physical particulates that block both UVA and UVB radiation (see Ch. 132). A facial foundation *without* any added organic sunscreen ingredients, such as ecamsule, octyl methoxycinnamate, oxybenzone or avobenzone, usually has a sun(burn) protection factor (SPF) of at least 4. Facial foundations that have greater coverage in order to camouflage underlying pigmentation defects usually possess an SPF of at least 8. The inclusion of additional sunscreen agents to a facial foundation can raise its SPF to 15. Thus, facial foundation is an excellent, cosmetically elegant facial photoprotectant.

An even, cosmetically acceptable application of facial foundation begins with a proper color match to the skin at the jawline and application with the fingertips. A dab of foundation should be placed on the forehead, nose, cheeks, and chin, and then blended with a light circular motion until it is evenly spread over the entire face, including the lips. Finally, a puff or sponge should be used, stroking in a downward direction, to remove any streaks and to flatten vellus facial hair. Special care should be taken to rub the foundation into the hairline, over the tragus, and beneath the chin. Foundation should also be blended around the eyes, and it may even be applied to the entire upper eyelid if desired. The foundation should be allowed to set or dry until it can no longer be removed with light touch. If additional coverage is desired, a second layer of foundation can be applied.

The most common adverse dermatologic effect related to the use of facial foundation is a condition patients describe as "breakouts". Patients typically note small follicular papules 48 hours after using a new facial foundation. The appearance resembles that of acne; however, the 48-hour time course is inconsistent with a diagnosis of acne. This condition may represent a follicular irritant contact dermatitis, since facial foundations tend to migrate to the follicular ostia as they mix with eccrine secretions and sebum, which break down the cosmetic film (Fig. 153.1). This observation may explain why facial foundations that have been found on clinical testing to be non-comedogenic and non-acnegenic cause acneiform eruptions in individuals with self-diagnosed sensitive skin. Overall, however, facial foundations are an infrequent cause of dermatologic problems.

COVERING ABILITY OF FACE POWDER INGREDIENTS
• Titanium dioxide*
• Kaolin (hydrated aluminum silicate)
• Magnesium carbonate
• Magnesium stearate
• Zinc stearate
• Prepared chalk
• Zinc oxide*
• Rice starch
• Precipitated chalk
• Talc (hydrated magnesium silicate)
*Hardness greater than platinum, gold, and silver so capable of producing black dermographism.

Table 153.5 Covering ability of face powder ingredients. Listed in order of increasing opacity.

PIGMENTS ALLOWED BY THE US FDA IN EYE SHADOW COSMETICS
• Iron oxides
• Titanium dioxide (alone, or combined with mica)
• Copper, aluminum, and silver powder
• Ultramarine blue, violet, and pink
• Manganese violet
• Carmine
• Chrome oxide and hydrate
• Iron blue
• Bismuth oxychloride (alone, or on mica or talc)
• Mica

Table 153.6 Pigments allowed by the US Food and Drug Administration (FDA) in eye shadow cosmetics.

Powders

One of the ways of preventing migration of facial foundation, improving its sun protective capabilities, and increasing oil absorption is to apply powder over the foundation. Facial powders contain predominantly talc (hydrated magnesium silicate) and increased amounts of covering pigments. The covering pigments used in face powder are listed in order of increasing opaqueness in Table 153.5. It is generally accepted that the optimum opacity is achieved with a particle size of 0.25 mcg. Black dermographism from earrings and rings can result when face powders contain ingredients, e.g. zinc oxide, that are harder than platinum, silver or gold.

Facial powders usually also contain magnesium carbonate and/or kaolin (hydrated aluminum silicate) to absorb oil and perspiration. Full-coverage face powders with increased pigments and light-reflective particles are usually packaged as a cake in a compact and applied to the face with a puff, loose in a jar and dusted over the face with a brush, or stroked over the face from an automatic brush dispenser. These face powders with increased pigments can be used as a facial foundation and are known as mineral make-ups. They are recommended for persons with sensitive skin and rosacea as they contain no liquids, fewer preservatives, and fewer ingredients. As a result, there is decreased potential for allergic and irritant contact dermatitis. Specially pigmented powders are used to redden the cheeks, known as blushes, and to color the eyelids, known as eye shadows.

Facial blushes

Facial blushes are typically powders designed to simulate rosy cheeks, occasionally an unwanted finding in rosacea patients. Blushes have the same basic formulation as face powders, except for the presence of different surface characteristics that can vary from a matte dull finish to a frosted shine or metallic glow, depending on current fashion trends[29]. Some of the rough-edged particles designed to produce light reflection can cause irritation in people with sensitive skin. Powder blush can be used to absorb facial oil and blend the facial erythema of rosacea across the cheeks, as well as to add color to a sallow face by dusting on the central chin, cheeks, nasal tip, and forehead.

Eye shadows

Eye shadows are similar to powder blushes in formulation and surface characteristics, except that the color variation is broader, but limited in the US by the Food and Drug Administration (FDA) to the purified natural colors or inorganic pigments listed in Table 153.6[30]. Eye shadow can be used to camouflage misshapen eyes, provide sun protection to the upper eyelid, and minimize the appearance of unwanted periorbital pigmentation. Eye shadows are a common concern to dermatologists, since they may be responsible for eyelid dermatitis. They may contain the same light-reflective particles as blushes and cause pruritus of the eyelids due to irritant contact dermatitis until discontinued (Fig. 153.2).

In one series, the North American Contact Dermatitis Group determined that 12% of cosmetic reactions occurred on the eyelid, but only 4% could be linked to eye make-up use[31]. When allergic contact dermatitis is due to eye shadows, the most common culprits are the red pigments used in pinkish eye shadows. Unfortunately, it can be difficult to determine the etiology of allergic contact eyelid dermatitis with routine patch testing[32], since many substances can be transferred to the eye area by the hands, complicating the dermatologic evaluation[33]. However, eye shadows are a rare cause of eye infections, since the dry powder cake does not support bacterial growth.

Fig. 153.2 Upper eyelid dermatitis. Upper eyelid dermatitis may be exacerbated by the use of heavily pigmented, light-reflective eye shadows.

Mascaras

Mascaras are eyelash cosmetics, as opposed to eye shadows which are eyelid cosmetics. Mascaras are designed to color, camouflage, elongate and thicken the eyelashes, which frame the eyes. They must be carefully formulated to allow easy and even application without smudging, irritancy or toxicity. Some of the coloring agents employed include iron oxide to produce black, ultramarine blue to create navy, and umber, burnt sienna, or synthetic brown oxide to create brown[34].

Most modern mascaras are formulated as liquids, then stored in a tube with a multitufted applicator brush or comb. The applicator is inserted into the tube between uses, providing numerous opportunities to inoculate bacteria into the cosmetic. The most dangerous bacterial infection is a corneal infection due to *Pseudomonas aeruginosa*, which can permanently diminish visual acuity[35,36]. *Staphylococcus epidermidis, S. aureus* and fungal organisms may also proliferate in contaminated mascaras[37,38]. Infections are more common if the globe is traumatized by the infected mascara wand. Even though mascaras contain antibacterials, it is still wise to discard all mascara tubes after three months and not allow multiple persons to use the same mascara tube[39].

There are several mascara formulations that are less likely to support bacterial and fungal growth (Table 153.7). Mascaras are available as water- or solvent-based and as a water/solvent hybrid. Water-based mascaras are easily removed with water and less likely to cause eye area irritation, but the presence of water provides a welcome medium for bacterial growth. Solvent-based mascaras are manufactured without water, must be removed with a special cleanser, and are more irritating; however, they are less likely to support bacterial growth and are therefore the formulation of choice for individuals who are carriers of *Staphylococcus* or *Streptococcus* spp[40]. The water/solvent hybrid mascaras are an attempt to provide a water-resistant cosmetic with the

DIFFERENT TYPES OF MASCARA FORMULATIONS		
Mascara formulation	**Composition**	**Advantages/Disadvantages**
Water-based	Waxes, pigments, resins	Easy to remove with water; runs with tearing; supports bacterial growth
Solvent-based waterproof	Petroleum distillates, pigments, waxes	Must be removed with solvent; waterproof; does not support bacterial growth
Water-resistant water/solvent hybrid	Oil-in-water emulsion, pigments	Removal with water and cleanser; resists running with tearing; less likely to support bacterial growth
Compressed cake	Pigments, talc	Removal with water; runs with tearing; least allergenic; does not support bacterial growth

Table 153.7 Different types of mascara formulations.

CAMOUFLAGE FOR ABNORMALITIES OF FACIAL PIGMENTATION OR COLOR		
Facial color	**Disease process**	**Undercover foundation color**
Red	Rosacea, psoriasis, lupus erythematosus, port-wine birthmark, telangiectasias	Green
Yellow	Solar elastosis, chemotherapy, dialysis	Purple
Brown hyperpigmentation	Melasma, lentigines, nevi	White
Hypopigmentation and depigmentation	Postinflammatory, congenital, vitiligo	Brown

Table 153.8 Camouflage for abnormalities of facial pigmentation or color.

benefits of both. Recent analyses of waterproof mascaras, as well as long-lasting lipsticks, have found high levels of fluorine, suggesting the presence of per and polyfluoroalkyl substances (PFAS).

Another dermatologic side effect of the use of mascara is conjunctival pigmentation, resulting from the washing of mascara into the conjunctival sac by lacrimal fluid[41]. This colored particulate matter can be observed on the inferior tarsal (palpebral) conjunctiva. Histologically, the pigment is seen within macrophages and extracellularly in association with a variable lymphocytic infiltrate. Electron microscopy suggests that ferritin, carbon, and iron oxides are present within the tissues[42]. Unfortunately, there is no treatment for the condition, which is usually asymptomatic.

Specialty mascaras are available for curling and elongating the eyelashes. These mascaras contain pigmented polymers that polymerize on the eyelash as they dry. The polymer then shrinks, curling the eyelash and placing a thin, long-wearing, pigmented film around the hair which thickens and elongates the lash. In addition, a prescription cosmeceutical containing bimatoprost 0.03% (Latisse®; originally indicated for the treatment of glaucoma) is available to elongate eyelashes via prostaglandin modulation (see Ch. 129)[43]. Side effects include iris and eyelid pigmentation, which may be permanent.

Lipsticks

Lipstick is a lip cosmetic designed to frame the teeth. Traditional lipsticks are mixtures of waxes, oils and pigments in various concentrations to yield the characteristics of the final product. For example, a lipstick designed to remain on the lips for a prolonged period of time is composed of high wax, low oil, and high pigment concentrations, whereas a product designed for a smooth creamy feel on the lips is composed of low wax and high oil concentrations[44]. The waxes commonly incorporated into lipstick formulations are white beeswax, candelilla wax, carnauba wax, ozokerite wax, lanolin wax, ceresin wax and other synthetic waxes. Usually, lipsticks contain a combination of these waxes carefully selected and blended to achieve the desired melting point. Oils for pigment dispersion are then selected, such as castor oil, white mineral oil, lanolin oil, hydrogenated vegetable oils or oleyl alcohol, to form a film suitable for application to the lips[45,46].

Newer lipstick formulations contain long-wearing polymers that create a waterproof film over the lips that remains in place indefinitely until worn away with speech or eating. These long-wearing lip products can cause cheilitis, due to their non-moisturizing formulations. In addition, lip products are marketed that claim to plump the lips. These products contain irritants, such as capsaicin, that create a mild irritant contact dermatitis resulting in short-lived lip edema.

Certain common lipstick ingredients can cause problems in the sensitized patient[47]. Castor oil, found in almost all lipsticks due to its excellent ability to dissolve bromo acid dyes, can cause allergic contact dermatitis[48]. Even the bromo acid dyes, such as eosin (D & C Red No. 21), found in indelible lipsticks can cause allergic contact dermatitis[49]. Other lipstick ingredients reported to cause allergic contact dermatitis include: waxes (e.g. propolis[50]), preservatives (e.g. propyl gallate[51], benzoic acid[52]), sunscreens (e.g. oxybenzone[53], benzophenone-3[54]), colors (e.g. lithol rubine BCA [Pigment Red 57-1][55]), fragrances (e.g. peppermint oil), vitamin E, and ricinoleic acid[56].

Facial cosmetics for camouflaging

All of the colored cosmetics previously discussed are used in combination for facial camouflaging purposes in order to minimize facial defects while accentuating attractive facial features. Camouflage cosmetics are used by paramedical aestheticians, dermatologists, plastic surgeons, and cosmetic consultants[57]. Their successful use requires a well-formulated, quality product applied with the skill of a stage make-up technician and the artistic abilities of a painter[58]. Facial defects requiring camouflaging are defects of pigmentation and/or contour[59].

Pigmentation defects represent abnormalities limited to the color of the skin, whereas contour defects are defined as areas where the facial skin is hypertrophic or atrophic, with textural changes due to the absence of appendageal structures. Table 153.8 lists examples of pigmentary abnormalities frequently encountered by dermatologists that arise from inflammatory disorders, systemic diseases, or extrinsic effects (e.g. sun exposure). Pigmentation defects or discolorations can be camouflaged either by applying an opaque cosmetic that allows none of the abnormal underlying skin tones to be appreciated or by applying foundations of complementary colors. For example, red discoloration can be camouflaged by applying a green foundation, since green is the complementary color to red. The blending of red skin with green foundation yields a brown tone, which can be readily covered by a more conventional facial foundation. Furthermore, yellow skin tones can be blended with a complementary-colored purple foundation to also yield brown tones.

The camouflaging of facial contour abnormalities is based on the principle that dark colors make protuberances appear to recede while light colors make surface depressions appear shallower. Creating an even-appearing surface on a scarred face is achieved through artistic shading. Powdered blush-type products are best suited for this purpose. Areas of the face that need to be lightened should be brushed with a light pink or peach pearled blush or buffer. Areas of the face that need to be darkened should be brushed with a deep plum or bronze matte-finish blush or highlighter.

Hair Care Products

Some of the material discussed previously is applicable to hair care products, since shampoos can be likened to skin cleansers, while conditioners are analogous to skin moisturizers.

Hair shampoos

Shampoos are simply designed to cleanse the hair; however, this is a complicated task considering that the average woman has 4–8 m^2 of hair surface area to clean[60]. Shampoos are intended to remove sebum, sweat components, desquamated stratum corneum, styling products, and environmental dirt from the hair and scalp[61]. They contain detergents, foaming agents, conditioners, thickeners, opacifiers, softeners, sequestering agents, fragrances, preservatives, and specialty additives[62]. Synthetic detergents remove sebum and dirt; however, excessive removal of sebum leaves the hair dull, susceptible to static electricity, and difficult to comb, creating the need for hair conditioners[63].

Shampoo detergents can be chemically classified as anionics, cationics, non-ionics, amphoterics, and natural surfactants (Table 153.9)[64]. The basic difference between bar soap and shampoo is the addition of a higher concentration of sequestering agents to chelate magnesium and calcium ions, preventing the formation of other salts or insoluble soaps known as soap scum. Without sequestering agents, shampoos would leave the hair dull and contribute to scalp pruritus. There are many different types of shampoo, designed to meet various hair cleansing needs (Table 153.10). Nowadays, a number of shampoos claim to be sulfate-free, meaning the requisite cleansing detergent is not sodium lauryl sulfate or sodium laureth sulfate.

A more recent development is dry shampoo, which consists of a powder that is dusted on the scalp while avoiding the hair, and then is brushed out. The powder absorbs oil and is removed without water contact. The advantage of dry shampoos is the prolongation of the effect of artificial hair coloring agents that occurs when water contact is avoided.

Hair conditioners

The need for hair conditioners arises from the inability of shampoos to remove just enough sebum to leave the hair clean, without removing too much sebum and thus creating dry, unmanageable, dull hair[65]. Conditioners are also required because permanent waving, permanent coloring, and other chemical hair treatments damage the cuticle, making the hair harsh, brittle, and difficult to disentangle (Table 153.11; Fig. 153.3)[66]. Hair conditioners are designed to reverse this hair damage by improving sheen, decreasing brittleness, decreasing porosity, increasing strength, and repairing degradation in hair proteins[67,68].

Hair conditioners improve manageability by decreasing static electricity. Following combing or brushing, the hair shafts become negatively charged, causing the hairs to repel one another. Conditioners deposit positively charged ions on the hair shaft, neutralizing the electrical charge. They also improve manageability by reducing hair shaft combing friction by as much as 50%, leading to enhanced disentangling. Conditioners also smooth the cuticular scale to increase hair shine (Fig. 153.4)[69,70]. Maximum hair shine is produced by large-diameter, elliptical hair shafts with a sizable medulla and intact, overlapping cuticular scales[71]. Hair that lacks shine is missing its cuticle (Fig. 153.5).

Special hair conditioner formulations attempt to repair split-ends by temporarily reapproximating the frayed remnants of remaining medulla and cortex. This is accomplished by including hydrolyzed animal proteins that can minimally penetrate the hair shaft, enhancing hair tensile strength by 5% until the hair is next shampooed. There are several types of conditioners formulated for a variety of needs (Table 153.12). Leave-in conditioners are specially designed for Afro-textured hair in order to maintain hair water content despite the unavoidable loss that occurs following hair straightening[72].

Safety issues

Hair care products are generally safe, especially since they are rinsed from the hair and skin by water. However, patients can develop allergic contact dermatitis, in particular to paraphenylenediamine (PPD) which is contained in permanent hair dyes. The dermatitis more commonly affects the face and neck rather than the scalp alone[73]. Gradual coloring with metallic dyes and temporary coloring can be used in patients who are allergic to PPD, but they need to be warned of possible cross-reactions to chemically related topical and systemic medications (see Table 153.11)[74].

In addition to applying chemical relaxers to "permanently" straighten curly or kinky hair, a semi-permanent technique, known by several names including Brazilian hair straightening, keratin blowout and Brazilian keratin treatment, can be utilized, with straightening effects lasting for 10–16 weeks. A keratin- and formaldehyde-containing solution is applied to the hair followed by the use of a heated straightening iron. The health concern is the release of toxic levels of formaldehyde gas. In solution, formaldehyde can be in equilibrium with methylene glycol and it has multiple chemical names; therefore hair products labeled as "formaldehyde-free" but containing methylene glycol, formalin, methanal, methyl aldehyde, methylene oxide, oxomethane, oxymethylene, oxymethyline, formic aldehyde or formol are still an issue. In contrast, Japanese hair straightening (also known as thermal reconditioning) utilizes ammonium thioglycolate in combination with a heated straightening iron and is permanent (see Table 153.11).

SHAMPOO DETERGENTS		
Surfactant type	**Chemical class**	**Characteristics**
Anionics	Lauryl sulfates, laureth sulfates, sarcosines, sulfosuccinates	Deep cleansing; may leave hair harsh
Cationics	Long-chain amino esters, ammonio esters	Poor cleansing; poor lather; impart softness and manageability
Non-ionics	Polyoxyethylene fatty alcohols, polyoxyethylene sorbitol esters, alkanolamides	Mildest cleansing; impart manageability
Amphoterics	Betaines, sultaines, imidazolinium derivatives	Non-irritating to eyes; mild cleansing; impart manageability
Natural surfactants	Sarsaparilla, soapwort, soap bark, ivy, agave	Poor cleansing; excellent lather

Table 153.9 Shampoo detergents.

SPECIALTY SHAMPOOS		
Shampoo type	**Function**	**Unique ingredients**
Oily hair	Provide excellent cleansing to remove sebum with minimal conditioning	Strong surfactants such as sodium lauryl sulfate or the sulfosuccinates
Dry hair	Provide mild cleansing and excellent conditioning	Milder surfactants such as sodium laureth sulfate Sulfate-free formulations based on betaine and sulfosuccinates
Conditioning	Contain added conditioners to enhance shine and minimize static electricity	Hydrolyzed proteins designed to penetrate the hair shaft
Baby	Utilize mild detergents that anesthetize the conjunctiva to prevent stinging, burning, and irritation	Detergents from the amphoteric group such as the betaines
Medicated	Designed to treat dandruff and seborrheic dermatitis through the use of keratolytics as well as antiproliferative and anti-inflammatory agents	Tar, salicylic acid, sulfur, selenium disulfide, ketoconazole, and zinc pyrithione
Professional	Designed for use following hair coloring to reduce hair shaft swelling	Cationic acidic shampoos to neutralize residual hair shaft alkalinity following permanent hair coloring
Dry	Absorb oil without water contact, prolonging the effect of permanent, semipermanent, and temporary hair coloring agents	Absorbent powder

Table 153.10 Specialty shampoos.

CHEMICAL HAIR TREATMENTS: COLORING, PERMANENT WAVING, AND RELAXING				
Treatment	**Definition**	**Chemicals used**	**Process**	**Adverse effects**
Permanent coloring	Color persists indefinitely (until new growth appears)	• H_2O_2 (referred to as the developer or oxidizing agent) • Ammonia • Dye (e.g. *p*-phenylenediamine [PPD], aminophenols)	• H_2O_2 lightens ("lifts") the previous color by oxidizing melanin, and it causes the dye to "develop" and deposit color • Alkaline pH leads to swelling and disruption of the cuticle, allowing the dye to penetrate into the cortex • To dye dark hair to a light blonde color, the hair must first be bleached (e.g. with a mixture of ammonium persulfate and H_2O_2)	• Dull, brittle hair (especially with permanent color) • Allergic contact dermatitis, in particular to PPD • In patients allergic to PPD, potential cross reactivity to textile dyes, sulfonamides, benzocaine, procaine, para-aminobenzoic acid • Staining of the skin and seborrheic keratoses
Demi-permanent coloring	Color lasts 2–3 months (12–24 shampoos)	• Low concentration of H_2O_2 • Non-ammonia alkali (e.g. monoethanolamine) • Dye (e.g. *p*-phenylenediamine, aminophenols)	• Similar to permanent color (but to a lesser degree)	
Semi-permanent coloring	Color lasts 4–6 weeks (6–12 shampoos)	• No H_2O_2 • Mild non-ammonia alkali • Azo dyes, henna, polymerized dyes, aminophenols ± *p*-phenylenediamine	• Small dye particles both coat the cuticle and penetrate into the cortex, or dye polymers coat the cuticle • The hair is not lightened	
Gradual coloring	Color slowly builds up over time	• Metallic dyes (e.g. salts of lead, bismuth or silver)	• Dye particles slowly accumulate in the cuticle, darkening the hair within a limited (brown–black) range	
Temporary coloring	Color is removed with 1–2 shampoos	• Azo and other FD&C dyes	• Dye coats the cuticle of the hair shaft (particles are too large to penetrate the cuticle)	
Permanent waving ("perm")*	Chemical treatments "permanently" curl hair (until new growth appears)	• Ammonium or sodium thioglycolate (pH 9–10; "alkaline perm") –or – • Glycerol monothioglycolate (pH 6.5–8; "acid perm"; requires application of heat) – *or* – • Bisulfites or mercaptamine (low/neutral pH, "thioglycolate-free perms")	• The hair is wrapped around rods and the chemical solution is applied to break disulfide bonds between keratin polypeptide chains • Neutralizing solution is then used to reform the disulfide bridges, and the hair takes the shape of the rod	• Dull, brittle hair (especially with alkaline perms) • Irritant contact dermatitis • Allergic contact dermatitis, in particular to glycerol monothioglycolate • Glycerol monothioglycolate may be retained in hair for up to 3 months
Chemical relaxing (lanthionizing)*	Chemical treatments "permanently" straighten hair that is curly or kinky (until new growth appears)	• Sodium hydroxide (lye) – *or* – • Guanidine hydroxide (calcium hydroxide cream + guanidine carbonate activator solution; "no-lye" relaxers) – *or* – • Ammonium thioglycolate ("thio" relaxers)	• Disulfide bonds between keratin polypeptide chains are broken and reformed in a similar manner to permanent waving • Relaxer cream is brushed onto the hair, which is mechanically smoothened section by section; this is followed by use of a neutralizing shampoo	• Dull, brittle hair (breakage may be substantial, especially with sodium hydroxide) • Irritant contact dermatitis/chemical burns • Scarring from sodium hydroxide chemical burns • Allergic contact dermatitis

*Permanent waving or relaxing should be performed before coloring hair, since the former procedures can produce irreversible color loss; to minimize damage to the cuticle, it is best to wait 2–4 weeks before color is applied.

Table 153.11 Chemical hair treatments: coloring, permanent waving, and relaxing. See the text for a description of Brazilian and Japanese hair straightening techniques. FD&C, Federal Food, Drug and Cosmetic Act; H_2O_2, hydrogen peroxide.

Nail Care Products

There are a variety of nail care products (Table 153.13). The focus of this section is on nail polish and the use of nail sculptures while nail changes associated with a manicure or a pedicure are outlined in Table 71.11.

Nail polish

Nail polish is a cosmetic designed to temporarily place a pigmented layer over the natural nail plate. It consists of pigments suspended in a volatile solvent to which film-forming agents have been added[75]. Nitrocellulose is the most commonly employed primary film-forming agent in nail lacquer. It produces a shiny, tough film that adheres well to the nail plate. The film is somewhat oxygen-permeable, thus allowing gas exchange between the atmosphere and the nail plate, which is required to maintain nail strength. It also decreases nail water vapor loss from 1.6 to 0.4 mg/cm^2/h, preventing nail plate dehydration[76].

A resin, such as tosylamide formaldehyde (also referred to as toluene sulfonamide–formaldehyde resin), must be added to the nitrocellulose to decrease hardness, but some individuals are sensitive to this substance, which is found on the standard dermatology patch test tray. This resin has been eliminated in hypoallergenic nail enamels, which instead contain a polyester resin or cellulose acetate butyrate, but allergic contact dermatitis is still possible and the enamel is less durable[77].

A professional nail enamel application requires three layers of polish: a base coat, a pigmented nail enamel, and a top coat. The base coat ensures good adhesion to the nail plate and prevents polish chipping. The second layer is the actual pigmented nail enamel, while the third layer or top coat provides gloss and resistance to chipping. A newer professional nail enamel application technique is known as nail shellac. Nail shellacs utilize either an ultraviolet light-cured pigmented polymer, identical to that used in nail sculptures (discussed below), or an LED-cured polymer to create a thin, hard pigmented film over the natural nail plate.

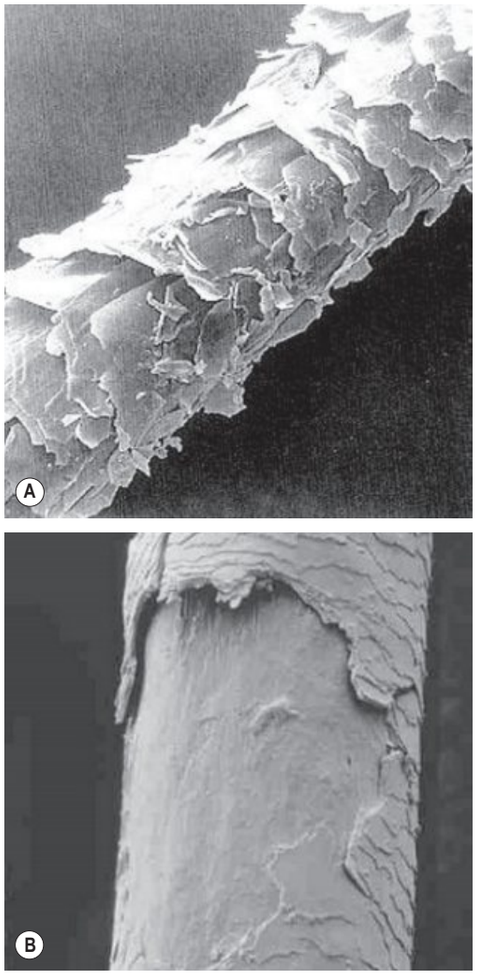

Fig. 153.3 Electron photomicrographs of chemically damaged hair shafts. A Loose cuticle, compared to the tightly overlapping cuticle of normal hairs (see Fig. 153.5). **B** Missing cuticle with exposed cortex.

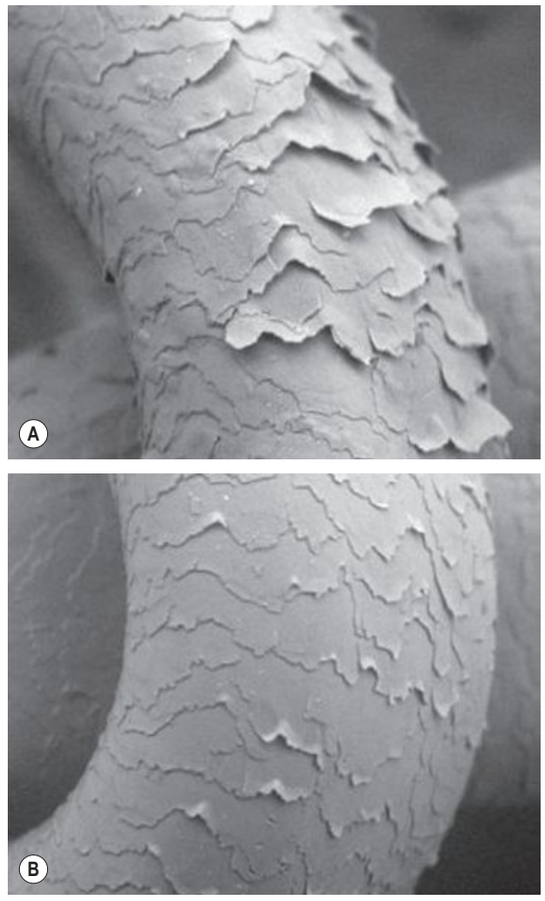

Fig. 153.4 Electron photomicrographs demonstrating the effect of hair conditioners. A Unconditioned hair shaft with uplifted cuticle. **B** Conditioned hair shaft with tightly adherent cuticle.

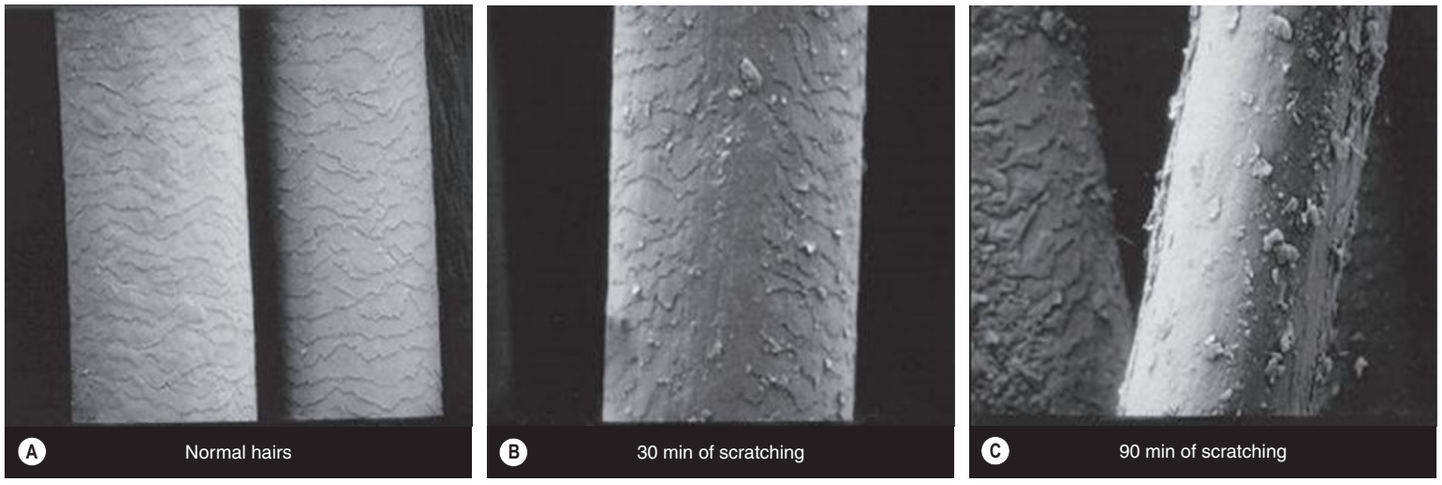

Fig. 153.5 Electron photomicrographs demonstrating the progressive removal of the hair cuticle as a result of scratching. The most common cause of cuticle removal is scratching and this leads to dull fragile hair. Note that the normal hairs have a tightly overlapping cuticle.

Problems associated with nail enamels include nail plate discoloration and allergic contact dermatitis. Nail staining is most commonly seen following the use of deep red nail polishes containing D & C Reds No. 6, 7, 34, or 5 Lake[78]. The nail plate will be stained yellow after 7 days of continuous nail polish wear and will fade without treatment in approximately 14 days, once the enamel has been removed (Fig. 153.6)[79]. Allergic contact dermatitis is seen in persons sensitive to tosylamide formaldehyde, who may develop proximal nail fold erythema and edema, fingertip tenderness and swelling, and/or eyelid dermatitis[80]. In one series, the North American Contact Dermatitis Group determined that 4% of positive patch tests were due to tosylamide formaldehyde resin allergy[32].

Nail sculptures (artificial nails)

Nail polish is designed to color the nail plate. It may make the nail somewhat stronger due to the presence of the resin layer, but it cannot elongate fingernails. Since long fingernails are considered attractive by some women, this has led to the development of an industry dedicated to the application of nail prostheses. These nail prostheses, known as nail sculptures, are applied over the natural fingernails and toenails (Table 153.14).

Nail sculptures are formed by mixing liquid ethyl or isobutyl methacrylate monomers with powdered polymethyl methacrylate polymer. This mixture polymerizes in the presence of a benzoyl peroxide accelerator and a formable acrylic is produced, which hardens in 7–9 minutes[81]. Usually, hydroquinone, monomethyl ether of hydroquinone, or pyrogallol is added to slow down polymerization[82].

Many patients are not aware that the finished nail sculptures require more care than natural fingernails. With continued wear of the sculpture, the acrylic loosens from the natural nail, especially around the edges. These loose edges must be clipped and new acrylic applied approximately every 3 weeks to prevent infection and onycholysis[83,84]. However, damage to the natural nail plate is inevitable with the use of nail sculptures (Fig. 153.7). After 2 to 4 months of wear, the natural nail plate becomes yellowed, dry, thin, and bendable. This is due to interference with the nail's normal vapor exchange, nail plate trauma during the removal process, and damage to the underlying nail bed[85]. For this reason, it is not advisable to wear sculptured nails for more than 3 months consecutively, allowing 1 month between applications (Fig. 153.8). Oftentimes nail sculptures are adorned with nail polishes to create special visual effects (Table 153.15).

Allergic contact dermatitis is an important dermatologic issue, since isobutyl, ethyl, and tetrahydrofurfuryl methacrylate are strong sensitizers[86,87]. However, the polymerized, cured acrylic is not sensitizing, only the liquid monomer[88]. Therefore, a careful operator who avoids skin contact with the uncured acrylic can avoid sensitizing the patient. Patch testing should be performed in suspected sensitized individuals with methyl methacrylate (2% in petrolatum) and ethyl acrylate (0.1% in petrolatum) as a screen and then, if additional analysis is required, the meth(acrylate) series for artificial nails, including 2-hydroxyethyl methacrylate (2-HEMA), 2-hydroxypropyl methacrylate (2-HPMA), and triethyleneglycol diacrylate (TREGDA). Patch tests consisting of monomers should be avoided as this may lead to sensitization[89].

HAIR CONDITIONERS		
Type	**Use**	**Indication**
Instant	Apply following shampoo; rinse	Minimally damaged hair; aids wet combing
Deep	Apply for 20–30 minutes; shampoo; rinse	Chemically damaged hair
Leave-in	Apply to towel-dried hair; style	Prevents hair-dryer or hair-straightening damage; aids in combing and styling
Rinse	Apply following shampoo; rinse	Aids in disentangling if creamy rinse; removes soap residue if clear rinse

Table 153.12 Hair conditioners.

Hydroxy Acid Cosmeceuticals

The discussion so far has focused on products intended to function purely in a cosmetic realm, yet there are cosmeceuticals in the current marketplace known as hydroxy acids. These hydroxy acids address the scaliness and roughness of aged skin that is not due to an inherently lower stratum corneum water content[90]. The roughness associated with mature skin may be due to abnormal desquamation associated with a possible failure in intercellular communication[91]. This observation has led to the enormous popularity of α- and β-hydroxy acids.

Alpha-hydroxy acids

This group of organic carboxylic acids is distinguished by a substituted hydroxy group covalently bonded to the α-carbon of a carboxylic acid. The linear, aliphatic nature of the α-hydroxy acid (AHA) structure accounts for its water-soluble or hydrophilic properties (Fig. 153.9). The three subcategories of AHA consist of: (1) monocarboxylic acids – glycolic (2-hydroxyethanoic acid), lactic (2-hydroxy-propanoic acid), and mandelic acid (2-hydroxy-2-phenylethanoic acid); (2) dicarboxylic acids – malic (2-hydroxy-1,4-butanedioic acid) and tartaric acid (2,3-dihydroxy-1,4-butanedioic acid); and (3) tricarboxylic acids – citric acid (2-hydroxy-1,2,3-propanetricarboxylic acid). The intricacies of the formulation are more important than the nature of the AHA, since the exfoliative effect is similar[92].

AHAs induce immediate epidermal effects through corneocyte disadhesion, which is thought to require disruption of ionic bonding[93,94]. The corneocyte disadhesion occurs initially in the stratum corneum at the level of the stratum granulosum; once the cutaneous barrier has been disrupted, this is followed by dermal penetration[95].

Fig. 153.6 Yellow nail staining due to wearing deeply pigmented red and orange nail polishes. This type of staining is common and reversible.

NAIL COSMETICS			
Nail cosmetic	**Main ingredients**	**Function**	**Adverse reactions**
Nail polish	Nitrocellulose, tosylamide formaldehyde resin*, plasticizers (e.g. dibutyl phthalate, camphor), solvents, colorants	Add color and shine to nail plates	Allergic contact dermatitis to tosylamide formaldehyde resin Nail plate staining
Nail hardener	Formaldehyde, acetates, acrylics or other resins	Increase nail strength and prevent breakage	Allergic contact dermatitis to formaldehyde
Nail enamel remover	Acetone, alcohol, ethyl acetate or butyl acetate	Remove nail polish	Irritant contact dermatitis
Cuticle remover	Sodium or potassium hydroxide	Destroy keratin that forms excess cuticular tissue on nail plate	Irritant contact dermatitis Paronychia
Nail bleach	Hydrogen peroxide	Remove nail plate stains	Irritant contact dermatitis
Nail white	White pigments	Whiten free nail edge	Practically none
Nail polish drier	Vegetable oils, alcohols or silicone derivatives	Speed drying time of nail polish	Practically none
Nail buffing cream	Pumice, talc or kaolin	Smooth ridges in nails	Practically none
Nail moisturizer	Occlusives, humectants, lactic acid	Increase water content of nails	Practically none

*Also referred to as toluene sulfonamide–formaldehyde resin.

Table 153.13 Nail cosmetics. A nail wrap is a thin sheet of material (e.g. linen, silk, fiberglass) that is glued to a torn or split nail plate as a means of repair.

NAIL SCULPTURE APPLICATION
Nail sculpture application is an involved process requiring approximately 2 hours to sculpt 10 fingernails. The basic process is as follows: • All nail polish and oils are removed from the nail. • The nail is roughened with a coarse emery board, pumice stone, or grinding drill to create an optimal surface for sculpted nail adhesion; this can damage the nail plate surface. • An antifungal and antibacterial liquid, such as decolorized iodine, is applied to the entire nail plate to minimize onychomycosis and paronychia. • The loose edges of the cuticle are trimmed, removed or pushed back, depending on the operator; this can lead to paronychia and nail dystrophy. • A flexible template is fitted beneath the natural nail plate, upon which the elongated sculpted nail will be built, or a preformed plastic nail tip is used for this purpose. • The acrylic is mixed and applied with a brush to cover the entire natural nail plate and extended onto the template or preformed nail tip to obtain the desired nail length. • The final sculpture is sanded to a high shine. • Nail polish, jewels, decals, decorative metal strips, or airbrushed designs may be added.

Table 153.14 Nail sculpture application. UV- or LED-cured gel-based *extensions* also contain photoinitiators. For dip powder manicures, primed nails are dipped into colored acrylic powder following by application of an activator polish which does not require UV light for curing.

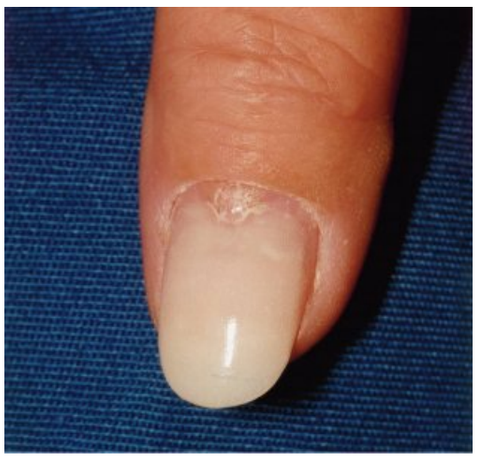

Fig. 153.7 Onychodystrophy of the central nail due to wearing a nail prosthesis. The nail prosthesis grows out with the nail plate and new polymer must be applied to the proximal nail fold. The polymer has damaged the cells of the central nail matrix.

Fig. 153.8 Continuous use of a nail prosthesis can result in dramatic nail plate damage.

NAIL POLISH – SPECIAL EFFECTS		
Special polish categories	**Technology**	**Advantages/ Disadvantages**
Polish strips	Polish applied to an adhesive layer with removable backing	No mess, must be cut to fit the nail and pressed in place
Color changing polish	Polish contains molecules that change with temperature or UV light exposure from a non-conjugated to conjugated configuration	Can be used to determine if UV light exposure has occurred/color change cannot be completely controlled
Textured polish	Polyethylene terephthalate fibers give 3D woven fiber effect or glass beads give a caviar finish	Can create unique fashion effects
Magnetic polish	Contains magnetic particles, such as iron oxide, that align when exposed to a magnetic field	Can create one-of-a-kind nail effects/metal allergy a possibility
Crackle polish	Top coat nail polish contains ethyl alcohol that evaporates rapidly creating surface tension change and crackle effect	Can create two-tone nail polish effect/less durable nail polish

Table 153.15 Nail polish – special effects. UV, ultraviolet.

CHEMICAL STRUCTURE OF GLYCOLIC ACID

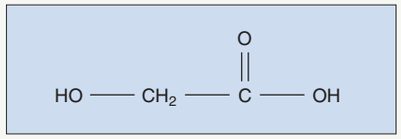

Fig. 153.9 The chemical structure of glycolic acid, accounting for its hydrophilic properties.

The epidermal effects of AHAs are a thinned stratum corneum with acanthosis and decreased melanogenesis. The dermal effects of AHAs are delayed and include increased synthesis of glycosaminoglycans, prevention of topical corticosteroid atrophy, and increased dermal thickness, possibly due to enhanced production of collagen via fibroblast proliferation, in a dose-dependent manner[96,97].

Disruption of corneocyte adhesion is ultimately valuable in a large variety of dermatologic conditions (Table 153.16)[98]. For example, AHAs can be incorporated into an acne treatment regimen, given their ability to induce epidermolysis and dislodge comedones; however, AHAs cannot enter the milieu of the pore[99]. Monthly glycolic acid peels have been shown to be of benefit in the treatment of rosacea[100]. Sloughing of corneocytes and smoothing of seborrheic keratoses, verrucae and calluses have also been reported[101,102]. Glycolic acid preparations, either formulated as topicals or short-contact peels, appear to be appropriate for both lightly and darkly pigmented skin[103]. Lastly, AHAs have been purported to function as anti-inflammatory agents and antioxidants by alleviating the erythema associated with cutaneous ultraviolet light exposure[104]. Glycolic acid appears to confer an SPF of ~2.4 to the skin[105].

Beta-hydroxy acid

A similar, but chemically different, member of the hydroxy acid family is salicylic acid (ortho-hydrobenzoic acid), the only so-called β-hydroxy acid (BHA). Salicylic acid is an organic aromatic carboxylic acid with a hydroxy group in the beta position (Fig. 153.10).

Salicylic acid is unique among the hydroxy acids, since it can enter the milieu of the sebaceous unit, inducing exfoliation in the oily areas of the face[106]. For this reason, it has been used for years as a comedolytic in over-the-counter (OTC) preparations designed to improve comedonal acne[107,108]. Salicylic acid is approved for the treatment of acne as an OTC drug, monographed by the FDA at a level of 2% or less. It is also an excellent keratolytic, inducing exfoliation of calluses, corns and warts[109]. Salicylic acid is incorporated into many shampoos designed to remove undesquamated corneocytes from the scalp of patients with seborrheic dermatitis and psoriasis[110].

Salicylic acid is thought to function through solubilization of intercellular cement, thereby reducing corneocyte adhesion. It appears to eliminate the stratum corneum layer by layer from the outermost level downward[111]. This is in contrast to the α-hydroxy acids, which appear

DERMATOLOGIC USES OF HYDROXY ACIDS AS TOPICAL PREPARATIONS AND PEELS
Skin conditions
• Photodamaged skin • Ichthyosis • Xerotic eczema • Acne • Acne rosacea • Seborrheic keratoses (improves appearance) • Actinic keratoses • Lentigines (improves appearance) • Verrucae
Cutaneous effects
• Moisturizing exfoliant • Skin peeling agent • Penetration enhancer • Preventative for corticosteroid-induced skin atrophy

Table 153.16 Dermatologic uses of hydroxy acids as topical preparations and peels.

CHEMICAL STRUCTURE OF SALICYLIC ACID

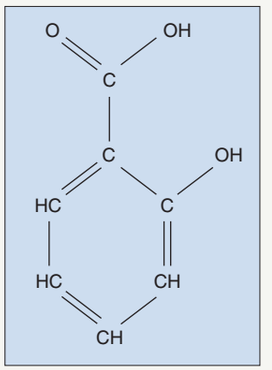

Fig. 153.10 The chemical structure of salicylic acid, accounting for its lipophilic properties.

POPULAR INGREDIENTS IN COSMECEUTICAL FORMULATIONS		
Cosmeceutical category	**Ingredient**	**Comments**
Antioxidant carotenoids	Retinol	Oxidized to retinaldehyde and then retinoic acid for activity
	Astaxanthin	Found in high concentration in salmon
	Lutein	Extensive conjugated double bonds in polyene side chain
Antioxidant flavonoids	Soy	Contains genestein and diadzein which function as phytoestrogens and protect against lipid peroxidation
	Curcumin	Active ingredient is tetrahydrocurcumin – quenches oxygen radicals and inhibits NF-κB
	Silymarin	Milk thistle plant extract; contains antioxidants silybin, silydianin, silychristin
	Pycnogenol®	French marine bark extract; contains antioxidants taxifolin, catechin, procyanidins
Antioxidant polyphenols	Green tea	Contains antioxidant polyphenols: epicatechin, epicatechin-3-gallate, epigallocatechin, epigallocatechin-3-gallate
	Pomegranate	Extract contains pantothenic acid, polyphenols
Endogenous antioxidants	Vitamin E	Primary antioxidant in skin
	Vitamin C	Secondary antioxidant in skin
	Ubiquinone (coenzyme Q10)	Tertiary antioxidant in skin
Anti-inflammatory	Aloe vera	Mucilage contains choline, choline salicylate
	Ginkgo	Contains bilobalides, ginkgolides, ginkgolic acid
Pigment lighteners	Vitamin C	May interrupt melanogenesis by interacting with copper ions
	Licorice extract	Contains liquiritin and isoliquertin, which disperse melanin, and glabridin, which inhibits tyrosinase
	Kojic acid	A hydrophilic fungal derivative; inhibits tyrosinase activity *in vitro*
	Aloesin	Naturally occurring hydroxymethylchromone; inhibits tyrosinase by competitive inhibition
	Arbutin	A naturally occurring gluconopyranoside; decreases tyrosinase activity and may inhibit melanosomal maturation
Peptides	Signal peptides	Peptides composed of amino acids attached to palmitic acid, a penetration enhancer; mimic peptides including fragments of collagens 1 and 3; an example is the palmitoylated derivative of the collagen pentapeptide Lys-Thr-Thr-Lys-Ser (Pal-KTTKS)
	Carrier peptides	Carry ingredients, such as copper (Cu), with a plasma protein fragment; an example is Gly-His-Lys (GHK)-Cu
	Neurotransmitter peptides	Purported to inhibit release of acetylcholine at the neuromuscular junction and relax muscles; an example is acetyl hexapeptide-3
Human stem cell-conditioned media	Growth factors	Growth factors (e.g. fibroblast growth factor [FGF], epidermal growth factor [EGF], keratinocyte growth factor [KGF]) released into the media of cultured neonatal foreskin fibroblasts are added to moisturizers
Microbiome ingredients	Prebiotics	Sugars (e.g. fructo-oligosaccharides [FOS], galacto-oligosaccharides [GOS]) or plant oils that promote the growth of beneficial bacteria on the skin surface
	Probiotics	Dairy propionic acid bacteria (PAB) such as lactobacilli and bifidobacteria; the bacteria are usually sonicated unless product is sold refrigerated
	Postbiotics	Non-viable bacterial products or metabolic by-products from probiotic bacteria (e.g. enzymes, peptides, peptido-glycan-derived muropeptides, polysaccharides, cell surface proteins, organic acids)

Table 153.17 Popular ingredients in cosmeceutical formulations. These are in addition to the hydroxy acids. NF-κB, nuclear factor kappa-light-chain-enhancer of activated B cells. Adapted from refs 113–117.

to diminish cellular cohesion between the corneocytes at the lowest levels of the stratum corneum. This difference is probably due in part to the water-soluble characteristics of the α-hydroxy acids, which readily penetrate into the stratum corneum, and the oil-soluble characteristics of salicylic acid, which remains on the stratum corneum.

Topical application of salicylic acid can also take the form of short-contact cutaneous peels. Salicylic acid can be used alone in concentrations of 10%–50% or combined with the α-hydroxy acid lactic acid in Jessner's solution (see Table 154.4). Salicylic acid will remain in solution at concentrations of ≤20% in 95% ethyl alcohol; however, at concentrations of 30% and above, it precipitates, necessitating shaking of the solution prior to use. In contrast to glycolic acid peels, salicylic acid is a self-neutralizing peel that ends with the formation of white salicylic acid crystals on the skin[112]. The crystals are easily rinsed from the skin surface with water, but they remain in the follicular ostia, providing a prolonged keratolytic effect.

Additional Cosmeceuticals

As a group, cosmeceuticals can offer other skin benefits in addition to those previously described for the hydroxy acids (Table 153.17; Fig. 153.11).

Fig. 153.11 Lightening of facial lentigines. **A** Numerous facial lentigines due to photodamage. **B** Lightening of lentigines after treatment with a formulation containing kojic acid, emblica extract, and glycolic acid.

FUTURE DIRECTIONS

Improved understanding of the physiology of the stratum corneum is leading to new dermatologic developments within the realm of cosmetics and skin care products. This has spurred the growth in cosmeceuticals that promise to improve cutaneous function and enhance appearance. In addition, technology that was originally developed for skin keratin can be directly transferred to hair and nail keratin. Future research will undoubtedly explore methods of preventing cutaneous inflammation, which represents a common thread between dermatologic disease and potential adverse effects of cosmetics.

Chemical and Mechanical Skin Resurfacing 154

Gary D. Monheit and Katherine Hrynewycz

Chapter Contents

Preoperative History and Considerations *2633*
Chemical Resurfacing Procedures *2636*
Mechanical Resurfacing Procedures *2643*
Postoperative Care *2646*
Complications *2647*

Synonyms: ■ Chemical resurfacing: chemical peeling, chemexfoliation ■ Mechanical resurfacing: dermabrasion (includes dermasanding) ■ Jessner's peel: Combes' peel ■ Baker–Gordon peel: deep phenol peel ■ Microneedling: percutaneous collagen induction

Key features

- Chemical peeling, dermabrasion, and laser ablation are the three main methods of skin resurfacing
- Chemical and mechanical resurfacing procedures have a long history of safety and efficacy in ameliorating various skin conditions and improving cutaneous photoaging
- Resurfacing procedures represent one part of a comprehensive skin care program that should include photoprotective measures and topical medical and/or cosmeceutical agents
- Each resurfacing procedure injures the skin to a specific depth to promote the regrowth of new skin with improved surface characteristics
- The degree of clinical improvement, the length of the recovery period, and the risk of complications are all proportionate to the depth of tissue injury chosen and skin type
- Selection of suitable patients and proper choice of resurfacing procedure are critical to success
- Both dermabrasion and the "TCA CROSS" technique are methods for treating acne scars
- Microdermabrasion and microneedling are additional approaches for facial rejuvenation
- Prolonged erythema, pigmentary or textural irregularities, infection, delayed healing, and scarring are potential complications of resurfacing
- Resurfacing procedures are a rewarding part of dermatologic practice, both for the patient and for the physician

INTRODUCTION AND HISTORY

Resurfacing procedures to improve the health and appearance of the skin have been utilized by humans for thousands of years. The ancient Egyptians applied various chemicals to the skin and may have even used abrasives like sandpaper to obtain a smoother skin surface[1,2]. Resurfacing methods within the practice of dermatology were initially described over 100 years ago. Early on, chemical cauterants were used primarily for proliferative lesions and skin disorders, with pioneers such as Hebra and Jessner discovering the usefulness of acidic and basic compounds for skin exfoliation. Over the past several decades, the role of chemexfoliation has expanded dramatically to include textural and cosmetic revisions. Our society's increasing emphasis on a youthful image and aesthetic appearance has resulted in an explosion in public demand for commercial skin care products, professional assistance from physicians and non-physicians to assure proper medical and cosmeceutical skin therapy, and procedural intervention. However, the development and application of safe and effective procedures needs to be based upon sound reproducible data.

All ablative resurfacing procedures injure the skin, in a controlled fashion, to a specific depth and thereby promote the growth of new skin with improved surface characteristics. The three fundamental methods used to create this controlled injury are chemical resurfacing (chemical peeling), mechanical resurfacing (motorized dermabrasion or manual dermasanding), and laser resurfacing (see Ch. 137). Chemical resurfacing entails the application of acidic or basic abrasive chemical substances that can destroy selective levels of the epidermis or dermis. Mechanical resurfacing involves smoothing the skin surface with an abrasive surface which physically removes portions of the epidermis and dermis.

In general, skin resurfacing procedures can be classified as superficial, medium-depth, or deep, according to their level of injury (Table 154.1). Skin resurfacing is usually performed only on the face and neck, in part because of the critical aesthetic value of this area. Caution must be exercised in treating the neck, arms, and trunk due to a propensity for complications; only superficial procedures should be performed on the lower one-third of the neck and other non-facial areas. Resurfacing of sites such as the hands and arms has yielded less predictable and less impressive results as well as a higher risk for scarring.

In comparison to the other resurfacing modalities available for skin rejuvenation, chemical resurfacing probably has the longest and most well-documented history[1]. Experimentation with various peeling compounds in the late nineteenth and early twentieth centuries led to sporadic reports in the medical literature describing their use. The initial reports were met with skepticism, but further investigation by both dermatologists and plastic surgeons verified their effectiveness in facial skin rejuvenation and as a treatment for skin disorders. Subsequently, chemical peeling experienced a tremendous growth in popularity and has become an important part of our armamentarium in the management of various cosmetic as well as non-cosmetic skin problems. Currently, chemical peeling is the third most commonly employed cosmetic procedure, after injectable neurotoxins and soft tissue fillers.

Since Kromayer's original report of motorized dermabrasion in 1905, there has been considerable growth not only in chemical resurfacing procedures, but also in mechanical resurfacing. Mechanical resurfacing is most often known as dermabrasion, but it refers to any procedure that involves surgical planing of the skin using an abrasive surface. The use of dermabrasion was originally limited to the treatment of scars, but its role expanded during the latter half of the twentieth century to include a multitude of indications including improvement of elevated skin grafts and rejuvenation of photodamaged skin[2]. Recent adaptations of the traditional techniques of dermabrasion have led to the development of a less invasive procedure, known as microdermabrasion[3]. Dermasanding, which is a manual technique of dermabrasion utilizing abrasive paper, has been in use for centuries, but recently has experienced a resurgence[4,5]. Although overshadowed by ablative and non-ablative laser resurfacing (see Ch. 137), mechanical resurfacing procedures remain a popular option for both patients and physicians.

PREOPERATIVE HISTORY AND CONSIDERATIONS

Indications

The preoperative consultation is important in identifying at-risk patients who are best avoided or who require an extra-cautious approach, as well

CLASSIFICATION OF ABLATIVE SKIN RESURFACING METHODS
Superficial – very light
• Low-potency formulations of glycolic acid or other α-hydroxy acids • 10%–20% TCA (weight-to-volume formulation) • Tretinoin • 20% salicylic acid • Jessner's solution (see Table 154.4)
• Microdermabrasion
Superficial – light
• 50%–70% glycolic acid • Jessner's solution (greater number of coats than for very light peel) • 25%–30% TCA • Solid CO_2 slush • 30% salicylic acid
• Microdermabrasion
Medium-depth
• Jessner's–35% TCA (most popular combination) • 70% glycolic acid – 35% TCA • Solid CO_2–35% TCA (most potent combination) • 40% TCA (not recommended) • 88% phenol (rarely used)
• Conservative manual dermasanding • Erbium:YAG laser resurfacing • Conservative fractional CO_2 laser resurfacing • Ablative fractional erbium:YAG laser resurfacing
Deep
• Unoccluded or occluded Baker–Gordon phenol peel (see Table 154.6) • TCA in concentrations >50% (not recommended)
• Wire-brush or diamond-fraise dermabrasion • Aggressive manual dermasanding • Manual dermasanding or motorized dermabrasion after a medium-depth peel • Aggressive erbium:YAG laser resurfacing • CO_2 laser resurfacing • Combination erbium:YAG/CO_2 laser resurfacing • Ablative fractional CO_2 laser resurfacing

Table 154.1 Classification of ablative skin resurfacing methods. Although this classification represents an oversimplification because the depth of injury actually varies somewhat along a continuum for each different type of resurfacing procedure, it is helpful when discussing the various options with a patient. The lighter shade represents chemical methods and the darker shade mechanical methods. TCA, trichloroacetic acid.

MAJOR INDICATIONS FOR CHEMICAL AND MECHANICAL SKIN RESURFACING
• Actinically damaged skin and rhytides • Scarring • Multiple pre-neoplastic or neoplastic epidermal lesions (e.g. actinic keratoses, lentigines) • Acne, rhinophyma • Pigmentary dyschromias (including tattoos) • Demarcation lines secondary to other resurfacing procedures

Table 154.2 Major indications for chemical and mechanical skin resurfacing.

CONTRAINDICATIONS TO CHEMICAL AND MECHANICAL SKIN RESURFACING
Absolute
• Poor physician–patient relationship • Lack of psychological stability and mental preparedness • Unrealistic expectations • Poor general health and nutritional status • Isotretinoin therapy within the last 6 months*,† • Complete absence of intact pilosebaceous units on the face • Active infection or open wounds such as HSV, excoriations, or open acne cysts
Relative
• Medium-depth or deep resurfacing procedure within the last 3–12 months* • Recent facial surgery involving extensive undermining, such as a rhytidectomy* • History of abnormal scar formation or delayed wound healing • History of therapeutic radiation exposure • History of certain skin diseases (e.g. rosacea, seborrheic dermatitis, atopic dermatitis, psoriasis, vitiligo) or active retinoid dermatitis • Fitzpatrick skin types IV, V and VI*
*These contraindications apply only to medium-depth and deep resurfacing procedures. †General consensus for mechanical dermabrasion and fully ablative laser surgery.

Table 154.3 Contraindications to chemical and mechanical skin resurfacing. HSV, herpes simplex virus.

as in selecting patients who are ideal candidates for intervention. The dermatologist must evaluate the prospective patient and his or her skin condition carefully, in order to determine if a chemical or mechanical resurfacing procedure is indicated. When resurfacing is deemed appropriate, selection of the proper procedure for each patient is critical to assure that the desired results are achieved in a safe and effective manner. The depth of the injury that must be created by resurfacing to achieve significant improvement is related to the degree of skin surface irregularities and their depth. There are six major indications for resurfacing (Table 154.2).

Pre-neoplastic or neoplastic skin lesions can certainly be removed or improved with resurfacing procedures. Those originating in the epidermis, such as actinic keratoses, lentigines, and seborrheic keratoses are more amenable to treatment than those with a dermal extension or origin. Although some dermatologic conditions may be aggravated by resurfacing, acne and pigmentary dyschromias such as melasma respond favorably to superficial chemical peeling or microdermabrasion, especially when accompanied by appropriate cosmeceutical products and sunscreens. Another indication for chemical and mechanical skin resurfacing is to blend the effects of other procedures, e.g. ablative laser resurfacing of periocular or perioral rhytides, by preventing or eliminating lines of demarcation.

Photoaging is probably the single condition for which skin resurfacing procedures are most often performed. For patients with photoaging, the Glogau system (see Ch. 152) is helpful in deciding upon the most appropriate skin rejuvenation program. It classifies patients into one of four groups based on degree of severity. Patients in category I are often young with minimal to mild photoaging and are best managed with superficial chemical peels or microdermabrasion in conjunction with topical medications or cosmeceuticals (e.g. retinoids, glycolic acids, exfoliants, antioxidants, vitamin C, vitamin E). Patients in category II would likely benefit from a medium-depth chemical peel as well as long-term medical therapy to include a retinoid and/or an α-hydroxy acid (AHA). Individuals in category III typically need prolonged medical treatment in conjunction with one of the following: a medium-depth chemical peel (with or without dermasanding), a deep chemical peel, dermabrasion, or laser resurfacing. For patients with category IV photoaging, interventions utilized for category III individuals are also recommended, but the addition of an invasive surgical operation such as a rhytidectomy or blepharoplasty is often required to achieve the desired results. Nowadays, reconstruction of facial form and correction of deep furrows with injectable neurotoxins and soft tissue fillers is such that resurfacing techniques represent a final stage in the combination approach to facial rejuvenation (see Chs. 158 and 159).

Contraindications and Patient Selection

When evaluating a patient for chemical or mechanical resurfacing, a careful history and physical examination are important to assess the skin problems which prompted his or her presentation and to identify any factors that may contribute to intraoperative or postoperative difficulties (Table 154.3). It is best not to inject soft tissue fillers on the same day as a chemical peel. The patient should also be asked about prior resurfacing procedures, rhytidectomy (facelift), or oral isotretinoin therapy within the last six months, as these can increase the risk of complications following medium-depth and deep resurfacing[6,7].

Although some clinicians no longer require a six-month waiting period post isotretinoin administration, the authors still adhere to this recommendation. Any history of abnormal scar formation or therapeutic radiation exposure warrants extreme caution when considering a patient for skin resurfacing. Individuals with prior radiation exposure should be examined closely for the presence of intact facial hair to ensure that there are enough pilosebaceous units to promote re-epithelialization[8].

Another important element of the patient's history is the presence or absence of a prior herpes simplex viral (HSV) infection. Because recurrence of oral HSV can be triggered by a resurfacing procedure, especially in the perioral and periorbital regions, antiviral therapy (e.g. valacyclovir) is administered prophylactically (see below). Risk factors for HIV infection or viral hepatitis should be identified, and in the authors' opinion, routine laboratory screening is recommended in individuals undergoing dermabrasion with a powered engine. A history of abnormal wound healing from trauma or previous procedures, such as hypertrophic scarring or dyschromia, may be a contraindication to peeling or dermabrasion. The general health and nutritional status of the patient is also an important consideration, especially for medium-depth and deep resurfacing procedures, to ensure timely and complete healing.

Patients with certain cutaneous disorders, such as rosacea, seborrheic dermatitis, atopic dermatitis, psoriasis or vitiligo, may be at increased risk for postoperative complications, including disease exacerbation, prolonged erythema, contact dermatitis, or even delayed healing. In particular, individuals with rosacea have vasomotor instability and may develop an exaggerated inflammatory response to the resurfacing procedure. Caution should also be exercised for patients with autoimmune connective tissue diseases, including cutaneous lupus and systemic sclerosis, as the trauma of chemical peeling may exacerbate the disease. Evaluation of the patient's Fitzpatrick skin type (see Ch. 0) is helpful in predicting the chance of postoperative hyper- or hypopigmentation. Individuals with Fitzpatrick skin types I or II are at low risk for dyspigmentation after medium-depth or deep resurfacing, whereas those with types III through VI are at greater risk for these complications[9].

The patient should understand that chemical and mechanical resurfacing procedures cannot reliably reduce pore size, and their ability to improve lax skin or deeper wrinkles and scars is limited and depends upon the type of intervention being performed. While dermabrasion may sometimes eliminate telangiectasias, chemical peels cannot accomplish this and can even unmask them by removing the pigmentary irregularities. The patient must fully understand the potential benefits, limitations and risks of the procedure, and an informed consent must be signed.

A test spot (e.g. along the lateral hair line) may be useful in some patients to assess their suitability for resurfacing and may be particularly helpful when there is a great deal of concern about the chances of postoperative pigmentary dyschromias[10]; test spots are definitely recommended for individuals with skin types III–VI. Of note, while a favorable test spot result does not guarantee a positive outcome following full-face resurfacing, an unfavorable test spot result is useful in identifying high-risk patients. The latter include those at risk for postinflammatory hyperpigmentation, spotting, irregular coloration, hypopigmentation, or poor or delayed healing. If the dermatologist feels any uncertainty about the patient's suitability or the likelihood of a favorable result, the procedure should not be performed.

Pre-treatment photographs – full-face frontal, lateral and oblique views as well as problem areas – are essential for documenting baseline appearance. They also allow for accurate assessment of postoperative improvement.

Preoperative and Intraoperative Preparations

Another purpose of the preoperative consultation is to ensure that the patient is adequately prepared for the procedure. Almost every patient desiring facial rejuvenation for cutaneous photoaging would benefit from botulinum toxin injections to alleviate dynamic wrinkles (see Ch. 159). These injections appear to enhance the results of deeper resurfacing procedures by immobilizing the muscles implicated in the development of dynamic rhytides during the critical time of postoperative collagen remodeling. In patients with photoaging, it is recommended that botulinum toxin injections be administered as an adjunctive therapy at least 3 days prior to medium-depth or deep chemical peels, dermabrasion, or laser resurfacing.

Due to the significant morbidity associated with herpetic infections during the healing period, patients who undergo medium-depth or deep resurfacing (see Table 154.1) should be treated prophylactically with an antiviral agent, regardless of whether there is a history of HSV infections[11]. These drugs are not routinely given to patients having a superficial chemical peel or microdermabrasion, because the injury is generally not sufficient to activate the virus. However, preventive therapy may be considered in conjunction with superficial resurfacing in patients with a strong personal history of recurrent HSV infections. Recommended prophylaxis consists of acyclovir 400 mg three times daily, valacyclovir 500 mg twice daily or famciclovir 250 mg twice daily, beginning on the day of the procedure. It is advisable to administer the drug for at least 10 to 14 days thereafter[12]. The reason for such a long duration of therapy is that viral replication is possible only in intact epidermal cells, making clinical infection unlikely during the first few days postoperatively. The risk of an eruption increases dramatically with the onset of re-epithelialization and remains high until healing is complete.

It is important that the patient adhere to a strict skin care regimen during the immediate preoperative and postoperative periods to achieve optimal results. The authors treat patients with topical tretinoin on a nightly basis prior to the procedure. Retinoids increase epidermal proliferation and presumably lead to more rapid re-epithelialization after the chemical peel. Because of the tendency for retinoids to cause irritation within 1 to 2 weeks of starting therapy (i.e. retinoid dermatitis), a retinoid formulation with lower irritation potential should be used in patients with sensitive skin. The retinoid should be discontinued one week prior to the chemical peel. In patients with active retinoid dermatitis, resurfacing should be delayed because this condition may lead to a prolongation in postoperative erythema. Decreasing the frequency of application or switching to a less irritating retinoid will allow the inflammation to subside, so that the procedure can be performed[13].

All-*trans*-retinoic acid, or tretinoin, has been classified as a superficial chemical peeling agent, but it is best considered as an integral component of a complete skin rejuvenation program. With chronic use, this drug has been shown to improve actinically damaged skin both clinically and histologically[14]. The use of tretinoin prior to chemical peeling, dermabrasion, or laser resurfacing speeds epidermal healing and enhances the effects of the procedure[13,14]. For chemical peels in particular, use of preoperative topical tretinoin to reduce areas of hyperkeratosis and decrease the thickness of the stratum corneum allows for greater penetration of the peel solution, resulting in a more homogeneous peel and a deeper peel. Use of tretinoin is restricted, however, during the postoperative healing period, until there is diminished inflammatory erythema and complete re-epithelialization with a fully mature epidermis.

Hydroquinone inhibits the enzyme tyrosinase and can reduce the production of epidermal melanin during the healing phase. Patients with skin type III or higher may benefit from twice-daily application of 2% to 4% topical hydroquinone during the preoperative and postoperative (post-healing) periods – even if there is no history of pigmentary abnormalities[9]. It is also necessary to use hydroquinone in patients of any skin type when peeling is done to treat pigmentary dyschromias such as melasma or postinflammatory hyperpigmentation[9]. While a Wood's lamp was used in the past to localize melanin pigment to either the epidermis or dermis (i.e. epidermal versus dermal melasma), histopathologic studies and confocal microscopy have shown that there is often a mixture of the two forms in an individual patient. Nonetheless, in both melasma and postinflammatory hyperpigmentation, increased melanin within the epidermis responds better to superficial peels than does dermal pigment. The use of non-inflammatory peeling agents, e.g. salicylic acid, is preferred for disorders such as melasma as there is less tendency for postinflammatory hyperpigmentation (Fig. 154.1).

All patients undergoing any type of skin resurfacing procedure must adhere to strict photoprotective measures during the postoperative period. This issue is critical in patients whose Fitzpatrick skin type is III or higher, in patients with pigmentary abnormalities, in patients taking exogenous estrogens, and in all patients having medium-depth or deep resurfacing. Specific methods to minimize sun exposure and proper use of sun blocks should be discussed. Patients are also counseled to avoid tobacco use, as smoking in the postoperative period may interfere with the healing process, thereby limiting the effectiveness of the resurfacing and increasing the risk of poor wound healing.

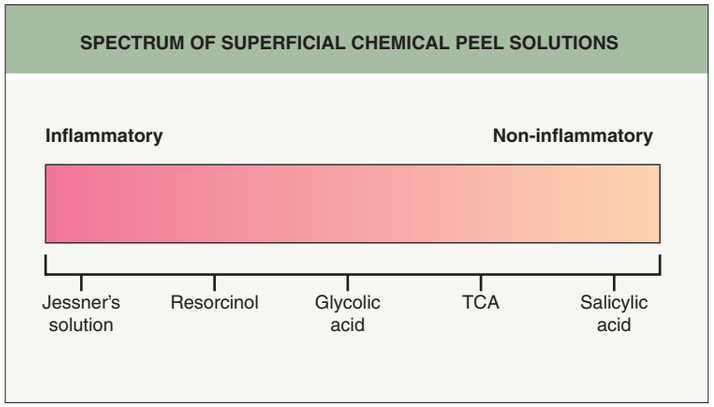

Fig. 154.1 Spectrum of superficial chemical peel solutions. Inflammatory chemical peel solutions are used primarily for photoaging, while non-inflammatory chemical peel solutions are best for Fitzpatrick skin types III–VI, melasma, and postinflammatory hyperpigmentation. TCA, trichloroacetic acid.

The need for intraoperative sedation and analgesia is also discussed with the patient preoperatively, so that plans are made accordingly. Superficial resurfacing procedures usually require only "talkesthesia," a technique that is extremely helpful in awake patients undergoing a procedure, i.e. talking calmly to the patient with encouragement during the procedure. Medium-depth chemical or mechanical resurfacing usually requires a limited degree of perioperative sedation and analgesia, which may include the application of topical amide anesthetics and regional blocks of the supraorbital, infraorbital, and mental nerves (see Ch. 143), as well as oral diazepam, intramuscular meperidine hydrochloride, and/or intramuscular hydroxyzine hydrochloride. Although deep resurfacing procedures can be accomplished entirely with nerve blockade, local injections of lidocaine, and mild sedatives, some patients require intravenous or general (endotracheal tube) anesthesia. Application of the tumescent technique (see Ch. 156) to resurfacing has allowed many patients to undergo deep resurfacing procedures without the additional risks of intravenous or general anesthesia[15]. The patient's inherent pain tolerance, level of anxiety, concomitant medical conditions, and willingness to pay the extra costs of heavier sedation are important topics to discuss during the preoperative consultation that is used to plan for appropriate anesthesia.

Preoperatively, the patient must be given specific instructions to follow, both for the day of the procedure and for postoperative care. These should be carefully reviewed verbally prior to the procedure, with the same instructions provided in written form. On the day of the procedure, the patient washes his or her face with a gentle cleanser and preferably avoids the application of any cosmetics. Individuals undergoing procedures requiring minimal or no sedation are encouraged to eat a light breakfast, but patients receiving deeper anesthesia should have nothing by mouth except for their usual medications. Particularly for medium-depth and deep resurfacing procedures, the dermatologist should meet with the patient and his or her family preoperatively to re-establish rapport, answer last-minute questions, discuss perioperative and postoperative expectations and instructions, and assure compliance with antiviral prophylaxis as needed.

CHEMICAL RESURFACING PROCEDURES

Although there is currently a wide variety of resurfacing procedures available for facial rejuvenation, chemical peeling remains a popular choice for both patient and physician. In comparison to some of the newer options, chemical peels have a longstanding safety and efficacy record, are performed with ease, are low in cost, and have a predictable and relatively quick recovery time. Various acidic and basic compounds are used to produce a controlled skin injury and are classified as superficial, medium-depth, and deep peeling agents, according to their level of penetration, destruction, and inflammation (see Table 154.1). In general, superficial peels cause epidermal injury and occasionally extend into the papillary dermis, medium-depth peels cause injury through the papillary dermis to the upper reticular dermis, and deep peels cause injury down to the mid-reticular dermis[16].

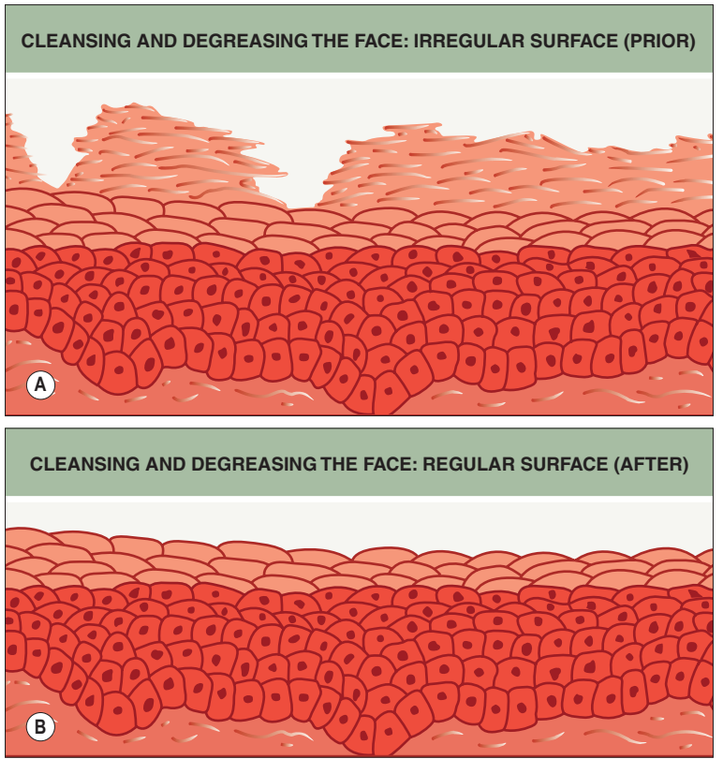

Fig. 154.2 Cleansing and degreasing the face. A Irregular surface (prior). **B** Clean, regular surface (after).

Prior to the application of peeling solutions, the skin surface must be vigorously cleansed to remove residual oils, debris, and excess stratum corneum. The authors use gauze pads with an effective detergent cleanser, followed by rinsing with water and drying. Because of the defatting and degreasing properties of acetone, gauze pads moistened with an acetone preparation are then used to cleanse the skin even further. Finally, the cleansed skin is palpated immediately prior to peeling to check for the presence of residual oil and if any is felt, the process is repeated. *The importance of cleansing prior to the peeling procedure cannot be overemphasized*. A thorough and evenly distributed cleansing and degreasing of the face assures uniform penetration of the peeling solution and leads to an even result without skipping areas (Fig. 154.2).

The effect of a chemical peel is dependent upon the agent used, its concentration, and the techniques employed before and during its application. Each wounding agent used in peels has unique chemical properties and causes a specific pattern of injury to the skin[15–20]. It is important for the physician using these solutions to be familiar with their cutaneous effects and proper methods of application, to assure correct depth of injury. The marketplace has been flooded with numerous proprietary formulations of peeling agents with each product claiming unique advantages. These products are often expensive and have not been shown to be safer or more effective than the conventional solutions. Their advantage rests in the prepackaging of materials and ease for the physician. The following discussion on superficial, medium-depth, and deep peeling will therefore focus on the specific chemical agents that are responsible for producing the various patterns of injury rather than proprietary products.

Superficial Chemical Peeling

Superficial chemical peels are indicated in the management of acne and its postinflammatory sequelae, mild photoaging (Glogau I and II), and epidermal lesions such as lentigines and keratoses, as well as melasma and other pigmentary dyschromias[21]. A series of peels is usually necessary to obtain optimal results[22]. The frequency of peels and degree of exposure to the peeling agent may be increased gradually as necessary. Results are enhanced by medical or cosmeceutical therapy, including a retinoid, antioxidants and, if necessary, a bleaching agent. All superficial chemical peels share the advantages

JESSNER'S SOLUTION (COMBES' FORMULA)	
Resorcinol	14 g
Salicylic acid	14 g
85% lactic acid	14 g
95% ethanol (q.s.ad)	100 ml

Table 154.4 Jessner's solution (Combes' formula). q.s.ad, a sufficient quantity up to.

of only mild stinging and burning during application as well as minimal time (a few days) needed for recovery.

Superficial chemical peels are divided into two varieties – very light and light (see Table 154.1). With *very light* peels, the injury is usually limited to the stratum corneum and only creates exfoliation; however, the injury may extend into the stratum granulosum. The agents used for these peels include low-potency formulations of glycolic acid, 10%–20% trichloroacetic acid (TCA), tretinoin, 20% salicylic acid, and Jessner's solution (Table 154.4)[23–25]. *Light* peels injure the entire epidermis down to the basal layer, stimulating the regeneration of a fresh new epithelium. Agents used for light peels include 50%–70% glycolic acid, 25%–30% TCA, Jessner's solution (greater number of coats than for very light peels), 30% salicylic acid, and solid CO_2 slush[23,24]. During the application of superficial peeling agents, there may be mild stinging followed by a level I frosting, defined as the appearance of erythema and streaky whitening on the surface (Fig. 154.3).

Alpha-hydroxy acids (AHAs) are naturally found in foods and have been used widely in skin rejuvenation regimens since the early 1990s. The depth of injury is determined by the specific AHA used, its pH, the concentration of free acid, the volume applied to the skin, and the duration of contact. In low concentrations, AHAs have been shown to decrease the cohesion of corneocytes at the junction of the stratum corneum and the stratum granulosum[26]. Higher concentrations are associated with complete epidermolysis. With chronic use of AHA-containing products on a daily basis, there is an increase in skin thickness, acid glycosaminoglycans (mucopolysaccharides), and the density of collagen, as well as an improvement in elastic fiber quality[19]. The most popular of the AHAs, **glycolic acid**, is available in a variety of over-the-counter preparations and can be purchased by physicians in buffered as well as unbuffered concentrations as high as 70% for chemical peels. Twice monthly or every other week applications of 40%–70% glycolic acid (with cotton swabs, a sable brush, or 2×2-inch gauze pads) have been used most often for acne, mild photoaging, and melasma[27]. The time of application is critical for glycolic acid, as it must be rinsed off with water or neutralized with 5% sodium bicarbonate after 2 to 4 minutes. It is the only peeling agent that is time-dependent, requiring neutralization to end its action.

Application of 10%–20% **TCA** with either a saturated gauze pad or sable brush produces erythema and a very light frost within 15 to 45 seconds. The depth of penetration of the peeling solution is related to the number of coats applied. Epidermal protein denaturation results in exfoliation without vesiculation. Concentrations of TCA up to 25% can be used alone as a superficial peeling agent but may create an injury and inflammation that extends partially into the upper dermis. **Jessner's solution** is a combination of keratolytic ingredients that has been used for over 100 years in the treatment of inflammatory and comedonal acne as well as hyperkeratotic skin disorders (see Table 154.4). Jessner's solution has intense keratolytic activity, initially causing loss of corneocyte cohesion within the stratum corneum and subsequently creating intercellular and intracellular edema within the upper epidermis if application is continued[28]. The mode of application for the Jessner's peel is similar to that of the 10%–20% TCA peel. The clinical endpoint of treatment is erythema with blotchy frosting (when used prior to application of TCA in medium-depth peels) or a more uniform frosting (when used alone for superficial peels). While Jessner's peel can be used in extrafacial sites, care must be taken to restrict the total amount of peel solution, as salicylic acid is absorbed systemically.

Salicylic acid, also referred to as a β-hydroxy acid, is one of the ingredients in Jessner's solution. It can be used alone for superficial chemical peeling and is a preferred therapy for comedonal acne and inflammatory rosacea as it is lipophilic and concentrates within the pilosebaceous apparatus (Fig. 154.4)[25]. Salicylic acid is quite effective as an adjunctive therapy for both open and closed comedones and for resolving post-acne erythema. As noted previously, salicylic acid produces less inflammation than other superficial peeling agents (see Fig. 154.1) and therefore is associated with a lower risk of postinflammatory hyperpigmentation. Salicylic acid is the preferred peeling agent for removing the excess pigmentation in melasma and postinflammatory hyperpigmentation. It is safer and more effective in reducing epidermal pigment, especially when combined with a bleaching agent (e.g. hydroquinone) and sunscreens.

Fig. 154.3 Levels of frosting. A Level I frosting as found with light chemical peeling: erythema with streaky frosting. **B** Level II frosting: erythema with diffuse white frosting. **C** Level III frosting: solid white enamel frosting.

Fig. 154.4 Salicylic acid peels. These peels are effective for the treatment of acne, including comedones. Repetitive peels over 6 weeks combined with medical acne treatment will hasten resolution of the condition. Note the perifollicular frosting seen with salicylic acid, a lipophilic chemical.

Prior to the initial treatment, the patient must understand that the net effect of repetitive superficial chemical peels never approaches the beneficial effect obtained with a single medium-depth or deep peel. The improvements in cutaneous photoaging following superficial peels are usually subtle because there is little to no effect on the dermis. These peels thus cannot produce an appreciable effect on textural changes such as deep wrinkles and furrows, which originate within the dermis. Nonetheless, their ease of use and minimal downtime makes these "lunchtime" peels rewarding for patients with realistic expectations and are a favorite of busy patients. Superficial peels are best employed in combination with cosmeceutical agents and other minimal- to no-downtime procedures such as botulinum toxin A injections, microneedling, and intense pulsed light treatments. Desired and expected results include a "brightened" skin appearance with a more uniform color and texture.

Medium-Depth Chemical Peeling

Medium-depth chemical peels consist of controlled damage through the epidermis and into the papillary dermis, with variable extension to the upper reticular dermis. Both medium-depth and deep chemical peels produce epidermal necrosis plus papillary dermal edema and homogenization with a sparse lymphocytic infiltrate within the first several days[15]. Postoperatively, over a period of 3 months, there is increased collagen production with expansion of the papillary dermis and the development of a mid-dermal band of thicker collagen fibers. These changes correlate with the clinical improvement in texture, fine lines, and color observed over time (Fig. 154.5).

For many years, 40%–50% TCA was the prototypical medium-depth peeling agent because of its ability to ameliorate fine wrinkles, actinic changes, and "pre-neoplasias". TCA as a single agent for medium-depth peeling has fallen out of favor because of the high risk of complications, especially scarring and pigmentary alterations, when used in strengths approaching 50% and higher[29]. Today, most medium-depth chemical peels are performed utilizing 35% TCA in combination with Jessner's solution, 70% glycolic acid, or solid CO_2 as the "priming" agent. These combination peels have been found to be as effective as 50% TCA alone, but safer with fewer risks[30]. The level of penetration is better controlled with these combination peels, thereby preventing the "hot spots" seen with higher concentrations of TCA that can produce dyschromia and scarring.

Brody and Hailey[31] developed the use of solid CO_2 to freeze the skin prior to the application of 35% TCA. This causes epidermal necrosis and significant dermal edema, thereby allowing deeper penetration of the TCA in selected areas. This technique is particularly useful for effacing the edges of mild acne scars and destroying thicker epidermal growths. Monheit[28] then described a combination medium-depth peel in which Jessner's solution is first applied, followed by 35% TCA, with comparable clinical results. Similarly, Coleman and Futrell[32] have demonstrated the usefulness of 70% glycolic acid prior to the application of 35% TCA for medium-depth peeling. Jessner's solution and glycolic acid both appear to effectively weaken the epidermal barrier and allow deeper, more uniform and more controlled penetration of 35% TCA.

Current indications for medium-depth chemical peeling include Glogau group II cutaneous photoaging, epidermal lesions such as actinic keratoses, pigmentary dyschromias, and mild acne scarring, as well as blending of the effects of deeper resurfacing procedures. The most popular of the medium-depth peels for facial rejuvenation is the Jessner's–35% TCA peel. This peel has been widely accepted because of its broad range of uses, the large number of individuals in whom it is indicated, its ease of modification according to the patient or situation, and its excellent safety profile.

The Jessner's–35% TCA peel is particularly useful for the improvement of mild to moderate photoaging (Fig. 154.6). It freshens sallow, atrophic skin and softens fine rhytides, with minimal risk of textural or pigmentary complications. Collagen remodeling occurs for as long as 3 to 4 months postoperatively during which time there is continued improvement in texture and rhytides. Deep furrows, however, are not eliminated with this peel and there is no significant skin retraction as is seen with ablative fractional laser resurfacing or deep chemical peels. When used in conjunction with a retinoid, bleaching agent, and sunscreens, a single Jessner's–35% TCA peel lessens pigmentary dyschromias and lentigines more effectively than repetitive superficial peels. Epidermal growths such as actinic keratoses

Fig. 154.6 Medium-depth chemical peel used to treat moderate photoaging of the skin. A Preoperative, demonstrating actinic keratoses plus aging textural changes. **B** Application of 35% trichloroacetic acid (TCA) directly after Jessner's solution. **C** White enamel frosting (level III) from 35% TCA. **D** Desquamation and inflammation 4 days after peel. **E** Final results 6 months later.

also respond well to this peel. In fact, the Jessner's–35% TCA peel has been found to be as effective as topical 5-fluorouracil in removing both grossly visible and clinically undetectable actinic keratoses while having the added advantages of lower morbidity and greater improvement in associated photoaging[33,34].

Another indication for the Jessner's–35% TCA peel is to blend the effects of other resurfacing procedures with the surrounding skin[35]. Patients who have undergone ablative fractional CO_2 laser resurfacing, deep chemical peeling or dermabrasion to a localized area such as the periorbital or perioral region often develop a sharp line of demarcation between the treated and untreated skin. The treated skin may appear hypopigmented (also known as pseudohypopigmentation) in comparison to the untreated photodamaged skin. These irregularities are often conspicuous and are troubling to the patient. A Jessner's–35% TCA peel performed on the adjacent untreated skin helps to blend the treated area into its surroundings. For example, a patient with advanced photoaging in the periorbital region and moderate photoaging on the remaining face may desire fractional CO_2 laser resurfacing only around the eyes. In this patient, medium-depth chemical peeling of the areas not treated with the laser would improve the photoaging in these regions and avoid a line of demarcation[36] (Fig. 154.7). Similarly, a patient with acne or surgical scars having spot or regional dermabrasion or ablative fractional laser resurfacing to a facial cosmetic unit would benefit from a Jessner's–35% TCA peel to the remainder of that cosmetic unit or to the rest of the face. It is important to note that when used in combination with other resurfacing procedures such as laser ablation or dermabrasion, the peel should be performed first, in order to avoid accidental application of the peeling agent onto previously abraded or laser-treated areas, which may lead to scarring (Fig. 154.8).

Using either cotton-tipped applicators or gauze pads, a single, even coat of Jessner's solution is applied first to the forehead, then the cheeks, nose and chin, and, lastly, the eyelids. Proper application of Jessner's solution causes minimal discomfort and creates a faint frost within a background of mild erythema (Fig. 154.9A)[37]. After waiting 1 to 2 minutes for the Jessner's solution to completely dry, 35% TCA is applied evenly with one to four cotton-tipped applicators (Fig. 154.9B). The ultimate effectiveness of this peel is directly dependent upon the depth of penetration of the peeling solutions, and this depth is a function of the adequacy of degreasing and the amount of both solutions applied. The use of cotton swabs, particularly for the application of TCA, is advantageous because it allows the surgeon to quantitatively vary the amount of solution applied according to the patient's specific needs. *The amount of TCA delivered to the skin surface is determined by the number of applicators used, their degree of saturation, the amount of pressure applied to the skin surface, and the duration of their contact with the skin*. Four moist cotton-tipped applicators are applied in broad strokes over the forehead and on the medial cheeks. Two mildly soaked cotton-tipped applicators can be used across the lips and chin, and one damp cotton-tipped applicator on the eyelids (Fig. 154.9C). In addition to location, these parameters are varied based on skin thickness and degree of photodamage.

When applying TCA, anatomic areas of the face are peeled sequentially from the forehead to the temple to the cheeks and finally to the lips and eyelids. Careful feathering of the solution into the hairline and around the rim of the jaw and brow conceals the demarcation line between peeled and non-peeled skin. Areas of wrinkled skin are stretched taut with the help of an assistant, to allow even application of the solution into the folds and troughs. This technique is particularly

helpful on the skin of the upper and lower lips. For perioral rhytides, TCA is applied with the wooden portion of a cotton-tipped applicator and extended onto the vermilion border (Fig. 154.9D).

Eyelid skin must be treated delicately and carefully to avoid over-application to this thinner skin and to prevent exposure of the eyes to the TCA solution. The patient should be positioned with the head elevated at 30°. Excess peel solution on the cotton tip should be squeezed out so that the applicator is semi-dry. With the eyes closed, a single applicator is rolled gently from the periorbital skin onto the upper eyelid skin without going below the superior aspect of the tarsal plate. Another semi-dry applicator is then rolled onto the lower eyelid skin within 2 to 3 mm of the lid margin while the patient is looking superiorly.

Fig. 154.7 Combination of medium-depth peel of the face plus CO_2 laser ablative resurfacing of the periorbital region. A Before treatment. **B** After treatment.

Excess peel solution should never be left on the lids because it can roll into the eyes. Any tears should be immediately dried with a cotton-tipped applicator because they may pull the solution into the eye by capillary action (see Fig. 154.9C). Tears can also travel down the cheek and carry TCA onto the neck, resulting in a linear streak.

The white frost from TCA application appears on the treated area within 30 seconds to 2 minutes. This response is representative of keratocoagulation and indicates that the TCA's physiologic reaction is complete. The Jessner's–35% TCA combination takes longer to frost than phenol preparations, but a shorter period of time than the superficial peeling agents. The desired endpoint for medium-depth peeling is level II to level III frosting. Level II frosting is defined as uniform white-coated frosting with a background of erythema (see Fig. 154.3B). Level III frosting, which is associated with penetration to the reticular dermis, is a solid white enamel frosting with no background of erythema (see Fig. 154.3C). A deeper level III frosting should be restricted solely to areas of thick skin and heavy actinic damage. Most medium-depth chemical peels achieve a level II frosting and this is especially important over the eyelids and areas of sensitive skin. Areas with a greater tendency to form scars, such as the zygomatic arch and the bony prominences of the jawline and chin, should receive no greater than level II frosting.

Before re-treating an area, the surgeon should wait at least 3 to 4 minutes after the application of TCA, to ensure that frosting has reached its peak. Each cosmetic unit is then assessed, and areas of incomplete or uneven frosting are carefully re-treated with a thin application of TCA. Additional applications of TCA increase the depth of penetration as well as the risk of complications, so one should apply more solution only to the underfrosted areas. In other words, do not apply 35% TCA to fully frosted areas as this may cause inflammation beyond the level expected and potentially lead to scarring. Thicker keratoses do not frost as well as the surrounding skin, so vigorous rubbing of the lesion may be needed for adequate TCA penetration. If necessary, thicker epidermal lesions may be treated with liquid nitrogen cryotherapy for several seconds prior to the application of TCA. As will be discussed later, mechanical abrasion can also be performed in selected areas at the completion of the Jessner's–35% TCA chemical peel, to enhance the results.

Although there is an immediate burning sensation as the peel solution is applied, the discomfort begins to subside as frosting occurs and resolves fully by the time of discharge. If necessary, a topical amide anesthetic can be applied under occlusion prior to a medium-depth peel for pain relief[38]. Cool saline compresses offer symptomatic relief at the conclusion of the peel. Unlike the compresses utilized in glycolic acid peels, the saline following a TCA peel simply provides relief and does not "neutralize" the acid.

TCA CROSS

The "TCA CROSS" (TCA *c*hemical *r*econstruction *o*f *s*kin *s*cars) technique is an innovative approach to deep ice-pick and fibrotic acne scars (Fig. 154.10A). Rather than a peel or method of exfoliation, it is

Fig. 154.8 Combination procedure utilizing perioral–periorbital CO_2 laser resurfacing with Jessner's–35% trichloroacetic acid (TCA) peel to the remainder of the face. The peel will blend the color and texture of the laser-treated areas. **A** Preoperative: the eyelids and lips need deeper resurfacing than do the cheeks, which require only medium-depth injury. **B** Four days postoperative: note difference in the rate of healing between laser- and peel-treated areas. **C** One year postoperative.

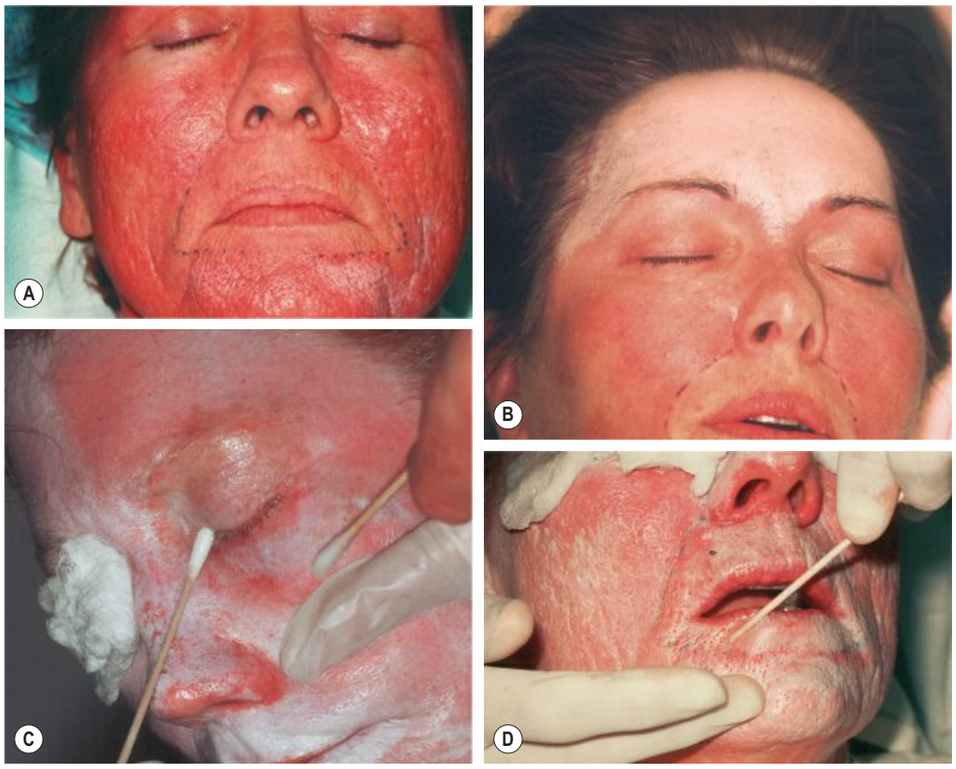

Fig. 154.9 Technical aspects of the Jessner's–35% trichloroacetic acid (TCA) peel. A Appearance of level I frosting after application of Jessner's solution – erythema with blotchy frosting. **B** 35% TCA applied, after Jessner's solution dries, with an even application using cotton-tipped applicators (one to four). A level III or white enamel frosting is obtained. **C** Eyelids are treated with one cotton-tipped applicator moistened with 35% TCA. A dry applicator is used to absorb tears during eyelid peeling. **D** Lip rhytides are peeled with saturated cotton-tipped applicators. The wooden shaft is used to rub peel solution further into the lip rhytides.

Fig. 154.10 "TCA CROSS" technique used as a destructive method for ice-pick scars. A Preoperative with ice-pick scars of the nose and cheek. **B** Frosting limited to just the ice-pick scars. **C** Postoperative.

the use of 90% TCA as a full-thickness destructive tool. When applied to an ice-pick scar, it destroys the epidermis and its deep dermal tunnel, creating a full-thickness skin wound which will heal with the formation of new collagen, thus filling the depressed scar. This method offers a simpler approach to these full-thickness depressions in which the alternatives are surgical: punch grafts, excision, and scar revision. The procedure is performed independently of other resurfacing procedures such as peeling, laser resurfacing or dermabrasion.

After the face is cleansed and degreased with acetone (see above), the ice-pick and depressed fibrotic scars to be treated are outlined with a skin marker and photographed. This serves as a guide for further treatment sessions. The 90% TCA is applied to the interior of the ice-pick scar with a toothpick, being careful not to drip the acid onto normal skin as this could lead to additional scarring. Of note, this is a full-thickness destruction of skin and not a peel, so the TCA should be applied *only* to the interior of the scar itself[39]. Each of the scars is treated until a brilliant white frosting appears (Fig. 154.10B). A topical antibiotic is then placed on each treated site. The procedure is performed with no anesthesia or sedation, as it only produces a brief stinging equivalent to the sensation of cryosurgery.

Healing occurs over the next 2 to 3 weeks, with granulation tissue, fibroplasia, and remodeling of new collagen, which will elevate and soften the depressed scars (Fig. 154.10C). The procedure is then repeated 3 to 6 times at 6-week intervals until substantial elevation has been achieved. This can be followed by a more superficial resurfacing procedure such as medium-depth peeling, laser resurfacing, or dermabrasion to smooth the more superficial scars and blend them with other treated areas.

The physician must warn the patient about potential dyschromia, especially in Fitzpatrick skin types III through VI, as skin destruction of this depth can depigment the treated areas. The multiple procedures may not be able to raise all the scars to the surface but they will surely provide improvement. The TCA CROSS technique does add another simple therapeutic option for treating scars.

Deep Chemical Peeling

Patients in Glogau groups III and IV may require deep chemical peeling, motorized dermabrasion, or laser resurfacing to improve their greater degree of skin damage. Deep chemical peeling leads to production of new collagen and ground substance down to a level in proportion to the depth of the peel. Deep chemical peels create an injury through the papillary dermis and into the superficial reticular dermis, which may extend into the mid-reticular dermis. For deep peeling, either TCA in concentrations >50% or a phenol-containing preparation is used. Because of the risk of scarring and other complications with such potent concentrations of TCA, this agent is not recommended for deep chemical peeling. Therefore, solutions containing phenol remain the preferred formulation for deep chemical peels[40–46].

A deep chemical peel is one of the most permanent cutaneous rejuvenation procedures (Table 154.5)[46]. Histologically, it leads to a dense neocollagenesis zone with new elastic fibers that increases over 6 weeks (Fig. 154.11). The classic Baker–Gordon formula is outlined

DEEP PHENOL–CROTON OIL CHEMICAL PEELS	
• Phenol–croton oil formulas lead to deeper penetration than full-strength phenol* (see Table 154.6 for composition of Baker–Gordon formula) • Used for rejuvenation of severely photoaged skin (Glogau III and IV), with significant improvement or even elimination of deep furrows as well as other textural and pigmentary irregularities the expected result (Fig. 154.11)	
Potential specific complications and contraindications	
Cutaneous	• Scarring (Fig. 154.12), a "plastic" or alabaster appearance with an effacement of normal skin texture, hypopigmentation (greater problem in darker skin phototypes and men), persistent postoperative erythema for months
Systemic	• Cardiotoxicity
Contraindications	• History of cardiac arrhythmias or taking a medication known to precipitate arrhythmias
Relative contraindications	• History of hepatic or renal disease (phenol undergoes hepatic and renal elimination)
Preoperative evaluation and procedure	
Preoperative evaluation	• CBC, LFTs, BUN, crt, electrolytes, baseline electrocardiogram
Procedure	• Before administration of anesthesia (general or deep sedation), patient is examined while in a seated position and appropriate landmarks are noted • After thorough cleansing and degreasing of skin, chemical agent is applied sequentially to six aesthetic units: forehead, perioral region, right cheek, left cheek, nose, and periorbital region • The peel is extended slightly beyond the mandibular rim to conceal the demarcation between treated and untreated skin, but should not be extended to the vertical neck because of the risk of scarring in this area • Periorbital skin is treated cautiously and conservatively to avoid overpenetration, which can lead to ectropion or scarring; notably, diluting a phenol compound with water may increase its penetration so mineral oil (rather than water) should be used to flush the eyes if contact occurs • Cotton-tipped applicators are used; the technique is similar to that for a Jessner's–35% TCA peel (see text), but less solution is used because frosting occurs very rapidly • Following application, there is a burning sensation that lasts for 15–20 seconds, subsides for 20 minutes, and then returns for the next 6 to 8 hours • A 15-minute time interval between the treatment of each cosmetic area is recommended so the entire procedure requires 60 to 90 minutes
*Pure, undiluted 88% phenol is rarely used because it causes rapid and complete coagulation of epidermal keratin proteins and this blocks further penetration.	

Table 154.5 Deep phenol–croton oil chemical peels. BUN, blood urea nitrogen; CBC, complete blood count; crt, creatinine; IV, intravenous; LFTs, liver function tests; PAC, premature atrial contraction; PVC, premature ventricular contraction. Data from references 40–46.

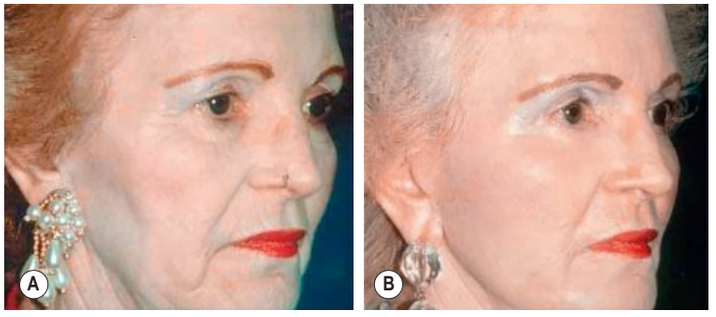

Fig. 154.11 Deep phenol–croton oil peel. A Before treatment. **B** 3 months after treatment with obvious reduction in rhytides.

THE BAKER–GORDON FORMULA		
Ingredient	**Amount**	**Comments**
88% liquid phenol, USP	3 ml	Final concentration of phenol is 50%–55%
Tap water	2 ml	Dilution increases penetration
Septisol® liquid soap (0.25% hexachlorophene)	8 drops	A surfactant that reduces skin tension, allowing more even penetration
Croton oil	3 drops*	A vesicant and epidermolytic agent that enhances phenol absorption Efficacy may be more related to the amount of croton oil than it is to that of phenol[40,42]
*Using 1 or 2 drops of croton oil, rather than the 3 in the Baker–Gordon formula, can limit the risk of phenol complications such as textural effacement or hypopigmentation.		

Table 154.6 The Baker–Gordon formula. The mixture or suspension of ingredients is freshly prepared and must be stirred vigorously prior to application due to its poor miscibility. USP, United States Pharmacopeia.

in Table 154.6. While it was originally thought that phenol was the active agent, in 1996 Hetter proposed, based upon careful data and animal studies, that croton oil was the active agent[40]. Others have subsequently confirmed the correlation of croton oil concentration with depth of wounding and there are various formulas of the Hetter peel (Table 154.7). While the expanded range of phenol–croton oil peels has increased their clinical applications and safety, performance of deep chemical peels requires experience.

The deep peel is indicated for moderate to severe photodamage (Glogau IV) and extensive rhytides in patients with skin types I–III. Associated lightening is an unwanted side effect in darker skin phototypes. Care must be taken in choosing the appropriate patient given the prolonged recovery and need for close monitoring to ensure proper healing. In addition, sedation and pain control, including the use of opioids, nonsteroidal anti-inflammatory drugs (NSAIDs) and benzodiazepines, are required during and after the procedure. A dull to moderately severe discomfort begins during the procedure and extends for up to 4 hours afterwards.

The peel solution should be freshly mixed and it separates easily without agitation. The face is divided into 6 cosmetic units and application time for each unit is 20 minutes such that the duration of a full-face treatment is 1½ to 2 hours. Because absorption occurs, this time spacing is required to limit serum phenol concentrations as it has both cardiac and renal toxicities. Intravenous hydration is administered prior to and during the procedure to assist in reducing phenol levels and the patient is monitored for cardiac arrhythmias.

After thorough cleansing with a detergent and acetone, the phenol–croton oil peel solution is applied with cotton-tip applicators, utilizing the correct number of passes and pressure to produce a visible solid white frosting. The latter appears very quickly after application and gradually resolves into a gray color with edema within an hour. While tape occlusion is the classic approach for creating deeper penetration, a lighter version is the *untaped* phenol–croton oil peel which heals faster and lessens the risk of overpenetration and scarring (Fig. 154.12). For the following 2 to 3 weeks, mild debriding soaks and ointments are

HETTER CHEMICAL PEELS WITH VARYING CONCENTRATIONS OF PHENOL AND CROTON OIL			
Type of peel	**Phenol (%)**	**Croton oil (%)**	**Cosmetic unit/indication**
Light	2.5	0.1	Eyelids, neck
Medium-depth	33	0.7	Cheeks, nose, chin; *not* for eyelids
Deep	33	1.1	Full-face except eyelids
Very deep (Baker–Gordon formula)	50	2.1	Lip rhagades, severe photodamage with pale skin

Table 154.7 Hetter chemical peels with varying concentrations of phenol and croton oil.

Fig. 154.12 Complications from a Baker–Gordon phenol peel. There was prolonged non-healing, resulting in hypopigmentation and marbled scarring.

regularly applied. Prolonged postoperative care is required, along with medical supervision to assess for healing and early signs of potential complications (see below). Post-peel erythema may last as long as 6 weeks while collagen rejuvenation is occurring.

MECHANICAL RESURFACING PROCEDURES

For over 50 years, dermabrasion utilizing a rotating abrasive surface attached to a power-driven hand engine was considered the premier skin resurfacing procedure for facial scars. It has generally been regarded as a deep resurfacing modality based on its depth of injury and its prolonged healing time. The original descriptions of modern dermabrasion involved the use of a wire brush (which remains in use today), but there has been a movement toward more superficial methods of mechanical resurfacing. In 1957, the diamond fraise was introduced and became the preferred instrument for dermabrasion by some surgeons because it is less aggressive and more forgiving than the wire brush[47]. There has also been a resurgence of interest in manual dermasanding, which allows for more deliberate and controlled skin planing[4,5]. Microdermabrasion and microneedling are the mechanical resurfacing procedures developed most recently and represent the most conservative forms of mechanical resurfacing[3].

Microdermabrasion

Because microdermabrasion removes the stratum corneum and superficial spinous layer and the injury rarely extends past the basal layer, this modality is considered superficial in depth. Whether it is classified as very light or light in comparison to other superficial resurfacing procedures depends upon the technique and aggressiveness of the operator. The microdermabrasion unit's handpiece is a closed system, which propels aluminum oxide crystals at the skin at high speeds and simultaneously removes them with suction. These units were developed commercially in the mid-1990s and are currently in widespread use in both physicians' offices and non-medical aesthetic spas. Variants of this superficial resurfacing modality include hydrafacials and DermaSweep™ (DermaSweep, Inc.).

ADVANTAGES OF MANUAL DERMASANDING OVER MOTORIZED DERMABRASION
• Greater control over depth of injury, particularly on the lips and orbital rims • Blending of abraded areas into adjacent unabraded areas accomplished more easily and with better results • Lower cost and greater simplicity of instrumentation and set-up • Risk of aerosolizing infectious particles is far less • Possibly lower incidence of postinflammatory hypopigmentation

Table 154.8 Advantages of manual dermasanding over motorized dermabrasion.

Microdermabrasion may be indicated for acneiform conditions, pigmentary dyschromias, and as a "lunchtime" procedure for facial rejuvenation in all skin types[48], but in general it is not considered effective for improving the appearance of rhytides[49,50]. Both the patient and physician must understand that the degree of objective improvement with microdermabrasion may be limited. It is best used in conjunction with a regimen of topical "cosmeceuticals" including a retinoid, a bleaching agent, antioxidants and sunscreen, with the repeated superficial exfoliation of microdermabrasion enhancing the overall efficacy of the therapeutic program.

Ideal candidates for microdermabrasion typically desire facial rejuvenation without downtime. Appropriately selected patients have a subjective perception of improvement usually exceeding the objective signs depicted with photographs. Patients often report that their skin has a smoother texture and that cosmetics are easier to apply and they blend in with their skin more easily. Microdermabrasion has also been successfully combined with intense pulsed light (IPL) therapy to enhance penetration of the light.

Although the role of microdermabrasion in facial rejuvenation grew dramatically after its initial development, the scientific data to justify its use were lacking until more recently. An increase in epidermal and dermal thickness, flattening of the rete pegs, papillary dermal hyalinization, and newly deposited collagen and elastic fibers have all been observed[51]. Following microdermabrasion, there also appears to be a significant alteration in epidermal barrier function[52]. In addition, investigators have observed an elevation of transcription factors, cytokines, and matrix metalloproteinases following microdermabrasion[53]. This can lead to an enhancement of the effectiveness of topical agents. Microdermabrasion can also be used in combination with very light chemical peels (e.g. DermaSweep™).

Manual Dermasanding

Manual dermasanding involves abrading the skin by hand using silicon carbide sandpaper or wallscreen that is commercially available at any hardware store. It is gaining in popularity for skin resurfacing because it has several advantages over power-driven dermabrasion (Table 154.8). Its classification as a wounding agent is entirely dependent upon the type of paper used, the force applied by the surgeon, and the duration of contact with the skin. Although manual dermasanding can be used to produce a wound as deep as with wire-brush dermabrasion or several passes with a pulsed CO_2 laser, it is probably most commonly used as a medium-depth or "minimally deep" resurfacing modality.

Manual dermasanding can be used to resurface an entire face, but because it is so labor-intensive it is most often utilized for resurfacing localized regions to minimize the appearance of a scar[54] or to blend or enhance the effects of a medium-depth chemical peel or a combination procedure[55]. It can be used following a fractional laser resurfacing to feather the transition into hair-bearing areas that are inaccessible to the laser. Manual dermasanding of the eyebrows and hairline and gently abrading the upper neck at the inferior aspect of the laser-irradiated zone are all effective at minimizing lines of demarcation between treated and untreated skin (Fig. 154.13). It can also be useful immediately after laser resurfacing for stubborn rhytides, particularly in the perioral region; manual dermasanding can improve the outcome by producing a slightly greater depth of injury in a controlled fashion where further thermal injury would be risky. It will also remove adherent necrotic debris and thermal damage after laser resurfacing, thus enhancing the healing process. Similarly, a medium-depth chemical peel can be immediately followed by manual dermasanding of the more troublesome areas to enhance results as well as along the borders of the peeled skin to blend the effects.

Fig. 154.13 Dermasanding. Manual dermasanding utilizing G-320 grit silicon carbide sandpaper to blend CO_2 laser resurfacing into the eyebrow area. The sterilized sandpaper has been wrapped around rolled-up gauze pads and moistened with saline or soap-free cleanser for lubrication.

Our clinical experience suggests that dermasanding after a Jessner's–35% TCA peel may yield impressive postoperative results that approach those seen with either motorized dermabrasion or fractional CO_2 laser resurfacing in patients with cutaneous photoaging (Fig. 154.14). This combination is particularly helpful in patients who may not tolerate the greater degree of sedation often necessary with CO_2 laser resurfacing or who cannot afford the additional fees to cover anesthesia services.

The necessary materials for manual dermasanding include silicon carbide sandpaper or wallscreen. Both may be purchased in a variety of grades: fine grade (G-400), medium grade (G-220–320), and coarse grade (G-180). The sandpaper is easier to use because of its flexibility; it is also more easily cut into smaller pieces, which can be steam autoclaved. A 1.5-inch (4 cm) × 3-inch (8 cm) piece of sterilized sandpaper is wrapped around either the barrel of a 3 ml syringe or a rolled-up gauze pad and moistened with saline or a soap-free cleanser for lubrication. A 1% solution of lidocaine with epinephrine (adrenaline) may be used if additional anesthesia is necessary. The skin is stretched and both back-and-forth and circular motions are used to gradually abrade the skin, layer by layer, until the hills and valleys are softened or adjacent areas are blended to the desired degree. Coarser grades (G-320) may be used initially for "debulking", followed by finer grades (G-400) later in the procedure. The fine grade is used to blend delicate areas of skin such as around the eyelids. At the completion of the procedure, the dark-colored silicon carbide particles remaining on the skin surface should be rinsed off because there is a risk of their becoming implanted, creating a pigmented tattoo.

Fig. 154.14 Medium-depth chemical peel plus manual dermasanding. Jessner's–35% trichloroacetic acid was applied to the face followed immediately by manual dermasanding of the cutaneous lips and chin. **A** Preoperative with obvious perioral rhytides. **B** Postoperative with significant improvement.

Motorized Dermabrasion

Although various abrasive materials have long been used for mechanical resurfacing, the development of a power-driven unit to facilitate the procedure was revolutionary. Some of the units most commonly used today are the Bell Handengine (Bell Handengine®, Inc.), the AEV-12 hand engine (Ellis International), and the Osada surgical handpiece (Osada, Inc.). A topical refrigerant spray was routinely used to produce anesthesia and to harden the skin as it is abraded (Fig. 154.15). The spray immobilizes the topographic features so that there is no distortion by the pressure of the abrasive instrument. Concerns regarding potential harm to the environment from cryogenic sprays have limited the availability of topical refrigerant sprays in several countries, including the US. Utilizing liquid nitrogen or agents that cryopreserve tissue specimens is *not* recommended because they create a colder temperature that can lead to hypopigmentation and/or scarring. Options include tumescent anesthesia as a means of firming the tissue or use of the diamond fraise without a cryogen.

Fig. 154.15 Mechanical dermabrasion. This technique is performed with a diamond fraise over rigid skin cooled with a topical refrigerant spray. More recently, the latter has been replaced by tumescent anesthesia.

The two abrasive instruments most often employed with these motor-driven units are the wire brush and the diamond fraise. The wire brush has numerous small-caliber, stainless steel wires that project circumferentially from the curved side of a cylindrical hub. A diamond fraise consists of a stainless-steel cylinder to which industrial-grade diamonds are bonded to create the abrasive surface. Compared with wire-brush instruments, diamond fraises are manufactured with a greater variety in their shape, width of abrasive surface, wheel diameter, and coarseness

of grit. While there continues to be considerable controversy regarding which one of these instruments is superior[47], surgeons generally agree that the wire brush is more aggressive. The wire brush cuts more quickly and more deeply into the skin with each stroke, thereby posing a greater risk for injury and requiring more skill to operate. Although the diamond fraise is generally safer and more forgiving, it may not yield the degree of improvement possible with the wire brush, especially for more stubborn conditions such as acne scarring.

Because dermabrasion with either instrument is highly technique-dependent and the learning curve is steep, there may be considerable variability in the clinical results obtained by different operators. To be adequately trained, it is very important for beginner dermabraders to receive hands-on instruction from an experienced operator. The proper techniques for motorized dermabrasion have also been the subject of comprehensive reviews in the literature[47]. Careful evaluation of the depth of injury throughout the procedure is critical to assure a sufficient depth for optimal results without penetrating beyond the desired level and risking scar formation. Because of the potential for aerosolization of infectious particles during dermabrasion, appropriate precautions are mandatory to protect the operating room staff (see Ch. 136). This includes protective masks, face shields, and an air evacuation system.

Although the resurgence of manual dermasanding and the development of laser technology have led to a decline in the number of motorized dermabrasion procedures, it remains a reliable treatment for moderate-to-severe acne scarring (Fig. 154.16). Dermabrasion selectively planes off the "hilltops" that surround the atrophic "valleys", whereas chemical peeling and laser resurfacing may produce an injury of equivalent depth in both areas. This explains that while it is possible to efface the edges of atrophic scars with the CO_2 laser or the solid CO_2–35% TCA peel[31], it may prove more difficult to achieve desired results (compared to dermabrasion).

The physician must choose the scars most amenable to dermabrasion alone. These include shallow fibrotic scars, hypertrophic scars and undulating, rolling scars, in addition to atrophic and boxcar scars. Deeper fibrotic scars, ice-pick scars, and scars with significant tissue loss may require a lifting or filling procedure prior to dermabrasion. In these patients, the results are significantly enhanced by performing one or more of the following adjunctive procedures 4 to 6 weeks preoperatively: punch or scalpel excision, TCA CROSS technique, punch grafting, dermal grafting, fat grafting, or scar undermining (subcision)[56].

Subcision

Deeper fibrotic scars can be excised or they can be elevated prior to resurfacing[57]. Subcision represents a surgical option for elevating scars in which the scars are outlined, photographed, cleansed, and injected with local anesthesia. A specialized undermining needle (e.g. Nokor™) or a tri-beveled 18-gauge needle is inserted at an acute angle through an incision at the edge of the scar (Fig. 154.17). The needle is then advanced under the scar, horizontally and parallel to the skin surface. Fan-like motions break fibrotic dermal scar bands, releasing the overlying skin to raise upward. A pressure dressing is placed to evacuate blood from the pocket that is created under the scar. During wound healing, this pocket fills with new collagen fibers leading to scar elevation[58]. The procedure is usually repeated 2 to 5 times. Sometimes to further enhance filling in of the scar, a dermal graft harvested from the retroauricular area can be inserted with jeweler's forceps into the pocket generated by the Nokor™ needle.

Microneedling

Microneedling represents a minimally invasive procedure in which the device contains multiple fine-gauge needles 0.5–3 mm in length that penetrate the skin and trigger wound healing. One goal is to induce dermal remodeling and skin rejuvenation via increased production of collagen and elastin[59,60]. The devices vary from manually operated to battery- or electric-powered and are designed as rollers, automated pens, and patches in which the operator can often toggle between different lengths of needles. Clinical indications include acne, surgical, traumatic and burn scars, photoaging, striae, skin laxity, dyschromias, alopecia, and potentially transdermal drug delivery (Table 154.9).

Preoperatively, a topical anesthetic may be applied and multiple sessions are frequently needed to obtain desired results. Transient erythema is the most common side effect and rarely hypersensitivity reactions, scar formation, or dyspigmentation occur. Advantages include relatively low cost, wide spectrum of applications, overall ease of use, and favorable side effect profile including its relative safety in skin of color[61]. However, there is a lack of high-quality, prospective, randomized controlled trials comparing microneedling with other resurfacing modalities.

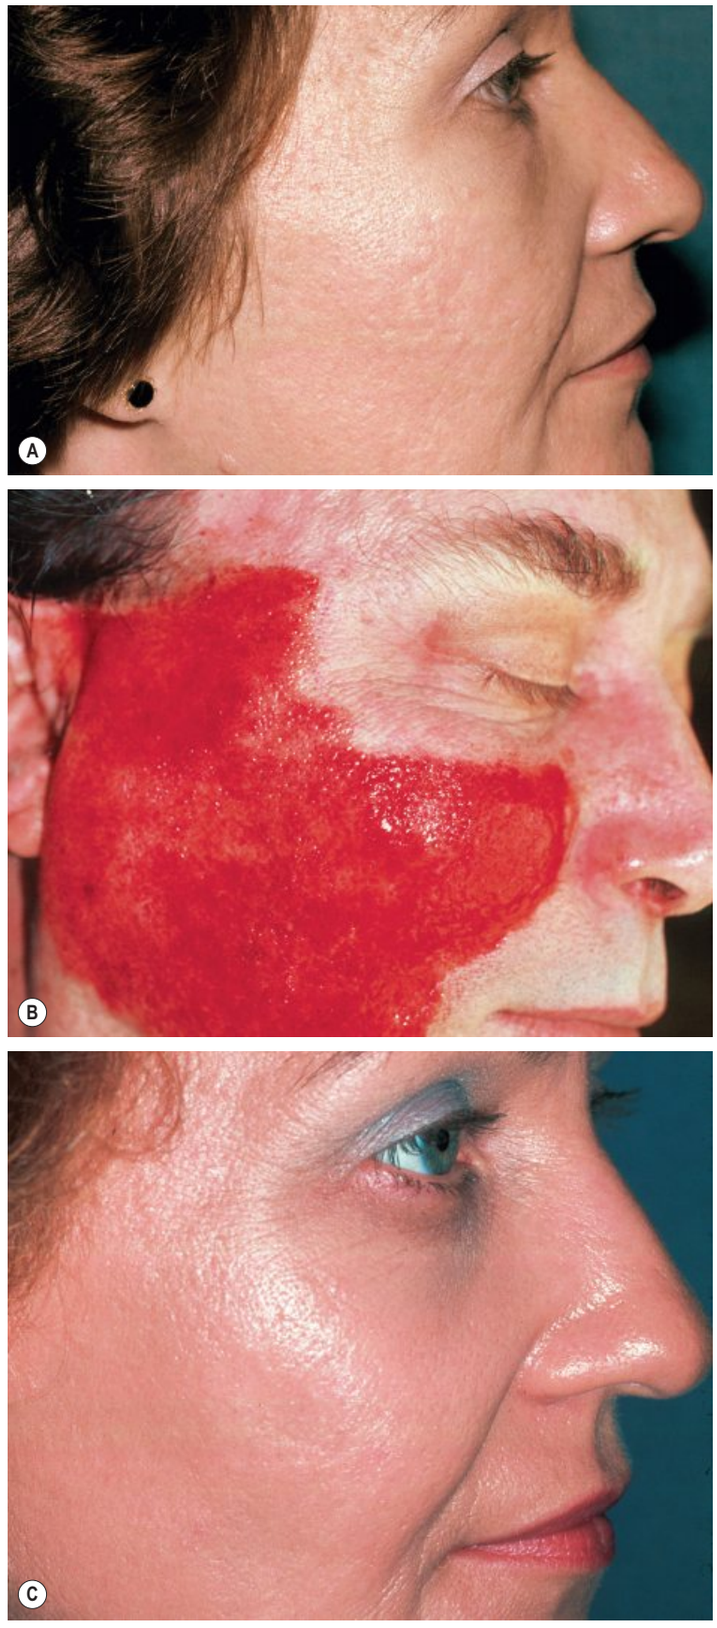

Fig. 154.16 Full-face dermabrasion performed for acne scars. A Preoperative: shallow and atrophic scars that are most amenable to dermabrasion. **B** Postoperative: dermabrasion prior to biosynthetic dressing. **C** Three months postoperative.

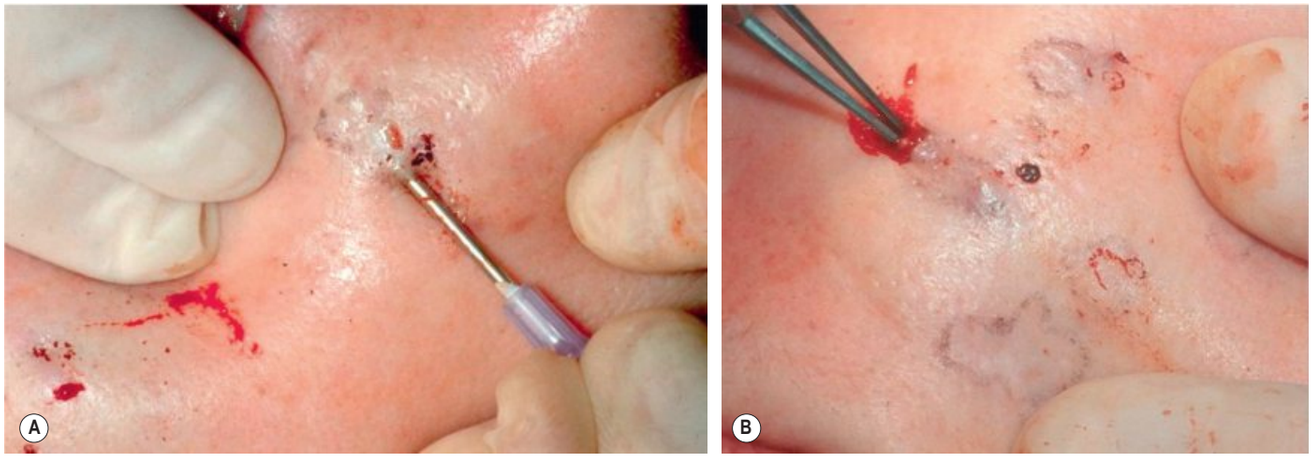

Fig. 154.17 Treatment of facial scars by subcision. A Scars to be treated have been outlined with a skin marker, photographed, and anesthetized. A Nokor™ needle is inserted into the dermis underneath a scar and advanced horizontally parallel to the skin surface. **B** To further enhance filling in of the scar, a dermal graft can be inserted with jeweler's forceps into the pocket generated by the Nokor™ needle.

EXAMPLES OF DRUGS DELIVERED TRANSDERMALLY VIA MICRONEEDLING	
Drug	**Treatment/indication(s)**
Anesthetics (topical)	Enhance anesthetic effect prior to minimally invasive procedures
Bimatoprost	Hypopigmentation
Bleomycin	Refractory verrucae vulgares
Botulinum toxin	Increased pore size, skin texture irregularities
Corticosteroids	Scars, bulky flaps
Cosmeceuticals	Melasma (transexamic acid), photoaging, skin texture irregularities
Platelet rich plasma (PRP)	Alopecia (e.g. androgenetic), photoaging

Table 154.9 Examples of drugs delivered transdermally via microneedling.

A promising variant is radiofrequency (RF) microneedling in which thermal-assisted microneedles stimulate new collagen formation by inflaming and destroying the dermis or subcutaneous tissue. Because the energy source is an electric current and the energy is not emitted until the dermal–epidermal junction is breached, there is minimal risk of hyperpigmentation[62]. Indications are those of traditional microneedling and cellulite improvement. See Chapter 137 and Table 137.1 for additional details.

POSTOPERATIVE CARE

Because superficial resurfacing procedures generally do not extend beyond the epidermis, the dermal wound healing mechanisms are not activated. In contrast, medium-depth and deep resurfacing procedures stimulate the following four stages of dermal wound healing (see Ch. 141): (1) inflammation and coagulation; (2) re-epithelialization; (3) fibroplasia and matrix formation; and (4) collagen remodeling.

Because the pronounced edema following medium-depth and deep resurfacing procedures may minimize the appearance of scars, rhytides and other irregularities, the patient's initial perception of his or her improvement may be exaggerated. As swelling subsides postoperatively, patients should be reassured and advised that collagen remodeling continues for several months and leads to further clinical improvement. At some point in the postoperative course, patients often want to know when another resurfacing procedure can be performed if it is necessary. The presence of persistent postoperative erythema may indicate continued collagen remodeling and may serve as a warning that a similar resurfacing procedure performed prematurely could produce scarring. To assure their safety, patients undergoing medium-depth resurfacing should not undergo another medium-depth or deep procedure for the next 3 to 9 months. An individual having a deep resurfacing procedure should avoid another one for at least 12 months postoperatively. Touch-up procedures for revision of a prior suboptimal outcome are also best avoided during these time periods, especially if erythema is still present.

Healing time is generally proportional to the depth of the resurfacing procedure. *Superficial* resurfacing procedures cause minimal downtime and necessitate little postoperative care. They usually produce mild erythema and desquamation that last from 1 to 4 days depending on the wounding agent and the techniques used. Regular washing with a mild cleanser and the use of routine moisturizers and sunscreens are generally sufficient during the healing period.

Following *medium-depth* resurfacing procedures, there is a considerably longer healing time and more intensive postoperative care is necessary. Follow-up visits are scheduled regularly to monitor the patient's postoperative course. After a medium-depth chemical peel, occlusive dressings are not necessary because the epidermis, which is not removed intraoperatively, functions as a biologic dressing until peeling occurs. Because areas of medium-depth peeling which have been enhanced by manual dermasanding do not possess residual epidermis, occlusive dressings may be used on these areas during the first 3 postoperative days.

The patient is instructed to soak the areas four times daily with warm compresses and to apply an emollient after each soak and during the intervening periods as necessary. A solution of 0.25% acetic acid (one tablespoon of white vinegar added to one pint of warm water) is preferred for the soaks because the mild acidity is physiologic for healing granulation tissue. It is also a mild debridant and has antibacterial effects, especially against *Pseudomonas* spp. and other Gram-negative organisms. Occlusive emollients, such as petrolatum, Aquaphor® or Eucerin® ointment, speed the process of re-epithelialization and lessen the tendency for delayed healing[63]. These emollients are also helpful in wound debridement and in the prevention of crust formation and infection. Showers, soaks, and emollients are continued for a week postoperatively.

Following medium-depth resurfacing, edema begins to appear almost immediately and progressively worsens during the first 48 hours. It can even be severe enough to close the eyelids and impair the patient's visual fields. If tolerated, aspirin or other NSAIDs can be administered, preoperatively and during the first 24 hours postoperatively, to alleviate discomfort and reduce swelling. After a medium-depth chemical peel such as the Jessner's–35% TCA peel, there is initially a brawny, dusky erythema which is followed by the formation of a brownish crust that begins to separate from the skin surface between days 4 and 8 postoperatively. Although the initial darkening can be disturbing to the patient, it represents an expected separation of the epidermis. The underlying, newly formed epithelium is brightly erythematous but fades to a pink color that resembles a sunburn (see Fig. 154.6D). By postoperative day 7 to 10, re-epithelialization has occurred and the erythema can be camouflaged with cosmetics. Within 2 to 4 weeks after the procedure, the erythema usually resolves fully, and retinoids and sunscreens can be restarted as tolerated.

Deep resurfacing procedures, such as the Baker–Gordon phenol peel or dermabrasion, require a follow-up visit the next day, several visits during the first week, and very close monitoring thereafter. At each visit, instructions for wound care are reviewed with the patient

and any questions are answered. The immediate postoperative course after deep resurfacing is similar to that following medium-depth procedures, except that edema and erythema may be even more severe and persistent. NSAIDs can provide some relief, but an intramuscular corticosteroid injection is often administered on the day of surgery, even though its effects on wound healing are not completely understood. Pruritus may occur during the healing phase following a resurfacing procedure of any depth but is particularly prevalent after deeper resurfacing. This problem can be alleviated by the use of emollients, ice packs, NSAIDs, and antihistamines until the pruritus spontaneously resolves. Milia formation, which commonly occurs 3 to 4 weeks after deep chemical peeling or mechanical resurfacing, is easily managed with needle extraction.

Patients undergoing deep mechanical resurfacing with either motorized dermabrasion or manual dermasanding can have an occlusive hydrogel biosynthetic dressing (e.g. Vigilon®, 2nd Skin®) applied immediately after the procedure. In patients undergoing a Baker–Gordon phenol peel, occlusive tape or a biosynthetic dressing is usually utilized postoperatively. Occlusive tape dressings must be removed on the first postoperative day and this procedure may require analgesia and sedation. For this reason, the authors prefer untaped phenol peels with application of ointment or bio-occlusive dressings. Whenever a biosynthetic dressing is used, it must be removed daily and replaced with a new one for the first 2 or 3 days postoperatively so that the face can be gently debrided with saline soaks and moistened cotton tips. The patient should be instructed to regularly apply an occlusive ointment to areas around the mouth, eyelids, and hairline that are not adequately covered by the dressing. Occlusive biosynthetic dressings have been shown to enhance collagen synthesis and hasten re-epithelialization in superficial wounds. They also minimize the amount of discomfort and obviate the need for repeated soaks by the patient during the first few days after the procedure.

By the third day following deep mechanical or chemical resurfacing, the patient begins open wound care with 0.25% acetic acid soaks four to six times daily and regular applications of an occlusive ointment. By the 7th to the 14th day postoperatively, re-epithelialization is usually complete and the ointment is replaced by a heavy moisturizer. The marked edema and erythema typically seen after dermabrasion or dermasanding generally resolve after several weeks. The erythema resulting from deep peeling may be more persistent but is rarely present beyond 2 to 4 months. Strict sun avoidance is critical for 3 to 6 months after dermabrasion or deep chemical peeling. The patient typically restarts sunscreens and retinoid therapy within a couple of weeks of re-epithelialization, as tolerated.

COMPLICATIONS

Complications may occur following any method of skin resurfacing involving injury to any depth but are more common after medium-depth and deep procedures. It is far simpler to prevent the development of a complication than to manage it once it has occurred. Complications may be prevented by proper selection of suitable patients and appropriate resurfacing modalities, precise intraoperative technique, and proper patient management before and after the procedure (see Table 154.3). The dissatisfied patient represents a complication even when the cosmetic result is favorable. An explanation of realistic results and review of photographs of "average" rather than best results during the pre-treatment consultation is recommended. Any information provided at this time is included within informed consent.

Improper wound care, trauma to healing areas resulting from overzealous debridement, compulsive picking or scratching, and premature use of irritating substances such as depilatories or wax for the removal of hair can each cause the depth of injury to extend beyond the threshold of safety. As discussed below, the development of infection in the postoperative period can also extend the depth of injury and increase the risk of permanent sequelae.

With specific regard to chemical peeling, excessive injury to the skin can result from poor technique during application or problems with the chemical agents utilized. The degree of frosting is monitored closely to assure that the agent has been applied evenly and that the injury extends to the proper depth (Table 154.10). Although it does not always correlate completely with the depth of injury, the level of frosting is a very valuable guide for determining the appropriate endpoint of treatment

CLINICAL SIGNS THAT REFLECT DEPTH OF WOUNDING
• Level of frosting (see Fig. 154.3)
• Time for frosting to appear
• Time for frosting to disappear
• Skin turgor
• Epidermal slide*
*Sliding of the epidermis off the dermis due to separation of the two tissues.

Table 154.10 Clinical signs that reflect depth of wounding.

(see Fig. 154.3). Injuring the skin too deeply during a chemical peel, as suggested by an excessive degree of frosting, may result not only from over-application but also from the use of excessively concentrated peeling solutions. The latter error can be caused by the surgeon's choice of an improper peeling agent, such as 50% TCA, or it can be related to unexpected disturbances in a solution's pharmacologic mixture. For Baker–Gordon peels, a new batch should be mixed by the surgeon prior to each procedure to be certain that the preparation is made correctly; the other peeling solutions are available in various formulations and strengths for purchase directly from medical supply dealers. Reputable dealers mix and label these solutions properly according to standard *weight-to-volume* formulas. It should be noted that the latter accurately reflect the TCA percentages cited in the medical literature, while volume-to-volume and weight-to-weight preparations of TCA do not.

Storage of peeling solutions in proper containers away from sunlight and immediate replacement of expired solutions are important measures to ensure chemical stability of the agents being used[64]. Immediately prior to peeling, an ample volume of the solution should be poured from the primary storage container into a smaller, secondary cup. The peeling agent is applied directly to the skin surface from this cup and the excess subsequently discarded to avoid contamination of the storage container and to avoid the accidental transfer of concentrated crystals from the neck of the storage container to the patient's skin.

Errors during mechanical resurfacing procedures may also lead to an injury of excessive depth and a higher risk of adverse sequelae. This problem can result from poor technique in the handling of the instruments or from failure to recognize the appropriate treatment endpoint. The beginner should first start by conservatively dermasanding small areas to get a comfortable feel for the skin's response to this type of injury. As knowledge and experience is gained, one can then progress on to diamond fraise dermabrasion and later to the use of the wire brush. Observation of experienced surgeons and hands-on training are invaluable. The beginner should always err on the side of conservatism, while still yielding favorable results, to avoid excessively deep tissue injury that could produce long-term complications.

During chemical peeling or mechanical resurfacing, intraoperative exposure of vital structures to the resurfacing agent may occur and can have serious adverse consequences. Extreme care must be exercised when dermabrading with a power-driven, rotating instrument, assuring that the dominant hand maintains complete control continuously and free skin edges (e.g. eyelid, lip) are not caught up in the wire brush or diamond fraise, as the latter may result in tearing of the skin. During chemical peeling, the moistened applicator should never be passed over the central face, in order to avoid inadvertent exposure of a vulnerable surface such as the eye to the solution. There should always be appropriate fluids readily available to rinse the area in case such an exposure does occur. In particular, saline is used to dilute TCA, mineral oil is used to dilute phenol solutions, and sodium bicarbonate is used to neutralize glycolic acid.

Adverse systemic effects related to a resurfacing procedure are very uncommon but can usually be traced to an identifiable causative factor in the perioperative period. Peeling with phenol solutions has been associated with systemic toxicities, so these procedures must be performed slowly and only on properly selected, healthy patients in an appropriate clinical setting. The use of Jessner's solution poses a theoretical risk of systemic salicylate or resorcinol toxicity, but this is probably not clinically significant when application is limited to the face and neck. Undoubtedly, the most common cause of systemic problems related to resurfacing procedures is an adverse allergic or physiologic reaction to a medication used for anesthesia. It is imperative that the surgeon knows all the physiologic effects and the potential adverse consequences of each drug administered systemically, unless there is an

attending anesthesiologist who assumes this responsibility. Fortunately, the chemical and mechanical resurfacing procedures utilized most often can be performed with little or no sedation.

It is important to make a distinction between a true complication and an expected side effect of a resurfacing procedure. With medium-depth and deep resurfacing, transient erythema, flushing, increased skin temperature, pruritus, edema, and milia formation are typical occurrences, so they should not be classified as true complications. Patient reassurance may be all that is necessary, since these problems usually resolve spontaneously. True complications that may develop within a treated area include infection, delayed wound healing, persistent erythema, scarring, and pigmentary or textural abnormalities[65,66]. Any of these true complications can occur despite proper patient and procedure selection, perfect surgical technique, and appropriate management before and after the operation.

Infection is an uncommon complication that develops during the postoperative period and may be caused by bacterial, viral, or fungal organisms. An important preventive measure is the repeated use of soaks for adequate wound debridement. Frequent postoperative visits are also helpful to assure early recognition and treatment of any infection so that scarring does not result. An infection may present with delayed wound healing, ulcerations, excessive necrotic material and crusting, purulent drainage, or odor. An acneiform eruption or pustular folliculitis can also be a manifestation of infection and should be treated as such. Infection with streptococcal and staphylococcal organisms can occur under biosynthetic membranes or thick, occlusive ointments, so these are best avoided, except in the immediate postoperative period. Other organisms, such as *Escherichia coli* or *Pseudomonas* spp., may infect the area if there is improper wound care. *Candida* infections can also occur and are sometimes related to the use of prophylactic antibiotics or occlusive wound care. Clinical suspicion of a wound infection necessitates immediate institution of empiric antimicrobial therapy, laboratory culture for identification of the organism(s), and wound debridement as necessary[67].

Herpes simplex viral infections can occur during the healing period following medium-depth or deep resurfacing and have the potential for devastating sequelae. An outbreak can even occur in patients on the recommended 10- to 14-day prophylactic antiviral regimen. The keys to avoiding scar formation are rapid recognition and aggressive therapy begun early in the course of the infection. The dosage of antiviral drug should be increased to the recommended maximum in cases of active herpetic infections.

Persistent erythema beyond 2 months after a medium-depth procedure may be precipitated by the use of topical or systemic retinoid therapy, contact with various allergens or irritants, an underlying skin condition, genetic susceptibility, or the presence of active infection[65,68]. Persistent erythema may indicate the impending development of scar formation. Especially when indurated, it should be treated promptly and aggressively. Management includes massage therapy, topical, intralesional or even systemic corticosteroids, silicone gel sheeting, and pulsed dye laser therapy. In most cases, scarring can be prevented. Mild scarring may even fade away spontaneously. Rarely, ectropion or eclabium can occur when aggressive resurfacing creates scarring or excessive tightening of periorbital or perioral skin, respectively, in a susceptible patient.

Textural abnormalities, skin atrophy, and dyspigmentation are additional complications that may occur with medium-depth and deep resurfacing procedures. The return of normal pigmentation in patients with Fitzpatrick skin type IV or higher is less predictable, so an extra measure of caution is necessary. Postoperative hyperpigmentation may be prevented and/or treated after re-epithelialization with a topical retinoid, a 4%–8% hydroquinone preparation, and strict photoprotection, but the hypopigmentation that can follow deeper resurfacing is typically permanent. Another potential pigmentary problem following deeper resurfacing procedures is a conspicuous demarcation line separating the untreated and treated areas. Although this problem can usually be avoided with adequate planning and proper technique, the approach to its management should focus on lightening the pigment in the adjacent untreated areas.

CONCLUSIONS AND FUTURE TRENDS

The sheer number of patients demanding medical therapy or procedural intervention to rejuvenate their skin mandates that dermatologists be well versed in this area. The field of resurfacing is constantly changing, with the development of new techniques and procedures as well as fluctuations in patient demands and expectations. In all areas of cosmetic surgery, there has been a recent trend in favor of less invasive procedures. Dermatologists often choose to learn and implement only a handful of resurfacing procedures that best fulfill the needs of their practice and meet the demands of their patient population.

Chapter Contents

Venous Anatomy, Physiology, and Pathophysiology 2650
Physical Examination of the Phlebology Patient 2651
Laboratory Evaluation of the Superficial Venous System. 2652
Compression in Sclerotherapy and Venous Disease 2653
Sclerosing Solutions. 2654
Techniques for Treating Telangiectasias and Reticular Veins. 2656
Larger Varicose Veins 2657
Postsclerotherapy Compression 2660
Complications 2660
Ambulatory Phlebectomy 2662
Targeting the Saphenofemoral Junction 2663

Key features

- Superficial telangiectasias, reticular veins, and varicose veins of the lower extremities are interconnected and develop after impairment of venous return
- Poor venous return results from venous valvular incompetence or primary muscle pump failure
- A pretreatment physical examination to assess the extent and cause of the venous abnormalities should be performed with the patient in a standing position
- The physical examination should be supplemented by duplex ultrasonography when saphenous vein reflux is suspected
- Both preoperative and postoperative compression are important in the management of venous insufficiency
- Sclerosing agents should destroy the entire vascular wall, producing permanent fibrosis of the vessel
- The minimal concentration and volume of sclerosing agent needed to achieve the desired results should be used
- All affected portions of the superficial venous system should be treated, ideally in one session and starting with the most proximal
- Large veins should be treated before smaller veins, and veins should be treated from proximal to distal
- FDA-approved sclerosing agents include sodium tetradecyl sulfate and polidocanol, both liquid and microfoam formulations
- Hypertonic saline (11.7%–23.4%) and glycerin (72% mixed 2:1 with 1% lidocaine, with or without epinephrine) are not FDA-approved for vein sclerosis, making their usage off-label
- The most common local side effects following injection of sclerosing agents are hyperpigmentation and telangiectatic matting and much less often cutaneous ulcers
- Patients generally require one to three sclerosant injection treatment sessions, spaced at 6- to 8-week intervals
- Utilizing tumescent anesthesia, incompetent saphenous veins and large tributaries over 4 mm in diameter can be effectively treated by ambulatory phlebectomy, radiofrequency or laser thermal ablation, or cyanoacrylate adhesive closure

INTRODUCTION

Varicose and telangiectatic leg veins increase in extent and severity with increasing age. The evolution of safe and effective treatment options has made sclerotherapy, ambulatory phlebectomy, endovenous laser ablation (LA), and radiofrequency (RF) ablation expanding areas within dermatologic surgery[1]. The utilization of improved diagnostic modalities, more efficient sclerosing agents, and simplified surgical techniques has rendered the treatment of venous disease safe, efficient, and highly satisfying for both patient and physician. This chapter presents the most recent advances in sclerotherapy, ambulatory phlebectomy, endovenous LA, RF ablation, and cyanoacrylate adhesive closure (CAC) as they relate to the management of telangiectasias, reticular veins and varicose veins, both non-saphenous and saphenous.

VENOUS ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY

The peripheral venous system functions both as a reservoir to store extra blood (e.g. during pregnancy) and as a conduit to return blood from the periphery to the heart and lungs. The correct function of the venous system depends on a complex series of pumps and valves that are individually frail, yet the system as a whole performs well under extremely adverse conditions[2] (Fig. 155.1). Superficial veins carry less than 5% of venous blood, while the deep venous system carries 95% of venous blood.

The *superficial* venous system is a complicated, variable network of interconnecting veins[3]. A few of the larger truncal superficial

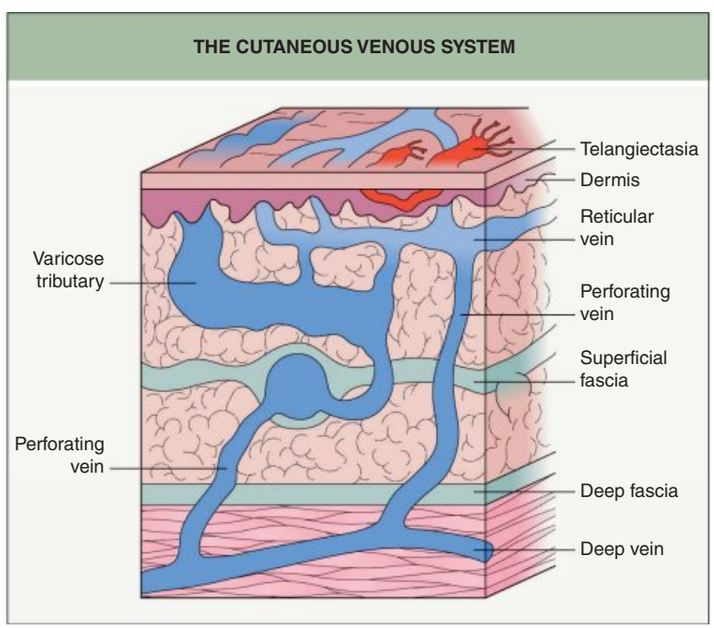

Fig. 155.1 The cutaneous venous system. The deep venous system drains the superficial venous system, which, in turn, is fed from the skin surface by telangiectasias within the dermis. The latter drain via reticular veins into the larger venous channels located in the reticular dermis and subcutaneous compartments. *Redrawn from Somjen GM, Ziegenbein R, Johnston AH, Royle JP. Anatomical examination of leg telangiectases with duplex scanning. J Dermatol Surg Oncol 1993;19:940.*

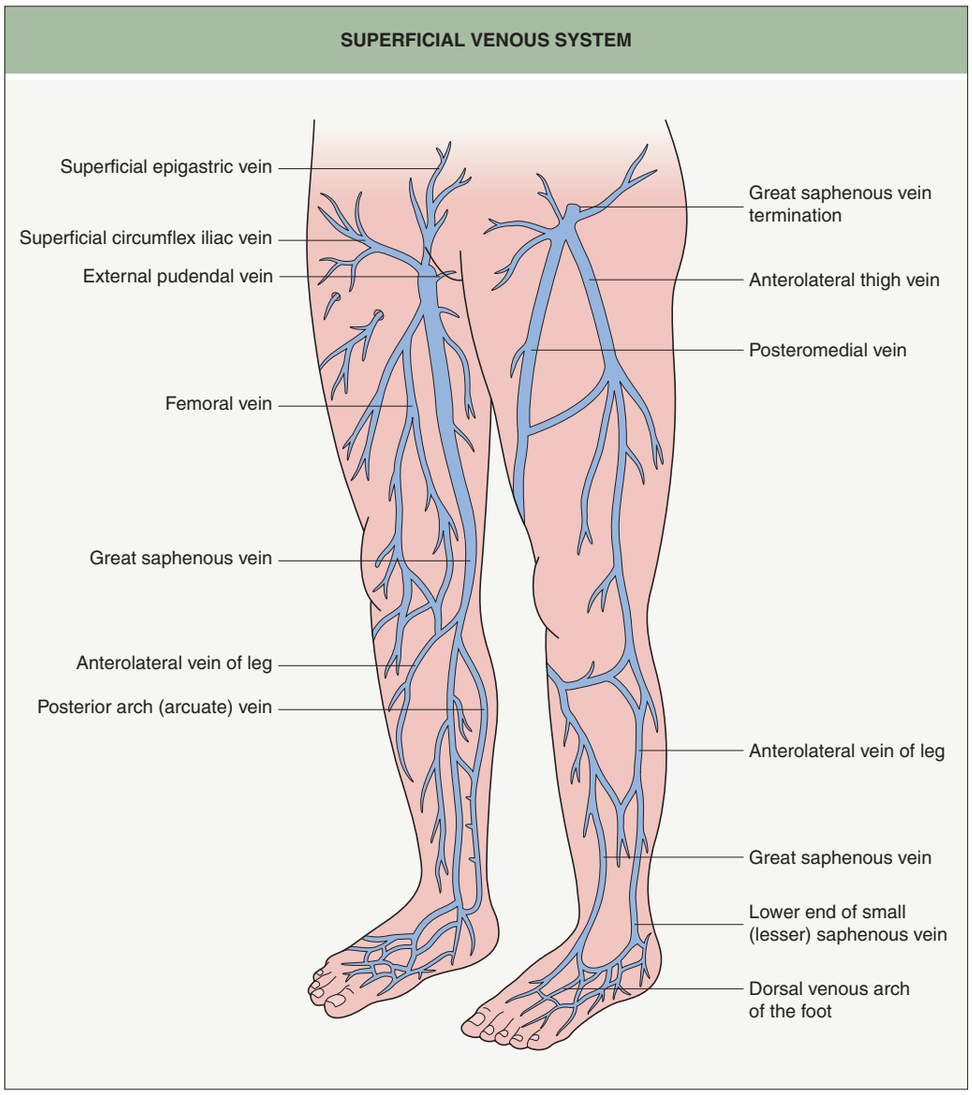

Fig. 155.2 Superficial venous system. Lateral and medial views of the distribution of the major axial trunks of the superficial venous system, the great and small saphenous veins, and associated tributaries. The anterolateral thigh vein was previously referred to as the lateral circumflex vein.

veins are fairly constant in location. These truncal superficial veins serve as a conduit to pass blood centrally into the deep venous system. The two principal named superficial veins are the small saphenous vein (SSV), which runs from the ankle to the knee, and the great saphenous vein (GSV), which runs from the ankle to the groin[4] (Fig. 155.2).

An interconnecting system of *perforating* veins that pass through the deep fascia connects the superficial veins to the deep veins of the calf or thigh (Figs. 155.1, 155.3 & 155.4). All venous blood eventually is received by the deep venous system on its way back to the right atrium.

Blood is propelled back to the heart via the pumping action of the foot and calf muscles, which squeeze blood out of a venous segment through one-way valves when muscle contractions increase the pressure within the fascial muscle compartment (Fig. 155.5). Venous pathology can result from primary muscle pump failure due to venous obstruction (thrombotic or non-thrombotic) or from venous valvular incompetence[5].

A genetic predisposition for the development of varicose veins has been observed, with both autosomal dominant and recessive patterns of inheritance described. Approximately 70% of patients can identify superficial venous disease as a familial trait. Hormonal influences from pregnancy or estrogen and progesterone supplementation are believed to be additional predisposing factors.

In summary, telangiectasias, reticular veins, and varicose veins reflect hereditary and hormonal factors as well as static gravitational pressures and dynamic muscular forces transmitted through failed venous valves. While genetic traits cannot be altered, the influence of hemodynamic forces and hydrostatic pressure can be modified, both by sclerotherapy and surgical techniques.

PHYSICAL EXAMINATION OF THE PHLEBOLOGY PATIENT

The purpose of the clinical examination is to survey the main venous trunks and determine where the primary or highest points of reflux are located. During the examination, the patient should be standing, preferably on a platform. It is important to determine the grade of venous insufficiency[6]. The recommended CEAP classification system is based on clinical manifestations (C), etiologic factors (E), anatomic distribution of disease (A), and the underlying pathophysiologic findings (P) (Table 155.1)[7]. The venous severity scoring (VSS) system is based on three elements: the number of anatomic segments affected, grading of symptoms and signs, and disability. The consensus statement on this approach to clinical assessment was published worldwide in 25 journals and books in eight languages.

For the practicing physician, CEAP is an instrument for establishing the correct diagnosis, guiding treatment, and assessing prognosis. It is important to stress that CEAP is a descriptive classification, while VSS and quality-of-life (QoL) scores represent instruments for longitudinal clinical research and assessing outcomes. In modern phlebologic practice, the vast majority of patients will have a duplex scan of the venous system of the leg, which will provide data on E, A, and P. In basic CEAP, the single highest descriptor should be used for clinical class; e.g. a patient with varicose veins, swelling and lipodermatosclerosis

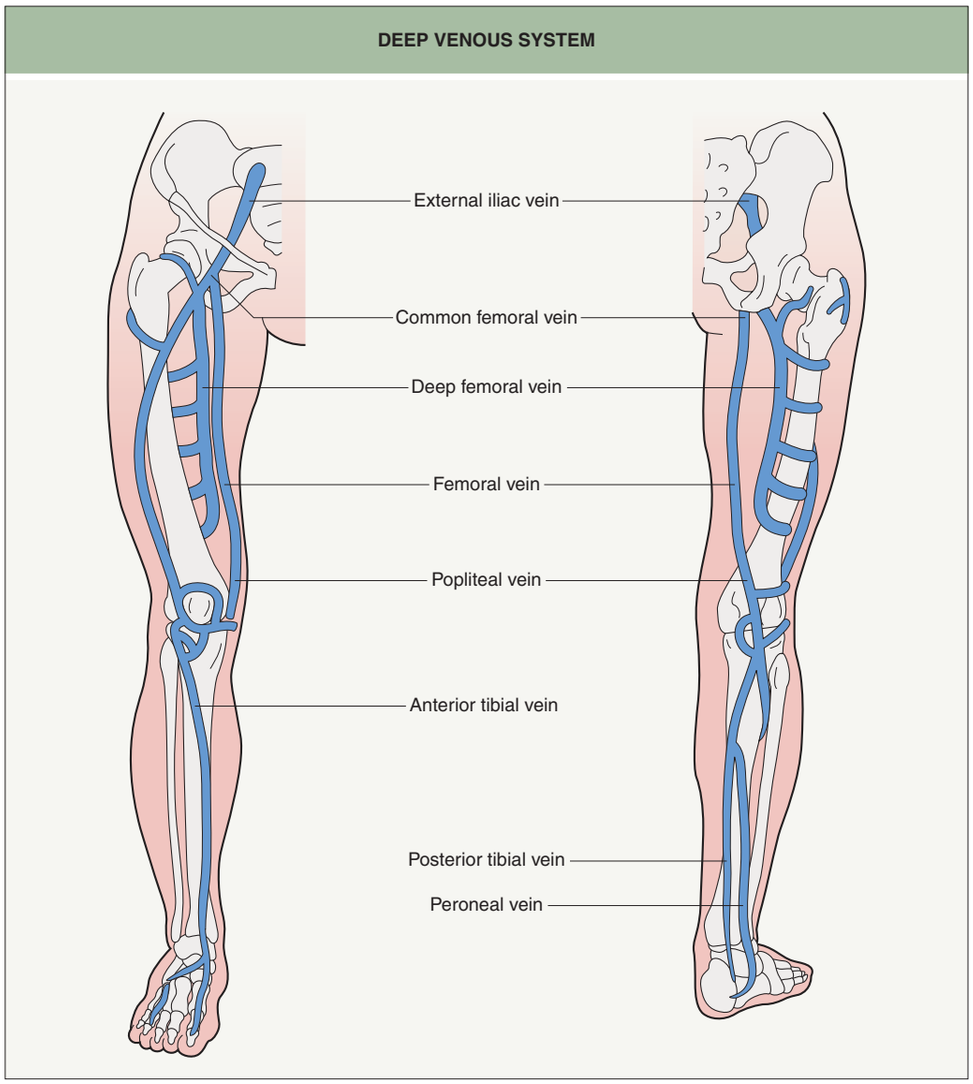

Fig. 155.3 Deep venous system. The major drainage vessel for below the knee is the popliteal vein, while the femoral vein is the major portal of drainage in the inguinal area (great saphenous distribution).

will be C4b (see Table 155.1). However, use of just the C-classification provides no advantage over previous classification schemes that were based solely on clinical appearance. Even in basic CEAP, where a duplex scan is performed, classification of E, A, and P with multiple descriptors is recommended. For A (anatomic classification), the simple superficial (s), perforator (p), and deep (d) descriptors should be used; e.g. a symptomatic patient with stasis dermatitis, primary disease of the superficial and deep veins, and reflux would be classified as C4aS; Ep; As,d; Pr. While venous disease is complex, it can be described using this system, and clinicians are encouraged to use all four components of CEAP.

A disposable sclerotherapy garment is an excellent means for preserving patient modesty while gaining full access to the entire lower extremity. A two-step examination stool also aids in the clinical assessment. The medial plantar and ankle regions are examined for the presence of specific skin changes, including clusters of telangiectatic veins (referred to as "corona phlebectasia"), hemosiderin deposition, livedoid vasculopathy (atrophie blanche), lipodermatosclerosis, and/or active or healed ulceration (see Ch. 105). These findings suggest a chronic state of venous insufficiency located in either the saphenous veins or the deep venous systems. The lateral posterior malleolar region is similarly examined. Skin changes in this area most often indicate small saphenous vein insufficiency.

There are three branch veins that are important for evaluating the saphenofemoral junction (SFJ)[8]. Attention is first directed toward the anterior abdominal wall. The presence of varices in this area ("caput medusae") indicates insufficiency of the superficial epigastric vein (see Fig. 155.2); this is always abnormal and should alert the phlebologist to underlying deep venous obstruction, usually in the iliofemoral segment (see Fig. 155.3). The posteromedial thigh vein and the anterolateral thigh vein are often also insufficient in patients with GSV insufficiency and this usually presents as dilated reticular veins and telangiectasias within the involved anatomic zones[7].

LABORATORY EVALUATION OF THE SUPERFICIAL VENOUS SYSTEM

Vascular testing is indicated for symptomatic patients in whom the source of reflux is unclear by physical examination as well as several other clinical situations (Table 155.2). In the past, a key instrument was a handheld Doppler device, which detects increased or decreased frequency shifts from ultrasound waves that are reflected from blood cells coming toward or going away from the Doppler ultrasound probe, respectively[9]. Handheld Doppler devices have 4 MHz probes that penetrate more deeply (up to 8 cm) and 8 MHz probes that penetrate more superficially (0.5–2 cm).

When utilizing a Doppler device, the examiner places the probe over the vein in question and then compresses distal to the probe to create a flux sound (Fig. 155.6A)[10]. Because the veins have one-way valves, if a vein is normal there will be no reflux or reversal of flow upon release of the distal compression. If a reflux sound is heard after release of the distal compression, this is abnormal and diagnostic of venous valvular insufficiency (Fig. 155.6B). It is best to hold the probe at a 30° to 45° angle[11]. Reversal of blood flow, as the patient increases abdominal pressure with the Valsalva maneuver, indicates incompetent valves from the SFJ to the distal-most site of the probe. When placed on the medial superior thigh over the GSV a few centimeters distal to the

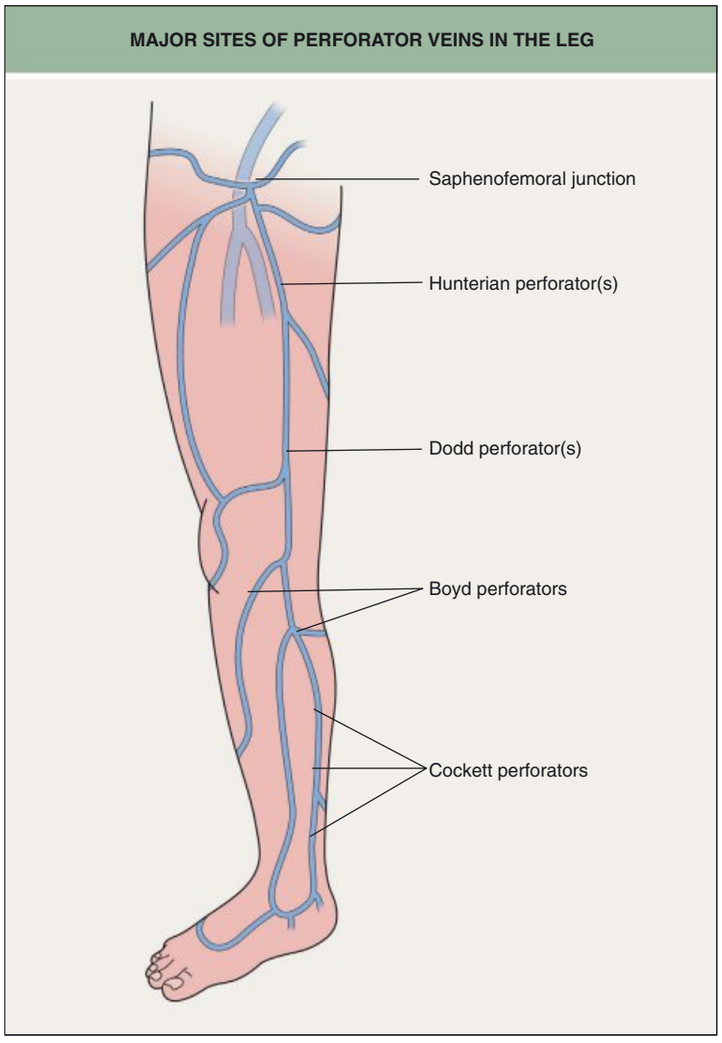

Fig. 155.4 Major sites of perforator veins in the leg. Posteriorly, additional perforating vein sites include the popliteal fossa, midportion of the gastrocnemius muscle belly, and two near the ankle.

SFJ, reversal of blood flow for >0.5 seconds indicates an incompetent SFJ. These patients require endovenous RF or laser closure of the GSV before any treatment of the distal varicose, reticular, and/or telangiectatic leg veins.

Nowadays, most vein experts utilize duplex ultrasonography (also referred to as duplex scanning) which is a faster, highly accurate, non-invasive technique that can provide both anatomic and physiologic information regarding the venous system[12] (Table 155.3). It is the modality of choice, not only for pretreatment assessment of varicose veins, but also for guidance during endovenous RF and laser procedures and for performing follow-up studies. Duplex examination of normal veins involves the use of a 7.5–12 MHz high-resolution B-mode scanner. In B-mode (brightness mode) ultrasonography, a linear array of transducers simultaneously scans a plane through the body and creates a two-dimensional image on a screen (Fig. 155.7). This type of scanning is more commonly known as 2D mode. Velocity information is presented as a color-coded overlay superimposed on a B-mode image and is called color Doppler.

COMPRESSION IN SCLEROTHERAPY AND VENOUS DISEASE

Graduated compression has many benefits in patients with venous disease including providing symptomatic relief, hastening venous ulcer healing, and minimizing the risk of venous ulcer recurrence[13,14]. By reducing the diameter of veins, compression therapy increases flow velocity and decreases the chance of thrombus formation. Following sclerotherapy (which is essentially a *controlled* thrombophlebitic reaction), compression reduces the diameter of the resulting thrombosis of the treated vein, which minimizes the inflammatory reaction, thereby decreasing the extent and incidence of post-treatment hyperpigmentation, recanalization of the vein, and telangiectatic matting. Compression also increases the contact between the sclerosant and the endothelial lining of the vessel wall, potentiating pan-vessel obliteration. There are three main types of graduated compression: graduated elastic compression stockings or bandages, inelastic compression garments or bandages, and pneumatic compression pumps[15]. Compression bandages are not recommended, as they are difficult to apply in a graduated manner and hold their compression for only a few hours after application.

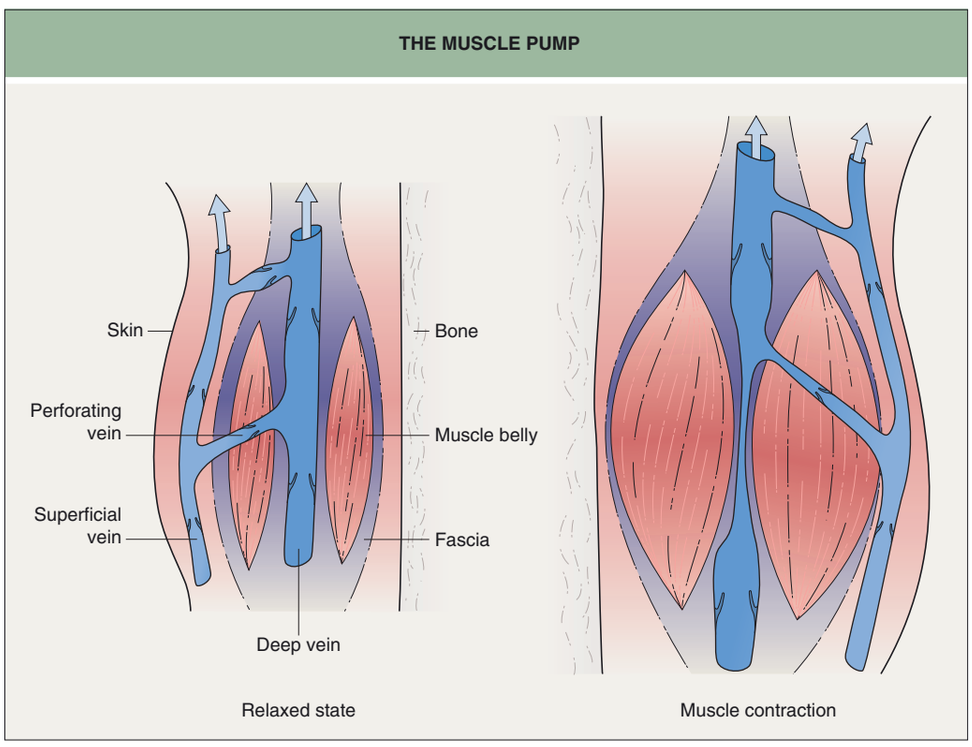

Fig. 155.5 The muscle pump, or "peripheral heart". The pump is located primarily in the calves. During muscle contraction, compression of veins transports blood to the heart by means of the deep venous system. *Adapted from Goldman MP, et al. Sclerotherapy, 5th ed. London: Mosby, 2011.*

Graduated elastic compression stockings are most commonly employed following sclerotherapy. They come in four classes, based on the pressure generated by the stocking at the level of the ankle, ranging from 20–30 mmHg (class I) to 50–60 mmHg (class IV) (see Ch. 105)[16]. Most sclerotherapy patients wear thigh-high or pantyhose stockings. In addition, most manufacturers now offer so-called "fashion hose" which approximate 18 mmHg pressure and are sheer, leading to greater patient compliance. In a multicenter study performed by Weiss et al.[17], 20–30 mmHg graduated compression stockings were shown to increase sclerotherapeutic efficacy and diminish post-treatment hyperpigmentation. At least 3 days of compression were necessary to produce this positive effect and 3 weeks of daytime wear was found to be the optimal time required for maximal effect[17].

We recommend that all patients wear graduated compression stockings for 1 week ("24/7") after the procedure. It is important for the patient to wear the stockings 24 hours a day, even while in the shower and when sleeping. If one removes the stockings in the shower, the superficial veins dilate. If one removes the stockings at night, the superficial system also dilates. Because stockings are worn around-the-clock for the first week, it is recommended that all patients wear thigh-high stockings, as these are more hygienic and easier to use than pantyhose, which extend up to the waist.

CEAP CLASSIFICATION OF CHRONIC VENOUS DISORDERS
Clinical classification (C)
C0: no visible or palpable signs of venous disease C1: telangiectasias or reticular veins C2: varicose veins C3: edema C4a: hemosiderin pigmentation, eczematous dermatitis (stasis dermatitis) C4b: lipodermatosclerosis, livedoid vasculopathy (atrophie blanche) C5: healed venous ulcer C6: active venous ulcer S: symptoms including aches, pains, tightness, skin irritation, heaviness, muscle cramps, and other complaints attributable to venous dysfunction A: asymptomatic
Etiologic classification (E)
Ec: congenital Ep: primary Es: secondary (post-thrombotic) En: no venous etiology identified
Anatomic classification (A)
As: superficial veins Ap: perforator veins Ad: deep veins An: no venous location identified
Pathophysiologic classification (P)
Pr: reflux Po: obstruction Pr,o: reflux and obstruction Pn: no venous pathophysiology identified

Table 155.1 CEAP (Clinical, Etiologic, Anatomic, Pathophysiologic) classification of chronic venous disorders.

SCLEROSING SOLUTIONS

The optimal sclerosing agent is one that induces pan-endothelial destruction or removal[18]. Thrombosis alone will not obliterate vessels because intact endothelium contains tissue plasminogen activator that can dissolve thrombi, leading to recanalization. The ideal sclerosing agent should possess no systemic toxicity and produce local endothelial destruction that fully extends to the adventitia with minimal thrombus formation[19]. The resultant vascular destruction induces an inflammatory reaction which leads to fibrosis and eventual obliteration of the vessel.

INDICATIONS FOR VASCULAR TESTING
1. Any varicosity greater than 2 mm in diameter extending the length of the calf or thigh 2. Presence of a "starburst" cluster of telangiectasias over sites of perforating veins (medial distal calf, mid-posterior calf, medial knee, medial mid-thigh) 3. Evidence of incompetent perforating veins (they connect the superficial and deep venous systems), e.g. lichen aureus 4. Varicose veins, either truncal or saphenous 5. Clinical signs of venous insufficiency (see Ch. 105) 6. Symptomatic veins of any diameter 7. History of deep venous thrombosis and/or thrombophlebitis 8. History of previous venous surgery or sclerotherapy with poor results or recurrence of varicosities

Table 155.2 Indications for vascular testing.

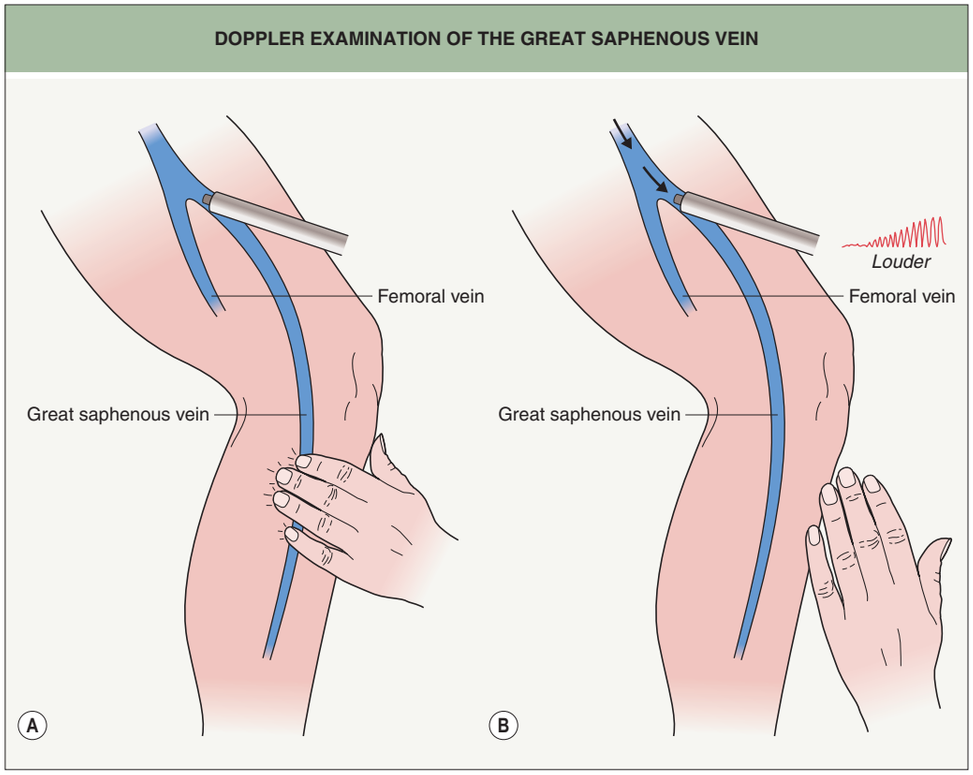

Fig. 155.6 Doppler examination of the great saphenous vein and detection of reflux. A The Doppler probe is held at a 30° to 45° angle and distally the vein is compressed by the examiner. **B** Detection of reflux following the release of distal compression denotes venous valvular insufficiency. *Courtesy Neil Sadick, MD.*

COMPARISON OF DOPPLER ULTRASOUND DEVICE AND DUPLEX ULTRASOUND SCANNER FOR PRESCLEROTHERAPY EVALUATION		
	Doppler	**Duplex**
Portability	Yes	Yes
Easy to use	Yes	Yes
Information obtained	1. Patency, competence of venous valves 2. Detection of deep venous thrombosis in thigh	1. Patency, competence of venous valves 2. Detection of deep venous thrombosis with greater accuracy (thigh > calf) 3. Velocity of reflux 4. Anatomy and anomalies of venous system (e.g. number of great saphenous veins) 5. Termination of small saphenous vein 6. Thrombosis versus sclerosis
Reliability	Less reliable because of blind, non-timed, pulsed sound beam	More reliable because of actual visualization of venous anatomy

Table 155.3 Comparison of Doppler ultrasound device and duplex ultrasound scanner for presclerotherapy evaluation.

Fig. 155.7 Duplex ultrasonography. In the two-dimensional (2D) B-mode duplex image, reverse flow (shown in blue) is seen coming from a branch of the great saphenous vein (GSV) that is superior to the GSV.

There are several important points to remember when choosing a particular sclerosing solution and determining the appropriate sclerosant concentration (Table 155.4)[20]:

1. If the sclerosant is too weak, insufficient endothelial damage will occur, leading to thrombosis secondary to varicose vessel wall damage. However, there will be no fibrosis and recanalization of the vessel occurs.
2. Too strong a solution may lead to uncontrolled destruction of vascular endothelium as well as additional vessel wall layers, which may eventuate in hyperpigmentation, neoangiogenesis (telangiectatic matting), and ulceration secondary to sclerosant extravasation. Excessive inflammation can also develop, leading to painful superficial thrombophlebitis.
3. Choose the minimal sclerosant concentration (MSC) that will cause irreversible damage to the cellular wall of the abnormal vessel.

Sclerosing agents are classified into three groups based upon the mechanism whereby they cause injury to the endothelium (Table 155.5):

1. ***Hyperosmotic agents*** **–** the osmotic agents include hypertonic saline, hypertonic saline–dextrose, and non-chromated glycerin. Their primary mechanism of action involves endothelial cell damage via dehydration (Fig. 155.8A).
2. ***Chemical irritants*** – the chemical irritants include chromated glycerin (glycerin plus potassium chromate) and polyiodide iodide. They injure cells by acting as corrosives; their cauterizing effect is thought to be due to the associated heavy metal (Fig. 155.8B).
3. ***Detergent sclerosants*** – the detergent sclerosants include sodium tetradecyl sulfate, polidocanol, ethanolamine oleate, and sodium morrhuate. This group of agents causes vascular injury by altering the surface tension around endothelial cells (Fig. 155.8C).

A GUIDE FOR THE SELECTION OF SCLEROSING SOLUTION CONCENTRATION AND VOLUME BY VESSEL TYPE		
Vessel	**Solution concentration**	**Volume (per region)**
Telangiectatic matting (after previous treatment)	Glycerin, 72%, diluted 2:1 with 1% lidocaine with 1:100 000 epinephrine	0.1–0.2 ml
Telangiectasias (up to 1 mm)	Glycerin, 72%, diluted 2:1 with 1% lidocaine with 1:100 000 epinephrine	0.1–0.3 ml
	Sodium tetradecyl sulfate, 0.1%–0.25% Polidocanol, 0.25%–0.5%	
	Hypertonic saline, 11.7%	
	Hypertonic saline, 10%, and dextrose, 25%	
Venulectasias (1–2 mm)	Sodium tetradecyl sulfate, 0.25%–0.5% Glycerin, 72%	0.2–0.5 ml
	Polidocanol, 0.5%–0.75%	
	Hypertonic saline, 11.7%–23.4% Hypertonic saline, 10%, and dextrose, 25%	
Reticular veins (2–4 mm subcutaneous blue veins)	Sodium tetradecyl sulfate, 0.1%–0.25%, *foam*	0.5 ml (may increase to 1–3 ml if filling of reticular vein by foam is observed)
	Polidocanol, 0.25%–0.5%, *foam*	
Non-saphenous varicose veins (3–8 mm)	Sodium tetradecyl sulfate, 0.5%–1%, *foam*	0.5 ml for liquids, 3 ml of foam per injection site in a large-capacity vein
	Polidocanol, 1–3%*	
Saphenous varicose trunks (usually >5 mm)	Polidocanol *foam* (Varithena®), 1%	0.5 ml for liquids (low-volume injection critical at high concentrations), 3 ml with foam
	Sodium tetradecyl sulfate, 1%–3%, *foam*	
	Polidocanol, 3%–5%†	
*1% is the highest concentration available in the US. †Not available in the US.		

Table 155.4 A guide for the selection of sclerosing solution concentration and volume by vessel type. The sclerosing agents are listed in order of preference.

The only agents that are Food and Drug Administration (FDA)-approved for sclerotherapy in the US are sodium tetradecyl sulfate, sodium morrhuate (fatty acids in cod liver oil), and polidocanol[21], including the 1% foam formulation (Varithena® [Boston Scientific]). Hypertonic saline is approved as an abortifacient rather than for the treatment of varicose veins. Glycerin is approved as a hyperosmotic agent for the treatment of acute intracerebral edema and acute angle glaucoma. Polyiodide iodide, a chemical irritant, lacks FDA approval for any indication. Glycerin (50%–72%), hypertonic saline (11.7%–23.4%), polidocanol (0.25%–5%), and sodium tetradecyl sulfate (0.1%–3%) are the current sclerosants of choice in the US.

Determining the minimal volume and concentration of the most appropriate sclerosing agent is a key factor in producing effective sclerotherapy results. This concept, termed the minimal sclerosant concentration (MSC), will enable the sclerotherapist to achieve maximal results while minimizing the complication profile[22,23]. A guide to suggested sclerosing agents and initial choices of sclerosant concentrations and volumes for instillation as related to vessel type and diameter is presented in Table 155.4.

IMPORTANT CHARACTERISTICS OF SCLEROSING SOLUTIONS					
Sclerosing solution (brand name)	**Class**	**Allergenicity**	**Risks**	**FDA approval**	**Dose limitation**
Hypertonic saline [11.7%–23.4%®]	Hyperosmotic	None	Pain* and cramping Necrosis of skin Hyperpigmentation	Yes, as abortifacient [18%–30%]	6–10 ml
Hypertonic saline [10%] and dextrose [25%] (Sclerodex®)	Hyperosmotic	Low (due only to added phenethyl alcohol)	Pain* (much less than with hypertonic saline alone)	No (sold in Canada)	10 ml of undiluted solution
Sodium tetradecyl sulfate (Sotradecol® [US], Fibrovein®, Thromboject®)	Detergent	Very rare anaphylaxis	Pain* with perivascular injection Necrosis of skin (with higher concentrations) Hyperpigmentation	Yes	10 ml of 3%
Polidocanol (Asclera® [US], Asklerol®, Aethoxysklerol®, Aetoxisclerol®, Sklerovein™, Varithena® [US])	Detergent	Very rare anaphylaxis	Lowest risk of pain Necrosis usually from arteriole injection Hyperpigmentation (with higher concentrations) Disulfiram-like reaction	Yes	5 ml of 3% (depends on body weight, see ref. 5)
Sodium morrhuate (Scleromate®)	Detergent	Anaphylaxis, highest risk	Pain* Necrosis of skin Hyperpigmentation	Yes	10 ml
Ethanolamine oleate	Detergent	Urticaria, anaphylaxis	Pain* Necrosis of skin Hyperpigmentation Viscous, difficult to inject Acute renal failure Hemolytic reactions	Yes (used primarily for esophageal varices)	10 ml
Polyiodide iodide (Varigloban®, Variglobin®, Sclerodine®)	Chemical irritant	Anaphylaxis Iodine hypersensitivity reactions	Pain* Necrosis of skin Dark brown color makes intravascular placement more difficult to confirm	No	5 ml of 3%
Glycerin [72%] with chromium potassium [8%] (Chromex®, Scleremo®); glycerin [172%] diluted 2:1 with 1% lidocaine, with or without epinephrine	Chemical irritant (plain glycerin may be an osmotic agent as well)	Very rare anaphylaxis (none for glycerin alone)	Pain* and cramping Low risk of hyperpigmentation Viscous, difficult to inject Hematuria with injections >10 ml	Yes (for treatment of acute intracerebral edema and acute angle glaucoma)	10 ml

*Includes burning.

Table 155.5 Important characteristics of sclerosing solutions. Sclerosing agents are classified into three groups: hyperosmotic agents, detergents and chemical irritants.

It is also important to have a working knowledge of the complication profile of each sclerosing solution (see Table 155.5). For example, hypertonic saline, an osmotic sclerosant, is associated with burning and cramping on injection and an increased incidence of ulcerative necrosis secondary to extravasation.

Sodium tetradecyl sulfate and polidocanol have been associated with a low incidence of allergic reactions, ranging from urticaria to anaphylaxis (<0.01%). However, with increasing usage, it is now thought that the risk of type I (i.e. immediate hypersensitivity) reactions is actually extremely low. In fact, after over 35 years of use in over 100 000 patients, the authors have never seen an allergic reaction except for one case of urticaria. Hyperpigmentation has been reported in 5%–30% of patients treated with all sclerosing solutions except glycerin, which has a <1% incidence of pigmentation. In the authors' experience, the incidence of hyperpigmentation is related more to the concentration of the sclerosing agent as well as patient skin type, vessel type, and other vascular fragility factors[24–26].

Creating foaming detergent solutions by mixing them with air or CO_2 (typically in a mixture of 1 ml of solution with 4 ml of air or CO_2) has been found to increase the potency of the sclerosing solution twofold while decreasing its adverse effect profile fourfold. Foam displaces blood and remains for an extended time in the target vessel. This makes the sclerosing solution more efficient, so that it may be utilized at lower concentrations. The use of CO_2 rather than room air allows the gas–sclerosant bubbles to break down faster, minimizing the possibility of gas embolization into the arterial circulation via a patent foramen ovale. Of note, the detergent moiety in the foam is broken down within seconds and/or within centimeters of its injection. As a result, the foam bubbles that reach the heart are purely air with no toxicity, similar to the release of air bubbles after a SCUBA dive.

TECHNIQUES FOR TREATING TELANGIECTASIAS AND RETICULAR VEINS

The treatment of telangiectasias and reticular veins is most commonly performed for cosmetic improvement, but up to 50% of these patients also report a variety of symptoms from dull aching legs to throbbing pain over the telangiectasia[27,28]. Telangiectasias are best defined as nearly flat, red to blue vessels 0.1–1 mm in diameter (Table 155.6). Venulectasias are blue- to violet-colored vessels, sometimes distended above the skin surface and most often 1–2 mm in diameter. Reticular veins have a cyanotic blue to blue–green hue and are visually 2–4 mm in diameter. When a complex of reticular veins is located on the lateral thigh, it is felt to be a vestige of embryonal development known as the lateral subdermal plexus[29,30].

The treatment of telangiectasias and reticular veins is undertaken only after all sources of reflux have been addressed, as it is important to treat proximal sites of reflux first and to treat larger vessels before smaller veins. Alone or in combination with laser or intense pulsed light technology, sclerotherapy of small-diameter vessels is the most common challenge faced by the dermatologic surgeon who performs sclerotherapy. Preoperative photographic documentation and full informed consent outlining all possible risks and complications as well as treatment expectations should be obtained prior to therapy[31,32].

Materials employed in the treatment of telangiectasias and reticular veins are relatively simple. They may include:

- cotton balls soaked with 70% isopropyl alcohol
- protective gloves
- 3 and 5 ml disposable syringes
- Female-to-female adaptor for mixing air with detergent solution
- 30-gauge disposable ½-inch transparent hub needles

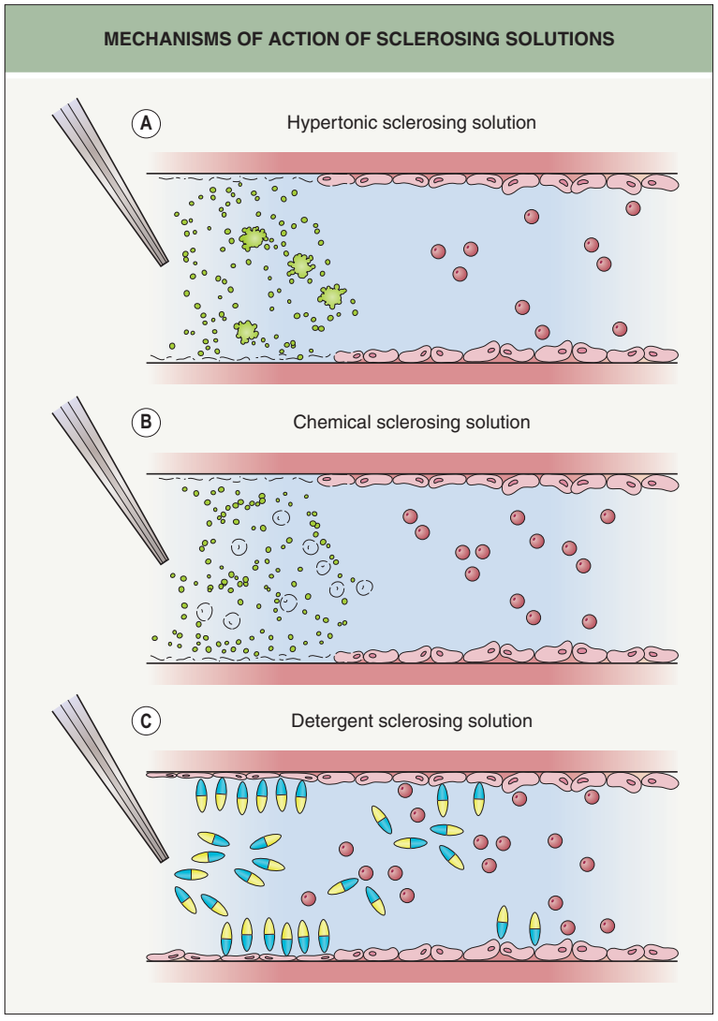

Fig. 155.8 Mechanisms of action of sclerosing solutions. A Hypertonic, which induces endothelial damage via a gradient dehydration effect. **B** Chemical, which injures cells by acting as a corrosive. **C** Detergent, where the hydrophobic portion of the detergent molecule (blue) attaches to the endothelial cell wall while the hydrophilic portion (yellow) draws water into the cell, leading to an overhydrated maceration effect. *Adapted from Goldman MP, et al. Sclerotherapy, 5th edn. London: Mosby, 2011.*

- magnifying lens (2–3×), possibly with cross-polarized light
- nitroglycerin paste for prolonged blanching
- bronchodilator inhaler in case of bronchospasm
- 1:1000 epinephrine (adrenaline) in case of anaphylaxis.

Flow sheets with segmental numerical division of the legs are helpful in documenting areas that are treated at each session. Because successful sclerotherapy that results in pan-luminal endofibrosis can take up to 6 weeks, it is recommended that treatment sessions should not be repeated for at least this interval of time.

There are four variable components that may be employed in the treatment of telangiectatic and reticular veins including[33–35]:

1. ***Aspiration.*** Aspiration of a small amount of blood into the needle hub may ensure that the dermatologic surgeon has adequately cannulated the vein. Of note, the vein may collapse if aspiration is too strong.
2. ***Direct puncture without aspiration.*** This technique relies on the feeling associated with perforating the vein wall. Although it is slightly more precarious for beginners, this technique can be mastered with time.
3. ***Air bolus variant*** (Fig. 155.9A). Injection of <0.5 ml of air prior to introduction of the sclerosant will displace blood in the vein. Once intravascular access is confirmed, the sclerosant can be safely injected. Air inadvertently introduced into the tissues is not as damaging as the sclerosant might be. Too strong of a push may lead to truncal distention and rupture. The small air bolus technique is ideal for hypertonic saline, as even slight extravasation of solution will cause ulceration.
4. ***Empty vein variant.*** In an attempt to remove as much blood as possible, the leg is elevated and kneading with gentle pressure is performed before the sclerosant is injected. The persistence of varicose veins after treatment is usually due to recanalization of the intramural thrombus that develops, and the empty vein technique may reduce the amount of thrombus. This concept is more important when treating larger veins. Other advantages of this technique are that an empty vein has minimal volume and therefore the endothelium is exposed to a concentration of sclerosant similar to that injected. Also, a smaller volume of sclerosant is necessary to ensure contact with the endothelial surface and lower concentrations of sclerosant may be employed since there is less blood in the vein to dilute the solution[36]. Foamed sclerosing agents, discussed later, displace blood from veins, thereby automatically resulting in the empty vein technique and enhanced efficacy.

Injection Technique

Injection is performed utilizing one or more of the previously described techniques. The needle may be bent at an angle of 30°. Hand traction is used by either the dermatologic surgeon or an assistant to keep the skin taut (Fig. 155.9B). Large vessels are injected before smaller vessels, i.e. injection of the reticular veins feeding smaller telangiectasias or venules may eradicate the latter, minimizing side effects such as hyperpigmentation. Areas of vascular arborization (Fig. 155.10) should be treated before single discrete linear vessels are cannulated[37].

The utilization of alcohol in swabbing the skin prior to injection will decrease the index of refraction of light and thus make the vessels more visible at the skin surface. In addition, cross-polarized light can be used to enhance vessel visualization by eliminating reflection of light from the skin surface. Brisk cannulation of veins causes minimal vascular trauma, less vasoconstriction, and less chance of extravasation of blood. Injection pressure is kept to a minimum by performing the injection slowly to prevent vascular distention and to allow adequate time for the sclerosing agent to interact with the endothelium. A small amount of sclerosant is used at each injection site (0.1–0.4 ml) to minimize side effects such as telangiectatic matting, post-sclerosis pigmentation, and ulcerative necrosis due to extravasation. The sclerosing injection is stopped when the solution has filled the targeted veins and the injector no longer sees the vessel clearing of blood. Injections are carried out at approximately 3–6 cm intervals until the entire vessel has been treated.

Treatment Protocol

Treatment sessions are scheduled at 6- to 8-week intervals to allow enough time for full endosclerosis to occur, for post-treatment inflammation to resolve, and to evaluate the results of the previous treatment session. Most patients will require one to three treatment sessions to clear their legs of unwanted telangiectatic and reticular vessels. If a poor response is seen at the end of this treatment schedule, the dermatologic surgeon may:

- increase the concentration of sclerosant
- switch to another sclerosant
- re-examine the patient to find a possible source of reflux previously missed.

Lasers and Intense Pulsed Light Sources for Treatment of Telangiectasias

Laser and intense pulsed light (IPL) therapy of lower extremity vessels may have a synergistic effect when used in combination with sclerotherapy (see Ch. 137).

LARGER VARICOSE VEINS

The treatment of large-diameter blood vessels requires greater and more precise attention to detail regarding anatomy and points of reflux[38]. Contraindications to treatment of large-diameter veins include pregnancy, lactation, allergy to the sclerosing agent, a hypercoagulable state (see Table 105.9 for causes of thrombophilia), non-ambulation, and non-compliance[39]. A foamed detergent is currently recommended

CLASSIFICATION OF VEINS AND CLINICAL APPROACH TO TREATMENT OF VENOUS PATHOLOGY

	Type	Description	Diameter (mm)	Color	Treatment	
	I	Telangiectasias (spider veins) Telangiectatic matting	0.1–1	Usually red network	• Microsclerotherapy • Intense pulsed light • Laser (e.g. pulsed dye, 1064 nm Nd:YAG)	
	II	Venulectasias	1–2	Violaceous	• Sclerotherapy • Laser (e.g. 1064 nm Nd:YAG)	
	III	Reticular varicosities	2–4	Cyanotic blue to blue–green	• Sclerotherapy • Ambulatory phlebectomy • Laser (e.g. 1064 nm Nd:YAG)	
	IV	Varicosities (secondary saphenous branch or perforator-related)	3–8	• Blue to blue–green	• Ambulatory phlebectomy • Sclerotherapy	
	V	Saphenous varicosities (truncal or axial varicosities including main saphenous trunks and first-generation branch varicosities)	≥5	• Blue to blue–green • May be palpable and not visible	• Ambulatory phlebectomy • Endovenous radio-frequency closure • Sclerotherapy • Endovenous laser ablation (EVLA)

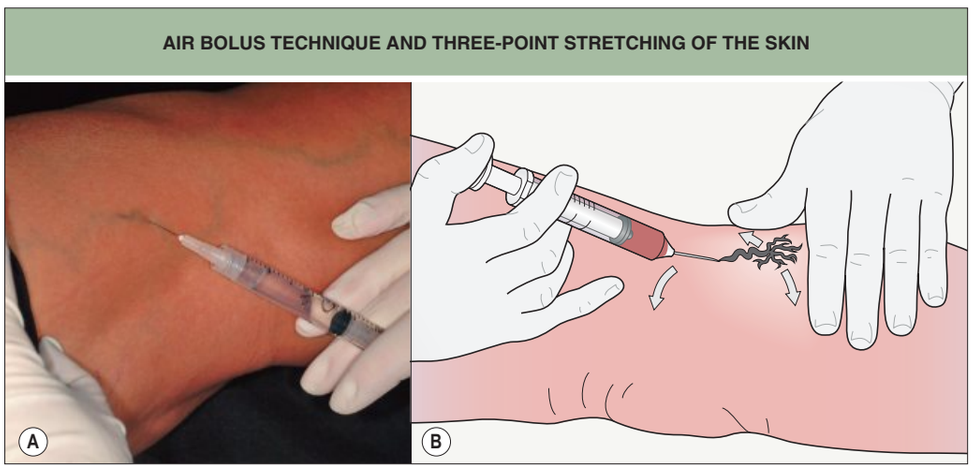

Fig. 155.9 Air bolus technique and three-point stretching of the skin. A Injection of an air bolus (<0.5 ml) prior to injection of sclerosant can displace blood in the vein and ensure intravascular needle location. Air inadvertently introduced into the tissues is not as damaging as the sclerosant might be. **B** Three-point stretching of the skin allows for more accurate cannulation of the vessel. *B, Redrawn from Goldman MP, et al. Sclerotherapy, 5th edn. London: Mosby, 2011.*

as the sclerosing agent (see below), with the concentration determined by the size of the vein to be injected (see Table 155.4).

Factors of importance in the treatment of large-diameter veins include:

1. An understanding of the precise anatomy of the varicosity under consideration for treatment.
2. Adherence to a rational treatment plan in which injections begin at the highest point of reflux, with progression to the next highest point in a proximal-to-distal direction.
3. Determination of the most significant reflux point[40,41].

The dermatologic surgeon must determine whether reflux originates in the deep venous system, the SFJ, saphenopopliteal junction (SPJ), GSV,

Fig. 155.10 Treatment of arborizing feeder veins. This therapeutic approach (arrow) diminishes the number of injections required in a given sclerotherapy session, thus minimizing potential side effects. *Courtesy Jean L. Bolognia, MD.*

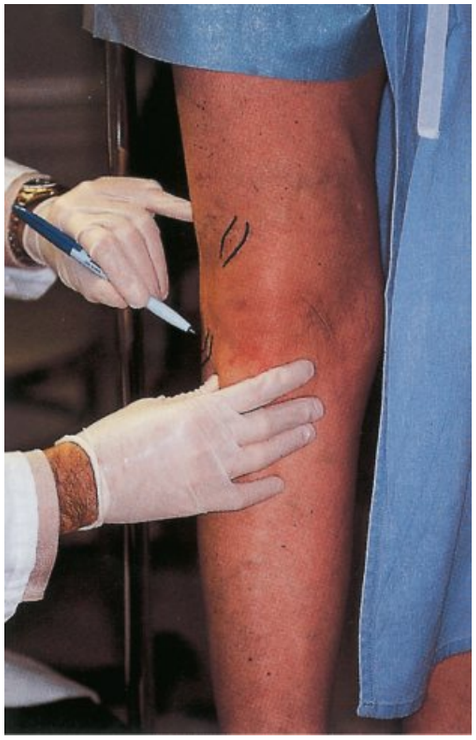

Fig. 155.11 Initial step prior to large-vein sclerotherapy. Marking of treatment sites in a standing position by indelible marker. *Courtesy Neil Sadick, MD.*

SSV, or a perforator (see Fig. 155.2 & 155.3). The veins which represent the primary source of reflux must be treated before secondary sources of reflux are treated. Guidance via duplex ultrasonography (see Table 155.3) is often helpful in the therapeutic approach to larger-diameter vessels, particularly in those patients where the anatomy is so intricate that the point of reflux would otherwise be difficult to detect.

Several slightly modified techniques and/or positions for large-vein sclerotherapy have been described. Three positions for treating large-diameter vessels are: (1) the standing supine elevation direct cannulation technique; (2) the multiple precannulation sites (MPS) technique; and (3) the supine cannulation (SC) technique[41,42].

In the *standing supine elevation direct cannulation* technique, the patient stands at first, causing the varices to bulge and become more visible (Fig. 155.11)[30]. Injection points are marked at primary sites of reflux into the superficial venous system and approximately every 3–4 cm along the vein to be treated. The patient is then placed in a supine or prone position, the vein is emptied to maximize sclerosant–endothelial contact, and a small volume of sclerosant is injected at each of the marked points along the vein to be treated. A 27- to 30-gauge needle on a 3 ml syringe is often employed for this technique. The needle is advanced while aspirating into the syringe until aspiration of dark venous blood indicates penetration of the lumen. Concentrated sclerosant (0.5–1.5 ml) is injected at each site, followed by massage to ensure maximum sclerosant–endothelial contact. The vein will appear visually contracted at the end of the treatment. Leg elevation for a minute following the injection of foam allows the larger veins to contract. This may result in further spread and better contact of the sclerosant with the endothelium, improving the clinical results.

In the *multiple precannulation sites* (MPS) variation, the patient initially stands so as to induce the varices to bulge and become more visible. Injection points are marked at proximal *and* distal sites along the distended vein. The veins are subsequently cannulated with either a 23-gauge butterfly needle and tubing or a plastic intravenous cannula and extension tubing at *both* the proximal and distal sites[43].

The butterfly needles or cannulas must be firmly secured, as the patient then moves to the treatment table and elevates the extremity undergoing treatment. After an intravascular position has been verified, 2–3 ml of sclerosant is infused into the cannula and subsequently into the vein while the surrounding area is observed for swelling or other evidence of extravasation. In most patients, a single proximal and a single distal injection point are sufficient to sclerose a large tortuous vessel[44].

The authors routinely use the *supine cannulation* (SC) position, as it is faster and has less risk of a vasovagal reaction when compared to the upright position. Larger veins are treated proximally to distally with an appropriate concentration of sclerosing solution (see Table 155.4). Foamed detergent solutions are recommended for sclerosis of larger varicose veins, and if foaming with room air or CO_2 is chosen (see next section), this is performed just prior to injection[45].

Foamed Detergent Solutions

Polidocanol 1% injectable foam (Varithena®)

Polidocanol 1% injectable foam (Varithena®) is FDA-approved for the treatment of incompetent GSVs, accessory saphenous veins, and visible varicosities of the GSV system above and below the knee. Physicians administering this polidocanol 1% foam must be experienced with venous procedures, possess a detailed working knowledge of duplex ultrasonography of veins, and be trained in its administration. The formulation is based upon a patented technology that produces cohesive, low-nitrogen microfoam coupled with a microfoam-generating device which injects an O_2:CO_2 (65:35) gas mixture with <0.8% nitrogen, leading to small bubbles (median diameter <100 microns). The resulting microfoam produces endothelial destruction with a very low polidocanol concentration of 1% in a 1:7 ratio of liquid:gas phases. The cohesive microfoam fills the vein lumen leading to circumferential contact and displacement of blood resulting in more efficient vein sclerosis.

Spontaneous foaming with room air

Before the approval of polidocanol 1% foam (Varithena®), a detergent solution such as sodium tetradecyl sulfate or polidocanol was foamed to a thick consistency by rapidly agitating it with room air in a ratio of solution to gas of 1: 4. As noted previously, using foam is advantageous when treating larger varicosities. For instance, an increased quantity of solution can be injected over longer segments of veins. Also, a foamed sclerosing solution retains more of its potency, as the full concentration of the sclerosant is present on each microbubble, residing on the outer micelle. Due to persistence and increased potency, foamed agents reduce the number of required treatments and allow treatment of larger vessels.

In contrast, for smaller vessels, non-foamable glycerin and hypertonic saline are rapidly diluted, acting only within their concentration gradients and thus limiting the extent and intensity of sclerosing action. It is not practical to treat large veins with glycerin or hypertonic saline, as more frequent injections would be necessary, and the potency rapidly diminishes due to the concentration being rapidly diluted by blood within the treated vein.

Duplex Ultrasonography

In addition to delineating vascular anatomy, duplex ultrasonography (see Fig. 155.7) can be used to assess the vascular response to sclerotherapy, including that of large non-junctional varicose veins. Incomplete endosclerosis has a pattern of intravascular thrombosis (multiple echoes), with the vein lumen remaining partially patent. When sclerotherapy has been successful, the vein wall is thickened and non-compressible (non-echogenic)[38,46]. Duplex ultrasonography can also provide guidance during sclerotherapy with *foamed* sclerosing agents. The distribution of foamed sclerosant as it flows into the targeted vein is easily visible as a sparkling echo. This also decreases the chance for inadvertent arterial injection.

POSTSCLEROTHERAPY COMPRESSION

Cotton-roll pads or foam pads may be applied along the entire course of the treated vessels and held in place by a compression garment. Graduated compression stockings that are class I (20–30 mmHg) or preferably class II (30–40 mmHg) are suggested for all patients following sclerotherapy of telangiectasias and reticular veins[17]. Patients should be instructed to walk for 30 minutes after each treatment session in order to minimize thromboembolic events as well as to decrease the diameter of the superficial veins. The optimal duration of compression was shown in a more recent study to be a minimum of 3 weeks of daytime wear, although 3 days of daytime compression led to better results than did no compression[17]. After large-vein sclerotherapy, we recommend 7 days of uninterrupted compression (24/7), during which the patient may bathe or shower by either placing a large plastic bag over the compression bandage or stocking or just allowing the stocking to get wet and then drying it with a hairdryer. After the first 7 days, the compression pads or cotton rolls are discarded and patients are permitted to remove the stocking, as needed, for bathing and sleeping. Ambulation is begun immediately post-treatment.

COMPLICATIONS

There are three major considerations when anticipating and managing complications of sclerotherapy (Table 155.7). The first is that fastidious technique will minimize the incidence of side effects. Second is an appropriate understanding of maneuvers that may be instituted if something is thought to have gone wrong. Finally, an appreciation of the management options available for adverse sequelae can minimize the intensity of complications when they occur[47].

SCLEROTHERAPY COMPLICATIONS	
Cutaneous complications	**Extracutaneous complications**
Early	**Early**
• Localized urticaria • Urticarial or morbilliform eruptions • Bruising • Edema • Ischemia/necrosis (e.g. due to arterial injection, vasospasm, extravasation)	• Systemic allergic reactions (e.g. anaphylaxis) • Scotomata (with foam sclerosants) • Migraine with aura • Vasovagal syncope
Delayed	**Delayed**
• Superficial thrombophlebitis • Ulceration (secondary to ischemia/necrosis) • Hyperpigmentation • Telangiectatic matting (neoangiogenesis) • Hypertrichosis • Compression-related problems (folliculitis, irritant contact dermatitis)	• Deep venous thrombosis/pulmonary embolus • Nerve damage

Table 155.7 Sclerotherapy complications.

Postsclerotherapy Pigmentation

The incidence of postsclerotherapy hyperpigmentation (Fig. 155.12) varies from 5% to 30%[26,45,48,49]. The purple–brown discoloration has been shown to be due to extravascular deposits of hemosiderin[50]. Hypercoagulability syndromes such as antithrombin III, protein C or protein S deficiencies, use of nonsteroidal anti-inflammatory drugs (NSAIDs), high total body iron stores, use of minocycline, or vessel fragility, commonly noted in the elderly, may predispose to this adverse sequela[51]. Methods to minimize the incidence of postsclerotherapy pigmentation are outlined in Table 155.8. Although various treatment modalities have been tried for this complication, only the Q-switched ruby laser has shown any degree of reproducible success[52–54]. The hyperpigmentation usually resolves over 6–12 months. If it persists, the dermatologic surgeon should search for a vessel with persistent reflux into the area or an underlying predisposition.

Telangiectatic Matting

Blushes or nets composed of very fine telangiectasias may occur around sites of previously injected veins or sites of previous surgical interruption, e.g. ligation or ambulatory phlebectomy (Fig. 155.13). They may occur from days to months after treatment and are seen in 5%–15% of patients[26,45,55]. Sites of predilection include the thighs, medial malleolus, and medial and lateral calves. Risk factors include obesity, use of estrogen-containing

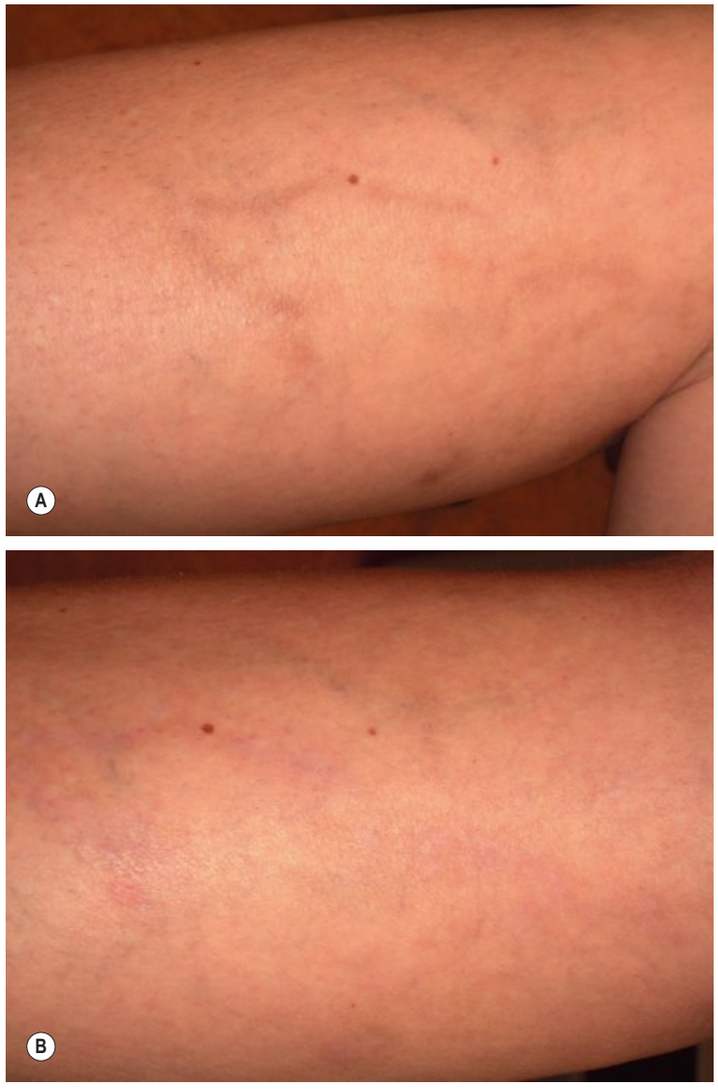

Fig. 155.12 Sclerotherapy-induced hyperpigmentation. A Development of hyperpigmentation along the course of a 3–4 mm diameter reticular vein three months after treatment with sodium tetradecyl sulfate 0.5% foam. **B** Six months after treatment with the Q-switched ruby laser at 6 J/cm^2, 5 mm diameter spot. Note complete resolution of hyperpigmentation. The melanocytic nevus serves as a landmark.

medications, and pregnancy. Excessive postsclerotherapy inflammation may also predispose individuals to this complication, due to inadequate compression or exceeding the MSC of the sclerosing solution.

Generally, telangiectatic matting resolves within 3–12 months without specific treatment. Persistence should lead the dermatologic surgeon to attempt to locate a source of reflux in the area (usually a feeding reticular vein), although matting may be a sign of underlying saphenous vein insufficiency. Low injection pressure utilizing the MSC is the most effective way to minimize this complication. Additional measures include the use of no more than 1 ml of sclerosant per injection site, limiting the injection blanch to 1–2 cm, encouraging normalization of weight, and discontinuation of oral contraceptives for 1 month prior and 2 months following sclerotherapy. Short-wavelength lasers (595–600 nm) and intense pulsed light sources as well as reinjection of vessels utilizing a glycerin solution are the most effective ways of managing this problem (see Table 155.4)[56].

Ulceration

Cutaneous necrosis may occur with any sclerosing agent (although the authors have never seen this with glycerin). It may be the result of extravasation of a sclerosing agent into the perivascular tissues, which is especially common with the use of hypertonic saline, non-foamed sodium tetradecyl sulfate, or polidocanol that is >1% in concentration; injection into a dermal arteriole or an arteriovenous anastomosis; reactive vasospasm of such a vessel; or excessive cutaneous pressure created by compression techniques[57]. If there is extravasation of hypertonic saline into the perivascular tissue, infiltration of the area with normal saline may dilute the sclerosant. A hemorrhagic bulla may form at the site within 12–24 hours and later progress to an ulcer. If a porcelain-white area appears within the skin immediately after injection, this indicates arteriole injection or spasm. To reduce the likelihood of ulceration, the physician may rub a small amount of 2% nitroglycerin ointment into the area until a reactive hyperemia is seen. Since most ulcerations are less than 4 mm in diameter, second intention healing usually results in an acceptable scar. Larger ulcerations may be excised (as early as possible) and closed for faster healing and a smaller scar. Application of topical silicone gel (e.g. Stratacel® [Stratpharma]) may reduce the pain associated with the ulcer and speed the rate of healing[58].

METHODS TO MINIMIZE POSTSCLEROTHERAPY HYPERPIGMENTATION
Pretreatment planning
• Evaluate for a hypercoagulable state in patients with a history of venous thrombosis (see Table 105.9) • Avoid treating patients with known defects in iron transport (e.g. hemochromatosis) • Avoid concomitant use of minocycline, aspirin, or NSAIDs
Treatment technique
• Eliminate high-pressure reflux before treating smaller vessels • Select a sclerosant with the least inflammatory effects • Use a sclerosant concentration appropriate for the vessel size (see Table 155.4) • Minimize intravascular pressure by elevating the leg during treatment • Direct treatment at the deepest site in a telangiectatic cluster • Minimize risk of vessel rupture (e.g. by slow injection) • Avoid excessive syringe pressure
Post-treatment care
• Apply compression immediately after treatment • Remove postsclerotherapy thrombi as early as possible

Table 155.8 Methods to minimize postsclerotherapy hyperpigmentation. NSAIDs, nonsteroidal anti-inflammatory drugs.

Systemic Allergic Reaction

True allergic reactions following sclerotherapy treatments are extremely rare. Delayed hypersensitivity reactions, which may be urticarial or morbilliform in nature, can occur from 8 to 16 hours after treatment. Type I immediate reactions, varying from urticaria to bronchospasm to anaphylaxis eventuating in cardiovascular collapse, have been rarely reported. Intrinsically, only hypertonic saline has no potential to act as an allergen. However, the presence of additives such as benzoate or lidocaine may lead to the development of hypersensitivity reactions.

Sodium tetradecyl sulfate has a surprisingly low allergic potential (<0.01%). The most commonly reported hypersensitivity reactions are morbilliform eruptions developing 30–90 minutes after injection[59]. Reactions to polidocanol are similarly rare (<0.01%). Both urticarial and morbilliform reactions have been reported, as well as an extremely rare anaphylaxis-related fatality[59].

Antihistamines and oral corticosteroids (e.g. prednisone 40–60 mg/day for 7–10 days) can be used for the milder reactions, whereas intravenous corticosteroids and subcutaneous epinephrine are often required for more severe reactions.

Arterial Injection

The most feared complication in sclerotherapy is inadvertent injection into an artery. Arterial injection of a sclerosing agent produces a sludge embolus that obstructs small arteries as well as the microcirculation. The most common location for an arterial injection to occur is the popliteal fossa, when attempting to inject the SSV. After an intra-arterial injection, the patient usually notes immediate pain, but not always.

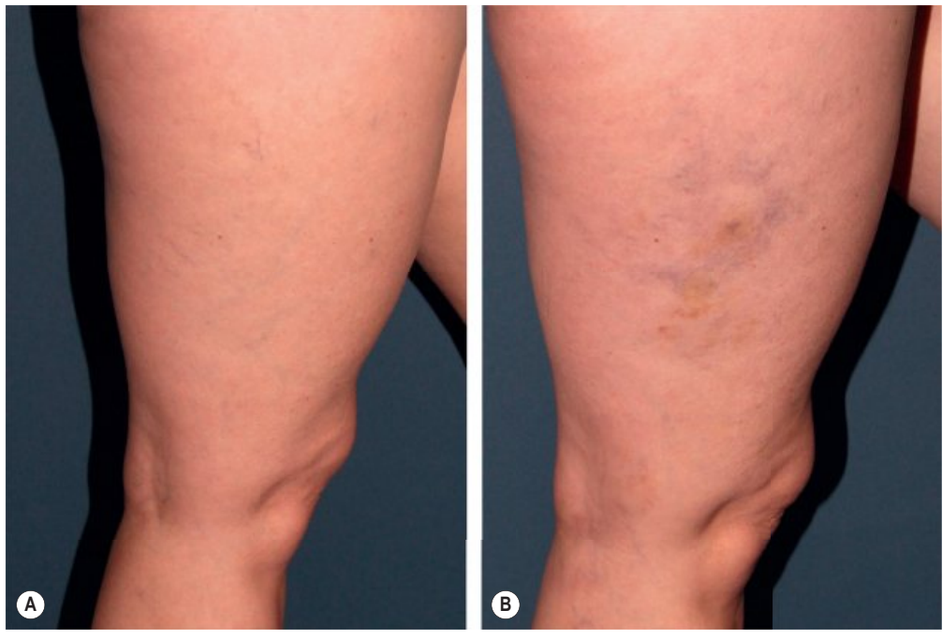

Fig. 155.13 Telangiectatic matting (neoangiogenesis). **A** Prior to vein surgery. **B** After vein surgery – development of telangiectatic matting at the site of the scar.

A dusky cyanotic hue and pallor in the distribution of the injected artery usually occurs within a few minutes to several hours. Arterial pulsations of the posterior tibial or dorsalis pedis arteries are usually not affected. Sloughing of superficial tissues may result in significant scarring or may even require amputation[60].

Arterial injection is a true sclerotherapy emergency. Immediate intervention has been advocated but has never been proven to affect outcome. Procaine (1%), administered via periarterial infiltration, forms a complex with sodium tetradecyl sulfate, rendering it inactive; however, procaine is not effective for polidocanol. Cooling of the limb to minimize tissue anoxia, followed by immediate heparinization for 7–10 days and administration of intravenous dextran (10%, 500 mg daily) for 3 days is recommended. Thrombolysis and the utilization of long-term vasodilator therapy (e.g. calcium channel blockers) should be considered.

Miscellaneous Complications

Localized urticaria following injection is common and is most likely related to mast cell degranulation and cytokine release. No treatment is indicated, although pretreatment with an H_1 antihistamine or immediate application of a class I ultra-potent topical corticosteroid may ameliorate the erythema, if bothersome to the patient. Compression stocking-related problems such as ulcers, pressure bullae, contact dermatitis and folliculitis may be minimized by adherence to appropriate compression application and fitting guidelines[47].

Nerve damage may occur secondary to direct injection of sclerosant or as a result of perivascular inflammation around nerve sheaths. The saphenous and sural veins of the inner leg and foot are high-risk sites and special care should be taken when injecting these locations. The utilization of NSAIDs may shorten the duration of symptoms[61].

Superficial thrombophlebitis develops 1–3 weeks after injection, presenting as a tender erythematous induration of the injected vein. This complication is observed less often if compression is maintained for an adequate period of time following sclerotherapy. When superficial thrombophlebitis occurs, the thrombus should be evacuated and adequate compression, frequent ambulation, and aspirin or an NSAID instituted. The concomitant presence of deep vein thrombosis (DVT) must be considered[47], and a search for underlying causes for thrombophlebitis other than the sclerotherapy, such as an internal malignancy, may be warranted.

AMBULATORY PHLEBECTOMY

Ambulatory phlebectomy is an in-office surgical procedure designed for the complete removal of diseased venous segments by means of hook avulsion of the targeted vessel. It was developed in the 1950s by the Swiss dermatologist Robert Mueller[62]. All superficial veins, except for the groin termination of the GSV, may be easily avulsed utilizing this technique. Large veins – in particular, well-demarcated branches of the GSV, SSV or perforators – can be avulsed through microstab incisions[62,63].

Preoperative Considerations

Doppler and duplex ultrasonography are necessary to confirm the competence of the SFJ and the SPJ, as well as that of the deep venous system[64]. The varicose veins to be removed are outlined with an indelible marking pen with the patient in a standing position. Marking of appropriate venous segments is the most important aspect of this procedure because it allows rapid isolation of desired venous segments to be removed. Because of potential shift of the vein up to 1 to 2 cm when moving from an upright vertical to a transverse horizontal position, the patient is then asked to lie in the operative position and confirmation of venous position by transepidermal illumination (Veinlite® [TransLite LLC] or Venoscope® II [Venoscope LLC]) with separate marking over the veins is performed. This double-marking technique has been found to be helpful in determining positional shift[65,66] (Fig. 155.14).

Anesthesia and Intraoperative Materials for Ambulatory Phlebectomy

Tumescent anesthesia has several advantages when performing ambulatory phlebectomy. These include: (1) rapid anesthesia of an extensive segment of diseased vein; (2) compression of the vein, allowing it to be removed through a 2–3 mm incision; and (3) easier location of the vein owing to the temporary swelling and firmness of the soft tissues which press the vein against the skin. In addition, tumescent anesthesia reduces blood loss, diminishes bruising, eliminates multiple needle sticks, and produces greater postoperative comfort. Most commonly, tumescent anesthesia comprised of 0.05% lidocaine with 1:1 000 00 epinephrine is employed (see Table 156.3)[67,68].

Fig. 155.14 Double-marking technique for ambulatory phlebectomy. Outlining of the varicose veins while the patient is standing (black ink) and then while the patient is lying down in the operative position (green ink) utilizing transillumination.

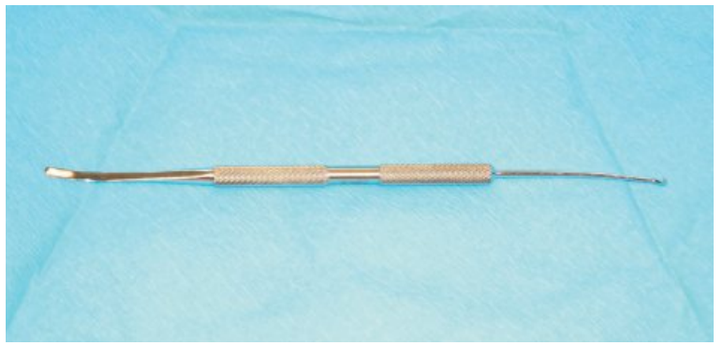

Fig. 155.15 Phlebectomy hook. A classic Mueller type of hook at one end and a Varady dissector at the other end ("Goldman hook").

Instrumentation for ambulatory phlebectomy should include several varied hook devices, which come in small, medium, and large diameters (sizes 2 to 4) from various manufacturers. The ideal hook should have a comfortable grip to prevent fatigue and a sharp harpoon to catch the adventitia of the vein[62,69] (Fig. 155.15).

Ambulatory Phlebectomy Technique

Microincisions measuring from 1 to 3 mm in length and parallel to the long axis of the extremity are made with an 18- or 16-gauge hypodermic needle or a #11 blade. The microincisions are made vertically and should follow the relaxed skin tension lines. The interval between incisions varies between 3 and 5 cm according to the type of vein being removed. Separation of the vein from the surrounding adventitia may be accomplished by utilizing an iris scissor or blunt probe and should also follow the skin tension lines[66].

The vein is then exteriorized utilizing the phlebectomy hook. Next, the exteriorized vein is clamped proximally and distally and pushed or pulled, depending on operator preference, from each end until the vein is avulsed (Fig. 155.16). A gentle rotation or rolling motion of the clamp in the same and/or opposite direction pulls and frees the vein from its secondary connective tissue sheath. The process is repeated at 3–5 cm intervals along the entire length of the marked vein, until the entire diseased vein has been removed or adequate interruption has been made[70,71].

Special care is required in difficult anatomic zones such as the knees, ankles, and feet. The "hooking" should be gentle and slow. Once the vein is hooked, it should come out easily. If it is difficult and if removal of the vein requires a lot of traction, it is possible that a fascial strand structure

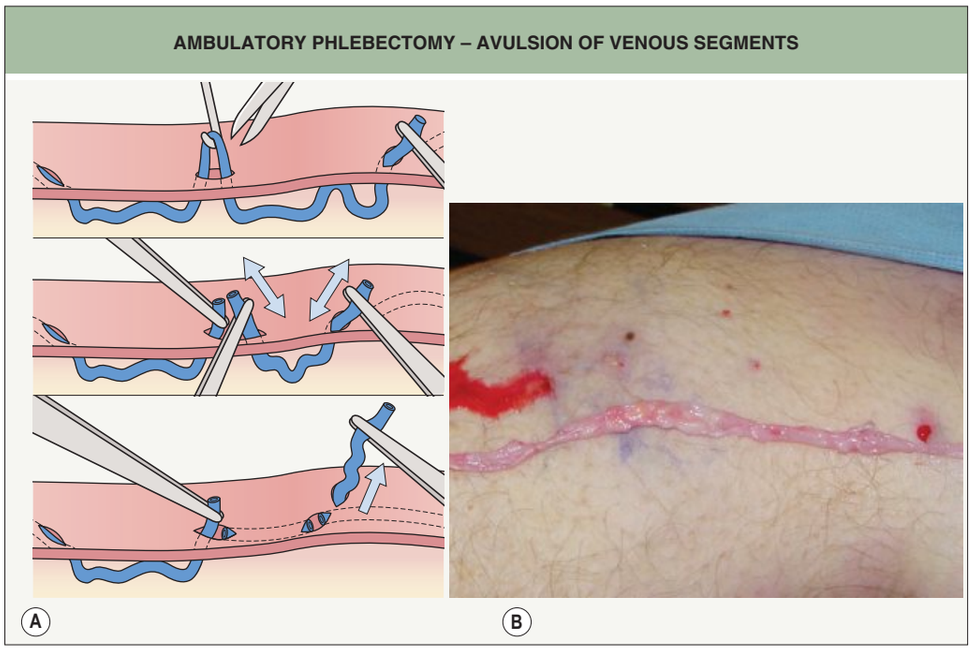

Fig. 155.16 Ambulatory phlebectomy – avulsion of venous segments. A After pinpoint incisions, the dilated vein is hooked at several sites and incised; the venous segments are clamped both proximally and distally and then pulled and rolled to free them from their attachments to the surrounding adventitia. **B** Avulsed segment of the varicose vein next to pinpoint incisions. *A, Redrawn from Ricci S, Georgiev M, Goldman MP. Ambulatory Phlebectomy: A Practical Guide to Stab Avulsion Variectomey, 2nd edn. London: Taylor & Francis, 2005.*

has been hooked. The hook should be removed, reintroduced, and another attempt made. Ambitious "hooking" in the ankle and foot region should be avoided in order to eliminate complications such as swelling, hematoma, and lymphatic and nerve damage. Phlebectomy in the pretibial area should also be performed very carefully because many lymphatic vessels are normally located in this area. Aggressive damage to lymphatic vessels can result in a lymphocele. Phlebectomy in the popliteal area should be particularly gentle since the skin of the back of the knee is very soft and microincisions are very easily enlarged by overzealous "hooking".

Postoperative Considerations for Ambulatory Phlebectomy

Postoperatively, the area is cleansed and antibiotic ointment applied to the puncture sites. The leg is then wrapped, first with cotton gauze and then with an elastic compression dressing extending from the dorsum of the foot to the groin. This dressing helps to promote hemostasis, reduces swelling of the foot and leg, and speeds wound healing. The bandage is removed in 24 hours and a class II (30–40 mmHg) graduated compression stocking is then worn continuously for 1 week (24/7) and after that during waking hours for 2–4 weeks.

Walking while the patient is still in the office is encouraged to help mold the pressure wrap and to uncover any persistent bleeding. This allows the patient to quickly return to a normal gait, thus generating normal function of the calf muscle pump and minimizing potential thromboembolic complications.

Complications of Ambulatory Phlebectomy

Ambulatory phlebectomy satisfactorily removes varicosities of different sizes and results in a series of micro-scars that are cosmetically pleasing to the patient and dermatologic surgeon. The entire procedure can be performed under local tumescent anesthesia on an ambulatory basis[72,73]. Complications may be divided according to the system that has been affected (Table 155.9). The most common complication is the development of a lymphocele, which presents as a firm subcutaneous nodule. Simple aspiration of yellow–clear lymphatic fluid with a 22-gauge needle should be performed every week, with immediate compression over the drained area. Resolution typically occurs after two to three drainage sessions.

COMPLICATIONS OF AMBULATORY PHLEBECTOMY
Anesthetic complications
• Allergic reaction • Purpura at injection site
Vascular complications
• Bleeding, seroma • Superficial thrombophlebitis • Deep venous thrombosis/pulmonary embolus • Telangiectatic matting • Lymphocele • Persistent edema
Neurologic complications
• Nerve damage around the ankle • Hypesthesia (temporary) • Dysesthesia (temporary or permanent) • Traumatic neuroma
Cutaneous complications (other than vascular sequelae)
• Skin necrosis (blistering, ulceration) related to the procedure or compression bandage • Postoperative infection (e.g. cellulitis) • Hypo- or hyperpigmentation of the microincision • Dimpling • Tattooing with marking pen ink • Talc granuloma

Table 155.9 Complications of ambulatory phlebectomy.

TARGETING THE SAPHENOFEMORAL JUNCTION (SFJ)

Whereas saphenofemoral ligation and stripping was previously the only reliable method to address SFJ incompetence, this surgical procedure has gradually been replaced due to the development of a variety of minimally invasive procedures. Foremost amongst these are endovenous laser ablation and endovenous radiofrequency ablation; when compared to conventional surgery, they are equally or more efficacious with lower complication profiles[74]. Additional techniques, e.g. endovenous steam ablation, catheter-directed or ultrasound-guided foam sclerotherapy, mechanochemical endovenous ablation, are also available as are new products, e.g. polidocanol 1% foam (Varithena®), cyanoacrylate adhesive (VenaSeal™ [Medtronic]).

Endovenous Laser Ablation (EVLA)

In endovenous laser ablation (EVLA), the mechanism of action varies depending upon the wavelength of the laser (Table 155.10). Those wavelengths that primarily target tissue water (e.g. 1320 nm Nd:YAG laser) have proven to be superior to those that primarily target hemoglobin (810–1064 nm)[75,76]. Prior to EVLA, the patient is evaluated clinically in both a standing and a supine position and double-marked,

as with ambulatory phlebectomy (see above). Tumescent anesthesia is then delivered along the course of the vein to be treated and may be introduced within the fascial sheath aided by duplex ultrasonography.

A laser fiber with a 600 micron diameter is inserted into the vein (Fig. 155.17A). When the laser is on, a helium–neon (He:Ne) aiming beam is continuously illuminated, helping to ensure that the laser fiber is in the superficial venous system. Correct placement of the laser fiber tip approximately 2 cm distal to the SFJ is confirmed via direct visualization with duplex ultrasonography and secondarily by laser fiber measurement and viewing of the He:Ne aiming beam through the skin. Utilization of an automated catheter drawback system, set at 1 mm/second, provides uniform heating of the vessel (Fig. 155.17B).

Endovenous laser treatment is stopped when the distal tip of the fiber reaches a point 1 to 3 cm from the vein entry site. This can also be confirmed with direct visualization of the aiming beam through the skin or by duplex ultrasonography. Total laser application time is then recorded. Repeat duplex ultrasonography of the saphenous vein is performed to confirm successful treatment. The terminal portion of the vein (immediately adjacent to the point of entry) is thermocoagulated. If the vein had been accessed through phlebectomy, then it is tied with a 3-0 polyglactin 910 suture. If clinically indicated, ambulatory phlebectomy and/or sclerotherapy of tributaries are then performed, either immediately or, more commonly, two months later since most distal varicosities resolve once the refluxing GSV or SSV has been treated.

Endovenous Radiofrequency Closure (Ablation)

An endovenous catheter-based approach is employed in which a specially designed, insulated electrode that is 7 cm in length delivers radiofrequency (RF) energy-induced heat directly to the vein wall (ClosureFast™ catheter [Medtronic]; Fig. 155.18). The endovenous electrode is held in place while energy heats it to a temperature of 120°C. The elevated temperature remains localized to a narrow rim around the active electrode. Proper use of the RF device does require close, stable contact between the active electrode and the vessel wall and the procedure requires tumescent anesthesia to allow contact of the vein wall with the central 7 cm metal core. By strictly controlling the temperature, boiling, vaporization and carbonization of the tissue are avoided. Twenty years of clinical experience suggest that RF endovenous closure, like EVLA, is highly effective at occluding saphenous veins and abolishing reflux. Of note, it is associated with a rapid reduction in lower extremity pain, fatigue, aching, and CEAP clinical class.

General anesthesia is the most significant risk factor for developing DVT and the failure to use tumescent local anesthesia is the major risk factor for developing skin burns. In our clinical practices, tumescent anesthesia is always employed and no skin injuries or thrombi have been observed to date. Some bruising from tumescent anesthesia can occur and anesthesia of the treated portion of the leg may persist for 8 to 24 hours. It is advisable to limit endovenous RF treatment to the GSV segment above the knee to minimize the risk of paresthesias due to injury of the saphenous nerve. Collectively, two of our patients have developed focal numbness (4 cm in diameter) on the lower medial leg, which resolved within 6 months.

ENDOVENOUS LASER ABLATION (EVLA) – MECHANISM OF ACTION		
Wavelength (nm)	**Target**	**Mechanism of action**
810–1064	Hemoglobin	• Heating of blood causes thermal destruction and contraction of the vein wall
1320, 1440, 1550	Water	• Direct targeting of tissue water results in a more controlled, uniform heating of the vein wall • The presence of red blood cells within the vessel is not required

Table 155.10 Endovenous laser ablation (EVLA) – mechanism of action. The mechanism of action of EVLA is dependent on the wavelength of the laser and the subsequent selective target.

Combination with Ambulatory Phlebectomy

Based upon our experience in over 2000 patients, the combination of endovenous ablation techniques with ambulatory phlebectomy can be very effective in eliminating saphenous reflux along with varicose tributaries. Indeed, the two procedures may even provide a synergistic effect as single isolated phlebectomies have shown benefit in reducing GSV incompetence[77]. As outlined above, following double-marking of the varicose veins, the area surrounding the GSV and distal tributaries that are to be treated is infiltrated with tumescent anesthesia. Usually 20 cm inferior to the SFJ (mid medial thigh), the GSV can be accessed through a 2–3 mm incision. The GSV is then treated with the endovenous ablation technique (RF or laser) and the varicose tributaries are removed via standard ambulatory phlebectomy technique. A ligature is placed on the exposed portion of the GSV.

At the conclusion of surgery, the entire leg is wrapped in a short stretch compression bandage over copious padding that has been placed on the sites where the varicose veins were removed via phlebectomy. The tiny incisions are not sutured as these open 2–3 mm incisions allow for drainage of the anesthetic solution over the next 24 hours. This helps to minimize swelling and bruising. The patient is seen the next day, the compression bandage is removed, and the leg is examined

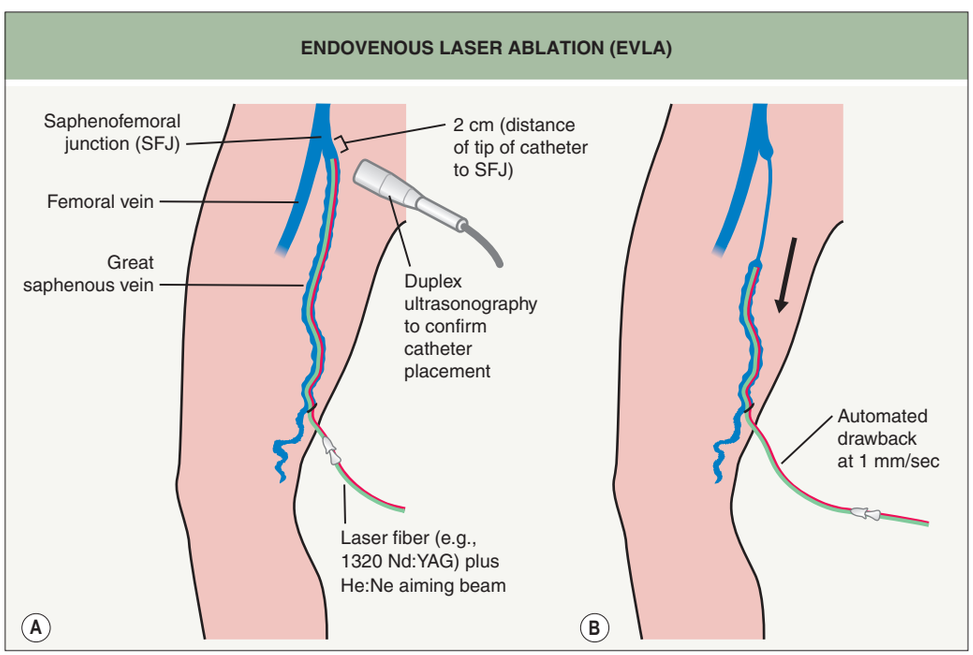

Fig. 155.17 Endovenous laser ablation (EVLA). **A** The laser fiber is inserted into the vein and when the laser is on, a helium–neon (He:Ne) aiming beam is continuously illuminated, helping to ensure that the laser fiber is in the superficial venous system. Correct placement of the laser fiber tip is confirmed via duplex ultrasonography and secondarily by laser fiber measurement and viewing of the He:Ne aiming beam through the skin. **B** Utilization of an automated catheter drawback system provides uniform heating of the vessel.

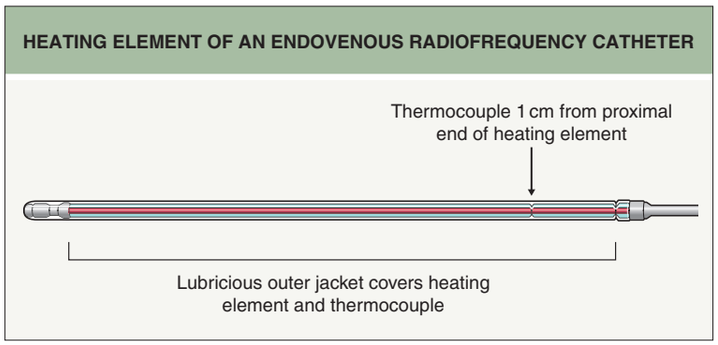

Fig. 155.18 Heating element of an endovenous radiofrequency catheter (ClosureFast™ catheter). After heating to 120°C, 7-cm segments of the varicose vein are treated.

for hematoma formation or other adverse sequelae. All incisions are covered with antibacterial ointment and an adhesive bandage, e.g. BAND-AID®. A class II (30–40 mmHg) graduated compression stocking is applied to the leg. The latter is left on 24 hours a day for 1 week (as compared to 3 days if only RF ablation is performed).

The major complications of endovenous laser or RF treatment plus ambulatory phlebectomy are temporary pigmentation over the treated vein, temporary nerve damage, hematoma, localized superficial thrombophlebitis, and temporary lymphocele. All other adverse effects are extremely rare. For a complete discussion, see reference 78.

Comparative Clinical Trials

Multiple randomized clinical trials have now established the equivalent efficacy of endovenous laser ablation and endovenous RF closure when each is compared to conventional surgery[28,74,79]. The cost effectiveness of these two minimally invasive procedures also appears to be comparable to surgery[80] with superior complication profiles[81]. As a result, endovenous laser and RF ablation have increasingly become first-line therapies[82,83].

Other Endovenous Procedures for the Treatment of Saphenofemoral Junction Incompetence

Ultrasound-guided foam sclerotherapy (UGFS) is a technique whereby the GSV is sclerosed with a foaming agent such as sodium tetradecyl sulfate or polidocanol utilizing ultrasonography for guidance. This procedure can be effective at abolishing SFJ incompetence and improving clinical outcome in patients with venous disease[84–86]. When compared to conventional surgery, UGFS has been equally efficacious in ameliorating reflux, but multiple treatment sessions may be required[74,85]. *Endovenous thermal ablation with steam* is a more recently introduced technique that has been utilized to achieve both radiologic and clinical improvement of SFJ incompetence[87]. Initial reports have suggested that it is not inferior to EVLA[88].

Several novel techniques have been developed for closure of the GSV that do not require tumescent anesthesia. Injection of *polidocanol endovenous microfoam 1%* (Varithena®; see above section for details) has led to improvement in both clinical symptomatology due to SFJ incompetence as well as aesthetic appearance[89]. Similarly, a proprietary *cyanoacrylate adhesive* (VenaSeal™) has been developed for permanent closure of incompetent superficial truncal leg veins and was approved by the FDA in 2015. The adhesive is delivered via a hydrophobic catheter advanced to a point 5 cm below the SFJ. *Mechanochemical endovenous ablation* is a technique that combines a rotating wire and the infusion of liquid sclerosant to simultaneously induce endothelial injury. It is currently undergoing comparative trials with radiofrequency ablation[90].

CONCLUSIONS

Sclerotherapy, ambulatory phlebectomy, and endovenous vein ablation techniques are excellent treatments for both cosmetic and symptomatic venous disease[91]. Although they all require some additional training and knowledge of superficial venous anatomy and physiology, remarkable medical and cosmetic improvements in the sensation and appearance of legs can be achieved. Thus, the dermatologic surgeon now can treat all forms of varicose and telangiectatic leg veins from the largest to the smallest.

Key features

- Liposuction is indicated for spot reduction of localized adiposities
- Liposuction is ideally suited for healthy patients who are near their ideal body weight
- The tumescent local anesthetic technique is the safest approach to anesthesia for liposuction
- Non-invasive technologies offer the benefits of less downtime compared to liposuction
- Careful selection of the appropriate treatment for each patient is necessary to achieve the best results

INTRODUCTION AND BACKGROUND

Liposuction is an effective method for surgically improving localized areas of excess subcutaneous fat. Liposuction has undergone many changes since initial reports in the late 1970s[1–3]. Modern liposuction is performed using dilute local anesthesia, via the tumescent technique, together with small cannulas connected to a vacuum aspirator. When performed correctly using the tumescent techniques, liposuction can be safely performed in an office setting with very few complications. Substantial amounts of fat can be aspirated with minimal blood loss and excellent aesthetic results. Patient selection remains paramount in achieving good results.

Liposuction is currently among the most common invasive cosmetic procedures performed in the US. However, recent survey data have shown a decrease in the number of liposuctions being performed. This is likely due to the increased availability of non-invasive technologies that are currently approved by the FDA for the treatment of localized adiposity. These technologies generally have fewer side effects than tumescent liposuction but deliver more modest results. When choosing between liposuction and non-invasive treatments, it is important that patients have realistic expectations.

CONSULTATION

As with any other medical or surgical consultation, a pertinent review of past medical history, medications, and allergies is essential. The review of systems should be comprehensive enough to exclude any underlying abnormalities which would preclude or modify treatments[4]. Social and psychiatric histories may reveal details which would make the patient an inappropriate candidate for cosmetic treatments.

The physical examination for body contouring should be performed with the patient completely unclothed in the body areas of concern to them. The patient should be examined standing up so that the full effects of gravity are apparent. Physical examination consists of both observation and palpation to reveal the thickness and firmness of underlying fatty tissue. The physician should look for asymmetries, scars, hernias, musculoskeletal abnormalities, dimples, skin laxity, and overlying cutaneous lesions. During this examination, it is important to point out any of these features that may affect results. This will add to the patient's understanding about what may or may not be able to be achieved through body contouring procedures. It is important to accurately describe individual body parts in words that the patient will understand. A diagram of typical anatomic sites may prove helpful (see Fig. 156.6). Also, it is important to remember that patients have a different vantage point; photography and/or full-length mirrors may be helpful during the consultation to ensure their understanding.

A frank discussion about the patient's goals should also be had; many patients have unrealistic expectations with regard to body contouring procedures. Patients should also appreciate the pros and cons of the currently available options for body contouring. Patients undergoing non-invasive treatments must understand that results are inferior to tumescent liposuction and that multiple treatments will likely be required. Patients undergoing liposuction procedures must recognize the surgical risks as well as the need for external compression garments.

The presence of obesity and/or poor muscle tone are warning signs that the patient may not be an appropriate candidate. Generally, obese patients do not make good candidates for body contouring procedures. These patients may have underlying disorders that place them at higher procedural risk; also, due to their excess weight, these procedures will often create minimal, if any, improvement.

Occasionally, patients, mostly male, present with a large amount of visceral fat. Palpation of the abdominal tissues reveals a firm underlying musculature with very little fat on the pinch test. These patients are not only poor candidates for body contouring procedures but are also at increased risk for cardiovascular disease. It is important to recommend consultation with a primary care physician and appropriate nutritional experts.

LIPOSUCTION

Indications and Contraindications

Tumescent liposuction is indicated for improving localized adiposities. Certain areas of subcutaneous fat are often not fully responsive to diet and exercise alone, and there are no exercises capable of spot reduction of adiposity.

Most liposuction patients complain that the troublesome areas of fat excess "run in the family". Furthermore, areas of excess subcutaneous fat can be resistant to caloric restriction or exercise. Tumescent liposuction is able to specifically target these localized areas of excess subcutaneous fat as a complement to, not a replacement for, diet and exercise.

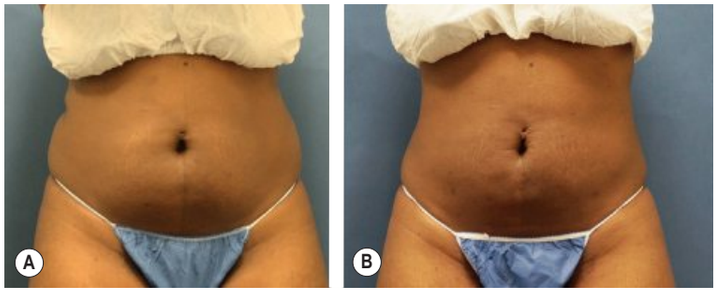

Fig. 156.1 Liposuction of the upper and lower abdomen. A Preoperative. **B** Postoperative, showing improved contours. *Courtesy K.M. Coleman, MD.*

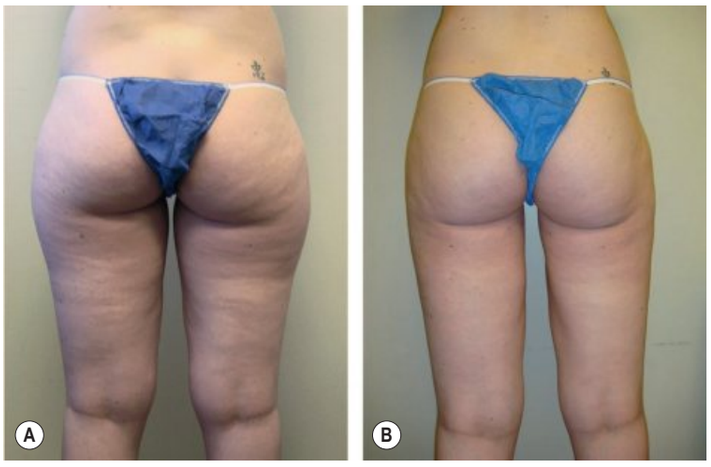

Fig. 156.2 Liposuction of the inner and outer thighs and hips. A Preoperative. **B** Postoperative, showing improved contours. *Courtesy K.M. Coleman, MD.*

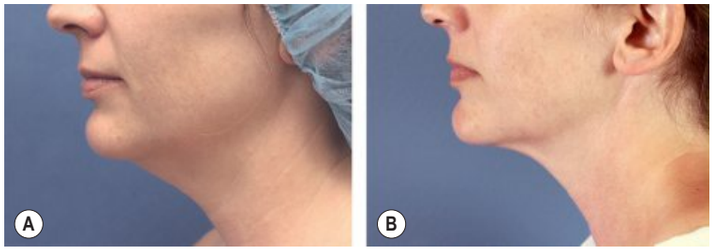

Fig. 156.3 Liposuction of the neck and jowls. A Preoperative. **B** Postoperative, showing improved appearance. *Courtesy K.M. Coleman, MD.*

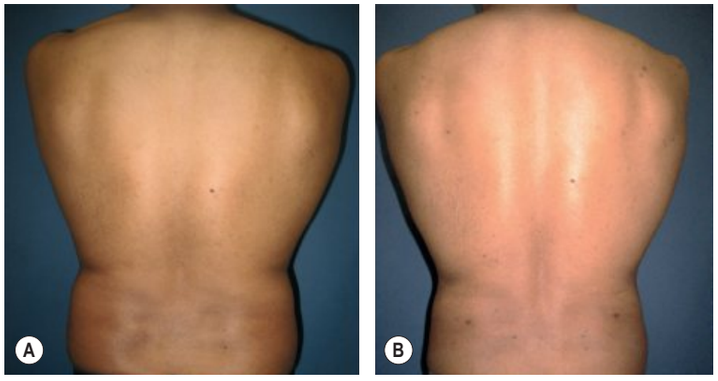

Fig. 156.4 Liposuction of male flanks. A Preoperative. **B** Postoperative, showing the improvement. *Courtesy K.M. Coleman, MD.*

Liposuction can be used to treat localized areas of adiposities throughout the body. Common areas improved by liposuction include the abdomen (Fig. 156.1) and inner and outer thighs (Fig. 156.2). Other sites include the neck and jowls (Fig. 156.3), male and female breasts, back, flanks (Fig. 156.4), hips (Fig. 156.2), buttocks, upper arms, knees (Fig. 156.5), calves, and ankles (Fig. 156.6). Genetic predisposition determines the location of excess fat storage in each individual.

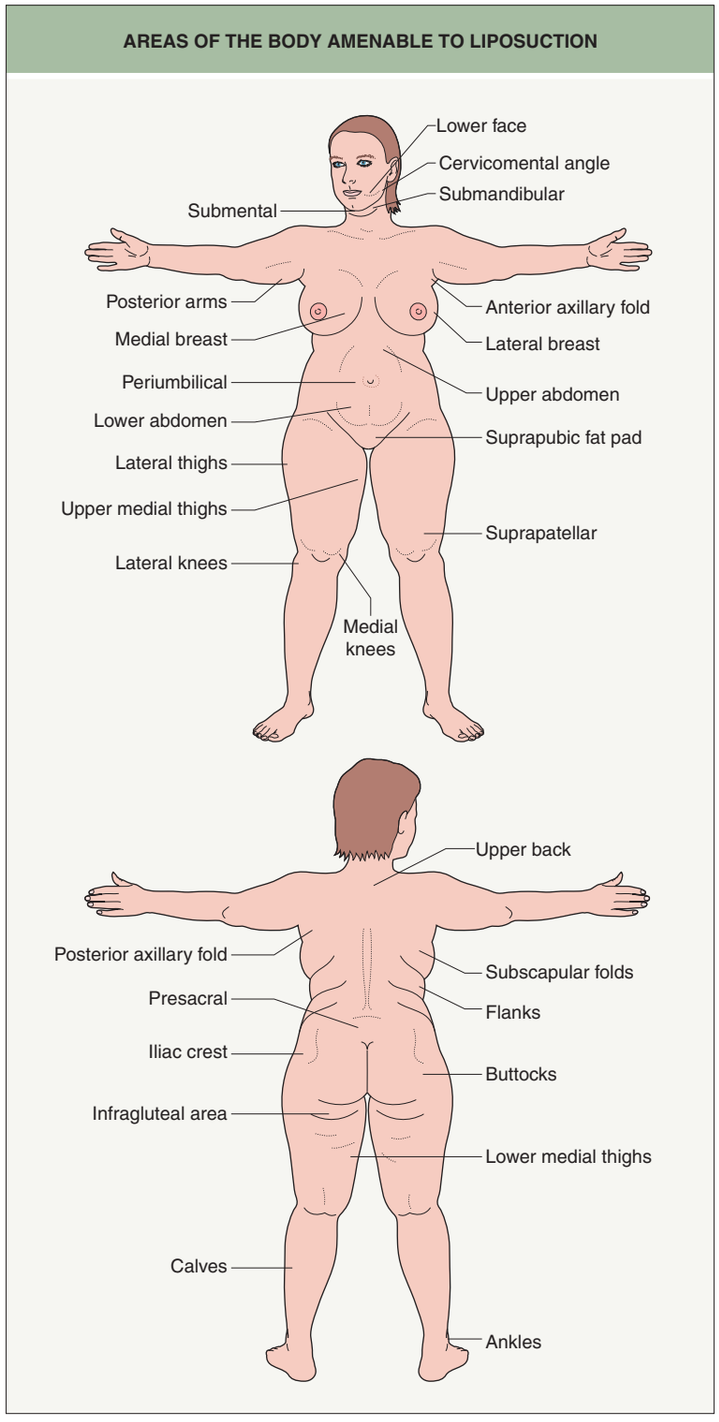

Fig. 156.6 Areas of the body amenable to liposuction.

NON-COSMETIC INDICATIONS FOR LIPOSUCTION
Lipomas
Familial multiple lipomatosis
Adiposis dolorosa (Dercum disease)
Gynecomastia
Pseudogynecomastia
Insulin-induced lipohypertrophy
"Buffalo hump" due to Cushing syndrome
Lipodystrophy in HIV-infected patients
Axillary hyperhidrosis (Fig. 156.7)
Flap undermining
Lymphedema following axillary lymphadenectomy

Table 156.1 Non-cosmetic indications for liposuction. ART, antiretroviral therapy.

Fig. 156.7 Superficial liposuction of the axilla is performed for improvement of hyperhidrosis. *Courtesy W.P. Coleman III, MD.*

In general, operating on over 10% of the body increases liposuction risks. Guidelines of care published by dermatologic organizations recommend fat extractions of less than 4500–5000 ml[5,6]. This volume should be considered as an uppermost limit; beyond this, profound fluid shifts may occur, resulting in cardiovascular compromise. Many experienced liposuction surgeons rarely, if ever, remove anywhere near 5000 ml in a single session. Larger extractions also necessitate larger infiltrations of local anesthetics. When the tumescent technique is employed, guidelines of care recommend not exceeding a lidocaine dose of 55 mg/kg[7–10]. In slender patients, this should probably be adjusted down to 45 mg/kg. These dose limits also restrict the number of areas that can be treated during a single liposuction procedure.

If, in the physician's judgment, it is risky to treat all of the areas that concern the patient, serial liposuction should be recommended. These separate surgeries can be spaced days or months apart, according to the patient's preference.

Non-cosmetic indications for liposuction include pseudogynecomastia and aspiration of lipomas[11–13] (Table 156.1). Liposuction can be effective for debulking larger tumors with a minimal scar. It can also be used as an alternative for treating axillary hyperhidrosis by destroying eccrine and apocrine glands (Fig. 156.7)[13].

Contraindications are outlined in Table 156.2.

The Preoperative Visit

A carefully planned preoperative visit is usually scheduled two or more weeks prior to the actual date of the surgery. Generally, a complete blood count and a complete metabolic profile are obtained; a prothrombin time and partial thromboplastin time may be indicated based on history. Some physicians also perform a urinalysis and tests for infectious diseases such as viral hepatitis and HIV.

Detailed pre- and postoperative instructions should be provided to the patient during this visit. Preoperative instructions should include a list of over-the-counter medications that should be avoided. Aspirin, non-steroidal anti-inflammatory drugs (e.g. ibuprofen), vitamin E, fish oil, and alcohol are common anticoagulants that patients should carefully avoid preoperatively. Herbal remedies may also have anticoagulant activity and should be avoided for 2 weeks preoperatively.

CONTRAINDICATIONS TO TUMESCENT LIPOSUCTION
Absolute
Severe obesity
Individuals seeking liposuction as a weight-loss procedure
Body dysmorphic syndrome
Untreated psychiatric illness
Excessive scarring in the areas to be improved
Hernia in area of proposed treatment
Relative
Moderate obesity
Poor wound healing (including Ehlers–Danlos syndrome)
Hypertrophic or keloidal scarring
Coagulation or bleeding disorders
Allergy to lidocaine
Adverse reaction to epinephrine (e.g. tachycardia)
Significant medical illnesses
Unstable psychiatric illnesses
Hernia in area of proposed treatment

Table 156.2 Contraindications to tumescent liposuction.

Drugs that affect the hepatic cytochrome P450 system should be discontinued if possible (see later). In addition, patients should be counseled about proper nutrition. Trying to lose weight rapidly or eating excessively should both be discouraged. Some patients benefit from nutritional counseling on a pre- and postoperative basis.

Description of Techniques

Tumescent anesthesia

The technique of using tumescent local anesthesia for liposuction was developed by the dermatologist Dr Jeffrey Klein. In 1987, Klein published his technique for the infiltration of a dilute solution of lidocaine with epinephrine (adrenaline) into fat, allowing for liposuction to be performed under local anesthesia[7]. Due to significantly reduced bleeding, the previous common complications of seroma and hematoma became uncommon[14]. Bruising was also minimized. The procedure has proven to be remarkably safe.

Klein demonstrated that dilute concentrations of lidocaine with epinephrine are not absorbed into the circulation to the same degree as higher 1%–2% concentrations of lidocaine, even when the total doses are equal. He confirmed that using only dilute solutions of lidocaine with epinephrine safely allowed lidocaine dosages of up to 35 mg/kg body weight[8]. This advance allowed larger amounts of fat to be removed with only local anesthesia.

A typical tumescent anesthetic formulation is shown in Table 156.3. Dilute solutions of lidocaine with epinephrine provide safe local anesthesia with excellent vasoconstriction. Sodium bicarbonate is added to adjust the solution to a more physiologic pH. The combination of a dilute solution of lidocaine with the vasoconstrictive effect of epinephrine ensures minimal systemic absorption of lidocaine[15].

The tumescent technique provides a number of advantages (Table 156.4). Local anesthesia persists for up to 24 hours after tumescent liposuction, reducing the need for postoperative analgesia[16]. The extensive vasoconstriction produced by dilute epinephrine reduces the volume of whole blood for each liter of pure fat removed by liposuction to less than 12 ml[14,16]. With rapid postoperative recovery, patients can return to their normal lives quickly. Improved aesthetic results are also seen with tumescent liposuction because smaller cannulas can be used, reducing irregularities of the skin[17].

An important advantage is the decrease in anesthetic risk observed with tumescent anesthesia for liposuction, as compared to intravenous or general anesthesia[18–21]. Systemic anesthesia can be associated with a significant risk of serious complications[22]. More recent research has indicated that the maximum safe dosage of lidocaine, when used with the tumescent technique for liposuction, is 55 mg/kg[9,10]. Klein recommends an upper limit of 45 mg/kg for thinner individuals[17].

Fresh tumescent anesthetic solution must be correctly and carefully prepared in a sterile fashion prior to each procedure by a trained healthcare professional. Standardization is important in order to avoid confusion and limit risk. The concentration of lidocaine or epinephrine can be varied depending on the anatomic site. The standard formula of

TYPICAL TUMESCENT ANESTHETIC FORMULATION (LIDOCAINE 0.05%, EPINEPHRINE 1 : 1 000 000)
50 ml 1% plain lidocaine (500 mg)
1 ml 1 : 1000 epinephrine from ampule (1 mg)
10 ml sodium bicarbonate (8.4% $NaHCO_3$ solution)
1 liter normal saline (0.9% NaCl solution)

Table 156.3 Typical tumescent anesthetic formulation (lidocaine 0.05%, epinephrine 1 : 1 000 000).

ADVANTAGES OF TUMESCENT LIPOSUCTION
Complete regional anesthesia without the need for nerve blocks
Local anesthesia persists for up to 24 hours, reducing the need for postoperative analgesia
Minimizes blood loss
Minimal postoperative ecchymoses
Rapid postoperative recovery
Smaller cannulas can be used, reducing skin irregularities
Decreased anesthetic risk compared to intravenous or general anesthesia

Table 156.4 Advantages of tumescent liposuction.

0.05% lidocaine with 1 : 1 000 000 epinephrine plus sodium bicarbonate works well for most sites (see Table 156.3). Occasionally, fibrous areas such as the periumbilical area or breast require a higher concentration of lidocaine, up to 0.1%.

Proper infiltration of tumescent anesthesia is important. The skin is prepped with an antimicrobial scrub. Insertion sites for the infiltration needles are anesthetized with small wheals of 1% lidocaine with epinephrine. The prepared tumescent anesthetic bags are suspended from an intravenous pole. Infiltration tubing is connected to the anesthetic bags and then passed through a peristaltic pump. Air is expressed from the infiltration tubing and a small-gauge, blunt-tipped infiltrating cannula or spinal needle is connected. Warming the anesthetic solution to body temperature prior to infiltration may reduce the pain of infiltration.

The anesthetic fluid may initially be infiltrated into the subcutaneous fat using 20-gauge spinal needles. More extensive infiltration is then performed using a blunt-tipped 16- to 18-gauge infiltrating cannula (Fig. 156.8). These small-diameter infiltration cannulas can be passed through tiny incisions created in the skin with a #15c or #11 blade or a 1–2 mm punch. A peristaltic pump facilitates infiltration of the anesthetic fluid into the subcutaneous fat compartment. The cannula must be repositioned to ensure an even distribution of the tumescent anesthetic. Needle movement is associated with increased pain; consequently, a gentle, slow infiltration technique is preferred. In certain areas with more sensitivity, infiltration must be done even more slowly. An infiltration speed of 100 ml/min is usually well tolerated.

Once sufficient tumescent anesthetic has been infiltrated, the surgeon should wait at least 15 minutes to allow for maximal vasoconstrictive effect of the epinephrine. An overlying blanching of the skin will gradually appear. The patient is then properly "tumesced" and ready for aspiration of adipose tissue. Allowing up to an hour between conclusion of infiltration and the onset of suctioning may result in fat removal with even less infranate.

Drug interactions must be considered when using any form of anesthesia[23]. Caution must be exercised with patients on β-blockers, especially non-selective ones. Although rapid absorption of epinephrine may result in hypertension and bradycardia in these patients, when the epinephrine is absorbed slowly, as in the case of tumescent anesthesia, there is minimal risk.

Tumescent anesthesia and certain sedatives may have significant interactions[23]. Some sedatives (such as diazepam) can reduce the rate of lidocaine metabolism after liposuction. Lidocaine is rapidly eliminated by hepatic metabolism, but a number of drugs can inhibit lidocaine metabolism, possibly leading to an increase in lidocaine toxicity[17]. Examples of such drugs are provided in Table 156.5. These medications should be avoided or discontinued prior to liposuction, or the total dose of lidocaine should be reduced.

Surgeons performing tumescent anesthesia should understand the symptoms of lidocaine toxicity and potential treatments (see Ch. 143).

Fig. 156.8 Infiltration of tumescent anesthetic into the previously marked patient. Concentric circles denote areas of increased fat. Sterile towels are positioned to absorb leaking fluid. *Courtesy W.P. Coleman III, MD.*

EXAMPLES OF POSSIBLE DRUG INTERACTIONS WITH LIDOCAINE	
Drug	**Comments**
Anesthetics	
• Bupivacaine	Lidocaine is displaced from plasma binding proteins by bupivacaine
• Halothane plus nitrous oxide	Increase in lidocaine plasma concentration (lowers maximum safe dose)
Amiodarone	Sinus bradycardia, seizures; competes with lidocaine for binding to CYP3A4
Tramadol	Lowers seizure threshold
Phenytoin	Additive cardiac depressant effects
Benzodiazepines, e.g. alprazolam, diazepam	Inhibit lidocaine metabolism
Azole and triazole antifungals, e.g. ketoconazole, itraconazole, fluconazole	Inhibit lidocaine metabolism

Table 156.5 Examples of possible drug interactions with lidocaine. *Adapted from Klein JA. Lidocaine toxicity and drug interactions. In: Tumescent Technique. Tumescent Anesthesia and Microcannular Liposuction. St. Louis: Mosby; 2000.*

Because bupivacaine cardiac toxicity can be subtle, is not preceded by convulsions, and is often unresponsive to resuscitation efforts, bupivacaine is contraindicated for liposuction[24]. In contrast, lidocaine usually gives warning signs of CNS toxicity long before the onset of dangerous cardiotoxic effects. Prilocaine has been used in Europe for tumescent anesthesia instead of lidocaine[25]. However, rigorous comparative studies have not been performed; and, in the US, prilocaine does not have Food and Drug Administration (FDA) approval to be marketed for local anesthesia for dermatologic surgical procedures. Prilocaine can also produce methemoglobinemia[25].

Liposuction surgical technique

The patient is taken to the preoperative area, where he or she changes into surgical garments. Vital signs including blood pressure and heart rate are obtained. Photographs from multiple views should then be taken if they have not been done preoperatively. Areas should be completely unclothed so as not to distort the surgical site(s).

Next, the surgeon marks the patient, who is standing to allow for the effects of gravity. Marking can be done according to the custom of the surgeon, but should be devised so that the subsequent distortion by local anesthetic infiltration will not obscure the various thicknesses of the adiposity. One way to mark is to use concentric circles, as in a topographic map (see Fig. 156.8). Existing dimples and dents should also be outlined for later identification during surgery so that they can be avoided.

The previously marked patient is then positioned on the surgical table. If significant sedation is to be employed, intravenous lines and monitoring devices such as pulse oximeters and cardiac monitors can be utilized. While patients undergoing the tumescent technique usually require very little ancillary sedation, most patients do appreciate pre-sedation with mild oral sedatives such as lorazepam. Those who are pain-sensitive can receive minor additional sedation such as 25 mg of meperidine intramuscularly, a dose which does not impair protective reflexes.

Once the patient is relaxed, tumescent infiltration can begin (see Fig. 156.8). Peristaltic pumps can be regulated for a comfortable rate of infiltration, e.g. 100 ml/min. Of note, more aggressive forms of systemic anesthesia and deeper sedation put patients at higher risk for abdominal perforation. Another disadvantage of deep sedation is that, because of concerns about total anesthesia time, there is usually little or no delay between infiltration and the onset of the procedure leading to less vasoconstriction. As noted previously, significant vasoconstriction from the infiltration of the tumescent fluid does not occur for at least 10–15 minutes after infiltration.

LIPOSUCTION INSTRUMENTATION

The basic instruments required for liposuction are suction cannulas, tubing, and an aspirator[26]. Liposuction can be performed using many different types of cannulas and aspirators. The number of holes arranged along the shaft of the cannula is probably unimportant, although two or more holes increase the flow of fat through the instrument. The most important parameter for choosing cannulas is size: the smallest possible cannula should be employed. Smaller-diameter cannulas (≤3 mm) create smaller tunnels through the fat and achieve smoother results (Fig. 156.9). In addition, smaller-diameter cannulas penetrate the fat more easily and create less tissue trauma. Longer cannulas allow the surgeon to work from fewer skin insertion sites, leaving fewer scars, while shorter cannulas are easier to control as they pass through subcutaneous tissue. The tiny incisions required for insertion of 3 mm cannulas leave nearly invisible scars in most patients, but can be an issue if the patient has a tendency towards keloid formation or hyperpigmentation.

Liposuction is based on the technique of criss-crossing tunnels (from multiple insertion sites) through the subcutaneous tissue. Each area to be suctioned should be tunneled from at least two different directions, but often three or four are more effective. Multiple small tunnels ultimately provide the smoothest contraction of the overlying skin and the most thorough removal of fat. Subsequent contraction of the fatty layer occurs much like a wet sponge contracting into a dry one (Fig. 156.10).

The liposuction aspirate should be yellow or slightly blood-tinged (Fig. 156.11). A red aspirate in the suction tubing indicates excessive bleeding and the surgeon should immediately move on to a different tunnel. The surgeon's instrument hand acts as the piston moving the instrument in and out of the tissue smoothly. The free hand pulls, presses, and squeezes the skin to facilitate penetration of the cannula and provides important tactile information about the thickness of the underlying fat. The final surgical endpoint should be a skin thickness in the suctioned areas which is similar to that of the surrounding untreated skin.

Cannula insertion sites are routinely left open rather than being sutured closed. Closing insertion sites with sutures leads to an increase in postoperative edema due to decreased drainage. The authors generally prefer the use of a #15c blade to create insertion sites leading to less visible scarring. Klein[17] has advocated the use of small 1–2 mm openings made with a punch biopsy instrument.

Liposuction Devices

Ultrasound-assisted

External ultrasound involves preoperative use of an ultrasonic probe over the areas to be suctioned, in an attempt to liquefy or loosen the fat. However, double-blind studies found no benefit to this approach[27]. *Internal* ultrasonic liposuction employs a probe or cannula with an ultrasonic vibration at the tip. These instruments have been shown to liquefy fat prior to suction. Although this makes subsequent liposuction easier, studies have shown increased potential for seromas and burns[28].

Fig. 156.9 A variety of small-diameter liposuction cannulas. The presence of two or more holes increases the flow of fat through the instrument, and while longer cannulas allow the surgeon to work from fewer skin insertion sites, shorter cannulas are easier to control. *Courtesy W.P. Coleman III, MD.*

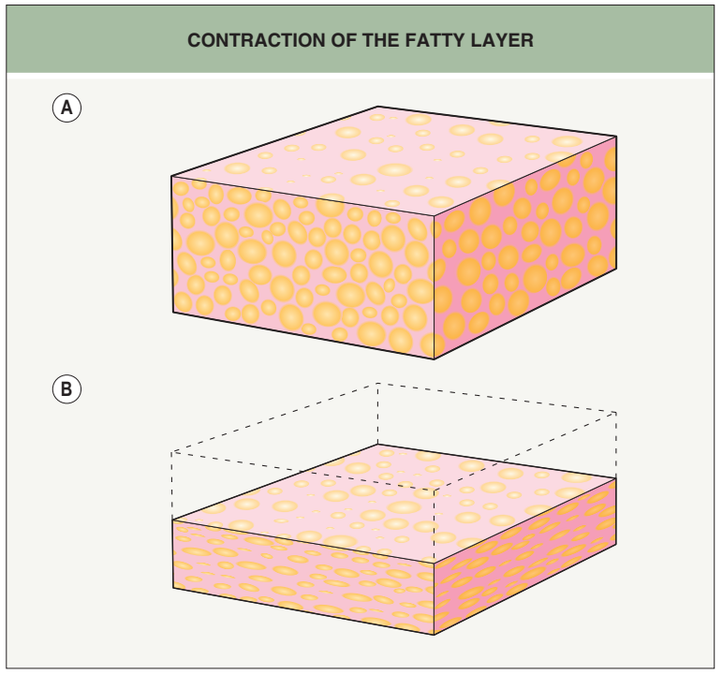

Fig. 156.10 Contraction of the fatty layer. A Immediately after liposuction, the fatty layer resembles a wet sponge. With subsequent subtraction of the fat cells, the thickness of the subcutaneous tissue decreases. **B** Much like a dry sponge, the subcutaneous tissue has compacted.

Fig. 156.11 Bloodless liposuction aspirate. Typical, nearly bloodless liposuction aspirate using the tumescent technique. *Courtesy W.P. Coleman III, MD.*

Ultrasonic probes pass through the tissue like a "hot knife through butter" and do not provide the usual tactile feedback from tissue resistance that manual cannulas do. This makes it difficult for the surgeon to determine in exactly what level of the fat the cannula is located and increases the possibility of intra-abdominal perforation or "end hits" to the opposing dermis. These devices should only be used by experienced surgeons and may be advantageous for skin tightening or if there is excessive fibrous tissue, e.g. gynecomastia.

Power-assisted

These instruments feature a motorized cannula, which moves in a back and forth or swirling motion (Fig. 156.12). The short, motorized strokes vary according to the instrument and allow the surgeon to precisely sculpt small areas of excess fat. Powered liposuction instruments also allow easier penetration of fat, when compared to manual cannulas, but retain some feel of tissue resistance[29]. Studies have shown that powered liposuction increases the fat aspirated (per minute) by 30% or more[29]. There have been no significant complications reported with the use of this approach, although some early users described an increase in seromas. Powered instruments create a larger tunnel than a manual instrument of the same diameter; this should be taken into account when choosing the appropriate size cannula.

Laser-assisted

Laser-assisted devices are designed to transmit infrared laser energy, via a fiber, subcutaneously during liposuction in order to generate heat. Early iterations of these devices had very low power and showed very little difference compared to manual liposuction[30]. Diode and Nd:YAG laser liposuction devices are available from several manufacturers in a variety of wavelengths. Newer devices have higher power and longer wavelengths that are more selective for fat, potentially increasing their efficacy. Benefits include emulsification of fat to make aspiration easier, decreased blood loss[31], and potential for increased skin tightening. The laser fibers can cause burns if used incorrectly, although newer devices have real time temperature feedback mechanisms to reduce this risk. Laser liposuction does take more time to perform and increases costs. Skin tightening seems to be the main purported advantage to these devices. Although this has been difficult to quantify, studies using subcutaneous laser alone have shown significant improvement in skin laxity[32]. However, manual liposuction alone also produces significant tightening and external energy-based tightening devices may provide the same effect.

Radiofrequency-assisted

Several newer devices have employed subcutaneous radiofrequency technology in order to try to increase skin tightening. Some of these devices use monopolar radiofrequency while others use bipolar technology. The purported advantage over laser- and ultrasound-assisted liposuction is better control of the heat produced. Radiofrequency-assisted liposuction has been shown to be safe, but when compared to manual liposuction, enhanced skin contraction is still unproven and a direct comparison trial will be difficult. However, several studies have shown that there is potential for this technology to aid in skin contraction[33].

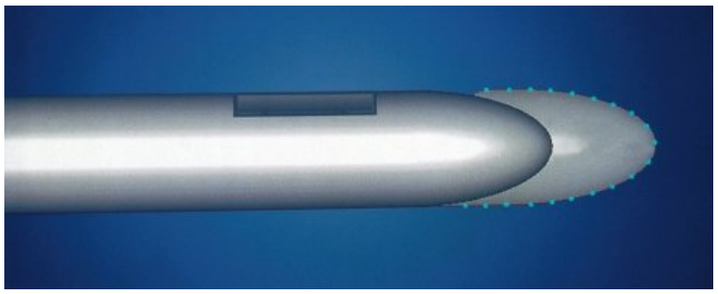

Fig. 156.12 Reciprocating powered cannula. This reciprocating powered cannula has a 3 mm to-and-fro motion. *From Coleman WP III, Katz B, Bruck M, et al. The efficacy of powered liposuction. Dermatol Surg 2001;27:735–8.*

Water-assisted

These devices employ powerful streams of water directed into the fat layer to create tunnels to facilitate fat removal. Proponents of this approach claim that this reduces the volume of tumescent fluid required. This makes very little sense since the anesthetic effect of the fluid takes several minutes to take effect, long after the tunnel has already been bored by the water jet. There may be potential benefits with this technology when performing fat transplantation as the fat cells may be better preserved than through physical avulsion, but this remains speculative.

Manual liposuction versus device-assisted

The major potential advantage of these devices is skin tightening; however, as stated previously, this is difficult to assess. In patients with more laxity or fibrous tissue, there may be some advantage. However, in individuals with good skin quality, these devices are likely unnecessary as manual liposuction alone provides good skin contraction. Also, it is important to recognize the increased cost associated with using these devices, including disposable costs. Each surgeon needs to determine which instrument he or she is most comfortable with and stick with the approach that is most successful. Each instrument can have a steep learning curve. Excellent liposuction results may be achieved with any of these devices, but only if the surgeon is experienced and well trained.

LIPOSUCTION VARIATIONS

Guidelines of care published by dermatologic organizations recommend that liposuction be performed as a solo procedure and not combined with other techniques[5,6]. However, there are cases in which liposuction is employed as a fundamental part of a combined surgical procedure. For instance, in rhytidectomy, liposuction of the neck and pre-tunneling of the cheeks are often performed prior to flap dissection and advancement. In patients in whom the neck alone is to be treated, liposuction may be combined with submental resection and platysmal plication, with each surgical component contributing to the final result. External light-based and radiofrequency devices may also be combined with neck liposuction to improve skin contraction.

In other anatomic sites, skin excision may be combined with liposuction. Where there is a significant abdominal panniculus, a suprapubic incision may be used to remove excess skin in conjunction with liposuction of the rest of the abdomen. However, in most patients with a moderate panniculus, this may be unnecessary because of the significant skin retraction that occurs after liposuction of the lower abdomen. Experience shows that most patients who consult for abdominoplasty achieve excellent results with liposuction alone. Abdominoplasty is a much more aggressive procedure, with significantly increased morbidity and mortality. The final scar is significant and often unattractive as well.

Liposuction is an excellent option for improvement of pseudogynecomastia in men. In these patients, the breast enlargement results primarily from excess fat rather than the excess glandular tissue present in true gynecomastia. Aggressive liposuction is required to remove what is usually thicker and more fibrotic fat. Powered or ultrasonic liposuction is sometimes useful in tunneling through this more fibrous fat. In patients with true gynecomastia, the glandular tissue must also be removed, usually through a submammary or periareolar incision, to obtain sufficient flattening of the breast. Liposuction can also be used for moderate breast reduction in females. The best results are seen in women with soft breasts. Very firm glandular breasts of younger patients do not respond well to liposuction, nor do ptotic breasts, which may sag more after the procedure. These patients are better served with excisional breast reduction.

NON-COSMETIC LIPOSUCTION

Liposuction may also be used for non-cosmetic indications (see Table 156.1). The chief among these are hyperhidrosis and lipoma removal[11]. When topical preparations are ineffective, botulinum toxin injections, sympathectomy, external focused microwave, and liposuction can be performed. For axillary hyperhidrosis, subdermal liposuction is used aggressively to remove as much of the subdermal fat in the axilla

as possible (see Fig. 156.7). Since many of the eccrine and apocrine sweat glands reside in the upper fat, liposuction can diminish sweating postoperatively. The goal is to make the patient sweat normally, but not to become anhidrotic. Preoperatively, a starch iodine test identifies the areas of greatest sweating (see Ch. 39). The liposuction should be aggressive enough to create some subdermal fibrosis, in an attempt to eliminate as many dermal eccrine and apocrine structures as possible. Patients are usually comfortable within 24 hours and able to resume normal activities within 2–3 days. Often, there is immediate diminished sweating with a rebound 2–3 weeks postoperatively, followed by a gradual decrease in sweating as fibrosis develops in the subdermal region.

Larger lipomas can also be reduced efficiently using liposuction. The goal here is to flatten out the lipoma but not necessarily remove the entire lesion. The advantage of liposuction over standard excisional surgery is that the former leads to a much smaller scar. As with any adiposity, the lipoma is tunneled in a criss-cross direction until flat. Subsequent healing and fibrosis usually flattens the remaining lipoma further, resulting in a normal contour. It is difficult to suction smaller lipomas and these are best removed through direct puncture excision. However, lipomas the size of a golf ball or larger are excellent candidates for liposuction. Since the entire lesion is not surgically removed, lipomas treated in this fashion may be more likely to recur; the patient should be made aware of this possibility. Liposuction should be reserved for lesions that are in cosmetically sensitive areas or those of a size which would necessitate a larger incision.

POSTOPERATIVE CARE

Following liposuction, patients are usually quite comfortable during the initial postoperative period. It is important to remind patients, well before the procedure takes place, that they are going to have significant drainage for the first day following liposuction surgery. Barrier protection is recommended for car seats, furniture, and bed linens during this period.

The patient's insertion sites may be coated with petrolatum or antibiotic ointment prior to application of absorbent materials. Modern absorbent pads are capable of absorbing significant amounts of drainage from the insertion sites thereby decreasing the need for patients to change pads. Most individuals will experience continued drainage for 24–48 hours following liposuction. Patients are advised to take their first shower with the absorbent bandages and the tape in place, as the shower assists in the removal of the tape.

Following the application of sufficient amount and layers of absorbent pads, a compression garment or a compression bandage is fitted. Numerous styles of postoperative liposuction compression garments are available. Postoperative compression minimizes bruising and aids in drainage. Gravitational drainage minimizes postoperative edema. It is important to use firm compression immediately following tumescent liposuction[34]. Compression assists patients in feeling more secure and decreases pain by restricting movement of the treated tissue. Many patients actually enjoy the comfort and feel of a compression garment due to the soreness sometimes associated with movement in the immediate postoperative period. Patients with pre-existing laxity or large amounts of fat removal may benefit from a longer period of compression.

Infections have occasionally been reported with liposuction and oral antibiotics may provide prophylaxis against more serious infections. Of note, lidocaine is bactericidal[35]. This may explain, in part, the relatively few infections seen with tumescent liposuction. Careful local wound care and cleanliness are essential in producing a good liposuction outcome.

Most patients can return to work within 48 hours following their liposuction. It is important to ask the patients to ambulate regularly beginning the day after surgery. This movement encourages drainage as well as remodeling of the subcutaneous tissue. Movement has the additional benefit of increasing lymphatic drainage through intermittent pumping action of skeletal muscles. Light exercise may begin 24–48 hours after surgery, but patients should be advised to start at 25% of their normal routine. Generally, patients are back to normal exercise routines after the first postoperative week.

All patients are given a set of written postoperative liposuction instructions including important phone numbers should the patient need to contact the physician. These postoperative instructions remind the patient that swelling and firmness beneath the skin and a reduced sensation in the skin are common. This will usually resolve over the first 3 to 4 weeks after the surgery. The postoperative instructions also remind patients that the final results are not seen until 6–12 months following the liposuction.

Patients return for their first postoperative appointment 1 day following liposuction. This visit is important to check for problems and reassure the patient. The next visit usually occurs during the first 3 weeks. It is often necessary to remind patients that improvement from liposuction is a gradual process. This postoperative visit is a good opportunity for encouraging patients to exercise, maintain an active and healthy lifestyle, and eat a reasonable diet. Patients are seen for 3-month and 6-month follow-up visits. If touch-ups are required, it is wise to wait 1 year before proceeding to be certain that the final results have been achieved. Secondary liposuctions that are performed too early in the postoperative period may lead to skin irregularities.

COMPLICATIONS OF LIPOSUCTION

Complications of liposuction must be differentiated from common sequelae. After liposuction, it is common to have prolonged swelling, areas of numbness, bruising, and red incisions. Infections, hematomas, and seromas are rare complications that require medical attention but can usually be resolved rapidly.

Serious complications of liposuction are closely linked to the type of sedation employed. There have been a number of deaths from liposuction in patients who had moderate or deep sedation[18,19,36]. The authors are not aware of any deaths from liposuction in patients who underwent the procedure with true tumescent local anesthesia[37].

Deep vein thrombosis and pulmonary embolism postoperatively are surgical complications generally associated with non-ambulatory patients and prolonged procedures under general anesthesia. An advantage of the tumescent local anesthetic technique is that patients are ambulatory immediately after surgery, thus minimizing the risk of this potential problem. Patients who are obese and inactive are more at risk for the development of this complication; this should be taken into consideration during the preoperative evaluation.

Abdominal perforation is one of the leading causes of liposuction death[38]. This is exclusively a complication of liposuction under general anesthesia[20]. Deeply sedated patients have decreased muscle tone and are unable to alert the physician to the pain of penetration of the liposuction cannula. Occult abdominal hernias may contribute to this complication. The treating physician should be aware of any abdominal scars and palpate for hernias during the preoperative visit.

General anesthesia also increases risks of respiratory failure and cardiac death[22]. Besides the direct effect of systemic anesthesia, fluid overload may contribute to these problems. Anesthesiologists who are not accustomed to working with patients who have been infiltrated with tumescent anesthetic fluids may inadvertently overhydrate the patient with additional intravenous fluids. A significant amount of the saline infused subcutaneously is absorbed systemically, automatically correcting for surgical fluid losses. Compounding this problem is the discovery that intravenous fluid bags are typically overfilled by at least 10%, leading to further errors in calculating fluid replacement in liposuction[39].

The keys to avoiding complications in liposuction lie in proper patient selection, appropriate patient evaluation, realistic patient expectations, monitoring according to the degree of sedation, good surgical technique, avoidance of excessive fat removal or overzealous additional simultaneous procedures, and adequate postoperative care.

NON-INVASIVE BODY CONTOURING

Liposuction is now a mature procedure and most patients obtain predictable results[40,41]. However, as with all cosmetic procedures, there is a general trend toward trying to accomplish similar results with less invasive techniques. Several non-invasive modalities are currently approved for the treatment of localized subcutaneous fat (Table 156.6). Some of these treatments, such as injection lipolysis, have been in existence for many years, but recently have garnered more interest; other technologies, such as external ultrasonic devices, external cryolipolysis, external radiofrequency, and low-level light treatments, are relative newcomers to the field.

NON-INVASIVE BODY CONTOURING MODALITIES	
Non-invasive modality	**Mechanism of action**
Injection lipolysis (deoxycholate)	Fat cell membrane disruption (adipocytolysis)
High-intensity focused ultrasound	Thermal destruction of adipocytes
Non-thermal focused ultrasound	Cavitation disruption of adipocytes
Cryolipolysis	Cold-induced apoptosis/panniculitis
Radiofrequency (mono-, uni-, bi-, tri-polar)	Thermal destruction of adipocytes
Low level light therapy	Photochemical membrane pore creation (theoretical)

Table 156.6 Non-invasive body contouring modalities.

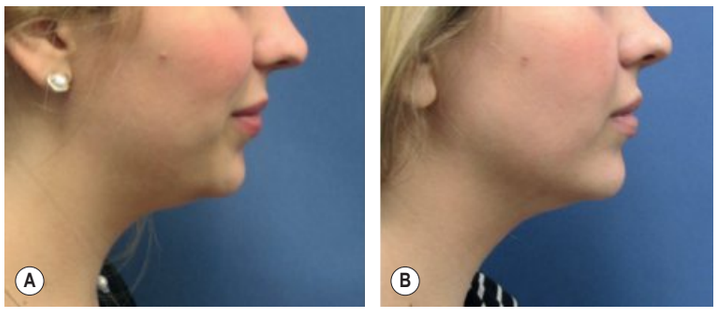

Fig. 156.13 Phosphatidylcholine/deoxycholate injection to the submental area. A Pre-treatment. **B** 1 month post-treatment, showing improved contour of the neck. *Courtesy K.M. Coleman, MD.*

Injection Lipolysis

Mesotherapy, which was originally developed in the 1950s, has re-emerged as a treatment for localized adiposities. Most commonly, this technique involves the subcutaneous injection of a formulation containing phosphatidylcholine plus a detergent solvent that leads to the dissolution of fat cells[42]. More recent work has shown that the detergent solvent, usually deoxycholic acid, is more likely the active ingredient in this solution[43]. Deoxycholic acid works by causing adipocytolysis, leading to a decrease in fat volume via contraction and remodeling. In 2015, deoxycholic acid was approved by the FDA for the reduction of moderate to severe submental fullness. The injections consist of small aliquots (0.1–0.2 ml) placed ~1 cm apart from each other[44]. Treatment volume used varies depending on the amount of adiposity present. Most patients will require several treatments, at least one month apart, for best results. Of note, many physicians are lengthening the time between sessions to allow post-treatment edema to subside more completely prior to the next set of injections. Full results are not apparent until 12 weeks post-therapy (Fig. 156.13).

Post-treatment sequelae include edema, ecchymoses, decreased sensation, and hair loss. For most patients, edema is self-limited but in some instances, persistent edema may occur necessitating treatment with intralesional triamcinolone acetonide or anti-inflammatory medications. Post-treatment edema tends to lessen with subsequent deoxycholic acid injections.

There have been several reports of off-label use of deoxycholic acid, including for jowls, pre- and post-axillary bra fat, suprapatellar fat pads, and small truncal adiposities[45,46]. The therapeutic efficacy of deoxycholic acid injections is limited to smaller adiposities. Its use for larger areas has not been established and would not be clinically or financially feasible.

Low Level Light Therapy (LLLT)

An external 635 nm diode laser (Zerona™; Erchonia) is FDA-cleared for fat reduction around the waist. Theoretically, this device reduces the size of subcutaneous fat by induction of a photochemical reaction which creates small pores in the adipocyte cell membrane[47]. However, early reports of the results of these treatments had only short follow-up times and no weight control. In addition, several studies have shown that the minimal results produced seem to abate over time, with long-term results still in question as well.

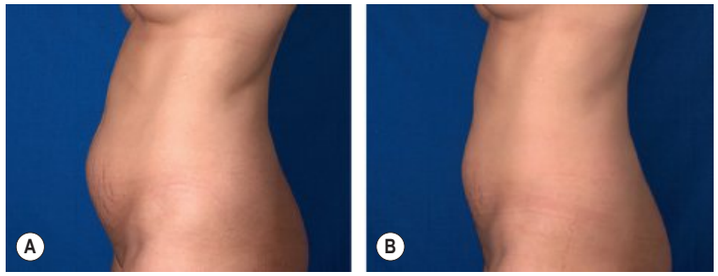

Fig. 156.14 Non-thermal focused ultrasound (UltraShape™) treatment of the abdomen. A Pre-treatment. **B** 42 days post-treatment.

High-Intensity Focused Ultrasound

High-frequency ultrasound, HIFU (LipoSonix™; Innovations Medical), relies upon ultrasound-induced thermal destruction of adipocytes. This device is based on technology currently employed in the treatment of malignant tumors, in particular prostate cancer. The ultrasound has a focal depth of 1.3 cm and creates tissue temperatures up to about 70°C. The thermal destruction of adipocytes at this depth leads to tissue contraction and reduction of adiposities over an 8- to 12-week period[48]. The FDA cleared this technology for non-invasive waist circumference reduction in 2011 and reduction in waist circumference from a single treatment has been reported to be about 2–3 cm. Patients complain of discomfort during the treatments which can be moderate to severe in some. The most common sequelae from HIFU include post-procedural pain, numbness, edema, and ecchymoses.

Non-thermal Focused Ultrasound

Non-thermal, external ultrasound (UltraShape Power®; Candela™) produces targeted cavitation of fat cells without producing significant heating; this allows the device to achieve lipolysis without creating damage to blood vessels and nerves[49,50]. Disruption of the adipocytes leads to release of fatty acids. The device has been cleared by the FDA for abdominal circumference reduction. Treatments are performed every 2 weeks; generally, 3 treatments are recommended. During treatment, patients experience minimal if any discomfort. The focal depth of the ultrasound is 1.5 cm and care should be taken over bony prominences to avoid reflection of the waves.

Post-procedural sequelae are rare and are likely related to technique. Blistering can result from inadequate contact with the device or treatment over a bony area. Patients may resume all activities immediately after treatments and generally have no pain, edema, or bruising. Patients are advised to avoid excessive fat consumption during the first 2 days post-procedure. Treatment results appear gradually with improvement over a 6- to 8-week period. After 3 treatments, an average reduction in waist circumference of 3–5 cm has been reported (Fig. 156.14).

Cryolipolysis

Cryolipolysis (Coolsculpting®; Zeltiq Aesthetics) involves the targeted production of adipocyte apoptosis via thermal energy extraction (without damage to the epidermis). Porcine and human trials have shown significant reduction in subcutaneous fat. This device utilizes vacuum suction to elevate tissue into contact with cooling plates within the device[51,52]. There are now several different applicators to fit different body types and areas. The treatment involves placing the treatment applicator over the selected area and starting the vacuum and cooling process; the applicator remains in place for 1 hour. Separate body areas can be treated at the same time or sequentially. Current recommendations are to retreat the area in 1 month, with results occurring gradually over a period of 2–3 months.

During the treatment, there is mild discomfort. Immediately after treatment, the treated area is cold and indurated; this resolves over about thirty minutes (Fig. 156.15). A randomized trial has shown that vigorous massage of the treated tissue can lead to greater reduction in

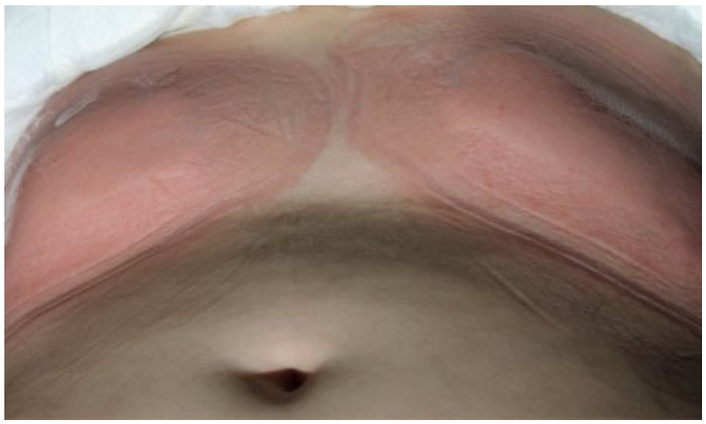

Fig. 156.15 Immediate post-treatment response of cryolipolysis. The treated skin is elevated, cold to the touch, clay-like, and erythematous.

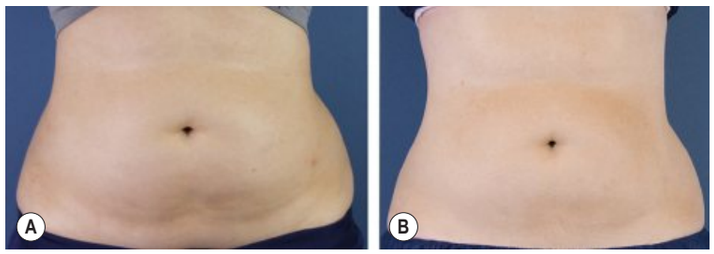

Fig. 156.16 Cryolipolysis (Coolsculpting®) of the abdomen. A Pre-treatment. **B** 6 months later, after 2 treatments. *Courtesy K.M. Coleman, MD.*

adiposities. Commonly, there is some erythema for the first few hours; patients complain of transient pain, numbness, bruising, and edema, which all generally resolve over 2 weeks. Rarely, prolonged pain can occur; this usually responds to oral anti-inflammatory agents. There have been several reports of paradoxical adipose hyperplasia which may require liposuction for correction[53]. Results of these treatments is highly dependent on proper patient selection and proper application of the device (Fig. 156.16). Multiple treatment tips are usually needed to adequately treat an area.

Radiofrequency

Radiofrequency devices utilize an oscillating electrical field to create heat in target tissues; lower frequencies are able to penetrate more deeply. Several radiofrequency devices are available for multiple aesthetic uses. Devices can be monopolar or unipolar (1 electrode), bipolar, or multipolar. For fat reduction, results with radiofrequency devices have been mixed with some newer devices reportedly more successful.

A selective, contactless radiofrequency device (Vanquish Me™; BTL Aesthetics) uses focused field radiofrequency to target adiposities. A prospective trial showed a 4.93 cm reduction in abdominal circumference after 4 weekly treatments; however, 3 patients showed no reduction at all[54]. Use of a vacuum-assisted bipolar device that utilizes software to maintain constant temperature control (Evolve®; Inmode) led to a 2.7 cm decrease in abdominal circumference after 6 weekly treatments[55]. Currently, this device combines non-vacuum bipolar heads with suction-assisted heads in order to treat more superficial adiposity and skin laxity.

CELLULITE

Cellulite is a common problem for most women with variable presentations. It can present as dimples, rippling of the skin, and/or superficial adiposities. The morphology of cellulite stems from superficial fat deposits, skin laxity, and perpendicular dermal bands which lead to dimpling. For years, treatment options have been less than satisfying in their durability and effectiveness. However, more recently introduced technologies have shown promise for providing durable improvement in the appearance of cellulite (Table 156.7).

CELLULITE TREATMENT OPTIONS	
Treatment	**Mechanism of action**
Manual subcision*	Manual release of dermal bands
External radiofrequency	Skin tightening, reduction of superficial adiposity
Subdermal side-firing (1440 nm Nd:YAG) laser	Release of dermal bands, skin tightening, reduction of adiposity
Subdermal radiofrequency	Skin tightening, reduction of adiposity
Vacuum-assisted subcision	Controlled release of dermal bands
Injectable collagenase	Lysis of dermal bands
*Sometimes followed by injection of fillers such as calcium hydroxylapatite and poly-L-lactic acid microspheres.	

Table 156.7 Cellulite treatment options.

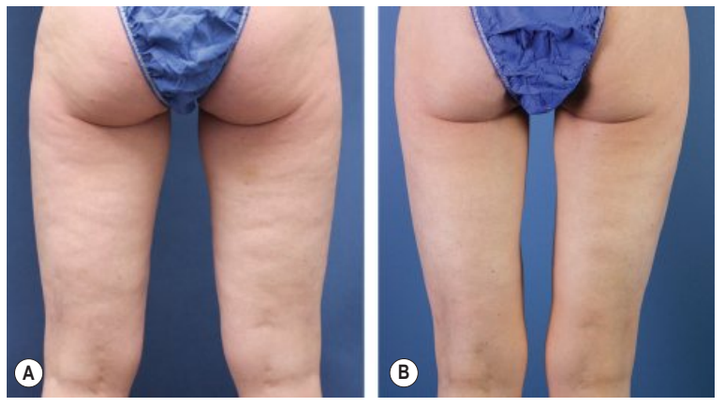

Fig. 156.17 Subdermal laser treatment (Cellulaze®) of posterior thigh cellulite. A Pre-treatment. **B** 6 months post-treatment. *Courtesy K.M. Coleman, MD.*

External Devices

There are several commercially available external treatments that attempt to improve cellulite. Most of them are minimally, if at all, effective in providing long-term improvement. For example, body wraps and massages can temporarily improve the appearance of cellulite, but there is no durable improvement. Most of the devices employed for the external treatment of cellulite rely on radiofrequency-induced heat to tighten skin and reduce superficial adiposity. Because these devices only address two of the three causes of cellulite – laxity and superficial adiposity – their effectiveness is limited. They require numerous treatment sessions to produce any improvement and results tend to not be durable.

Rapid Acoustic Pulse™ technology, which utilizes high intensity, high frequency, ultrashort acoustic wave pulses, is said to be capable of disrupting fascial connections, rendering the dimpling less evident. However, the results may not be durable beyond the treatment period.

Subdermal Devices

Since cellulite is created by subdermal bands and adiposity, these devices target the subdermal plane. This approach is minimally invasive and generally performed with tumescent anesthesia. The first device that incorporated subdermal treatment of cellulite was the 1440 nm side-firing laser (Cellulaze®; Cynosure). Its laser fibers are designed to refract the beam into two perpendicular beams which allow for treatment in two directions. One beam treats skin laxity and superficial adiposity while the second helps to cut the cellulite bands. Although results have been mixed, some authors have reported very good results that were durable (Fig. 156.17)[56]. Other subdermal technologies such as radiofrequency devices can be used in patients with cellulite; however, they address the laxity and superficial adiposity without cutting the dermal bands.

Subcision

Manual subcision of cellulite dimples has long been effective in some physicians' hands. When performed by those experienced in this technique, durable results have been observed. Subcision is generally performed with an 18-gauge filter needle under local anesthesia.

The needle is used to horizontally cut the dermal bands and release the dimples.

Vacuum-assisted subcision

Since manual subcision can be technically challenging and time-consuming, attempts have been made to enhance effectiveness and reproducibility. With a vacuum-assisted subcision device (cellfina®; Merz Aesthetics), the vacuum secures and elevates the tissue with the dimple, allowing for insertion of an oscillating blade into the correct tissue plane to release the dermal bands[57]. This leads to more exact targeting of the dermal bands and more rapid treatments. Results have been reported as very durable, lasting up to several years. As these vacuum-assisted devices only target dermal bands, they work best for dimpled cellulite and are not very effective in patients with laxity or rippled cellulite.

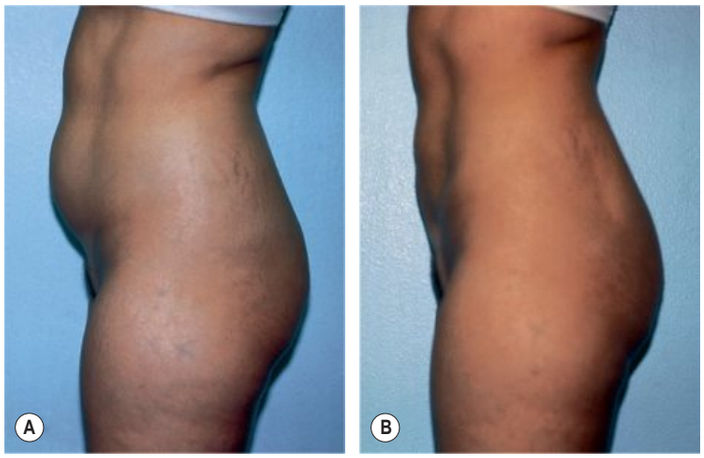
Fat Transfer and Fillers

For severe dimpling of cellulite, subcision of dimples alone may not be sufficient. Placement of fat or fillers can help to further smooth these lesions. Based upon their collagen stimulatory properties, fillers such as calcium hydroxylapatite and poly-L-lactic acid microspheres are also being used to treat cellulite[58]. They are injected in a dilute fashion in order to improve skin laxity.

Collagenase

Injectable collagenase (Qwo®; Endo Pharmaceuticals) is the most recent addition to the therapeutic armamentarium for cellulite, and it has shown some promise in clinical trials[59]. In order to release dimpling, the collagenase is injected into dermal bands. There is no need for anesthesia and serial injections are performed every 3 to 4 weeks per current protocols. However, the latter may undergo further revisions. Based upon early results, improvement may be durable (up to at least 2 years). A significant drawback is the potential for developing large ecchymoses that lead to hemosiderin deposition in some patients.

CONCLUSION



Technology is constantly providing physicians with new ways to minimize localized adiposities. Regardless of what instrumentation is used, it is likely that in the future liposuction will remain one of the most popular and predictable cosmetic procedures. As more non-invasive treatments become available, it is important to recognize the pros and cons of each of these devices. No matter which type of treatment is performed, the single most important aspect in choosing a therapy is patient selection.

157 Hair Restoration

Marc R. Avram and Nicole E. Rogers

Key features

- A mainstay of correcting androgenic alopecia is transplantation of follicles harvested from the non-alopecic posterior scalp as 1–4 hair follicular units
- Follicular unit grafts can be obtained either manually or mechanically and are placed into small "recipient" sites (0.5–1 mm in diameter) produced by a blade or needle
- There are two major surgical methods: (1) elliptical donor harvesting (follicular unit transplantation [FUT]); and (2) follicular unit excision (FUE)
- Patient expectations and continued progression of androgenic alopecia, as well as donor site hair density, quantity and quality, are key considerations
- Although men and women have different patterns of androgenic alopecia, properly selected patients can undergo successful hair transplantation

INTRODUCTION

Hair frames our face and its length, color, and style reflect our personality and how we perceive ourselves. The framing preserves a youthful facial appearance by shortening the face and returning the viewer's focus to the center of the face. While hair is one of the few physical characteristics we can easily control, the inability to correct hair loss can lead to concerns regarding appearance and psychological stress. In the case of androgenetic alopecia, some individuals accept hair thinning as an unavoidable aging phenomenon, whereas others actively seek medical and/or surgical treatment options.

HISTORICAL PERSPECTIVE

The first hair transplantation procedure for male pattern hair loss was successfully performed in the 1950s, using large punch autografts. Alternative techniques such as hair-bearing flaps and scalp reductions were also performed in an effort to redistribute hair or reduce the size of bald scalp. However, because of unsightly large "plugs", unnatural orientation of hair, and obvious scars revealed by continued hair loss, these techniques were largely abandoned in favor of follicular unit grafts. The latter are placed into small "recipient" sites (0.5–1 mm in diameter) produced by a blade or needle. Follicular unit grafts can be obtained either manually or mechanically.

MALE AND FEMALE PATTERN HAIR LOSS (ANDROGENETIC ALOPECIA)

Pathogenesis

Miniaturization of terminal pigmented anagen hairs to fine hypopigmented vellus hairs is the hallmark of androgenetic alopecia (AGA; Fig. 157.1). Androgens, in particular testosterone and dihydrotestosterone (DHT), are required for the progressive reduction in hair follicle size with each cycle. The enzyme 5α-reductase, which is inhibited by drugs such as finasteride, converts testosterone to DHT (see Fig. 69.10). In addition to 5α-reductase isoenzymes, multiple androgen-metabolizing enzymes actually reside within the hair follicle itself, providing an explanation for "end-organ" sensitivity (see Ch. 69).

Stem cells, which reside in the hair follicle bulge, are responsible for hair follicle cycling and when these cells are destroyed, there is loss of the follicle. In mice, combining bulge cells with neonatal dermal cells can give rise to a hair follicle as well as the sebaceous gland and epidermis[1]. Within the hair follicle, stem cells give rise to secondary germ cells with each hair cycle; the latter cells represent a progenitor population that is responsible for the production of the hair shaft during anagen (but undergoes apoptosis at the end of anagen)[2]. In a study that compared bald scalp with hair-bearing scalp in men, the stem cell population was maintained in the bald scalp but there was a marked reduction in progenitor cells, suggesting that study of this second population of cells could provide further insight into male pattern hair loss[3].

In gene expression arrays, increased expression of the gene that encodes prostaglandin D2 synthetase was observed in bald scalp as compared to haired scalp in men with AGA[4]; the latter enzyme converts prostaglandin H2 (PGH2) to PGD2. Balding scalp was also found to have increased levels of PGD2, and PGD2 was shown to inhibit hair growth in explants of human hair follicles. This inhibition of hair growth by PGD2 required interactions with one of its receptors, pointing to a potential therapeutic target.

Population studies have pointed to a polygenic inheritance pattern, with both maternal and paternal genetic influences. Of the associated genes identified to date, the androgen receptor gene (*AR*), present on the long arm of the X chromosome (Xq11–12), has been identified as a major determinant of hair loss in men (AGA2)[5–7]. Within exon 1 of *AR* is the *AR*-CAG polymorphism, which refers to the number of repeat sequences of cytosine–adenine–guanine (CAG) present, with the normal range of CAG repeats being 10–40. The number of CAG repeats appears to *inversely* correlate with the degree of androgen sensitivity. Men with fewer CAG repeats have an increased risk of developing AGA and a higher cellular sensitivity to androgens; they also demonstrate a greater response to finasteride treatment[8]. In contrast, men with >40 repeats appear to be protected and have androgen insensitivity[9]. Variants in *AR* may influence hair loss in women as well[10].

AR also has single nucleotide polymorphisms (rs6152; see Ch. 54) and White men with the A (adenine) allele have a low likelihood of developing AGA[11] while those with the G (guanine) allele have a 70% lifetime risk of developing AGA, which increases to >80% if there is a positive paternal family history. Other implicated genes include *EDA2R*, which encodes the ectodysplasin A2 receptor and is also found on the X chromosome (see Ch. 63)[12], as well as genes located at 20p11 (AGA3)[13] and 3q26 (AGA1)[14]. As more insight is gained into the interplay of these genes, it may be possible to diagnose AGA at an early age and predict who may benefit from therapy. Of note, it is important for patients to realize that while a family history of AGA provides useful information, it does not predict the rate and extent of hair loss in a particular individual.

Clinical Features

The diagnosis of AGA is usually straightforward, especially in men. This is based upon the characteristic pattern, the miniaturization of hairs, and the lack of clinical inflammation or scalp symptoms (see Ch. 69). Occasionally, an unusual presentation requires clinicopathologic correlation, and if there is evidence of perifollicular erythema, the possibility of a scarring (cicatricial) alopecia needs to be excluded[15]. In women, patterned alopecia may first become clinically apparent as a result of a superimposed telogen effluvium, perhaps following a febrile illness or birth of a child. These patients require an evaluation for telogen effluvium as outlined in Table 69.4 and possible hyperandrogenemia (e.g. serum free testosterone, DHEA-S), especially in the setting of hirsutism and/or recalcitrant acne vulgaris or any signs of virilization. Female pattern hair loss has to be distinguished from other causes of alopecia, including diffuse alopecia areata, early lichen planopilaris (LPP), frontal fibrosing

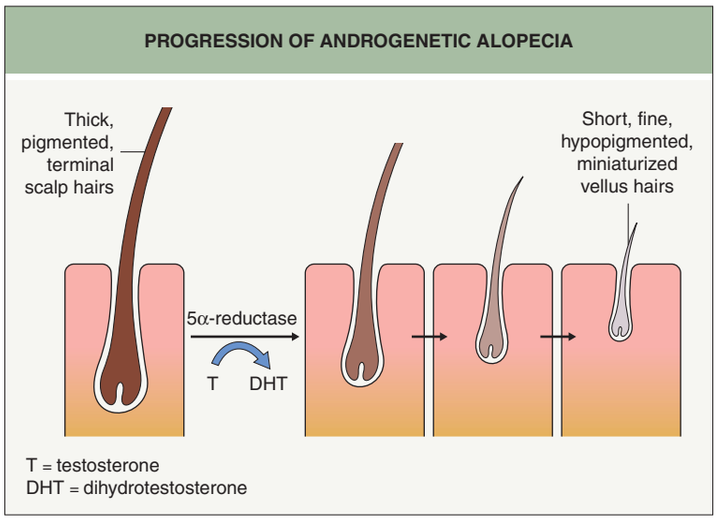

Fig. 157.1 Progression of androgenetic alopecia. Testosterone is metabolized into dihydrotestosterone (DHT) by the enzyme 5α-reductase and this conversion can occur within the hair follicle. *Courtesy Dowling B. Stough, MD.*

alopecia (FFA), or fibrosing alopecia in a pattern distribution (FAPD), and central centrifugal cicatricial alopecia (CCCA); as a result, histologic evaluation may be required.

There are grading systems for AGA that allow assessment of severity, progression and response to therapy. In men, the Norwood classification (Fig. 157.2) is used more often than the Hamilton classification system. Patterned hair loss in women is classically given a Ludwig grade (I, II or III; Fig. 157.3), even though the hair loss often has a Christmas tree pattern. Occasionally, the classification scheme for men is used if women present with vertex thinning or deep bitemporal recession.

Treatment (Other Than Transplant Surgery)

Medical therapies

Topical minoxidil as a 5% solution is FDA-approved for men[16] whereas the 2% solution and 5% foam are approved for both women and men. In general, the therapeutic effects are modest, but it may prove beneficial as an adjunct to hair transplantation[17]. Topical minoxidil can be helpful during the postoperative period to enhance and hasten growth of transplanted hairs. Minoxidil has multiple known mechanisms of action, but its effect on hair follicles is generally attributed to its vasodilatory or angiogenic properties and perhaps its effect on potassium channels[18].

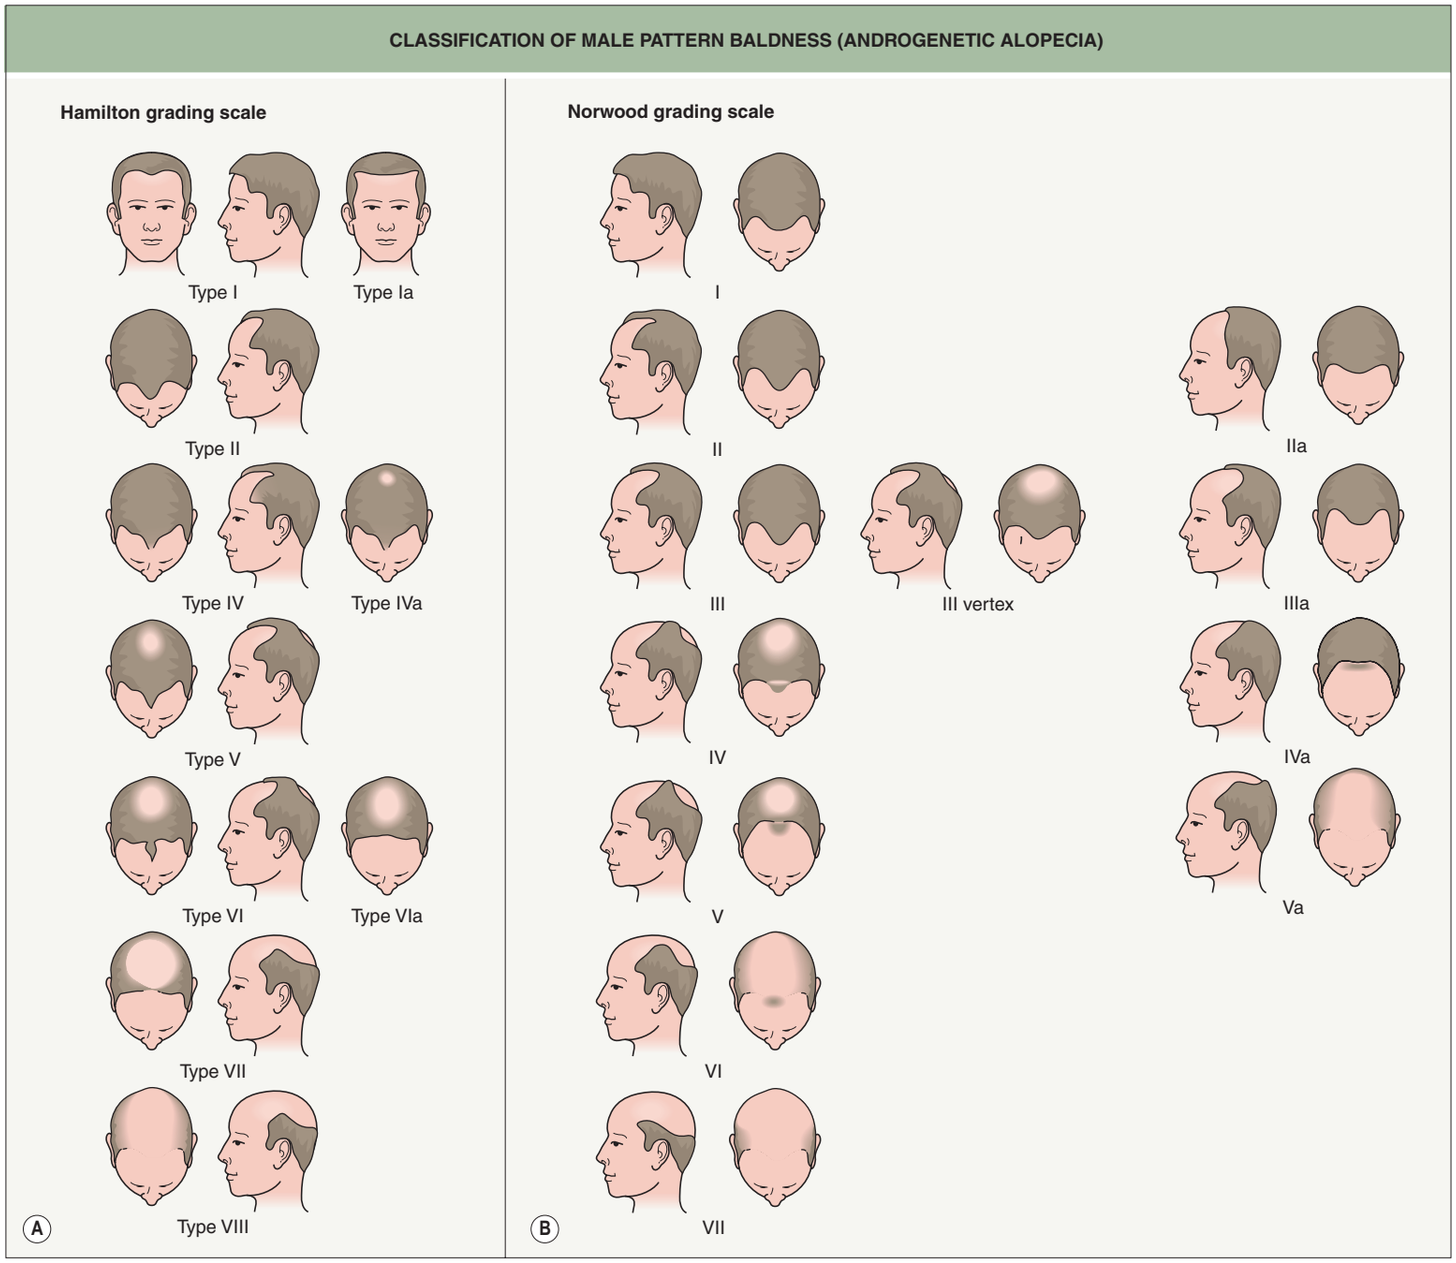

Fig. 157.2 Classification of male pattern baldness (androgenetic alopecia). A Hamilton grading scale. **B** Norwood grading scale. *Adapted from Hamilton JB. Male hormone stimulation is prerequisite and incitant in common baldness. Am J Anat 1942;71:451–80; and Norwood OT. Male pattern baldness: classification and incidence. South Med J 1975;68:1359–65.*

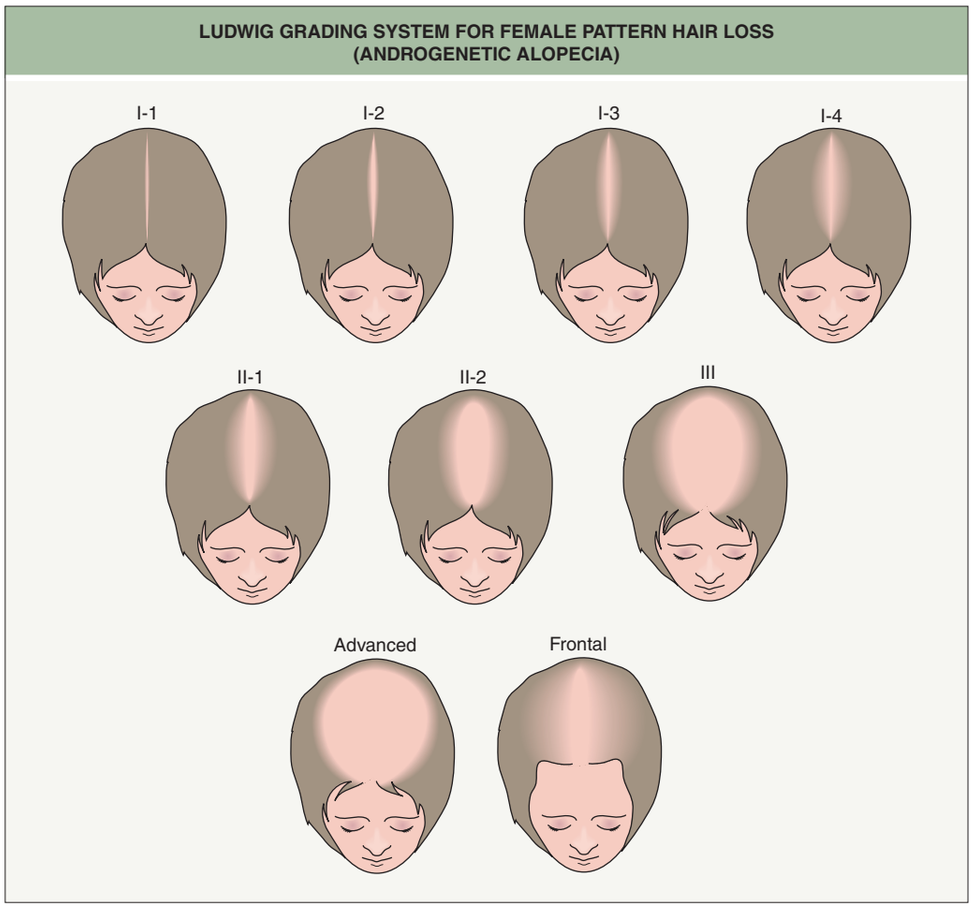

Fig. 157.3 Ludwig grading scale for female pattern hair loss (androgenetic alopecia). Midline hair loss in a Christmas tree pattern is a clue to androgenetic alopecia in women but is not depicted in the Ludwig grading scale. The Sinclair grading scale has five stages: normal (1); widening of the central part (2) plus volume loss lateral to the part (3); bald spot anteriorly (4); and advanced (5).

Increased proliferation of dermal papilla cells[19], an increase in hair caliber, a decrease in the rate of apoptosis of cells in the germinative pool, and more time spent in the anagen phase have all been observed[20]. A possible explanation for the variability in therapeutic responses amongst individuals is differing levels of sulfotransferase activity (which catalyzes minoxidil sulfate) within their hair follicles. There is evidence that aspirin may inhibit this sulfotransferase activity[21].

There has been growing interest in the use of *low-dose oral minoxidil* for AGA in both men and women[22]. Doses vary from 0.625 to 2.5 mg once or twice daily, with lower doses in women and lower doses initially. Multiple studies have demonstrated safety and efficacy in the treatment of male and female pattern hair loss.

Side effects of minoxidil include unwanted hypertrichosis of the cheeks or forehead, headache, ankle edema, and for topical preparations, allergic or irritant contact dermatitis. With regard to the latter, propylene glycol in the vehicle is often the culprit and it has been removed from the 5% foam product (Rogaine®). Facial hypertrichosis is more commonly observed with oral minoxidil and the risk may be greater in those with a genetic propensity for dark facial hair. In women, oral spironolactone can be prescribed to potentially reduce this side effect, in addition to its use as a treatment for female pattern hair loss (see Ch. 69). Fetal hypertrichosis has also been reported and so use of minoxidil is discouraged in pregnant or breastfeeding women. Lastly, reported cardiovascular side effects from oral minoxidil (uncommon with low doses) include hypotension, tachycardia, and pericarditis.

Finasteride inhibits type II 5α-reductase, which converts testosterone to DHT and is present in hair follicles (see Fig. 69.10). Oral finasteride (1 mg daily) is FDA-approved for men with AGA. In a randomized trial of 1553 men given either finasteride 1 mg or placebo for 1 year (with a blinded extension for a second year), significantly greater hair counts in the balding vertex were observed in those receiving finasteride[23]. Five-year results from the same study demonstrated that hair growth peaked at 1–2 years, but hair counts still remained well above baseline for 90% of patients[24]. Although finasteride was FDA-approved for stimulating the growth of vertex hairs, it also stimulates regrowth of frontal scalp hairs[25]. Its use in combination with hair transplantation has yielded statistically greater hair counts 48 weeks after surgery in comparison to the control/placebo group[26]. There is also some evidence that finasteride may work better in men with higher levels of DHT (such as those in their mid-twenties)[27].

Patients are advised to allow at least 6 months before expecting to see a therapeutic effect. If they discontinue the finasteride, the AGA will return to its pre-treatment appearance. Because finasteride is metabolized extensively in the liver, it should be used with caution in patients who have known liver disease[28]. Finasteride also artificially lowers the serum prostate-specific antigen (PSA) level by ~50%[29]. Therefore, both the primary care physician and the patient need to be made aware of this effect. Although early data from prostate cancer trials suggested that finasteride might increase the histologic grade (i.e. severity) of prostate cancer,[30] subsequent analyses suggested a detection bias[31].

Overall, the drug is well tolerated. Side effects that occur in <2% of men taking finasteride include decreased libido, erectile dysfunction and ejaculation disorder, compared with their occurrence in 1% of the placebo group. Rarer side effects include gynecomastia, breast tenderness, and depression[32]. In a double-blind, placebo-controlled, multicenter trial in young men, no changes in spermatogenesis or semen production were observed[33]. However, there have been two reports of severe azoospermia leading to impaired fertility[34]. While the authors feel comfortable prescribing finasteride for men who are planning to have children, it should be discontinued if there are fertility issues, before embarking upon more invasive infertility treatments. Sexual dysfunction, even after discontinuation of finasteride, has been reported, but with selection bias, recall bias, and lack of control for confounding factors[35]. Prolonged libido effects in conjunction with other findings such as brain fog and depression have been collectively coined "post-finasteride syndrome"; Merck has updated its packaging to reflect this possibility but the diagnosis remains controversial and poorly understood. Most recently, the FDA added suicidal ideation and behavior to the package insert despite the lack of reasonable evidence of a causal link. Patients who are reluctant to take oral finasteride may benefit from a compounded (off-label) formulation of topical finasteride[36].

We encourage surgical candidates to stabilize their hair loss by taking finasteride, or another medical therapy, for 6 to 12 months prior to hair transplantation. Most men benefit from combination therapy (Fig. 157.4). Patients who report sexual dysfunction side effects should discontinue oral finasteride and, after an interval of 1–2 weeks, try every second- or third-day dosing.

Fig. 157.4 Combination of hair transplantation and oral finasteride (1 mg daily). A 38-year-old man with male pattern hair loss (baseline). **B** Appearance following 1 year of finasteride plus hair transplantation (500 grafts).

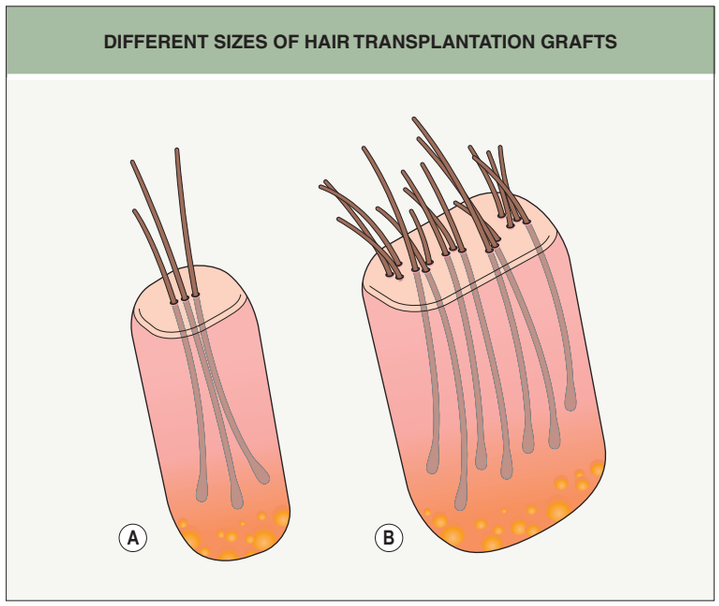

Fig. 157.5 Different sizes of hair transplantation grafts. A The newer technique uses 1- to 4-hair follicular unit grafts. **B** The older technique uses larger 10- to 15-hair grafts.

Finasteride is not FDA-approved for women with AGA, and at a dosage of 1 mg daily, no improvement was observed in clinical trials[37]. Of note, finasteride can cause feminization of the male fetus. In an uncontrolled series of post-menopausal women, higher doses of 2.5 mg and 5 mg daily led to improvement in hair density in 62% and 81% of patients, respectively[38,39]. Excellent tolerability has been observed in women on long-term finasteride, with minimal-to-no side effects[40].

Dutasteride differs slightly from finasteride in that it blocks both type I and type II 5α-reductase isoenzymes. It has been used off-label at a dosage of 0.5 mg daily for AGA in men who did not respond to finasteride, and increased hair counts were observed in a randomized, placebo-controlled trial[41]. However, the drug's half-life is 5 weeks, compared with 6–8 hours for finasteride. Thus, side effects are longer-lasting (several months) and more difficult to reverse. In a double-blind, placebo-controlled trial, men who received oral dutasteride (0.5 mg daily) versus placebo for 1 year had significant decreases from baseline in sperm count: by 28.6% at 26 weeks, 25% at 52 weeks, and 23% at 24 weeks after the trial ended[42]. Sperm motility was also reduced at the latter time point. This potentially irreversible drop in sperm count and motility is an issue for men who still desire to have children.

Low-level light therapy

Photo-biostimulation via low-level light therapy (LLLT) is another possible treatment for hair loss. This was initially based upon the observation that laser hair removal can sometimes trigger paradoxical hair growth in the surrounding skin[43]. Based upon their approval by the FDA as a medical device (rather than a drug), multiple LLLT products are commercially available. The patient combs light (650–700 nm) through the hair two to three times per week or wears a laser cap for a prescribed amount of time daily, with the expectation of hair growth. However, there have only been a limited number of published studies examining the effects of LLLT on hair growth[44,45]. Patient expectations should be managed, and while it is very safe (e.g. can be used in pregnant women), the authors seldom recommend it as monotherapy but rather utilize in combination with minoxidil, platelet-rich plasma, or finasteride[46].

Platelet-rich plasma

Platelet rich plasma (PRP) has emerged as an appealing therapy for hair loss given its autologous nature. It was first described in conjunction with hair surgery to increase growth of transplanted follicles[47]. This technique involves obtaining 10–40 ml of the patient's blood followed by centrifugation in order to achieve a platelet-rich concentration that is 4–7× baseline. Activated platelets have been shown to release platelet-derived growth factor, epidermal growth factor, transforming growth factor, and vascular endothelial growth factor[48]. The PRP is then injected into areas of alopecia, either alone or in combination with adjuvants such as calcium chloride or calcium gluconate. Numerous proprietary PRP "kits" have been developed for dental, orthopedic, and now dermatologic applications.

While most studies have focused on its use for AGA, PRP has also shown some promise in the treatment of alopecia areata[49] and LPP[50]. In one clinical trial in patients with AGA, three monthly injections followed by a booster injection 3 months later led to more rapid hair thickening and regrowth than did injections every 2 months over 6 months[51]. However, in a randomized controlled trial of patients with AGA, injection of PRP versus saline into two equivalent sites on the scalp resulted in similar results[52]. This and other studies have led some to question the effectiveness of PRP[53]. More research is therefore needed to further refine optimal dosing and treatment guidelines.

HAIR TRANSPLANTATION

Hair transplantation is a procedure performed in an outpatient setting under local anesthesia. It is based on the theory of donor dominance, i.e. terminal hair from the unaffected posterior scalp will continue its growth pattern even when transplanted to the balding frontal scalp[54]. Unfortunately, until the 1990s, hair transplants often had an unnatural appearance due to unsightly and obvious "plugs", sometimes likened to a "Barbie-doll" appearance. Over the past two decades, there has been a revolutionary movement away from 3–4 mm grafts containing 15–30 hair follicles to grafts containing groupings of one to four hair follicles, referred to as individual follicular units (Fig. 157.5). This has resulted in the transplanted hair having a more natural appearance (Figs. 157.6 & 157.7).

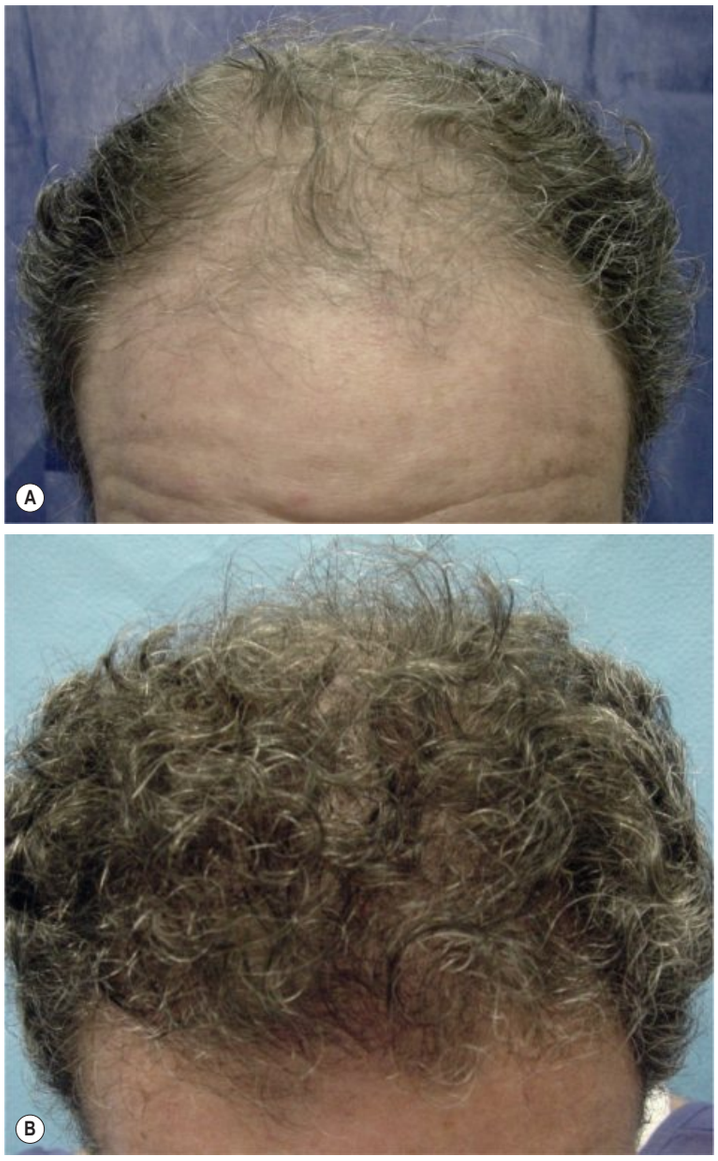

Fig. 157.6 Hair transplantation for male pattern hair loss. A Norwood IV pattern (baseline). **B** Appearance following transplantation of 900 hair grafts, each with one to three hairs.

Fig. 157.7 Hair transplantation for female pattern hair loss. A Ludwig II pattern (baseline). **B** Appearance following transplantation of 750 hair grafts, each with one to three hairs.

The net perceived density from a hair transplant is equal to the number of successfully transplanted follicles minus ongoing hair loss. In order to maximize long-term results, all patients undergoing this surgical procedure are encouraged to continue topical minoxidil, low-dose oral minoxidil, and/or oral finasteride (see above). Halting or at least slowing the miniaturization process allows for the perception of greater hair density.

Candidate Selection

As with all surgical procedures, the preoperative consultation is key to the success of the procedure. The consultation establishes whether the patient is an appropriate candidate for hair transplantation, both from a medical and a psychological perspective. In addition, it allows for an assessment of areas of greatest concern and whether the patient has realistic expectations of what a hair transplant can achieve.

A complete medical, surgical, and hair loss history is obtained, including previous hair transplants and scalp surgeries as well as scar formation. The etiology of the hair loss is determined, primarily via physical examination of the scalp. Occasionally, additional sites need to be examined and/or clinicopathologic correlation is required. The stage of patterned hair loss also needs to be established (see Figs. 157.2 & 157.3). All medications, prescription, over-the-counter and herbal, are reviewed with regard to their effects on hair growth and hemostasis (see Chs. 21 & 133).

The basic criteria for assessing the appropriateness of a candidate for hair transplantation are outlined in Table 157.1. In particular, the density of donor hair in the occipital scalp and the caliber of the hair need to be appraised, as both have an impact on the perceived density of the transplant (Table 157.2). Obviously, greater donor density and more grafts to transplant as well as thicker hairs rather than fine hairs lead to a fuller-appearing transplant.

Key Concepts

Both men and women should be made aware that AGA represents an ongoing process, i.e. it will progress despite undergoing hair transplantation. Medications (e.g. oral finasteride, minoxidil) or PRP and LLLT can help to maximize hair density from a transplant by minimizing ongoing hair loss. However, in planning for the transplant procedure, the surgeon should always assume that in the future these medications may be discontinued (see Table 157.2). Also, the progressive nature of AGA means that additional hair transplants may be required. The physician should therefore emphasize *before* the procedure how ongoing hair loss will affect the density and cosmetic appearance of the transplant as well as how this influences the placement of the grafts so as to assure a long-term natural appearance.

The number of expected procedures to accomplish both short- and long-term goals should be reviewed, as well as the limits on available

FIVE BASIC CRITERIA FOR ASSESSING CANDIDATES FOR HAIR TRANSPLANTATION	
Age	Patients over the age of 25 years are preferable. While patients younger than 25 years of age often seek consultation, there is a hesitancy to operate. The predictive value of future hair loss is much lower for individuals between 15 and 25 years of age. Even with the theoretical safety net of finasteride, physicians should carefully choose candidates under 25 years of age. This subgroup also tends to desire a return to a full head of hair as opposed to a mature pattern of restoration that is routinely performed in older age groups.
Hair shaft caliber	The caliber of the hair shaft is crucial. Those with large-caliber hair shafts (greater than 70 microns) obtain much denser coverage than individuals with corn silk quality hair. This can be demonstrated mathematically in that very small volume increases in hair shaft diameter result in exponential increases in surface area coverage.
Donor hair	A variety of instruments are available to measure donor hair density. Measuring a 0.25 cm^2 field and multiplying by four is the preferred method. Patients seeking hair transplantation who have >80 follicular units/cm^2 are excellent candidates. Those with donor hair density <40 follicular units/cm^2 are considered poor candidates.
Degree of baldness	The degree of baldness is perhaps the most important criterion in candidate selection. Those with complete baldness of the frontal scalp as opposed to baldness limited to the vertex are excellent candidates. When frontal baldness is corrected, this creates the most dramatic positive change in appearance.
Hair color	Follicular unit grafting has made hair color less of an issue than when punch grafts were employed. Color contrast between hair and skin can make grafts apparent if not transplanted with great care. Individuals with "salt-and-pepper" hair, red hair, or blonde hair are preferential to those with jet-black hair. Black-haired individuals are not exempt as hair transplant candidates, but should receive only one-hair follicular units in the frontal hairline for the most natural result. Proper technique eliminates most problems with dark-haired candidates.

HAIR TRANSPLANTATION – CLINICAL FINDINGS AND REALISTIC EXPECTATIONS		
Clinical findings	**Realistic expectations**	**Comment**
• High donor density • Large-caliber (thick) hair • Stabilized hair loss via topical minoxidil, low-dose oral minoxidil, and/or oral finasteride	1000–1500 graft sessions will create the perception of increased hair density	Need to plan the procedure *assuming* the patient may stop the medication(s) and the hair loss will resume
• Poor donor density • Thin-caliber (fine) hair • Ongoing hair loss	1000–1500 graft sessions may create little increase in *perceived* density	Although the transplant will result in more hair, this may not be apparent due to ongoing hair loss and thin-caliber hair

Table 157.2 Hair transplantation – clinical findings and realistic expectations. The net density from a transplant = number of follicles transplanted minus ongoing hair loss.

donor hairs. Reasons for preferring to transplant primarily the frontal scalp as opposed to the vertex need to be explained – the vertex can consume donor grafts and it exhibits a continued 360° progression of hair loss which can lead to a peripheral rim of bald scalp which will appear unnatural over time. In addition, transplanting the frontal scalp, not the vertex, produces the maximum cosmetic impact. Therefore, transplanting the vertex should be approached with caution, particularly in younger patients. Concentrating the transplants in the frontal scalp will allow maximum long-term density with minimal long-term cosmetic risk.

Fig. 157.8 Occipital scalp scar secondary to elliptical donor harvesting. *Courtesy Dowling B. Stough, MD.*

Patients have to realize that elliptical donor harvesting will lead to a permanent scar of the posterior scalp (Fig. 157.8). The scar is of no practical concern unless the patient has his or her hair closely cut. If the patient expresses an interest in having closely cropped hair, follicular unit extraction (FUE) should be considered (see below). However, the possibility of small "white dots" following FUE should also be discussed. Lastly, the patient must appreciate the need for a conservative approach to placement of the anterior hairline so that it will have a natural appearance over a lifetime as the temporal and posterior hairlines recede.

Staff Training for Manual Hair Transplantation

Contemporary hair transplantation is a team procedure, and an efficient, high-quality transplant requires a well-trained surgical team. Assistant technicians should be motivated and interested in learning and mastering the procedure. In addition, they need to be able to do repetitive tasks without tiring, losing concentration, or becoming frustrated. Technicians are utilized primarily for cutting and planting. The first task involves sectioning of the donor strip into slivers, followed by further meticulous sectioning into follicular units and prompt placement into chilled saline or other holding solution (Fig. 157.9). After the physician creates recipient sites, technicians can help insert the follicular unit grafts into the scalp. Recipient sites are generally designed at a density of 35–40 follicular units/cm^2 but a lower density may be employed in areas where there is already pre-existing hair growth.

During the procedure, the physician closely monitors the quality of graft creation and placement. It is recommended that physicians learning the procedure have a staff member train at the same time. In order to avoid repetitive strain syndrome, technicians should position their elbows or forearms on a firm, supportive surface while using wrist and finger movements to plant grafts. Rotation of duties can also prove helpful.

Donor Region

The amount of available donor hair is the primary limiting factor in hair transplantation. In general, there are 65–85 follicular groupings/cm^2 in the occipital donor scalp[55]. If there are <40 follicular units/cm^2, the patient is considered a poor candidate (see Table 157.1). The mid-occipital scalp between the upper and lower occipital protuberances is the recommended donor site, given its density of hair and the ability to camouflage the donor scar due to the lack of involvement by AGA. If the harvesting is done too superiorly on the occiput, progressive AGA may reveal the surgical sites. Of note, donor density does not correlate with the extent of current or future hair loss in the frontal scalp or vertex. Harvesting of donor hair is performed via two different techniques: (1) elliptical donor harvesting; and (2) FUE (Table 157.3).

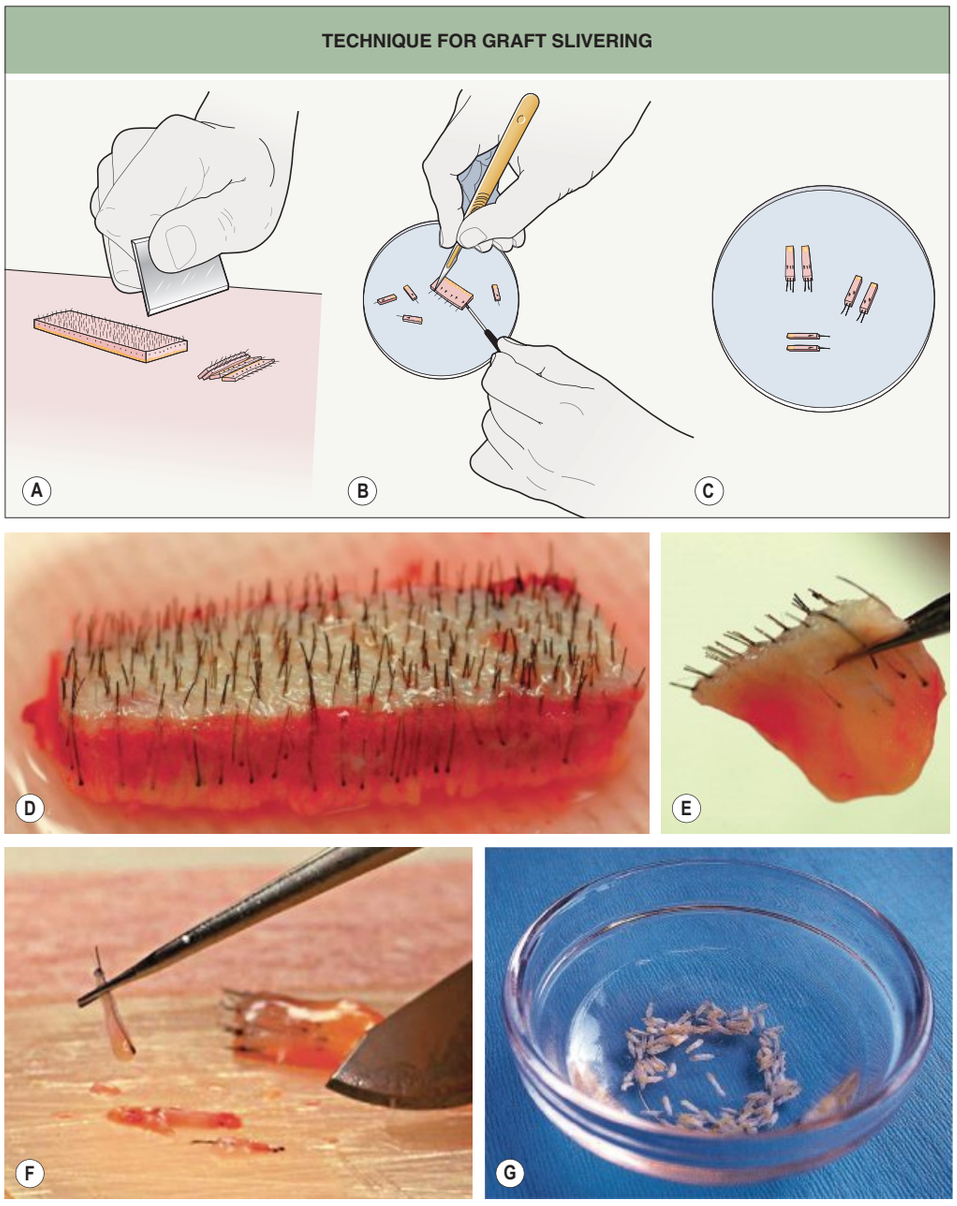

Fig. 157.9 Technique for graft slivering. COMPARISON OF ELLIPTICAL DONOR HARVESTING VERSUS FOLLICULAR UNIT EXTRACTION		
	Elliptical donor harvesting	**Follicular unit extraction**
Visible scar if short hair cut	Yes	No
Transection of hair follicles	Minimal	Variable
Time required to perform harvest	10–20 minutes	30–90 minutes
Time needed to create grafts	Lengthy	Minimal
Quality of resulting transplant	Excellent	Excellent

Table 157.3 Comparison of elliptical donor harvesting versus follicular unit extraction.

Elliptical donor harvesting (follicular unit transplantation [FUT])

Elliptical donor harvesting is still performed in a large number of patients because it allows for the safe and rapid removal of a large number of hair follicles, with minimal transection of hairs[56]. In addition, if patients will never wear their hair closely cropped, the resultant linear scar is not a concern and in contrast to follicular unit extractions, there is no need to trim hairs to 1 mm prior to the procedure. Elliptical donor harvesting is also referred to as follicular unit transplantation (FUT) or follicular unit strip surgery (FUSS).

The length and width of the donor ellipse depends on the number of follicular groupings required for the patient. For example, if 1000 follicular groupings are needed for the frontal scalp and a patient has an average donor density of 75 follicular units/cm^2, a 13.5 cm by 1 cm strip should contain approximately 1000 follicular grafts. It is important to remember that if a greater number of grafts are required, the ellipse should be lengthened rather than widened since increasing the width of a donor ellipse creates more wound tension which may lead to a hypertrophic or wide scar.

Ideal local anesthesia is obtained by infiltrating 1% lidocaine with epinephrine (adrenaline) superficially into the dermis. Once anesthesia has been achieved, bacteriostatic normal saline can be injected to provide further anesthesia, hemostasis, and dermal turgor. Turgor helps to reduce the transection of hair follicles. The blade(s) should be oriented parallel to the exiting follicles to avoid transection of hair follicles. The incision should be into the subcutaneous fat, and not deeper, in order to avoid transecting the occipital arteries (Fig. 157.10). Lateral retraction around the ellipse using fine skin hooks creates good visibility for the surgeon harvesting the ellipse (Fig. 157.11). The ellipse can be removed by scissors or a scalpel, carefully avoiding damage to any follicles in the subcutaneous tissue.

Fig. 157.10 Elliptical donor harvesting. To avoid transection of the hair follicles, the double blades should be oriented parallel to the exiting follicles. The incision should extend into the subcutaneous fat but not deeper (~5 mm into the scalp). Some surgeons prefer a single blade for performing the ellipse.

Fig. 157.11 Elliptical donor harvesting. Lateral retraction using fine skin hooks exerts tension away from the excision and creates good visibility. The ellipse can be removed by scissors or a scalpel, being careful to avoid damage to any follicles in the subcutaneous tissue.

If the incision does not go any deeper than the subcutaneous fat layer, the ellipse can be removed without the use of electrocoagulation or thermal coagulation. Also, if the donor ellipse is <1 cm in width, it can often be primarily repaired without undermining. Some surgeons utilize a two-layer closure with absorbable sutures while others perform a single-layer closure. Staples or sutures can be utilized and then removed 7–10 days postoperatively. In some patients in which there is good surgical technique and optimal wound healing, the donor area from a single strip procedure may be more natural-appearing than with FUE. However, one cannot predict donor site healing following strip harvesting.

Follicular grafts

Hair naturally grows in groupings of 1–4 hair follicles, referred to as follicular units (see Fig. 157.5)[57]. During the 1960s to 1990s, 3–4 mm grafts that contained multiple follicular units were employed, leading to an unnatural appearance with obvious bundles of hair. Nowadays, each graft contains one follicular grouping with 1–4 hair follicles. Thus, these grafts mimic the normal grouping of scalp hairs and create a natural appearance.

When an ellipse is harvested, surgical teams carefully separate 500–2000 follicular units from the donor strip over 1–3 hours (see Fig. 157.9). Cutting instruments vary but include #11 and #15 blades as well as #10 prep blades. Good lighting, comfortable chairs, and well-designed instruments are prerequisites for producing follicular units with minimal follicular transection. Most surgeons believe microscopic dissection or magnification reduces transection of follicles during the separation process (Fig. 157.12).

Fig. 157.12 Use of magnification to separate follicular units from the donor strip.

It is important to create intact, minimally traumatized follicular units and place the transplanted hair into the recipient sites as efficiently and quickly as possible. As soon as the follicular unit grafts are separated from the donor ellipse, they must be put into a holding solution until they are placed into the recipient sites. Commercially available holding solutions can enhance survival of these hair follicles, in part by reducing apoptosis[58]. If grafts desiccate for even a few minutes they will die and not grow. One of the advantages of the FUE technique is that following visual inspection, harvested grafts can be transplanted immediately.

The number of follicular units required for each surgery depends on the extent of hair loss, available donor hair, and density of pre-existing terminal hair follicles in the recipient area. This can vary from 100 to 2500 follicular groupings per procedure. Larger cases may be done over two days to avoid technician fatigue and reduce the chance of undesirable sequelae.

Follicular unit excision (FUE)

In the FUE technique, single follicular units consisting of groupings of 1–4 hair follicles are surgically removed from the occipital scalp. Tiny punch devices (~0.75–1.2 mm in diameter) are used to remove the grafts[59,60]. The incisions are so small that they usually leave no visible scar after they heal; however sometimes small "white dots" are seen. For patients who like to have closely cropped hair, FUE is generally preferred. It is also an option for patients who have significant tension or extensive scarring from previous elliptical donor harvesting.

Although manual FUE requires more time than elliptical donor harvesting, the introduction of automated mechanical instruments and robotic technology has led to a reduction in extraction times. Important considerations when performing manual FUE are outlined in Table 157.4. Potential disadvantages of FUE include a higher rate of transection of follicular groupings when compared to strip harvesting as well as the risk of "thinning out" the donor area due to repeated extractions[61]. In one small series, the number of lifetime follicles was similar for FUT and FUE[62].

Numerous devices exist for performing FUE[59,60]. Earlier devices utilized manual or motorized dull punches to gently extract the grafts in order to avoid damage to bulb anatomy. Subsequently, motorized, sharp punches

MANUAL FOLLICULAR UNIT EXTRACTION (FUE) – PROCEDURAL CONSIDERATIONS
• The incision should follow the **follicular exit angle** from the scalp, taking into account individual hair follicle characteristics and the observation that follicles grow in a curve with the concavity of the follicle on the acute angle side of the follicle.
• Because the length of the trimmed hair dictates the *apparent* **angle of hair growth**, hair follicles must be trimmed to the preferred length of ~1 mm so as to identify the *true* angle of emergence; if the hair follicle is trimmed too long, the apparent angle is more acute than the true angle and if the hair is trimmed too short, tumescence can conceal both the follicle and its angle of hair growth. Cross polarization may assist in visualizing the hair growth angle.
• To minimize initial **wound size**, one can first incise shallowly perpendicular to the skin surface followed by a deeper incision directed along the angle of hair growth; if an incision with a cylindrical punch follows the angle of hair growth, the wound will be an ellipse.
• Optimally, the targeted follicles should be in the center of the punch instrument or needle, and because hair grows at an acute angle, the inferior side of the punch instrument will first contact the skin.
• If the **axial force** created by the inferior side of the punch instrument is too great, the bulb of the follicle may be displaced inferiorly and amputated; a predominantly tangential force, rotation, or oscillation minimizes follicle displacement as does skin tension applied via tumescence or skin traction.
• To avoid graft torsion, **frictional forces** between the punch instrument and the skin must be minimized by using a very sharp, well-designed instrument with a thin wall and by minimizing incision depth.
• In order to free up intact follicles, deeper incisions are required if the ORS is strongly attached to surrounding adipose tissue and if the ORS is weakly attached to the IRS.
• Because of **follicular splay** within a grouping, use of a punch instrument with a greater diameter may be required to excise intact grafts and minimize follicle transection rates; with manual harvesting, one can expect an average 2.10–2.25 follicles/graft with a 0.8–0.9 mm punch instrument.

Table 157.4 Manual follicular unit extraction (FUE) – procedural considerations. IRS, inner root sheath; ORS, outer root sheath.

were employed to speed up excisions. Punch instruments with a flared or trumpet shape were introduced more recently to try to reduce transection of hair bulbs. Robotic systems such as ARTAS® (Venus Concepts) can be used to minimize physician fatigue and eliminate the need to acquire all the surgical skills needed to dissect grafts.

With FUE, the surgeon can target follicular groups of a specific size or hairs with a specific diameter or pigmentation. Single hairs may be harvested for eyebrow restoration, or larger 3–4 hair groupings may be targeted to add density over the mid scalp. Because of minimal scarring, harvesting from the beard region or other terminal hair-bearing areas is also an option. In addition, harvesting can be done even after multiple strip surgeries have led to a very tight donor area.

For optimal cosmetic results and to preserve symmetry, one should irregularly harvest from the entire *safe donor area* (SDA) rather than from just a small shaven area. Of note, the surgeon should not be pressured to over-harvest, lest the donor area be depleted. Unfortunately, patients sometimes seek less expensive "black market" hair transplants and then can present with donor and/or recipient site necrosis and soft tissue infections, resulting in few options for repair.

Hairline Design and Recipient Site Creation

In men, the hairline defines the cosmetic success of a hair transplant. Most women have stable frontal, temporal and posterior hairlines, making recreation of a hairline unnecessary. As with hair graft creation, hairline design should mimic, as closely as possible, what occurs in nature. However, patients and physicians often try to mimic the hairline a patient had before their male pattern hair loss began. Even with follicular unit transplants, this approach to hairline design often leads to cosmetic failure. This is due to not considering the slow steady recession of the temporal and posterior hairlines in addition to the frontal hairline.

The design of the frontal hairline should be such that over time it will remain balanced with the temporal and posterior hairlines.

Fig. 157.13 Immediate postoperative appearance with graft placement and hairline design. *Courtesy Dowling B. Stough, MD.*

This requires recreating a frontal hairline which is higher and more receded than the one which was present before the process began. Initially, some patients will resist the idea of a higher, more receded hairline, but explaining and demonstrating with a mirror how their temporal and posterior hairlines preclude a low frontal hairline usually changes their opinion.

Rather than considering the hairline to be a fixed boundary, it should be thought of as a natural transition zone of gradually increasing density from skin to terminal hair-bearing skin. This ill-defined "feathering zone" is created by placing, in an irregular pattern, follicular unit grafts (with 1–4 follicles) along the newly created hairline (Fig. 157.13)[63]. Dense packing of grafts should not be performed along the frontal hairline because a densely packed hairline has an unnatural appearance. The level at which the hairline is placed varies from individual to individual and it is important to examine each patient in a global, 360° manner before determining placement of the hairline.

While male pattern hair loss is progressive, transplanted hair will have long-term growth. Therefore, when evaluating patients, the surgeon must assume that all patients will progress to the highest grade of involvement, i.e. the worst-case scenario. As noted previously, for several reasons, including the progressive nature of AGA leading to an unnatural appearance, transplanting into the vertex should be approached with caution.

Anesthesia and Recipient Site Creation

A combination of supraorbital/supratrochlear nerve blocks, field blocks, and local infiltration with 1% lidocaine with epinephrine is performed. Hemostasis is essential for good visibility when creating recipient sites and for graft placement. The epinephrine in the local anesthetic (placed into the dermis, not the subcutaneous space) is usually adequate for providing excellent hemostasis. While most surgeons use "off-the-shelf" 1% lidocaine with 1 : 100 000 epinephrine, concentrations of the latter may range from 1 : 50 000 to 1 : 500 000.

Recipient sites should mimic the natural 30–45° angle of hair growth on the scalp (Fig. 157.14). There are a variety of needles, in particular 18, 19, 20 and 21 gauge needles, that are used to make recipient sites for 4, 3, 2, and single hair groupings, respectively. When creating recipient sites, surgeons must be careful not to transect existing hair follicles. Most advocate using magnification to place recipient sites in order to limit the loss of existing hair during surgery[64]. The key to success is to arrange recipient sites in a random, irregular pattern with 10–30 sites/cm^2, depending on the density of existing hair on the scalp.

Graft Placement and Postoperative Course

Microvascular forceps are used by surgical assistants to place the grafts. These forceps gently grasp the follicular units by their perifollicular tissue, avoiding trauma to the hair follicles. Placement of the grafts into recipient sites is often the most challenging component of the hair

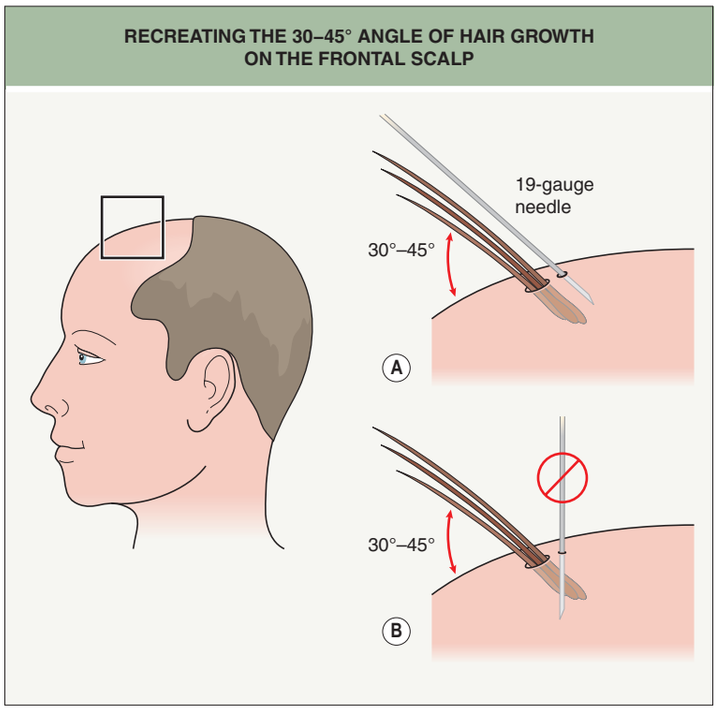

Fig. 157.14 Recreating the 30–45° angle of hair growth on the frontal scalp. Correct (**A**) versus incorrect technique (**B**). Grafts should not be oriented perpendicular to the scalp surface.

HAIR TRANSPLANTATION – POSTOPERATIVE INSTRUCTIONS	
Day of the procedure	• Apply non-adherent dressing overnight • Oral acetaminophen (paracetamol) 300 mg/codeine 30 mg every 4–6 hours as needed with food* • Oral prednisone 40 mg daily for 3 days to reduce frontal scalp edema • Resume regular activities, but no heavy lifting or strenuous exercise until staples/sutures removed • Sleep with head elevated
Postoperative days 1–3	• Day 1 – remove dressing • Shower each day and allow water to run over grafts • Comb hair without allowing comb's teeth to hit perifollicular crusts • Do not pick or scratch at perifollicular crusts • Apply emollient to the donor site(s) daily • Days 1, 2 – continue prednisone (see above)
Postoperative days 4–7	• Resume light exercise • Follow instructions outlined above for showering, combing, and emollient application
Postoperative days 7–10	• Staples/sutures removed • Resume regular exercise regimen • Perifollicular crusts gradually disappear
*In general, only required on the day of surgery.	

Table 157.5 Hair transplantation – postoperative instructions. Patients should not wear a hairpiece for at least 2 weeks after the procedure.

transplant procedure, both for novice and experienced hair transplant teams. The major challenges include hemostasis and "popping" of grafts from recipient sites after they are placed. However, it is difficult to predict which patient will have "popping" grafts. This phenomenon is overcome by applying light pressure over a placed graft for 5–15 seconds with a saline-soaked cotton swab before placing the next graft.

After the procedure, an overnight dressing is placed to protect the grafts. The entire dressing should be non-adherent and removed by the patient the next morning (Table 157.5). Staples or sutures are removed during a 7- to 10-day postoperative visit. The transplanted hair begins to appear 3–6 months after the procedure and is fully grown by 9–14 months. Patients must be warned of the possibility of post-transplant telogen effluvium.

Complications

Medical and surgical complications from a hair transplant procedure are unusual. The extensive vascular supply to the scalp results in rapid wound healing and a low risk of infection. In addition to reactions to medications and vasovagal episodes, complications include excessive swelling (~5%), postoperative bleeding (<0.5%), folliculitis, a temporary headache, and temporary pruritus or numbness of the scalp. Persistent problems include permanent numbness in the donor or recipient sites, abnormal scarring around the grafts, hypertrophic scarring of the donor site, and poor growth of hair grafts. The latter can be minimized by keeping the grafts constantly moist.

Hypopigmentation often occurs at extraction sites within the donor region but its occurrence is not predicable. It is often larger in diameter than the punch instrument used to obtain the graft. Scalp micropigmentation has been used to successfully camouflage this hypopigmentation. Telogen effluvium of nonreplaced hair, also referred to as "shock" hair loss, is an uncommon complication that in the authors' experience resolves on its own. It stems from overharvesting of grafts in a specific region. In general, *maximal* harvesting during a single procedure should be 25% of the total number of follicular units. Because the number of safely harvested grafts depends on the density of follicular groupings and hair caliber, individuals with fine hair and older individuals (number of follicular groupings decreases with age) who undergo harvesting of higher numbers of follicular groupings are at risk for this complication. Lastly, a hair transplant-triggered flare of LPP has been reported. It is unclear if a hair transplant actually triggered a flare of LPP or subclinical preexisting disease became more active.

Corrective Hair Transplant Surgery

When patients present for corrective surgery due to previous transplantation of 3–4 mm punch grafts that have led to unnatural large "plugs", i.e. a "pluggy" transplant, three major options exist: (1) add a large number of follicular unit grafts containing one to four hairs between the larger plugs; (2) surgically remove the large grafts; and/or (3) perform laser-assisted hair removal. Which option is best suited for an individual patient is determined during the consultation.

Adding follicular unit grafts

Transplantation of a large number of follicular unit grafts containing one to four hair follicles – in front of, in between, and behind large grafts – will soften the "pluggy" appearance (Fig. 157.15). This option is appealing for many patients because it allows for both cosmetic improvement and increased density (Fig. 157.16). Unfortunately, some patients with an unnatural hairline have a depleted donor supply from previous transplant procedures while others are reluctant to have another surgery following the emotional trauma from the initial transplant.

Surgical removal of grafts

Some hairlines are so cosmetically inappropriate that there is no worthwhile corrective option other than surgically removing the grafts. This option is also indicated for large grafts with perifollicular white scar tissue. The grafts can be removed by either a 2–4 mm punch instrument or an elliptical excision. Another option is to perform FUEs from larger grafts via 1 mm punch instruments. The latter procedure reduces the "pluggy" appearance of the larger grafts while allowing a more natural appearing graft to remain.

In general, scars on the scalp heal well with minimal evidence of the surgical procedure. However, all patients should be warned that cosmetically evident scars develop in a small minority of cases. If unacceptable scars do arise, pulsed dye, ablative, non-ablative, or fractional ablative laser treatments can be used to help improve the cosmetic appearance.

Laser-assisted removal of large grafts

As with other parts of the body, lasers only remove pigmented terminal hair follicles (see Ch. 137)[65]. Typically 5–10 treatments are needed to permanently remove the majority of follicles. Similar to FUE of larger

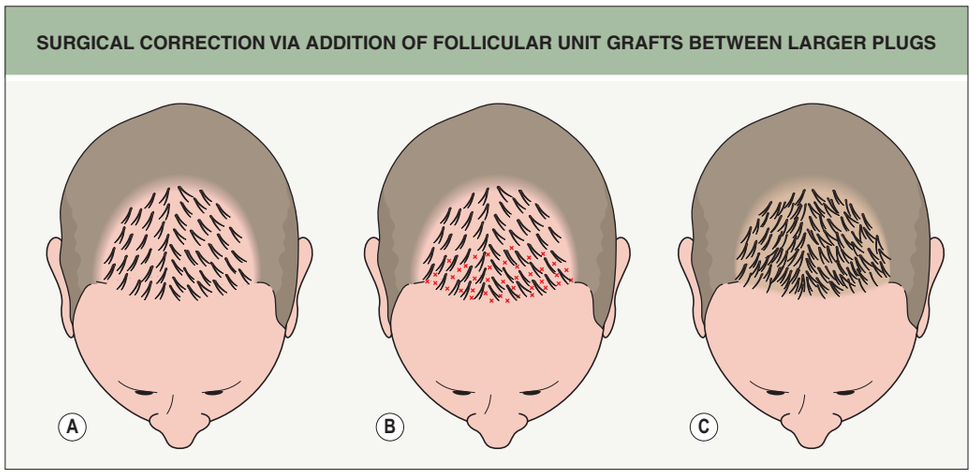

Fig. 157.15 Surgical correction via addition of follicular unit grafts between larger plugs. A Previous transplantation of 3–4 mm punch grafts can lead to unnatural large "plugs" of hair. **B**, **C** Addition of follicular unit grafts between and in front of the larger grafts softens the hairline and the overall appearance.

Fig. 157.16 Corrective hair transplant surgery. A Widely scattered large plugs with significant contrast between the lightly pigmented scalp and the black hairs. **B** Softened and improved appearance after the transplantation of 1000 follicular unit grafts containing one to three hairs.

grafts, laser-assisted removal eliminates the majority, but not all, of the hairs, thus providing a substantial cosmetic improvement of the unnatural plugs while retaining some of the transplanted hair for a more natural appearance. Laser therapy is an excellent option for patients who want to improve their cosmetic appearance in a safe, non-invasive manner.

Hypertrophic or broad scars in the donor region

All patients have a permanent scar from elliptical donor harvesting, but the majority of scars are 1–2 mm wide and are of no practical concern (see Fig. 157.8). That said, patients should be made aware of this permanent donor scar *before* they have a transplant. If the patient expresses a possible interest in having their hair cut short, FUE should be considered (see above).

When wide donor scars occur, they can be a major cosmetic problem without an easy solution for repair. Scar revision leads to variable improvement. Pulsed dye, non-ablative, or fractional ablative lasers may be used to help reduce the thickness and erythema of hypertrophic scars. The best method for minimizing the risk of a wide scar is to keep the width of the donor strip to ≤1 cm. While this does not guarantee a fine, thin scar, it does reduce the risk of a wide scar. Another option is to transplant a large number of follicular groupings into the scar in an attempt to provide camouflage.

Hair Transplantation in Scarring Alopecias

Hair transplantation can be successfully performed to improve the appearance of scarring due to previous cosmetic or cranial procedures. However, if there is any concern regarding active inflammation, a biopsy specimen should be obtained. Any inflammation, whether from a primary scalp dermatosis, infection or previous surgery, must be resolved completely before hair is transplanted. In the case of inflammatory scalp dermatoses, patients should have no evidence of inflammation for at least 6 months off therapy before the transplant procedure is performed.

Patients undergoing surgery for cicatricial alopecias such as LPP, FFA, or CCCA must understand that even if their disease is quiet at the time of surgery, any subsequent flares may compromise the future growth of the grafts. In other words, when there is any active inflammation, the transplanted hair may not grow and all patients should be informed of this *before* their first transplant. Of note, in a retrospective review of 51 patients who received hair transplants for FFA, most of them lost grafts over the following 5 years but there was still very high patient satisfaction[66].

Compared to sites without scarring, the yield is less when hair is transplanted into scar tissue. How large the difference will be varies from patient to patient. In general, more transplant sessions are needed in patients with scarring alopecia.

Hair Transplantation in African-Americans

In addition to pattern hair loss in men and women of African ancestry, traction alopecia and CCCA are also commonly seen in women (see Ch. 69)[67]. If there is a question regarding the precise diagnosis, clinicopathologic correlation is recommended prior to transplantation. For CCCA, there should be no evidence of inflammation for 6 months (off therapy) before the transplant procedure is performed. While patients can wear wigs or hair pieces, hair transplantation is the only way to permanently fill in the areas of alopecia (Fig. 157.17A).

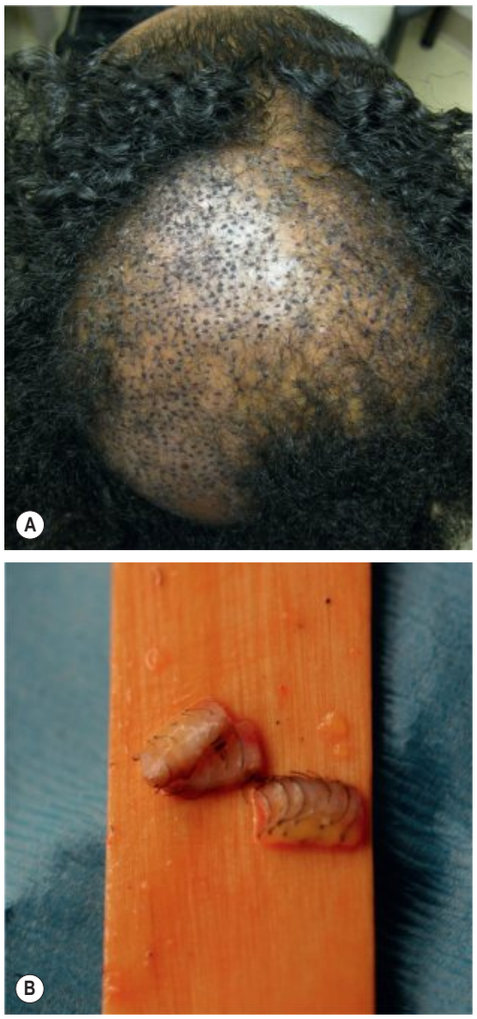

Fig. 157.17 Hair transplantation for central centrifugal cicatricial alopecia. **A** Appearance 1 week following transplantation of 1200 follicular unit grafts in an African-American woman. **B** Cross-section of Afro hair follicles demonstrating their characteristic C-shaped curve.

When transplanting Afrocentric type 4 hair, it is important to note that the curl of the follicles and the C-shaped curve of the hairs make separation of the follicles slightly more difficult (Fig. 157.17B). Rather than using a straight blade, the blade must be bent in order to not transect the hair follicles. Also, the grafts may be slightly larger, requiring a larger bore needle (e.g. 16 gauge) to create recipient sites. Lastly, there is an increased risk of keloid or hypertrophic scar formation in patients with darker skin phototypes, more often in the donor region than in the recipient sites. Injecting triamcinolone acetonide suspension prior to donor site closure may help lessen the risk of such scar formation.

FUTURE TRENDS

Regeneration and cloning of hair follicles represents the next step in revolutionizing hair transplantation. With an unlimited supply of hairs, there will no longer be constraints based upon the density of hairs in the donor region. Keratinocyte tubulogenesis has been induced by cultured dermal papilla cells[68]; bone marrow- and umbilical cord-derived mesenchymal stem cells were shown to be a reservoir for follicle regeneration[69]; and epidermal wounding, with upregulation of Wnt proteins, led to hair follicle regeneration in adult mouse skin[70]. In addition, erythropoietin has been found to promote the growth of dermal papilla cells as well as to prolong the anagen phase of cultured human hair follicles[71]. Lastly, ongoing research utilizing a mouse model for AGA should provide insights into mechanisms of disease and therapies[72].

Acknowledgment

The authors wish to thank Dowling B. Stough, MD, for his contribution to this chapter in the previous editions.

Injectable Soft Tissue Augmentation 158

Amelia K. Hausauer and Derek H. Jones

Chapter Contents

Historical Perspective 2692
General Injection Protocols 2692
Injectable Soft Tissue Filler Materials 2694
Platelet-Rich Plasma 2699
Complications 2699

Key features

- Fillers are used to soften the appearance of superficial wrinkles and to recontour and smooth the deep folds of the face
- Other indications include reducing the appearance of atrophic, traumatic, and acne scars; lip augmentation; and volumizing the face in areas of lipoatrophy or senescence-associated fat loss
- Agents include hyaluronic acid derivatives, synthetic materials, autologous fat, and platelet-rich plasma
- Selection of an agent depends on the size, depth, and location of the volume deficiency as well as the cost and longevity of the product
- Agents are injected into the dermis, subcutaneous fat, or supra-periosteal space via a needle or cannula; various techniques, such as serial puncture, linear threading, fanning, cross-hatching or depot injection, are utilized and require an understanding of anatomy and best injection practices
- Fillers can be used as monotherapy or as an adjunct to other rejuvenating injectable techniques or surgical procedures in order to maximize longevity and aesthetic correction
- Complications are technique-dependent or material-related, and include hypersensitivity reactions, granuloma formation, bacterial biofilms, contour irregularities, and vascular occlusion, in addition to common injection-related phenomena such as pain, edema, and purpura

CAUSES OF CUTANEOUS DEFECTS AND CONTOUR CHANGES AMENABLE TO FILLERS FOR CORRECTION
Chronologic aging
• Loss of subcutaneous fat • Gravity • Bone resorption (e.g. mandible, maxilla, zygoma)
Photodamage
• Degradation of collagen, elastin, hyaluronic acid, and other components of the extracellular matrix leading to decreased skin turgor and rhytides
Other
• Exercise-induced lipoatrophy • Scarring (e.g. due to acne, varicella, trauma, surgery) • Inflammation (e.g. lipoatrophy due to lupus panniculitis or other panniculitides; see Ch. 100) • Lipodystrophy (inherited, acquired, drug-induced; see Ch. 101)

Table 158.1 Causes of cutaneous defects and contour changes amenable to fillers for correction.

SOFT TISSUE AUGMENTATION INDICATIONS
FDA-approved (see Table 158.4 for indications for specific products)
• Moderate to severe facial wrinkles and folds, such as nasolabial folds • Submucosal implantation for lip augmentation and perioral rhytides • Deep injection for cheek augmentation to restore age-related volume loss in the midface • Volumization of the dorsal hands • Chin augmentation to improve prominence and profile • HIV-associated lipoatrophy • Acne scars
Off-label
• Non-dynamic rhytides and folds – nasojugal folds, marionette lines, glabellar folds, etched-in radial cheeks lines, horizontal neck rhytides • Volume deficits – lipoatrophy (including buttocks and body deficits), sunken temples, tear trough deformity, atrophic earlobes • Structural prominences – jawline, nasal bridge, lateral eyebrow elevation • Distensible scars – trauma, surgery • Skin laxity • Nipple contouring

Table 158.2 Soft tissue augmentation indications. FDA, US Food and Drug Administration.

Interventions for the aging face can be broadly categorized into the four "R's" of facial rejuvenation: **R**esurfacing (chemical peels, dermabrasion, and ablative and non-ablative lasers); **R**edraping (the various pulling and lifting facial surgical procedures); **R**elaxing (chemodenervation with paralytic agents); and **R**eplacement/**R**econtouring (the use of filling agents for superficial and deep soft tissue augmentation). This fourth "R" has witnessed remarkable growth as patient demand for safe and effective minimally invasive aesthetic techniques has increased. In concert, the number of available dermal fillers and agents for soft tissue augmentation has expanded exponentially. More recently, there has been a shift from filling wrinkles and lines to replacing volume loss associated with atrophied fat and bone[1].

Patients often do not adequately appreciate the degree and significance of their volume deficit and must first be educated about the underlying anatomy of what is producing their "wrinkle". In addition to explaining the significance of volume deficits adjacent to the areas of primary concern, a distinction must be made between dynamic versus static lines as well as cutaneous changes due to photodamage versus those due to chronologic aging (senescence) (Table 158.1). Although these defects often appear in combination, they must be assessed individually. Patients should be made aware of newer, commercially available injectable products so that the physician is able to personalize their treatment and cater to subtle nuances of their faces. Many of the newer products have unique characteristics and indications that make them more suitable for certain patients (Table 158.2).

While the type of defect is clearly important, so are its size, depth, and location, in addition to the appearance and integrity of the adjacent tissue. A discussion regarding therapeutic options should include alternatives such as surgery (e.g. rhytidectomy, excision), resurfacing (see Ch. 137), and chemodenervation agents (see Ch. 159), as well as no intervention at all. Patients should understand the indications, technique, advantages, disadvantages, and inherent risks of each procedure, and they should be given an estimate of the financial cost and "downtime". As with any treatment, the degree of overall success is largely proportional to the creation (and achievement) of realistic and appropriate goals and expectations. Patients undergoing elective rhytide effacement and optimization with injectable fillers must realize that replacing lost or atrophic subcutaneous tissue is often temporary. Monotherapy with

one agent may not be adequate, and multiple agents may be required. All wrinkles are not created equal; they come in many shapes and sizes, and there is no one filler agent that is suitable for all defects. The choice of an appropriate dermal or subcutaneous implant requires knowledge of the available options and their characteristics.

HISTORICAL PERSPECTIVE

Dating back to 1893, Neuber used blocks of autologous fat harvested from the arms for tissue augmentation of depressed facial defects. Eighteen years later, Brunings first described using the syringe technique to transfer free fat. Then, in 1953, Baronders published a review of permanent soft tissue augmentation with liquid silicone. Finally, in 1981, bovine collagen became the first US Food and Drug Administration (FDA)-approved xenogeneic agent for soft tissue augmentation, and it remained the standard filler for over 20 years (Table 158.3).

In 1981, Zyderm® I was the first bovine collagen filler, followed by Zyderm® II and Zyplast®. As a group, they have a long safety track record having been used in more than a million patients[2]. All three were derived from a closed US cattle herd carefully monitored to prevent transmission of bovine spongiform encephalitis, a prion-mediated disease. Cutaneous hypersensitivity reactions occurred in 3% of patients; therefore, pre-treatment skin testing became mandatory[3]. The longevity of these bovine collagen fillers was ~2–3 months. Bovine collagen is historically important as it set the standard against which the next generation of soft tissue fillers was initially compared.

In an attempt to reduce the risk of hypersensitivity reactions, a series of dermal fillers were developed that did not require skin testing, some of which were longer lasting – CosmoDerm®/CosmoPlast® (bioengineered human collagen); Evolence® (porcine type I collagen, potentially lasting up to one year)[4]; and a family of injectables from preserved particulate cadaveric connective tissue (Dermalogen®, Cymetra®, and Fascian®). With the exception of Renuva®, an allograft adipose matrix, most are no longer commercially available due to high manufacturing costs and low demand.

In 2003, the FDA approved Restylane®, which ushered in a new era of agents made from hyaluronic acid (HA). Many of the HA formulations proved to be superior in longevity compared to their collagen predecessors and had more feasible manufacturing. Globally, HA quickly became the most popular soft tissue filler. Currently available FDA-approved formulations of HA are outlined in Table 158.4. Historic HA formulations that are no longer available in the US are listed in Table 158.3.

TEMPORARY SOFT TISSUE FILLERS THAT ARE NO LONGER AVAILABLE IN THE US
Bovine-derived collagen
• Zyderm® I, Zyderm® II, Zyplast®
Porcine-derived collagen
• Evolence®
Non-cadaveric human collagen
• CosmoDerm® 1, CosmoDerm® 2, CosmoPlast®
Autologous human collagen
• Autologen®
Cadaveric human collagen
• Dermalogen®, Cymetra®
Cadaveric fascia lata
• Fascian®
Cadaveric adipose matrix
• Renuva®
Porcine-derived gelatin
• Fibrel®
Avian-derived hyaluronic acid
• Hylaform®, Hylaform Plus®
Non-animal stabilized hyaluronic acid
• Captique®, Elevess®, Prevelle Silk®
Autologous fibroblast therapy
• Isolagen®

Table 158.3 Temporary soft tissue fillers that are no longer available in the US. This is due to discontinuation by the manufacturer or decreased demand because of popularity of other products.

GENERAL INJECTION PROTOCOLS

Prior to performing any filler procedure, injectors must have a firm grasp of vascular anatomy to ensure safety and help guide optimal injection techniques and product selection. This forms the foundation of all treatments; its importance cannot be overemphasized, since accidental injection into facial arteries can have catastrophic consequences, as outlined by the American Society for Dermatologic Surgery (ASDS) Task Force on evidence-based guidelines for prevention and treatment of adverse events from injectable fillers[5]. While intravascular injection is possible at any location on the face (e.g. lips' labial arteries), the nose, glabella, forehead, superior nasolabial fold, and medial cheek are considered significant danger zones, from highest to lowest, for vascular complications, visual compromise, and cerebrovascular events[6,7].

Studying anatomy and appreciating its variability are the underpinnings of all injection techniques, which vary by location, and represent a life-long learning endeavor. The facial artery is a branch of the external carotid artery that crosses the jawline periosteally at the antegonial notch just anterior to the border of the masseter muscle (see Fig. 142.3). It takes a circuitous course deeply from the lower lateral cheek to the nasolabial fold, branching off as the inferior and superior labial arteries, then becoming the angular artery near the superior nasolabial fold (see Fig. 142.15). More superficially, the angular artery runs along the medial cheek/lateral nose in variable patterns[8]. It anastomoses with four arteries: (1) dorsal nasal artery; (2) distal ophthalmic artery, which connects to the retinal and cerebral vasculature; (3) supratrochlear artery; and (4) supraorbital artery; the two latter arteries are end branches of the distal ophthalmic artery. The supratrochlear and supraorbital arteries traverse the supraorbital ridge periosteally at the glabella and medial brow, respectively, then run superiorly toward the scalp. These pathways explain the danger zones referenced above[5].

There is no one completely safe injection protocol only safer strategies based upon location, which are briefly outlined here.

Nose, Glabella, and Forehead

These three regions present the highest risk. Therefore, to minimize the potential for disastrous outcomes, only the most experienced injectors should approach treatment in these areas. Although rare, the chance of blindness is greatest with nasal injections into the dorsal nasal artery. Based on cadaveric studies, the safest plane on the dorsal nose appears to be pre-periosteal or pre-perichondrial[9]. Yet, due to vascular variability, the dorsal nasal artery may lie on the midline periosteum[10].

The glabella also carries higher risk because of the periosteal exit of the supratrochlear and supraorbital arteries. Injecting deeply within this region is contraindicated. Experts may consider correcting glabellar rhytides that do not respond to neuromodulators with intradermal injections using small needles. However, the vessels are variable, potentially running more superficially, especially in those with thin tissue[11,12]. These arteries course cephalad to caudal and surface superficially within the frontalis muscle superior to the brow. Consequently, forehead correction is safest with cannulas placed in the pre-periosteal, subgaleal plane at least 2 cm superior to the orbital rim and in a horizontal direction, perpendicular to the vasculature.

Nasolabial Fold, Cheek

Two additional danger zones are: (1) the superior nasolabial fold where the angular artery becomes subcutaneous; and (2) the cheek medial to the midpupillary line (medial cheek), where the infraorbital artery runs periosteally and the angular artery subcutaneously. Both needles and cannulas are FDA-approved for injection in these regions, but given the different vascular depths and pathways, a cannula with a minimum size of 25-gauge (G) may be safer (see below)[13–16]. In contrast, the lateral cheek along the zygomatic prominence is considered less risky, although the zygomaticofacial artery does sit on the periosteum. Injection along the periosteum with a needle or cannula is appropriate[5].

FDA-APPROVED INDICATIONS FOR SOFT TISSUE FILLERS CURRENTLY EMPLOYED IN THE US	
Trade name (®,™)	**FDA-approved indication**
Hyaluronic acid	
Restylane, Restylane-L*	• moderate to severe facial wrinkles and folds • lip augmentation
Restylane Refyne* Restylane Defyne*	• moderate to severe facial wrinkles and folds • augmentation of the chin region (Defyne only)
Restylane Silk* Restylane Kysse*	• lip augmentation • correction of perioral rhytides
Restylane Lyft* (formerly Perlane-L)	• moderate to severe facial folds and wrinkles • age-related volume loss and augmentation of the midface • volumization of the dorsal hands
Restylane Contour*	• cheek augmentation
Juvéderm Ultra, Juvéderm Ultra XC*	• moderate to severe facial wrinkles and folds • lip and perioral augmentation
Juvéderm Ultra Plus, Juvéderm Ultra Plus XC*	• moderate to severe facial wrinkles and folds
Juvéderm Voluma XC*	• age-related volume loss in the midface • augmentation of chin region
Juvéderm Vobella XC*	• lip augmentation • correction of perioral rhytides
Juvéderm Vollure XC*	• moderate to severe facial wrinkles and folds
Juvéderm Volux XC*	• improving jawline definition
Belotero Balance, Belotero Balance + *	• moderate to severe facial wrinkles and folds
Resilient HA (RHA) 2, 3, 4*	• moderate to severe dynamic facial wrinkles and folds
RHA Redensity*	• moderate to severe dynamic perioral wrinkles
Synthetic†	
Polymethylmethacrylate microspheres plus bovine collagen (Bellafill)*	• correction of nasolabial folds • acne scars
Poly-L-lactic acid‡ (Sculptra and Sculptra Aesthetic)	• HIV-associated lipoatrophy • shallow-to-deep smile lines (nasolabial folds), contour deficiencies, and other facial wrinkles
Calcium hydroxylapatite‡ (Radiesse)	• HIV-associated lipoatrophy • moderate to severe facial wrinkles and folds • volumization of the dorsal hands
Calcium hydroxylapatite plus lidocaine (Radiesse +)*	• moderate to severe facial wrinkles and folds
Silicone	• none¶
Autologous	
Autologous fat	• not regulated as long as not modified in any way
Azficel-T (LAVIV)	• moderate to severe nasolabial fold wrinkles in adults

*Contains 0.3% lidocaine.
†Bellafill® contains bovine collagen.
‡Plus carboxymethyl-cellulose.
¶Silikon 1000 is FDA-approved for intraocular use.

Table 158.4 FDA-approved indications for soft tissue fillers currently employed in the US. In general, soft tissue fillers are approved for use in adults and not in the pediatric population. FDA, US Food and Drug Administration. For updates, see www.fda.gov.

SOFT TISSUE AUGMENTATION: PREINJECTION CONSIDERATIONS
Medical background

• Medications (anticoagulants, antiplatelet agents)
• Medical history
  • Autoimmune connective tissue disease, e.g. systemic sclerosis
  • Granulomatous disorders, e.g. sarcoidosis
  • Scarring conditions (e.g. keloids) or tendency to form hypertrophic scars
  • Previous facial herpes simplex viral infection
  • Previous hypersensitivity reactions/allergies
• Pregnancy and lactation
• Surgical history, including cosmetic procedures
  • Rhytidectomy, blepharoplasty
  • Reconstructive surgery
  • Facial implants
  • Previous injections of soft tissue fillers and neurotoxins

Defect parameters
• Location • Volume required • Alternative and simultaneous treatments
Patient goals

• Defect of concern
• Expectations regarding
  • Degree of correction
  • Product longevity
• Recuperation time (“downtime”)
• Risk/benefit ratio

Table 158.5 Soft tissue augmentation: preinjection considerations.

Temple

Periosteal depots, deep to the superficial temporal vessels, are used to correct an atrophic temple. The needle is injected inside the “safe zone” whose border is 1 cm superior to the superior orbital rim, 1 cm lateral to the temporal fusion line, and 2.5 cm superior to the zygomatic arch where the middle temporal vein lies[17,18].

Lips

Injections should be superficial, as the labial arteries usually course more deeply between the mucosa and orbicularis oris at the wet–dry border[19].

Chin, Jawline

Because the facial artery crosses the mandible just anterior to the border of the masseter muscle, injections along the rami in this region must sit above the bone. Periosteal injection at the gonial angle appears to be safer when sharpening the contour and widening the jaw or the midline mandible to create anterior or inferior chin projection[20].

Consultation and Evaluation

With a firm knowledge of anatomy, injectors can then approach patient consultation and evaluation. Baseline asymmetry, subjective defects, and realistic expectations should be discussed with the patient (Table 158.5). To fully appreciate the depth and scope of the defect, patients should be placed in a gravity-dependent or seated position with adequate lighting. The latter should be at an acute angle in order to accentuate surface irregularities and deficits. A careful patient selection process will assist in determining ideal candidates for soft tissue augmentation. Contraindications include prior allergy to the filler material or its constituents (e.g. lidocaine). Pre-existing conditions in the planned treatment area such as dermatitis, acne, or infection may require postponement of the procedure. The expected level of improvement and longevity are also key discussion points.

Prior to the procedure, patients should be instructed to abstain from all *nonessential* medications that can inhibit coagulation and platelet aggregation. For example, aspirin is avoided for 10–14 days and NSAIDs for 5–7 days in order to decrease the risk of bleeding and bruising. In addition, omega-3 fatty acids, fish oil, and a number of over-the-counter supplements should be discontinued (see Table 133.3). Prior to the procedure, written consent is obtained and both make-up and cutaneous debris are removed[21]. Pre- and post-treatment photographs are strongly recommended.

Preparation

Clean technique is critical in preventing contamination during the initial handling, mixing, and injecting of the filler. The skin is cleansed with alcohol, chlorhexidine (avoiding the ear canal and eye), hypochlorous acid or other antimicrobial agent, and gloves are changed after intraoral manipulation. Percutaneous injections of fillers can be painful, necessitating the consideration of adding anesthesia to the treatment protocol. Although the physician can combine fillers with an anesthetic, most commercial products are now premixed with lidocaine (see Table 158.4). Some injectable products may require nerve blocks and/or regional anesthesia (see Ch. 143). More commonly, however, ice or topical anesthetic preparations are sufficient.

Injection Techniques

Proper placement of the filler material is crucial. Common injection techniques include serial puncture, linear threading, fanning, cross-hatching, and depot injection[22]. In the *serial puncture technique*, small amounts of filler are sequentially deposited along the wrinkle or fold. The injections are placed close to one another so that the filler can blend in a continuous fashion; post-injection massage can also help to blend the filler so that it is evenly distributed. Using the *linear threading technique*, the full length of the needle/cannula is inserted into the proper dermal or subcutaneous plane, and the filler is injected in a retrograde manner as the needle is withdrawn. Conversely, the material can be injected as the needle is advanced (anterograde), creating blunt dissection within the tissue space. The *fanning technique* involves multiple passes in different, but evenly spaced, directions without withdrawing the needle/cannula from its original site of insertion. The *cross-hatching* or *radial injection technique* involves evenly spaced, linear injections in a grid-like pattern; this technique is used for filling large areas and for the oral commissures[23]. Finally, *depot injections* are useful when placing volumizing fillers within the subcutaneous fat or along the periosteum. Occasionally, small depot aliquots are also placed along the infraorbital ridge, with a movement toward using cannulas in this region. Massage immediately after depot placement of filler helps to blend the product into the natural contour of the region.

Additional important recommendations[5]:

- *Inject small volumes slowly, under low pressure*. When there is arterial cannulation or compression from deposition adjacent to arteries, large volume, high pressure boluses may be more detrimental.
- *Retract the syringe plunger (reflux test) prior to injection*. If positive for blood, then intravascular placement is possible. Stop straight away and reposition. However, a negative reflux test does not exclude possible intravascular injection[15,24].
- *Continually move the needle or cannula tip to minimize the risk of prolonged intravascular injection of a larger bolus*.

Needles and Cannulas

Evolving consensus supports the use of blunt-tipped cannulas, especially those with a larger bore (e.g. 25 G)[25], to reduce the risk of vascular injury. Cadaveric and reflux studies suggest that larger diameter cannulas are less likely to perforate vasculature, when compared to smaller diameter cannulas (e.g. 27 G) or needles[14–16]. This is of particular importance in areas (e.g. cheeks, lips) where both needles and cannulas are FDA-approved. Blunt-tipped cannulas are best suited for injecting in the subdermal plane and are not appropriate for intradermal injections. One of the authors (DJ) demonstrates high-risk anatomy and the use of cannulas in Video 158.1.

INJECTABLE SOFT TISSUE FILLER MATERIALS

There is an ever-expanding array of fillers for soft tissue augmentation (see Table 158.4). Table 158.6 lists the characteristics of the ideal filler. While soft tissue fillers can be subdivided based upon derivation, depth of placement or duration of effect, most physicians develop preferences based upon location of desired augmentation.

Hyaluronic Acid Derivatives

Hyaluronic acid derivatives are currently the most commonly employed soft tissue fillers (Table 158.7). The term *hyaluronic acid* is derived from the Greek word for glass, *hyalos*, and is so named because of its clear appearance. Hyaluronic acid (HA) is a key glycosaminoglycan (GAG; previously referred to as mucopolysaccharides) within the extrafibrillar matrix of the dermis (see Ch. 95). It is a ubiquitous component of connective tissue and is conserved amongst mammals, making it species-nonspecific. Within connective tissue, HA forms a gelatinous matrix that surrounds collagen and elastic fibers and creates volume via its water-binding capability. HA also plays a role in cellular migration and therefore it is important in the development and remodeling of tissues. A direct correlation exists between the amount of HA in the dermis and its water content as well as between HA content and the viscoelastic properties of the extracellular matrix. The concentration of naturally occurring HA within the skin decreases with age, resulting in a decreased ability to retain water, rendering the dermis less voluminous and increasing its propensity to wrinkle.

The HA molecule consists of a polysaccharide chain comprised of numerous repeating disaccharides of N-acetylglucosamine and D-glucuronic acid. The longer the chain, the higher the molecular weight. All currently available, FDA-approved HA fillers are derived from bacterial (*Streptococcus*) fermentation. "Raw" or non-crosslinked HA is supplied as a powder, forming a viscous liquid when exposed to water. If injected in this unmodified state, exogenous HA imparts a duration of correction of only 12 to 24 hours. In order to increase tissue residence time, HA molecules must be stabilized via chemical crosslinking of the polysaccharide chains; this modification slows enzymatic breakdown and provides an acceptable duration of correction. Most commercially available, FDA-approved HAs are crosslinked by BDDE (1,4-*b*uane*d*iol *d*iglycidyl *e*ther), with each filler differing in its manufacturing process.

Following the initial crosslinking, HA exists as a gel similar in consistency to Jell-O®. Subsequent post-crosslinking modifications, which vary depending upon the specific product, impart different attributes. For example, with the Restylane® family, the gelatin is passed through a sieve that creates microscopic particles of identical shape and size. Restylane® (approved in 2003) is then suspended in phosphate-buffered saline at a concentration of 20 mg/ml with 100 000 gel particles/ml. By comparison, Restylane® Lyft (formerly Perlane-L®) has a larger mean gel particle size with 10 000 particles/ml. Refyne, Defyne, Contour, and Kysse are more recent additions to the Restylane® family (see Table 158.4).

The Juvéderm® family relies on a proprietary technology that creates particles of random shapes and sizes. Juvéderm® products (first approved in 2006) have an HA concentration of 24 mg/ml, with Juvéderm® Ultra Plus being more heavily crosslinked than Juvéderm® Ultra (Fig. 158.1). Belotero Balance® is a monophasic, non-particulate gel crosslinked in two consecutive reactions, resulting in a cohesive HA

PARTIAL LIST OF THE CHARACTERISTICS OF THE IDEAL FILLER SUBSTANCE	
• FDA-approved • Non-allergenic (minimal risk of hypersensitivity, no pretesting required) • Non-carcinogenic and non-teratogenic • User-friendly product (e.g. easy flow, ergonomic syringe) • Versatile syringe volumes (e.g. touch-up syringes) • Easy storage (no need for refrigeration) • Long shelf-life	• Affordable • Long-lasting • Predictable level of correction • Painless • Minimal recuperation • Minimal adverse sequelae (e.g. infection, ecchymosis) • No migration • No overt cutaneous change (undetectable) • Correctable post-injection (e.g. with hyaluronidase)

Table 158.6 Partial list of the characteristics of the ideal filler substance. FDA, US Food and Drug Administration.

BENEFITS OF HYALURONIC ACID DERIVATIVES
• Identical in all species and all tissue types • Minimal risk of hypersensitivity reaction (no skin test required) • Room temperature storage • Biodegradable • Long-lasting and stable • High degree of safety (biocompatible, resorbable, reversible)

Table 158.7 Benefits of hyaluronic acid derivatives.

Fig. 158.1 Hyaluronic acid – volumization in a patient with lean body mass. A Pre-treatment. **B** One week following injection of large volumes of Juvéderm® Ultra Plus to the cheeks and Juvéderm® Ultra to the brow area, nasolabial folds, and oral commissures.

gel with varying zones of crosslinking density. The HA concentration in Belotero Balance® (approved in 2011) is 22.5 mg/ml.

The pivotal, phase III trials leading to FDA approval of Restylane®, Juvéderm®, and Belotero Balance® were six-month, randomized, blinded, multicenter, split-face, controlled trials (RCTs) that compared Zyplast® collagen to the respective HA for the treatment of moderate to severe nasolabial folds[26–28]. At six months, all three HA fillers demonstrated superiority over Zyplast® collagen, with inter-study design and results having more similarities than differences (Fig. 158.2A). The HA products have been shown to be safe in all skin types. Further studies, focusing on repeat treatment after six months, suggest that less volume is required to regain optimal correction[28–30]. Often, an extended duration of 1–2 years or more was observed (Fig. 158.2B).

For the treatment of moderate to severe wrinkles and folds, HA products are usually injected into the immediate subdermal plane or superficial subcutis. If injected too superficially into the dermis, contour irregularity as well as a bluish discoloration due to the Tyndall effect may occur. The latter results from the optical scatter of different wavelengths of light encountering a clear substance. Recent studies suggest that Belotero Balance®, if injected more superficially (intradermally), integrates more smoothly into the dermis as compared to the Restylane® and Juvéderm® families. The former is also less likely to create a Tyndall effect[31]. This makes Belotero Balance® particularly well suited for treatment of superficial, etched-in lines such as vertical lip lines (Fig. 158.3 & 158.4)[32]. Both Restylane® and Juvéderm® Ultra are FDA-approved for lip augmentation (Fig. 158.5), although Belotero Balance® is often used off-label for this indication[33].

In 2013, Juvéderm Voluma® XC ("Voluma") was the first HA filler to be FDA-approved for deep injection for cheek augmentation as a means of restoring age-related volume loss in the mid face (Video 158.2). This filler consists of a 20 mg/ml mixture of low- and high-molecular-weight HA. Voluma® differs from other HA fillers in that the lower-molecular-weight component, composed of shorter polysaccharide chains, allows for more efficient crosslinking (Vycross® technology). This, in turn, produces a highly cohesive gel with greater lift capability. Results from the pivotal phase III multicenter, single-blinded RCT showed significant improvement in moderate to severe, age-related midfacial volume loss at six months (compared to the no-treatment control group; Fig. 158.6). Data suggest that nearly half of the patients maintained correction up to 24 months, emphasizing its long-term effectiveness.

Reported adverse events with Voluma® were similar to other HA fillers and included swelling, tenderness and purpura, which resolved within a week in the majority of individuals[34]. Recent data have

pointed to an increased incidence of delayed adverse events (e.g. edema, nodules) in up to 1% of treated individuals. They occur months after injection, possibly due to the degradation process triggering an inflammatory response, either spontaneously or after an immunologic trigger[35]. Juvéderm Voluma® XC is intended for injection into deeper subcutaneous and periosteal planes and should not be injected intradermally; nor should it be injected into the lip or glabellar areas.

In 2016 and 2017, two additional fillers based upon Vycross® technology received FDA approval. Vobella XC® is indicated for lip augmentation and correction of perioral rhytides in adults over the age of 21 years, whereas Vollure XC® corrects moderate to severe wrinkles and folds such as the nasolabial fold (see Table 158.4). Unlike previously FDA-approved products with these indications, Vollure® is the first HA filler reported to last up to 18 months within the nasolabial folds in the pivotal trials.

The most recently introduced family of products in the US (approved in 2017 but distributed in 2020) is Resilient HA (RHA®). They contain 23 mg/ml and are produced with similar, but fewer modifications than other HA families. Double-blind RCTs of RHA® 2–4 had a primary six-month endpoint and were compared to control HA filler or no

treatment of nasolabial folds; based upon follow-up through 64 weeks, there was non-inferiority[36,37].

A unique feature of HA is its reversibility, and complications from HA fillers can often be easily corrected. Injections of hyaluronidase (Vitrase®, Hylenex®) can dissolve previously injected HA; this is very helpful if the filler has been misplaced, there is a complication post-injection (e.g. vascular occlusion, delayed granulomatous reaction), or there is impending vascular necrosis. An *in vitro*, dose-response study suggested that Juvéderm® was more resistant to hyaluronidase when compared to Restylane®. In the authors' experience, 10 units (U) of hyaluronidase (Vitrase®) per 0.1 cc of Juvéderm or 5 U per 0.1 cc of Restylane® may be the most appropriate dose to dissolve the HA[38]. Up to 30–40 U of Vitrase® may be required per 0.1 cc of Voluma®[39]. The need for the greater amount of hyaluronidase for correction of these products likely reflects their more highly crosslinked nature.

All currently FDA-approved HA families have a product that is pre-packaged admixed with lidocaine, which significantly reduces pain on injection (see Table 158.4).

Poly-L-Lactic Acid

Polymerized poly-L-lactic acid (PLLA; Sculptra®) augments soft tissue by stimulating the production of collagen. In 2004, it was FDA-approved for the correction of HIV-associated facial lipoatrophy. Five years later, the FDA approved Sculptra® Aesthetic for the correction of shallow-to-deep nasolabial fold contour deficiencies and other facial wrinkles. It is often injected off-label for panfacial rejuvenation in immunocompetent individuals with limited lipoatrophy, improvement of nonfacial skin laxity[40], and nonsurgical gluteal augmentation[41]. However, effects are often subtle with many treatments required for optimal results.

Sculptra® is powdered lyophilized suture material (Vicryl® [polyglactin 910]); the freeze-dried preparations of PLLA can be stored at room temperature. Based upon early study designs, the current aesthetic label recommends that each vial be reconstituted two hours prior to deep dermal injection with a total of 5 ml of liquid: 4 ml of sterile water and 1 ml of lidocaine. This results in a thick suspension of 4.45% PLLA. Refinements in protocol have led to the common off-label practice of a >24-hour hydration time with higher dilutions, e.g. addition of up to 9–11 ml of liquid (or higher for the body), to generate a more uniform suspension and reduce the risk of papule formation[42].

Immediately prior to injection, the mixture is vigorously agitated. A 25–26 G needle is used to place the filler in the subcutaneous plane and care is taken to avoid overcorrection. Intradermal injection can result in visible papules. Frequent needle changes may be necessary, as the material has a tendency to form clumps and clog the bore. There may be the appearance of some immediate augmentation from saline in the reconstituted solution and some edema. However, to achieve optimal correction and prolonged neocollagenesis, the recommended protocol is a series of three or more sessions at 3- to 6-week intervals. Persistence of augmentation varies, but some improvement can be seen for up to 1.5 to 2 years.

Palpable, but not visible, papulonodules develop in some patients, and a granulomatous reaction at sites of injection can also arise. All of these complications tend to persist for months to years before resolving. To try to minimize papule formation, the following can be done: use greater dilution volumes, increase the time interval between reconstitution and injection, avoid intradermal injection, inject smaller aliquots per site, and vigorously massage the injected areas to eliminate any lumpiness. In addition to massaging during and post-treatment, it is often recommended that the patient follow the "rule of 5 s": massage for 5 minutes 5 times daily for 5 days. That said, a small study found that this advice had no significant impact on nodule formation or treatment outcomes[43].

Calcium Hydroxylapatite

In 2006, Radiesse® was FDA approved for the correction of moderate to severe facial folds and wrinkles (e.g. nasolabial folds) and for the correction of signs of HIV-associated lipoatrophy. Correction of volume loss of the dorsal hands was a later indication, receiving FDA approval in 2015[44]. It is safe in all skin types (Fig. 158.7)[42,45,46]. Radiesse® is a milky white suspension comprised of two components: (1) an aqueous gel carrier containing glycerin, sodium carboxymethylcellulose, and water; and (2) 25–45 micron microsphere particles of calcium hydroxylapatite (CaH). CaH is a non-allergenic (inert) bioceramic that is identical to the primary mineral constituents found in bone and teeth. This biocompatible product contains no human, bacterial, or animal products and poses minimal risk for hypersensitivity reactions. Utilization of the product was initially limited due to the significant discomfort and throbbing after injection, so the FDA approved the practice of pre-mixing Radiesse® with 2% lidocaine immediately prior to injection. Subsequently, a lidocaine-containing version, Radiesse® (+), became available. The material is deposited deeply at the dermal–subcutaneous junction. Injection provides immediate results, and no overcorrection or undercorrection is required[1].

As the gel carrier correction gradually resolves, it is replaced by new collagen formation stimulated by the scaffold of calcium hydroxylapatite particles. While histologic studies have demonstrated the presence of CaH and neocollagenesis for up to 78 weeks, the duration of clinical correction has not been well documented beyond 12 months[1]. Lip augmentation is contraindicated, as mucosal granulomas may form and the constant motion of the lip and compression from contraction of the orbicularis oris may cause migration and clumping of the filler (Fig. 158.8)[47]. Off-label uses of this product include revolumizing the face of immunocompetent individuals[1,47] as well as improving skin laxity via biostimulation with dilute and hyperdilute mixtures injected over repeated sessions[48].

Since Radiesse® is radio-opaque, the patient should be informed that it may be visible on radiographs as well as CT scans. However, there is no evidence that calcium hydroxylapatite particles obscure underlying structures or mask abnormal pathology[49].

Lipotransfer

Historically, autologous fat has always been considered one of the safest fillers, with estimates of success as high as 70%, but two concerns have remained. The original *en bloc* technique required excision of the donor tissue and a resultant second defect; essentially, patients traded one

Fig. 158.7 Treatment of age-related facial lipoatrophy with Radiesse®.
A Pre-treatment. **B** Post-treatment (2 weeks).

Fig. 158.8 Formation of papules and nodules due to placement of Radiesse® into the lip. A, B The size can vary from a few millimeters to over a centimeter. *A, Courtesy Seth L. Matarasso, MD.*

Fig. 158.9 Lipotransfer and subcision to correct scarring due to previous surgical excision of a cyst. A Pre-treatment. **B** Post-treatment.

defect for another. Furthermore, the non-particulate solid nature of the tissue required implantation, with the potential for incisional scars. The arrival of tumescent liposuction in the 1980s solved many of these existing problems. A by-product of liposuction, the suctioned fat was easily accessible and could be reinjected through small cannulas/needles, leading to a resurgence of autologous fat grafting (AFG).

Areas amenable to AFG include the nasolabial folds, cheeks, infraorbital region, marionette lines, and lips. Scars as well as stable disease processes associated with idiopathic facial subcutaneous atrophy (e.g. linear morphea, Parry–Romberg syndrome) can also benefit (Fig. 158.9). The dorsal hands often share all of the signs of aging found in sun-exposed areas, and replacing fat in the dorsal hands masks the appearance of protruding tendons and blood vessels, imparting a more youthful appearance. Adipose transfer has also been shown to be effective in treating HIV-associated lipoatrophy in patients who have a suitable donor reserve.

There is great variability in the techniques used to procure, purify, and inject adipose tissue, resulting in great variability in outcomes. Table 158.8 reviews basic concepts, but a detailed discussion of the evolving nuances is beyond the scope of this chapter.

LIPOTRANSFER
Advantages
• Biocompatibility with avoidance of allergy • Abundant graft supply • Three-dimensional volumization • Potential long-standing correction
Disadvantages
• Need for donor fat harvesting • Percentage of graft that survives is unpredictable • Inability to remove after placement • Requires a two-step procedure: harvesting and insertion of the fat • Significant “downtime”, e.g. post-procedural edema • Rare risk of fat emboli and vision changes including blindness
Key components of procedure

• Anesthesia – general or local tumescent (see Ch. 143)
• Fat harvesting
  • From easy-to-access areas that are relatively insensitive to dietary fluctuation – upper outer buttock/flank, medial knee
  • Donor fat aspirated with a 12–14 G, single-holed microcannula mounted on a conventional hypodermic (10–20 ml) Luer-Lok® syringe or by traditional liposuction methods (see Ch. 156)
  • Processing via different methods (e.g. sterile saline washing; centrifugation to separate excess fluid, erythrocytes, and nonviable cells; use of an FDA-cleared filtration system such as PUREGRAFT)
  • Limited postoperative morbidity
• Fat re-injection
  • Processed, pure supernatant injected into subcutaneous plane using a large-bore (16–18 G) cannula/needle
  • Great variability in technique – multiple passes with layering of small fat droplets, intramuscular placement, superficial nanofat*
  • Repeat smaller volume injections over time have greater viability than a single large implantation; passive diffusion within the recipient bed cannot sustain the latter
  • Massage to disperse and contour
• Postoperative care
  • Systemic antibiotics
  • Pain management, avoiding aspirin-containing products

*Nanofat is highly emulsified and the adipocytes are mechanically disrupted such that there are no viable cells; the injection contains adipose-derived stem cells and growth factors.

Table 158.8 Key features of lipotransfer[7,50–56].

Silicone

Silicone (polydimethylsiloxane) consists of repeating units of dimethylsiloxane terminated with trimethylsiloxane. Centistoke (cs) refers to the viscosity of silicone oil and is directly related to the chain length of the repeating units. A 1 cs product is equivalent in consistency to water, a 350 cs product is similar in consistency to mineral oil, and a 1000 cs product is similar in texture to honey. While silicone has had a tumultuous history and continues to be controversial, it has largely been replaced by HA, PLLA, and CaH fillers.

Medical grade (350 cs) liquid silicone was never approved by the FDA for injection into humans and such use remains prohibited in the US. However, there is an FDA indication for AdatoSil® (5000 cs; approved in 1994) and Silikon® (1000 cs; approved in 1997) which is intraocular injection to produce tamponade to treat retinal detachment. Under the US FDA Modernization Act of 1997, physicians gained the right to use medical devices in an off-label manner, so after years of being banned for cosmetic implantation, physicians could legally use these FDA-approved and standardized silicone oils.

Silikon® 1000 is the most appropriate form of injectable liquid silicone currently available for off-label soft tissue augmentation. It is injected in a microdroplet, serial puncture method, most often for severe HIV-associated lipoatrophy (Fig. 158.10). As placement of the product results in permanent augmentation, there is very little margin

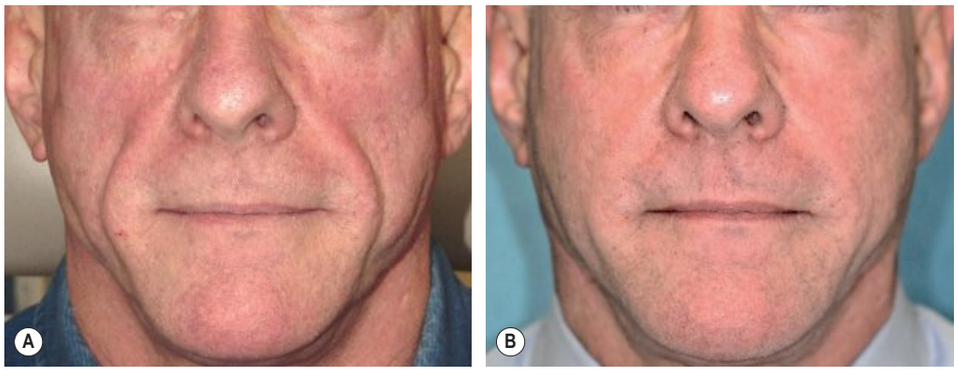

Fig. 158.10 Correction of HIV lipoatrophy with injectable silicone (Silikon® [1000 cs]). **A** Pre-treatment. **B** Five years post-treatment.

for error, and experience plus meticulous technique are essential. Since HIV-associated facial volume loss has become less common and there are safer alternative fillers with excellent outcomes, it is the authors' opinion that even when expertly injected, the incidence of adverse events is too high to justify its continued use. These complications include facial edema, overcorrection, superficial beading, movement of the product to a distant site (drift)[57,58], and granulomatous or inflammatory reactions with delayed firmness and nodules. In a 10-year retrospective follow-up of patients treated for HIV-associated facial lipoatrophy, adverse events were observed in 7%[58].

Polymethylmethacrylate (PMMA) Microspheres

Bellafill® (formerly Artefill®) is the only FDA-approved soft tissue filler that is a non-resorbable implant. It is indicated for the correction of nasolabial folds and acne scars. Polymethylmethacrylate (PMMA) microspheres are suspended in a solution of 3.5% bovine collagen and 0.3% lidocaine; the collagen serves as a carrier and is degraded within 1–3 months following injection. As a result, Bellafill® is currently the only commercially available filler in the US that requires skin testing for bovine collagen hypersensitivity. The remaining intact, inert, non-biodegradable 30–40 micron PMMA beads, similar to Lucite™ or Plexiglas™, are large enough to avoid phagocytosis but small enough to promote permanent augmentation. Once the host's collagen has encapsulated the microspheres, the augmentation has been purported to be permanent[42,59].

Bellafill® is a third-generation product whose predecessors were Arteplast® and Artecoll®. Improvements include PMMA particles that are more uniform in size and rounder with a smoother surface. Microspheres <20 microns, which were responsible for a high incidence of granuloma formation in previous generations, have been removed. However, even with this newer formulation which has a higher safety profile[59], there continues to be a risk of disfiguring delayed granulomas. The latter occur more commonly with off-label use[60], and in our experience, inevitably recur and never fully resolve. While the results may be permanent and therefore more economical, so are any adverse effects, which may require serial treatment with intralesional injections of 5-fluorouracil plus triamcinolone, oral antibiotics, or surgical excision[61].

PLATELET-RICH PLASMA

Platelet-rich plasma (PRP), an autologous solution with a high concentration of platelets and fibrin in a small volume of plasma, may be used to enhance one's complexion and less often as an injectable filler. Given the high number of growth factors implicated in extracellular matrix remodeling that it contains, PRP has become an increasingly popular option for rejuvenation. While the quality of published studies has appeared to lag behind quantity, there is a growing number of small RCTs, albeit with different designs, that have reported benefit from intralesional PRP.

One split-face, randomized, rater-blinded study of 20 Asian patients found good to moderate improvement in lower eyelid wrinkles and skin tone after three injection sessions (compared to saline control)[62]. One month after a single PRP session, an 89% increase in collagen density was observed histologically compared to baseline and 93% more collagen induction compared to the saline control injections[63]. However, the latter also led to improvement, possibly due to a needling effect. In another study of a single session of PRP versus saline in which photographs were reviewed at six months, masked subjects, but not two expert dermatologists, saw significantly better fine and coarse skin texture[64]. The authors argued that this discrepancy may stem from the failure of imaging to detect nuanced changes and patients' intimate understanding of their own skin topography. A more recent three-session, saline-controlled trial found statistically significant improvement in wrinkles, texture, and pores using a VISIA® system[65]; the latter may better detect subtle changes in the skin canvas than does global photography. An *in vitro* arm of this trial demonstrated that PRP mitigated ultraviolet B-induced matrix metalloproteinase-1 and tyrosinase upregulation and induced fibrillin and tropoelastin (precursor to elastin) expression. Perhaps this may explain the effects of PRP on skin photoaging and its enhancement of visible complexion metrics. Histologic improvement of solar elastosis following PRP injections has also been reported[66].

Taken together, these results support a potential role for PRP in improving skin texture, softening fine lines, and ameliorating degenerative soft tissue changes. While meaningful changes may be seen with a single treatment, more robust aesthetic outcomes seem to come from a series of sessions. However, the studies to date remain small, with a wide variation in protocols and outcome measures, many of which are subjective. There is a need for rigorous, larger scale RCTs to better standardize therapy[67]. Lastly, the combination of PRP plus HA fillers and platelet-rich fibrin matrix (derived from a true clot but often misclassified in the literature) should be investigated for any synergistic biostimulatory activity.

COMPLICATIONS

The popularity of soft tissue fillers is in part due to their favorable side-effect profile. Common injection-related phenomena include erythema, swelling, pain, and bruising. These generally resolve within a week without treatment. The erythema and swelling often appear immediately after injection. Minimizing the number of skin punctures and applying ice may reduce pain, erythema, and swelling[68]. To limit bruising, patients should be instructed to abstain from medications that inhibit platelet aggregation for at least 7–10 days prior to injection. Vigorous exercise with its associated blood pressure elevation should also be avoided for the first 24 hours after the injections. The use of a small-gauge needle, slow injection technique with small aliquots of product as well as blunt cannulas and fewer puncture sites may further minimize bruising. However, bruises are often inevitable and treatment with intense pulsed light or pulsed dye and potassium titanyl phosphate (KTP) lasers may be effective therapies, as they all can target the hemoglobin chromophore contained in the extravasated blood[69]. Superficial bruising from fillers often lightens substantially within a day following laser- or light-based treatment.

More serious complications from soft tissue fillers may occur and include: (1) nodules, beading, and Tyndall effect from superficial placement; (2) infection; (3) hypersensitivity reactions; (4) delayed nodule formation; and (5) vascular compromise (Fig. 158.11A; Table 158.9). Inappropriate placement of fillers may result in the development of papulonodules, which are palpable and often visible. Injecting too superficially with an HA filler may lead to beading as well as blue–gray discoloration due to the Tyndall effect. Hyaluronidase

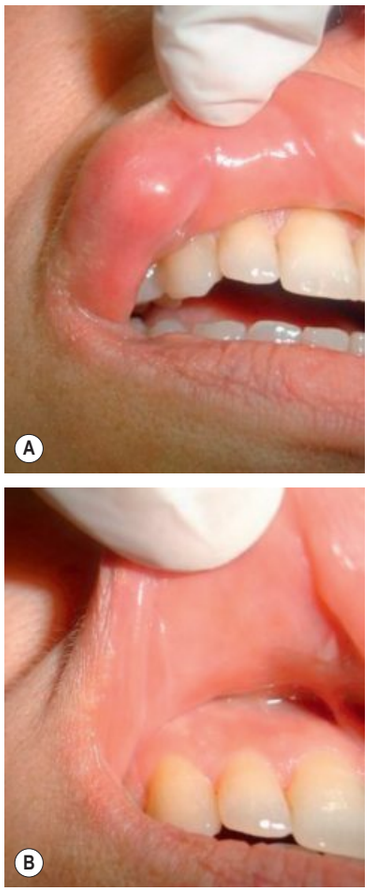

Fig. 158.11 Foreign body reaction to hyaluronic acid. A Nodule due to granulomatous inflammation arose six weeks after injection. **B** Resolution following intralesional hyaluronidase and triamcinolone. *Courtesy Mahmoud Abdallah, MD.*

can be used to treat these complications (see above; Fig. 158.11B). Vitrase® and Hylenex® are the two FDA-approved formulations of hyaluronidase that may be used off-label for dissolving unwanted previously injected HA. Hylenex® is a genetically engineered human recombinant hyaluronidase, whereas Vitrase® is ovine testicle-derived hyaluronidase. In the ophthalmologic literature, the reported incidence of allergic reactions to hyaluronidase is ~1 in 2000. While to date no cases of allergy or anaphylaxis have been reported in the dermatologic literature, a preliminary intradermal skin test with a few units can be considered to exclude hypersensitivity. Because there is a theoretical risk of cross-reactivity in patients who are allergic to honeybees and yellow jackets, patients who have had severe reactions or anaphylaxis to bee stings should be skin tested prior to treatment[70]. Persistent papules can also occur following injection of PMMA microspheres, poly-L-lactic acid, and silicone. Methods to reduce this complication are outlined in Table 158.9.

Any time there is a breach in the integrity of the skin, infection can occur. To minimize the risk, the skin should be cleansed with an antimicrobial agent such as isopropyl alcohol, chlorhexidine (avoiding the ear canal and eye), or hypochlorous acid prior to injection. Patients with an infection may present with tender erythematous fluctuant nodules or abscesses. These skin findings may be accompanied by systemic symptoms such as fever. When an infection is suspected, a microbiological culture of exudate, if present, should be obtained and/or the lesion biopsied for histopathologic examination and tissue culture. Therapeutic interventions include incision and drainage and empiric broad-spectrum antibiotics such as dual therapy with a macrolide (e.g. clarithromycin) and quinolone until the culture results are available[5,71]. Trauma from injections may also trigger a recurrence of herpes simplex viral infection. Prophylactic antiviral treatment (e.g. valacyclovir) should be considered if a patient has a history of a post-procedure recurrence and when treating the perioral area in a patient with a history of recurrent herpes labialis[69].

Prior to the introduction of HA fillers, hypersensitivity reactions were more commonly observed (see above). There are a few reported cases of hypersensitivity reactions to HA (Fig. 158.12), and these may be due to residual proteins or impurities from the manufacturing process or they may be due to low-molecular-weight HA fragments[71]. Hypersensitivity reactions to HA fillers often resolve spontaneously after several months, but resolution may be accelerated by application of tacrolimus ointment, intralesional corticosteroids, intralesional hyaluronidase, and/or incision and drainage[68].

Delayed nodules are variable in their etiology and difficult to precisely diagnose without histopathologic and/or culture results. They may be secondary to a hypersensitivity reaction, soft tissue infection, development of a biofilm, or formation of a foreign body granuloma (see Table 158.9). Although delayed nodules occur more commonly with permanent fillers such as PMMA or silicone (hence our recommendation to avoid their routine use), they can develop following injection of temporary fillers including HA. Hypothetically, delayed nodules secondary to an *immune reaction* may be triggered by residual proteins in the product or, in the case of HA fillers, by low-molecular-weight fragments of HA[71]. As noted above, these fragments provide a theoretical explanation for the increased incidence of delayed reactions (~1%–4%) seen with the Vycross® fillers, which consist of a mixture of both high- and low-molecular-weight HA[34,72–75].

There are some data to suggest a greater risk of delayed reactions after influenza-like illnesses, following vaccinations, and during cold and flu season[72,76,77]. More recently, delayed filler reactions have been observed following administration of SARS-CoV-2 mRNA vaccines. These reactions were typically mild to moderate and resolved within a few days, often without treatment. In a case series, the ACE (angiotensin-converting enzyme) inhibitor lisinopril at a dose of 5–10 mg daily led to a rapid reduction in edema[78].

Biofilms may also cause delayed nodules. When filler is injected, it can become coated with colonies of bacteria that secrete a protective and adhesive matrix. This results in a low-grade chronic infection resistant to antibiotics and the immune system. Often bacterial cultures will be negative as standard culturing techniques are not sensitive enough to detect this type of infection. Delayed nodules due to formation of biofilms can present as a "sterile" inflammatory nodule, an abscess or other form of soft tissue infection, or a foreign body granuloma[71]. In order to try to prevent biofilm formation, it is important to cleanse the skin with an antimicrobial agent (e.g. chlorhexidine [avoiding the ear canal and eye]) prior to injection. Infectious delayed nodules may be related to biofilms, but can also be due to less common organisms such as atypical mycobacteria.

As all synthetic fillers represent foreign bodies, an intense host response can occur resulting in the formation of *foreign body granulomas*. Although infrequent, this presentation is more common with permanent fillers and has been well documented histologically (see Fig. 94.11)[79].

While there are several therapeutic interventions for delayed nodules (see Table 158.9), they should be guided by clinical judgment (e.g. inflammatory versus non-inflammatory, sterile versus infected) as well as culture results and/or histopathologic findings when available. Treatment options for removal of as much of the filler as possible include intralesional hyaluronidase (if an HA filler), incision and drainage, and excision. Delayed nodules are often immune-mediated and can be treated with a 1- to 2-week course of oral corticosteroids (e.g. prednisone 30 mg daily). If there is concern regarding an active infection, empiric oral antibiotics are advisable (see above)[5]. Additional therapies employed for delayed nodules include topical or intralesional corticosteroids, oral immunosuppressants, and lasers (see Table 158.9)[80].

While the majority of adverse events are reversible, vascular complications can be devastating and often irreversible (Table 158.10). Tissue necrosis may occur if filler is injected directly into the vasculature, resulting in ischemic or embolic phenomena. Of particular concern are the arteries in the mid central face that connect to the ophthalmic circulation, i.e. where the facial artery continues as the angular artery immediately superior to the nasolabial fold (see above). The angular artery then branches into the lateral nasal artery and other collateral vessels, which connect the internal and external carotid artery systems[95] (see Fig. 142.15).

Signs and symptoms of vascular compromise include pain, arborizing blanching, duskiness, and reticulated erythema that may extend along the artery and its branches (Fig. 158.13). Over time, this can progress to a necrotic eschar, ulceration, and scarring. Treatment should be instituted immediately at the first sign of vascular compromise[68]. If blanching occurs while injecting, immediately discontinue[5]. If the complication occurs with an HA filler, injection of hyaluronidase is recommended.

COMPLICATIONS FROM SOFT TISSUE FILLERS	
Complication	**Prevention and management strategies**
• Injection site reactions (erythema, swelling, pain, bruising)	• Avoid anticoagulants and antiplatelet agents such as aspirin • Consider cannulas to minimize bruising • Smaller needles may reduce pain and bruising • Ice application for swelling and pain • Intense pulsed light or vascular lasers can be used to treat bruising
• Nodules, beading, and Tyndall effect	• Avoid superficial placement; inject smoothly • Treat with massage, hyaluronidase (if HA filler), or aspiration/excision
• Persistent papules	• More common with certain products • For Bellafill®, inject smoothly • For Sculptra®, greater volume dilution • For silicone, use microdroplet technique
• Infection	• Pre-cleanse the skin with an antimicrobial agent, e.g. chlorhexidine* • Consider incision and drainage and/or antibiotics if infection occurs
• Herpes simplex virus reactivation	• Treat with oral antiviral medication if: (1) history of post-procedure reactivation; (2) injecting the perioral area in a patient with a positive history of herpes labialis; or (3) evidence of active outbreak
• Hypersensitivity†	• Avoid injection in patients with known sensitivity • Skin test for bovine collagen in the case of Bellafill® • Hypersensitivity after HA fillers often resolves spontaneously, but consider treatment with tacrolimus ointment, intralesional corticosteroids, intralesional hyaluronidase, and/or incision and drainage

• Delayed nodules:
  • Inflammatory/immune-mediated (hypersensitivity)
  • Biofilm-related
  • Infectious
  • Foreign body granuloma
	• Pre-cleanse the skin with an antimicrobial agent prior to injection, e.g. chlorhexidine*
	• Incision and drainage plus culture and/or biopsy for histopathologic examination
	• Hyaluronidase (if HA filler) or surgical excision
	• Oral broad-spectrum antibiotics for 2–6 weeks, e.g. clarithromycin, minocycline
	• For non-infectious etiologies, consider topical, oral or intralesional corticosteroids; intralesional 5-fluorouracil; oral immunosuppressants; or laser therapy

• Vascular compromise (necrosis, blindness)	• Injectors should have a thorough knowledge of facial vascular anatomy and the depth at which a filler should be placed • Aspirate before injecting • Use a cannula or smaller gauge needle in high-risk areas • Inject product slowly and in small aliquots; use low pressure to prevent retrograde injection • Discontinue the injection immediately if blanching occurs or if the patient complains of significant pain or vision changes • If vascular compromise of the skin occurs, begin warm compresses, massage, and oral aspirin; if HA filler, inject hyaluronidase along artery and its branches (for additional measures, see Table 158.10) • If blindness or visual compromise occurs, see protocol in Table 158.10

*Avoid the ear canal and eye.
†Dermal perivascular and periappendageal mononuclear infiltrate, with infiltration of the implanted filler by neutrophils, lymphocytes, histiocytes, and eosinophils.

Table 158.9 Complications from soft tissue fillers. HA, hyaluronic acid.

Different formulations of hyaluronidase are available, which makes it difficult to establish standardized dosing. Variable doses have been reported in the literature, from 10–30 units per $2 \times 2\,cm^2$ area along the artery and its branches[96] up to a total of 1500 units injected within the affected region[97]. Larger doses may be required for higher cross-linked fillers such as Voluma®[38]. As outlined in Tables 158.9 and 158.10, additional conservative measures can also be initiated. A thorough assessment and detailed treatment plan should be instituted for each patient. Immediate and ongoing care with frequent monitoring ensures optimal outcomes and decreases the risk of permanent complications[89].

Although very rare, more serious complications can occur secondary to *embolism* of the filler into the ocular circulation, leading to blindness and/or ophthalmoplegia, or into the brain, causing a cerebrovascular accident. Blindness may occur when there is sufficient pressure and retrograde arterial displacement of injected material from the peripheral vessels into the ocular circulation[98].

The anatomic sites most commonly associated with visual complications include the nose, glabella, forehead, and nasolabial fold[99], with the first three sites accounting for 85% of reported cases in a recent review. Here, the filler can travel through the branches of the internal carotid system (e.g. supratrochlear, supraorbital, dorsal nasal artery) to the ophthalmic artery, which further branches into the retinal artery. Alternatively, at sites such as the nasolabial fold, the filler can enter the ocular circulation via rich anastomoses between the external and internal carotid systems (see Ch. 142).

MANAGEMENT OF SUSPECT VASCULAR OCCLUSION/INJURY WITH OR WITHOUT VISUAL COMPROMISE FOLLOWING INJECTION OF FILLER
Hyaluronic acid filler with blindness or visual compromise – time is crucial
• Halt injection at first signs of visual compromise, usually occurring unilaterally during or immediately post injection

• *Prior* to intervention, evaluate and document visual status in each eye independently including:
  • ability to read letters (Snellen chart, near card, magazine print)
  • ability to count fingers
  • ability to perceive hand motion
  • presence of light perception
  • extraocular muscle function
  • pupillary light response
• Photograph face in frontal position

• Immediately contact an ophthalmologist familiar with management of such cases   • As swift care is crucial and to avoid a delay in care, highly recommend establishing a pre-existing relationship and plan with an oculoplastic surgeon, ophthalmologist, and/or retina specialist
• Prompt hyaluronidase injections with >150 units into the treated region, ischemic skin, and along arterial paths leading to the eye • Consider injecting similar doses at the supraorbital and supratrochlear foramina • Repeat in quick succession as needed
• Retrobulbar and peribulbar hyaluronidase injections may be beneficial, but remain controversial

• Additional conservative measures:
  • Breathing into a paper bag to increase CO_2
  • Ocular massage with firm manual pressure to globe for 5–15 seconds alternating with rapid release for a total of 5 minutes; wait a few minutes, then repeat. Cyclical pressure inducing rapid reperfusion may dislodge embolus
  • Topical timolol (0.5%) and oral acetazolamide (500 mg) may decrease intraocular pressure

Hyaluronic acid filler with blindness or visual compromise and CNS involvement
• If signs or symptoms of CNS involvement, contact 911 and your local emergency stroke services • If no overt signs or symptoms, always evaluate for CNS involvement after addressing visual compromise
Hyaluronic acid filler without blindness/visual compromise
• Halt injection if "flash" in the syringe (vascular regurgitation) or tissue blanching or reticulation in treatment area (Fig. 158.13)

• Prompt high-dose hyaluronidase injection into skin at occlusion site as well as peripheral regions
  • Unanimously supported intervention[81–91], but optimal dosing unclear and based on anatomic region and product
  • Hundreds of units, perhaps pulsed in 15-minute intervals (500 units in increments of 125 units superior to single bolus)[92]

• Additional conservative measures:
  • Skin massage
  • Intralesional or systemic corticosteroids
  • Warm compresses
  • Oral aspirin
  • Nitroglycerin less beneficial
  • Hyperbaric oxygen for wound healing

Calcium hydroxylapatite
• Preliminary evidence of filler dissolution with sodium thiosulfate injection (0.1–0.2 ml of 250 mg/ml)[93,94], but its use for vascular occlusion remains unknown

Table 158.10 Management of suspect vascular occlusion/injury with or without visual compromise following injection of filler. Recommendations adapted from evidence-based guidelines from the American Society for Dermatologic Surgery (ASDS) Task Force[5]. Of note, there is no current standard of care for managing iatrogenic retinal embolism from hyaluronic acid filler (conditional recommendations, low certainty evidence). For vascular occlusion *sans* ocular event, the recommendations are strong with more moderate certainty evidence. CNS, central nervous system.

Fig. 158.13 Evolving vascular occlusion following injection of Juvéderm® Ultra XC into the cheek. Note the arborizing blanching, duskiness, and reticulated erythema that is observed in addition to pain.

The signature feature of ocular embolism is immediate visual impairment, which may be accompanied by ocular pain, nausea, and vomiting. Such events represent an ophthalmologic emergency. If any of these signs or symptoms occur, the patient should be sent urgently for ophthalmologic consultation, since treatment aimed at recanalizing the affected vessel(s) and restoring tissue perfusion needs to be performed within a short window of time. The most frequently cited interval is 90 minutes, but more recent investigations have suggested an interval as short as 10–15 min[100]. Therefore, a predetermined and detailed action plan is required. In an attempt to restore vision, prebulbar and retrobulbar injections of hyaluronidase can be performed immediately[7], but this intervention remains controversial (see Table 159.10)[101–103]. Because treatment of embolic blindness is usually unsuccessful, prevention is of critical importance[98].

When performed with care, soft tissue augmentation is a highly effective and safe procedure. To ensure the best outcomes while minimizing any adverse events, a thorough understanding of facial anatomy as well as proper injection technique are imperative. Injectors should be aware of both prevention and management strategies to minimize complications and improve patient outcomes (see Tables 158.9 and 158.10).

CONCLUSION

The vast array of available filler products, and those that are on the horizon, are only one means to improve tissue loss associated with aging and trauma. The optimal result may be best achieved by combining fillers of different depth, origin, and durability with other aesthetic procedures. The science of soft tissue augmentation is continuously evolving. Keeping abreast of advances and perfecting a few techniques will be most advantageous for patients; it is not only what is injected, but how it is injected, that determines the degree of success. Finally, regardless of the treatment chosen, it is the combination of clinical judgment, realistic expectations, meticulous preparation, and surgical skill that provides optimal results.

Properties of Botulinum Toxins 2705
Cosmetic Use of Botulinum Toxin Type A 2706
Medical Uses of Botulinum Toxin Type A 2714
Complications 2715
Safety 2716

Synonyms:
- Botulinum toxin type A, botulinum A exotoxin, BoNT-A; onabotulinumtoxinA – BOTOX®/BOTOX® Cosmetic; abobotulinumtoxinA – Dysport®, Azzalure®; incobotulinumtoxinA – Xeomin®/Bocouture®; prabotulinumtoxinA-xvfs – Jeuveau®; daxibotulinumtoxinA-lanm – DAXXIFY®
- Botulinum toxin type B, BoNT-B; rimabotulinumtoxinB – MYOBLOC®

Key features

- Botulinum toxin (BoNT) causes chemodenervation of muscles by blocking acetylcholine release
- BoNT is also capable of inhibiting the release of other neurotransmitters, such as substance P, noradrenaline, calcitonin gene-related peptide, and glutamate from a variety of synaptosomal and neuronal systems
- Injections of BoNT type A (BoNT-A) that weaken or relax muscles can smooth hyperfunctional lines and change the contour of the face and neck
- Adjunctive use of BoNT-A with soft-tissue augmentation or laser resurfacing is beneficial, particularly in active regions such as the perioral and periocular areas
- The cosmetic effects of BoNT-A typically last months and may increase with subsequent injections
- In addition to its effect on musculature, BoNT-A successfully denervates sweat glands, serving as an effective alternative treatment for hyperhidrosis, and it can also improve the pain, swelling, and discoloration associated with Raynaud phenomenon
- Complications (e.g. eyelid ptosis) are generally caused by diffusion of the toxin to non-targeted muscles and can be minimized by using concentrated doses and careful technique

INTRODUCTION

Botulinum toxin (BoNT) injections are commonly used to improve facial aesthetics by smoothing hyperdynamic rhytides of the face and neck. In recent years, the use of BoNT has evolved to reflect a more three-dimensional approach to facial rejuvenation, often in combination with soft-tissue augmentation or other restorative procedures. Moreover, a better understanding of its mechanism of action has led to innovative indications across a number of therapeutic fields.

PROPERTIES OF BOTULINUM TOXINS

Various strains of the bacterium *Clostridium botulinum* produce seven distinct serotypes of BoNT that affect neural function: A, B, C1, D, E, F and G[1]. Although all serotypes produce chemodenervation and atrophy of skeletal muscles by blocking acetylcholine release from motor neurons at the neuromuscular junction (Fig. 159.1), they differ with regard to cellular mechanism of action and clinical profile.

Formulations

BoNT type A (BoNT-A), the first serotype developed for use in humans, is available in seven formulations worldwide (Table 159.1). Five have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of glabellar rhytides and have been assigned specific drug names to avoid confusion and reduce the potential for dosing errors: onabotulinumtoxinA (onaA; BOTOX®/BOTOX® Cosmetic), abobotulinumtoxinA (aboA; Dysport®, Azzalure®), incobotulinumtoxinA (incoA; Xeomin®/Bocouture®), prabotulinumtoxinA-xvfs (praboA; Jeuveau®), and daxibotulinumtoxinA-lanm (DAXI; DAXXIFY®). Outside of North America, BoNT-A formulations include Prosigne® and Neuronox®. One formulation of BoNT type B (BoNT-B; rimabotulinumtoxinB (rimaB; MYOBLOC®/NeuroBloc®) is also available in North America (see Table 159.1). All preparations of BoNT differ in terms of purification procedures, potency, and clinical effect and may not be used interchangeably.

Clinical Differences

Clinical differences between onaA and aboA have been debated, in particular the possibility of greater diffusion and migration by aboA[2–4]. However, digital image correlation at various time points utilizing speckle-tracking photogrammetry demonstrated no significant differences between aboA and onaA in the reduction of dynamic glabellar rhytides[5]. Similar efficacy for onaA and aboA has also been observed for non-cosmetic indications, such as facial synkinesis[6]. While suggested dosing ratios have ranged from 1 : 2 to 1 : 4 (onaA : aboA), a dosing ratio of 1 : 2.5 has been shown to increase the field of anhidrotic effect[2], and a higher dose ratio of 1 : 3 has been reported to result in greater longevity[3,7,8], as well as a faster onset of action[8]. Although no clear consensus on a conversion factor between products has been reached, current guidelines recommend a dose ratio of 1 : 2.5 or less than 1 : 3[2,9].

The first BoNT formulation without complexing proteins, incoA, has been shown to be as safe and effective as onaA for the treatment of glabellar rhytides, with a rapid onset of effect and duration of effect of up to 5 months or more[10–12]. In contrast to aboA (see above), incoA has similar dosing to onaA. Researchers had initially speculated that complexing proteins would limit diffusion of the active neurotoxin within the target muscle[13], but human and animal studies have suggested otherwise[2,14]. For example, Kerscher and colleagues found no difference in the size of the anhidrotic area after injection with incoA or onaA[2].

In a multicenter, randomized, double-blind, controlled clinical trial that enrolled 540 patients with moderate to severe glabellar rhytides, a single treatment with praboA (20 U) was found to be as safe and effective as onaA; no serious side effects were observed with this more recently approved formulation of BoNT-A[15]. One comparison study of the effectiveness of rimaB versus onaA reported similar findings[16]. Of note, rimaB was FDA-approved in 2000 for cervical dystonia but is used off-label to treat facial rhytides.

When used for the treatment of hyperkinetic lines in the face, there are several key differences between rimaB and onaA: rimaB has a more rapid onset of action but a shorter duration of effect, diffuses more widely, and is associated with greater pain and other side effects when compared to onaA[17]. That said, one study which examined seven doses of rimaB found all to be safe and effective for the treatment of hyperfunctional rhytides, with a dose-related duration of effect[18].

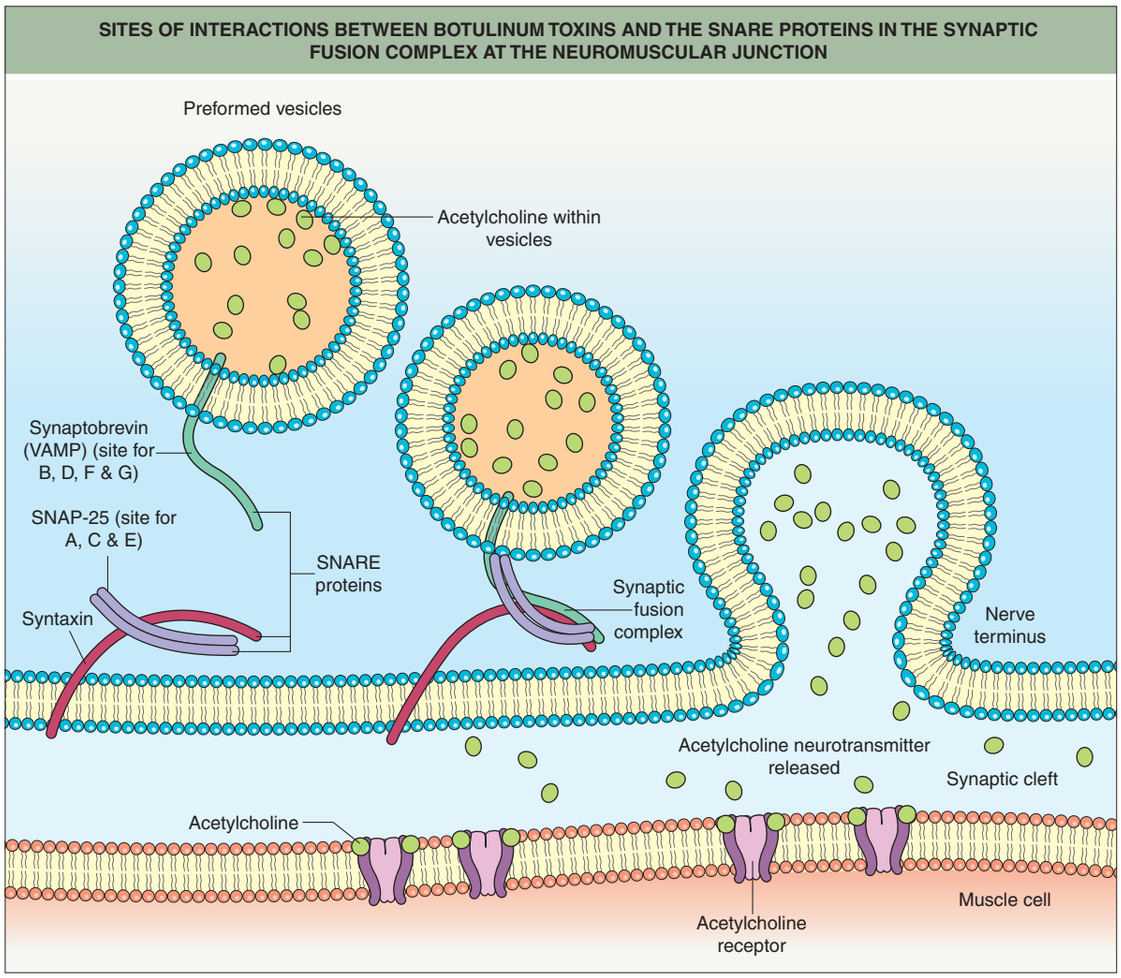

Fig. 159.1 Sites of interactions between botulinum toxins and the SNARE proteins in the synaptic fusion complex at the neuromuscular junction. Botulinum toxins A, C, and E catalyze the cleavage of the SNAP-25 protein. Botulinum toxins B, D, F, and G catalyze the cleavage of synaptobrevin (or the vesicle-associated membrane protein, VAMP). *Adapted from Rohrer TE, Beer K. Background to botulinum toxin. In: Carruthers A, Carruthers J (eds). Botulinum Toxin. Philadelphia: Saunders, 2005.*

Topical BoNT-A

Percutaneous delivery of topical BoNT has been limited by its inability to cross the stratum corneum. As a result, it has been combined with mechanical, chemical, and thermal techniques in an attempt to enhance percutaneous delivery[19–21]. Despite early promising reports of the treatment of lateral canthal rhytides (Fig. 159.2) and primary axillary hyperhidrosis[22–25] with topical formulations of BoNT-A, to date, no such formulations have been approved by the FDA. For example, in contrast to the effectiveness of injectable daxibotulinumtoxinA[26], topical daxibotulinumtoxinA gel did not meet primary endpoints for efficacy in a phase III trial. Nonetheless, topical BoNT-A remains a potential approach for the treatment of anatomic areas that are difficult to manage or particularly painful to inject.

A Note About Dosing

Most of the published information regarding the cosmetic uses of BoNT pertains to the use of onaA, followed in recent years by aboA and incoA. Data are scarce regarding other formulations of BoNT-A. Since most of our experience pertains to the use of onaA, the following discussion (including units and description of techniques) focuses on this formulation specifically. However, a conversion rate of 1 : 1 U may be considered for all 100-U product vials (incoA, Prosigne®, and Neuronox®) and 1 : 2.5 U for aboA.

COSMETIC USE OF BOTULINUM TOXIN TYPE A

Hyperkinetic lines result from the repeated contraction of muscles perpendicular to the rhytides. Weakening or relaxing these muscles with BoNT-A can smooth horizontal lines on the forehead (from frontalis contraction), vertical lines in the glabellar region between the eyebrows (from corrugator contraction), horizontal creases across the bridge of the nose (from procerus contraction), "crow's feet" and lateral lines along the lower eyelid (from lateral orbicularis oculi contraction), and perioral lines (from orbicularis oris contraction). Deep grooves or folds elsewhere that are exacerbated by muscle activity are also amenable to treatment. Patients 30–50 years of age may be most responsive to BoNT-A, because their rhytides are more likely to be caused by muscle activity rather than by the loss of skin elasticity that occurs with aging.

Injections for aesthetic indications may be given intramuscularly, subcutaneously, or intradermally. We use intradermal injections, especially in the crow's feet area, to minimize bruising. All of the usual precautions prior to any injection should be followed. The area may be chilled with ice before injection to minimize any discomfort in sensitive individuals. Alternatively, a topical anesthetic can be applied 15 to 30 minutes prior to injection to minimize discomfort.

The effects of BoNT-A injections are usually apparent within a day or two and are obvious for 3 or 4 months, although they may last for 6 months or more. In comparison to other BoNT-A formulations, injectable daxibotulinumtoxinA (DAXI) has been reported to have a longer duration of effect on glabellar lines[26]. There is also a tendency for repeated BoNT-A injections to provide more prolonged aesthetic improvement.

Glabellar Frown Lines

Frown lines in the glabellar region are caused by contraction of the corrugator supercilii and orbicularis oculi muscles, which move the brow medially, and the procerus and depressor supercilii muscles, which pull the brow inferiorly. Because the corrugator and procerus are used only to control facial expression, the goal of treatment should be to produce a significant weakening of these muscles. The treatment sites and doses should be individualized because the location, size, and use of the frown muscles vary greatly between individuals. We currently use five injection sites when treating glabellar frown lines and vary the dosage depending on the individual brow (Fig. 159.3; Table 159.2). If the extent of the frown reaches the midpupillary line, additional injection sites may be warranted (Video 159.1) The procedure effectively smooths the glabellar lines at rest and prevents their appearance when the patient attempts to frown, for an average of 3 to 4 months (Fig. 159.4)

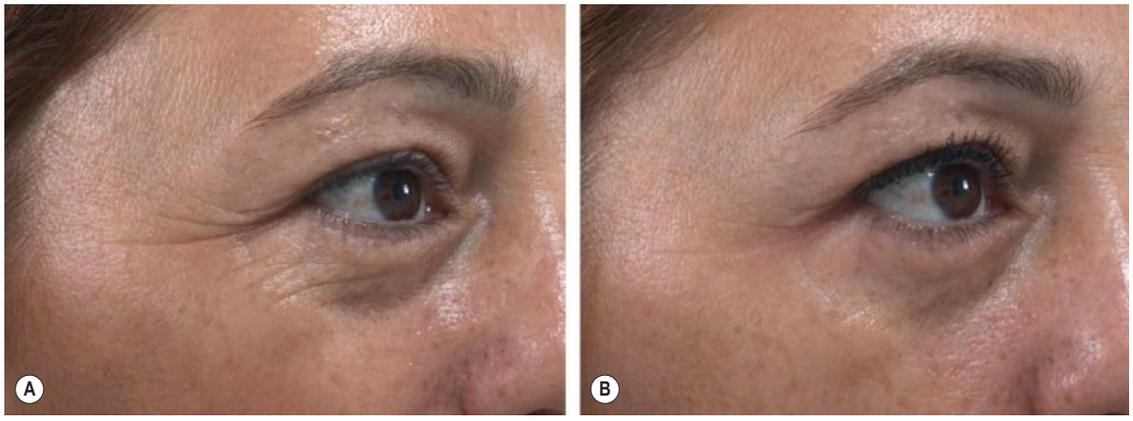

Fig. 159.2 Topical BoNT-A for lateral canthal rhytides (crow's feet). Before (**A**) and after (**B**) treatment.

Crow's Feet

Contraction of the lateral fibers of the orbicularis oculi muscle produces "crow's feet", lines that radiate from the lateral canthus. Since forceful closure of the eyelids requires orbicularis contraction, the goal of treatment is to produce weakening just in the lateral orbital area, rather than a complete paralysis of the muscle. Because the orbicularis oculi is diffusely innervated, multiple injections are required to weaken broad areas of the muscle. Doses and sites vary among clinicians – we evenly distribute the BoNT-A into two to four separate injection sites (Fig. 159.5; see Table 159.2) while others may employ up to seven injection sites (Video 159.2). Results last approximately 3 months (Fig. 159.6).

Horizontal Forehead Lines

Deep horizontal creases in the forehead are produced by the repeated contraction of the frontalis muscle. This large, vertically oriented muscle is the brow elevator; it inserts superiorly into the galea aponeurotica and inferiorly into the skin of the brow. Unfortunately, weakening the

frontalis muscle sufficiently to eliminate hyperkinetic forehead lines can result in undesired brow ptosis or a complete lack of expressiveness. Therefore, it is our practice to divide the BoNT-A amongst multiple sites distributed horizontally across the midforehead (Fig. 159.7; see Table 159.2). The goal of treatment is to only soften, rather than completely eliminate, forehead lines. Ideally, the individual will still be able to elevate the eyebrows, albeit to a lesser extent, after treatment (Fig. 159.8). We believe that the brow depressors should *always* be treated at the same time as the frontalis, and so we employ the technique described in the next section. Effects typically last from 3 to 6 months (Video 159.3).

Brow Lift and Shaping

Brow ptosis often occurs during aging, resulting in an angry, scowling expression. Notably, the shape and height of the eyebrows are

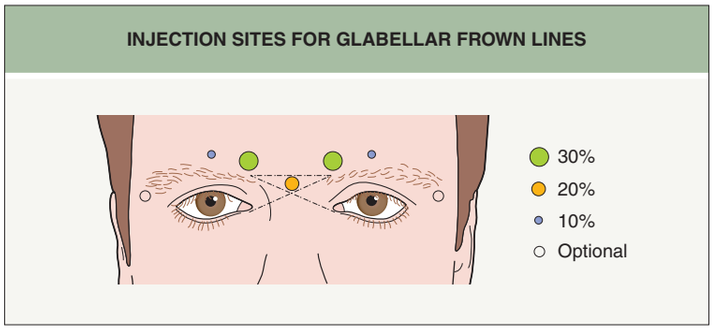

Fig. 159.3 Injection sites for glabellar frown lines. The authors currently use five injection sites when treating glabellar frown lines and vary the dosage depending on the individual brow. The injection in the midpupillary line may be omitted if eyebrow ptosis seems likely or possible. Sometimes, an injection is made above the lateral canthus or into the tail of the eyebrow.

USE OF onaA IN THE UPPER FACE: DOSING AND TECHNIQUES

Treatment area	Injection sites and tips
Glabellar rhytides	• Men: starting dose 60 U, titrate to 100 U; women: starting dose 30 U, titrate to 50 U • 7–10 U (women) or 15–20 U (men) just above the superior bony orbital rim directly above the inner canthus on each side (Fig. 159.3) • 5–10 U into procerus muscle at midline • For horizontal brows: 4–5 U 1 cm above bony supraorbital rim in the midpupillary line* • Sometimes necessary to inject above lateral canthus or into the tail of the eyebrow to improve lateral eyebrow position
Lateral canthal rhytides (crow's feet)	• 12–15 U/side, distributed amongst 2–4 sites (Fig. 159.5) • Inject when patient is *not* smiling to avoid affecting the ipsilateral zygomaticus complex (which can lead to upper lip ptosis) • Inject lateral to the lateral orbital rim; more medial injections can cause lower eyelid droop • Superficial injections (as few as possible) will avoid bruising • Avoid injecting superficial veins
Horizontal forehead rhytides	• 10–15 U amongst multiple sites horizontally across the midforehead, 2–3 cm above the eyebrows (Fig. 159.7) • 5 injection sites for broad foreheads†; 4 injection sites and a slightly lower dose for narrow foreheads
Hypertrophic orbicularis oculi muscle	• Subcutaneous injections of 2–4 U in the midpupillary line, 3 mm below the ciliary margin (Fig. 159.9) • Higher doses can result in keratoconjunctivitis sicca (dry eye)

*Injection site most likely to cause ptosis.
†More than 12 cm between the temporal fusion lines (the slight prominence at the point where the temporalis fascia joins the skull) at the midforehead level.

Table 159.2 Use of onaA in the upper face: dosing and techniques.

Fig. 159.4 Effect of BoNT-A injections for glabellar frown lines. A subject at rest (**A**) and during frowning (**B**). Same subject at rest (**C**) and attempting to frown (**D**) two weeks after BoNT-A treatment.

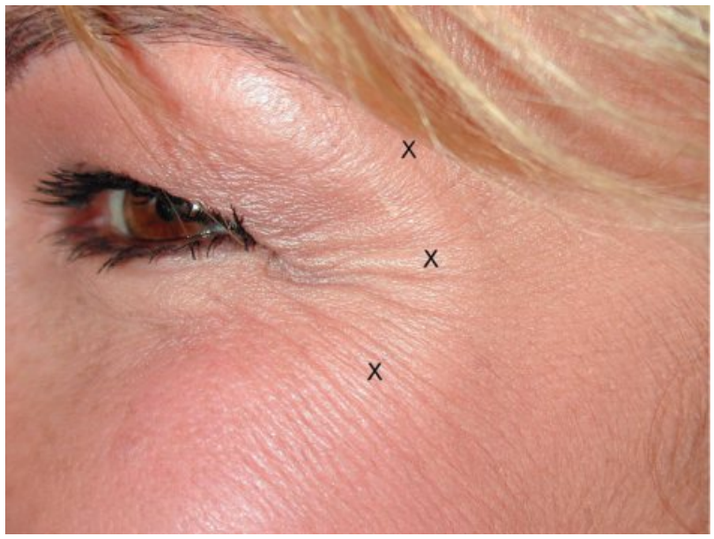

Fig. 159.5 Injection sites for lateral canthal rhytides (crow's feet). The authors inject 12–15 U of onaA per side among two to four injection sites.

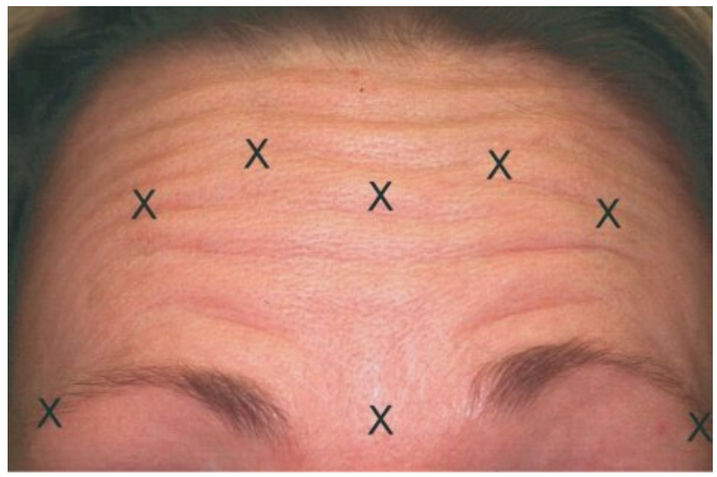

Fig. 159.7 Injection sites for horizontal forehead lines. Injection sites must be kept well above the brow. The lower X's mark the sites of injection of the brow depressors.

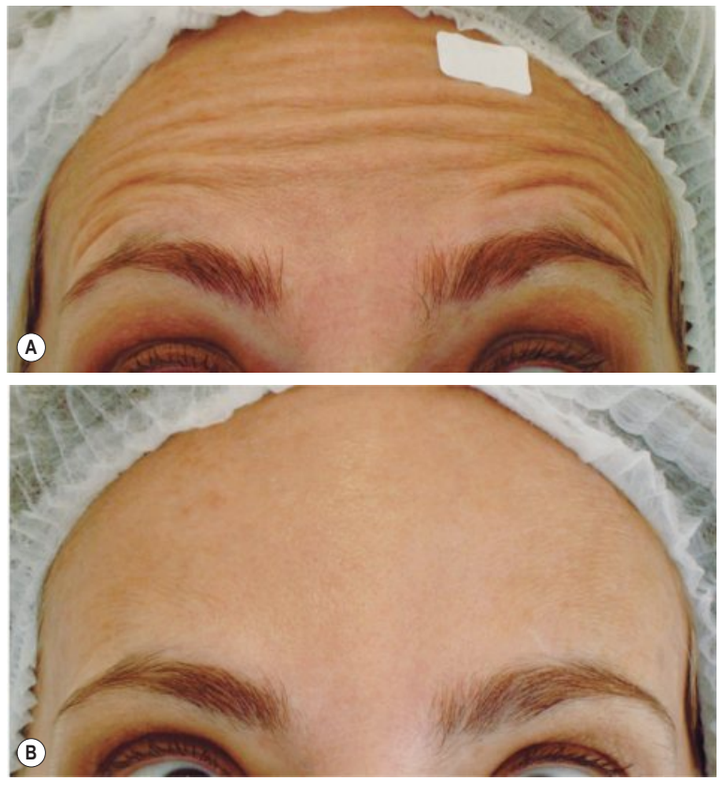

Fig. 159.8 Effect of BoNT-A injections for horizontal forehead lines. The subject elevates the brows before (**A**) and after (**B**) BoNT-A treatment.

determined by the opposing activity of the frontalis muscle, which elevates the brow, and the brow depressors. The medial brow depressors are the corrugator supercilii, the procerus, and the medial portion of the orbicularis oculi; the lateral depressor is the lateral portion of the orbicularis oculi (that is lateral to the temporal fusion line). Although we initially believed that brow lifts were a result of the inactivation of the brow depressors, subsequent research showed that central injections of 20–40 U of onaA into the glabella alone (with the most lateral injection at the midpupillary line) led to a dramatic lateral eyebrow elevation, followed by an entire brow lift that peaked 12 weeks after treatment, while too little (10 U) led to a brief fall in eyebrow position[27]. We now believe that the change in eyebrow position after glabellar injection in women is due to diffusion of the toxin into the lower frontalis muscle, which causes an improved resting tone in the remainder of the muscle and in eyebrow position.

Hypertrophic Orbicularis Oculi

The pretarsal portion of the orbicularis oculi muscle is involved in the blink reflex. Contraction of the pretarsal orbicularis during smiling tends to decrease the size of the palpebral aperture. Hypertrophy of this muscle can give a "jelly roll" appearance to the lower eyelid, enough that some individuals may complain that they look overweight. We have found that injection of 2 U (or occasionally 4 U) of onaA into the lower pretarsal orbicularis (Fig. 159.9) opens the palpebral aperture both at rest and during smiling (Fig. 159.10; see Table 159.2)[28].

Midface Injections

Contraction of the upper nasalis muscle causes fanning rhytides ("bunny lines") at the nasal root (Fig. 159.11). BoNT-A treatment weakens the upper nasalis and dramatically softens these lines. Bunny lines are typically treated in conjunction with the glabellar complex (Table 159.3).

Fig. 159.9 Injection sites for hypertrophic orbicularis oculi muscle. 2–4 U of onaA are injected into the lower pretarsal orbicularis oculi muscle.

Fig. 159.10 Effect of BoNT-A injections for hypertrophic orbicularis oculi muscle. Treatment of the lower pretarsal orbicularis opens the palpebral aperture. Note the position of the lower eyelids in the subject before (**A**) and after (**B**) BoNT-A treatment.

Fig. 159.11 Injection sites for bunny lines. 2–4 U of BoNT-A injected in each belly of the upper nasalis, at the lateral bony dorsum of the nose.

USE OF onaA IN THE MIDFACE: DOSING AND TECHNIQUES	
Treatment area	**Injection sites and tips**
Bunny lines	• 2–4 U into the upper nasalis muscle, usually 1 injection/side (Fig. 159.11) • Inject well above nasofacial groove* to avoid lip ptosis (due to relaxing the levator labii superioris muscle) • Injection followed by gentle massage
Repeated nasal flare	• 5–10 U bilaterally into lower nasalis muscle fibers covering the lateral nasal ala • Inject the most active area of contraction
Nasolabial folds	• Select patients only, e.g. those with a naturally shorter cutaneous upper lip • 1 U into each lip elevator complex above the nasofacial groove
Nasal tip droop	• 2–3 U into depressor septi nasi muscle at the base of the columella
*Refers to groove between the nose and cheek.	

Table 159.3 Use of onaA in the midface: dosing and techniques.

Some individuals repeatedly and embarrassingly dilate their nostrils in social situations. The sides of the columella/septum become visible when the nostrils are prominently flared. Contraction of the nasalis muscle accentuates the nasal flare. Small doses of BoNT-A can produce a satisfactory decrease in involuntary nostril flare in some patients for 3 to 4 months (see Table 159.3).

The nasolabial folds extend from the lateral nasal ala to a point lateral to the external angle of the mouth. Young adults have a shallow indentation, but older individuals who smile excessively or sustain photodamage can develop a permanent, deep crevice. The most common treatments for nasolabial folds have been soft-tissue fillers and laser resurfacing. Although muscle contraction contributes to the appearance of the folds, injecting BoNT-A directly into the area of the fold is not recommended, because it is likely to result in an asymmetric smile, flaccid cheek and flattening of the midface, along with a vertical lengthening of the cutaneous upper lip, leading to incomplete or disappointing results. However, for some individuals who have a naturally shorter cutaneous upper lip, very small doses of BoNT-A can be beneficial for improving nasolabial folds (see Table 159.3), particularly when the injections are given concurrently with fillers or resurfacing. Because duration of effect of this procedure is relatively long (~6 months), it is important to be very careful in patient selection and to be clear about the potential results of the procedure.

Nasal tip droop is common during aging. Contraction of the depressor septi nasi, a small muscle located at the external base of the nasal septum, pulls the tip of the nose downward. BoNT-A slightly elevates the nasal tip (see Table 159.3). Caution should be taken with individuals who already have a long non-vermilion upper lip, because of an associated risk of lip ptosis.

Vertical Lip Rhytides (Perioral Lines)

During aging, the mouth undergoes characteristic changes: the lateral portions of the lips recede to produce a "rosebud mouth"; the vertical distance between the columella and the vermilion border of the upper lip increases, and the substance of the vermilion lip rolls inside, producing the thin and disappointed lips characteristic of old age. The cutaneous upper lip lengthens, and dense vertical perioral rhytides appear. These vertical lines are commonly referred to as "smokers' lines" but they can have other causes, such as heredity, photodamage, or activities

such as playing a musical instrument that require pursing of the lips. Radial upper lip rhytides are exaggerated by the pursestring-like action of the orbicularis oris sphincter muscle of the lip. Multiple fine rhytides of the upper lip can be effectively treated with fillers such as hyaluronic acid or with mid-depth or deeper resurfacing. However, deeper rhytides may be resistant to these treatments.

BoNT-A treatment of the lip sphincter is recommended only for deep lines. Small doses that produce localized microparesis of the orbicularis oris can dramatically reduce radial lip lines and improve the appearance of the lips (Table 159.4). To maintain competence of the mouth, it is important to be conservative with dosing, and superficial injections are recommended over deep injections (Fig. 159.12) (Video 159.4). Even with conservative dosing, however, BoNT-A treatment of perioral lines may result in lip sphincter weakening that subtly affects mouth function. This procedure may not be desirable for musicians who play wind instruments and professional singers or speakers. Some patients have difficulty with lip proprioception after treatment, but eating, drinking and singing are typically not affected. BoNT-A injections for radial lip lines may be particularly useful in combination with perioral laser or electrosurgical resurfacing or in combination with a soft-tissue-augmenting agent such as hyaluronic acid (Fig. 159.13).

USE OF onaA IN THE LOWER FACE AND NECK: DOSING AND TECHNIQUES

Treatment area	Injection sites and tips
Perioral rhytides	• 4 U/lip (2 U/lip quadrant); typically 1 U/vertical lip line (Fig. 159.12) • Inject into area of muscle contraction adjacent to the creases at the vermilion border on either side of Cupid's bow • Avoid injecting lip corners (can lead to drooping of the lateral lip and drooling) as well as the midline (can lead to flattening of Cupid's bow)
Upper gum show	• 1–2 U into levator labii superioris alaeque nasi muscle (on each side of the bony nasal prominence) • Younger patients
Mouth frown	• 2–3 U into the posterior aspect of the depressor anguli oris (DAO) muscle on each side, close to the mandible (Fig. 159.15) • Additional 3 U into each mentalis muscle insertion • Asking the patient to frown can aid in identifying the DAO muscle • Not recommended for singers or musicians
Marionette lines	• 2–5 U into each DAO muscle immediately above the angle of the mandible and 1 cm lateral to the lateral oral commissure; amount injected depends upon size of the muscle • Injection must be lateral and low, at the junction of the depressor and the superior margin of the mandible • An injection too medial or too high can cause ipsilateral weakness of the depressor labii inferioris muscle and flattening of the lower lip contour when the mouth attempts to form an "O"; an injection too high may compromise sphincter function and cause mouth incompetence
Mental crease	• 3–5 U/mentalis muscle band
Peau d'orange chin	• 5–10 U into mentalis muscle at the most distal point from the orbicularis oris muscle (i.e. the prominence of the chin; Fig. 159.18)
Masseteric hypertrophy	• 20–35 U into each masseter muscle
Platysmal bands	• 5 U into contracted platysma muscle; 3 sites at 1–1.5 cm intervals for a total of 15 U/band (Fig. 159.20A) • Single treatment typically involves 2 bands and a total dose of 30 U into the neck • Recommended only for patients who have obvious platysmal bands, good cervical skin elasticity, and minimal submental fat accumulation

Table 159.4 Use of onaA in the lower face and neck: dosing and techniques.

Facial Asymmetry: Functional Muscle Imbalance

Injections of BoNT-A can be used to correct facial asymmetry resulting from facial nerve palsies, dystonias, surgery, or trauma[29]. In cases of hemiparesis, BoNT-A is used to decrease muscle activity on the unaffected side; for hyperkinesia, the affected muscles are treated.

Midfacial asymmetry may have bony tissue, soft tissue, innervational or muscular causes. BoNT-A treatment can be invaluable for patients with facial asymmetry caused by neuromuscular abnormalities. In hemifacial spasm, repeated clonic and tonic facial movements draw the facial midline over toward the hyperfunctional side. BoNT-A treatment of the hyperfunctional zygomaticus, risorius and masseter muscles allows the face to be centered at rest. Hypofunctional asymmetry, such as that seen in Bell palsy due to unilateral seventh nerve dysfunction, can be relieved by small doses of BoNT-A injected into muscles on the normally functioning side. Only 1–2 U of onaA into the zygomaticus, risorius, and orbicularis oris muscles and 5–10 U into the masseter muscle are needed to restore facial symmetry (Fig. 159.14).

For patients with asymmetric jaw movement, intraoral injection of 10–15 U of onaA into the internal pterygoid on the hyperfunctional side can relax the jaw and relieve discomfort. Unilateral surgical or traumatic injury of the orbicularis oris or the risorius muscle can cause the mouth to be pulled off-center by the unopposed actions of the partner muscles on the uninjured side. Chemodenervation of the risorius immediately lateral to the corner of the mouth on the uninjured side re-centers the mouth when the face is at rest. Similarly, facial asymmetry is evident in individuals with congenital or acquired unilateral weakness of the depressor anguli oris (DAO) muscle, who are unable to depress the corner of one side of the mouth. In these cases as well, BoNT-A treatment of the partner muscle restores aesthetic balance.

Mouth Frown

The frowning expression created when the lateral corners of the mouth are permanently angled downward can create an impression of disapproval and unpleasantness. The DAO muscle pulls down the corner of the mouth in opposition to the zygomaticus major and minor muscles. BoNT-A can be used to weaken the DAO and reset muscular balance (Fig. 159.15), allowing the zygomaticus to elevate the corners of the mouth and return them to a horizontal position (Fig. 159.16). The effects of this procedure may be potentiated with repeated treatment.

It is always important to be cautious when injecting toxin close to the mouth. A misplaced injection could result in complications, including a flaccid cheek, incompetent mouth, or asymmetric smile. This treatment is not recommended for singers or musicians, or for patients who use their perioral muscle with intensity. With this procedure, as for others in the perioral area, the most pleasing results may be obtained with BoNT-A injections in combination with laser resurfacing.

Melomental Folds (Marionette Lines)

Melomental folds ("drool grooves" or marionette lines) extending from the down-turned corner of the mouth to the lateral mentum

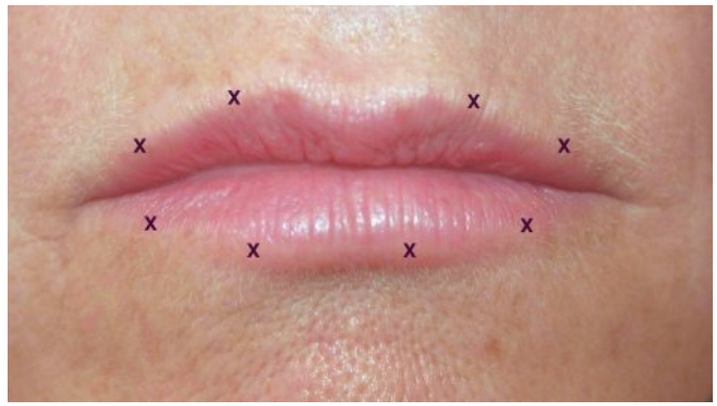

Fig. 159.12 Injection sites for perioral rhytides. The authors typically inject 1 U of onaA per lip line.

Fig. 159.13 Effect of BoNT-A injections for radial lip lines. This treatment is particularly efficacious when used in combination with a soft-tissue-augmenting agent such as hyaluronic acid. Before (**A**) and after (**B**) BoNT-A treatment.

Fig. 159.14 Left-sided Bell palsy. Before (**A**) and after (**B**) BoNT-A treatment of the right side, with improvement in asymmetry. The authors typically inject 1–2 U of onaA into the zygomaticus, risorius, and orbicularis oris muscles and 5–10 U into the masseter muscle.

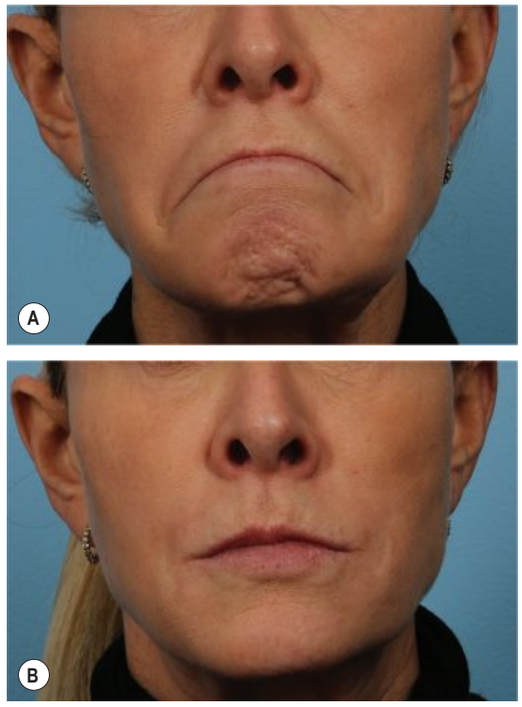

Fig. 159.16 Effect of BoNT-A injections for mouth frown. Before (**A**) and after (**B**) BoNT-A treatment. The authors typically inject 2–3 U of onaA into the posterior aspect of the depressor anguli oris muscle and 3 U into each insertion of the mentalis muscle.

Fig. 159.15 Injection sites for mouth frown.

involuntarily produce a sad expression and give the appearance of advancing age. Because contraction of the DAO muscle exacerbates the melomental folds, BoNT-A treatment is a useful adjunct to soft-tissue augmentation (see Table 159.4). Best results in this area are obtained with combined therapy as BoNT-A treatment prevents the repeated molding and contortion of the implant, enhancing and extending the duration of the soft-tissue augmentation. When performing a comprehensive approach to the entire aging face, BoNT-A treatment of the DAO muscle is often included (Video 159.5)

Mental Crease

The convexity between the lower lip and the prominence of the chin is called the mental crease. Contraction of the mentalis muscle can produce a deep groove in this region. This area is closely tethered to the bony mentum (chin), and soft-tissue augmentation of the mental crease is often unsuccessful because the filling agent visibly beads. BoNT-A injections at the level of the crease may also give unsatisfactory results because the orbicularis oris is weakened, sometimes resulting in an incompetent mouth. However, injection of the mentalis muscle gives a satisfactory softening of the crease while avoiding complications from weakening of the orbicularis oris (see Table 159.4). Injections into the mentalis are especially valuable in individuals who have had previous trauma or surgery to this area (Fig. 159.17).

Peau d'Orange (Apple Dumpling) Chin

An "orange peel" appearance of the chin during aging results from the loss of dermal collagen and subcutaneous fat at the mentum.

Fig. 159.17 Effect of BoNT-A injections on a mental crease. Subject puckers before (**A, B**) and two weeks after (**C, D**) chemodenervation of a traumatically damaged mentalis muscle with BoNT-A.

Fig. 159.19 Effect of BoNT-A injections on masseteric hypertrophy. Subject before (**A**) and after (**B**) BoNT-A treatment. The authors inject 20–35 U onaA into each masseter muscle.

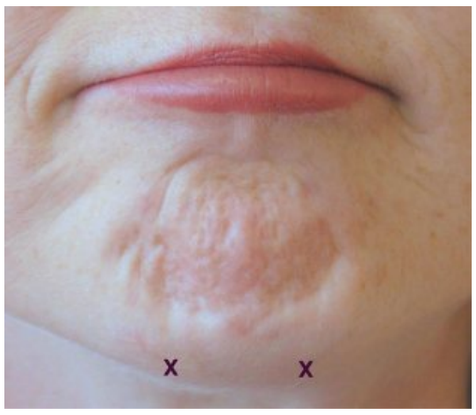

Fig. 159.18 Injection sites for a *peau d'orange* chin. The authors inject 5–10 U of onaA into the mentalis muscle at these sites.

The appearance worsens when the mentalis and depressor labii inferioris muscles are used together with the orbicularis oris muscle during mastication or speech. *Peau d'orange* chin is frequently seen asymmetrically during and after recovery from unilateral facial paresis (Bell palsy). Previous treatment options have included soft-tissue augmentation to fill in the tissue gaps and ablative and non-ablative laser resurfacing. Depending upon the patient's aesthetic need for chin augmentation, BoNT-A and soft-tissue augmentation can be used together, or BoNT-A can be used alone to improve the appearance of the chin (Fig. 159.18; see Table 159.4) (Video 159.6). Following treatment, the chin is massaged to facilitate diffusion of the toxin.

Masseteric Hypertrophy

A number of studies have observed a reduction of muscle thickness in Asian and White[30] patients with masseteric hypertrophy who were treated with BoNT-A. Reductions in muscle bulk ranged from 20% to 50% and lasted from 3 to 6 months, depending upon the doses used. Effective sculpting of the jawline can be achieved (Fig. 159.19; see Table 159.4). When investigated in a White versus East Asian population, smaller doses were required for aesthetic improvement in the former versus the latter, and patients experienced a 6- to 7-month improvement in symptoms of bruxism[30].

Platysmal Bands

Platysmal bands are formed when the anterior fibers of the platysma separate into two discrete vertical bands. The bands often tighten and become more visible when the neck is animated, as when the patient speaks, exercises, or plays a musical instrument. The emergence of platysmal bands during aging is often accompanied by other senescent changes, including loss of cervical skin elasticity and accumulation of submental fat. BoNT chemodenervation of the anterior part of the platysma muscle can soften the platysmal bands (Fig. 159.20) and produce a gentle anterior neck lift. However, in aging necks with jowl formation and bone resorption, BoNT-A treatment of the platysma may emphasize, rather than soften, the muscle cords. Thus, chemodenervation of the platysma is recommended only for patients who have obvious platysmal bands, good cervical skin elasticity, and minimal submental fat accumulation.

Large doses of BoNT-A must be used cautiously in the neck. The platysma is external to the larynx and the muscles of deglutition and neck flexion. Doses from 75–100 U of onaA can produce weakness in the neck flexors and dysphagia, and we have reported one patient treated with only 60 U in her neck who developed such profound dysphagia that she required a nasogastric tube until she could swallow again[31]. Therefore, we recommend that the physician proceed with caution and inject no more than 30–40 U of onaA spread over multiple sites per cervical treatment session (see Table 159.4).

Adjunctive Use

BoNT-A is beneficial in many patients as adjunctive therapy in order to enhance or prolong the results of other cosmetic procedures. Prior to surgery, BoNT-A treatment to chemodenervate specific muscles can facilitate subsequent manipulation of tissues during the surgery and permit a greater surgical correction or a better concealment of the surgical incision. BoNT-A can also be used to reduce tension exerted on a wound or surgical incision by the underlying muscles, thereby promoting better healing with less scar formation[32].

Combination treatment with lasers, light-based modalities, and soft-tissue augmentation offers a synergistic approach to the treatment of facial aging. BoNT-A in conjunction with ablative resurfacing leads to optimal improvement of dynamic rhytides, with superior and longer-lasting outcomes[33]. Regular postoperative injections, given every 6 to 12 months, prolong the effects of resurfacing, and many clinicians

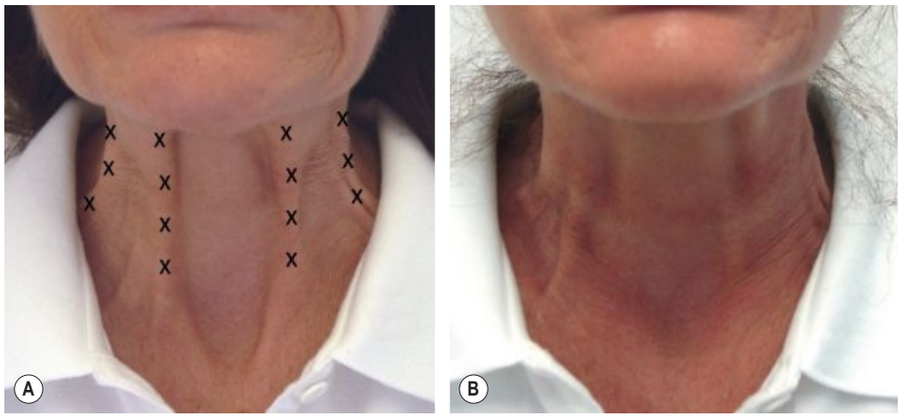

Fig. 159.20 Effect of BoNT-A injections on platysmal bands. Before (**A**) and after (**B**) treatment. Each band is injected in three sites at 1 to 1.5 cm intervals with 3–4 U of onaA per site.

now use BoNT-A injections as part of their standard laser resurfacing protocol. Likewise, combination treatment with BoNT-A and intense pulsed light (IPL) leads to greater global aesthetic benefits, with a reduction in fine lines and rhytides and improvement in skin tone, texture and erythema, compared to IPL alone[34]. Of note, BoNT-A injections delivered immediately into areas of moderate to severe edema due to laser resurfacing procedures or IPL can lead to increased and unwanted neurotoxin diffusion. Therefore, caution is recommended in this situation[34], especially since neurotoxin injections are often performed as a second procedure due to concern regarding neurotoxin inactivation by heat-producing lasers or light- and energy-based devices[34].

BoNT-A is also frequently used in combination with soft-tissue augmentation, where it prevents the distortion of the filler and prolongs the beneficial effects of tissue augmentation. Preceding the injection of filling agents by approximately 1 week, BoNT-A may work on several levels, including reducing the dynamic component of rhytide formation in newly remodeled skin and allowing more permanent eradication of rhytides[32]. Together, BoNT-A and fillers produce greater aesthetic improvements of longer duration than either modality alone[35].

MEDICAL USES OF BOTULINUM TOXIN TYPE A

Hyperhidrosis

Dramatically effective with minimal side effects, BoNT-A was approved for the treatment of axillary hyperhidrosis in Canada and the US in 2001 and 2004, respectively, and a high level of efficacy has been established in clinical trials for this indication (level A recommendation)[36,37]. Along with a decrease in perspiration lasting from 6 to 24 months, injections can improve quality of life and decrease body odor for up to 7 months[38,39].

Studies comparing onaA with aboA or incoA have shown similar levels of safety and efficacy[40,41], with a non-significant trend toward a more rapid onset of action with aboA[41]. RimaB, while effective, is associated with a greater amount of pain on injection and systemic adverse events (e.g. xerostomia, flu-like symptoms)[42].

Typically, 50–150 U of onaA per axilla are divided among 10–20 injection sites spaced 1.5–2 cm apart (Video 159.7). BoNT-A is injected intradermally or immediately subdermally. Injections are usually repeated at 6- to 12-month intervals, although, in the experience of the authors, most subjects are far below their pre-injection degree of hyperhidrosis when they present for reinjection. Alternatively, BoNT-A topically applied in large doses (200 U) has been shown to be safe and may prove to be an effective method for treating axillary hyperhidrosis[43].

The efficacy of BoNT-A in palmar hyperhidrosis is less assured (level B, probably effective), with a limited number of blinded, prospective trials[36,37]. Some consider BoNT-A only after failure of traditional treatment approaches, due to the necessity of anesthesia and the high doses required[38]. Typical doses of onaA for the palm range from 50–200 U distributed among 50–100 injection sites, including the distal wrist crease and the thenar and hypothenar eminences. Although studies show significant decreases in sweat production for 3–4 months (Fig. 159.21), most patients experience some degree of hand weakness that can last up to 2 weeks, with the thumb–index finger pinch significantly affected[44].

Fig. 159.21 Effect of BoNT-A injections on palmar hyperhidrosis. Only the right palm was treated as the right hand is the primary one used in social interactions. Small residual areas of sweating may be treated at a follow-up visit 2–4 weeks later.

Given that sweating, as well as friction, can exacerbate Hailey–Hailey disease, injections of BoNT-A into lesional skin can lead to clinical improvement. One approach is to utilize a total of 100 U, injecting 2 U into every cm^2 of involved skin.

Raynaud Phenomenon

BoNT-A is an increasingly utilized treatment for Raynaud phenomenon, defined as an exacerbated, transient vasospasm of the digital arteries, particularly in the hands, that is triggered by cold or emotional stress (see Ch. 43). Patients may experience three phases of skin discoloration: white (resulting from vasoconstriction and interruption of regional vascular flow), blue (cyanosis corresponding to blood de-oxygenation), and red (when reperfusion occurs). Pain and paresthesia due to sensory nerve ischemia may occur during an attack, and the condition may progress to ulcerations and gangrene[45].

BoNT-A injections appear to target both neural and vascular abnormalities responsible for the clinical manifestations of the syndrome, leading to a significant decrease in pain and improvements in color, mobility, blood flow and oxygen saturation, as well as healing of persistent digital ulcers[46–49]. BoNT-A is believed to work via two mechanisms: at the level of the vessel, promoting vasodilation due to the blockade of norepinephrine and acetylcholine release, and at the nerve, blocking receptors, and neurotransmitters that stimulate both pain (substance P, calcitonin gene-related peptide, and glutamate) and vasoconstriction[46].

Injection may be performed into the palmar region, wrists, and/or fingers. There is no consensus yet with regard to dose, dilution, or injection sites. The simplest technique involves 5 U onaA into the medial and lateral aspects of each finger at its base, using insulin syringes (BD Ultrafine II, 0.3 ml) for a total of 50 U onaA per hand. Some clinicians avoid injecting the thumb unless there is significant symptomatic involvement. Response can be perceived within days to a week with remarkable improvement of numbness and pain. Side effects, which are minimal and temporary, include local pain triggering a vasospastic attack.

These results warrant further investigation of clinical effect and optimal dosing with larger controlled trials.

Migraine

In 2011, the FDA approved onaA for chronic migraine prophylaxis. In addition to inhibiting release of acetylcholine from nerve endings (see Fig. 159.1), it can inhibit the release of glutamate, substance P, and calcitonin gene-related peptide (CGRP)[50]. The pathogenic role of the latter has led to the approval of several monoclonal antibodies (e.g. erenumab) and oral medications (e.g. ubrogepant) for migraine prophylaxis or treatment that target CGRP.

Typically, 100 U of onaA are distributed within the brow, temple and occipital regions, in addition to injections into any trigger sites. Historically, there have been mixed results, but a recent meta-analysis of randomized, double-blind, placebo-controlled trials reported a reduction in episode frequency and improved quality of life for up to three months after injections[50]. However, because the clinical effects on facial muscles are readily detectable, this has led to the criticism that trials are not truly blinded.

Depression

Research indicates that BoNT injections – and subsequent inability to frown – correlates with an improvement in symptoms of depression[51,52], suggesting that muscles of facial expression may play a role in mood regulation. A double-blind, randomized, placebo-controlled trial of 30 patients with major depression found that scores on the Hamilton Depression Rating Scale, Beck Depression Inventory, and Clinical Global Impressions Scale decreased by an average of 47% after one treatment with BoNT-A in the glabella, compared to a 9% reduction in patients who received saline[53]. Results were maintained over the 16-week follow-up period. In a second randomized, placebo-controlled trial, half of the patients with major depression responded to BoNT-A injections to the corrugator and procerus muscles, with an ~50% reduction in scores on the Montgomery–Åsberg Depression Rating Scale[52]. Only 15% of patients who received placebo reported such improvement.

COMPLICATIONS

BoNT-A occasionally affects non-targeted muscles or glandular tissue in the areas surrounding the injection, which can result in effects such as eyelid ptosis (Fig. 159.22), lower eyelid laxity, epiphora (excessive tearing), diplopia, brow ptosis, decreased strength of eye closure, dry eye, mouth incompetence, difficulties in speech, and the inability to whistle. Use of both careful injection technique to target the toxin to the appropriate muscles and concentrated low doses to limit its diffusion to non-targeted muscles or glands are recommended to prevent the occurrence of these adverse effects[53]. In general, a higher concentration allows for more accurate placement, greater duration of effect and fewer side effects, since lower concentrations may encourage the spread of toxin. Of note, there is an area of denervation associated with each point of injection of about 1–1.5 cm (diameter, 2–3 cm) that is due to toxin spread.

A quizzical or "cockeyed" appearance can occur in the brow when the lateral fibers of the frontalis muscle have not been injected adequately and these untreated lateral fibers pull upward on the brow (Fig. 159.23). Brow ptosis may last upwards of 3 months, while upper eyelid ptosis can persist for 2–12 weeks. When upper eyelid ptosis occurs, options include: (1) thrice daily 0.5% apraclonidine eyedrops, an α_2-adrenergic agonist used for glaucoma, which leads to contraction of the Müller muscle and a 1–2 mm elevation of the upper eyelid[54]; (2) oral pyridostigmine bromide (60 mg 3–4 times daily), an anticholinesterase drug used for myasthenia gravis that inhibits acetylcholine breakdown, whose side effects include hypersalivation, blurred vision, muscle cramps, vomiting, and diarrhea[54]; and (3) precise injections of 0.5–1 U of BoNT-A into the subdermal plane just above the eyelash line at the extreme medial and lateral aspects of the upper eyelid, thereby reducing the strength of the orbicularis oculi muscle and allowing the Müller muscle and the levator muscle to become less opposed[55].

Bruising, diplopia, ectropion, a drooping lateral lower eyelid, and an asymmetric smile (caused by the spread of toxin to the zygomaticus major) are also reported complications of BoNT-A injections in the periorbital area. Transient local bruising, ptosis, dry eyes, diplopia, and facial droop can occur with injections into the cheek.

Fig. 159.23 Cockeyed eyebrow. Untreated lateral fibers of the frontalis muscle pull upward on the lateral brow. The result is a quizzical appearance.

Fig. 159.22 Blepharoptosis. Diffusion of toxin into the levator of the upper eyelid resulted in eyelid ptosis (**A**) with partial recovery after 3 weeks (**B**) and complete recovery after 5 weeks (**C**). See text for therapeutic options.

Complications of the lower face involve effects on muscle function and facial expression, usually due to use of BoNT-A in large doses. Injections placed too close to the mouth, injection into the mental fold, and interaction with the orbicularis oris muscle can all result in a flaccid cheek, incompetent mouth, or asymmetric smile. Large doses (>100 U) of onaA in the platysma have resulted in reports of dysphagia and weakness of the neck flexors.

Although one of the greatest concerns associated with the use of BoNT-A is the formation of neutralizing antibodies leading to non-response of subsequent injections, the overall risk is actually low (<1%) when BoNT-A is used at recommended doses for cosmetic applications. Of note, the protein content in current lots of BoNT-A is significantly lower than in previous batches and has been shown to be less antigenic than the original product. Although antibody formation has occurred with current lots of BoNT-A[56], it is usually associated with the use of large doses for therapeutic, rather than cosmetic, purposes[57]. The lack of complexing proteins in incoA reduces the antigenicity[56] but does not appear to eliminate it entirely[58]. Injecting the lowest effective doses, with the longest feasible intervals between injections, minimizes the potential for immunogenicity.

Allergic reactions to BoNT-A are rare but have been described in the literature. Additional reactions include serious or non-serious cutaneous eruptions[59] as well as granulomas[60]. After large doses for therapeutic purposes, anaphylactic reactions and severe respiratory failure have occurred[61,62].

SAFETY

No long-term adverse effects have been reported, and no systemic safety problems have been associated with FDA-approved uses of BoNT. A review of the long-term safety of BoNT-A for cosmetic purposes revealed no serious adverse events (AEs) in over 850 treatment sessions for up to 9 years[63]. An interim analysis of 768 patients enrolled in phase 3 clinical trials, who received up to six treatments of aboA, found that multiple treatments over 17 months were well tolerated[64]. A large-scale, comprehensive phase III program of onaA for crow's feet and glabellar rhytides comprising three trials, 684 patients, and up to four treatment cycles found no serious treatment-related AEs, evidence of distant spread of the toxin, or immunogenicity over a 12-month period[65]. Side effects were mostly mild and included hematoma, headache, and injection-site hemorrhage. Treating both the crow's feet region and glabellar rhytides at the same time did not result in an increased incidence of AEs, and side effects appeared to decline with repeated treatments.

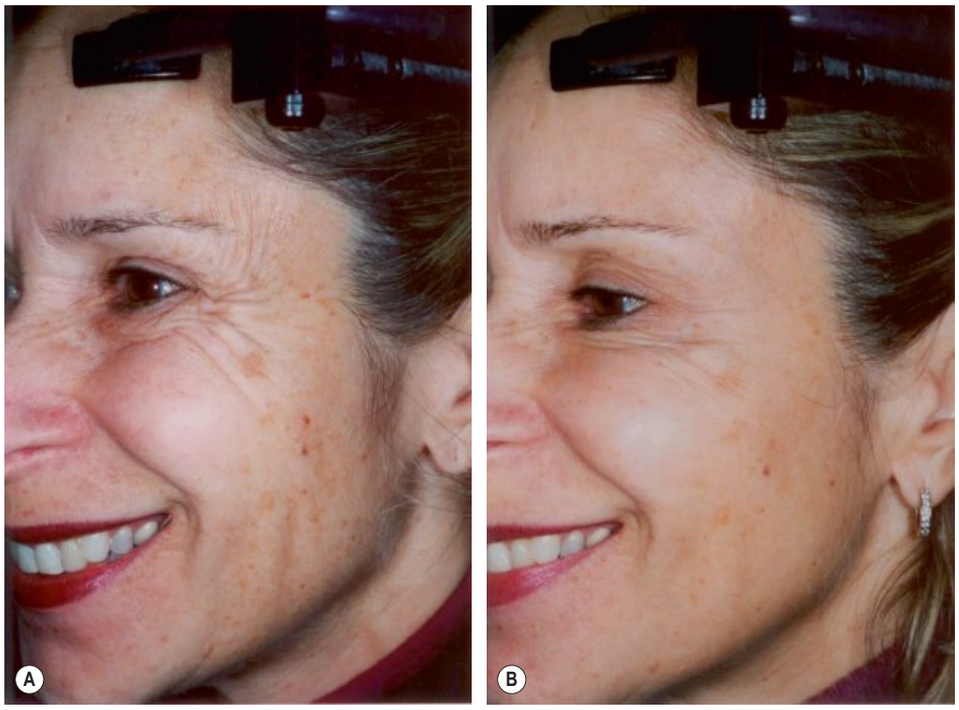
However, the risk of serious complications increases with higher doses: in an analysis of 1031 AE reports submitted to the FDA, 407 occurred with higher therapeutic doses, including 28 deaths and other serious cardiovascular complications[59]. The FDA could not determine a causal relationship between the fatalities and BoNT-A injections, especially since 26 patients who died had underlying cardiovascular diseases with an elevated mortality risk. Notably, no deaths or cardiovascular complications were associated with cosmetic doses. Similarly, another investigation of 658 FDA-submitted AEs, which included 180 cases of aspiration, dysphagia and/or pneumonia and 16 deaths, involved only therapeutic doses in already compromised individuals[66]. As a result, the FDA requested safety label changes with black box warnings and a *r*isk *e*valuation and *m*itigation *s*trategy (REMS), including a consumer guide outlining the risks associated with treatment, for all BoNT products[67].

FUTURE TRENDS

The use of BoNT continues to evolve, with new applications that deepen our understanding of clinical effect and mechanism of action. There have been anecdotal reports of tighter, smoother skin after BoNT-A injections, as well as a lower incidence of acne[68]. Current research indicates that BoNT-A acts on the biological behavior of fibroblasts, including reducing production of matrix metalloproteinases (MMPs), responsible for the slow degradation of type I collagen, and stimulating the production of procollagen I. Collagen production and degradation has been investigated *in vitro* by measuring procollagen type I carboxy-terminal peptide (PIP) and MMPs, respectively. Levels of PIP increased significantly when fibroblasts were grown in the presence of BoNT, with upregulation of type I collagen and a decrease in MMPs[69]. In an *in vivo* investigation of the effects of BoNT on photodamaged skin, mice were pretreated with BoNT-A and subsequently irradiated with ultraviolet B light[70]. Compared to control mice, those injected with BoNT-A had significantly decreased secretion of inflammatory cytokines associated with photodamage and postinflammatory hyperpigmentation.

Intradermal injection of BoNT-A has been used with success to treat oily skin and enlarged pores. When the T-zone (forehead and nose) was injected in a series of 20 patients, 17 reported an improvement in skin oiliness[71]. Significantly lower sebum production was noted in 25 patients treated with 3 to 5 U of aboA in each of ten injection sites across the forehead, as measured by a sebometer[72]. The authors speculated that blockade of local acetylcholine receptors in the pilosebaceous unit with BoNT-A could result in altered rates of sebum production.

SUMMARY



BoNT-A remains the treatment of choice for smoothing hyperkinetic lines in the face and neck, creating a more pleasant and youthful appearance. Alone or in combination with surgery, soft-tissue augmentation, or ablative and non-ablative laser resurfacing, BoNT-A treatment is both an art and a science, with its use in facial sculpting and enhancing, along with dermatologic correction. Intramuscular injections of BoNT-A have also become first-line therapeutic options for a number of disorders characterized by muscular hyperactivity, such as strabismus, blepharospasm, hemifacial spasm, and cervical dystonia. In addition, the ability of BoNT to block acetylcholine release and other neurotransmitters from autonomic nerve endings innervating glandular tissue or smooth muscle has led to its use for hyperhidrosis, migraine prophylaxis, and Raynaud phenomenon. Easy to use, minimally invasive, and well tolerated, BoNT carries an impressive safety record, and there is no doubt its number of indications will continue to grow.
